Electrochemical properties: Electrochemical characterisation involved the preparation of electrode samples using 24K tows of carbon fibres. To facilitate the electrode performance and repeatability, the tows were divided into two 12K tows prior to assembly. To establish electrical contact, copper strip current collectors were bonded to the carbon fibres using silver paint. Nickel foil was used as a current collector in the counter electrode. The assembled carbon fibre electrodes were dried under vacuum at 50 °C overnight before transfer to an argon-filled glovebox (with H_2O and O_2 levels <1 ppm).

The electrochemical testing employed a two-electrode pouch cell configuration. Lithium metal foil served as both counter and reference electrode. Glass microfiber separator was used to insulate the two electrodes. The liquid electrolyte was then added to the cell prior to sealing it. The complete cell was sealed in a pouch bag prior to testing. Galvanostatic charge/discharge cycles were conducted to determine specific capacity, coulombic efficiency, and first-cycle losses. Testing was carried out on a Neware CT-4008-5V10mA-164 battery cycler (Neware, China). For half-cell cycling studies, the voltage window was set from 0.01 V to 1.50 V versus Li/Li^+. The applied current densities were based on graphite's theoretical capacity (372 mAh g^{-1}), corresponding to 0.05C (for the conditioning cycles), 0.1C, 0.2C, and 0.4C. The sequence included ten cycles at 0.05C, followed by five each at 0.1C, 0.2C and 0.4C, and concluding with twenty-five additional cycles at 0.1C. A resting period of two hours was applied after each charge/discharge phase.

Results and Discussion

For comparison purposes, we report the results of the partially carbonised fibre, labelled PC900, and two IM carbon fibres investigated in previous studies. These are commercially available T800 carbon fibres and the cool temperature profile (CP) carbon fibres from Tavano et al. (which are referred to as fully carbonised (FC) in the coming sections)[24]. The importance of comparing the fibres from this study to the FC fibres lies in the almost identical manufacturing process. The only difference was a passage in the high-temperature carbonisation furnaces for the FC fibres, which made them similar to other IM carbon fibres. This difference attributes peculiar microstructural differences to the two fibres.

Physical Properties:

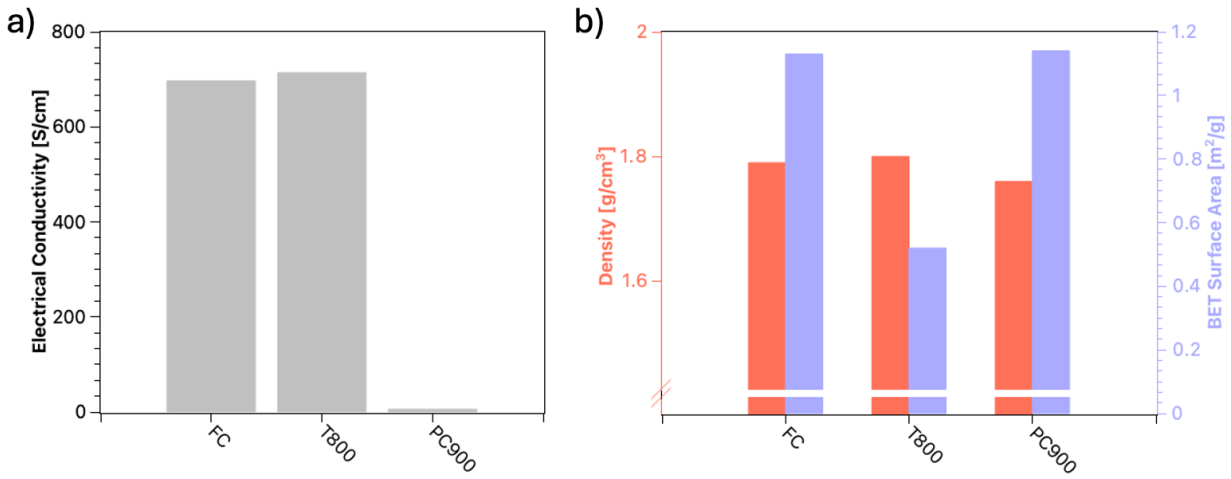

Figure 1 Physical, mechanical and electrochemical properties overview for two IM carbon fibres (FC and T800) and the partially carbonised carbon fibre (PC900). a) Electrical conductivity; b) Density and BET surface area.

Electrical conductivity is needed for energy storage applications since the active material needs to be conductive enough to transport electrons to and from the current collector. No clear requirements in terms of minimum conductivity have been reported in the literature. In Figure 1a, a comparison of the three

fibres is shown for the electrical conductivity. Values more than two orders of magnitude lower were measured for the PC900 fibres compared to the IM fibres.

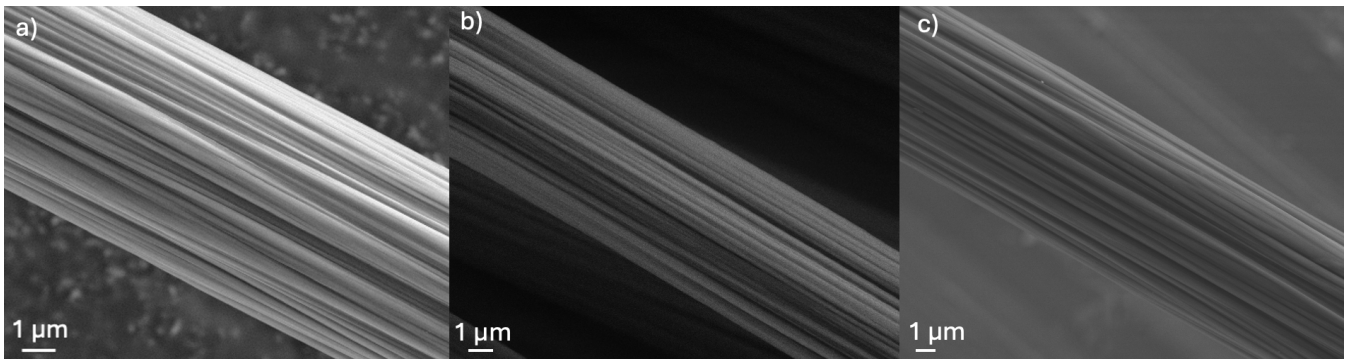

Figure 2. SEM surface images of the three carbon fibres at x10k magnification of the. a) FC fibres from Tavano et al[24]; b) T800 fibres; c) PC900 fibres manufactured in the current study.

A comparison of density and BET surface area for the three fibres is shown in Figure 1b. Comparable densities were measured for the two IM carbon, while slightly lower values were measured for the PC900 fibre. The BET surface area is highly influenced by the type of precursor fibre used for the manufacturing. The values measured for all the fibres were very low, below 1.2 m^2 g^{-1}, and comparable, indicating that the precursor was produced with a similar wet spinning process[25–27]. These results are confirmed by the SEM images shown in Figure 2a-c, where no significant differences are evident. Similar crenulations along the fibre length are visible for all fibre types.

Raman Spectroscopy: The three fibre types were characterised via Raman spectroscopy to obtain information about the carbonaceous microstructure and its possible differences due to the different carbonisation process. Different spectra were obtained for the three fibres, with different intensities of the D and G peaks along with differences in the Raman shift values.

In Figure 3a, the three spectra are shown in the 500-2500 cm^{-1} Raman shift range with a zoomed-in view of the D and G peaks in the inset. Similar G' peaks were observed in all the samples, indicating a low degree of crystallisation, small domains and a turbostratic or amorphous microstructure[28]. For the IM fibres, the intensity is similar for the D and the G peaks, resulting in a ratio between the intensity of the two equal to 1.0 and 0.9 for FC and T800, respectively. This is most likely due to the FC fibre being carbonised at a slightly lower temperature compared to the commercial T800 fibre. For the partially carbonised fibre, the intensity of the D peak is significantly higher, consistent with a more disordered, less graphitised carbonaceous microstructure of this fibre type. In this case, a ratio of 1.2 was calculated between the intensity of the D and G peaks. Additionally, by using the Tuinstra-Koenig approach, the average crystal length in the carbon fibres could be estimated from the peak intensity ratio[29]. Smaller crystallites were calculated for PC900 fibres compared to the two IM fibres with an average crystal length equal to 42 Å, compared to approximately 52 Å for IM fibres. Furthermore, the D and G peaks for the PC900 fibres are slightly shifted towards smaller Raman shifts compared to IM fibres, as can be seen in Figure 3b. This could be caused by residual strains in the microstructure due to the partial carbonisation, as well as a higher amount of heteroatoms and structural disorder[18].

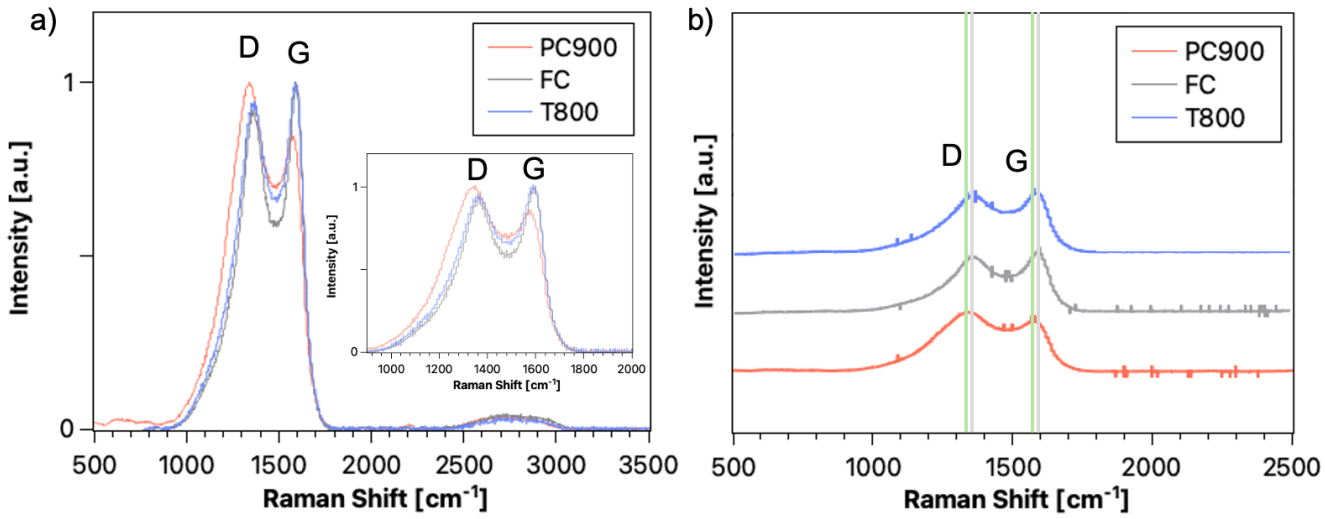

Figure 3 Raman spectroscopy results for IM fibres FC and T800, and partially carbonised fibre PC900. a) Full Raman spectra in the 500-3500 cm^{-1} Raman shift range, with zoomed-in view of the D and G peaks in the inset; b) View of the spectra with movement along the vertical direction. The D and G peaks are slightly shifted towards higher Raman shifts for the IM fibres.

Mechanical Properties: The mechanical properties of carbon fibres are mainly influenced by the tension applied during the stabilisation step and the temperature reached in the carbonisation step[30]. T800 carbon fibres showed the highest mechanical performance with a strain to failure, breaking strength and tensile modulus between 10% and 20% higher than FC fibres. This is most likely due to the maximum reached temperature in the carbonisation step, which was 1300 °C for FC fibres and is unknown for T800 fibres. However, the differences are small when compared to the values measured for PC900 fibres, with a tensile modulus around half that of IM fibres and a breaking strength and strain to failure 40% and 70% lower compared to IM fibres, respectively. All the mechanical properties are shown in Table 1.

Table 1. Mechanical properties for FC, T800 and PC900 carbon fibres.

Sample	Tensile modulus [GPa]	Tensile strength [GPa]	Strain to failure [%]
FC	204.5	2.8	1.4
T800	241.4	3.9	1.7
PC900	99.2	1.0	1.1

Mechanical properties are known to be affected by crystallite size and orientation[18,31]. For partially carbonised carbon fibres, as evidenced by the Raman spectra, smaller crystalline domains were achieved. The difference in the intensity between D and G peaks also suggests that PC900 fibres have a more disordered and less graphitised microstructure, which is further confirmed by the lower mechanical properties compared to IM fibres.

Electrochemical properties: For simplicity purposes and since the differences in the electrochemical behaviour between the FC and T800 fibres were reported to be small, in the following section, the partially carbonised PC900 fibres will only be compared to T800 fibres.

In Figure 4a-f the voltage profiles for charge and discharge for the two fibre types are depicted for various cycles at different current rates. For all the current rates, the PC900 fibres reached a higher specific capacity compared to the IM fibres, here illustrated for the T800 fibre. For the first conditioning cycle in Figure 4a, differences between the two fibres were very conspicuous, especially for the discharging part of the profile. Furthermore, the shapes of the charge and discharge curves were very different, with a

more linear trend observed for PC900. For the other voltage profiles in Figure 4b-e, the differences were more significant for the charging phase, while the discharging phase showed a similar trend. The difference between the curves was also influenced by the current rate used: by increasing the current rate, the voltage curve for T800 fibres got closer to that of PC900 fibres, almost overlapping at a specific current of 150 mA g^{-1} (0.4C rate). In Figure 4f, the reversibility of the behaviour is demonstrated. The 15th and 30th cycles overall, performed at a specific current of 35 mA g^{-1} (0.1C rate), showed an almost perfect overlapping of the curves, indicating reversibility of the lithium insertion/extraction process.

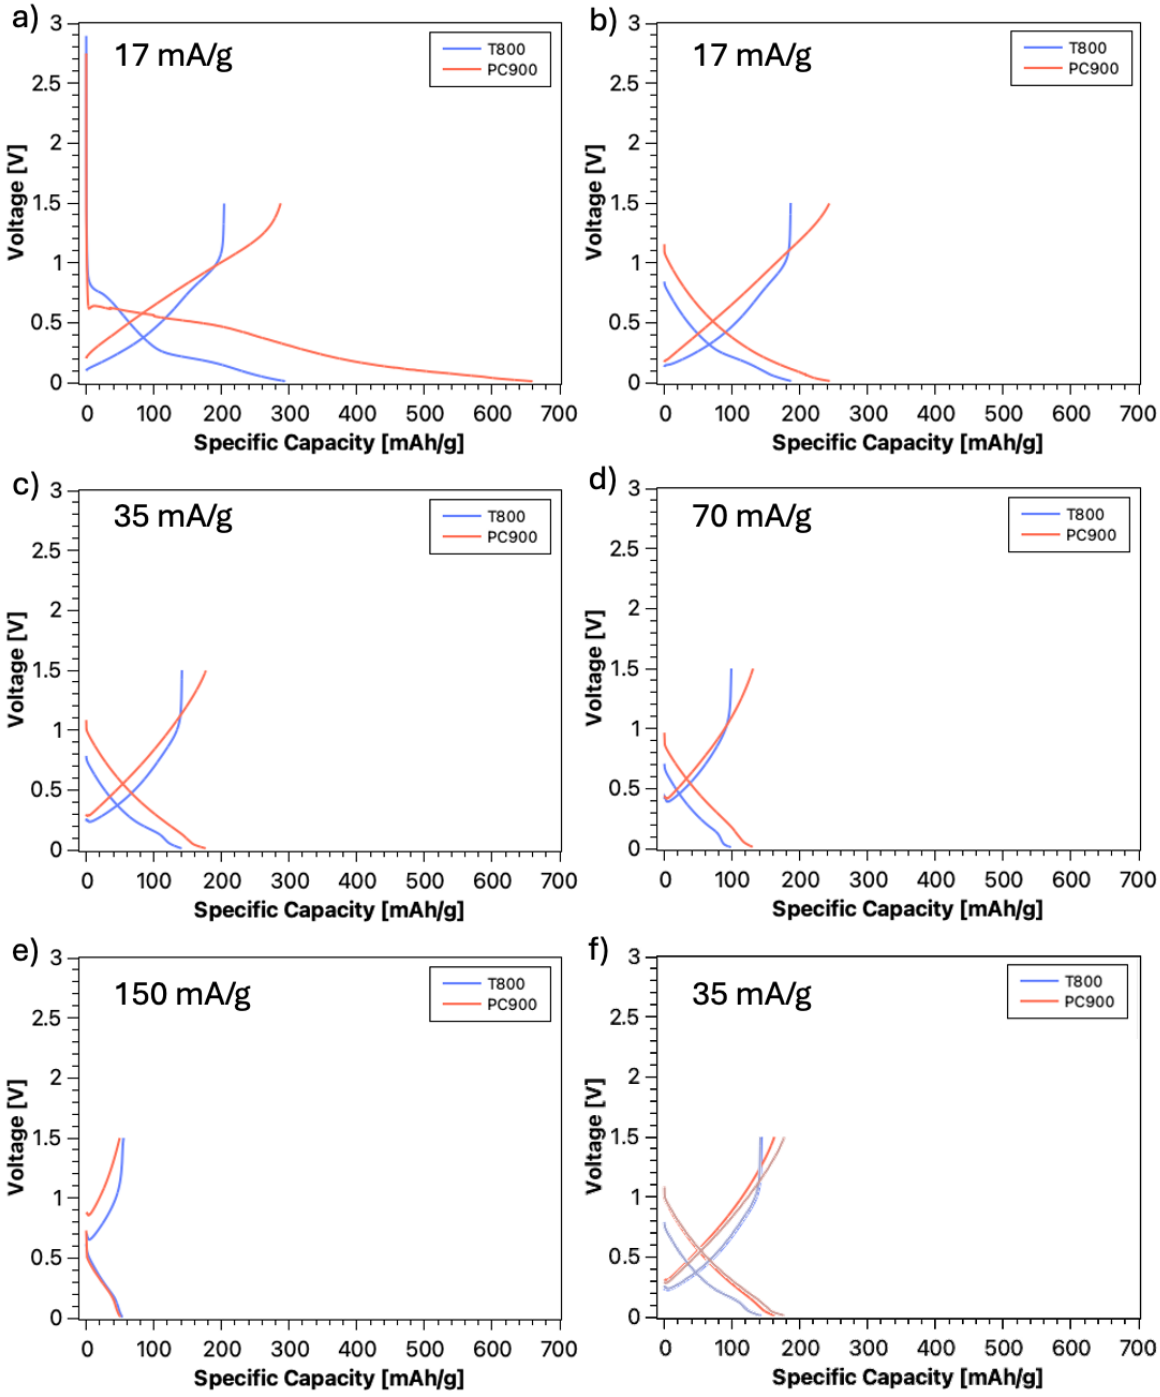

Figure 4. Charge/discharge voltage profiles for T800 and PC900 fibres. a) 1st conditioning cycle at 0.05C rate; b) 10th conditioning cycle at 0.05C rate; c) 5th cycle at 0.1C rate; d) 5th cycle at 0.2C rate; e) 5th cycle at 0.4C rate; f) 30th cycle and 15th cycle (overlayered in grey colour, same as b)) at 0.1C rate.

In Figure 5a, the specific capacities for both fibre types are shown for the different current rates. As expected, with increased current rates, lower specific capacities were measured. However, significant differences in specific capacities were observed between the two fibres, with PC900 performing better at all the current rates and equalling the specific capacity of T800 only at the fastest 0.4C rate. Additionally, the previously mentioned good reversibility of the capacity was observed, as well, when returning to a 0.1C rate after the 25th cycle.

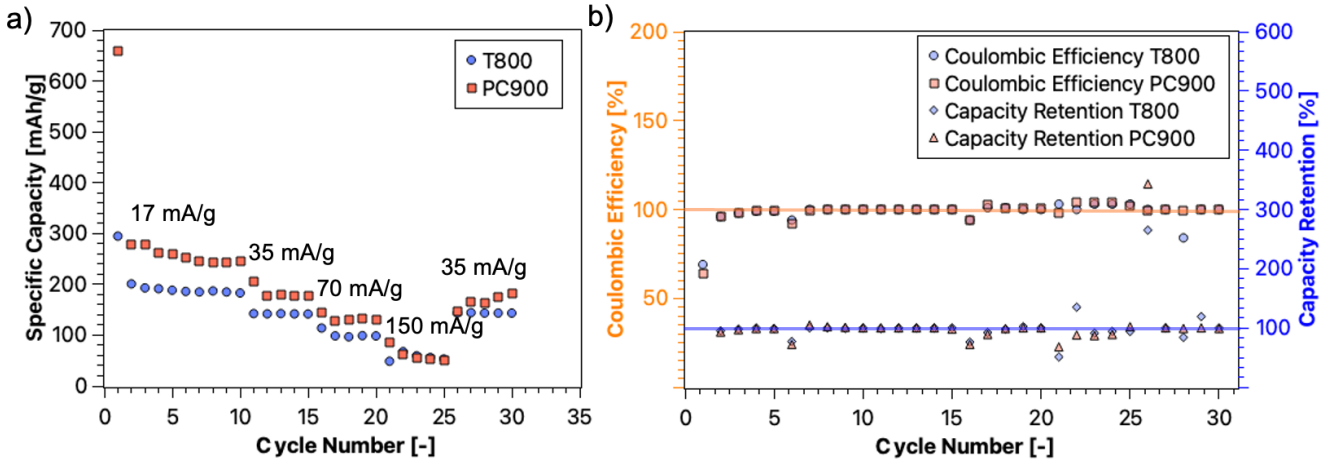

Figure 5 Overall view of the electrochemical cycling results. a) Specific capacity at different current rates at different cycle numbers for T800 and PC900; b) Coulombic efficiency and capacity retention for T800 and PC900.

For the partially carbonised PC900 fibre, an unmatched 1st cycle capacity was measured at more than double the value for T800 fibres. This was accompanied by a much larger 1st cycle loss for PC900 (56% compared to 36%). The reason for this is likely related to more of the inserted lithium ions remaining trapped in the active material due to the more disordered microstructure, as previously reported by Johansen et al.[32]. Furthermore, the results of the electrochemical characterisation are in line with previous studies and the Raman spectroscopy results[18,23,24,33–35]. Previous studies have shown that carbon fibres with a turbostratic microstructure and small crystallite size exhibit lithium storage behaviour similar to that of amorphous carbon. However, unlike fully amorphous materials, these fibres retain some graphitic domains where limited lithium intercalation can still occur. In what is referred to as the "single-layer model," amorphous regions surrounding the disordered crystalline structures impede lithium insertion into graphitic layers. As a result, lithium ions are primarily stored in the amorphous areas and at structural defects such as nanocavities. A prevalence of amorphous domains, more defects and nanocavities, and small crystalline domains in the partially carbonised carbon fibres could explain the better electrochemical performance. In the case of PC900 fibres, higher reversible capacities, with up to 40% better performance for the slower current rates, were observed compared to T800 fibres.

In Figure 5b, the good reversible behaviour for the electrochemical cycling is further evidenced. Comparable Coulombic efficiencies and capacity retentions were measured for both fibres**.** Coulombic efficiency serves as an indicator of how effectively the cell recovers its stored charge, calculated as the proportion of discharge capacity relative to the charge input within a single cycle. In contrast, capacity retention tracks the stability of performance over time by comparing each cycle's discharge capacity to that of the cycle immediately before it. This provides a detailed view of how the cell responds to changing current rates. During the initial cycle, a noticeable decline in efficiency was observed, primarily due to irreversible lithium loss associated with SEI formation and trapped ions. However, from the second cycle onward, Coulombic efficiency rapidly stabilised near 100%, signalling minimal parasitic reactions and excellent reversibility. Capacity retention data further showed that the electrodes maintain consistent performance even when subjected to fluctuations in current rates. Minor dips were correlated with current rate changes but recovered swiftly in the subsequent cycles. This behaviour underscores the

electrochemical reliability of both fibres under dynamic operating conditions. Together, the near-perfect Coulombic efficiency and strong capacity retention present compelling evidence for the durability and reliability of these carbon fibre-based structural anodes in longer-term cycling scenarios. Long-term cycling experiments (i.e. up to 1000 cycles) were not included in this study, in line with previous methodologies that focused on coulombic efficiency as an initial metric. Full-cycle durability testing will be carried out in future investigations once these fibres are integrated into structural full cells, where system-level longevity becomes a central concern[23].

Conclusion

In this study, partially carbonised carbon fibres have been characterised to assess their possible use as active material in a structural negative electrode. Partially carbonised fibres demonstrate an electrical conductivity more than two orders of magnitude lower than IM fibres. Nonetheless, the low conductivity is still sufficient for the electrochemical functioning. The lower temperature used during carbonisation of the partially carbonised fibre resulted in a lower number of graphitic domains and smaller crystallites. As a consequence, the mechanical properties of the partially carbonised fibres were reduced, with a tensile modulus reaching less than half of the IM fibres' value. In contrast, the electrochemical performance highly benefited from the achieved microstructure, with specific capacity values which were up to 40% higher compared to IM fibres. These results confirm what was previously observed, with a clear trade-off in terms of multifunctionality. The results from this study expand the previous results from Xu et al. and Tavano et al., highlighting how the multifunctionality window can be enormously expanded by using less conventional production methods[23,24].

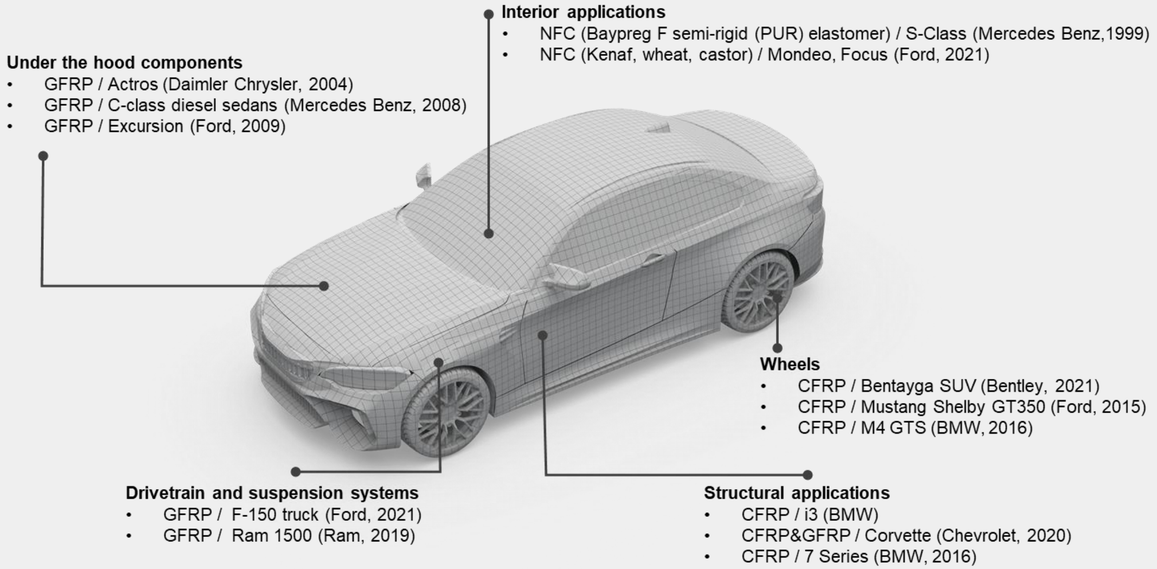
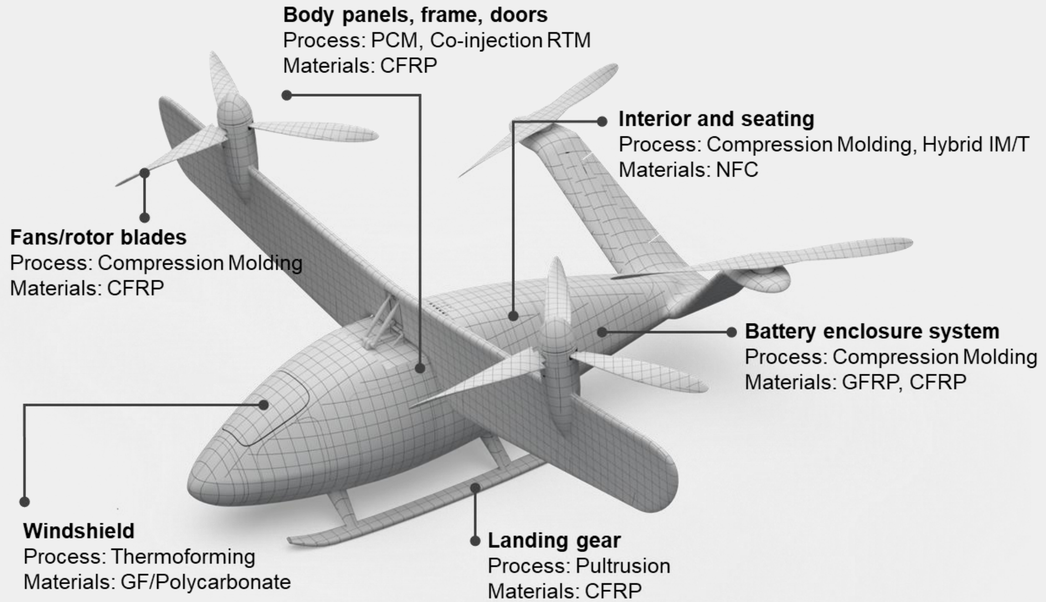
Summary & Future Works

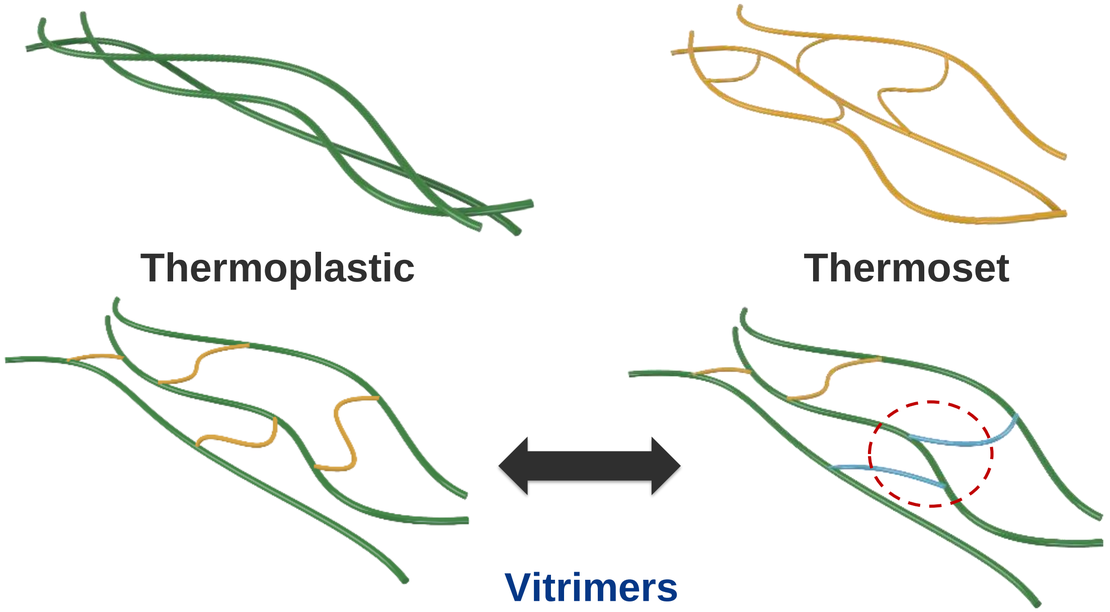


Utilization of Composites



Driving Factors for Utilization of Composites

- For future mobility to integrate with existing infrastructure, lightweight components are required for maximized driving range
- Pressure is placed on car manufacturers to satisfy legal regulations to alleviate greenhouse gas (GHG) emissions



Potential of Composites

- In 2021, composites market was valued at $88.8 billion, and the market is forecasted to expand to $144.5 billion by 2028
- With composition of metals for automobiles being 63% by weight, 10% weight reduction can increase fuel efficiency by 6-10%

Choi, Jun Young, et al. “Current Applications and Development of Composite Manufacturing Processes for Future Mobility.” International Journal of Precision Engineering and Manufacturing-Green Technology, vol. 10, no. 1, Jan. 2023, pp. 269–91.

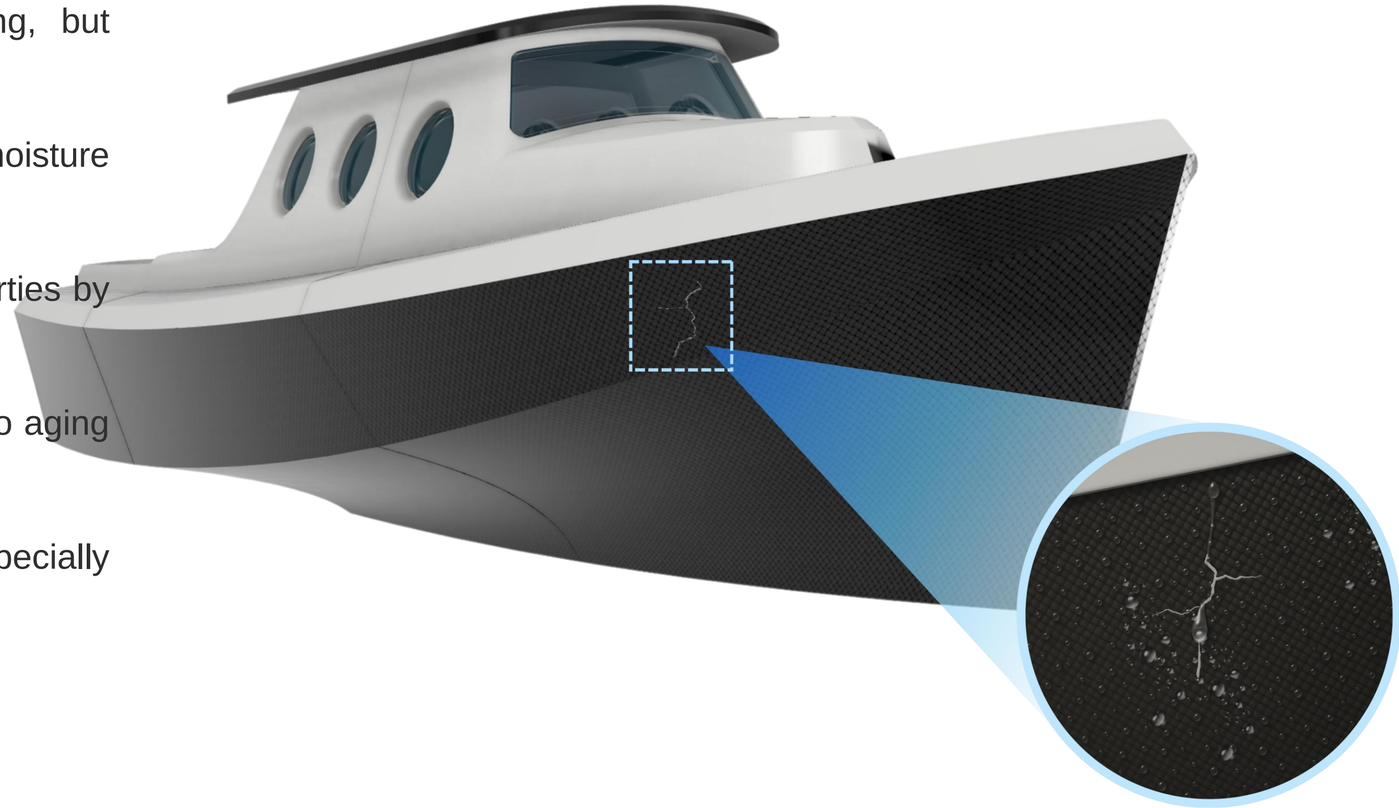
Property	Thermoset	Thermoplastic	Vitrimer
Strength	High (crosslinked network)	Moderate to High	High (similar to thermoset)
Reshapability	✗ Permanent shape after cure	✓ Heat-softenable and reshaped	✓ Reprocessable via bond exchange (no melting)
Repairability	✗ Difficult; requires scarfing + long thermal cycles	✗ Poor; needs melting and reprocessing	✓ Fast healing via heat/stimulus; no structural prep needed
Recyclability	✗ Incineration or grinding (energy-intensive, fiber loss)	✓ Re-meltable and reusable	✓ Chemically recyclable; enables clean fiber separation for reuse

Vitrimers: A New Matrix for Composites

What Are Vitrimers?

- A specific class of polymer materials with dynamic covalent bonds for reversible cross-linking
- Discovered in 2011 by French researcher Ludwik Leibler

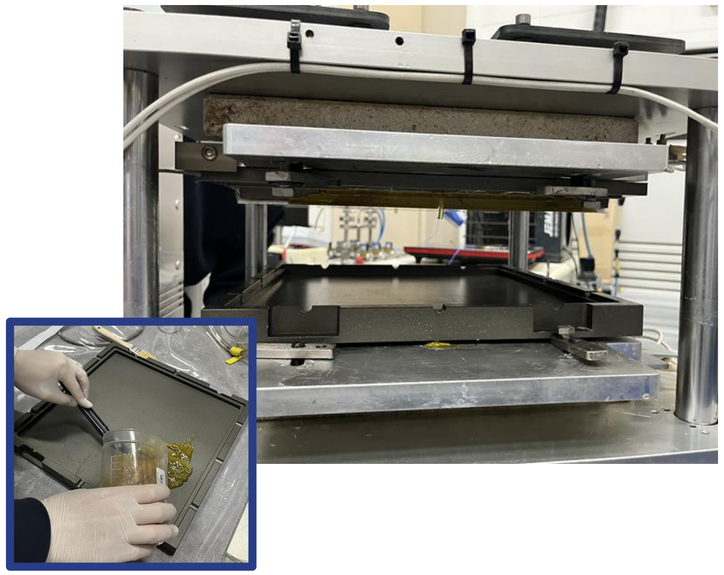
Key Characteristics of Vitrimers



- Like thermosets, can crosslink at certain temperatures
- Like thermoplastics, can be softened and reformed at higher temperatures

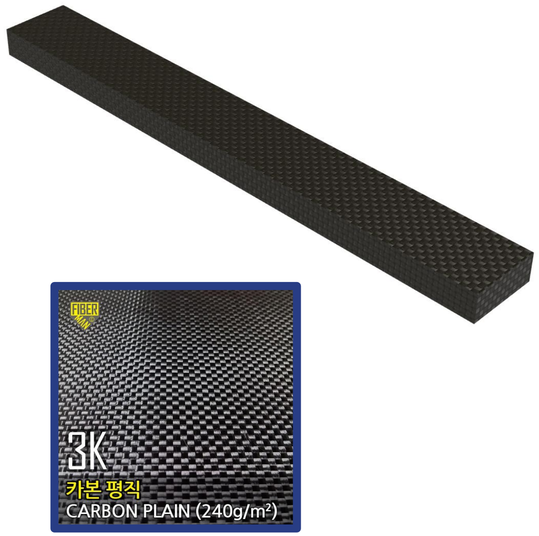
Vitrimers in Composite Manufacturing

- Vitrimers can be used to make fiber reinforced composites
- Potential to use reversible cross-linking ability for efficient material recycling



Problem Statement

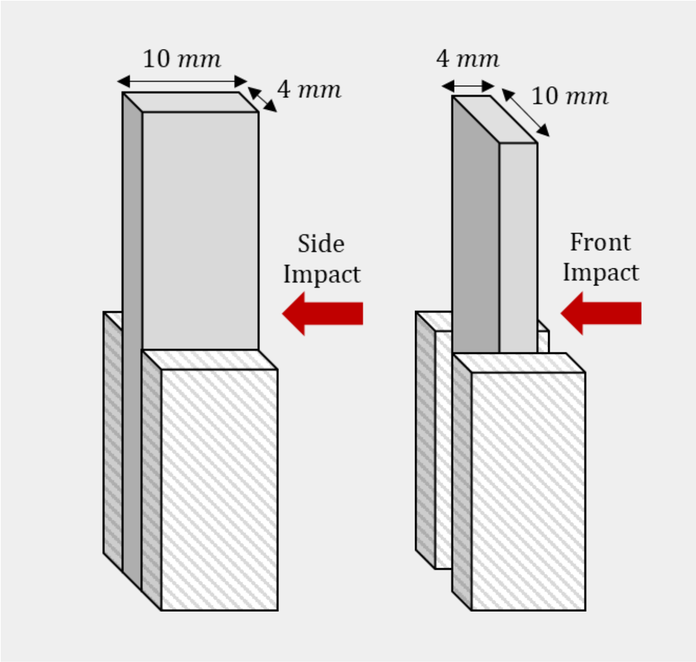
- Vitrimer composites offer self-healing and reshaping, but impact behavior remains underexplored
- Existing studies neglect real-world factors like moisture exposure (e.g., seawater, humidity)
- Environmental moisture can degrade composite properties by lowering impact strength
- Current protection methods (coatings) are vulnerable to aging or mechanical damage
- Repairability post-environmental aging is unclear, especially for fiber-reinforced vitrimers.



Fabrication of Vitrimer Composites

- **Reinforcement Types**: Milled (60 μm), Forged (6 mm), and Woven (3K fabric) carbon fibers used at 8%, 15%, and 40% V_f
- **Resin System:** Vitrimax T100™ epoxy + hardener; hardener preheated at 80 °C for 2 h
- **Milled, Forged CFRV:** Fibers dispersed in epoxy, hardener added, degassed at 1 MPa for 1 min
- **Woven CFRV:** 12 layers (259.2 g) for 40% V_f
- **Molding:** Compression molded at 130 °C, 0.8 MPa for 4 h in 300 × 300 × 4 mm mold

Impact Testing



- **Equipment:** QM700A digital tester with 1.114 kg pendulum, 0.3 m arm
- **Specimens:** 80 × 10 × 4 mm, tested in edgewise parallel and flatwise normal orientations
- **Purpose:** Edgewise simulates interlaminar failure; flatwise tests through-thickness resistance.

$$v = \sqrt{2gH}$$

$$H = L_p\left(1 - cos\theta_i \frac{\pi}{180}\right)$$

$$E = mgL_p\left(cos\theta_f \frac{\pi}{180} - \cos\theta_i \frac{\pi}{180}\right)$$

Environmental Conditioning

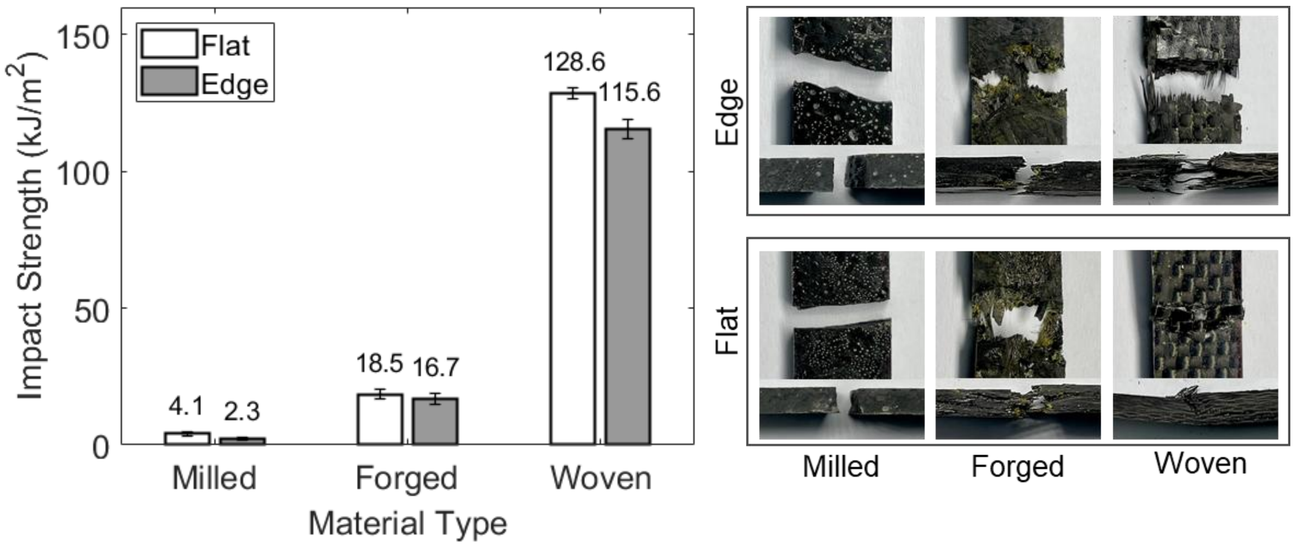
- **Pre-conditioning:** All specimens oven-dried at 50 °C for 24 h to set dry mass baseline
- **Aging Protocols:**
  - Seawater: Immersion at 25 °C and 50 °C using synthetic salt mix (~33.3 g/L)
  - Humidity: 90% Relative Humidity (RH) at 25 °C and 50 °C per ISO 6270-2 CH standard
- **Fickian Modeling:** 10-term Fickian diffusion series; *D* extracted via nonlinear least-squares fit (MATLAB)
- **Key Estimate:** $t_{95}\%$ ≈ 19 days (25 °C), 2 days (50 °C) for 4 mm thickness.

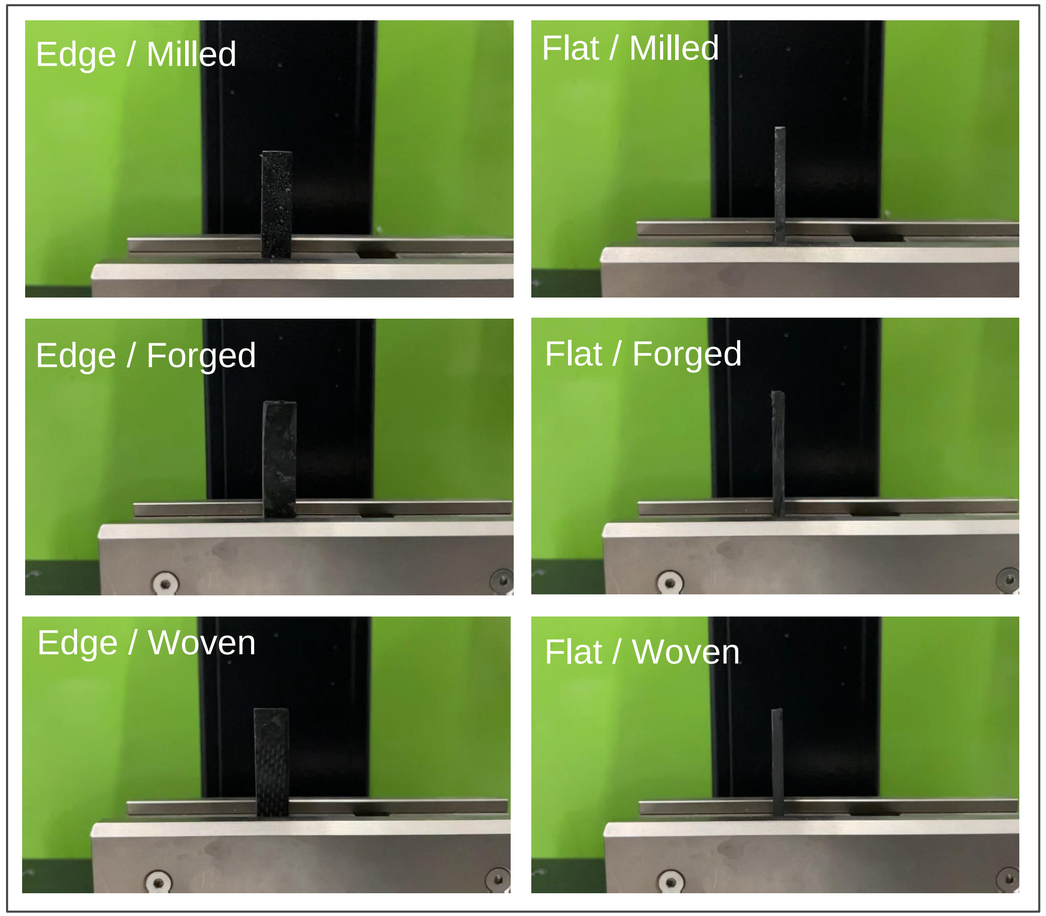
Material Type	Environment	Temperature (°C)	RH (%)	Duration (h)
Milled, Forged, Woven	Seawater Immersion	25, 50	–	1, 2, 4, 24, 48, 72
Milled, Forged, Woven	Humidity Exposure	25, 50	90	1, 2, 4, 24, 48, 72

$$\frac{M(t)}{M_\infty} = 1 - \Sigma \sum_{n=0}^{\infty} \frac{8}{\pi^2(2n+1)^2} exp\left(-\frac{\pi^2(2n+1)^2 Dt}{4h^2}\right)$$

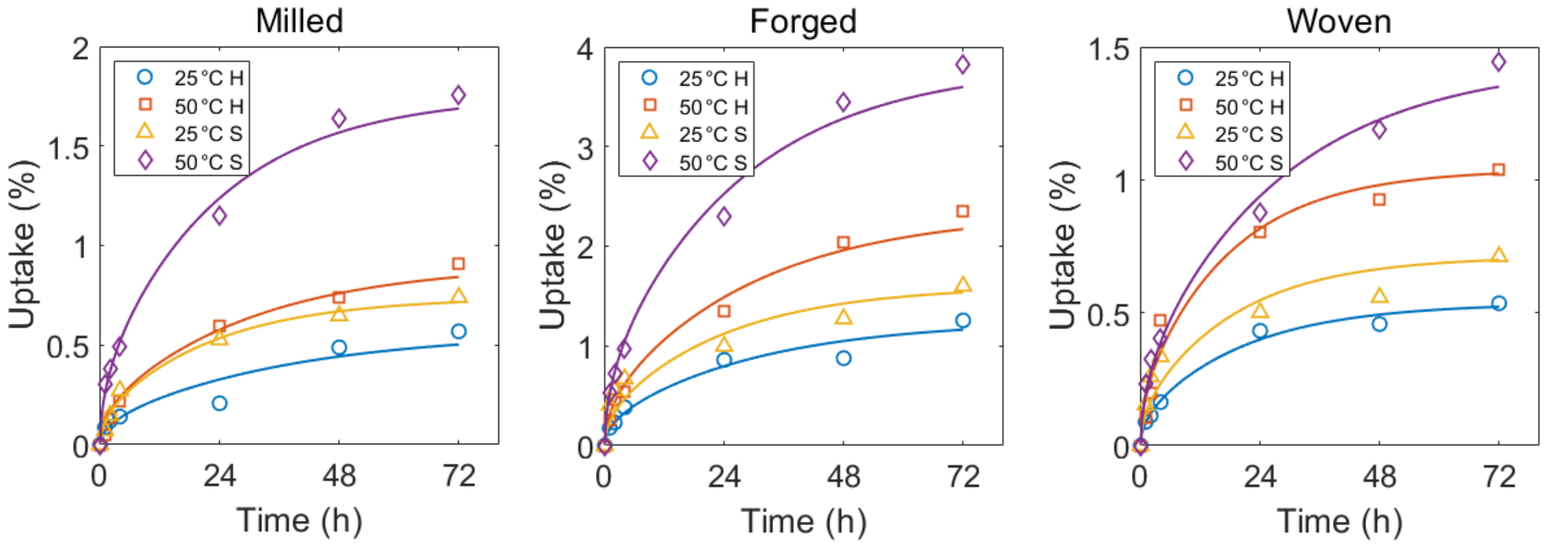
$$\frac{M(t)}{M\infty} \approx 1 - \frac{8}{\pi^2} exp\left(-\frac{\pi^2 Dt}{4h^2}\right) \qquad t_{95}\% \approx \frac{4h^2}{\pi^2 D}$$

$$D(T) = D^0 exp\left(-\frac{E_a}{RT}\right)$$





Effect of Orientation on Impact Damage



- ❑ Milled Composites: Very low impact strength (4.1 kJ/m² flat, 2.3 kJ/m² edge); brittle fracture due to short, random 7 µm fibers.
- ❑ Forged Composites: Moderate strength (~18.5/16.7 kJ/m²); isotropic behavior with delamination and full fiber breakage.
- ❑ Woven Composites: Highest strength (~128.6/115.6 kJ/m²); flatwise impact resisted better due to fiber face exposure.
- ❑ Fracture Observations:
  - Flatwise: partial fiber fracture + bulging → high energy absorption
  - Edgewise: fiber pull-out, interlayer fracture

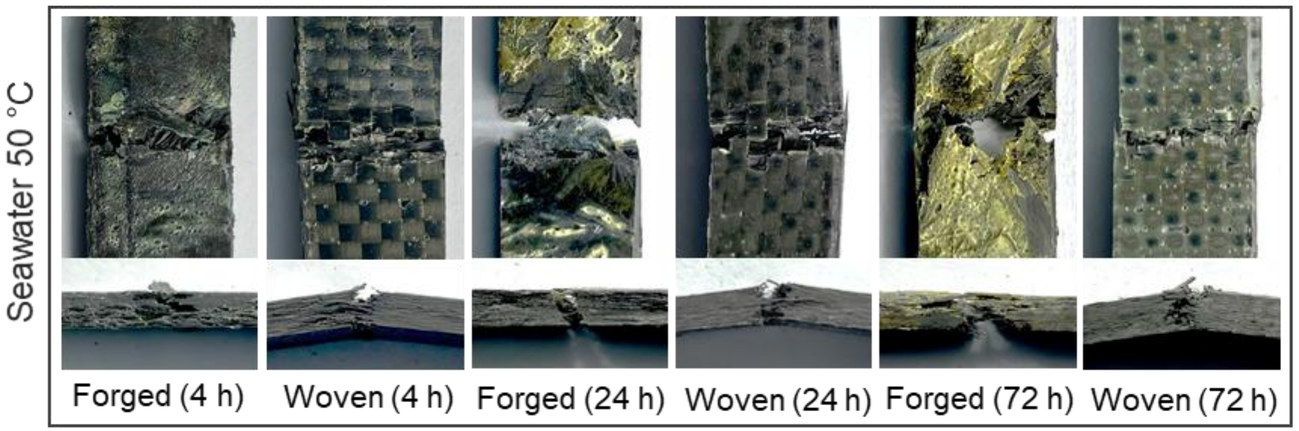
Moisture Uptake of Carbon Fiber Reinforced Vitrimer Composites

- Milled, forged, and woven CFRVs aged in 25 °C/50 °C under humidity (90% RH) and seawater immersion.
- **Fickian Fit Results:** humidity *D* ↑ with *T*, seawater *D* showed anomalies (25 °C > 50 °C in some cases).
- Seawater → faster uptake than humidity
- 50 °C → higher total absorption despite some lower *D* values
- *Forged CFRVs:* Highest uptake (~3.8%) due to voids and microcracks → capillary-driven diffusion.
- Early-time *D* estimates affected by microgram-scale fluctuations; trends remain consistent and meaningful.

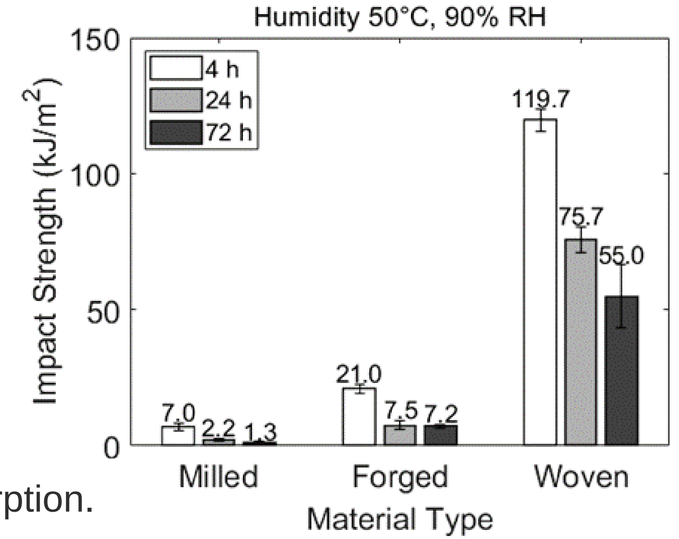
Type	Condition	Temperature (°C)	D (m²/s)
Milled	Humidity	25	1.19×10^{-11}
		50	1.57×10^{-11}
	Seawater	25	1.94×10^{-11}
		50	1.87×10^{-11}
Forged	Humidity	25	1.47×10^{-11}
		50	1.50×10^{-11}
	Seawater	25	1.91×10^{-11}
		50	1.64×10^{-11}
Woven	Humidity	25	2.07×10^{-11}
		50	2.37×10^{-11}
	Seawater	25	2.34×10^{-11}
		50	1.57×10^{-11}

Effect of Moisture on Impact Damage

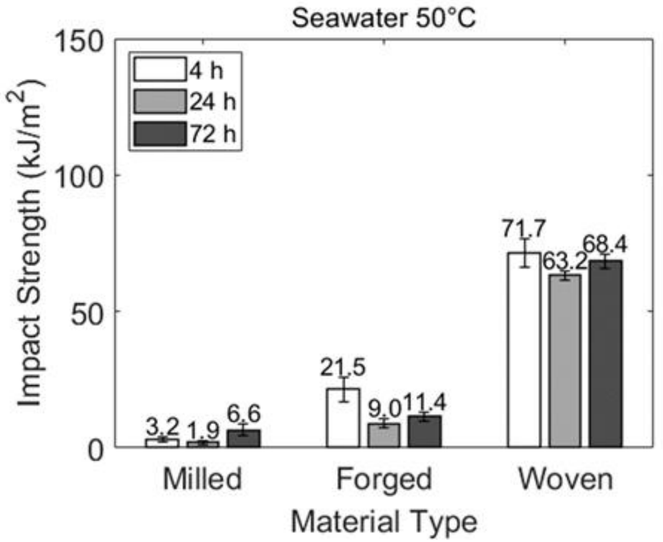
Humidity Exposure



- ❑ Sharp declines after 4 h; no recovery observed at 72 h
- ❑ Milled: −81.4%, Forged: −65.7%, Woven: −54.0% (4 h vs. 24 h)



Seawater Immersion



- ❑ Initial drop (4–24 h), followed by partial recovery at 72 h
- ❑ Milled: -40.6%, Forged: -58.1%, Woven: -11.9% (4 h vs. 24 h)
- ❑ Recovery attributed to moisture-induced plasticization enhancing ductility and energy absorption.

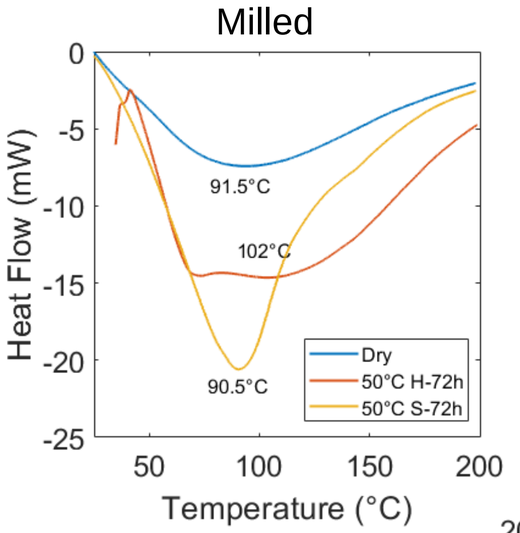
Fracture Observation

- ❑ • Forged: surface degradation, mold-like appearance
- ❑ • Woven: multilayer fractures, visible resin flow with time

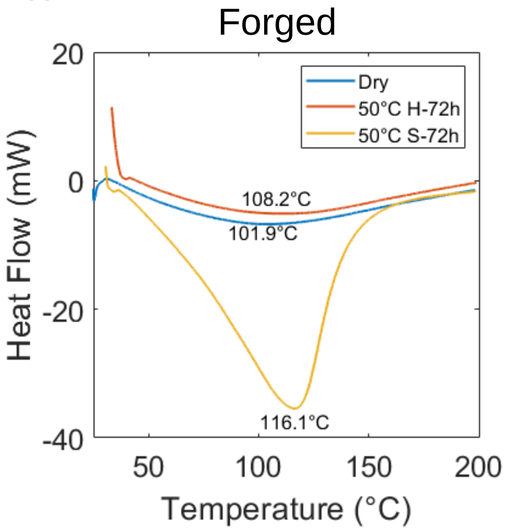
Effect of Moisture on Impact Damage

Milled

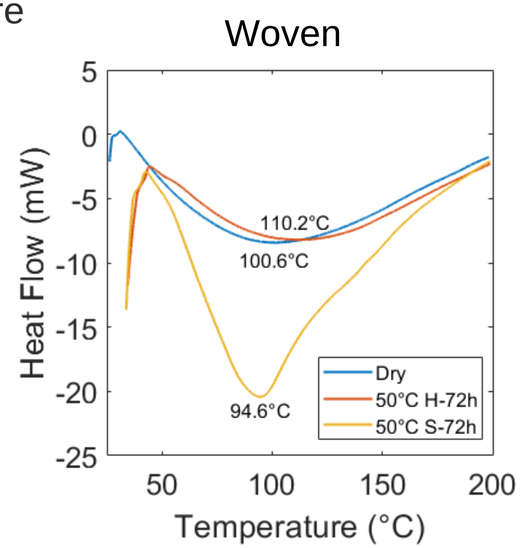
- ❑ T_g ↑ from 91.5 °C (dry) → 102 °C (humidity)
- ❑ T_g ↓ to 90.5 °C (seawater); large endothermic peak → plasticization dominant



Forged



- ❑ T_g consistently ↑ from 101.9 °C → 108.2 °C (humidity) → 116.1 °C (seawater)
- ❑ Suggests post-curing or plasticizer loss, leading to stiffer network



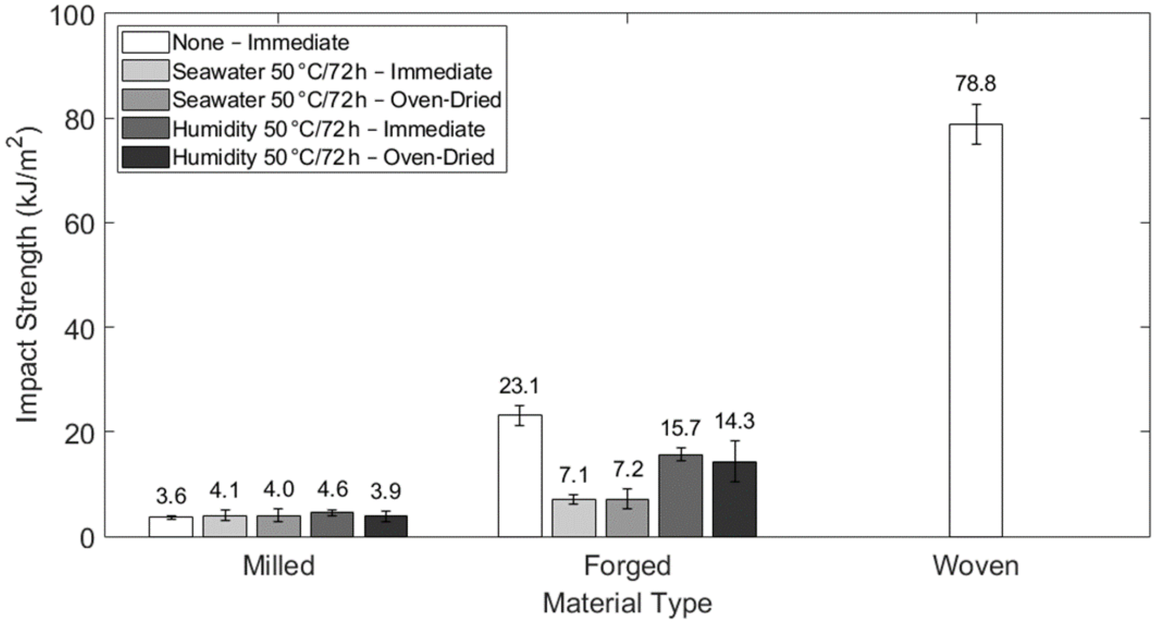
Woven

- ❑ T_g ↑ to 110 °C (humidity), then ↓ to 94.6 °C (seawater)
- ❑ Indicates initial curing, followed by strong plasticization due to deep moisture ingress

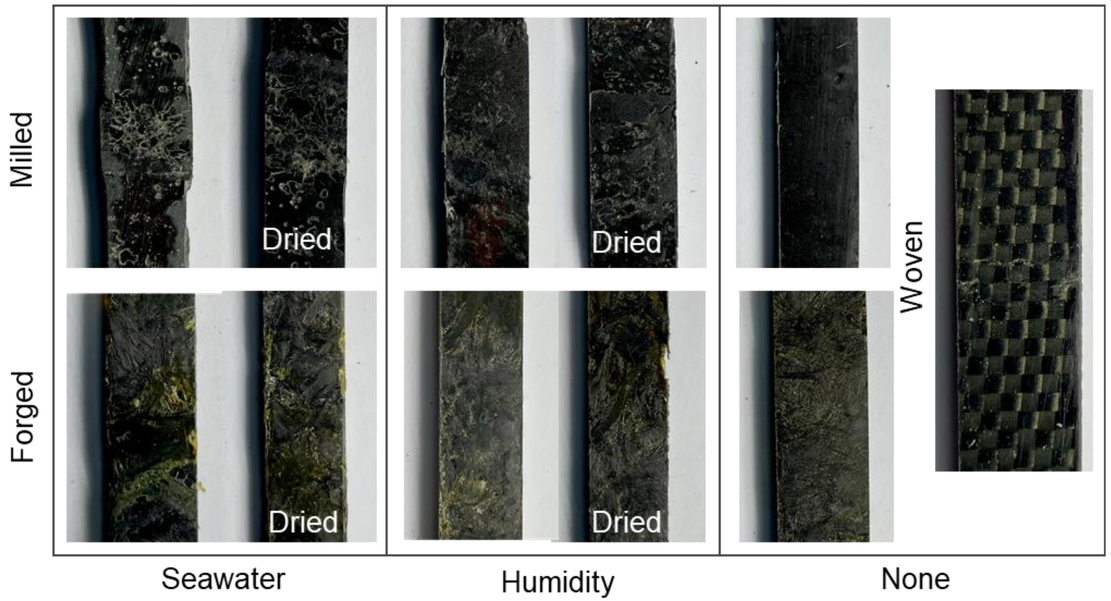
Note: Deepest endothermic peaks in seawater → confirms high moisture absorption and enthalpic relaxation

Effect of Moisture on Recovery from Impact

Milled CFRV



- ❑ High recovery (89–111%) across all conditions → resilient structure
- ❑ Seawater-induced voids seen, but minimal strength loss



Forged CFRV

- ❑ Excellent dry recovery (125%) from heat-press compaction
- ❑ Seawater severely reduced recovery (~38%) → fiber–matrix debonding
- ❑ Humidity: moderate recovery (77–85%)

Woven CFRV

- ❑ Limited dry recovery (61%); no recovery post moisture → fiber fracture irreversible
- ❑ **Oven-Drying:** Removed moisture (0.3–2.2% mass loss), but did not restore mechanical integrity → damage is structural, not just moisture retention
- ❑ **Fracture Surfaces:** Seawater → more porosity; woven → visible delamination and unrecoverable breakage

Conclusions

- Moisture exposure significantly degrades impact strength, especially under prolonged seawater or humidity at elevated temperatures.
- Forged CFRVs absorbed the most moisture, leading to severe mechanical deterioration due to voids and microcracks.
- Woven CFRVs showed irreversible damage post-immersion, with minimal repair recovery due to continuous fiber fracture.
- Milled CFRVs exhibited the most stable performance, showing high recovery and low moisture uptake.
- T_g shifts revealed competing effects of plasticization and post-curing, influenced by fiber type and environment.

Keywords: Nanocomposite sensor, Omnidirectional, Carbon nanotubes, Structural health monitoring

ABSTRACT

Strain-based structural health monitoring (SHM) is essential for composite structures due to their complex and unpredictable failure mechanism. However, conventional strain sensors are inherently limited by their unidirectional sensitivity and their inability to distinguish strain from temperature effects without additional sensors, leading to complex configurations and extensive wiring. To address these challenges, a carbon nanotube (CNT)-based omnidirectional sensing system was developed, designed as a structurally integrated nanocomposite surfacing layer for composites. This novel sensor system enables the detection of strain in all directions using a single nanocomposite sensor, while simultaneously measuring temperature to isolate its effects. Experimental validation demonstrated that the sensor accurately measured the full in-plane strain tensor under tensile loading, closely matching the output of a 3-element strain gauge rosette. It also achieved high temperature sensing accuracy, with a maximum error of just 0.3%. By maintaining reliable strain and temperature measurement capabilities while simplifying system architecture, this CNT-based sensor system offers a promising solution for efficient and multifunctional SHM in aerospace and other advanced applications.

1 INTRODUCTION

Advanced composite materials have become widely adopted in engineering applications due to their high mechanical performance and low density [1,2]. In the aerospace industry, where minimizing structural weight is of paramount importance, fiber-reinforced polymer (FRP) composites are increasingly replacing conventional metals in primary load-bearing structures [3]. However, the heterogeneous composition of FRP—comprising distinct fiber and matrix phases—leads to more complex failure mechanisms than those observed in metallic structures [4,5]. This complexity, which includes failure modes such as matrix cracking, delamination, and fiber breakage, complicates accurate failure prediction [6]. As a result, structural health monitoring (SHM) plays a more critical role in composites than in metals, enhancing structural reliability and life-cycle management. Moreover, the inherently brittle characteristic of FRP composites makes early damage detection essential to mitigate degradation and prevent failure. Real-time SHM technologies capable of identifying damage at its onset are vital for reducing maintenance costs and avoiding catastrophic events. Although non-destructive inspection (NDI) methods such as ultrasonics, acoustic emission, and infrared thermography have shown effectiveness [7,8], their applicability to in-service structures—such as aircraft during operation—is limited [8].

Real-time SHM systems operate by tracking physical parameters through permanently embedded sensors. Strain is one of the most informative parameters, directly reflecting deformation and potential damage under load. Metallic strain gauges are commonly used in traditional SHM systems due to their low cost and ease of integration [9]. Fiber Bragg grating (FBG) sensors, embedded in composite laminates, have also gained popularity in aerospace structures for their high-resolution strain monitoring and minimal intrusion [3,10–14]. However, both metallic and FBG sensors are inherently unidirectional, measuring strain along a single axis [10,15]. To capture full in-plane strain states, at least three sensors oriented in different directions are required. Furthermore, their sensitivity to temperature necessitates an

additional sensor, such as a thermocouple, for thermal compensation, which increases system complexity and sensor count. In wired SHM systems, sensor cabling alone can constitute over 75% of the total installation time and around 25% of the system cost [16].

Carbon nanotube (CNT)-based nanocomposite sensors have attracted increasing interest due to their high conductivity and low weight since their discovery [17]. When dispersed into polymers, conductive nanofillers like CNTs yield nanocomposites with piezoresistive properties. Their electrical response can be tuned through material composition and filler ratio, enabling applications in both structural strain monitoring [18–24] and flexible wearable sensors [17,25–27]. Moreover, nanocomposite sensors possess an omnidirectional piezoresistive characteristic [28-31], a key feature that can be utilized to simplify the SHM systems.

Despite these advantages, the development of multi-directional nanocomposite sensors remains limited. Most studies emphasize high sensitivity and flexibility, often overlooking the importance of omnidirectional sensing. Typically, nanocomposite sensors utilize a two-probe method that only enables unidirectional measurement, restricting their multi-directional sensing potential. Furthermore, the coupled piezoresistive and thermoresistive characteristics of nanocomposites complicates accurate strain measurement under varying temperatures [32]. Most existing approaches isolate one variable while fixing the other, which limits practical implementation. Therefore, developing methods that allow simultaneous or decoupled measurement of strain and temperature is essential.

This study introduces a novel sensing system that enables simultaneous omnidirectional strain and temperature monitoring using a single nanocomposite sensor. The proposed approach incorporates two main innovations: (1) a sensing mechanism that accounts for both piezoresistive and thermoresistive characteristics to extract strain and temperature concurrently, and (2) a multi-directional measurement configuration that captures resistivity in four independent directions from a single sensor with reduced wiring complexity. These features allow for the formulation of four independent equations, enabling the simultaneous determination of the in-plane strain components (ε_x, ε_y, ε_{xy}) and temperature (T).

2 FRAMEWORK OF OMNIDIRECTIONAL STRAIN AND TEMPERATURE SENSING SYSTEM

This section outlines a semi-empirical framework for detecting omnidirectional strain and temperature using a nanocomposite sensor. Initially, a conduction model incorporating both piezoresistive and thermoresistive behaviors of the nanocomposite is introduced and experimentally validated within typical strain and temperature ranges of composite structures. A multi-directional resistivity measurement method is then presented to exploit the sensor's omnidirectional sensitivity. Finally, a system of equations based on the validated conduction model is formulated, enabling the estimation of in-plane strain tensor components and temperature from four electrical properties measurements.

2.1 Conduction model of omnidirectional nanocomposite sensor

Several conduction mechanisms, including tunneling [33] and hopping [34], have been considered for nanocomposite sensing. Among them, the fluctuation-induced tunneling conduction (FITC) model was selected due to its strong correlation with the resistivity behavior of CNT networks under varying strain and temperature conditions [35–38]. The FITC model describes resistivity as a function of temperature affecting tunneling probability, as follows [35]:

$$\rho = \rho_0 \cdot exp\left(\frac{T_b}{T + T_0}\right) \tag{1}$$

, where ρ is the resistivity, ρ_0 is empirical resistivity constant, T_b is the energy required to transport an electron through the tunneling gap, T is the temperature of the nanocomposite, and T_0 is the temperature at which thermally activated voltage is generated. T_b and T_0 are empirically determined by examining the temperature variation in the zero-strain resistivity. Furthermore, the model can be extended by incorporating normal strain, based on the relationship between the junction distance of conductive nanofillers and the occurrence of tunneling effects, as expressed below [36].

$$\rho = \rho(0, T_r) \cdot exp\left(\frac{\varepsilon}{\lambda} + \frac{T_b \cdot \exp(dT_b/d\varepsilon \cdot \varepsilon)}{T + T_0 \cdot \exp(dT_0/d\varepsilon \cdot \varepsilon)} - \frac{T_b}{T_r + T_0}\right) \quad (2)$$

$\rho(0, T_r)$ is the resistivity at room temperature T_r (297 K) with zero strain, and λ is an empirical strain sensitivity constant. ε denotes the strain in the nanocomposite that aligns with the direction of resistivity. The derivatives of $dT_b/d\varepsilon$ and $dT_0/d\varepsilon$ with respect to strain are approximated as $1.48 \cdot T_b$ and $0.020 \cdot T_0$ based on the assumption of image-force corrected rectangular potential barrier [36].

To assess the fit of the FITC model to the resistivity data of the nanocomposite under varying strain and temperature conditions, a CNT/epoxy nanocomposite sensor as fabricated and tested (fabrication details are in the Experimental section). The resistance of fabricated sensor was monitored with two-probe method under conditions of either varying strain or temperature, with the other variables held constant. By fitting the experimental data to determine the empirical parameters of Eq. 2, the resistance of the nanocomposite was accurately predicted with a strain parameter λ of 0.48 (R^2 = 0.9941), and temperature parameters T_b and T_0 of 118.92 K and 10.04 K, respectively (R^2 = 0.9965), as shown in Fig. 1a and b. The FITC model could accommodate strain values up to 0.63%, a range comparable to conventional FBG sensors (0.2% - 1.0%) [39-41]. Beyond 0.63% strain, a sudden increase in resistance was observed, suggesting potential morphological rearrangement in the CNT network or possible delamination of the Cu electrodes from the nanocomposite layer. Of note, a sharp resistance increase indicates possible network rearrangement or electrode delamination, consistent with prior findings [29]. The temperature parameters were fitted up to a maximum of 120°C, aligning with aerospace structure operating conditions [42].

2.2 Resistivity measurement method of nanocomposite sensor

Nanocomposite sensors have traditionally been constrained to detecting unidirectional strain due to limitations in their resistivity measurement methods. The two-probe method, which is the most commonly employed technique, measures resistivity along a single direction between a parallel pair of electrodes. This setup fails to utilize the potential for multidirectional strain detection inherent in nanocomposite materials. To address this limitation, the van der Pauw (vdP) method [43], a well-established four-probe technique for characterizing the resistivity of thin conductive films, was adopted for the nanocomposite sensor system. Among various extensions of the vdP method, the approach developed by Kleiza et al. enables determination of the resistivity tensor in anisotropic materials [44]. Their method allows for calculating the resistivity tensor components ($\rho_x, \rho_y, \rho_{xy}$) of a rectangular conductive medium equipped with four corner-mounted electrodes, as illustrated in Fig. 1c. These tensor elements are derived from four sets of resistance and current measurements (R_1, R_2, I_1, I_2), as demonstrated in Fig. 1d. The calculations are governed by the following equations:

$$\exp\left(-\frac{\pi \cdot d \cdot R_1}{\rho_{iso}}\right) + \exp\left(-\frac{\pi \cdot d \cdot R_2}{\rho_{iso}}\right) = 1 \quad (3)$$

$$\rho_x = \frac{a}{b}\eta\frac{A_{\alpha,k}}{A_{\alpha,1-k}}, \qquad \rho_y = \frac{b}{a}\eta\frac{A_{\alpha,1-k}}{A_{\alpha,k}}, \qquad \rho_{xy} = -\eta\cos(\alpha\pi) \quad (4)$$

Here, d represents the thickness of the conductive layer, while a and b are the side lengths of the rectangular nanocomposite sample shown in Fig. 1c. ρ_{iso} is the determinant of resistivity tensor [45]. The parameters are defined as follows: $\alpha = 1/(1+I_1/I_2)$, $\eta = \rho_{iso}/\sin(\alpha\pi)$, $k = \exp(-\pi \cdot d \cdot R_1/\rho_{iso})$, and $A_{\alpha,k} = \int_0^1 |f_{\alpha,k}(q)| dq$ where $f_{\alpha,k}(q) = q^{\alpha-1} \cdot (1-q)^{-\alpha} \cdot (1-kq)^{\alpha-1}$. By employing the vdP method, the resistivity tensor of the nanocomposite can be comprehensively obtained using only four electrodes positioned on a single sensor. In contrast to conventional applications of the vdP method, which are typically restricted to static characterization of conductive materials, this study implements it in real time to monitor resistivity variations in the nanocomposite under dynamic strain and temperature conditions.

2.3 System of equations determining omnidirectional strain and temperature

Given the omnidirectional piezoresistive behavior of the nanocomposite, the FITC model (Eq. 1) can be generalized to any direction under the assumption that the material is homogeneous and isotropic. By substituting the resistivity measurements taken in four independent directions $(\theta_1, \theta_2, \theta_3, \theta_4)$, obtained via the vdP method into the FITC model, the following system of nonlinear equations is established:

$$\rho_{\theta_i} = \rho(0, T_r) \cdot exp\left(\frac{\varepsilon_{\theta_i}}{\lambda} + \frac{T_b \cdot \exp\left(dT_b/d\varepsilon \cdot \varepsilon_{\theta_i}\right)}{T + T_0 \cdot \exp\left(dT_0/d\varepsilon \cdot \varepsilon_{\theta_i}\right)} - \frac{T_b}{T_r + T_0}\right), \qquad i = 1,2,3,4 \qquad (5)$$

Since the in-plane strain tensor can be fully described by strain components in three independent directions, ε_{θ_4} can be expressed as a function of ε_{θ_1}, ε_{θ_2}, and ε_{θ_3}. Consequently, the four unknowns, the in-plane strain tensor elements and temperature, can be simultaneously determined by solving this system of four independent equations. As summarized in Fig. 1e, the developed nanocomposite sensor system enables the theoretical estimation of both the full in-plane strain tensor and temperature using just four directional resistivity measurements obtained from a single sensor.

Although thermal expansion effects were not explicitly incorporated into this study, the strain measured by the sensor includes both mechanical and thermal contributions. Therefore, future work should aim to extend the FITC model to explicitly account for thermal strain. With this enhancement, the sensor system would be capable of fully decoupling temperature effects from mechanical strain, thereby improving the accuracy and reliability of multidimensional strain sensing.

(e) Flowchart of the in-plane strain and temperature sensing process.

3 EXPERIMENTAL

To validate the proposed omnidirectional strain and temperature sensing framework, experimental studies were conducted by comparing sensor outputs with reference data from conventional strain and temperature sensors. This section is organized into two subsections: fabrication of the nanocomposite sensor and the experimental setup for measurement using both the nanocomposite and conventional

sensors. The fabrication subsection details the materials and manufacturing process for constructing the CNT/epoxy nanocomposite sensing layer on the composite substrate. The subsequent subsection describes the real-time measurement setup used to record the four sensing parameters of the nanocomposite sensor, along with data acquisition from conventional sensors.

3.1 Materials and fabrication of nanocomposite

A carbon fiber-reinforced-polymer (CFRP), commonly used in aerospace structures, was chosen as the composite substrate for sensor installation. The CFRP laminates were fabricated using unidirectional carbon fiber-reinforced epoxy prepreg (MCP125NS, TB Carbon) with a layup sequence of $[0/90/45/-45]_{2s}$. The fabricated laminates were then cut to dimensions of 250 mm x 25 mm in accordance with ASTM D3039M standards for tensile testing. High-conductivity CNT buckypaper (MWCNTs, US Research Nanomaterials, Inc.), with a purity of 99.9%, a thickness of 50 µm, and an areal density of 30 gsm, was used as the piezoresistive material for the nanocomposite sensor. As shown in Fig. 2a, the CNT buckypaper was cut into square films of different dimensions (10 mm x 10 mm, 20 mm x 20 mm) using a scalpel to assess the size effect of the sensor. Then, the films were attached to the CFRP surface using an epoxy adhesive film (Loctite EA 9695K, Henkel), which infiltrates the CNT network to form a CNT/epoxy nanocomposite surfacing layer during curing. The CNT films were oriented not only at 90° in the tensile direction, but also at 120° for shear strain measurements (See the coordinate axis of the sensor illustrated in Fig. 1c). Four copper films, each 10 µm thick, were then connected to the corners of the buckypaper as electrodes for the vdP method using a one-part silver epoxy (EO-98HT, Hightemp Korea). The assembled specimens were vacuum bagged as shown in Fig. 2c and cured at 120°C for 1.5 h in a convection oven, forming CNT/epoxy nanocomposite layer on the CFRP laminates.

(b) Surface image of CNT buckypaper from a scanning electron microscopy (SEM). (c) Manufacturing process of the sensor specimen. (d) Fabricated nanocomposite sensor specimen for tensile test. (e) Cross-section image of nanocomposite sensor using SEM. (f, g) Top and side view of fabricated nanocomposite sensor.

3.2 Measurement setup

The developed omnidirectional strain and temperature sensor system was experimentally validated under uniaxial tensile loading by comparing its measurements with data from conventional strain gauges and an infrared (IR) camera, as shown in Fig. 3. Real-time, automated four-probe resistivity measurements were conducted using a Keithley 2400 sourcemeter which is synchronized with a switch matrix (Keithley 3706A & 3730), enabling real-time measurements with a 0.1-second delay without the need for manual probe switching. Conventional strain data were obtained from metallic strain gauges (FRA 2-11, Tokyo Instruments) configured in a rosette layout to capture strain in three independent directions. These strain gauges were installed on the rear surface of each specimen and connected to a data acquisition system (cDAQ-9174 and NI-9237, National Instruments) with a sampling rate of 2 kHz.

Concurrently, surface temperature data of the nanocomposite sensor were captured using a FLIR A700 infrared camera.

Given that the vdP method assumes a homogeneously conductive layer, the calculated strain tensor reflects an averaged strain across the nanocomposite sensing region. To evaluate the impact of this spatial averaging, digital image correlation (DIC) analysis was performed using VIC 2D software (Correlated Solutions, Inc.). A speckle pattern was airbrushed onto the nanocomposite surface, and high-resolution images were acquired to assess the local strain field. Uniaxial tensile loading was applied using a universal testing machine (INSTRON 4482), while sinusoidal cyclic loads were applied via a servo-hydraulic testing system (INSTRON 1350) to examine dynamic sensing performance across varying frequencies and amplitudes. Each test configuration was repeated with five specimens to compute the average response and standard error.

To further evaluate the sensor's ability to simultaneously detect strain and temperature under varying thermal conditions, additional experiments were conducted. For stress-free conditions, specimens were placed on a programmable hot plate (HP-61A-2, Torrey Pines Scientific) and gradually heated, while both electrical resistance and surface temperature were monitored using the sourcemeter and IR camera, respectively. Under quasi-static tensile loading, external heating was provided via a heat gun, introducing simultaneous changes in strain and temperature. These tests were conducted to validate the sensor's real-time capability in decoupling strain and temperature for structural health monitoring (SHM) applications.

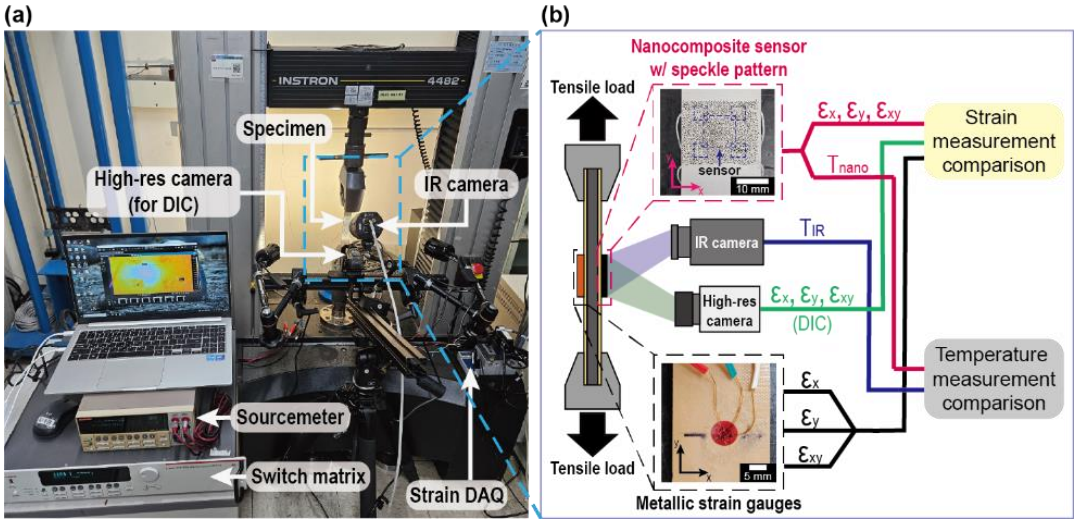

Figure 3: Experimental setup for the validation of nanocomposite sensor system. (a) Image of the real-time measurement setup, including the nanocomposite sensor and references (strain gauge, DIC analysis and IR camera) during the tensile test. (b) Schematic illustrating the validation process of the nanocomposite sensor system by comparing its measurement data with reference data.

4 Results and discussion

This section details the morphological characterization of the fabricated nanocomposite sensor and presents the experimental evaluation of its omnidirectional strain and temperature sensing performance under tensile loading. Performance validation was conducted by comparing the sensor's four outputs with reference measurements obtained from metallic strain gauges and an IR camera. Quasi-static tensile tests were used to assess the sensor's accuracy and operational range, while cyclic tensile tests evaluated its real-time monitoring capability. Additionally, the system's capacity to measure strain and temperature simultaneously under varying thermal conditions was examined both in unloaded states and during uniaxial tension.

4.1 Morphological analysis

Fig. 2b shows a scanning electron microscopy (SEM) image of the commercial MWCNT buckypaper,

revealing a randomly oriented, homogeneous CNT network. The nanotubes, with diameters ranging from 30 to 50 nm, form a nanoporous structure that allows epoxy resin to penetrate during oven curing [46,47]. This ensures complete infiltration of the epoxy into the CNT network without disrupting the random alignment, as confirmed in Fig. 2e. This morphology is critical because isotropic strain sensitivity has been associated with randomly dispersed CNTs [28,29,48], while aligned CNTs tend to produce anisotropic responses [31,49].

To verify the isotropic electrical properties of the buckypaper, resistivity tensor elements were measured using the vdp method. The off-diagonal component ρ_{xy} was approximately zero, and the anisotropy ratio—calculated as the ratio of ρ_x to ρ_y [50]—was calculated to be 0.9817 ± 0.0123 (mean ± SE), indicating near-isotropic behavior. In contrast, aligned CNT films typically exhibit an anisotropy ratio of around 1.44 ± 0.19 [49]. Given this isotropy, a constant gauge factor λ c can be uniformly applied in all directions in the FITC model.

Beyond electrical uniformity, the low thickness (i.e., ~50 µm) and areal density (i.e., 30 gsm) of CNT buckypaper allow it to be embedded into structural surfaces without significantly altering their shape or mass. Accordingly, a CNT/epoxy nanocomposite layer was successfully formed on the CFRP substrate, maintaining the integrity of its surface morphology (see Fig. 2g).

4.2 Omnidirectional strain and temperature monitoring performance under quasi-static tensile loading

Fig. 4 shows the results of quasi-static tensile tests, where the nanocomposite sensor's measurements were compared with those of strain gauges and an IR camera across a strain range of 0.18%. When oriented 90° to the loading axis, the sensor simultaneously captured the full in-plane strain tensor and temperature (Fig. 4a). It accurately recorded both axial tension and transverse compression due to the Poisson effect, with negligible shear strain. The temperature measurement was also highly precise, with a maximum error of only 0.03%.

Slight discrepancies in strain measurement arose from the temporal mismatch between individual electrical readings, due to sourcemeter switching delays. With a sampling time of ~2 seconds, the system showed some limitations in accuracy compared to conventional strain gauges. However, these could be mitigated by employing faster electrical measurement systems. Despite this, the nanocomposite sensor offers a significant advantage by combining multi-directional strain and temperature sensing into a single sensing layer.

When the sensor was rotated to 120°, it was subjected to shear strain, yet it still managed to resolve the strain tensor and temperature (Fig. 4b). Some loss in measurement accuracy was observed due to instability in electrical readings caused by sensor shape distortion under shear strain. This is attributed to the limitations of the vdP method, which assumes rectangular geometry; deformation distorts resistivity calculations. A more advanced version of the vdP method for parallelogram-shaped conductors [51] could address this issue, albeit with added complexity and the need for five probes.

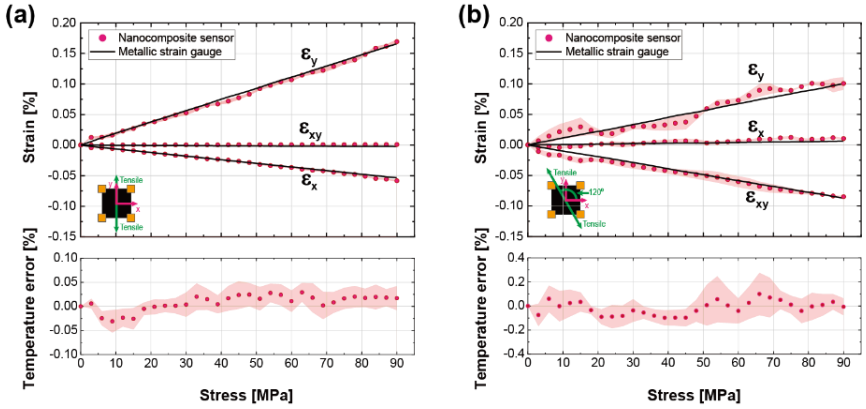

Figure 4: Sensing performance of nanocomposite sensor system monitoring omnidirectional strain and temperature under quasi-static tensile loading. (a-b) Comparison of in-plain strain tensor

measurements with strain gauges and difference in temperature measurements between nanocomposite sensor and IR camera in tensile direction of (a) 90° and (b) 120°, respectively (Mean ± SE). The error bands represent the standard error of the nanocomposite sensor specimens.

4.3 Size effect of nanocomposite sensor

As shown in Fig. 5a-b, sensor specimens of various sizes were subjected to tensile loading under the same conditions as those applied during the quasi-static tensile tests. The strain distribution across the composite surface was evaluated using DIC, as depicted in Fig. 5c-f. The strain patterns observed on the nanocomposite sensor surface were in close agreement with those on the surrounding composite substrate, demonstrating that the sensor accurately reflects the structural surface strain. When the applied tensile strain reached 0.18%, approaching the upper boundary of the sensor's measurement capability, localized strain concentrations were observed near the sensor's electrode regions (Fig. 5e-f). This occurrence is attributed to the relatively poor adhesion of the copper electrodes compared to the structurally embedded CNT buckypaper within the epoxy matrix. Although the nanocomposite sensor's strain estimation based on the FITC model remains valid up to 0.63% strain (as indicated in Fig. 1a), premature delamination caused by weak electrode adhesion may arise before the irreversible rearrangement of the CNT network begins, ultimately limiting the operational strain range of the sensor. This limitation becomes especially critical in failure detection of composite structures, considering that the average yield strain of typical CFRP materials is approximately 1.4% [52]. To overcome this constraint, it is necessary to reinforce the nanocomposite sensor by enhancing the electrode materials and refining the sensor design to reduce strain concentration at the electrode boundaries, as identified through DIC analysis. Furthermore, no discernible differences in strain distribution were observed across nanocomposites of varying sizes, indicating that the presence of the nanocomposite layer does not influence the strain distribution on the epoxy surface layer, regardless of the sensor's size.

Fig. 5 g-h present a comparison between the strain data acquired from the nanocomposite sensor and the average surface strain measured via DIC over the sensor region. The nanocomposite region is outlined with white dashed lines in Fig. 5 c-f, excluding the electrode regions, which are marked with black dashed lines. The sensor system calculates an effective strain tensor by averaging the non-uniform strain field within the nanocomposite layer. This outcome arises from the inherent averaging characteristic of the vdP method, which interprets a heterogeneous resistivity distribution as an equivalent uniform resistivity field [53]. As a result, the piezoresistive nanocomposite sensor determines an effective strain tensor that represents the overall mechanical response of the sensing layer. Due to this averaging mechanism, even when the sensor area was increased by a factor of four, the calculated effective strain tensors under the same tensile conditions remained consistent between sensors, regardless of their dimensions. Moreover, in the quasi-uniform strain field induced during uniaxial tensile loading, the effective strain values measured by the nanocomposite sensor aligned closely with the mean strain over the entire nanocomposite region. This response is analogous to the behavior of conventional metallic strain gauges, where the measured strain corresponds to the average resistance change across the gauge section, with the gauge length defining the effective sensing area.

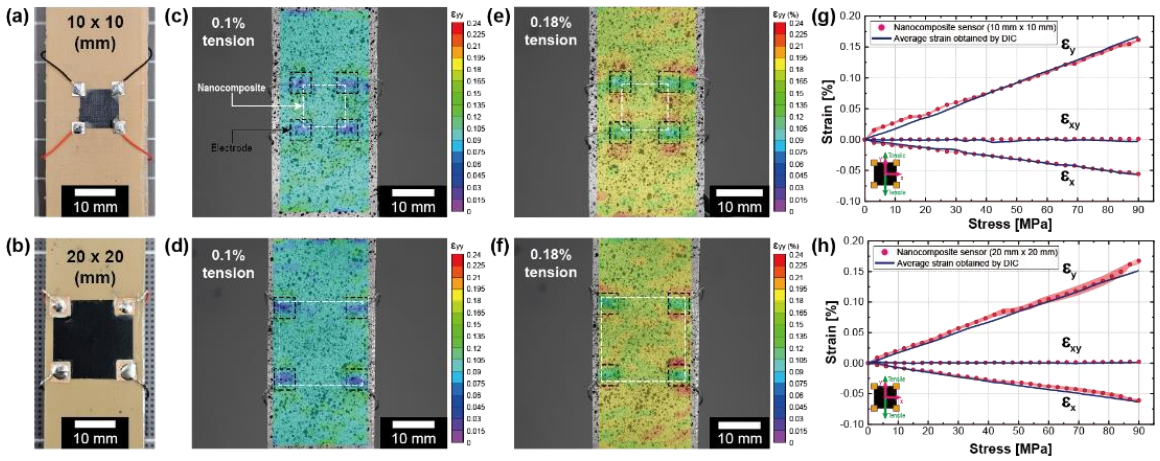

Figure 5: Size and averaging effect of strain measurements for nanocomposite sensor in different side dimensions. (a-b) Top view of nanocomposite sensors with different side lengths of 10 mm and 20 mm. (c-f) Strain distribution obtained by digital image correlation (DIC) in the tensile direction of 90°, under tensile strains of (c-d) 0.1% and (e-f) 0.18%. (g-h) Comparison of strain measurements from the nanocomposite sensors with the average strain of nanocomposite obtained via DIC. The error bands indicate the standard error of the nanocomposite sensor specimens.

4.4 Real-time monitoring performance of nanocomposite sensor

To assess dynamic performance, nanocomposite sensors (oriented 90° to the tensile axis) were preloaded by 0.4 mm (corresponding to strain of 0.55%) to avoid compression during cyclic loading, as they were specifically designed for tensile deformations. Following this pre-stretching, the specimens were then subjected to sinusoidal tension at two conditions: 0.025 Hz with 0.2 mm amplitude for 10 cycles, and 0.0125 Hz with 0.1 mm amplitude for 5 cycles. Measurements were recorded using the nanocomposite sensor, strain gauges, and an IR camera.

The real-time monitoring performance of the nanocomposite sensor specimens is shown in Fig. 6. The nanocomposite sensor reliably tracked all three in-plane strain components in agreement with the strain gauges (Fig. 6a), with average errors of 4.06% for the strain in the tensile direction (ε_y), 8.06% for the strain perpendicular to the tensile direction (ε_x), and approximately zero for the shear strain (ε_{xy}). The average strain error of the nanocomposite sensor is comparable to the reported average measurement errors of FBG sensors embedded in wind turbine blades, which are within 2.25% [54]. Future improvements should aim to enhance measurement accuracy to match that of conventional sensors by refining the calibration of strain and temperature sensitivities or by increasing the sensor's sampling rate. Nevertheless, the nanocomposite sensor maintained a low relative standard error in strain measurements, with a maximum value of 4.68%, demonstrating consistent real-time monitoring performance in all samples.

In addition to strain, the nanocomposite sensor also exhibited precise real-time temperature sensing, with a maximum deviation of only 0.203% from IR camera readings (see Fig. 6b). This accuracy indicates the sensor's ability to successfully decouple thermal effects from piezoresistive responses during dynamic loading. Notably, the temperature error from the nanocomposite sensor showed cyclic fluctuations aligned with the frequency of the applied mechanical loading, particularly at higher frequencies. These periodic variations were not observed in the IR camera data, as illustrated by the comparison in Fig. 6c. A frequency-domain analysis using fast Fourier transform (FFT) revealed distinct peaks at the loading frequencies (0.025 Hz and 0.0125 Hz) in the nanocomposite sensor data, while no such peaks were present in the IR camera data. Since the FITC model concurrently resolves both strain and temperature from the composite's resistive response, calibration mismatches in strain sensitivity may contribute to residual temperature errors, generating synchronized variations in both strain and temperature outputs. As a result, although strain changes are the dominant factor influencing resistivity during loading, minor cyclic variations in temperature data also emerged. Despite these fluctuations, the nanocomposite sensor achieved close agreement with reference sensors, affirming its capability for simultaneous strain and temperature monitoring.

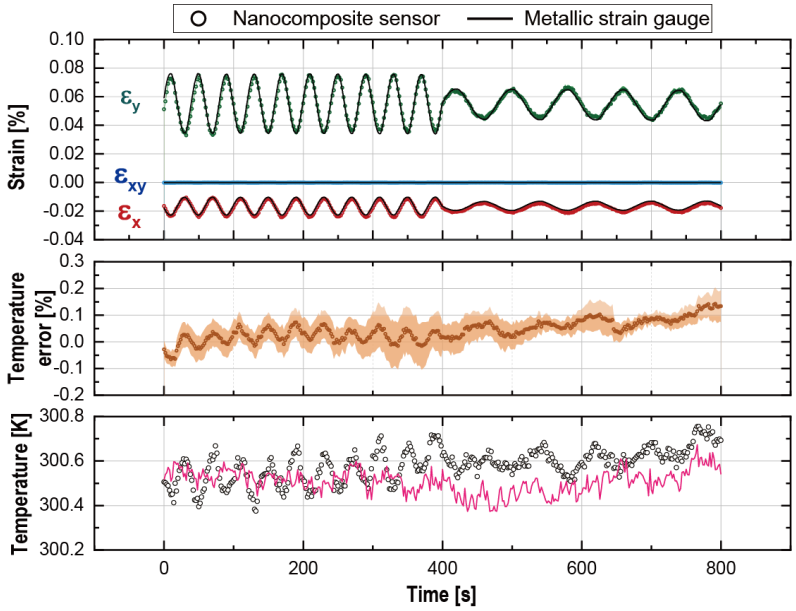

Figure 6: Real-time monitoring performance of nanocomposite sensor system under cyclic tensile loading (Mean ± SE). (a) Comparison of in-plane strain measurements with strain gauges. (b) Difference in temperature measurements between nanocomposite sensor and IR camera. The error bands represent the standard error of the nanocomposite sensor specimens. (c) Comparison of temperature measurements between one of the nanocomposite sensor and IR camera.

While the previous section focused on validation under room temperature with minor thermal variations, Fig. 7 evaluates the sensor's performance under substantial temperature changes induced by external heating. When the sensor's temperature increased by more than 30 K due to a heated plate without mechanical loading, the nanocomposite sensor measured temperature with less than 1% error, and strain readings remained near zero, as shown in Fig. 7a. Since the strain parameter in the FITC model is the sum of mechanical strain and thermal strain, a slight increase in strain measurements was observed in the stress-free condition due to the positive thermal expansion coefficient in the CFRP substrate. However, the strain in the x-direction increased less than in the y-direction unless the substrate was a quasi-isotropic laminate, indicating the presence of errors in strain calculations. As discussed in the cyclic tension test, this mismatch in temperature sensitivity is reflected in the measurement error of strain tensor elements, arising from coupled strain-temperature estimation in the FITC framework.

When convective heating was applied to the nanocomposite sensor during quasi-static tensile loading under the same conditions as depicted in Fig. 4b, the sensor system successfully tracked changes in both strain tensor components and temperature, thereby confirming the decoupling capability between piezoresistive and thermoresistive effects. The heater was activated while the tensile strain ranged between 0.03% and 0.06%, and again between 0.1% and 0.12%, as marked by the orange-shaded regions in the figure. During these heating intervals, strain measurement errors increased, particularly when the temperature ramp rate was relatively high; however, as the ramp rate decreased, the strain measurements closely realigned with the reference data. The rise in measurement error during rapid variations in strain or temperature is attributed to the low sampling rate caused by switching delays in electrical property acquisition. Despite this, the temperature readings from the nanocomposite sensor remained highly accurate, with a maximum deviation of just 1%.

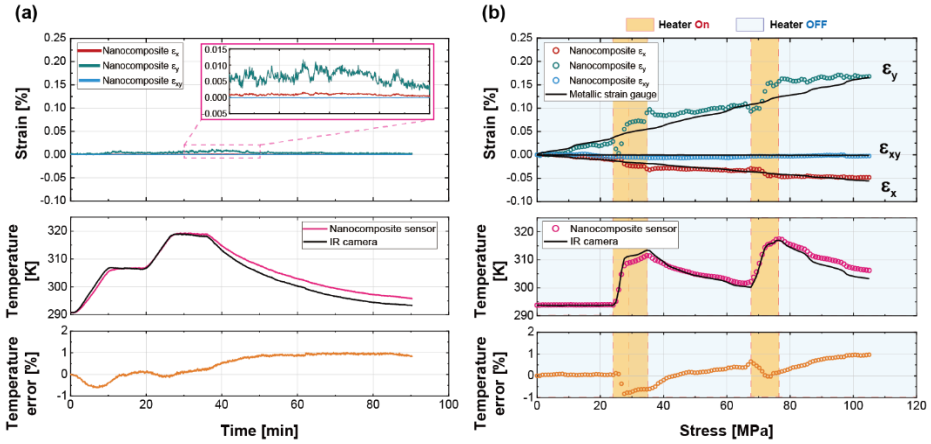

Figure 7: Sensing performance of nanocomposite sensor system monitoring omnidirectional strain and temperature under varying temperature conditions. (a) Stress-free condition. (b) Quasi-static tensile loading.

5 Conclusions

The developed sensor system enables simultaneous monitoring of the in-plane strain tensor and temperature by utilizing the omnidirectional sensitivity of nanocomposites, based on a conduction model that incorporates both piezoresistivity and thermoresistivity, alongside a multi-directional resistivity measurement technique. This strategy significantly reduces the number of required sensors to 25% and cuts down the number of electrodes by 50%, needing only four electrodes per sensor. For system validation, CNT/epoxy nanocomposite sensing layers were fabricated directly onto CFRP substrates. These sensors act as structurally integrated layers on composite surfaces, offering smooth, paintable finishes similar to standard surfacing layers while enabling real-time detection of structural anomalies. SEM-based morphological characterization and resistivity testing verified that the nanocomposites exhibit isotropic piezoresistive characteristic, owing to their uniformly dispersed, randomly oriented CNT networks. Experimental evaluations confirmed the system's accuracy, with strain and temperature measurements closely matching those from traditional metallic strain gauges and IR cameras under both mechanical and thermal loading. Measurement accuracy was particularly high when shear deformation in the sensor was limited. Cyclic tensile tests validated the system's capability for simultaneous strain and temperature monitoring, supporting its application in real-time health monitoring of composite structures. Furthermore, strain distribution assessed via DIC showed that the strain tensors derived from the nanocomposite sensors correspond to the effective strain across the sensor area, regardless of sensor size, and mirrored the surface strain distribution of the structure. These results demonstrate the feasibility of simplifying SHM systems by embedding multi-directional strain and temperature sensing functionalities into a single sensing layer. Additionally, implementing appropriate insulation methods to mitigate electrical interference with the CFRP substrate may enable full structural integration of nanocomposite sensors within CFRP laminates, paving the way for multifunctional composite structures.

ACKNOWLEDGEMENTS

This research was supported by the National Research Council of Science and Technology (NST) [Project ID: CPS22201-110]. The authors gratefully acknowledge Professors Han-Sohl Cho and Minkyun Noh from Korea Advanced Institute of Science and Technology (KAIST) for their helpful advice and valuable discussions. The morphological analysis via SEM was conducted with support from KAIST Analysis center for Research Advancement (KARA).

ABSTRACT

We develop a novel A-staging approach for manufacturing a stable, frontally curable prepreg, to address the challenges of in-space composite manufacturing. The prepreg achieves room temperature stability through two key innovations: (1) physical separation of the reactive components via microencapsulation of the polymerization initiator and (2) the use of unreacted monomer (i.e. A-stage) resins that are solid at room temperature. A two-step dip-coating and infusion process was developed to manufacture the prepreg. Systematic studies of the dip-coating process reveal predictable and repeatable microparticle uptake that varies linearly with the dip-coating suspension concentration. Leveraging these results, we demonstrate control over the resin composition by achieving a desired initiator:monomer ratio in the prepreg despite introducing them in separate steps. When properly packaged, the prepreg remains below 20% conversion for at least 30 days at room temperature and pressure—a 300-fold improvement in shelf-life compared to B-staged DCPD prepregs.

1 INTRODUCTION

Large space structures, such as the international space station, are currently assembled in space from terrestrially manufactured components. This approach imposes mass and deployment constraints that limit the scale and robustness of space infrastructure.[1, 2] In-space manufacturing (ISM) offers a transformative paradigm to reduce the cost and increase the scale of space structures.[3, 4]

Continuous fiber reinforced composites are well-suited for ISM due to their high specific strength and stiffness.[5-7] However, current composite manufacturing methods and materials are poorly suited

for ISM due to their complex tooling, multi-step processing, energy intensive curing, and/or reactive feedstocks with limited shelf-life. Thermoset prepregs pose the most promising pathway to ISM of composites by eliminating the complexity of resin mixing and infusion on-orbit. A typical thermoset prepreg consists of reinforcement pre-impregnated with resin that is partially gelled or "B-staged."[8, 9] Conventional prepregs such as Hexcel's M21 or Toray's 3960 require high temperature, multi-hour cure cycles and must be stored at sub-ambient temperatures to achieve storage lives longer than 2 months.[10, 11] Highly reactive "snap-cure" prepregs such as Hexcel's M77 series reduce cycle time but suffer from very short shelf-lives, up to 2 months at 0°C, which are incompatible with 6-month launch timelines.[12] New prepreg systems are needed for ISM that combine long term stability at room temperature with rapid, low-energy curing.

Frontal curing (FC) offers a pathway towards stability and rapid conversion of monomer. Frontal curing leverages the heat of polymerization to generate a self-sustaining polymerization front that passes through the material.[13-15] A front can be initiated using a small local stimulus (e.g. UV, heat) which consumes 10^5 to 10^{10} less energy than conventional oven cures.[16] Frontally curable epoxy- and olefin-based resins have found success in composites manufacturing via additive, vacuum infusion, and wet layup methods, though these pose substantial risk for ISM.[17-24]

Shelf-stable FC prepregs remain elusive due to the limited pot life of formulated resins; Parikh developed the first FC prepreg material using dicyclopentadiene (DCPD) resin but found 80% conversion after 8h at room temperature or 14 days at -20°C, likely due to degradation of the phosphite inhibitor.[24, 25] More recently, Davydovich et al. achieved 8 months of stability at room temperature in unreinforced DCPD resins by microencapsulating the polymerization initiator (Hoveyda-Grubbs Second-Generation Catalyst).[26] However, the microencapsulation strategy precludes B-staging as the sequestered Grubbs-type catalyst remains inactive until thermally triggered release, at which point frontal curing begins immediately.

In this work, we introduce a novel frontally curable DCPD prepreg system tailored for ISM of carbon fiber composites. The prepreg (Figure 1) leverages polysulfone-encapsulated Grubbs' Second-Generation Catalyst (G2) and unreacted (i.e. A-stage) monomer that is solid at room temperature. We develop the manufacturing process for this A-stage prepreg and evaluate prepreg stability as well as cured composite performance as a function of storage time at room-temperature.

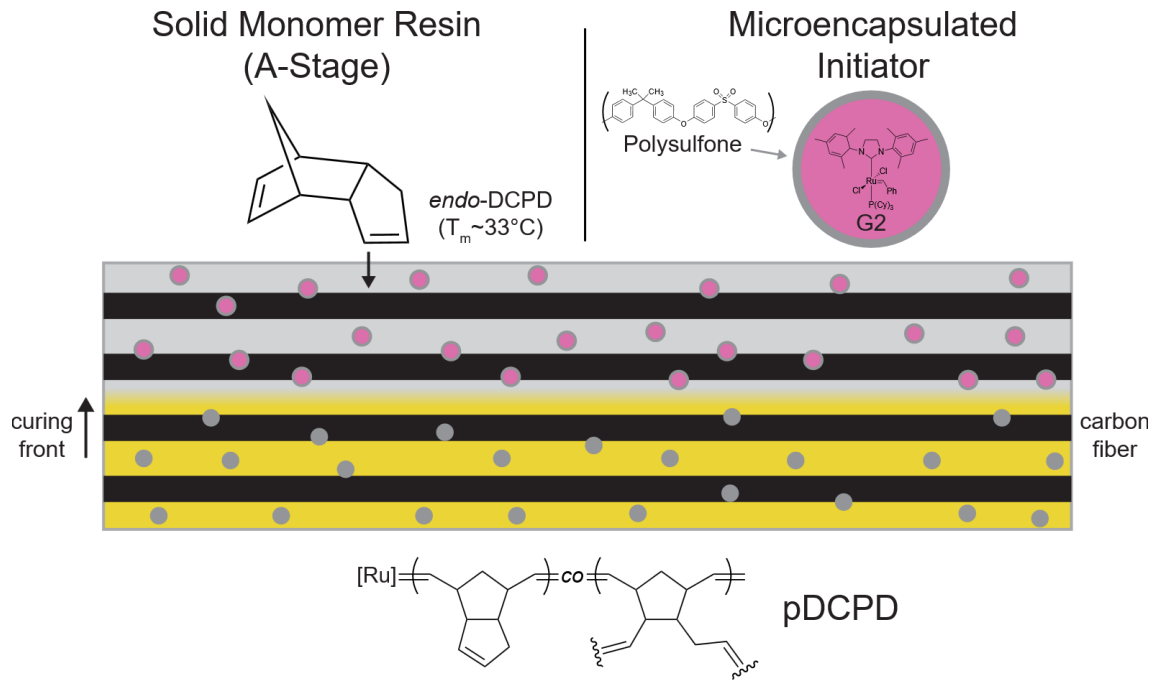

Figure 1: Microparticle Prepreg Strategy. The proposed "A-stage" prepreg material combines high purity endo-dicyclopentadiene resin, which is solid at room temperature, with polysulfone encapsulated Grubbs' Second-Generation Catalyst (G2) to achieve long term stability at ambient

temperature while enabling low-energy on-demand curing via frontal curing due to the thermally triggered release of G2 from the microparticles.

2 MATERIALS AND METHODS

2.1 Constituent Materials

Endo-dicyclopentadiene (DCPD) was purchased from Cymetech Corporation (UltreneTM 99, >99%, T_m=32-34°C). Grubbs' Second-Generation Catalyst (G2) was purchased from Chemscene Corporation. Polysulfone (PSU) was purchased from Sigma Aldrich Corporation. Poly(ethylene-alt-maleic anhydride) (EMA) was purchased from Aurorium (ZemacTM E400). Dichloromethane was purchased from Fischer Scientific. All chemicals were used as received without further purification. The reinforcing phase consisted of 5 plies of T300 2x2 twill weave carbon fiber fabric from Rock West Composites (1300D, 3K tow, 204 g/m^2). The fabric was cut to size (100 mm x 125 mm) and dried in an oven at 110°C for at least 2 hours to remove residual moisture. The plies were cooled and stored in a desiccator prior to use.

2.2 Catalyst Microparticle Preparation and Characterization

PSU microparticles containing G2 (PSU-G2) were manufactured using an oil-in-water emulsion technique similar to the work of Davydovich *et al.*[26] The oil phase was prepared using dichloromethane (56mL), PSU (5g), and G2 (0.7g), and the aqueous phase (200mL) was prepared with the EMA surfactant (7.6g). After emulsification using a homogenizer, the solvent was removed by evaporation. The microparticle-containing emulsion was centrifuged, and the supernatant was decanted. After two subsequent aqueous washing steps to remove EMA, the microparticles were freeze-dried to yield a free-flowing light pink powder (Figure 2A, ~4g, ~70% yield).

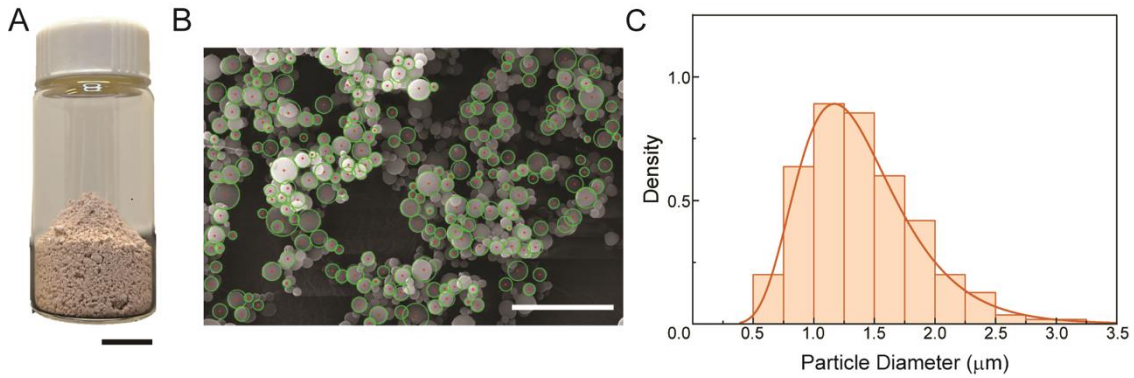

Figure 2. Microparticle Characterization. (A) Image of the PSU-G2 microparticles. Scale bar (black) 1 cm. (B) SEM image of PSU-G2 microparticles after applying an edge detection algorithm to determine microparticle size distribution. Green circles represent detected edges and red denotes the centroid. Scale bar (white) 10 μm. (C) Histogram of microparticle diameter from automated edge detection applied to SEM images with log-normal fit.

^{1}H nuclear magnetic resonance spectroscopy (NMR) was used to determine the average mass ratio of G2 to PSU in microparticles. NMR was conducted on a Bruker CB500. Spectra are referenced to residual $CDCl_3$ (δ=7.26 ppm), with chemical shifts reported in parts per million. The molar ratio of G2 to PSU repeat units was determined by comparing the integration of the peaks corresponding to the benzylidene proton from G2 (δ=19.15 ppm) against the four aromatic protons from polysulfone (δ=7.84 ppm). The mass ratio G2/PSU was calculated from the molar ratio using the molar masses of G2 (848.98 g/mol) and the polysulfone repeat unit (472.60 g/mol).

The morphology and size distribution of the PSU-G2 microparticles were characterized using scanning electron microscopy (SEM). SEM samples were coated with Au/Pd using a Denton Desk II TSC turbo-pumped sputter coater. SEM was performed on a FEI Quanta 450 FEG. The size of individual

PSU-G2 microparticles was measured by applying a custom Hough-circle-transform-based Python script to detect particle edges in the SEM images (Figure 2B).

The PSU-G2 microparticle preparation method produced microparticles with narrower size distribution and lower initiator loading compared to prior work. Replicate preparations exhibited slight variability in G2 loading with average G2/PSU mass ratios of 0.024 and 0.042. In contrast, Davydovich *et al.* reported a higher loading of 0.105 using Hoveyda-Grubbs' Second-Generation Catalyst, which could be due to differences in catalyst structure or encapsulation process.[26] To evaluate particle size, we analyzed SEM images using a custom Hough circle transformation algorithm to identify ca. 220 particles. The resulting size histogram (Figure 2C) follows a log-normal distribution with high correlation. The median particle diameter was 1.34 μm with standard deviation 0.35 μm, representing a significantly narrower distribution than prior work.[26] Moreover, the maximum microparticle diameter was also much smaller in this study. In this work, none exceeded the fiber diameter whereas the largest particles in prior studies exceeded the diameter of carbon fiber.

2.3 Prepreg and Composite Characterization

Differential scanning calorimetry (DSC) was performed in triplicate on prepreg samples and cured laminates at each time point in the longitudinal study. DSC was conducted using a TA Instruments Discovery DSC 2500 on 4-7 mg samples in Tzero pans. Cure kinetics experiments were conducted on prepreg samples from 0-200°C at 10°C/min. Heat-cool-heat post-cure DSC cycles were performed on cured composite samples from 0-250°C at 10°C/min. For both cure kinetics and post-cure DSC, the polymerization exotherm was measured over the range of 50-150°C using TA Trios software. The measured exotherm was corrected for reinforcement mass by burning off the matrix of the DSC samples in a thermogravimetric analyzer (TGA) similar to ASTM D3171 Method I Procedure H.[28] TGA was also conducted on unreinforced polymer to account for carbonization of the matrix as described in the standard. TGA was conducted on a TA Instruments Q500 in platinum pans with a 10°C/min ramp to 600°C and 30-min isothermal hold at 600°C. The degree of cure α was calculated for prepregs and cured laminates using Equation 1 where H_{res} is the observed residual exotherm corrected for reinforcement mass and H_r is the total enthalpy of reaction determined from a freshly prepared prepreg sample corrected for reinforcement mass.

$$\alpha = 1 - H_{res}/H_r \quad (1)$$

Soxhlet extractions were also performed on cured laminates at each point in the longitudinal study to determine the soluble fraction of the cured material. While the DSC provides a reactivity-based measure of curing, extraction provides a mass-based assessment of incorporation which provides valuable insights for space qualification where residual volatile material and off-gassing are critical considerations though the technique is no substitute for thermal vacuum characterization.[29] The extractions were performed under nitrogen over 20h on 25 mm x 50 mm cured samples using dichloromethane (DCM) heated to 65°C. This procedure was selected over the 4h 260°C procedure described in ASTM C613 to minimize the effects of oxidative crosslinking at elevated temperatures which could lead to under-estimation of the unincorporated mass fraction.[30]

Dynamic mechanical analysis (DMA) was performed on cured laminates during the longitudinal study to characterize their thermomechanical performance. DMA was conducted on a TA Instruments RSA-G2 in a 3-point bend configuration using the provided fixture with a 25mm span. Samples were cut and polished to 30 mm x 5 mm x ~1.1 mm. An oscillation heat ramp was applied at 2°C/min from 20-250°C with dynamic loading of 0.01% strain amplitude at 1 Hz. All experiments were conducted in a nitrogen environment. The average glass transition temperature T_g was taken as the peak of the tanδ curve determined using TA Trios software for n=2 samples. The reported error is the range of values.
The fiber volume fraction V_f for each laminate in the longitudinal study was characterized according to ASTM D3171 Method II using Equation 2 where n is the number of plies (5), h is the average laminate thickness, and A_r and ρ_r are the areal (204 g/m^2) and bulk (1.76 g/cm^3) reinforcement densities respectively.[28] The average laminate thickness was determined from n=8 measurements. The reported uncertainty represents the range due to thickness variation in the laminate. The void content V_v of each laminate was characterized using a polished 20 mm cross-section from each laminate. The void area was

manually identified using ImageJ software and V_v taken as the ratio of the void area to the total cross-sectional area.

$$V_f = (A_r n)/(\rho_r h) \quad (2)$$

3 RESULTS AND DISCUSSION

3.1 Prepreg Preparation

The A-stage prepreg was prepared by functionalizing the reinforcement with microparticles then infusing DCPD into the functionalized reinforcement (Figure 3). The dip-coating procedure was developed instead of infusing a pre-mixed microparticle resin to minimize filtering of the microparticles by the reinforcement, ensuring uniform G2 distribution. T300 2x2 twill carbon fiber plies were functionalized with the PSU-G2 microparticles by dip-coating each ply individually in a suspension of PSU-G2 microparticles in deionized water. The functionalized plies were immediately removed after submersion and oven-dried at 110°C for 2h to remove moisture. Microparticles ostensibly adhere to the fiber surface through Van der Waals interactions after drying.

After drying, the functionalized reinforcement was infused with DCPD using the vacuum assisted resin transfer molding (VARTM) setup described in Figure 3C. Resin was infused at 50°C (η~1 cp), which is above the melting temperature of the monomer (T_m~32°C), using a vacuum pressure of at -15 kPa.[27] After infusion, the preform was cooled to room temperature to solidify the DCPD monomer and allow the 5-ply prepreg to be removed from the bagging as a self-supporting solid—unlike liquid DCPD resin, which would immediately de-wet the reinforcement. The molar ratio of G2:DCPD, or resin formulation, was calculated from the G2 and DCPD masses added during dip-coating and infusion, respectively.

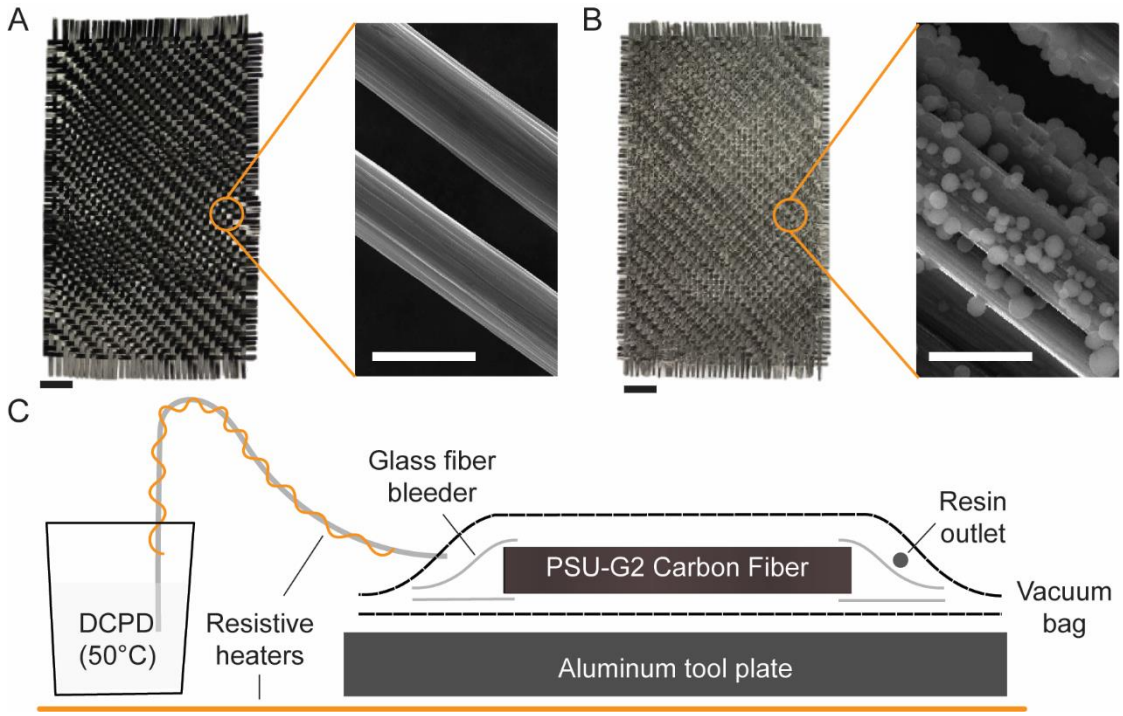

Figure 3. Prepreg Preparation and Curing. Optical and SEM images of reinforcement (A) before and (B) after dip-coating in an aqueous suspension of 5wt% PSU-G2 microparticles. Scale bars 1 cm (black) and 10 µm (white). (C) Schematic of the VARTM infusion of endo-DCPD into PSU-G2 functionalized reinforcement at 50°C to manufacture the A-stage prepreg.

3.2 Reinforcement Microparticle Functionalization

Unlike traditional prepreg processes, this manufacturing scheme introduces the polymerization initiator (G2) and monomer (DCPD) into the reinforcement in subsequent steps: reinforcement functionalization with catalyst microparticles followed by monomer infusion. Consequently, accurately predicting the final resin formulation, defined here as the molar ratio of initiator to monomer, is essential. We investigated the feasibility of this two-step approach in controlling resin formulation by systematically characterizing the dip-coating process.

The aqueous dip-coating procedure delivered reproducible and predictable microparticle uptake by the carbon fiber plies, enabling precise control of the final resin composition. The microparticle mass gain in the reinforcement increased linearly with the microparticle concentration in the dip-coating suspension (Figure 4A), consistent with prior work using different microparticles and reinforcement.[31] Notably, the trend was independent of the G2 loading within the microparticles. Using this data and the mass of DCPD added during infusion, we calculated resin formulation in the prepreg (Figure 4B). The resulting linear relationship allows prediction of the dip-coating suspension concentration needed to achieve a desired resin formulation. However, the predictive power is limited to A-stage DCPD prepregs of identical reinforcement architecture and microparticle composition.

We generalized this relationship for microparticles of arbitrary G2 loading. Since microparticle uptake (Figure 4A) is independent of G2 loading, the linear fit of resin formulation for microparticles containing 0.024 G2/PSU (Figure 4B, blue) can be scaled for other G2/PSU loadings by multiplying by the ratio $x/0.024$ where x is the G2/PSU mass ratio of interest. We validated this approach by targeting 100 ppm G2:DCPD using microparticles with 0.042 G2/PSU. The target ratio of 100 ppm was selected as this formulation has been extensively studied for phosphite inhibited pDCPD composites.[16-21] The calculated suspension concentration of 1.0 wt% PSU-G2 indeed resulted in 100 ± 10 ppm G2:DCPD after infusion (Figure 4B, orange). This demonstrates a single set of experiments (Figure 4, blue) can be extended to predict resin formulation for any G2 loading in PSU microparticles. However, additional studies are required to evaluate the effect of reinforcement architecture for further generalization.

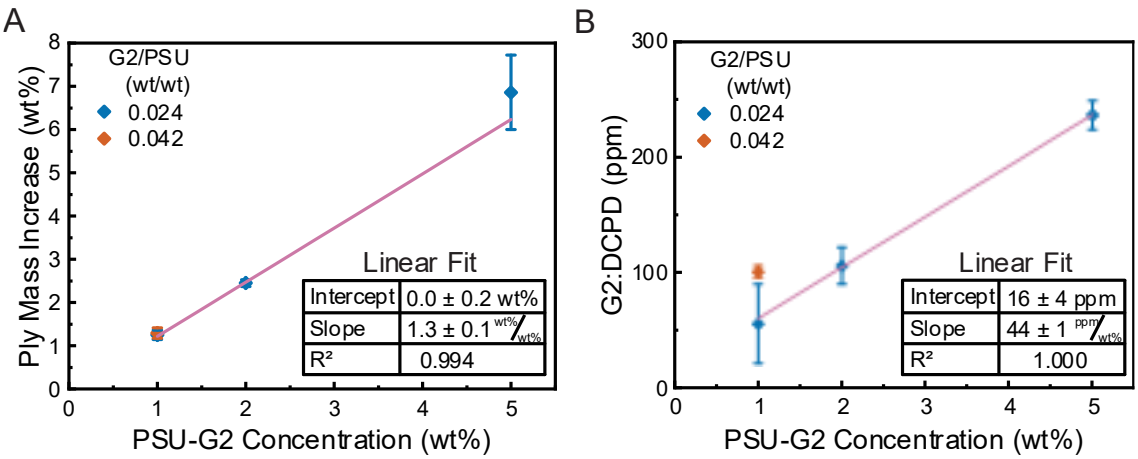

Figure 4. Prepreg Resin Formulation. (A) The PSU-G2 microparticle mass gained by the fabric plies during dip-coating as a function of suspension concentration for microparticles containing different G2 loading. Error bars represent one standard deviation on the mean (n=5). (B) Corresponding resin formulation calculated using the PSU-G2 mass gain in (A), the G2/PSU ratio in the microparticles, and the mass of resin infused into the reinforcement. Error bars represent measurement uncertainty due to mass loss during handling. Pink lines represent linear fits of the data for microparticles containing 0.024 G2/PSU (blue). Orange data points represent the prepreg used in the longitudinal study for which the suspension concentration was determined using (A) to achieve a target formulation of 100 ppm G2 using microparticles containing 0.042 G2/PSU.

3.3 Prepreg Stability

As an initial probe of the prepreg's stability, we examined the resin retention over time. Immediately after infusion, a prepreg sample was removed from the vacuum bagging material and stored in a heat-sealed polyethylene (PE) bag at ambient conditions. After 14 days in the PE bag at room temperature and pressure, 85% of the resin mass was lost (Figure 5A). We attribute this to the volatilization of DCPD monomer, given its moderate vapor pressure of 1.4 mm Hg at 20°C.[32] A systematic study using neat DCPD (Figure 5B) confirmed PE's permeability to DCPD vapor as 20% of the mass was lost within 8 days. However, a typical nylon vacuum bag with sealant tape effectively retained DCPD for the same duration and was used for subsequent longitudinal testing (Figure 5C). In contrast, typical DCPD-based resins that are liquid at room temperature immediately de-wet the reinforcement during re-pressurization and debagging after infusion, prohibiting storage at ambient conditions for any length of time. DCPD's volatility underscores the need for low-volatility monomers, though this limitation can be mitigated by packaging the prepreg in DCPD-impermeable materials.

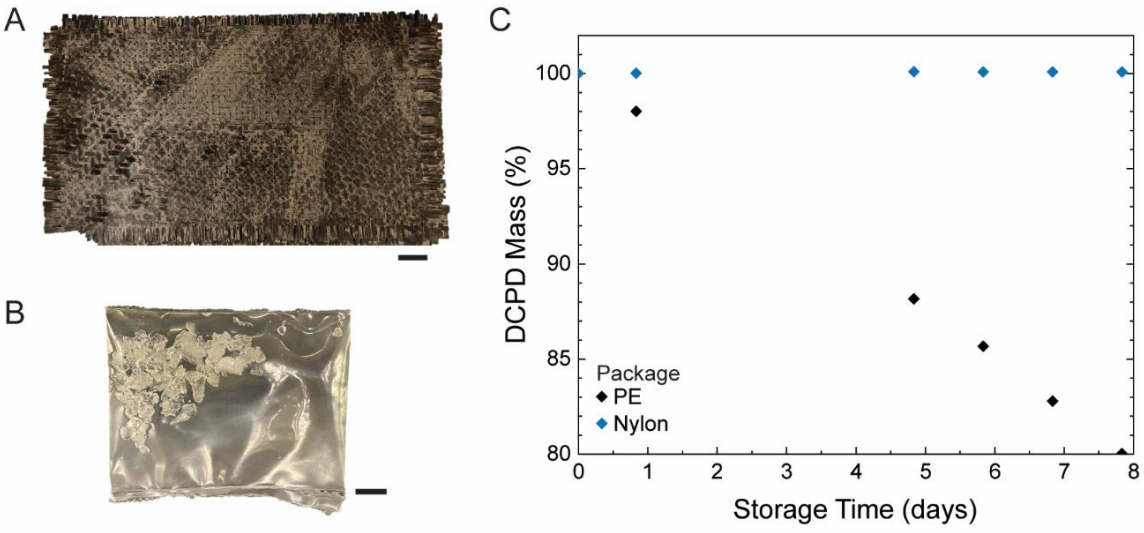

Figure 5. Prepreg Packaging. (A) A prepreg sample after 14 days stored at room temperature in a polyethylene (PE) bag with 85% of the initial resin mass lost to volatilization. (B) A sample of solid endo-DCPD monomer without reinforcement or PSU-G2 used to examine the permeability of packaging materials to volatile DCPD. (C) Comparison of DCPD mass loss in heat-sealed PE and a typical tape-sealed nylon vacuum bag. The tape-sealed nylon bag was used for the longitudinal study.

3.4 Longitudinal Study

The stability of the A-stage prepreg was evaluated through a 30-day longitudinal study examining properties of both the uncured prepreg and a frontally cured composite manufactured at each time point. After manufacturing prepreg, four 50-mm square coupons were cut to size with a rotary cutter and individually packed in a fresh nylon vacuum bag with sealant tape. The thermochemical properties of the prepreg coupons were characterized by differential scanning calorimetry (DSC) after storage at room temperature and atmospheric pressure for 0, 7, 14, and 30 days. At each time point the remaining prepreg material was used to frontally cure a laminate (Figure 6A). The coupons were first consolidated using 345 kPa applied by a hand press before FC was initiated through the thickness of the laminate by a resistive heater (Omega Engineering, 10W/in^2). The curing trigger consisted of a 2.5-min ramp to 180°C followed by a 2.5-min hold at 180°C controlled by a custom Arduino-Uno-based PID. A representative thermal profile measured by the thermocouple during curing is reported in Figure 6B. The cured prepreg coupons (Figure 6C) achieve excellent fiber distribution (Figure 6D).

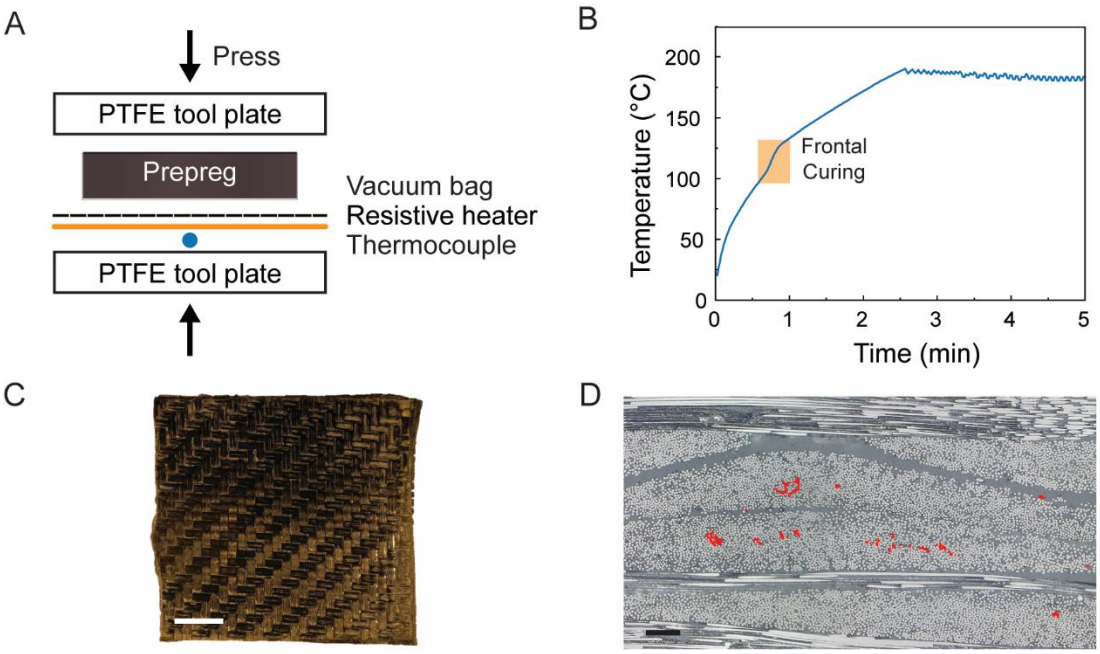

Figure 6. Prepreg Curing. (A) Schematic of through-thickness frontal curing of the A-stage prepreg with external consolidation from a press. (B) A representative temperature profile measured by the thermocouple during the applied cure cycle. (C) A representative cured composite coupon from the A-stage prepreg and (D) corresponding optical micrograph with voids false colored in red (V_v=0.5%). Scale bars 1 cm (white) and 100 μm (black).

The A-stage prepreg maintained α < 20% and frontally cured to achieve α > 99% at all time points in the 1-month study (Figure 7A). This demonstrates the stability of this system compared to B-staged DCPD prepregs, which reach α > 20% within 2 to 4 hours at room temperature.[24] Once cured, the prepreg coupons achieved robust properties summarized in Table 1; the laminates exhibited fiber volume fractions approaching 50% and low void fractions near 2%. The variation in constituents is attributed to variability in hand-pressing and the absence of vacuum during curing. Thermomechanical characterization (Figure 7B) showed glass transition temperatures T_g near 160°C with variation in the storage modulus again attributed to nonuniform consolidation causing local thickness and V_f variation. The extracted fraction of each laminate approximates the maximum possible mass loss due to vacuum in space (Table 1). While not a substitute for standardized thermal vacuum (TVAC) characterization, the screening approach provides valuable insights into the monomer incorporation beyond DSC. Mass loss remained below 2% at each time point, an encouraging preliminary indication of the material's off-gassing stability once cured. Overall, the longitudinal study confirms A-stage retains reactivity when properly packaged as well as its capacity to form high-performance composites via rapid, energy-efficient frontal curing.

Storage time [days]	V_f [%]	V_v [%]	T_g [°C]	Extracted mass [wt%]
0	46 ± 5	2 ± 1	160 ± 1	1.0 ± 0.3
7	48 ± 5	2 ± 1	153 ± 1	1.8 ± 0.6
14	45 ± 6	4 ± 1	163 ± 1	1.5 ± 0.4
30	49 ± 6	2 ± 1	166 ± 2	1.8 ± 0.4

4 CONCLUSIONS

We developed a novel A-staging approach to create a shelf-stable, frontally curable prepreg by physically separating reactive components. Through microencapsulation of the polymerization initiator coupled with unreacted (A-stage) monomer that is solid at room temperature, the A-stage microparticle prepreg achieves long-term stability. We developed a two-step dip-coating and infusion process to manufacture the unique prepreg. Systematic variation of microparticle concentration in the aqueous dip-coating suspension enabled tunable initiator loading on the reinforcement. Importantly, we demonstrated control over the resin formulation by achieving a target initiator-monomer ratio in the final prepreg despite introducing the initiator and monomer in separate processes. The use of solid monomer prevents de-wetting immediately after infusion, though the monomer volatility necessitates careful packaging to prevent de-wetting during long-term storage. When properly packaged, the prepreg retains degree of cure under 20% over one month and successfully undergoes frontal curing, yielding a high-quality composite. The A-stage prepreg method developed in this work represents a 300-fold increase in shelf life over previously reported B-staged frontally curable DCPD prepregs. The A-stage prepreg's combination of months-long stability; low-energy, on-demand curing; and robust composite properties addresses the unique challenges of large-scale in-space manufacturing and marks a pivotal advancement in the viability of composite manufacturing via frontally curable prepregs.

ACKNOWLEDGEMENTS

Authors Contributions

Manuscript title: Prepreg Development for Rapid On-Orbit Composites Manufacturing via Frontal Curing

Please describe the contributions of each author, referring to the taxonomy below.

Author 1 (Tsai Award Applicant): Tyler Price

- ☒ Conception
  Specify contribution in more detail (optional; no more than one sentence)
- ☒ Data curation
  Specify contribution in more detail (optional; no more than one sentence)
- ☒ Formal Analysis
  conducted the analyses of the microparticle size distribution (Fig. 2), dip-coating (Fig. 4), packaging (Fig. 5), and longitudinal study (Fig. 6-7; Table 1) data and contributed to the analysis of the nmr data.
- ☒ Investigation
  Conducted manufacturing, dip-coating, infusion, packaging, and longitudinal studies.
- ☒ Methodology
  Specify contribution in more detail (optional; no more than one sentence)
- ☐ Software
  Specify contribution in more detail (optional; no more than one sentence)
- ☒ Validation
  Verified reproducibility of the prepreg manufacturing/curing and select time points in the longitudinal study.
- ☒ Visualization
  Specify contribution in more detail (optional; no more than one sentence)
- ☒ Wrote the paper (original draft)
  Specify contribution in more detail (optional; no more than one sentence)
- ☒ Wrote the paper (review and editing)
  Specify contribution in more detail (optional; no more than one sentence)
- ☐ Other contribution
  Specify contribution in more detail (required; no more than one sentence)

Author 2: Po-Wen Wang

- ☒ Conception
  Specify contribution in more detail (optional; no more than one sentence)
- ☒ Data curation
  Specify contribution in more detail (optional; no more than one sentence)
- ☒ Formal Analysis
  Contributed to the analysis of the nmr data (Fig. 2)
- ☒ Investigation
  Manufactured catalyst microparticles and conducted SEM imaging.
- ☒ Methodology
  Developed the methodology to manufacture catalyst-containing microparticles.
- ☒ Software
  Contributed to the development of the microparticle SEM image analysis software.
- ☒ Validation
  Conducted validation of the microparticle identification software by manual analysis.

Conceptualization
Ideas; formulation or evolution of overarching research goals and aims.

Data Curation
Management activities to annotate (produce metadata), scrub data and maintain research data (including software code, where it is necessary for interpreting the data itself) for initial use and later reuse.

Formal Analysis
Application of statistical, mathematical, computational, or other formal techniques to analyze or synthesize study data.

Investigation
Conducting a research and investigation process, specifically performing the experiments, or data/evidence collection.

Methodology
Development or design of methodology; creation of models.

Software
Programming, software development; designing computer programs; implementation of the computer code and supporting algorithms; testing of existing code components.

Validation
Verification, whether as a part of the activity or separate, of the overall replication/reproducibility of results/experiments and other research outputs.

Visualization
Preparation, creation and/or presentation of the published work, specifically visualization/data presentation.

Writing – Original Draft Preparation
Creation and/or presentation of the published work, specifically writing the initial draft (including substantive translation).

Writing – Review & Editing
Preparation, creation and/or presentation of the published work by those from the original research group, specifically critical review, commentary or revision – including pre- or post-publication stages.

SURROGATE MODEL-DRIVEN AUTOMATION FOR RVE DESIGN AND VALIDATION OF LONG DISCONTINUOUS CARBON FIBER COMPOSITE STRUCTURES

ABSTRACT

A physics-informed surrogate-modeling framework is presented for automated RVE generation, validation, and rapid prediction of effective stiffness in aligned discontinuous carbon fiber composites. A fully Python-driven workflow within Abaqus creates 2D representative volume elements (RVEs) parameterized by fiber length, gap, width, angle, and volume fraction. Convergence studies show that including three repeating units of the fiber-gap pattern within the RVE is sufficient to capture microstructural variability without requiring periodic boundary conditions. A 200 sample 0 degree dataset trains three Random Forest regressors: one each for E_{11} G_{12}, and the Halpin–Tsai shape factor $\xi_{E_{11}}$. Validation on $\theta = 0°$ yields $R^2 > 0.970$ and MAE < 0.07 GPa for E_{22} and G_{12}, while $\xi_{E_{11}}$ achieves $R^2 > 0.975$. Embedding these predictions in a Classical Laminate Theory (CLT) framework enables accurate modulus prediction across arbitrary fiber angles, with E_{11} and E_{22} remaining within 10% of full-FEA across arbitrary fiber angles. This consistency inspires confidence in the FEA data as its trends align with well-established composite analytical models. Beyond prediction, the surrogate model is used to identify and filter anomalous simulations, a particularly important capability for angled fibers, where meshing and loading artifacts frequently corrupt results. By integrating micromechanical models, laminate theory, and machine learning, this hybrid framework bridges physical intuition with data-driven inference. It enables the rapid generation of large, validated property datasets at a fraction of the cost of full FEA. These datasets are well-suited for future inverse design workflows, where optimal discontinuous fiber architectures must be identified for target stiffness requirements.

1 INTRODUCTION

Discontinuous fiber-reinforced composites (DFRCs) combine fiber segments within a polymer matrix, offering scalability and automation advantages over continuous fiber composites (CFRCs). While CFRC processes often involves high labor and tooling costs, DFRCs offer a cost-effective alternative with improved recyclability, and compatibility with complex geometries [1,2]. Recent advances in robotic fiber placement and AI-driven control have significantly enhanced DFRC mechanical performance, bringing tensile strength and stiffness closer to CFRC benchmarks [3,4]. Moreover, aligned DFRCs enable spatial control of stiffness, strength, and energy absorption, allowing mechanical behavior to be tailored to application specific loading through inverse design. The success of such inverse design efforts, aimed at identifying optimal microstructures to achieve target macroscopic properties, relies on the ability to generate large, accurate datasets that reflect the influence of fiber architecture on mechanical response.

Existing FEA based datasets are often constrained by manually generated fiber geometries, inconsistent boundary condition implementations, and limited control over key design parameters such as fiber length, gap, and orientation. Numerous prior studies utilize idealized or overly simplified microstructures, which fail to reflect the parametric complexity of aligned discontinuous fiber configurations. For such systems, accurate prediction of load transfer and stiffness anisotropy demands

precise geometric fidelity and consistent numerical formulations. Furthermore, meshing artifacts and numerical instability, particularly in off axis fiber alignments, result in high simulation failure rates and reduce the reliability of computed property data [5,6]. Automated workflows for representative volume element (RVE) generation and validation in aligned DFRCs remain limited, restricting the scalability and fidelity of data driven inverse modeling.

