Improved flammability characteristics have also been observed in ZT-CFRP using UL-94 testing, a standard for assessing the fire hazard of plastic materials. It was shown that ZT-CFRP took on average only 34.95 seconds to self-extinguish, while CFRP samples took on average 86.8 seconds. Self-extinguishing time for ZT-CFRP took only 40% of the time it took for CFRP samples. ZT-CFRP also showed a reduced chance of flame propagation in comparison to CFRP. None of the ZT-CFRP samples burned all the way to the clamp holding the specimen during testing, whereas 60% of the CFRP samples did [7].

A previous study on ILSS failure performance during extreme heat exposure provided evidence of improved strength capabilities and retention in extreme temperature environments of ZT-CFRP in comparison to CFRP. In this study an apparatus was designed and used to replicate the loading of a short beam shear (SBS) test within a muffle furnace chamber. Both CFRP and ZT-CFRP samples were placed inside the apparatus within the chamber and a static loading was exerted onto them. The temperature of the furnace was allowed to increase based on a consistent heating schedule until failure was observed within the testing samples. It was observed that the average failure temperature range for ZT-CFRP was between 384.0 ˚C to 398.4 ˚C, whereas CFRP samples failed on average at temperatures ranging from 349.6 ˚C to 368.2 ˚C. This was an approximate 30 ˚C increase in temperature handling capabilities exhibited by ZT-CFRP over CFRP [8].

Based on the temperature failure ranges observed from the previously mentioned study, there is evidence that ZT-CFRP may be better equipped at retaining strength during thermal degradation caused by extreme temperature exposure in comparison to traditional CFRP. This study examined the

retention of ILSS between CFRP and ZT-CFRP when exposed to extreme elevated temperatures that can cause thermal degradation within the matrix. This was accomplished by heat treating specimens at 350 ˚C within a muffle furnace for 10 minutes. The treated specimens were then removed and underwent SBS testing to experimentally determine their ILSS. Specimens subjected to no heat treatment were also tested to show how much strength was lost due to heat exposure and potential matrix degradation. Specimens for both cases were prepared and tested based on the specifications provided in ASTM D2344 [9]. Microscopic image analysis was also performed to determine how the z-threaded CNF microstructure may have contributed to the failure observed. The process of manufacturing and testing the specimens, testing data, and microscope images of the specimens are provided within this document.

1.1 Review of the Effect of Extreme Temperature Exposure on CFRP Behavior

Quintiere et al. [10] reported that the typical temperature range for the degradation of common aerospace CFRP composites is between 300 ˚C to 500 ˚C. The reduction in material properties observed at these elevated temperatures is not only due to the weakening molecular bonds but is also a result of the internal pressure caused by resin vaporization and the reinforcing fibers that hinder its escape. Bazli et al. [11] reported a similar degradation temperature range while also observing that composites loaded in either shear or compression failed at much earlier temperatures in comparison to those loaded in tension or flexure. Ningyun and Evans [12] performed short beam shear tests on fiber reinforced thermoplastic composites between 20 ˚C and 300 ˚C. Failure at low temperatures was found to be largely due to interlaminar shear and delamination. Large-scale inelastic deformation was observed within the test specimens at higher temperatures. These studies provide evidence that matrix sensitive material properties are more sensitive to extreme temperatures.

Nema et al. [13] found that both flexural strength and ILSS decreased linearly as temperature was increased to 200˚C. Significant decreases in flexural modulus were also observed at around 200 ˚C which was above the glass transition temperatures of the resin systems being used. Hegde et al. [14] also observed that composite strength and stiffness consistently fell as temperature began to approach the glass transition temperature. With steel and CFRP double strap joints, Nguyen et al. [15] saw load carrying capabilities diminish by 30% when exposed to temperatures around the glass transition temperature.

2 EXPERIMENTATION

2.1 Materials

All testing specimens utilized unidirectional HexTow AS7 carbon fiber from Hexcel with a density and areal weight of 1.79 g/cm^3 and 190 g/m^2, respectively, for reinforcement. The tow size was 12 K. CNFs used for z-thread nanomaterial reinforcement were PR-24-XT-PS grade from Pyrograph/ Applied Sciences Incorporated. This grade of nanofibers was reported to have an average diameter of 100 nm and lengths ranging between 50 μm to 200 μm. The base resin system utilized for all specimens consisted of a mixture of Epon-862, a diglycidyl ether of bisphenol F, and Epikure-W, a non-MDA aromatic amine curing agent containing diethylmethylbenzenediamine, both purchased from Miller-Stephenson Chemical Company. The surfactants Disperbyk-191 and Disperbyk-192, both purchased from BYK USA, were used in cases with CNF reinforcement to better disperse the nanomaterial within the resin mixture.

2.2 Prepreg Production

Two different cases of composite panels were manufactured for this study: control containing no nanomaterial reinforcement and ZT-CFRP. All prepreg used for the panels was manufactured through a proprietary production process developed by the Hsiao research group at the University of South Alabama that is illustrated within a pending patent application US20240149541A1 [16]. Both control and ZT-CFRP utilized a base blend of Epon-862 and Epikure-W mixed at a stochiometric ratio of

100:26.5, respectively. For the ZT-CFRP prepreg, CNF was added at 0.5 wt% of the overall resin matrix mixture. Both Disperbyk-191 and Disperbyk-192 were added at a ratio of 1:1:1 with CNF for better dispersion within the mixture. The resin mixture used for control prepreg manufacturing only contained Epon-862 and Epikure-W.

Both the control and ZT-CFRP resin mixture underwent five minutes of manual stirring once the components were measured out and combined as appropriate. For the ZT-CFRP mixture that contained nanomaterial reinforcement and surfactants, one hour of high shear mixing at 900 rpm using a Stir-Pack Laboratory Mixer was performed. The rotational direction of the mixer was alternated after 30 minutes. The high shear mixed reinforced resin then underwent two hours of sonication using a QSONICA Q700 sonicator. This step was taken to further disperse and reduce agglomerations of CNF within the resin mixture. A sample of the resin mixture was taken after this step to determine the quality of CNF dispersion underneath a Nikon Eclipse LV 150 microscope. Figure 2 provides an image of the final CNF dispersion quality within the resin mixture prior to moving to the next step of prepreg production.

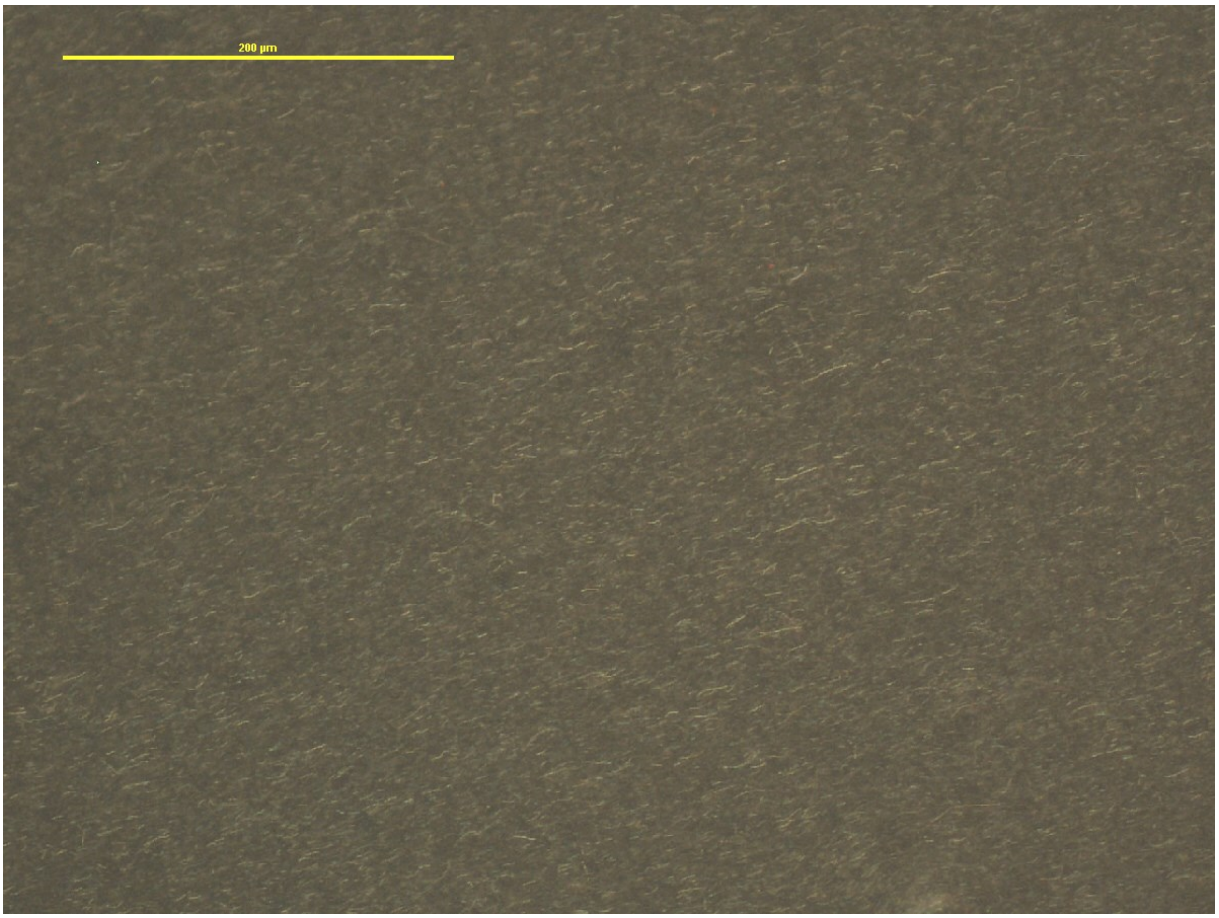

Figure 2: A microscope image showing dispersion quality of the CNF within the resin blend prior to prepreg manufacturing.

The appropriate amount of Epikure-W curing agent was added and manually stirred for 5 minutes into the dispersed CNF mixture to begin the B-staging process. The blend was then placed for approximately 1 hour inside a vacuum oven at 110 ˚C and -0.09 MPa. The vacuum applied to the resin during this process allowed for the removal of any trapped air within the mixture while also allowing it to partially cure. The control resin mixture also underwent the same B-staging process once Epikure-W was added.

The partially cured resin mixtures were then used in the proprietary ZT-CFRP prepreg production line to create hot melt resin films. An additional alignment process was performed to orientate the CNF reinforcement within the ZT-CFRP film. Alignment is accomplished through reinforced film

exposure to an electrical field for 150 seconds. The hot melt films created for both cases were then used to impregnate dry AS7 fiber fabric arrays. The alignment quality of the created ZT-CFRP prepreg was checked underneath a microscope. An example image of aligned prepreg is provided in Figure 3. Figure 4 provides a diagram detailing the process of making prepreg from start to finish.

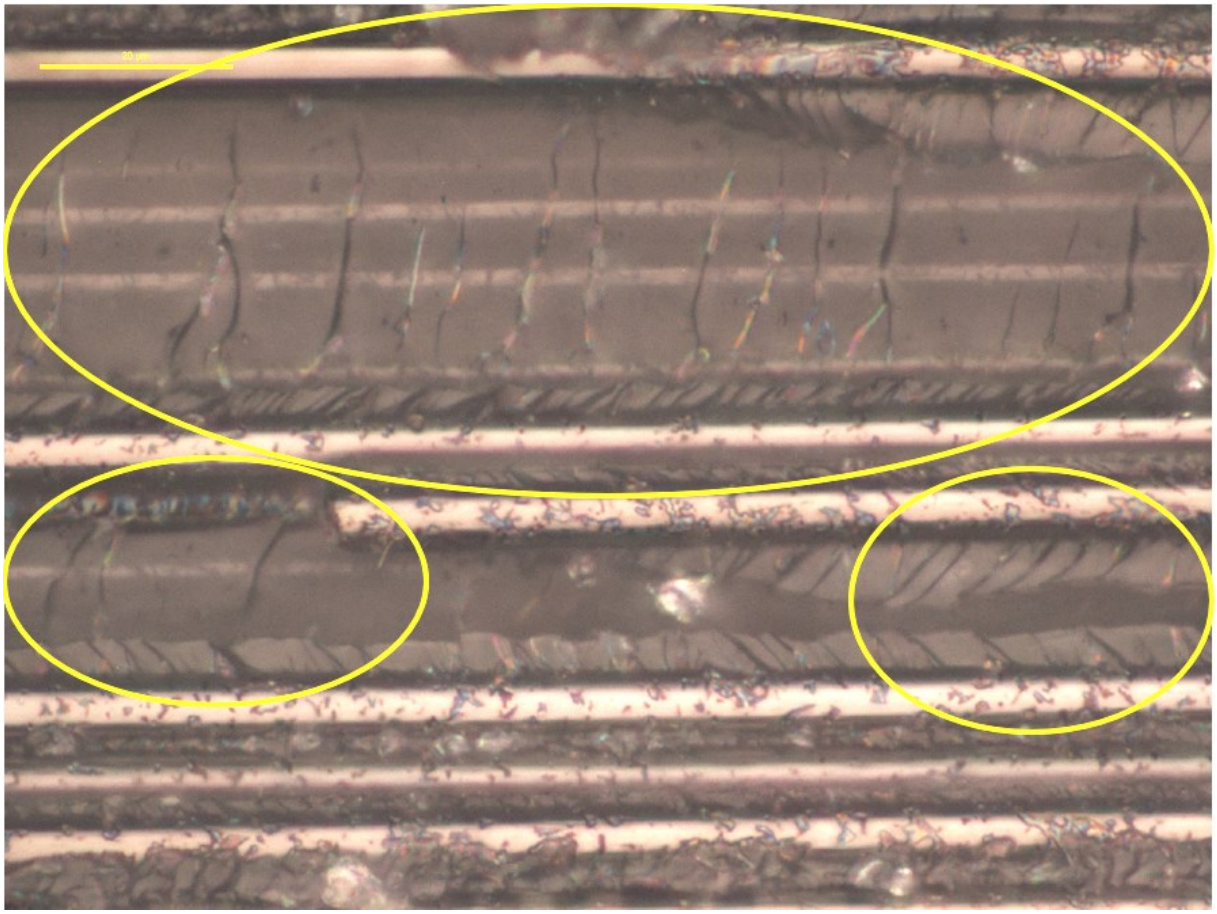

Figure 3: A microscope image of CNF alignment between carbon fibers (lines that are running horizontally) taken from a cured sample of prepreg

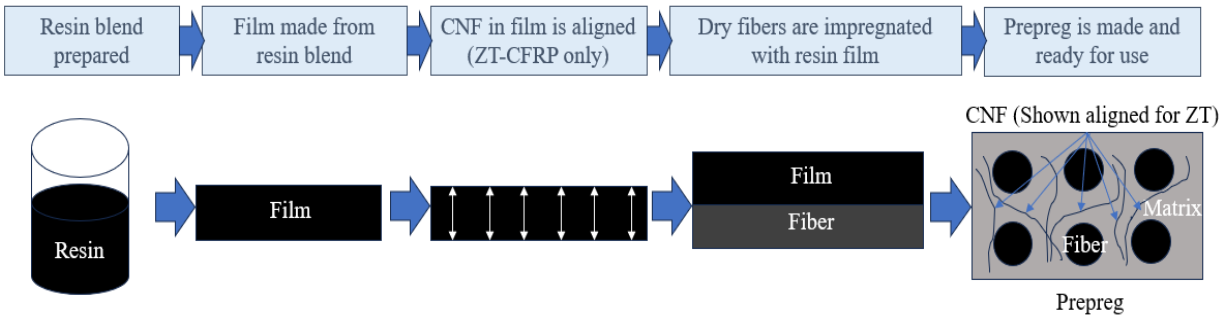

Figure 4: The prepreg making process is detailed in the diagram from preparing the resin blend to making prepreg.

2.3 Composite Panel and Test Specimen Production

The prepreg for both cases was cut into 127 mm x 127 mm sheets. Prepreg stacks of 16 plies were prepared by hand for both test cases. The prepreg was laid unidirectionally for both cases. The stacks were then cured using the out-of-autoclave vacuum bag-only (OOA-VBO) process detailed in Figure 5. In this process, an individual stack of prepreg is placed onto a release agent coated metal plate and is then covered by a vacuum bag after the peel ply, breather fabric, and other components are laid sequentially as shown in Figure 5. A vacuum pressure of -0.09 MPa was applied to the OOA-VBO assembly. A hot press was utilized to provide the necessary curing temperatures. The hot press was only used to simulate an oven and did not exert any force onto the OOA-VBO assembly. The temperatures and pressures utilized during the curing cycle for both composite panels are provided in Table 1.

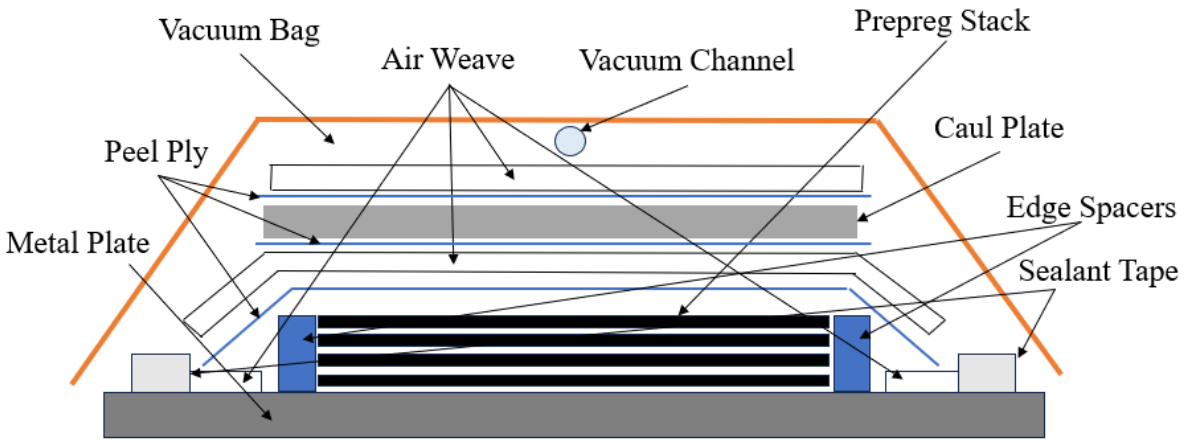

Figure 5: The OOA-VBO assembly and components are detailed in the diagram.

Composite Laminate Curing Cycle		
Time	**Temperature**	**Vacuum Applied**
60 minutes	22 ˚C (Room Temperature)	Yes
120 minutes	120 ˚C	Yes
360 minutes	180 ˚C	No

Table 1: The curing cycle that was utilized for manufacturing both the control and ZT-CFRP composites used in this study.

Once fully cured, the 127 mm x 127 mm laminate panels were cut to produce samples that fulfilled the criteria specified by the ASTM D2344 standard for SBS testing of fiber reinforced composites. The standard recommends the ratio between specimen thickness, width, and length should be 1:2:6, respectively [9]. With 16 plies, the nominal thickness of the two composite panels made for this study was 2.5 mm. Based off the recommendation by ASTM D2344, the dimensions of the test specimens were approximately 2.5 mm x 5 mm x 15 mm. The 15 mm length was parallel with the direction of the fibers. The ASTM D2344 standard requires that at least five specimens for each case are tested.

2.4 Specimen Heat Treating

An FB1400 model muffle furnace made by Barnstead Thermolyne Corporation was used for heat treating the test samples at 350 ˚C. The chamber was first preheated to 370 ˚C. The test specimens were put on a ceramic tray to be inserted within the chamber of the furnace. Once the chamber temperature stabilized, the ceramic tray with the specimens was placed inside the furnace. After two minutes of the ceramic tray being placed inside the chamber and the furnace door closing, the temperature setting of the oven was reduced to 350 ˚C. This heating procedure allowed the temperature of the specimens to rapidly increase to and hold at the desired exposure temperature of 350 ˚C. After 10 minutes within the furnace chamber, the ceramic tray and specimens were removed and allowed to cool to room temperature. Only five specimens at a time were heated within the furnace.

2.5 SBS Testing

The short beam shear tests done for this study were done using a Tinius Olsen 10ST universal testing machine. The loading nose and supports of the testing apparatus were both in compliance with ASTM D2344 with diameters of 6 mm and 3mm, respectively. The ASTM D2344 requires that the ratio between span length, or the distance between supporting pins, be four times the thickness of the testing specimen [9]. Since the testing specimens used in this study had a nominal thickness of 2.5mm, the span length was set to 10 mm. The crosshead movement rate of the loading nose was also in compliance and set at a rate of 1.0 mm/min. Data on the position of the loading crosshead and force during testing was output. Figure 6 provides a picture of the testing setup used for this study.

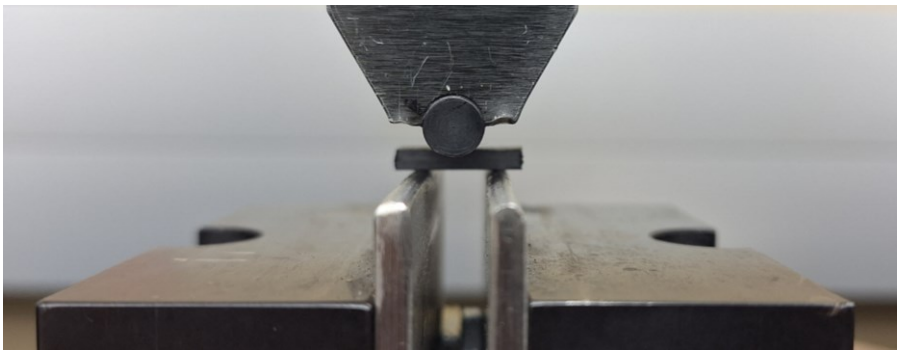

Figure 6: Photo of the SBS setup that was used for this study with a sample loaded.

3 RESULTS

3.1 Testing Data

The force testing output data was used to find the interlaminar shear stress acting on the specimens during SBS testing using the following formula from ASTM D2344:

$$F^{sbs} = 0.75\, x\, \frac{P}{b\, x\, h} \tag{1}$$

Where F^{sbs} is the interlaminar shear stress, P is the force due to the loading, b is the testing specimen width, and h is the testing specimen thickness [9]. The calculated stress values and crosshead displacement data from testing are plotted in Figure 7 for all four cases of specimens tested: control at room temperature, control after being heat treated at 350 ˚C, ZT-CFRP at room temperature, and ZT-CFRP after being heat treated at 350 ˚C

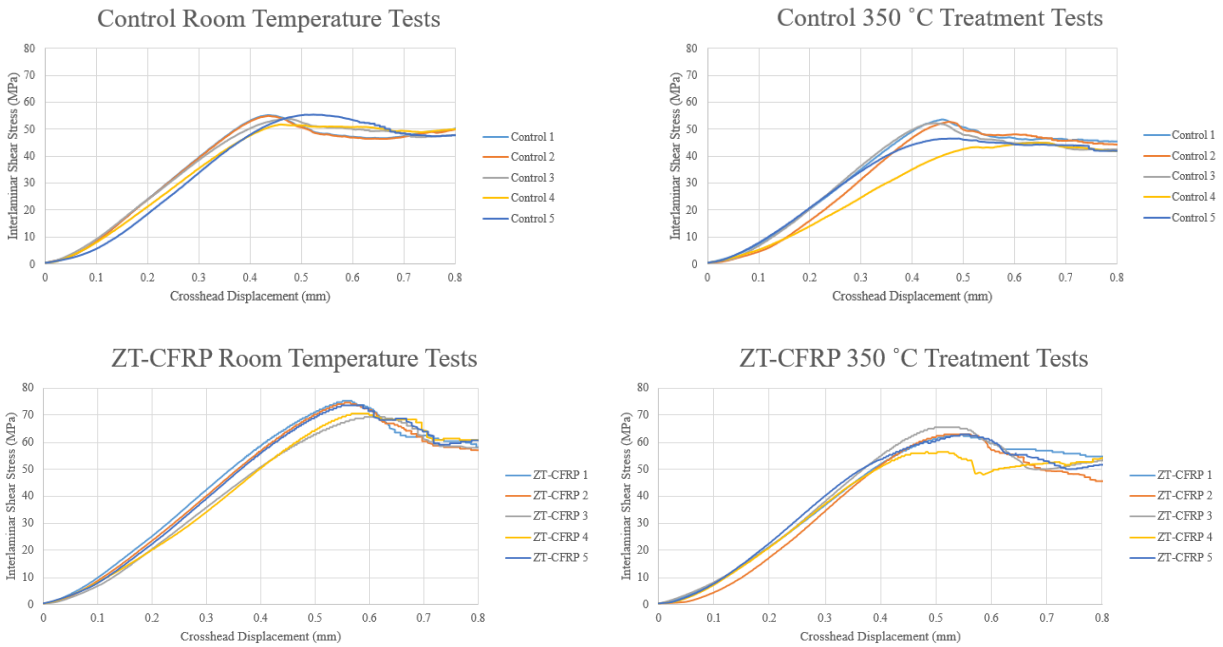

Figure 7: Crosshead displacement and interlaminar shear stress curves taken for the tested specimens.

The ILSS for each test sample is recorded in Table 2. The average ILSS for room temperature and 350 ˚C treated control CFRP samples was 54.253 MPa and 49.626 MPa, respectively. Based on the average control ILSS values, this was a 4.627 MPa (-8.53%) decline in strength after exposure to 350 ˚C for 10 minutes. A 10.584 MPa (-14.56%) decline in ILSS was observed between the average for room temperature and 350 ˚C treated ZT-CFRP samples, which was 72.676 MPa and 62.092 MPa, respectively. At room temperature, the average ILSS for ZT-CFRP was 18.423 MPa higher than that of control. Heat treated ZT-CFRP also had a higher average ILSS than heat treated control, with an observed 12.466 MPa difference between the two. It is interesting to note that the treated ZT-CFRP still had a higher ILSS (62.092 MPa) than that of the control CFRP without exposure of heat treatment (54.253 MPa).

ILSS (MPa)							
Room Temperature				**350 ˚C Treatment**			
Control 1	55.254	**ZT-CFRP 1**	75.308	**Control 1**	53.591	**ZT-CFRP 1**	62.759

3.2 Microscope Image Analysis

Tested specimens were viewed underneath a Nikon Eclipse LV 150 microscope to provide a visualization of what mechanisms may have contributed to the interlaminar failure and strength discrepancies between the four test cases observed. Figure 8 provides images taken along the end of two specimens: one control and one ZT-CFRP that received no heat treatment. As can be seen, a much smaller interlaminar crack formed within the ZT-CFRP sample in comparison to the control sample.

This was likely due to the reinforcing CNF z-threads that helped to resist the formation and propagation of a larger scale crack.

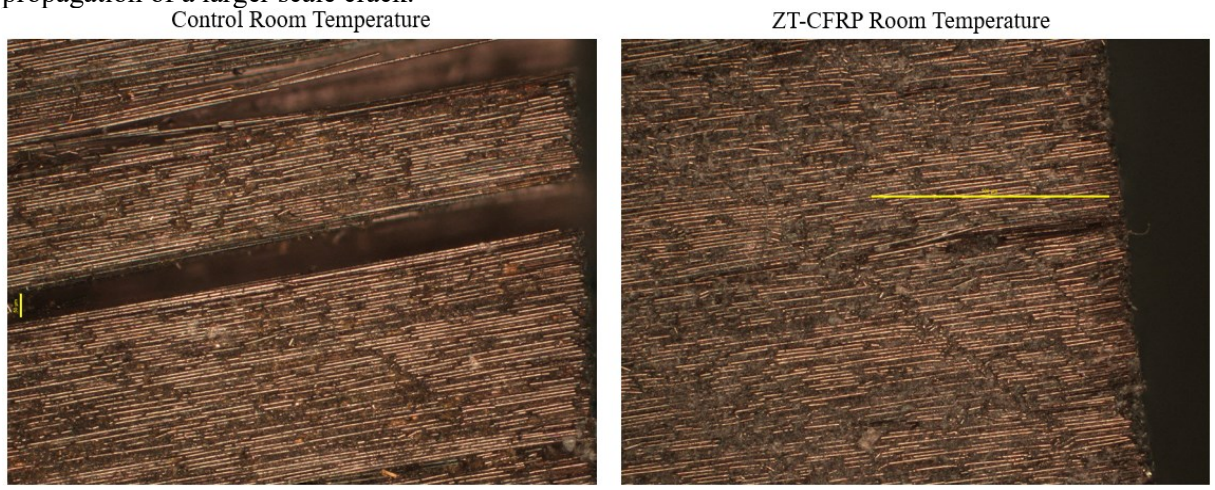

Figure 8: Images taken along interlaminar crack formed on the end of room temperature tested Control Sample 3*(left)* and ZT-CFRP Sample 5 *(right)*.

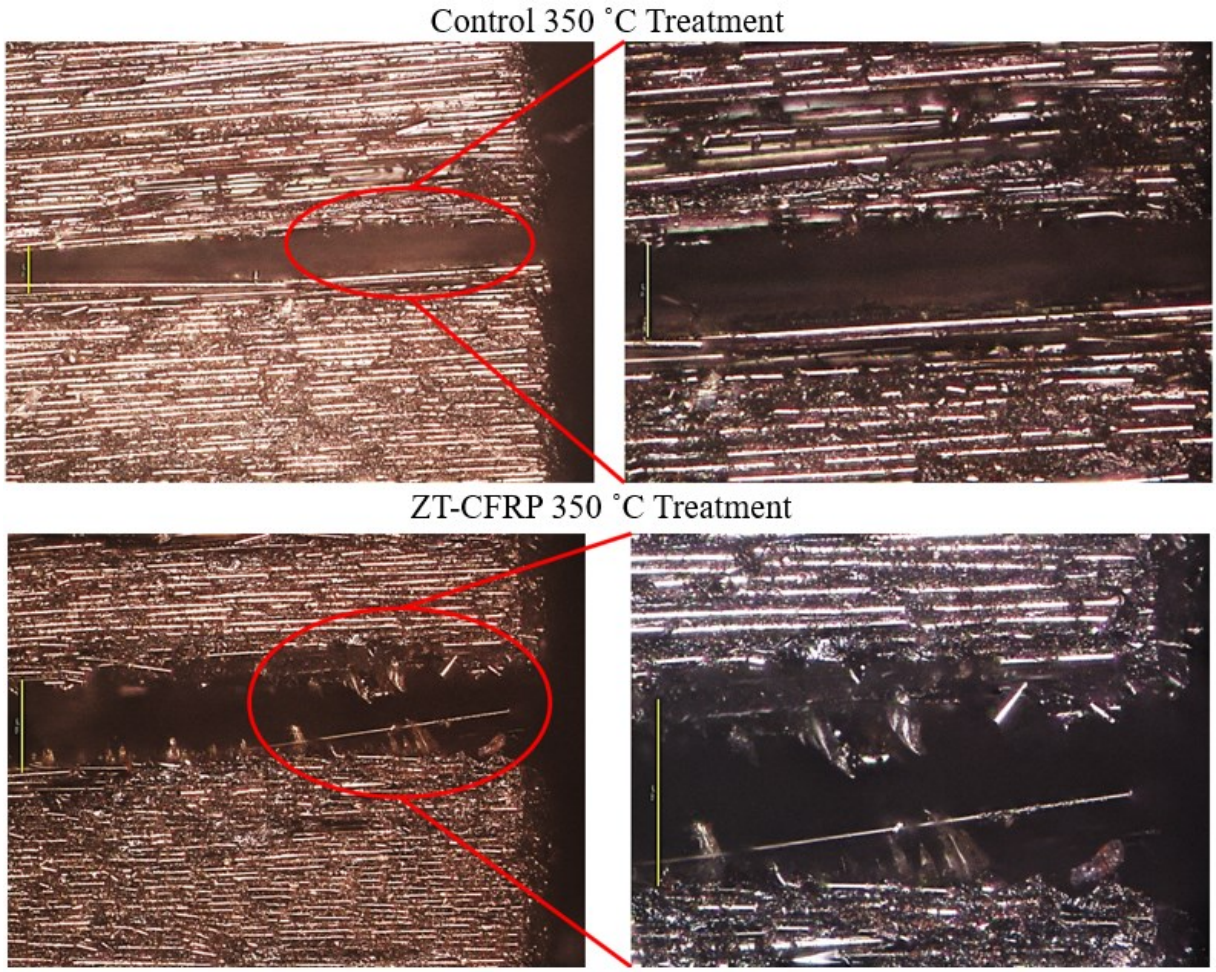

Figure 9: Images taken along interlaminar crack formed on the end of 350 ˚C treated tested Control Sample 1*(top)* and ZT-CFRP Sample 1 *(bottom)*.

Figure 9 shows images taken from two 350 ˚C pretreated samples: one control and one ZT-CFRP. As can be seen within the images taken along the interlaminar crack formation, the ZT-CFRP sample had a much more jagged edge in comparison to the control sample. Exposed CNF z-threads can also

be seen along the length of the crack formation. There also appears to be more misaligned carbon fibers near the interlaminar crack with the ZT-CFRP sample. The jagged edge, exposed z-threads, and greater fiber misalignment of the ZT-CFRP samples may help to support the argument made in the preceding paragraph that the CNF z-threads act as anchoring mechanism that resists delamination and interlaminar failure. The control samples only have the strength of the epoxy bond between layers to prevent delamination.

4 CONCLUSION

This study examined how the inclusion of CNF z-threads contributed to the retention of ILSS within CFRP composites after they have been exposed to extreme elevated temperatures. It was found that ZT-CFRP exhibited improved ILSS over traditional CFRP both with and without extreme temperature exposure. ZT-CFRP exhibited an average ILSS of 72.676 MPa without heat exposure and 62.092 MPa with a 350 ˚C heat treatment. The traditional CFRP samples exhibited an average ILSS of 54.253 MPa without heat exposure and 49.626 MPa with a 350 ˚C heat treatment. From the obtained ILSS data and microscope images taken of tested samples, there is evidence to suggest that the CNF z-threads provided a reinforcing mechanism that resisted interlaminar failure and crack propagation of the composite. This could be seen well in the extreme heat-treated samples where there was a diminished matrix due to thermal degradation. The CNF z-threads were apparent along the edges of the formed cracks and were likely significant contributors for ZT-CFRP heat treated samples still having higher ILSS than traditional CFRP samples that received no extreme heat exposure.

It was expected that the traditional CFRP samples would have a more diminished ILSS after heat exposure than was observed. This may have been a result of the CFRP samples being more resin dry in comparison to the ZT-CFRP samples despite having similar dimensions and being composed of the same amount of prepreg plies. There may have already been areas of diminished matrix in the CFRP samples in comparison to the ZT-CFRP samples that would not have been as affected by thermal degradation caused by the elevated temperatures.

The claims made in this publication can be further supported through additional testing in the future. Unaligned CNF reinforced CFRP would help to show that it is the z-threads and not just nanomaterial reinforcement that improves the ILSS capabilities. However, this has already been shown in samples with no extreme heat exposure [6]. Testing different exposure temperatures and/or times would also provide more insight into the effect of thermal degradation of the matrix on CFRP and ZT-CFRP interlaminar strength capabilities. Different CNF weight fractions could also better show the significance of z-threads for strength retention with smaller weight fractions likely not being able to retain ILSS as well as higher weight fractions.

ABSTRACT

Previous studies have shown that carbon nanofiber (CNF) z-threaded carbon fiber-reinforced polymer (ZT-CFRP) laminates exhibit improved mechanical performance in comparison to traditional carbon fiber-reinforced polymer (CFRP) laminates when exposed to extreme elevated temperatures. Z-threaded reinforcement is a technique for strengthening the through-thickness of a laminate by introducing perpendicularly aligned carbon nanomaterial to be threading into the continuous fiber array. Improved performance has already been observed in properties such as interlaminar shear strength (ILSS) without extreme heat exposure, but there has also been evidence that z-thread inclusion may mitigate strength loss due to thermal degradation of the matrix. This study examined how ILSS was diminished in both CFRP and ZT-CFRP samples with matrix degradation caused by extreme temperature exposure. Test samples were heated to 350 ˚C for 10 minutes and then allowed to return to room temperature. SBS testing in accordance with ASTM D2344 was conducted on both untreated and heat-treated samples for comparison. All samples were at room temperature during testing. It was found that ZT-CFRP samples (with 0.5wt% CNF concentration the matrix) exhibited higher ILSS with and without heat treatment over the traditional CFRP samples with and without heat treatment by +33.96% and +25.12%, respectively. ZT-CFRP ILSS was found to decrease by 10.584 MPa (-14.56%) after the extreme heat treatment, while CFRP ILSS decreased by only 4.627 MPa (-8.53%). Microscopic image analysis was also performed to provide insight into how the CNF z-threads may have provided a mechanism for retaining ILSS performance even with matrix thermal degradation.

1 INTRODUCTION

The high strength-to-weight ratios of carbon fiber reinforced polymers (CFRP) have caused it to become an increasingly used and researched material for structural designs. One of the disadvantages of CFRP is that they are anisotropic, with higher mechanical performance being restricted to loadings acting in the direction of the embedded reinforcing fibers. Even with the use of different stacking orientation techniques that can introduce more planar isotropy tendencies, there is still no reinforcing mechanism along the through-thickness of the composite. All reinforcement is confined to the plane of the fiber arrays. The novel Z-threaded nanomaterial reinforcement technique is a proven method for

increasing the through-thickness capabilities of CFRP. Within Z-threaded CFRP (ZT-CFRP), carbon nanomaterial is aligned and threaded perpendicularly through the reinforcing fiber array. A depiction of the concept of ZT-CFRP is provided in Figure 1 with carbon nanofibers (CNF) acting as the nanomaterial reinforcement.

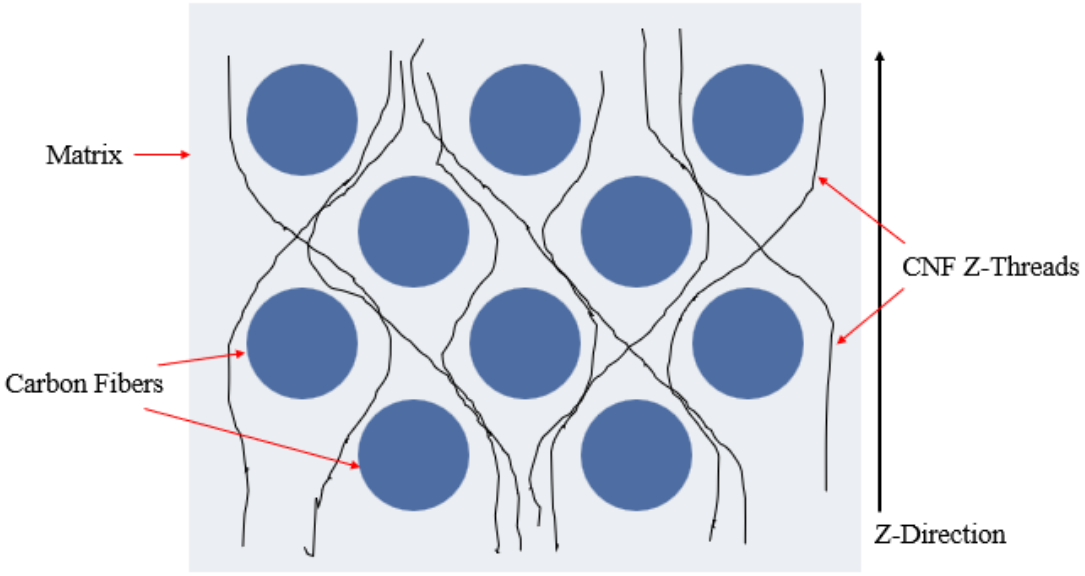

Figure 1: Illustration of ZT-CFRP showing how the nanomaterial reinforcement is threaded perpendicularly through fiber array.

Previous studies have already shown that ZT-CFRP exhibits improved through-thickness dependent material properties in comparison to traditional CFRP composites. This includes strengthened mechanical properties such as Mode-I delamination toughness [1] and longitudinal compressive strength [2], along with improved electrical [3, 4] and thermal conductivities [5]. Interlaminar shear strength (ILSS) is a mechanical property that saw significant increase in performance in comparison to traditional CFRP. With the inclusion of 1 wt% CNF z-threads, a 17% improvement in ILSS was observed. Traditional CFRP samples exhibited an average ILSS of 64.89 MPa while ZT-CFRP samples exhibited an average of 75.92 MPa [6].

Improved flammability characteristics have also been observed in ZT-CFRP using UL-94 testing, a standard for assessing the fire hazard of plastic materials. It was shown that ZT-CFRP took on average only 34.95 seconds to self-extinguish, while CFRP samples took on average 86.8 seconds. Self-extinguishing time for ZT-CFRP took only 40% of the time it took for CFRP samples. ZT-CFRP also showed a reduced chance of flame propagation in comparison to CFRP. None of the ZT-CFRP samples burned all the way to the clamp holding the specimen during testing, whereas 60% of the CFRP samples did [7].

A previous study on ILSS failure performance during extreme heat exposure provided evidence of improved strength capabilities and retention in extreme temperature environments of ZT-CFRP in comparison to CFRP. In this study an apparatus was designed and used to replicate the loading of a short beam shear (SBS) test within a muffle furnace chamber. Both CFRP and ZT-CFRP samples were placed inside the apparatus within the chamber and a static loading was exerted onto them. The temperature of the furnace was allowed to increase based on a consistent heating schedule until failure was observed within the testing samples. It was observed that the average failure temperature range for ZT-CFRP was between 384.0 ˚C to 398.4 ˚C, whereas CFRP samples failed on average at temperatures ranging from 349.6 ˚C to 368.2 ˚C. This was an approximate 30 ˚C increase in temperature handling capabilities exhibited by ZT-CFRP over CFRP [8].

Based on the temperature failure ranges observed from the previously mentioned study, there is evidence that ZT-CFRP may be better equipped at retaining strength during thermal degradation caused by extreme temperature exposure in comparison to traditional CFRP. This study examined the

retention of ILSS between CFRP and ZT-CFRP when exposed to extreme elevated temperatures that can cause thermal degradation within the matrix. This was accomplished by heat treating specimens at 350 ˚C within a muffle furnace for 10 minutes. The treated specimens were then removed and underwent SBS testing to experimentally determine their ILSS. Specimens subjected to no heat treatment were also tested to show how much strength was lost due to heat exposure and potential matrix degradation. Specimens for both cases were prepared and tested based on the specifications provided in ASTM D2344 [9]. Microscopic image analysis was also performed to determine how the z-threaded CNF microstructure may have contributed to the failure observed. The process of manufacturing and testing the specimens, testing data, and microscope images of the specimens are provided within this document.

1.1 Review of the Effect of Extreme Temperature Exposure on CFRP Behavior

Quintiere et al. [10] reported that the typical temperature range for the degradation of common aerospace CFRP composites is between 300 ˚C to 500 ˚C. The reduction in material properties observed at these elevated temperatures is not only due to the weakening molecular bonds but is also a result of the internal pressure caused by resin vaporization and the reinforcing fibers that hinder its escape. Bazli et al. [11] reported a similar degradation temperature range while also observing that composites loaded in either shear or compression failed at much earlier temperatures in comparison to those loaded in tension or flexure. Ningyun and Evans [12] performed short beam shear tests on fiber reinforced thermoplastic composites between 20 ˚C and 300 ˚C. Failure at low temperatures was found to be largely due to interlaminar shear and delamination. Large-scale inelastic deformation was observed within the test specimens at higher temperatures. These studies provide evidence that matrix sensitive material properties are more sensitive to extreme temperatures.

Nema et al. [13] found that both flexural strength and ILSS decreased linearly as temperature was increased to 200˚C. Significant decreases in flexural modulus were also observed at around 200 ˚C which was above the glass transition temperatures of the resin systems being used. Hegde et al. [14] also observed that composite strength and stiffness consistently fell as temperature began to approach the glass transition temperature. With steel and CFRP double strap joints, Nguyen et al. [15] saw load carrying capabilities diminish by 30% when exposed to temperatures around the glass transition temperature.

2 EXPERIMENTATION

2.1 Materials

All testing specimens utilized unidirectional HexTow AS7 carbon fiber from Hexcel with a density and areal weight of 1.79 g/cm^3 and 190 g/m^2, respectively, for reinforcement. The tow size was 12 K. CNFs used for z-thread nanomaterial reinforcement were PR-24-XT-PS grade from Pyrograph/ Applied Sciences Incorporated. This grade of nanofibers was reported to have an average diameter of 100 nm and lengths ranging between 50 μm to 200 μm. The base resin system utilized for all specimens consisted of a mixture of Epon-862, a diglycidyl ether of bisphenol F, and Epikure-W, a non-MDA aromatic amine curing agent containing diethylmethylbenzenediamine, both purchased from Miller-Stephenson Chemical Company. The surfactants Disperbyk-191 and Disperbyk-192, both purchased from BYK USA, were used in cases with CNF reinforcement to better disperse the nanomaterial within the resin mixture.

2.2 Prepreg Production

Two different cases of composite panels were manufactured for this study: control containing no nanomaterial reinforcement and ZT-CFRP. All prepreg used for the panels was manufactured through a proprietary production process developed by the Hsiao research group at the University of South Alabama that is illustrated within a pending patent application US20240149541A1 [16]. Both control and ZT-CFRP utilized a base blend of Epon-862 and Epikure-W mixed at a stochiometric ratio of

100:26.5, respectively. For the ZT-CFRP prepreg, CNF was added at 0.5 wt% of the overall resin matrix mixture. Both Disperbyk-191 and Disperbyk-192 were added at a ratio of 1:1:1 with CNF for better dispersion within the mixture. The resin mixture used for control prepreg manufacturing only contained Epon-862 and Epikure-W.

Both the control and ZT-CFRP resin mixture underwent five minutes of manual stirring once the components were measured out and combined as appropriate. For the ZT-CFRP mixture that contained nanomaterial reinforcement and surfactants, one hour of high shear mixing at 900 rpm using a Stir-Pack Laboratory Mixer was performed. The rotational direction of the mixer was alternated after 30 minutes. The high shear mixed reinforced resin then underwent two hours of sonication using a QSONICA Q700 sonicator. This step was taken to further disperse and reduce agglomerations of CNF within the resin mixture. A sample of the resin mixture was taken after this step to determine the quality of CNF dispersion underneath a Nikon Eclipse LV 150 microscope. Figure 2 provides an image of the final CNF dispersion quality within the resin mixture prior to moving to the next step of prepreg production.

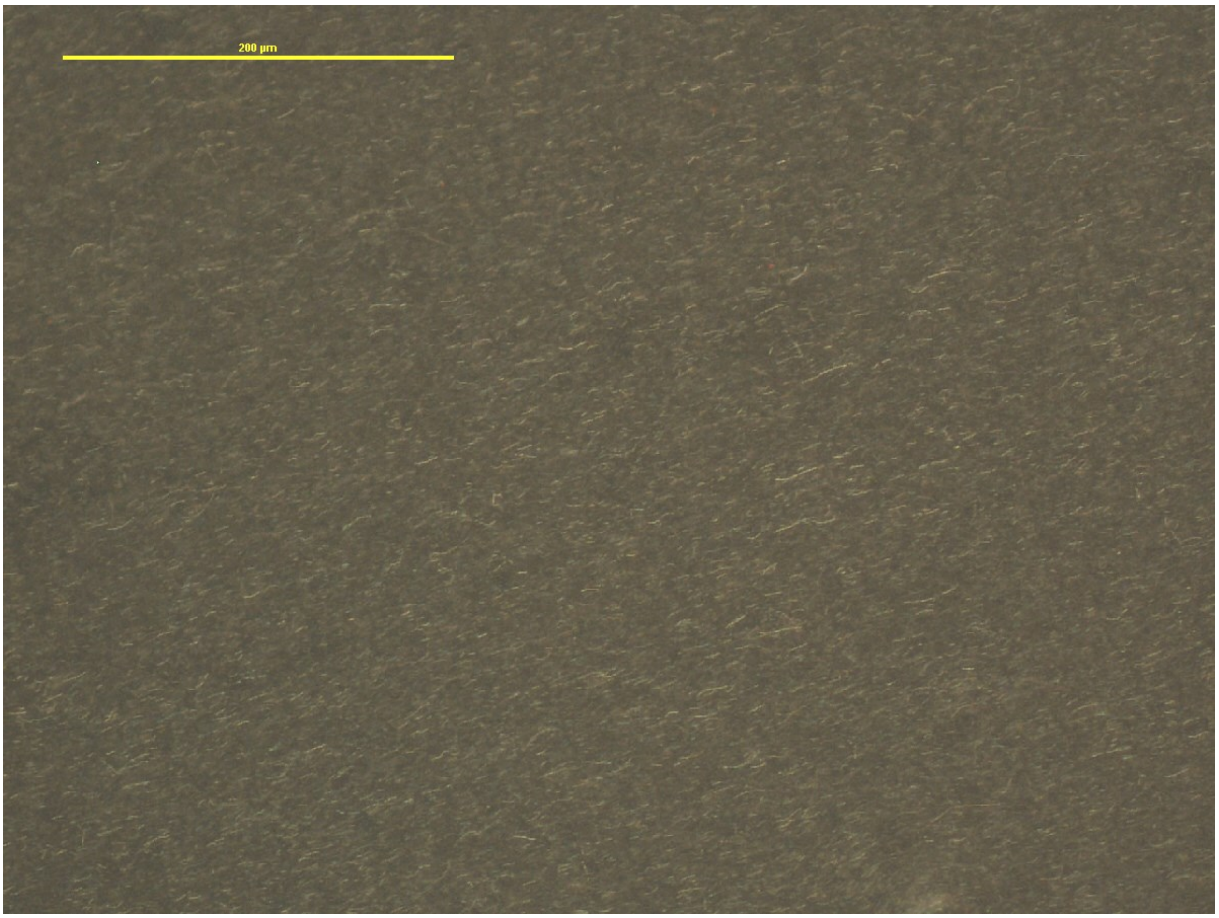

Figure 2: A microscope image showing dispersion quality of the CNF within the resin blend prior to prepreg manufacturing.

The appropriate amount of Epikure-W curing agent was added and manually stirred for 5 minutes into the dispersed CNF mixture to begin the B-staging process. The blend was then placed for approximately 1 hour inside a vacuum oven at 110 ˚C and -0.09 MPa. The vacuum applied to the resin during this process allowed for the removal of any trapped air within the mixture while also allowing it to partially cure. The control resin mixture also underwent the same B-staging process once Epikure-W was added.

The partially cured resin mixtures were then used in the proprietary ZT-CFRP prepreg production line to create hot melt resin films. An additional alignment process was performed to orientate the CNF reinforcement within the ZT-CFRP film. Alignment is accomplished through reinforced film

exposure to an electrical field for 150 seconds. The hot melt films created for both cases were then used to impregnate dry AS7 fiber fabric arrays. The alignment quality of the created ZT-CFRP prepreg was checked underneath a microscope. An example image of aligned prepreg is provided in Figure 3. Figure 4 provides a diagram detailing the process of making prepreg from start to finish.

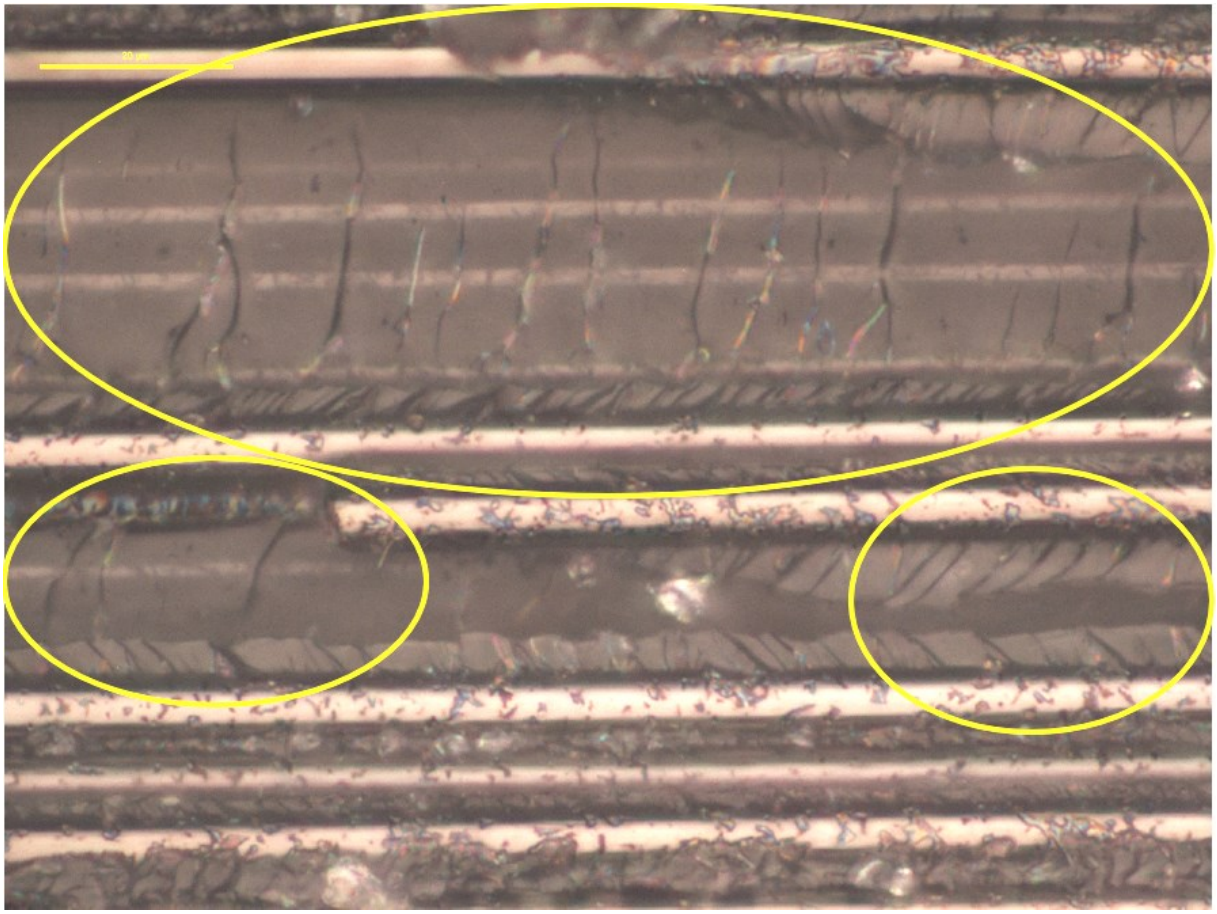

Figure 3: A microscope image of CNF alignment between carbon fibers (lines that are running horizontally) taken from a cured sample of prepreg

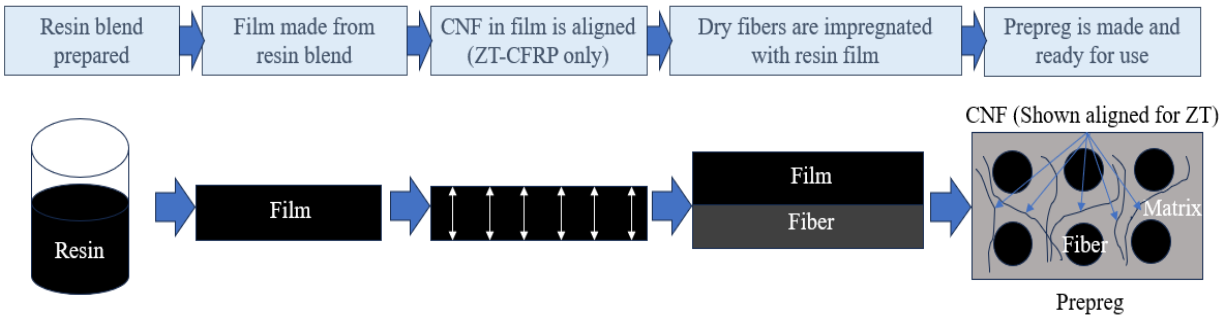

Figure 4: The prepreg making process is detailed in the diagram from preparing the resin blend to making prepreg.

2.3 Composite Panel and Test Specimen Production

The prepreg for both cases was cut into 127 mm x 127 mm sheets. Prepreg stacks of 16 plies were prepared by hand for both test cases. The prepreg was laid unidirectionally for both cases. The stacks were then cured using the out-of-autoclave vacuum bag-only (OOA-VBO) process detailed in Figure 5. In this process, an individual stack of prepreg is placed onto a release agent coated metal plate and is then covered by a vacuum bag after the peel ply, breather fabric, and other components are laid sequentially as shown in Figure 5. A vacuum pressure of -0.09 MPa was applied to the OOA-VBO assembly. A hot press was utilized to provide the necessary curing temperatures. The hot press was only used to simulate an oven and did not exert any force onto the OOA-VBO assembly. The temperatures and pressures utilized during the curing cycle for both composite panels are provided in Table 1.

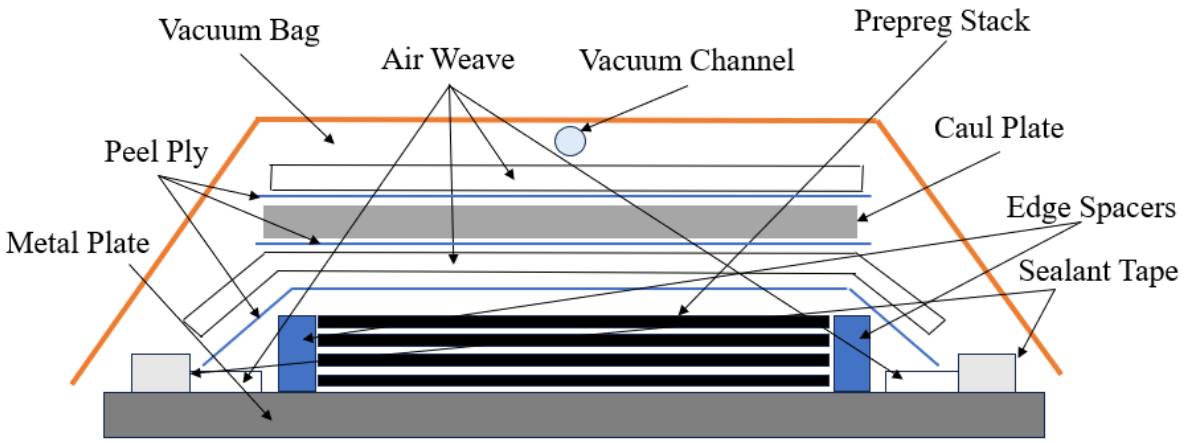

Figure 5: The OOA-VBO assembly and components are detailed in the diagram.

Composite Laminate Curing Cycle		
Time	**Temperature**	**Vacuum Applied**
60 minutes	22 ˚C (Room Temperature)	Yes
120 minutes	120 ˚C	Yes
360 minutes	180 ˚C	No

Table 1: The curing cycle that was utilized for manufacturing both the control and ZT-CFRP composites used in this study.

Once fully cured, the 127 mm x 127 mm laminate panels were cut to produce samples that fulfilled the criteria specified by the ASTM D2344 standard for SBS testing of fiber reinforced composites. The standard recommends the ratio between specimen thickness, width, and length should be 1:2:6, respectively [9]. With 16 plies, the nominal thickness of the two composite panels made for this study was 2.5 mm. Based off the recommendation by ASTM D2344, the dimensions of the test specimens were approximately 2.5 mm x 5 mm x 15 mm. The 15 mm length was parallel with the direction of the fibers. The ASTM D2344 standard requires that at least five specimens for each case are tested.

2.4 Specimen Heat Treating

An FB1400 model muffle furnace made by Barnstead Thermolyne Corporation was used for heat treating the test samples at 350 ˚C. The chamber was first preheated to 370 ˚C. The test specimens were put on a ceramic tray to be inserted within the chamber of the furnace. Once the chamber temperature stabilized, the ceramic tray with the specimens was placed inside the furnace. After two minutes of the ceramic tray being placed inside the chamber and the furnace door closing, the temperature setting of the oven was reduced to 350 ˚C. This heating procedure allowed the temperature of the specimens to rapidly increase to and hold at the desired exposure temperature of 350 ˚C. After 10 minutes within the furnace chamber, the ceramic tray and specimens were removed and allowed to cool to room temperature. Only five specimens at a time were heated within the furnace.

2.5 SBS Testing

The short beam shear tests done for this study were done using a Tinius Olsen 10ST universal testing machine. The loading nose and supports of the testing apparatus were both in compliance with ASTM D2344 with diameters of 6 mm and 3mm, respectively. The ASTM D2344 requires that the ratio between span length, or the distance between supporting pins, be four times the thickness of the testing specimen [9]. Since the testing specimens used in this study had a nominal thickness of 2.5mm, the span length was set to 10 mm. The crosshead movement rate of the loading nose was also in compliance and set at a rate of 1.0 mm/min. Data on the position of the loading crosshead and force during testing was output. Figure 6 provides a picture of the testing setup used for this study.

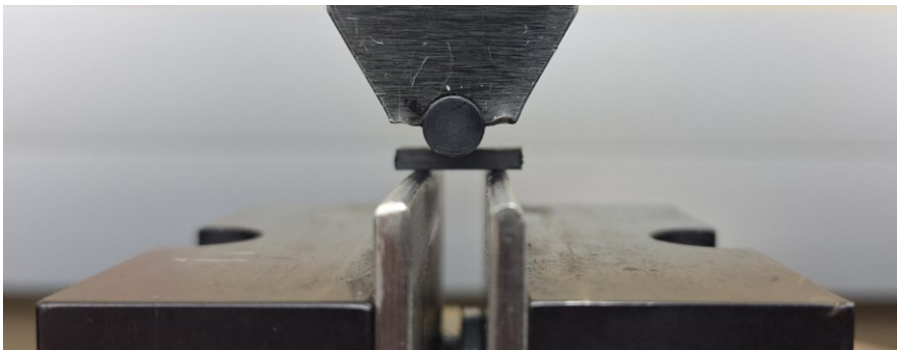

Figure 6: Photo of the SBS setup that was used for this study with a sample loaded.

3 RESULTS

3.1 Testing Data

The force testing output data was used to find the interlaminar shear stress acting on the specimens during SBS testing using the following formula from ASTM D2344:

$$F^{sbs} = 0.75\, x\, \frac{P}{b\, x\, h} \tag{1}$$

Where F^{sbs} is the interlaminar shear stress, P is the force due to the loading, b is the testing specimen width, and h is the testing specimen thickness [9]. The calculated stress values and crosshead displacement data from testing are plotted in Figure 7 for all four cases of specimens tested: control at room temperature, control after being heat treated at 350 ˚C, ZT-CFRP at room temperature, and ZT-CFRP after being heat treated at 350 ˚C

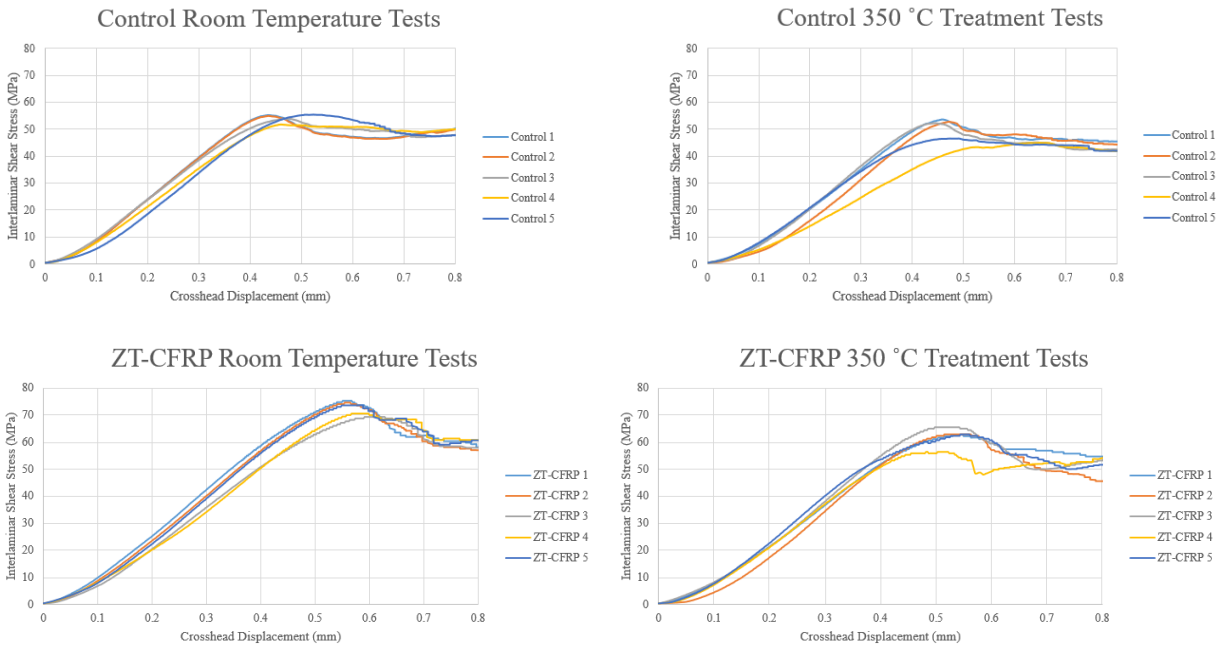

Figure 7: Crosshead displacement and interlaminar shear stress curves taken for the tested specimens.

The ILSS for each test sample is recorded in Table 2. The average ILSS for room temperature and 350 ˚C treated control CFRP samples was 54.253 MPa and 49.626 MPa, respectively. Based on the average control ILSS values, this was a 4.627 MPa (-8.53%) decline in strength after exposure to 350 ˚C for 10 minutes. A 10.584 MPa (-14.56%) decline in ILSS was observed between the average for room temperature and 350 ˚C treated ZT-CFRP samples, which was 72.676 MPa and 62.092 MPa, respectively. At room temperature, the average ILSS for ZT-CFRP was 18.423 MPa higher than that of control. Heat treated ZT-CFRP also had a higher average ILSS than heat treated control, with an observed 12.466 MPa difference between the two. It is interesting to note that the treated ZT-CFRP still had a higher ILSS (62.092 MPa) than that of the control CFRP without exposure of heat treatment (54.253 MPa).

ILSS (MPa)

3.2 Microscope Image Analysis

Tested specimens were viewed underneath a Nikon Eclipse LV 150 microscope to provide a visualization of what mechanisms may have contributed to the interlaminar failure and strength discrepancies between the four test cases observed. Figure 8 provides images taken along the end of two specimens: one control and one ZT-CFRP that received no heat treatment. As can be seen, a much smaller interlaminar crack formed within the ZT-CFRP sample in comparison to the control sample.

This was likely due to the reinforcing CNF z-threads that helped to resist the formation and propagation of a larger scale crack.

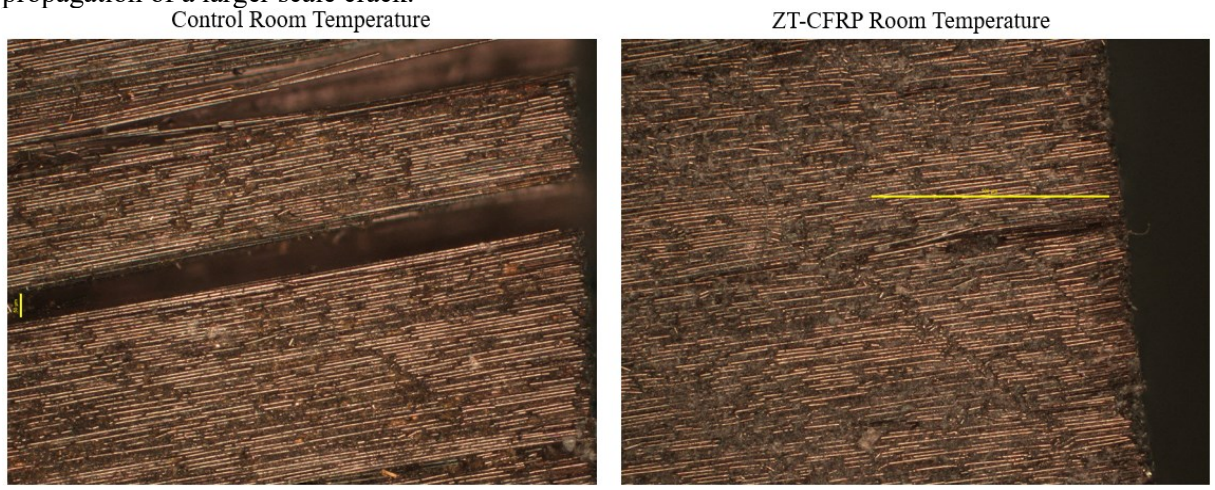

Figure 8: Images taken along interlaminar crack formed on the end of room temperature tested Control Sample 3*(left)* and ZT-CFRP Sample 5 *(right)*.

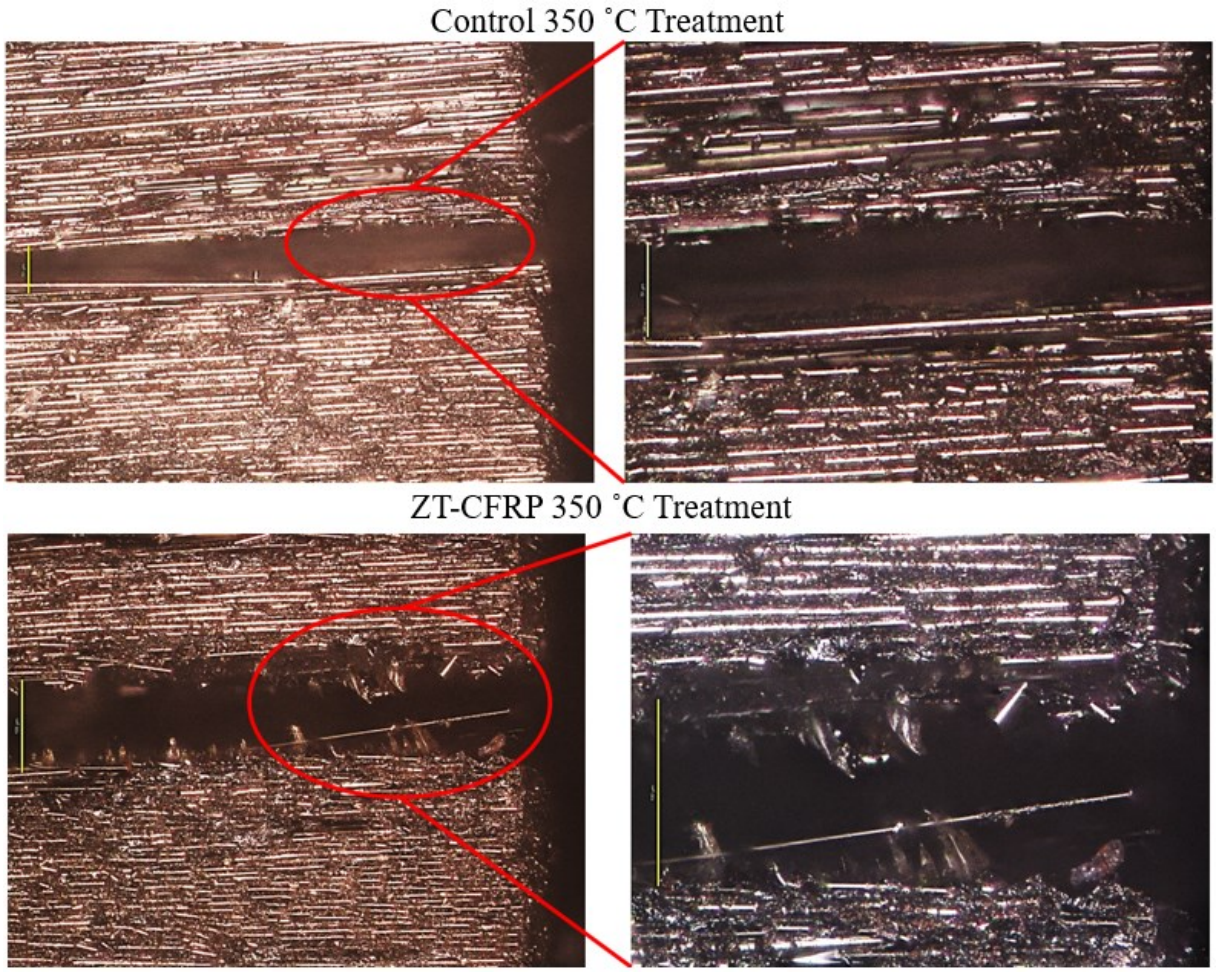

Figure 9: Images taken along interlaminar crack formed on the end of 350 ˚C treated tested Control Sample 1*(top)* and ZT-CFRP Sample 1 *(bottom)*.

Figure 9 shows images taken from two 350 ˚C pretreated samples: one control and one ZT-CFRP. As can be seen within the images taken along the interlaminar crack formation, the ZT-CFRP sample had a much more jagged edge in comparison to the control sample. Exposed CNF z-threads can also

be seen along the length of the crack formation. There also appears to be more misaligned carbon fibers near the interlaminar crack with the ZT-CFRP sample. The jagged edge, exposed z-threads, and greater fiber misalignment of the ZT-CFRP samples may help to support the argument made in the preceding paragraph that the CNF z-threads act as anchoring mechanism that resists delamination and interlaminar failure. The control samples only have the strength of the epoxy bond between layers to prevent delamination.

4 CONCLUSION

This study examined how the inclusion of CNF z-threads contributed to the retention of ILSS within CFRP composites after they have been exposed to extreme elevated temperatures. It was found that ZT-CFRP exhibited improved ILSS over traditional CFRP both with and without extreme temperature exposure. ZT-CFRP exhibited an average ILSS of 72.676 MPa without heat exposure and 62.092 MPa with a 350 ˚C heat treatment. The traditional CFRP samples exhibited an average ILSS of 54.253 MPa without heat exposure and 49.626 MPa with a 350 ˚C heat treatment. From the obtained ILSS data and microscope images taken of tested samples, there is evidence to suggest that the CNF z-threads provided a reinforcing mechanism that resisted interlaminar failure and crack propagation of the composite. This could be seen well in the extreme heat-treated samples where there was a diminished matrix due to thermal degradation. The CNF z-threads were apparent along the edges of the formed cracks and were likely significant contributors for ZT-CFRP heat treated samples still having higher ILSS than traditional CFRP samples that received no extreme heat exposure.

It was expected that the traditional CFRP samples would have a more diminished ILSS after heat exposure than was observed. This may have been a result of the CFRP samples being more resin dry in comparison to the ZT-CFRP samples despite having similar dimensions and being composed of the same amount of prepreg plies. There may have already been areas of diminished matrix in the CFRP samples in comparison to the ZT-CFRP samples that would not have been as affected by thermal degradation caused by the elevated temperatures.

The claims made in this publication can be further supported through additional testing in the future. Unaligned CNF reinforced CFRP would help to show that it is the z-threads and not just nanomaterial reinforcement that improves the ILSS capabilities. However, this has already been shown in samples with no extreme heat exposure [6]. Testing different exposure temperatures and/or times would also provide more insight into the effect of thermal degradation of the matrix on CFRP and ZT-CFRP interlaminar strength capabilities. Different CNF weight fractions could also better show the significance of z-threads for strength retention with smaller weight fractions likely not being able to retain ILSS as well as higher weight fractions.

InVIsion Carbon: Project Background

- What is Inductive sensing?
  - Eddy current testing (ECT)
  - Non-contact, non-destructive
  - Small electromagnets excite current flow within material; detect changes in the magnetic field produced by the material
- What can it do?
  - Fibre orientation, stacking sequence, local fibre volume fraction, consolidation, missing tows, sub-surface waviness.
- What is the current state of the technology?
  - Limited versatility in commercially available ECT systems
  - Limitless possible CFRP components with fixed sensor properties

Position history of Eddy current scans over a defect

Eddy current scan image formed by combining multiple scans

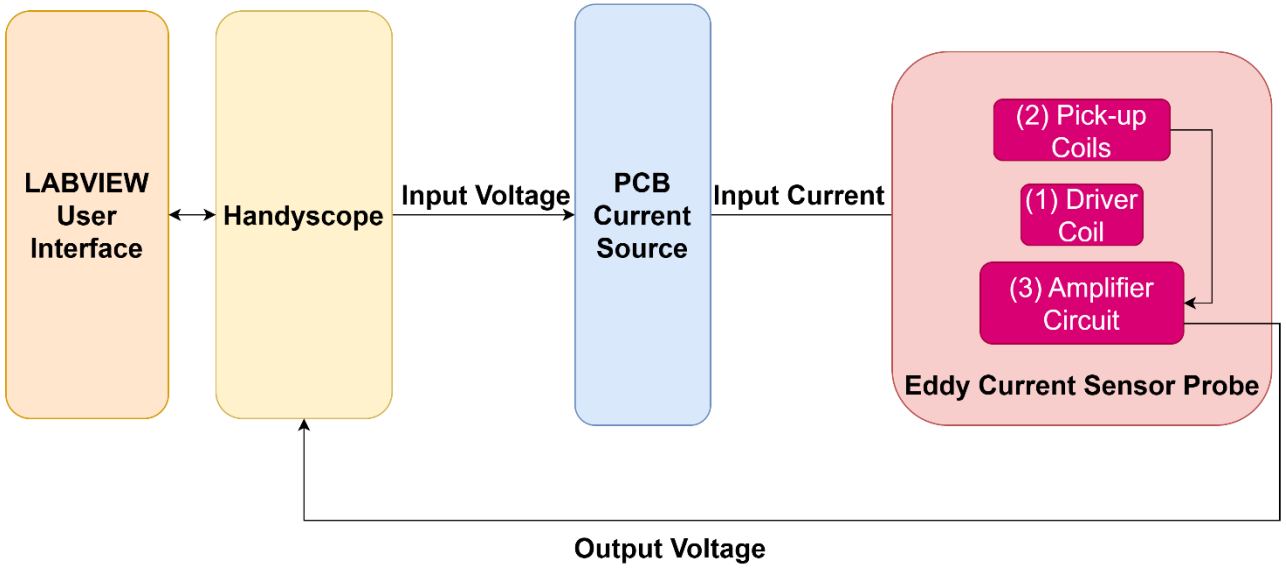
InVIsion Carbon: Project Overview

- Challenge
  - In-line ECT monitoring in realistic CFRP manufacturing environments
  - Quantify and minimise noise and measurement uncertainties
  - Characterise sensitivity to material properties or features of interest

- Project Aim
  - Demonstrate and evaluate ECT on two automated manufacturing applications: **Automated Tape Laying** and **Filament Winding**

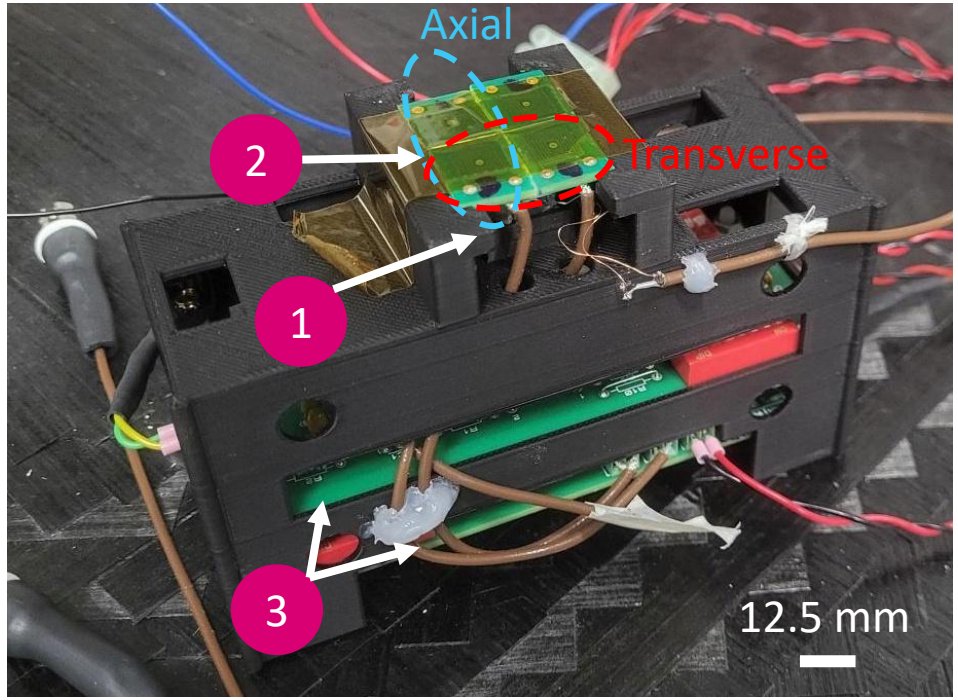
- Benefit
  - Non-contact, allowing for in-process inspection
  - High speed, applicable to industrial scale manufacturing
  - Quality monitoring, enabling early detection of manufacturing flaws
  - Improved manufacturing rates, due to reduction in inspection times

Integration of the Eddy-current probe in the ATL application



Integration of the Eddy-current probe in the FW application

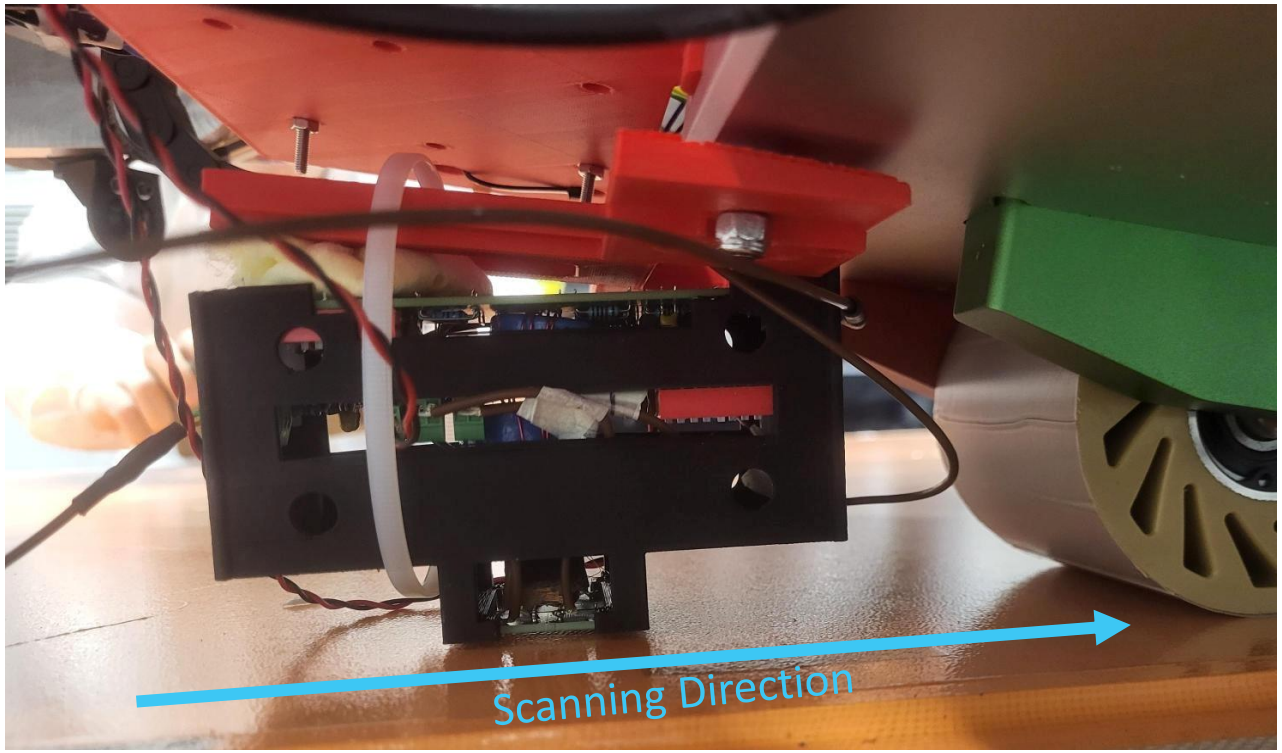
Eddy Current Sensing Probe



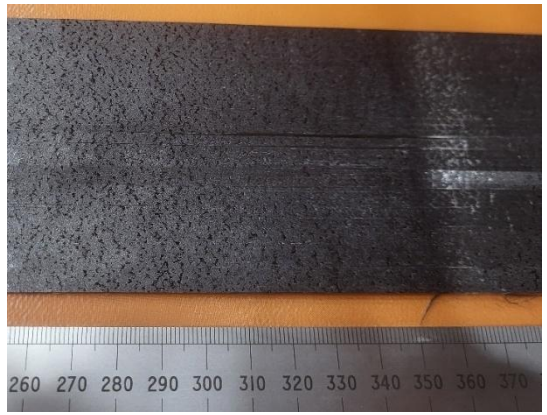
The Eddy current sensing probe consists of three main components, including;

1. Driver coil to generate magnetic field
2. Pick-up coil to detect changes in the magnetic field, positioned in axial and transverse orientations.
3. Amplifier boards to on-board process the signal

Signal generated by the probe are transmitted to an USB oscilloscope (Handyscope) and interfaced via a LABVIEW PC program over USB

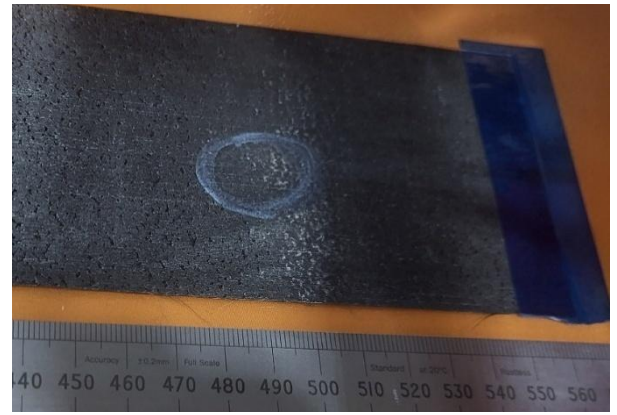


Electrical integration of the Eddy current sensing probe

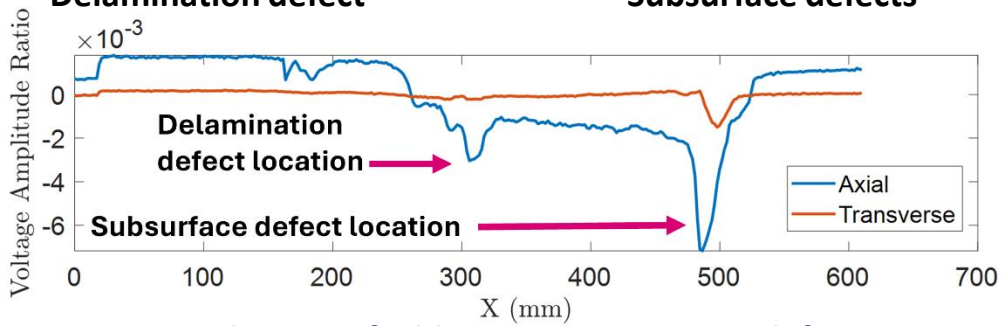


The Eddy current sensing probe with its key components highlighted

EC in Automated Tape Laying

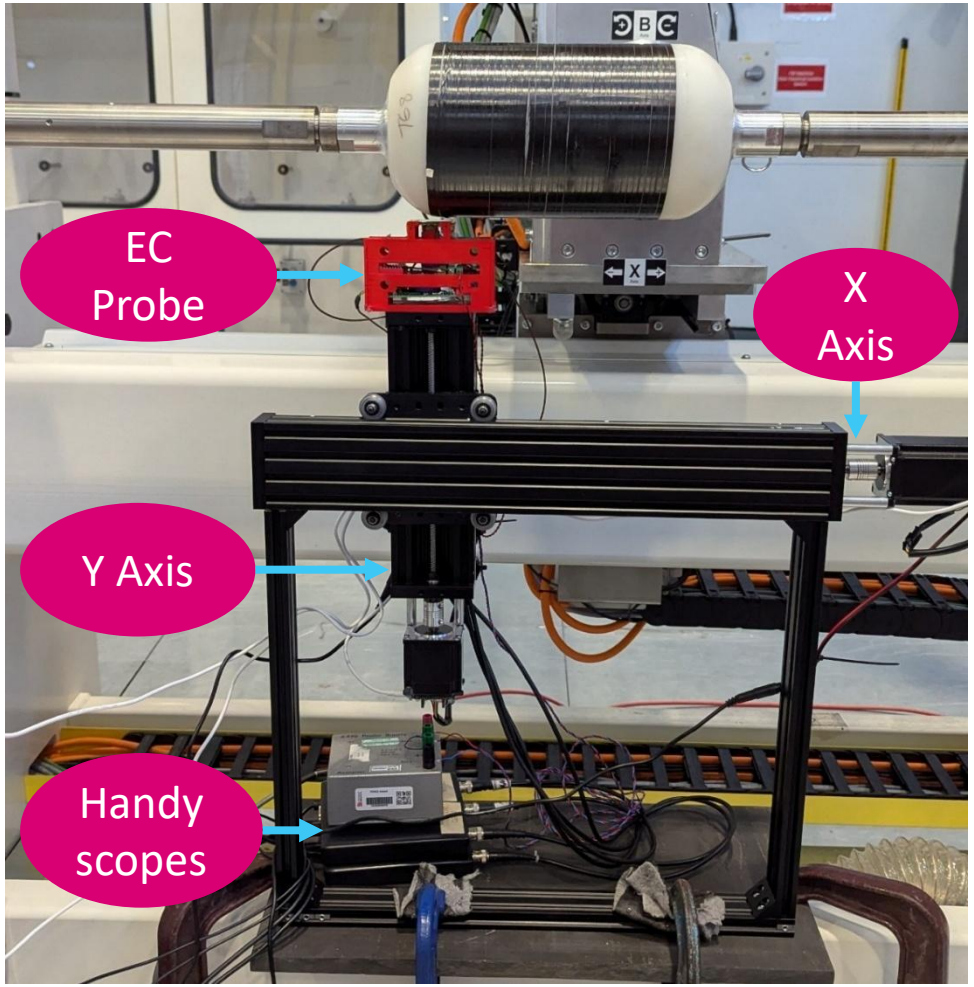


Within the ATL application, the eddy current sensor was optimised and integrated into the ATL machine, and was proven to detect features including: Apparent defects (Delamination) and Subsurface defects
However, due to material availability and the project timelines, the data collection effort was shifted to the FW application.

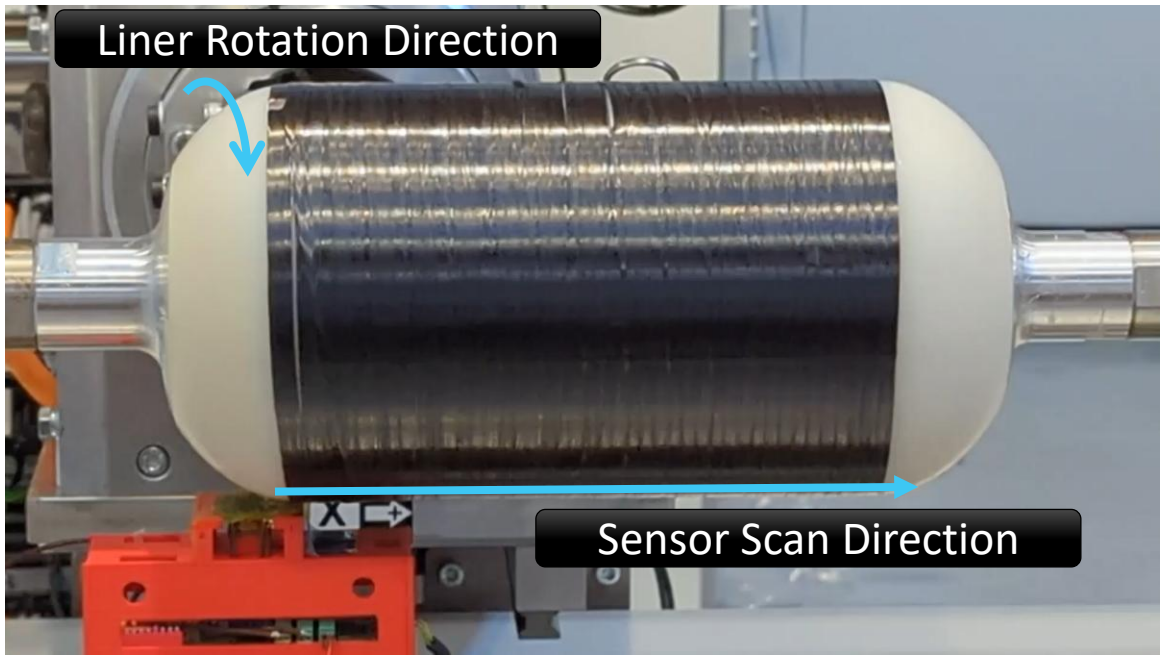


EC Sensor integrated into the ATL Machine

Delamination defect



Subsurface defects



Position history of Eddy current scans over defects in ATL

Filament Winding Sensing Bench

The FW Sensing Bench positioned within the cell

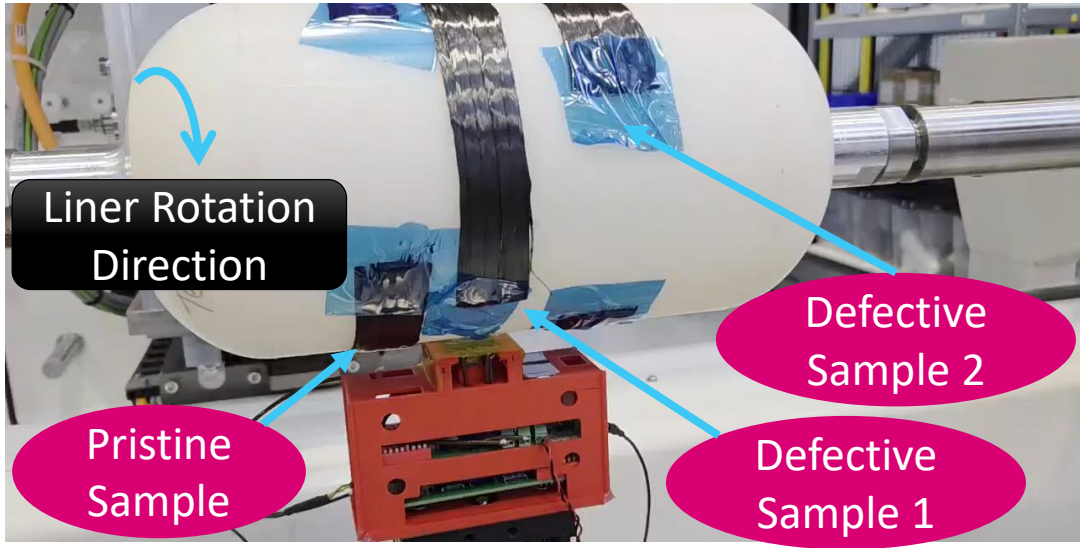
The operating principles of the FW Sensing Bench

A sensing bench was developed, featuring;

1. X axis for continuous movement across the liner
2. Y axis to automatically adjust the lift-off from the material surface

During scanning, the liner was continuously rotated as the probe scanned. This allowed for the complete characterisation of the liner.

Initial Defect Testing

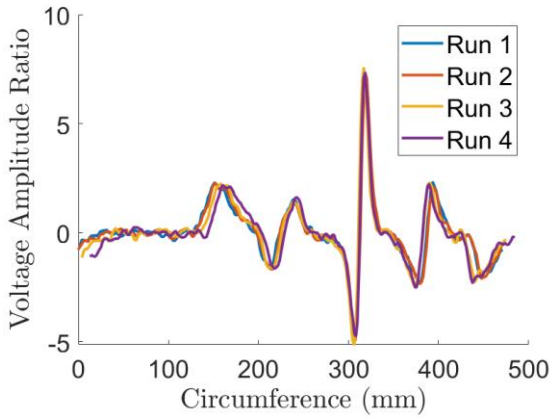


To test the effectiveness of the sensor, samples with apparent defects were generated, featuring;

1. In-plane waviness defects generated by hex keys, which were used to create wrinkles of 0.5 to 4 mm. These wrinkles were pushed perpendicular to the fibre direction after the hex keys were removed, and covered by a secondary layer of tow-preg to create subsurface defects.
2. A pristine defect-free sample for comparison.

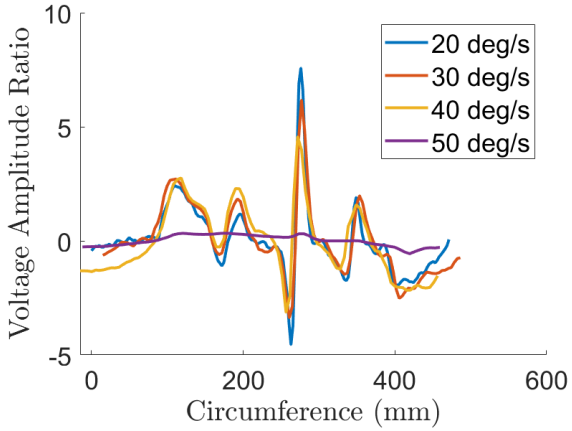
The samples were scanned with the sensing probe stationary and rotating the liner at a constant speed.

Generating in-plane waviness of varying sizes within the tow-preg samples



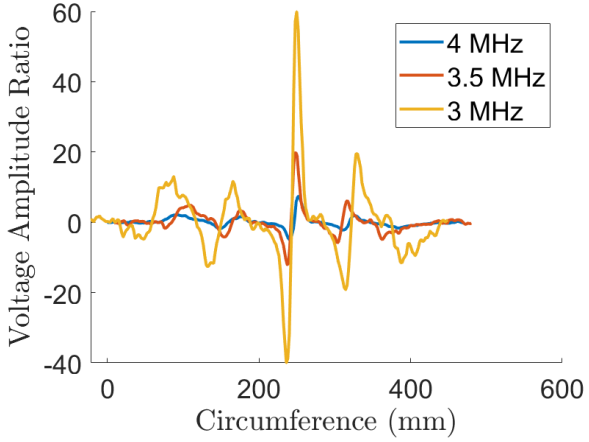
Scanning the pristine and the defective samples with the FW sensing bench stationary

Initial Defect Testing –Results

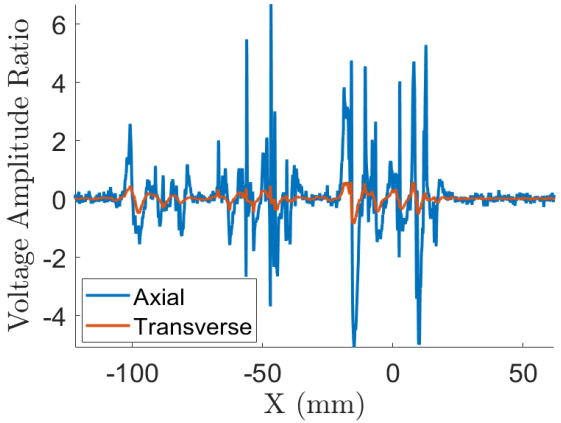


Initial calibration results showed that;

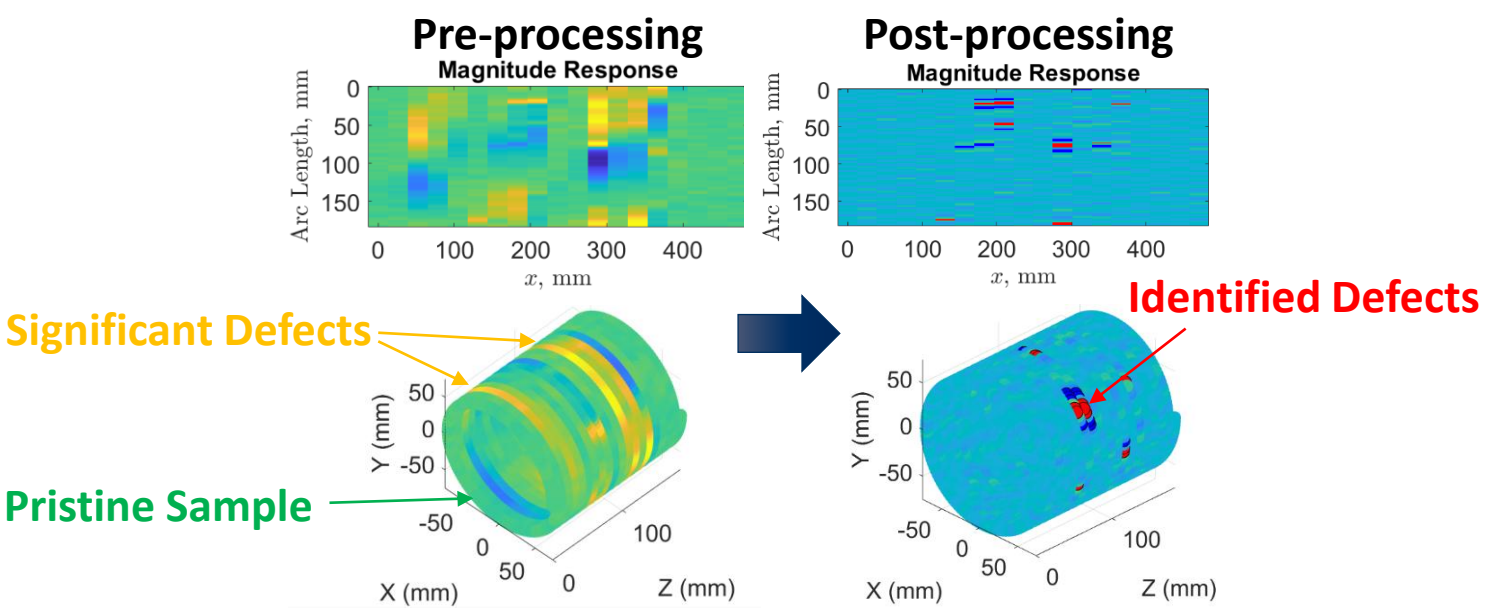
1. The data collected are repeatable across multiple runs.
2. High quality defect data can be collected up to 40 deg/s (6.67 RPM), corresponding to a linear speed of 52 mm/s.
3. The sensor response improved at operating frequencies closer to 3 MHz.
4. When the sensor is actuated as the liner rotates, the complete geometry can be scanned (continued in the next slide).



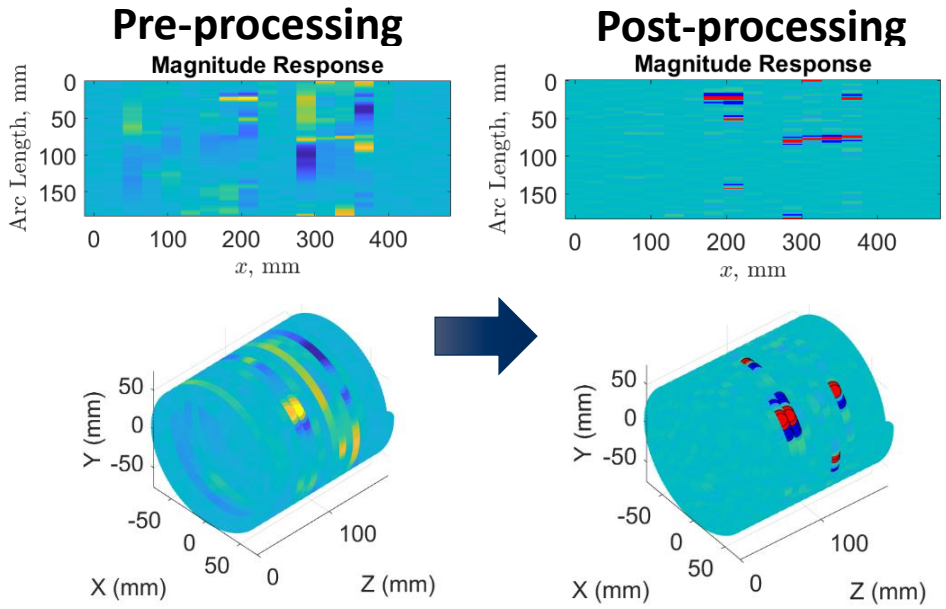
Repeatability Testing



Varying Speed



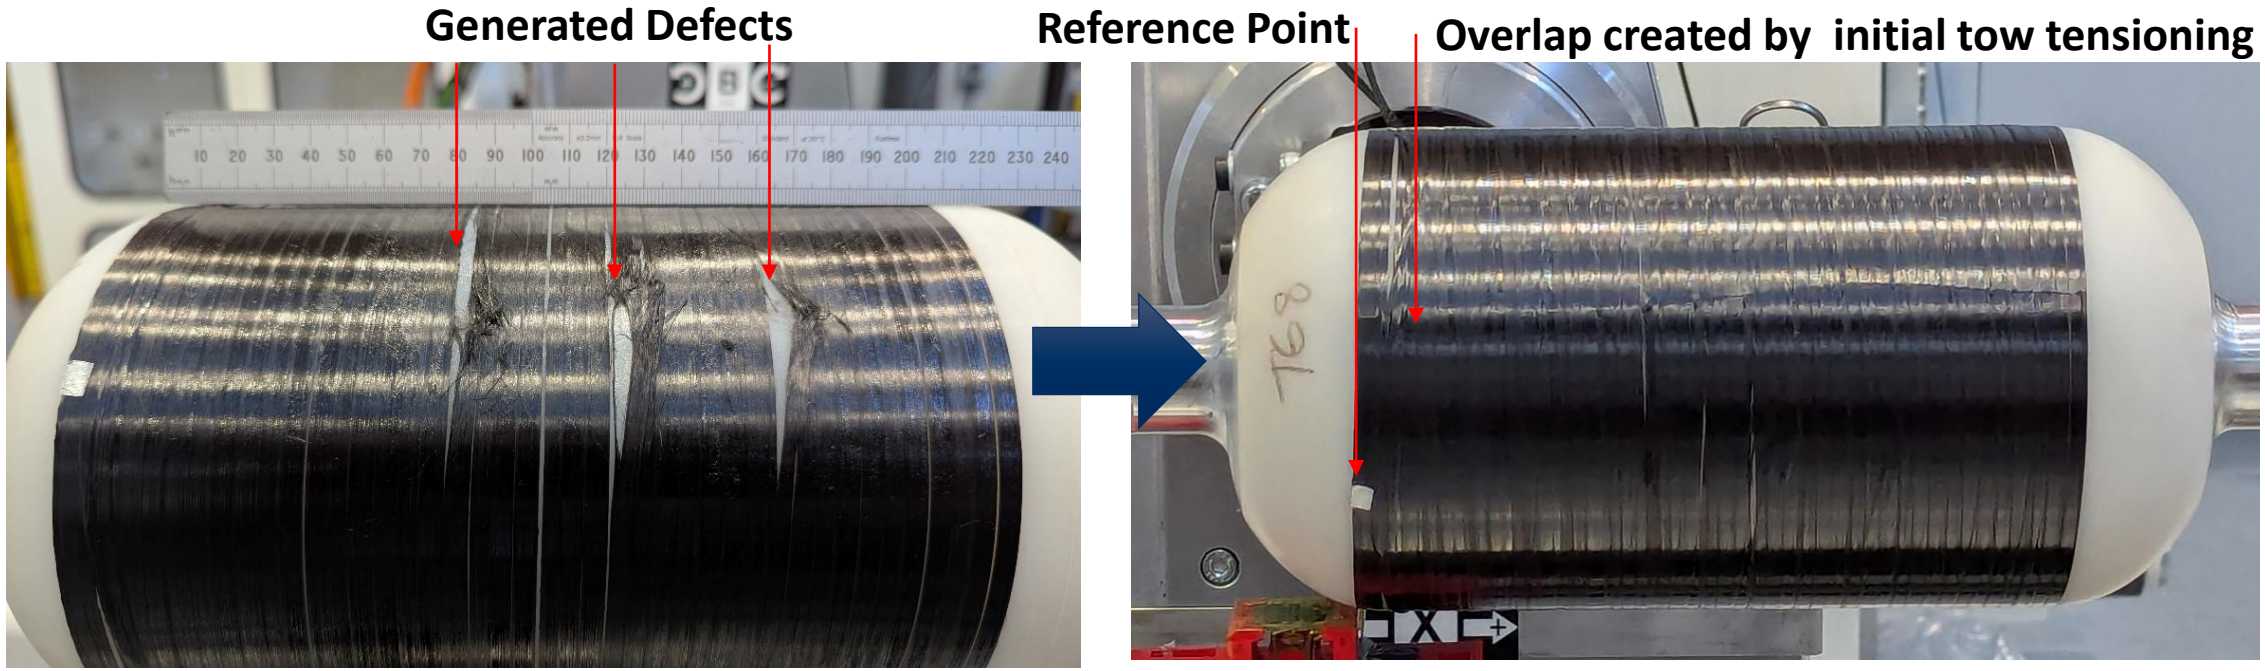
Varying Frequency



Scanning while Moving

Initial Defect Testing –Scan While Move

Axial Response



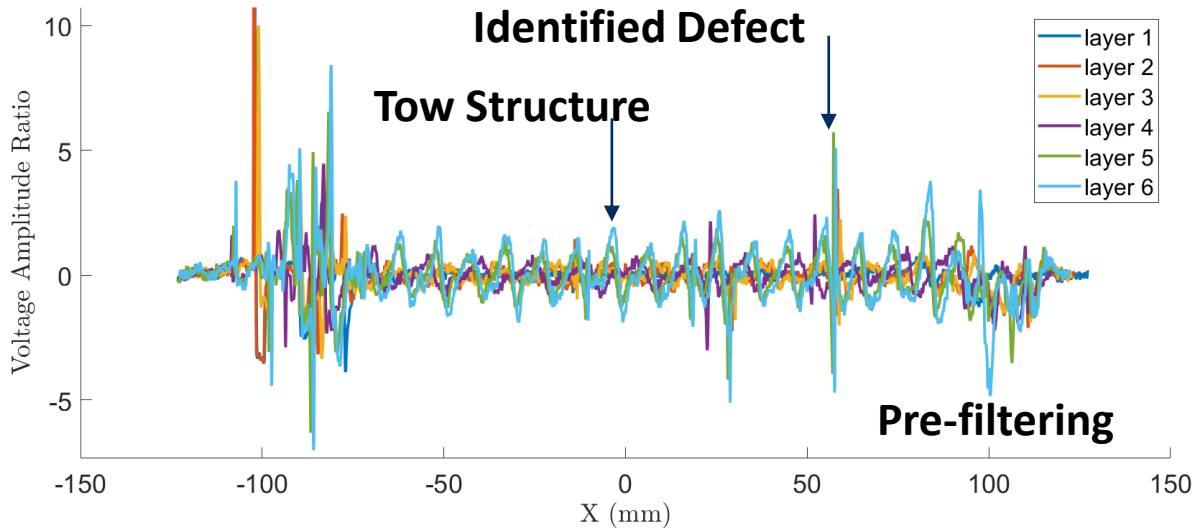
Transverse Response

By actuating the sensor while rotating the liner, defects and tow structure within the geometry were identified, where;

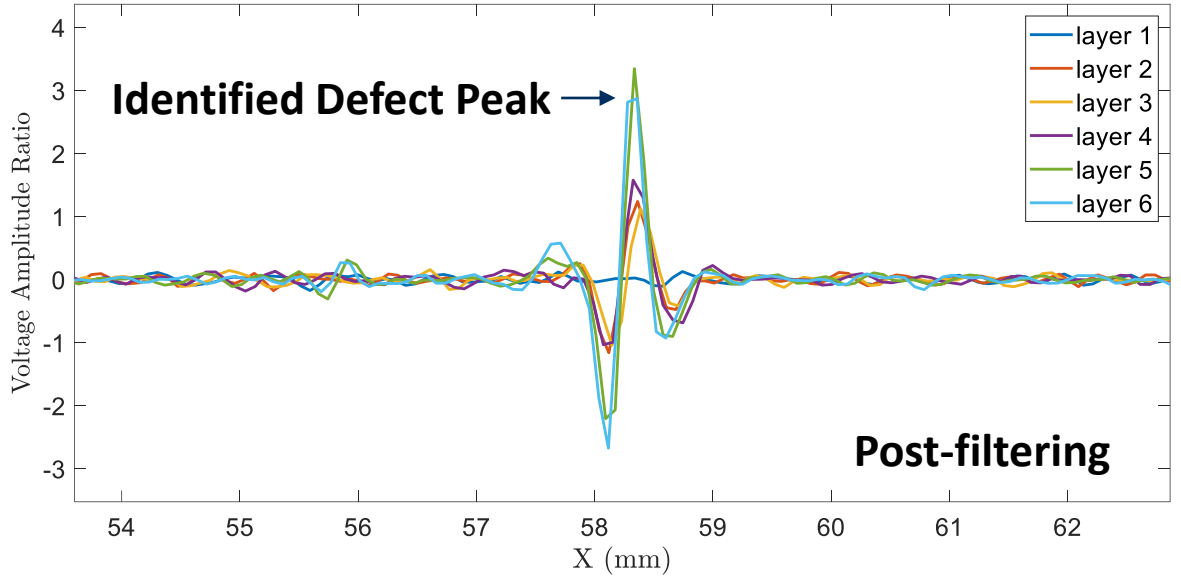
1. It was observed that the axial sensor responded more to the major changes in the tow structure (such as gaps in-between the tows) whereas the transverse sensor responded to the in-plane waviness more.
2. Post-processing allowed for subtracting the underlying tow structure and identifying locations of defects.

Multiple Hoop Layers Deposition

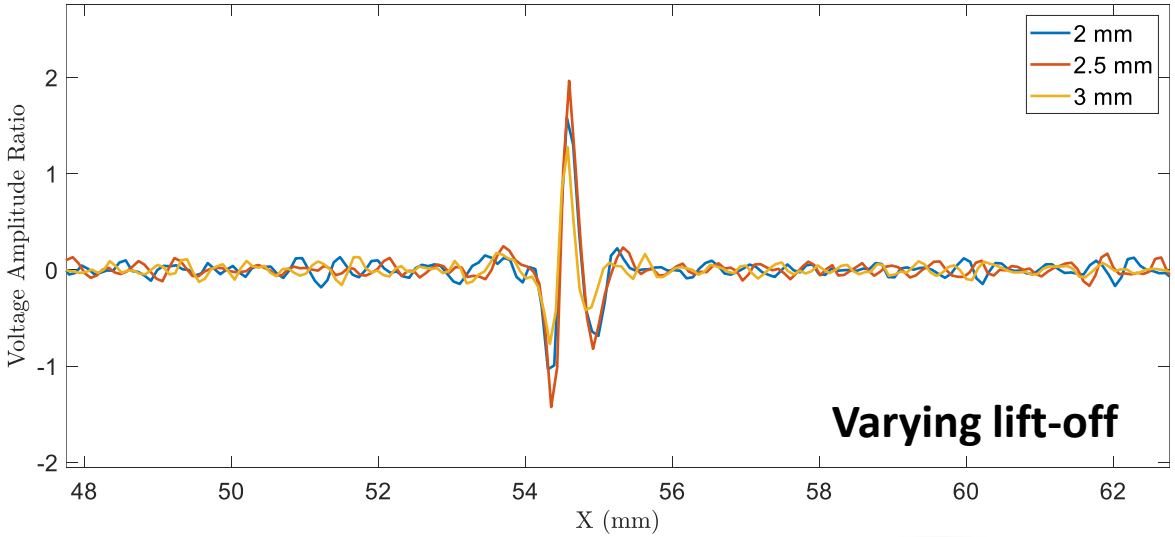
Defects generated in the first hoop layer



Covering the defects with multiple hoop layers



Following the initial calibration, multiple hoop layers were deposited to assess the effectiveness of the sensor, where;



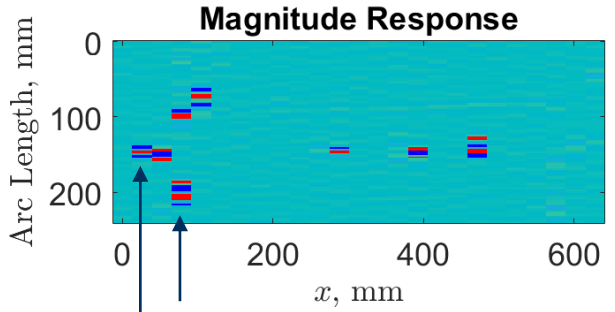
1. An initial hoop layer was wound around the liner and several defects were embedded, along with a reference point.
2. This initial layer with defects was covered with multiple layers (six with the first layer) to assess the effectiveness of the sensor in detecting underlying defects.

The geometry was scanned at each layer for incremental quantification, along with optimising the lift-off from the surface.

Multiple Hoop Layers

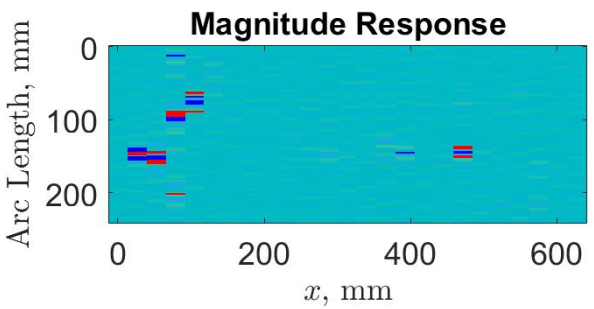
Scans of the multi-layer hoop geometry showed that;

1. Defects and tow structure visible after multilayer depositions.
2. EC response increased after multiple layers were deposited (possibly due to better contact between layers).
3. An optimum lift-off of 2.5 mm from the surface should be aimed for ideal response.



Multiple Hoop Layers Deposition

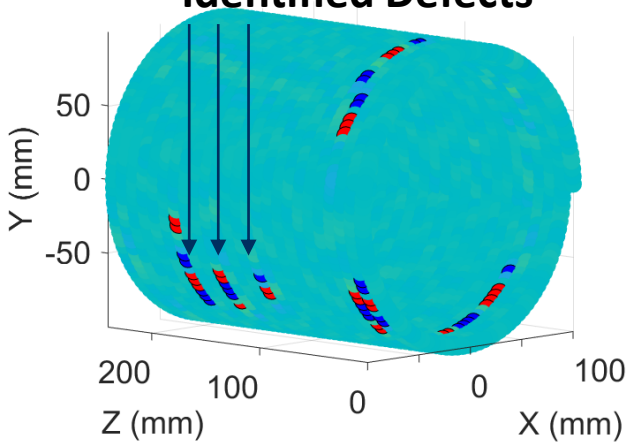
Applying post-processing to the sixth layer scan and analysing the complete geometry also showed that;



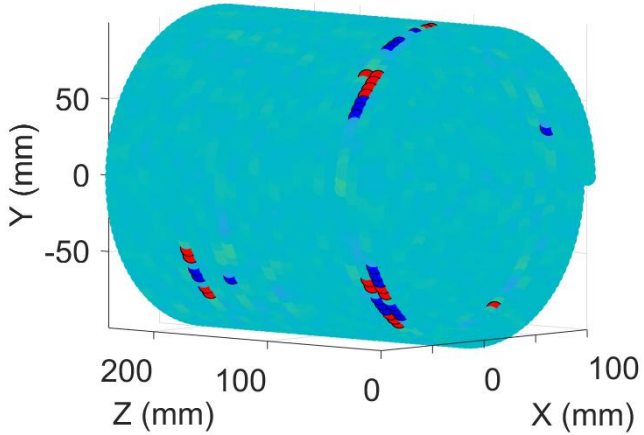
1. The axial sensor was able to identify all three defects, the reference point, and the initial tow tensioning defect even after five consecutive layers were deposited.
2. The transverse response can identify only some of the features, which could be due to the nature of the defects generated (in-plane waviness).
3. Tow structure can be subtracted by applying the post-processing to highlight only the defects.

This demonstrated the sensors capability in detecting sub-surface defects, as well as providing information regarding the nature of the defects detected.

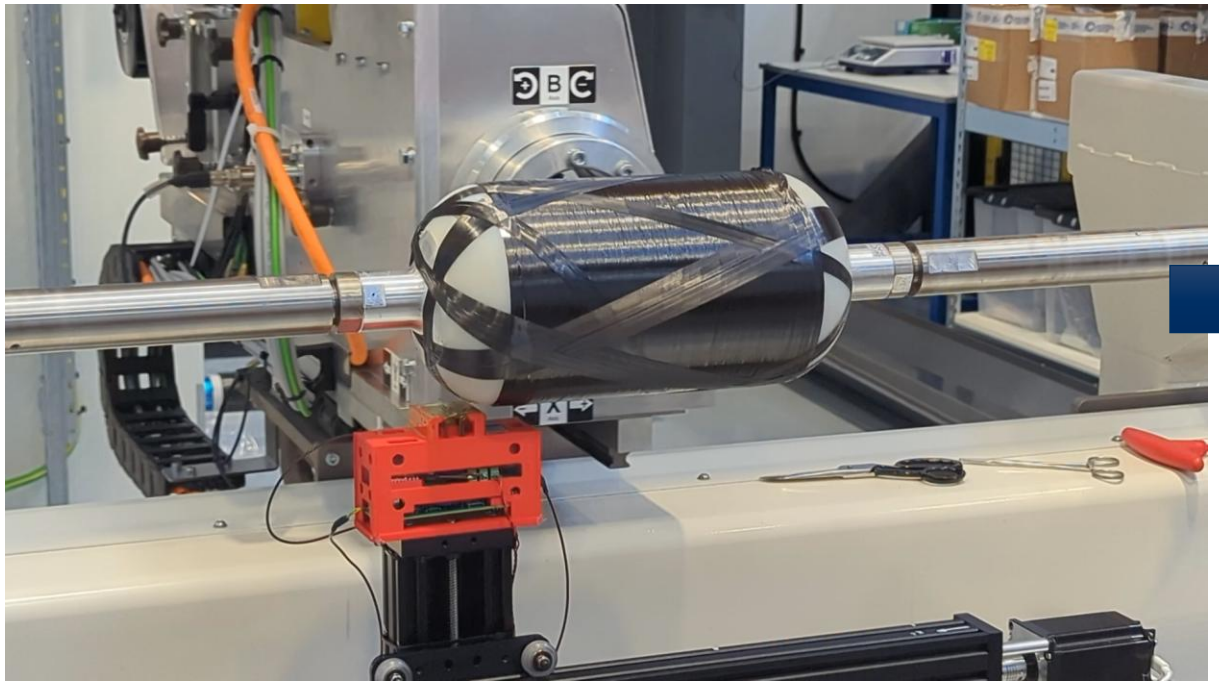
Axial Response



Transverse Response

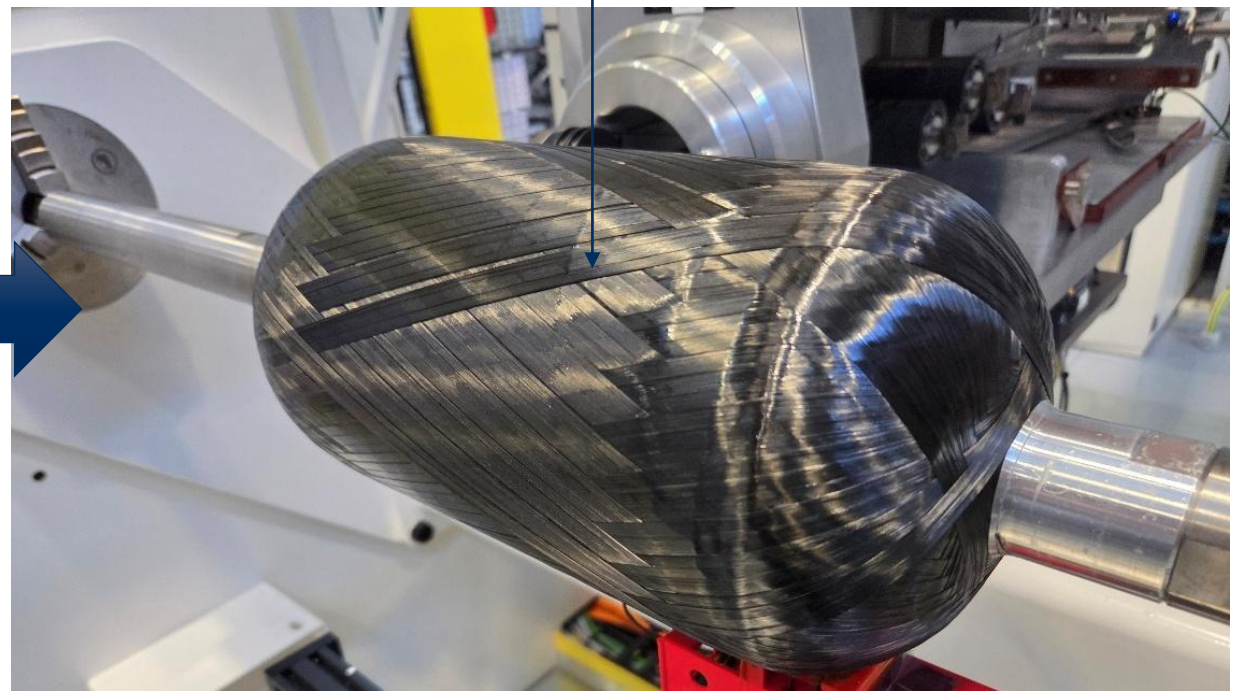


Tow Tensioning Defect



Reference Point

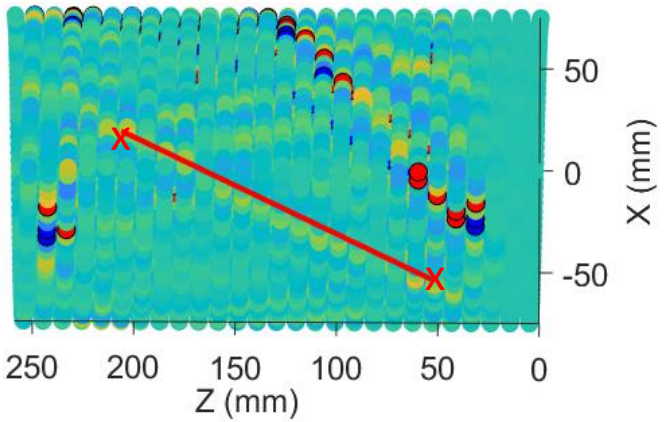
Identified Defects



Depositing 22 Degree Layers

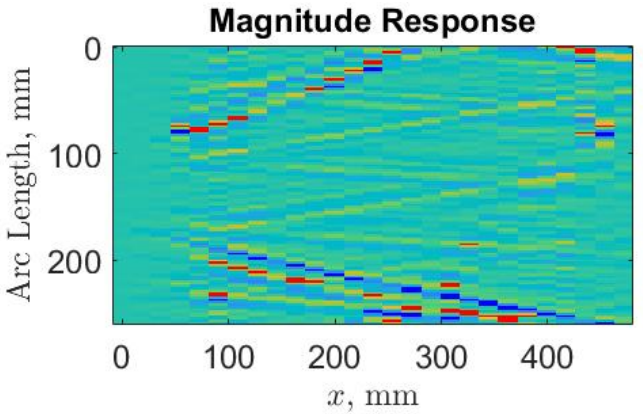
Winding the 22-degree layer on the geometry

22-degree layer after deposition

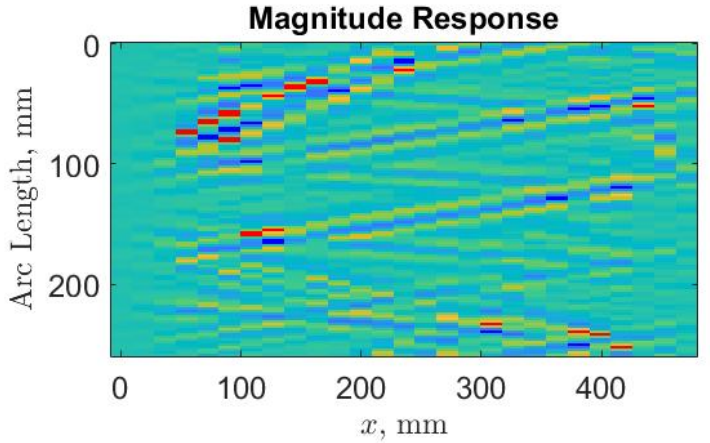


Following the hoop-layer investigation, a 22-degree layer was deposited on top of the hoop layers, where;

1. The material was wound onto the liner after the technician adjusted the machine, resulting in a down-time. This could be a window to EC scans in a live implementation.
2. The wound geometry was scanned using the previous methodology.

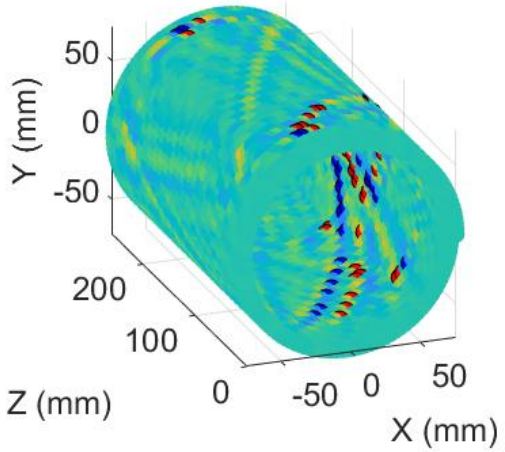


Depositing 22 Degree Layers

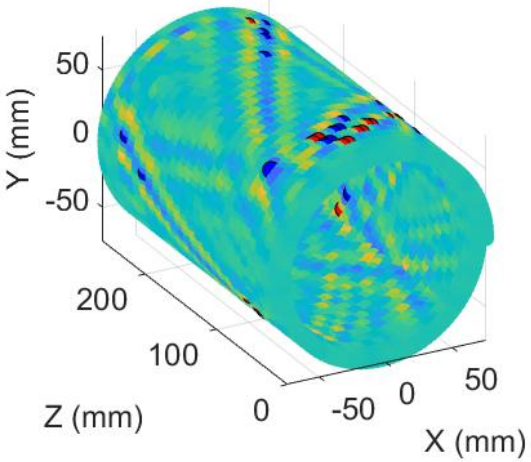


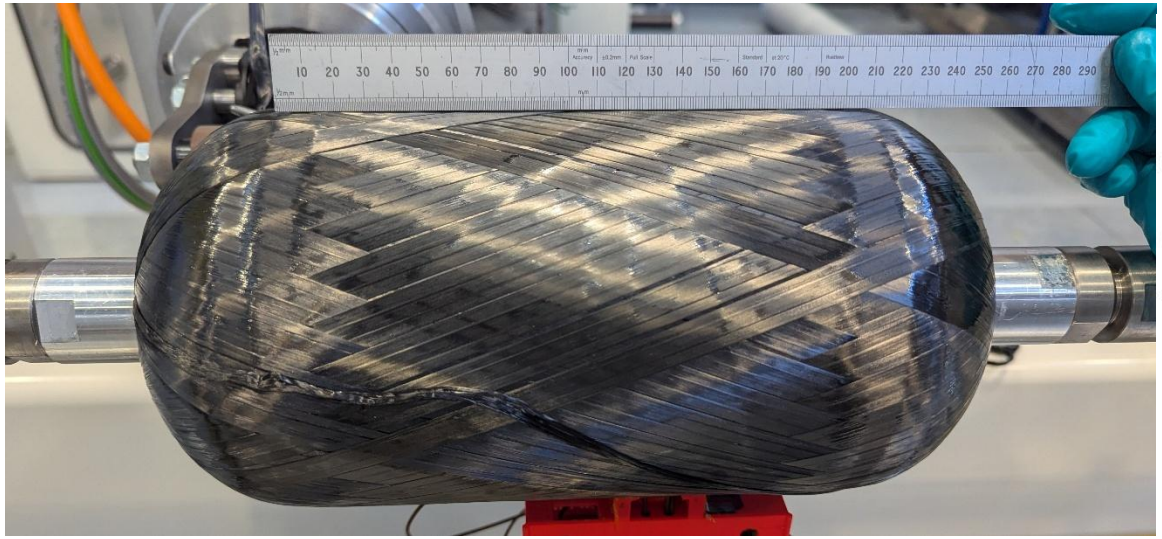
Post-processing the scans after the deposition demonstrated that;

1. Several features were highlighted as defects, which could correspond to gaps, overlaps, end points of the deposition, as well as defects in the underlying layers.
2. The EC data can be used calculate deviations in the tow angles by tracing the detected features.



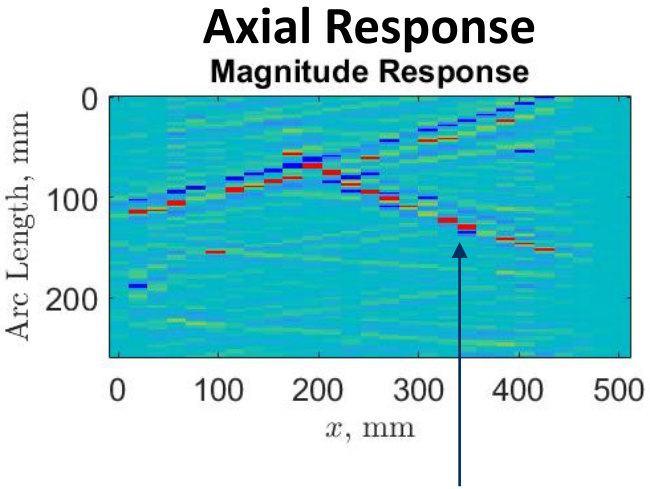
$$\tan^{-1}\frac{(0-55)}{(50-200)} = 0.34\,rad = \sim 20\,deg$$



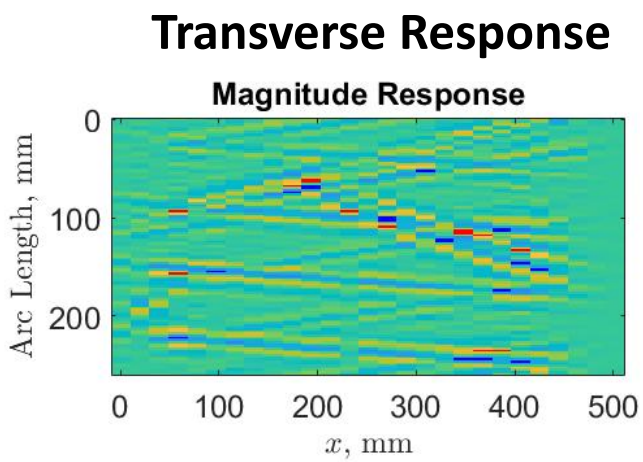


Axial Response

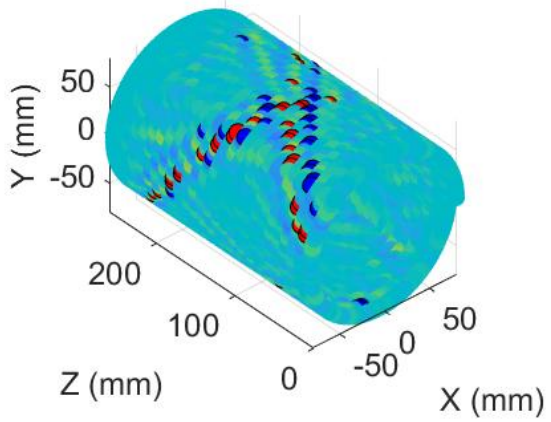
Transverse Response



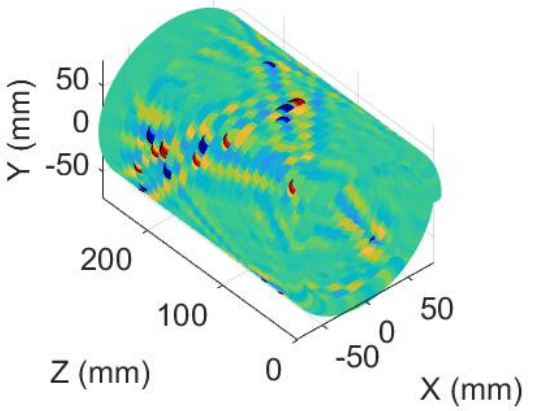
Depositing 22 Degree Layers



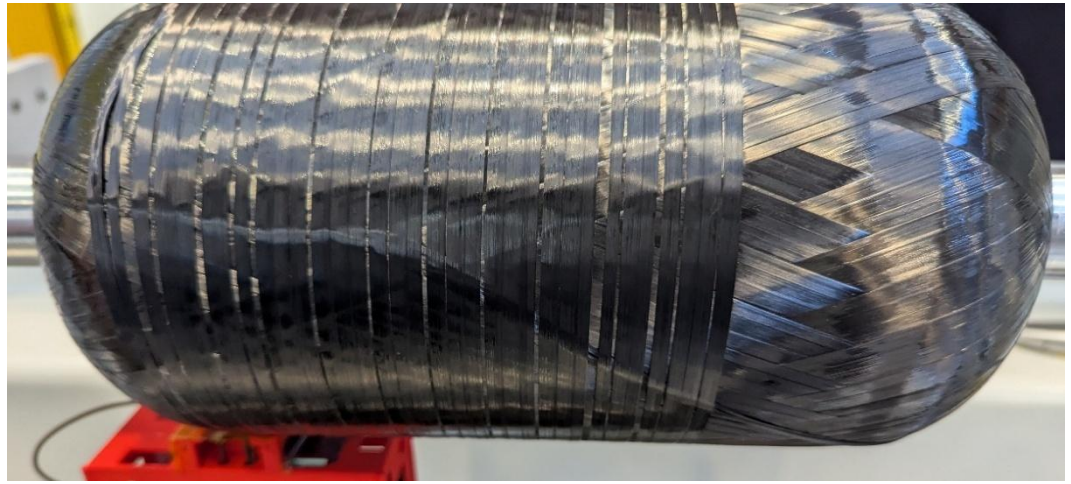
Defect embedded in the 22-degree layer



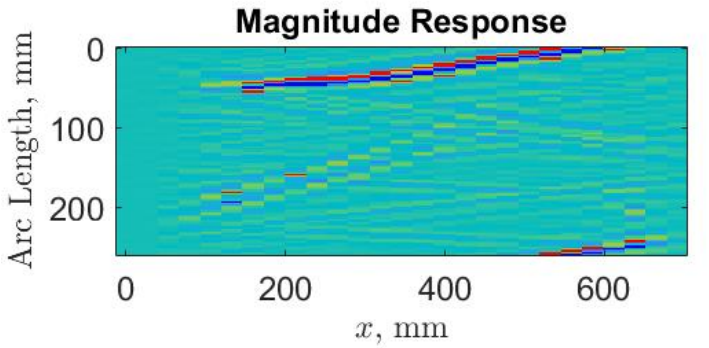
Following this quantification, a defect was embedded in the 22-degree layer and scanned, where;

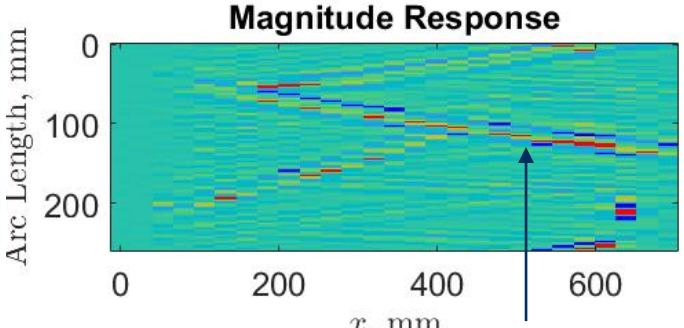


1. The embedded defect was detected both by the axial and transverse sensors.
2. The underlying tow structure was still visible within the scans.

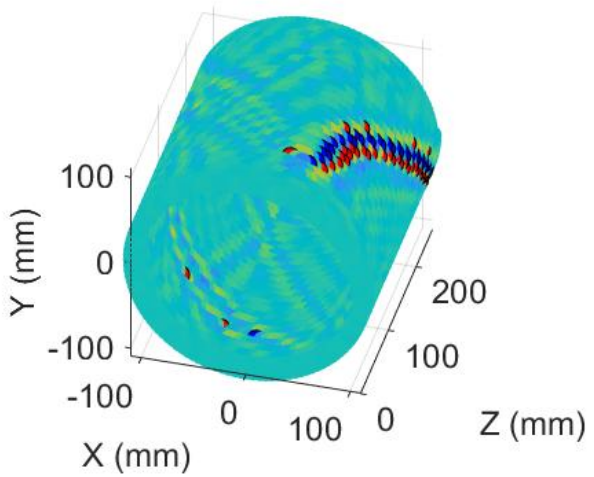


Embedded Defect

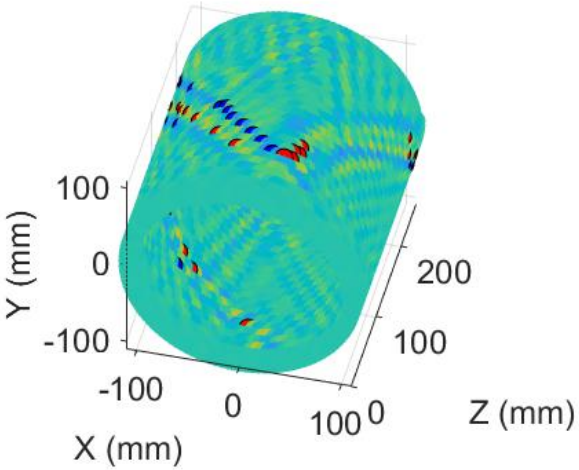




Defect Covered with Hoop Layer

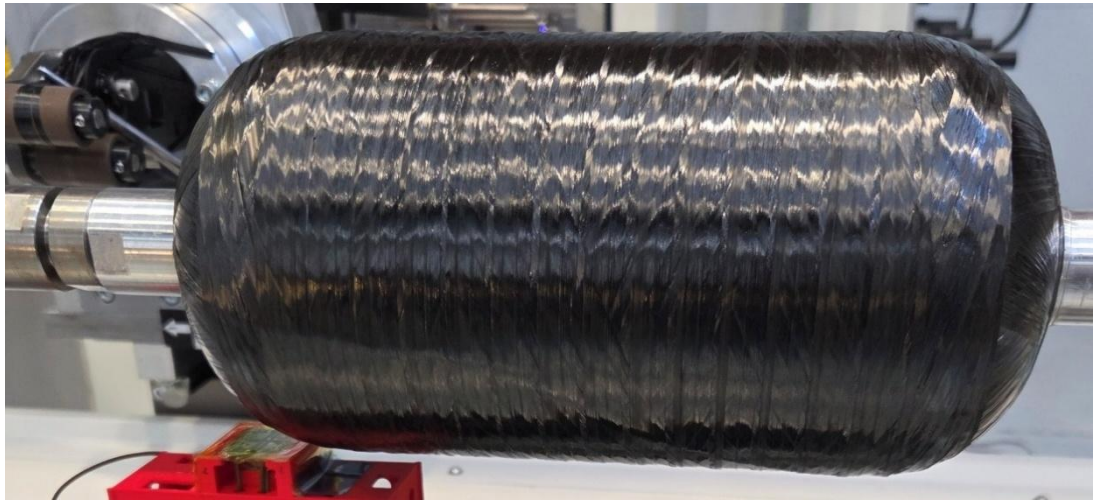


Hoop layer deposited on top of the 22-degree layer with the defect



Embedded Defect

Axial Response

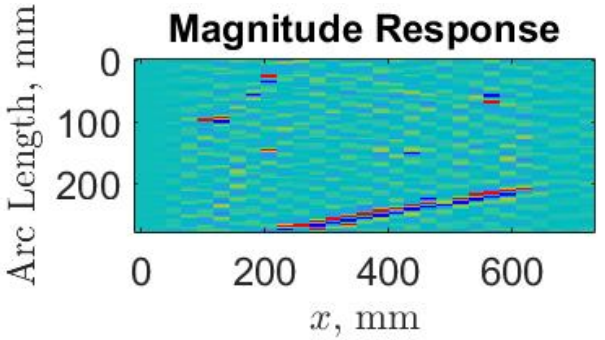


Transverse Response

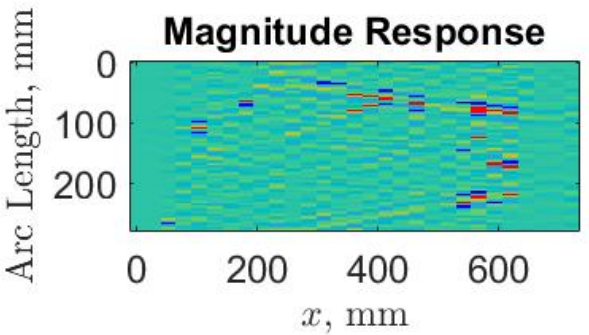
The 22-degree layer with the defect was then covered with another hoop layer and scanned. The results showed;

1. The embedded defect was still detected by the transverse sensor, whereas the axial sensor highlighted a different feature in the 22-degree layer.
2. The 22-degree layer was still visible within the scans.

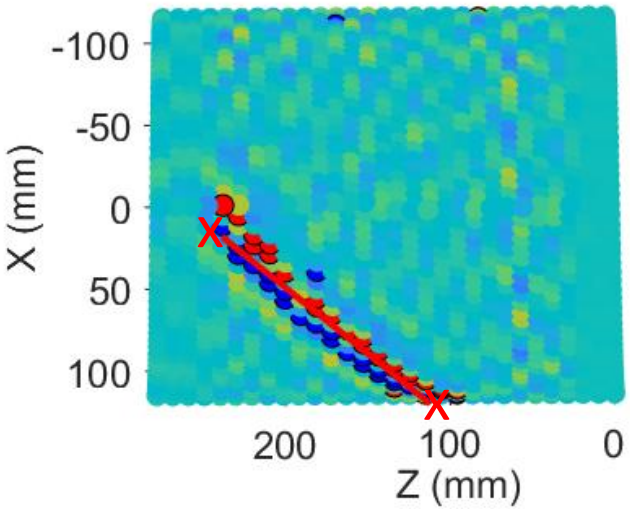
Depositing 70 Degree



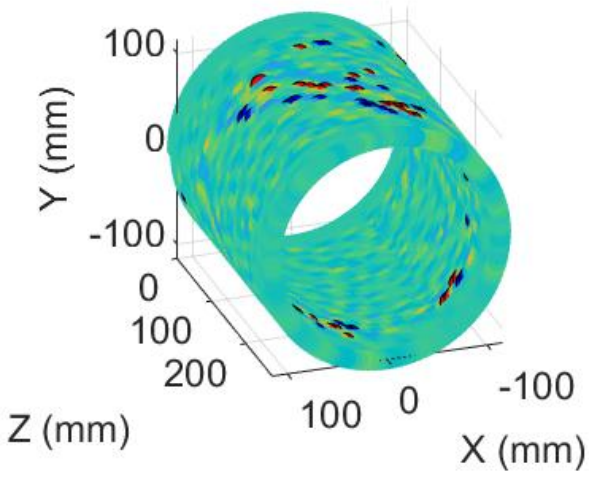
Hoop layer deposited on top of the 70-degree layer



The final two layers involved depositing a 70-degree layer, followed by another hoop layer. Final scans showed;

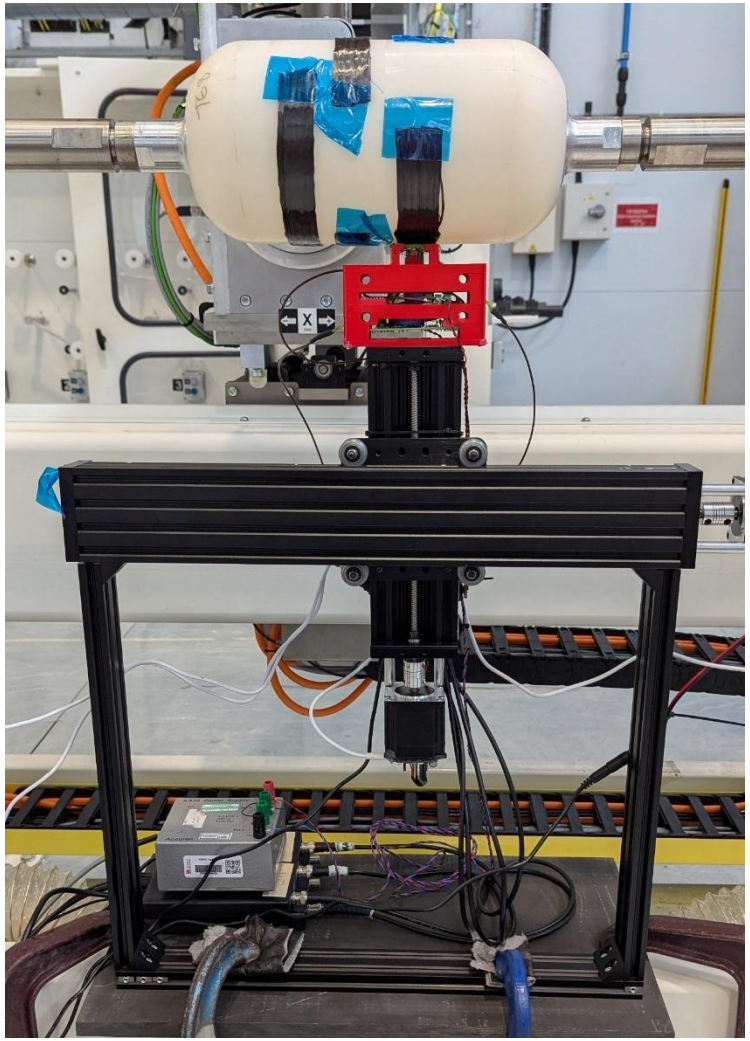


1. Due to the shallower angle of the 70-degree layers, the calculating the fibre orientation is more difficult. This could be improved by conducting measurements at a higher resolution.
2. The defect in the 22-degree layer was still visible within the scans.



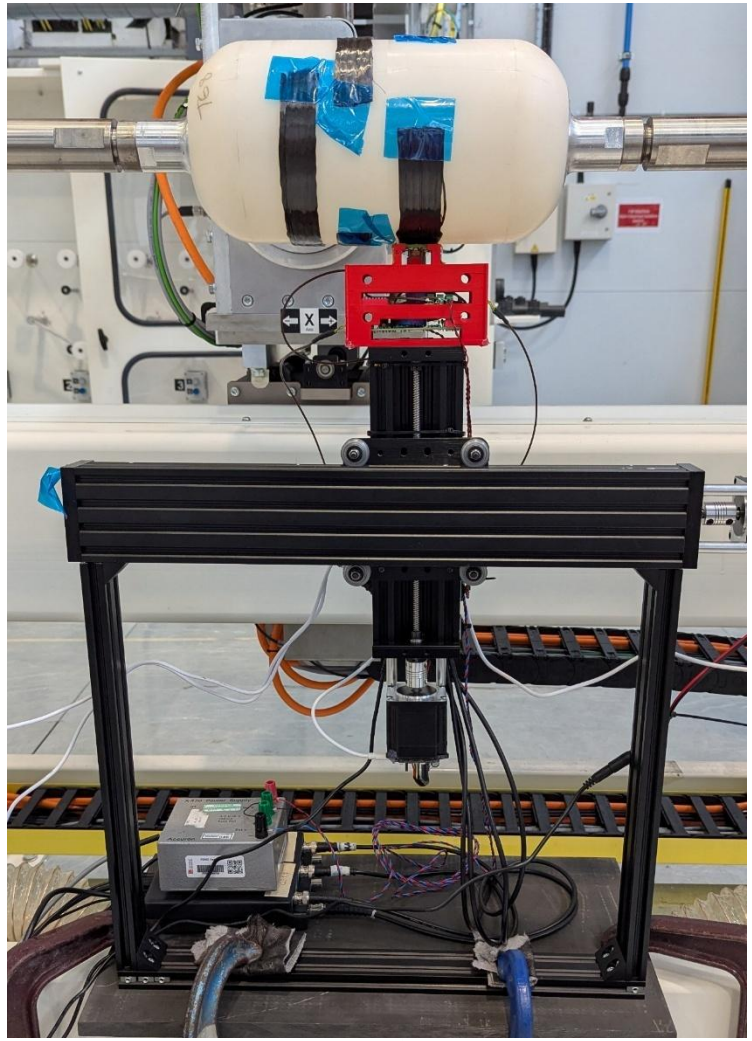
Axial Response

Transverse Response



Conclusions & Future Work

Key Lessons Learned



- The manufactured geometries during ATL and filament winding processes can be in-line characterised using EC sensors.
- Automated defect detection allows for identifying features of interest.
- The performance of EC Sensor improves as more material is deposited, especially with different fibre orientations (even when the defects are buried deeper in the material.)
- Optimum parameters were selected, improvements to make for future measurements were identified (Liftoff, frequency, sampling rate…).

Conclusions & Future Work

Continuing the trials/ Finalising the TPT Project

- Comparison with XCT Data
- Developing capabilities to characterise the tank at the domes for validating models and CAM programming **(Request from FW team)**.
- In-process characterisation of a functional part e.g. hydrogen tank and/or varying process tension to create realistic defects.
- Development of the final EC probe resistant to environmental noise.
- Documenting the process within a journal article.

ABSTRACT

Automated manufacturing of thermoplastic composites has gained increasing interest due to its potential for low-cost, high-rate production of composite structures. The matrix-dominated mechanical properties of a laminate manufactured by laser-assisted automated tape placement of thermoplastic composites are highly influenced by the selected processing parameters. Within this work, experimental analysis was conducted to investigate the effect of processing parameters and pass frequency on the laminate microstructure and short beam strength. In conjunction with mechanical characterisation, the process uses a thermo-mechanical model to simulate the thermal history of the manufacturing process. Two cylindrical mandrels with different diameters were used to vary the pass frequency whilst keeping the remaining process parameters constant. Findings show that increasing the pass frequency gradually increases the substrate temperature, reduces the specimen void content, and increases the short beam strength.

1 INTRODUCTION

Due to the long shelf life, high fracture toughness, and perceived recyclability, thermoplastic composites have gained interest in the aerospace industry. With composite materials making up more than 50% of structural weight of modern commercial aircraft, there is a growing need to manufacture thermoplastic composites more efficiently than by autoclave processing [1, 2]. As such, out-of-autoclave manufacturing, such as laser-assisted automated tape placement (LATP), may result in the production of low-cost thermoplastic composites with the potential for high-rate production. Additional benefits of in-situ consolidation of thermoplastic tape by LATP include lower energy consumption compared to autoclaving and reduced material waste [3]. However, as both the nip-point temperature and time under compaction are functions of time, manufacturing at high placement rates often results in a laminate with high porosity and lower levels of interlaminar bonding [4]. Therefore, processes need to be developed to ensure high levels of interlaminar bonding without compromising the production rate of composite laminates.

Several studies have compared the effect of placement rate on the short beam strength (SBS) of LATP laminates [5, 6]. Kirchhoff *et al.* [6] found that increasing the placement rate by 6 m/min at a constant processing temperature reduced the SBS of the laminate by 27% due to an increase in the void content. However, processing temperature can only be increased up to a certain level, noting that exceeding this critical temperature results in matrix degradation and reductions in SBS [7, 8].

Post-processing of LATP laminates in an autoclave has been demonstrated to reduce void content and increase SBS, resulting in laminates with properties comparable to those of autoclaved laminates [9]. However, the requirement for post-processing of LATP manufactured laminates may negate some of the cost and environmental benefits associated with in-situ consolidation. Alternative methods to post-processing, such as repass treatment or the use of a heated tool, have been studied as a means for improving laminate quality. However, repass treatment extends the required manufacturing time,

reducing the overall production rate [10], while the use of a heated tool may not prove beneficial for thick laminates [1] and involves greater energy costs. Therefore, alternative modifications to the manufacturing process may be necessary to increase laminate production without compromising quality.

Within this work, the time-temperature relationship during LATP manufacturing is studied, as well as the influence of substrate temperature on laminate microstructure and subsequent SBS. Specifically, while previous studies [11-13] have indicated that maintaining the substrate temperature of a laminate during manufacturing reduces the void content and increases the SBS, there is limited research on methods for maintaining substrate temperature without the use of an additional heat source.

3 MATERIAL AND METHODOLOGY

3.1 Material and Manufacturing Methods

Manufacturing trials were conducted using an AFPT GmbH produced laser-assisted automated tape placement system located within the University of Limerick. The LATP system consisted of a 3kW laser heat source attached to a Kuka robotic arm (Kuka, KR 240 L210-2). A thermal camera monitors the temperature of the incoming tape, substrate, and nip point, adjusting the laser power to maintain the programmed target temperature in a closed-loop system.

Unidirectional, 12 mm wide, carbon fibre/PEEK tape was used to manufacture a total of 14 wound specimens, with a layup of $[0°]_{30}$, using the processing parameters defined in Table 1. Specimens were manufactured with a constant pneumatic piston pressure of 2.5 Bar. Two cylindrical mandrels with two diameters were used: a large mandrel (diameter 250 mm) and a small mandrel (diameter 70 mm), to study the influence of pass frequency on the laminate microstructure and mechanical properties. Within the scope of this work, specimens are identified by the mandrel size (L or S, where Group L and S represent the specimens manufactured by large and small mandrels, respectively), the placement rate, and the processing temperature, as shown in Table 1. The pass frequency is defined as the inverse of the time required for one complete rotation of the mandrel, with different mandrel diameters resulting in different pass frequencies at the same placement rate, as shown in Table 2. Applying this naming convention, a specimen produced on the larger diameter mandrel at a placement rate of 9 m/min with a nominal nip point temperature of 450 °C is designated L-9-450.

Water jet cutting was used to extract specimens from the hoop laminate, ensuring a length of 40 mm for all specimens, as depicted in Fig. 1(a).

Parameters	Placement Rate (m/min)		
Temperature (°C)	3	9	15
400	3-400	9-400	15-400
450	3-450	9-450	15-450
500	3-500	9-500	15-500

Table 1: Processing parameters used during manufacturing. ID protocol consists of S or L (small or large, respectively) followed by process parameters.

Placement Rate (m/min)	Group S (Hz)	Group L (Hz)
3	0.228	0.058
9	0.680	0.173
15	1.136	0.287

Table 2: Pass frequency for two mandrel diameters and three placement rates used during manufacturing.

3.3 Characterisation and Analysis

Specimen void content was analysed using digital microscopy. The interlaminar bond line thickness was measured via point-to-point measurements at three locations within the overall specimen cross-section. Using the mandrel surface as a datum (0%) and the outer surface as the maximum value (100%), the bond line measurements were taken at 25%, 50%, and 75% of the specimen thickness.

As the degree of crystallinity can influence matrix-dominated mechanical properties, such as the short beam strength, digital scanning calorimetry (DSC) was conducted using a Netzsch 214 Polyma. The degree of crystallinity was tested for both the lower and upper surfaces of the specimen. Samples of 5-10 mg were taken from the specimens. A heating rate of 10 °C/min was used up to a maximum temperature of 400 °C. The degree of crystallinity is calculated from:

$$X_c = \frac{\Delta H_m - \Delta H_c}{\Delta H_{100} \times w_m} \times 100 \tag{1}$$

where ΔH_m is the melt enthalpy (J/g), ΔH_c is the cold crystallisation enthalpy (J/g), w_m is the mass fraction of the matrix (0.34), and ΔH_{100} is the full crystallisation enthalpy of PEEK (130 J/g) [14].

Mechanical testing of the short beam strength (SBS) was conducted in accordance with ASTM D2344 [15] for a curved specimen as depicted in Fig. 1(b). Specimens were loaded with a constant displacement rate of 1 mm/min using a Tinius Olsen H25K-S with a 5 kN load cell. The maximum load was recorded for each specimen, with SBS calculated using:

$$SBS = 0.75 \frac{P}{t \times w} \tag{2}$$

where P is the maximum load (N), t is the sample thickness (mm), and w is the sample width (mm).

A 2D thermo-mechanical model was developed to simulate the incoming tape and substrate on both mandrel diameters, providing the through-thickness temperature distribution during manufacturing. This model aids the discussion and understanding of the mechanisms at play during manufacturing. The model is based on, and validated by, previous work completed by Ma *et al.* [16]. Due to computational power limitations, only the initial four plies placed are modelled in this work. Further details of the computational model can be found in Tobin *et al.* [17].

4 RESULTS AND DISCUSSION

4.1 Computational Temperature Evolution

Thermo-mechanical modelling of the manufacturing process helps develop an understanding of the observed failure mechanisms. An initial comparison of the small and large mandrel models indicates that the simulated peak temperature on the incoming tape shows good agreement with the experimental processing temperature, indicating the acceptable accuracy of the model predictions.

When comparing the temperature evolution as shown in Fig. 2(a) and Fig. 3(a), it is apparent that higher substrate temperatures are reached in the small rather than the large mandrel. When placing ply two at a placement rate of 3 m/min and a processing temperature of 400 °C, ply 1 of S-3-400 reached a

maximum temperature of 400 °C, compared to 330 °C for L-3-400. However, it is worth noting that the substrate of L-3-400 remains below the melt temperature of PEEK during manufacturing, inhibiting interlaminar bonding. As the target temperature increases, computational thermal analysis indicates that the substrate reaches higher temperatures (Fig. 2(b) and Fig. 3(b)), with the large mandrel specimens being more sensitive to an increase in process temperature. The temperature sensitivity observed in the large mandrel specimens likely results from the difference in laser reflection patterns for the two mandrel diameters, which can be considered a limitation associated with the use of different mandrel diameters [17]. Analysing the temperature of the substrate for each layer suggests that the substrate temperature gradually increases with each rotation of the small mandrel, but not with the large mandrel. This observation becomes more apparent when comparing S-9-500 (Fig. 2(c)) and L-9-500 (Fig. 3(c)). For S-9-500, the first ply reaches a minimum temperature of 210 °C after the third layer is placed, however, L-9-500 cools to room temperature between each laser pass. When comparing L-9-500 to L-3-500, it is noted that the substrate temperature is lower for L-9-500 due to reduced time during the heating phase. While there is no thermo-mechanical model for placement rates of 15 m/min, it can be surmised that the observed trends when increasing the placement rate from 3 m/min to 9 m/min remain for higher placement rates. When considering the thermal history shown in Fig. 2 and Fig. 3, the influence of processing parameters can be inferred: increasing the processing temperature increases the substrate temperature, and increasing the placement rate can reduce the maximum temperature reached in the substrate while also reducing the cooling time. Additionally, comparing the thermal history displayed in both Figs. 2 and 3, it is noted that increasing the laser pass frequency can introduce gradual heating in the substrate, which can increase the degree of interlaminar bonding when manufacturing at high placement rates.

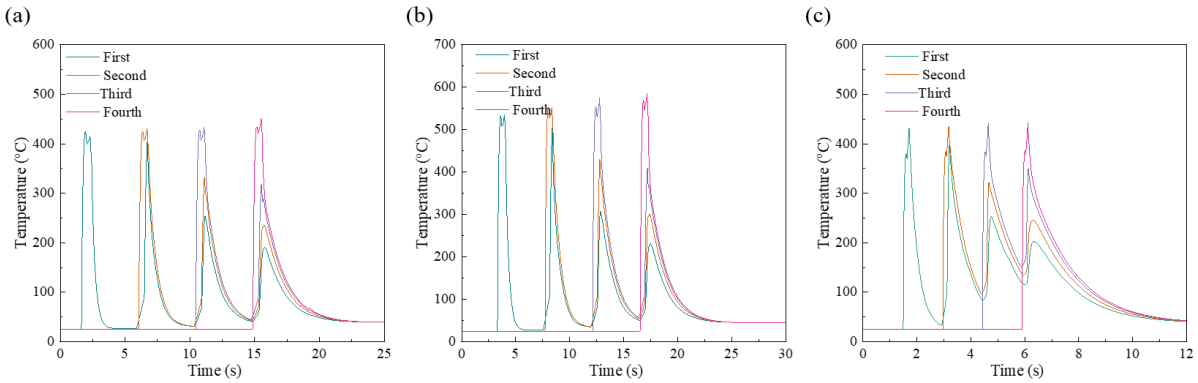

Figure 2: Thermal history of (a) S-3-400, (b) S-3-500 and (c) S-9-500. Different colours correspond to the ply placed (first ply to fourth ply).

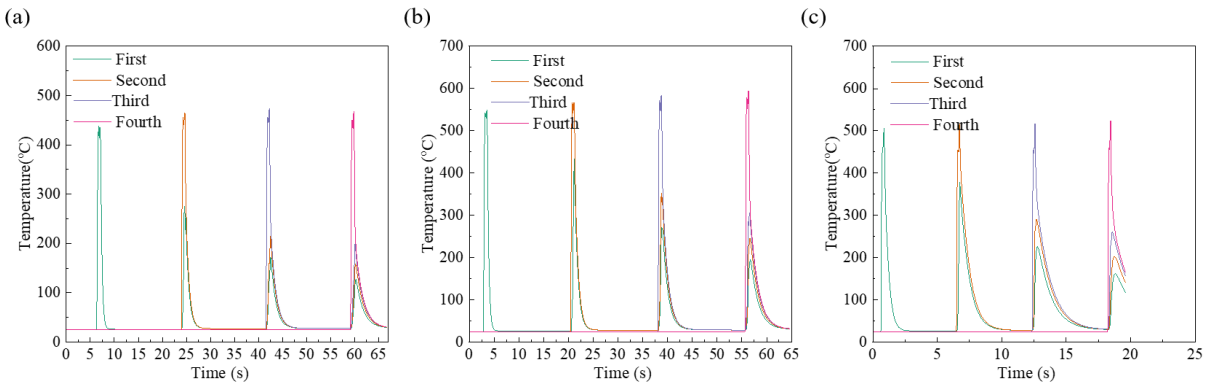

Figure 3: Thermal history of (a) L-3-400, (b) L-3-500 and (c) L-9-500. Each colour corresponds to the thermal history of the ply placed (first ply to fourth ply).

4.2 Microstructure Variation

Initial, qualitative comparison between laminate microstructures indicates that mandrel diameter and processing parameters affect the void content, location, and interlaminar bond line thickness. Specimen S-9-450 had the lowest overall void content (0.2%), whereas the highest void content was for L-3-400 (2.25%). When comparing the void content within both specimen groups at equivalent processing parameters, the void content in the small mandrel specimens was found to be lower than that in the large mandrel specimens (Fig. 4(a)). This difference was most apparent when manufacturing at 500 °C and 15 m/min, where the void content difference was 1.75% (Fig. 4(a)).

When considering the influence of processing parameters on void content, at low placement rates (3 m/min), increasing the processing temperature reduced the overall void content of the laminate. When considering the thermal history of the specimens, increasing the processing temperature resulted in a higher substrate temperature, which facilitates higher levels of interlaminar bonding due to increased matrix flow across the interlaminar bond line. By increasing the placement rate at a constant processing temperature, the void content increases, with the most prominent increase in void content observed when manufacturing on the large mandrel at 15 m/min. As previously mentioned, the level of interlaminar bonding is a function of the processing time, with an increase in placement rate reducing the laminate time under temperature or consolidation force. Fig. 3(c) shows that an increase in placement rate for the large mandrel reduces the maximum temperature reached by the substrate, which can serve to explain the void content observed in L-15-500. However, due to the gradual substrate heating with high pass frequency (Fig. 2(c)), S-15-500 has a lower void content than L-15-500 despite the maximum substrate temperature being relatively low.

In addition to void content variation, the predominant type of void observed, interlaminar or intralaminar, varied with processing parameters and mandrel diameter. Within the small mandrel specimens, intralaminar voids were the dominant void type for all processing parameters. However, specimens manufactured on the large mandrel exhibited both types of voids. At low placement rates (3 m/min), intralaminar voids were more prominent within specimens manufactured on the large mandrel, with few interlaminar voids observed. At higher placement rates, interlaminar voids became prominent. The void type occurs as a function of the tape temperature. According to thermal simulations, the substrate of L-9-500 remains below the melt temperature of PEEK, which can inhibit intimate contact formation, causing interlaminar voids to occur. While simulations were not conducted for a 15 m/min placement rate due to the associated computational costs, it can be assumed that this temperature difference would be exacerbated. Intralaminar voids can occur due to tape deconsolidation, as heating the tape can introduce void growth and migration, and rapid cooling reduces matrix flow [18]. Increasing the tape temperature to ensure the matrix is above the melt temperature allows intralaminar voids to be fully compacted during consolidation [19]. Additionally, increasing the pass frequency above 1 Hz at a constant placement rate can maintain a temperature above the glass transition temperature, which facilitates void compaction.

While there was little evidence of interlaminar voids within the small mandrel specimens, there were observed differences in the interlaminar bond line between the two mandrel size groups. An interlaminar resin-rich bond line is readily observed in all specimens; it was noted that increasing the processing temperature at a constant placement rate reduces the bond line thickness. For example, L-3-400, L-3-450, and L-3-500 had a resin-rich bond line thickness of 12.44, 8.74, and 7.92 μm, respectively. However, the bond line thicknesses for the small mandrel specimens are significantly lower than those for the equivalent large mandrel specimens, with S-3-400, S-3-450, and S-3-500 having bond line thicknesses of 9.73, 7,93, and 6.60 μm, respectively. Increasing the placement rate resulted in an increase in the bond line thickness at a constant processing temperature for both mandrel diameters. Despite an increase in the resin-rich bond line thickness with increasing placement rate, the observed trend of small mandrel specimens having a thinner resin-rich region was consistent. Additional observed differences between the mandrel size groups reflect the ply structure, with small mandrel specimens displaying significant out-of-plane ply waviness at high placement rates.

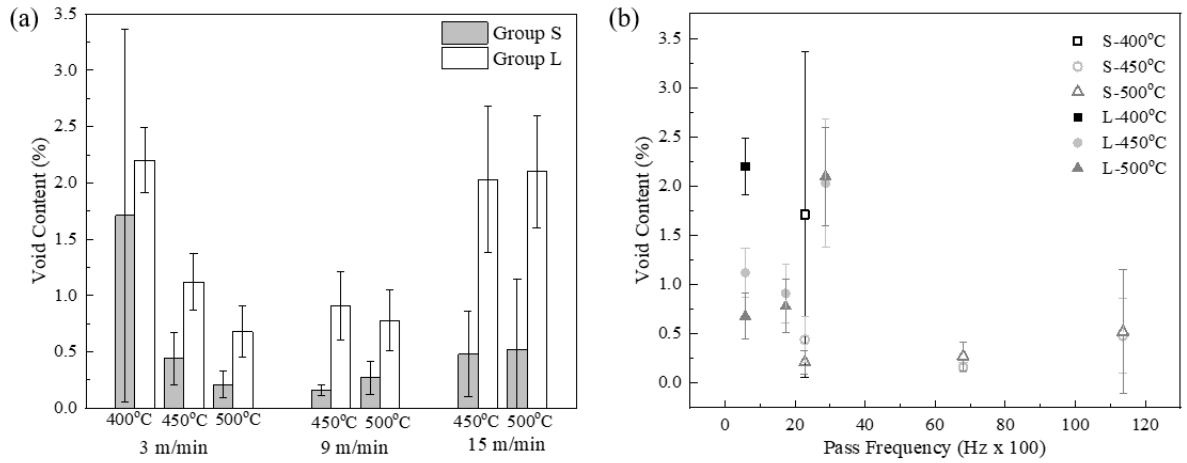

Figure 4: (a) Void content for processing parameters and (b) Void content variation with pass frequency

The degree of crystallinity can influence the mechanical properties of the matrix and, therefore, affect the SBS. When comparing the degree of crystallinity between the upper and lower surfaces, it is observed that the lower surface has a lower degree of crystallinity than the upper surface. Additionally, the upper surface's microstructure was found to be insensitive to changes in process parameters. When considering the degree of crystallinity at the lower surface, it is noted that at 3 m/min, increasing the processing temperature results in a five percent increase in the degree of crystallinity for both mandrel types. However, the average degree of crystallinity ranges between 20% and 25% (Fig. 5(a)), with the mandrel size and pass frequency having little effect on the average degree of crystallinity (Fig. 5(b)). When comparing the two mandrel sizes with equivalent processing parameters, it is observed that there was a 2-5% difference in degree of crystallinity, falling within the error margin of this analysis, despite the difference in pass frequency.

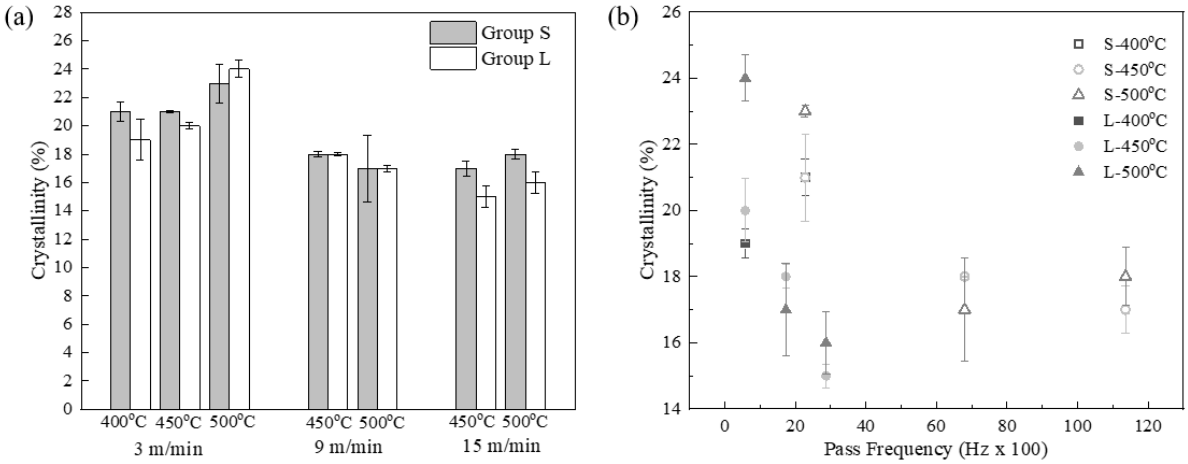

Figure 5: (a) Average crystallinity for specimens and (b) Crystallinity variation with pass frequency

4.3 SBS and Failure

The influence of processing parameters on SBS values is displayed in Fig. 6(a), with the effect of pass frequency shown in Fig. 6(b). A maximum SBS of 58 MPa is achieved with S-9-450. However, this value is still significantly lower than the expected SBS from an autoclave specimen (112 MPa [1]). From Fig. 6(a), it is noted that the specimens manufactured on the small mandrel have a higher SBS than the equivalent large mandrel specimens. Initial assumptions for this apparent difference are based on geometric differences; however, according to finite element simulations (Details on simulation available in Tobin *et al.* [17]), geometrical differences in specimens in this study have a negligible effect

on the SBS value. Additionally, the difference between SBS values for small and large mandrels is not consistent across the process parameters. This observation, combined with the knowledge that the degree of crystallinity can be considered equivalent for the two mandrel types, indicates that the pass frequency affects the SBS.

Comparing the influence of processing parameters on the SBS of both mandrel diameters indicates that the large mandrel specimens are more sensitive to variations in temperature and placement rate (Fig. 6(a)). Comparing L-3-500 to L-9-500, the increase in placement rate results in a reduction in substrate temperature in the large mandrel specimen, correlating with a 6% decrease in SBS. With an increased placement rate, there was a reduction in exposure time to laser flux, thereby reducing the maximum temperatures reached in the substrate. At a placement rate of 9 m/min and temperature of 500 °C, the first ply of L-9-500 reached a temperature of roughly 350 °C, with no subsequent ply reaching the melt temperature. Although above the matrix melt temperature (343 °C), as shown in Fig. 3(c), a rapid drop in temperature occurs due to the cooling effect of the consolidation roller. It can be assumed that a similar thermal history trend exists when further increasing the placement rate to 15 m/min. As a result, void growth, void migration, and fibre decompaction can occur during the heating phase, but the rapid temperature drop during consolidation prevents matrix flow [18]. The high void content in the large mandrel specimens, as a result of low processing temperature, can serve to explain the further reduction in SBS at 15 m/min, as there is a documented correlation between void content and SBS.

The range of SBS observed for large mandrel specimens is 23-47 MPa, compared to a variation of 48-58 MPa for the small mandrel specimens. The consistency of SBS results for the small mandrel specimens indicates that higher pass frequency can be beneficial for SBS. As there is a correlation between void content and SBS [20], specimens with low overall void content have higher SBS values. As observed with void content measurements, the large mandrel specimens were more sensitive to the temperature increase than the smaller mandrel specimens due to the difference in substrate temperatures. It was determined that increasing the processing temperature resulted in a reduction in void content and interlaminar bond line thickness for both mandrel diameters when processing at a speed of 3 m/min. The simulated thermal history for both mandrels indicates that increasing the processing temperature results in an increase in the substrate temperature. The increase in substrate temperature reduces matrix viscosity, which facilitates void compaction during manufacturing. This reduction in void content and matrix bond line width increases the SBS for the specimen, as voids act as stress concentrations and therefore serve as crack initiators.