To address these constraints and enable scalable inverse design, a set of computational tools is being developed in conjunction with a gantry mounted robotic aligned DFRC manufacturing platform engineered to physically implement the methods established in this study. In parallel, a fully automated process for RVE generation, validation, and surrogate model training has been established to overcome modeling limitations associated with manual fiber placement and simulation inconsistency. A Python driven Abaqus workflow generates 2D RVEs parameterized by fiber length, interfiber gap, width, orientation angle, and volume fraction. Convergence studies determine the minimum number of fiber segment repetitions required to capture statistically representative behaviour without the need for periodic boundary conditions. Physics informed validation is performed using micromechanical models, including the Halpin–Tsai formulation for predicting longitudinal stiffness and a series rule model for estimating transverse and shear stiffness components [7–9]. Until the manufacturing platform is fully operational, high fidelity FEA datasets generated within the research group serve as the primary basis for training and validating inverse design methodologies.

Building on this validated dataset, a machine learning surrogate is trained to predict both the Halpin–Tsai shape factor and effective stiffness components from a curated 0 degree dataset. The surrogate is incorporated into Classical Laminate Theory (CLT) calculations to enable rapid and accurate property prediction for arbitrary fiber orientations, significantly reducing computational cost compared to full FEA. In addition, the surrogate aids in simulation quality control by identifying anomalous cases, particularly in angled cases, where mesh distortion and boundary artifacts are common. This automated approach enables scalable, physics informed generation of validated property datasets, supporting efficient inverse design of aligned DFRCs.

2 BACKGROUND AND THEORY

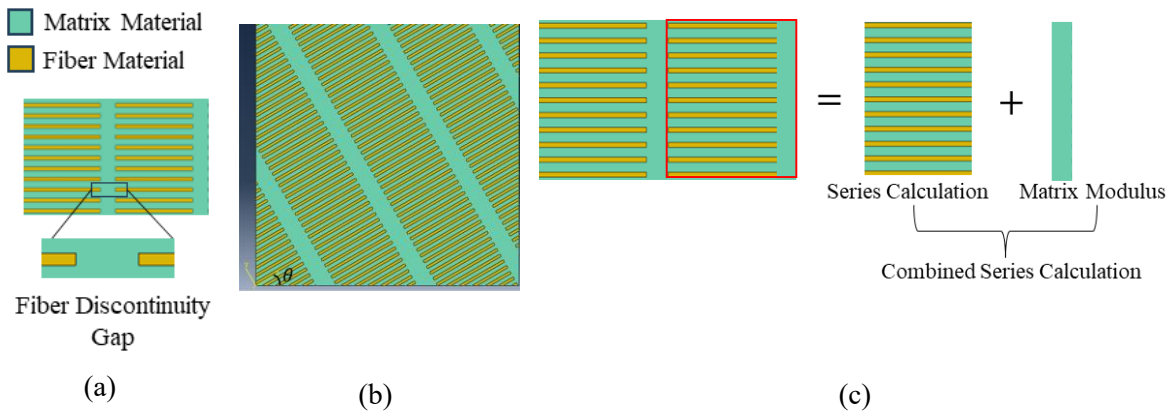

Figure 1: (a) Basic RVE Model (b) RVE with fibers orientated at angle θ (c) Combined series calculation example for E_{22} and G_{12}

In the RVE workflow, two distinct but complementary micromechanical approaches are used to characterize, estimate, and predict composite stiffness under different loading directions: the Halpin–Tsai model for axial modulus E_{11}, and a simple series-rule model for transverse modulus E_{22} and in-plane shear G_{12}. These models are complimented by Classical Laminate Theory (CLT) via the ply-

stiffness matrix Q to rotate those base moduli to arbitrary fiber angles. Each approach is explained below in terms of its mathematical formulation, physical rationale as it relates to the RVE geometry as shown in Figure 1a and 1c, and specific examples of its application within this work.

2.1 Micromechanical Models

The stiffness of the DFRC RVE can be evaluated by analyzing the mechanics of the load transfer through its microstructural constituents. In the fiber axis direction, apart from the localized fiber to fiber gap region, where the fiber gap is small in absolute terms, most structural elements are aligned in parallel with high length to width aspect ratios. Under these conditions, the Halpin-Tsai formulation as shown in Equation 1, accurately captures the composite's longitudinal stiffness [10]**.** In this configuration, each RVE is defined by a global fiber volume fraction V_f, fiber modulus E_{f1}, and matrix modulus E_m, with the parameter η defined in Equation 2.

$$E_{11} = E_m \frac{1 + \xi \eta V_f}{1 - \eta V_f} \tag{1}$$

$$\eta = \left(\frac{E_{f1}}{E_m} - 1 \right) \Big/ \left(\frac{E_{f1}}{E_m} + \xi \right) \tag{2}$$

Here, ξ is a dimensionless shape factor that encapsulates fiber aspect ratio, spacing, and interphase stiffness. As discussed previously, this factor is often determined experimentally based on fiber to fiber interactions [8,10]**.** As ξ approaches zero, the Halpin-Tsai equation predicts a lower bound consistent with the classical Reuss Model [11], while in the limit as ξ approaches infinity, the model converges to an upper bound akin to the Rule of Mixtures. For aligned discontinuous fiber based RVEs, ξ must account not only for the fiber aspect ratio but also for the efficiency of load transfer through the longitudinal matrix gaps between fibers.

In contrast, when the RVE is subjected to transverse loading or in-plane shear, the microscopic load path intersects matrix dominated regions before reaching the fiber reinforced domains. For example, the representative cross-sectional used to determine the transverse modulus E_{22} differs significantly from that used in the longitudinal case, both in geometry and in local stiffness distribution. As a result, applying the same Halpin-Tsai model to E_{22} and G_{12} yields inaccurate predictions, with the lower bound failing to capture the behavior observed in finite element simulations. To address this, a hybrid Reuss series model [7,12] is employed to estimate the transverse and shear moduli by decomposing the RVE into two distinct subregions; one consisting of a fiber and matrix region, and other composed solely of matrix filled fiber gap zones, as described in Equations 3 and 4. In this formulation, E_{f2} denotes the fiber transverse modulus, and the associated microstructural configuration is illustrated in Figure 1c).

$$E_{22} = \left(\frac{f_{stripe}}{E_{22_{stripe}}} + \frac{1 - f_{stripe}}{E_m} \right)^{-1} \tag{3}$$

$$E_{22_{stripe}} = \left(\frac{f_{fiber}}{E_{f2}} + \frac{1 - f_{fiber}}{E_m} \right)^{-1} \tag{4}$$

A similar modeling approach is used to calculate the shear modulus. Since the matrix gaps function as the weakest link under loading, even a modest value of f_{gap}, defined as the length fraction

of transverse fiber gaps as shown in Figure 1a, can significantly reduce both E_{22} and G_{12}, driving them toward the matrix properties E_m or G_m. As a result, rather than using the Halpin–Tsai model, which assumes a uniformly mixed fiber and matrix medium, a simple series model more accurately captures the reduced transverse and shear stiffness observed in RVE data. This series model serves as a physically meaningful baseline estimate and does not require any fitted parameters such as ξ, thereby providing additional confidence in the quality of the initial training data. Nonetheless, machine learning models remain essential to account for the complex nonlinear interactions among geometric and material inputs that are not adequately captured by analytical formulations alone.

2.2 Stiffness Matrix

Once the base-case ply moduli have been determined and validated, they can be extended to RVEs with rotated fiber orientations (Figure 1b) to predict the composite's overall behavior. Using Classical Laminate Theory, the validated values of E_{11}, E_{22} and G_{12} are implemented into the plane-stiffness matrix, Q**,** thereby transforming the 0 degree ply properties into the local coordinate system of an angled fiber system and allowing for the extraction of global moduli [13]. Equations 5-7 detail the basics of this transformation where values of Q_{xy} are functions of the global E_{11}, E_{22} and G_{12} for a 0 degree ply. The Q matrix is then rotated by transposition matrix $T(\theta)$ and inverted into a global compliance matrix **S** which holds the rotated values for E_{11}, E_{22} and G_{12} [11].

$$Q = \begin{bmatrix} Q_{11} & Q_{12} & 0 \\ Q_{12} & Q_{22} & 0 \\ 0 & 0 & Q_{66} \end{bmatrix}, \begin{cases} Q_{11} = \dfrac{E_{11}}{1 - v_{12}v_{21}} \\ Q_{22} = \dfrac{E_{11}}{1 - v_{12}v_{21}} \\ Q_{12} = \dfrac{v_{12}E_{22}}{1 - v_{12}v_{21}} \\ Q_{66} = G_{12} \end{cases} \tag{5}$$

$$\boldsymbol{S} = (T(\theta)QT(\theta)^{-T})^{-1} \tag{6}$$

$$S = \begin{bmatrix} S_{11} & S_{12} & 0 \\ S_{12} & S_{22} & 0 \\ 0 & 0 & S_{66} \end{bmatrix} \begin{cases} E_{11}(\theta) = \dfrac{1}{S_{11}} \\ E_{22}(\theta) = \dfrac{1}{S_{22}} \\ G_{12}(\theta) = \dfrac{1}{S_{66}} \end{cases} \tag{7}$$

These expressions describe how in-plane stiffness of a ply changes as its fibers rotate from 0 degrees to an arbitrary angle θ. In this study, once the stiffness values for plies with 0-degree fiber orientation are validated, they are incorporated into the transformed reduced stiffness matrix Q to estimate the mechanical properties of plies with rotated fibers. This approach enables the validation of more complex FEA geometries involving arbitrary fiber orientations.

3 METHODOLGY

3.1 Automated Representative Volume Element Generation

In this study, RVEs of aligned DFRCs were generated using a fully automated Python-driven workflow within the Abaqus environment. A Python driver script invokes Abaqus to generate 2D unit-cell models of aligned discontinuous fiber composites. Each cell contains a square polymer matrix of

size $L_x \times L_x$ and a prescribed number of straight fiber segments. Each RVE geometry was parameterized by four key microstructural variables: fiber length (L_f), fiber discontinuity gap (F_g), fiber width (F_w), fiber angle (θ) and fiber volume fraction (V_f).

In conventional composite RVE FEA, it is common practice to impose periodic boundary conditions (PBCs). These conditions enforce compatibility of displacement and traction across opposing faces, allowing the RVE to behave as part of an infinite periodic microstructure. This ensures accurate homogenization of effective mechanical properties [14,15]. However, in the present study, PBCs were not applied due to challenges introduced by angled fiber configurations. These configurations result in irregular meshing along the boundaries of RVE, making it impractical to maintain node to node correspondence across opposite faces, which is necessary for enforcing periodicity.

Instead, mechanical properties are extracted from global reaction forces generated by applied boundary conditions. In this approach, one edge of the RVE is fully constrained, while the opposite edge is subjected to a prescribed strain, ε. The resulting reaction forces on the boundaries are used to compute effective stiffness moduli, as shown in Equation 8. The quantity F_i represents the reaction force in either the longitudinal or transverse direction and is used to compute the corresponding modulus. The shear modulus is calculated using the built-in stress and strain volume averaging functionality within the FEA environment.

$$E_i = \frac{F_i * L_x}{\varepsilon} \tag{8}$$

To ensure that the RVE is statistically representative despite the absence of PBCs, a convergence study is conducted. The side length L_x of the RVE is systematically increased according to the relation:

$$L_x = N\left(F_l + F_g\right) + \delta, N = 1, 2, 3, \ldots \tag{9}$$

where δ is a small buffer added to avoid edge truncation artifacts, and N is the number of repeated fiber and gap units included in the simulation domain. Simulations are conducted for each value of L_x at a fiber orientation angle of 0 degrees, and the corresponding moduli E_{11} and E_{22} are tracked. Once the moduli exhibit convergence with increasing L_x, the RVE is considered sufficiently large to capture microstructural variability and yield reliable estimates of bulk mechanical properties. To verify consistency across different configurations, additional simulations are performed using randomly generated angles θ, confirming convergence across all phases of interest.

3.2 Dataset Generation

The driver script functions as the primary tool for dataset generation. It automates the creation of a large set of RVE simulations, specifically targeting 0 degree fiber orientation cases. A master script controls this process by systematically modifying key geometric parameters, L_f, F_g, F_w, and V_f across a wide range of values as shown in Table 1. Sampling these parameter spaces enables the construction of a comprehensive dataset suitable for training predictive models. As discussed in Section 2, the 0 degree ply configuration serves as the baseline case for the modeling framework. These baseline simulations are validated through a combination of analytical predictions using the Halpin–Tsai model and the Reuss series formulations, as well as visual inspection of the simulated fiber and matrix microstructure. This validation process ensures that the generated data accurately captures the governing mechanics and provides a reliable foundation for model development.

In parallel, a second dataset was generated using the same automated workflow, varying the same geometric parameters as before, but with fiber angles assigned within $\theta \in [0°,\ 90°]$. This dataset captures a broader spectrum of microstructural variability and is intended for testing the generalization capability of the surrogate models. Unlike the baseline 0 degree cases, these angled configurations are

not used for training but rather serve as validation and application scenarios. Due to the computational expense associated with running full FEA for thousands of fiber angle combinations and manually validating results, this dataset highlights the necessity of the surrogate modeling approach. The combination of a targeted training dataset at 0 degrees and a broader set including randomized fiber orientations provides both accuracy in model calibration and coverage of geometrically diverse cases. This approach supports efficient property prediction across a wide range of composite configurations while reducing the computational cost associated with full finite element simulations.

Table 1: Key geometric parameters with respective ranges

Geometric Parameter	Variation Range
Fiber Length, (L_f)	5.0 – 40.0 mm
Fiber Discontinuity Gap (F_g)	0.1 – 4.0 mm
Fiber Width (F_w)	0.1 – 4.0 mm
Target Volume Fraction (V_f)	0.1 – 0.55

3.3 Surrogate Model Training and Application

To enable scalable and efficient prediction of effective mechanical properties across a wide range of fiber architectures, a surrogate modeling framework was developed. This framework is based on machine learning models trained exclusively on the high-fidelity simulation results from the 0 degree fiber orientation dataset. The surrogate combines direct regression models with a Classical Laminate Theory formulation to generalize predictions to arbitrary fiber angles, thereby significantly reducing the computational cost associated with full FEA runs. The surrogate model development begins with training three separate regression models to predict transverse modulus E_{22}, in-plane shear modulus G_{12}, and the Halpin–Tsai shape parameter ξ, which governs the longitudinal modulus E_{11} through a physics based equation. While E_{22} and G_{12} are directly predicted by regression models, the prediction of E_{11} requires an additional modeling step. This is due to complex load transfer mechanisms introduced by fiber discontinuities, which limit the ability of purely data driven models to directly capture the relationship between geometric parameters and the longitudinal modulus. Therefore, E_{11} is calculated using the Halpin-Tsai equation with the predicted value of ξ.

The input features for models include the fiber volume fraction, fiber gap length, fiber length, and fiber width. Random Forest Regression was selected due to its ability to capture nonlinear relationships, resistance to overfitting, and minimal hyperparameter sensitivity [16,17]. Each model was trained using standardized input features with an 80 to 20 training and testing split. Model performance was evaluated using the coefficient of determination R^2 and mean absolute error (MAE), with results showing high predictive accuracy and good agreement between model outputs and FEA data. Once trained, the regression models were coupled with Classical Laminate Theory to estimate global stiffness for fiber orientations beyond zero degrees. The predicted values of $E_{11}, E_{22},$ and G_{12} for the base 0 degree case were rotated using transformation matrices (Equations 5 through 7) to compute moduli for arbitrary fiber angles. This approach allows rapid estimation of in-plane moduli for any fiber angle without additional simulation, enabling efficient evaluation of a broad design space.

In addition to property prediction, the surrogate model is also used to detect erroneous data within the larger dataset of randomly oriented fiber configurations. When applied to this broader set, the surrogate helps identify cases that produce nonphysical results or exhibit large deviations from expected trends. These errors result from issues such as poor mesh quality, incorrect material assignment, or fiber placement failures, particularly in angled configurations where boundary conditions are more difficult to apply consistently. Anomalous cases are flagged and removed for further inspection, helping to ensure that only valid simulation results are used in future inverse design tasks. A representative instance of datapoint failure is visualized in Figure 2 showing improper assignment of fiber material to matrix regions, which would result in uncharacteristically high mechanical properties reported by FEA.

Through this entire process, the surrogate model not only accelerates property prediction but also ensures the reliability and physical consistency of the overall dataset.

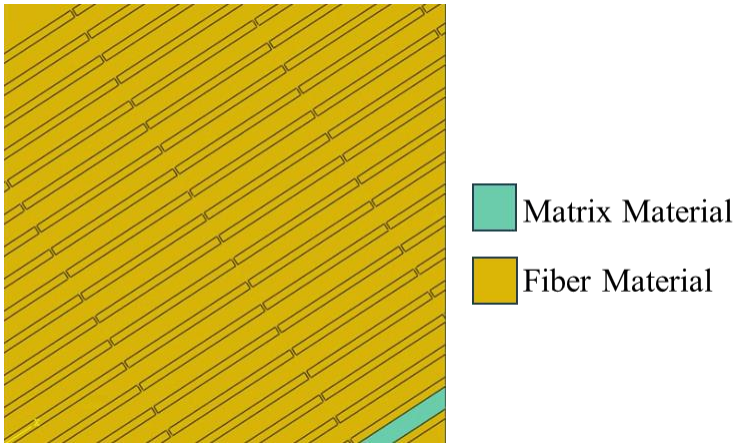

Figure 2: Angled fiber geometry generated with erroneous material assignment

4 RESULTS AND DISCUSSION

As discussed in section 3.1, Figure 3 displays the results of the convergence study used to initially size RVEs for accurate statistical representation. For each N as shown in Equation 9, E_{11}, E_{22}, and G_{12}, were calculated for a variety of permutations of geometric variables. Three representative cases are shown in the figure. As N increased from 1 to 7, all three moduli changed by less than 2% variation beyond $N = 3$ in every trial. Based on this result, $N = 3$ was selected as the minimum RVE size that balances convergence of effective properties with computational efficiency. While the surrogate is trained on baseline FEA simulations and relies on their accuracy, it is also leveraged as a secondary validator when applied to large datasets with random fiber angles. In this role, the surrogate acts as a filter, flagging FEA cases that yield nonphysical or inconsistent results typically due to meshing, fiber placement, or boundary condition errors thereby enforcing dataset quality and reliability.

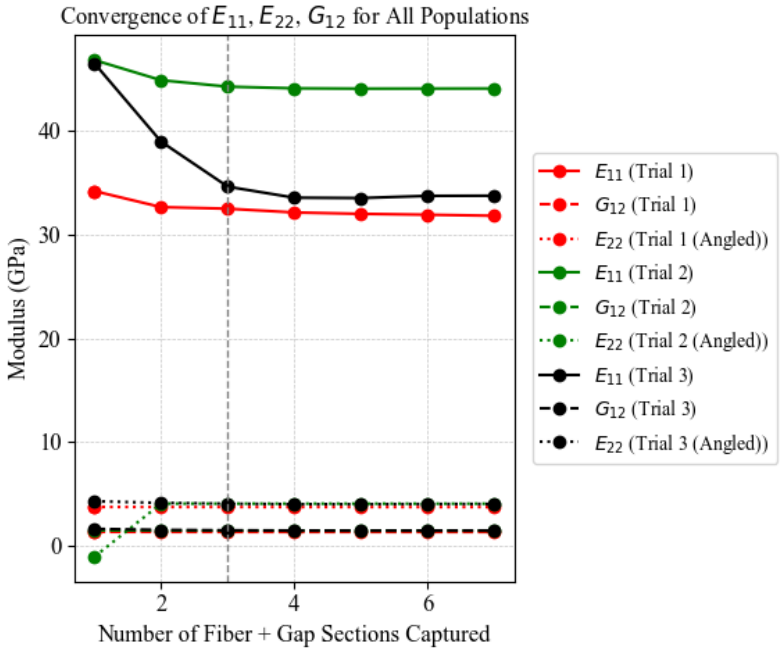

Figure 3: Moduli convergence with variation in number of simulated fiber and gap sections

Following the confirmation of RVE size, a dataset of 200 with 0 degree fiber orientations and varying geometric parameters was generated to train the Random Forest Regression model. Figure 4 presents parity plots illustrating the performance of each surrogate model. Figure 4c and 4d show predicted versus actual values for, E_{22}, and G_{12}, while Figures 4a and 4b display the predicted versus actual values for the Halpin-Tsai shape factor $\xi_{E_{11}}$, with Figure 4a showing the full range and Figure 4b focusing on a zoomed view to better illustrate accuracy in the relevant domain.

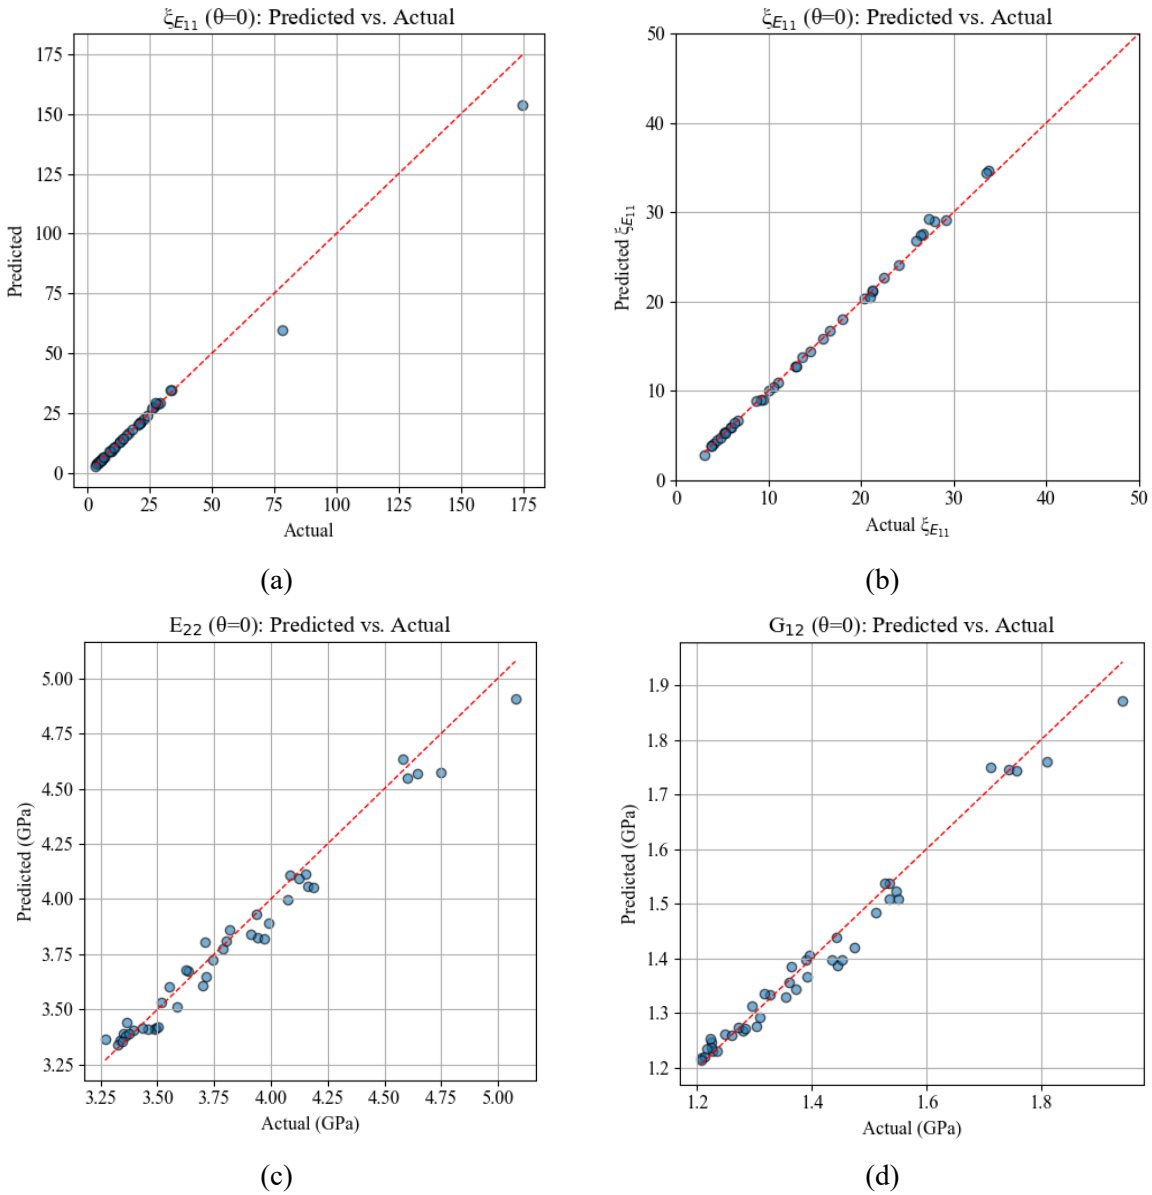

Figure 4: Random Forest parity plots for (a) $\xi_{E_{11}}$ (b) $\xi_{E_{11}}$ with range 0-50 (c) E_{22} and (d) G_{12}

While the full parity plot for $\xi_{E_{11}}$ in Figure 4a reveals a few outliers at higher values, their impact on the predicted E_{11} is minimal. Visual inspection of the corresponding data indicates that these outliers are associated with cases involving very high fiber lengths, where the resulting error in $\xi_{E_{11}}$ translates to deviation of less than 5% in the predicted modulus E_{11}. In the more relevant operational range shown in Figure 4b, the predicted and actual values of $\xi_{E_{11}}$ are nearly perfectly alignment, with overall $R^2 = 0.975$ and $MAE = 1.21$. The parity plots for E_{22}, and G_{12} also show tight clustering around the identity

line, demonstrating strong predictive accuracy. The computed performance metrics are $R^2 = 0.970$ and $MAE = 0.061$ GPa for E_{22} and $R^2 = 0.977$ with $MAE = 0.021$ GPa for G_{12}. Collectively, these results confirm that the Random Forest Regression models, when trained on data with $\theta = 0°$ fiber orientations, are capable of accurately predicting transverse and shear stiffness and of reliably estimating the shape factor $\xi_{E_{11}}$. This estimated shape factor can then be used in the Halpin-Tsai equation to produce a representative value of E_{11}. The high level of agreement between predicted and actual values supports the use of these models in CLT-based validation for fiber angles beyond 0 degrees.

Applying the trained regressors to geometries with fiber orientations different from 0 degrees revealed important insights into the behavior of aligned discontinuous fiber composites under CLT. Initially, any trial in which either E_{11} or E_{22} deviated by more than 10% from the FEA result was discarded. However, this percentage-based criterion incorrectly flagged cases where one modulus was inherently much larger than the other. For example, when fibers are closely aligned with the loading direction, E_{11} may be significantly higher than E_{22}, or when a moderate angle is selected, both moduli may approach their minimum values. In such cases, even a small absolute discrepancy (e.g. 0.5 GPa) in modulus can correspond to a relative error exceeding 10 %. To address this issue, a dual thresholding method was implemented. A trial was retained if the absolute error in E_{11} or E_{22} was below 3 GPa and only excluded if both the percent error exceeded 10% and the absolute error was greater than 3 GPa. This approach ensures that low-modulus cases with small absolute deviations are preserved, while still eliminating predictions with both large relative and large absolute errors.

While this dual-threshold filtering improves the retention of valid data points, it also accepts lower accuracy in directions with inherently low stiffness. This compromise is reasonable for highly anisotropic plies, where structural performance is primarily governed by axial stiffness. It is also applicable to symmetric configurations that exhibits low values of both E_{11} and E_{22}, where accurate predictions across all directions remains essential to fully characterize composite behavior. Across the validation set, the mean absolute error was 0.98 GPa for E_{11} and 2.2 GPa for E_{22}, suggesting a bias introduced by training with 0 degree fiber orientation which favors accurate prediction of E_{11}. Figures 5a and 5b display retained data points for E_{11} and E_{22}, respectively. In conjunction with these plots, Figure 5d illustrates that many of the erroneously discarded points were in fact valid E_{11} or E_{22} dominated cases, or intermediate cases, in which 0.5 GPa error translated to a > 10 % discrepancy.

In contrast, the surrogate model for shear modulus G_{12} performed poorly, with a mean absolute error of 1.35 GPa, even though typical G_{12}values remain below 4 GPa. As shown in Figure 5c, the model consistently overpredicts shear stiffness for aligned discontinuous fiber composites. Further analysis indicates that this discrepancy is not due to surrogate error but rather limitations in the underlying FEA data for rotated plies. Specifically, the simulated G_{12} values show minimal variation across fiber angles, clustering tightly around 1 GPa, despite expectations of greater anisotropy. This suggests that the global shear loading conditions in the current FEA configuration may not effectively engage the angle-dependent shear response of the fiber–matrix system. Importantly, this behavior highlights the surrogate model's utility in identifying and flagging erroneous or unphysical FEA outputs. While G_{12} accuracy remains a limitation, it does not impact the validation of E_{11} and E_{22}, which are the primary moduli of interest in inverse design applications.

Although validation based CLT does not perfectly match FEA results, it provides a reasonable confidence range for E_{11} and E_{22}. In practice, CLT and other analytical methods are inherently approximate and cannot fully capture the complexity of microscale fiber interactions. Nonetheless, their ability to bound trends observed in simulation data lends credibility to the FEA results and justifies their use in inverse modeling where longitudinal and transverse stiffness are primary targets.

Looking ahead, future work must focus on improving both the FEA shear loading methodology and the surrogate model's ability to predict lower stiffness values for E_{11} and E_{22}. This may include a wider range of off-axis fiber configurations and exploring hybrid modeling strategies that more

effectively integrate analytical theory, data-driven methods, and microscale physics.

6 CONCLUSIONS

An automated, surrogate-model-driven pipeline was demonstrated for generating and validating 2D RVEs of aligned discontinuous carbon fiber composites. Convergence studies confirmed that three repeated fiber gap units are sufficient to capture representative moduli without the use of periodic boundary conditions, offering a practical balance between accuracy with computational efficiency. A training dataset of 200 samples with 0-degree fiber orientation was used to train three Random Forest Regression models to predict transverse modulus $E_{22,}$ shear modulus G_{12}, and the Halpin–Tsai shape factor $\xi_{E_{11}}$. The models achieved $R^2 > 0.97$and MAE < 0.07 GPa on held out test data. The trained regression models were integrated into a Classical Laminate Theory based validation approach, enabling

rapid prediction of longitudinal and transverse moduli across arbitrary fiber orientations. Predictions for most configurations remained within 10% of corresponding FEA results. In addition to property prediction, the surrogate model was applied during post-processing to identify and flag anomalous FEA outputs from large datasets with random fiber orientations. This filtering step removed results that deviated from expected physical behavior, improving consistency and reliability of the dataset.

Together, this approach reduces computational expense by several orders of magnitude while generating a high-fidelity dataset appropriate for inverse design tasks. By combining physics-informed micromechanics with machine learning, it offers a scalable approach for tailoring composite microstructures to target properties. Future work must focus on improving both the FEA shear loading strategy to correctly analyze angle-sensitive G_{12} behavior, and the surrogate model's precision in predicting low moduli E_{11} and E_{22} cases more precisely.

Parametric identification

- Optimization cost function :

$$(\mathbf{P}) = \underset{\mathbf{P} \in \mathbb{R}^{+k}}{arg\,\min} \left\{ \sum_{i=2}^{4} \left(\sum_{j=1}^{N_i} \left(\bar{\epsilon}_i^{e,j} - \epsilon_i^{s,j} \right)^2 \right) \right\}, \tag{1}$$

- The optimization is performed on the sections 2 to 4 which are the first cooling, second heating and second cooling.

- The translated strains $\bar{\epsilon}_i^{e,j}$ are derived from the experimental strains $\epsilon_i^{e,j}$ such as the final experimental state and simulated ones superpose.
- The extra strains recovered from section 1 (heating 1) are the residual/drying strains

Parametric identification

Initial residual and drying strains

- Residual/drying strains as defined as :

$$\bar{\epsilon}^{ini} = \bar{\epsilon}^{e}_{1} - \epsilon^{s}_{1}$$

- The identified initial irreversible strain release will be modeled using neural Ordinary Differential equations.

Initial strain release

- The initial irreversible strain ϵ^{ini} release can be generated by residual strains and drying of the prepregs.
- Neural Ordinary Differential Equation (Neural ODE) will be used to identify the strain release.

$$\frac{\partial \epsilon^{ini}}{\partial t} = \mathcal{F}(t, \Delta T_0, \epsilon^{ini}, \epsilon^s)$$

- To guarantee stability, the following stabilized neural ODE formulation is

$$\frac{\partial \epsilon^{ini}}{\partial t} = \epsilon^{ini} \cdot \mathcal{G}(t, \Delta T_0, \epsilon^{ini}, \epsilon^s) + \mathcal{H}(t, \Delta T_0, \epsilon^s)$$

- For stability $\mathcal{G}$ is a neural network imposed to output negative values by construction.

Initial strain release

- The initial irreversible strain ϵ^{ini} release can be generated by residual strains and drying of the prepregs.
- Neural Ordinary Differential Equation (Neural ODE) will be used to identify the strain release.

$$\frac{\partial \epsilon^{ini}}{\partial t} = \mathcal{F}(t, \Delta T_0, \epsilon^{ini}, \epsilon^s)$$

- To guarantee stability, the following stabilized neural ODE formulation is

$$\frac{\partial \epsilon^{ini}}{\partial t} = \epsilon^{ini} \cdot \mathcal{G}(t, \Delta T_0, \epsilon^{ini}, \epsilon^s) + \mathcal{H}(t, \Delta T_0, \epsilon^s)$$

- For stability $\mathcal{G}$ is a neural network imposed to output negative values by construction.

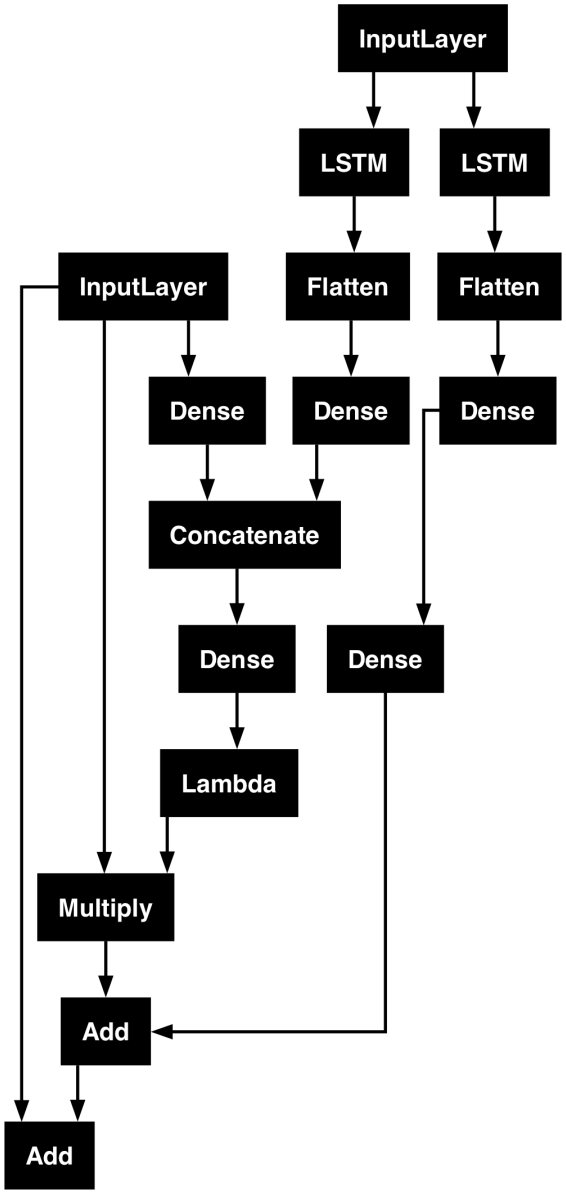
Neural ODE model



- Training performed over 100 epochs with ADAM algorithm.
- A custom built learning rate update function is used
- the LSTM takes in memory the last two values in the input parameters (t, T, ϵ^s)
- Only the last value of $\bar{\epsilon}^{ini}$ is passed into the next time step

Neural ODE model

  - On Testing region : 0.07% strain
- The Neural ODE relied the most on the simulated strains from the viscoelastic model.

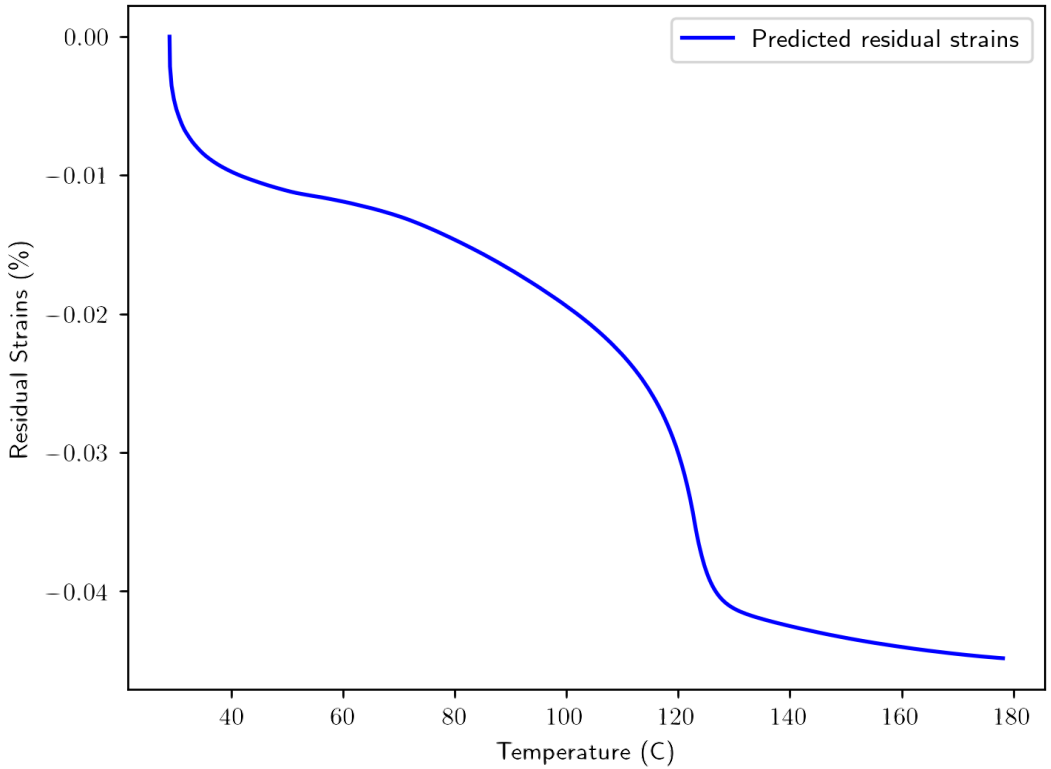
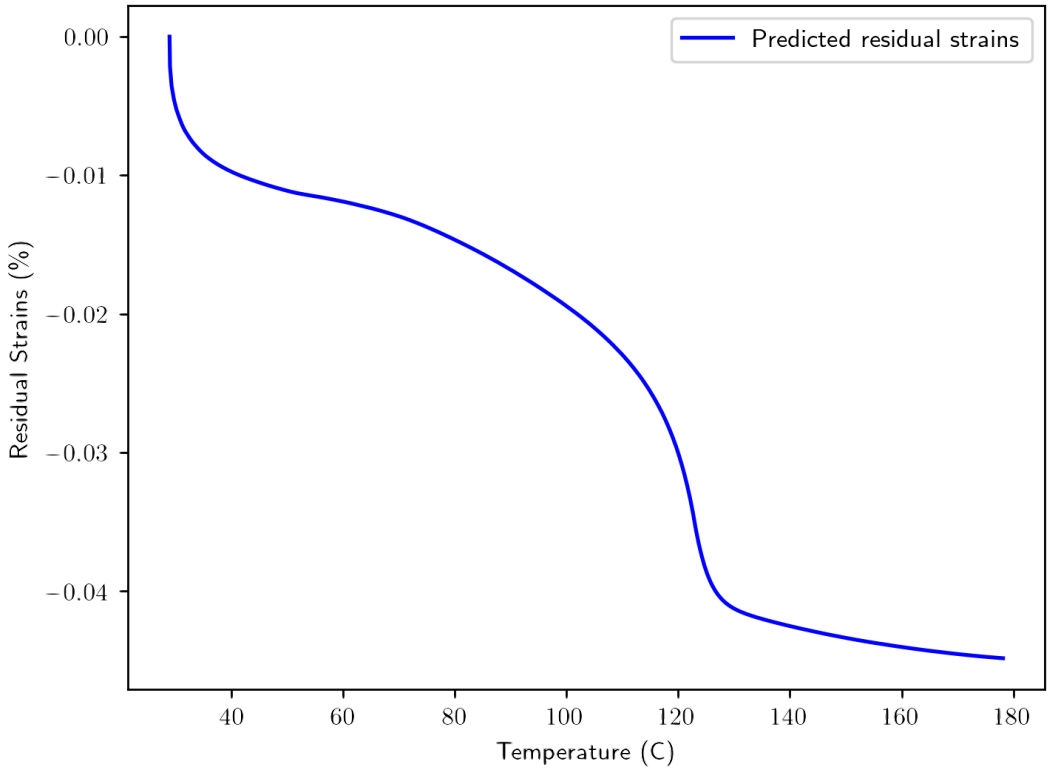
Derivative functions

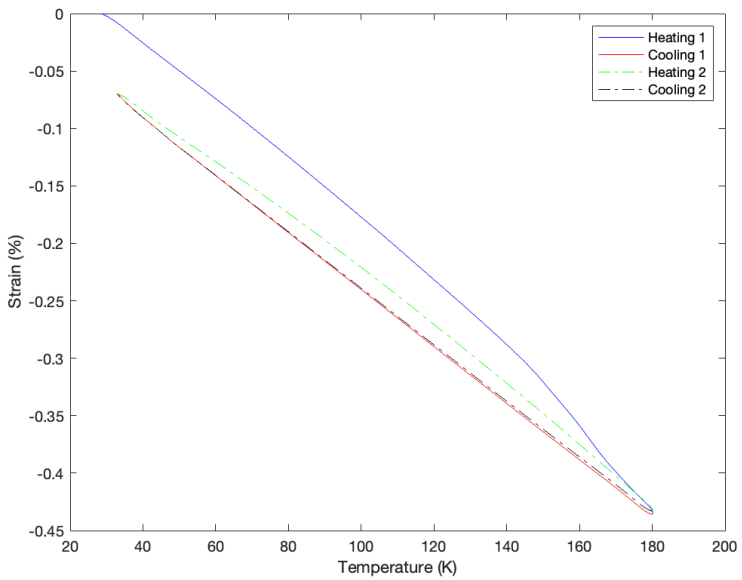


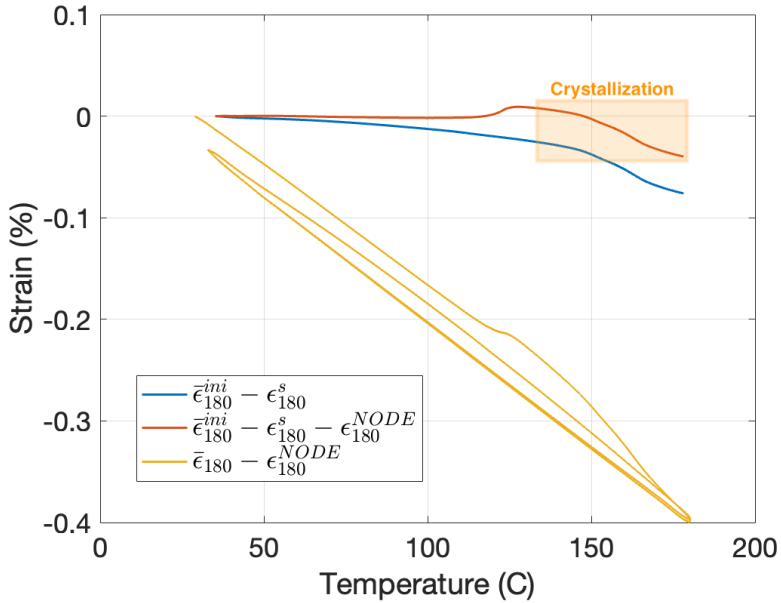


Prediction on the 180C experiment

- The prediction can be performed on the experiment with the temperature increasing up to $180C$ on section "heating 1".
- The neural network predicted the saturation of the residual/drying stresses.

Prediction on the 180C experiment

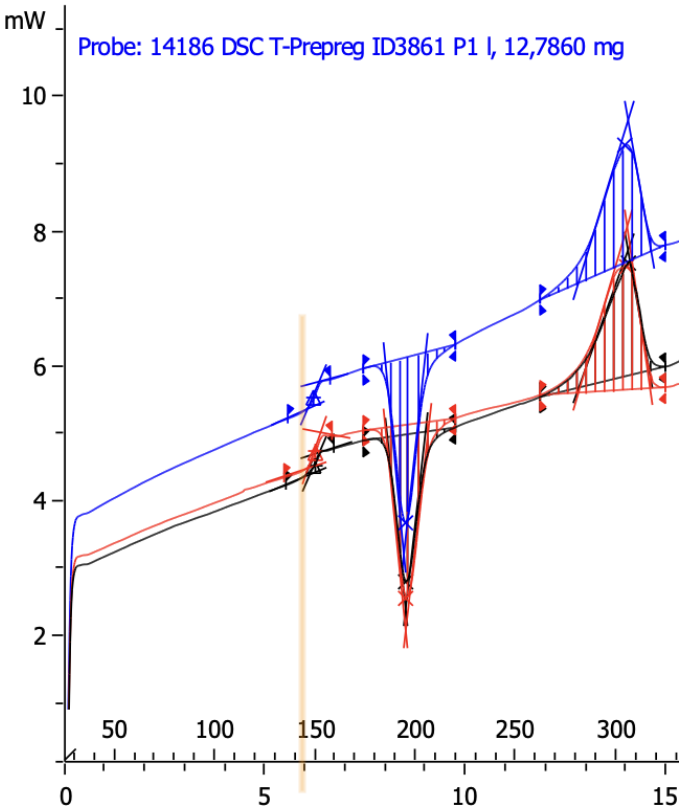




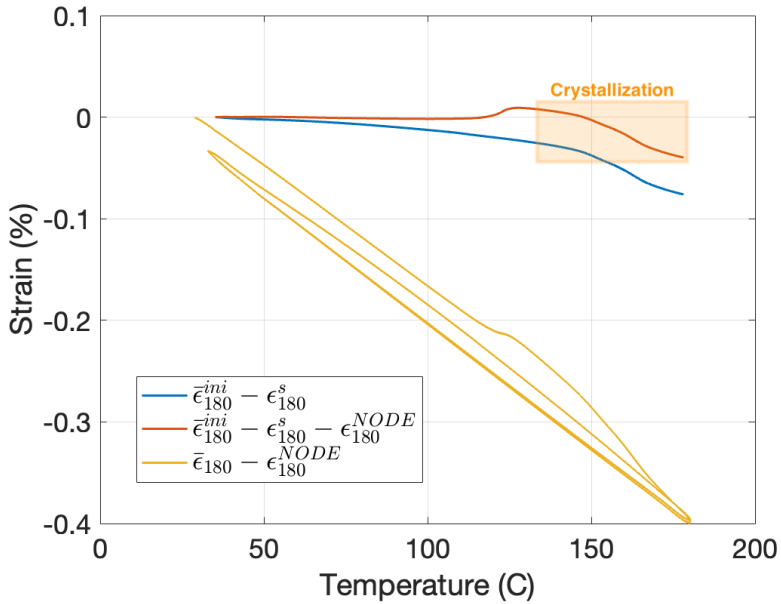
- The prediction can be performed on the experiment with the temperature increasing up to $180C$ on section "heating 1".
- The neural network predicted the saturation of the residual/drying stresses.

Viscoelastic + residual strains model

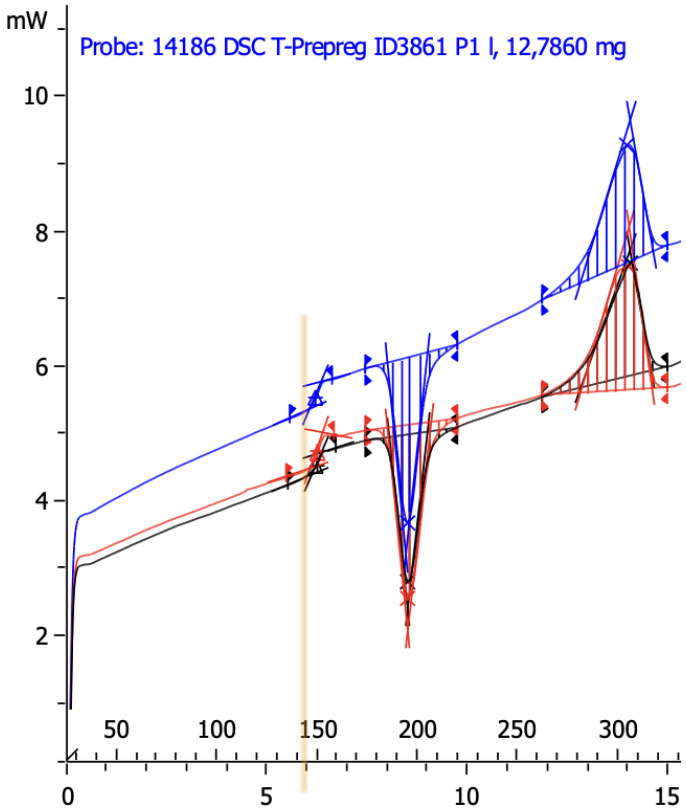
- The crystallization strains are defined as :



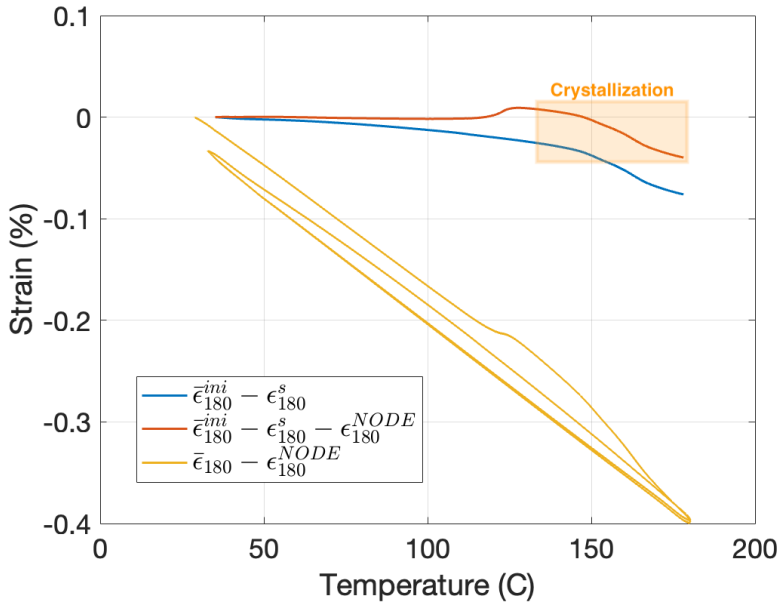
$$\epsilon_{180}^{crys} = \bar{\epsilon}_{180} - \epsilon_{180}^{s} - \epsilon_{180}^{ini}$$

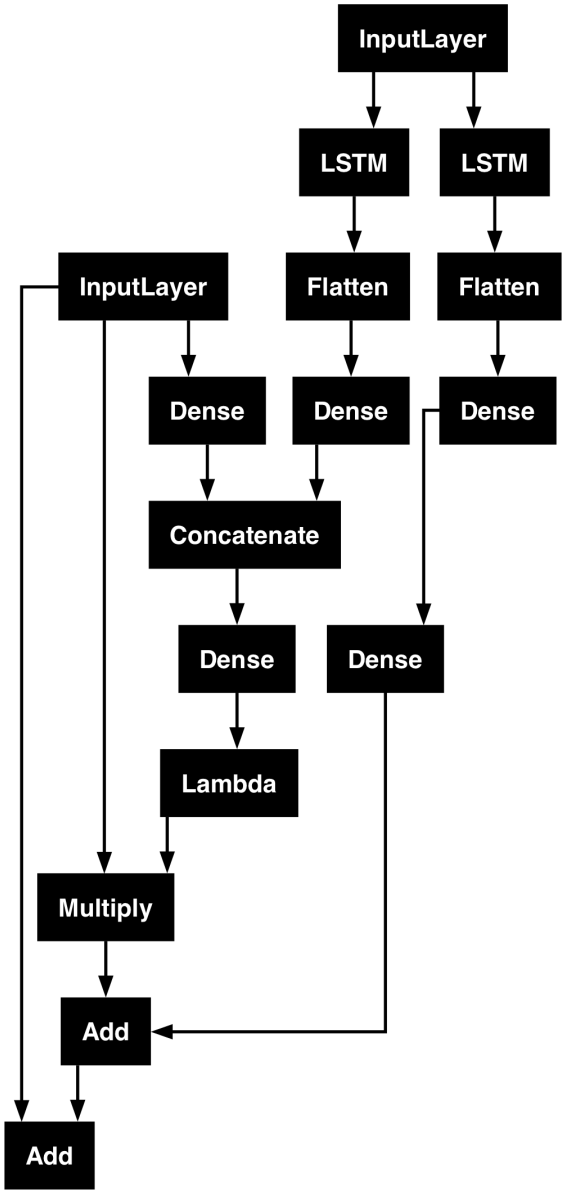


Correlation with DSC experiment



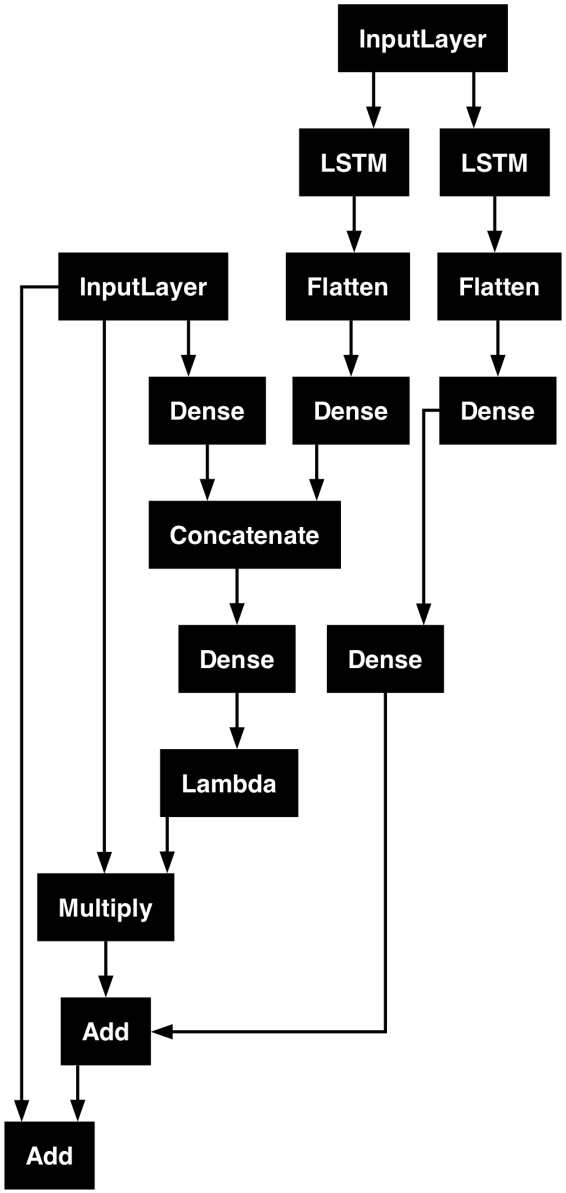
- The DSC experiment shows an glass transition temperature around $146.7^{o}C$ during the first heating phase.
- The strains shows a decrease in value starting $147^{o}C - 148^{o}C$.



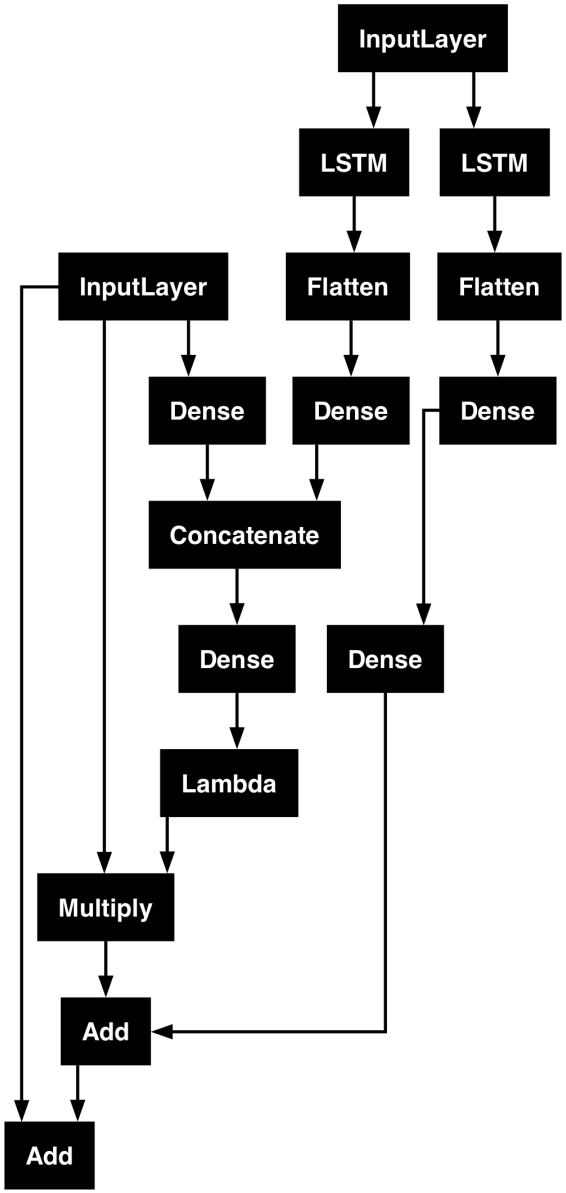


Correlation with DSC experiment

- The DSC experiment shows an glass transition temperature around 146.7^oC during the first heating phase.
- The strains shows a decrease in value starting $147^oC - 148^oC$.



Crystallization Neural ODE



- Training performed over 100 epochs with ADAM algorithm.
- A custom built learning rate update function is used
- LSTM takes as memory input the last two values in the input parameters (t, T, ϵ^s)
- Only the last value of $\bar{\epsilon}^{crys}$ is passed into the next time step

Crystallization effect

- Crystallization can generate further changes in $\mathbf{E}$ and α
- To avoid the need to identify the parameters at every cycle, we build a hybrid model
- The modeling compensate the strains using :

$$\epsilon^{cryst}|_{T>147} = \epsilon^{exp}|_{T>147} - \epsilon^{s}|_{T>147}$$

- The same Neural ODE used for crystallization is extended throughout the experiment to predict the effect of the crystallization using :

$$\epsilon^{cryst}|_{T>147} = \epsilon^{pred} - (\epsilon^{pred}(t_0) + \epsilon^{s}(t_0))H(t - t_{cryst})$$

- The training is performed on the first three stages of the experiment, and testing is performed on the last one.

Crystallization effect

- Crystallization can generate further changes in $\mathbf{E}$ and α
- To avoid the need to identify the parameters at every cycle, we build a hybrid model
- The modeling compensate the strains using :

$$\epsilon^{cryst}|_{T>147} = \epsilon^{exp}|_{T>147} - \epsilon^{s}|_{T>147}$$

- The same Neural ODE used for crystallization is extended throughout the experiment to predict the effect of the crystallization using :

$$\epsilon^{cryst}|_{T>147} = \epsilon^{cryst} \cdot \mathcal{G}_2(t, T, \epsilon^s, \epsilon^{cryst}) + \mathcal{H}_2(t, T, \epsilon^s)$$

- The training is performed on the first three stages of the experiment, and testing is performed on the last one.

Crystallization effect

- Crystallization can generate further changes in $\mathbf{E}$ and α
- To avoid the need to identify the parameters at every cycle, we build a hybrid model
- The modeling compensate the strains using :

$$\epsilon^{cryst}\big|_{T>147} = \epsilon^{exp}\big|_{T>147} - \epsilon^{s}\big|_{T>147}$$

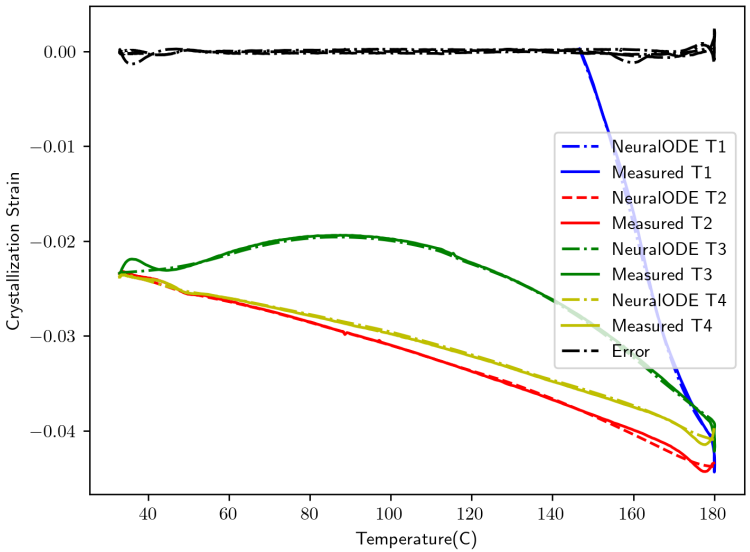
- The same Neural ODE used for crystallization is extended throughout the experiment to predict the effect of the crystallization using :

$$\epsilon^{cryst}\big|_{T>147} = \epsilon^{cryst} \cdot \mathcal{G}_2(t, T, \epsilon^s, \epsilon^{cryst}) + \mathcal{H}_2(t, T, \epsilon^s)$$

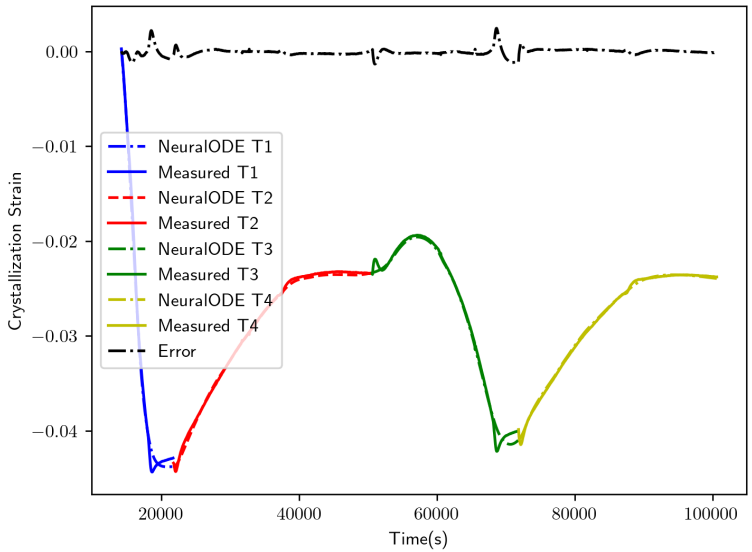
- The training is performed on the first three stages of the experiment, and testing is performed on the last one.

Crystallization effect

- Crystallization can generate further changes in **E** and α
- To avoid the need to identify the parameters at every cycle, we build a hybrid model
- The modeling compensate the strains using :



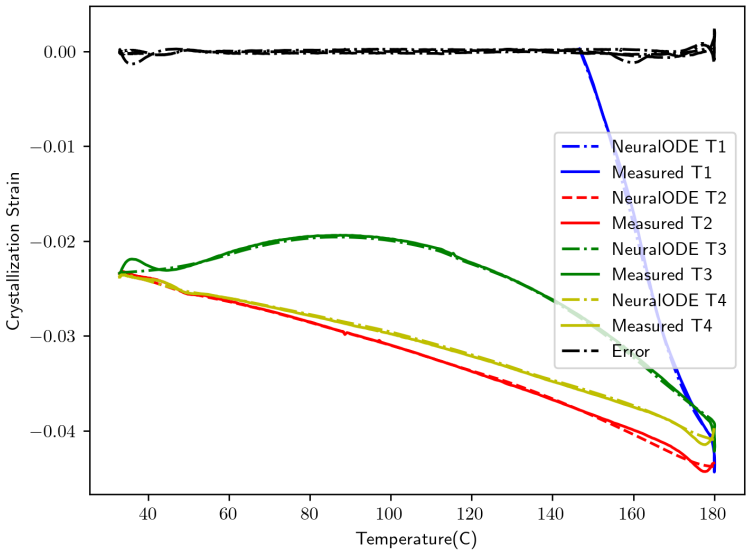
$$\epsilon^{cryst}|_{T>147} = \epsilon^{exp}|_{T>147} - \epsilon^{s}|_{T>147}$$



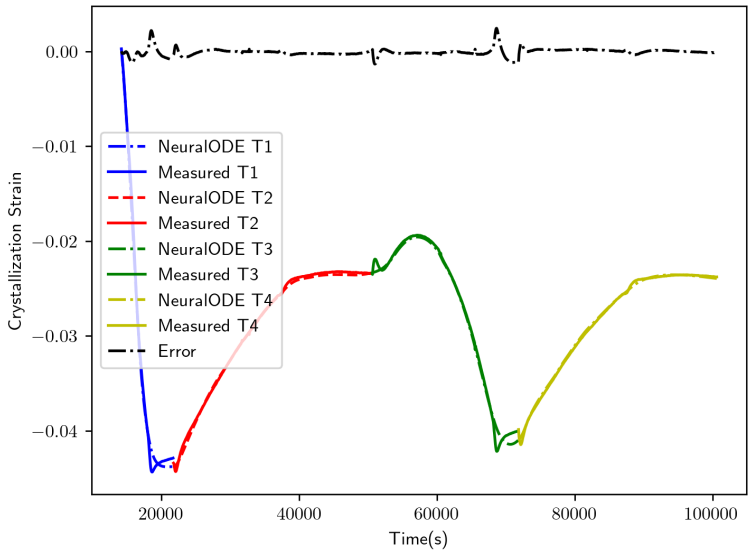
- The same Neural ODE used for crystallization is extended throughout the experiment to predict the effect of the crystallization using :

$$\epsilon^{cryst}|_{T>147} = \epsilon^{cryst} \cdot \mathcal{G}_2(t, T, \epsilon^s, \epsilon^{cryst}) + \mathcal{H}_2(t, T, \epsilon^s)$$

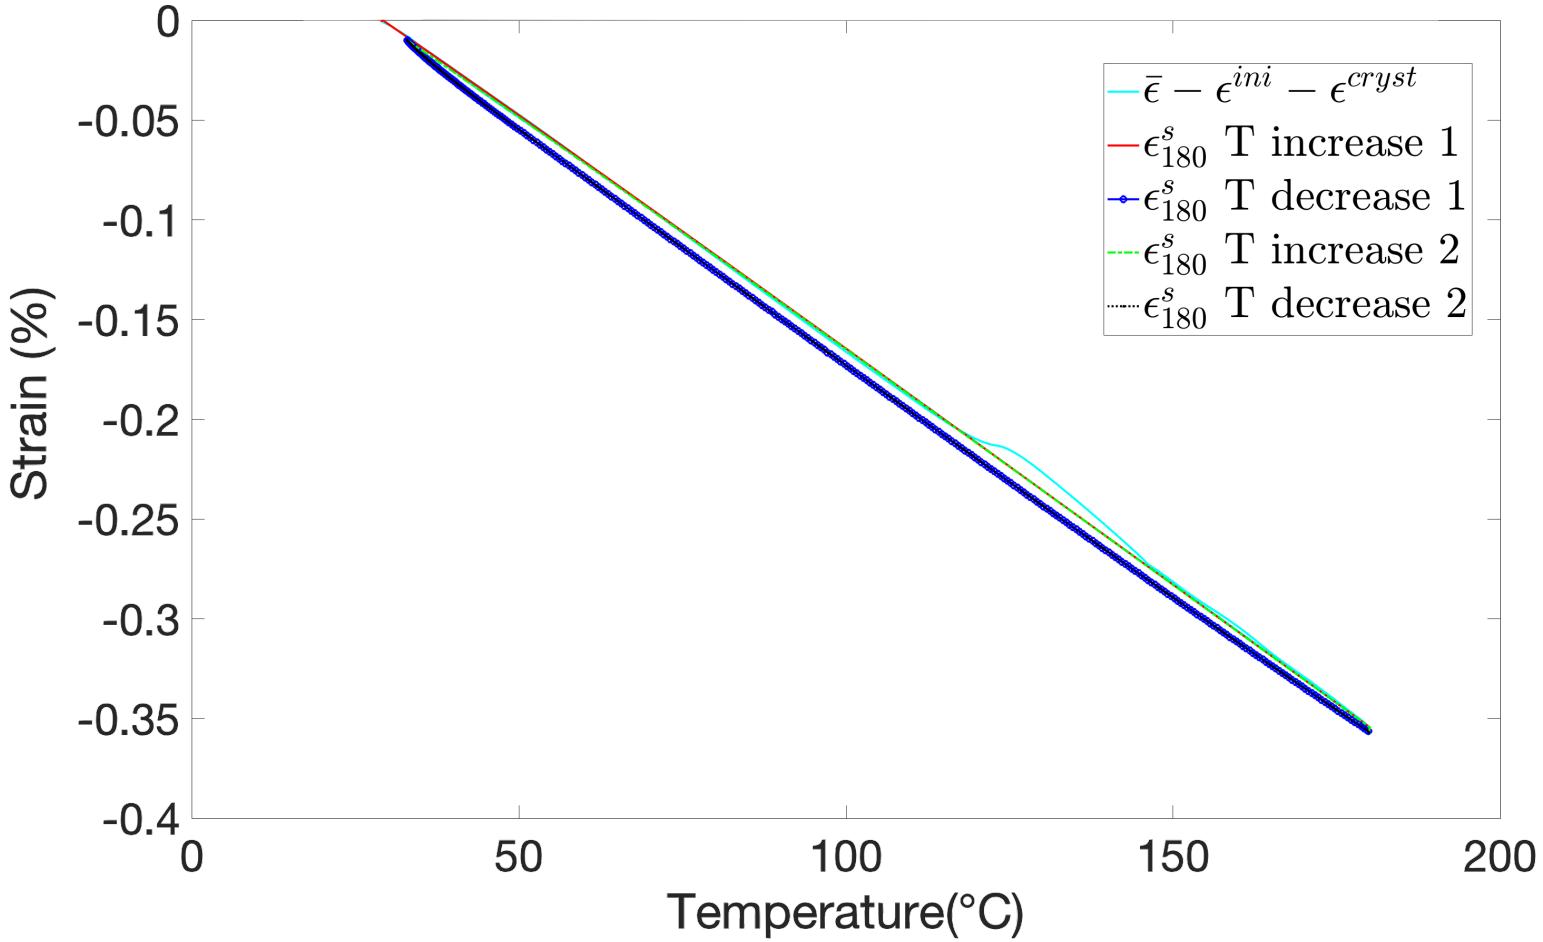
- The training is performed on the first three stages of the experiment, and testing is performed on the last one.



Crystallization model



- Beyond the first onset of crystallization the effect becomes limited due to limited changes in material properties
- The errors in the testing region are similar to the ones obtained on the training data.



Crystallization model

- Beyond the first onset of crystallization the effect becomes limited due to limited changes in material properties
- The errors in the testing region are similar to the ones obtained on the training data.

Crystallization model

- Final result when accounting for the initial strains and the crystallization effect.

Conclusion

- We can identify the viscoelastic material properties of robotic 3D printed prepregs.
- The effect of drying and residual strains is modeled and used on unseen data.
- The predictions generalize well far beyond the training region.
- The effect of the Crystallization on the trains and material performance is modeled using stabilized Neural ODEs.
- The prediction generalizes outside the training region.
- Stabilized neural ODEs are stable for data applications.

Conclusion

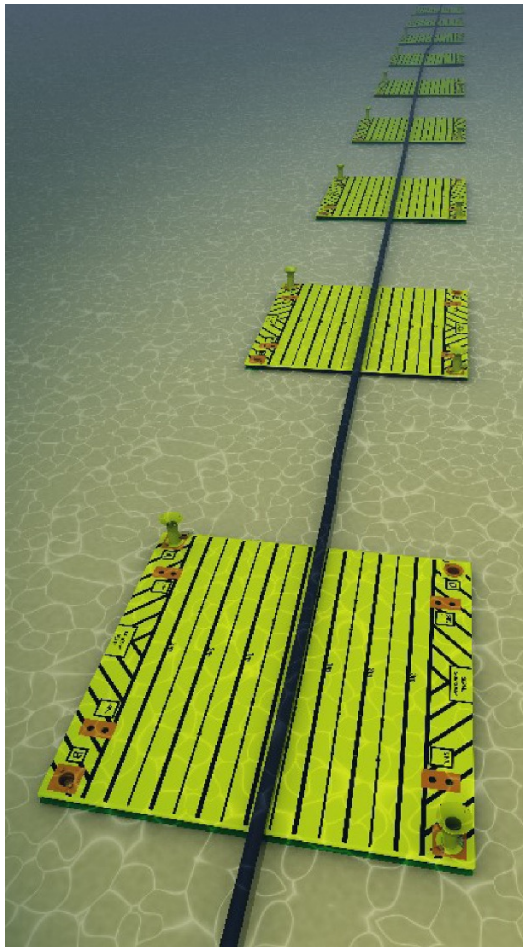
From corrosion management to corrosion free: the non-metallic path



Courtesy: Novel

Courtesy: Composite worlds

Courtesy: Calcul Meca – HHR Roof.

- No classical corrosion,
- Ideal for coastal, offshore, sour gas contexts,
- Reduced OPEX, lighter infrastructures,
- Huge potential for localizing the supply chain

Courtesy: CSUB

The non-metallic path: an enabler to sustainability

- Hydrogen value-chain:

  No hydrogen embrittlement

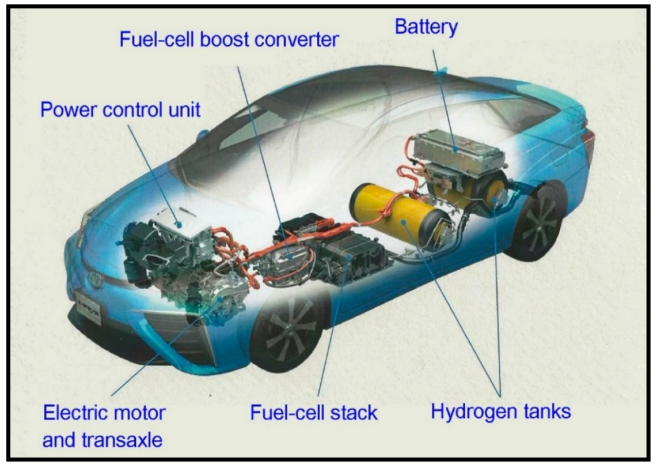
- Carbon capture and storage context:

  Wet CO_2

  CO_2 mixed with impurities (Sox, Nox, etc..)

J. Sonke, W. Bos, and S. Paterson, “Materials challenges with CO2 transport and injection for carbon capture and storage,” Int. J. Greenhouse Gas Control, vol. 114, p. 103601, 2022

Two applications to be discussed



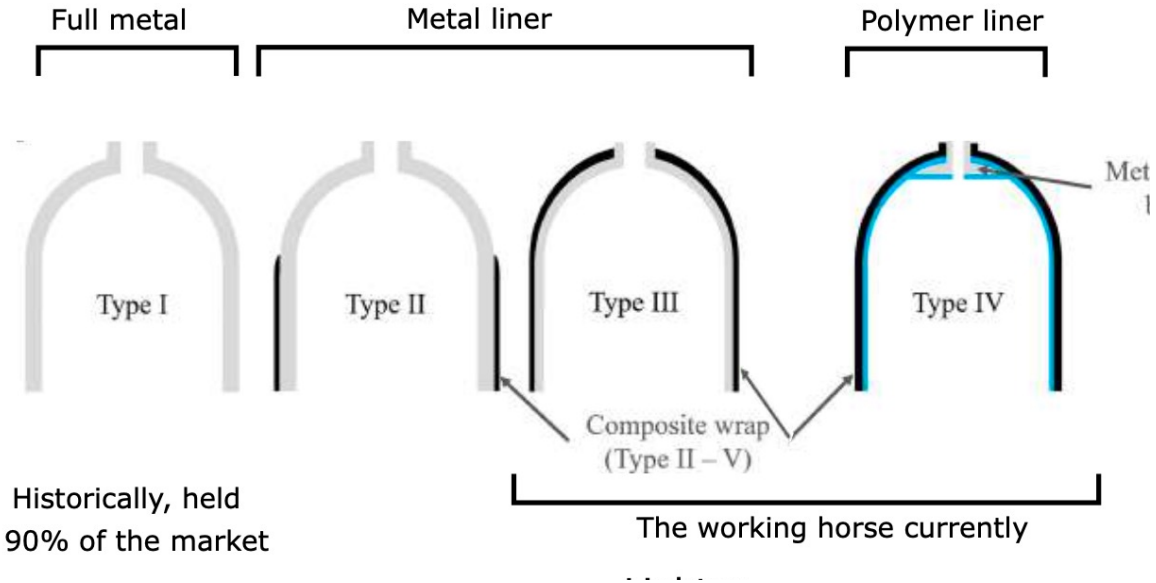
- Compressed hydrogen storage,
- Monitoring of high-performance thermoplastic pipes

Thermoplastics thin-plies for compressed hydrogen storage

Mechanics of Composites for Energy and Mobility

جامعة الملك عبدالله للعلوم والتقنية
King Abdullah University of Science and Technology

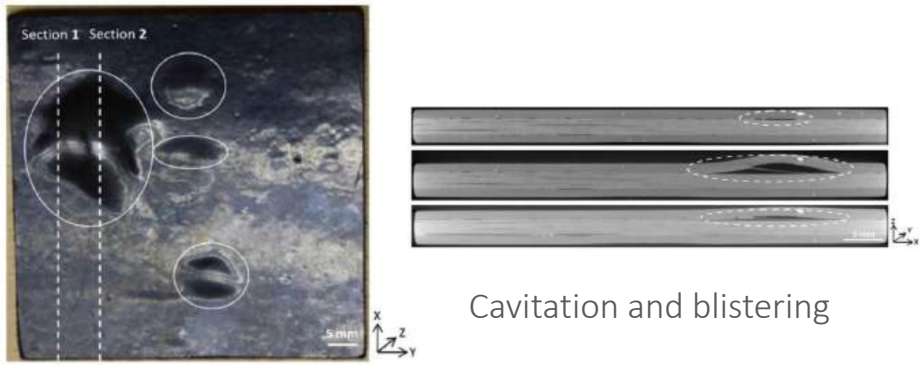
Compressed mobile hydrogen storage: a need for the hydrogen value-chain



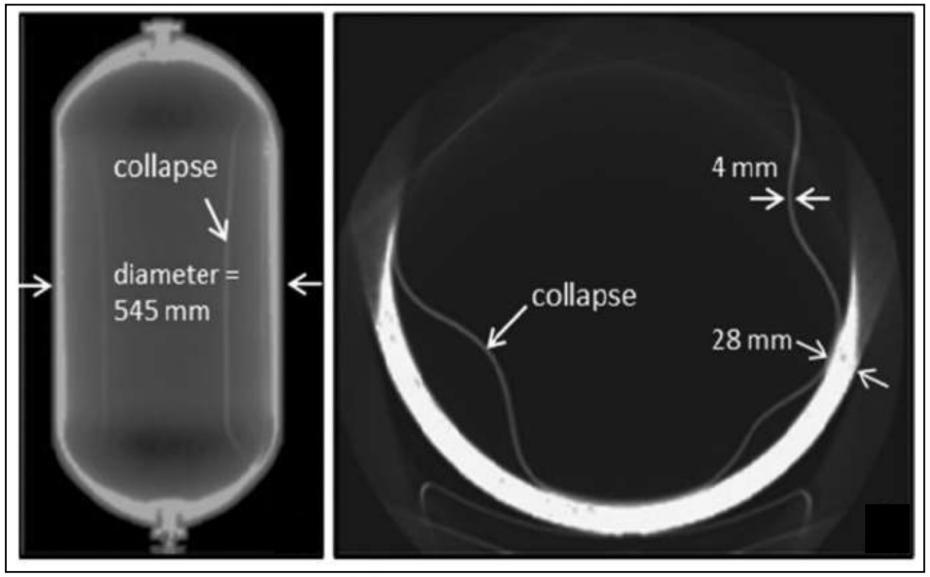
Toyota Mirai car
with hydrogen tanks

Hydrogen power
Jupiter H2 Drone

- Compressed Hydrogen tanks are essential for **mobile applications**,
- Typical conditions:
  - RT, **[300-700] bars**,
  - Multiple refueling cycle,
  - Safe to impact,
  - Maximum leak rate (app. 0.05g/h/Kg H_2)



Getting Compressed hydrogen storage lighter: type IV tank



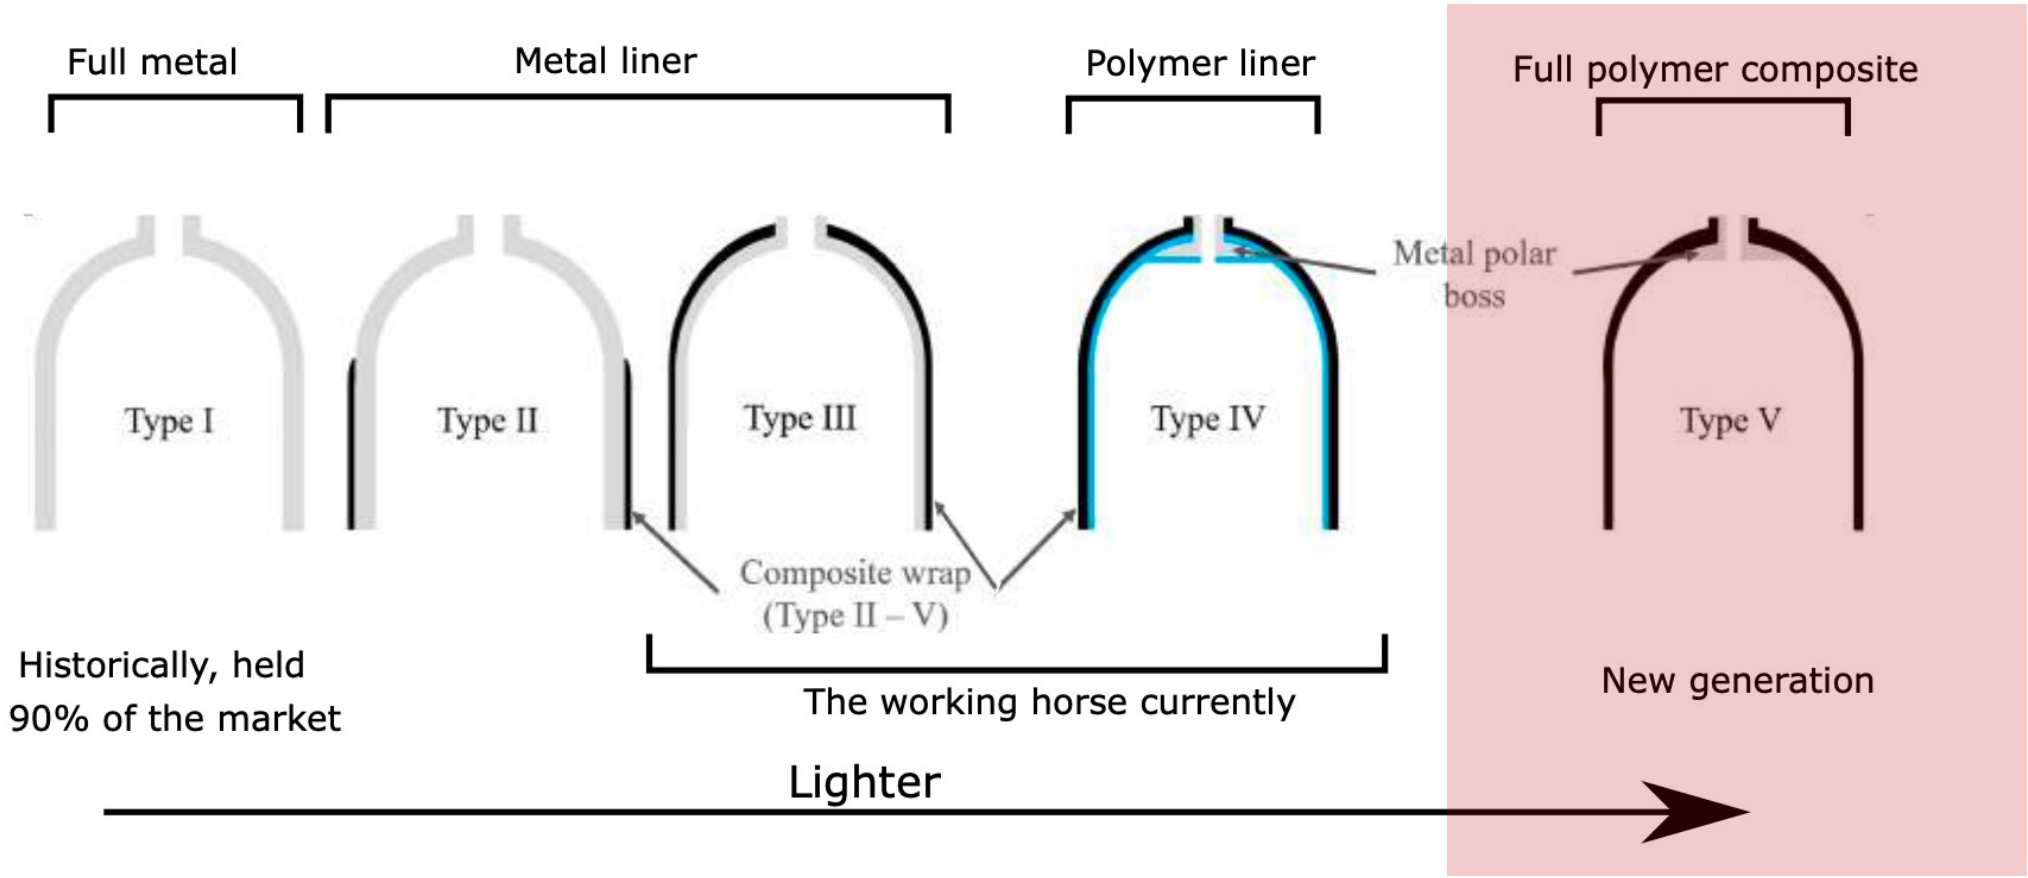
- In all cases, **most of the weight** of a filled tank, **is the tank**,
- Composites enable **larger tank-to-hydrogen weight ratio**:
  - In Type III tanks:
    [~22]
  - In Type IV tanks:
    [~12]

H. Barthélémy, M. Weber, F. Barbier, Hydrogen storage: Recent improvements and industrial perspectives, International Journal of Hydrogen Energy 42 (11 (2017) 7254-7262.

Compressed mobile hydrogen storage: the challenges of type IV tank

Cavitation and blistering

Liner collapse



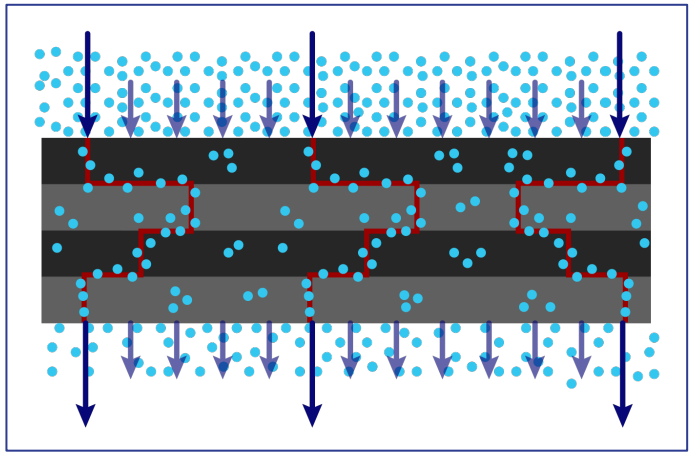
- **Cavitation** during **depressurization** in the liner or interface,
- **Collapse of the liner** due to
  - Liner/wall interface,
  - Lack of structural bearing capabilities of the liner

How to simultaneously

- Bring more structural stability?
- Save more weight ?

J. Pépin, E. Lainé, J.C. Grandidier, G. Benoit, D. Mellier, M. Weber, C. Langlois, Replication of liner collapse phenomenon observed in hyperbaric type IV hydrogen storage vessel by explosive decompression experiments, International Journal of Hydrogen Energy 42 (9) (2018) 4671-4680.

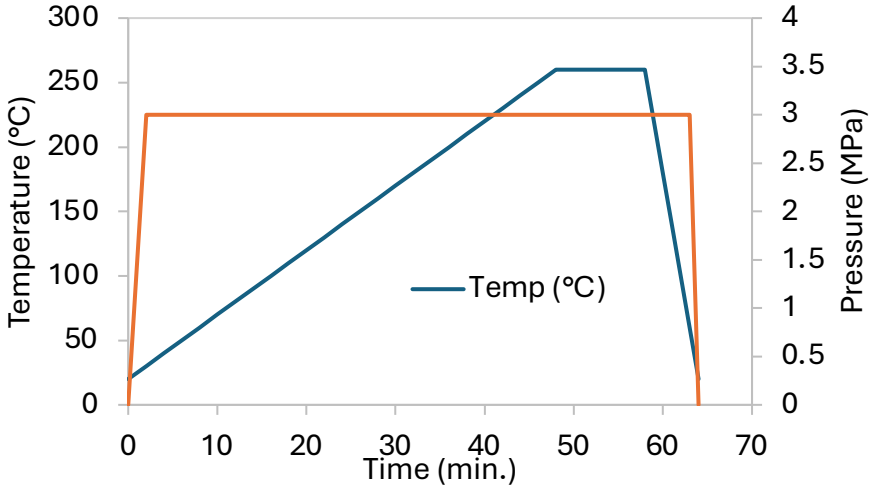
Getting Compressed hydrogen storage lighter : Moving to Type V tanks



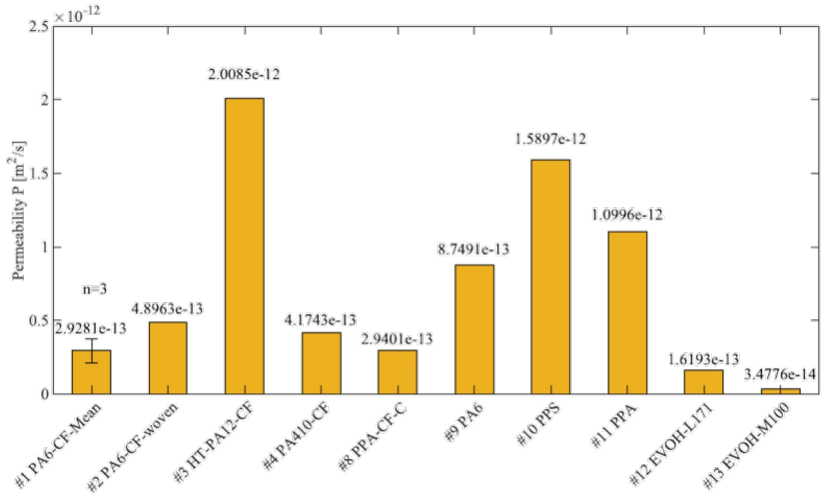
H. Barthélémy, M. Weber, F. Barbier, Hydrogen storage: Recent improvements and industrial perspectives, International Journal of Hydrogen Energy 42 (11 (2017) 7254-7262

Classical type V tanks: thermoset based with classical ply thickness

Mikroni et al. “Design, Analysis and Testing of a Type V Composite Pressure Vessel for Hydrogen Storage”. Polymers, Vol.16, 2024.



- Prone to **transverse cracking**,
- **Transverse cracking induces local delamination** close to the tips of transverse cracks .
- **Leakage criterion get compromised** due to a percolating network of crack throughout the thickness.
- The percolated regime **is not an acceptable regime, permeability criteria should be met on diffusion regime**
  - Bring more structural stability?



Our study: moving to thin-ply thermoplastics

Unidirectional Carbon-Fiber Prepreg(CF/PA6)

Fiber tensile modulus [GPa]	230	Material configuration	Sheet roll

Vf [%]	53	Sheet width [mm]	250
RC [%]	36	Matrix resin Melting point [°C]	225
T_g [°C]	50	Thickness [μm]	42

Test items	Test Resalts	Test Method
0° tensile strength [MPa]	2300	JIS K 7165
0° tensile modulus [GPa]	120	JIS K 7165

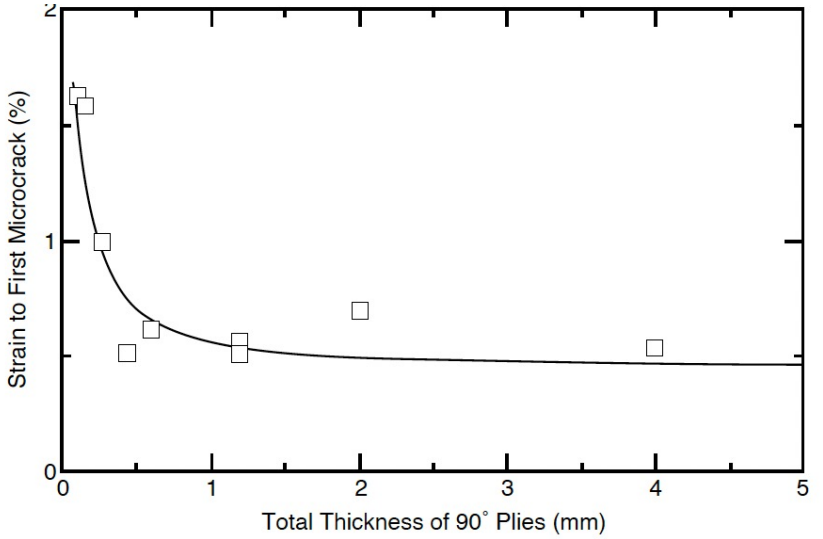
Conde-Wolter et al. "Hydrogen permeability of thermoplastic composites and liner systems for future mobility applications", Composites Part A: Applied Science and Manufacturing, (2023).

Our study: moving to thin-ply thermoplastics

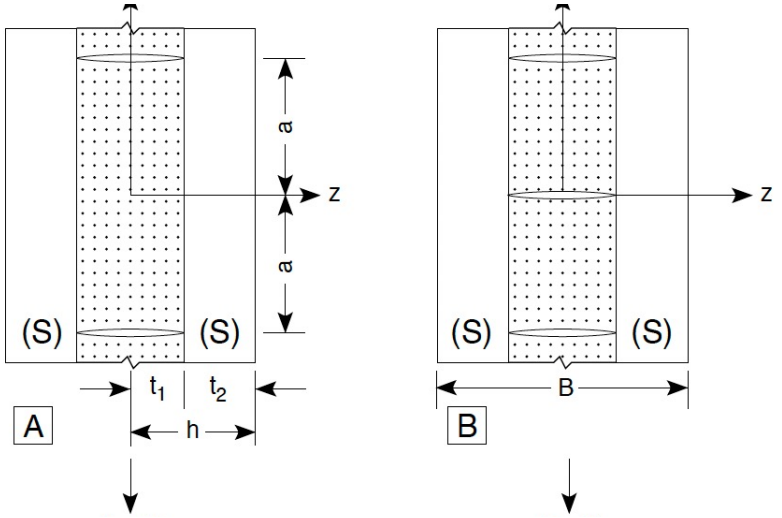
3 advantages:

- 2 from “thin”,
- 1 from “thermoplastics”

Our study: moving to thin-ply thermoplastics



3 advantages:



- 2 from “thin”,
- 1 from “thermoplastics”

Advantage 1:

Thin plies eliminates transverse cracks

- Well-known Finite Fracture Mechanics result,
- Well-accepted observation in thermosets,
- Can be readily extended to thermoplastic laminates.

Nairn, Hashin, Parvizi, Hutchinson, Ladevèze and Lubineau [70s,80s,90s]

Our study: moving to thin-ply thermoplastics

3 advantages:

- 2 from “thin”,
- 1 from “thermoplastics”

Advantage 1:

Thin plies eliminates transverse cracks

- Well-known Finite Fracture Mechanics result,
- Well-accepted observation in thermosets,
- Can be readily extended to thermoplastic laminates.

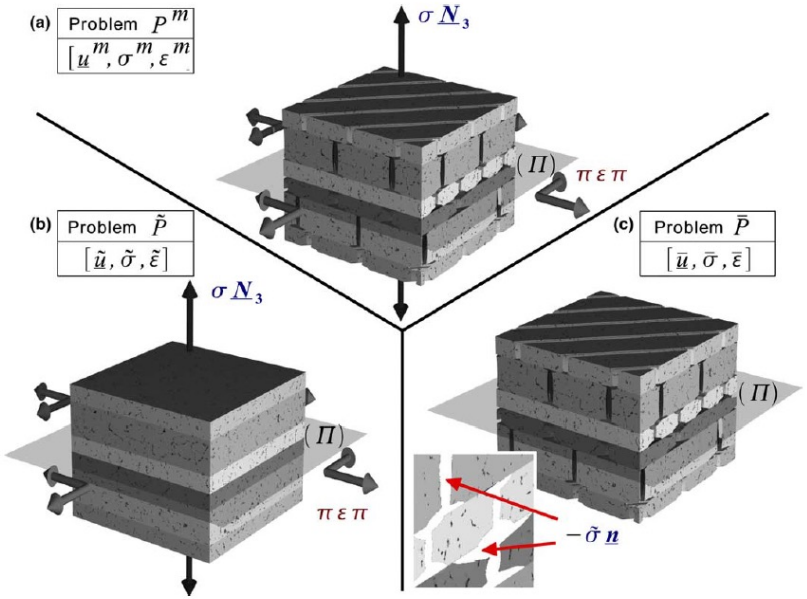


Fig. 4. The fundamental micro–meso link.

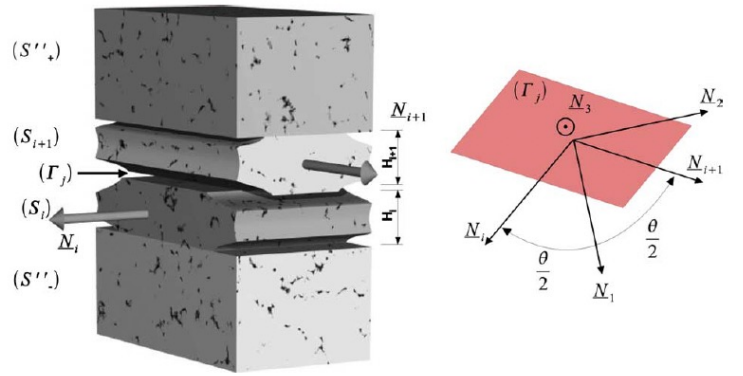

Fig. 5. Problem $\bar{\mathcal{P}}|_{\Gamma_j}$: approximate solution of $\bar{s}$ around an interface Γ_j.

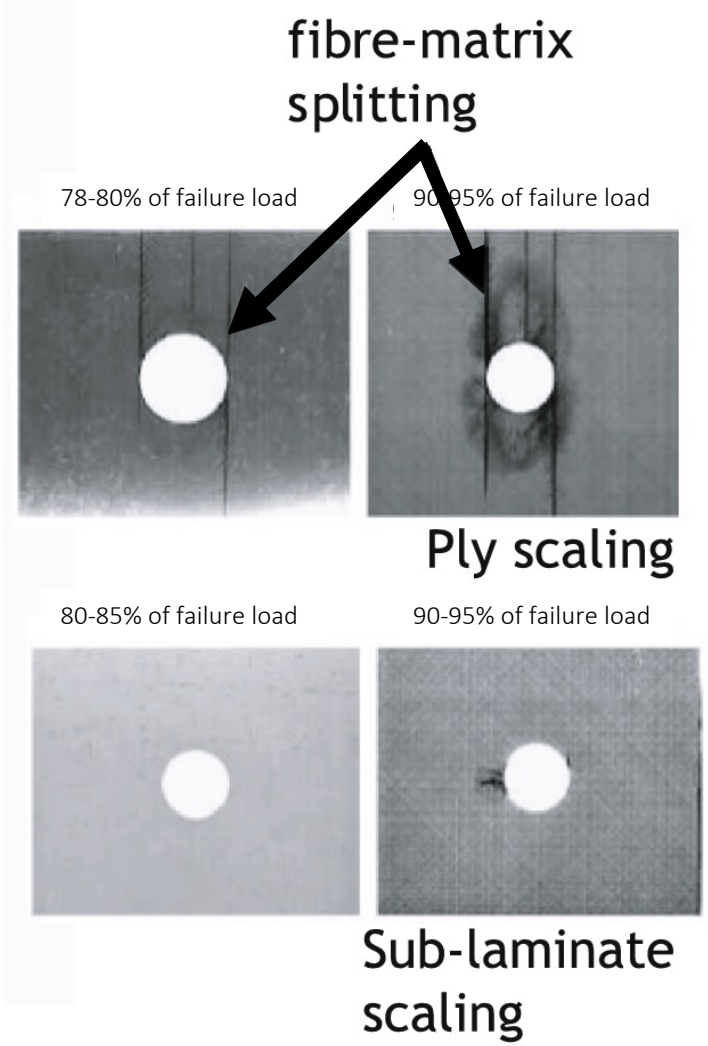
Micro-meso relations
Ladeveze and Lubineau – LMT Cachan
[2000-2009]

Our direction: moving to thin-ply thermoplastics



3 advantages:

- 2 from “thin”,
- 1 from “thermoplastics”

Advantage 1:

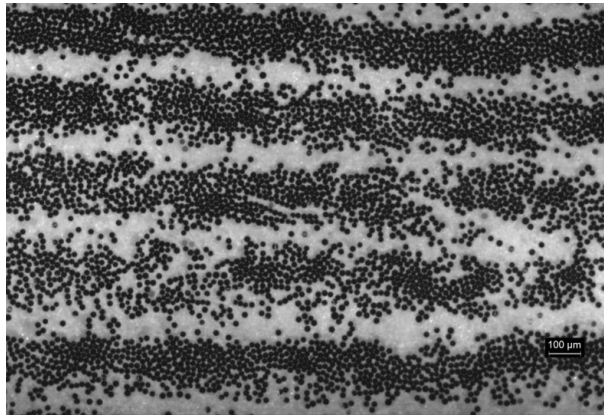
Thin plies eliminates transverse cracks

- Well-known Finite Fracture Mechanics result,
- Well-accepted observation in thermosets,
- Can be readily extended to thermoplastic laminates, with additional dissipation sources.

Lee J, Soutis C. Measuring the notched compressive strength of composite laminates: specimen size effects. Compos Sci Technol 2008;68:2359–66.

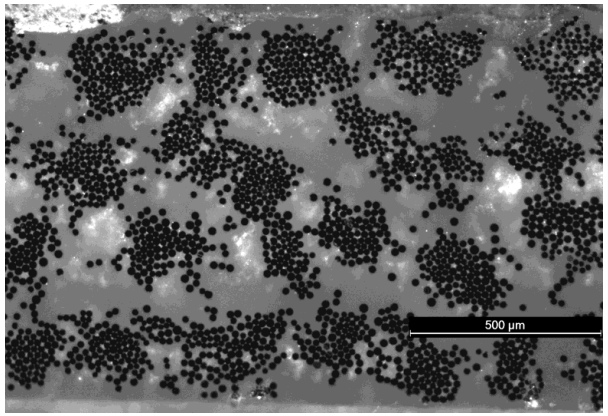
Our direction: moving to thin-ply thermoplastics

3 advantages:



- 2 from “thin”,
- 1 from “thermoplastics”

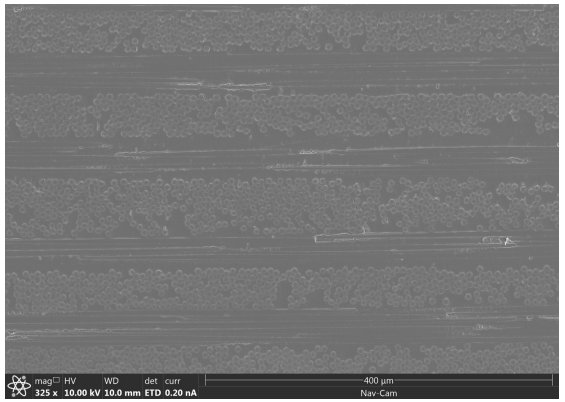
Advantage 2:



Thin plies come with “better” microstructures

- Obtained by two spreading,
- Resulting in more “uniform” fiber distribution,
- Might be interesting for permeability.

Classical “Thick” Thermoplastics PP tapes

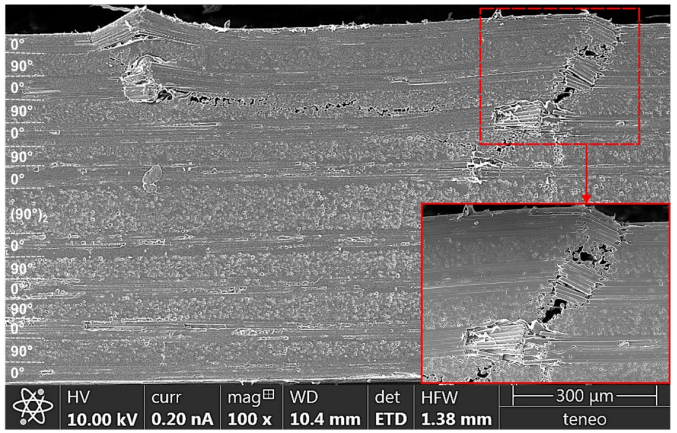


“layered-like” structures

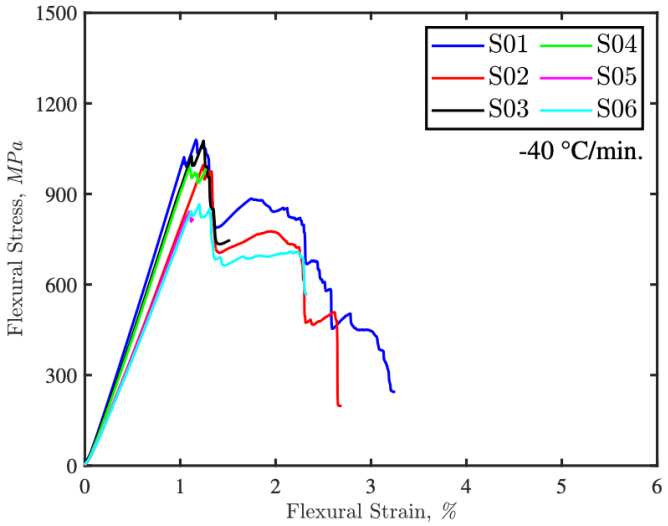
“Bindle” structures

Thin 42 microns tapes

Our direction: moving to thin-ply thermoplastics



3 advantages:

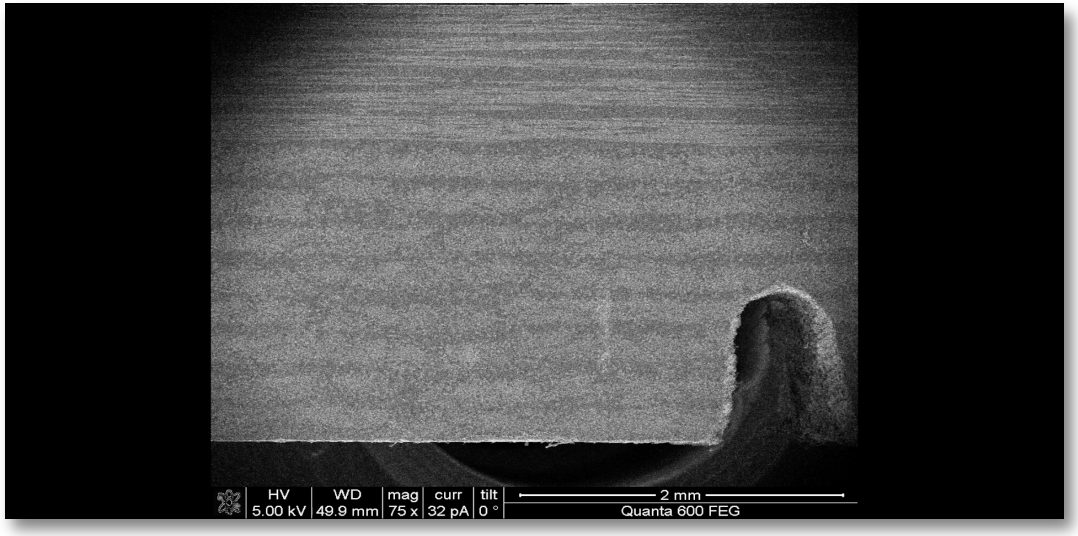


- 2 from “thin”,
- 1 from “thermoplastics”

Advantage 2:

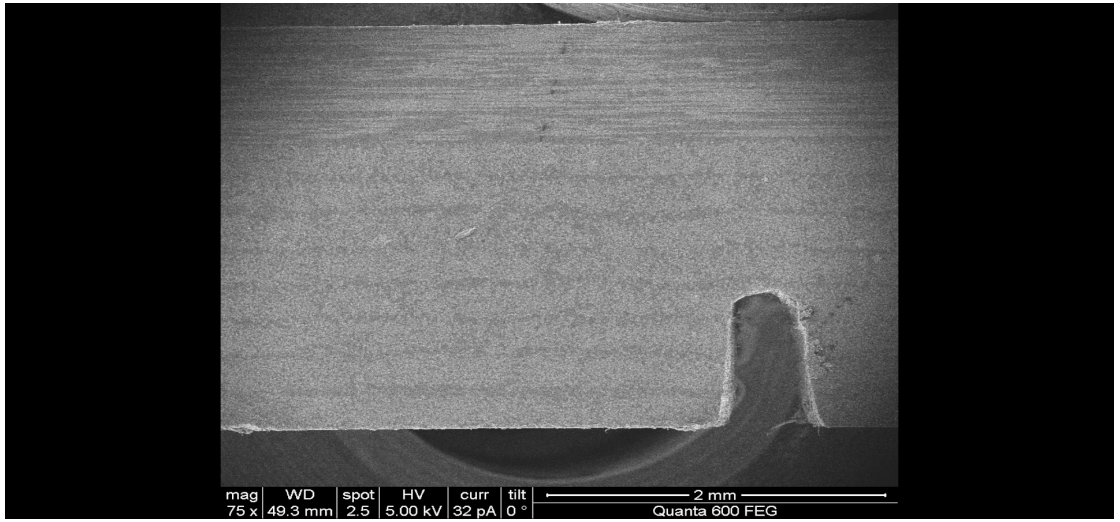
Thermoplastic bring more ductility, leveraging the classical “brittleness” of thin-plies

- Thermoset thin-plies are known to be very brittle,
- Moving to their thermoplastic counterpart brings the best of both worlds.



(a) $t_l = 42\ \mu$m

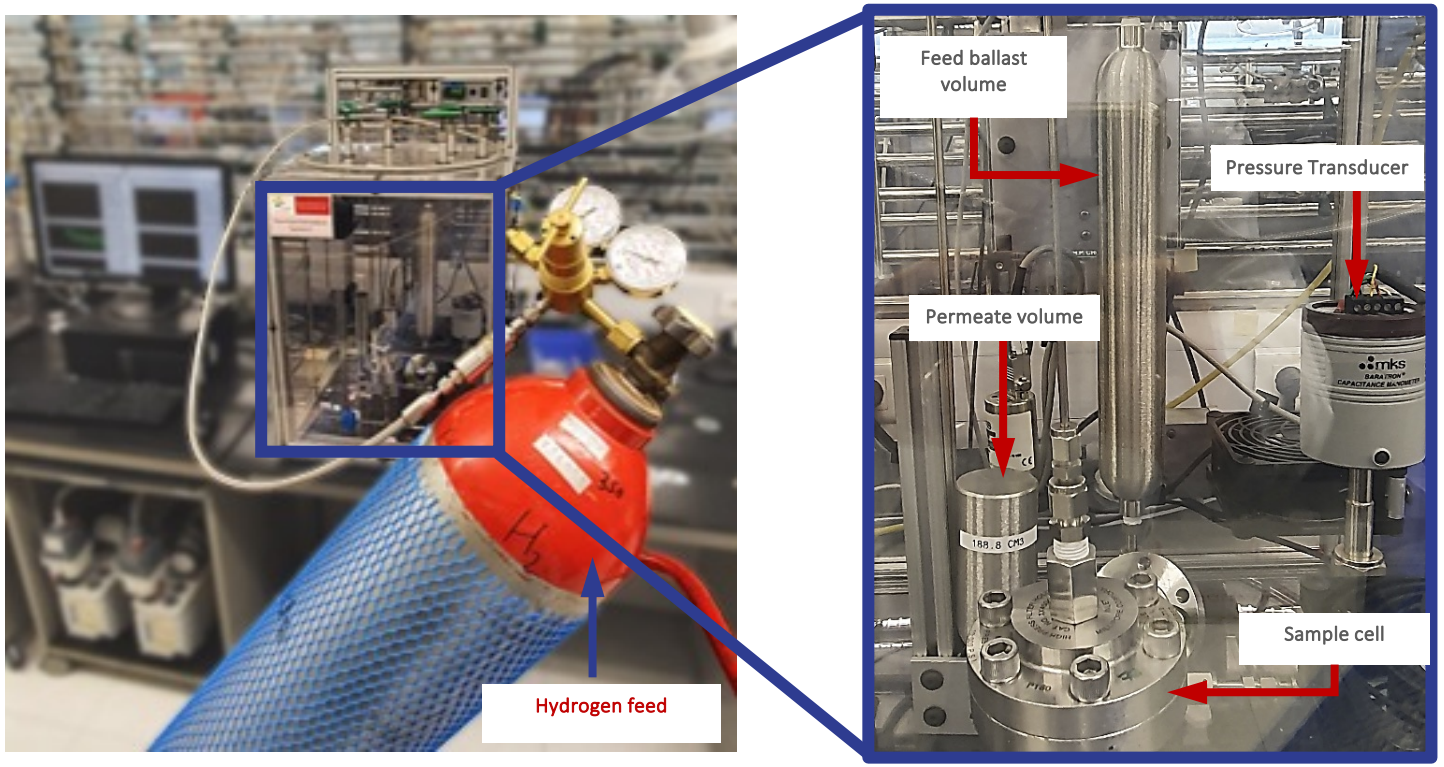
F. Oz, A. Wagih, Y. Kara, M. Bahabri, G. Lubineau, Thin-shell thermoplastic composites with tunable out-of-plane properties: The interplay of layer thickness and cooling rate, Composites Part B: Engineering, 2025, Vol 299, 112381

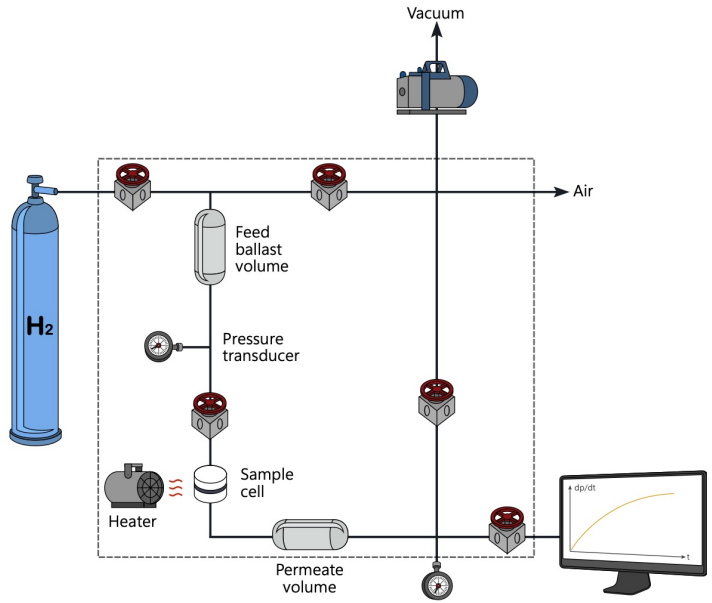


Our direction: moving to thin-ply thermoplastics

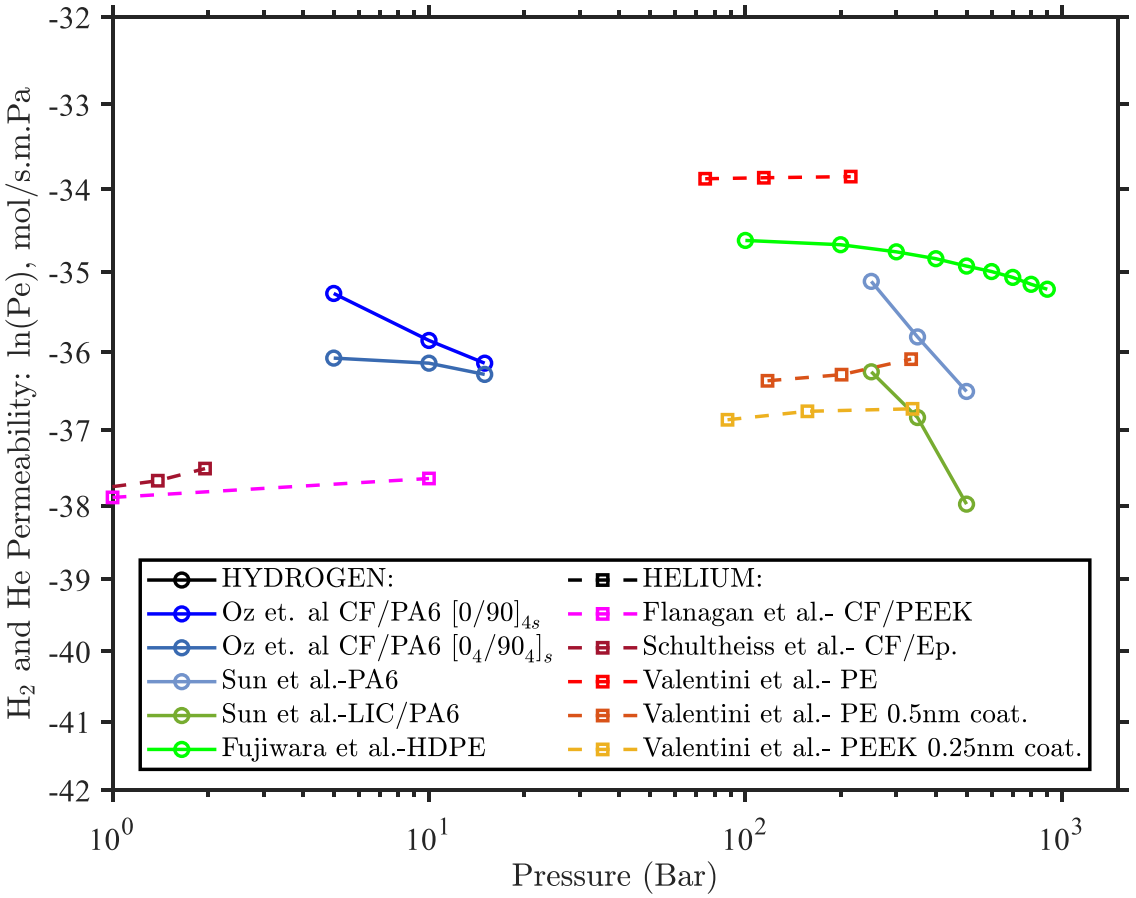
Advantage 2:

Thermoplastic bring more ductility, leveraging the classical “brittleness” of thin-plies





Damage transition in GFPP with Matrix “C” (less ductile)



Damage transition in GFPP with Matrix “H” (more ductile)

Insights about Permeability of thin-plies based composites

Permeability of thin-plies based composites
Point 1: testing with H_2 (not with helium) is key

- Many studies use **Helium as a surrogate,**
- This may result in **totally different permeability/pressure trends.**

Hydrogen

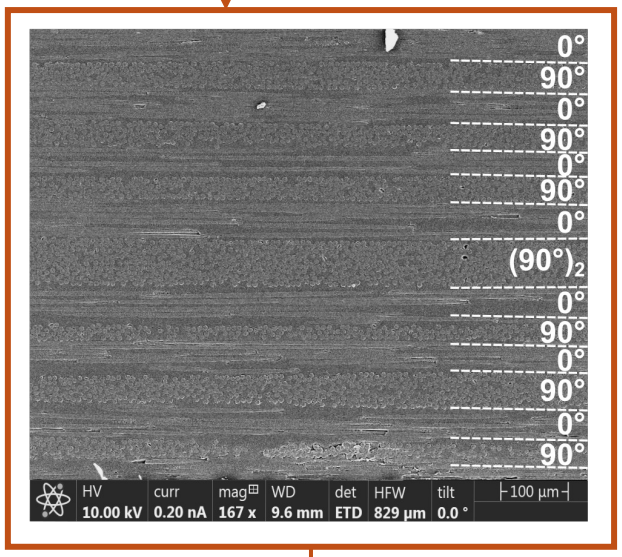
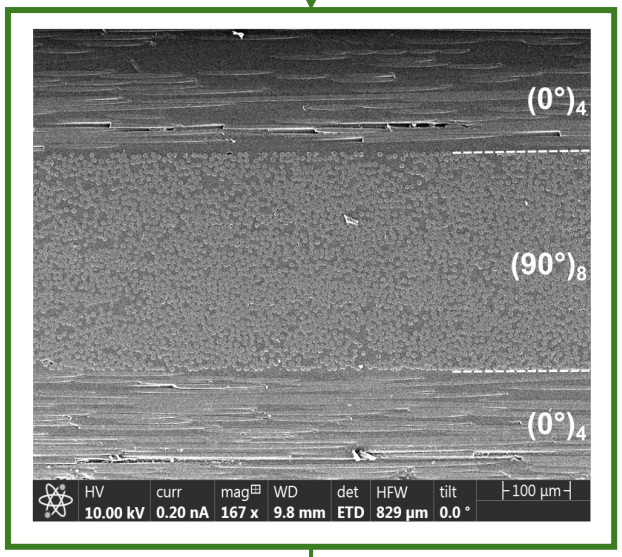
- D. Schultheiß, permeation barrier for lightweight liquid hydrogen tanks, Universität Augsburg, PhD Dissertation (2007)

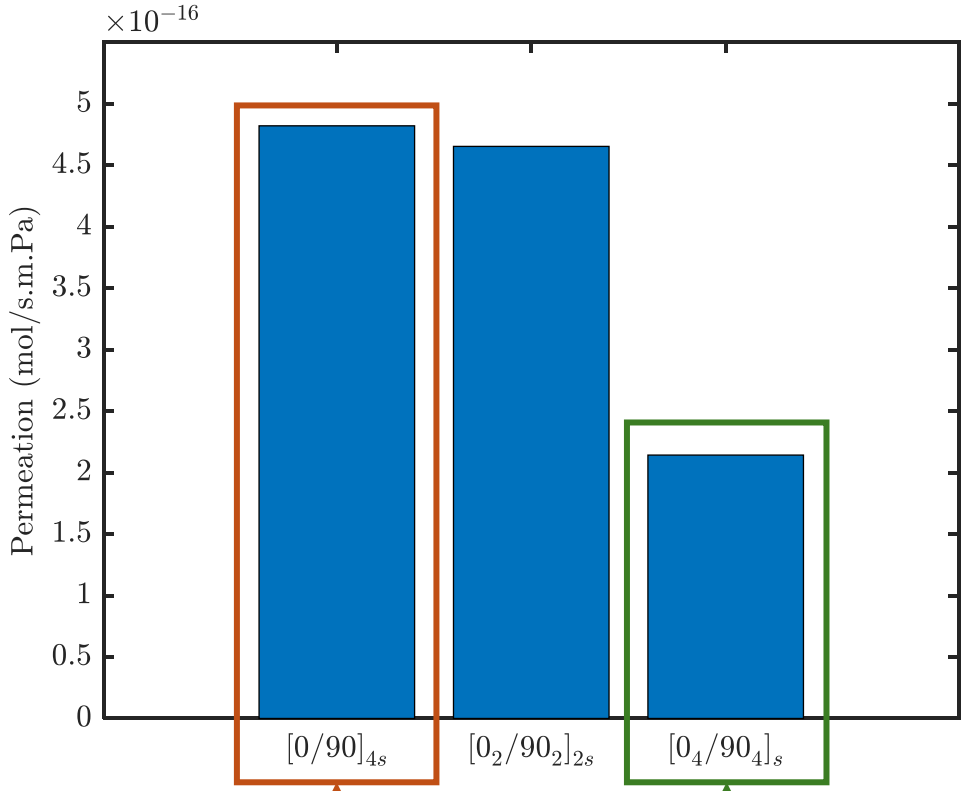
Permeability of thin-plies based composites

Point 1: testing with H_2 (not with helium) is key



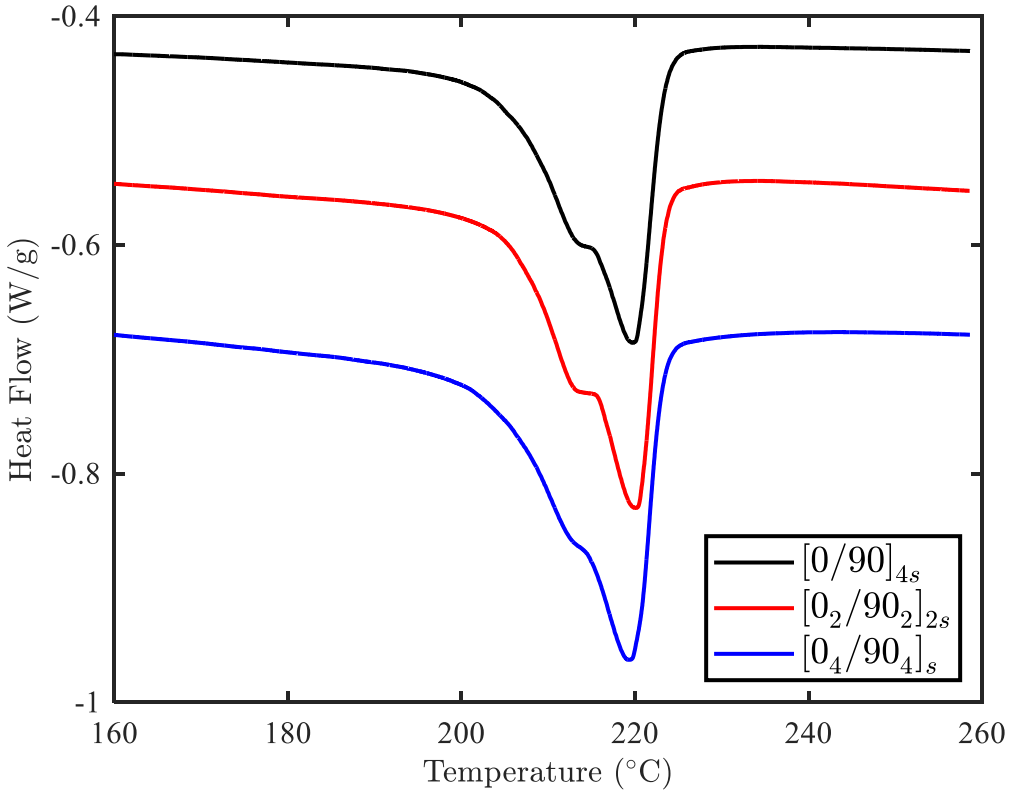


- Permeability **is decreasing with pressure,**
- **True for all tested sequences,**
- Usually attributed to **reduction of free volume under high pressure,**
- **Permeability at low-pressure is a safe design quantity** if no additional damage

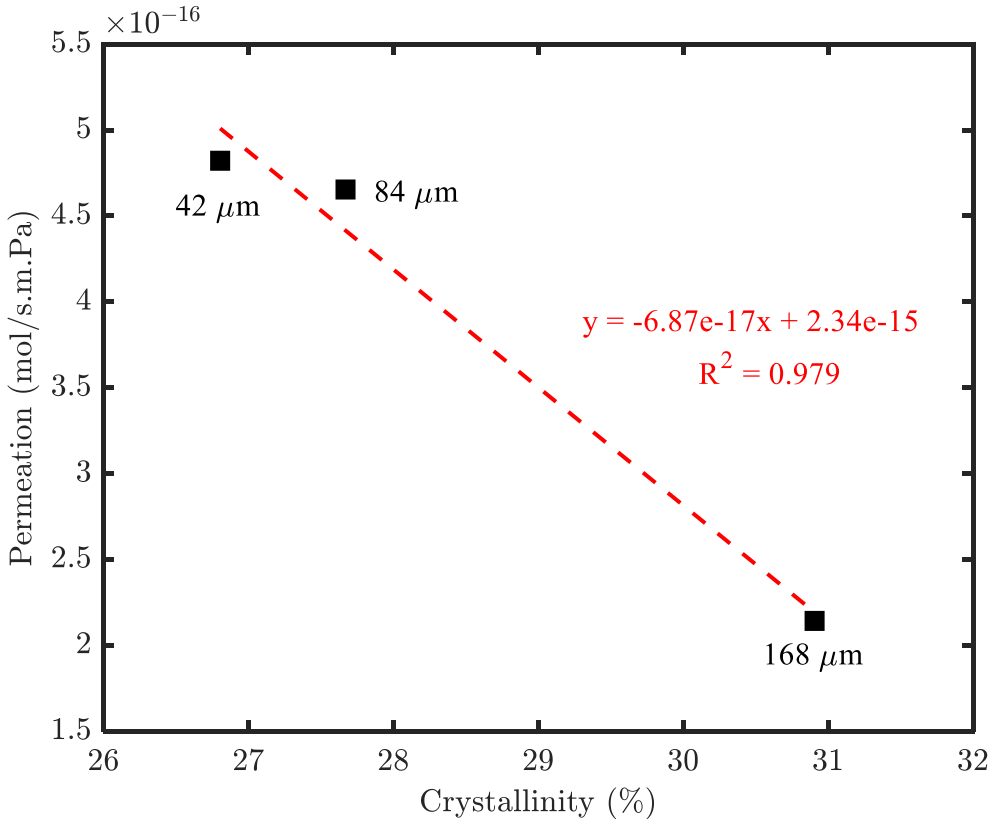


Permeability of thin-plies based composites

Point 2: thicker layers result in lower permeability (initially)



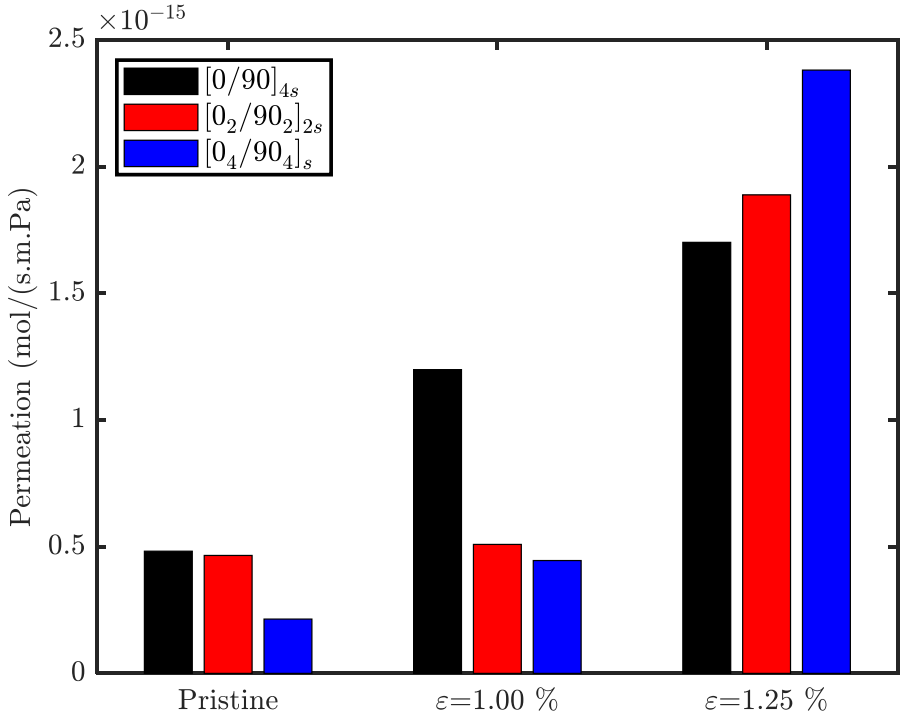
Laminate	Layer thickness (μm)
$[0/90]_{4s}$	42
$[0_2/90_2]_{2s}$	84
$[0_4/90_4]_s$	168



Permeability of thin-plies based composites
Point 2: thicker layers result in lower permeability (initially)

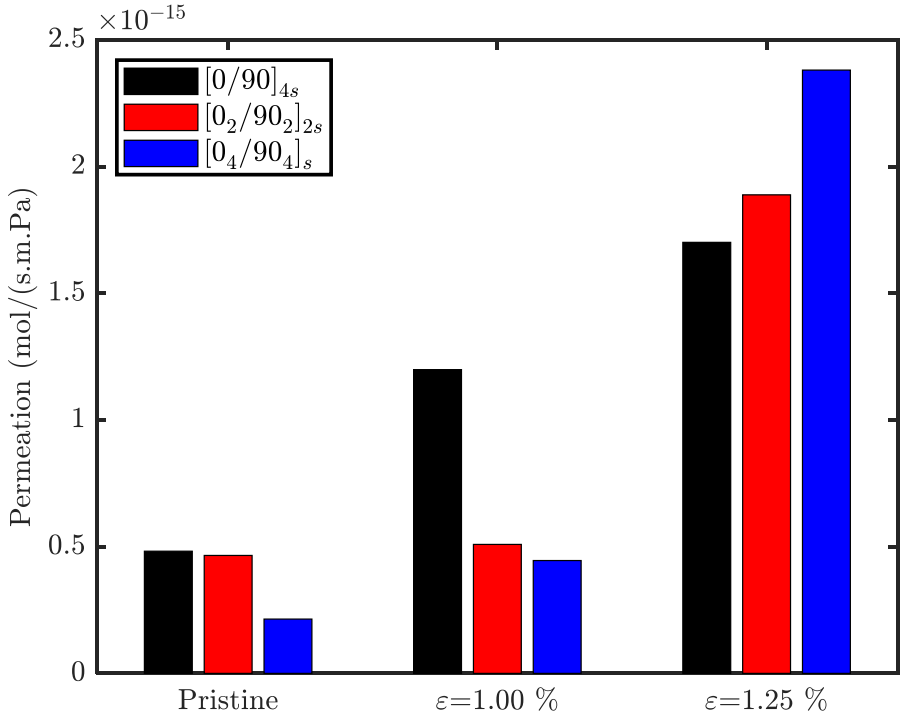
- All samples **have been analyzed by DSC,**
- Observation of **a large proportion of γ phases, meaning that equilibrium was not fully reached,**
- Clearly **more crystallinity in thick samples.**

Permeability of thin-plies based composites

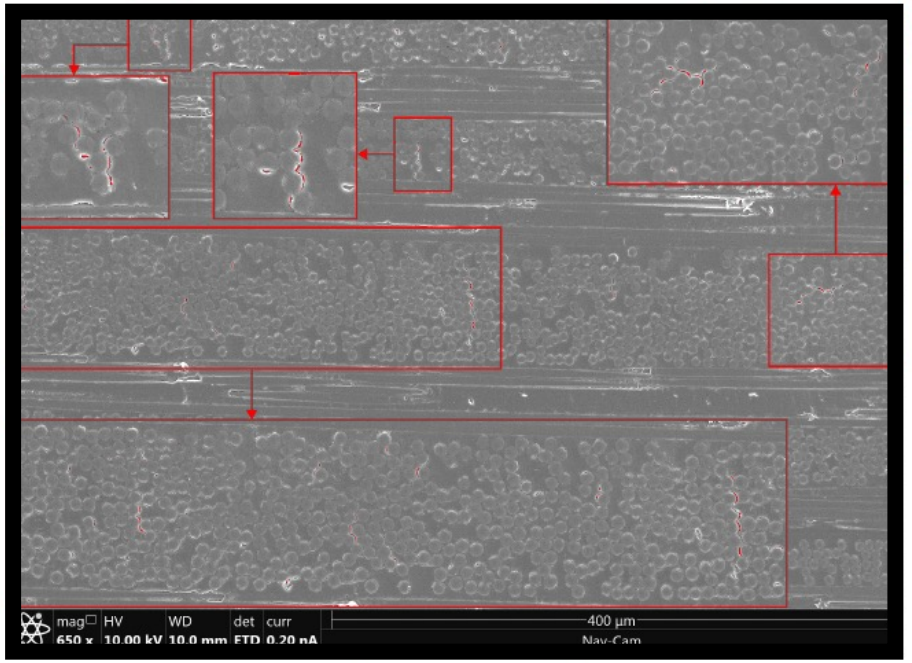


Point 2: thicker layers result in lower permeability (initially)

- Permeability is **decreasing quickly with crystallinity,**
- From a strict "permeability" criterion, **thicker layers are better in the pristine state due to high crystallinity**



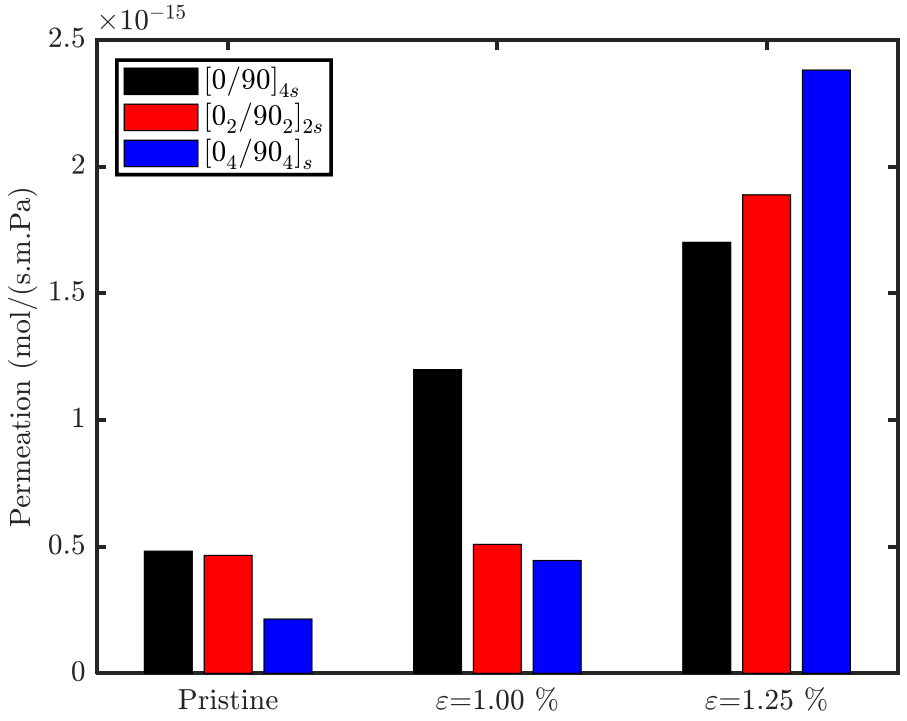
Permeability of thin-plies based composites

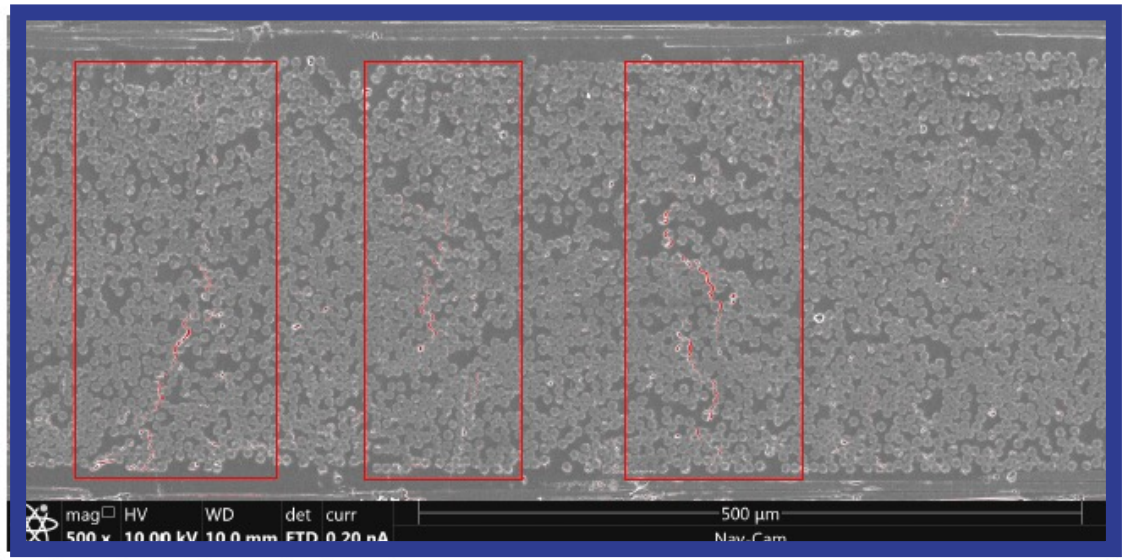


Point 3: think layers will however remain competitive at higher strains

Permeability of thin-plies based composites

Point 3: think layers will however remain competitive at higher strains



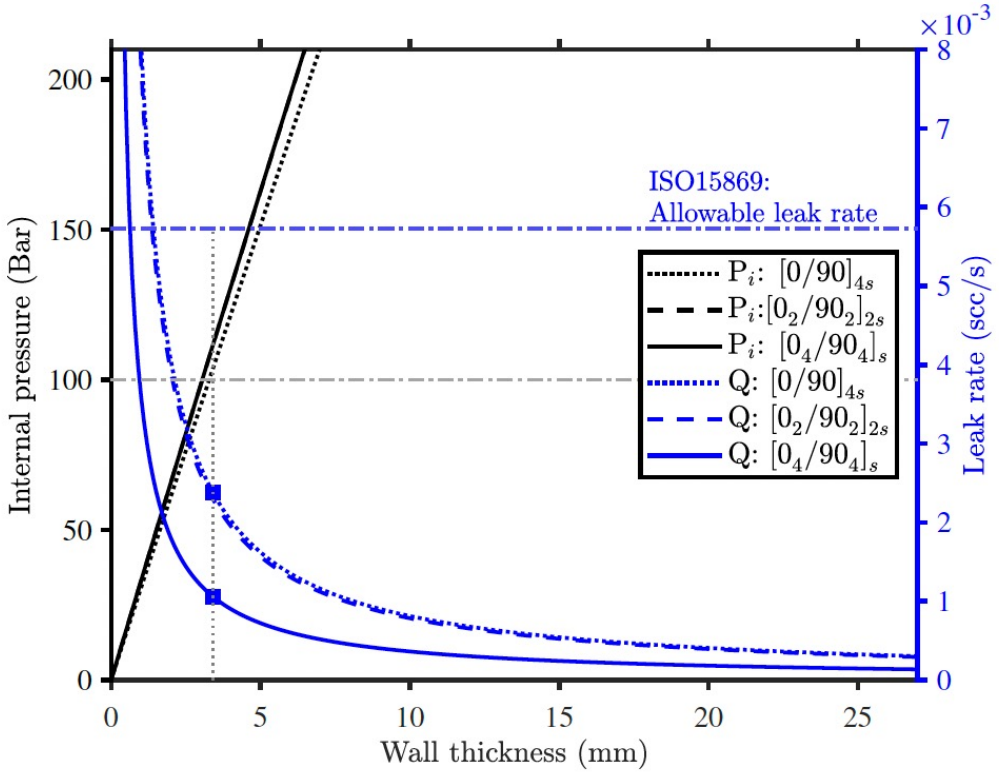


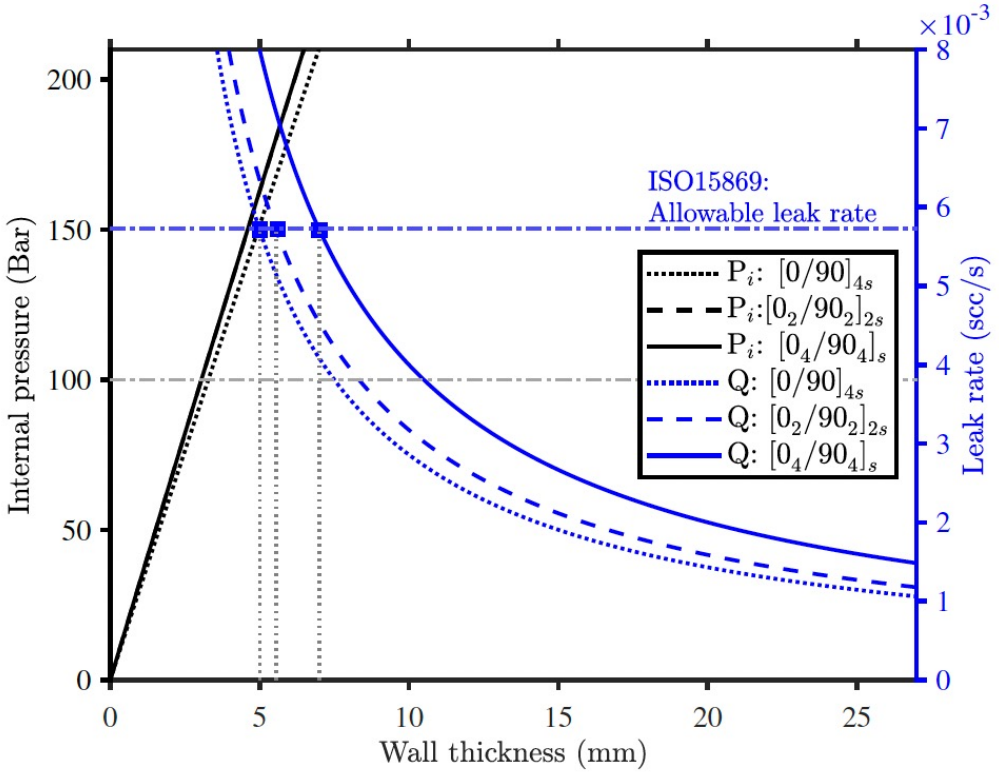
(b) $[0/90]_{4s}$ at 1.25 % strain.

Limited cracking at higher strain with thin plies, as expected

Permeability of thin-plies based composites

Point 3: think layers will however remain competitive at higher strains

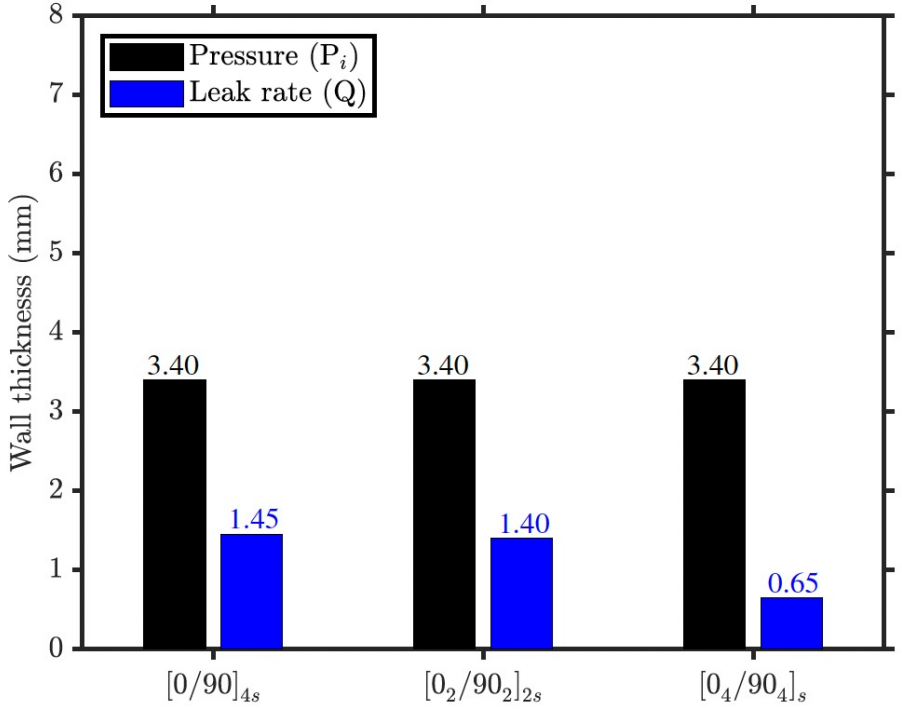




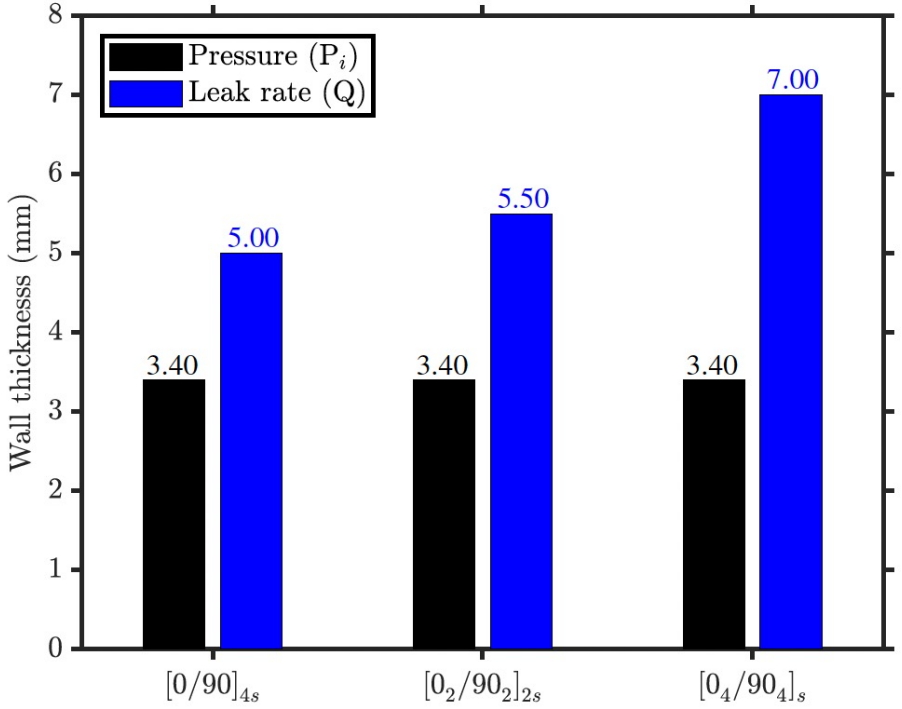
(f) $[0_4/90_4]_s$ at 1.25 % strain.

Even based on thin-plies, **thick layers are more prone to percolating damage.**

Permeability of thin-plies based composites
Point 4: design of a 100 bars thin-plies tank



(a) P_i and Q as a function of t_w (pristine).



(b) P_i and Q as a function of t_w (compromised).

Permeability of thin-plies based composites
Point 4: design of a 100 bars thin-plies tank

(c) Required t_w for each criteria (pristine).

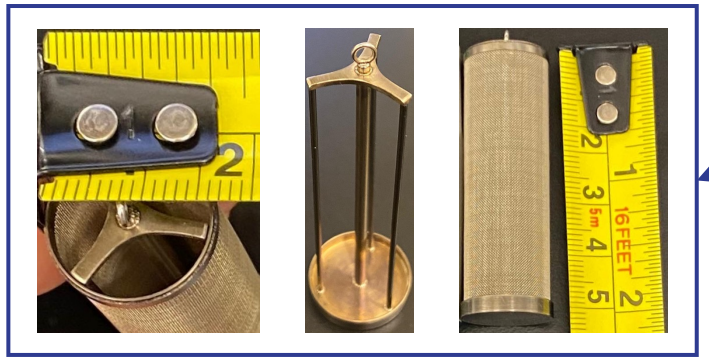
(d) Required t_w for each criteria (compromised).

Quick math about the total wall thickness:

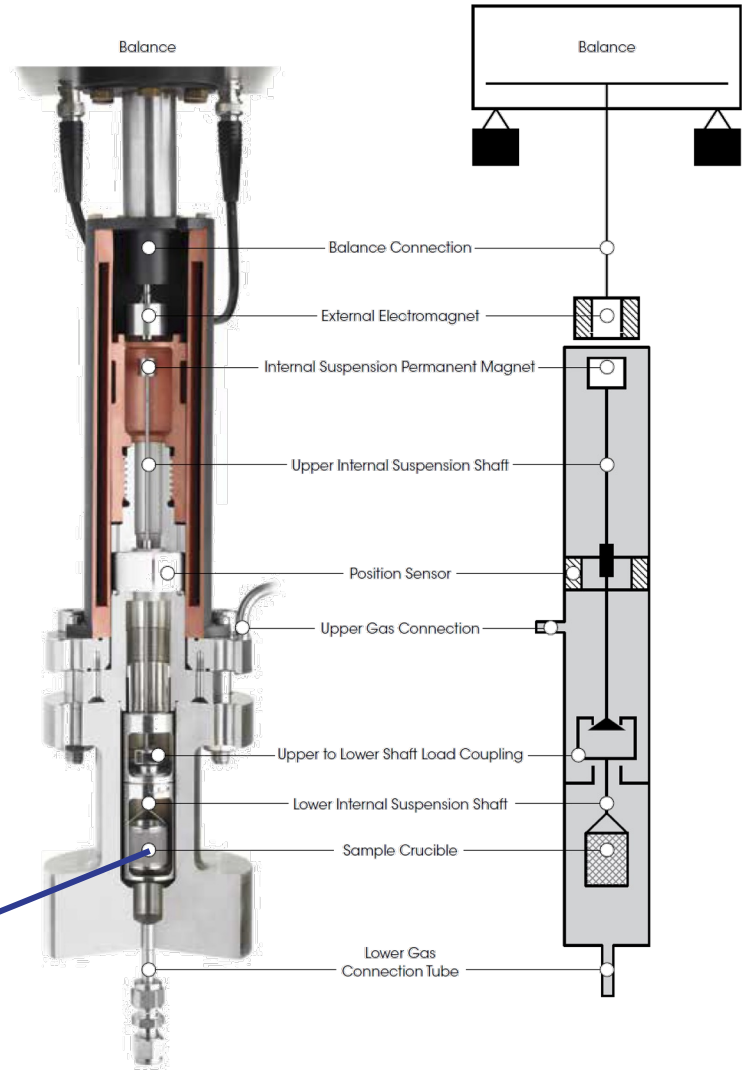
Type IV: ˜8 mm, Type V ”Thick layers Th Pl”: 7 mm, Type 5 “Thin layer Th”: 5-6 mm

Conclusions

- **Moving to type V tank** requires to bring **more stability to the inner lay**er (load-bearing liner) and to avoid permeation through the wall,
- Thin-plies thermoplastics are ideal to **mitigate catastrophic cracking-induced leakage,**
- Processing conditions and lay-up **influence the crystallinity and by then the initial permeability,**
- This-plies used as “thin-plies” reduce the permeability under loading train, showing potential for wall-reduction.



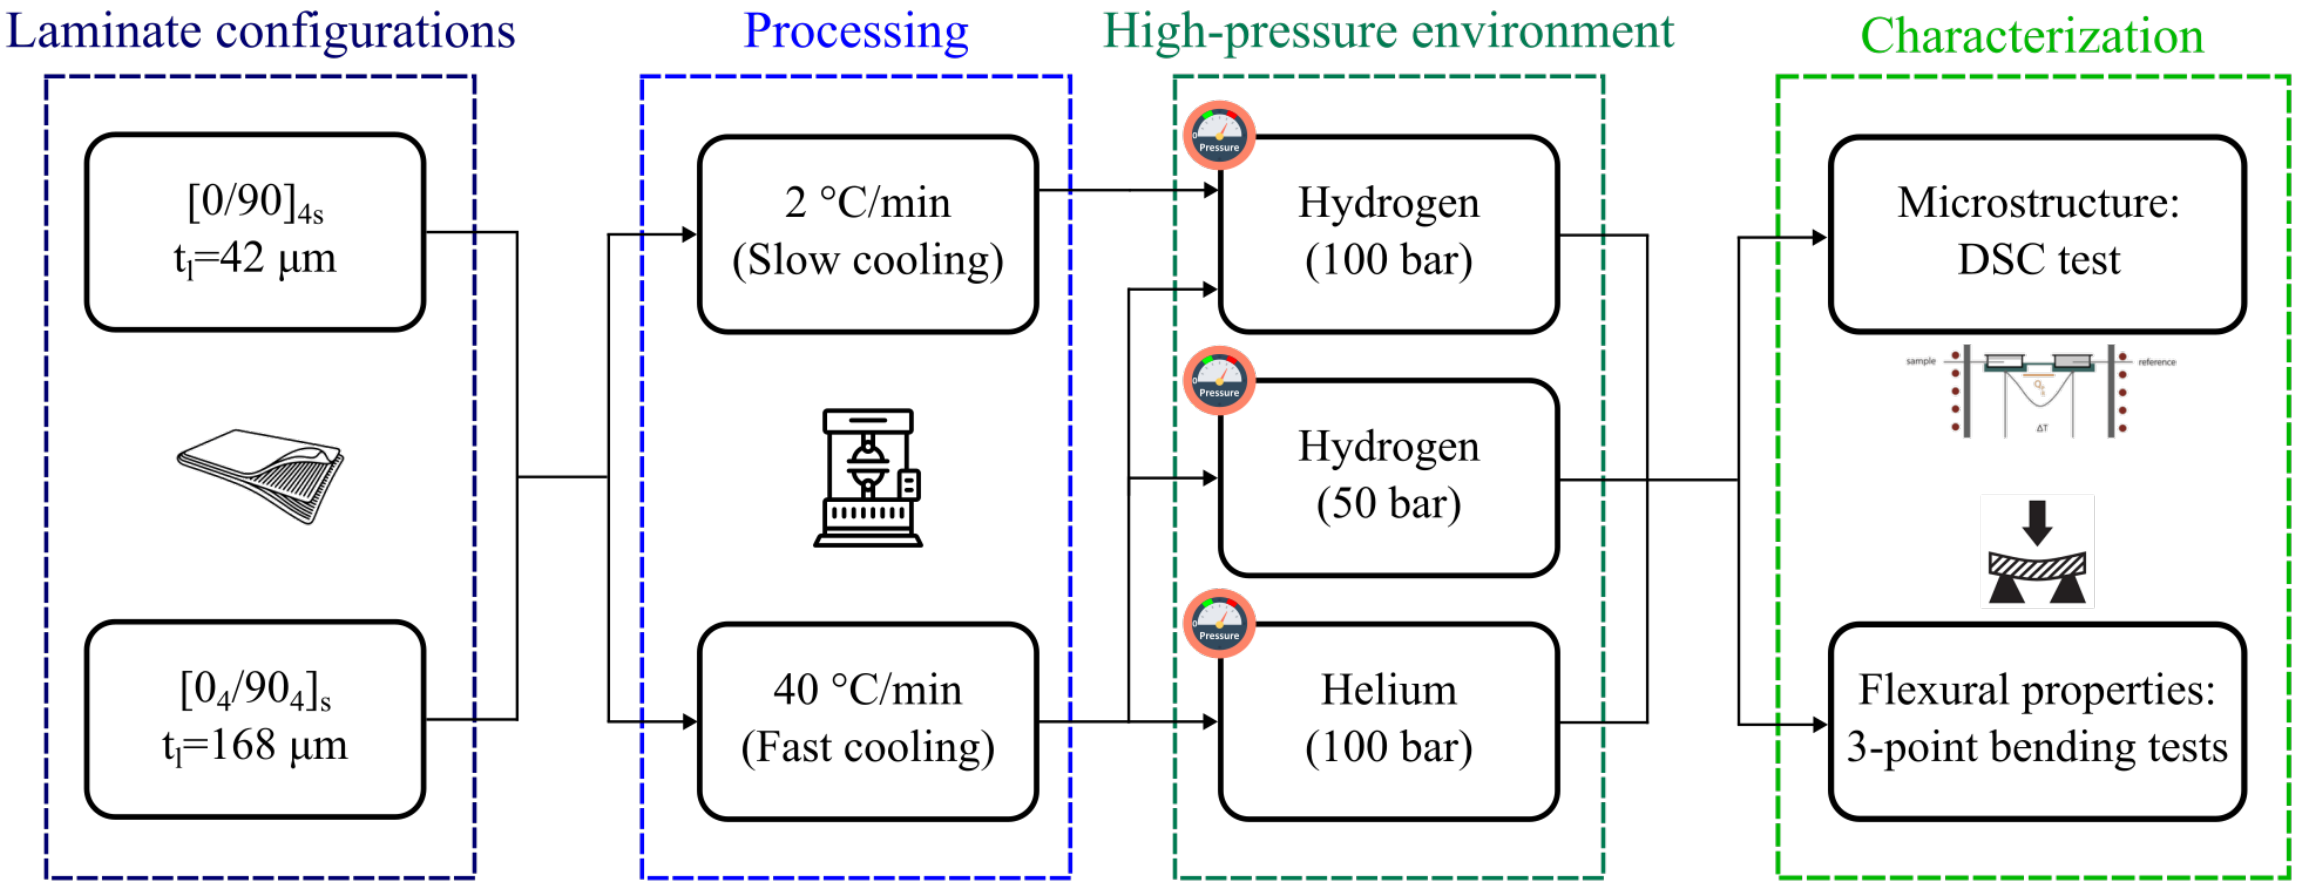
IsoSORP: Gravimetric Gas Sorption Analysis with Magnetic Suspension Balance



Mechanics of Composites for Energy and Mobility

Magnetic Suspension Balance

- High-resolution mass determination under extreme conditions
  - At high pressures: < 700 bars
  - Temperature: -196 °C (77 K) – +1550 °C
  - In corrosive environments
  - Sample weight: < 25 g (10 µg balance resolution)



- Main application area:
  - Measuring gas sorption on porous particles for gas separation and storage
    - ➢ CO_2, H_2, CH_4

Expert Knowledge Intelligentized in CompositesAI

how to compute the upper bound of young's modulus for a two-phase isotropic composite

CompositesAI

To compute the upper bound of Young's modulus for a two-phase isotropic composite, you generally use the Voigt rule of mixtures. The Voigt upper bound assumes isostrain conditions (i.e., the strain is uniform across the phases). For constituents with equal Poisson's ratios ($\nu_f = \nu_m$), the upper bound is given by:

$$E_V^* = V_f E_f + V_m E_m$$

where:

- E_f and E_m are the Young's moduli of the fiber and matrix (the two phases),
- V_f and V_m are their respective volume fractions.

However, if the two isotropic phases have different Poisson's ratios ($\nu_f \neq \nu_m$), the simple rule above is not the strict upper bound. In this case, the upper bound is obtained by extracting Young's modulus from the effective stiffness matrix calculated according to the Voigt rule, incorporating both moduli and Poisson's ratios. The result is always greater than the simple mixture rule due to the influence of differing Poisson's ratios.

Thus, for most accurate results, when $\nu_f \neq \nu_m$, you should compute the effective stiffness matrix using the Voigt approach and then extract the effective Young's modulus from that matrix, rather than relying solely on the simple mixture formula

  - Live on CompositesAI (AC)

for a unidirectional fiber reinforced composites, I would like to know G13 and G23, do you have a tool to help me compute it?

CompositesAI

Yes, I have a specialized tool that can compute the shear moduli G_{13} and G_{23} (as well as other engineering constants) for unidirectional fiber-reinforced composites. This tool requires the following inputs:

Fiber and matrix elastic properties (E, ν or full set if anisotropic)
Fiber volume fraction
Packing arrangement (e.g., hexagonal, square)

If you provide:
Fiber modulus (E_f) and Poisson's ratio (ν_f)
Matrix modulus (E_m) and Poisson's ratio (ν_m)
Fiber volume fraction (V_f)
Packing type (default is hexagonal if not specified)

I can obtain G_{13} and G_{23} for your system. Please supply the above inputs or confirm if you want to use prior examples.

isotropic fiber with E=300 GPa, nu=0.3; isotropic matrix with E=20 GPa, nu =0.4, hexagonal, Vf=68%

CompositesAI

View Result from **homogenize_elastic_constants**

For a unidirectional fiber-reinforced composite with isotropic fibers ($E_f = 300\,\text{GPa},\ \nu_f = 0.3$), isotropic matrix ($E_m = 20\,\text{GPa},\ \nu_m = 0.4$), hexagonal packing, and a fiber volume fraction of 68%, the calculated shear moduli are:

$G_{13} = 28.86$ GPa
$G_{23} = 31.58$ GPa

These values are computed using physics-based homogenization methods appropriate for your specified microstructure and constituent properties.

Your numbers are a bit high. Try Ef = 231 GPa, Poisson's ratio of the fiber is 0.35. Em = 4 GPa, Poisson's ratio of matrix is 0.3.

CompositesAI

View Result from **homogenize_elastic_constants**

For a unidirectional fiber-reinforced composite with the following properties:

Isotropic fiber: $E_f = 231\,\text{GPa},\ \nu_f = 0.35$
Isotropic matrix: $E_m = 4\,\text{GPa},\ \nu_m = 0.3$
Hexagonal packing, fiber volume fraction $V_f = 68\%$

The computed shear moduli are:

$G_{13} = 7.50\,\text{GPa}$
$G_{23} = 7.21\,\text{GPa}$

These values reflect a physically realistic shear response for your specified composite system.

PROCESS MONITORING FOR DEFECT CONTROL – FROM RTM TO SANDWICH PANEL CO-CURE

Steven Nutt, M. Anders, and T. Centea

M.C. Gill Composites Center, University of Southern California
3651 Watt Way-VHE-406, Los Angeles, CA, 90089, USA
Email: nutt@usc.edu, web page: https://composites.usc.edu

Keywords: Process monitoring, Defects, RTM, Co-cure

ABSTRACT

Insights into process phenomena provide understanding necessary to eliminate manufacturing defects, yet process hardware (autoclaves, moulds, and tools), renders these phenomena opaque. At USC, we have developed instrumented testbeds that replicate common process conditions and afford real-time observation and insights into key phenomena leading to defects. In one example, a lab-scale RTM mould features a transparent window, allowing observation of mould filling and porosity evolution. In a second example, a pressurized cavity replicates autoclave conditions for co-cure of honeycomb panels, providing real-time observations of bond-line formation at core-skin junctions. Such observations were use to support the construction and validation of physics-based process models for co-cure. The combination of conventional systematic characterization of resin properties with the instrumented testbeds provide a method for process optimization, understanding of defect formation, and a basis for developing strategies for defect reduction.

1 INTRODUCTION

Manufacturing defects cause variations in performance levels that lead to knockdowns in property levels used for design. The opacity of production hardware – autoclaves, tooling, and moulds – prevent direct observation of defect formation. As a result, attempts to understand defect origins rely primarily on "post-mortem" analysis of polished sections, leaving ample room for speculation and imagination, but providing scant guidance to adjust process parameters. Instrumented testbeds provide useful insights into defect formation mechanisms, and when combined with resin characterization tools – primarily thermal analysis and rheometry – constitute a framework for analyzing and mitigating defects.

In this work, two case studies are presented that illustrate a methodology that relies on conventional materials characterization complemented by data and observations acquired from lab-scale testbeds that replicate manufacturing conditions. The thermal analysis and rheological data can be presented alongside video observations on a synchronized time axis. Thus, the physical state of the resin (degree of cure, viscosity) can be correlated with flow phenomena, void nucleation, and other phenomena. The combined use of conventional and customized analytical tools provide rich datasets and useful insights into how, when, and where defects arise. These insights can be used to develop and validate process models, and to guide parametric adjustments to reduce/eliminate defects.

The first case study involves an effort to develop a benoxazine-epoxy formulation for liquid molding, specifically for RTM[1]. The formulation included a solvent(s), and increasing the risk of void formation if volatiles left the solution during molding. A lab-scale RTM mold was designed and built to monitor the mold filling and curing processes directly, and the data acquired were combined with the use of a suite of conventional characterization tools, and led to specific recommendations for mitigating process-induced defects. The second case study focuses on co-cure of honeycomb sandwich panels, and attempts to develop physics-based models.[2] The name of the process derives from the simultaneous curing of facesheets and the film adhesive used to attach the core. Despite the appeal of a one-step process, the process is difficult to manage, and the facesheets prevent observation of bondline formation. A customized testbed was designed and built that afforded direct observation of the bondline during co-

cure under autoclave conditions.[3] The project led to process models for co-cure and validation of predictions.

2 EXPERIMENT

The lab-scale RTM tool built for Case Study 1 (CS1) is shown in Figure 1 and described in detail in reference [1]. The main body of the mold was an anodized aluminum block containing inlet and outlet ports with ‘‘line injection” grooves used to generate a one-dimensional flow front. A ‘‘picture frame” plate with a rectangular cavity was placed against the main body to define the thickness (3.2 mm) and in-plane dimensions (76 × 127 mm) of the part. The second tool face was a 20 mm thick tempered glass plate, rated for pressures up to 1200 kPa. This glass plate formed a rigid window that afforded direct *in situ* observation of in-mold phenomena, including air evacuation, preform saturation during injection, and the time and location of any subsequent void formation.

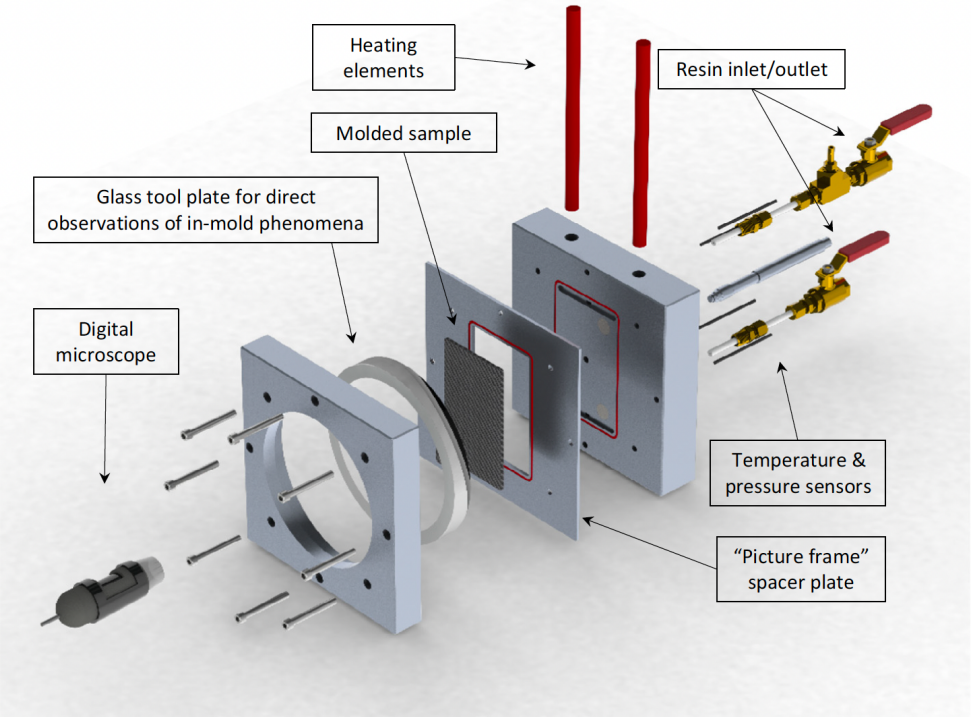

Figure 1: Expanded view of lab-scale RTM tool.[1]

For Case Study 2 (CS2), attention focused on co-cure of sandwich panels under autoclave conditions. The elements to be assembled included a honeycomb core (Nomex), a toughened epoxy film adhesive (Loctite EA 9658 AERO 060UNS, Henkel Corp.), and CF-epoxy prepreg plies (Syensco 5320-1 or Hexcel 8552S). To view phenomena associated with bond-line formation, a cell was designed that replicated autoclave pressure and temperature while affording direct observation of the bondline during co-cure. A half-panel sample was used (one face sheet, one adhesive film, and a core of half-thickness) in a testbed shown in Figure 2. Note that the glass viewport on the lower side allowed video observation of film adhesive redistribution during co-cure, a process called reticulation, that was intended to result in fillet formation at cell wall-facesheet junctions (adhesive remaining between cell walls amounted to parasitic weight).

The reticulation process – which can be performed in several ways [11,31] – results in adhesive located only along the edges of the honeycomb cell walls, with an opening in the film at the center of each cell. Fig. 4 shows the stages of adhesive reticulation. First, the adhesive film was placed onto the top side of the honeycomb core and manually perforated in the center of each honeycomb cell using a ~1mm diameter needle. Then, heated air was blown over the surface of the film using a handheld hot-air gun. As the film softened under the applied heat, surface tension caused the holes to

widen, reshaping the film into an adhesive bead along the edges of the cell walls. Temperatures were monitored using a thermocouple and did not exceed 70 °ΔC. Reticulation was completed in < 3 min, ensuring that the process did not advance the cure of the adhesive.

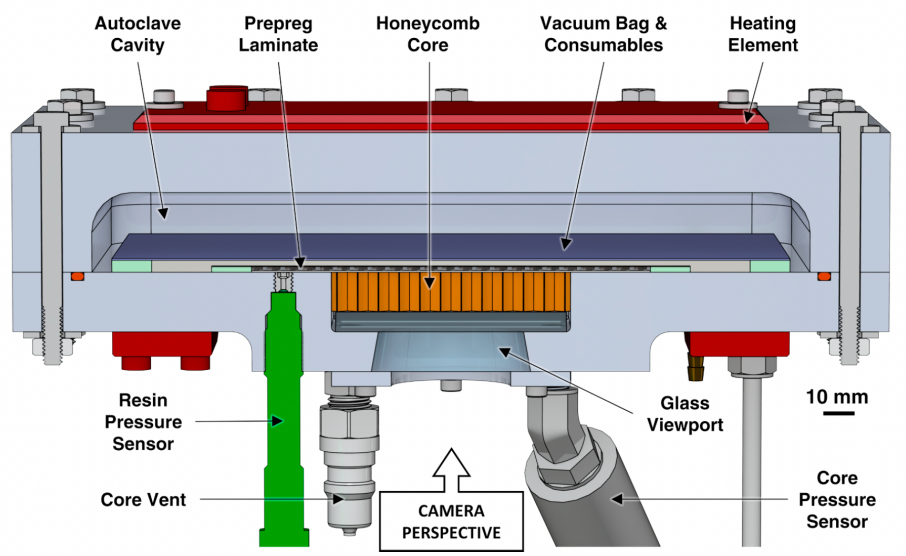

Figure 2: Section view of co-cure fixture with sample and consumables.[3]

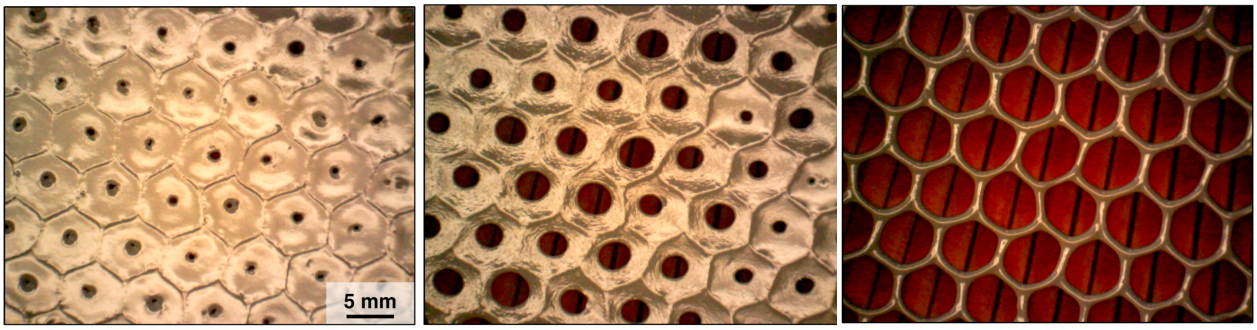

Figure 3. Stages of adhesive reticulation process. Left: film applied to core and perforated. Center: Film softening and perforations expanding due to surface tension. Right: Process completed – adhesive forms a fillet along edges of cell walls.

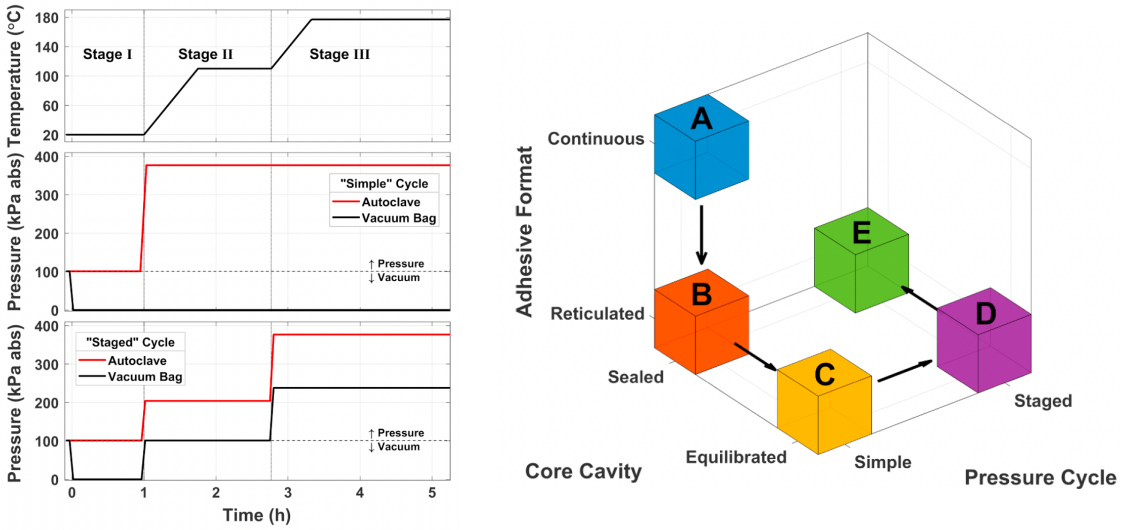

Figure 4. Temperature cycle used for all tests (top left), and the two cycles used for autoclave and vacuum bag pressures. On right, diagram of Cases A-E, where the three axes denote the test variables.

The process parameters for CS 2 are summarized in Figure 4a. The temperature cycle resembles the manufacturer-recommended cure cycle for the prepreg. The three temperature stages – RT, 110C, and 177C, are labeled Stages I, II, and III. Three parameters were varied between cases – the initial adhesive format, the core breathability, and the imposed P_{auto} and P_{bag} pressure cycles. The five test cases are presented as a cube diagram in Figure 5a. Each of the three axes corresponds to one of the varied parameters. (1) The adhesive was applied either as a continuous film or reticulate onto the HC core. (2) The core cavity was either sealed or connected via the "core vent" to equilibrate the gas pressure in the core cavity with that of the vacuum bag. (3) Autoclave and vacuum bag pressures were applied according to either of two cycles – "simple" or "staged" – as shown in Fig. 4a.

5 RESULTS

For CS1, neat resin BOX-e samples were produced without entrapped air during injection. The test results are summarized in Figure **5** as a process map relating cure temperature, imposed mold pressure, and defect growth. Each point represents one sample. Temperature and pressure combinations that resulted in the generation of voids are shown in red, while samples that did not grow voids are shown in blue. In cases when voids did develop, they nucleated on the hottest side of the mold cavity (the tool side that contains the heating elements), grew rapidly, sometimes detached and floated upwards, and eventually were fixed in place when the resin gelled. Application of pressures of 200kPa were sufficient to suppress voids in molded plates of neat-resin.

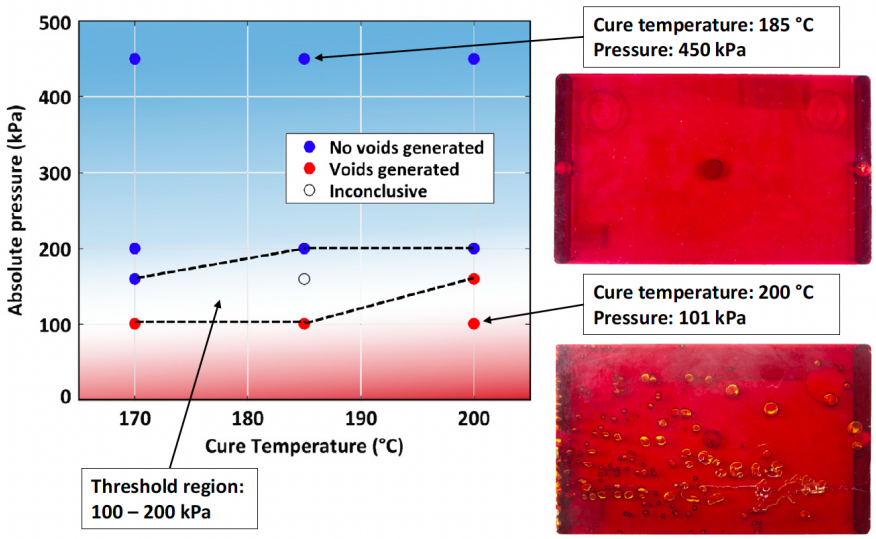

Figure 5: Temperature-pressure map of neat-resin tests. Red (on graph) indicates conditions that lead to void growth, while blue corresponds to conditions that suppress void growth. Points correspond to individual tests and background shading is used to highlight the general trend.

While applied pressures >200kPa sufficed to prevent bulk porosity, surface porosity developed, typically on the cooler side of the mold cavity (with the glass plate). The window in the mold afforded visual confirmation that, initially after injection, the surfaces of all samples were bubble-free. However, porosity developed on the window side during high-temperature dwells late in the cure cycle. The aluminum tool side (which was slightly hotter, since it contained the heating elements) had effectively no defects for all samples, and micrographs of polished cross-sections confirmed that internal porosity was also negligibly low. For this reason, only the quality of the cold sides is considered below.

In situ data and porosity formation mechanisms are revealed from the measured sensor data for a composite sample, shown in Figure 6, for formulation F1 cured under Cycle A, which resulted in 26% surface porosity. The temperature graph consists of the controller temperature (black) and the temperatures of the hot and cold sides of the mold cavity (in red and blue, respectively). The hot side,

being closest to the heating elements, followed the control temperature to within 1°C, while the cold side lagged by roughly 4 min (or, equivalently, 8°C) during ramps and stabilized at 4°C below the hot side at steady-state conditions during high-temperature dwell.

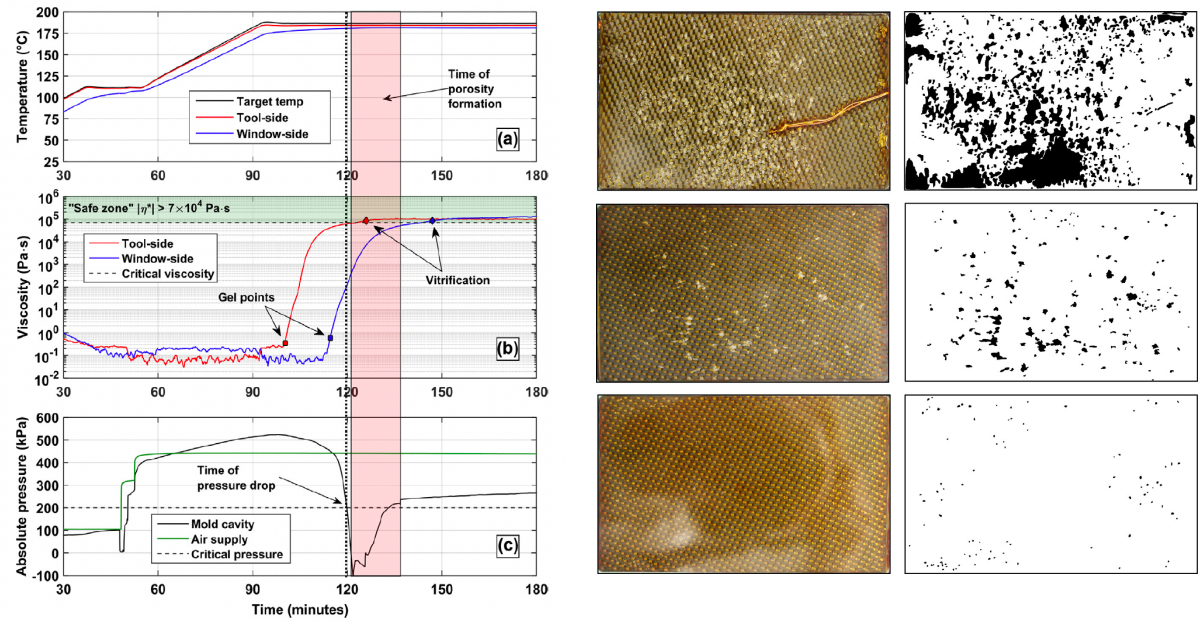

Figure 6: Temperature, viscosity, and pressure for formulation F1, Cycle A. Surface porosity measurements are shown at right, where the top row is formulation F1, Cycle A, the middle row is F2, Cycle A, and bottom row is F2, Cycle B. The thermocouple is visible in the first image.

Surface porosity occurred because of the relative timing of the pressure drop and the increasing viscosity at the coldest location of the mold cavity. The pressure drop occurred when the cold-side viscosity was in the vicinity of 100 Pa·s, which is past the gel point, but far below the critical value of 7 × 104 Pa·s that has been shown to suppress volatile release. The hot-side, meanwhile, had already reached a high viscosity level, and therefore did not off-gas. Once the mold cavity pressure decreased below the critical value, voids began to form at the cold surface. The period of void formation was clearly observable through the window in the mold, and is indicated on Fig. 6a.

Fig. 7 shows a series of images recorded in situ for the same sample, beginning with an initially defect-free surface just before the pressure drop. Almost immediately after the pressure fell below the critical value, voids began to form and continued to grow for 15 min. All void growth finally ceased as the cold-side viscosity reached the ‘‘safe” zone, where the resin was nearly vitrified. In cases of extreme porosity such as in Fig. 7, much of the surface separates from the tool face, clearly manifest through the window because of the change in refractive index (compare Fig. 7c and d), and accompanied by a concurrent spike/drop in measured cavity pressure (see Fig. 6 at 136 min). The volatile gasses are less dense than the liquid resin, so their release at the cold surface relieves the tensile stresses generated by cure shrinkage. This phenomenon can be seen in Fig. 6 by the gradual recovery in pressure during the time of porosity formation. Note that since the pressure drop occurred when most of the resin was already approaching high viscosities (and due to the presence of the fibrous preform), the total volume of volatiles released was much less than for the ambient-pressure neat resin samples (which began to grow bubbles earlier, during the ramp to the high-temperature dwell).

In summary, the tendency of this resin to exhibit surface porosity in RTM processing stems from a combination of two factors: significant potential for volatile release during cure, and rapid, highly temperature-dependent gelation, which increases the material sensitivity to in-mold temperature gradients. Additionally, the distribution of the porosity – concentrated on the cold surface – is determined by the direction of the temperature gradient. Additional information regarding process monitoring with the RTM testbed is included in reference [1].

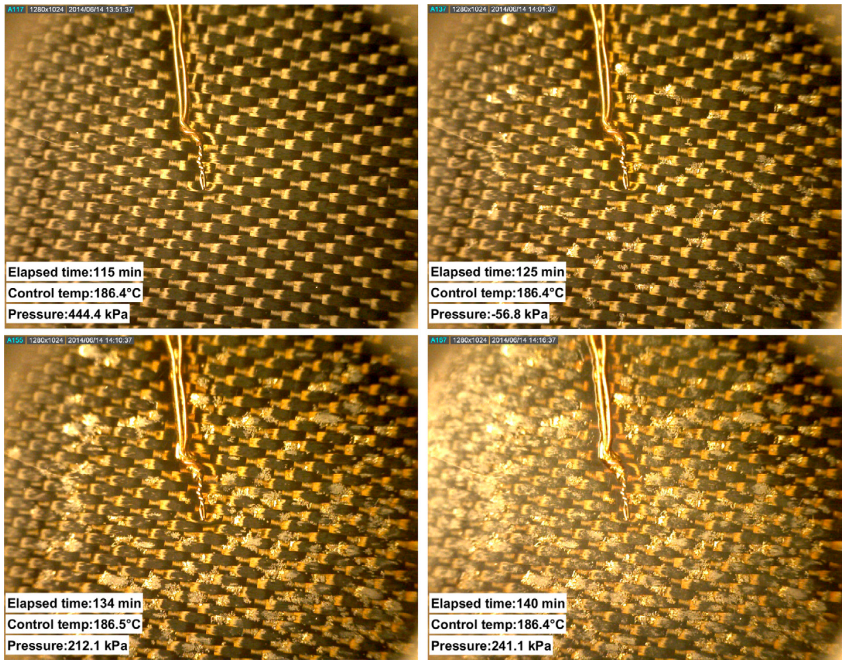

Figure 7: Formation of surface porosity recorded *in situ* for the composite sample with formulation F1, Cycle A. Time labels correspond to the data in Fig. 6. The thermocouple used to measure the window-side temperature history is visible in the frame.

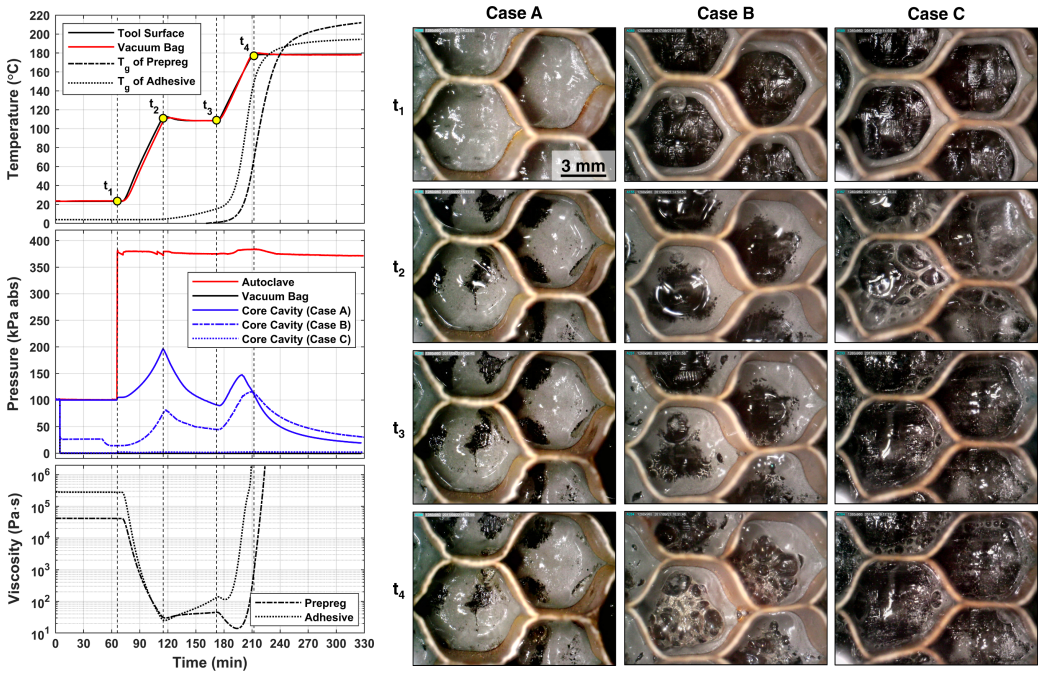

Figure 8: (a) Temperature data for the three cases using the "simple" pressure cycle (A, B, and C). Models for the glass transition temperature and viscosity (for both the prepreg resin and the adhesive) are shown, computed from the temperature history recorded outside the vacuum bag, near the center of the laminate. (b) *In situ* images of the bond-line during processing Columns correspond to Cases A, B, and C (left to right), and rows correspond to the times of interest t_1 though t_4 indicated in (a).

CS2 entails the use of a similar approach to monitor defect evolution during co-cure of sandwich panels in an autoclave, with the expectation that the insights would provide a basis for a process model. Measured data for Cases A, B and C is shown in Fig. 8, and *in situ* images from these tests are shown in Fig. 8b. For Cases D and E, measured data and corresponding in situ images are shown in Figs. 9a and 9b, respectively. To fully appreciate the dynamic behavior captured in the visual data, readers are encouraged to view the timelapse videos from which the images in Figs. 8 and 9 were taken.[1]

Case A. Figure 8(a) shows the measured temperatures (top) and pressures (middle) for Case A, which featured a continuous adhesive film, a sealed core, and the simple pressure cycle. Models were used to compute the glass transition temperature T_g of the prepreg and adhesive, as well as the viscosity μ profiles (bottom graph). The indicated times of interest t1 through t4 correspond to the images in the left column of Fig. 8(b).

Upon application of vacuum in the bag, P_{core} remained unchanged, and the continuous adhesive film acted as a barrier for gas transport. Negligible change was observed visually during Stage I, although flow occurred as the temperature was raised between t_1 and t_2. First, prepreg resin (which appears clear, while the aluminum-powder-filled adhesive is gray) pushed through the adhesive film in a grid-like pattern, clearly emanating from the "pinholes" between the fiber tows in the fabric weave. Additionally, the mixture of adhesive and prepreg resin migrated toward the cell walls, forming fillets. During this period, P_{core} increased to ~200 kPa due to ideal gas law expansion (and likely some volatile generation). During the intermediate temperature dwell, little change was observed, and P_{core} ecayed due to continual application of vacuum to the bag.

During the second temperature ramp (between t_3 and t_4), the adhesive fillets appeared to "inflate" and bubbles appeared in the locations where the prepreg resin had created discontinuities in the film adhesive. After t_4, all motion abruptly ceased, as the adhesive had gelled. Note that during the second temperature ramp, the adhesive viscosity was already rapidly increasing, whereas the prepreg resin was just reaching its minimum viscosity. Thus, during this ramp, bubbles could still nucleate and grow within the prepreg resin. However, they became trapped by the adhesive film. The section view of the sample confirms that the fillet "inflation" was due to the growth and entrapment of bubbles between the adhesive film and the first ply of prepreg. P_{core} followed a similar trend during Stage III as in Stage II, first increasing during the ramp (although to a lesser extent), and decaying during the dwell.

Case A showed that the continuous adhesive film was disrupted by the behavior of the prepreg resin. Specifically, the mismatch in gel times was such that, during the second temperature ramp, the prepreg resin formed bubbles that distorted – and became trapped by – the rapidly gelling adhesive layer. To prevent the adhesive from acting as a barrier for gas transport, the film was reticulated onto the core in Case B.

Case B. Figure 8(a) shows P_{core} (all other temperatures and pressures were identical to Case A). The core evacuation during Stage I, in the absence of a continuous adhesive film, depended on the prepreg permeability. Initial evacuation was rapid, but halted as the skin compacted (analogous to the behavior observed by Kratz [20]). A new pathway for gas transport formed after ~45 min (the delay caused by gradual displacement of the highly viscous prepreg resin), allowing core evacuation to continue. During the remainder of the cycle, P_{core} followed a similar trend as in Case A, although shifted downward due to the lower initial pressure upon heating.

In Fig. 8 (Case B, t_1) the reticulated adhesive is visible along the edges of the cell walls, and the first prepreg ply is visible in the center of each cell. During the room-temperature vacuum hold, minor bubble formation was observed in the adhesive and prepreg resin. As the temperature was increased between t_1 and t_2, the adhesive fillets formed, and a mixture of prepreg resin and bubbles could be seen pushing out from the pinholes in the fabric weave. By t_2, most of the bubbles had disappeared, leaving a layer of resin at the skin/core interface and creating a continuous meniscus with the adhesive. During the dwell between t_2 and $t3$, bubbles gradually reappeared in the prepreg resin. During the final temperature ramp, the bubbles grew, yet none burst before resin gelation, resulting in a large cluster of bubbles at the center of each cell.

Contrasting this behavior to Case A reveals that the bubbles in the bond-line in Case A were not solely due to the adhesive acting as a barrier, but also a consequence of the core pressure. Even

without the barrier (i.e., Case B), Pcore was low enough to allow bubble growth within the resin at the skin/core interface, yet not so low that the bubbles burst. Considering this insight, the modification for Case C was chosen to afford improved control over P_{core}.

Case C. Case C simulated the conditions of a vented sandwich structure – in which P_{core} can equilibrate with P_{bag} – by connecting the core vent to the vacuum line. During the room temperature vacuum hold, thin-walled bubbles grew from the pinholes in the fabric and burst, indicating that air initially trapped between the prepreg plies was evacuating into the core. Previously, in Cases A and B, vacuum was only applied on the upper surface of the skin, so air in the core had to travel upwards through the skin to escape. Conversely, in Case C, the core was evacuated directly and simultaneously with the vacuum bag, so air was not driven through the skin, and air initially entrapped within the skin could evacuate in either direction (up through the perforations in the release film, or down into the core), along the path of least resistance.

Upon initial heating, the vacuum in the core pulled a foamy mixture of gas and resin out from the fabric pinholes. Towards the end of the first ramp (see Fig. 8, t_2), vigorous frothing was observed, with large bubbles growing and bursting repeatedly. Bubble formation slowed during the intermediate-temperature dwell, but, by that point, much of the adhesive had been spattered onto the cell walls, leaving little at the skin/core interface to form fillets (see Fig. 8, t_3). Small bubbles remained along the edges of the cell walls against the skin, which grew during the second temperature ramp and became fixed at gelation (t_4). The section view of this sample provides a complementary perspective of the small, void-filled fillets and the adhesive coating the cell walls.

Case D. The staged pressure cycle used for Case D was designed to avoid the observed defect formation phenomena, by applying positive pressure within the vacuum bag to suppress the release of gasses that could not be evacuated prior to gelation. Stage I was identical to Case C: reticulated adhesive and full vacuum in the bag and core, to maximize air removal from the skin while the resin and adhesive were still at high viscosity ("equilibrated" P_{core} in Case D matched P_{bag} exactly (Fig. 9). During Stage II, to avoid the fillet disruption that occurred in Case C and duplicate the undisrupted flow seen in Case B, the vacuum bag was vented with N_2 to ~100 kPa. To prevent excess resin exuding toward the skin/core interface, P_{auto} was increased to only 205 kPa, maintaining the same compaction pressure ($P_{auto} - P_{bag}$) as in Stage I. Finally, in Stage III, recall that during the second temperature ramp in Cases A and B, a P_{core} range of ~50–150 kPa caused bubbles to grow yet remain sessile until gelation. In Case C, vacuum pressure in the core caused bubbles to burst, but this also caused severe fillet disruption. Therefore, in Case D, the opposite approach was used to prevent defects in Stage III: the application of positive pressure to suppress bubble formation and growth. First, P_{auto} was increased to 377 kPa to maintain compaction on the sample, and then P_{bag} was increased to 239 kPa.

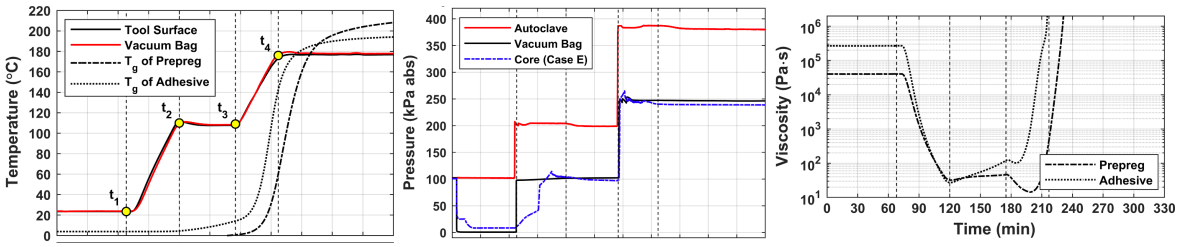

Figure 9: Temperature and pressure data for the cases D and E, using the "staged" pressure cycle. Models for T_g and viscosity (for prepreg resin and adhesive) are computed from temperature history.

The images in the left column of Fig. 10 correspond to the times indicated on Fig. 9. During the initial vacuum hold, thin-walled bubbles similar to Case C appeared and burst, indicating air evacuation from the skin. During the temperature ramp and dwell of Stage II, fillet formation occurred, the flow undisrupted by bubbles (similar to Case B t_2 but without the bubble formation seen at ~50 kPa in Case B t_3). The image captured at t_3 for Case D (Fig. 10) was taken in the brief time after P_{auto} was increased, but before P_{core} was increased. Momentarily, resin containing small bubbles exuded from the fabric pinholes due to the increased compaction pressure. However, once the bag/core

pressure was set to the final value, the excess resin receded into the skin, and the bubbles disappeared. The equal gas pressures on the upper and lower boundaries of the skin (i.e. P_{bag} and P_{core}, respectively) resulted in a hydrostatic condition in which no gas was driven through the skin. Furthermore, the gas pressure in the core/bag imposed a lower bound for the resin pressure in the skin, which prevented the formation of bubbles. The resin and adhesive remained effectively motionless during the second temperature ramp and until gelation (t_4).

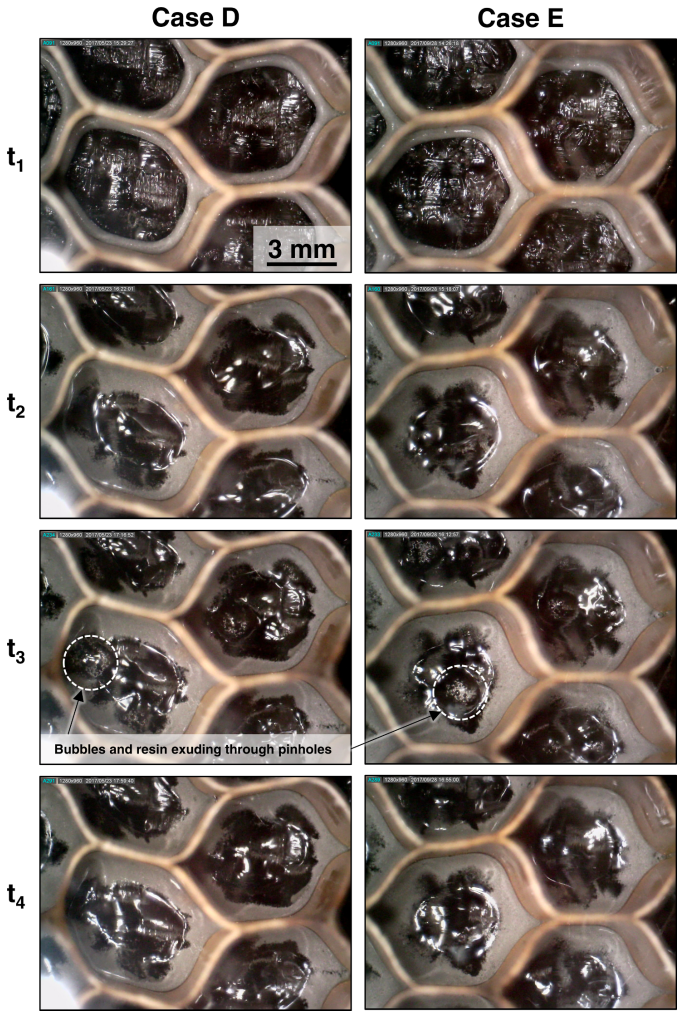

Figure 10: In situ images of the bond-line during processing. Columns correspond to Cases D and E (left to right), and rows (top to bottom) correspond to the times t_1 through t_4 indicated in Fig. 9.

CONCLUSIONS

We have demonstrated a methodology for understanding the origins of defects in composites, and controlling those defects through process modifications. The method relies on process monitoring through the use of instrumented testbeds that afford direct observation of process phenomena. These observations are closely coupled with systematic characterization of resin properties by more conventional methods, such as thermal analysis and rheology. Visual data acquired with these tools revealed the occurrence and timing of defect-formation mechanisms. For CS2, these included (a) gas entrapment by early gelation of the adhesive, (b) bond-line bubble growth at intermediate core pressure, and (c) fillet disruption from the bursting of bubbles at low core pressures. In CS1, the defect formation mechanisms during RTM included pore formation from volatile evolution, surface porosity from cure shrinkage, and the times and temperatures at which these occurred.

The case studies demonstrate the utility of *in situ* visualization for composites manufacturing (for both RTM and autoclave co-cure). Through visual observations, the process conditions corresponding

to defect formation can be identified, informed process modifications can be made, and theories about the relevant physical phenomena can be validated. Altogether, this approach can provide understanding and insight into manufacturing processes that could not be attained by traditional inspection of the structures after manufacturing. Most importantly, much of the guesswork can be eliminated from process troubleshooting, and the interactions between materials and phenomena can be analyzed in realistic conditions.

ACKNOWLEDGEMENTS

The work on RTM process monitoring was supported jointly by the M.C. Gill Composites Center and by Kaneka Corporation. Process monitoring of co-cure of sandwich panels was supported by NASA NRA NNL16AA13C and was undertaken in collaboration with S. Advani of University of Delaware. The work presented was performed by Drs. Mark Anders and Tim Centea.

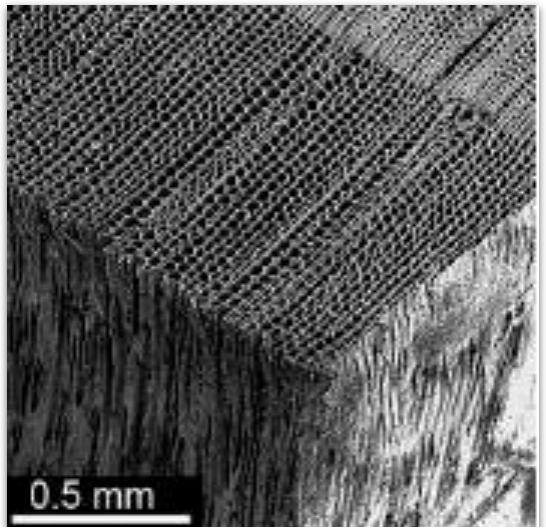
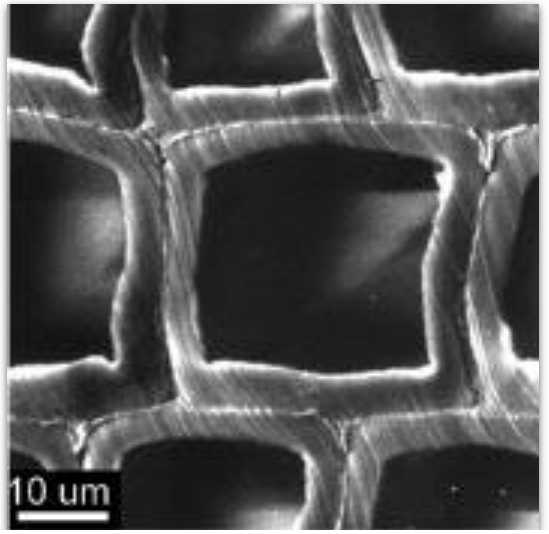
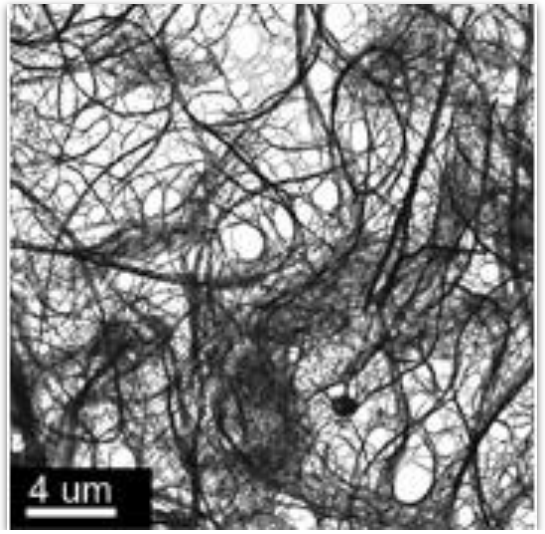
Advanced Biocomposites

High-Performance Cellulose-Based Composites for Sustainable Materials Engineering



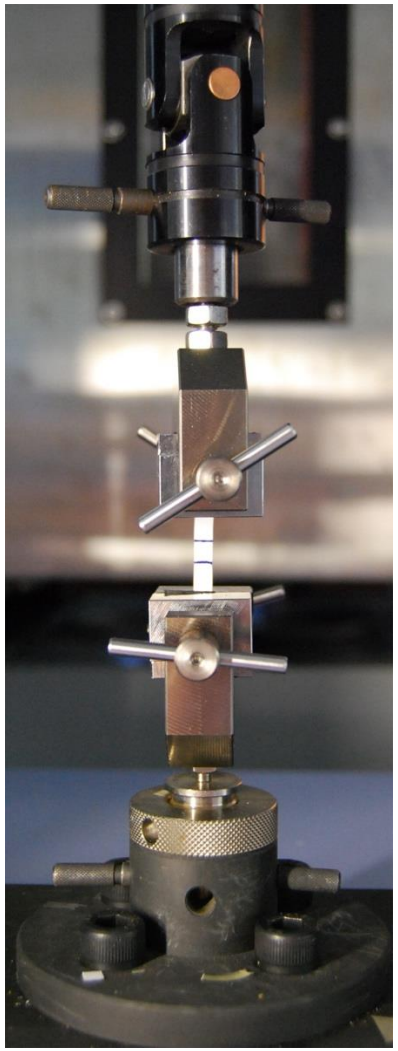


Outline



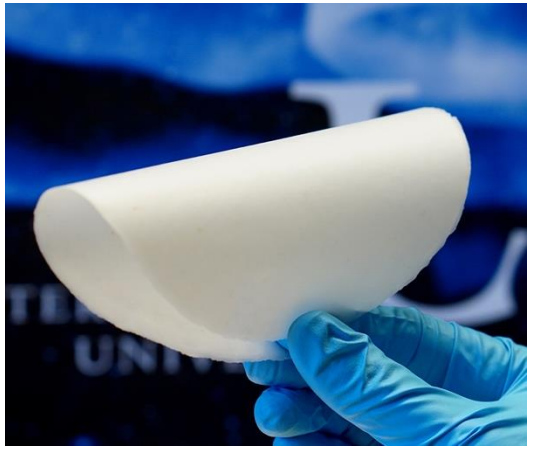
- Cellulose nanofibers
- Cellulose nanocomposites
- Cellulose filaments with different size scales spun of cellulose nanofiber gels
- Filament properties
- Composite properties,both experimental and estimated
- What challenges do we face in development of composites?

What are cellulose nanofibers?



- Soft wood fiber, diam 20-30 µm, length 2-5 mm
- Nanofibers, diam <100 nm, length µm-scale, can be separated from cell wall combining chemical and mechanical methods
- Mechanical properties increases with the decreased size scale
- E-modulus estimated to 140 GPa and strength 10000 MPa compared with soft wood E-modulus 12 GPa and strength 100 MPa

Why cellulose nanofibers?



- Natural resources, and can be extracted from residues
- Sustainable
- High mechanical properties
- Large surface area
- Forming gel in low concentration
- Forming strong network when dried
- Lightweight
- High thermal stability compared to many natural polymers

Cellulose nanofiber network properties

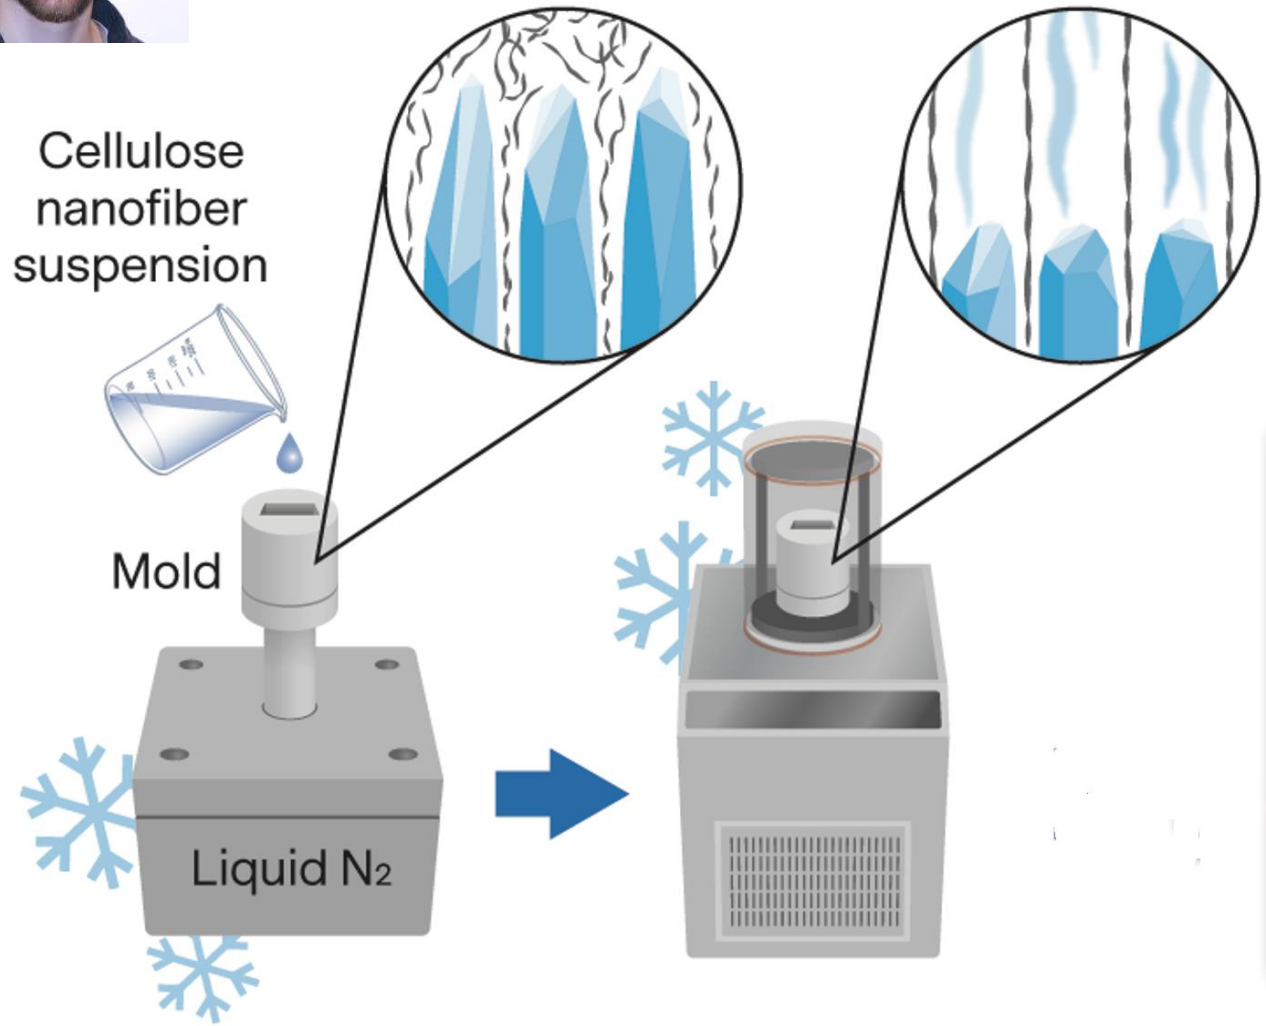
Nanofiber networks are prepared by vacuum filtration and pressing

	E-Modulus (GPa)	Strength (MPa)	Strain at break (%)
$Wood_{nanofiber}$	**11.2 ± 0.8**	**183 ± 14**	**5.0 ± 0.9**
*$TEMPO_{oriented}$	**24.6 ± 0.4**	**428 ± 15**	**2.5 ± 0.2**

*Sehaqui et al ACS Appl Matr & Inter 2012

Nanocomposites by impregnation of nanofiber network

- High mechanical properties but the resin impregnation process is challenging and time consuming
- Reduce viscosity of the polymer and / or increase porosity of the network to be able to use conventional composite processing methods such as vacuum infusion
- Is it possible to align the nanofibers?



Cellulose nanofiber preforms for resin impregnation

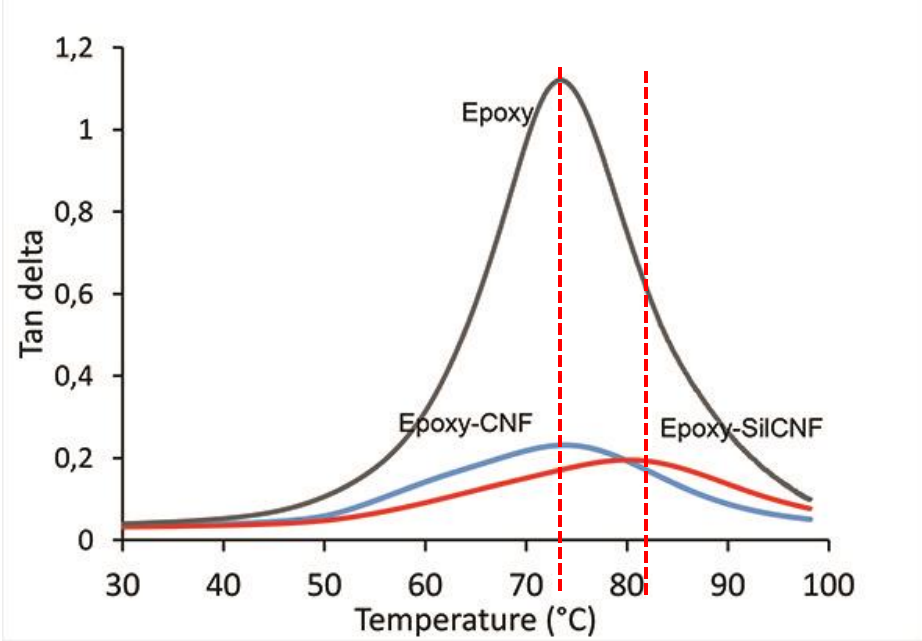
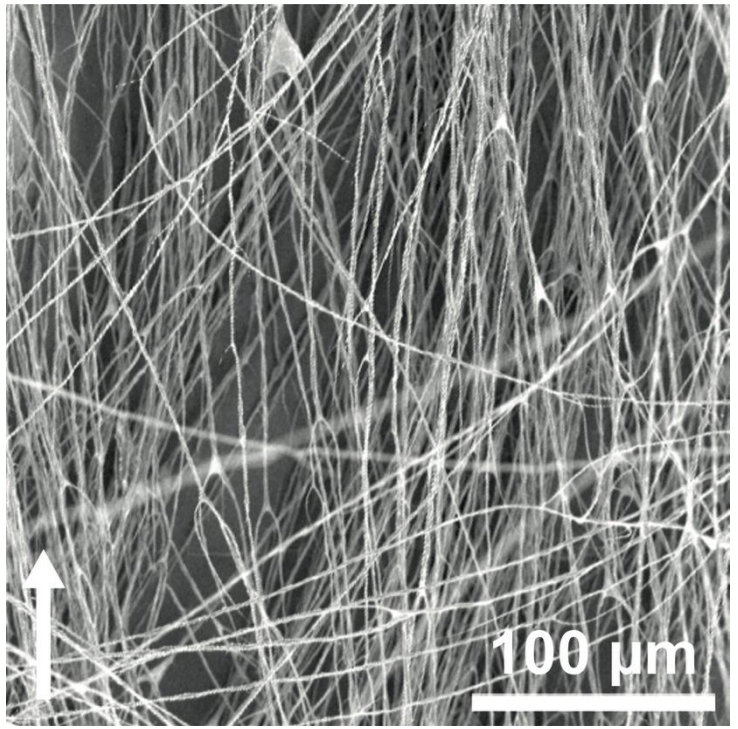
Orientation of cellulose in the composite structure

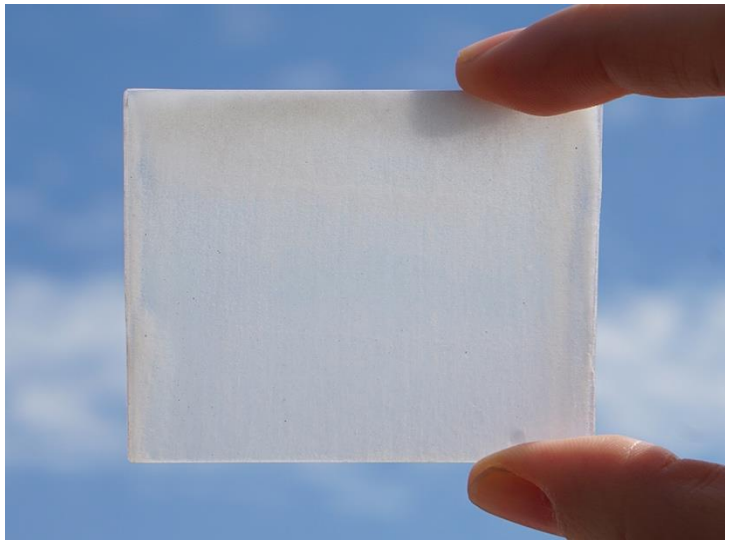


Nissilä et al Nanomaterials 2021,11(2), 490; doi.org/10.3390/nano11020490

Composite properties

- Storage modulus increased from 2.2 to 5.4 GPa with 13 vol% cellulose filament content at room temperature
- Filaments treated with chemical surface deposition of amino silane
- Silane treated filaments resulted in better interaction with the resin as tan delta moved towards higher temperature (73 to 81 ℃)



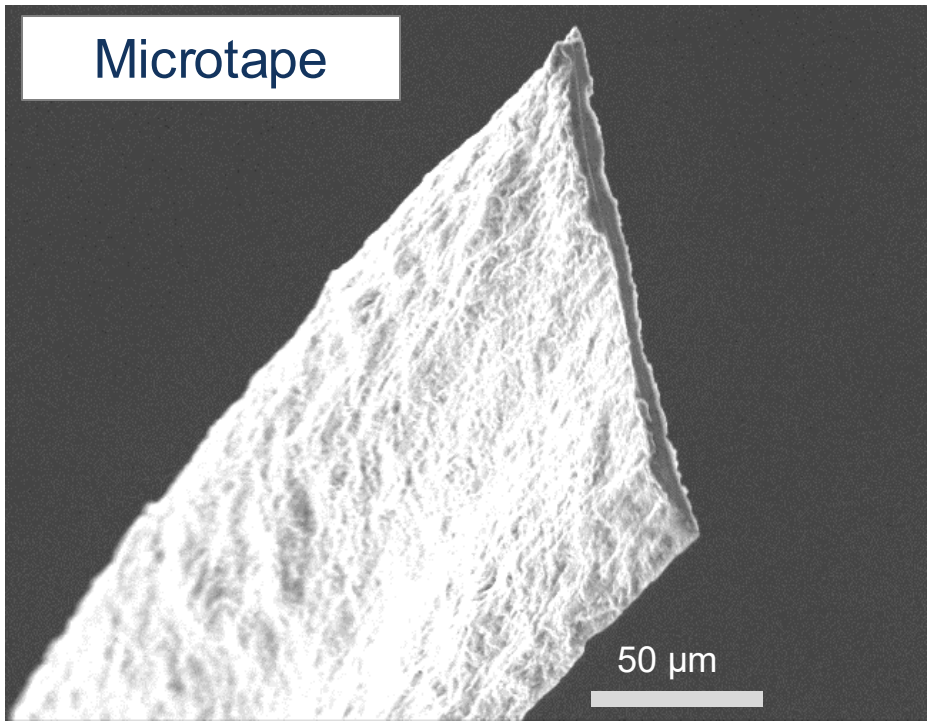


Nanomaterials **2021**, *11*(2), 490; doi.org/10.3390/nano11020490

Conclusions on ice-templated filaments

- Ice-templated nanocellulose filament preforms can be one way to improve the impregnation and ice-templating resulted in oriented preform structure, but it is time consuming and difficult to make large quantities
- Vacuum infusion resulted in cellulose filament content of 13 vol%
- Composites mechanical properties were increased compared to epoxy (2.5 times)
- Cellulose content was limited
- Silane treatment improved the interaction

SPINNOVA® Textile Material Innovation Company in Finland



Spun cellulose filaments

- Spun from cellulose nanofiber /microfibril dispersion without harsh chemicals
- Continuous and lightweight
- Sustainable and bio-based
- Can we create high-performance and sustainable biocomposites of cellulose filaments?
- Develop a composite process which is leading to aligned filaments

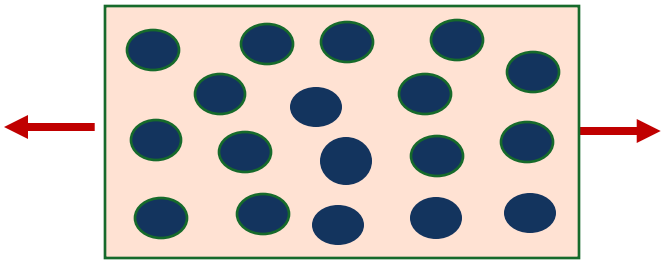
Motivation

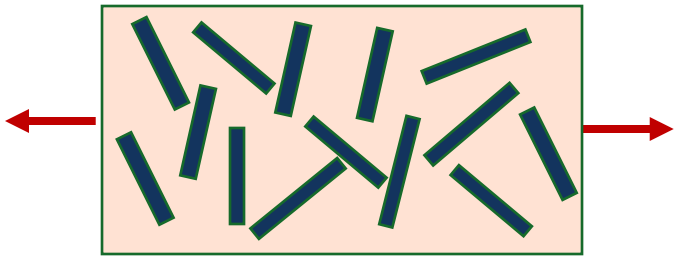
Thickness 2 μm
Width 80 μm



- Unique micro-tape shape
- Stress transfer of microtape-shaped fiber is expected much more efficient
- Performance of microtapes in the composite is also expected to lead better properties compared to circular fibers
- Better packing is expected

Effect of shape for elastic properties

Estimated in-plane transverse modulus

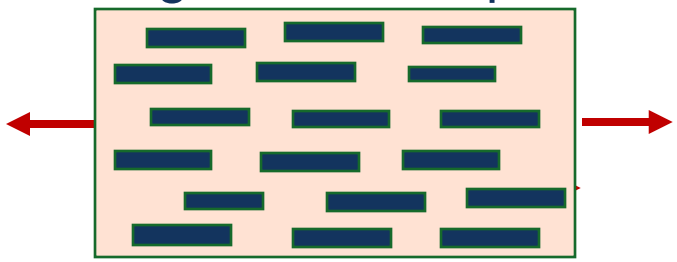


Circular fibers

Halpin-Tsai

Random oriented microtapes

Krenchel's model



$$E_{Trandom} = 3/8 E_f t \eta_l V_f + E_m V_m$$

η_θ: Orientation efficiency.

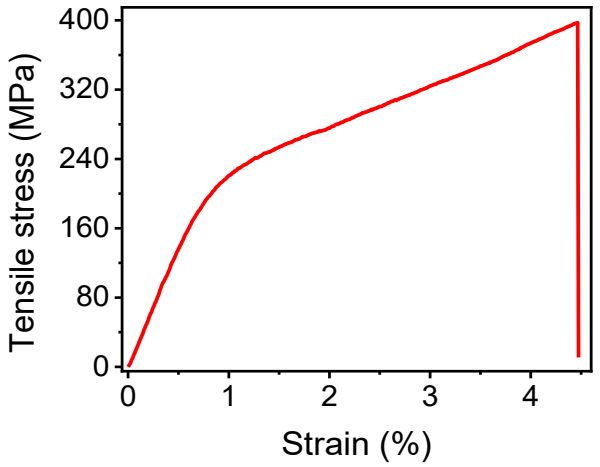
$E_T^{circular}$ 3.3 GPa

E_T^{random} 3.8 GPa

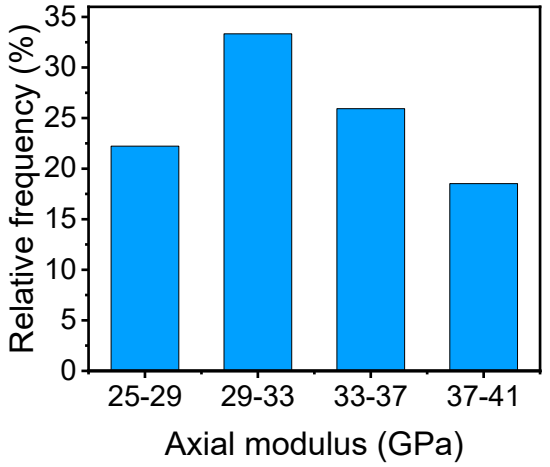
Aligned microtapes

Shear lag model

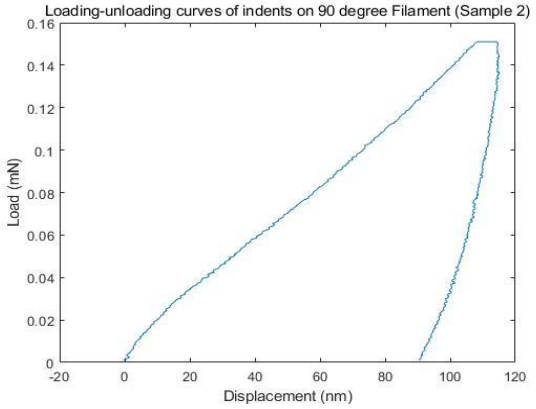
$$E_T = E_f V_f \eta_l + E_m V_m$$



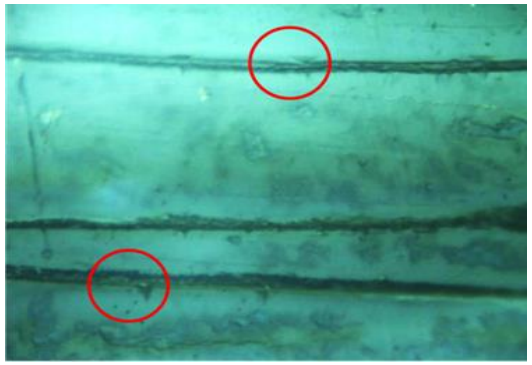
$$\eta_l = 1 - \frac{2}{\beta_l} tanh \frac{\beta_l}{2} \quad ; \beta_l = \frac{1}{r_f} \sqrt{\frac{4G_m}{E_f ln\, 1/V_f}}$$



η_l: Length correction factor



$E_T^{aligned}$ 6 GPa

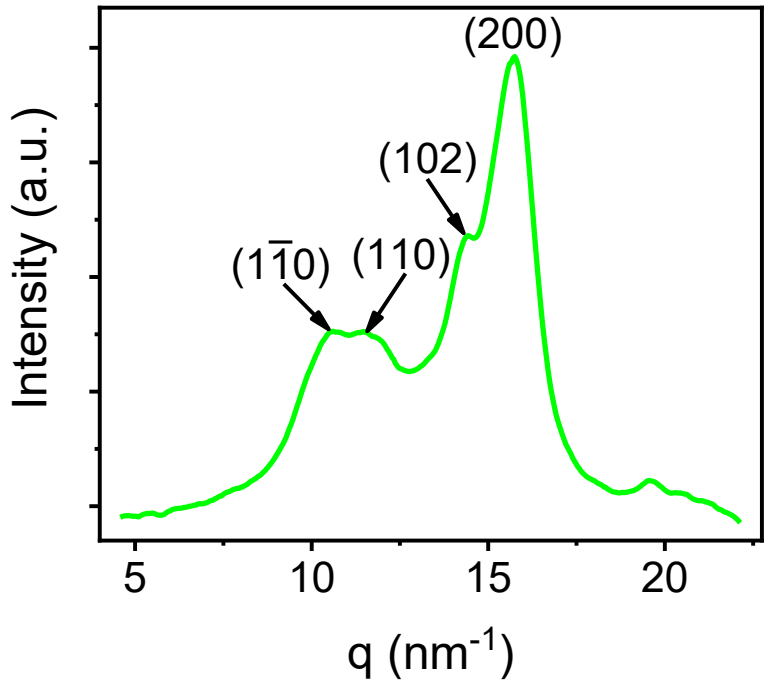


Filament properties

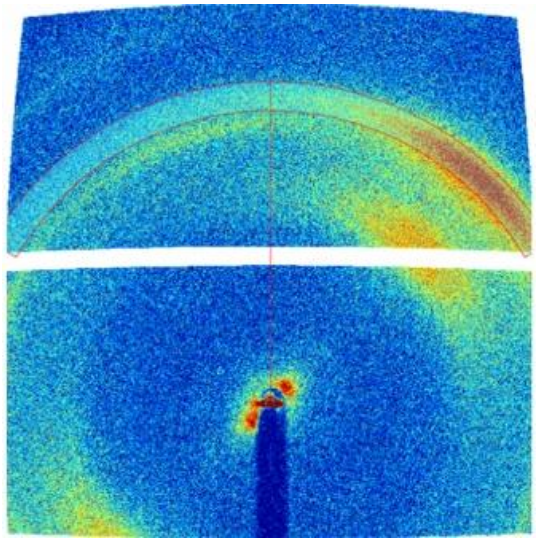
- Average filament strength 367 MPa
- Average modulus 33 GPa
- Nanoindentation was used to measure in-plane transverse modulus, 12 GPa (needed for the micromechanical modelling)
- Challenging and time consuming to measure single filaments
- Cross section have large impact and here average cross-section was used
- Nanoindentation and the sample preparation was difficult

Ben Kahla et al Composites Part A 2025, 109153

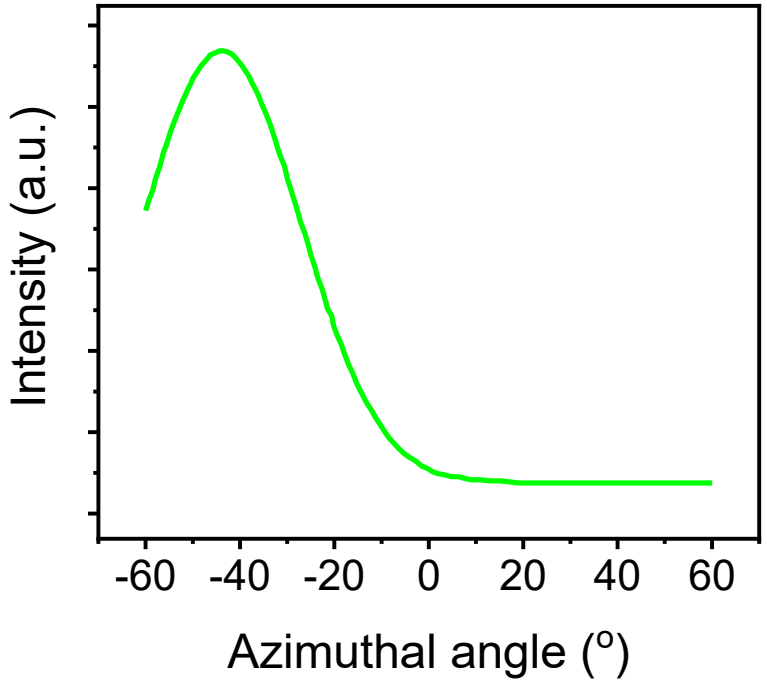
Micromechanical modelling of filaments



- Using Halpin-Tsai model we estimated E-modulus would be around 100 GPa, if the cellulose nanofibers are completely oriented (η_f = 1)
- Experimentally measured values are lower
- Factors:
  - Orientation of the cellulose along the filament axis, and their length efficiency
  - Porosity, composition, bond between the nanofibers (G_m), Poisson's ratio
  - Need correct cross section



$$E = \eta_f \, \eta_o \, E_f \, \mathcal{V}_f + \left(1 - \mathcal{V}_f\right) E_m$$



$$\eta_f = 1 - \frac{\tanh(\beta l/2)}{\beta l/2}$$

$$\beta = \frac{1}{r_f} \sqrt{\frac{2G_m}{E_f \ln(R/r_f)}}$$

Orientation of cellulose nanocrystals in the filament measured with Wide Angle X-ray Spectroscopy (WAXS)

Orientation index 0.78 show that cellulose nanofibers are oriented along the microtape axis (bundle)

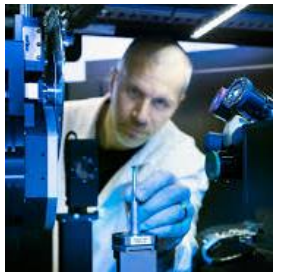
Micromechanical modelling of mechanical properties

Ben Kahla et al Composites Part A 2025, 109153

Conclusions



- Promising results, so far and we believe we can improve from this initial study
- We have filaments/fibers which can be further developed for composite use
- Optimize the testing of filaments, measure correct cross-section
- Optimize the composite manufacturing process
  - Control in-plane orientation distribution of the filaments
  - Increase the filament content and decrease void content

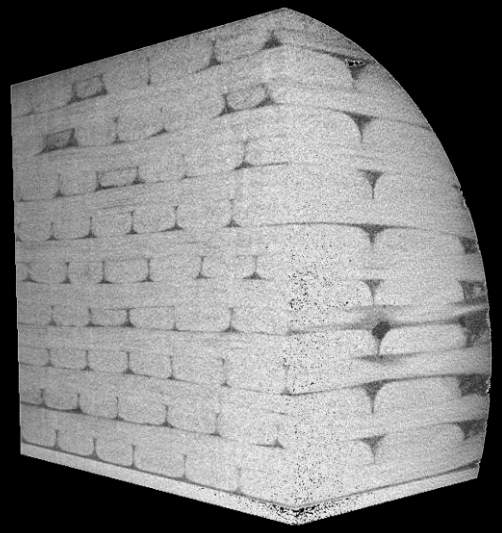
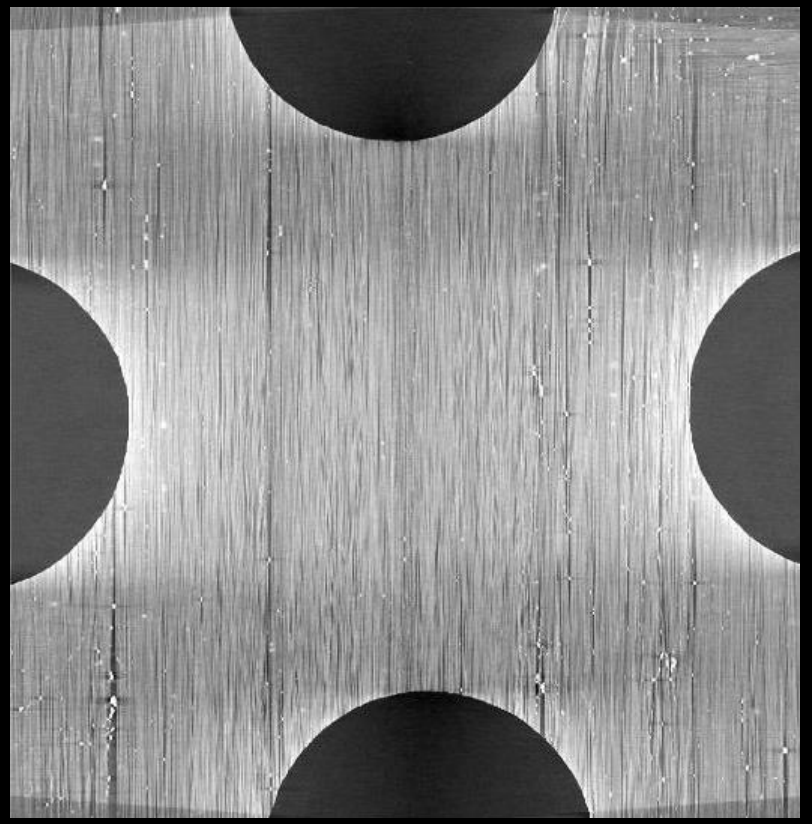
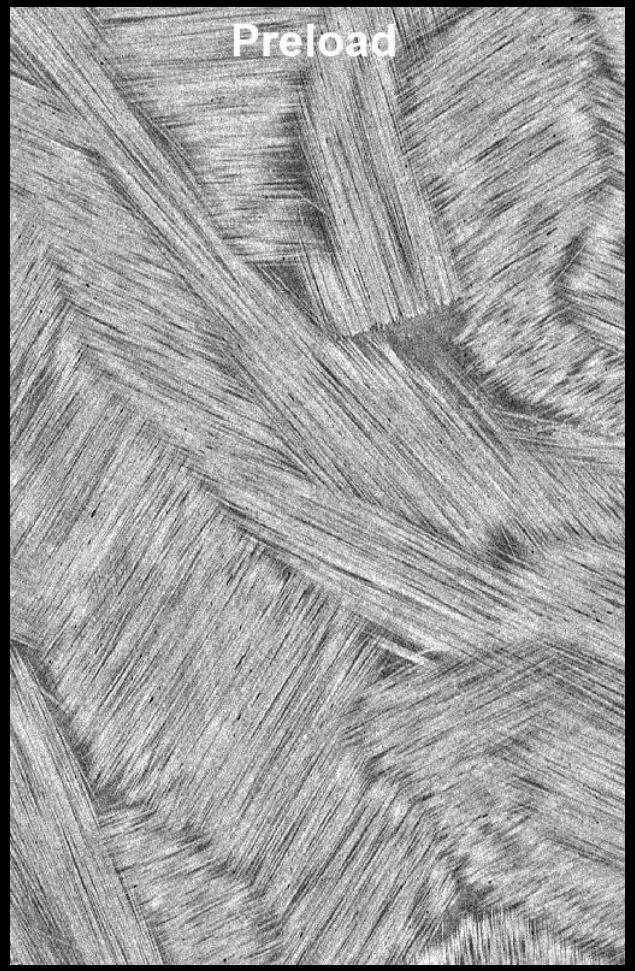
What is computed tomography?



The specific nature of X-ray computed tomography

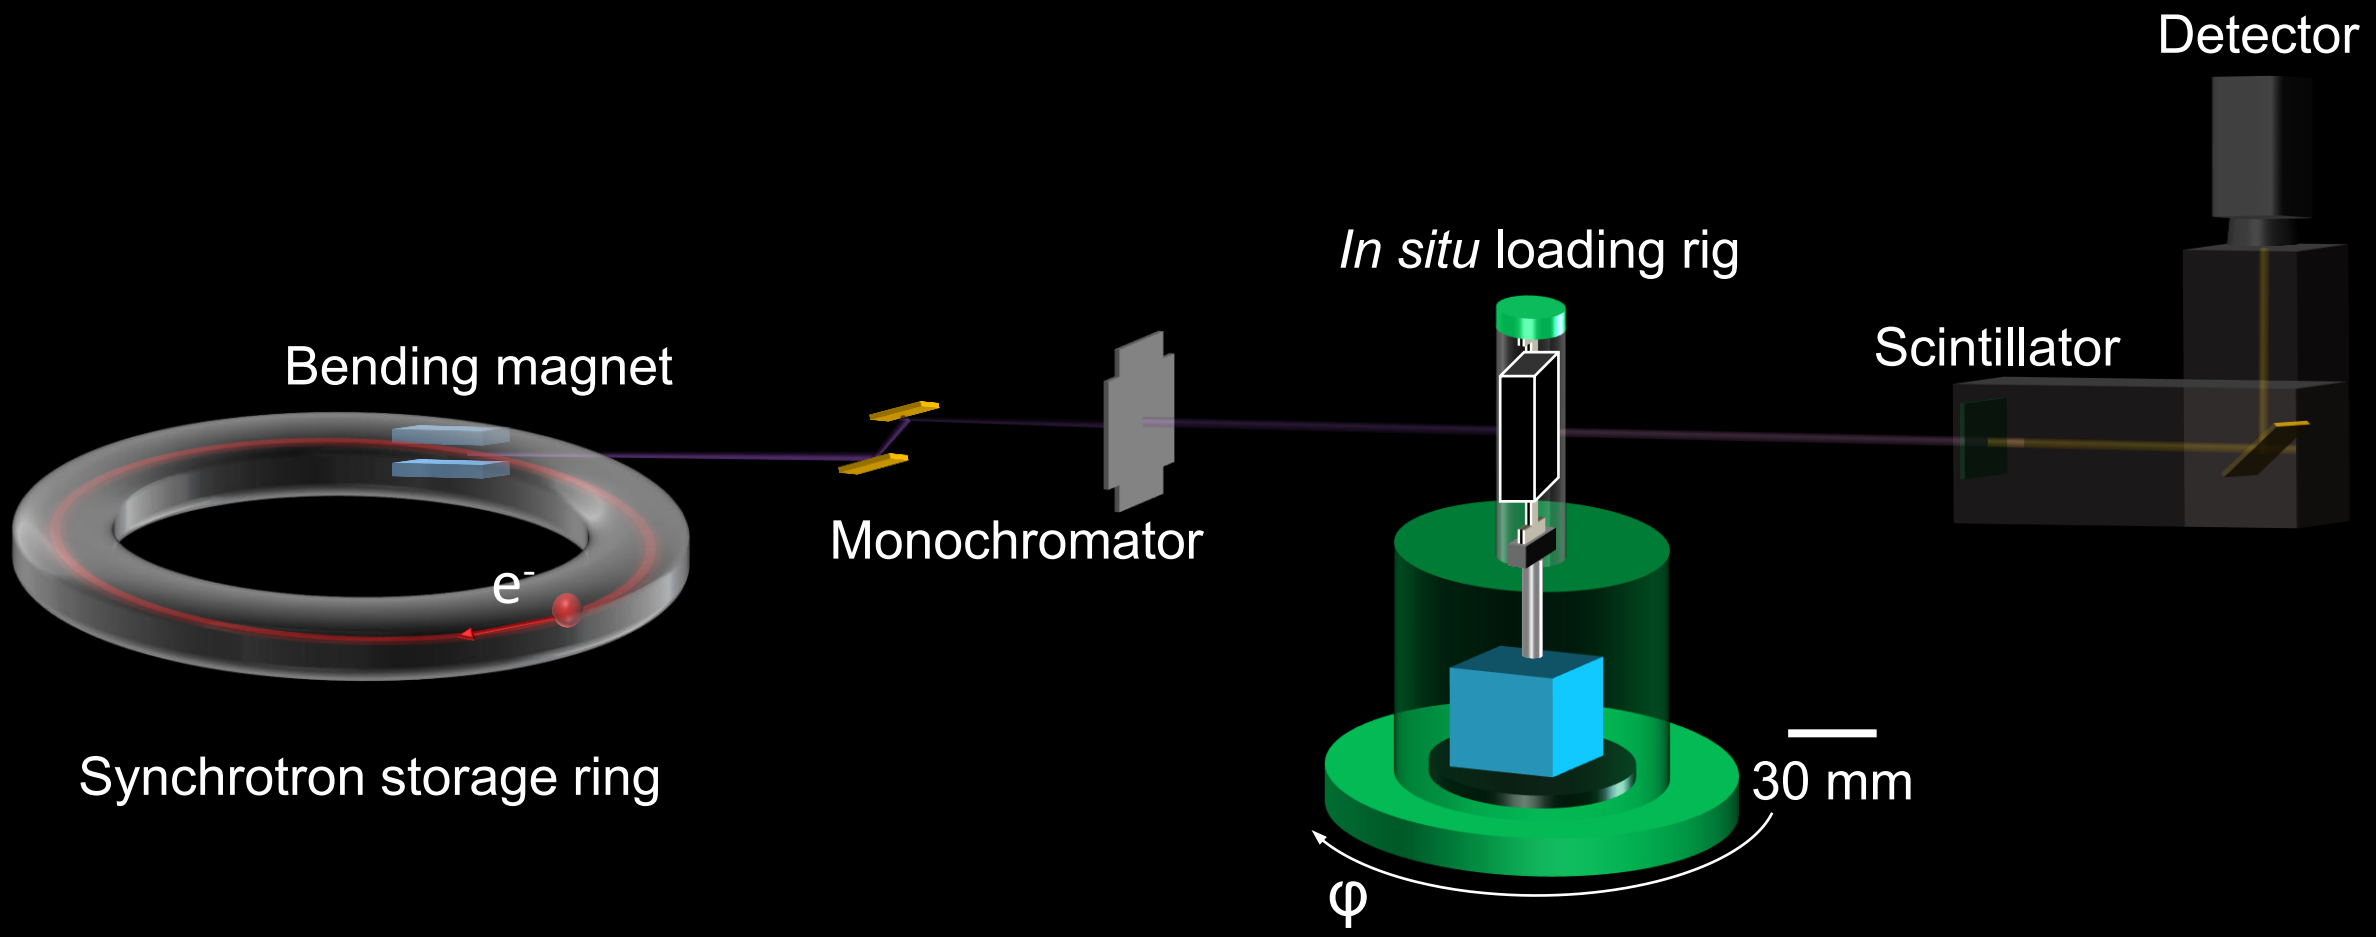


Getting 3D images = easy



Getting the best possible 3D images efficiently = difficult

What do you need?

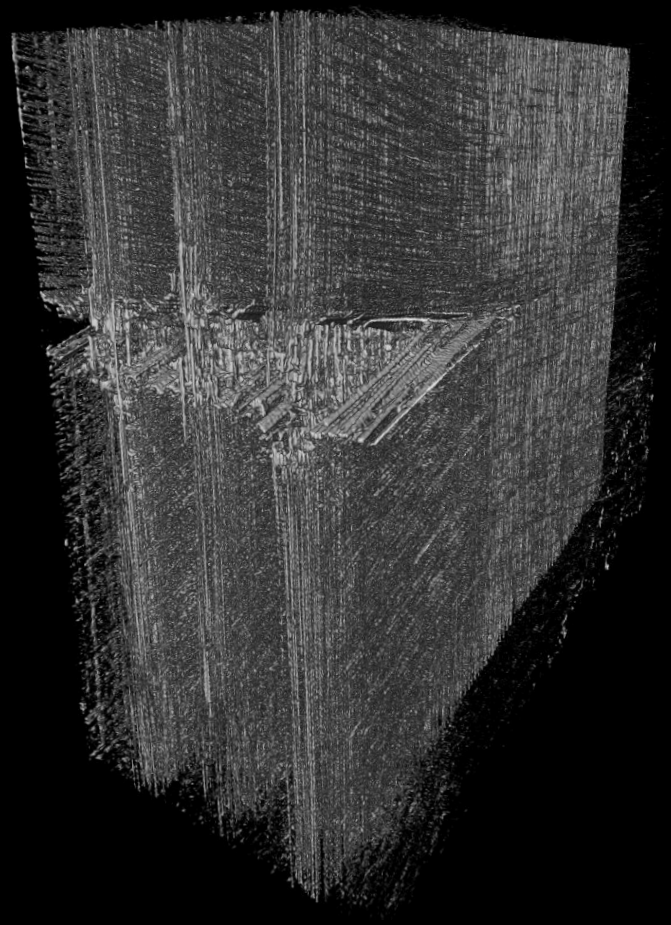


- A device suited to your needs/material
- Suitable software
- (Years of) experience

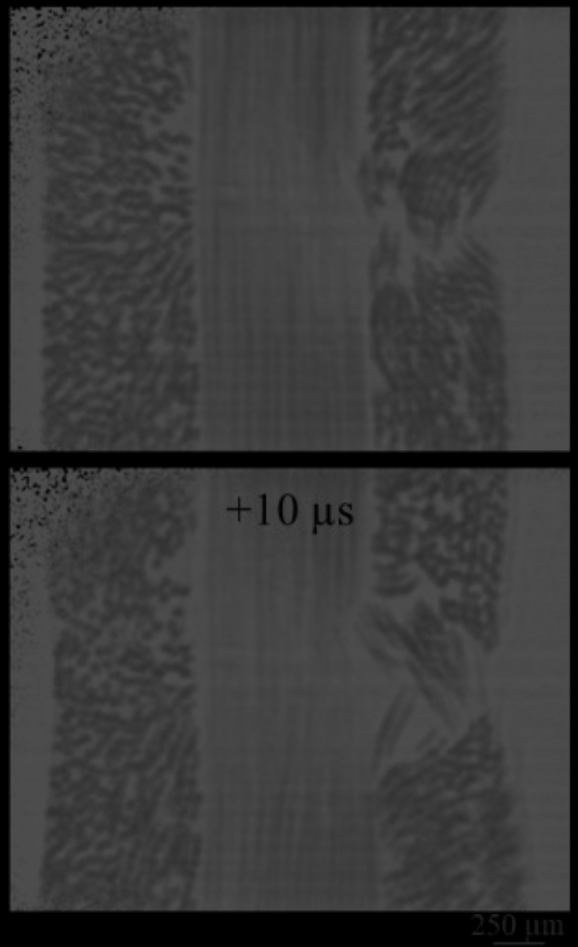
Typical layout of an XCT beamline

The specific nature of synchrotron computed tomograpy

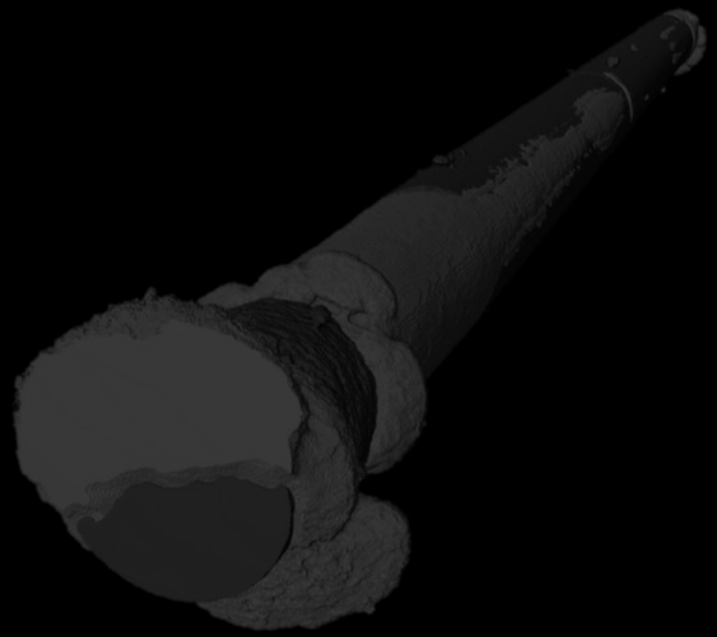
Mostly parallel beams
- No geometric magnification
- Ample space for load rigs



Voxel size can be smaller
- Not necessarily!

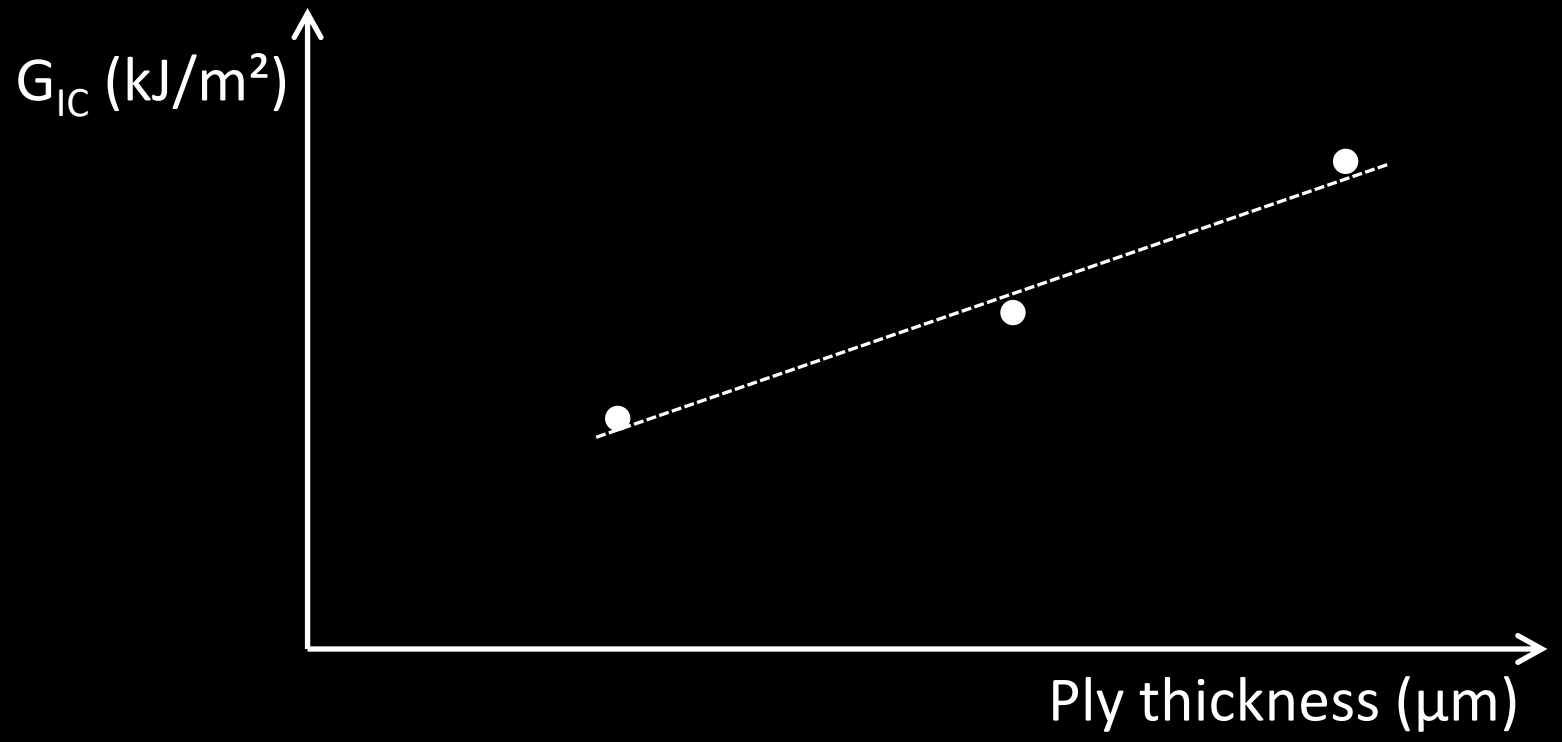


More phase contrast present
- Can be tweaked via propagation distance

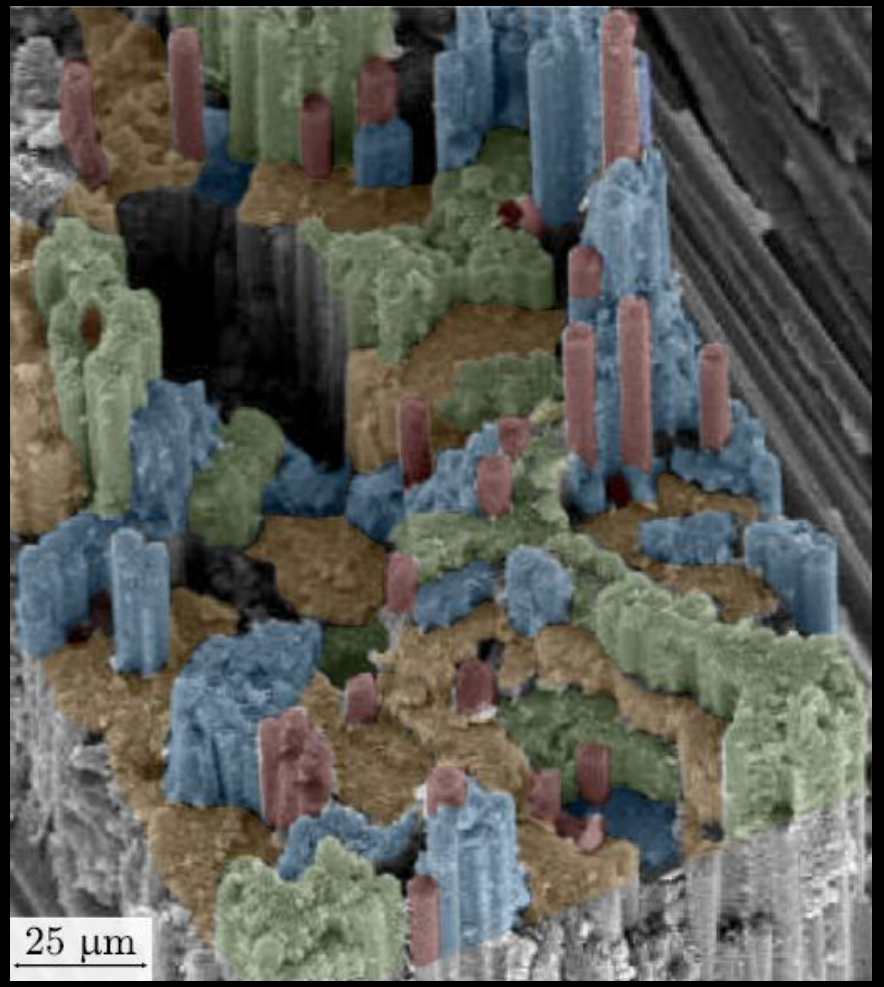


Much higher flux
- Faster experiments
- Monochromatic light or pink beam

Three synchrotron techniques

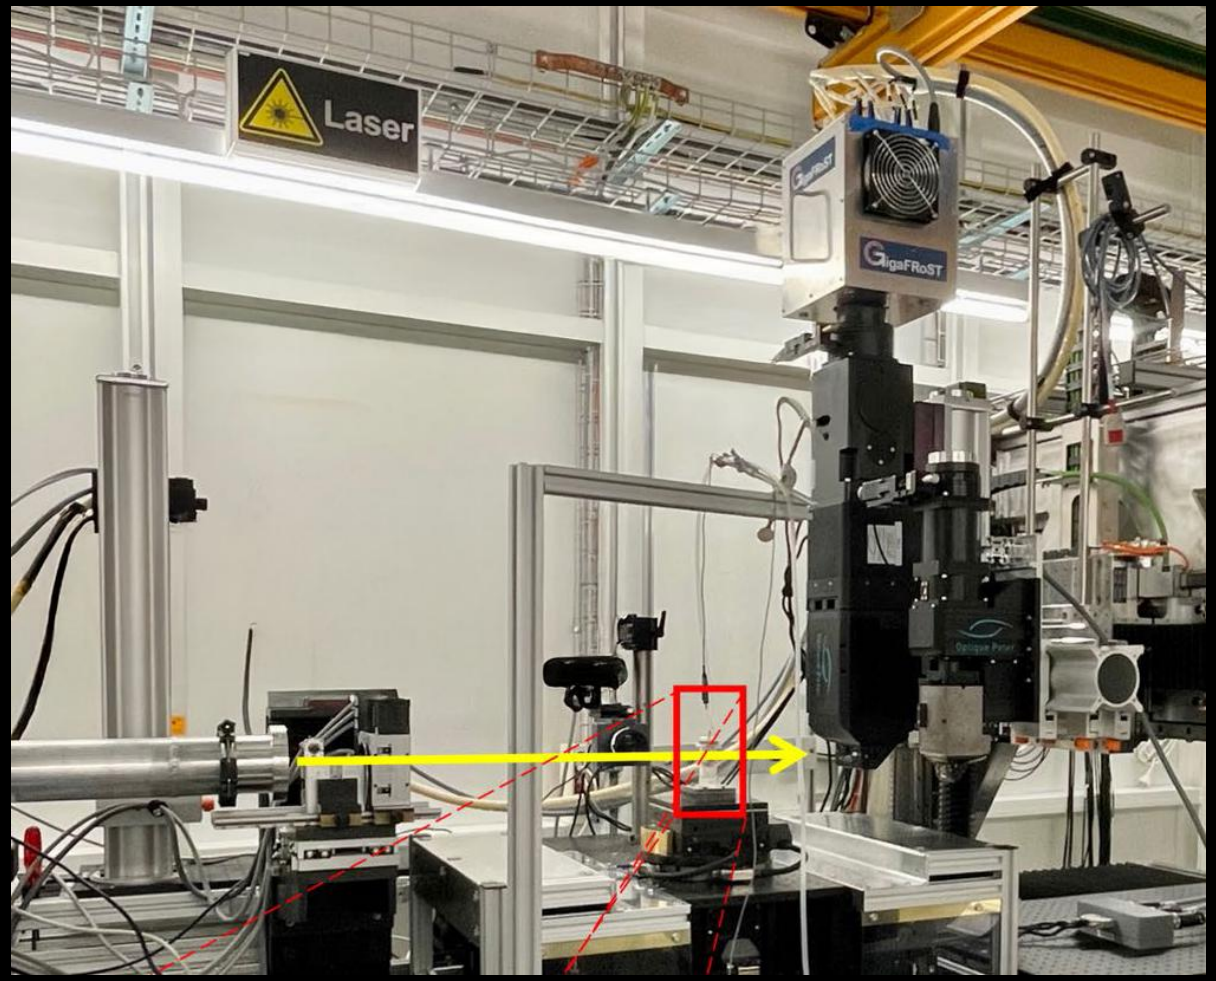


Continuous acquisition | Ultrafast radiography | Holotomography



The ply thickness effect for translaminar fracture toughness

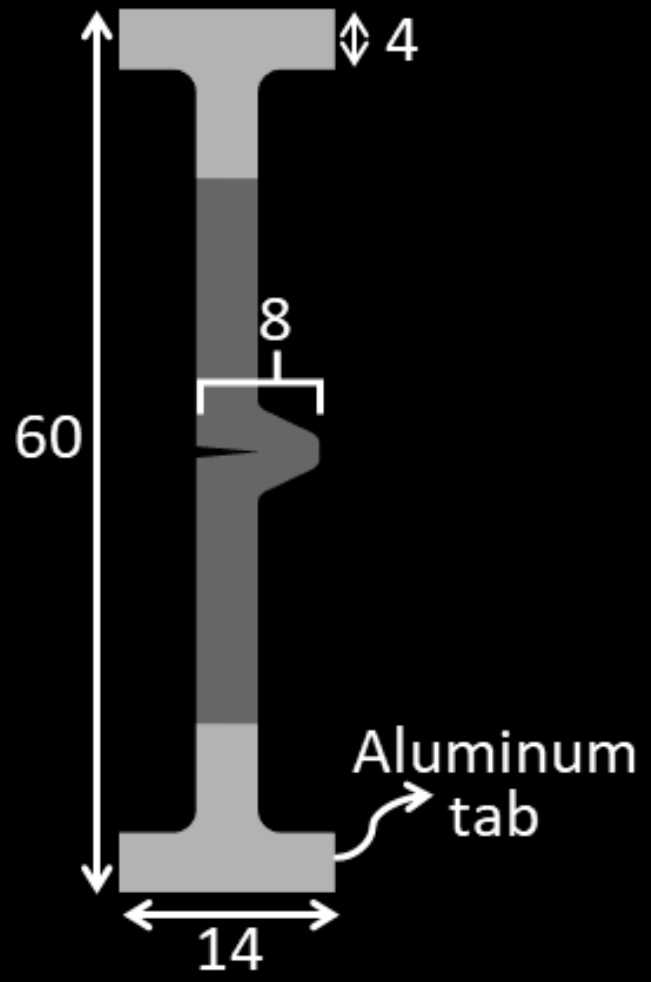
Only one micromechanical model available



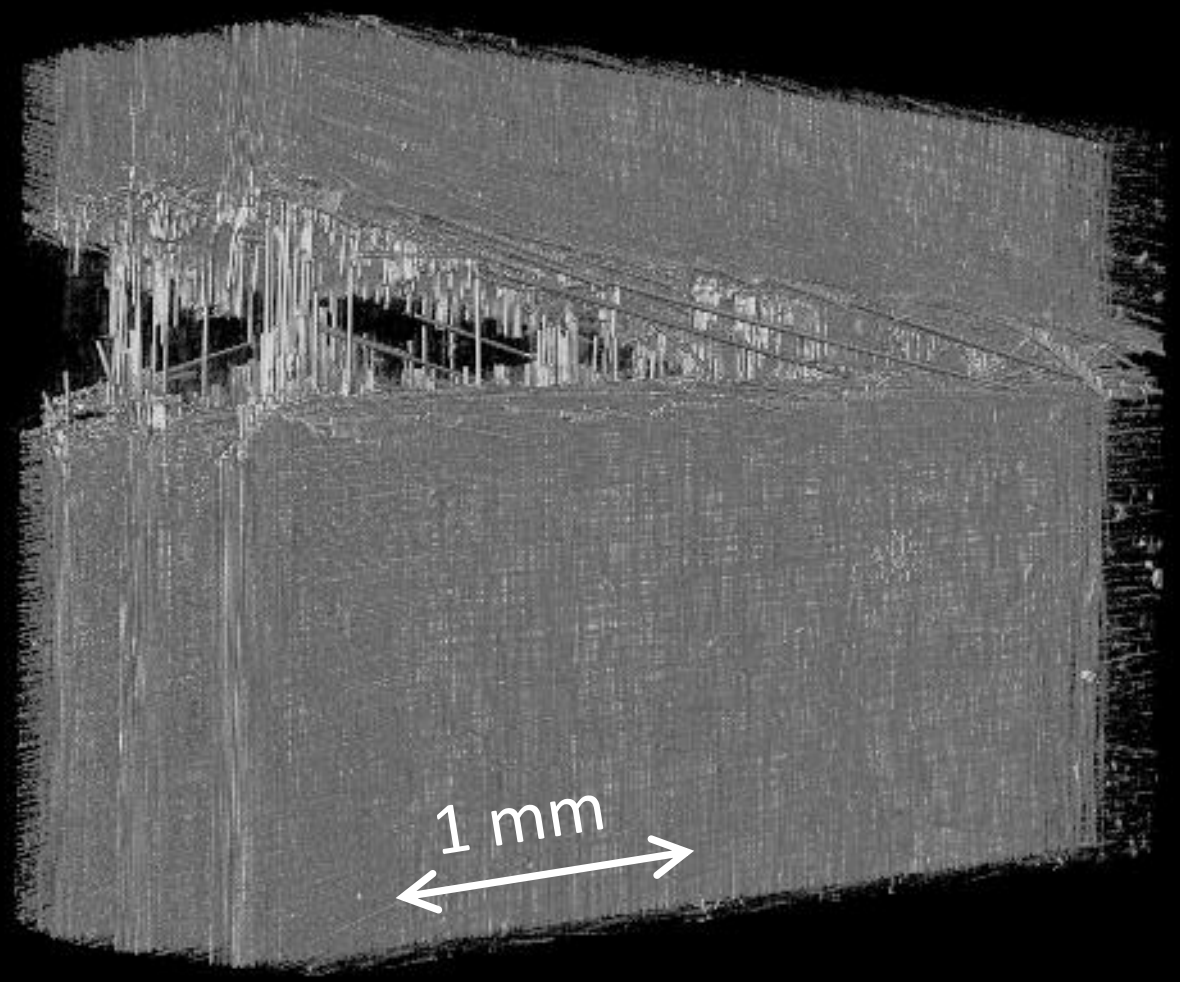
Pimenta and Pinho (2014)

The TOMCAT beamline and GigaFRoST detector

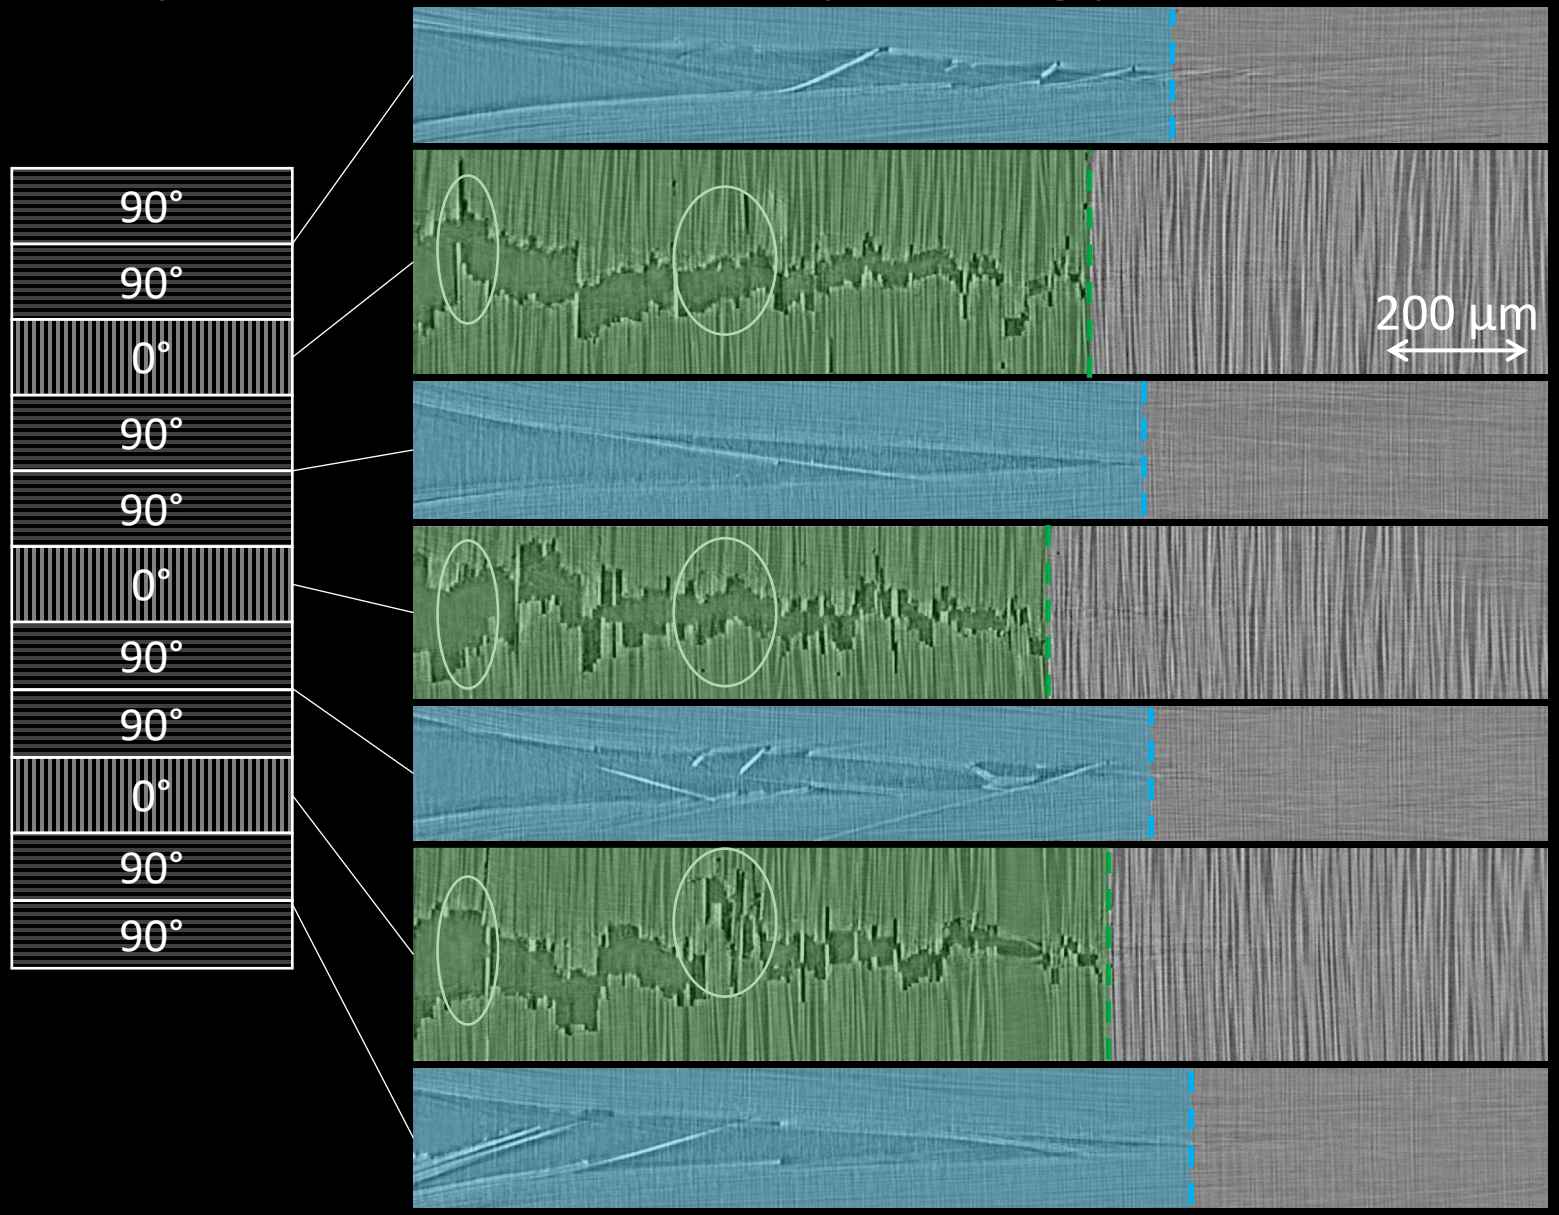
800 nm, 2s per scan



Superfast read-out system:



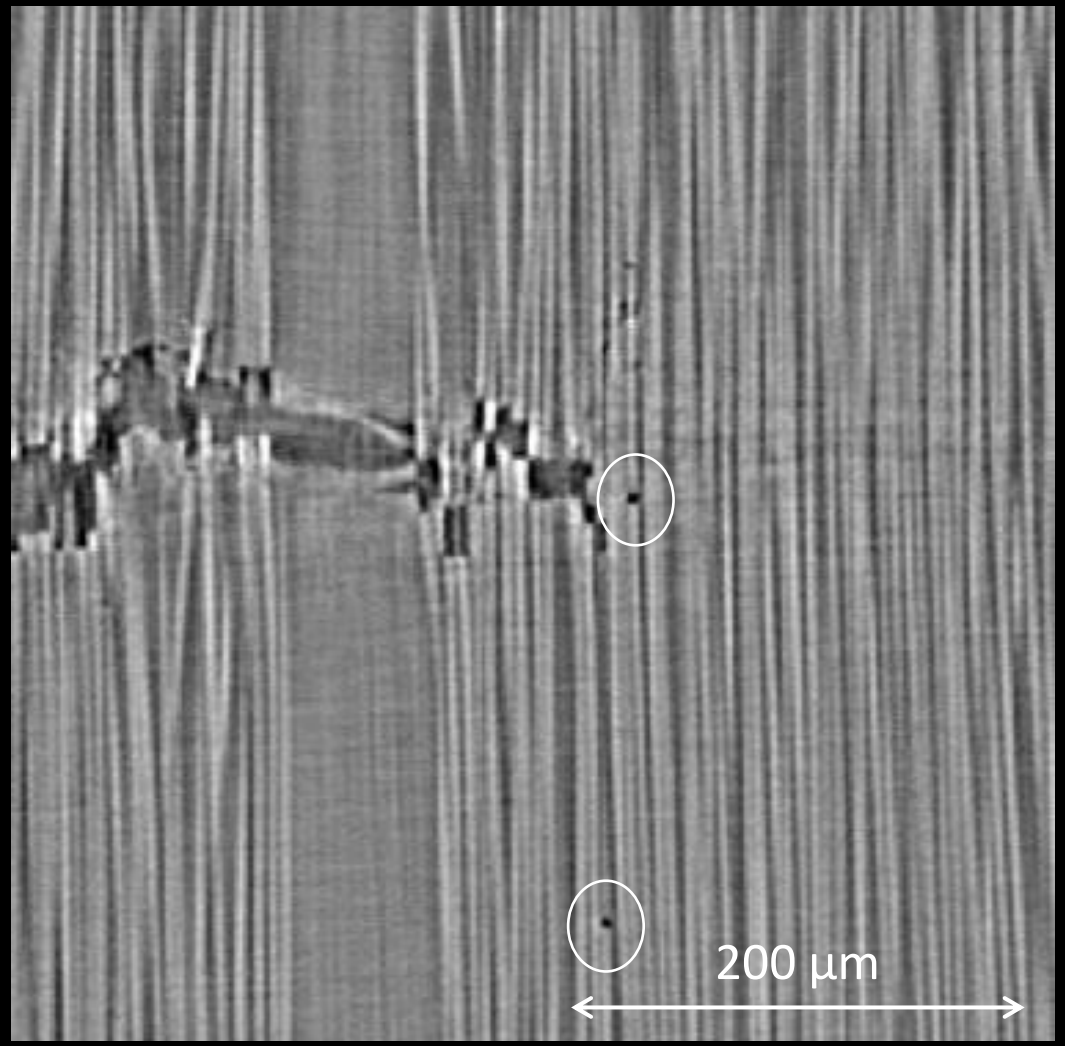
60.000 radiographs in 2 min



Ivanovic et al. (2024)

Miniaturised compact tension specimen

Complex fracture morphology



Detailed pull-out characterisation

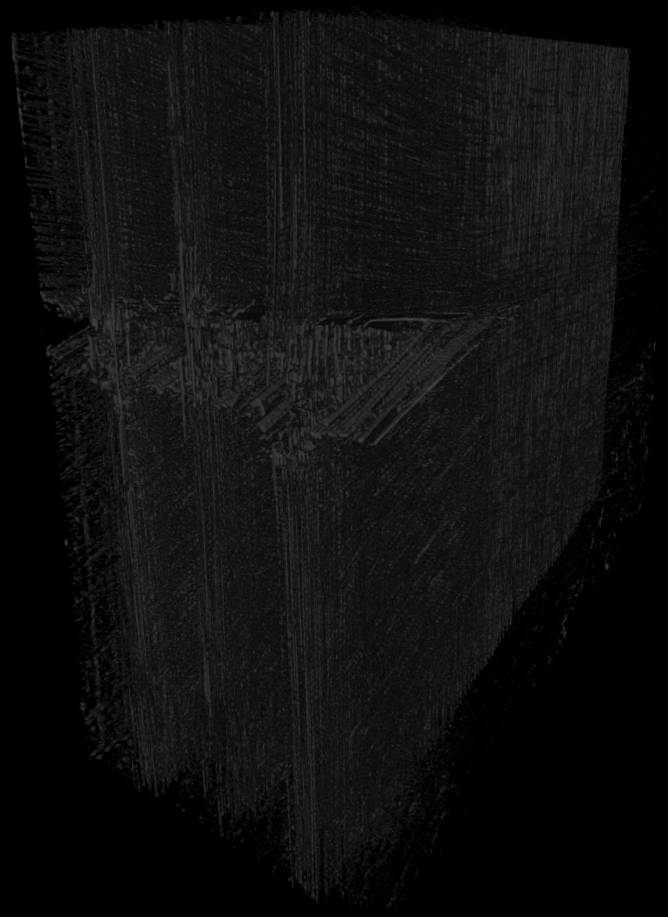
Independent 0° cracks

90° cracks ahead of 0° cracks

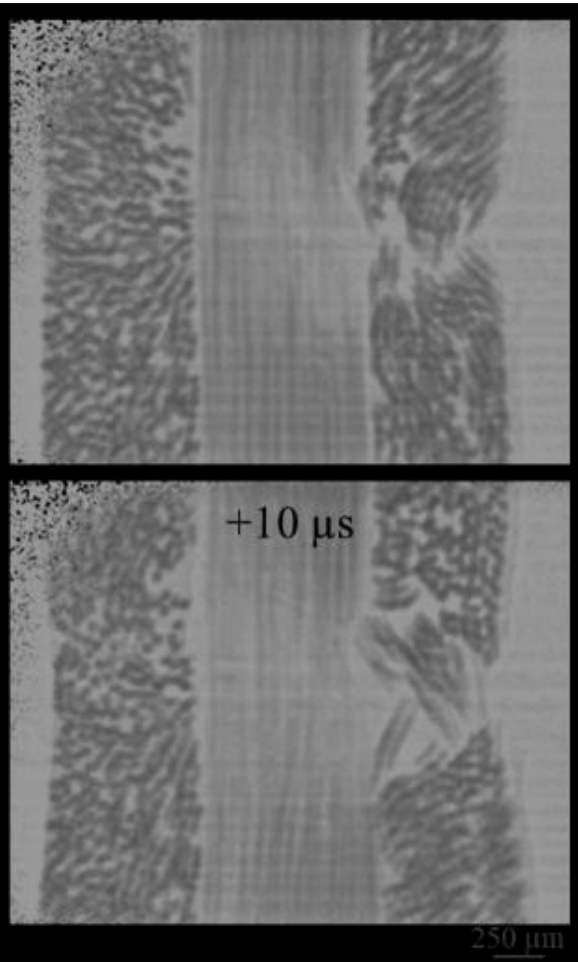
Fibre breaks near crack tip

Future challenges and opportunities

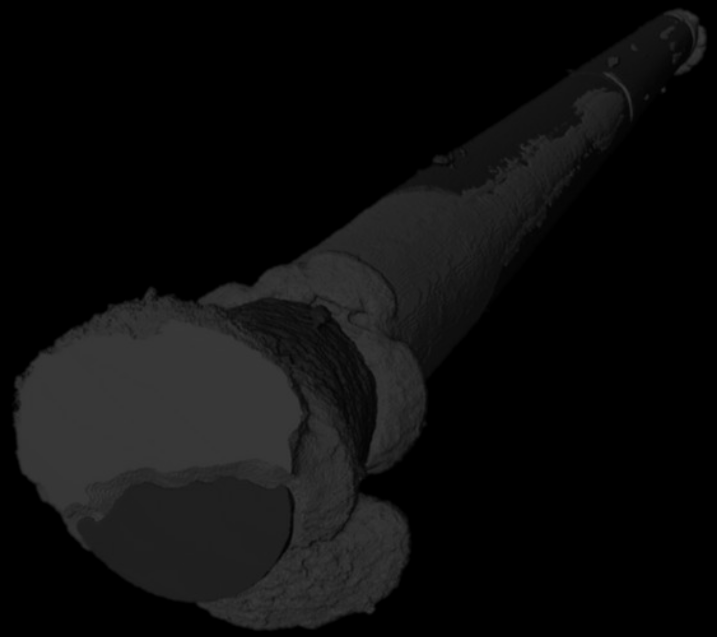
Challenges:



- Unique camera only available at TOMCAT beamline
- Fast rig rotations → stability concerns



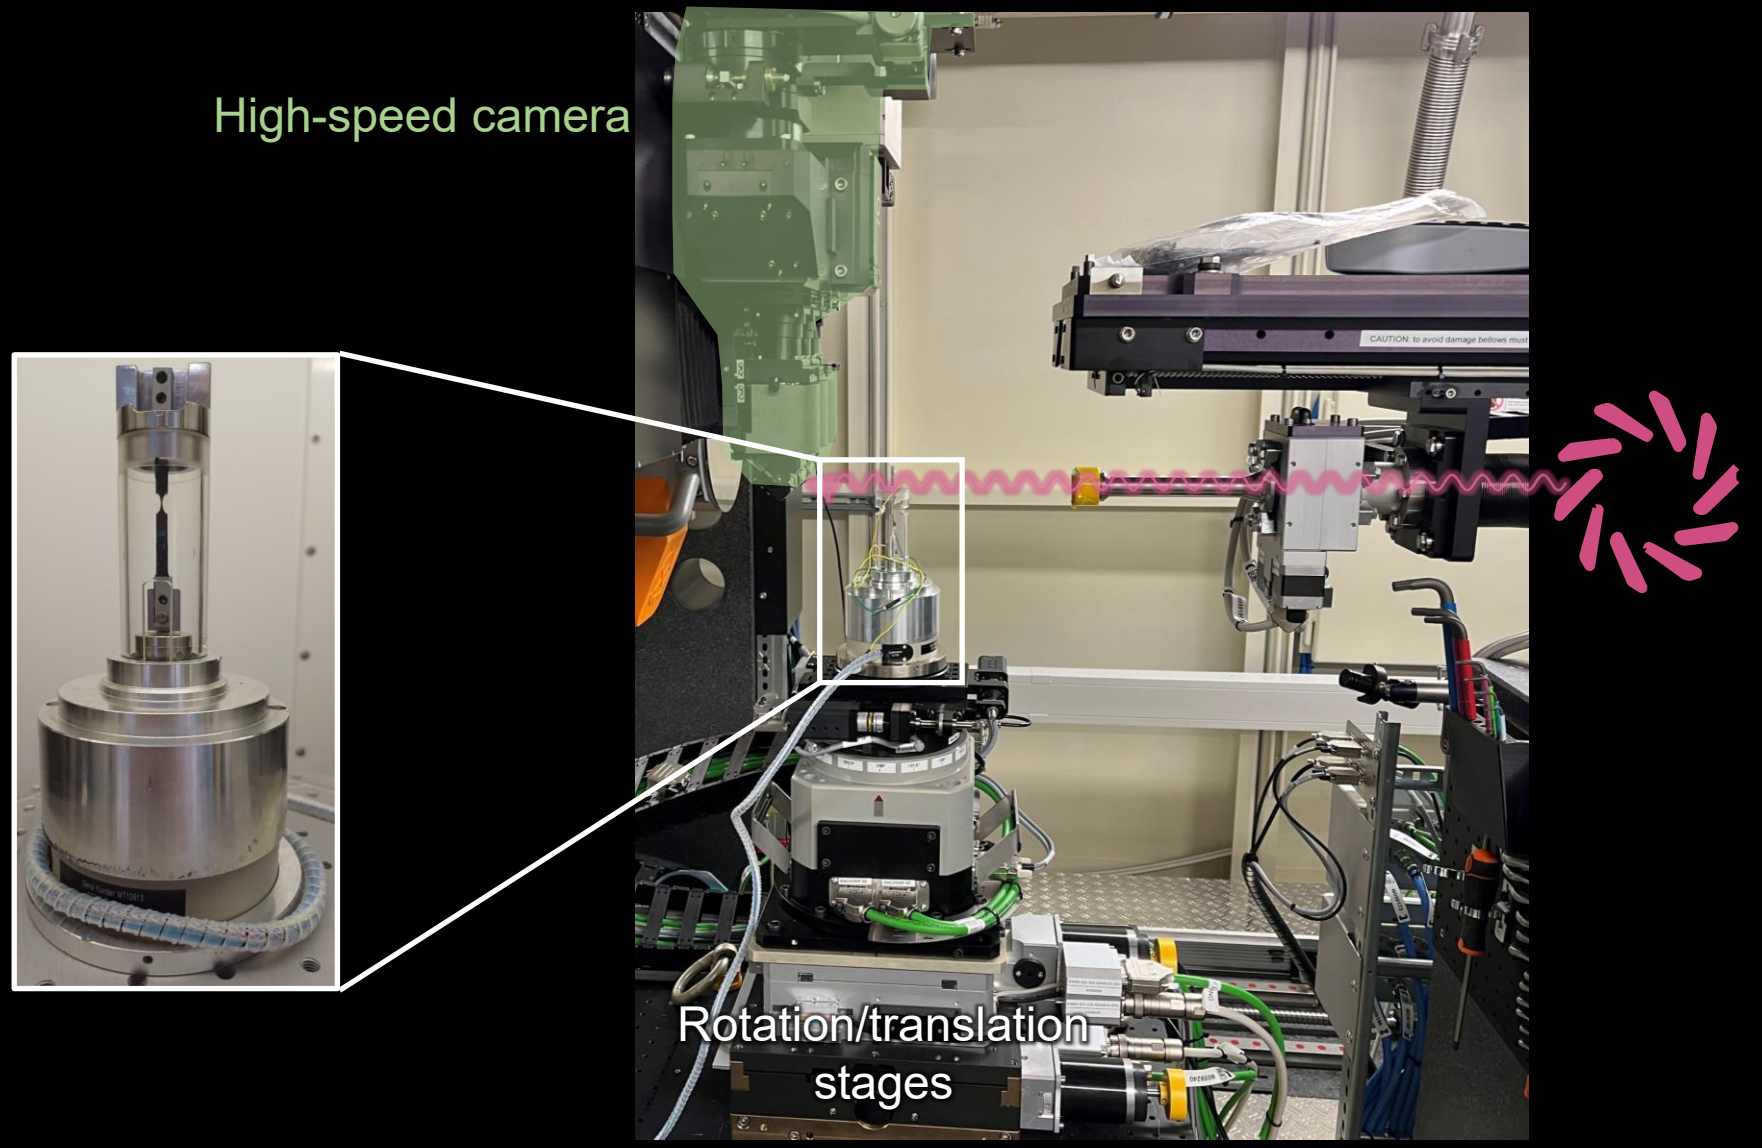
Opportunities



- Swiss Light Source 2.0 upgrade → brighter
- 2 TOMCAT beamlines

Three synchrotron techniques

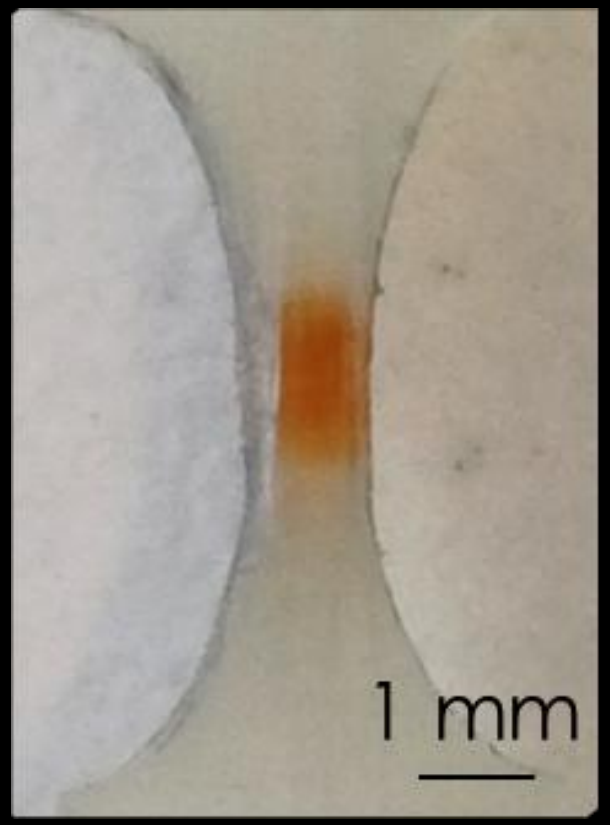
Continuous acquisition | **Ultrafast radiography** | Holotomography