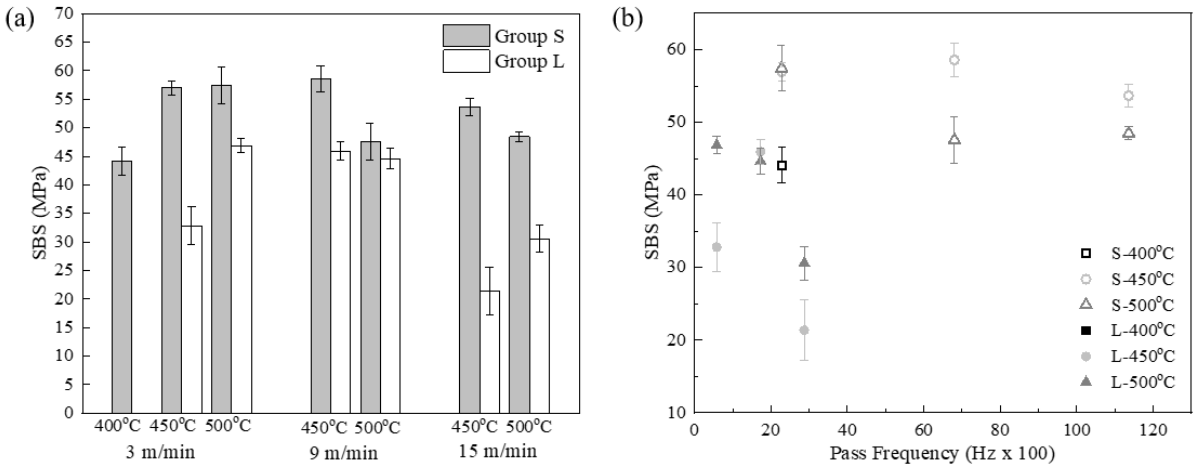

Figure 6: (a) Average SBS for processing parameters and (b) SBS variation with pass frequency

To understand the failure mechanism of SBS specimens, microscopical analysis was conducted to compare the failure locations and fracture surfaces. Fig. 7(a-b) displays the failure crack for the specimen with the lowest (L-3-400) and the highest SBS values (S-9-450). From Fig. 7(a), it is noted that failure occurs along the interlaminar bond line, with little to no crack deflection observed. This failure likely

occurs due to relatively poor interlaminar bonding as a result of a substrate temperature that was too low, as indicated in Fig. 3(a). When analysing the fracture surfaces of L-3-400, which had clear interlaminar failure, no sign of matrix deformation is observed (Fig. 7(c)), further indicating poor interlaminar bonding. Contrary to the interlaminar failure observed for L-3-400, failure S-9-450 occurred within the ply with significant crack deflection (Fig. 7 (b)). When analysing the failure surface of S-9-450 in Fig. 7(d), there are signs of matrix deformation correlating with the higher SBS value. Additionally, S-9-450 has significant matrix remaining on the fibre surfaces, indicating high levels of fibre-matrix adhesion, probably due to increased processing temperature, which improves the fibre-matrix bonding.

4.4 The effect of pass frequency on SBS

While the effect of processing parameters on the SBS has been documented within Section 4.3, the influence of pass frequency on the microstructure and subsequent SBS variations has yet to be discussed. While there may be a difference in residual stress formation within the specimens due to the different mandrel diameters, Ma *et al.* [16] showed that variations in residual stress do not correlate with changes in the SBS. Changes, therefore, occur as a result of differences in the specimen's microstructure. As the consolidation force was held constant during manufacturing, the difference in microstructure between the two mandrel geometries can be explained by comparing their thermal histories.

In order to ensure intralaminar void compaction, the matrix should be held above the melt temperature [19]. However, once the matrix is above the glass transition temperature, it is possible to compress interlaminar and intralaminar voids [21]. From Fig. 2(c) and Fig. 3(c), it is noted that the substrate temperature of S-9-500 gradually increases, whereas for L-9-500 it does not. The increases in substrate temperature occur due to an increase in pass frequency from 0.173 Hz to 0.680 Hz. At elevated pass frequencies, the LATP head completes a full rotation of the mandrel before the previous ply fully cools, with the next ply being placed onto a warm substrate. The increase in substrate temperature at high pass frequencies is similar to the higher substrate temperature introduced while manufacturing on a heated tool, which has been shown to reduce void content and increase SBS [22]. Although the thermal history of manufacturing at 15 m/min was not simulated, the trends observed for S-9-500 and L-9-500 are likely to occur at a higher placement rate. Specifically, the substrate temperature of the specimens manufactured on the small mandrel at 15 m/min will not have fully cooled at a pass frequency of 1.136 Hz. This effect is due to the higher pass frequency, which results in lower void content in S-15-450 and S-15-500 compared to both L-15-450 and L-15-500. Despite the substrate temperature being lower at

high placement rates (Fig. 2 and Fig. 3), the substrate remains above the glass transition temperature for longer, which facilitates void compaction and interlaminar bonding.

The thermal history variation between the two mandrels highlights that increasing the pass frequency can aid in maintaining the substrate temperature, thereby reducing void content, and subsequently increasing the SBS. However, from Fig. 5(b) and Fig. 6(b), it is noted that the relationship between pass frequency and SBS is non-monotonic, with a maximum SBS being achieved (S-9-450) and subsequently decreasing. However, it is also worth noting that the maximum SBS value also varies with mandrel geometry, as the laser flux varies with diameter. Using the relationship between void content and pass frequency as a metric for optimisation, with the lowest void content being considered optimum, it was noted that this optimum was achieved at 9 m/min and 450 °C (0.680 Hz), and with the void content increasing with increases in pass frequency. However, when manufacturing large structures, this level of pass frequency is likely unattainable when manufacturing with a single LATP head. Therefore, future developments of the LATP systems, such that they are similar to the thermoplastic pipe manufacturing industry, where multiple heads work in unison, may facilitate the required high pass frequency [23]. Based on the thermal histories displayed in Fig. 2 and Fig. 3, the maximum substrate temperature is highly dependent on the placement rate. In order to further increase the pass frequency, it is necessary to increase the processing temperature further. However, when comparing the maximum temperatures achieved when processing at a pass frequency of 0.173 Hz and 0.680 Hz, it is noted that with the same nip-point temperature, the higher pass frequency results in a substrate temperature approximately 100 °C higher. This temperature difference indicates that although there is a requirement for increasing the target nip-point temperature with higher placement rates, increasing the pass frequency results in a lower temperature being needed, reducing the potential for matrix degradation.

6 CONCLUSIONS

LATP manufacturing was used to produce specimens on various diameter mandrels, allowing for the study of the effect of pass frequency on the specimen microstructure and subsequent variations in SBS. A thermo-mechanical finite element model was utilised to determine the thermal history of the laminates, providing a deeper understanding of the influence of processing on microstructural changes. Characterisation tests were conducted to analyse the influence of the microstructural changes due to pass frequency on the interlaminar bond strength through SBS testing.

Results show that increasing the placement rate increases the overall laminate void content due to insufficient matrix temperatures being reached. While the temperature is above the matrix glass transition temperature, at high placement rates (15 m/min), the substrate does not reach the melt temperature. This scenario facilitates tape deconsolidation while also inhibiting matrix flow, thereby increasing the void content. Due to an increase in void content, the maximum SBS obtained is 32 MPa (0.287 Hz). However, increasing the pass frequency to 1.136 Hz (57 MPa) at the same placement rate and temperature causes the substrate to gradually heat, increasing the window of time for consolidation to occur. Due to this gradual substrate heating, the void content reduced and SBS increased for equivalent process parameters, but at a higher pass frequency.

However, there are limitations associated with this study. While the use of two mandrel diameters introduced methods for varying the pass frequency, it became apparent that the laser flux was different for the two mandrel diameters. As a result, the maximum temperatures reached during ply placement differed for the same processing parameters. However, despite the temperature differences observed during initial placement, the thermal history trends with increasing pass frequency are expected to be representative. From the results and discussion presented in this work, it is apparent that a pass frequency of 0.680 Hz at 450 °C provided the highest SBS. However, for large-diameter structures, this pass frequency is likely unattainable with a single LATP head. Therefore, this study aims to highlight potential future developments in LATP manufacturing optimisation, aiming to achieve high-rate manufacturing without compromising interlaminar bond strength.

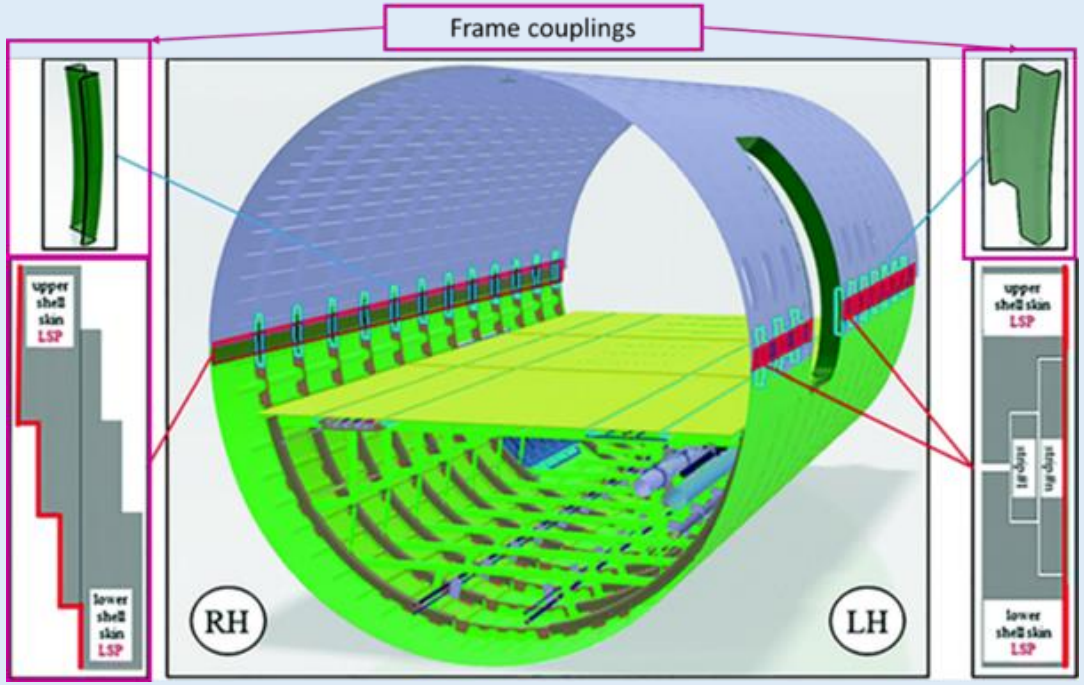
Process Understanding

Equipment manufacturing

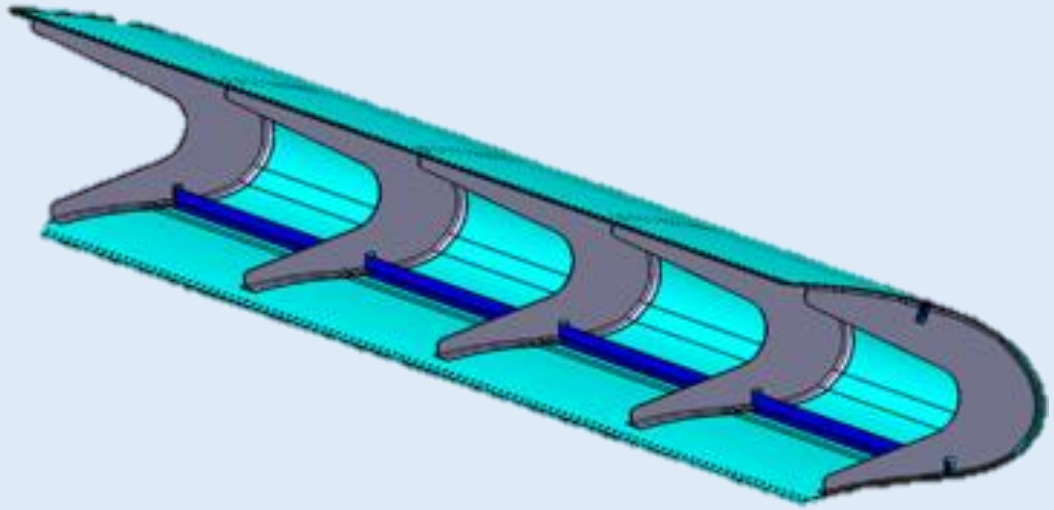


Automation and Monitoring

INTRODUCTION - WELDER

Resistance Welding
The frame couplings

Scale-up challenge:



- Multiple in-series welds
- Automatic process
- Uniform performance

This Project has received funding from Clean Sky 2 Joint Undertacking (JU) under grant agreement Nº101007814

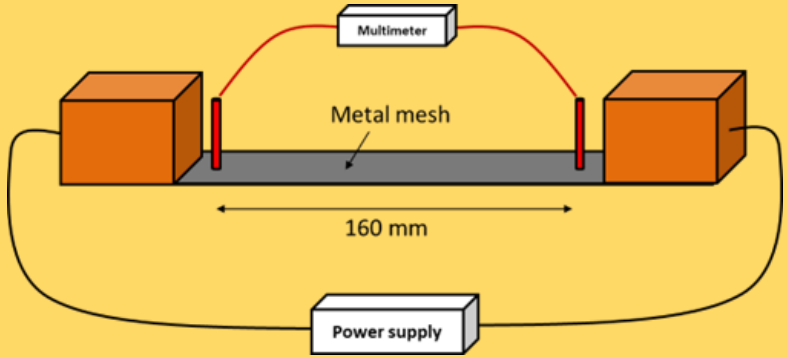
INTRODUCTION - HERWINGT

Sequential Resistance Welding Thermoplastic Leading Edge

Scale-up challenge:

- 2.5 m structure
- Variable thickness
- Uniform performance
- Controllable temperatures
- High key performance

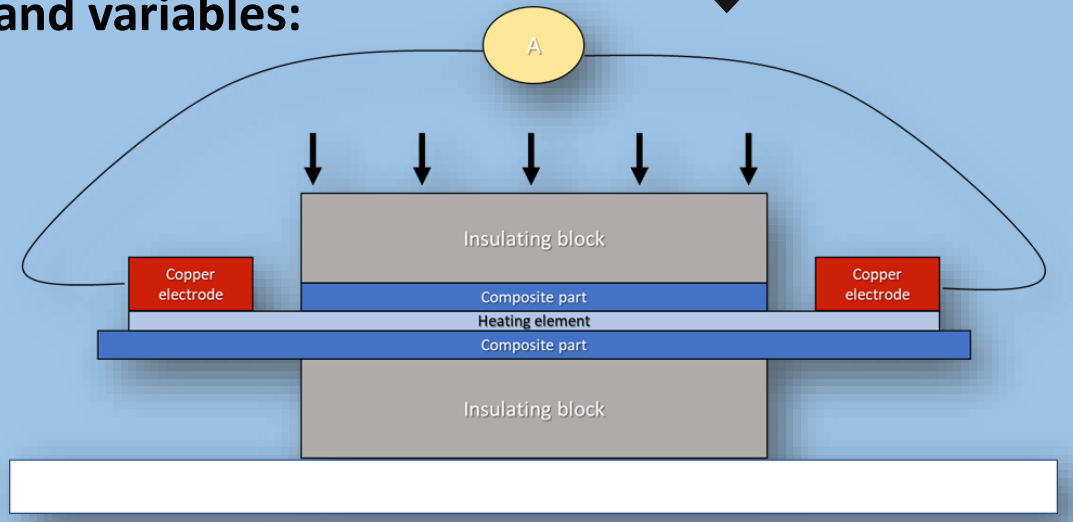
BASE MATERIAL :
High Temperature Thermoplastic Composites



INTRODUCTION

Current aeronautic needs:

- Innovative materials: Thermoplastics among these
- Flexible and adaptable manufacturing systems
- Shorter manufacturing cycles
- Environmental friendliness
- Energy efficiency
- Higher productivity



THERMOPLASTIC WELDING

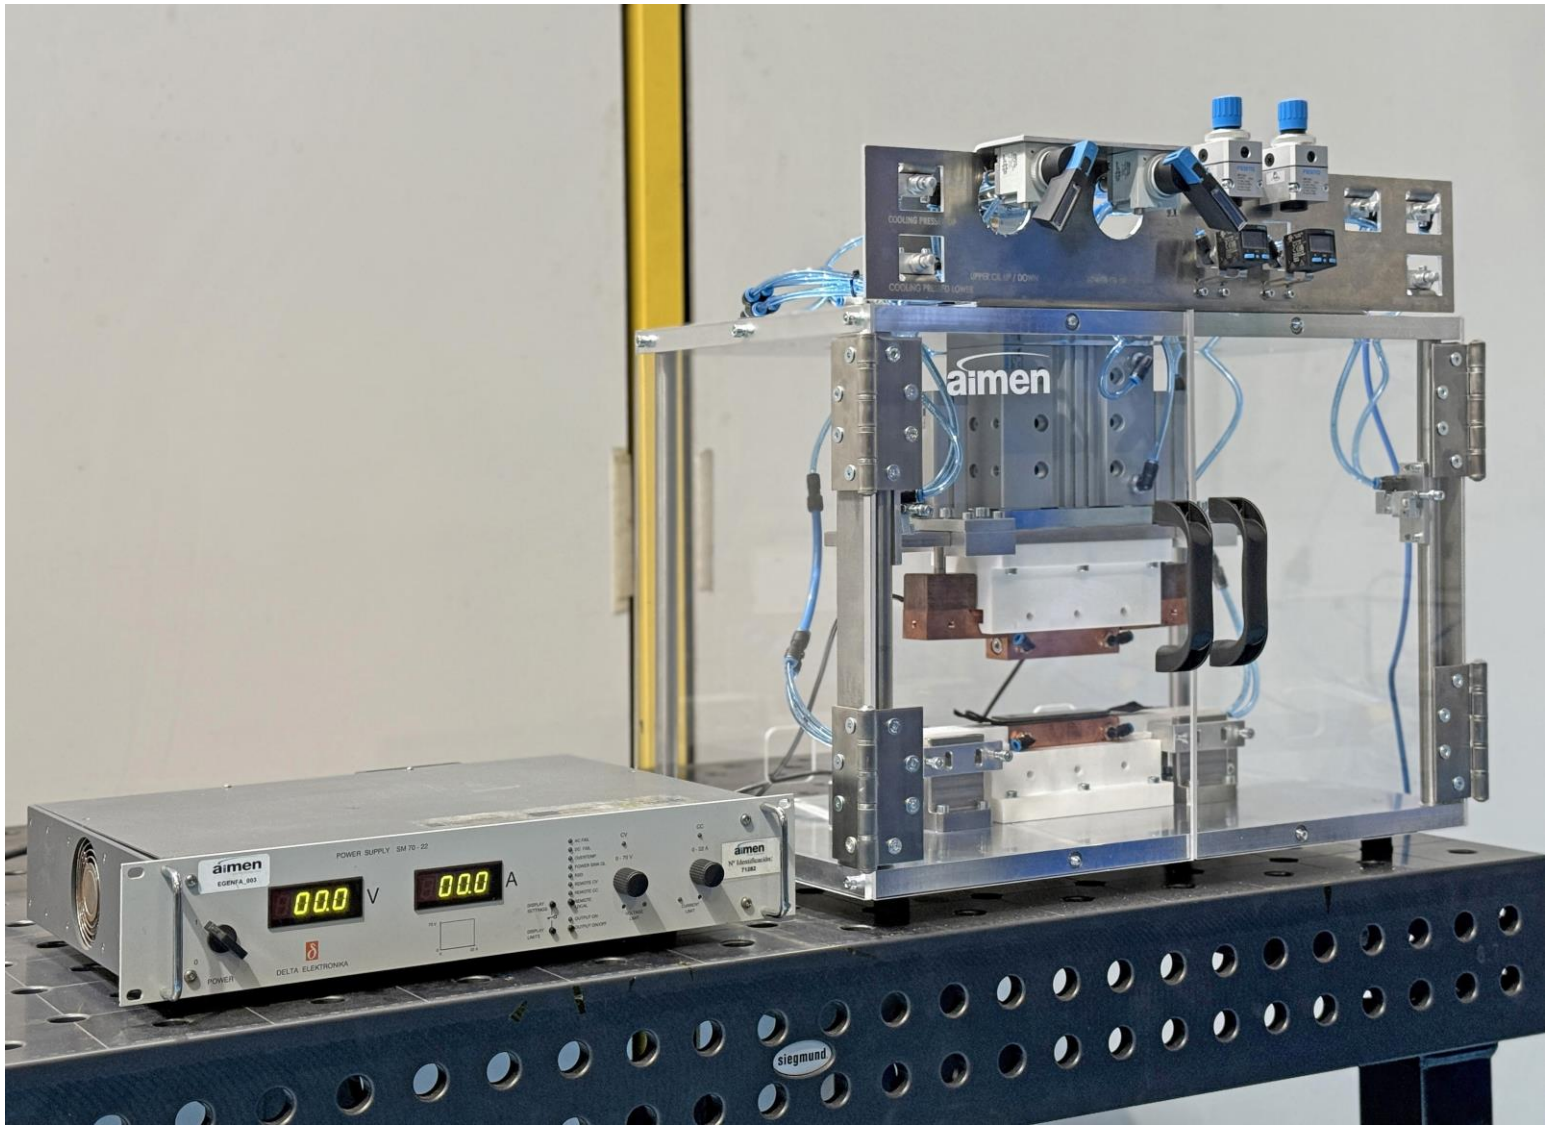
- ✓ ROBUST
- ✓ RELIABLE
- ✓ EFFICIENT
- ✓ COMPATIBLE
- ✓ SAFE

Parameters and variables:

- Pressure
- Power/Current
- Time
- Cooling
- Part layup and size
- Conductivity
- Thickness

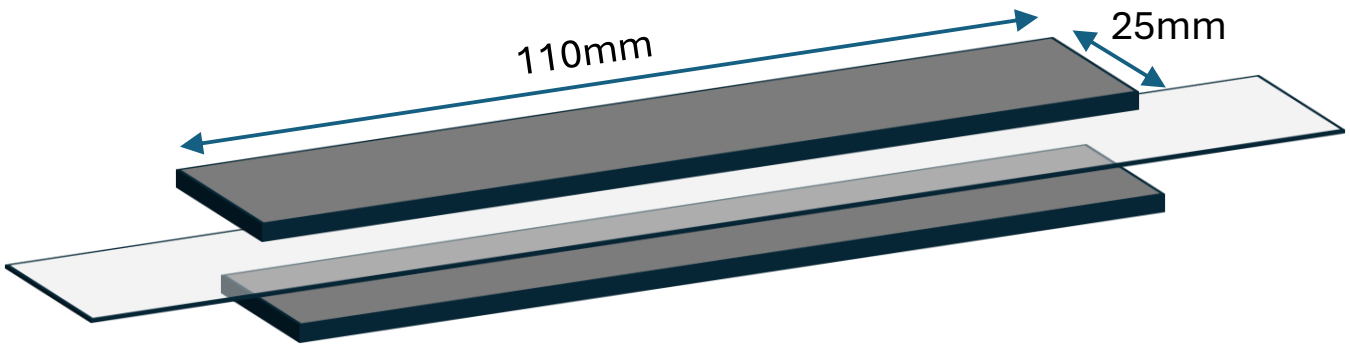
THE SCALING-UP CHALLENGE

Scale-up challenge



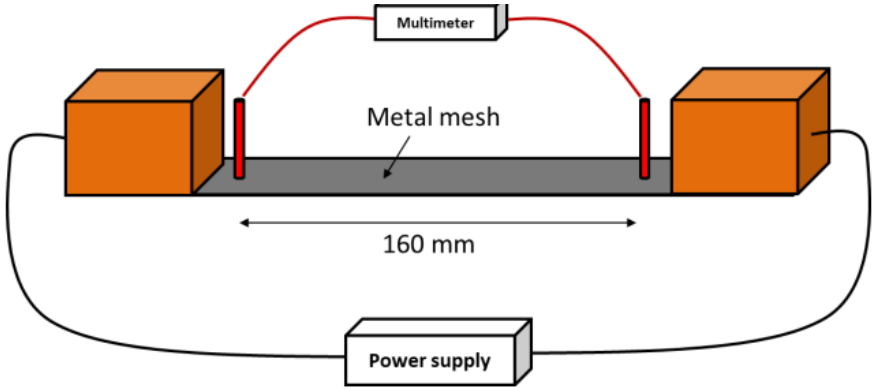
Welding: Setups and Parameters investigation

Monitoring:



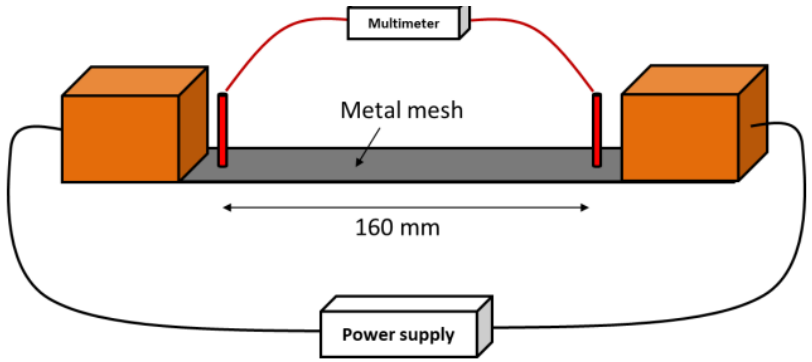
Process investigation involving technological and process parameters, in-use monitoring

Analysis, Testing and data interpretation: Performance, robustness, processability.

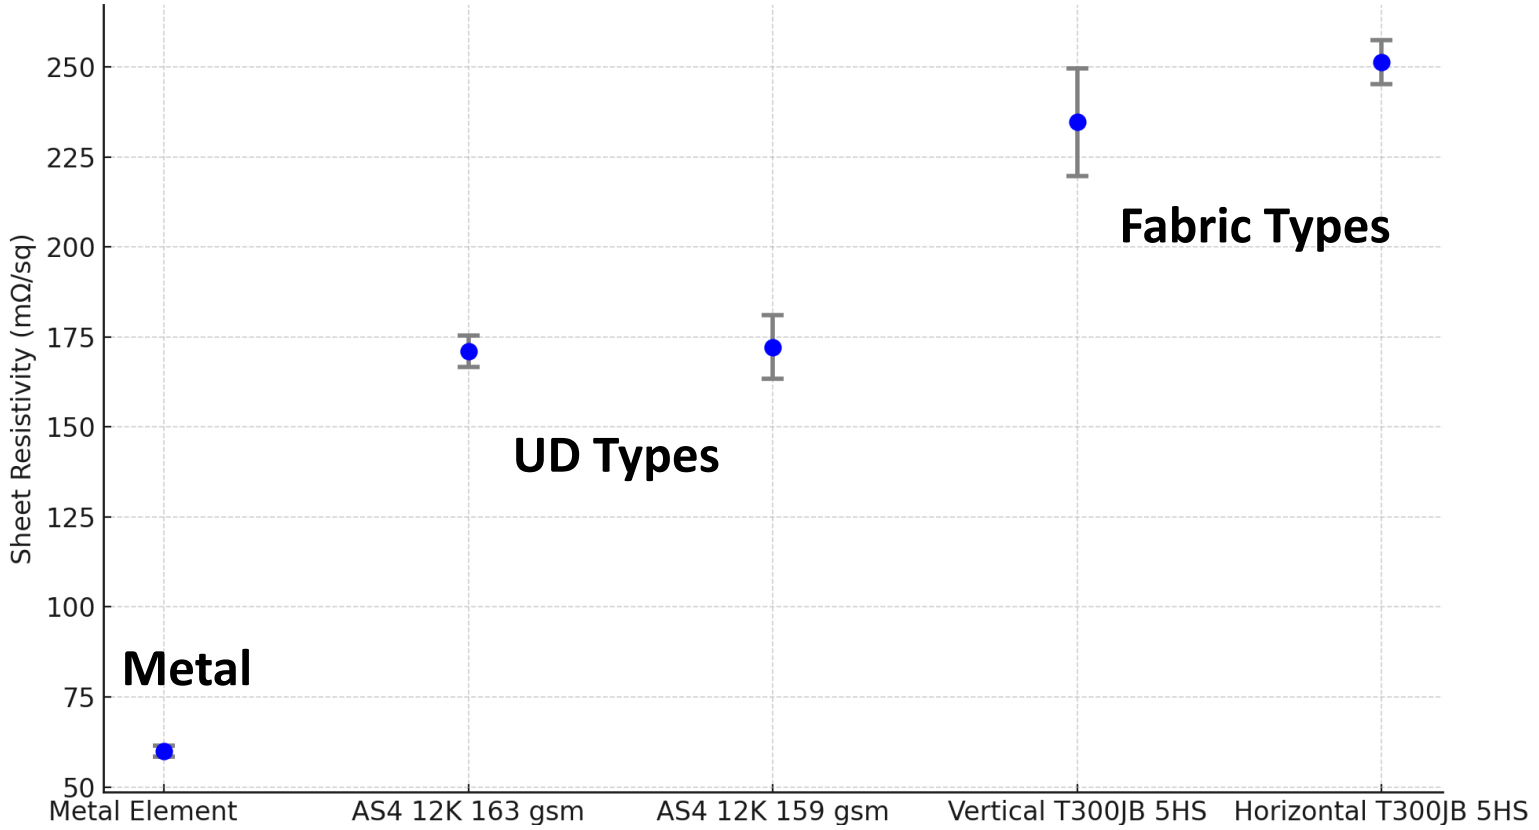


Progressive Scale-up

The Heating Element

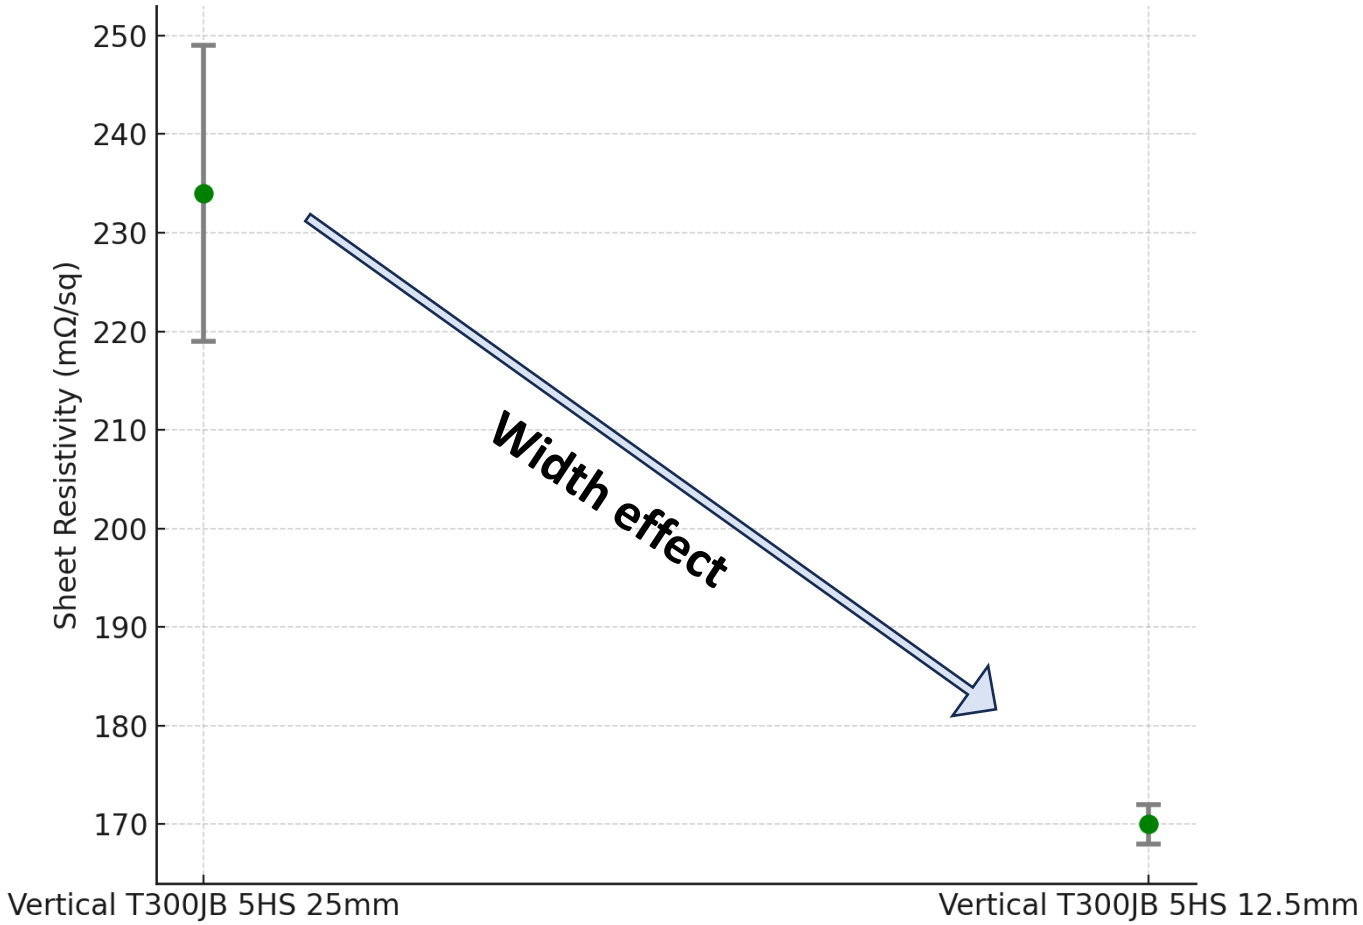


Metal Heating Element



Carbon Based Heating Element

$$\rho_s(m\Omega) = \frac{R(\Omega) \cdot w(mm)}{l\,(mm)} \cdot 1000$$



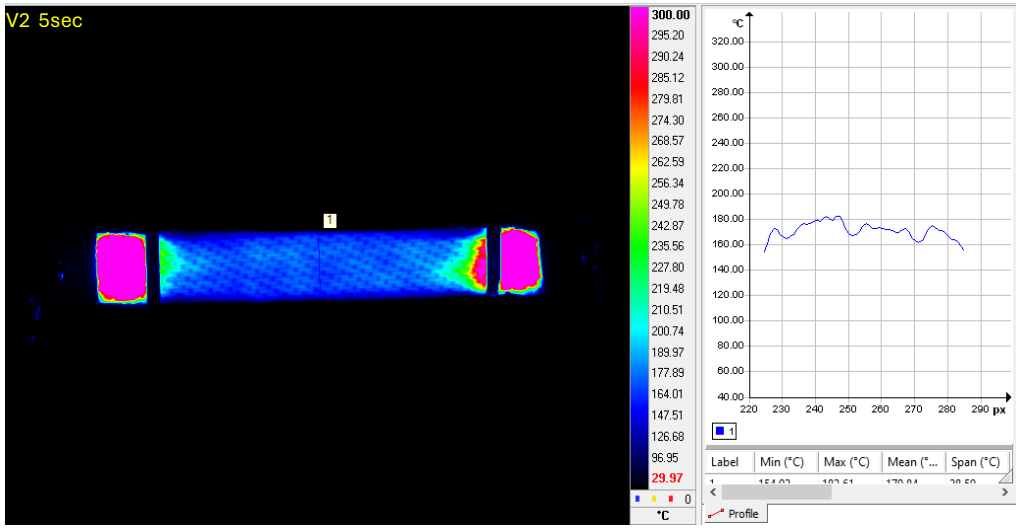
The Heating Element – Electrical Properties

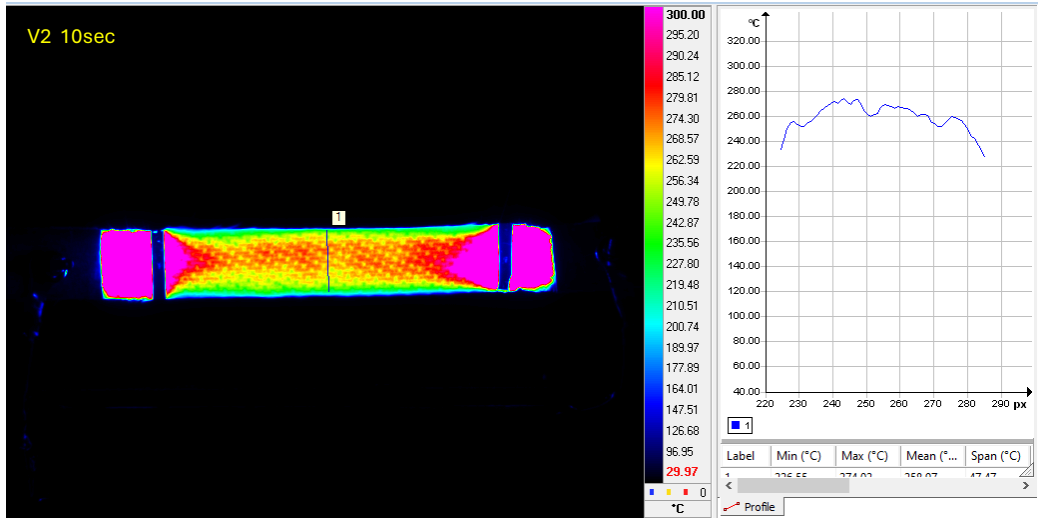
The effect of the Heating element Width

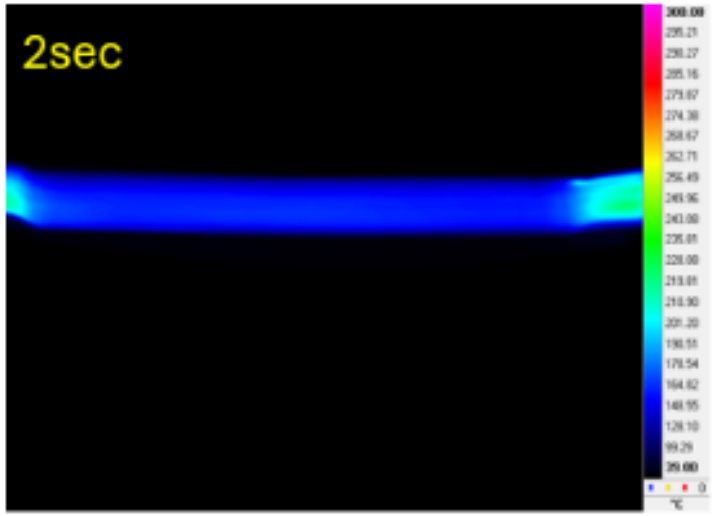
Monitoring of the Heating Element

MONITORING ADVANTAGES

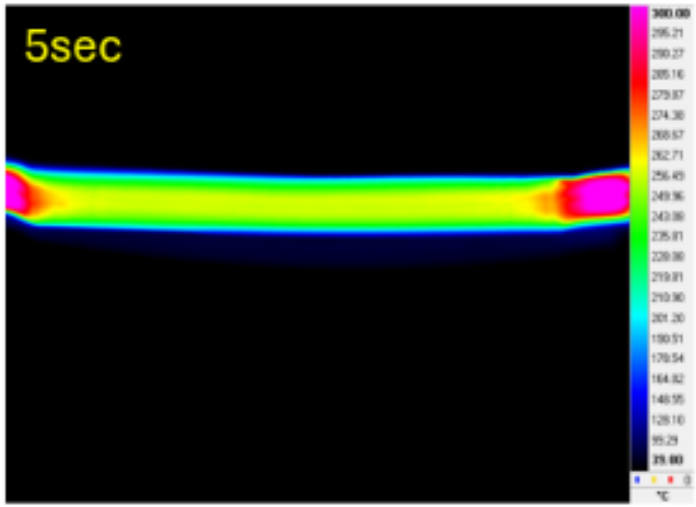
- ✓ Correlate the technological parameters to the physical changes







Thermal Characterization



UD Type

Fabric Type

Scalability Issues

Electrical Signal → **Tuned Thermal Output**

Issues

- Heating element Reliability and Consistency (Electrical and Thermal Properties)
- Component to be welded (Material, Length, Thickness)
- Control and Monitoring

Possible Solutions

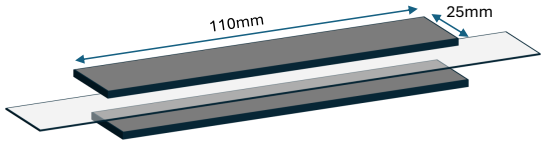
- Definition of acceptable processing windows
- Development of a Calibration processes
- Development of a Control and Monitoring System

Scalability Issues

Thermal Output

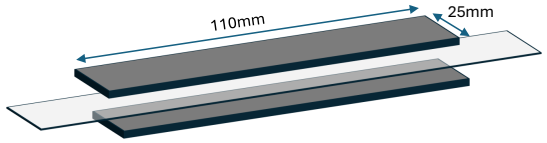
- Constant Electrical Input >> Time-Variable Thermal Output

- Variable Electrical Input >> Tuned Thermal Output
  - Batch Calibration >> Affected by Variability and Setup Variations
  - Individual Calibration >> No affected by Variability but affected by setup variation
  - Individual Calibration on Specific Setup >> No affected by Variability nor by Setup Variations
  - Real-Time control by Feedback > No affected by Variability nor by Setup Variations (Complex)

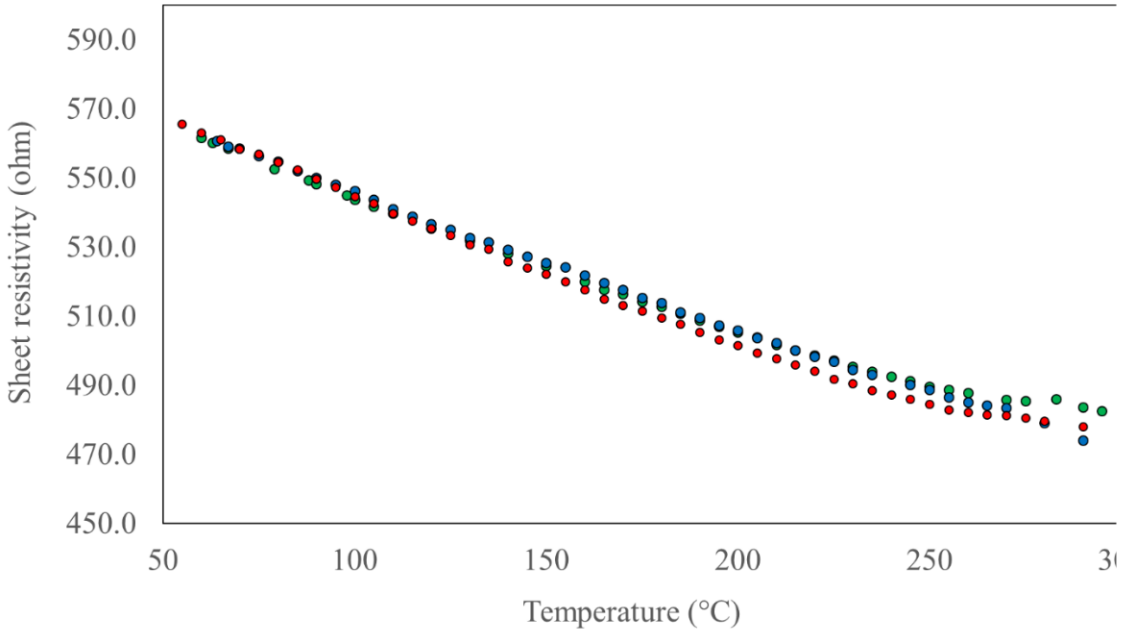


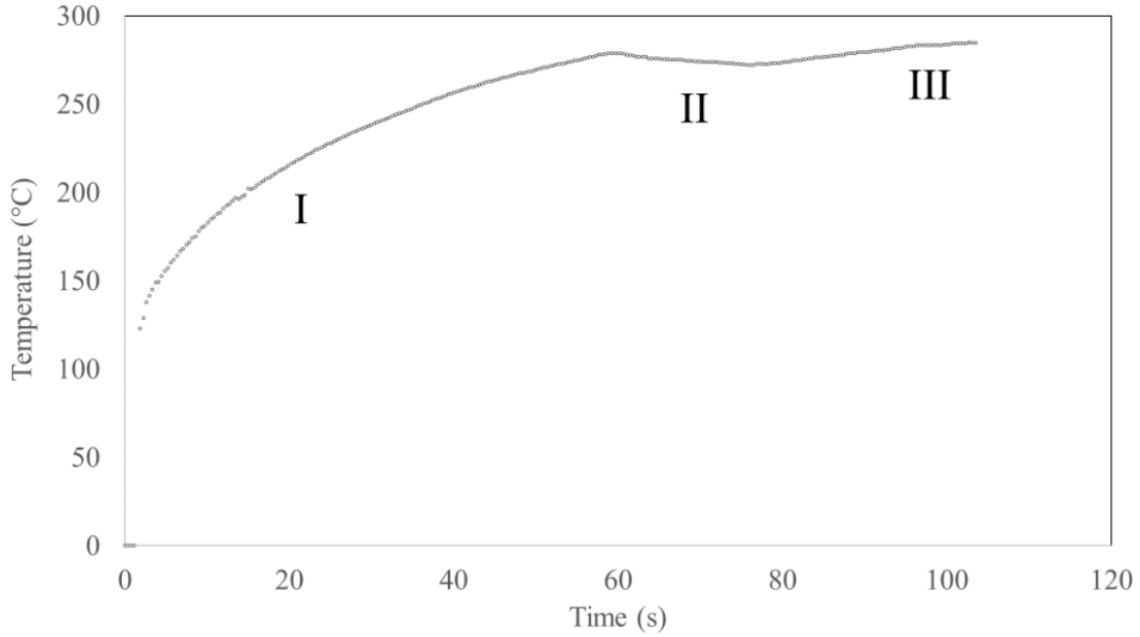
Batch Calibration

Individual Calibration



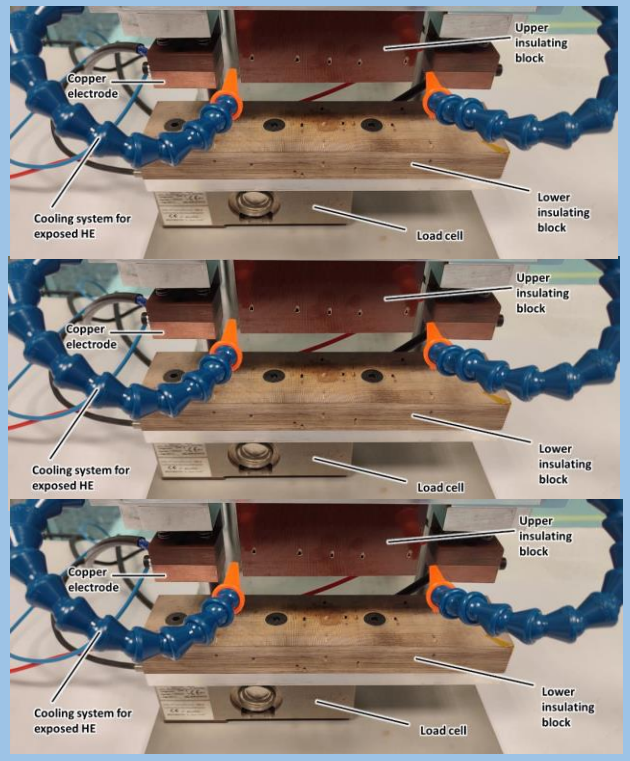
Individual Calibration on Setup

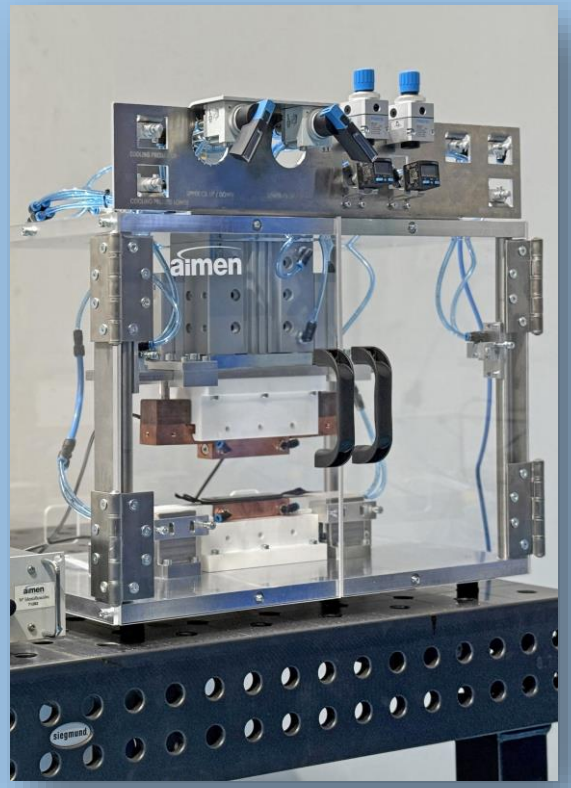




Real-Time Monitoring and Control

Real-Time Monitoring and Control

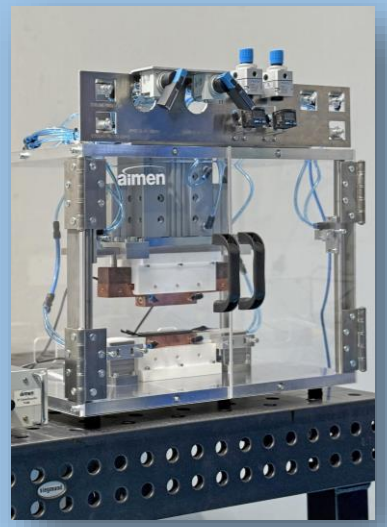


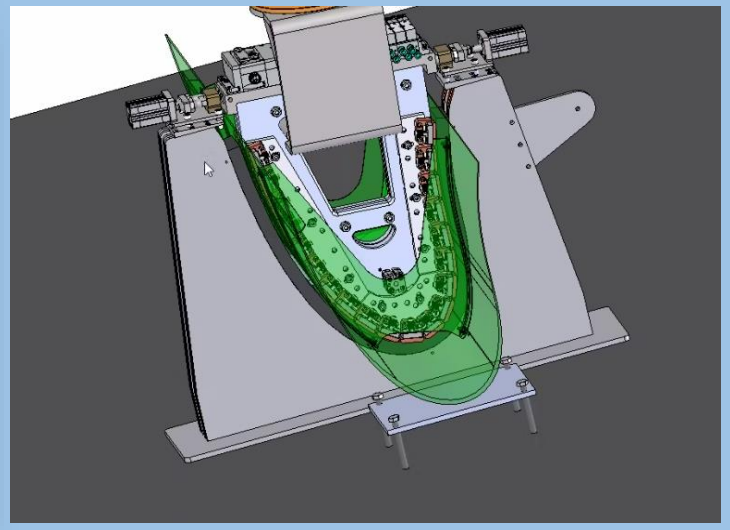


$$T = T_0 + \frac{\rho - \rho_0}{\omega}$$

LABORATORY SCALE TESTING

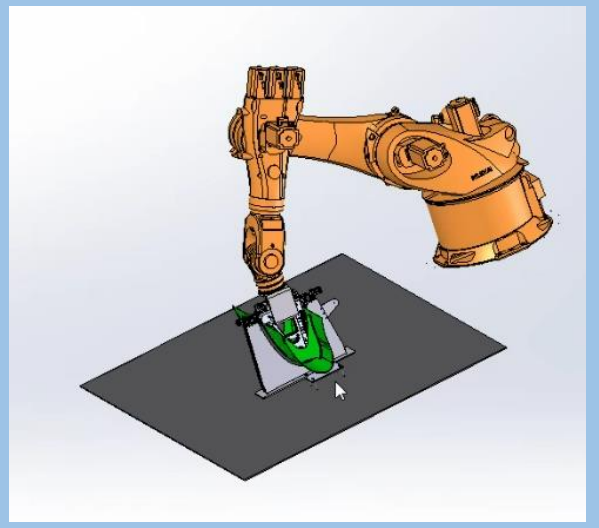
Laboratory scale….



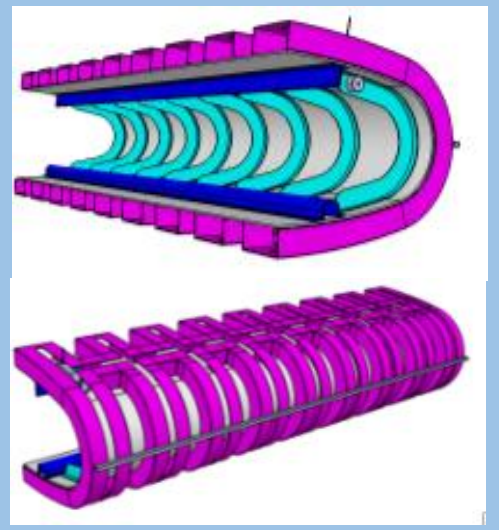


This Project has received funding from Clean Sky 2 Joint Undertacking (JU) under grant agreement Nº101007814

SCALE UP PROCESS



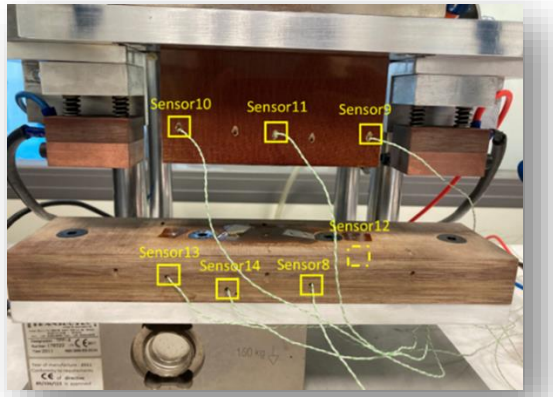
Demonstrator scale….

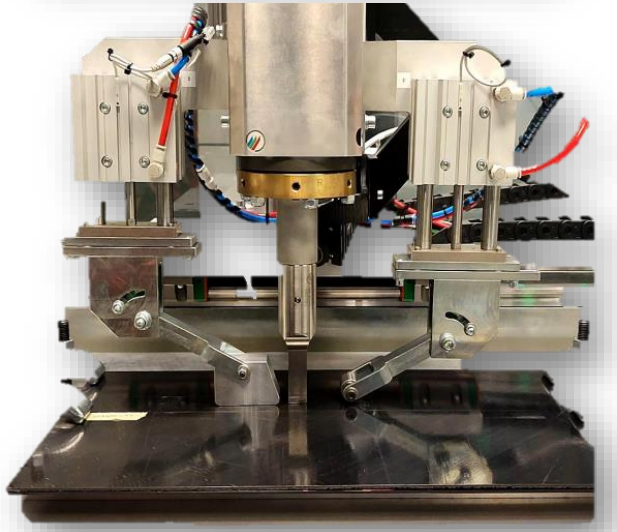


Energy director installation

Tooling and Head design

Automation and control systems





Final Welding Process

This Project has received funding from Clean Sky 2 Joint Undertacking (JU) under grant agreement Nº101007814

SCALE UP PROCESS

Other Success Stories

This Project has received funding from Clean Sky 2 Joint Undertacking (JU) under grant agreement Nº101007814

CONCLUSION

REMARKS

- Future applications of current manufacturing, assembly, and welding technologies are being developed in the direction of rapid, reliable and efficient processes.
- In the aviation industry, as well as other industries, research and analysis on the scalability of manufacturing methods can have a significant impact on future applications.

This Project has received funding from Clean Sky 2 Joint Undertacking (JU) under grant agreement №101007814

Molecular dynamics (MD): Curing simulation

Arrhenius-type reaction model

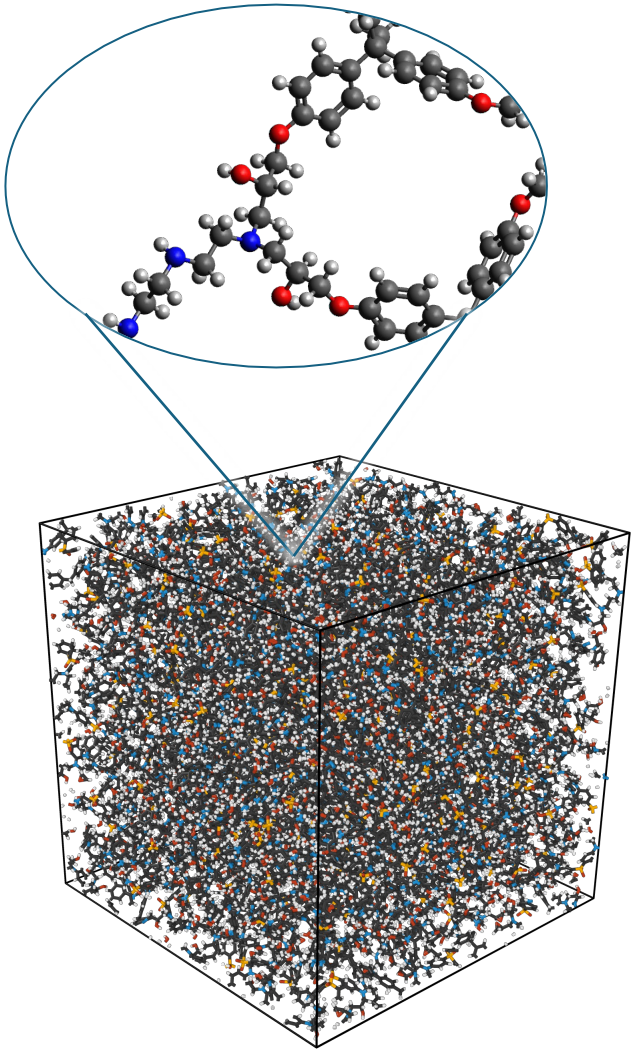
Base resin (DGEBA)

Curing agent (DETA)

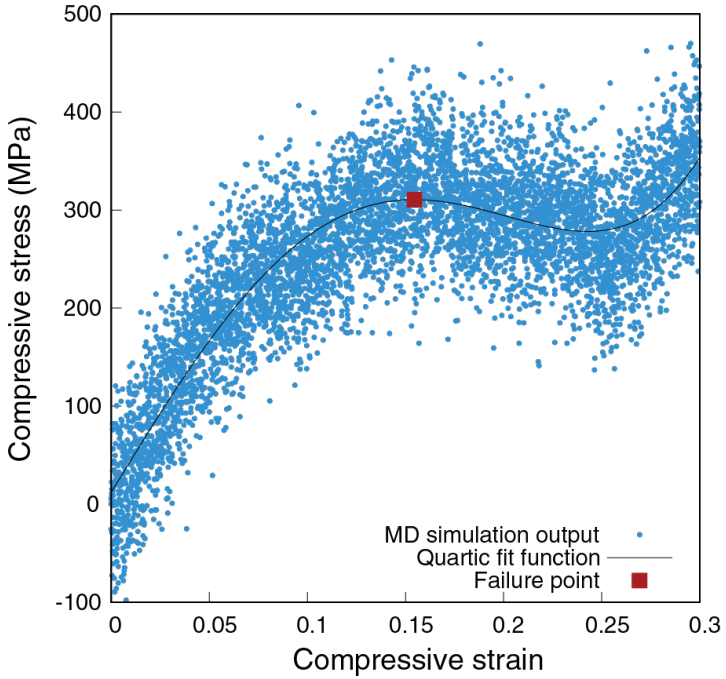
Reaction probability

$$p = A \exp\left(-\frac{E_a}{RT}\right)$$

Heat of formation



$$E_{\mathrm{Kin,after}} = E_{\mathrm{Kin,before}} + H_f$$

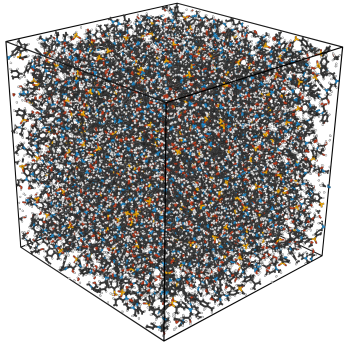


Curing simulated via MD with explicit molecular structures

→ Resin model constructed

T. Okabe, et al. Polymer 54 (2013) 4660e4668

MD : Numerical mechanical testing

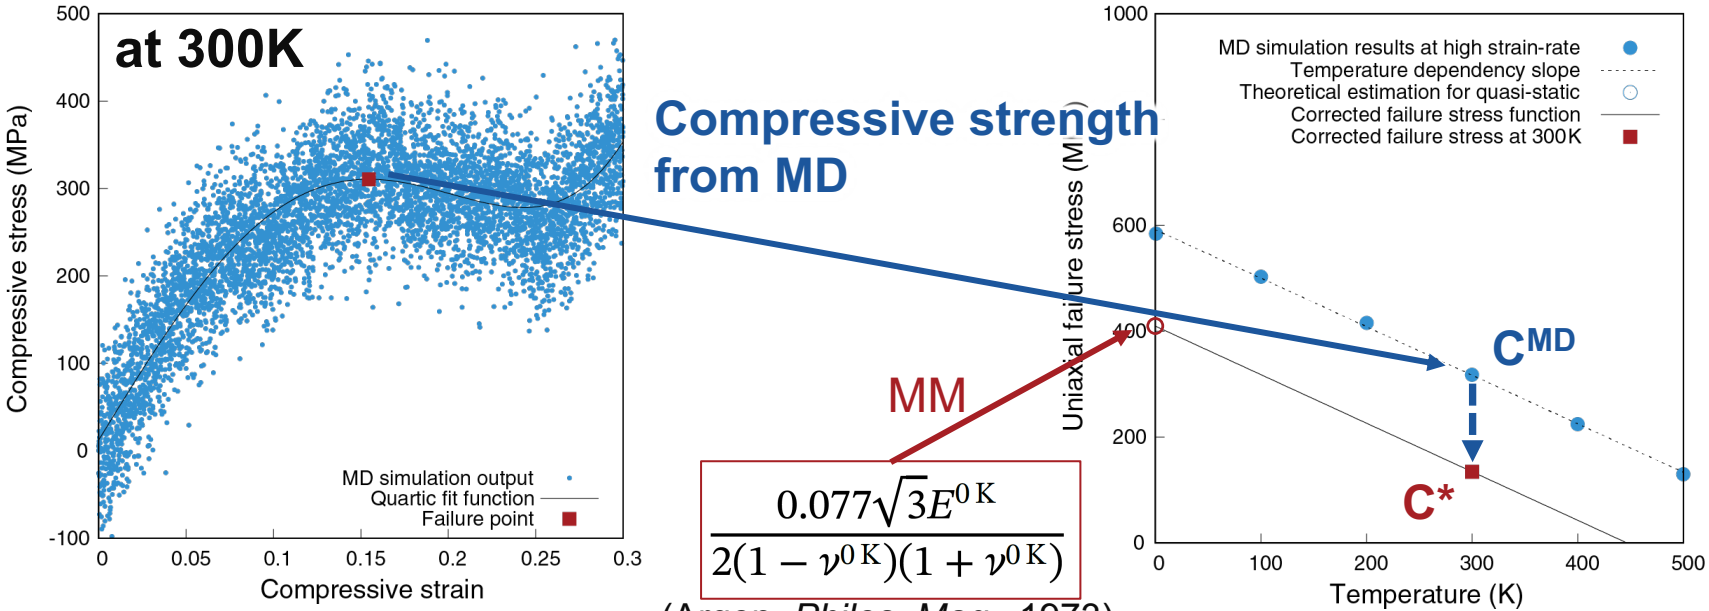


Mechanical behavior of the resin model evaluated numerically

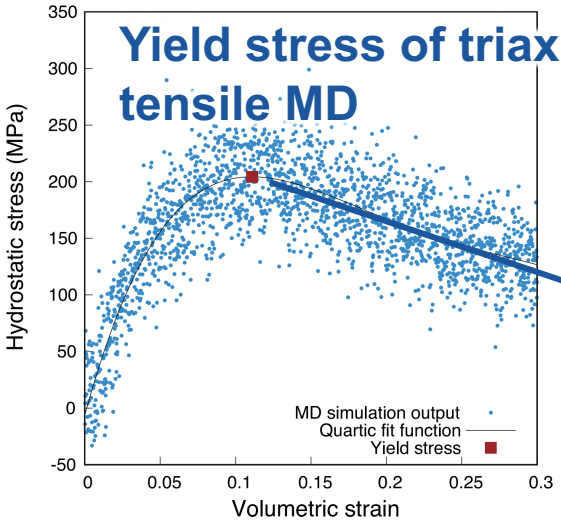
→ Obtained properties: **strength**, stiffness, **nonlinear response**, and CTE

Y. Kawagoe, et al. Mechanics of Materials 170 (2022) 104332
T. Watanabe, et al. International Journal of Solids and Structures 283 (2023) 112489

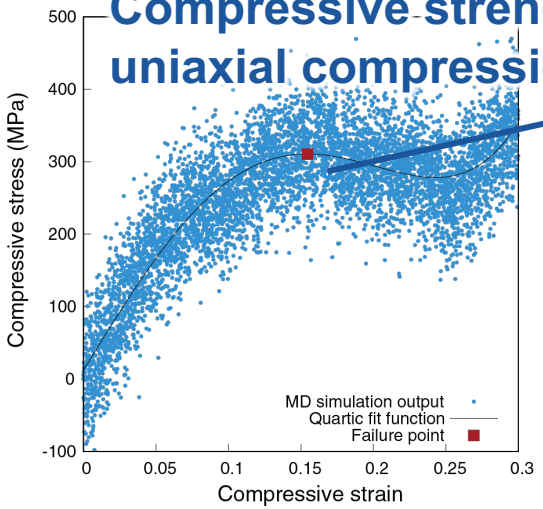
MD : Resin strength estimation



Limitations of mechanical testing via MD



Simulation times (~ns) → Extremely high strain rates



→ **Strength tends to be significantly overestimated**

Strain-rate adjustment using Argon's theory of molecular chain buckling (Sundararaghavan and Kumar, *Int. J. Plasticity*, 2013)

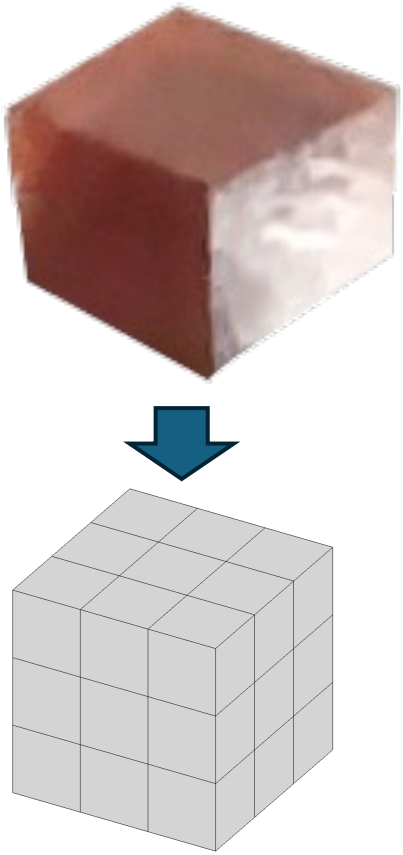
MD : Resin strength estimation

Christensen's failure criteria:

$$3\left(1-\frac{T}{C}\right)\frac{\sigma_{\mathrm{m}}}{C}+\left(\frac{\bar{\sigma}}{C}\right)^{2}\leq\frac{T}{C}$$

(Christensen, *J. Appl. Mech.*, 2019)

Lload is applied hydrostatically
→ von Mises stress is zero



$$\frac{T}{C}=\frac{3\sigma_{\mathrm{m}}^{\mathrm{f}}}{C+3\sigma_{\mathrm{m}}^{\mathrm{f}}}$$

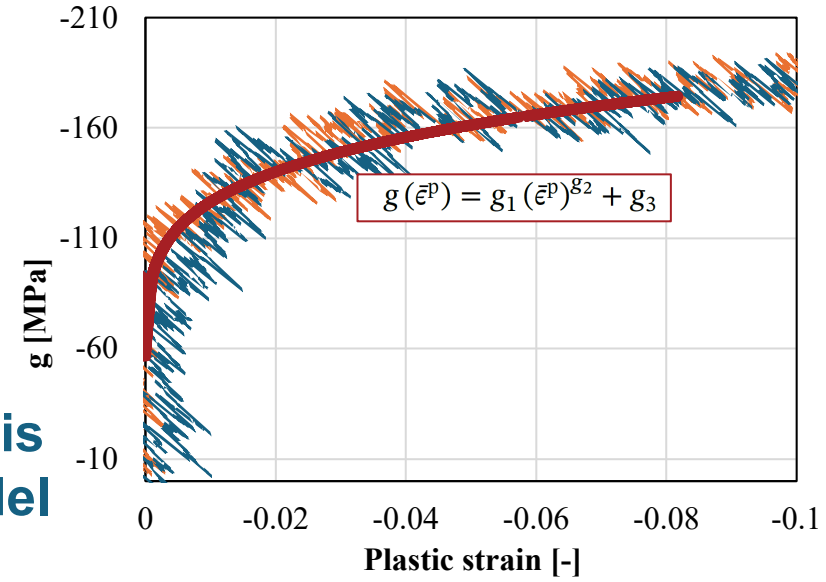
※ T/C is strain-rate independent

As a result, the following strengths are obtained:

- ✓ **Strain-rate corrected compressive strength: C***
- ✓ **Brittle–ductile index: T/C**
- ✓ **Corrected tensile strength: T* = (T/C)·C***

MD : Resin nonlinear response

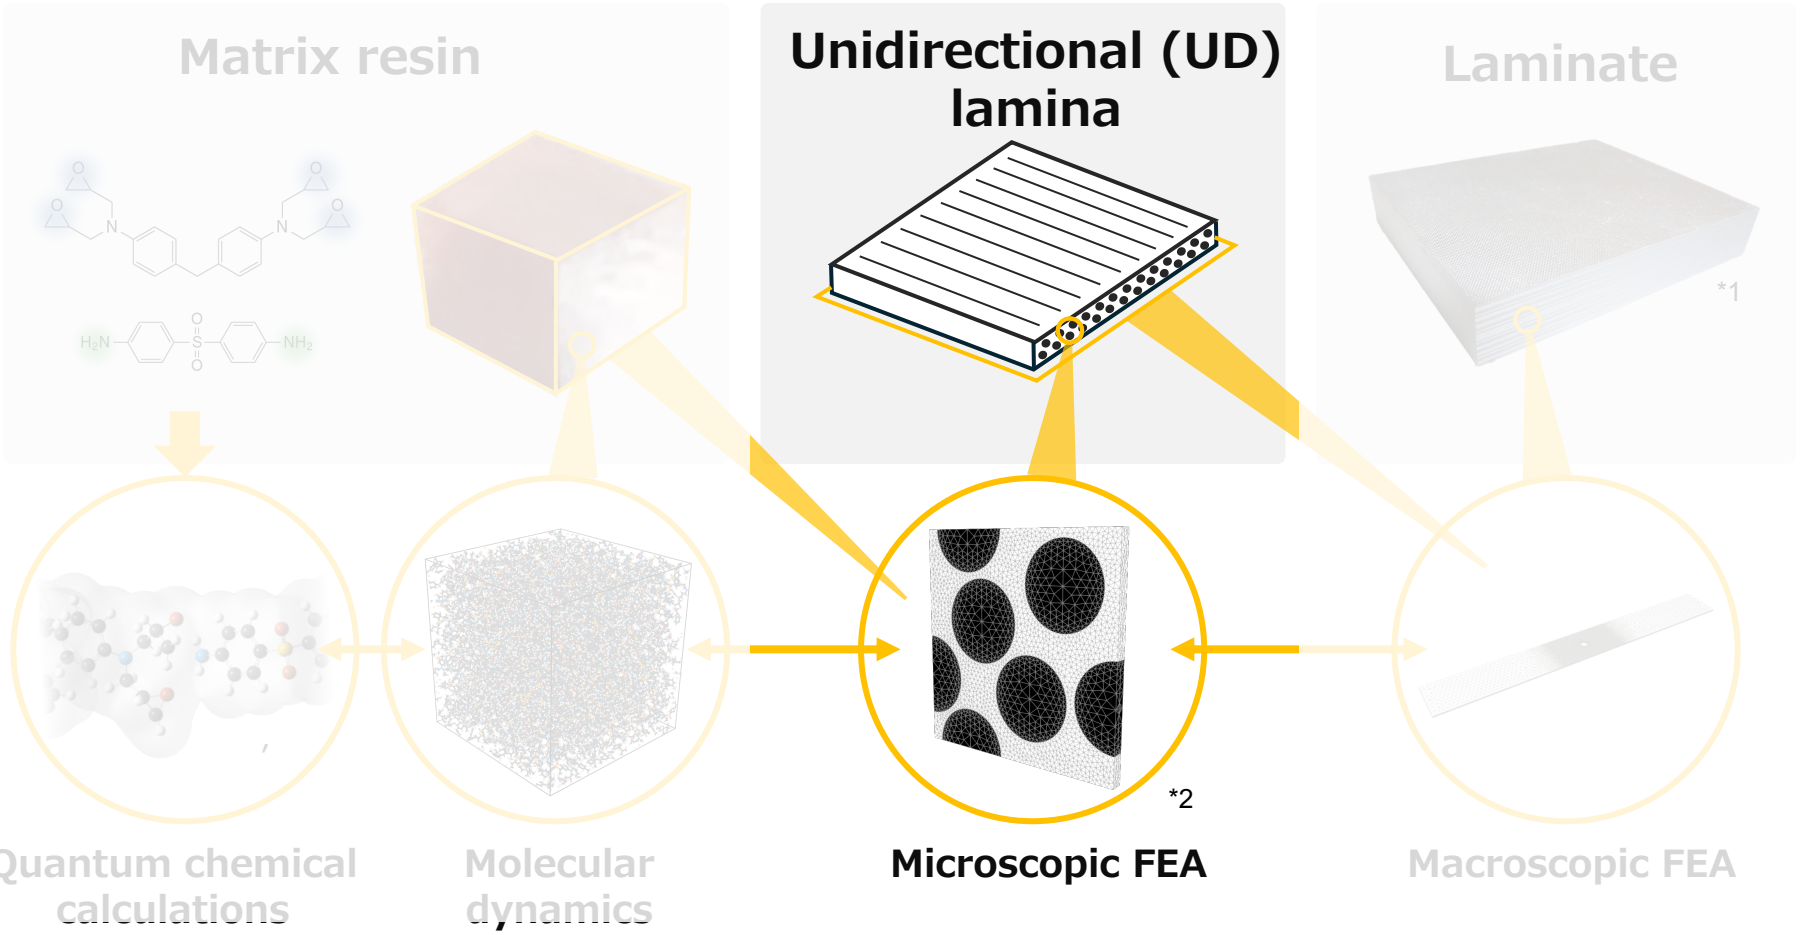
Elasto-viscoplastic constitutive law



(Kobayashi, *Transaction of JSME Series A*, 2004)

$$\dot{\boldsymbol{\sigma}} = \boldsymbol{C}_{\mathrm{m}} : \dot{\boldsymbol{\epsilon}} - \frac{3\mu\dot{\bar{\epsilon}}^{\mathrm{p}}}{\bar{\sigma}}\boldsymbol{\sigma}'$$

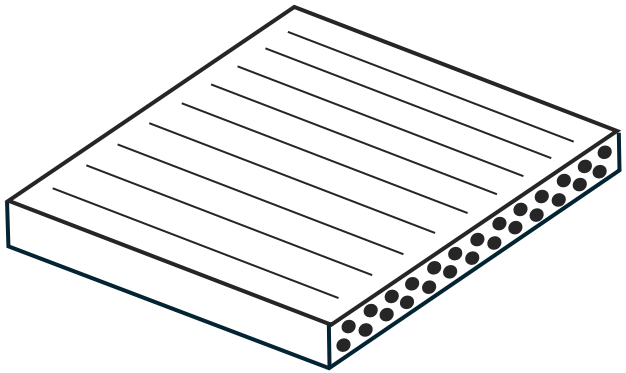
$$\dot{\bar{\epsilon}}^{\mathrm{p}} = \dot{\epsilon}_{\mathrm{r}}\left(\frac{\bar{\sigma} + \beta\sigma_{\mathrm{m}}}{g\left(\bar{\epsilon}^{\mathrm{p}}\right)}\right)^{\frac{1}{k}} \qquad g\left(\bar{\epsilon}^{\mathrm{p}}\right) = g_1\left(\bar{\epsilon}^{\mathrm{p}}\right)^{g_2} + g_3$$



E_{m} , ν_{m} : Elastic parameter

g_1 , g_2 , g_3 : Plastic parameter

Plastic response obtained from MD is approximated by a constitutive model



Introduction: Hierarchical structure of CFRP

Objective:

CFRP strength parameters are estimated in a bottom-up manner through multiscale modeling, combining models specialized for each scale

Summary and Applications

- ✓ In this study, **five composite strength** parameters were estimated in a bottom-up manner by integrating **quantum chemical calculations,** molecular dynamics (**MD**), finite element analysis (**FEA**), and **theoretical models.**
- ✓ The seamless linkage of these methods enables both bottom-up and top-down analyses, clarifying the correlation between microscopic **molecular structure** and **macroscopic strength**.
- ✓ The five obtained strength parameters can be applied to **laminate-scale analyses**, such as open hole tension (OHT) and compression (OHC) simulations.

Butt-joint Single-Stringer Specimen

Tracking Delamination Growth in Post-Buckling

Current Challenge

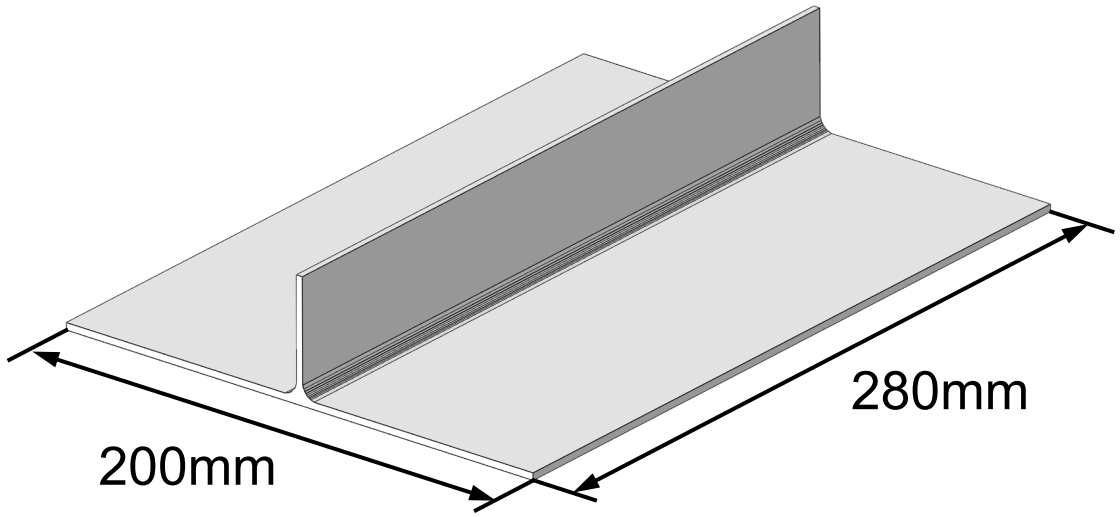
Experimental methods cannot continuously capture skin-stringer delamination growth in detail during post-buckling.

Why It Matters

Lack of detailed data limits calibration and validation of advanced numerical damage models.

Research Objective

Experimental tracking of skin-stringer delamination growth in post-buckled composite panels.

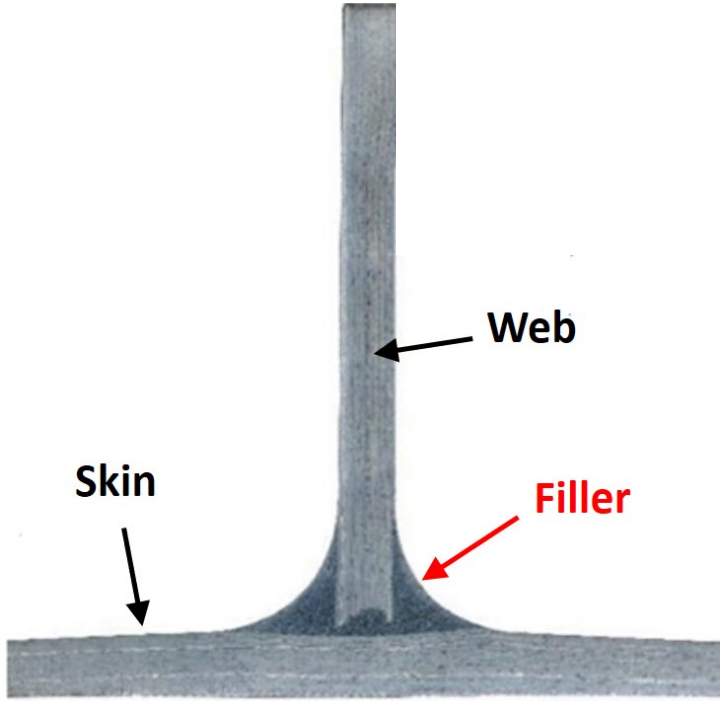


Opportunity

High-fidelity experimental data can improve prediction accuracy, supporting certification of composite airframe post-buckling designs.

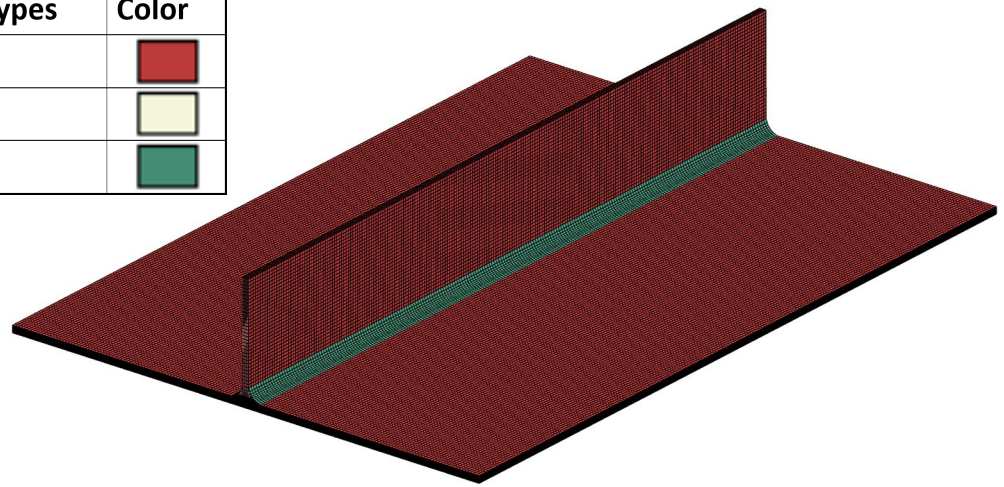
Outline

- ✓ **Design of Experiment**
- ✓ **Monitoring Methodology**
- ✓ **Results**
- ✓ **Conclusions & Future Work**

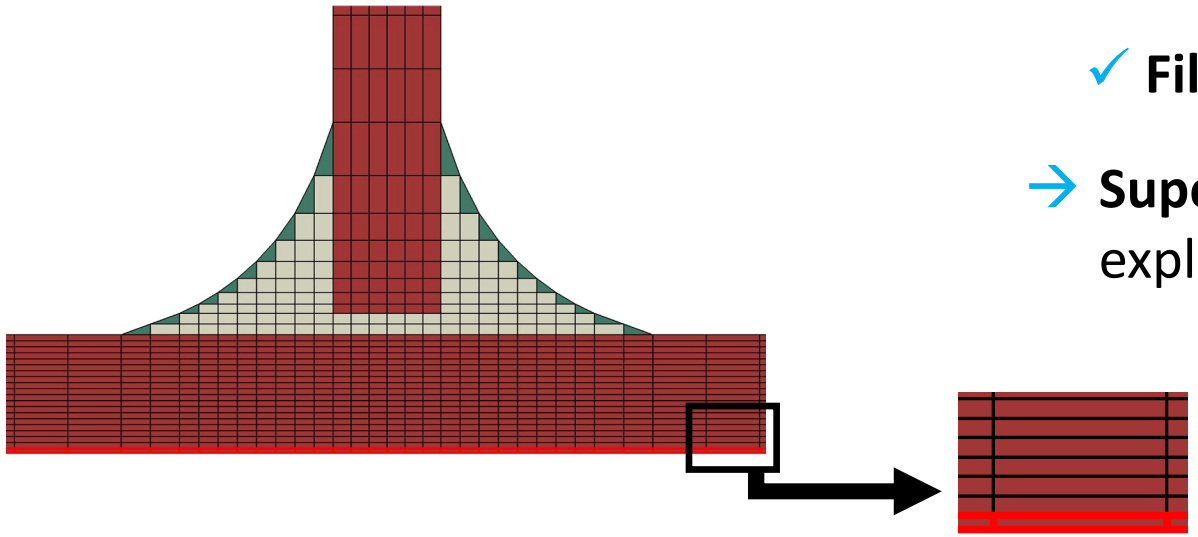


Design of Experiment: Specimen

Component	Material
Skin	UD AS4D/PEKK
Web	UD AS4D/PEKK
Filler	SCRP CF/PEKK



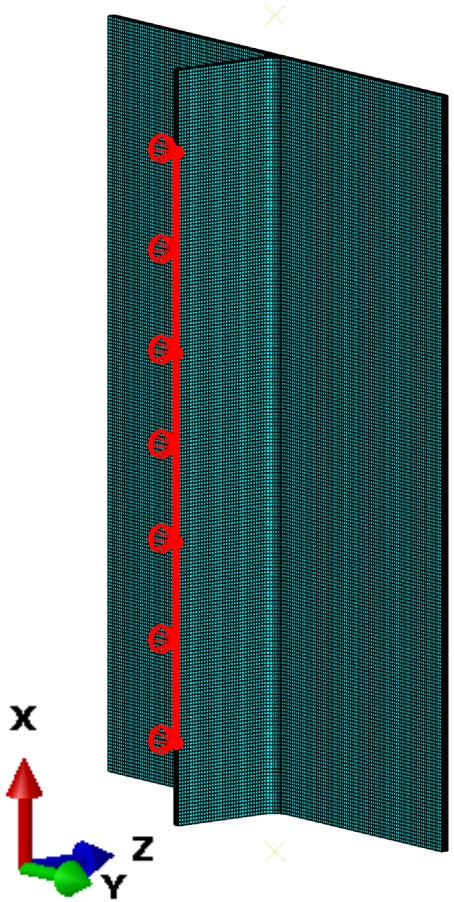
DoE Objective:



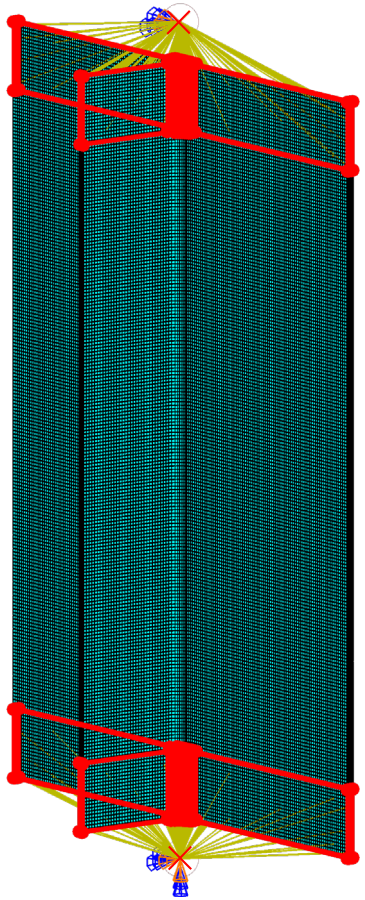
Dimensions, layups and boundary conditions were optimized using FEA to maximize stable skin-stringer delamination growth.

Design of Experiment: FEM Setup

Element Types	Color
SC8R	
C3D8I	
C3D6	



FE Software: Abaqus 2023



Model Details:

- **Mesh seed size**: 1.25mm
- **Local mesh refinement** at the stringer
- **Total elements**: 869,568
  - ✓ **Laminated components**: SC8R elements
  - ✓ **Filler**: C3D8I and C3D6 elements
- **Superficial resin layer** on OML side explicitly modeled (SC8R elements)

Design of Experiment: Boundary Conditions

Keywords: CFRP, Fatigue testing, 3-point bending, Load introduction, Cyclic loading

ABSTRACT

CFRP is widely used in lightweight structures subjected to cyclic loading. However, the fatigue performance at the structural level, particularly with mechanical joints, remains insufficiently understood. This study investigates the fatigue behavior of quasi-isotropic CFRP square tubes under cyclic 3-point bending, with a focus on a load introduction concept using bolted connections with structured surface plates. The specimens are tested under fully reversed loading at 1 Hz. Quasi-static baseline tests reveale linear behavior up to failure and high reproducibility between specimens. Cyclic tests show a clear increase in fatigue life with decreasing load amplitude. Hysteresis analysis reveals asymmetric behavior and narrowing around the zero-crossing prior to failure, especially in high-cycle specimens. The specimen with the highest cycle count exhibited a distinct fiber fracture on the tensile side, suggesting a change in failure mode compared to quasi-static loading. The results highlight the relevance of the hysteresis loop shape as a potential indicator for fatigue damage and structural monitoring. The findings underscore that fatigue failure may occur in locations different from those under static loading, suggesting that conventional design approaches based on static safety factors may be insufficient for the design of CFRP structures.

1 INTRODUCTION

Carbon fiber reinforced polymers (CFRP) are increasingly used in lightweight structural applications due to their excellent strength-to-weight ratio, corrosion resistance, and stiffness. They are well established in high-performance industries such as aerospace, automotive, and wind energy [1]. With rising production volumes and falling costs, CFRP has also become economically viable for

simpler structural components, such as square tube profiles, where mechanical performance and cost-efficiency must be balanced [2]. These components are gaining relevance in applications that demand robustness under repeated mechanical loading.

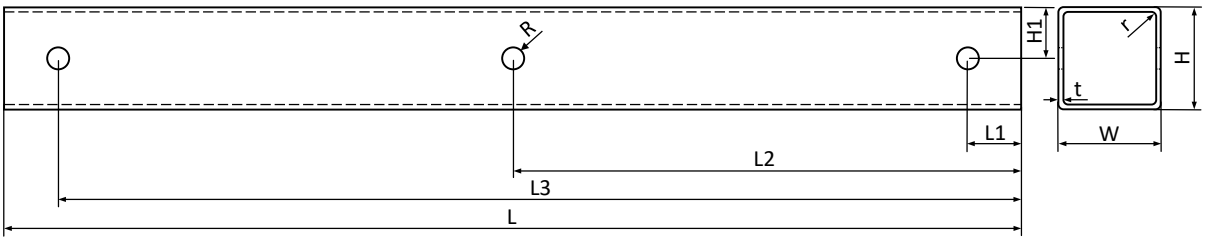
Cyclic loads are common in many operational environments. Despite the damage-tolerant nature of CFRP laminates under fatigue loading, the long-term performance of composite structures remains difficult to predict – especially at the structural level [3]. Most studies are limited to small-scale coupon specimens or highly application-specific configurations, leaving a research gap between elementary material tests and full-scale system evaluations [4].

A critical factor for structural CFRP components is a reliable load introduction. Bolted connections are widely used due to their mechanical reliability and ease of disassembly. However, they locally interrupt the fiber alignment and induce matrix cracking or delamination, making the joint region particularly vulnerable to fatigue degradation. Previous research has shown that structured surfaces at the interface can improve the load transfer capabilities of bolted joints by enhancing both mechanical interlocking and friction [5]. Understanding the fatigue behavior of such connections under realistic loading is essential for ensuring structural reliability and safe design margins. Moreover, being able to detect or predict fatigue-induced degradation is highly relevant for the development of structural health monitoring systems. In particular, hysteresis loop evolution under cyclic loading offers a promising approach for characterizing internal damage states [6], [7].

This study aims to address the outlined gap by investigating the fatigue performance of quasi-isotropic CFRP square tube beams under cyclic 3-point bending. A special focus is placed on the role of bolted load introduction with structured surfaces. The work builds upon earlier investigations of small-scale joint behavior and evaluates the structural-level fatigue response, with attention to both global mechanical performance and fatigue-induced changes in hysteresis characteristics.

2 RESEARCH PROBLEM AND OBJECTIVE

Fatigue in CFRP laminates is generally considered damage-tolerant, with gradual degradation rather than sudden failure. However, the load introduction zone remains a critical weak point, where local stress concentrations can initiate damage and accelerate failure processes [8]. Current research on cyclically loaded CFRP connections is fragmented and often based on simplified coupon tests, which limits its applicability to structurally relevant components [4].



Bolted connections are widely used for load introduction in CFRP due to their mechanical robustness, disassembly capability, and suitability for high force transfer. The load is transmitted through bearing stress, directly from the bolt into the laminate. However, the required drilling of holes leads to fiber interruption, causing matrix cracking and delamination in the surrounding region, which compromises structural integrity [9]. The fatigue strength of such connections can be improved through interference fits [8] and clamping pressure, although these effects depend strongly on geometry and assembly parameters [9]. Failure mechanisms in bolted CFRP joints can be categorized into four main types, each influenced by geometry and boundary conditions [10]. Bearing failure is considered the most desirable mode. It occurs as a localized compression failure near the bolt, typically characterized by resin crushing and fiber buckling. This failure is less brittle and more damage-tolerant, and is favored when a high plate width-to-hole diameter ratio is maintained [11]. In contrast, net-tension failure is a brittle mode resulting from high tensile stresses across the remaining ligament between the hole and the edge. It typically occurs when large bolts are used in narrow components, leading to sudden transverse cracking and rapid failure. Shear-out failure is another brittle mechanism, characterized by shear fracture along the bolt axis, often occurring when the end distance is too small. It frequently appears as a secondary failure following bearing damage, particularly in in-plane loading scenarios [12]. Lastly, cleavage failure combines features of net-tension and shear-out. It initiates at the end of the plate, especially when both edge and end distances are insufficient and the longitudinal fiber content is high, leading to crack propagation along an inclined path. Ensuring proper geometric ratios helps to avoid this mode [13]. To mitigate these failure mechanisms, it is essential to maintain precise hole manufacturing and sufficient edge distances [14]. Additional measures, such as embedded metal foils or localized reinforcement layers, can improve bearing strength and reduce sensitivity to geometric constraints [15]. Despite these measures, fatigue failure in bolted CFRP

connections remains difficult to predict, as it is highly dependent on load spectra, joint design, and laminate configuration [16].

Previous research has primarily focused on idealized test coupons. To address the lack of structural-level data, the present study investigates the fatigue performance of quasi-isotropic CFRP square tubes under cyclic 3-point bending. The aim of this study is to provide experimental data on the fatigue behavior of CFRP components at the structural level and to evaluate the effectiveness of a load introduction concept based on bolted connections with structured surfaces. By applying cyclic bending loads to full-scale square tube specimens, this work seeks to identify dominant failure mechanisms and assess the stability of the connection under fatigue.

3 SPECIMEN DESIGN AND TESTING APPROACH

The fatigue behavior of CFRP structures is investigated using a 3-point bending test setup. The test specimens consist of CFRP square tubes with dimensions of 75 × 75 × 750 mm and a wall thickness of 3 mm. The geometric dimensions of the specimens are shown in Figure 1, including mean values across all beams and their maximum deviations. Dimensions up to 75 mm were measured using a micrometer, while larger values were obtained with a caliper. The corner radius was determined via optical microscopy. Notable deviations are observed in the wall thickness and corner radius, whereas all other dimensions exhibited high dimensional accuracy. For the milled bolt holes, the measured radius deviation is at the limit of the measurement accuracy.

	W	H	L	$L1$	$L2$	$L3$	$H1$	R	r	t	$m\,(g)$
Ø (mm)	75.00 ± 0.002	75.00 ± 0.002	750.00 ± 0.1	40.00 ± 0.002	375.00 ± 0.1	710.00 ± 0.1	37.50 ± 0.002	8.00 ± 0.001	3.50 ± 1.011	3.15 ± 0.062	972.67 ± 6.30

Figure 1: Dimensions of the test specimens.

The laminate was manufactured using a prepreg process in an aluminum negative mold and featured a 12 layer quasi-isotropic layup, following the stacking sequence $[0°, 60°, -60°, 0°, -60°, 60°]_S$. To introduce the load, a bolted connection with structured surface plates is developed (see Figure 2). The bearing plates with structured contact surfaces are mounted on threaded pieces, which are pressed against the CFRP square profile by a locknut. These threaded elements are then fitted onto bolts through which the load is applied. This design enables both form-fit and clamping effects, aiming to enhance load transfer by increasing contact friction and minimizing stress concentrations. The structured surfaces featured pyramidal elements with a tooth height of 0.3 mm. The tooth geometry was selected based on literature [17] to ensure high friction and allowable surface pressure. The holes in the CFRP profile are manufactured with high dimensional accuracy to ensure a precise fit between bolt and laminate, as literature shows that even small clearance gaps can lead to a significant reduction in load transfer capacity [14].

To prevent overheating during high-cycle testing, compressed air is introduced through the hollow interior of the CFRP beam to provide active cooling. On the opposite side of the profile, an FFP2 filter is installed. This serves a dual purpose: first, to collect fine dust particles that might be expelled by the cooling airflow; and second, to create flow resistance, thereby improving air distribution through the beam and enhancing the overall cooling efficiency.

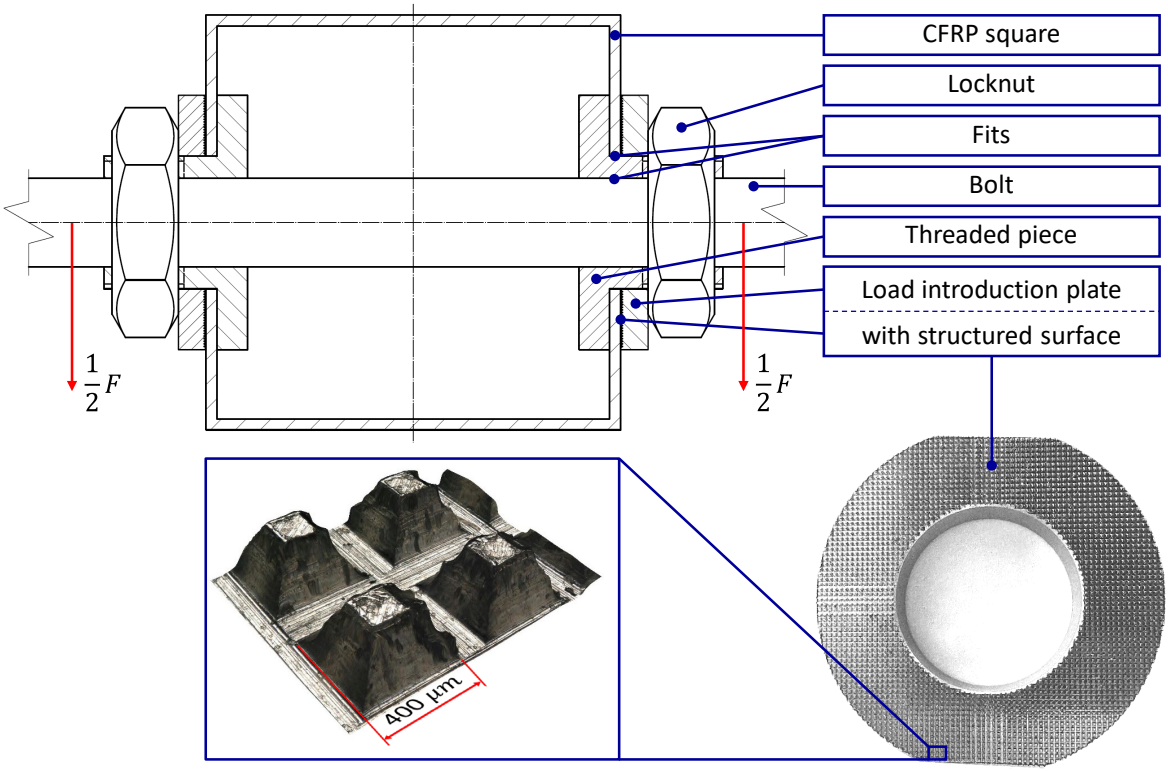


Figure 2: Load introduction design with structured surface and three-dimensional enlargement of the pyramid-shaped surface structure.

The experiments were carried out on a servo-hydraulic testing system with a maximum actuator force of 125 kN. The two outer supports are equipped with roller-bearing guides to compensate for axial displacement caused by beam deflection. Load is measured via a 125 kN load cell, and displacement is recorded both by the integrated actuator position sensor and an external laser displacement sensor, which is aligned with the midplane of the test setup. In addition, the temperature at the top flange of the CFRP profile is monitored using a Type K thermocouple.

At the beginning of the test series, two quasi-static destruction tests were performed to determine the maximum load capacity of the CFRP beams. This value serves as the basis for selecting the amplitude for the subsequent fatigue tests. The following cyclic tests were conducted under fully reversed loading at a frequency of 1 Hz. The first fatigue test was carried out at 85% of the previously determined maximum load, while the load amplitude was gradually reduced in the subsequent tests to assess the fatigue performance at lower stress levels.

4 RESULTS AND DISCUSSION

The structured surface embedding using the pyramidal profile was successfully implemented. No loosening of the locknuts was observed during cyclic testing, indicating stable mechanical fixation throughout the test duration. The cooling system proved effective, with a maximum temperature increase of only 1 °C at the measurement point. In contrast, a reference test without internal cooling, conducted at 1 Hz and a cyclic load of 45 kN, resulted in a temperature rise of approximately 23 °C after 30 minutes.

4.1 Quasi-static testing

The quasi-static tests reveal a linear force–displacement behavior up to the point of failure, indicating elastic material response across the tested load range. Maximum load capacity is observed at approximately 53 kN. Figure 3 shows the force–displacement diagram obtained from the quasi-static bending tests. Failure occurs suddenly, suggesting a brittle failure mechanism under bending load. A very good agreement is observed in the linear-elastic range of the force–displacement response.

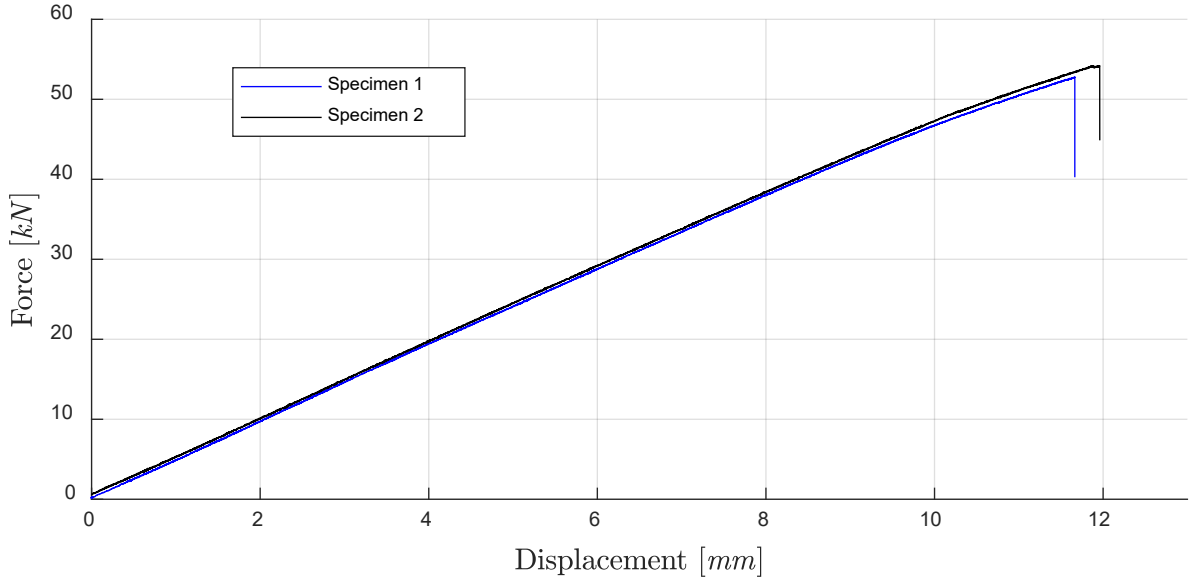

Figure 3: Force-displacement diagram of quasi-static tests.

Figure 4 presents the failure patterns of the two quasi-static specimens. The beams exhibit local buckling at the lower flange, combined with matrix detachment and interlaminar delamination, consistent with typical compression-induced failure mechanisms in fiber-reinforced polymer structures under bending. These failures are driven by local instability in matrix-dominated regions, which are especially sensitive to interlaminar shear stresses and separation. Notably, Specimen 1 failed at an off-center position, rather than directly at midspan where the highest bending moment occurs, and thus the failure, would be expected. A possible explanation for this behavior is that the load introduction locally reinforces the beam, especially the vertical webs of the square tube, thereby stabilizing the midsection and shifting the critical failure zone outward.

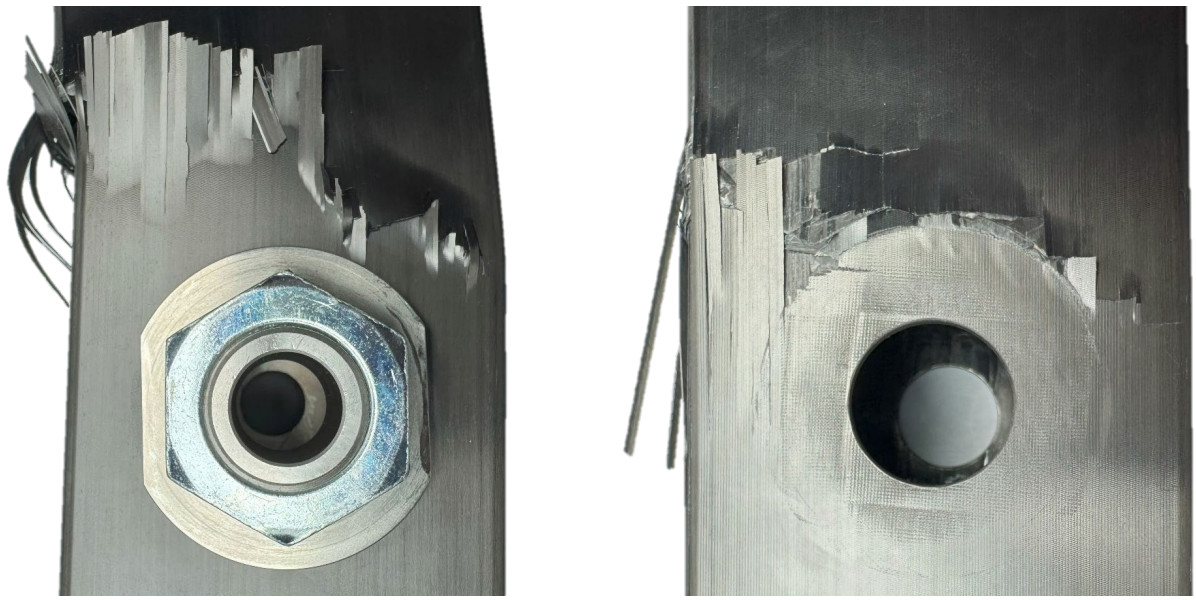

Figure 4: Failure of Specimen 1 with load introduction (left) and Specimen 2 without load introduction (right).

Specimen 2 exhibited a central failure fracture, as shown in Figure 4 (right). The fracture path runs around the load introduction region. As with Specimen 1, this suggests a stabilizing effect of the load introduction unit, likely due to the local reinforcement.

4.2 Cyclic testing

To evaluate the fatigue performance of the CFRP beams under cyclic loading conditions, a series of 3-point bending tests was carried out at decreasing load amplitudes. Table 1 summarizes the applied maximum force and the corresponding number of cycles to failure for each specimen. As expected, the number of cycles to failure increases with decreasing load level, indicating a typical fatigue response. While specimens tested at higher loads failed within a few thousand cycles, Specimen 7, sustained nearly 150,000 cycles before failure. The comparatively low cycle count of Specimen 5 suggests a potential outlier.

Test Specimen	Force [kN]	Number of Cylces to Failure
Specimen 3	45	2077
Specimen 4	43	10312
Specimen 5	40	2681
Specimen 6	38	12977
Specimen 7	35	149480

Table 1: Overview of tests.

Figure 5 compares the hysteresis behavior of Specimen 7 at cycle 100 and cycle 149,479, the cycle before final failure. A reduction in hysteresis area is observed at the later stage, indicating decreased energy dissipation, which is characteristic of advanced material degradation [18]. The loading and unloading paths converge near the zero-crossing, suggesting a nearly elastic response with no measurable plasticity or damping, a sign of structural exhaustion. While the overall stiffness appears unchanged, internal damage accumulation is likely near critical. A slight asymmetry and narrowing of the curve further points to localized effects such as delamination, matrix cracking, or fiber-matrix debonding. This observation is consistent with findings, where individual fiber bundles delaminated at the sides or corners of the beam, away from the eventual failure location, prior to global failure. This indicates that localized damage initiation can occur independently of the final fracture zone and further supports the interpretation of progressive internal degradation despite externally stable load-displacement behavior.

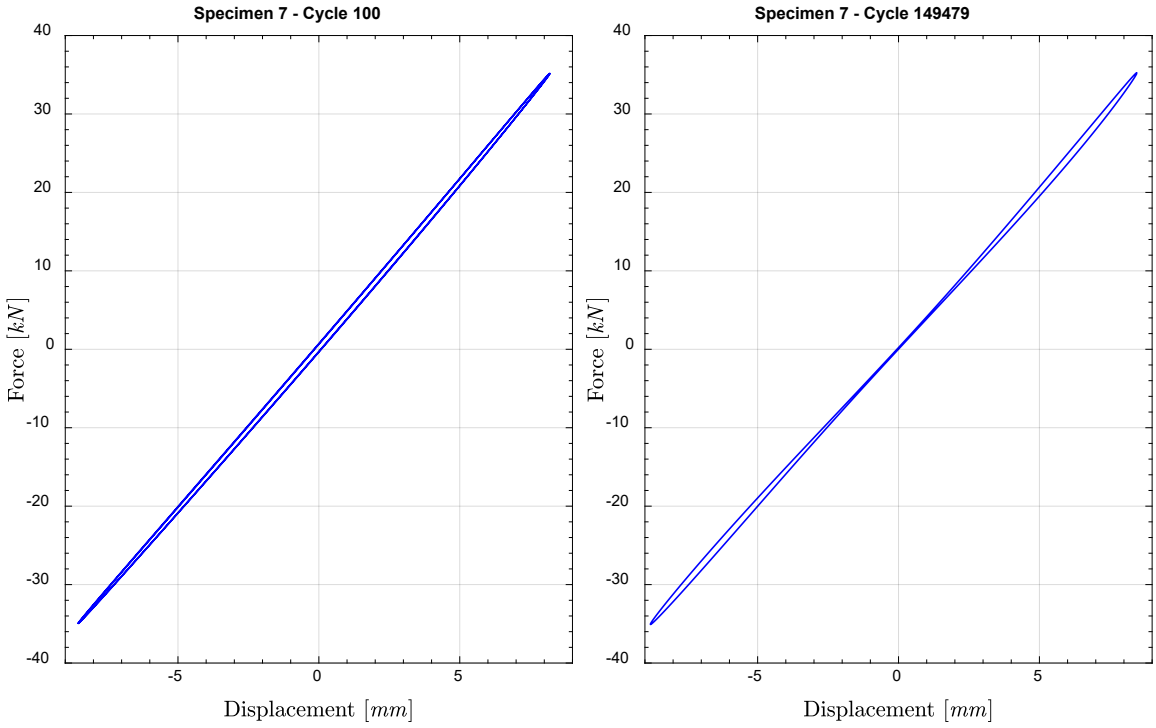

Figure 5: Hysteresis behavior of Specimen 7 at cycle 100 and 149479.

These features collectively indicate that the material has exhausted its damage tolerance and that failure is imminent. This progression highlights how the collapse of the hysteresis loop at the neutral axis could be precursor of final failure in fatigue-loaded composites. Such behavior could be relevant for structural health monitoring, as it highlights the need to detect early-stage internal damage. Localized delamination or fiber–matrix debonding could serve as early indicators of fatigue degradation. This aspect will be investigated in future tests. To enable a more detailed analysis of local damage progression, strain gauges will be applied at critical locations on the beam surface. This will allow for a broader and more spatially resolved dataset.

The convergence of the loading and unloading paths near the zero-crossing in Specimen 7 developed progressively over the final 40,000 cycles. A similar trend is observable in Specimens 4 and 6, where the hysteresis loops also narrow around the neutral axis as failure approaches. Furthermore, all specimens exhibit increasing asymmetry in their hysteresis behavior toward the end of their fatigue life, though with varying degrees of intensity.

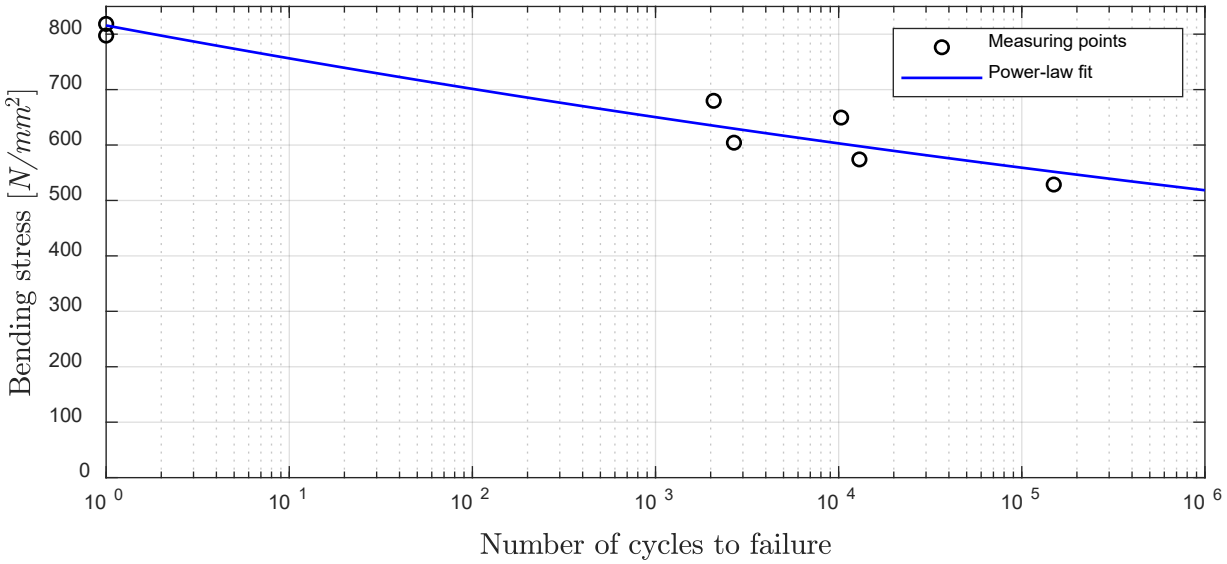

Figure 6: S-N curve with power-law fit trendline.

Figure 6 displays the bending stress versus the number of cycles to failure for all tested specimens. The results from the quasi-static tests are included as reference points with a cycle count of 1. To illustrate the overall trend in fatigue behavior, a power-law fit is applied to the data. This trendline provides a first approximation of the fatigue life curve, highlighting the expected decrease in maximum stress with increasing cycle number.

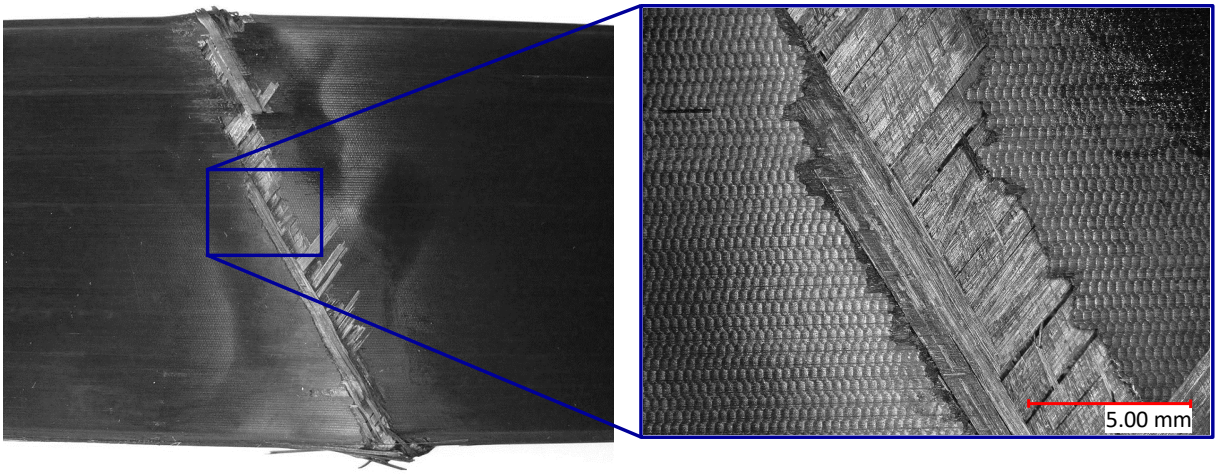

Figure 7: Failure of Specimen 7 with magnified view.

At low cycle counts, the observed failure modes are similar to those in the quasi-static tests, characterized by local buckling and delamination at the lower flange. However, at cycle numbers exceeding 10^4, delamination occurs on both sides of the specimen, which is consistent with the alternating loading applied during fatigue testing.

An exception appears in Specimen 7, where a distinct failure mode emerges. Instead of buckling on the compression side, as typically seen, the failure occurred on the tension side of the profile, where a fiber fracture accrued. This result is shown in Figure 7. Such a shift in failure location under fatigue loading is particularly relevant for design practice, as it challenges the assumption that fatigue failure occurs at the same critical location as static failure. In many current design approaches, fatigue is accounted for by applying a global safety factor to the static strength. This strategy may be insufficient when fatigue failure initiates in different regions of the structure. Since only a single specimen was tested in this high-cycle regime, further tests are planned to statistically validate this observation and assess its reproducibility.

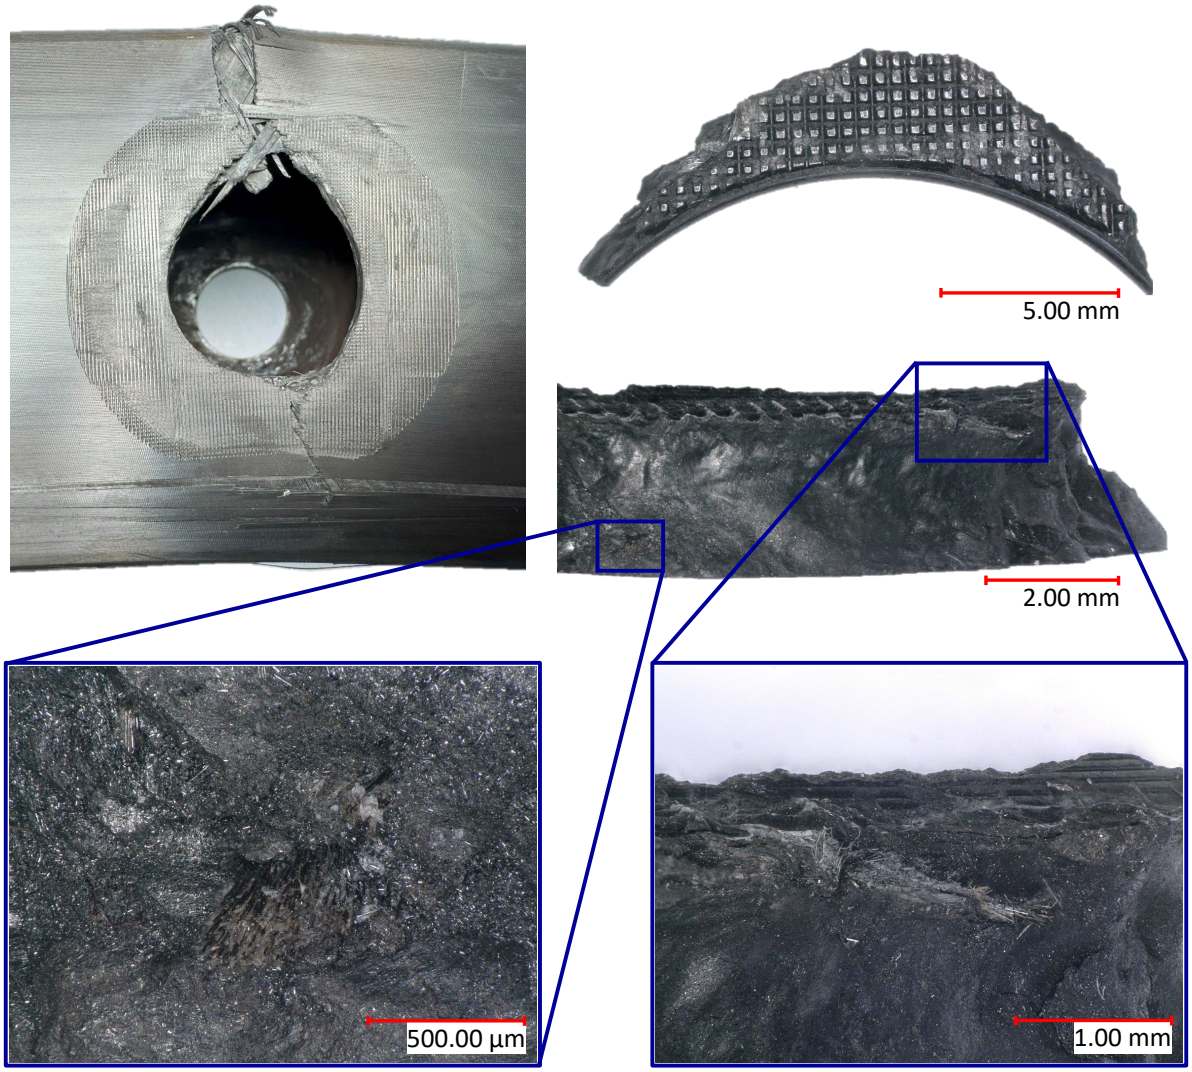

Figure 8: Top view of the damage on Specimen 7 (top left) and the detached fragment (top right). The fracture surface is shown in the middle right image, with magnified views of the fracture edge and exposed fiber bundles (bottom).

None of the tested specimens exhibited catastrophic failure at the load introduction area. However, in two cyclically tested specimens, seizure (galling) occurred between the bolt and the threaded insert. In both cases, localized damage to the CFRP in the load introduction zone is observed (see Figure 8).

The material appears brittle, and during disassembly, a portion of the laminate fractured and detached, shown on the right top in Figure 8. Below that, the fracture surface of the detached laminate fragment is shown. The surface exhibits a dark, discolored appearance, which visually resembles thermal damage or burning. Only two small areas with visible fibers can be identified, which are shown in magnified view in the lower part of the figure.

A possible explanation is that localized frictional heating during galling led to temperatures exceeding the glass transition temperature of the CFRP matrix, resulting in material degradation. Although this was not the primary failure mode of the beams, the finding emphasizes the critical importance of the load introduction zone in the fatigue design of CFRP structures. Even if structural failure occurs elsewhere, thermo-mechanical interactions at the interface may compromise long-term performance and must be accounted for in design and monitoring strategies.

5 CONCLUSION

This study contributes to the understanding of the fatigue performance of CFRP structures at the component level. CFRP square beams were tested under both quasi-static and cyclic 3-point bending, with the load introduced via structured bolted plates that ensured both form-fit and force-fit conditions. The quasi-static tests showed good repeatability across specimens, with linear behavior up to failure, followed by sudden collapse. The load introduction concept demonstrated a stabilizing effect on the beam structure.

Under cyclic loading up to 45 kN, the expected increase in the number of cycles to failure with decreasing load amplitude was observed. Notably, several specimens exhibited distinct hysteresis behavior prior to failure, including asymmetry and a progressive narrowing near the zero-crossing in high-cycle regimes. The specimen with the highest cycle count failed through a fiber break on the tensile side, suggesting a different failure mechanism compared to the quasi-static case.

These observations highlight the potential of hysteresis behavior as an indicator of internal damage, making it a promising approach for future structural health monitoring applications. Upcoming test series will focus on high-cycle regimes and will incorporate strain gauge measurements to further investigate the link between hysteresis characteristics and damage evolution. From a design perspective, the findings emphasize that fatigue failure may occur at locations different from those predicted by static analysis. Therefore, applying conventional safety factors to static designs may be insufficient for fatigue-critical CFRP structures. A more nuanced approach to fatigue assessment is needed – especially when mechanical connections are involved.

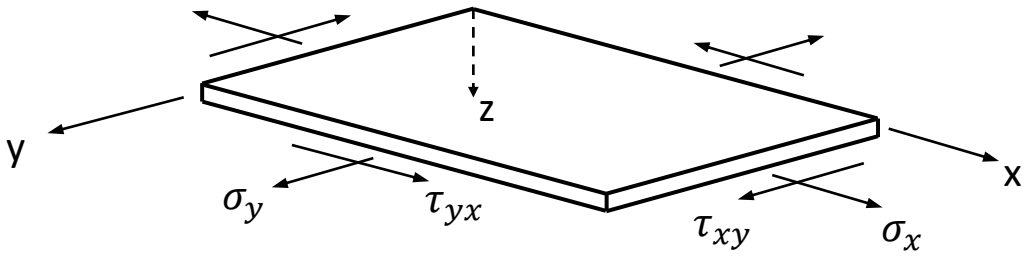
Impact of Stacking Sequence on Tensile and Fatigue Performance of Quasi-isotropic Carbon/Epoxy Laminates

Marc Gadinger, Torben Deutschmann, Dieter Krause, Sandro Wartzack

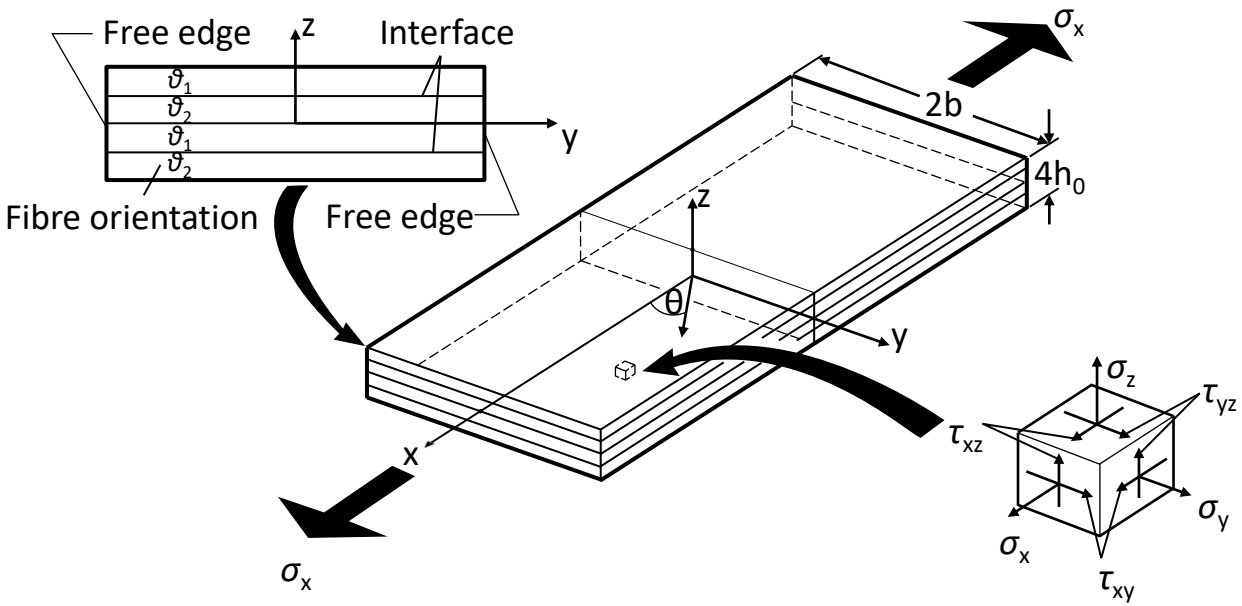
Outline



- Interlaminar stresses
- Research problem and research goal
- Methods and procedures
- Results and discussion

Interlaminar stresses

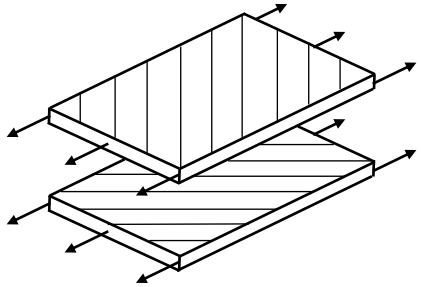
Problems with classical laminate theory



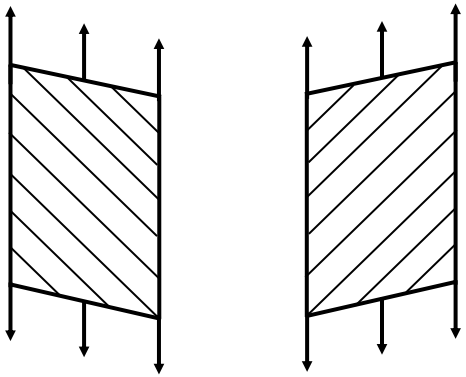
Classical laminate theory

- Only stresses within the plane $\sigma_x, \sigma_y, \tau_{xy}$
- Neglecting the spatial stress components σ_z, τ_{xz}, τ_{zy}
- Prediction of physically impossible stress states, e.g. along the free edges

Interlaminar stresses

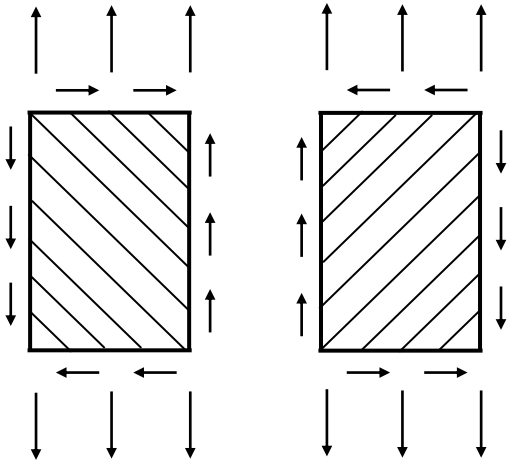


- Between the layers, as well as along free edges, borders and surfaces of the laminate
- Triggering various failure mechanisms in many composite materials



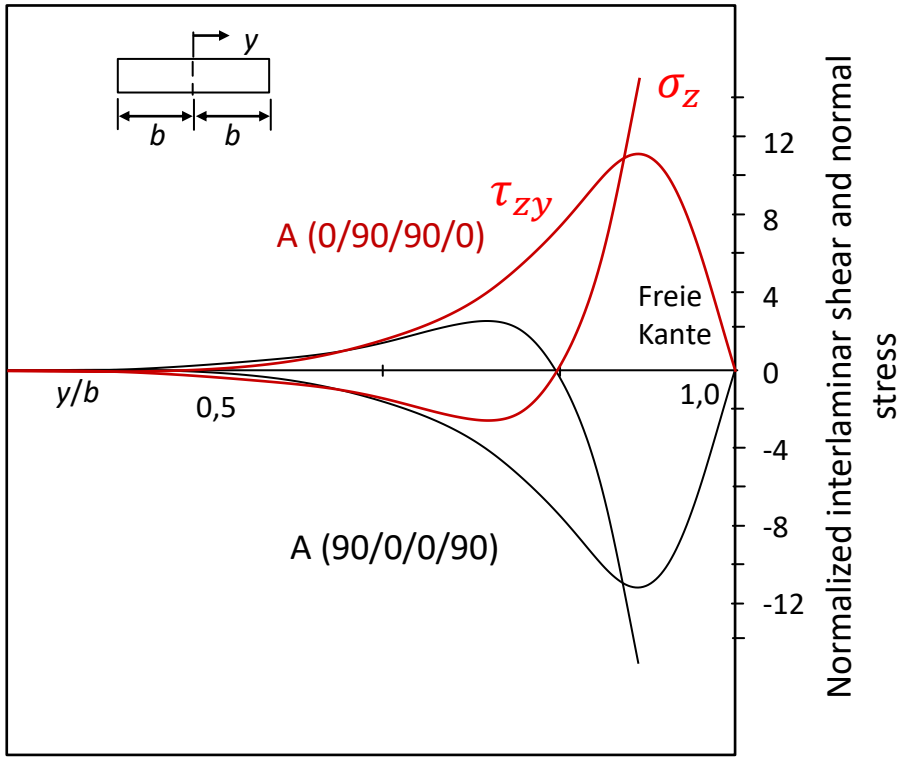
Jones, R.M. Mechanics of Composite Materials. 2nd Ed. Taylor & Francis. 1999.

Interlaminar stresses



Ausgeglichener Winkelverbund

Layers under tension



Layers under tension and shear (no shear deformation)

Stress distribution at free edge

- Complex curves with high stress peaks
- Can be influenced by changing the stacking sequence

Jones, R.M. Mechanics of Composite Materials. 2nd Ed. Taylor & Francis. 1999.

Research problem and research goal

- Problem statement
  - Free-edge delamination can dominate strength & fatigue life in quasi-isotropic carbon/epoxy laminates

- Research goal
  - Compare two quasi-isotropic lay-ups with opposite edge stress signatures
    1. [90°, 45°, 0°, –45°]s → outer 90° plies → compressive edge σ_z
    2. [45°, –45°, 0°, 90°]s → outer ±45° plies → tensile edge σ_z
  - Assess effects on:
    - Ultimate tensile strength
    - Stiffness degradation & damage evolution under fatigue
    - Cycles-to-failure at constant max load

Methods and procedures

Materials & Specimens

- Material system: unidirectional carbon/epoxy prepreg
- Lay-ups tested:
  - Quasi-isotropic, 8 plies (symmetrical)
  - Thickness per ply = 0.2 mm
- Specimen geometry & preparation
  - Rectangular coupons per ASTM D3039-76 (tension) / D3479-96 (fatigue)
  - Tabs bonded to prevent grip damage

Test Setup & Environment

- Test machine: ZwickRoell servo-hydraulic, 25 kN load cell
- Lab conditions: 21 ± 1 °C, 50 ± 4 % RH
- Instrumentation
  - Force & grip-to-grip displacement logged continuously
  - IR thermometer maintained surface temp stability
- Test regimes
  - Quasi-static tension: monotonic pull to failure
  - Fatigue: sinusoidal, R = 0.1, f = 4 Hz, Pmax = 25 kN

Results and discussion

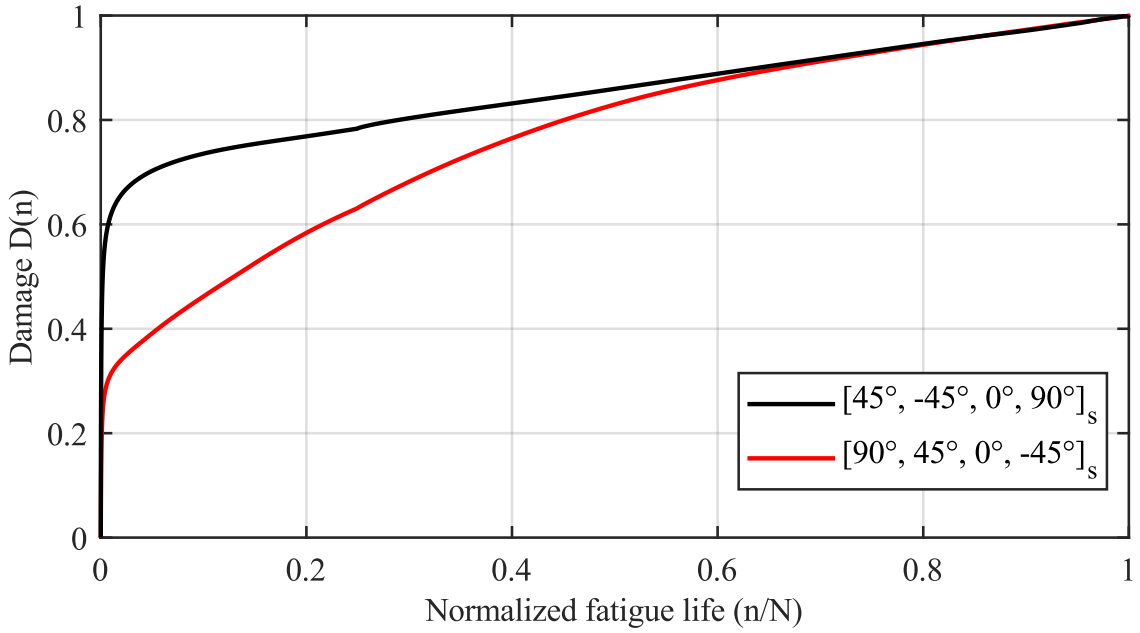
Quasi-Static Tension

Metric	[90°, 45°, 0°, –45°]s	[45°, –45°, 0°, 90°]s	Δ
UTS (MPa)	582.4 ± 2.8	520.9 ± 15.5	**+11 %**
Tensile Modulus (GPa)	40.93	40.80	~equal
Failure Strain (%)	1.88	1.98	~equal

Damage observations

- 90°-outer lay-up: no delamination; matrix cracking ruled failure
- ±45°-outer lay-up: early edge delamination between 90° plies

Results and discussion



Fatigue Behavior

Stiffness-degradation trends

- ±45°-outer: sharp early drop due to edge delamination
- 90°-outer: gradual decline; matrix cracks dominate

Cycles-to-failure

- Both lay-ups ≈ 18 k cycles (no significant difference) at 25 kN max load
- Highlight distinct initial slopes; annotate similar end-of-life points

Results and discussion

Edge stress state governs initiation mechanism

- Compressive σ_z (90°-outer) delays delamination → boosts UTS
- Tensile σ_z (±45°-outer) accelerates edge delamination → lowers UTS

Why fatigue life converged

- Once delamination achieved steady growth, both stacks relied on matrix crack propagation & fiber rupture → similar life

Design takeaway

- For static strength-critical parts, place 90° outermost in quasi-isotropic laminates
- For fatigue-critical parts at moderate R-ratios, edge stress tailoring alone may not extend life; need multi-scale damage mitigation

Next steps

- Vary stress ratio & amplitude
- Extend to thicker laminates / different ply drop

Thank you for your attention!

ABSTRACT

Fatigue in composite tidal turbine blades presents a critical challenge for the long-term viability of tidal energy systems. These blades are subjected to millions of high-load cycles in harsh marine environments, and predicting their fatigue performance numerically is difficult due to complex material behaviour, loading conditions, and modelling assumptions. Offshore mechanical testing has emerged as a practical solution, enabling equivalent oceanic loads to be applied within accelerated timeframes in a controlled environment, thereby allowing for reliable structural assessments.

FastBlade, a unique facility developed by the University of Edinburgh, addresses longstanding issues in fatigue testing through a regenerative digital displacement hydraulic pump/motor system. This innovative approach enables precise, programmable cyclic loading of full-scale blades, resulting in up to 75% reduction in energy consumption compared to conventional hydraulic systems. FastBlade's platform is particularly suited for stiff composite structures that cannot be tested at resonance due to thermal limitations.

This paper, as part of the MaxBlade project, synthesises a review of research conducted at FastBlade, focusing on fatigue tests of a tidal blade using both single and multi-actuator configurations. Target hydrodynamic loads were derived from site-specific velocity data and simulated using Reynolds-Averaged Navier–Stokes (RANS) methods. During testing, the blade endured the equivalent of 20 years of tidal loading without catastrophic failure. However, variations in tip

displacements and strain responses across different actuator configurations highlighted the importance of refined load introduction methods and monitoring strategies.

Analysis of the test data informs improvements in control algorithms, actuator coordination, sensor placement, and calibration techniques. These enhancements enhance the reliability and repeatability of fatigue tests, contributing to the development of more robust and efficient blade designs. FastBlade's approach demonstrates the future of sustainable structural testing and offers broader applications across marine, wind, aerospace, and civil sectors.

1 INTRODUCTION

The increasing urgency to transition from fossil fuels to renewable energy has led to a surge of interest in marine energy systems, particularly tidal stream turbines. Tidal energy offers a unique advantage: it is a predictable and consistent source of power that complements intermittent sources, such as solar and wind [1]. As global energy systems evolve, the tidal energy sector is poised to play a critical role, especially in coastal regions with strong and reliable tidal currents [2].

The tidal energy industry traces its roots to early installations such as the La Rance tidal barrage in France (1967) [3]. Since then, advances in technology—particularly horizontal axis tidal turbines (HATs)—have enabled more practical, scalable, and less environmentally intrusive solutions [4]. The potential for tidal stream energy to contribute up to 100 GW to the EU grid by 2050 underscores its strategic importance [5]. However, realising this potential requires addressing key engineering challenges, most notably the structural reliability and fatigue life of turbine blades operating in a dense, high-load marine environment [6-7].

Tidal turbine blades must withstand millions of load cycles in harsh underwater conditions characterised by strong currents, turbulence, and biofouling. The risk of structural failure is significant, with consequences that extend beyond repair costs to include downtime and safety issues [8]. Unfortunately, much of the data informing blade design remains proprietary, and in situ testing, though valuable, is limited by uncontrolled environmental variables. Hydrodynamic model testing in flumes or tanks, such as at the FloWave facility in Edinburgh [9-10], provides controlled insight at a more minor scale, but cannot replicate the full complexity of real-world, full-scale blade behaviour [11-12].

To address these limitations, full-scale fatigue testing has emerged as an essential tool. Among recent advancements, the FastBlade facility in Scotland represents a significant leap forward [13]. Utilising a regenerative digital displacement hydraulic actuation system, FastBlade enables precise and energy-efficient cyclic loading of full-scale blades [14-15]. In 2022, FastBlade conducted high-load tests simulating over 21 years of tidal cycles, both with single- and triple-actuator setups, and continued testing until blade failure occurred, thereby setting a new benchmark in composite blade validation [13, 16, 17].

FastBlade's design directly addresses the inefficiencies of conventional servo-hydraulic rigs, particularly for stiff composite blades that cannot be excited at resonance without thermal damage. The facility's integration of simulation technologies, digital twins, and advanced monitoring further exemplifies a new paradigm in structural validation [18].

This paper synthesises research from across FastBlade's development and testing campaigns. Specifically, we investigate the structural performance and fatigue behaviour of a full-scale composite tidal turbine blade under both static and fatigue loading. We compare blade responses under single-and multiple-actuator configurations, examining how load frequency and control strategies affect displacement and strain. The study aims to inform future improvements in blade testing, design validation, and certification practices, supporting the development of more efficient and reliable tidal energy systems.

2 OVERVIEWS OF THE FASTBLADE FACILITY

FastBlade, located in Rosyth, Scotland, is the world's first test facility to implement regenerative digital displacement hydraulics designed explicitly for the large-scale fatigue testing of long, stiff composite structures, such as tidal turbine blades measuring between 2 and 14 meters. The facility enables both accelerated fatigue and static loading, providing high-fidelity data on structural performance under simulated real-world marine conditions. It can resist a moment of up to 11.96 MNm and a shear load of 2.13 MN in static tests, as well as a moment of 4.70 MNm and a shear load of 0.94 MN during accelerated fatigue tests.

At the heart of FastBlade is a 70-tonne reaction frame (see Figure 1), engineered to withstand substantial loads during both static and dynamic fatigue tests. The structural setup includes a reaction plane, support wall, T-Slot bed plates, and a custom adapter plate, all anchored on bridge bearings recessed into a 2.5-meter-deep floor pit, ensuring stability and repeatability during high-load testing scenarios.

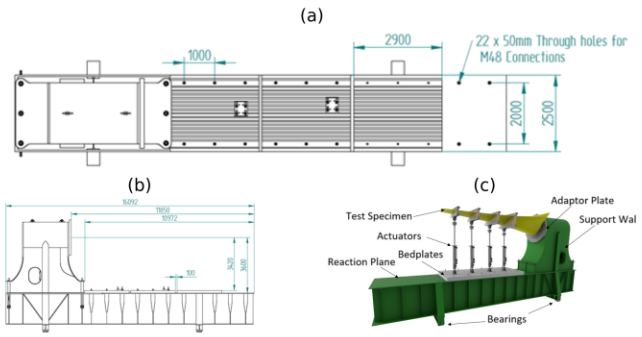

Figure 1: General arrangement and dimensions of the reaction frame at FastBlade. (a) Top view, (b) Lateral view, and (c) General view [13].

The facility's hydraulic actuation system is powered by four Digital Displacement™ reversible pumps developed by Danfoss. These pumps deliver a reversible hydraulic flow rate of 880 litres per minute, enabling precise actuator control and the simulation of complex ocean interaction loads. Additionally, the regenerative nature of the hydraulic system allows energy recovery, making FastBlade up to 75% more energy-efficient than conventional hydraulic testing systems of a similar scale. FastBlade is a cutting-edge platform designed not only to validate the structural integrity of tidal blades but also to support the advancement of sustainable marine energy technologies through efficient, data-rich, and environmentally conscious testing methodologies

3 ENERGY EFFICIENCY AND HYDRAULIC INNOVATION

FastBlade's hydraulic innovation lies in its use of Digital Displacement Pump (DDPMs) [19], which form the backbone of its regenerative hydraulic actuation system (see Figure 2). Unlike traditional servo-valve hydraulic setups, which lose significant energy as heat during load cycling, DDPMs offer a smarter, energy-efficient alternative. These digitally controlled units dynamically regulate flow and pressure by precisely timing valve openings in sync with the rotating shaft, eliminating the need for energy-wasting throttling.

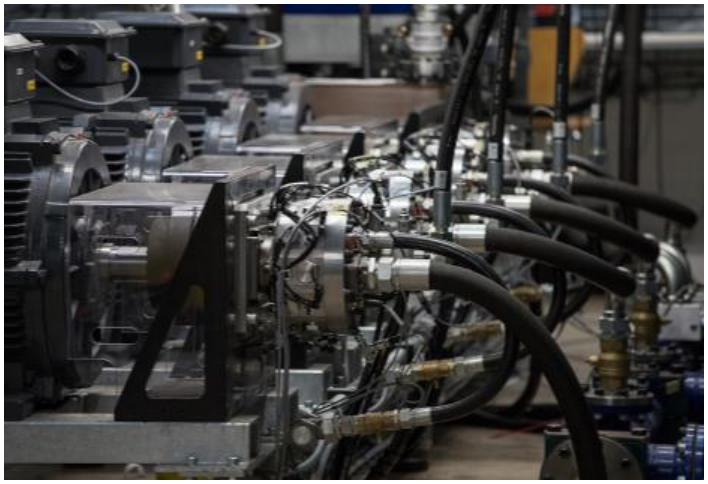

Figure 2: Digital Displacement Pumps and Motors at FastBlade.

A key advantage of this system is its ability to recover and reuse energy. During cyclic loading, the mechanical energy that would typically be dissipated is instead captured from the rotating inertia of the hydraulic drive and fed back into the system. This bidirectional flow capability means the actuators can alternate between applying loads and harvesting energy, depending on the structural response of the test specimen, as shown in Figure 3 for a test in which the power from the grid was cut and the system ran solely on the accumulated inertia.

This innovation results in energy savings of up to 75%, making FastBlade significantly more efficient than conventional fatigue testing systems. Such efficiency is particularly valuable when testing large, thick composite structures, such as tidal turbine blades, where resonant testing is impractical due to high damping properties and the risk of thermal buildup [20]. In addition to reducing power consumption, the regenerative system also enables more prolonged and more intensive test campaigns without compromising sustainability. The precise control afforded by DDPMs allows engineers to replicate complex, real-world marine load conditions, including quasi-steady flows and asymmetric stresses, while minimising environmental impact.

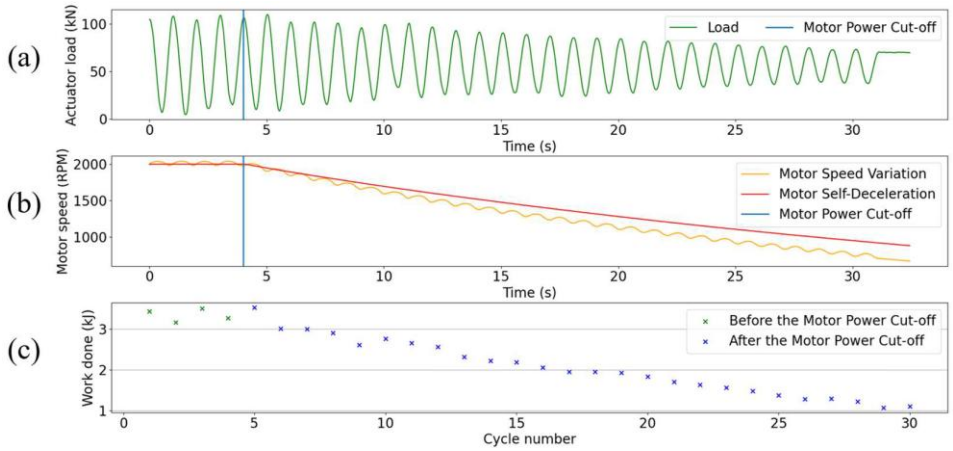

Figure 3: In the regeneration test, power to the VLT (Variable Load Terminal) is cut at 5 seconds. (a) The loading cycle continues even without power, with the amplitude gradually decreasing. After 25 cycles, the transferred energy drops to about one-third of its original level. (b) The motor slows down once power is cut. If loading is also stopped, the system slows down smoothly (as shown by the red trace). If loading continues, the motor decelerates slightly faster. This slight difference shows the high energy recovery (round-trip efficiency) of the system. (c) The energy transferred between the flywheel and the load also decreases over time, though not in a classic exponential (logarithmic) pattern. For the first 3 seconds after the power cut, the energy remains relatively steady, as the flywheel supplies the required power. [19].

5 FATIGUE TESTING

FastBlade enables accelerated life-cycle testing of full-scale composite tidal blades using static and fatigue test protocols aligned with IEC TS 62600-3 [21]. Tests are run at non-resonant frequencies to prevent internal heating, particularly for thick-sectioned tidal blades made of carbon or glass-fibre composites. Advanced sensing technologies such as strain gauges, DIC, and embedded instrumentation capture strain localisation, damage progression, and global stiffness. Actuators apply loads in both single-point and multi-point configurations to replicate the hydrodynamic moments observed in real-world deployments.

The 5.25 m long tidal turbine blade, tested, with a cross-section based on the NACA 63-4XX aerofoil series, was initially designed by Tidal Generation Limited and manufactured by Aviation Enterprises Limited for the DeepGen project. It came from a decommissioned 500 kW tidal stream turbine that operated at EMEC's Fall of Warness site for approximately two years. Some original design documents were unavailable, and Airborne has since acquired the design rights. Structurally, the blade features an 8 mm-thick glass-fibre skin, 3 mm GFRP ribs, and a spar cap made of 75% unidirectional carbon fibre epoxy prepreg. ±45° carbon fibre epoxy shear webs provide additional torsional strength. A rear GFRP spar, positioned 100 mm from the trailing edge, helps reduce peel stresses and improve fatigue performance.

To obtain the testing loads, high-fidelity simulations are a central component of FastBlade's methodology [22]. Actuator line modelling and RANS-based CFD simulations derive realistic load distributions from site-specific data. This includes modelling flow shear during ebb and flood tides and translating it into spatially and temporally varying blade loads (see Figure 4). These simulations guide the placement of actuators and force profiles. Furthermore, synthetic resonance, a method that mimics structural response through non-resonant actuation, bridges the gap between real-world conditions and laboratory constraints. This simulation-informed testing reduces the risk of over-conservatism and allows designers to optimise blade mass, stiffness, and geometry.

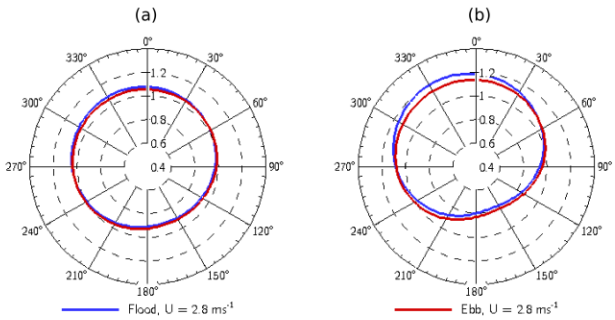

Figure 4: Hydrodynamic Simulation Results. The azimuthal variation of the normalized blade root bending moments in (a) the flapwise and (b) edgewise directions is depicted for both flood (blue) and ebb (red) tides. The rotor operates at a hub-height flow speed of U=2.8 m/s. [13]

The blade was tested under different setups (see Figure 5), following [21], the natural frequency was taken at the beginning and the end of the entire test program in setup (see Figure 5(a)), later on, the blade was tested with a single actuator which is a conventional test setup (see Figure 5(b)), a three actuator setup (see Figure 5(c)) to compare the benefits and challenges of more contact points as shown in [8] and finally a three actuator setup for extreme loads (see Figure 5(d)). The root bending moments for setups 5b and 5c were 1000 kNm for the static test and 650 kNm for the fatigue test. Nevertheless, after approximately 120000 cycles, the loads were changed to test different clamping system materials (see [24]) and evaluate the blade's response to higher load fatigue cycles. For setup 6d, the root bending moments during the static tests were up to 1400, 1600, 1800, and 3060 kNm. For fatigue with configuration 6d, first, a series of cycles at 1330 kN.m (almost twice the mean water velocity load) is applied to scale up to 1750 kN.m (nearly 2.7 times the mean water velocity load).

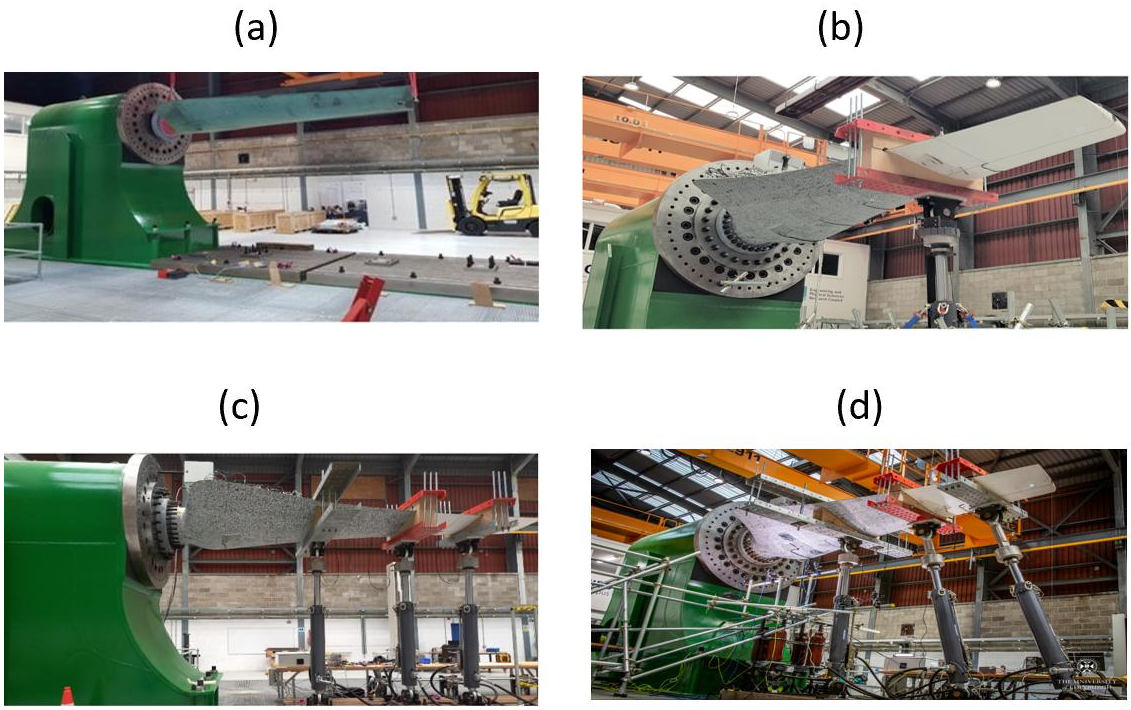

Figure 5: Testing setups. (a) No actuators for natural frequency, (b) Single actuator, (c) three actuators for design loads, (d) three actuators for extreme loads.

Testing credibility is reinforced through statistical validation techniques. FastBlade integrates real-time Process Capability Indices (PCIs) to monitor how closely the applied loads match prescribed values [15]. Load traces from historic and real-time data are compared to identify anomalies and deviations. These metrics ensure traceability, allowing engineers to diagnose actuator drift or calibration errors. Combined with redundant sensors, specialised anomaly detection algorithms[23] and automated control systems, this statistical approach guarantees repeatable and certifiable test outcomes, aligning with emerging marine energy certification frameworks. As a result of these controls, the results of displacement and root bending moments for the different fatigue tests are presented in Figure 6.

FastBlade has significantly advanced the understanding of tidal turbine blade mechanics under operational conditions. The research outputs inform the development of the next generation of certification standards, reduce design conservatism, and enable predictive maintenance strategies. FastBlade's principles, energy-efficient actuation, integrated simulation, and digital intelligence are extendable to aerospace wings, bridge components, offshore platforms, and wind turbine blades. As such, the facility serves as a model for structural testing in high-capital, high-reliability industries. Using all these valuable lessons, FastBlade approaches the new MaxBlade project.

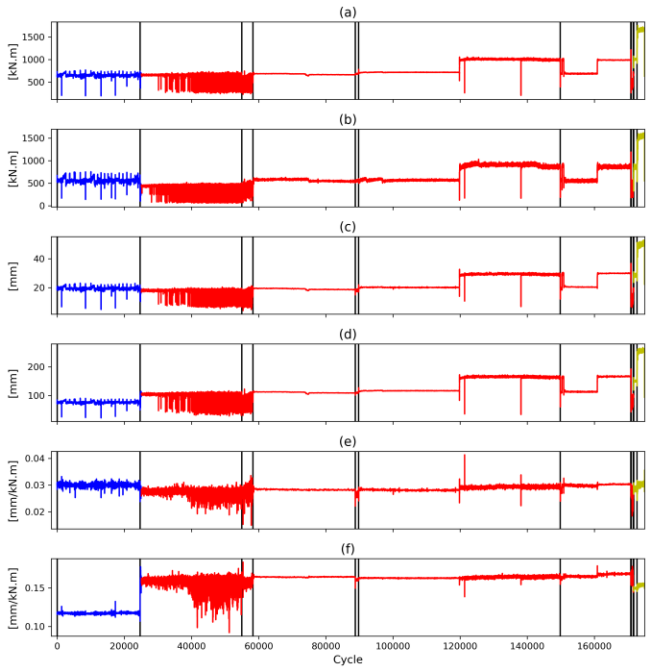

Figure 6: . Results from the different fatigue tests. The vertical black lines indicate a static test. The colour blue indicates the single actuator test, the colour red indicates the use of 3 actuators, and the colour yellow indicates the use of 3 actuators for high loads: (a) Root Bending Moment at the crest of each cycle, (b) Twice the amplitude of the Root Bending Moment at each cycle (c) Displacement at the blade's centre during the crest of each cycle, (d) Displacement at the blade's tip during the crest of each cycle, (e) Relation between displacement at the blade's centre and the root bending moment during the crest of each cycle, and (f) Relation between displacement at the blade's tip and the root bending moment during the crest of each cycle.

9 CONCLUSIONS

FastBlade represents a significant advancement in structural testing for tidal energy systems. By combining regenerative hydraulic actuation, simulation-informed load design, and advanced monitoring systems, it enables efficient and realistic fatigue testing of full-scale composite blades. The facility's use of digital displacement pump/motors (DDPMs) reduces energy consumption by up to 75%, making long-duration, high-load testing both feasible and cost-effective, particularly for stiff, high-damping structures where resonant testing is impractical.

Through a combination of static and fatigue tests, FastBlade has demonstrated the ability to simulate decades of tidal loading in a matter of weeks. Configurable actuator setups and precise control systems allow replication of realistic hydrodynamic moments, while embedded instrumentation provides valuable data on strain, displacement, and damage progression.

Simulation plays a key role in test planning, with hydrodynamic loads derived from RANS-based models and actuator line methods that capture the complex effects of tidal direction and flow shear. These simulations ensure that laboratory loads reflect real-world operational conditions. Quality assurance is further enhanced through statistical control tools such as Process Capability Indices, which support consistent and traceable testing.

The integration of digital twin technology adds a forward-looking dimension to FastBlade's approach. These models, ranging from data-driven to physics-informed, enable predictive insights, inform control strategies, and offer potential pathways for real-time condition monitoring of deployed blades.

Overall, FastBlade provides a practical and forward-compatible platform for validating the structural integrity of tidal turbine blades. Its contributions extend beyond marine energy, offering applicable methodologies for other sectors requiring high-fidelity fatigue testing. As the industry continues to evolve, facilities like FastBlade will play a crucial role in supporting safer, more efficient, and cost-effective renewable energy solutions.

Compression-Compression Fatigue of Glass-Fibre Non-Crimp Fabric Composites by Four-Point Flexure

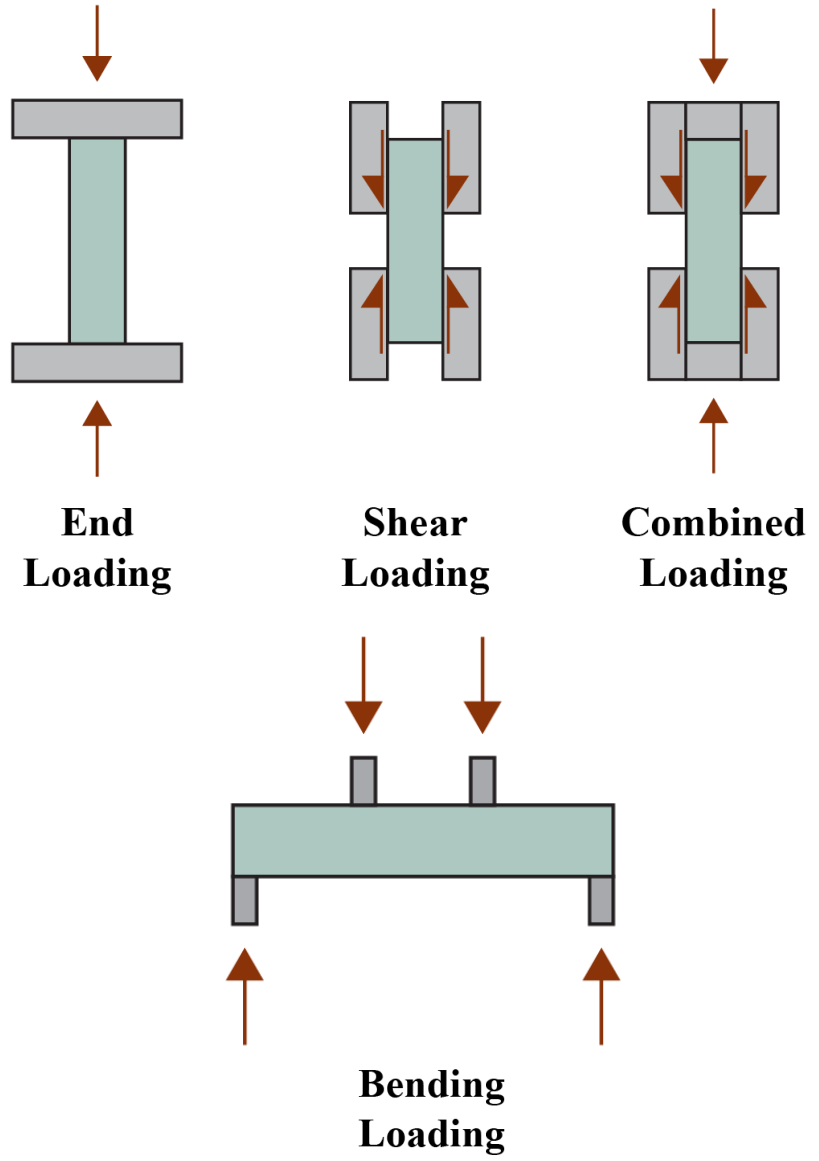
N. Shepherd, T. Allen, and M. Battley

Centre for Advanced Materials Manufacturing and Design
The University of Auckland
Auckland, New Zealand

UNIVERSITY OF AUCKLAND
Waipapa Taumata Rau
NEW ZEALAND

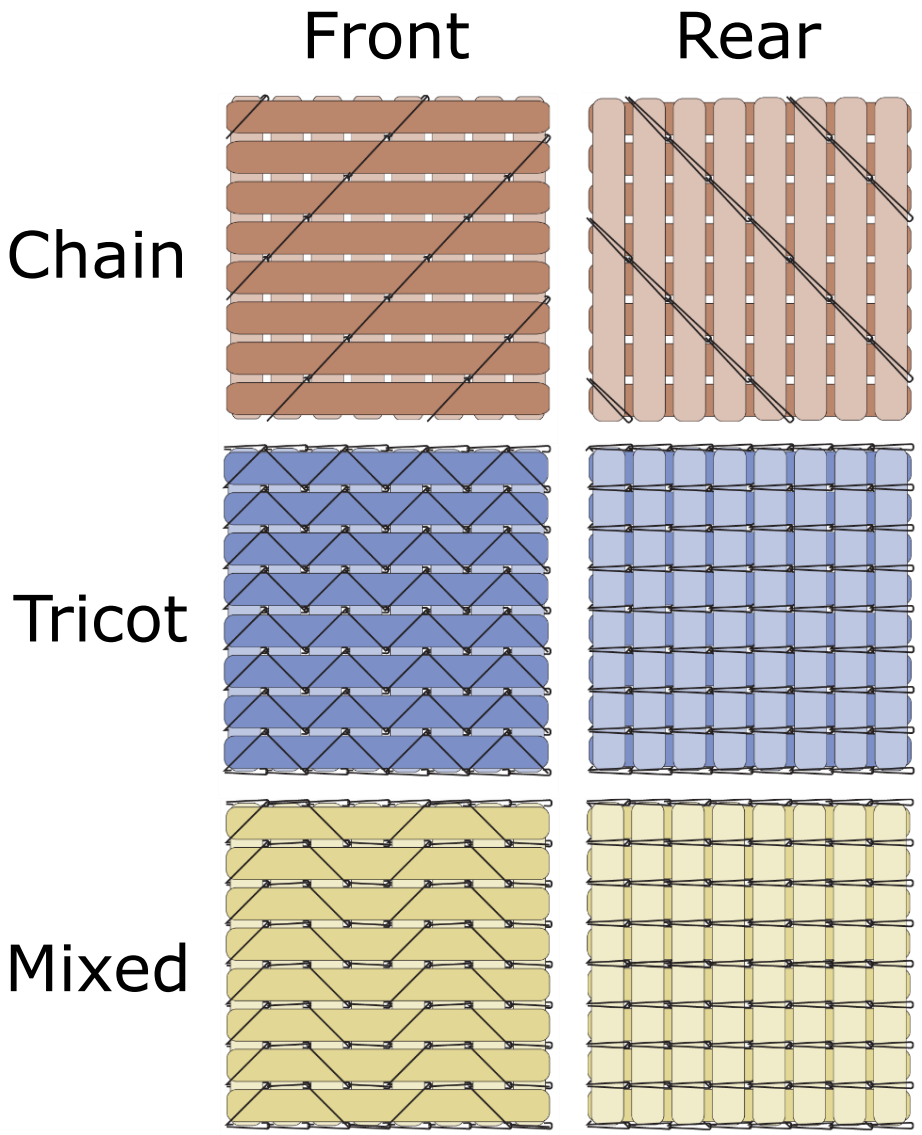
CENTRE FOR ADVANCED MATERIALS MANUFACTURING & DESIGN

Introduction: Compression Fatigue



Important but often neglected load case.

Lacking in standardised guidance for testing and specimen design.



Simple end- or shear-loading tests may not meet requirements:

- Global buckling instability
- Short gauge length
- End crushing
- Stress concentrations at tabs or grips

Four-point bending provides a promising alternative.

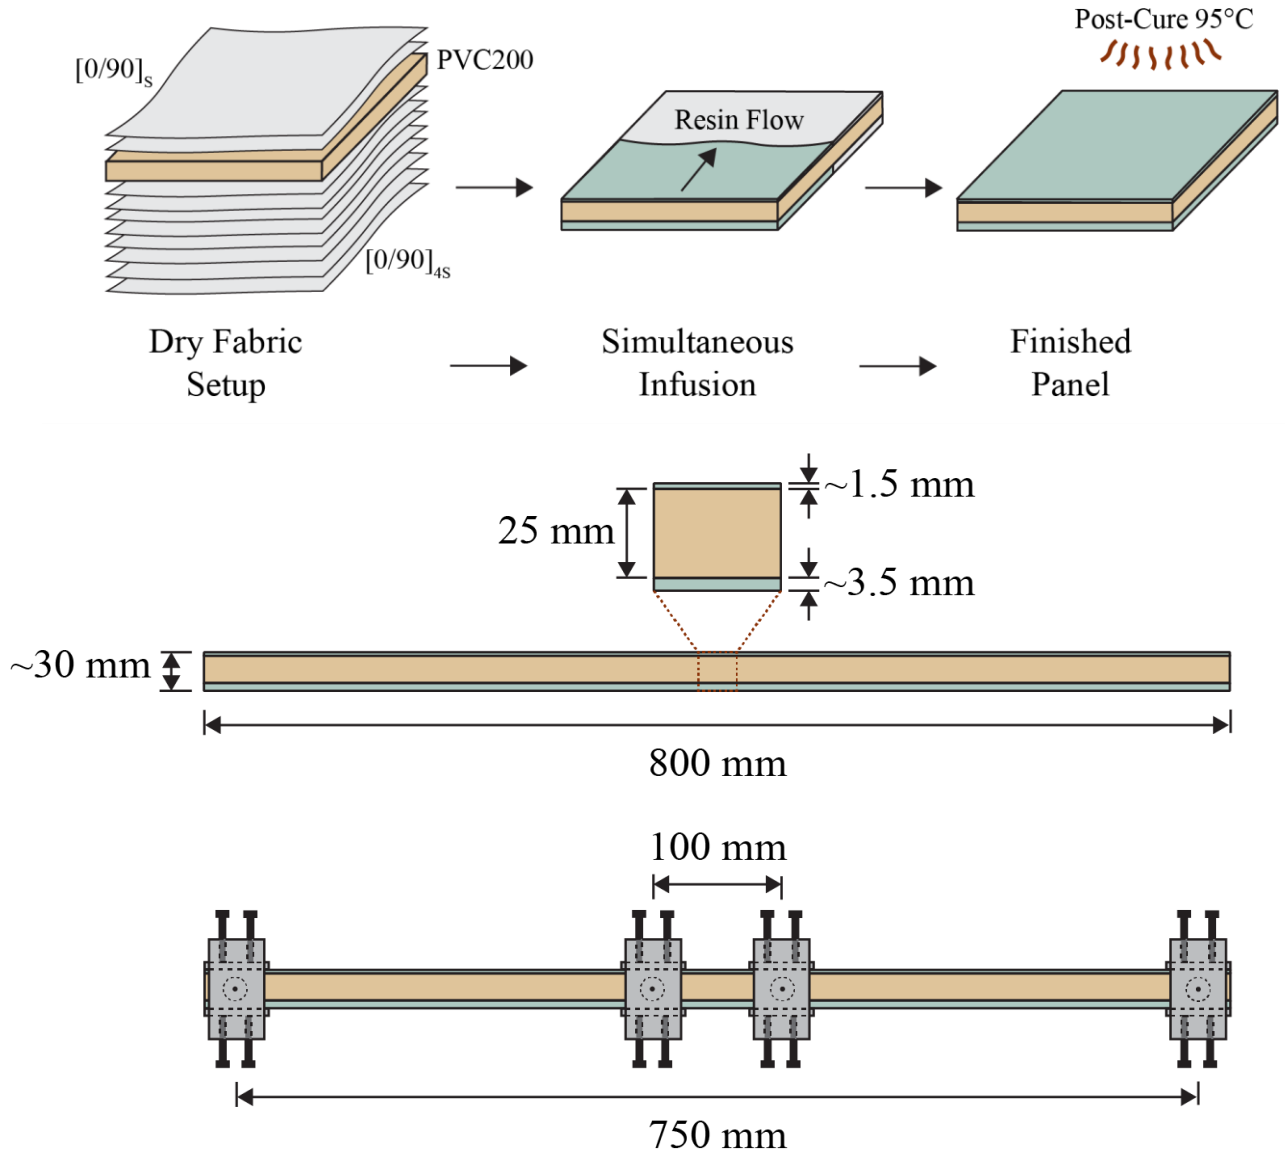
Introduction: Stitched Fabrics

'Pattern' refers to the geometry or weave-type of the stitching thread

Can influence fibre alignment:

- key for static compression behaviour
- May also play a influence compression-compression fatigue

Characteristic	Stitch Pattern		
	Chain	Tricot	Mixed
Fabric areal weight, reported (gsm)	820	825	825
Fabric areal weight, measured (gsm)	828	803	815
Fabric as-manufactured fibre orientation (°)	[+45/-45]	[0/90]	[0/90]
Stitch thread linear density (dtex)	84.5	107	108
Stitch gauge (mm)	5.15	3.99	4.30
Stitch length (mm)	2.57	6.94 (3.47)	14.84 (3.71)



Goals

1) Develop a specimen geometry to test stitched glass-fibre fabrics in compression-compression fatigue

2) Determine if fatigue behaviour varies between fabrics with different stitching patterns

3) Determine whether this variation can be linked to the previously-measured variation in fibre misalignment

Specimen Design and Manufacture

Asymmetric sandwich based on ASTM D5467 for static compression

Maximum compression strains up to 1.5%

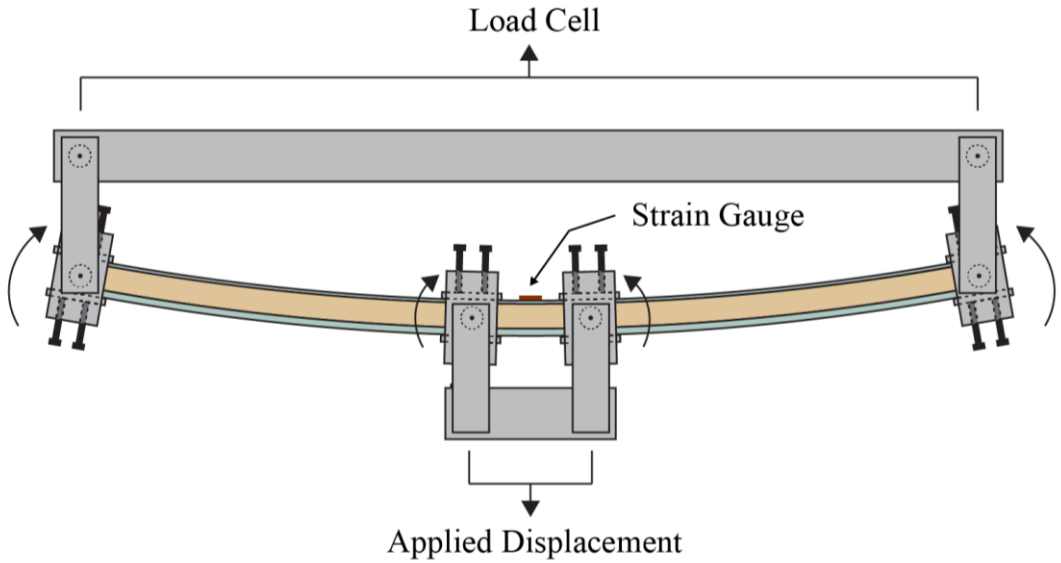
Compression facesheet strain gradient 3.95%

Identical rear (tension) facesheets

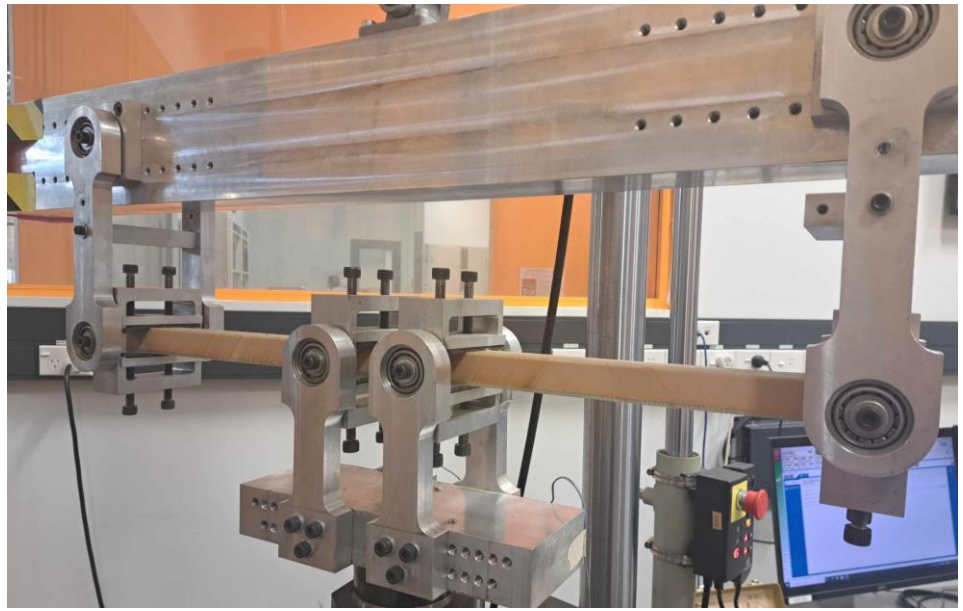
50 mm gauge length

Test Apparatus and Procedure

Controlled sinusoidal displacements at 0.5 Hz



Continuous load / displacement measurement

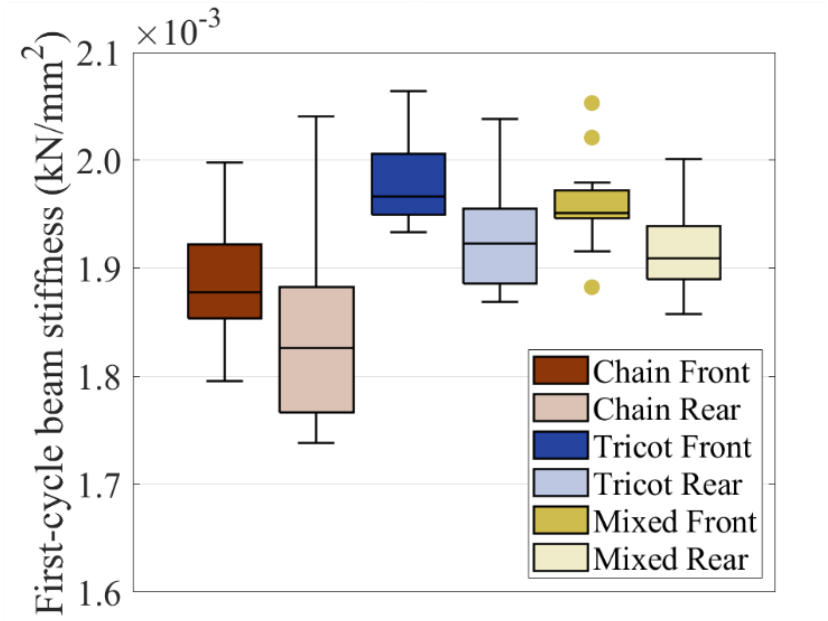


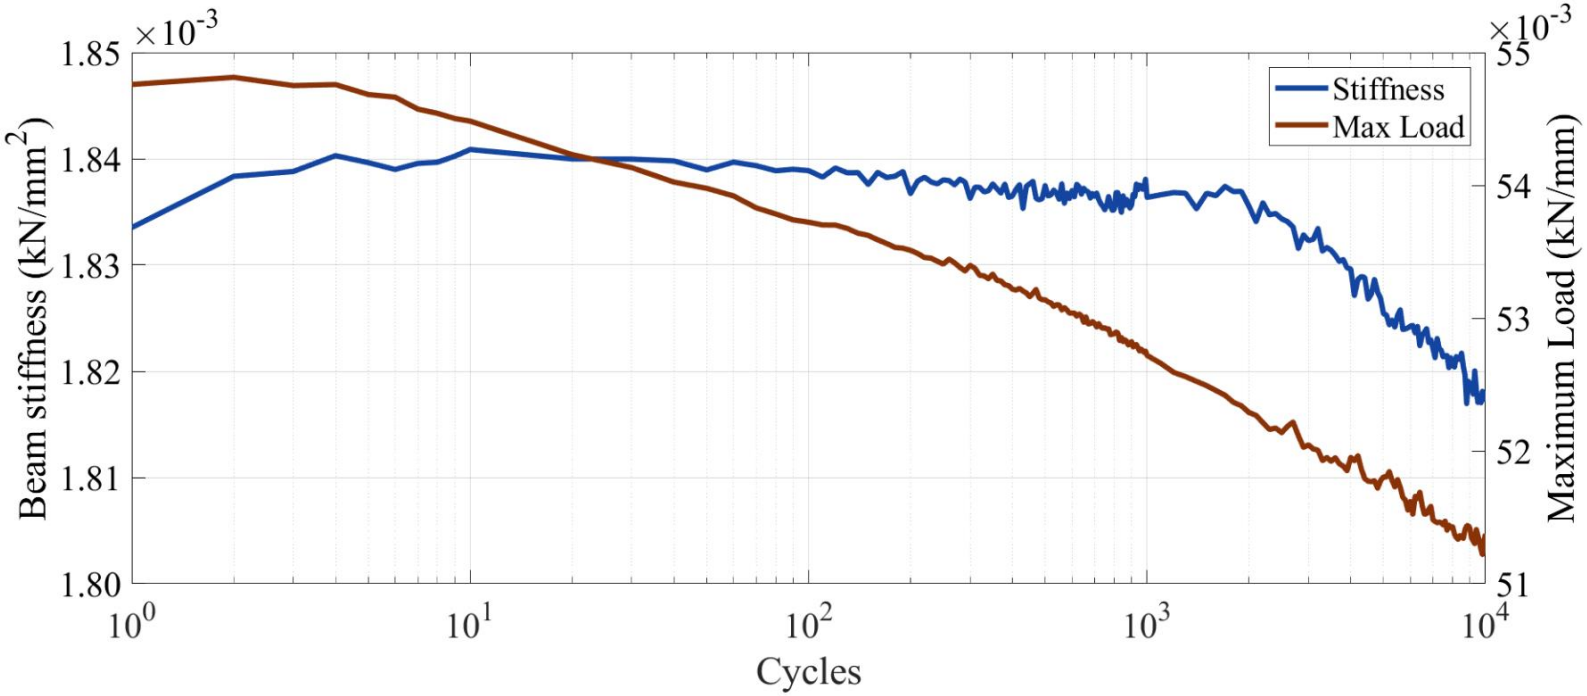
Direct strain measurement for first 150 cycles

Minimum displacement 5 mm, Maximum displacements 25, 30, 35, 40 or 45 mm

Maximum compressive strains 0.85 – 1.5%

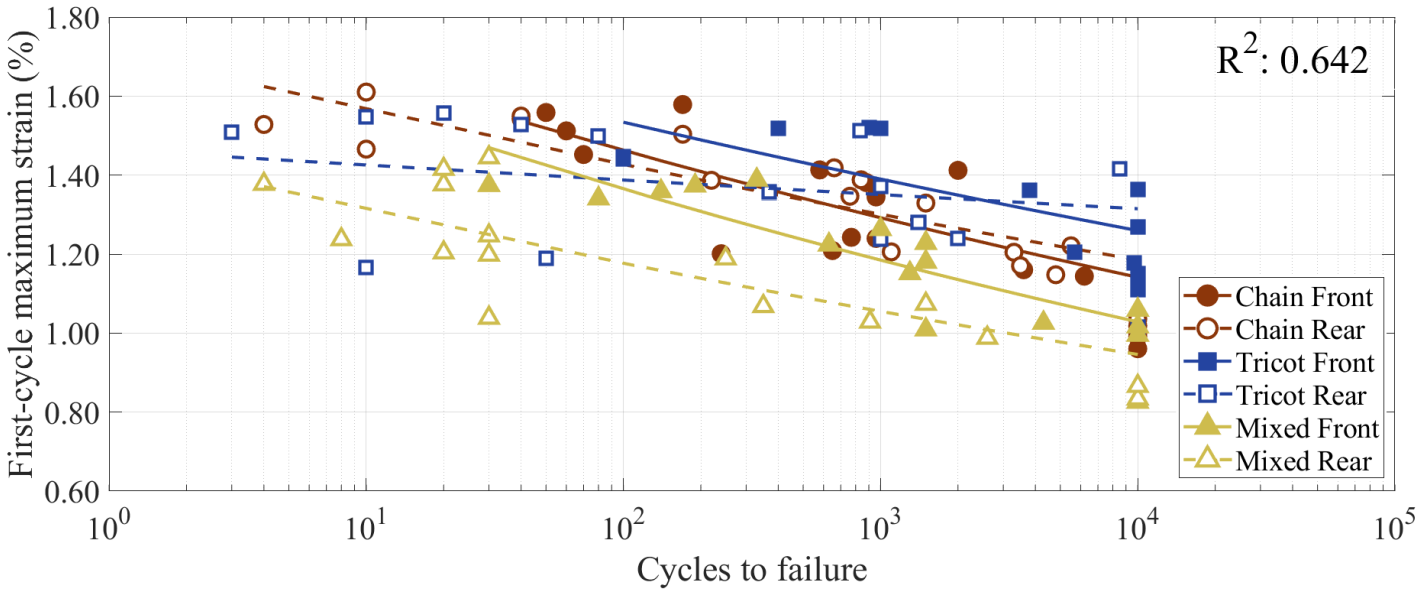
Run-out at 10,000 cycles





Beam Load and Stiffness

'Stiffness' contains both flexural rigidity (EI) and transverse shear stiffness



Transverse load and stiffness change over time, possibly due to:

- Change in core shear stiffness
- Change in facesheet stiffnesses (tension, compression, or both)
- Permanent core deformation

Fatigue Life

Fabric	A	B	R^2
Chain Front	1.87	–0.0538	0.578
Chain Rear	1.72	–0.0402	0.768
Tricot Front	1.87	–0.0428	0.526
Tricot Rear	1.46	–0.0117	0.0735

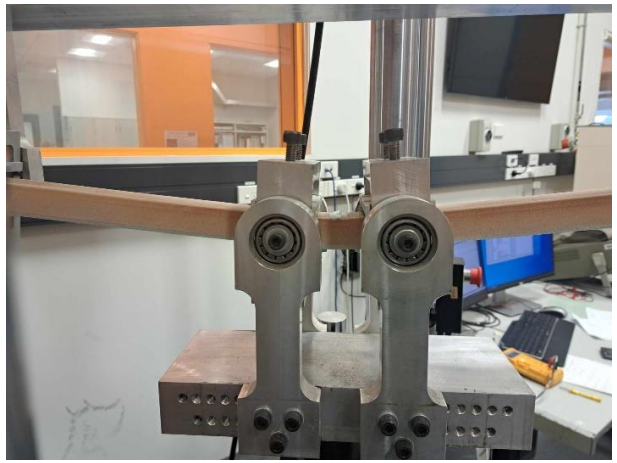
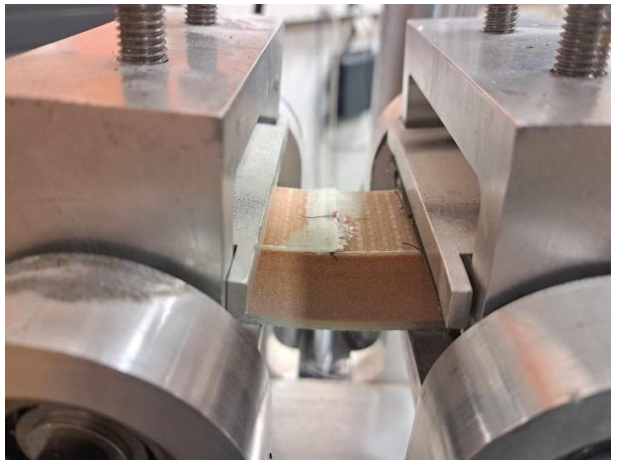
M_R	0.718	0.574	0.830	0.0471	0.477	X	
	Slope						

Fatigue Life Explained by Misalignment

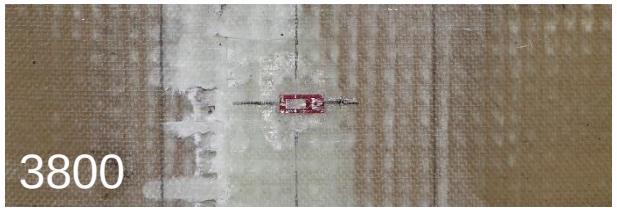




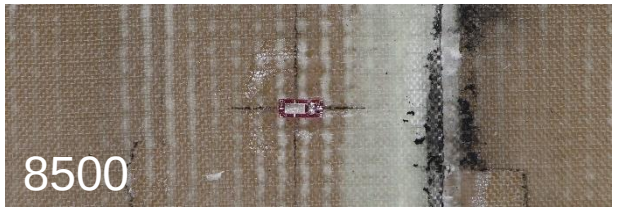
Weak positive relationship between intercept (*A*) and misalignment

Weak negative relationship between slope (*B*) and misalignment

Weak relationships are likely statistical artifacts due to the high scatter.