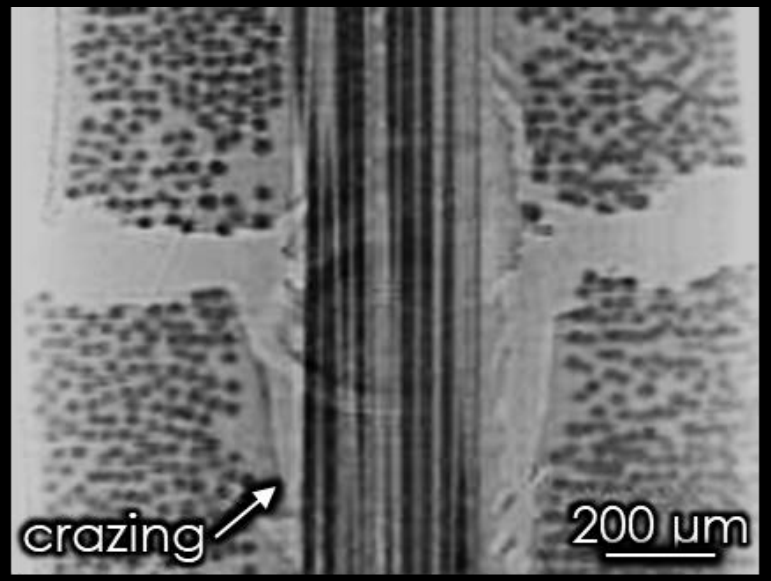
Ultrafast camera

Shimadzu HPV-X2

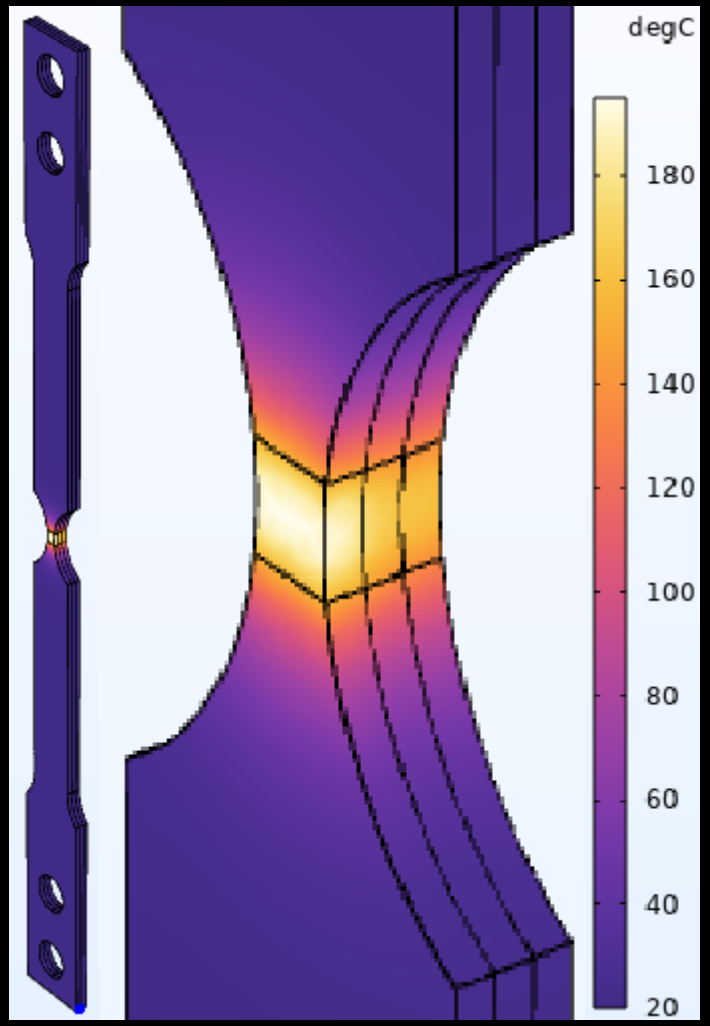
- Up to 10 MHz
- Up to 256 frames
- 250x400 pixels



Setup at FORMAX



Specimen degradation



Imaged at 0.1-1 MHz ➔ 256-2560 µs

Degradation due to dose

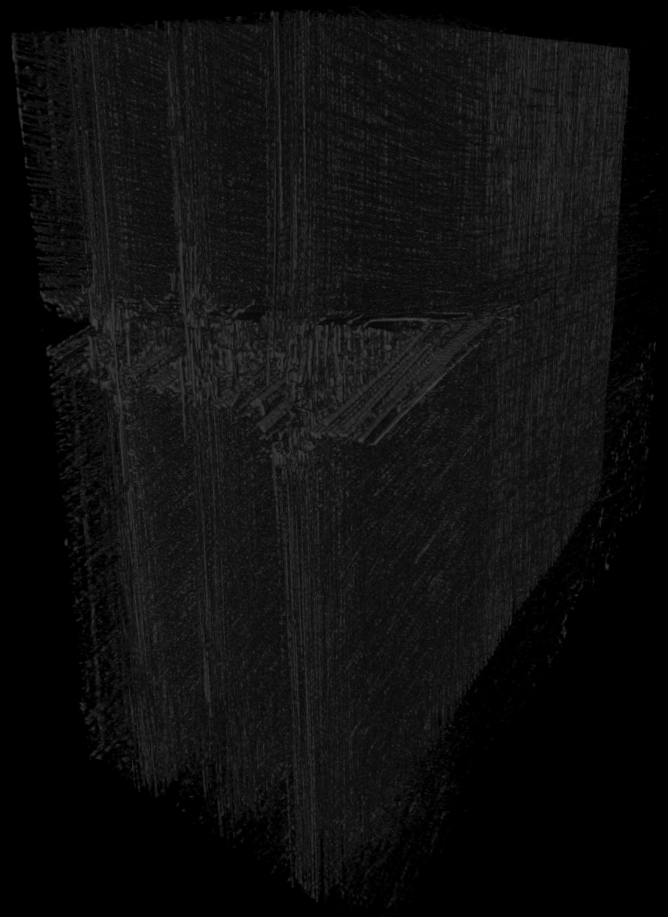
Degradation due to dose rate

Ultrafast radiography:
Future challenges and opportunities

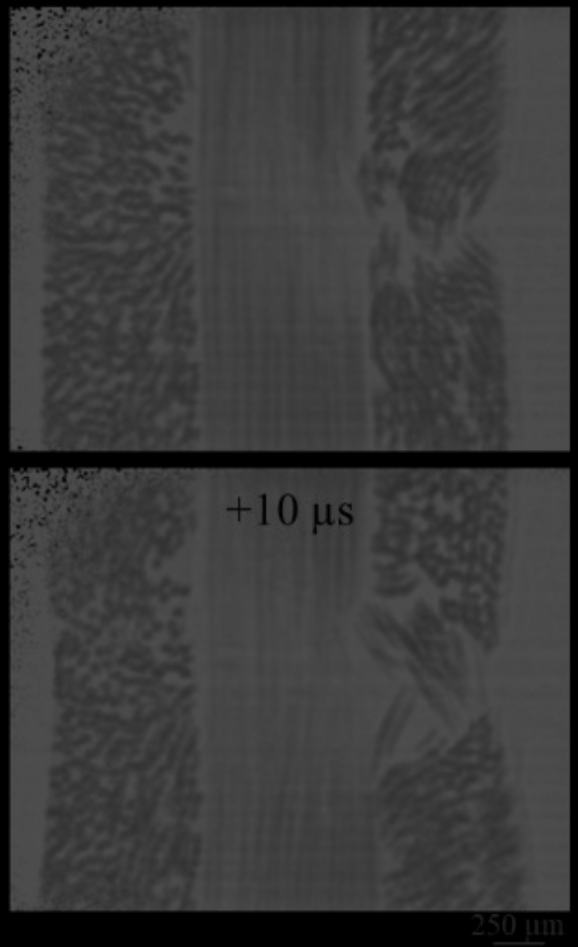
Challenges:

- High enough flux without degrading specimen
- Triggering

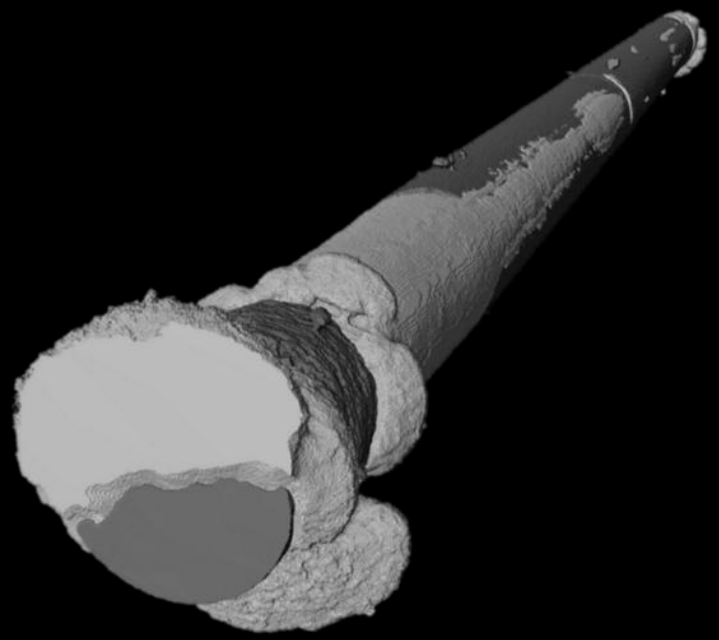
Opportunities



- HPV-X3 just launched
- Slower but more sensitive camera alternatives

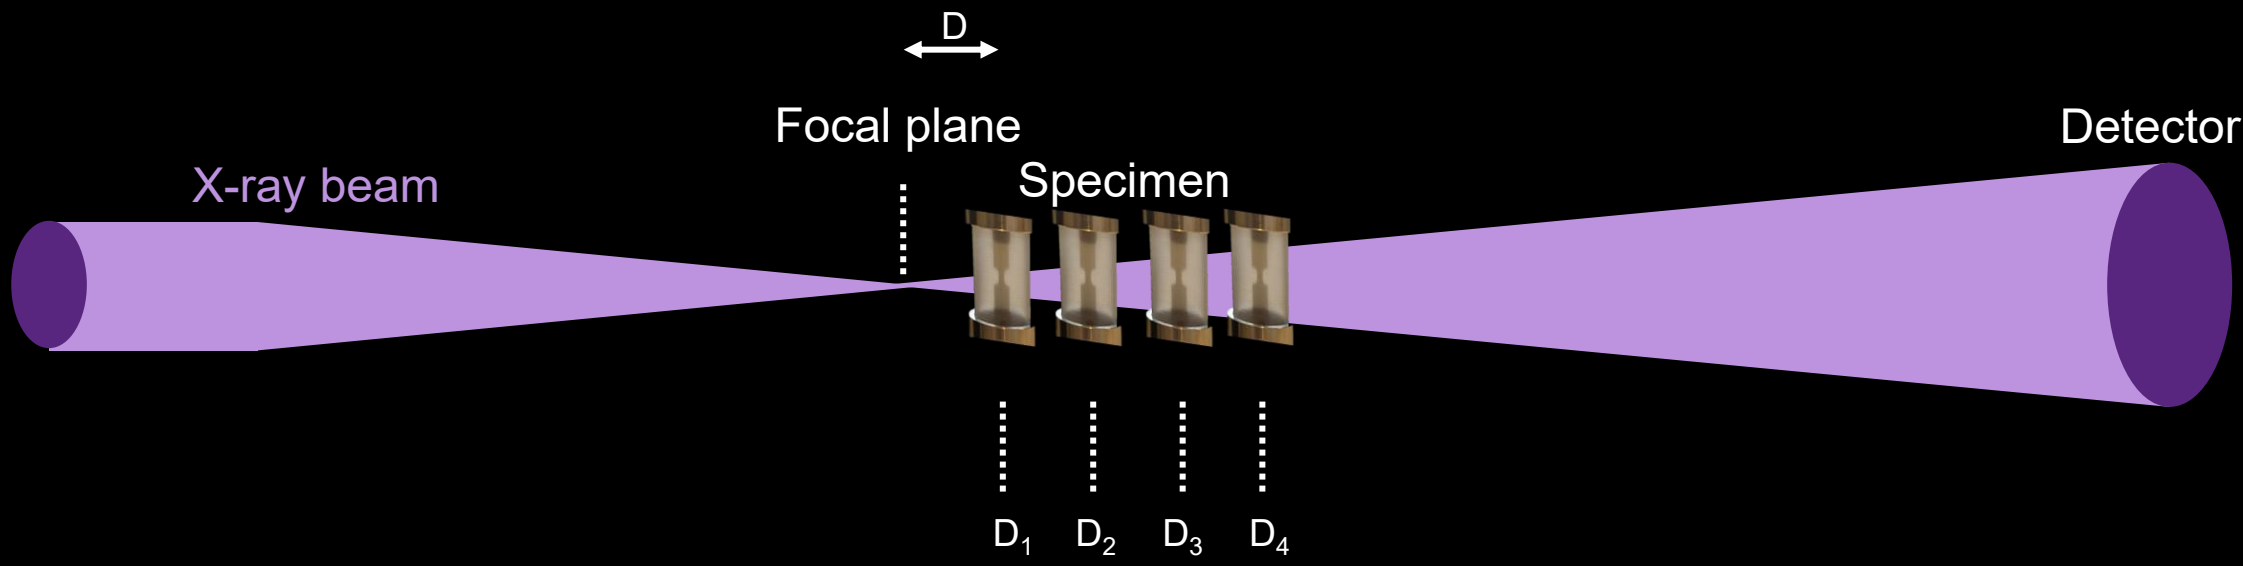


Three synchrotron techniques



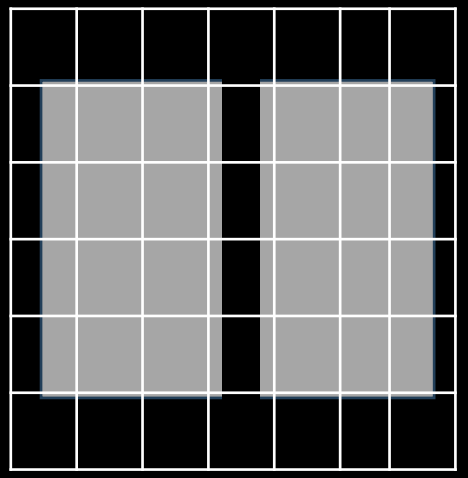
Continuous acquisition

Ultrafast radiography



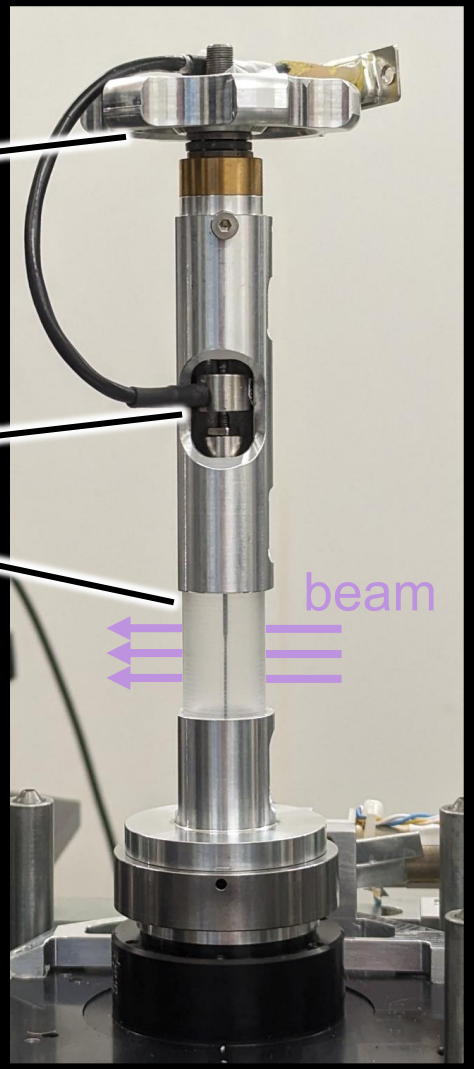
Holotomography

The basics of holotomography

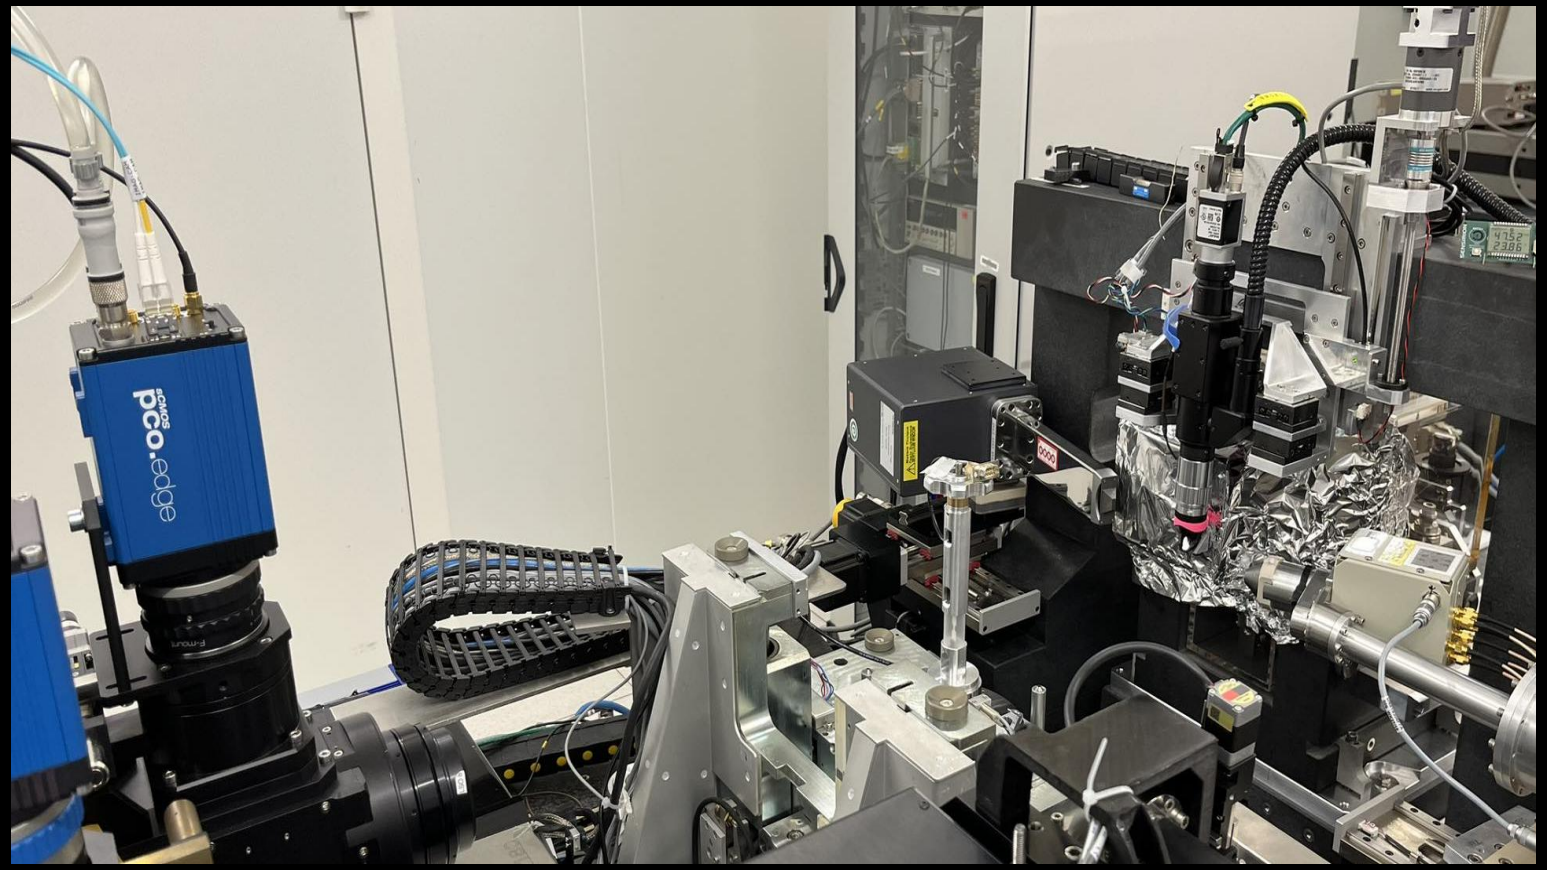


The benefits of full phase contrast retrieval

Attenuation contrast: $I = I_0 e^{-\mu d}$ (Beer-Lambert law)

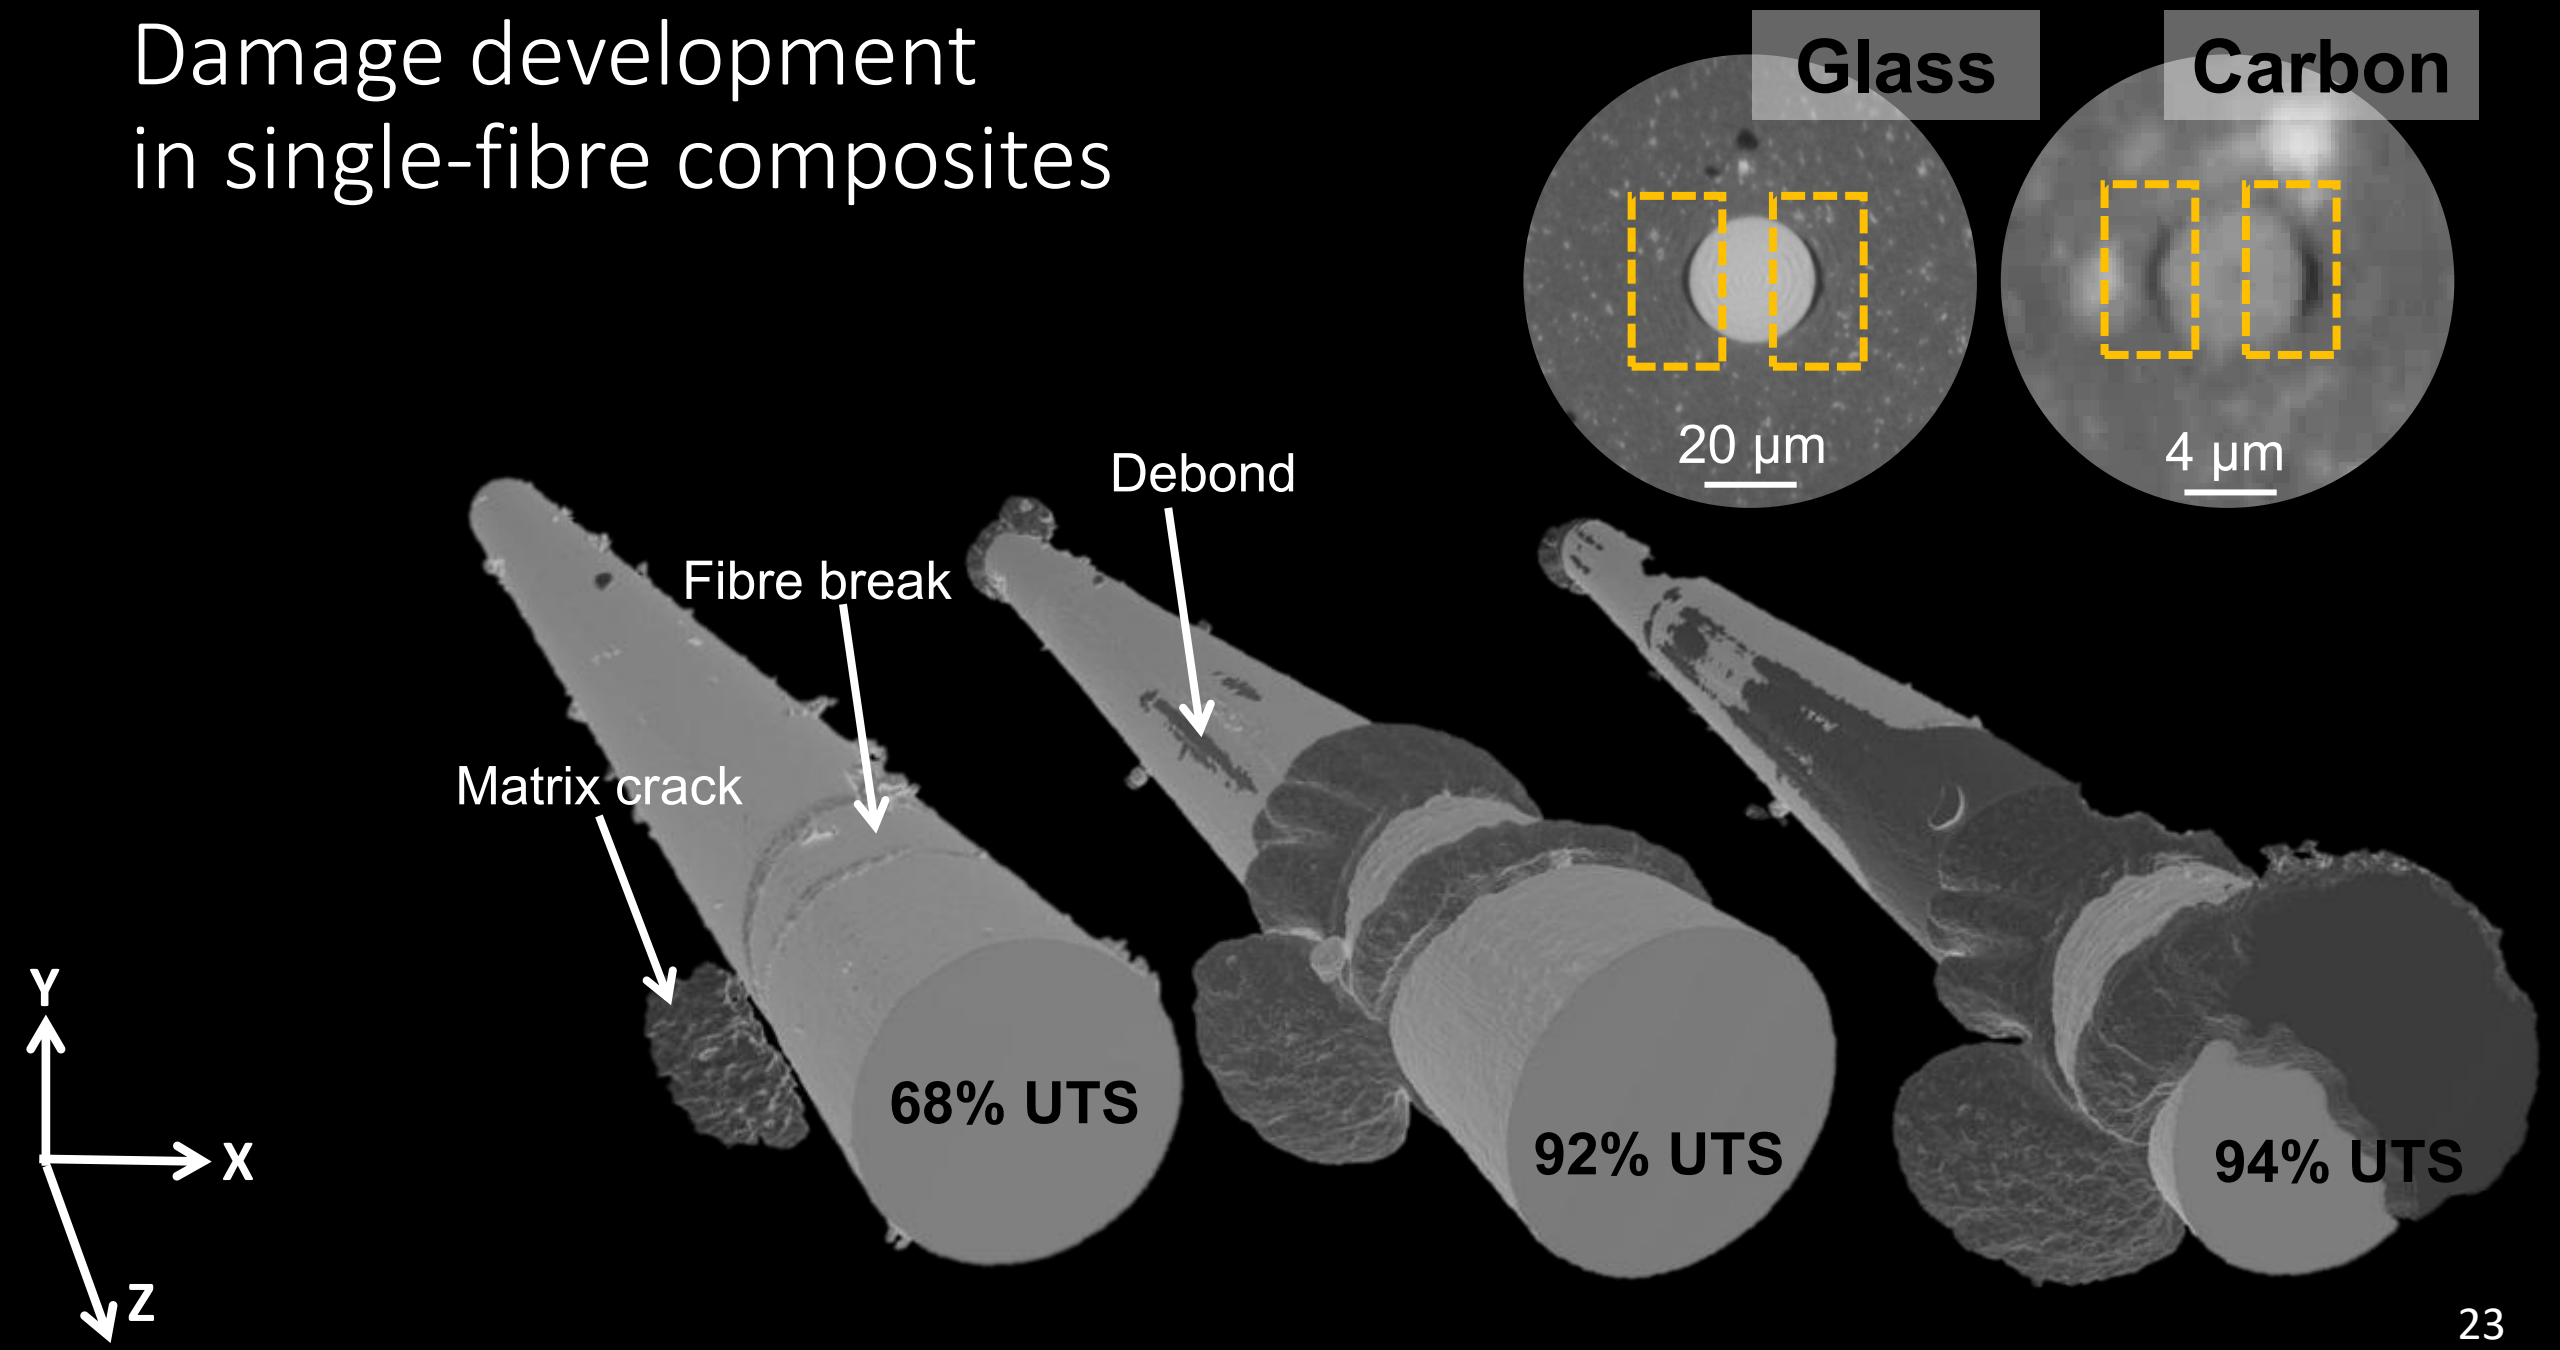


- μ = attenuation coefficient ~ Z^4
- d = thickness of material

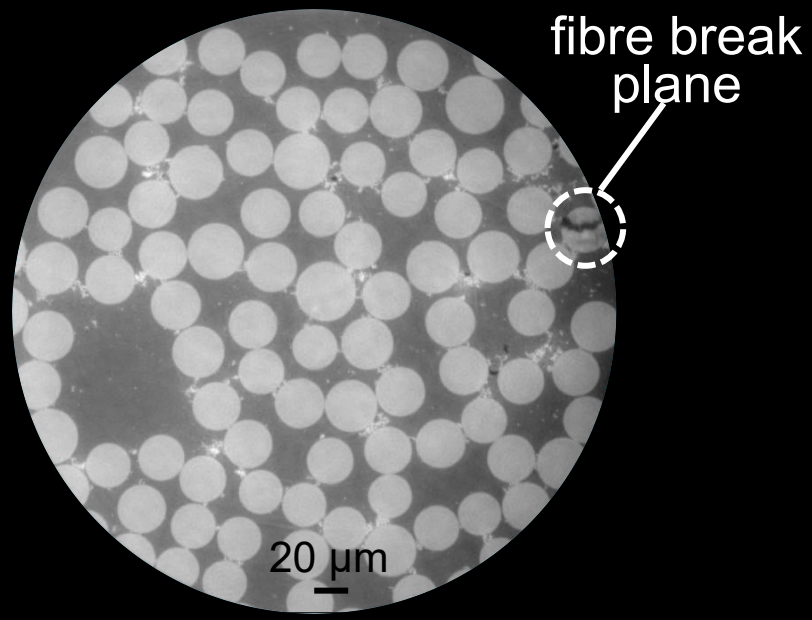


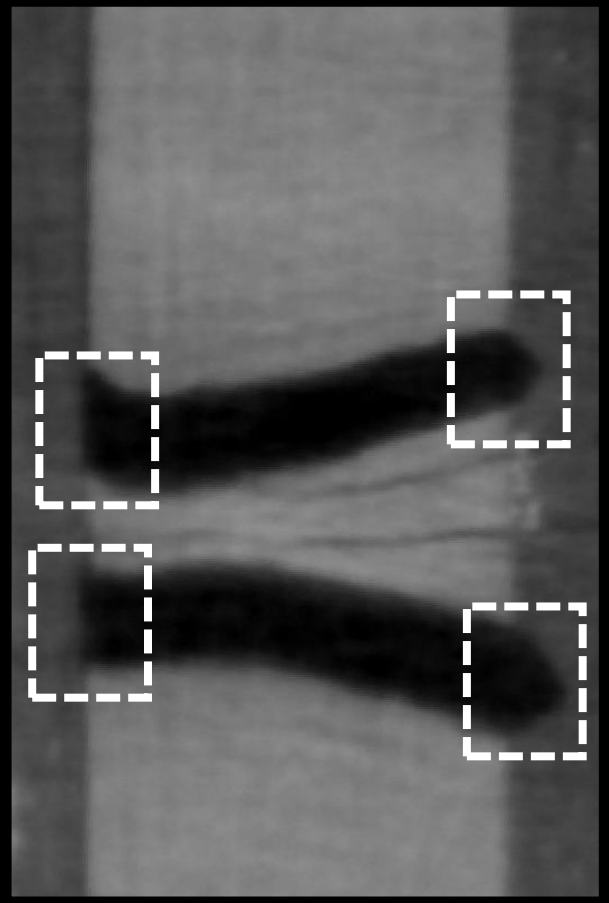
Phase contrast:

- Very sensitive to changes in refractive index
- ➔ Great at matrix-air and air-fibre interface



Setup and load rig at ID16B (ESRF)





Damage development in single-fibre composites

Damage development in glass multi-fibre composites

90% UTS

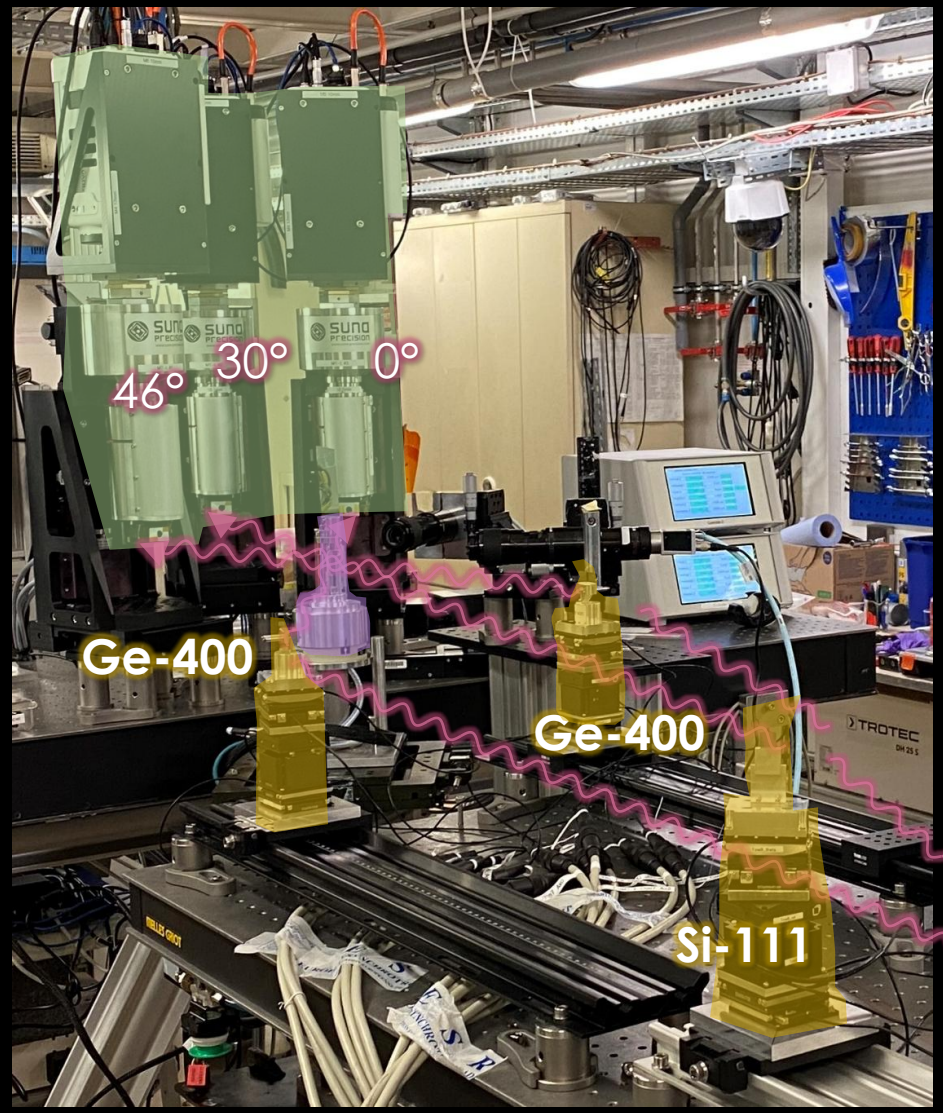
Holotomography
Future challenges and opportunities

Challenges:

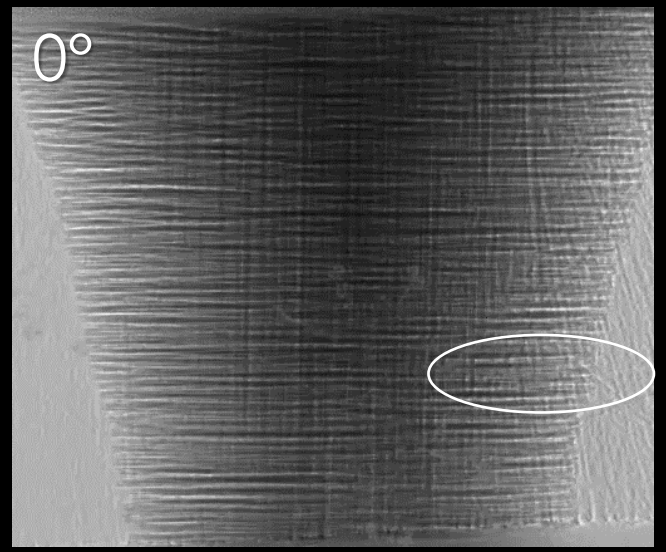
- Availability: ESRF ID16B (and potentially PETRA III P05)
- Reconstruction
- Rigs

Opportunities

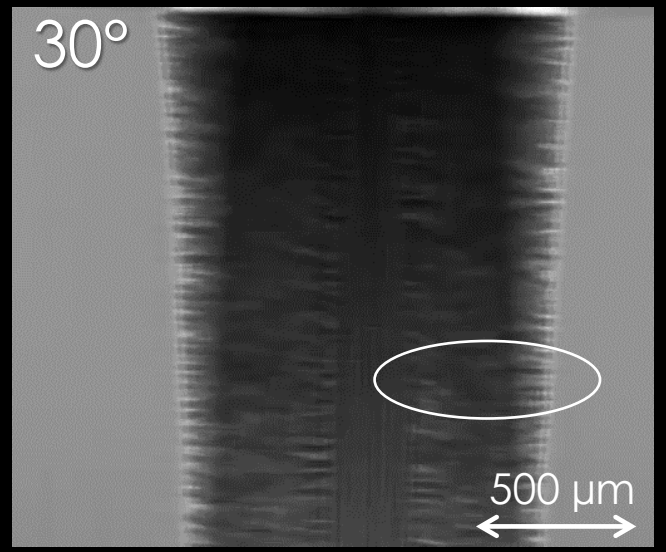
- Even higher resolutions (50 nm!)
- Ptychography (ID16A)



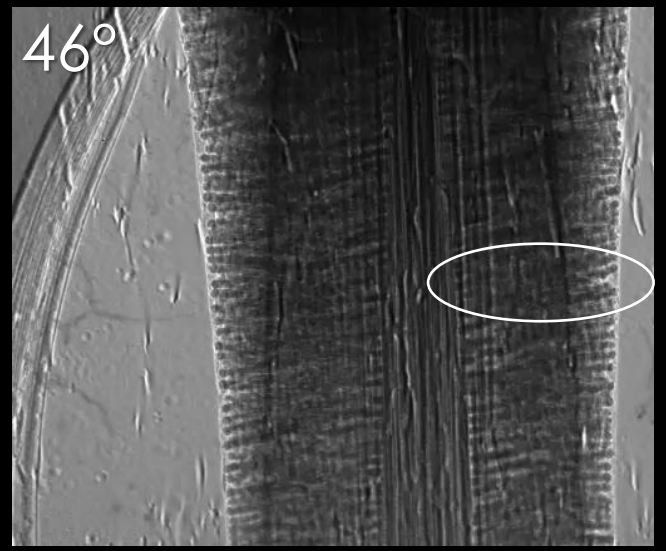
Conclusion



New technique development
- Multidisciplinary work
- Requires beamline scientists
- Specialised rigs

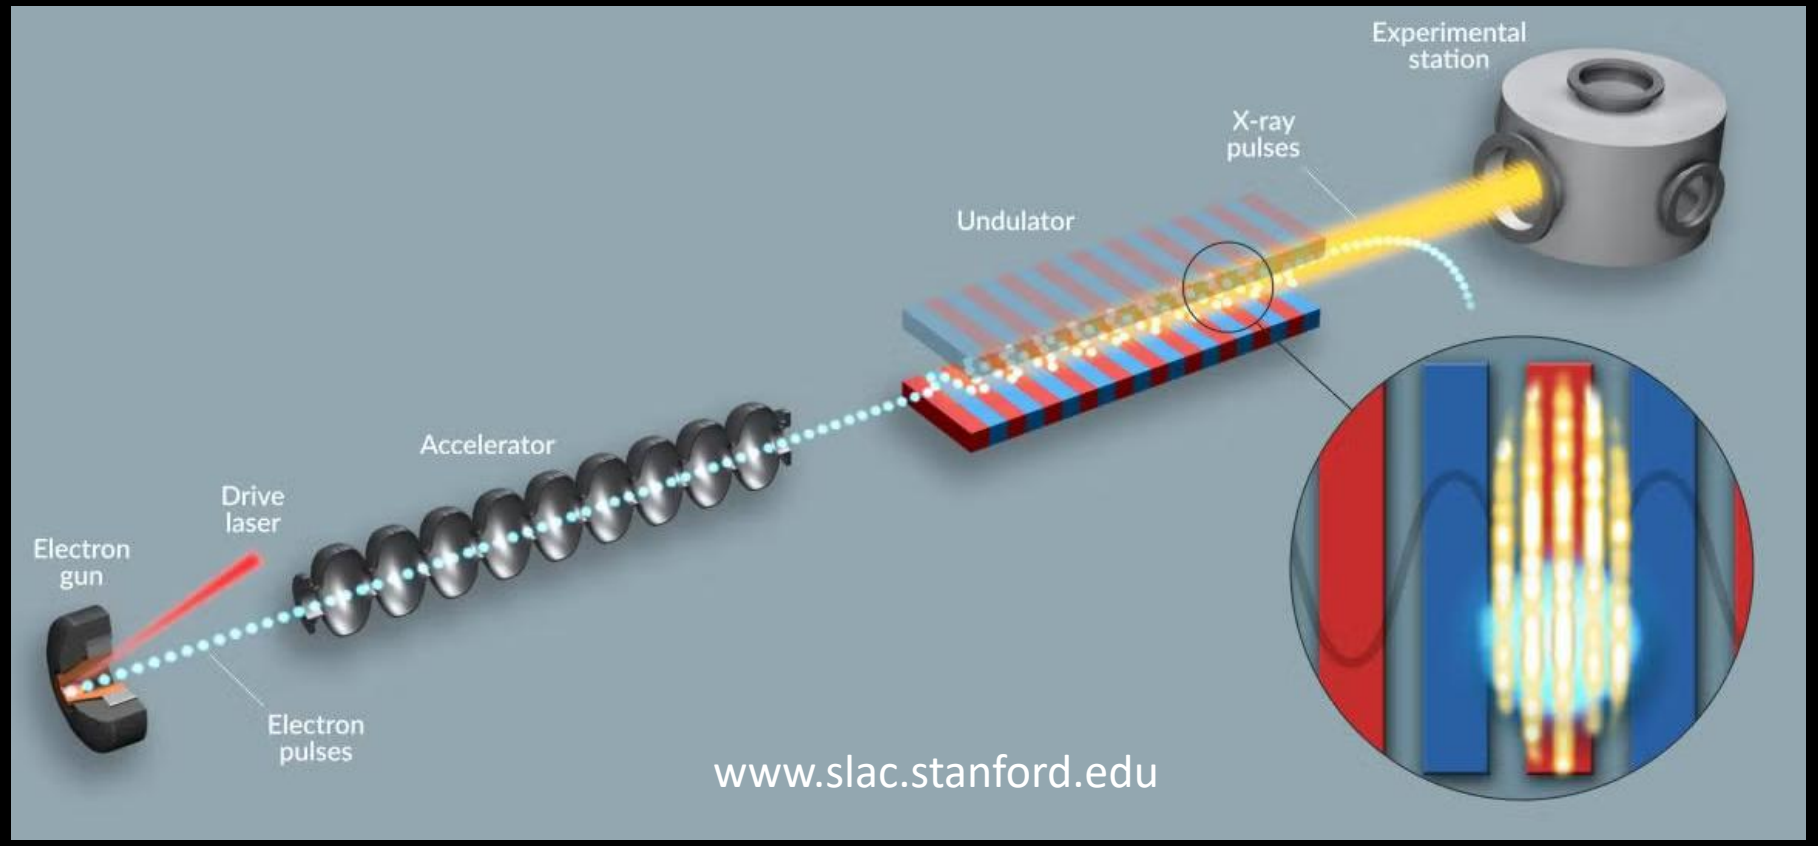


New capabilities
- Enable new insights
- Challenge models



Software needs
- Ultrafast = lots of data
- Reconstruction algorithms

What's next? - Multiprojection imaging



What's next? – X-ray free electron laser (XFEL)

Much brighter than conventional synchrotron light

Conclusions

- We introduced a framework that integrates fast testing, high-fidelity simulations, and machine learning to enable autonomous calibration and digital estimation of allowables.
- Key potential benefits:
  - AI-assisted screening of materials and lay-ups
  - Uncertainty quantification and risk-aware certification
  - Reduced reliance on extensive physical testing
  - Automated, efficient process qualification

- Acknowledgments

Keywords: Uncertainty quantification, failure prediction, composite wing, large structure

ABSTRACT

Composite materials are widely adopted in civil aircraft, as they contribute to lightweight, strong structures and offer the possibility of innovative structural concepts. However, traditional and empirical tools are often inadequate for evaluating such novel designs in the early stages of development, limiting the exploration of their full potential. To address this limitation, fast prediction models are needed to efficiently explore the design space. A key challenge in modelling large composite structures is the curse of dimensionality caused by detailed laminate stacking sequences, which greatly increases the demand for training data and computational resources. In this study, we propose a fast uncertainty quantification (UQ) model for predicting failure in composite wing boxes using Bayesian Neural Networks. The model predicts the mean failure response across various wing box geometries while quantifying the influence of different composite layups with stochastic terms. We focus on a novel structural concept, a Z-beam wing box, which is designed to achieve favourable bending–torsion coupling. Unit cells of the Z-beam structure are simulated under periodic boundary conditions. Failure indices are computed using refined local models at stress concentrations, based on the LaRC05 failure criterion. A diverse set of geometries and layups is sampled to train the UQ model. Results show that the proposed approach can accurately and quickly predict the probability distributions of failure indices for different wing box designs under varying load conditions. The predicted bounds of maximum failure indices provide valuable insights for structural assessment and highlight the need for further layup optimization when necessary.

1 INTRODUCTION

Europe's aviation sector has launched the "Destination 2050" initiative, aiming for net-zero emissions in aviation by mid-century [1]. One key strategy is increasing the wing aspect ratio to reduce induced drag [2]. For instance, Boeing's 777-X incorporates folding wingtips to extend wingspan [3]. Similarly, Airbus' ZEROe program [4] and the University of Bristol's Ultra-Green Wing (BUG) project [5], among others, are investigating the opportunities and challenges associated with high-aspect-ratio wings (HARW) [2]. A primary challenge lies in the significant structural weight increase associated with higher aspect ratios [6].

Aeroelastic tailoring has emerged as a promising passive technique to enhance both aerodynamic and structural performance [7]. Stodieck [8 and Airbus 9] introduced a Z-beam structural concept designed to improve aeroelastic tailoring, especially in reducing maneuver and gust loads. This approach shows potential in overcoming the aeroelastic limitations of HARW designs. As illustrated in Figure 1, the black lines represent the wing box spars and ribs, the grey lines indicate stringers, and the red lines highlight the Z-beams.

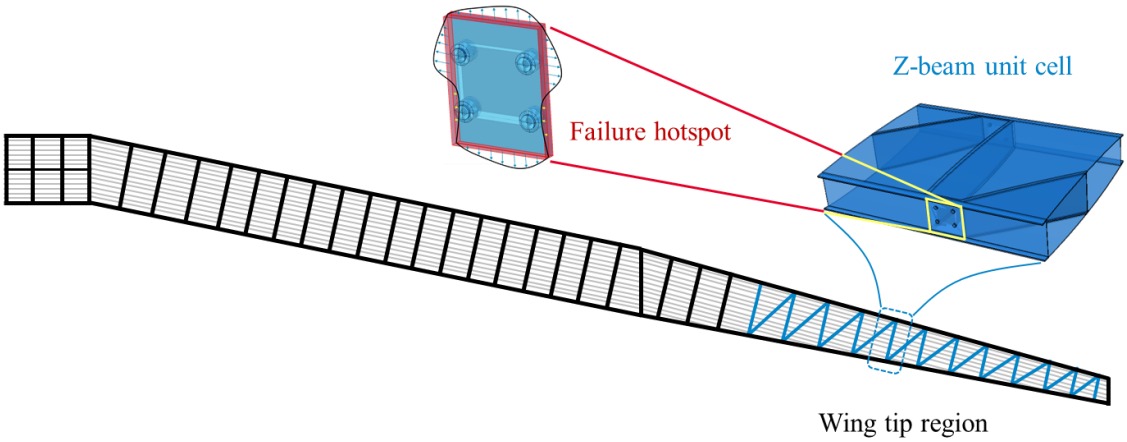

Figure 1: Z-beam structures in the wing tip region of BUG wing, and the hotspot for failure

This paper proposes an uncertainty quantification framework based on Bayesian neural networks for rapid prediction of novel wing structures. The Z-beam concept is selected as a representative case study. To model the behaviour of the Z-beam wing box at the wing tip, the structure is divided into multiple repeating unit cells, as illustrated in Figure 1. Each unit cell is analysed under periodic boundary conditions to capture its response to tension, bending, and torsion. Following this, the primary failure hotspot within the composite structure is identified. A refined local model is then developed for detailed failure analysis at this critical region.

2 PARAMETRIC MODELLING AND COMPUTATIONAL METHODS

2.1 Parameters of the Z-beam Unit Cell

The Z-beam unit cell comprises the upper and lower cover skins, front and rear C-shaped spars, a zigzag I-shaped beam, and titanium bolts. The bolts are made from aerospace-grade Ti-6Al-4V, while all other components use IM7/8551-7 carbon/epoxy composite. For simplicity, the design is parameterized using three independent geometric variables ($\Theta = [t_{\text{spar}}, t_{\text{beam}}, \alpha_{\text{beam}}]$), as illustrated in Figure 2. The definitions and ranges of these parameters are provided in Table 1. It is important to note that the spanwise length (L_z in mm) is a function of the beam angle α_{beam}.

The composite layup configuration of the wing box components is denoted by Γ, which encodes the ply orientation angles for all layers across all structural components. As a result, Γ is a high-dimensional parameter, because there are often hundreds of plies in laminates for large structures. Additionally, its dimensionality varies with laminate thickness, as different components may have different numbers of plies. These characteristics make modeling Γ particularly challenging for fast prediction models.

In this study, the geometric parameters are uniformly sampled within the ranges specified in Table 1 to generate a training dataset. For each wing box geometry, composite layups for the spars and Z-beam are then sampled. To ensure design feasibility, the layups are selected from a predefined set of candidate configurations. The front and rear spars share the same layup, while the cover skin layup is fixed to nominal values throughout this work.

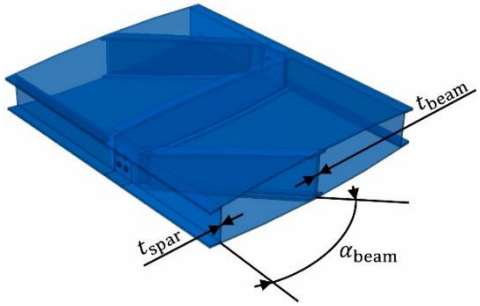

Figure 2: Geometric parameters of the Z-beam unit cell model [10]

Variable	Meaning	Range
t_{spar} (mm)	thickness of spar	[5, 25]
t_{beam} (mm)	thickness of beam	[10, 22]
α_{beam} (°)	angle between diagonal member of the beam and the spar	[20, 60]

Table 1: Independent geometric parameters

2.2 Finite Element Models

The training data for machine learning is obtained from multiscale simulations; the simulation process is shown in Figure 3. Abaqus is used as the numerical solver in this work. The behaviour of the complete zigzag beam in the wing tip region of BUG wing, as shown in Figure 1, is approximated by Z-beam unit cells arranged in a one-dimensional series. The aeroelastic deformation of the full wing box can be simulated by reduced order models [11], which only requires the homogenized stiffness matrix of each unit cell:

$$\begin{bmatrix} F_z \\ M_z \\ M_x \\ M_y \end{bmatrix} = \begin{bmatrix} C_{11} & C_{12} & C_{11} & C_{14} \\ C_{21} & C_{22} & C_{23} & C_{24} \\ C_{31} & C_{32} & C_{33} & C_{34} \\ C_{41} & C_{42} & C_{43} & C_{44} \end{bmatrix} \begin{bmatrix} \epsilon_z \\ \kappa_z \\ \kappa_x \\ \kappa_y \end{bmatrix} \tag{1}$$

At the structural element level, the loads (Δ) applied on the unit cell model include the axial strain in z-axis (ϵ_z), twist rate about z-axis (κ_z, rad/mm), and the curvature about x/y-axis (κ_x, κ_y, 1/mm). The loads are employed using periodic boundary conditions (PBCs), and the displacement boundaries ($\boldsymbol{u}$) around failure hotspots are determined.

At the hotspot level, stress ($\boldsymbol{\sigma}$) and strain ($\boldsymbol{\epsilon}$) fields are assessed on a finer mesh using a global-local approach. Then, failure indices (FIs, $\boldsymbol{v}$) are calculated using the LaRC05 failure criteria [13]. By analysing various strain states, a failure index map is generated by identifying the maximum failure index within the structure. Consequently, the failure envelop can be obtained from the FI map. The details can be found in [10,14] and are therefore not repeated here.

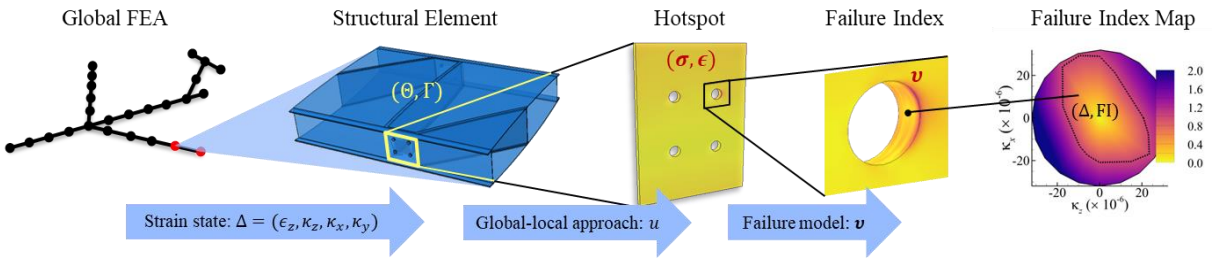

Figure 3: Multiscale simulation of composite Z-beam wing box elements

3 MACHINE LEARNING FOR Z-BEAM WING BOXES

3.1 Database

There are 1400 valid unit cell samples in the database. The homogenized stiffness matrix [C] and mass matrix [M] are extracted. Figure 4 shows the relationship between the stiffness components with geometry parameters, when the composite layup are set to nominal values. It shows that t_{spar} dominates C_{11}, C_{33}, C_{13}; t_{beam} dominates C_{23}; t_{spar} and t_{beam} have same level of influence on C_{22}.

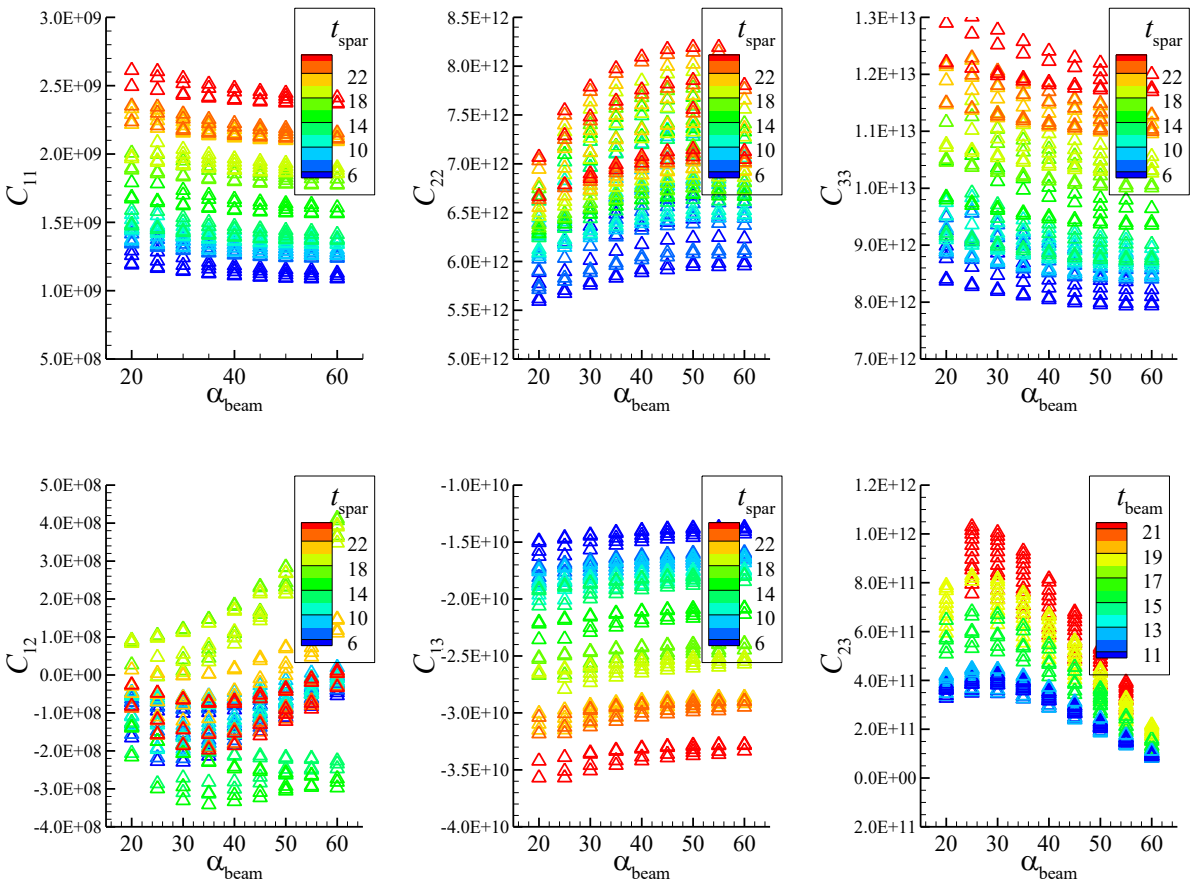

Figure 4: Distribution of stiffness components in the database

3.2 A Machine Learning Model for Z-beam Unit Cell's properties

A machine learning model is used to predict the properties of Z-beam unit cell that are independent of the loads, i.e., the weight and homogenized stiffness matrix. The model input is the geometric parameters Θ and superlayer parameters ($\Omega = [r_{0,\text{beam}}, r_{90,\text{beam}}, r_{0,\text{spar}}, r_{90,\text{spar}}]$), the output is the weight (w) and the homogenised stiffness matrix ($[C]$), as shown in Figure 5. The superlayer parameters, i.e., percentage of plies in the beam and spar are used to predict the homogenised stiffness. It is because the structure dimension (i.e., wing box height) is much larger than the laminate thickness, consequently, the stacking sequence details have insignificant influence on $[C]$.

A simple artificial neural network (ANN) is employed, which contains three hidden layers with 512 neurons. The loss function is the mean square error (MSE) between the predicted values and the real values. The initial learning rate is 0.001 for 500 epochs. Adam optimizer[15] is used for training. 20 samples are randomly selected for testing. Figure 6 shows the prediction error on the training set and testing set during training. It shows that the model can achieve a good prediction accuracy.

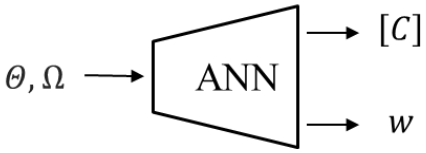

Figure 5: ANN for the prediction of weight and stiffness

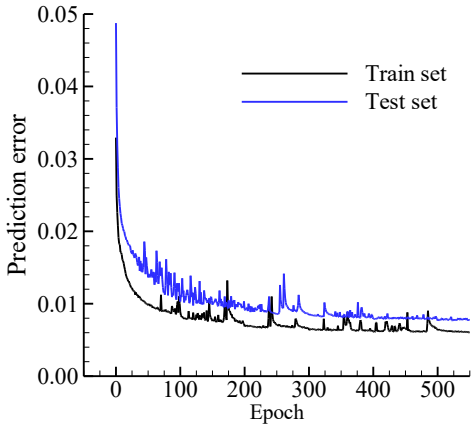

Figure 6: Prediction error on the training set and testing set during training.

3.3 Bayesian Neural Networks for Failure Prediction

Bayesian neural networks are trained on the wing box database. The loss function is the evidence lower bounds (ELBO) on the training set. The initial learning rate is 0.001 for 2,000 epochs. Adam optimizer is again used for training. Figure 7 presents a predicted maximum failure index map of a Z-beam geometry. The details of the proposed uncertainty quantification model and more results will be presented in the conference.

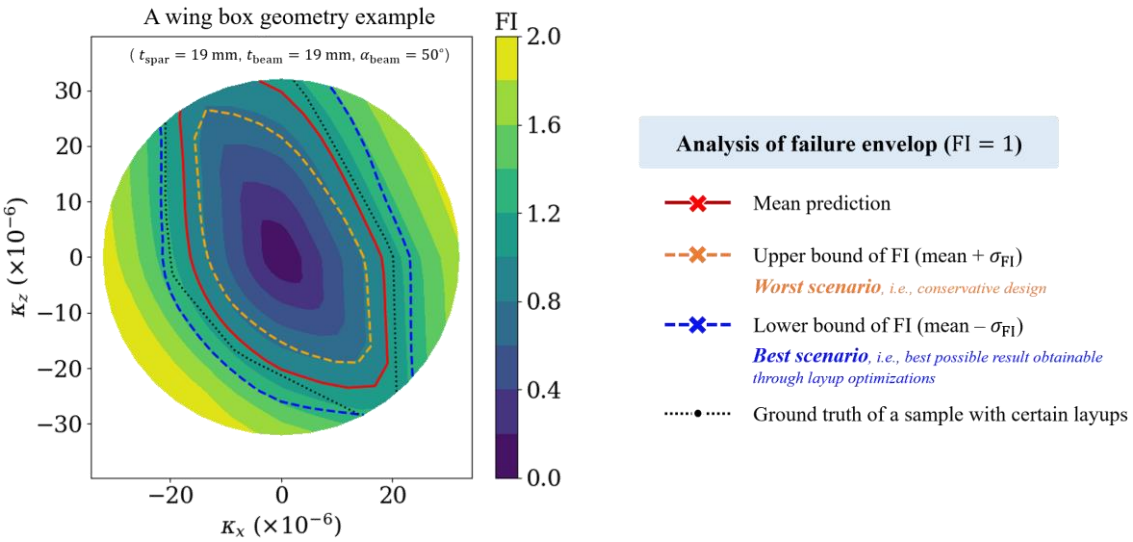

Figure 7: The expected maximum failure index map of a Z-beam wing box geometry. The wing box is under bending strains (κ_x) and torsional strains (κ_z), the geometric parameters are $t_{\text{spar}} = 19, t_{\text{beam}} = 19, \alpha_{\text{beam}} = 50°$. The solid red line shows the expected failure envelop ($\mu(\text{FI}) = 1$), the orange and blue dashed lines show the upper and lower bounds of FI (or 1σ confidence interval). The black dashed lines show the failure envelop of the wing box geometry with the nominal layup.

3 CONCLUSIONS

The Z-beam structure enables tailored bending–torsion coupling through geometric modifications, making it well-suited for high aspect ratio wing applications. A simple neural network is trained to predict the homogenized stiffness of the Z-beam unit cell, enabling fast and accurate evaluations for preliminary design. To assess structural reliability, an uncertainty quantification model is developed and trained to predict failure behavior and capture the influence of composite layup variations. Results demonstrate that the proposed method can efficiently and accurately predict the probability distributions of failure indices across different wing box configurations under varying loading conditions. This

approach is therefore well-suited for early-stage design and evaluation of novel composite wing concepts.

ACKNOWLEDGEMENTS

The authors would like to gratefully acknowledge the funding from Innovate UK under the Next Wing project No. 10002372 (https://gtr.ukri.org/projects?ref=10002372). The authors also thank Nicolae Lucian Iorga from Airbus UK for the support and helpful discussions.

$$a_{yy} = a_{22} = \frac{1}{N}\sum_{i=1}^{N} \cos^2(\beta_i)\ \sin^2(\varphi_i)$$

$$a_{zz} = a_{33} = \frac{1}{N}\sum_{i=1}^{N} \cos^2(\beta_i)\ \cos^2(\varphi_i)$$

$$sin\,\beta = \frac{a}{b}$$

Manual

Weighted average tensor calculated manually:

$[0.11533, 0.78703, 0.09764]$

Weighted average tensor:

$$\bar{T} = \frac{\sum_{i=1}^{N} \frac{1}{z_i} \cdot T_i}{\sum_{i=1}^{N} \frac{1}{z_i}}$$

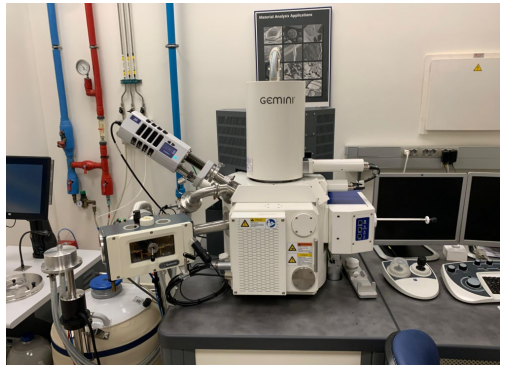
Deep Learning

Weighted average tensor calculated with Deep Learning:

$[0.10507, 0.72362, 0.17130]$

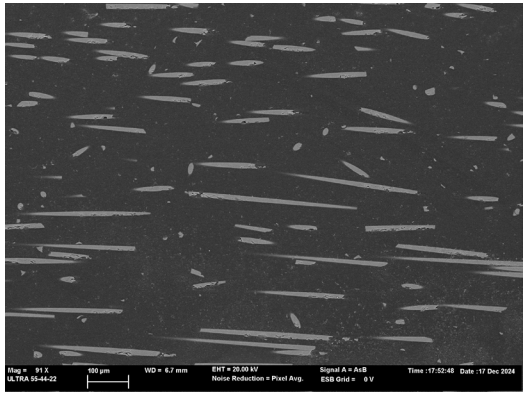
$\bar{T}$: Weighted average tensor.

T_i: Tensor corresponding to the i-th image.



z_i: Zoom level of the i-th image.

$\frac{1}{z_i}$: Weight assigned to the i-th image, inversely proportional to the zoom.



N: Total number of images.

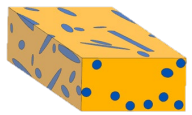
$Mean\ Angular\ Error = 6.93º$

Workflow

Obtaining Images

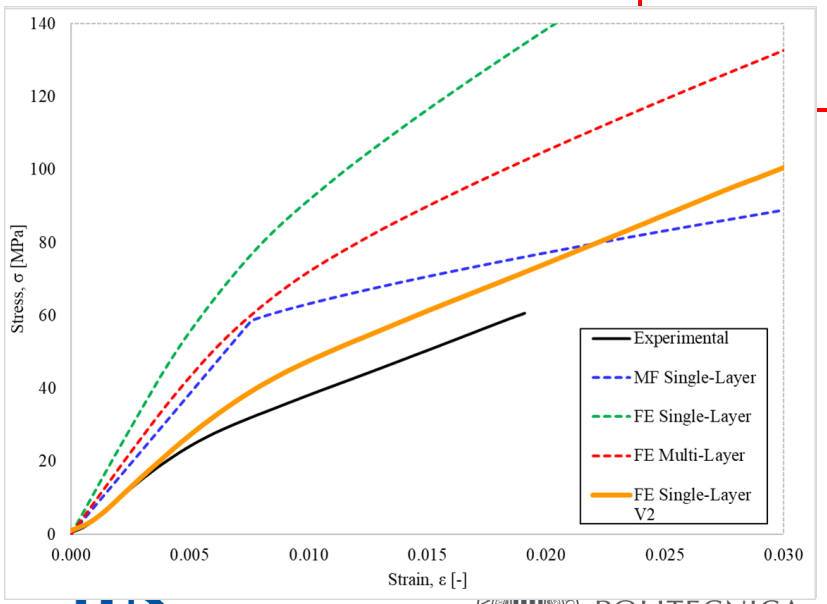
Binarize the images

Neural Network



$[a_{xx}, a_{yy}, a_{zz}]$

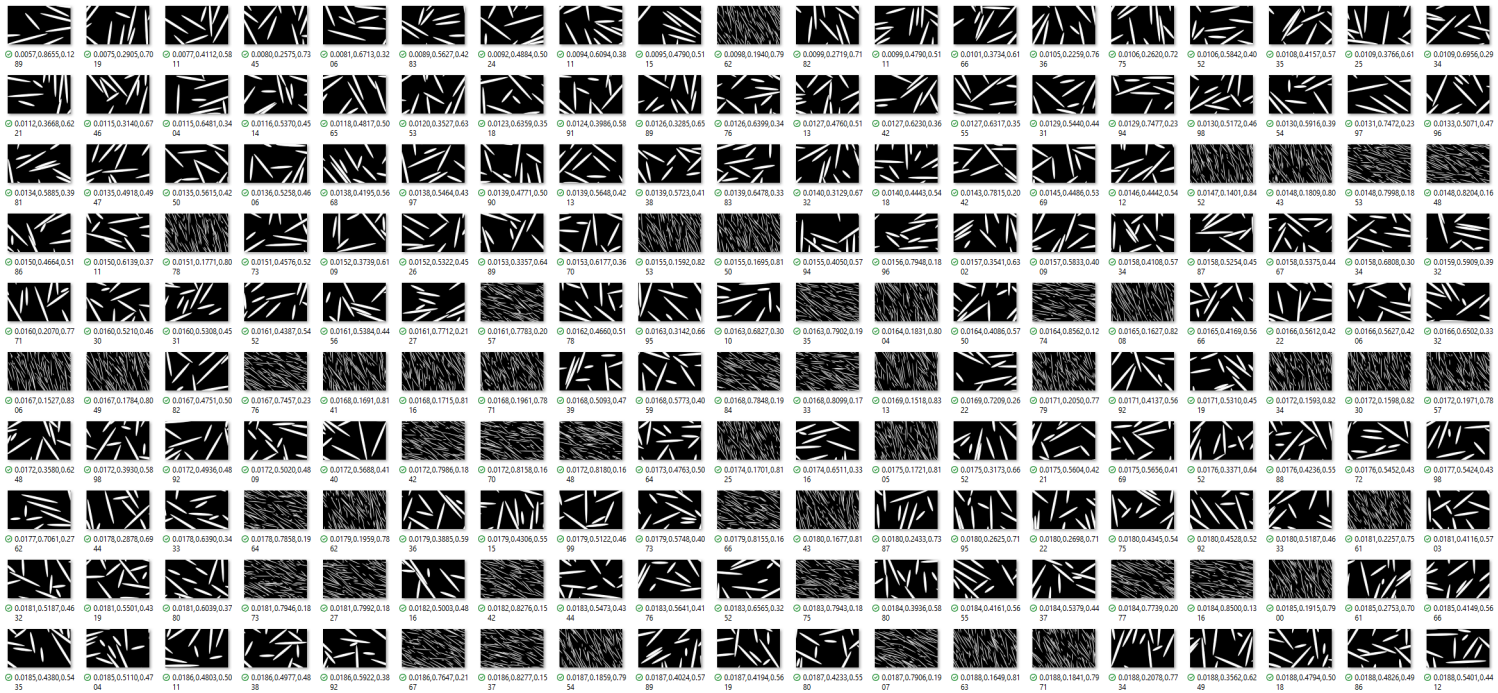
This process is repeated for each image



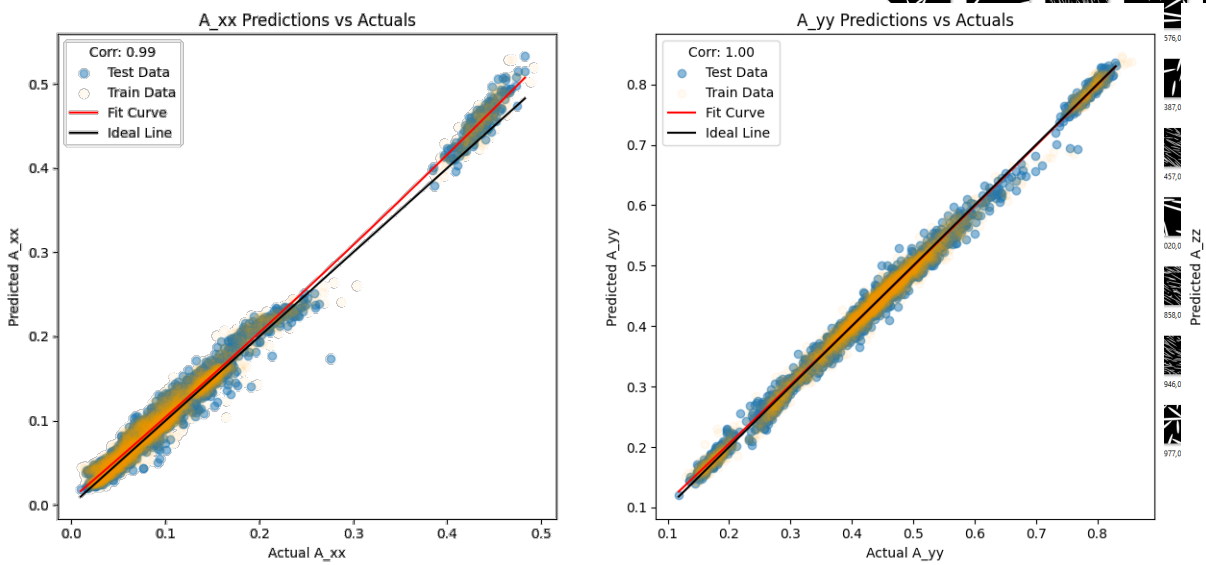
Store tensor and corresponding magnification of the image

$$\bar{T} = \frac{\sum_{i=1}^{N} \frac{1}{z_i} \cdot T_i}{\sum_{i=1}^{N} \frac{1}{z_i}}$$

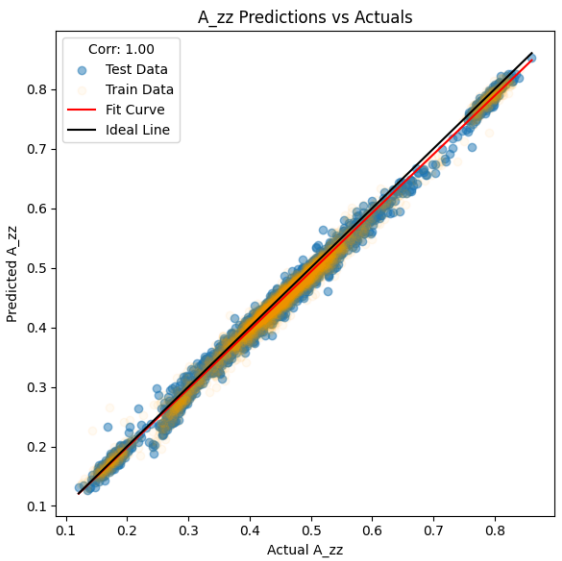
Weighted Average Orientation Tensor



Generate microstructure and create numerical model in DIGIMAT



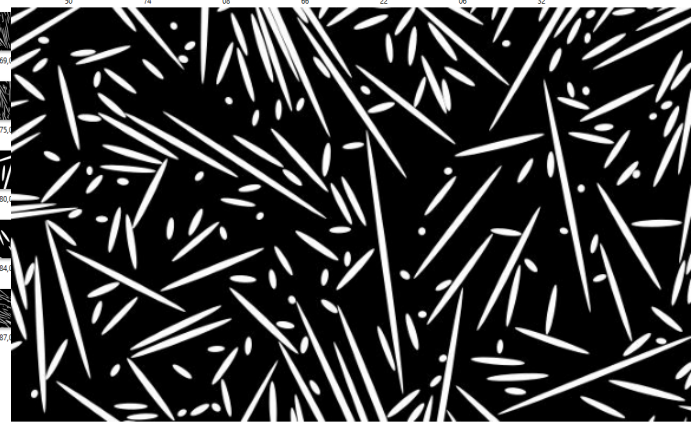
Conclusions

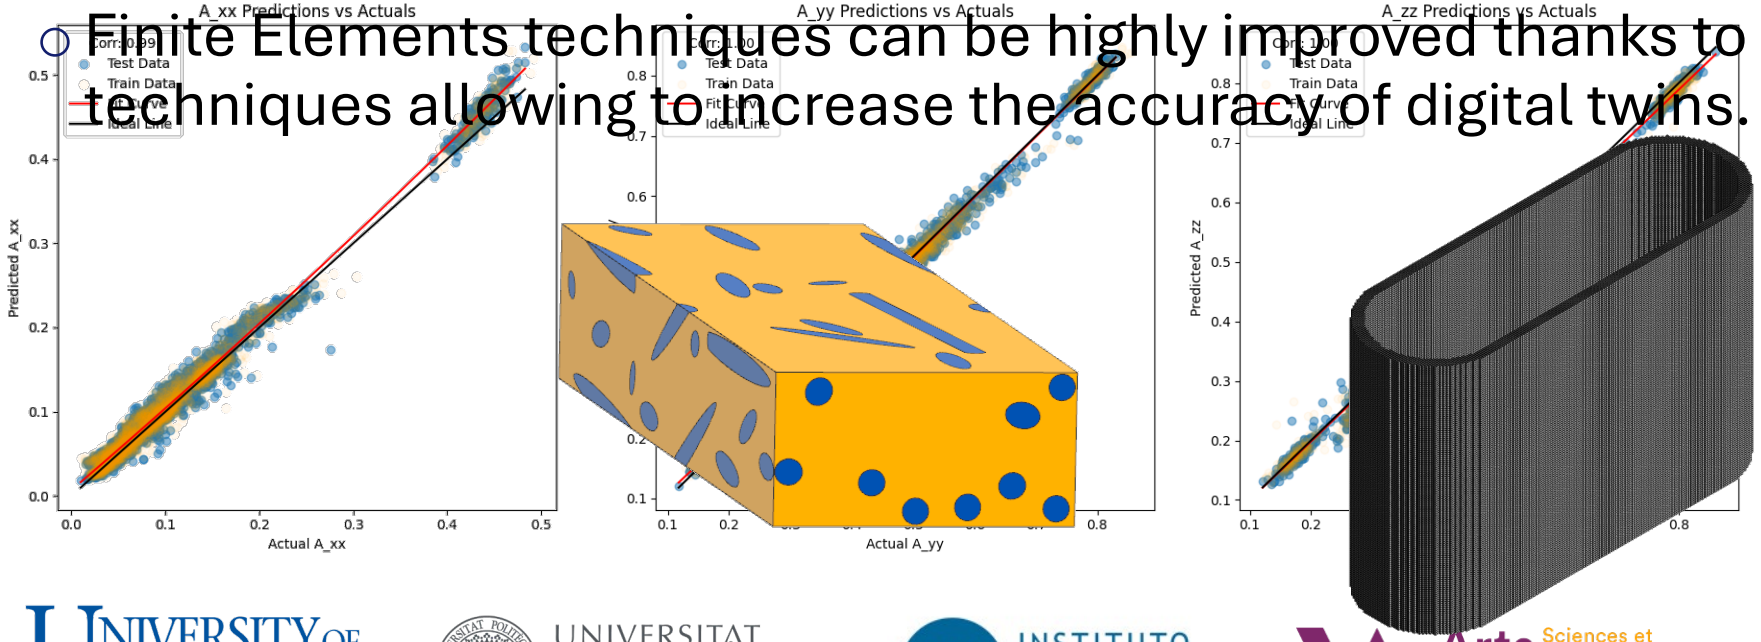


- Data augmentation techniques are a powerful tool to overcome data scarcity: more than 40000 images generated

Conclusions

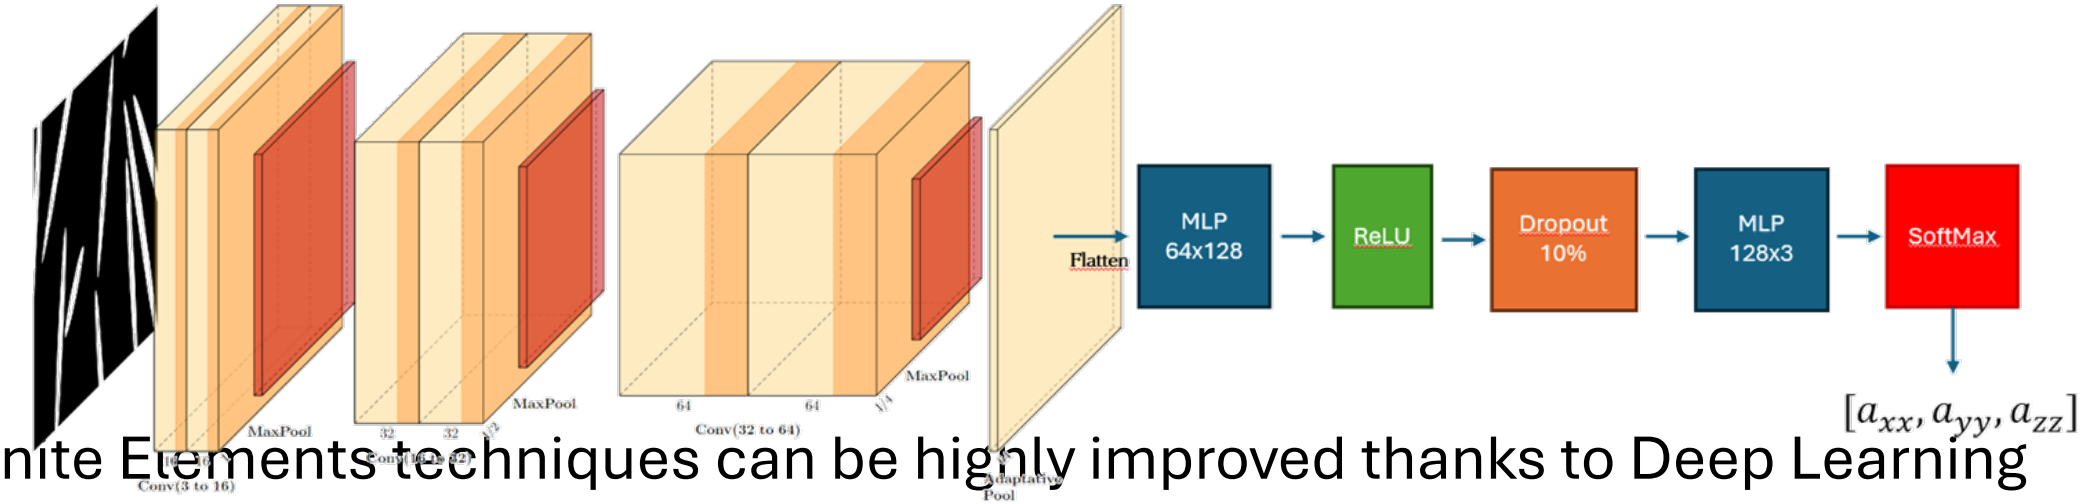
- Data augmentation techniques are a powerful tool to overcome data scarcity: more than 40000 images generated
- Using Deep Learning as a tool to measure the Orientation Tensor allows to process a big amount of images effortless with high accuracy





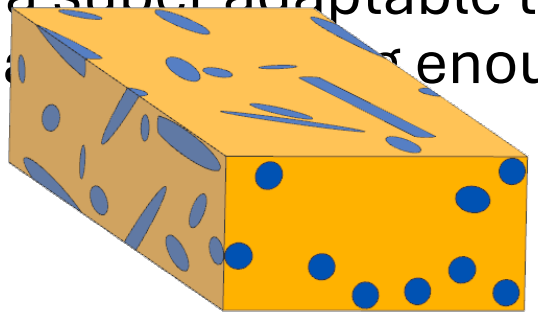
Real: [0.104, 0.132, 0.764]

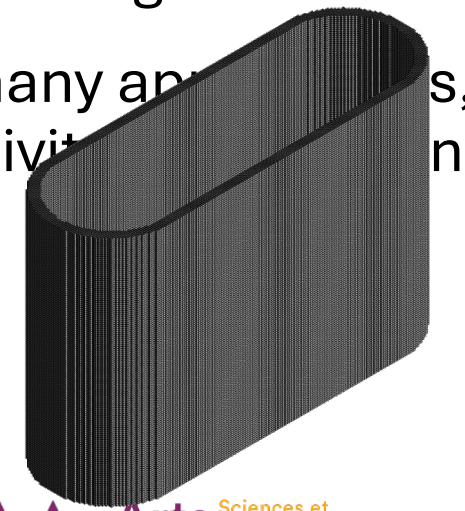
Mean angular error: 0.56°



Conclusions

- Using Deep Learning as a tool to measure the Orientation Tensor allows to process a big amount of images effortless with high accuracy
- Finite Elements techniques can be highly improved thanks to Deep Learning techniques allowing to increase the accuracy of digital twins.





Conclusions

- Finite Elements techniques can be highly improved thanks to Deep Learning techniques allowing to increase the accuracy of digital twins.
- Deep Learning is a super adaptable tool for many ap s, where the main 2 difficulties are: D enough creativit n is the limit.

The Midlands

Midlands advanced ceramics for industry 4.0

SIPF investment: £18 million

The Midlands Industrial Ceramics Group (MICG) is a consortium of researchers, manufacturers and end-users. Together, the group will develop streamlined processes for proving and bringing new advanced ceramics technologies to market faster, with less energy usage and lower carbon emissions. This will enable effective problem-solving and faster commercialisation of new products, unlocking improved performance for next generation products including:

- fuel cells and batteries
- 5G communications
- ceramic-matrix composites for aero engines
- medical devices.

It will also boost the competitiveness of manufacturers in the region by developing a robust advanced ceramics supply chain, able to export into one of the fastest growing international industry sub-sectors. Advanced ceramics are vital 'enablers' for many manufacturing sectors

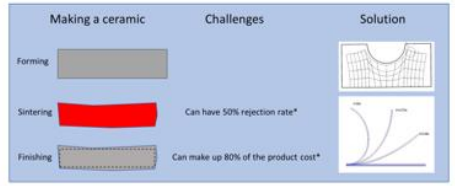
Vision



Our vision is to revolutionise ceramic manufacturing by enabling seamless, real-time interactions between computer simulations and real-world processes. We continuously update finite element models (FEM) with real-time data to eliminate uncertainties and enhance precision

Through **Digital Twinning**, we aim to optimise manufacturing efficiency and address critical industrial challenges, such as controlling sintering shrinkage and distortion, ensuring precision in advanced ceramics and other high-value applications.

Leveraging Machine Learning & Artificial Neural Networks (ANNs):
Improving the accuracy of sintering simulations by replacing empirical laws in finite element analysis with nested ANNs trained with experimental data, enhancing industrial processes like flash sintering.

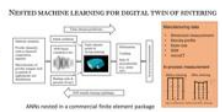
Predictive Accuracy & Custom Subroutines: By developing custom UMAT, CREEP and MATLAB unites for ABAQUS and COMSOL (using Fortran, Python, and MATLAB), we integrate machine learning and physics-based neural networks, optimizing manufacturing processes and advancing predictive accuracy in critical industrial applications.

Industrial Challenge: Controlling Sintering **Shrinkage** and **Distortion**

Digital Twin Lab: Shaping Future Ceramic Manufacturing

Funded for £2.1 million by UKRI's Strength in Places Fund

Impact: Transforming Advanced Ceramics Manufacturing through real-time data integration and digital twin models nested with ANNs, we aim to reduce inefficiencies, lower rejection rates, and minimize post-sintering costs. This approach fine-tunes manufacturing conditions, reducing waste and energy consumption, and promoting sustainable practices.



Collaborative Network: UK Industries and Universities (logos displayed) contribute data, research, and testing environments, ensuring effective integration of digital twins into real-world processes.

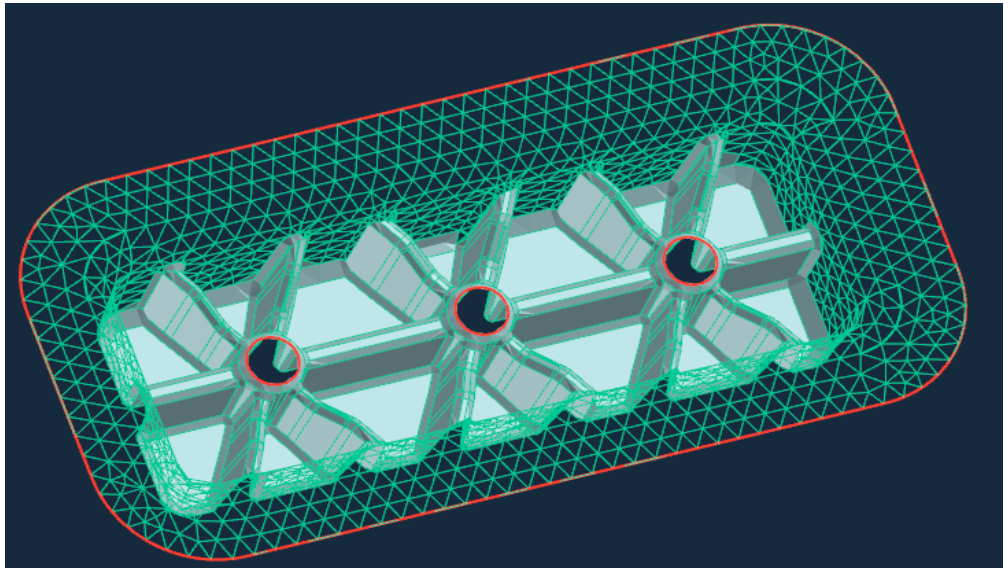
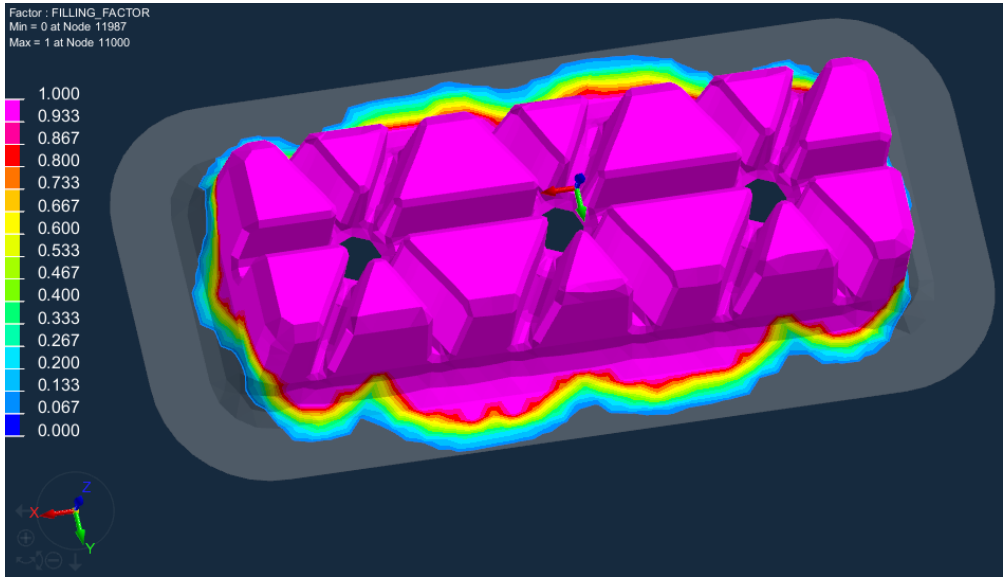
This project has received funding from the European Union's **Horizon Europe** Research and Innovation programme under Grant Agreement No. 101091449



Motivation

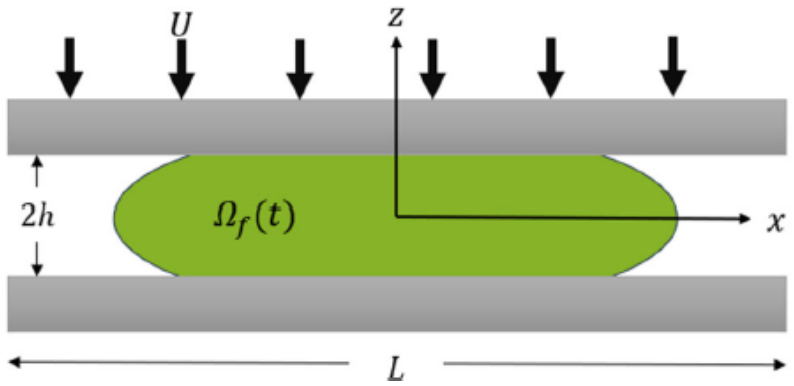
The Sheet Molding Compound (SMC) process is widely used for producing composite structures in high-volume manufacturing due to its efficiency and scalability.



- **Challenges associated with complex mold geometries**
  - What is the initial charge shape for optimal mold filling and low material overflow ?
  - How to reduce flow bouncing on the boundary since it could perturbate fiber orientation ?

- **State of the art solution**
  - If assumed initial charge shape, simulation can predict final material distribution along with fiber orientation.
  - Requires trial and error to find the initial shape.
  - No scientific approach or adapted simulation tool.
  - **Limitation**:
    - Computationally expensive
    - Non-optimized initial charge shapes

- **Objectives**:
  - Develop a reverse flow simulation tool that can compute the initial charge shape if given final mold geometry.
  - Create a digital twin of the SMC reverse simulation that can predict initial charge shape in real-time.
  - In this research, we first limit our approach for 2D molds.

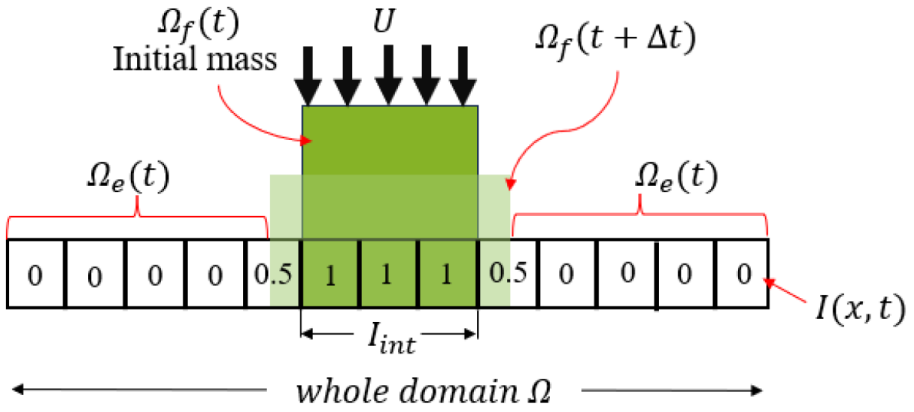


SMC simulation on a part manufactured by MARELLI as a technology demonstrator for the SMC process

Reversing the SMC flow simulation

SMC flow simulation:

- SMC simulation enabled by solving [1, 2] :
  - Stokes equation simplified for narrow gaps by lubrication theory : $\boxed{\nabla \boldsymbol{P} = \eta \Delta \boldsymbol{v}}$
    - η = dynamic viscosity,
    - $\boldsymbol{P}$ = Pressure field
    - $\boldsymbol{v}$ = velocity field
  - Constant mesh grid



- We distinguish fluid domain $\Omega_f(t)$ where $\boldsymbol{P}$ is to be computed from empty domain $\Omega_e(t)$ where $\boldsymbol{P}$=0
- By setting appropriate BCs, the average velocity field in 2D : $\boxed{\tilde{\boldsymbol{v}}(\boldsymbol{x},\mathrm{y}) = -\frac{h^2}{3\eta}\nabla \boldsymbol{P}}$
- Since the fluid domain is evolving, we need to describe the fluid front by :

$$\boldsymbol{I}(\boldsymbol{x},t) = \begin{cases} 1 \text{ if } & \boldsymbol{x} \in \Omega_f(t) \\ 0 \text{ if } & \boldsymbol{x} \in \Omega_e(t) \end{cases} \text{ with: } \boldsymbol{I}(\boldsymbol{x}, \ t=0) = I_{init}$$

- $\boldsymbol{I}(\boldsymbol{x},t)$ is described by: $\boxed{\frac{\partial \boldsymbol{I}(\boldsymbol{x},t)}{\partial\, t} + \boldsymbol{v}(\boldsymbol{x},t).\nabla \boldsymbol{I}(\boldsymbol{x},t) = 0}$ (1)
- Combining the equations of $\boldsymbol{P}$ and $\boldsymbol{I}$ leads to the weak-formulation:

$$\boxed{\int_\Omega \left(\boldsymbol{I}\nabla\widehat{\boldsymbol{P}}\left(\frac{h^2}{3\eta}\nabla \boldsymbol{P}\right) + (\boldsymbol{1}-\boldsymbol{I})\widehat{\boldsymbol{P}}\boldsymbol{P}\right)d\Omega = \int_\Omega \left(\boldsymbol{I}\widehat{\boldsymbol{P}}\widetilde{\boldsymbol{U}}\right)d\Omega} \quad (2)$$

[2] F. Ebrahimian, S. Rodriguez, D. Di Lorenzo and F. Chinesta, Optimization of precharge placement in sheet molding compound process. International Journal of Material Forming. Vol. 17, 2024.

SMC flow simulation:

- Solving eq.(1) and eq.(2) numerically includes using flux limiters for $\boldsymbol{I}$:

$$\frac{\partial \boldsymbol{I}(\boldsymbol{x},t)}{\partial\, t} + \boldsymbol{v}(\boldsymbol{x},t).\nabla \boldsymbol{I}(\boldsymbol{x},t) = 0$$

$$\int_{\Omega} \left(\boldsymbol{I}\nabla\widehat{\boldsymbol{P}}\left(\frac{h^2}{3\eta}\,\nabla \boldsymbol{P}\right) + (\mathbf{1}-\boldsymbol{I})\widehat{\boldsymbol{P}}\boldsymbol{P} \right) d\Omega = \int_{\Omega} \left(\boldsymbol{I}\widehat{\boldsymbol{P}}\widetilde{\boldsymbol{U}}\right) d\Omega$$

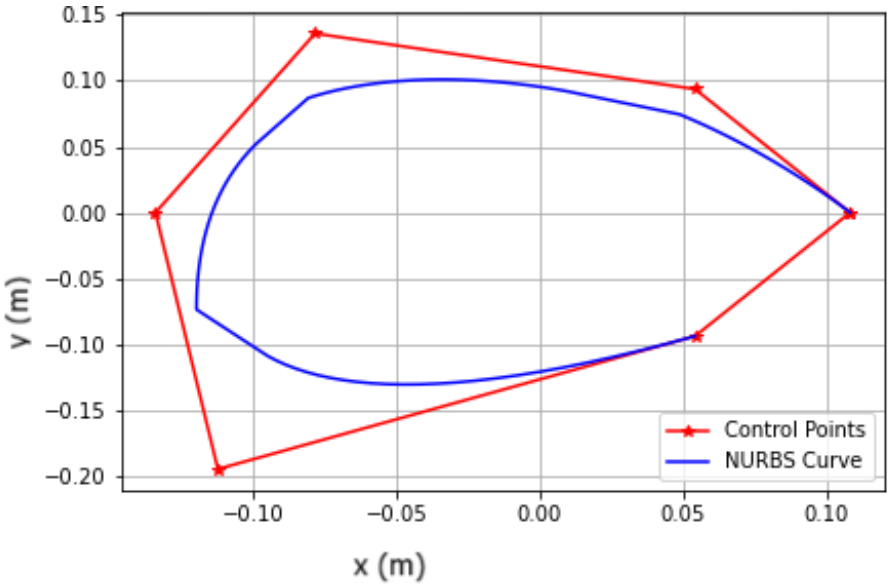
- For cell e, field values at time step t_{i+1} are deduced from time step t_i:

$$\boldsymbol{I}_{i+1}^{e} = \boldsymbol{I}_{i}^{e} - \boxed{\frac{\Delta t}{A(e)} \sum_{j=1}^{3} l^{ej} \hat{\boldsymbol{f}}^{ej}.\boldsymbol{n}^{ej}} \rightarrow \boldsymbol{\Phi} = \text{flow flux}$$

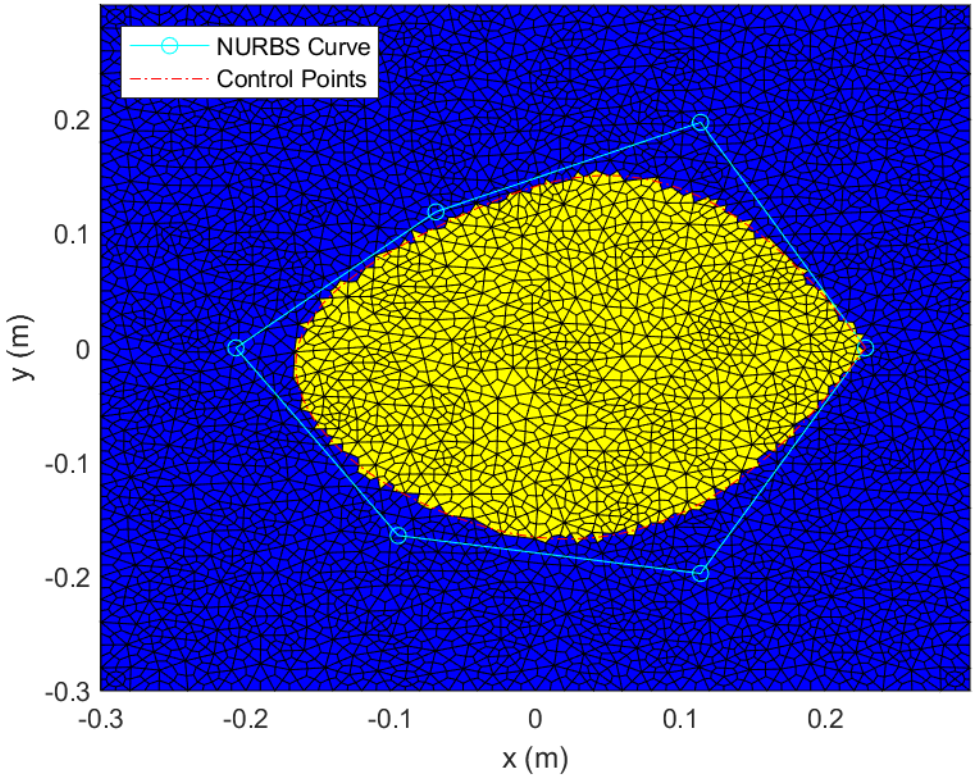
$$h(t_{i+1}) = h_0 - \frac{U * t_{i+1}}{2}$$

Reverse SMC flow

$$\boldsymbol{I}_{i+1}^{e} = \boldsymbol{I}_{i}^{e} + \boxed{\frac{\Delta t}{A(e)} \sum_{j=1}^{3} l^{ej} \hat{\boldsymbol{f}}^{ej}.\boldsymbol{n}^{ej}}$$



$$h(t_{i+1}) = h_0 + \frac{U * t_{i+1}}{2}$$

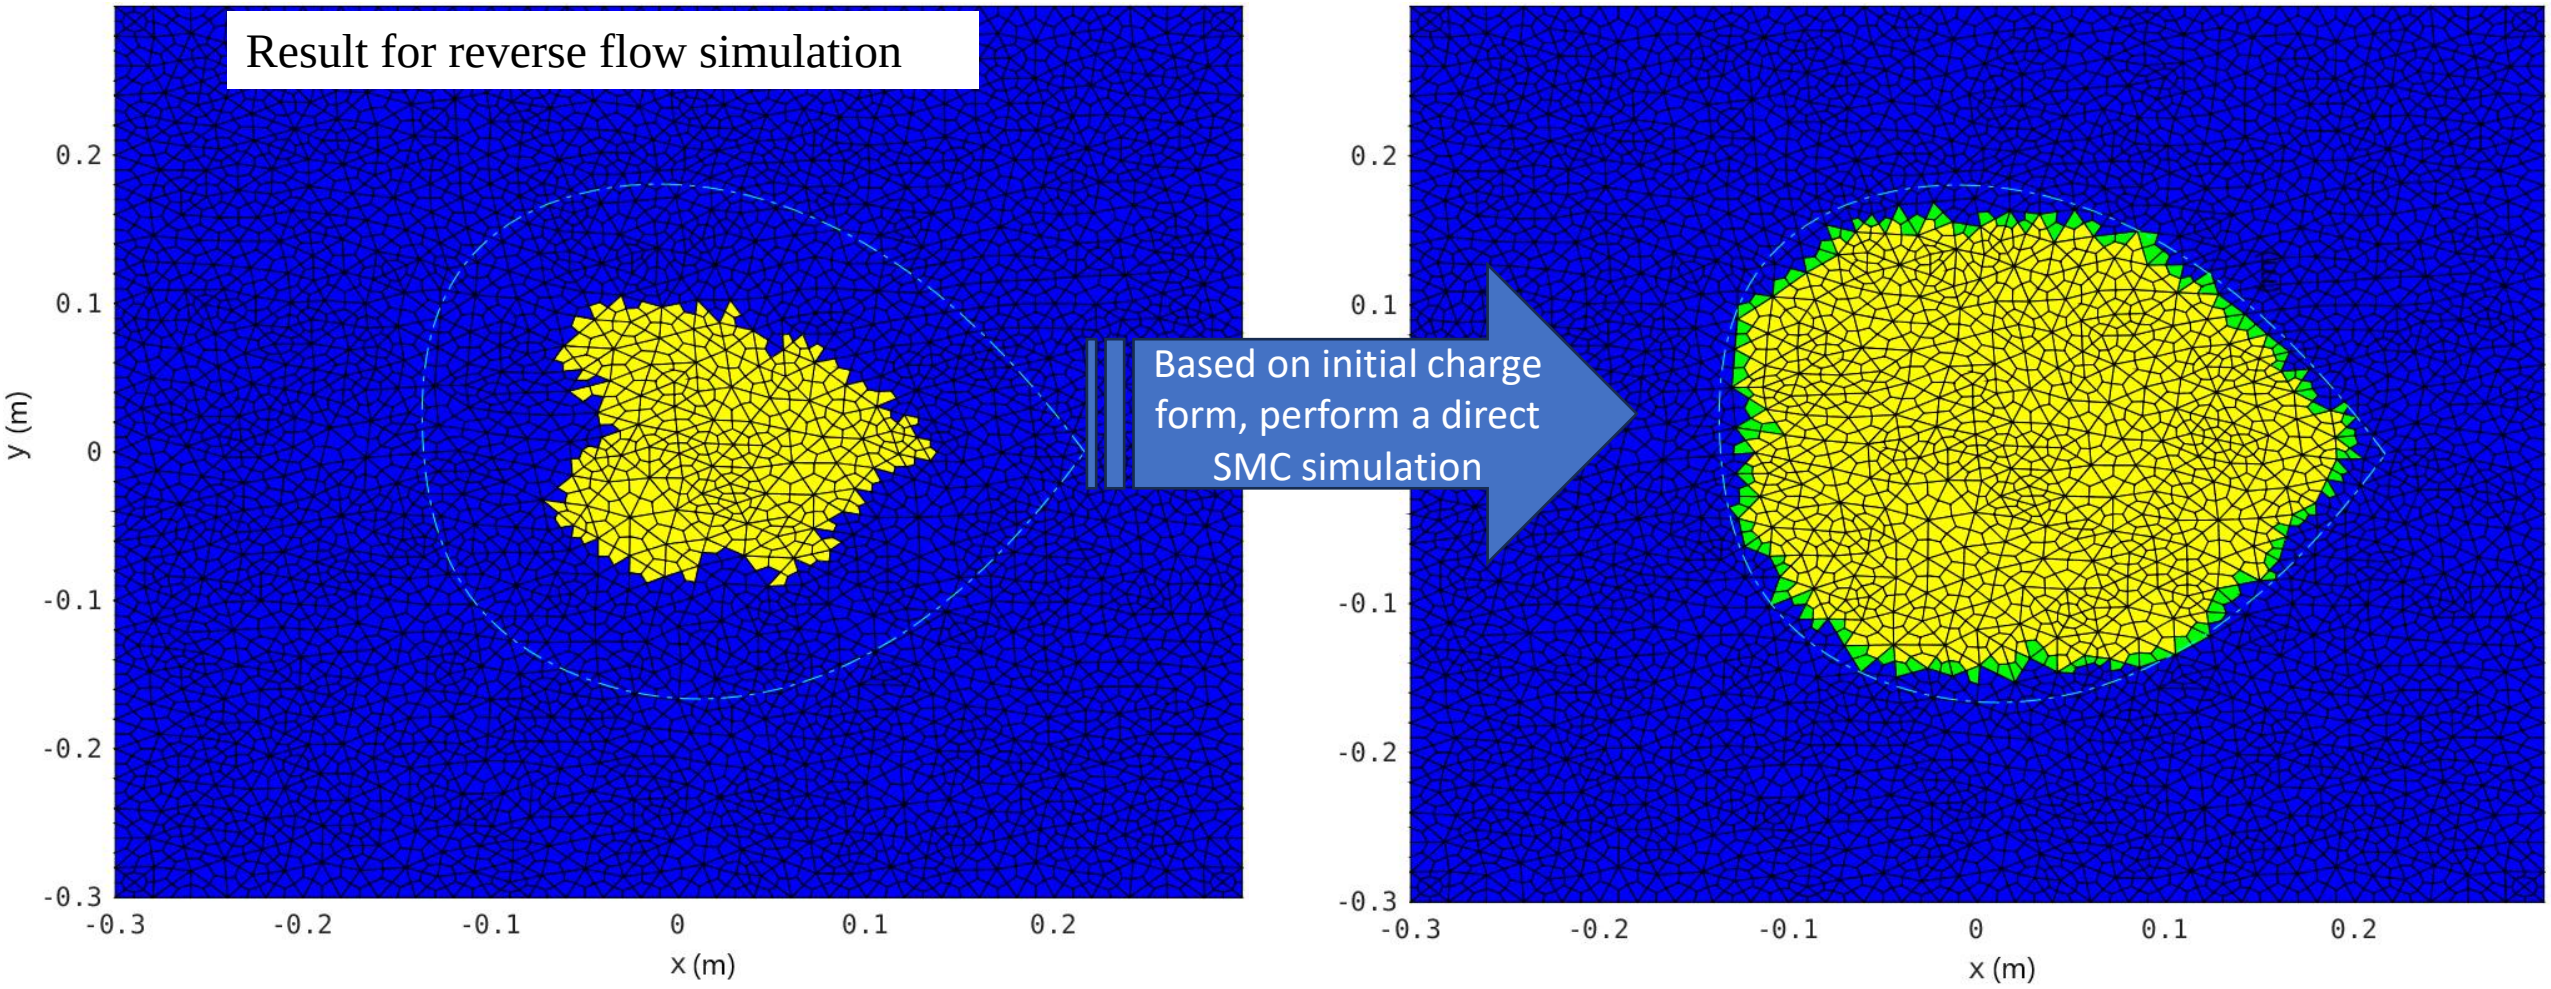


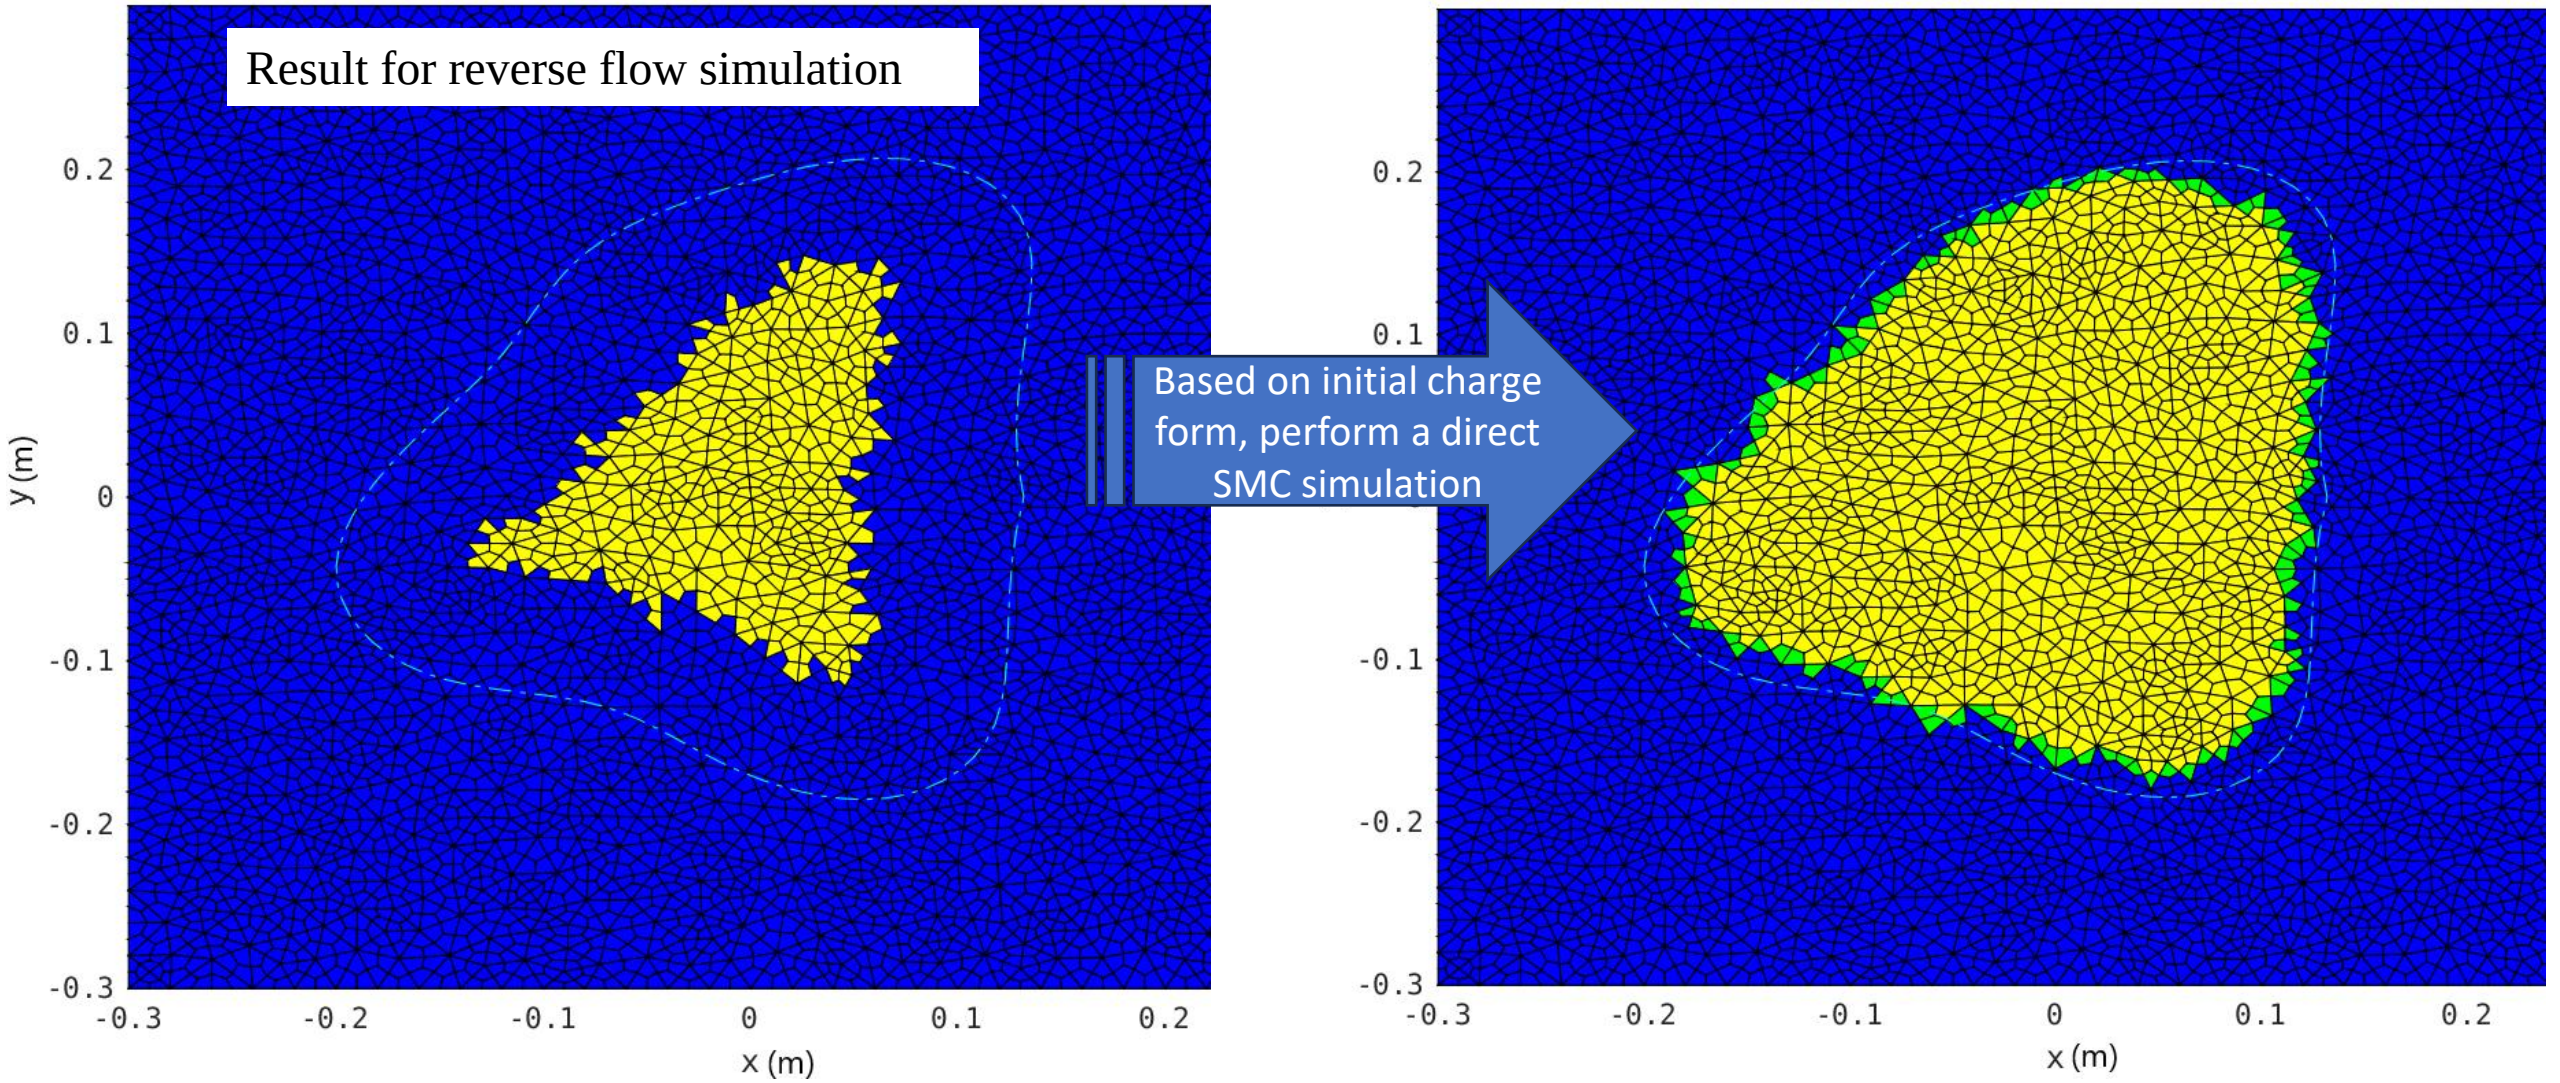
- With:
  - $A(e)$ is the area of the control volume
  - $\boldsymbol{n}^{ej}$ is the outward unit vector on the common edge of control volumes e and j
  - l^{ej} is the length of that edge
  - $\hat{\boldsymbol{f}}^{ej}.\boldsymbol{n}^{ej}$ represents the fluid flux across this edge.

Simulation conditions

- 1000 simulation performed for diverse 2D mold shapes

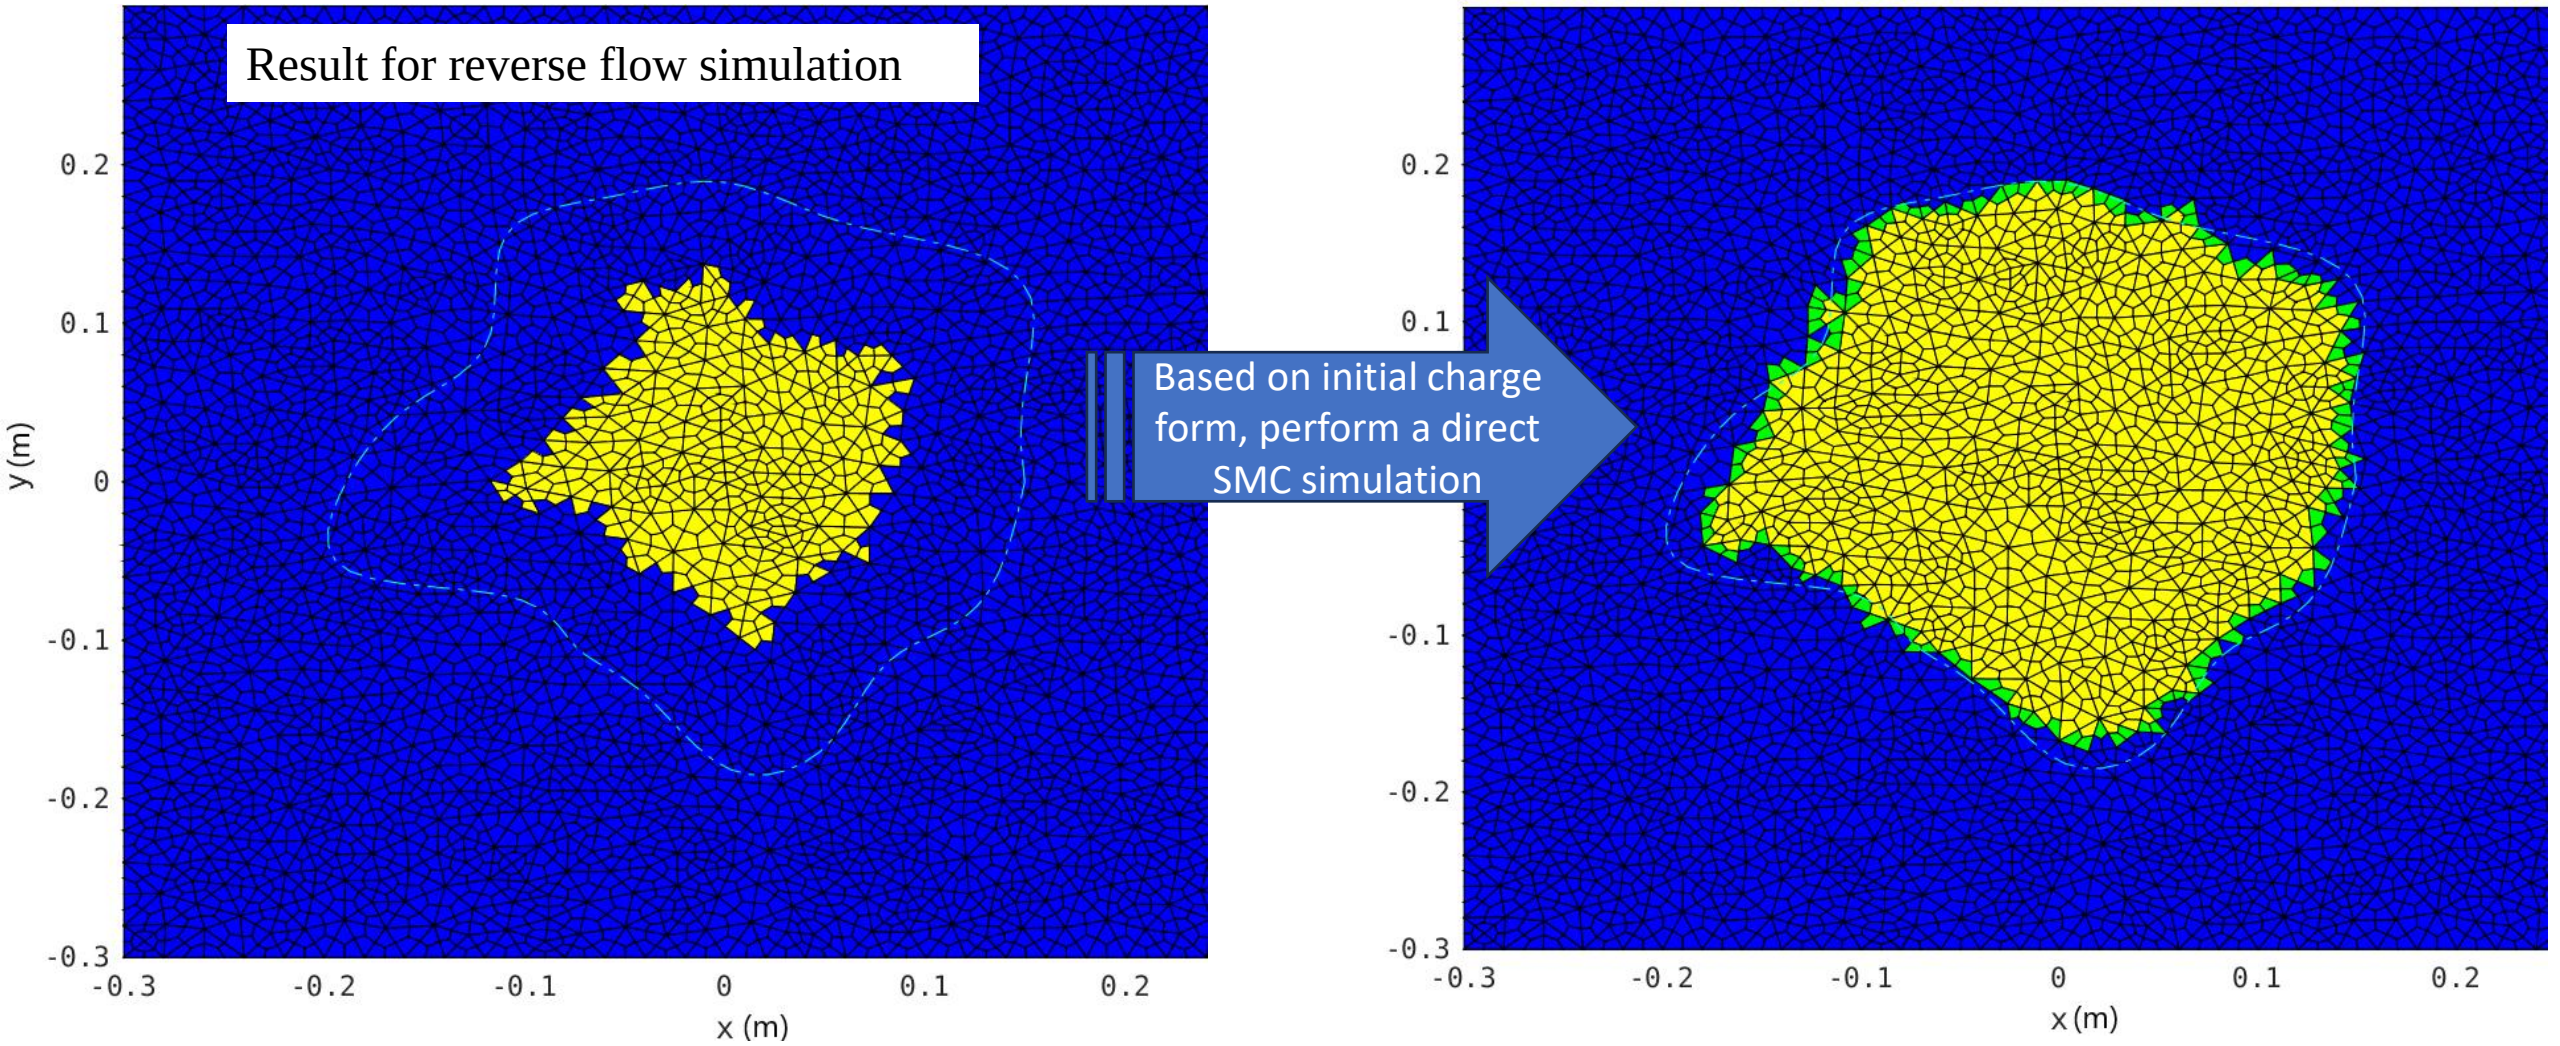
- Reverse flow simulation starting with a charge thickness of 5mm.
  - Define fluid domain using control points forming a closed curve
  - Use NURBS to avoid sharp corners



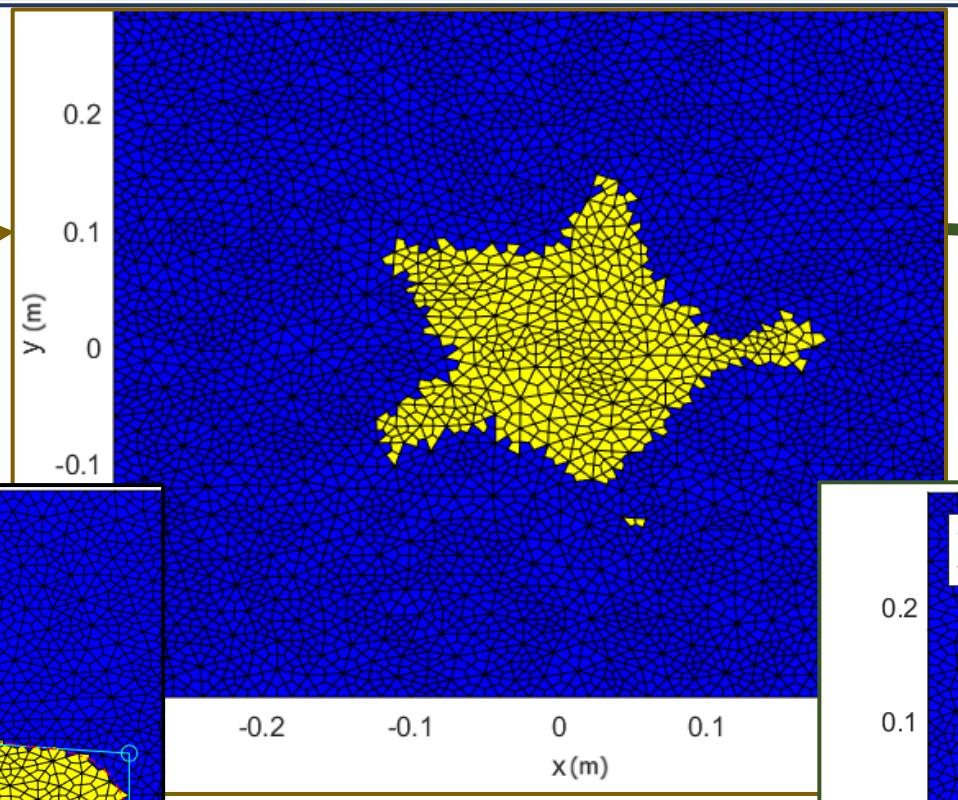


- Mold velocity 1 mm/s for 36s with 12 000 time steps.

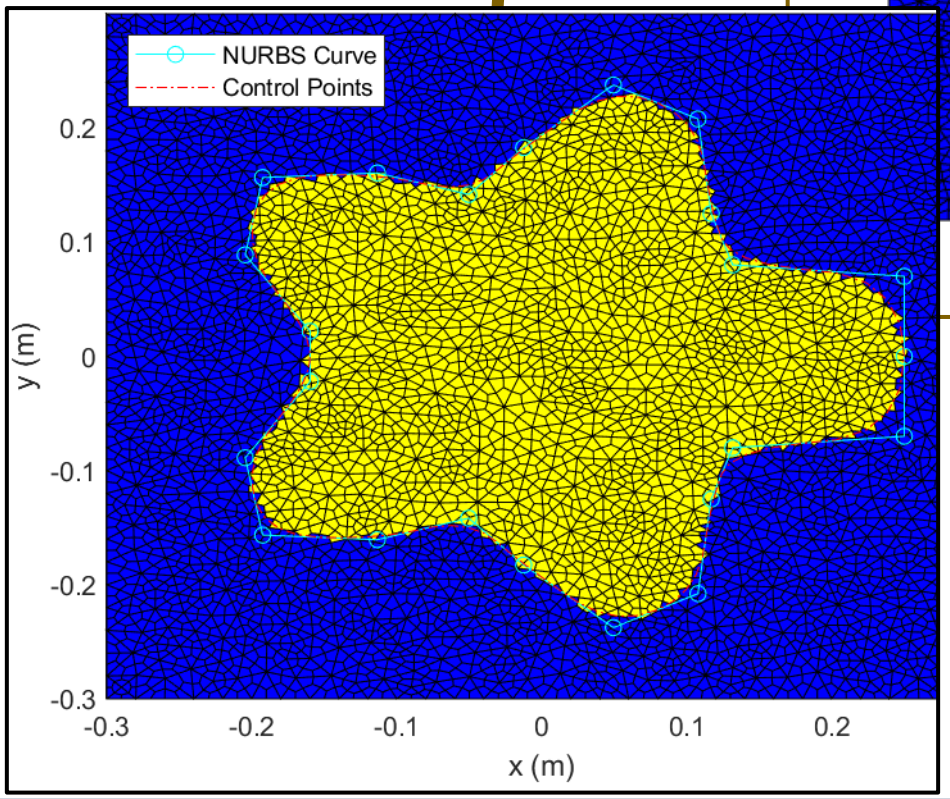
- Computational cost: ~12 min on a: 13th Gen Intel Core i9-13950HX CPU clocked at 2.20 GHz and equipped with 32GB of memory.

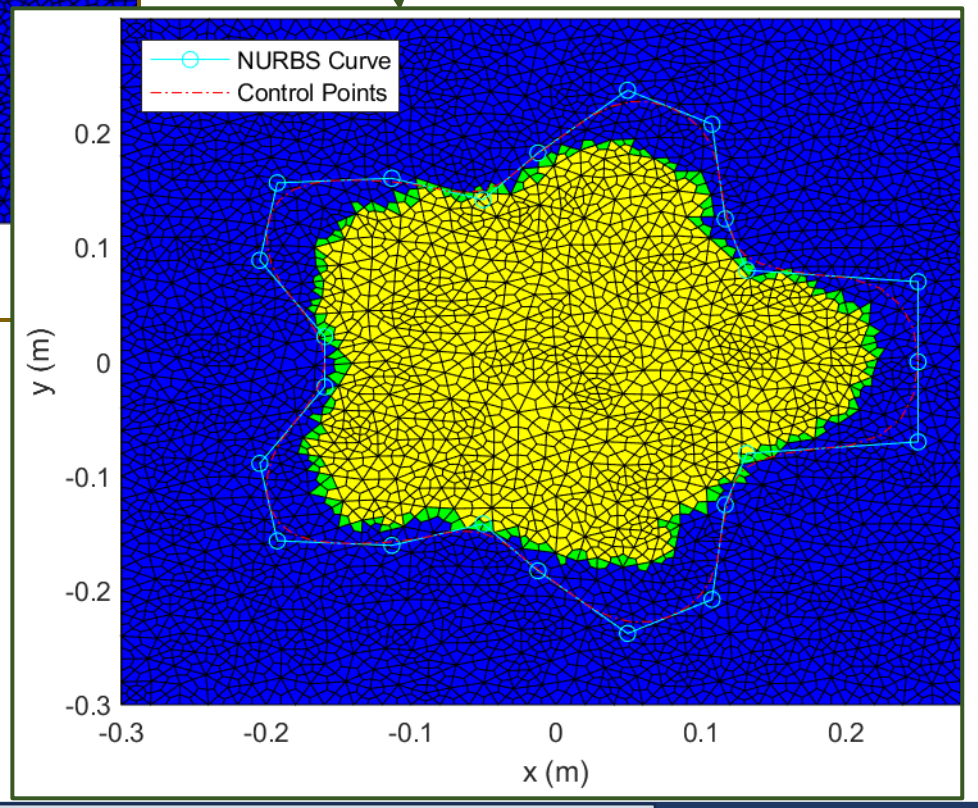


Simulation applications and results



Simulation applications and results





Simulation applications and results

Pushing the method to the extreme

Basic conclusions

- Reverse simulation is a powerful tool to predict initial charge shape for the SMC process
- Computational cost is low when considering 2D flow over a flat 2D mold.
- Computational cost could scale if mold is 3D
- When performing reverse SMC simulation to compute initial charge shapes and then based on the computed initial shape perform a standard SMC simulation, we notice that some elements are lost (mass is not fully conserved).
- Simulation is dependent on mesh size, time steps and other numerical parameters: need to fine tune such parameters for optimized outcome

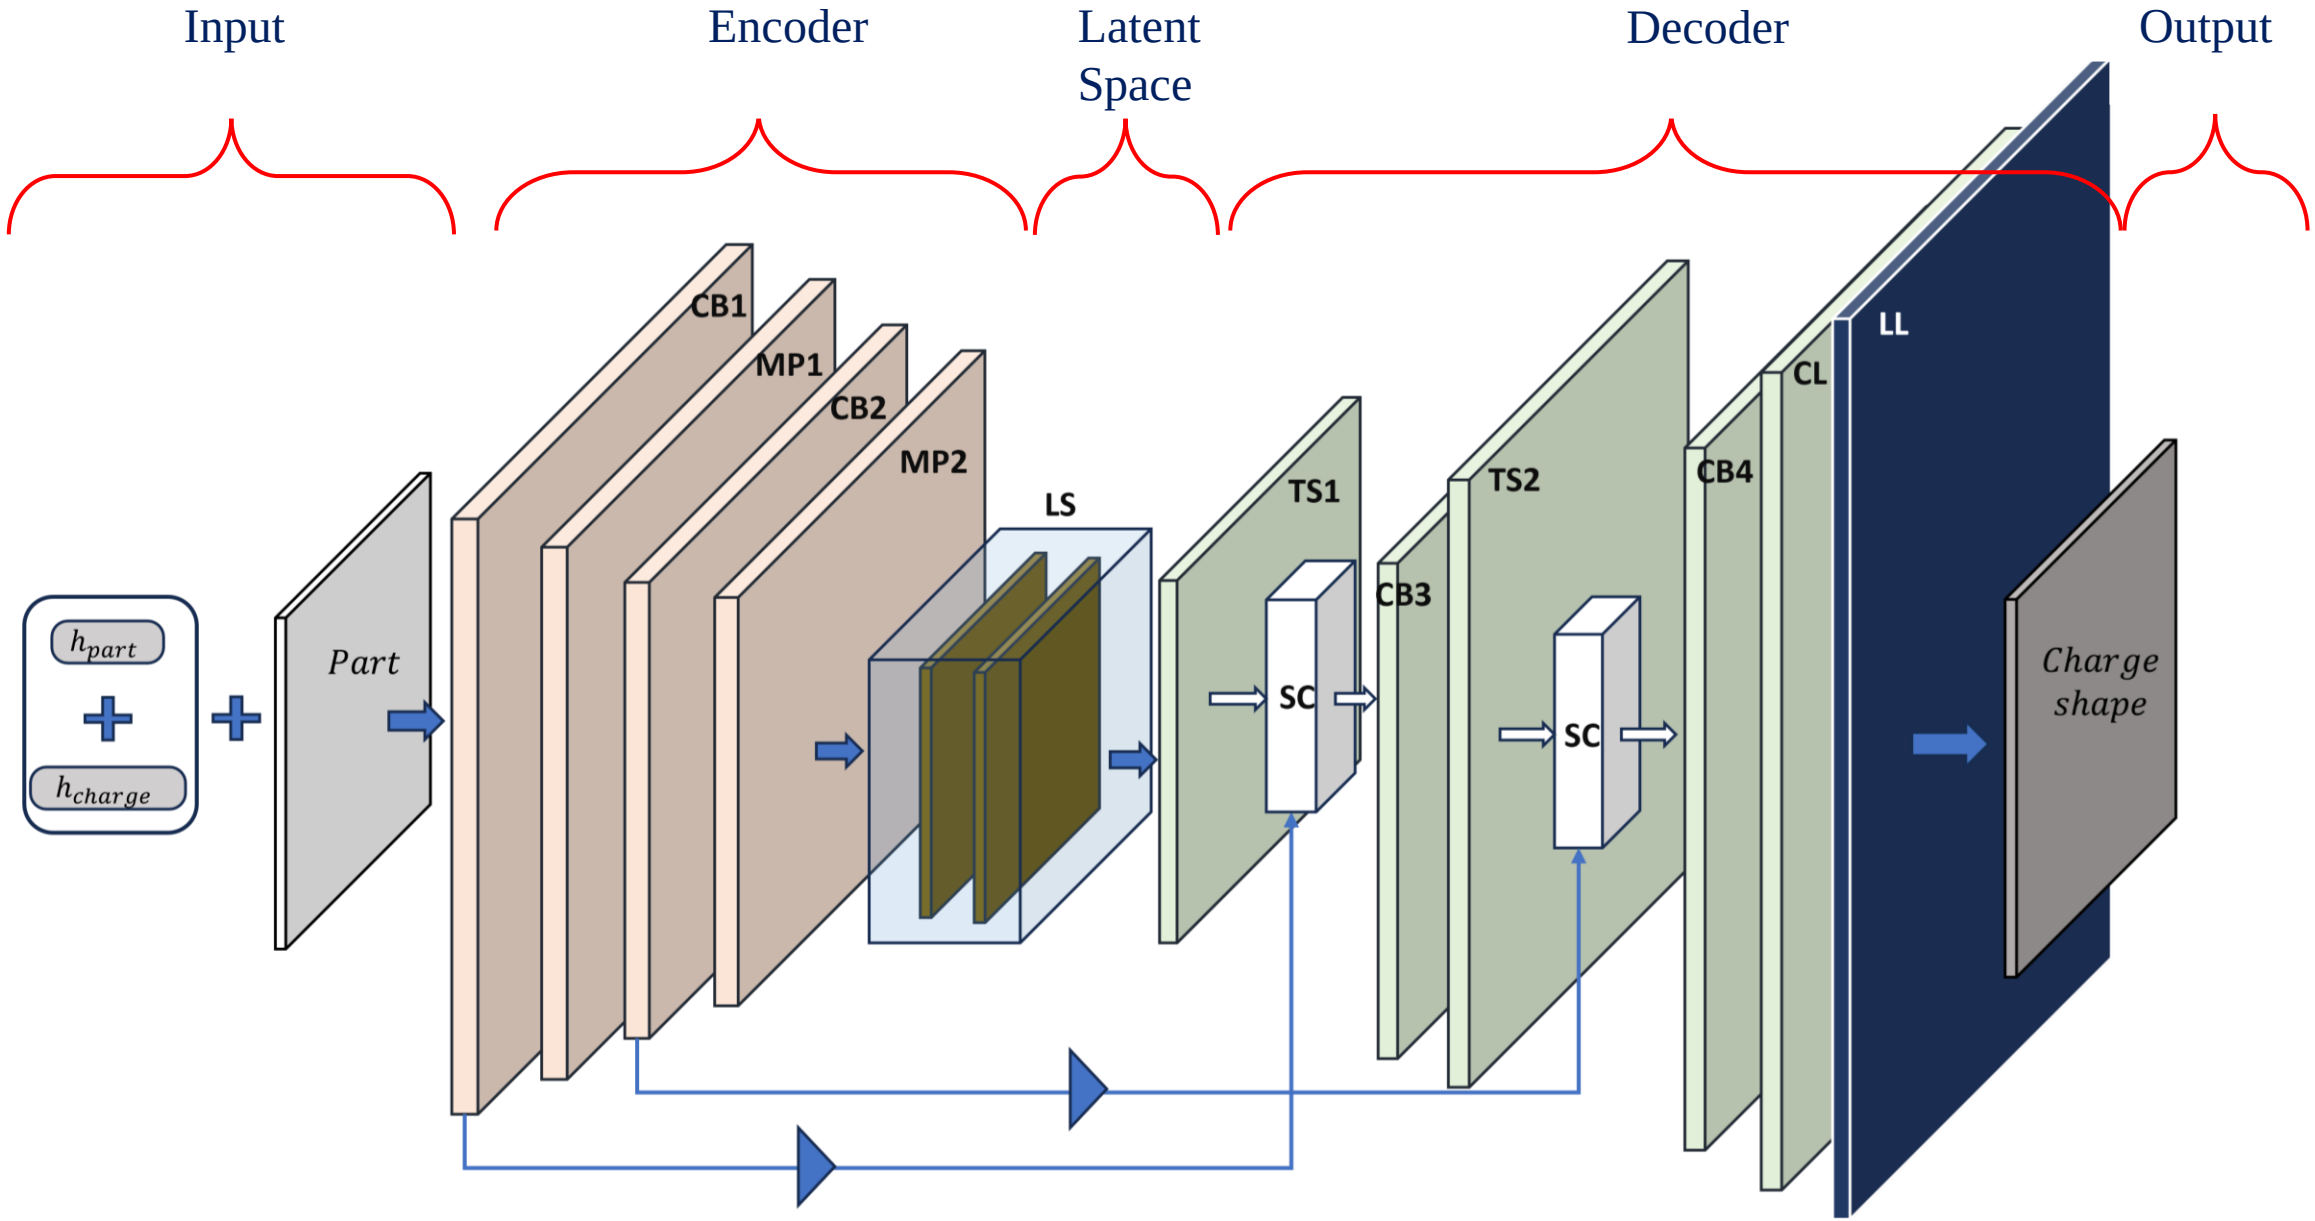
Motivation for a machine learning based digital twin

- Machine learning :
  - could provide equivalent accuracy with faster computational cost
  - could work in real-time on SMC machines
  - is independent of mesh size and numerical parameters
- Machine learning is to be evaluated as a tool for creating digital twin when SMC simulation is extended to include
  - 3D applications including
  - fiber orientation

} Increased computational cost

Generating a Digital Twin of the SMC Process: choosing a ML architecture

Requirements



- Inputs and outputs are both images and can't be dealt with differently.
- Grey image only considered with 1 indicating SMC material and 0 indicating no material.
- Other important inputs are:
  - charge initial thickness
  - charge final thickness.