Failure and Damage

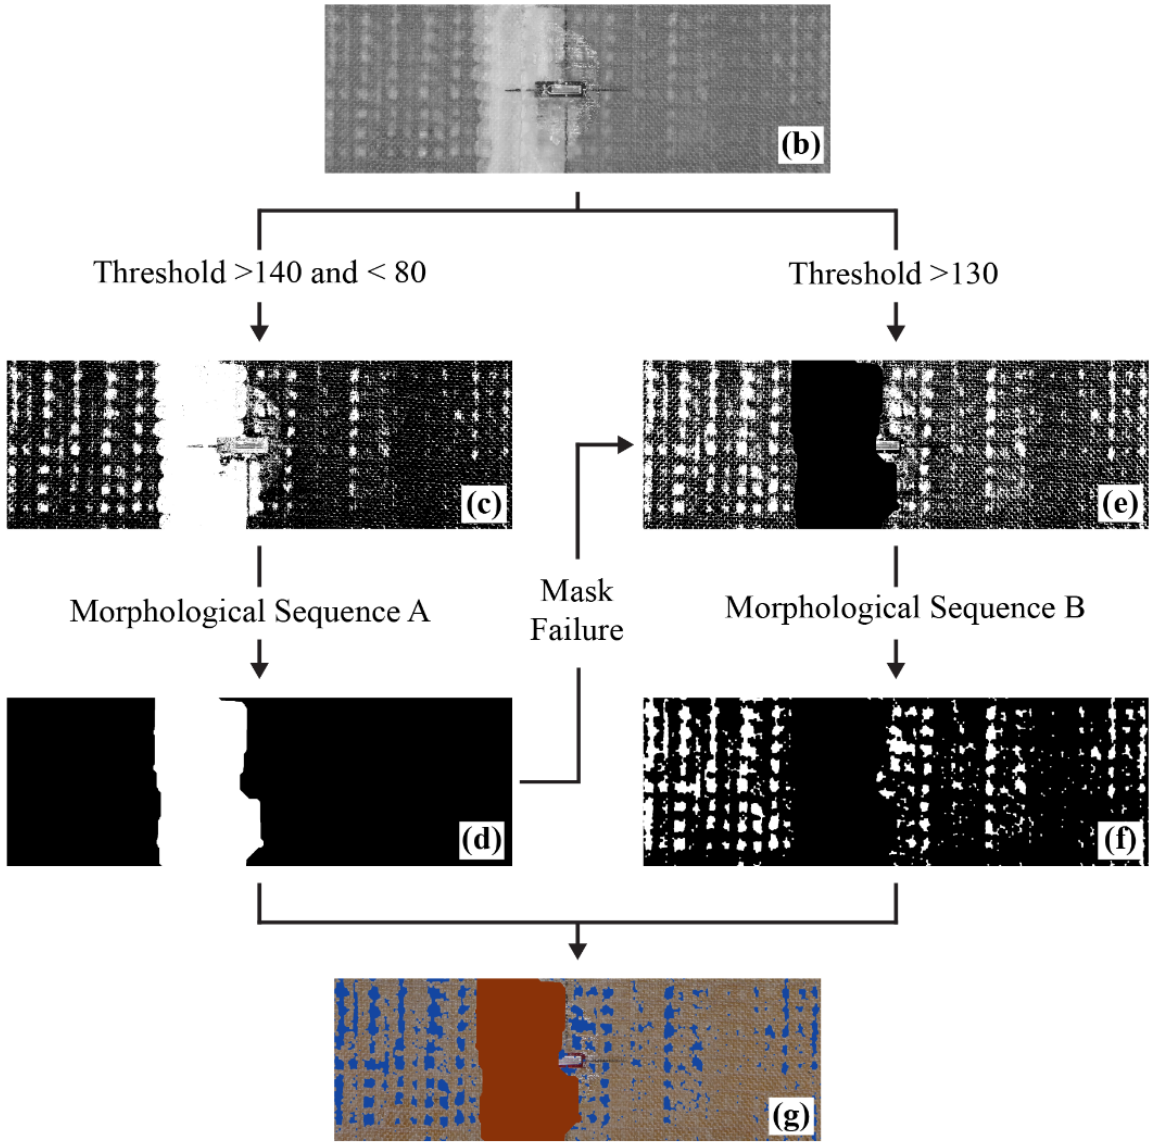


40 mm maximum displacement until failure

77.1% failed in compression within the gauge section. 18.1% survived to run-out

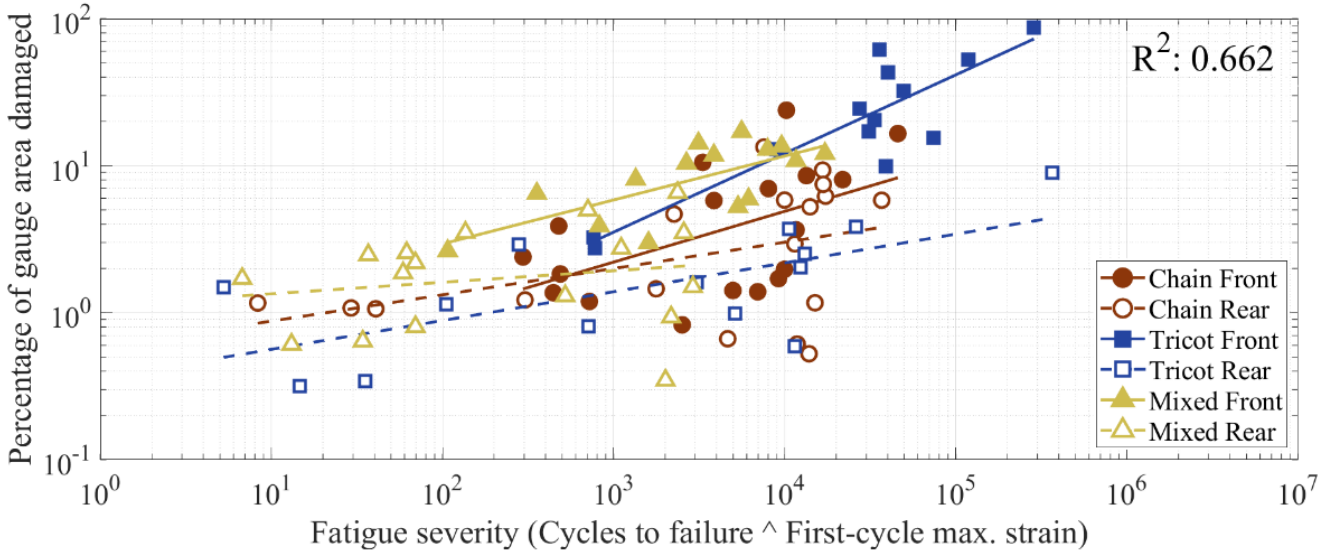
Visible ‘whitening’ observed in the top facesheet.

- Matrix damage?
- Interlaminar damage?
- Interfacial damage?
- Micro-cracking?



Inconsistent degrees of damage at failure

Image Analysis to Isolate Damage



Damage isolated from digital photographs

Morphological transformations identify and isolate:

- Damage created at the moment of failure
- Damage present before failure
- Other undesirable white reflections

Damage Related to Fatigue Severity

Fabric	A	B	R^2
Chain Front	0.203	0.345	0.274
Chain Rear	0.581	0.179	0.188
Tricot Front	0.0877	0.535	0.778
Tricot Rear	0.359	0.196	0.441
Mixed Front	0.742	0.299	0.486
Mixed Rear	3.18	0.0783	0.0399

Proposed relationship:

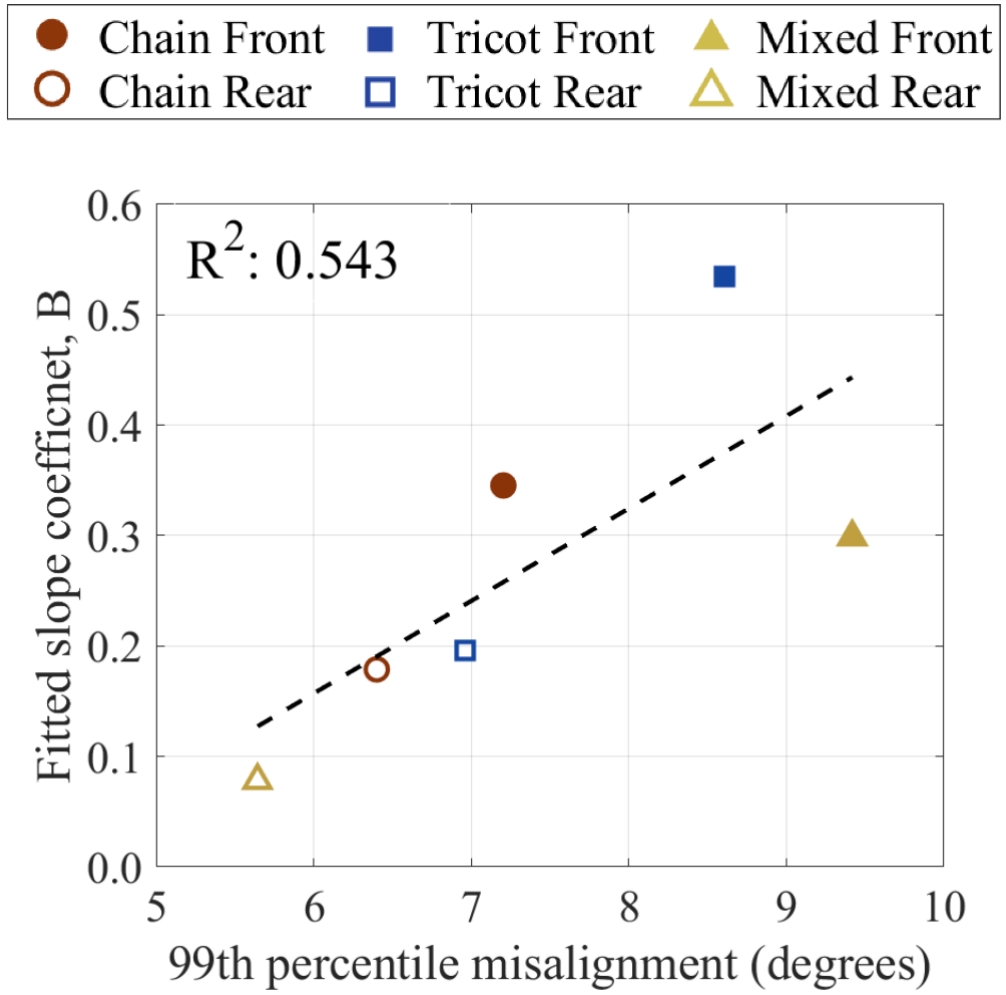
$$\log(D) = \log(A) + B \log(F)$$

D: Proportion of gauge area damaged

F: 'Fatigue severity', combining both applied strain and fatigue life:

$$F = N^S$$

Run-out specimens included



Damage Explained by Misalignment

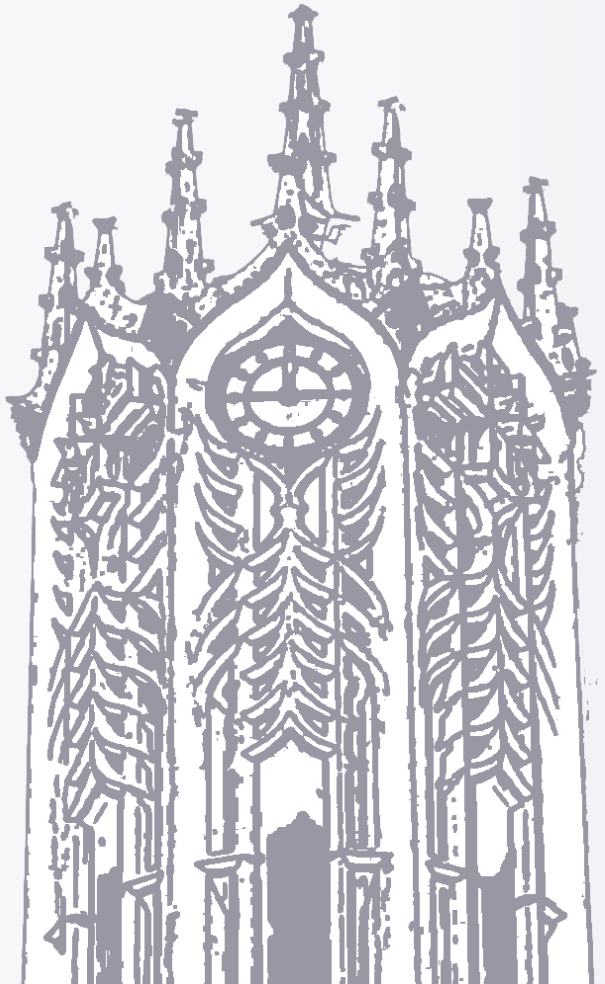
Moderate positive relationship between misalignment and damage slope, *B*

Implies:

- More visible damage at the same fatigue severity
- Faster accumulation of damage under increasing fatigue severity (either strain or cycles)

Stronger relationship than between misalignment and fatigue life.

Conclusions



Four-point flexure was successful for testing in compression-compression fatigue, but scatter and variability are high

Failed specimens show visible whitening of the top facesheet, but exact damage mechanism requires further investigation

Weak relationships suggest higher misalignment may result in shorter fatigue lives and greater damage accumulation

Recommend further development to gather more repeatable data

Thank you

THE ROLES OF PORE DISTRIBUTION AND HIERARCHICAL STRUCTURE OF MARINE MUSSEL PLAQUE CORES

Yulan Lyn[1], Yong Pang[1] and Tao Liu[1]

Keywords: Pore distribution, Sandwich core, Hierarchical structure, Mussel plaque cores

ABSTRACT

The thread-plaque system of marine mussels demonstrates strong adhesion and high deformability, enabling it to stick to various wet surfaces. The plaque has a sandwich structure with a porous core enclosed by a dense cuticle layer. Although the microstructures of plaque cores have been reported, the impact of their unique porous structure on high deformability remains unclear. This study used scanning electron microscopy (SEM) to investigate the porous structure of mussel plaque cores. Two-dimensional (2D) porous representative volume elements (RVEs) with scaled distribution parameters were generated, and the calibrated phase-field modelling method was applied to analyse the effect of pore distribution and multi-scale porous structure on the failure mechanisms of porous RVEs. SEM analysis revealed that large-scale pores have a lognormal size distribution and a uniform spatial distribution. Simulations indicated that increasing the normalized mean radius value of the large-scale pore distribution statistically leads to a decrease in final failure strain, strength, and strain energy density, but cannot solely determine their values. The interaction between pores can result in two different failure modes under the same pore distribution: progressive failure mode and sudden failure mode. Additionally, the hierarchical structure of multi-scale porous RVEs can increase the final failure strain by 40–60% compared to single-scale porous RVEs by reducing stiffness, suggesting that the hierarchical structure could be another key factor contributing to high deformability. These findings enhance our understanding of how pore distribution and multi-scale porous structure in mussel plaque cores contribute to their high deformability and affect other mechanical properties, offering valuable insights for designing highly deformable composite materials in the future.

1 INTRODUCTION

The mussel byssus system, comprising protein threads and porous plaques (Fig. 1a–b), enables strong anchoring to diverse surfaces in harsh marine environments [1–7]. Notably, mussel plaques exhibit exceptional ductility, allowing significant deformation under tensile loads without failure (Fig. 1c), a property with promising implications for bioinspired material design. Despite extensive research into their adhesive performance [8–11], the underlying mechanisms contributing to their high ductility remain poorly understood.

Structurally, mussel plaques feature a porous core encased by a protective cuticle (Fig. 1b) [12]. The core contains randomly distributed nano- and micro-scale pores (75–100 nm to 1–3 μm in diameter; Fig. 1e) [12]. Prior studies suggest that modifying pore arrangement can enhance ductility [13]. Gockowski et al. (2020) proposed that increasing crack path tortuosity through tailored pore structures may account for this effect [14]. However, these studies largely

employed idealized, ordered pore geometries, differing from the natural pore architecture of mussel plaques [13,14]. As such, the role of the native, multi-scale porous structure in enhancing mechanical performance—particularly ductility—remains insufficiently explored.

This study aims to bridge that gap by investigating how pore distribution (Figs. 1d and f) and hierarchical porosity (Fig. 1e) affect the mechanical behavior of mussel plaques. Pore morphology was characterized using scanning electron microscopy (SEM), and two-dimensional porous representative volume elements (RVEs) were generated with scaled distribution parameters for both numerical and experimental analysis. A validated phase-field fracture model incorporating a Neo-Hookean hyperelastic material law was used to simulate the influence of pore structure on failure mechanisms. This work offers insights into the ductility mechanisms of mussel plaques and informs the design of bioinspired, highly deformable metamaterials.

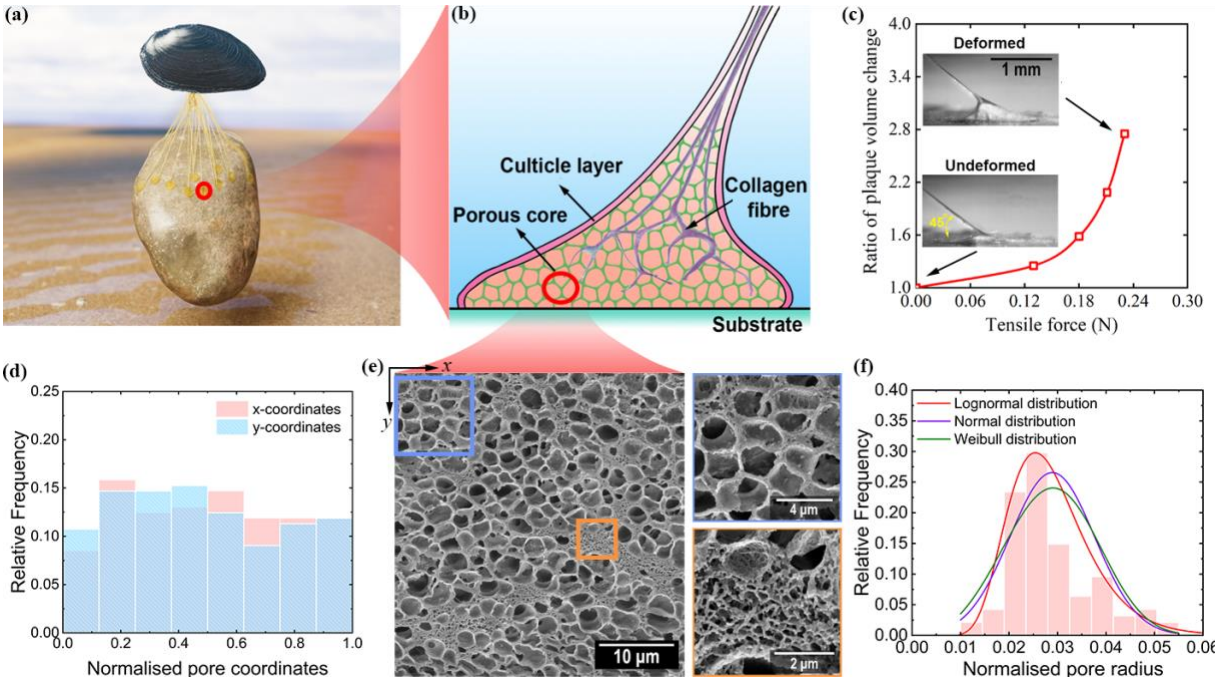

Figure 1: (a) Mussel byssus system attached on a rock, (b) schematic diagram of the mussel plaque's microstructure, (c) large deformation of mussel plaque under tension, (d) the distribution of normalized x and y coordinates for large pore centres within the mussel plaque core, (e) the SEM photo showing the multi-scale porous structure of mussel plaque core and (f) the distribution of normalized radius for large pores within the mussel plaque core.

2. THE SEM CHARACTERISATION OF MUSSEL PLAQUE CORE

Two-dimensional (2D) SEM images have suggested that the pores within the plaque cores are of two different scales, ranging in diameter from 75-100 nm (small-scale pores) to 1-3 μm (large-scale pores) (Fig. 1d). The pore distribution of large-scale pores within those SEM photos was first examined. In order to ensure the representativeness of the large-scale pore distribution in these photos, a total of nine SEM photos from different plaques or different locations of the same plaque were analysed. The irregular large-scale pores were simplified as equivalent circular pores to obtain the pore distribution during the SEM image analysis. The longest axis

of the irregular large-scale pores was considered as the diameter of the equivalent circular pores. Meanwhile, the radii of large-scale pores and the coordinates of the pore centres were normalised by dividing the length of SEM image (l_s) edges for the distribution analysis.

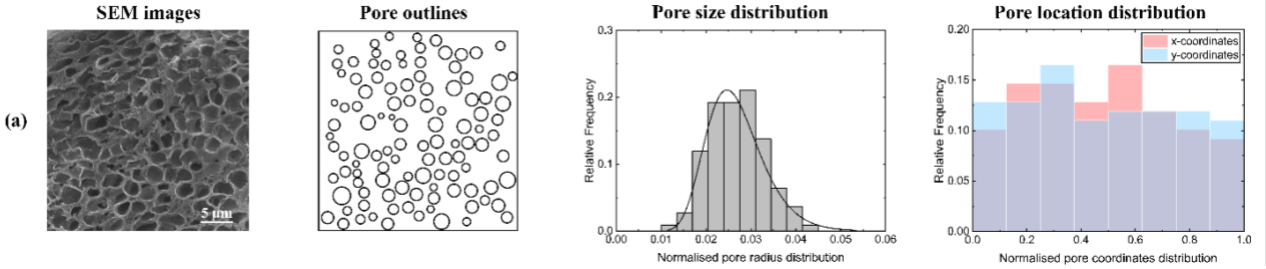

Figure 2: Pore distribution analysis of mussel plaque SEM images.

3. THE GENERATION OF THE RVES FOR THE POROUS STRUCTURE

Two types of porous RVEs were generated for numerical study. The first RVE type investigates the effect of large-scale pores, while the second RVE type examines the impact of the multi-scale architecture of the mussel plaque core.

The first type RVE was generated by scaling the plaque pore sizes by a factor of 1000, transitioning from microns to millimetres. Two-dimensional (2D) square shaped porous RVEs were generated by using the scaled distribution parameters of the large-scale pores (v_l=27%, μ_p^*=1.12 mm and s_p^*=0.34 mm). The dimensions of the RVEs are 30 x 30 mm, comprising solely large-scale pores with the remaining volume filled with solid material, see Fig.3.

The second type RVE representing multi-scale porous structures were generated via removing 2D elements in the FE models and connecting the nodes using truss elements of circular cross sections (i.e. coupled temperature-displacement truss element T2D2T) (Fig. 3). The radius of the truss elements was determined to ensure that the newly generated RVEs reflected the same overall porosity ($v = v_s + v_l = 32\%$) with the SEM image (Fig. 1e). Here, v_s represents the volume fraction of smaller pores.

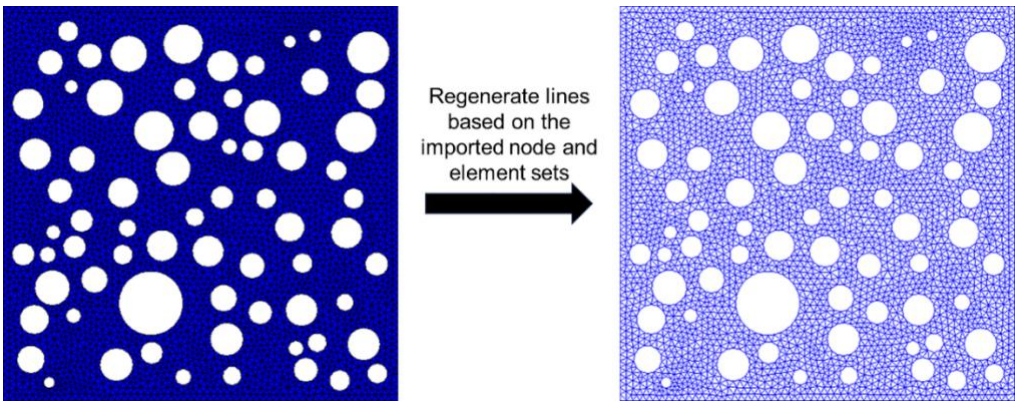

Figure 3: The first type RVE (left) and the second type RVE (right)

4. ABAQUS IMPLEMENTATION AND EXPERIMENTAL CALIBRATION OF THE PHASE FIELD MODELLING METHOD

The phase field method was numerically implemented in ABAQUS, based on heat transfer analogy, using combined User subroutines UHYPER and HETVAL. The comparison of numerical modelling and experimental measurement is shown in Figs. 4 and 5.

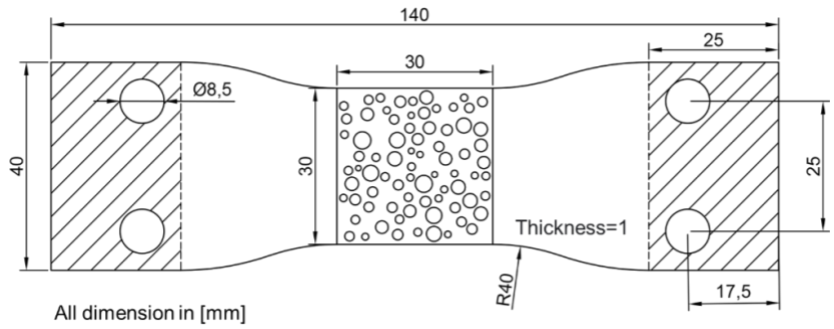

Figure 4 : Schematic drawings of the porous samples for tensile testing

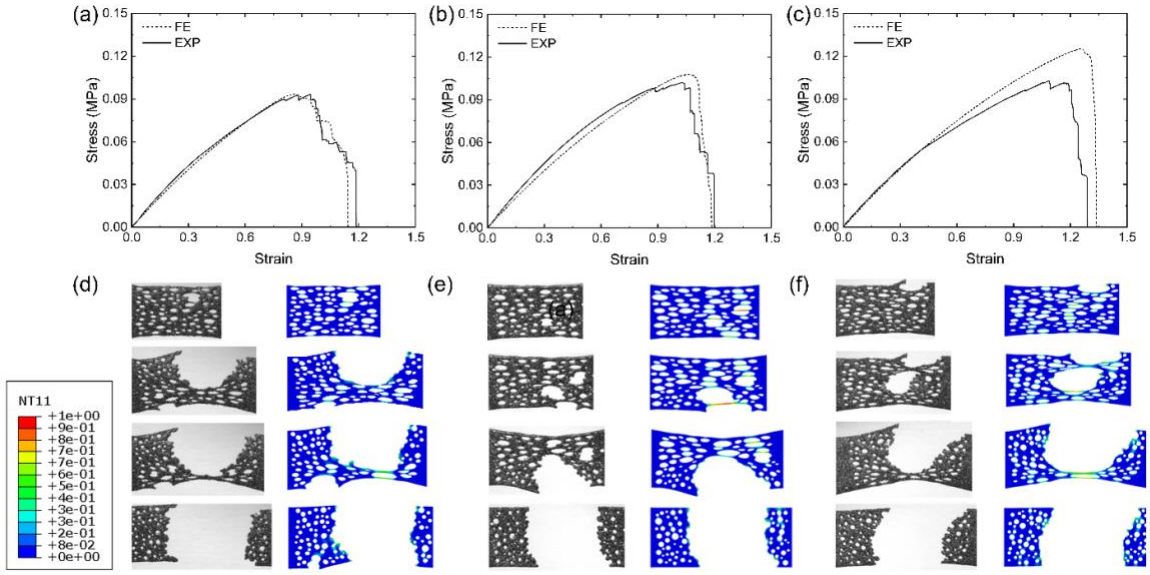

Figure 5: Comparison between the (a-c) numerical and experimental stress-strain curves and (d-f) fracture paths for three porous samples in tension.

5. RESULTS OF THE RVES ANALYSIS

Figure 6 shows the macroscopic stress-strain curve and crack propagation of Sample A, which had the highest values of $\Delta\varepsilon$, ε_{ff}, and φ among the 400 RVE results. Here, $\Delta\varepsilon$ denotes the difference between the initial and final failure strain, ε_{ff} the final failure strain and strength and the strength (σ_{max}). For comparison, the stress-strain curves and crack propagation of two additional samples, B and C, are also presented in Figure 6. It is noted that samples A, B and C have nearly identical normalised standard deviation ($\bar{s}$) and mean ($\bar{\mu}$) values for radius of pores, with a difference of only ±0.001.

Two different failure modes were identified from the stress-strain curves of the samples: progressive failure and sudden failure (Fig. 6A). For the progressive failure sample (Sample A), the Δε value was approximately 50% of the final failure strain. In contrast, the Δε value for the sudden failure sample (Sample C) was close to 0 (Fig. 6A). The final failure strain of the progressive failure sample (Sample A) was about 1.5 times that of the sudden failure sample (Sample C), but its strength was only approximately 85% of Sample C's strength (Fig. 6A). Interestingly, the strength of these samples decreased with increasing Δε (Fig. 6A), indicating that the high ductility of the plaques may have been achieved by sacrificing strength.

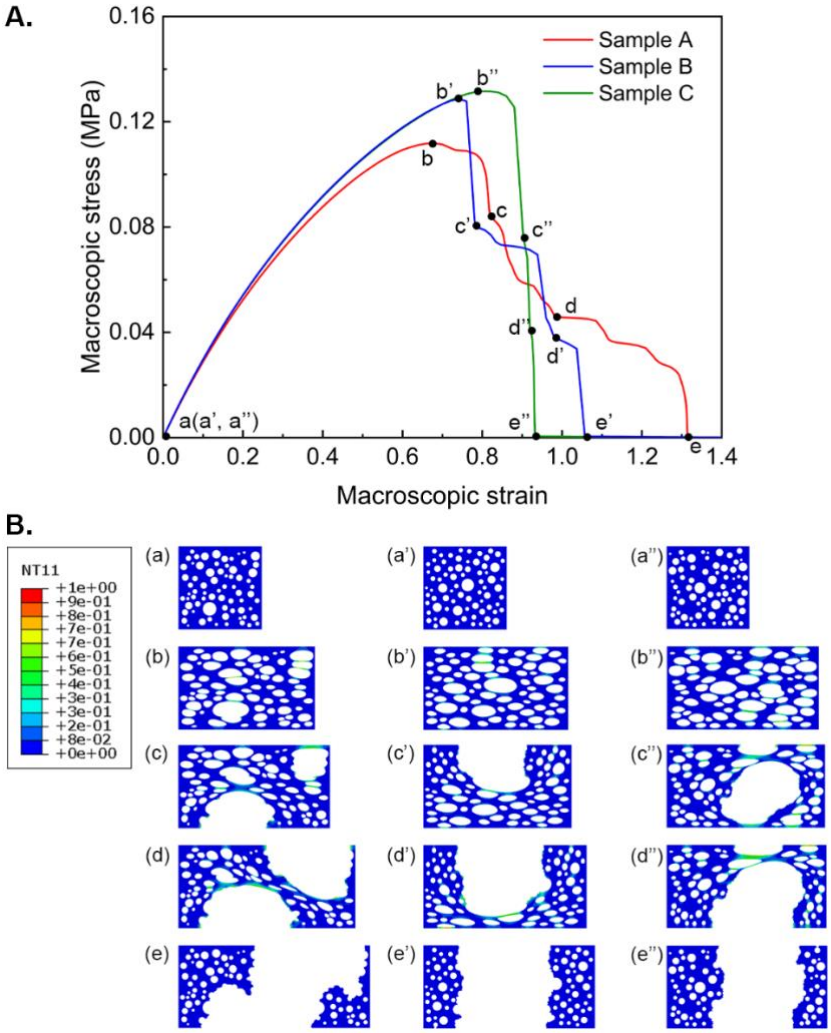

Figure 6: (A) The macroscopic stress-strain curves, and (B) crack paths of selected samples with different failure modes.

The normalised mean ($\bar{\mu}$) and standard deviation ($\bar{s}$) of pore radius reflect the statistic characteristic of the pore distribution within the single-scale RVEs, raising the question of whether these two parameters have a dominant effect on mechanical behaviour. To address this, the simulation results for 400 samples were analysed to establish the functional relations between the initial and final failure strain (Δε), final failure strain (ε_{ff}), strength (σ_{max}), and strain energy density (φ) and the normalized mean ($\bar{\mu}$) and standard deviation ($\bar{s}$).

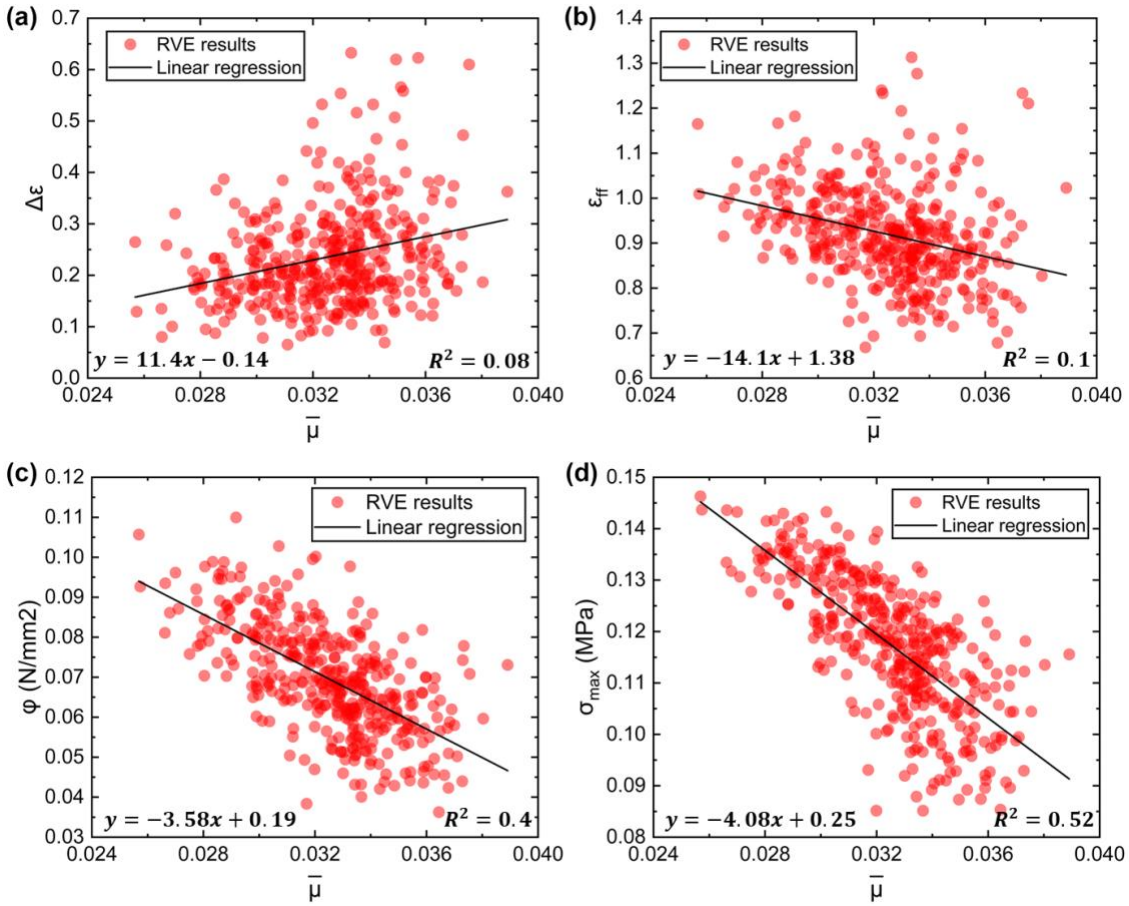

Figure 7: The 2D linear regression analysis between the normalised mean value standard $\bar{\mu}$ of the large-scale pore radius and (a) Δε, (b) final failure strain (ε_{ff}), (c) strength (σ_{max}), and (d) strain energy density (φ).

The results of the linear regression demonstrate that the overall effects of the normalised standard deviation ($\bar{s}$) on Δε, ε_{ff}, σ_{max}, and φ were statistically insignificant for the 400 samples. Conversely, the regression analysis indicates that an increase in the normalised mean radius ($\bar{\mu}$) led to an overall decrease in strength (σ_{max}), strain energy density (φ), and final failure strain (ε_{ff}), respectively (Figs. 7b, c and d). While a different overall trend was observed for Δε: as $\bar{\mu}$ increased, the value of Δε exhibited a slight increase (Figure 7a).

It is important to note that linear regression analysis only illustrates the overall trend of the effect of the normalised mean ($\bar{\mu}$) and standard deviation ($\bar{s}$) on these parameters and cannot capture the high dispersion of the results (Figure 7). It can be seen from Figure 7 that the same $\bar{\mu}$ can always return scattered Δε, ε_{ff}, σ_{max}, or φ values. This may suggest that, while the normalised mean value ($\bar{\mu}$) of pore radius can influence the ductility or other macroscopic material properties of the single-scale RVE, it might not be the sole determining factor. Other factors such as the distance between pores or the multi-scale structure could also play an important role.

Keywords: Shape Memory Polymer Composite, Atomic Oxygen Exposure, Durability of Shape Memory Polymer Composites, Graphene Nano platelets.

ABSTRACT

The use of shape memory polymers (SMPs) in space applications is a rapidly developing field. Therefore, the development of SMPs that are compatible with space environments can be a game-changing innovation for manufacturing specific satellite components and space structures. This study presents the durability evaluation of a cyanate ester-based shape memory polymer composite (SMPC) to be used in a lower Earth orbit (LEO) environment. SMPCS were fabricated with and without graphene nanoplatelets (GNP). Then SMPCs were exposed to Atomic Oxygen (AO) for a period of 48 hours, mimicking 300 days in a 550 km LEO orbit, and thereafter the effect due to AO exposure was tested and compared. The GNP-filled SMPC showed lower erosion in terms of weight loss and morphology compared to the SMPC without GNP. Thermo-mechanical, tensile, and flexural properties showed slight changes to the storage onset temperatures, tensile modulus, and flexural modulus, respectively, due to the AO exposure. Further, the shape recovery process has been slowed down by the AO exposure in all SMPCs, but 100% shape recovery was achieved at the end. It is concluded that GNP has slowed down the AO erosion, and the SMPC shows promising results for its future use in space applications.

1 INTRODUCTION

Shape memory polymers (SMPs) are considered a smart material due to their ability to be programmed into temporary shapes and then to be recovered using external stimuli such as heat, electricity, light, or magnetism [1,2]. Due to their excellent shape memory properties, SMPs are often being researched to develop deployable components and structures that can be used in biomedical, civil and space applications [3]. With rapid development of the space industry, SMPs that can withstand the harsh environment of space are being researched increasingly in recent years.

SMP and their composites can be used in deployable components of LEO satellites such as rolled-out solar arrays, hinges, booms, etc [2]. However, the SMP should be durable against the LEO orbital

environmental conditions such as high temperatures, UV radiation, thermal cycles, high vacuum, charged particle irradiation, as well as atomic oxygen irradiation [4]. AO irradiation in the LEO environment can erode almost every material in its way. Being hydrocarbons, polymers are highly susceptible to erosion by AO bombardments. However, the density of AO decreases with increasing orbital elevation, enabling the SMP to be used in higher altitude LEO regions. Furthermore, protective measurements such as silicon coatings can be used to protect SMPs against AO irradiation [5].

Cyanate ester is one of the most widely researched epoxy polymer families. In recent years, cyanate ester has been modified as a polymer with shape memory properties by adding oligomers and elastomers [6]. Furthermore, cyanate ester resins have performed well during many space durability tests [7–9]. In this research work, the authors are focusing on utilising the synthesised cyanate ester-based SMP reinforced with ±45° glass fibre for optimum directional shape memory programming and recovery. Moreover, graphene nanoplatelets (GNP) were added as a thermal conductive filler. Then the SMPC with and without GNP was exposed to AO irradiation, and the effect on SMPC was tested.

This work can be considered one of the pioneering works to utilise cyanate-based SMPCs for LEO applications. The outcome of this experiment has provided a basic understanding of the behaviour of SMPCs after being exposed to AO irradiation.

2 MATERIALS AND METHODS

2.1 Materials

For the SMP synthesis, Bisphenol A Cyanate Ester (BACE, M_n = 278.31) monomer was purchased from Wenzhou Blue Dolphin New Material Co., Ltd, China and PEG600 (PEG, M_n = 600) was purchased from Chem Supply Australia. Graphene Nano Platelets (GNP, surface area 750 m^2/g) were purchased from Sigma Aldrich, Australia, to be used as a thermally conductive filler. Glass fibre fabric (200 gsm) was purchased from ATL Composites, Australia, and it was used to reinforce the SMP. All the chemicals, fillers and fibres were used as purchased.

2.2 SMPC Fabrication

Initially, SMP was synthesised by mixing BACE and PEG600 (9:1 stochiometric ratio) at 90°C using a mechanical stirrer. GNP (0.6% w/w) was added afterwards and mixed using a sonicator for 20 mins (Figure 1). The ±45° plain weave glass fibre layers were cut into 300×300 mm^2 six sheets and laid inside a glass mould using double-sided tapes. The chemical mixture was poured into the glass mould and then cured for 2 hours at 100°C, 5 hours at 120°C, 2 hours at 180°C and 5 hours at 210°C. The cured 3 mm SMPC sheet was cut by a waterjet cutter into testing samples according to the ASTM standards. For the ease of identification, SMPC with GNP was named as GX and without GNP was named as NX. The Glass fibre layup configuration of NX SMPC can be observed under the microscope as shown in Figure 2.

Figure 1: Sonication of the GNP-filled chemical mixture.

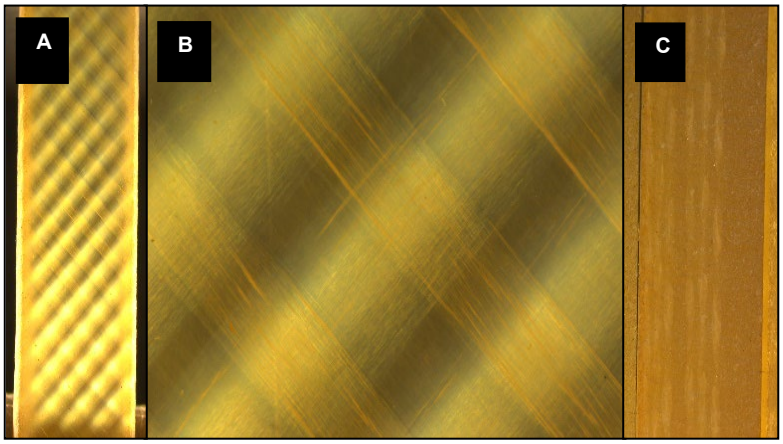

Figure 2: (a) Fabricated NX SMPC, (b) microscopic view of ±45° glass fibre layup configuration, (c) sectional view of SMPC with 6 glass fibre layers.

2.3 Atomic Oxygen Exposure

SMPCs with and without GNP were exposed to Atomic Oxygen (AO) using the AO interaction facility at the National Space Test Facility (NSTF), Australian National University, Canberra. Initially, SMPC samples were fixed into a sample holder to avoid AO exposure from other directions except for the top surface (Figure 3 (A)). During the test, SMPCs were exposed to AO plasma (Figure 3 (B)) with a 6.76×10^{13} atoms/cm^2.s flux under 30 Pa (0.3 mbar) of pressure at room temperature. At first, SMPCs were weighed and then exposed to AO continuously for 24 hours. After 24 hours, the SMPCs were weighed again and kept under AO exposure for another 24 hours. Then, SMPC samples were weighed again and cut into standard samples for characterisation and mechanical testing. In total, the SMPC samples were kept under the AO exposure for 48 hours, which is equivalent to 21 days at a 400 km LEO orbit (orbit of International Space Station) or 300 days at a 550 km LEO orbit [10].

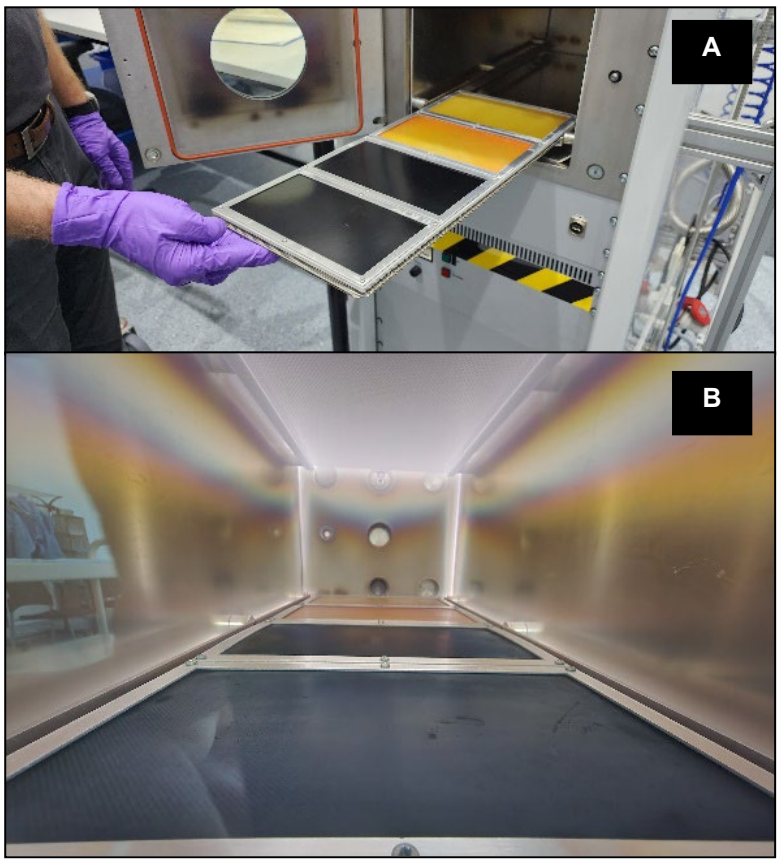

Figure 3: (a) SMPCs on the sample holder and (c) SMPCs under the AO plasma.

2.4 Characterisation Methods of SMPC.

The surface morphology of the AO exposed and unexposed was observed with a digital microscope (LEICA DMS300) and SEM (JEOL JCM-6000) at an acceleration voltage of 10 kV. The SEM images were further analysed using an SPM data visualization and analysis tool (Gwyddion 2.64).
Both AO exposed and unexposed surfaces were characterised for chemical structure changes using Fourier Transformation Infrared (FTIR) analysis in the wavelength range of 400-4000 cm^{-1} using SHIMADZU IRAffinnity-1S FTIR.

Thermomechanical properties such as storage modulus and tan(δ) changes of the SMPCs were studied by dynamic mechanical analysis (DMA) using the Hybrid Rheometer Discovery HR-2 (TA Instruments). 40×8×3 mm^3 SMPC samples were tested using the dual cantilever fixture with 25µm deflection and in 1 Hz oscillation. The samples were heated from 30 to 220°C by 5°C/min (ASTM D7028).

The tensile tests (with an extensometer) and the flexural tests were performed using MTS 100 kN uni-axial tensile testing machine according to ASTM D638 and ASTM D790 standards respectively.
Shape memory property changes were tested using the fold-deploy test method [11]. By measuring the fixed and recovery angles of the SMPCs, shape fixity ratios (R_f) and shape recovery ratios (R_r) were calculated. 100×10 mm^2 SMPC strips were bent into 90° and shape recovery was measured at temperatures from 20 to 220°C with 20°C intervals. All samples were kept at each temperature level for 30 min before measuring the recovery angle.

3. RESULTS AND DISCUSSION

3.1 Surface Morphology Analysis

After a total of 48 hours (12+12 hrs.) of AO exposure, the surface of the SMPCs has been eroded and is visible as shown in Figure 4. Total weight loss after 48 hours of exposure was measured as 0.5g in NX and 0.4g in GX. Morphology of the unexposed and exposed SMPC was observed with SEM. Both SMPCs with and without graphene showed rough surfaces with small grooves between 1-3 µm wide (Figure 5). However, SMPC with GNP showed wider grooves and smoother surfaces according to the analysed images compared to SMPC without GNP (Figure 6). Furthermore, GX showed shallow grooves (~121 nm) compared to NX (~187 nm) in the analysed figures.

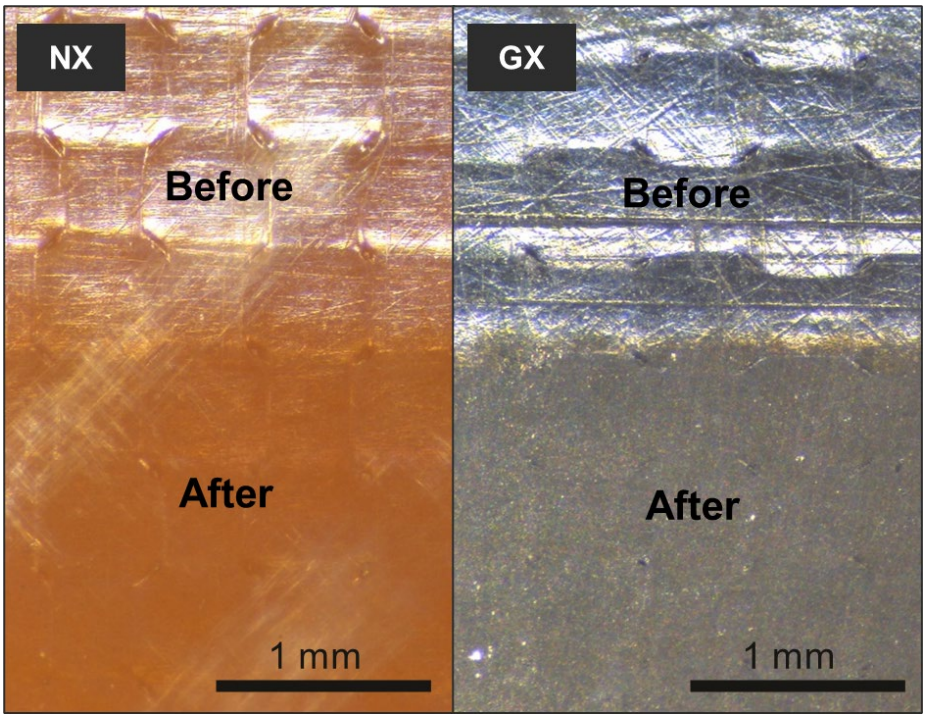

Figure 4: Digital microscopic image of NX and GX before and after 48 hours of AO exposure.

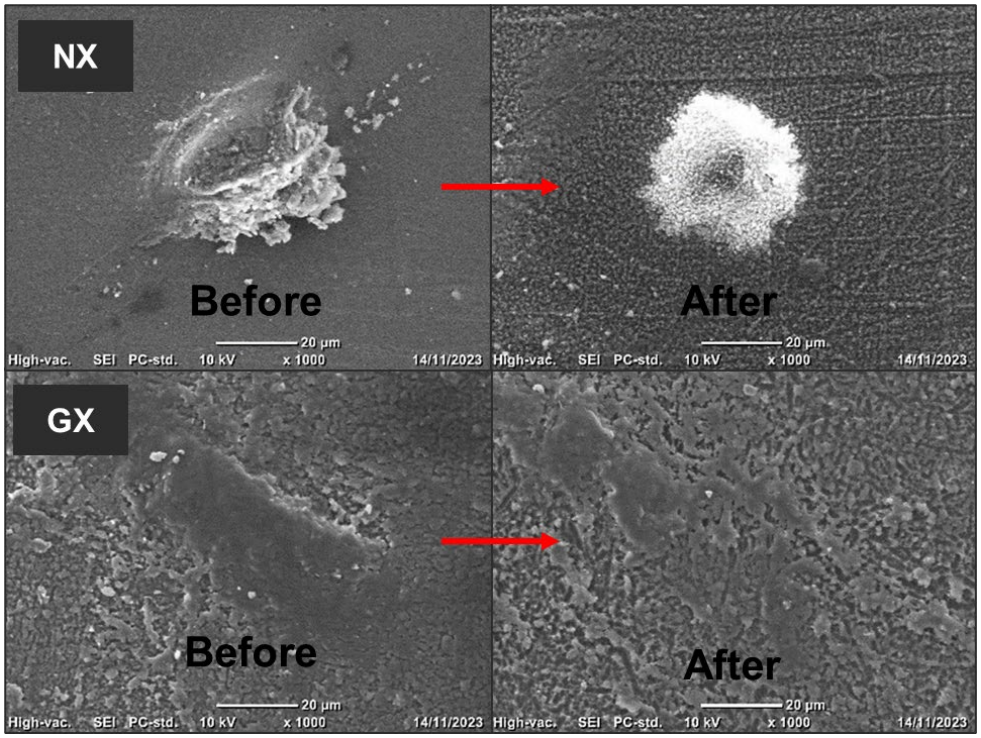

Figure 5: SEM images of NX and GX before and after 48 hours of AO exposure.

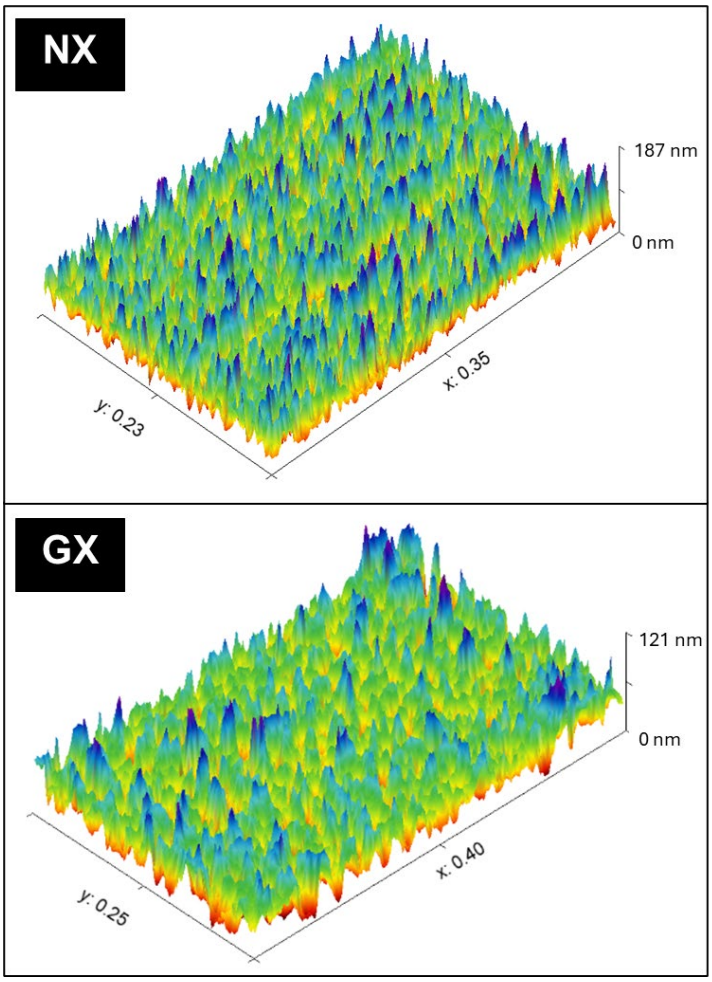

Figure 6: Surface roughness analysis of NX and GX after 48 hours of AO exposure.

3.2 Chemical Structure

FTIR spectra of SMPCs before and after AO exposure were compared (Figure 7). According to the spectrum analysis, the peaks at 1357 cm^{-1} and 1558 cm^{-1} show the existence of triazine rings, and 1465 cm^{-1} shows the existing groups of Isocyanurate in the SMPC matrix. The presence of PEG can be identified by the peaks at 1072 cm^{-1} from (-C-O-C-) and 2862 cm^{-1} from ($-CH_2-$). This confirms the formation of the cyanate ester structure with the shape memory properties [12]. Even after the AO bombardment, the above-mentioned bonds remain unchanged due to the high bond energy (over 2000 kJ/mol) of triazine rings.

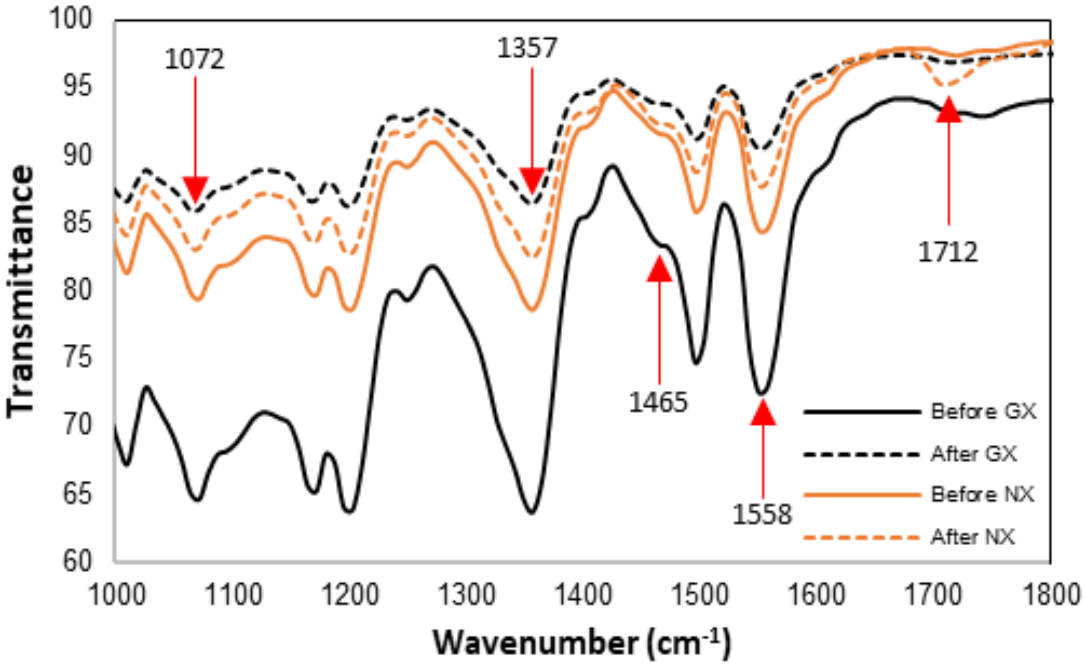

Figure 7: FTIR spectra of NX and GX before and after AO exposure.

The only change in the spectrum series can be identified in the spectrum of NX after the AO exposure. This peak at 1712 cm^{-1} corresponds to the carbonyl C=O bond stretching and vibration. This can be due to AO reacting with broken C-H and C-C bonds. It is worth noting that this only change has happened in SMPC without GNP fillers.

Considering the weight loss data, surface roughness analysis and chemical structure changes, it can be concluded that GNP-filled GX SMPC has built up a certain resistance to AO erosion compared to NX SMPC.

3.3 Thermomechanical Properties

Storage modulus and tan(δ) behaviour of AO exposed and unexposed SMPCs were plotted as shown in Figure 8. During this research work, the storage onset temperature (T_s) of the SMP was considered as the SMP's glass transition temperature (T_g) value. Initial T_g values of AO unexposed NX and GX were calculated as 128.51±0.6°C and 120.04±1°C, respectively. Moreover, both T_g calculated with storage modulus onset and tan(δ) peak temperatures (T_δ) are shown in Table 1.

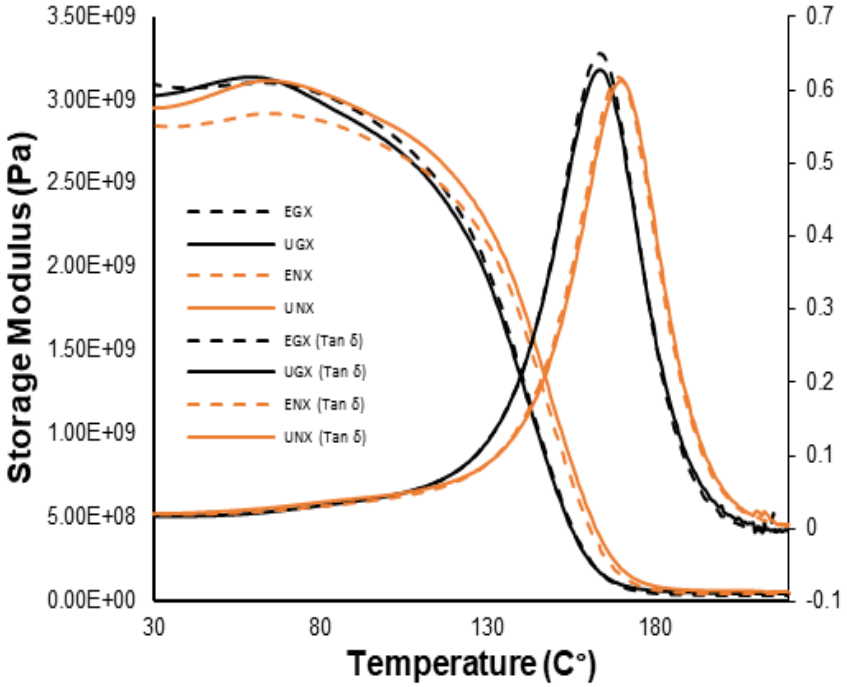

Figure 8: Thermomechanical behaviour of NX and GX before and after 48 hours of AO exposure.

Sample	T_s (Storage Onset)/°C		T_δ (Tan(δ) peak)/°C	
	Unexposed	Exposed	Unexposed	Exposed
NX	128.51±0.6	126.31±0.6	169.72±0.01	169.09±0.2
GX	120.04±1	121.11±1.5	162.87±0.7	164.23±0.2

Table 1: Glass transition temperatures (T_g) of NX and GX samples before and after AO exposure.

The addition of GNP has affected the thermomechanical properties of the SMPCs. T_g values of the GX SMPC have been reduced from a considerable value according to Table 1. This can be due to GNP interrupting the formation of triazine rings and isocyanurate groups in the SMP matrix during the curing stage. Apart from slight variations of the storage modulus graphs of the same SMPC groups, it is safe to assume that the thermomechanical behaviour of the SMPCs is unchanged upon the AO exposure.

3.4 Mechanical Properties

Tensile property and flexural property changes after the AO exposure are depicted in Figure 9 and Figure 10, respectively. Initially, NX showed a tensile modulus of 12.1 GPa with an ultimate tensile strength (UTS) of 82.5 MPa, and GX showed a tensile modulus of 7.8 GPa and a UTS of 60.48 MPa. The drop in modulus and UTS of GX can be due to the interruption of triazine ring bonds and isocyanurate bonds in the SMPC matrix by the GNP. However, after the AO exposure, the tensile modulus of both NX and GX dropped to 4.41 GPa. It can be noted that the tensile modulus drop of AO-exposed NX is higher than that of AO-exposed GX, from 4.3 GPa, showing the AO resistance of GNP-filled GX SMPC.

According to the flexural behaviour analysis, both AO-exposed and unexposed showed a flexural modulus in the range of 3.24-3.5 GPa initially. While GNP-filled GX showed higher modulus afterwards, resisting the three-point bending movement, NX samples have shown much flexibility with lower flexural modulus. This can be due to GNP fillers obstructing the polymeric structure from bending. Proving that AO-exposed GX samples have shown lower flexural modulus due to the removal of some amount of GNP from the SMPC matrix, and yet the flexural behaviour of the NX sample remains in the same region, even after the AO exposure.

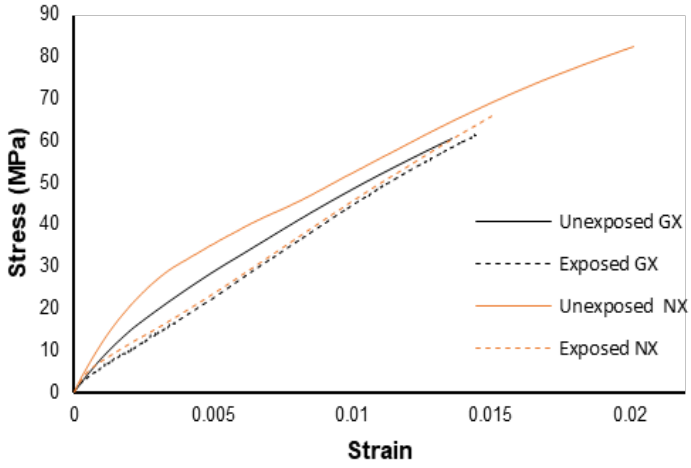

Figure 9: Tensile behaviour of NX and GX before and after AO exposure.

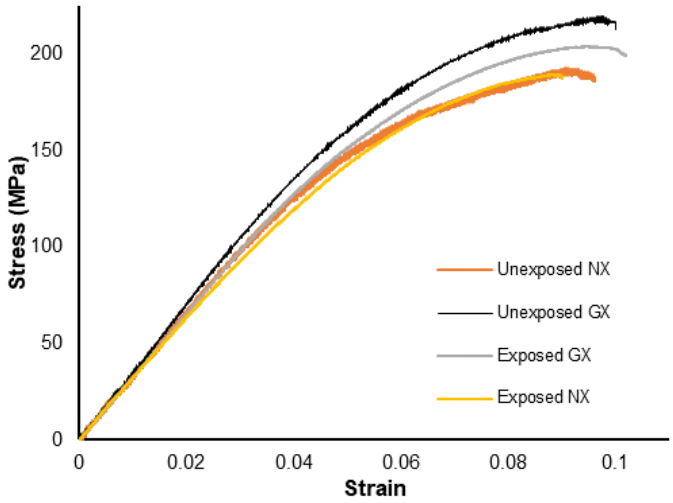

Figure 10: Flexural behaviour of NX and GX before and after AO exposure.

3.5 Shape Memory Behaviour

Shape memory behaviour is primarily studied using the shape fixity and recovery of the SMP or SMPC. The R_f value of all the AO exposed and unexposed SMPCs was calculated as 100%. However, the shape recovery of the SMPC showed interesting behaviour during their recovery even though they recovered their initial shape 100% at the end as shown in Figure 11 and Figure 12. An indication of the efficiency of the recovery can be studied by looking at the R_r value of the SMPC at the T_g at the tan(δ) peak (Table 2). It is interesting to mention that the SMPC with GNP showed a much quicker shape recovery compared to the SMPC without GNP. While the R_r of NX is around 33.7% at 169.72°C, GX has recovered around 42.5% at 162.87°C. This can be due to higher thermal conductivity inside the matrix of GX due to GNP fillers. However, it can be observed that the shape recovery has been delayed overall after the AO exposure in both NX and GX samples.

	T_g value	NX		GX	
		Unexposed	Exposed	Unexposed	Exposed
R_r	at T_s	~2.5%	~2%	~2%	~2%
	at T_δ	~33.7%	~15%	~42.5%	~15%

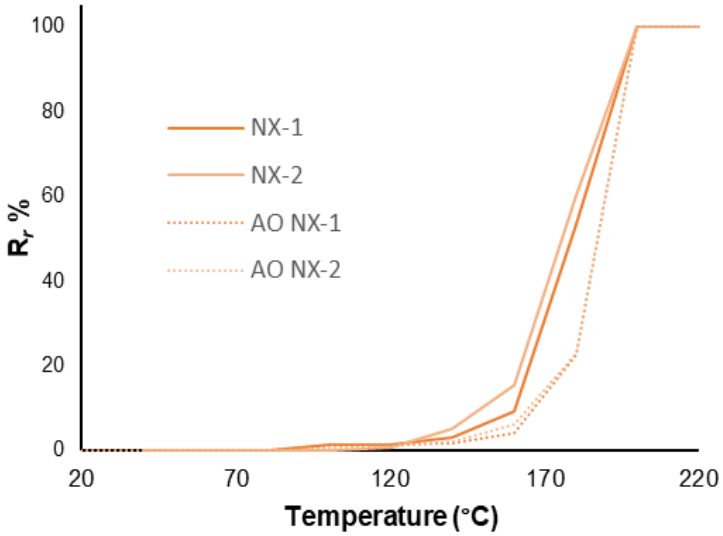

Figure 11: Shape recovery behaviour of NX before and after AO exposure.

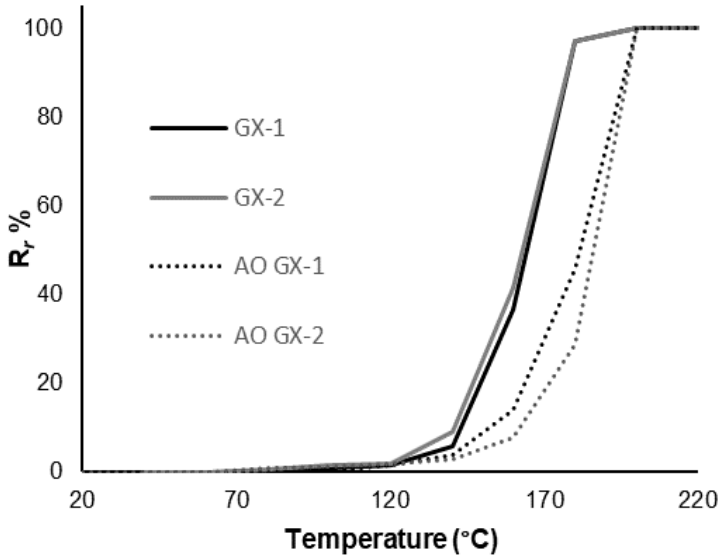

Figure 12: Shape recovery behaviour of GX before and after AO exposure.

4. CONCLUSION

According to the outcomes of this research work, it is clear that polymer surface erosion due to AO bombardment is inevitable. However, while being a good thermal conductive filler, GNP has acted as an AO erosion-resistive material compared to the performance of the SMPC without GNP filler. It is worth noting that the fabricated SMPCs are capable of surviving without significantly losing their shape memory and thermo-mechanical properties in a simulated 300 days in a 550 km LEO orbit. Further durability tests can be warranted to study the synergistic effects on the SMPC with protective measurements before the deployable components and structure development stage.

ACKNOWLEDGEMENTS

The authors would like to acknowledge the support given to this research by the National Space Test Facility (NSTF), Australian National University (ANU), to utilise the Atomic Oxygen interaction facility. Also, the main author would like to convey his sincere gratitude to Mr Oliver Kinder (Senior Technical Officer) and Mr. Nathan Strenzel (Technical Officer) at the University of Southern Queensland, for their valuable assistance in this research.

ABSTRACT

Cracks in aging concrete structures reduce mechanical integrity and often require localized repair. However, assessing the effectiveness and long-term performance of such repairs remains a challenge, especially in inaccessible or load-critical zones. In this study, I propose a carbon nanotube (CNT)-reinforced epoxy composite combined with aggregates to form a self-sensing concrete system capable of monitoring local compressive stress in real time. The system leverages the piezoresistive properties of CNTs within a polymer matrix to detect mechanical loading. I explored the influence of CNT concentration on electrical conductivity, mechanical performance, and sensing repeatability. The composite with 0.25 wt% CNT content exhibited high electrical sensitivity, mechanical robustness, and reproducibility under cyclic loading. This research highlights the potential of CNT-epoxy concrete as a multifunctional repair material that offers both reinforcement and embedded sensing.

1 INTRODUCTION

The deterioration of concrete structures due to aging and environmental exposure remains a major challenge in civil infrastructure. Surface and internal cracks not only weaken structural capacity but also accelerate corrosion and degradation processes. Repair strategies are often employed to restore mechanical integrity; however, assessing the long-term performance of these repaired areas is difficult with conventional inspection methods. Visual inspections and acoustic techniques require human involvement and do not offer continuous or real-time assessment, which leads to uncertainty and delayed responses to potential failure.

To address this limitation, self-sensing repair materials have been proposed, aiming to integrate sensing capabilities directly into the repair matrix. Among the various approaches, cementitious composites with embedded conductive fillers such as steel fibers, graphite, or carbon nanotubes (CNTs) have been studied for their piezoresistive behavior. For example, Jung et al. [1] developed ultra-high-performance concrete (UHPC) with embedded CNTs for both electrical field curing and crack detection. The system showed piezoresistive response under loading, demonstrating potential for field casting and real-time sensing. However, like many cement-based systems, the approach faced limitations related to CNT dispersion quality and sensitivity, particularly in the pre-cracking regime.

While such cement-based approaches offer some advantages in durability and structural integration, their low elasticity and limited CNT dispersion efficiency often result in insufficient sensitivity and poor repeatability. Polymer-based matrices, particularly epoxy resin, have shown better potential in this regard. Epoxy's high viscosity allows for improved CNT dispersion when aided by techniques

such as ultrasonication and three-roll milling. Moreover, the superior adhesion, chemical resistance, and toughness of epoxy make it a common material for high-performance repairs. Jung and Jang [2] previously proposed a CNT–polyurethane composite "smart skin" for detecting cracks in concrete, confirming the feasibility of CNT/polymer systems for localized sensing applications.

Despite these advancements, CNT-polymer systems incorporating structural aggregates—capable of functioning not only as a sensing layer but also as a load-bearing repair material—have not been fully explored. Most existing studies either neglect aggregate inclusion or limit the application to thin coatings. However, for practical field use, it is essential that self-sensing repair materials possess both structural robustness and effective signal responsiveness.

To bridge this gap, this study develops and characterizes a CNT-epoxy concrete, a hybrid repair material designed to achieve compressive sensing functionality and structural reinforcement simultaneously. The material combines CNTs with an epoxy matrix and coarse aggregates, forming a bulk composite suitable for crack region replacement. The effects of CNT concentration on conductivity, mechanical performance, and rheology were investigated in detail. Furthermore, its strain-sensing behavior under static and cyclic compression was analyzed to determine its viability as a localized SHM-enabled repair material for damaged concrete infrastructure.

2 MATERIALS AND METHODS

2.1 Materials

To develop a structurally applicable self-sensing repair material, a composite system was formulated using multi-walled carbon nanotubes (MWCNTs), epoxy resin, and aggregates. The MWCNTs used in this study were MWCNT-210P (Kumho Petrochemical, Republic of Korea), synthesized by chemical vapor deposition. These nanotubes have diameters of approximately 10–15 nm and lengths of 10–20 μm, with a carbon purity exceeding 95 wt%. The epoxy matrix was based on a super-low viscosity bisphenol-A type resin (DH-150, Daehwa Precision, Republic of Korea), selected for its high fluidity (120 mPa·s), high compressive strength (76 MPa), and excellent bonding properties (adhesive strength: 9.1 MPa). Analytical-grade acetone (99.7%, Samchun Chemical, Republic of Korea) was used to facilitate the dispersion of CNTs in the epoxy matrix. Standard sand (KS L ISO 679) was used as the aggregate, due to its consistent particle size and compatibility with epoxy matrices. An 80:20 volumetric mixing ratio between aggregate and CNT-epoxy composite was adopted, based on prior optimization studies that achieved a balance between compressive performance, elasticity, and flowability. This configuration allows the material to mimic the load-bearing characteristics of typical crack repair regions in concrete structures.

2.2 Fabrication Process

The fabrication sequence of the CNT-epoxy concrete. The process was designed to achieve uniform CNT dispersion while maintaining the structural integrity of the composite during aggregate mixing and curing. First, CNTs were dispersed in approximately 50 mL of acetone together with the epoxy resin using an ultrasonicator (Q700, Qsonica, USA) at 90% amplitude in pulse mode (15 s on, 15 s off) for 40 minutes. This ultrasonic treatment was critical to overcome van der Waals attractions between CNTs, facilitating homogeneous dispersion. To prevent thermal degradation of the resin during sonication, the beaker was immersed in an ice bath. Following dispersion, the mixture was heated on a hot plate at 60 °C for 24 hours to evaporate the acetone. An epoxy hardener was then added in a 3:1 ratio (resin:hardener), and the mixture was further homogenized using a three-roll mill (TR50M, Trilos, USA) to remove remaining agglomerates and ensure uniform CNT distribution. This step was particularly important for consistent electrical conductivity and reproducible sensing behavior. The final CNT-epoxy composite was manually blended with aggregates and poured into cylindrical molds (40 mm diameter, 25 mm height). Curing was performed at room temperature for 48 hours. After demolding, both top and bottom surfaces were coated with high-purity silver ink to form low-resistance electrical contacts.

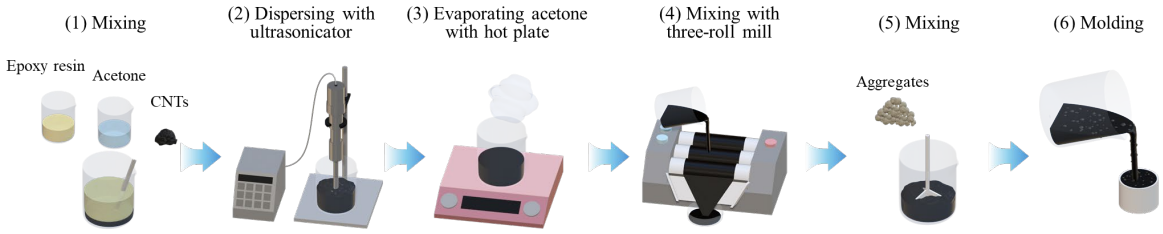

Figure 1: Fabrication process of CNT-epoxy concrete.

2.3 Characterization Methods

Electrical conductivity was measured using a two-probe setup. For samples with resistance above 10^6 Ω, a high-resistance meter (6517B, Keithley, USA) was used; for those below this threshold, a source meter (2450, Keithley, USA) was applied. The electrical conductivity σ (S/m) was calculated using

$$\sigma = L/RA \tag{1}$$

where R is the resistance, L is the electrode spacing, and A is the electrode cross-sectional area. Silver ink was applied to reduce contact resistance, and copper leads were attached during mechanical tests.

Mechanical and piezoresistive tests were conducted using a universal testing machine (Instron 8861, USA). Static compression tests were performed at a loading rate of 1.3 mm/min. Electrical resistance was recorded in real-time during mechanical loading using a multimeter (2700, Keithley, USA) connected to the copper-taped electrode surfaces. Rheological behavior of the CNT-epoxy composite was measured using a parallel-plate rheometer (MCR 302e, Anton Paar, Austria). A constant shear strain of 1.01% was applied across a frequency sweep from 0.05 to 450 rad/s to evaluate viscoelastic responses relevant to processability and field application.

3 RESULTS AND DISCUSSION

3.1 Electrical Properties

The electrical conductivity of the CNT-epoxy composite exhibited a strong dependence on the CNT concentration. In specimens without CNTs or with less than 0.05 wt.% loading, the material behaved as an insulator, with conductivity below 10^{-8} S/m [3]. This is attributed to the isolated and randomly distributed CNTs, which were insufficient to form continuous pathways for electron transport. However, as the CNT concentration approached 0.10 wt.%, a dramatic increase in conductivity was observed. This behavior corresponds to the percolation threshold, where conductive clusters begin to connect and establish long-range networks through the matrix [4].

Between 0.10 wt.% and 0.50 wt.%, the conductivity rose by over three orders of magnitude, reaching values in the range of 10^{-5} to 10^{-3} S/m depending on sample geometry and aggregate presence. This exponential growth indicates efficient CNT network formation, enabling both direct conduction and electron tunneling. The results are consistent with previous findings in CNT/epoxy composites, where the percolation threshold is often reported between 0.05 and 0.3 wt.% depending on dispersion quality and processing method [5].

Beyond 0.50 wt.%, conductivity growth plateaued, suggesting saturation of the network. At these higher concentrations, additional CNTs are more likely to form redundant bundles or agglomerates rather than contributing to new connections [6]. This saturation effect limits further gains in sensing performance and suggests diminishing returns at higher loading levels.

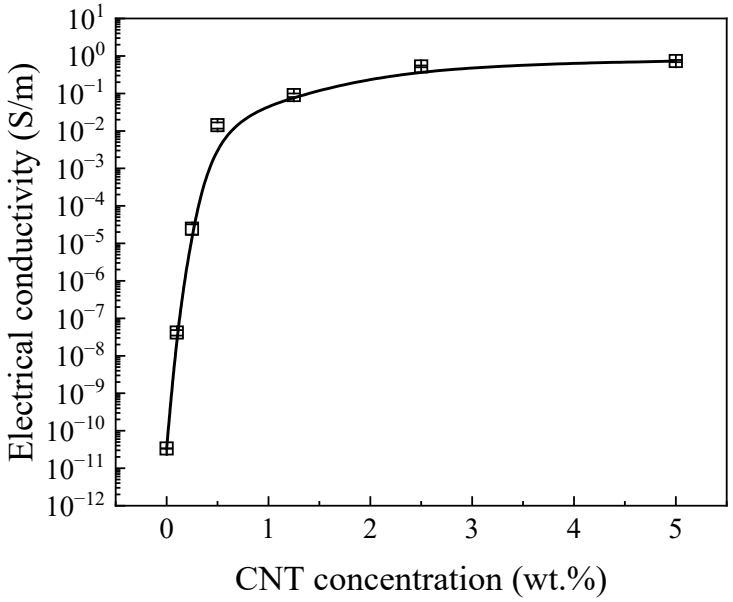

Figure 2: Electrical conductivity of CNT-epoxy composites at different CNT concentrations.

3.2 Rheological Properties

The rheological characteristics of the CNT-epoxy composites were evaluated to understand how increasing CNT concentration affects processability. Table 1 presents the complex viscosity as a function of angular frequency for four CNT loadings: 0.00, 0.25, 0.50, and 2.50 wt.%.

The control sample with 0.00 wt.% CNT exhibited Newtonian-like flow behavior, maintaining a nearly constant viscosity of approximately 1 Pa·s across the entire frequency range. This low and stable viscosity is suitable for uniform mixing with aggregates and effective casting. Upon adding 0.25 wt.% CNT, a noticeable increase in viscosity was observed, particularly in the low-frequency range. The composite began to exhibit mild shear-thinning behavior, suggesting the onset of a weak particle–matrix interaction. Although the viscosity rose by nearly an order of magnitude, the material remained sufficiently flowable for practical mixing and casting processes. At 0.50 wt.%, the shear-thinning effect became more pronounced. The low-frequency viscosity further increased to above 10^4 Pa·s, indicating the development of a more interconnected CNT network within the epoxy. This enhanced viscoelastic response implies that the CNTs were forming physical linkages that resisted deformation under low shear conditions. A substantial rheological change was observed at 2.50 wt.%, where the composite reached a complex viscosity exceeding 10^6 Pa·s at low frequencies. The material became highly viscoelastic and showed significant resistance to flow. Such high viscosity can severely compromise workability, leading to poor dispersion of aggregates, increased air entrapment, and inhomogeneous distribution during casting. In practical applications, these issues could reduce both structural reliability and sensing stability.

The progressive increase in viscosity with CNT content is primarily driven by van der Waals forces between nanotubes, which promote physical entanglement and the formation of a pseudo-solid network. While beneficial for electrical conductivity, this network formation adversely affects flowability, especially in systems containing solid fillers such as sand [7].

Table 1: Complex viscosity of CNT-epoxy composites at different CNT concentrations.

CNT concentration (wt.%)	Complex viscosity (Pa·s)

0.00	~1
0.25	~1.2 × 10^3
0.50	~8 × 10^3
2.50	~4 × 10^5

3.3 Mechanical Behavior

The compressive performance of CNT-epoxy concrete was evaluated to investigate how varying CNT concentrations influence the mechanical response and to ensure that the sensing functionality does not compromise structural integrity. Figure 3 presents the compressive stress–strain curves for composites containing 0.00, 0.25, and 0.50 wt.% CNTs. The 2.50 wt.% formulation was excluded from mechanical testing due to workability issues during mixing and casting.

The control sample without CNTs exhibited brittle failure, with a peak strain of approximately 6.2% and a compressive strength of about 38 MPa. Incorporating 0.25 wt.% CNTs led to a strength increase of around 19%, reaching nearly 45 MPa, while the strain at failure more than doubled to 13.5%. This improvement is attributed to the reinforcing effect of CNTs, which can bridge microcracks, delay crack propagation, and enhance stress transfer between the matrix and the aggregates [8].

At 0.50 wt.%, the compressive strength was slightly lower than at 0.25 wt.% but still exceeded that of the control. The strain capacity remained comparable to the 0.25 wt.% sample, suggesting that the toughness improvements were retained. This result implies that moderate CNT loading can improve both strength and ductility without significantly affecting casting quality or material homogeneity.

These findings highlight the importance of identifying an optimal CNT range that provides both mechanical reinforcement and sensing capability. While low-to-moderate CNT contents enhance material performance, concentrations above 0.50 wt.% may lead to severe rheological limitations that hinder practical application. Therefore, a target range of 0.25–0.50 wt.% is recommended for CNT-epoxy concrete designed for use as a structural repair material with integrated self-sensing functionality.

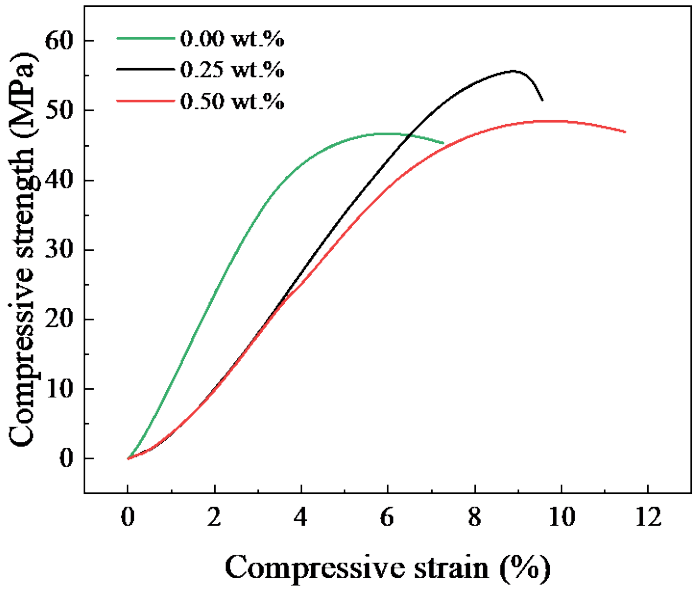

Figure 3: Compressive stress–strain curves of CNT-epoxy concrete.

3.4 Electromechanical Response under Compressive Loading

Figure 4 presents the relative resistance change ($\Delta R/R_0$) of CNT-epoxy concrete specimens with 0.25 and 0.50 wt.% CNT content under uniaxial compression. As compressive stress increased, both samples exhibited a continuous decrease in electrical resistance, indicating the formation and densification of conductive paths within the matrix.

At the initial stage of loading, a steep decline in $\Delta R/R_0$ was observed, particularly for the 0.25 wt.% specimen. This behavior is attributed to the rapid reduction in tunneling distances between CNTs as the matrix is compressed, thereby enhancing conductive network density[9]. As the stress level increased further, the slope of the $\Delta R/R_0$ curve gradually decreased, reaching a near-plateau region. This transition suggests that the CNT network had reached a mechanically stable configuration, where additional compression induced relatively minor changes in resistance.

Compared to the 0.50 wt.% sample, the 0.25 wt.% specimen showed a greater initial sensitivity, reflected by a steeper slope in the low-stress regime. This indicates that the composite near the percolation threshold is more responsive to mechanical perturbations due to its loosely connected network[11], which is more susceptible to rearrangement under strain. On the other hand, the 0.50 wt.% composite exhibited a more moderate and stable resistance change[10], likely due to a denser and more saturated conductive network. These results confirm that CNT-epoxy concrete possesses piezoresistive properties suitable for self-sensing applications. In particular, composites near the percolation threshold (e.g., 0.25 wt.%) are more sensitive to compressive stress and thus may be more effective for detecting minor structural loads. However, higher CNT concentrations may offer better signal stability under sustained loading conditions.

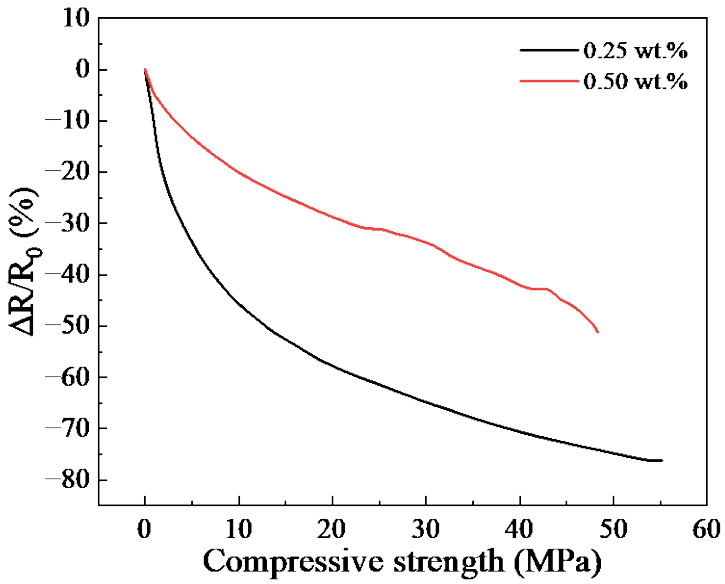

Figure 4: Relative resistance change of CNT-epoxy concrete under compressive loading.

4 CONCLUSIONS

This study investigated the electrical, rheological, mechanical, and electromechanical behavior of CNT-epoxy concrete for use as a self-sensing repair material. The results demonstrated that a CNT concentration between 0.25 and 0.50 wt.% offers the best balance between conductivity, processability, and mechanical performance.

Electrical conductivity increased sharply near 0.10 wt.%, indicating a clear percolation threshold. Rheological analysis showed that viscosity rose significantly with CNT content, especially above 0.50 wt.%, which negatively affected workability. Compressive tests revealed that 0.25 wt.% CNT

improved both strength and ductility, while higher concentrations showed diminishing returns. The electromechanical response confirmed the piezoresistive behavior of the composites, with 0.25 wt.% offering higher sensitivity and 0.50 wt.% showing more stable responses under compression.

Overall, CNT-epoxy concrete with 0.25–0.50 wt.% CNT is suitable for practical structural repair applications with built-in sensing capability. Further work is needed to evaluate long-term durability and field-scale implementation.

COMPOSITE MATERIALS SUSTAINABILITY – WHERE ARE WE TODAY AND WHERE DO WE NEED TO GO

Edward (Ned) Patton, Ph.D., P.E.

Oceaneering International Inc.
Hanover, MD

Patton Engineering
San Diego, CA

Keywords: Composite Sustainability, Bio-based Composites, Composite Recycling, Recyclability

ABSTRACT

When engineers and composite material practitioners talk about sustainability and composites, they could be talking about any one of the several aspects of this idea. But the basic question is how do we make our composite structures sustainable, and what do we do with them when they come to the end of their current usefulness. This is the over-riding concern for the industry today, especially as our most prevalent composite structures come to the end of their useful life. The most visible example of this is the current mountain of used wind turbine blades that are piling up in Sweetwater, Texas. But this is not the only problem that the industry faces, it is just the most visible one.

There are many challenges that engineers face when it comes to what to do about sustainability and composites, not the least of which is how sustainability is defined. Is it just being able to recycle these materials and keep them from landfills, or potentially does it mean that the industry needs to wean itself off of the use of petroleum feedstocks for the building blocks for advanced composites of tomorrow.

On the recycling front, several techniques for reuse have emerged in the last decade, from grinding up used composites and using the ground up material as reinforcement for things like concrete or sheet molding compound, to pyrolyzing the resin and keeping the fiber, to complete separation of the matrix from the fibers through thermal or chemical means and reusing both in new composites. This last challenge is of course the most technically difficult to actually achieve, since great pains were taken to make the fibers adhere to the resins in the first place. It also has been perceived as cost prohibitive.

On the inherently sustainable front, there is also a move toward using bio-based precursors for both fiber and resin, and using resin chemistries that are inherently recyclable. This trend is expanding rather rapidly but has yet to reach a tipping point where bio-based or plant-based precursors for composites become the standard.

Clearly there is more work to be done. What follows provides an up to date assessment of where all of the composite materials sustainability efforts are and offers a guide or roadmap to where each part of the industry needs to go and what needs to be done to achieve true sustainability.

To achieve this eventual goal all sectors of the industry need to be involved. This includes at least the manufacturers (growers?) of the precursors, the resin and fiber manufacturers, the manufacturers and purveyors of the different product forms that need to be made available, the fabricators and composites manufacturers, the end users, and the recycling / reuse community.

To achieve true sustainability in the industry will cost money and take time and effort on the part of every sector of the industry. In addition, there is inherent risk associated with upending business models that have worked for the last few decades which are not going to be workable in the future. The challenge is transforming the business without going out of business. This paper provides a roadmap to accomplish just that.

1 INTRODUCTION

Several schools of thought have emerged in this field in the last decade, and there is considerable ongoing work in the industry to achieve sustainability. While the technologies to recycle composites have been demonstrated in the laboratory and even at small scale, the work ongoing now is in scaling up these newly developed methods to recycle large composite parts that have come to the end of their life. This work is driven both by the wind energy industry as large composite wind turbine blades come to the end of their lives, and the marine industry in recycling of end of life boat hulls. Most of this work is for fiberglass composites, since fiberglass is the highest tonnage waste problem that the industry faces. These developments are also mostly in the EU because of the new environmental laws that require that boat manufacturers not only bake in the cost of recycling their end of life boat hulls but also accept them

for recycling when they come to end of life,. It is also because of the early adoption of offshore wind in the North Sea where wind turbines need to be repowered regularly because of the extraordinarily harsh environment they must withstand.

There is, of course, more to the story than just recycling of existing parts. Other practitioners and composites designers view sustainability from different angles than just how to keep wind turbine blades and old boat hulls from being put in a landfill. There is now, however, a movement in the industry to develop and use design and fabrication methods that take into account how the part is going to be recycled and its constituents reused at the end of use of the part that they are designing. Essentially what all of this means is how do we close the design-fabrication-use-recycle-reuse circle in order to avoid having to make new fibers and resin systems every time we want to make a composite part or structure.

Figure 1 illustrates this idea of creating a circular economy for composite materials to achieve real sustainability of these materials.

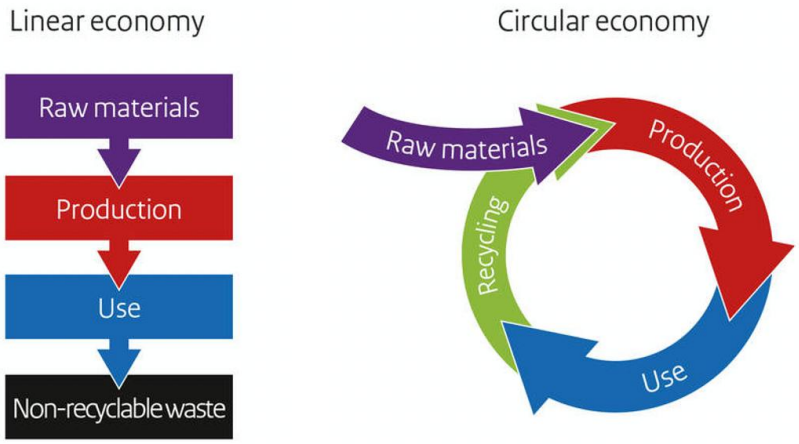

Figure 1: Linear vs Circular Economy (© Government of the Netherlands)

This figure was chosen to present here because it demonstrates what is meant by the creation of a circular economy for composite materials as compared and contrasted with the current linear economy where end of life composites are mostly put in landfills. This is of course where the industry is tending and needs to go to make these materials sustainable.

There is also a movement in the industry to formulate resins that can be more easily reverted into their initial liquid state through either chemical or thermal means so that they can be more readily separated from the fibers. There are even means of thermally removing the resin from the fibers without damaging the fibers and without burning up the resins so that both recycled materials can then be reused.

Sustainability in composites also means moving away from the use of petroleum as a feedstock for both fibers and resins and moving to plant-based fiber and resin precursors. To that end, plant fibers like flax have begun to be used effectively in a number of composite structures. Research is also going on to develop composite resins from wood product waste that behave like epoxies. The paper industry uses the cellulose from wood and essentially throws away the lignin that binds the cellulose fibers together. Use of this discarded lignin as a precursor to an epoxy resin is a very active field of technology development.

Finally, there is a large movement to enable design of composite parts in a manner that takes into account the entire life cycle of the material from design to material selection to fabrication to use and eventual recycling and reuse once the part has ended its usefulness. This is called Design for Sustainability, which is a very important initiative that has been started in Europe by the European Composites Industry Association – EuCIA.

This paper presents not only the challenges that engineers, chemists, and other scientists face in creating a model of sustainability for composites that is cost effective and accomplishes the goals of sustainability, but also provides a roadmap to sustainability as well as a snapshot of where the industry is today on that road to true sustainability. This includes first a look at the challenges that the industry

faces in moving from the current linear business model to a circular business model for these materials, then provides a presentation of the state of the art in this field of endeavor and who is working on what part of the problem. The story that unfolds here then continues by providing a roadmap for engineers and practitioners in composite material design, fabrication, use, and recycling/reuse. Finally what is presented is a look at the state of the art in composites sustainability and a discussion of not only where we are on that road but also what it is going to take in terms of technology development, capital expense, and time.

2 CHALLENGES FACED BY THE INDUSTRY

The major challenge that the composites industry faces in the very near future stems fundamentally from the properties of composite materials in that their major benefit is also their Achilles heel. Composites provide an infinite number of different ways that you can combine a fiber or other reinforcement and a matrix material – whether that be a plastic, metal, or even ceramic – to make a material that is greater than the sum of its parts so to speak. This wonderful benefit, when the composite comes to the end of its useful life, makes the material very difficult to separate into its constituent parts and reuse those parts. This means that there is a large amount of this waste that is no longer allowed to be landfilled in most countries. This is especially true of the wind turbine industry where it is believed that by 2034 there will be on the order of 200,000 tons of blade waste produced per year [2]. And, of course, since wind turbines are getting much larger in terms of blade length, there is a move to migrate to an all carbon/epoxy blade design from the current carbon fiber/epoxy spar with a glass/epoxy skin to minimize swing weight of the propellor blades. This will only make the recycling problem more challenging.

2.1 Wind Turbine Industry Challenges

The fundamental challenge facing this industry is realizing a positive cost/benefit in real dollars from recycling used fiberglass wind turbine blades when the market for the recycled materials has historically been nearly non-existent. This has been true for decades which is why so many wind turbine blades are rotting in landfills all over the developed world. There are news stories about this problem, and some infamous pictures from places like Sweetwater Texas where there is an enormous pile of used wind turbine blades stacked up and just sitting in the Texas sun that have been there for more than a decade without a single blade being moved to a recycling center.

Figure 2: Used Wind Turbine Blades in Sweetwater, Texas (photo by Eli Rosen, Yucca Films)

There are similar piles of these blades in the UK and in Northern Europe where they used to commonly be landfilled. This is changing, however because the EU and the UK have both banned the

landfilling of wind turbine blades, so there are significant efforts ongoing to deal with this problem in a responsible way.

Currently the process for recycling these blades when they come to their end of use is to chop up the blade into smaller pieces and use these pieces in a discontinuously reinforced composite. This has its own drawbacks because of the loss of the stiffness and strength of the original continuous fiber composite. Some authors and practitioners have suggested that pyrolyzing the blades to remove the resin and leave just the remaining fiber is one way to preserve at least the continuous fiber. This process in itself poses many challenges. First, the blades that are coming into the waste stream now, as mentioned above, are a mix of carbon/epoxy and glass/epoxy materials. Each of these components needs to be separated from the others and treated in a different manner, especially if pyrolysis is the method used to remove the resin from the fibers. And pyrolysis is not effective for fiberglass composites because the temperatures involved merely melt the glass and all you get is a pile of useless trash.

The major challenges with this method are both that pyrolysis does not preserve the resin (a petroleum based product) for reuse in another application, and also pyrolysis itself is not an eco-friendly process. The byproducts of epoxy resin pyrolysis are toxic and need to be extracted from the exhaust stream of the pyrolysis oven. The carbon from the original resin also is typically vented to the atmosphere and therefore adds to the carbon burden in our upper atmosphere. For these reasons, pyrolysis, while it may be a good place to start with recycling large end of life composite parts, is not the eventual answer to development of a sustainable, circular economy for the composite materials industry.

2.2 Recreational Marine Industry

The recreational marine industry has a very similar problem in recycling of the fiberglass boat hulls as exists in the wind turbine industry. Fiberglass boat hulls have an average life of about 30 years, with some lasting more than 50 years, but most, especially those exposed to seawater, have a shorter life span. And, like wind turbine blades, the fiberglass structures are very large, complex, and have all sorts of things attached to them that are not fiberglass.

The National Marine Manufacturers Association estimates that in the US some 200,000 boats reach the end of their useful life each year [2]. In the EU that number is more like 80,000 boats. If you consider that each boat hull is about a ton to a few tens of tons, this makes the problem nearly as difficult as the wind turbine blade waste problem. In addition to that, wind turbine blades are usually not widely disbursed whereas boat hulls are everywhere, so a centralized recycling strategy will not work.

2.3 Aging Aircraft

The Boeing 787 Dreamliner was introduced in 2012, and the Airbus A350 was introduced in 2013. These two commercial aircraft now have been manufactured at a high enough rate to meet demand, so there are several hundred of each in service today. These are the two best examples of a primarily composite large transport aircraft. As of February 2023, there had been 1041 Boeing 787's put into service and 524 Airbus A350's. Even though the pandemic has reduced both aircraft production rates substantially (14 787's per month in 2020 and 10 A350's per month in 2019) at their current production rates (9 per month for both Boeing and Airbus) [3], more than 2000 of these composite aircraft are going to have to be recycled and reused in the next 20-30 years.

To date there has only been a modicum of research and development work done to effectively recycle the composite material portions of these aircraft. While there has been considerable research into this topic, which is gaining some traction both here in the U.S. and in Europe, development of all of the technologies required to effectively recycle and reuse the composite parts of these large transport aircraft have yet to be developed.

2.4 Automotive Industry

In the last decade or so a considerable number of composite material parts have been integrated into new cars and trucks, both light duty and also heavier over-the-road trucks. Ford for instance makes some of their light duty truck driveshafts out of composites. And increasingly composites are being used for things like leaf springs, trunk liners, and some body parts. With the coming of electrification of the mass auto market, things like battery cases are also being made out of composites [4].

Composites have been used in mass market automobiles and light trucks since 1953 with the introduction of the Corvette. Since then, every Corvette has had a fiberglass body. Since the advent of the Corvette fiberglass body, several composite components have been introduced, until finally composites entered the mainstream of the auto industry in 1984 with the Pontiac Fiero and continued in 1990 with the introduction of the Saturn [5]. Since that time with the perfection not only of the injection molding and vacuum assisted resin transfer molding as well as thermoset and thermoplastic based sheet molding compounds, nearly all trunk liners, fender well liners, interior door panels, and even some exterior fenders, door panels, and hoods of standard high production rate automobiles have been made using composite materials. Since these materials are a mix of thermoset and thermoplastic resin composites, they pose different challenges than the primarily glass and carbon fiber reinforced epoxy resin composites used in the wind turbine and air transport sectors.

It has been said that as soon as carbon fiber gets down to on the order of $5 a pound, the auto industry will stop using steel. While this is a very good thing for the environment, since lighter weight autos burn less fuel, when these composite parts come to the end of their useful life in 20-30 years, there will be a need for a well-developed and cost effective means of recycling these materials that allows the reuse of the original constituents of the composite.

2.5 Other Composites

There are a number of other smaller industries that albeit do not create a large tonnage in each, are large enough that in total they are also becoming a problem. Most of these are smaller parts and widely distributed enough that only local recycling centers will receive them. A good example is sporting goods – golf club shafts, tennis rackets, skis, football and hockey helmets, paddleboards and paddles, surf boards, canoes and kayaks, and more.

Unfortunately most of these smaller composite goods are such that new “better” models are released on a regular basis, and the old model either gets put in the closet, or worse, sent to the dump. This means that when a golfer replaces their clubs with the “new and improved” carbon fiber shaft clubs, the old ones are thrown out. Unfortunately most of these items are too small and are too widely dispersed for there to be a national or even regional effort to recycle them. This means that most are merely buried in landfills rather than being recycled.

3 STATE OF THE ART IN COMPOSITES RECYCLING AND REUSE

The current state of the art in composite recycling is that by and large these materials are not being recycled to any great extent. There have been some efforts in reuse of these materials, specifically used wind turbine blades, but these are mostly demonstration projects and there are not enough applications of the used blades to make this a long term solution.

There is, however, some light at the end of this long tunnel. The European Union has been leading the way in this regard, primarily because of the environmental sensitivity of the European public and the support of National leadership in the EU. Quite unlike in the US, there has been a concerted effort ongoing for some time to achieve sustainability in all European activities, including and most importantly the industrial sector. This culminated in the European Green Deal, which was adopted in the EU in 2019, and has formed the backbone of the European environmental regulatory environment. Efforts in the composites industry had been ongoing for some time, based on the “Waste Framework Directive” which was adopted in 1991 and has spawned a number of companies in the composites recycling business.

Another European directive, called the “Extended Producer Responsibility” where producers of composite structures are responsible for their end of life management. This rule has been applied fairly recently in both the recreational marine and wind turbine or renewable energy sectors.

Along with these regulations, also quite unlike in the US, the EU is providing support in terms of direct funding and support for collaborations between companies and universities at no cost to companies that develop composite recycling technologies that have the potential to scale up to a size appropriate for the sector that the company wants to work in.

3.1 Fiberglass – Mostly Wind Turbine Blades and Boat Hulls

One Italian company – Korec in Bientina, Italy (Tuscany) – is working with Owens Corning here in the US to scale up their fiberglass recycling technology. Owens Corning has taken it upon themselves to reduce their carbon footprint by 50% and using 100% renewable energy for processing by 2030. This is a fairly ambitious goal.

Korec's patented process (US Patent Number 10,308,784) is a thermo-chemical process where they use CO_2 in the absence of Oxygen to dissolve the resin at high temperature. When they extract the hot gas from the chamber, all of the resin has been depolymerized and is contained in the gas, which is then condensed out of the gas and reprocessed.

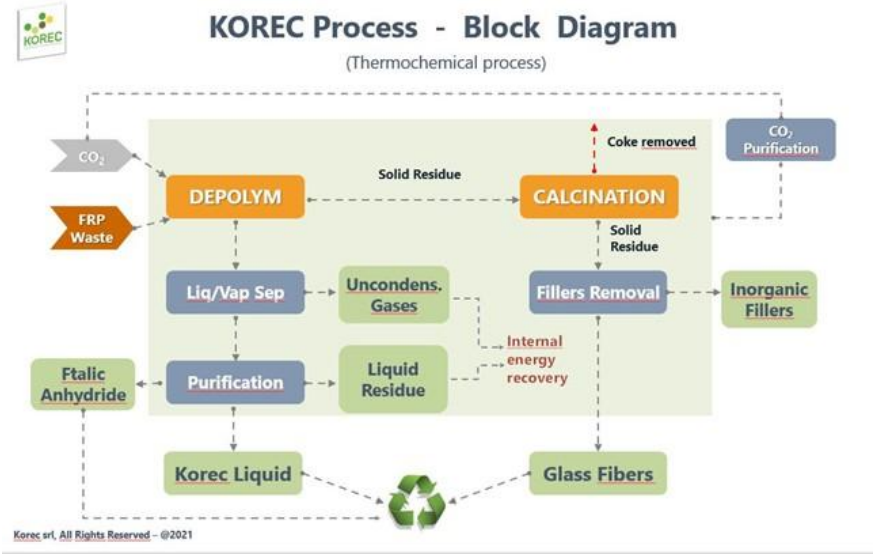

Figure 3. Korec Process (with permission from Korec)

Another company in the French speaking part of Switzerland – Composite Recycling – has also developed a process along the same lines as Korec primarily for end of life wind turbine blades. They use another proprietary pyrolysis-like process that they call thermolysis, in the absence of oxygen to depolymerize the resin from waste glass fiber composite materials and recover most of the resin in the form of what they call "thermolysis oil". This company is working with an engineering firm in Sweden, Fiberloop, that developed this process and is building their industrial scale machines. The process is able to separate the resin from the fibers, and recovers not only polyester resins, but also epoxies, albeit at a slightly higher temperature but still not as high as traditional pyrolysis. Fiberloop is in the business of designing and assembling machines for clients with specific needs like Composite Recycling. Their business relationship has Fiberloop building each machine to Composite Recycling's specifications based on each client's needs, and Composite Recycling operates the machine at the site where the recyclable material exists. In addition, Composite Recycling has done all of the testing required to get both their reclaimed glass fiber and their thermolysis oil certified as ready to use for the wind turbine industry as well, and they have already established supply chains for selling their product into the marketplace.

The one unique thing that Composite Recycling has done is to bring their fiberglass recycling machine to the site of the recyclable composite materials – as in at a wind turbine blade dump – rather than having used wind turbine blades shipped to a central recycling facility. They have been able to fit their entire glass fiber composite recycling process and equipment along with all of the chemistry required in a 40' ISO container. And they have recently joined a consortium led by Beneteau to enable the recycling of end of life boat hulls. This consortium includes Beneteau, Composite Recycling, specialty resin company Arkema, waste management company Veolia, Owens Corning, and textile specialists Chomarat. All of these companies are leaders in their sector of their businesses, especially in Europe.

Figure 4. Rendering of Composite Recycling Containerized Recycling Machine (Courtesy Composite Recycling)

3.2 Carbon Fiber – Mostly End of Life Fighter Aircraft

Quite a bit less work has been done in recycling of carbon fiber composites primarily because they are a much lower tonnage problem than fiberglass. Carbon fiber composites have not been in general use until fairly recently except for the high performance aerospace structures required for both spacecraft and modern fighter aircraft. Of the space applications of carbon fiber composites, there has been zero effort to reclaim or recycle them for obvious reasons, but for aging fighter aircraft this is not the case. There are now several early generation fighter aircraft, both in the US and the EU that have been retired because their airframes have been used up. There has therefore not been the need nor the demand to recycle carbon fiber composites to any large extent.

That is, however changing and changing rather rapidly. To wit, there are a few efforts that have been successful, and a few companies have sprung up to begin commercialization of their recycled carbon fiber products. The initial recycling efforts for these materials used to involve a pyrolysis step where the resin is effectively burned off of the carbon fiber, leaving the fiber relatively intact while exhausting the combustion products from the resin pyrolysis into the atmosphere.

In the last several years, a few newer and less carbon intensive technologies have arisen that are in the process of being scaled up to the level where they could be called industrial scale. One company in South Carolina, Carbon Conversions, which got its start from an SBIR grant developed a process in collaboration with MIT that can reclaim nearly virgin carbon fiber from nearly any source of end of life carbon fiber composites. They fairly recently got funding from Boeing and demonstrated the reclamation of carbon fiber from an F-18 and used that fiber to create a Corvette body.

Another company in the Denver area, Vartega, has taken on the process of recycling uncured carbon fiber prepreg scrap into usable carbon fiber. In a similar development, a much larger company based in Paris, Fairmat, has also developed a process for recycling scrap carbon fiber prepreg at a much larger scale. They recently announced an agreement with Hexcel in Salt Lake City to recycle all of the scrap uncured carbon fiber prepreg from Hexcel's manufacturing facility. This is an extension of an ongoing relationship between Hexcel and Fairmat that started in Europe, but this is a fairly large undertaking because the Salt Lake Hexcel facility is the largest of all of the Hexcel manufacturing facilities. In another similar development, Toray's Pacific Northwest facility in Tacoma, Washington which services mostly Boeing, has signed an MOU with Elevated Materials in Gardena, CA to do much the same thing as Vartega and Fairmat.

While none of these is an actual recycling method for end of life carbon fiber composites that retains both the fiber and the resin, there have been demonstrations of this technology at least in the EU. The Fiberloop / Composite Recycling partnership has demonstrated that their thermolysis process works well on typical aerospace epoxy resins in high performance carbon fiber composites. Apparently what they do is to process the epoxy-based composites at a somewhat higher temperature than the typical polyester resins in most fiberglass composites.

4 INHERENTLY RECYCLABLE COMPOSITE RESINS

There are several approaches to making inherently recyclable composites, some based just on the resins, some focusing only on the fiber, and some based on both the resin and the fiber. The approach to making recyclable resins falls into two categories, those using petroleum feedstocks and those using plant-based oils or plant-based compounds as precursors. So, let's start there and then move on to sustainable composites in general

4.1 Petroleum-Based Recyclable Resins

In the petroleum based world, typically what this means is that the chemistry of the epoxy precursors is modified in such a way that the cross-linking that makes the epoxy a solid can be unlinked through the use of special catalysts and/or specific organic acids. Quite a bit of this chemistry was developed some time ago, but it has not found broad use in the past because there was not a perceived need to make these materials inherently recyclable. An additional hurdle has also been that the inherently recyclable epoxies typically do not possess the same high level of mechanical properties (strength, stiffness) as traditional epoxies. There have been some recent developments in this area but none have made it out of the laboratory.

4.2 Plant-Based Recyclable Resins

Plant-based recyclable resins are something of a mixed bag. While there are a few partially bio-based resins and some mixes of these that are inherently recyclable, there are only a handful of fully plant-based and inherently recyclable resin systems.

One good example of these is a fairly recent development by NREL in Golder, Colorado. Researchers at NREL created an entirely plant based resin system they call PECAN [6] (PolyEster Covalent Adaptable Networks) that is essentially a high performance epoxidized polyester-type resin that has roughly equivalent mechanical and processing properties as typical aerospace epoxies. NREL demonstrated the efficacy of this resin system by building and testing a 9 meter long wind turbine blade. The effort at NREL was in the Wind Energy Technology Center there and was focused on sustainability in the wind energy sector, which is why the first full demonstration of this new resin system was to make a commercially viable wind turbine blade.

Another good example is from a Taiwanese company named Swancor. They have developed a paired system they call EzCiclo and CleaVER. EzCiclo is a fully recyclable thermosetting epoxy resin system that has properties equivalent to aerospace grade epoxies. This system was developed for the growing wind energy industry in Asia to provide a sustainable alternative to the standard petroleum-based and non-recyclable epoxies used for wind turbine blades. While Swancor does not disclose the chemistry of their EzCiclo resin and CleaVER chemical treatment, they have demonstrated this technology successfully for several industries.

5 PLANT-BASED SUSTAINABLE COMPOSITES

In order for the industry to become truly sustainable, and to become more than just carbon neutral but become a carbon sink, the industry understands that at some point the precursors for making fibers and resins must come from plants, and the process energy to make the fibers and resins must come from renewable sources. Fortunately there is considerable ongoing work in this area with some actual commercialization beginning to happen.

5.1 Natural Fibers

The most common natural fiber that has been adopted by the composites industry is flax fiber. This is the fiber of the linen textile industry, and the two areas that produce the most of it are France and North America, with France being the largest of the two. There are established supply chains for flax fiber and flax fiber textiles, and these fibers have been adopted by a number of high volume industries. In the automotive industry, flax fiber is used for interior door panels not only because it is inexpensive and easy to work with, but also because flax fiber composites have both heat and sound insulating properties that neither glass nor carbon fibers possess. Flax fiber also has a better strength to weight ratio than other industrial fibers, so the auto industry has used it also to save weight primarily in

automobile bodies. In Europe, BMW, VW, and Audi have all adopted flax fiber composites for secondary structure in all of their products, with BMW and Porsche actually making entire car bodies out of flax fiber composites. There is even a French company, Bcomp, that has expanded into this space and has made body work for cars on the racing circuit.

There are also some natural fiber products in the developing world that are beginning to see incorporation into composites. Hemp fiber has been in use in the automotive sector in the EU for a number of years because of its easy availability. It is used a bit less than flax primarily because flax fiber textiles have been made for hundreds of years whereas hemp fiber has only been used fairly recently to any great extent.

Bamboo fiber has also been made into composites, albeit at much lower quantity than either flax or hemp, primarily because of the logistics burden of getting the bamboo fiber from where it is grown – in the underdeveloped part of the world – to where it will be used – in the more developed world of Europe and North America.

5.2 Plant-Based Carbon Fiber Precursors

Typical carbon fiber is made using acrylonitrile as a backbone to making a polyacrylonitrile (PAN) fiber. The current source of acrylonitrile is based on the chemistry of propylene from petroleum feedstocks. Several attempts have been made in the past to use plant oils to generate propylene, but all of them to date have been more expensive than what can be produced from crude oil.

A newer process recently developed by Southern Research [7] uses a sugar alcohol from plant sources, glycerol, with a different chemistry to produce acrylonitrile. In this process they initially remove a water molecule from the glycerol to produce hydroxyacetone, then they add ammonia to this through a process called ammoxidation and remove an oxygen molecule to produce acrylonitrile. Figure 5 below demonstrates this chemistry.

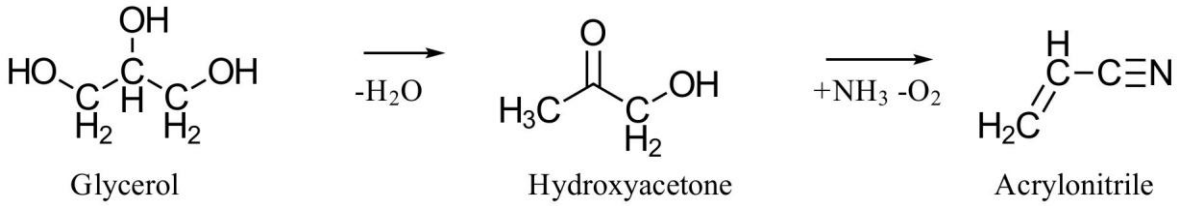

Figure 5: Acrylonitrile from Glycerol (drawn by author)

Using funding from the Department of Energy, Southern Research perfected this process and demonstrated that they could use agricultural or forest products waste to extract the glycerol and make their plant-based acrylonitrile at 20% less cost than petroleum based acrylonitrile. This process has been scaled up by Trillium Renewable Chemicals which is building a pilot plant to make fiber from this plant-based acrylonitrile in partnership with Syensqo (formerly Solvay) at the INEOS acrylonitrile plant in Port Lavaca, Texas. This plant is home to the largest acrylonitrile producer in the U.S., and with their partnership with Syensqo will make this the largest entirely plant-based carbon fiber production facility in the world once it is completely scaled up.

Another company in the Netherlands called AnQore has gone the route of using propylene and ammonia to make their acrylonitrile. The propylene that they source comes from both agricultural waste and recycled plastics, and they state that they can make their biomass and recycled plastics based acrylonitrile for an equivalent cost to petroleum based acrylonitrile since the raw material is effectively free to them. They did make a good decision about the siting of their first plant to do this because the site that they chose has both a plastics recycling facility and a carbon fiber producer (Saudi Basic Industries Corporation or SABIC) so AnQore has a ready supply of recycled plastics to input into their process and a ready customer in SABIC for their product, without the logistics burden of moving materials long distances.

5.3 Plant-Based Resins

There have been many attempts at making an entirely plant-based bisphenol-A to use as the backbone of an epoxy resin system. None of these has actually come to fruition as yet, and since bisphenol-A is

not a naturally occurring compound, synthesis of it from plant-based precursors is typically more expensive than sourcing it from the petrochemical industry.

Bisphenol-F which is a naturally occurring compound found in prepared mustard and the roots or rhizomes of plants used in traditional Chinese medicine, has found use in the marine industry and consumer goods for a number of years. These are the "BPA free" plastics and resins that are suitable for use for food preparation as well as other consumer goods. Epoxies made using bisphenol-F are roughly equivalent in stiffness to their BPA cousins, with slightly lower strength and also slightly lower viscosity, making them good candidates for things like VARTM. This is why they have found use in the pleasure marine industry since quite a few production boat hulls are made using this vacuum assisted resin infusion method.

In the Netherlands, Frog Biosystems B.V. has produced an epoxy resin from rapeseed oils that they blend with traditional petroleum based epoxy to make what they call Fairpoxy. This resin has a 29% plant-based epoxy content and is equivalent to modern aerospace epoxies.

In the U.S., Entropy Resins which was recently acquired by the Gudgeon Brothers of West System fame has also developed a plant-based epoxy that they also mix with petroleum based epoxies to various extents to make a variety of different resin systems.

Finally, one fairly recently concluded project in the EU – the ECOxy Project – was a consortium of 13 partners focused on the R&D necessary to convert all sorts of plant precursors into useful epoxy resins, along with several other composites sustainability goals. While that Project concluded in late 2020, one of their partners – Specific Polymers SP – wrote an article on the Project site that has a wonderful graphic about making resin precursors from wood dust, algae, and vegetable oils. This graphic is actually from Specific Polymers because they are commercializing the results of the ECOxy project.

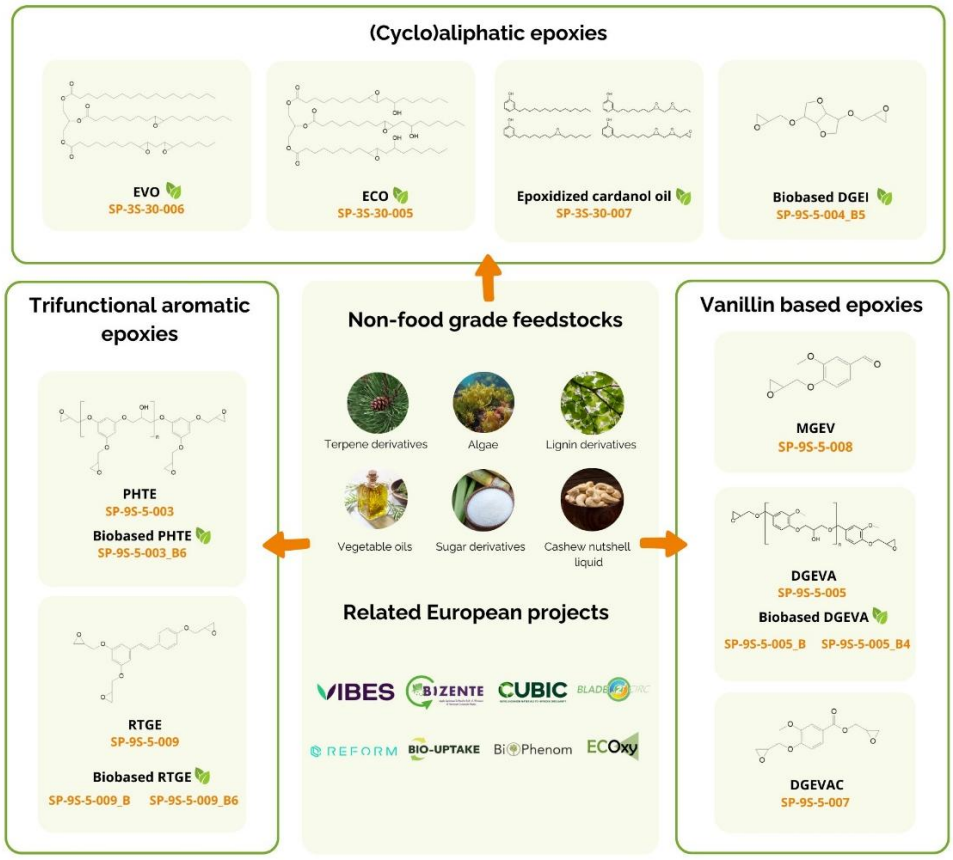

Figure 6: Specific Polymers Bisphenol-Free Plant Based Epoxy (courtesy Specific Polymers)

Specific Polymers now has a complete line of these bio-based epoxy resins that they have for sale on the open market. They are marketing them as bisphenol-A free epoxies based on forest products waste (wood dust), algae, and agricultural waste in the form of plant oils. Two products that they have on the

market are DGEVA – a vanillin-based epoxy resin, and PHTE (Phloroglucinol Triglycydil Ether).

In addition to the creation of the bisphenol backbone for epoxies, another molecule also needs to be added in order to put epoxide groups on the bisphenol backbone to make the epoxy resin itself. The molecule that is the most prevalent in this chemistry is epichlorohydrin. Epichlorohydrin is traditionally made using propene from petroleum based sources, but it can also be readily made from glycerol, and is actually somewhat easier to make from glycerol than it is to make from propene. And, since glycerol is a byproduct of the production of biodiesel, it is also readily available.

There are several companies in the business of making epichlorohydrin from bio-based glycerol. Sicomin sells their products under the trade name of GreenPoxy, Advanced Chemical and Advanced Biochemical in Thailand also sells a plant-based epichlorohydrin as does Syensqo, a Louisiana company named Louisiana Chemical Equipment Company, a UK based company called TechnipFMC with main officed in Houston, as well as a plant in India that also makes plant-based epichlorohydrin. All of these companies sell their products mainly into the traditional plastics manufacturing business and have very nearly taken over the epichlorohydrin manufacturing business from the petrochemical industry. This is one of the real success stories in bio-based plastics precursors.

The bottom line here is that the future of plant or bio-based resins is rather bright, and companies on nearly every continent in the developed world are moving rapidly away from petroleum feedstocks. So, while there is still quite a bit of work to do here, at least this part of the business is trending in the right direction.

6 ROADMAP TO A SUSTAINABLE FUTURE FOR COMPOSITES

While what is presented in this paper paints a fairly optimistic picture of the state of the art in recyclability, lowering the carbon footprint of composites and also the transition to an entirely sustainable plant-based future for composites, there is still considerable work to be done. There are developments ongoing on several fronts, from the development of technologies that can separate traditional resins from their fibers (thermolysis and solvolysis), to inherently recyclable resin systems that can be easily taken apart at the end of their useful life, to plant-based precursors for both fibers and resins.

What remains to be done is for the industry to transform itself from its current non-sustainable large carbon footprint to a more sustainable business model that can actually become a carbon sink, all while staying in business and being in business making these materials into the far future. There is a road to get to this end result, and it will require considerable capital investment and work in scaling up all of these technologies while still providing the current products that are needed today. That is the challenge, and there is a way to get there.

Here are some recommendations to get everyone started:

- **RECOMMENDATION 1 – Create Sustainable Strategies –** Find or create sustainable strategies for your specific products and base the strategies on things that you can accomplish both in the short term and the long term. In other words, make an actionable plan for the future with measurable milestones and stretch goals to get to a completely sustainable model for the business that you are in.
- **RECOMMENDATION 2 – Partner with Startups –** Larger companies have a tendency to have bureaucratic inertia that does not permit them to make drastic changes to their business model rapidly or easily. They might also not have the right technical resources and creative personnel required to make these changes. Startups that have good ideas and that are run by technical expert entrepreneurs make good partnerships with larger companies and can have a very positive effect on the outcome of the implementation of these technologies.
- **RECOMMENDATION 3 – Be Willing to Accept Risk –** This is rather difficult for large more traditional companies, but to make the transformation and potentially to begin to lead rather than follow, it is necessary to accept the risk that you won't get it right the first time. This is difficult for traditional companies like those in heavily regulated industries like the petrochemical industry, so if necessary, form a "skunk works" of your own and establish separate management of that so that the larger company does not have to take all of the risk.
- **RECOMMENDATION 4 – Work With Others and With National Societies and Not-For-**

Profits – There is a wealth of talent available to materials and manufacturing businesses if they join and participate in societies like SAMPE, ASME, ACS, and on boards of composites manufacturing associations like ACMA and EUCIA.

- **RECOMMENDATION 5 – Seek Government funding for Transformative Technologies** – There are multiple opportunities with the Federal Government in a number of agencies and Departments (Agriculture, Commerce, Defense, etc.) to get funding for transformative technologies. And, while it used to be that the Government wanted to own the intellectual property resulting from Government-Industry collaborations, such is not necessarily the case anymore. Starting with the Baye-Dole act in 1980 (43), companies and universities who develop technology in partnership with the federal government and with federal funding are no longer required to relinquish the patent rights to that technology to the government.
- **FINAL RECOMMENDATION / STRATEGIC IMPERATIVE – Don't go Out of Business While Changing the Business** – this is probably the most important concept and/or mantra to take into this arena. No matter what, it is imperative that companies making this transition not lose focus on their current business while in the process of transforming their business.

7 CONCLUSIONS

This paper has hopefully provided not only the state of the art in composite materials sustainability, but also the status of some ongoing efforts that show promise in reducing or eliminating the carbon footprint of the industry. In addition, a roadmap with realistic recommendations has been presented here to enable the industry to follow a path to sustainability that will allow them to stay in business making a profit while fundamentally transforming their business.

It is clear that this transformation will take time, money, and the concerted efforts of everyone in the business in order to be successful. What is clear is that every sector of this industry and every aspect of how we make, use, and deal with end of life composites needs to be part of this overall roadmap. True circularity is quite literally philosophical in that what comes from the earth must at some point be sent back to the earth in such a way that the earth can make more of the stuff that needs to come from the earth again. And while this may seem naïve at first or even impossible to some, it is actually the definition of a circular economy.

Of course, this road is still long and full of potential potholes and dead ends. In other words, it is going to take time, a lot of very hard work, an ability to accept and embrace failures along the way, and an enormous investment on the part of the industry to make this come to pass.

It is also going to take enlightened and capable leadership in all of the companies that are in this industry. It is the leaders of this industry that are going to be the drivers of change in each of their companies that will lead us to success and a sustainable, circular economy as the future of this industry. These leaders must be politically savvy, willing to take on calculated risk, and motivated by an understanding that their long term success depends on the decisions they make now and the path that they lead their companies down. Those are the leaders and the companies that will survive and prosper in a newly transformed and circular composites industry.

ABSTRACT

The production of polyacrylonitrile (PAN)-based carbon fibre (CF) is highly energy-intensive, contributing significantly to its embodied carbon. With global demand for CF projected to more than double by 2030, reducing the global warming potential (GWP) of CF manufacturing is critical to supporting the decarbonisation of transport, energy, and industrial sectors. This study presents a life cycle assessment (LCA) to evaluate the cradle-to-gate GWP of PAN-based CF production, with a UK-specific case study, and explores a range of decarbonisation strategies including energy efficiency, electrification, and green gas substitution.

The LCA identifies major GWP hotspots across precursor and fibre production stages, particularly during high-temperature oxidation and carbonisation processes. Electrification of these stages, powered by low-carbon electricity, offers the most immediate and impactful emissions reductions. However, abatement systems for hazardous exhausts remain a key technical challenge. Complementary strategies include the adoption of bio-based acrylonitrile (Bio-ACN), energy recovery technologies, and the substitution of natural gas with BioMethane or eMethane.

Scenario modelling using projected UK grid decarbonisation pathways reveals that electrification delivers the fastest route to net zero CF production. Nevertheless, the effectiveness of decarbonisation varies with regional grid composition, underlining the importance of site-specific strategies. A multi-horizon roadmap is proposed, outlining near-, mid-, and long-term actions to support CF producers in aligning technology development with emissions reduction goals. This study provides a foundation for industry and policy stakeholders to prioritise interventions and accelerate the transition toward low-carbon CF manufacturing.

1 INTRODUCTION

The current global demand for carbon fibre (CF) is estimated to be 115 kt per year as of 2023, and projected to grow to 280 kt per year by 2030 [1]. While lightweighting using carbon fibre reinforced polymers (CFRP) has played a critical role in transportation decarbonisation, CFRP is now required for decarbonised energy generation and storage solutions. Despite the high-performance benefits of CF, its production is highly energy-intensive, resulting in significant embodied carbon. Sphera Managed LCA Content reports that the globally aggregated global warming potential (GWP) of polyacrylonitrile (PAN) based CF can reach up to 35 kg CO_2e. per kg of CF produced [2]. Considering global CF demand in 2023 (115 kt, [1]) and current GWP of PAN-based CF, the global demand for CF is projected to generate up to 4 Mt CO_2e annually. To enable the further decarbonisation of transportation and renewable energy sectors, it is imperative to reduce the GWP associated with CF production.

The CF production process consists of several energy-intensive stages, including PAN fibre precursor production, stabilisation/oxidation, carbonisation, and surface treatment, all of which contribute to the overall embodied energy. Michaud et al. reviewed the literature and reported a wide range of energy

consumption values, from 171 to 1169 MJ per kg of CF produced. Dér et al. [3] compiled energy consumption data for each stage of production from various sources, noting that energy requirements for producing PAN-based precursors range from 245 to 394 MJ per kg of PAN [4][5], while the energy demands for manufacturing CF itself range from 219 to 704 MJ per kg of CF [4][5][6][7]. Carbonisation is the most energy-demanding phase [8], where the stabilised fibres are heated in an inert atmosphere at extremely high temperatures, typically between 1000 °C and 2000 °C.

Lifecycle assessment (LCA) is a widely used method to evaluate the environmental impacts of a product throughout part or all of its life cycle, from raw material extraction through to disposal or recycling. In the case of CF, LCA is particularly important as it enables a thorough evaluation of the material's high energy consumption during production, as well as its potential environmental advantages, such as reduced weight in transportation applications. Multiple studies have employed LCA to assess the GWP of CF production [4][9][10], with reported values ranging from 12.2 to 55.8 kg CO2e per kg of CF [11]. Although there is significant variability in the literature, the GWP of CF remains substantially higher than that of other commonly used structural materials [12]. This elevated GWP is primarily driven by the significant energy demand during production, which is met by fossil fuels, through the regional electricity grid and / or the direct combustion of natural gas during high temperature manufacturing stages. The GWP of CF production is therefore dominated by three sources: 1) GHG emissions associated with grid electricity generation used to power the high temperature ovens, 2) direct GHG emissions associated with NG combustion in the high temperature ovens and abatement systems, and 3) the GHG emissions associated with PAN fibre precursor production [4][3][8][13][14][15].

In addition to developing lower impact precursor materials, strategies to reduce the embodied carbon of CF products should therefore reduce the energy demand of CF production and/or use decarbonised energy sources. The former will likely require adaption of legacy or development of a new generation of CF production lines which are able to operate at higher energy efficiency. On the other hand, the latter may be achievable passively through the transition to renewable energy sources.

Several authors have investigated interventions to mitigate the impact from energy used during CF production. Prenzel et al. found that the energy consumption is responsible for 59% of the climate change associated with CF manufacturing, which can be reduced by 53% by transitioning to renewable electricity [16]. Stróżyk et al. demonstrated a 67% reduction in energy demand during CF production through the utilisation of microwave heating, when compared to conventional heating technologies [17]. Reducing processing time for CF production, such as rapid oxidation, has demonstrated a 70% reduction in energy required for fibre oxidation [18].

Recent research into CF production has explored alternatives to the traditional PAN precursor, focusing on non-PAN and bio-based materials to reduce the high energy consumption and GWP associated with CF manufacturing. PAN can be made from bio-based sources, creating a potential drop-in replacement for the CF manufacturing process. Bio-derived acrylonitrile (Bio-ACN) has been studied for several years [19][20][21][22], and can be produced from biomass waste using various methodologies described in [23]. Bio-ACN production using wood-based biomass has been licensed by Trillium Renewable Chemicals who are working with Solvay to assess Bio-ACN as a drop-in replacement for petroleum-based ACN in PAN fibre production [24][25].

There is currently limited data available on the GWP of Bio-ACN production, and the authors were unable to find specific GWP data for CF products manufactured using Bio-ACN as a precursor. Goyal reported the GWP of Bio-ACN produced from sugars through a three-stage process involving hydrocracking, dehydration, and ammoxidation [20]. The GWP of Bio-ACN was found to be 0.29 kg CO_2e per kg of Bio-ACN, representing a substantial reduction compared to ACN derived from crude oil, which has a reported GWP of 6.05 kg CO_2e per kg of ACN. Goyal also used scanning electron microscopy to compare the morphology of CFs produced using Bio-ACN and standard crude oil-derived ACN, observing no significant differences in fibre shape or structure [20]. However, mechanical properties were not tested, leaving it uncertain whether the use of Bio-ACN affects the mechanical performance of the resulting CFs.

While many studies have used LCA to assess the impact of CF production, no studies have quantified and compared the impact of prominent decarbonisation strategies. This study aims to examine how the cradle-to-gate GWP of PAN-based CF production may be reduced through the adoption of green energy solutions. Using LCA, it seeks to identify GWP hotspots in a UK case study to provide insights that

could inform global decarbonisation strategies for CF production. The LCA also models upstream production of raw materials, ammonia, ACN, and PAN fibres, to account for future energy scenarios on CF raw materials impact. The impact of using BioMethane, and synthetic methane (eMethane) in place of NG were also assessed. Additionally, the UK's Net Zero roadmap was used to assess how the transition to net zero grid power and electrification will affect GWP of CF production. Multivariable analysis was used to rank solutions for CF decarbonisation up to the year 2050 and identify optimal timelines for deploying decarbonisation solutions.

2 METHODOLOGY

This work has been conducted with reference to the methods provided in the international standards series ISO 14040 related to the preparation of LCA [26]. LCA is a standardised approach to evaluating the environmental impacts of a product over its life cycle. For CF production, the LCA methodology involves four key stages: goal and scope definition, life cycle inventory (LCI), impact assessment, and interpretation. The goal and scope stage outlines the purpose of the study and sets the system boundaries. This is followed by the impact assessment, which quantifies environmental effects such as GWP. Finally, in the interpretation phase, the results are analysed to identify opportunities for reducing environmental impacts, making LCA essential for improving the sustainability of CF production.

2.1 Goal and scope

The primary aim of the LCA is to evaluate the cradle-to-gate GWP of PAN based CF production, and to assess the potential of green energy solutions to reduce the GWP of CF production. The UK was used as a case study; however, it is the ambition to provide insight that can inform CF decarbonisation strategies globally. The LCA aims to evaluate the CF production phases and upstream processes to produce the feedstock materials for CF production. It is intended to find GWP hotspots and direct future sustainable development to mitigate these.

The following developments have been included in the analysis:

- Future electricity grid mix used in the production of CF and raw materials ACN and PAN fibre.
- Replacing NG with BioMethane for ACN, PAN, and CF production.
- Replacing NG with eMethane for ACN, PAN, and CF production.
- Electrification of processes utilising NG in ACN, PAN, and CF production.

2.2 Functional unit

The main function of structural CF is to provide strength and stiffness in composite materials. CF are produced at various grades; therefore, do not all provide the same reinforcement potential. The scope of this study is limited to assessing a single CF grade in isolation to maintain functionality across the scenarios. The Functional Unit for this LCA study is defined as: the production of 1 kg of CF. The reference flow for the study is 1 kg of CF.

2.3 Processes

Figure 1 depicts a simplified process flow for the current production of CF products, including the upstream production of petrochemical precursors. Methyl acrylate and ACN are the key components in the production of PAN fibres, which undergo thermal treatment in high-temperature ovens to yield CF. Subsequently, the CF is subjected to surface treatment and sizing. The various processes are presented in more detail in the authors' previous publication [27].

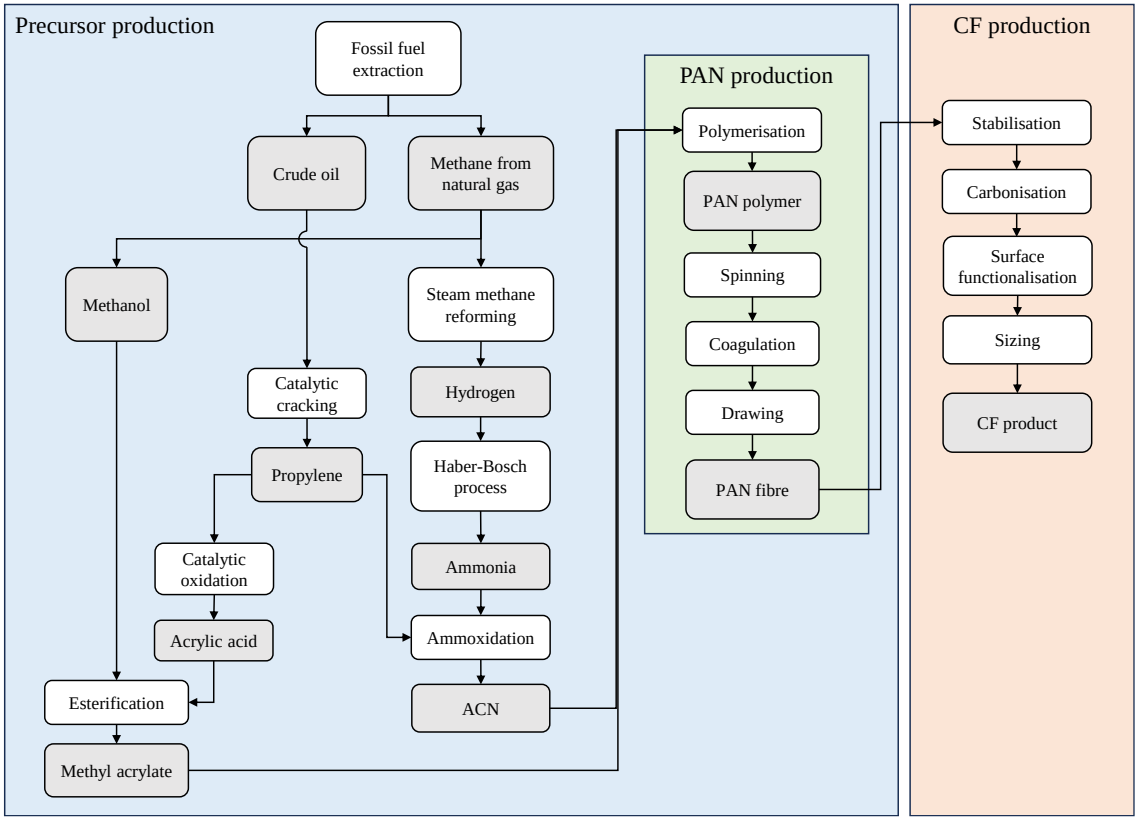

Figure 1 Process flow for CF production, including upstream production of petrochemical precursors

2.4 Lifecycle impact assessment

In accordance with the defined LCA goal and scope, this study as focused on the following Environmental Impact Indicator: Global Warming Potential (GWP 100 years) [kg CO_2e.].

2.5 System boundary, Lifecycle inventory, Allocation, Cut-off criteria

Refer to the authors' previous LCA publication for details on the system boundary, life cycle inventory, allocation methods, and cut-off criteria [27].

3 RESULTS AND DISCUSSION

3.1 Energy consumption breakdown: PAN and carbon fibre production

Figure 2 shows a representative energy consumption breakdown for PAN fibre and CF production, based on the use of electrified oxidation and carbonisation ovens in CF manufacturing. The percentages reflect the share of total energy demand per unit mass of CF produced, including both PAN fibre and CF production stages. Natural gas use in PAN fibre production—mainly for solvent recovery at temperatures below 200 °C—and for CF drying, can be readily electrified.

A key barrier to full electrification lies in the abatement systems used to treat emissions from the oxidation and carbonisation ovens. For example, hydrogen cyanide (HCN), a hazardous byproduct, requires treatment at temperatures up to 1000 °C to ensure complete combustion, leading to high natural gas consumption. This accounts for approximately 28% of the total energy demand across PAN and CF production, representing the critical "hard-to-decarbonise" energy source.

Energy efficiency gains in abatement systems could be achieved by reducing airflow and integrating regenerative thermal oxidizers (RTOs) for oxidation oven exhaust, which are effective for high-airflow, moderate-VOC streams and can recover up to 95% of heat. However, while these approaches lower natural gas use, they do not fully eliminate the resulting GHG emissions and must be combined with

broader decarbonisation strategies. Potentially more challenging to decarbonise is the use of direct-fired thermal oxidizers (DFTOs) for low-flow, high-VOC exhaust streams, such as those from the carbonisation furnace. While DFTOs effectively treat tar-rich and HCN-laden emissions, they lack heat recovery and consume more fuel, contributing significantly to the remaining natural gas demand in CF production.

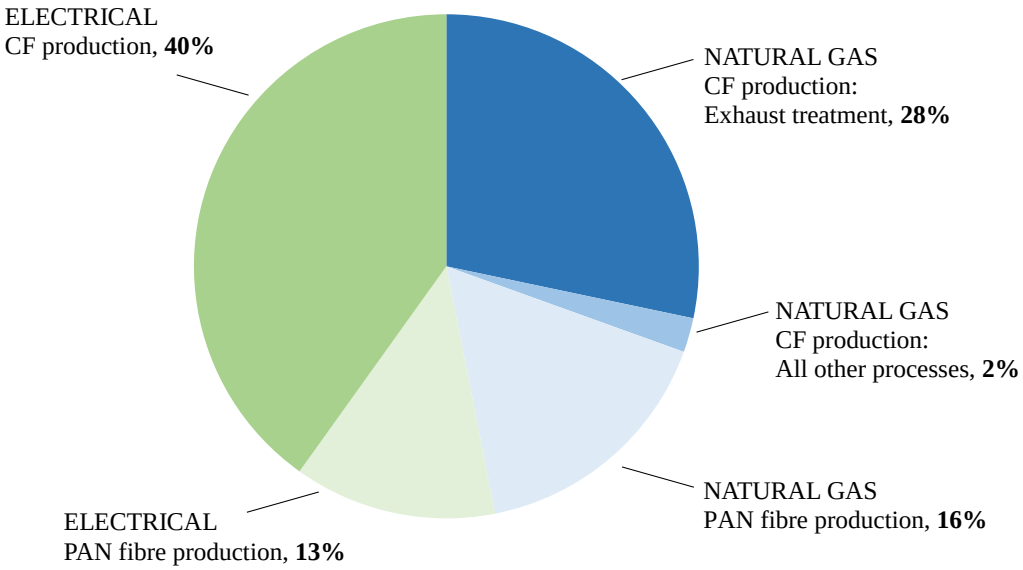

Figure 2 Representative energy consumption breakdown for CF production using electrified oxidation and carbonisation ovens

3.2 Impact of decarbonisation strategies

Figure 3 presents a comparison of various CF decarbonisation pathways, including electrification, BioMethane, and eMethane strategies, building on previous studies [27]. The assessment assumes the UK National Grid ESO projection for decarbonising electricity to net zero by 2050. In each scenario, natural gas is replaced on an energy-equivalent basis by the respective alternative energy source. The use of bio-based acrylonitrile is also assumed, as it is essential for achieving fully net zero CF products (discussed in more detail in author's previous publication [27]).

Figure 3 shows that electrification offers the fastest route to net zero CF production and should be prioritised by manufacturers. While electrification may necessitate substantial modifications to existing equipment currently reliant on natural gas, these upgrades are within the control of CF producers and do not depend on the future scalability of emerging technologies, such as BioMethane and eMethane. Although initial retrofit costs may be significant, electrification offers the potential for long-term cost savings through more efficient use of renewable electricity and can deliver considerable emissions reductions, positioning it as a viable and strategic decarbonisation pathway as technology and renewable energy infrastructure continue to advance.

Figure 3 also evaluates a 50% reduction in electricity demand (dashed green line), reflecting the potential of technologies such as microwave heating and rapid oxidation, which have demonstrated energy savings of up to 67% [17] and 70% [18], respectively. Early adoption of these energy efficiency measures is key, as they offer the most impact while the electricity grid is still carbon intensive. Beyond 2040, as the grid approaches net zero emissions, the primary motivation for further energy reductions will shift from carbon savings to economic benefits.

For processes where electrification faces technical challenges—such as exhaust gas treatment in abatement systems—green gas options may offer viable alternatives. In the near term (5–10 years), BioMethane is favoured over eMethane due to its independence from net zero electricity. However, in the long term, eMethane may offer greater emissions reductions as low-carbon electricity becomes more

accessible. In the near term, particularly within the UK, CF producers can support decarbonisation by purchasing gas backed by Renewable Gas Guarantees of Origin (RGGOs), facilitating market-based allocation of BioMethane, which currently comprises a small share of the national gas supply.

Figure 3 shows that net zero CF production is possible with synthetic methane; however, eMethane is expected to remain significantly more expensive than natural gas due to the energy demands of green hydrogen and CO_2 capture [28]. Given its uncertain viability and timeline, sole reliance on eMethane is high-risk. CF producers should instead prioritise electrification, process efficiency, and heat recovery to enable a more resilient decarbonisation pathway. Hydrogen combustion offers a potential alternative, bypassing the need for CO_2 capture, though the required process modifications are still unclear. While synthetic fuels are compatible with existing systems, their high cost and limited scalability reinforce the need for a balanced strategy—advancing fuel technologies while focusing on near-term, demand-side solutions.

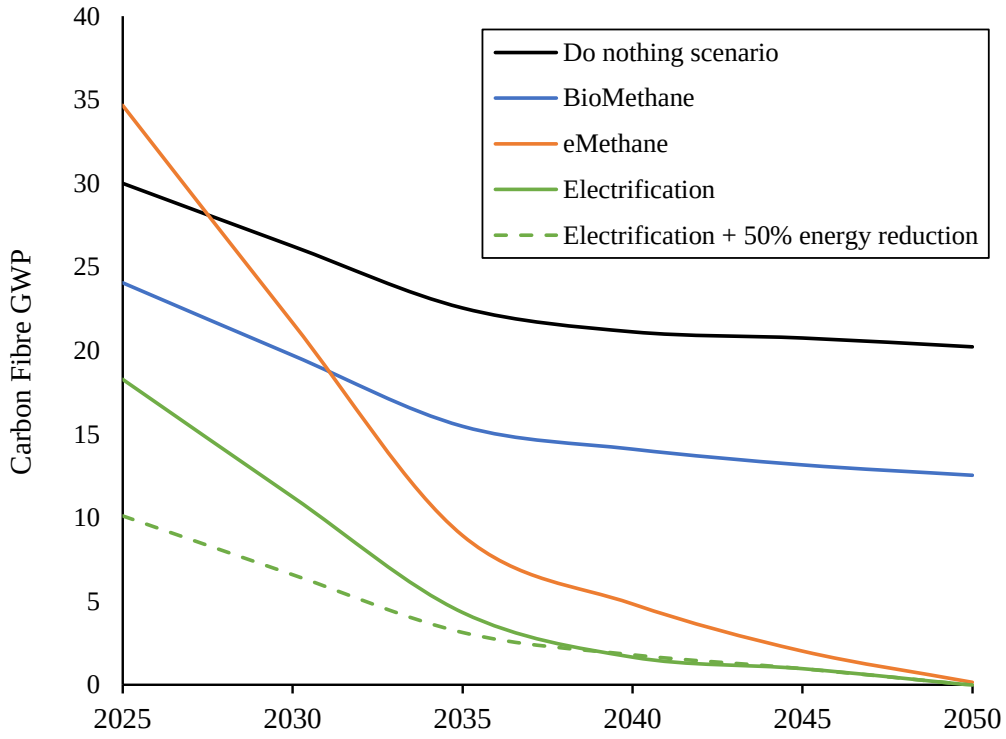

Figure 3 Comparison of electrification and green gas solutions on CF production decarbonisation (assumes electronification of heat from natural gas in PAN and CF production processes on an equal calorie basis)

3.3 Accelerating emissions reduction through electrification

It is important to note that the effectiveness of electrification in reducing CF GWP depends heavily on the regional energy mix. In the UK, where the electricity grid already contains a high share of renewables, electrification leads to lower GWP. In contrast, in regions with fossil fuel-dominant grids, direct natural gas use for heat may result in lower GWP than electricity-based alternatives. This highlights the need for region-specific assessments and decarbonisation roadmaps that reflect local energy infrastructure and grid composition.

Moreover, the future electricity grid compositions remain uncertain, and the projections in Figure 3 are based on average grid mix scenarios. Even when considering the UK as a sole case study, there are large uncertainties in the timeline for grid scale renewable deployment which poses challenges in precisely mapping out the decarbonisation trajectory for CF. Relying passively on network level transition leaves CF producers with little control over the timing of net zero energy generation,

introducing uncertainty into decarbonisation roadmaps. To address this uncertainty and actively expedite the decarbonisation of their electricity consumption, CF producers could incorporate local or onsite renewable electricity generation technologies, such as solar or wind power, to displace some or all the grid electricity used. An example being SGL Carbon Fibers Ltd.'s Moses Lake site, which purchases renewable energy from local hydropower plants [29].

Electrified thermal oxidisers present a potential pathway to decarbonise high-temperature exhaust gas treatment in CF production by eliminating the need for natural gas or synthetic fuels / green gases in current abatement systems. When powered by low-carbon electricity, these systems could mitigate GHG emissions associated with thermal energy used for gas cleaning. Electrified RTOs (eRTO) are commercially available and may be suited for oxidation oven exhaust treatment. Electrically powered flameless thermal oxidisers (eTO) may also replace DFTOs currently used for high-temperature, high-VOC exhaust streams from carbonisation ovens. While promising, these technologies have not yet been deployed in CF production, and their ability to safely and reliably process hazardous emissions such as HCN and tar-laden streams remains unproven. Further research, pilot-scale trials, and performance validation of eRTO and eTOs under CF production conditions are required to determine their technical feasibility and facilitate industry uptake. Key barriers to implementation include likely higher upfront capital costs compared to conventional gas-fired systems, the potential need for complete system redesigns when retrofitting existing infrastructure, and grid constraints that may necessitate upgrades or energy storage solutions to manage peak electricity demand.

3.4 Multi-horizon CF decarbonisation strategy

Figure 4 presents a multi-horizon strategy for CF production decarbonisation, encompassing energy sourcing, technology development, and deployment timelines. This roadmap is designed to provide high-level guidance and actionable steps for CF producers aiming to transition towards net zero carbon fibre products. It integrates the carbon footprints of the various decarbonisation strategies assessed in this study alongside pragmatic considerations of the current and emerging technology landscape, market readiness, and infrastructure requirements. By aligning near-, mid-, and long-term actions with both impact potential and feasibility, the strategy supports informed decision-making and prioritisation of interventions that can accelerate progress toward net zero CF production.

Energy strategy

- Ahead of the UK grid reaching net zero emissions, CF producers should procure electricity backed by Renewable Energy Guarantees of Origin (REGOs) to both support the growth of renewable energy and achieve net zero electricity consumption through market-based allocation. Additionally, producers should explore opportunities for on-site renewable energy generation at existing facilities or consider siting new developments in regions with access to local renewable resources to further accelerate decarbonisation.
- While electrified solutions for hard-to-decarbonise processes—such as exhaust gas treatment—are under development, CF producers should purchase gas backed by Renewable Gas Guarantees of Origin (RGGOs) to support the expansion of green gas production and achieve net zero gas consumption through market-based mechanisms.

Technology deployment

- CF producers should transition to PAN fibre suppliers utilising bio-based acrylonitrile feedstocks. This advanced technology is anticipated to reach commercial availability by the end of the decade and should be implemented independently of other process modifications, allowing for adoption as soon as market access becomes feasible.
- Electrification of currently viable technologies—particularly oxidation and carbonisation ovens—should be prioritised. This includes retrofitting existing infrastructure where feasible and ensuring that all electrifiable processes are implemented in new CF production facilities.
- Established energy recovery technologies should be implemented to improve the energy efficiency of carbon fibre production and reduce overall energy consumption. This could include deploying

high-efficiency RTOs for oxidation ovens and incorporating heat recovery systems for high-temperature DFTOs. Prioritising these measures is critical, as energy-saving strategies offer the greatest benefits in the near term while energy-related impacts remain significant.

*Technology development**

- Lower-power electric heating technologies should be developed to further enhance the benefits of electrifying oxidation and carbonisation ovens. While their near-term emissions reduction potential is high, commercial readiness may limit their contribution to decarbonisation. Nonetheless, development should continue given their potential for long-term cost savings and efficiency gains in future CF infrastructure.
- Electrifying exhaust gas cleaning systems is anticipated to be the most technically challenging aspect of CF production decarbonisation. These systems currently account for approximately 25–30% of the total energy demand across PAN fibre and CF manufacturing. Therefore, their electrification is essential. To achieve this, CF producers must actively support the development and integration of electric gas cleaning technologies, which would enable the sector to reduce emissions without depending on the uncertain future availability of green gases (such as BioMethane and synthetic fuels).

** Note that there are many other proposed technology developments for CF production that could support decarbonisation; their exclusion from this proposed strategy is not indicative of a lack of potential but rather reflects current limitations in data availability, technology readiness, or alignment with the near- and mid-term priorities outlined in this roadmap.*

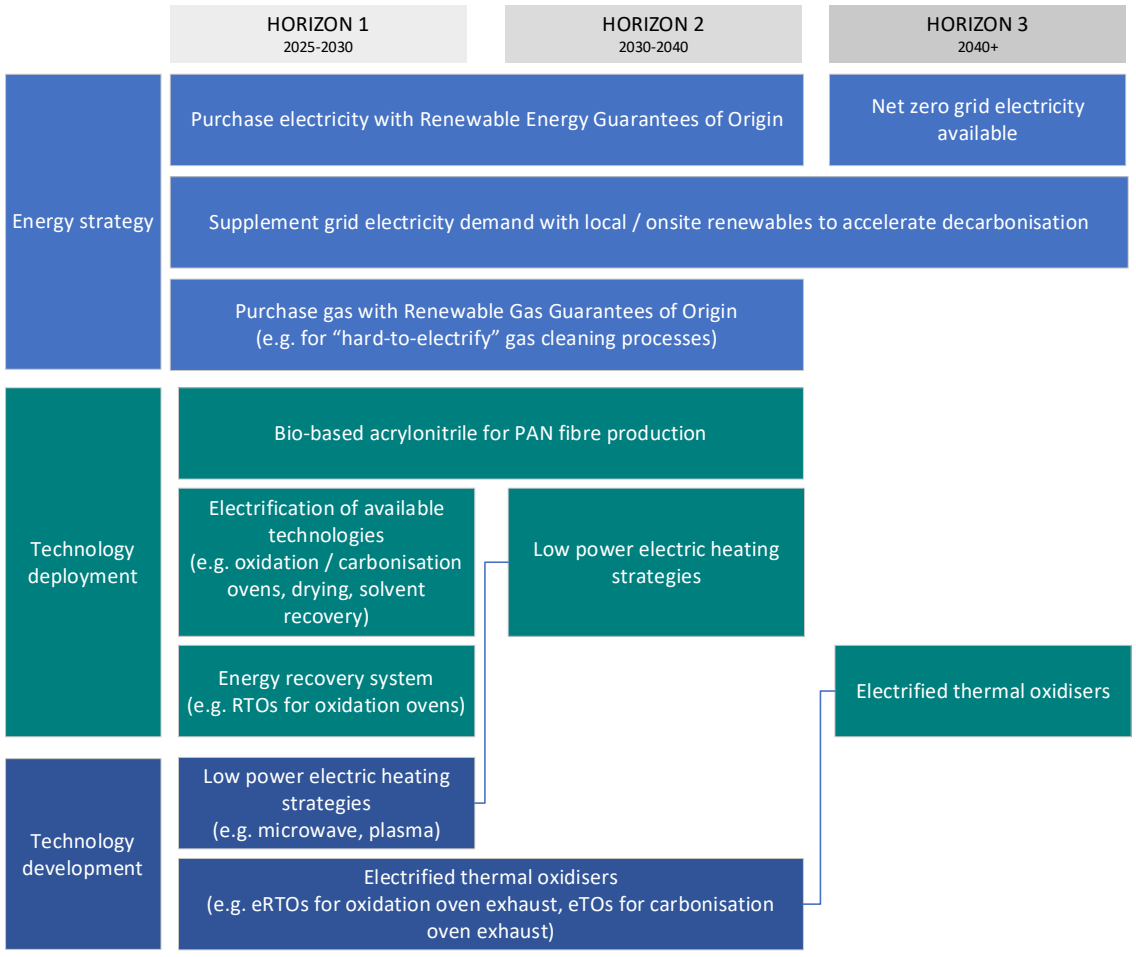

Figure 4 Multi-horizon strategy for CF production decarbonisation

4 CONCLUSIONS

This study provides a life cycle assessment of PAN-based CF production, identifying key GWP hotspots and evaluating decarbonisation strategies. Electrification of CF manufacturing processes, particularly oxidation and carbonisation ovens, offers the most immediate and impactful emissions reductions—especially when powered by low-carbon electricity. However, abatement systems for hazardous exhausts remain a significant barrier, currently accounting for a large share of energy demand and requiring further technological development.

Complementary strategies such as using bio-based acrylonitrile feedstocks, energy recovery systems, and alternative fuels like BioMethane or eMethane may support emissions reduction, particularly where electrification is currently limited. Regional grid composition plays a critical role in the effectiveness of electrification, highlighting the need for site-specific strategies.

A multi-horizon strategy is proposed to guide CF producers through near-, mid-, and long-term decarbonisation actions. This roadmap considers both emissions impact and technological feasibility, offering pragmatic steps toward net zero CF production. While uncertainties remain—particularly around grid decarbonisation timelines and technology readiness—proactive industry action is essential. Early investments in electrification, renewable energy sourcing, and technology innovation will be crucial to reducing reliance on fossil fuels and supporting the transition to low-carbon composite materials.

Keywords: Composite materials, polypropylene, recycled carbon fiber, 3D printing

ABSTRACT

The composites industry is experiencing steady growth worldwide. However, the recycling of composite fiber reinforced polymer (CFRP) materials, which make up a significant proportion of composite materials used in engineering applications, is still a challenge. The process of recycling the high value fiber part of thermoset materials requires ad hoc processes for the recovery (mechanical, thermal or chemical process) and reuse of this valuable resource.
The work presented, based on recycled carbon fiber, evaluates the possibility of transforming the recycled fiber into a new thermoplastic composite material through a technological approach of extrusion and then using the material obtained through injection molding and 3D printing, promoting the adoption of a circular and innovative approach to the recycling of composite materials.
In particular, the recycled carbon fibers (fillers) were ground to obtain short fibers and characterized by particle size and electron microscopy. The filler was compounded with the thermoplastic matrix (polypropylene) by twin-screw extrusion.
The extrusion of the composite material took place in the form of a filament that was collected on reels and pelletized into granules. Characterization of the mechanical properties of the composite material was carried out by means of tensile tests on standard specimens (type 5A) according to ISO 527, obtained by injection molding. Finally, the pellets were used as raw material in an additive fused granules fabrication process and the printed objects were further characterized after 3D printing.
The process of transforming and obtaining materials in terms of mechanical and thermal properties has been optimized, comparing them with those of unfilled virgin materials.
In addition, recycled carbon fibers were valorized by upcycling them as structural fillers for polymer matrix composites, with a view to a sustainable circular economy.

1 INTRODUCTION

In recent years, the growing demand for lightweight, high-performance materials in industries such as aerospace, automotive, and sports has highlighted the critical role of carbon fiber-reinforced polymers

(CFRPs) due to their exceptional strength-to-weight ratio and durability [1]. However, these materials unfortunately face a significant challenge: the environmental and economic cost associated with their end-of-life disposal. Landfilling remains the predominant disposal method to date, exacerbating environmental issues and contradicting modern sustainability goals [2].

One possible and virtuous way to overcome this problem is through the reuse of recycled carbon fibers (rCF), obtained from waste CFRP components, as reinforcement in new composite materials [3-5]. This work shows the feasibility of incorporating pyrolysis-recovered rCFs into a polypropylene (PP) matrix to develop composite materials that combine sustainability and mechanical performance. In addition, the use of polypropylene grafted with maleic anhydride (PP-g-MA) as a compatibilizer is evaluated to improve interactions at the interface between the fibers and the polymer matrix and implement mechanical performance accordingly. The composite materials are processed by both traditional injection molding and fused granules fabrication (FGF) 3D printing, allowing comparison of different manufacturing techniques.

2. MATERIALS AND METHODS

The starting polymer matrix is PP (Moplen HP456J), chosen for its mechanical versatility, chemical resistance and cost-effectiveness. However, its nonpolar and low surface energy characteristics may hinder compatibility with rCFs, necessitating the use of PP-g-MA to improve wettability at the interface. Carbon fibers recycled by pyrolysis (Carbiso), retain remarkable mechanical properties (tensile strength up to 5 GPa, Young's modulus around 240 GPa). They were milled to achieve optimal homogeneous dispersion in powder form and their size distribution characterized by laser granulometry.

Six composite formulations were prepared: three with increasing content of rCF (10%, 20%, 30%- named PP-rCF10, PP-rCF20, and PP-rCF30, respectively) and two incorporating 10% rCF with 2.5% and 5% maleic anhydride-functionalized polypropylene (called PPPP-gMA2.5-rCF10 and PPPP-gMA5-rCF10, respectively), in addition to pure PP. The compounds were obtained with a twin-screw extruder, producing filaments that were then pelletized for further processing by injection molding, which provides high dimensional stability, and FGF 3D printing, which directly uses the granules to form objects layer by layer. The latter approach certainly offers greater freedom in making objects of complex shape, but it presents challenges related to the inherent anisotropy of the finished object. For both printing technologies dumbbell specimens were obtained and used for the subsequent characterizations. For FGF 3D printing it was essential to understand how the addition of fibers affects the adhesion between layers. For this reason, two configurations were prepared with two raster angles, 0° and 90°, indicating the alignment of the strands, respectively parallel and perpendicular to the tensile direction of the specimen.

3. RESULTS AND DISCUSSION

Various analytical techniques were used to assess the structural and mechanical properties of the materials. Laser granulometry reveals a fairly wide size distribution of rCF (between 1 and 300 µm), with an average volumetric diameter of around 70 µm (Fig. 1(a)), while scanning electron microscopy (SEM) images confirm the typical size and morphology of carbon fibers, highlighting the presence of a certain surface roughness that could favor adhesion and mechanical interlocking (Fig. 1(b) and (c)).

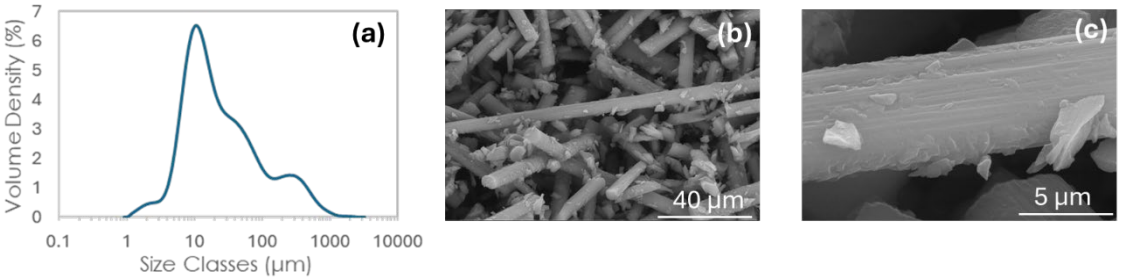

Figure 1: Size distribution curve (a) and SEM images at different magnification (b) and (c) of rCF.

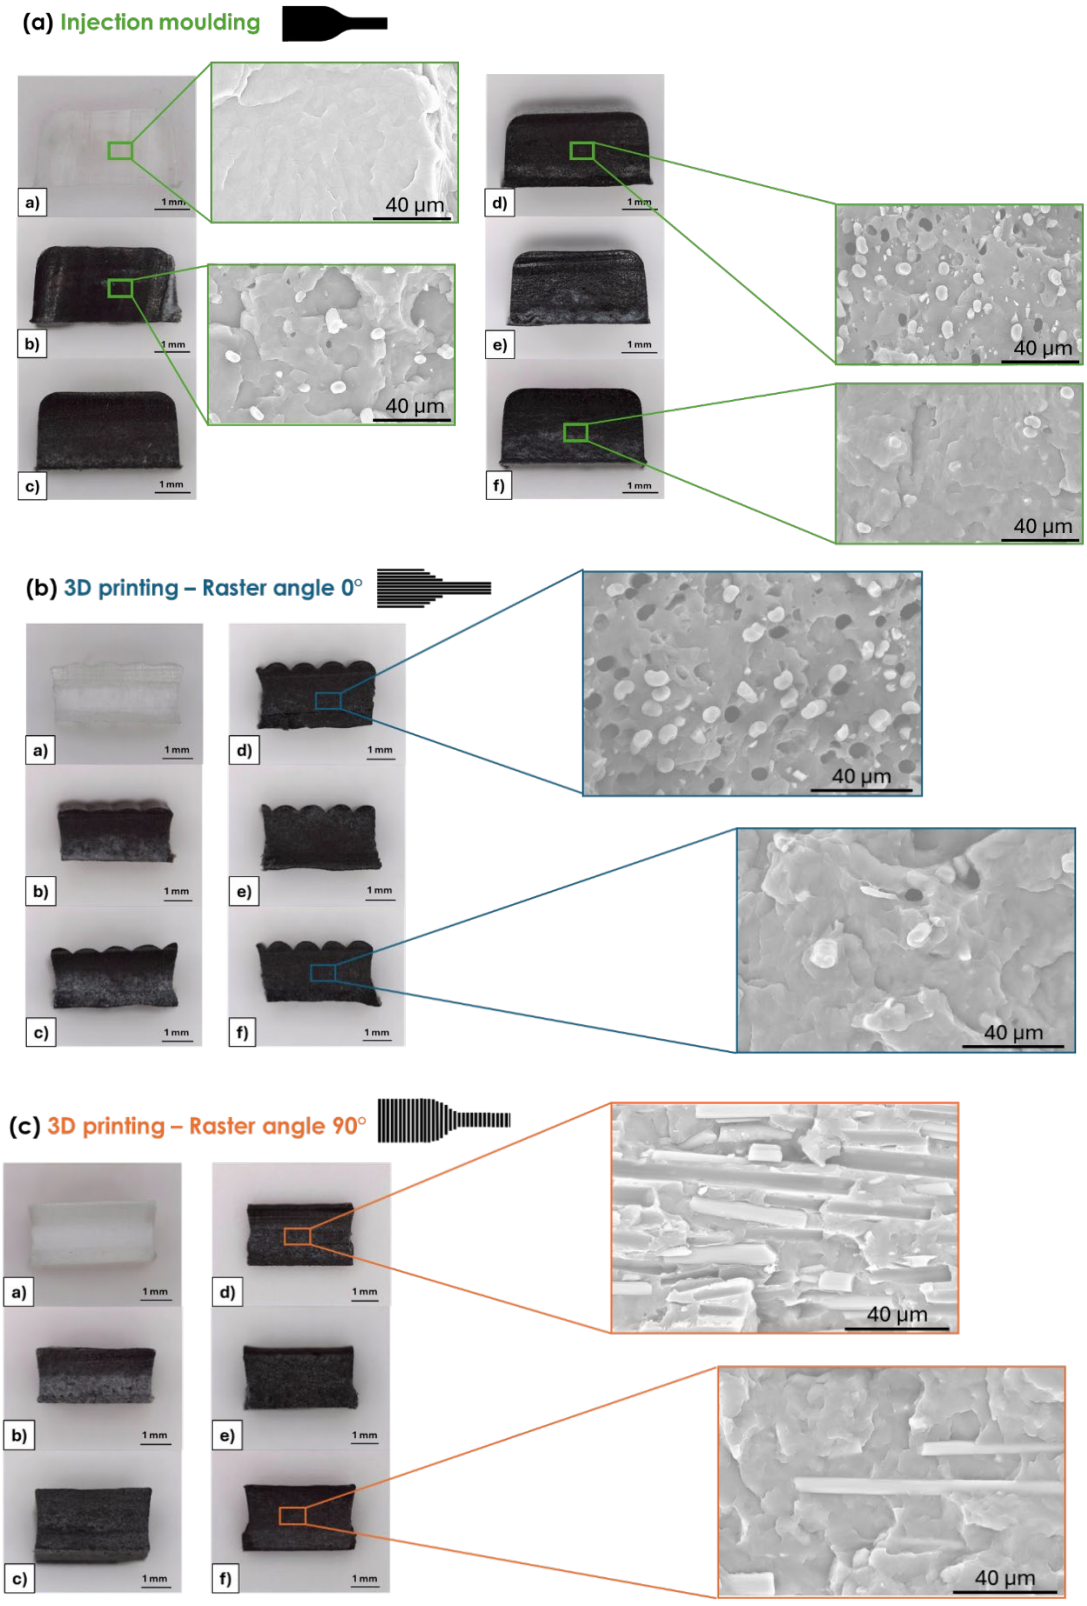

Figure 2: Optical and SEM images of specimen cross sections obtained by injection molding (a), FGF 3D printing with a raster angle of 0° (b) and 90° (c). The letters in the inset of the optical pictures indicate the composition of the sample: a) pure PP, b) PP-rCF10, c) PP-rCF20, d) PP-rCF30, e) PPPP-gMA2.5-rCF10 and f) PPPP-gMA5-rCF10.

SEM images of the composite cross sections show the microstructure of the injection-molded and 3D-printed samples (Fig. 2 (a), (b) and (c)). The fibers are homogeneously dispersed and distributed in all samples: in particular, the fibers are oriented mainly along the direction of the molding flow. In maleic anhydride-compatibilized samples, the fibers are wet by the polymer matrix and are effectively incorporated in the PP. Maleic anhydride, when grafted onto the polymer chain, introduces polar groups (specifically, the anhydride ring) that can interact with hydroxyl, carboxylic or epoxy groups on the fiber surface, due to the partial oxidation of fiber carbon atom.

The results of the melt flow index (MFI) measurement show how the fiber content influences the processability of the composite (Fig. 3): increasing the rCF concentration leads to a reduction in the MFI [6], while the addition of PP-g-AM brings the melt flow behavior back to values closer to those of pure PP [7]: MFI increases when the compatibilizing agent is used because the improved interfacial adhesion reduces internal resistance to flow, promotes better fiber dispersion, and minimizes agglomeration, resulting in a more uniform, less viscous melt.

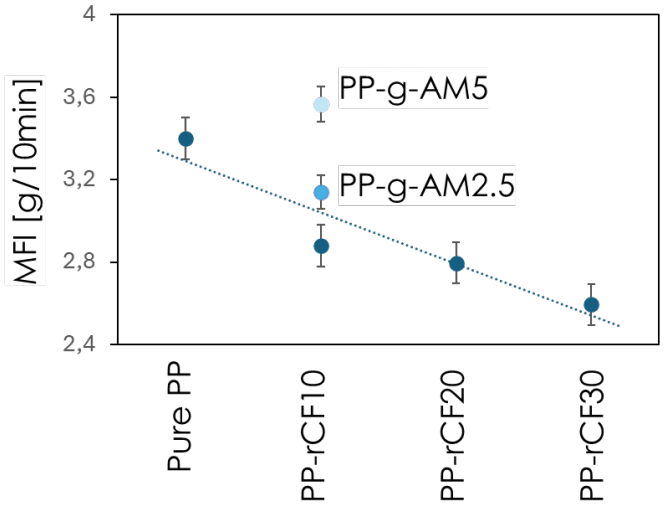

Figure 3: MFI values as a function of material composition.

However, the most critical insights are provided by the tensile tests. These are conducted on samples from injection molding and 3D printing processes, with the latter being further divided into 0° and 90° raster orientations to assess their anisotropy in terms of mechanical properties (Fig. 4 and 5).

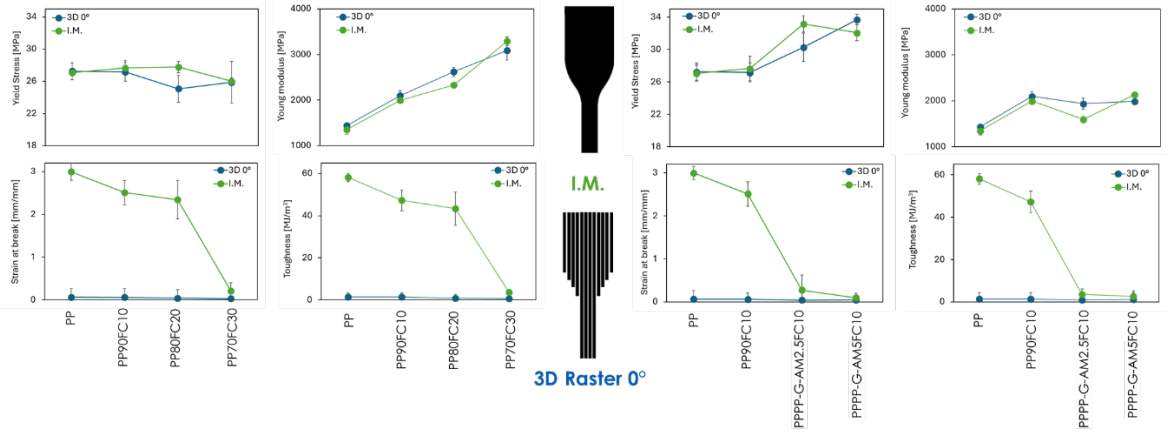

Figure 4: Comparison of mechanical parameters between injection-molded and 3D-printed (with the raster angle of 0°) samples.

Tensile tests reveal that the addition of fibers substantially increases the stiffness of the composites [8]. For injection-molded samples, the Young's modulus increases from about 1350 MPa in pure PP to

over 3200 MPa in the composite at 30% rCF. Interestingly, the yield strength remains almost constant between the various compositions, suggesting that the fibers contribute mainly to stiffness rather than ultimate strength. However, a drastic decrease in ductility and toughness is observed at higher rCF contents, reflecting the transition from ductile to brittle fracture behavior.

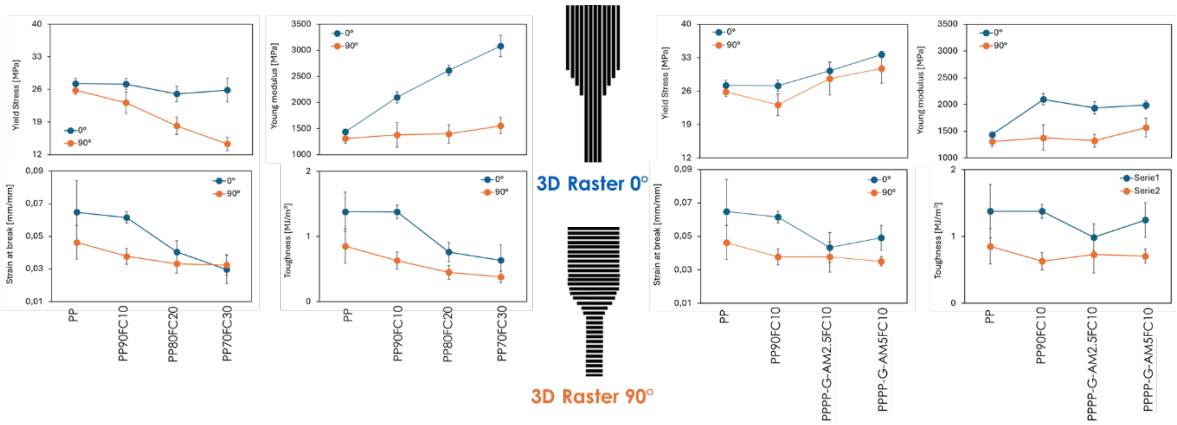

Figure 5: Comparison of mechanical parameters between 3D-printed samples with the raster angle of 0 and 90°, respectively.

For 3D-printed samples, anisotropy plays a significant role. Samples printed at a raster angle of 0° (aligned with the tensile stress) show better mechanical performance than those printed at 90°, which yield to lower deformations due to weaker adhesion between the layers [4]. The addition of the compatibilizer (PP-g-MA) increases performance in both cases, with significant improvements in mechanical performance compared to the unfilled material [9], and reduces anisotropy compared to the composite filled with the same percentage of rCF. The use of PP-g-MA facilitates better dispersion and adhesion of the fibers, favoring the transfer of stresses from the matrix to the fiber and validating its role as a crucial additive in rCF-reinforced PP composites.

The Halpin-Tsai equations [10], widely used to estimate the modulus of composites based on volume fraction and geometry of the fibers, are applied to validate experimental data (Fig. 6). Specifically, for determining the elastic modulus of 3D short-fiber composites, the Lavengood-Goettler equation is also used, serving as a complementary empirical tool in these calculations [11]:

$$E_c = \frac{1}{5} E_{11} + \frac{4}{5} E_{22} \qquad \text{Eq. 1}$$

Equation 1 applies to randomly in space oriented short fiber composites where E_{11} and E_{22} are the longitudinal and transverse modulus of a unidirectional discontinuous fiber composite having the same volume fraction of fibers:

$$E_{11} = \frac{1+2(\frac{l_f}{2r_f})\eta_L V_f}{1-\eta_L V_f} E_m \qquad \text{Eq. 2}$$

$$E_{22} = \frac{1+2\eta_T V_f}{1-\eta_T V_f} E_m \qquad \text{Eq. 3}$$

where:

$$\eta_L = \frac{\frac{E_f}{E_m}-1}{\frac{E_f}{E_m}+2(\frac{l_f}{2r_f})} \qquad \text{Eq. 4}$$

$$\eta_T = \frac{\frac{E_f}{E_m} - 1}{\frac{E_f}{E_m} + 2} \qquad \text{Eq. 5}$$

where E_m is the elastic modulus of the PP matrix, E_f is the elastic modulus of the carbon fiber, l_f and r_f are length and radius of the fiber, V_f is the fiber volume fraction.

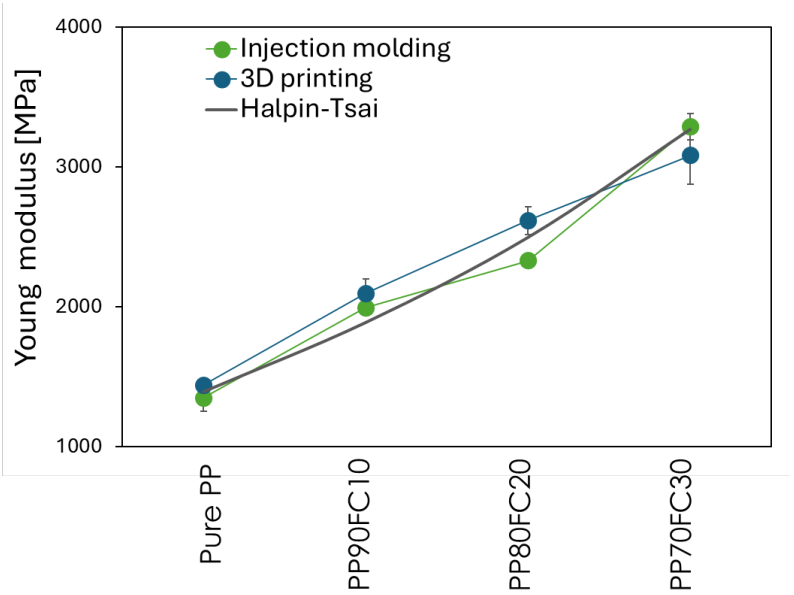

Figure 6: Comparison of Young's modulus values obtained with the Halpin-Tsai model, injection molded and 3D printed samples, respectively.

Using average fiber dimensions obtained from particle size and densities measured through helium pycnometry, theoretical moduli were calculated and found to be very similar to experimental results. This alignment strengthens the validity of the physical evidence and suggests that the behavior of the composite adheres to established mechanical models.

4. CONCLUSION

Experimental results demonstrate the technical feasibility of developing olefin-based composites reinforced with pyrolyzed rCF, highlighting the dual benefits of improving mechanical performance and promoting environmental sustainability through the circular use of high value engineering materials. The incorporation of PP-g-MA as a compatibilizer significantly reduces the compatibility problems typically encountered with PP and carbon fibers, thus expanding the potential application of these composites.

Injection molding remains the method of choice in terms of scalability and mechanical performance, but 3D printing via FGF shows promising results, particularly for prototyping and customized applications. Further research could focus on refining the 3D printing parameters to minimize anisotropy, which is in any case reduced with the use of the compatibilizer.

Ultimately, this work contributes to increasing knowledge aimed at closing the loop on composite materials, aligning with the broader goals of resource efficiency and sustainable engineering, with a view to processing scalability and production at industrial levels.

ABSTRACT

Industries are working to reduce their dependence on petroleum-derived polymers, substituting them with biobased, sustainable, and sustainable alternatives in response to the climate crisis produced by gases. Agricultural waste generates huge amounts of lignocellulosic biomass, a sustainable resource for the development of various bioproducts. Bioplastics, which are made from renewable or recycled natural materials, can help make plastic use more sustainable by supporting a circular economy. Biocomposites, consisting of a bioplastic matrix and reinforcing fibers, have developed as unique materials with diverse applications serving as alternatives to conventional composite materials. Due to their biodegradability, bioplastics have attracted a lot of interest from a variety of industries, despite being a little expensive. Consequently, a number of methods have been put out to broaden their industrial uses. Some of them are blending with other polymers, using green additives, and adding inexpensive fillers to manage the production cost. A special kind of bio-based polymer made by microbes is called a bacterial polyester. For instance, PHAs are a natural polyester that may be produced enzymatically in vivo by microbes for intracellular storage. Poly(3-hydroxybutyrate-co-3-hydroxyvalerate) (PHBV) is an aliphatic polyester and is a highly desirable bioplastic due to its marine biodegradable and home-compostable nature. PHBV is widely used to make rigid packaging items. Therefore, to achieve that, biocomposites were developed by melt-blending PHBV with natural fiber are becoming very popular. Some additives like peroxides, maleic anhydride-grafted polymer, a compatibilizer, are added to the formulation to enhance the interaction between the polymer matrix and the filler. To maintain proper melt flow for injection molding applications and increase flexibility, plasticizers are added. Adding a high content of natural filler will also help in improving the biodegradability of the materials, thereby adhering to the circular economy principles.

1 INTRODUCTION

Polymers have a wide range of material characteristics, including hydrophilic or hydrophobic, flexible or stiff, and permeable or impermeable. The structure of the repeating monomers, which are the building blocks of polymers, controls these properties. After undergoing processing—usually involving heat—to take on a specific shape, polymeric materials are commonly known as plastics in their final, usable form.[1] These materials are extensively used and play a vital role in everyday life, particularly in industries related to transportation, food, healthcare, and energy. Plastics are now an essential component of human life due to their many desirable qualities, which have resulted in an increase in production volumes. Unfortunately, plastic trash has kept on accumulating and is posing a threat to our

ecosystem because production and use were initially planned for a linear economy (use and throw) and single-use, short-term applications. Utilizing plastics derived from petrochemicals has led to an increase in plastic trash, which is harmful to the environment and ends up in landfills, the ocean, and other habitats. By their very nature, discarded plastics remain unaltered for decades or even centuries, leading to the buildup of plastic garbage. If the plastic disintegrates, even then, fragmented micro- and nanoparticles are produced, which are harmful to the environment. Sadly, these particles have a detrimental effect on human health, especially when ingested, which exacerbates the threat of microplastics.[2,3]

Although plastics have improved our lives significantly and made society sustainable only during their use phase, new plastic materials need to be designed and developed following the circular (bio)economy (CE) principles.[4] In 1962, the European Union introduced the concept of which includes a variety of managerial, technological, economic, and quality assessment practices, with the assistance of numerous national governments, including those in China, Japan, the United Kingdom, France, Canada, the Netherlands, Scotland, Sweden, Germany, Finland, and other countries.[5] The CE definition has been interpreted in about as many different ways as there are circular economy practitioners and scholars, as explained by Kirchherr et al.[6] The requirement to use resources more effectively is arguably the only thing that all definitions have in common; however, it is still up for debate what exactly qualifies as "better."[7]

Nonetheless, it is evident that while waste mountains and related pollution are still accumulating, the world's natural resource depletion and related carbon emissions are increasing. For this reason, it makes sense that a circular economy would aim to minimize resource exploitation and maximize waste prevention.[7,8] A circular economy is being implemented by governments worldwide, including the EU, China, Tokyo, New York, and London, as well as through transnational initiatives.[9] A third of CEOs worldwide stated in 2013 that they were actively interested in the circular economy due to their own values, commercial objectives, and sustainability considerations.[7] The "CE100" program from the Ellen MacArthur Foundation provides businesses with a supportive atmosphere for learning and implementing circular practices.[7] Global leaders actively implementing a practice-based circular economy approach include companies such as Coca-Cola, Apple, and Rolls-Royce.[9]

The circular economy (CE) model, when applied to polymers, emphasizes maximizing the utility and lifespan of polymeric materials by reducing waste generation, having better end-of-life options, and promoting the reuse, recycling, and regeneration of plastic products. This approach transforms the traditional linear lifecycle of polymers (from production—use—disposal) into a closed-loop system, where materials are cycled back into their original state, supporting both environmental sustainability and economic efficiency. However, the concept of sustainability points out that every element of social and economic institutions should actively advance environmental preservation and economic growth simultaneously.[10]

Canada, along with multiple countries, is creating new laws and regulations to transition towards a plastic-free economy..[11] Single-use packaging is a significant source of pollution, making up around 46% of global plastic waste; fixing this issue will significantly lower the amount of plastic garbage produced. [12] Thus, it is clear that there is widespread interest in discovering practical equivalent packaging options that are also sustainable. While recycling plays a role in managing plastic waste, it contributes to just about 6% of the total plastic recovered, as a result, a significant portion of plastic continues to accumulate in landfills.[13] As such, using biobased and biodegradable polymers in conjunction with recycled polymers can be seen as an effective strategy to help reduce our reliance on petro-based plastics and minimize CO_2 emissions.[14]

Bioplastics are a class of materials that can be made from renewable sources. Therefore, materials made by biological processes, biobased materials, biodegradable materials, or a mix of these are often referred to as bioplastics. In this case, the building blocks (monomers) are obtained or synthesized from biomass, like plant-derived sugars, and then polymerized to create plastics that have properties similar to traditional ones or introduce new functionalities. Globally, around 2.5 million tonnes of bioplastics are produced annually. They are looked upon as essential to building a circular economy and addressing key United Nations Sustainable Development Goals. This includes reducing dependence on fossil fuels, creating new recycling or degradation pathways, and lowering the use of harmful chemicals during production. Moreover, bioplastics also offer benefits such as reduced carbon emissions, potential

biodegradability at end-of-life, and equivalent performance in certain applications compared to petro-derived chemicals.[1]

Polyhydroxyalkanoates (PHAs), a type of bacterial polyester, are amongst the most commonly used bio-based polymers, which are completely biodegradable in soil and marine settings and may be produced by a wide range of microorganisms under growth-limited circumstances. Because of their biodegradability, they are a viable alternative to popular petroleum-based polymers, including polypropylene (PP) and polyethylene (PE). They are particularly used in many single-use applications, like rigid packaging and flatware.[15] However, the production of PHAs is very expensive, which can be a limiting factor for their widespread use. PHAs are currently made by fermenting sugars and fatty acids that are obtained from food crops such as vegetable oil, corn starch, and sugarcane. Over half of the production costs are related to the cost of the feedstock alone.[15] This can be addressed by using lignocellulosic biomass, which is abundant and inexpensive or free, as a source of carbon for the manufacture of PHA. According to reports, approximately 300 bacterial species (both Gram-positive and Gram-negative strains) may produce PHAs in extreme circumstances and both aerobic and anaerobic settings.[16]

PHBV, or poly(hydroxybutyrate-co-hydroxy valerate), a commonly used PHA, is drawing a lot of interest in the production of sustainable materials.[17] PHBV is a copolymer of 3-hydroxybutyrate and 3-hydroxyvalerate and can be synthesized effectively using *H. bluephagenesis*. [18] PHBV shows biodegradation in marine, home, and industrial environments.[19] To counter the expensive nature of PHBV, it is frequently mixed with low-cost filler materials to develop biocomposites. These fillers can further enhance biodegradability while improving polymer performance.[14]

Therefore, biocomposites are composite materials developed by mixing biodegradable polymer matrix and a natural filler or fiber. Biocomposites made from bioplastic and plant-derived fiber (natural/biofibre), are thought to be more environmentally friendly. These composites are known as "green composites." The primary benefits of biocomposites are their sustainability, complete degradation, and environmental friendliness; in other words, they are genuinely "green" in every way. They can be composted or disposed of easily at the end of their life cycle without harming the environment. Biocomposites have been effective as materials in numerous applications, including mass-produced consumer goods with limited lifespans, single-use goods, or brief use before being discarded sustainably. Green composites have a several-year functional life and can even be utilized indoors. [20,21] Biofiber can have a reinforcing effect on the biocomposite matrix; however, it depends on many factors. The overall properties of fibres are largely influenced by factors such as their chemical composition, structural defects, cell dimensions, microfibrillar angle, and internal structure.[21] Some of the most important biofibers used for biocomposite fabrication are Abaca, Bagasse, Bamboo, Banana, Broom root, Cantala, Caroa, China jute, Coir, Cotton, Curaua, Date palm, Flax, Hemp, etc. [20]

As a result, research on PHBV-based biocomposites has also been conducted during the past decades using different fillers and fibers and evaluating the fiber performance on material properties. In some of the studies, Singh et al.[22] developed PHBV/natural bamboo fiber-based biocomposites, while Vandi et al.[23] developed PHBV/wood fiber-based biocomposites and measured the effect of processing conditions on the mechanical performance; Berthet et al.[24] made biocomposites from PHBV/wheat straw fibres for rigid applications. In another study by Nath et al. [14] the authors developed PHBV biocomposites by adding cellulose fibers (20 and 25%) and then added a compatibilizer [MA-grafted PHBV (MA-g-PHBV)] to see the impact of compatibilization on the biocomposite. To enhance the melt flow during processing, a plasticized TBC was added, which enhanced the melt flow suitable for injection molding, along with improving the impact strength and flexibility. The MA-g-PHBV compatibilizer was incorporated for enhancing the matrix-fiber adhesion, resulting in enhanced properties. During melt blending, a compatibilizer can be introduced to the composite to improve the matrix–fiber interaction. The most popular method for creating natural fiber/filler composites is the use of functional polymers grafted with maleic anhydride (MA). By reacting with free hydroxyl groups on the surface of the CF, it forms covalent linkages within the composite, enhancing interfacial bonding.[25] This proceeding paper later briefly explains a few works on PHA-based biocomposites to develop a consistent and robust composite for different application.

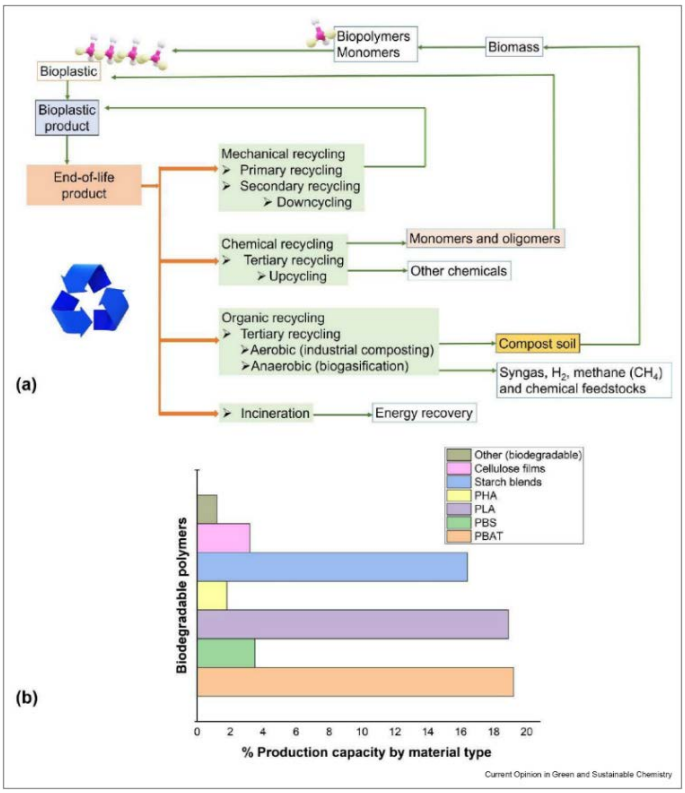

Figure 1: (a) Potential recycling pathways for biodegradable plastics (b) Based on global production capacities reported for the year 2021. Adopted from Kalita et al. [4] Copyright 2023 Elsevier, Open Access (CC BY 4.0)

2 Development of Biocomposites

For biocomposite formulations to be successfully adopted in industry, they must be compatible with standard production equipment typically employed in the plastics sector. This allows for easy transition from laboratory to industry, cost effectiveness, and scalability. As a result, biocomposites should be processable using typical procedures such as injection moulding, compression moulding, melt extrusion, thermoforming, blown film extrusion, and blow moulding. These processes are commonly used to manufacture many commercial everyday plastic products, and allowing the novel biocomposites to be created using these techniques would significantly increase the possibility for integration into mainstream applications such as packaging, automotive, consumer goods, and others.

2.1 Melt Extrusion

In the plastics processing industry, extrusion is a continuous production method that is mostly widely used to create products having a predetermined cross-sectional profile. In the process, a substance is forced out, much how toothpaste is squeezed out of a tube. The method of plastic extrusion involves forcing melted polymer(s), frequently in the form of strands, through a die. During the extrusion process via the die, the melt assumes the shape of the die opening. [26]

The polymer in the hopper is transferred into the heated barrel via the feed throat and a rotating screw. The polymer is melted by the screw's shear and barrel heating before being forced past the filter screen, into the die, and ultimately out. The extrusion techniques' main mechanics are solid conveying, homogeneous melting or plasticating, and melt pumping. The screw controls feeding, compression, and metering, making it the most significant factor in determining an extruder's effectiveness. Twin-screw extrusion is one of the most widely used processing methods in both research and industrial settings for producing polymer blends and biocomposites. In this process, biopolymers are exposed to a combination of high shear forces and elevated temperatures generated by the rotating screws and external heaters. This not only melts the polymer but also ensures uniform dispersion of fillers within the molten matrix.

2.2 Injection Molding

Injection moulding is a popular and adaptable process for creating polymer mixtures and composites. Plastic materials are heated till they become molten and viscous. This molten polymer is then poured into a closed mould, which specifies the desired shape of the finished product. Once within the mould, the material is allowed to cool and harden before opening, and the developed piece is taken out. This technology enables the accurate and economical manufacturing of complicated forms with high detail. Injection moulding is particularly useful in large-scale production due to its cost-effectiveness, consistency, and capacity to make high-quality products on a large scale. Its accuracy and reproducibility make it a popular choice for creating complicated patterns and components in a variety of industries. [27–29]

2.3 Blown Film Extrusion

Blown film extrusion is increasingly being adapted to produce films from biodegradable polymers, moving away from traditional plastics. This technology is widely used in the packaging sector to produce thin films that are generally no more than 100 microns thick. The polymer is first melted using a single-screw extruder, and then air is fed through the centre of a circular die to inflate it into a tubular film bubble. As the bubble rises, it cools and flattens into a two-layer film with nip rollers before being coiled into rolls. Blown film extrusion is a highly flexible process that may produce anything from basic monolayer bags to complicated multilayer films like those used in food packaging. Coextrusion is used to make multilayer films, which are formed by combining two or more molten polymer streams. Advanced commercial systems may coextrude up to seven to eleven layers, giving us great control regarding film functionality and performance.[30,31]

3 End-of-Life (EoL) options for Biocomposites

To transition to completely circular materials, it's important to design materials with effective EoL management. Figure 1 shows some EoL pathways for bioplastics. Biodegradable polymers disintegrate under specified circumstances near the end of their life cycle. Compostable polymers, a category of biodegradable plastics, degrade in industrial composting facilities. Biodegradable and compostable polymers can be made from either fossil fuels or biological resources. Biocomposites are typically designed with EoL biodegradation in mind under various conditions, rather than with a focus on recyclability.

The process of biodegradation is the transformation of organic components into residual biomass and biogas by microorganisms (bacteria and fungi) that use plastic as a carbon source. Biodegradation can take place inside the biosphere because microorganisms play a critical part in the process.

More than 90 microorganisms—aerobes, anaerobes, photosynthetic bacteria, and archaebacteria are responsible for degrading and catabolizing bioplastics. These bacteria are abundant in soil and compost.[32] There are five primary stages in the microbial breakdown of plastic wastes: colonisation, biodeterioration, biofragmentation, absorption, and mineralization. [33]

There are different environments for biodegradation apart from soil and compost like marine, landfill, and sewage sludge, where each environment has its specific conditions for degradation. Different organizations such as ASTM, and ISO have established specific standards to assess the biodegradability of bioplastics under different environmental conditions.

Standards for biodegradation testing

Aerobic biodegradation

- Marine biodegradation: ASTM D6691-17, ASTM D7473-12, ASTM D7991-15, ISO 18830-16
- Soil biodegradation: ASTM D5988-18, ISO 17556, ASTM D5526-18, and ISO 14855
- Compost biodegradation: ASTM D5338, ISO 14855, ISO 117088, EN 13432, ASTM D5929, ASTM D6400, AS 5810, and AS 4736

Anaerobic biodegradation

- Sewage sludge biodegradation: ASTM D5210-92 and ISO 14853

- Landfill biodegradation: ASTM D5526-18 and ASTM D7475-11

Biodegradable polymers are exposed to a mixture of decomposed components at elevated temperatures during the composting process. Industrial composting is carried out at 60 °C, and with a high relative humidity in presence of oxygen. Home composting operates under milder conditions compared to industrial composting, primarily due to the smaller volume of biodegradable materials at temperature around 28 °C. [34]
Degradation under marine conditions is distinguished by low temperature, high salinity, high pressure, low nutrient levels, and currents compared to soil and compost.[35] Seawater is an intricate mixture rich in inorganic ions. The salinity of seawater is affected by factors such as evaporation, precipitation, river discharge, and seawater currents. The offshore and estuary waters are typically below 30% salinity, while the ocean's surface salinity varies between 32% to 37%. With pH values spanning between 8.0-8.5, seawater is weakly alkaline.[35] It has been found that small pH changes (< 1) can modify the composition of the bacterial population. Moreover, the concentration of dissolved oxygen in seawater is substantially lower than in soil, and both are influenced by temperature and linked to biological activities, such as the amount and variety of marine organisms.[19]

4 RESEARCH ON PHBV BASED BIOCOMPOSITES

PHBV based biocomposites are becoming increasingly popular as they are biodegadable under soil, marine, home, and industrial settings. Also, by making the PHBV biocomposites high filler, the high processing cost of the PHBV polymer can be counteracted and the biodegradation rate can also be increased.

With this idea in mind, Nath et al. [14] developed a PHBV, and cellulose fiber (CF) based biocomposites having different concentrations of CF (10, 20, and 25%). With high concentrations of filler, the melt flow becomes very less, which reduces its processability. As a result, a plasticizer, tributyl citrate (TBC) was added to make the melt flow suitable for injection molding. Also, since there is an incompatibility between fiber and matrix, a compatibilizer MA-g-PHBV, was added at different concentrations. Additionally, three different types of MA-g-PHBV, with variation in grafting percentage, were tested on the biocomposites to evaluate the effectiveness of grafting percentage on biocomposite performance. Different characterizations, like mechanical properties, thermal, and morphological analysis, were conducted to evaluate the samples. TBC addition to PHBV decreased tensile, flexural strength, and modulus due to weakened intermolecular bonding, whereas CF addition increased modulus. Incorporating MA-g-PHBV improved all mechanical characteristics, particularly at 7% loading, due to improved filler-matrix adhesion. The addition of TBC led to an improvement in both the elongation at break (EAB) and the impact resistance of PHBV. The EAB improved monotonously with higher compatibilizer content. However, the impact strength increased after CF addition, as incorporation of long fibers sometimes led to improvement in impact strength, but no change was observed after MA-g-PHBV addition. Scanning electron microscopy and atomic force microscopy also showed improved interfacial adhesion with fewer gaps, voids, and pull-out fibers after the addition of compatibilizers. The observation demonstrates that MA-g-PHBV incorporation results in enhanced matrix/fiber interaction. The thermal stability analysis showed that adding TBC and cellulose fibers lowered the onset degradation temperature (T_{onset}), indicating reduced thermal stability, but the maximum degradation temperature (T_{max}) remained mostly unaffected. Overall, the thermal stability exhibited by the biocomposites was sufficient to allow melt processing at 170 °C with no adverse effect. Additionally, it was reported that the addition of MA-g-PHBV, having the highest grafting percentage, proved to be the most promising compatibilizer showing the highest improvement. This can be attributed to the presence of more MA groups, which facilitate more bonding sites for the OH present in the CF. Figure 2 shows the atomic force microscopy images of compatibilized and uncompatibilized samples showing reduced gap at the matrix and less fiber pullouts.

In another study by Ahankari et al.[36], agro-residues such as maize straw (CS), soy stalk (SS), and wheat straw (WS) were effectively incorporated into PHBV, using the melt mixing process to create novel green composites. The effective use of agro-residues as a great substitute for wood and synthetic fibres was the main emphasis of this study. This is because they are not only renewable, biodegradable, and advantageous for the environment and technology, but they are also affordable, widely available,

and easily accessible. The authors examined the impact of these biomass fibres on PHBV's performance. Reinforcing PHBV with 30% agricultural byproducts increased its tensile and storage modulus by up to 255% and 305%, respectively. Additionally, the tensile and flexural moduli of PHBV composites were much greater than those of equivalent PP composites for identical quantities of (30%) biomass fibres. Wheat straw fibers treated with alkali showed approximately a 35% improvement in both elongation at break and impact strength in PHBV composites, while having minimal effect on tensile strength and modulus when compared to untreated fibers. DMA research showed that the PHBV-biomass interaction was better than PP. However, tensile and flexural strength decreased with 40% biomass fibres addition because of a greater probability of agglomeration development in the polymer matrix. The addition of stiff lignocellulosic fibres to PHBV and PP composites also decreased their notch impact strength.

Mazur et al.[37] in their study used injection molding to develop biodegradable composites made of PHBV reinforced with either 7.5% or 15% of wood fibres (WF) or basalt fibres (BF). While WF composites had a decrease in strength and impact characteristics, but exhibited an increase in Young's modulus values, BF reinforced composites showed improvements in all these attributes. Composites containing 15% of BF demonstrated a 74% improvement in Young's modulus and a 41% increase in impact strength when compared to the unmodified polymer. Scanning electron microscopy was used to analyze the morphological structure of the biocomposites in order to determine the fibres' distribution and interfacial adhesion. Furthermore, biodegradation experiments of the biocomposites were conducted in saline solution to investigate weight loss and mechanical characteristics. It was discovered that the presence of fibres influences the rate of water absorption, with the maximum rate recorded in composites containing 15% of WF. After the first and second weeks, mechanical characteristics fell by around 10%. These findings demonstrate that biodegradable PHBV-based composites, including natural fillers, may be utilised to create long-lasting products. Table 1 provides a summary of some of the work conducted on PHBV-based biocomposites. In another study by Nagarajan et al.[38], injection-molded biocomposites were developed using switchgrass as filler in a PHBV and PBAT (poly(butylene adipate-co-terephthalate) blend (45%PHBV55%PBAT). The effect of incorporating switchgrass fibre at loading levels ranging from 20-40 wt% was examined. Due to poor fiber matrix adhesion, a compatibilizer poly diphenylmethane diisocyanate (pMDI) was added at different concentrations. It was found that the compatibilizer was effective in improving the mechanical properties of the biocomposites. Scanning electron microscopy (SEM) was used to analyse fracture surface morphology, which revealed increased fiber-matrix adhesion in compatibilized biocomposites. FTIR data revealed an interaction between the PHBV/PBAT combination and switchgrass fibres with the addition of pMDI.

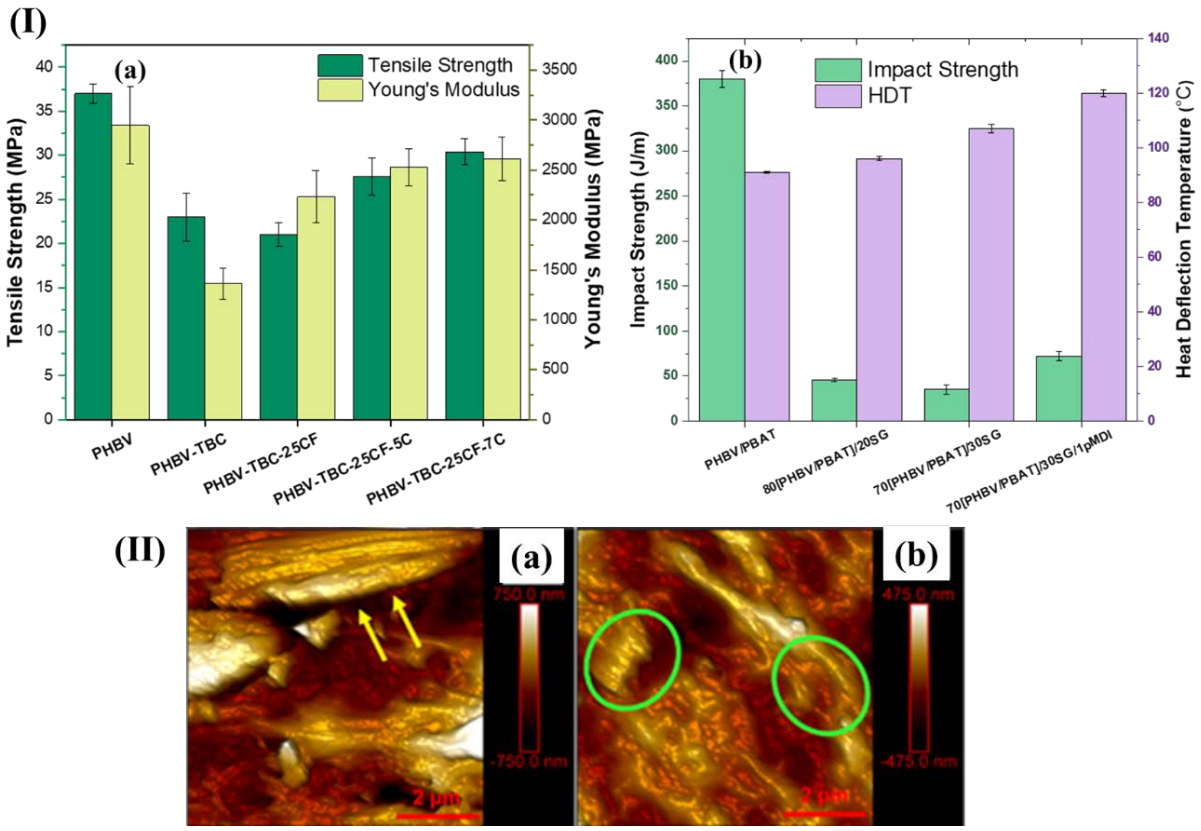

Figure 2: (I) (a) Mechanical Properties of PHBV/cellulose fiber (CF) composites with and without compatibilizer (MA-g-PHBV; referred to as "C" in the figure) [14] and (b) Impact strength and heat deflection temperature (HDT) of PHBV toughened with PBAT (45%PHBV55%PBAT), using switchgrass (SG) as a filler and poly(diphenylmethane diisocyanate) (pMDI) as a compatibilizer [38] (figure prepared by the authors); (II) Atomic force microscopy image of PHBV and cellulose fiber composite to show improved fiber-matrix adhesion after compatibilizer addition (a) PHBV-TBC-25CF (b) PHBV-TBC-25CF-7C [14] [CF stands for cellulose fiber and C stands for compatibilizer (MA-g-PHBV)](image taken by authors)

Table 1: Summary of studies conducted on PHBV-based composites.

Polymer used	Filler or Fibers used	Additives	Results observed	Reference
PHBV	Bamboo Pulp Fiber	Boron Nitride and MA grafted PHBV	• Fibers increased crystallinity, strength, modulus, and impact resistance of PHBV composites, with slight elongation improvement at low loadings. • MA-PHBV enhanced strength and stiffness through better fiber-matrix bonding but reduced toughness due to restricted fiber pullout.	[39]
PHBV	Bamboo Fiber	Silane and rare-earth coupling agents	• High-modulus fibers significantly improved tensile and flexural properties and thermal stability compared to low-modulus fibers. • Surface modification with silane and rare-earth coupling agents enhanced fiber-matrix adhesion and further boosted mechanical performance.	[40]

PHBV	Cellulose nanocrystals and aluminum oxide nanoparticles	• Adding up to 3 wt% CNC improved tensile strength, thermal stability, and crystallinity, though higher loadings caused nanoparticle agglomeration and reduced performance. • SEM showed nanoparticle clustering at higher concentrations, while DSC confirmed increased glass transition temperature and enthalpy of fusion with CNC. • CNC proved more effective than Al_2O_3 in enhancing PHBV's mechanical and thermal properties.	[41]
PHBV	Human hair waste (HHW), sawdust (SD) and chitin	• PHBV was compounded with HHW, SD, and chitin to reduce cost and valorize waste. • Tensile tests showed SD slightly improved strength, while HHW and chitin had no reinforcing effect. • Soil burial tests revealed enhanced biodegradation with fillers, with HHW composites showing the highest weight loss (~35%).	[42]

5 CONCLUSION

Simply using renewable resources does not ensure sustainability. With advances in technology, bioplastics have the potential to help in the transition of many plastic-heavy sectors to a circular economy. Presently, bio-based replacements are now available for most fossil-based plastic applications. However, these alternatives are often produced in small numbers, at a higher cost, and do not always provide clear environmental benefits. In addition to typical first-generation biomass sources, agricultural waste and lignocellulosic biowastes are more readily available, sustainable, and inexpensive. To make these alternatives really practical, biorefinery technologies must become more efficient and comply with green chemistry principles, such as avoiding toxic chemicals and reducing energy consumption, in order to generate the essential monomer in a sustainable manner. While efforts to achieve environmental sustainability are increasing, financial sustainability remains a difficulty. The affordability of fossil fuels, which is driven by low oil prices, tight business margins, and government support, makes it difficult for bio-based producers to compete economically. Advanced research is paving the way for lower production cost of biodegradable plastic resins. Moreover, adding low-cost natural fillers and fibers to the matrix for making biocomposites can help tremendously in reducing the price of the overall product. And these materials should be biodegradable more effectively in natural conditions.

ABSTRACT

The increasing use of plastics demands effective end-of-life waste management, yet recycling facilities remain inaccessible in many areas, especially remote regions seeking sustainable solutions. The "Zero Plastic" project explores innovative methods to reuse waste plastics with minimal processing. This study focuses on two plastic waste streams: stretch wraps—typically made of LLDPE, LDPE, or HDPE and PET bottles, including labels and caps, evaluating the mechanical properties of recycled molded products. Stretch wrap samples were compression molded at 180 °C under 2 MPa for 10 minutes, yielding a flexural strength of 15 MPa and a modulus of 420 MPa. Recycled PET (rPET) molded at 265 °C under 1 MPa for 4 minutes achieved 76 MPa strength and 2800 MPa modulus. However, labels and caps introduced immiscibility challenges. Using 10-wt% Lotader AX8840 compatibilizer reduced rPET's flexural strength and modulus to 64 MPa and 2000 MPa, respectively, while increasing elongation to 4.5%, correlating with higher creep compliance due to enhanced flexibility. Despite these improvements, PET bottle waste blended with compatibilizer remained brittle and was unsuitable for further testing. Various parts, including bricks and sheets of thicknesses 6.35 mm to 19 mm and lengths from 40 cm to 86 cm, were successfully molded from stretch wrap, demonstrating a feasible, cost-effective recycling pathway. Preliminary life cycle assessments showed significant environmental benefits: recycling stretch wrap could save 52,300 MJ of embodied energy and prevent 558 metric tons of CO_2 emissions (44% and 13% reductions, respectively). PET bottle recycling offers even higher potential, with 146,000 MJ energy savings and a 4900-metric-ton reduction in CO_2 emissions (53% and 39% reductions). Future work will enhance manufacturing processes and explore plastic blending strategies to establish sustainable, decentralized recycling facilities where such infrastructure is currently lacking.

1 INTRODUCTION

Recent research underscores both the opportunities and limits of mechanical recycling for plastics. Mechanical recycling remains the most energy-efficient and environmentally favorable option, particularly for single-polymer streams like PET, HDPE, or LDPE, and can achieve significant reductions in carbon footprint when properly implemented. However, studies show that even with optimized collection and sorting, mechanical recycling will typically only capture 30 to 40% of plastic waste, constrained by challenges such as polymer degradation, contamination, and the presence of complex multi-material products. As Klotz et al. noted, mechanical processes are limited in addressing

diverse plastic grades and achieving high-quality recycled outputs suitable for demanding applications [1]. This gap highlights why efforts to decentralize recycling via smaller, stand-alone facilities must consider the technical feasibility of handling mixed waste streams without compromising product quality or environmental gains [2].

In addition to mechanical approaches, chemical and solvent-based recycling processes are emerging as potential solutions for plastics unsuitable for melting and reprocessing. Techniques like pyrolysis, gasification, and depolymerization can transform mixed or contaminated plastics into valuable monomers or fuels, theoretically producing outputs comparable to virgin materials. However, these technologies remain costly, energy-intensive, and largely unproven at industrial scale, with uncertainties in life-cycle impacts and process economics. Life cycle assessments emphasize the importance of evaluating recycling technologies not just by greenhouse gas emissions but also by factors like net fossil carbon balance, landfill diversion, and plastic leakage to the environment [3-4]. As such, while small-scale recycling plants offer promise for rural and remote areas, their viability hinges on careful integration of mechanical and chemical pathways, robust sorting infrastructure, and economic models capable of offsetting high capital and operational costs.

Even though mechanical recycling remains the preferred method for plastic waste management, the cost of establishing a conventional Materials Recovery Facility (MRF) is prohibitively high for most communities, particularly in rural or remote regions. To address this challenge, Zero Plastic LLC and Oklahoma State University collaborated under a U.S. Army SBIR Phase I effort (Contract No. W51701-23-C-0246) [5] to explore the feasibility of developing a self-contained, mobile recycling facility housed inside a shipping container. The goal was to create a compact system capable of recycling common plastic waste streams, such as stretch wraps and plastic bottles, into useful products with minimal sorting and processing requirements. Building on this work, the present study investigates the feasibility of producing value-added products from post-consumer plastics using such stand-alone facilities. We focused on characterizing recycled stretch wrap materials and recycled PET blends, both in their raw state and with compatibilization strategies aimed at improving mechanical properties. A range of thermal and mechanical analyses was conducted to evaluate material performance and processing behavior. The following sections describe the materials used, the experimental methods employed, and the results obtained, offering insights into the technical viability and limitations of decentralized recycling systems for mixed plastic waste streams.

2 MATERIALS AND METHODS

2.1 Materials

This study utilized post-consumer plastic waste streams, specifically stretch wrap waste composed of linear low-density polyethylene (LLDPE), low-density polyethylene (LDPE), and high-density polyethylene (HDPE), as well as recycled polyethylene terephthalate (rPET) flakes obtained from commercial reclaimers. Recycled polypropylene (rPP) was also incorporated for blending studies with rPET. To enhance interfacial compatibility between immiscible polymers, Lotader AX8840 (Arkema Inc.), an ethylene-acrylic ester-glycidyl methacrylate terpolymer, was employed as a compatibilizer at concentrations of 5-wt% and 10-wt%.

2.2 Sample Preparation

Post-consumer plastics were initially cut or shredded into small flakes using a Vecoplan VAZ 800 shredder. Blends involving rPET and rPP, with or without compatibilizer, were compounded using a Brabender Plasti-Corder torque rheometer at 235°C for 5 minutes at a rotor speed of 60 rpm to achieve homogeneous dispersion. Compression molding was performed on a Carver hydraulic press under different conditions depending on the polymer type: stretch wrap samples were molded at 180°C under 2 MPa for 10 min., while rPET-based samples were molded at 265°C under 1 MPa for 4 min. The resulting products included sheets and bricks, with thicknesses ranging from 6.35 mm to 19 mm, and lengths and widths between 40 cm and 86 cm.

2.3 Thermal and Mechanical Characterization

Thermal and mechanical characterization of the recycled plastics was performed to evaluate their suitability for manufacturing applications. Thermal transitions were analyzed using a TA Instruments Q2000 Differential Scanning Calorimeter (DSC), with samples of 5–10 mg subjected to a heat-cool-heat cycle from 30 °C to 300 °C at a rate of 3 °C/min under a nitrogen atmosphere. The key parameters measured included glass transition temperatures (Tg), melting points (Tm), and crystallization behaviors. Mechanical properties were assessed through flexural testing conducted using an Instron Universal Testing Machine following ASTM D790 standards, employing a span length of 50 mm and a crosshead speed of 2 mm/min to determine flexural strength, modulus, and elongation at break. Additionally, dynamic mechanical properties were examined using a TA Instruments Q800 DMA in dual cantilever mode across a temperature range of 30 °C to 80 °C, capturing data on storage modulus, loss modulus, creep compliance, and time-temperature superposition behavior.

The analytical techniques were crucial for understanding the inherent challenges of recycling mixed plastic waste streams, such as polyolefin films and PET bottles, which differ significantly in chemical structure, melting behavior, and mechanical performance. In this study, recycled plastic streams—including stretch wraps composed of polyethylene blends and rPET materials—were systematically analyzed to evaluate their thermal behavior and mechanical integrity, both in their unmodified states and after the addition of compatibilizers. The results from DSC and DMA provided critical insights into the compatibility of blended polymers and the effectiveness of processing methods used, informing the design and feasibility of stand-alone, containerized recycling facilities capable of converting heterogeneous plastic waste into functional products.

2.4 Life Cycle Assessment

A preliminary life cycle assessment (LCA) was performed to quantify the environmental impacts of the recycling operations, focusing on embodied energy and greenhouse gas emissions, using the LCA calculator provided by the REMADE Institute, of which Oklahoma State University was a member during the SBIR project [6]. Calculations integrated process-specific energy data and emissions factors drawn from literature and operational data obtained during the SBIR Phase I project. These assessments provided insights into the potential sustainability benefits of implementing localized, stand-alone recycling facilities.

2.5 Fabrication of Molded Products and Equipment Used

Post-consumer plastics, including stretch wrap and rPET bottles, were first shredded into flakes using a Vecoplan VAZ 800 industrial shredder, producing fragments approximately 10–20 mm in size to facilitate further processing. For blends requiring improved homogeneity, the shredded material was fed into a Filabot EX6 single-screw extruder, operated at barrel temperatures between 170°C and 220°C and screw speeds ranging from 10 to 40 rpm. In certain trials, extruded strands were cooled and pelletized using a Filabot Pelletizer, yielding uniform feedstock suitable for consistent molding operations. This sequence ensured adequate mixing, particularly in blends containing compatibilizers such as Lotader AX8840. The key equipment used in these processes—including the shredder, extruder, pelletizer, and compression molding press is shown in Figure 1.

Final products, including sheets, bricks, tiles, and other molded components, were fabricated using a Carver hydraulic compression molding press. Process parameters varied depending on the polymer type: stretch wrap blends were molded at 180°C under 2 MPa for 10 min, while rPET and rPET blends were molded at 265 °C under 1 MPa for 4 min. Custom-designed steel molds were utilized to shape parts into dimensions ranging in thickness from 6.35 mm to 19 mm, with lengths and widths between 40 cm and 86 cm. These molded parts were subsequently evaluated for mechanical performance and surface quality to assess the feasibility of producing durable products from localized, stand-alone recycling operations.

Figure 1. Key equipment used for stand-alone recycling, including the shredder, extruder, pelletizer, and compression molding press.

To further illustrate the stand-alone recycling system developed in this study, Figure 2 presents a schematic layout of the self-contained manufacturing facility housed inside a standard shipping container. This diagram shows the workflow and spatial arrangement of the main processing equipment, including the shredder, extruder, pelletizer, and compression molding press, all integrated into a compact footprint designed for deployment in remote or rural settings. The layout enables localized recycling operations, minimizing the need for transportation to centralized facilities.

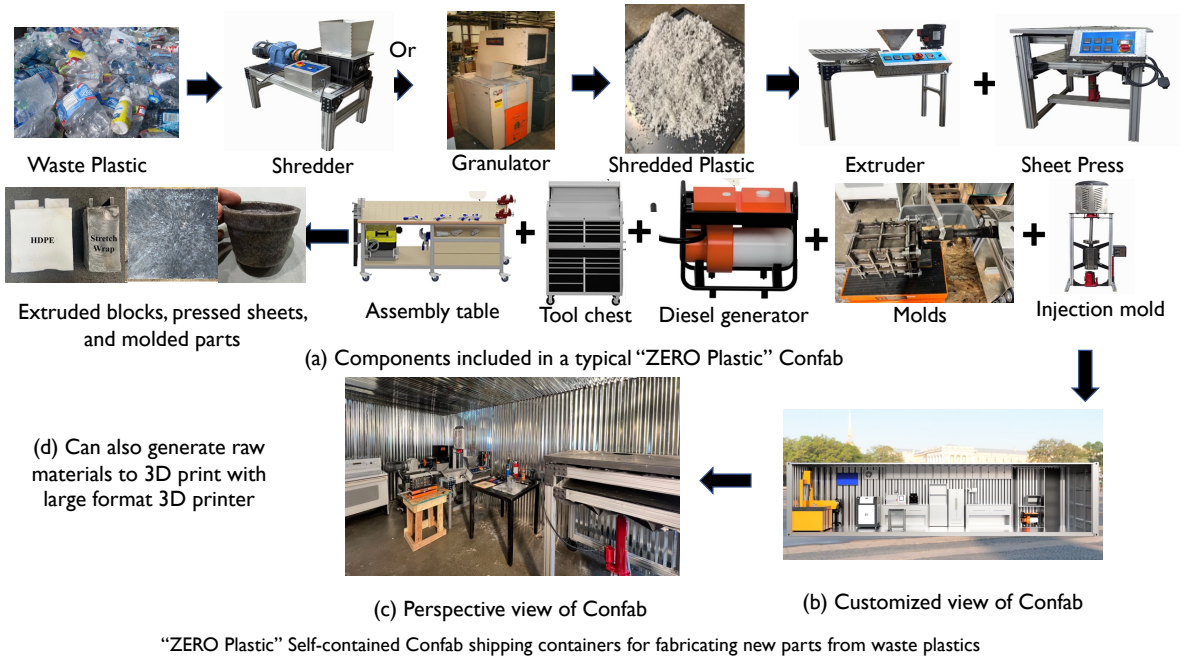

Figure 2. Schematic of the shipping container with the various equipment.

Figure 3 shows photographs of some of the primary equipment used in the recycling process. The Brabender Prep Center (Figure 3a) served as the primary compounding system for blending recycled polymers and compatibilizers under controlled temperature and shear conditions. It enabled thorough mixing of rPET, rPP, and Lotader AX8840, producing homogenous blends for subsequent molding operations. The Vecoplan VAZ 800 industrial shredder (Figure 3b) was employed for the initial size reduction of post-consumer plastics, producing flakes (Figure 3c) approximately 10–20 mm in size to facilitate downstream processing.

(a) (b) (c)

Figure 3. (a) Brabender prep center (b) Industrial shredder (c) shredded pieces.

Custom-designed steel molds, illustrated in Figure 4, were fabricated to produce a variety of product geometries, including beams, bricks, and flat sheets, tiles. The molds varied in size to accommodate different applications, with part thicknesses ranging from 6.35 mm to 19 mm and lengths and widths between 40 cm and 86 cm. These molds were engineered to endure high processing temperatures and pressures, ensuring proper consolidation and dimensional accuracy in the recycled polymer products.

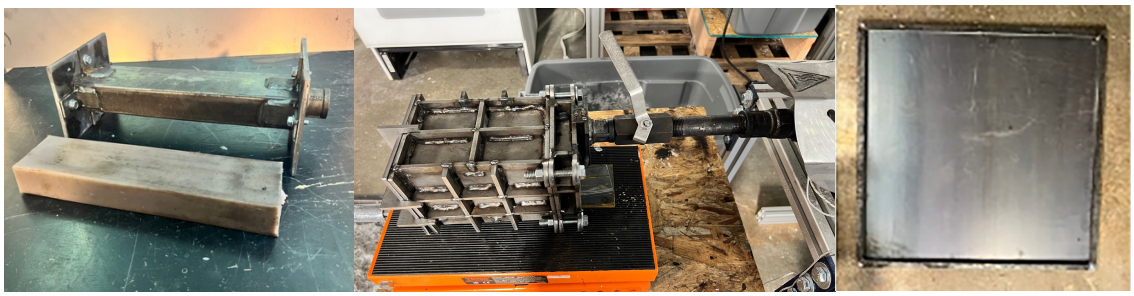

Figure 4. Molds for beams, bricks and sheets.

Finally, Figure 5 displays examples of finished products manufactured during the project. These images showcase the successful conversion of recycled stretch wrap and rPET blends into functional items such as panels, tiles, and construction bricks. The molded products provide visual evidence of the system's capacity to create usable, value-added components from heterogeneous plastic waste streams, reinforcing the technical feasibility of decentralized recycling solutions.

Figure 5. Examples of recycled parts fabricated on the equipment shown in Figure 1 – stackable blocks made from HDPE and stretch wrap (150 mm x 100 mm), beams made from stretch wrap (250 mm x 100 mm), and 900 mm x 900 mm x 6.5 mm thick sheets.

3 RESULTS AND DISCUSSION

The following sections present the thermal and mechanical characterization of recycled plastic materials processed using the stand-alone, containerized recycling system. Results are discussed in the

context of polymer compatibility, processing behavior, and the feasibility of producing durable, value-added products from post-consumer plastic waste streams. Where relevant, findings are compared with literature data and insights gained during the project to highlight both the potential and limitations of localized recycling solutions.

3.1 DSC Analysis of Stretch Wrap

DSC thermograms for post-consumer stretch wrap samples (Figure 6) revealed the thermal complexity of mixed polyethylene waste streams. Two distinct melting endotherms were observed: one around 109–114 °C, attributed to low-density polyethylene (LDPE) components, and another near 122 °C, corresponding to high-density polyethylene (HDPE) fractions. The presence of multiple melting peaks reflects the varied composition of the stretch wrap waste, which includes LDPE, LLDPE, and potentially blends with other polyolefins. Additionally, the broadness and reduced intensity of these peaks, compared to neat HDPE or LDPE, suggest lower crystallinity and possible molecular weight degradation resulting from prior processing and recycling steps, a typical phenomenon in recycled polyolefin materials.

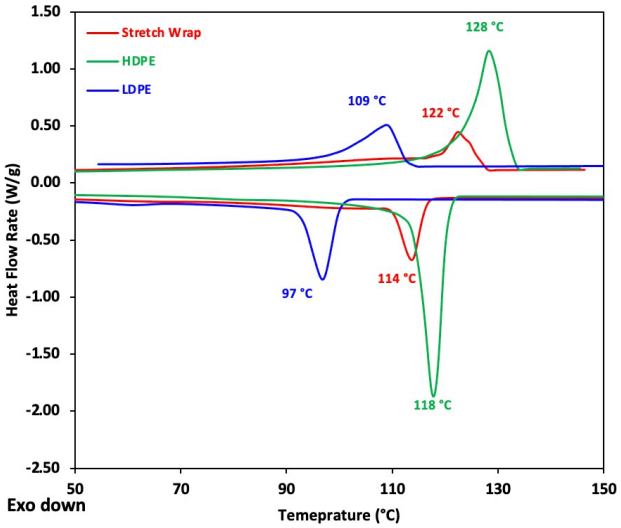

Figure 6. DSC thermograms for stretch wrap and polyethylene blends.

3.2 DSC Thermograms of rPP and rPET

DSC thermograms for recycled PET (rPET) and recycled polypropylene (rPP) are shown in Figures 7 and 8, with corresponding thermal transitions summarized in Table 1. The thermogram for rPET (Figure 7) exhibits a crystallization exotherm at approximately 187 °C and a prominent melting endotherm at 248 °C, consistent with the thermal behavior of semi-crystalline PET materials. These results confirm that the recycled PET retains significant crystalline character, suggesting it may still be suitable for remanufacturing applications requiring thermal stability.

The thermogram for rPP (Figure 8) displays multiple thermal transitions. A primary melting peak is observed at approximately 162 °C, which corresponds to isotactic polypropylene. Additionally, smaller melting and crystallization features at approximately 126 °C and 116 °C, respectively, indicate the presence of polyethylene (PE) contamination within the rPP stream. This overlapping of thermal transitions suggests partial immiscibility and heterogeneity in the recycled rPP material. Such PE contamination is common in post-consumer recycled streams and can influence both mechanical properties and processability.

These thermal analyses indicate that while both rPET and rPP exhibit recognizable melting and crystallization behavior, the presence of impurities and mixed phases, particularly in rPP, could complicate subsequent processing or blending operations. This underscores the importance of careful material characterization when designing stand-alone recycling systems to produce consistent, high-quality recycled products.

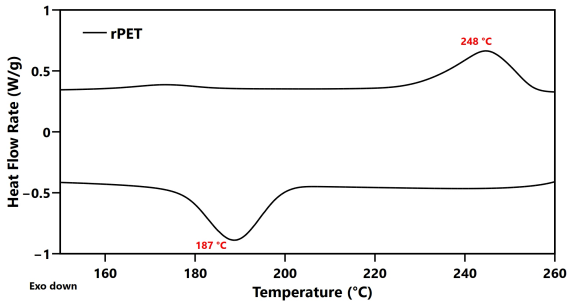

Figure 7. DSC thermogram for rPET.

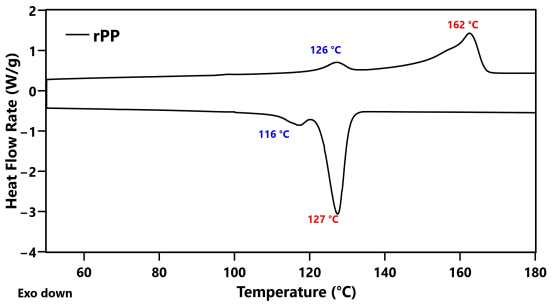

Figure 8: DSC thermogram for rPP.

Sample	Melting temperature, °C (T_m)	Crystallization temperature, °C (T_c)
rPET	248	187
rPP with PE (as a contamination)	162	127
	126	116

Table 1. Obsrved thermal transitions for rPET and rPP.

3.3 DMA Results for rPET Blends

Dynamic mechanical analysis (DMA) was conducted to evaluate the viscoelastic behavior of recycled stretch wrap materials. The time-temperature superposition (TTS) creep compliance curve for stretch wrap, shown in Figure 9, displays a steadily increasing trend over time. This behavior reflects the inherently lower stiffness and higher ductility typical of polyolefin-based films, indicating that under sustained stress, these materials exhibit significant time-dependent deformation. This is consistent with flexural test results, which showed lower modulus values for stretch wrap compared to recycled PET. For recycled PET (rPET) samples, substantial differences in viscoelastic behavior were observed depending on compatibilizer content, as shown in Figure 10.

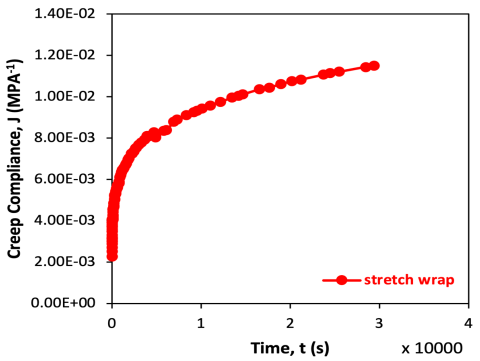

Figure 9. Time-temperature superposition (TTS) curve for stretch wrap.

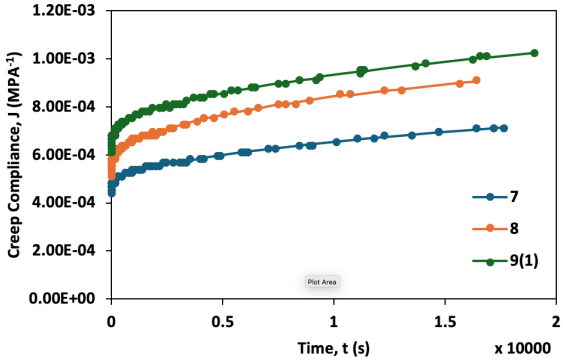

Figure 10. Time-temperature superposition (TTS) curve for rPET with and without compatibilizer (showing sample #s).

Pure rPET exhibited the lowest creep compliance, reflecting its stiff and brittle nature with minimal deformation under sustained loading. In contrast, blending rPET with Lotader AX8840 compatibilizer led to progressively higher creep compliance values. The rPET/compat 95/5 blend showed increased compliance relative to pure rPET, while the 90/10 blend exhibited the highest compliance among the samples tested. These results indicate that the addition of compatibilizer softens the polymer matrix,

enhancing ductility and flexibility but simultaneously reducing stiffness. This behavior aligns with the flexural test results, where compatibilized blends displayed increased elongation at break and lower modulus compared to pure rPET. The DMA data thus confirm that compatibilization effectively modifies the viscoelastic properties of recycled PET, improving toughness and processability at the expense of rigidity.

3.4 Compatibilization

The recycling of mixed plastic waste streams poses significant challenges due to the inherent immiscibility between different polymer types, which leads to poor interfacial adhesion and compromised mechanical properties. Studies such as those by Maris et al. [7] and Imamura et al. [8] emphasize that while compatibilization offers a promising pathway to blend polymers like PET, PP, and PE, it frequently comes with trade-offs. Compatibilizers can reduce interfacial tension and promote morphological stability, but they also often lead to decreased tensile strength and modulus, driven by disruption of crystalline domains or the introduction of softer segments into the polymer matrix. Friedrich et al. [9] further demonstrate that purely chemical approaches might be insufficient and that morphological strategies—such as creating microfibrillar structures can significantly enhance the mechanical performance of polymer blends, particularly in PET/PP systems.

Our current study mirrors many of these literature findings. The addition of Lotader AX8840 compatibilizer to rPET/rPP blends indeed led to an increase in elongation at break from 2.5% to 4.3%, signalling improved ductility and toughness. However, consistent with observations by Imamura et al. [8], we also recorded a significant reduction in flexural strength and modulus dropping from 76.8 MPa and 2810 MPa in pure rPET to 64.0 MPa and 2000 MPa, respectively, in the 10-wt% compatibilized blend. This aligns with Maris et al. [7], who highlight that compatibilizers, while beneficial for morphology, can disrupt crystalline structures and lower overall stiffness. Our DMA results similarly showed decreased storage modulus and increased creep compliance with higher compatibilizer content, underscoring this classic trade-off between toughness and stiffness in recycled polymer blends.

Despite partial improvements, our compatibilization strategy has not entirely overcome the mechanical limitations posed by mixing recycled PET with polyolefins like PP. Persistent phase separation, as evident from our DSC and morphological analyses, suggests that Lotader AX8840 alone may be insufficient for achieving a fully homogeneous blend. Additionally, the presence of contaminants such as bottle labels and caps introduces further complexity, often leading to brittleness in processed samples even when compatibilizers are used. Our results thus reflect the broader conclusion in the literature: chemical compatibilization can mitigate immiscibility but may fall short in delivering mechanical properties suitable for high-performance applications, particularly when dealing with highly heterogeneous waste streams [7–9].

To address these challenges, future research should explore combined strategies that integrate chemical compatibilization with physical morphology control. One promising avenue is microfibrillar reinforcement, as demonstrated by Friedrich et al. [9], where cold drawing transforms PET domains into fine microfibrils that enhance mechanical interlocking and stress transfer within the blend. Additionally, optimizing the concentration of compatibilizers as Imamura et al. [8] found—could balance improvements in ductility without excessively compromising stiffness, particularly if lower loading levels (~3 phr) are sufficient. Emerging approaches using nanoparticle-based compatibilizers, as noted by Maris et al. [7], also warrant investigation for their ability to migrate to polymer interfaces and stabilize morphologies. Finally, incorporating advanced sorting technologies or selective pre-treatment steps could reduce contamination levels, enabling more effective compatibilization and yielding higher-performance recycled materials. These multi-pronged strategies will be critical for enabling stand-alone recycling facilities to produce structurally viable products from mixed plastic waste streams.

3.5 Life Cycle Assessment

Beyond mechanical performance, the sustainability of recycling processes was evaluated through preliminary life cycle assessments (LCA) [6]. For stretch wrap waste, the analysis showed significant environmental benefits, with estimated savings of approximately 52,300 MJ of embodied energy and avoidance of about 558 metric tons of CO_2 emissions. These figures correspond to a 44% reduction in

embodied energy and a 13% reduction in CO_2 emissions compared to virgin material production, as illustrated in Figures 11 and 12.

Recycling PET bottles demonstrated even greater potential impact. The LCA results indicated energy savings of approximately 146,000 MJ and a reduction of about 4,900 metric tons of CO_2 emissions, translating to a 53% decrease in embodied energy and a 39% reduction in CO_2 emissions relative to virgin PET production. These improvements are also shown in Figures 11 and 12.

These analyses were based on the following assumptions regarding material composition in the waste streams: stretch wrap consisted of a 50:5:25:20 ratio of LLDPE stretch wrap, polypropylene (PP) packaging tape, LDPE stretch wrap, and HDPE packaging films, respectively. PET bottle waste was modelled as a 90:9:1 ratio of PET bottles, PP caps, and PE labels.

Overall, these findings highlight the substantial environmental benefits achievable through localized recycling operations, including reduced greenhouse gas emissions, lower energy consumption, and decreased reliance on landfill disposal or incineration in burn pits. Stand-alone recycling facilities thus offer not only technical feasibility but also meaningful contributions to resource conservation and sustainability goals [5-6].

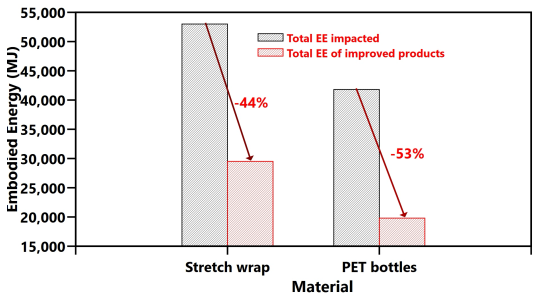

Figure 12. Embodied energy reduction for stretch wrap and PET from bottles.

3.6 Mechanical Test Results

The mechanical properties of recycled plastics are critical indicators of their suitability for producing durable, value-added products. To evaluate the structural potential of various recycled polymer systems, flexural tests were conducted on both pure materials and compatibilized blends, providing insights into the balance between strength, stiffness, and ductility achievable through recycling processes. These results are shown in Table 2.

Sample Type	Flexural Strength (MPa)	Flexural Modulus (MPa)	Elongation at Break (%)
HDPE	23.1 ± 0.5	630 ± 20	9.2 ± 0.3
LDPE	15.3 ± 0.4	420 ± 15	8.7 ± 0.4
Stretch Wrap	15.0 ± 0.6	420 ± 10	5.3 ± 0.3
rPET	76.8 ± 1.1	2810 ± 40	2.5 ± 0.2
rPET + 5% Lotader AX8840	66.1 ± 1.0	2460 ± 35	3.6 ± 0.2
rPET + 10% Lotader AX8840	64.0 ± 1.2	2000 ± 30	4.3 ± 0.3

4 FINANCIAL FEASIBILITY OF CONTAINERIZED RECYCLING FACILITIES

Assessing the economic viability of standalone, containerized materials recovery facilities (MRFs) is crucial for understanding their practical implementation, particularly in rural and remote communities. Financial analyses suggest that such systems require a minimum processing volume of approximately 400–600 tons of recyclables per year to break even, covering both capital and operational costs through

a combination of revenue from recycled material sales and savings from avoided landfill tipping fees.

The economic feasibility of these decentralized systems is highly sensitive to commodity market prices and regional tipping fees. Higher recovered material prices (≥ $100/ton) and elevated landfill tipping fees (≥ $50–$70/ton) significantly enhance the potential for a positive financial return. However, many rural communities face challenges due to lower commodity prices and reduced tipping fees, which can undermine the financial sustainability of small-scale recycling operations.

Regional collaboration emerges as a key strategy to improve economic outcomes. Small towns individually often generate insufficient recyclable material volumes to sustain operations. For instance, a low-volume town with a population of approximately 5,000 may produce only around 200 tons/year of recyclables. Under a scenario of $100/ton in revenue and avoided tipping fees, this would generate roughly $20,000 in annual benefits, insufficient to offset estimated autonomous operating and capital costs of about $40,000/year, resulting in a net loss of $20,000 annually. Conversely, a regional model consolidating materials from several communities (population ~20,000) could yield around 800 tons/year of recyclables, translating to $80,000/year in revenue and avoided costs. In this scenario, the same estimated operational and capital expenses would yield a positive net balance of $40,000/year, demonstrating clear economies of scale.

Despite advances in automation and lower labor requirements, upfront capital costs for standalone containerized systems remain significant, typically around $250,000 per unit. Consequently, grants, low-interest loans, or other financial incentives are often essential for rural communities with constrained municipal budgets to establish such facilities. Overall, while standalone containerized MRFs show promise for sustainable waste management, their deployment is most viable in regions where collaborative collection networks can be established, commodity markets are stable, and external funding support is available to bridge the gap between capital investment and operational profitability. This analysis is shown in Table 3.

Parameter	Low-Volume Town	Regional Model
Population	5,000	20,000
Tons/year recyclables processed	200	800
Annual revenue + avoided tipping fees ($100/ton)	$20,000	$80,000
Autonomous O&M + capital cost per year	~$40,000	~$40,000
Net annual balance	–$20,000	+$40,000

Table 3. Financial Analysis of Standalone Containerized Recycling Facility Scenarios.

*Autonomous O&M" refers to estimated annual operation and maintenance costs for largely automated recycling systems, excluding significant manual labor costs.

5. CONCLUSIONS

This study demonstrates the feasibility of producing value-added products from post-consumer plastic waste using stand-alone, containerized recycling systems. Stretch wrap waste, composed primarily of mixed polyolefins, was successfully processed into molded products such as sheets and bricks, albeit with lower mechanical properties compared to engineering polymers. Recycled PET (rPET) displayed significantly higher stiffness and strength; however, blending rPET with polyolefins presented challenges due to inherent immiscibility. The use of Lotader AX8840 compatibilizer improved ductility and elongation at break in rPET blends but resulted in reduced flexural strength and modulus, highlighting the classic trade-off between toughness and stiffness in recycled polymer systems.

Thermal analyses via DSC confirmed the presence of multiple melting transitions in stretch wrap materials, indicating their heterogeneous composition, and revealed retained crystallinity in recycled PET suitable for processing applications. Dynamic mechanical analysis further demonstrated the impact of compatibilizer content on creep compliance, underscoring its role in modifying viscoelastic behavior and mechanical performance.

Life cycle assessment indicated substantial environmental benefits for decentralized recycling operations. Recycling stretch wrap waste could save approximately 52,300 MJ of embodied energy and reduce CO_2 emissions by 558 metric tons, while PET bottle recycling offers even greater savings of about 146,000 MJ and a reduction of 4,900 metric tons of CO_2 emissions, compared to virgin material production. These results support the environmental sustainability of localized recycling solutions.

Financial analyses revealed that while standalone containerized recycling facilities are technically feasible, their economic viability depends heavily on processing volume, market conditions, and regional collaboration. Smaller communities may not generate sufficient material to sustain operations independently, emphasizing the importance of pooling resources and securing financial support through grants or subsidies to offset capital and operational costs.

Overall, this work highlights both the technical potential and the challenges associated with decentralized recycling of mixed plastic waste streams. Future research should explore advanced compatibilization strategies, process optimization, and scalable economic models to enhance the viability of localized recycling systems and contribute to circular economy goals.

ACKNOWLEDGEMENTS

The authors would like to acknowledge funding support from the U.S. Army SBIR Phase I program under Contract No. W51701-23-C-0246, and from the National Science Foundation through the I-Corps Teams project "I-Corps Carpet-Polyolefin Recycled Composites R-Polyblend" (NSF Award No. 2414963). The authors also gratefully acknowledge Ms. Abigail Rice of the U.S. Army Corps of Engineers, Illinois, for her guidance and technical discussions during the course of this work.

Keywords: Recycled Carbon Fibre, Filament Winding, UD Composites, Mechanical Testing, Sustainability

ABSTRACT

High-performance composites are integral to aerospace, automotive, and renewable energy sectors, but their reliance on virgin carbon fibres poses significant environmental and economic sustainability challenges globally. While recycled carbon fibres (rCF) offer a more environmentally friendly solution, their discontinuous nature significantly limits their mechanical performance, restricting their application in high-performance recycled carbon fibre-reinforced polymers (rCFRP). This study addresses this critical limitation by introducing and fully characterizing a novel continuous rCF material that retains fibre continuity, enabling superior mechanical performance and broadening the range of applications for rCF in demanding engineering contexts.

This research fills a significant knowledge gap by being the first to comprehensively characterize the mechanical properties of rCFRP manufactured with continuous rCF reclaimed from end-of-life carbon/epoxy Type III pressure vessels. The continuous rCF was produced using a thermal recycling technology, which stripped the polymer matrix, allowing the rCF to be unwound and tow length to be retained. Unidirectional (UD) panels were fabricated using a custom filament winding process optimized to achieve high fibre alignment, fibre volume fractions, and uniform resin distribution.

Mechanical testing of the panels, including tensile (ASTM D3039), compression (ASTM D6641), flexural (ASTM D7264), and short-beam shear testing (ASTM D2344), revealed that the mechanical properties of continuous rCFRP match or exceed those of industrial-grade virgin carbon fibre composites. Comparative analysis with virgin fibres (T700S-50C-12K and T300-50B-6K) showed that continuous rCF composites achieve performance metrics positioned between high-strength T700 and industrial-grade T300 composites. These results demonstrate that the retention of fibre length and alignment in continuous rCF directly addresses the performance limitations associated with conventional discontinuous rCF.

By demonstrating that continuous rCF can achieve performance comparable to standard virgin carbon fibre composites, this study establishes a critical pathway for integrating recycled fibres into high-performance applications. The enhanced directional properties, comparable fibre volume fractions, and

compatibility with existing manufacturing processes make continuous rCF a transformative material for sustainable engineering.

1 INTRODUCTION

The global demand for carbon fibre (CF) was estimated at 115 kilotonnes (kt) in 2023 and is projected to more than double to 280 kt by 2030 [1]. This growth is driven by the widespread use of carbon fibre-reinforced polymers (CFRPs) across sectors committed to decarbonisation, particularly transportation, renewable energy, and hydrogen storage. In the wind energy sector, CFRPs are increasingly used in multi-megawatt turbine blades due to their exceptional stiffness-to-weight ratio. As a result, wind energy is expected to surpass aerospace as the leading consumer of carbon fibre, with estimated demand reaching 20 kt for wind turbine blades alone [1][2].

Similarly, in the hydrogen economy, CFRPs are critical for constructing lightweight, high-pressure storage vessels. These composites improve safety and transport efficiency while reducing system weight. Currently, the pressure vessel segment accounts for approximately 12% of global CF demand and is poised for significant expansion alongside the hydrogen sector [1][3][4].

Despite its performance benefits, carbon fibre production is highly energy-intensive, contributing up to 50% of the total carbon footprint of offshore wind turbine blades [5]. Globally, CF manufacturing results in over 4 million tonnes of CO_2-equivalent emissions each year [6]. At the end of their service life, CFRP components present substantial recycling challenges. Most recycled carbon fibre (rCF) is recovered in chopped or discontinuous forms, which compromises fibre alignment and mechanical performance. Consequently, applications for rCF remain limited to non-structural or low-performance uses, reducing its commercial value and its ability to offset virgin CF consumption.

A key step toward a circular composite economy is the development of recycling technologies capable of retaining fibre continuity. Continuous rCF has the potential to deliver mechanical performance comparable to virgin fibre composites, enabling structural applications and reducing the environmental impact of CFRP systems. This study investigates such a solution focusing on the manufacturing and mechanical characterisation of unidirectional (UD) composites made from continuous recycled carbon fibre.

The reclaimed fibres in this study originate from end-of-life Type III carbon/epoxy pressure vessels and are recovered using a thermal process that preserves fibre length. Through a custom filament winding process, these fibres are reconstituted into continuous UD laminates and benchmarked against virgin fibre panels. The goal is to demonstrate that continuous rCF can close the performance gap that has historically limited recycled composites, and thereby support scalable, high-value reuse of CFRPs in demanding structural applications.

2 MATERIALS AND METHODS

Panel fabrication was performed using a flat mandrel system designed to simulate industrial-grade unidirectional layups. To ensure repeatability, each batch used identical processing conditions, and samples were drawn from the same tool. Environmental controls during resin infusion (ambient humidity and temperature ~22°C) were maintained to limit variability. Post-processing included oven curing and standardised trimming to generate test coupons according to ASTM specifications.
Recycled carbon fibre was recovered from end-of-life Type III carbon/epoxy pressure vessels using a thermal recycling process. This method effectively removes the matrix while retaining the fibre tow length and orientation. The reclaimed fibres were processed into continuous tows suitable for filament winding. Two virgin fibre grades (T700 and T300) were used as benchmarks. An epoxy system, Araldite LY556 with Aradur 917 hardener and accelerator DY070—was used for both reclaimed and virgin fibre panels.

3 MANUFACTURING PROCESS

The filament winding process (Figure 1) was executed on a modified flat-panel mandrel to enable consistent unidirectional (UD) layering. The process required precise environmental control, as the resin system's viscosity and curing profile are highly temperature-dependent. The resin bath was equipped with an immersion heater and maintained between 50–60°C to ensure optimal flow and wet-out characteristics. A tensioning system ensured even fibre delivery, while programmable creel rotation and mandrel speed facilitated the accurate layering of fibres. To improve panel quality, wide flash tape and square rubber rope were used around mandrel edges to minimize resin leakage and edge defects. The introduction of a reinforced PTFE film as a release layer helped mitigate warpage and surface irregularities caused by mandrel thermal expansion. Banding trials were crucial to establish the correct number of layers and minimize tow overlap, which could lead to increased void content or fibre misalignment. Vacuum bagging followed immediately after winding, ensuring thorough compaction and air evacuation during curing. The wrapped mandrel was cured in a Carbolite Gero oven with thermocouples for thermal tracking.

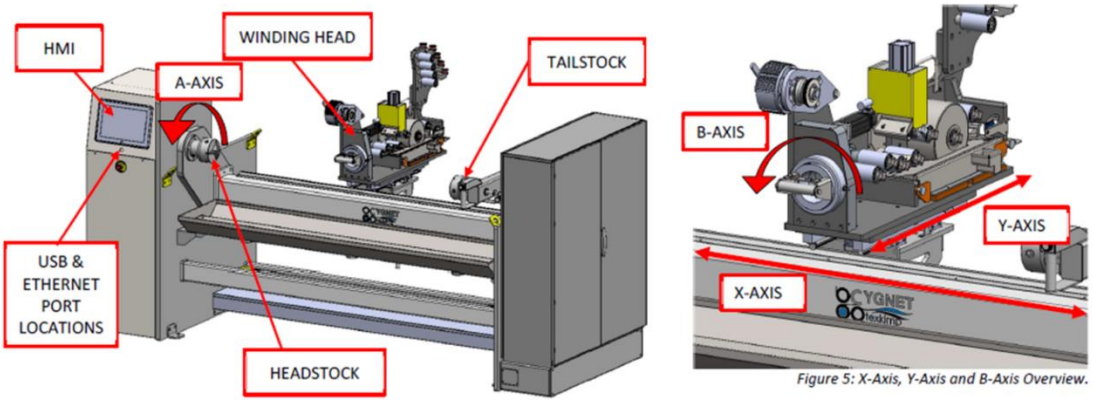

Figure 1: Filament Winding Schematic

Flat panel filament winding was used to manufacture unidirectional (UD) composite panels. The winding mandrel was treated with Frekote 700NC release agent and lined with Tooltec CS5 PTFE film. Bandwidth trials ensured consistent tow coverage and panel thickness. The resin bath was preheated to 50°C with nip pressure set to 0.5 bar and fibre tension at 10 N/tow. During winding, defects such as tow fluff, splicing, char deposits, and entanglement were observed (Figure 3). Excess resin was allowed to drip off before caul plates were bolted on, and vacuum bagging was performed before curing in a Carbolite Gero oven.

4 MECHANICAL TESTING

The mechanical testing program adhered to internationally recognized ASTM standards and focused on characterizing different failure modes and load responses. Test listed in Figure 2 were performed to characterise the vCF and rCF UD Panels. Tensile testing utilized dogbone specimens with hydraulic wedge grips to avoid slippage, and extensometers were mounted to measure axial strain directly. Compression tests used anti-buckling fixtures to stabilize the specimen and ensure valid compressive failure modes. Flexural tests were performed in three-point bending mode, with supports modified to account for composite anisotropy and prevent stress concentration at the loading nose. Short beam shear (SBS) testing was used to assess interlaminar shear strength (ILSS), providing insight into fibre-matrix adhesion and resin distribution. Each test was performed on a minimum of five specimens to ensure statistical validity. X-ray computed tomography (XCT) scans were conducted pre- and post-test to

investigate internal failure mechanisms such as delamination, fibre pull-out, and void evolution. Test data were plotted as stress-strain curves and benchmarked against the performance of virgin CFRP panels under identical conditions.

Mechanical characterisation followed ASTM standards: tensile testing (ASTM D3039), compression (ASTM D6641), flexural (ASTM D7264), and short beam shear (ASTM D2344). Non-destructive testing was performed using X-ray CT scanning to examine internal defects, fibre distribution, and porosity. Key test parameters included dogbone specimens for tensile tests and torque-controlled gripping to prevent slippage or misalignment.

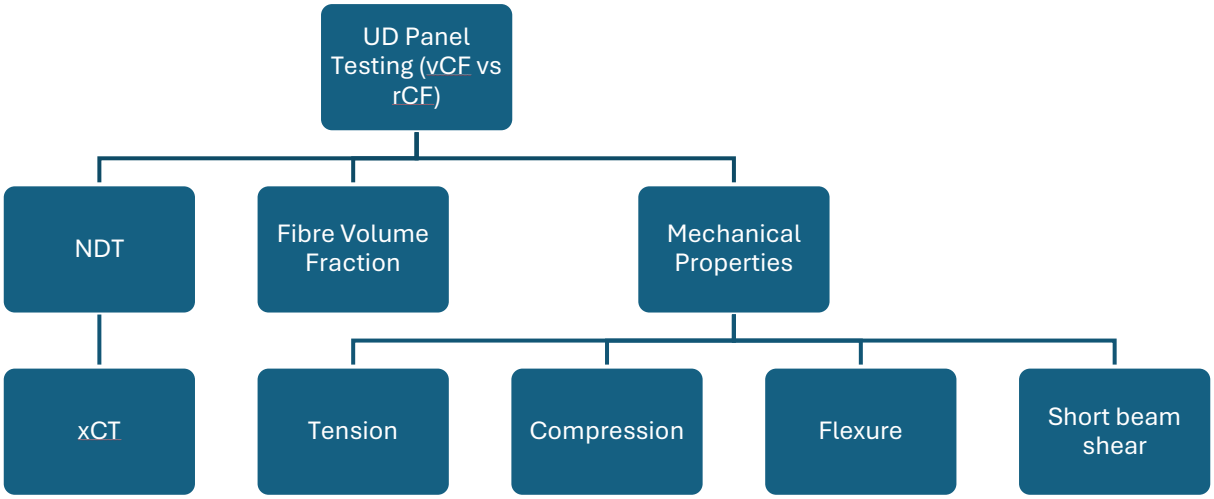

Figure 2: Tests performed on vCF and rCF UD Panels

5 RESULTS AND DISCUSSION

During the filament winding process of reclaimed carbon fibres, defects such as tow fluff, splicing, char deposits, and entanglement were observed (Figure 3).

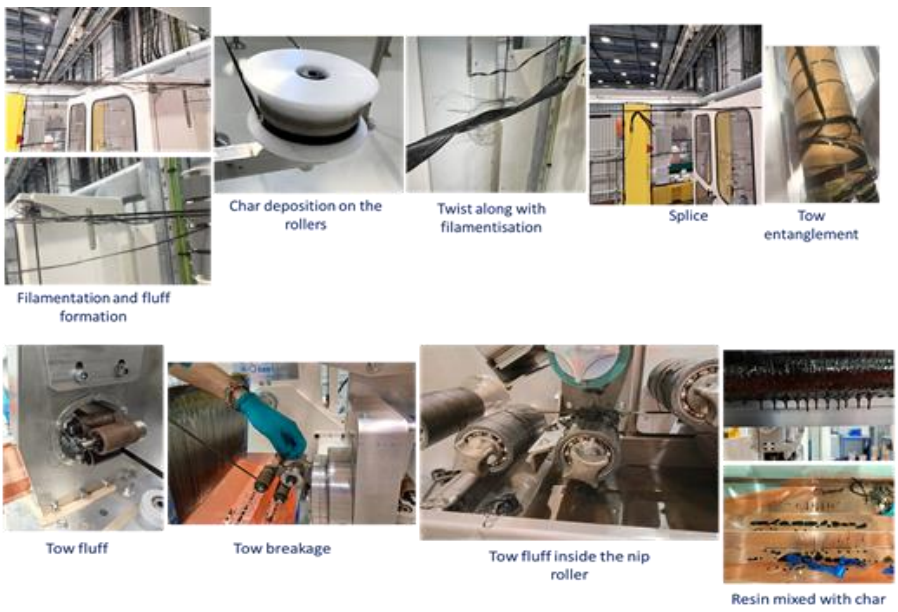

Figure 3: Defects observed with reclaimed carbon fibre filament winding process

CT scan analysis revealed consistent internal structures in virgin and recycled panels. The fibre volume fraction (Vf) was highest in T700 panels (64.7%), followed by T300 (60.8%), and reclaimed rCF panels (46.3%). Mechanical properties of continuous rCF panels showed intermediate performance, positioned between T700 and T300, proving their capability for high-performance applications. Despite the challenges with wet winding heads, towpreg-based manufacturing improved consistency and reduced defect incidence. Fluff formation and tow breakage were the primary causes of irregularity. Panels demonstrated sufficient integrity for structural applications with good matrix-fibre interaction and fibre alignment.

The tensile properties of continuous rCF composites were found to be within 10–15% of T300 virgin panels, indicating a significant improvement over conventional discontinuous rCF. Compression strength also showed promising results, with the rCF panels demonstrating good fibre alignment and minimal buckling artifacts. The flexural modulus and strength values confirmed the stiffness and energy absorption potential of the material. Short beam shear tests revealed that while interfacial strength was slightly lower in rCF composites, the values remained within acceptable engineering margins. XCT analysis of cured panels indicated low porosity levels (~3–5%), especially in panels fabricated using the towpreg head. Defect mapping through XCT visualisation showed uniform fibre distribution and fewer voids in virgin panels, but reclaimed fibre panels exhibited consistent morphology post-winding. Failure surface examination revealed fibre pull-out and matrix cracking in rCF panels, whereas virgin panels showed more brittle failure. Overall, the mechanical performance supports the suitability of continuous rCF for structural applications, particularly in cost-sensitive sectors seeking sustainability.

6 CONCLUSIONS

This study demonstrates that continuous recycled carbon fibre composites manufactured through filament winding can achieve mechanical properties comparable to commercial virgin fibre composites. Optimisation of winding parameters and defect control is essential to ensure quality. The results validate continuous rCF as a viable and sustainable alternative for high-performance composites, enabling integration into critical sectors such as aerospace and automotive manufacturing. Future work will focus on further automation, improved quality control, and performance under environmental ageing and fatigue loading.

ACKNOWLEDGEMENTS

The authors gratefully acknowledge the support of the National Composites Centre for providing access to equipment, expertise, and facilities. Special thanks to the development and engineering teams involved in winding, processing, and testing.

Quantification of Alignment Quality of Aligned Discontinuous Fibers using 2D-FFT (Fast Fourier Transform)

John J. Tierney, Alex Vanarelli, John Morris, Shridhar Yarlagadda, John W. Gillespie Jr.
Center for Composite Materials, University of Delaware, Newark DE 19716

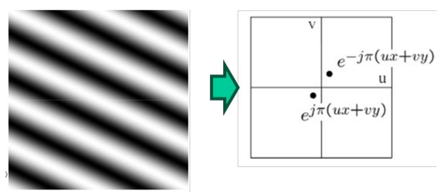
Introduction

- Highly aligned discontinuous fiber composites developed at UD-CCM called TuFF (Tailorable Universal Feedstock for Forming) produces formable aerospace grade properties equivalent to continuous fiber composites.
- The manufacturing process creates a dry bed of aligned fibers at low areal weight that needs to be quantified for alignment quality
- 2D FFT (Fast Fourier Transform) creates a frequency domain representation of an image and can be used to observe order and orientation within the microstructure.
- This effort looks to enable in-line QA-QC measurement of fiber alignment using FFT light-transmission processed images.

FFT Theory

Definition

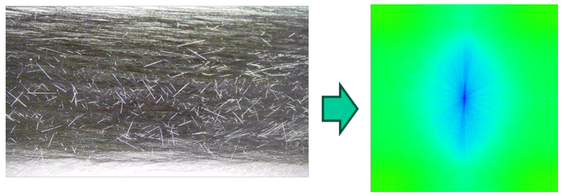
$$F(u,v) = \int_{-\infty}^{\infty}\int_{-\infty}^{\infty} f(x,y)e^{-j2\pi(ux+vy)}\,dx\,dy,$$
$$f(x,y) = \int_{-\infty}^{\infty}\int_{-\infty}^{\infty} F(u,v)e^{j2\pi(ux+vy)}\,du\,dv$$



where u and v are spatial frequencies.

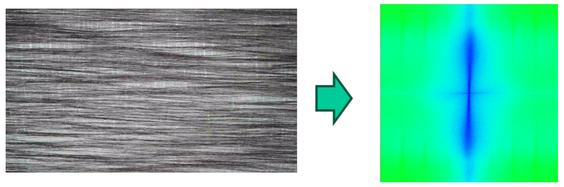
Also will write FT pairs as $f(x,y) \Leftrightarrow F(u,v)$.

- $F(u,v)$ is complex in general,

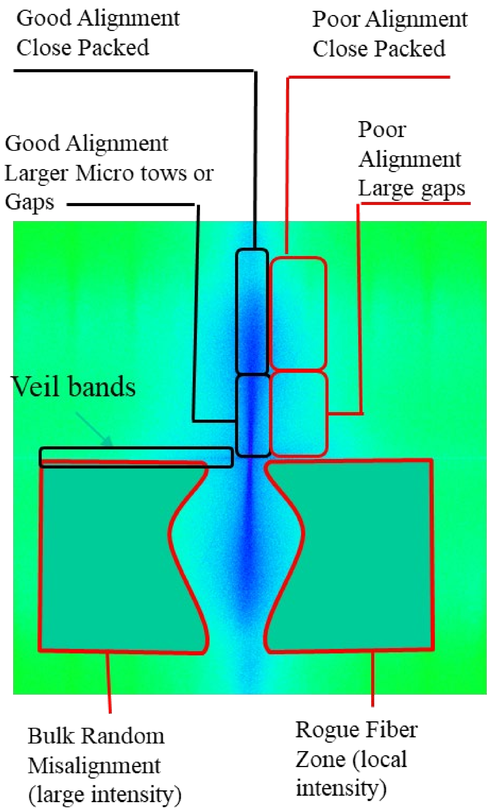


$$F(u,v) = F_{\mathrm{R}}(u,v) + jF_{\mathrm{I}}(u,v)$$

- $|F(u,v)|$ is the magnitude spectrum
- $\arctan(F_{\mathrm{I}}(u,v)/F_{\mathrm{R}}(u,v))$ is the phase angle spectrum.
- Conjugacy: $f^*(x,y) \Leftrightarrow F(-u,-v)$
- Symmetry: $f(x,y)$ is even if $f(x,y) = f(-x,-y)$

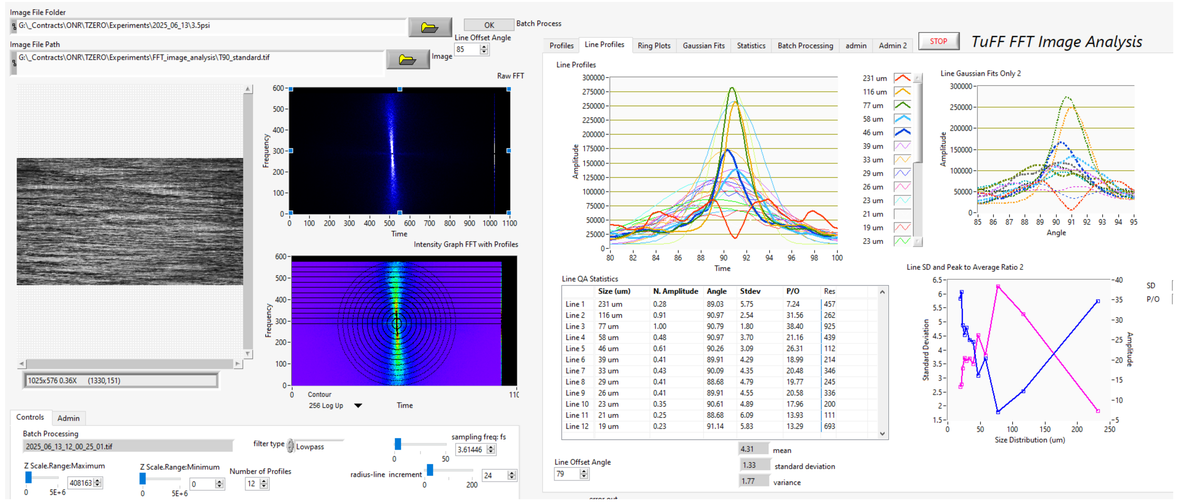


FFT Processing of TuFF

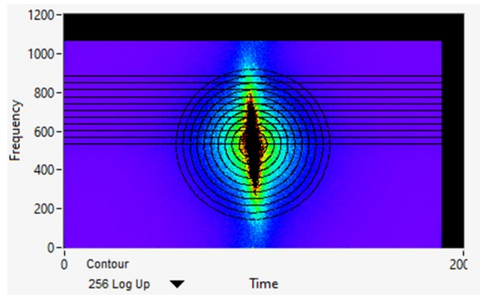


Poorly Aligned TuFF material

Highly Aligned TuFF material



2D-FFT intensity spectrum indicates the overall alignment quality of the material based on the intensity and 'shape' of the frequency domain



In-Line QA-QC Inspection Software

- LabVIEW based Software for real-time in-line alignment quantification
- Line profiles at different frequencies show alignment at different length scales from bulk to filament level based in image resolution
- Software captures entire production datasets for process repeatability and consistency

Post Processing Data

- Profiling the FFT image resolves alignment at multiple length scales based on image resolution

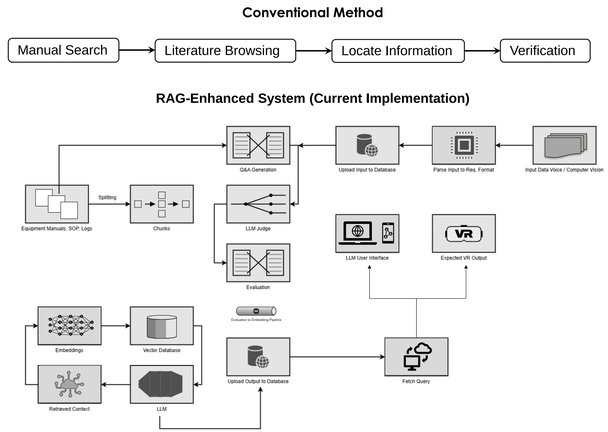
Intelligent Manufacturing Support: Specialized LLMs for Composite Material Processing and Equipment Operation

Kevin Mora-Gonzalez, Komal Chawla, Seokpum Kim — Oak Ridge National Laboratory



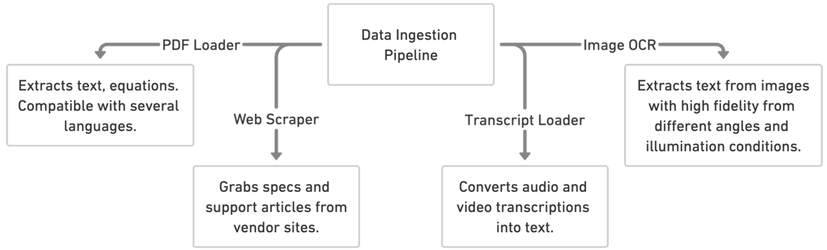
Introduction

- **Manufacturing Equipment Challenges**
  - Manuals are distributed across multiple PDF files and formats
  - Equipment troubleshooting requires immediate, accurate information
  - Operators need instant access to specifications, procedures, and safety protocols
  - Critical documentation often lacks remote or mobile accessibility
  - Operators face challenges accessing immediate specifications and procedures, leading to increased training costs due to traditional search limitations
  - Expert technicians' knowledge is not consistently recorded or easily shared

Objectives

1. Provide instant, contextually-aware answers from equipment manuals
2. Implement AI-powered validation of source document relevance
3. Deploy secure network tunneling for global accessibility
4. Accelerate troubleshooting through intelligent query processing
5. Improve operational efficiency and reduce downtime

Overview



System Architecture

Core Components

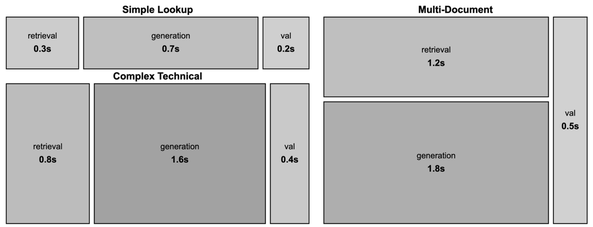
Component	Technology	Function
Document Processing	PyMuPDF, NLTK, Mistral OCR, Whisper API	PDF extraction, image OCR, audio transcription, and chunking
Vector Storage	FAISS	High-performance similarity search
Embeddings	mxbai-embed-large	Semantic vector generation
Language Models	Ollama (Llama3.2, Mistral Large 2, Gemma3)	Answer generation and reasoning
Citation Validation	Semantic similarity, Cross-encoder, BERT	Source relevance verification
User Interface	Streamlit	Interactive web application
Networking	ngrok	Make the system available to specified networks or public

- **Data Ingestion Layer**

- **Indexing Layer**
  - Chunks documents into 200-500 token passages
  - Embeds chunks via Ollama embeddings API
  - Stores embeddings in FAISS for fast similarity search
- **Retrieval Layer**
  - Accepts user query, and applies basic preprocessing
  - Executes k-nearest neighbor search on FAISS index
  - Returns top-k passages ranked by cosine similarity
- **Large Language Model Layer**
  - Integrates diverse Ollama models for flexible, cost-efficient deployment
  - Feeds retrieved passages plus query into RetrievalQA chain
  - Facilitates semantic search via vector embeddings
  - Pipeline ingests and indexes vast proprietary data into vector store for efficient, updated information retrieval

RAG System Evaluation

- **Traditional NLP Metrics**

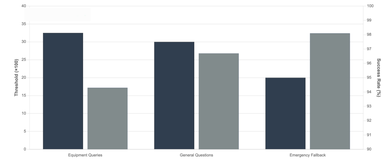


Metric	Score	Function	Benchmark
F1 Score	0.847	Token-level precision and recall	0.75+ (Good)
BLEU	0.723	N-gram overlap with reference answers	0.60+ (Acceptable)
ROUGE-L	0.812	Longest common subsequence matching	0.70+ (Good)
BERT Score	0.889	Semantic similarity using BERT embeddings	0.80+ (Very Good)

- **Hallucination Detection**

Metric	SelfCheckGPT BERT Score	SelfCheckGPT NLI
Score	0.891	0.934
Function	Consistency across multiple generations	Natural Language Inference contradiction detection
Benchmark	0.85+ (Very Good)	0.90+ (Excellent)

This RAG System Evaluation outlines a comprehensive methodology, utilizing traditional NLP metrics like F1 Score (0.847), BLEU (0.723), ROUGE-L (0.812), and BERTScore (0.889) to assess text generation quality. Hallucination detection is also rigorously performed using SelfCheckGPT BERTScore (0.891) and NLI (0.934) for consistency and contradiction checks.

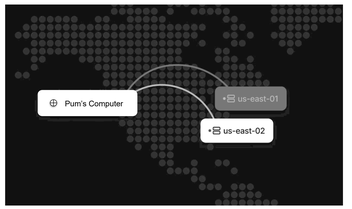


- **Response Time Analysis**

Treemap presents a 'Response Time Analysis' for different query types, detailing average time (in seconds) and its breakdown into retrieval, generation, and validation, with an overall average response accuracy of 89.2% on technical equipment questions. Simple lookups average 1.2 seconds, complex technical queries 2.8 seconds, and multi-document queries 3.5 seconds, each with proportional component contributions.

Citation Validation Framework

- **Validation Performance**
  - The citation validation achieved an average accuracy of 92.4%
  - False positive rate was <8%, effectively filtering irrelevant results
  - Processing overhead remained under 2 seconds per query
  - Emergency fallback activates when citation relevance falls below the set threshold



This dual-axis bar chart shows confidence thresholds and success rates for three citation validation applications, where the first bar represents confidence threshold ranges scaled by 100 and the second bar shows success rate percentages. Equipment Queries use higher thresholds (0.25-0.40) for safety critical operations, while Emergency Fallback uses lower thresholds (0.20+) to maximize availability, achieving success rates from 94.3% to 98.1%.

Method	Purpose	Weight	Technology	Validation Score
Semantic Similarity	Conceptual Relevance	40%	Sentence Transformers	0.876
Cross-encoder	Deep Contextual Analysis	35%	RoBERTa based score	0.902
BERT Score	Token-level similarity	25%	Contextual embeddings	0.889

$$R_{\text{BERT}} = \frac{1}{|x|} \sum_{x_i \in x} \max_{\hat{x}_j \in \hat{x}} \mathbf{x}_i^\top \hat{\mathbf{x}}_j$$

Network Tunneling Implementation

- **Security and Performance**
  - Tunnel establishment typically takes less than 3 seconds
  - Bandwidth capacity supports multiple concurrent users
  - Utilizes HTTPS encryption with TLS 1.3 via ngrok for secure data transmission
  - Ensures 99.9% availability with auto-reconnect, quickly applying critical codebase changes for continuous uptime
  - Latency overhead ranges from 2 to 60 milliseconds, varying by user location. Controlled access management, allowing specification of tunnel access and IP-based content locking

Performance & Cross Platform

- **System Capabilities**
  - Processes over 100 PDF manuals and polymer literature simultaneously, allowing for fast information access
  - Supports multiple simultaneous queries and it is scalable
  - Offers full functionality across smartphones, tablets, and computers, independent of their operating system

Limitations and Future Work

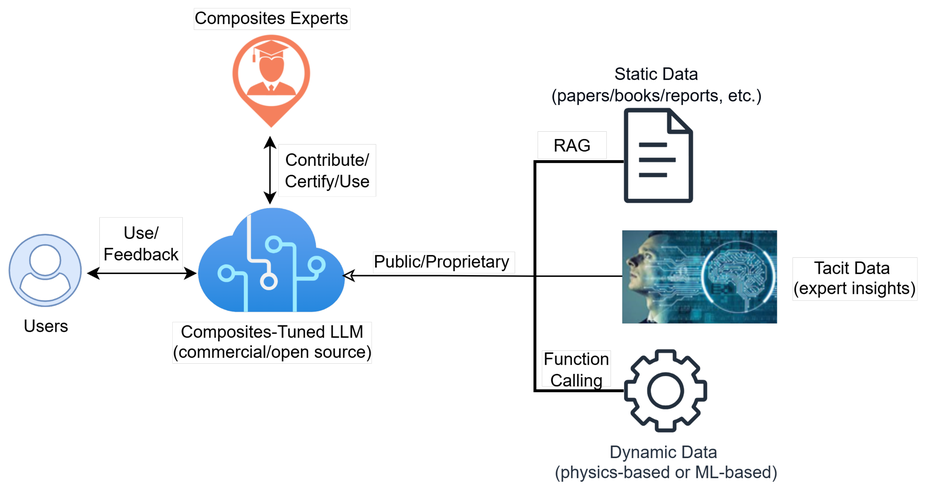
- Local inference performance is constrained by host GPU machine capabilities
- Future work explores Virtual Reality integration, allowing manufacturing users immersive access to documentation
- Addressing potential knowledge gaps within specialized or emerging equipment documentation

CompositesAI™

An AI-Powered Expert System for Composites

Try me at CompositesAI.com

OVERVIEW **CompositesAI consolidates and delivers expert knowledge through LLMs fine-tuned for composites. It delivers answers with authority of world-leading experts and precision of advanced simulation codes.**



Challenges

➢ Access to data and resources

- ❑ Static data: technical papers, books, reports, database, etc.; siloed and disparate sources
- ❑ Dynamic data: physics-based models, machine learning models; disconnected and not available for entire supply chain
- ❑ Expensive computing hardware and software
- ❑ Some in public domain (commercial or free) and some proprietary

➢ Access to talent

- ❑ Most composites engineers lack formal training in the field. Composites-related typically courses taught at graduate level
- ❑ PhDs needed for executing sophisticated composites software for reliable simulation
- ❑ PhDs trained in narrow subdomains, multiple PhDs needed for the entire production workflow, not affordable for lower tiers of the supply chain (SMEs)

Solutions by Composites AI

➢ Large language model (LLM)

- ❑ Leverages general knowledge, intelligence, and natural language processing capabilities of LLM
- ❑ Is designed to be LLM-agnostic, ensuring seamless integration with emerging and advanced models
- ❑ Delivers highly technical knowledge through intuitive, natural language chat prompts

➢ Retrieval-augmented generation (RAG)

- ❑ Consolidates multimodal, publicly available static data using a federated vector database
- ❑ Optimizes RAG by applying best practices in data storage, chunking, retrieval, and ranking
- ❑ Intelligentizes proprietary corporate knowledge within a private and secure environment

➢ Function calling

- ❑ Integrates simulation software through APIs
- ❑ Enables automatic execution of simulation codes and linking them into seamless workflows
- ❑ Democratizes simulation by chats, eliminating complexity of preparing inputs and interpreting outputs
- ❑ Performs parametric studies and optimization automatically, requiring simple prompts without extra coding

➢ Human-in-the-loop reinforcement learning

- ❑ User provides questions and feedbacks
- ❑ Admin reviews user feedbacks and assign experts to reviews
- ❑ Expert reviews feedbacks and generates new knowledge as structured questions-pairs
- ❑ CompositesAI updates with the new knowledge

➢ Versatile front end

- ❑ Signup/Login using email, Google, Microsoft, or LinkedIn
- ❑ Ask questions using text or voice in your own language
- ❑ User can provide detailed responses including numerical score, reason, and text comments
- ❑ Different users can access to different customized models

➢ Ecosystem for community development

- ❑ Powerful workspace allows expert to create their own AI assistants (private, or shared with others)
- ❑ Model-agnostic design allows experts to experiment with different models
- ❑ A marketplace for all the agents developed by experts.
- ❑ User-friendly interface for experts to submit knowledge & tools

CMSC Composites Manufacturing & Simulation Center™

A Typical Use CASE (Simulation using Prompts)

An engineer needs to determine the relative difference between the longitudinal and transverse shear moduli of UDFRC but lacks the expertise to operate FEA-based multiscale software such as SwiftComp. CompositesAI bridges this gap by allowing engineers to obtain accurate results without needing to learn or run complex simulation codes. By understanding the engineer's intent, CompositesAI identifies the appropriate computational tool, gathers the necessary inputs through natural, intuitive prompts, and delivers results efficiently and precisely.

for a unidirectional fiber reinforced composites, I would like to know G13 and G23, do you have a tool to help me compute it?

CompositesAI

Yes, I have a specialized tool that can compute the shear moduli G_{13} and G_{23} (as well as other engineering constants) for unidirectional fiber-reinforced composites. This tool requires the following inputs:

Fiber and matrix elastic properties (E, ν or full set if anisotropic)
Fiber volume fraction
Packing arrangement (e.g., hexagonal, square)

If you provide:
Fiber modulus (E_f) and Poisson's ratio (ν_f)
Matrix modulus (E_m) and Poisson's ratio (ν_m)
Fiber volume fraction (V_f)
Packing type (default is hexagonal if not specified)

I can obtain G_{13} and G_{23} for your system. Please supply the above inputs or confirm if you want to use prior examples.

isotropic fiber with E=300 GPa, nu=0.3; isotropic matrix with E=20 GPa, nu =0.4, hexagonal, Vf=68%

CompositesAI

View Result from **homogenize_elastic_constants**

For a unidirectional fiber-reinforced composite with isotropic fibers ($E_f = 300\,\text{GPa},\ \nu_f = 0.3$), isotropic matrix ($E_m = 20\,\text{GPa},\ \nu_m = 0.4$), hexagonal packing, and a fiber volume fraction of 68%, the calculated shear moduli are:

$G_{13} = 28.86$ GPa
$G_{23} = 31.58$ GPa

These values are computed using physics-based homogenization methods appropriate for your specified microstructure and constituent properties.

Your numbers are a bit high. Try Ef = 231 GPa, Poisson's ratio of the fiber is 0.35. Em = 4 GPa, Poisson's ratio of matrix is 0.3.

CompositesAI

View Result from **homogenize_elastic_constants**

For a unidirectional fiber-reinforced composite with the following properties:

Isotropic fiber: $E_f = 231\,\text{GPa}, \nu_f = 0.35$
Isotropic matrix: $E_m = 4\,\text{GPa}, \nu_m = 0.3$
Hexagonal packing, fiber volume fraction $V_f = 68\%$

The computed shear moduli are:

$G_{13} = 7.50\,\text{GPa}$
$G_{23} = 7.21\,\text{GPa}$

These values reflect a physically realistic shear response for your specified composite system.

Powering the Global Composites Community

cdmHUB Community

- **Vision:** to be the premier resource for composites design and manufacturing
- **Mission:** to convene and serve the global composites community by creation, education, evaluation, and sharing of resources for composites design and manufacturing

WRAPTOR BAMBOO TRUSSES: QUANTIFYING THE IMPACT OF CULM GEOMETRY VARIATION ON BENDING PERFORMANCE

Matthew Enrico Lillywhite, Terence Macquart, Byung Chul Kim, and Benjamin King Sutton Woods

Bristol Composites Institute, University of Bristol
Queens Building, University Walk, Bristol BS8 1TR, United Kingdom
Email: matthew.e.lillywhite@bristol.ac.uk

Keywords: Natural Materials, Composite Trusses, Bamboo

ABSTRACT

Full culm bamboo is a natural material which could be used as the primary constituent as elements in efficient truss geometries that could subsequently be used to assemble larger hierarchical spaceframes. Using bamboo in such structures removes limitations on bamboo constructions imposed by the natural size and shape of the grown plant that cannot be controlled. Traditional truss manufacturing methods are unsuitable for bamboo as it is comprised of longitudinally aligned fibres prone to splitting, thus the Wrapped Tow Reinforced (WrapToR) truss manufacturing process, originally developed for fibre reinforced polymers, is adapted here. WrapToR produces composite material trusses via winding a continuous composite tow around pultruded tubes mounted on a mandrel. If bamboo were to be substituted for the pultruded tubes, the innate geometric variation between and within bamboo culms will cause challenges in truss winding and performance prediction of WrapToR trusses. A non-concentric circle culm model of bamboo culms is developed here to measure and represent this geometry variation. This method operates at a middle fidelity between simpler prismatic estimations of shape and higher fidelity measurements of the full 3D geometry. It uses physical measurements from a bespoke rig to estimate circular cross sections of a culm at regular length intervals, which are then lofted into a full culm. These models are then used to provide geometry responsive path planning for the winding machine, and are also used within finite element analysis to provide estimates for individual culm bending performance and full WrapToR truss performance. The FEA models are then validated against data gathered from mechanical testing.

1 INTRODUCTION

An ever increasing focus on the development of sustainable construction methods has motivated research into the use of bamboo as an alternative material in buildings and infrastructure. Historically, bamboo was widely used for construction throughout its naturally occurring range, but today it is usually overlooked in favour of more common materials such as concrete, steel, masonry, and timber [1]. The primary advantage of using bamboo is that it has mechanical properties competitive with timbers, whilst having a faster growth rate, reaching maturity within 3-5 years [1,2]. Faster replenishment time of construction material provides environmental benefits such as lower levels of deforestation, as less land is required to grow the same amount of material [2]. These factors have recently lead to a resurgence in research into the use of bamboo and its usage has been demonstrated in a variety of showcase applications [2,3,4].

The stalk or ‘culm’ of the Bamboo plant can be used directly ‘as harvested’ as tubular beam like elements, or they can be split down into smaller segments and reformed into composites to allow more geometrical freedom. Using the full culm as a beam can be advantageous, allowing for the utilisation of the efficient natural structure of bamboo as a thin walled, hollow tube comprised of longitudinally oriented fibres. The limitation of using full culm bamboo is that the size and shape of what can be built are limited by the size of culm that can be grown. The material properties of bamboo, while impressive for natural materials, are also lower than conventional construction materials such as steel, further reducing what applications that it is suitable for.

The efficient structure of bamboo culms can be leveraged by using them as members in truss or space frame structures. Trusses takes advantage of highly non-linear structural scaling laws by putting small amounts of material into localised members which are spaced far away from each other, allowing them to balance large forces and bending moments with minimal stress. These members are also loaded axially which suits the structure of full culms. However, there is still a limit on the size, stiffness, and strength of the individual elements of these trusses stemming from the growth size limitations of the culm. In order to make larger and more highly loaded structures, one promising approach is the use of hierarchical space frames (HSFs), where the beam like members of the larger truss or spaceframe are themselves made from trusses. These truss beams could be made from longitudinally aligned bamboo culms that are held apart from each other by some form of shear web structure. These truss beams would have much higher second moment of area, and therefore stiffness and strength, than the culms on their own, and would therefore provide a way around the limitations on size and shape imposed by natural growth. These truss beams could then be connected together to form HSFs with a significant amount of design freedom with regards to size, geometry, and load carrying capacity. The key enabling element to this concept of bamboo based HSFs is the ability to quickly and efficiently manufacture truss beams from bamboo culms.

1.1 Wrapped Tow Reinforced Composite Trusses and Space Frames.

Similar work on attempting to fully utilise impressive properties of structures comprised of longitudinally oriented fibres has been conducted for the Wrapped Tow Reinforced (WrapToR) method which produce efficient truss structures from advanced composite materials such as carbon fibre reinforced polymer (CFRP) or glass fibre reinforced polymer (GFRP). WrapToR is an adapted form of filament winding, where composite pultruded tubes are mounted on a rotating mandrel where a single wetted composite tow is wound around the mounted pultruded tubes. The wetted composite co-cures to the surface of the pultrusion and forms a rigid truss beam such as the one shown in Figure 1. Because the WrapToR process only utilises adhesive co-curing and no physical fasteners, stress concentrations forming at fastener holes that propagate into large cracks are not seen in WrapToR trusses. WrapToR minimises the complexity of composite assembly, offering a simple, automated method of producing composite trusses.

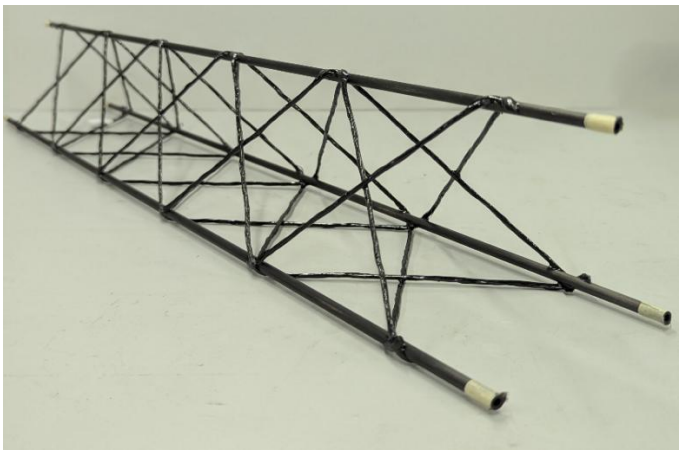

Figure 1: Wrapped Tow Reinforced truss.

The structural performance of WrapToR trusses has to date mostly been explored within the context of lightweight, high performance aerospace structures made from carbon fibre reinforced polymer (CFRP) [5,6], where it has shown exceptional performance. For example, outperforming unidirectional pultruded carbon fibre reinforced polymer tubes of a similar mass in a three-point bending test by 1006% in terms of stiffness and 181% in terms of maximum load at failure. WrapToR achieves this performance through its geometry by spacing the chord members far from the centre of the truss, maximising second moment of area, and therefore bending rigidity, for the same mass. The orientations of the fibres for both the chord members are also aligned in the axial direction for each member, which is the optimal direction

for this type of structure, which helps to get the most of the material used. Furthermore, the WrapToR method imparts a twist to the tow during winding in order to change the tow's shape from a thin ribbon into a circular cross section, increasing the buckling resistance of the wound shear members and the load carrying capacity of the truss beam [6]. Hierarchical space frames made from CFRP WrapToR truss beams have been previously explored using numerical modelling and structural optimisation [7].

1.2 Bamboo WrapToR HSFs: Potential and Challenges

The fundamental geometric advantages provided by WrapToR truss beams should be transferable to natural materials, given the top-level similarities in the structure of bamboo and pultruded composite tubes. A bamboo WrapToR HSF carries multiple advantages over using only a bamboo culm as a singular beam member. Because the truss beam geometry significantly increases the stiffness and strength of the bamboo material, while also loading the culm in a way which is very well suited to its inherent structural design, WrapToR HSFs can help mitigate the discrepancy in material properties between bamboo and other construction materials, especially when considered in a mass normalised manner. Another potential advantage of WrapToR bamboo HSFs would be the fundamental scalability of the design. If a comprehensive method of joining trusses together is developed, trusses can be assembled end to end allowing truss beam to be lengthened. This modular approach eliminates the issue that full culm bamboo structures are limited by the size and shape that they can be grown at. The WrapToR method also has advantages over conventional trusses as it is a simple, rapid and automated production method. In conventional truss structures many individual smaller elements must be carefully manufactured and then carefully assembled, a process which typically carries a high time and labour cost. In contrast, a WrapToR beam is composed of only 4 parts, the three chord members and the continuously wound shear web. A full truss winding can be carried out quickly by an automated machine and then left to cure [8].

However, significant challenges, particularly the geometric variation of bamboo culms, must be addressed before bamboo can be effectively used in WrapToR trusses. Geometric variation, both between different culms and across individual culms is a challenge that has to be solved to get the most performance out of bamboo in a WrapToR truss. As with all natural materials, geometric variation occurs as part of the growth process and cannot be fully predicted, controlled or prevented. In other natural materials that are more commonly used, for example timber, geometric variation is handled via sawing logs down into standardised and regularly shaped sections. Conventional sawing or machining processes are less useful for bamboo because the structure of bamboo culms is predominately a thin-walled tube, so the size of solid members than can be cut out of them are small.

Geometric changes such as changes in tube diameter and wall thickness; the number and position of nodes; or naturally occurring bends in the material will all have some effect on the overall stiffness and load bearing capacity of the culm. Furthermore, variation will also cause difficulty in the winding process for WrapToR trusses. The WrapToR winding process is controlled via G-code and open-loop control of the motors, hence the machine is 'blind' to the mandrel and the chord's mounted positions [8]. This means that the quality and accuracy of the winding is determined by the initial position of the chord members. In a regular composite pultrusion WrapToR truss the chord members are prismatic, and such the winding path can be easily calculated through simple trigonometry because the points of contact between the shear members and chord members are consistently placed. In WrapToR trusses with bamboo chord members path calculation is not trivial as the positions of the chord member and shear member connections change, dependent on the unique variation of the bamboo culm used. Furthermore, any combination of three bamboo culms each with their own variation can make manufacture difficult. An illustration of the challenge is shown in Figure 2.

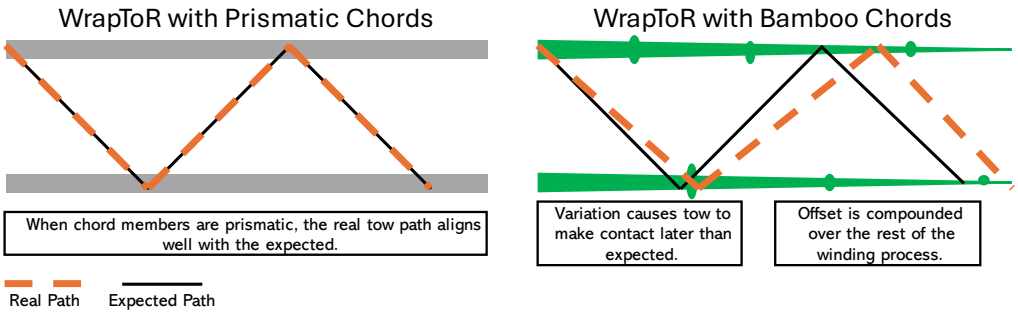

Figure 2: Winding challenges due to geometric variation

A method of capturing and representing the geometry of the culm that incorporates geometric variation will aid in addressing these challenges. Such a method should help in understanding the effects of variation on culm structural performance and allow for more precise winding within the WrapToR manufacturing process.

A simple method of culm representation is presented in the ISO standard for testing bamboo culm performance, namely BS ISO 22157. This approach takes two perpendicular measurements of culm width from an area in between two nodes, then assume a thin-walled tube with a diameter equal to the average of the two measurements [9]. This approximation does not effectively represent the geometry in a manner that would allow for the winding challenges depicted in Figure 2 to be solved, thus a higher fidelity model is required here. Higher fidelity approaches have been considered in other work, for example the use of a laser scanner to capture the full three dimensional outer geometry of bamboo culms, which were used within the computer aided design of a bamboo structure [10]. While this method captures the surface geometry in full, allowing for all the required analysis to be undertaken, it requires specialist equipment such as a full-field 3D laser scanner and actuating robotic arm control [10], and takes significant time to capture high quality scans [11]. Furthermore, these scans tend to be computationally expensive to use in analysis due to the large size of data sets created.

In order to better balance the fidelity of the geometry representation against the amount of effort required to create and use it, this work introduces a non-concentric circle culm model for bamboo culm geometries that sits at an intermediate fidelity. It is intended to be accurate enough to capture the first order impact of the geometry while also being significantly easier and faster to measure than a full laser scan, while also producing much smaller data sets that are easier to use within numerical modelling. The following section details how the non-concentric circle culm model measures and captures the geometry of bamboo culms. We then compare finite element analysis models, produced from the captured geometry to physical bending tests conducted on the scanned culms to assess the effectiveness of the models and to determine whether non-concentric circle based models can predict performance better than simple prismatic models. We then conduct the same study on manufactured trusses to determine its effectiveness for modelling the bending performance of WrapToR truss beams made with the measured bamboo culms.

2 NON-CONCENTRIC CIRCLE CULM MODEL

In the non-concentric circle culm model, the cross section of the culm at any point along its length is approximated as a circle, with the culm itself being composed of many linked circles of various sizes and positions. The centres of these circles are not assumed to be colinear however, instead the effective centre of each circle is measured in three-dimensional space, allowing for curvature and other discontinuities along the length of the culm. Therefore, this approach is able to capture the diameter changes and lack of straightness that are typical of bamboo culms. The calculated circles are lofted together to produce the model of the culm surface.

The bespoke rig used to take the surface measurements is shown in Figure 3. This rig is comprised of five different potentiometers and a sliding mount to hold the culm at a fixed reference location. In this rig physical potentiometers are used although precision single point laser distance sensors may also be appropriate. As shown in Figure 3, four potentiometers (5V Gefran PY2-50, Gefran) are mounted on a circular frame at the centre of the rig. Because the positions of each of the four potentiometers is fixed and known, this establishes a reference area where the measurements taken can be related to a cartesian position within the area, where the centre is taken to be the origin. The fifth potentiometer is a CD50S string potentiometer which records the longitudinal position of the culm. An Arduino control board was used which provided a resolution of 0.05 mm with the four surface measurement potentiometers and a resolution of 1 mm for the string potentiometer. This provides measurements for 1000 cross sections for a 1 m culm. The mounted culm is passed through the potentiometers using the slider, and measurements are taken from each. For each cross section, five different values are obtained, four relate to the surface distance from the potentiometer mount and one value for the longitudinal position of that particular cross section along the culm.

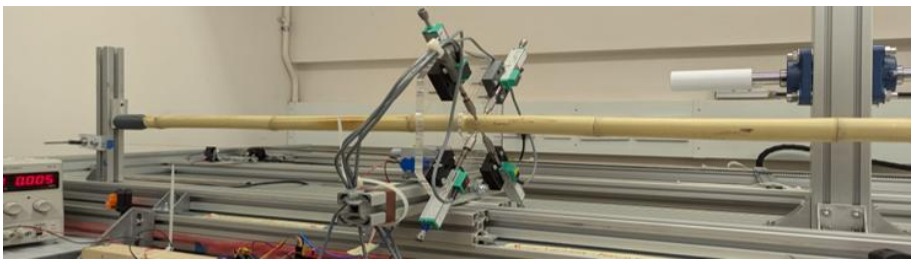

Figure 3: Bespoke culm measurement rig.

Each of the four surface measurements are related to a cartesian coordinate within a reference area defined by the known position of the potentiometers as shown in Figure 4. Three of the four coordinates calculated are substituted into the set of simultaneous equations shown in Equation 1 to define the cross section of the culm as a circle with the radius, r, and the centre of the circle (a, b).

$$\begin{aligned} (x1 - a)^2 + (y1 - b)^2 &= r^2 \\ (x2 - a)^2 + (y2 - b)^2 &= r^2 \\ (x3 - a)^2 + (y3 - b)^2 &= r^2 \end{aligned} \tag{1}$$

This process is repeated four times for each possible set of three coordinates. The final circle is calculated as the averaged from each circle produced using Equation 1. The averaged circle calculated from four measurements are taken rather than the minimum three as it is possible that certain surface features like divots are overrepresented and skew the resulting model when only three measurements are used. To create the external surface model of the culm as shown in Figure 5Figure 4, the centre of each circle is placed at its calculated position in all three dimensions. A point cloud is then generated from these stacked circles by seeding a fixed number of points around the circumference of each circle.

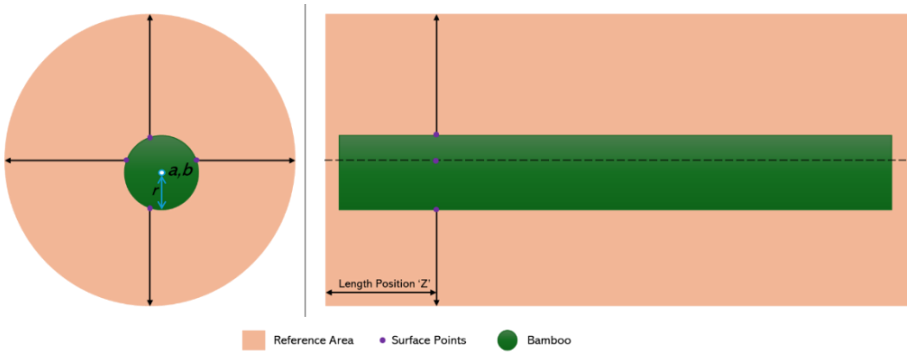

Figure 4: Representation of how measurements are taken for non-concentric circle culm model

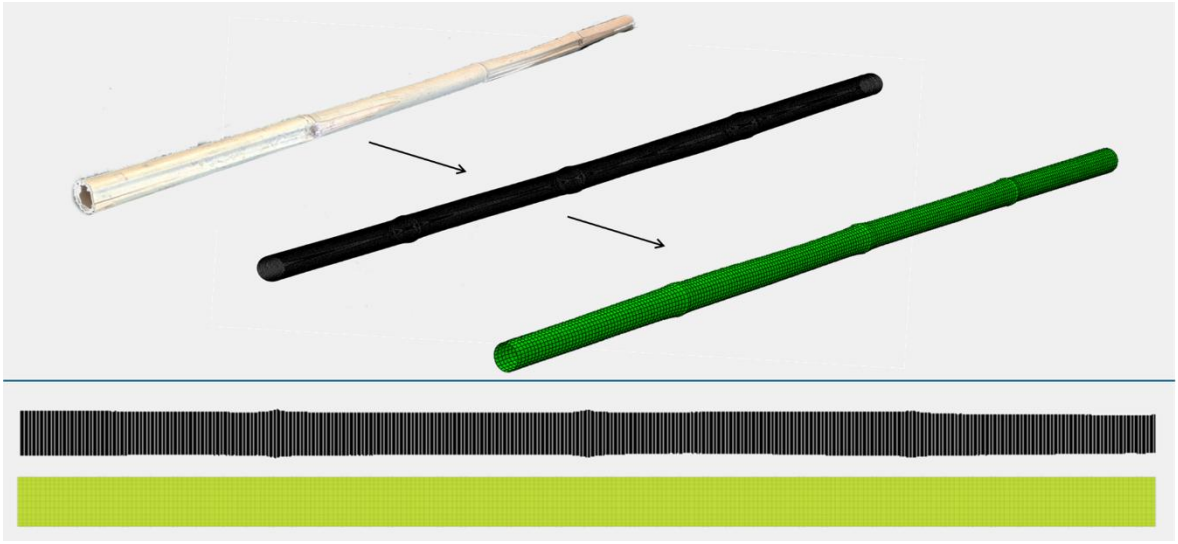

Figure 5: Top: progression from real culm to NCCM point cloud, to FEA mesh. Bottom: Comparison of NCCM model of a culm to the equivalent prismatic model

3 INDIVIDUAL CULM FEA MODELS AND VALIDATION

After using the non-concentric circle culm model to produce a point cloud that is representative of the culm geometry, the point clouds are then converted into Abaqus finite element analysis models using an automated process. A bespoke Matlab code is used to write the coordinates of the point clouds into an Abaqus input file. The meshes generated directly from the point cloud produce FEA models with high element numbers, in the order of millions, and so mesh convergence analysis was carried out to determine how much the mesh can be reduced without impacting the results of the model. This found that removing every 7th cross section and limiting the number of seeded surface points to 16 was suitable. The progression of this process and the reduced mesh size for the FEA models are shown in Figure 5

S4R shell elements were used to model the bamboo culm. Shell elements were chosen due to the desire to strike a balance between fidelity and computation time, where shell elements are significantly less expensive than brick elements in FEA. These element types are commonly used for the modelling of composite parts and as such it is sensible to use them in a ‘composite like’ material such as bamboo. It is not expected that the transverse properties of the structure will carry significant effects, especially in the load cases being tested and as such this element choice is justified. It is possible for a variety of load cases to be simulated, of particular interest has been the prediction of deflections under three-point and four-point bending loads as a means to validate the produced models against mechanical tests.

Each generated model possesses the same material properties and element types. The material properties used in the FEA models are taken from material testing done on the same batch of bamboo culms used in the validation experiments, and were tested in accordance with BS ISO 22157. The wall thickness of each bamboo culm was calculated by first determining the density of that particular culm, by measuring the mass and volume of smaller samples cut from the ends of the culm. By measuring the mass of the whole culm the volume can be calculated which can be used to determine an average wall thickness value given that the length of the culm and outer diameter are known.

3.1 FEA Model Validation

To verify the effectiveness of finite element analysis models, mechanical testing was conducted on bamboo culms of various lengths in three-point bending. In these tests the culm is suspended on two rollers and bending displacements of 20mm were imposed on each culm at the midspan point. A single measurement of displacement was taken at the lower surface on the midpoint of the culm using a

potentiometer. Moso Bamboo, with diameters 22mm to 26mm were used as these are the desired culms to be used in future WrapToR trusses. Three lengths of culm were used, 750mm, 875mm and 1000mm, to ensure that the models are valid for a range of lengths.

For each bamboo culm tested for model validation two FEA models were produced, one which uses geometry generated though the non-concentric circle culm model and the other which uses a prismatic tube geometry where the diameter has been measured in accordance with BS ISO 22157. This comparison has been made to determine if the using the scanned geometry to generate FEA models is advantageous for modelling bending behaviour for bamboo culms rather than using the established, existing methodology.

Figure 6 shows the results from 3-point testing compared to the results predicted by the non-concentric circle based FEA model and the prismatic tube FEA model. Both models are able to predict the culm's response reasonably well as demonstrated by the agreement between the three lines. The calculated bending stiffness of the culms based on the initial linear region of the deflections from both the models and experiments are shown in Figure 7. The average experimentally measured stiffness was 300.8 N/m, with a standard deviation of 73.4. This results in a coefficient of variation of 0.244, which is a relatively high value and demonstrates the variation in mechanical performance for bamboo, even in culms of the same species and roughly similar size. Of the two sets of model results, the Non-Concentric based model is more accurate to the experimental data with an average 11.8% difference in calculated stiffness, whereas the prism based models have an average difference of 21.1%. Whilst the average percentage difference is significantly different between the two models, the averages are somewhat skewed due to outliers where the prism model is very poor, specifically culms 4, 5, 6 and 7. This correlates to culms which had noticeably larger variations in their geometry, and underlies the increased importance of the higher fidelity representation when the culms themselves have more variation.

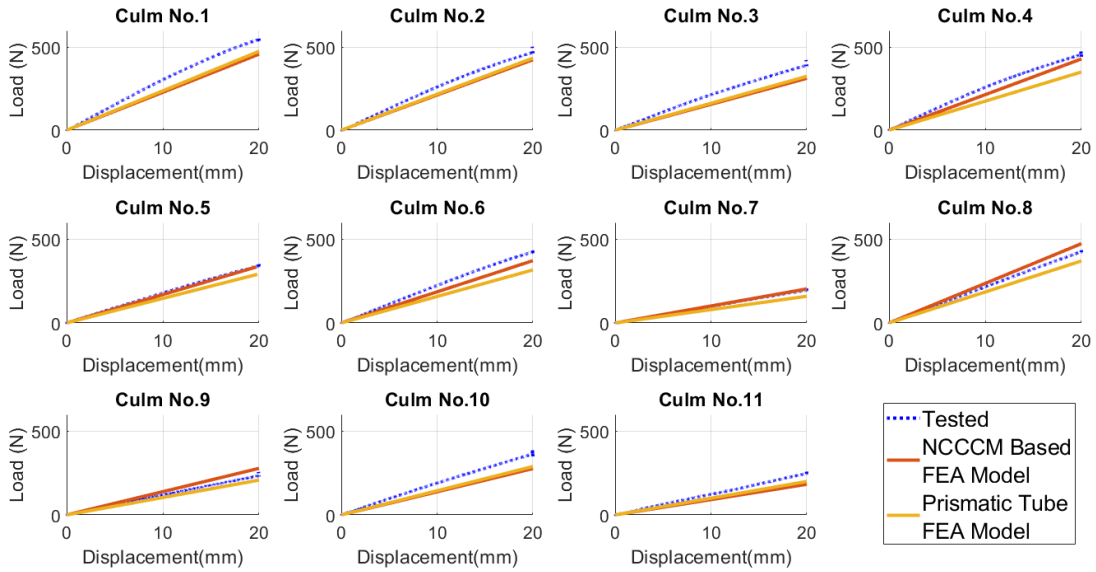

Figure 6: Load Vs Displacement for Bamboo Culms Comparison of NCC Based FEA, Prismatic Based FEA and Experimental Results

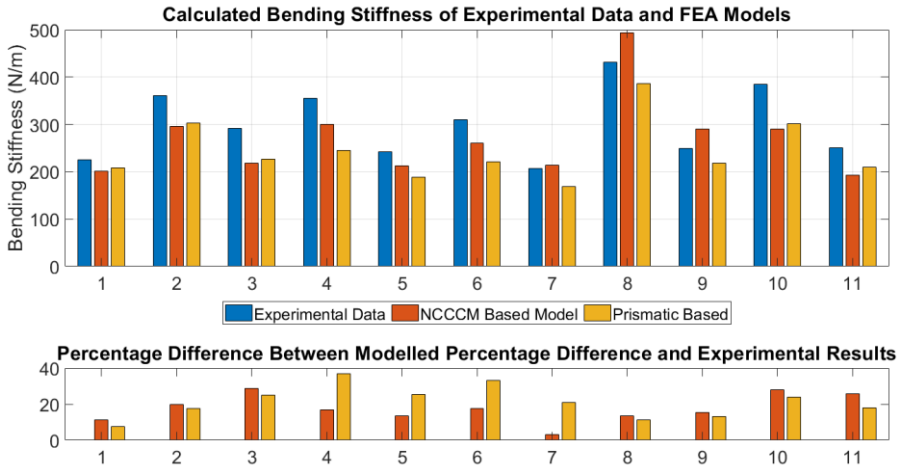

Figure 7: Calculated bending stiffness of culms and models alongside percentage differences between FEA and experiments.

An area where the non-concentric circle culm model may carry a significant benefit is in the prediction of failure loads and damage onset. The irregular geometry of bamboo culms may lead to stress concentrations developing at certain areas on the surface of the culm such as the nodes. These stress concentrations may then lead to failure onset such as a crack forming at that area. The geometry produced via the Non-concentric circle culm model will be able to more accurately determine the locations of such stress when compared to a prismatic model. This can be shown through a comparison of the modelled FEA stress maps shown in Figure 8 where the Non-Concentric circle FEA model also predicts a stress concentration at the node location. In the prismatic model the stress is evenly and symmetrically distributed across the surface and the peak value is slightly lower than what is present in the Non-Concentric circle FEA model. In order to validate this against experimental results, testing to failure would be required. This was not done as a part of these tests and exploration of this aspect of performance is left to future work.

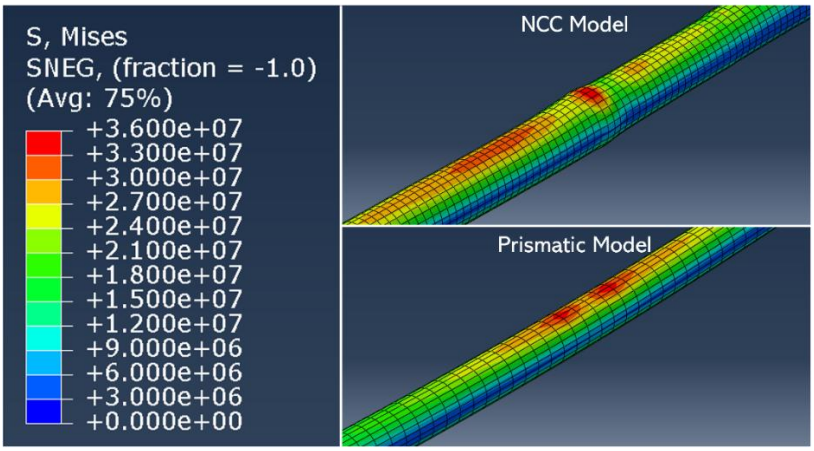

Figure 8: Stress maps from non-concentric circle and prismatic tube FEA models for Culm 5.

4 BAMBOO WRAPTOR TRUSS FEA MODELLING AND VALIDATION

WrapToR trusses have also been manufactured from bamboo culms. These trusses have been manufactured using flax fibre tow wetted out with epoxy resin for the shear members. An example of a manufactured truss is shown in Figure 9. WrapToR trusses are defined by as set of parameters which describe the geometry of each truss. These are labelled on Figure 9 and are described in

Table 1. The WrapToR geometry used for the trusses in this investigation are also shown in Table 1 and each truss was manufactured to these specifications.

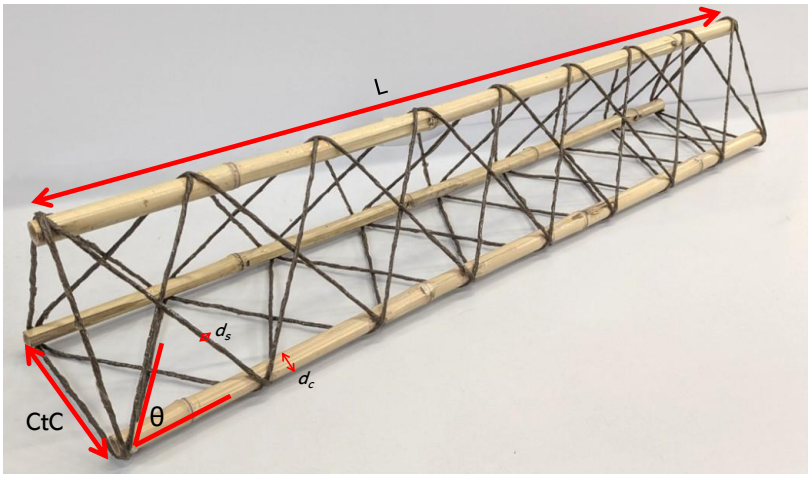

Figure 9: Wound Bamboo/Flax WrapToR truss with labelled geometric parameters.

Parameter	Symbol	Description	Value Used
Centre to centre distance	CtC	Distance between the centre of the chord member cross sections.	160 mm
Winding angle	θ	Angle between shear member and chord member.	45°
Truss Length	L	Length of truss beam.	1 m
Chord member diameter	d_c	Diameter of the chord member used.	Varies between 22mm and 26 mm
Shear member diameter	d_s	Diameter of the wound composite tow which forms the shear web.	4 mm

Table 1: WrapToR geometry parameters and parameters used in manufactured trusses.

During the manufacture of these trusses the non-concentric circle culm model was used to modify the winding process to mitigate the impact of the geometry variation. Because variation in the culm can cause discrepancies in the winding path geometry, as shown in Figure 2, care needs to be taken in the positioning of the chord members on the winding mandrel to account for this. An adjustable mandrel which allows for the culms to be tilted along its length was designed and this was used alongside a companion tool for the WrapToR winding machine which uses the non-concentric culm model to optimise the initial position of the culm. The companion tool calculates the WrapToR node position based on the combination of culm rotation and mandrel tilt. This tool calculates every possible combination and returns the set of parameters which aligns closest with the projected WrapToR node positions if the chord members were prismatic. Such an approach is not possible with a lower fidelity representation of the culm geometry which demonstrates the value of the non-concentric circle culm model for WrapToR truss manufacture.

Similarly to the individual culm tests, each culm used in the trusses was scanned for the non-concentric circle culm model and thus FEA models of these trusses have been able to be produced. Again, both prismatic tube models and those based off the non-concentric circle culm model have been developed. The models developed here differ from those used in previous WrapToR studies in that they are produced with Abaqus rather than a bespoke Matlab code. Additionally, they represent the connection between the shear members and chord members in a different way. The MSA models used previously represent the geometry of the WrapToR joint through the use of an inextensible, shear

deformable element, which offsets the shear from the surface of the chord [6]. This element is useful as it is able to represent the shear deformations in the joint itself and allow for a more accurate representation of shear member length. Because we have an actual surface rather than the beam element in the MSA code, we can map the geometry of joint more accurately onto the chord member itself. The result is a model such as that shown in Figure 10. This provides an accurate model for shear member length which is its most important geometric property. Currently this connection is only representative, with kinematic ties connecting the chord and shear members but future work will include implementation of joint mechanics which can ideally model the interactions of the adhesive joint and help predict failure due to the bond failure, which is a common failure mode for WrapToR trusses [6].

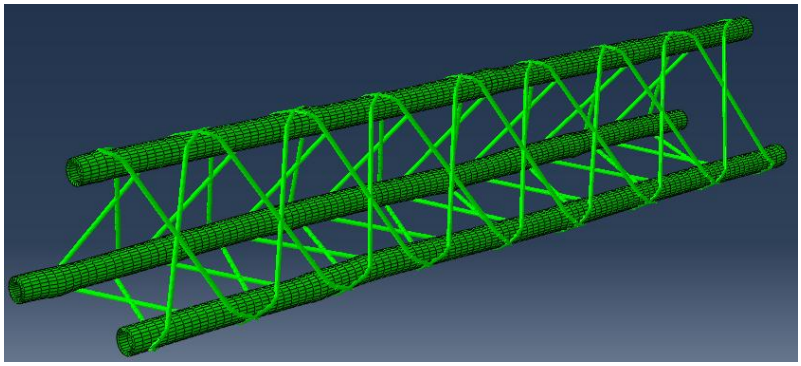

Figure 10 WrapToR model in Abaqus with accurate geometry nodes and NCC based culms.

4.1 Model Validation

Results from the FEA analysis are compared to four-point bending experiments for six different truss beam specimens. Four-point bending was chosen over three-point bending in this case due to the low aspect ratio of the trusses which promotes a shear dominated response. Because a four-point test causes an area of no shear forces between the loading points the performance in bending can be solely assessed. Four-point bending also allows for the load to be distributed across two loading points which is useful in preventing early crack propagation in a brittle material such as bamboo. Each truss was tested to failure. The results of this testing and comparative modelled responses are shown in Figure 11.

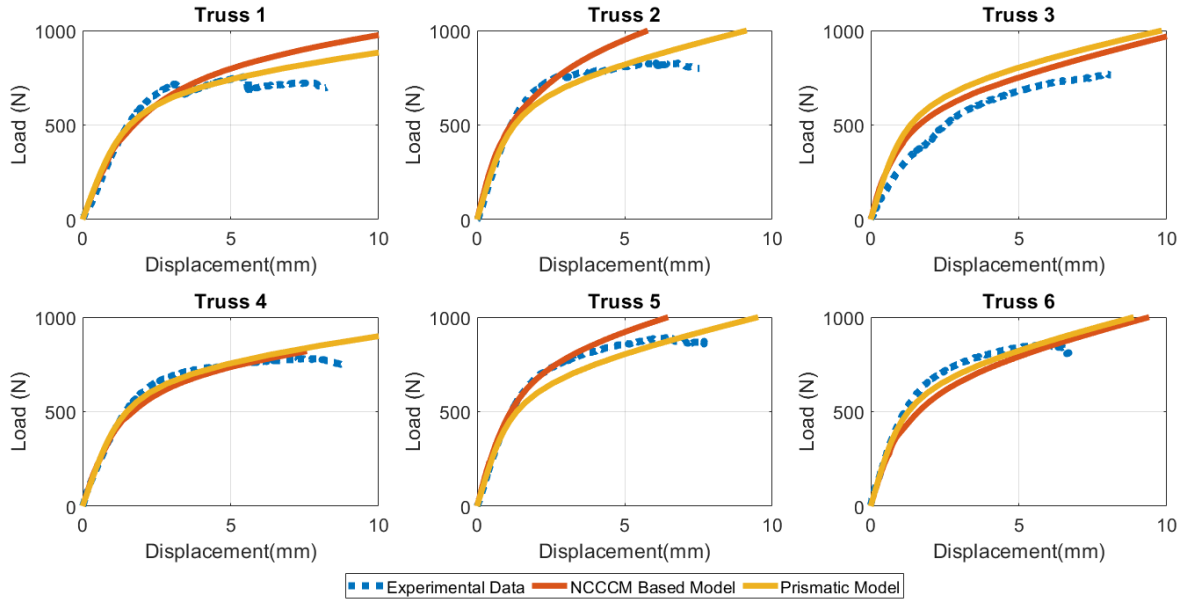

Figure 11: Results of Truss Testing

Figure 11 shows a nonlinear response in bending which is associated with the truss shear members buckling. Shear members buckling and subsequently snapping was the most common failure most observed in testing and the softening behaviour has been able to be captured by the FEA models which is a positive indication that the modelled response is accurate to the real response. Overall, the FEA models themselves are a good match to the experimental results and can predict the response of the tested trusses to a reasonable degree of accuracy. There does not appear to be a significant difference between the prismatic models and the models based on the non-concentric circle. The FEA modelled responses in the linear region seem to align very closely together which is due to the primary deformation in that region being linked to shear member deformations that are modelled very similarly between models. The tested trusses have an average initial linear stiffness of 7880 N/m with a standard deviation of 1452 N/m, resulting in a 0.1842 coefficient of variance. This is lower than the coefficient calculated from the individual culm tests, but is still high. It may be the case that the truss geometry has some moderating effect on the variance, as individual culm performance is bending dominated, whereas the culms within truss beams will generally be loaded in a more axial manner, and bending performance is more non-linear with geometry than axial performance, This inherent geometrical mitigation could be further enhanced with careful pre-selection of culms to balance out culm level variation at the truss beam level mechanical performance.

5 CONCLUSIONS

This work presents the Non-concentric circle culm model as a measurement method and representation of bamboo culms. The model takes many measurements of the distance of the truss surface to a known reference point for and calculate a circle to represent that cross section. These circles are placed at a calculated centre based on the measurements taken which captures geometric features such as pre-bends in the culm. This model has been developed for the explicit purpose of aiding manufacture and performance predictions for bamboo based Wrapped Tow Reinforced trusses.

This method has demonstrated usefulness in the manufacture of WrapToR trusses by allowing for an optimisation of the position of chord members in the mandrel to provide an even tow path during winding, resulting in more uniform, higher quality manufacture. This is an important step in the development of Bamboo WrapToR trusses which may help address current challenges surrounding bamboo construction.

The models have also been used to produce finite element analysis models of individual culms and as part of FEA models for WrapToR trusses. In both cases model validation shows that there is a good match between the prediction of the FEA models and the experimentally gathered data. There is confidence that FEA models using the non-concentric circle culm model can be used to model bamboo culm performance. On average, the non-concentric circle culm model more closely aligns with the experimental data than modelling culms as a prism suggesting that it offers a slightly better method of approximating culm performance in bending. Given the significant variation in mechanical performance between culms and trusses, the non-concentric circle culm model can be useful to help predict variation and allow for a more informed design process to take place without the need for overly conservative estimations.

There are also some indications that the non-concentric circle FEA model may be able to identify areas where there are stress concentrations which could aid in failure prediction, but more comprehensive work to gather appropriate material properties, and improve the data collection for experiments must first take place.

Keywords: Compression Molding, Additive Manufacturing, Polymer Composites, Toolpath, Finite Element Analysis

ABSTRACT

This study explores the optimization of toolpaths for short fiber polymer composite additive manufacturing (AM) printed molds in compression molding applications, an emerging trend driven by advancements in 3D printing technology. AM printed molds offer reduced tooling costs and greater design flexibility, particularly for prototyping and low-volume production. The proposed optimization approach evaluates mold performance using two key metrics: deformation and shape accuracy. Multiple toolpaths are generated, and finite element (FE) simulations capture fiber orientation and material properties, which are then integrated into a mechanical performance model. Shape accuracy is assessed by comparing the deformed mold shape with the original using surface normals as a descriptor. The analysis identifies the toolpath that delivers the best overall performance, establishing it as the most suitable option for achieving optimal mold characteristics in compression molding applications.

1 INTRODUCTION

The adoption of additive manufacturing (AM) using short fiber polymer composites for producing molds has gained traction, particularly in the context of molding applications [1, 2]. This emerging trend is driven by advancements in 3D printing technology, which offers significant advantages over traditional mold production methods. Notably, AM printed molds provide reduced tooling costs and greater design flexibility, making them ideal for prototyping and low-volume production scenarios [3, 4].

A critical aspect of additive manufacturing is the planning of the printing path, also known as the toolpath. The toolpath plays a pivotal role in determining the quality of the mold surface and its subsequent performance during use [5-7]. In this study, a novel approach to optimize toolpaths is

proposed with the aim of enhancing the performance of AM printed molds specifically designed for compression molding applications.

The optimization strategy focuses on evaluating mold performance through two essential metrics: deformation and shape accuracy. The process begins with generating multiple toolpaths for a chosen AM mold geometry and material. For each generated toolpath, Finite Element (FE)-based simulations were conducted to investigate the resulting fiber orientation and material properties throughout the mold structure. These properties were then integrated into a mechanical performance model, enabling to assess the mold's deformation under compression loading conditions.

In addition to deformation, shape accuracy was assessed by comparing the deformed mold shape to its original, as-printed form. This evaluation was accomplished using surface normals as shape descriptors, which allowed to analyze the orientation of the mold surface at various points and quantify any shape deviations.

After analyzing the deformation and shape accuracy metrics for all considered toolpaths, the toolpath that offered the best overall mold performance was identified. This optimized toolpath was determined to be most appropriate for achieving the desired characteristics of molds used in compression molding applications.

Through this work, the aim was to contribute to the field of additive manufacturing by providing a systematic approach for toolpath optimization, ultimately enhancing the efficacy of AM printed molds.

2 MATERIAL, GEOMETRY AND DISCRETIZATION

The geometry of the mold considered for the present task was a double dome. The printed double dome mold consisted of a thicker base (Fig. 1) for the purpose of maintaining a continuous toolpath during the print, however the excess material at the base is later removed or machined for obtaining the actual mold. Thus, the printed mold geometry was considered for the AM process simulation while the actual mold geometry was considered for the performance simulation.

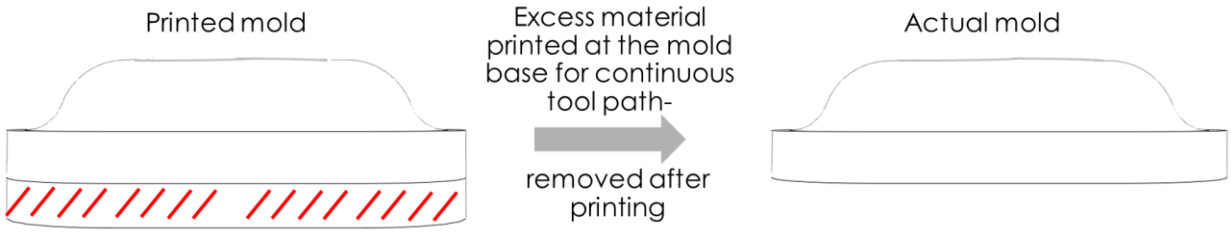

Figure 1: Illustration of the printed mold (left) and the actual mold (right) used for performance analysis.

20wt% CF/PLA was the chosen material for the numerical evaluation of the double dome structure. The double dome printed geometry was discretized for the AM simulation (Fig. 2). Accordingly, the element size for the discretization was chosen equal to the bead dimensions, with the bead height equating to the layer thickness. The same mesh was used further for the performance analysis, except that the elements making up the excess material at the base of the mold were removed.

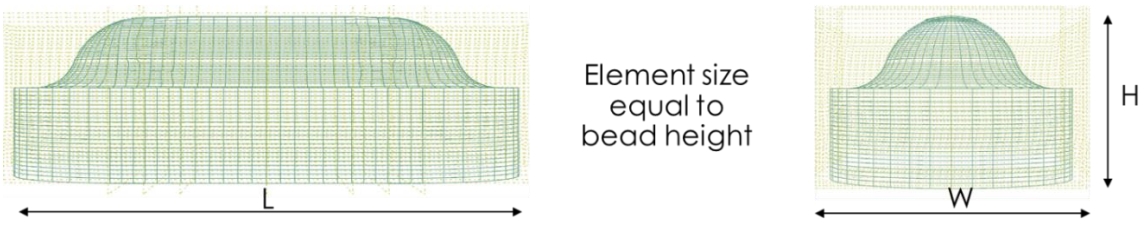

Figure 2: Discretization of printable mold, element size (~5mm) chosen equal to the bead height, overall mold dimensions, L = ~550mm, W = ~300mm, printed height H =200mm, actual mold height H’ = 150mm.

The material properties of the CF/PLA composite were determined using the MCQ chopped software [8]. Accordingly, the constituent material properties of CF (Table 1) and PLA (Table 2), along with the fiber orientation distribution for a bead thickness of 5mm (Table 3) were provided as input to the micromechanical model. The fiber orientation distribution was defined by assuming a paper-ply based approach, however a more accurate method of defining fiber orientation distribution in case of short-fiber reinforced composites is by defining a fiber orientation tensor.

Table 1: Properties of the PLA matrix required to perform micromechanical simulations.

Matrix Property		PLA
Elastic Modulus (E)	[GPa]	3.6

3 TOOLPATH AND BUILD ORIENTATION

Next, three cases of AM printing consisting of different combinations of build orientation and toolpath were selected for evaluation. The three cases were termed H0, H90 and V90 where ‘H’ or ‘V’ referred to a horizontal or vertical build orientation and ‘0’ or ‘90’ referred to the toolpath in x or y direction (Fig. 3). Note that each figure was enlarged to show the toolpath representing the material orientation.

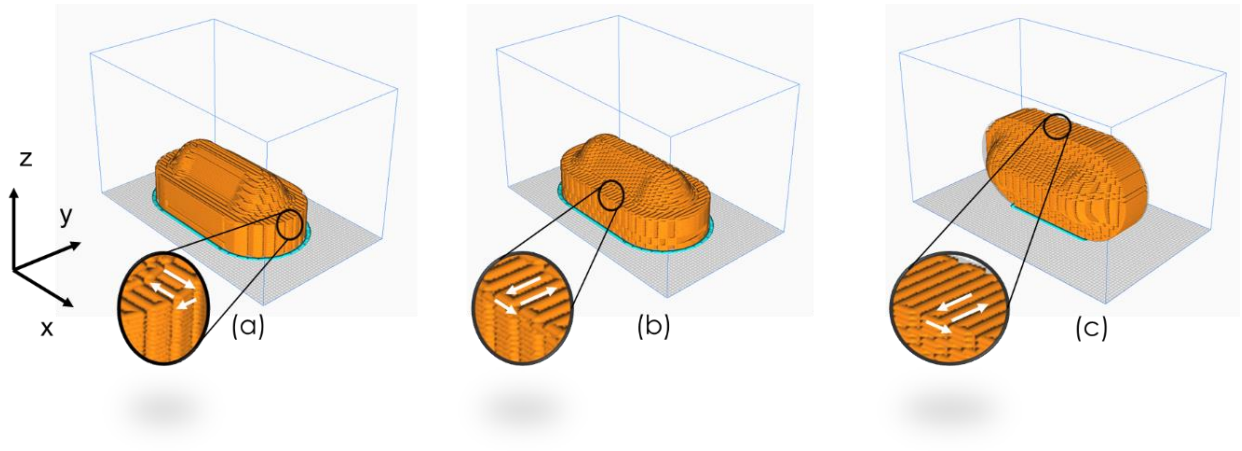

Figure 3: Printed mold configurations (a) H0, (b) H90, and (c) V90 used for performance evaluation.

The first step in the evaluation of the above cases was the determination of their elemental material orientation. Due to the tortuous nature of the toolpath used for the AM process, the material coordinates change as a function of the toolpath. This was captured in the AM process simulation such as each element was assigned to a local coordinate system that defined the material deposition

direction. Further, the elements of the discretized geometry that intersected the toolpath were activated during the process simulation. Only those active elements were assigned the local coordinates in the process simulation. Thus, for each of the three cases, an AMs process simulation was performed to determine the active elements in the model and to obtain their local coordinates.

In each of the cases, more than 99% of the elements were determined to be active and their local coordinates were extracted in a text file using a python script. This data was then incorporated into the input file for the performance analysis. The material orientation for the three cases can be seen in (Fig. 4).

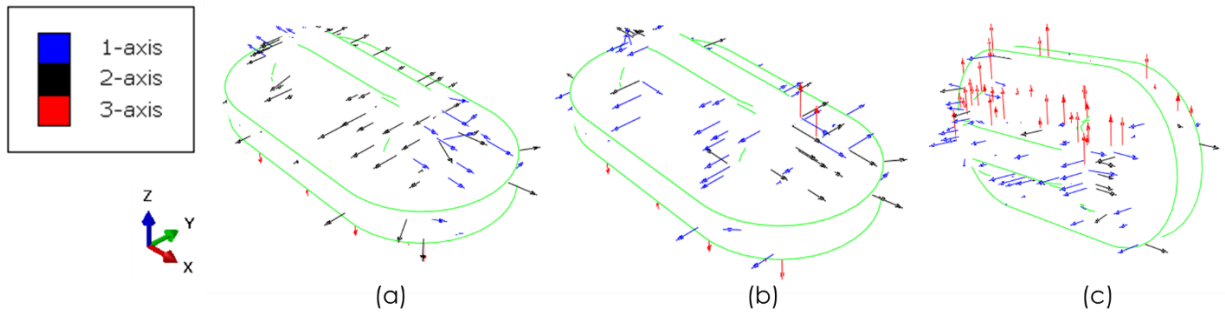

Figure 4: Elemental Material orientation (1-2-3 axes) obtained from the AM process simulation for (a) H0, (b) H90, and (c) V90 cases, plotted only for few elements on the wireframe geometry of the actual mold.

4 PERFORMANCE MODEL

In order to evaluate the performance of the mold, two metrics were used including deformation and shape accuracy. For evaluation of the mold deformation consisting of different toolpaths, a performance model was setup using Abaqus Standard. The performance model was set up by defining the displacement BCs and loading condition (Fig. 5). A non-linear static analysis was performed to evaluate the structural performance of the three cases.

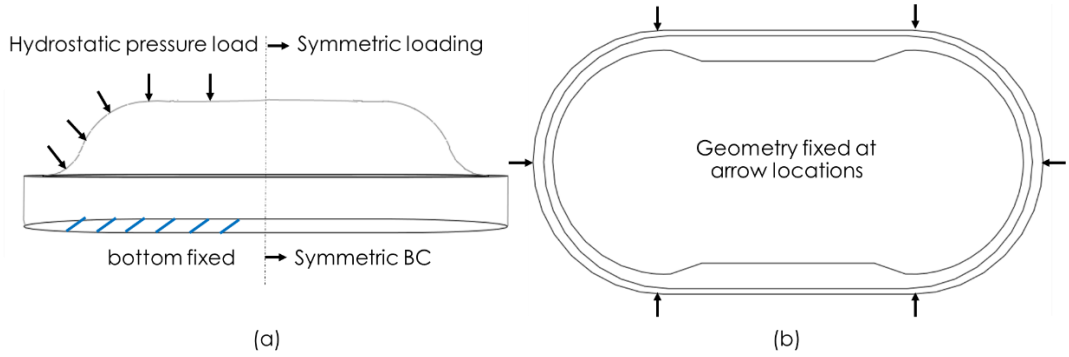

Figure 5: Displacement BCs and loading conditions for the performance analysis of double dome structure (a) Front view shows hydrostatic pressure loading and fixed bottom face, (b) Top view shows locations used to fix the structure.

Shape accuracy was evaluated by comparing the mold's deformed shape to its original, as-printed form. This was done by using surface normals as a shape descriptor. The surface normal descriptor compared the orientation of the mold surface at each point to assess shape deviation. The concept of surface deviation is illustrated in (Fig. 6).

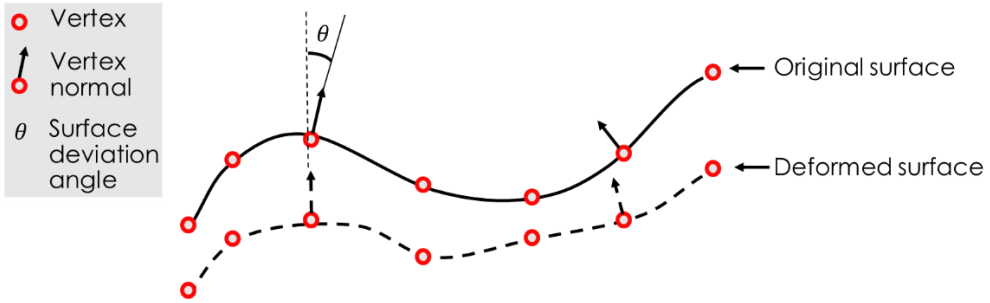

Figure 6: Surface deviation angle calculated from the vertex normal to the original and deformed mold surfaces.

The surface deviation angle θ_i is calculated at a vertex/node on the surface as follows:

$$\theta_i = cos^{-1}(\hat{a}_i \cdot \hat{b}_i), \qquad i = 1, \dots n \tag{1}$$

Where $\hat{a}_i$, $\hat{b}_i$ are the unit normal vectors to the original and deformed surfaces, respectively, at a vertex i, and n is the number of vertices/nodes on the surface. Further, the variance of the surface deviation angles for the mold surface was calculated as:

$$\sigma^2 = \frac{\sum(\theta_i - \bar{\theta})}{n} \tag{2}$$

Where $\bar{\theta}$ is the mean surface deviation. Accordingly, the surface deviation data including the deviation angles, their maximum and minimum magnitudes, and the average and variance were determined for all three cases under study.

5 RESULTS

The results of the performance analyses provided insights into 1) the structural integrity of the AM mold and 2) the quality of part manufactured using the mold through compression molding. The key observations from the predicted stress and deformation results are presented here. The von Mises stress contour plots for the three cases can be observed in (Fig. 7). The scale of the contour plot was set at a maximum of 45MPa and a minimum of 0MPa.

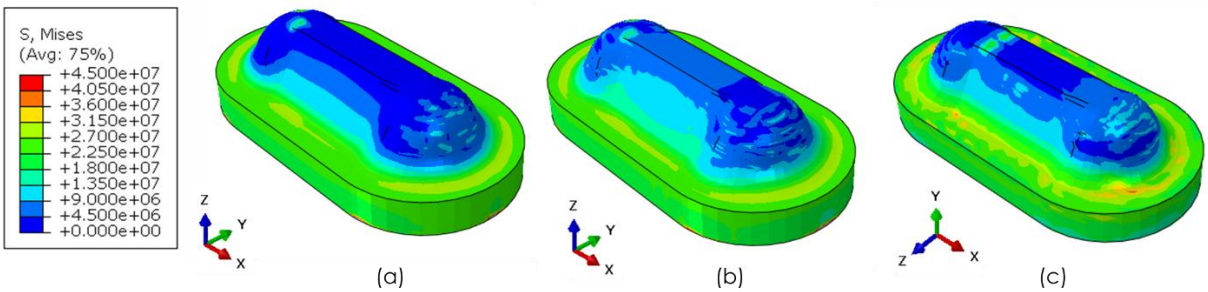

Figure 7: Von Mises stress contour plots for (a) H0, (b) H90, and (c) V90 cases, scale set to a Max = 45 MPa and Min = 0 MPa.

It was observed that the average stress magnitudes for all cases were similar with certain disparity visible on the top face. The stress contours were expected to be similar because the loading condition was pressure-based. Thus, the deformation results were determined to be more valuable for the purpose of comparison. The deformation magnitude for the considered cases can be seen in (Fig. 8). The maximum deformation magnitudes for H0, H90 and V90 cases were 1.056mm, 1.067mm and 0.441mm respectively. Unlike cases H0, and H90, V90 case has material axis 1 that is the fiber axis in the loading direction, thus provided higher stiffness, resulting in lower deformation by >50.

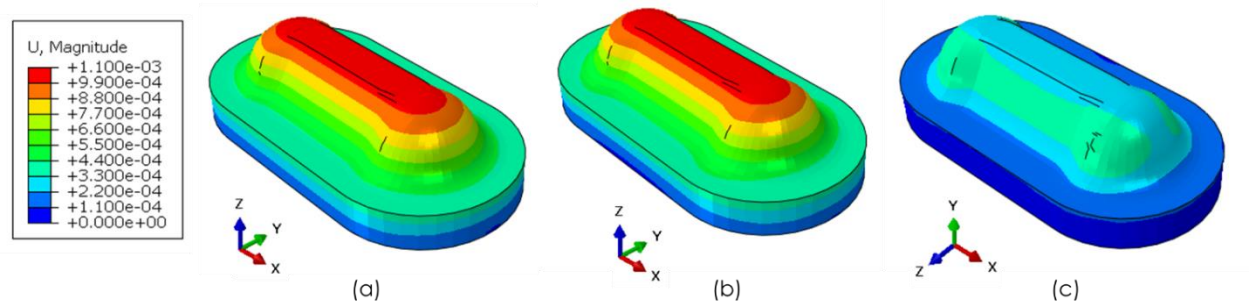

Figure 8: Deformation magnitude contour plots for (a) H0, (b) H90, and (c) V90 cases, scale set to Max = 1.1 mm and Min = 0.0 mm.

Considering deformation magnitude as the criterion for performance evaluation of the AM mold, considerable improvement was achieved with V0 case (>50%) compared to the H0 and H90 cases. Thus, it would be logical to determine V90 toolpath as the optimum from a performance perspective. However, it was recognized that an equally important criterion for evaluation of the optimum toolpath was the quality of part manufactured using the mold via compression molding. In the present instance, the part quality was defined by surface deviation of the deformed mold relative to the original mold surface.

Accordingly, the surface deviation data including the deviation angles, their maximum and minimum magnitudes, and the average and variance were determined for all three cases under study. The deviation or the error values are provided in (Table 5). The maximum deviation and variance metrics were considered significant for the part quality. Thus, the H90 toolpath case was determined the optimum case in terms of the part quality.

Table 5: Surface deviation values used as error metric to choose the optimum toolpath.

Error metric	Case H0	Case H90	Case V90
Max deviation (°)	3.137	2.591	4.197
Min deviation (°)	0.002	0.002	0.001
Avg deviation (°)	0.211	0.210	0.122
Variance of deviation	0.034	0.027	0.059
Optimum ranking	Next to optimum	Optimum	Second next to optimum

6 CONCLUSIONS

This study focused on toolpath optimization for an additive manufacturing (AM) printed mold to enhance its molding performance, evaluated through mold deformation and shape accuracy metrics. Three toolpaths including H0, H90, and V90 were assessed using finite element (FE) simulations and statistical analysis. The results indicated that the V90 toolpath was optimal for compression molding applications due to its lowest mold deformation, attributable to favorable fiber alignment in the loading direction that enhanced material stiffness. However, shape accuracy analysis revealed that the V90 case exhibited the highest maximum deviation and variance from the original mold shape. In contrast, the H90 toolpath demonstrated the lowest deviation and variance, indicating superior shape accuracy, albeit with slightly higher mold deformation than the V90. Therefore, considering the trade-offs between mold deformation and shape accuracy, the H90 toolpath is recommended as the optimal choice.