  Initial and final thicknesses are different from one use case to the other
- SMC process simulation is not history dependent. GRU, LSTM and similar RNNs are not necessary.

Options

- Convolutional Neural Network should be used to deal with images
- Combining image input with initial and desired thicknesses of charges require an embedding layer
- Possible architectures include :
  - Convolutional Autoencoders
  - GANs (Generative Adversarial Networks) or more specifically Conditional GANs (cGAN)
  - Variational Autoencoders (VAEs) or U-Net Autoencoder
- Best match is a U-Net Autoencoder with skip connections between corresponding layers of the encoder and decoder. This helps propagate fine details from the higher-resolution layers in the encoder directly to the decoder, avoiding loss of spatial information

ABSTRACT

Resin Transfer Molding (RTM) is a widely adopted manufacturing technique for polymer matrix composites (PMCs), especially in aerospace and automotive sectors. However, accurate prediction of resin flow during the injection stage is computationally intensive, making real-time optimization unfeasible with conventional numerical solvers. This study proposes advanced deep learning-based surrogate models as a viable alternative to accelerate simulation and facilitate smart manufacturing. Specifically, it emphasizes the importance of architectural choices in surrogate modeling and presents a systematic comparison between two architectures: a fully convolutional encoder-decoder and a MIONet neural operator, both trained on synthetic datasets generated via OpenFOAM simulations.

The encoder-decoder model leverages densely connected convolutional layers to learn spatially structured mappings, while MIONet approximates nonlinear operators via coordinate-wise predictions using a dual-branch and trunk network formulation. Both models are evaluated on their ability to predict temporal evolutions of pressure and impregnation fields given information regarding the permeability field, the inlet pressure and the spatiotemporal coordinates. Two study cases, permeability fields with sharp and smooth permeability variations, are considered to account for different injection process disturbances. Results show that while both architectures demonstrate strong agreement with ground truth simulations, encoder-decoder model achieves higher predictive accuracy, particularly in capturing sharp resin fronts and local pressure gradients, as convolution-based inductive biases improve the fidelity of field reconstructions. Additionally, both models offer significant speedups, up to four orders of magnitude compared to OpenFOAM, highlighting the role of surrogate models as key enabling technologies for Digital Twin systems, which facilitate resilient and adaptive RTM Smart Manufacturing by enhancing the process's responsiveness to real-time disturbances.

1 INTRODUCTION

Resin Transfer Moulding (RTM) is a cost-competitive manufacturing process for Polymer Matrix Composites (PMCs), suitable for large complex parts and large scales, and ideal for structural lightweight applications such as those required in aerospace and automotive industries. Its effectiveness is mainly related to the quality of resin impregnation in the fibers during injection, therefore, resin flow dynamics within the preform are modelled in early design stages to ensure an optimal injection strategy by using numerical filling simulations. However, inherent distortions to the manufacturing process usually arise, such as fiber misalignment, thickness variations and curvatures or mould gaps, being impractical to address real-time process optimization with numerical filling simulations because of their high computational and runtime demand. To overcome these drawbacks, surrogate modelling emerges as an alternative to numerical filling simulations, providing approximate

results in significantly reduced time with low computational cost associated. It allows real-time application, being one of the key enabling technologies for Digital Twins, essential to make the RTM manufacturing process resilient and insensitive to processing distortions towards Smart Manufacturing.

Data-driven surrogate models replicate complex physical processes by learning input–output relationships directly from data, usually collected from physical models or simulations, bypassing the need for explicit physical equations since they are assumed implicitly in data. In this context, Deep Learning (DL) models, a subset of Machine Learning, stand out due to their robustness and efficacy in handling complex, large-scale datasets. Among the various data-driven approaches, fully convolutional encoder-decoders [1] and neural operator-based models such as DeepONets [2], have gained significant popularity. In essence, if the learning task is viewed as a mapping from function-valued inputs, such as initial conditions, boundary conditions, or source terms, to function-valued outputs representing physical fields or system responses, both approaches aim to approximate the same underlying functional relationship, and the distinction, therefore, lies not in the nature of the learning task, but in the architectural choices that govern how data is processed and generalized. The architecture of a deep learning model plays a critical role in determining how effectively it captures patterns within complex datasets. It defines the pathway by which information flows from input to output, influencing both the model's expressive capacity and its ability to generalize beyond the training distribution.

In this work, we conduct a systematic comparison between a fully convolutional encoder-decoder model and a MIONet architecture, a variant of DeepONet which includes two branch nets, employed as surrogate models for the RTM injection stage. The synthetic dataset generation process, including the two-phase fluid flow forward model and the dataset design, is described in Section 2. Section 3 details the architectures of both the convolutional encoder-decoder and the MIONet models, along with the training procedures. Section 4 presents a comparative analysis of the two approaches in terms of performance and inference time and finally, Section 5 outlines the key conclusions and reflects on their relevance for the optimization of the RTM process.

2 SYNTHETIC DATASET GENERATION

2.1 Two-phase fluid flow forward model

The flow of resin through porous media such as fiber preforms can be modeled by Darcy's law, which links the average velocity of the fluid to the pressure gradient via a proportionality involving the material's permeability and the fluid's viscosity (1). Under the assumption of mass conservation, this relation leads to a pressure field equation that, together with proper boundary and initial conditions, allows the transient flow to be determined. As the liquid front progresses through the domain, the problem can be formulated as one with a moving boundary, where classical finite element methods can be used to iteratively resolve the pressure and velocity fields.

$$\boldsymbol{v}(\boldsymbol{x}, t) = -\boldsymbol{K}(\boldsymbol{x}) \cdot \nabla p(\boldsymbol{x}, t)/\mu \tag{1}$$

In the context of resin injection processes, where two immiscible fluids such as resin and air interact, the interface evolution can be modeled using the Volume of Fluid (VOF) technique. This method introduces a variable denoted as α, which takes values between 0 and 1 to distinguish air (α = 0) from resin (α = 1). It is governed by the advection equation (2), allowing the interface to evolve consistently throughout the simulation. In this work, simulations were carried out using OpenFOAM, a widely used open-source platform for computational fluid dynamics. Specifically, the interFoam solver designed to simulate isothermal, incompressible two-phase flow using the VOF method, was employed.

$$d\alpha/dt + \nabla \cdot (\alpha \boldsymbol{v}) = 0 \tag{2}$$

2.2 Dataset design

Simulations were run on a 96×96 structured mesh with a single cell of thickness created with Abaqus, assuming in-plane flow in the mould. The left wall of the domain was defined as an inlet, where a fixed pressure condition (3) was imposed, the right one was treated as a pressure outlet, with a fixed pressure of 0 bar, and the remaining ones were set as slip-free walls. Figure 1a) depicts the computational domain and boundary conditions employed.

$$p_{inlet} = p_0(1\text{-}e^{-\gamma t}) \tag{3}$$

In order to account for process disturbances occurring during the injection stage, which lead to distinctive flow front deformations, two representative scenarios were considered: smooth and strong permeability variations. The first case represents the effects of fiber misalignment or non-uniform compaction, which result in an inhomogeneous flow front. It was modeled by sampling a Gaussian Random Field (GRF). The second case emulates the formation of preferential flow paths along the mould edges due to fiber gaps, where the resin advances faster. These channels, usually known as race-tracking, were modeled as regions of higher permeability compared to the bulk material ($\beta_{RT} = K/K_0$) [3]. Figure 1b) c) shows a permeability field example resulting from each disturbance scenario.

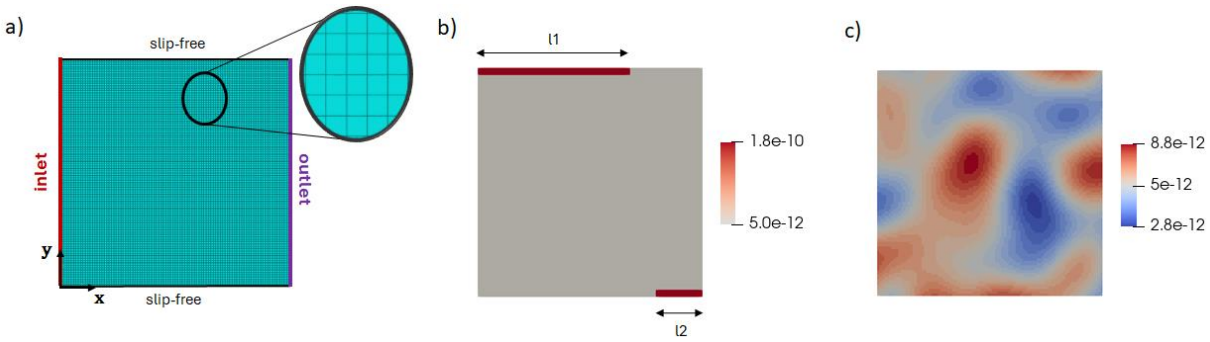

Figure 1: a) Computational domain and boundary conditions: inlet (left), outlet (right), and slip-free walls. A zoomed view of the structured mesh is highlighted. Permeability field with b) strong variations and c) smooth variations.

A diverse dataset of simulations was generated by sampling parameter tuples with Latin hypercube to ensure a uniform coverage of permeability and inlet pressure variations. Table 1 shows the range of the sampled parameters. The entire simulation pipeline, parameter generation, OpenFOAM configuration, execution, and output extraction, was automated via Python scripts and libraries such as PyFoam, Meshio and Gstools. A preprocessing step was carried out to non-dimensionalize the dataset, enabling the surrogate models to generalize to different process conditions, such as changes in resin viscosity, part scale, or maximum injection pressure (p_0), after being trained as long as they remain homothetic. Spatial coordinates were non-dimensionalized by the mold length L_0, pressure values by the maximum applied pressure p_0, and time by a characteristic filling time defined as $t_0 = \mu_0 L_0^2/2 K_0 p_0$ which represents the duration required to fill a mould of length L_0 when the flow occurs under steady conditions with constant viscosity μ_0 and bulk permeability K_0. Data normalization was also applied to improve the training stability and convergence of the surrogate models.

3 ADVANCE DEEP LEARNING TECHNIQUES

3.1 Fully convolutional encoder-decoder

The fully convolutional encoder-decoder architecture employed in this work is the one proposed in [1]. This architecture employs a sequence of densely connected convolutional blocks [4], where each layer obtains inputs not only from the preceding layer but from all previous layers within the block, using k=24 as feature map growth rate. Transition layers follow each dense block to modulate feature map resolution via strided convolutions and deconvolutions in the encoder and decoder, respectively. The entire architecture contains approximately 3.5 M trainable parameters. An schematic overview is shown in Figure 2.

Its purpose is to represent high-dimensional input information by means of the encoder into a latent space of low dimensionality, to then reconstruct high-dimensional predictions via the decoder. Particularizing for the RTM process, the permeability field of the fibre preform (a 96x96 image) is encoded and then concatenated with gamma (γ), a pressure build-up parameter, and a time vector. In this way, the latent space contains all the key process information. After that, from this low dimensional latent space, data is reconstructed to predict fluid field and pressure fields over time (96x96 images) using two separated decoders.

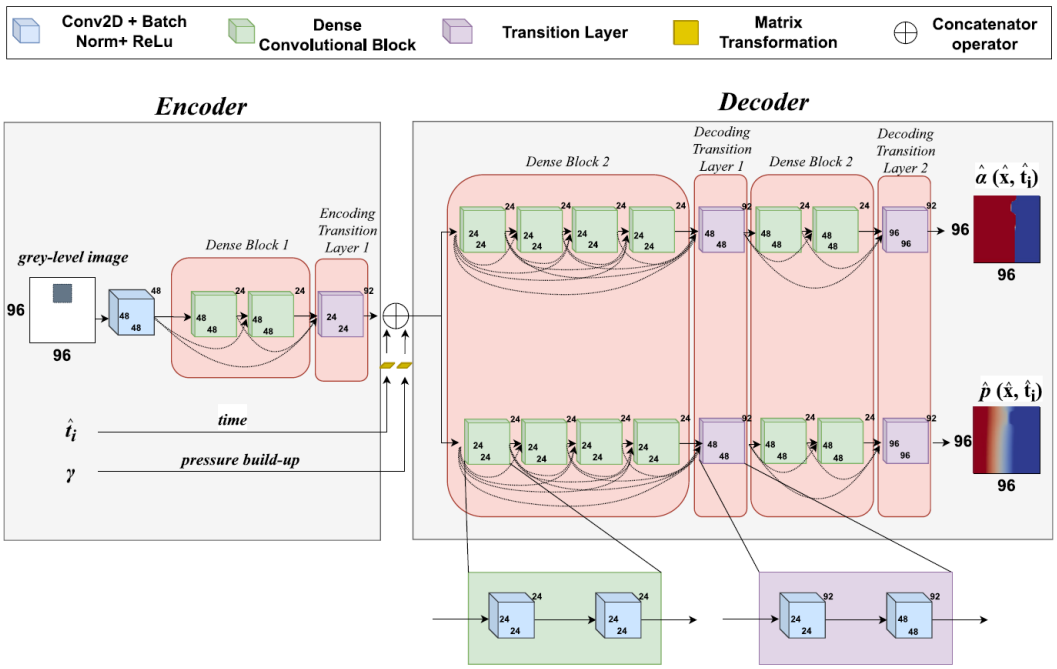

Figure 2: Architectural overview of the fully convolutional encoder-decoder surrogate model [1].

3.2 MIONet

MIONet architecture consists of three interacting subnetworks: two branch networks that encode distinct input functions, and a trunk network that processes the spatial or temporal coordinates where predictions are to be made. The outputs of the branch and trunk networks are subsequently combined through an element-wise product followed by a sum to generate the final output function. Its purpose is to approximate nonlinear operators by learning mappings from function-valued inputs, such as initial conditions, boundary conditions, or source terms, to function-valued outputs corresponding to physical fields or system responses. In the context of the RTM process, the first branch network receives the permeability field as input, while the second branch network takes a discretized representation of the inlet pressure function, sampled at 25 time points. The trunk network, in turn, is provided with the spatial and temporal coordinates corresponding to the target prediction locations.

With respect to the backbone architectures of the branch and trunk networks, this study considers two MIONet configurations that differ in the implementation of the first branch network. The first configuration is the originally proposed in [5], named as Vanilla MIONet, which adopts fully connected neural networks (FNNs) for all three components, both branch networks and the trunk network. The second configuration remains the second branch and trunk networks fully connected, whereas the first branch network is replaced with a densely connected convolutional encoder identical to the one described in the previous section. To optimize the performance of both configurations, a systematic exploration of FNN hyperparameters was carried out by evaluating different combinations of network depth [2,4,6,8,10] and width [128,256,512,800,1024]. An schematic overview of the two proposed MIONet configurations is shown in Figure 3. Vanilla MIONet of width=6 and depth=800, with a total of approximately 17 M trainable parameters, achieved the best performance and is therefore adopted as the reference model for all subsequent comparisons in this study.

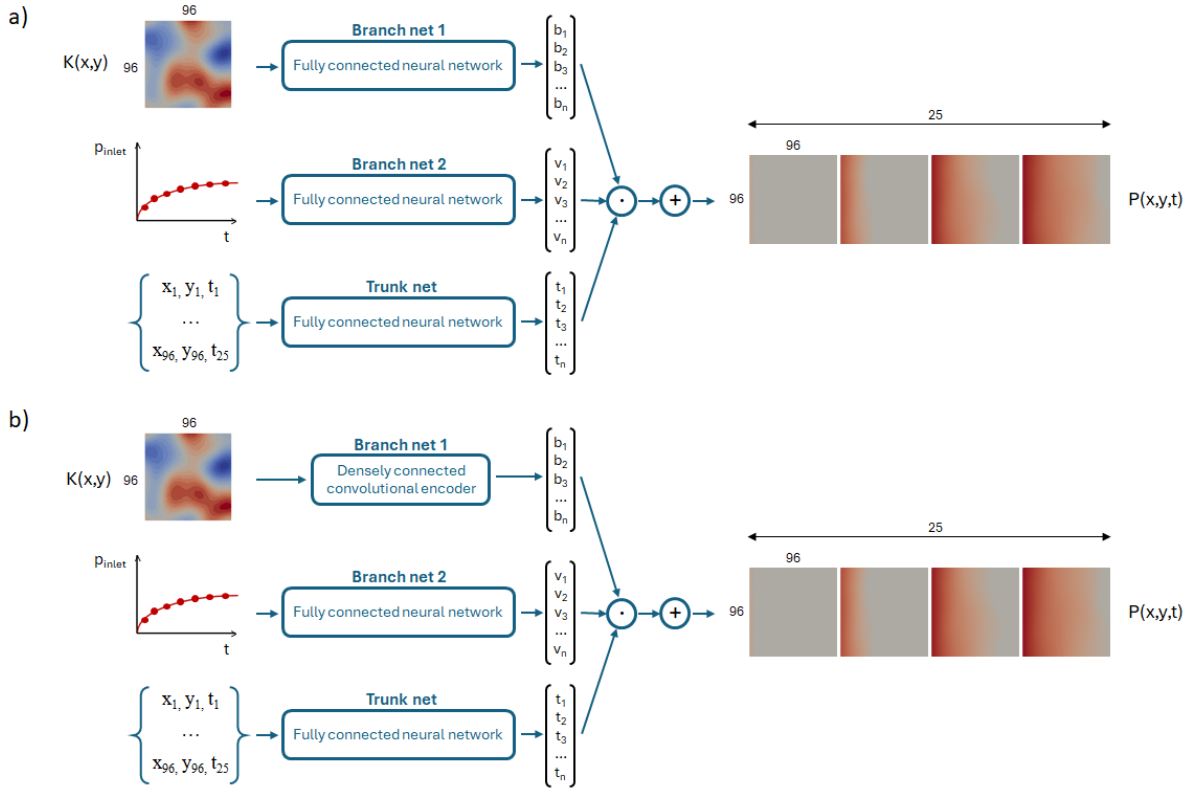

Figure 3: Overview of the MIONet configurations considered in this study. (a) Vanilla MIONet, composed entirely of fully connected networks. (b) MIONet variant incorporating a densely connected convolutional encoder as the first branch network.

3.3 Training

The training process was structured in two distinct phases: the first one focused on learning the pressure field and the second one, the impregnation field. To ensure a fair and rigorous comparison between the encoder-decoder and MIONet architectures, multiple training configurations were systematically evaluated to determine the most effective setup for each model. This included variations in regularization strategies (with or without batch normalization), optimization algorithms (SGD, Adam, L-BFGS, and NNCG), and loss functions (MAE, MSE and $L_{n\text{-}log}$ composite loss).

During the first training stage, a $L_{n\text{-}log}$ composite loss function was employed. This loss function combines power and logarithmic terms in a piecewise manner to enhance convergence in scenarios where residuals exhibit a bimodal distribution, an aspect commonly encountered in dual-phase flow simulations. Additional information regarding this loss function can be found in [1]. Normalization

was applied through batch normalization, weights were initialized using He initialization and ReLU was used as activation function. The Adam optimizer was used in combination with a learning rate scheduling strategy based on the ReduceLROnPlateau scheduler. The initial learning rates were set to 0.01 for the encoder-decoder model and 0.001 for MIONet. Patience values of 20 and 50,000 iterations were configured respectively for learning rate reduction, with a decay factor of 0.1. To prevent undertraining due to time constraints, early stopping was implemented with patience values of 60 and 100,000 iterations, and the maximum number of training epochs was set to 500 and 250.000 for the encoder-decoder and MIONet models, respectively. Overall, training times were approximately 3 hours for the encoder-decoder and 2 days and 7 hours for MIONet.

The second training phase was carried out differently for the encoder–decoder and MIONet architectures. For the encoder-decoder, the prediction of the impregnation field was formulated as a binary classification task, distinguishing resin (1) from air (0), and trained using the binary cross-entropy (BCE) loss function. In contrast, due to the design of DeepONet, in which the outputs of the branch and trunk networks are combined via an inner product, the model cannot guarantee output values constrained to the [0, 1] interval. This structural limitation renders a binary classification approach unsuitable for MIONet. To address this, the impregnation field for MIONet was modeled as a level-set function, a continuous scalar field where the resin–air interface (flow front) is identified by a sharp gradient. This level-set representation was constructed using information from the pressure field, leveraging the physical correlation between pressure gradients and flow front propagation in RTM processes. As such, the task was reformulated as a regression problem, and the $L_{n\text{-}log}$ composite loss function was employed to guide training. After inference, the predicted impregnation field was thresholded to obtain a binary mask, enabling a direct comparison with the encoder–decoder output. All remaining training settings were kept consistent with those described previously. The total training duration was approximately 3 hours for the encoder-decoder and 2 days and 10 hours for MIONet.

4 COMPARATIVE ANALYSIS

Figure 3 and Figure 4 illustrate the predictive performance of both the encoder-decoder and MIONet surrogate models for resin impregnation and pressure field across different time steps, using two representative permeability cases with strong variations and smooth variations, respectively. Both models exhibit high agreement with the target fields, successfully capturing the global behavior of the impregnation and pressure distributions. Among the two models, the encoder–decoder exhibits greater predictive accuracy, particularly in tracking the advancing resin front and capturing the spatial pressure gradients across the domain. MIONet, while successfully reproducing the overall flow behavior, presents slightly larger deviations. This is due to the encoder-decoder processes the entire input field as a structured image, preserving spatial locality through convolutions and hierarchical feature extraction, which enables the model to capture fine-grained spatial patterns, such as sharp interfaces at the resin front and local pressure gradients. In contrast, MIONet operates on coordinate-wise predictions, evaluating the output at individual spatial points without modeling the global structure of the output field, as each prediction is made independently of its neighbors.

From a computational standpoint, Table 2 demonstrates that both surrogate models achieve a substantial reduction in simulation time, decreasing inference time by several orders of magnitude compared to traditional OpenFOAM solvers. While the encoder-decoder achieves predictions in just 12 ms and MIONet in 83 ms, conventional simulations require nearly 4 minutes per case. This drastic improvement in computational efficiency highlights the potential of both approaches for accelerating resin transfer molding simulations. In particular, their speed and responsiveness make them strong candidates for real-time simulation and control applications within manufacturing environments.

5 CONCLUSIONS

This work has investigated and compared the performance of two advanced deep learning architectures, fully convolutional encoder-decoder and MIONet, as surrogate models for the RTM injection stage. Two representative scenarios were addressed to reflect inherent disturbances that appear during the RTM injection: one involving sharp heterogeneities in the permeability field and another representing smooth heterogeneities in the permeability field. By analyzing their predictive performance on the estimation of the impregnation and pressure fields over time, the study provides valuable insights into the trade-offs between spatially structured models and operator-learning frameworks in simulating two-phase flow dynamics during resin injection. While both architectures capture the global flow dynamics and pressure distributions with high fidelity, the encoder–decoder consistently outperforms MIONet in predictive accuracy, particularly for sharp resin fronts and spatial pressure gradients, due to its ability to leverage spatial inductive biases through convolutional processing. These findings underscore the critical importance of architectural design in deep learning-based surrogate modeling. Moreover, both models significantly accelerate simulation time, achieving speedups of several orders of magnitude over conventional solvers. This real-time execution enables their integration into Digital Twin frameworks for Smart Manufacturing, facilitating real-time process monitoring and control to make the manufacturing process more robust and resilient to unexpected disturbances that naturally arise during operation.

ABSTRACT

Resin transfer molding (RTM) is widely used to manufacture composite materials, where maintaining control over resin flow is crucial to avoid defects such as dry spots and voids that can compromise structural integrity. We introduce a Bayesian framework specifically designed to predict race tracking effects in RTM, which result from unpredictable high-permeability channels formed during the manufacturing process. By integrating Bayesian inference with pressure sensor data collected during resin injection, we estimate race tracking strength with uncertainty, enabling predictions of resin flow behavior under varying race tracking conditions.

Although Bayesian inference offers valuable insights for race-tracking prediction, the computational demands of RTM simulations present a challenge, particularly for real-time applications. To address this, a neural network surrogate model is introduced to approximate the complex, discontinuous behavior of RTM simulations caused by race tracking. This surrogate model accurately captures the resin flow patterns generated by traditional finite element-control volume (FECV) methods, enabling significantly faster computations within the Bayesian framework. We demonstrate that utilizing a neural network surrogate within the Bayesian framework can accurately predict both race tracking strengths and non-homogeneous permeability fields in a preform. This integrated approach enables real-time monitoring and control, supporting adaptive RTM systems that respond dynamically to variations in race tracking and produce higher-quality composite products. The findings contribute to the optimization of the RTM process, offering a pathway to reduce manufacturing defects and increase reliability in composite material production.

1 INTRODUCTION

Resin transfer molding (RTM) is widely used in industrial applications due to its relatively rapid production cycle and straightforward experimental setup, which enables the production of parts with shapes close to their final form. However, the production of complex parts is limited by the resin filling stage. This stage is particularly critical for simulation efforts, as it involves careful planning of the injection and venting layout to ensure complete impregnation of the preform and to avoid air entrapment. Trapped air pockets become voids after curing, compromising the composite's structural integrity. For composite parts with complex geometries, this becomes increasingly difficult.

Although simulation tools can be used to design mold injection sites and exit vents, theoretically ensuring complete resin impregnation, there is variability in resin movement. The permeability of the reinforcement primarily influences these deviations. Permeability is typically measured through experiments or estimated numerically [1] [2], and assumed to be constant through the reinforcement and between different preform samples. In reality, the permeability in the preform will vary due to variations or issues in the manufacturing process or draping. In some cases, the inaccurate lay-up of the fabric can

result in regions of lower fiber density on certain edges of the mold, which can act as high-permeability *race tracks* [3] [4] [5]. Race tracks can also be created at bends within the mold.

This research aims to predict the spatially varying permeability of the preform based on pressure measurements made during fill time. This is an inverse modelling problem, which we choose to tackle using Bayesian inference. Bayesian inference provides a principled approach to inverse problems, such as permeability estimation, by incorporating uncertainty directly into the modeling process. We consider both the prediction of only race tracking strengths, modelling the rest of the preform as a homogeneous field, and the prediction of a more general spatially varying field.

2 BAYESIAN INFERENCE IN RESIN TRANSFER MOULDING

We now briefly describe the mathematical model used to describe the resin impregnation stage of RTM. We then explain how this model can be integrated into the Bayesian framework for estimating permeability.

2.1 Mathematical Model

Darcy's law adequately describes the flow of resin through a porous medium [6] [7] [4] [8] [9] [10] [11]:

$$q(x,t) = -\frac{K(x)}{\mu}\nabla p(x,t), \tag{1}$$

where x is a vector denoting position, q is the resin flux vector, p is the pressure, μ is the fluid viscosity, K is the permeability tensor and t is time. Assuming that the flow is quasi-static, conservation of mass gives:

$$\nabla \cdot q(x,t) = 0. \tag{2}$$

The volume of resin is modelled with a fixed pressure of $p = p_{in}$ at the injection sites, and $p = 0$ at any exit vents, along with the moving flow front. Where the resin reaches the mold walls, impermeable slip boundaries ($q(x,t) \cdot n(x) = 0$) are enforced. The following model applies only to the region of the mold where resin is present. For the remainder of the dry mold, the pressure is fixed at $p = 0$.

2.2 Computational Model

The most common method for simulating this process is the Finite Element-Control Volume (FECV) method [12] [7] [8] [13] [14] [15] [16]. This method employs a typical finite element mesh to solve for the pressure distribution. Offset from those finite elements are control volumes, which monitor the saturation of the preform. After the pressure is solved, the flow between control volumes can be computed, and the saturation of incompletely filled control volumes can be updated.

2.3 Bayesian Inference

The Bayesian approach to inverse problems is widely adopted, as it provides a systematic means of incorporating and quantifying uncertainty. We are considering an inverse problem with an additive error model, where we attempt to estimate parameters x (in this case, a parameterization of the permeability) from measurements y (in this case, pressure measured from discrete sensor locations during fill time). In the Bayesian framework, the solution to the inverse problem is the posterior probability density (or simply *the posterior*) $\pi(x|y)$, i.e. the conditional distribution of x given y. For in-depth discussions on the Bayesian approach, see [17] [18] [19], among many.

Bayes' formula allows us to express the posterior as

$$\pi(x|y) \propto \pi(x)\pi(x|y) \tag{3}$$

where $\pi(y|x)$ is the likelihood function and $\pi(x)$ is the prior distribution on the parameters x. We suppose that the collected data and parameters of interest are linked by a setup of the form

$$y = f(x) + e \tag{4}$$

where f denotes a model relating parameters to outputs of interest and e denotes a measurement error, which signifies noise present in experimental measurements. We assume a Gaussian distribution for this error term $e \sim N(0, \Gamma_e)$. In this case, the likelihood $\pi(y|x)$ can be expressed as

$$\pi(y|x) = \pi_e\big(y - f(x)\big) \propto \exp\left(-\frac{1}{2}\left\|L_e\big(y - f(x)\big)\right\|_2^2\right) \tag{5}$$

where $L_e^T L_e = \Gamma_e^{-1}$. We also postulate a Gaussian distribution for the prior $\pi(x) \sim N(x_0, \Gamma_x)$, which mathematically can be written

$$\pi(x) \propto \exp\left(-\frac{1}{2}\|L_x(x_0 - x)\|_2^2\right) \tag{6}$$

where $L_x^T L_x = \Gamma_x^{-1}$. Based on the above expressions for the prior (Equation (6)) and the likelihood (Equation (5)), the posterior can be expressed through Equation (3) as

$$\pi(x|y) \propto \exp\left(-\frac{1}{2}\left\|L_e\big(y - f(x)\big)\right\|_2^2 - \frac{1}{2}\|L_x(x - x_0)\|_2^2\right) \tag{7}$$

A variety of approaches exist for characterizing the posterior for a given problem. For nonlinear inverse problems involving expensive-to-evaluate forward models (as is the case here), high-dimensional parameters, and/or a need for rapid results, fully characterizing the posterior presents a challenge. Complete characterization using methods such as Markov chain Monte Carlo (MCMC) is generally infeasible. In such cases, one approach would be to take the Laplace approximation [20]. Here, we use optimization methods such as Gauss-Newton to find the value of x that maximizes $\pi(x|y)$. This is termed the maximum a posteriori (MAP) estimate, x_{MAP}. Once this is known, we can linearize $f(x)$ about x_{MAP} with a Taylor series expansion:

$$f(x) \approx f(x_{MAP}) + F_{MAP}(x - x_{MAP}), \qquad F_{MAP} = \frac{\partial f}{\partial x}\Big|_{x = x_{MAP}}. \tag{8}$$

Substituting this expression into Equation (7) gives $\pi(x|y) \approx N(x_{MAP}, \Gamma_{post})$, with $\Gamma_{post} = (F_{MAP}^T \Gamma_e^{-1} F_{MAP} + \Gamma_x^{-1})^{-1}$.

3 NEURAL NETWORK SURROGATES

The use of a surrogate model - one that closely approximates the actual process but runs significantly faster - is driven by two key advantages in our application. First, the FECV model within LIMS is highly computationally intensive: every time the moving flow-front boundary changes, it must re-solve the entire FEM problem. By replacing this with a lightweight approximation of the permeability–pressure relationship, we can evaluate the posterior distribution in a fraction of the time without sacrificing essential fidelity.

Second, choosing a neural network as our surrogate ensures a smooth, continuous mapping between permeability and pressure. In contrast, the FECV model exhibits parameter-induced discontinuities that hinder accurate posterior inference: its permeability–pressure curve is not reliably characterized [21]. A neural network built with smooth activation functions naturally overcomes these discontinuities, yielding a more realistic and stable posterior estimate.

We now discuss how the inputs and outputs of the NN are defined for our problem. In Section 3.4, we then discuss how the NN is structured and trained. In Section 3.5, we discuss how inaccuracies in the NN can be accounted for in the Bayesian framework.

3.1 Model Inputs – Parameterization 1

In this first parameterization, we assume that the permeability of the preform is homogeneous, apart from the race tracking regions. Each race tracking region i is assigned a strength x_i, which is related to the permeability in that region K_i with

$$K_i = \exp(x_i) K_{bulk} \tag{9}$$

where K_{bulk} is the homogeneous permeability outside of the race tracking regions. Upon $x = [x_1, x_2, \dots]$, we postulate an independent Gaussian prior with mean $x_0 = 2.0$, $\sigma_x = 2.0$, i.e. $\Gamma_x = \sigma_x^2 I$.

3.2 Model Inputs – Parameterization 2

In an alternative and more interesting parameterization, we allow the permeability to vary throughout the mold, with increased variation in the race tracking regions. To parameterize this, we consider an element-wise log-permeability parameter k, defined by

$$K_i = \exp(k_i)\, K_{bulk} \tag{10}$$

where i is the element number and K_i is the permeability assigned to that element. On k, we postulate a Gaussian prior that encodes a correlation between the permeabilities of neighboring elements and allows for greater variation in the race tracking regions. We achieve this by firstly neglecting the race tracks, and considering a correlated Gaussian exponential squared covariance of the form

$$\hat{\Gamma}_k[i,j] = \sigma_k^2 \exp\left(-\frac{1}{2l^2}\left\|\mathrm{x}_i - \mathrm{x}_j\right\|_2^2\right) \tag{11}$$

where $\sigma_k^2 = 0.2$, $l = 0.015$m is a scalar characteristic length that controls the extent of the correlation and x_i is the location of the center of element i. We then encode the increased variation in the race tracks by applying the following transformation:

$$\Gamma_k = W \hat{\Gamma}_k W, \tag{12}$$

where W is diagonal, and defined as

$$W[i,i] = \begin{cases} 2, & \text{if element } i \text{ is in a race track} \\ 1, & \text{otherwise.} \end{cases} \tag{13}$$

In addition, we have a non-zero prior mean k_0 on k, which is zero in a race tracking element and zero otherwise. Sampling from $k \sim N(k_0, \Gamma_k)$ produces permeability strength for every element as required.

To reduce the dimensionality of this parameterization, we take a principal component analysis (PCA) of this prior to represent k as a lower-dimensional x. Use of PCA is a standard approach to dimensionality reduction [22] [23], so we omit the mathematical details here. We have the truncated singular value decomposition of $\hat{\Gamma}_k$

$$\hat{\Gamma_k} \approx V_n \Sigma_n V_n^T \tag{14}$$

where Σ_n is a diagonal matrix containing the first n eigenvalues, ordered by magnitude and V_n is the first n eigenvectors. In the numerical experiments discussed in Section 4.2, we choose $n = 100$.

We then consider the following transformation

$$k = W V_n x, \qquad x = V_n^T W^{-1} k. \tag{15}$$

This transformation converts k, which contains the same number of entries as elements in a finite element model, to x - which is only 100-dimensional.

3.3 Model Outputs

Regardless of the choice of model parameterization, we consider the simulated pressures for the model output. To simulate this, we consider fixed pressure sensor locations throughout the mold. We then extract the simulated pressures at those locations, at specific measurement times t. These measurements have an assumed measurement error $e \sim N(0, \Gamma_e)$ associated with them. We postulate the following covariance on e:

$$\Gamma_e = \sigma^2_{measurement} I + \sigma^2_{sensor} \text{diag}(\mathbb{1}, \mathbb{1}, \dots) \tag{16}$$

where $\mathbb{1}$ is a square matrix of ones, with one row/column for each measurement time. This allows for some independent measurement error, along with a systematic sensor error, applied uniformly to every measurement from a single sensor. We choose $\sigma^2_{measurement} = \sigma^2_{sensor} = 2e^{-4}$ for the numerical experiments here.

As with the second permeability parameterization, we have a very high-dimensional output, which presents difficulties for the learning of the NN. As such, we again reduce the dimension of the output using PCA. After generating training and testing data for $f(x)$ using the LIMS model, we consider the fitted Gaussian on those outputs, $f(x) \sim N(f_0, \Gamma_f)$. We then take

$$\Gamma_f = U_m \Sigma_m U_m^T \tag{17}$$

$$f^*(x) = U_m^T (f(x) - f_0) \tag{18}$$

where Σ_m is the first m eigenvalues diagonalized and F_m are the corresponding eigenvectors. $f^*(x)$ now represents a model that produces only m outputs that represent the predicted pressures. For the numerical experiments described here, we choose $m = 100$.

In this reduced data space, we can still create Bayesian posteriors. This is a novel approach we take here, for reasons that we will soon describe. Consider applying a similar PCA transform as in Equation (18) to the data y, starting from Equation (4):

$$U_m^T (y - f_0) = U_m^T (f(x) + e - f_0). \tag{19}$$

We can then define $y^* = U_m^T (y - f_0)$ and $e^* = U_m^T e$, which gives

$$y^* = f^*(x) + e^*. \tag{20}$$

By conducting Bayesian inference with these alternatives to y, $f(x)$ and e, the usual Bayesian equations derived in Section 2.3 still apply, with the respective changes to notation. The significance of approaching the problem in this way is that it allows for the simple integration of the NN into the Bayesian framework, which will only produce outputs in this PCA space, rather than the original data space. In what follows, it will be useful to note

$$\Gamma_{e^*} = U_m^T \Gamma_e U_m \tag{21}$$

3.4 Network Design

The neural network is designed to match the input-output relationship of $f^*(x)$ created by LIMS (and the PCA). While alternative approaches to NN surrogate modelling of a physical process, most notably the physics-informed neural network (or PINN) [24] [25], this approach is chosen for its simplicity. The neural network is minimizing the loss between the NN outputs, which we term $g(x)$ and $f^*(x)$. We generate 100000 samples using LIMS for training, and 10000 each for training and testing.

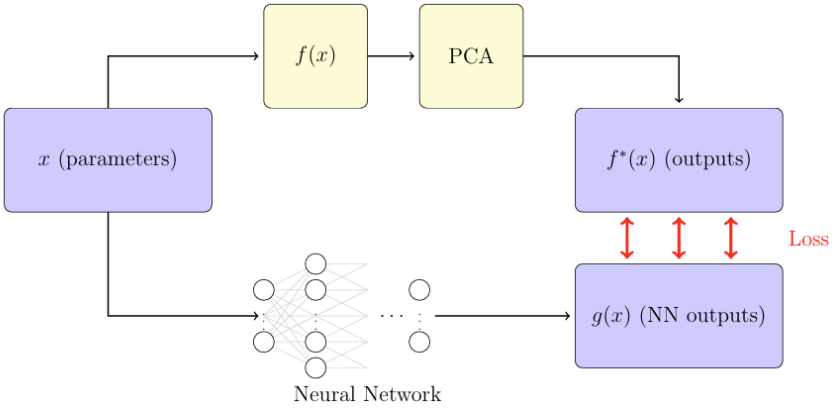

Figure 1: Neural network surrogate framework

3.5 Bayesian Approximation Error

Using a surrogate $g(x)$ instead of the underlying model (in this case, LIMS) $f(x)$ introduces surrogate approximation error. Approaching this inverse problem within the Bayesian framework enables the systematic incorporation of this error by augmenting the error term. This is referred to as the Bayesian approximation error (BAE) approach. Consider the following definition for the approximation error ε:

$$\varepsilon(x) = f^*(x) - g(x). \tag{22}$$

We postulate a Gaussian on ε, conditional upon x, of the form $\varepsilon \sim N(\varepsilon_{0|x}, \Gamma_{\varepsilon|x})$, where

$$\varepsilon_{0|x} = \varepsilon_0 + \Gamma_{\varepsilon x}\Gamma_x^{-1}(x - x_0) \tag{23}$$

$$\Gamma_{\varepsilon|x} = \Gamma_\varepsilon - \Gamma_{\varepsilon x}\Gamma_x^{-1}\Gamma_{x\varepsilon} \tag{24}$$

These matrices can all be determined by considering the joint Gaussian of x and ε. ε can then be simply incorporated into the Bayesian framework by defining a new total error term $\eta = e^* + \varepsilon$. Combining this with Equation (23) gives

$$y^* = g(x) + \eta, \tag{25}$$

where we can define $\eta|x \sim N(\eta_{0|x}, \Gamma_{\eta|x})$

$$\eta_{0|x} = \varepsilon_0 + \Gamma_{\varepsilon x}\Gamma_x^{-1}(x - x_0) \tag{26}$$

$$\Gamma_{\eta|x} = F_m^T\Gamma_e F_m + \Gamma_\varepsilon - \Gamma_{\varepsilon x}\Gamma_x^{-1}\Gamma_{x\varepsilon} \tag{27}$$

Using this augmented total error term, we can accurately account for both measurement and surrogate approximation errors in our results. It will also be useful to define $L_{\eta|x}^T L_{\eta|x} = \Gamma_{\eta|x}$.

In summary, the expression in Equation (7) expresses $\pi(x|y)$, based on the FECV LIMS model. If we substitute the NN surrogate (considering the problem in PCA space), but don't account for the approximation errors, we have

$$\pi_{NN}(x|y) \propto exp\left(-\frac{1}{2}\left\|L_{e^*}\left(y^* - g(x)\right)\right\|_2^2 - \frac{1}{2}\|L_x(x - x_0)\|_2^2\right) \tag{28}$$

where $L_{e^*}^T L_{e^*} = \Gamma_{e^*}$. However, if we incorporate the surrogate approximation error correctly, we have

$$\pi_{BAE}(x|y) \propto exp\left(-\frac{1}{2}\left\|L_{\eta|x}(y^* - g(x) - \varepsilon_0 - \Gamma_{\varepsilon x}\Gamma_x^{-1}(x - x_0))\right\|_2^2 - \frac{1}{2}\|L_x(x - x_0)\|_2^2\right) \quad (29)$$

4 RESULTS

We now present the results of numerical experiments. Here, we create a theoretical truth for the permeability parameterization x_{ref}, generate synthetic data by running LIMS to create $f(x)$ and add error e, sampled from the error distribution $N(0, \Gamma_e)$. Based solely on y, we then construct or attempt to estimate the posterior $\pi(x|y)$ and compare this prediction to x_{ref}. We consider the two parameterizations, although both use the same geometry, shown in Figure 2. We use a rectangular preform sheet, bent at four positions to create a ridge. The edges of the mold and those ridges act as potential regions of race tracking.

There are two injection sites, as indicated in Figure 2. These injection sites both inject with a fixed pressure of 100kPa. We use the bulk permeability of $K_{bulk} = 1e^{-10}\text{m}^2$ a viscosity of 0.2Pa s.

4.1 Race tracking only

When we consider the parameterization of only the race tracking regions, as discussed in Section 3.1, we are estimating only eight parameters. For this relatively low-dimensional parameterization, it is possible to obtain a view of the posterior using LIMS ($\pi(x|y)$). We can then compare this to the posterior produced by the NN surrogate, both with and without the Bayesian approximation error. To do this, we consider the problem marginally. That is, we fix all $x = x_{ref}$ and we then change one component of x between a range of values, evaluating the posterior at each instance. This 'gridding' of the posterior is done to visualize the effects of the NN posterior and this methodology but would not work in practice, as knowledge of x_{ref} is needed. The results of this analysis are shown in Figure 3. Note that these posteriors are exact, without any approximation.

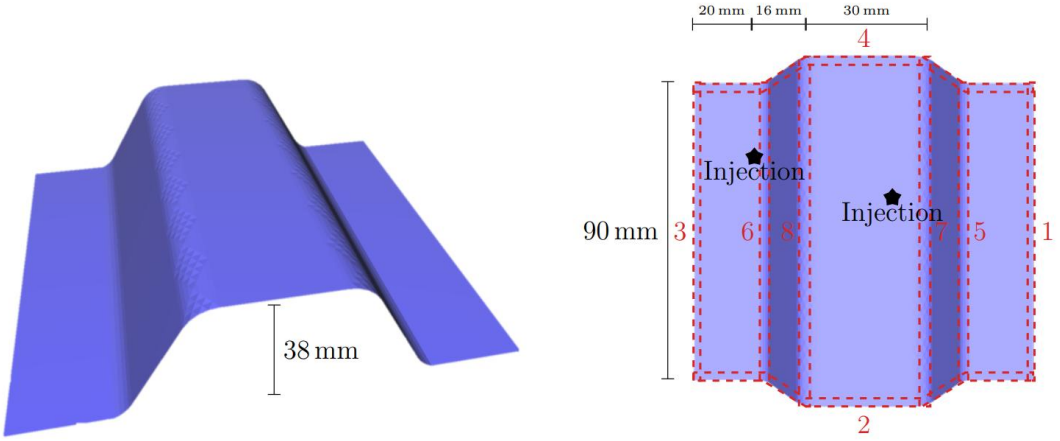

Figure 2: Mold geometry for the numerical experiments in this paper. Injection sites are indicated with black stars, and the race tracking regions are indicated in red.

The Bayesian posterior using LIMS ($\pi(x|y)$) is shown in red. This posterior is narrow and incorporates the truth, indicated by the dashed black line. However, this posterior is very coarse. Posteriors of this shape are difficult to discover in higher-dimensional problems. A Gaussian approximation of this posterior would not be an appropriate fit, and finding the MAP estimate will become infeasible in high dimensions using optimization algorithms.

$\pi_{NN}(x|y)$ has a similar narrow range to $\pi(x|y)$, as they use a very similar error model. However, as we have not incorporated the surrogate approximation error, $\pi_{NN}(x|y)$ often is incorrect in the predictions and confident with the incorrectness. When the approximation error is considered, we have $\pi_{BAE}(x|y)$, which is wider to accommodate the larger error term, but always contains the truth within

the range of predictions. In addition, $\pi_{BAE}(x|y)$ is orders of magnitude faster than $\pi(x|y)$ to generate and use, due to the computational speedup of $g(x)$ over $f(x)$.

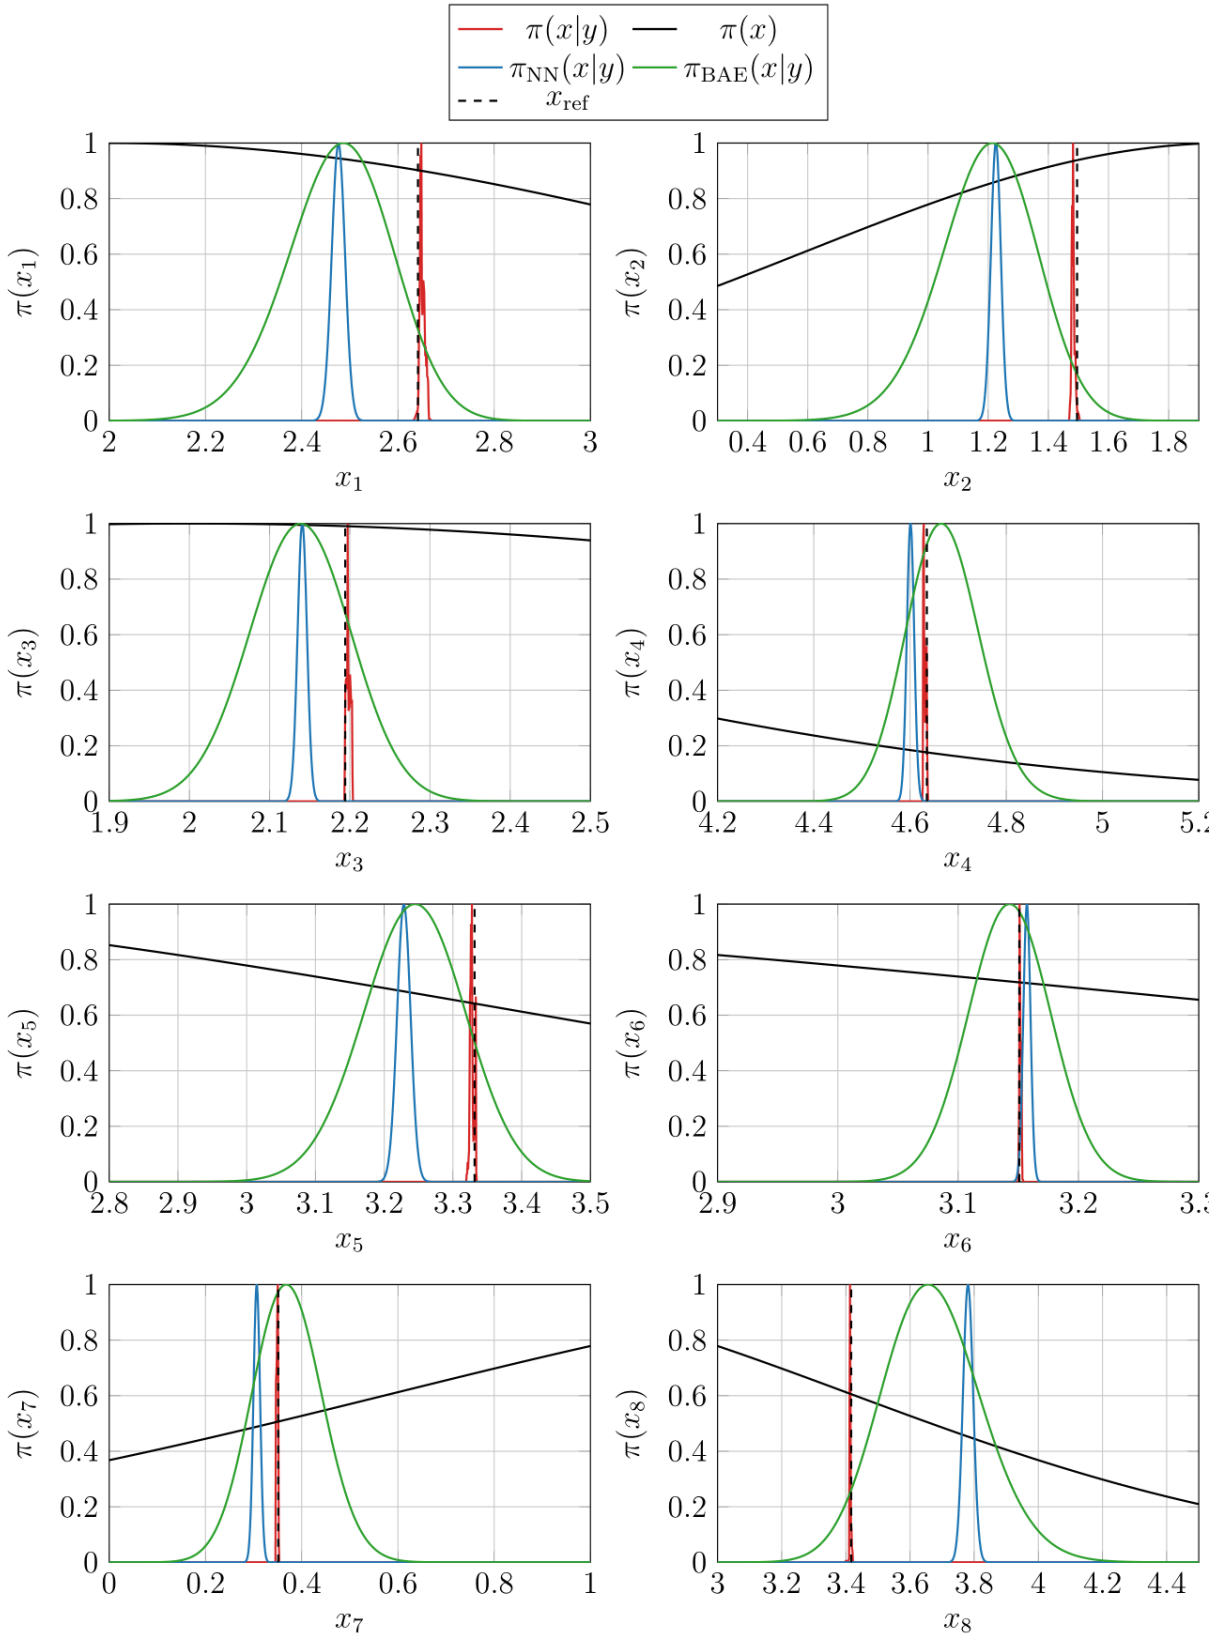

Figure 3: Prior and posteriors, normalized to a height of one. The x axis is zoomed to better show the shape of the posteriors.

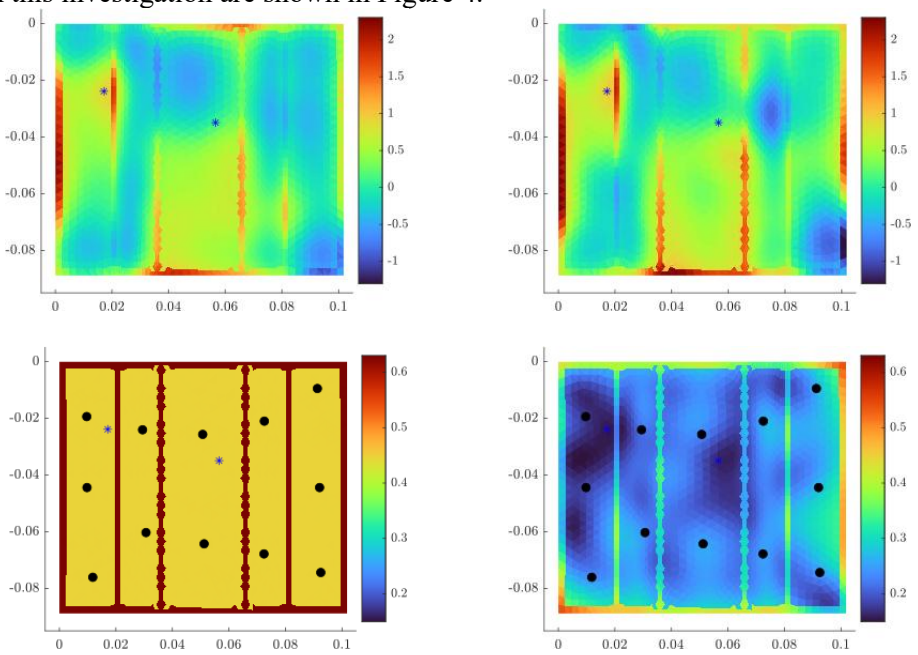
General Field

We now consider the higher-dimensional parameterization described in Section 3.2. With the 100-dimensional parameter x, it is no longer possible to use LIMS to generate the posterior $\pi(x|y)$, or even to fully characterize the BAE posterior $\pi_{BAE}(x|y)$. Instead, we take a Laplace approximation, as described in Section 2.3, computing a MAP estimate and posterior covariance matrix about that estimate. Results from this investigation are shown in Figure 4.



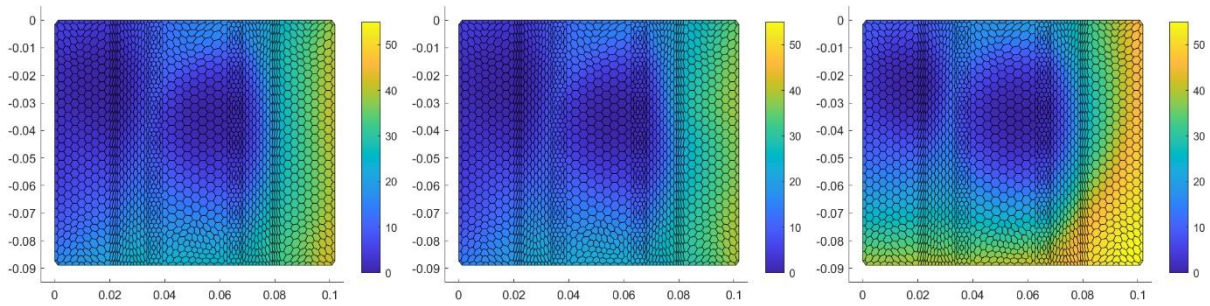


Figure 4: MAP estimate (top left) vs the truth (top right). The prior uncertainty is shown in the bottom left plot, and the posterior in the bottom right. Injection sites are marked with blue stars, while black dots denote sensor locations.

In Figure 4, we reverse the PCA transform on our estimations to visualize k, the permeability strengths or σ_k^2 in the case of the uncertainty plots. Note the similarity between the MAP estimate and the truth – our algorithm correctly identifies a race tracking region in the center of the left mold boundary and accurately estimates the strength of the race track. It also correctly identifies the increased permeability at the bottom-center of the mold.

In this example, we observe a posterior covariance with much lower uncertainty than in the prior, as expected. As with the prior, there is greater uncertainty in the race tracking regions. The uncertainty is greatest in the corners of the mold and on the right boundary. This result is logical because the resin reaches these regions last, and the permeability there has a minimal effect on the pressures and movement of the resin away from them. We observe reduced uncertainty near injection sites; however, interestingly, there is no correlation between the sensor locations and the uncertainty. Measurements at the sensors are affected by permeability throughout the mold, not just in the vicinity.

To further compare our estimations, we can examine the difference in flow front movement when both x_{MAP} and x_{ref} are simulated, as well as when the permeability is homogeneous. These are shown in Figure 5. When the permeability is homogeneous, as is typically modelled, the resin takes over 50 seconds to fill the mold, finishing in the bottom right corner. However, our MAP estimate and the truth match very closely, predicting that the mold filled in roughly 40 seconds. They also both predict that the resin moves quickly to the bottom left corner of the mold, then races along the bottom of the mold, finishing not in the bottom right corner but uniformly along the right edge.

Figure 5: Flow front visualized, for three different permeability scenarios. Each control volume is colored according to the time it takes to fill that control volume (in seconds).

5 CONCLUSIONS AND FUTURE WORK

We proposed a Bayesian framework for predicting preform permeability based on pressure measurements taken during the RTM filling process. To avoid numerical issues caused by the FECV method implemented by LIMS, which is commonly used to model RTM, we use a neural network surrogate and incorporate the approximation error into our Bayesian posteriors. The NN surrogate has the additional advantage of being incredibly fast to run, whereas the FECV method can be very computationally expensive.

We first demonstrated our methodology for a low dimensional parameterization of permeability, considering the estimation of only the race tracking strengths. Our results showed that a posterior that included the surrogate approximation error ($\pi_{BAE}(x|y)$) could correctly encompass the true permeability within its uncertainty. Neglecting these approximation errors when using the surrogate ($\pi_{NN}(x|y)$) creates precise but inaccurate posteriors that are misleading or erroneous. We next demonstrated the same methodology with a larger parameterization, which considers general variations in permeability throughout the preform, with greater variation in the race tracks. Using 12 pressure sensors distributed throughout the mold, we can estimate an unknown permeability field sampled from the prior with high precision. Using our estimate for permeability, we can accurately predict the resin flow pattern.

The following steps in this research involve using real-time permeability estimates for online control of the resin flow. Our research has shown that accurate estimations of the permeability field can be made with a limited number of pressure sensors and almost instantly, using the NN surrogate. Approaches such as an extended Kalman filter [26] [27] are designed to adapt the classical Bayesian approach into a real-time updating posterior. As the mold is filled, we can use the posterior to consider the range of permeability scenarios that may be occurring and take control action (such as adjusting the pressure at one of the two sensors) to minimize the chance of creating voids within the part.

ABSTRACT

Machine learning-based approaches, especially neural network models, have achieved remarkable success in diverse scientific applications, where the deep neural operator (DNO) enables the learning nonlinear operators between infinite-dimensional function spaces and is able to approximate governing equations of time-dependent engineering processes. This paper presents two novel applications of DNO learning to accelerate the design of composite materials and their manufacturing processes. First, we develop a DNO-based surrogate model for finite element simulations of transient mechanical response of 3D interpenetrating phase composites (IPCs) fabricated via additive manufacturing. These IPCs consist of randomly structured metallic phases with different elastic moduli. DNO is trained using a sequence-to-sequence incremental learning approach based on 5,000 finite element simulations of an IPC beam subject to random strain loads, resulting in a 98% prediction accuracy on transient stress at various cross-sections of the IPC beam under dynamic loading. The trained DNO enables real-time prediction of mechanical properties, significantly reducing the design iterations for composites. Second, we introduce an enhanced physics-informed DNO (PIDNO+) model for predicting the particle size distribution in biomass comminution processes. PIDNO+ integrates a population balance model into a hybrid DNO+ architecture that incorporates both material and processing parameters. This integration enables high accuracy with a limited small dataset while preserving physical consistency. The shared parameter network with the embedded physical model allows for differential operation in parameter space and enables inverse design of manufacturing parameters to meet target outcomes. Both DNO applications demonstrate the potential of operator learning for fast and accurate surrogate modeling in composite material design and accelerated optimization of manufacturing processes.

1 INTRODUCTION

Although deep learning algorithms have been implemented into physical problems by many researchers [1-3], it is still challenging to solve the mapping problem between time-dependent and space-dependent functions using traditional deep neural networks (DNNs). There are, in general, two possible scenarios when we develop a DNN model for composite materials. First, if we have sufficient prior physical knowledge on the composite materials and know their governing equations explicitly, i.e., in the form of partial differential equations (PDEs), it becomes possible to encode the PDEs into the DNN, which leads to the physics-informed neural network (PINN) models [4]. Second, if we lack physical knowledge of the given composites (i.e., with three or more enforcing phases) and do not know the explicit form of its governing equations, we need to learn the implicit governing equations or operators from available observed data. This motivated the development of deep neural operator (DNO) methods [5], which learn nonlinear operators between infinite-dimensional function spaces and can

approximate governing equations of time-dependent engineering processes. Deep Operator Network (DeepONet) [6], as one type of DNO, brings a new solution to find the operators. DeepONet can learn the diverse continuous nonlinear operator between input and output, so that it can be used to solve various explicit and implicit mapping functions. In the present paper, two examples of DNO application will be introduced, including DNO acting as a surrogate of physics-based composites models in time-dependent problems, and DNO enabling inverse design of manufacturing process based on small experimental dataset.

The first example of DNO application introduced in Section 2 is on neural operator learning acting as surrogate of physics-based composite model to offer real-time prediction of transient mechanical response of composites under dynamic loading. The mechanical behavior of composites, especially under dynamic loading, is highly sensitive to their 3D structural design. However, evaluating their dynamic response subject to dynamic loading typically requires time-intensive finite element analysis (FEA) or physical testing, which can take hours to days for each design. To overcome this limitation, a DNO model is developed to learn the transient mechanical response of interpenetrating phase composites (IPCs) under dynamic strain loads. DNO consists of one trunk network to encode the domain of the output functions and one DNN or multiple DNNs to encode the discrete input function space as its branch network [7]. A 3D IPC beam composed of two metals with a Young's modulus ratio of 2.7 is used to generate training data through 5,000 FEA simulations with random strain inputs. Once trained, DNO serves as a fast and reliable surrogate to predict stress fields in seconds, greatly accelerating IPC design and optimization.

The second example of DNO application introduced in Section 3 is on inverse design of manufacturing processes based on a small experimental dataset, where an enhanced Deep Neural Operator (DNO+) model is designed to learn how comminution outcomes are influenced by a parameter space consisting of both manufacturing parameters and material properties. To reduce the reliance of DNO+ on experimental data and enable effective DNO+ training on small experimental datasets, we integrate a transport equation of a population balance model (PBM) into the DNO+ framework, creating a physics-informed enhanced deep learning operator (PIDNO+) model. PIDNO+ integrates physics into the DNO+ model to combine the strengths of deep learning and physics-based modeling, therefore, it can reduce the data requirements and improve physical consistency of the model. This integration endows the PIDNO+ model with robust predictive capabilities across diverse conditions and enables inverse design of manufacturing processes for target product features.

2 A SURROGATE OF PHYSICS-BASED COMPOSITE MODEL

We start with the introduction of the physical problem setup. As shown in Figure 1(a), an IPC beam with a cuboid structure composed of stainless steel and aluminum alloy is considered, with one fixed end and one free end, where an arbitrarily dynamic strain loading is applied to the free end. The typical dynamic strain loads created by a Gaussian random process are shown in Figure 1(b). The mechanical response of interest is the time evolution of the normal stress along the x-direction σ_{xx} inside the IPC beam, where x denotes an arbitrary location in the IPC beam. The IPC beam is set to 500 mm in length with a cross section of 100 mm by 100 mm. The beam structure is divided into 40 identical cubic subdomains, each with a side length of 50 mm. Stainless steel and aluminum alloy are randomly assigned to these cubes to form a composite beam.

When the applied strain exceeds the yield point, both the elastic and plastic responses of the constituent materials (stainless steel and aluminum alloy) with significant different elastic moduli and tensile strengths should be considered. This introduces pronounced nonlinearity into the dynamic behavior of the IPC composite beam. The elasticity of the constituent materials is determined by the Young's modulus and Poisson's ratio, while the plasticity deformation is described using a multilinear isotropic hardening model derived from available stress-strain curves [8]. As shown in Figure 1(c), under a given dynamic strain loading, the IPC beam exhibits coupled deformation modes, including bending, axial stretching/compression, and twisting, due to asymmetrical distribution of material properties within the IPC beam structure.

To simulate the dynamic mechanical response, the IPC beam is discretized using the finite element method and solved numerically using the commercial software ABAQUS. The time-evolution of stress

distribution is analysed under varying dynamic strain loadings. A time-dependent strain function is created by drawing from a random Gaussian process. To ensure smooth strain loading conditions, the strain function is modulated by a sine envelope, $\sin(\pi t)$, so that the strain applied to the free end of the IPC beam always starts from a zero strain at $t = 0$ s and ends with a zero strain at $t = 1$ s, as illustrated in Figure 1(b).

A total of 5,000 FEA simulations are performed, each corresponding to a different realization of the dynamic strain loading, to generate enough data for DNO training. Each simulation runs from $t = 0$ s to $t = 1$ s with a sampling interval $\Delta t = 0.01$ s, and generates one dataset consisting a time sequence t_i with i = (1, 2,…, 101), a time-dependent input $Y_i = \varepsilon(t_i)$, and a time-dependent output $U_i = \sigma(\boldsymbol{x}, t_i)$ with $\boldsymbol{x}$ being an arbitrary location inside the IPC beam. Both the branch net and the trunk net of DNO have one input layer, five hidden layers, and one output layer, with a neural network architecture of 101×200×200×300×200×200×101, in which the integers represent the number of neurons in those layers. The model is trained using the Adam optimizer with a learning rate of 0.001 to minimize the mean squared error (MSE) between the DNO predictions and the FEA results. Of the 5,000 datasets, 4,900 are used for training and the rest for testing. The DNO model is iteratively updated until the desired accuracy is achieved or the predefined maximum number of iterations is reached.

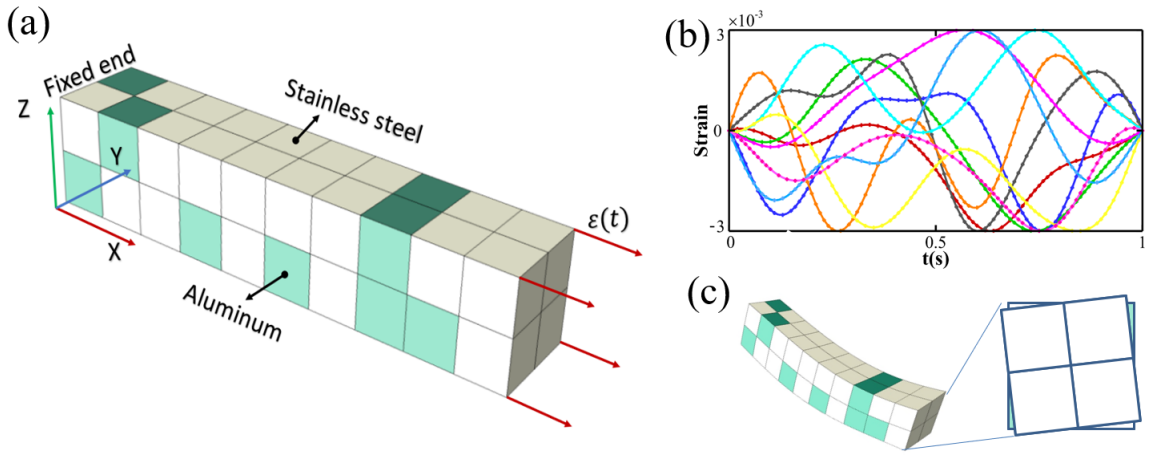

Figure 1: (a) Computational domain and boundary condition of an IPC beam subject to dynamic strain loading. (b) Arbitrary dynamic strain loading is created by drawing a smooth time-dependent function between 0 to 1 seconds from a Gaussian random process. (c) Coupled bending, stretching/compression, and twisting deformation of the IPC beam under strain loading.

Figure 2(a1) and 2(a2) show the stress distribution at the central cross-section (perpendicular to the x-axis) of the IPC beam at $t = 0.5$ s for the FEA simulation and DNO prediction, respectively. The DNO model achieves an average prediction accuracy of 98%. The corresponding error distribution, as shown in Figure 2(a3), reveals that the prediction error is minimal in the central region and increases toward the edges. This pattern of error distribution could be attributed to the higher material uniformity in the central area and increased heterogeneity near the edge of the structure. The maximum error occurs in the upper-right corner, which is consistent with the fact that edge region has high structural complexity and freedom due to the boundary condition - only one end of the IPC beam is fixed. Under compressive loading, this boundary condition allows the structure to bend and twist simultaneously, as observed in Figure 1(c), which makes the stress distribution more complicated.

At the end of the dynamic loading, i.e., $t = 1$ s, although the applied strain at the free end returns to zero, residual stresses remain in the structure, as shown in Figure 2(b1), These residual stresses arise due to irreversible plastic deformation accumulated during the dynamic loading process. Interestingly, even if the applied strain passes through the zero point one or more times, different internal stress states may result each time due to the path-dependent plasticity. This reflects the fact that the process is both time- and space-dependent, making it hard to predict using traditional neural networks. In general, the trained DNO model demonstrates robust prediction capability, achieving stress prediction accuracies ranging from 95% to 99% across various cross-sections when compared to FEA results.

This establishes the DNO as an effective surrogate of physics-based FEA models for real-time prediction of the transient mechanical behavior of composite structures under dynamic loading, which will significantly accelerate computational analysis in composite design and material discovery.

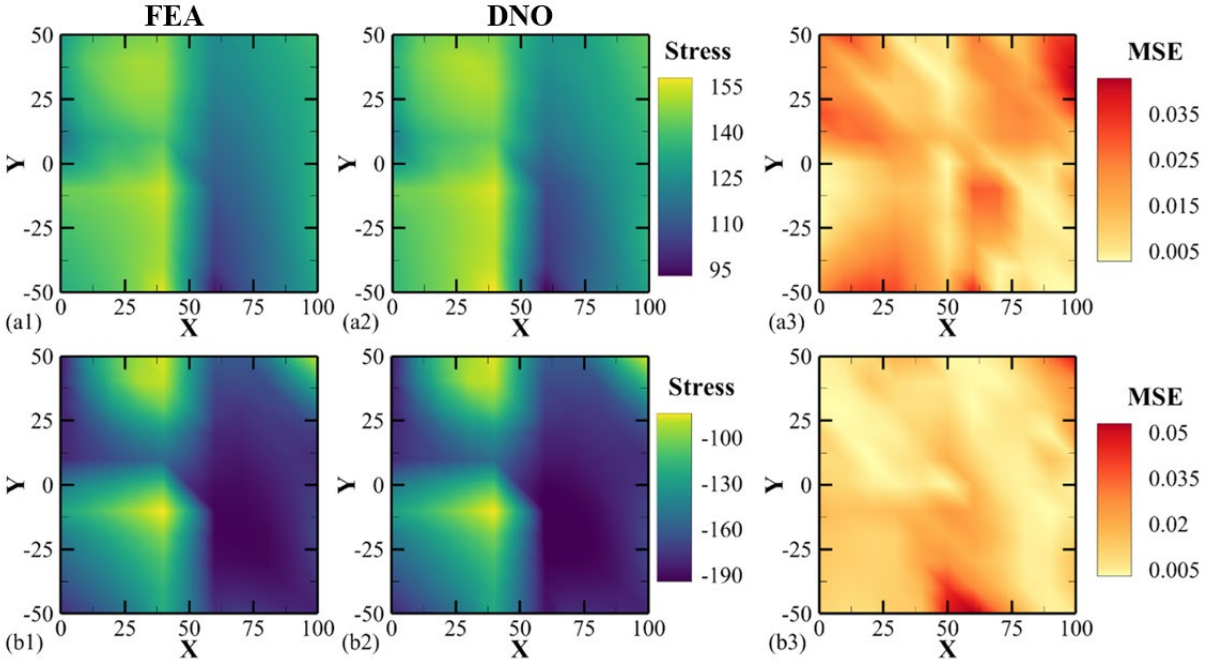

Figure 2: DNO as a surrogate of FEA model to predict the cross-section stress distribution. (a1) and (b1) show the transient stress distribution of a selected cross-section from FEA model at 0.5 s and 1.0 s respectively. (a2) and (b2) illustrate the DNO prediction of stress distribution of the selected cross-section at 0.5 s and 1.0 s respectively. (a3) and (b3) show the prediction error distribution within the cross-section at 0.5 s and 1.0 s respectively.

3 INVERSE DESIGN OF MANUFACTURING PROCESSES

3.1 An Enhanced Physics-informed Deep Neural Operator (PIDNO+) Model

To enable inverse design of a manufacturing process by optimizing adjustable manufacturing parameters, we must enable differential operations in the manufacturing parameter space. To this end, an enhanced deep neural operator (DNO+) model developed by Lu et al. [9] is adopted to map the relationship between the system's input and output while incorporating additional variables that impact the mapping. The DNO+ model consists of a trunk net, a branch net, and a parameter net, as shown in Figure 3. In particular, the branch network takes the cumulative mass distribution with reference to the particle size sequence as input, the trunk net handles the particle size sequence through the entire comminution process, and the parameter network correlates the impact of important feed material properties and manufacturing parameters on the resultant particle size distribution (PSD) of comminuted material.

The primary input of the biomass comminution DNO+ model is the feed-in cumulative mass distribution $\boldsymbol{\Phi}_{\text{in}}$ with reference to a particle size sequence $\boldsymbol{x}$, and the influence parameters $\boldsymbol{p}$. The cumulative mass distribution $\boldsymbol{\Phi}_{\text{out}}$ as output is then expressed as

$$\boldsymbol{\Phi}_{\text{out}} = \mathscr{F}(\boldsymbol{\Phi}_{\text{in}})\cdot\mathscr{R}(\boldsymbol{x}) + \mathscr{L}(\boldsymbol{p})\cdot\mathscr{R}(\boldsymbol{x}), \tag{1}$$

where $\mathscr{F}$, $\mathscr{L}$, and $\mathscr{R}$ represent different operators and are approximated by the neural network. Here, a fully connected neural network is used in the trunk net to process each input feature independently, while convolutional neural networks are used in the branch and parameter networks to extract features from spatially structured data by virtue of their shared-weight architecture. The introduction of additional parameter networks enables the DNO+ model to consider the impact of material or process

parameters on system results and thus more effectively capture the relationship between system input and output.

To address the challenge of training DNO+ on limited experimental data, a physical model is integrated into the DNO+ structure to reduce the data requirements for training the DNO+ model. In this work, a population balance model (PBM) [10] for modeling particle breakage and the evolution of PSD is used to constrain DNO+ training. The core concept of PBM is to track the statistical distribution of a population of particles over time or space, accounting for key phenomena such as breakage and aggregation. PBM describes how larger particles disintegrate into smaller ones under the influence of mechanical stress (e.g., compression, shear, or impact), which is suitable for this biomass comminution DNO+ model.

Let the breakage matrix of PBM be X, and the classification matrix for considering the effects of screen size and passing efficiency be C. The mapping function between the feed PSD (F_{PSD}) and the product PSD of milled materials (P_{PSD}) can be expressed as

$$P_{\mathrm{PSD}} = \sum_{k=1}^{\infty} C\cdot(1-C)^{k-1}\cdot X^{k}\cdot F_{\mathrm{PSD}}. \tag{2}$$

However, Eq. (2) lacks a description of the impact of material properties or manufacturing parameters on the system. To address this limitation, the advantage of high-dimensional expression of neural networks can be used to establish a complex relationship by allowing the matrices X and C to be functions of material properties and manufacturing parameters.

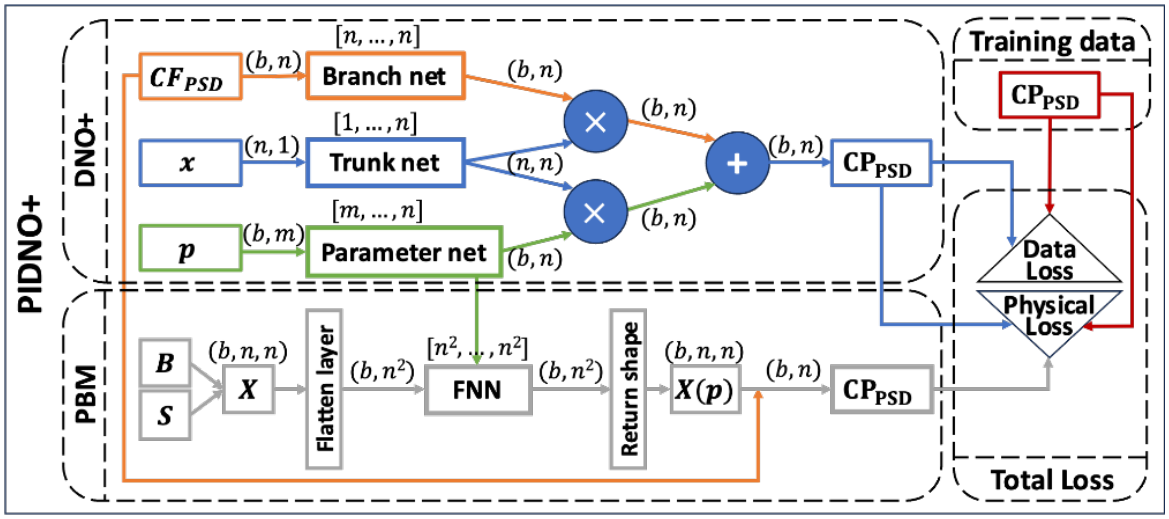

Figure 3: The structure of physics-informed deep neural operator (PIDNO+) model. The PIDNO+ model combines the population balance model (PBM) and DNO+ and establishes the connection between PBM and model parameters through neural networks. The total loss of the PIDNO+ model is the summation of data loss and physical loss. Data loss enables the model to learn from the available data, while physical loss aids the model in learning from the physical-based model.

Figure 3 illustrates the structure of a physics-informed deep neural operator (PIDNO+) model by integrating a PBM into a DNO+ model. The original breakage matrix X in PBM is defined by the breakage function B and the breakage probability S. From Eq. (2), it can be observed that if a connection can be established between matrix X and parameters $\boldsymbol{p}$, which represent feed material properties and manufacturing parameters, the influence of these parameters on the system can be determined. In the PIDNO+ model, X is a matrix with size (b, n, n), where b is the batch size and n the data length. After a flattening process, X changes into X_{flat} with size (b, n^2). The influence of parameter net is introduced in the fully connected neural network, which establishes a relationship between a parameter dependent breakage matrix $X(\boldsymbol{p})$ and X_{flat}. Therefore, the breakage matrix X in Eq. (2) can be replaced by $X(\boldsymbol{p})$, resulting in the milled materials P_{PSD} various with respect to the parameters $\boldsymbol{p}$.

The overall loss function L_{total} in PIDNO+ is formulated by combining three key components: the data-fitting loss between the real data U_{real} and the DNO+ model data $U_{\mathrm{DNO+}}$, the data-fitting loss

between the real data U_{real} and the physical model data U_{phys}, and the consistency loss between the DNO+ model data U_{DNO+} and the physical model data U_{phys},

$$L_{total} = \lambda_1 \cdot MSE(U_{real}, U_{DNO+}) + \lambda_2 \cdot MSE(U_{real}, U_{phys}) + MSE(U_{DNO+}, U_{phys}), \quad (3)$$

where λ_1 and λ_2 serve as weights to determine the significance of different losses. $MSE(U_{real}, U_{DNO+})$ ensures the accuracy of the data-driven part in fitting the data within the entire model. $MSE(U_{real}, U_{phys})$ helps the embedded PBM find suitable built-in parameters. $MSE(U_{DNO+}, U_{phys})$ ensures the auxiliary role of the physical model in the prediction results of the PIDNO+ model.

3.2 Inverse Design of Manufacturing Processes

To validate the PIDNO+ model proposed in this paper, corn stalks were used as an example and experiments were conducted on the comminution process of corn stalks. The material was prepared to have different moisture content levels that represent typical ranges found in corn stover feedstocks in the U.S. Midwest and South. The preparation involved conditioning the corn stalks to achieve the desired moisture levels before comminution. A G1635 Granulator knife mill was configured with a motor capable of operating at different frequencies to adjust the blade tip speed. Different output frequencies were employed from 40 Hz to 60 Hz, corresponding to blade tip speeds ranging from 6.5 $m \cdot s^{-1}$ to 9.8 $m \cdot s^{-1}$. Different discharge screen sizes were chosen to investigate their impact on the particle size distribution of the comminuted material.

To test the feasibility of the model and its data requirements, training and testing datasets need to be prepared. The information contained in one training dataset includes distribution of feed mass versus sieve size, feed moisture content, discharge screen size, and distribution of discharged mass versus sieve size. When the DNO+ model is trained with sufficient data, i.e., 400 datasets, it demonstrates high prediction accuracy for any input within the feasible domain. However, in many cases, sufficient data may not always be available, and the performance of DNO+ without a physical model will be negatively affected. Figure 4(a) shows the prediction results of DNO+ model trained on 100 datasets. It can be observed that although the prediction results generally follow the trend, they deviate a little from the actual values. More extremely, some data points may exceed 100%, rendering the results physically meaningless. In contrast, the PIDNO+ model, trained on a much smaller dataset, achieves an average prediction accuracy of 98% without any values exceeding 100% of cumulative mass, as shown in Figure 4(b). This high accuracy is attributed to the support of the integrated physical model, which not only requires less training data but also conforms to certain physical rules.

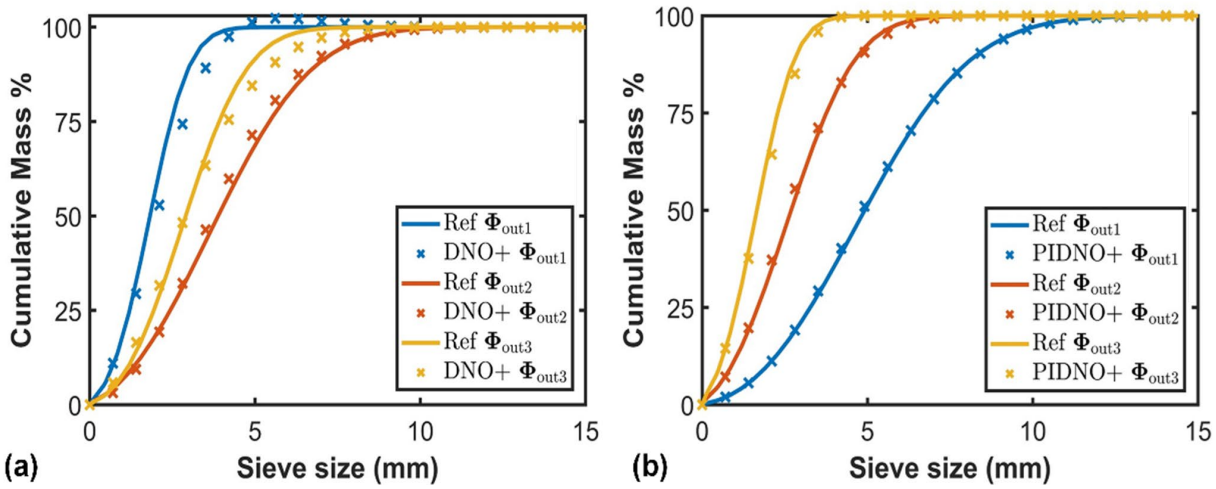

Figure 4: Comparison of the prediction results on the cumulative mass percentage changed with various sizes of sieve: (a) DNO+ with 100 datasets, (b) PIDNO+ with 50 datasets.

The additional parameter network in PIDNO+ enables differential operations in the parameters space, which includes the influence of feed material properties and manufacturing parameters. The trained PIDNO+ model will approximate the nonlinear mapping between the PSD of feed material,

moisture content, screen size, and the resulting PSD of the milled material, which can be optimized to determine the ideal combination of the feed material PSD, moisture levels and screen size to achieve the desired product PSD. Figure 5 demonstrates an inverse design of corn stalks comminution process using PIDNO+. By giving an expected cumulative particle size distribution (PSD) and a feed material PSD, PIDNO+ can determine the moisture content of 30.71% and a screen size of 20.52 mm for the milling machines to produce a cumulative PSD of milled materials consistent with the expected PSD. As a result, the corresponding cumulative PSD outputs are successfully obtained for each case. The real-time prediction of comminution products and inverse design of manufacturing parameters not only enhance manufacturing process control but also reduces energy consumption and operational costs by minimizing trial-and-error experimentation.

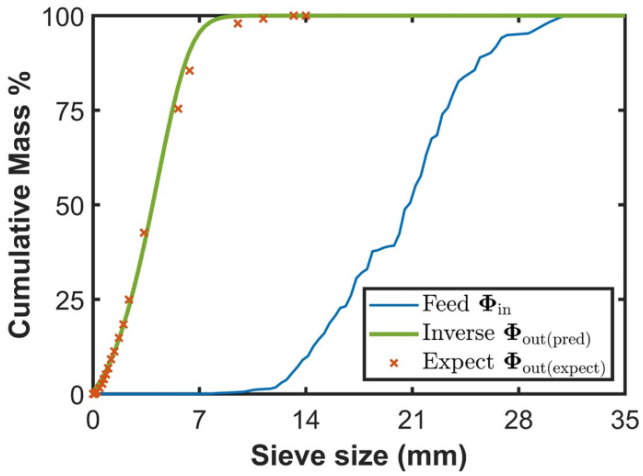

Figure 5: Inverse design of comminution manufacturing parameters. Given an expected cumulative particle size distribution (PSD) with a feed material PSD, PIDNO+ predicts that the moisture content should be adjusted to 30.71% and a screen size of 20.52 mm, which produces a cumulative PSD of milled materials consistent with the expected PSD.

4 CONCLUSIONS

Two significant advancements in modeling and prediction of complex material systems using neural operator learning were presented. First, a Deep Neural Operator (DNO) model was developed to serve as a superfast and accurate surrogate for finite element analysis (FEA) in predicting transient mechanical response of interpenetrating phase composites (IPCs) under dynamic loading. Unlike conventional FEA-based methods that require repeated simulations for different loading conditions, the trained DNO can offer real-time prediction of mechanical responses for arbitrary strain sequences. The use of arbitrary random strain loads in DNO training improves its ability to be generalized for extended temporal inputs. The high accuracy of DNO in predicting stress distributions promises to significantly accelerate composites design and material optimization. Future work may involve integrating Bayesian neural networks [11] for improved uncertainty quantification in noisy data scenarios.

Second, an enhanced Physics-Integrated Deep Neural Operator (PIDNO+) model with an additional parameter network was introduced for predicting particle size distributions (PSD) in a comminution process, offering a flexible and interpretable deep learning framework by integrating a DNO+ model with a physics-based population balance model (PBM). The PIDNO+ model reduces data dependency by embedding physical laws directly into the learning architecture. By incorporating multi-physics relationships and empirical laws from PBM into DNO+, the model captures the influence of material properties and manufacturing parameters on particle breakage with improved generality and adaptability across different regimes, which were validated on experimental comminution data of flexible materials (corn stalks). PIDNO+ offers fast and interpretable predictions of PSD evolution in comminution processes, in which the differentiable parameter network enables the inverse design of manufacturing processes through optimizing feed material properties and manufacturing parameters.

With differentiable parameter network for optimizing manufacturing parameters, this DNO+ inverse design framework will be applied to manufacturing processes of composites, including the inverse design of thermoforming processes for carbon fiber reinforced polymer composites [12], and the inverse design of injection molding parameters for thermoplastic composites [13], based on experimental data generated at the University of Delaware Center for Composite Materials.

Keywords: Biopolymerization; Carbon mat; Lignin fibers.

ABSTRACT

The growing demand for renewable materials has driven interest in lignin as a sustainable precursor for bio-based carbon fibers (CFs). However, its low molecular weight and limited thermal performance restrict its direct applicability. This study explores the enzymatic modification of Kraft lignin (KL) using an oxidative cocktail (LADEBIO-*Pys*) derived from *Pycnoporus sanguineus*, aiming to enhance its structural and processing characteristics for CF production. KL was treated with LADEBIO-*Pys* and *Trametes versicolor* laccase (KL-*Pys* and KL-Tvs, respectively). Both treatments significantly increased molecular weight (by over 150%) and polydispersity (over 110%), indicating efficient polymerization. FT-IR analysis showed intensified bands at 1700 and 1600 cm^{-1}, associated with carbonyl formation, Cα oxidation, and the emergence of conjugated structures. ^{1}H NMR revealed reduced methoxyl protons and increased aliphatic hydroxyls, especially in KL-Tvs, suggesting extensive oxidation, demethylation, and radical coupling reactions (C–C and C–O), leading to a restructured lignin matrix. Thermal analysis indicated higher thermal instability in enzymatically treated lignins, with ~58% mass loss, reflecting side-chain degradation and structural rearrangements involving β-O-4 and β-1 linkages. Despite reduced stability, the treatments resulted in high-molecular-weight, reactive lignin structures with improved processability. Electrospinning experiments confirmed the benefits of enzymatic treatment. While untreated KL yielded brittle, discontinuous fibers, KL-*Pys* produced flexible, homogeneous mats. The addition of 1% polyethylene oxide (PEO) further improved fiber uniformity and mechanical integrity, yielding nanofibers with average diameters of ~ 0.20 µm. The resulting material shows strong potential as a scalable, sustainable precursor for CFs and other high-performance biobased materials.

1 INTRODUCTION

Global demand for carbon fibers (CFs) has grown substantially over the past decade and a half [1–3]. From 42,900 metric tons in 2010, demand rose to 115,000 metric tons by 2023, an increase of approximately 168% [4]. This trend is projected to continue, reaching 280,300 metric tons by 2030, which would represent an additional 144% growth [4]. This expansion reflects CF's increasing relevance across a diverse range of sectors, including wind energy, automotive, pressure vessels, and construction [2,3]. As the market diversifies and scales up, there is a growing imperative to identify sustainable, cost-effective alternatives to petroleum-based precursors [2]. In this context, lignin, a widely available and chronically underutilized byproduct of the pulp and paper industry, has attracted increasing interest as a renewable precursor to produce lignin-based carbon fibers (LCFs) [1,2,5]. It is estimated that nature produces between 0.5 and 3.6 billion tons of lignin annually, with more than 70 million tons commercially generated, largely discarded as industrial waste [5]. Despite its abundance, the industrial application of lignin in CF production remains limited, constrained by its structural complexity and unresolved processing challenges [1,5].

The conversion of lignin into high-performance LCFs faces significant challenges due to its intrinsic structural complexity and the presence of contaminants such as ash, cellulosic residues, and inorganic salts, all of which can compromise fiber quality [6]. Unlike synthetic precursors such as PAN, lignin lacks a standardized conversion pathway [2]. Its transformation into spinnable fibers typically begins with compositional and rheological characterization, followed by targeted purification steps and spinning processes, such as melt, electrospinning, dry, or wet, chosen according to its physicochemical properties[1,5,7].

To improve LCFs' quality and mechanical performance, various strategies have been explored, including chemical, physical, and enzymatic treatments and their combinations. Among these, enzymatic approaches are particularly promising, leveraging oxidative enzymes such as laccases (Lac), lignin peroxidases (LiP), and manganese peroxidases (MnP). These enzymes catalyze the oxidation of phenolic and non-phenolic substructures in lignin, facilitating the cleavage of its resistant aromatic bonds [8]. As a result, they can promote increased molecular linearity, structural homogeneity, and hydroxyl group removal, yielding lignin with higher molecular weight and greater suitability as a PAN alternative in the production of high-performance CFs [9].

Despite these advantages, the industrial application of enzymes remains limited by factors such as low catalytic efficiency, narrow substrate specificity, and incomplete degradation [10,11]. In contrast to cellulose, which is efficiently hydrolyzed by well-optimized cellulolytic cocktails [12–14], lignin requires enzyme blends specifically tailored to address its heterogeneous and highly cross-linked structure. Effective cocktail design must consider the lignin source, pretreatment method, and desired end-products. While the synergistic interactions of cellulolytic enzymes are well-characterized and widely applied to enhance bioethanol yields from lignocellulosic biomass [15], lignin-directed enzymatic systems remain underdeveloped at an industrial scale.

This gap highlights a key biotechnological challenge: the development of enzymatic strategies that are not only effective but also economically and environmentally viable for lignin valorization. Within this framework, ligninolytic enzyme cocktails derived from white-rot fungi have emerged as a compelling solution. The basidiomycete *Pycnoporus sanguineus* has shown promise in producing key oxidative enzymes capable of targeting and cleaving lignin's aromatic framework. This study aimed to enhance Kraft lignin (KL) via enzymatic modification using a customized oxidative enzyme cocktail (LADEBIO-*Pys*) derived from *P. sanguineus*. The objective was to improve KL's polymerization behavior and processing characteristics, thereby reinforcing its potential as a sustainable precursor for CF production.

2 MATERIALS AND METHODS

2.1 Production of the Enzymatic-Oxidative Cocktail from *P. sanguineus*

The oxidative enzymatic cocktail (LADEBIO-*Pys*) was produced by submerged cultivation of *P. sanguineus* (strain 2512, CCIBt/SP) in a bubble column reactor (Biostat B, B. Braun Biotech, USA) under fed-batch conditions for nine days. The culture medium was based on Mandels and Reese's [16]

formulation, optimized with a specific carbon-to-nitrogen ratio and supplemented with enzymatic inducers. The secretome was concentrated by tangential flow filtration (TFF), combining microfiltration (0.2 µm) and ultrafiltration (10 kDa), as previously described in our early study [17]. To evaluate the efficiency of the concentration process, three parameters were determined: the membrane rejection coefficient (ω) (equation 1); the volumetric concentration factor (Fc) (equation 2); and the overall process yield efficiency (R) (equation 3).

$$\omega\ (\%) = \left(1 - \frac{C_{UF}}{C_{PER}}\right) x100 \quad \text{Equation (1)}$$

$$F_c = \frac{V_{Eb}}{V_{UF}} \quad \text{Equation (2)}$$

$$R\ (\%) = \ (F_c)^{(\omega-1)} x100 \quad \text{Equation (3)}$$

Where C_{UF} is the enzymatic concentration in the ultrafiltration retentate (U/L); C_{PER} is the residual enzymatic concentration in the permeate (U/L); V_{Eb} is the initial volume of crude extract (L); V_{UF} is the final volume after 10 kDa ultrafiltration (L).

2.2 Enzymatic Activity Assays and Protein Quantification

Lac, MnP, and LiP activities were measured by the oxidation of ABTS (420 nm), phenol red (610 nm), and veratryl alcohol (310 nm), respectively, following established protocols, Wolfenden and Willson and Tien and Kirk [18–20]. Xylanase (XyL), β-glucosidase (β-G), avicelase (AV), FPase (FP), and CMCase (CMC) were quantified according to Eveleigh et al.[21]. One enzymatic unit (U) corresponds to the oxidation of 1 µmol of substrate per minute. Total protein (PTN) content was determined using the Bradford method with BSA as a standard (595 nm) [22]. The enzymatic cocktail was evaluated by SDS-PAGE to assess its protein diversity, using 12–15% denaturing polyacrylamide gels under standard Laemmli [23] conditions. Protein visualization was performed using Coomassie Brilliant Blue staining, and molecular weight markers (Pierce, Thermo Scientific) were used for reference [24].

2.3 Enzymatic Oxidation of KL

Enzymatic modification was performed in a reaction medium containing 10 g/L of KL, an enzyme load of 30 mg/g (based on total protein), using either the LADEBIO-*Pys* cocktail or a commercial laccase from *Trametes versicolor* (> 0.5 U/mg). The medium also included ABTS (25 mg/g), H_2O_2 (10 mg/g), and $MnSO_4$ (10 mg/g), in 2 mmol/L sodium phosphate buffer (pH 5.0). Reactions were performed in 250 mL bioreactors at 40 °C, 400 rpm for 48 h with continuous air flow (2 L/min). After treatment, the enzymes were thermally inactivated (80 °C, 10 min), washed three times with deionized water, centrifuged (25,000 g, 15 min), and oven-dried at 60 °C for 48 h.

2.4 Physicochemical Characterization of Modified Lignin

Molecular weight distribution was determined by Advanced Polymer Chromatography (APC) using DMSO/LiBr (0.5% w/v) as solvent at 90 °C and a 0.5 mL/min flow rate [25]. Calibration was performed with polystyrene sulfonate standards. Thermal stability was assessed using thermogravimetric analysis (TGA) on a Q500 analyzer under nitrogen (30 mL/min), heating samples from 30 °C to 800 °C at 10 °C/min. Differential scanning calorimetry (DSC) was used to determine glass transition temperature (T_g), employing a heating protocol from 50 °C to 200 °C (20 °C/min), followed by controlled cooling and second heating (10 °C/min), under nitrogen flow (50 mL/min). Structural analysis by FT-IR was performed with KBr pellets (2 mg lignin + 200 mg KBr, pressed at 10 MPa), scanning from 4000 to 400 cm^{-1}. Oxidation degree (Θ) was determined by calculating the absorbance ratio between the characteristic oxidation bands and the reference band at 1510–1513 cm^{1}, which corresponds to aromatic

skeletal vibrations and remains largely unaffected by oxidative reactions, thus serving as an internal standard [26]. ^{1}H NMR spectra were acquired after dissolving 20 mg of dried lignin in 600 µL DMSO-d_6 with 22 µL pentafluorobenzaldehyde (PFB) as internal standard. Analyses were performed at 25 °C, using the *zgpr* pulse sequence with 128 scans and 10 s relaxation delay. Peaks were referenced to PFB (10.28 ppm) and DMSO-d_6 (2.50 ppm) [27].

2.5 Electrospinning and Morphological Analysis

Electrospinning was performed using a custom-built setup with a 30 kV power source, syringe pump, and metallic collector. The voltage was fixed at 16 kV, with a 0.05 mL/min flow rate, 8.0 cm needle-to-collector distance, and stainless-steel 18G 1/2 needle. Two formulations were evaluated: KL enzymatically treated with the LADEBIO-*Pys* cocktail alone and blended with 1% (w/w) polyethylene oxide (PEO). The solutions were prepared at a 2:3 (w/w) solid-to-solvent ratio in DMF: acetone (9:1, w/w) [28,29]. Resulting lignin fibers were characterized by Scanning Electron Microscopy (SEM) using a Hitachi TM3030Plus at 15 kV, with magnifications from 200× to 6000×. Samples were analyzed, and average fiber diameters (θ) were calculated using ImageJ software.

3 RESULTS AND DISCUSSION

3.1 Obtention and Characterization of the LADEBIO-*Pys* Cocktail

Figure 1 presents the enzymatic activities of Lac, LiP, MnP, and PTN following TFF and concentration using a hollow fiber system. As shown, sequential microfiltration and ultrafiltration steps led to the recovery of four enzymatic cocktails highly enriched in ligninolytic enzymes. Lac and MnP activities reached their maximum values in the third batch, while LiP activity peaked in the first. This variation reflects the dynamics of enzyme secretion during cultivation and recovery.

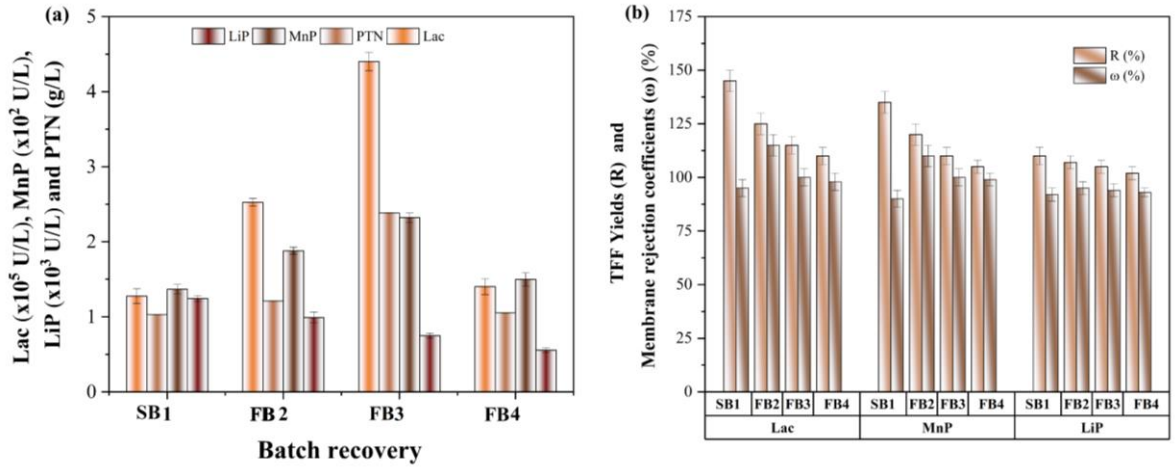

Figure 1: Batch recovery and tangential flow filtration (TFF) performance of the oxidative enzymatic cocktail LADEBIO-Pys from *P. sanguineus*. (a) Enzyme recovery in batch mode for Lac, LiP, MnP, and PTN (b) TFF yield (R) and membrane rejection coefficient (ω) for SB1 and FB2–FB4. SB1: first single batch; FB2–FB4: fed-batch recoveries performed after alimentation on the seventh, eighth, and ninth days, respectively.

Ultrafiltration using a hollow fiber system with a 10 kDa molecular weight cut-off resulted in substantial increases in enzymatic activity (>100%, Fig. 1b), primarily due to the removal of low-molecular-weight compounds and water. This led to volumetric concentration and enrichment of active enzymes. The membrane rejection coefficients (ω) remained consistently high for all enzymes (89.81%–98.78%, Fig. 1b), indicating strong selectivity and process efficiency, with LiP exhibiting the highest retention. These results reinforce the robustness of the TFF system (Fig. 1) in concentrating enzymatic cocktails while minimizing losses and denaturation. Kinetic monitoring revealed an increasing trend in

R and ω values post-filtration, likely due to progressive membrane fouling caused by pigment accumulation, especially cinabarin, a red phenoxazinone compound secreted in large amounts by *P. sanguineus* (Fig. 2b). This fouling may contribute to enhanced enzyme retention by forming a secondary filtration layer, as visually supported by the crude extract's color profile (Fig. 2a-c). These values position *P. sanguineus* as a potent producer of ligninolytic enzymes, corroborated by prior studies [24,30,31].

The enzymatic profile of the LADEBIO-Pys cocktail, produced by *P. sanguineus*, reflects the cumulative outcome of four sequential batches obtained through TFF and reveals a remarkable co-secretion of lignin-modifying enzymes (LMEs) alongside cellulolytic hydrolases, as illustrated in Figure 2. Post-filtration activity levels for Lac, LiP, and MnP reached 6.8×10^5, 3.0×10^4, and 1.5×10^3 U/L, respectively, reflecting the strain's strong oxidative capacity. Concomitantly, substantial activities of β-G, Xyl, AV, FP, and CMC were also detected, with β-G and CMC activities ranging from 4 to 5,000 U/L, indicating a robust polysaccharide-degrading potential (Fig.2e).

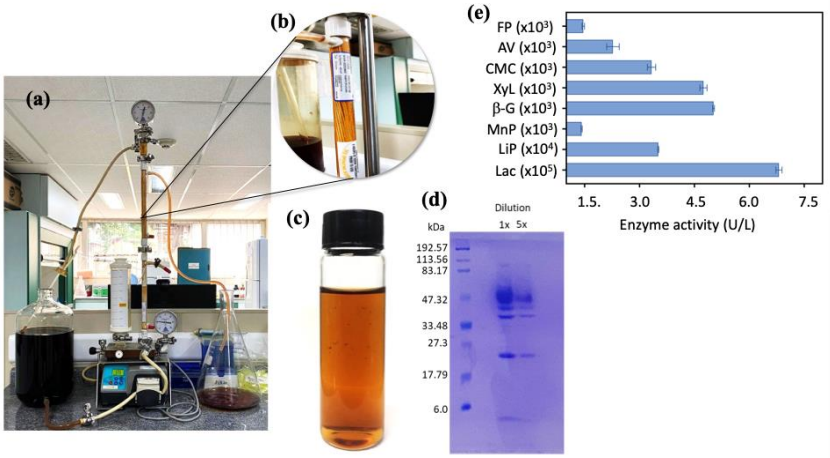

Figure 2: Recovery and partial characterization of the oxidative enzymatic cocktail LADEBIO-*Pys* from *P. sanguineus*. (a) Hollow fiber filtration system used for TFF and concentration; (b) membrane segment showing crude extract pigmentation; (c) LADEBIO-*Pys* after ultrafiltration; (d) protein profile by SDS-PAGE (MW marker, 1x and 5x dilutions); (e) enzymatic activity profile of the lignocellulolytic complex.

The observed enzymatic profile is consistent with prior reports: Pereira Scarpa et al. [32] identified a similar range of enzymes, including LMEs and glycoside hydrolases, during solid-state fermentation; Azmi, Jalil, and Kalil [33] reported elevated FP, CMC, and exoglucanase activities under α-cellulose fermentation; and Sahaid Kalil et al. [34] demonstrated peak cellulase production within 48 h of cultivation. The coexistence of oxidative and hydrolytic activities in a single fungal secretome not only underscores the metabolic flexibility of *P. sanguineus* but also reinforces its biotechnological relevance for integrated biorefinery strategies focused on the enzymatic valorization of lignocellulosic biomass into high-value compounds such as platform chemicals and functional biomaterials.

3.2 Molecular Characterization of Enzymatically Modified KL

Figure 3 shows that the enzymatic treatments of KL using either *T. versicolor* commercial laccase (KL-Tvs) or the LADEBIO-*Pys* cocktail (KL-*Pys*), both in the presence of ABTS mediator, resulted in a significant increase in molecular weight (Mw) and polydispersity index (PDI) after 48 hours of reaction, when compared to the untreated control (KL).

Mw values rose by 157% (Lac-Tv) and 152% (LADEBIO-*Pys*), while PDI increased by 110% and 115%, respectively. These findings align with those reported by Ibarra et al. [35], who observed a 1.8-fold Mw increase with bacterial laccase SiLA (SiLA-KL1) and a 1.7-fold increase with fungal laccase MtL (MtL-KL1), accompanied by similar increases in PDI. According to Areskogh et al. [36], such

outcomes are attributed to the non-selective radical–radical coupling reactions triggered by the oxidation of terminal phenolic groups in lignin, wherein free radicals spontaneously couple without spatial or steric control (Fig. 3b). This leads to broad molecular weight distributions, thereby increasing polydispersity.

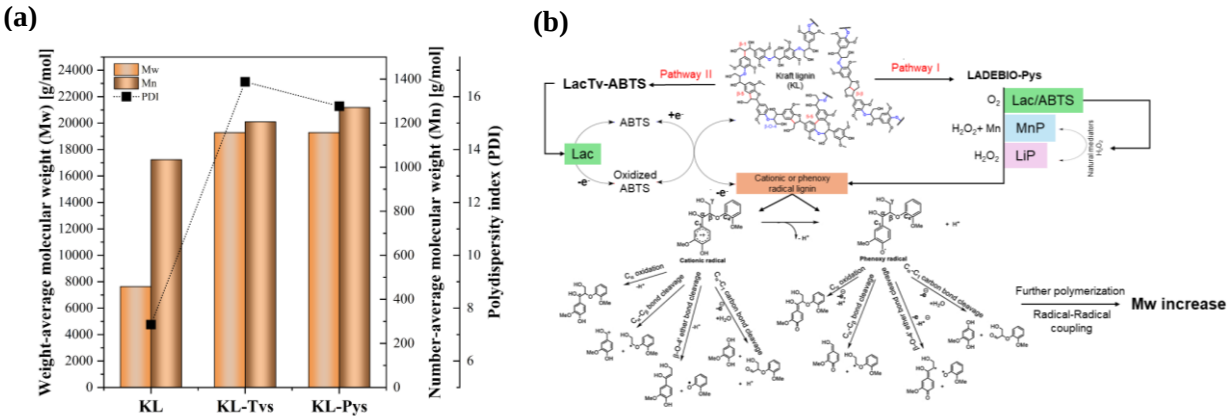

Figure 3: Enzymatic modification of Kraft lignin (KL). (a) GPC analysis and (b) Oxidation pathways: (I) LADEBIO-*Pys* system promotes radical formation and synergistic polymerization; (II) LacTv-ABTS acts via redox cycling.

Despite the longer reaction time applied in our study (48 h), the results suggest that the LADEBIO-*Pys* system efficiently promotes structural remodeling of lignin not only through oxidative polymerization, but also via cleavage of key interunit linkages such as β–O–4, β–5, β–β, 4–O–5, and 5–5, as proposed by Vignali et al. [37] and Zhu et al. [36] (Fig. 3b). Our findings support the literature postulate that polymerization is initiated by single-electron abstraction from the phenylpropanoid moieties of lignin by either LacTv or the LADEBIO-*Pys*/ABTS system, generating phenoxyl radicals that activate the lignin surface [38,39]. Given the extended π-conjugation systems in lignin, the unpaired electron is delocalized to more stable resonance structures. Phenolic units are oxidized to phenoxyl radicals, whereas non-phenolic regions form β-aryl and benzylic radicals. These species act as reactive intermediates that undergo radical–radical coupling, involving either lignin–lignin or lignin–mediator linkages. This process results in covalent polymer growth and an overall increase in Mw, as illustrated in Figure 3, thus demonstrating the dual oxidative and structural modification capabilities of the enzymatic systems evaluated [38,39].

3.3 Structural Modifications Detected by FT-IR and ^{1}H NMR

FT-IR spectroscopic analysis (Figure 4a-b) indicated that, although the aromatic scaffold of KL remained largely conserved following enzymatic oxidation, substantial alterations were observed in specific functional groups, notably in the ν(OH), ν(COOH), ν(C=O), and ν(OCH_3) absorption regions. The broad ν(OH) stretching band (3300–3600 cm^{-1}), present across all spectra, showed a marked attenuation at approximately 3441 cm^{-1} in the KL-Tvs sample.

This reduction suggests a significant depletion of – OH, likely attributable to the pronounced oxidative potential of *T. versicolor* laccase, especially when operating within the ABTS-mediated redox system [40]. Conversely, the KL-*Pys* sample exhibited a comparatively moderate decrease in this band, possibly resulting from simultaneous oxidative cleavage and regeneration of hydroxyl functionalities at the side chains, a phenomenon that may be enhanced by the synergistic action of accessory oxidoreductases present in the LADEBIO-*Pys* enzymatic cocktail. Additionally, both enzymatically treated samples displayed a discernible decline in the ν(C–H) stretching bands (2800–2900 cm^{-1}), corresponding to aliphatic methylene and methyl groups (Fig. 4b) [41]. This behavior is indicative of partial demethylation and demethoxylation processes, in agreement with previously reported depolymerization and structural simplification mechanisms for lignin matrices subjected to oxidative biocatalysis [42].

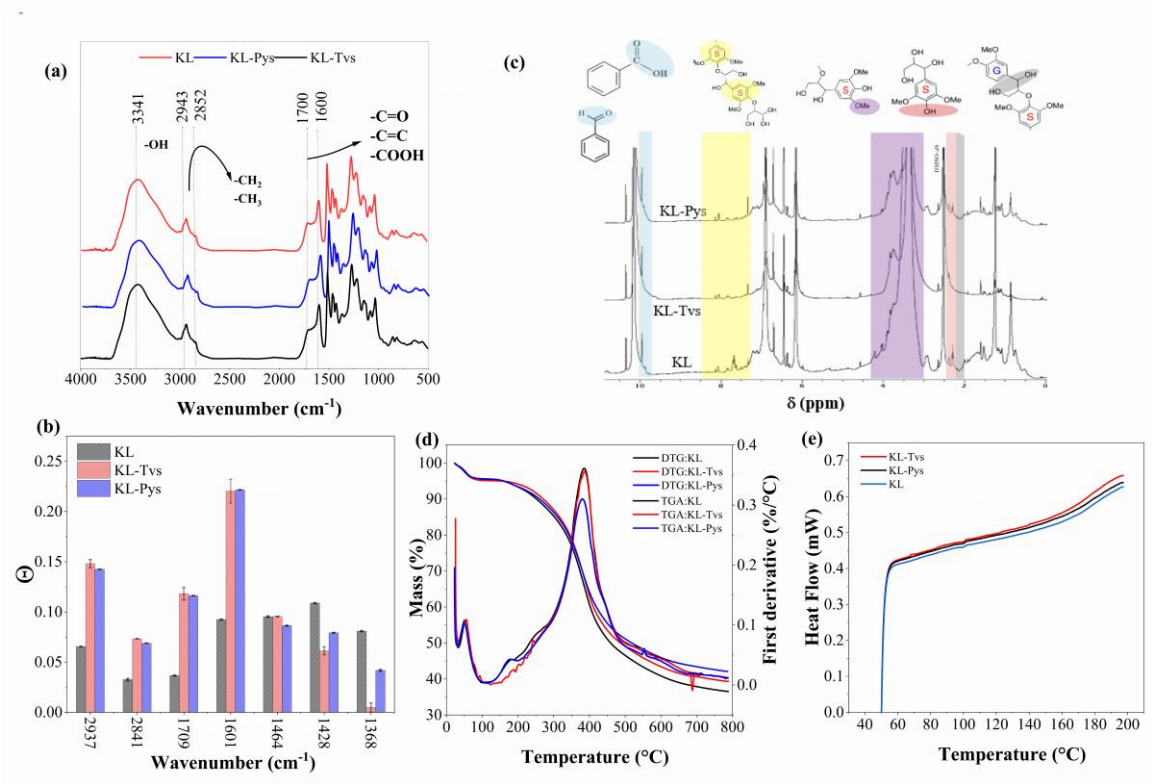

Figure 4: Structural and thermal characterization of Kraft lignin (KL) before and after enzymatic treatment with LADEBIO-*Pys* and *T. versicolor* laccases. (a) FTIR spectra acquired via KBr pellet method; (b) Quantitative comparison of main functional group peaks (Θ); (c) ^{1}H NMR spectra; (d) TGA and DTA thermograms; (e) DSC curves.

More notably, oxidative effects were evident in the carbonyl domain: normalized intensities at ~1600 cm^{-1} (ν(C=O) in conjugated systems) and ~1700 cm^{-1} (non-conjugated ν(C=O)) increased by up to 2.88-fold and 1.71-fold, respectively, in both treatments (Figure 4b). These spectral changes are consistent with oxidative cleavage of Cα–OH groups, quinone formation, and disruption of interunit linkages such as β–O–4, α–O–4, and 4–O–5, as proposed by Gouveia *et al.* [43]. Concurrent reductions at 1464, 1428, and 1368 cm^{-1} support partial loss of –OCH_3 and aliphatic –OH moieties, indicating demethylation reactions [42]. Visual darkening of lignin samples (data not shown) corroborates the formation of extended π-conjugated systems.

^{1}H NMR analysis (Fig. 4c) revealed marked structural changes across KL, KL-*Pys*, and KL-Tvs, particularly in regions assigned to aromatic protons (Ar–H, 8.6–6.28 ppm), methoxyl groups (–OCH_3, 4.2–3.1 ppm), aromatic hydroxyls (Ar–OH, 2.5–2.25 ppm), aliphatic hydroxyls (Al–OH, 2.25–2.0 ppm), and aliphatic acetates (–O–$COCH_3$, ~2.23 ppm). The signal reduction in Ar–OH and Al–OH was more pronounced in KL-Tvs, indicating a greater oxidative impact. A significant decrease in the –OCH_3 region, particularly in KL-Tvs, suggests extensive demethylation, corroborated by FT-IR analysis. Simultaneously, the increase in –O–$COCH_3$ signals indicates the formation of new Al–OH groups through oxidative cleavage and rearrangement. The marked reductions in Ar–H signals support the occurrence of oxidative coupling reactions (C–C and C–O–C), leading to aromatic ring condensation. Collectively, these transformations point to complex biochemical mechanisms, including direct oxidation of phenolic units, demethylation of –OCH_3 groups, formation of quinones and carbonyl functionalities (–CHO, –CO–), and radical-mediated polymerization.

3.4 Thermal Properties and Stability of Modified Lignin

The thermal analysis (TGA-DTA and DSC) of enzymatically treated KL provides critical insights

into the structural transformations as shown in Figure 4d-e and Table 1, both KL-*Pys* and KL-Tvs exhibited a decrease in the onset ($T_{d,onset}$) and maximum degradation temperatures ($T_{d,max}$), accompanied by a higher total mass loss (~58%) compared to the untreated control (KL, 64.1%).

	$T_{d,\ onset}$ (ºC)	$T_{d,\ máx}$ (ºC)	Mass loss (%)	T_g (ºC)	Tc (ºC)
KL	236	389	64.10	154.95	
KL-Tvs	226	374	57.88	164.78	n.d.
KL-Pys	229	379	57.63	163.65	

Table 1: Thermal parameters of native and enzymatically modified KL samples.

This reduction in thermal stability suggests that enzymatic oxidation, despite leading to polymerization and molecular weight increase as evidenced by GPC (Fig. 3), also introduces thermolabile functional groups such as C=O, COOH, and conjugated systems, as confirmed by FT-IR and ^{1}H-NMR (Fig. 4c). These functionalities weaken the internal cohesion of the lignin matrix, facilitating early-stage degradation. The DTG profiles (Fig. 4e) further substantiate this interpretation, indicating a shift in the degradation of propanoid side chains and aryl-ether bonds to lower temperature ranges. This behavior likely stems from the oxidative cleavage of interunit linkages (β-O-4, β-5), followed by cross-linking and radical coupling reactions, as discussed in the mechanistic analysis (Fig. 2b), resulting in a KL structure that is simultaneously more condensed yet more chemically reactive and thermally sensitive.

DSC analysis (Fig. 4e) revealed an approximately 6.5 % increase in T_g for both KL-*Pys* and KL-Tvs, compared to KL, indicating restricted polymer chain mobility due to oxidative crosslinking. Despite the reduced thermal stability observed by TGA, this elevation in T_g suggests the formation of rigid, high-molecular-weight domains (e.g., β–1, β–β), which counterbalance the presence of low-molecular-weight fragments introduced during oxidation. This dual thermal behavior aligns with FT-IR and ^{1}H-NMR evidence of desmethoxylation, C=O incorporation, and radical-induced condensation. Interestingly, KL-*Pys* exhibited a T_g comparable to KL-Tvs, despite showing milder spectroscopic changes, indicating that the multienzymatic nature of the LADEBIO-*Pys* cocktail (rich in Lac, LiP, and MnP) may promote broader oxidative diversification than a single purified laccase.

Notably, no crystallization temperature (T_c) was detected in any sample. Although enzymatic oxidation modifies lignin's macromolecular structure, it does not induce long-range order or crystallinity, consistent with the amorphous nature of lignin. These thermal features, summarized in Table 1, reinforce those enzymatic treatments, particularly with broad-spectrum oxidative cocktails, enhance lignin's rigidity and thermal behavior without altering its fundamental amorphous character, improving its suitability for FC precursor applications.

3.5 Electrospinning Performance and Mat Morphology

Electrospinning assays demonstrated that oxidative enzymatic modification of KL using the LADEBIO-*Pys* cocktail significantly enhanced its ability to form lignin-based FC precursors. As shown in Figure 5a–b, native KL, either with or without the addition of polyethylene oxide (PEO), resulted in electrospraying, producing non-fibrous, brittle mats composed of aggregated lignin droplets. These outcomes underscore the structural limitations of unmodified KL for direct fiber formation via electrospinning, the first step in the CF production chain. In contrast, KL-*Pys* generated continuous lignin fibers (Fig. 5c), indicating that oxidative modifications conferred by the LADEBIO-*Pys* cocktail effectively adjusted the physicochemical properties of KL, enabling filament formation. The inclusion of PEO (Fig. 5d), used here as a rheological aid rather than a structural matrix, further improved the quality and cohesion of the lignin fiber mats. However, SEM analysis revealed bead formation in KL-*Pys*:PEO samples, indicating the need for further optimization of the lignin-to-PEO ratio to minimize defects and promote uniformity.

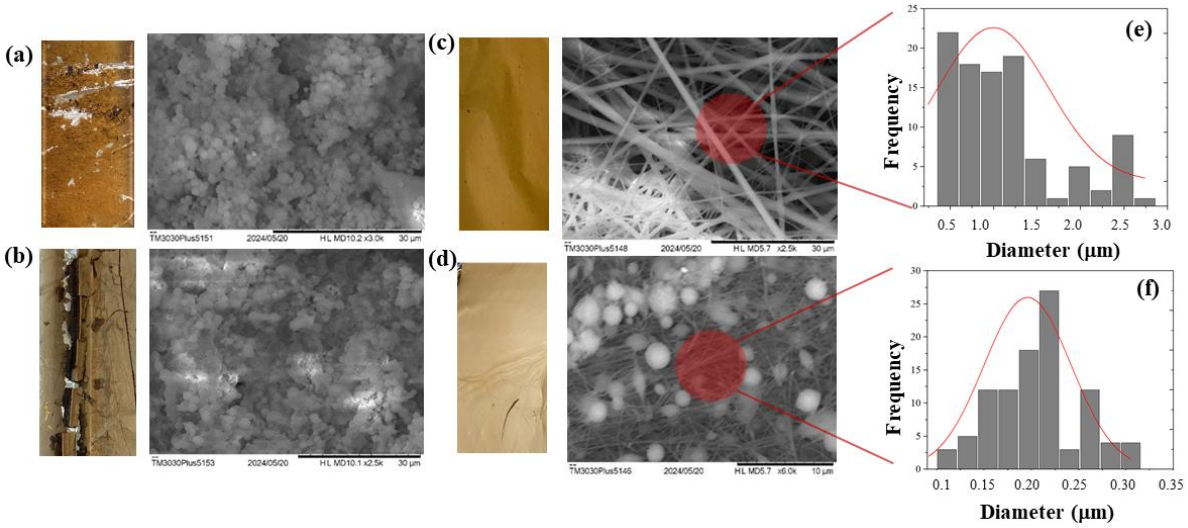

Figure 5: Electrospinning performance of Kraft lignin (KL) samples. (a–b) optical and SEM images of untreated KL with and without PEO (c) 100 % KL-*Pys*; (d) 99% KL-*Pys*:1 % PEO; (e–f) Diameter distribution histograms for KL-Pys and KL-*Pys*:PEO fibers, respectively

Diameter distribution histograms (Fig. 5e–f) confirmed a significant reduction in average fiber diameter from 0.99 µm in KL-*Pys* to 0.20 µm in KL-*Pys*:PEO along with a decrease in the coefficient of variation (6.4% to 4.2%), suggesting improved control over lignin fiber deposition when PEO is used as a processing aid. These findings agree with previous reports that emphasize the importance of polymer additives in modulating solution viscosity and electrospinning behavior, particularly for lignin-rich systems [38].

3.6 Technological Potential of LADEBIO-*Pys*

The oxidative enzymatic cocktail LADEBIO-*Pys*, obtained from *P. sanguineus* via submerged fermentation and concentrated using single TFF, stands out as a low-cost, high-performance biocatalyst for KL modification. With high activities of Lac, LiP, and MnP along with relevant cellulolytic enzymes, this ultrafiltrate enabled effective oxidative depolymerization and repolymerization. Together, the results confirm that the enzymatic oxidative modification of KL promotes the formation of continuous lignin nanofibers. The improvements in spinnability are attributed to structural transformations such as partial depolymerization, oxidative repolymerization, and the introduction of oxygenated functionalities, reflected in increased M_w, higher T_g, and new IR-active groups positioning KL-*Pys* as a promising renewable precursor for FC production.

Notably, the LADEBIO-*Pys* system combines catalytic efficiency with operational simplicity; it circumvents the need for costly and time-consuming downstream purification. Given that downstream processing is often cited as a major economic bottleneck in enzyme production, the ability to obtain a crude yet highly active oxidative cocktail that performs on par with purified enzymes is of considerable industrial relevance. The synergistic interplay among its enzymes enables not only oxidative cleavage but also controlled radical polymerization, yielding structurally reorganized lignin with enhanced thermal behavior and processability. As Perna et al. [38] emphasize, such enzyme synergy is crucial for tailoring polymer architectures, and our results confirm this principle even in non-purified enzyme systems.

Despite its demonstrated potential, oxidative enzymatic cocktails like LADEBIO-*Pys* remain underdeveloped and largely unavailable in the commercial market. This scarcity is especially notable considering increasing interest in lignin valorization and the rise of "Lignin-First" strategies, which prioritize early-stage lignin processing in biorefinery models. The limited availability of such catalytic systems hampers innovation in lignin-derived materials, not only for FC production, but also for high-performance composites, adhesives, supercapacitors, and fine chemicals. Therefore, expanding the development, accessibility, and application of multienzymatic oxidative systems represents a critical

step toward democratizing lignin bioconversion technologies, reducing processing costs, and enabling sustainable pathways for the transformation of lignin into high-value biomaterials.

4 CONCLUSIONS

The findings of this study demonstrate that the oxidative enzymatic cocktail LADEBIO-Pys is a powerful and scalable tool for the structural modification of KL. By promoting efficient polymerization and oxidation, the system significantly enhanced the molecular weight, thermal stability, and chemical reactivity of KL. When combined with PEO, the enzymatically modified lignin yielded electrospun mats with superior morphological and structural integrity. Their nanofibrous architecture and improved uniformity make them strong candidates for FC precursors. Altogether, LADEBIO-*Pys* offers a promising route for lignin valorization within integrated and sustainable biorefinery platforms.

Keywords: Coconut Fiber, Biochar, Composite

ABSTRACT

The coconut (Cocos nucifera) is a tropical fruit of significant economic importance in Brazil, largely consumed in its immature stage, which contains a high volume of coconut water. However, its widespread consumption results in considerable waste generation. The accumulation of this lignocellulosic biomass contributes to the reduction of landfill lifespan, raising environmental concerns. As an abundant and renewable resource, this biomass represents a promising alternative to fossil-derived materials and a potential feedstock for producing biochar via thermochemical processes such as pyrolysis. Biochar exhibits properties like high hydrophobicity, improved compatibility with polymer matrices, and enhanced thermal stability compared to conventional filler materials. In this context, coconut fiber was investigated for composite applications. Its physicochemical characterization revealed an amount of lignin (insoluble Klason lignin) of approximately 32.0% (w/w). Pyrolysis of the fiber yielded a significant amount of biochar, with CHNSO elemental analysis confirming a high carbon content. Subsequent FTIR spectroscopy verified the successful conversion of biomass into biochar, while TGA/DTG analysis demonstrated its thermal stability. Finally, mechanical testing indicated that coconut-derived biochar holds promise as a sustainable filler for polymer composites.

1 INTRODUCTION

The coconut fruit (*Cocos nucifera*) originates from the coconut palm and is cultivated in over 90 countries, with its primary use in the food industry [1]. According to the latest data from Faostat (2021), the global harvested area of coconuts covers approximately 11.8 million hectares, yielding 62.9 million tons. Three countries - Indonesia, Philippines, and India – account for 73.0% of the cultivated area and 74.1% of the total production. Brazil ranks as

the world's fourth-largest coconut producer, with an estimated output of 2.8 million tons from 257,000 hectares, of which around 15% is destined for the green coconut market [2].

The rising consumption of coconut water (100 to 350 million liters per year), fueled by increasing health-conscious behavior among Brazilians, led to a challenge regarding the disposal of coconut shells, which constitute 80 - 85% of the fruit´s total weight. Commonly discarded in open dumps, landfields and unauthorized areas, these residues not only cause visual pollution and unpleasant odors but also promote disease transmition. Under anaerobic conditions, their decomposition generates methane, a potent greenhouse gas. Although organic in nature, coconut waste is highly resistant to degradation and can take more than 8 years to fully decompose [3].

Extracted from the coconut mesocarp, these fibers are primarily composed of cellulose and hemicellulose and contain a high lignin content (20–48%) [4]. To add value and reduce the environmental impact of this waste, various alternatives have been explored for the utilization of coconut fiber. As a lignocellulosic material, it represents a promising renewable and eco-friendly alternative to fossil resources, especially as a raw material for energy production. Pyrolysis is among the most widely adopted processes for converting biomass into biochar, gas, and bio-oil [5,6]. his process involves the thermal decomposition of the three main components—cellulose, hemicellulose, and lignin—in the absence of oxygen [7,8]. Coconut fiber and its pyrolysis product, biochar, are both promising for various applications. The high lignin content in coconut fibers gives them notable hardness and durability compared to other natural fibers [9] , and their incorporation into composite materials has been widely studied [10,11]. The thermal and acoustic properties of coconut fiber-based materials can vary depending on origin and processing, but they have demonstrated thermal conductivity and sound absorption values comparable to those of conventional synthetic insulation materials such as polyurethane boards, glass wool, and rock wool[11].

Biochar, because of its carbon-rich and porous structure, stands out as a multifunctional material[12]. Beyond its role in carbon sequestration—preventing CO_2 release into the atmosphere [13] —biochar also improves soil fertility, water retention, and microbial activity when applied as a soil amendment [14,15] More recently, its potential as a filler in polymer composites has gained attention. Biochar can enhance the mechanical strength, thermal stability, and even flame-retardant properties of composites [16], making it an attractive material for the development of high-performance, sustainable products.

This study aims to contribute to the development of environmentally friendly materials with enhanced performance. The objective was to produce biochar from coconut fiber, characterize the physical-chemical, structural, and thermal properties of both raw and pyrolyzed materials, and prepare composite materials using coconut fiber and biochar as fillers. Finally, the mechanical properties of the resulting composites were evaluated.

2 MATERIAL AND METHODS

The materials used in this study included coconut fiber supplied by Coco Verde Reciclado, epoxy resin (Epoxy Fiber MC 130) and curing agent (Epoxy Fiber 129), both provided by Epoxyfiber LTDA, and absolute ethanol obtained from Isofar LTDA. The coconut fiber was initially ground using a knife mill (model SL-31, Solab), and the resulting fractions were classified using a set of sieves (Figure 1).

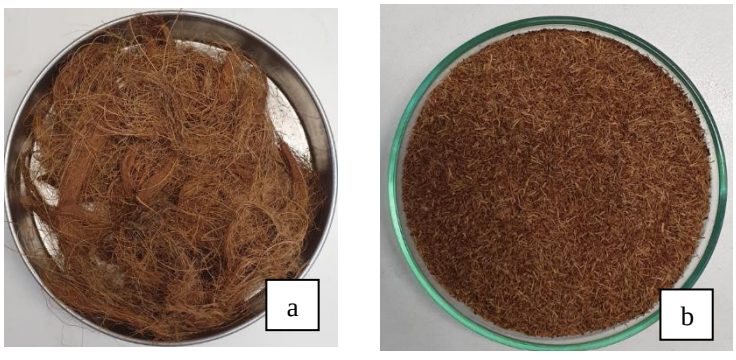

Figure 1: Original coconut fiber (a) and coconut fiber ground (b)

BIOCHAR PRODUCTION

The pyrolysis reaction was performed using coconut fiber to study the reaction conditions. The process was conducted in a bench-scale stainless steel reactor under a continuous nitrogen flow to ensure an inert atmosphere. A total of 5 g of coconut fiber (20 mesh), previously dried to constant weight, was used. The nitrogen (N_2) flow rate was set at 80 mL/min, the reaction temperature was 500 °C, and the total residence time was 30 minutes. Gaseous products were collected during the reaction in Tedlar bags. The mass yields of the condensable fraction and solid residue were determined by direct weighing, while the yield of the gaseous fraction was calculated by difference. The resulting material was referred to as laboratory coconut fiber biochar (LCFB).
A second pyrolysis process was carried out in a semi-pilot stainless steel reactor (6 L capacity) under similar conditions. A total of 1000 g of coconut fiber (60–100 mesh), also dried to constant weight, was used. The nitrogen flow rate was 200 mL/min, the temperature was maintained at 500 °C, and the reaction time was extended to 120 minutes. The condensable fraction and solid residue were quantified by direct weighing of the collection vessels, while the gaseous fraction was obtained by mass balance. The solid product was identified as coconut fiber biochar (CFB) from the pilot unit.

Physical and chemical characterization

Coconut fiber with a particle size of 0.85 mm (20 mesh) was used for physicochemical analysis. Samples were dried at 60 °C until constant weight for the determination of extractives, lignin content, and CHNSO elemental composition.
The analyzed samples included raw coconut fiber and the corresponding biochar. Moisture content, ash content, and pH of both coconut fiber and CFB were determined using standard procedures established by EMBRAPA [17]. The percentages of extractives and lignin in the fiber were also determined. Elemental analysis (CHNSO) was performed using a UNICUBE elemental analyzer (Elementar, Germany).

Structural and thermal analysis

Fourier Transform Infrared Spectroscopy (FTIR) was performed using a PerkinElmer Frontier FT-IR spectrometer. Samples were pelletized with potassium bromide (KBr) at a concentration of 1% (w/w). Spectra were obtained by averaging 32 scans at a resolution of 4 cm^{-1}. Thermogravimetric analysis (TGA) was conducted using a PerkinElmer Pyris One TGA instrument under an inert nitrogen atmosphere, with a flow rate of 25 mL/min and a heating rate of 10 °C/min, from room temperature up to 800 °C.

TENSILE STRENGTH OF COCONUT FIBRE AND COCONUT FIBRE BIOCHAR COMPOSITES

Composite of coir fiber and coconut fiber biochar

To prepare the test specimens, the following materials were used: epoxy resin (Epoxy Fiber MC 130), amine hardener (Epoxy Fiber 129), absolute ethanol, and coconut fiber with a particle size of 0.85 mm (20 mesh). For the composite formulations, coconut fiber biochar (CFB) was used in fine powder form. Both the fiber and biochar materials were dried in an oven at 105 °C prior to use.
The test specimens were prepared using a 100 mm × 100 mm Teflon mold spacer. Fillers (either FC or CFB) were randomly dispersed within the epoxy matrix. The resin-to-filler ratio was set at 60:40 (by weight). For every 10 parts of resin, 1 part of hardener and 1 part of ethanol were added to aid mixing and dispersion, as detailed in Table 1. The curing process involved compression molding: 10 minutes in a cold press, followed by 10 minutes in a hot press, and an additional 10 minutes in a cold press.

.

Materials	Mass (g)	Volume (ml)
Epoxy Resin (Fiber MC 130)	27.0	---
Amine Hardener (Epoxy Fiber 129)	2.7	---
Ethanol	2.7	3.42
FC or CFB	18.0	---

Table 1: Materials and quantities used in the composite

Mechanical properties and standards used

Mechanical testing was conducted using an Instron Electropuls E3000 universal electromechanical testing machine, equipped with a 5 kN Dynacell load cell, an Instron 2630-106 extensometer, and 3 kN-capacity Instron mechanical grips. Thickness measurements were taken using a Digimess digital external micrometer (model 113.054 B). The crosshead speed was set at 2.0 mm/min under ambient conditions of 27 ± 2 °C and 46 ± 5% relative humidity.
The mechanical properties of the epoxy composites containing FC or CFB were evaluated according to ASTM D3039/D3039M standards.

3 RESULTS

Physical and chemical characterization

The physicochemical characteristics of the coconut fiber used in this study are presented in Table 2 and were obtained following rigorous standardized methods. The values obtained slightly differ from those reported in the literature, as such parameters are strongly influenced by the geographic origin and processing conditions of the biomass. Ash content showed the greatest variation, which is likely related to the mineral salts present in the cultivation area. Other parameters exhibited strong agreement with values reported in the literature.

Analisys	Coconuts Fiber	Reference
Moisture (%)	8.79 ± 0,16	6.75 [18]
Ash (%)	1.02 ± 0,01	3.38 [18]
pH	6.06 ± 0,07	6.4[4]
Insoluble lignin[a] (%)	32.07 ± 0,20	20−48[4,19]
Extractives (%)	2.66 ± 0.21	-
C (%)	47.42 ± 0,07	47.6 [20]
H (%)	5.92 ± 0,01	5.7 [20]
N (%)	0.28 ± 0.01	0.2 [20]
S (%)	0.12 0.01	-

a. Ash and protein free; (-): not observed.

Table 2: Physical and chemical characterization of coconut fiber

Biochar production

Pyrolysis reactions were conducted both at the laboratory scale to achieve the best reaction conditions and at the pilot scale to produce sufficient quantities for composite fabrication. Following pyrolysis, three product fractions were obtained: condensable liquids, volatile gases, and solid residue (biochar). Table 3 presents the yields of biochar produced from coconut fiber under identical temperature conditions at the laboratory scale (LCFB) and pilot scale (CFB). It was observed that the yield of solid residue from the laboratory-scale pyrolysis was slightly higher than that obtained from the pilot plant (CFB). This difference is attributed to the higher nitrogen flow rate used in the pilot plant, which favored the formation of volatile products.

Sample	Mass (g)	Condensable (%)	Volatile (%)	Solid residue (%)
LCFB	5	48,2	20,4	31,4
CFB	1000	40,1	36,5	23,4

Table 3: Results of pyrolysis reactions of coconut fiber

Structural and thermal analysis

Figure 6 shows the ATR-FTIR spectra of coconut fiber (CF) samples and biochar obtained from coconut fiber (CFB). In the coconut fiber spectrum, the broad band observed between 3600 and 3200 cm^{-1} corresponds to O–H stretching vibrations associated with the hydroxyl groups present in the biomass macromolecules, namely cellulose, hemicellulose, and lignin. The presence of lignin is confirmed by characteristic signals attributed to aromatic rings (5). The band near 2900 cm^{-1} corresponds to aliphatic C–H stretching linked to the aromatic ring [21]. The intense band at 1747 cm^{-1} (3) indicates the presence of ketone, carbonyl, and ester functional groups [4]. This is followed by peaks at 1607 cm^{-1} and 1506 cm^{-1} (4 and 5), which are assigned to the C=O conjugated and C=C stretching in the aromatic rings of lignin [22]. The peak at 1467 cm^{-1} (6) is attributed to C–H bending vibrations. The peak at 1321 cm^{-1} (7) corresponds to C–H deformation of methyl groups and O–H of phenolic structures [4].

The peak at 1238 cm^{-1} (8) is related to C–C, C–O, and C=O stretching in the guaiacyl units of lignin [22]. Peaks observed between 1160 and 990 cm^{-1} (9) are attributed to β-glycosidic bonds present in cellulose.

In the CFB spectra, a reduction in several characteristic peaks of coconut fiber is observed, notably the absorption band between 1400 and 907 cm^{-1} (10). Furthermore, the peak attributed to the β-glycosidic bond (peak 9) is no longer detected, indicating that pyrolysis effectively decomposed cellulose components.

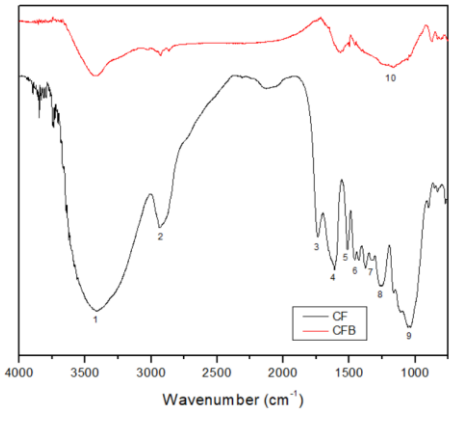

Figure 2: FTIR results for coconut fiber (CF) and coconut fiber biochar (CFB).

The thermal stability of coconut fiber and coconut fiber biochar was evaluated by thermogravimetric analysis (Figure 3). The decomposition of coconut fiber components occurs within characteristic temperature ranges: hemicellulose, because of its amorphous structure, decomposes between 200–260 °C; cellulose between 240–360 °C; and lignin between 280–360 °C [23].

In the thermogram of coconut fiber, two major events were observed. The first, occurring below 100 °C, corresponds to moisture loss. The second event comprises two degradation stages. The first stage, from 203 °C to 315 °C, is associated with the decomposition of hemicellulose and part of the cellulose. The second stage, from 315 °C to 492 °C, corresponds to the degradation of lignin and the remaining cellulose. The maximum rate of mass loss was observed at 301 °C (T_{onset}). Therefore, significant lignin degradation and the formation of biochar only occur above 492 °C, which is the temperature range of interest for this study.

For the coconut fiber biochar, the thermogram indicated enhanced thermal stability, consistent with the thermal behavior observed for lignin-derived pyrolysis products [24]. The DTG curve for the biochar showed two main events. The first was a minor peak associated with residual moisture loss. The second, a single-stage degradation event, occurred between 337 °C and 640 °C, with a maximum degradation rate (T_{onset}) at 446 °C and a peak degradation temperature at 547 °C. These findings are in agreement with values reported in the literature and are attributed to the carbonization of biomass and the formation of stable carbon structures [25].

Tensile strength of coconut fibre and coconut fibre biochar composites

The tensile strength and tensile modulus of epoxy resin-based composites were evaluated to investigate the effect of incorporating coconut fiber and biochar. The addition of biochar significantly influenced the mechanical performance of the composites. Acting as a reinforcing filler, biochar enhanced the load-bearing capacity of the material, likely because of its porous structure and high surface area, which improve interfacial adhesion within the polymer matrix [26].

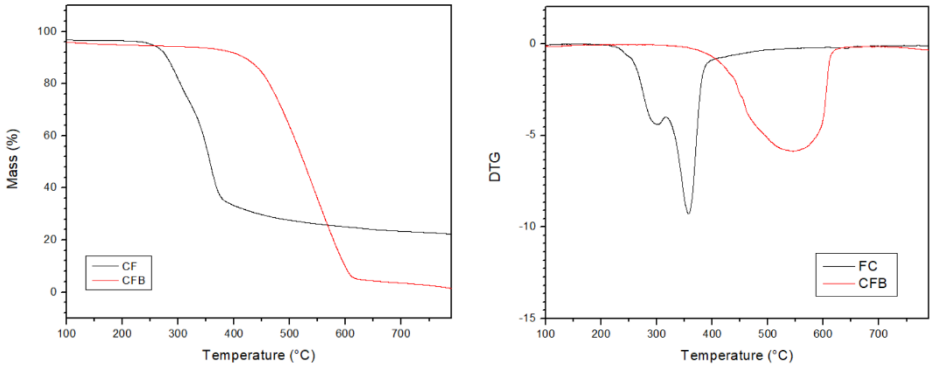

Figure 3: TGA and DTG results for coconut fiber (CF) and coconut fiber biochar (CFB)

In this study, the final composite plates produced with coconut fiber or coconut fiber biochar as fillers and epoxy resin as the matrix exhibited homogeneous structure, smooth surfaces, and moderate gloss (Figure 4). No bubbles or surface roughness were observed. The composite reinforced with coconut fiber showed a tensile modulus of 3.63 GPa, whereas the composite containing biochar (CFB) exhibited a higher modulus of 4.48 GPa. This indicates that incorporating biochar significantly enhances the stiffness of the composite, likely due to improved filler–matrix interfacial interactions. Table 4 presents the tensile test data for both composites, and the corresponding results are graphically represented in Figure 5.

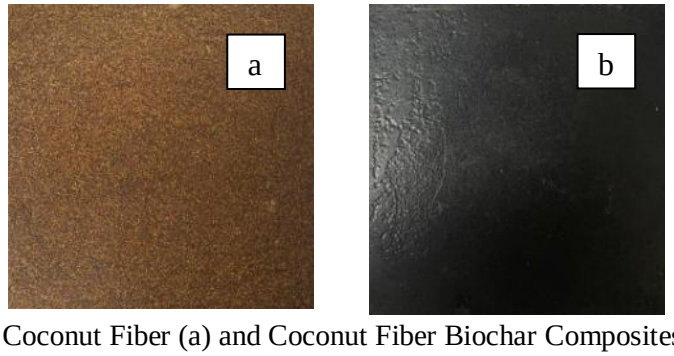

Figure 4: Coconut Fiber (a) and Coconut Fiber Biochar Composites (b)

Sample	Strain (MPa)	Stress (%)	Tensile modulus (GPa)
FC	26.59 ± 0,99	0.79 ± 0.05	3.63 ± 0.18
CFB	20.42 ± 2.21	0.45 ± 0.02	4.48 ± 0.53

4 CONCLUSIONS

Coconut fiber is a natural lignocellulosic material with a high lignin content compared to other plant-based fibers, which makes it a promising candidate for applications across various industrial sectors. This study evaluated the use of biochar derived from coconut fiber as a reinforcing filler in epoxy resin composites.