Keywords: CFRTP, Fiber Discontinuity, DIC, FEM Analysis, Three-points Bending Test

ABSTRACT

This study presents the observation of damage behavior under bending of carbon fiber reinforced thermoplastics (CFRTP) with fiber discontinuity. CFRTP with high strength is utilized for a variety of situations such as airplane and foot orthoses. However, CFRP is well-known as weak for compression, especially the buckling in the situation of remolding foot orthoses. The resin rich region existing in fiber discontinuity is considered to reduce the buckling. The three-points bending test result indicates the discontinuous CFRTP has 82.0% bending strength and 84.0% shear strength compared to the continuous CFRTP. The continuous CFRTP is damaged on the compression side surface. A tiny crack may cause injury in the situation of utilization for foot orthoses. Micro scale tensile test using laser microscope for the consideration of fracture mechanism shows the strain concentration at both edges of resin rich region. This strain concentration is considered to cause damage. This means the discontinuous CFRTP is useful for foot orthoses.

1 INTRODUCTION

Foot orthoses require light weight, high strength, design ability. CFRTP with a high specific strength and modulus is utilized such as vehicle and aircraft. In recent years, CFRTP has become relatively more affordable, and its application in medical devices such as orthoses is considered. When CFRTP is utilized for foot orthoses, it is subjected to bending stress in order to adjust to physical growth. However, fiber's buckling is occurred on the compression side under bending. Delamination also tends to appear on CFRTP laminates. A tiny crack may cause injury in the case of foot orthosis. The resin-rich region existing in the fiber discontinuity is considered to reduce the fiber deformation under bending. This study presents an observation of the damage behavior under bending of CFRTP (CF/PMMA) laminates with fiber discontinuity. Digital image correlation (DIC) is utilized to observe displacement and strain distributions.

2 THREE-POINTS BENDING TEST

Prepregs with a length of 40mm are stacked with a shift of 10mm to make fiber discontinuity as shown in Fig. 2.1. After molding, the laminated plate is cut into test specimens for three-points bending test. In three-point bending test, a total of six types of test specimens, with thicknesses of 3.0 mm, 3.5 mm, and 4.0 mm, are prepared from CFRTP laminates with fiber discontinuities and continuous fiber CFRTP laminates. Three samples of each type are tested. The test specimen names are assigned as shown in Table 2.1 for identification. Due to dimensional variations when cutting the specimens, the measured dimensions after cutting each specimen are shown in Table 2.2.

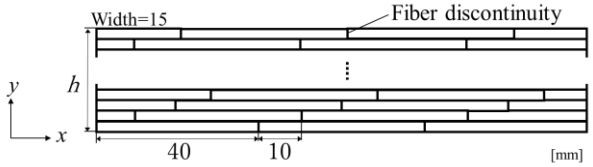

Fig. 2.1. Schematic diagram of discontinuous CFRTP specimens

Table 2.1. Numbering of specimens

	Thickness		
	3.0mm	3.5mm	4.0mm
Continuous	c3-1, c3-2, c3-3	c3.5-1, c3.5-2, c3.5-3	c4-1, c4-2,c4-3
Discontinuous	d3-1, d3-2, d3-3	d3.5-1, d3.5-2, d3.5-3	d4-1, d4-2, d4-3

Table 2.2. Thickness and width of specimens

Number	h[mm]	b[mm]	Number	h[mm]	b[mm]
c3-1	2.97	15.40	d3-1	3.05	15.30
c3-2	2.95	15.41	d3-2	3.03	15.22
c3-3	2.93	15.39	d3-3	3.00	14.95
c3.5-1	3.40	15.58	d3.5-1	3.59	14.93
c3.5-2	3.37	15.46	d3.5-2	3.67	15.00
c3.5-3	3.48	15.01	d3.5-3	3.51	15.08
c4-1	3.94	15.25	d4-1	4.03	15.07
c4-2	3.98	15.35	d4-2	4.03	14.93
c4-3	4.09	15.49	d4-3	3.98	14.89

In this experiment, the span between the supports is set to 25 mm, and the testing speed is 1.0 mm/min. A schematic diagram illustrating the testing setup is shown in Fig. 2.2.

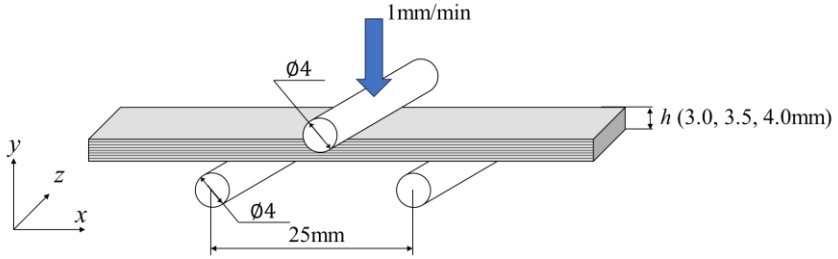

Fig. 2.2. Three-points bending test

Figure 2.3 shows displacement and strain distribution obtained from d3-1. Focusing on the strain in the *y*-direction, interlaminar delamination (stripe-shaped strain concentration) is observed on the center

in the thickness direction of the specimen. Figure 2.4 shows displacement and strain distribution obtained from c3-1. Compression damage (strain concentration on the diagonal direction) is observed on the surface of the specimen. The bending and shear strengths are evaluated based on the loads at which these damages are observed.

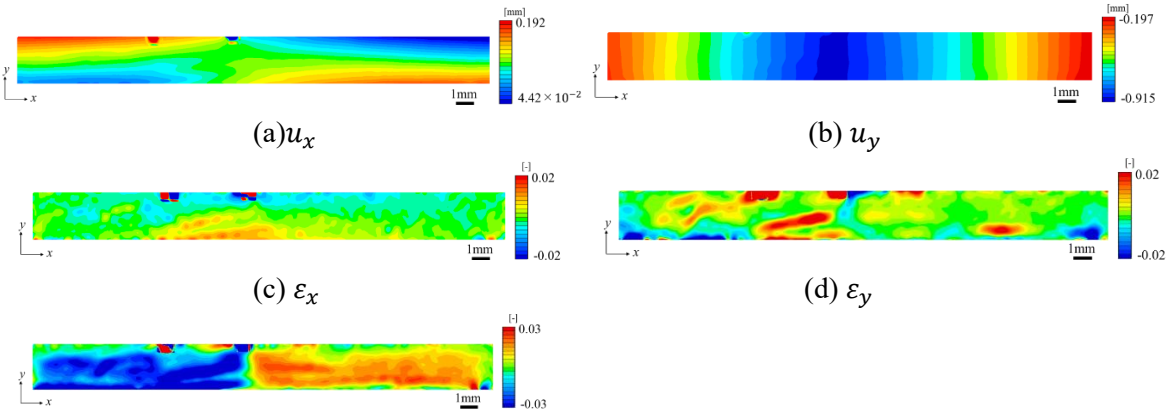

Fig. 2.3. Displacement and strain distribution of d3-1 at 140s

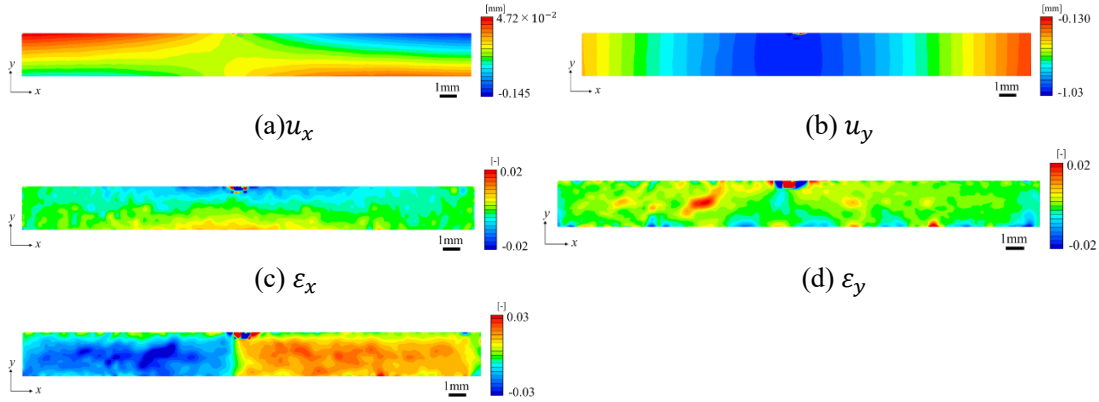

Fig. 2.4. Displacement and strain distribution of c3-1 at 140s

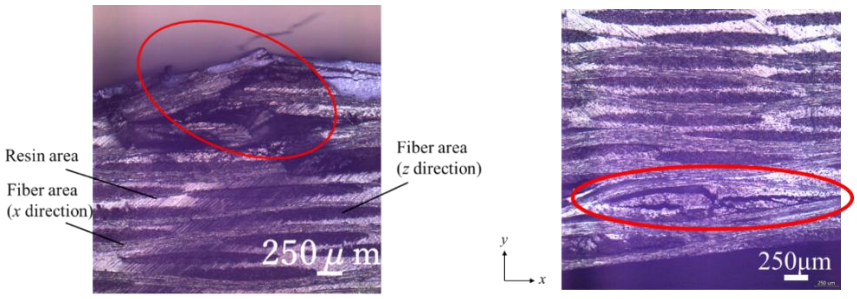

Table 2.3 shows the flexural strength or shear strength obtained from each specimen. When comparing the shear strength of the 3.5 mm-thick specimens and the flexural strength of the 4.0 mm-thick specimens, it was found that the CFRTP laminates with fiber discontinuities retains 82.0% of the flexural strength and 84.0% of the shear strength compared to the continuous fiber CFRTP laminate.

Table 2.3. Bending strength and Shear strength

By observing the detected damage with a laser microscope, the influence of such damage on practical applications, such as orthoses, is considered. Figure 2.5 shows the compressive fracture and interlaminar delamination caused by bending observed by the laser microscope. The white, stripe-like features visible in

the image correspond to fiber area oriented in the *x*-direction. Since the specimen used in this experiment is a plain-woven fabric, fiber area aligned in the z-direction appear as dark, elliptical shapes. Compressive fracture due to bending is accompanied by fiber buckling. The fracture surface of fibers exposes on the specimen's surface.

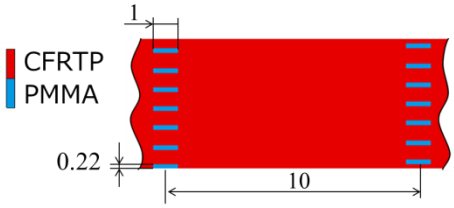
(a) Fiber buckling (b) Delamination

Fig. 2.5. Damage behavior observed by laser microscope

Finite element analysis (FEM) is used to simulate the three-point bending test, calculating the stress distribution as well as the displacement and strain distributions. The FEM software used for the analysis is Marc Mentat, and an elastic-plastic analysis is performed. A resin-rich region made of acrylic is introduced within the CFRTP to reproduce the fiber discontinuity. The material properties used in the analysis are shown in Table 2.4. Additionally, the model and boundary conditions used in the analysis are shown in Fig. 2.6.

Table 2.4. Material constant for FEM

PMMA	CFRTP		
E=1.0GPa ν=0.35	E_{xx}=53.1GPa	ν_{xy}=0.20	
	E_{yy}=1.0GPa	ν_{yz}=0.20	G_{xy}=2.5GPa
	E_{zz}=53.1GPa	ν_{zx}=0.05	



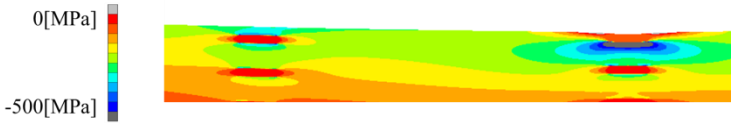


Fig. 2.6. Fiber discontinuities for FEM model

Figure 2.7 shows the stress distributions obtained by FEM. Since the maximum compressive and shear stresses occur below the indenter, damage may be expected in this area. However, due to the indenter constraining out-of-plane deformation, the damage does not appear. It is considered that the deformation is small. When the fiber discontinuity is close to the surface, stress concentrations for both compressive and shear stresses occur. The location where the fiber discontinuity is situated in the second layer from the surface is where the compressive and shear stresses are most likely to concentrate.

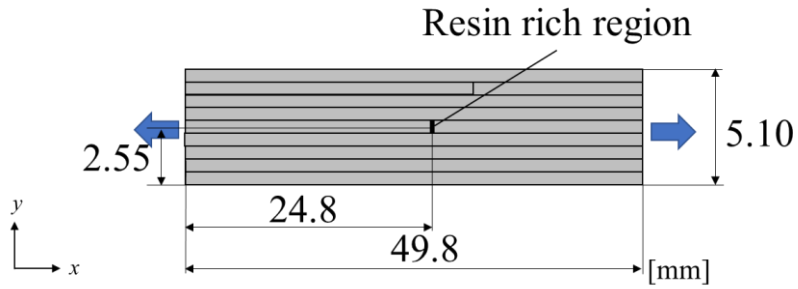
(a) Stress distribution in *x*-direction

(b) Shear stress distribution

Fig. 2.7. Stress distribution obtained by FEM

3 TENSILE TEST

To focus on a single fiber discontinuity within the specimen, the specimen is cut that the fiber discontinuity is located at the center of the specimen. The dimensions of the specimen and the position of the fiber discontinuity are shown in Fig. 3.1. In order to observe the specimen with a laser microscope, the specimen is polished with sandpaper in the following order: 600, 800, 1000, 1500, and 2000 grit, and finally polished with a polishing compound to confirm the position of the fiber discontinuity. The fiber aligned in the *x*-direction appears as white streaks under observation. Since the test specimen used in this experiment is woven fabric, fibers in the *z*-direction appear black and elliptical. The resin portion appears bright white. The image of the fiber discontinuity captured with the laser microscope is shown in Fig. 3.2, where a 1.39 mm resin-rich area is observed.



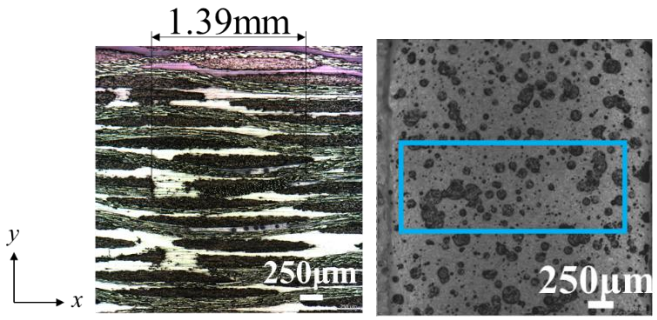


Fig. 3.1. Schematic diagram of discontinuous CFRTP specimen

(a) Resin rich region (b) Random pattern for DIC

Fig. 3.2. Resin rich region and random pattern for DIC observed by laser microscope

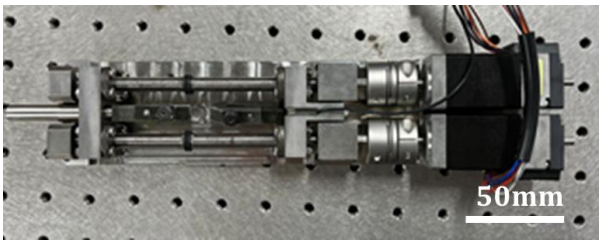

Fig. 3.3. Tensile test machine

Figure 3.4 shows a load-time diagram obtained from tensile test. The displacement and strain distributions at 190 seconds are shown in Fig. 3.5. The black dashed line in the distribution indicates the location of the resin-rich region at the fiber discontinuity. Focusing on the strain in the *x*-direction, strain concentrations are observed at both ends of the resin-rich region.

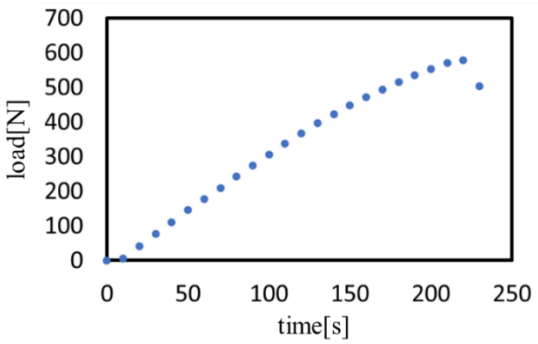

Fig. 3.4. Load-time diagram

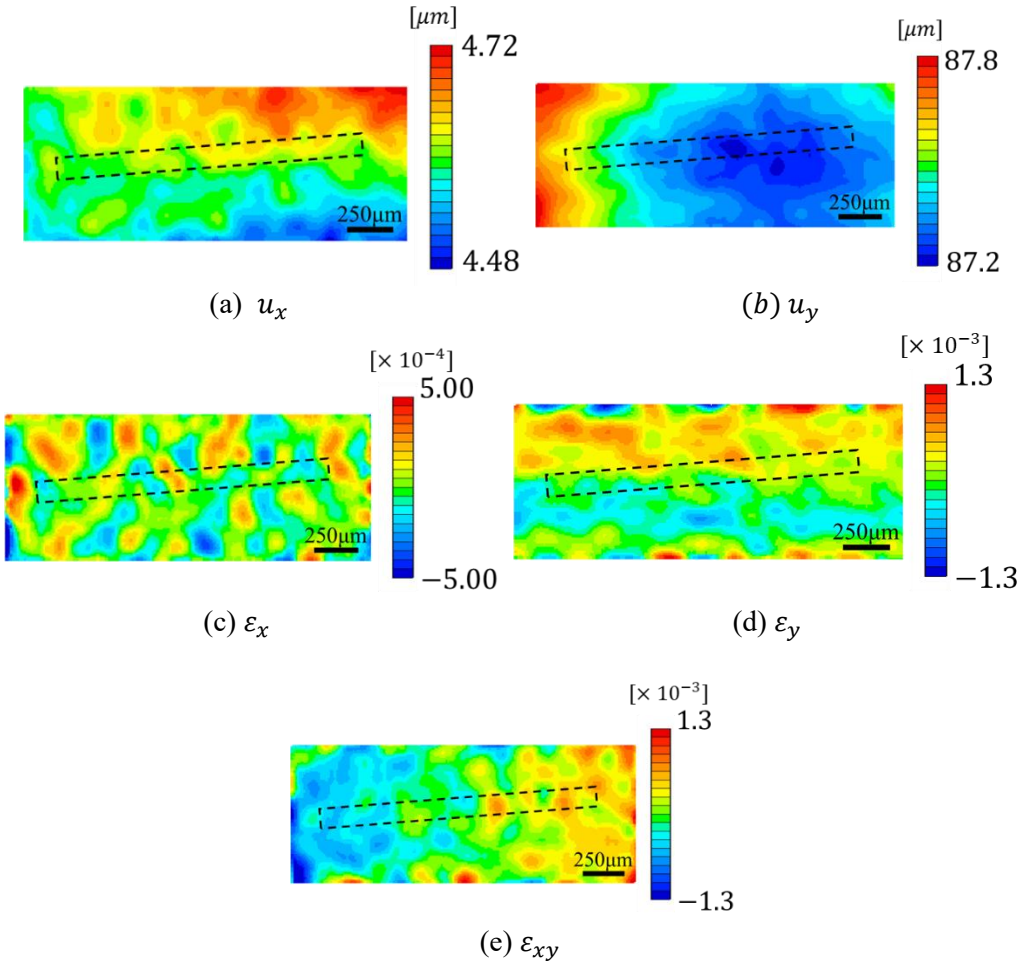

Fig. 3.5. Displacement and strain distribution

FEM is used to simulate the tensile test, calculating the stress distribution as well as the displacement and strain distributions. The FEM software and the material properties used in the analysis are the same as the previous section. The model and boundary conditions used in the analysis are shown in Fig. 3.6. The boundary conditions are set to fixed displacements at both ends, as in the experiments. The applied load is set to 500 N, based on the load-time curve obtained from the experiment.

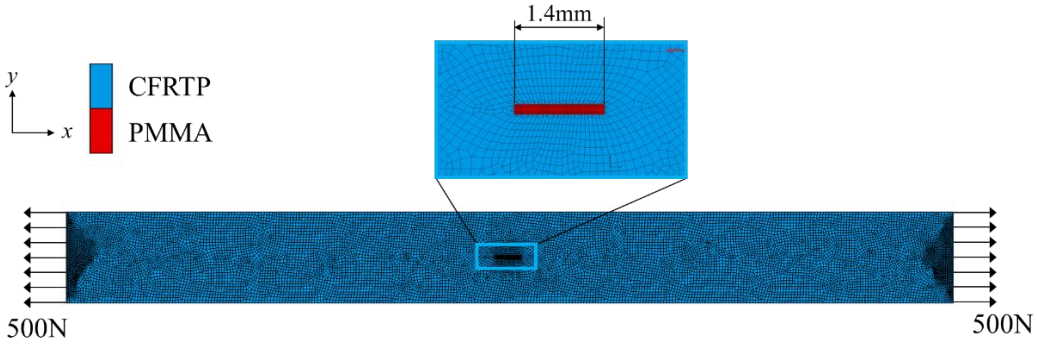

Fig. 3.6. Fiber discontinuity of FEM model

Fig. 3.7 shows the displacement and strain distribution obtained from the FEM analysis. Focusing on the strain in the *x*-direction, strain concentrations are observed at both ends of the resin-rich area, consistent with the experimental results. However, in the strain distribution obtained from the experiment, strain concentration appeared in a scattered manner.

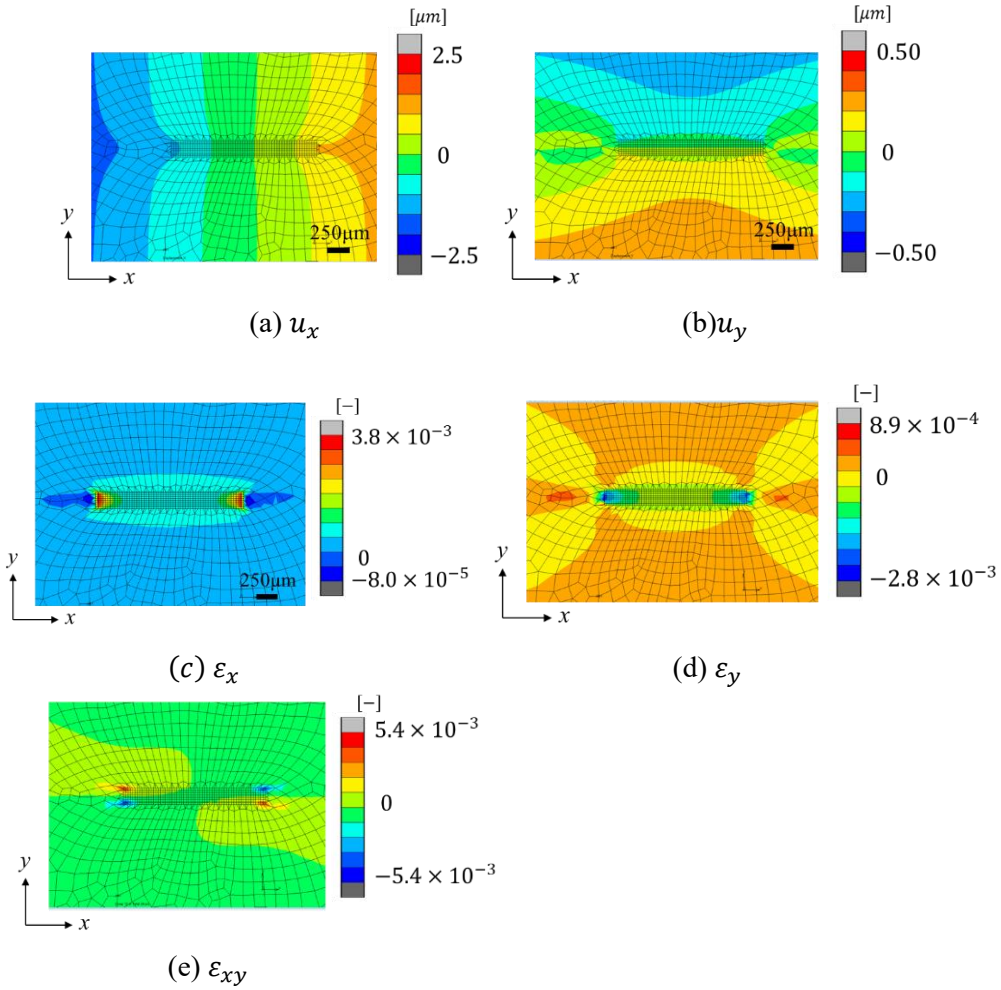

Fig. 3.7. Displacement and strain distribution calculated by FEM

4 CONCLUSION

To explore the application of carbon fiber reinforced thermoplastic (CFRTP) laminates in orthoses, three-point bending tests were conducted using short-beam specimens. Two distinct failure modes were observed: Mode II interlaminar shear failure, and compressive failure on the compressive surface caused by fiber buckling. The CFRTP laminates with discontinuous fibers retained 84.0% of the shear strength

and 82.0% of the flexural strength compared to their continuous-fiber counterparts. Thin CFRTP laminates were found to be more susceptible to interlaminar delamination. Additionally, continuous-fiber CFRTP laminates tended to exhibit compressive failure under bending, which was accompanied by the occurrence of micro-damage on the surface. Considering the potential for such micro-damage to cause injury in the context of orthoses, the use of discontinuous fibers is considered beneficial.

To investigate the potential for discontinuous fiber regions to serve as damage initiation sites on the tensile surface during bending, tensile tests using a laser microscope were performed. Strain concentration was observed at both ends of the resin-rich region associated with the discontinuous fiber area. A similar tendency was confirmed through finite element method (FEM) analysis, suggesting that these strain concentrations may act as origins of damage.

Keywords: Double-Double laminates, Lamination parameters, Layup optimization

ABSTRACT

Novel Double-Double (DD) laminates family provide a new solution for the design and optimization of composite structure. This article analyses the characteristics of the stiffness matrix of the extended DD laminates based on laminate parameters (LPs), and applies it to a classic benchmark problem. The explicit LPs expressions of extended DD laminates are first derived, and the explicit functions of the feasible region of the LPs are derived through the Lagrange multiplier method, which better explains the characteristics of the DD family mathematically. Subsequently, the classical 18-plane horseshoe benchmark problem is optimized based on the feasible region of DD LPs. The optimal solutions with blending constraint are analytically obtained, and the whole problem is summarized as a linear programming problem in LPs feasible region. The optimal solution is compared with the iterative solution obtained by evolutionary algorithm, which further illustrates the advantages of DD. The exploration of DD in this study can contribute to the discovery of new laminate families and promote the application of DD laminates.

1 INTRODUCTION

The traditional ply angles of laminates are usually 0°, ±45° and 90°, which is also called QUAD. QUAD laminates contain a large number of permutations by changing the ply orientation of each layer. Flexible stacking sequence enables QUAD laminates to satisfy the majority of application requirements, but it also leads to the emergence of high-dimensional discrete design challenges. In order to solve this problem, in theory, researchers usually use the intermediate continuous variable: lamination parameters (LPs) to design the stacking sequence [1]. The advantages of using LPs are obvious. According to the classical lamination theory (CLT), each stiffness coefficient of the laminate can be expressed as a linear combination of laminate parameters. The ply numbers are integrated into LPs by orthogonalizing the thickness, which significantly reduces the number of design variables. When LPs are considered as independent variables, they are interrelated continuous design variables in the interval [-1,1], it makes the optimization problem usually have a global optimal solution.

The discreteness of ply angle and the constraints of design criteria make the disadvantages of traditional QUAD laminates in layup optimization obvious: inefficient fiber layup, high calculation cost of optimization, complex strength calculation, etc. To overcome these disadvantages, Tsai [2] proposed a novel double-double (DD) laminate. DD laminate is composed of repeated stacking of a four-ply sublaminate, and its classical expression is $[\pm\Phi/\pm\Psi]_r$, where r is the number of repetitions. Research showed that when r is greater than or equal to 4, DD laminates are homogeneous and membrane/bending and bending/torsion coupling can be ignored [3]. Moreover, DD can achieve a simpler and larger taper ratio through the card sliding technology, and the manufacturing is simple and not prone to error. The properties and advantages of DD laminate have been widely studied, and have been applied in some structures.

The unique layup characteristic makes DD laminates have significant advantages in design and manufacturing. However, the current research mainly focuses on the performance test and layup design of classic DD laminates $[\pm\Phi/\pm\Psi]_r$. In theory, DD family also contains laminates with other layup characteristics. Therefore, breaking through the limitation of classical DD and analyzing DD family from a more general perspective will help the understanding and application of DD. In this paper, the

classical $[\pm\Phi/\pm\Psi]_r$ DD stacking sequence is extended to the general $[\theta_1/\theta_2/\ldots/\theta_l]_r$ case. The lamination parameter expressions of the extended DD laminates are derived, and the corresponding feasible region is studied by using Lagrange multiplier method. Based on the obtained expressions, the laws of DD family are summarized. Then, the classical 18-panel horseshoe benchmark problem is optimized by using the LPs feasible region of DD, and the optimal solutions with/without blending constraint are analytically obtained. The results show that the optimal solutions are obtained at the lower bound of the feasible region, regardless of the categories of DD, and the results are compared with the iterative solutions obtained by evolutionary algorithm.

2 EXTENDED DD LAMINATES BASED ON LPS

2.1 Lamination parameters of general extended DD laminate

The extended DD laminates were first introduced in [3], and the ξ_1^A-ξ_2^A lamination parameter design spaces of two types of extended laminates $[\pm\Phi_n/\pm\Psi]_r$ and $[\pm\Phi/\pm\Psi/\theta]_r$ ($\theta\in\{0°,90°\}$) were studied in [3] to illustrate the characteristics of classical $[\pm\Phi/\pm\Psi]_r$ DD laminates. However, the characteristics of extended DD laminates have not been further studied.

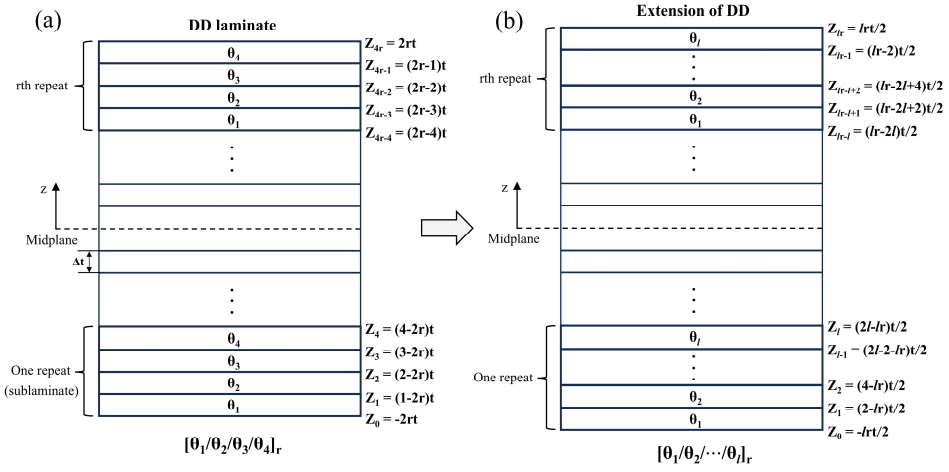

Fig. 1. Layup information of laminate. (a) Classical DD laminate, (b) General extended DD laminate.

In Fig. 1, a general DD extended laminate and a classical DD laminate are presented. In the classical DD laminate, it contains four types of layup categories, which are staggered 1: $[+\Phi/-\Psi/-\Phi/+\Psi]_r$, staggered 2: $[+\Phi/+\Psi/-\Phi/-\Psi]_r$, staggered 3: $[+\Phi/-\Psi/+\Psi/-\Phi]_r$, and staggered 4: $[\pm\Phi/\pm\Psi]_r$. When the specific stacking sequence is not considered, the sublaminate of the DD laminate has four angles, represented by θ_1, θ_2, θ_3 and θ_4, respectively. Assuming the repetition number of the sublaminate is r and the thickness of each layer is t. The entire laminate contains $4r+1$ nodes, and the coordinates z corresponding to each node are shown in Fig. 1(a). In the general extended DD laminate, it is assumed that the sublaminate contains l layers. The total number of layers is lr, and the general laminate can be represented as $[\theta_1/\theta_2/\ldots/\theta_l]_r$. The corresponding node coordinates z are related to the values of l and r, which are also shown in Fig. 1(b). Defining trigonometric functions $f_1(\theta) = \cos(2\theta), f_2(\theta) = \cos(4\theta), f_3(\theta) = \sin(2\theta)$ and $f_4(\theta) = \sin(4\theta)$. The lamination parameters $\xi_{[1,2,3,4]}^{A,B,D}$ of general extended DD laminate can be calculated as follows:

For $\xi_{[1,2,3,4]}^{A}$,

$$\xi_j^A = \frac{1}{2}\sum_{k=1}^{r}\sum_{i=1}^{l}\int_{-1+2(lk-l+i-1)/lr}^{-1+2(lk-l+i)/lr} f_j(\theta_i)\mathrm{d}\bar{z} \tag{1}$$

where j = 1, 2, 3, 4. Integrating each ply through the thickness and summing the repetition number k leads to,

$$\xi_j^A = \sum_{i=1}^{l}\frac{1}{l}f_j(\theta_i) \tag{2}$$

It can be seen that the value of ξ_j^A are only related to the type of sublaminate ply angle θ_i, and the contribution of each ply angle is equal.

Similarly, $\xi_{[1,2,3,4]}^B$ can be obtained as

$$\xi_j^B = \sum_{k=1}^{r}\sum_{i=1}^{l}\int_{-1+2(lk-l+i-1)/lr}^{-1+2(lk-l+i)/lr} \overline{z} f_j(\theta_i)\mathrm{d}\overline{z} \tag{3}$$

Integrating each ply through the thickness and summing the repetition number k,

$$\xi_j^B = \sum_{i=1}^{l}\frac{2(-l+2i-1)}{l^2 r} f_j(\theta_i) \tag{4}$$

It can be seen that ξ_j^B are inversely proportional to the number of repetition number r. Therefore, increasing the number of plies results in the coupling stiffness matrix $\boldsymbol{B}$ tending to $\mathbf{0}$. The type and stacking sequence of the sublaminate ply angles can affect the minimum value of r that required to satisfy the homogeneity criterion of DD laminate. Specific homogenization criterion is defined as [2],

$$\left|\boldsymbol{B}^*\right| < I*(Q_{11}+Q_{22}+2Q_{66}) \tag{5}$$

$$\left\|[\boldsymbol{A}^*]-[\boldsymbol{D}^*]\right\| < I*(Q_{11}+Q_{22}+2Q_{66}) \tag{6}$$

$$\boldsymbol{A}^*, \boldsymbol{B}^*, \boldsymbol{D}^* = \left[\frac{1}{h}\boldsymbol{A}, \frac{2}{h^2}\boldsymbol{B}, \frac{12}{h^3}\boldsymbol{D}\right] \tag{7}$$

where $Q_{11}+ Q_{22}+ 2Q_{66}$ is the Tasi modulus [4], I is the percentage of the Tasi modulus and is usually set to be 2%. [$\boldsymbol{A}^*$, $\boldsymbol{B}^*$, $\boldsymbol{D}^*$] are the thickness normalized stiffnesses. Similarly, for $\xi_{[1,2,3,4]}^D$,

$$\xi_j^D = \frac{3}{2}\sum_{k=1}^{r}\sum_{i=1}^{l}\int_{-1+2(lk-l+i-1)/lr}^{-1+2(lk-l+i)/lr} \overline{z}^2 f_j(\theta_i)\mathrm{d}\overline{z} \tag{8}$$

Integrating each ply through the thickness and summing the repetition number k leads to,

$$\xi_j^D = \sum_{i=1}^{l}\left[\frac{1}{l}+2\frac{(l-i)^2-(4i-3)(l-i)+(i-1)(i-2)}{l^3 r^2}\right] f_j(\theta_i) \tag{9}$$

It can be seen that ξ_j^D are inversely proportional to the square of the number of repetition number r. As the number of plies increases, the coefficient of $f_j(\theta_i)$ tends to be constant $1/l$, ξ_j^D tends to be equal to ξ_j^A. The angles of the sublaminate ply determine whether the values of the lamination parameters ξ_3^D, ξ_4^D can approach to 0.

2.2 The characteristics of general extended DD laminates

Each set of lamination parameters of general extended DD laminates can be obtained through an equation, as shown in Eqs. (2), (4), and (9). Through the study of these equations, the characteristics of extended DD laminate can be explored, which is also applicable to classical DD laminates.

In Eq. (2), the coefficients of each ply angle trigonometric function $f_j(\theta_i)$ are the same as $1/l$. However, in Eqs. (4) and (9), the coefficients of $f_j(\theta_i)$ are related to i, this indicates that the stacking sequence will affect the value of the coefficients, and it will further affect the minimum r value required for the laminate to satisfy the homogeneity. To illustrate the relationship between trigonometric function coefficient with stacking sequence, the following functions are defined:

$$\begin{cases} g_B(i) = \dfrac{2(-l+2i-1)}{l^2 r} \\ g_D(i) = \dfrac{1}{l}+2\dfrac{(l-i)^2-(4i-3)(l-i)+(i-1)(i-2)}{l^3 r^2} \end{cases} \tag{10}$$

where i ($\in[1, l]$, N^*) represents the i-th ply of sublaminate in Fig. 1, l and r are positive integers. For sublaminate with the number of plies l, the sub-midplane coordinate is $lt/2$, and the number of i-th ply symmetrical about the sub-midplane is l-i+1. Substituting l-i+1 into Eq. (10), it can be obtained that:

$$\begin{cases} g_B(l-i+1)=\dfrac{2(l-2i+1)}{l^2 r}=-g_B(i) \\ g_D(l-i+1)=\dfrac{1}{l}+2\dfrac{(i-1)^2-(4l-4i+1)(i-1)+(l-i)(l-i-1)}{l^3 r^2}=g_D(i) \end{cases} \tag{11}$$

It can be seen that in the sublaminate panel, the layers that are symmetrical about the sub-midplane contain opposite values of the ξ_j^B trigonometric coefficient, and the same values of the ξ_j^D trigonometric coefficient. Considering the coupling term coefficients $\xi_{3,4}^A$, ξ_j^B and $\xi_{3,4}^D$ in the LPs, combining Eq. (11) with Eqs. (2), (4) and (9), some characteristics of the general extended DD laminate can be obtained as follows:

(1) When the sublaminate satisfies the balance constraint (with the same number of $+\theta$ and $-\theta$ angles), it can be obtained that $\xi_{3,4}^A = 0$, and as the value of r increases, both ξ_j^B and $\xi_{3,4}^D$ tend to 0. The balance of sublaminate is a sufficient and necessary condition for general extended DD laminates achieving homogenization.

(2) When the sublaminate is antisymmetric about the sub-midplane, it can be obtained that $\xi_{3,4}^{A,D} = 0$ and $\xi_{1,2}^B = 0$.

(3) When the sublaminate is symmetric about the sub-midplane, it can be obtained that $\xi_j^B = 0$.

The essence of characteristics (2) and (3) is that for the general extended DD laminate, the laminate midplane coincides with the sub-midplane or is on the boundary of the sublaminate, as shown in Fig. 2. Therefore, when the sublaminate is antisymmetric or symmetric about the sub-midplane, the corresponding entire laminate will be antisymmetric or symmetric about the global midplane. In addition, a special type of fully decoupled ($\xi_{3,4}^{A,D} = 0$, $\xi_j^B = 0$) laminate can be derived from the above analysis results. The trigonometric coefficients of Eq. (4) ξ_j^B have the following relationship:

$$g_B(1)+g_B(\frac{l}{2})=\cdots=g_B(i)+g_B(\frac{l}{2}-i+1)=-\frac{2}{lr} \tag{12}$$

where the number of layers l in the sublaminate is even, and i = 1, 2, ⋯, l/2. When the sublaminate satisfies feature (2) and the layers 1 to l/2 are balanced, ξ_3^B and ξ_4^B are also equal to 0. Therefore, the number of decoupled DD sublaminate layers should not be less than 8, and the basic expression is $[+\Psi/-\Psi/-\Psi/+\Psi, -\Psi/+\Psi/+\Psi/-\Psi]_r$, or $[-\Psi/+\Psi/+\Psi/-\Psi, +\Psi/-\Psi/-\Psi/+\Psi]_r$. The above two types of decoupled DD laminates were initially proposed by Miravete and Tasi [5], and this laminate family is called 'Metalite'. In this section, the mechanism of 'Metalite' laminate decoupling is explained from the analysis of lamination parameters of general extended DD laminate, and the laws are summarized.

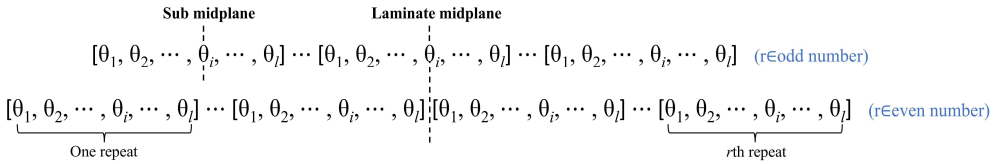

Fig. 2. Relationship between sub-midplane and global midplane of general extended DD laminate.

2.3 Feasible region of extended DD laminate

Compared with QUAD layups, the complexity of the feasible region of DD laminate is reduced due to their simple stacking concept. In this section, based on the derived lamination parameters expressions, the ξ_1^A-ξ_2^A feasible region of extended laminates is mainly studied and summarized.

It is assumed that the layup of general extended laminate is balanced, including l/2 types of ply orientations (the number of sublaminate is even), and the layup is defined as $[\pm\theta_1/\pm\theta_2/\cdots/\pm\theta_{l/2}]_r$. The Lagrange multiplier method is used to obtain the feasible region between two lamination parameters [6]:

$$H(\theta_1,\cdots,\theta_{l/2})=F(\theta_1,\cdots,\theta_{l/2})+\lambda(G(\theta_1,\cdots,\theta_{l/2})-x) \tag{13}$$

where F, G are two lamination parameters related to the layup orientation θ, and λ is a Lagrange multiplier. The solution of feasible region can be expressed as minimizing and maximizing $y = F(\theta_1,\cdots, \theta_{l/2})$ subject to $x = G(\theta_1,\cdots, \theta_{l/2})$. The conditions to be satisfied at each stationary point are:

$$\begin{cases} \dfrac{\partial H}{\partial \theta_1} = \dfrac{\partial F}{\partial \theta_1} + \lambda \dfrac{\partial G}{\partial \theta_1} = 0 \\ \vdots \\ \dfrac{\partial H}{\partial \theta_{l/2}} = \dfrac{\partial F}{\partial \theta_{l/2}} + \lambda \dfrac{\partial G}{\partial \theta_{l/2}} = 0 \\ \dfrac{\partial H}{\partial \lambda} = G(\theta_1,\cdots, \theta_{l/2}) - x = 0 \end{cases} \tag{14}$$

For the feasible region between the lamination parameters ξ_1^A-ξ_2^A, it can be seen from Eq. (2) that $\xi_{1,2}^A$ are related to the types of layup orientations. According to the type and number of layup orientation variables, the feasible region of extended laminates can be roughly divided into the following three categories, and the corresponding characteristics can be further summarized.

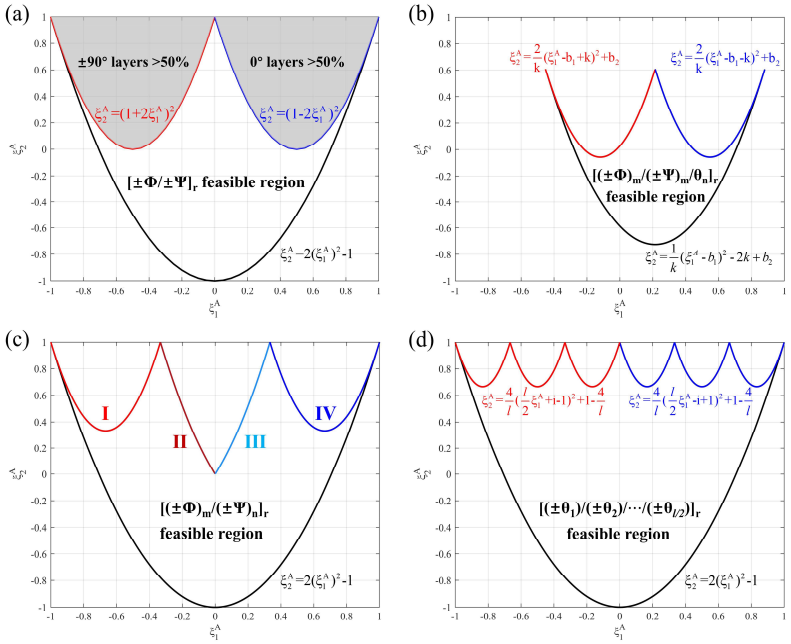

Fig. 3. Feasible regions and boundary equations of ξ_1^A-ξ_2^A for different categories of DD laminates. (a) Classic $[\pm\Phi/\pm\Psi]_r$, (b) $[(\pm\Phi)_m/(\pm\Psi)_m/\theta_n]_r$, (c) $[(\pm\Phi)_m/(\pm\Psi)_n]_r$, (d) $[(\pm\theta_1)/(\pm\theta_2)/\cdots/(\pm\theta_{l/2})]_r$.

2.4.1 Feasible region of $[(\pm\Phi)_m/(\pm\Psi)_m/\theta_n]_r$

Firstly, the feasible region of extended DD laminates with two ply angle variables, Φ and Ψ, is considered. In the classic $[\pm\Phi/\pm\Psi]_r$ DD laminates, due to the special layup stacking, the ξ_1^A-ξ_2^A LP feasible region is missing the area where 0° and 90° ply accounts for more than 50%, as shown on Fig. 3(a). In literature [3], $[0/90/\pm\Phi/\pm\Psi]_r$, $[\pm45/\pm\Phi/\pm\Psi]_r$ and $[0/\pm\Phi/\pm\Psi]_r$ laminates were studied to explore areas outside the boundary. According to the characteristics of this kind of laminates, the general expression $[(\pm\Phi)_m/(\pm\Psi)_m/\theta_n]_r$ is given. Here m is the number of occurrences of ±Φ and ±Ψ angles, θ_n is the known n ply angles, m and n are positive integers, satisfying the equation $4m+n = l$. According to Eq. (2), the expressions of lamination parameters ξ_1^A and ξ_2^A are given as follows:

$$\xi_1^A = \frac{\sum_{i=1}^{n}\cos(2\theta_i)}{l} + \frac{2m}{l}(\cos 2\Phi+\cos 2\Psi) = b_1 + k(\cos 2\Phi+\cos 2\Psi) \tag{15}$$

$$\xi_2^A = \frac{\sum_{i=1}^{n}\cos(4\theta_i)}{l} + \frac{2m}{l}(\cos 4\Phi+\cos 4\Psi) = b_2 + k(\cos 4\Phi+\cos 4\Psi) \tag{16}$$

The coefficients b, k ($\in$(-1,1)) are used to simplify the equation, which are independent of the ply angle variables Φ and Ψ, and can be considered as constants in the equation. According to the Lagrange multiplier method of Eqs. (13) and (14), the boundary equations are obtained as follows:

$$\begin{aligned}
&\xi_2^A \geq \frac{1}{k}(\xi_1^A - b_1)^2 - 2k + b_2, \quad \xi_1^A \in [b_1 - 2k, b_1 + 2k] \\
&\xi_2^A \leq \frac{2}{k}(\xi_1^A - b_1 + k)^2 + b_2, \quad \xi_1^A \in [b_1 - 2k, b_1] \\
&\xi_2^A \leq \frac{2}{k}(\xi_1^A - b_1 - k)^2 + b_2, \quad \xi_1^A \in [b_1, b_1 + 2k]
\end{aligned} \tag{17}$$

Fig. 3(b) provides a schematic diagram of the obtained feasible region. According to the diagram and Eq. (17), it can be seen that, the feasible region of the general extended laminate $[(\pm\Phi)_m/(\pm\Psi)_m/\theta_n]_r$ is obtained by scaling and translating the feasible region of the classical $[\pm\Phi/\pm\Psi]_r$ laminate. The coefficient k determines the scaling size of the boundary parabolic equations on the x and y axes, while b_1 and b_2 determine the translation distance of the parabolas on the x and y axes, respectively.

2.4.2 Feasible region of $[(\pm\Phi)_m/(\pm\Psi)_n]_r$

When the number of ply angle variables Φ and Ψ is different, the general expression of laminate is $[(\pm\Phi)_m/(\pm\Psi)_n]_r$. Here m and n are the occurrence number of ±Φ and ±Ψ angle pairs respectively, satisfying the equation $2m+2n = l$. The expressions of lamination parameters ξ_1^A and ξ_2^A are given as follows:

$$\begin{aligned}
&\xi_1^A = \frac{2}{l}(m\cos 2\Phi + n\cos 2\Psi) \\
&\xi_1^A = \frac{2}{l}(m\cos 4\Phi + n\cos 4\Psi)
\end{aligned} \tag{18}$$

When $m>n$, the boundary equations of the feasible region are as follows:

$$\begin{aligned}
&\xi_2^A \geq 2(\xi_1^A)^2 - 1, \quad \xi_1^A \in [-1, 1] \\
&\mathrm{I}: \xi_2^A \leq \frac{l}{n}(\xi_1^A + \frac{m}{m+n})^2 + \frac{m-n}{m+n}, \quad \xi_1^A \in [-1, \frac{n-m}{m+n}] \\
&\mathrm{II}: \xi_2^A \leq \frac{l}{m}(\xi_1^A - \frac{n}{m+n})^2 + \frac{n-m}{m+n}, \quad \xi_1^A \in [\frac{n-m}{m+n}, 0] \\
&\mathrm{III}: \xi_2^A \leq \frac{l}{m}(\xi_1^A + \frac{n}{m+n})^2 + \frac{n-m}{m+n}, \quad \xi_1^A \in [0, \frac{m-n}{m+n}] \\
&\mathrm{IV}: \xi_2^A \leq \frac{l}{n}(\xi_1^A - \frac{m}{m+n})^2 + \frac{m-n}{m+n}, \quad \xi_1^A \in [\frac{m-n}{m+n}, 1]
\end{aligned} \tag{19}$$

Fig. 3(c) provides the schematic diagram of the obtained feasible region. When $m<n$, the boundary equations of the feasible region are the m, n value exchange of the above formula. It can be seen from the diagram and Eq. (19) that the boundary constraint equations on the feasible region increase, and they are still parabolic. The values of m and n both determine the characteristics of the parabolas.

2.4.3 Feasible region of $[(\pm\theta_1)/(\pm\theta_2)/\cdots/(\pm\theta_{l/2})]_r$

Further consider the increase of ply angle variable dimension. Assuming that the more general DD laminate contains $l/2$ ply angle variables, the expression of the laminate can be written as $[(\pm\theta_1)/(\pm\theta_2)/\cdots/(\pm\theta_{l/2})]_r$. The corresponding lamination parameter ξ_1^A and ξ_2^A are given as follows:

$$\begin{aligned}
&\xi_1^A = \frac{2}{l}(\cos 2\theta_1 + \cos 2\theta_2 + \cdots + \cos 2\theta_{l/2}) \\
&\xi_2^A = \frac{2}{l}(\cos 4\theta_1 + \cos 4\theta_2 + \cdots + \cos 4\theta_{l/2})
\end{aligned} \tag{20}$$

The boundary equations of the feasible region are as follows:

$$\begin{aligned}
&\xi_2^A \geq 2(\xi_1^A)^2 - 1, \quad \xi_1^A \in [-1,1] \\
&\xi_2^A \leq \frac{4}{l}(\frac{l}{2}\xi_1^A + i - 1)^2 + 1 - \frac{4}{l}, \quad \xi_1^A \in [\frac{-2i}{l}, \frac{4-2i}{l}] \\
&\xi_2^A \leq \frac{4}{l}(\frac{l}{2}\xi_1^A - i + 1)^2 + 1 - \frac{4}{l}, \quad \xi_1^A \in [\frac{2i-4}{l}, \frac{2i}{l}]
\end{aligned} \tag{21}$$

where i is an odd or even set, depending on the value of $l/2$. When $l/2$ is even, $i \in \{2, 4, \cdots, l/2\}$, and when $l/2$ is odd, $i \in \{1, 3, \cdots, l/2\}$. Fig. 3(d) provides a schematic diagram of the obtained feasible region. Combining Eq. (21), it can be seen that the upper boundary of the feasible region is a quadratic function related to the value of l. Due to the same number of each ply angle variable, $l/2$ parabolic lines with the same shape and different symmetry axes contain the equal interval span of ξ_1^A axis, evenly dividing the [-1,1] interval. When the value of t tends to infinity, the upper boundary of the whole feasible region is the straight line ξ_2^A=1.

2.4.4 Summary of the feasible region for general extended DD laminates

The explicit expression of feasible region boundary equations and the comparison with classical DD laminate illustrate the characteristics of the aforementioned three types of extended DD laminates. In addition, some general conclusions regarding the ξ_1^A-ξ_2^A feasible region of extended DD laminate are summarized as follows:

(1) All the extended DD laminates have the same equation form for lamination parameters ξ_1^A and ξ_2^A, which can be expressed by a general expression, as shown in Eq. (22). Where m_i is the occurrence number of the i-th ply angle variable, d is the dimensionality of the variable, b_1 and b_2 are the coefficients corresponding to the known ply angles. When the research object is a combination of any two laminating parameters, similar expressions can still be obtained.

$$\xi_1^A = b_1 + \frac{2}{l}m_i \cos 2\theta_i \ , \ \xi_2^A = b_2 + \frac{2}{l}m_i \cos 4\theta_i \quad (i \in \{1, 2, \cdots, d\}) \tag{22}$$

(2) All boundary curve equations in the feasible region of ξ_1^A - ξ_2^A are quadratic functions. By combining Eqs. (14) and (22), it can be concluded that the shape of the feasible region is determined by the trigonometric function pairs $m_i\cos2\theta_i$~$m_i\cos4\theta_i$. Therefore, adding known ply angles and proportionally changing the occurrence number of ply angle variables will only scale and translate the existing feasible region. Changing the proportion of the occurrence number of ply angle variables, and the dimensionality of the variables, the shape of the feasible region and the number of boundary equations will change, and the entire feasible domain space can be further expanded.

The general analysis and discussion of extended DD laminates from the perspective of laminate parameters and feasible region is helpful to further explain the characteristics of DD laminates from the theoretical level. From the above analysis, it can be concluded that increasing the variable dimension of sublaminate can expand the feasible region space of DD, and the gray feasible region of classical DD laminates in Fig. 3(a) can be further filled. However, in practical applications, the increase in the ply number of sublaminate will lead to the need for more plies to satisfy the homogeneity of laminates, which will affect the weight saving by tapering. In addition, with ply number increase in sublaminate, the appearance of ply drops corresponds to a higher taper ratio, and this may lead to high stress concentration [3]. The research on the homogeneity of the extended DD laminates will be carried out in our future work.

3 BUCKLING OPTIMIZATION OF HORSESHOE PROBLEM BASED ON DD LPS

3.1 Problem description

The 18-panel horseshoe configuration is shown in Fig. 4, the dimensions and local loadings of each panel are marked in the figure. All panels are assumed to be simply supported on four edges and loaded in bi-axial compression. The Graphite/Epoxy IM7/8552 unidirectional prepreg is used for each ply, where E_1 = 141 GPa (20.5 Msi), E_2 = 9.03 GPa (1.31 Msi), G_{12} =4.27 GPa (0.62 Msi), ν_{12} = 0.32, the ply thickness is 0.191mm (0.0075 in), and the prepreg density is 1.57g/cm^3. The optimization objective is

to find the lightest horseshoe panel design without individual panel failure under buckling. A simply supported panel in bi-axial compression has a sinusoidal buckling mode. The panel is loaded such that critical buckling loads are $N_{xcr} = \lambda N_x$ and $N_{ycr} = \lambda N_y$, where λ is a scalar load amplitude factor. The value of λ corresponds to buckling is given by Eq. (23).

$$\lambda(m,n)=\frac{\pi^2[D_{11}(m/a)^4+2(D_{12}+2D_{66})(m/a)^2(n/b)^2+D_{22}(n/b)^4]}{(m/a)^2N_x+(n/b)^2N_y} \tag{23}$$

where m and n are the buckling half-wave numbers in the x and y directions respectively. a and b are the length and width dimensions of the plate. D_{11}, D_{12}, D_{66}, D_{22} are the bending stiffness coefficients of the laminated plate.

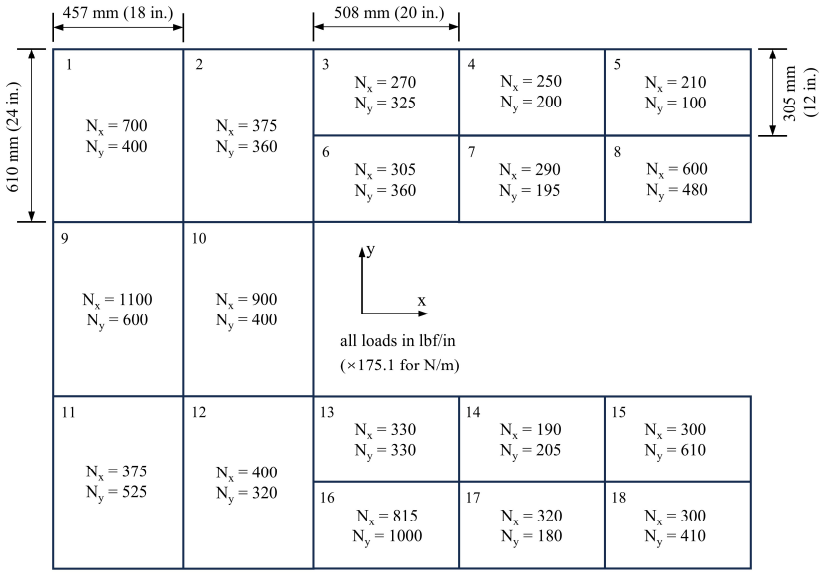

Fig. 4. Geometry and loads of 18-panel horseshoe optimization case [7].

3.2 DD optimization with blending constraint

When blending constraint is considered. The DD layup orientations of each plate are the same $[\pm\Phi/\pm\Psi]_1=\cdots=[\pm\Phi/\pm\Psi]_k=\cdots=[\pm\Phi/\pm\Psi]_n$, and all plates have the same LPs. In this case, the design variables are the continuous layup angles and the plate thickness related to the number of layers.

Substituting the expression of the bending stiffness coefficients with respect to LPs into Eq. (23), Eq. (24) can be obtained. Here k_1, k_2 and k_3 are constants related to the respective plate dimensions and applied loads, as shown in Eq. (25). U_1-U_5 are the material stiffness invariants corresponding to IM7/8552 materials. The plate thickness h in Eq. (24) can be converted into Eq. (26). The optimization problem turns into obtaining the optimal LPs set that makes the total weight of the structure in Eq. (27) is minimized.

$$\begin{aligned}\lambda(m,n)&=\pi^2[D_{11}k_1+2(D_{12}+2D_{66})k_2+D_{22}k_3]\\&=\frac{h^3}{12}\pi^2[\xi_1^D U_2(k_1-k_3)+\xi_2^D U_3(k_1+k_3-6k_2)+(U_1k_1+U_1k_3+2U_4k_2+4U_5k_2)]\\&=\frac{h^3}{12}\pi^2F(\xi_1^D,\xi_2^D)\end{aligned} \tag{24}$$

$$\begin{cases}k_1=\dfrac{(m/a)^4}{(m/a)^2N_x+(n/b)^2N_y}\\[2ex] k_2=\dfrac{(m/a)^2(n/b)^2}{(m/a)^2N_x+(n/b)^2N_y}\\[2ex] k_3=\dfrac{(n/b)^4}{(m/a)^2N_x+(n/b)^2N_y}\end{cases} \tag{25}$$

$$h_i = \sqrt[3]{\frac{12}{\pi^2 F_i(\xi_1^D, \xi_2^D)}} \tag{26}$$

$$W = \sum_{i=1}^{18} \rho a_i b_i h_i = \rho[\mathrm{a_1 b_1} \sum_{i \in \mathrm{P_1}} \sqrt[3]{\frac{12}{\pi^2 F_i(\xi_1^D, \xi_2^D)}} + \mathrm{a_3 b_3} \sum_{j \in \mathrm{P_2}} \sqrt[3]{\frac{12}{\pi^2 F_j(\xi_1^D, \xi_2^D)}}] \tag{27}$$

$$\begin{cases} \dfrac{F_i(\xi_1^D, \xi_2^D)}{F_1(\xi_1^D, \xi_2^D)} = \dfrac{(m/a)^2 (N_x)_1 + (n/b)^2 (N_y)_1}{(m/a)^2 (N_x)_i + (n/b)^2 (N_y)_i} = k_i^{'}, \quad i \in \mathrm{P_1} \\ \dfrac{F_j(\xi_1^D, \xi_2^D)}{F_3(\xi_1^D, \xi_2^D)} = \dfrac{(m/a)^2 (N_x)_3 + (n/b)^2 (N_y)_3}{(m/a)^2 (N_x)_j + (n/b)^2 (N_y)_j} = k_j^{'}, \ j \in \mathrm{P_2} \end{cases} \tag{28}$$

$$W = \rho(\mathrm{a_1 b_1} \sum_{i \in \mathrm{P_1}} k_i^{'} \sqrt[3]{\frac{1}{F_1(\xi_1^D, \xi_2^D)}} + \mathrm{a_3 b_3} \sum_{j \in \mathrm{P_2}} k_j^{'} \sqrt[3]{\frac{1}{F_3(\xi_1^D, \xi_2^D)}}) \tag{29}$$

The plates in the respective sets of $\mathbf{P_1}$ and $\mathbf{P_2}$ have the same size and LPs, it can be obtained from Eq. (24) and Eq. (25) that the function $F(\xi_1^D, \xi_2^D)$ corresponding to the plates in the two sets are proportional as shown in Eq. (28). Define the function $F(\xi_1^D, \xi_2^D)$ ratio of each plate in the $\mathbf{P_1}$ set with respect to plate 1 as $k_i^{'}$, and define the function $F(\xi_1^D, \xi_2^D)$ ratio of each plate in the $\mathbf{P_2}$ set with respect to plate 3 as $k_j^{'}$. The weight of the entire plate is only related to the function F corresponding to plates 1 and 3, as shown in Eq. (29). F_1 and F_3 are interrelated functions related to variables ξ_1^D and ξ_2^D. Therefore, minimizing the weight of the structure is equivalent to doing a linear program to find the minimum value on the feasible region composed of $\frac{1}{\sqrt[3]{F_1}}$ and $\frac{1}{\sqrt[3]{F_3}}$.

The linear programming of Eq. (29) in the feasible region of an extended DD laminate is shown in Fig. 5, where the boundary equations are implicitly derived from the section 2.3. It can be concluded that the minimum value of the structure weight is also obtained at the lower bound of the DD feasible region, and the optimal layups are also single DD. Since the number of layers is even, the optimal solution of LPs is the value interval. The optimal LPs values are $\xi_1^D \in$ [-0.166, -0.124], $\xi_2^D \in$ [-0.945, -0.969], and the optimal ply angles are single DD interval [±49.79°, ±48.56°].

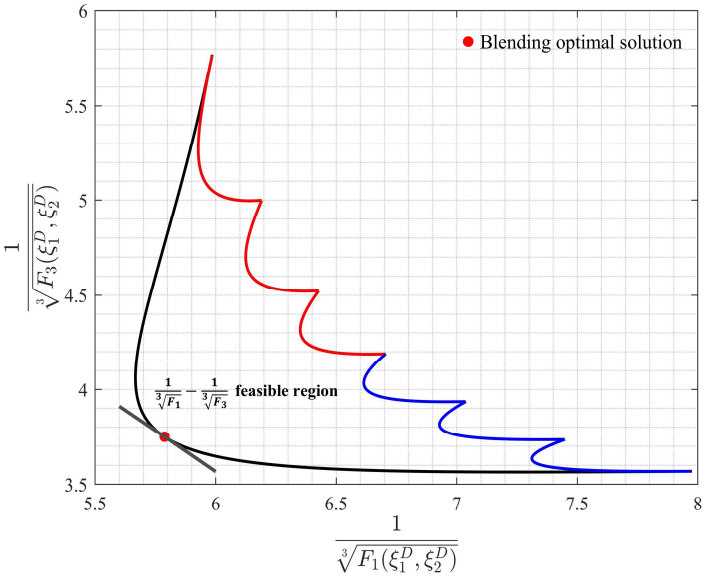

Fig. 5. LPs optimal solution of benchmark problem with blending constraint in the feasible region of an extended DD laminate.

Table 1 shows the number of plies and buckling factor of each plate when the single DD ply angle taken as ±49°. When the number of DD layers is rounded up to the even, the weight of the whole plate is 28.67kg, the residual buckling factor of each plate is also given in the table, and all plates satisfy the homogeneity criterion.

3.3 Results analysis and comparison

Based on the obtained lamination parameters and the feasible region design space of DD laminates, the optimization results of the classic horseshoe benchmark problem are derived analytically. Most of the previous studies used evolutionary algorithms to optimize the benchmark problem. In order to further reveal the characteristics and advantages of DD in layup optimization, the results of DD and evolutionary algorithm optimization are compared and analyzed.

Table 1 provides the optimization results of each plate based on PDS (ply drop sequence) layup strategy under genetic algorithm and compares them with DD optimization results with even number of plies satisfying blending constraint. PDS is a layup design method for internal ply drops proposed by Yang et al [8]. This method conveniently expresses layup information and realizes the satisfaction of blending constraint. Under the balanced and symmetrical design criteria, PDS selects QUAD (0°, ± 45°, 90°) and General (0°, ± 15°, ± 30°, ± 45°, ± 60°, ± 75°, 90°) two types of ply angles for optimization. When the PDS selects QUAD orientations and the number of layers is even, the optimal weight of the structure is 28.76kg after 2500 iterations optimization. As the current optimization algorithm with strong performance, the optimized solution obtained by PDS using QUAD layer is inferior to the solution obtained by DD satisfying the homogeneity optimization. In addition, the convergence time of the optimization algorithm iteration takes several hours, while DD only needs a few milliseconds to obtain the optimal solution. When PDS selects the General ply angle and the number of plies is allowed to be odd, the optimal weight of the structure is 28.47kg after 2800 iterations optimization, which is 0.29kg lighter than QUAD solution and better than DD solution.

Table 1. Results comparison for DD with PDS.

Panel	PDS (QUAD)		PDS (General)		DD	
	Ply number (even)	λ_{min}	Ply number (odd)	λ_{min}	Ply number (even)	λ_{min}

Fig. 6 shows the distribution of DD and PDS QUAD optimization solutions in the feasible region of ξ_1^D-ξ_2^D. The areas enclosed by the blue curve and black dotted line are DD feasible region and QUAD feasible region, respectively. The special stacking characteristic makes the optimal solution obtained by

DD unique. For QUAD laminates, in order to satisfy the blending constraint and ensure the continuity of the layup, the stacking sequence of each plate is different, and the solution set is distributed on the right side of the lower boundary of the feasible region. In theory, each plate approaches the theoretical optimal solution as closer as possible to minimize weight, but the discrete ply angle variables, blending constraint, and other design criteria make the solution values compromise and aggregate.

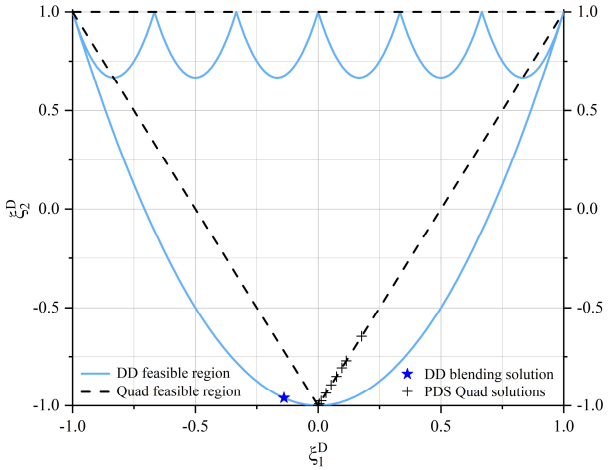

Fig. 6. Distribution of DD optimal solution and PDS QUAD optimal solution in feasible region of lamination parameters.

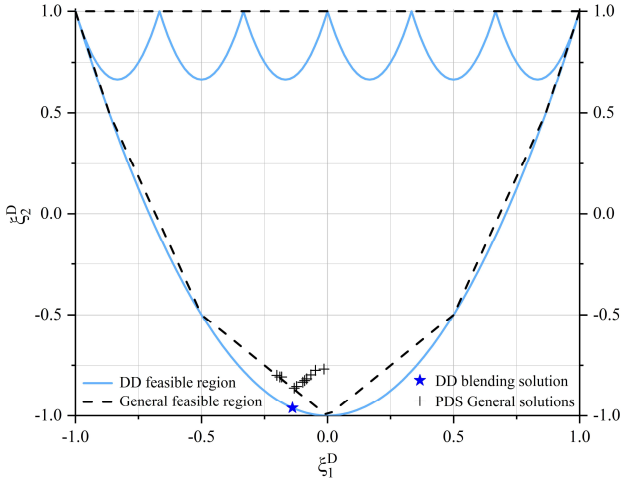

Fig. 7. Distribution of DD optimal solution and PDS General optimal solution in feasible region of lamination parameters.

Fig. 7 shows the distribution of DD and PDS General optimization solutions in the feasible region of ξ_1^D-ξ_2^D, where the area enclosed by the black dotted line is the General laminate feasible region. It can be seen from the figure that the optimal solutions obtained by using General ply angle are also distributed discretely at the lower boundary of the feasible region. However, compared with QUAD solutions, PDS General solutions are more concentrated and closed to DD solutions. This is because the increase of ply angle variables expands the feasible region, and the distribution of the optimal solution set is further optimized. Moreover, the number of plies can be taken as an odd number further utilize the buckling margin for design.

In this 18-plane benchmark problem, it can be concluded from the comparison of all optimization solutions that the dimension of ply angle variable and the existence of design constraints determine the optimization efficiency and convergence of the traditional optimization algorithm. The higher dimension of the ply angle variable brings larger feasible region design space, better solution and higher

computational cost, while the existence of design constraints could affect the distribution of solution set. When the coupling deformation is not desired and the better material homogeneity is expected. DD has obvious advantages over traditional QUAD laminates, including faster optimization efficiency, better solutions, simple and convenient manufacturing layups. Although lighter structural weight can be obtained by increasing the type of QUAD ply angles, the calculation cost and manufacturing difficulty also increase, and the complex internal ply drops will bring more design challenges.

4 CONCLUSIONS

In this paper, the general extended DD laminates are analyzed and applied based on lamination parameters and feasible region. The explicit LPs expressions and feasible region of general extended DD laminates are derived, and the characteristics of DD laminates family are revealed. Based on the feasible region of extended DD lamination parameters, the classical 18-plane horseshoe benchmark problem is optimized. The conclusions of this paper are summarized as follows:

(1) In the general extended DD laminate $[\theta_1/\theta_2/\ldots/\theta_l]_r$. Lamination parameter ξ^A is only related to the type of sublaminate ply angles, and the ξ^B and ξ^D are inversely proportional to the number of sublaminate repetitions r and r^2. When the value of r increases, ξ^B tends to 0, and the ξ^D tends to be equal to ξ^A. The balance of sublaminate is a sufficient and necessary condition for DD laminate family achieving homogenization, and the symmetry and antisymmetry of sublaminate can further directly eliminate coupling deformation.

(2) The lamination parameters ξ_1^A and ξ_2^A of all extended DD laminates have the same equation form. In addition, all boundary curve equations in the feasible region of ξ_1^A-ξ_2^A are quadratic functions.

(3) The classical 18-plane horseshoe benchmark problem is more intuitively optimized by using derived DD feasible regions. The whole problem is summarized as a linear programming problem in the LPs feasible region of DD, and the optimal solution is obtained at the lower bound of the feasible region, regardless of the categories of DD. When the blending constraint is considered, the optimal weight of the structure is 28.67kg, and the optimal DD layup is $[\pm 49°]_r$.

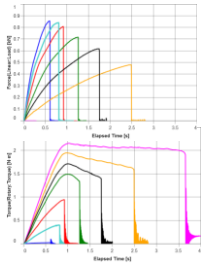
Using Multiaxial Fatigue to Investigate the Anisotropic Performance of Additively Manufactured Material

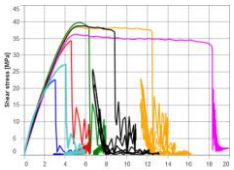
P. B. S. Bailey, Instron Dynamic Systems, UK

Combined axial-torsion loading

A majority of materials testing is based on uniaxial, planar stress states, but this can be a great simplification of real loading cases. This is often still adequate for design, but the analytical tools for multiaxial stress can also offer ways to extract more data.



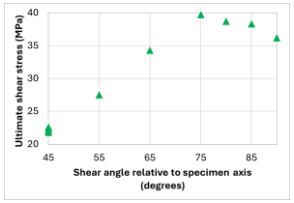
Combining tension and torsion, on a tubular specimen, effectively rotates the direction of loading relative to the specimen axis.



Additive manufacture by polymer filament deposition, creates a laminated structure, so building in the specimen axis direction, and using Mohr's circle, we can assess the apparent tensile or shear strength behaviour at different orientation relative to the laminae.

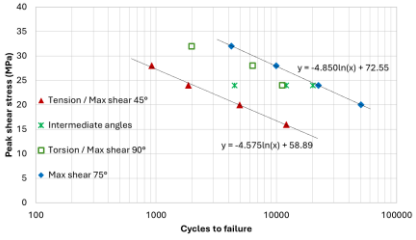
These graphs show how the measured stress-strain curves for tensile axial stress and torsional shear stress combine to form a total curve for maximum shear.

The results imply that the material exhibits higher shear strength and drawing capacity with decreasing shear biaxiality



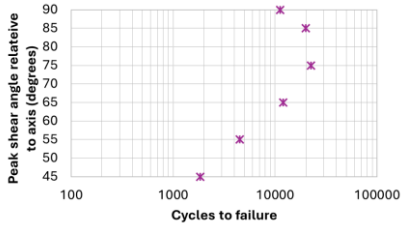
Equipment availability

Multi-axial loading used to require specialised, custom test equipment, but for over 15 years now, combined axial-torsional fatigue load frames have been an off-the-shelf product and there are around 2000 machines installed worldwide, from multiple manufacturers.



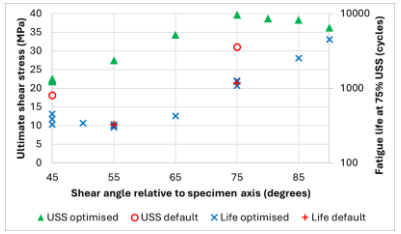
Effects of rotating principal axes

Specimens were manufactured with a nominal outer gauge diameter 7.7 mm and wall thickness 0.8 mm, with parallel length of 20 mm, using a partially-optimised molten filament deposition process for PLA polymer, resulting in 100% density.



Using the combined loading approach, the apparent ultimate shear stress initially increases as the maximum shear angle is rotated away from 45° to the axis (pure tension).

When considering fatigue life, under multiaxial loading, ISO TR 121102 advises that this is most strongly related to the maximum shear amplitude applied.



Plotting a series of investigative S-N curves at different levels of maximum shear stress with different rotations relative to the axis, shows a similar slope, but significant uplift in fatigue strength with rotation away from simple tension.

However, like the ultimate shear stress, it shows a peak at around 30° rotation relative to the specimen axis, but this seems more profound in fatigue.

Process and microstructure effects

Taking the fully dense material as a baseline, a number of replicates were run at several angles, to give a basic indication of variability. The scatter is very low in this initial study, and this is probably due to the choice to build specimens individually (some parallel investigations indicate multi-specimen builds can result in 2 or more distinct populations of fatigue strength).

Now with only a small sample of specimens using a "de-optimised" process (the default process settings recommended) it is immediately visible that there is a reduction in monotonic shear strength. Note that the monotonic measurements were conducted at considerably higher strain rate, to provide a degree of comparability with that present in 3Hz fatigue loading waveforms.

However, when applying a waveform at R=0.1 with maximum shear stress at 75% of the monotonic strength, the fatigue life is rendered almost indistinguishable. Simple examination of the cross-section at moderate magnification, shows that the de-optimised specimen has considerable void between filament passes, thus reducing the true cross-section for stress. The fully-dense process, is not without some form of laminate structure either.

Further investigations are ongoing, including extending the sample for better statistical significance. It may also be valuable to consider a fracture mechanics approach to the analysis as Mode I – III mixity.

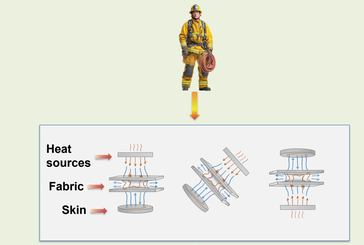
ICCM24 — 24TH INTERNATIONAL CONFERENCE ON COMPOSITE MATERIALS



OBJECTIVES

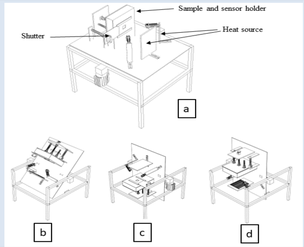
- Develop a novel bench-scale instrument capable of testing TPP at any orientation (0° to 180°).
- Integrate advanced heat flux sensors with orientation adjustment systems.
- Validation of the instrument's measurement
- Provide comprehensive understanding of orientation impact on thermal protection.

BACKGROUND

- Current bench scale testing methods are limited to fixed orientations, which limits real-world scenarios
- As the orientation changes, the heat transfer changes
- When there is a significant temperature difference across the air gap, density variations cause buoyancy forces that drive convective motion.
- Gravity enters the problem through these buoyancy forces, and the effect can be quantified by dimensionless numbers such as Boussinesq approximation, Grashof and Rayleigh numbers.
- Protective performance at different orientations may bring new opportunity to redesign thermal protective clothing.

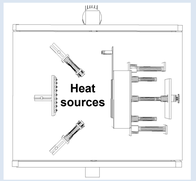
$$q_{total} = q_{conduction} + \boldsymbol{q_{convection}} + q_{radiation}$$

$$\boldsymbol{q_{conv}} = \boldsymbol{h}.A.(T_1 - T_2)$$



$$\boldsymbol{h} = \frac{\boldsymbol{N_u}.K}{L}$$

$$\boldsymbol{N_u} = C.(\boldsymbol{Gr}.\boldsymbol{Pr})^{n}$$



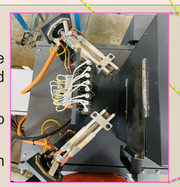
$$Rayleigh\ number\ (Ra) = \boldsymbol{Gr}.\boldsymbol{Pr} = \frac{g\beta\Delta T d^3}{\nu\alpha}$$

CONCEPTUALIZATION AND PLANNING

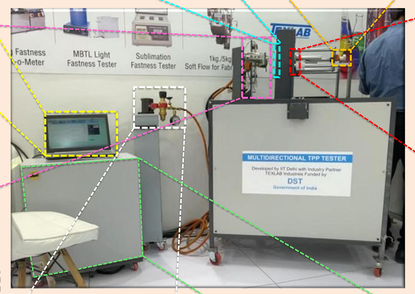
- Heat source which mimic outside environment
- Sensor to mimic human skin
- Arrangement to change the direction
- Attachment to bring airgap
- Sample holder
- PLC based controls
- Software interface to control

Top view

INSTRUMENT



Sample Holder
- Size: 15×15 cm²
- Firm holding
- Can support fabrics with different thickness



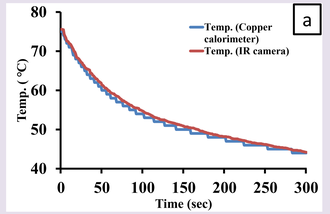
Air gap
- Air gap can be provided from 0 mm to 40 mm.
- Knob with scale for precise air gap

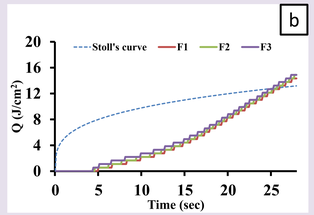
Heat sources
- Variable heat source
- Radiant source: Nine 500W quartz infrared lamps
- Convective source: Two Meker burners
- Protective shutter system for controlled exposure

Sensor system
- Copper calorimeter heat flux sensor
- Type J thermocouple
- Sensor weighted to 1000 ± 10 g with flat black coating (absorptivity ≥ 0.9)
- Data acquisition system with programmable logic control (PLC)

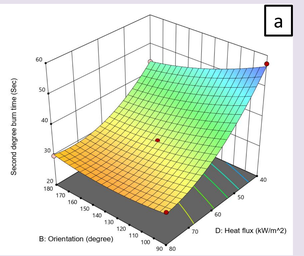
TESTING CAPABILITIES

- Orientation range: 0° to 180° rotation and heat flux of 0 to 100 kW/m²
- Variable air gap adjustment between heat source and specimen
- Automated testing sequences with safety interlocks
- Real-time data logging and burn time calculation
- Can measure second degree burn time
- Measurement of stored energy

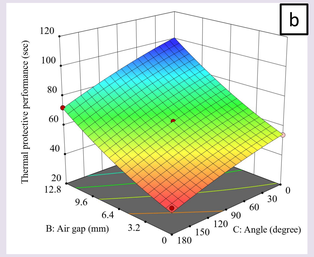




Pressure valve
- Pressure control
- Wide pressure range
- Robust construction



PLC system
- Real time control
- Data logging capabilities
- Input/output versatility



VALIDATION

RESULTS

CONCLUSION

- Developed a novel bench-scale instrument for testing thermal protective performance at variable orientations
- The instrument can test 0 to100 kW/m², 0 to 180 degree
- There is significant impact of orientation on heat transfer rates
- The technology transfer to industry partner
- The instrument may help in development of thermal protective clothing
- Bridged the gap between laboratory testing and real-world firefighting scenarios
- Can be used for materials other than textile
- Filed for patent

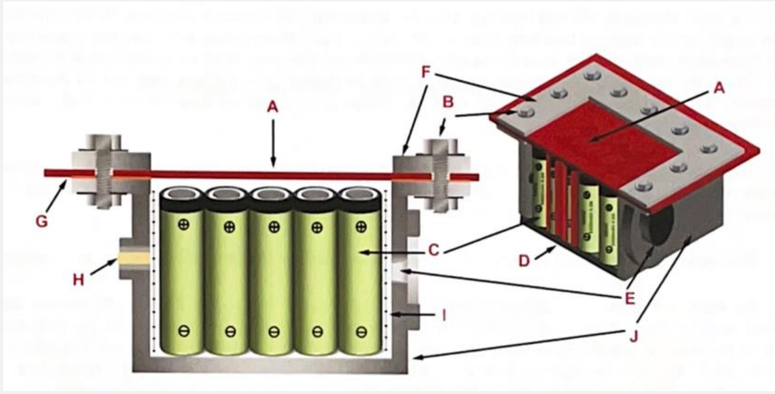
Thermal and mechanical analysis of Li-ion battery fire containment

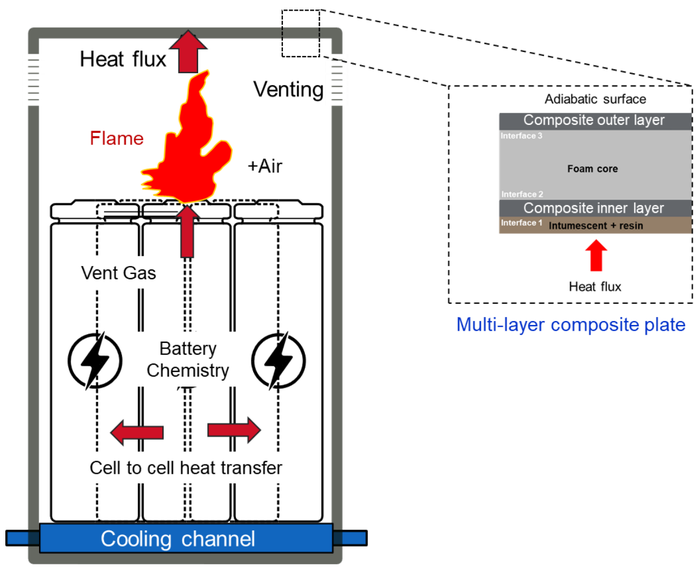
Sindhu Bushpalli, Changmin Cao, Gearoid Clancy, Hariharan Kallath, El Hassan Ridouane



Problem statement

Vision

- Battery systems in aircrafts play significant role in reducing environmental footprint
- Modular and scalable technologies support multiple market segments
- High energy density batteries are required for all systems
- Significant certification risks related to **safety & containing cell failures**



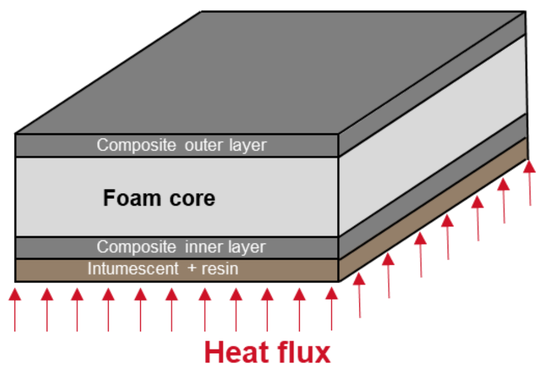
Scope

- Thermal Runaway modelling of battery pack solutions
- Develop light-weight and safe composite battery containment
- Proof-of-Concept testing of integrated battery pack solutions

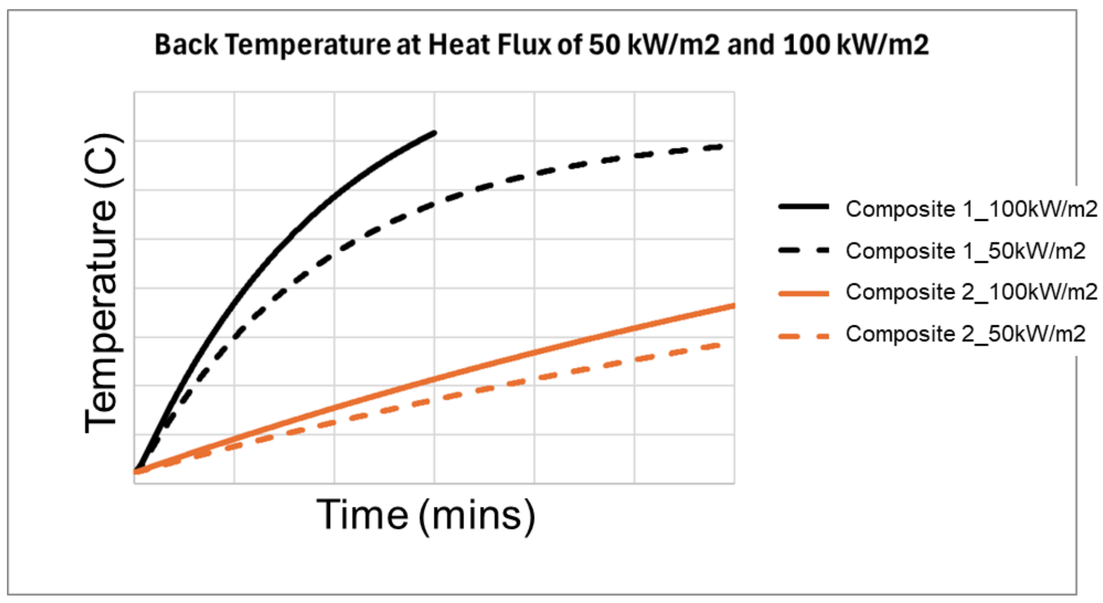
Battery package from UL2596

Li-ion battery containment overview

Multi-layer composite plate



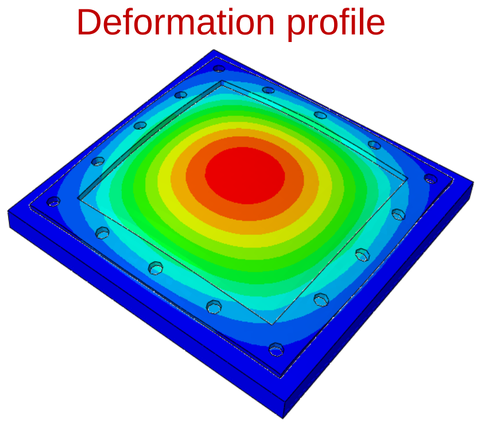
- Contain thermal runaway while retaining structural integrity
- Weight savings: light weight materials – different composite configurations
- Limit box outside temperature and reduce thermal risk to other systems
- Evaluate performance: Cone calorimetry testing, UL2596
- Develop and validate numerical models

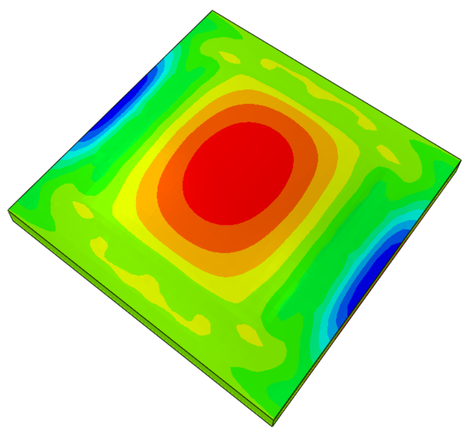


UL solutions battery enclosure lab

Results

Thermal analysis of composite solution





- Collins composite material thermal model was validated using test data. Composite material selection was completed and candidates with better performance were identified, and full module tests are planned.

Structural analysis

Deformation profile

Stress profile

Next Steps and Challenges

- Coupon level testing planned for several material configurations
- Testing small scale demonstrator – few cells in thermal runaway
- Develop and validate numerical models using test data

ICCM24 – 24TH INTERNATIONAL CONFERENCE ON COMPOSITE MATERIALS

1. INTRODUCTION

Buildings with **double curvature façades** can be aesthetically pleasing, being capable of enchanting both architects and the general public. Though, manufacturing of such façades can be a challenge in both technologic and economic terms. **Traditional molding technologies demand a unique mold for each panel geometry**, resulting in **substantial costs** related to raw materials and storage space, and **long lead times for designing and manufacturing**. A **reconfigurable multipoint mold** has been identified to solve this issue, where an array of moving pins can have their height quickly adjusted to form the required shape and molding surface. Another present technological challenge is the **highly demanding fire resistance requirements**. Certain European countries require that public and civil buildings comply with the highest grades of EN 13501 standard, A2, s1, d0 and B, s1, d0. That is a serious constraint when developing lightweight sandwich fiber reinforced polymer (FRP) composites, as polymeric materials do not naturally present good reaction to fire behavior. Furthermore, the polymeric raw materials should present suitable **processability** with the reconfigurable multipoint mold and supporting processing equipment and allow the manufacturing of **sandwich structures**. Sandwich composites structures are **lightweight** solutions with high stiffness, consisting of two composite laminate faces, separated by a lightweight core material, commonly made of foam or honeycomb.

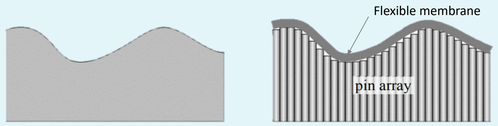

Fig. 1 traditional rigid mould versus reconfigurable multipoint mould

2. OBJECTIVES

The project aims at selecting adequate polymeric based materials for the manufacture of **lightweight double curvature lightweight sandwich** panels, with a **minimum curvature radius of 300 mm**, using a reconfigurable multipoint mould, considering the following **requirements** and **constraints**:

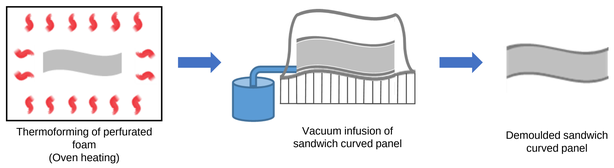
1. Processing temperatures below 200 °C;
2. Processable by Vacuum Assisted Resin Infusion (VARI) or Vacuum assisted Thermoforming (VAT);
3. Thermoformable rigid foam core to conform to the double curvature molding surface;
4. High drapability fabrics (e.g. twill) to conform to the minimum curvature radius;
5. Compliant with the highest grades of EN 13501 standard (A2, s1, d0 and B, s1, d0);
6. Long term UV radiation resistance.

Furthermore, this project aims at optimizing the manufacturing processes of the double curved sandwich panels and developing the attachment solution to the building walls.

Fig. 2 Buildings inspiring the development of this project: (left) Heydar Aliyev Center, Baku – Azerbaijan, Architect Zaha Hadid (2013) and (right) Central Park OfficeTower, Utrecht – The Netherlands, Architects: Group A

3. METHODOLOGY

This work is testing several material combinations to obtain (a) fully thermoplastic and (b) thermoset based composite sandwich for double curvature panels solutions. All tested sandwich composites used a thermoformable foam.

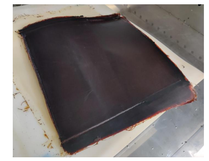


In a first stage, flat sandwich panels were manufactured to assess their reaction to fire, observed during ignition tests, conducted according to ISO 11925-1 standard, and to assess UV radiation resistance of different coating formulations.

Sandwich manufacturing was parallelly optimized on a small scale rigid mould. Depending on the constituent materials, either one of two manufacturing methods were conducted:

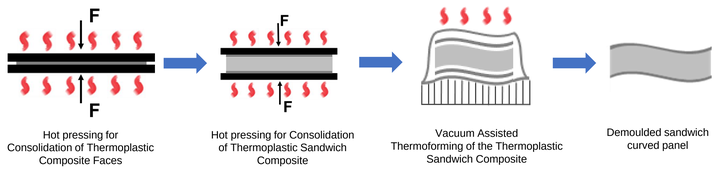
1. VARI when liquid thermoset matrices are used for the manufacturing of composite faces;
2. VAT when thermoplastic films are used for the manufacturing of composite faces.

MATERIALS and MANUFACTURING PROCESSES



Vacuum Assisted Resin Infusion

Fibre fabric reinforcements
- Basalt fibre with 2/2 twill structure and areal weight of 220 g/m²
- Glass fibre fabric reinforcements with 2/2 twill structure and areal weight of 195 g/m²



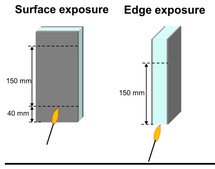
Foam core: Fire-retardant structural Airex® T90 PET foam from 3A Core Materials, 25 mm thick

Matrices:
- Fire-retardant epoxy resin system SR1124/SD4771, with SGi 128 gelcoat from Sicomin
- Biobased furan resin Furolite 106A25 2ST from TFC, with H3PO4 (85 wt% phosphoric acid) and HM 1448 (85 wt% (2-hydroxyethyl) ammonium nitrate)

Example of small scale sandwich prototype with double curvature made of furan resin/ glass fibre composite skins and PET structural foam, 500 mm x 500 mm, manufactured by VARI,

Vacuum Assisted Thermoforming

Fibre fabric reinforcements
- Basalt fibre with 2/2 twill structure and areal weight of 220 g/m²
- Glass fibre fabric reinforcements with 2/2 twill structure and areal weight of 195 g/m²



Foam core: Fire-retardant structural Airex® T90 PET foam from 3A Core Materials, 25 mm thick

Matrices:
- Fire retardant low density polyethylene (FR-LDPE) film, 60 µm thick
- Fire retardant polypropylene (FR-PP) film, 125 µm thick

Example of small scale sandwich prototype with double curvature made of FR-LDPE/ glass fibre composite skins and PET structural foam, 500 mm x 500 mm, manufactured by VAT

IGNITION TESTS

Test conditions (ISO 11925-2 standard)
- Three specimens for each condition, measuring approximately 250 mm x 90 mm, with thicknesses between about 27 – 29 mm
- Flame application for 30 seconds
- Verify whether the flame front reaches 150 mm above the application point, and recording of incurring time
- Presence of flaming droplets/particles
- Presence of flaming droplets/particles which caused ignition of the filter paper

Sample	Exposure condition	Occurrence of ignition	Fs > 150 mm	t150 (s)	Presence of flaming droplets/ particles	Ignition of the paper
Furan resin/ Basalt fibres – Airex T90 PET foam	Front face	yes	no	-	no	no
	Lateral bottom edge				yes

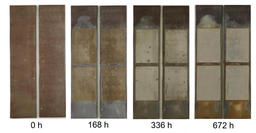
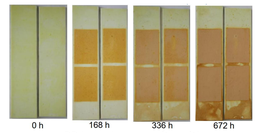
FLUORESCENT UV LAMP RADIATION EXPOSURE

Test conditions (ISO 4892-3 standard)
Cycles of Exposure to UVA-340 (type 1A) lamp, with irradiance of 0.76 $W.m^{-2}$ x nm^{-1} at 340 nm, for 8 hours, at 60 ± 3 °C, followed by 4h period of condensation, with UV lamps off, at 50 ± 3 °C. Cycling test conducted for a total of 672 h.

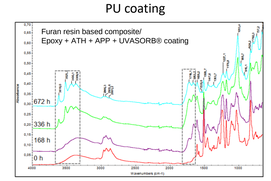


The surface chalking was measured prior to and at the end of testing, and measurement of Brightness, Color coordinates (ΔL*, Δa*, Δ b*) and color change (ΔEab*) and FTIR analysis conducted at 0, 168, 336 and 672 hours of testing

Sample	Coating formulation	Chalking	Gloss 60º (GU)		Color difference at 672h			
			0h	672h	ΔL*	Δa*	Δb*	ΔE*ab
PP/ glass fibres	PU	2.9%	7.0	6.6	0.0	0.1	0.3	0.3
	PU + ATH + APP	7.5%	2.3	2.3	0.4	0.1	0.4	0.5
	PU + ATH + APP + UVASORB®	5.5%	2.4	2.4	0.3	0.2	0.6	0.7
	Epoxy + ATH + APP + UVASORB®	63.4%	28.6	2.1	-20.1	24.8	-8.2	33.0
Furan resin/ glass fibres	PU	4.1%	6.1	3.4	-0.2	0.1	0.4	0.5
	Epoxy + ATH + APP + UVASORB®	56.1%	27.0	1.7	30.2	-3.8	1.7	30.5



Polyurethane (PU), Aluminium Trihydroxide (ATH), Ammonium polyphosphate (APP), UVASORB®



Furan resin based composite with PU coating

Furan resin based composite with Epoxy + ATH + APP + UVASORB® coating

PP based composite with Epoxy + ATH + APP + UVASORB® coating

Main Conclusions
- All PU based coating formulations did not show significant changes when subjected to the mentioned conditions, with the exception of the Furan resin based composite with PU coating which showed a colour change on the non-exposed region of the specimens;
- The epoxy based coating formulations revealed powderiness and severe colour changes. Changes on the FTIR spectra are also noticeable.

FUTURE WORK

Single Burning Item (SBI) test to be conducted, following EN 13823

Manufacturing of full scale (2000 mm x 1000 mm) sandwich panels with double curvature

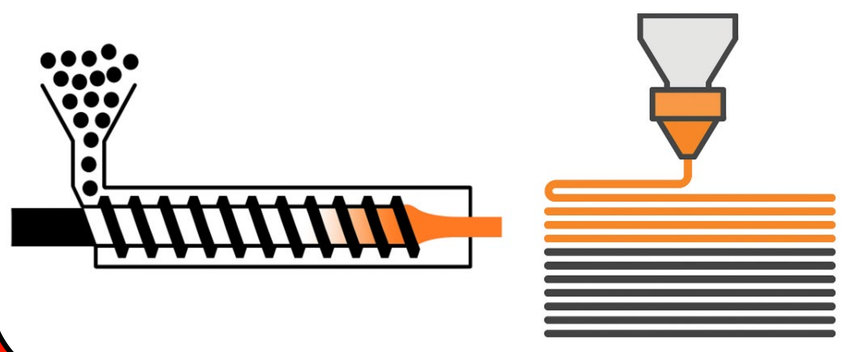
[b] Centre de recherche sur les systèmes polymères et composites à haute performance (CREPEC), Montréal, Canada
[c] Composites Additive Manufacturing and Simulation Center, Purdue University, West Lafayette, IN, USA



Motivation

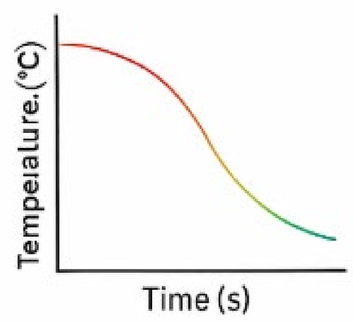
- Large-format additive manufacturing (LFAM) requires precise **control of bead geometry** to ensure part accuracy and mechanical performance.
- Synchronizing screw-driven extrusion flow with gantry motion is critical to **avoid over and under extrusion.**
- Thermal history during printing plays a key role in **interlayer bonding** through reheating and polymer diffusion mechanics.
- Infrared thermography enables real-time monitoring of surface temperature evolution, **cooling and reheating** behavior.

Experimental Workflow for Bead Synchronization and Thermal Imaging

Pellet-fed LFAM Printing

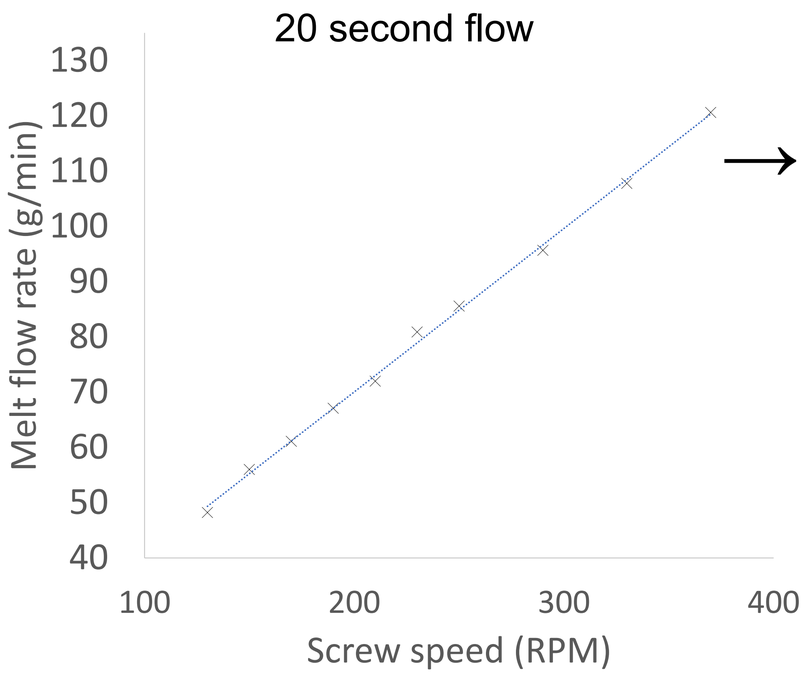
- Carbon fiber reinforced polycarbonate (PC-CF)
- Nozzle diameter : 0.3in Ø
- Barrel & Nozzle Temperature 310°C
- RPM range tested: 130-370 RPM

Bead Size Calibration

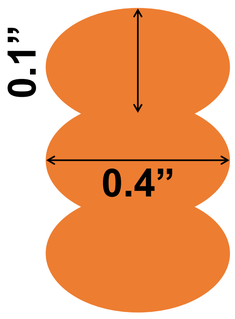


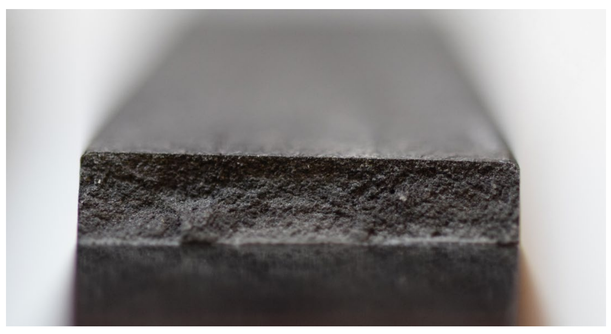
- 20 seconds extrusion trials at fixed RPM
- Material collected and weighed to determine melt flow rate
- Flow rate used to tune slicer deposition speed

$$Melt\ Flow\ Rate\ (MFR)$$
$$\downarrow$$
$$Bead\ height\ x$$
$$Bead\ width\ x$$
$$Deposition\ speed$$



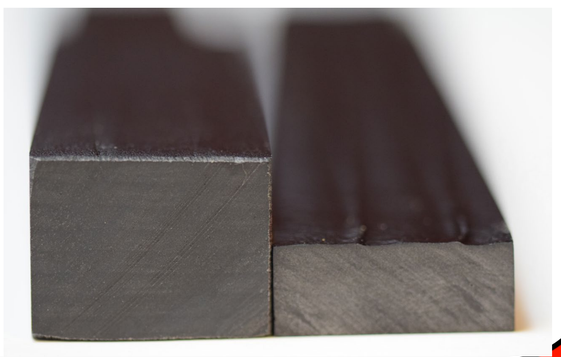
Thermal History Acquisition



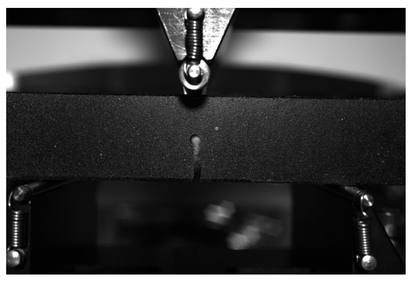


- 40-layer vertical wall (2 beads wide)
- FLIR T62101 IR camera fixed on bed, front-facing view
- Dwell times controlled to achieve desired later time

Bead Size Synchronization

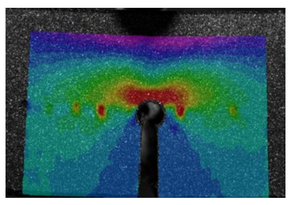


Calibrated output = Consistent beads

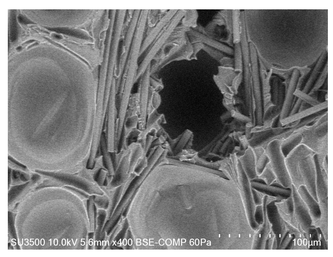


Enables consistent bead geometry

No voids

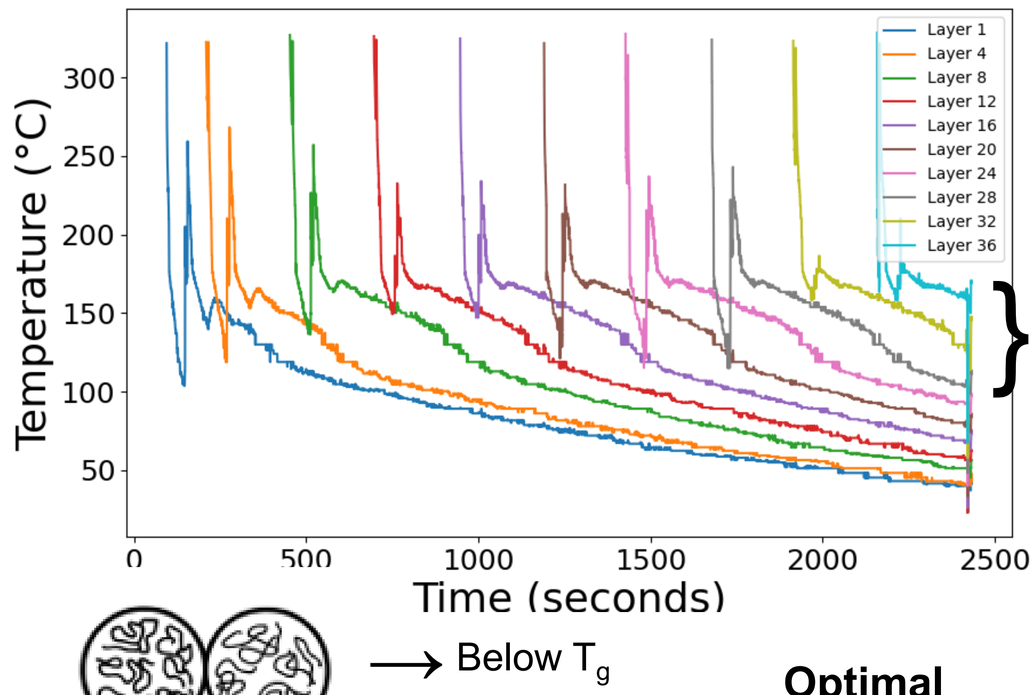


Additional work



Fracture mechanics

DIC



SEM

Thermal History

60 second layer time → 230 RPM, 1.69 in/sec

→ Below T_g

→ Above T_g

Optimal interlayer bonding

Conclusion and Insights

- The findings show a direct linear relationship between screw RPM and volumetric output, enabling bead size control.
- Consistent bead dimensions are critical for layer quality and mechanical repeatability in LFAM.
- IR thermography effectively captured layer-specific thermal histories.
- Higher layers experience extended high-temperature exposure due to thermal mass, potentially enhancing interlayer bonding.
- This methodology provides a framework for experimentally tuning process parameters to optimize part quality.

Keywords: Shape memory polymer composites, Carbon woven fabric, Constitutive behavior, Anisotropic properties, Phase transition

ABSTRACT

This study presents a novel anisotropic constitutive model for carbon fabric-reinforced shape memory polymer composites (SMPCs) based on the phase transition concept, addressing the limitations of existing models in describing viscoelastic yielding and shape memory mechanisms. A new dual-phase decomposition strategy is proposed, wherein the rubbery phase is described as a coupling of the SMP's hyperelastic response and the fabric's orthotropic behavior, while the glassy phase combines SMP viscoelasticity with fabric kinematic constraints. Each phase is independently modelled to capture distinct thermomechanical characteristics. The nonlinear behavior of the SMP matrix is characterized using the Mooney-Rivlin free energy formulation, and the anisotropic hyperelastic response of the fabric reinforcement is described by a polynomial constitutive function. To quantify shape memory effect of SMPCs, a storage strain concept is integrated into the thermodynamic framework. Constitutive equations are derived through energy decomposition, based on the Clausius-Duhem inequality and Helmholtz free energy, with phase effectiveness factors introduced to capture non-ideal behaviors. The model is validated against extensive thermomechanical and shape memory experiments on SMPCs with various fiber orientations. Good agreement is achieved between simulations and experimental results, confirming the model's capability to predict anisotropic mechanical behavior and shape memory performance. The validated framework offers new insights into strain storage mechanisms during phase transitions and provides practical guidance for the design and optimization of SMPC-based structural systems.

1 INTRODUCTION

Carbon fabric-reinforced shape memory polymer composites (SMPCs) have emerged as pivotal materials in aerospace and smart structural applications, owing to their exceptional strength-to-weight ratio and programmable shape memory functionality. While significant progress has been made in material fabrication, performance characterization, and structural integration, the development of theoretical constitutive models has lagged behind experimental advancements [1]. To enable intelligent control and precision engineering of SMPC-based systems, the development of robust constitutive models capable of predicting complex thermomechanical responses becomes imperative.

Compared to neat SMPs, theoretical studies on the mechanical behavior of carbon fabric-reinforced SMPCs remain limited. Roh et al. [2] explored the nonlinear viscoelastic behavior of thin-wall SMPC arms and demonstrated that time-dependent strain energy relaxation can significantly degrade shape recovery capability. Su et al. [3] proposed a viscoelastic constitutive model by decomposing the total free energy of SMPCs into matrix and fiber components, introducing a correction factor to account for the fiber's evolving contribution. Hong et al. [4] developed a homogenized constitutive framework incorporating thermally induced residual stresses, which was validated against three-point bending experiments on SMPCs with varying fiber volume fractions. Despite recent progress, the aforementioned models primarily focus on the viscoelastic properties of SMPs and the anisotropic nature of the reinforcing fabrics. However, they often overlook the significant mismatch in elastic moduli and thermal expansion coefficients between the fabric and the matrix, and fail to fully explain the mechanisms of

strain storage and release during phase transitions. To address this issue, Chen et al. [5] introduced a modified Eshelby model that incorporates these mismatches to derive the effective elastic modulus of SMPCs. They further proposed the storage strain concept to simulate the shape memory behavior and validated the model using experimental data from SMPCs with varying fiber contents. Nevertheless, this model does not consider the intrinsic anisotropy of the fibers. More critically, existing models fall short in accurately capturing the viscoelastic yielding behavior observed in experiments, as they primarily focus on the temperature-dependent elastic moduli of SMPCs [6].

In this work, we propose an anisotropic constitutive model for SMPCs that integrates viscoelasticity and phase transition concept. The model innovatively decomposes SMPCs into a new rubbery phase and a new glassy phase. The rubbery phase consists of the SMP rubbery matrix bonded with fabric, and the glassy phase comprises the SMP glassy matrix bonded with fabric. The distinct thermodynamic behaviors of these two phases are separately described and SME of SMPCs is directly captured through the storage strain concept, leveraging the phase transition between the two phases.

2 CONSTITUTIVE MODEL FOR SMPC

2.1 General consideration

The thermomechanical behavior of SMPCs is fundamentally governed by the intrinsic property contrast between the isotropic viscoelastic SMP matrix and the anisotropic hyperelastic carbon fabric reinforcement. This dichotomy stems from their distinct energy storage mechanisms: the fabric exhibits temperature-independent hyperelastic behavior governed by fiber architecture [7], in contrast to the temperature- and deformation-dependent energy evolution of the SMP matrix during thermomechanical cycling. A critical temperature-dependent interfacial interaction emerges, where strong fiber-matrix bonding dominates below T_g due to matrix rigidity, while fiber-driven deformation prevails above T_g as the matrix softens [8]. Additionally, residual stresses at the interface, arising from thermal expansion mismatch and modulus disparity, significantly impact the nonlinear deformation behavior of SMPCs.

In the phase transition framework, SMPs are phenomenologically treated as a homogeneous material comprising rubbery and glassy phases [9]. At high temperatures, the rubbery phase dominates, making the material hyperelastic. Conversely, at low temperatures, the glassy phase dominates, making the material viscoelastic. This model not only directly captures the SME through the concept of storage strain, but also decouples the model parameters from temperature, thereby simplifying the parameter determination process. Therefore, to capture the complex thermodynamic behaviors of SMPCs, we extend the SMP phase transition framework in this work, as illustrated in Fig. 6. The proposed model introduces dual-phase decomposition, partitioning SMPCs into fabric-coupled rubbery and glassy phases with independent thermodynamic descriptors. The SMP matrix implementation follows our previous work [10], where the hyperelastic behavior of the rubbery phase is represented by a single spring element. The viscoelastic behavior of the SMP glassy phase is modeled using a parallel spring element connected with a Maxwell element. Additionally, a storage strain element is added in series to the rheological model of the SMP glassy phase representing the storage and release of pre-deformation in the shape memory cycle. The fabric reinforcement is modeled as temperature-invariant hyperelastic springs in both phases. The thermal part represents the thermal expansion or contraction of the SMPCs.

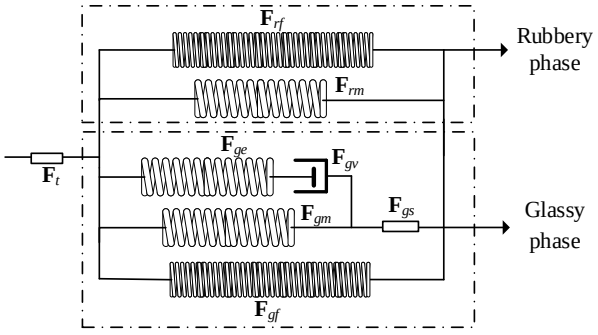

Fig. 1 Rheological representation of the proposed constitutive model for SMPC.

2.2 Kinematics

The total deformation gradient **F** of SMPC is unified for both the glassy and the rubbery phases, and it can be multiplicatively decomposed into mechanical and other deformation gradients:

$$\mathbf{F} = \mathbf{F}_{rc} \cdot \mathbf{F}_t = \mathbf{F}_{gc},\ \mathbf{F}_t,\ \mathbf{F}_{rc} = \mathbf{F}_{rf} = \mathbf{F}_{rm},\ \mathbf{F}_{gc} = \mathbf{F}_{gf} = \mathbf{F}_{gm} \cdot \mathbf{F}_{gs} = \mathbf{F}_{ge} \cdot \mathbf{F}_{gv} \cdot \mathbf{F}_{gs} \tag{1}$$

where the subscript t represents the thermal deformation part of SMPC. The subscripts rc and gc denote the total mechanical deformation gradients of rubbery and glassy phases of the SMPC. The subscripts rf and gf represent the fiber mechanical deformation gradients in the rubbery and glassy phases of SMPC. The subscripts rm, gm, ge, gv and gs correspond to the single spring element in the rubbery and glassy phases of SMP matrix, the elastic part and viscous part in the Maxwell element, the storage strain part, respectively. The related right and left Cauchy-Green tensors are defined as:

$$\mathbf{C}_i = \mathbf{F}_i{}^T \cdot \mathbf{F}_i,\ \mathbf{B}_i = \mathbf{F}_i \cdot \mathbf{F}_i{}^T \tag{2}$$

where the subscript $i = rf, gf, rm, gm, ge, gv$ and gs. Define the Green-Lagrange tensors as:

$$\mathbf{E}_i = \frac{\mathbf{1}}{\mathbf{2}}(\mathbf{C}_i - \mathbf{I}) \tag{3}$$

where **I** is second-order identity tensor. The related invariants of $\mathbf{C}_i$ are defined as:

$$I_1^i = tr(\mathbf{C}_i),\ I_2^i = \frac{1}{2}[(tr(\mathbf{C}_i))^2 - tr(\mathbf{C}_i)^2],\ I_3^i = det\ (\mathbf{C}_i) \tag{4}$$

Specially, for dry woven fabrics, the primary deformation modes include extension along the fiber yarns and angular variations between the weft and warp yarns. To capture these behaviors, invariants representing fiber stretch and fiber-fiber shear are introduced:

$$I_4^a = \mathbf{a}_0 \cdot \mathbf{C}_i \cdot \mathbf{a}_0,\ I_4^b = \mathbf{b}_0 \cdot \mathbf{C}_i \cdot \mathbf{b}_0,\ I_7 = \Delta\varphi = \left(I_4^a I_4^b\right)^{-\frac{1}{2}} \mathbf{a}_0 \cdot \mathbf{C}_i \cdot \mathbf{b}_0 - \mathbf{a}_0 \cdot \mathbf{b}_0 \tag{5}$$

Here, the subscripts $i = rf$ and gf. The invariants I_4^a and I_4^b represent the stretches of yarns, while I_7 represents the angle change $\Delta\varphi$ between the two yarn families and the associated cross-over shear deformation. The unit vectors along the initial directions of the weft and warp yarns are defined as $\mathbf{a}_0 = [cos\theta \quad -sin\theta \quad 0]$ and $\mathbf{b}_0 = [sin\theta \quad cos\theta \quad 0]$, respectively. Here θ denotes the angle between the fiber direction and the loading direction. After deformation, the vectors for the two fiber families can be expressed as:

$$\mathbf{a} = \mathbf{F}_i \cdot \mathbf{a}_0/\lambda_f^a, \mathbf{b} = \mathbf{F}_i \cdot \mathbf{b}_0/\lambda_f^b \tag{6}$$

where λ_f^a and λ_f^b are the stretch ratios of the weft and warp fiber yarns, respectively.

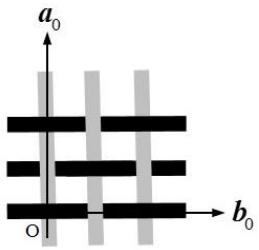

Fig. 2 The original directions of weft and warp yarns.

2.3 Constitutive model derivation

Based on the multiplicative decomposition of deformation gradient presented in Eq. (1), the total Helmholtz free energy of SMPCs per unit reference volume, $\mathbf{\Psi}\left(\mathbf{C}, \mathbf{C}_{ge}, \mathbf{C}_{gv}, \mathbf{a}_0, \mathbf{b}_0, T\right)$, can be expressed as follows:

$$\begin{aligned}\mathbf{\Psi} = \varphi_g(T)(\varphi_m(\mathbf{\Psi}_{gm}(\mathbf{C}, T) + \mathbf{\Psi}_{ge}\left(\mathbf{C}_{ge}, \mathbf{C}_{gv}, T\right) + \mathbf{\Psi}_{gs}(T)) + \varphi_f \mathbf{\Psi}_{gf}(\mathbf{C}, \mathbf{a}_0, \mathbf{b}_0))\\ +\varphi_r(T)(\varphi_m \mathbf{\Psi}_{rm}(\mathbf{C}, T) + \varphi_f \mathbf{\Psi}_{rf}(\mathbf{C}, \mathbf{a}_0, \mathbf{b}_0)) + \mathbf{\Psi}_T(T)\end{aligned} \tag{7}$$

where $\boldsymbol{\Psi}_T$ represents the Helmholtz free energy related to temperature only. $\varphi_r, \varphi_g, \varphi_f$ and φ_m denote the volume fractions of the rubbery and glassy phase of SMPC, fabric, and SMP matrix, respectively. The relations $\varphi_m + \varphi_f = 1$ and $\varphi_r + \varphi_g = 1$ are always satisfied. The volume fraction of glassy phase can be calculated as [11]:

$$\varphi_g = 1 - \frac{1}{1+\exp[-(T-T_r)/A]} \tag{8}$$

where T_r is the reference temperature close to the glass transition temperature, and A is a parameter describing the width of the glass transition temperature range. The second Piola-Kirchhoff stress $\mathbf{S}_c$ of SMPCs can be decomposed into the stresses $\mathbf{S}_{rc}$ and $\mathbf{S}_{gc}$ corresponding to the rubbery phase and glassy phase, respectively:

$$\mathbf{S}_c = \varphi_r \mathbf{S}_{rc} + \varphi_g \mathbf{S}_{gc} \tag{9}$$

And the Clausius-Duhem inequality is expressed in terms of the second Piola-Kirchhoff stress and the Helmholtz free energy:

$$\frac{1}{2}\mathbf{S}_c : \dot{\mathbf{C}} - \left(\dot{\boldsymbol{\Psi}} + \dot{T}\eta\right) - \mathbf{q} \cdot \nabla T/T \geq 0 \tag{10}$$

where η is the entropy, $\mathbf{q}$ is the heat flux vector and ∇ is the gradient operator. Substituting Eqs. (2), (3), (7) and (9) into Eq. (10) leads to the following equations:

$$\begin{gathered}
\mathbf{S}_{rc} = 2\varphi_m \frac{\partial \boldsymbol{\Psi}_{rm}}{\partial \mathbf{C}} + 2\varphi_f \frac{\partial \boldsymbol{\Psi}_{rf}}{\partial \mathbf{C}} = \mathbf{S}_{rm} + \mathbf{S}_{rf} \\
\mathbf{S}_{gc} = 2\varphi_m \frac{\partial \boldsymbol{\Psi}_{gm}}{\partial \mathbf{C}} + 2\varphi_m \frac{\partial \boldsymbol{\Psi}_{ge}}{\partial \mathbf{C}} + 2\varphi_f \frac{\partial \boldsymbol{\Psi}_{gf}}{\partial \mathbf{C}} = \mathbf{S}_{gm} + \mathbf{S}_{gf} \\
\mathbf{L}_{gv} = \frac{1}{\xi}\mathbf{C}_{ge} \cdot \frac{\partial \Psi_{ge}}{\partial \mathbf{C}_{ge}},\ \eta = -\frac{\partial \boldsymbol{\Psi}}{\partial T},\ \mathbf{q} = -k\nabla T, k > 0
\end{gathered} \tag{11}$$

where $\mathbf{S}_{rm} = 2\varphi_m \frac{\partial \boldsymbol{\Psi}_{rm}}{\partial \mathbf{C}}$ and $\mathbf{S}_{rf} = 2\varphi_f \frac{\partial \boldsymbol{\Psi}_{rf}}{\partial \mathbf{C}}$ represent the second Piola-Kirchhoff stresses coming from the rubbery phase of SMP matrix and the woven fabric reinforcement, respectively. Similarly, $\mathbf{S}_{gm} = 2\varphi_m \frac{\partial \boldsymbol{\Psi}_{gm}}{\partial \mathbf{C}} + 2\varphi_m \frac{\partial \boldsymbol{\Psi}_{ge}}{\partial \mathbf{C}}$ and $\mathbf{S}_{gf} = 2\varphi_f \frac{\partial \boldsymbol{\Psi}_{gf}}{\partial \mathbf{C}}$ represent the second Piola-Kirchhoff stresses coming from the glassy phase of SMP matrix and woven fabric reinforcement, respectively. $\mathbf{L}_{gv} = \dot{\mathbf{F}}_{gv} \cdot {\mathbf{F}_{gv}}^{-1}$ is the viscous velocity gradient. k is the heat conduction coefficient, ξ is a material parameter with the same unit as viscosity [12]. To describe the nonlinear mechanical behavior of the rubbery and glassy phases of the SMP matrix, the free energy form of the Mooney-Rivlin model is employed:

$$\boldsymbol{\Psi}_i = C_{10}^i \left({I_3^i}^{-1/3} I_1^i - 3\right) + C_{01}^i \left({I_3^i}^{-2/3} I_2^i - 3\right) + \frac{1}{D_i}\left({I_3^i}^{1/2} - 1\right)^2 \tag{12}$$

where $i = rm, gm$ and ge represent the single spring element of the SMP rubbery and glassy phases, and the elastic part of the Maxwell element, respectively. C_{10}^i, C_{01}^i and D_i are temperature-independent material parameters in this paper. Based on Eqs. (2), (4), (11) and (12), the Cauchy stress of SMPs can be further expressed by $\boldsymbol{\sigma}_m = {I_3^i}^{-1/2}\mathbf{F}_i\left(2\frac{\partial \boldsymbol{\Psi}_i}{\partial \mathbf{C}}\right){\mathbf{F}_i}^T$ as:

$$\begin{gathered}
\boldsymbol{\sigma}_m = \varphi_r \left(\begin{array}{c} 2C_{10}^{rm} {I_3^{rm}}^{-\frac{5}{6}} \left(\mathbf{B}_{rm} - \frac{1}{3} I_1^{rm}\mathbf{I}\right) + 2C_{01}^{rm} {I_3^{rm}}^{-\frac{7}{6}} \left(\mathbf{B}_{rm} - \mathbf{B}_{rm}\cdot\mathbf{B}_{rm} - \frac{2}{3} I_1^{rm}\mathbf{I}\right) \\ + \frac{2}{D_{rm}}\left({I_3^{rm}}^{\frac{1}{2}} - 1\right)\mathbf{I} \end{array} \right) + \\
\varphi_g \left(\begin{array}{c} 2C_{10}^{gm} {I_3^{gm}}^{-\frac{5}{6}} \left(\mathbf{B}_{gm} - \frac{1}{3} I_1^{gm}\mathbf{I}\right) + 2C_{01}^{gm} {I_3^{gm}}^{-\frac{7}{6}} \left(I_1^{gm}\mathbf{B}_{gm} - \mathbf{B}_{gm}\cdot\mathbf{B}_{gm} - \frac{2}{3} I_2^{gm}\mathbf{I}\right) \\ + \frac{2}{D_{gm}}\left({I_3^{gm}}^{\frac{1}{2}} - 1\right)\mathbf{I} \end{array} \right) + \\
\varphi_g \left(\begin{array}{c} 2C_{10}^{ge} {I_3^{gm}}^{-\frac{1}{2}} {I_3^{ge}}^{-\frac{1}{3}} \left(\mathbf{B}_{ge} - \frac{1}{3} I_1^{ge}\mathbf{I}\right) + 2C_{01}^{ge} {I_3^{gm}}^{-\frac{1}{2}} {I_3^{ge}}^{-\frac{2}{3}} \left(I_1^{ge}\mathbf{B}_{ge} - \mathbf{B}_{ge}\cdot\mathbf{B}_{ge} - \frac{2}{3} I_2^{ge}\mathbf{I}\right) \\ + \frac{2}{D_{ge}} {I_3^{gm}}^{-\frac{1}{2}} \left(I_3^{ge} - {I_3^{ge}}^{\frac{1}{2}}\right)\mathbf{I} \end{array} \right)
\end{gathered} \tag{13}$$

Due to the limited rearrangement of molecule chains with shear resistance, the glassy phase of SMP is demonstrated the yield and post-yield softening response. To describe the viscoplastic flow process, a nonlinear flow rule and a modified Eyring model are employed by the plastic shear strain rate $\dot{\gamma}_{gv}$:

$$\mathbf{D}_{gv} = \dot{\gamma}_{gv}\mathbf{n}$$

$$\dot{\gamma}_{gv} = \frac{s_y}{Q_s} T \exp\left(-\frac{B}{T}\right) \sinh\left(\frac{Q_s \bar{\tau}}{s_y T}\right),\ \bar{\tau} = \left(\frac{1}{2}\boldsymbol{\sigma}_{gv} : \boldsymbol{\sigma}_{gv}\right)^{\frac{1}{2}} \tag{14}$$

where the deformation rate tensor $\mathbf{D}_{gv}$ is defined as the symmetric part of the velocity gradient tensor $\mathbf{L}_{gv}$, excluding the rotational part. The flow direction is given by $\mathbf{n} = \boldsymbol{\sigma}'_{gv} / \left\|\boldsymbol{\sigma}'_{gv}\right\|$, where $\boldsymbol{\sigma}'_{gv} = \boldsymbol{\sigma}_{gv} - \frac{1}{3} tr(\boldsymbol{\sigma}_{gv})\mathbf{I}$ represents the deviatoric stress of the viscous part. Q_s is the activation energy, B is the activation parameter, and s_y is the activation stress, which evolves as follows:

$$\dot{s}_y = h_0 \left(1 - \frac{s_y}{s_s}\right) \dot{\gamma}_{gv},\ s_y(0) = s_0 \tag{15}$$

where h_0 is the softening slope, s_0 is the initial value of s_y, and s_s is the final stabilized value, ensuring $s_s < s_0$. Substituting Eqs. (8), (14) and (15) into Eq. (13), the Cauchy stress of SMP matrix can be calculated in entire glass transition temperature range.

Considering the mechanical properties of the fabrics are temperature-independent, both the constitutive models of the fabrics in both the glassy and rubbery phases of SMPCs share a unified expression, enhancing the model's applicability. Taking into account the unique deformation characteristics of woven fabrics, the Helmholtz free energy can be decomposed into two distinct components: the fiber stretch part, $\boldsymbol{\Psi}_{ten}$, and the fiber-fiber shear part, $\boldsymbol{\Psi}_{she}$ [7]:

$$\boldsymbol{\Psi}_f(\mathbf{C}, \mathbf{a}_0, \mathbf{b}_0) = \boldsymbol{\Psi}_{ten}(\mathbf{C}, \mathbf{a}_0, \mathbf{b}_0) + \boldsymbol{\Psi}_{she}(\mathbf{C}, \mathbf{a}_0, \mathbf{b}_0) \tag{16}$$

where $\boldsymbol{\Psi}_{ten}$ and $\boldsymbol{\Psi}_{she}$ can be further represented by a polynomial function of I_4^a, I_4^b and I_7:

$$\boldsymbol{\Psi}_{ten} = k_1\left[(I_4^a - 1)^4 + \left(I_4^b - 1\right)^4\right] + k_2\left[(I_4^a - 1)^3 + \left(I_4^b - 1\right)^3\right] + k_3\left[(I_4^a - 1)^2 + \left(I_4^b - 1\right)^2\right]$$

$$\boldsymbol{\Psi}_{she} = k_4(I_7)^4 + k_5(I_7)^3 + k_6(I_7)^2 \tag{17}$$

where k_1, k_2, k_3, k_4, k_5 and k_6 are constant material parameters with unit of stress. The Cauchy stress tensor of fabric is given by $\boldsymbol{\sigma}_f = I_3^{-1/2}\mathbf{F}\left(2\frac{\partial \boldsymbol{\Psi}_f}{\partial \mathbf{C}}\right)\mathbf{F}^T$. Consequently,

$$\boldsymbol{\sigma}_f = I_3^{-\frac{1}{2}}\left(2\frac{\partial \boldsymbol{\Psi}_{ten}}{\partial I_4^a} - \frac{I_7}{I_4^a}\frac{\partial \boldsymbol{\Psi}_{she}}{\partial I_7} - \frac{\mathbf{a}_0 \cdot \mathbf{b}_0}{I_4^a}\frac{\partial \boldsymbol{\Psi}_{she}}{\partial I_7}\right)\mathbf{a}\otimes\mathbf{a} + I_3^{-\frac{1}{2}}\left(2\frac{\partial \boldsymbol{\Psi}_{ten}}{\partial I_4^b} - \frac{I_7}{I_4^b}\frac{\partial \boldsymbol{\Psi}_{she}}{\partial I_7} - \frac{\mathbf{a}_0 \cdot \mathbf{b}_0}{I_4^b}\frac{\partial \boldsymbol{\Psi}_{she}}{\partial I_7}\right)\mathbf{b}\otimes\mathbf{b}$$

$$+ I_3^{-1/2}\frac{\partial \boldsymbol{\Psi}_{she}}{\partial I_7}\left(I_4^a I_4^b\right)^{-\frac{1}{2}}(\mathbf{a}\otimes\mathbf{b} + \mathbf{b}\otimes\mathbf{a}) \tag{18}$$

Accordingly, the fabric stress calculated via Eq. (5), when substituted into Eq. (18), faithfully captures its anisotropic mechanical response. Building upon the theoretical framework established in Eqs. (1), (8), (9), (13), and (18), the Cauchy stress tensor for SMPCs can be decomposed into rubbery phase $\boldsymbol{\sigma}_{rc}$ and the glassy phase $\boldsymbol{\sigma}_{gc}$ components through phase superposition:

$$\boldsymbol{\sigma}_c = \varphi_r\boldsymbol{\sigma}_{rc} + \varphi_g\boldsymbol{\sigma}_{gc} = \varphi_r\left(\boldsymbol{\sigma}_{rm} + \boldsymbol{\sigma}_f\right) + \varphi_g\left(\boldsymbol{\sigma}_{gm} + \boldsymbol{\sigma}_{ge} + \boldsymbol{\sigma}_f\right) \tag{19}$$

This formulation inherently assumes ideal deformation mechanics characterized by perfect fiber-matrix load transfer and interface integrity. However, practical material behavior deviates from this idealized state due to multiscale interfacial phenomena including inter-yarn friction dissipation in woven architectures, matrix damage induced by yarn rotation kinematics, void nucleation/propagation mechanisms, and temperature-dependent interfacial adhesion degradation. To systematically address these non-ideal effects while maintaining model tractability, we introduce temperature-independent phase effectiveness factors that modulate the respective stress contributions:

$$\boldsymbol{\sigma}_c = \varphi_r\rho_r\left(\boldsymbol{\sigma}_{rm} + \boldsymbol{\sigma}_f\right) + \varphi_g\rho_g\left(\boldsymbol{\sigma}_{gm} + \boldsymbol{\sigma}_{ge} + \boldsymbol{\sigma}_f\right) \tag{20}$$

where ρ_r and ρ_g are the effectiveness factors of rubbery and glassy phases of SMPC, respectively. When $\rho_r = 1$ or $\rho_g = 1$, it signifies perfect interfacial bonding. When $0 < \rho_r < 1$ or $0 < \rho_g < 1$, it signifies progressive interfacial compromise. Experimental calibration through stress-strain curve fitting at T_l and T_h reveals distinct orientation-dependent trends. For 0°/90° fiber orientation, the constrained molecular mobility facilitates near-perfect bonding, allowing for $\rho_g = \rho_r = 1$ and requiring only parametric adjustments in the SMP matrix constitutive model. Conversely, for -45°/45°orientation, reduced fiber constraint preserves the reconfirmed matrix parameters while requiring $0 < \rho_r < 1$ and $0 < \rho_g < 1$ to account for the non-ideal effects.

In the shape memory cycle, a pre-strain $\boldsymbol{\varepsilon}_{pre}$ is applied at T_h, where the SMPCs consist solely of the rubbery phase. As the material cools, the strain applied in the rubbery phase transforms into the strain of the new glassy phase and is stored as the storage strain $\boldsymbol{\varepsilon}_{gs}$. Since the fibers do not possess a shape memory function, this process is mainly governed by temperature and the volume fractions of two phases. The storage strain $\boldsymbol{\varepsilon}_{gs}$ can be calculated as:

$$\frac{\mathrm{d}\boldsymbol{\varepsilon}_{gs}}{\mathrm{d}T} = \left(\boldsymbol{\varepsilon}_{pre} - \boldsymbol{\varepsilon}_t - \boldsymbol{\varepsilon}_r\right)\frac{\mathrm{d}\varphi_g}{\mathrm{d}T} \tag{21}$$

where $\boldsymbol{\varepsilon}_r$ represents the thermal residual strain, arising from the differences of CTE and elastic moduli between the fabric and SMP matrix. Based on the Eshelby's eigenstrain theorem, the average thermal residual stress in polar coordinates is expressed as follows:

$$\sigma_{rr}^{mean} = \left(2\sqrt{\frac{\varphi_f}{2}} - \frac{\varphi_f}{2}\right)\sigma_{rr}^{in}, \sigma_{\theta\theta}^{mean} = \frac{\varphi_f}{2}\sigma_{rr}^{in}, \sigma_{zz}^{mean} = \frac{\varphi_f}{2}\sigma_{zz}^{in}$$

$$\sigma_{ij}^{in} = \left(1 - \frac{\varphi_f}{2}\right)\left[\left(P_{kkmn}\varepsilon_{mn}^{**} - \varepsilon_{kk}^{**}\right)\lambda_m\delta_{ij} + 2\mu_m\left(P_{ijmn}\varepsilon_{mn}^{**} - \varepsilon_{ij}^{**}\right)\right] \tag{22}$$

where the subscripts rr, $\theta\theta$ and zz are transformed by setting $ij = 11$, 22 and 33, respectively. δ_{ij} is the Kronecker delta function. λ_m and μ_m are the Lamé constants of the matrix. ε^{**} represents the eigenstrain, which corresponds to the strain under zero applied stress. When a load is applied to the heterogeneous regions, differences in modulus and CTE between the fabric and matrix generate disturbance strain, which is related to the eigenstrain via the fourth-order Eshelby tensor **P**. The components of the Eshelby tensor for infinitely long elliptical cylinders are presented in Table. 1.

Table. 1 Eshelby tensor components for cylindrical long fiber ($v_f = 0.25$ is the Poisson's ratio).

$P_{1111} = P_{2222} = \dfrac{5 - 4v_f}{8\left(1 - v_f\right)}, P_{3333} = 0$
$P_{1122} = P_{2211} = -\dfrac{1 - 4v_f}{8\left(1 - v_f\right)}, P_{3311} = P_{3322} = 0$
$P_{1133} = P_{2233} = \dfrac{v_f}{2\left(1 - v_f\right)}, P_{1212} = \dfrac{3 - 4v_f}{8\left(1 - v_f\right)}, P_{1313} = P_{2323} = \dfrac{1}{4}$

The thermal deformation tests show that the thermal strain of SMPCs exhibits a strong linear relationship with temperature within the glass transition temperature range. Therefore, the thermal strain can be calculated using the following equation:

$$\boldsymbol{\varepsilon}_t = \alpha_c \Delta T \mathbf{I} \tag{23}$$

where α_c is the CTE of SMPCs. Combined with Eqs. (8) and (19)-(24), the storage strain of SMPC in the cooling process can be determined. During unloading at low temperature T_l, a small amount of rebound occurs, governed by Hooke's law. The fixed strain can be calculated as:

$$\boldsymbol{\varepsilon}_{fix} = \varphi_m \boldsymbol{\varepsilon}_{gs}(T_l) + \boldsymbol{\varepsilon}_t(T_l) \tag{24}$$

As the fiber orientation varies from 0°/90° to -45°/45°, the loading direction is inconsistent with fiber direction. Since the thermal residual stress calculated based on Eq. (22) is defined along the fiber directions, it must be transformed into the loading direction using the appropriate stress transformation

formula. Given that the SMP matrix predominantly undertakes the shear deformation and the deformation of the thickness direction in SMPCs [13], it simplifies to a plane stress problem and the conversion formula is expressed as follows:

$$\begin{bmatrix}\sigma_x\\ \sigma_y\\ \tau_{xy}\end{bmatrix}=\begin{bmatrix}(cos\theta)^2 & (sin\theta)^2 & -2sin\theta cos\theta\\ (sin\theta)^2 & (cos\theta)^2 & 2sin\theta cos\theta\\ sin\theta cos\theta & -sin\theta cos\theta & (cos\theta)^2-(sin\theta)^2\end{bmatrix}\begin{bmatrix}\sigma_1\\ \sigma_2\\ \tau_{12}\end{bmatrix} \tag{25}$$

where θ is the angle between the fiber direction and the loading direction. And σ_{zz}^{mean} in Eq. (22) is assumed to be approximately equal to the shear stress τ_{12}. Furthermore, the elastic modulus of SMPCs with varying fiber orientations in loading direction can be expressed as:

$$E_c=\varphi_g E_{gc}+\varphi_r E_{rc} \tag{26}$$

where E_{gc} and E_{rc} are the elastic modulus of glassy and rubbery phases of SMPCs in loading direction. Thus, the average thermal residual strain in loading direction can be calculated using Eqs. (21)-(26).

Considering the occurrence of non-ideal behaviors during shape memory cycling, which can adversely affect the SME performance, similarly, an effective factor is introduced to evaluate the overall macroscopic shape memory properties for SMPCs with various fiber orientations. Consequently, Eq. (24) is revised as follows:

$$\boldsymbol{\varepsilon}_{fix}=\rho_s(\varphi_m\boldsymbol{\varepsilon}_{gs}(T_l)+\boldsymbol{\varepsilon}_t(T_l)) \tag{27}$$

where ρ_s is the effectiveness factor. It is important to note that the destructive effect of yarn rotation on the matrix during the cooling stage is intensified during the reheating stage due to shape recovery, leading to a reduction in ρ_s during the cooling stage compared to the reheating stage. To minimize mechanical dissipation, the energy released by SMPCs during heating is exactly the opposite to the energy stored during cooling. This implies that the variation of $\boldsymbol{\varepsilon}_{gs}$ in reheating is inherited from the $\boldsymbol{\varepsilon}_{gs}(T)$ which is previously determined during cooling. This relationship can be used to describe the shape storage during the cooling process and the shape recovery during the reheating process.

4 MODELS VERIFICATION AND DISCUSSION

Following the parameter identification procedure for SMPCs with varying fiber orientations in Ref. [6], the model parameters summarized in Table. 2 were determined. Based on Eq. (13), (18) and (20), the uniaxial tensile response of SMPCs with different fiber orientations was simulated using fsolve and ODE45 functions in MATLAB. The numerical results of engineering stress versus engineering strain at different temperatures are presented in Figs. 3-5. Among these, the tensile curves at 20°C and 80°C were used to fit the model parameters, while the other four curves were employed to validate the predictive capability of the constitutive model. Subsequently, the initial tensile modulus of SMPCs with various fiber orientations was computed across the temperature range using the identified parameters, as shown in Fig. 6. A comparison with the experimental data confirms that the proposed model can effectively capture the anisotropic and temperature-dependent thermomechanical behavior of SMPCs over the entire glass transition temperature range.

Table. 2 Model parameters for SMPCs.

Parameters	Values	Units	Parameters	Values	Units
$C_{10}^{rm}, C_{01}^{rm}, D_{rm}$	24, 4.8, 0.001	MPa	h_0, s_0, s_s	300, 38, 18	MPa
$C_{10}^{gm}, C_{01}^{gm}, D_{gm}$	24, 4.8, 0.001	MPa	Q_s	1000	mJ
$C_{10}^{ge}, C_{01}^{ge}, D_{ge}$	360, 72, 0.001	MPa	B	2830	K
A	7	°C^{-1}	k_1, k_2, k_3	2090, 2280, 2.15	MPa
T_r	45	°C	k_4, k_5, k_6	0.15, 0.001, 0.06	MPa

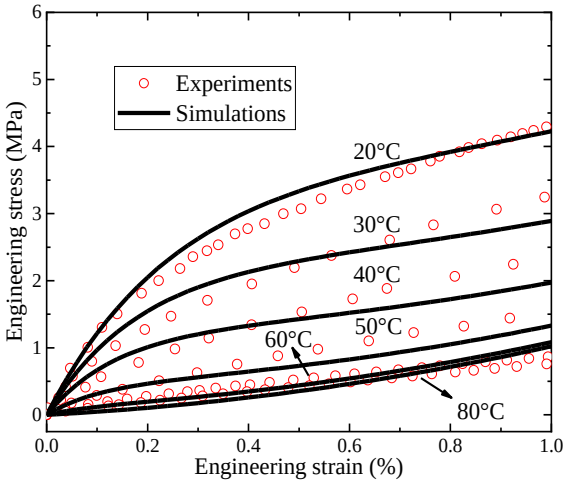

Fig. 3 Simulation results for the isothermal loading for 0°/90° oriented SMPCs.

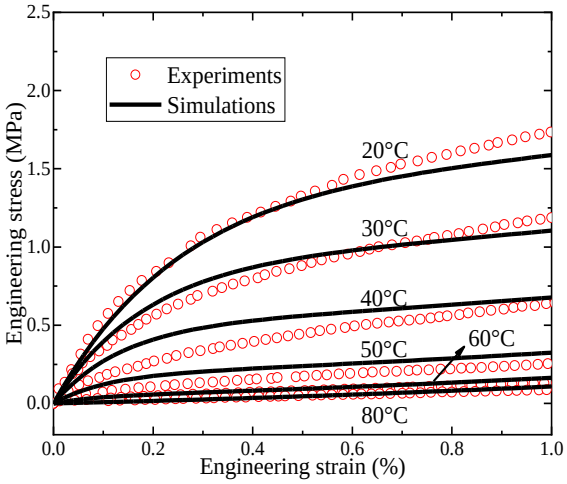

Fig. 4 Simulation results for the isothermal loading for -30°/60° oriented SMPCs.

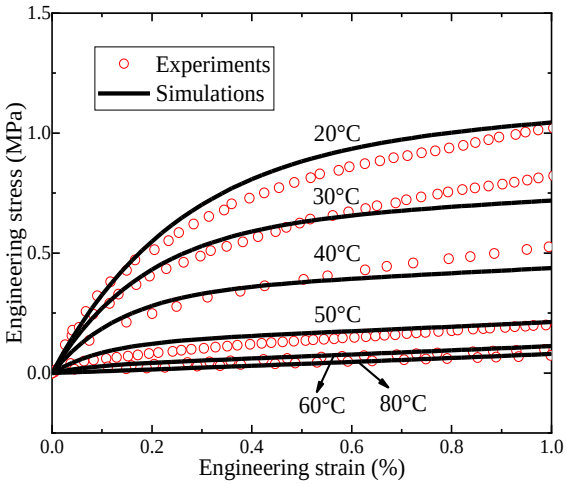

Fig. 5 Simulation results for the isothermal loading for -45°/45° oriented SMPCs.

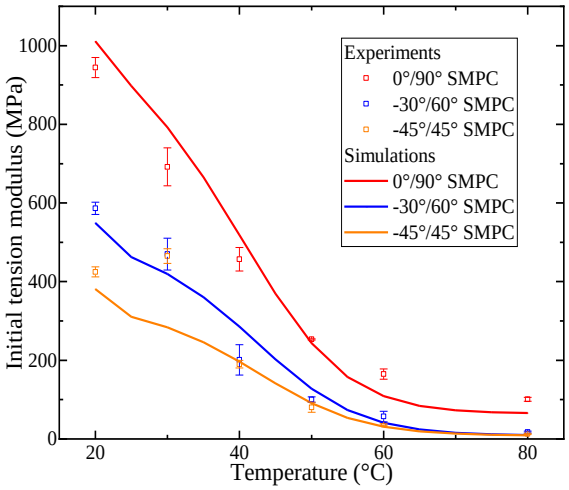

Fig. 6 Simulation results for the initial tension modulus for SMPCs with various fiber orientations.

Based on Eqs. (8) and (21)-(27), the free shape recovery process can be simulated using a 1D analysis model implemented in MATLAB. The engineering strain curve for -45°/45° oriented SMPCs in Fig. 7 was used to determine the effective factor ρ_s, while ρ_s was set to 1 for the 0°/90° oriented SMPCs due to no yarn rotation. The engineering strain-temperature curves for SMPCs with 0°/90° and -30°/60° fiber orientations are presented in Figs. 8 and 9. For the 0°/90° oriented SMPCs, the developed model predicts a shape fixity ratio of 0.85, which is 3.8% higher than the experimental value, and a shape recovery ratio of 0.804, which is 4.5% lower than the experimental result. For the -30°/60° oriented SMPCs, the predicted shape fixity ratio is 0.887, exceeding the experimental value by 3.9%, while the predicted recovery ratio is 0.708, 2.5% lower than the measured result. Overall, the simulation curves exhibit a trend consistent with the experimental observations, confirming the proposed model's ability to accurately capture the anisotropic shape memory behavior of SMPCs with various fiber orientations.

5 CONCLUSIONS

This study establishes a phase transition-based anisotropic constitutive framework for carbon woven fabric-reinforced shape memory polymer composites (SMPCs), advancing the modeling of their thermomechanical and shape memory behaviors. Three key advancements characterize our approach:

(1) A novel decomposition of SMPCs into modified rubbery and glassy phases, each incorporating fiber–matrix interactions to enable independent characterization of temperature-dependent responses.

(2) Implementation of Mooney-Rivlin free energy formulation for capturing SMP matrix nonlinearity, combined with an orthotropic polynomial hyperelastic model for the fabric reinforcement, allowing accurate prediction of multi-axial mechanical behavior.

(3) Introduction of a temperature-invariant effectiveness factor to quantitatively describe the loss of reinforcement constraints.

The developed model exhibits excellent agreement with experimental data across various fiber orientation configurations, demonstrating its capability to capture the complex anisotropic thermomechanical and shape memory responses of SMPCs.

ADVANCED COMPOSITE BONDING USING ENERGY EFFICIENT LOCALISED CURING BASED ON NANO-MODIFIED EPOXY

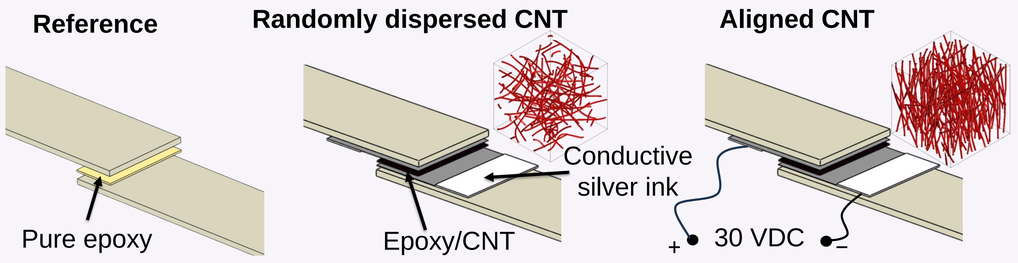
Karina Dragasiute, Gediminas Monastyreckis, Daiva Zeleniakiene

Department of Mechanical Engineering, Kaunas University of Technology
Studentu 56, Kaunas 51424, Lithuania, daiva.zeleniakiene@ktu.lt

INTRODUCTION

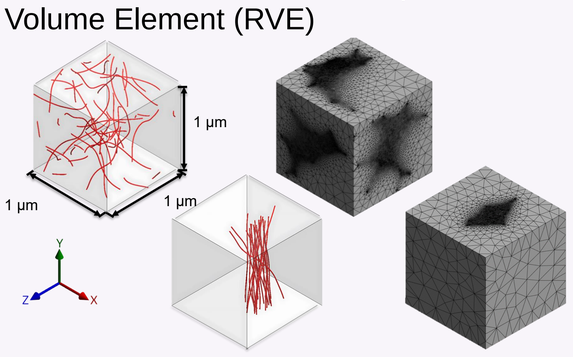
Motivation

Traditional bonding processes require high-temperature ovens, leading to:



- high energy consumption
- long curing cycles
- scalability challenges for large components

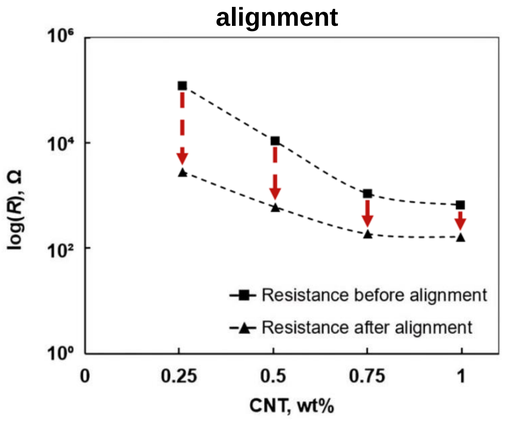
Aim



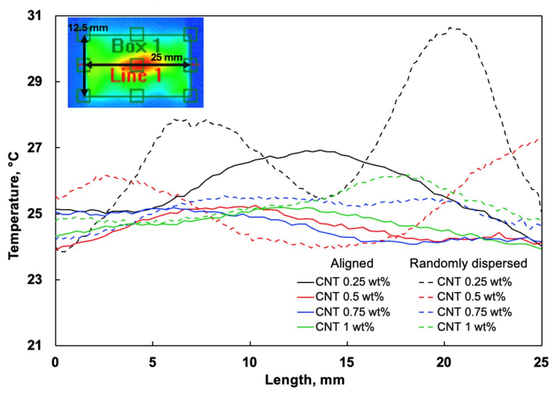
To develop a scalable, energy-efficient bonding process for composite materials using CNT-enhanced epoxy adhesives.

METHODOLOGY

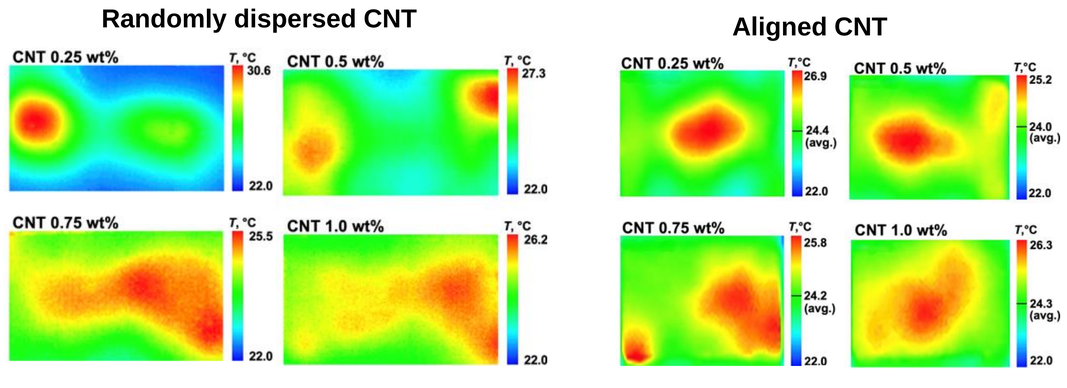
- Sample preparation and electrical characterisation
- Local curing and IR thermal imaging
- Single lap tensile test (ISO 4587)



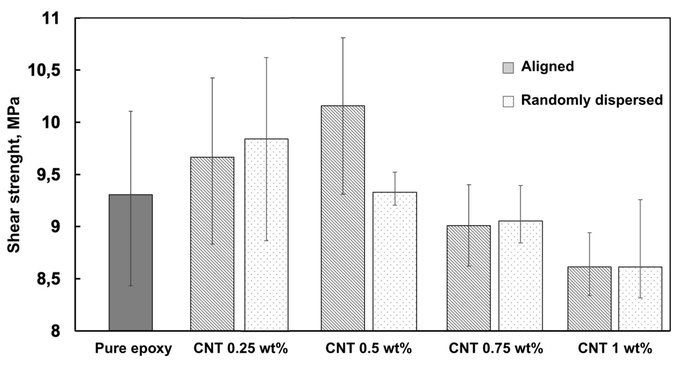
- Thermal transient FEA via Representative Volume Element (RVE)



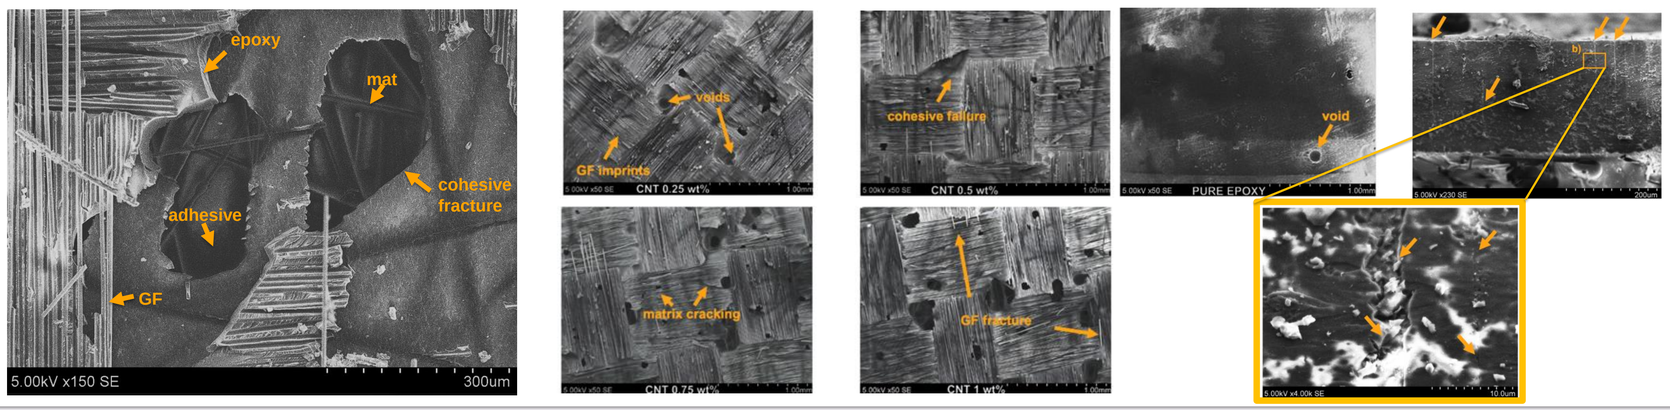
RESULTS



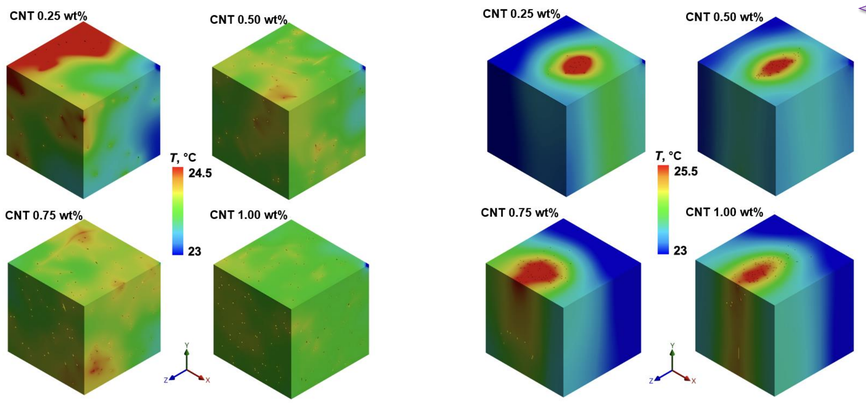
Resistance before and after CNT alignment



Temperature profile along the length of the aligned and randomly dispersed CNT 400 specimens

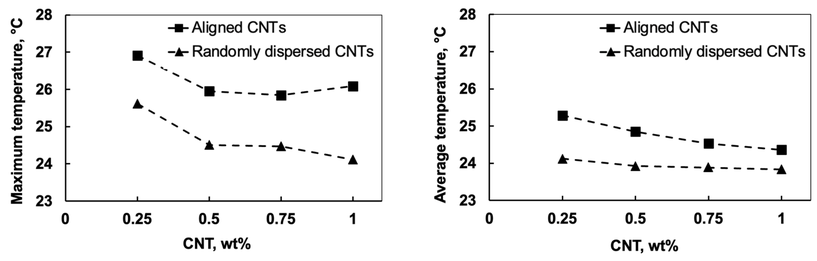


Infrared imaging of temperature distribution during Joule heating-based curing



Comparison of shear strength of single-lap specimens and pure epoxy adhesives

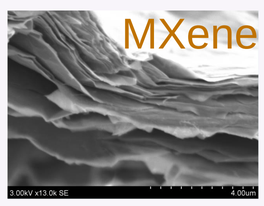
SEM results after lap-shear tests



Randomly dispersed CNT | **Aligned CNT**

FEA temperature distribution of RVE models

Maximum and average temperatures from transient thermal FEA of RVE models



Most of the results presented in this poster have recently been published in the *Polymers* journal. Further findings and insights can be found in the article:
Dragasiute, K.; Monastyreckis, G.; Zeleniakiene, D. *Electrically Conductive Nanoparticle-Enhanced Epoxy Adhesives for Localised Joule Heating-Based Curing in Composite Bonding*. Polymers 2025, 17, 1176. https://doi.org/10.3390/polym17091176.

CONCLUSIONS

This study demonstrates that CNT-enhanced epoxy adhesives enable effective Joule heating-based curing in composites. Optimal CNT loading (0.5 wt%) improved conductivity, shear strength, and heat localisation. Alignment methods further enhanced targeted heating efficiency. Overall, CNTs enable efficient, localised curing with improved mechanical bonding properties.

FUTURE RESEARCH

The next stage of this research will investigate electrically conductive MXene nanoparticles for localised Joule heating in structural composites. $Ti_3C_2T_x$ coatings and interlayers will be used, supported by advanced nanocomposite technologies to produce materials with enhanced properties and reduced energy demand, contributing to more sustainable solutions.

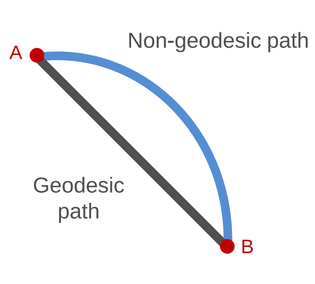
Friction behaviors of carbon fiber tows and their effect on the manufacturability and mechanical properties of composite pressure vessels



Su Hyun Lim, Wonvin Kim, Wonki Kim, and Seong Su Kim*
Department of Mechanical Engineering, Korea Advanced Institute of Science and Technology (KAIST)

CF tow spreading ››› Intra-tow friction

CF tow positioning ››› Inter-tow friction

The friction behavior of carbon fiber tows is decisive in composite manufacturing processes such as molding, braiding, and filament winding by affecting the deformation and positioning of the tow. It is essential to consider the tow friction from the design stage, thereby allowing better control of process parameters and ensuring high product quality.

Herein, we propose a systematic framework that addresses the friction behaviors of CF tows and their impact on manufacturability and mechanical properties of filament wound composites through experimental approach.The results showed the significant multi-scale relationship between CF, tow, and composites in terms of their fricion behavior and interfacial properties, directly related with manufacturability and burst properties of filament wound cylinders, which is not addressed through previous studies.

ABSTRACT

In recent years, the development of multi-material components combining metals with carbon fiber reinforced plastics (CFRP) has attracted growing attention, particularly in the automotive industry. This approach aims to achieve both weight reduction and cost efficiency, which are essential for enhancing vehicle performance and supporting sustainable manufacturing. Among various types of CFRP, thermoplastic CFRP (CFRTP) offers advantages such as short cycle times and recyclability, making it suitable for high-volume production. This study investigates the feasibility of a press forming method for metal/CFRTP laminated sheets as a preliminary step toward continuous forming processes for hybrid structures. Laminates were fabricated by hot pressing plain-woven CF/PA66 with two types of metal sheets: aluminum alloy A5052 and ferritic stainless steel SUS430. Forming was conducted using a V-type press die under controlled thermal conditions. While the specimens were not bent into full L-shaped profiles, the focus was placed on evaluating interfacial integrity and formability under simplified bending conditions. Experimental results revealed that the die corner geometry and temperature uniformity are critical factors for defect-free forming. In particular, appropriately designed die corners helped suppress delamination and fiber–matrix separation at the metal–CFRTP interface. These findings offer valuable guidance for the design of forming tools and process parameters in hybrid metal/CFRTP manufacturing. This work contributes to the advancement of lightweight multi-material forming technologies and supports the future implementation of efficient, high-speed production methods in automotive applications.

1INTRODUCTION

In recent years, carbon fiber reinforced plastics (CFRP) have attracted significant attention as advanced composite materials due to their exceptional combination of light weight and high mechanical strength. These properties make CFRP particularly appealing for automotive applications, where reducing vehicle weight is directly linked to improved fuel efficiency. Consequently, the use of CFRP in structural components such as frames and body panels has been steadily increasing.

However, despite its advantages, the widespread adoption of CFRP remains limited by two major challenges: its relatively high production cost and instability in the supply chain, which restrict its availability for large-scale manufacturing.

To overcome these limitations, recent research has focused on the development of multi-material structures that combine metals with CFRP[1-5]. These hybrid structures aim to exploit the complementary strengths of both materials—metals for their formability and cost-efficiency, and CFRP for its light weight and high strength.

In this context, the present study investigates the feasibility of a press forming technique for metal/CFRTP (carbon fiber reinforced thermoplastic) laminated sheets. This work serves as a preliminary step toward the development of roll forming processes, which are better suited for high-speed, large-scale production of hybrid materials. Specifically, laminated plates consisting of metal and

plain-woven thermoplastic composite (CF/PA66) were fabricated using a heat press method. A series of forming experiments was conducted to identify and evaluate the optimal processing conditions for achieving high-quality laminates.

2 EXPERIMENTAL METHOD

The test specimens consisted of a 2.0 mm thick CFRTP core and 0.5 mm thick metal face sheets, using two types of metals: SUS304 stainless steel and A5052 aluminum alloy.

The CFRTP core was composed of a plain-woven carbon fiber fabric impregnated with a PA66 (polyamide 66) thermoplastic matrix. The material used was Tepex® 201-C200(x)/50% (LANXESS), with a nominal fiber volume fraction of 50%. Each sheet was cut to a width of 30 mm and a length of 60 mm using a fine cutter.

Two types of metal surface conditions were prepared: untreated and roughened using #240 sandpaper. Surface roughening was performed by placing one side of the metal sheet on a flat surface and evenly abrading it with the sandpaper.

To investigate the effect of interfacial bonding, some specimens included a sheet-type hot-melt adhesive (Aron Melt PPET-1200, TOAGOSEI) placed between the CFRTP and the metal layers, while others were laminated without adhesive. The experiments were conducted under various conditions: with and without adhesive, with and without metal surface treatment, and with or without applied molding pressure.

N	No	No	No

3 RESULTS AND DISCUSSION

Figure 2 shows photographs of the test specimens after V-die press forming. Delamination was observed in both SUS/CFRTP and AL/CFRTP specimens, particularly in Specimens S-P-A and S-A. However, this delamination was not consistently correlated with the application of pressure during lamination. For example, while no delamination was observed in press-formed specimens A-P and S-P, delamination occurred in S-P-A despite being formed under pressure. These observations suggest that delamination is caused by factors beyond the initial bonding process.

Figure 3 provides a magnified view of the delaminated regions. Notably, significant dents were found in the metal layers near the upper corners, supporting the hypothesis that local stress concentration causes failure. Furthermore, in specimens without delamination, such as S-P and S, clear interlaminar slippage was observed within the CFRTP layer. This slippage is considered to play a key role in accommodating deformation and thereby preventing delamination.

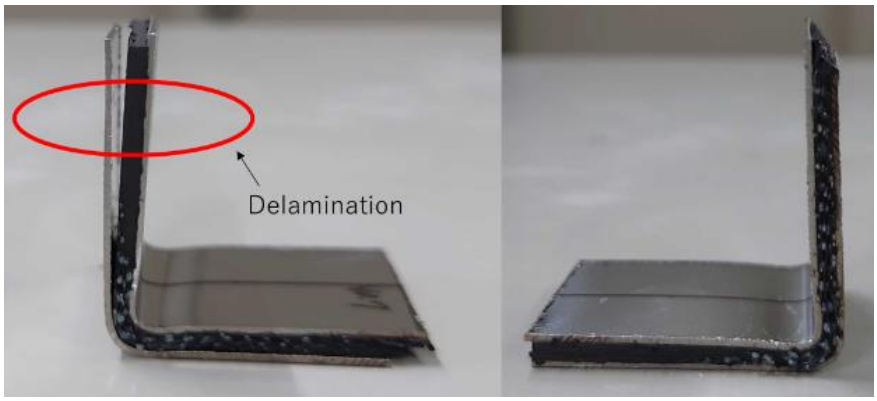

Figure 2: Photographs of test specimens after V-die press forming: specimens exhibiting delamination (e.g., S-P-A, S-A) and specimens without delamination (e.g., S-P, S).

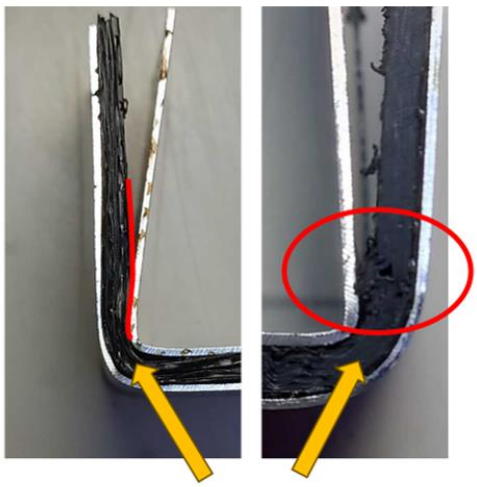

Figure 3: Evidence of delamination mechanisms: left—local denting in the metal layer due to stress concentration at the upper die corners; right—out-of-plane deformation of the CFRTP layer caused by constrained interlaminar slippage.

Figure 4 shows the bending angles of the SUS/CFRTP and A5052/CFRTP specimens after forming. The results revealed significant variations in the corner angles. Notably, specimens without delamination (e.g., Specimens S-P, P, S, and N) exhibited corner angles close to 90°, suggesting that delamination inhibits proper angle formation. This phenomenon is attributed to the sharpness of the upper die corners, which induces localized plastic deformation in the metal layer.

Furthermore, as shown in Figures 4 and 5, most specimens exhibited bending angles less than 90°, indicating a trend opposite to the typical spring-back behavior observed in metal forming. Detailed analysis revealed that this deviation resulted from a mismatch in the bending angles between the upper and lower dies used in the press. This effect was present in all specimens but was particularly pronounced in Specimens S-P-A, P-A, S-A, and A.

From the above findings, delamination was found to occur primarily due to two mechanisms:

(1) local stress concentration at sharp upper die corners, which induced out-of-plane deformation (denting) in the metal layer, and

(2) suppression of interlaminar slippage in the CFRTP layer due to non-uniform forming temperature, causing the layers to bend outward and separate from the metal.

These results indicate that appropriate die corner curvature and temperature control are critical for preventing delamination.

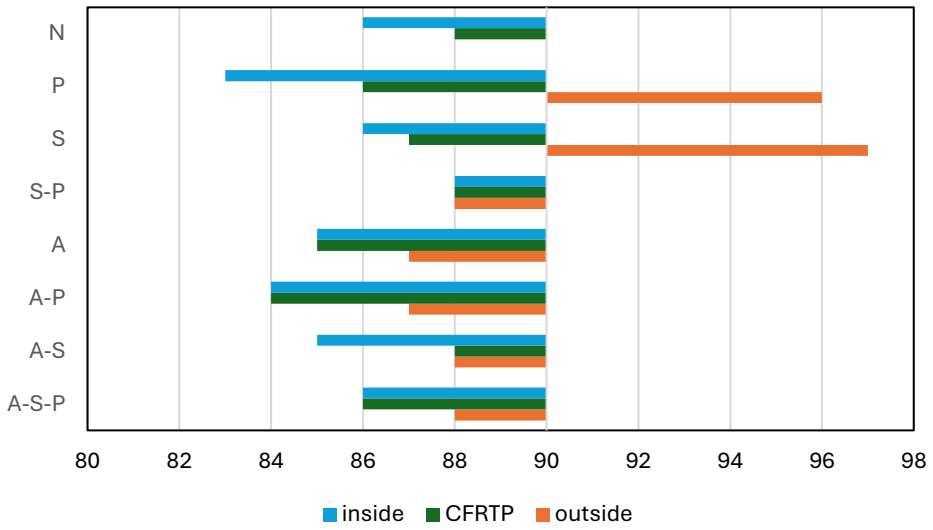

Figure 4: Bending angles of SUS/CFRTP and A5052/CFRTP specimens after V-die press forming, showing the influence of delamination on angle formation. Specimens without delamination (e.g., S-P, P, S, N) maintained angles close to 90°, while delaminated specimens exhibited more deviation.

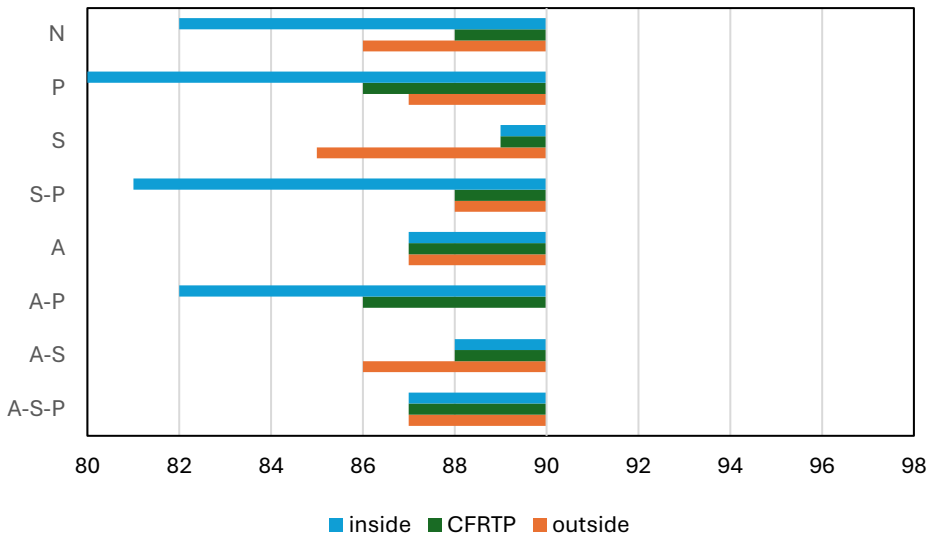

Figure 5: Deviation of actual bending angles from the nominal die angle, highlighting reduced spring-back behavior. The mismatch between upper and lower die angles contributed to angles less than 90° across all specimens.

4 IMPROVEMENT OF A PRESS MOLD

4-1 EXPERIMENTAL METHOD

To suppress spring-in deformation during V-bending, an improved mold was employed, in which the corner radius of the upper die was increased and unified with that of the lower die (both set to R2). The same materials as in the previous experiments were used, and all specimens included a sheet-type hot-melt adhesive between the CFRTP core and the metal face sheets to ensure consistent interfacial bonding.

Prior to pressing, the specimens were heated in an electric furnace for a total of 8 minutes—4 minutes per side—with flipping at the midpoint to achieve uniform temperature distribution. The V-bending process was then conducted using the improved mold.

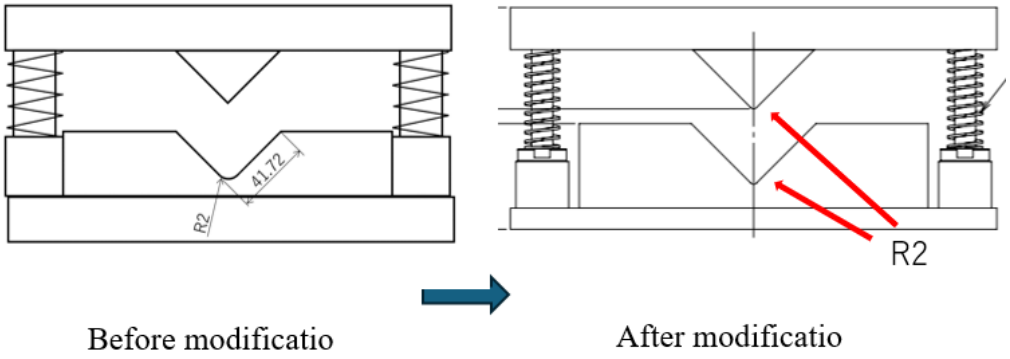

Figure 6: Improved die design for V-shaped pressing with unified corner radius (R2).

4-2 RESULTS OF PRESS BENDING

As shown in the figure, V-bending was successfully achieved without inducing spring-in deformation. Most specimens exhibited interlaminar slippage, and delamination was effectively suppressed. These findings indicate that the combination of uniform heating and improved die geometry contributed to stable and defect-free forming behavior.

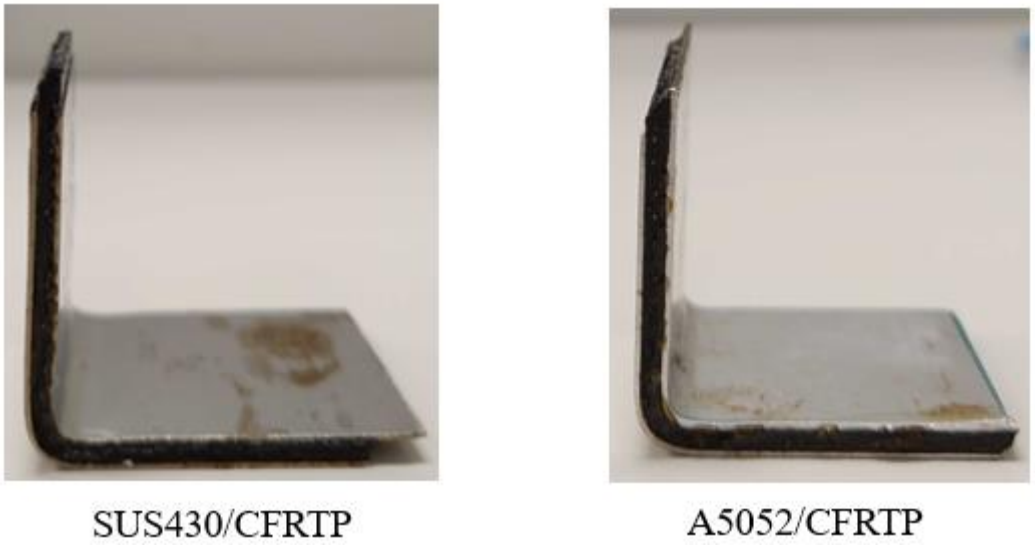

Figure 7: Test specimens after V-shaped pressing using the improved mold.

5 TENSILE PROPERTIES OF METAL/CFRTP LAMINATES

5-1 EXPERIMENTAL METHOD FOR TENSILE TESTING

To evaluate the tensile properties of SUS430/CFRTP and A5052/CFRTP laminated plates, tensile tests were conducted according to standard procedures. Photographs of the test specimens are shown in Figure 8.

Figure 8: Test specimens of SUS430/CFRTP and A5052/CFRTP laminates for tensile testing.

5-2 FINITE ELEMENT MODELING USING ABAQUS

Finite element analysis was performed to obtain the corresponding stress–strain curves. The metal layers were modeled as elastoplastic materials, while the CFRTP core was treated as orthotropically elastic. Tensile loading was applied until the metal layers reached their respective yield strains: 1.3% for SUS430/CFRTP and 8% for A5052/CFRTP.

To complement the experimental results, finite element models were developed in Abaqus to simulate the same sandwich configurations under uniaxial tensile loading. Second-order solid elements were employed to accurately represent geometry and deformation behavior.

5-3 RESULTS AND DISCUSSION

Figure 10(a) shows the stress–strain curves for SUS/CFRTP, and Figure 10(b) shows those for AL/CFRTP. In Figure 10(a), the curve for SUS/CFRTP showed yielding at approximately 0.001 strain, followed by a nearly linear increase in stress up to 0.0058 strain. At this strain, the slope changed, indicating the onset of delamination. Beyond a strain of 0.0083, the strain increased sharply, and further measurement became impossible. This indicated that the metal layer and CFRTP had completely delaminated.

On the other hand, in Figure 10(b), the AL/CFRTP curve exhibited a linear increase in stress up to a strain of 0.0032, followed by delamination at that strain, and complete delamination occurred at a strain of 0.0039. Therefore, no clear yield point was observed in this material. This was attributed to the smaller stiffness difference between the aluminum alloy and CFRTP compared to SUS. However, since yielding occurred when the stress in the AL layer reached the yield condition, yielding had already taken place in the AL layer of AL/CFRTP at a strain of 0.003, and residual stress remained after unloading.

For both materials, CFRTP remained elastic even after the complete yielding of the metal layer, so the stress continued to increase. This indicated that defining the 0.2% proof stress was difficult, unlike in the case of a bare metal.

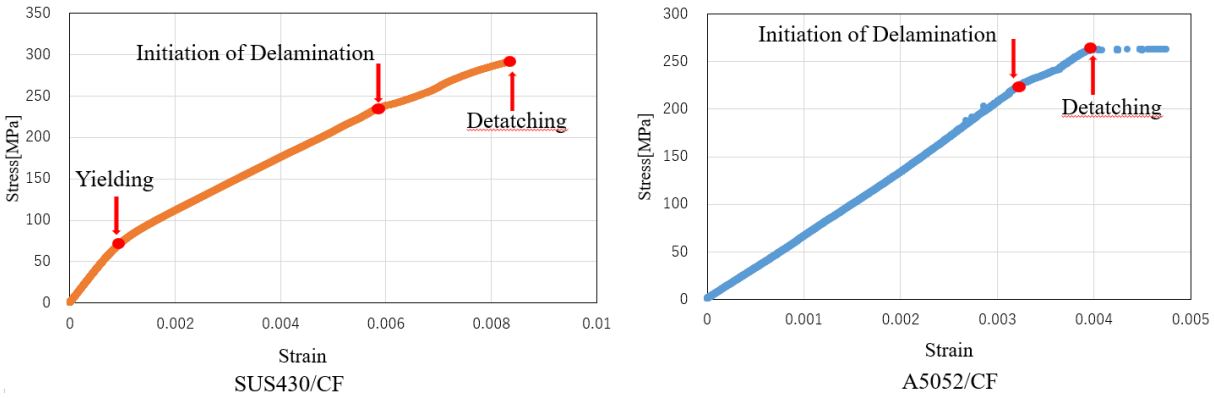

Figure 10: Stress-strain curves of SUS430/CFRTP and A5052/CFRTP

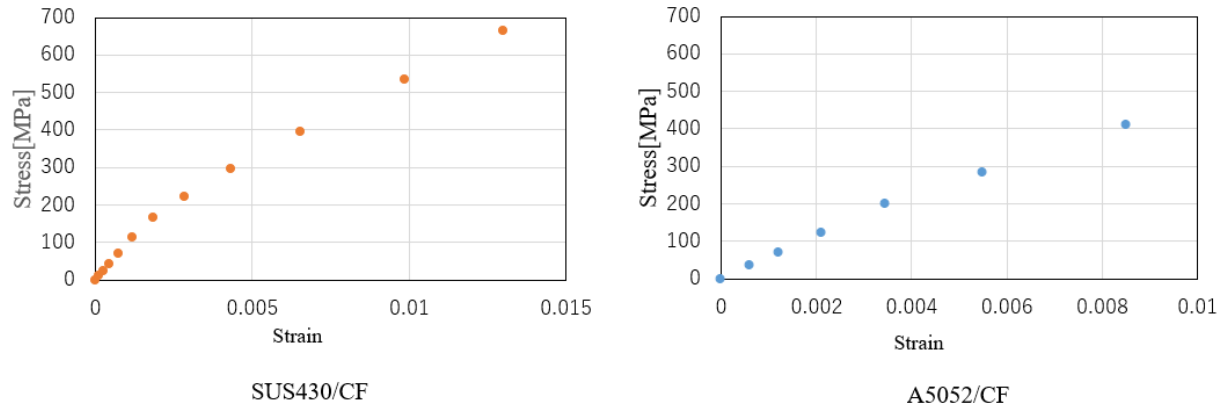

Figure 11: Stress-strain diagram of sus430/CFRTP and A5052/CFRTP(Abaqus)

The results indicate that the overall behavior of both laminates closely resembles the experimental findings. A distinct yield point was observed in the SUS/CFRTP laminate, whereas such a point was not evident in the AL/CFRTP laminate.

The calculated Young's modulus was 94 GPa for SUS/CFRTP and 58 GPa for AL/CFRTP. The former exceeded the experimentally measured value, while the latter was lower. This discrepancy is likely attributed to the presence of an adhesive layer approximately 100 μm thick in the experimental specimens, which was not included in the simulations.

Based on these results, it can be concluded that the stiffness and strength of FMLs using SUS are inferior to those of bare SUS, whereas in the case of AL, both the stiffness and yield stress are only slightly lower than those of the bare metal. However, after yielding, the load is elastically supported by the CFRTP layer, suggesting that the ultimate tensile strength of the laminate may exceed that of the metal alone. These mechanical properties are expected to vary significantly depending on the layup configuration, and thus optimization of the laminated structure is essential for application-specific performance.

6 CONCLUSIONS

This study investigated the press forming behavior and mechanical performance of metal/CFRTP laminates using V-shaped dies. Key findings are summarized as follows:

- Delamination suppression requires both uniform heating of the CFRTP core and appropriate die corner geometry. Interlaminar slippage plays a crucial role in absorbing deformation without damaging the laminate interface.

- Spring-in behavior was mitigated by matching the upper and lower die radii and ensuring consistent temperature distribution during molding.
- Tensile tests and FEM analysis revealed that CFRTP layers remain elastic after metal yielding, contributing to the post-yield load-bearing capacity. A clear yield point was observed in SUS/CFRTP but not in AL/CFRTP due to differences in stiffness contrast.
- Young's modulus discrepancies between experiment and simulation were mainly attributed to the neglected adhesive layer in FEM. Additionally, thickness variation during molding reduced structural uniformity.

Future improvements should focus on better thickness control and test configurations that load both metal and CFRTP layers more uniformly. Such refinements will enable the design of optimized laminates with enhanced formability and strength for automotive applications.

ACKNOWLEDGEMENTS

The authors would like to express their sincere gratitude to Associate Professor Akio Otani and the students of the Otani Laboratory at Kyoto Institute of Technology for their generous support in providing access to the experimental equipment used in this study. The authors also deeply appreciate the valuable guidance and insightful advice provided by Professors Tatsuro Kosaka and Kazuhiro Kusukawa throughout the course of this research.

ABSTRACT

Carbon fibre reinforced polymers (CFRP) are widely used in aerospace and automotive industries due to their excellent mechanical properties. However, detecting manufacturing defects such as scratches, delamination and wrinkles remains challenging, particularly for small to medium-sized manufacturers who lack affordable automated inspection solutions. This paper presents two automated computer vision systems designed to address this gap; a 2D imaging system for large, flat structures, and a 3D imaging system for smaller components with complex geometries. Both systems utilise a robot mounted computer vision camera and a custom image stitching pipeline, implemented using open-source software to generate high-fidelity composite images or 3D models. Defect detection is implemented using a YOLOv8n convolutional neural network. Initial testing of the 2D system on a turbine blade demonstrates effective defect identification within 8 minutes, producing a 585 megapixel composite image. The proposed framework offers a low-cost, easily deployable inspection solution to enhance quality control and support industry 4.0 initiatives in composite manufacturing.

1 INTRODUCTION

Carbon fibre reinforced polymers (CFRP) possess advantages such as low density, high specific strength, and low coefficient of thermal expansion, and are widely used in aerospace, automobile, and construction materials [1,2]. However, various manufacturing defects, such as voids, delamination, wrinkles and foreign objects, are practically inevitable due to the complexity of the manufacturing process [3,4].

Computer Vision (CV) has proven itself to be a simple, fast and low-cost solution to automated detection of CFRP manufacturing surface defects [5]. The use of CV for automated detection of surface defects (among other quality controls) within the aerospace industry is well established [6], however smaller institutions such as small to medium sized manufacturers of composite components and structures often lack the budget or resources to develop their own automated solutions to often manual processes such as visual inspection, in particular for complex geometric parts. Furthermore, the proprietary inspection methods developed by the larger institutions often remain undisclosed with little detail entering the literature or industry reports, making it more difficult for smaller institutions to develop this capability.

There are many challenges faced when visual inspection is manual, including; challenges in securing labour, the training required for each new person, the variability of each individual (skill/practice level, natural ability, speed etc.), the variability within each individual human with regards to concentration and energy levels, motivation etc. which could change throughout a single day as well as on separate days. There are many changeable areas which can lead to a variable outcome or inconsistencies in reliability, which is undesirable within the manufacturing and quality control of potentially safety critical components.

Automating visual inspection offers improvements in all of these areas as well as reduces cost and allows for the workforce to be redeployed in other critical areas of production. In general, the literature supports higher success in defect detection with fewer defect-misses by computer vision systems when compared with human inspection [7–12] . However, from those same studies, there is a definite consensus that CV offers much more with regards to repeatability and speed. While the use of computer vision inspection has grown rapidly in recent years, and the techniques encompassed within this area are used widely throughout industry for many applications, the area is ever-expanding and is crucial for facilitating movement towards Industry 4.0.

Machine learning, more specifically convolutional neural networks (CNNs) with regards to CV, has also proven itself in recent years as a significant addition to defect detection, showing improvements in accuracy, speed and overall automation in general [13] with studies showing their efficacy in detecting visual surface defects with success rates of 90% and above [11,14].

However, the current offerings of computer vision systems are dominated by single 2D image capture inspection solutions with few options for capturing, measuring and evaluating the geometry and surface of manufactured parts in 3D or in high or even Gigapixel resolution.

In-order to facilitate the generation of full-scale high-resolution image sets, multiple images would need to be captured from different camera placements and subsequently stitched together using CV techniques. This would be very difficult and labour intensive to conduct manually as the accuracy of a hand-held camera placement and resulting image quality (which can be affected by the stability of the camera) is paramount. The camera may also need to be held in positions not easily reachable by a human being (particularly for large composite structures such as wind turbine blades, airplane fuselages etc.) while ensuring imaging accuracy.

Compiling a set of local images into one single digital image record requires a method of stitching the images together. Stitching the images into one large composite image/model is important for providing easily discernible and intuitive context on defect locations for human operators. This is a requirement as it will more readily facilitate determining subsequent action following defect detection, whether this might be rework, tagging, further investigation or scrapping the component.

This system is intended to be low cost and simple to implement, with the aim being that small to medium sized composite manufacturers could easily implement such a system without requiring a large budget and extensive resources.

This work will explore the potential of two fully automated imaging and defect detection systems for achieving this. Both systems automatically provide a digital record for easy further analysis or to refer back to at a later date, which is highly beneficial and often lacking in manual inspection practices:

1. 2D Imaging system – Intended for large and generally flat composite structures such as large planar composite panels and turbine blades. The output from this system will be a very high-resolution composite stitched image with surface defects highlighted in bounding boxes.
2. 3D Imaging system – Intended for smaller components with complex geometry. The output from this system will be a 3D model (reverse digital twin) of the component with a low-resolution surface texture and defects highlighted in bounding boxes.

This work introduces the term ‘reverse digital twin’ to describe a digital record created from the as-manufactured physical part, such as a 3D model generated via scanning or photogrammetry. Unlike a traditional digital twin, which typically begins with the original CAD model and supports manufacturing and operation of the physical object, the reverse digital twin is derived from the final manufactured artifact and exists digitally. This representation captures real-world characteristics such as the true manufactured geometry, deviations, surface finish and wear. This makes it valuable for quality assurance, maintenance, comparison against nominal designs and general record keeping.

The reverse digital twin serves as a digital snapshot of the physical part’s actual state, bridging the gap between nominal CAD models and reality, much like how photography and computer vision help document finished products but with the added dimensional and geometric context of a 3D model.

2 METHODOLOGY

This section will provide an overview of both systems architecture and how images are captured and processed within the automated pipeline. Both systems share the same general structure with regard to hardware:

- A Kuka iiwa R820 collaborative robot and Sunrise controller were utilised to hold and move a vision camera to pre-programmed positions.
- The camera mounted to the robot arm was a Basler Ace 2 (20MP) with a 35mm lens. This was connected to a PC running OpenCV.
- The PC and the Sunrise controller communicate over TCP/IP, when the robot reaches a new position it will pause for 0.5 seconds and then send a 'Take Image' command to the PC where OpenCV receives it and captures and stores the image.
- Once the robot has completed all positions it sends a 'Stitch' command to OpenCV and then terminates the connection, OpenCV will then move onto the next step in the pipeline, which differs for the two systems.

Defect Detection:

The defect detection method is the same for both systems, through OpenCV v4.11.0 [15,16] a YOLOv8n [17] model was trained and used. This model is still under development and so far, has only been trained on one type of surface defect (scratch) which is currently present on a turbine blade which is being used to develop the 2D system. In the current model a training set of 96 images has been used, consisting of 23 original images and 73 augmented images. All training images were resized to a resolution of 1280 x 1280 pixels.

Lighting:

Lighting is a key component of all computer vision systems, it is important that there is enough light for a correct exposure level while also ensuring a suitable shutter speed [18]. This is particularly important for the YOLO model, as suboptimal lighting conditions can reduce successful object/defect recognition in some CNNs by more than 20% [18]. To solve this problem, a lighting frame was constructed out of extruded aluminium profile with one main centre panel measuring 1m across and two side panels measuring 0.5m across which fold against the main panel for storage. LED strip lighting is then held across the full span of the frame by way of hook and loop tape and the cross members in the centre panel can be moved up and down to adjust the height of each light strip. This frame allows for light to be spread across the full surface of any component from all angles, the frame is shown as part of the 2D imaging system later in Figure 3.

2D System:

The overall architecture of the 2D system can be seen below, in Figure 1.

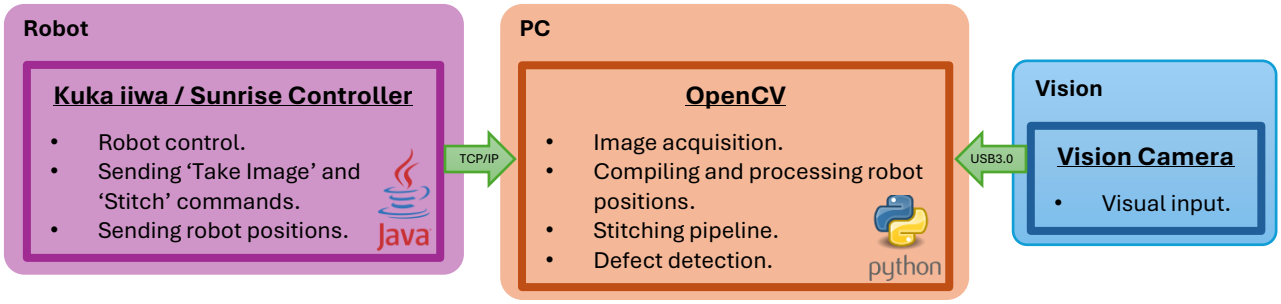

Figure 1: 2D System Architecture

For the 2D system, a custom stitching algorithm was required for the reasons below:

- It needs to ensure true representation of the surface geometry in a way that does not risk feature distortion. Therefore, the only transformation applied to each image will be translation, there will be no rotation of the camera between images to remove the need for any image warping steps in the stitching process.
- It needs to align the images accurately and reliably without the feature detection and matching steps of traditional image stitching techniques being impacted by the repeating patterns, or sometimes featureless surfaces, of CFRP.
- There are no readily available stitching models or software to account for the requirements above.

To ensure true representation of the surface geometry with no warping, the robot arm was programmed to capture all images in a 2D grid pattern with a perfectly level camera normal to the imaging plane for all images, therefore allowing translational movement only with no rotational movement between images. As shown in Figure 2, camera rotation can result in surface geometry being skewed or distorted if the camera is not positioned normal to the surface, requiring a warping step during stitching to correct this in an attempt to fit them together correctly with the other images, which is undesirable for this application.

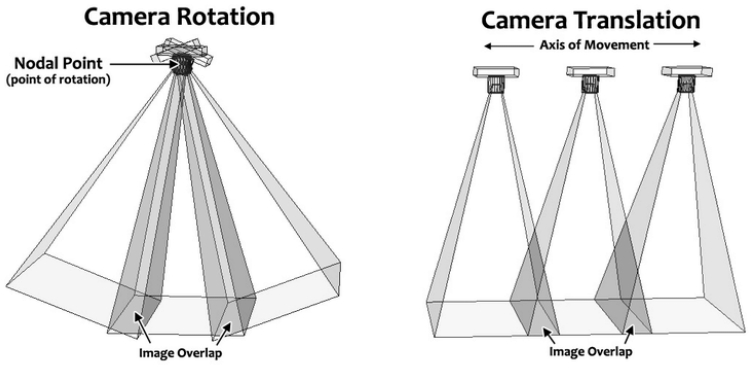

Figure 2: Camera Rotation vs Camera Translation [19]

In order to not allow the feature detection and matching steps to be impacted by the repeating patterns or sometimes featureless surfaces of CFRP (depending on the material), the stitching algorithm utilises the known robot cartesian coordinates from each camera position to align the images relative to one another.

The full homography relationship connecting 2D coordinates of features in the captured image, or on the camera sensor, to the 3D world coordinates of the same features through camera position and intrinsic properties is given in Equation 1. Removing the rotational matrix from the equation greatly simplifies the relationship between the position of features in the image and the real-world. From here, the camera intrinsic properties (f_x, f_y, c_x and c_y together represent internal camera characteristics such as focal length and optical centre) can be provided by way of prior camera calibration and the real-world coordinates can then also be supplied by knowing the robot positions for each image.

$$s\begin{bmatrix} u \\ v \\ 1 \end{bmatrix} = \begin{bmatrix} f_x & 0 & c_x \\ 0 & f_y & c_y \\ 0 & 0 & 1 \end{bmatrix} \begin{bmatrix} r_{11} & r_{12} & r_{13} \\ r_{21} & r_{22} & r_{23} \\ r_{31} & r_{32} & r_{33} \end{bmatrix} \begin{bmatrix} t_1 \\ t_2 \\ t_3 \end{bmatrix} \begin{bmatrix} X \\ Y \\ Z \end{bmatrix} \quad (1)$$

From this, Equations 2 and 3 can be used to determine t_x and t_y, the translational movement of each image (in pixels) within the image coordinate system ($t_z = 0$ as the camera only moves in an xy grid). f_x and f_y represent the focal length in pixels by combining lens focal length and sensor pixel dimensions, these are obtained from the intrinsic matrix through camera calibration. dX and dY are the camera translational movement (in mm) and S is the scene depth (distance from the camera to the scene/surface, in mm).

$$t_x = \frac{f_x dX}{S} \tag{2}$$

$$t_y = \frac{f_y dY}{S} \tag{3}$$

Following image placement, seam finding and blending are performed using functions provided by the OpenCV library v4.11.0. There is a 30% overlap across all images taken in the grid pattern, this is to allow for seam finding and blending to successfully account for potential minor pixel misalignments between neighbouring images.

SAHI (Slicing Aided Hyper Inference) [20] was also utilised with YOLO for the 2D system to breakdown the very high-resolution stitched image into tiles for individual inspection. This is required to perform the defect detection step on the composite image as a whole. This method was chosen over performing the inspection on each individual image prior to stitching them all together as the output from the latter method results in slight breaks and misalignments in the bounding boxes and inconsistencies in confidence values shown in the final composite when a defect is split across multiple images.

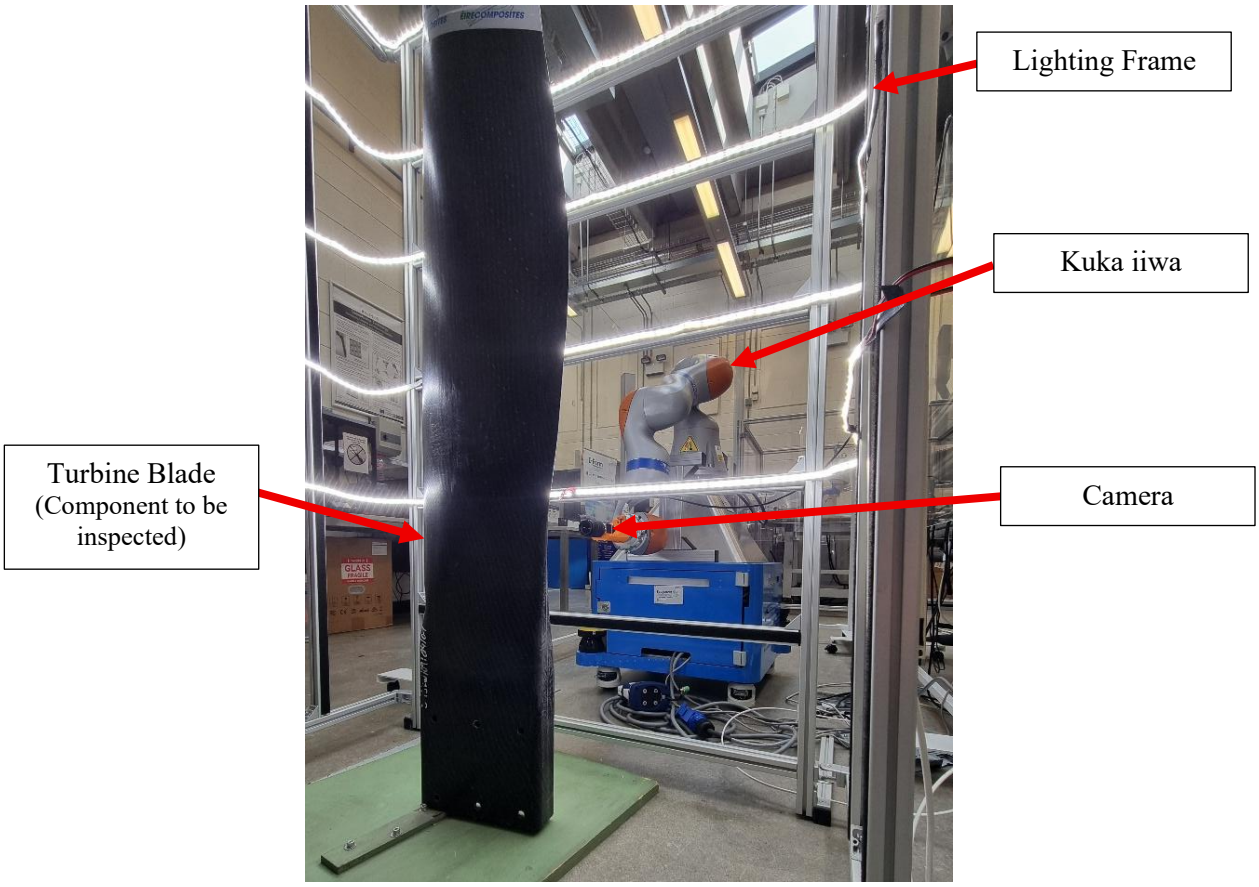

Figure 3: 2D Imaging System Inspecting a Turbine Blade

3D System:

The overall architecture of the 3D system can be seen below, Figure 4.

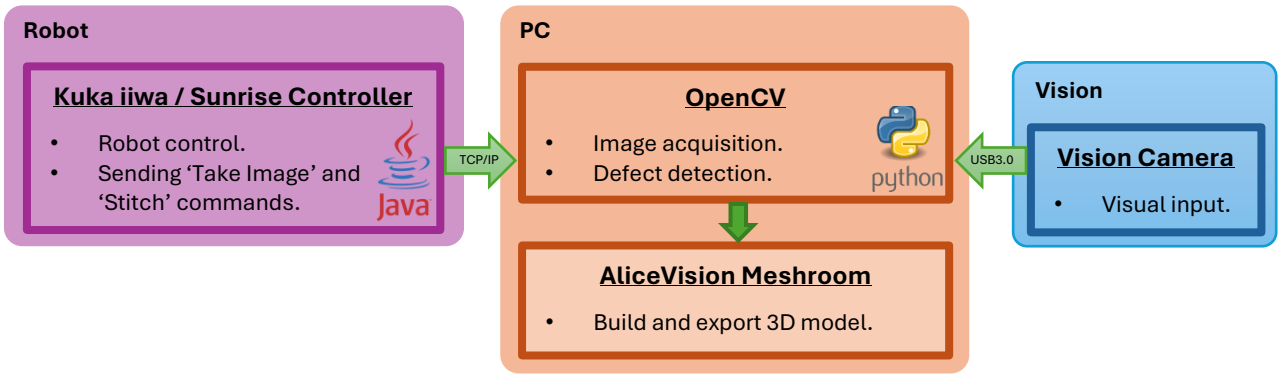

Figure 4: 3D System Architecture

As can be seen above, the 3D system is very similar to the 2D system however the image acquisition is from different angles around the component rather than in a 2D grid and the stitching takes place in open-source photogrammetry software AliceVision Meshroom [21], where a 3D model is generated as the output (reverse digital twin). The camera intrinsic properties (f_x, f_y, c_x and c_y representing focal length and optical centre) are also given to Meshroom to simplify the homography calculations and to allow the software to accurately account for scaling. Meshroom also creates a surface texture from the image set which is wrapped around the 3D model generated to provide a realistic representation of the component exterior. Command line interface (CLI) is also utilised to integrate Meshroom into the automated pipeline by allowing communication between the Python script running OpenCV and Meshroom.

3 TESTING AND RESULTS

2D System:

This inspection system completed a full automated inspection of a 1.32m length of the composite turbine blade in 8 minutes and 15 seconds while highlighting 3 surface scratches, the system output image can be seen in Figure 5.

The PC used to run OpenCV for image stitching and defect detection in this system was a Dell Precision 7680 laptop, equipped with a Core i7-13850 CPU, 32 GB of RAM and an Nvidia RTX 2000 Ada GPU with 8 GB of VRAM.

The output image is 585Megapixels and generated from 62 raw images in total.

System Element	Time
Capturing images	5 mins 10 secs
Stitching images	50 secs
Defect detection	2 mins 15 secs
Total	**8 mins 15 secs**

Table 1: Time Breakdown of 2D System Operation

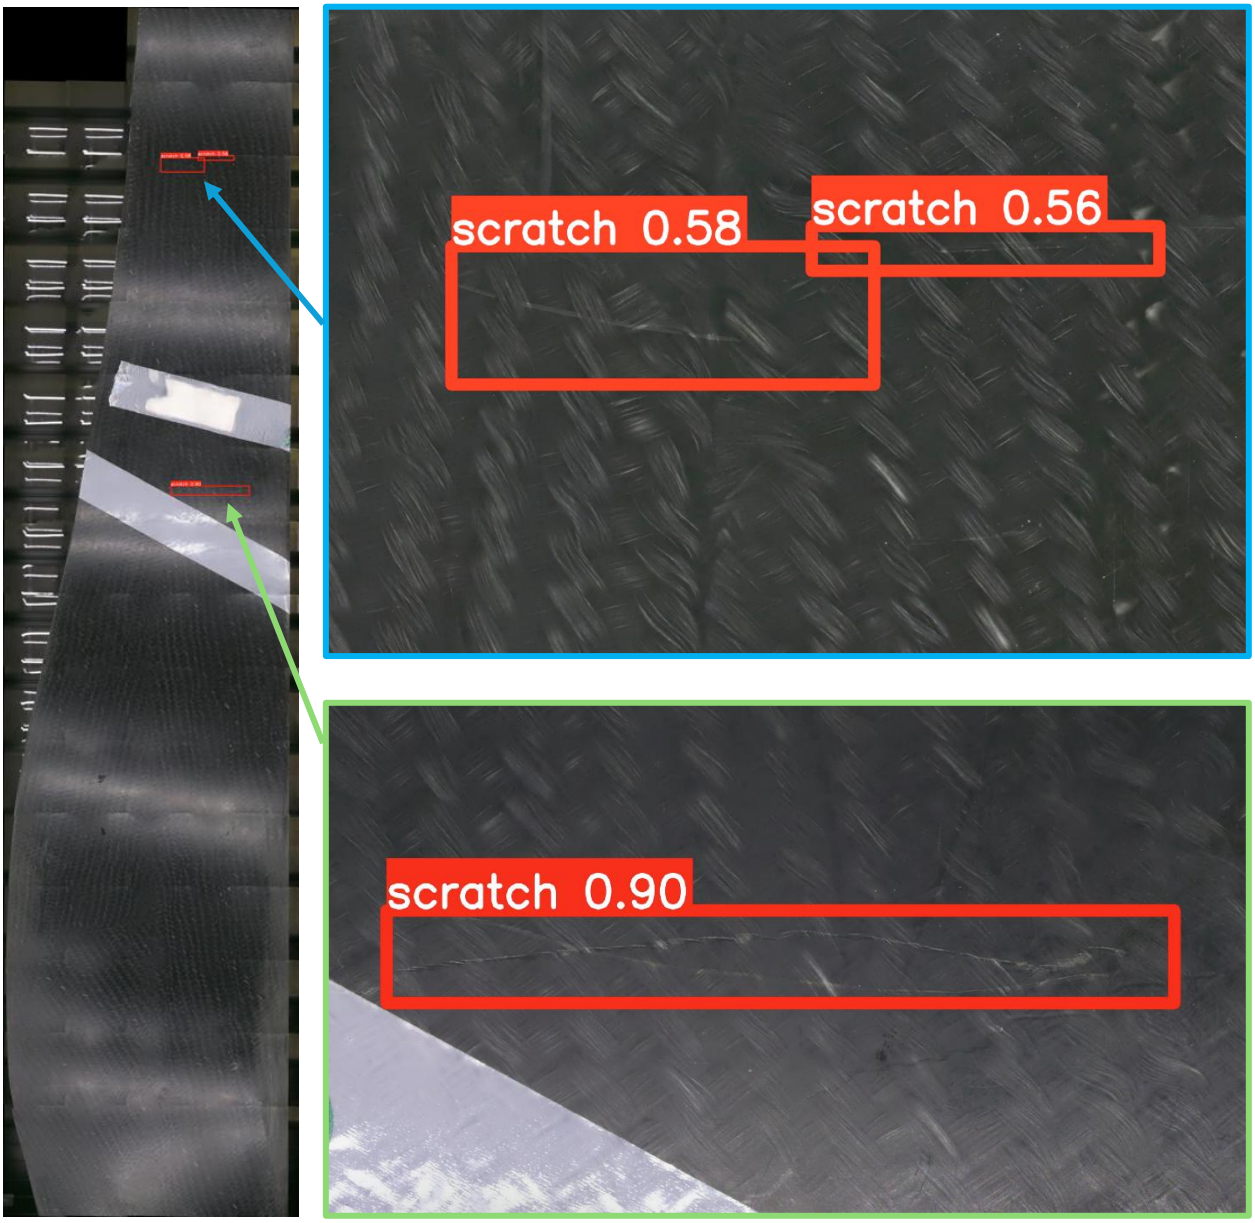

Figure 5: 2D System Output

With the seam finding and blending operations switched off inside the stitching algorithm, the total time of the system is reduced by 30 seconds, making the total 7 minutes and 45 seconds. This would reduce the stitching quality but would still fulfil the function of permitting defect identification and location context. There is also some potential for optimisation of the robot movement and image capture phase.

This could also be brought down by a further 1 minute and 45 seconds if SAHI was not used for the defect detection step and each individual image was processed by the YOLO model and marked where required before stitching. This would also create a slightly less desirable output but would still fulfil the function of detecting and highlighting defects on the single compiled output image. If this modification was implemented, the total time is 6 minutes for a fully automated inspection.

4 DISCUSSION

The results so far demonstrate that the proposed 2D system can complete a fully autonomous inspection of large composite structures in a reasonably small timeframe and effectively identify surface defects with high accuracy.

Furthermore, this framework is simple and relatively budget friendly to implement, creating a good starting point for small to medium sized composite manufacturers to work with in beginning their inspection automation journey. There is also opportunity to reduce cost even further by implementing this system with a simple cartesian robot, which would also easily allow for a larger inspection reach compared to the Kuka iiwa used here. This would however limit operation strictly to the 2D system but at the same time would create an in-expensive and effective approach to automated visual inspection of composite panels and other large structures.

The LED strip lighting could be further optimised by including a diffuser for each strip. It can clearly be seen in Figure 5 that there are strong reflections on the turbine blade surface, this is not ideal for defect detection, as it provides extra variability in visual input which the YOLO model needs to overcome and could lead to more false negatives. An even exposure is needed over the full surface of the blade to reduce differences in pixel luminosity between the brighter and darker areas.

To simplify the setup and reduce costs even more, the lighting frame could be replaced by a simple large, powerful and diffused ring light mounted with the camera on the robot. The lighting frame was constructed as part of this work due to the requirement in early development of a stationary and wide-spread light source to reduce the negative impact a moving light source has on feature detection and matching which were already disadvantaged due to the repeating patterns. However, these steps were subsequently not needed once known camera positions were implemented.

However, a possible improvement to the 2D system could be to re-introduce feature detection and matching and use them to refine image alignment once the initial placement has been attained from the robot positional coordinates, this is common practice in systems where rough camera positions are known [22,23]. The reason for this is because there are stitching artifacts in the composite image, in earlier development of the system a smaller section of a flat surface was used instead of the turbine blade which led to very close alignment across all images without any refinement needed, but imaging across larger areas reduces the accuracy of each position relative to the others for the Kuka iiwa.

A possible extension of this tool includes modifying the 2D system to include a thermal camera and heat source, this would provide a very simple and effective automated thermography system for large composite structures. Such a system is currently lacking within the literature as well as in commercial offerings. The stitching algorithm developed within this work would be ideally suited to thermography as well due to the lack of features common in thermal imaging.

The model and scene scaling within the 3D system is handled by providing the calculated intrinsic camera properties. Testing is still yet to confirm the accuracy of this method. A potentially more accurate method would be to have one or more reference objects in the scene, such as a calibrated cube, which the system can use as a reference to scale the scene correctly.

5 CONCLUSIONS

This work has demonstrated the feasibility of an automated computer vision inspection system for composite components. The 2D imaging system successfully created a very high-resolution image of a large composite structure, identifying surface defects such as scratches with promising accuracy and efficiency. The integration of robot assisted image acquisition, simple but effective custom stitching algorithms, known camera positions and YOLO-based defect detection creates a practical, cost-effective solution ideally suited to small to medium sized manufacturers.

This framework represents a key step towards industry 4.0 in the wider realm of composite manufacturing by providing scalable and adaptable automated inspection tools that can be implemented easily without the need for large budgets and resources. By making automation more accessible, smaller manufacturers can improve product quality, reduce costs and increase competitiveness.

6 FUTURE WORK

While initial results are encouraging, further work is needed to see both systems working fully. The defect detection model requires more training to include a wider range of defect types and diversity to improve robustness, the 3D imaging system's accuracy and integration need validation and the light source needs to be diffused.

HI_MOV Corredor Tecnológico Transfronterizo de Movilidad con Hidrógeno Renovable

1. INTRODUCTION

Hydrogen storage in the mobility sector predominantly relies on high-pressure tanks, particularly Type IV Composite Overwrapped Pressure Vessels (COPVs), which combine carbon-fibre composites with thermoplastic liners. While effective, conventional thermoset resin matrices present challenges regarding its poor recyclability. Replacing them with thermoplastic matrices enhances sustainability, facilitates reparability, which ultimately may lead to reduced lifecycle costs.

2. AIM

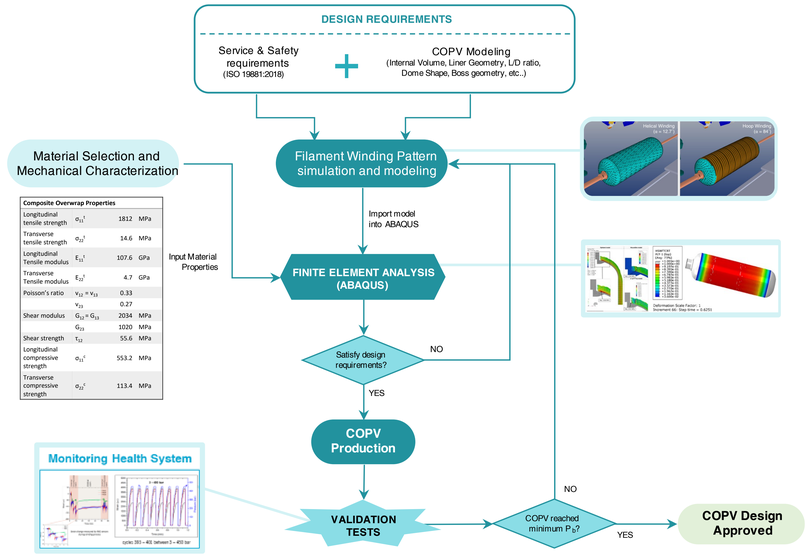
To develop a **fully thermoplastic Type IV pressure vessel rated for 700 bar,** using an innovative manufacturing technology. The vessel will integrate **embedded fiber Bragg grating (FBG) optical sensors** for **real-time structural health monitoring** during testing and fuelling and defueling.

3. METHODOLOGY

The development of the thermoplastic COPV followed the **ISO 19881:2018 standard** which specifies requirements for onboard gaseous hydrogen storage in vehicles. This includes safety and service conditions, material selection, design, manufacturing, testing, and periodic inspections using non-destructive methods.

MATERIAL SELECTION & CHARACTERIZATION	WINDING PATTERN DEVELOPMENT	STRUCTURAL ANALYSIS (FEA)	MANUFACTURING & PROCESS OPTIMIZATION (AFP)	PROTOTYPE FABRICATION & TESTING
▪ Selection of suitable thermoplastic materials ▪ Perform mechanical characterization	▪ Design fiber winding architectures ▪ Simulate and refine patterns for strength and manufacturability	▪ Conduct Finite Element Analysis ▪ Target burst pressure: 1575 bar	▪ Implement Automated Fiber Placement (AFP) ▪ Use IR laser source for thermoplastic tape heat and consolidation ▪ Apply Design of Experiments (DOE) to optimize process parameters	▪ Manufacture prototype using optimized process ▪ Embedment of FBG sensors ▪ Conduct validation tests (burst & cyclic testing) ▪ Monitor structural integrity using embedded FBG sensors

4. PROJECT CONSTRAINTS AND CHALLENGES



Thermoplastic Liner	Metallic Boss	Composite Overwrap
- Thermoplastic material with **low hydrogen permeation coefficient** (e.g. HDPE or PA); - Thermoplastic material compatible with **Rotomoulding process** for Liner Manufacturing; - Liner material must have a good mechanical properties and high **thermal and dimensional stability within -40°C to +85°C.**	- Material must be **compatible with gaseous hydrogen** (e.g. S31603, Al6061); - Must have a **strong adhesion** with the thermoplastic liner material; - Good **mechanical integration** into the thermoplastic liner.	- Thermoplastic Carbon-Reinforced UD tapes **compatible with AFP** in-house system; - Thermoplastic matrix with $T_g \geq 105°C$ (accord. to ISO 19881:2018); - Thermoplastic matrix **compatible with the liner base material**; - Design winding patterns that **comply with the maximum burst pressure** (2,25 x 70MPa = 157.5 MPa – accord. ISO 19881:2018).

5. TANK SPECIFICATIONS

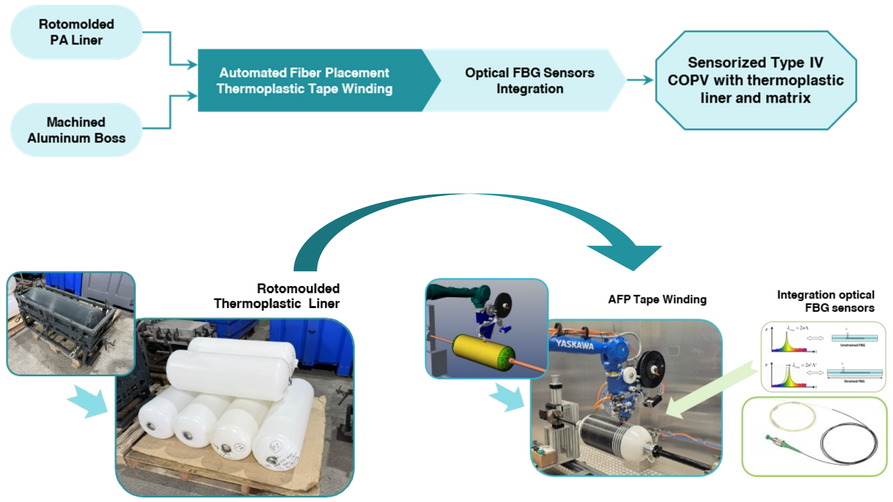


Table 1. Design specifications for the COPV.

Fully-thermoplastic Type IV COPV - Design Specifications		
Target Working Pressure	70	MPa
Tank Geometry	Cylindrical with semi-elliptical domes	
Tank Diameter	296	mm
Boss Diameter	65	mm
Length-to-diameter (L/D) ratio	3	
Internal volume capacity	≈ 54	L
Design Safety Factor	2.25	
Maximum Burst Pressure (P_b)	157.5	MPa
Liner material	PA11	
Boss material	Al6061-T6	
Composite tape material	UD Carbon-Fiber thermoplastic PPA tape

PROJECT SATUS & FUTURE WORKS

This work is currently under development under the HI_MOV project umbrella. The safety and service requirements, as well as the COPV modeling, material selection, and characterization, are complete. Structural numerical simulations will be conducted to the full optimization of the composite shell for the target burst pressure (P_b). Once this phase is complete, the COPV with integrated sensorization will be manufactured, followed by experimental validation, through burst testing, to confirm its ability to withstand the projected pressures.

Introduction

- Hydrogen storage vessels are categorized into types I through V.
- Among these, Type IV composite-structured vessels achieve high-efficiency lightweight characteristics by utilizing polymer liners instead of traditional metal liners. Moreover, Type V hydrogen vessels integrate polymer liners into composite structures to achieve maximum efficiency.
- In the case of hydrogen storage vessels for vehicles, the structure is constrained, necessitating structural optimization to maximize spatial efficiency. Type 4 storage vessels are primarily composed of a polymer liner for hydrogen storage and a composite structure that withstands load and pressure. Therefore, the characteristics of the liner and the design of the pressure vessel structure are critical.
- This study thus focuses on the design and simulation of a multi-cylinder, curved hydrogen storage vessel to transportation applications. Additionally, the Polyamide 12(PA12), intended as the liner material, was reinforced by the addition of graphene nanoplatelets (GNPs) to examine and enhance its properties. Finally, the properties of the hydrogen storage vessel were verified through pressure test.

Experimental

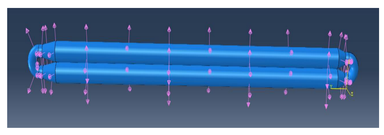
1. Materials

- Polyamide 12(PA12, Grilamid L 25A NZ, Griltech, Switzerland)
- Graphene nanoplatelets (GNPs, Sigma Aldrich (USA)
- T-700 12K UD prepreg(Toray, Japan)

2. Manufacturing

- Resin
  - 3 Kg master batch
  - Dried over 30 mins with vacuum dry oven
  - Hot press – 15 bar, 180 ℃
- Composites
  - Single braided winding

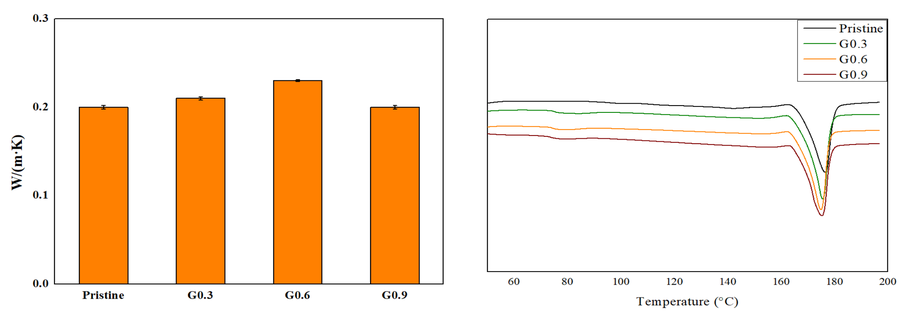
Samples	GNPs wt.%
Pristine	0.0
G0.3	0.3
G0.6	0.6
G0.9	0.9



PA12 Resin component with GNPs

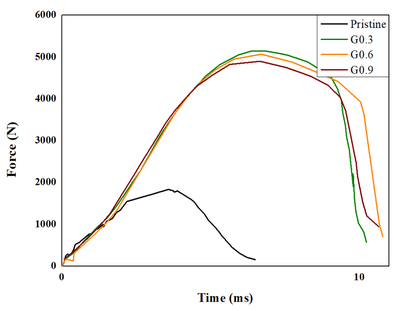
3. Characterization

- Thermal conductivity
- DSC
- X-ray CT
- Drop weight



4. Numerical analysis

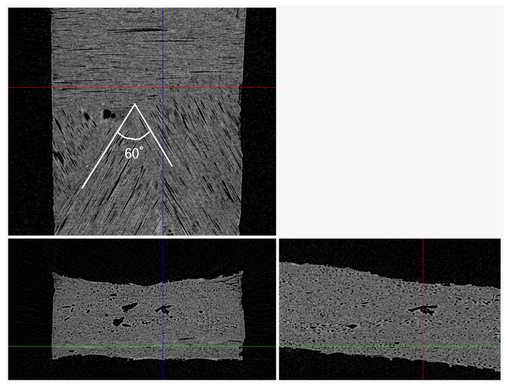
- ABAQUS/Implict
- Shell structure with inner pressure



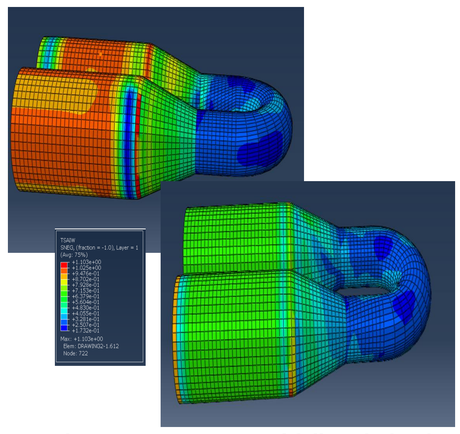
Results & Discussion

PA12 resin

Thermal conductivity(left) and DSC curves(right) of PA12 resin according to GNPs content

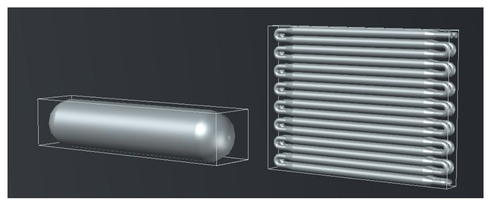


- A thermal conductivity analysis was conducted to examine the thermal properties of liners with indicating an increase according to GNPs content. However, a decrease was observed at G0.9. The trend suggests that better dispersion of GNPs, which act as thermal conductors, and it can be optimized.
- Differential Scanning Calorimetry (DSC) analysis was conducted to measure changes in melting point and enthalpy. The melting points for Pristine, G0.3, G0.6, and G0.9 were 176.54°C, 175.57°C, 174.85°C, and 175.17°C respectively, with no significant changes. However, the enthalpy increased by 3.1% at G0.3 and 8.5% at G0.6, while it decreased by 6.8% at G0.9 compared to G0.6.



Representativ Drop weight impact result of PA12 resin according to GNPs content

- The peak forces measured for Pristine, G0.3, G0.6, and G0.9 were 2030, 4961, 5007, and 4633 N, respectively. The peak energies were 12.15, 53.18, 54.08, and 49.25J, and the total energies were 41.76, 119.08, 121.24, and 117.38 J, respectively.
- This increase is attributed to the uniform distribution of GNPs within the PA12 panel, which enhances impact absorption. However, a decreasing trend was observed at G0.9, likely due to the agglomeration of GNPs, which results in uneven dispersion and reduced impact absorption.



CFRP pressure vessel

Representative X-ray CT image of CFRP composite vessel

Hydrogen storage vessel failure behavior. Uniform thickness model (top) and Uniform material model (bottom)

Efficiency of hydrogen storage. Typical single cylinder model (left) and multi-cylinder model (right)

- CFRP composite samples were fabricated for hydrogen storage vessels and analyzed through numerical simulations. Initially, the manufacturing process was verified using micro-CT to examine the internal structure. Although voids were present, the samples were manufactured stably without issues regarding fiber orientations, and no significant problems were found at the resin interfaces.
- Numerical analysis was conducted to optimize the curved structure. The analysis simulated a multi-cylinder curved structure to assess potential failure at bends or cross-sectional changes upon fabrication. The results shows that a uniform material model naturally thickens in areas of decreasing diameter, confirming the structural integrity of the design.
- Finally, the multi-cylinder curved structure was shown to be more efficient compared to the single-cylinder structure. The storage efficiency of the multi-cylinder model was found to be 7.4% higher than that of a typical single-cylinder model In actual vehicle storage compartments, which typically have a rectangular structure, and the efficient interconnection of the multi-cylinder model resulted in an efficiency improvement of over 15%.

Conclusion and further works

- In this study, we explored polymer resins suitable for use as liner materials for the production of high-efficiency, lightweight hydrogen storage vessels for vehicles.
- A multi-cylinder, curved Type IV hydrogen storage vessel utilizing these resins. The PA12 resin, enhanced with graphene nanoplatelets (GNPs), exhibited excellent mechanical properties and hydrogen barrier performance, facilitating efficient hydrogen storage vessel design.
- Moreover, the proposed curved hydrogen storage vessel achieves over 7% greater area efficiency and more than 15% greater space efficiency compared to conventional single-cylinder structures. The feasibility of this design was examined through numerical analysis and experimental.

- This research was supported by the Ministry of Trade, Industry and Energy (Project Number 20011899), and further studies on the hydrogen barrier properties of the resin, as well as pressure and charging tests of the actual multi-cylinder hydrogen storage vessel, are currently underway.

Effect of Incorporating Additional Thermoplastic into Carbon Fiber/Epoxy Composites Prepared by Electrodeposition Resin Molding Method

Md Tansirul Islam [1], Shinya Honda [2], Kazuaki Katagiri [3], Katsuhiko Sasaki [2] and Ryo Takeda [2]

1) Graduate School of Engineering, Hokkaido University 2) Faculty of Engineering, Hokkaido University
3) Graduate School of advanced Engineering Application, Hiroshima University

* e-mail: tansir1303129@gmail.com

Background and Objective

- Thermoplastic polymer composite has exceptional combination of mechanical performance, design flexibility, and recyclability.
- Carbon fiber reinforced thermoplastic (CFRTP) has widespread application in aircraft

Fig. 1. Application of CFRTP in aircraft [1]

Subject

Electrodeposition resin molding method (EDRM) only works on thermoset (epoxy) polymer.

Preparing Nylon 6 based carbon fiber reinforced epoxy composite

Objective

To check the compatibility of nylon 6 and epoxy into carbon fiber/nylon 6/epoxy and check its effect on the composite properties

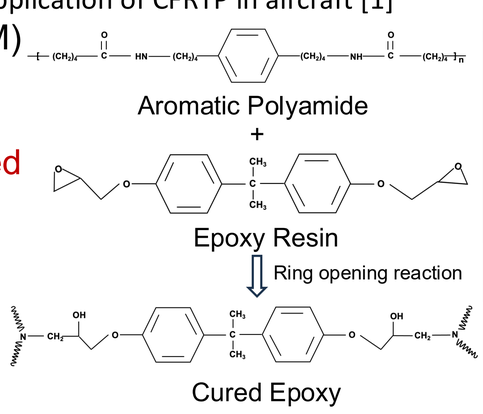

Fig. 2. Reaction between nylon 6 and epoxy [2]

What is EDRM?

- EDRM – Electrodeposition Resin Molding Method
- Coating techology for automobile bodies had been adopted

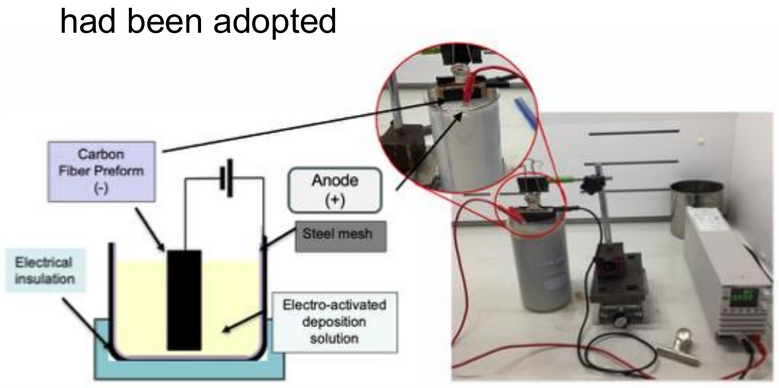

Fig. 3. Graphical representation and actual setup of EDRM

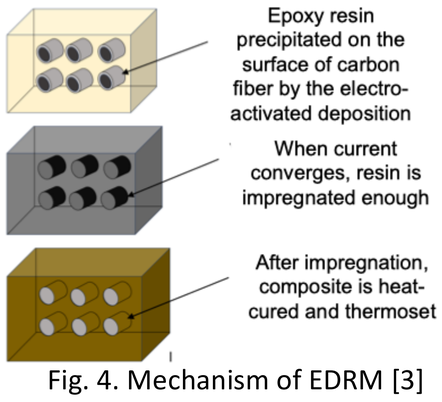

Fig. 4. Mechanism of EDRM [3]

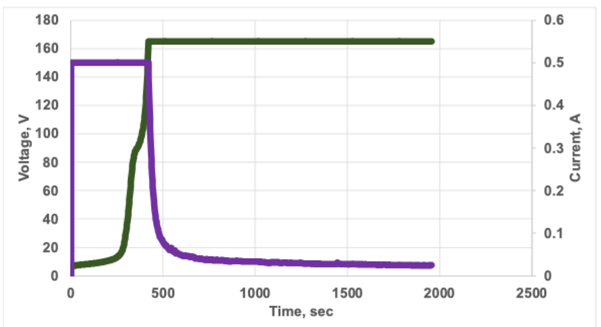
Advantages of EDRM

- ✓ Less void
- ✓ Easy handling
- ✓ Uniform mixture of fiber and matrix
- ✓ Autoclave not required
- ✓ No need of vacuum bag or moulding



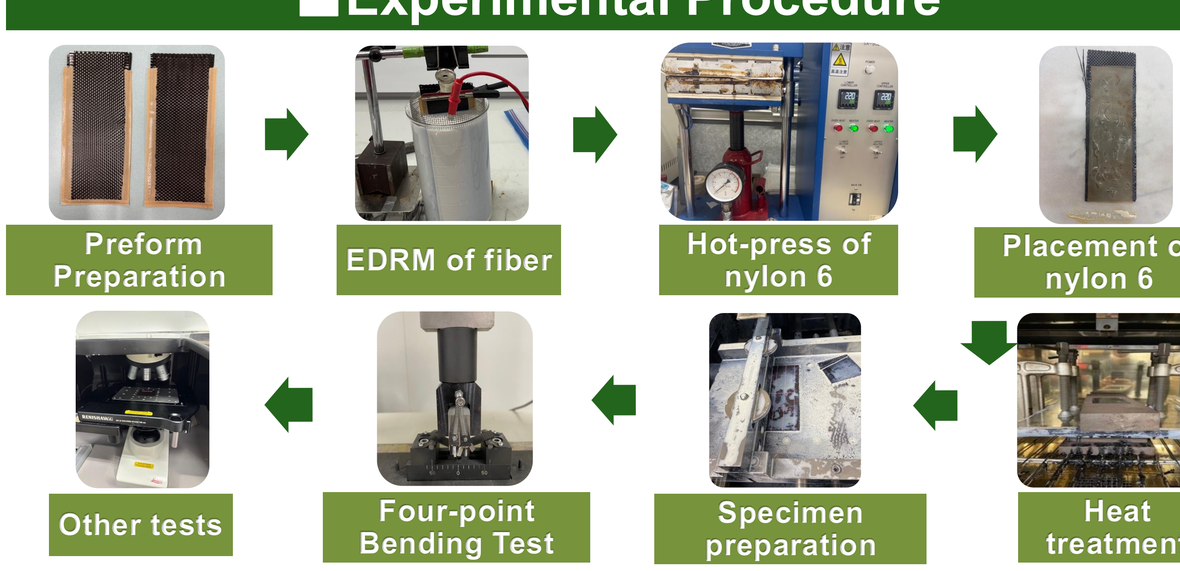


Fig. 5. Relationship of voltage/current with time

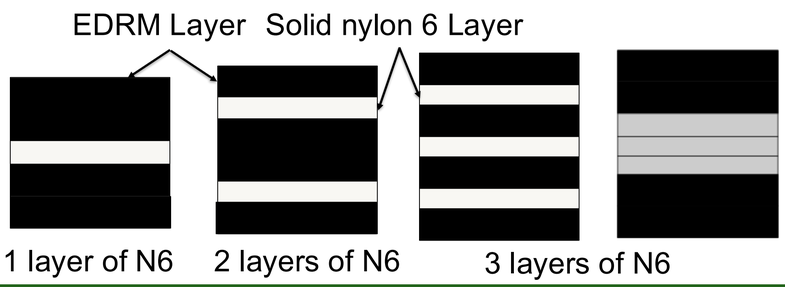
Experimental Procedure

Stcking sequence



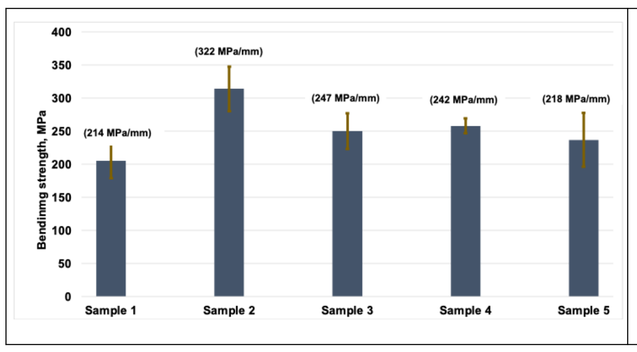


Table 1. Expermental condition

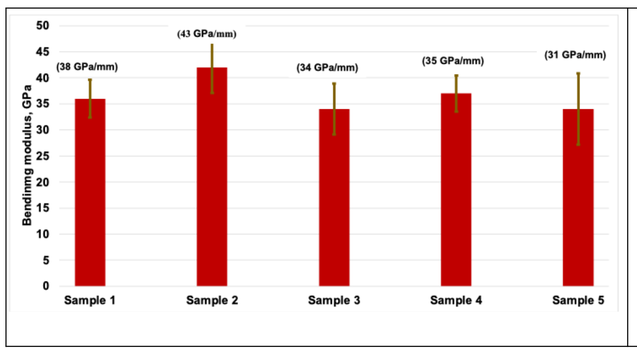
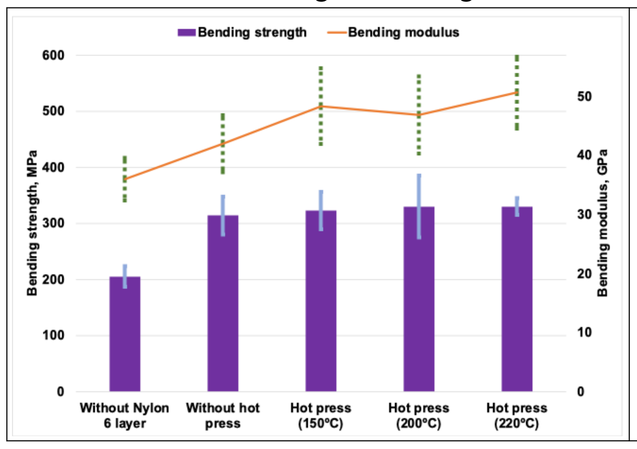
Sample	Stacking Sequence
1	No N6
2	1 Layer of N6
3	2 Layers of N6
4	3 Layers of N6 (Alternate)
5	3 Layers of N6 (Middle)



Results and Discussion

The results obtained from the Four-point bending test, Roughness test and Raman Spectroscopy are displayed below.



Inserting nylon 6 sheet into CFRP can significantly increase the bending strength of CFRP, however, surprisingly adding one layer of nylon 6 has higher flexural strength than adding multiple layers

Fig. 6. Bending strength of carbon fiber/nylon 6/epoxy composites

The same scenerio was also observed in case of flexural modulus. The maximum bending modulus was achieved when 1 layer of nylon 6 was inserted into CFRP.

Fig. 7. Bending modulus of carbon fiber/nylon 6/epoxy composites

The CFRP including the hot-pressed nylon 6 layer showed 59% increase in bending strength than the CFRP without any nylon 6 layer. Moreover, using the hot-pressed nylon 6 layer increased the bending strength by 6% of CFRP with nylon 6 layer that wasn't hot-pressed.

Fig. 8. Bending strength and modulus of carbon fiber/hot-pressed nylon 6/epoxy composites

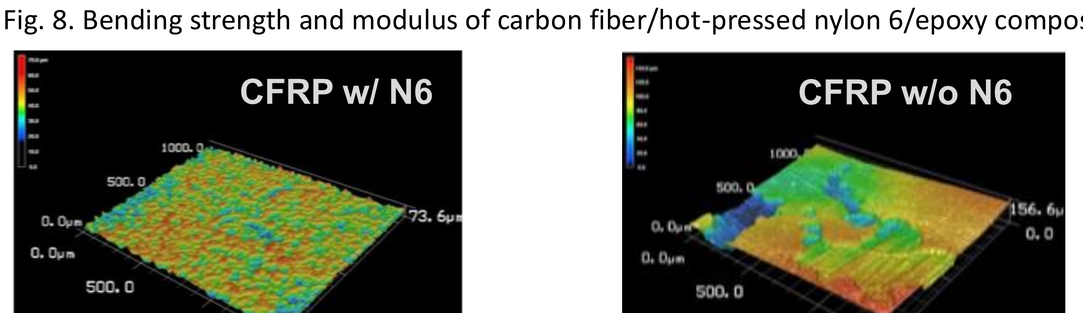


Fig. 9. Surface topography of carbon fiber/nylon 6/epoxy composites

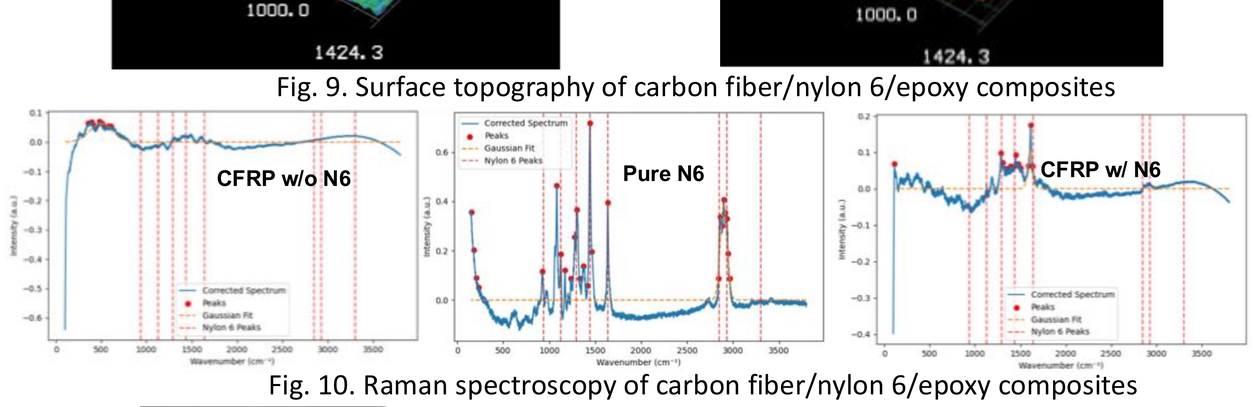

Fig. 10. Raman spectroscopy of carbon fiber/nylon 6/epoxy composites

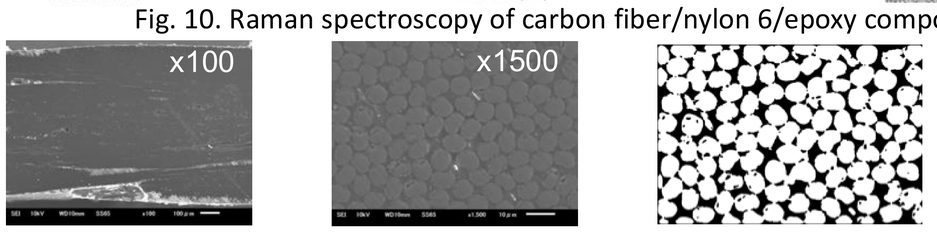

Fig. 11. SEM image of CFRP fabricated by EDRM

Conclusion

- ➢ The effect of adding Nylon 6 into CFRP were investigated
- ➢ Nylon 6 has a great compatibility with epoxy which results in higher bending strength and impact energy

Future Studies

- ➢ Effect of adding other thermoplastics other than nylon 6 with epoxy to check compatibility and made a comparative study

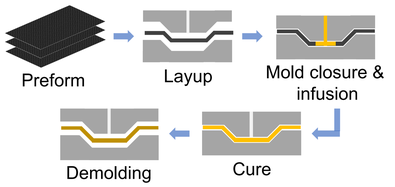
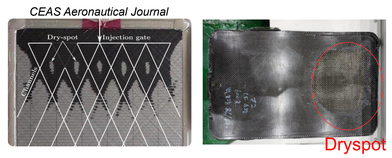
Real-time Flow-front Prediction in Resin Transfer Molding Using Electromechanical Behavior and Generative Adversarial Network



Dahun Lee[a], Björn Beck[b], Frank Henning[b], In Yong Lee[c] and Young-Bin Park[a]



[a]Department of Mechanical Engineering, Ulsan National Institute of Science and Technology, Ulsan, Republic of Korea, [b]Fraunhofer Institute for Chemical Technology, Pfinztal, Germany
[c]Department of Mechanical Engineering, Dong-A University, Busan, Republic of Korea

Background

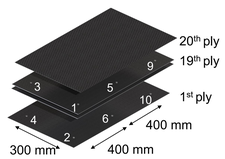
- Increase of demand for CFRPs due to its superior mechanical properties
- Thermoset CFRPs : Higher mechanical properties and thermal resistance
- Large-scale products such as wind turbine blade, airplane, automotive panels.

- Resin transfer molding (RTM) is widely utilized for producing thermoset CFRPs but, vacuum assisted resin transfer molding (VARTM) provide cost-effective manufacturing.
- Defects, particularly dryspots, commonly occur during infusion stage
- Real-time monitoring is essential to ensure full impregnation → defect-free composites

- Problem statements

1) Is it applicable to large-scale products?
2) What approach ensures reliable prediction of diverse flow-front behavior?

Methodology

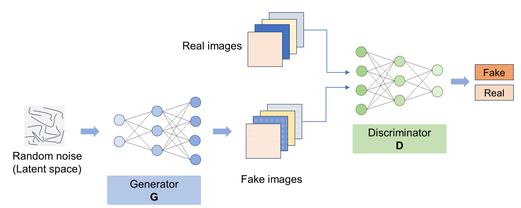


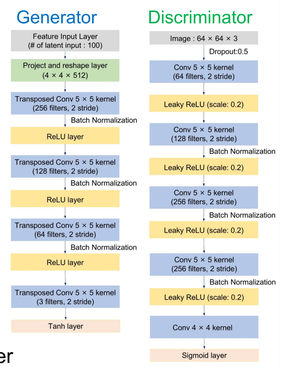
Experimental setup

Plain woven (204 g/m²)

Epoxy resin (240 mPas @ 25 °C)

Preform & electrode setting



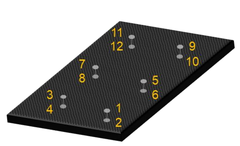


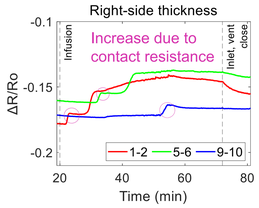
Experimental setup

- Real-time measurement on 24 channels (thickness, crosswise and lengthwise)
- Set R_o as atmospheric state and calculate $\Delta R/R_o$ for normalization
- Atmospheric state: 10 min, vacuum state: 10 min, infusion: 55 min

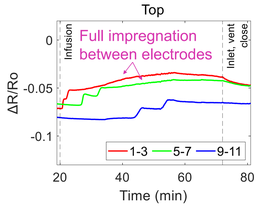
Generative Adversarial Network (GAN)

- Artificial intelligence tools for generating realistic images (e.g., computer vision, design, image synthesis, etc.)





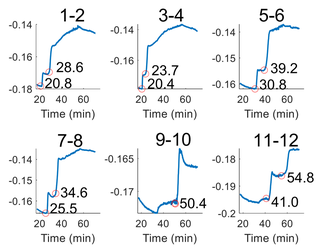
Generator
- Generates realistic fake data to fool the discriminator

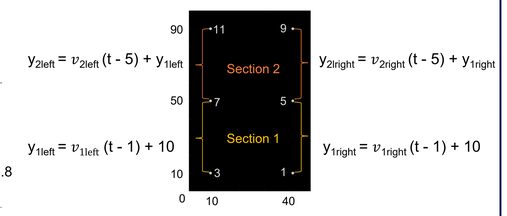


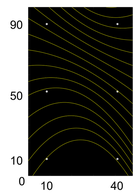
Discriminator
- Classifies inputs as real or fake; acts as a binary classifier

Results

Electromechanical Behavior

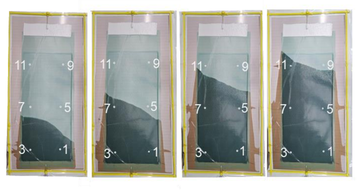


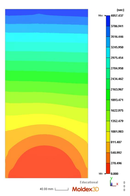




- Resin impregnation on the electrodes → abrupt increase in electrical resistance
- Governing equation : $P_{Compaction} = P_{Applied} - P_{Resin}$ ($P_{Compaction}$ ↑ → $\Delta R/R_o$ ↓)
- $P_{Compaction}$ results in changes in electrical network between electrodes.
- Full impregnation was observed based on the gradual increase in electrical resistance.

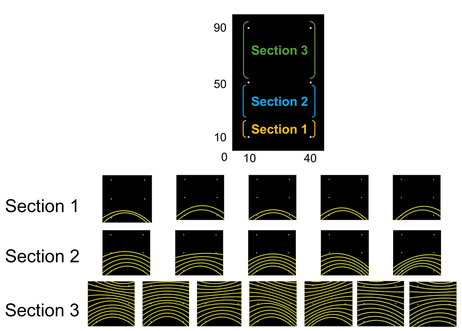
Flow-front Identification



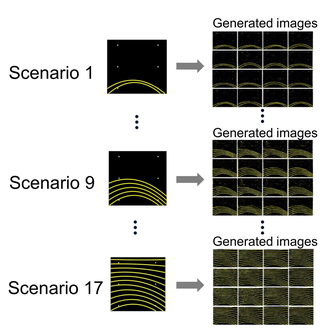


- Abrupt increase in electrical resistance → identify resin arrival time on electrodes
- Linear equations for identifying resin location along electrodes
  → derive parabolic equation and plot to represent flow-front

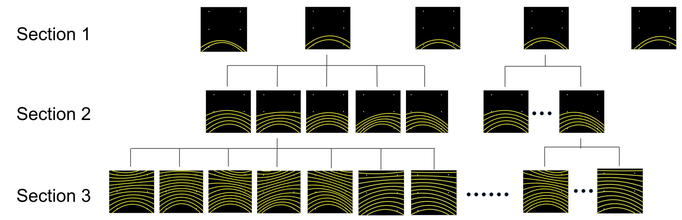
Identified result



Experimental result

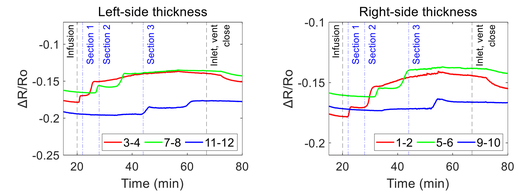


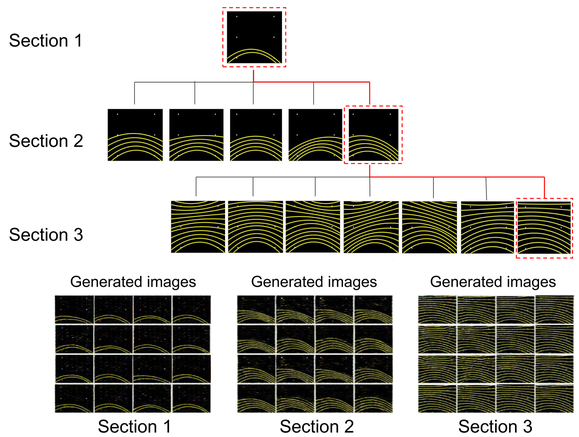
Numerical analysis



- Identified result closely matched the actual resin flow behavior.
- Resin flow predicted by numerical analysis was inconsistent with experimental result.

Flow-front Prediction





- 17 possible flow-front scenarios defined across 3 sections.
- While training set was plotted based on linear equations, a GAN produce various configurations.
- Realistic flow-front images were generated using GAN, including racetracking effects.

- Possible resin flow-front scenarios were presented on tree model based on sections.

- The flow-front scenario was determined based on resin arrival time at Section 1.
- Possible resin flow scenarios on Section 2 were identified based on probability.
- Sequential prediction was performed using resin arrival time at electrodes.
- Once the scenario was determined, a GAN generated multiple flow-front configurations to represent the current and its future resin flow behavior.
- Identified flow-front configurations allowed early prediction of potential dry spots.

Conclusions

1. A CFRP panel was monitored during the VARTM process using electromechanical behavior during resin infusion.
2. A novel flow-front identification and prediction method was developed by combining a tree-based decision model with a GAN, enabling accurate sequential identification of resin flow.
3. The model can predict dry spot locations, providing a robust system for real-time defect prevention and improved composite quality.

Keywords: Bimodal sensing, Coaxial fiber sensor, Multi-layer structure, Composite cure strain monitoring, Composite residual strain monitoring.

ABSTRACT

Coaxial structured fibers have gained significant attention in sensor applications due to their design flexibility and ability to enable multi-functionality. However, when utilized for strain monitoring in composite manufacturing processes, the sensor's complex and thicker structure can lead to stress concentration and signal interference. To address this issue, we propose a multifunctional coaxial fiber sensor capable of simultaneous temperature and strain measurement during composite manufacturing process. To achieve multi-functional sensing, we employ a multi-shell structure consisting of a multi-conductive layer and PEDOT:PSS layer, applied to a creep-enhanced ultra-high molecular weight polyethylene core fiber using a simple dip-coating method.

1 INTRODUCTION

Fiber-reinforced composite materials are fabricated by physically mixing reinforcing fibers and polymer matrix, resulting in enhanced mechanical properties. However, a significant challenge arises from the mismatch of the coefficient of thermal expansion (CTE) between the fiber and the matrix[1]. At the macroscopic level, this CTE mismatch leads to warpage and distortion of the structure after the curing reaction. At a microscopic level, during the cooling stage of the composite manufacturing process, there is a possibility of interfacial debonding between the fiber and matrix, which can degrade the material properties of the composite[2]. Therefore, it is crucial to employ real-time strain and temperature monitoring during the manufacturing process of composite structures to reduce residual stress by optimizing the curing cycle.

Conductive particle-reinforced nanocomposite sensors offer a potential solution due to their design flexibility[3]. Over the years, numerous studies have focused on developing multi-functional or multimodal sensors capable of detecting multiple physical signals in a single device[4]. For instance, Saeidi-Javash et al. developed printable multi-functional sensors that utilize MXene and graphene nanosheets to measure both strain and temperature[5]. Zhao et al. fabricated a flexible multi-functional sensor using thermosensitive platinum ribbons and a flexible polyimide substrate to measure pressure and temperature stimuli[6]. Xu et al. demonstrated bio-inspired electronic skins that employ gold/thermoplastic polyurethane/cellulose membrane to measure multiple signals, including temperature, electroencephalogram, and electrocardiogram[7]. Xue et al. developed a flexible dual-parameter sensor array using PDMS-MXene/CNT piezoresistors and PDMS-MXene thermistors to detect pressure and temperature, respectively[8]. However, most of these studies have primarily focused on developing flexible sensors for healthcare or wearable applications. Moreover,

conventional multimodal sensors face two limitations when applied to composite monitoring applications: a usable temperature range that is too low compared to the curing temperature of composite materials (~125 °C) and a thickness and size that are too large to embed into composite structures. This is because most research implements the multimodal function through the stacking or arraying of sensing elements.

In this work, we present a multi-functional coaxial fiber sensor capable of simultaneously measuring the strain through resistance changes in the multi-conductive layer and temperature through thermoelectric voltage changes at the junction between multi-conductive layer and poly-ethylenedioxythiophene:poly-styrenesulphonate (PEDOT:PSS) layer during the composite cure process. The ultrahigh molecular weight polyethylene (UHMWPE) core fiber and multi-conductive layer was fabricated using a dry-jet wet spinning with a microwave-assisted cross-linking method, as well as a dip-coating process based on our previous works. To create the junction point between multi-conductive layer and PEDOT:PSS layer, laser etching was employed to effectively remove a partial area of the outer polyurethane (PU) layer and expose the multi-conductive layer. The surface morphologies and damage on the multi-conductive layer after the etching process were investigated using an optical microscope and Raman spectroscopy, respectively. Furthermore, strain sensitivity (i.e. gauge factor) measurement and cyclic tests were performed under various strain ranges using electronic test equipment to examine the effect of junction fabrication and PEDOT:PSS coating. The thermoelectric voltage change was investigated under various temperature and strain ranges.

2 EXPERIMENTAL

2.1 Fabrication of core fiber

The UHMWPE fibers was fabricated by using a dry-jet wet spinning method with 4 wt.% spinning solution at a lab-scale spinning instrument (Wet spinning system, DISSOL, Republic of Korea) as shown in Figure 1. The spinning solution was fed to the 0.65 mm diameter of spinneret under 170 °C. The UHMWPE fibers were formed by solidification of the polymer solution extruded from the spinneret in a coagulation bath containing distilled water at 25 °C. The residual solvent after solidification process was removed by rinsing process using hexane (Sigma-Aldrich Inc., USA) for 24 h at 25 °C. The hot-stretching process was introduced to enhance the initial crystallinity of the as-spun UHMWPE fibers. The stretching ratio and treatment temperature was adjusted by 14 and 120 °C, respectively.

Figure 1: Dry-jet wet spinning of UHMWPE core fibers.

2.1 Dip coating processes

Figure 2 shows the schematic configuration of the multi-functional coaxial fiber sensor consisting of the following sequence from the core: UHMWPE core fiber for load bearing, 1st PU layer, MWCNT

conductive layer for strain sensing, 2nd PU layer. A role of the double PU layers is to reduce the noise level and enhance the linearity of the fiber sensor by preventing failure of electrical networks. This sensing layer was fabricated by the dip coating processes. At first, the UHMWPE core fiber was submerged into the aqueous PU solution (CRP 26301, T&L Co., Ltd., Republic of Korea) and withdrawn from the bath after 20 sec. Subsequently, the PU coated fiber was dried at 80 °C for 3 min and this process was repeated in 3-times. Thereafter, the electrically conductive layer was formed on the PU coated UHMWPE fiber by using the same method with the aqueous MWCNT solution (K-Nanos 100P, Kumho petrochemical Co., Ltd., Republic of Korea). In the case of the sandwich-structured multi-conductive layer to improve sensitivity and linearity from the combination of varying concentration of MWCNT, the same coating procedures were adopted from the bottom layer of 3 wt.% MWCNT, the middle layer of 2 wt.% MWCNT, and the top layer of 3 wt.% MWCNT, respectively. The thickness of each conductive layers was controlled by varying the number of the dip coating process to minimize the variation of resistance due to the thickness change. Subsequently, the conductive layer coated UHMWPE fiber was dried in a 60 °C oven for 1 hour to remove excessive water in the MWCNT conductive layer. Lastly, 2nd PU layer was coated with the same procedure of the 1st PU layer.

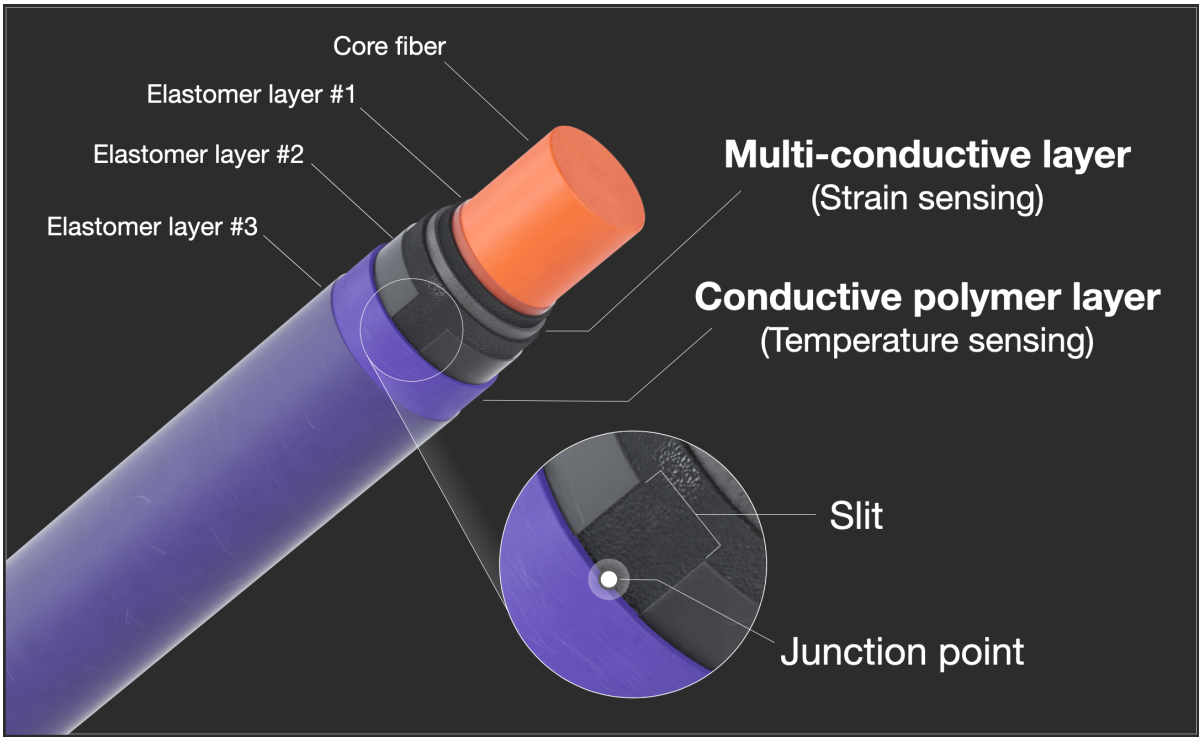

Figure 2: Schematics of multi-functional coaxial fiber sensor

2.2 Sensing performance of multi-functional coaxial fiber sensors

Figure S7a shows the schematic diagram for measuring the relative resistance change ($\Delta R/R_0$) and relative thermoelectric voltage change ($\Delta V/V_0$). These signals were simultaneously measured using LCR meter (E4980A, Keysight Technologies, USA) and high-precision multimeter (DMM6500, Keithley Instruments LLC., USA), and the signal measurement equipment was controlled by LabView (LabView 2022, National Instruments Corp., USA). To avoid signal interference, resistance was measured by an AC-based signal with a 1,200 Hz frequency, and the thermoelectric voltage was measured by a DC-based signal. The relative resistance change under static and cyclic loading conditions was measured using an LCR meter and universal testing machine (INSTRON 5969, Illinois Tool Works Inc., USA). The repeatability of the bimodal coaxial fiber sensor was estimated by measuring the changes in the resistance during the cyclic tensile test with 2.0 mm/min^{-1} crosshead speed under 10, 20, 30, and 40% of the failure strain of the bimodal coaxial fiber sensors.

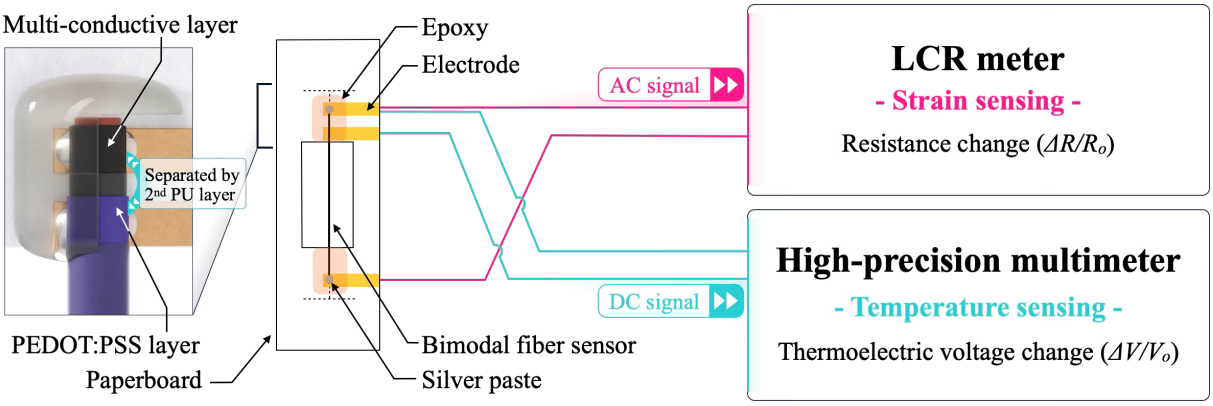

Figure 3: Measurement for sensing performance of coaxial fiber sensor

3 RESULTS AND DISCUSSION

3.1 Surface morphologies of multi-functional coaxial fiber sensor

Figure 4 presents the surface morphologies and cross-section images of PEDOT:PSS layer-coated fiber sensors. FE-SEM and EDS mapping images confirmed that the PEDOT:PSS layer was effectively coated on fiber sensor. The cross-section images of the multi-functional coaxial fiber sensor in Figure 4b confirmed the multilayer structure from the core fiber to the 3rd PU layer with respect to the coating sequence.

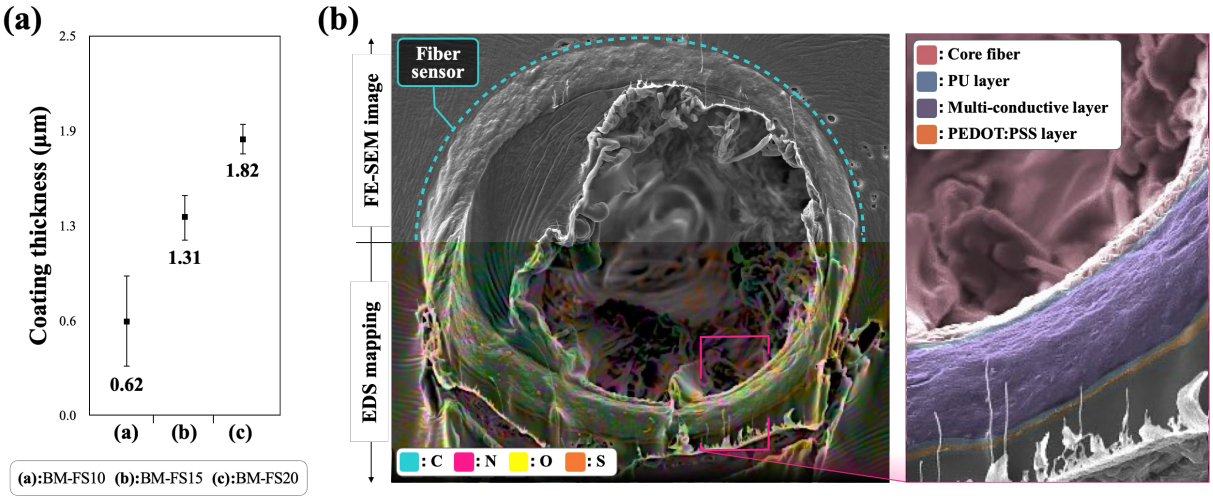

Figure 4: Coating thickness and cross-section images of multi-functional coaxial fiber sensor

3.2 Sensing performances

The repeatability with various strain ranges from 10% to 40% of the failure strain of the bimodal coaxial fiber sensor, shown in Figure 5, confirmed that the resistance change from the multi-conductive layer can be stably measured over various strain ranges without degradation by the PEDOT:PSS layer.

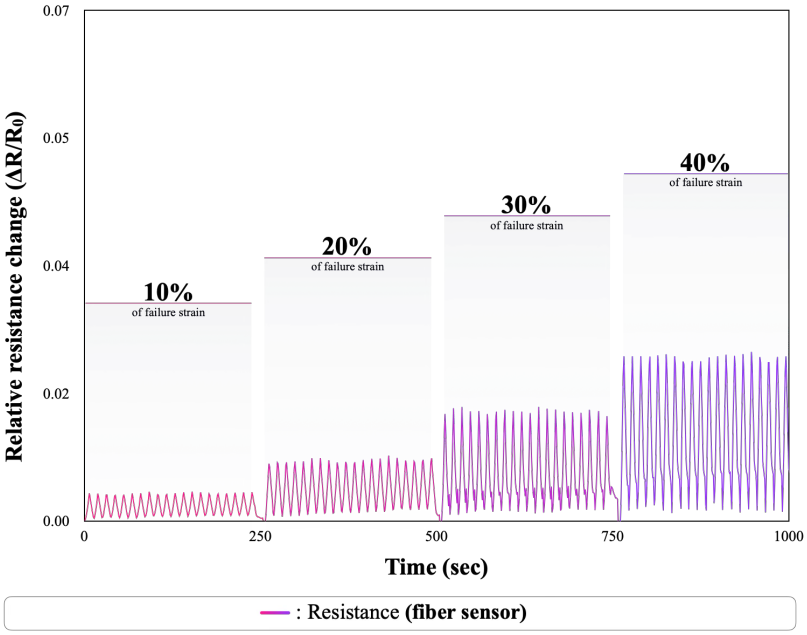

Figure 5: Repeatability of sensor fibers under various strain ranges

Figure 6 shows the monitoring results of the thermoelectric voltage and relative resistance change during a stepwise temperature cycle ranging from 35 to 125 ºC, with 30 ºC increments, to investigate the simultaneous measurement of these parameters without signal interference. The results indicated that both the thermoelectric voltage and resistance could be measured simultaneously without any signal interference. Therefore, it can be concluded that the bimodal coaxial fiber sensor can be applied to composite manufacturing processes without the need for an additional compensation process to correct thermoelectric voltage measurement errors resulting from external strain.

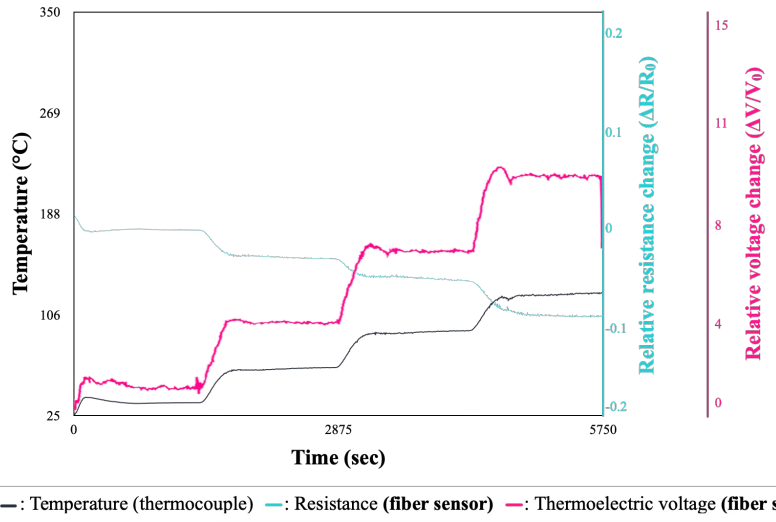

Figure 6: Measurement of sensing performance of multi-functional coaxial fiber sensor.

4 CONCLUSIONS

In this study, a multi-layer structured coaxial fiber sensor was introduced to simultaneously measure the temperature and strain. The effects of bimodal coaxial fiber sensors were investigated by measurement of surface morphologies, sensing response change which is including static and cyclic deformation, and monitoring of temperature and strain signal.

Keywords: Gold nanorods, Nano mica platelets, Zinc oxide quantum dots, Surface-enhanced Raman scattering, *Helicobacter pylori*

ABSTRACT

A highly sensitive and reproducible surface-enhanced Raman scattering (SERS) platform was developed for the noninvasive detection of *Helicobacter pylori* by integrating gold nanorods (AuNRs), nano mica platelets (NMPs), and ZnO quantum dots (QDs) into a ternary hybrid system. AuNRs were uniformly anchored onto the delaminated NMP surface via electrostatic interactions enabled by a cationic interfacial activator. The high surface charge and large specific area of NMPs not only stabilized AuNR growth but also promoted the formation of three-dimensional electromagnetic "hotspots" through particle self-assembly. These AuNRs/NMPs nanohybrids exhibited a significant Raman enhancement effect, achieving a limit of detection (LoD) of 10^{-9} M for adenine with an enhancement factor (EF) of 2.0×10^8. To further amplify the SERS performance, ZnO QDs were incorporated to introduce additional chemical enhancement via charge transfer. The resulting AuNRs/NMPs/ZnO QDs exhibited a lower LoD of 10^{-10} M, a higher EF of 1.6×10^9. Remarkably, the same substrate demonstrated excellent sensitivity for *H. pylori* detection, with an LoD of 90 CFU mL^{-1} and a relative standard deviation of 9.70%. This performance is attributed to the synergistic interplay among localized surface plasmon resonance, semiconductor-mediated charge transfer, and nanoscale self-assembly. The positively charged substrate surface also facilitated efficient physical adsorption of the negatively charged bacterial membrane. Overall, this hybrid SERS platform offers a promising strategy for rapid, label-free, and ultrasensitive detection of *H. pylori*, even in complex biological matrices, and holds great potential for clinical diagnostics and point-of-care applications.

1 INTRODUCTION

Helicobacter pylori (*H. pylori*) is a gram-negative, microaerophilic, spiral-shaped bacterium that colonizes the human gastric mucosa and is recognized as a major etiological factor in a range of gastrointestinal disorders, including chronic gastritis, duodenal ulcers, gastric adenocarcinoma, and mucosa-associated lymphoid tissue lymphoma [1]. Since its discovery by Warren and Marshall in 1982 [2], *H. pylori* has remained a global health concern, with an estimated infection rate exceeding 50% worldwide and a considerable risk up to 2% of progression to gastric cancer in untreated individuals [3]. Epidemiological data reveal stark regional disparities in prevalence, ranging from less than 20% in some developed countries to over 80% in regions with poor sanitation and healthcare access [4]. These statistics underscore the urgent need for effective, scalable, and accurate diagnostic methods to manage this prevalent pathogen. Diagnostic approaches for *H. pylori* are typically classified into invasive and noninvasive methods, depending on whether gastric tissue biopsy is involved. Invasive techniques such as histopathology, rapid urease testing, and bacterial culturing offer high specificity but require endoscopy, which is costly, uncomfortable for patients, and dependent on

clinical infrastructure and trained personnel [5]. Noninvasive methods including stool antigen assays, serological antibody tests, and urea breath tests (UBTs) are more accessible, but often suffer from trade-offs in sensitivity, specificity, or safety. In particular, the use of radioactive ^{14}C in UBTs poses potential health risks and limits widespread deployment, while serological assays fail to distinguish active infection from past exposure [6]. Collectively, these limitations highlight the need for a next-generation diagnostic platform that is rapid, label-free, noninvasive, and capable of achieving high sensitivity and specificity across diverse clinical settings.

Surface-enhanced Raman scattering (SERS) has emerged as a powerful molecular fingerprinting technique for ultrasensitive and multiplexed detection, leveraging the intense localized electromagnetic fields ("hotspots") generated by the localized surface plasmon resonance (LSPR) of metallic nanostructures [7]. Among noble metals, gold nanorods (AuNRs) have gained prominence due to their anisotropic morphology, tunable LSPR into the near-infrared region, and excellent biocompatibility [8]. However, colloidal AuNR systems often suffer from nanoparticle aggregation, poor interparticle distance control, and batch-to-batch variability, which compromise signal reproducibility and restrict real-world biosensing applications. To address these challenges, we introduced a hybrid strategy using delaminated nano mica platelets (NMPs) a two-dimensional (2D) silicate material with high surface area, mechanical rigidity, and strong anionic surface charge to support the self-assembly and stabilization of AuNRs into 3D architectures [9]. This approach enables uniform distribution and alignment of AuNRs, enhancing electromagnetic hotspot density and signal reproducibility. Furthermore, NMPs facilitate strong physisorption of bacterial components via electrostatic and polar interactions, providing an ideal substrate for biosensing. Nevertheless, the signal enhancement in such plasmonic systems remains largely dependent on electromagnetic enhancement mechanism (EM), and further sensitivity gains require incorporation of additional synergistic enhancement modalities.

Despite recent progress, the integration of semiconductor materials into SERS substrates to simultaneously enhance sensitivity and biocompatibility remains underexplored. Composite SERS platforms incorporating semiconductors with high chemical stability, excellent biocompatibility, and large specific surface areas have attracted increasing attention. Such hybrids aim to overcome the inherent limitations of noble-metal-only substrates, particularly through the inclusion of wide-bandgap semiconductors (e.g., ZnO, TiO_2) [10]. Nevertheless, the rational design of these systems is still in its early stages, underscoring the need for a deeper understanding of the underlying enhancement mechanisms. These mechanisms are broadly categorized into EM, governed by LSPR, and chemical enhancement mechanism (CM), primarily driven by charge transfer (CT) processes [11, 12].

Herein, we report the design and application of a novel ternary nanohybrid SERS platform composed of AuNRs, NMPs, and ZnO quantum dots (QDs), specifically tailored for the ultrasensitive and reproducible detection of *H. pylori*. In this system, AuNRs are electrostatically anchored onto the negatively charged NMP surface and further functionalized with ZnO QDs through hydrogen bonding interactions. The resulting AuNRs/NMPs/ZnO QDs exhibit synergistic dual-mode enhancement via LSPR-induced EM and CT-mediated CM, along with 3D hotspot generation from nanoscale self-assembly. This platform achieves an exceptionally low limit of detection (LoD = 90 CFU mL^{-1}) for *H. pylori*, and demonstrates high reproducibility, signal uniformity. To our knowledge, this is the first report applying a Au-based SERS nanoplatform for *H. pylori* detection. By bridging materials engineering with plasmonic–semiconductor synergy, this study provides a robust and scalable strategy for real-time, noninvasive bacterial diagnostics and sets the foundation for future point-of-care applications.

2 EXPERIMENTAL SECTION

2.1 Materials

$HAuCl_4$ (99.9%) and $NaBH_4$ (98% purity) were purchased from Echo Chemical Co. (Taiwan). Cetyltrimethylammonium bromide (CTAB) was purchased from Echo Chemical Co. (Taiwan). $AgNO_3$ (99.9%) was purchased from Alfa Aesar Co. (USA). Ascorbic acid (99%) was purchased from Acros Organics Co. (USA). H_2SO_4 (95–98%) was purchased from Echo Chemical Co. (Taiwan). Synthetic fluorinated mica (SOMASIF ME-100), composed of Si (26.5 wt%), Mg (15.6 wt%), F (8.8 wt%), Na (4.1 wt%), Al (0.2 wt%), and Fe (0.1 wt%), was purchased from CO-OP Chemical Co.

(Japan). Jeffamine-T403 was purchased from Huntsman Chemical Co. (USA). Bisphenol A epoxy resin BE-188 was purchased from Echo Chemical Co. (Taiwan). HCl (37%) was purchased from Echo Chemical Co. (Taiwan). NaOH was purchased from Macron Fine Chemicals (Avantor Performance Materials, Center Valley, PA, USA). Ethanol (95%) was purchased from Echo Chemical Co. (Taiwan). $Zn(CH_3COO)_2 \cdot 2H_2O$ (99%) was purchased from Showa Chemical Industry Co. (Japan). KOH (>85%) was purchased from Shimakyu Pure Chemicals Co. (Japan). Methanol (99%) was purchased from Echo Chemical Co. (Taiwan). Tetraethoxysilane (98%) was purchased from Acros Organics Co. (USA). Adenine (99.9%) was purchased from Sigma-Aldrich Chemical Co. (USA). *Helicobacter pylori* (ATCC 43504) was purchased from Academia Sinica. Blood agar plates (TSA with 5% sheep blood) were purchased from Creative Life Science Co. (Taiwan). Ultrapure water (resistivity = 18.2 MΩ cm at 25 °C) was obtained using a Milli-Q water purification system. All reagents were utilized in their original state without any additional purification or treatment. All glassware was subjected to a thorough cleaning, which involved washing with aqua regia, rinsing with water, and drying.

2.2 Preparation of AuNRs/NMPs

NMPs were prepared in accordance with a previously reported procedure [13]. Polyetheramine (Jeffamine-T403) and epoxy resin (BE-188) were dissolved in ethanol at a 2:1 molar ratio. The solution was stirred for 6 h at 60 °C until a light yellow color was observed, which indicated reaction completion and delaminating agent (T403 AEO) formation. Subsequently, mica (1.0 g, 1 wt%) was expanded at 80 °C for 1 h. A mixture of T403 AEO (4.8 g) and HCl (0.75 g) was ultrasonicated for 30 min (to facilitate the protonation of the amine group and form a quaternary ammonium salt) and added to the expanded mica slurry, and the resulting dispersion was stirred for 5 h to induce mica delamination. The mixture was purified through extraction with dilute ethanolic NaOH, and the solid was redispersed in deionized water to form a 1 wt% NMPs dispersion. Mixtures of NMPs and $HAuCl_4$ (0.024 M, 0.2 mL) with different weight ratios were supplemented with the gold seed solution (0.1 mL) and CTAB (0.1 M, 10.9 mL) and stirred for 1 h. Subsequently, $AgNO_3$ (0.01 M, 0.08 mL) and H_2SO_4 (0.5 M, 0.2 mL) were added, and the mixture was dropwise supplemented with ascorbic acid (0.1 M, 0.08 mL). Then, the gold seed solution (0.024 mL) was added, and the dispersion was thoroughly mixed for ~1 min and allowed to stand for ~2 h. The resulting nanohybrid (AuNRs/NMPs) solution was centrifuged at 6,000 rpm for 30 min, and the pellet was washed at least twice with deionized water to remove residual CTAB. The purified solution of AuNRs/NMPs was analyzed using UV–vis spectroscopy, zeta potential measurements, transmission electron microscopy (TEM), and SERS.

2.3 Preparation of AuNRs/NMPs/ZnO QDs

ZnO QDs were prepared using a sol-gel synthesis method [14]. A methanolic solution of KOH (1 M, 25 mL) solution was slowly added to that of $Zn(CH_3COO)_2 \cdot 2H_2O$ (0.1 M, 12.5 mL) at room temperature (25 °C), and the mixture was stirred for 1 h at 1,000 rpm. The presence of ZnO particles was confirmed by the observation of bright yellow fluorescence under UV light. Subsequently, tetraethoxysilane (0.125 mL) was added to regulate particle growth, and deionized water (0.25 mL) was introduced into the resulting gel solution to facilitate a sol-gel reaction on the particle surface. After purification by at least two-fold centrifugation with methanol and deionized water to remove residual reactive molecules, the gel was redissolved in deionized water to form a solution of ZnO QDs. Given the abundance of hydroxyl groups on the silicate nanoclay surface, AuNRs/NMPs with varying weight ratios were physically mixed with ZnO QDs for 15 min to facilitate the stabilization of the two materials through hydrogen bonding and form AuNRs/NMPs/ZnO QDs, which were characterized by TEM, and SERS.

2.4 Culturing of Bacteria and Preparation of SERS Substrate

Prior to bacterial culturing, all glassware was sterilized via autoclaving at an elevated pressure and

temperature (~120 °C, 50 min). The broth was prepared in a 250 mL serum bottle, and *H. pylori* (ATCC 43504) was transferred into the broth (2 mL) using an inoculation ring. Subsequently, the sample was smeared in blood culture medium and cultured in an anaerobic culture tank with microaerobic gas packs at 37 °C for 7 days. The colonies were collected and transferred to a microcentrifuge tube containing 2 mL of the broth using an inoculating loop. The collected bacterial suspension was divided into two 1 mL portions, one of which was used to spread the blood culture medium for the subsequent round of culturing to ensure the continuity and stability of the culture, while the other was subjected to UV–vis analysis and OD600-adjusted to 0.6. Thereafter, the growing colonies were quantified. The bacterial solution was centrifuged at 6,000 rpm for 3 min. The upper layer was removed and washed three times with phosphate-buffered saline (PBS) and then prepared for SERS. Subsequently, solutions of AuNRs/NMPs, and AuNRs/NMPs/ZnO QDs (0.01 mL) were drop-coated onto clean aluminum sheets with dimensions of 10 mm × 10 mm and oven-heated at 80 °C. Analyte solutions were prepared at concentrations of 10^{-4}–10^{-11} M for adenine (volume = 0.01 mL). The *H. pylori* solution (0.01 mL) was combined with the SERS substrate in a nutrient-free environment and subsequently dried for Raman detection.

2.5 Characterization

UV–vis spectra were recorded using a Shimadzu UV-2450 instrument (Kyoto, Japan). For TEM imaging (JEOL JEM-2100), a 0.01 mL droplet of the SERS substrate suspension was placed on a copper mesh and allowed to dry at 80 °C for 24 h. Confocal micro-Raman spectroscopy (Horiba-LABRAM HR800, 785 nm laser) was used to for SERS analysis in the 400–4000 cm^{-1} range (exposure = 10 s, power = 20 mW). Zeta potential analysis was conducted using a Zetasizer Nano ZS90 instrument. Samples for scanning electron microscopy (SEM, JSM-6500F) were prepared by drop-coating clean glass surfaces with the desired dispersions followed by oven-drying at 80 °C for 2 h, affixing to a conductive carbon adhesive, and coating with a thin layer of Pt.

3 RESULTS AND DISCUSSION

3.1 Synthesis and Analysis of AuNRs/NMPs

Delaminated layered silicates, such as synthetic fluorinated mica, offer a 2D platform with high surface charge density, mechanical rigidity, and exceptional self-alignment properties ideal for nanoparticle immobilization via cation exchange [15]. In this work, NMPs with lateral dimensions of 300–1000 nm and a thickness of ~1 nm were utilized as a robust scaffold to facilitate the in situ growth and stabilization of AuNRs. As shown in Figure 1a, the negatively charged NMP surface enabled electrostatic adsorption of gold precursors and promoted seed-mediated reduction of AuNRs directly onto the nanosheet surfaces. The reduction process, monitored via UV–vis spectroscopy (Figure 1b), completed within approximately 125 minutes, substantially faster than conventional nanohybrid fabrication approaches. Zeta potential measurements (Figure 1c) confirmed distinct surface potential shifts upon nanoparticle loading, supporting successful AuNR anchoring. To optimize the component ratio, AuNRs/NMPs composites were synthesized at varying weight ratios. At suboptimal NMP concentrations, AuNRs showed pronounced aggregation and irregular morphology, while excessive NMPs led to heterogeneity in particle size and shape due to ionic charge imbalances (Figure 1d, 1e). The optimal dispersion and alignment were achieved at a 1:1 weight ratio (Figure 1e (3)), which yielded the highest SERS signal-to-background (S/B) ratio and signal intensity (Figure 1f). The ultrathin nature of NMPs permits dual-surface adsorption of AuNRs, enabling anisotropic self-assembly and interparticle coupling in the vertical (z-axis) dimension. This hierarchical configuration results in the formation of dense 3D electromagnetic hotspots, significantly amplifying localized field intensity. The optimized substrate demonstrated a LoD for adenine of 10^{-9} M and a surface enhancement factor (EF) of 2.0×10^8 (Figure 1g, 1h). These values were derived using the standard EF equation [16, 17]:

$$EF = (I_{SERS}/C_{SERS})/(I_{norm}/C_{norm}) \quad (1)$$

where C_{norm} and C_{SERS} represent the analyte concentrations under normal and SERS conditions,

respectively, and I_{norm} and I_{SERS} denote the corresponding Raman signal intensities. Collectively, these results demonstrate that AuNRs synthesized and assembled on NMPs under optimized conditions yield uniform, highly active SERS substrates with enhanced signal reproducibility and sensitivity, attributed to well-regulated nanoparticle arrangement and the strong localized field effects at the nanorod tips.

(h) Linear correlation between log(integrated intensity in the range of 704–764 cm^{-1}) and log(adenine concentration).

3.2 Synthesis and Analysis of AuNRs/NMPs/ZnO QDs

To further enhance the SERS performance of AuNRs/NMPs, ZnO QDs were incorporated to introduce CT–driven CM alongside EM from plasmonic nanostructures. ZnO, a biocompatible wide-bandgap semiconductor [18], facilitates CM by promoting interfacial electron transfer when the energy levels of the analyte align with the conduction band (CB) and valence band (VB) of the ZnO substrate. This alignment leads to modulation of molecular polarizability and intensification of the Raman signal. ZnO QDs were anchored onto the surface of NMPs through hydrogen bonding with surface silanol (Si–OH) groups (Figure 2a). UV–vis spectroscopy and Tauc plot analysis determined the ZnO QD bandgap to be 3.44 eV (Figure 2b), while energy level mapping revealed favorable alignment between adenine's highest occupied molecular orbital (HOMO)/lowest unoccupied molecular orbital (LUMO) and ZnO's CB/VB, confirming the potential for CT-mediated enhancement (Figure 2c). The ternary nanohybrids (AuNRs/NMPs/ZnO QDs) exhibited significantly stronger SERS responses to adenine compared to AuNRs/NMPs alone (Figure 2d). Systematic optimization of component ratios revealed that a AuNR/NMP/ZnO QD weight ratio of 1/1/2 produced the most uniform QD dispersion and maximal SERS response (Figure 2e–f), with a LoD of 10^{-10} M and EF of 1.6×10^{9} (Figure 2g–h). The pronounced enhancement arises from the synergistic interplay between EM and CM mechanisms: AuNRs generate highly localized electromagnetic fields, while ZnO QDs enable CT pathways that increase analyte polarizability. Concurrently, the NMP substrate facilitates 3D hotspot formation via AuNR self-assembly, enhancing interparticle coupling and EM field localization. Overall, the integration of ZnO QDs into the AuNRs/NMPs framework significantly amplified SERS performance through complementary EM and CM mechanisms, establishing a robust platform for highly sensitive and reproducible biomolecular detection.

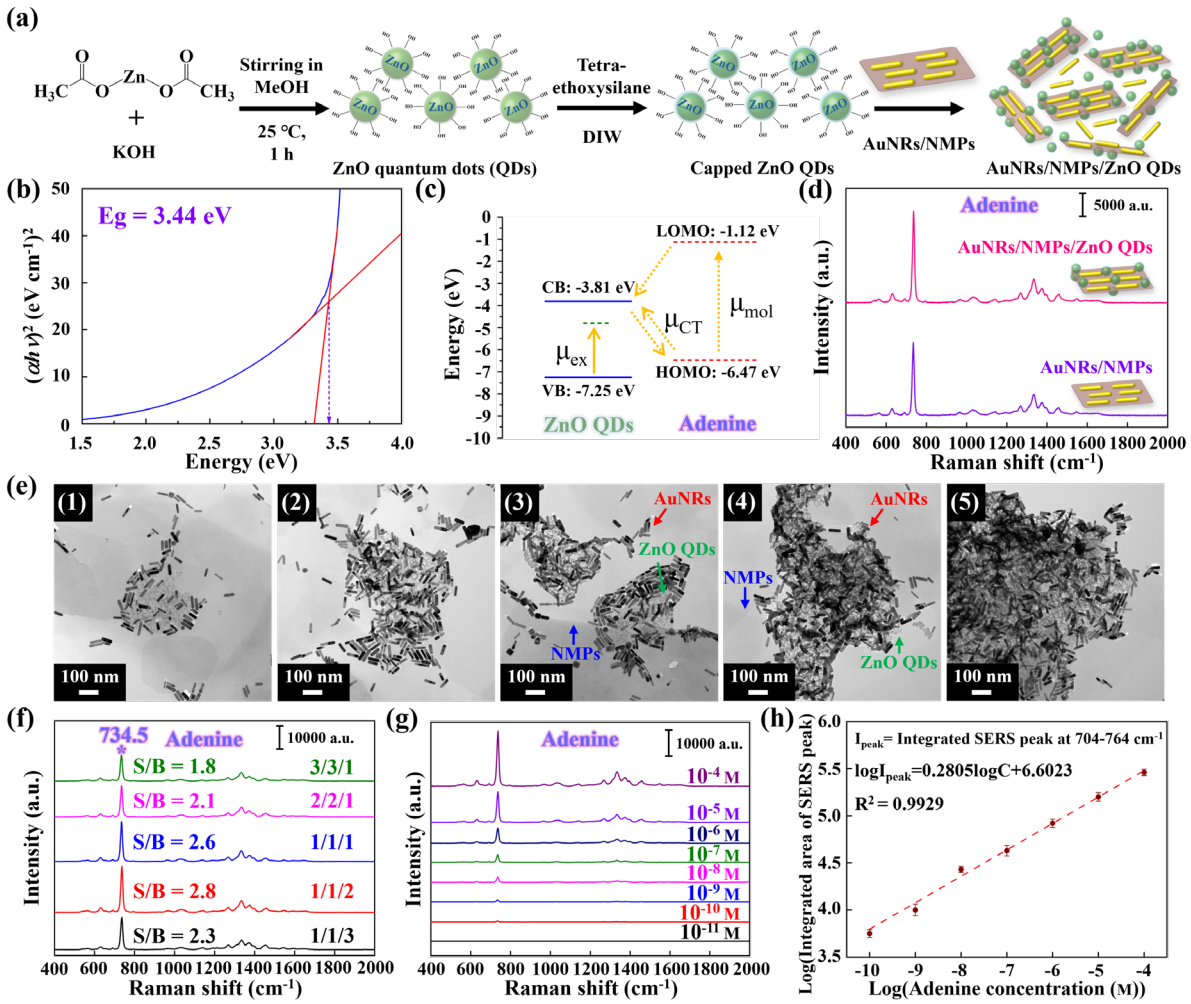

Figure 2. (a) Schematic synthesis of AuNRs/NMPs/ZnO quantum dots (QDs). (b) Tauc plot of ZnO QDs. (c) Energy level diagram illustrating charge transfer between ZnO QDs and adenine. (d) SERS responses of AuNRs/NMPs/ZnO QDs (1/1/2, w/w) and AuNRs/NMPs (1/1, w/w) to adenine (10^{-4} M). (h) Linear fit of the log(integrated intensity in the range of 704–764 cm^{-1})–log(adenine concentration) plot.

3.3 Interaction of AuNRs/NMPs/ZnO QDs with *H. pylori* and SERS Detection

The AuNRs/NMPs/ZnO QDs hybrid substrate enabled sensitive and reproducible detection of *H. pylori* through synergistic EM and CM. As illustrated in Figure 3a, the detection strategy involved physical adsorption of *H. pylori* onto the positively charged nanohybrids, followed by SERS analysis. A strong Raman response was obtained at a bacterial concentration of 1.8×10^7 CFU mL^{-1} (Figure 3b), with a LoD of 90 CFU mL^{-1} (Figure 3c) and an excellent linear correlation ($R^2 = 0.9818$; Figure 3d). Signal mapping across 50 random points (relative standard deviation = 9.70%; Figure 3e) and a 400 μm^2 area confirmed outstanding spatial uniformity and reproducibility (Figure 3f). The high sensitivity is attributed to the electrostatic interaction between the negatively charged lipopolysaccharides and phosphoglycerol groups on the *H. pylori* surface and the positively charged CTAB-modified AuNRs/NMPs/ZnO QDs. Figure 3g demonstrates the physical adsorption of *H. pylori* onto the SERS substrate. After a seven-day culture period, the bacteria were washed, centrifuged in PBS, dehydrated with ethanol, and incubated with the AuNRs/NMPs/ZnO QDs substrate for a defined duration. The subsequent formation of a visible precipitate confirmed successful bacterial capture. SEM analysis of the precipitate (Figure 3h) revealed pronounced substrate adhesion to *H. pylori*, observed as distinct white protrusions. Figure 3h (1) shows *H. pylori* cultured without the substrate, serving as a control. Upon increasing contact time, a greater amount of substrate was observed accumulating around the bacterial surface, supporting the hypothesis that *H. pylori* can be effectively captured via physisorption, thereby enabling enhanced SERS detection. Benchmarking against existing SERS platforms (Table 1) highlighted the enhanced performance of our approach in terms of LoD and EF. Unlike UBTs or immunoassay-based fecal detection, which suffer from enzymatic interference or antigen instability, this method provides a rapid, label-free, and noninvasive alternative with high accuracy [19, 20]. Furthermore, its scalable fabrication and compatibility with complex biological matrices underscore its strong potential for clinical diagnostics and point-of-care applications in gastrointestinal pathogen screening.

4 CONCLUSION

This work presents a rationally engineered ternary SERS platform integrating AuNRs, NMPs, and ZnO QDs for the ultrasensitive, selective, and reproducible detection of *H. pylori*. The nanohybrid design leverages the synergistic contributions of multiple enhancement mechanisms: (i) strong EM fields arising from the LSPR of AuNRs, (ii) CM via interfacial CT enabled by the wide-bandgap ZnO QDs, and (iii) a highly ordered 3D hotspot network promoted by the self-assembly of AuNRs on the anionic surfaces of delaminated NMPs. NMPs serve not only as a structural scaffold for uniform AuNR immobilization but also as a physicochemically active interface that enhances particle dispersion, promotes hotspot density, and facilitates the stable incorporation of ZnO QDs through hydrogen bonding. This integrated architecture enables efficient analyte adsorption and amplifies Raman signals through both plasmonic and semiconductor-mediated pathways. The resulting AuNRs/NMPs/ZnO QDs exhibit exceptional analytical performance, achieving a LoD of 10^{-10} M for adenine and 90 CFU mL^{-1} for *H. pylori*, with high signal reproducibility (RSD = 9.70%). Taken together, these findings demonstrate the potential of this multi-component SERS platform as a powerful tool for next-generation, noninvasive bacterial diagnostics. The integration of plasmonic, silicate, and semiconducting nanomaterials within a single, scalable framework opens new avenues for high-performance biosensing in clinical and point-of-care environments.

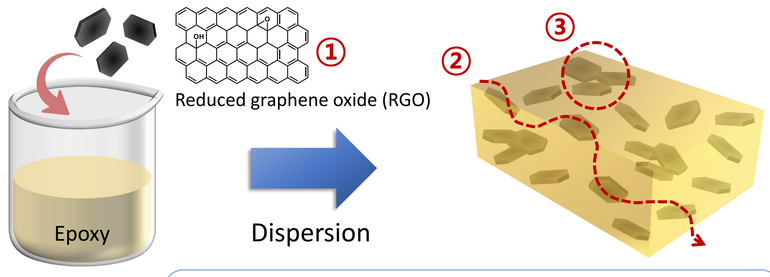
INTRODUCTION

▪ Limitations of Conventional Thermally Conductive Polymer Nanocomposites

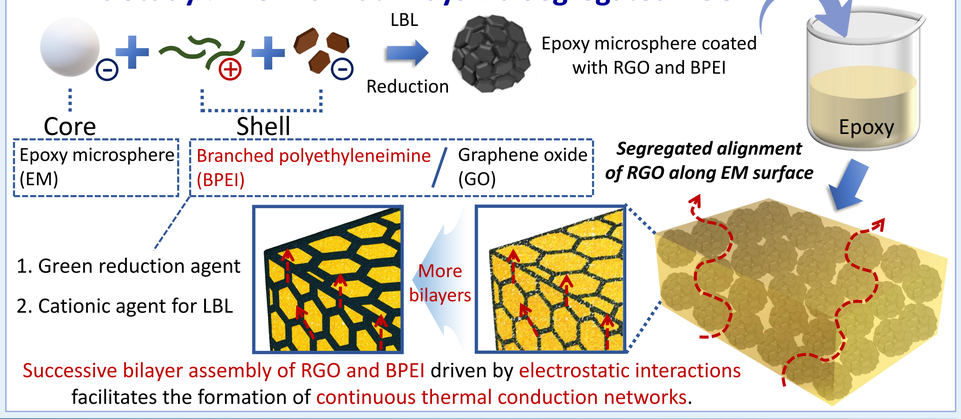


Disadvantages

Low thermal conductivity of only 0.2 W/mK

Simple approach for enhancing thermal conductivity

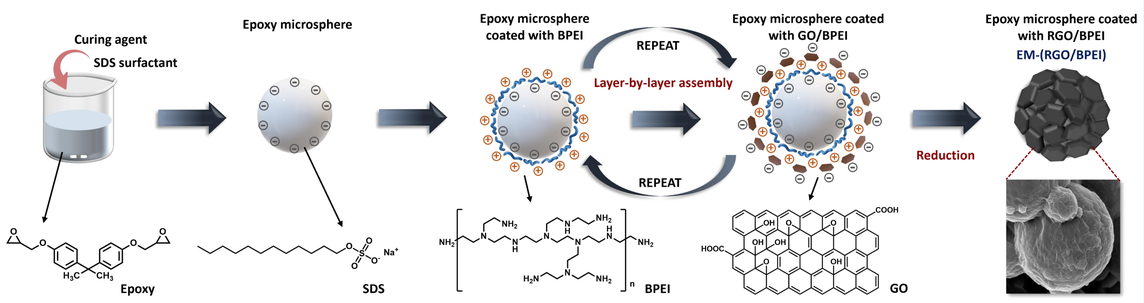
Integration of fillers into the polymer matrix



Limitations

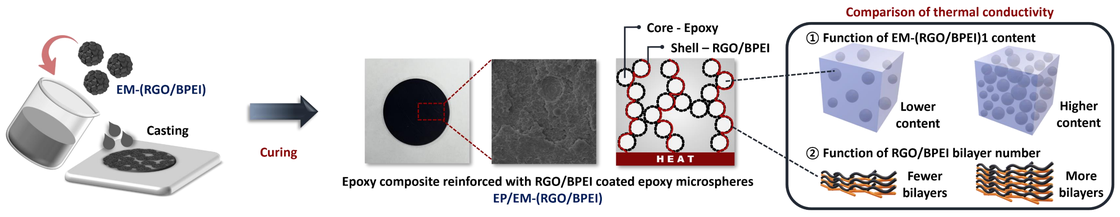
① Only a few W/mK along out-of-plane direction

② Alignment primarily along in-plane direction



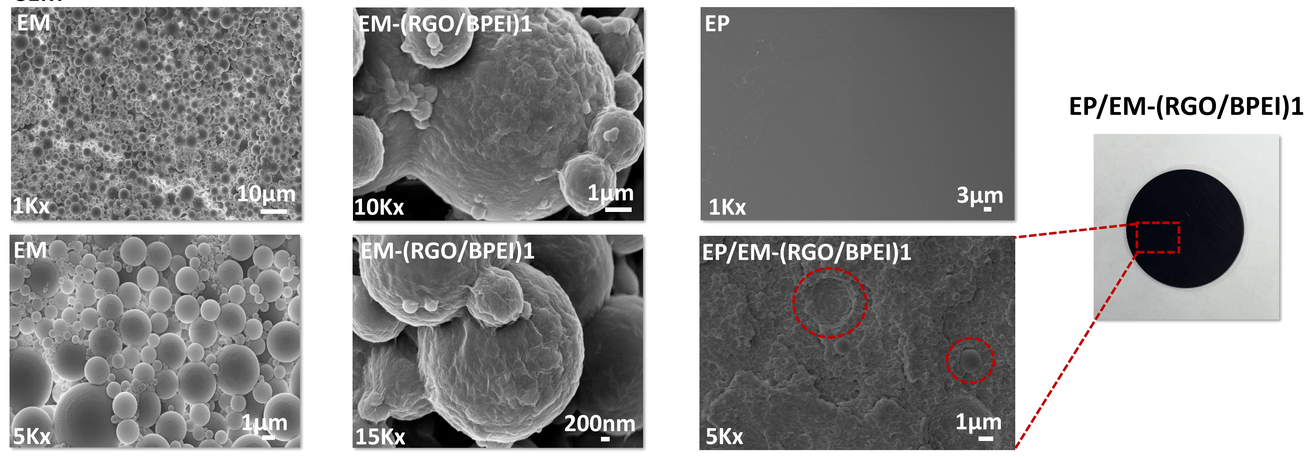
③ Tendency to aggregate by a large specific area

▪ This Study : Thermal Pathways via Segregated RGO



EXPERIMENT

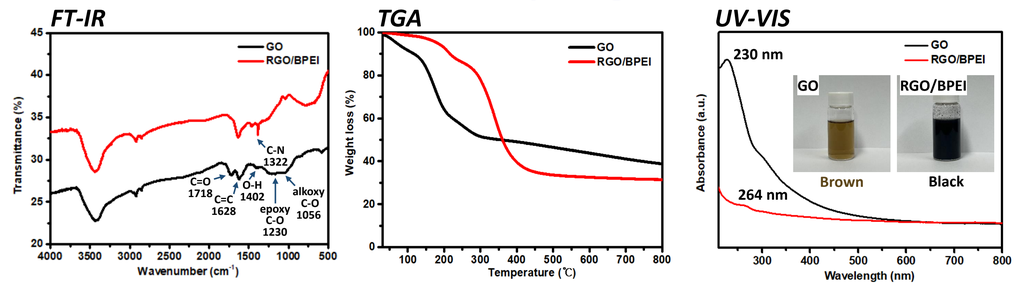
▪ Preparation of Epoxy Microspheres Coated with RGO and BPEI via LBL Method



▪ Fabrication of Epoxy Composite Reinforced with EM-(RGO/BPEI)

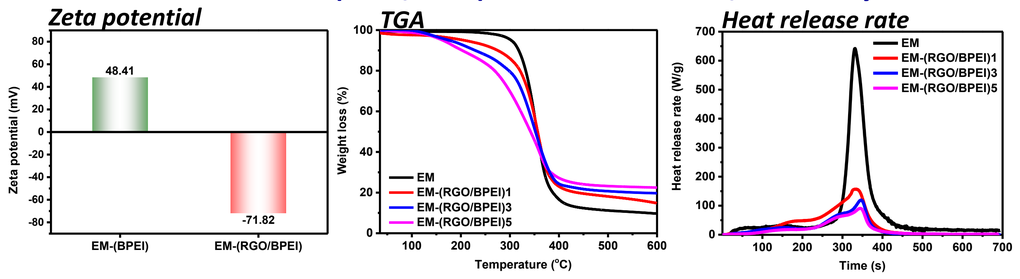
RESULTS AND DISCUSSION

▪ Morphological Studies of EM-(RGO/BPEI) and EP/EM-(RGO/BPEI)



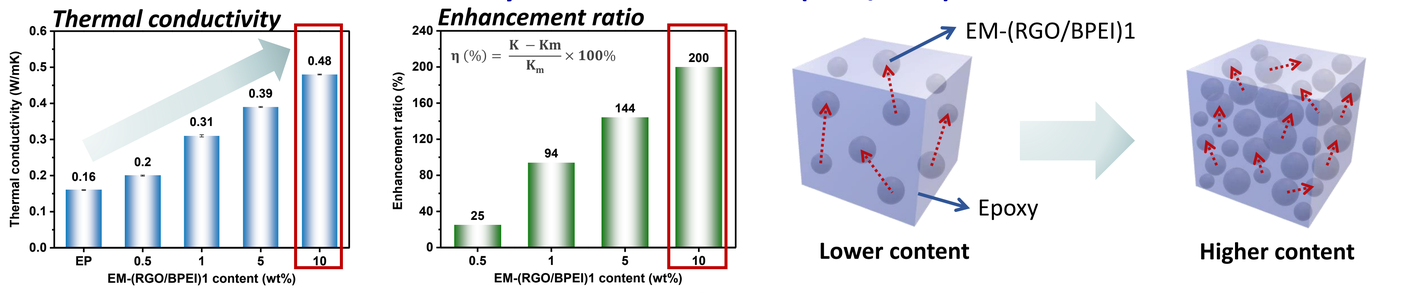
SEM

- Compared to EM with a smooth surface, EM-(RGO/BPEI)1 showed **increased surface roughness** due to the formation of **homogeneous RGO/BPEI coating**.
- This structure facilitated the development of **continuous thermal conduction pathways** by enabling **interparticle connections** between coated microspheres.



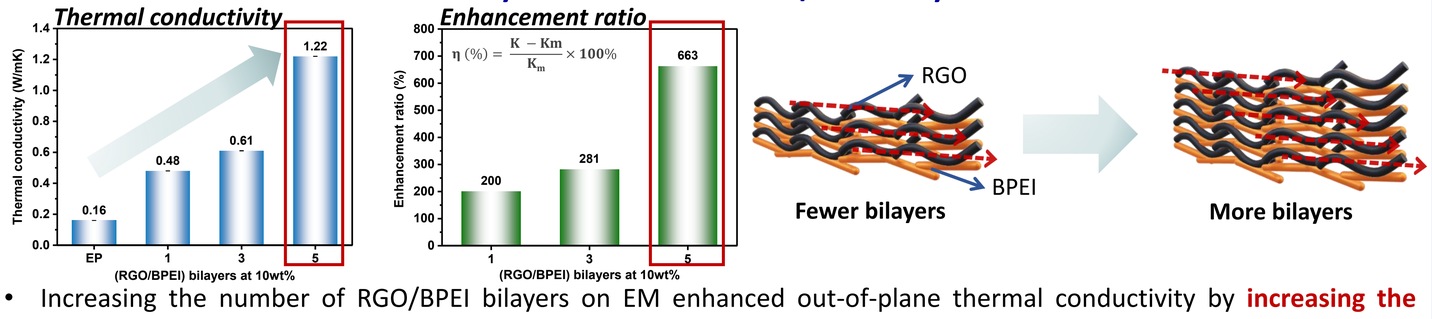
RESULTS AND DISCUSSION

▪ Characterization of GO Reduction by Using BPEI



- Oxygen-containing groups were effectively removed and the conjugated structure was restored, confirming the **successful chemical reduction of GO by BPEI**.

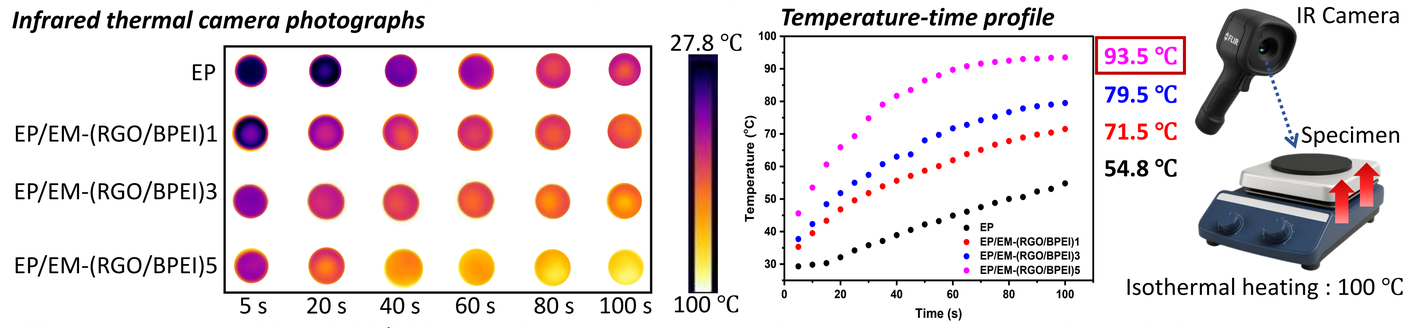
▪ Confirmation of EM-(RGO/BPEI) with Various RGO/BPEI Bilayers



- Uniform and controllable RGO/BPEI coating was successfully achieved on the EM as the **number of deposition cycles increased**.

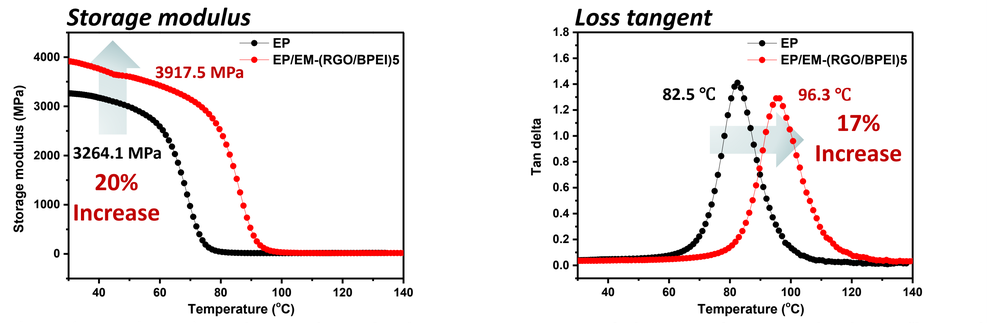
▪ Out-of-Plane Thermal Conductivity as a Function of EM-(RGO/BPEI)1 Content

- The thermal conductivity increased with higher EM-(RGO/BPEI)1 content up to 10 wt% as the greater number of coated EM promoted **more frequent contact points** and resulted in **more effective heat transfer**.



▪ Out-of-Plane Thermal Conductivity as a Function of RGO/BPEI Bilayer Number

- Increasing the number of RGO/BPEI bilayers on EM enhanced out-of-plane thermal conductivity by **increasing the network density** and **improving the connectivity of thermally conductive domains** through a reinforced bridging effect.



RESULTS AND DISCUSSION

▪ Visualization on Thermal Properties of EP/EM-(RGO/BPEI)

- The incorporation of EM-(RGO/BPEI) into the epoxy **accelerated heat propagation** through the thickness, as evidenced by **faster surface temperature rise** and **more rapid thermal response** under isothermal heating conditions.

▪ Dynamic Mechanical Analysis of EP/EM-(RGO/BPEI)

- EP/EM-(RGO/BPEI)5 showed a higher storage modulus and Tg, which reflected **restricted chain mobility** and **increased structural integrity** of the composite.

CONCLUSION

- This study demonstrated a scalable approach to enhance the out-of-plane thermal conductivity of epoxy composites by **constructing 3D conductive networks using epoxy microspheres uniformly coated with RGO/BPEI bilayers** through a LBL assembly process.
- The incorporation of **EM-(RGO/BPEI)5** resulted in a composite with an out-of-plane thermal conductivity of **1.22 W/mK**, corresponding to a **665% enhancement** compared to neat epoxy, offering a structurally controllable and novel design framework with **fundamental potential for high thermal conductivity applications**.

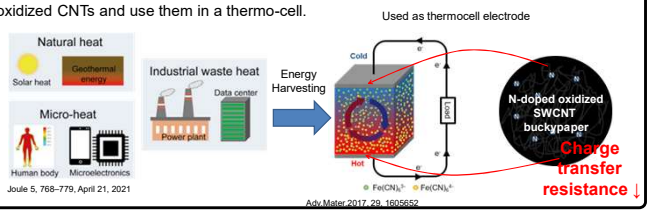
Abstract

- Low-temperature waste heat below 200℃ generated from nature, industry, and the human body exists everywhere, but is easily discarded due to a lack of technology to recover it. Thermogalvanic cells based on ion transport are inexpensive devices that directly convert heat into electricity and are flexible in material selection. Carbon nanomaterials are known to have excellent properties as thermogalvanic cell electrodes due to their large specific surface area and fast electron transport properties. This study explores the potential application of nitrogen-doped (N-doped) oxidized carbon nanotubes with melamine as thermogalvanic cell electrodes.

Introduction

➢ **Low-grade heat**



- Low-grade heat is abundant and ubiquitous but is generally discarded owing to a lack of cost-effective recovery technologies.
- To efficiently recover low-grade waste heat, thermoelectric technology offers an approach to convert heat directly into electrical energy without moving parts or audible noise.

➢ **Thermogalvanic cell**

- A disadvantage of solid-state thermoelectric devices is that their performance relative to cost has so far limited their application for waste heat recovery and they are expensive due to the use of rare elements.
- Thermogalvanic cells, also called thermo-cells, that utilize ion transport, provide a cost-effective solution for converting heat directly into electricity and present flexible device options for a variety of applications.
- To improve the performance of thermogalvanic cells, carbon nanomaterials with fast redox processes, high thermal and electrical conductivity, and high gravimetric surface area are selected.

➢ **Nitrogen-doped (N-doped) oxidized SWCNTs with melamine**

- In this study, we aimed to prepare electrodes with reduced charge transfer resistance by utilizing the improved electrical conductivity and increased specific surface area of N-doped oxidized CNTs and use them in a thermo-cell.

Experimental

➢ **Defect introduction into SWCNTs**

1. Purification (acid treatment)

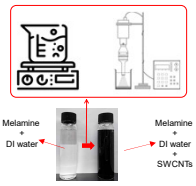
- Acid: H_2SO_4/HNO_3 solution (volume ration of 3:1 = H_2SO_4:HNO_3)
- Method: sonication (6 h)

2. Introduction of defects and oxidation

- Acid: H_2SO_4, $KMnO_4$
- Method: stirring

3. Nitrogen-doping

- Nitrogen source: Melamine (SWCNT:melamine 1:8)
- Method: stirring (12 h) tip sonication (12 h)
- Thermal treatment:
  - ramping rate (10 ℃/min)
  - target temperature (800 ℃)
  - duration time (2 h)



➢ **Thermo-electrochemical cell**

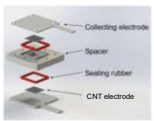
1. Cell components

- 5 mm thick spacer
- Electrolyte: 0.4 M $K_3Fe(CN)_6$/$K_4Fe(CN)_6$
- Active electrodes: Pristine CNT, $KMnO_4$ treated CNT, N-doped CNT(stirring, tip sonication)

2. Temperature

- Hot source/Cold sink T: 45/15 ℃
- △T between active electrodes: 15.1-16.1 ℃

Mixing methods



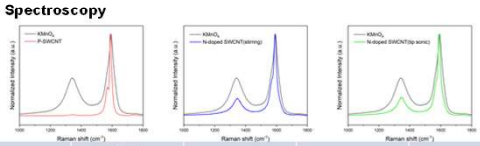


Illustration of the thermocell structure

Result & Discussion

✓ Four different types of electrodes were analyzed: pristine SWCNTs, SWCNTs with increased surface area achieved by introducing defects through $KMnO_4$ treatment, and nitrogen-doped oxidized SWCNTs prepared using two different melamine mixing methods (stirring and tip sonication).

❖ Structure analysis

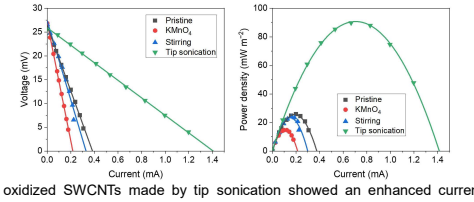
➢ **Raman Spectroscopy**

	Pristine SWCNT	$KMnO_4$	Stirring	Tip sonication
I_G/I_D ratio	82.35(±14.48)	1.86(±0.50)	3.7(±0.65)	3.1(±0.19)

- After $KMnO_4$ treatment, defects and functional groups are formed on the CNT surface, which reduces the G/D ratio. Phys. Status Solidi B2019,256, 1800742
- N-doped SWCNTs showed reduced D band and increased G/D ratio compared to KMnO4-treated SWCNTs. This indicates that defects can be rearranged towards the formation of sp^2-bound SWCNTs after heat treatment under N_2 atmosphere Chemical Physics Letters 424 (2006) 345–352
- If melamine was mixed with SWCNTs, the use of tip sonication resulted in the introduction of more defects compared to stirring, leading to a further decrease in the G/D ratio.

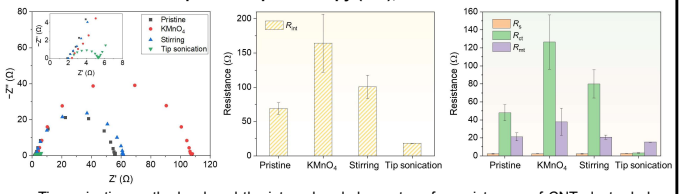
➢ **X-ray Photoelectron Spectroscopy (XPS)**

- When melamine was mixed with SWCNT through stirring and heat treated, the N atomic % was 6.43, and when mixed and heat treated through tip sonication, it was 4.51. Stirring resulted in a Pyridinic-N content approximately twice that of Graphitic-N, while tip sonication produced similar amounts of bot nitrogen species.



➢ **Scanning Electron Microscope (SEM)**

- In pristine SWCNTs, large bundles are observed due to the influence of van der Waals interactions, and after $KMnO_4$ treatment, the bonding effect is reduced due to defects formed on the surface, leading to the exfoliation of CNT bundles. Appl. Sci. 2021, 11, 8452, Surfaces and Interfaces 14 (2019) 1–8
- Compared to the $KMnO_4$ treated samples, the N-doped samples exhibit larger bundles and the tip sonication method tends to shorten the CNTs with longer processing times, resulting in a rougher surface compared to the stirred samples. Nanomaterials 2021, 11, 1469



❖ Thermo-electrochemical cell test

➢ **Voltage-current and power density**

- N-doped oxidized SWCNTs made by tip sonication showed an enhanced current and power density while stirring exhibited poor performance.

➢ **Electrochemical impedance spectroscopy (EIS), Internal resistance**

- Tip sonication method reduced the internal and charge transfer resistances of CNT electrode by 73% and 93%, respectively. This is likely attributed to the synergistic interaction between the elevated Graphitic-N content and oxygen functional groups on the CNT surface, which will be explored in future studies.

Summary

- **We chose a thermocell for harvesting low-grade heat and utilized N-doped oxidized SWCNTs as electrodes to reduce charge transfer resistance.**
- **Mixing CNT and melamine by tip sonication led to a significant reduction in internal resistance and improved thermocell performance, likely due to the synergistic interaction between the increased Graphitic-N content and oxygen functional groups on the CNT surface.**

Experimental Investigation of Mechanical Fiber Bundle Spreading

Hannah Rabe[1], Ewald Fauster[1]

1 Processing of Composites Group, Department Polymer Engineering and Science, Technical University Leoben, Austria

Introduction

Fiber bundles are commonly used in the production of fiber-reinforced composites to achieve high mechanical performance at low weight. For efficient processing – especially during impregnation or placement – precise control of fiber guidance, spreading, and tension is essential.

However, varying fiber properties, complex interactions between tension, path, and cross-section, as well as the need for reproducibility, pose significant challenges.

A modular test rig provides a controlled environment to systematically investigate these factors and gain valuable insights for process optimization.

Test Rig

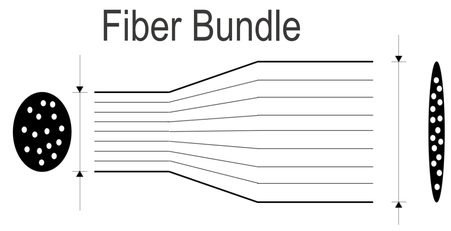
Basic setup:

- Two motor-driven axes (unwinding and winding) for continuous fiber movement
- Fully modular test section between the axes
- Integration of various measurement and process modules possible

Roving Test Rig

Available components:

- Linear axis
- Light section sensors (LSS)
- Tension sensor
- Rotary encoder
- Infrared heater



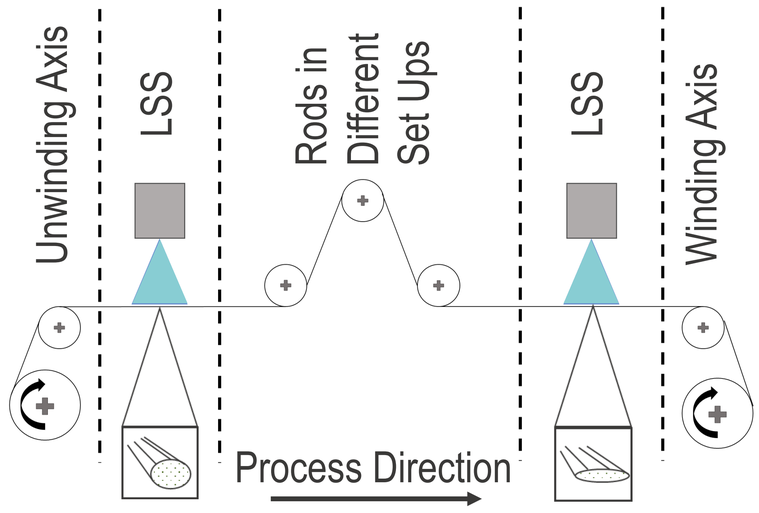
Example Applications:

- Winding experiments on spherical geometries
- Quality assessment of thermoplastic impregnated tapes [1]
- Binder application on fiber bundles:
  - Application methods of binder powder
  - Melting binder using infrared heating

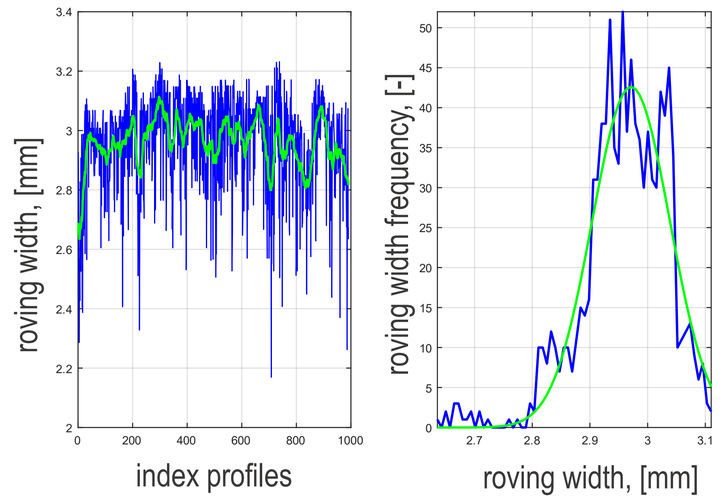
Fiber Bundle Spreading

Efficient impregnation is crucial to obtain high-performance fiber-reinforced composites. It directly impacts the mechanical properties of the final part.

- Mechanical spreading of fiber bundles:
  - Increases surface area
  - Reduces matrix flow paths
  - Leads to better wetting and fewer voids
- Test rig was adjusted to investigate spreading behavior
- Fiber bundles are mechanically spread over rods
- Width and height of fiber bundle measured using light section sensors (LSS)
- Wilson's model [2] is used to predict the expected fiber bundle width ω



Scheme of Spreading Fiber Bundle



Various Rod Shapes

Guiding Fiber Bundle over Rods

Scheme of Test Rig Modification for Spreading

Presentation of Results Evaluation, Roving Width (left), Roving Width Frequency (right)

Outlook

The modular test rig enables controlled investigation of fiber bundle spreading and its impact on impregnation quality. Future work will focus on sustainable fiber materials and their specific processing challenges:

- the processing properties of staple fibers, including plant-based and recycled fibers
- the behavior of natural fibers under changing moisture conditions (e.g., water absorption, swelling, shrinkage)
- suitable strategies for quality stabilization in hygroscopic fiber systems

Keywords: Biodegradable Polymers, Mechanical Recycling, Biocomposites, Natural Fibers, Thermomechanical Properties

ABSTRACT

This work explores the influence of multiple reprocessing cycles and the incorporation of natural fillers on the properties of a post-consumer biodegradable polymer blend composed mainly of PLA and PBS. The blend, originally used for the production of single-use cutlery, was subjected to up to eight extrusion/injection molding cycles to simulate mechanical recycling and to evaluate thermal, morphological, and mechanical stability. The results demonstrate that reprocessing does not significantly affect the mechanical properties of the blend, likely due to the stabilizing effect of the inorganic filler. A slight decrease in the PLA degradation peak was observed via TGA analysis, from 346.6 °C (Ext 1) to 343.3 °C (Ext 8), attributable to thermo-mechanical degradation phenomena such as chain scission. The incorporation of agro-industrial residues, such as wheat and rice straw (10 wt.%), enhanced both the tensile and flexural moduli of the composites. However, the presence of these natural reinforcements resulted in a slight reduction in both the onset degradation temperature and the PLA degradation peak, with decreases of 1.5% and 5.8% for wheat straw, and 3.4% and 5.5% for rice straw, respectively. These findings demonstrate that biodegradable blends can be recycled through multiple mechanical processing cycles without significant loss of performance. Furthermore, the integration of natural lignocellulosic fillers offers an effective solution to enhance mechanical properties while reducing reliance on virgin polymer content. This approach supports the development of sustainable and cost-effective composite materials aligned with circular economy principles.

1 INTRODUCTION

Originally designed as a symbol of technological progress, fuel-based plastics have revolutionized the modern world by making human life easier [1] thanks to their versatility, low weight, durability and low production costs [2]. The first plastics were introduced in the 1920s and production expanded in following years [3]. In 1965, the yearly production was about 15 million tons (Mt) and increased to 360

million tons (Mt) in 2018 [4]. As a result, the global annual production of plastics has continuously grown since their initial development. However, the use of plastic has created serious environmental problems due to their inability to undergo biological degradation and aging, leading to pollution and persistence in the environment for many years after disposal [5, 6]. This has caused large amounts of waste to accumulate in landfills or in natural environment [7]. Furthermore, the production processes of synthetic polymers, such as ethylene or propylene, require the use of harmful compounds and result in the formation of toxic by-products [8]. This has prompted the need to find alternatives to fuel-based polymers. In recent years, biodegradable polymers produced from natural raw materials, such as cellulose, starch and chitosan [6] have been introduced to the market. These materials are capable of biodegrading. Compared to petroleum-based polymers, they are more compatible with the principles of the circular economy, making them a preferred choice. Bioplastic production has grown significantly in recent years, rising from 2.4 million tons (Mt) in 2021 to an estimated 7.5 million tons (Mt) by 2026 [9]. The use of these polymers could represent a solution to plastic accumulation at the end of their life cycle, thanks to their ability to degrade through biological processes involving microorganisms capable of breaking the polymer chains [10]. However, biodegradation requires specific environmental conditions to occur, such as oxygen concentration, moisture, temperature [10, 11, 12], as well as a concentration of microorganisms, which play a crucial role in determining both the rate and degree of biodegradation, making it an inadequate rapid solution for waste disposal. Furthermore, although biodegradable polymers are often promoted as environmentally friendly alternatives to conventional plastics, their degradation is typically limited to controlled industrial composting facilities. Under natural environmental conditions, such as soil or marine ecosystems, the specific parameters required for biodegradation (temperature, humidity, oxygen levels, and microbial activity) are often not met. As a result, these materials may persist in the environment for extended periods, raising concerns about their actual end-of-life sustainability and environmental impact [13]. In addition, biodegradable polymers, as polylactic acid (PLA), polybutylene succinate (PBS) and poly(3-hydroxybutyrate-co-3-hydroxyvalerate) (PHBV) are more expensive than fossil-based polymers [14, 15].

Various strategies have been proposed to solve this issue, such as mechanical and chemical recycling, as well as incineration [16]. Chemical recycling involves solvolysis, pyrolysis, or hydrolysis reactions that break down the polymer chain into monomeric units and the recovered material can be repolymerized an indefinite number of times to produce the corresponding biopolymers [16]. On the other hand, it is the most expensive method due to the large amount of energy required to reach the temperature needed for the reaction to take place such as depolymerization [17]. Meanwhile incineration is able to produce energy but, besides being high-cost, could produce unsafe exhaust gases [18]. Mechanical recycling could be the most efficient solution to reduce landfill waste because it is cost-effective and without significant alteration in the chemical structure of materials [11, 19, 20]. Nevertheless, repeated mechanical reprocessing can lead to thermo-mechanical degradation phenomena, such as chain scission, resulting in mechanical property losses. Investigating the extent of these effects and how to mitigate them is essential for designing sustainable circular solutions. The use of agro-waste products can also be a viable solution to reduce landfill waste, as they often originate as residues from crop cultivation and agro-industrial operations. Materials such as rice straw, wheat straw, and coconut shells are renewable, abundantly available, and contribute to preserving the bio-based and biodegradable nature of the final product [21]. The incorporation of natural lignocellulosic fillers has gained significant attention as a strategy to enhance the stiffness, reduce polymer consumption, and improve the sustainability of the final bio-based polymer composites [22]. Recent studies have shown that combining mechanical recycling with the addition of natural fibers can not only recover post-consumer polymer waste but also improve or stabilize the mechanical properties of degraded polymers through fiber reinforcement [23]. The present study aims to evaluate the effect of reprocessing on a commercial post-consumer biodegradable polymer blend, as well as the influence of incorporating natural fillers derived from agricultural waste. This investigation addresses the performance evolution across multiple recycling cycles and assesses the feasibility of valorizing agro-waste as reinforcing fillers in bio-based composites.

The blend was reprocessed through eight cycles of extrusion and injection molding. The blend, used for the production of single-use cutlery, is PLA-based with PBS and inorganic filler. Mechanical properties were studied through tensile and three-point bending tests. Thermal properties were evaluated by

thermogravimetric analysis (TGA) and differential scanning calorimetry analysis (DSC), meanwhile thermo-mechanical tests as Heat Deflection Temperature (HDT) and Vicat (VST) were conducted. The effect of adding 10 wt.% of wheat straw (WS) and rice straw (RS) to the reprocessed blend was also investigated in terms of mechanical and thermal characterization of the final composite. Fracture surface analyses of the reprocessed polymer and the natural fiber composites were performed using Scanning Electron Microscopy (SEM) to assess morphological changes and filler dispersion. Potential effects on the blend compostability after subsequent mechanical reprocessing were evaluated through aerobic tests in controlled composting conditions.

2 MATERIALS

Disposable cutlery, including knives and forks, was crushed into pellets. The material was dried at 60 °C for 1 day before the extrusion (corotating twin-screw extruder, Thermo Scientific Process 11, ThermoFisher Scientific)/injection molding (Haake MiniJet IIPro, Thermo Fisher Scientific) reprocessing cycles. The rotational speed was set at 150 rpm and the following temperature profile was used from zone 1 to 8: 160 °C-165 °C-170 °C-170 °C-175 °C-180 °C-185 °C-180 °C. During the injection molding, the mold and the cylinder were maintained at 70 °C and 180 °C, respectively. To reproduce several reprocessing cycles, the polymer was pelletized after each injection and subjected to successive extrusion/injection cycles, up to eight times. The resulting samples were denoted as “Ext n”, where n represents the number of extrusion/injection cycles. Rice straw (RS) was supplied by Azienda Riso Milano (Italy), while wheat straw (WS) was obtained from Agriturismo Cascina Scanna (Italy). Both RS and WS were washed with tap-water and dried at 60 °C for 24 h. In the final stage, the materials were milled using a knife mill. To recover the inorganic filler, the polymer was dissolved using chloroform.

3 METHODS

Tensile and flexural tests were conducted with a Zwick/Roell Z010 universal testing machine. Tensile tests were conducted in displacement control with a 10 mm/min crosshead speed at room temperature according to ISO 527-2 (type 1BA, L_0 = 30 mm) using dog-bone specimens with a thickness of 1.5 mm and a width of 5 mm. Flexural properties were measured through three-point bending tests according to ISO 178. The crosshead speed was set at 5 mm/min and the sample dimensions were 80 × 10 × 4 mm. Thermogravimetric analysis (TGA) was conducted from room temperature to 800 °C in nitrogen atmosphere using a heating ramp of 10 °C/min (TG209 F1 Libra by Netzsch). Differential scanning calorimetry analysis (DSC) was performed using DSC 214 Polyma by Netzsch under a nitrogen flow of 60 mL/min, following this thermal program: first heating from -40 °C to 200 °C (5 min hold interval), cooling to -40 °C (5 min hold interval) and second heating to 200 °C. All heating and cooling steps were carried out with a rate of 10 °C/min. The softening point of materials was evaluated using Vicat test (VST), according to ISO 306_A120. The heat deflection temperature (HDT) was determinate using method A with a flexural stress of 1.80 MPa, in accordance with ISO 75. Both HDT e VST tests were carried out with Amsler Allround heat deflection tester by Zwick/Roell. Fracture surface morphologies were studied using scanning electron microscopy (FE-SEM Mira3 by Tescan) equipped with an Octane Elect Energy Dispersive Spectroscopy (EDS) System by EDAX (AMETEK GmbH). All specimens were sputter-coated with gold before the analysis. The particle size distribution (PSD) of WS and RS was determined using a Microtrac Sync laser diffraction analyzer (Verder Scientific S.r.l.). Analyses were carried out in dry mode, with a dispersion pressure set at 100 kPa and a suction pressure of 70 kPa. The PSD results are expressed in terms of percentile values: D10, D50, and D90. Specifically, D10 indicates the particle diameter below which 10% of the sample (by mass or volume) is smaller; D50 refers to the median particle size, meaning that 50% of the particles are smaller; and D90 corresponds to the diameter below which 90% of the particles fall.

Aerobic biodegradability was evaluated following ISO 14855-1. Bioplastics (Neat, Ext 1 and Ext 8) were mixed with mature compost (1:10 TS ratio, 50% moisture) in 1-L reactors and incubated at 58 °C for 180 days. Biodegradation was assessed monitoring CO_2 production with an infrared gas analyzer. Blank tests were conducted to measure the residual CO_2 production of compost. Cellulose control tests were conducted to ensure experimental validity. Residual bioplastics were sampled from the reactors

after 1 and 3 months of degradation and subjected to TGA to monitor potential changes in the polymeric matrix.

4 RESULTS AND DISCUSSION

The disposable material adopted in this study was analyzed using thermal analysis techniques to identify the polymer components. PLA was identified based on the presence of a glass transition temperature (T_g) at 49.1 °C, a melting peak (T_m) at 160.3 °C [24], and a crystallization peak (T_c) at 100.5 °C [25], while PBS was recognized by its T_m of 111.4 °C [26]. The T_g observed for PLA is lower than the values typically reported in the literature [27]. Thermogravimetric analysis revealed a main degradation peak at 347.7 °C [28], characteristic of PLA, and a second, less intense peak around 400 °C, associated with PBS [29]. Since the PLA degradation peak is more prominent than that of PBS, it can be inferred that PLA is the predominant component in the blend, accounting for around 50%. A residue of about 27.9% was measured at 800 °C. To evaluate the nature of the inorganic filler, the pellet was dissolved in chloroform and the residue was analyzed by EDS, which revealed the presence of talc and titanium dioxide. The former is typically used as a nucleating agent [30], while the latter is added to enhance the stability of polymer blends [31]. Subsequently, the polymer blend was reprocessed through eight extrusion/injection cycles. Thermal analysis results for samples 1, 6, and 8, as well as for composites containing wheat and rice straw, are reported in Table 1. TGA results revealed a shift both in the PLA degradation peak and in the temperature at 50% weight loss ($T_{50\%}$), decreasing from 346.6 °C to 343.3 °C and from 347.5 °C to 344.9 °C between Ext 1 and Ext 8, respectively. This trend is attributed to thermo-mechanical degradation and polymer chain scission occurring during repeated reprocessing cycles [11]. PBS, on the other hand, appeared unaffected by reprocessing.

While reprocessing did not significantly influence the blend's onset degradation temperature ($T_{5\%}$), the incorporation of agricultural waste caused a reduction in this parameter: 277.2 °C for wheat straw and 271.7 °C for rice straw. Similarly, the main degradation peak associated with PLA decreased to 323.2 °C for wheat straw and 324.4 °C for rice straw. This is attributed to the partial replacement of the more thermally stable polymer matrix with hemicellulose and cellulose components from wheat and rice straw, which are less thermally stable. This behavior is consistent with the findings reported by Eustathios Petinakis et al. [32], where increasing filler content leads to a reduction in PLA degradation temperature. DSC analysis did not show any significant changes in thermogram trends of the blend after reprocessing, likely due to the presence of titanium dioxide, which limits PLA chain mobility and contributes to thermal stability [33]. Furthermore, the incorporation of wheat and rice straw did not significantly affect the characteristic thermal transitions, in agreement with the results reported by Morreale et al. [34], who observed that natural fillers do not markedly influence the thermal behavior of biodegradable polymer matrices.

Sample	$T_{5\%}$ (°C)	$T_{50\%}$ (°C)	$T_{max\ degradation}$ (°C)
Ext 1	281.4	347.5	346.6
Ext 6	282.9	346	344.6
Ext 8	281.2	344.9	343.3
Ext 8 + 10%WS	277.2	337.4	323.2
Ext 8 + 10%RS	271.7	328.7	324.4

Table 1: TGA results of reprocessed polymer blend and composites.

Tensile and flexural quasi-static tests were conducted on both the reprocessed polymer blend and composites, and the findings are reported in Table 2.

It can be observed that reprocessing does not significantly affect the mechanical properties of the blend, either in terms of flexural or tensile behavior. This can be attributed to the presence of titania, as the literature reports the ability of titania to form bonds with the carboxylic groups of PLA [35]. The presumed reduction in PLA molecular weight due to reprocessing is expected to increase the number of terminal carboxylic groups available for interaction with the titania surface. Such enhanced interfacial interactions between the PLA matrix and the filler may contribute to mitigating the decline in mechanical

properties associated with PLA degradation [11]. As a result, it progressively reinforces the polymer matrix more effectively.
The addition of 10 wt.% of rice and wheat straw leads to an increase in both flexural and elastic moduli, accompanied by a decrease in maximum flexural and tensile strength. This behavior is attributed to the poor interfacial adhesion between the fiber and the matrix, as can be observed in the representative SEM micrograph (Figure 1). Particle size analysis revealed that the particle dimensions of RS are larger than those of WS by approximately 57.7%, 36.7%, and 44.8%, corresponding to the cumulative distribution percentiles D10, D50, and D90, respectively. As a result, the higher specific surface area of wheat straw contributes to increased matrix stiffness, as further supported by Berthet et al. [36]

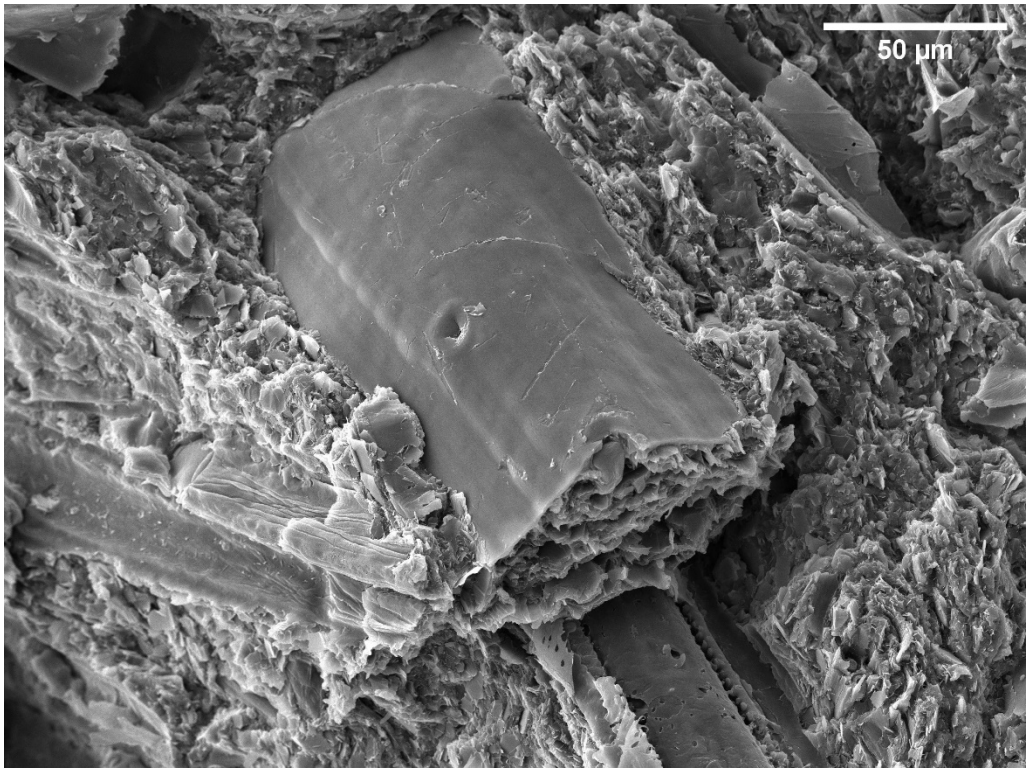

Figure 1: SEM micrograph of Ext 8 with 10 wt.% of WS.

Sample	Tensile Strength (MPa)	Young's Modulus (GPa)	Flexural Strength (MPa)	Flexural Modulus (GPa)
Ext 1	42.0 (± 0.5)	3.0 (± 0.2)	62.0 (± 0.4)	6.1 (± 0.7)
Ext 6	42.6 (± 0.8)	3.2 (± 0.1)	65.4 (± 0.5)	6.2 (± 0.2)
Ext 8	43.9 (± 0.2)	3.3 (± 0.1)	64.8 (± 0.5)	6.1 (± 0.1)
Ext 8 + 10%WS	34.4 (± 0.8)	7.3 (± 0.5)	46.5 (± 1.8)	6.5 (± 0.4)
Ext 8 + 10%RS	29.7 (± 2.6)	7.0 (± 0.7)	36.4 (± 4.3)	5.8 (± 0.7)

Table 2: quasi-static mechanical tests results.

The effect of reprocessing cycles was also assessed through Heat Deflection Temperature (HDT) and Vicat Softening Temperature (VST) tests. In the HDT test, the sample is subjected to bending under a specified load, whereas in the VST test, the sample undergoes penetration by a standard indenter. The results are reported in Table 3.

Sample	HDT (°C)	VST (°C)
Ext 1	49.3	52.3
Ext 6	49.5	53.8
Ext 8	49.4	53.5
Ext 8 + 10%WS	50.9	54.5
Ext 8 + 10%RS	49.1	56.6

Table 3: HDT and VST results.

The HDT and VST results are consistent with those obtained from quasi-static mechanical tests, confirming that the addition of natural fillers contributes to an enhancement of the stiffness of the final composites [37, 38].
Biodegradation tests revealed that reprocessing had no significant impact on the biodegradability of the polymer blend. All the tested samples exhibited a comparable biogas evolution in terms of kinetics and yields achieving a biodegradation degree in the range 72 – 76% in 180 days. TGA indicated a preferential degradation of PLA, which was no longer detectable in the bioplastic samples after 1 and 3 months of testing. After four months testing, residual bioplastic particles were no longer visually detectable, but based on the biodegradation degree attained, it can be reasonably concluded that PBS was not fully degraded. In contrast, the addition of natural fillers in the composites led to an increased degradation rate. This behavior can be attributed to the superior hydrophilicity of the composites, which facilitates water uptake, the promotion of microbial colonization on the fibrous surface, and the intrinsic biodegradability of the lignocellulosic fillers, which degrade more readily under composting conditions [39, 40].

5 CONCLUSIONS

This study investigated the thermal, morphological, and mechanical behavior of a post-consumer biodegradable polymer blend. Reprocessing led to a slight reduction in PLA thermal stability due to thermo-mechanical degradation, with minimal effect on PBS. Despite this, mechanical performance remained stable, likely due to a better dispersion of inorganic fillers over cycles. The incorporation of wheat and rice straw slightly reduced the onset degradation temperature but did not significantly affect DSC results, indicating that natural fillers had limited impact on the blend's thermal behavior. Mechanical tests showed increased stiffness but reduced strength, due to weak matrix-filler adhesion. Wheat straw showed better performance compared to rice straw, possibly due to its higher cellulose content and smaller fiber dimensions. Overall, the results highlight the potential of combining mechanical recycling of biodegradable polymer blends with agro-industrial residues to create composites with balanced thermal and mechanical performance while preserving their potential for compostability. Future developments should focus on improving the interfacial adhesion between the polymer matrix and natural fillers through surface treatments or compatibilizers, in order to enhance strength and toughness without compromising biodegradability.

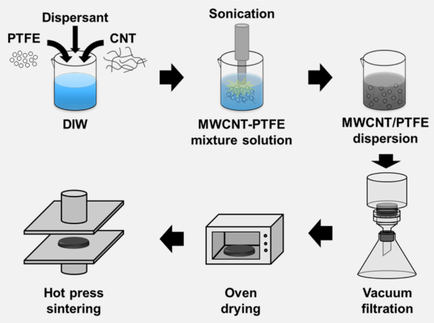
ICCM24 — 24TH INTERNATIONAL CONFERENCE ON COMPOSITE MATERIALS

MCSI Lab — Multifunctional Composites & Structural Integration Lab

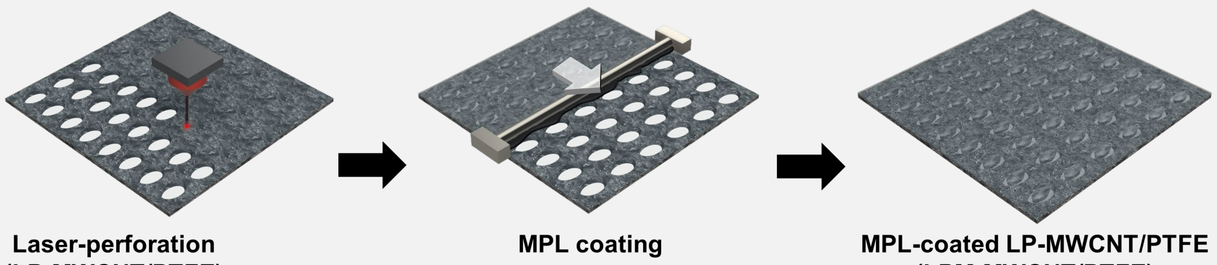
Introduction

Gas and water mass transfer remain significant challenges in **proton exchange membrane fuel cells (PEMFCs)**, making the surface properties and structural configuration of the **gas diffusion layer (GDL)** critical for performance. A newly proposed **gas diffusion nanocomposite layer (GDNL)** features a **multi-walled carbon nanotube/polytetrafluoroethylene (MWCNT/PTFE) nanocomposite film with a laser-perforated pattern filled with carbon black/PTFE (CB/PTFE) microporous material**, forming a **hydrophilic–superhydrophobic columnar interface**. In this design, laser irradiation induces hydrophilicity along the inner walls of the perforations, directing water transport through the hydrophilic interface. Meanwhile, the superhydrophobic CB/PTFE filling channels gas transport inside the structure and repels water outward, ensuring separated and efficient pathways for gas and water movement. **This unique columnar interface in the LPM-GDNL design results in ~40% and ~50% improvements in current and power density** in the concentration loss region at relative humidity levels of 50% and 100%, respectively, compared to conventional commercial carbon paper GDLs.



Enhancement of power and improvement of mass transport

Experiment

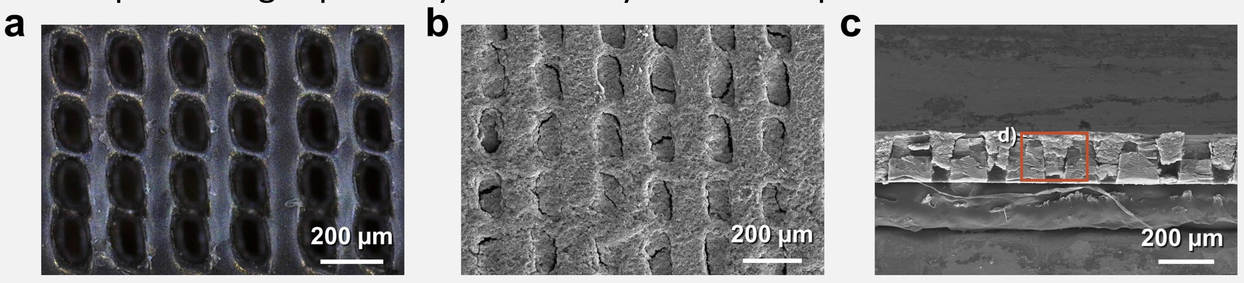


◆ Film fabrication

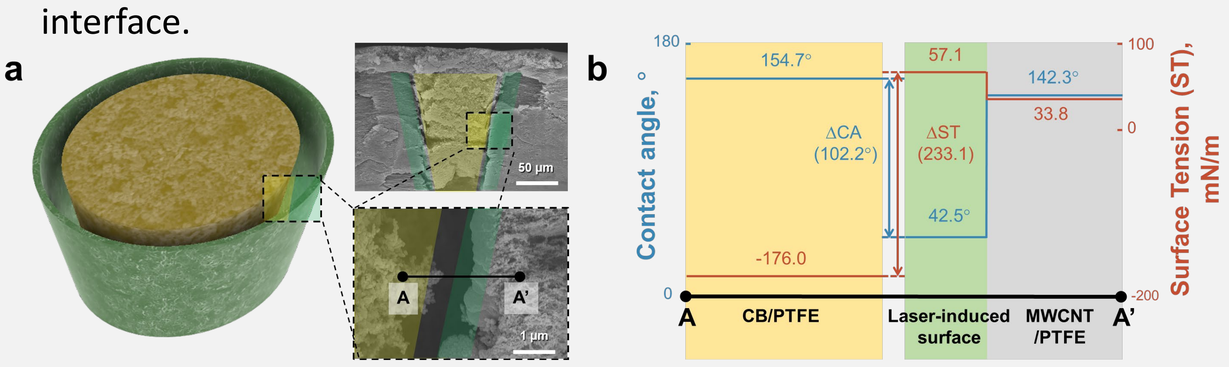
- MWCNT and PTFE were mixed with a dispersant.
- A film was prepared by vacuum filtration.
- The fabricated film was sintered by hot pressing at 350 °C.

◆ Laser perforation and MPL coating

- Holes (60 x 110 µm) were perforated at 200 µm intervals using a laser.
- CB/PTFE MPL was coated on the perforated film and sintered.