FTIR and TGA analyses confirmed that the pyrolysis conditions were favorable for biochar production, evidencing structural and thermal transformations. Mechanical testing demonstrated the viability and effectiveness of incorporating biochar, with a modest but significant increase in tensile modulus—from 3.6 GPa for the coconut fiber composite to 4.3 GPa for the biochar-reinforced composite.

These findings suggest that both coconut fiber and its biochar can serve as sustainable, environmentally friendly alternatives to conventional fillers in composite materials.

ACKNOWLEDGEMENTS

The authors acknowledge to Coco Verde Reciclado LTDA for donating the coconut fibre material used and to the IMA's Lapin laboratory for the FTIR analyses.

ABSTRACT

Polyamides (PA, “nylon”) is a class of thermoplastic polymers characterized by good heat/chemical resistance, mechanical properties, and processability, leading to widespread use in various automotive components. The two most common varieties, PA6 and PA66, are petroleum-based and carry a relatively large carbon footprint. Thus, bio-based alternatives such as PA11 have been introduced in recent decades. However, these polymers tend to have longer alkyl chains and exhibit lower mechanical properties than their traditional counterparts. In this work, glycol-modified lignin (GL) biomass is added to PA11 to create a blended matrix for short-carbon fiber composites in order to improve performance while maintaining a high biomass content. Characterization of the structure and properties of the resulting blends shows that PA11 and GL are highly compatible with uniform dispersion, which is essential for improving mechanical properties without sacrificing processability. Furthermore, the tensile modulus and strength of the short-fiber composites containing lignin exceeds that expected from the rule of mixtures, reaching performance comparable to super engineering plastic compounds like PEEK/GF30. The applicability of these biomass composites for more sustainable automotive components is discussed.

1 INTRODUCTION

The growing demand for sustainable materials has accelerated the development of biomass-based composites, particularly those using bio-derived plastics and additives. These composites offer a compelling alternative to conventional petroleum-based materials, driven by the need for environmentally friendly options that also deliver high performance in demanding applications. Recent advances have focused on incorporating bio-derived thermoplastics, such as polylactic acid (PLA), polyhydroxyalkanoates (PHA), and bio-based polyamides (PA11, PA1010, etc), into composite formulations [1-7]. These bio-based matrices not only address environmental concerns but also provide high mechanical properties, making them viable candidates for industries ranging from automotive to electronics and aerospace.

However, despite these advancements, there remain several challenges in bringing them into high-performance applications. Bio-derived plastics often exhibit limitations in processing, thermal stability, and mechanical properties compared to their petroleum-based counterparts. Issues like brittleness, low-temperature performance, and moisture sensitivity can hinder their widespread adoption, especially in demanding environments where durability and reliability are essential [5,6]. Furthermore, achieving uniformity and consistency in the bio-plastic matrix during composite fabrication, while maintaining environmental sustainability, presents significant technical challenges. In the specific case of PA11, its long alkyl segment and relatively low hydrogen bond (HB) density compared to conventional PA6 gives it low modulus (~1.5 GPa) and strength (~40 MPa). Thus, simply adding reinforcing fibers will not make

it competitive with conventional engineering plastic composites. Overcoming these barriers requires innovative approaches to both material design and manufacturing techniques.

In this context, lignin, a natural polymer obtained as a byproduct of the pulp and paper industry, has gained attention as a promising additive in biomass-based composites [8]. Lignin's complex aromatic structure and high antioxidant properties make it a suitable candidate for enhancing the performance of petroleum- and bio-derived polymers alike [9]. Recent studies have shown that lignin can significantly improve the oxidative stability of polyolefins [10] and PA6 [11], protecting the material from degradation under UV exposure and high temperatures. Additionally, lignin can enhance the mechanical properties of composites by acting as a reinforcing agent [10]. However, the main issue impeding widespread use is the typically poor compatibility with many polymers used in composites. The phenolic and hydroxyl groups in lignin have the potential to interact with functional groups on the host polymer and thus increase tensile strength and modulus. Various approaches to improve lignin's dispersibility such as alkyl, acetyl, and hydroxyl modifications have been met with varying degrees of success [12,13].

This work reports the fabrication of PA11/carbon fiber (CF) composites using a PEG-grafted glycol lignin (GL) in a scalable melt-mixing process. Synergistic interactions between the three constitutents lead to unprecedented improvements in tensile modulus and strength, rivalling conventional super engineering plastics like PPS and PEEK. Material characterization results and implications for future work are discussed.

2 EXPERIMENTS

2.1 Materials and fabrication

The polymer used in this study was an unreinforced, standard-grade PA11 (BML OTLD, Arkema). The glycol lignin (GL) was produced by acid-catalyzed PEG solvolysis of softwood biomass yield lignin derivatives grafted with about 26 wt% PEG400, as described elsewhere [14]. Chopped carbon fibers (PYROFIL™ TR06NLB5K) having length of roughly 6 mm and diameter of about 7 μm were purchased from Mitsubishi Chemical.

PA11 and GL were both dried at 90 °C for 24 hr before blending in a twin-screw extruder (S1KRC, Kurimoto) at 240-250 °C. Blends containing different amounts of GL and CF ranging from 0-30 wt% were then injection molded (Mini JET II, Thermo Scientific) into ISO 527-2 dumbbell specimens at cylinder and mold temperatures of 230 °C and 80 °C, respectively. No other heat treatments were applied before characterization.

2.2 Characterization

Mechanical behavior was evaluated by tensile testing according to ASTM D638 using an electromechanical testing machine (EZ-LX, Shimadzu) equipped with a 5kN load cell and video extensometer, at a crosshead speed of 5 mm/min. FTIR spectra were collected at room temperature over the range 500-4000 cm^{-1} in ATR mode (IR Affinity, Shimadzu).

Differential scanning calorimetry (DSC7020, Hitachi Hi Tech) was performed over the range 20-250 °C at a heating/cooling rate of 10 °C/min, using 2-3 mg of sample. The crystallinity (X_c) was approximated by the equation:

$$X_c = \frac{\Delta H_m}{(1-f)\Delta H_m^0} \quad (1)$$

where f is the mass fraction of filler (e.g., GL), and ΔH_m and ΔH_m^0 are the melting enthalpies of the specimen (taken from the first DSC scan) and a perfect crystal (taken as 220 J/g [15]), respectively.

3 RESULTS

3.1 Composite fabrication and structure

Melt-mixing of the blends and composites was successfully performed in a twin-screw extruder, without significant changes in processibility even up to 20 wt% GL loading, although an increase was noticed for 30 wt% GL loading. Figure 1 depicts the fabrication process along with a schematic of the expected material structure. The abundant hydroxyl groups on lignin, supplemented with grafted PEG chains allows for polar and HB interactions between GL and PA11. Additionally, the aromatic backbone of lignin should exhibit high affinity for the surface of carbon fibers.

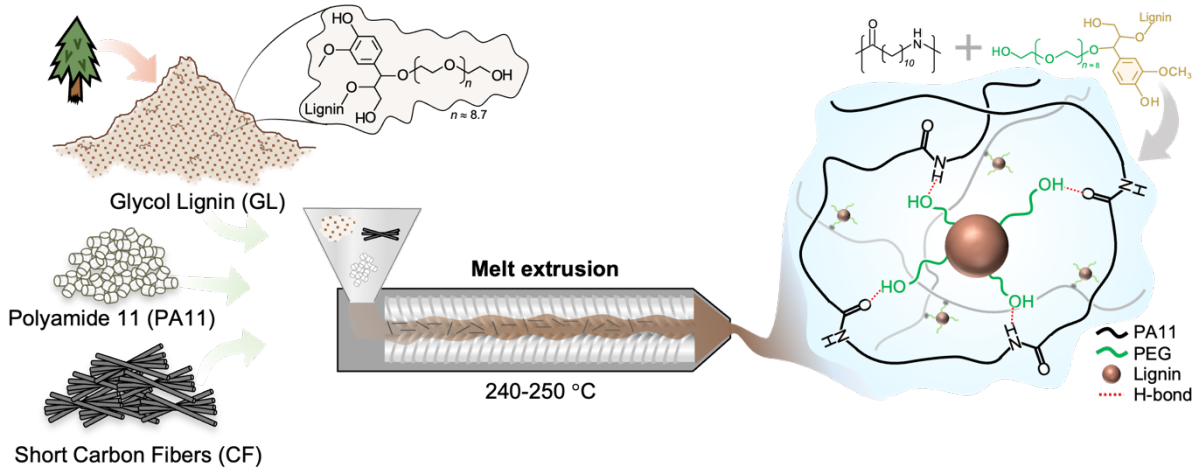

Figure 1: Fabrication of short-carbon fiber composites using PA11/GL blends via melt-mixing, with the proposed polymer/lignin interactions.

FTIR did not show significant presence of GL, despite the substantial loading (0-30 wt), but slight shifts in the carbonyl region of amide II (1640 cm^{-1}) indicated HB interaction. FTIR can be useful for studying HB interactions in polymers, but the changes tend to be small when comparing different forms of H-bonds, rather than the increase or decrease in their number. Recent work has indicated that GL may form H-bonds with polyamide in a disordered configuration, which does not appear the same as so-called “free” carbonyls [11]. The melting temperatures and enthalpies shifted noticeably with increasing GL content (Figure 2), which can be attributed to a change in the crystal phase composition due to the presence of lignin [11]. In addition, the crystallinity increased by several percent while the crystallization temperature decreased by several degrees, which indicates that lignin has a retardation effect that promotes slower crystal growth (Table 1).

Sample	T_m (°C)	T_c (°C)	X_c (%)
PA11	189.7	159.5	28.3
PA11-GL10	187.9	157.8	28.5
PA11-GL20	187.7	154.5	29.5
PA11-GL30	187.4	153.7	30.1

Table 1: Thermal properties of PA11/GL blends.

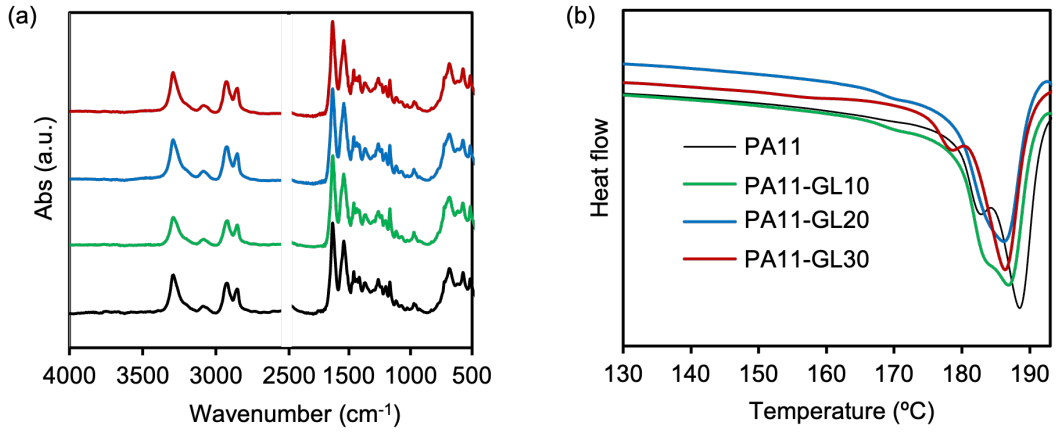

Figure 2: (a) FTIR spectra and (b) DSC thermograms of PA11/GL blends.

3.2 Tensile properties

The addition of GL alone did not significantly increase the tensile strength or modulus of PA11 until 30 wt% loading, as seen in Figure 3(a,b). The failure strain was for 10 wt% GL blends did not change drastically, and although higher GL content resulted in lower failure strains compared to neat PA11, over 100% was still achieved at 30 wt% GL.

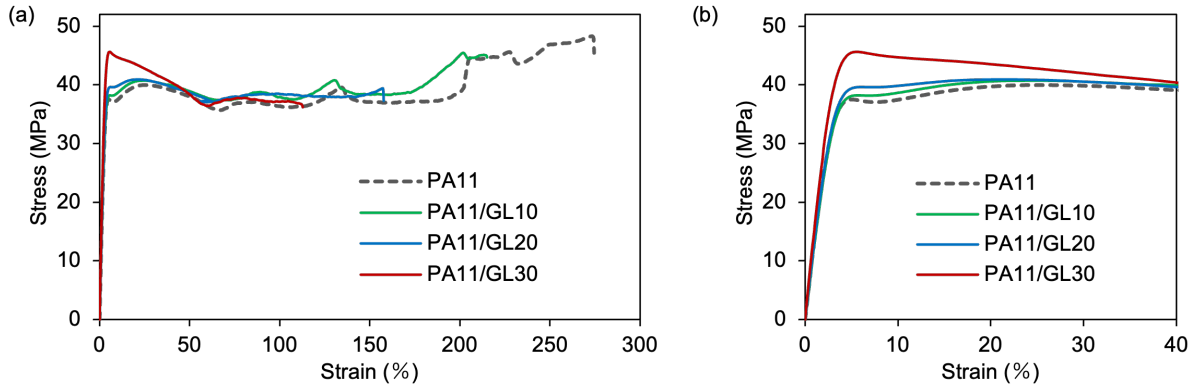

Figure 3: Stress-strain curves for PA11/GL blends for the (a) full and (b) elastic strain regions. (c) Stress-strain curves for PA11/CF composites. Stress-strain curves of biomass composites fixed at (d) 10 wt% CF and (e) 20 wt% CF to highlight the effect of lignin.

Figure 4(a) shows typical tensile behavior of short-fiber composites was observed for PA11/CF. Despite the minimal reinforcing effect of GL on PA11, a drastic improvement in reinforcing efficiency was observed for the biomass-matrix short fiber composites. This is demonstrated in Figure 4(b) by fixing CF at 10 wt% whereby the strength increases by 10% and 40% for GL loadings of 10 wt% and 20 wt%, respectively. The same trend is observed for 20 wt% CF composites in Figure 4(c). Such a drastic synergistic reinforcing effect has never been reported in the literature before, although a similar (but less drastic) effect was reported for PP/GL composites [9]. This suggests that PEG-grafted glycol lignin possesses a unique ability to aid in stress transfer between fibers. The full set of data for all composites in the study is summarized in Figure 4(d,e), with comparison to typical values of PEEK-GL30 for reference. In particular, an exceptionally high modulus of 16 GPa was achieved for the GL30-CF30 composite (70% biomass by weight), which is (to the authors' knowledge) the highest reported for a high-biomass-content composite.

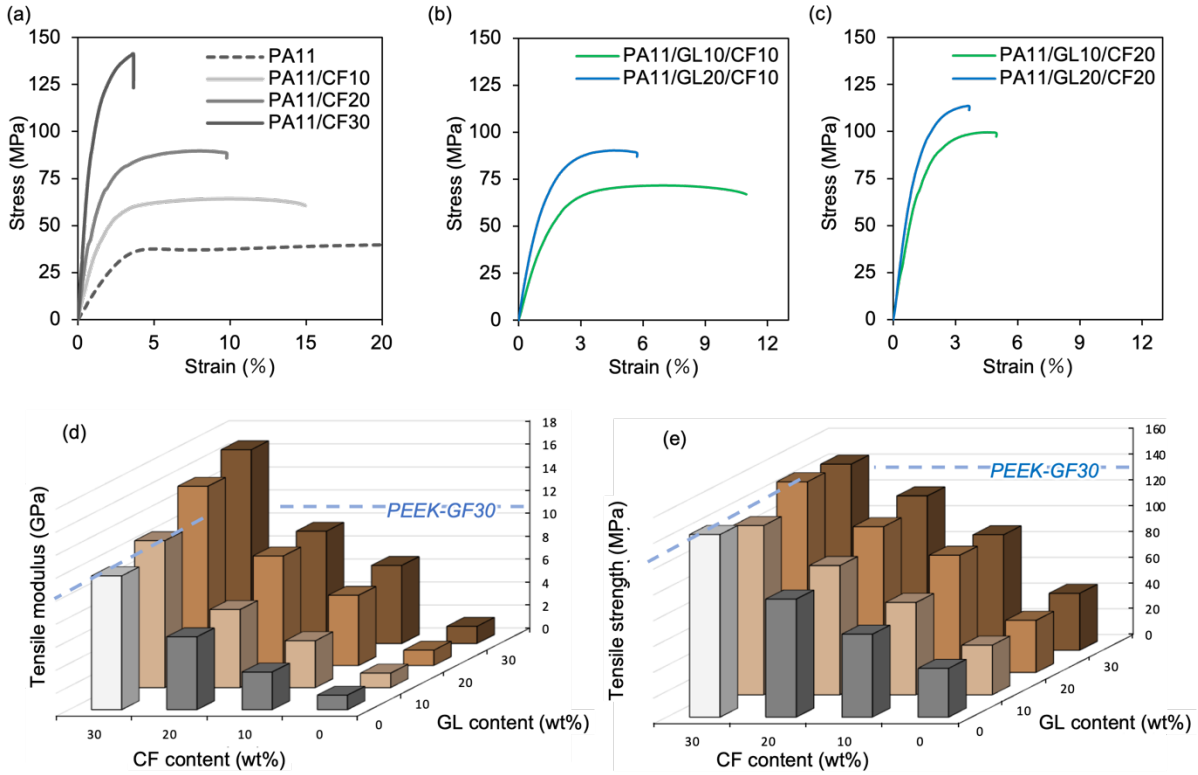

Figure 4: (a) Stress-strain curves for PA11/CF composites. Stress-strain curves of biomass composites fixed at (b) 10 wt% CF and (c) 20 wt% CF to highlight the effect of lignin. Summarized results for (d) tensile modulus and (e) tensile strength for all composites in this study.

9 CONCLUSIONS

In this study, all-biomass matrix materials of PA11 and PEG-grafted glycol lignin were prepared by scalable melt-mixing, then combined with short carbon fibers to create biomass composites. Polar and HB interactions between the GL and PA11 did not significantly increase the tensile properties of the polyamide itself, but the blend exhibited a synergistic reinforcing effect that drastically improved the tensile properties of the short fiber composites. The tensile modulus for some blends reached levels similar to PEEK-GF30. More study is needed to understand the detailed mechanisms of how lignin influences crystallization and deformation behavior of PAs, but this work demonstrates that PA11/GL composites have potential for high-performance applications.

ACKNOWLEDGEMENTS

This work was supported by MAFF (Ministry of Agriculture, Forestry and Fisheries), Japan commissioned project “Development of Glycol Lignin–Based High-Value-Added Materials” (Grant Number J008722). The authors also thank T. Akagawa (Hosei University) and M. Kamon (NIMS) for assistance with sample preparation with mechanical testing.

Airframe Design, Analysis, and Certification Process

Top-Level Technical and Programmatic Issues:

- *Overall scope (non-recurring cost/span, strategic teaming/sub-contracting, recurring-cost, anticipated production quantity/span, mods/sustainment/lifecycle cost-span, etc) is defined by similar legacy programs and current customer requirements.*
  - *New programs must generally stay within the historical norms;*
  - *Airframe structure is a relatively minor part of the overall program scope, and generally targeted to be low-risk and not the biggest cost- or schedule-driver (though it sometimes becomes so).*
- *Different decision-making in various phases of air vehicle lifecycle:*
  - *Pre-design*
  - *Lay-out*
  - *Drawing-release*
  - *Full-Scale-Testing*
  - *Final Strength Summary & Operating Restrictions*
  - *Factory MRB support*
  - *Field support*
  - *Modification, repair, sustainment, life-extension*

2024: Digital tools can potentially automate portions of every phase and reduce span

Airframe Design, Analysis, and Certification Process

Top-Level Technical and Programmatic Issues, Roles and Responsibilities:

- *Designers determine form/fit/function and influence manufacturing, assembly, and make/buy sourcing decisions.*
- *Stress Analysts assure static and fatigue structural integrity, organize/lead structural certification process, and influence weight efficiency.*
- *Materials and Process, and Manufacturing Engineers ensure that raw materials and manufacturing/assembly processes are reliable/repeatable and in control.*
- *Integrated Product Teams work together to make optimum collective decisions regarding airframe weight/cost/span;*
  - *Many non-structural constraints drive airframe design decisions, including machining and assembly limitations, fuel/environmental sealing, systems installation, maintenance access, etc.*
  - *Generally, IPT's choose whichever material or manufacturing process works best for each individual part, or as a system.*

Form/fit/function and applied loads generally determine material choice (no bias for or against particular materials or processes)

Airframe Design, Analysis, and Certification Process

Building-Block Certification Logic, Composite Stress Methods:

- **Buckling Ratios-To-Requirements (not failure):**
  - **Linear Eigenvalues**
  - **Snap-Thru (nonlinear)**
- **Typical composite mid-bay MS's:**
  - **FHT/FHC for durability/repairability**
  - **Damage Tolerance MS only if fracture-critical (civil different, see later chart)**
- **Typical land MS's:**
  - **Bearing/by-pass**
  - **Bolt strength**
  - **Pull-thru**
  - **Interlaminar shear (ILS) - beam-shear, pressure, and/or heel-toe induced stress**
- **Edge-of-Part Notch MS's:**
  - **UNT/UNC at characteristic distance**
- **Hat (or similar features, like free flange) MS's:**
  - **Crippling**
  - **ILT/ILS in corners**

Main objective of point stress analysis is to predict the *absence of failure*; not failure.

Thus, accuracy can be traded against simplicity/cost/span.

Examples of conservative deterministic rules which allow reduced cost/span:

- *Top-of-scatter loads, lower-bound strengths;*
- *1.50*DLL static factor of safety;*
- *Assume presence of damage;*
- *Design for 2+ lifetimes;*
- *No detrimental deformation at 1.15*DLL;*
- *No load redistribution;*
- *No damage growth (in composites);*
- *Fibers in (0/45/90) & stacking limited to 3 plies of same orientation*
- *Etc.*

©2025 Lockheed Martin Corporation. All Rights Reserved

Airframe Design, Analysis, and Certification Process

Building-Block Certification Logic, Composite Allowables:

Why Notched-Strength Design Allowables Are Prevalent:

- *Enables much-reduced development cost/span relative to more-complex alternatives*
- *Accounts for typical manufacturing and design realities*
  - *Bag surfaces*
  - *Ply drops*
  - *Slight in-plane and out-of-plane fiber waviness*
  - *Fiber orientation deviation from design*
  - *Small inclusions / resin rich areas*
- *Allows for bolted repair*
- *Covers nuisance durability level damage criteria (“6 ft-lbs”)*
- *Covers fatigue endurance (for fixed-wing airframe structures with modest ILS/ILT stresses)*
- *Usually covers DoD clearly-visible damage criteria*
  - *HW FHC or OHC < (1.5/1.15) x CSAI*
- *Caution – moving away from a notched-strain-controlled design would bring many of these items back into play*

Main objective of point stress analysis is to predict the *absence of failure*; not failure.

Ramifications for Air System Risk vs. Efficiency

Overall Air System Priorities vs Airframe Cost/Performance:

Global Lessons Learned

- **Large programs must aggressively manage risk**
  - *Overall risk divided into small increments (IPTs)*
  - *Long term benefits of advanced technology may conflict with near term program requirements*
  - *Difficult to capture costs of advanced technology developments in estimation process for new programs*
  - *As cost estimates are refined, design decisions often favor mature technology*
  - *System level cost considerations may over-rule local performance benefits*
- **Recognize that risk management – not technology insertion – is the paramount issue on large programs**
- **Risk adjusted return on investment has to be >> 1**
- **Technology Transition must address:**
  - *Production-friendly methodology gap*
  - *TRL gap*

©2025 Lockheed Martin Corporation. All Rights Reserved

Ramifications for Air System Risk vs. Efficiency

Composites vs. Metals for Various Airframe Components:

Wings

- *Most clean-sheet designs now sport composite wing skins (big, contoured, tailored stiffness).*
- *Spars are also often composite – due to thermal-mismatch for long wings – except for tactical fixed wing aircraft with a ballistic survivability requirement (need metal flanges that yield under hydraulic-ram loading).*
- *Ribs, shear clips, etc often still metal due to small size, min-gauge, and complex shapes.*

Fuselages

- *Design constraints vary widely by application and size … "loads tell you what mat'l part wants to be made from".*
- *Skins most likely to be composite (min-gauge and post-buckling inhibit composite usage).*
- *Frames rarely composite, due to min-gauge and complex shapes (braided RFI 787 frames a notable exception).*
- *Keel beams and fighter carry-thru bkhds almost always metal (most complicated shapes, min-gauge, highly post-buckled)*

Empennages

- *Almost all-composite for weight/CG/dynamic reasons.*
- *H/C control surfaces have given composites bad reputation for poor reliability.*

©2025 Lockheed Martin Corporation. All Rights Reserved

Certification/Qualification of New Materials

- **For successful transition of structural materials**
  - *Must have a good set of generic notched laminate allowables ready when program requests the material*
  - *Recently projects are satisfying this need, and thus new material transition story is getting better*
  - *We don't need new cert/qual guidance*

2024: please stop all the "virtual allowables" nonsense!

- **LM Aero opinion - all ~~multi-functional~~ materials in use today only have non-structural applications**

2024: multi-functional = nano

  - *Since non-structural, then cert/qual not truly an issue*
  - *Thus, no need for special cert/qual plans for these materials*
- **Would we like to speed up the qualification process for new materials?**
  - *Yes, however understand that in the big picture, the material qualification funding is small relative to the large-scale certification tests performed on an SDD aircraft*

2024: still can't beat IM7/977-3 and/or IM7/5250-4 tape… if we ever got better mat'ls, qualifying them and generating design values is no big deal.

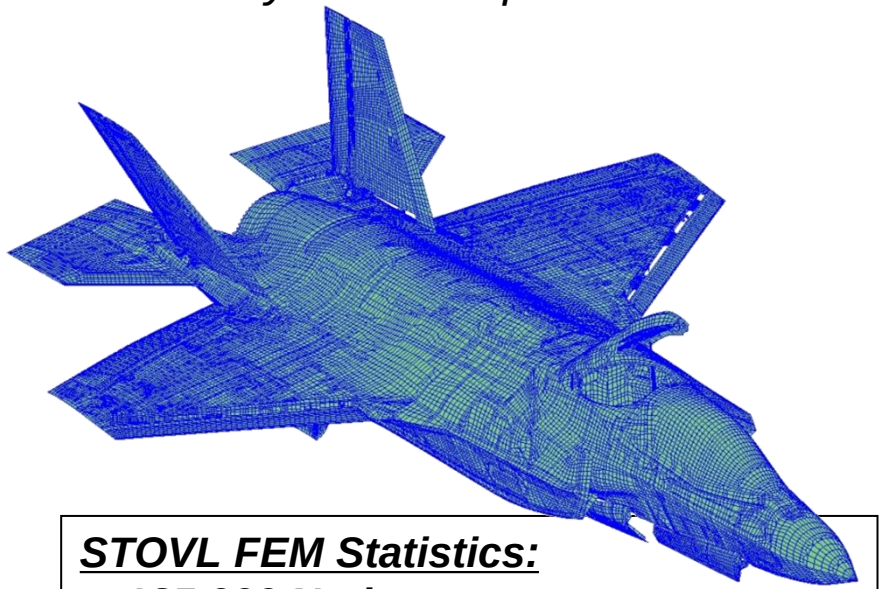
Airframe Design, Analysis, and Certification Process

Building-Block Certification Logic, Internal Loads-Development:



- *Performed by FEM specialists at Air-Vehicle-level and IPT stress analysts at assembly- and component-levels.*

•STOVL aircraft structure is modeled and solved in numerous configurations based on parameters specified for any given load condition:

- **Positions of Control Surfaces**
- **Positions of Doors**
- **Positions of Landing Gear**
- **Engine Types**
- **Weapon Adapter Types**
- **Access Panel Stiffness Assumptions**

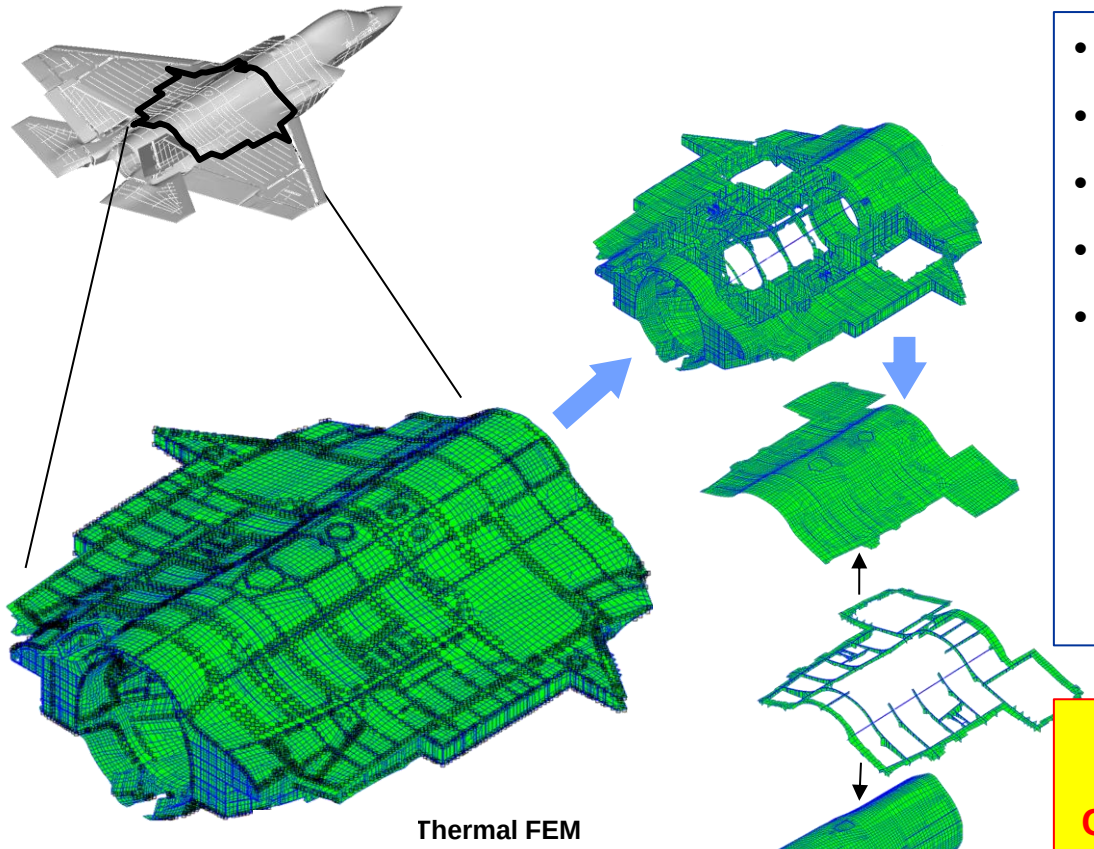
Cost/span = approximately 18 man-years over 9 months (industry average)

2024: opportunities for simplification/automation

STOVL FEM Statistics:

- **185,000 Nodes**
- **260,000 Elements**
- **1,100,000 Degrees of Freedom**
- **26,194 Load Conditions**
- **2300 Configurations of Control Surface, Door and Gear Positions.**

Element Topology:



- **Skins, floors and webs modeled with SHELL elements.**
- **Stiffeners modeled with shell elements if the cross section is wide compared to its length and the resulting shell aspect ratios are acceptable, otherwise BEAM elements are used.**
- **3D (SOLID) elements are used for core applications and other areas where volume is significant as compared to surface area.**

©2025 Lockheed Martin Corporation. All Rights Reserved

Airframe Design, Analysis, and Certification Process

Building-Block Certification Logic, Internal Loads-Development:

- *IPT stress analysts build/run multiple fine-grid FEMs (fgFEMs) at assembly- and component-levels.*

Hybrid metal-composite thermal loads captured by springing skins off sub-structure

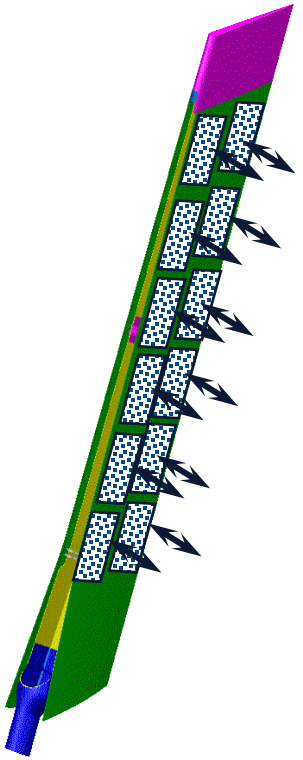
- **Refined meshes yield FEMs with as many/more DOF than AVFEM**
- **Linear buckling always checked**
- **Non-linear response often also done (fuel pressure, snap-thru, etc)**
- **Fastener locations modeled with beam elements**
- **Element groups used to define mid-bays, lands, stiffeners, etc**
  - **Composite point stress analyses batch-post-processed for mid-bays, notch features, and each bolt location (not done w/in FEM) – very efficient**
  - **Metallic point stress analyses done in semi-automated manner using spreadsheets**

Generally (not for specific structure shown)

Cost/span (stress ONLY) = approximately 1-3 man-months/part over 12 months

Span = 70% FEM-building, 30% batch-generation of MS's & report-writing

©2025 Lockheed Martin Corporation. All Rights Reserved



Airframe Design, Analysis, and Certification Process

Building-Block Certification Logic, Composite Stress Methods:

Element / Sub-Component / Component-Level Testing

Required for Strength-Prediction Methods Verification/Validation

- *Component-Level Example: Rudder Static and Fatigue Tests*
- *Overall:*
  - *Empirical verification/validation required for all failure criteria, so high-fidelity (e.g., expensive to develop/install/train/use in both cost and span) failure models don't start saving test-costs until at least their second use … but many features are design-specific.*
  - *Best cost/span solution is thus to use simple failure criteria with empirical correction factors.*
  - *These BBT levels also used to demonstrate certification requirements such as "no delamination growth", residual strength-after-damage, fail-safety, etc.*

2024: typically, this testing does not impact development span due to time req'd to build full scale test articles

©2025 Lockheed Martin Corporation. All Rights Reserved

Airframe Design, Analysis, and Certification Process

Composite and Metallic Damage Tolerance:

Very Cursory Overview (much has been done/written on this)

- FAA Part 25.571 and JSSG-2006 section 3.12 differ in certain details.
  - Terminology – fatigue vs durability
  - Load levels – 1.50*DLL vs Pxx*DLL (Pxx usually 1.05-1.15)
- General requirement to maintain adequate residual strength in the presence of defects and damage until detected is similar for civil and military, and independent of material.
- Means of *compliance* with this requirement differs significantly between metals and composites.
  - Physics of damage initiation and growth is very different in metals vs composites.
  - Metals exhibit self-similar fatigue crack initiation/growth from intrinsic flaws, but static strength is still adequate (*thus DT compliance demonstrated via FCGR fatigue life prediction and critical crack-length determination*).
  - Composites exhibit diffuse matrix cracking/delamination, and significant/sudden loss of static strength due to in-service delamination damage, but little/no loss of fatigue life (*thus DT compliance demonstrated via residual-static-strength-after-damage strain limit*).

Damage Tolerance requirements are material-independent.
Means of compliance with requirements are not.

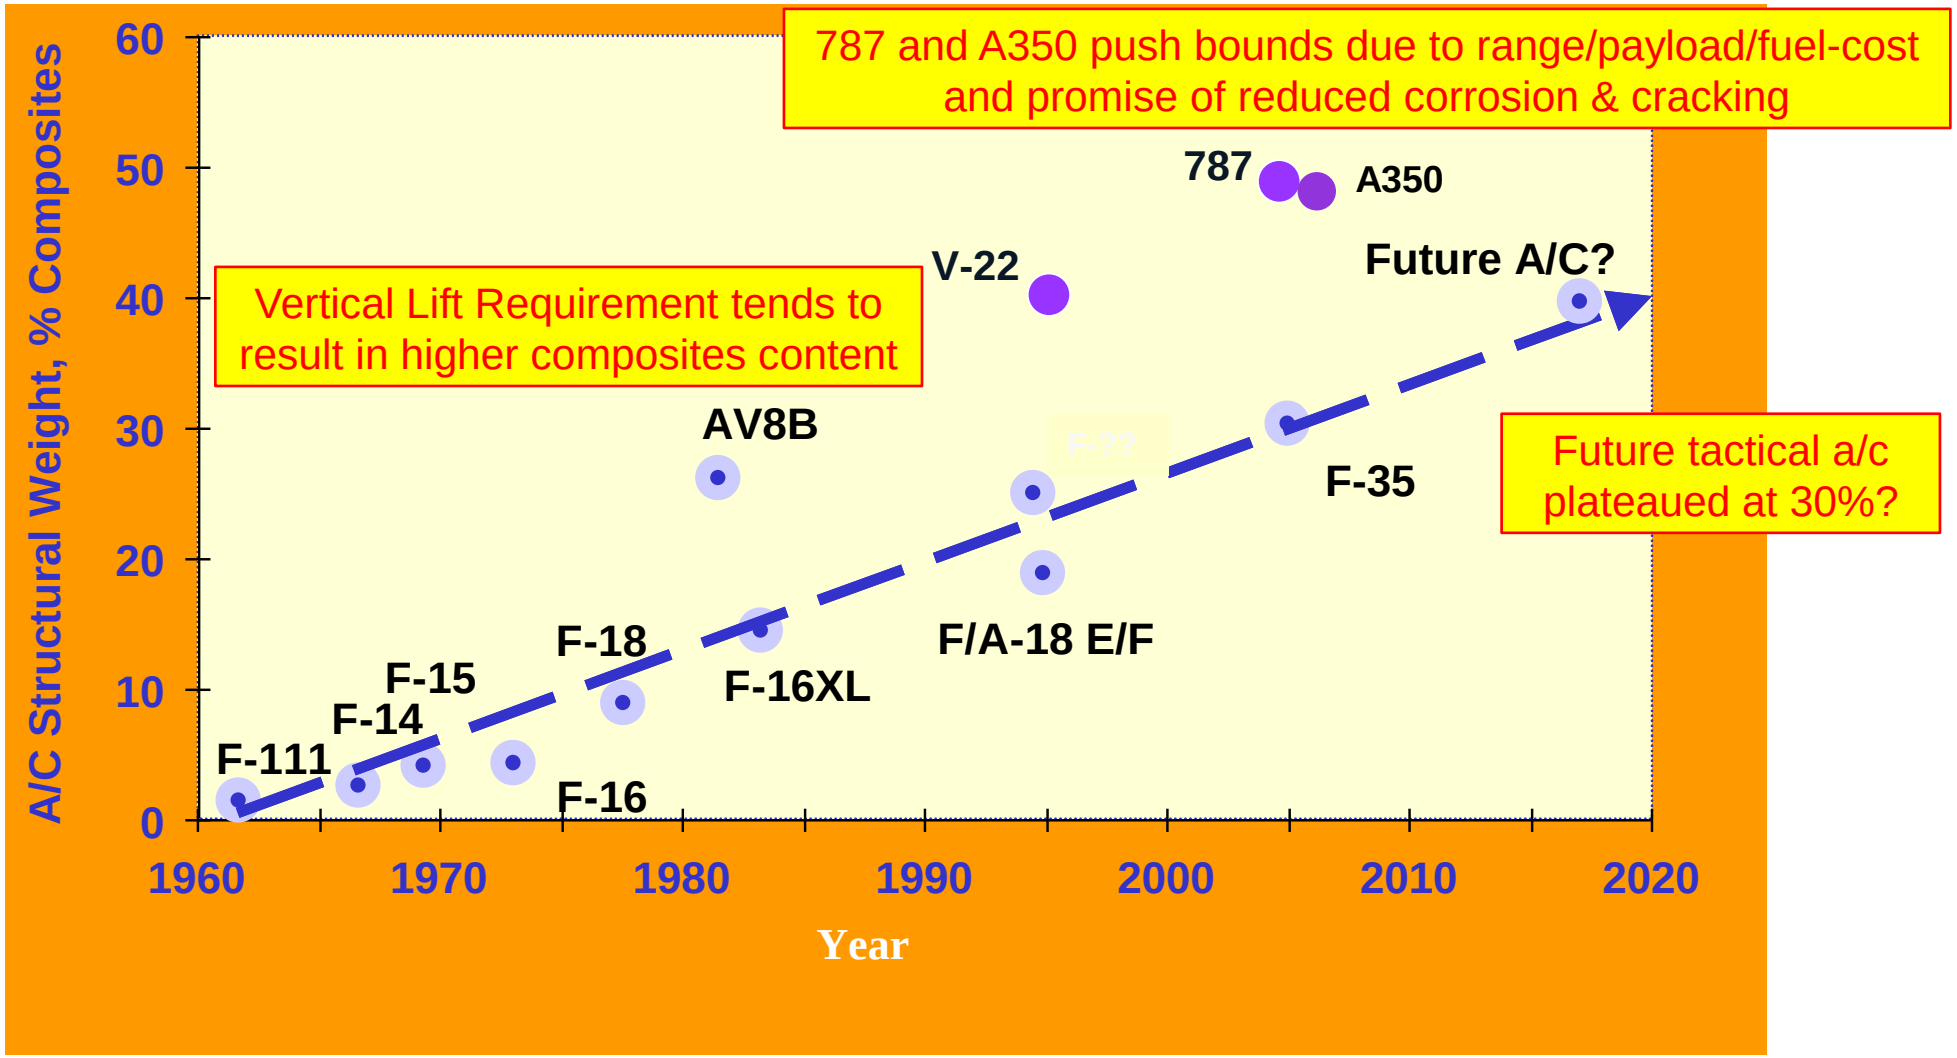
Ramifications for Air System Risk vs. Efficiency

Overall Air System Priorities vs Airframe Cost/Performance:

Air System vs. Airframe

- *Air System includes Air Vehicle (Airframe, Vehicle Systems, Mission Systems, Software), Production Operations, Logistics/Support, Supply Chain Mgmt (at least).*
- *Airframe is often the least-costly (and thus least-important) of the broad management areas noted above, so Program managers are often dis-inclined to accrue risk on the airframe.*
- *Of all the above-noted areas, airframe is also often the most mature technology.*
- *Airframe Cost vs Weight*
  - *Weight-savings can generally only be realized during development when big bones are designed/sized (research only helps new programs).*
  - *Non-recurring cost savings in certification and tooling also only accrue in the development phase.*
  - *Recurring cost-savings, however, can be implemented throughout the lifecycle of existing Programs, and positively influence Prod Ops, Logistics, and SCM.*

Airframe is not biggest driver in Air System cost/performance



Significant R&D has been directed at Airframe recurring cost savings in recent time, but little toward weight-saving performance improvements

Airframe technology must be better, faster, AND cheaper (not just 2 of 3)

©2025 Lockheed Martin Corporation. All Rights Reserved

Ramifications for Air System Risk vs. Efficiency

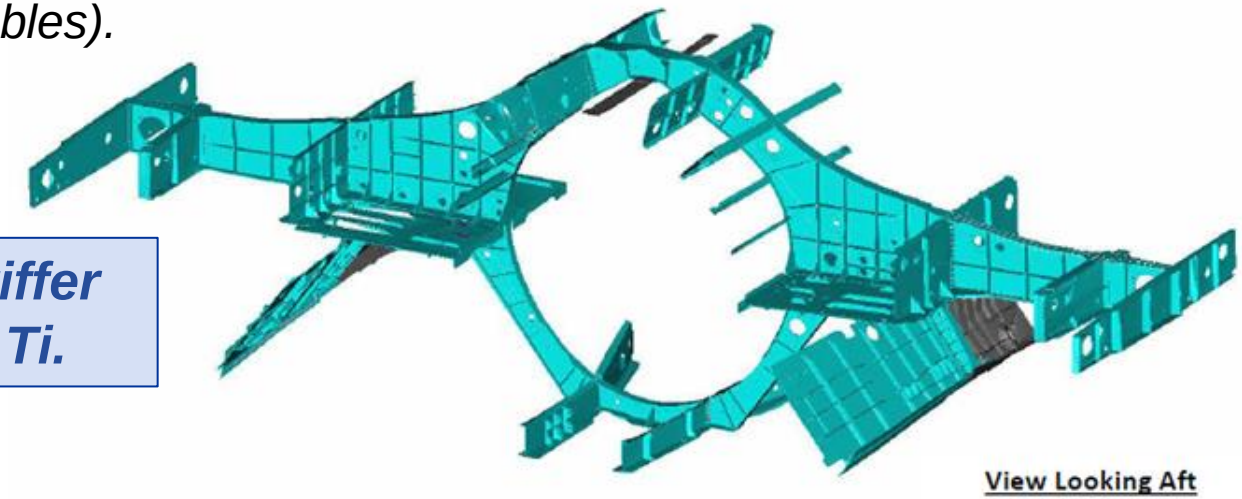
Composites vs. Metals for Various Airframe Components:

©2025 Lockheed Martin Corporation. All Rights Reserved

LOCKHEED MARTIN

Ramifications for Air System Risk vs. Efficiency

Composites vs. Metals for Various Airframe Components:



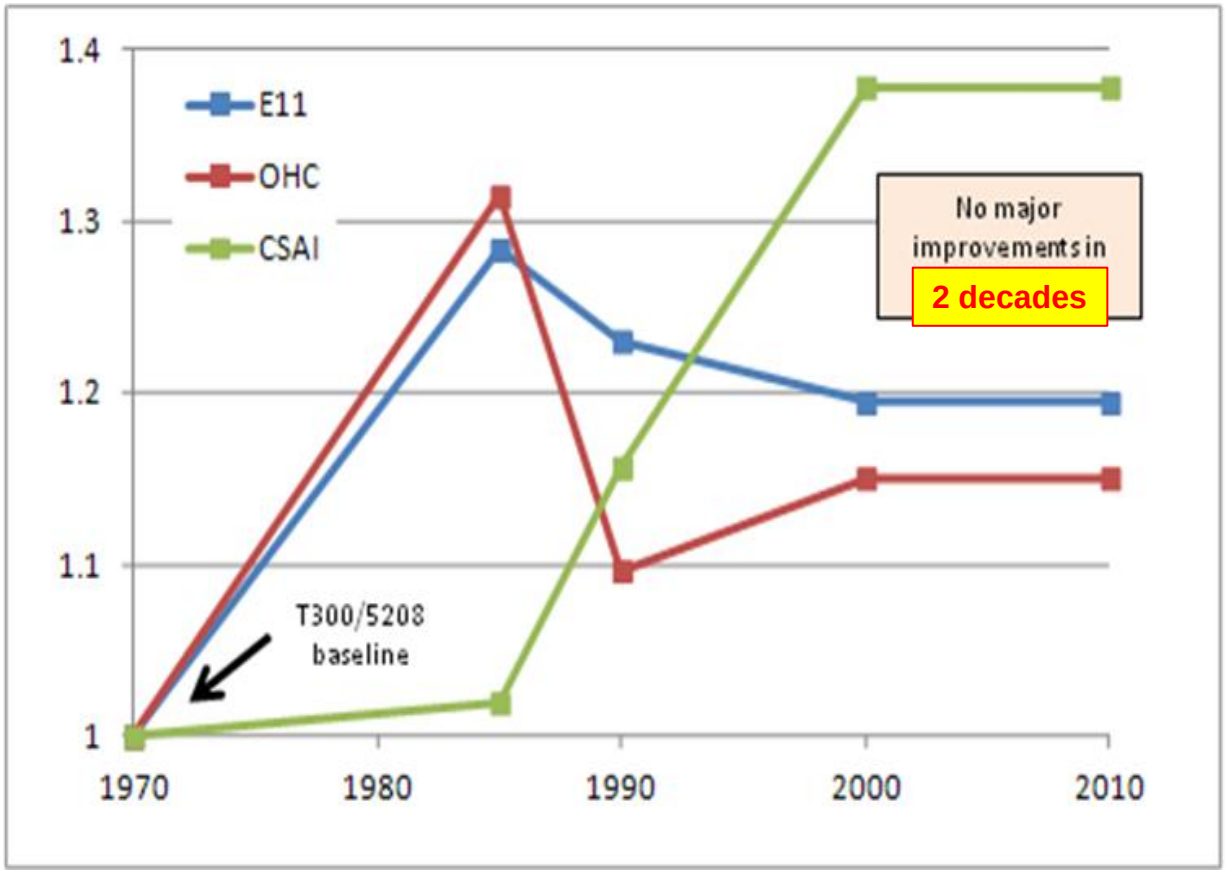
Metals

- *Despite forgings being the longest-lead item of all, and DaDT-based design allowables strain-limiting the composite skins, Ti-6V-4Al and 7050 are still preferred for most complex parts.*
- *Metal parts are easier to "tweak" after initial design release (add stiffeners, change radii, etc).*
- *Steeper ramps, far better flange-bending capability, and thinner min-gauge make metal sub-structure parts lighter than the same part designed/built with composites (plus they are cheaper/faster to design/build).*

Composites

- *In-plane fatigue endurance limit above 0.67*F_{UNC}, so generally considered to have infinite fatigue life.*
- *More sub-element strength validation required for composites, than for metals (despite uncertainty in decades-old metallic empirical factors and MIL-HDBK-5 allowables).*

2024: some structure is just hard to make stiffer and stronger out of anything but Al or Ti.



©2025 Lockheed Martin Corporation. All Rights Reserved

Ramifications for Air System Risk vs. Efficiency

Composites vs. Metals for Various Airframe Components:

Improved Materials?

Normalized Carbon/Epoxy Stiffness and Strength vs. Time

- **Aerospace grade carbon/epoxy has seen one 20 – 30% improvement in stiffness (the change from standard- to intermediate-modulus fiber) over 30 years ago**
- **Steady, dramatic improvement in Compression Strength After Impact (CSAI) (at a given impact energy level) since the mid-1980's**
  - *CSAI (damage tolerance) improvement came at the expense of Open Hole Compression (OHC) strength and axial modulus (E11)*
  - *OHC strength decrease is due to tougher resins not allowing as much beneficial matrix cracking to blunt the stress concentration due to the hole*
  - *E11 decreased as resin content was increased in order to improve processability and impact damage resistance*

2024: will there ever be any breakthrough to increase CFRP tape F11cu (kink band)?

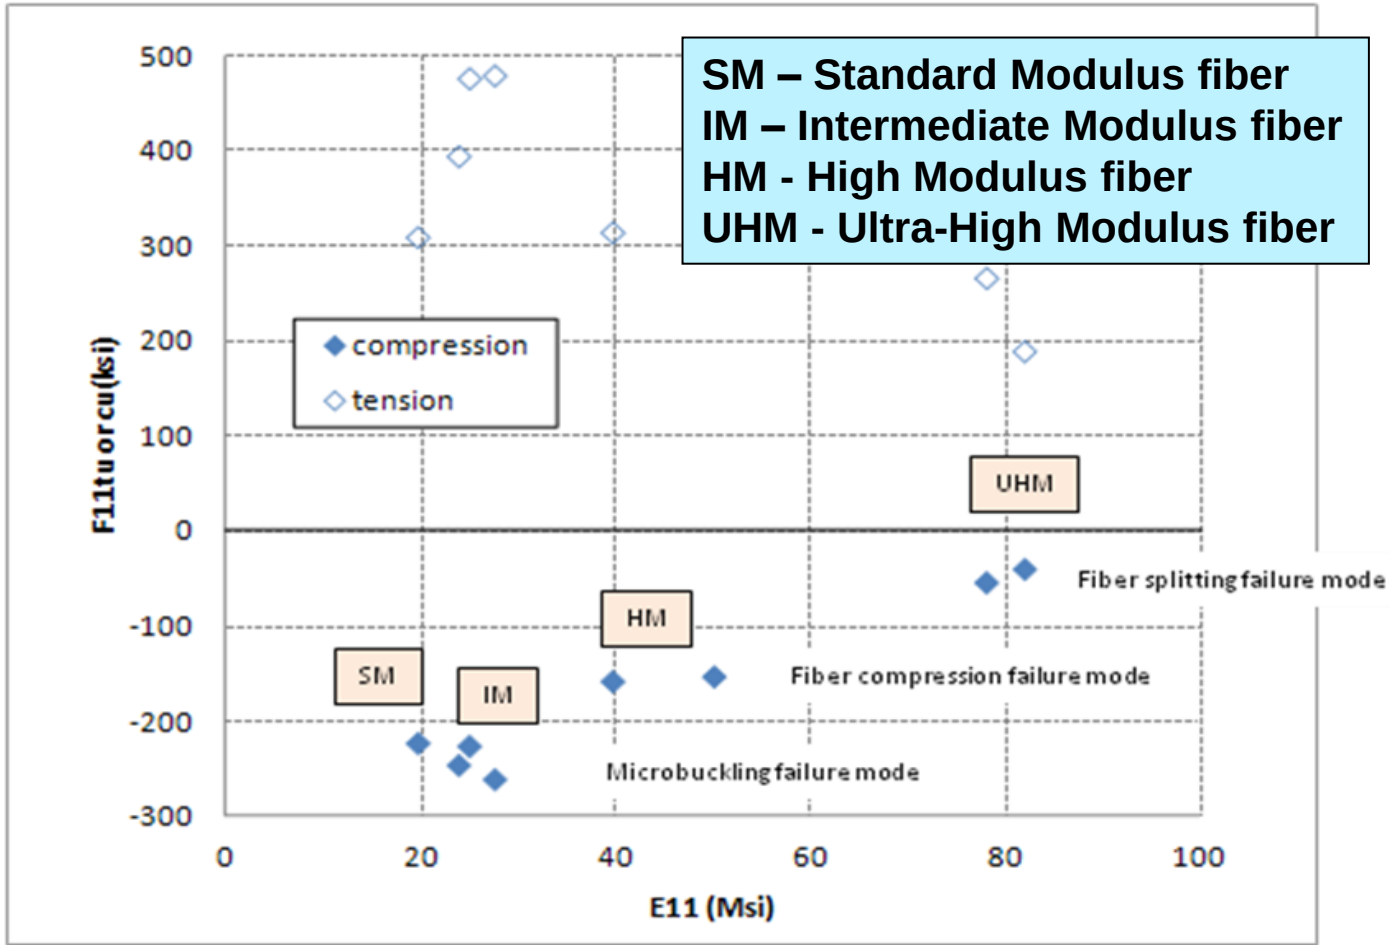
©2025 Lockheed Martin Corporation. All Rights Reserved

Ramifications for Air System Risk vs. Efficiency

Composites vs. Metals for Various Airframe Components:

Improved Materials?

- **Perhaps the toughest challenge for industry and academia is how to simultaneously improve both fiber-direction stiffness and compressive strength**
  - **Reduction in compression strength with increased fiber modulus is due to a change in failure mode from**
    - *Microbuckling in PAN-based intermediate-modulus (IM) fibers to*
    - *Fiber compression and/or interface failure in PAN-based high modulus (HM) fiber and*
    - *Transverse splitting in pitch-based ultra-high modulus (UHM) fiber*
- **Thus, it is obvious that research into increasing HM fiber compressive strength is necessary if significant gains in practical weight efficiency of composite structure are to be realized**



2024: can Boron fiber and/or HyBor hybrid mat'l be cost-competitive?

©2025 Lockheed Martin Corporation. All Rights Reserved

Ramifications for Air System Risk vs. Efficiency

Composites vs. Metals for Various Airframe Components:

Improved Materials?

Fiber-Direction Carbon/Graphite Tape

Compression/Tension Strength vs. Modulus

- *Carbon/graphite fiber technology development has yielded no practical improvement in intermediate-modulus fiber for the past 20+ years*
- *For today's HM fibers, tensile strength is reduced and, most importantly to airframe designs, compression strength goes down drastically*
- *OEM's have generally failed to devise ways to take advantage of high-stiffness/low-strength carbon fibers in local applications (e.g., spar caps, panel breakers, etc)*
- *"low cost" low performing carbon fibers offer very little benefit for aircraft primary structure*

©2025 Lockheed Martin Corporation. All Rights Reserved

LOCKHEED MARTIN

Ramifications for Air System Risk vs. Efficiency

Composites vs. Metals for Various Airframe Components:
Improved Materials?

- **CSAI increase may or may not increase damage tolerance (BVID or CVID) allowable strength, depending on the certification criteria being imposed**
  - **Dents are more visible in certain brittle resin systems, and thus can lead to lower impact energies and higher effective CSAI strengths than for "tough" resins**
  - **Differences in civil and military damage tolerance requirements (1.5*DLL vs Pxx*DLL) have led to**
    - *Use of very tough resin systems in recent civil aircraft designs (at the expense of hot/wet OHC strength)*
    - *Military applications continue to use older less-tough resin systems since CSAI does not size as much structure as does bolted joint strength, which is related most closely to OHC strength*

2024: is there a better damage tolerance criteria than BVID/CVID/dent-depth?

©2025 Lockheed Martin Corporation. All Rights Reserved

Ramifications for Air System Risk vs. Efficiency

Overall Air System Priorities vs Airframe Cost/Performance:

Global Lessons Learned Resulting from Legacy Composite R&D Efforts

- **Industry Conservatism Manifests Itself in:**
  - *Flight certification process/requirements*
  - *Problem resolution at the technology level*

- **Developmental Gap Between Technology and Program Communities**
  - *Program-critical factors not always realistically captured or accounted for during tech transition (design details, certification cost, design flexibility, subsystem integration)*
  - *Technology community often does not have the funding and/or expertise to develop Production-friendly stress analysis methods (e.g., simple, robust, highly-automated)*
    - *SDD BTP stress analysis must be done at a very fast pace and be performed concurrently by a large number of stress analysts, all of whom cannot be composites experts or 20-year veterans*
  - *Development lead times are long and SDD programs are schedule driven*

    …so program specific developmental work needs to start prior to the SDD funding availability (for both lead time and "buy-in" time)

Keywords: Elastomer matrix composites, Fabrics, Anisotropic hyperelasticity, Identification, Properties, Computational modelling, Finite element modelling

ABSTRACT

The study mainly focuses on the instantaneous mechanical behavior of glass-fabric rubber composites. Aside from principal-invariant-driven isotropic hyperelasticity, the strain energy contribution of fabric layer to the overall constitutive behavior of the composite can be defined by pseudo-invariant-driven anisotropic hyperelasticity. The approach accounts for the anisotropy of the silicone rubber matrix reinforced by plain-wave glass fabric using pseudo-invariants defined by vectors aligned with the warp and weft directions. Subsequently, the composite specimens with 0- and 45-degree fabric orientations were considered for the uniaxial tensile tests on top of the tests on pure rubber under different modes. The parameters of the analytical models with the above-mentioned approach were then identified from the test results. Moreover, different anisotropic hyperelastic material models were scripted and subsequently implemented into Abaqus using the UANISOHYPER_INV material subroutine. After checking the developed material subroutines with the coupon tests, this paper constructively paves a path to delve deeper into bending behavior of fabric rubber composites with the developed methodology accompanied with 3-point bending tests.

1 INTRODUCTION

Fabric rubber composites have been prominently utilized in industries such as space [1], aerospace [2-4], and automotive [5] due to their great sealing capacity and durability under harsh environmental conditions. In particular to aero-engine seals, the sealing performance is directly correlated to engine performance since they reduce leakage and optimize clearances [6,7]. Sealing of the cooling systems in aero-engines also greatly contributes to the performance by controlling clearances, as seen in Fig. 1 from the Turbine Case Cooling (TCC) seal improvement on High-Pressure Turbine (HPT) tip clearance [7]. An example of TCC seal is also provided in Fig. 2 [8].

On top of the performance contributions of seals, aero-structure seal malfunctioning would result in serious consequences, as highlighted by Shabbir [9]. In the same study, it was noted that a design defect in the knife edge seal of Pratt&Whitney's (P&W) GTF (geared turbofan engine) on Airbus A320neo caused sudden shutdowns during flight or take-off, resulting in a call back of these engines. Similarly, the failure of the Auxiliary Power Unit compressor carbon seal caused oil leakage and subsequent heavy smoke, resulting in the urgent evacuation of the Airbus A330-323 P&W turbofan engine in 2016 at London Heathrow Airport [10]. Besides the substantial benefits of seals on aero-engine performance, seal malfunctioning issues have highlighted how seals play an important role in aircraft. Thus, this study aims to shed light on the macro mechanical properties of fabric rubber composite seals of interest under different deformation modes, providing reliable numerical models to support composite seal design.

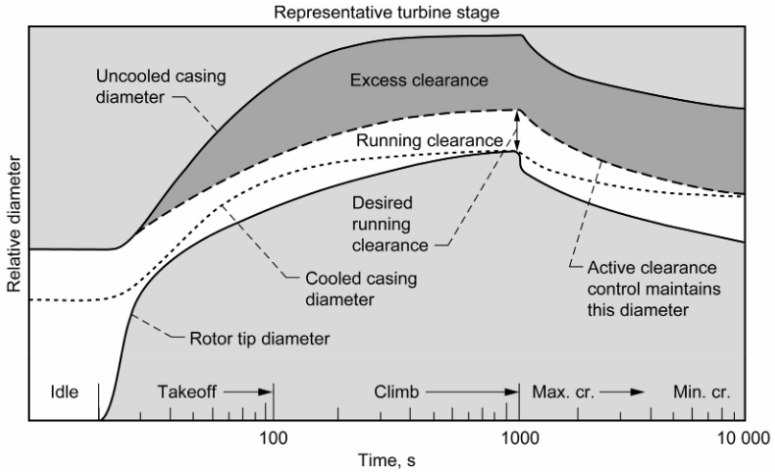

Figure 1: TCC effect on HPT blade tip clearance [7]

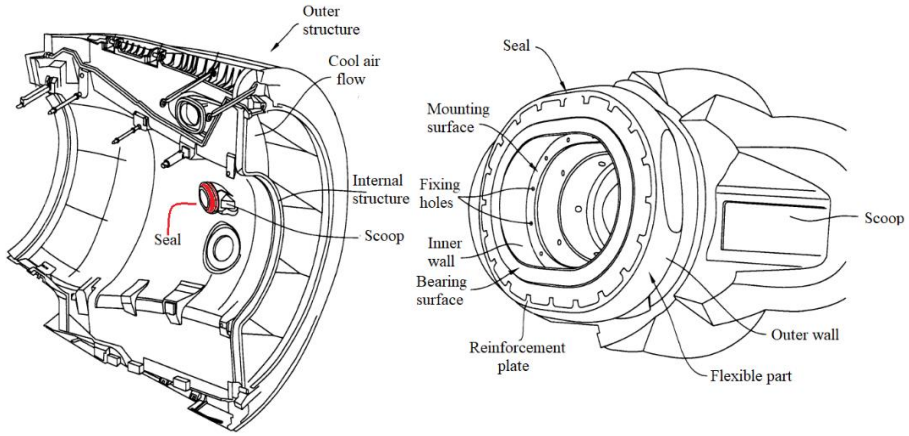

Figure 2: Turbine case cooling seal (left) and zoom on the seal (right) [11]

Fabric rubber composite seals usually include several layers of fabric reinforcement to provide stiffness, fireproofing, and abrasion resistance, as seen from a "P" seal drawing in Fig. 3. Thus, the composite exhibits anisotropic properties on top of hyperelastic, viscoelastic, and Mullins effects [12]. In this study, a set of coupon tests has been performed on pure rubber and plain-wave glass-fabric-rubber composites, accounting for different fabric orientations to characterize anisotropy. In particular, the campaign included uniaxial and equibiaxial tensile tests and uniaxial and planar compression tests for pure rubber and uniaxial tensile tests for composites. Then, the test results of pure rubber are used to identify invariant-based isotropic hyperelastic material models' parameters such as Neo-Hookean [13], Mooney [14]-Rivlin [15], and Ogden [16]. Furthermore, Spencer's theory [17] proposes some pseudo-invariants, based on the principal invariants defined with vectors, to account for anisotropy introduced by fabric reinforcement, analytically estimating the contribution of fabric layer in terms of strain energy. One of the most used anisotropic hyperelastic material models based on Spencer's theory is the Holzapfel-Gasser-Ogden (HGO) [18] model whose strain energy density function is given in Table 1 with other similar models. The material parameters of the anisotropic hyperelastic constitutive models are then identified from the coupon test results of fabric rubber composites. Finally, the anisotropic material models presented in Table 1 are scripted and implemented into Abaqus using UANISOHYPER_INV subroutine. It should be noted that the first parts of the strain energy potentials, i.e., defined by principal invariants, presented in Table 1 belong to isotropic hyperelasticity and the rest of the potential terms to account for fabric contributions.

Since most seals undergo bending deformation to provide sufficient sealing between the counterparts as seen in Fig. 2 from the TCC seal, pointing out that the bending behavior of fabric rubber composites is a crucial validation step in providing reliable numerical models for the composite seals. Hence, an in-

plane driven material identification methodology is developed to account for anisotropy and then implemented into Abaqus. Having preliminary results of bending tests reported, this study paves a path on the future bending behavior studies of fabric rubber composites with the developed methodology.

Table 1: Constitutive models for fabric rubber composites

2 EXPERIMENTAL CAMPAIGNS

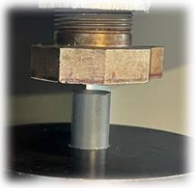
In this section, an experimental campaign is performed to characterize the mechanical behavior of pure rubber and fabric reinforced rubber composite under various loading conditions. In a first step, coupon tests enable to access materials response whereas in a second step, structural behavior is investigated through three points bending tests.

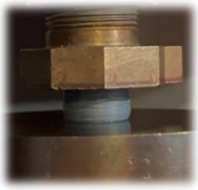
The vulcanized rubber and plain-wave glass fabric was processed at Elanova Laboratory in Paris. A set of moving-die-rheometer (MDR) tests was carried out for the vulcanized rubber subjected to different temperatures as per ISO3417, optimizing the manufacturing process parameters such as vulcanization temperature and duration. The test has revealed that the 100% vulcanization is secured after 20 min under 150°C. Accordingly, 2 mm silicone rubber sheets were vulcanized with a compression moulding setup under 150°C for 20 min while the 3 mm thick composites with one layer of composite sheets were kept 30 min under the same temperature. In addition, a 15 mm thick composite plate with 3 layers of 0.2 mm-thick glass fabric evenly placed through the thickness, keeping the fabric orientations identical for all layers, was also processed within the same setup for 45 min under 150°C. In addition, a different die was utilized to process pure rubber cylindrical specimens to be tested under compression. Lastly, the average density of pure rubber was measured as 1.289 g/cm3, while that of composite was found to be 1.333 g/cm3. Consequently, the processed materials were cut by die whose precision is regularly validated at Elanova laboratory.

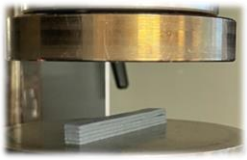
2.1 Coupon tests

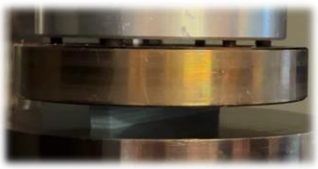
In order to check that the material model applies to any deformation modes, four different deformation modes in Table 2, i.e., uniaxial tensile (UT) and compression (UC), planar compression (CPL), and equibiaxial tensile (ET), were considered for pure rubber testing campaigns. VMQ represents silicone rubber while CVMQ represents composite silicone. The results of the above-mentioned tests on

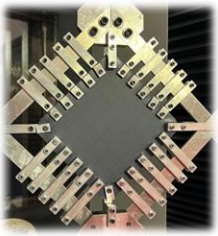
pure rubber are plotted in Figure 4. As expected, the responses of the equibiaxial tensile and planar compression are stiffer than that of uniaxial tensile and uniaxial compression, respectively. A small dispersion of the uniaxial tensile test results would be caused by the unidirectional manual mixing procedure of unvulcanized rubber. Overall, the repeatability of the tests, with a small dispersion margin, shows the reliability of the tests.

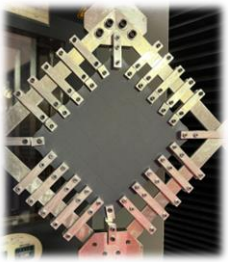












Initial state	Dimensions and Material	Boundary conditions	Final state
	Diameter 18 mm Height 25 mm Pure rubber VMQ	Uniaxial compression (UC) 8 N pre-load 0.25 mm/min loading pace	
	Size 10x10x100 mm Pure rubber VMQ	Planar compression (CPL) 8 N pre-load 0.10 mm/min loading pace	
	Size 2x10x60 mm Pure rubber VMQ	Uniaxial tensile (UT) 0.6 N pre-load 0.6 mm/min loading pace	
	Size 2x110x110 mm Pure rubber VMQ	Equibiaxial tensile (ET) 2 N pre-load 1.10 mm/min	
	Size 3x30x180 mm Composite 1 layer of glass fabric (CVMQ) 0 and 45 degree fabric orientations	Uniaxial tensile (UT) 8 N pre-load 1.8 mm/min	

Table 2: Coupon test matrix for pure rubber and composite

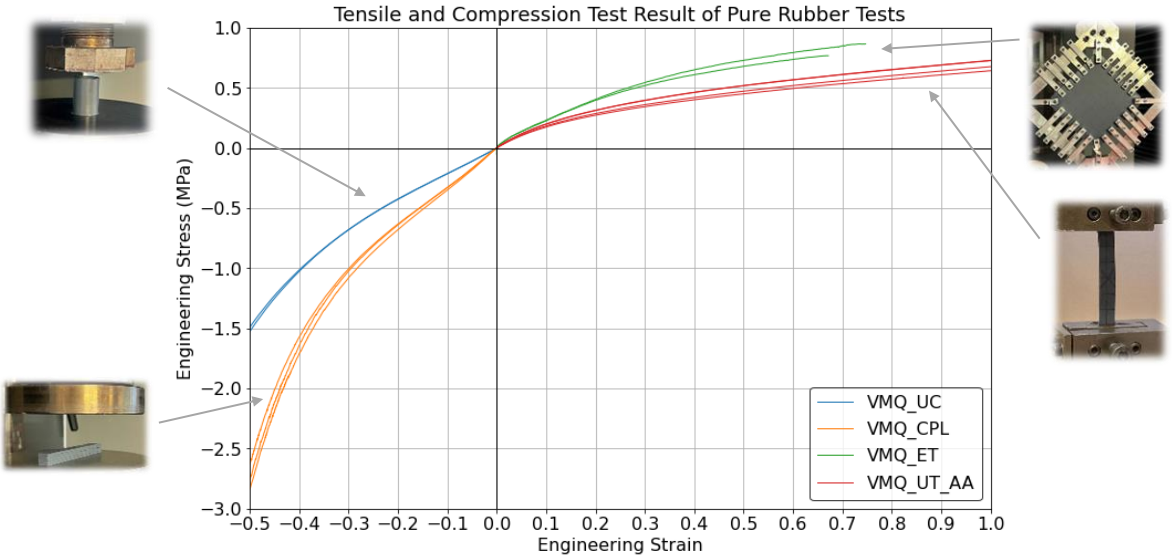


Figure 4: Tests results of pure rubber specimens under various loading conditions

On the other hand, the composite specimens were tested under 2 different fabric orientations, i.e., 0 and 45 degrees, to account for the anisotropy. The initial and final states of the tests as well as boundary conditions and dimensions were shared in Table 2. The test results of the composite with 2 different fabric orientations were plotted in Figure 5 where CVMQ_UT_0 indicates a 0-degree fabric-orientated composite while CVMQ_UT _45 is for 45-degree fabric-oriented composites. It can be clearly seen in Figure 5 that the material is highly anisotropic and non-linear, especially in the 45-degree case where the fabric is free to shear.

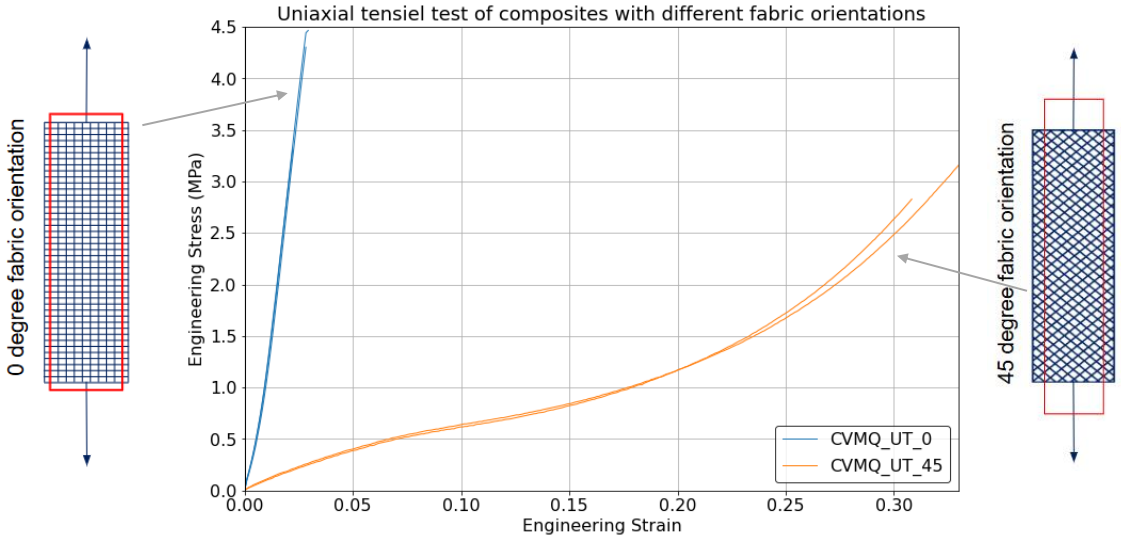

Figure 5: Tests results of composite specimens with one layer of glass fabric

Finally, a set of tests on pure rubber and composite with one layer of glass fabric has been conducted to initiate material modeling process that is going to be detailed in the following sections.

2.2 Three points bending campaign

Three-point bending tests have been carried out on composite specimens that include 3 layers of plain-wave glass fabric whose warp and weft directions are identical in all 3 layers. The experiments consider two different fabric orientations, i.e., 0- and 45-degree fabric orientations according to the axis along the length of specimens. The specimens with the dimensions of 15×15×70 mm were subjected to

0.5 mm/min displacement at the middle of the 50 mm middle span, as illustrated in Figure 6. The specimens were loaded till 6 mm middle displacement and the force output was recorded for each sample. The three point bending test results re plotted in Fig. 7. There is a clear difference between the results with the change of fabric orientation. The maximum load measure at 6 mm mid-span displacement is 37.22 N for the composite with 0-degree fabric orientation while it is 28.37 N for the composite with 45-degree orientation, indicating 30% increased force from 0 to 45 degree orientations.

3 MODELING STRATEGY AND MATERIAL PARAMETER IDENTIFICATION

3.1 Constitutive model

Cauchy stress tensor can be defined in terms of strain energy as follows

$$\sigma = \frac{2}{J}\boldsymbol{F}\cdot\frac{\partial W}{\partial \boldsymbol{C}}\cdot\boldsymbol{F}^{T} - p\boldsymbol{I} \tag{1}$$

where W is strain energy function, $\boldsymbol{F} = \partial \boldsymbol{x}/\partial \boldsymbol{X}$ is deformation gradient, $\mathbf{C} = \boldsymbol{F}^{T}\cdot\boldsymbol{F}$ is right Cauchy-Green deformation tensor, $J = \det(\boldsymbol{C})$ is compressibility term, p is arbitrary pressure, and $\boldsymbol{I}$ is an identity tensor. The strain energy function W is defined as a function of the principal strain invariants for isotropic hyperelasticity and also as a function of pseudo-invariants to account for anisotropy as follows

$$W = W(I_1, I_2, I_3, I_4, I_6, I_8, I_i) \tag{2}$$

The first three invariants are the principal invariants and are defined as follows

$$I_1 = \mathrm{tr}\mathbf{C}$$
$$I_2 = \frac{1}{2}[(\mathrm{tr}\mathbf{C})^2 - \mathrm{tr}(\mathbf{C}^2)] \quad (3)$$
$$I_3 = \det(\mathbf{C})$$

I_4 and I_6 are the pseudo-invariants that account for fiber stretches in the two fiber directions. Moreover, I_8 is an interaction term that characterizes the interaction between rubber and fabric accounting shearing behavior between materials. The pseudo-invariants are derived from the vector definitions, N and M, aligned with the warp and weft directions of the fabric, on top of Cauchy-Green deformation tensor C. Having two vectors in the directions of two perpendicular fiber families, N and M vector expressions with respect to the Cartesian axes X and Y, are

$$\mathrm{N} = \begin{bmatrix} \sin\alpha \\ -\cos\alpha \\ 0 \end{bmatrix}, \mathrm{M} = \begin{bmatrix} \cos\alpha \\ \sin\alpha \\ 0 \end{bmatrix} \quad (4)$$

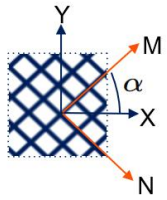

Figure 8: (N, M) vectors used to define the warp and weft directions of the fabric

Finally, based on the above-described vectors and the deformation tensor, the pseudo-invariants are derived with double-dot (:) and dyadic product ($\otimes$) as follows

$$I_4(\mathrm{M}) = \mathbf{C}:\mathrm{M}\otimes\mathrm{M},\ \ I_6(\mathrm{N}) = \mathbf{C}:\mathrm{N}\otimes\mathrm{N},\ \ I_8(\mathrm{M},\mathrm{N}) = \mathbf{C}:\mathrm{M}\otimes\mathrm{N} \quad (5)$$

Furthermore, considering the loading modes, e.g., uniaxial tensile and planar compression, one can easily define the deformation gradient for incompressible isotropic materials. In a specific case of uniaxial loading conditions and incompressible isotropic material, the deformation gradient is written as $F = \boldsymbol{diag}[\lambda, \lambda^{-\frac{1}{2}}, \lambda^{-\frac{1}{2}}]$. It should be noted that the second and third components of the deformation gradient become equal due to isotropy and incompressibility assumption. However, in the case of the anisotropic materials, obtaining deformation gradient is not a straight-forward step and requires an update of the deformation gradient at every load step. This paper will delve deeper into this topic in the following identification process.

In addition to the anisotropic strain energy functions provided in the introduction, the isotropic incompressible strain energy functions used in this study are listed in Table 3. It should be noted that the incompressibility assumption makes the third principal invariant zero ($I_3 = 0$).

Model Name	Strain energy potentials
Neo-Hookean [13]	$W = C_{10}(\bar{I}_1 - 3)$
Mooney [14]-*Rivlin* [15]	$W = C_{10}(\bar{I}_1 - 3) + C_{01}(\bar{I}_2 - 3)$
Ogden [16]	$W = \sum_{p=1}^{N} \frac{\mu_p}{\alpha_p}(\lambda_1^{\alpha_p} + \lambda_2^{\alpha_p} + \lambda_3^{\alpha_p} - 3)$

Table 3: Constitutive models for isotropic materials such as pure rubber

Consequently, the Cauchy stress tensors are derived substituting these potentials into Equation 1. Applying simple deformation modes, this method allows identification of the material parameters of the constitutive models for the material of interest.

3.2 Identification of material parameters

The identification process of the material parameters was achieved by minimizing, in the sense of least squares, the difference between the stress and strain curves between experimental results on uniaxial tensile loading mode and the analytical formulations of the models. Pure rubber models were identified prior to composites. For that purpose, a Python program, relying on the trust region optimization algorithm available in SciPy library [21] was developed. To have a complete stress equation, upon substituting all the components into Equation 1, one can calculate the arbitrary pressure p knowing that stress in the thickness direction is zero ($\sigma_{33}=0$) for all the loading conditions used in this study. Having p substituted back in Equation 1, the equation now is ready for the optimization process for isotropic hyperelastic models. On contrary, obtaining deformation gradient F is not straightforward for anisotropic hyperelasticity due to anisotropy. For example, considering incompressibility, the deformation gradient for the uniaxial loading case is now a function of first and second principal stretches due to possible inequality of second and third principal stretches because of anisotropy, seen below. Thus, at every step of imposed λ_{11}, λ_{22} was estimated by solving high order non-linear equation for $\sigma_{22}=0$. This equation is numerically solved at every λ_{11} step since there is no direct analytical solution for such complex equations.

$$\mathbf{F}_{\text{uniaxial}} = \begin{bmatrix} \lambda_{11} & 0 & 0 \\ 0 & \lambda_{22} & 0 \\ 0 & 0 & (\lambda_{11}\lambda_{22})^{-1} \end{bmatrix} \tag{6}$$

Based on the identification procedure explained above, one can obtain all stress equations for all above-mentioned material models with each given loading condition. As examples, only the stress equations of isotropic Mooney [14]-Rivlin [15] and anisotropic model by Gong et al. [20] under uniaxial boundary conditions are derived, in Equation 7 and 8, respectively. It is not possible here to state the stress equation for the Gong et al. [20] model explicitly for every updated deformation gradient. Thus, more general definitions are made in Equation 8.

$$\sigma_{11} = 2\left(C_{10} + \frac{C_{01}}{\lambda_{11}}\right)\left({\lambda_{11}}^2 - \frac{1}{\lambda_{11}}\right) \tag{7}$$

$$\boldsymbol{\sigma} = 2[W_1\mathbf{C} - W_2\mathbf{C}^{-1} + I_4W_4\mathbf{M}\otimes\mathbf{M} + I_6W_6\mathbf{N}\otimes\mathbf{N} + \frac{W_8(\mathbf{M}\otimes\mathbf{N}+\mathbf{N}\otimes\mathbf{M})}{2}] \tag{8}$$

where **M** and **N** are now tensors in which the above defined vectors multiplied with deformation gradient and its transpose as described in Equation 1 and W_i is the derivation of strain energy potential with respect to i^{th} strain invariant. Based on the identification performed on pure rubber, one can now identify the material constants associated with anisotropy (k_1, k_2, k_3 in Table 1). Remembering that I_4 and I_6 pseudo-invariants account for fiber extensions in fiber directions, associated k_1 and k_2 parameters can be then identified based on the uniaxial tensile test of the composite with 0-degree fabric orientation. The parameter k_3 associated with I_8 is optimized based on the uniaxial tensile test of the composite with 45-degree fabric orientation.

Furthermore, the above described and derived constitutive equations were scripted in Fortran and implemented into Abaqus using the UANISOHYPER_INV material subroutine. The developed material subroutines were then used to simulate composite tests with the same conditions, checking the subroutines. It must be noted that all the simulations employed implicit solution scheme and 0.5 mm hybrid brick elements considering geometric non-linearity assumption.

The material parameter identification process has resulted in material parameters presented in Table 4. Simulating the same coupon test conditions, the results were evaluated comparatively with experimental and analytical results. The numerical results with identified k_1 and k_2 parameters for the HGO [18] model are plotted in Fig. 9. Even if the numerical and analytical curves are in satisfactory agreement in this case of composite with 0 degree fabric orientation under tensile, it can be clearly seen that the model underestimates the material response for the 45-degree fabric orientation case. A very

similar observation was made for the model of Dong et al. [19] where no improvement in 45-degree case was observed, seen in Fig. 10 despite the new terms added into both isotropic and anisotropic parts of the strain energy function. Moreover, the parameter k_3 was identified to account for the shearing behavior between fabric and rubber. As seen in Fig. 11, the inclusion of I_8 resulted in improved results, which indicates the importance of modelling the shearing behavior of the composite with the additional pseudo-invariant. The identified material constants and the error metrics of the optimization studies were also shared in Table 4. In Table 5, one can easily notice the similar outcomes in the stress distribution results of the simulations at two different stretch values for Dong et al. [19] and Gong et al. [20] models with 45 degree fabric orientation, resulting in higher stress in Gong et al. [20] model around the transition zone as a result of the inclusion of shearing parameter.

Model Name	Strain energy functions

4 CONCLUSIONS

In this paper several hyperelastic models, dedicated to pure rubber and fiber reinforced rubber, have been studied. In a first step, the model has been described, and the stress equations have been derived on specific loading cases of interest for identification purposes. Secondly, an identification process of pure rubber and composite materials has been conducted to obtain material parameters. Compared with the experimental results, the capabilities of different anisotropic material models, for composite modeling, were highlighted. The material models that do not include pseudo-invariant I_8 to account for shearing behavior between rubber and fabric are clearly seen incapable of reproducing material response especially for 45-degree fabric-oriented composite specimens. Moreover, the material model with I_8 defined resulted in satisfactory results in terms of the reproduction of material response. In the third step, the models with the identified material parameters were implemented in a finite element implicit framework using material subroutines. The composite simulations carried out with the developed subroutines under uniaxial loading conditions have resulted in a satisfactory mechanical response in comparison with experimental and analytical data. To conclude, this numerical modeling methodology provided and the 3-point bending tests pave the path for modeling bending behavior of fabric rubber composites for further studies.

Molecular Dynamics (MD) for Nanoscale Insight

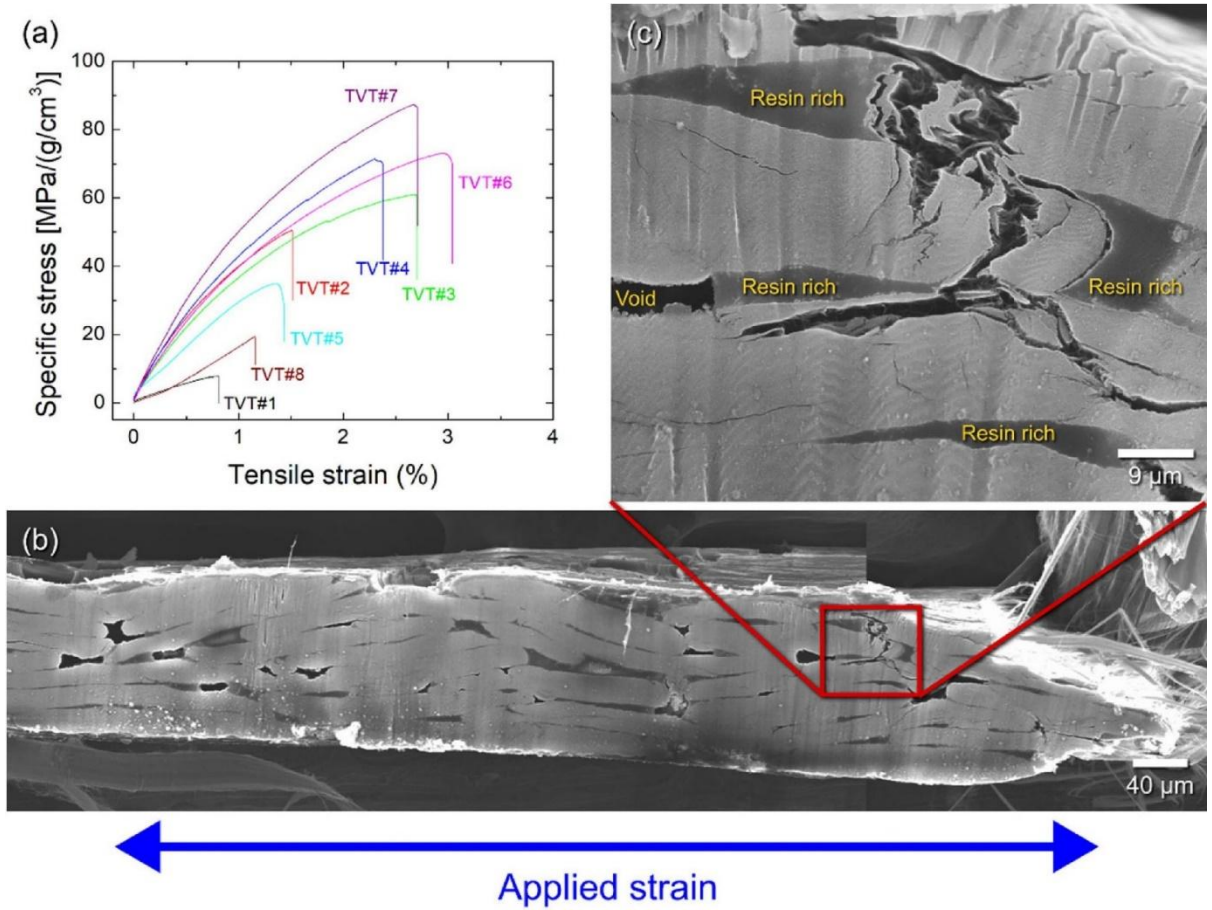
- Molecular dynamics (MD) is a computer simulation technique for modeling the motion and interaction of atoms and molecules
- Atomic positions are updated using a small timestep and Newtonian mechanics, $a = F/m$
- In traditional MD, bonded connections are defined once at beginning of simulation and not changed during the simulation
- Mechanical properties can be predicted at the nanoscale (ultimate strength, elastic modulus, interfacial shear strength)

Nanocomposites have Advanced Properties

- Composites have replaced many components of aircraft, cars, sports equipment and other technologies such as energy storage
- Interfaces and defects are nucleation sites for mechanical failure
- Failure mechanisms of composite materials are complex, and difficult to relate back to processing conditions
- Molecular dynamics (MD) models can help us understand the origin and propagation of material failure
- **<u>Grand Challenge:</u> Developing Materials that can Serve Both as Temperature-Resistant and High-Strength Structural Components**

Aerospace

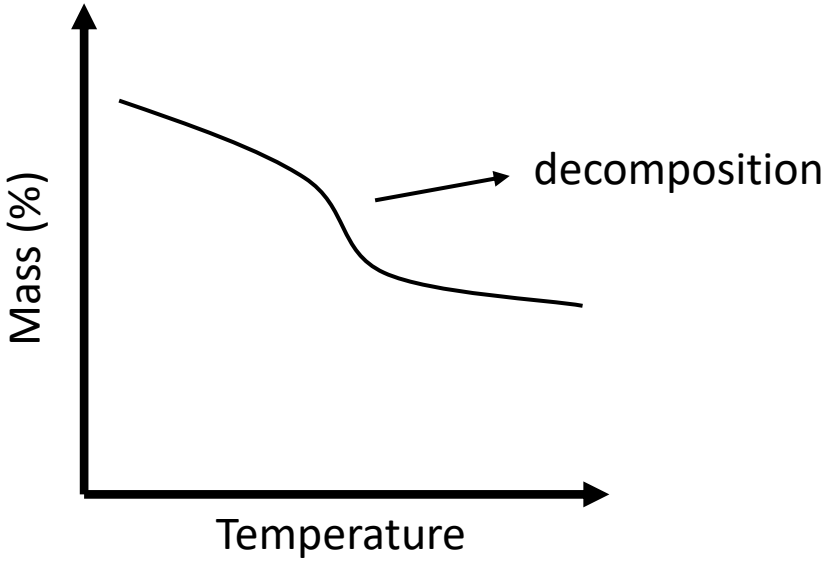
Automotive



NASA’s Orion spacecraft recovered after Artemis I test flight

Interfacial Interactions are Critical

- The properties of composite materials remain well below their theoretical values
- Interfacial interactions and defects often determine the material's ultimate properties!
- Embedded interfaces are difficult to probe using experimental techniques
- Atomistic MD can predict the properties and dynamic response of complex multicomponent systems



Tensile tests of CNT fiber reinforced polymer composites.

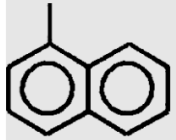
Why is Char Yield Important?

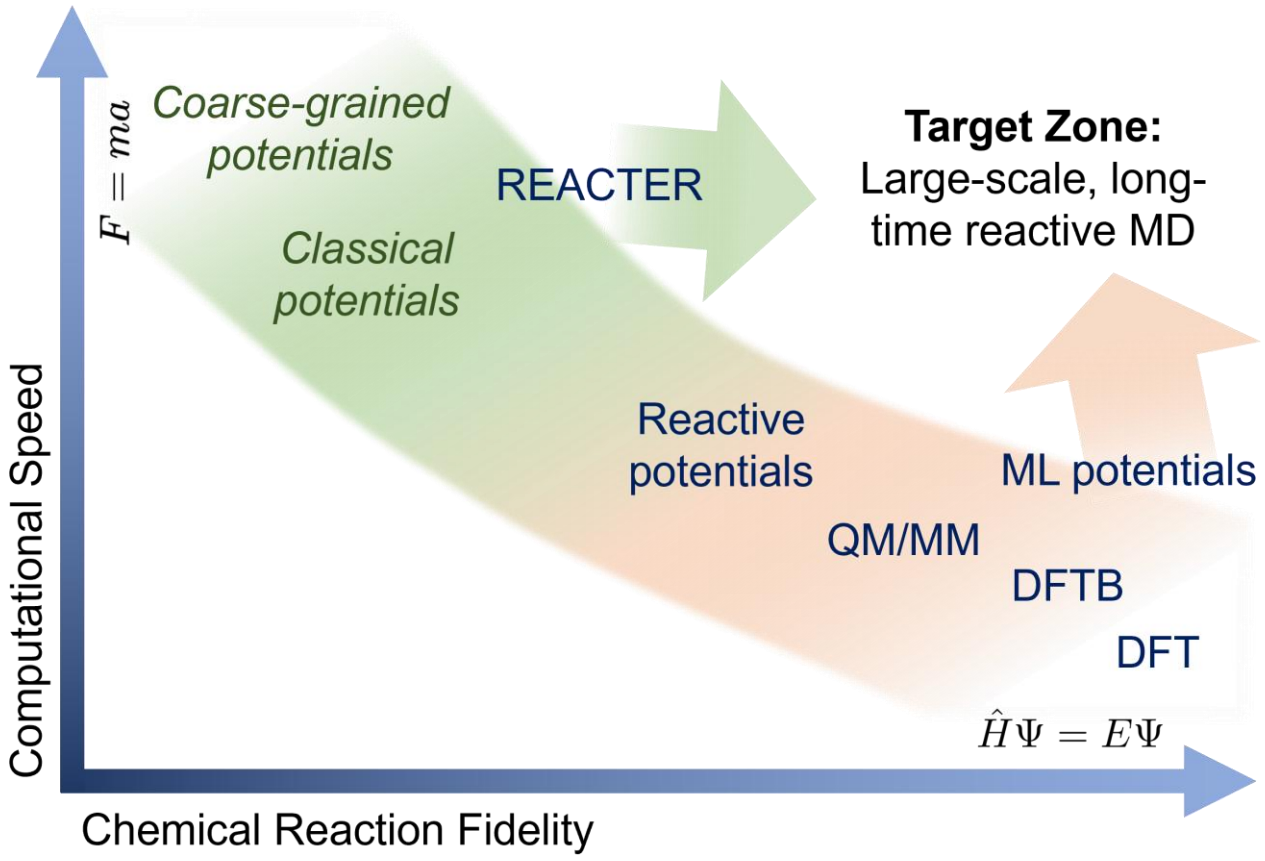
- Char yield is the amount of material left over after subjecting it to high temperature pyrolysis
  - Thermogravimetric analysis (TGA) is used to obtain plots of mass vs time and/or temperature (typically ramped up to 800°C -1000°C)
- High char materials require fewer cycles of carbonization and resin infiltration to achieve desired properties



Typical TGA plot

Prior Efforts to Predict Char Yield

- Correlate existing literature data with empirical formulas
  - Element ratios, molecular group analysis, quantitative structure-property relationships (QSPR)
  - Achieves reasonable correlations with low-char yield resins
- Not enough chemical intuition to predict outlier behavior



Molar group contribution values.

Chemical group[a]	Type[b]	Molar group contributions			Ψ_i/M_i J/g K
		Ω_i MJ/mol	X_i g/mol	Ψ_i kJ/mol K	
$-C(CH_3)_2-$	B	2.63	0	85.5	2036
$-CH_3$	S	0.50	0	18.5	1233
$-CH_2-$	B	0.51	0	14.4	1029
	S	4.84	0	108.6	855
–O–	B	0.12	0	11.1	694

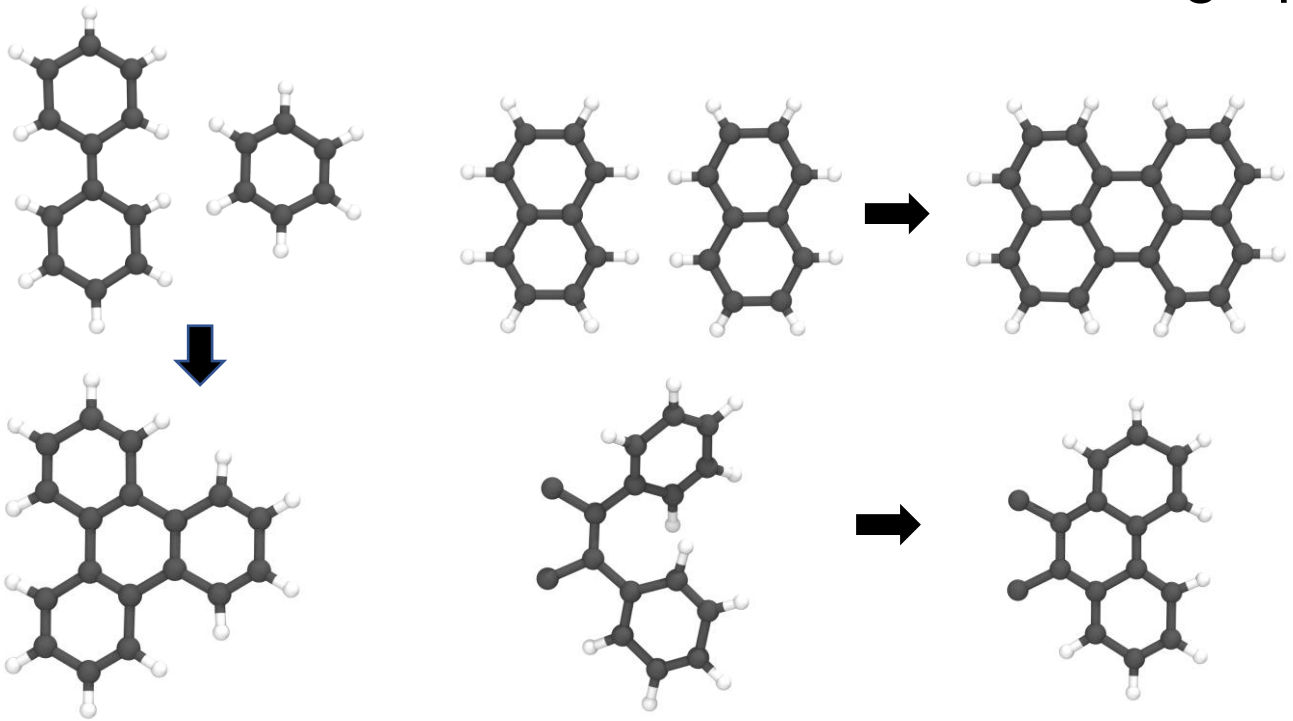
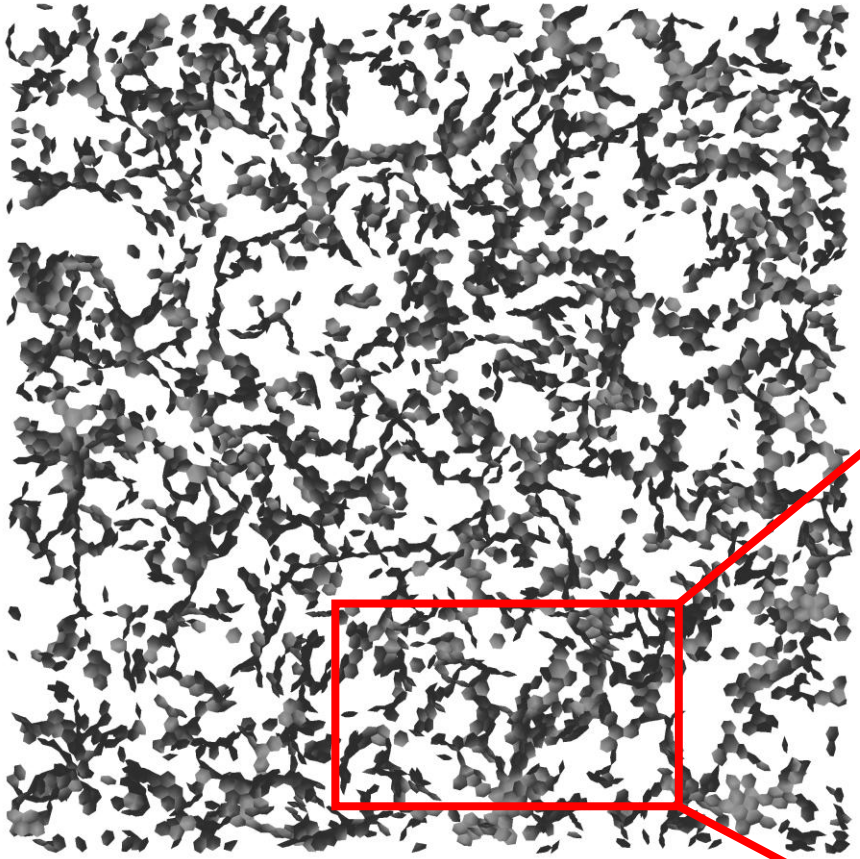
Large-Scale Reactive MD is Challenging

- Quantum mechanics can model reactions from first principles
- Levels of abstraction come with a tradeoff: accuracy *vs.* speed
- Reactive force fields can achieve near-DFT accuracy
  - Much faster than DFT, much slower than classical molecular dynamics (MD)



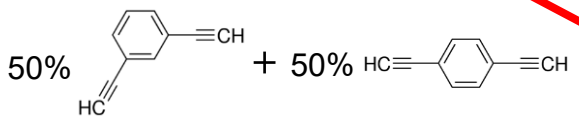
Gissinger et al. "Modeling chemical reactions in classical molecular dynamics simulations." *Polymer* 128 (2017): 211-217.

Case Study: Carbonization Reactions



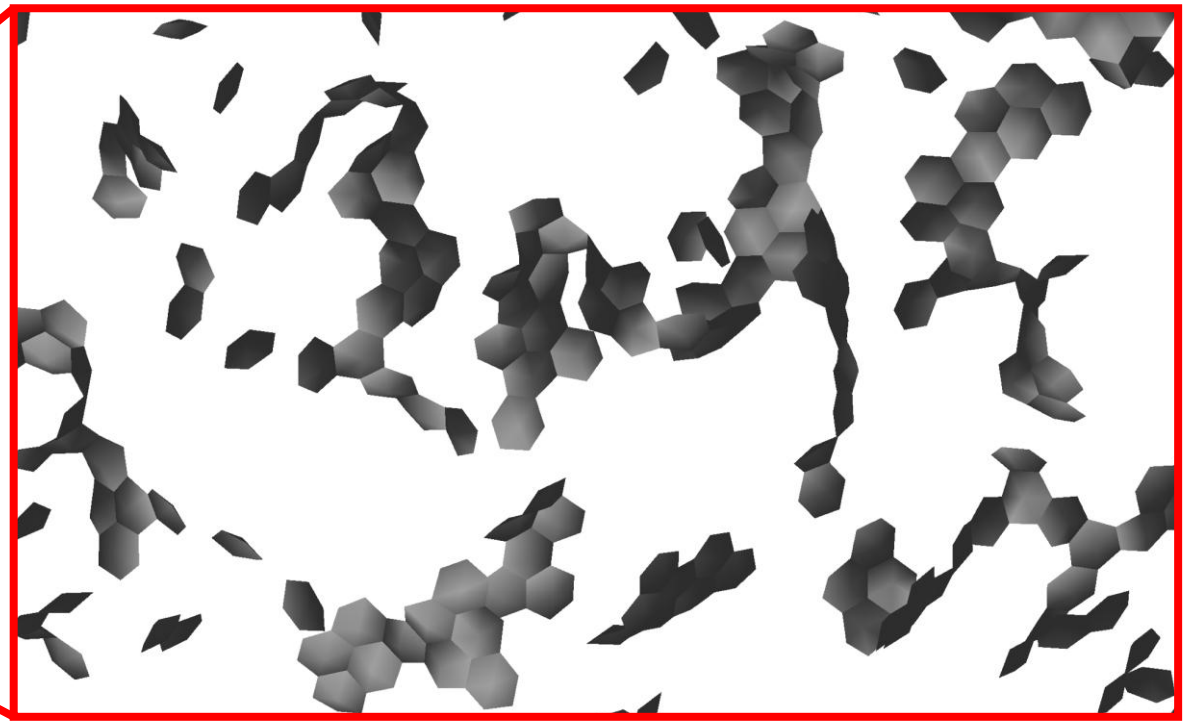
- Starting point: diethynylbenzene polymerized via linear and cyclotrimerization reactions
- Define carbonization moves from polymerized polyarylacetylene (PAA) motifs, as well as ring-closing and Diels-Alder reaction
- End goal: Approximate model of the carbonization and/or graphitization process

polyarylacetylene (PAA)



Case Study: Nanoribbon Formation

Slice is 7 Å thick; only rings shown



Density: 1.0 g/cm^3

Box Size: 13.8 nm

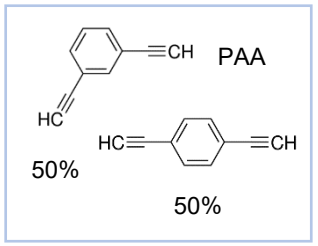
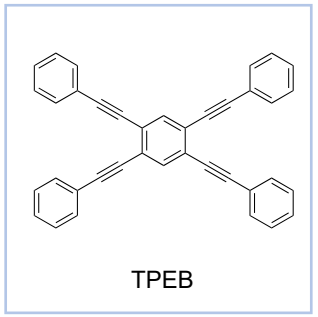
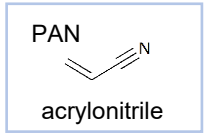
Char Yield Simulation Protocol



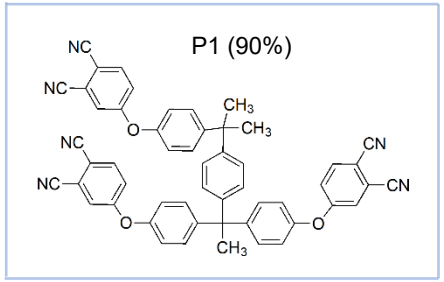
- Temperature ramp cycle
  - 300 K - 3000 K at 10 K/ps
  - High temperatures/rates to accelerate reactions
- Anneal at high pressure (1 GPa) to achieve final densities of 1.8 g/cm^3 - 2.0 g/cm^3
- ReaxFF with periodic removal of outgassing products to allow for carbonization and densification
- Initial system size: 36000 atoms

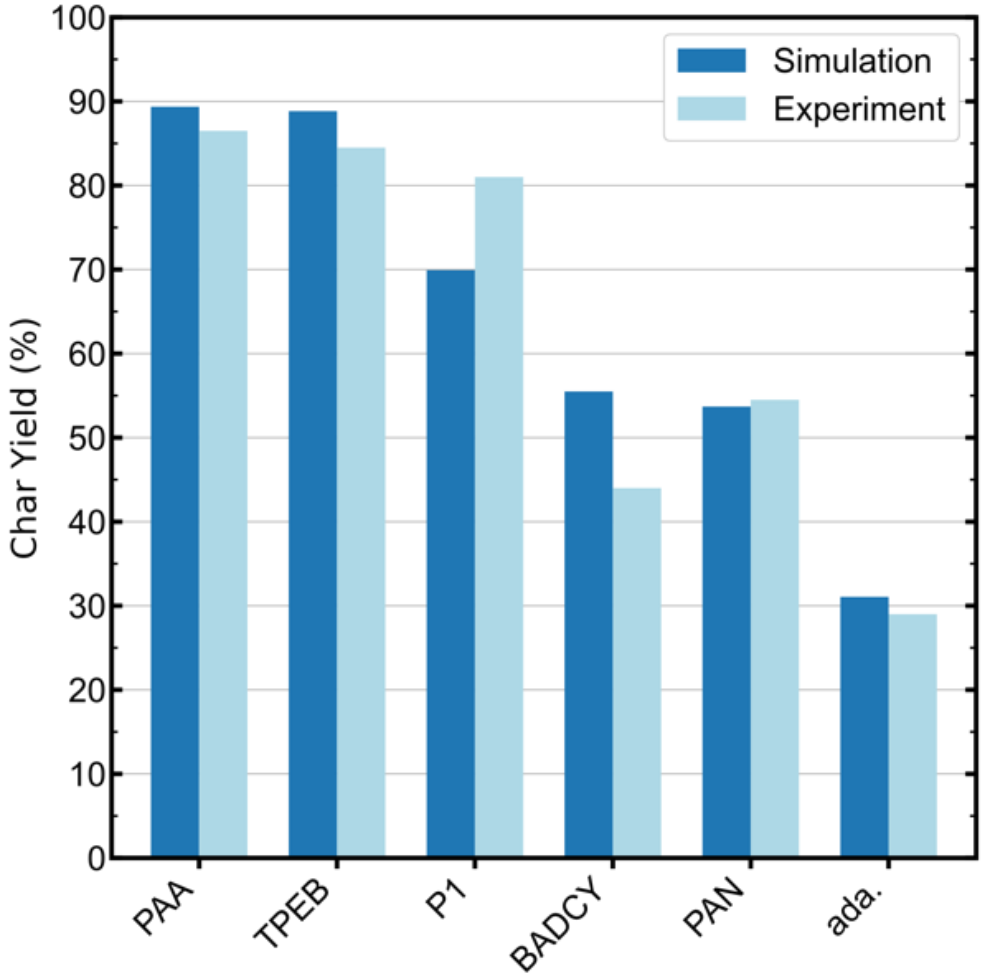


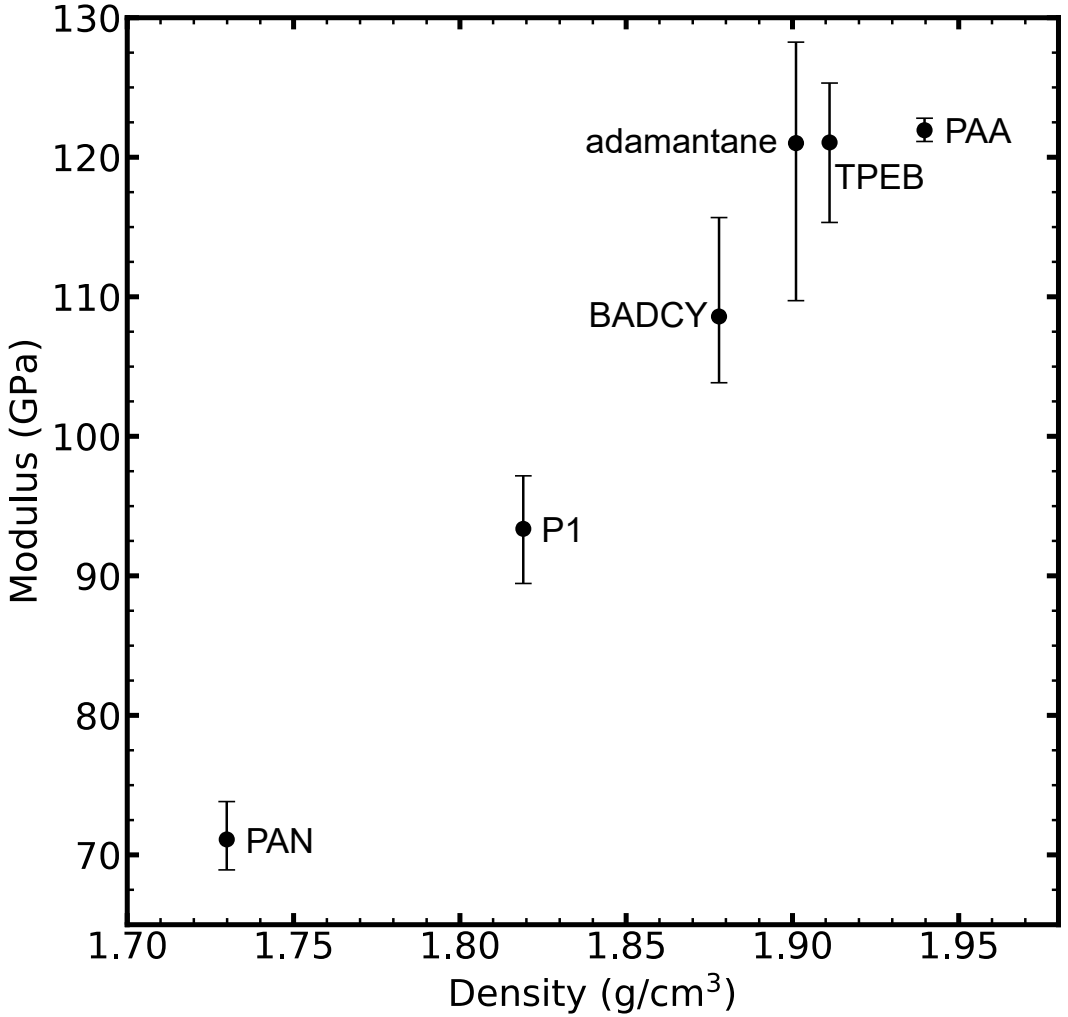
Char Yield Results for Various Chemistries

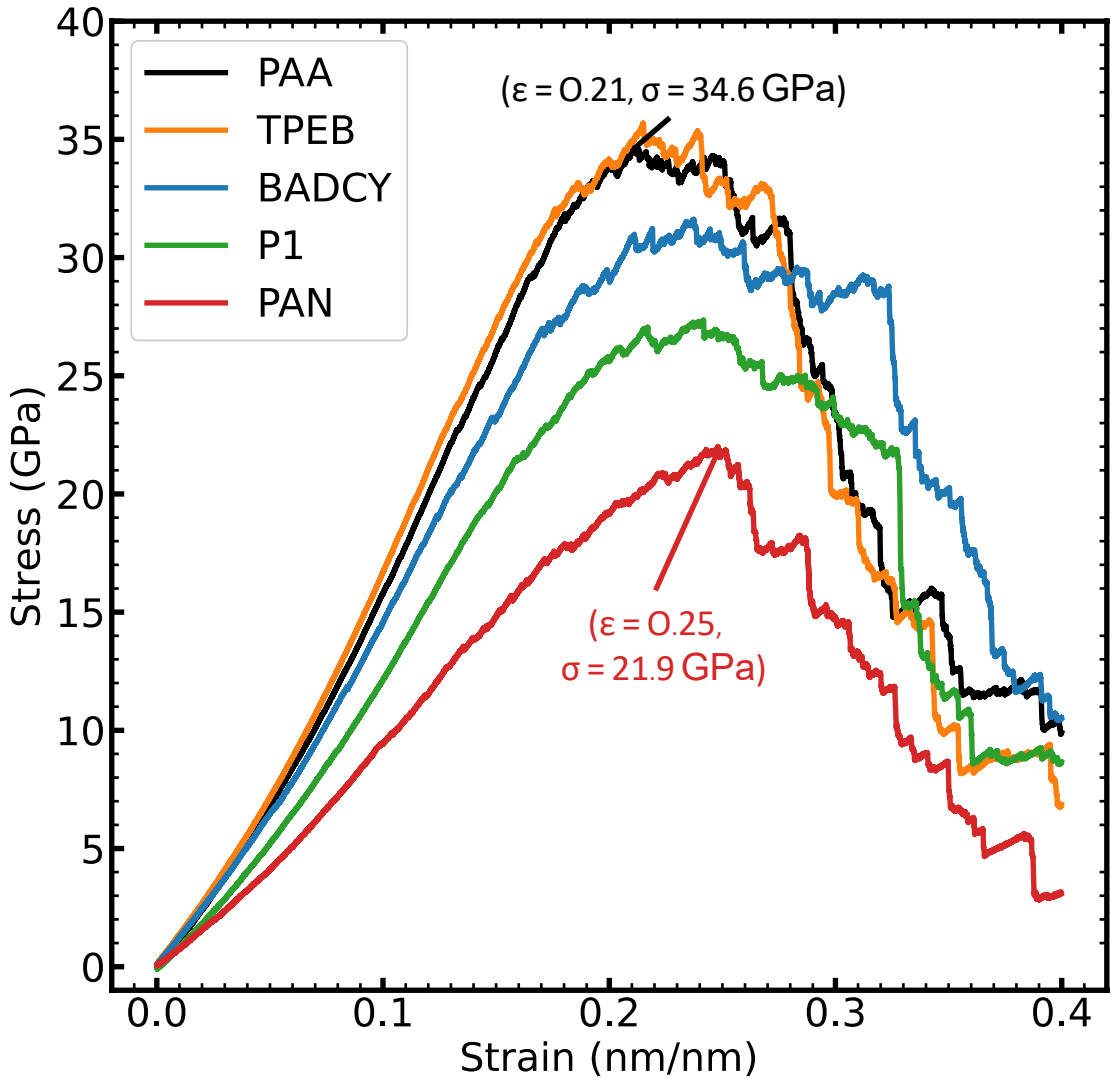


- Simulation protocol able to accurately predict char yield trends across a wide range of functional groups, heteroatom content and char yield values
- Chemically specific method
- No assumptions or fitting of experimental results

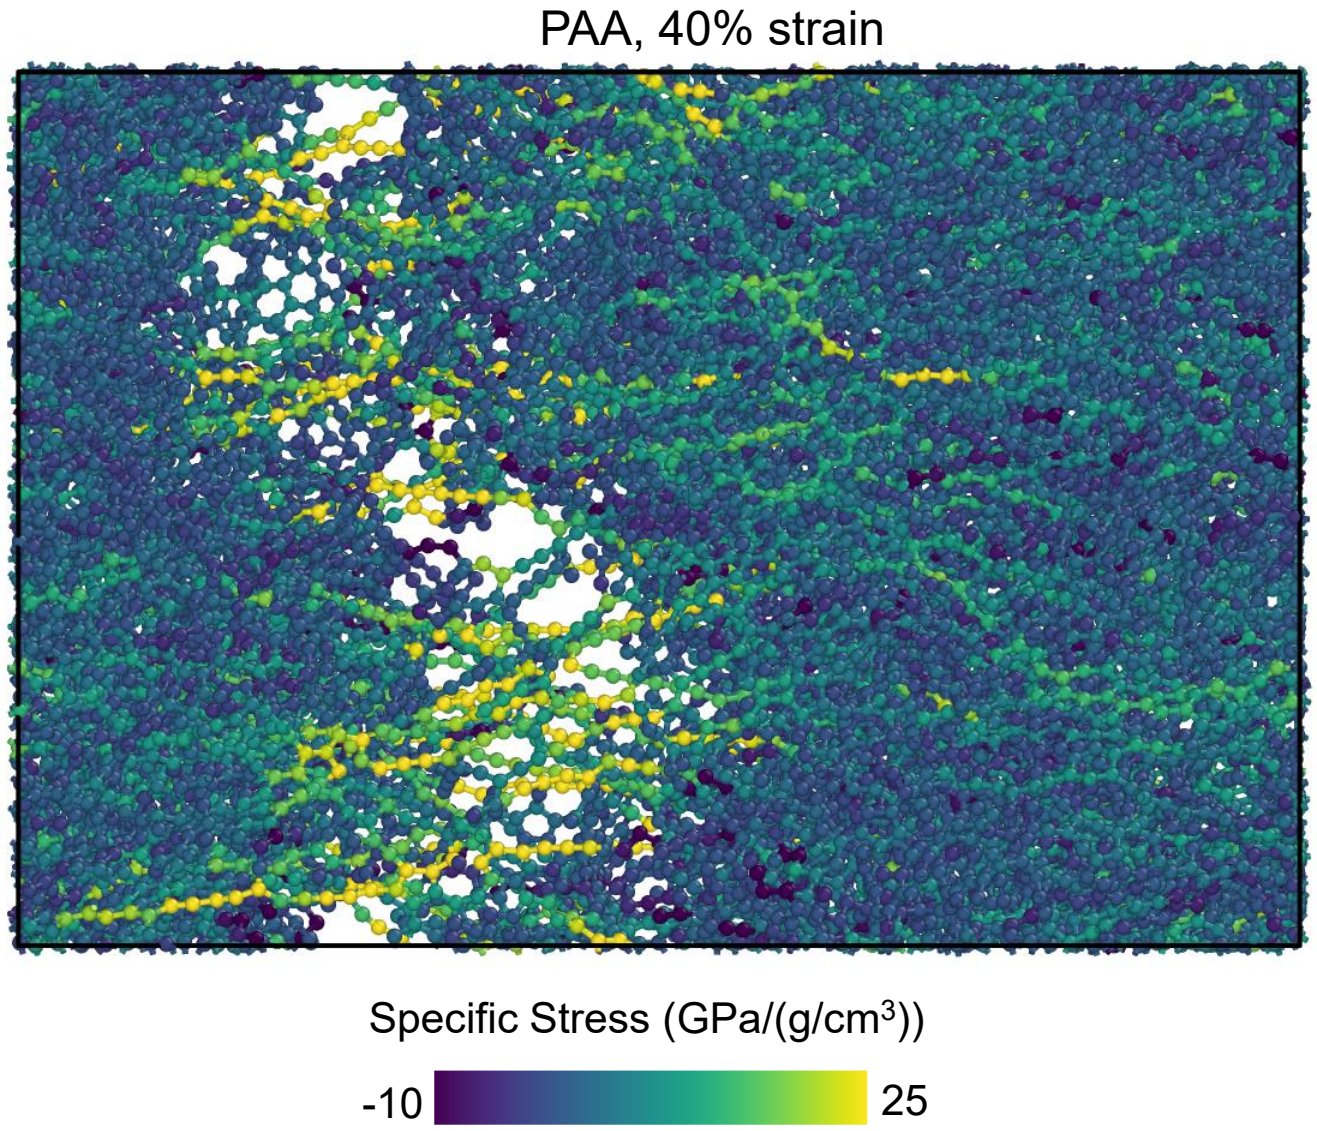






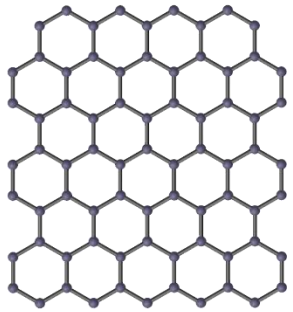


Gissinger et al. "Predicting char yield of high-temperature resins." *Carbon* 202 (2023): 336-347.



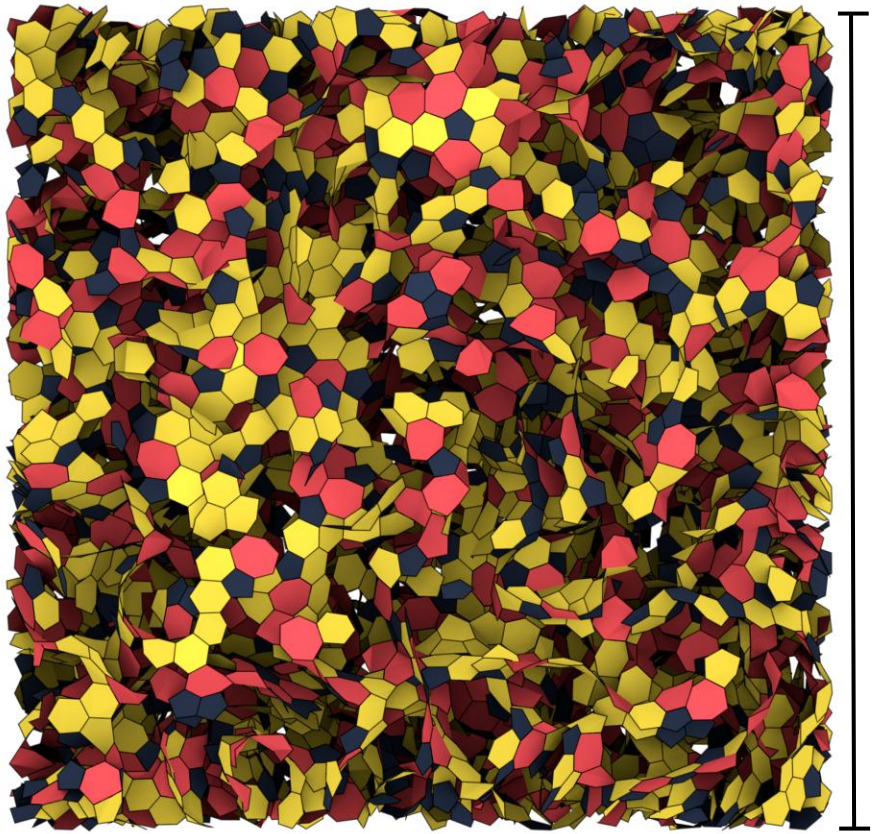
Mechanical Properties of Glassy Carbon

- Nonporous char morphology results in high predicted elastic moduli
- Predicted values in expected range for glassy carbon (~30 GPa @ 1.5 g/cm^3), but far lower than high modulus carbon fibers
- Highlights importance of achieving structures with high density and low defects, porosity

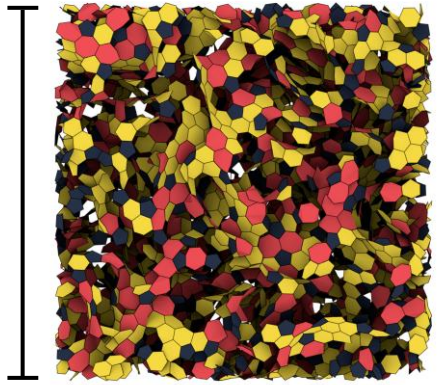


Strain to Failure

Carbon Hybridization/Heteroatoms Evolution



All precursor resins converge to glassy sp^2 carbon as heteroatoms are removed and the system densifies

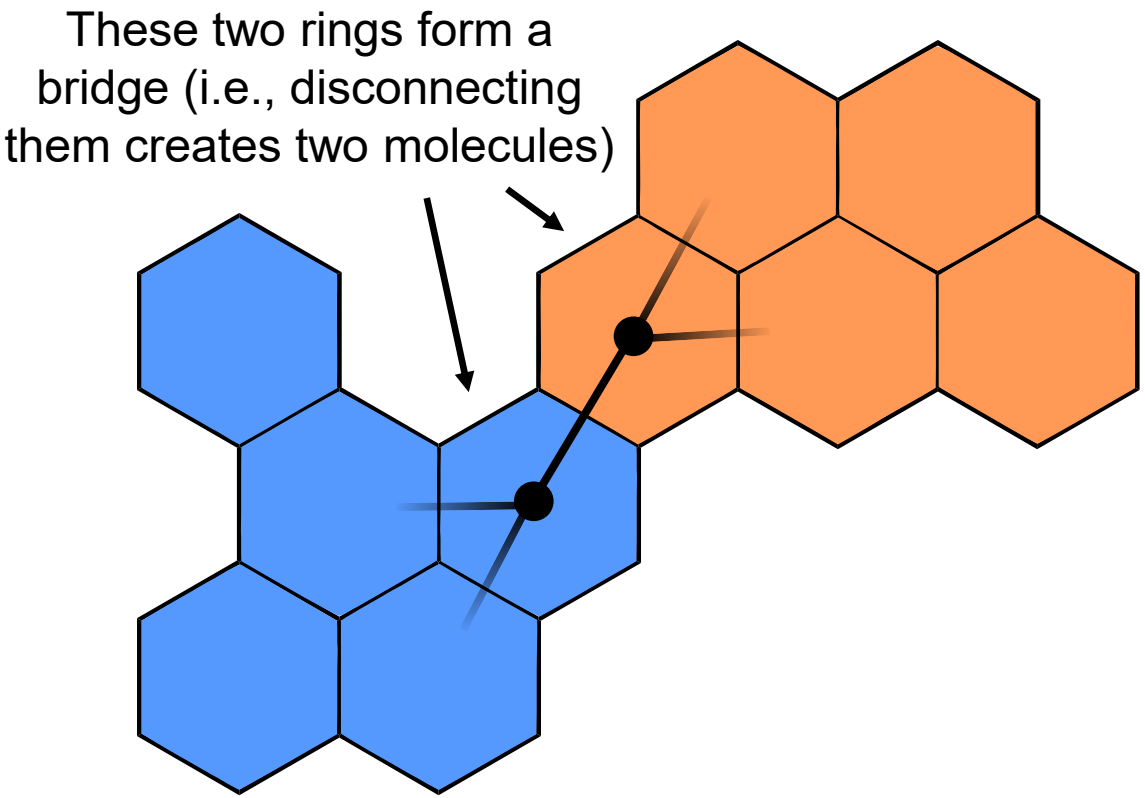


Ternary 'glassy carbon' phase diagram. Axes = fractional number of atoms

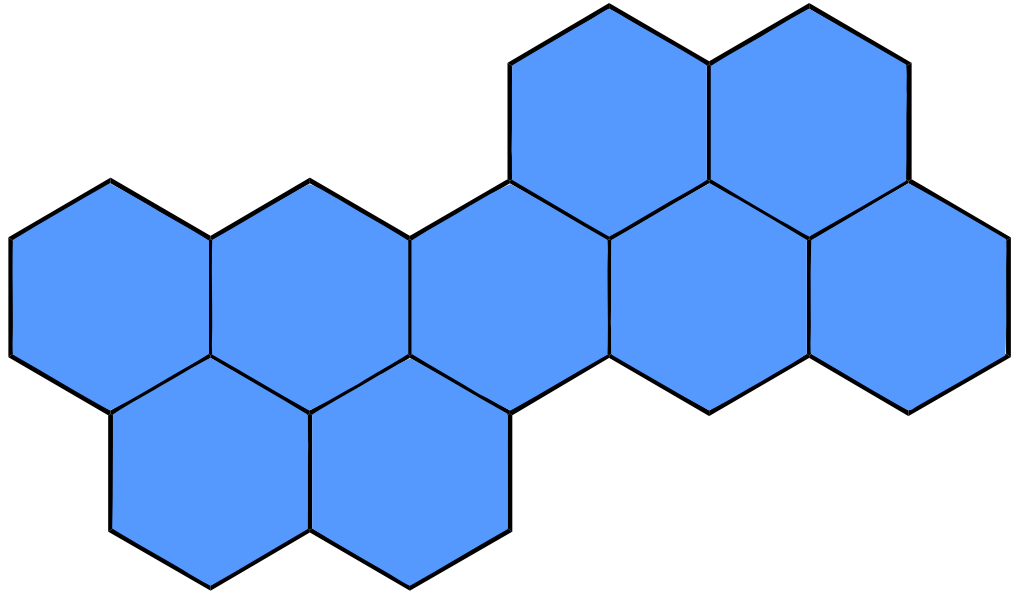
Final Morphology: Ring Distribution

- Final carbonized structure consists primarily of fused five-, six- and seven-membered carbon rings
- Twice as many six-membered rings as other sizes, but rings are well distributed with respect to ring size
- Similar final morphology obtained for lower char yield resins

Polyarylacetylene (PAA)



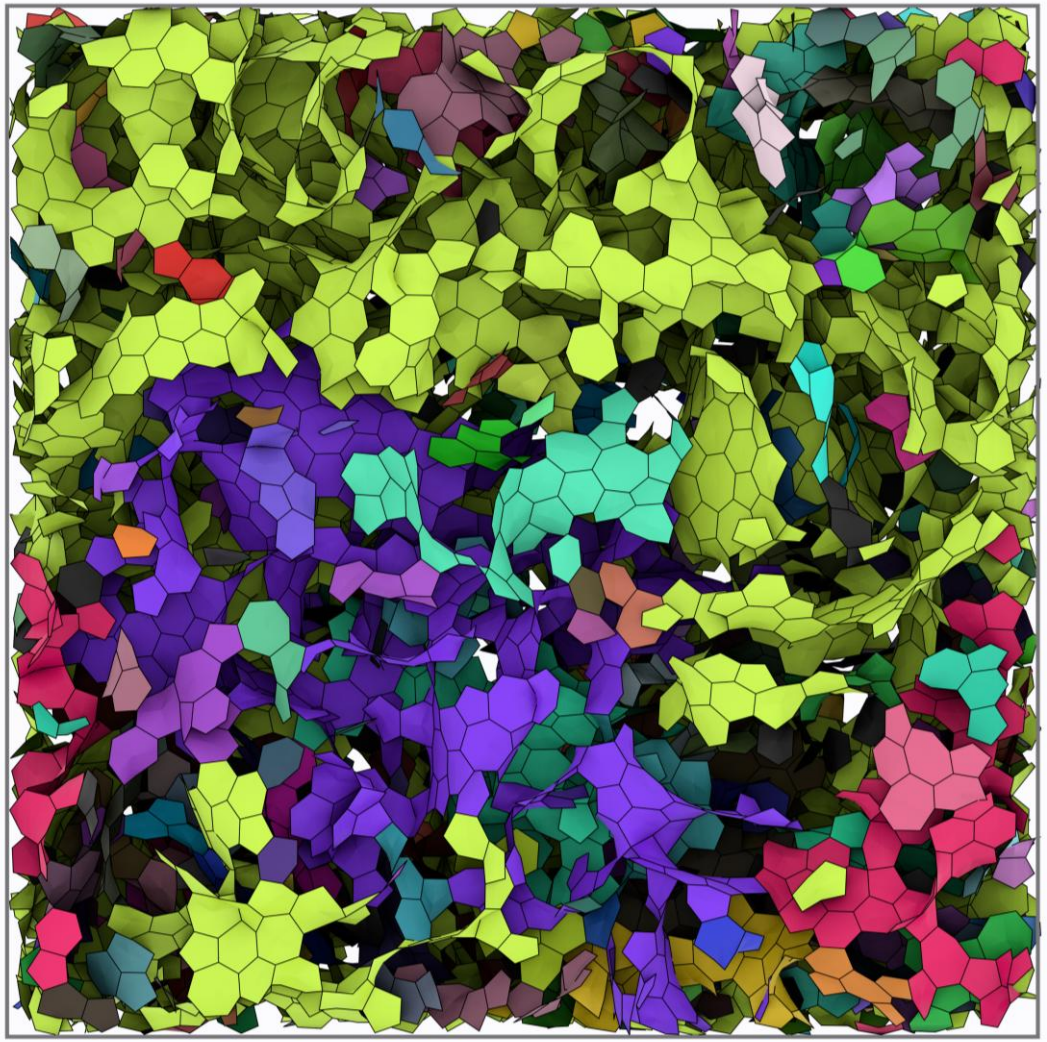
Cyanate ester (BADCY)



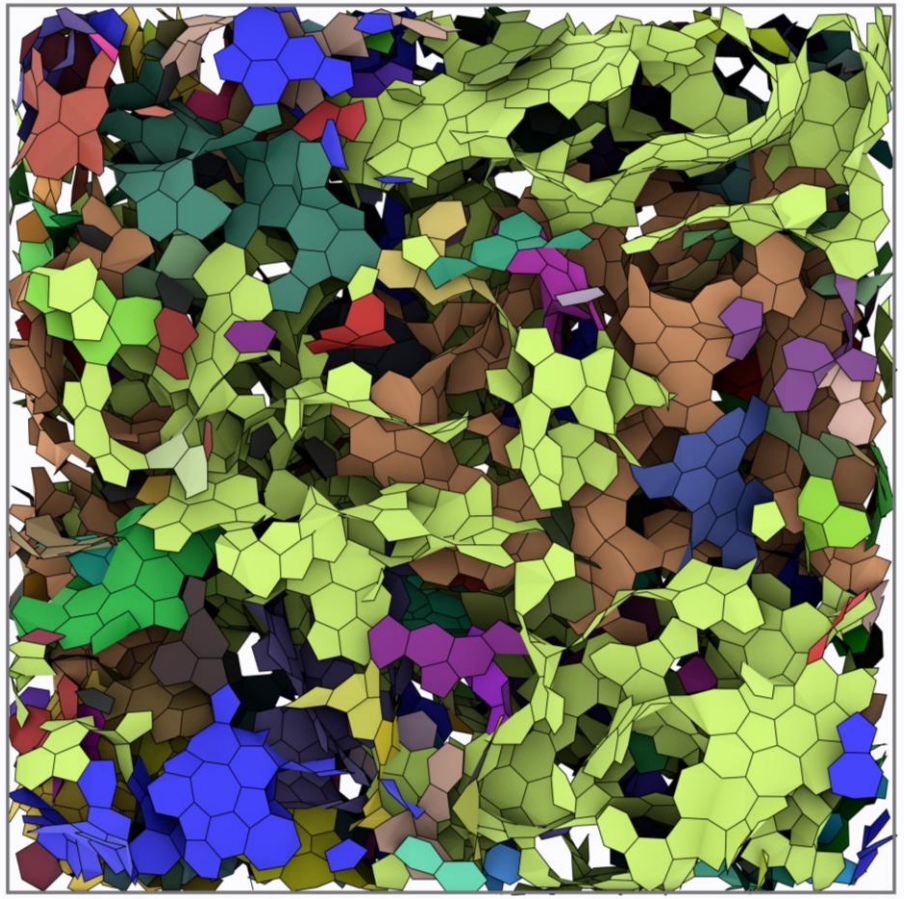
Gissinger et al. *Carbon* 202 (2023): 336-347.