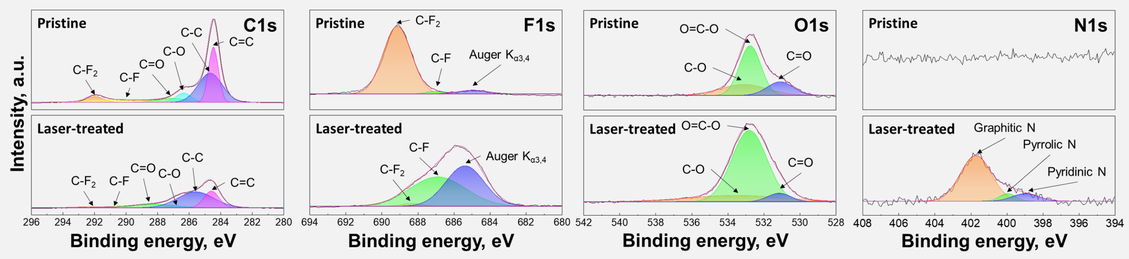


Laser-perforation (LP-MWCNT/PTFE) → MPL coating → MPL-coated LP-MWCNT/PTFE (LPM-MWCNT/PTFE)



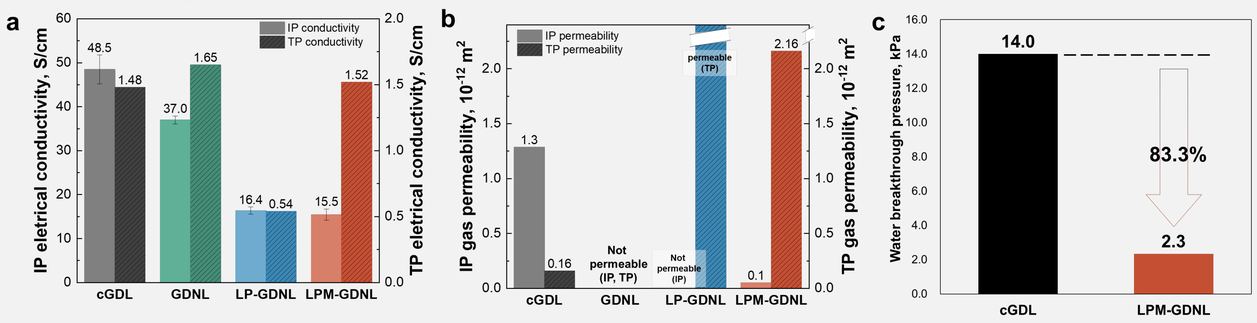
Results & Discussion

◆ Characterization

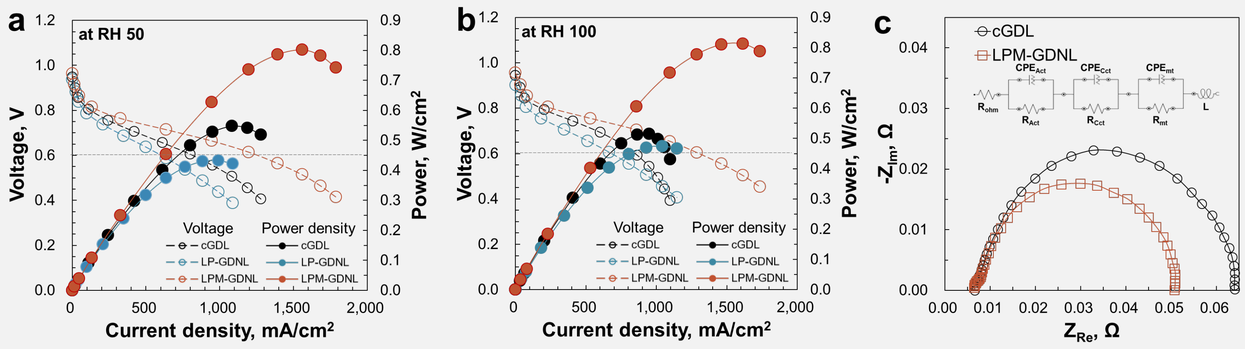


- Laser irradiation produced uniformly spaced, truncated cone-shaped holes with a bumpy texture in the C50P50 film.
- These holes were filled with CB/PTFE slurry, forming a porous MPL layer that provides gas pathways and firmly anchors in place.

- Laser irradiation increased surface hydrophilicity and tension by changing chemistry and microstructure.
- This enabled unique gas and water transport through a nano-micro hybrid interface.

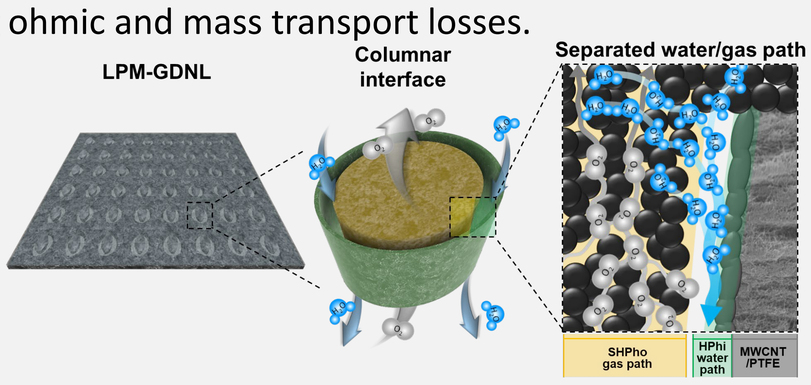


- XPS analysis showed that laser irradiation reduced C=C and C-F bond intensities while increasing oxygen and nitrogen content.
- These compositional changes enhanced surface hydrophilicity and altered the nanocomposite's chemical structure.



◆ GDL properties

- Laser perforation reduced the conductivity of the film, but CB/PTFE coating restored conductivity and increased compressibility significantly.
- LPM-GDNL exhibited much higher through-plane gas permeability than commercial GDLs due to vertical perforations and porous MPL coating.
- Water breakthrough pressure was greatly reduced in LPM-GDNL, indicating enhanced water removal through the hydrophilic interface.



◆ PEMFC performances

- LPM-GDNL showed significantly improved PEMFC performance under both RH50 and RH100 by combining enhanced conductivity with a hydrophilic–superhydrophobic columnar interface.
- This structure reduced ohmic and mass transport resistance, as confirmed by EIS analysis, leading to better charge transfer and water management.
- Compared to commercial GDLs, LPM-GDNL achieved up to 59% higher power density, demonstrating the effectiveness of combining perforation and surface energy control.

Conclusions

- Laser-perforated MWCNT/PTFE films with CB/PTFE filling created a hydrophilic–superhydrophobic columnar structure that improved water removal and gas transport.
- This design lowered electrical resistance and enhanced PEMFC performance by reducing ohmic and mass transport losses.
- Further optimization of composition and perforation is expected to boost mass transport even more, supporting sustainable hydrogen energy.

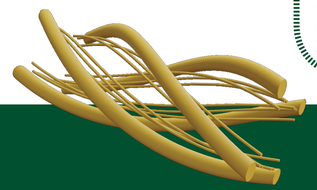
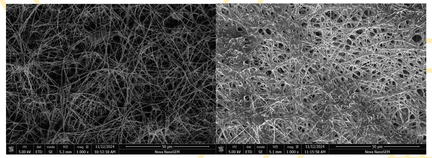
NOVEL ELECTROSPINNING PVDF/BI2O3/CEO2 COMPOSITE YARN: A VERSATILE APPROACH TOWARDS FUNCTIONAL X-RAY SHIELDING TEXTILE

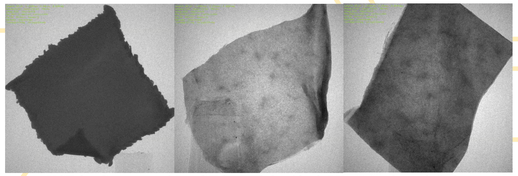


Siyuan Zhao, Lindsey Waterton Taylor, Vien Cheung and Yu Shi

Recent environmental challenges, particularly concerns regarding nuclear waste management, have heightened the urgency for developing practical radiation protection solutions suitable for daily use. While existing nanofiber membranes exhibit promising radiation shielding capabilities, their inherent limitations in flexibility and processability significantly restrict their integration into wearable applications. Traditional lead-based protective materials, despite their effectiveness, present substantial weak points in terms of weight and mobility constraints.



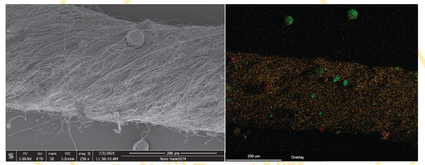
This study presents a novel approach to developing functional X-ray shielding textiles through Electrospinning PVDF/Bi_2O_3/CeO_2 composite yarns. With increasing concerns about nuclear waste management and radiation protection in daily applications, there is an urgent need for lightweight, flexible protective materials that overcome the limitations of traditional lead-based shields. Considering the heavyweight of conventional lead garments, PVDF was selected as the polymer matrix due to its lightweight nature and versatile wearable applications. This research introduces an innovative composite system incorporating Poly(vinylidene fluoride) (PVDF) with high-Z elements, specifically Bismuth Oxide (Bi_2O_3) and Cerium Oxide (CeO_2) nanoparticles, to achieve an optimal balance between protection efficacy and textile functionality.



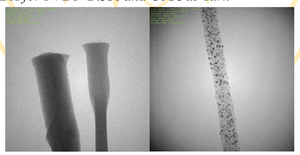
Material Synthesis

The composite was developed using PVDF nano powder (Mw = 534,000, Sigma-Aldrich) as the polymer, integrated with high-Z elements Bi_2O_3 and CeO_2 (Sigma-Aldrich) as X-ray attenuating materials. This combination leverages PVDF's mechanical flexibility and chemical stability, while the Bi_2O_3 and CeO_2 provide effective X-ray attenuation. The solvent comprised a 3:1 ratio of dimethyl sulfoxide (DMSO) to acetone.

SEM for PVDF & PVDF-Bi_2O_3 and CeO_2



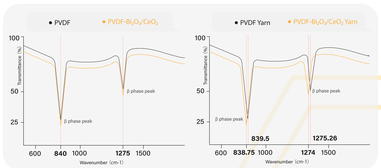
Morphological analysis via scanning electron microscopy elucidates the structural characteristics of the fabricated fibrous networks at 1000 magnification. The pristine PVDF architecture exhibits well-defined nanofibrous formations with consistent dimensional uniformity, while the PVDF matrices containing Bi_2O_3 and CeO_2 display marginally enhanced fiber diameters attributed to the successful incorporation of high-Z elements.



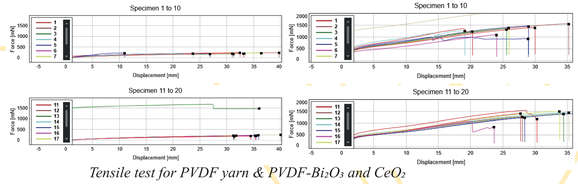
XCT for Commercial Lead Film and thin/thick PVDF-Bi_2O_3 and CeO_2

These images are captured by ZEISS Xradia 410 Versa. By comparing it to the lead film, this is conducted on three samples with the same X-ray energy parameters, 80 kV-10.00 W, revealing the relative attenuation capabilities through grayscale contrast. The commercial lead film exhibits maximal attenuation (darkest contrast), and the thick PVDF-based composite achieves comparable X-ray shielding performance.

Yarn & Strength



SEM & EDX for PVDF-Bi_2O_3 and CeO_2 as Yarn



XCT for different ratio of metal oxides as PVDF-Bi_2O_3 and CeO_2

Under the same X-ray condition, comparative analysis between hand-twisted thick membranes and electrospun yarns reveals notable differences in shielding performance. The electrospun yarns demonstrated stable and consistent characteristics, but a lower density of metal oxide nanoparticles.

FTIR Spectra Analysis for PVDF yarn & PVDF-Bi_2O_3 and CeO_2

Tensile test for PVDF yarn & PVDF-Bi_2O_3 and CeO_2

PVDF - Bi_2O_3 and CeO_2 composite exhibits a significantly enhanced tensile strength of 1.27 N compared to pure PVDF. However, the tensile displacement at break for pure PVDF averages 32.3, while the PVDF-Bi_2O_3/CeO_2 composite fails at 29.6 mm, indicating reduced elasticity.

Discussion

Through current characterisation and tensile testing, a stable composite comprising PVDF with bismuth oxide and cerium oxide has been identified. However, the fabrication of yarns via electrospinning technology necessitates further optimisation of the ratio balance between these materials, as several key challenges have emerged:

1- **High metal oxide concentrations** enhance both X-ray shielding efficacy and mechanical strength but promote agglomeration prior to spinning, compromising electrospinning solution stability.

2- **Reduced metal oxide concentrations** preserve PVDF's inherent elasticity but fail to achieve the desired X-ray shielding performance.

3- **Establishing an optimal balance** between processability and functional properties remains a critical challenge requiring systematic investigation of compositional ratios.

Conclusions

The incorporation of high-Z elements (Bi_2O_3 and CeO_2) into PVDF demonstrates excellent X-ray shielding performance while enhancing the polymer's β-phase mechanical properties, showing promising potential for functional protective textiles. The experimental results confirm that these high-Z elements contribute to X-ray shielding capabilities.

Keywords: Lightweight design, CFRP, Tribological testing, Tool interface, Lubrication

ABSTRACT

Carbon fiber reinforced plastics (CFRP) offer great potential for lightweight construction due to their high specific stiffness and strength, especially in electric drive systems with rotating components. However, the substitution of steel by CFRP in highly stressed, tribologically relevant interfaces, such as hollow shank taper interfaces (HSK), is hindered by numerous influencing factors. To systematically investigate these factors, particularly the winding angle and lubrication, the tribological properties of CFRP are analyzed on an application-oriented test rig.

For this purpose, pin-on-tube tests are conducted using CFRP tube samples with three winding angles (±10°, ±45°, ±89°), as well as hardened steel references tested against steel counterfaces are conducted. The samples undergo linear reciprocating motion under a normal force of 450 N over 20,000 cycles. The friction coefficients are determined under dry conditions as well as under flood lubrication with a water-miscible coolant lubricant.

The results show that lubrication with coolant lubricant significantly reduces the dynamic coefficient of friction. The lowest friction coefficients, 0.17, are achieved at a winding angle of ±10°. In lubricated tests, the specific wear was below the measurement resolution. Microscopic images show typical fiber-matrix damage in unlubricated samples, which is significantly less pronounced under lubricated conditions. A comparison with literature values for steel HSK interfaces demonstrates the influence of the pin-on-tube arrangement for reference samples. The investigations show the suitability of CFRP for tribologically stressed interfaces. However, further studies are necessary for transfer to real applications such as HSK.

1 INTRODUCTION

Lightweight construction in various application areas, such as aerospace or electric drive systems with rotating components, aims to increase energy efficiency. The replacement of steel components with lighter materials is particularly important in applications where the drive itself is in motion, such as in machine tools. A low component weight combined with high stiffness, thermal stability, and dynamic damping represents a significant competitive criterion for drive components [1]. With increasing demands on the power density of electric drive systems, conventional materials are reaching their physical limits [2]. A promising solution lies in the use of CFRP. Due to its excellent ratio of strength and stiffness to weight, CFRP offers a high lightweight potential and allows for a significant reduction

in component mass. Interfaces to other drive components are still predominantly made of steel, as CFRP interfaces, such as bearing seats or the hollow-shank taper interface, have been scarcely investigated with regard to surface quality, coefficient of friction, and wear behavior.

The HSK interface according to DIN 69893-1 [3] between the machine tool spindle and tool holder is a tribologically highly stressed interface. This interface demands tight tolerances for flatness and concentricity (< 3 µm) to ensure interchangeability, repeatability, secure torque transmission, and high bending stiffness [4]. However, clamping processes and dynamic loads lead to wear mechanisms that reduce the service life of these interfaces. In particular, wear on the taper surface, which primarily serves for alignment, can impair the required high precision in terms of concentricity and repeatability [Bre16]. In material-removing machining of workpieces, coolant lubricant (KSS) is used [5]. The main function of KSS is to dissipate heat and reduce friction. Additionally, during a tool change, KSS is used to clean the taper surfaces of impurities, thereby reducing HSK wear [6]. According to Landmann [7], KSS affects the mechanical properties of CFRP depending on exposure duration, diffusion rate, and type of coolant lubricant. While the carbon fibers themselves are hardly affected by contact with coolants, the matrix undergoes intermolecular interactions, hydrolysis, oxidation, and leaching, which lead to a deterioration of mechanical properties [7].

Compared to conventional metallic materials, CFRP offers considerable advantages. Higher specific stiffness and strength enable higher rotational speeds and accelerations, improving the efficiency of relevant systems. However, replacing steel with CFRP also increases the complexity of tribological influencing factors, especially due to material-dependent parameters such as the type of fiber and matrix materials, fiber content, and fiber orientation. According to Friedrich [8], fiber orientation significantly influences the tribological behavior of fiber-reinforced composites. The lowest friction and wear values occur when fibers are oriented perpendicular to the friction surface (N-orientation), whereas parallel (P) and antiparallel (AP) orientations lead to significantly higher friction and wear rates.

To investigate influencing factors, model tests such as pin-on-plate tribometers have been conducted [9, 10]. However, with increasing abstraction of the tribological system, the transferability of results decreases, making application-oriented investigations necessary [11]. Since the use of CFRP involves a multitude of influencing factors that cannot be isolated in field tests, an application-near test rig is necessary, allowing targeted variation and analysis of individual parameters. The aim of this work is to systematically investigate the influencing factors on the tribologically stressed HSK interface caused by the substitution of steel with CFRP. For this purpose, an application-near tribometer is used to analyze the effects of the degree of abstraction of the test geometry, lubrication, and fiber orientation on friction and wear behavior, thereby providing a basis for the industrial application of CFRP interfaces.

2 EXPERIMENTAL STUDIES

To investigate cost-effectively and individually the high number of influencing factors, the tribological system is abstracted so that model tests are carried out in a pin-on-tube arrangement according to Kilian et al. [12]. In this arrangement, a rounded block rubs against the inside of a tube specimen, which undergoes a linear reciprocating motion. The schematic setup of the arrangement with the functional principle and the measurement technology is shown in the half-section in Figure 1. By using tube specimens, the same manufacturing process as in the application case can be employed, as well as the simulation of the same type of motion and surface pressure. A reduction of the influencing factors compared to the application case is achieved through the cylindrical geometry of the tube specimens, since this test setup avoids an overlap of axial and radial forces, as occurs in the force transmission in an HSK, and additionally allows conclusions to be drawn about other tribologically stressed interfaces such as bearing seats.

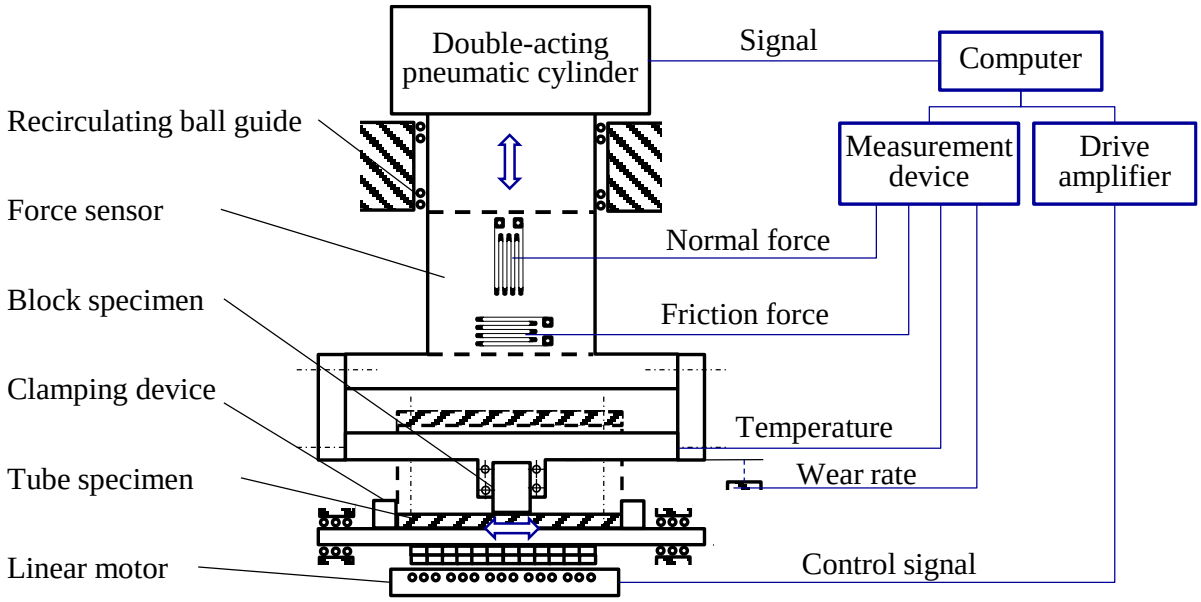

Figure 1: Schematic setup of the model tests in pin-on-tube arrangement in half-section with the functional principle and measurement technology.

2.1 MATERIALS AND SAMPLE PREPARATION

The CFRP samples are manufactured using the filament winding process with T700 carbon fibers (company Toray) and the epoxy winding resin LY556 (company Huntsman). To investigate the influence of the winding angle, three CFRP specimens with balanced winding angles of ±45°, ±89°, and ±10° are wound. Hardened steel specimens (material 16MnCr5) with a Rockwell hardness, scale C of 56±4 HRC serve as reference samples. The specimens are ground to an inner diameter of 52 mm, an outer diameter of 60 mm, and a length of 40 mm. The form and positional tolerances are chosen in accordance with the HSK interface 63 according to [3], whereby, for example, the concentricity and roundness of the tubes are tolerated within 3 µm.

Figure 2: CFRP specimens in the orientations from left to right:
winding angles of ±10°, ±45°, and ±89°.

As the tribological counterbody, rounded steel blocks with the dimensions 10 × 10 × 20 mm are chosen. The steel blocks are made of 16MnCr5 and are case-hardened (56±4 HRC) like the reference specimens. The functional surface, i.e., the rounded area, is ground to a nominal radius of 26 mm with tolerance limits of +0.000 and –0.025 mm to enable area contact between the friction partners. Additionally, a surface form tolerance of 3 µm is maintained. A borehole in the rounded block allows the use of water cooling during the tests.

2.2 EXPERIMENTAL SETUP

The tribological investigations of the influencing factors are carried out using the LRT test rig (Linear-Reciprocating Tribological test bench) in the pin-on-tube arrangement. In this test rig, a linear motor drives a tube specimen while a block, rounded to match the tube specimen, is pressed against it to induce friction. Figure 2 shows the LRT test rig on the left and a close-up of the friction partners in the pin-on-tube arrangement on the right. The block is loaded with a normal force via a double-acting pneumatic cylinder. The tube specimen, exemplarily shown with balanced winding angles of ±45°, undergoes a linear reciprocating motion.

A 3-axis force sensor of the type K3D120 from the manufacturer ME-Meßsysteme GmbH, with a nominal force of 1 kN per axis, continuously measures the normal, lateral, and friction forces above the sample holder of the block. For displacement measurement in the vertical direction, a laser sensor of the type optoNCDT 1220 from the manufacturer MICRO-EPSILON with a measuring range of 0-25 mm is used, while for displacement measurement in the horizontal direction, a laser sensor of the type optoNCDT 1402 with a measuring range of 0-200 mm is employed. Temperature measurement is conducted using two surface thermoelements of type K, which are attached with polyimide adhesive tape to the outer surface of the specimen and placed on the surface of the steel holder close to the steel block.

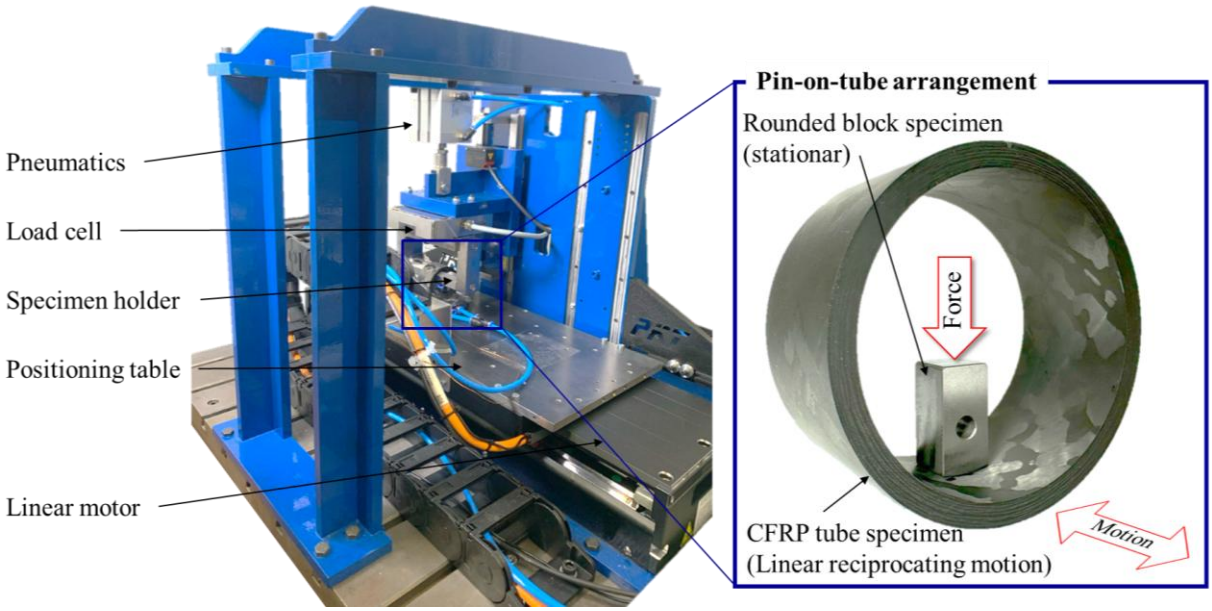

Figure 3: LRT test rig with a close-up of the pin-on-tube arrangement.

The test procedure is divided into four steps, which are followed for each test (see Figure 4). To ensure a plane-parallel contact between the triboelements, the steel block is ground with 800-grit sandpaper before the test (a). During this process, 300 grinding cycles are performed under a normal force of 50 N under dry conditions. The specimen is then cleaned with isopropanol, and the surface roughness is determined using the roughness measuring instrument MarSurf UD 120 from the manufacturer Mahr. The CFRP specimens are conditioned over a period of eight hours at a temperature of 50 °C to remove any absorbed moisture from the material and to avoid potential measurement distortions. The weight determination is carried out using the laboratory precision balance Sartorius Basic BA110S from the manufacturer Sartorius. Subsequently, the specimens are reinstalled in the LRT test rig.

Depending on whether testing is to be performed with or without lubricant, coolant lubricant is added to a bath (b). For this purpose, a water-miscible, mineral oil-based coolant concentrate from the manufacturer unitech Kühlschmierstoffe GmbH with the trade name HOSMAC-S 3630 is used. To use a solution that is as critical as possible for carbon fiber-reinforced plastics, the maximum possible coolant concentration is chosen during mixing, corresponding to an eight percent solution. For each test, 50 ml of coolant is added so that the contact area between the CFRP specimen and the steel stamp is

completely surrounded by coolant, thus achieving flood lubrication.

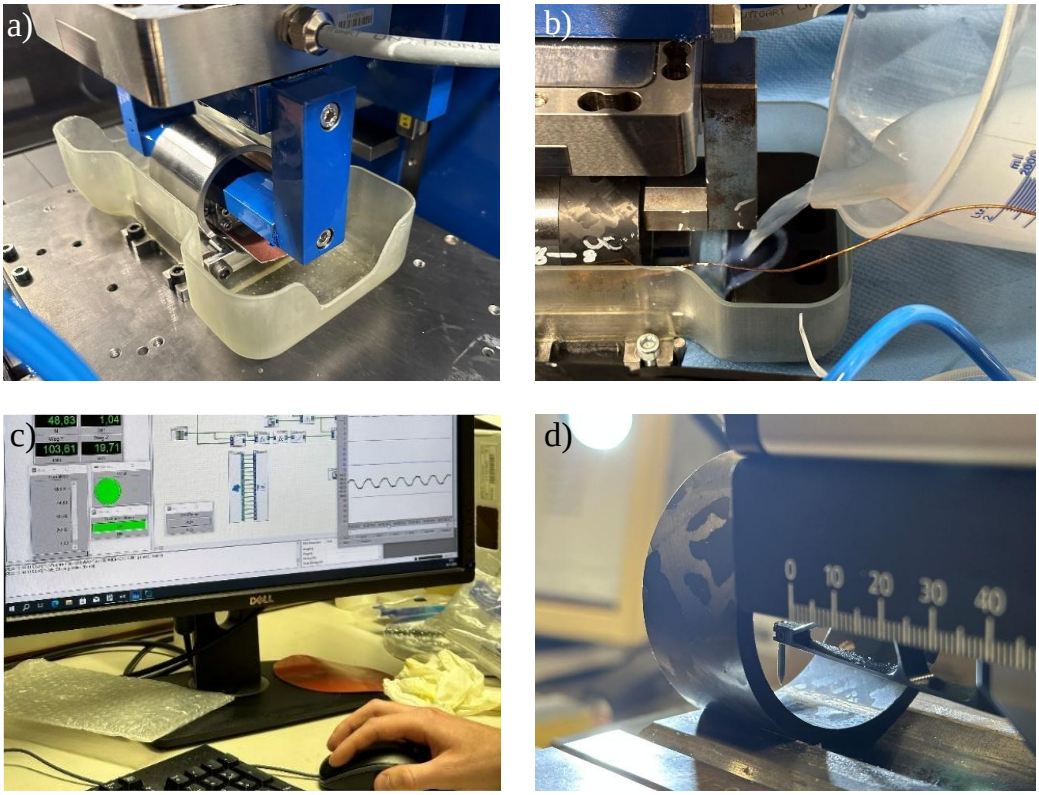

Figure 4: Steps in tribological testing: a) Running-in, b) test evaluation, c) test execution d) test evaluation.

For the tribological investigations, 20,000 cycles with a stroke length of 2 mm are conducted per test (c). The stroke length corresponds to the typical insertion path when inserting a tool holder into an HSK chuck of size 63 [13]. At a 4-axis machining center (Heller MC 12), the speed during the clamping and ejection process was determined to be 2 mm/s. Tests examining the influence of sliding speed on the coefficient of friction have shown that the effect of the sliding speed between 2 mm/s and 36 mm/s lies within the scatter of the coefficient of friction at identical sliding speeds. To reduce the test duration, a sliding speed of 6 mm/s is therefore selected, resulting in an average test duration of 6.4 hours. The test parameters are listed in Table 1.

Test parameters	Values and Properties
Sliding velocity	6 mm/s
Normal force	450 N
Surface pressure	5.4 MPa
Cycles	20000
Stroke	2 mm
Total test distance	80 m
Test temperature	21±4°
Humidity	40±5° RH
Medium	dry, coolant lubricant

Table 1: Test parameters for tribological tests

2.3 DETERMINATION OF THE COEFFICIENTS OF FRICTION AND THE SPECIFIC WEAR RATES

The recording of the forces is carried out continuously at a sampling frequency of 100 Hz over the entire test duration. The coefficient of friction is calculated from the normal force and the friction force. To determine the dynamic coefficient of friction, 20% of the friction coefficient of the half-cycle is used for the calculation. The midpoint of the half-cycle is determined via the zero crossings of the displacement. Starting from the midpoint, 10% before and after the midpoint of the cycle are used for the calculation of the dynamic coefficient of friction, as the friction force is constant in this region [14]. Subsequently, the mean values over the cycles from 10,000 to 20,000 are computed.

For the characterization of wear, the specific wear rate is determined based on the wear volume, the normal force, and the wear distance [15]. The wear volume is calculated as the product of the worn area and the linear wear amount. For the calculation, a worn area of 101 to 104 mm² is used. The linear wear amount is determined based on a contour measurement of the worn surface of the specimen. For this purpose, a perthometer from the manufacturer Mahr, type MarSurf UD 120, is used, where the surface of the specimen is scanned with a diamond tip and the contour of the worn area is traced. The measurement is then evaluated in MATLAB®.

3 RESULTS AND DISCUSSION

In the following section, the results obtained from the tribological investigations are presented and discussed. First, the influence of the KSS on the coefficient of friction is shown. Subsequently, the effect of fiber orientation in tribological tests with lubricant is examined. Finally, the coefficients of friction of the reference specimen are compared with a corresponding value from the literature.

3.1 LUBRICATION

To investigate the influence of the intermediate medium, six tests were conducted with CFRP tube specimens having a winding angle of 45° and steel counter bodies. The averaged dynamic coefficient of friction and the corresponding standard deviation for three tests each with and without lubrication are shown in Figure 5. The average coefficient of friction in the tests without lubrication is 0.31, and in the tests with KSS lubrication, it is 0.18. Lubrication of the contact area leads to a significant reduction in the dynamic coefficient of friction.

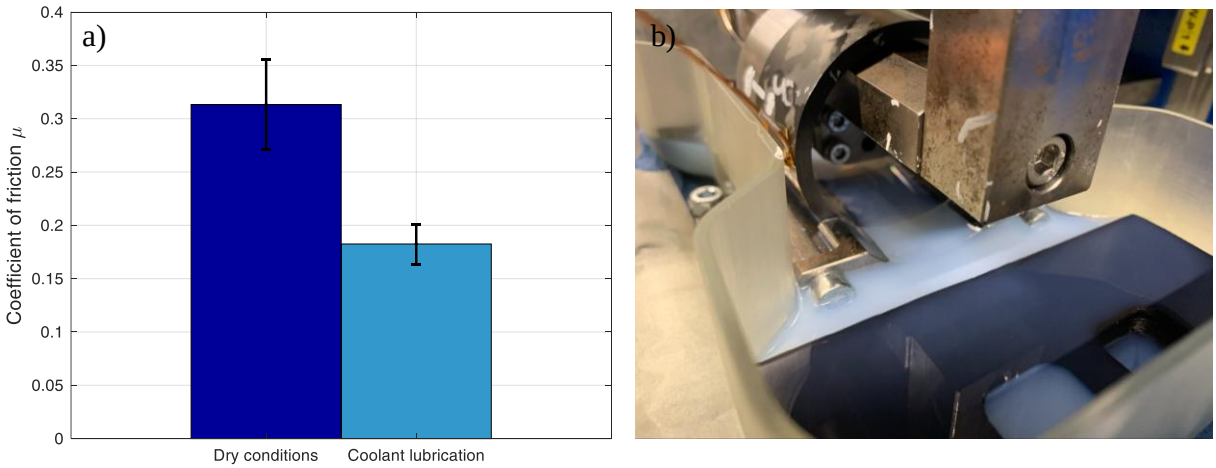

Figure 5: Tests on the influence of KSS on CFRP tube specimens with a winding angle of 45° against steel counter bodies, a) Comparison between the coefficients of friction with and without lubrication, b) mounted CFRP specimen.

In the tribological tests with KSS lubrication, no specific wear rate could be determined, as the contour changes are below the measurement resolution of the contour measurement. To visualize the wear mechanisms, the surface of the CFRP tube specimen with 45° orientation was examined using a digital microscope, the Keyence VHX-500F. Figure 6 shows a 500-fold magnification of the contact surfaces before the test (a), after the test without lubrication (b), and after the test with KSS lubrication (c) and (d). The bright elongated areas are the carbon fibers, surrounded by the darker matrix areas. After the tribological tests, fiber abrasion, breakage, and wear particles are visible both in the tests without lubrication (a) and with lubrication (b). In the test without lubrication (a), fiber-matrix debonding and matrix failure due to shear are significantly more pronounced compared to the tests with lubrication (b). These failure mechanisms were also identified by Friedrich et al. [15] in unidirectional fiber composite materials without lubrication at 0° orientation. In Figures 6 c) and d) show abrasive wear in the form of grooves along the sliding direction. Furthermore, the images demonstrate that the fibers do not run parallel to the sliding surface but pass through the crossover zone into or out of the viewing plane, resulting in fiber ends in the contact zone. Such a crossover zone is visible in Figure 6 c) after the test with KSS lubrication. Due to the winding process and the subsequent grinding process, fibers on the surface are cut, causing a local change in fiber orientation between the two winding directions. This is visible in Figure 3 by the differently bright areas on the CFRP tube with 45° orientation, which is attributable to varying light reflections due to the changing fiber layers. In Figure 6 c), it can also be seen that the fibers from the right side run under the fibers from the left side, and ´that there is no contact between the fibres and the friction partner in the transition area. The change in fiber orientation and the resulting transition zones may be reasons for the fluctuations in the dynamic coefficient of friction and the wear rate.

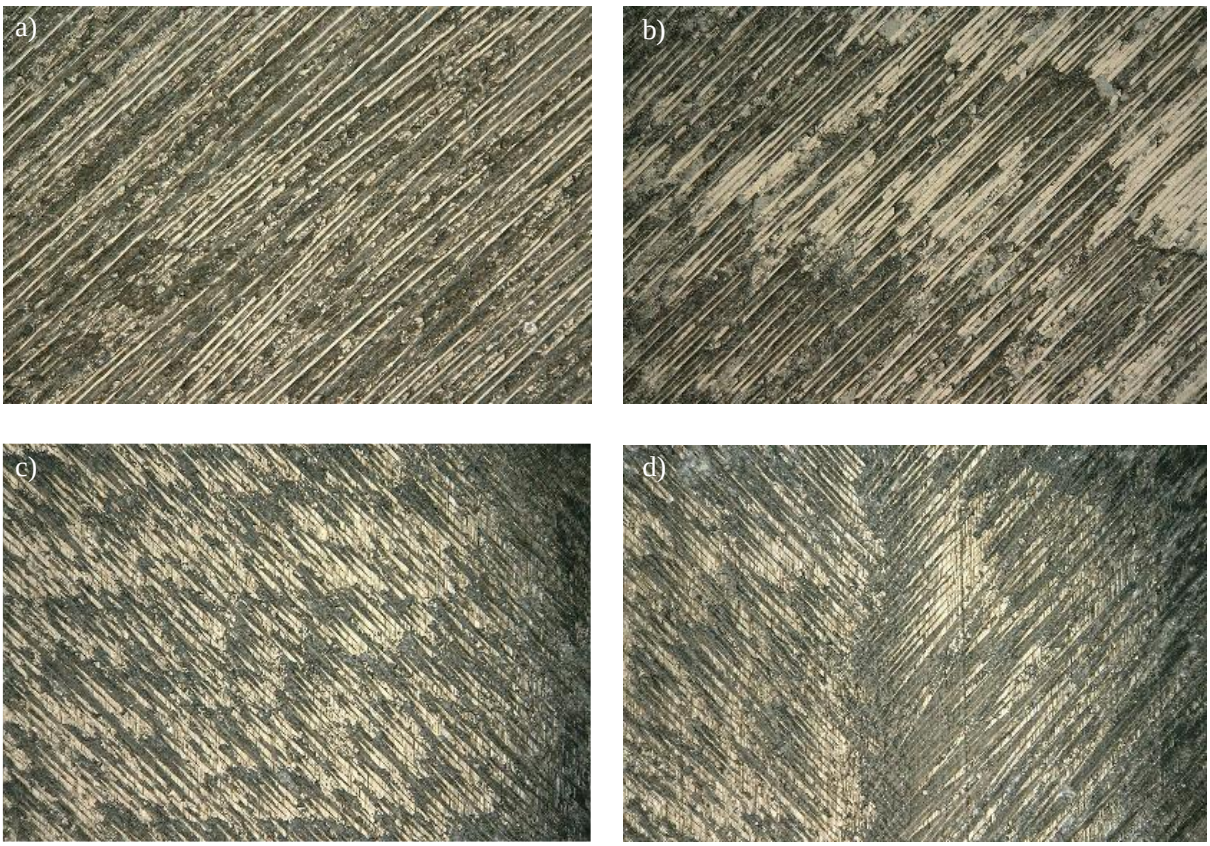

Figure 6: Microscopic images at 500x magnification of the inner surface of the CFRP tube specimen with 45° orientation and sliding direction upwards, a) before the test, b) after the test without lubrication, c) and d) after the test with lubrication.

3.2 FIBER ORIENTATION

The influence of the fiber angle on the dynamic coefficient of friction, surface quality, and specific wear rate is investigated on the CFRP specimens with different fiber angles and steel counter bodies under lubrication with KSS. In the tests, a winding angle of 0° means that the fibers are aligned parallel to the sliding direction. For the CFRP specimens with balanced winding angles of ±10°, ±45°, and ±89°, the dynamic coefficient of friction is determined. The dynamic coefficient of friction is lowest at a winding angle of ±10°, with a value of 0.17. At winding angles of ±45° and ±89°, the coefficient of friction is around 0.18. A similar influence of the fiber angle was observed by Sharma et al. [16] in tribological investigations of unidirectional carbon fibers with a polyetherimide matrix in a pin-on-disc (horizontal) configuration without lubrication. At an orientation of 0°, i.e., with the UD CFRP fibers aligned parallel to the sliding direction, the lowest coefficients of friction were found compared to 45° and 90°. Weidmann [17] confirmed this influence of the fiber angle for the orientations 0° and 90°, antiparallel to the sliding direction, in linear reciprocating pin-on-plate tests.

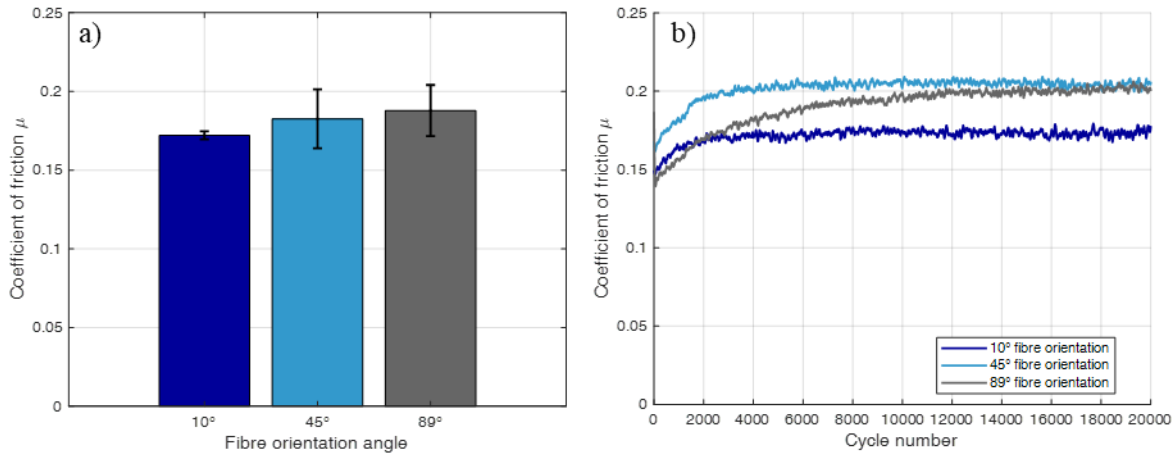

Figure 7: Coefficients of friction over fiber orientation (a), coefficients of friction over the number of cycles for different fibre orientations (b).

The influence of the tribological tests with lubrication by KSS on the surface roughness of the CFRP specimens is listed in Table 2. The surface roughness values are measured in the sliding direction, axial to the tube specimen, using the perthometer MarSurf UD 120 and averaged over three measurements. Subsequently, the roughness values are averaged across three tests, and the corresponding standard deviation is calculated. The specimen with a ±89° winding angle exhibits the highest surface roughness before the test. The surface roughness values of the specimens with ±10° and ±45° are lower. Since the same grinding parameters were used during the manufacture of the specimens, this difference is presumably due to the measurement direction of the perthometer relative to the fiber orientation and the fiber orientation itself. In grinding tests, Brouschkin et al. [18] assumed a influence of measurement direction on roughness depth as well as the influence of fiber orientation on surface quality. The tribological tests lead to a reduction in both the arithmetic mean roughness (Ra) and the average maximum profile height (Rz) values. The Ra values are reduced by 0.1 to 0.3 µm before and after the tests. A decline in Rz values is also observed for all specimens. The greatest reduction in Rz occurs in the specimen with ±89° orientation, where the Rz value decreases from 13.3 µm to 10.4 µm.

Fiber orientation	Surface roughness before test		Surface roughness after test	
[°]	Ra in µm	Rz in µm	Ra in µm	Rz in µm
10	0.7 ± 0.1	7.0 ± 1.6	0.6 ± 0.1	6.5 ± 0.9
45	1.0 ± 0.2	8.7 ± 0.5	0.7 ± 0.1	6.7 ± 2.0
89	1.0 ± 0.2	13.3 ± 2.9	0.9 ± 0.1	10.4 ± 0.5

Table 2: Surface roughness of CFRP specimens before and after tribological tests with KSS lubrication, based on Ra and Rz. Values are presented as mean ± standard deviation.

4.1 INFLUENCE OF THE PIN-ON-TUBE ARRANGEMENT

To ensure the transferability of the results obtained from the pin-on-tube arrangement to the application case, it is important to determine the influence of the arrangement. In addition to the CFRP tube specimens, tests were conducted with hardened steel tube specimens to reduce the abstraction between the application case and the specimens. Figure 8 compares the coefficients of friction in the pin-on-tube arrangement for CFRP and steel specimens under KSS lubrication with literature values for HSK interfaces according to Müller [19] and VDMA 34181 [4].

To visualize the comparison, the respective arrangements are shown above the coefficients of friction in the pin-on-tube arrangement and above the simplified HSK interface. The average coefficient of friction for the CFRP tube specimen with 10° orientation against the steel block is 0.17. For the steel tube specimen, the average coefficient of friction is 0.12 ± 0.02.

Müller [19] reports coefficients of friction between 0.12 and 0.4 for HSK interfaces based on field tests. According to VDMA 34181 [4], a coefficient of friction of 0.15 is typically used for the calculation of HSK interfaces. The guideline further states that lower values can be expected when using KSS or oil-based lubrication [4]. These literature values are shown on the right side of the figure, beneath the simplified HSK interface.

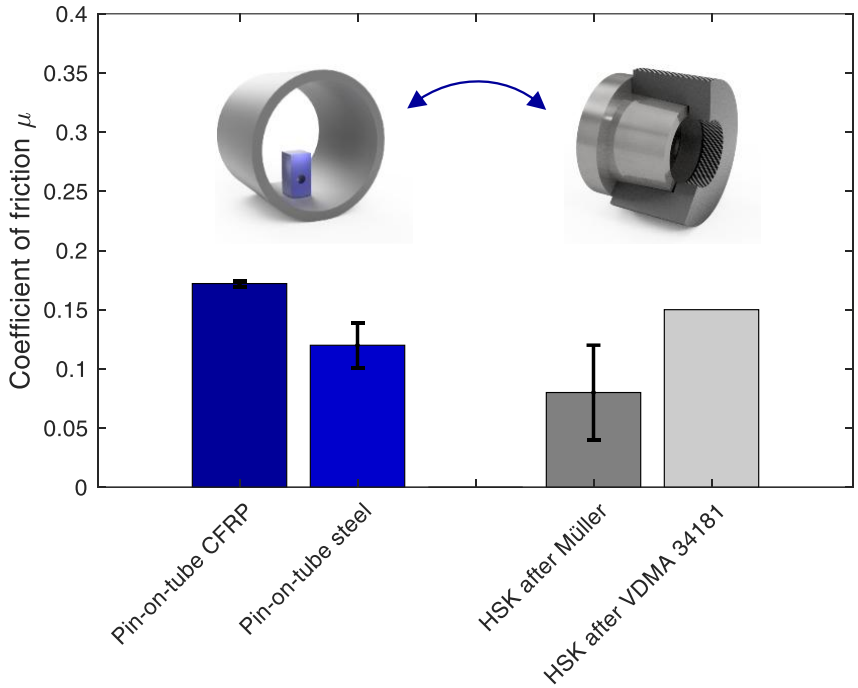

Figure 8: Coefficient of friction in the pin-on-tube arrangement for CFRP tube specimens with 10° orientation and for steel specimens against steel counter bodies compared to HSK interfaces according to Müller [19] and VDMA 34181 [4].

The closest match in boundary conditions, particularly regarding the material and the use of lubrication, is found between the steel pin-on-tube arrangement and the HSK interface described by Müller [19]. The average coefficient of friction obtained from the steel pin-on-tube tests lies at the upper end of the range reported in the literature. Since visible wear marks were observed in the pin-on-tube tests and Becher et al. [20] state that wear in HSK interfaces leads to increased friction, a transferability of the pin-on-tube results to real HSK interfaces can be assumed.

Furthermore, the observed differences in the coefficients of friction are likely attributable to variations in contact pressure and intermediate media arising from the specific test setups. These deviations must be considered to ensure a reliable transfer of the findings to the application context.

The coefficient of friction is particularly important for the HSK interface, as the frictional force opposes the insertion and ejection of the tool holder. Assuming a degree of transferability, the tests using the CFRP tube specimen suggest that, when applied to an HSK interface with a CFRP spindle, higher

frictional forces during tool clamping can be expected. These increased friction forces can be compensated by increasing the clamping force, thereby enabling the use of CFRP in such applications.

Wear in the pin-on-tube tests could not be quantified, as it remained below the measurement resolution for both CFRP and steel tube specimens. To enable a reliable assessment of wear, additional tests with a higher number of cycles should be conducted. Nevertheless, the lack of detectable wear suggests that the chosen setup is appropriate for transferability considerations. Moreover, it indicates that CFRP performs comparably to steel and does not show any disadvantages under the tested conditions. Accordingly, the test results suggest that CFRP can be used in tribologically loaded interfaces. However, further investigations using the pin-on-tube arrangement should be conducted to improve the transferability of the findings to practical applications.

5 CONCLUSIONS AND OUTLOOK

The results of this study demonstrate that CFRP is fundamentally suitable as a material for tribologically stressed interfaces. The conducted pin-on-tube tests reveal that the dynamic coefficient of friction is influenced both by the fiber orientation and by lubrication with KSS. Particularly low friction was achieved with CFRP specimens featuring a winding angle of ±10° tested against a steel counterbody, resulting in a coefficient of friction of 0.17. Under lubricated conditions, no measurable wear was detected, enabling the use of CFRP under these operating conditions. However, further tests with higher cycle numbers should be conducted to determine the specific wear rate. Microscopic analyses of the wear surfaces show that tribological loading leads to typical fiber-matrix damages such as fiber abrasion, fiber fracture, and the formation of wear particles, which are more pronounced in unlubricated specimens than in lubricated ones.

The influence of the pin-on-tube arrangement on the coefficient of friction was investigated for both CFRP and steel tube specimens and compared with literature values. The coefficient of friction measured for the steel reference specimens lies within the range of published values for HSK interfaces, indicating a reasonable degree of transferability of the findings.

The insights gained allow for further cost-effective studies on more wear-resistant polymer materials or with thermally conductive fillers. For transferability to real applications such as HSK interfaces, further investigations are necessary, for example regarding the influence of stroke and surface pressure on friction behavior and wear. To confirm the applicability of CFRP in highly stressed tribological interfaces, tribological investigations with real component geometries should be conducted.

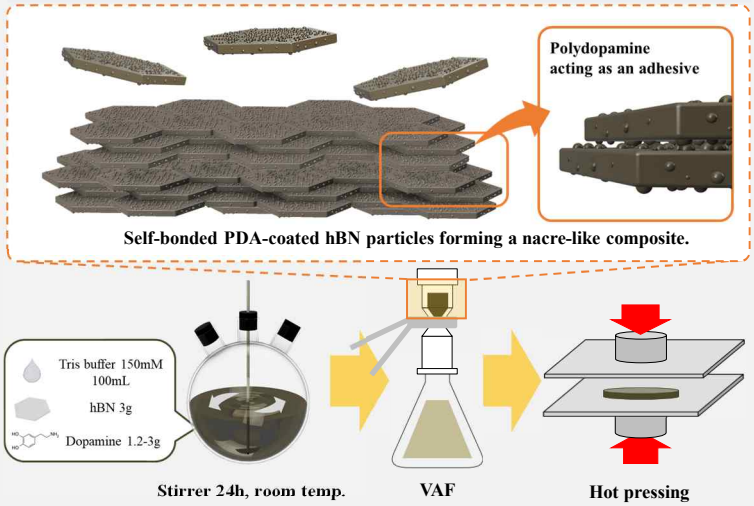
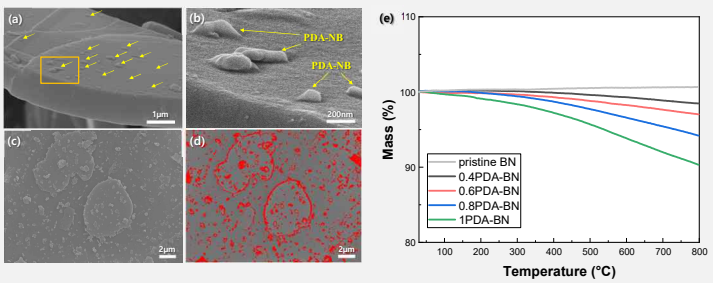
Introduction



With the ongoing miniaturization of high-density electronic devices, the demand for high-performance thermally conductive materials for efficient heat management has grown increasingly critical [1]. Heat buildup in confined spaces can degrade performance, shorten device lifespan, and cause system failures, underscoring the importance of reliable thermal interface materials (TIMs) [2]. To improve the thermal conductivity of polymer-based composites, ceramic fillers are typically added. Among them, hexagonal boron nitride (hBN) is a promising candidate due to its platelet morphology, offering high in-plane thermal conductivity (up to 600 W/m·K), electrical insulation, and chemical stability [3]. However, anisotropic conductivity of hBN strongly depends on particle orientation; random dispersion disrupts thermal pathways and reduces efficiency [4].

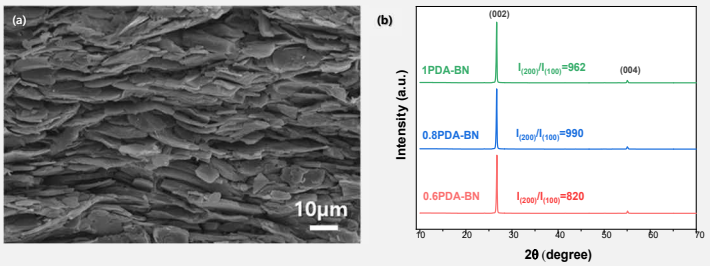
In this study, a self-binding hBN structure was developed using polydopamine (PDA) as a binder. A well-aligned brick-and-mortar architecture was constructed without any polymer matrix by inducing direct bonding between hBN platelets. Uniform PDA coating and nanobumps (NBs) formation during polymerization promoted localized secondary aggregation and strong interfacial adhesion, enabling effective in-plane heat transfer.

Experiment



- Self-polymerization of DA occurred in a 150mM tris buffer solution.
  - Extensive PDA coating on the hBN surface was induced by high concentrations of Tris buffer and DA.
- PDA-NB-hBN composites were fabricated via vacuum assisted filtration (VAF) followed by hot pressing.

Fig. 1. Fabrication of PDA-NB-hBN composites



Results & Discussion

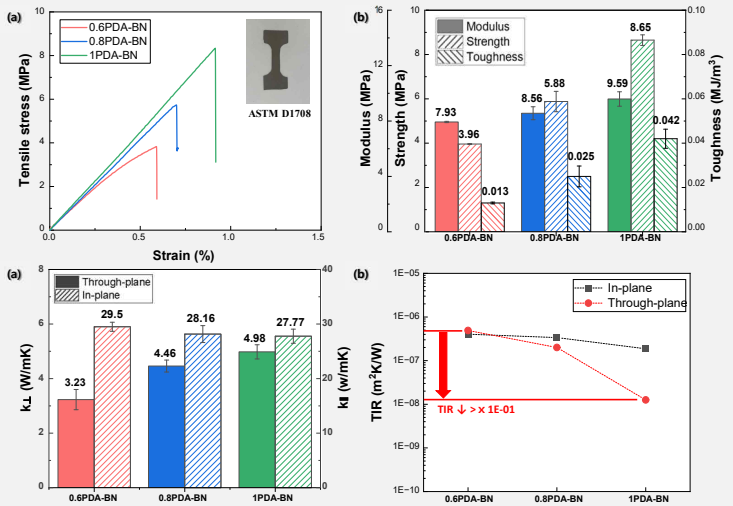
Fig. 2. (a)-(c) Surface morphology of PDA coated hBN and (d) PDA induced NBs marked in red. (e) TGA graph of PDA coated hBN.

- Two-stage PDA deposition induced by controlled polymerization
  - Uniform coating (PDA layer) → Localized aggregation (NBs)

Fig. 3. (a) Cross-sectional microstructure and (b) XRD pattern of PDA-NB-hBN.

- A well-aligned brick-and-mortar structure formed by self-bonding of PDA-coated hBN particles during VAF and hot pressing

Fig. 4. (a) Stress-strain curve, (a) tensile properties, (c) thermal conductivity and (d) thermal interfacial resistance (TIR) of PDA-NB-hBN composites.



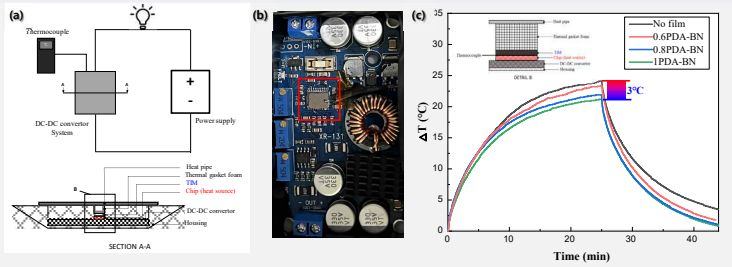


Fig. 5 (a) Schematic of the thermal dissipation test, (b) thermocouple setup and (c) time-dependent temperature difference (ΔT) of the chip

Conclusions

- Extensive PDA coating containing NBs was polymerized on the surface of hBN particles, imparting self-binding characteristics to the material.
- PDA-NBs-hBN film exhibited a nacre-inspired brick-and-mortar architecture, in which hBN and PDA functioned as the brick and mortar, respectively.
- Without the use of external binders or polymer matrices, the film achieved mechanical stability with a tensile modulus of 9.59 MPa and a tensile strength of 8.65 MPa.
- Localized interfacial adhesion by PDA-NBs reduced thermal resistance, achieving multidirectional thermal conductivity of 4.82 W/mK in the k⊥ and 27.77 W/mK in the k∥.
- The film demonstrated practical heat dissipation performance as a TIM, by reducing the maximum operating temperature by approximately 3 °C.

INTRODUCTION

As a next generation composite material, carbon fiber reinforced polymer (CFRP) has great potential to be widely used in manufacturing industries due to its outstanding mechanical properties. However, the inherent anisotropic nature of CFRP renders it vulnerable in the through-thickness direction, particularly when subjected to complex loads like as bending [1]. It is hypothesized that long carbon nanofibers aligned in the z-direction act as reinforcing pillars when the CFRP is subjected to compressive loads on the top surface. Simultaneously, the interlocked nanofiber networks are believed to enhance fiber–matrix bonding, thereby improving load transfer efficiency when tensile stresses develop on the bottom surface.

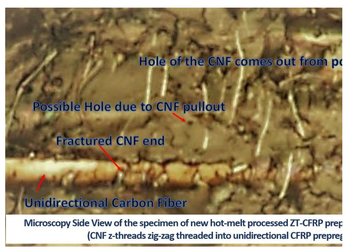

Fig 1: Top: princle behind z-threaded CFRP (ZT-CFRP) and Bottom: microscope picture of sideview of ZT-CFRP prepreg

EXPERIMENTATIONS

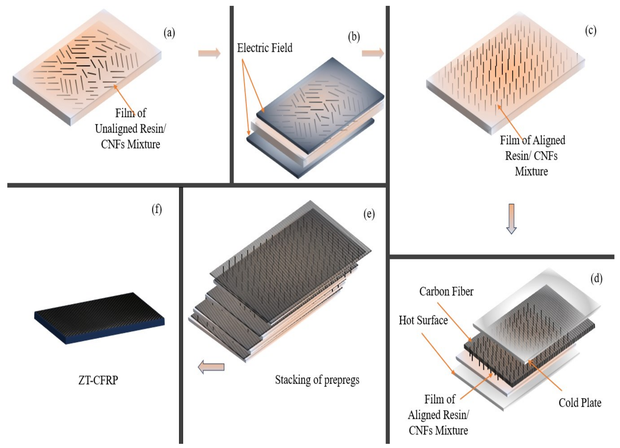

Fig 2: Depiction of the ZT-CFRP prepreg production processes.

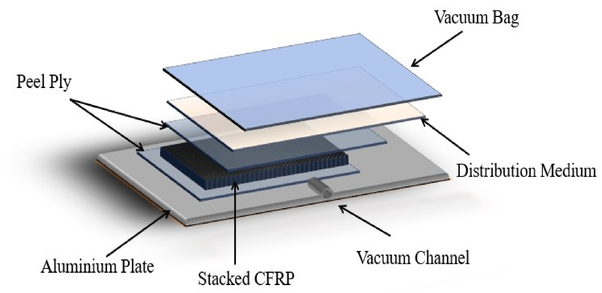

Fig 3: Schematic Diagram of OOA-VBO (Autoclave vacuum bag only) Setup

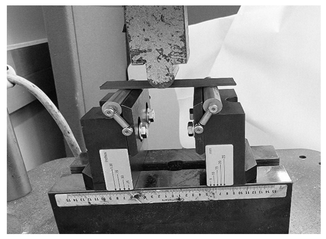

Fig 4: Experimental Setup for 3 Point Bending Test

RESULTS

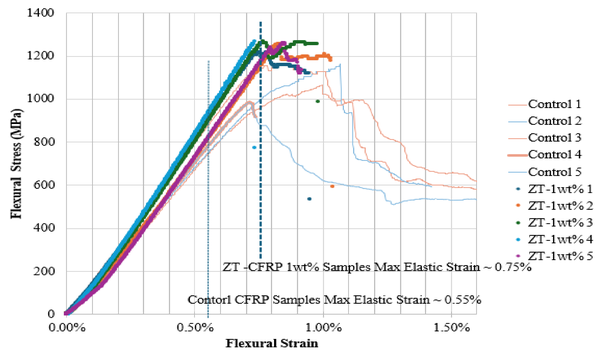

Fig 5: Flexural stress strain curve for control CFRP and ZT-CFRP.

The flexural stress, strain and movement of the cross head were calculated according to ASTM D790. The average flexural stress for control CFRP was 1067 MPa while 1228 MPa for ZT-CFRP showing 15% higher strength. The ZT-CFRP also showed 36% enhancement in the linear elastic strain compared to control CFRPs

Table 1: Flexural properties of control and ZT-CFRPs

CFRPs	Fiber Volume Fraction (%)	Avg. Force (N)	Avg. Flexural Strength (MPa)	Max. Linear Elastic Strain (%)	Max. Linear Elastic Stress (MPa)
Control CFRP	53	1076	1067	~0.55	~800
1.0 wt.% ZT-CFRP	52	1230	1228	~0.75	~1228
Improvement of ZT-CFRP	-	-	+15.1%	+36.4%	+53.5%

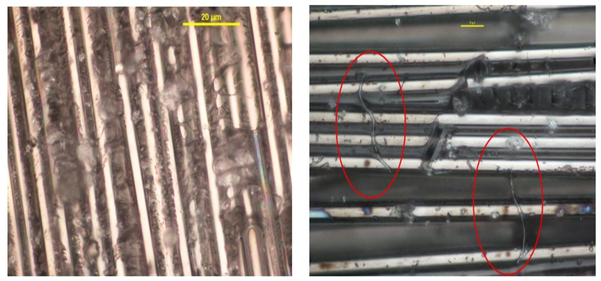

Fig 6 : Top-side microscopic images of the control CFRP (left) and ZT-CFRP (right), captured at 1000x and 1250x highlight significant microstructural differences between the two materials. The control CFRP surface appears relatively smooth whereas the ZT-CFRP clearly exhibits an interlocked network of nanofibers.

CONCLUSIONS

In the three-point bending test, the control CFRP exhibited higher deflection compared to the ZT-CFRP, indicating that it is more flexible and less stiff. This greater deflection suggests that the control sample has lower resistance to bending, potentially due to weaker fiber–matrix interactions or lower structural reinforcement. In contrast, the reduced deflection observed in the ZT-CFRP implies improved stiffness, likely resulting from enhanced interfacial bonding.

Keywords: vertically aligned carbon nanotubes (VACNT), chemical vapour deposition, industrialisation, nanoengineered interleave, carbon fiber reinforced polymers, mechanical properties

ABSTRACT

The incorporation of vertically aligned carbon nanotubes (VACNT) at the interply region of laminated structures has demonstrated significant reinforcement of carbon fiber reinforced polymers (CFRP) composite materials [1]. This reinforcement mechanism results from the deflection of micro-cracks towards strong intralaminar regions instead of their propagation along weak interlaminar ones [2], thus reducing delamination. Furthermore, VACNT interplies have been shown to enhance the thermal, electrical, and gaz impermeability properties of structural composites, thereby opening more opportunities to benefit from multifunctionalities [3].

Traditionally, the integration of such a reinforcing nanoengineered layer at the interface between plies involves the direct transfer of the VACNT layer from its original substrate (utilized during the synthesis process via catalytic CVD [4]) onto the surface of a carbon fiber ply pre-impregnated with resin (Figure 1a), the subsequent steps of the composite manufacturing process remaining unchanged. However, despite the simplicity and straightforwardness of this approach, it suffers from limitations in terms of cost-efficiency, scalability and carbon footprint for practical deployment at large scale.

A more industrially viable solution would involve the development of a VACNT supporting film (Figure 1b) that would be fully integrable into the final CFRP structure as an interleave. This methodology would significantly facilitate the commercial distribution and seamless integration of VACNT into existing manufacturing processes of advanced laminated composite parts.

In this study, we report recent progress towards developing such a nanoengineered interleave.

1 INTRODUCTION

In today's competitive engineering landscape, industries like aerospace, energy, infrastructure and sporting goods increasingly rely on composite materials to meet stringent design requirements. These applications demand materials that are lightweight, strong, cost-effective and easy to manufacture. A notable innovation is the integration of VACNT in between plies of laminated composites, commercially available and known as NAWAH Stitch.

NAWAH Stitch is a cutting-edge 3D nanocarbon interface for laminated composites materials. It provides enhanced mechanical, electrical and thermal properties to fiber reinforced plastics (FRP) without altering the part design and manufacturing process. Incorporating NAWAH Stitch between composite layers (Figure 1) improves toughness and impact resistance, reduces delamination and prolongs service life. Additionally, the use of NAWAH Stitch allows composite parts to be functionalized for advanced applications such as de-icing, in-situ matrix curing and structural health monitoring [5].

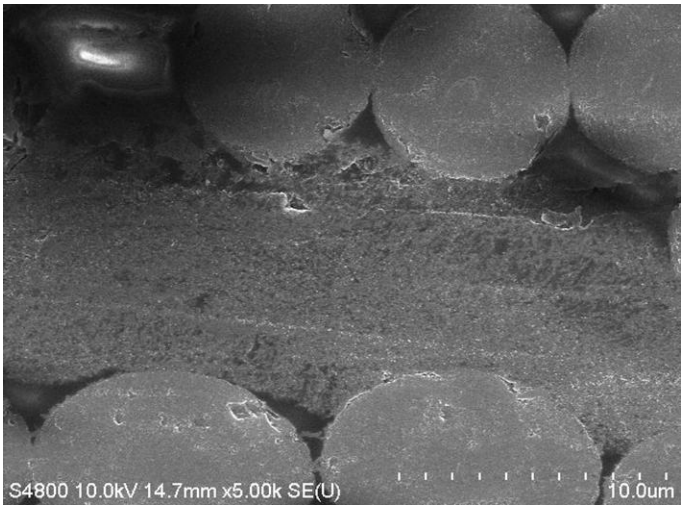

Figure 1 SEM of VACNT inserted between two carbon fiber composite plies

NAWAH is a global manufacturer of VACNT that produces this material at industrial scale on flexible metal sheets in a roll-to-roll fashion (Figure 2). This is done through a continuous atmospheric pressure chemical vapour deposition (APCVD) process at two production sites located in Rousset (France) and Dayton, Ohio (USA).

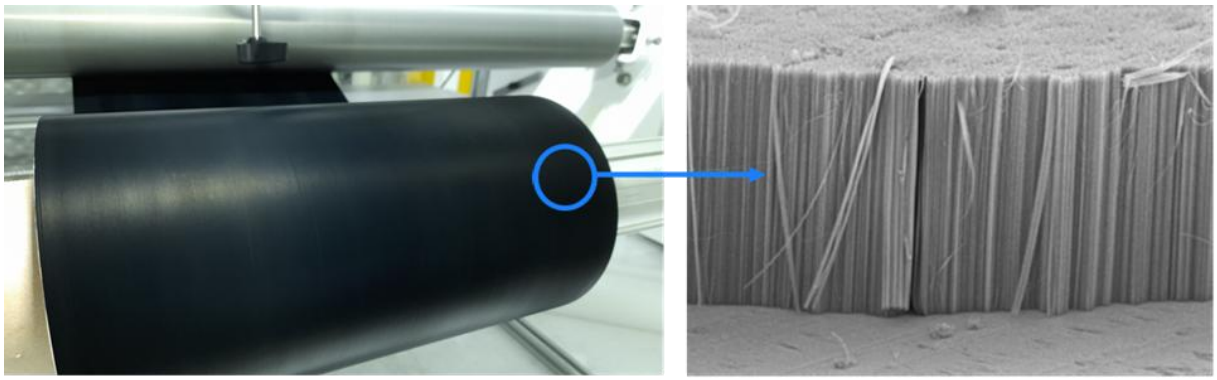

Figure 2 Vertically Aligned Carbon Nanotube synthesized by APCVD Roll-to-Roll process at NAWAH (left – post-synthesis optic visualisation and right – SEM VACNT on metallic support)

2 STATE OF THE ART

The added values of integrating VACNT at interplies have already been demonstrated by many previous studies [6,7]. These demonstrations always involved a direct transfer of VACNT onto the surface of prepreg plies. This approach (Figure 3), although efficient, suffers from several drawbacks that hinder their industrial scale deployment and adoption by the composite industry including:

- high logistics cost and CO2 footprint,
- reduced prepreg shelf lifetime.

This is mainly because thermosetting resins like epoxy must be stored at low temperature and have a limited shelf lifetime.

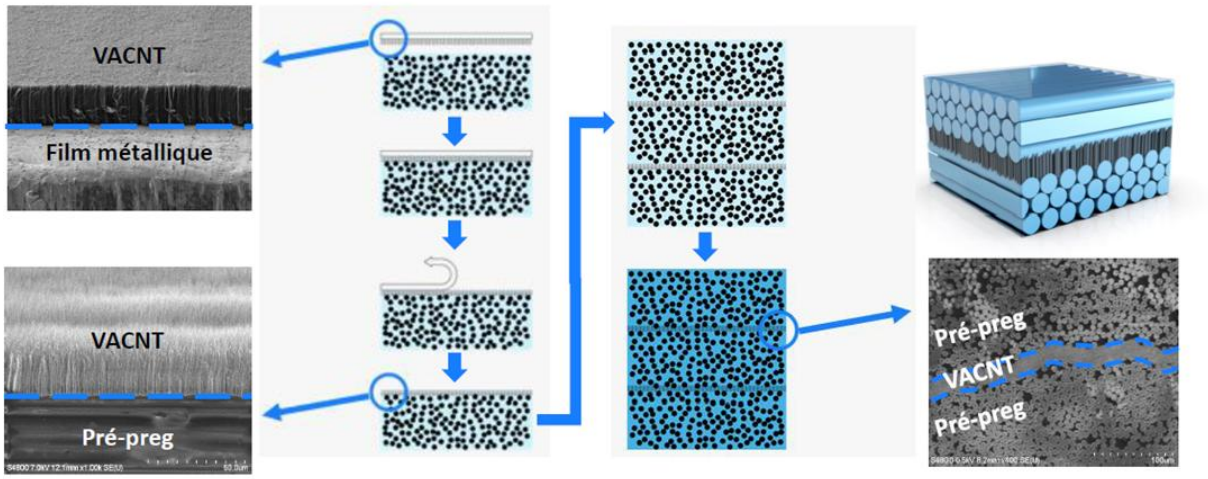

Figure 3 Standard process flow for integration of NAWAH Stitch

Therefore, a new method allowing for room temperature storage and easy handling would be highly advantageous. We report here below such a method.

3 NEW RESULTS

Thermoplastic (TP) polymers are stable at room temperature and some of them are miscible in epoxy resins [8]. Several epoxy-miscible thermoplastic films have thus been tested as support film for VACNT with the aim of:

(a) allowing for efficient transfer of VACNT from their original growth substrate,
(b) minimizing the weight and volume increase of the composite part due to the addition of the thermoplastic film as an interleave between prepreg plies,
(c) ensuring good compatibility with epoxy systems by avoiding any alteration of the original properties,
(d) retaining the beneficial properties of the inserted VACNT by providing a direct bridging of the fibers of adjacent plies by the carbon nanotubes,
(e) providing a low cost, scalable and stable at room temperature solution
(f) allowing for an easy handling and utilisation by the customer as an interleave in his composite manufacturing process.

The VACNT integration process with this method is illustrated in Figure 4.

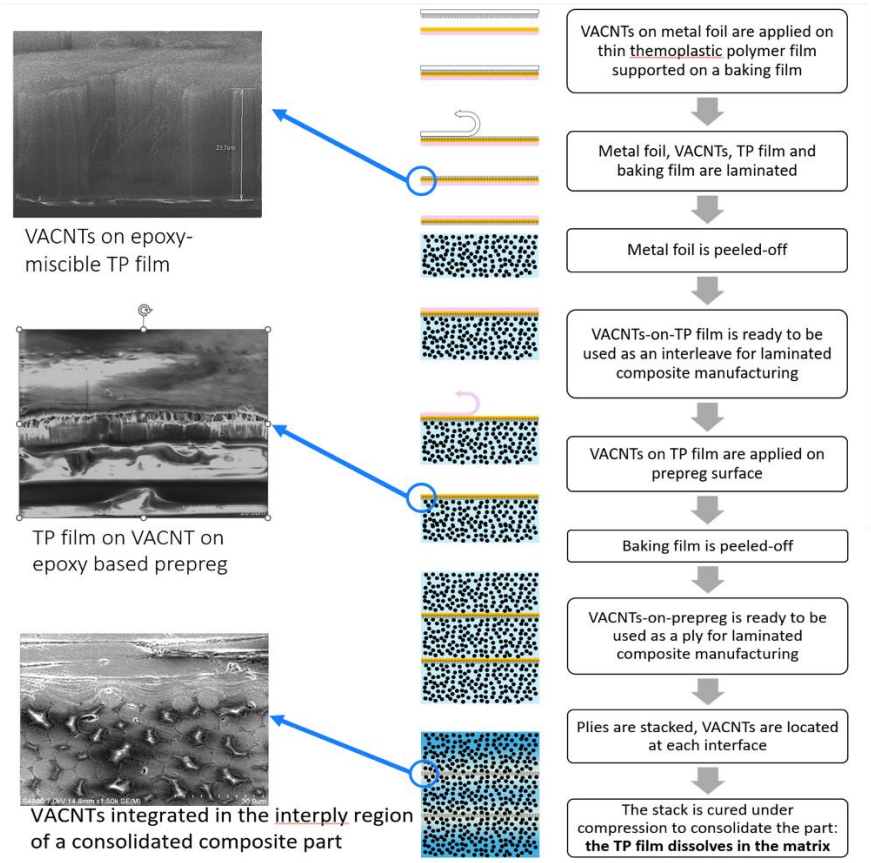

Figure 4 NAWAH's interleave method: integration via interleaving an epoxy-miscible thermoplastic polymer film supporting the VACNT

Several thermoplastic polymers have succesfully been used to practically implement this new method. As an illustration, Figure 5 shows a reference roll of VACNT directly transfered on a prepreg and an exemple of a roll of VACNT transferred on a thin (typically 1µm thick) thermoplastic film.

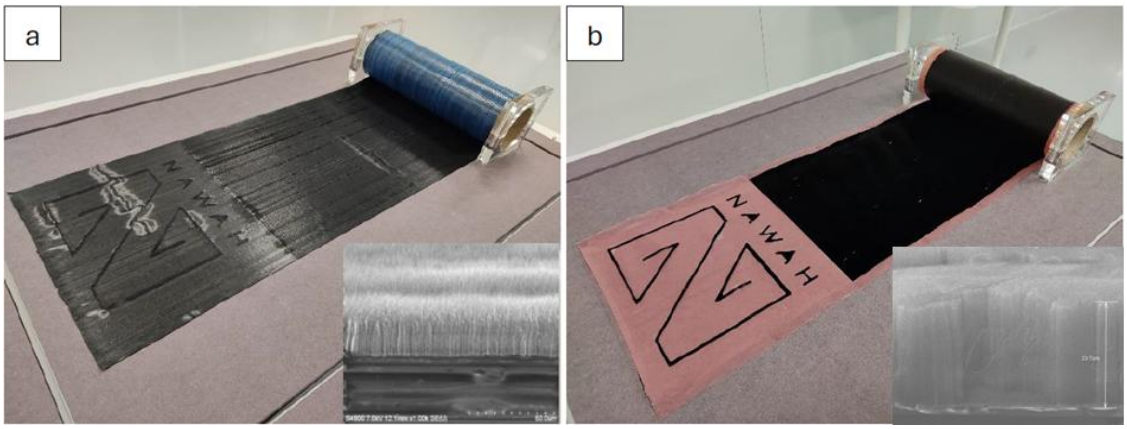

Figure 5 a) Roll of VACNT layer directly transfered on carbon fiber ply pre-impregnated with resin, b) Roll of VACNT layer tranfered on thin thermoplastic film (both with SEM image inserts).

To demonstrate that all requirements specified above are met, reference composite panels have been prepared without NAWAH Stitch (Baseline) and compared with similar parts integrating NAWAH Stitch with the interleave method.

For this comparison, the selected prepreg system and layup was the HexPly® 8552S/37%/AGP280/C woven system from Hexcel with a $[0]_{12}$ layup. The panels were assembled and cured in autoclave according to the specifications of the prepreg manufacter with the only difference for the NAWAH Stitched panel being the insertion of a TP film supported VACNT interleave beween every prepreg ply. The thickness of the two cured panels were measured and the difference was found to be unsignificant (lower than 5%).

A morphology comparison of the resin-rich interply regions was captured by scanning electron microscopy (SEM) cross sections (Fig. 6). It confirms that the interply thickness (between yellow arrows on Figure 6) remains unchanged with or without NAWAH Stitch (typically 10-15µm). In particular, the VACNT supporting thermoplastic film is no longer visible after curing, thus confirming its dissolution into the epoxy matrix. As targeted, the VACNT layer bridges the carbon fibers from adjacent plies, this configuration being the most favorable to achieve enhanced mechanical properties.

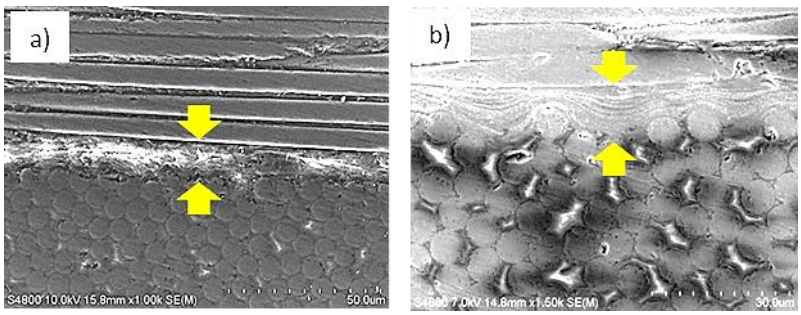

Figure 6 a) SEM Cross-section of baseline CFRP , b) SEM Cross-section of CFRP with integrated NAWAH Stitch interleave

4 CONCLUSIONS

VACNT layers inserted between plies of laminated composites, commercially available and known as NAWAH Stitch, have long proven their advantages but the adoption of this technology by the composite industry has been limited so far by the classical method for transferring them directly on prepreg surface. A new method involving the transfer of VACNT on an epoxy-miscible thermoplastic film and the subsequent use of this film as an interleave in the composite manufacturing process was reported. The successful bridging of fibers from adjacent plies in a laminated epoxy-based CFRP composite was demonstrated by using this new method, without measurable increase of thickness.

Further steps at NAWAH include static mechanical testing for strength under short-beam shear (SBS) interlaminar shear stress (ILSS) and fatigue life testing under 3-points bending cycles. Besides, efforts continue towards full roll-to-roll scale up of this technology at the level of VACNT synthesis, thermoplastic film production and VACNT transfer on this film.

These results pave the way for lower cost, lower CO2 footprint, easier processability and wider adoption of VACNT technology by the composite industry.

ACKNOWLEDGEMENTS

The whole manufacturing and R&D teams at NAWAH are gratefully acknowledged for their active contribution to the achievements presented here.

Keywords: Nanocomposites, *In-situ* polymerization, Phenolic Resin, Nanodiamond

ABSTRACT

In this study, the effects of nanodiamond (ND) on the structure and properties of phenolic resin nanocomposites were investigated. It was found that ND was well dispersed in the nanocomposites at low contents below 0.05 wt%. Regarding thermal properties, the nanocomposites containing 0.01 wt% ND exhibited the highest thermal decomposition temperature. In contrast, the rate of increase in thermal decomposition temperature was significantly reduced at higher filler contents above 0.5 wt%, suggesting the formation of severe agglomerates. Both the flexural modulus and flexural strength increased with the incorporation of ND at low contents, indicating that the strong reinforcement effects of ND were due to its high dispersibility and favorable interfacial interactions.

1 INTRODUCTION

So far, high-tensile steel and aluminum alloy materials have often been used for transportation equipment. In recent years, global environmental concerns have driven efforts to reduce the weight of car and aircraft to improve fuel efficiency. Therefore, polymer composites, which have a lower specific gravity than metallic materials, have attracted a great deal of attention as alternative materials.

Phenolic resin (PF) is well known for their excellent electrical insulation, heat resistance and flame resistance. They have been used in industrial applications such as insulators for automotive parts and circuit boards. Due to its rigidity, it is difficult to incorporate other materials to PF by conventional methods such as solvent mixing or melt mixing. To the best of our knowledge, there are very few reports on PF composites with improved mechanical or thermal properties.

In this study, we prepared PF nanocomposites with nanocarbons by *in-situ* polymerization. We used nanodiamond (ND) as filler. ND is a nanocarbon with a particle size of less than 10 nm with primary diamond particles in the core. It shows high strength, high elastic modulus and high thermal conductivity derived from diamond. In addition, ND can disperse at nano-scale in water due to abundant oxygen-containing functional groups, such as hydroxy groups, carboxy groups and carbonyl groups, on the surface. Prior to the polymerization, ND was dispersed in the solvent and then PF was polymerized under the presence of ND. The structure and the properties of the PF/ND nanocomposites were evaluated.

2 SAMPLE PREPARATION

PF was mixed with ND/ethanol dispersion and sodium hydroxide. The mixture was stirred and heated in an oil bath for 20 minutes. When the temperature reached 80 ℃ formaldehyde solution was added to the mixture. After the reaction, the mixture was cooled to room temperature and then cased on aluminum cups, vacuum dried followed by curing. PF/ND nanocomposites with the filler content of 0 ~ 0.5 wt% with a thickness of about 1 mm were prepared.

3 RESULTS AND DISCUSSION

3.1 SEM

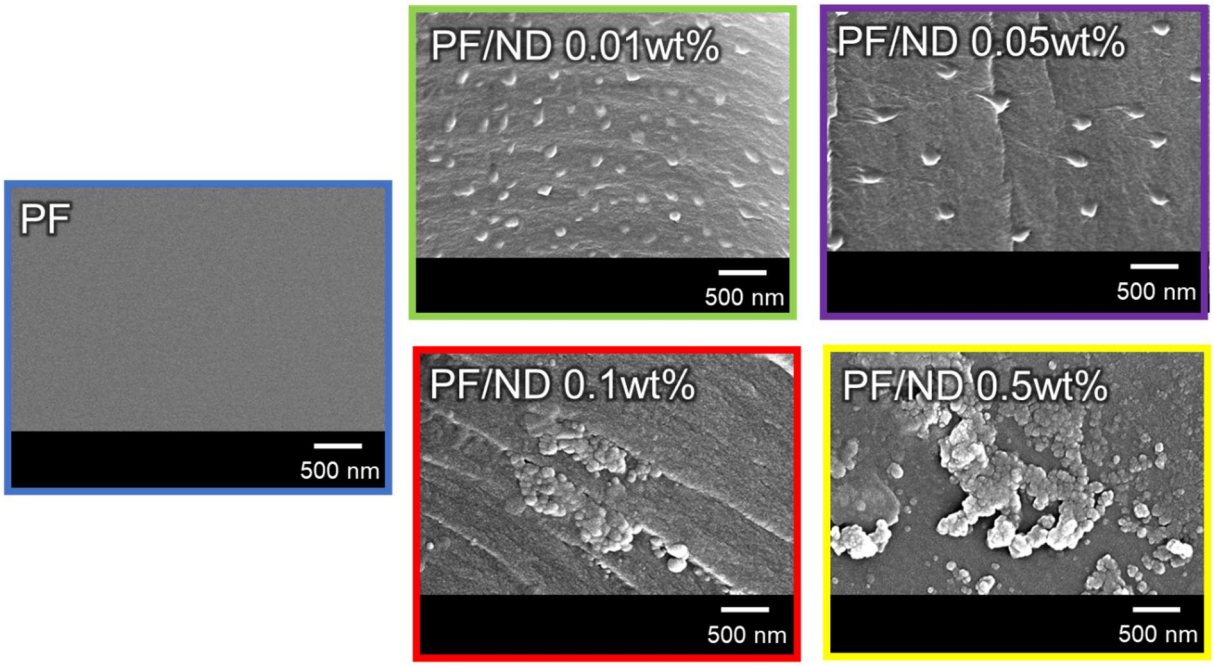

Figure 1 SEM images of PF and PF/ND nanocomposites.

Figure 1 shows SEM images of PF and PF/ND nanocomposites. It was found that ND were well dispersed in the nanocomposites at filler contents of 0.01 wt% and 0.05 wt%. On the other hand, agglomerates of ND were observed in the nanocomposites with 0.1 wt% or higher. The size of the agglomerates increased as the filler content increased, suggesting that agglomeration was promoted as the inter-particle distance decreased.

3.2 Thermal Properties

Figure 2 shows thermogravimetric traces of PF and PF/ND nanocomposites. The 5% weight loss on this curve is defined as the thermal decomposition temperature. The thermal decomposition temperature increased by the addition of ND.

Figure 3 shows thermal decomposition temperature of PF and PF/ND nanocomposites. The nanocomposites with a filler content of 0.1 wt% showed the highest thermal decomposition temperature, and it was 44 ℃ higher than that of PF. It was suggested that the movement of PF molecular chains were effectively suppressed by the highly dispersed ND with high interfacial area, resulted in significant improvement of resistance. On the other hand, the thermal decomposition temperature decreased for the nanocomposites with a filler content of more than 0.5 wt%. As shown before, ND formed serious agglomerates at high filler content. Therefore, the reinforcement effect decreased due to the decreased interfacial area. In addition, these agglomerates could cause heat concentration, that brought the thermal decomposition of the material.

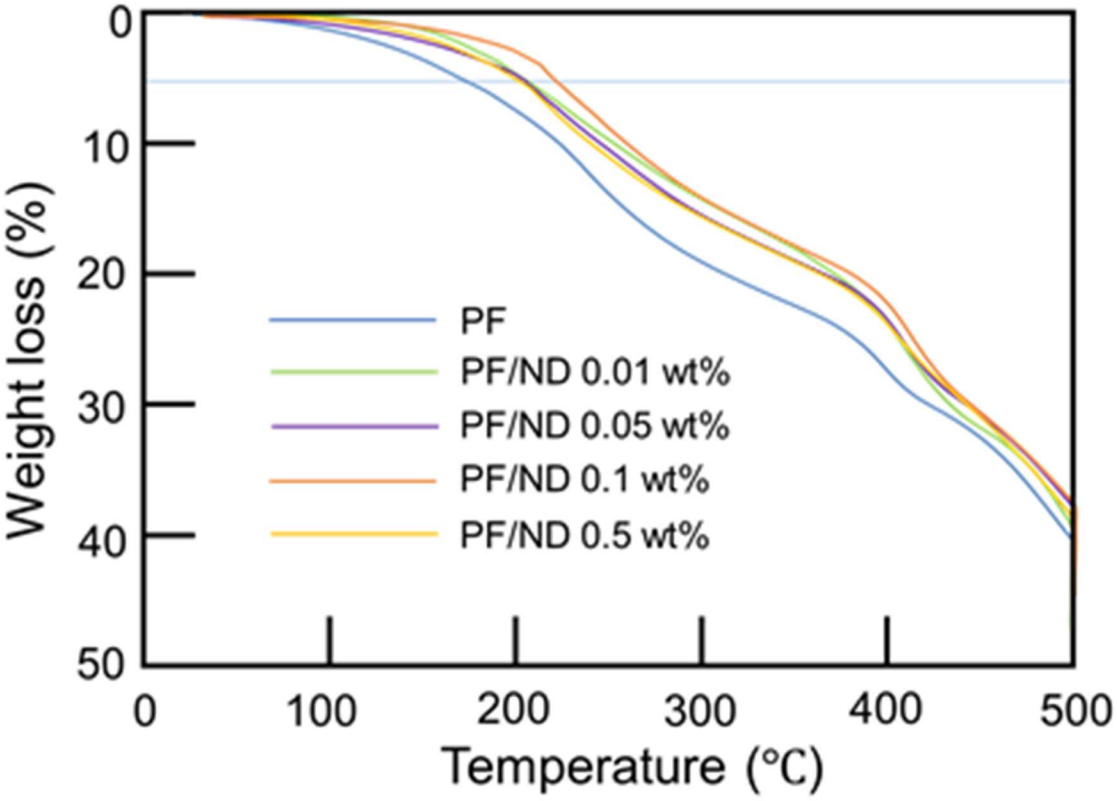

Figure 2 Thermogravimetric traces of PF and PF/ND nanocomposites.

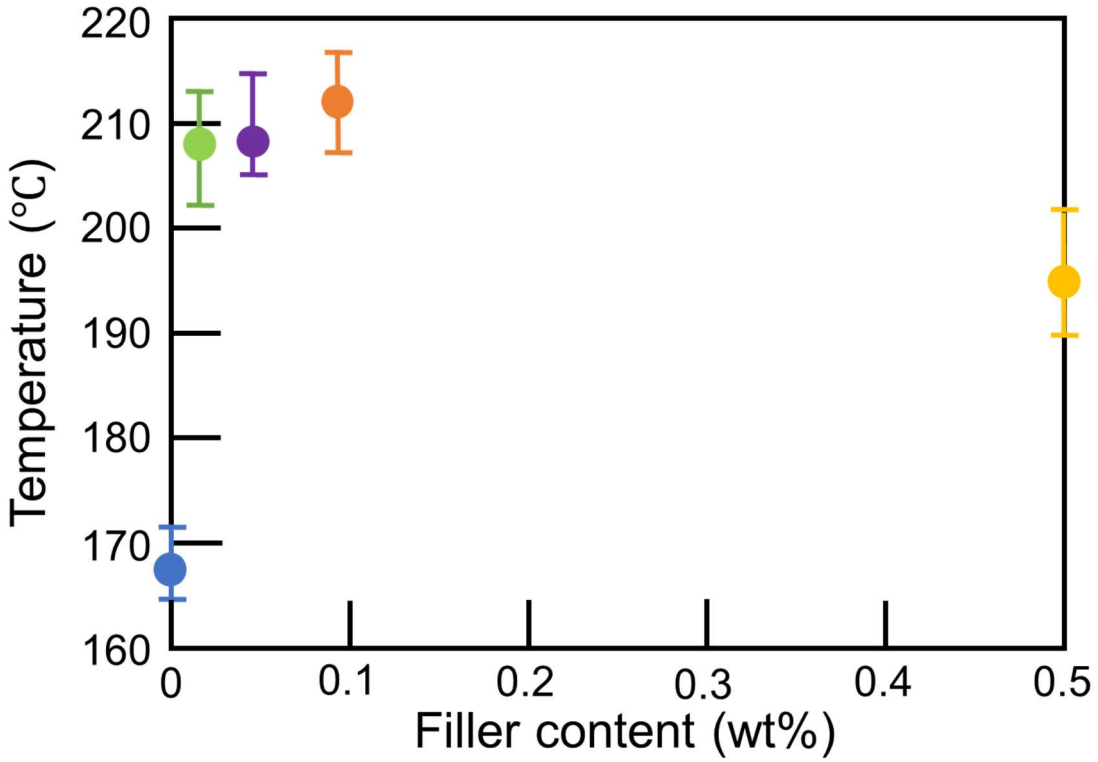

Figure 3 Thermal decomposition temperature of PF and PF/ND nanocomposites.

3.2 Mechanical Properties

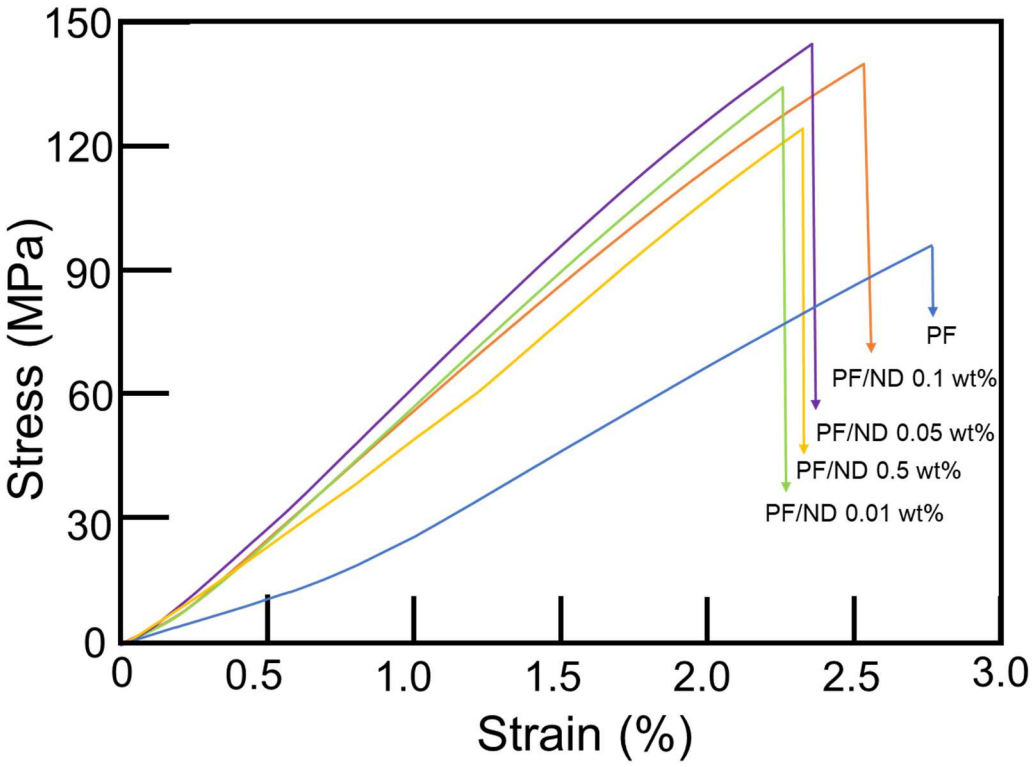

Figure 4 Stress-strain curves of PF and PF/ND nanocomposites.

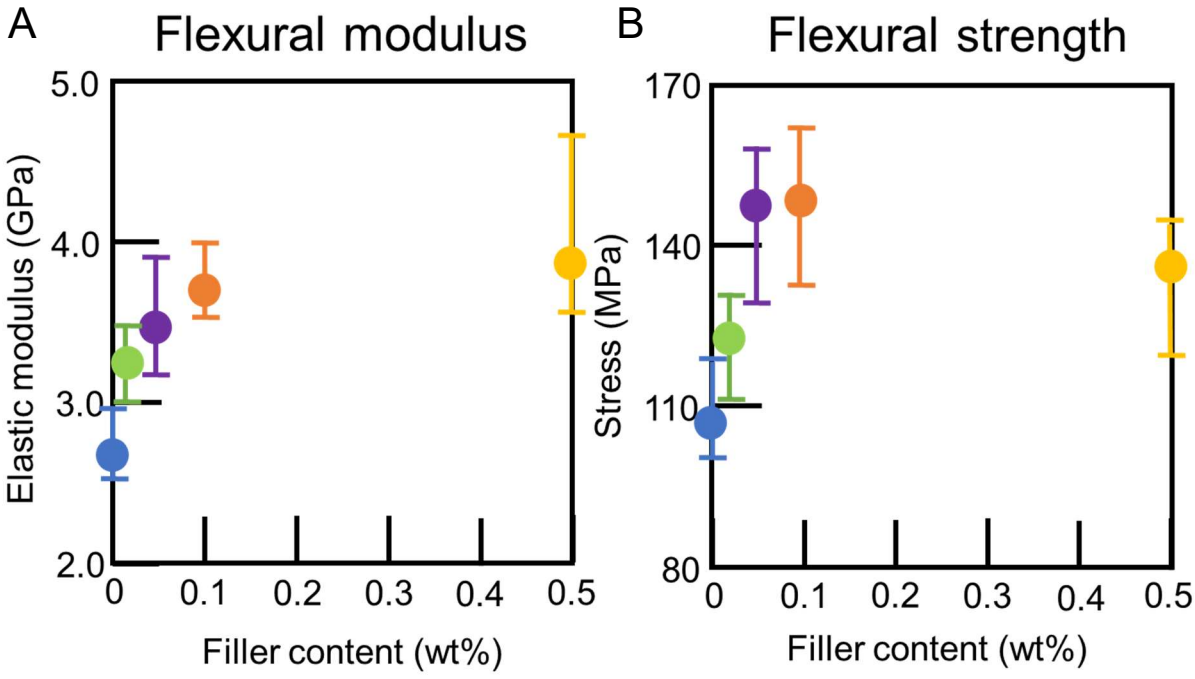

Figure 5 Flexural modulus and flexural strength of PF and PF/ND nanocomposites.

Figure 4 shows stress-strain curves of PF and PF/ND nanocomposites. The maximum stress corresponds to the flexural strength, and the initial gradient corresponds to the flexural modulus.

Figure 5 (A) shows flexural modulus and Figure 5 (B) shows flexural strength of PF and PF/ND nanocomposites. The flexural modulus increased with the increasing of ND content. Compared to PF, the flexural modulus increased by 38% at a filler content of 0.1 wt% and increased by 50% at a filler content of 0.5 wt%. Similarly, the flexural strength increased with increasing of ND content up to 0.1 wt%. Compared to PF, the flexural strength increased by 36% at a filler content of 0.1 %. However, the increasing rate started to decrease at the filler content of 0.5 wt%. In the low filler content region, ND were highly dispersed in PF, resulting in an excellent reinforcing effect. On the other hand, above a filler content of 0.5 wt%, the nanocomposites showed brittle behavior due to stress concentration caused by aggregates.

3.3 Interfacial interactions

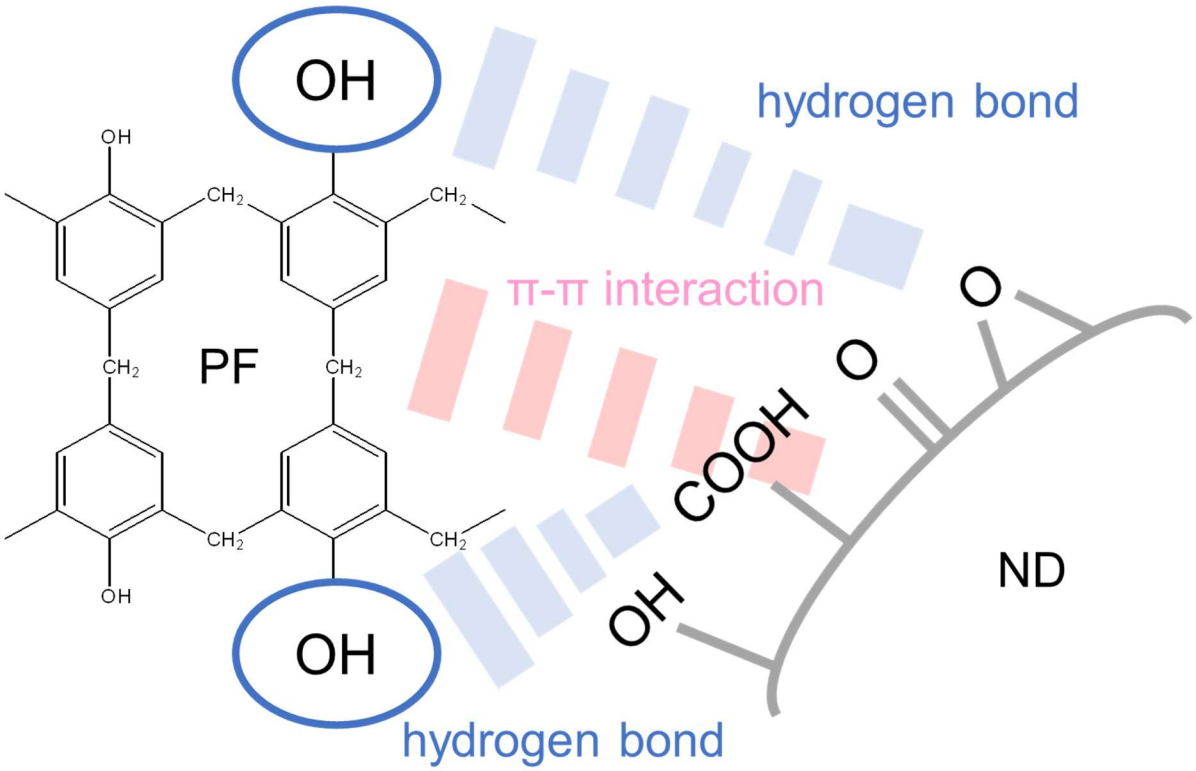

Figure 6 Scheme of interfacial interactions in PF/ND nanocomposites.

Figure 6 shows scheme of interfacial interactions in PF/ND nanocomposites. The thermal and mechanical properties shown above are thought to be largely influenced by the dispersibility of ND in PF and the interaction at the interface between PF and ND. As mentioned before, ND has abundant oxygen-containing functional groups on their surface. Therefore, ND can form hydrogen bonds with phenolic groups of PF. In addition, it was assumed that π-π interactions were formed at the interface between the graphite of ND and the benzene ring of PF. These strong interfacial interactions together with the high dispersibility can be the main factor for the enhancement in the mechanical properties as well as the thermal properties.

4 CONCLUSIONS

PF/ND nanocomposites were prepared by *in-situ* polymerization. In the PF nanocomposites ND were well dispersed in the nanocomposites up to 0.1 wt% or lower. The thermal decomposition temperature increased by the incorporation of ND. The flexural modulus and the flexural strength increased by the incorporation of ND.

IN-SITU SYNTHESIS OF POLYAMIDE COMPOSITES WITH RECYCLE CARBON FIBER

ABSTRACT

Here in, rCF and polyamide 66 (PA66) were prepared by *in-situ* polymerization. As a result, rCF was highly dispersed in PA66. Due to the low interfacial area as well as the poor interfacial interaction, the thermal decomposition temperature decreased by the addition of a small amount of rCF. On the other hand, at high content region, the excellent reinforcement effects of rCF were exploited. The composites with high content of rCF also exhibited significant improvement in the mechanical properties.

1 INTRODUCTION

In recent years, polymer composite materials are expected to replace metal materials due to their light weight and ease of processing. In particular, carbon fiber-reinforced plastics are attracting attention as materials for automobiles and aircraft because of their light weight, high strength, and heat resistance. However, the high cost of manufacturing carbon fiber (CF) and the environmental impact of the manufacturing process have slowed the spread of CF despite its demand. One countermeasure is to recycle CF. Although recycled carbon fiber (rCF) has the problem of uneven quality due to the fact that it is a recycled material, it is attracting attention as a solution to environmental problems such as global warming, which has become an issue in recent years.

In this study, composite materials of rCF and polyamide 66 (PA66) were prepared by in-situ polymerization. In in-situ polymerization, the filler is added to the solvent used to synthesize the polymer, and the polymer is synthesized in the presence of the filler. Since the synthesis proceeds while the filler remains dispersed in the solvent, the dispersibility of the polymer composite can be improved.

PA66, which was selected as the base material this time, is in demand in a wide range of fields such as automobile parts and electrical and electronic equipment because of its high strength, heat resistance, and chemical resistance among polymeric materials. Therefore, it is a substance that is being researched for further improvement of its mechanical and thermal properties.

2 SAMPLE PREPARATION

Hexamethylenediamine was added to rCF water dispersion, and then sodium hydroxide was added. The mixture was stirred for one hour to obtain solution A. Solution A was added to a mixture of carbon tetrachloride and adipoyl chloride and polymerized at the interface. The resultant was then purified by reprecipitation, dried and melt-pressed to obtain PA66/rCF composites with a thickness of 0.2 mm. The filler content was 0 to 30 wt%.

3 RESULTS AND DISCUSSION

3.1 Optical image

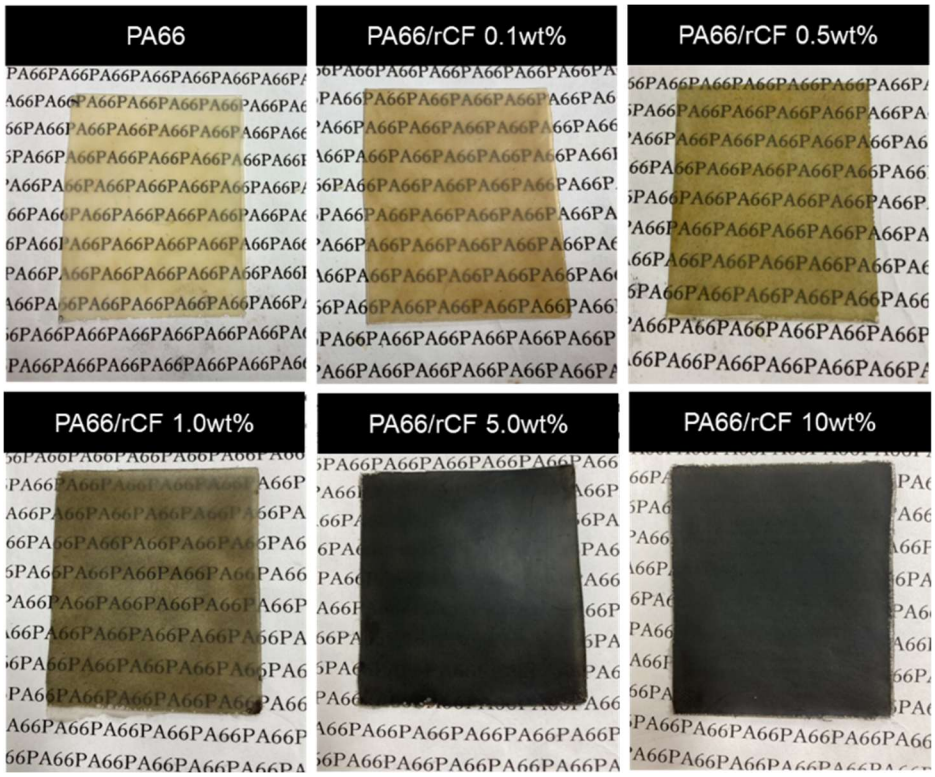

Figure 1: Optical image of PA66 and PA66/rCF composites.

Figure 1 shows optical images of PA66 and PA66/rCF composites. The transparency of the composites decreased with increasing of the filler content. The composites with more than 5.0 wt% of rCF is almost opaque. From these images of the composites, the agglomerates of rCF were not observed.

3.2 SEM

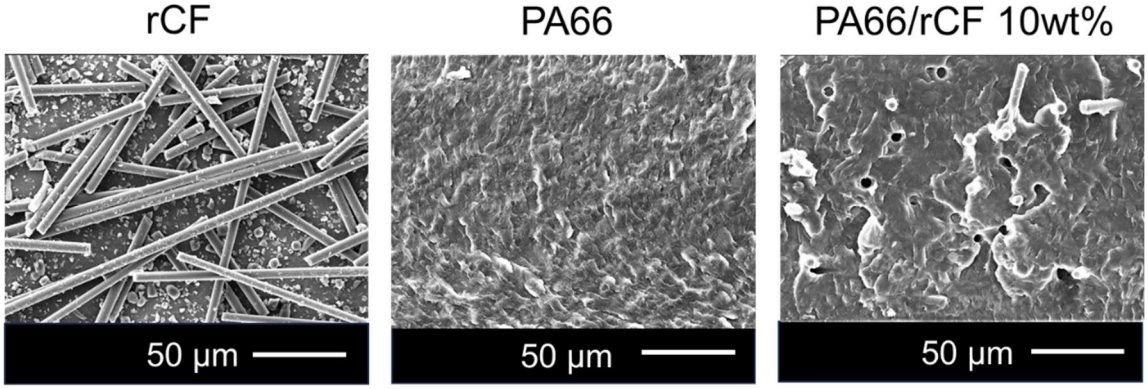

Figure 2: SEM images of rCF and fracture surfaces of PA66 and PA66/rCF composites.

Figure 2 shows SEM images of rCF and fracture surfaces of PA66 and PA66/rCF composites. In the

PA66/rCF composite aggregate of rCF was no observed, showing that rCF was highly dispersed in the composite. In the composites, a number of holes can be seen where the rCF has been pulled out. This indicates that the interaction between PA66 and rCF is weak.

3.3 XRD

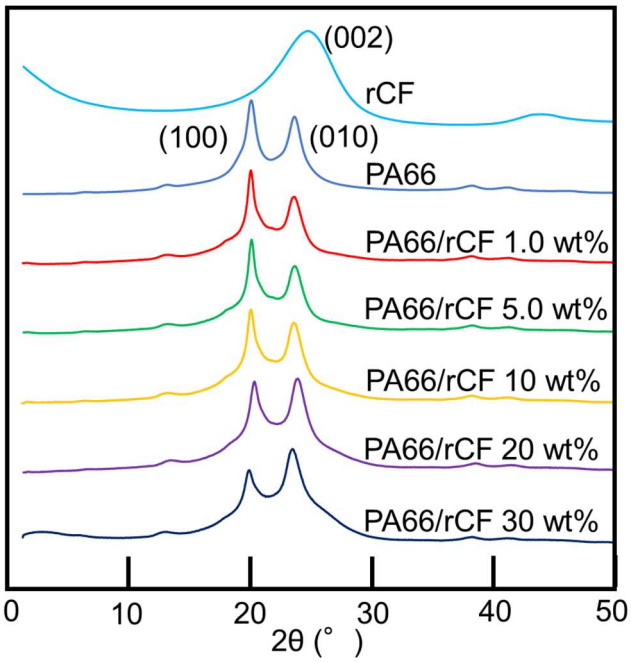

Figure 3: X-ray diffraction profiles of PA66 and PA66/rCF composites.

Figure 3 shows the X-ray diffraction profiles of rCF, PA66 and PA66/rCF composites. In the profile of rCF, (002) was appeared at around 2θ of 25°. Peaks corresponding to (100) and (010) of PA66 were observed at approximately 2θ of 21° and 25°, respectively. These peaks were also observed at the same 2θ in the profiles of the PA66/rCF composites, suggesting that crystalline structure of PA66 was maintained even after the addition of rCF. In addition, since the (010) of PA66 overlaps with the (002) derived from rCF, the intensity of the peak at 2θ of 25° increases with increasing rCF content.

3.4 Thermal Properties

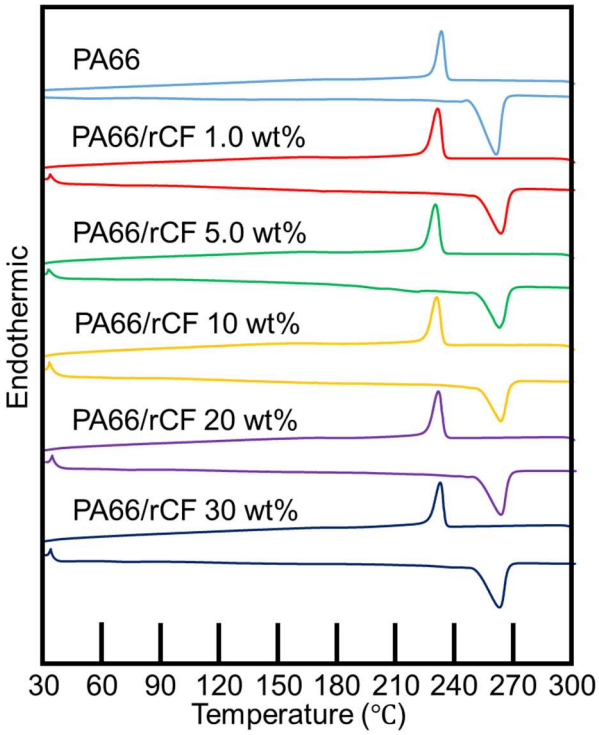

Figure 4: DSC thermogram of PA66 and PA66/rCF composites.

Figure 4 shows DSC thermogram of PA66 and PA66/rCF composites. The endothermic peak appeared at around 263 °C corresponds to the melting point, while the exothermic appeared at around peak near 230 °C corresponds to the crystallization temperature. Both the melting point and the crystallization temperature were not affected by the addition of rCF even at high content. These results indicate that the crystalline structure of PA66 is maintained despite the increased rCF content.

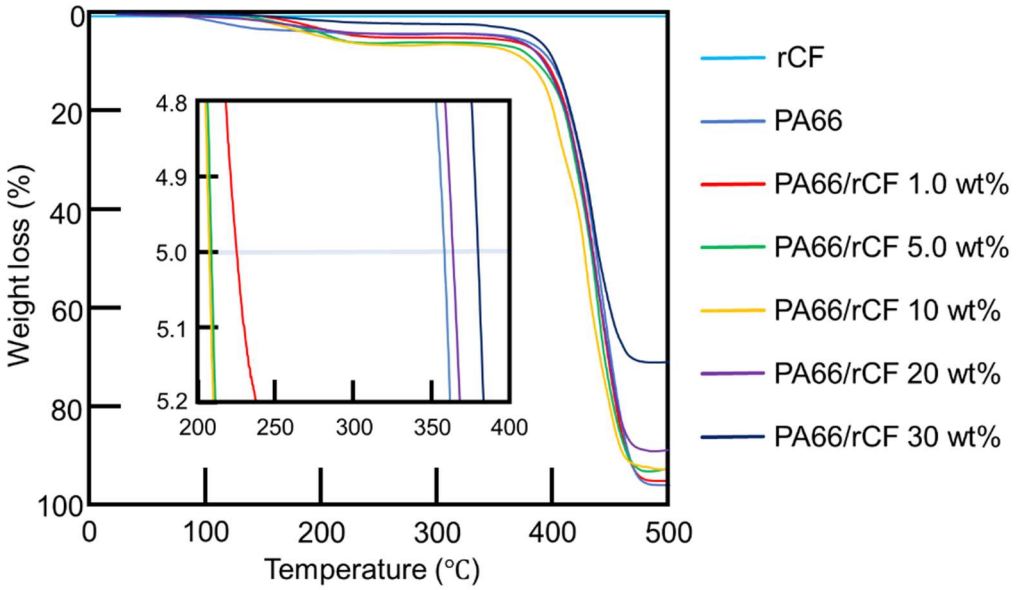

Figure 5: Thermogravimetric traces of rCF, PA66 and PA66/rCF composites.

Figure 5 shows thermogravimetric traces of rCF, PA66 and PA66/rCF composites. The 5% weight loss was defined as thermal decomposition temperature. At the filler content up to 10 wt%. The thermal decomposition temperature largely decreased. It was suggested that rCF inhibited the polymerization of PA66. Therefore, the decrease in the thermal decomposition temperature of the polymer matrix resulted in the lower thermal decomposition temperature of the composites. In the process of in-situ polymerization, resulting in a lower molecular weight.

On the other hand, the thermal decomposition temperature increased at the high filler content more than 20 wt%. For example, the thermal decomposition temperature increased about 20°C by the addition of 30 wt% of rCF. It was assumed that the molecular weight of PA66 in these composites with high filler content also decreased. However, the excellent reinforcement effect of rCF, derived from its rigid structure was dominant for these composites, resulted in the high thermal resistance.

3.5 Mechanical Properties

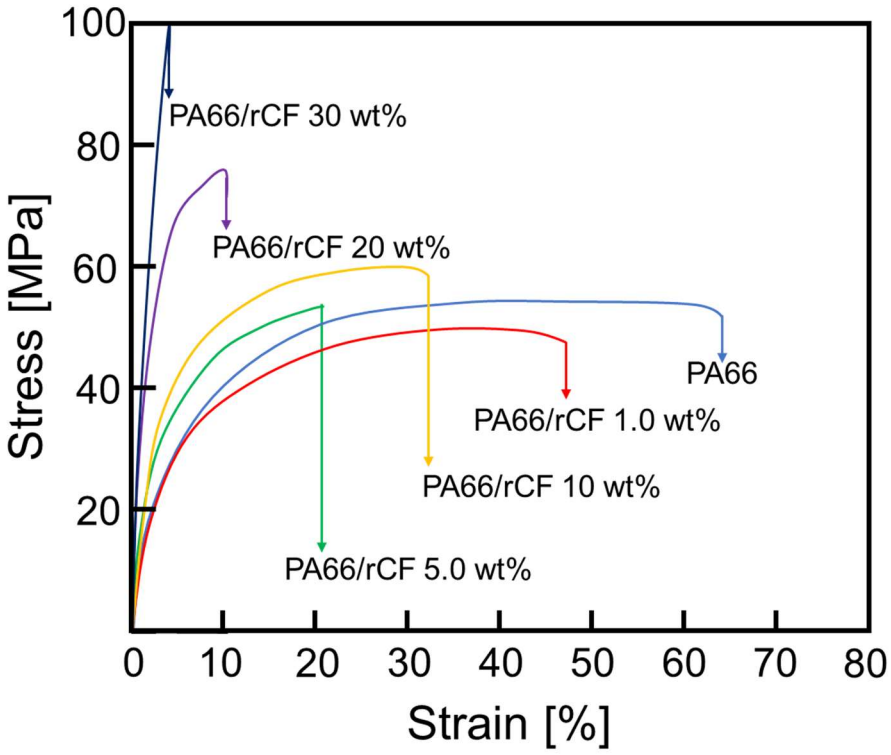

Figure 6: Stress-strain curves of PA66 and PA66/rCF composites.

Figure 6 shows stress-strain curves of PA66 and PA66/rCF composites. The Young's modulus which corresponds to initial gradient, significantly increased by the addition of rCF. In addition, the tensile strength, the maximum stress, increased for the composites with high content.

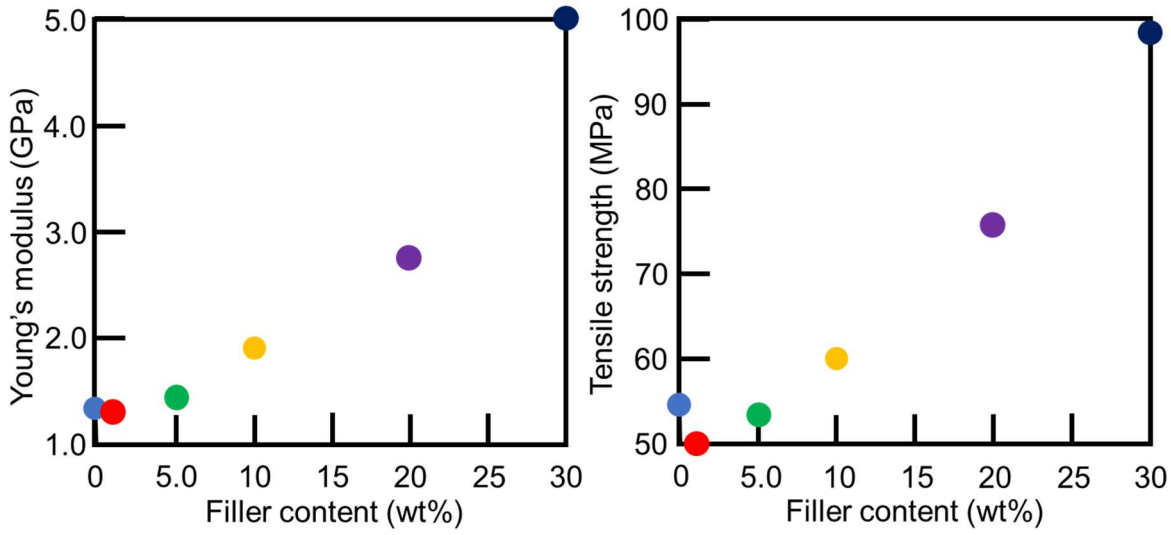

Figure 7: Young's modulus and tensile strength of PA66 and PA66/rCF composites.

Figure 7 on the left shows the Young's modulus and the figure on the right shows the Tensile strength of PA66 and PA66/rCF composites. The Young's modulus increased with increasing of rCF content. Especially in the region of high filler content, the composites showed high Young's modulus. For example, compared to PA66, the Young's modulus increased by 3.6 times by the addition of 30 wt% of rCF. On the other hand, the tensile strength decreased, for the composites with low filler content. As mentioned before, the molecular weight could be decreased by the addition of rCF, due to the process of in-situ polymerization, resulted in decrease in the mechanical properties of the polymer matrix. However, the tensile strength increased for the composites with high filler content. It increased by 1.8 times by the addition of 30 wt% of rCF, showing the excellent reinforcement effect of rCF.

4 CONCLUSIONS

In the PA66 composites, rCF was highly dispersed by in-situ polymerization. The thermal decomposition temperature was significantly reduced by adding small amounts of rCF, but increased at 20 wt% of rCF. The Young's modulus and the tensile strength increased by the addition of rCF. A significant increase in the Young's modulus was observed at more than 10 wt%.

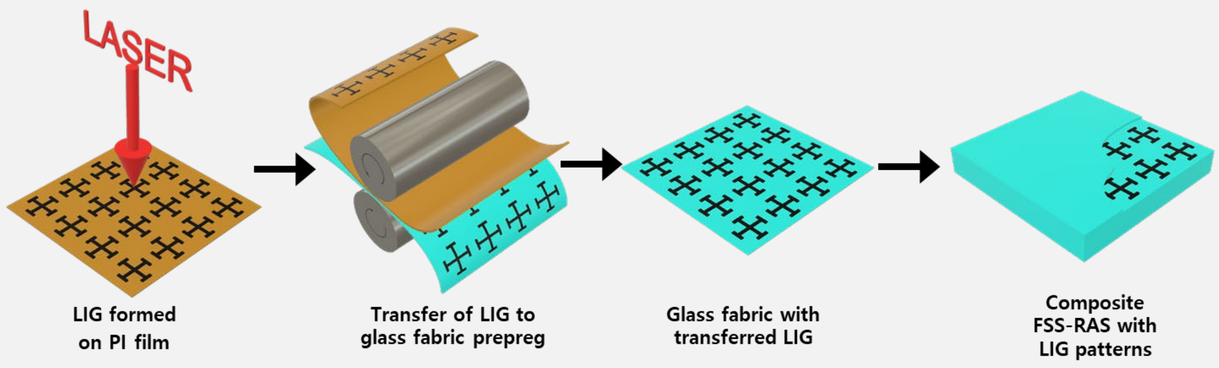
ICCM24 — 24TH INTERNATIONAL CONFERENCE ON COMPOSITE MATERIALS

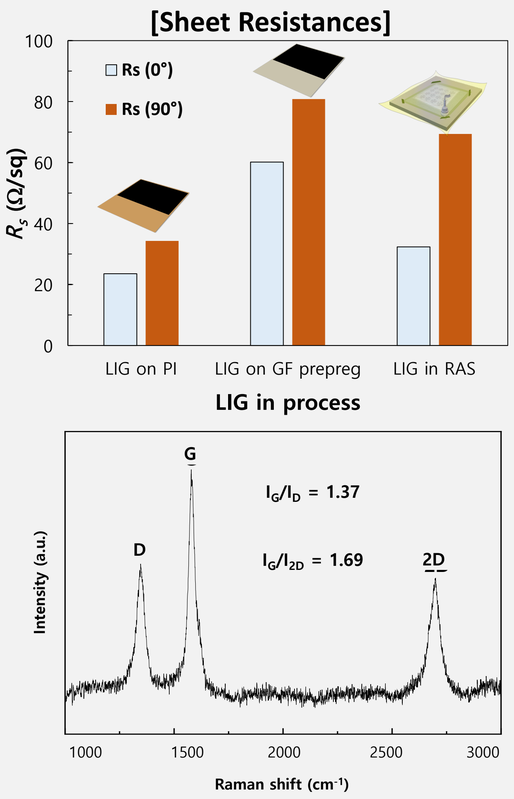
MCSI Lab — Multifunctional Composites & Structural Integration Lab



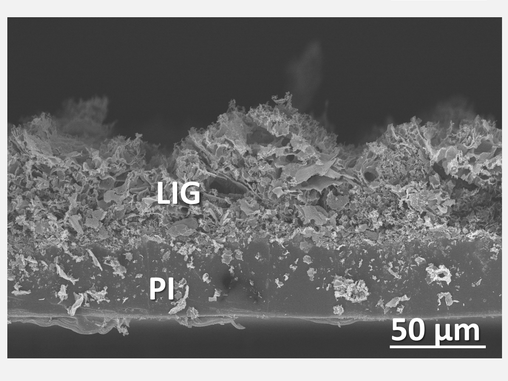
Introduction

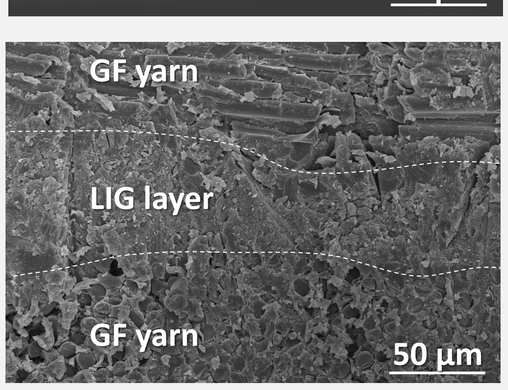
Frequency-selective surface-based **radar absorbing structures** (FSS-RAS) fabricated in traditional manner involves dispersing conductive fillers in polymer matrix and using metal masks for bar-coating or screen-printing on dielectric substrates. This study investigates an **alternative technique** of FSS-RAS that uses **laser-induced graphene (LIG)** periodic patterns with controllable sheet resistance engraved on polyimide (PI) precursor, **transferred** onto **glass fiber (GF)** dielectric fabric. We successfully designed and fabricated RAS using frequency-selective Jerusalem cross LIG pattern. The resulting structure, with a thickness of 2.91 mm, demonstrates 90% radar signal absorption across X-band. Additionally, short-beam shear tests revealed that **interlaminar shear strength (ILSS)** of the composite RAS can be **enhanced** when LIG layers are integrated between glass fiber fabric laminates. This study not only visualize a new type of wideband composite RAS with LIGs but also demonstrates a **straight-forward scalable fabrication process** including a series of LIG deposition and transferring.

Experiment



- LIG was patterned on PI film using a CO_2 laser.
- Transferred onto glass fabric to avoid PI-related delamination.
- Composite RAS fabricated via vacuum-bagging process.

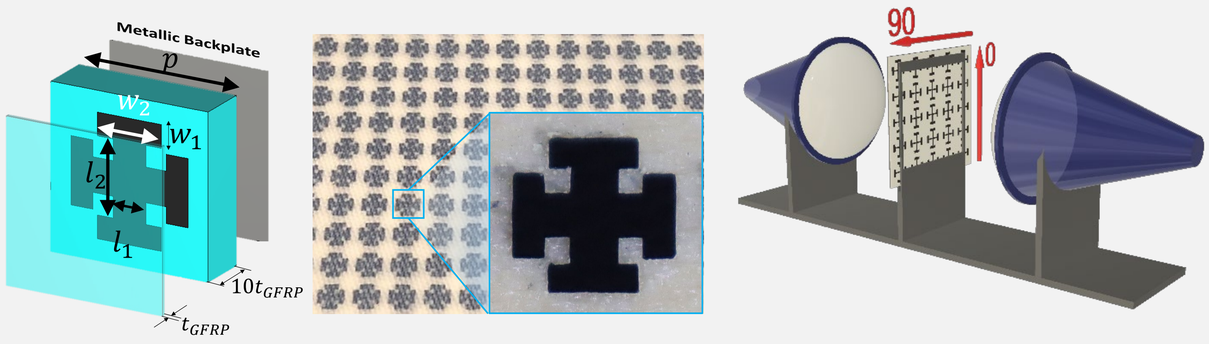


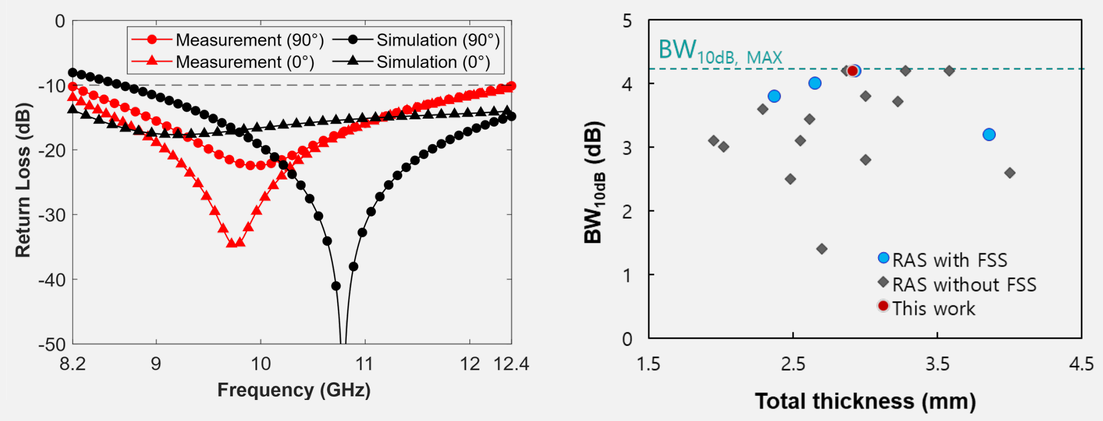


Results & Discussion

◆Characterization

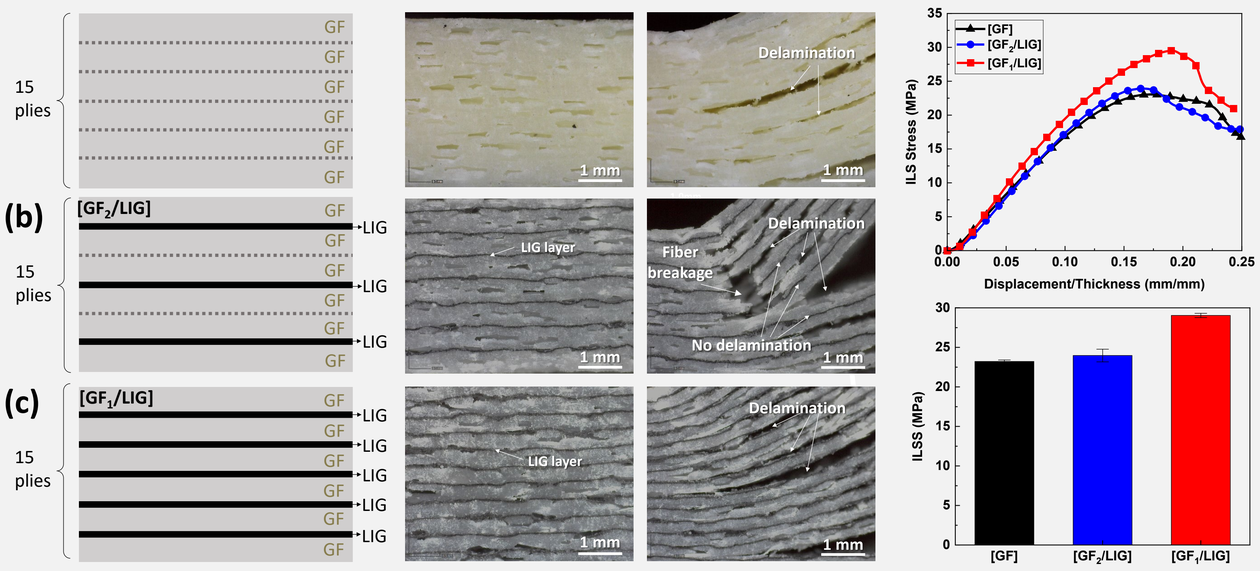
- Sheet resistance of LIG evolved through each fabrication step.
- Process-dependent resistance changes were observed.
- LIG flakes and mountain–valley surface morphology identified.
- Raman spectra confirmed LIG formation.
- LIG interlayer embedded between glass fiber yarns.





◆Design & Fabricated Samples Comparison

- Optimized RAS parameters:
  $p = 8.6mm, l_1 = 1.8mm, l_2 = 4mm, w_1 = 1.2mm, w_2 = 3.5mm,$
  $t_{GFRP} = 0.2675mm$



◆Microwave Absorption at X-band

- FSS-RAS shows >90% absorption over target bandwidth
- The fabricated RAS cover wide bandwidth, while remain thin (2.91mm) compared with existing literatures

◆Interlaminar-Shear Strength (ILSS)

- For the [GF$_2$/LIG] specimens, delamination occurred only at the interfaces without LIGs, while the interfaces containing LIGs remained intact, even after fiber breakage.
- The ILSS values for [GF] and [GF$_2$/LIG] are similar, while [GF$_1$/LIG] shows a distinct increase in ILSS.

Conclusions

- Introduced a method for composite FSS-RAS fabrication based on a new type of "porous nano-materials (LIGs)" deposited PI film
- We successfully fabricated broadband composite FSS-RAS with Jerusalem-cross pattern thin thickness capable of absorbing 90% of EM waves
- We showed that ILSS could be enhanced by embedding LIGs in between layers of glass fabric

ABSTRACT

Thermal protection systems (TPS) are essential for protecting spacecraft and hypersonic vehicles from extreme heat. However, traditional TPS materials such as carbon fiber-reinforced polymer composites (CFRPs) require substantial thickness to achieve thermal resistance, leading to increased structural weight. In this study, we propose an enhanced thermal protection strategy by embedding silicone elastomer microparticles as interlayers within CFRP laminates. The microparticles, synthesized via a thixotropic emulsion method using Ecoflex elastomer and sodium alginate solution, are incorporated at 6 vol.% levels in the mid-plane of 10-ply CFRP preforms. Laminates are fabricated via vacuum-assisted resin transfer molding (VARTM) and subjected to oxy-hydrogen flame ablation testing at ~2000 °C. The Si-containing interlayers decompose under high heat to generate silica, forming a thermal barrier that delays carbon fiber degradation. Notably, the ablation resistance increases for composites with PDMS microparticles. These results demonstrate a lightweight yet highly effective approach to improve ablative resistance through in-situ silica formation and suggest the potential of PDMS-based interlayers for next-generation aerospace TPS applications.

1 INTRODUCTION

Thermal protection systems (TPS) are essential in hypersonic and space vehicles to withstand severe aerodynamic heating [1]. Composite materials, particularly carbon fiber-reinforced polymers (CFRPs), are widely used due to their high specific strength and adaptability. For extreme environments where reusable TPS materials such as ceramic and metal matrix composites may fail [2,3], ablative TPSs are employed. These rely on the formation of gaseous boundary layers during decomposition, which insulate against heat flux due to their low thermal conductivity [4,5].

CFRPs typically use the polymer matrix as the sacrificial layer while carbon fibers provide structural reinforcement. Despite their favorable properties, sufficient ablation resistance often requires increased material volume, adding undesirable weight. Various enhancements have been explored, such as particle incorporation [6], surface coatings [7], and resin modifications [8]. Among these, particulate inclusion is attractive due to its processability and minimal impact on mechanical performance. Yet ceramic particles increase composite density, limiting their use in weight-sensitive applications.

Silicone elastomers, with their low density and ability to form protective silica during ablation [9], offer a promising alternative. While prior work has focused on elastomer matrices or coatings [10,11], the use of silicone microparticles as a discrete interlayer within CFRP remains underexplored, partly due to fabrication challenges [12].

Here, we present silicone elastomer microparticles embedded carbon fiber/epoxy laminates (Si-CFRP), as shown in **Figure 1**. The integration of polydimethylsiloxane (PDMS) microparticles within the matrix of CFRP laminates combines the structural benefits of CFRPs with the thermal protection

advantages of silicone elastomers (Figure 1a). Unlike traditional TPSs, silicone elastomers offer unique thermal protection capabilities. In detail, when exposed to high temperatures, they undergo thermal decomposition releasing silicon-based compounds, thereby forming protective layers of silicon dioxide (silica). This method not only reduces material weight but also significantly enhances thermal resistance, making it highly suitable for aerospace and defense applications. The thermal protection mechanism comprises three steps (Figure 1b). First, silicone elastomer decomposes under high temperatures, releasing silicon-based gases. These gases subsequently react with oxygen to form a silica layer on the composite surface and within fiber interspaces. This silica layer acts as a thermal shield, reducing heat penetration. Lastly, the high melting point of silica ensures sustained thermal protection during prolonged high-temperature exposure.

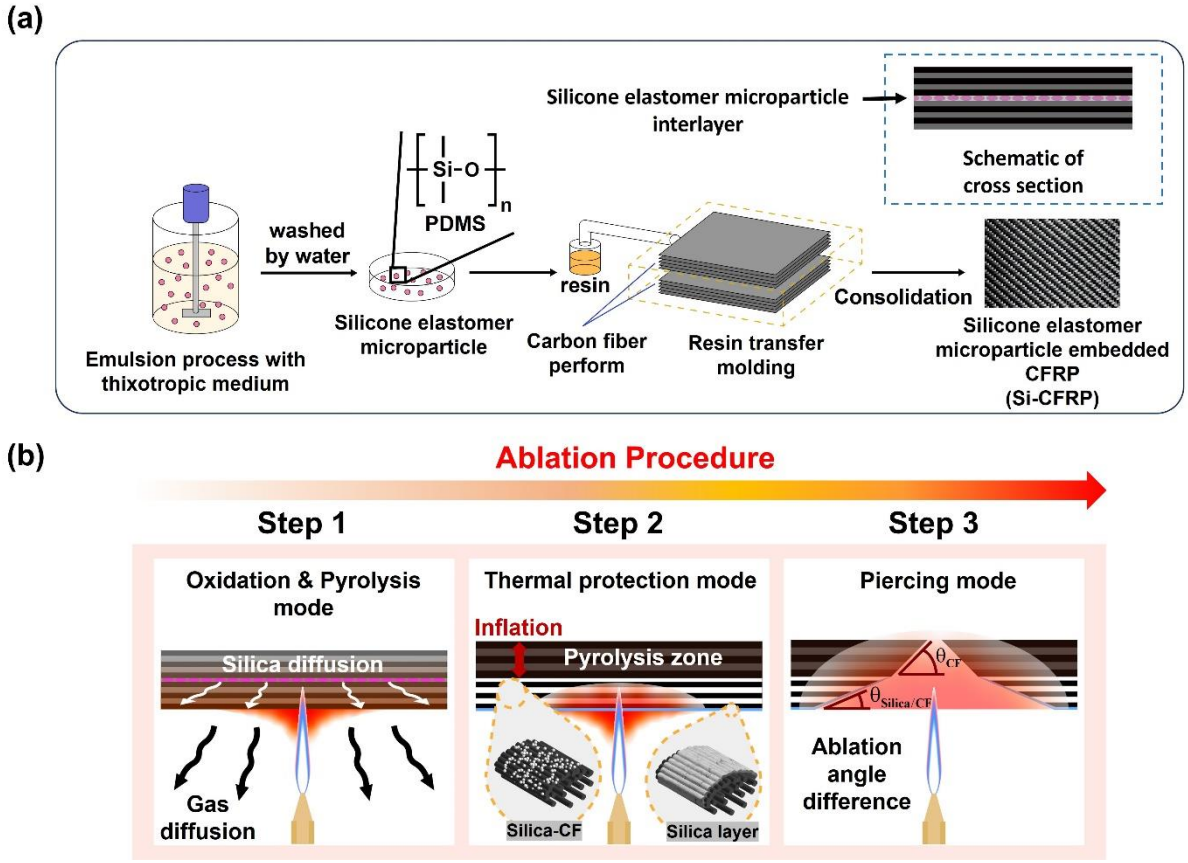

Figure 1. Overview of preparation and thermal protection mechanism of Si-CFRP. (a) Schematic of manufacturing process of silicone elastomer microparticle embedded carbon fiber-reinforced polymer (Si-CFRP) (b) Ablation mechanism of Si-CFRP with 3-step procedure.

2 MATERIALS AND EXPERIMENTAL METHODS

PDMS microparticles are synthesized using a thixotropic emulsion process with 4 wt.% sodium alginate/DI water medium. Two parts silicone elastomers (Ecoflex 00-30, Smooth-On) are premixed in a 1:1 ratio and stirred at 200 rpm in the sodium alginate/DI water medium to create microparticles. Particles are retrieved after washing process.

Laminated composites are fabricated using vacuum assisted resin transfer molding (VARTM), embedding 6 vol.% PDMS microparticles in the middle layer of 10-ply carbon fiber preforms infused with an epoxy/amine resin system (INF114, 212). Laminates were cured at 120 °C for 3 hours and machined into 400 mm × 400 mm specimens.

Ablation tests are conducted with an oxy-hydrogen torch at temperatures above 1500 °C. Specimens are exposed to the flame until the complete piercing, and ablation resistance is calculated as the inverse of the linear ablation rate which is calculated as,

$$LAR = t / \tau \tag{1}$$

where t is thickness of specimen and τ is ablation time until the flame pierces the specimen.

3 RESULTS AND DISCUSSION

Figure 2 showcase the test-set up for measuring the ablation resistance, and surface morphologies of specimen after ablation. After decomposition of epoxy matrix, carbon fibers of Neat CFRP also decompose immediately due to the high flame temperature (Fig 2a). After the flame pierce the specimen, graphitic region nearby piercing point is identified as the result of the ablation process. In contrast, Si-CFRP resists to thermal attack from the oxyhydrogen flame after decomposition of epoxy matrix (Fig 2b). Furthermore, the generation of white colored debris on the surface of Si-CFRP after ablation procedure is identified. The debris on the surface is presumably assumed as silica, because of presence of the silicon at the chemical structure of PDMS.

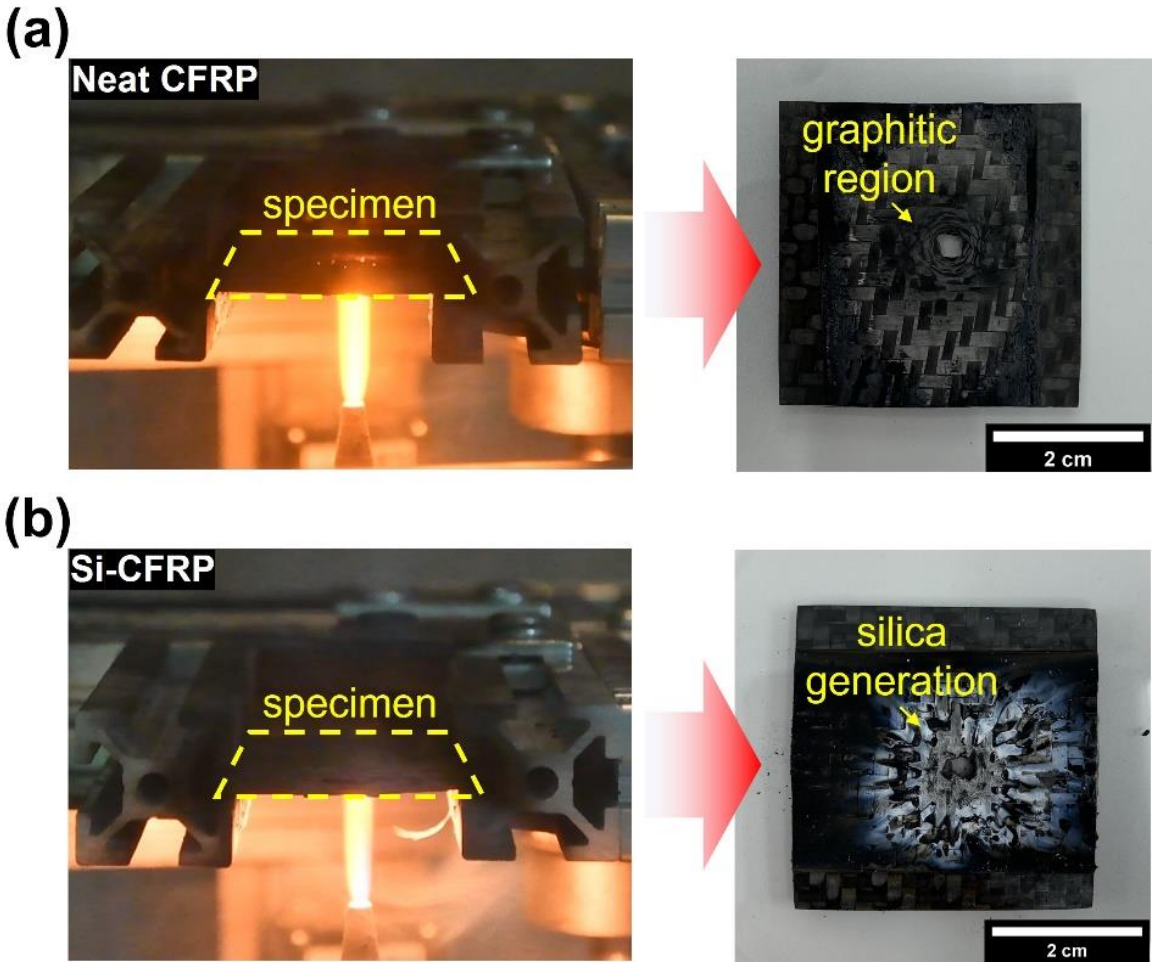

Figure 2. Ablation test set up and surface morphologies of Neat CFRP and Si-CFRP after ablation. Ablation test of (a) Neat CFRP and (b) Si-CFRP specimen from 10-ply laminate with and without silicone elastomer particle interlayer (6 vol.%).

Figure 3 presents SEM images comparing the ablated surfaces of Neat CFRP and Si-CFRP. In Neat CFRP (Fig. 3a), fine carbonaceous debris is observed, attributed to the oxidative degradation of carbon fibers. In contrast, the ablated surface of Si-CFRP (Fig. 3b) exhibits the formation of spherical silica particles (~160 nm) on the carbon fiber surface, indicating in-situ generation of thermally protective silica during ablation.

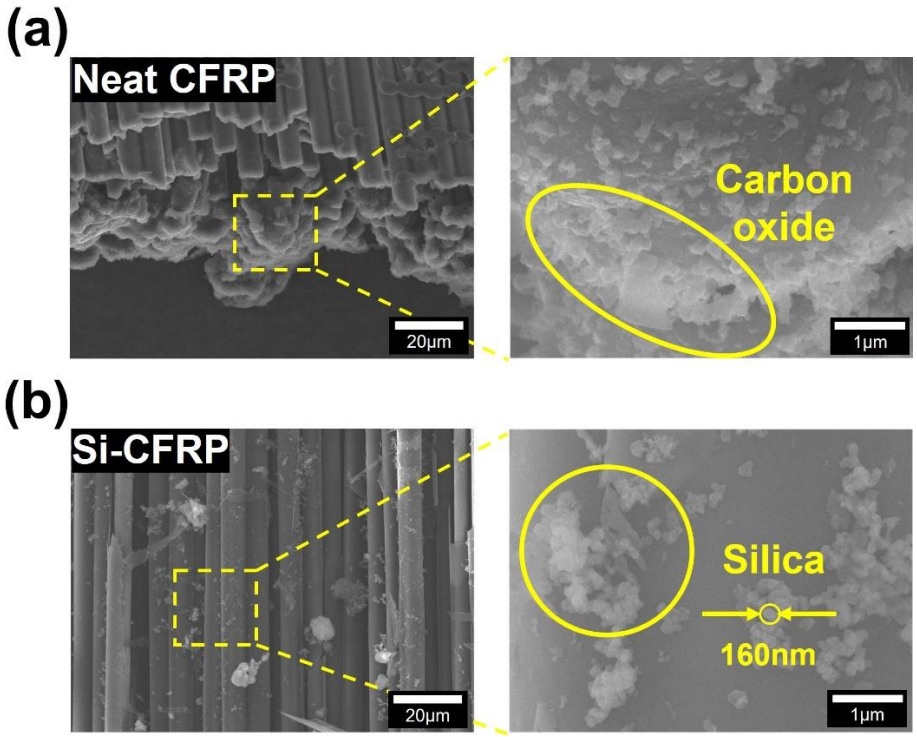

Figure 3. Morphological characteristics of the ablated zone. Scanning electron microscopy (SEM) images of (a) Neat- and (b) Si-CFRP.

Figure 4 indicates that Si-CFRP specimens significantly enhance ablative resistance compared to Neat CFRP laminates. The incorporation of silicone elastomer microparticles facilitate the formation of silica layers on the composite surface, effectively delaying material degradation. Specimens containing 6 vol.% PDMS exhibit an ablation resistance of 129 mm/sec^{-1}, more than double that of Neat CFRP (55.8 mm/sec^{-1}).

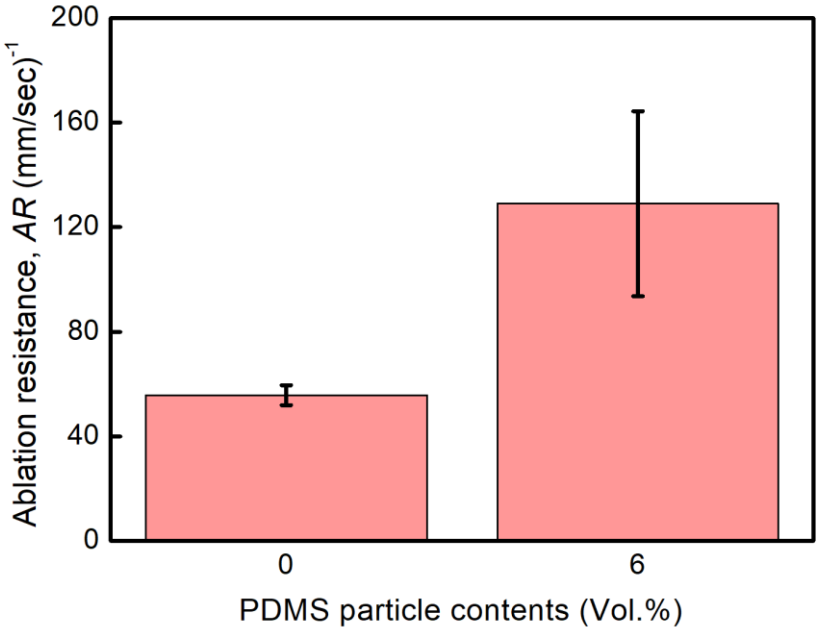

Figure 4. Summary of ablation resistance of composite specimen with respect to contents of silicone elastomer particles.

4 CONCLUSIONS

The ablative resistance of carbon fiber-reinforced polymer composites (CFRPs) is enhanced through the incorporation of silicone elastomer, polydimethylsiloxane (PDMS), as an interlayer of microparticles. The results showed that CFRPs embedded with 6 vol.% silicone elastomer microparticles achieved more than double the ablation resistance of Neat CFRP. These findings confirm the potential of Si-CFRP laminates for demanding aerospace applications where high-performance thermal protection systems (TPS) are desired.

Future work will focus on optimizing the distribution and volume fraction of silicone elastomer microparticles within the laminate structure. Additionally, investigating the bonding properties between PDMS and the CFRP matrix will provide insights into further improving mechanical and thermal performance. These advancements aim to establish Si-CFRP as a versatile solution for next-generation TPS materials.

Keywords: Carbon fiber reinforced thermoplastics, Sheet molding compound, Hybrid composites, Impact properties, Finite element analysis

ABSTRACT

Carbon fiber reinforced thermoplastic sheet molding compound (CFRTP-SMC) presents a promising alternative to the conventional continuous fiber composites due to its superior formability, in-plane isotropy, high production efficiency, and recyclability, particularly through the reutilization of end-of-life waste and prepreg scrap. In automotive applications, where environmental regulations and large-scale production are critical, CFRTP-SMC is increasingly investigated for its potential in future mobility. However, there are concerns regarding adoption of discontinuous based composite for structural members of an automobile where high energy absorption is required to ensure the safety of passengers. This study examines the impact behavior of CFRTP-SMC under three-point bending, along with a hybrid unidirectional (UD) carbon fiber over-molded CFRTP-SMC variant. Different tape lengths are investigated to identify the critical tape length for enhanced energy absorption and impact strength. Additionally, the influence of UD carbon fiber over-molding on impact performance is assessed. A multi-scale microstructural model analysis is conducted to estimate the material's engineering constants for experimental-analytical correlation using finite element methods. Results indicate that the critical tape length identified significantly increase the impact performance of CFRTP-SMC, and further improvements in energy absorption can be achieved through the utilization of UD carbon fiber over-molding without compromising weight reduction objectives.

1 INTRODUCTION

Carbon fiber reinforced plastics (CFRP) are widely employed in engineering applications due to their high specific strength and stiffness. In particular, discontinuous-carbon fiber reinforced plastics have gained attention in automotive sectors for their superior formability and production efficiency – key considerations in mass production. In addition, more progressive and demanding environmental regulations targeting carbon emission reduction has accelerated interest in thermoplastic-based CFRP, which offer notable advantages in recyclability [1-3]. However, the use of discontinuous thermoplastic composites in structural members of automobiles remains limited due to concerns over their impact performance, which is critical for passenger protection.

In response, recent research has focused on discontinuous composites reinforced with long carbon fibers, such as carbon fiber reinforced thermoplastic sheet molding compounds (CFRTP-SMC). CFRTP-SMC is a type of SMC consisting of carbon fiber reinforcements in the form of tapes or tows with a thermoplastic resin, offering advantages in forming complex shapes, cost-effectiveness for large-scale production, and excellent mechanical properties. The bundled morphology of the carbon fibers in CFRTP-SMC results in superior mechanical performance compared to the conventional injection-molded composites while maintaining quasi-isotropic behavior. Building on these advantages, Takahashi and Wan developed methods for fabricating quasi-isotropic SMC using randomly distributed carbon fiber prepreg tapes [4]. They analyzed the influence of tape length on mechanical performance through X-ray micro-computed tomography scanning with estimations using Monte Carlo stochastic simulation [5]. Similarly, Alves et al. examined the properties of quasi-isotropic tow-based SMC [6, 7], while Katsivalis et al. extended this work by developing predictive models for failure behavior [8].

While the static mechanical properties of SMC have been extensively studied, the influence of tape length on their impact performance remains largely unexplored. Furthermore, the potential of hybridizing SMC with unidirectional (UD) carbon fiber through over-molding has not yet been systematically investigated. In this paper, the critical tape morphology that saturates the impact properties of CFRTP-SMC is assessed. In addition, the effect of UD carbon fiber over-molding on enhancing impact characteristics is examined.

The proposed framework highlights the influence of tape morphology on the impact performance of CFRTP-SMC, as well as effective utilization of UD reinforcements without compromising weight reduction goals. These results emphasize the strong potential of CFRTP-SMC and its hybrid variants for structural applications in the automotive industry, particularly in the context of large-scale and sustainable manufacturing.

2 MATERIALS AND METHODS

2.1 Molding and specimen preparation

This study investigates CFRTP-SMC with two distinct tape lengths, alongside a hybrid variant combining CFRTP-SMC with UD reinforcement. The SMC preform sheets were manufactured by randomly distributing chopped prepreg tapes consisting of carbon fiber (TR50S, Mitsubishi Chemical Co.) and polyamide-6 resin (PA6, DIAMIRON^{TM} C, Mitsubishi Chemical Co.). The SMC preform was stacked with approximately 95-100 grams of pure SMC sheets, where its hybrid variant was stacked with 85-90 grams of SMC sheets and a single layer of UD ply on one side of the outermost surface so that the total material weight remained equivalent. Figure 1 and Table 1 provide details of the material configurations and their respective designations. SMC_10 and SMC_30 refer to SMC plates reinforced with 10 mm and 30 mm tapes, respectively. Hybrid_L and Hybrid_U denote SMC plates with 30 mm tapes, further reinforced with a single layer of UD carbon fiber layer on the lower and upper surfaces, respectively.

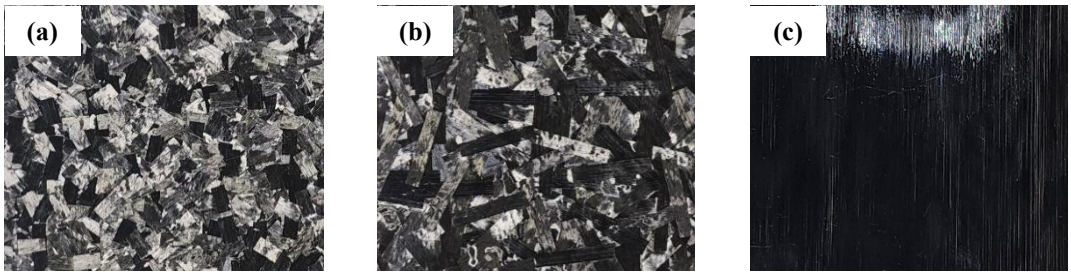

Figure 1: Material representation: (a) SMC 10 mm tapes, (b) SMC 30 mm tapes, (c) UD carbon fiber

Material type	Tape length SMC [mm]	No. SMC plies	No. UD plies	Total weight [g]
SMC_10	10	8	0	95-100
SMC_30	30	8	0	95-100
Hybrid_L	30	7	1 lower layer	95-100
Hybrid_U	30	7	1 upper layer	95-100

Table 1: Material identification.

The preformed sheets were then compression-molded into panels measuring 250 x 125 mm with a nominal thickness of 2.0 mm. Both the SMC and hybrid panels were molded under identical conditions using a press machine (265 °C, 50 bars, 25 mins) with the carbon fiber volume fraction of 50% to ensure direct comparability. The molded panels were subsequently sectioned into 120 x 60 mm specimens using a composite material cutting machine (MARUTO Testing Machine Company, AC-500CF), as illustrated in Figure 2.

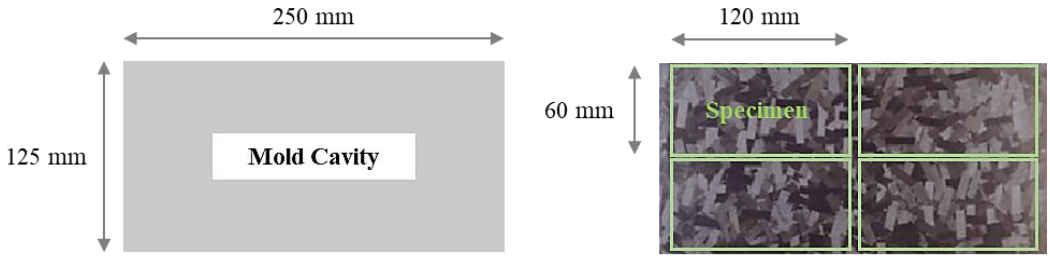

Figure 2: Schematics of mold cavity, plate, and specimen geometry

2.2 Impact experiment

Three-point bending impact tests on the materials listed in Table 1 were conducted with a high-speed impact testing machine (Hydroshot HITS-P10, Shimadzu Corporation) under the JIS K7084 standards with three different impact velocities. The sample dimensions and testing conditions are detailed in Table 2. To evaluate the impact properties, a minimum of five samples were prepared for each condition. The maximum impact stress, σ_{max} and the specific energy absorption, *SEA* are calculated using equations (1) and (2). The force, F and work W are measured from the testing machine, while the dimensions L, w, and t represent the gauge length, width, and thickness, respectively. The variable m denotes the mass of the specimen.

Dimensions			No. of specimens	Impact velocity [m/s]
Gauge length [mm]	Width [mm]	Thickness [mm]		
80	60	2	> 5	1.5, 2.0, 2.5

Table 2: Sample dimensions and testing conditions for the three-point bending impact experiment.

$$\sigma_{max} = \frac{3FL}{2wt^2} \tag{1}$$

$$SEA = \frac{W}{m} \tag{2}$$

2.3 Multi-scale modelling

The theoretical material properties and associated engineering constants for both SMC and UD materials were estimated using Digimat-MF (Hexagon AB), a multi-scale modelling platform based on mean-field homogenization theory for composites behavior prediction. The raw material properties of carbon fiber (Young's modulus: 230 GPa) and Polyamide-6 (Young's modulus: 3 GPa) were used as input parameters to estimate the composite properties. The twelve engineering constants include Young's moduli (E_{xx}, E_{yy}, E_{zz}), Poisson's ratios (ν_{xy}, ν_{yx}, ν_{xz}, ν_{zx}, ν_{yz}, ν_{zy}), and shear moduli (G_{xy}, G_{xz}, G_{yz}), where the subscripts denote the axes of planarity.

2.4 Finite element model

Engineering constants were then implemented in a FE model developed using LS-DYNA (Ansys inc.). The material configuration and corresponding FE model setup are shown in Figure 3 and Figure 4. The model consisted of three primary parts: the impact striker and supports were modelled as rigid bodies using *MAT_RIGID* (MAT_020), while the specimen was defined using the *MAT_ENHANCED_COMPOSITE_DAMAGE* (MAT_054/055).

Boundary conditions were applied such that the impact striker motion was constrained to vertical translation (z-direction), replicating the actual experimental impact setup. The supports were fully

constrained in all degrees of freedom (translation and rotation in x, y, and z axes), while the specimen was simply supported with all degrees of freedom unrestrained. The impactor was given an initial velocity matching the experimental conditions, where the peak impact force was recorded for comparison with experimental results.

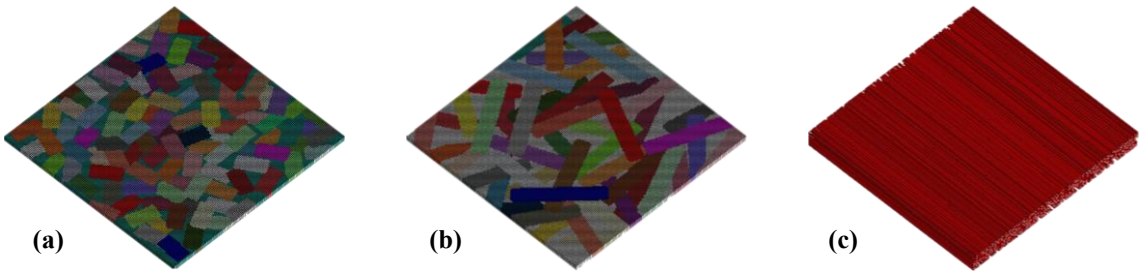

Figure 3: Material configuration: (a) SMC 10 mm tapes, (b) SMC 30 mm tapes, (c) UD carbon fiber

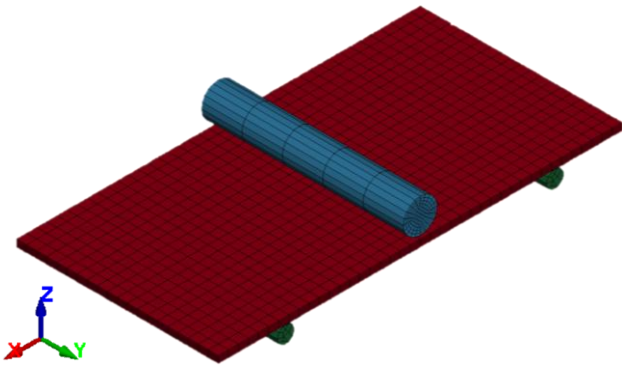

Figure 4: Finite element model for three-point bending impact

3 RESULTS AND DISCUSSIONS

3.1 Impact properties

The results of the three-point bending impact experiments are presented in Figure 5 and Figure 6. Both the impact strength and SEA increased as the tape length of SMC increased from 10 mm to 30 mm. This improvement is attributed to enhanced load transfer efficiency with longer tapes, which facilitate more effective stress transfer from the matrix to the fibers during impact, thereby increasing the overall energy absorption. In shorter tapes, the number of tape-ends per unit volume is higher, acting as stress concentrators and sites for crack initiation. In contrast, longer tapes are preferable for bridging cracks, promoting more progressive damage, and contributing to improved impact resistance and SEA.

In hybrid configurations, where UD carbon fiber was over-molded on either the lower or upper surfaces of the SMC, SEA increased while impact strength decreased relative to the SMC specimens with 30 mm tape lengths. Although the UD layer possesses superior in-plane properties compared to SMC, their off-axis properties are significantly lower, which limits their performance under flexural impact conditions present in the three-point bending impact test. Furthermore, UD materials tend to be more brittle than SMC, and are prone to delamination upon impact, which can serve as a stress concentrator and reduce impact strength.

Despite reduction in strength, delamination increases the range of failure mechanisms and facilitates more distributed energy dissipation over time, leading to increased overall energy absorbed per unit mass. This trade-off is a common phenomenon in hybrid structures, where maximizing energy absorption is of greater importance than peak load capacity. In automotive applications, where crashworthiness and passenger safety are prioritized, materials that fail in controlled, energy dissipating mechanisms are preferred over those that fail catastrophically at higher loads. This highlights a strategic

design consideration in which functional performance regarding safety takes precedence over peak strength alone.

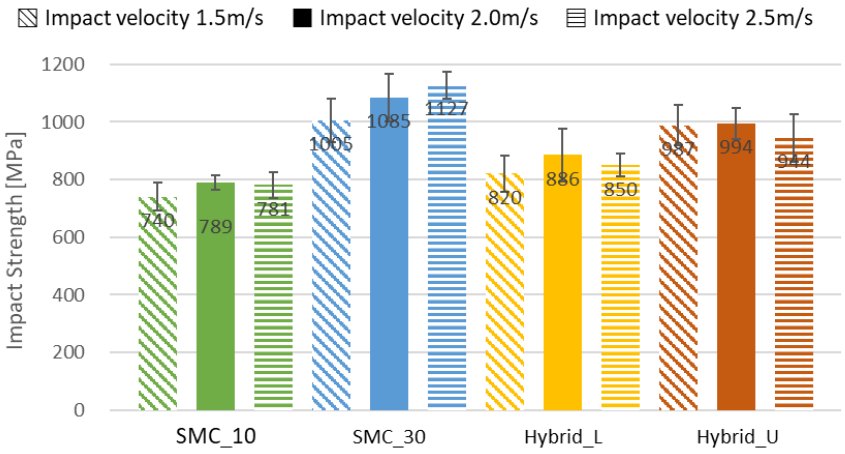

Figure 5: Impact strengths

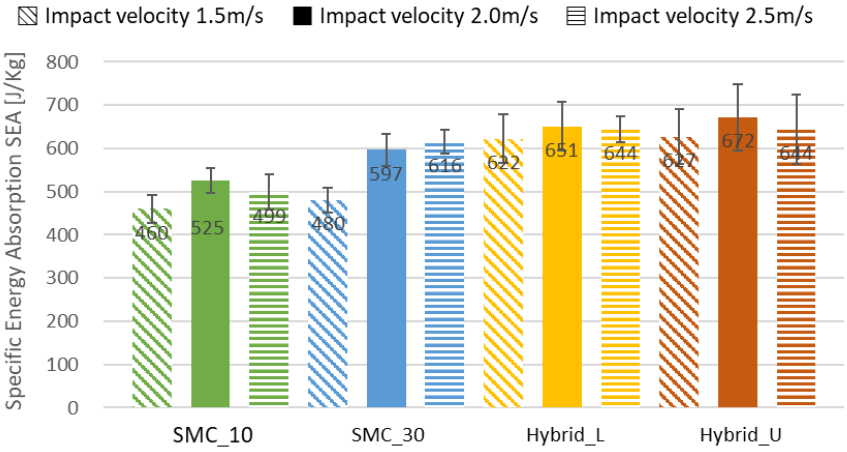

Figure 6: Specific energy absorption

Figure 7 presents the damaged specimens following the impact test. The SMC specimens exhibited a distinct failure pattern characterized by a straight-line fracture at the midpoint, with minimal signs of delamination. In contrast, the over-molded hybrid specimens showed extensive delamination, indicating a different failure mechanism influenced by the presence of the UD layer.

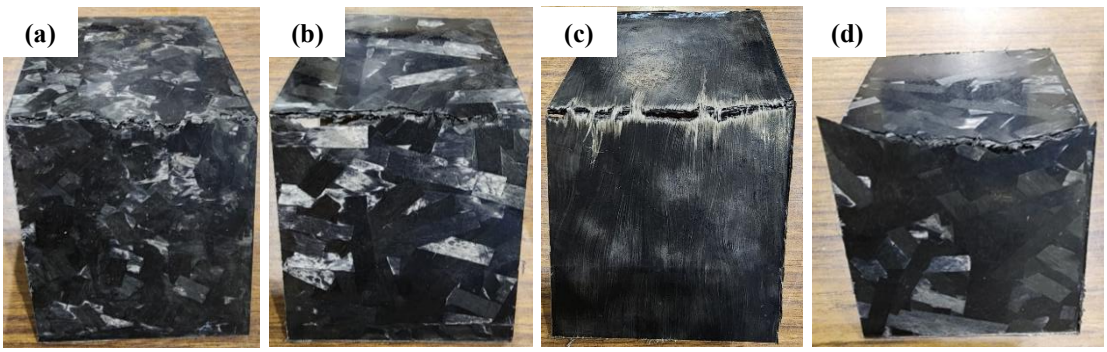

Figure 7: Damaged specimen: (a) SMC_10, (b) SMC_30, (c) Hybrid_L, and (d) Hybrid_U

3.2 Engineering constant estimation

To predict the engineering constants of the materials used in this study, multi-scale modelling was performed. The raw material data of carbon fiber and polyamide-6, along with their volume fraction and fiber morphology, were used as direct input parameters. The Young's moduli obtained from previous studies, were compared to check the validity of the model.

The predicted Young's moduli for SMC with 10 mm tapes, SMC with 30 mm tapes, and the UD carbon fiber were 33.9 GPa, 42.5 GPa, and 127.9 GPa respectively. The obtained engineering constants highly resembled material properties tested in previous studies, indicating that the model reliably correlates tested data with predicted outcome. The mean-field homogenization provides a simple and efficient method for estimating the bulk properties of composites as presented in Table 3-5. Additionally, since unknown engineering constants can be estimated using relatively few input parameters, this approach serves as a practical starting point for simulations in FE analysis.

Engineering constant	Type	Values
E_{xx}	Young's modulus	33.9 GPa
E_{yy}		33.5 GPa
E_{zz}		11.4 GPa
v_{xy}	Poisson's ratio	0.31
v_{yx}		0.32
v_{xz}		0.39
v_{zx}		0.13
v_{yz}		0.39
v_{zy}		0.13
G_{xy}	Shear modulus	12.9 GPa
G_{xz}		2.6 GPa
G_{yz}		2.6 GPa

Table 3: Predicted engineering constants for SMC with 10 mm tapes

Engineering constant	Type	Values
E_{xx}	Young's modulus	42.5 GPa
E_{yy}		42.5 GPa
E_{zz}		11.9 GPa
v_{xy}	Poisson's ratio	0.32
v_{yx}		0.32
v_{xz}		0.37
v_{zx}		0.10
v_{yz}		0.37
v_{zy}		0.10
G_{xy}	Shear modulus	16.1 GPa
G_{xz}		2.6 GPa
G_{yz}		2.6 GPa

Table 4: Predicted engineering constants for SMC with 30 mm tapes

Engineering constant	Type	Values
E_{xx}	Young's modulus	127.9 GPa
E_{yy}		10.2 GPa
E_{zz}		10.2 GPa
v_{xy}	Poisson's ratio	0.28
v_{yx}		0.02
v_{xz}		0.28
v_{zx}		0.02

v_{yz}		0.58
v_{zy}		0.58
G_{xy}	Shear modulus	3.6 GPa
G_{xz}		3.6 GPa
G_{yz}		3.2 GPa

Table 5: Predicted engineering constants for UD carbon fiber

3.3 Finite element analysis and correlation

The engineering constants obtained from multi-scale modelling were implemented as input parameters for the FE analysis. The FE model, as shown in Figure 7, illustrates the progress stress distribution in the specimen immediately after impact and up to just prior to failure.

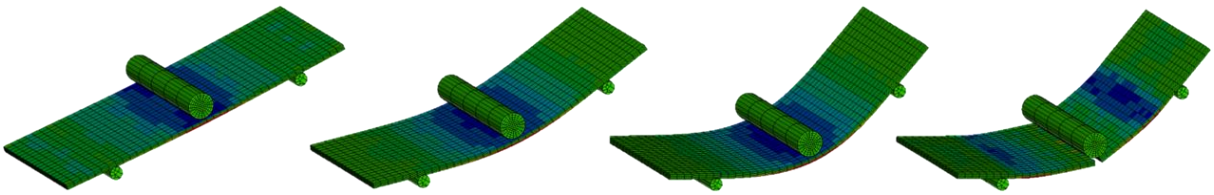

Figure 8: Finite element model of SMC specimen

The analytical results were correlated with the experimentally measured impact strength of SMC specimens tested at an impact velocity of 2.0 m/s. Due to limitations in accurately modeling the delamination behavior between the SMC and over-molded UD carbon fiber layers, the hybrid configurations were excluded from the current FE analysis. Based on the simulation results, the SMC with 10 mm tapes exhibited a peak impact force of 1.61 kN, corresponding to a calculated strength of 892 MPa, while the SMC with 30 mm tapes reached peak force of 1.99 kN corresponding to 1,102 MPa. These predicted values showed good agreement with the experimental results, achieving accuracies of 87% and 98% respectively. The comparison of peak impact forces for both materials is illustrated in Figure 9.

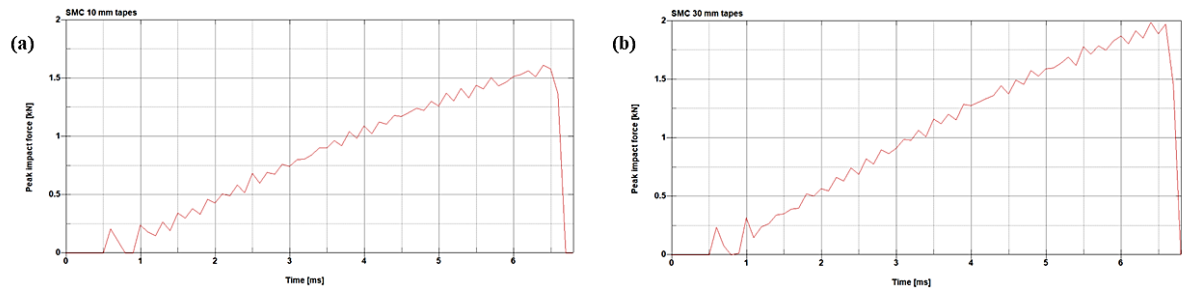

Figure 9: Peak impact forces: (a) SMC_10, and (b) SMC_30

To accurately characterize the delamination behavior of the hybrid materials, material models capable of capturing interlaminar failure – such as cohesive zone elements or contact-based debonding models are required. However, implementing such models necessitates more rigorous experimental characterization of interlaminar properties, along with extensive material data to properly define the delamination behavior. These efforts, while beyond the scope of the current study, would be essential for advanced modelling of hybrid composite systems and are recommended for future work.

4 CONCLUSIONS

CFRTP-SMC offers distinct advantages in forming complex shapes, cost-effectiveness for large-scale production, and favorable mechanical properties. However, the influence of tape length and over-molding with UD carbon fiber on their impact behavior remains insufficiently understood. This study examined the impact properties of SMC with different tape lengths, and evaluated the effect of UD carbon fiber over-molding through three-point bending impact test, multi-scale model analysis for engineering constant estimation, and FE analysis to validate the experimental findings. The methodologies, key findings, and interpretations are discussed in detail. The principal conclusions are summarized as follows:

- Tape length effect: tape length was found to significantly influence the impact performance of SMCs. Increasing the tape length from 10 mm to 30 mm resulted in notable improvements in both impact strength and specific energy absorption. These enhancements were primarily attributed to improved load transfer efficiency and more effective stress transmission from the matrix to the fibers during impact.
- Effect of UD carbon fiber over-molding: the over-molding of UD carbon fiber introduced a performance trade-off. While delamination between the UD layer and SMC reduced the peak impact strength, it expanded the range of failure mechanisms and enhanced energy dissipation, leading to increased overall energy absorption.
- Multi-scale modelling: the mean-field homogenization approach used in the multi-scale model proved effective for estimating bulk material properties and unknown engineering constants with limited input data. This method served as a practical foundation for subsequent FE simulations.
- FE analysis validation: the FE analysis demonstrated good agreement with experimental results in predicting the impact strength of SMC with different tape lengths. Although hybrid materials were not modelled in this study due to limitations in characterizing interfacial delamination, future work incorporating cohesive zone models and interlaminar failure criteria is recommended.
- Design implications: the findings emphasize the critical role of tape length and highlight the potential of UD carbon fiber over-molding as a design strategy. When properly engineered, over-molding can enhance crashworthiness and energy absorption, offering significant benefits for passenger safety in automotive applications.

Structural Integrity of Composite Manipulator Applied to the Automated Ropeway Inspection Using Flexible Multibody Dynamics Analysis

ChiHyun Song[1], ChangHo Kim[1], JaeYoul Lee[2], *KwangBok Shin[1]

[1]Department of Mechanical Engineering, Hanbat National University, Daejeon, Korea / [2]Interactive Robotics R&D Division, Korea Institute of Robotics & Technology Convergence

ABSTRACT

- In this study, the structural design and structural integrity evaluation of CFRP frame applied to a ropeway structure inspection manipulator were conducted. The ropeway structure inspection manipulator is a device that remotely inspects defects and wear of ropeway wheel devices of rope facilities used as transportation, such as cable cars or ski lifts.
- In the case of the existing ropeway structure inspection manipulator, it was made of aluminum, but in order to lightweight of the manipulator and reduce deflection, the existing aluminum material was replaced with CFRP material. In order to apply CFRP materials to manipulators, the stiffness design of the CFRP frame is essential, and structural integrity evaluation due to the external environment occurring during inspection and the load generated during operating motion also be secured. For the motion reflected in the analysis, the maximum deflection of the end device equipped with the camera was confirmed in the motion state where the inspection manipulator, which occurred to have the maximum deflection, was horizontally spread out.
- To evaluate the structural integrity of the CFRP frame reflecting the actual inspection environment based on the selected stacking pattern, flexible multibody dynamics analysis (FMBD) was performed. The maximum wind loads and railway wheel structure inspection motion in the actual inspection environment were applied according to the Facility Standards for Construction and Equipment for Tramway Facilities' Regulations. structural integrity was confirmed.

INTRODUCTION

Background and significance

- A ropeway system is a transportation method that uses wire ropes to carry passengers or cargo. To ensure optimal performance, regular inspections of ropeway systems are essential.
- Traditionally, ropeway inspections were performed manually by workers. However, recent research has focused on developing remote robotic ropeway inspection systems to enhance worker's safety and maintain consistent operational efficiency.
- The manipulator attached to the inspection robot is equipped with a camera mounted on its end effector, enabling remote inspection of rope structures. As the robot moves along the facility's wire ropes, lightweight design is essential for efficient operation.
- In this study, to achieve both lightweight construction and structural integrity, carbon fiber based on composite materials with high specific stiffness and strength were applied to the manipulator components. The structural integrity was evaluated through flexible multibody dynamic analysis, considering actual operating conditions.

Fig. 1. Conventional method for inspecting ropeway system

Fig. 2. Remote robot manipulator system for inspection

METHODS

Design for manipulator stacking pattern and deflection analysis

- For laminated composites, the stacking pattern and fiber orientation can be designed according to the designer's specifications. Consequently, the strength and stiffness of the structure under external loads vary depending on the lamination pattern.
- Since ropeway structures are exposed to complex loading conditions, the lamination pattern and thickness were set as design variables considering the composite manufacturing environment. Optimal lamination patterns were selected through deflection analysis of the manipulator's end tool.

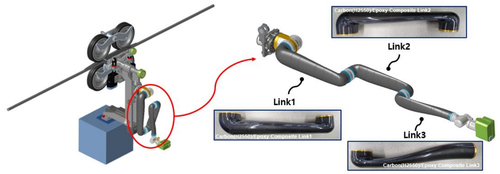

Fig. 3. Components of manipulator

- The deflection amounts based on the layup patterns presented in Table 1 were compared. For the motion environment, deflection analysis was performed under the condition shown in Fig. 3, where the manipulator is fully extended horizontally, causing maximum deflection at the end effector.

Table.1 Descripition of stacking pattern

Pattern	Stacking Pattern [Carbon(H2550)/Epoxy Composite]	Deflection of end tool [mm]
Pattern 1	$[0/90]_{10T}$	8.112
Pattern 2	$[0_3/\pm30]_s$	5.168
Pattern 3	$[0/90/\pm45/+45]_s$	4.875
Pattern 4	$[0/90/\pm45/0]_s$	4.061

- Based on the deflection analysis results for each layup pattern, the $[0/90/\pm45/0]_s$ layup configuration was selected. Subsequently, deflection analysis was performed and compared for varying composite thicknesses.
- As a result, the optimal composite thicknesses were determined to be 4T/3T/3T, which maximize the stiffness of the manipulator while satisfying the design mass criteria.

Table.2 Results of deflection analysis for link thickness

Case	Link1 Thickness	Link2 Thickness	Link3 Thickness	Mass [kg]	Deflection of Endtool [mm]
Case1	3T	3T	3T	3.106	2.832
Case2	4T	4T	4T	4.141	1.980
Case3	4T	4T	3T	3.912	2.036
Case4	4T	4T	2T	3.682	2.189
Case5	4T	3T	3T	3.576	2.262
Case6	4T	3T	2T	3.346	2.410
Case7	4T	2T	2T	3.010	2.901

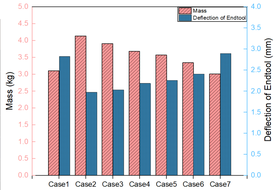

Fig. 4. Comparison of total mass and deflection

Structural Integrity evaluation of composite manipulator

- The structural integrity of the manipulator's composite link is evaluated using flexible multibody dynamics analysis.
- The applied loads include forces generated by the motion during ropeway structure inspection and the maximum wind load, as specified by facility standard regulations for the construction of track facilities.

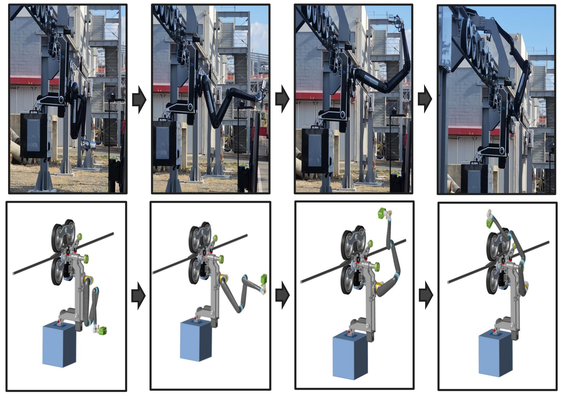

Fig. 5. Inspection motion of the manipulator

- Joint conditions were created to fully constrain the links and motors for flexible multi-body dynamics analysis and motor conditions were created using the Altair Inspire program.
- At Time 0.06 sec, the motion time when the maximum load and moment occur, the absolute max. Principal stress of 32.84 MPa was derived from the third CFRP link, and the maximum displacement of 0.249 mm was confirmed.

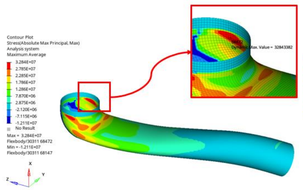

Fig. 6. Absolute Max. principal stress of FMBD link3

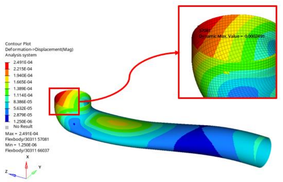

Fig. 7. Displacement of FMBD Link3

RESULTS

- In order to verify the reliability of the results derived from flexible multibody dynamics (FMBD) and structural analysis, the maximum principal stress and displacement results were compared.
- As the result of analysis, the maximum principal stress and displacement results between flexible multibody dynamics and structural analysis were confirmed to be the same, verifying the reliability.

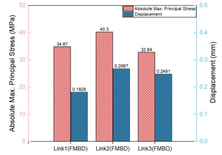

Fig. 8. Results of flexible multibody dynamic analysis(FMBD)

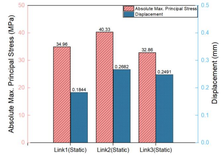

Fig. 9. Results of static analysis

- The Tsai-Wu Index of each manipulator CFRP link in the composite part was confirmed to be up to 0.079, confirming structural integrity.

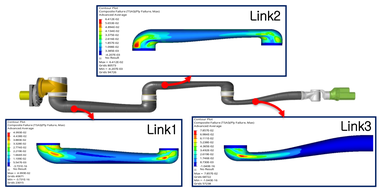

Fig. 10. Results of static analysis for composite manipulator

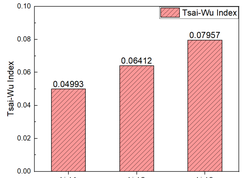

Fig. 11. Maximum Tsai-Wu Index of CFRP link

CONCLUSION

Summary

- In this study, the optimal composite stacking sequence and laminate thickness were determined to ensure the structural stiffness of the manipulator through deflection analysis. Furthermore, the structural integrity under complex loading conditions generated during the manipulator's inspection motion was evaluated. The failure analysis of the CFRP components under the maximum load and moment conditions was conducted using the Tsai–Wu failure criterion. The Tsai–Wu failure index remained below 1.0 for all CFRP links, validating the structural integrity of the manipulator design.

Keywords: Polymer recycling, Bio-based composites, Thermosetting resins, Accelerated aging

ABSTRACT

This work aims to investigate the impact of salt-fog exposure on the mechanical performance and recyclability of flax fabric-reinforced bio-based epoxy resins, with the goal of assessing their suitability for marine environments. In such a context, three bio-based epoxy systems—Polar Bear, Green Turtle, and Plankton (having bio-carbon contents of 28–70%), were combined with recyclable (Recyclamine™ R*101) and non-recyclable hardeners to produce flax fibre-reinforced biocomposites. Before assessing the aging resistance of the composites, a preliminary investigation was conducted to identify the most promising bio-based epoxy systems based on a thorough assessment of their initial mechanical and thermal characteristics. This preliminary investigation showed that Polar Bear and Green Turtle systems demonstrated quite good mechanical and thermal properties, while Plankton with recyclable hardener exhibited incomplete curing and poor mechanical performance.

Subsequently, four biocomposites were manufactured using the vacuum infusion technique, with the pre-selected bio-based epoxy systems as polymeric matrices and bidirectional flax fabrics as reinforcement. To simulate the aggressive conditions of marine and coastal environments, mechanical tests were systematically conducted on fibre reinforced composite samples exposed to accelerated salt-fog aging up to 3 months. The evolution of the mechanical performance of biocomposites during aging was analysed through flexural and low-velocity impact tests.

Similarly to the mechanical characterization, an optimized recycling process was carried out on bio-based composites aged under salt-fog spray conditions for 30, 60, and 90 days, as well as on unaged samples as a reference.

1 INTRODUCTION

Today, fibre reinforced polymer materials (FRPs) are a cornerstone of modern industry. Their widespread adoption is due to the powerful combination of their reinforcement and matrix phases, which work together to deliver exceptional strength, stiffness, and durability without adding significant weight. On the other hand, these materials have a significant environmental impact, stemming from both the high energy consumption and environmental footprints associated with the extraction and synthesis of their raw materials (i.e., synthetic fibres and petroleum-based polymers) and the substantial challenges in their end-of-life management, especially for thermoset-based composites [1]. Rigid and cross-linked thermoset matrices make most FRPs difficult to reprocess and reuse [2].

Given the imperative to reduce carbon dioxide emissions and the finite nature of fossil resources, there is a global push for more sustainable materials. Consequently, the full or partial replacement of synthetic fibres with their natural counterparts represents a valid choice to mitigate the environmental impact of traditional FRPs [3, 4]. Furthermore, to comprehensively address this issue, attention must also be directed toward the matrix phase, given that the development and utilization of bio-based, recyclable and/or biodegradable polymer matrices are critical for eliminating the environmental impact of FRPs.

In this context, significant recent research has focused on bio-based polymers as environmentally friendly and economically viable alternatives to traditional petroleum-derived materials. Specifically, bio-based thermoset resins, partially derived from renewable resources like plant oils and lignin, are gaining traction as eco-friendly composite matrices [5]. These bio-based thermoset resins present a greener alternative to conventional epoxies, not only maintaining desirable mechanical properties and chemical resistance but also promising a reduced carbon footprint and less reliance on non-renewable resources, thereby aligning with a circular economy.

To further enhance sustainability, the recyclability and end-of-life management of bio-based epoxy composites are crucial research areas. Therefore, developing novel bio-based epoxy chemistries that allow for easier depolymerization or reprocessing without significant performance loss is a critical advancement. While thermal and mechanical recycling of fibre-reinforced composites have limitations, chemical recycling offers a promising alternative for recovering clean fibres and valuable monomers [6]. Cleavable amine-based epoxy systems, which allow for the recovery of thermoplastics and intact fibres under mild aqueous conditions, have shown technical and environmental effectiveness, though their long-term durability, especially with natural fibres, needs further investigation [7]. Due to these reasons, the present study comprehensively investigates the aging resistance of bio-based epoxy composites reinforced with flax fibres by evaluating their durability under harsh environment (i.e., salt-fog spray condition) also evaluating the impact of salt-fog exposure on durability of novel and potentially recyclable bio-based epoxy resins and their flax fibre reinforced composites.

Before assessing composite aging resistance, a preliminary investigation identified the most promising bio-based epoxy systems based on their initial mechanical and Thermal characteristics. Subsequently, four fibre-reinforced composites were manufactured through vacuum infusion technique, utilizing the pre-selected bio-based epoxy systems as polymeric matrices and bidirectional flax fabrics as reinforcement.

These composite materials were then exposed to salt-fog spray conditions for up to three months to assess the impact of this harsh environment on their mechanical performance and recyclability. For this purpose, a comprehensive mechanical characterization (including flexural tests, and low-velocity impact tests) was conducted on unaged samples (used as reference) and on samples aged for 30, 60, and 90 days. Similarly, following a preliminary optimization of the recycling process on unaged biocomposite samples, the recycling yield was investigated as function of the salt-fog exposure time.

2 MATERIALS AND METHODS

Three bio-based epoxy monomers - Polar Bear, Green Turtle, and Plankton - supplied by R*Concept, were used in this work. In particular, the monomer Polar Bear, with a bio-carbon content exceeding 28%, was mixed with the recyclable hardener Recyclamine™ R101 (100:22 by weight). This system serves as a reference in this work because it was already studied recently by other authors regarding its recyclability and usability as a polymeric matrix for FRPs [8-10]. Its recyclability is attributed to Recyclamine, an amine-based hardener containing cleavable bonds within its structure. Specifically, this polyamine hardener, 2,2-Bis(aminoethoxy)propane, reacts with epoxy rings during curing to form acid-cleavable groups. These groups enable the recycling of epoxy thermosetting plastics and their composites. The process yields soluble monomeric or oligomeric products suitable for reuse, along with valuable fibres that retain their properties. The presence of these cleavable bonds allows the thermoset to transform into a thermoplastic polymer when crosslinks are broken via chemical treatment in an acetic acid solution [11-13].

The epoxy monomers Green Turtle (bio-carbon content >40%) and Plankton (bio-carbon content >77%) were each mixed with their non-recyclable hardeners (100:30 by weight) and with Recyclamine™ R101 (100:22 by weight) to obtain four additional epoxy systems.

Overall, five epoxy resins were initially evaluated for their mechanical and thermal properties. Mechanical tests involved three-point bending of five prismatic samples per resin (57.6 × 12.7 × 3 mm) using a Zwick-Roell Z005 machine (ASTM D790, 1.3 mm/min crosshead speed, 48 mm support span). Thermal behaviour was assessed via differential scanning calorimetry (DSC) on three 10 mg specimens per system using a Netzsch DSC 214 Polyma, heated from -20 °C to 210 °C at 10 °C/min under nitrogen flow.

After this preliminary comparison, the epoxy system obtained by mixing the Plankton monomer with the Recyclamine hardener was excluded from the subsequent biocomposite investigation due to its poor mechanical and thermal performance. Therefore, the remaining four epoxy systems were reinforced with six layers of flax balanced twill weave woven fabrics, supplied by Lineo, each having a nominal areal weight of 320 g/m^2. Rectangular panels (175 mm × 300 mm) were manufactured for each system using a vacuum infusion technique. The curing process involved an initial 24-hour cure at room temperature under vacuum, followed by post-curing. For the Polar Bear system, post-curing was conducted at 100 °C for 3 hours, while the Green Turtle and Plankton systems were post-cured at 80 °C for 4 hours. As indicated in Table 1, the investigated bio-based composites are coded F-PB-R, F-G-R, F-G-NR, and F-P-NR. 'F' denotes flax reinforcement, “PB”, “G”, and “P” represent Polar Bear, Green Turtle, and Plankton bio-based epoxy matrices, and “R” or “NR” indicate a recyclable (with Recyclamine) or non-recyclable epoxy matrix, respectively.

Composite	Nominal thickness [mm]	Fibre content [v/v%]	Experimental density [g/cm^3]	Theoretical density [g/cm^3]	Void content [v/v%]
F-PB-R	3.91	0.325	1.264	1.320	4.22
F-G-NR	4.01	0.317	1.252	1.309	4.31
F-P-NR	3.98	0.320	1.255	1.309	4.11
F-G-R	4.04	0.314	1.259	1.315	4.20

Table 1: Flax fibre-reinforced biocomposites.

2.1 Salt-fog spray aging conditions and characterization methods

The aging resistance of biocomposites was evaluated by exposing them to a salt-fog spray condition in a climate chamber (Ascott model CC1000IP) according to the ASTM B117 standard. Each panel was exposed to salt-spray fog (5 wt.% NaCl) at 35 °C ± 1°C for up to 3 months (90 days). A single set of specimens for mechanical characterization was removed from the climatic chamber and tested after 30, 60, and 90 days. Unaged specimens were also tested as a reference.

Three-point bending tests were conducted on prismatic specimens (80 mm × 17 mm) according to the ASTM D790 standard, using a Zwick-Roell Z005 universal testing machine. The span length and the crosshead speed were set to 64 mm and 1.7 mm/min, respectively

Low-velocity impacts were performed at room temperature with a 5 J energy level, using a 12.7 mm diameter hemispherical impactor weighing 3.05 kg. These impact tests were conducted using an Instron/Ceast 9340 instrumented drop-weight impact tower, following the ISO 6603-2 standard. For the tests, 7 cm × 7 cm square specimens were clamped between two steel plates, creating a 40 mm diameter circular unsupported area.

The morphology of the fractured surfaces of tensile samples was observed through a scanning electron microscopy (SEM, Quanta 450, USA).

The recycling process was applied to bio-based composites aged under salt-fog spray conditions for 30, 60, and 90 days, along with unaged reference samples. First, the recycling process was optimized on unaged composites made by Polar Bear resin. The selection of the optimum conditions for the recovery of thermoplastics was carried out starting from the methodology described by Saitta et al. [8]. Specifically, the variable parameters were the acetic acid concentration, the dissolution time, and the

ratio between the dissolved epoxy resin and acid. In a typical procedure, 10 g of epoxy resin were dissolved in an acetic acid solution (either 75% or 50% v/v) using resin-to-acid ratios of 1:30 or 1:20 (w/v). Dissolution was conducted at 80 °C for 90 or 180 minutes under constant mechanical stirring. After complete dissolution, flax fabrics were removed, washed in deionized water, and dried at 80 °C for 24 hours. The remaining solution was evaporated until its volume reached 75 mL. After cooling to 20 °C, it was neutralised with a 15% v/v ammonium hydroxide solution. The resulting precipitate was separated from the solution, washed with distilled water, and dried for 24 hours at 60 °C in a vacuum of 30 mbar. The optimal parameters and conditions for recycling the bio-based composite were finalised by evaluating recycling yield of the recovered thermoplastics.

The mass of recovered thermoplastics was taken into account to evaluate the recycling yield. The yield for the chemical recycling analyzed is determined by considering the Equation 1.

$$Yield\ (\%) = \frac{W_{initial}}{W_{product}} \cdot 100 \quad (1)$$

where $W_{initial}$ and $W_{product}$ represent the mass of the initial epoxy resin in the composite sample and the mass of the thermoplastic obtained after recycling, respectively.

Beyond yield analysis, the recovered thermoplastic's thermal properties were assessed, with differential scanning calorimetry (DSC) used to determine its glass transition temperature (T_g). The polymer degradation temperature was determined as a peak on the DTG curve.

3 RESULTS AND DISCUSSION

3.1 Bio-epoxy resins

Table 2 reports on the main mechanical and thermal properties of the bio-epoxy resins investigated. This preliminary investigation evidenced that all innovative systems (those obtained using Green Turtle or Plankton as bio-epoxy monomers) exhibit lower flexural strength and modulus, and higher deformation at break, compared to the reference (PB-R). Specifically, by mixing Plankton monomer (which has the highest bio-carbon content) with the recyclable hardener, dramatically decreases its flexural properties. In particular, the P-R epoxy system exhibits negligible strength and modulus values (2.0 MPa and 0.021 GPa, respectively), rendering it completely unsuitable as a polymeric matrix for biocomposites. Furthermore, the latter epoxy displayed a strain at break of 11.8%, a value notably higher than the typical range for fully cured thermoset polymers.

Composite	Flexural strength [MPa]	Flexural modulus [GPa]	Strain at break [%]	T_g [°C]
PB-R	97.6±8.1	2.8±0.2	4.1±0.7	67.9±0.2
G-NR	73.2±5.7	1.9±0.2	6.5±0.5	63.7±0.2
P-NR	83.9±3.7	2.8±0.1	4.9±0.1	76.3±0.2
G-R	39.9±0.6	1.1±0.02	7.9±0.2	31.0±0.2
P-R	2.0±0.2	0.02±0.004	11.8±1.3	18.6±0.3

Table 2: Mechanical and thermal properties of the bio-based epoxy resins.

Accordingly, calorimetric analysis showed that epoxy systems made with Green Turtle and Plankton monomers and non-recyclable hardeners (G-NR and P-NR) have glass transition temperatures (T_g) of 60 to 75 °C, similar to the reference system (PB-R). In contrast, using Recyclamine with either monomer significantly lowers the T_g values. Specifically, the P-R epoxy system shows a T_g of about 19 °C, much lower than typical room-temperature cured epoxy resins. These findings are likely due to an incomplete curing reaction between Recyclamine and the Plankton monomer, resulting in a thermoset structure with a relatively low cross-linking density. Indeed, the Plankton monomer is bisphenol-free, containing more than two epoxy rings in its chain. Consequently, it did not react properly with Recyclamine, which is designed to cure with DGEBA (such as Polar Bear and Green Turtle). Overall, the preliminary investigation indicated that this epoxy system is unsuitable as a composite matrix and will be excluded

from the subsequent phase of the work, which involves assessing biocomposites' performance during aging.

3.2 Bio-based epoxy composites

The flexural strength and modulus values of unaged bio-based composites are presented in Figure 1.

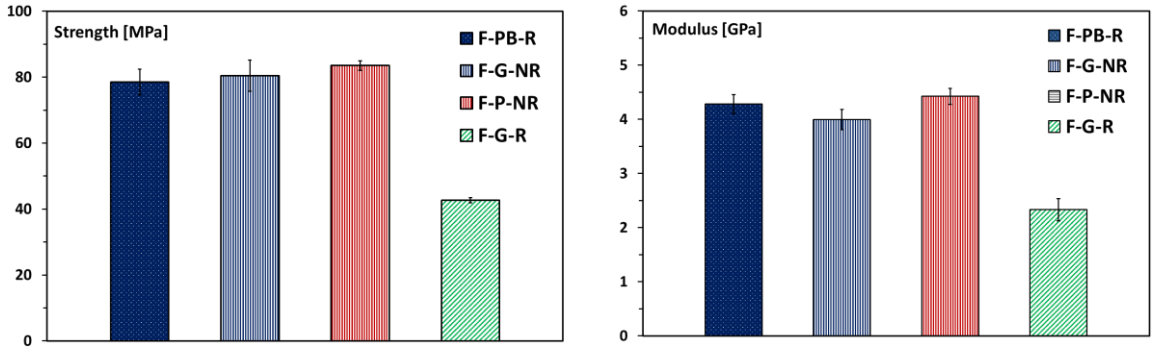

Figure 1: Flexural strength and modulus of unaged biocomposites.

By observing these graphs, it is possible to notice that biocomposite made with the G-R epoxy resin (i.e., obtained by combining Green Turtle monomer with Recyclamine hardener) exhibited approximately half the flexural properties compared to other investigated biocomposites whereas biocomposites derived using standard epoxy resins (G-NR and P-NR) as matrix exhibited mechanical performance in their unaged state comparable to those manufactured with the reference epoxy matrix (PB-R). These results are in full agreement with observations for neat (i.e., unreinforced) polymeric epoxy systems.

The impact of salt-fog exposure on the flexural properties (strength and modulus) of the investigated biocomposites is displayed in Figure 2.

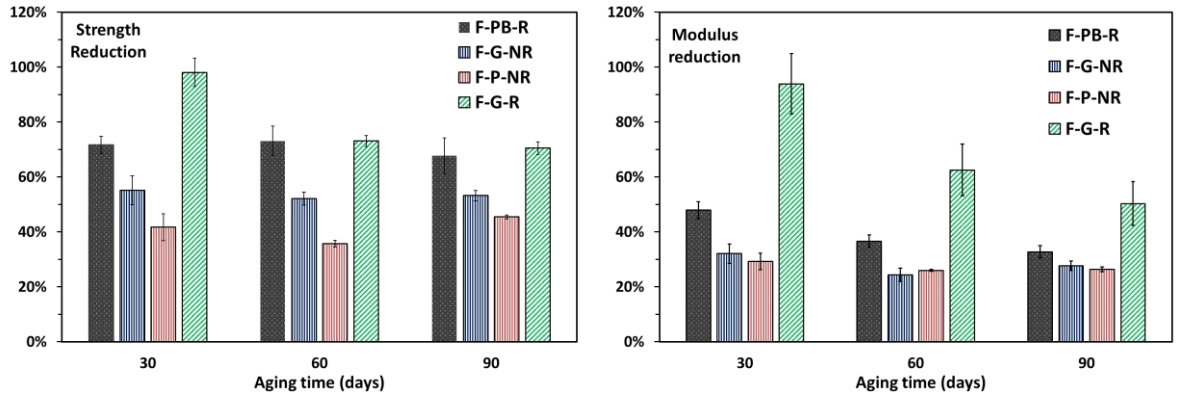

Figure 2: Variation of (a) flexural strength and (b) modulus of aged biocomposites for different aging times.

First, it is worth noting that, despite their initial high flexural properties, F-PB-R, F-G-NR, and F-P-NR laminates exhibited poor aging resistance, with significant declines in mechanical stability after just 30 days of salt-fog exposure. During this initial aging period, the flexural strength and modulus of F-PB-R composites decreased by 28.3% and 52.1%, respectively. Even more pronounced, the F-G-NR and F-P-NR samples exhibited flexural strength reductions of 44.8% and 58.3%, respectively, while their flexural modulus decreased by 67.9% and 70.7%. On the other hand, the F-G-R laminates surprisingly exhibited the best stability against salt-fog, demonstrating only slight decrements in flexural strength and modulus (1.9% and 6.1%, respectively) compared to their initial values after 30 days of exposure.

All bio-based composites experienced reduced mechanical performance when salt-fog exposure was prolonged to 60 and 90 days (2 and 3 months). In particular, F-G-R samples not only retained their mechanical performance after the first month of aging but also exhibited only gradual declines in properties even after 60 and 90 days of salt-fog exposure. After 90 days, for instance, flexural strength and modulus showed reductions of only 29.5% and 49.6%, respectively, in comparison to unaged samples.

These results can be explained by considering that, regardless of the bio-epoxy resin matrix, the main degradative mechanism during aging was matrix plasticization rather than internal damage at the fibre-matrix interface. As clearly shown in Figure 3, this led to reduced composite stiffness and increased flexibility for all bio-based composites.

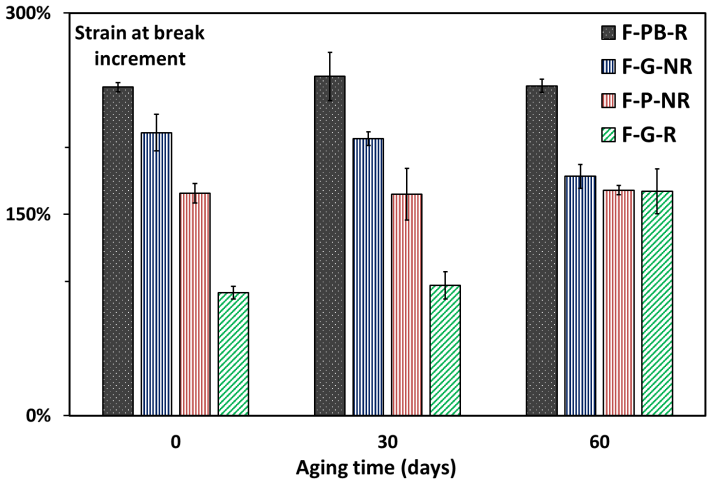

Figure 3: Variation of flexural strain at break of aged biocomposites for different aging times.

Specifically, F-PB-R, F-G-NR, and F-P-NR showed plasticization within the first 30 days of salt-fog exposure, whereas this phenomenon was time-delayed for F-G-R, which evidenced a noticeable strain at break increment in the last 30 days of aging.

Figure 4 includes the representative force-displacement curves related to the low-velocity impact (LVI) tests performed on unaged bio-based composites. The performance of the biocomposites in relation to impact energy is very similar. Indeed, all the curves are closed, meaning that no laminate penetration occurred, regardless of the matrix used and the aging condition. Furthermore, F-GT-R composites exhibit the worst initial impact properties, with the lowest maximum force. Conversely, biocomposites F-G-NR and F-P-NR show the best impact behaviour prior to salt-fog exposure.

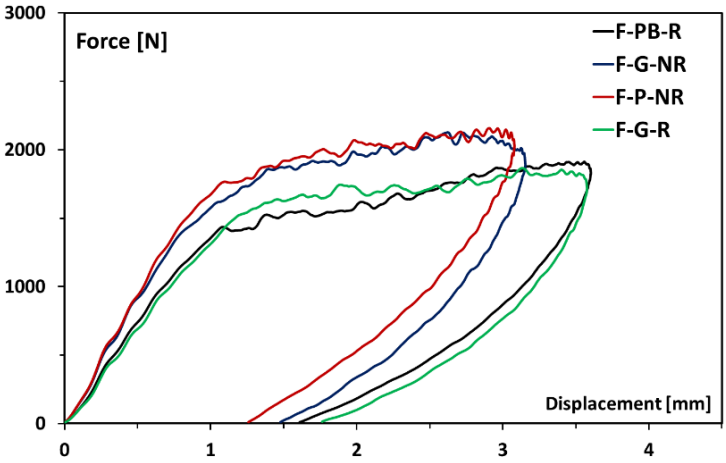

Figure 4: Representative load-displacement curves for all unaged biocomposites obtained during low velocity impact tests.

The impact of aging on impact behaviour is characterized by main parameters from LVI tests, detailed in Table 3 as a function of salt-fog exposure time. These include maximum displacement (D_{max}) and damage degree (DD), calculated as the ratio of absorbed to impact energy (5 J).

Comparing the mechanical behaviour of biocomposites under low-velocity impact after salt-fog exposure, we notice that the impact performance of F-G-R composites was minimally affected by aging, consistent with quasi-static results. In contrast, salt-fog exposure proved particularly detrimental for Plankton-based composites (F-P-NR), leading to the most significant increases in damage.

Composite	F_{max} [N]	D_{max} [mm]	DD
F-PB-R	1891.5±30.1	3.6±0.1	0.76±0.01
F-PB-R_30	1942.3±68.6	4.1±0.2	0.78±0.02
F-PB-R_60	2187.9±95.1	3.7±0.1	0.76±0.01
F-PB-R_90	2018.4±67.5	4.1±0.2	0.78±0.02
F-G-NR	2105.4±31.4	3.2±0.1	0.77±0.01
F-G-NR_30	2088.8±36.4	3.6±0.1	0.78±0.01
F-G-NR_60	2041.7±62.2	3.7±0.1	0.82±0.01
F-G-NR_90	2091.9±23.7	3.7±0.1	0.79±0.01
F-P-NR	2198.9±57.6	3.1±0.1	0.72±0.01
F-P-NR_30	1834.3±22.7	4.1±0.1	0.81±0.01
F-P-NR_60	1990.8±87.5	3.7±0.2	0.79±0.02
F-P-NR_90	2248.5±33.8	4.1±0.1	0.80±0.01
F-G-R	1808.3±59.7	3.6±0.1	0.79±0.01
F-G-R_30	1854.1±20.6	4.3±0.1	0.82±0.01
F-G-R_60	1947.5±82.3	3.9±0.2	0.81±0.01
F-G-R_90	1920.7±69.7	3.8±0.1	0.82±0.01

Table 3: Main parameters obtained by LVI tests.

Overall, the data reported in Table 3 reveal that all bio-based composites exhibit increased maximum force, impactor displacement, and damage degree with increasing salt-fog exposure time. Furthermore, an overall decline in linear stiffness is observed during aging for all bio-based composites.

These results represent an indication of the augmented compliance shown by all biocomposites after aging. The greater absorbed energy with increased salt-fog exposure time confirms matrix plasticization as the main degradative phenomenon, which also plays a significant role in mitigating some internal damage due to a deterioration in interfacial adhesion, as corroborated by the post-impact analysis of sample surfaces. Indeed, observations of the impacted samples' front and back surfaces revealed that all biocomposites exhibited a significant reduction in indentation on the impacted face and crack severity on the opposite face after just 1-month aging. Figure 5 displays the impacted and opposing faces of only F-G-R samples before aging and after one month of salt-fog exposure. All biocomposites behaved similarly, and therefore, their related images are not included here for the sake of conciseness.

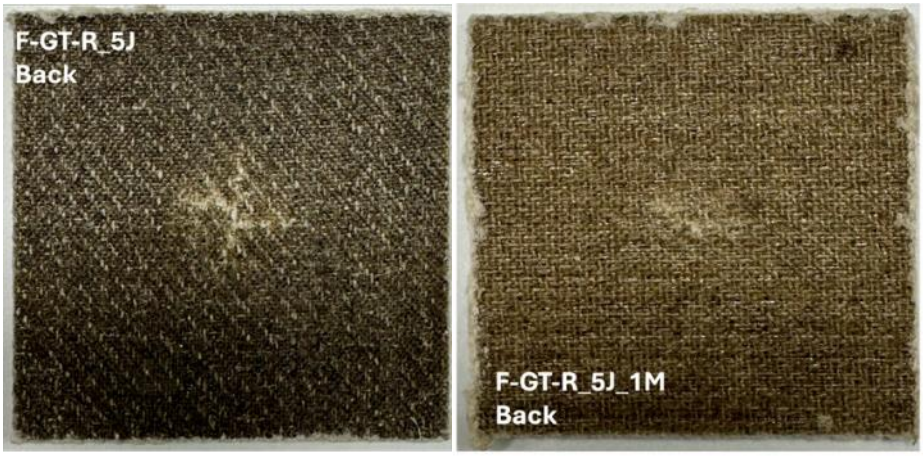

Figure 5: Observation of front and back surfaces of unaged and 1-month aged F-G-R biocomposites.

As concerns the recycling process, preliminary studies were conducted on the unaged F-PB-R composite samples. As detailed in Table 4, the investigation into the influence of chemical processing parameters—specifically acetic acid quantity, solution concentration, and dissolution time—demonstrated that a decrease in acid concentration from 75% to 50% correlated with a 32–65% reduction in product yield under consistent experimental conditions. The highest yield, 73.5%, was attained under optimum conditions: 200 ml of 75% v/v acetic acid and a dissolution time of 180 minutes. This indicates that peak yields necessitate high acidity and adequate dissolution time; conversely, diminished yields observed at 50% acidity and reduced dissolution periods are likely attributable to incomplete reaction kinetics and deviations from optimal pH levels. Furthermore, all recycled thermoplastic materials exhibited a glass transition temperature ranging from 73-82°C, indicating only slight variation based on recycling conditions. At lower acid concentrations (50% v/v), the T_g values were higher (~81°C), which may indicate lower cleavage of the cross-linked structures and reduced chain mobility. In contrast, samples processed under optimized conditions (75% v/v acetic acid, 200 mL, 180 min) showed the highest yield (73.5%) and a lower T_g (76.5°C), indicating a greater degree of depolymerization. These results demonstrate an inverse relationship between product yield and glass transition temperature, confirming that the use of high acid concentration and long reaction time effectively promotes efficient recycling.

Composite	Solution volume [mL]	Solution concentration [% v/v]	Dissolution time [min]	Recycling yield [%]	Glass transition temperature [°C]
F-PB-R	300	75	90	50.3	73.3
F-PB-R	300	75	180	34.2	75.6
F-PB-R	300	50	90	34.2	81.7
F-PB-R	300	50	180	34.9	79.4
F-PB-R	200	75	90	58.9	76.7
F-PB-R	200	75	180	73.5	76.5
F-PB-R	200	50	90	20.5	75.7
F-PB-R	200	50	180	25.1	81.1

Table 4: List of factorial experiments and main results for selecting optimal conditions for the recycling process.

In light of these findings, the optimized recycling conditions (200 mL solution volume, 75% v/v solution concentration, and 180 min dissolution time) were then employed to investigate the effect of aging on the efficiency of the bio-based composite. To this aim, recycling of both F-PB-R and F-GT-R samples was performed after 30, 60, and 90 days of salt-fog exposure.

As shown in Figure 6, the exposure to salt fog did not influence the recyclability of the biocomposites

to a high extent, regardless of the bio-epoxy resin used as matrix. Indeed, a slight increase in the recycling yield was found for both bio-based composites. Specifically, the unaged F-G-R sample exhibited an 80.7% thermoplastic yield under optimum conditions. This increased by about 4% to 84.7% after 90 days of aging in a climate chamber (F-G-R-90). On the other hand, the recycling yield of Polar Bear-based composites (F-PB-R) improved by 2.7%, from 73.5% (unaged sample) to 75.5% (90-day aged samples). Regarding the thermal behavior of the recycled material, limited reductions were observed in the glass transition temperatures for both bio-based epoxy resins across varying salt-fog exposure times.

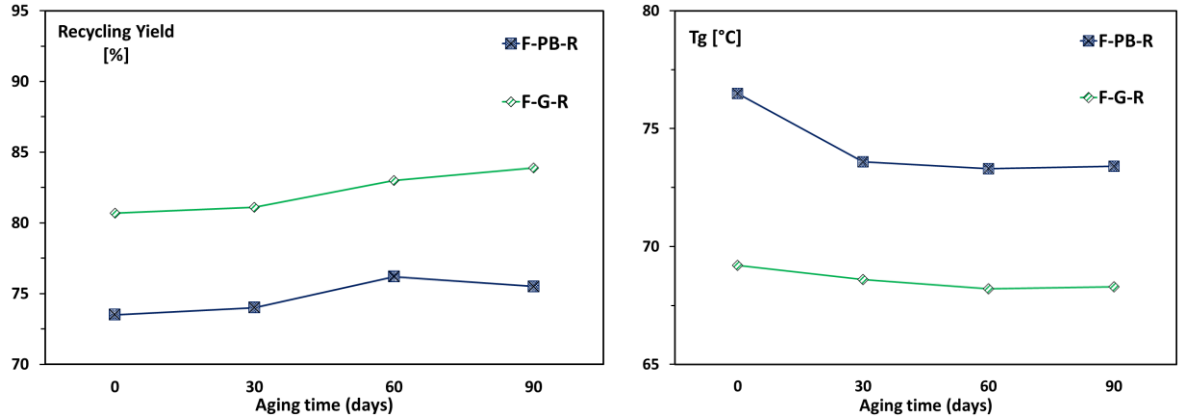

Figure 6: Recycling yield and glass transition temperature values at varying salt-fog exposure.

Overall, these findings clearly demonstrate that the recyclability of the investigated bio-based composites was not negatively impacted by their exposure to aggressive environmental conditions, such as salt-fog. In fact, their ability to be recycled remained robust even after significant environmental stress, highlighting their potential for sustainable applications. It is worth noting that this represents an ongoing research activity. Further investigation will be conducted to gain a more comprehensive understanding of the recycled material's primary thermal and mechanical properties.

9 CONCLUSIONS

The experimental results demonstrate that all bio-based thermosetting composites exhibited satisfactory performance when subjected to aggressive conditions simulating a marine environment. Notably, both systems with lower bio-content can be recycled, unlike the one with the highest bio-content. These findings indicate that lower bio-content correlates with higher environmental resistance. Both reinforced recyclable epoxy composites (Polar Bear and Green Turtle) exhibited quite good mechanical strength with minimal loss of performance over several months of aging. In contrast, the Plankton-reinforced composites experienced a significant and progressive decline in performance over the same period. Consequently, the Green Turtle epoxy matrix emerges as the most suitable option, exhibiting high bio-content and recyclability, even after exposure to salt-fog spray condition. This combination positions it as a prime candidate to replace fossil-based epoxy resins, aligning with the principles of eco-sustainability and circular economy.

ABSTRACT

There is a growing demand to increase the reliability of polymer composite materials by modifying their failure behavior. In this study, we developed and investigated a method that can be used to influence the damage processes and failure behaviour of composites by locally applying polycaprolactone (PCL) interlayer material. We manufactured locally interfacially engineered UD carbon/epoxy composite plates and conducted short-beam shear tests to investigate the effects related to the application and the geometry of PCL on the interlaminar shear strength, the damage processes and the final failure of the composite in case of interlaminar loading. Furthermore, we carried out finite element modeling using the cohesive zone method (CZM) to analyze the influence of PCL interlayer material on the initiation and propagation of damage. The results show that the application of PCL is suitable for modifying the damage and failure processes of UD carbon/epoxy composites when applied to interlaminar loading.

1 INTRODUCTION

Nowadays, polymer composites are gaining popularity, mainly due to their excellent mechanical properties and low density. With the widespread use of high-performance composite structures, they are emerging in structural components subjected to significant loads. However, in safety-critical applications, their failure process might be disadvantageous. To ensure the further spread of composites in structural applications, their damage and failure processes need to be influenced and controlled [1].

The failure of composites is a complex process. As a result of their complex microstructure and their manufacturing processes, polymer composites contain a wide range of flaws from different sources and in varying sizes. The failure process consists of several concurrent damage processes leading to the final failure of a composite part. With the proper design of the composite system, this failure behavior can be turned to our advantage, contributing to increased reliability of polymer composite materials [2].

Several methods can be used to influence and control the damage processes and failure behavior of polymer composites. One concept is to predefine the location of damage initiation and failure, which can be achieved by introducing artificial defects [3]. This method may simplify structural health monitoring and improve the repairability of the composite part. Another way is to influence damage propagation and the mode of failure, or even achieve a pseudo-ductile behavior with a gradual failure process on the macroscopic level. Several different methods can be related to this concept. Damage propagation can be influenced by modifying at least one phase – the matrix [4], the reinforcement [5], or the interface [6] – or by applying a fibrous [7] or thermoplastic [8] interlayer material. The concepts of predefining the location of the failure and influencing or controlling the failure mode can also be combined, providing a designed failure of the composite part [9].

Our research group developed a novel method to create composites with a designed interface via 3D printing specific patterns of polycaprolactone (PCL) interlayer material directly on the reinforcement

system [10-12]. The low melting temperature of PCL enables simple processability through additive manufacturing, which ensures a great freedom of design of the interlayer. PCL is soluble in epoxy; thereby, in the case of polymer composites with epoxy matrix, it does not create a new phase. PCL can modify the interfacial adhesion and the matrix material locally. Therefore, it can be used to modify the failure of composites by controlling delamination, increasing fracture toughness, and achieving a pseudo-ductile behavior. Furthermore, by applying PCL as clever interfacial patterns in the composite structure, the formation of damage and, finally, the location of the failure can be predefined in terms of mode and position.

The aim of the current research was to influence the failure behavior of UD carbon/epoxy composites by predefining failure location and modifying damage propagation in case of interlaminar loading, and to validate the method of local interface engineering carried out with polycaprolactone (PCL) interlayer material. A further goal of the study was to provide a better understanding of the effects related to the method in terms of damage initiation and propagation through finite element modeling (FEM).

2 EXPERIMENTAL

2.1 Materials

As matrix material of the manufactured composite plates, IPOX MR 3010 (IPOX Chemicals Kft., Budapest, Hungary), DGEBA-based epoxy resin (EP) was applied with IPOX MH 3124 amine type curing agent. The components were mixed in a weight ratio of 100:35 (mixture viscosity 500 mPa·s, pot life 30 min at 25°C). We used PX35FBUD0300 (Zoltek Zrt., Nyergesújfalu, Hungary) stitch-bonded unidirectional carbon fabric (309 g/m2 surface weight), consisting of Panex35 50k rovings as reinforcement material. The interlayer material was printed from eMorph175N05 (Shenzhen Esun Industrial Co. Ltd., Shenzhen, China) poly (ϵ-caprolactone) (PCL) filament (1.75 mm diameter, 60°C melting temperature, 180°C printing temperature).

2.2 Manufacturing of composite plates

For the experiments, composite plates with $[0°_6]$ layup sequence were manufactured by vacuum-assisted resin transfer molding (VARTM). Besides baseline composites, locally interfacially engineered composites containing PCL interlayer material were manufactured. For these plates, the PCL filament was printed directly on the surface of the carbon fabric by the fused filament fabrication (FFF) method (Fig. 1) using a CraftBot Plus 3D printer (CraftUnique Kft., Budapest, Hungary). In the case of interfacially engineered composites, the interlayer material was applied perpendicular to the fiber direction (Fig. 1) and was placed only between the two central plies. Regarding the geometry of PCL, the thickness of the interlayer material was, based on previous research [9], constantly 0.2 mm in order to avoid fiber waviness and focus on the effects related to other mechanisms of PCL, such as the local modification of the matrix material and the interfacial adhesion. However, the width (w) of the interfacially engineered zone varied, PCL interlayer materials with 1, 2, 4 and 6 mm width were applied.

Figure 1: PCL interlayer material 3D printed directly on the reinforcement material.

Specimens for the material testing were cut from the composite plates with a Mutronic Diadisc (Mutronic, Rieden am Forggensee, Germany) diamond disc cutter. Each interfacially engineered specimen contained one zone modified with PCL.

2.3 Methods

Short-beam shear (SBS) tests were carried out according to ISO 14130 standard using a Zwick Z250 (Zwick GmbH, Ulm, Germany) universal testing machine with a 20 kN load cell to investigate the effect of PCL and its geometry on the failure process. The test setup can be seen in Fig. 2. The measurements were conducted with a 1 mm/min test speed using specimens with a nominal thickness of 3 mm, a width of 15 mm, and a length of 30 mm. The supports had a radius of 2 mm, while the loading member had a radius of 5 mm. The short-beam shear tests were monitored with a 5 MPixel resolution IDS U3-3080CP-P-GL (Imaging Development Systems Inc., Obersulm, Germany) camera. We tested 10 specimens from each type.

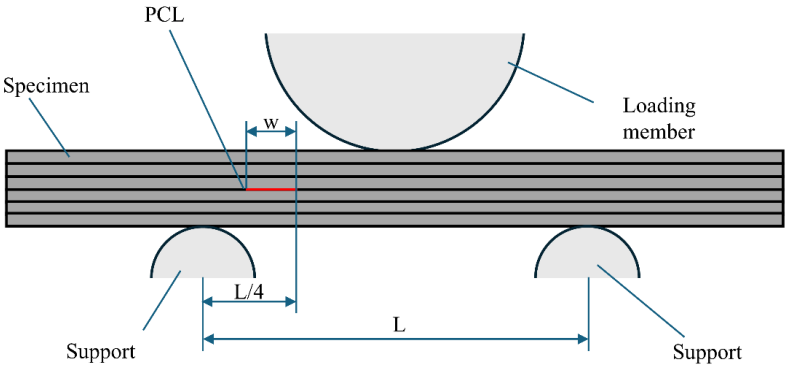

Figure 2: The test setup of the short-beam shear tests

3 FINITE ELEMENT MODELING

For modeling the delamination, we conducted finite element analysis for the loading and boundary conditions of the short-beam shear test with Ansys Workbench 2024R1 FEM software using the cohesive zone method (CZM). The model parameters were specified based on the relevant literature [12] and refined using our own data. To model the delamination process, we applied the fracture energy–based debonding model available in the software. A pure Mode II fracture model was adapted, reflecting the dominant shear-driven delamination mechanism in the short-beam shear test.

Two modeling concepts were used. The first approach involved introducing an artificial defect at the interface in the zone containing PCL. This was achieved by removing the contact definition between the adjacent surfaces of these plies over the width of the interlayer material. In this setup, no contact regions or cohesive separation definitions were assigned to the interfacially engineered zone, simulating an initial delaminated zone. In the subsequent simulations, the locally modified adhesion zone was modeled using the cohesive zone parameters of an interface modified with PCL. Non-modified interfacial regions were modeled with CZM using the parameters related to a baseline interface in each case.

To define the CZM model, interlaminar shear strength values, related to a baseline and a PCL-modified interface, determined during the short-beam shear tests, were used. Further CZM parameters and material properties are shown in Table 1.

Parameter		Value
E_1	[GPa]	123.3
E_2 *and* E_2	[GPa]	7.78
ν_{12} *and* ν_{13}	–	0.27
ν_{23}	–	0.42
G_{12} *and* G_{13}	[GPa]	5.00
G_{23}	[GPa]	3.08

G_{IIC} [12]	[J/m^2]	234.1
$G_{IIC,PCL}$ [12]	[J/m^2]	334.1

Table 1: Material properties and CZM parameters.

4 RESULTS AND DISCUSSION

4.1 Results of the short-beam shear tests

Initially, the force-deflection curves obtained from the measurements should be analyzed. Fig. 3 demonstrates the force-deflection curves of a characteristic specimen for each type.

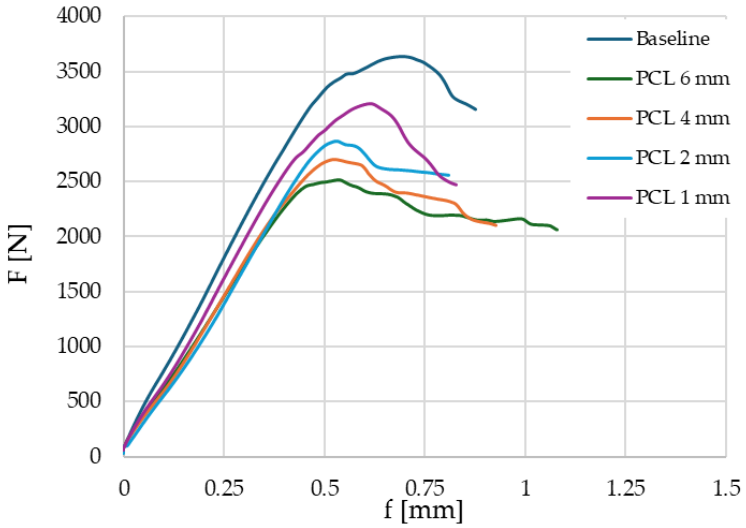

Figure 3: Characteristic force-deflection curves of the short-beam shear tests

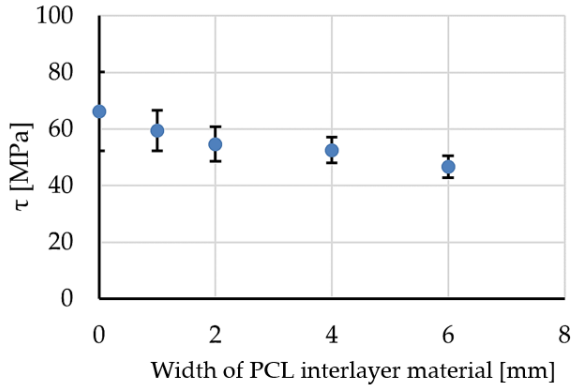
The curve of the baseline sample indicates sudden delamination propagation. Compared to the baseline specimens, the specimens with 1 mm and 2 mm wide PCL interlayer material exhibit a lower maximum force. However, the overall shape of the force-deflection curve is similar to that of the baseline samples, indicating relatively rapid crack propagation. In this case, PCL acts as a local defect, and crack initiation is expected to occur near the interfacially engineered region. In contrast, for the specimens containing 4 mm and 6 mm wide PCL interlayer material, a plateau appears after the reduced force maximum. This indicates that the interfacially engineered zone slows down the propagation of the delamination.

The calculated interlaminar shear strength values can be seen in Fig. 4. The results show that increasing the width of the PCL interlayer material reduces the interlaminar shear strength, while the standard deviation of the results decreases significantly as well, indicating a more predictable failure.



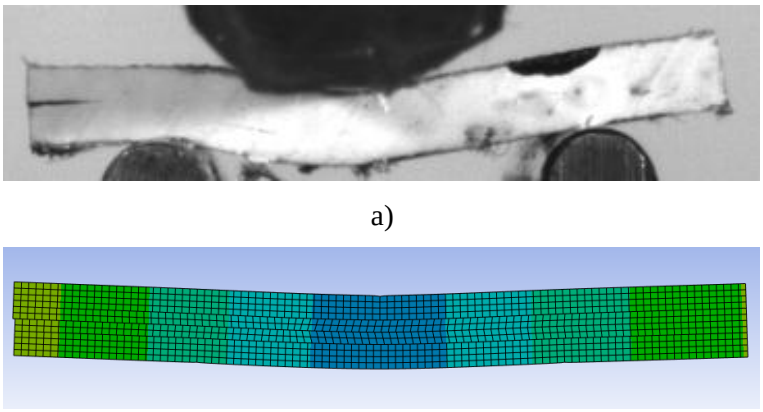


Figure 4: Interlaminar shear strength determined with the short-beam shear tests.

4.2 Results of the finite element analysis

The finite element analysis resulted in the delamination failure of the specimens similar to the short-beam shear tests (Fig. 5).

a)

b)

Figure 5: Delamination failure during a) a conducted short-beam shear test, b) finite element analysis of a short-beam shear test

As the contact status in Fig. 6 indicates, compared to the baseline model, the modified zone predefines the position of delamination initiation for both modeling concepts. This means that even in the case of the lowest width, the method is suitable for influencing the position of interlaminar crack initiation.

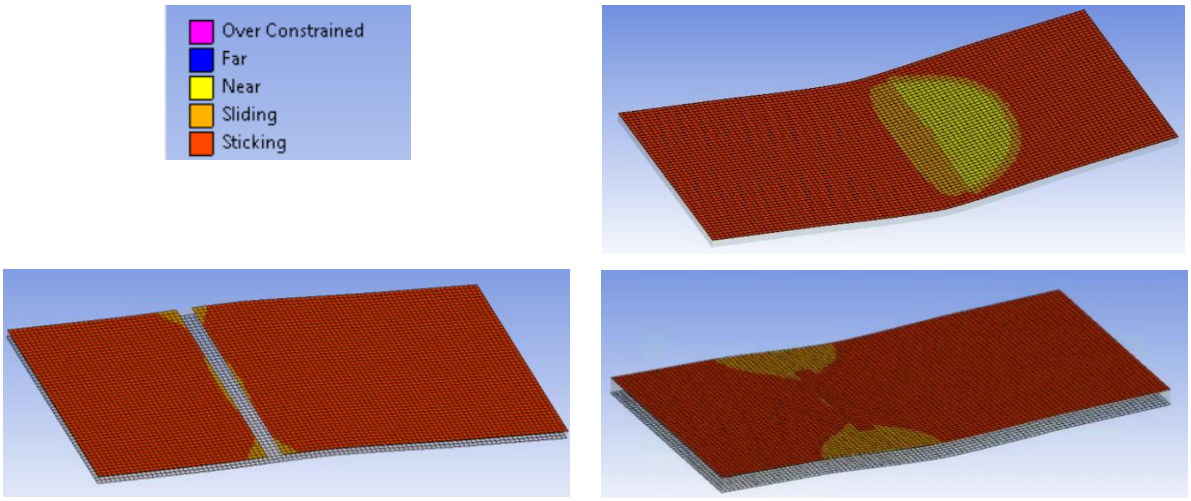

Figure 6: Contact status between the two central plies a) Status types, b) Baseline, c) PCL as initial delamination in 1 mm width, d) PCL interlayer material with 1 mm width

Table 2 contains the calculated interlaminar shear strength values, while the force-deflection curves of the simulations are shown in Fig. 7. Besides the baseline simulations, the curves include the results of the 1 mm and 4 mm wide simulations. In the experimental results, these two specimen types demonstrated completely different behavior. The 1 mm wide zone had an effect similar to an initial defect. Meanwhile, the 4 mm wide zone was the first to result in an extended plateau.

Type	Interlaminar shear strength [MPa]		
	Experimental	FEA	
		Initial delam.	PCL
Baseline	66.2	67.9	
1 mm	59.4	48.6	65.0
4 mm	52.5	39.6	56.3

Table 2: Interlaminar shear strength values

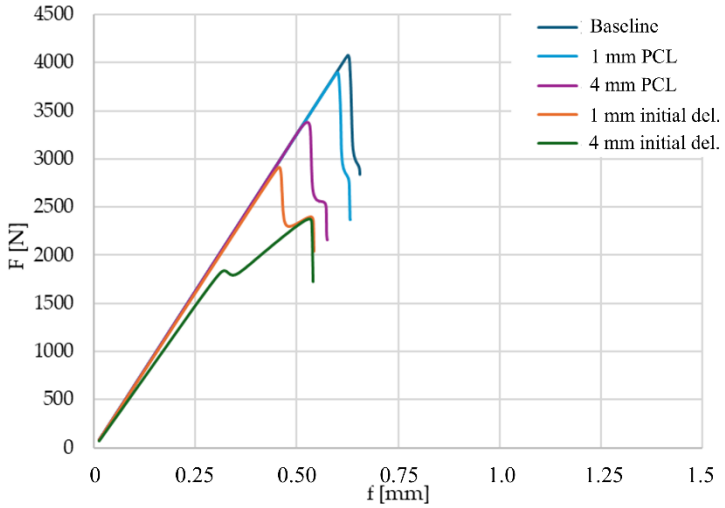

Figure 7: Force-deflection curves of the different simulations.

Based on the results of Fig. 7 and Table 2, the simulations including an initial delaminated zone, where contact was removed at the PCL location, better approximate the gradual failure process. However, in the simulations where a contact region with a cohesive zone was defined at the interfacially engineered zone, the interlaminar shear strength values more accurately reflect the experimentally measured values. Furthermore, similarly to the experimental results, in the case of the simulations, the increase of the width of the modified zone results in a more gradual failure process as well.

5 CONCLUSIONS

In our research, we manufactured locally interfacially engineered composites containing PCL interlayer material with different geometries. We carried out short-beam shear tests to investigate the effect of PCL and its geometry on the failure process. The results indicate that PCL can influence the initiation and propagation of delamination. With increasing width, the modified zone might be able to slow down crack propagation.

Finite element analysis with cohesive zone modeling was carried out for the loading conditions of the short-beam shear test. The simulations demonstrated similar results to the short-beam shear test, validating our method.

To further improve the modeling of the gradual failure process and the effect of PCL interlayer material, the introduction of a gradient region at the edges of the interfacially engineered zone is recommended. This could model the interphase created by the partial dissolution of PCL in the epoxy resin system.

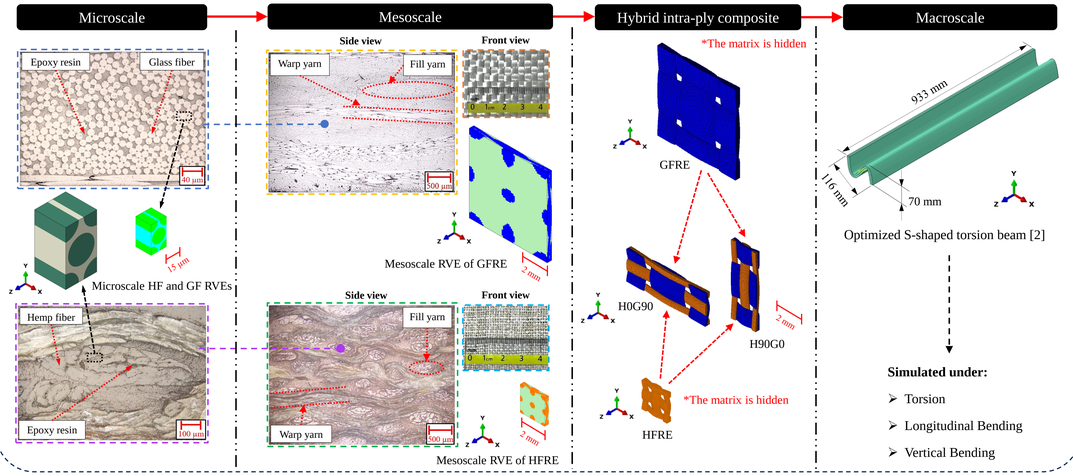
24TH INTERNATIONAL CONFERENCE ON COMPOSITE MATERIALS
AUG 4-8, 2025 • BALTIMORE CONVENTION CENTER • BALTIMORE, MARYLAND

Background & Objectives

The **torsion beam** in the **twist beam axle** plays a vital role in transferring forces and moments between the wheels and vehicle body, ensuring roll stability and safety. **Traditionally made of high-strength steel**, torsion beams can be enhanced with **fiber-reinforced polymer composites**, offering **superior strength, stiffness**, manufacturability, and corrosion resistance. **Hybrid composites**, combining synthetic and natural fibers, provide a promising solution to **reduce mass and carbon footprint** while **maintaining mechanical performance** comparable to purely synthetic composites.

Torsion beam axle in rear suspension [1]

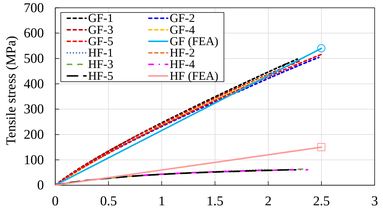


U-shaped baseline steel torsion beam [2]

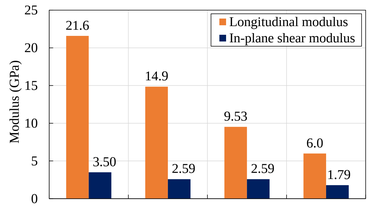
Objectives

- Analyze the elastic mechanical behavior of hemp fiber-reinforced epoxy (HFRE), glass fiber-reinforced epoxy (GFRE), and two hybrid intra-ply configurations (H0G90 and H90G0) to evaluate their potential for improving structural performance.
- Investigate the performance of quasi-isotropic plain-woven hybrid hemp/glass fiber-reinforced composites in torsion beams, focusing on torsional, vertical, and longitudinal stiffness using multiscale modeling.

Methods



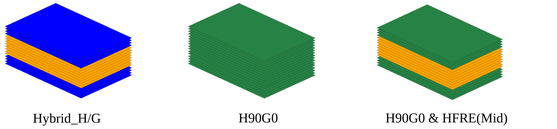
Validation of Elastic Properties of GFRE and HFRE compared to Hybrid Intra-ply Models



Hungta HT-2402 universal testing machine

Experimental tensile test setup for GFRE

Tensile test results of GFRE and HFRE [3]



Moduli of GFRE and HFRE compared to the hybrid intra-ply models

Stacking Sequence Design for Torsion Beam Modeling

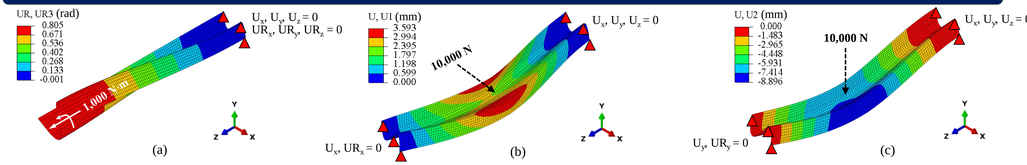


Table 1: Number of plies in various stacking sequences and the resulting thickness and mass of each torsion beam model with hemp fiber content in %.

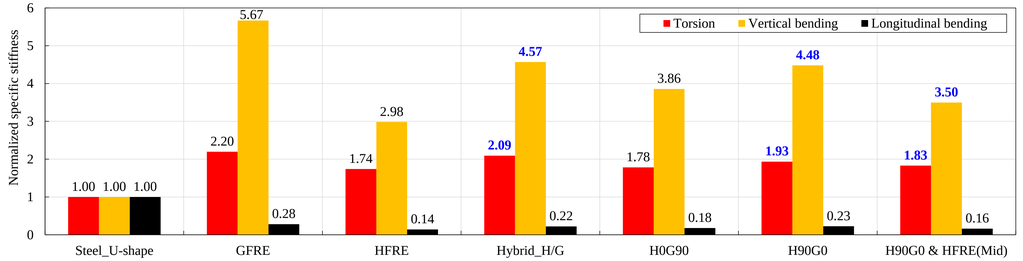
Model	No. of plies	Thickness (mm)	Mass (kg)	Hemp fiber content (%)
Steel_U-shape	-	6.0	8.26	-
GFRE	20	8.0	3.62	-
HFRE	40	16.0	4.84	100
Hybrid_H/G	26	10.4	3.87	53.8
H0G90	30	12.0	4.54	46.4
H90G0	28	11.2	4.24	46.4
H90G0 & HFRE(Mid)	32	12.8	4.36	73.2



Note: The **thickness** and **number of plies** in each composite stacking sequence **(0.4 mm/ply)** are based on the **torsional stiffness** of the **baseline steel U-shaped torsion beam**.

Torsion Beam Analysis

Deformed shape of the H90G0 & HFRE(Mid) S-shaped torsion beam under (a) torsional load, (b) vertical bending load, and (c) longitudinal bending load

Conclusions

- All composite torsion beams showed 1.74 to 2.2 times higher specific torsional stiffness (K_T) than the baseline steel beam, with GFRE achieving the highest K_T. The hybrid inter-ply model (H/G) performed similarly to GFRE, with only a 4.8% reduction in stiffness.
- The GFRE model had the highest specific vertical bending stiffness (K_V), while the hybrid composite models showed a 3.50 to 4.57 times improvement in K_V over the steel baseline.
- Hybrid intra-ply configurations, especially H90G0, demonstrated superior mechanical properties due to optimal fiber alignment, with the H90G0 & HFRE(Mid) model combining the benefits of both inter- and intra-ply hybridization and a high hemp fiber content (73.2%). However, the hybrid models showed limited effectiveness under longitudinal loading, indicating their suitability for torsional and bending applications.

A Novel Method for Evaluating the Biodegradability of Polymers by Tracking Changes in Tensile Properties During Degradation

Lovisa Rova*, Hiroki Kurita and Fumio Narita. Department of Frontier Sciences and Advanced Environment, Graduate School of Environmental Studies, Tohoku University, JAPAN. *E-mail: rova@dc.tohoku.ac.jp

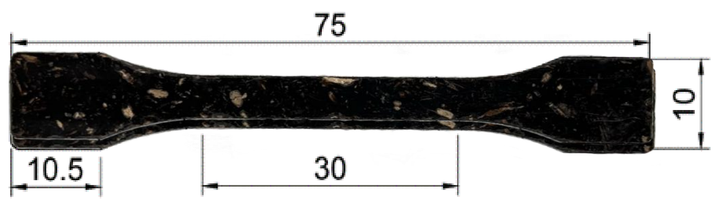
Introduction

What happens with our trash?

The majority of plastic waste is either landfilled or dumped into the environment. Due to environmental concerns, materials that biodegrade without leaving micro- and nano-plastics are being developed. For example, "green composites" consisting of biodegradable polymers combined with natural fibers or biomass. Typically, biodegradability is evaluated by monitoring the CO_2 evolution of the material as it biodegrades in a controlled environment. However, these methods have significant limitations:

1. They cannot be used to **evaluate biodegradability in natural environments**
2. Many researchers test in natural environments without standards, thus **results of different studies are not easily comparable**

Thus, there is a need for more versatile methods to evaluation degradation, that should be **applicable in any environment.**



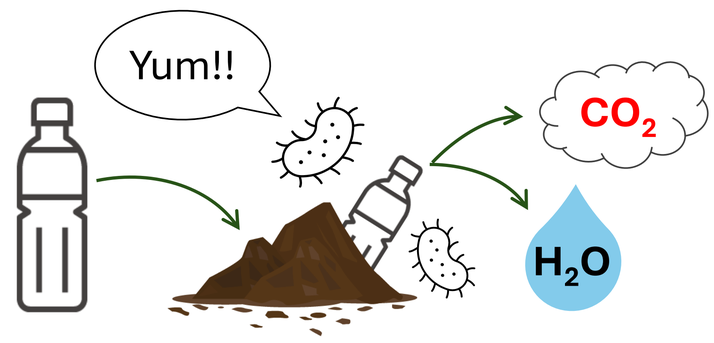
This research investigates...

...how the **mechanical properties of biodegradable materials change during degradation** and explore whether this relationship can be used to **evaluate biodegradability** in diverse environments

Experiments

1. Fabrication of test material

A prototype green composite was made from tree bark (60%) and polybutylene succinate (PBS, 40%). It was made by hot-kneading bark and PBS and then extrude into pellets. Dumbbell shapes were made by compression moulding of the pellets.



2. Biodegradation in simulated compost

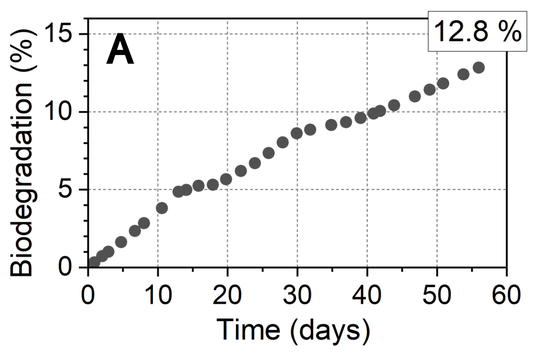
Samples were placed in compost and kept in an incubator at 58°C and 100% relative humidity. The biodegrading material turns into CO_2 which is used to calculate the degree of biodegradation:

$$\frac{m_{CO_2}^{test} - m_{CO_2}^{blank}}{ThCO_2} \cdot 100 = D_t$$

In addition, specimens were extracted every 2 weeks for tensile testing.

3. Biodegradation in outdoor soil

Specimens were buried in a garden, where CO_2 cannot be measured. Instead, samples were extracted periodically and the change in tensile properties was measured. The experiment lasted 30 weeks (6 months).



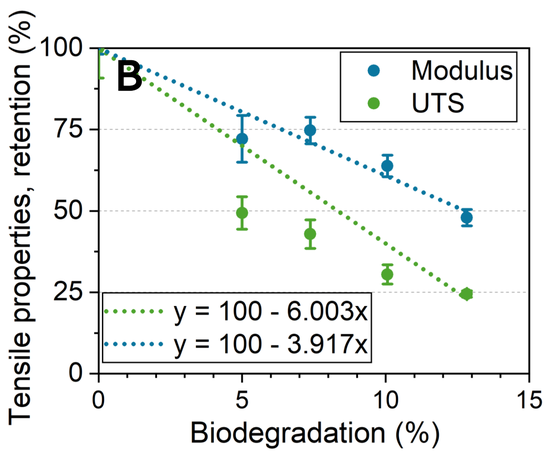
$$ThCO_2 = \frac{44}{12} \cdot m_{tot} \cdot C_{tot}$$

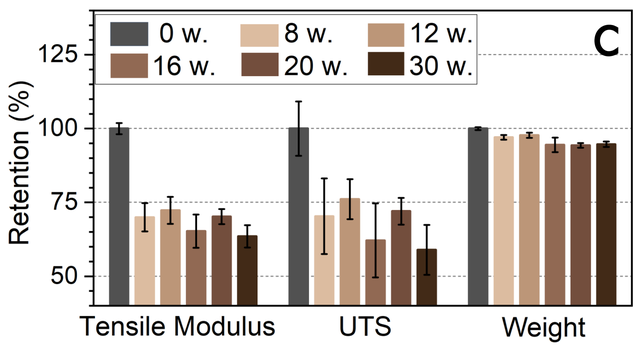
D_t : Degree of biodegradation (%)
$m_{CO_2}^{test}$: CO_2 from material in compost (g)
$m_{CO_2}^{blank}$: CO_2 from compost (blank) (g)
$ThCO_2$: CO_2 from material at 100% biodeg. (g)
m_{tot} : Dry solid mass of material (g)
C_{tot} : Organic carbon content of material (g/g)

Results and Discussion

Composting experiment

The test material reached a biodegradation of 12.8 % after 8 weeks (56 days) in compost, as shown in Figure A.





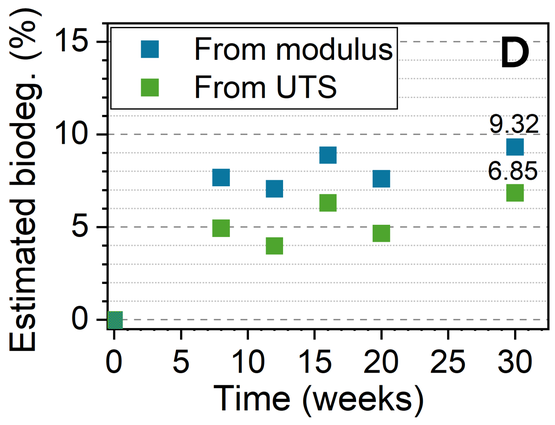


Figure B shows how the tensile modulus and the ultimate tensile strength (UTS) decreased as biodegradation progressed. Linear curves were fitted to these data points.

Outdoor soil experiment and biodegradation estimation

Similar to the composting experiment, biodegradation in soil caused the tensile modulus and UTS to gradually decrease over time (Figure C).

The degree of biodegradation was estimated by extrapolating the x values in the linear curves in Figure B using the data in Figure C. Thus, **it was estimated that after 6 months of soil burial, the composite had degraded by 7 to 9 %.**

Final Comment

The research continues with various biodegradable materials and specimen dimensions to investigate how tensile properties change during degradation in different natural environments, such as soil and seawater. We aim to develop evaluation methods that reflect the functional lifetime of materials, as opposed to traditional methods that focus solely on material conversion into CO_2.

ABSTRACT

Sandwich structures are widely used in engineering applications due to their high strength-to-weight radio, especially in the building materials, automotive component, ships structure and other daily use. This study investigates the mechanical bending behaviour of bio-sourced PLA/Flax composite sandwich fabricated by 3D printing, focusing on the influence of different core geometries. In this work, biodegradable polylactic acid (PLA) was used as the matrix, reinforced with flax fibres to improve mechanical performance. Various 3D-printed sandwich with different core geometries, including sinusoidal, triangular, double triangular and trapezoid were evaluated under 3-point bending tests.

Although various sandwich core structures have been extensively studied in recent years, contributions specifically dedicated to the development and investigation of biosourced sandwich materials with different core architectures remain rather limited. It is in this context that our work is positioned. It aims to compare different biosourced structures while keeping their relative density and thus their mass constant. With this in mind, the specimens were designed with the same mass requiring the development of a calculation method with both mutable and immutable parameters. Four different core geometries, i.e., sinusoidal (SN), triangular (TR), double triangular (DT), and trapezoidal (TP) were identified as representative sandwich structures capable of optimizing their performance. Consequently, these four geometries were subjected to the optimization program to ensure that their dimensions satisfied the above-mentioned iso-mass condition.

Fused Deposition Modeling (FDM) is widely used in PLA material manufacturing. A method called continuous extrusion printing, which is an optimization of FDM printing, was proposed and used in this study. This method enables uninterrupted material extrusion throughout the process, producing the part continuously until it is fully manufactured. Five samples of each core geometry were fabricated using this continuous extrusion printing technique. Mechanical tests of 3-point-bending were conducted on these specimens according to the ASTM C393 standard. The results showed that the bending performance significantly varied with the core geometry. It is observed that the DT structure outperforms the other three structures both in terms of maximum load and fitted stiffness, which gives a new guidance for choosing different core geometries sandwich structure for isomass.

1 INTRODUCTION

The needs for more environmentally friendly products in the industry are in strong growth. Sandwich structures have long been recognized for their remarkable combination of high stiffness, strength, and low weight, making them indispensable in a wide range of engineering applications [1]. Their ability to efficiently hold mechanical loads while minimizing material usage has driven continuous innovation in the design and fabrication. The fundamental concept of a sandwich structure relies on relatively thin, stiff face sheets bonded to a lightweight core. At the same time, the fabrication process FDM is widely used in PLA material manufacturing [2].

While numerous studies have investigated sandwich structures with synthetic cores [3], the exploration of 3D-printed bio-sourced sandwich composites remains limited, particularly in terms of systematically evaluating the influence of different core geometries. Indeed, most comparative studies do not account for differences in relative density or mass, making it difficult to isolate the effects of geometry alone. Recognizing this gap, the present work aims to advance the understanding of bio-based sandwich structures by proposing a comparative experimental framework in which the mass of each specimen is held constant. This approach requires the development of a tailored optimization methodology that adjusts the dimensions of each core geometry to satisfy the iso-mass criterion while preserving their functional integrity.

Specifically, this study investigates the bending behaviour of 3D-printed PLA/flax composite sandwich structures incorporating four representative core geometries: sinusoidal (SN), triangular (TR), double triangular (DT), and trapezoidal (TP). These geometries were selected based on their potential to enhance load distribution, increase energy absorption, and improve overall mechanical performance. Five specimens for each configuration were fabricated using continuous extrusion printing. Mechanical tests of 3-point-bending were conducted on these specimens according to the ASTM C393 standard [4].

This research contributes to the growing of knowledge on sustainable, high-performance materials by demonstrating that 3D-printed PLA/flax sandwich structures can achieve competitive mechanical properties while leveraging renewable resources and environmentally friendly manufacturing methods. By systematically isolating the effects of geometry under isomass conditions, the study establishes a foundation for future work aimed at sandwich architectures to specific engineering requirements. Furthermore, the application of continuous extrusion printing paves the way for scalable production of biosourced composite components with enhanced structural integrity and minimized waste.

2 EXPERIMENTAL PROCEDURES

2.1 Isomass calculate method

In prior research on sandwich composites, various core structures such as corrugated, honeycomb and lattice geometries were classified and studied extensively. These studies often focused on characterizing core geometries at different relative densities. However, direct comparisons between different core topologies with identical relative density remain limited.

In this study, four distinct core geometries were selected as representative sandwich structures: sinusoidal (SN), triangular (TR), double triangular (DT), and trapezoidal (TP). To ensure fair comparison and minimize the influence of density differences, all cores were designed to maintain the same relative density, thereby ensuring equivalent mass. The three external dimensions—length (L), width (b), and height (h)—serve as the foundation for the geom-etric description.

However, these dimensions alone do not capture the internal architecture, including the morphology, the number of repeating cells, and the material distribution along each axis. Therefore, two additional parameters were introduced to precisely define internal geometry in a unified way across all topologies:

- m, the number of representative elements, corresponding to the count of repeating motifs (waves, meshes, or cells) along the length L.
- n, the integer number of full extrusions across the width b, ensuring compatibility with the continuous extrusion strategy.

This approach was designed to balance generality and parsimony: the same (m, n) pair applies consistently to all four core types, facilitating cross-comparison while limiting the number of independent variables. As a result, the minimal parameter set {L, b, h, m, n} fully defines both the external and internal geometry and underpins subsequent calculations of volume, mass, and FDM print paths.

Due to the high number of variables, the height h and width b were defined based on dimensions suitable for later mechanical testing. If the resulting dimensions proved acceptable, they were directly validated; otherwise, additional iterative calculations were required. Python was chosen as the computational tool because of its simplicity, extensive scientific libraries, flexibility, and strong community support. Ultimately, final solutions were obtained and are presented in Table 1. All four core geometries share identical L, b, and h values—considered the principal parameters—while adopting

distinct m and n values to maintain nearly identical core volumes and thus constant mass. Note that the volumes fluctuate by a maximum of 2% from the average volume, which is very acceptable. Additionally, a 1.6 mm skin was incorporated into each design to enable subsequent study of complete sandwich structure properties in later subsection. The final dimensions were set at 138.56 mm length, 30.00 mm height, and 30.00 mm width, maintaining equal mass and relative density across all geometries.

Core type	L (mm)	b (mm)	h (mm)	n	m	V (mm^3)
SN	138.56	30.00	30.00	2	9	27196.17
TR				2	9	26759.73
DT				2	8	26604.30
TP				3	6	26132.46

Table 1: Solution of different core geometries sandwich structures in isomass

2.2 Fabrication processing

Fused Deposition Modeling (FDM) is one of the most common additive manufacturing techniques for thermoplastics. This method offers precise control over temperature, feed rate, and layer height, enabling the use of standard polymers like PLA as well as fiber-reinforced composites. Its flexibility and moderate cost make it widely used for prototyping and producing functional components in small series.

In this study, PLA reinforced with flax fibres was used, supplied by Nanovia Company. Printing was carried out on a Raise3D N2 printer. After loading the filament and heating the nozzle, material was deposited layer by layer onto the heated platform. Each pass in the *X*–*Y* plane formed a cross-section, followed by an upward *Z* increment until the part was complete and the thermal bonding ensured cohesion between layers. A custom MATLAB script was developed to regenerate G-code with higher precision comparing with the traditional way of slicing CAD model into G-code.

2.3 Assembly and 3-point-bending experiment

To study the different core geometries sandwich structures, three-point bending tests were performed on as-printed specimens, using an Instron universal testing machine. The experimental setup, illustrated in Figure 1, consists of a cylindrical punch with a diameter of 25mm and two cylindrical supports of the same diameter, spaced 100mm apart, in accordance with ASTM C393 standard.

The tests were conducted under displacement control with velocity of 1 mm/min, under standard atmospheric conditions and ambient temperature. The applied load and the displacement of the punch were recorded by the machine’s integrated sensors.

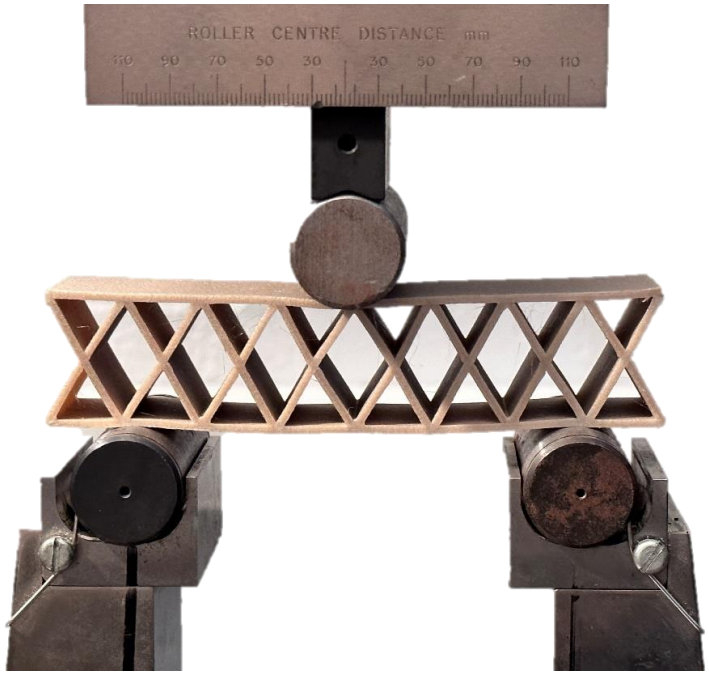

Figure 1: Experimental setup for the 3-point-bending tests on the composite DT structure

3 FINITE ELEMENT SIMULATION

Finite element analysis was performed to predict the composite sandwich structures with the same relative density and different core geometries were established using the finite element software ABAQUS 2020 (Dassault Systems). The CAD models of the four sandwich configurations - SN, TR, DT and TP cores - were created in Dassault CATIA based on the geometric parameters computed in Section 2.1. These models incorporated identical overall dimensions and relative densities to isolate the effect of core topology. The CAD assemblies were then imported into ABAQUS for meshing and simulation setup.

To replicate the experimental setup accurately, three loading cylinders were also modelled: one representing the upper loading punch and two representing the lower supports. Each cylinder had a diameter of 25 mm and was positioned in accordance with the ASTM C393 standard. The lower support cylinders were fully fixed, while the upper cylinder was assigned a reference point at its centre to which the displacement boundary condition was applied. A prescribed vertical displacement along the *Z*-axis was imposed on this reference point to simulate loading.

The sandwich structures and cylinders were discretized using 8-node linear hexahedral elements with reduced integration (C3D8R). A mesh convergence study was conducted to ensure that the element size provided a balance between computational efficiency and solution accuracy. Contact interactions were defined between the surfaces of the cylinders and the sandwich specimens using a surface-to-surface contact formulation, with a friction coefficient specified based on the literature for PLA-based composites. The material constitutive behaviour and parameters used in the simulation were derived from the constitutive relationships obtained through compression tests conducted on standard cylindrical specimens.

4 RESULTS AND DISCUSSION

The comparative testing of the four core geometries under 3-point-bending highlights distinct mechanical behaviour curves, thereby providing valuable insights for design choices depending on the intended applications, as shown in Figure 2. The DT configuration, characterized by the highest stiffness and maximum load, exhibits excellent load-bearing capacity. However, its failure is more abrupt, and its elongation is limited. Consequently, it is better suited for situations requiring high load support with

low tolerance for deformation.

The TR geometry demonstrates stiffness and strength levels comparable to those of the DT configuration while offering slightly greater ductility, thereby representing a relevant compromise when moderate displacements are acceptable without compromising load capacity. In contrast, the TP structure displays the lowest stiffness and maximum load but has by far the highest displacement at failure among all configurations. This capacity for gradual deformation and energy absorption prior to failure makes it a suitable candidate for applications involving impact protection, damping, or energy dissipation. The SN configuration occupies an intermediate position: neither the stiffest nor the most ductile, it constitutes a balanced and potentially more cost-effective solution for conventional applications in which the requirements for load-bearing capacity and energy absorption remain moderate.

These curves show that if the design objective is high load-bearing capacity with limited concern for large displacements, the DT configuration performs better. Conversely, if the application requires greater deformation tolerance, like the ability to undergo larger displacements prior to failure, the TP configuration offers advantages despite its lower maximum strength.

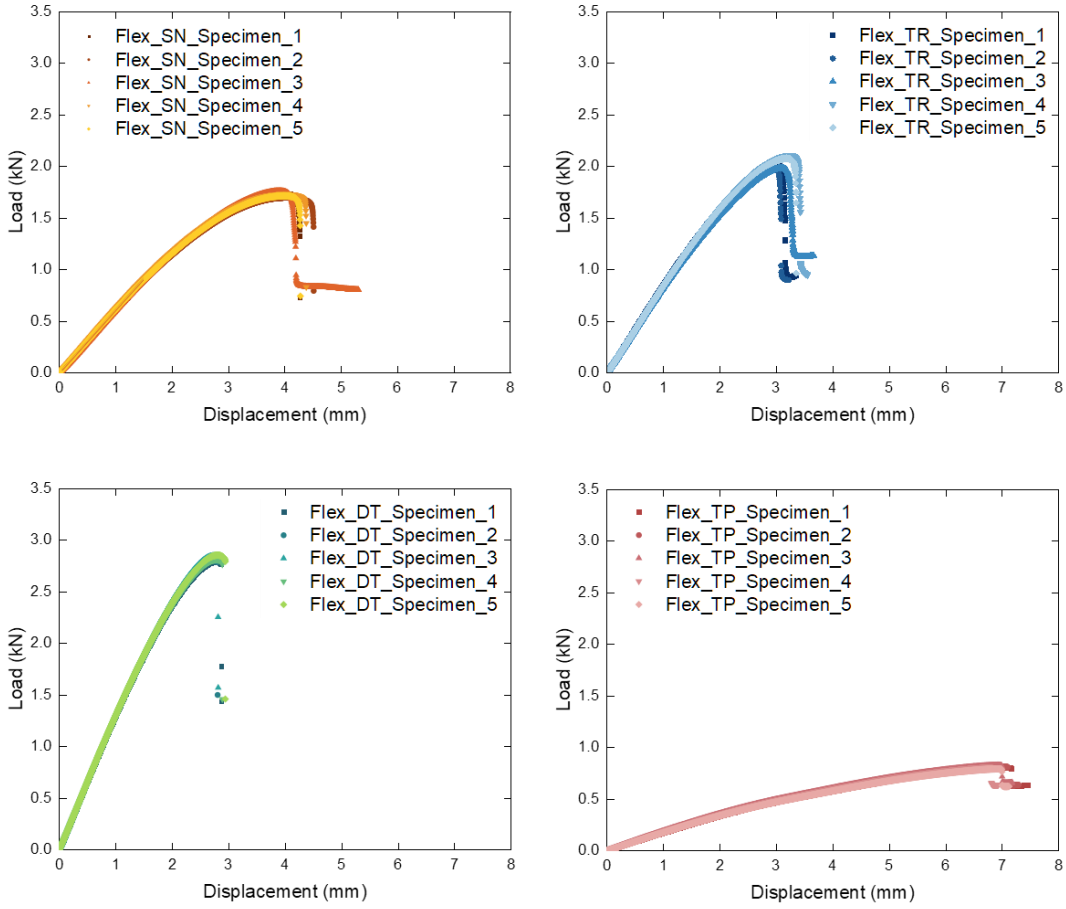

Figure 2: Load–displacement curves of four core geometries under 3-points-bending tests

The radar chart depicted in Figure 3 comparing the mechanical performance of the four core geometries across five normalized parameters: stiffness (E), elastic limit force (Fe), maximum force (Fmax), maximum displacement (dmax), and elastic displacement (de). The DT configuration consistently shows the highest normalized values of stiffness and force capacities, with de reaching approximately 0.85, indicating superior resistance and load-bearing performance. In contrast, the TP geometry exhibits the greatest maximum displacement and elastic displacement, suggesting higher deformability under loading conditions. The TR shows intermediate stiffness and force values, with E near 0.65, dmax of about 0.5 and Fe about 0.75, while SN combines a stiffness of about 0.5, dmax of

about 0.6 and Fe around 0.55. Both configurations maintain moderate levels. Overall, this visualization underscores the distinct mechanical behavior of each design, supporting the selection of an appropriate core geometry depending on whether stiffness or deformability is prioritized, particularly if the design objective is high load-bearing capacity with limited concern for large displacements.

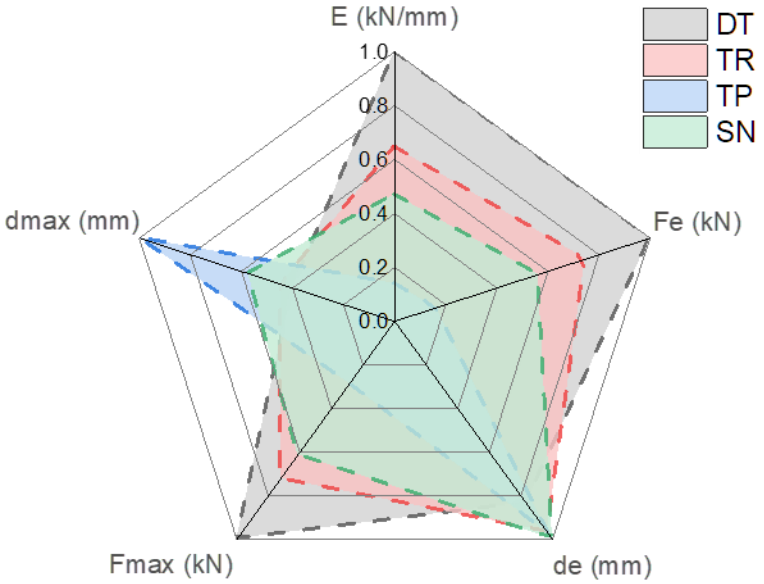

Figure 3: Radar of mechanical performance of four core geometries under 3-points-bending tests

The finite element simulations model accurately characterizes the load-displacement from the elastic stage up to fracture. By comparing the experimental responses with the simulation results shown in Figure 4, the numerical model was effectively validated. It is worth noting that the experimental and numerical curves are identical for stiffness, while a discrepancy of less than 15% is observed for maximum force (for 3 out of 4 configurations).

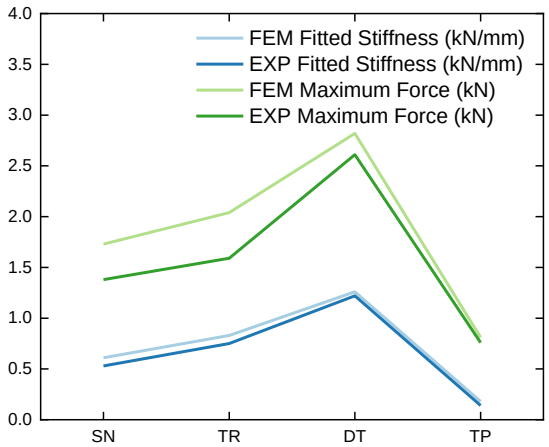

Figure 4: Comparison of FEM and EXP for Maximum Force and Fitted Stiffness with four different patterns

5 CONCLUSIONS

This study investigated the mechanical bending behaviour of 3D-printed bio-sourced PLA/flax composite sandwich structures with four distinct core geometries while maintaining identical mass and

relative density. Through both experimental three-point bending tests and finite element simulations, significant differences in mechanical performance were observed among the configurations.

The double triangular (DT) core exhibited the highest stiffness and maximum load capacity, making it an optimal solution for applications requiring high load-bearing performance with minimal deformation. The triangular (TR) geometry offered a comparable strength profile while demonstrating slightly greater ductility, providing a balanced compromise between stiffness and tolerance to deformation. The trapezoidal (TP) core achieved the highest displacement before failure, indicating superior energy absorption and suitability for impact protection or damping applications despite its lower maximum strength. Finally, the sinusoidal (SN) core presented intermediate properties, offering a practical balance between load capacity and deformability.

Overall, this work highlights the critical role of core geometry in tailoring the mechanical properties of sandwich composites. The findings provide valuable guidance for selecting core designs in lightweight structural components where specific performance trade-offs between stiffness, strength, and ductility are required. In addition, finite element modelling conducted in ABAQUS provided comparative simulations that closely matched the experimental results, validating the mechanical behavior of the sandwich structures and supporting the robustness of the proposed design approach.

This study investigates the bending behaviour of bio-sourced PLA/Flax composite sandwich structures manufactured by 3D printing. To ensure a fair comparison, four core geometries – sinusoidal (SN), triangular (TR), double triangular (DT), and trapezoidal (TP) were designed with identical mass. A continuous extrusion printing technique, optimized from conventional FDM, enabled uninterrupted material deposition and high-quality fabrication. Five samples of each geometry were produced and tested under 3-point bending according to ASTM C393. The experimental results revealed that core geometry strongly affects mechanical performance. Among all configurations, the double triangular structure achieved the highest stiffness and maximum load capacity. These findings provide valuable insights for selecting and optimizing core designs in lightweight sandwich structures where both mechanical efficiency and sustainability are essential considerations.

Perspectives

- Analysis of acoustic emission signals and microscopic observations to identify the damage mechanisms.
- Study of ageing, as it is particularly relevant for natural fiber composites.

Shear Thickening Fluid & Thermoplastic Matrix Composite Bulletproof Vests

M. J. A. Malheiro*, J.P. Nunes

IPC - Instituto de Polímeros e Compósitos, Universidade do Minho, Campus de Azurém, 4800-058 Guimarães,Portugal / *e-mail: mmalheiro@dep.uminho.pt

1. Introduction

In this study, composites incorporating two different matrices - UHMWPE GUR® 5113 and a urethane-based Shear Thickening Fluid (STF) DIC701N - were evaluated using impact tests at both low and high velocities. Two types of aramid fiber fabrics, Twaron® CT 608 and PT 900, were used in the composites under investigation. Test samples with 1 to 6 discrete fabric layers were prepared by compression molding and spread coating, respectively. In the compression molding method, samples were directly fabricated with the specified number of layers. In the spread coating method, the fabric was coated, then cut and stacked to obtain the desired number of layers. Preliminary low-velocity impact tests were first conducted using a CEAST Fractovis Plus drop impact tester, at an impact velocity of 4.429 m/s and an energy of 245.6 J, to provide an initial assessment of the composites' response. Subsequently, high-speed impact tests were performed in a custom laboratory setup employing a 5.5 mm caliber slug projectile, with a length of 11.8 mm and a mass of 2.74 g, fired via a compressed air system in accordance with the MIL-STD-662 F standard.

2. Materials

Reinforcements

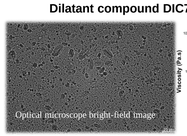
Twaron® CT608 (Teijin)

- Plain weaves
- **Areal density – 123 g/m²**
- Yarn properties:
  - Strength at break – 148 N
  - Chord modulus – 100 GPa
  - Strain at break – 3.5 %

Twaron® PT900 (Teijin)

- Satin and plain weaves
- **Areal density – 204,6 g/m²**
- Yarn properties:
  - Strength at break – 225 N
  - Chord modulus – 89GPa
  - Strain at break – 3.45 %

Matrices



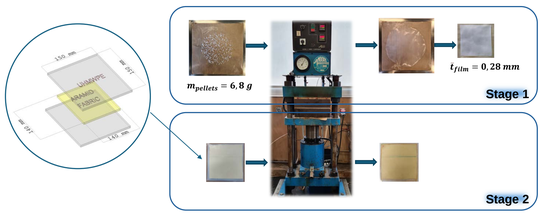
UHMWPE

GUR® 5113 (Celanese)

- Injection moulding grade
- Average molecular weigth – 3.7E6 g/mol
- Tensile modulus – 750 - 800 MPa
- Tensile stress at yield ≥ 17 MPa
- Strain at break – 430 %

Dilatant compound DIC701N (Polianswer)

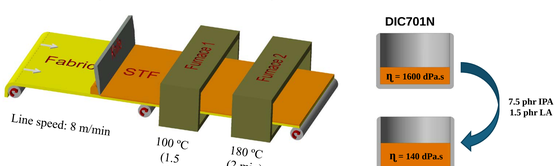
- STF (70 %) + Ethanol (30%)
- STF based on urethane chemical structure
- Liquid phase - unpolymerized urethane monomer
- Solid phase – polymerized particules



3. Preparation of Composites

Two types of composite laminates and STF-coated fabrics were produced using the Twaron® CT 608 and PT 900 aramid fabrics. The add-on weight percentage, $x(\%)$, was calculated for each sample as: $x(\%) = \frac{PF-NF}{NF} \times 100$, where PF is the weight of laminate or coated fabric, and NF is the weight of the neat fabric.

Composite Laminates (CL)



Composite laminates (CLs) were fabricated in two stages using a 500 kN Moore press. In both stages, the materials were preheated for 4 minutes at 260 °C, compressed for another 4 minutes, and demolded at 130 °C following water cooling. In the first stage, UHMWPE granules were pressed at 6.25 MPa to form thin films, which were subsequently cut into squares. In the second stage, 1 to 6 layers of aramid fabric were interleaved with the film squares and compressed at 13.62 MPa to produce the final laminates.

STF-Coated Fabrics (STFCF)

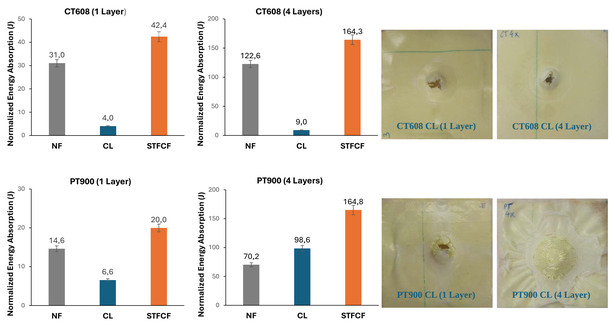
STF-coated fabrics (STFCFs) were prepared using the knife-over-air spread coating technique. The dilatant fluid was diluted to reduce its viscosity and facilitate proper application. To ensure coating on both sides, the fabric was flipped and the process repeated.

Fabric Spread Coating (Industrial Process Schematic)

DIC701N

4. Low-velocity drop weight impact testing

Low-velocity impact tests were performed on neat fabrics (NFs), STF-coated fabrics (STFCFs), and composite laminates (CLs) using a CEAST Fractovis Plus drop-weight tester, following the ISO 6603-2 standard. Samples (140 × 140 mm) were clamped between circular jaws, with teeth machined on the upper jaw and matching grooves on the lower jaw, to provide interlocking fixation during testing. For each material type, two configurations were tested: samples composed of a single fabric layer and samples composed of four fabric layers.

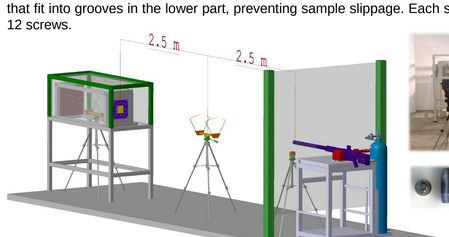


Low-velocity drop weight impact testing setup

Experimental Conditions

- Clamping force = 10 kN
- Hemispherical Impactor, Ø = 20 mm
- Impact Mass = 25.044 kg
- Drop Height = 1000 mm
- Impact Velocity = 4.429 m/s

Due to the different areal densities of the samples, the energy absorbed by the STFCFs and CLs was normalized with respect to their areal density, using the equation $E_n = \frac{E_a}{(1+x\%/100)}$, where E_n is the normalized absorbed energy (J), E_a is the absolute absorbed energy (J), and $x\%$ is the add-on percentage.

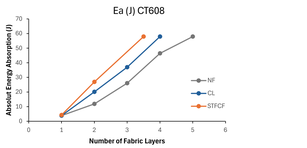


Results

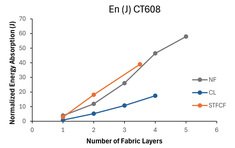
- STF-based composites exhibited improved impact resistance compared to neat aramid fabrics. This enhancement is likely attributed to the shear thickening effect, which restricts fiber mobility and promotes stress transfer, thereby increasing the area involved in energy absorption.
- For CT 608, using UHMWPE as the matrix, reduced both absolute and normalized absorbed energy, likely due to excessive fiber impregnation leading to quasi-brittle failure. For PT 900, UHMWPE increased absorbed energy, but normalized gains were significant only with four fabric layers. This is presumably due to partial impregnation, which enables additional energy absorption mechanisms (e.g., matrix/fabric debonding, yarn stretching, and delamination).

5. High-velocity impact (Ballistic testing)

Ballistic tests were performed on neat fabrics (NFs), STF-coated fabrics (STFCFs), and composite laminates (CLs) using a setup developed in our lab. A 5.5 mm caliber, 2.73 g ELR slug projectile was fired using a compressed air system, in accordance with the MIL-STD-662F standard. Samples (140 × 140 mm), consisting of one to six fabric layers, were clamped in a target-retaining frame featuring a 100 × 100 mm window. The frame included teeth machined into the upper part that fit into grooves in the lower part, preventing sample slippage. Each sample was secured using 12 screws.



5.5 mm caliber ELR Slug

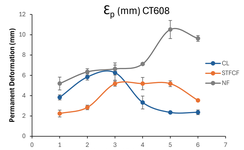


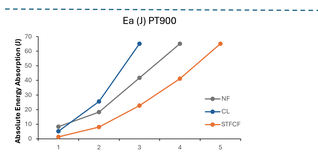
Impact velocities:

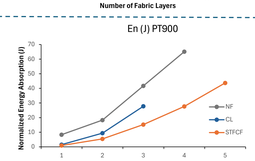
CT608 (4 layers)
V_{50} = 204,73 m/s
$V_{100} = V_{50} + 3\sigma$ = 210,3 m/s

PT900 (3 Layers)
V_{50} = 217,3 m/s
$V_{100} = V_{50} + 3\sigma$ = 220,9 m/s

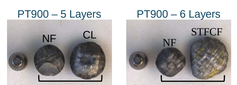
Results





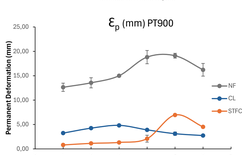


3 of 4 STFCF samples not perforated



- Ballistic Limit (3 layers STFCF) ≈ Impact Velocity
- 20% - 40% reduction in aramid fabric

- CL shows sharp drop in deformation from 3 to 4 layers → Ballistic Limit for 3 layers is near the Impact Velocity



Projectile before (a) and after (b) impact
Non-perforated samples

6. Conclusions

- ✓ Fabric impregnation by UHMWPE matrices plays a key role in low-velocity impact, where excessive impregnation leads to a reduced energy absorption. This effect was not observed under high-velocity impact, except when a single fabric layer was tested.
- ✓ Under high-velocity impact, excessive STF impregnation reduces fabric performance, likely due to a pronounced thickening effect that excessively limits fiber deformation, leading to premature fiber rupture. Shear rates are highest at impact point and decrease through the thickness, diminishing the thickening effect in deeper layers. This gradient allows greater energy dissipation, making STF-impregnated fabrics potentially more effective in the back layers by reducing back-face deformation.

ABSTRACT

Fused Filament Fabrication (FFF) builds polymer structures through layer-by-layer deposition, enabling the production of fiber-reinforced composites with enhanced strength. However, due to inherent polymer behaviors such as creep, shrinkage, and aging, 3D-printed components are prone to long-term deformation. These effects are amplified by the anisotropic, composite-like nature of printed structures, where filaments are only partially bonded. This research investigates the long-term viscoelastic and viscoplastic behavior of FFF-printed polymers to improve structural reliability.

1 INTRODUCTION

Additive manufacturing of polymers and their structures has been a fast-growing research space, with more than 100,000 papers published last year, and the industry due to the significant advantages over other manufacturing methods, e.g., design freedom, significant waste and energy reduction. This method offers high flexibility with the prototyping and optimization of different shapes, thus extending the applicability of polymers. With Fused Filament Fabrication (FFF), the polymer structure is built layer-by-layer through the deposition of feedstock materials. The FFF can be used to produce fiber composite structures with increased strength, further increasing the applications of this manufacturing method.

Despite these advantages, polymers produced with the FFF method have shown significant time-dependent behavior [1]. Part of the nonlinearity can be attributed to the material behavior itself, but a large part is due to the complex internal structure. Each printed filament is only partially bonded to the neighboring filaments, thus forming long aligned fibers, a composite-like structure (Figure 1) and creating an anisotropic material. Due to the novelty of this manufacturing method, these effects have not been studied, especially with regard to different environmental and material state effects. Appropriate modeling methods and models for these 3D printed structures have not been developed.

The most widely used nonlinear viscoelastic (VE) material models have been developed by Scapery [2], [3], [4]. In [5], it was modified to include the Zapas model for viscoplasticity [6] and damage and has been successfully used to simulate different materials 1D time-dependent behavior [7], [8].

$$\varepsilon = d(\sigma_{max}) \cdot \left(\varepsilon_0 + g_1 \int_0^t \Delta S(\psi - \psi') \frac{d(g_2\sigma)}{d\tau} d\tau + \varepsilon_{VP}(\sigma, t) \right) \quad (1)$$

Where

$d(\sigma_{max})$	Effect of damage
ε_0	Elastic strain in undamaged composite
g_1, g_2	Stress dependent material properties
$\Delta S(\psi)$	Time dependent part of the viscoelastic response, transient component of the linear viscoelastic creep compliance
ψ	Reduced time
ε_{VP}	Viscoplastic strain

It has shown high adaptability, which is crucial for modeling various environmental conditions. The complexity of different structures with 3D stress states demands models and tools able to predict 3D stress states [9]. Various models have been integrated into finite element method (FEM) to simulate stress and strain behavior under monotonic and uniaxial loading conditions [10], [11]. However, a more realistic 3D nonlinear material modeling tool, able to predict nonlinear VE response, is yet to be developed. In [9], this model was adapted for the 3D case.

In the modeling of material behavior, the balance between accuracy and complexity is a key consideration. While highly detailed models may offer precise predictions, they often require extensive parameter calibration and computational resources. The simplicity of models characterized by a minimal number of parameters is advantageous, as it facilitates implementation and reduces computational overhead by eliminating the need for complex optimization procedures [12]. Such models are also easier to interpret, validate, and apply in practical scenarios, especially when data availability is limited or computational efficiency is a priority.

Within this study, we tested the material at different stages (before printing and after printing) and scales (single filament and printed structures) of manufacturing. Statistical characterization showed nonlinear behavior for all sample groups. The elastic properties showed slightly higher values for printed filament and specimens than for filament as received. Uploading time to reach the load in the creep test result in higher initial strain values and more pronounced recovery behavior, indicating time-dependent viscoelastic effects. Creep compliances obtained from creep tests showed nonlinear viscoelastic behavior already at low stress levels, further proving the need for the use of nonlinear viscoelastic material models.

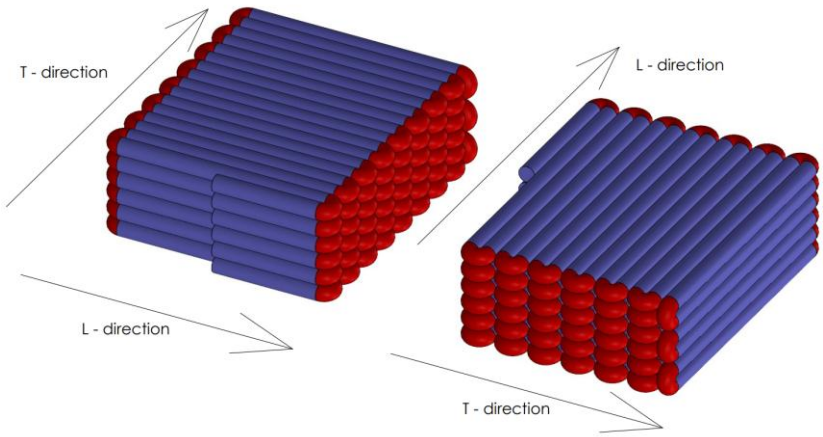

Figure 2: Printing schematic of layers

2 MATERIALS

The plastic industry is moving towards more sustainable alternatives and replacing non-renewable plastics and oil with competitive bio-based materials [13]. Within our study, we used Ultimaker Tough Black Polylactic acid (PLA), a technical PLA filament, which has been used. The PLA has a glass transition temperature of 62 °C, a melt temperature of 151 °C.

Material at three different phases of manufacturing has been used in the study (Figure 1):

a) Thick Filament as received from the manufacturer (Y);
b) Single filament printed using 3D printer (F);
c) Rectangular 3D printed specimens ($L_{printed}/T_{printed}$);
d) Cut-out of large 3D printed rectangular plate ($L_{cut\text{-}out}/T_{cut\text{-}out}$).

The specimens were manufactured using the Fused Filament Fabrication (FFF) technique, which is an additive manufacturing technique that uses a continuous filament of thermoplastic material. The filament is fed from a spool through a heated printer extruded head, which melts the material and deposits it layer by layer to build a 3D object. The print head moves in two dimensions to create each horizontal layer, and then the platform or head moves vertically to add subsequent layers (Figure 2).

Specimens were printed and kept in an enclosed environment, away from sunlight. All specimens were printed using the Ultimaker-2C-3AC2 model (Ultimaker B.V., The Netherlands). Specimens were printed using a 0.4 mm linewidth. The infill pattern was set to "Lines" with a specimen infill density of 100 %, layer thickness of 0.1 mm, printing nozzle diameter of 0.4 mm, print head speed of 20 mm/s, printing temperature of 225 °C, and a build plate temperature of 60 °C. Specimens were tested in the printed direction (0°, notation used in paper L) and perpendicular to the printing direction (90°, notation used in paper T). A schematic drawing of printing direction and notations used in paper is presented in Figure 2.

3 EXPERIMENTAL CHARACTERIZATION

Tensile tests were performed on an Instron ElectroPuls® E10000 machine equipped with a 10 kN load cell, mechanical clamps and extensometers with gauge lengths of 25 mm (for smaller ones - printed) and 50 mm (for larger ones – cut-out), see Figure 1, used according to specimen length (Dynamic extensometer Instron 2620-601). Quasi-static tensile tests for all rectangular specimens were performed in displacement mode, with the machine`s cross-head speed 1 mm/min (~0.75%/min). Before the tensile test until failure, elastic modulus was measured, by loading and unloading to 0.35% strain (see Figure 3). Tensile elastic modulus was calculated from stress-strain curves by linear fit of experimental data points in strain region 0.05-0.25%. Elastic modulus was calculated from the unloading step 2 part of the curve to reduce effects of loading, damage and developing nonlinear properties.

Tensile tests for single filament and thick filament specimens were performed on ElectroPuls® E10000 machine equipped with a 3 kN load cell, mechanical clamps in displacement-controlled mode with the cross-head speed 0.5 mm/min, (~ 0.75%/min). Since the extensometer cannot be attached to the filament specimens, strain was obtained from machines crosshead movement and machines compliance was calculated and taken into account (as described in the ASTM standard [14]).

Tensile tests were also conducted at a significantly lower displacement rate of 0.01 mm/min to evaluate the influence of loading rate on the material response.

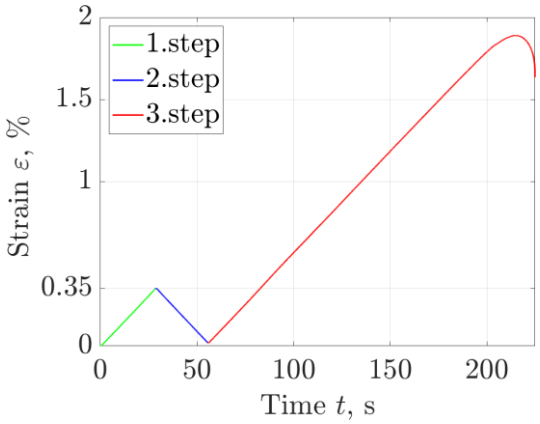

Figure 3: Loading procedure for tensile tests

A specially designed creep recovery test was performed on an Instron ElectroPuls® E10000 machine equipped with a 10 kN load cell, mechanical clamps and a dynamic extensometer Instron 2620- 601 with a gauge length 25 mm for shorter (printed) specimens and 50 mm for longer (cut-out) specimens. Initial tests were performed without an environmental chamber. One specimen per series was tested for the short-term creep test. The short-term creep test was performed in multiple steps in a load control mode with creep periods of 10, 20, 30, and 60 min (total 120 min), followed by 10 times longer recovery period (i.e., 100, 200, 300, and 600 min, respectively). Due to the limitations of the machine, the load during recovery was kept at 3 N, which corresponds to less than 2% of the creep stress level. Loading and unloading for the creep test were done with a loading rate of 100 N/s. Depending on the stress level or the magnitude of applied load, the duration of the uploading and unloading phases could extend to 10-13 s for the strongest specimens. A schematic drawing of the loading ramp and resulting strain response can be seen in Figure 4.

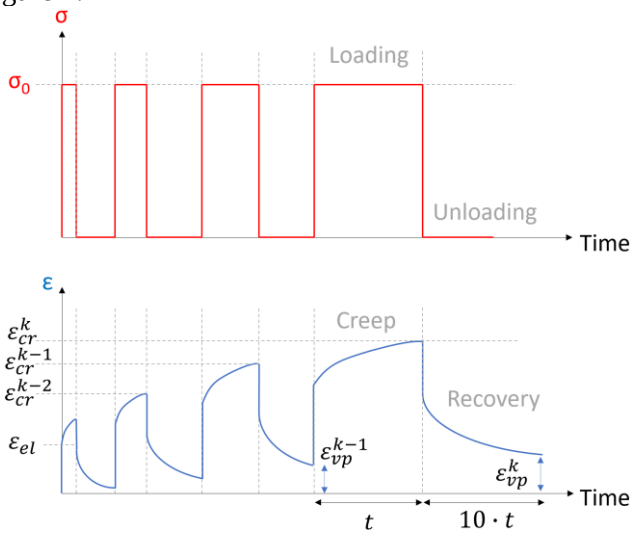

Figure 4: Schematic of the creep test methodology, the representation of the creep loading steps for one stress level

Six stress levels were tested using this methodology. In order to reduce scatter due to experimental data, we used a single-specimen methodology, described in [15]. It is worth mentioning that during the entire testing procedure, the specimen was not removed from the machine, in order to avoid introducing errors due to alignment and tests are performed in increasing order of the applied stress to minimize the influence of damage on results. The strain at the end of each recovery period was assumed purely viscoplastic (VP).

4 MATERIAL MODELS

Within this study, the main focus has been on VP modeling. We have used the Zapas and Crissman model [6] where VP strain growth during loading with specified time dependence of the applied stress is given by

$$\varepsilon_{VP}(\sigma,t) = C_{VP}\left\{\int_0^{t/t^*}\left(\frac{\sigma(\tau)}{\sigma^*}\right)^M d\tau\right\}^m \tag{2}$$

Where C_{VP} , M and m are constants to be determined experimentally, t/t^* is a normalized time where t^* is an arbitrarily chosen characteristic time constant [15]. We have used a single-specimen methodology described in [15]. Due to the previous loading history, the parameter identification is more complex than using a different specimen for each stress level. At the *k*-th stress level $n_k\sigma_0$, $(n_1 = 1)$ assuming that all previous creep tests at lower stress levels have the same total duration time Δt_0, VP strain is obtained as follows:

$$\varepsilon_{VP}(n_k,t) = C_{VP}\cdot\sigma_0^{mM}\cdot\left(\frac{\Delta t_0}{t*} + n_2^M\frac{\Delta t_0}{t*} + n_3^M\frac{\Delta t_0}{t*} + \ldots + n_k^M\cdot\frac{t-(k-1)\Delta t_0}{t^*}\right)^m \tag{3}$$

Since t^* is an arbitrarily chosen constant and the duration of all creep tests at lower stress levels is the same and t^* is taken equal to Δt_0, thus eq. (3) can be written:

$$\varepsilon_{VP}(n_k,t) = C_{VP}\cdot\sigma_0^{mM}\cdot\left(1 + n_2^M + n_3^M + \ldots + n_k^M\cdot\frac{t-(k-1)\Delta t_0}{t^*}\right)^m \tag{4}$$

In the "single specimen methodology," data obtained from one specimen at different stress levels are analysed. Eq. (5) applied for a sequence of stress levels renders the following relationships in *ln-ln* axes:

$$\ln\left(\varepsilon_{VP}(n_1,t)\right) = \ln({C_{VP}{\sigma_0}^{mM}}) + m\ln\left(\frac{t}{t^*}\right), \qquad \sigma = \sigma_0, \qquad t\in[0,\Delta t_0]$$

$$\ln\left(\varepsilon_{VP}(n_2,t)\right) = \ln({C_{VP}{\sigma_0}^{mM}}) + m\ln\left(1 + n_2^M\cdot\frac{t-\Delta t_0}{t^*}\right), \qquad \sigma = n_2\sigma_0, \qquad t\in[\Delta t_0, 2\Delta t_0]$$

$$\ln\left(\varepsilon_{VP}(n_k,t)\right) = \ln({C_{VP}{\sigma_0}^{mM}}) + m\ln\left(1 + n_2^M + n_3^M + \cdots + n_k^M\cdot\frac{t-(k-1)\Delta t_0}{t^*}\right), \tag{5}$$

$$\sigma = n_k\sigma_0, \quad t\in[(k-1)\Delta t_0; k\Delta t_0]$$

According to (5), the experimental relationship between VP strain and time has to be linear for each stress level, provided M is selected correctly. Hence, the first step in the procedure is to estimate M by varying it until the experimental data points in the *ln-ln* axes show a linear relationship. Obviously, the result of the M value is a compromise between the different "best" values for different stress levels. Afterwards, the first approximation of parameters m and C_{VP} can be found. These parameters have to be further adjusted, realizing that m has to be the same for all stress levels. Since for low stresses VP strains are small and the measurement accuracy is limited, weight factors have to be introduced, giving higher significance to accurate data fitting at higher stresses.

5 RESULTS AND DISCUSSIONS

5.1 Tensile tests

The experimental results of the macroscale rectangular specimen tensile test are presented in Figure 5 and Table 1.

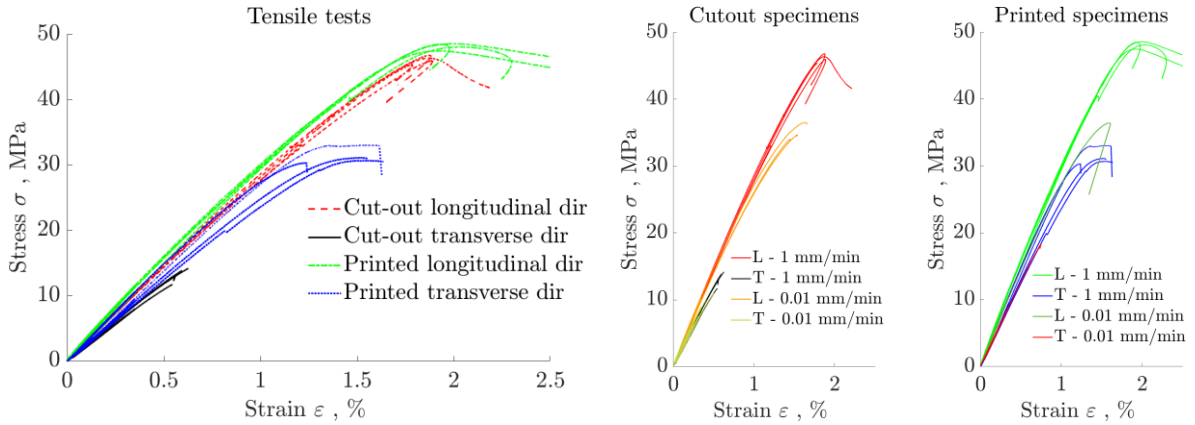

Figure 5: Tensile test results of rectangular specimens

Spec.	Rate [mm/min]	E_{mean} [MPa]	σ_{fail} [MPa]	ε_{fail} [%]
$L_{printed}$	1	3165±12	48.2	1.966
$L_{printed}$	0.01	2987±24	36.5	1.591
$T_{printed}$	1	2751±11	31.3	1.454
$T_{printed}$	0.01	2570±24	18.3	0.746
$L_{cut-out}$	1	2959±10	46.1	1.853
$L_{cut-out}$	0.01	2921±19	35.1	1.538
$T_{cut-out}$	1	2420±5	13.2	0.581
$T_{cut-out}$	0.01	2437±16	10.4	0.447

Table 1: Tensile test results of rectangular specimens

The results showed significant anisotropic behavior of 3D printed material. This was expected since the inner structure showed anisotropic filling of material (see Figure 1 and Figure 5).

Compared to cut-out specimensm printed specimens exhibit higher values in elastic modulus, as well as greater failure stresses and strains.

The properties in longitudinal direction do not differ significantly, however, in the transverse direction, specimens cut out of the printed plate show drastic differences in properties. This shows that specimens in the transverse direction are more sensitive to the printing direction.

When comparing test speeds of 1 mm/min and 0.01 mm/min, it is observed that almost all specimens tested at slower rate (0.01 mm/min) exhibit lower elastic modulus, failure stress, and failure strain, indicating a pronounced rate-dependent viscoelastic behavior [16].

We believe that changes in properties is due to the edges, where the material tends to join together, thus presenting a more longitudinal specimen.

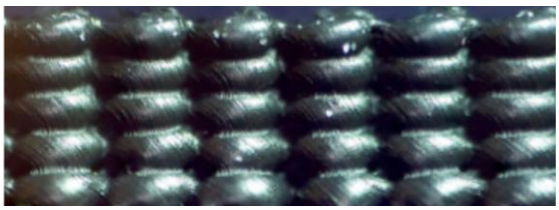

Figure 6: Typical side face of printed specimen [16]

The edge features of the printed specimen result from continuous pathing of the extrusion-based printing process. To initiate new lines, the print head redirects at the boundaries, forming rounded transitions. These curved edge paths, visible in the cylindrical structure (see red parts in Figure 2 and Figure 6), reflect directional changes necessary for consistent layer deposition.

Figure 7 and Table 2 show tensile test results of the thick filament as received from the manufacturer before printing, and 3D printed single filament specimens.

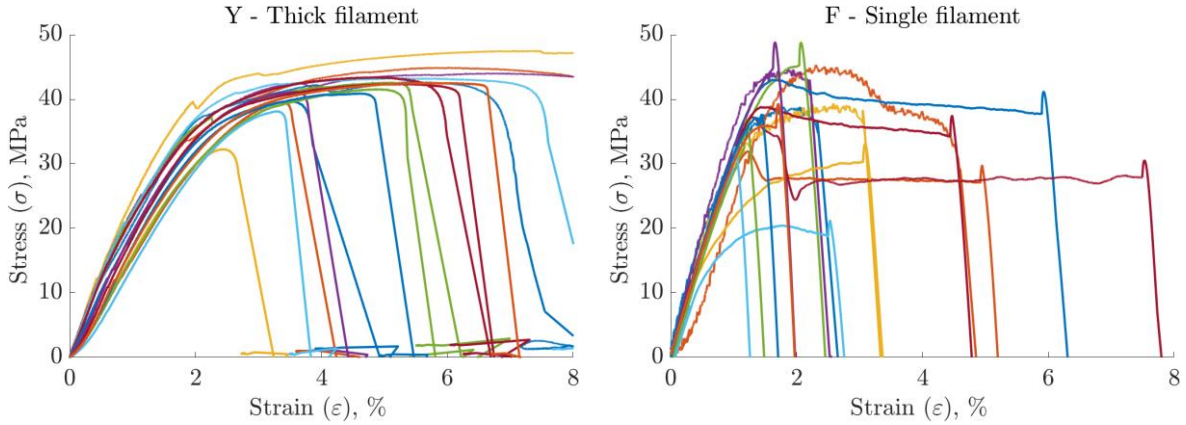

Figure 7: Tensile tests of thick filaments (left, Y) and single filaments (right, F)

A comparison between single filaments and thick filaments is presented in Table 2, as shown below. The single filament shows higher elastic modulus than thick filament, indicating that the properties were altered due to the printing process, which significantly influenced the mechanical behavior of the printed specimens. Similar trends can be seen also with printed specimens in L direction, where modulus is larger than the thick filaments values.

Spec.	E_{mean} [MPa]	σ_{fail} [MPa]	ε_{fail} [%]
Y-thick	2546±36	41.7	4.41
F-single	3547±296	38.8	1.79

Table 2: Tensile test results of single and thick filament specimens

5.2 Creep test results

The used stress levels for creep were 10, 15, 20, 24, 28, and 32 MPa and the obtained VP strains are presented in Table 3 for cut-out specimen.

Stress, MPa	Time, min	Time t/120	VP strain, %					
			10	15	20	24	28	32
ε_0	0	0	0.000	0.005	0.007	0.021	0.044	0.093
ε_{pl1}	10	0.083	0.000	0.003	0.006	0.026	0.054	0.113
ε_{pl2}	30	0.25	0.001	0.003	0.011	0.034	0.062	0.135
ε_{pl3}	60	0.5	0.004	0.005	0.015	0.039	0.074	0.169
ε_{pl4}	120	1	0.005	0.007	0.021	0.044	0.093	0.258

Table 3: Summary of all VP strain

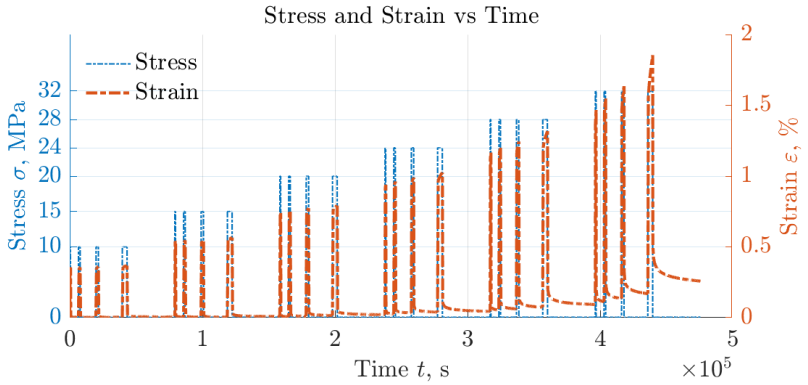

Figure 8: Strain development over time during creep tests at different stress levels

Curve fitting parameters has been calculated or chosen according to the Zapas and Crissman model, which has been explained in Section 4 . The obtained values are M = 7.0 and m = 0.54. The fitting of the parameter M can be seen in Figure 9. The obtained coefficients fit the experimental data at higher stress levels. At lower stress levels the experimental data are more scattered and the fit is poor. This trend is consistent with our previous tests, where values at lower stress levels do not fit the overall trend. This can be explained by the low strain values, that are close to the measuring device precision and different environmental effects on strains are higher than pure VP effects. In addition, in the initial stages of loading, the material is still aligning and thus can alter its behaviors after the initial loading steps.

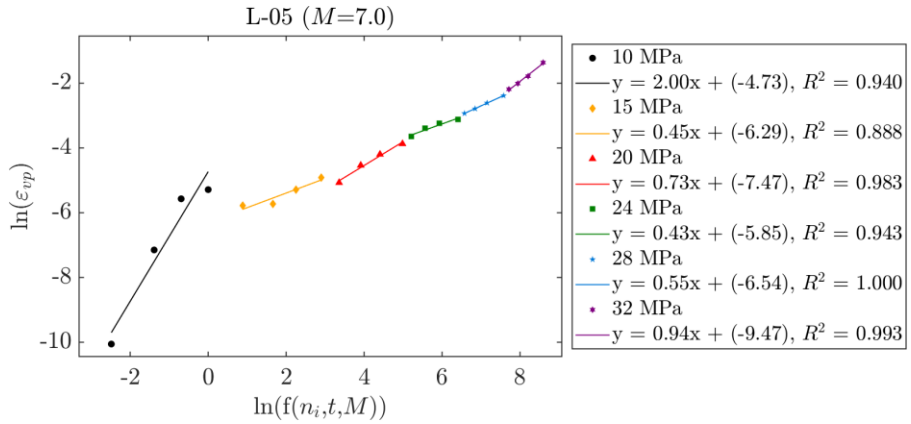

Figure 9: VP strain development

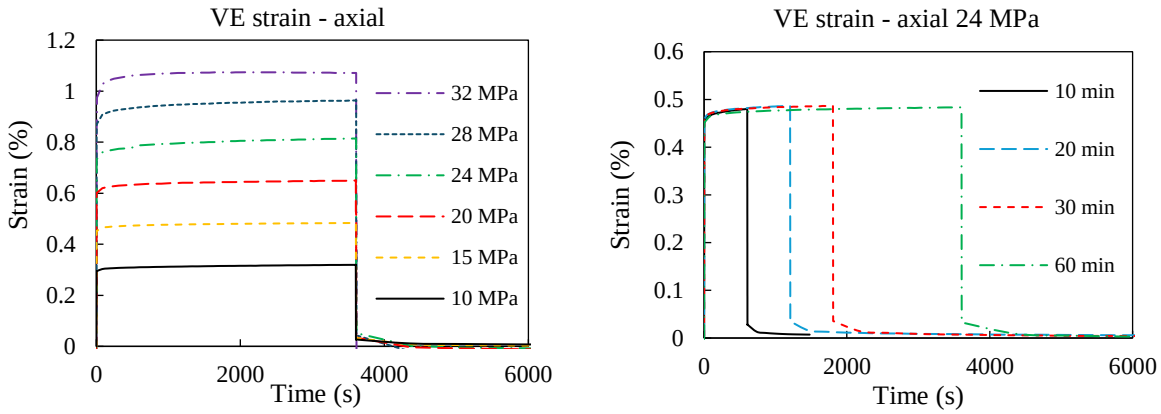

Figure 10: Creep recovery strain for all stress levels (left) and for 24 MPa (right)

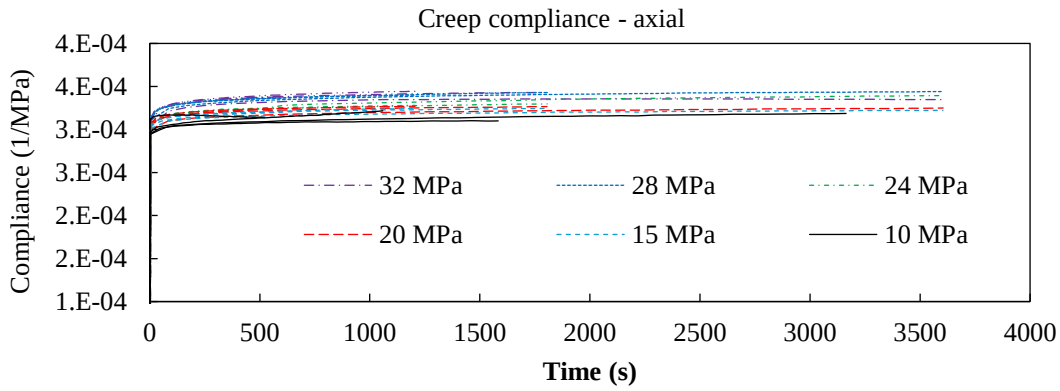

Figure 11: Creep compliance for all stress levels

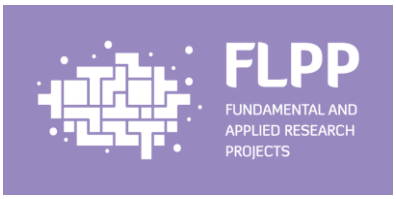
After obtaining the values, the VP part of the curves was removed from the total strain. The obtained VE strain is presented in Figure 10. The right side of Figure 10 also shows the VE strain at all time steps for 24 MPa stress. It can be seen that the curves overlap. This can be expected, since the VE is reversible and after recovery should follow the same path as before. This indicates that the VP strain has been removed properly.

Figure 11 shows creep compliances at different stress levels. From these curves we can see nonlinear viscoelastic behavior even at low stress levels. This nonlinearity can be further increased by change in environmental effects. We noticed that a slight change in the room environment due to the changing seasons (change in temperature, humidity) significantly altered the behavior of the strain. Thus, in future studies a more controlled environment will be used to study long-term behavior of this material. The effect of temperature and humidity conditions, as well as nonlinear characterization of micro and macro scales of polymer used in 3D printing will be analyzed. In addition, the development of a robust material model for finite element analysis (FEA) is a key objective, aimed at enabling the simulation of more complex geometries. The initial phase will involve validating the material model using simple specimen geometries. Once validated, the model will be applied to more intricate shapes to investigate how various manufacturing parameters affect the nonlinear mechanical properties of 3D-printed polymers. This approach will support the advancement of predictive modeling tools for additive manufacturing applications.

Moreover, the future goal of this study will be implementing the constitutive model into FEM program like ANSYS, to simulate more complex geometries and see if the simulations have good agreement with tested specimens. Although for one-dimensional cases this has already been done on PLA specimens using ABAQUS UMAT subroutine [17].

6 CONCLUSIONS

The initial tests have shown that their printed plates have distinctly anisotropic properties. The printed specimens showed smaller deviation between directions, while specimens that were cut out of a larger 3D printed plate showed significant differences in material properties. This can be expected, since the edges of the printed specimen are more infilled, adding reinforcement in the loading direction. This is in contrary to the specimens, which were cut out of the larger 3D printed plate, where polymer is held together only by the small joint region between individual polymer filaments.



When different scales of the polymer were analyzed, it was observed that the single filament, as well as printed plates, showed slightly higher elastic modulus than the filament as received. This might indicate that the molecules have been slightly aligned within the polymer in the printing direction, creating a slight anisotropy within the material.

Initial creep tests showed that material viscoplasticity can be characterized by the Zapas model. This can also be seen from pure viscoelastic curves, where after removing the viscoplasticity, all curves coincide, showing that the reversible viscoelasticity has been recovered. The creep compliance showed nonlinear viscoelastic behavior already at relatively low stress levels of 10 MPa. Thus, nonlinear viscoelastic models have to be used to characterize these materials.

It was also noticed that the material is very sensitive to environmental conditions – a small change in outside temperature significantly affected the behavior of the polymer. Moving forward, materials have to be tested in very controlled environments, removing any changes in the strains due to the environmental changes.

ACKNOWLEDGEMENTS

Experimental data have been analyzed within the project LZP-2023/1-0075: Multiscale time-dependent mechanical properties of 3D printed polymer structures - TiMe3D funded by the Latvian Council of Science.

ABSTRACT

Due to their cross-linked structure and stable polymer framework, epoxy resins are difficult to degrade or remelt, leading to significant environmental issues. In this study, the effective degradation rate of cured epoxy resin was investigated using hydrolysis and glycolysis reactions. Before degradation, the ratio of hydrolysis and glycolysis solvents, in which phase separation does not occur, was studied. Various solvent ratios were applied to the cured epoxy resin, and the degradation amount and rate were observed. Based on the experimental results, the effective decomposition rate of epoxy resin was determined using a modified shrinking-core model. The results were then compared with newly obtained experimental results, validating the model.

1 Introduction

Thermoset plastics are widely utilized in high-performance applications due to their excellent mechanical strength and chemical resistance, which are attributed to their cross-linked network structures. However, this same structural stability poses significant challenges for recycling and environmental sustainability. Unlike thermoplastics, thermosets cannot be remelted or reshaped after curing, making their end-of-life disposal difficult and often reliant on landfilling or incineration. To address this issue, various recycling strategies have been proposed, including mechanical grinding, pyrolysis, and chemical degradation. Among these, chemical recycling via controlled degradation has emerged as a promising approach, especially for thermoset resins containing degradable functional groups such as esters or anhydrides. When such polymers are exposed to water or nucleophilic agents, hydrolytic degradation can occur through cleavage of the labile bonds, resulting in molecular breakdown and partial solubilization [1], [2].

Chemical degradation methods, especially hydrolysis under alkaline conditions, have emerged as promising routes to address this challenge. Previous studies reported significant success using sodium hydroxide (NaOH) for effective hydrolysis of epoxy resins. Recently, glycolysis methods, employing diols like 1,4-butanediol (BDO), have shown potential due to enhanced penetration capability, even though glycolysis reactions were not directly observed in certain cases. Nevertheless, solvent optimization, specifically balancing water and glycol components under alkaline conditions, remains insufficiently explored [3], [4]..

In this work, we examined epoxy resin degradation using NaOH solutions mixed with varying volumetric ratios of water and 1,4-butanediol. We hypothesize that while BDO itself might not significantly contribute to glycolysis, its presence may substantially impact hydrolysis reactions by modifying the solution's physicochemical properties, including viscosity and ionic mobility. To quantify this, a modified shrinking-core model was applied, providing kinetic insight into the degradation behavior of epoxy resin under optimized conditions.

2 Materials and methods

2.1 Materials

All chemicals were used as received. A degradable thermoset epoxy system was prepared using KER9100 epoxy resin and KCA9110 hardener, both supplied by KUMHO P&B Chemicals (Korea).

The solvent employed for glycolysis was 1,4-Butanediol (CAS No. 110-63-4, liquid), while sodium hydroxide (NaOH) in bead form (CAS No. 1310-73-2) was used as the alkaline catalyst for hydrolysis.

2.2 Solvent miscibility

In the first stage, the objective was to determine the solvent ratios at which no phase separation occurs between water and 1,4-Butanediol under alkaline conditions. A 2 M sodium hydroxide (NaOH) solution was prepared by dissolving 4.8 g of NaOH in varying amounts of distilled water. Seven different volumetric ratios were tested: 10:0, 9:1, 8:2, 6:4, 5:5, 3:7, and 2:8, each with a total volume of 60 mL. After adding 1,4-Butanediol to the NaOH aqueous phase, the mixtures were heated to 100°C and stirred at 510 RPM for 2 hours. Visual observations were recorded every 30 minutes to identify phase separation, color change, or precipitation. These observations were used to determine the suitable mixing ratios for subsequent degradation studies.

2.3 Degradation of epoxy resin

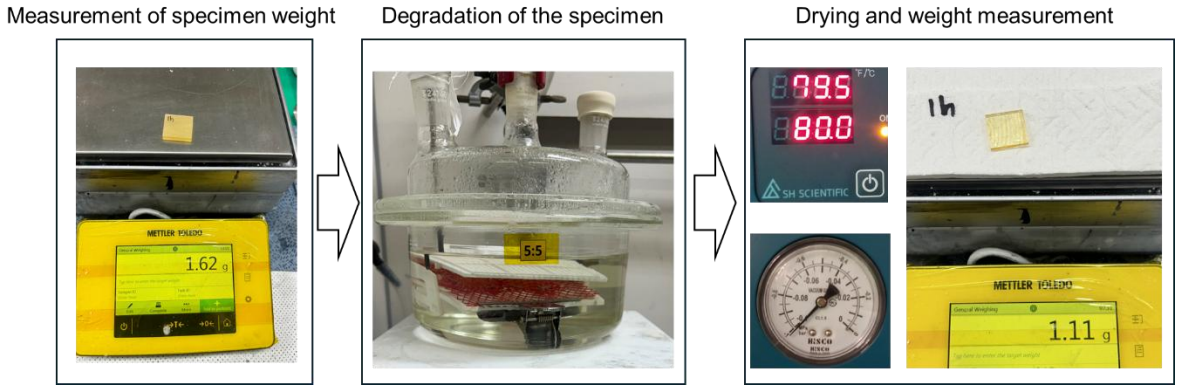

Figure 1 Experimental setup for chemical degradation of epoxy resin specimens using varying ratios of water and 1,4-butanediol (BDO) under alkaline conditions.

In the second stage, chemically decomposable cured epoxy resin specimens were cut into uniform shapes. Degradation solutions were prepared by mixing 1.5 L of the 2 M NaOH solution with 1,4-Butanediol at various miscible ratios. Epoxy specimens were enclosed in polyethylene mesh pouches and fixed with Teflon plastic holders. The samples were then immersed into the degradation media inside a three-neck round-bottom flask equipped with a reflux condenser and magnetic stirring system, maintaining both temperature and homogeneity throughout the reaction. Degradation experiments were conducted for 3, 4, and 5 hours, after which the samples were retrieved, washed, dried, and reweighed to assess the mass loss.

3 Modified shrinking-core model

To describe the degradation behavior of epoxy specimens, a modified shrinking-core model was applied, in which the cross-sectional area remains constant and only thickness (height) decreases over time. The decomposition reaction rate is defined as:

$$V = kSC_A \tag{1}$$

Where V is the reaction rate (g/s), k is the rate constant per unit surface area ($g \cdot cm^{-2} \cdot s^{-1}$), S is the reactive surface area (cm^2), and C_a is the concentration of active species (mol/L). Assuming a square plate with constant surface area (a × a) and height h(t) that decreases over time, the volume of the specimen is expressed as:

$$V = -dm/dt = -d(\rho a^2 h)/dt \tag{2}$$

The degree of degradation and the reactive surface area of the specimen can be defined as:

$$X = 1 - (m / m_0) = 1 - (h / h_0) \quad (3)$$

$$S = 4a \cdot h + 2a^2 = 2a(2h + a) = 2a[2h_0(1 - X) + a] \quad (4)$$

Rearranged into a first-order differential equation and solving this differential equation yields the closed-form solution for the degradation behavior over time:

$$X(t) = 1 + (a / 4h_0)(1 + a / 4h_0)exp(-4kC_A\, t / (a\rho)) \quad (5)$$

This model describes degradation behavior under the assumption that volume loss occurs only through thickness reduction while surface area remains constant. The model was validated against experimental data, and the rate constant *k* was estimated for each condition by nonlinear curve fitting of the degradation curves.

4 Results and discussion

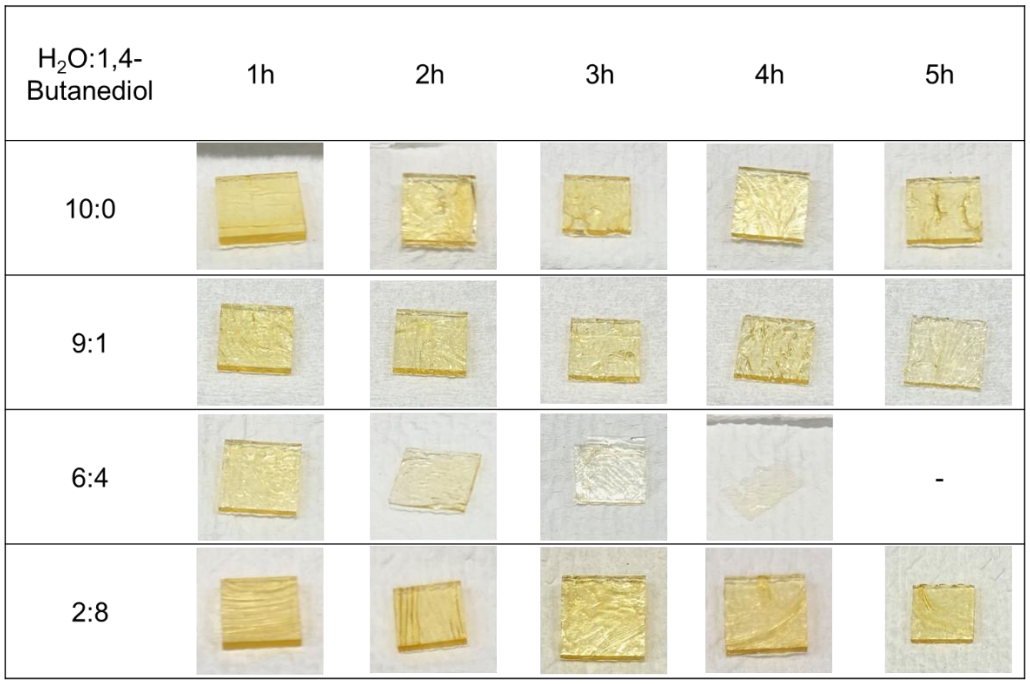

Figure 2 Visual comparison of epoxy resin degradation as a function of solvent composition (H_2O:BDO ratios) and reaction duration (1−5 hours).

Figure 2 displays the epoxy resin samples degraded under various solvent ratios (H_2O:BDO) and reaction times (1-5 hours). At initial stages (1-2 hours), samples retained structural integrity. However, increasing reaction time clearly resulted in significant thinning and transparency, indicative of ongoing degradation. Specifically, samples treated with the intermediate solvent ratio (6:4, H_2O:BDO) showed rapid and extensive degradation after just 3 hours, becoming visibly thinner and more transparent. In contrast, at higher or lower BDO ratios, the degradation was noticeably slower, consistent with the kinetic analysis discussed later.

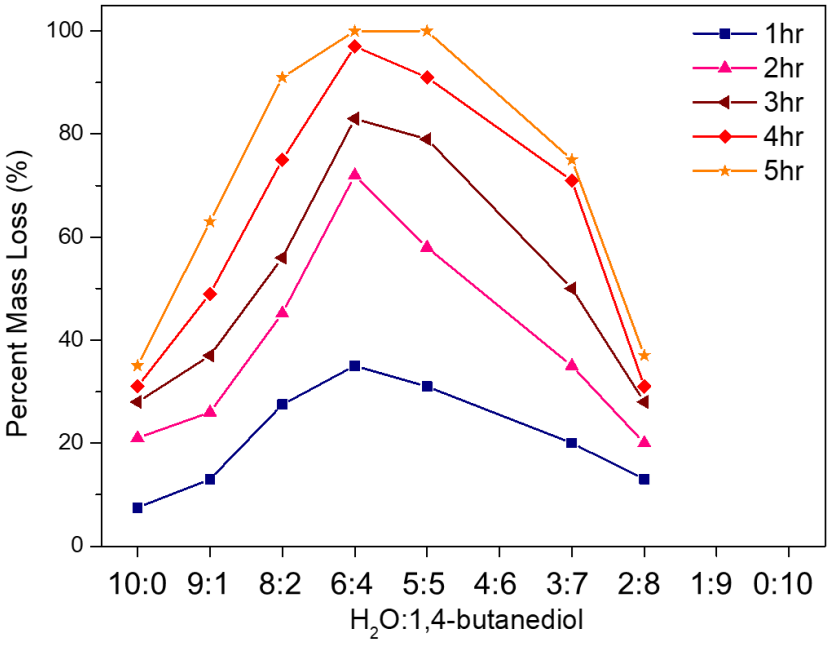

Figure 3 Experimental results of epoxy resin degradation as a function of solvent composition (H_2O:BDO ratios) and reaction duration (1–5 hours).

The relationship between solvent composition and degradation efficiency revealed a distinct optimum around the 6:4 (H_2O:BDO) ratio. Initially, increasing BDO content enhanced the degradation significantly. However, exceeding this optimal concentration resulted in reduced degradation rates. This behavior is attributed primarily to changes in ionization and catalytic activity within the solvent .

NaOH ionization predominantly occurs in water, producing hydroxide ions (OH^-), essential for epoxy hydrolysis. As the BDO fraction increases, the overall ionization degree of NaOH decreases due to reduced water content. Despite the reduced ionization at lower water ratios, the initial addition of BDO (up to 40%) significantly enhances solution penetration and hydroxide ion diffusion into the epoxy structure. This synergistic effect considerably increases degradation efficiency initially. However, beyond the critical ratio, the decreased ionization severely restricts hydroxide ion availability, reducing overall degradation efficiency.

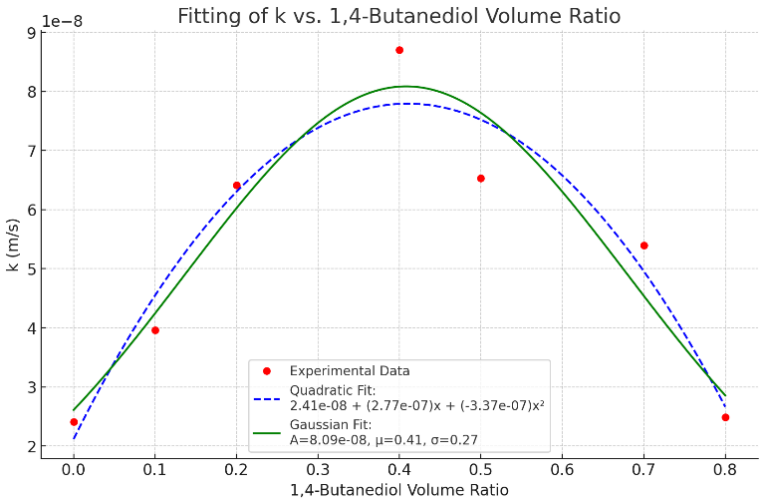

Figure 4 Gaussian fitting of degradation rate constant (k) as a function of solvent composition, identifying the optimal ratio (H_2O:BDO = 6:4).

Experimental degradation rate constants (k) fitted using Gaussian equations (Figure 3) yielded clear optimal solvent ratio insights. The fitting equation is:

$$k(x) = Aexp(-\frac{(x-\mu)^2}{2\sigma^2}) \quad (6)$$

The Gaussian fit gave parameter $A = 8.09 \times 10^{-8}\ m/s, \mu = 0.41$, and $\sigma = 0.27$, identifying 0.4 (H_2O:BDO = 6:4) as the optimal solvent ratio. This validates visual and physical observations, demonstrating that BDO enhances hydroxide ion penetration until reaching a critical concentration that negatively affects ionization and reactivity.

Under alkaline conditions, the epoxy resin primarily degrades through hydrolysis, catalyzed by hydroxide ions (OH^-). Despite initially hypothesizing potential glycolysis contributions by BDO, direct glycolysis reactions were not significantly evident from the observed data. Nevertheless, the presence of BDO significantly enhanced hydrolysis efficiency, attributed to increased hydroxide ion penetration facilitated by altered solvent physicochemical properties.

5 Conclusions

This study successfully demonstrated enhanced epoxy resin degradation under optimized alkaline hydrolysis conditions by controlling solvent ratios of water and 1,4-butanediol. Gaussian fitting provided clear quantitative identification of the optimal solvent composition, supported by visual observations and kinetic analysis via the modified shrinking-core model. Although glycolysis reactions were negligible, BDO significantly improved hydrolysis efficiency through increased hydroxide ion penetration up to a certain critical concentration, beyond which efficiency declined due to reduced ionization. These insights advance epoxy resin recycling strategies, presenting a promising route for environmentally sustainable management of thermosetting polymers.

Keywords: CFRTP, Recycled Carbon Fiber, Non-woven Fabric, Needle Punching, Dynamic Mechanical Properties

ABSTRACT

This study investigates the mechanical performance of recycled carbon fiber reinforced thermoplastic composites (rNW-CFRTP) with varying needle-punching densities. The research focuses on the effects of needle-punching treatment on material properties through comprehensive testing including three-point bending impact, fatigue tests, ash tests, and X-ray micro-CT scanning. Results indicate that needle-punching density significantly influences material performance, with P50 specimens (50 punches/cm²) demonstrating optimal mechanical properties. The fatigue analysis reveals that both NP (non-punched) and P28 groups achieve approximately 59% of their static bending strength at infinite life, while P50 reaches 48%. Edge flow stability measurements show an inverse relationship with needle-punching density, with stability distances ranging from 17.5 mm (unpunched) to 8.1 mm (P100). The findings provide valuable insights for optimizing the manufacturing process of rNW-CFRTP for industrial applications, particularly in offshore wind turbine and automotive sectors.

1 INTRODUCTION

In alignment with the Sustainable Development Goals (SDGs) [1] and growing environmental imperatives, increasingly strict carbon-emission regulations have driven intensive efforts to recycle carbon-fibre-reinforced thermoplastic composites (CFRTPs) for large-scale structural applications [2]. The aerospace and automotive industries face mounting pressure to reduce their carbon footprint while maintaining structural integrity under dynamic loading conditions [3]. Yet the industrial implementation of recycled CFRTPs for dynamically loaded components such as offshore wind-turbine blades, vehicle energy-absorption parts, or aircraft structural elements is still hindered by the scarcity of knowledge concerning their impact and fatigue behaviour under service conditions [4-5].

The critical importance of understanding dynamic mechanical performance stems from the fact that real-world applications often involve complex loading scenarios including impact events, cyclic stresses, and environmental degradation [6]. Previous studies have predominantly focused on static tensile or flexural performance, leaving the influence of fabrication-related parameters on dynamic response largely unexplored. This knowledge gap is particularly concerning for non-woven recycled carbon fibre reinforced thermoplastics (rNW-CFRTP), where the inherent anisotropy and processing-induced microstructural variations can significantly affect energy absorption mechanisms and damage tolerance.

This research focused on the dynamic impact mechanics and fatigue behaviour of rNW-CFRTP manufactured from 50 mm recycled carbon fibres and polyamide-6 binder fibres. The investigation of dynamic properties is essential because these materials are increasingly being considered for applications where impact resistance and long-term durability are paramount, such as wind turbine blade skins, automotive body panels, and marine structures [7]. Particular attention is devoted to how fibre-orientation anisotropy—defined by longitudinal and transverse directions—and needle-punch density

jointly dictate the energy-absorption capability and failure evolution under low-velocity impact and cyclic loading conditions.

When relatively long rCFs, such as the 50 mm fibers used in this study, can be obtained from recycling, it is crucial to exploit their potential for high mechanical performance. The ability to maintain fibre length during recycling processes is particularly important for dynamic applications, as longer fibres provide better load transfer and energy dissipation mechanisms [8]. To this end, a special carding and stretching process was introduced to create rNW-CFRTP mats by mixing rCF with matrix resin fibers. After producing the hybrid CF/PA6 carded nonwoven mats, a post-thermal treatment was applied to address their vulnerability to shape deformation and fragmentation due to the lack of friction between the fibers. This step involved using an isobaric double belt pressing machine (SGIC Inc., Japan) to partially melt the PA6 fibers, enabling bonding between fibers as shown in Figure 1 [9]. The result was a more compact and stable hybrid nonwoven mat. After that, carded non-woven mats were stretched and needle-punched to predetermined densities to improve handling stability without substantially disturbing the in-plane orientation and damage the properties.

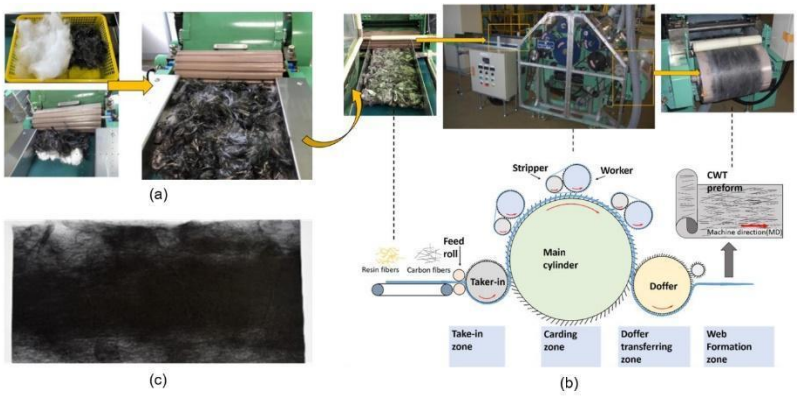

Figure 1: Carding process for nonwoven mats [9].

The investigation of needle-punching effects on dynamic performance is particularly significant because this process fundamentally alters the internal architecture of the composite, potentially affecting both impact resistance and fatigue life. In these research, three different needle-punching densities were tested, and the results investigated the structural stability of rNW-CFRTP with different punch density under dynamic tests including three-point impact and three-point fatigue tests. The fatigue performance evaluation is critical for ensuring long-term structural integrity, especially in applications where materials are subjected to millions of loading cycles over their service life. To future improve the handling properties of the nonwoven mats for mass production and enhance their material integrity, and flow stability without altering the overall fiber orientation distribution (FOD), needle punching process was used to prevent delamination. This method was chosen over conventional 3D weaving, which can introduce over-constraint problems [10].

The comprehensive understanding of dynamic mechanical behaviour is essential for enabling accurate prediction of material performance under real-world loading conditions, providing guidelines for optimising processing parameters to achieve desired mechanical properties, supporting the development of reliable design methodologies for structural applications, and facilitating the broader adoption of recycled carbon fibre composites in sustainable engineering solutions. By establishing clear process–structure–property relations for dynamically loaded rNW-CFRTP, this study reveals the existence of an optimal punching density that suppresses through-thickness flow while maintaining fibre planarity, thereby maximising specific impact energy absorption along the preferred load path. The findings fill a critical gap between laboratory-scale processing studies and real-world design requirements and lay the groundwork for finite-element simulations that can accelerate the adoption of recycled carbon-fibre composites in sustainable, high-performance structures.

2 FABRICATIONS OF MATERIALS

A material named rNW-CFRTP composed of discontinuous rCF of 50mm length, blended with PA6 fibers at varying needle-punching densities (Figure 2), was fabricated into 210 x 300 mm panels with a nominal thickness of 1.9 mm [11]. Polyamide resin was chosen as the base matrix due to its lower processing temperature and wide availability. The panels were molded under identical conditions using a press machine (280°C, 100 bars, 10 minutes), with a fiber volume fraction of 30% to allow for direct comparison. Specimens were cut into specific geometries according to ASTM standards using a composite material cutting machine (MARUTO Testing Machine Company, AC-500CF).

In this research the sample designations will include: U for unpunched rNW-CFRTP; P28, P50, and P100 for needle-punched specimens with densities of 28, 50, and 100 punches/cm², respectively. The orientation of specimens is indicated by L for longitudinal (machine direction) and T for transverse direction cuts.

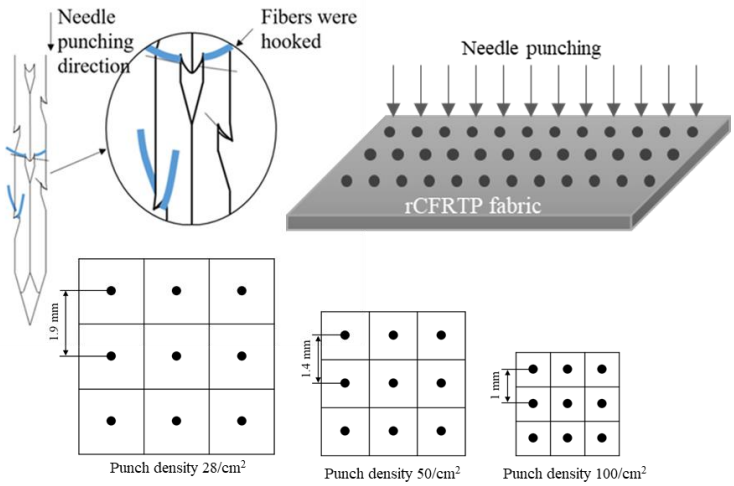

Figure 2: Schematic of needle-punching density [11].

3 EXPERIMENTS

3.1 Three-point bending impact test

In this research, both three-point bending impact and fatigue tests were conducted to evaluate the mechanical performance of the materials. Impact tests were proceeded by a high-speed puncture impact tester (Shimadzu Corporation HITS-P10, as shown in Figure 3) for both cores and sandwich structures under the ISO 179 standard, as detailed in Table 1. The testing speed is designed as 1.0, 1.5, 2.0m/s (deviation ± 0.1m/s) in this study. If the speed is deflected, velocity correction needs to be taken in the primary processor, and alternative samples will be tested until the deviation is reasonable. Since the impact process is the high-speed test, the results are unstable compared with the three-point bending test. The original results were smoothed with the same parameter in the primary processor in the high-speed puncture impact tester.

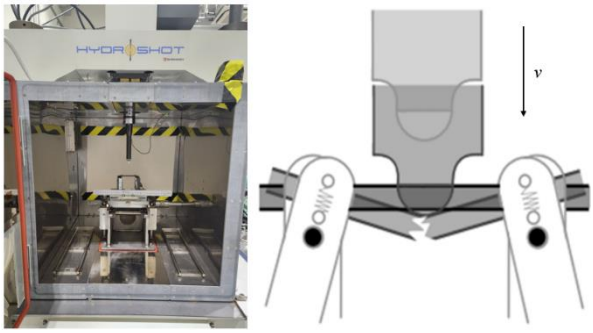

Figure 3: Impact test machine.

Dimensions		Gauge length [mm]	Stroke speed [mm/min]	Number of specimens	Standards
Length [mm]	Width [mm]				
60	15	50	1.0, 1.5, 2.0m/s	> 5	ISO 179

Table 1: Sample dimensions and testing conditions for the impact experiment.

3.2 Three-point bending fatigue test

The three-point bending fatigue tests were performed according to ASTM D7774 standards. The test machine is SERVOPULSER EHF-UB5-20L from SHIMAZU as shown in Figure 4. Samples were subjected to cyclic loading in a three-point bending fixture at a frequency of 5 Hz, with the load amplitudes set at 30%, 50%, and 70% of the material's static flexural strength, as detailed in Table 2. The tests continued until sample failure or up to 1 million cycles, and the results were used to construct stress-life (S-N) curves to assess the fatigue life and fatigue strength of the materials.

Figure 4: Fatigue test machine.

Dimensions		Gauge length [mm]	Loading condition	Frequency	Number of specimens	Standards
Length [mm]	Width [mm]					
60	15	50	60-80% σ_{max}	5Hz	> 5	ASTM D7774

Table 2: Sample dimensions and testing conditions for the fatigue experiment.

3.3 Ash test

To further characterize the mechanical properties, an ash test was conducted on the core material following the ASTM D5630 standard with HPM-2G from AZUWAN as shown in Figure 5. The test involved burning the samples in a nitrogen atmosphere at 500°C for two hours to determine the polymer matrix content, as detailed in Table 3. The remaining fibers were weighed after combustion to estimate the fiber content, with six samples used per test to ensure accuracy. The weights of the cups with the remaining carbon fibers were measured after cooling to room temperature. As a result, the volume fraction V_f can be calculated using Equation (1), the ash test will use the measured variables and densities

provided by the CPT manufacturer: $\rho_m\rho_m$ = 1.14 g/cm3 and $\rho_f\rho_f$ = 0.82 g/cm3. In this context, the variables W, V, and the subscripts f, m, c, and v represent the weight, volume, fiber, matrix, composite, and voids, respectively.

$$Vf=((W_f\rho_f+W_m\rho_m))/(\rho_c W_c)\times 100\% \quad (1)$$

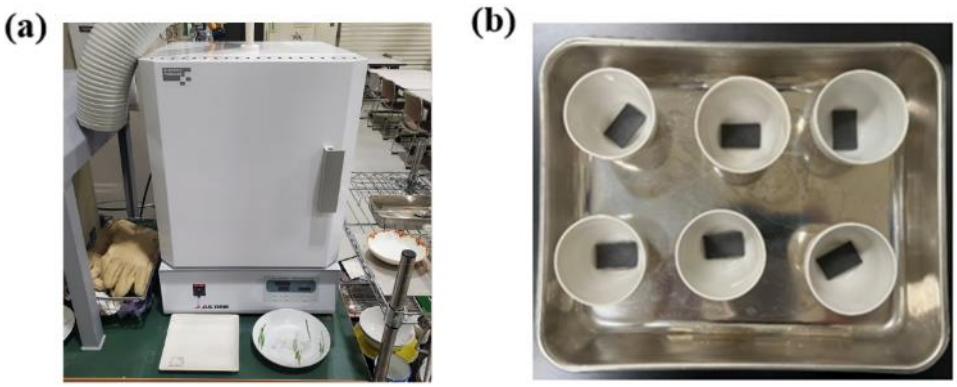

Figure 5: Gas replacement muffle furnace (As One HPM-2G) and (b) Samples for ash test.

Starting condition	Ash condition	End condition	Measure	Number of specimens	Standards
30min/100° C raise	180min/460° C burn	60min/100° C cool	Fiber volume fraction	> 5	ASTM D5630

Table 2: Sample dimensions and testing conditions for the fatigue experiment.

3.3 X-ray micro-CT scanning

The internal structural characteristics of the needle-punched specimens were examined using X-ray micro-computed tomography (micro-CT) scanning, as shown in Figure 6. To evaluate the influence of needle-punching density on material flow behavior, systematic measurements were conducted to determine the flow stability distance from panel edges. The analysis commenced at the panel periphery and progressed inward, with continuous monitoring of the fiber orientation distribution (FOD) until the orientation tensors reached equilibrium values. The experimental results revealed an inverse correlation between needle-punching density and edge flow stability distance, indicating that higher needle-punching densities resulted in reduced flow stability distances.

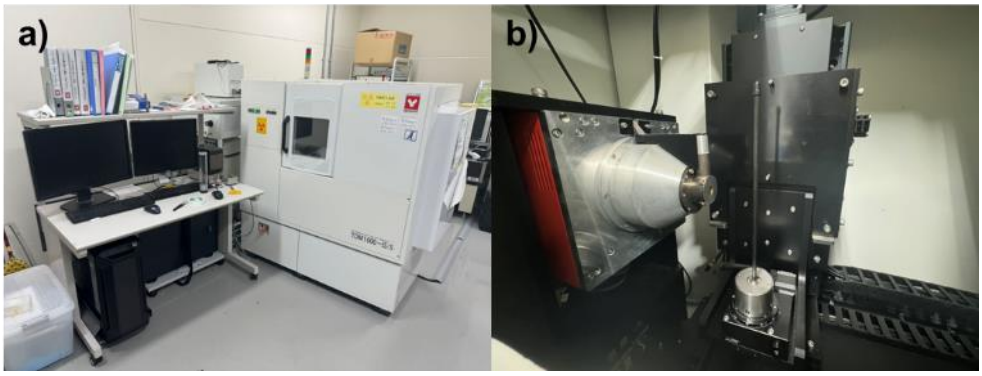

Figure 6: TDMIOOO-II system (Yamato Scientific Co., Ltd) (a); Fixing correction rod on stage (b).

4 RESULTS

4.1 Ash test results

Table 3 shows the results of ash testing, which determined the volume fractions (V_f), void content (V_v), and composite densities. The analysis revealed that needle-punching treatment significantly affected the material's volume fraction, with V_f measurements ranging between 25% and 29%. The void content, a critical factor influencing material performance, showed variations based on whether the specimens underwent needle-punching treatment.

	Vf [%]	Vv [%]	ρ [g/cm]
U	27.5	3.4	1.285
P28	28.6	1.9	1.298
P50	25.6	5.9	1.251
P100	27.8	3.0	1.291

Table 3: Fiber and void volume fraction and corresponding composite density.

4.2 Impact test results

The three-point impact test results were presented in Figure 8. A comparison of impact strength between longitudinal and transverse directions reveals significantly lower performance in the transverse direction compared to the longitudinal direction, demonstrating the pronounced directional characteristics of the processed rNW-CFRTP. This observation indicates that the material's resistance to bending deformation remains largely unchanged before and after the needle-punching process. Furthermore, when examining the influence of different needle-punching densities within each group, significant effects on three-point bending impact strength are observed. The P50 specimens exhibit performance comparable to NP (non-punched) specimens, while P28 and P100 specimens show slightly reduced performance. This phenomenon can be attributed to insufficient needle-punching density in P28 specimens, where fiber length reduction occurs without adequate interlocking, and excessive needle-punching in P100 specimens, where high density leads to excessive fiber breakage, preventing effective interlocking and formation of a strong non-woven structure. Similarly, in terms of modulus, P50 specimens demonstrate significantly higher modulus compared to materials with other punching densities.

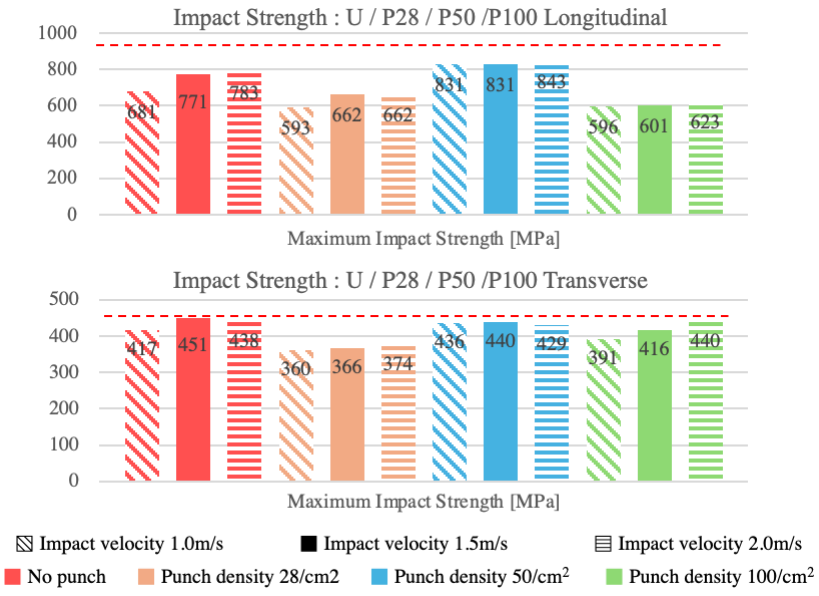

Figure 7: Impact strength with changing punch density.

Moreover, analysis of specific energy absorption reveals that NW-CFRTP under P50 conditions not only exhibits excellent stability across different impact velocities but also demonstrates energy absorption capabilities comparable to or even superior to NP specimens. This finding aligns with our predictions, as P50 specimens exhibit superior bending modulus and bending strength compared to specimens with other punching densities. Additionally, the small error values indicate that the needle-punching preforming process does not introduce uncertain cracks into the composite system.

4.3 Fatigue test results

The fatigue test results, as shown in Figure 8, revealed a clear relationship between applied load and cycle count, with decreasing loads corresponding to increasing cycles. However, this relationship was accompanied by an increase in the coefficient of variation (CV), likely due to the failure of specimens with initial defects under lower loads. Notably, some specimens exhibited cycle count below 500, which may be attributed to machine recognition errors caused by the material's low modulus. The P100 group demonstrated significantly inferior fatigue performance compared to the other three groups, making fatigue testing under identical conditions challenging.

The average fatigue data showed that the P28 group outperformed the other groups, while P50 and NP groups exhibited similar performance, except at 60% load where P50 showed better results than NP. To notice that, in this test P100 cannot withstand more than 1000 cycles even under 60% load, so it does not meet the minimum criteria for fatigue testing thus will not be shown in the results.

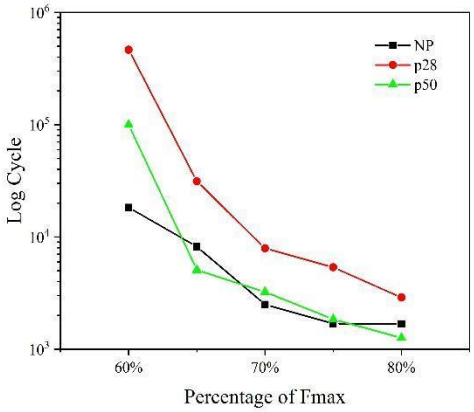

Figure 8: Result of fatigue tests.

Furthermore, to predict the fatigue strength at the infinite life, we the S-N curves which fitted using the equation:

$$S = -a * log(N) + b \tag{2}$$

where S represents stress and N denotes the number of cycles to failure, were employed to predict fatigue strength at infinite life. The analysis results, as shown in Figure 9, revealed that both NP and P28 groups achieved approximately 59% of their static bending strength at infinite life, while P50 reached only 48%.

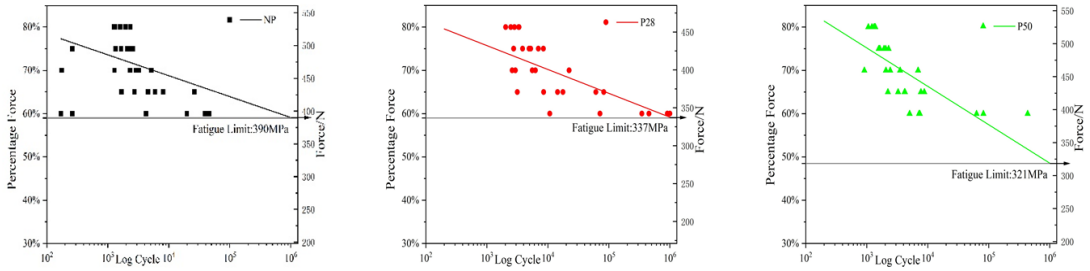

Figure 9: S-N curve of NP(a), P28(b) and P50(c).

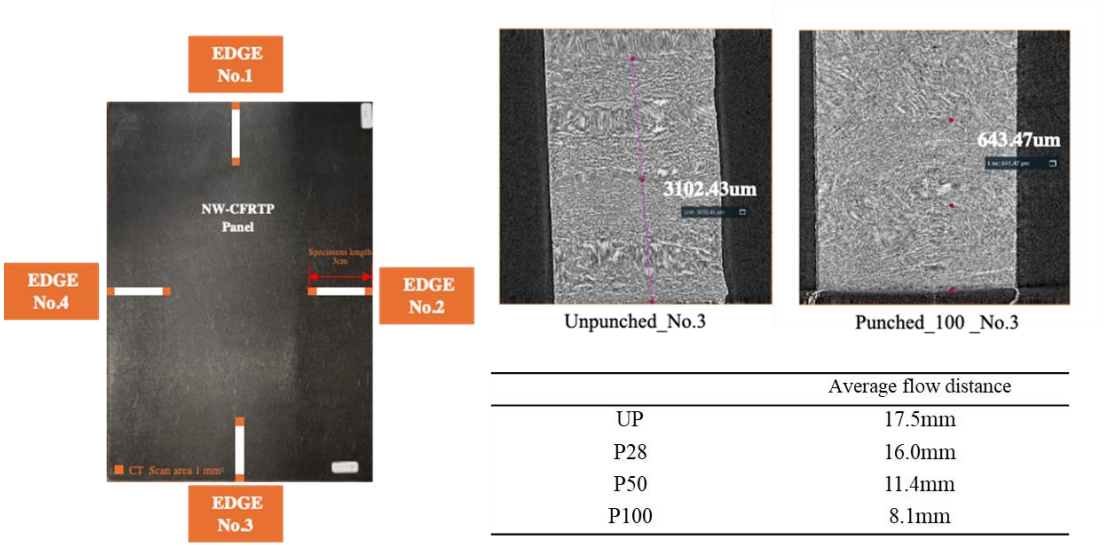
A detailed comparison of fatigue performance, as shown in Figure 10, between groups showed that P28 exhibited an increase in cycle count compared to NP. P50 performed comparably to NP at load intensities ranging from 80% to 65%, but surpassed NP at 60% load intensity. It can be observed that as the applied load decreases, the number of cycles increases. However, the coefficient variation (CV) also tends to increase. This is because the specimens with more initial defects may fail quickly, even under small loads. This observation also suggests that P50 material is more sensitive to stress variations, with its fatigue performance deteriorating more rapidly as stress increases.



Material	Force	Average number of cycles	STDEV / CV
NP	80%	1681	371 / 22%
	75%	1692	750 / 44%
	70%	2503	1554 / 62%
	65%	8188	8282 / 101%
	60%	18284	18537 / 101%
P28	80%	2893	508 / 18%
	75%	5365	1885 / 35%
	70%	6618	7304 / 110%
	65%	31306	29776 / 95%
	60%	465196	378064 / 81%
P50	80%	1261	113 / 9%
	75%	1849	257 / 14%
	70%	3232	1885 / 58%
	65%	5063	2368 / 47%
	60%	99744	152449 / 153%

Table 5: Detailed average fatigue data for each group.

4.4 CT scanning results

The influence of needle-punching density on edge flow behavior was investigated by measuring the flow stability distances from panel edges, as depicted in Figure 10. Measurements of FOD were conducted from the panel edge towards the interior until the orientation tensors reached stable values consistent with those presented in Table 7, here the corresponding tensors A_{xx}, A_{yy}, and A_{zz} represent the fiber orientation along the longitudinal, transverse, and out-of-plane directions, respectively. The

analysis revealed an inverse relationship between needle-punching density and stability distance, with measurements of 17.5 mm, 16.0 mm, 11.4 mm, and 8.1 mm for unpunched, P28, P50, and P100 specimens, respectively.

	Average flow distance
UP	17.5mm
P28	16.0mm
P50	11.4mm
P100	8.1mm

Figure 10: Results of edge flow distance by CT scanning.

Edge flow instability in discontinuous composites can significantly impact material properties through fiber orientation deviations and residual stress-induced warpage. The implementation of needle-punching technology effectively addresses this issue by controlling flow behavior during compression molding. This process enhancement leads to improved fiber distribution uniformity, thereby minimizing defects that could compromise the mechanical integrity of the final product.

	A_{xx} [%]	A_{yy} [%]	A_{zz} [%]	Total [%]
U	70.7	27.7	1.6	100
P28	73.9	24.9	1.2	100
P50	70.4	27.7	1.9	100
P100	72.4	25.7	1.4	100

Table 6: Fiber orientation tensors of rNW-CFRTP with varying needle-punching density.

5 CONCLUSIONS

This study comprehensively evaluated the mechanical performance of rNW-CFRTP materials with different needle-punching densities, focusing on their potential applications in offshore wind turbine and automotive sectors. Through a series of systematic experiments including three-point bending impact tests, fatigue tests, ash tests, and X-ray micro-CT scanning, we have gained significant insights into the relationship between needle-punching density and material performance. The research findings demonstrate that needle-punching treatment plays a crucial role in determining the mechanical properties and structural stability of rNW-CFRTP materials, with particular emphasis on their impact resistance, fatigue behavior, and edge flow characteristics. The key findings can be summarized as follows:

1. Needle-punching treatment significantly affects material properties, with P50 specimens demonstrating optimal performance in terms of impact strength and modulus.
2. Fatigue testing revealed that NP and P28 groups maintain approximately 59% of their static bending strength at infinite life, while P50 achieves 48%. The P100 group showed significantly inferior fatigue performance.

3. Edge flow stability analysis demonstrated that increased needle-punching density leads to reduced stability distances, with measurements ranging from 17.5 mm (unpunched) to 8.1 mm (P100).
4. The ash test results indicated that needle-punching treatment affects the material's volume fraction (Vf), with values ranging between 25% and 29%.
5. P50 specimens exhibited comparable or superior performance to NP specimens in terms of specific energy absorption and impact resistance, suggesting an optimal needle-punching density for industrial applications.

ACKNOWLEDGEMENTS

Part of this study was conducted under the framework of the Japanese NEDO project "New Energy and Industrial Technological Development Organization." The authors thank the members who have provided valuable information and useful discussion, and the Mirai Kasei Inc., for providing materials.