Five-membered ring Six-membered ring Seven-membered ring

Topological Analysis: Cluster Definition

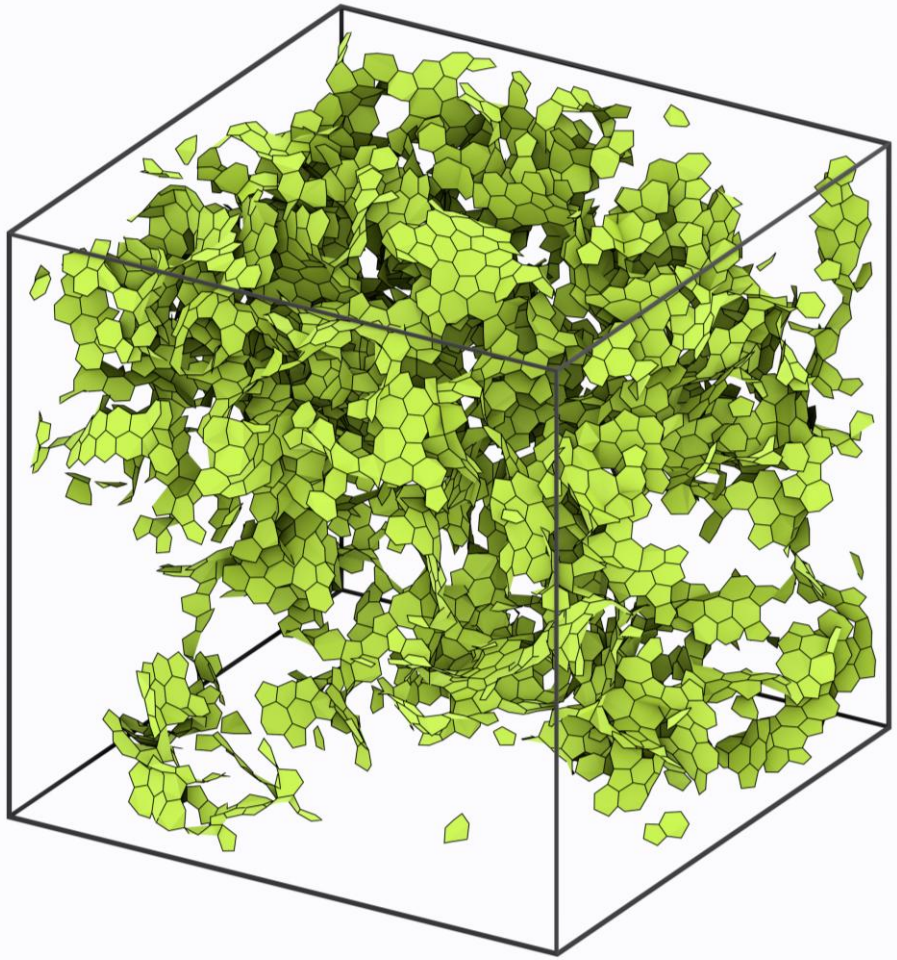


Two clusters

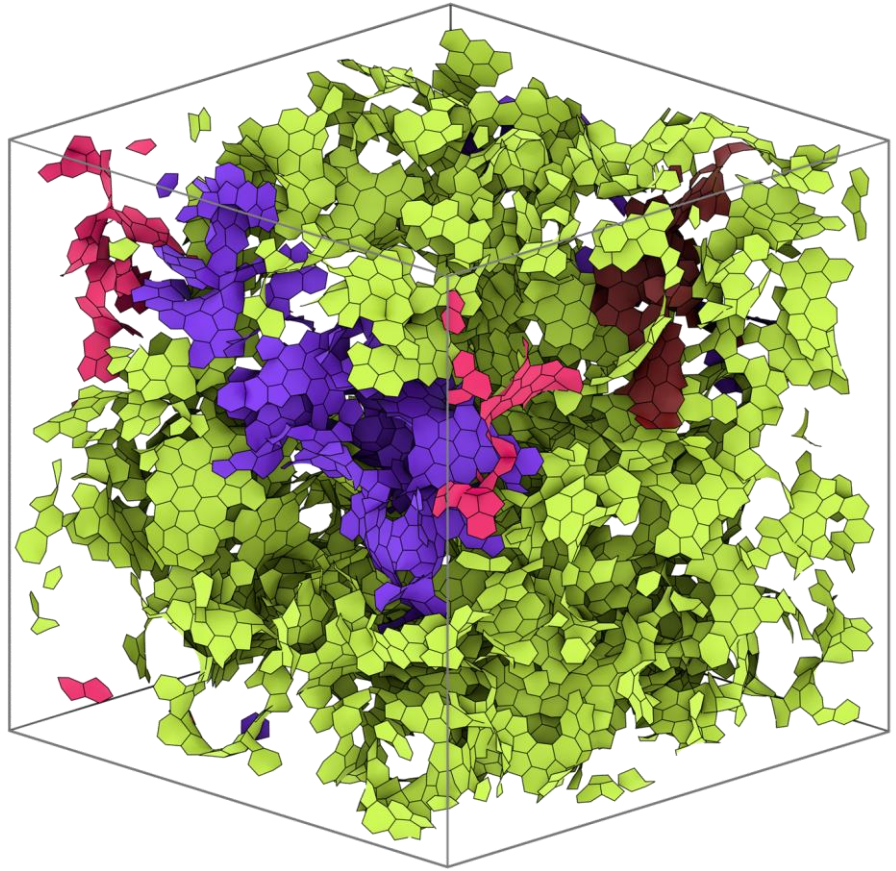


One cluster (no bridges, i.e. each fused ring pair shares at least one other ring)

Final Morphology: Cluster Distribution

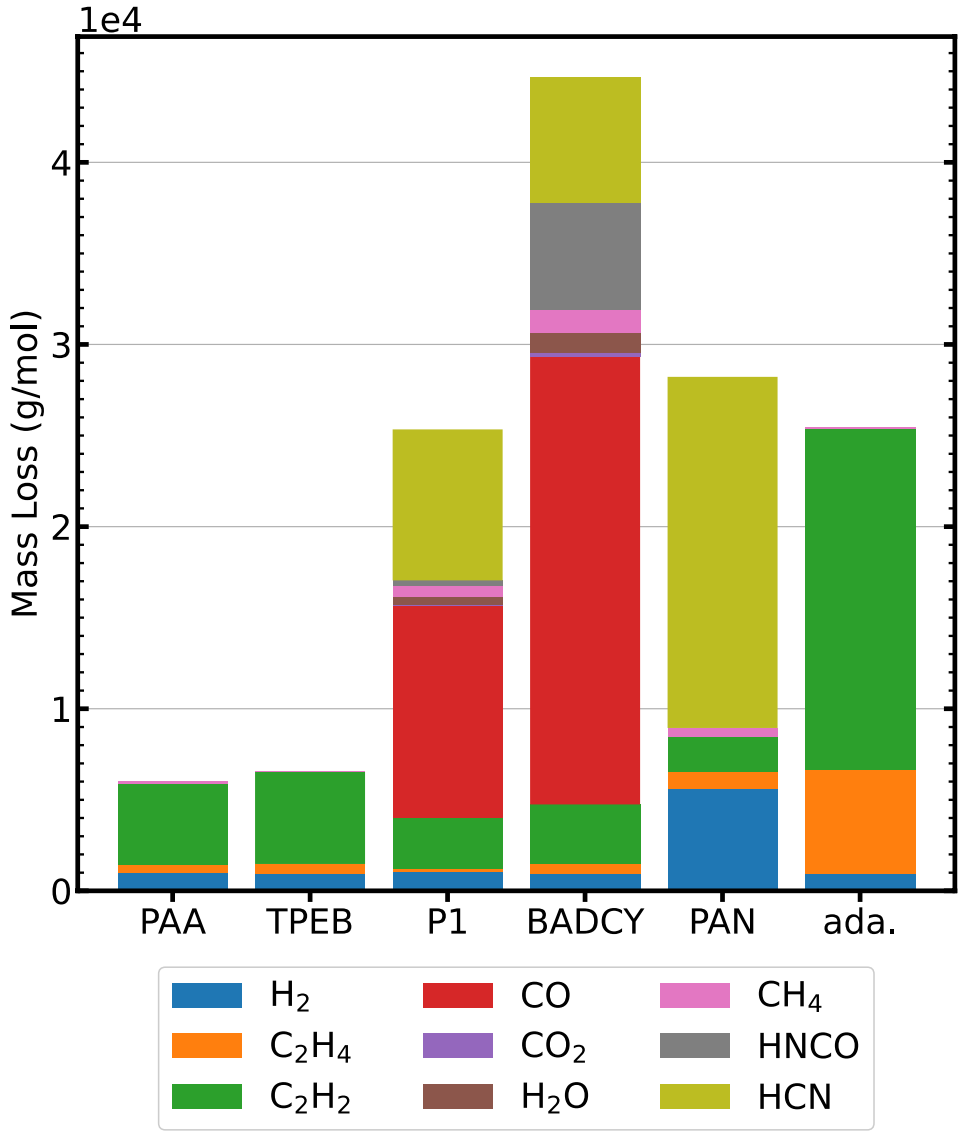


PAA



BADCY

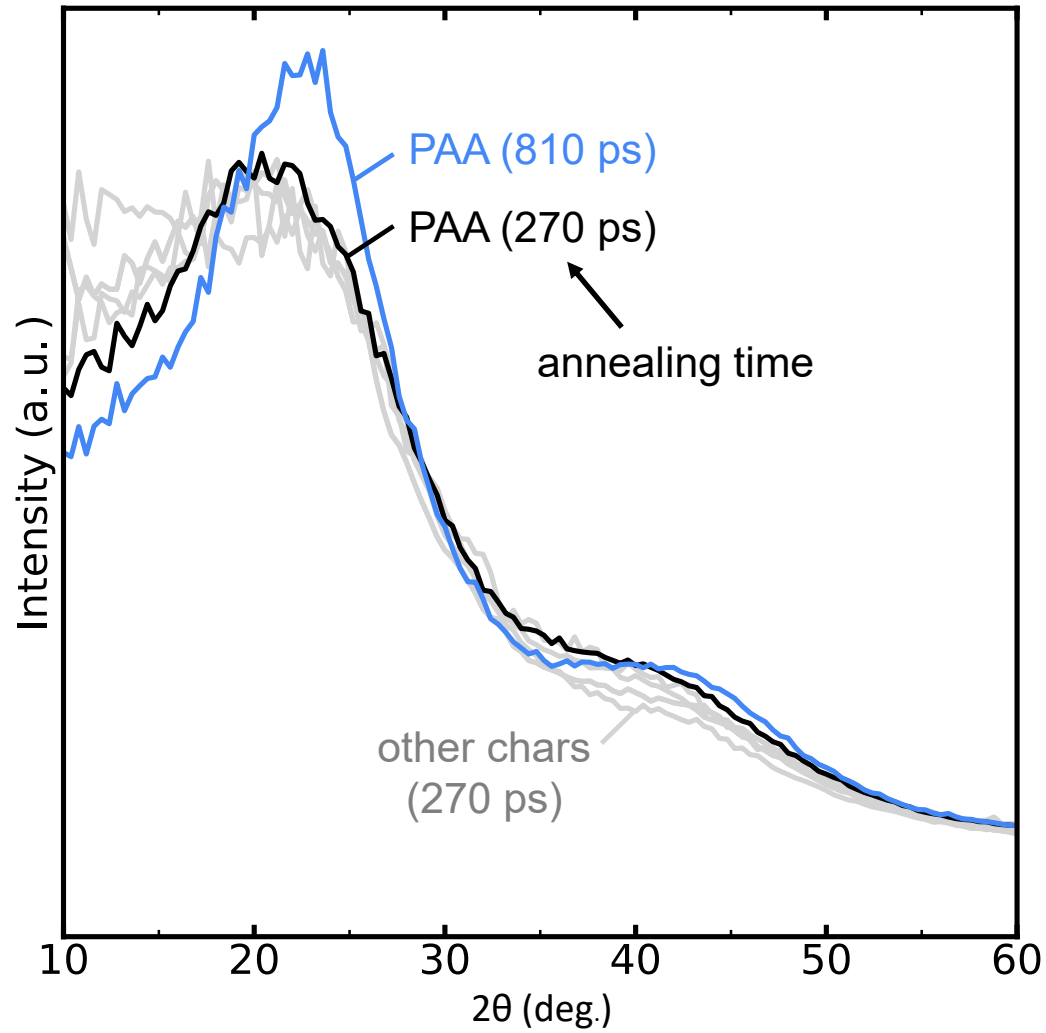
Final Morphology: Cluster Distribution



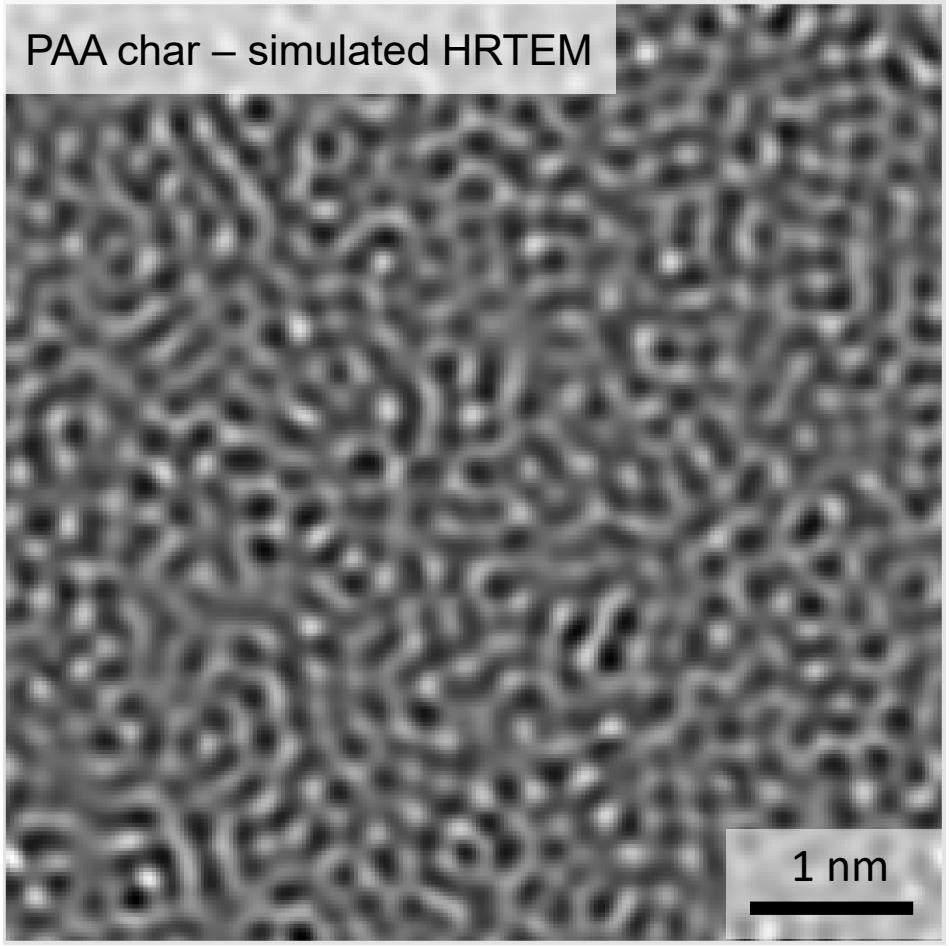
PAA, largest cluster

PAA, top four largest clusters

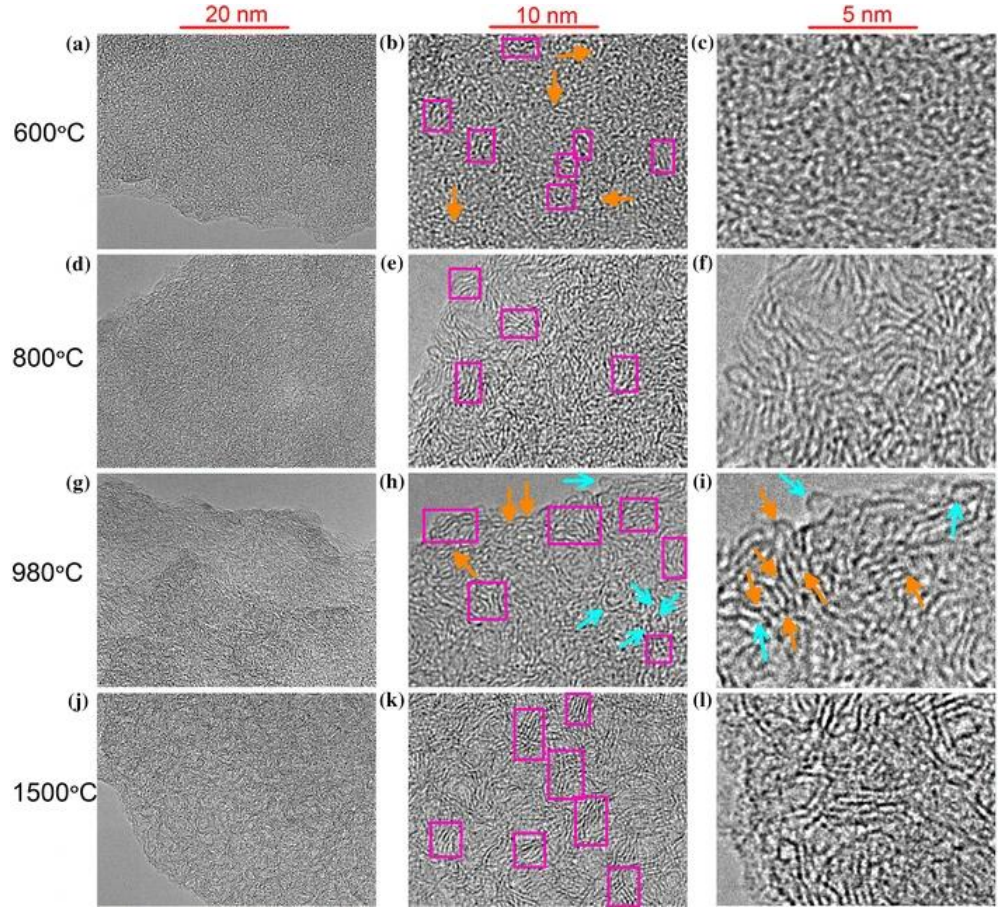
Outgassing Products



- Protocol keeps track of molecules removed from the system to mimic outgassing
- Primarily CO for oxygen-containing resins (highly stable bond)
- Useful metric to compare to experimental techniques such as TGA-mass spectrometry to confirm the chemistry is being captured accurately



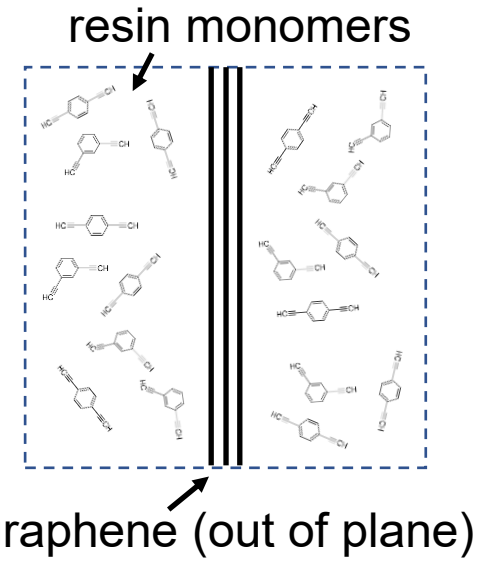
TGA: Thermal Gravimetric Analysis



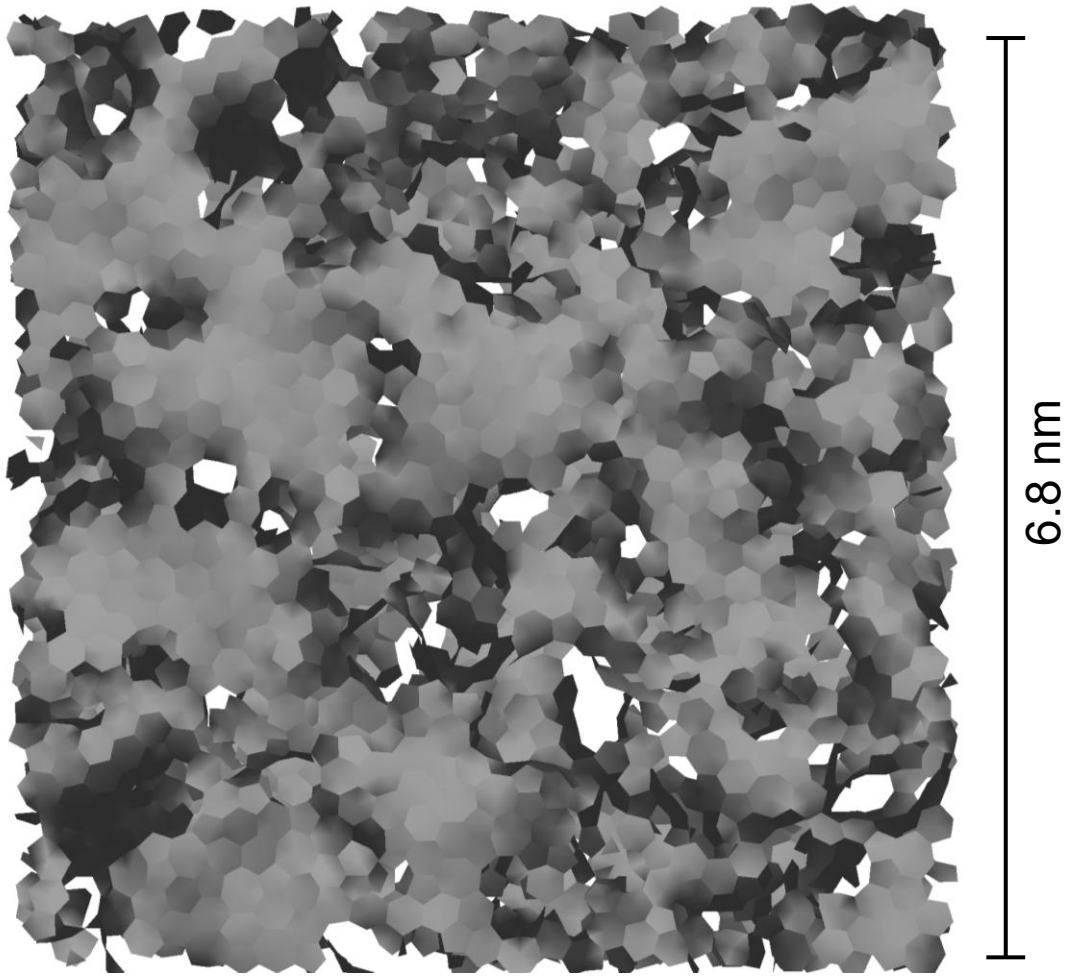
Tools for Direct Experimental Comparison

- Simulated XRD pattern allows for direct comparison with experimental morphologies
- Curve is typical of non-graphitized glassy carbon at lower carbonization temperatures
- The 002 peak, which indicates graphitic structure, notably sharpens after increasing the annealing time

Simulating High-Resolution Microscopy



Experimental HRTEM vs. carbonization temperature

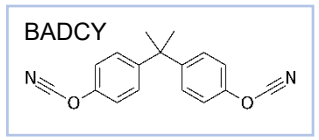


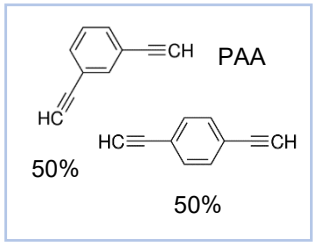
Jurkiewicz, Karolina, et al. "Evolution of glassy carbon under heat treatment: correlation structure–mechanical properties." *Journal of materials science* 53.5 (2018): 3509-3523.

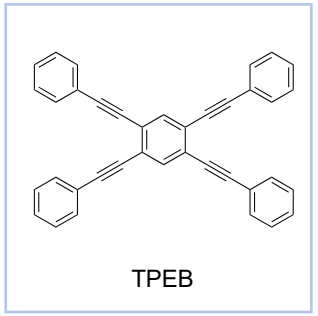
Simulated microscopy consistent with non-graphitized glassy carbon at lower temperatures

Adding Interfaces to the Model

- Triple-layer graphene inserted into initial monomer configuration for composite model
- Bulk PAN char: 54 wt%, 1.76 g/cm^3
- Confined PAN: 42 wt%, 1.96 g/cm^3
- Significantly larger regions of fused six-membered rings observed at interface due to templating effect of graphene

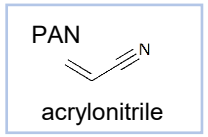




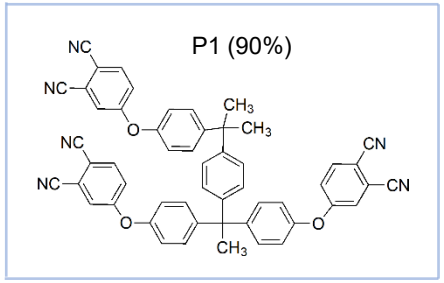


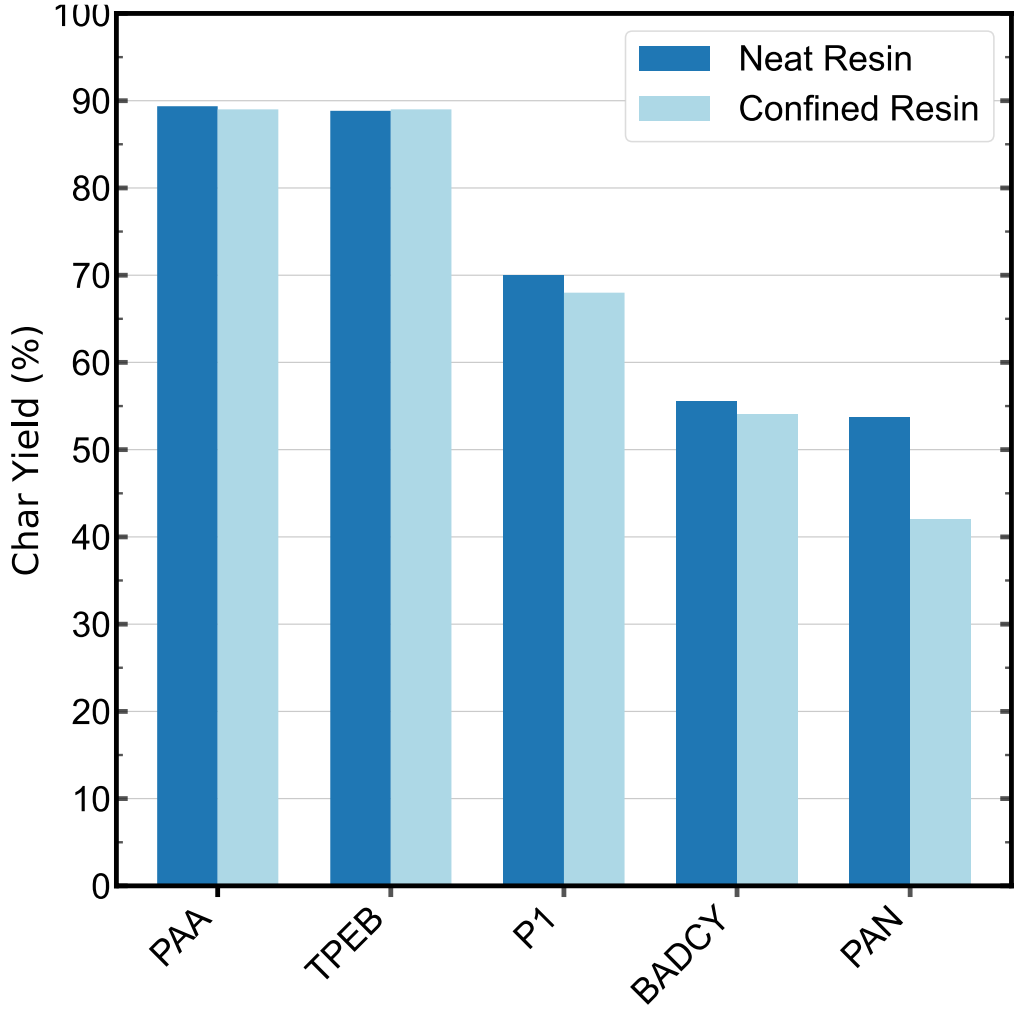
PAN char (graphene hidden)

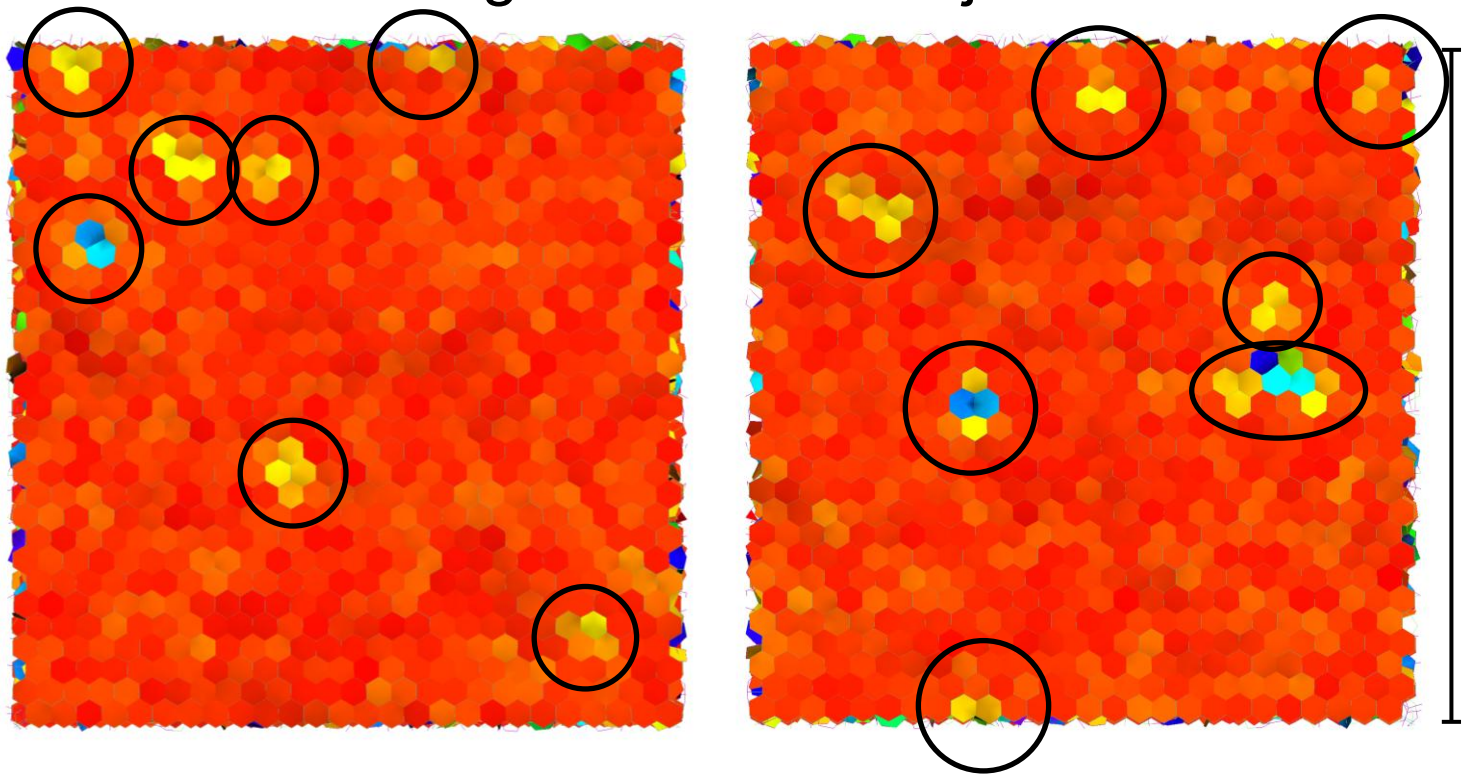
Neat vs Confined Resin Char Yields

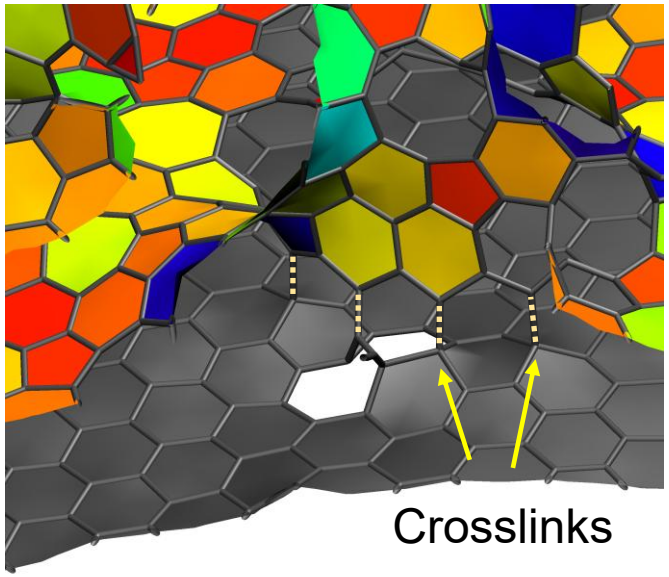


- Char yields for confined resins in composite systems matched those recorded for neat resin
- Implies that prediction of char yield is mostly independent of degree of confinement for this modeling protocol
- Technical Note: Graphene sheets should remain mobile to obtain realistic results



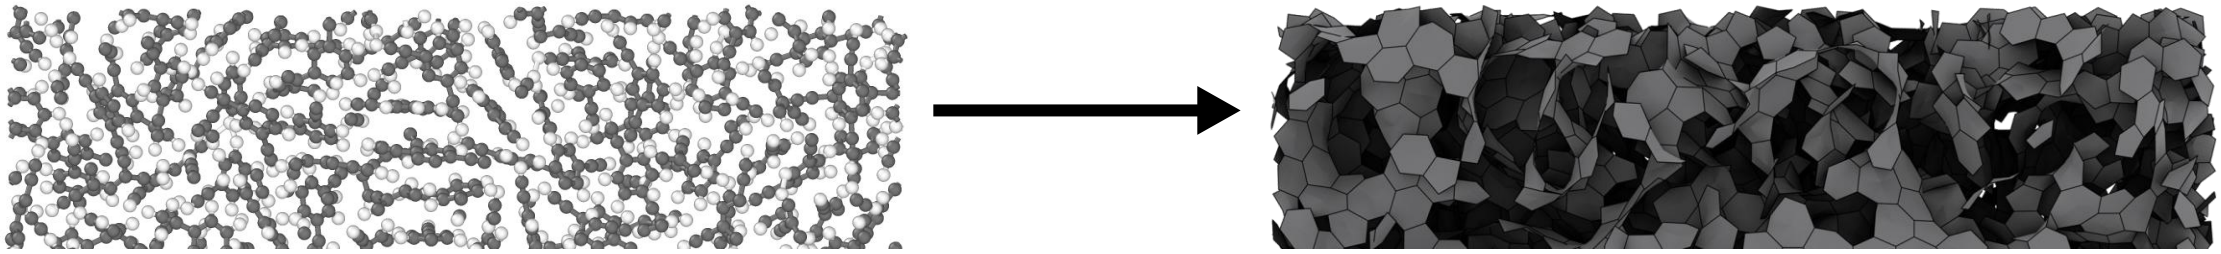






Reactivity at the Graphene Sheet Interface

- It was critical to keep graphene surface mobile to achieve charring behavior
- At each graphene-resin interface (~46 nm^2), crosslinking occurred at ~7 sites, often involving two or more adjacent crosslinks that distort the surface



Non-resin-facing side of graphene sheets with crosslinks indicated

Above, graphene sheets in gray and resin char in color

Promising Method for Predicting Char Yield

- A chemically specific protocol was developed to predict char yield for high temperature resins
  - No prior knowledge of high-temperature behavior required
- Validated for low, medium and high char yield resins with various chemical structures and number of heteroatoms
- Additional outputs include atomistic structure, composition, morphology, mechanical properties, chemical pathways, outgassing products
- Currently being used to investigate and screen new chemistries

Thank You!

Keywords: Automated Fibre Placement, Architected Materials, X-ray Computed Tomography, Finite Element Modelling

ABSTRACT

With the advent of advanced composite additive manufacturing techniques such as Automated Fibre Placement, enhanced control over the layup architectures of composite laminates has become feasible. One notable design opportunity arising from this advancement is the Advanced Placed Ply (AP-Ply) strategy which offers a promising possibility to substantially enhance delamination resistance and damage tolerance in composite laminates. As these architectures involve tows traversing across different laminate plies, conventional ply-wise modelling strategies are insufficient for accurately predicting their mechanical behaviour. A comprehensive understanding of their internal architecture, along with the effective translation of these structural characteristics into numerical models, is therefore imperative. To this end, the present work focuses on the detailed morphological characterisation of AP-Ply laminates and the subsequent development of morphology-informed numerical models. By overcoming the limitations of existing characterisation studies, this approach advances the mechanistic insight into AP-Ply architectures and simultaneously lays the groundwork for rapid and scalable performance prediction of numerous such configurations made possible through tow-level layup customisation.

1 INTRODUCTION

With the growing sophistication in composites manufacturing, there has been a search for novel design strategies that can enhance the critical mechanical properties of composite laminates. Such novel design strategies should be adaptable with advanced manufacturing methods, like Automated Fibre Placement (AFP), to enable their effective integration into current manufacturing practices and support scalable adoption. Among these, Advanced Placed Ply (AP-Ply) architectures present a promising approach to significantly improve delamination resistance and damage tolerance in composite laminates [1,2]. Numerous studies have explored the damage tolerance of these architectures through compression-after-impact (CAI) tests, reporting configuration-dependent enhancements of 5–26% relative to conventional unidirectional composites [2–6]. This is achieved by the strategic modification of the tow placement sequence, to create architectures akin to the textile laminates. The tow drop features formed by interweaving the tows from one ply to adjacent plies act as effective crack arrestors to resist delamination propagation.

The AP-Ply layup strategy strategically skips a defined number of adjacent tows during the initial deposition passes along a specific fibre orientation. Subsequent passes, executed in alternate fibre directions, are then used to populate these intentionally left gaps, resulting in a laminate with consistent overall thickness. An example of AP-Ply architecture employing a single tow skipping is presented in Figure 1.

Figure 1: Buildup of the most straightforward AP-Ply Pattern [0,90].

Altering the sequence of tow placement in AP-Ply laminates facilitates the creation of varied meso-architectures, each with distinct mechanical characteristics. However, determining the optimal configuration for a specific application through trial-and-error methods is resource-intensive and time-consuming. This highlights the necessity for a robust computational framework capable of accurately predicting both mechanical responses and failure mechanisms in such complex architectures.

Conventional ply-level modelling approaches are inadequate for representing AP-Ply laminates, as these architectures feature inter-ply tow transversal. To address this, several modelling strategies have emerged. Li et al. [7] developed a tow-wise modelling (TWM) methodology, which showed good agreement in predicting short beam strength [8], though it underperformed in simulating damage propagation under low-velocity impact [5]. Alternatively, Kok et al. [9] proposed a unit-cell-based model that homogenised undulation zones into simplified box-like elements. While this approach produced satisfactory results for quasi-static and dynamic tensile simulations [9,10], it also fell short in accurately predicting impact-induced damage [6].

These inconsistencies stem from oversimplifications in the representation of meso-scale features. Existing models often approximate tow cross-sections as idealised rectangles and address tow junctions using separation-based contact interactions or homogenisation techniques [7,9], rather than explicitly modelling the tapering of tows near the edges. Realistic simulation of deformation and damage progression at the tow level requires a detailed geometrical description of the mesoscale architecture, particularly the "tow drops", which are distinct geometric features formed where tows shift between plies.

Two principal domains have addressed meso-structural characterisation of tow drops. The first focuses on fibre waviness induced by defects such as gaps or overlaps during the layup process, which can degrade in-plane performance by up to 45% [11–13]. Here, parameters like undulation amplitude, wavelength, and angle are commonly extracted from optical micrographs, with sinusoidal representations often used to approximate tow trajectories [14–17]. However, these investigations primarily deal with isolated features and do not reflect the periodicity and complexity of patterned AP-Ply designs.

The second area relates to textile composites, where post-consolidation fibre geometry has been extensively studied using various characterisation techniques, particularly X-ray computed tomography (CT) [18–20]. Various segmentation strategies have been introduced to identify individual tow morphology, including automated approaches based on structure tensor analysis of greyscale intensity gradients [21,22]. However, challenges persist in resolving tow structures at lower voxel resolutions, that are required to capture large-scale architectural patterns, due to low phase contrast in carbon fibre-reinforced polymers (CFRPs). Even advanced techniques such as structure tensor filtering or contour stitching struggle to delineate tow boundaries when in-plane intensity gradients are weak.

This work presents the first comprehensive attempt to parametrically evaluate the post-consolidation tow morphology in AP-ply laminates using a combination of multiple characterisation techniques. High-resolution microscopic imaging is employed to capture out-of-plane undulation characteristics, while low-resolution CT scans with large scanning windows enable 3D visualisation of the periodic tow structure. A novel through-thickness morphological gradient based approach is introduced which leverages directional differences in X-ray attenuation caused by fibre orientation to enhance the visibility of low-contrast features, enabling more effective interpretation of internal geometry in CFRPs. The extracted morphological parameters are then incorporated into finite element simulations of tensile behaviour, with the numerical predictions validated against experimental results from corresponding AFP-fabricated specimens.

2 EXPERIMENTAL PROGRAM

2.1 Manufacturing

Three distinct AP-Ply laminate configurations with [0/90] design were fabricated (as shown in Figure 1), each differing in the spacing between adjacent tows. The first configuration followed the standard AP-Ply layup, incorporating a single tow gap that was subsequently filled during later passes in the same orientation. In contrast, the second and third configurations introduced additional inter-tow gaps measuring 40% and 80% of the tow width respectively, which resulted in final inter-tow gaps of 20% and 40% of the tow width after all passes were completed.

Carbon fibre epoxy prepreg tapes (HTS45E23/E−752-LT) by Park Aerospace, were used for the layup. Each tape measured 6.35 mm in width and 0.19 mm in thickness. The layup process was carried out using an AFP machine developed by Trelleborg Sealing Solutions® located at the University of New South Wales. For each configuration, ten AP-Ply style plies were deposited to form square panels measuring 300 mm × 300 mm. Curing was performed in an ASC autoclave at 177°C and 6.2 bar, following the supplier's recommended protocol.

Prior to consolidation, surface irregularities were evident across all panels. These were caused either by out-of-plane waviness in the no-gap configuration or by the presence of inter-tow gaps in the gapped variants. However, post-consolidation, all laminates exhibited smooth and uniform surfaces. This can be attributed to tow spreading, which not only filled the gaps but also led to a reduction in overall thickness for the gapped panels. Final thicknesses were measured at 2.55 mm and 2.2 mm for the 20% and 40% gap configurations, respectively. In contrast, the baseline and 0% gap panels retained a thickness of 3 mm, consistent with the material's standard specification. Figure 2 illustrates the layup progression for the 40% gap configuration.

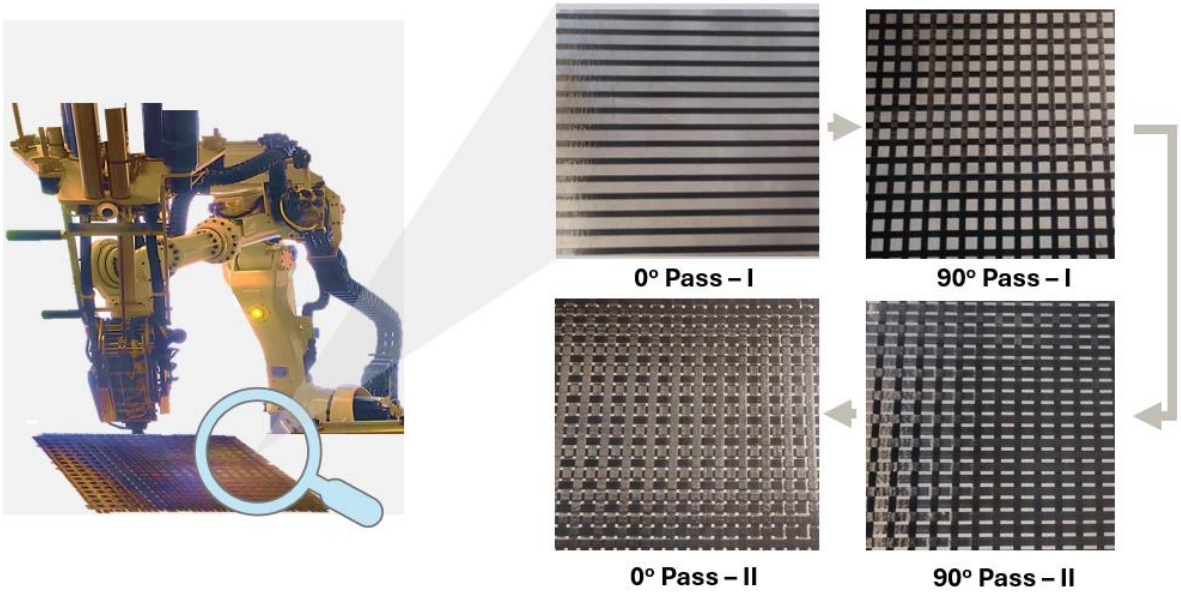

Figure 2: Hot gas torch-based AFP machine at UNSW Sydney. The right side of the figure presents a robot layup sequence during the fabrication of 40% gap AP-Ply configuration.

2.2 Optical Microscopy

The undulation patterns were analysed using optical microscopy to examine the internal structure of the laminates. For each configuration, small specimens were extracted along the midline of the undulating tows. Microscopic imaging was performed using a DSX510 optical microscope operating at 10× magnification. The boundaries of the undulating tows were extracted through digital image processing of the obtained high-resolution optical micrographs. A sine wave-like curve emerged when the manually traced coordinates were plotted on the X-Y axis. This curve was then fitted to a sine

function to characterise the undulation. By calculating the maximum slope of the fitted curve, the out-of-plane undulation angle was estimated. Figure 3 graphically illustrates the methodology described above.

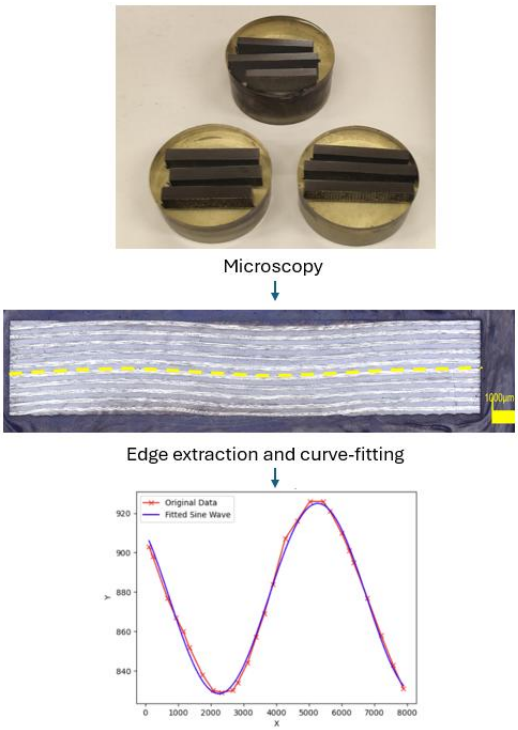

Figure 3: Characterisation methodology for optical microscopy method.

2.3 X-Ray CT scanning

To complement the 2D insights from optical microscopy, a three-dimensional understanding of the laminate morphology was obtained through X-ray computed tomography (CT). Using a HeliScan™ micro-CT system (Mark I), samples from each configuration measuring 44 mm x 35 mm were scanned. A voxel resolution of 29.44 µm was selected, balancing the need to capture at least twice the representative unit cell (RUC) size with sufficient detail to resolve the sinusoidal tow undulations.

Scans were conducted along a circular trajectory at 60 kV and 105 µA, with a 1 mm aluminium filter, and the rotation axis aligned parallel to the warp (1st pass) tows. This setup ensured that the warp fibres remained perpendicular to the X-ray beam throughout the scan, while the weft fibres rotated from perpendicular to parallel orientations. Due to their alignment with the X-ray beam during scanning, the weft fibres experienced increased attenuation, primarily caused by small-angle scattering. This resulted in slightly higher intensity values for such voxels. To verify that this contrast was directionally dependent, the laminate (20% gap configuration) was rotated so that the weft fibres remained perpendicular to the beam throughout the scan. Under this new orientation, the warp fibres exhibited increased intensity, confirming the influence of fibre orientation on X-ray attenuation.

Because the inter-ply spacing was much smaller than the voxel resolution and no universal threshold could reliably distinguish warp from weft tows, conventional segmentation techniques proved ineffective. To overcome these limitations, signal processing-based algorithms were developed to identify individual tows within the bulk laminate structure.

Prominent intensity peaks, attributed to the asymmetrical scanning setup, were observed in the through-thickness intensity profiles and corresponded to the weft tows. These peaks were used to precisely map the geometry of the weft tows. As demonstrated in the 20% gap configuration, rotating the CT scan setup proves to be an effective approach for characterising the geometry of warp tows.

To detect the most prominent peaks in the intensity data, the find_peaks function in Python was applied, using a minimum spacing parameter based on ply thickness. However, due to sub-peak

detection or missing prominent peaks, the number of detected peaks sometimes differed from the actual number of weft plies. To correct these inconsistencies, a sequence correction algorithm was introduced. This method replaced inaccurate peak sets, those with incorrect lengths, with corrected ones inferred from adjacent regions where the peak count matched the expected ply number. Figure 4 presents the flow chart for the above-described characterisation methodology.

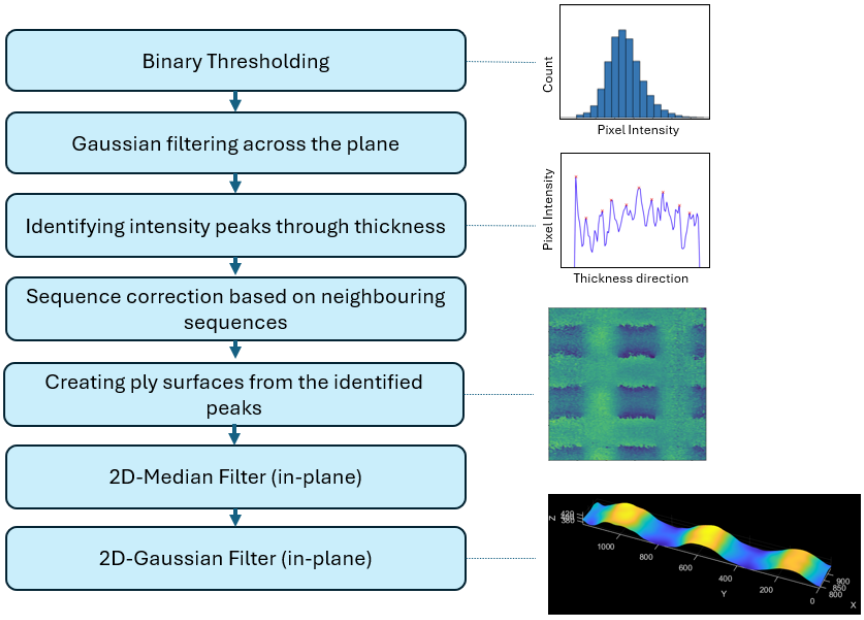

Figure 4: Characterisation methodology for individual tow segmentation using CT-scan data.

2.4 Tensile testing

Following ASTM D3039, tensile tests were conducted to evaluate the static mechanical performance of the fabricated laminates. Using a water-cooled diamond saw, five specimens per configuration were sectioned to 35.56 mm × 254 mm, with their length aligned along the warp direction. To mitigate fibre damage at the grips, 82 mm-long glass fibre tabs were bonded to both ends using epoxy resin. Testing was performed on an Instron 3369 machine, equipped with hydraulic grips to maintain secure clamping. A constant displacement rate of 2 mm/min was applied throughout the test. Strain measurement was achieved using unidirectional linear gauges placed on the underside of each specimen, directly above a non-undulating warp tow.

3 FINITE ELEMENT MODELLING

To preserve key architectural features while maintaining computational efficiency, several geometric simplifications were introduced in the AP-Ply laminate models:

1. Instead of manually modelling the unique undulation angle for each tow, the average undulation angle derived from microscopy data, was applied uniformly across all tows in both directions.
2. The sinusoidal out-of-plane tow paths were idealised as trapezoidal trajectories. This assumption, commonly adopted in textile composite modelling improves mesh conformity and eliminates voids, thereby enhancing computational performance.
3. A trapezoidal cross-section was assigned to each tow, to capture the tapering at tow edges. This choice complements the trapezoidal undulation profile and further facilitates the generation of a conformal mesh.

Figure 5 illustrates the representative geometric models constructed using these assumptions.

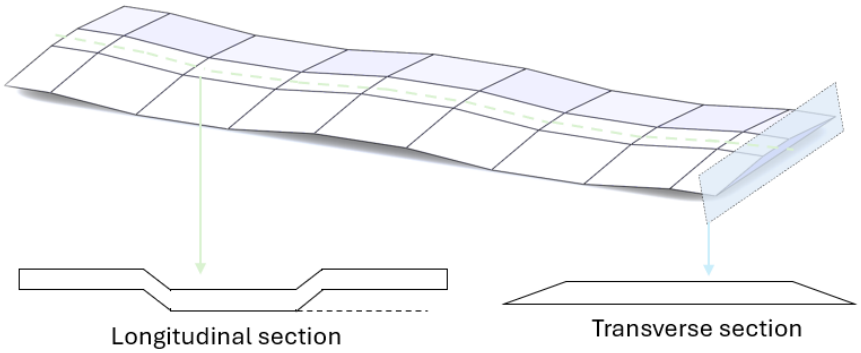

Figure 5: Representative geometry of the undulating tow along with longitudinal and transverse cross sections views.

To predict failure initiation in composite laminates, 3D Hashin criterion is employed due to its ability to differentiate between fibre and matrix damage under both tensile and compressive loads [23]. This extended formulation consists of four distinct sub-criteria, each addressing a specific failure mode.

Fibre tension failure:

$$F_{ft} = \left(\frac{\sigma_{11}}{X_t}\right)^2 + \left(\frac{\sigma_{12}}{S_{12}}\right)^2 + \left(\frac{\sigma_{13}}{S_{13}}\right)^2 \geq 1 \tag{1}$$

Fibre compression failure:

$$F_{fc} = \left(\frac{\sigma_{11}}{X_c}\right)^2 \geq 1 \tag{2}$$

Matrix tension failure:

$$F_{mt} = \left(\frac{\sigma_{22}+\sigma_{33}}{Y_t}\right)^2 + \left(\frac{\sigma_{23}^2-\sigma_{22}\sigma_{23}}{S_{23}^2}\right) + \left(\frac{\sigma_{13}}{S_{13}}\right)^2 + \left(\frac{\sigma_{12}}{S_{12}}\right)^2 \geq 1 \tag{3}$$

Matrix compression failure:

$$F_{mc} = \left(\frac{\sigma_{22}+\sigma_{33}}{2S_{23}}\right)^2 + \frac{\sigma_{22}+\sigma_{33}}{Y_c}\left[\left(\frac{Y_c}{2S_{23}}\right)^2 - 1\right] + \left(\frac{\sigma_{23}^2-\sigma_{22}\sigma_{23}}{S_{23}^2}\right) + \left(\frac{\sigma_{12}}{S_{12}}\right)^2 + \left(\frac{\sigma_{13}}{S_{13}}\right)^2 \geq 1 \tag{4}$$

Post-failure behaviour in composite laminates is heavily influenced by how damage evolves across different failure modes. Although various softening laws, like linear, exponential, or sigmoidal, have been proposed [9,24], the bilinear softening model offers the most accurate representation of tensile stress-strain response along the fibre direction [24,25] and hence been used to simulate fibre tensile damage evolution in this work. Damage evolution for the remaining failure modes is modelled through linear softening model.

To simulate inter-tow interactions, built-in contact algorithms in ABAQUS were used. Cohesive surfaces governed by a linear traction-separation law captured interlaminar behaviour, with delamination strength defining the peak traction. Normal and tangential contact forces were handled using ABAQUS' general contact algorithm, where a hard contact condition was applied to prevent ply interpenetration. The material parameters for the prepreg tapes (HTS45E23/E−752-LT) were utilised according to the specifications outlined in previous studies [8,26,27].

Displacement-controlled boundary conditions were imposed at one end of the laminate, while the opposite end was fully constrained in ABAQUS Explicit. A smooth ramp function was used to gradually increase displacement to reduce dynamic effects from sudden loading.

Mesh sensitivity analysis guided the selection of a 0.5 mm mesh size, ensuring reliable results without excessive computational cost. Given the trapezoidal tow geometry, wedge elements (C3D6) were employed to maintain uniform meshing. Element deletion was triggered when the fibre damage factor exceeded 1, indicating complete stiffness degradation in the fibre direction.

4 RESULTS

4.1 Optical Microscopy

To quantify tow undulation, edge coordinates from the fifth ply were extracted and fitted to a sine function, enabling derivation of undulation parameters for each laminate configuration. While the 0% gap configuration exhibited a near-perfect sinusoidal trajectory, and the 20% gap case followed a similar pattern, the 40% gap configuration deviated significantly. This disruption was caused by ply slippage, which introduced irregular overlaps and gaps at tow junctions, resulting in alternating steep and shallow undulation slopes.

Figure 6 reports the undulation angles along with associated uncertainties. In both the 0% and 20% gap cases, the weft direction exhibited higher undulation angles than the warp. However, the 20% gap configuration showed reduced undulation angles overall, attributed to thinner tows and increased spacing between them.

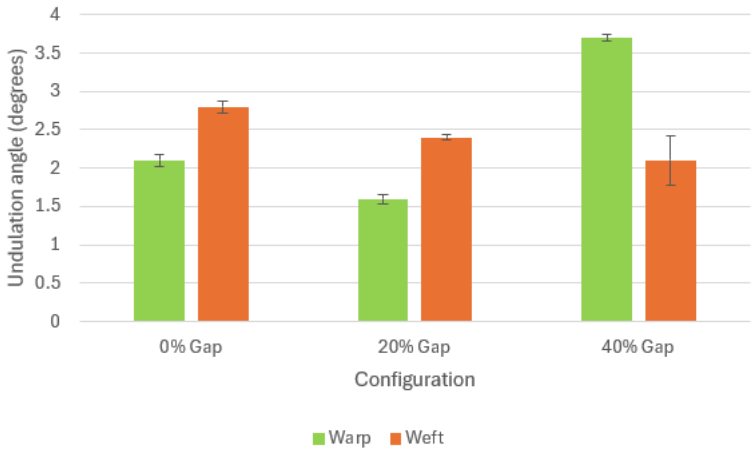

Figure 6: Microscopy derived undulation angle for each AP-Ply configuration in both warp ad weft direction. Error bars represent standard deviation.

4.2 X-Ray CT scanning

To locate the mid-planes of warp and weft tows, morphological gradients along the thickness direction were analysed. After filtering, the 3D geometry and mid-line trajectory of the same ply are visualised in Figure 7. The undulating tows in the 0% case closely follow sinusoidal path, where 20% gap case showed considerable deviation. This regularity breaks down further in the 40% gap configuration, where the trajectory shows altering pattern mirroring microscopy observations.

Doubly curved mid-planes of the weft tows at the crest zones were a unique morphology characteristic observed in 3D analysis. These curvatures are due to their location directly beneath the undulations of the warp tows. In contrast, peak regions above straight tows show no such curvature. However, CT scan analysis consistently reported angles 15–20% lower than microscopic observations for various directions and configurations. This discrepancy stems from the limited resolution of CT scans, where undulation heights are only 4–5 times the voxel size.

Still, CT-based measurements correctly captured key trends such as higher weft undulation angles in the 0% gap case than the warp angles and a general reduction in angle for the 20% gap configuration. While CT offers valuable 3D visualisation, its quantitative accuracy remains resolution-dependent.

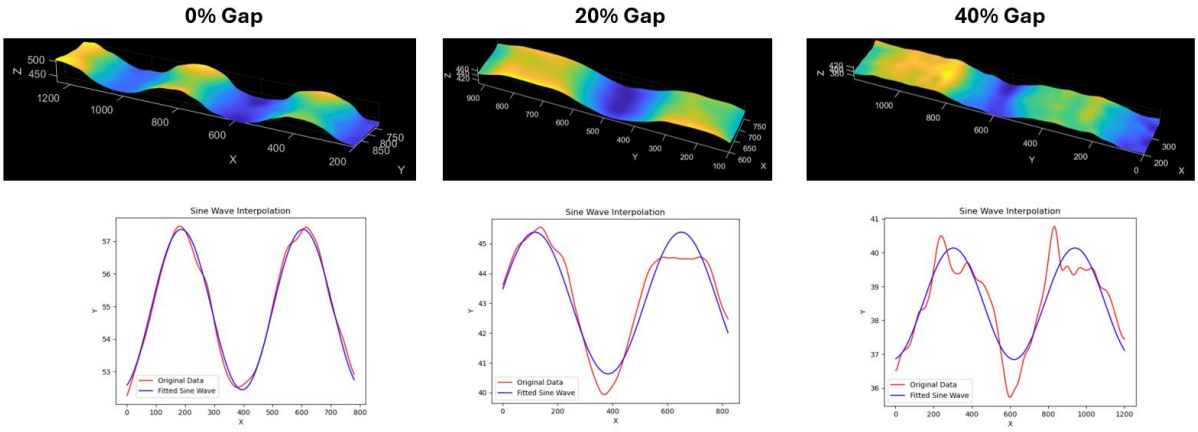

Figure 7: Visualisation of the undulating tows in each AP-ply configuration and their corresponding out-of-plane trajectory (with fitted sine-curve).

4.3 Tensile performance

The tensile response of AP-Ply laminates was simulated using the morphologically-informed model described in Section 3. Figure 8 compares the simulated tensile behaviour for each configuration with the experimentally observed response. Given the high degree of manufacturing inconsistencies observed in 40% gap laminate, this configuration was excluded from the FEA analysis. Table 1 presents a summarized comparison of the numerical and experimental strength values. Compared to conventional models [8,9], this approach significantly improves predictive accuracy.

Minor under-prediction of strength was observed across simulations, specifically for 0% gap configuration. This can be attributed to the to the sharp geometric transitions in the modelled laminate, which differ from the smoother contours found in actual specimens. Despite experimental results showing nearly identical strength, the simulation predicted slightly higher values for the 20% gap configuration than the 0% gap case. This discrepancy stems from minor defects found during characterisation of the 20% gap samples, which were not included in the model.

The numerical model effectively captured both the onset and evolution of tensile failure mechanisms. Owing to the lower strain-to-failure threshold in the matrix compared to the fibres, matrix tensile damage initiated early in the transverse tows. This damage mode progressively intensified, ultimately leading to complete matrix failure and a significant reduction in transverse stiffness within the failed tows much before fibre failure occurred.

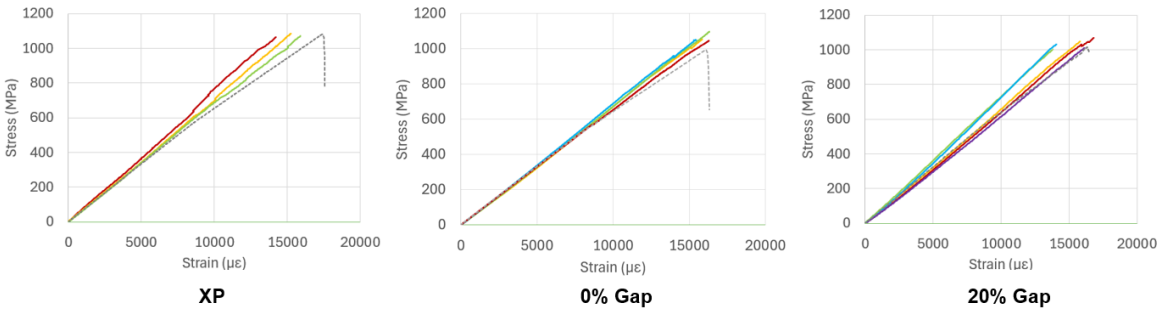

Figure 8: Stress-strain response obtained through simulation for each configuration.

Configuration	Strength, MPa (CV%)	Simulated Strength, MPa	Error (%)
XP	1087.92 (2.00%)	1082.08	-0.54%
0% Gap	1055.09 (2.60%)	997.38	-5.47%
20% Gap	1032.75 (2.70%)	1012.67	-1.94%

Table 1: Comparison of experimental and simulated tensile strength.

Figure 9 shows the stress field maps which identifies the stress concentration sites in longitudinal tows, particularly near nodes where transverse tows taper. These regions are formed by the intersection of flat and sloped surfaces which creates sharp edges that triggered fibre failure. Once initiated, failure propagated rapidly due to low fracture toughness in the fibre direction. Crack fronts in longitudinal tows develop in transverse direction, which is coherent with post-failure inspection of the tested samples.

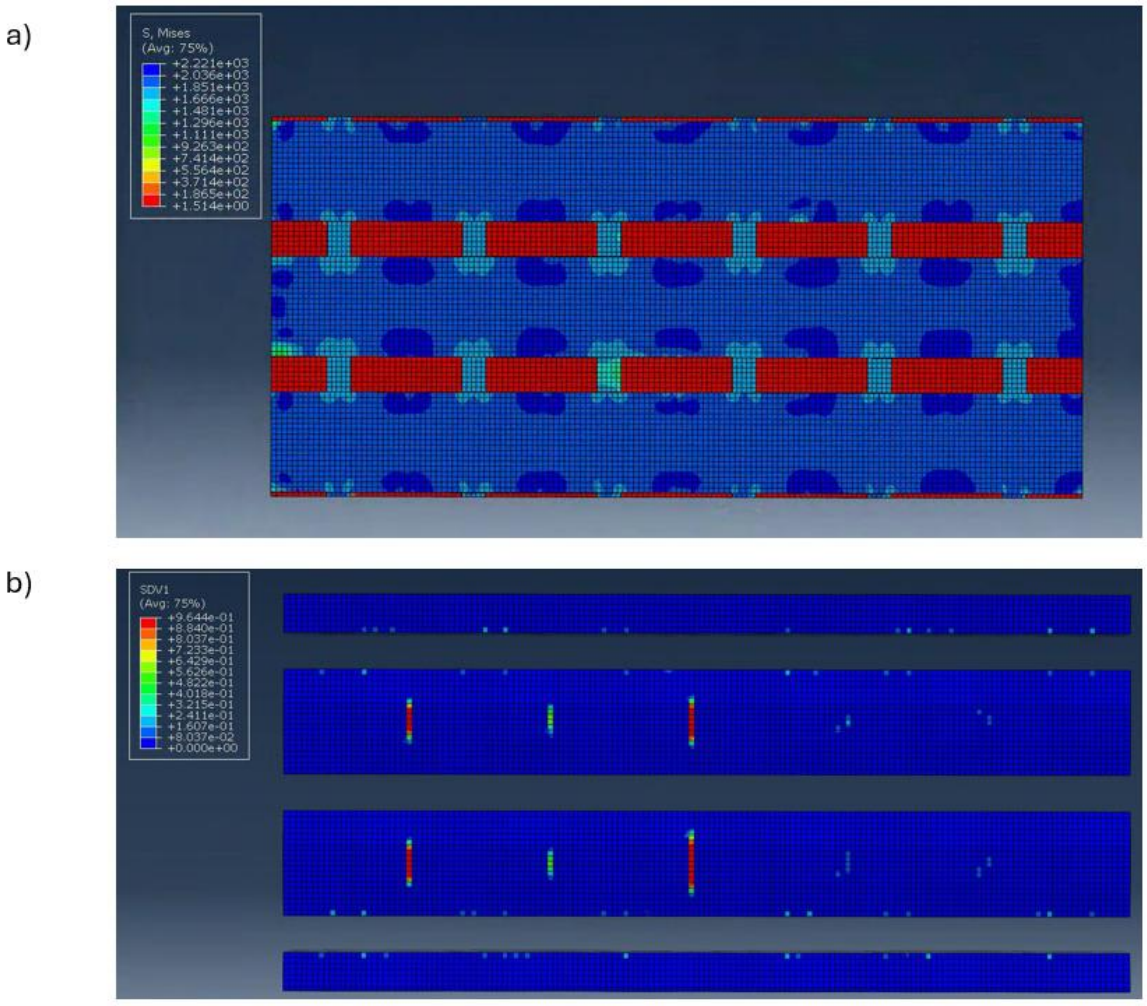

Figure 9: a) Stress distribution field showing principal stress in fibre direction when the fibre failure initiates; b) Fibre tensile damage initiation sites in longitudinal tow.

9 CONCLUSIONS

This study utilises detailed morphological characterisation of AP-Ply laminates to develop a high-fidelity finite element model capable of accurately predicting their tensile behaviour. Three distinct AP-

Ply architectures were fabricated using a hot-gas torch-based Automated Fibre Placement (AFP) system. While the layup process initially produced highly uneven surfaces, the developed protrusions or gaps were eliminated post-curing, primarily due to tow spreading. Internal geometries for these laminates were characterised using optical microscopy and X-ray computed tomography (CT), and the extracted meso-structural data were parameterised to construct representative geometries for numerical modelling.

Given the minimal inter-ply spacing after consolidation and the limited resolution of CT scans, conventional segmentation techniques proved inadequate. To address this, novel segmentation algorithms were developed to reliably isolate individual tows.

Notably, AP-Ply laminates maintained strength and stiffness performance close to baseline laminates, despite the presence of fibre undulations. This reinforces their suitability as replacements for conventional non-woven architectures, with the added benefit of enhanced toughness.

The morphologically informed numerical framework developed in this work demonstrated strong predictive capability, estimating tensile strength within a 6% margin of experimental results. Furthermore, the model successfully captured the initiation and evolution of distinct damage modes within individual tows. Overall, this research establishes a foundation for meso-scale modelling strategies that can accurately predict both mechanical behaviour and failure mechanisms in meso-architectured laminates, an essential step toward the design of next-generation composite structures.

ACKNOWLEDGEMENTS

The authors would like to acknowledge the following funding:
ARC LIEF: Australasian facility for the automated fabrication of high-performance bespoke components (LE140100082).
ARC ITTC: ARC Training Centre for Automated Manufacture of Advanced Composites (IC160100040).
ACM CRC: Australian Composites Manufacturing Cooperative Research Centre (ACM CRC) (CRCXXIIIA000003).
The authors further acknowledge the Tyree X-ray CT Facility, X-ray Analysis Facility, Mark Wainwright Analytical Centre, UNSW Sydney, for the acquisition of the 3D μXCT images.

ABSTRACT

Additive manufacturing (AM) of composite materials offers unmatched flexibility and tailored properties for aerospace structures. However, accurately predicting structural performance and fracturing behavior in additively manufactured composite joints remains complex due to intricate micro and mesoscale damage mechanisms. This work uses FastDM4C, an advanced discrete computational model specifically developed to simulate and optimize composite structural joints fabricated using Electroimpact's Scalable Composite Robotic Additive Manufacturing (SCRAM) system and Anisoprint PROM 500. SCRAM uniquely integrates Automated Fiber Placement (AFP) and Fused Filament Fabrication (FFF), enabling rapid production of aerospace-grade continuous fiber-reinforced thermoplastic composites with exceptional mechanical performance. While traditional continuum models effectively characterize the elastic response, they inadequately represent complex fracture behaviors at finer scales. FastDM4C addresses these shortcomings by utilizing a discrete, sub-lamina approach that captures microdamage initiation and propagation in a computationally efficient manner. This model enhances the original DM4C framework by employing edge-based constitutive laws, significantly improving accuracy and efficiency. In the current study, digital twins of composite structural joints are created directly from machine codes, providing exact virtual replicas of physical specimens. Integrating detailed experimental data and material properties, these digital twins enable comprehensive simulations using FastDM4C to predict mechanical responses under various conditions. Furthermore, a multi-stage optimization algorithm calibrates elastic and fracture parameters at multiple scales based on manufacturing parameters. By merging cutting-edge discrete modeling techniques, digital twin technologies, and advanced additive manufacturing processes, this study offers a powerful tool for optimizing composite structural joints, substantially accelerating the development and validation of aerospace structures.

1 INTRODUCTION

Additive manufacturing (AM) has significantly advanced the capability to produce complex structural components, especially within the field of composite materials [1, 2]. Despite these advancements, accurately ensuring the structural integrity of additively manufactured composite joints remains a substantial challenge due to intricate damage mechanisms at the micro and mesostructural levels. Composite materials typically exhibit complex behaviors such as fiber micro-buckling, fiber kinking under compression, fiber shearing, and matrix microcracking under shear, complicating accurate prediction and simulation [3-5]. Traditional continuum-based computational models attempt to characterize these damage mechanisms but often become mathematically cumbersome, limiting general

applicability and requiring extensive experimental calibration. These homogenized continuum models substitute the explicit fiber and matrix details with numerous complicated equations and parameters that lack clear physical interpretations. Consequently, their predictive capabilities are limited, and model calibration becomes labor-intensive.

This study introduces an advanced discrete computational model, the Fast Discrete Model for Composites (FastDM4C), designed to effectively overcome these limitations [6-10]. Unlike continuum models, FastDM4C explicitly represents fiber-matrix interactions through discrete, edge-based constitutive laws, significantly improving the accuracy of damage initiation and propagation simulations at reduced computational cost. Additionally, this research utilizes the Electroimpact Scalable Composite Robotic Additive Manufacturing (SCRAM) system integrating Automated Fiber Placement (AFP) and Fused Filament Fabrication (FFF) to manufacture composite structural joints. Digital twins are created directly from manufacturing machine codes, ensuring perfect virtual replicas of physical specimens. By incorporating detailed experimental data and specific material properties into these digital twins, FastDM4C simulations yield reliable predictions of mechanical behavior and structural performance. The enhanced computational efficiency and scalability of FastDM4C facilitate rapid iterations, sensitivity analyses, and optimization procedures, significantly accelerating design iteration cycles. The insights provided through virtual testing enhance reliability, safety, and performance, driving innovation in structural design for critical applications in aerospace, automotive, robotics, and beyond.

2 MODEL DESCRIPTION

The first iteration of FastDM4C was developed to model classical composite laminates using a Representative Unit Cell (RUC), whose dimensions are selected to match the average distance between splitting cracks observed in experimental results [11-13]. Within the RUC, fibers are discretized using the newly developed Discrete Fiber Model (DFM), while the matrix and shear behavior is captured using a second novel Discrete Matrix Model (DM2), combined with a new finite element called the FacetElement (FE). This methodology was later adapted to model composites manufactured by additive techniques, such as extrusion or tape deposition as discussed in this article but all the basic elements are the same.

The Discrete Fiber Model resembles a Timoshenko beam element but allows further monitoring of the energy dissipated by each integration point, which is critical during fracturing behavior. Each beam element in DFM has full six degrees of freedom (DOF) per node, so it is capable of handling axial, shear, bending, and torque forces. The major assumption of the fiber model is that the fracture localizes at the mid-section of an element. The mid-section is discretized as another generalized Finite Element mesh, so that many different shapes are possible. In Figure 1, a circular cross section is used even though any generalized cross section can be used. In the case of tape deposition as in the SCRAM, a rectangular cross section is generally used. Moreover, each beam is split into two segments of equal length. The two segments are separately tied to each of the nodes that define the beam and two segments from adjacent beams that share the same node form a rigid cell that is tied to the 6 DOF of the shared node. Using this methodology, there is no need of using element deletion or element erosion as once the fracture criterion is reached, the rigid cell is split into two segments each with a copy of the node. This is easily seen in Figure 2. Moreover, this implementation allows further control of the dissipation of energy of each integration point which is not possible to achieve by using a classical Timoshenko beam. The constitutive equation of the beam is a simple linear softening formulation [14]. Further detail is discussed in the next section.

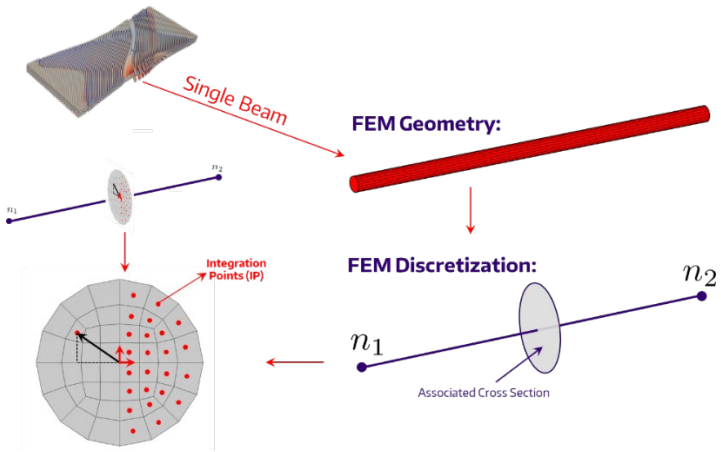

Figure 1: Visual representation of the Discrete Fiber Model (DFM). Each beam element is characterized by two nodes and it is assumed to fracture in the middle. The cross section in the middle is as well a generalized finite element mesh.

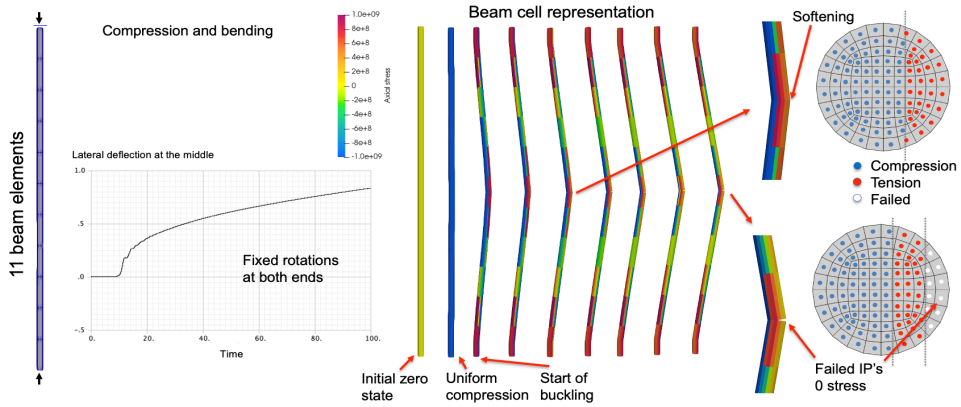

Figure 2: Practical considerations for the Discrete Fiber Model. While behaving similarly to Timoshenko Beam Elements, the DFM allows for further control of each integration point during failure, properly dissipating the right amount of energy needed for the element to fail.

The Discrete Matrix Model (DM2) and the associated new element called FacetElement (FE) are now presented. In DM4C, the matrix is represented by an embedded tetrahedral mesh where each element is further discretized into FacetElements oriented on multiple planes. In FastDM4C, the facet element is created upon a single edge element that is taken from the RUC or the deposited filament or tow. At the mid-point of the edge element, a polygonal facet is used to describe the damaging and fracturing behavior (equations discussed in the next section). In Figure 3, a graphical interpretation of a FacetElement is given together with plots of the constitutive response.

Once the additively manufactured layers are generated using the methods outlined above, the interlaminar connection between nodes from each layer needs to established. From node pairs of two plies, a 3D constrained Delaunay Triangulation is carried out to generate a temporary set of tetrahedral elements. However, non-co-planar edge elements are only retained. With these edge elements, all the mid-points are found and used to generate either a (i) Voronoi tessellation for standard laminates or (ii) mid-planar projection and tetrahedral intersection for printed complicated 3D parts. This process allows for a very robust generation of facets which are parallel to the printed layers and almost independent of the complexity of each layer.

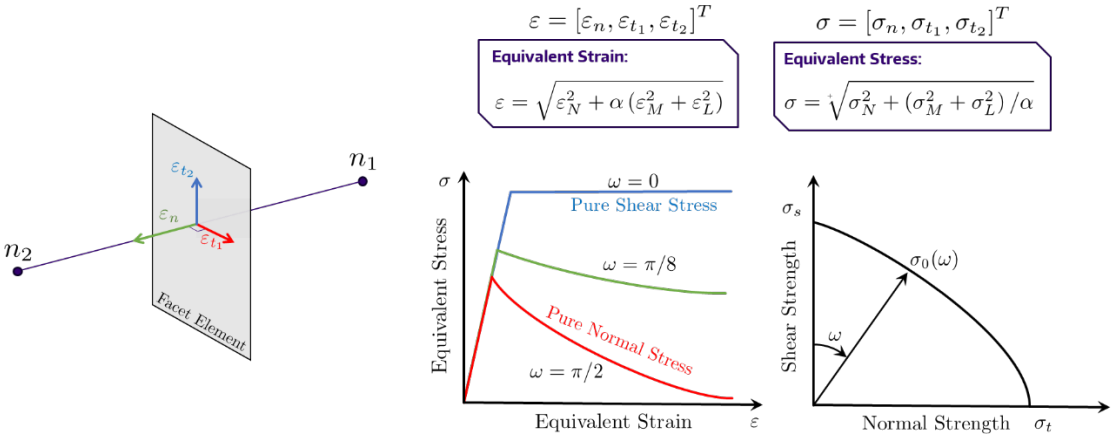

Figure 3: Discrete Matrix Model (DM2) and FacetElement (FE) graphical interpretation.

The final step involves model calibration and validation through carefully designed laboratory-scale specimens matching the geometrical and material characteristics of the composite and manufacturing system. Calibration tests include longitudinal tension/compression, transverse tension/compression, shear, and fracture energy-driven assessments such as Mode I (DCB) and Mode II (ENF) fracture toughness. To efficiently calibrate the model, an automated parallel computational procedure using the Message Passing Interface (MPI) framework is employed. In this parallel approach, a manager rank supervises parameter selection, while multiple worker ranks run concurrent simulations. Parameters are iteratively swept and adjusted until convergence with experimental data is achieved. After calibration, the validated model parameters reliably predict the behavior of other composite structures manufactured using the same equipment, materials, and processing conditions, greatly improving modeling accuracy and confidence.

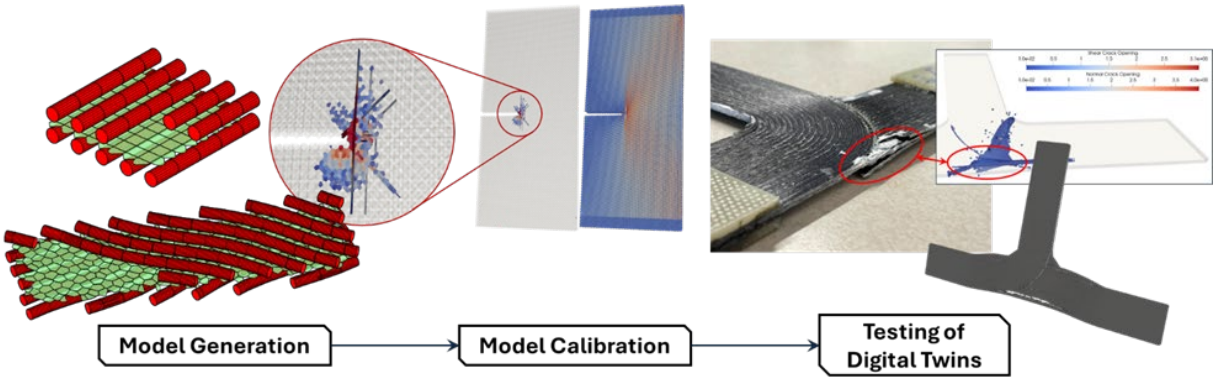

Figure 4: General steps for model generation, calibration and testing of the proposed framework.

3 THEORETICAL FRAMEWORK

3.1 Constitutive Law for Fiber Beams

Fiber tows are explicitly modeled as Timoshenko beam elements in the FastDM4C framework. The constitutive law for beam elements is defined in the integration points of each beam element. The elastic behavior of the beam elements resembles the Hooke's law in one dimension. The axial stress, σ_f, is linearly proportional to the elastic strain, ε_f, as presented in Equation 1:

$$\sigma_f = E_f \varepsilon_f \tag{1}$$

where E_f represents the modulus of fiber beams and is a calibration parameter which dominantly determines the modulus of a composite material in longitudinal direction, E_1.

Fiber beams exhibit a linear softening behavior when the axial stress goes over the strength limit, σ_c, under a tensile loading condition. The linear softening boundary is a function of the elongation of a beam element, δ, as shown in Equation 2:

$$\sigma_f(\delta) = \max\left[0, \sigma_c\left(1 - \frac{\delta - \delta_c}{\delta_f - \delta_c}\right)\right] \quad (2)$$

where the elongation limit, $\delta_c = \sigma_c L_0 / E_f$, indicates the initiation of the linear softening. L_0 is the length of a beam element. Once the elongation reaches the failure length, $\delta_f = (2G_f)/\sigma_c$ where G_f is the fracture energy of a fiber, the axial stress becomes zero.

3.2 Constitutive Law for Matrix Elements

The vectorial stress-strain relationship computed at each facet describes the constitutive behavior of a matrix. In this section, the elastic and the inelastic behavior for a matrix are introduced.

3.2.1 Elastic Behavior

The elastic relation between each vectorial stress component and each vectorial strain component resembles the Hooke's law in one dimension as shown in Equations 3 – 5:

$$\sigma_N = E_0 \varepsilon_N \quad (3)$$
$$\sigma_M = \alpha E_0 \varepsilon_M \quad (4)$$
$$\sigma_L = \alpha E_0 \varepsilon_L \quad (5)$$

where E_0 represents the modulus in the normal direction of a facet, and α is a parameter which indicates the shear-normal coupling. These two parameters are defined in the facet level and represent meso-scale properties. The calibration procedure determines their value such that the FastDM4C model will match the macroscopic elastic properties in transverse direction such as major Poisson's ratio, ν_{12}, and transverse modulus, E_2.

3.2.2 Fracturing Behavior in Tension

A facet with a positive normal strain ($\varepsilon_N > 0$) exhibits the fracturing behavior when the critical condition is met. This behavior is described with the relation between the effective strain, ε, and the effective stress, σ, following the Lattice Discrete Particle Model formulation introduced by Cusatis et al. [ref]. Two effective variables are defined in Equation 6 and 7.

$$\varepsilon = \sqrt{\varepsilon_N^2 + \alpha(\varepsilon_M^2 + \varepsilon_L^2)} \quad (6)$$
$$\sigma = \sqrt{\sigma_N^2 + (\sigma_M^2 + \sigma_L^2)/\alpha} \quad (7)$$

The effective stress has the incrementally elastic relation with the effective strain ($\Delta\sigma = E_0\Delta$). The tensile boundary $\sigma_{bt}(\varepsilon, \omega)$, which is a function of the normal-shear ratio variable, ω, and the history-dependent maximum effective strain ε_{max}, sets the exponential softening law.

$$\sigma_{bt}(\varepsilon, \omega) = \sigma_0(\omega) \exp\left(-H_0(\omega)\frac{\langle \varepsilon_{max} - \varepsilon_0(\omega) \rangle}{\sigma_0(\omega)}\right) \quad (8)$$

In Equation 8, Macaulay's bracket follows the notion: $\langle x \rangle = max(x, 0)$, and the normal-shear ratio variable, ω, is defined as

$$\tan\omega = \frac{\varepsilon_N}{\sqrt{\alpha}\varepsilon_T} \quad (9)$$

where the effective shear stress $\varepsilon_T = \sqrt{\varepsilon_M^2 + \varepsilon_L^2}$ is used. In a facet, ω can be used to evaluate the degree of interaction between normal and shear loads. For the tensile boundary, the strength limit, $\sigma_0(\omega)$, depends on the normal-shear ratio variable and is computed as shown in Equation 10:

$$\sigma_0(\omega) = \sigma_t \frac{-\sin(\omega) + \sqrt{\sin^2(\omega) + 4\alpha\cos^2(\omega)/r_{st}^2}}{2\alpha\cos^2(\omega)/r_{st}^2} \tag{10}$$

where $r_{st} = \sigma_s/\sigma_t$ represents the ratio between the shear strength, σ_s, and the tensile strength, σ_t. In Equation 8, the elastic limit, $\varepsilon_0(\omega)$, is computed using the strength limit following the expression: $\varepsilon_0(\omega) = \sigma_0(\omega)/E_0$. The rate of decay for the tensile boundary, $H_0(\omega)$, is a function of ω as expressed in Equation 20:

$$H_0(\omega) = H_t \left(\frac{2\omega}{\pi}\right)^{n_t} \tag{11}$$

where $H_t = 2E_0/(\ell_t/\ell - 1)$, and ℓ is the length of the edge on the tetrahedral element containing the facet in evaluation. The tensile characteristic length, ℓ_t is proportional to the fracture energy of the matrix, G_t, and is computed as $\ell_t = 2E_0G_t/\sigma_t^2$. In summary, four meso-scale parameters $(\sigma_s, \sigma_t, \ell_t, n_t)$ characterize the tensile failure of facets with positive normal strain; therefore, the calibration of these parameters allows to match the tensile strength and the fracture energy of a matrix.

3.2.3 Hardening Behavior in Compression

When a facet experiences the compression ($\varepsilon_N < 0$), the normal stress component exhibits the hardening behavior after it passes the elastic regime. The hardening behavior implemented in FastDM4C follows the formulation proposed in the LDPM formulation, which describes the hardening boundary dependent on both the volumetric strain, ε_V, and the deviatoric strain, $\varepsilon_D = \varepsilon_N - \varepsilon_V$ as expressed in Equation 12:

$$\sigma_{bc}(\varepsilon_D, \varepsilon_V) = \begin{cases} \sigma_{c0} \quad \text{for} \quad -\varepsilon_{DV} \le 0 \\ \sigma_{c0} + < -\varepsilon_{DV} - \varepsilon_{c0} > H_c(r_{DV}) \quad \text{for} \quad 0 \le -\varepsilon_{DV} \le \varepsilon_{c1} \\ \sigma_{c1}(r_{DV}) \exp\left((-\varepsilon_{DV} - \varepsilon_{c1})\frac{H_c(r_{DV})}{\sigma_{c1}(r_{DV})}\right) \quad otherwise \end{cases} \tag{12}$$

where σ_{c0} represents the compressive yielding strength of a facet. In the hardening boundary, $\varepsilon_{DV} = \varepsilon_V + \beta\varepsilon_D$ and $\varepsilon_{c0} = \sigma_{c0}/E_0$. The Macaulay bracket in the second line of Equation 12 follows the same notion used for the tensile boundary. In this study, β is set to be zero. The rehardening initiates when $|\varepsilon_{DV}| > \varepsilon_{c1}$ where $\varepsilon_{c1} = \kappa_{c0}\varepsilon_{c0}$. The rehardening stress is defined as $\sigma_{c1}(r_{DV}) = \sigma_{c0} + (\varepsilon_{c1} - \varepsilon_{c0})H_c(r_{DV})$. The initial hardening modulus, $H_c(r_{DV})$, is computed as defined in Equation 13:

$$H_c(r_{DV}) = \frac{H_{c0} - H_{c1}}{1 + \kappa_{c2} < r_{DV} - \kappa_{c1} >} + H_{c1} \tag{13}$$

where H_{c0}, κ_{c1}, and κ_{c2} are meso-scale parameters defined in facet level associated to the properties of a matrix and $H_{c1} = \kappa_{c3}E_0$ where κ_{c3} is set to be 0.1 in this study. The values of both σ_{c1} and H_c change based on the variable, r_{DV} which is computed following Equation 14:

$$r_{DV} = \begin{cases} -\frac{|\varepsilon_D|}{\varepsilon_V - \varepsilon_{V0}} \quad \text{for} \quad \varepsilon_V \le 0 \\ \frac{|\varepsilon_D|}{\varepsilon_{V0}} \quad \text{for} \quad \varepsilon_V > 0 \end{cases} \tag{14}$$

where $\varepsilon_{V0} = \kappa_{c3}\varepsilon_{c0}$. In summary, five meso-scale parameters $(\sigma_{c0}, H_{c0}, \varepsilon_{c1}, \kappa_{c1}, \kappa_{c2})$ characterize the hardening behavior of normal strain component in facets under compression.

3.2.4 Frictional Behavior in Compression

The shear components of the stress vector in a facet under compression experience the frictional behavior which can increase the shear strength depending on the magnitude of compressive normal stress. The effective stress, σ_T, expressed in Equation 15 behaves incrementally elastic until it reaches the frictional boundary, σ_{bs}, defined in Equation 16:

$$\sigma_T = \sqrt{\sigma_M^2 + \sigma_L^2} \tag{15}$$

$$\sigma_{bs} = \sigma_s + \alpha(\mu_0 - \mu_\infty)\sigma_{N0} - \alpha\mu_\infty\sigma_N - \alpha(\mu_0 - \mu_\infty)\sigma_{N0}\exp\left(\frac{\sigma_N}{\sigma_{N0}}\right) \tag{16}$$

where σ_s represents the shear strength of a facet without any compressive normal stress. σ_{N0} governs the transition between the initial friction coefficient, μ_0, and the asymptotic friction coefficient, μ_∞. In summary, four meso-scale parameters $(\sigma_s, \sigma_{N0}, \mu_0, \mu_\infty)$ characterize the frictional behavior of facets under compressive stress.

4 CALIBRATION AND COMPARISON TO EXPERIMENTAL DATA

Figure 5 presents the discretization workflow and resulting models for specimens manufactured by two additive processes: tape deposition with the SCRAM system and fused filament fabrication with the PROM system. Although the calibration values differ for each process, the workflow used to obtain them is identical. The machine's G-code is parsed into a sequence of 3D line segments that represent the toolpath, then resampled to create fiber segments of uniform length. For machines that follow complex 3D trajectories, the local nozzle orientation is also captured so that, when the segments are converted to beam elements, the accompanying normal reference frame is preserved. This orientation data is optional for circular cross sections, but it is essential for the SCRAM process because its rectangular cross section must be aligned correctly along the path to reproduce the actual extrusion geometry. Once the beam network is established, a constrained tetrahedral mesh is generated around it. The edges of this mesh define the facet elements that represent the matrix response. Many geometries have been printed and validated with this methodology with both systems; in this non confidential study, a representative T joint specimen printed with the PROM is used to demonstrate the approach.

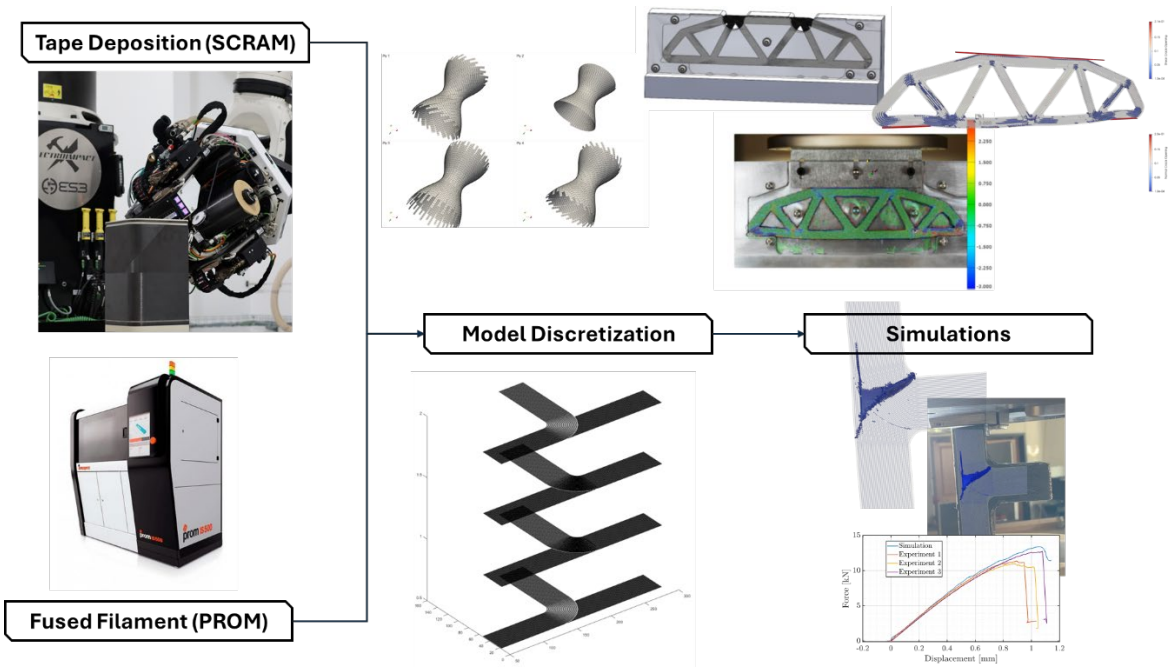

Figure 5: Both Tape Deposition (SCRAM) and Fused Filament (PROM) technologies can be used together with FastDM4C to generate Finite Element Models.

All the T-joint specimens were manufactured at ES3 using the PROM 500 and tested at the University of Washington in Seattle. Three specimens were produced for each configuration and loaded in tension on a 306 Bia West (formerly Shore Western) frame. One flange of the T-joint was gripped, the opposite flange was pulled along the joint's major axis, and the remaining flange was left free. All Joint A specimens completed testing without issue, while one Joint B specimen was misaligned during setup and its data were excluded. The finite element models were built with the FastDM4C framework as explained above. For each type of joints, a unidirectional laminate coupon model is extracted from a straight section to perform the calibration on FastDM4C parameters. After calibration, full-scale simulations were run and compared with the experimental curves. Figure 6 presents the comparison results for both types of structural joint.

Joint B delivered significantly higher stiffness and strength because its printing strategy avoided fiber interruptions along the loading direction. Joint A displayed a slight nonlinear response, typical of discontinuous fiber reinforcement, yet the DM4C model reproduced this behavior accurately. The formulation also captured the onset and progression of damage and fracture, as illustrated in Figure 6.

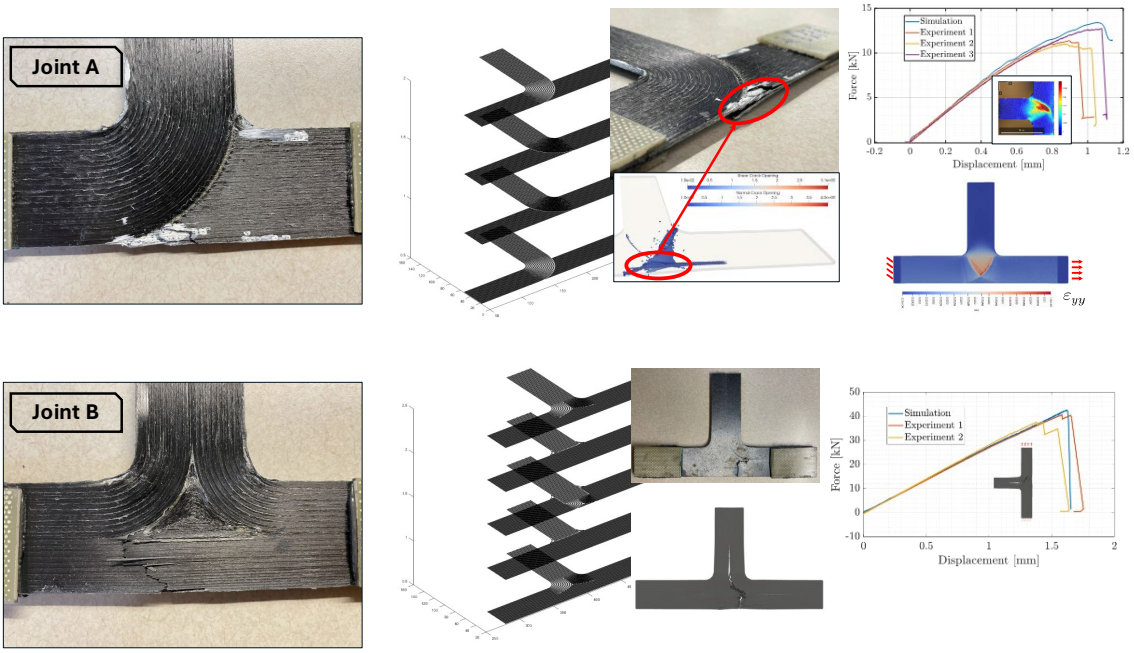

Figure 6: Comparisons between the experimental and computational results for both T-Joints.

5 CONCLUSIONS

This study introduces FastDM4C, an integrated and automated modeling framework for predicting the mechanical performance of additively manufactured composite joints produced using both the SCRAM tape deposition system and the PROM fused filament system. The methodology directly converts manufacturing G-code into a digital twin, discretizing continuous fiber paths into beam elements while embedding a tetrahedral mesh whose edges form facet elements to capture the matrix behavior. A parallel calibration process based on the Message Passing Interface (MPI) enables rapid tuning of both elastic and fracture parameters. Once calibrated, the model can be applied to full-scale specimens without further adjustments.

The validation shown in this article is based on experimental tests of T-joint specimens, and they showed strong agreement between simulation and measured data. In both cases, FastDM4C accurately predicts not only the global load-displacement response but also the onset and propagation of damage and fracture, as observed during physical testing.

The results of this study demonstrate that FastDM4C provides a robust and process-agnostic modeling pipeline that can accommodate different deposition technologies and geometries. Its edge-based constitutive formulation ensures that material parameters retain clear physical meaning, making the calibration transferable across machines and material systems. The computational efficiency of the MPI-based parameter sweep significantly accelerates convergence, allowing for practical integration into design workflows. Furthermore, the findings highlight the importance of continuous fiber paths in achieving optimal structural performance, reinforcing the need to reduce fiber interruptions during the printing process. This modeling framework enables more accurate simulations, informed design decisions, and faster validation of complex composite structures for aerospace and other demanding applications.

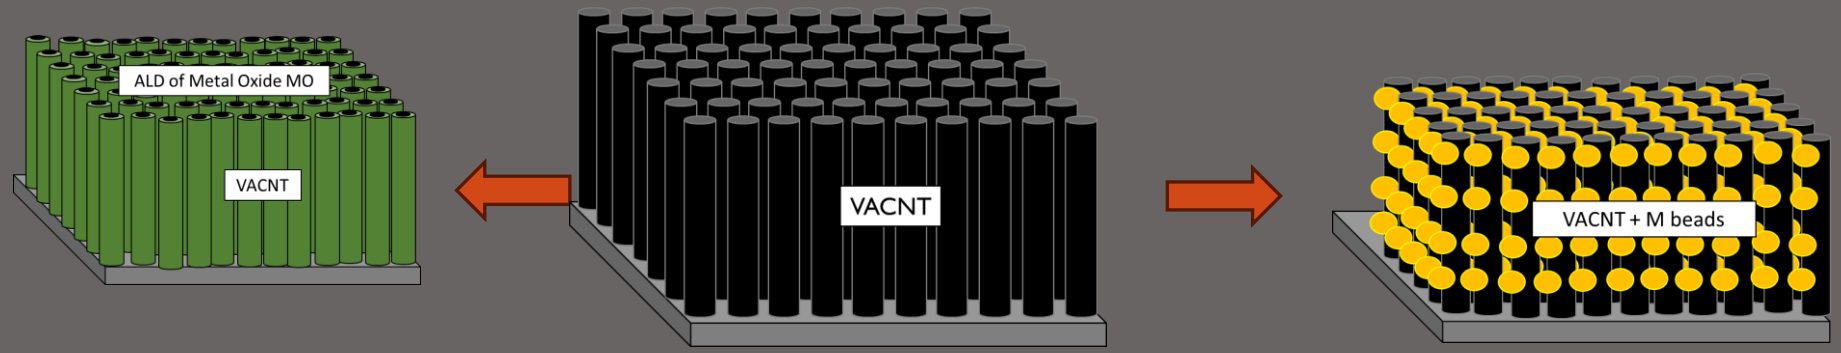
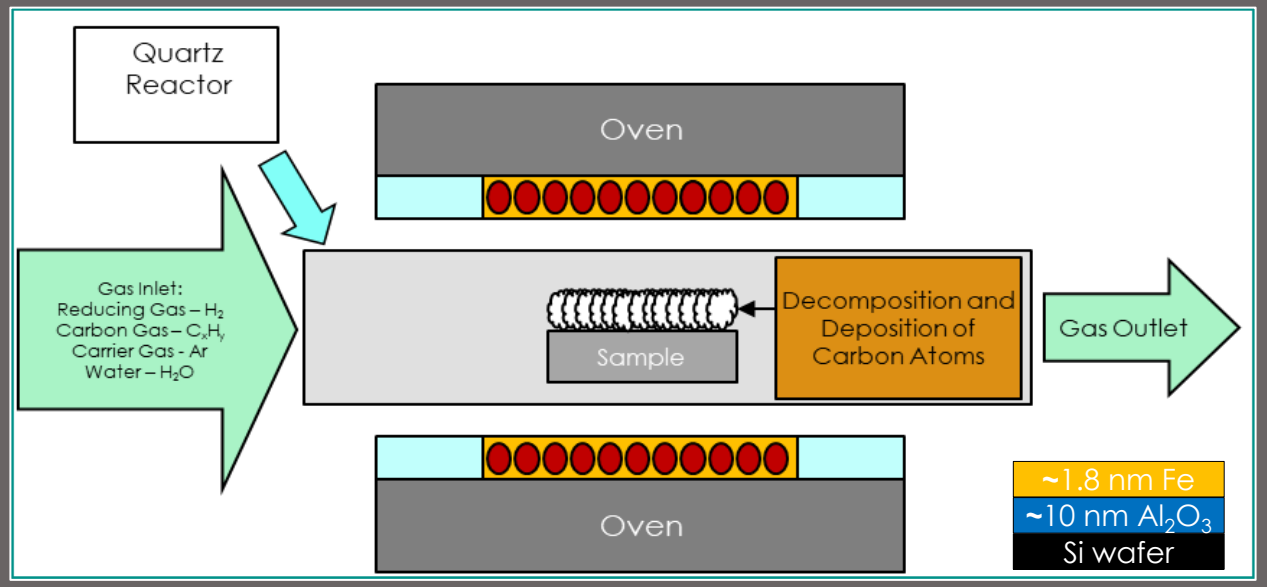
CSI Group



Vertically Aligned Carbon Nanotubes: Highly useful for Composite Materials



- Carbon nanotubes (CNT) have exceptional properties.
- Vertically aligned CNT (VACNT) retain anisotropic transport properties.
- Due to VACNT high porosity, immense surface is available for applications.

Property	Single-walled carbon nanotube	Double-walled carbon nanotube	Multiwalled carbon nanotube
Tensile strength (GPa)	50–100	23–63	10–60
Elastic modulus (TPa)	1	–	0.3–1
Elongation at break (%)	5.8	28	–
Density (g/cm^3)	1.3–1.5	1.5	1.8–2.0
Electric conductivity (S/m)	10^6	10^6	10^6
Thermal conductivity at room temperature (W/m K)	6000	3000	2000

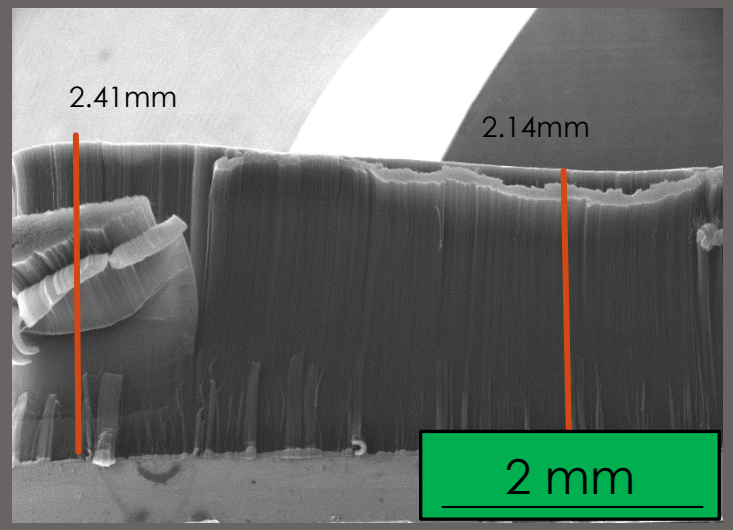
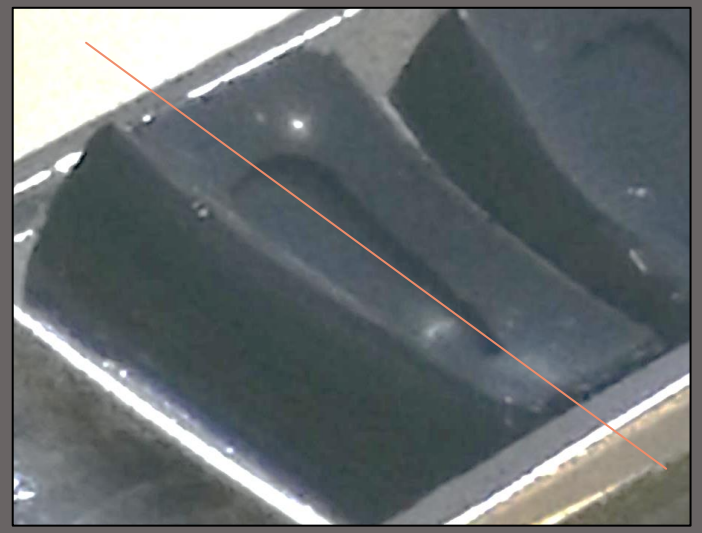
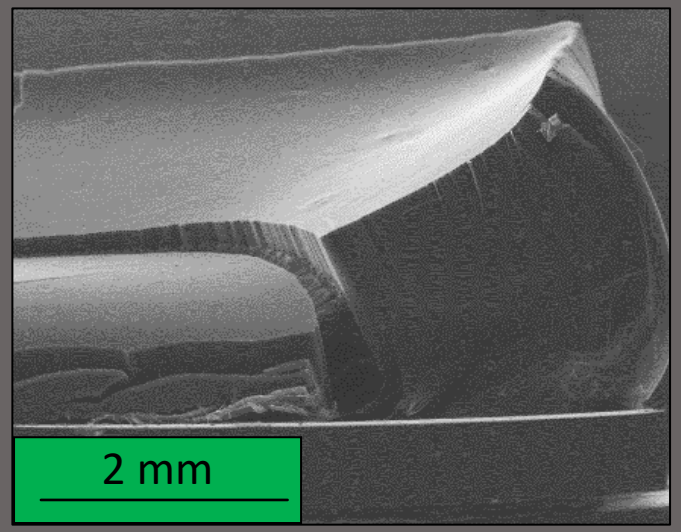
VACNT Synthesis: Chemical Vapor Deposition

Rovinsky *et al.* - 10.1021/acsanm.0c02681



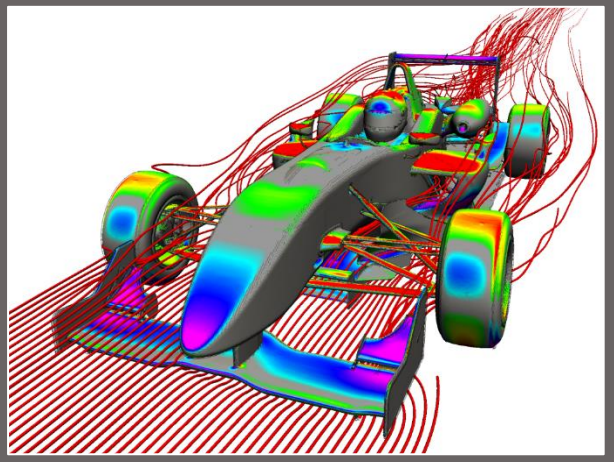


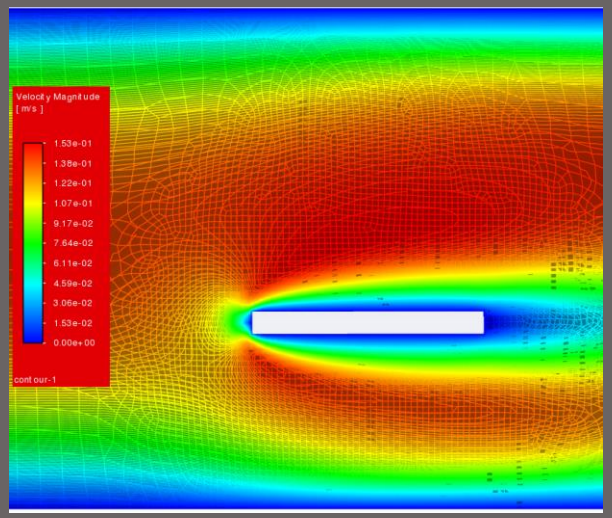


Taller VACNT reduces prominence of CNT-CNT contacts, weak links, both mechanical and electrically.

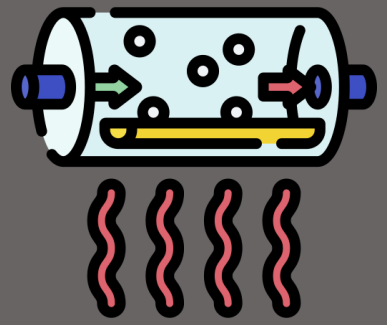
VACNT Synthesis and Challenges: Carbon Feeding Difference

- Different regions on the sample grow at different rates.
- Above certain heights, this becomes apparent and causes sinking.
- Extreme sinking results in the collapse of the sample centers.
- We started looking for an explanation.
- Can you help us?



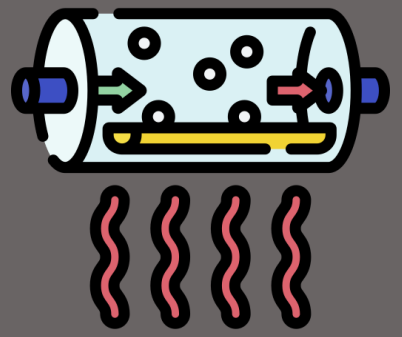


Computational Fluid Dynamics

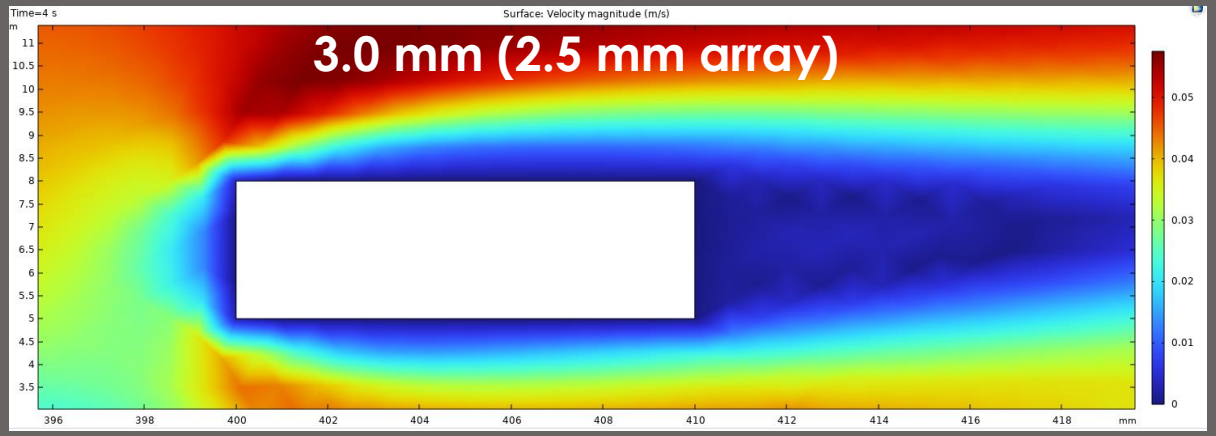


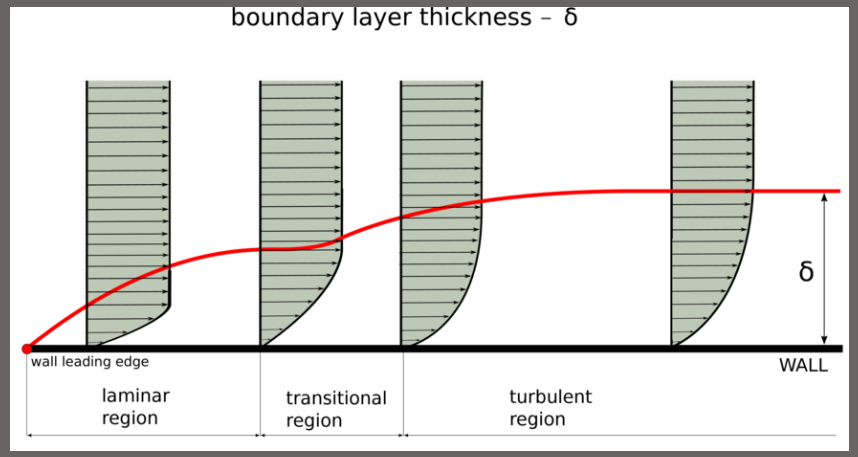
- A branch of finite-element analysis (FEA) deals with the movement and interaction of fluids. Gases are considered fluids.
- The fluid velocity during VACNT CVD was simulated in several times along the growth process.
- My assumptions (first-order approximation):
  - Inert (physical) flow, disregard heat and mass transfer.
  - Rigid sample, disregard porous structure.
  - Fluid properties are C_2H_4.

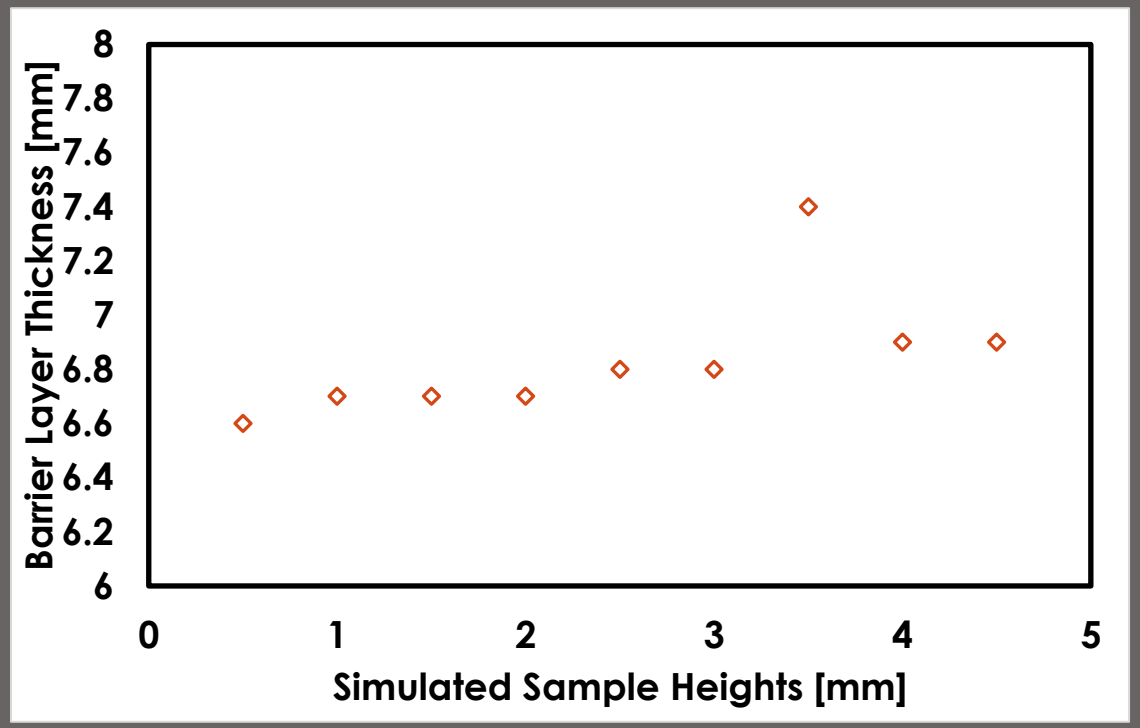
Methodology:
CFD/Real-life CVD Hybrid



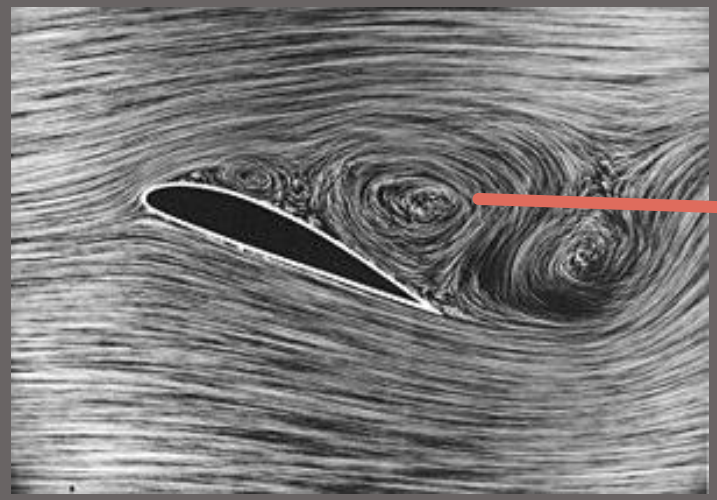
CVD → CFD → CFD2 → Tool → CVD2



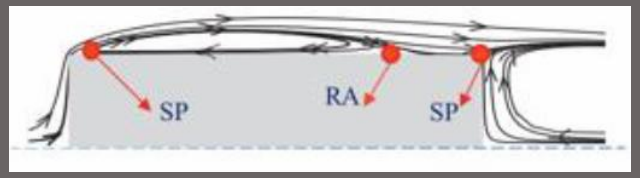


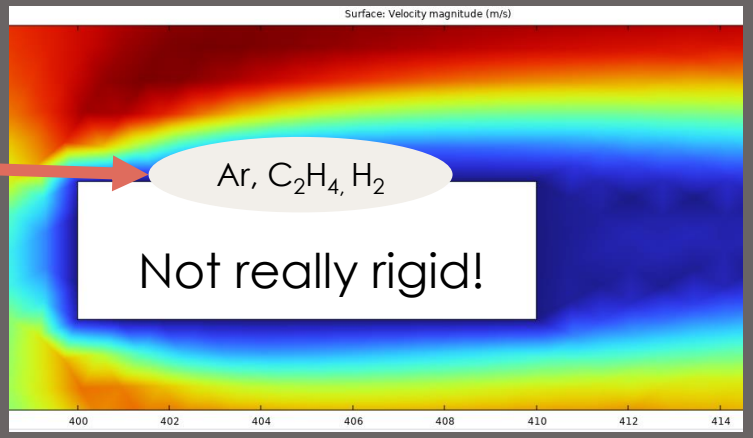


CFD Results



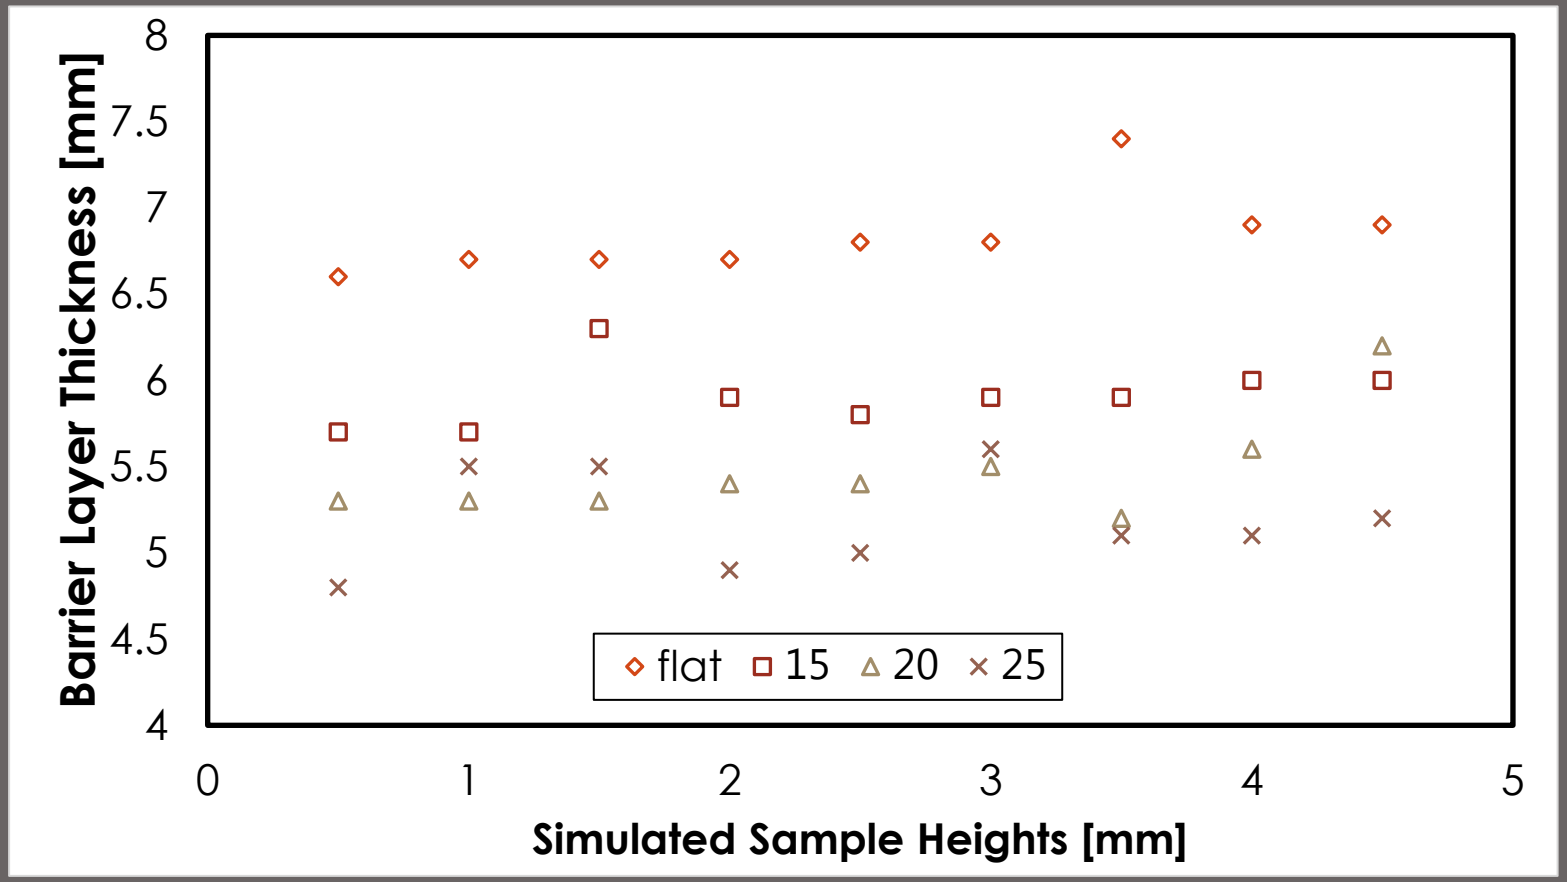
$$\delta = 99\% \cdot U\infty$$

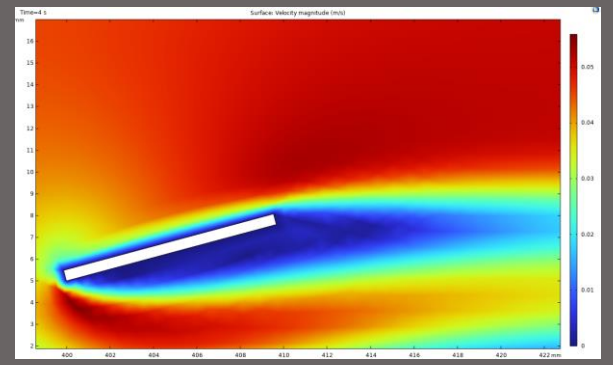




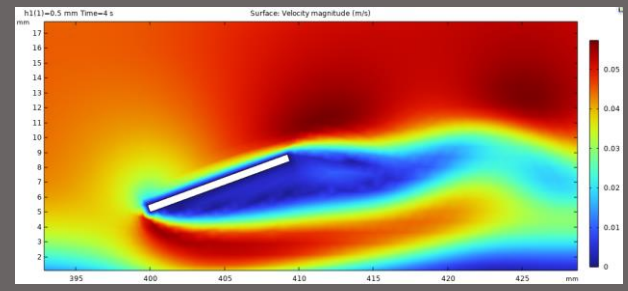
Assumed Phenomenon: Separation bubble

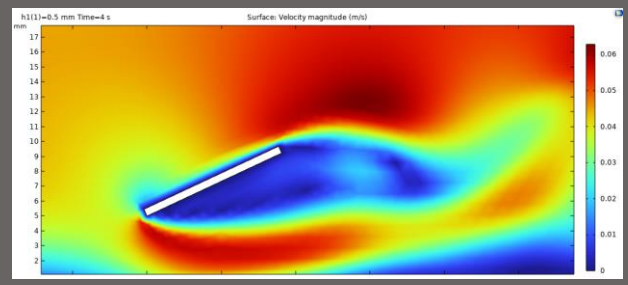
- The inbound flow traps a vortex on the surface, which decreases the growth rate in the middle of the sample.
- Higher step – larger trapped vortex.
- The angle decreases the dimensions of the trapped vortex.





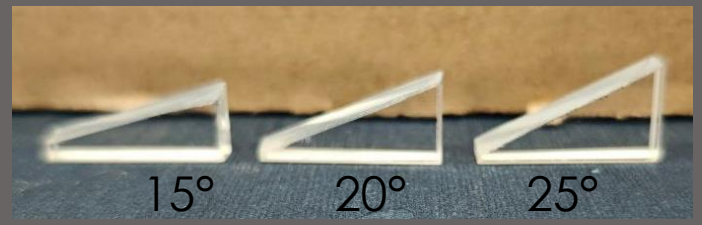
In VACNT case:

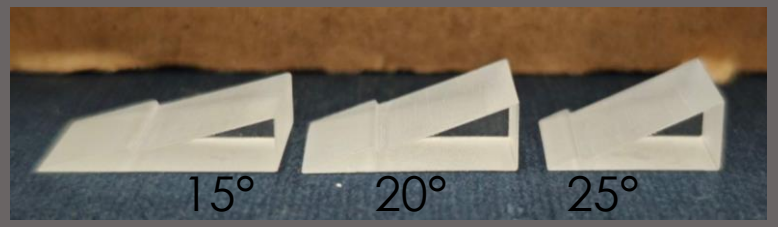




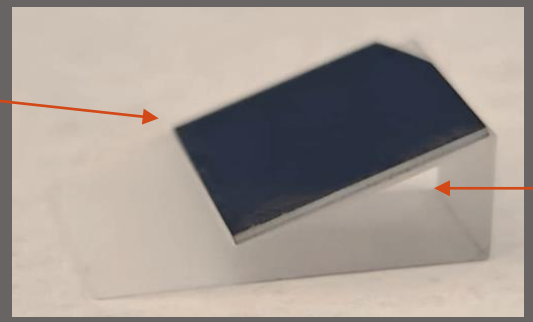
CFD Results – Attack Angle

- In an effort to reduce boundary layer thickness, the concept of attack angles was introduced.



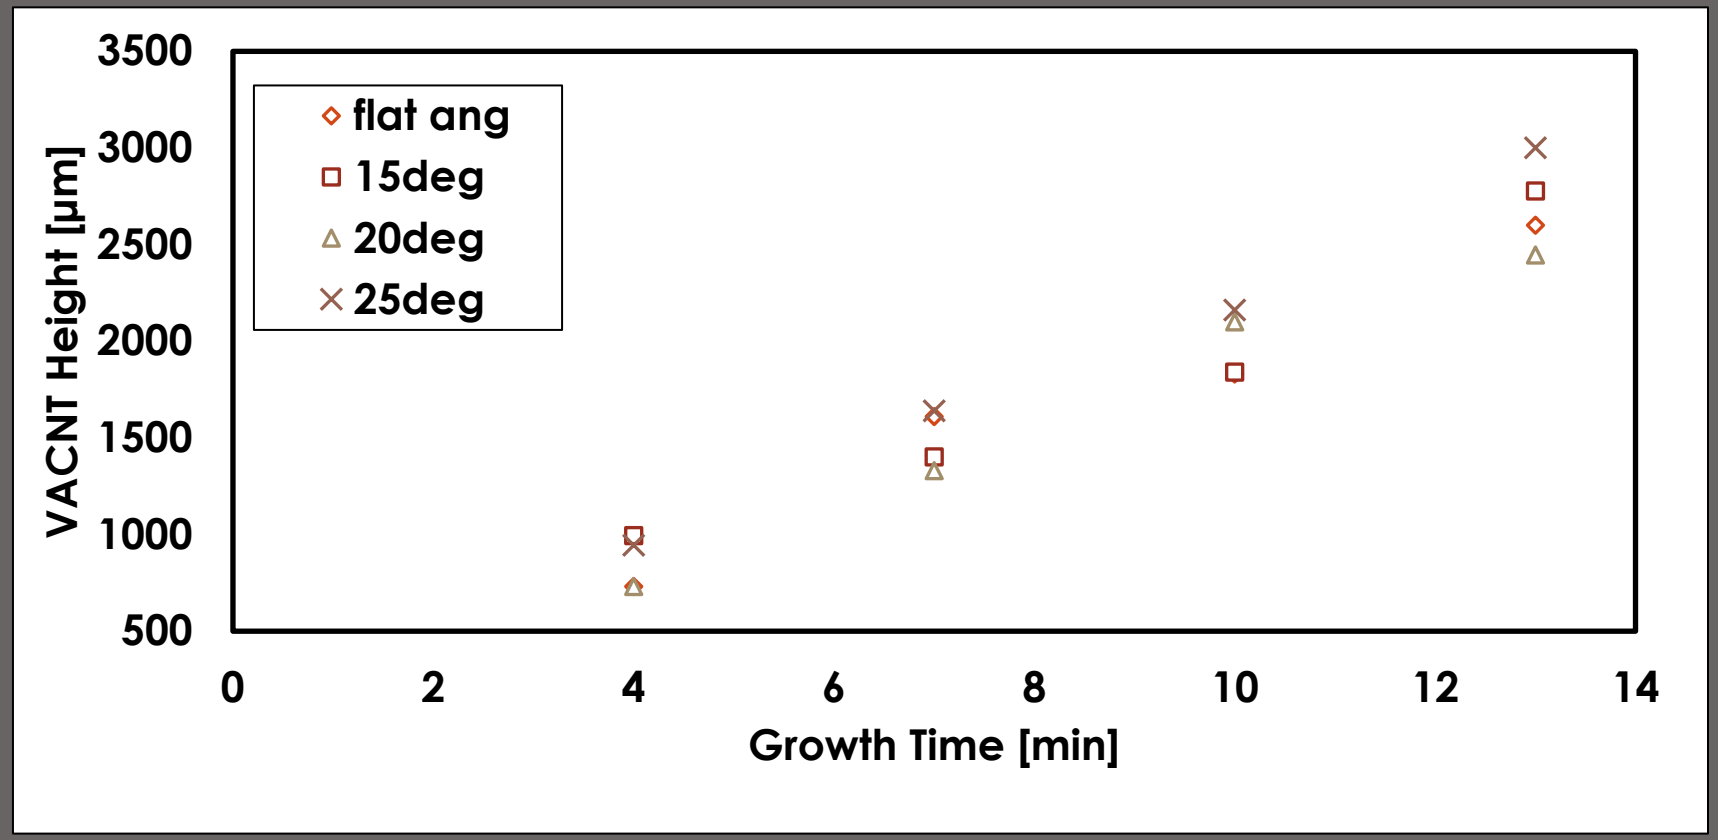


Quartz Substrate Jigs:



- Designed dedicated jigs with attack angles, so that the substrate would be at an angle.

Gig Generation 1



Gig Generation 2

Height of VACNT as f(θ), as f(growth t)

- Clear correlation between attack θ and sample height.
- Interestingly, best results are 25°, while in the simulations its 20°.

Conclusions

- The effectiveness of fluid dynamics becomes noticeable when ‘pushing the envelope’ of nanofabrication.
- VACNT samples’ centers sink, and even collapse during fabrication.
- CFD show barrier layer thickness increases as function of sample height.
- Some attack angles show decrease in the barrier layer thickness.
- VACNT sample height enhanced with attack angle.

ALTERNATIVE RECONSTRUCTION AND ACQUISITION TECHNIQUES FOR IMAGING LARGE CFRP SAMPLES

ABSTRACT

X-ray Computed Tomography (CT) is a powerful tool for non-destructive imaging of materials but is ill-suited for scanning the high aspect ratio geometries typical of standard test pieces and industrial composite panels. Computed Laminography (CL) offers a solution to overcome the current limitations of CT by using a tilted axis of rotation. This work demonstrates how a CL trajectory may be implemented on a conventional laboratory-based CT system with source and detector offsets. The performance of the technique was compared to a standard CT scan for region-of-interest imaging of a large carbon-fibre laminate plate. A low tilt angle of 20° was found to produce superior image quality to CT in slices through the face of the sample whilst mitigating the associated laminographic artefacts across horizontal views. The resulting fibre orientation analysis demonstrated CL to be an effective technique to accurately characterise the fibre architecture of large composite structures.

1 INTRODUCTION

X-ray computed tomography (CT) is becoming an increasingly important non-destructive imaging technique for the internal microstructural characterisation of fibre-reinforced polymers, both during manufacturing and under in-service conditions [1]. Despite recent advancements in the capabilities of laboratory-based CT systems, the constituent material properties of carbon-fibre reinforced polymers (CFRP) coupled with the typically high aspect ratio geometries of industrial components provide fundamental challenges to high-resolution X-ray imaging. One of the main concerns for CFRP and an important factor for feature detection is image contrast. The small difference in attenuation coefficient results in low contrast between the fibres and polymer resin within the greyscale image, for which a low tube voltage is likely required but at the expense of penetration depth through the sample [2]. Consequently making it more difficult to distinguish fibres for orientation analysis and/or defects such as narrow matrix cracks. Also, with individual fibre diameters between 5-7μm, the physical dimensions of real industrial components often impede on the geometric magnification necessary to resolve small bundles or strands giving a trade-off between sample size and spatial resolution. Further, flat plate-like geometries characteristic of industrial composite panels and specific standard test pieces are ill-suited conventional CT imaging. The high aspect ratio means that X-ray energies which optimise the dynamic range face-on are likely insufficient for imaging the plate edge-on. As such, the large difference in absorption through different projection angles result in pronounced reconstruction artefacts [3]. For region-of-interest (ROI) scanning of flat plate carbon-fibre sheet moulded compound, this constitutes sample sizes greater than 75% excess material experiencing a significant decline of in image quality [4].

A potential solution to overcome these challenges is computed laminography (CL). Rotary CL is the simplest trajectory, and like CT it consists of the acquisition of projection datasets, but the axis of rotation is inclined by an angle (<90°) instead of being perpendicular to the X-ray beam [5]. By tilting the axis of rotation planar samples can be positioned closer to the X-ray source and achieve a similar x-ray transmission through all projection angles to provide improvements in noise level and resolution. This technique has been successfully implemented using synchrotron radiation to provide

high-resolution, in-situ, three-dimensional analysis of structure failure in polymer composites, otherwise unattainable via CT [6]. It is possible to implement CL trajectories using commercial laboratory X-ray CT systems; however, its application so far has been dependant on sample manipulator arms which are not readily available at most facilities [7,8]. Although CL provides an efficient method to image flat samples its reconstruction is an ill-posed problem. Due to the tilted scanning trajectory, sampling of the object in the Fourier domain is incomplete, therefore, CL reconstruction inherently suffers from tail artefacts and inter-slice aliasing. The severity of which is proportional to the extent of laminographic tilt angle. Traditionally, this angle has been fixed to either 30° or 45° to reduce the X-ray path length through sufficiently dense samples such as printed circuit boards. Hence, it can be inferred that better quality laminography results are obtained with lower tilt angles (≤ 30°) and for more homogeneous samples [9]. It has been shown that suppression of laminography artefacts can be achieved using iterative reconstruction with total variation (TV) regularization [9,10] but this involves careful selection of the regularization parameter. A commonly observed drawback of TV-regularisation is the loss of fine details, as such, it is often advisable to search for a balance between artefact suppression and over-smoothing especially in cases that include important small features such as polymer composites.

This paper demonstrates how a CL trajectory can be accomplished using a conventional laboratory CT system, without the need for specialist equipment, through source and detector offsets. The performance of the method is compared to a standard CT scan for a large CFRP plate and is assessed in terms of image quality and its application for fibre orientation analysis. As this trajectory limits the maximum laminographic tilt angle, the achievable image quality for a low tilt angle across both vertical and side views are evaluated to explore if iterative reconstruction methods are necessary to perform characterization tasks for polymer composites.

2 EXPERIMENTAL METHODOLOGIES

2.1 Composite specimen

In this work, the composite material studied is a quasi-isotropic CFRP plate, as shown in Figure 1, obtained from Easy Composite (product code: CFS-RI-1-0056) with dimensions 250 mm × 230 mm × 4 mm. The layup schedule for the specimen consists of eight layers arranged symmetrically as follows: 210g 2/2 twill, 300g ±45° biaxial, four consecutive layers of 650g 2/2 twill, 300g ±45° biaxial, and 210g 2/2 twill layer.

2.2 CL Trajectory

The acquisition process is similar for both imaging techniques with projections obtained as the object rotates 360° around the rotation axis. For CL, the source and detector are positioned to different heights on opposite sides of the object stage. Specifically, the source is lowered, and the detector is raised to tilt the optical axis of the CT system and achieve a rotary CL trajectory (Figure 2). The extent of vertical translation for the detector permits a maximum laminographic tilt angle of 20° which was used in this study. A key benefit of this CL trajectory appears at magnifications corresponding to a ≥15μm voxel size, where the displacement is sufficient for larger samples to rotate freely above the source without risk of collision to enable higher resolutions otherwise unattainable with CT.

2.3 X-ray Acquisition

Both scan trajectories were performed on the TESCAN UniTom XL (TESCAN, Czech Republic) XCT system using a detector cropped to 2000-pixel square, 2005mm from the source, which with magnification of the sample, resulted in a 14μm voxel size. For fair comparison, the acquisition parameters remained constant between the CT and CL scans with the exception of exposure time. A voltage of 40kV was used to provide adequate penetration and contrast for both trajectories. The power was selected such that the spot size was approximately equal to pixel size, and exposure chosen

to maximise the dynamic range as described in the standardised setup process [2]. To minimise the X-ray path length for each scan the sample was mounted vertically in CT and horizontally in CL. Using the CT trajectory projections viewing the flat plate edge-on experienced propagation-based phase effects causing over-saturation, therefore, resulting in the difference between exposure times of 2.4s and 3.5s for CT and CL, respectively. A total of 3000 projections were collected using step-and-shoot mode and three averages. Both datasets were then reconstructed using the Feldkamp, Davis, and Kress (FDK) algorithm within Panthera.

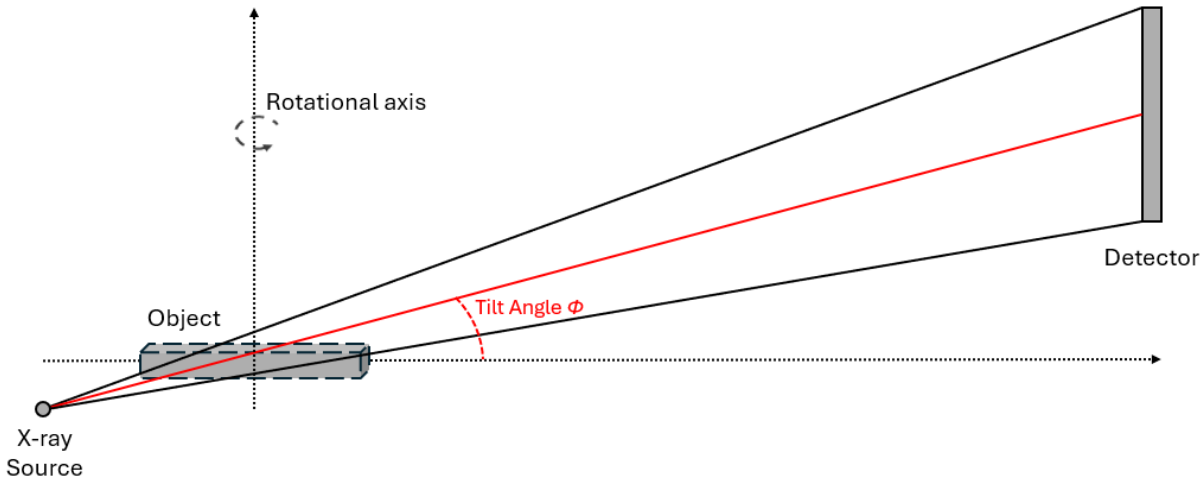

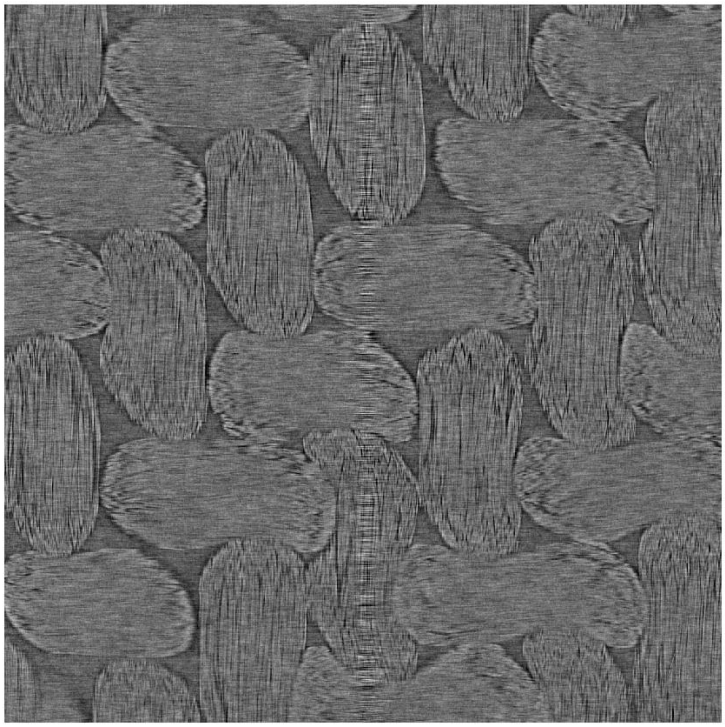

Figure 2: Schematic representation illustrating the CL acquisition geometry.

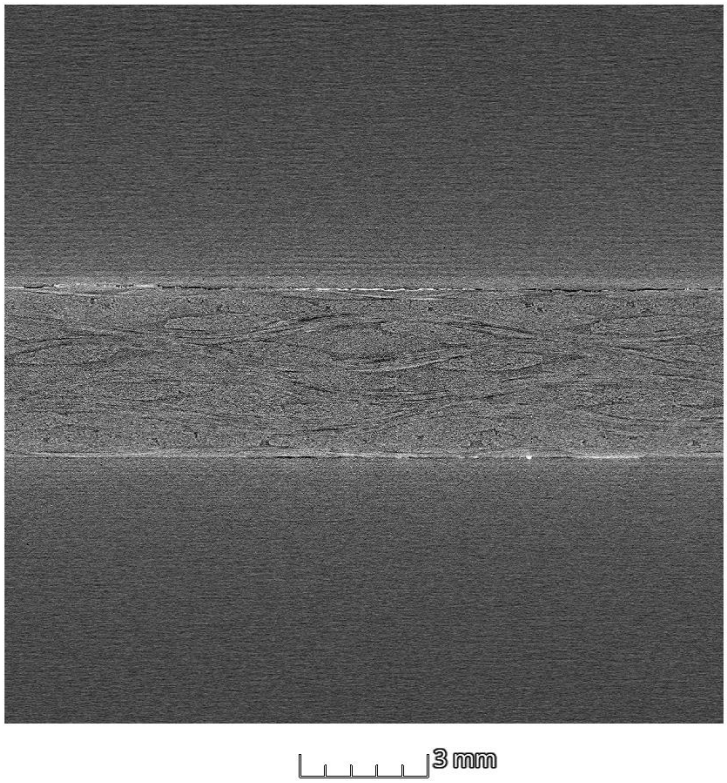
3 RESULTS AND DISCUSSION



The centre slice reconstructions are displayed in Figures 3 and 4 for CT and CL, respectively. Visually, the CT reconstruction does provide adequate image quality to observe the fibre architecture; however, the high aspect ratio geometry of the specimen contributed to several artefacts across each view. The view through the face of the specimen (3a) contains a pronounced ring artefact, characteristic of anisotropic attenuation, and due to its appearance it can obscure small defects and/or be mistaken for fibres during computational analysis. Additionally, horizontal fibres orientated parallel to the axis of rotation encounter a noticeable drop in sharpness. With CT, this issue presents another trade-off for flat plate laminates with 0°/90°/±45° ply orientations since any alternative positioning of the specimen to avoid this would further increase x-ray path lengths. When observing the plate edge-on (3b), the extent of image noise across the volume makes it difficult to distinguish the lay-up scheme or identify any defects. Alternatively, the CL reconstruction (Figure 4) produces superior image quality in terms of noise and suppression of attenuation-based artefacts especially in views through the thickness of the specimen. As shown in (4a), the ring artefact is effectively removed and fibres appear brighter, owing to the increased x-ray exposure time, and maintain sharpness of the fibre bundles in both the vertical and horizontal direction. In addition, the reduction of noise due to consistent absorption through projection angles can be quantified by CL having nearly double the signal-to-noise (SNR) ratio to that of CT with SNR values of 11.82 and 5.99, accordingly. It can therefore be inferred that thicker composites are likely to experience greater improvements in image quality from CL as they exhibit a higher proportion of projection angles associated with longer X-ray path lengths in CT. Due to the relatively low 20° tilt angle, the horizontal view (4b) does not extensively suffer from laminography artefacts which in this case consist of a cone beam artefact above the specimen proportional to the tilt angle and a slight inter-slice aliasing for plies orientated in the x-direction. With the significant reduction in noise and retention of spatial resolution of horizontal plies, the side view through CL is preferable to CT for visual observation of the specimen's lay-up scheme.

To evaluate the task-based effectiveness of each imaging technique fibre orientation analysis was performed for each volume using VGSTUDIO MAX 2024.1. The corresponding space orientation for each slice is shown in Figures 3(c-e) for CT and Figure 4(c-e) for CL. As illustrated in Figures 3(c) and 4(c), the analyses well replicate the 0°/90° weave pattern through the specimen's thickness and well match what can be observed from image slice. In both cases, some individual voxels within a bundle are subject to misorientation of 45° despite the improvement in image noise for CL. Since the investigation is on fibre bundles the small fluctuations can be resolved by increasing the integration area radius to up to half the bundle height, as shown in Figures 3(e) and 4(e) for the perpendicular view when this parameter is set to two voxels. The main difference between analyses of the weave fibre slices lies with the ring artefact in the CT reconstruction being incorrectly identified as horizontal fibres as seen by the blue strip through the centre of the image (3c). For side views facing the plate edge-on, the outer unidirectional and horizontal weave plies are more faithfully represented with CL (4d) than CT (3d) due to the significant decrease in image noise along this plane. The consequence of the slight inter-slice aliasing artefacts in CL is demonstrated within low depth areas of weave fibres orientated in the horizontal-x direction where voxels are misoriented to 45°. Although, increasing the area parameter to two voxels (4e) produces a more accurate portrayal of vertical fibres that reflect the results of CT (3d&e). Since for practical applications this parameter is optimised in accordance with the specimen's bundle size, the CL trajectory can be deemed an effective imaging technique to accurately characterise the fibre architecture of high aspect ratio structures. A 20° tilt angle effectively mitigated the expected tail artefacts associated with CL reconstruction using the normative FDK algorithm, as such, TV regularisation methods are likely unnecessary for fibre-based tasks at low laminography tilt angles. However, laboratory-based CL imaging of low-density materials may benefit from standard iterative reconstruction methods to aid high-throughput acquisition whereby the increased scan duration attained by additional exposure time could be offset by reducing the number of projections collected.

4 CONCLUSIONS

In this study, an alternative laminography trajectory was implemented to characterise the fibre architecture of a large high-aspect ratio carbon-fibre laminate. The CL reconstruction was found to produce superior image quality in the plane parallel to the plate's face compared to CT as quantified by an improvement in SNR of 11.89 from 5.99 for the central slice. CL also avoids the consequences of anisotropic attenuation as shown by the suppression of artefacts and preservation of image sharpness for horizontally aligned fibres. Notably, the main difference in computational analysis between the parallel slices was the pronounced ring artefact in the CT reconstruction being misidentified as horizontal fibres. In the side view, a low tilt angle of 20° alleviates the characteristic laminographic artefacts, at which, standard FDK reconstruction is sufficient for CL reconstruction when imaging composite materials. In fact, due to the significant reduction in image noise in this plane, CL provides more visual information of the specimen's lay-up scheme. Further, the results of orientation analysis demonstrate CL as an effective technique for the accurate calculation of fibre direction in laterally extended samples. Overall, the implementation of the CL trajectory is likely to facilitate the greatest benefit for thicker composites and/or structures larger than 400mm where the specimen is free to rotate over the source to achieve a higher resolution otherwise unattainable with CT. Future work will focus on the application of standard iterative reconstruction methods to CL to reduce acquisition times and facilitate high-throughput inspection.

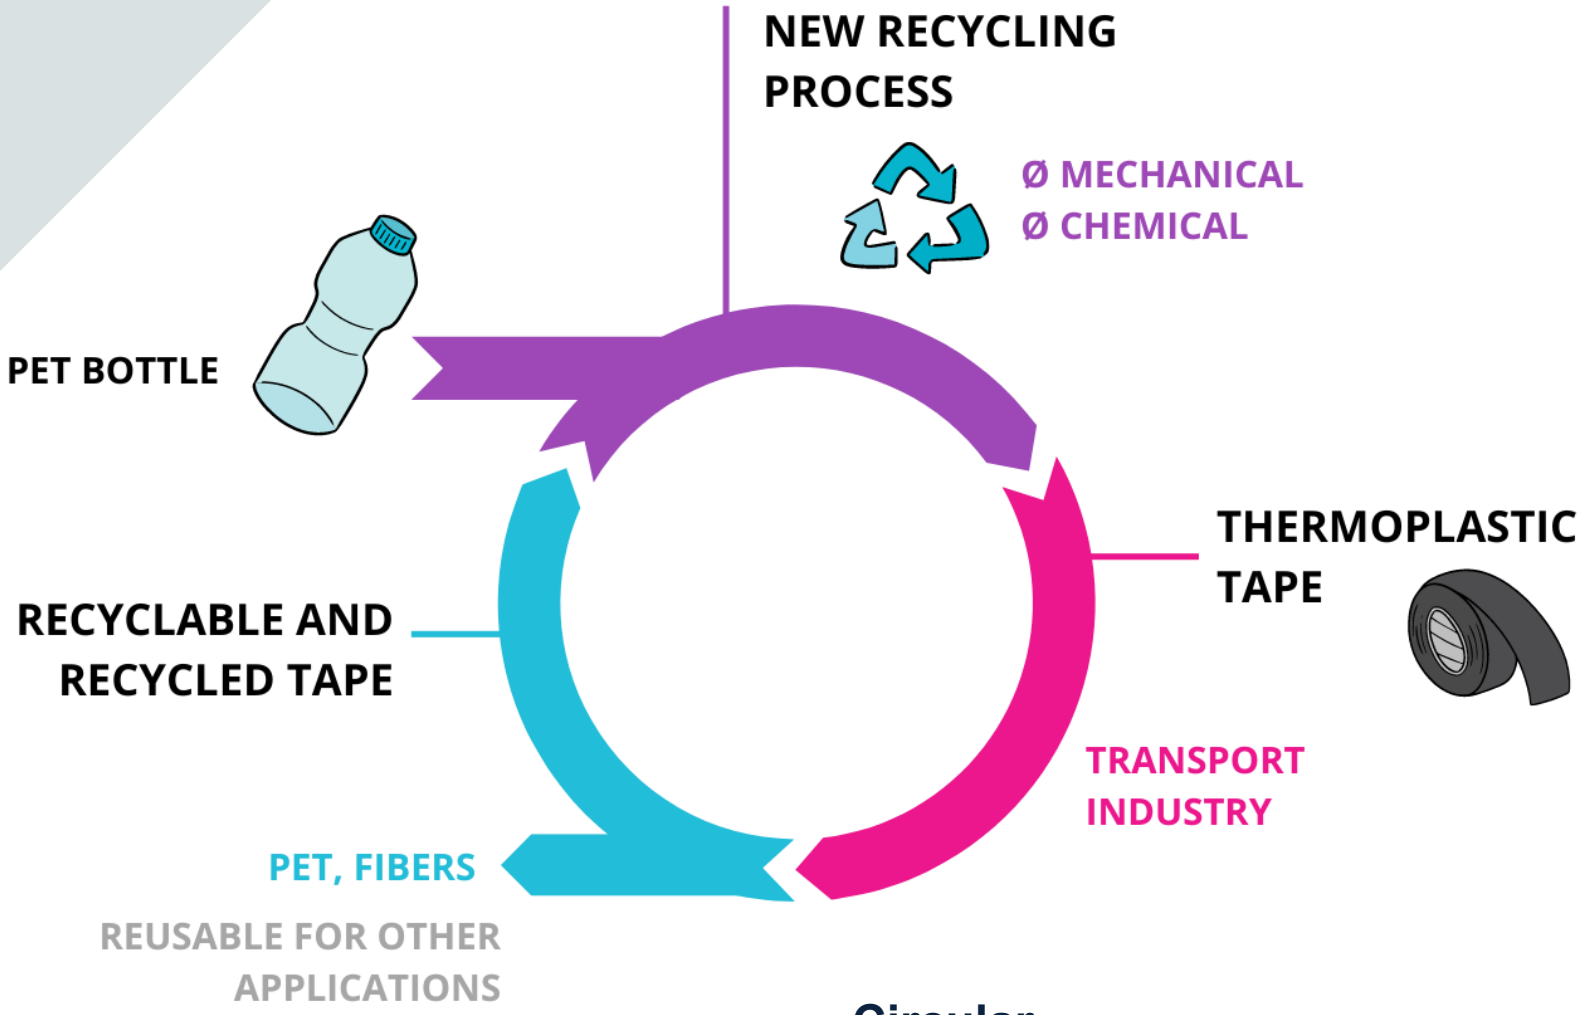
CONTEXT

Major environmental issues :

- One of the most widely used polymers [1] → **413 Mt of plastic produced in 2023** [2] → **6,2 %** of PET waste [2]
- Efficient, sustainable, circular and low-energy impact recycling method are **essential**



Current recycling method :

- Most plastics are **shredded**: mechanical recycling process → **degradation of mechanical properties** [3]
- New recycling method: impregnation of fibers to make thermoplastic tapes → **Capillarity characterization**

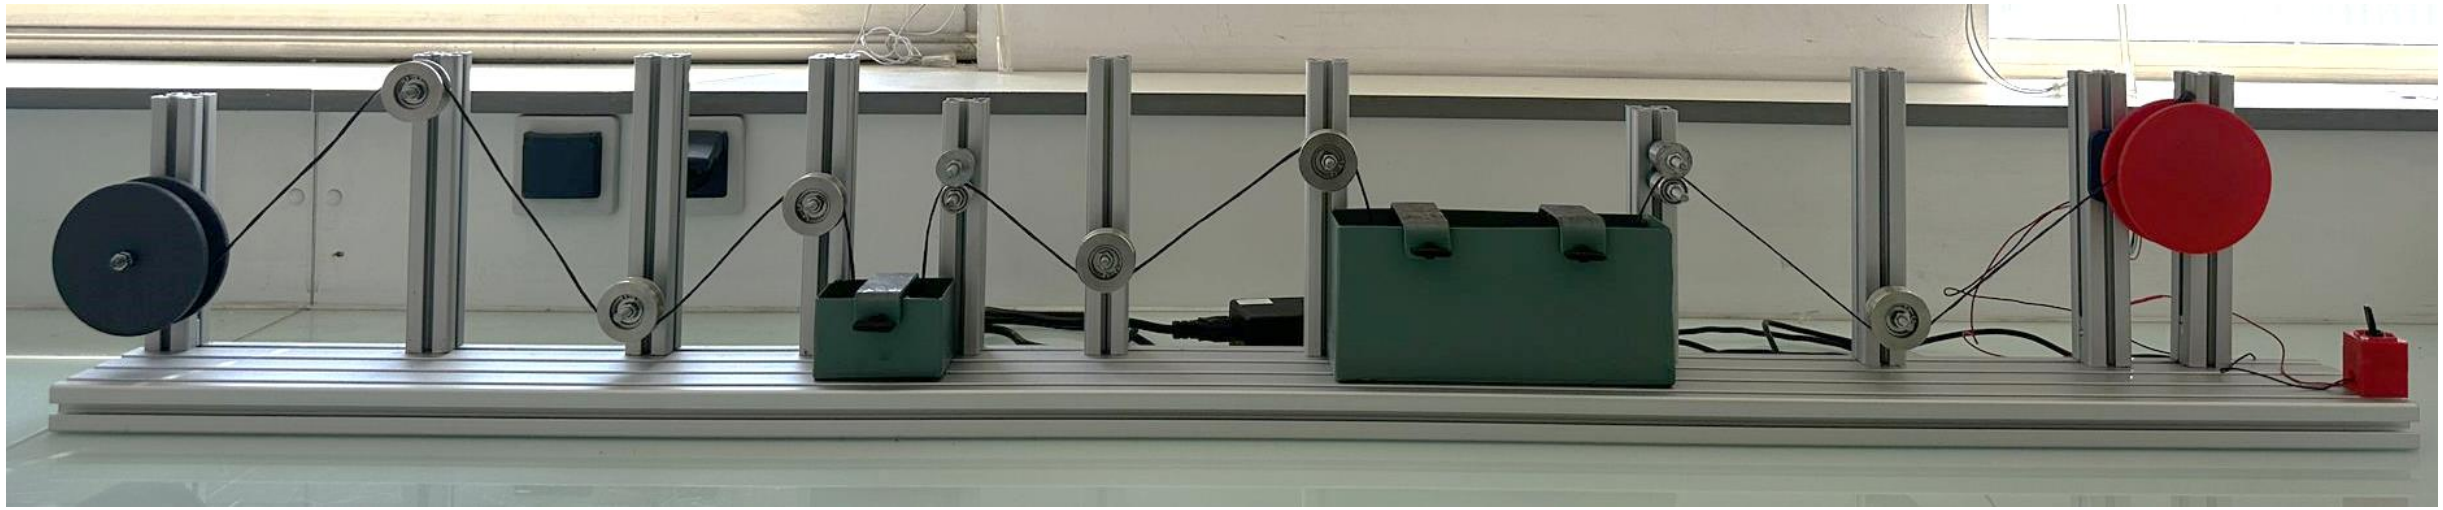
IMPREGNATION LINE – METHODOLOGY

MODULES OF IMPREGNATION LINE

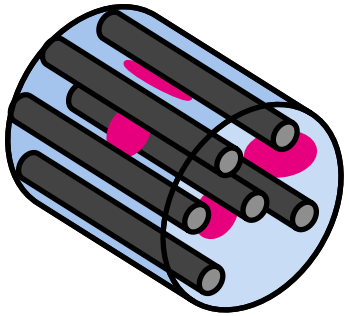
- Impregnation bath : polymer solution
- Precipitation bath : non-solvent
- Guide rollers
- Steamrollers
- Motorised winding coil



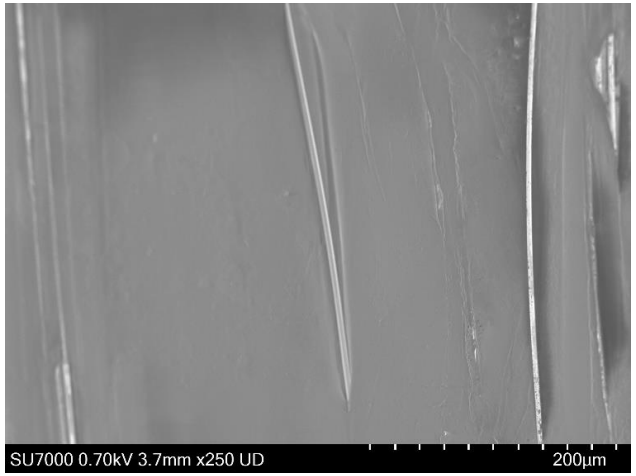
Parameters optimization

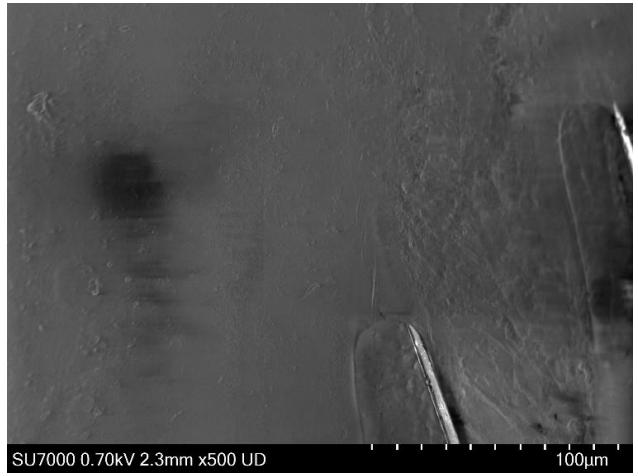
- **Impregnation** : impregnation speed, rollers tension, concentration of polymer
- **Precipitation** : precipitation speed, solvent recovery
- **Tapes characterization** : Morphology and porosity characterization, mecanical behaviour, fibres volumic fraction

IMPREGNATION LINE – METHODOLOGY

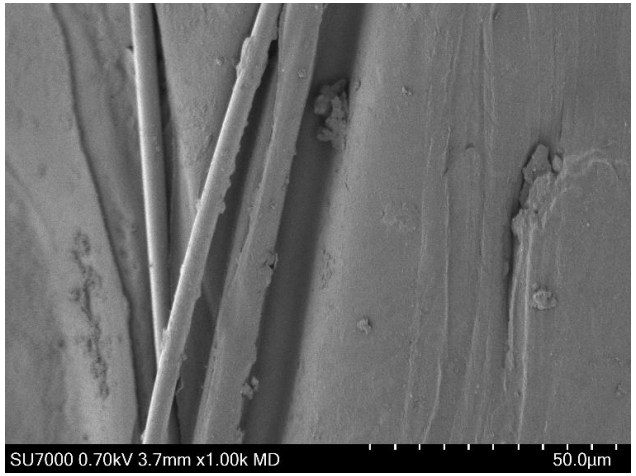


MODULES OF IMPREGNATION LINE

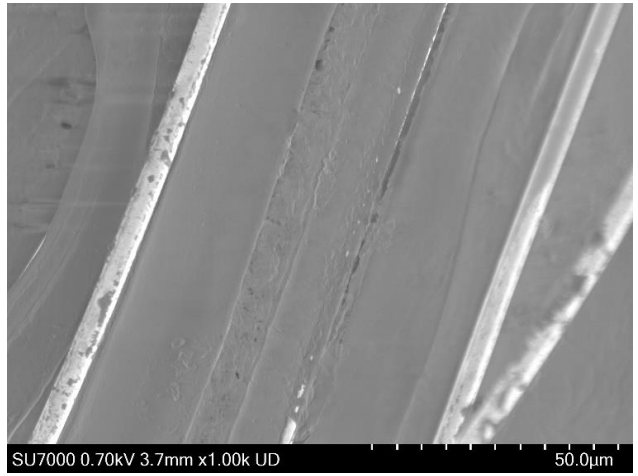




IMPREGNATION LINE – CHARACTERIZATION



SEM analyses – Morphology of the thermoplastic tapes

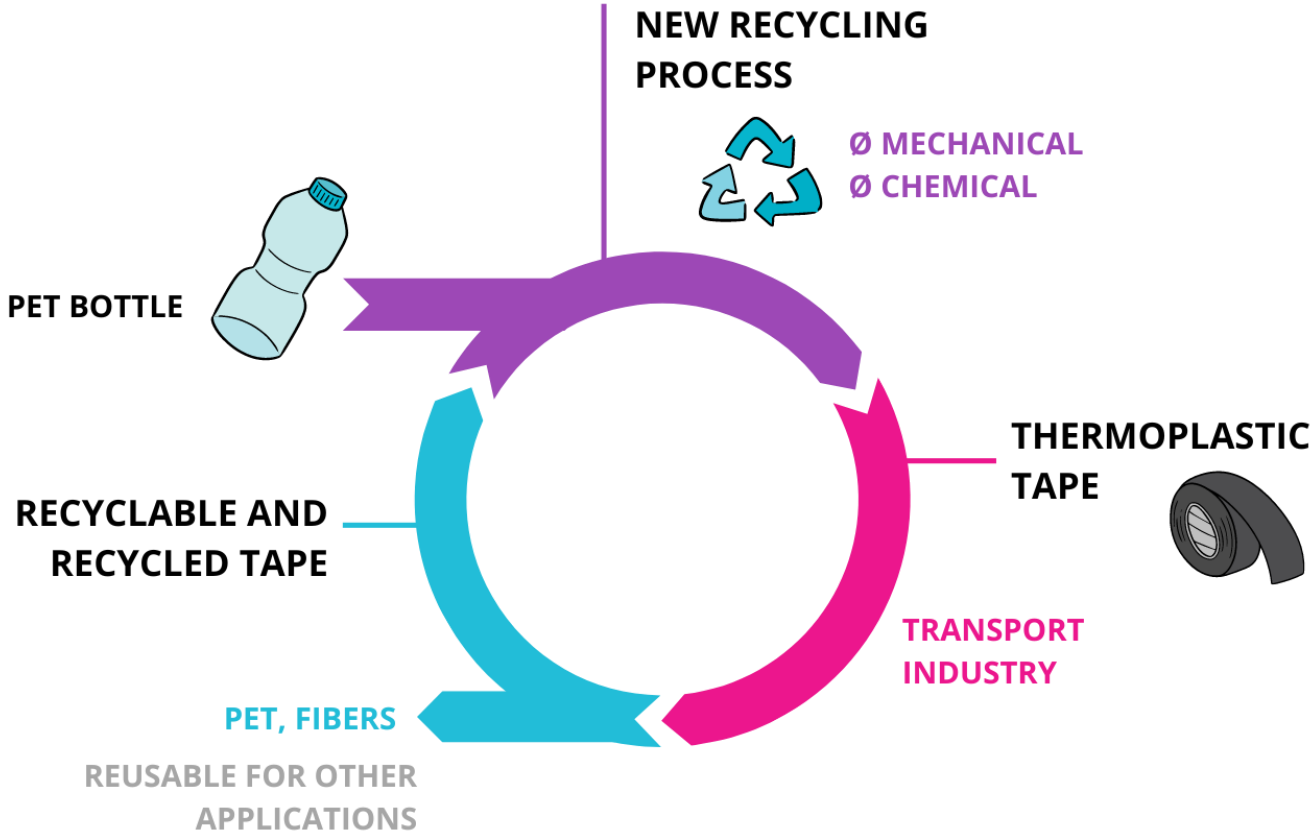


- Carbon fibers **IM7 12k** - Hexcel
- $V = 6mm/s$

CONCLUSIONS PROSPECTS

CONCLUSIONS

- **Dissolution / Precipitation method** has been selected and validated.
- **Innnovative and efficient method for recycling PET has been developped.**
- **Production of tapes** has started and is running successfully



PROSPECTS

- **Optimise** production parameters : speed, tension, concentration
- **Characterization** of the produced tapes
- Test with a **robotised draping process**

Background

- **Forged composite molding (FMC)**, originally developed for compression molding of chopped carbon fiber-reinforced thermosets, is widely used in the automotive sector.
- With growing focus on sustainability and circularity, **thermoplastic molding compounds** are gaining traction.
- **Thermoplastic BMCs/SMCs** also offer benefits better fracture toughness and faster cycle times, though they require higher processing temperatures than thermosets.
- This study investigates the use of a **high-temperature compression moulding** unit for **reprocessing thermoplastic waste** via bulk moulding.

Mitsubishi CF thermoset SMC
[https://www.m-chemical.co.jp/carbon-fiber/en/product/fmc/]

GF thermoset SMC used to produce battery box

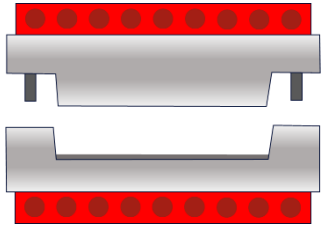
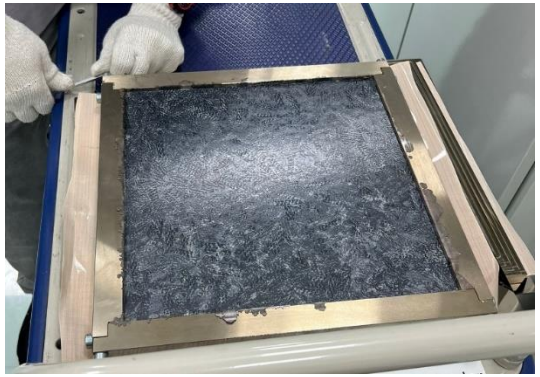
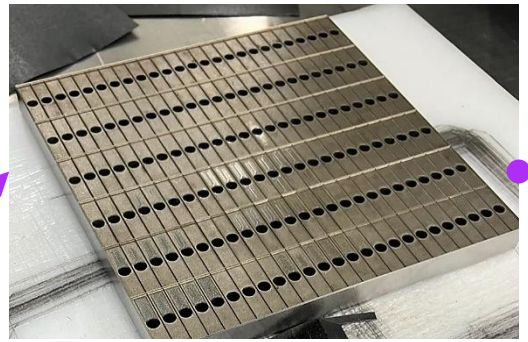
Toray chopped fiber thermoplastic BMCs
[https://www.toraytac.com/products/thermoplastic/bulk-molding-compounds]



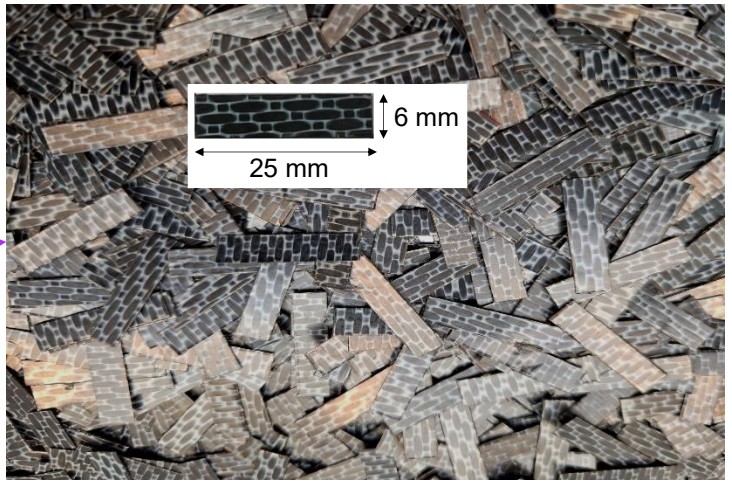
What is LCF?



- Trim waste, known as **Loose Chip Forms (LCF)**, is generated during prepreg cutting and is repurposed into **uniform rectangular chips** for recycling.
- A **die cutter** is used to shape the chips into consistent sizes.
- The uniform chips are then **recycled using a compression moulding process**.
- This approach gives **a second life to the trim waste**, turning it into useful material.



Fabricated LCF composite panel



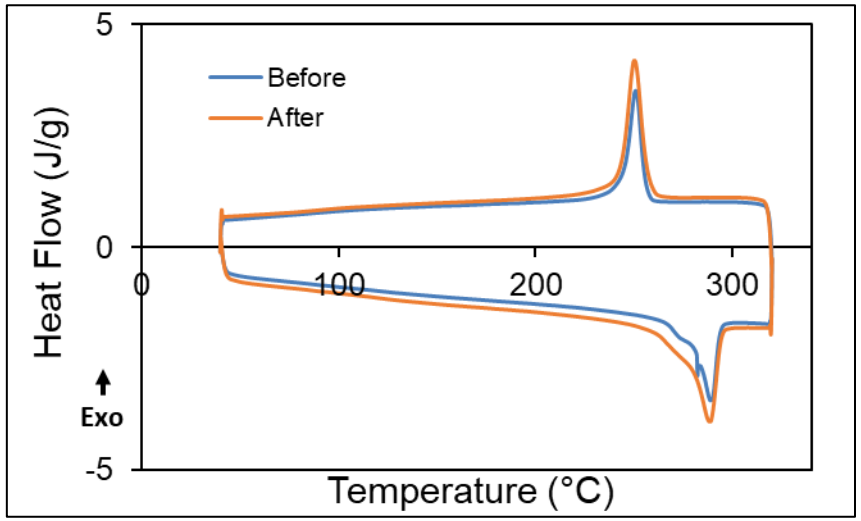
LCFs of 5HS CF-PPS (Polyphenylene Sulfide)

Excess, waste material

Die Cutter

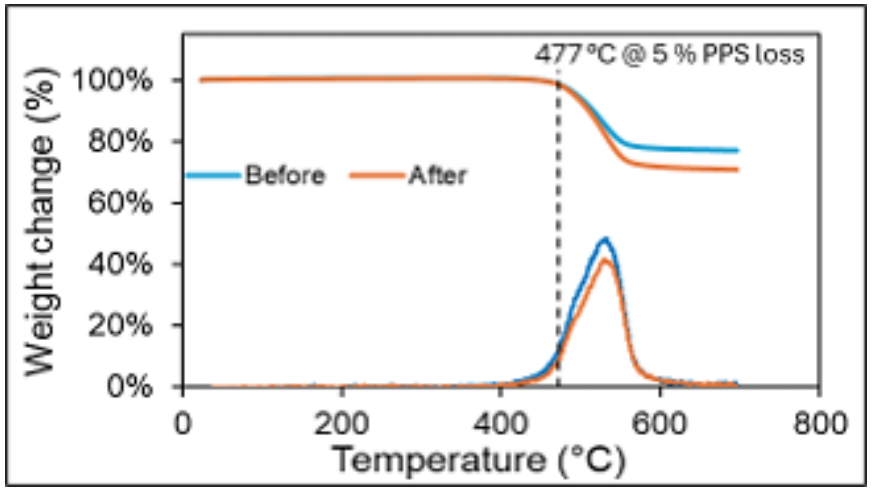
Uniform LCF

Shredder/Grinder



Non-uniform LCF

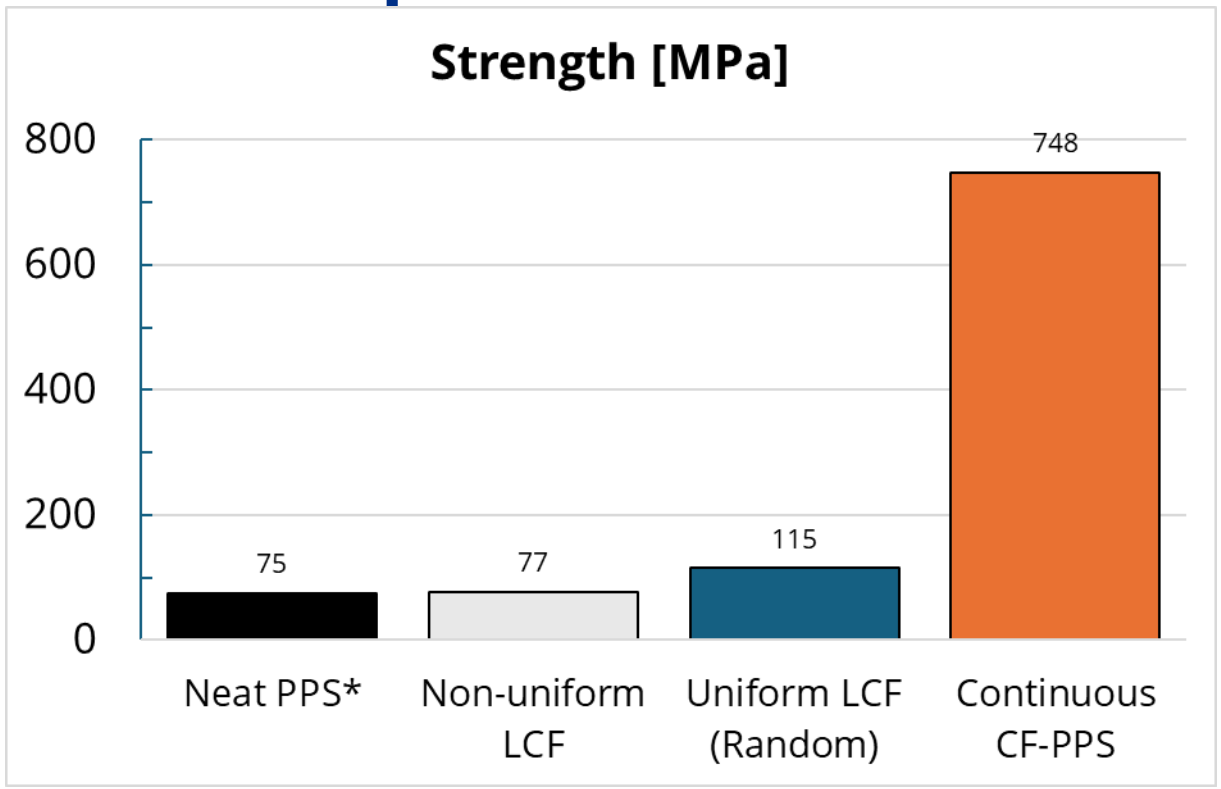
Thermal Characterization



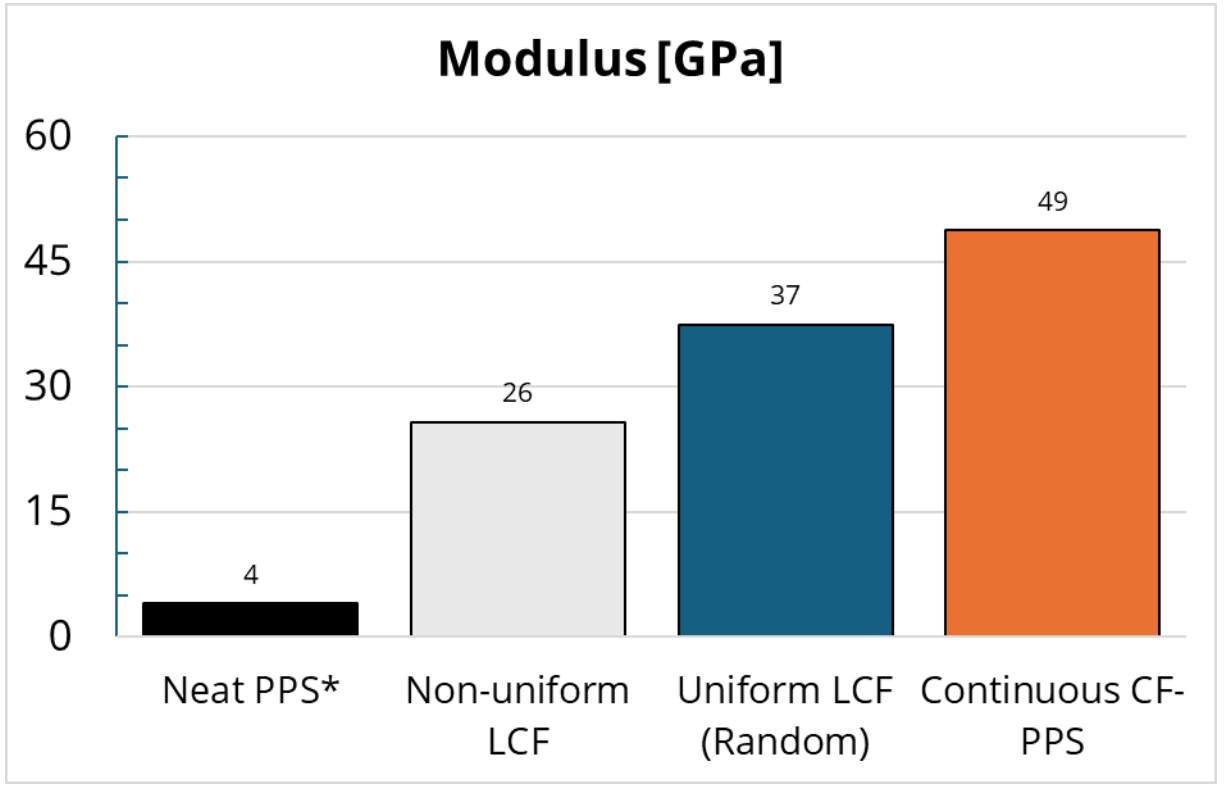
- **Melting, crystallization** (from DSC) and **degradation temperature** (from TGA) data shows **processing window** whereby PPS can flow and allow forming of the prepreg without degradation onset.
- Higher % crystallinity: polymer crystals are hard and strong, which affects **mechanical properties**.

DSC

- Melting point: **289°C**; Crystallisation point: **251°C**; Crystallinity: 45.3 (as received), 43.9 (after processing)



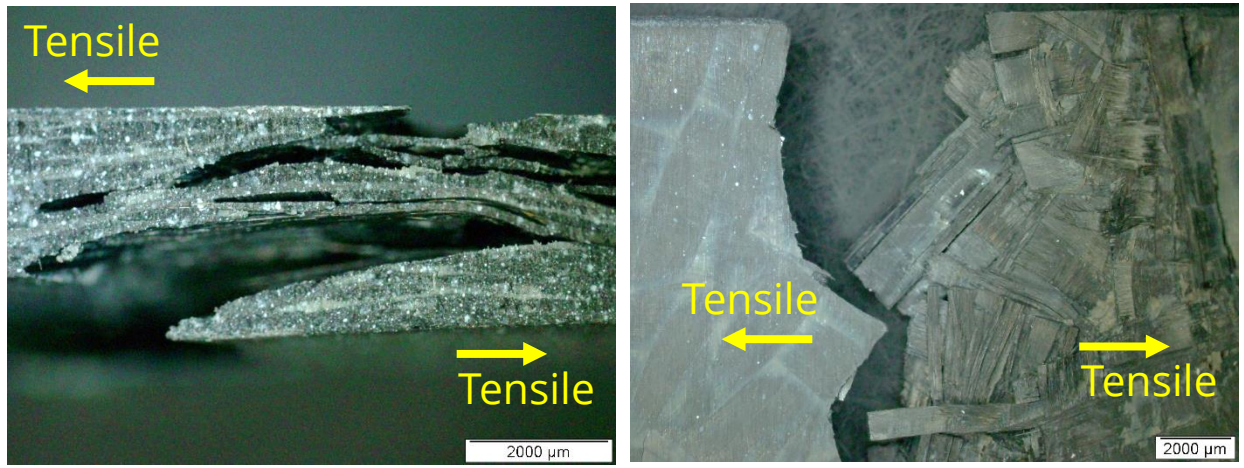
TGA



- Onset degradation temperature: **477°C** at 5% PPS loss; PPS content: 35.7 wt%.

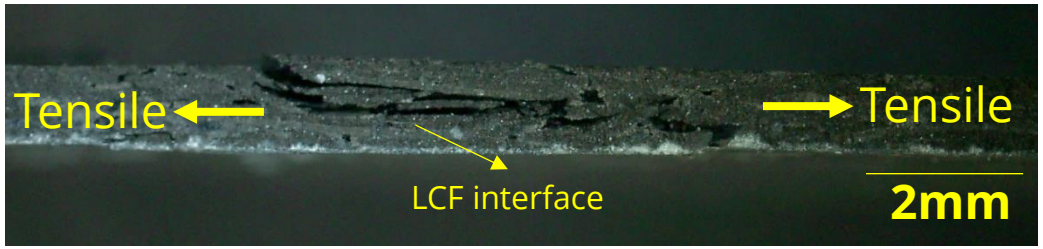
Processing parameters	
Heating temperature	320°C – 330°C
Cooling rate	10°C/min (quench)
Pressure	12.5 bar – 15 bar

Tensile performance: Uniform vs Non-uniform LCF

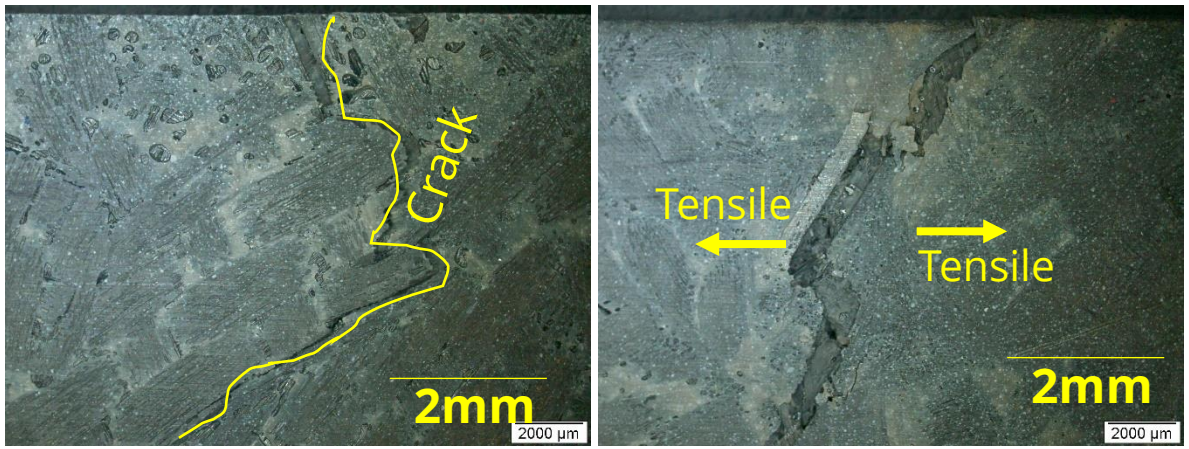


- Uniform LCF (random) outperforms non-uniform LCF by 49% in tensile strength.
- Non-uniform LCF shows no meaningful improvement over neat PPS in tensile strength.
- Uniform LCF achieves 15%, and non-uniform LCF only 10%, of the tensile strength of continuous CF-PPS.

- Non-uniform LCF shows a 6.5x improvement in tensile modulus over neat PPS, but is:
  - 30% lower than Uniform LCF
  - 47% lower than Continuous CF-PPS
- The lower tensile strength and modulus of **non-uniform LCF** is likely due to **more fiber fractures during the shredding process**, resulting in **shorter, damaged fibers** that reduce reinforcement efficiency.



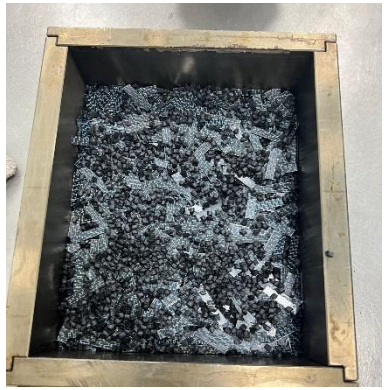
- [https://omnexus.specialchem.com/selection-guide/polyphenylene-sulfide-pps-plastic-guide] ; [https://www.mcam.com/en/products/pps]



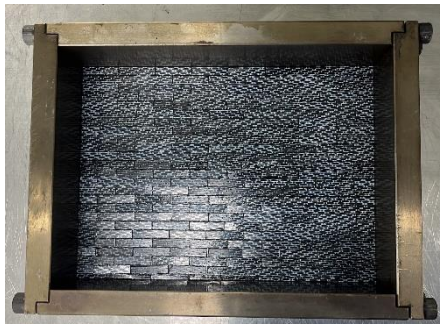
Failure of Uniform and Non-uniform LCF

Uniform LCF

Non-uniform LCF

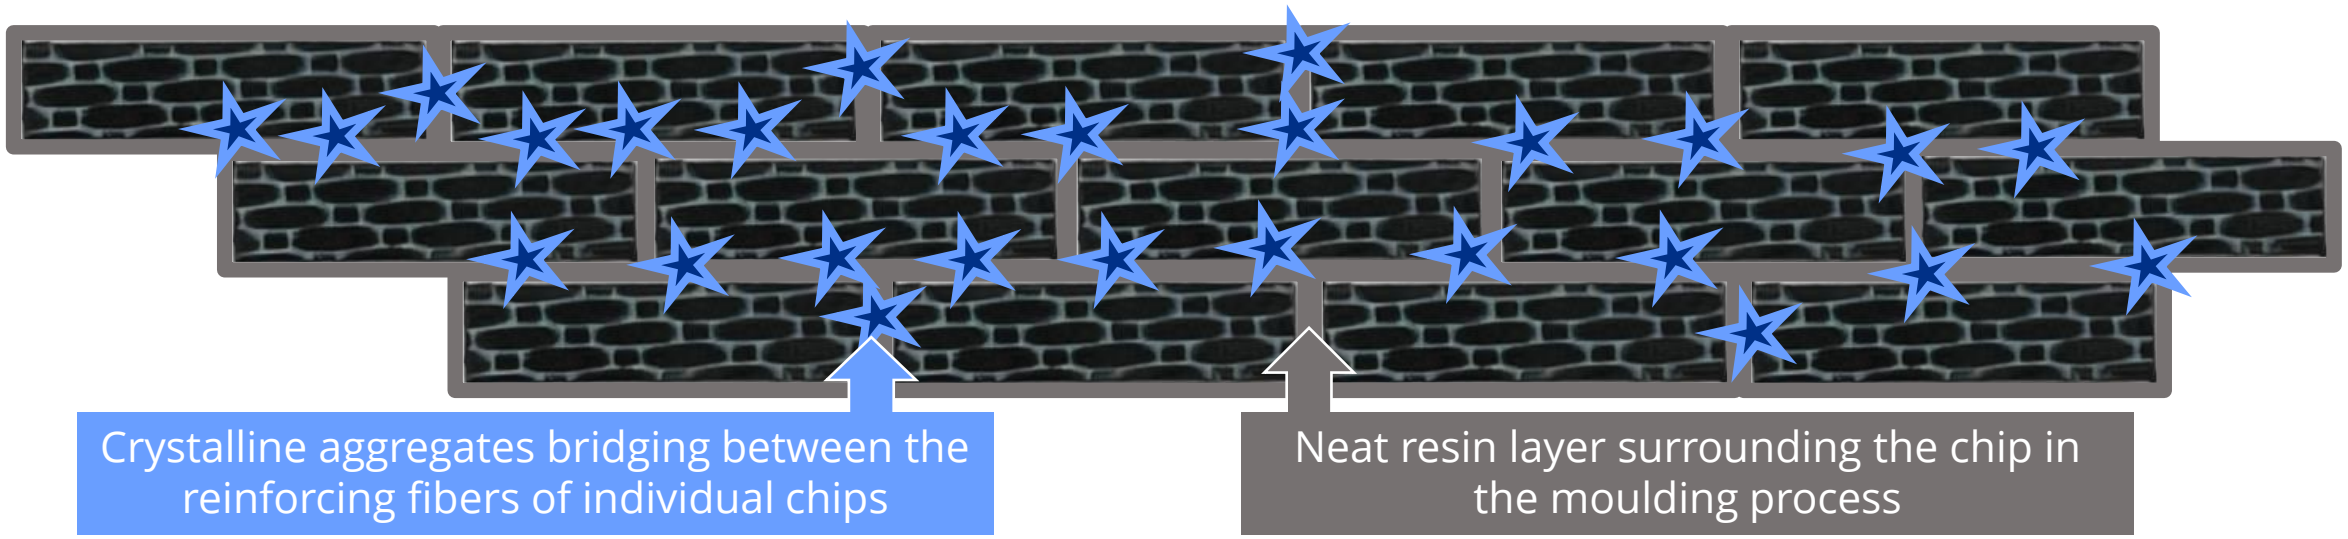


- **Both uniform and non-uniform LCF composites** primarily failed at **the fiber–matrix interface,** indicating **matrix-dominated failure mechanisms**.
- This is supported by cross-sectional fracture images, which show poor debonding rather than fiber breakage.
- As a result, the overall tensile strength of these composites remains relatively close to that of neat PPS.



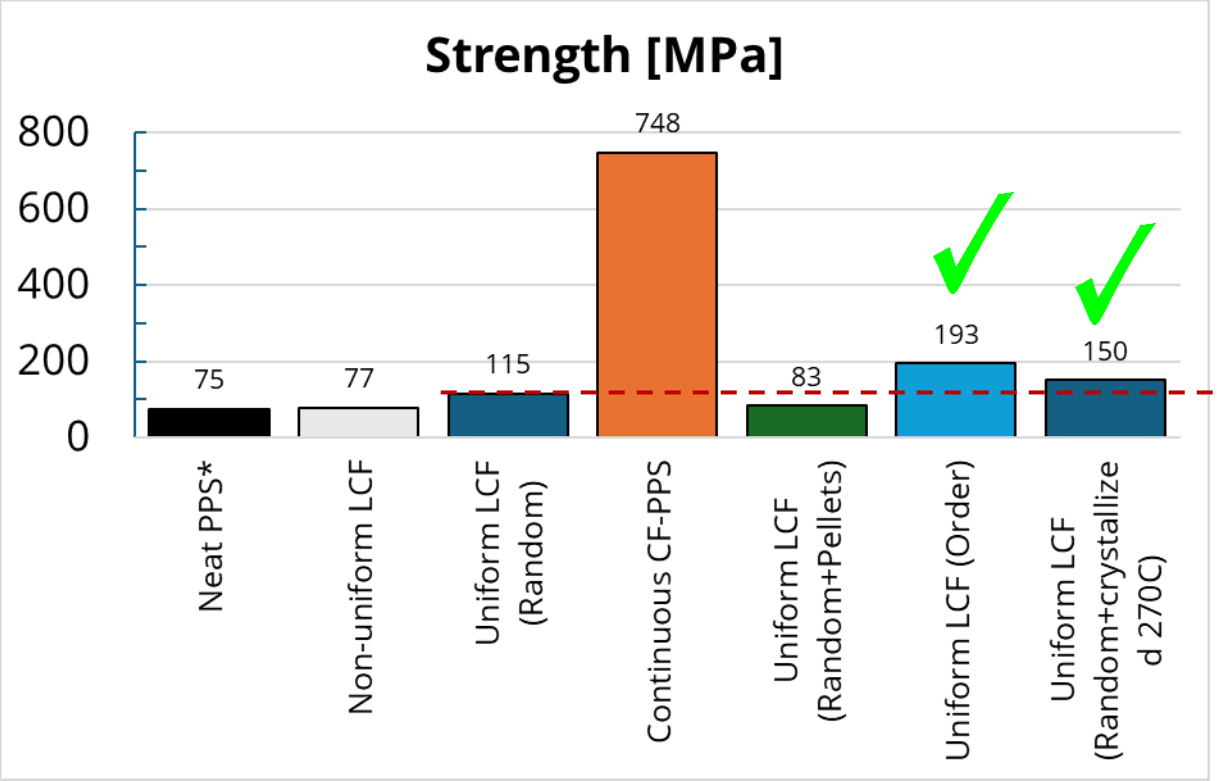
Efforts to Improve Mechanical Performance

1. **Material Blending**
   - Added uniform LCF to PPS pellets with 30% short fibers.
   - Aimed at increasing matrix-fiber interaction and strength.
2. **Chip Arrangement (Ordered)**
   - Used overlapping and stacked configurations of LCF.
   - Improved load transfer paths and reduced weak inter-chip interfaces.
3. **Processing Parameter Enhancement**
   - Applied isothermal crystallization at 270°C during compression moulding.
   - Targeted improved crystallinity and interfacial bonding for better mechanical integrity.

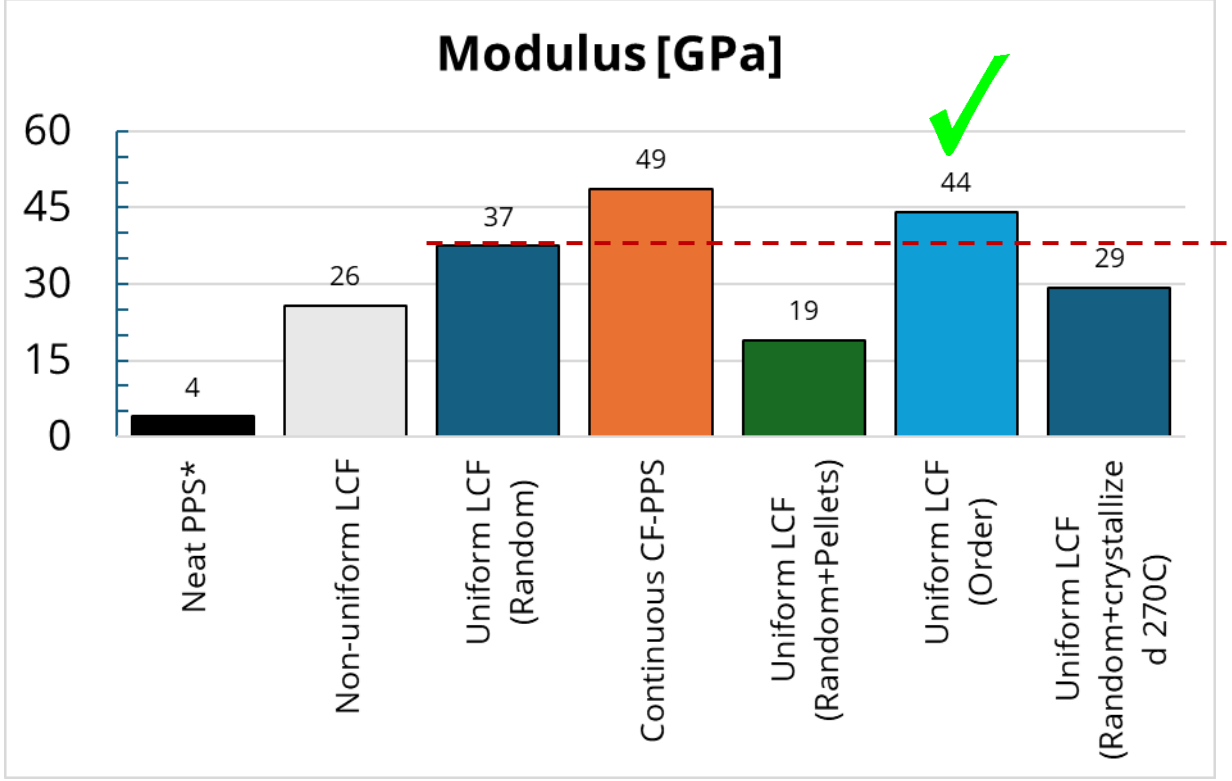


5HS CF-PPS (100g) + short fiber CF-PPS pellets (50g)

1. Blended with short fiber reinf. PPS pellets



2. Ordered

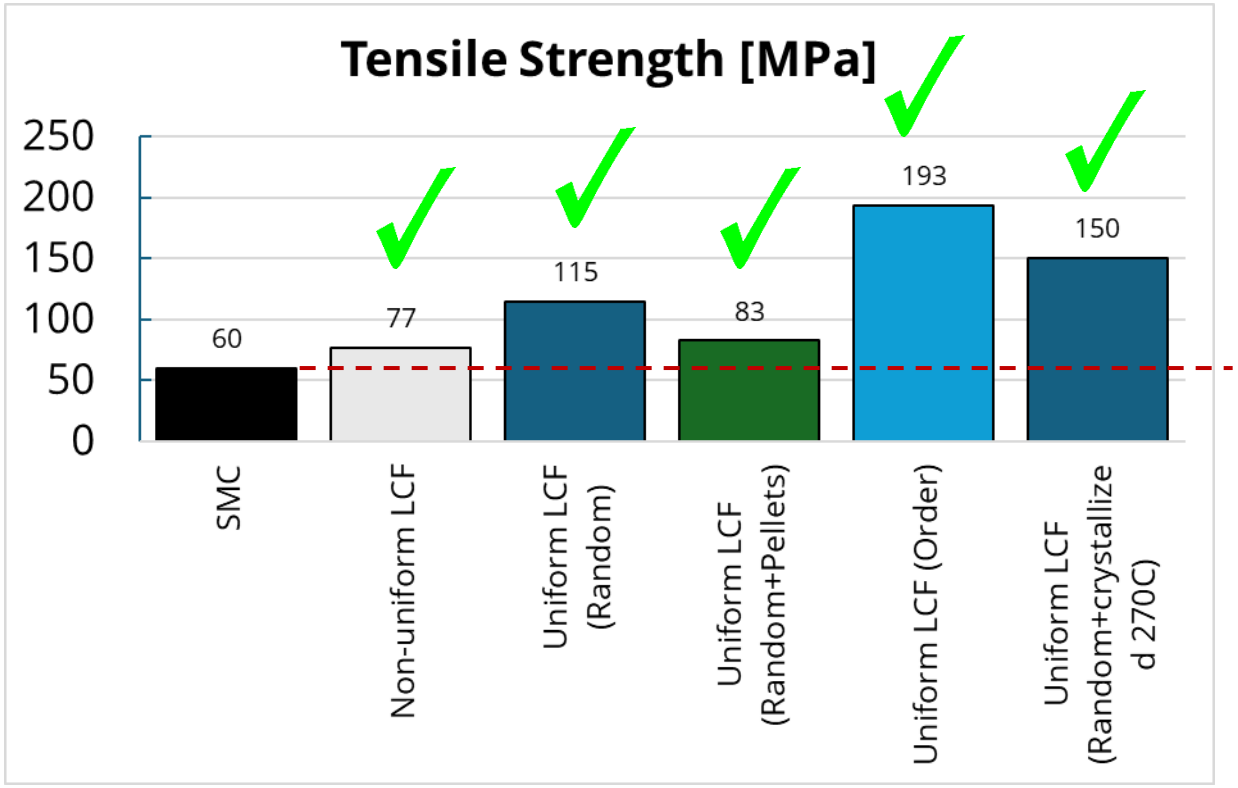


3. Processing parameters	Standard	Optimized
Heating temperature	320°C – 330°C	320°C – 330°C
Isothermal crystallization	-	**270°C for 30 mins**
Cooling rate	10°C/min	10°C/min
Pressure	12.5 bar – 15 bar	12.5 bar – 15 bar

- Manipulate crystallization process to promote larger crystal aggregates bridging between individual chips.
- This should allow for mechanically interconnected or interlocked the individual chips => stronger connection between the chips.
- Unlike method 2 (chip arrangement / ordered LCF), isothermal crystallization does not require additional time or automation for chip alignment.

Improvement on Tensile Properties

Compared to the Uniform LCF (Random):



- **Blending with short-fiber PPS pellets reduced both tensile strength and modulus**, reflecting limited fiber-matrix reinforcement and a more matrix-dominated structure due to reduced fiber content.
- **Aligning and stacking LCF chips enhanced tensile strength by 68% and modulus by 19%,** attributed to improved load transfer through better chip-to-chip connectivity.
- **Isothermal crystallization led to a moderate strength gain**, likely resulting from increased crystallinity.

Benchmarking against a Commercial Thermoset SMC

- SMC is commonly used for interior panels and cabin linings, including window surrounds, wall panels, galley modules, lavatory shells, and floor liners.

Aviation-certified glass-filled SMC from Polynt composites (HUP 27/25 RN-9010)

- All reprocessed LCF composites outperformed the commercial aviation-grade glass-filled SMC (60 MPa) in tensile strength demonstrating that even in their various forms, **reprocessed LCFs** offer superior mechanical performance and are **viable candidates for interior cabin applications**.

Conclusion

- **Non-uniform (shredded) LCF underperformed** compared to uniform LCF, with 30% lower tensile strength and modulus, likely due to fiber damage and shortened lengths.
- **Ordered LCF arrangement yielded the best mechanical enhancement**, achieving 2.6x higher tensile strength and 11x higher modulus than neat PPS, and reaching 26% of the tensile strength and 90% of the modulus of continuous CF-PPS.
- **The thermal processing (Isothermal crystallization)** approach also **showed a positive effect on the mechanical properties,** delivering 1.3x higher tensile strength than randomly aligned uniform LCF.
- **Material blending with short-fiber reinforced PPS pellets** showed **negligible improvement** in tensile properties.
- **The ability of reprocessed LCFs to meet or exceed the tensile strength of thermoset SMC highlights their potential for lightweight, recyclable thermoplastic alternatives** in aerospace interior applications, offering additional benefits in sustainability.

Future work

- Investigate the **effect of LCF size and aspect ratio** on mechanical performance.
- Evaluate **notch sensitivity** through open-hole tension (OHT) and open-hole compression (OHC) testing, benchmarking the results against neat PPS and continuous CF-PPS to assess damage tolerance and structural applicability.

Georgia Tech

What recycling methods are being used for PC and PP

- Mechanical recycling
- Chemical recycling

Our project focus:

- In-depth materials research for tailored material compositions for additive manufacturing

Broader aim:

- Increase community access to 3D printing.
- Drive localized and on-demand production.

1. Plastic recycling facts, 2024 American Chemistry Council, 2024

Questions this research will address

We aim to salvage both PC and PP, regardless of their feedstock or source.

- Is reprocessing affecting the performance of recycled PC and PP?
  - If yes, is degradation occurring and why?
  - Can additives combat this degradation?

Georgia Tech

Conclusions and going forward

Is reprocessing affecting the performance of recycled PC and PP?	Is degradation occurring, and why?	Can additives combat this degradation
Both PC and PP formulations withstand 10 melt cycles.	Extensive degradation not observed.	Additives didn't significantly affect our properties, except: 1. Enhanced performance in PP/WF-based formulations 2. Reduction in the tensile modulus of PC.

Moving forward:

- Study PC/PP blends across extrusion temperature, residence time, and reprocessing cycles.
- Conduct detailed rheology analysis of all formulations.
- Introduce reclaimed glass fiber into PP and PC (to combat the tensile modulus reduction).

ABSTRACT

This study presents an Artificial Neural Network–based Sequential Approximate Optimization (ANN-SAO) framework for the multi-dimensional design of curvilinear fiber paths in variable-axial composite laminates to maximize their fundamental natural frequencies. In each iteration, a feedforward neural network with four hidden layers, each composed of a linear transformation, layer normalization, SiLU activation, and dropout is trained on the current database of high-fidelity simulations. Early-stopping, weight decay, and adaptive learning-rate scheduling ensure both accuracy and generalization while keeping computational cost tractable. Covariance Matrix Adaptation Evolution Strategy (CMA-ES) is then applied to the ANN response surface to identify an exploitation point, whereas a companion Radial Basis Function based density function searches the sparsest region of the design space for exploration. The two candidates are evaluated with full Finite Element Analysis (FEA), their responses are appended to the training set, and the ANN surrogate is retrained. This cycle repeats until the maximum number of iterations is reached. Using this strategy, the number of expensive simulations is reduced while maintaining a global search capability. Numerical results for composite laminate plates show that the optimized curvilinear fiber architectures achieved by ANN-SAO yield substantial increases in the first natural frequency and favorable tailoring of the mode shape, thereby mitigating resonance risk and enhancing dynamic reliability. The proposed ANN-SAO framework thus provides an efficient, scalable, and accurate tool for vibration-driven design of advanced composite structures with free fiber trajectories.

1 INTRODUCTION

Carbon Fiber Reinforced Plastics (CFRP) are composite materials consisting of carbon fibers embedded within a resin matrix. These materials exhibit high strength and high stiffness [1], making them increasingly favored in industries such as aerospace and automotive [2]. The anisotropic nature of CFRPs enables the tailoring of fiber orientations to meet specific mechanical requirements, offering design advantages over isotropic materials, albeit with increased complexity. Recent advancements in fiber placement technologies have further expanded this design space. Automated Fiber Placement (AFP)

enables high-throughput deposition of steered tows along non-straight trajectories, yielding complex, load-adapted laminates [3], while Tailored Fiber Placement (TFP) stitches continuous fiber tows directly onto a substrate, realizing variable-axial paths with minimal waste [4]. Recent advancements in continuous fiber-reinforced polymer additive manufacturing techniques now enable the fabrication of continuous fiber-reinforced polymer composites with complex geometries and tailored fiber orientations, enhancing mechanical performance and expanding design possibilities for composite structures [5]. Previous studies have presented analytical methods for determining the natural frequencies and vibration modes of laminated plates with curvilinear reinforcing fibers. The results demonstrate that curvilinear fiber paths can significantly influence the dynamic behavior of composite structures [6-8]. To exploit this potential, researchers have applied a variety of optimization strategies. Early work focused on stacking-sequence or lay-up optimization of straight fiber laminates, using meta-heuristics such as particle swarm optimization (PSO) to maximize fundamental frequencies [6] and nonlinear lay-up optimization of variable stiffness composite cylindrical panels in free vibration using gradient-based methods, demonstrating enhanced fundamental frequencies through tailored fiber orientations [9]. While effective, these direct-search approaches require thousands of high-fidelity finite element evaluations and therefore become expensive when the design space expands to free (curvilinear) fiber paths.

The classical Sequential Approximate Optimization (SAO) framework encompasses various surrogate modeling techniques, such as Kriging, Radial Basis Function (RBF) networks, and Support Vector Regression (SVR). These methods are extensively applied in engineering optimization, particularly when dealing with computationally expensive numerical simulations, as they effectively reduce the number of function evaluations required [10]. More recently, artificial-neural-network (ANN) surrogates have exhibited higher approximation accuracy and better generalization than linear regression (LR), decision tree (DT) and random forest regression (RF) when learning highly non-linear composite behaviors, particularly for buckling and strength prediction [11]. Building on these advances, this study proposes an Artificial Neural Network-based Sequential Approximate Optimization (ANN-SAO) framework to optimize curvilinear fiber paths in variable-axial composite laminates. In each iteration of the ANN-SAO, an ANN surrogate model (response surface) is constructed, and its predicted optimum is taken as a new sample point for local refinement. To maintain global search coverage, a radial-basis-function-based density metric identifies sparsely sampled regions and guides the addition of exploratory sample points. Through these exploitation and exploration steps, the surrogate model's accuracy is progressively improved, facilitating the discovery of fiber path configurations that significantly enhance the structure's dynamic performance.

2 EXPRESSIONS OF CURVILINEAR FIBER PATHS BY RADIAL BASIS FUNCTIONS

As a first step, we describe how curvilinear fiber paths are parametrically represented using radial basis functions, which will serve as the design variables for optimization. To represent high-degree curvilinear fiber paths on a plane, a surface generated by radial basis functions (RBFs) is employed. This approach involves generating a surface using RBFs, through a linear combination of three Gaussian functions, as shown in Eq. (1).

$$f(x,y)_{surface} = \sum_{i=1}^{3} w_i \, exp\left(-\frac{\left(x-x_{c,i}\right)^2+\left(y-y_{c,i}\right)^2}{r_i^2}\right) \tag{1}$$

This approach can capture the shape of a surface with a a high degree of flexibility. Here $(x_{c,i}, y_{c,i})$ represents the center point, and the parameter r_i influences the surface smoothness: larger r_i values yield flatter shapes, whereas smaller r_i values produce sharper peaks. Each Gaussian component is multiplied by a weight factor w_i and summed to form the surface, which means the fiber path can be controlled by adjusting the parameters $x_{c,i}, y_{c,i}, r_i$ and w_i (where $i = 1, 2, 3$), the fiber path can be flexibly controlled (Fig. 1a). The contour lines of this RBF-generated surface define the nominal fiber paths. To ensure the path is manufacturable via the TFP process, the tool's vertical (z-axis) movement is modulated according to the fiber tow overlap rate α (Eq. 2), as illustrated in Fig. 1b.

$$\alpha = \frac{w_f - d}{w_f} \tag{2}$$

Where w_f is the width of a single fiber and d is the spacing of the centerline of the fiber tow. These contour lines are then discretized into segments using the curve's gradient from Eq. (3) to determine each segment's slope relative to the element centroid. This discretization facilitates their expression in a finite element model, as shown in Fig. 1c.

$$\theta_e = Tan^{-1}\left(\frac{\partial f/\partial y}{\partial f/\partial x}\right)\Big|_{x=x_e, y=y_e} \tag{3}$$

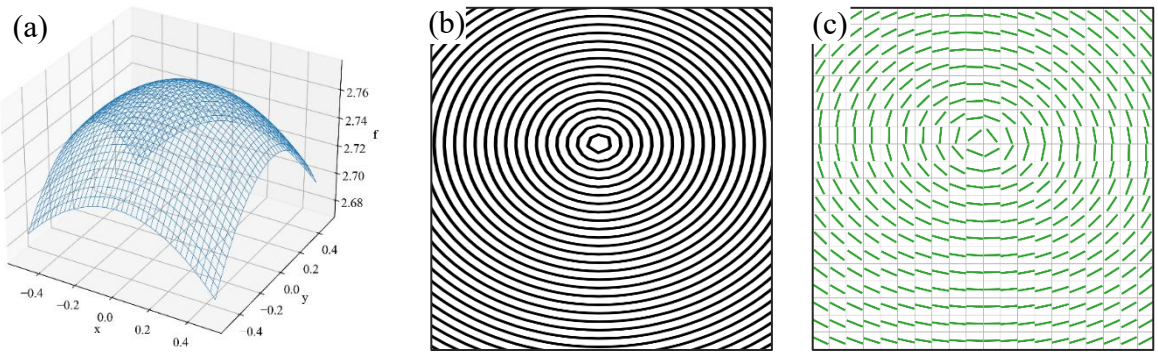

Figure 1: (a) Surface defined by three Gaussian functions; (b) adjusted fiber path considering fiber wots overlap; (c) discretized contour lines on a 20×20 FE mesh.

The natural frequencies of the composite laminate were determined through a structured computational workflow. Initially, ANSYS software was utilized to design the structural geometry, providing essential model parameters such as element count, nodal coordinates, and node numbering. Subsequently, Python scripts integrated the fiber orientation angles for each element into ANSYS Mechanical APDL to perform modal analysis. For visualization, the Matplotlib library was employed to graphically represent the fiber paths. This Python-based automation facilitated the execution of the aforementioned steps, streamlining the optimization process.

In the modal analysis, SHELL281 elements from ANSYS were employed. Each element comprises eight nodes with six degrees of freedom, suitable for analyzing thin to moderately thick shell structures. A 100 mm × 100 mm square plate was discretized into a 20 × 20 mesh, resulting in 400 elements. The laminate configuration, as depicted in Figure 2, consists of a symmetric eight-layer stack: [(TFP)$_2$/PW 45°/PW 0°]s. This arrangement includes layers of Plain Weave (PW) and TFP, designed to be compatible with future fiber stitching machinery. The base material comprises two PW layers oriented at 0° and 45°, forming the foundational structure. Two TFP layers with identical fiber paths are then superimposed, exhibiting contoured patterns that reflect their customized fiber orientations, stitched onto the outer surfaces of the base layers. This alternating configuration results in a symmetrically arranged laminate, aimed at enhancing frequency characteristics through variable fiber orientations within the TFP layers.

Material properties are summarized in Table 1. The thickness of the Plain Weave (PW) layer is defined as 0.191 mm. For the TFP layer, the local thickness is computed as a function of the fiber distribution determined by the overlap rate $\alpha(x, y)$. Assuming the fiber tow has a thickness of t_f when there is no overlap, the thickness at a point $(x,\ y)$ where the overlap rate is $\alpha(x, y)$ can be expressed as:

$$t(x, y) = \frac{t_f}{1 - \alpha(x, y)} \tag{4}$$

The spacing $d(x, y)$ between fiber tow at a point (x, y) is determined by the following relationship (Eq. 5):

$$\alpha(x, y) = 1 - \frac{|\nabla f(x, y)|}{|\nabla f|_{max}}(1 - \alpha_{max}) \tag{5}$$

Where$|\ \nabla f(x, y)\ |$represents the local gradient magnitude of the fiber orientation function at position (x, y), which is inversely proportional to the fiber spacing at that point. The quantity $|\ \nabla f\ |_{max}$

corresponds to the maximum gradient within the domain, occurring where the fiber tows are most densely packed, i.e., where the fiber spacing reaches its minimum. The maximum overlap rate α_{max} is set to 0.6. Substituting this into the thickness expression gives:

$$t(x,y) = \frac{|\nabla f|_{max}}{|\nabla f(x,y)|} t_{max} \tag{6}$$

Where $t_{max} = t_f/1 - \alpha_{max}$ represents the maximum thickness corresponding to the maximum overlap condition. This formulation ensures that the TFP thickness varies spatially in response to fiber curvature and distribution, approaching the actual fiber stacking behavior. In Table 1, "L" denotes the longitudinal fiber direction, and "T" signifies the transverse direction relative to the fibers.

3 SEQUENTIAL APPROXIMATE OPTIMIZATION USING ARTIFICIAL NEURAL NETWORKS

3.1 Sequential Approximate Optimization

Sequential Approximate Optimization (SAO) is particularly effective for addressing complex optimization problems characterized by nonlinearity, multidimensionality, and computationally intensive evaluations. Unlike conventional metaheuristic methods such as PSO and GA, which operate by directly moving design variables and require many costly evaluations, SAO adopts a model based strategy. It begins by constructing a surrogate model or response surface, that approximates the objective function based on a set of strategically selected sample points within the design space.

The optimization process proceeds by identifying candidate optima on the surrogate surface. These points are then evaluated using the high-fidelity objective function, and the results are used to iteratively update and refine the surrogate model. This cycle continues, with each iteration improving the model's accuracy and predictive power. To ensure adequate coverage of the design space and prevent premature convergence to local optima, a density function is introduced. This function identifies sparsely sampled regions, guiding the addition of exploratory points to improve the global search effectiveness of the algorithm.

One of SAO's key strengths lies in its capacity to generate accurate surrogate models that effectively

approximate complex physical phenomena. This makes it especially suitable for applications where direct evaluations are expensive, such as finite element analyses or experimental testing. By leveraging surrogate modelling, SAO significantly reduces the number of high-cost simulations required to identify optimal solutions [10]. A typical SAO framework follows a structured sequence of steps, as outlined in Fig. 3.

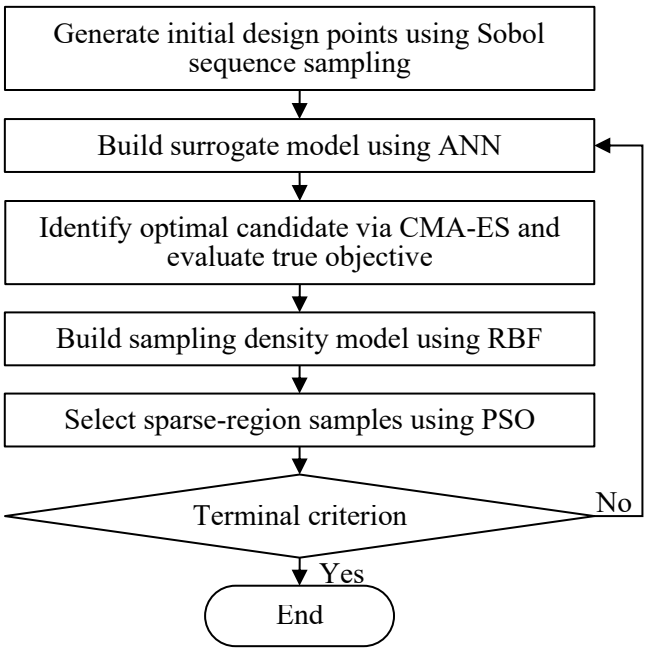

Figure 3: Workflow of the proposed Sequential Approximate Optimization framework.

In this study, a Sequential Approximate Optimization (SAO) framework is proposed using ANN as surrogate models. Initial sampling points are generated via Sobol sequences to ensure a well-distributed and space-filling design. An ANN-based response surface is then constructed to capture the nonlinear relationship between design variables and the objective function. To explore promising regions, the surrogate is optimized using the Covariance Matrix Adaptation Evolution Strategy (CMA-ES), and the obtained optimum is evaluated with the high-fidelity model. Simultaneously, a sampling density function is modeled using a RBF network, and PSO is employed to identify sparse regions in the design space, from which additional sampling points are selected. These new samples are incorporated into the dataset to refine both the surrogate and the density model. This iterative process continues until a predefined convergence criterion is met.

3.2 Artificial Neural Network

In this study, a feedforward Artificial Neural Network (ANN) with four hidden layers, each containing 126 neurons, is employed as the surrogate model to approximate the nonlinear relationship between the design variables and the objective function. The ANN architecture, training procedures, and implementation were adapted based on guidelines presented by Subramanian [12].

Specifically, for each hidden layer l, the pre-activation output is computed as:

$$\boldsymbol{z}^{(l)} = \boldsymbol{W}^{(l)}\boldsymbol{h}^{(l-1)} + \boldsymbol{b}^{(l)}, \quad l = 1, 2, \dots, L-1, \quad \boldsymbol{h}^{(0)} = \boldsymbol{x} \tag{7}$$

Each hidden layer applies the SiLU activation function defined as:

$$\phi(\boldsymbol{s}) = \boldsymbol{s}\sigma(\boldsymbol{s}), \quad \delta(\boldsymbol{s}) = \frac{1}{1+e^{-\boldsymbol{s}}} \Rightarrow h^{(l)} = \phi\left(z^{(l)}\right) \tag{8}$$

Layer normalization and dropout (rate = 0.1) are applied after each activation to enhance generalization and prevent overfitting. The final output of the network is given by:

$$\hat{y}(\boldsymbol{x}; \boldsymbol{w}) = \boldsymbol{W}^{(L)}\boldsymbol{h}^{(L-1)} + \boldsymbol{b}^{(L)} \tag{9}$$

where $w = \{\boldsymbol{W}^{(l)}, \boldsymbol{b}^{(l)}{}_{l=1}^{L}\}$ denotes all weights and biases in the model. The ANN is trained to minimize the regularized mean-squared error:

$$E(\boldsymbol{w}) = \sum_{i=1}^{m} (y_i - \hat{y}(\boldsymbol{x_i}; \boldsymbol{w}))^2 + \lambda \sum_{j} w_i^2 \tag{10}$$

An Adam optimizer is employed, along with an adaptive learning-rate scheduler and early stopping. After each iteration of the Sequential Approximate Optimization (SAO) process, the ANN surrogate model is retrained using the expanded dataset, thereby maintaining its accuracy and currency with newly sampled data points.

3.3 Density Function

To evaluate the distribution of sampling points across the design space, a sampling density function $D(\boldsymbol{x})$ is constructed using the same RBF structure defined in Eq. (1), where each existing sample point is assigned a nominal value of 1:

$$\boldsymbol{y}_D = (1, 1, \cdots, 1)^T \tag{11}$$

The normalized inputs $\boldsymbol{x}_D$ are obtained using the same scaling strategy as in the fiber path representation, with an expansion factor $\alpha = 1.2$ applied if necessary to ensure full basis coverage. The corresponding RBF weight vector $\boldsymbol{w}_D$ is solved via regularized least squares:

$$\boldsymbol{w}_D = (\boldsymbol{H}^T \boldsymbol{H} + \lambda \boldsymbol{I})^{-1} \boldsymbol{H}^T \boldsymbol{y}_D \tag{12}$$

The density function is then given by:

$$D(\boldsymbol{x}) = \sum_{i=1}^{m} w_i^D h_i(\boldsymbol{x}) \tag{13}$$

By minimizing $D(\boldsymbol{x})$ using PSO, the sparsest region of the current design space is located, enabling exploration beyond already-sampled areas and supporting global optimization.

4 FIBER PATH OPTIMIZATION

With the ANN surrogate and sampling strategies defined above, we next set up the specific fiber path optimization problem including design variables and objective function. The design variables for the curvilinear fiber path are defined by the RBF parameters (Eq. 14), while those for the straight fiber path consist of a single fiber orientation angle (Eq. 15). The objective function in both cases aims to maximize the fundamental frequency, reformulated as a minimization task by negating its value (Eqs. 16 and 17).

The ANN-based response surface is optimized using the CMA-ES, configured with an initial standard deviation (σ_0) of 0.15 and a maximum of 300 iterations. For the density function surrogate, PSO is employed with a swarm of 500 particles, inertia weight $w = 0.7$, and acceleration coefficients $c1 = c2 = 2.0$, with 60 iterations. The ANN-SAO algorithm is configured to perform a total of 600 evaluations of the objective function, regardless of whether the fiber path is curvilinear or straight. The number of initial sampling points N_{init} is determined by:

$$N_{init} = 2 \times (\mathrm{n} + 1) \tag{14}$$

where n is the number of design variables. The entire optimization process, including surrogate modeling and iterative updates, can typically be completed within approximately 100 minutes. The design variables and objective formulation are summarized in Table 2.

	Design variables	Objective function
Curvilinear fiber path	$x_{c,i}, y_{c,i}, r_i, w_i\ (i = 1,2,3)$ $-2 \le x_{c,i} \le 2$ $-2 \le y_{c,i} \le 2$ $0.5 \le r_i \le 4$ $-2 \le w_i \le 2$	$f(x_{c,i}, y_{c,i}, r_i, w_i) = -(f^{1st\ ferquency}) \rightarrow min$
Straight fiber path	$-89.9° \le \theta_{Fiber\ Angle} \le 90°$	$f(\theta) = -(f^{1st\ frequency}) \rightarrow min$

Table 2: Design variables and objective function formulations for the curvilinear vs. straight fiber path optimization.

The objective of this study is to optimize the fiber orientation of four TFP layers located at the outermost part of a symmetric eight-layer laminate using ANN-SAO. To ensure consistent material properties, the same TFP configuration is applied to both curvilinear and straight fiber paths. Boundary conditions are defined using 'F' for free edges. Fiber path optimization is carried out under all free boundary conditions to evaluate the effectiveness of the ANN-SAO framework.

5 NUMERICAL RESULTS

Under the FFFF boundary condition, the optimized straight fiber path exhibits a uniform orientation of −45°, achieving a fundamental frequency of 1038.42 Hz. Its mode shape reveals deformation primarily aligned parallel to the fiber orientation, with maximum displacement concentrated at the corners along the shortest fiber segments. In contrast, the optimized curvilinear fiber path forms concentric circular patterns centered at the midpoint of the plate, as shown in Fig. 3. This configuration enhances dynamic performance significantly, yielding a 24.41% increase in the fundamental frequency relative to the optimal straight fiber design. The mode shape exhibits that deflections are primarily confined to the four corners.

The detailed element wise distribution of fiber orientation and thickness resulting from the ANN-SAO optimization is depicted in Fig. 3. Although the thickness distribution under the curvilinear design exhibits slight spatial variation, the colorbar indicates that these fluctuations are minor. Notably, both designs share the same average thickness of 4.76 mm, confirming that the observed performance gains are attributed to fiber orientation tailoring rather than increased material usage. These results validate that the ANN-SAO framework effectively exploits smooth spatial variation in both fiber angles and layer thickness to optimize the fundamental frequency.

	Straight Fiber	Curvilinear Fiber	Difference
Fiber Orientation			—
Natural Frequency	1038.42	1291.87	+24.41%
Mode Shape			—
Thickness Distribution			—
Average Thickness	4.76	4.76	0%

6 CONCLUSIONS

This study proposed an Artificial Neural Network-based Sequential Approximate Optimization (ANN-SAO) framework to optimize curvilinear fiber paths in symmetric laminated composites. By employing ANN to construct the surrogate model and integrating density-based sampling strategies, the method efficiently captured nonlinear relationships and improved optimization convergence. Compared with straight fiber configurations, the ANN-SAO optimized curvilinear paths significantly increased the first natural frequency under the tested boundary condition, indicating the effectiveness of tailored fiber steering for vibration performance.

Future work will focus on experimental validation of the optimized designs and extending the ANN-SAO framework to more complex composite structures and loading scenarios, further assessing its robustness and practical applicability in advanced manufacturing environments.

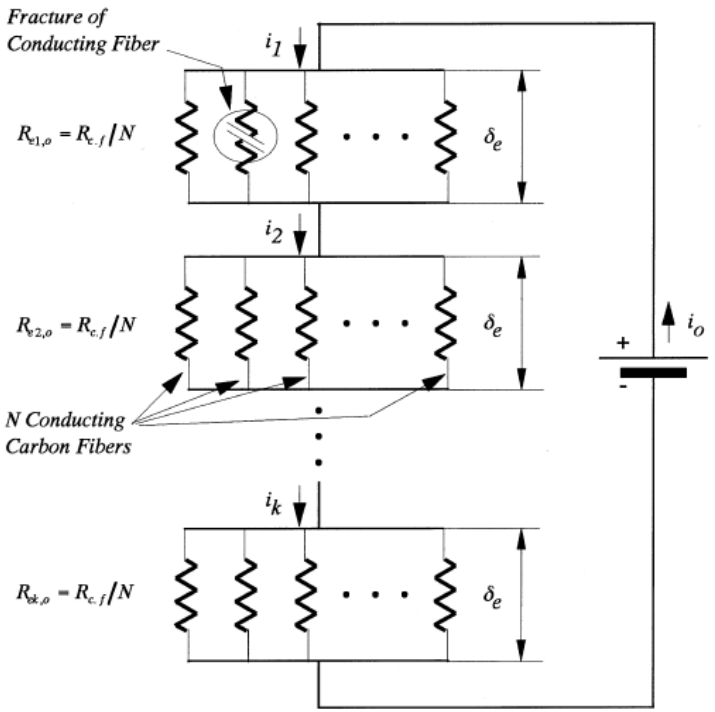
Suggestions on Degradation Model: Global Load Sharing

*CFRP: Carbon-fiber-reinforced polymer
*DC: Direct current

Assumptions



1. Load lost by fiber breakage will be transferred equally to all intact fibers.
2. Each fiber can be considered as a resistor; CFRPs can be approximated into DC circuit.

Stress-strain relation

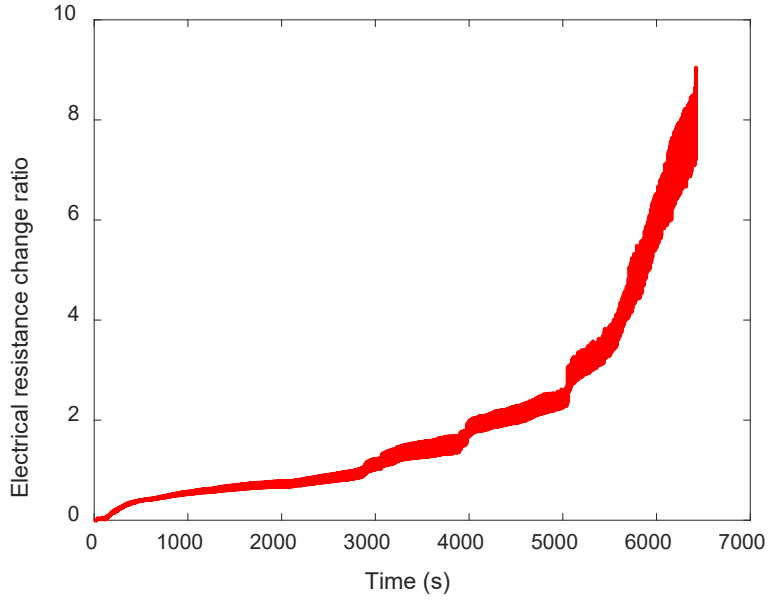
$$\sigma = \underbrace{fE_f\varepsilon\left(1-\frac{1}{2}\left(\frac{E_f\varepsilon}{\sigma_c}\right)^{m+1}\right)}_{\text{fiber}} + \underbrace{(1-f)\sigma_y}_{\text{matrix}} \qquad (1)$$

Apply (1) to circuit model

$$\frac{\Delta R}{R_0} = \frac{(1+\alpha\varepsilon)}{1-N_f/N} - 1 = \frac{(1+\alpha\varepsilon)}{exp\left[-\left(\frac{\delta_{ec}}{L_0}\right)\left(\frac{E_f\varepsilon}{\sigma_0}\right)^m\right]} - 1$$

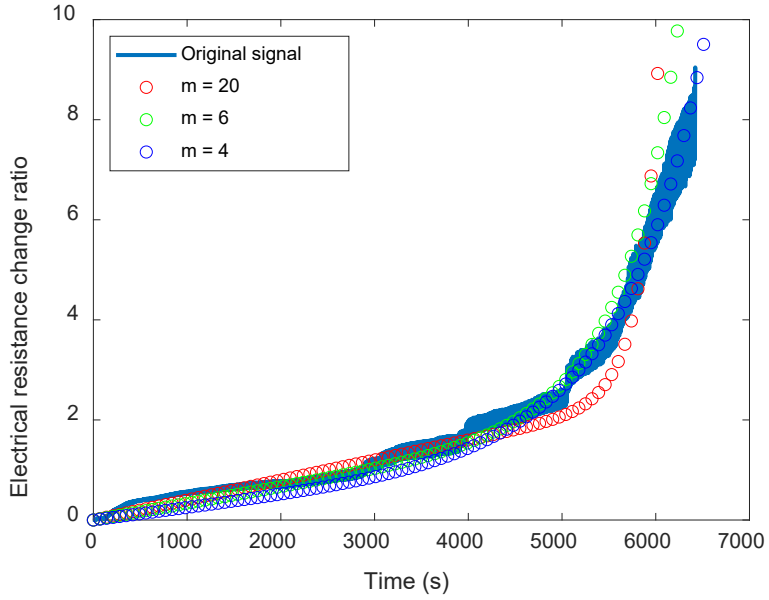
$$i_o = i_1 = i_2 = \cdots = i_k$$

$$R_{e1} > R_{e2} = R_{e3} = \cdots = R_{ek}$$



DC series circuit with equally spaced discrete parallel cells

[2] Park, J. B., et al. (2002). Compos Part A, 33(2), 267-275.



Suggestions on Degradation Model

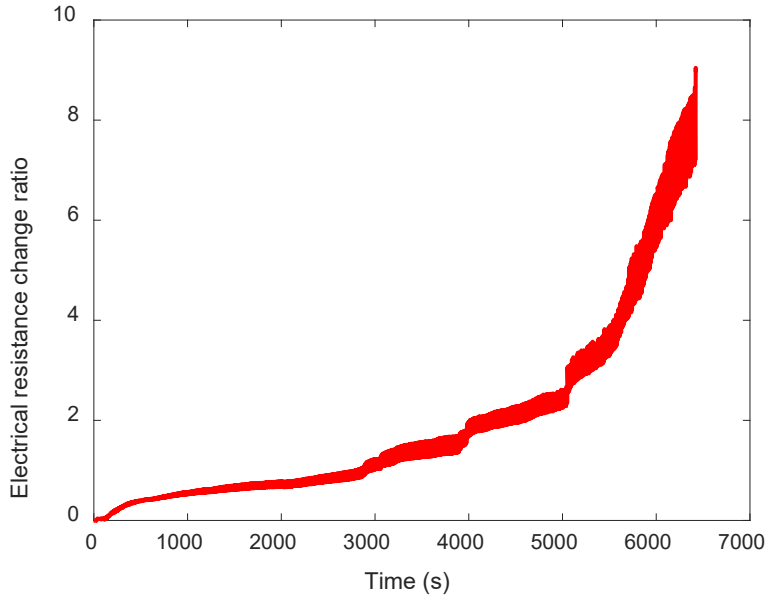
*GLS: Global load sharing
*CFRP: Carbon-fiber-reinforced plastic

Case I. Employ GLS model

Self-sensing signal during fatigue test

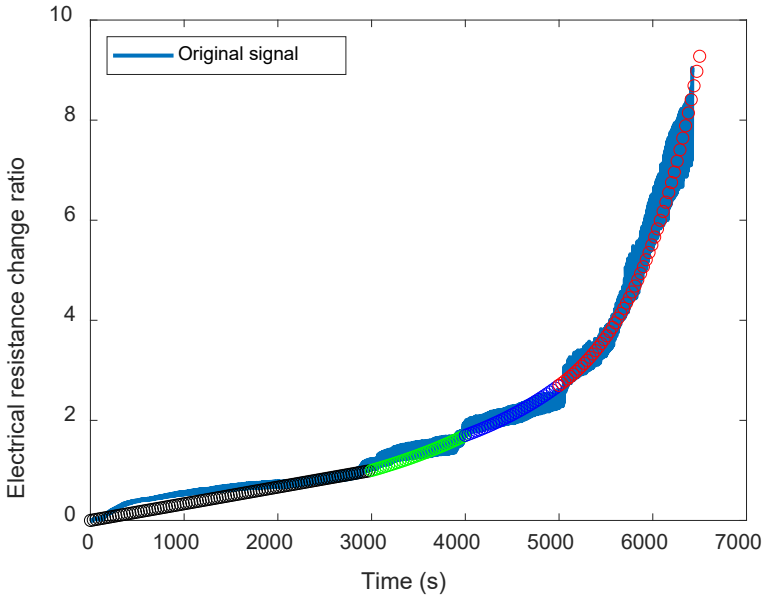
Suggested model

$$\frac{\Delta R}{R_0} = \frac{(1+\alpha\varepsilon)}{exp\left[-\left(\frac{\delta_{ec}}{L_0}\right)\left(\frac{E_f\varepsilon}{\sigma_0}\right)^m\right]} - 1$$



Simplify

$$\frac{\Delta R}{R_0} = \frac{(1+\alpha t)}{exp[-(\beta t)^m]} - 1$$

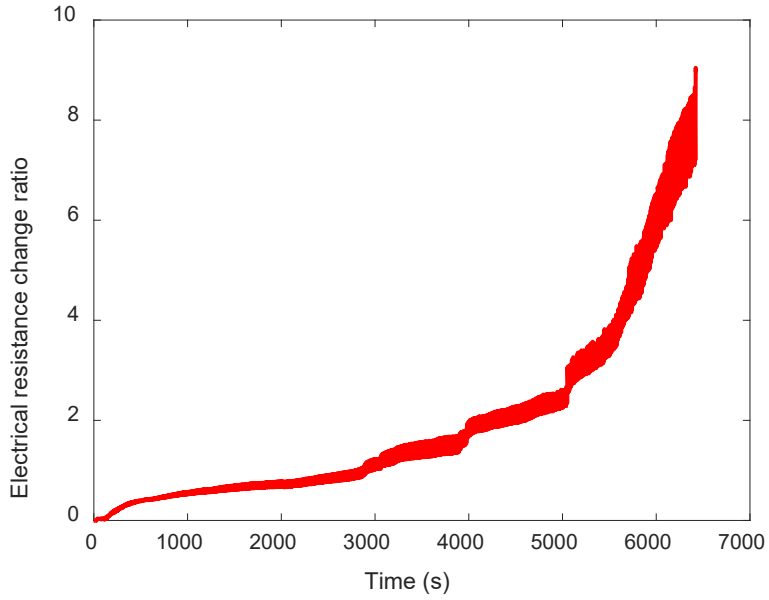


- Simplified GLS model can approximate the CFRP electromechanical behavior under fatigue.
- The exponent m and coefficients α and β can be adjusted based on observation.

Suggestions on Degradation Model

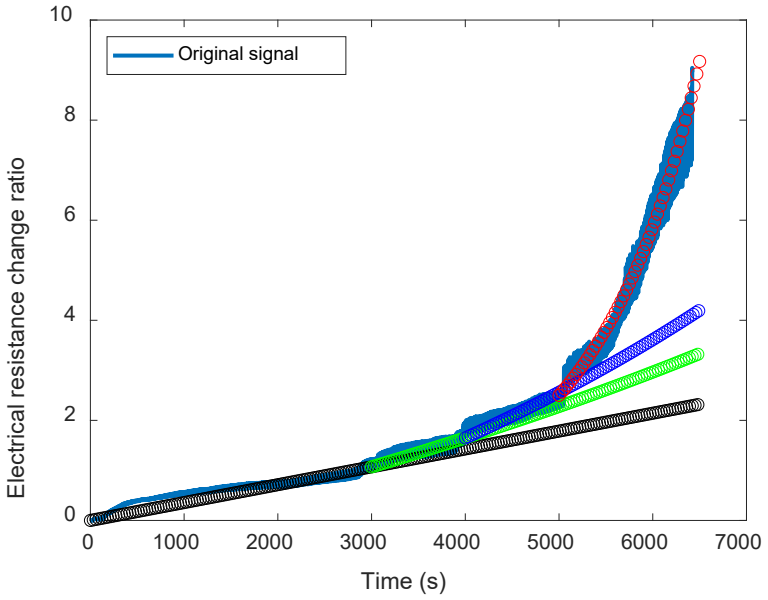
Case II. Apply different equations section-by-section

Self-sensing signal during fatigue test



Suggested model

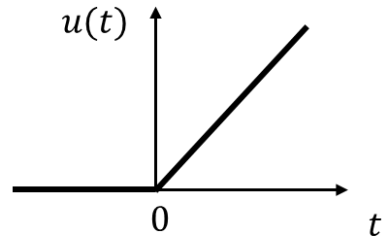
$$\frac{\Delta R}{R} = \begin{cases} a * x \\ (0 \le x < 3000) \\ \exp\left(b_1 * (x - 3000)\right) + b_2 \\ (3000 \le x < 4000) \\ \exp\left(c_1 * (x - 4000)\right) + c_2 \\ (4000 \le x < 5000) \\ \exp\left(d_1 * (x - 5000)\right) + d_2 \\ (5000 \le x < 6500) \end{cases}$$



- Data points that exhibit abrupt increases indicates severe damage occurrence.
- Based on those points, different exponential equations can be applied section-by-section.

Suggestions on Degradation Model

Case III. Adopt linear threshold function



Self-sensing signal during fatigue test

Suggested model

Linear threshold function

$$u(t) = \begin{cases} 0, & t < 0 \\ t, & t \geq 0 \end{cases}$$

$$\frac{\Delta R}{R} = a * x + \exp\left(b * u(x - 3000)\right) + \exp\left(c * u(x - 4000)\right) + \exp\left(d * u(x - 6500)\right) + e$$

- Linear threshold function can be applied to reduce values to be predicted.
- Each term in the model will be activated after abrupt increase by real-time monitoring.

Concluding Remarks

*RUL: Remaining useful life

Conclusions

- **Self-sensing electrical resistance signal** can act as a health indicator of composite materials.
- **DLG-PF hybrid approach** significantly reduced the computational cost and error compared to conventional RUL prediction tools.
- **Electromechanical material degradation models** were suggested.

Future Work

- **Apply DLG-PF algorithm into the suggested models** to precisely predict the future behavior of electrical resistance signal

ABSTRACT

This study presents a two-stage inverse-design framework for discontinuous carbon-fiber composites that generates variable-stiffness structures by linking macro-scale structural requirements with region-specific microstructural design. A genetic algorithm (GA) was used to determine macro-scale region-specific stiffness targets for a quarter-cornerhole geometry, reducing maximum local longitudinal S_{11} stress by 25% relative to a uniform stiffness baseline in which all fibers are aligned parallel to the applied load, while maintaining a longitudinal specimen stiffness above 30 GPa. Next, an Abaqus FEA pipeline generated a dataset of two-dimensional representative volume elements (RVEs) varying fiber volume fraction, length, width, orientation, and gap to characterize microstructural stiffness responses. Finally, a conditional GAN (cGAN), trained on this RVE dataset, inversely mapped the GA-derived stiffness targets to manufacturable microstructural parameters. FEA validation confirmed that the cGAN generated microstructures met the stiffness targets within 1 GPa and enabled a 13% reduction in average fiber volume fraction without compromising performance. This GA and cGAN workflow enable region-by-region generation of fiber microstructures that achieve target stiffness distributions and provides a scalable method for extending inverse design to three dimensional composite architectures and physical validation.

1 INTRODUCTION

Designing composite materials that simultaneously meet requirements for stiffness, strength, and geometry remains a critical challenge in aerospace and automotive applications. In such domains, precise control over material properties is essential to ensure structural performance under spatial and loading constraints [1]. Traditional composite design approaches have largely relied on empirically derived design rules from extensive experimental coupon testing regimes [2]. Due to their robust and conservative nature, such methods create initial designs where further optimization is constrained. Forward design using finite element analysis (FEA) simulations is limited due to computational cost, which increases significantly for nonlinear materials or complex geometries, making repeated simulation over large design spaces impractical [3]. Thus, FEA is generally used at later design stages to produce accurate assessments of mechanical behavior for predefined configurations of fibers and matrix systems [4]. To improve initial design, simple physics-based analytical models such as the rule of mixtures and Halpin–Tsai equations have been employed to estimate effective properties [5,6], however the models inherently break down for more complex design scenarios. While these different design methods have proven valuable, they are either too restrictive, too computationally expensive, or too inaccurate for the full complex inverse design problem of determining optimal material configurations that satisfy specific performance targets for realistic design parts [7].

To address these limitations, machine learning-based inverse design strategies have been introduced providing scope for improved accuracy and speed of computation [8]. Among them, generative modeling approaches offer a promising direction by directly constructing material configurations conditioned on target mechanical properties. Unlike regression-based surrogate models or traditional optimization, which improve existing designs within fixed spaces, generative models synthesize new designs that reflect desired physical behaviors. Generative adversarial networks (GANs) and other deep generative architectures such as variational autoencoders and conditional U-Nets have been applied in materials science to accelerate design workflows and reduce reliance on high-resolution simulations [9,10]. When trained on representative volume element (RVE) FEA datasets paired with mechanical response labels, these models can generate material structures aligned with specified performance metrics [3].

This study proposes a generative modeling framework for the inverse design of discontinuous fiber reinforced composites (DFRCs). Leveraging a FEA dataset of systematically varied RVE configurations and their corresponding stiffness values for training [11], the proposed approach aims to generate composite designs that satisfy user-defined mechanical targets [12]. This framework offers a scalable and efficient alternative to conventional FEA-based methods and supports performance-driven composite design.

2 RELATED WORKS

2.1 Surrogate modeling approaches in composite design

To mitigate the computational cost associated with simulation-based composite design, surrogate models trained on numerical results have been extensively employed. Techniques such as linear regression, polynomial response surfaces, and Gaussian process (GP) regression have been used to approximate mechanical responses within a reduced design space using a limited set of simulation samples [13]. These models enable rapid evaluation and are effective in capturing low-order design trends. However, their predictive accuracy diminishes significantly in high-dimensional or strongly nonlinear design spaces characteristic of complex composite systems. In response to these limitations, physics-informed machine learning (PIML) methods have been proposed to enhance the extrapolation and generalization capability of surrogate models [14]. These methods incorporate governing physical laws either as soft constraints in the loss function or via hybrid inputs combining simulation results and domain knowledge. While promising, PIML approaches often demand substantial training data and still struggle when operating beyond the distribution of the original training set [15]. Moreover, most surrogate modeling techniques are inherently constructed for forward prediction. As such, they are not directly suited for inverse design tasks, where the goal is to generate material configurations that achieve specified property targets or satisfy performance criteria under design constraints.

2.2 Deep generative modeling for inverse material design

Generative approaches have recently emerged as effective tools for inverse design, particularly in materials science domains characterized by high-dimensional, nonlinear, and non-convex design spaces. While generative adversarial networks (GANs) are widely studied, other frameworks such as variational autoencoders (VAEs), conditional U-Nets, and diffusion models have also demonstrated promising results in structural and microstructural synthesis [16, 17]. VAEs enable latent encoding of geometric and material features, facilitating efficient sampling and interpolation across the design space. Such models have been used to generate microstructure configurations aligned with target properties through structure–property mapping in the latent space [18]. Similarly, U-Net–based generative models have proven effective in pixel-wise or voxel-wise material structure prediction when conditioned on optimization results or segmentation masks [19]. More recently, diffusion models have been explored for the generation of high-resolution material topologies under physics-guided constraints. These models can produce diverse and stable outputs and can be conditioned on properties such as stiffness, porosity, or thermal conductivity during the iterative denoising process [20]. Despite their efficiency, generative models often require additional post-processing or constraints to ensure physical validity and manufacturability of the generated designs.

2.3 Inverse design in composite materials

Due to the inherent anisotropy and microstructural complexity of composite materials, inverse design requires handling diverse factors such as fiber orientation, stacking sequences, and matrix behavior. Several studies have adapted generative approaches specifically for composites by incorporating structure–property datasets based on RVEs [8]. These models learn latent design spaces where interpolation or sampling can yield new configurations aligned with mechanical targets. Such data-driven frameworks have shown particular promise for discontinuous fiber-reinforced composites, extending inverse design capability to discontinuous fiber reinforced composites (DFRCs) [19].

3 METHODOLGY

A two-stage framework integrating macro-scale structural optimization with micro-scale inverse material design is presented. First, a Genetic Algorithm (GA) identifies the optimal distribution of target mechanical properties for distinct regions within a structure to meet specified global performance criteria, such as stiffness and stress constraints. Second, the optimized regional properties are used to inversely generate manufacturable microstructural parameters. This inverse design process utilizes a conditional Generative Adversarial Network (cGAN) trained on a dataset of Representative Volume Elements (RVEs) obtained via finite element simulations. This integrated approach ensures that macro-scale structural requirements are practically translated into micro-scale design parameters, enabling efficient material usage with targeted performance.

3.1 Macro-scale structural optimization using GA

In this study, a GA was employed to optimize the discrete fiber composite material distribution of a quarter-cornerhole specimen loaded in uniaxial tension, see Figure 1. The objective of the GA optimization was twofold: (a) minimize the maximum local longitudinal stress, $S_{11,MAX}$, while (b) maintaining a minimum effective specimen longitudinal Young's modulus, $E_{11,SP}$, of 30 GPa. The structural domain was discretized into four distinct regions, and each region was assigned a set of orthotropic material properties as design variables. Specifically, directional Young's moduli (E_{11}, E_{22}), in-plane Poisson's ratio (v_{12}), and shear modulus (G_{12}) were allowed to vary in accordance with the range of material configurations in the RVE dataset, as detailed in Section 3.3 and summarized in Table 1. The GA optimization procedure, as illustrated in Figure 1, began with an initial population comprising 16 randomly generated sets of these material properties within the ranges [10, 30] GPa (E_{11}) and [1, 20] GPa (E_{22}, G_{12}). Each candidate solution (individual) within the population was evaluated through FEA using Abaqus, providing fitness scores based on the primary structural optimization goal of minimizing $S_{11,MAX}$ while only being accepted for further generations if they achieve the minimum effective specimen stiffness target, $E_{11,SP}^{T}$. Subsequently, genetic operators including selection, crossover, and mutation were applied iteratively to generate improved populations. The optimization loop continued until satisfaction of convergence criteria by either (i) change of the lowest found minimum of maximum local stress, $\Delta S_{11,MAX}^{min}(G) \leq$ minimum improvement value, MIV , of 1x10^{-3} (ii) number of iterations, G, reaches the maximum value, N, of 30. The outcome of the GA optimization was a set of optimal target mechanical properties defined for each region, reducing maximum stress concentrations and maintaining structural integrity. These optimized regional properties served as inputs for the subsequent micro-scale inverse design step, explained in Section 3.3, using the pre-trained cGAN model, explained in Section 3.2.

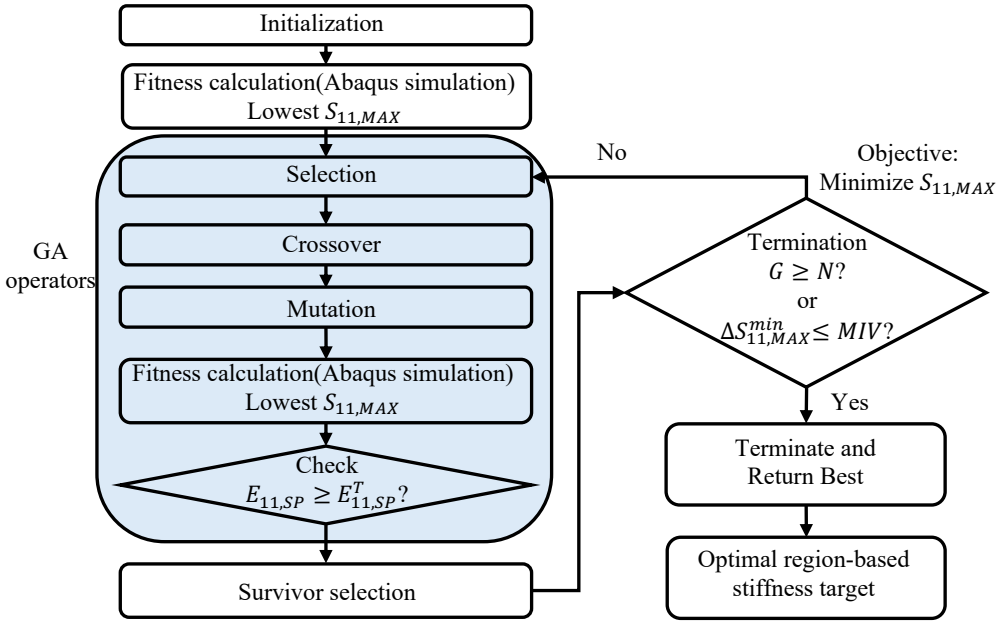

Figure 1: Architecture of genetic algorithm operators within each generation.

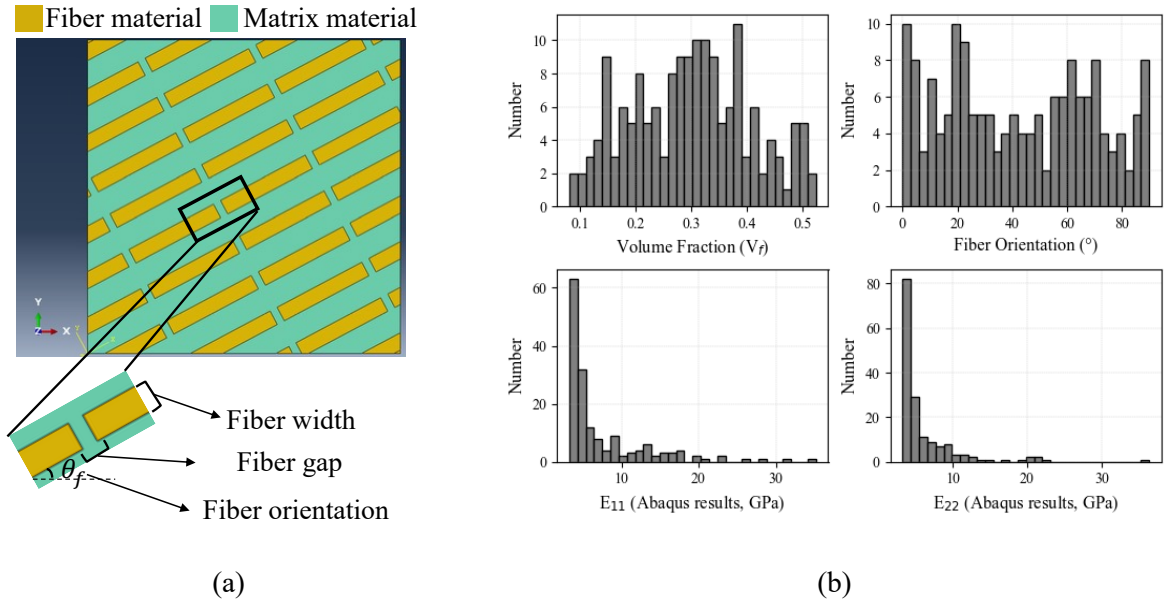
3.2 RVE dataset for cGAN model



To train the proposed conditional generative model for inverse design, a dataset was constructed using FEA of DFRC structures. Each data sample corresponds to a two-dimensional RVE, modeled as a square domain containing same direction fibers embedded in a continuous matrix. The geometrical and material configurations of the fibers were systematically varied to produce a wide range of mechanical responses under in-plane loading. The key design parameters considered during RVE generation include fiber gap, volume fraction, fiber length and width, orientation angle, and the elastic moduli of the fiber and matrix materials. These parameters were selected based on their known influence on in-plane stiffness characteristics of unidirectional composite plies. A subset of 200 RVE configurations was sampled from the full-factorial parameter space to ensure representative coverage across all key design variables. The parameter definitions and their corresponding ranges are summarized in Table 1.

Parameter		Range
Fiber gap (f_g)	$[mm]$	0.1-3.0
Volume fraction (V_f)	–	0.1-0.6
Fiber length (f_l)	$[mm]$	5-25
Fiber width (f_w)	$[\mu m]$	0.5-5
Fiber orientation (θ_f)	[°]	0-90
Fiber Young's modulus (E_{11})	$[GPa]$	231
Fiber Young's modulus (E_{22})	$[GPa]$	10
Fiber Young's modulus (G_{12})	$[GPa]$	5
Fiber Poisson's ratio (v_{12})	–	0.3
Matrix Young's modulus (E_m)	$[GPa]$	5
Fiber Poisson's ratio (v_m)	–	0.3

Table 1: Parameter ranges and increments used for generating the RVE dataset

For each configuration, static finite element simulations were conducted using Abaqus to evaluate the homogenized in-plane elastic properties, including directional Young's moduli and Poisson's ratios. The geometry generation, meshing, simulation, and data extraction were implemented in a unified workflow to ensure consistency across all samples. The RVE microstructures were generated as 2D

images with fiber regions shown in yellow and matrix regions in teal. Figure 2 (a) highlights the key geometric parameters: fiber width, fiber gap, and fiber orientation. The final dataset consists of approximately 200 samples, each comprising a paired input–output tuple: a binary microstructure image and the corresponding scalar stiffness value. This dataset serves as the training foundation for the cGAN. Figure 2 (b) presents representative the statistical distributions of the dataset parameters and mechanical responses obtained by randomly sampling values within the ranges specified in Table 1.

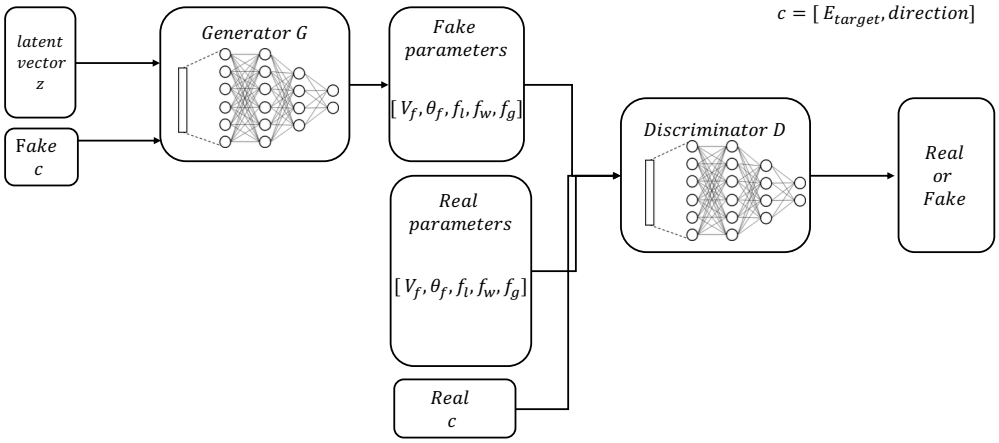
3.3 Micro-scale inverse design via cGAN

A cGAN was synthesized to predict the microstructural parameters of DFRC structures that satisfy user-defined stiffness targets. The model is based on the standard cGAN formulation, where both the generator G and discriminator D receive a condition vector c to guide the generation process. In this implementation, the condition vector consisted of the raw stiffness target and the desired loading direction. This structure allows the model to generate designs tailored to specific mechanical responses along the specified axis. The generator takes as input a concatenated vector $[z, c]$, where z is a latent noise vector sampled from a standard Gaussian distribution. The output is a vector of RVE design parameters, including fiber volume fraction, fiber orientation, fiber length, fiber width and fiber gap. These parameters define a composite structure that is expected to achieve the desired stiffness when evaluated under the given loading condition.

The discriminator is trained to distinguish between real (dataset-derived) and fake (generated) RVE configurations, conditioned on the same stiffness and direction input c. This enforces conditional realism in the generated structures. The training process employs adversarial loss, feature matching regularization, and label smoothing to stabilize convergence and improve the fidelity of the generated samples. An overview of the proposed generative design pipeline is illustrated in Figure 3. After training the generator G and discriminator D together, the generator G is used to predict parameters that are likely to result in the real vector c.



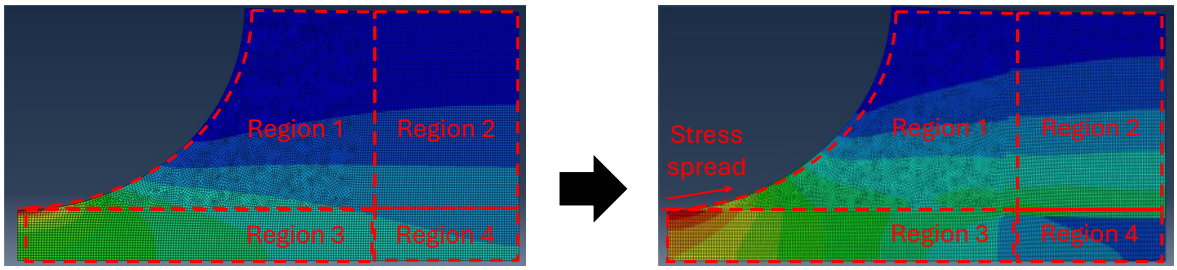


Figure 3: Architecture of the cGAN for inverse design of composite microstructures.

To quantitatively validate the generator output, a separate property prediction model is incorporated into the framework. Predictor is a fully connected neural network trained on the simulation-based dataset. It takes the generated RVE design parameters as input and estimates the corresponding equivalent stiffness. The predicted value is compared with the original target to assess inverse design accuracy and guide model refinement.

4 RESULTS AND DISCUSSIONS

4.1 Macro-scale optimization results

Macro-scale optimization was evaluated on a quarter-cornerhole specimen results using the GA-based method outlined in Section 3.1. A quarter-cornerhole specimen with four distinct stiffness regions was chosen as the representative geometry (Figure 4). The objective of the GA optimization was twofold: (a) maintain a minimum global Young′s modulus of 30 GPa, and (b) minimize the maximum S_{11} stress under uniaxial tension. The GA optimization began from randomly generated initial stiffness values within the ranges of [10, 30] GPa (E_{11}) and [1, 20] GPa (E_{22}, G_{12}), running for 30 generations with a population size of 16. Fitness evaluation involved running Abaqus finite element analyses to calculate effective stiffness and maximum S_{11} stress for each candidate. Results from the optimization demonstrate that region-wise tailored stiffness values significantly reduce local stress concentrations compared to a baseline uniform stiffness distribution. Specifically, the optimized design achieved a maximum stress reduction of approximately 25%, lowering the peak stress from 391 MPa to 289 MPa.

Stiffness (E_{11}): 30.02 GPa
Max Stress: 391.43 MPa

	Region 1	Region 2	Region 3	Region 4
E_{11} (GPa)	30.00	30.00	30.00	30.00
V_f	0.39	0.39	0.39	0.39

Stiffness (E_{11}): 30.46 GPa
Max Stress: 289.27 MPa

	Region 1	Region 2	Region 3	Region 4
E_{11} (GPa)	29.22	35.20	36.59	10.58
V_f	0.36	0.46	0.47	0.10

Figure 4: Von Mises stress contours for the quarter-cornerhole specimen under uniaxial tension: (a)

Baseline design with a uniform Young's modulus of 30 GPa (b) GA–optimized stiffness distribution reduces the maximum S_{11}

Furthermore, Figure 4 compares baseline and optimized designs. With fiber length fixed at 25 mm, the optimized design showed a reduction in the average fiber volume fraction from 0.39 (baseline) to 0.34, representing about a 12.8% material saving while still satisfying stiffness constraints. This result highlights the effectiveness of the proposed GA optimization in achieving both structural performance and material efficiency, which is beneficial for manufacturing.

4.2 Micro-scale inverse design results

Performance of the cGAN-based inverse design method described in Section 3.2 was evaluated. Experiments were conducted on simplified square-shaped RVEs. The trained cGAN model generated RVE design parameters fiber volume fraction (V_f), orientation angle (θ_f), fiber gap (f_g), fiber width (f_w), and fiber length (f_l) based on user-defined stiffness targets and loading directions (either E_{11} or E_{22}). Representative RVE designs obtained from the cGAN model and corresponding stiffness results computed via Abaqus simulations are summarized in Table 2.

	Sample 1	Sample 2	Sample 3	Sample4
Target	10 Gpa (E_{11})		4 Gpa (E_{22})	
Design parameters	V_f= 0.17, θ_f = 0 °, f_l = 19.79 mm, f_g = 2.5 mm, f_w = 2.06 μm	V_f= 0.24, θ_f = 15 °, f_l = 21.71 mm, f_g = 0.83 mm, f_w = 3.0 μm	V_f= 0.44, θ_f = 37 °, f_l = 10.00 mm, f_g = 0.79 mm, f_w = 1.51 μm	V_f= 0.38, θ_f = 28 °, f_l = 8.29 mm, f_g = 0.69 mm, f_w = 1.38 μm
Abaqus results (GPa)	9.86	9.96	4.47	4.04

Table 2: Representative RVE designs for target stiffness values, showing design parameters and the corresponding effective modulus obtained from Abaqus FEA.

For a 10 GPa E_{11} target, generated designs exhibited V_f values of 0.17, 0.24, and 0.44, producing moduli of 9.86 GPa, 9.96 GPa, and 10.04 GPa, respectively. For a 4 GPa E_{22} target, designs with V_f of 0.38 and 0.44 yielded 4.04 GPa and 4.47 GPa. The results illustrate that multiple distinct RVE configurations can satisfy the same stiffness target. Figure 5 further compares target stiffness values, Abaqus-computed stiffness, and predicted stiffness from the trained neural network predictor. The cGAN-generated designs accurately matched the target stiffness values, with a mean absolute error (MAE) of 0.78 GPa for E_{11} and 0.62 GPa for E_{22}..

4.3 Discussions

This study presented a two-stage inverse-design framework integrating macro-scale structural optimization using a GA and micro-scale inverse design using a cGAN. The results indicate that this combined approach effectively achieves region-specific stiffness targets while significantly reducing maximum stress concentrations compared to baseline uniform stiffness distributions. Specifically, the two-stage optimization process resulted in a reduction of approximately 25% in maximum stress and approximately 13% material savings through optimized fiber configurations. By automating the workflow between region-wise property optimization (GA) and microstructure generation (cGAN).

However, the current approach has several limitations that should be addressed in future research. The present RVE dataset was limited to two-dimensional microstructures; extending the data set and inverse-design space to 3D laminated regions is necessary for laminated composite part design. Practical considerations such as fiber misalignment, resin flow during manufacturing, and thermal residual stresses introduced during additive manufacturing, must be systematically investigated, as these factors critically affect the mechanical performance of composite structures. Extending the dataset to three-dimensional RVEs for a single lamina accounting for these manufacturing effects, and including experimental validation data, would enhance the model's predictive capability and broaden its practical application. This study was conducted on a simplified quarter-cornerhole geometry under uniaxial loading conditions; real-world structural components typically involve more complex geometries, curved surfaces and multi-axial loading conditions. Future research should focus on adapting and validating this inverse-design framework for complex three-dimensional geometries under realistic operational loading scenarios. Lastly, for practical deployment in additive manufacturing processes, key challenges such as printer resolution limitations, accuracy in fiber placement, and void formation must be addressed. Incorporating these manufacturing constraints into the inverse-design process will be critical to ensuring that optimized designs can be reliably and efficiently realized in practice.

5 CONCLUSIONS

This research introduced a two-stage inverse-design framework combining macro-scale structural optimization using a GA and micro-scale material design through a conditional Generative Adversarial Network cGAN. The proposed GA-cGAN framework successfully prescribed manufacturable fiber microstructure parameters that satisfied region-specific stiffness requirements while achieving up to 25% reduction in maximum stress compared to uniform-stiffness baselines. Additionally, optimized fiber configurations enabled approximately 13% material savings without compromising mechanical performance. Future studies will focus on extending the framework to fully three-dimensional microstructures, performing experimental validation of optimized designs.

ABSTRACT

Origami-inspired deployable structures require materials that balance mechanical stiffness with foldability, yet most composites cannot localize these properties without compromising integrity. In this study, we propose a dual-matrix fiber-reinforced composite laminate featuring spatially tailored stiffness, fabricated through a novel dual-resin dosing and wet compression molding process. By selectively impregnating para-aramid and carbon fibers with compliant and stiff epoxy systems, we created monolithic laminates with both foldable and load-bearing regions. Thermal and rheological analyses guided the simultaneous curing of the two resins, ensuring phase compatibility and clean interface formation. Mechanical testing confirmed high contrast in flexural strength—707.7 MPa in stiff regions, 23.9 MPa in compliant zones—while Izod impact tests revealed over twofold improvement in toughness with the compliant epoxy. DMA and cyclic folding tests demonstrated excellent durability under extreme deformation, retaining over 90% of the initial modulus after 1,000 cycles. The fabricated laminates enabled the construction of Kresling origami tubes and other morphing geometries with minimal hysteresis and high mechanical repeatability. This dual-matrix system offers a scalable solution for integrating spatially programmable stiffness and flexibility in next-generation deployable systems across robotics, protective structures, and aerospace applications.

1 INTRODUCTION

Deployable and compliant materials have become increasingly vital in modern robotic systems, particularly for applications involving complex morphing, spatial constraints, and cyclic actuation [1]. As robotics evolves towards more adaptive, human-interactive, and miniaturized systems, the demand for materials that combine mechanical robustness with structural adaptability has grown substantially. These materials must withstand repetitive mechanical stresses and accommodate varying geometries without compromising structural integrity, making them indispensable in fields such as aerospace deployables, soft robotic manipulators, and foldable sensing devices [2, 3].

Conventional polymeric materials commonly used in soft robotic applications—such as silicone, thermoplastic elastomers, and polyurethane-based elastomers—provide adequate compliance but often lack the necessary tensile and flexural strength, load-bearing capacity, and durability under repeated mechanical loading. These limitations significantly restrict their use in load-bearing or mission-critical scenarios [4, 5]. Typically, such materials require additional mechanical components such as hinges and joints to facilitate motion, complicating system designs and potentially compromising structural performance.

Origami-inspired structures have emerged as promising platforms for achieving reconfigurable, lightweight, and compact systems by transforming two-dimensional sheets into three-dimensional deployable forms through strategic creases and folding patterns [6, 7]. These fold-based expandable designs enable compact storage, lightweight construction, and programmable deformation pathways. However, typical origami structures made from homogeneous monolithic materials, such as paper or polymer films, struggle to fulfill the simultaneous demands of mechanical strength and flexural compliance. Furthermore, their fatigue performance under cyclic deformation remains insufficient, primarily due to a lack of structural segmentation that allows localized property tuning.

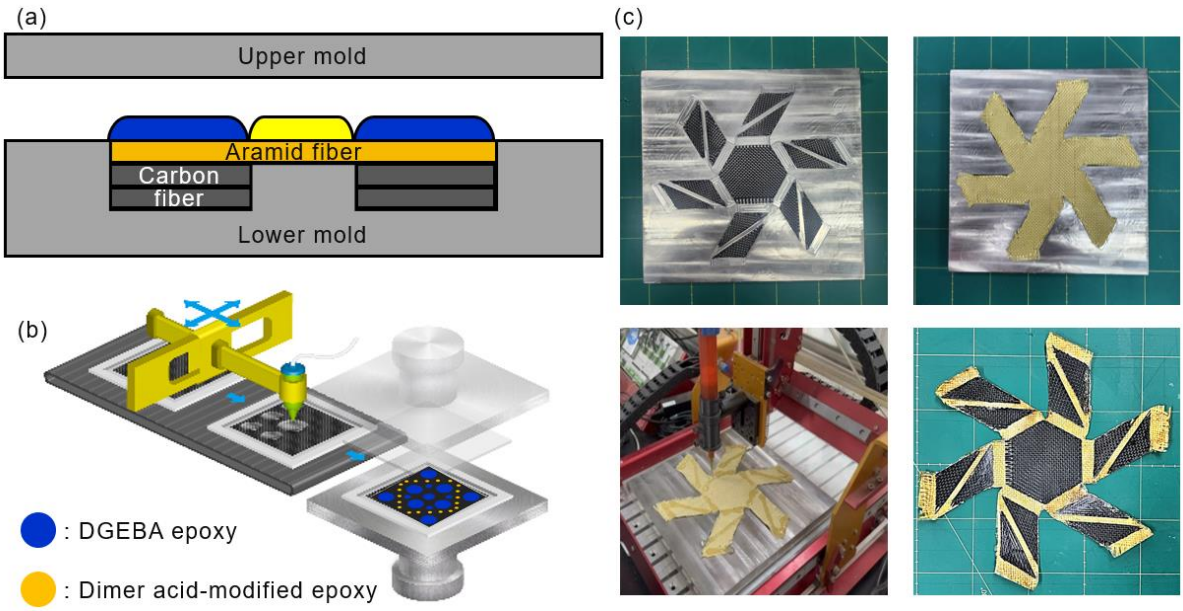

Figure 1: (a), (b) Schematic images and (c) images of the dual-matrix dosing process based on wet compression molding.

To overcome these challenges, this study introduces an advanced integrated composite laminate approach that combines stiff and compliant epoxy matrices through a novel dual-matrix dosing method coupled with wet compression molding. This hybrid laminate architecture allows for precise spatial control of stiffness and compliance, creating structures that integrate stiff load-bearing regions with compliant flexible zones [8, 9]. By controlling resin deposition patterns onto fiber preforms, we introduce tailored stiffness variations that are beneficial for structures requiring localized flexibility and directional deformation capability.

Unlike traditional composite systems that rely predominantly on fiber orientation for property differentiation, our strategy incorporates mechanical anisotropy through dual-matrix resin differentiation. Additionally, this approach circumvents the complexities associated with post-process adhesives or mechanical joints commonly required in segmented composite systems. Crucially, the compliant matrix—an aliphatic epoxy synthesized from dimeric fatty acids—features significantly reduced viscosity and a controlled curing profile compared to conventional urethane-modified epoxies, which enables precise resin dosing, clear interfaces, and thorough fiber impregnation [10].

The development of this dual-matrix laminate requires careful control over epoxide ring-opening reaction kinetics, viscosity evolution, and interfacial bonding strength. Accordingly, thermodynamic and rheological analyses were performed to optimize resin formulations and process parameters. These analyses ensured complete curing and minimal intermixing between resin phases, yielding integrated composite laminates capable of enduring extensive cyclic deformation without structural degradation.

To demonstrate the practical viability of this laminate concept, we fabricated and characterized deployable Kresling origami tubes utilizing the proposed dual-matrix composite system. Kresling tubes were selected due to their multi-degree-of-freedom deformation capabilities, including axial compression-extension, bending, and twisting motions, which are essential for advanced robotic actuators and deployable structural components [11]. Mechanical testing and cyclic deployment evaluations confirmed that the fabricated composite laminates maintained structural integrity, demonstrated highly repeatable actuation performance, and exhibited excellent durability under repeated mechanical loading cycles, highlighting their strong potential for next-generation deployable robotic and aerospace applications [12, 13].

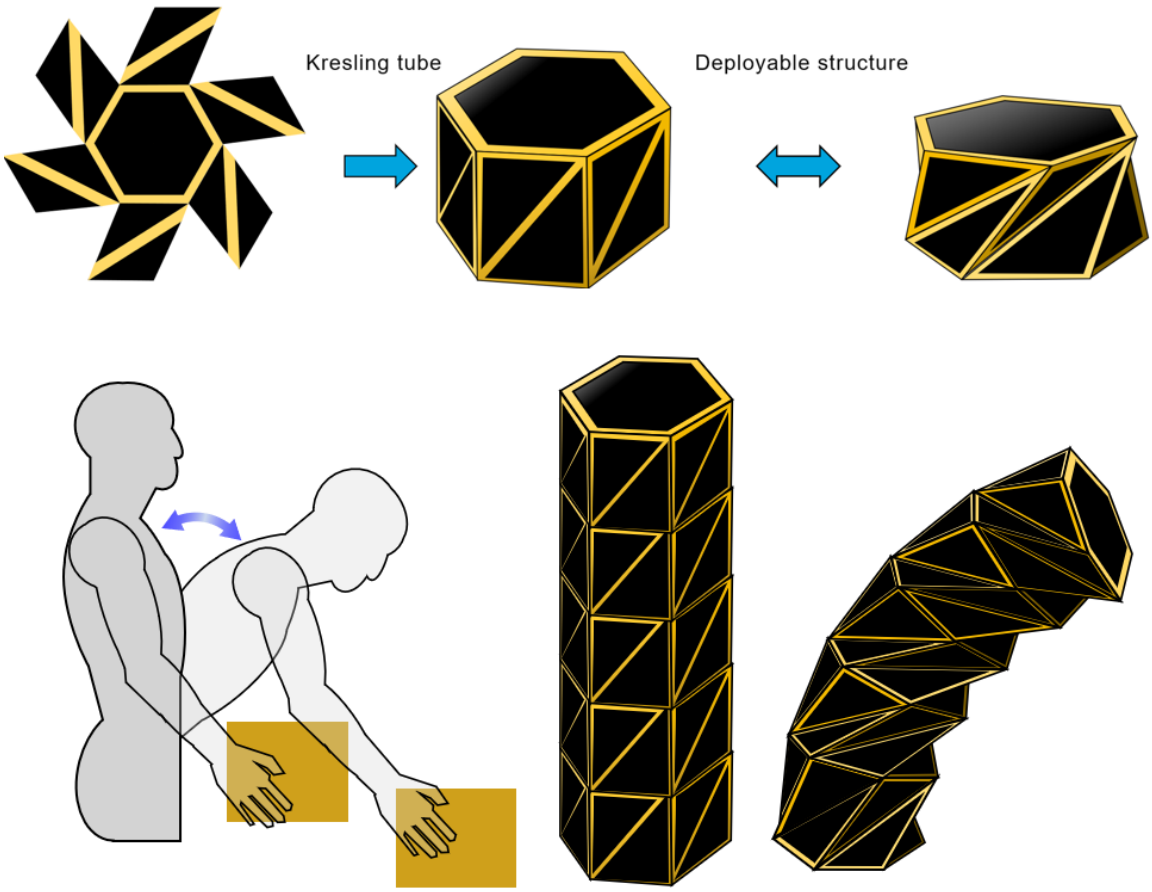

Figure 2: Kresling origami tube demonstrating reversible transformation between compact and expanded states. Stacked configurations enable multi-degree-of-freedom deformation, including axial, bending, and twisting motion, suitable for robotic articulation.

2 MATERIALS AND METHODS

2.1 Materials

Stiff epoxy consisted of Bisphenol A diglycidyl ether (DGEBA)-based epoxy (KFR-120V) with an epoxide equivalent weight (E.E.W.) of 200 g/eq and amine hardener (KFH-163) with an amine hydrogen equivalent weight (A.H.E.W.) of 58.1g/eq. Compliant epoxy was synthesized from dimeric fatty acid-based aliphatic epoxy with an E.E.W. of 430 g/eq and G640 hardener with an A.H.E.W. of 110 g/eq (Kukdo Chemical, Korea). Fiber reinforcements included plain-weave carbon (208 g/m², Hyundai Fiber) and para-aramid fabrics (180 g/m², Taekwang).

2.2 Resin characterization

To optimize the molding conditions for the dual epoxy resin system consisting of DGEBA and

aliphatic epoxy matrices, rheological and thermodynamic analyses were conducted using a rotational rheometer and differential scanning calorimetry (DSC), respectively. A rotational rheometer (MCR 702e, Anton Paar, Austria) equipped with a 25 mm parallel plate geometry was used to characterize the temperature-dependent viscosity of each resin system. A temperature sweep was conducted from 30 to 200 °C at a heating rate of 5 °C/min, 1 Hz frequency, and 0.1% strain. The curing behavior of each resin was investigated using a DSC (Q20, TA Instruments, USA) under a nitrogen atmosphere. Dynamic scans were performed from 30 to 220 °C at 5 °C/min to determine the total heat of epoxide ring-opening reaction and curing onset temperature. Isothermal scans were conducted to calculate the degree of cure, confirming that both resins achieved over 90% conversion within 30 min.

2.3 Composite fabrication

Composite laminates were fabricated using a dual-matrix dosing process combined with wet compression molding. Plain weave fiber reinforcements were precisely cut and arranged into designed laminate architectures, consisting of compliant and stiff regions. The compliant sections were composed of a single ply of plain-weave *p*-aramid fabric. The stiff sections were constructed by stacking two plies of plain-weave carbon fabric over one ply of *p*-aramid fabric in a [0/90] cross-ply configuration.

Each resin system was degassed under vacuum at 60 °C for 20 min to remove entrapped air. Resin dosing was performed by a programmable pneumatic dosing system (WINC V1, Nordson EFD, USA) equipped with a 55 mL syringe and a 0.063'' inner diameter tip. The dosing head traversed at a constant speed of 0.6 mm/s with a discharge pressure of 0.5 psi. The distance between the tip and the fiber surfaces was maintained at 0.5 mm, and the resin temperature was held at 60 °C during dosing to ensure stable viscosity and precise flow control.

Following deposition, the preforms were consolidated via wet compression molding at 160 °C under a pressure of 5 MPa for 30 min. This process ensured full curing of both resin systems, sharp interfacial boundaries between regions, and uniform fiber wet-out, resulting in a monolithic laminate with embedded spatially graded compliance suitable for deployable applications. The thicknesses of the obtained laminate's compliant section and stiff section were 0.25 mm and 0.70 mm, respectively.

2.4 Mechanical testing

To evaluate the mechanical performance of the dual-matrix composite system, separate specimens were fabricated using either the stiff or the compliant epoxy formulation. Compliant FRP specimens were prepared using four plies of plain-weave *p*-aramid fabrics while maintaining the same overall fiber volume fraction as the single ply of *p*-aramid fabric counterparts to ensure direct comparability.

Flexural properties were measured based on ASTM D790 using 60 mm × 25 mm rectangular specimens in a three-point bending configuration with a universal testing machine (RB301, Unitech, R&B, Korea). The span length was set to 32 mm, and the crosshead speed was 0.85 mm/min. The upper loading nose and lower support rollers had diameters of 9 mm and 3 mm, respectively.

Dynamic mechanical analysis (DMA, MCR 702e, Anton Paar, Austria) was conducted to evaluate the viscoelastic properties of stiff and compliant sections. Rectangular specimens measuring 60 mm × 10 mm were analyzed using a dual-cantilever bending configuration. Measurements were performed at a frequency of 1 Hz, a strain amplitude of 0.1%, and temperatures ranging from 50 to 200 °C at a heating rate of 5 °C/min. Additionally, cyclic bending durability tests were conducted on a 1 mm-thick compliant composite laminate (4-ply *p*-aramid), applying 1,000 bending cycles at a frequency of 1 Hz and a cyclic amplitude of 1,000% in single-cantilever mode.

Izod impact tests were performed according to ASTM D256 using an Izod pendulum impact tester (CEAST 9050, Instron, equipped with a 22 J hammer). Four different composite laminates—carbon/DGEBA epoxy, carbon/compliant epoxy, *p*-aramid/DGEBA epoxy, and *p*-aramid/compliant epoxy—were tested to systematically investigate the effects of fiber type and matrix stiffness on impact

resistance.

The compressive deployment behavior of the fabricated Kresling origami tubes was evaluated under cyclic strain conditions. The tubes were repeatedly compressed and re-expanded between 30% and 80% axial strain for 10 cycles. Load–displacement behavior and shape recovery were monitored to assess mechanical integrity, actuation repeatability, and fatigue resistance during transformation.

3 RESULTS AND DISCUSSION

3.1 Resin optimization for dual-matrix injection

To enable simultaneous impregnation and curing of the stiff and compliant epoxy systems, comprehensive thermal and rheological analyses were conducted to determine the optimal processing window.

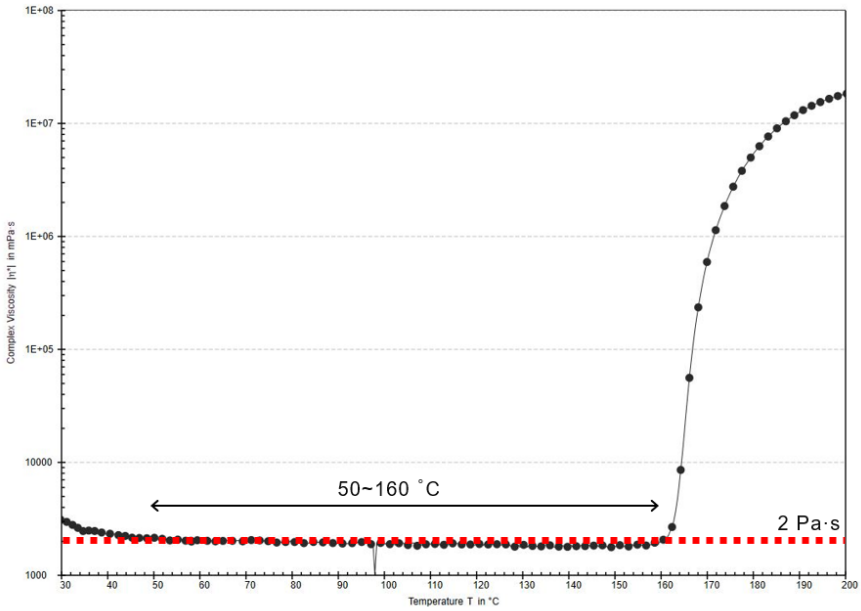

Figure 3: Temperature-dependent viscosity of the compliant epoxy measured by rheometer dynamic scan.

Rheological analysis was conducted to determine a suitable processing window for the compliant epoxy system. As shown in Figure 3, the complex viscosity remained relatively constant around 2 Pa·s across a broad temperature range from 50 °C to 160 °C, indicating excellent flow stability suitable for liquid molding. A sharp increase in viscosity was observed beyond 160 °C, corresponding to the onset of epoxide ring-opening and gelation reactions, marking the transition to rapid crosslinking and network formation.

Based on this behavior, the molding temperature was set to 60 °C to maintain low viscosity and ensure uniform resin distribution during dispensing. The curing temperature was set to 160 °C to initiate and complete crosslinking within a practical processing time. This temperature regime provided sufficient flowability during impregnation while ensuring rapid gelation and full curing during compression molding.

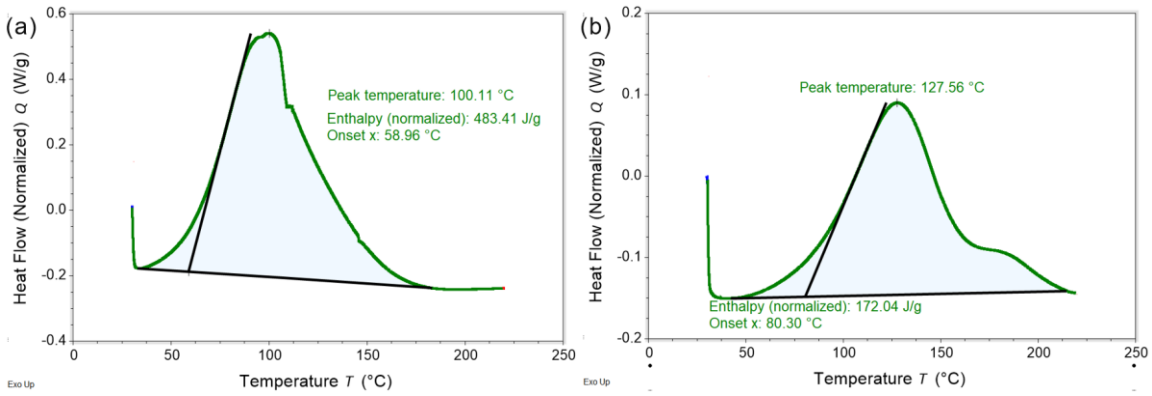

Figure 4: Dynamic DSC curves of (a) DGEBA epoxy and (b) compliant epoxy

As shown in Figure 4, dynamic DSC measurements revealed that the DGEBA-based stiff epoxy exhibited a reaction enthalpy of 483.41 J/g, indicating rapid crosslinking and high reactivity. In contrast, the compliant epoxy exhibited a lower enthalpy of 172.04 J/g, suggesting slower and more gradual curing behavior suitable for spatially controlled processing. To further assess curing kinetics, isothermal DSC scans were performed, and the degree of cure was calculated. The resulting conversion profiles confirmed that both epoxy systems reached over 90% cure within 30 min at 160 °C, demonstrating compatibility for concurrent curing in a dual-matrix system.

Based on these analyses, the processing conditions for the dual-resin system were established as follows: dispensing at 60 °C for low-viscosity flow and mold wet-out, followed by compression molding and curing at 160 °C, enabling complete crosslinking without premature gelation. These conditions ensured sharp interface formation, uniform fiber impregnation, and full structural integration between stiff and compliant regions.

3.2 Resin-fiber and resin-resin interface

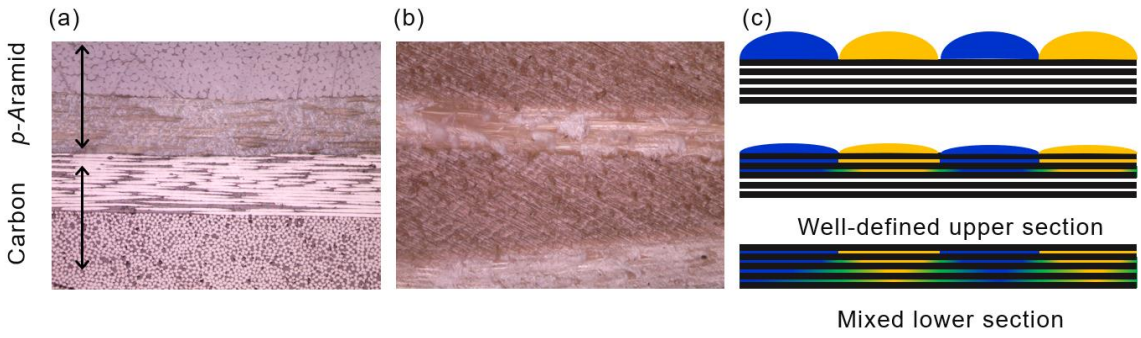

Figure 5: Resin intermixing behavior and interfacial compatibility in dual-matrix laminate structures. Cross-sectional optical microscopy images of (a) the stiff epoxy region and (b) the compliant epoxy region. (c) Schematic illustrating slight resin intermixing during impregnation.

Since both stiff and compliant matrices are epoxy-based thermoset processed via the liquid molding process, significant phase separation or poor interfacial adhesion was not observed. Due to resin impregnation dynamics, the lower side reveals some penetration of the DGEBA epoxy (~100 mPa·s, yellow) into the compliant epoxy region (~2 Pa·s, blue), resulting in indistinct boundaries and molecular-level mixing without notable phase separation. In Figure 5(a), Cross-sectional micrographs show carbon and *p*-aramid fiber layers within the stiff epoxy section, with a low void content. Similarly, Figure 5(b) indicates through impregnation of compliant epoxy within the *p*-aramid fiber region, it also exhibits low void content and confirms excellent resin-fiber compatibility.

3.3 Mechanical behavior of stiff and compliant sections

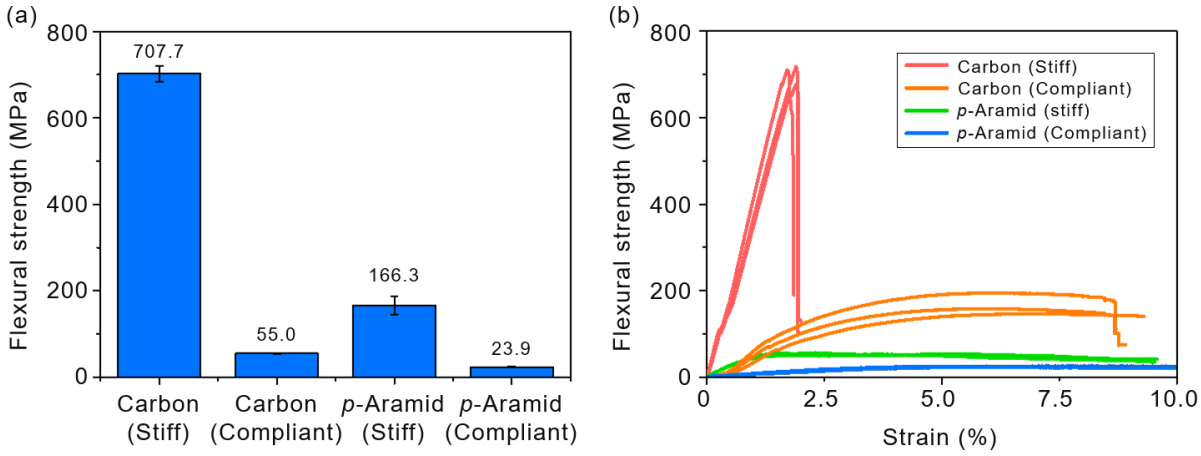

Figure 6: (a) Flexural strength of laminates with different fiber-resin combinations. (b) Corresponding flexural stress-strain curves.

To investigate the effect of the compliant epoxy matrix on flexural properties, four composite laminates were tested with different combinations of fiber type and matrix stiffness, as shown in Figure 6. The stiff section, composed of two plies of carbon fabric and one ply of *p*-aramid fabric impregnated with DGEBA epoxy, exhibited the highest flexural strength (707.7 MPa). This superior rigidity ensures that the stiff regions maintain their planar geometry during deployment, enabling well-defined crease lines in the origami structure. The DGEBA–*p*-aramid specimen also showed a relatively high flexural strength (166.3 MPa), although the lower fiber modulus compared to carbon led to more compliance. This confirms that structural rigidity in origami systems is primarily governed by the carbon fiber–DGEBA combination.

In contrast, the compliant section, composed of *p*-aramid fabric impregnated with the compliant epoxy, showed a significantly lower flexural strength (23.9 MPa), allowing for easy and localized bending. The laminate remained unbroken even when bent until the jigs made contact, indicating excellent ductility. Interestingly, the carbon–compliant epoxy laminate exhibited a flexural strength of 55.0 MPa, significantly lower than its DGEBA counterpart, confirming that matrix stiffness has a dominant influence on bending resistance. Moreover, the high strain-to-failure observed in both compliant laminates indicates their suitability for foldable zones within deployable structures.

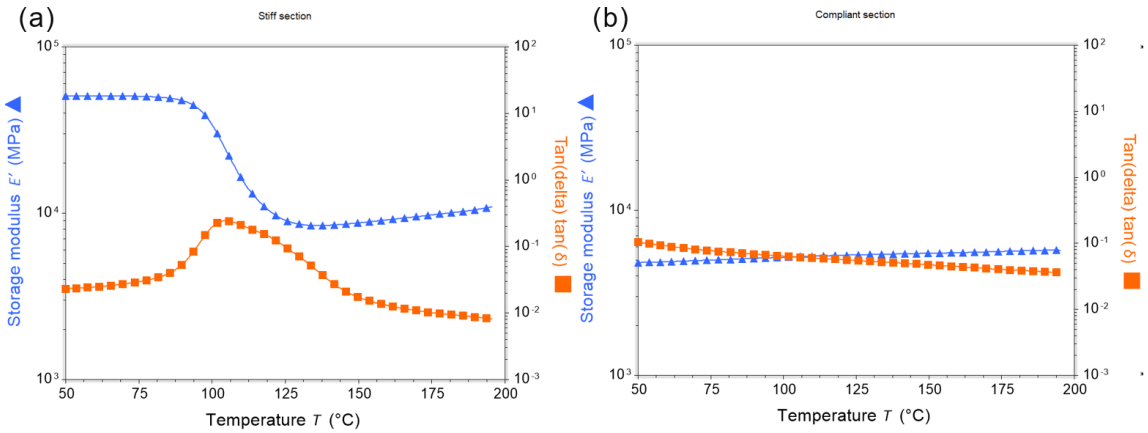

Figure 7: Temperature ramp DMA results of the (a) stiff and (b) compliant section

Dynamic mechanical analysis (DMA) results for the stiff and compliant composite sections are presented in Figure 7. Figure 7(a) shows the temperature-dependent viscoelastic behavior of the stiff section during a temperature ramp test. The storage modulus remains high up to approximately 100 °C, indicating that the stiff section effectively maintains its structural rigidity under typical use conditions. However, the sharp drop in modulus beyond 108 °C, coinciding with the tan δ peak (Tg), suggests that the material may lose its load-bearing capacity at elevated temperatures, becoming susceptible to folding or deformation. In contrast, Figure 7(b) demonstrates that the compliant section exhibits a relatively low but stable storage modulus across the entire temperature range. The nearly constant storage modulus and tan δ indicate thermally stable softness, making the compliant section highly suitable for applications requiring repeated bending. While the soft epoxy ensures excellent flexibility at room temperature, its Tg was separately confirmed to be below –20 °C, implying that the material becomes stiff under sub-zero conditions and may not be suitable for cryogenic or arctic applications. At room temperature, the storage modulus of the stiff section is nearly two orders of magnitude higher than that of the compliant section, establishing a clear mechanical contrast essential for origami-inspired deployment designs. Thus, the effective operating range for the dual-matrix laminate is approximately –20 °C to 100 °C, beyond which folding performance or rigidity may be compromised depending on the material region.

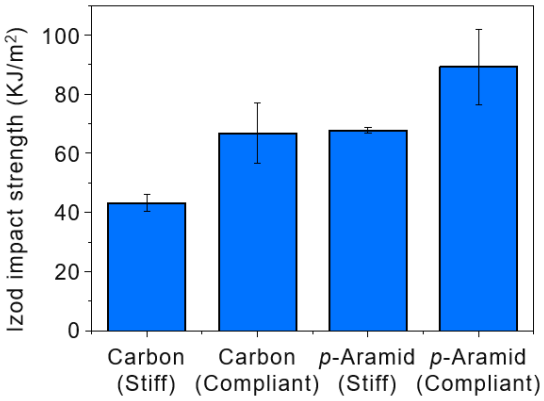

Figure 8: Izod impact strength of composite laminates with different fiber-matrix combinations.

Figure 8 presents the Izod impact strength of composite laminates with different fiber and matrix combinations. The conventional carbon fiber–DGEBA epoxy configuration exhibited the lowest impact resistance at 43.2 kJ/m², consistent with the known brittle nature of stiff epoxy systems. In contrast, the *p*-aramid–compliant epoxy system achieved the highest impact resistance at 89.2 kJ/m², more than doubling that of the carbon fiber–DGEBA epoxy. This significant enhancement is attributed to the high elongation and energy-absorbing nature of both the compliant epoxy and *p*-aramid fibers.

Interestingly, the carbon–compliant configuration also demonstrated markedly improved impact performance (66.8 kJ/m²), comparable to or exceeding that of the *p*-Aramid–Stiff system (67.8 kJ/m²), which is widely used in protective composite applications. These results suggest that the compliant matrix plays a dominant role in enhancing impact toughness, even when paired with inherently brittle fibers, such as carbon.

The combination of compliant matrix and high-ductility fibers not only enhances the material's ability to withstand direct impact but also holds promise for use in deployable origami structures. In such structures, deformation-based energy dissipation can further amplify impact resistance through mechanical motion, such as controlled folding, buckling, or twisting. Therefore, the *p*-Aramid–Compliant laminate emerges as a highly promising candidate for applications requiring both impact tolerance and deployability, such as protective soft robotics, aerospace shielding, or wearable armor systems.

3.4 Performance validation of the Kresling origami tube and other structure

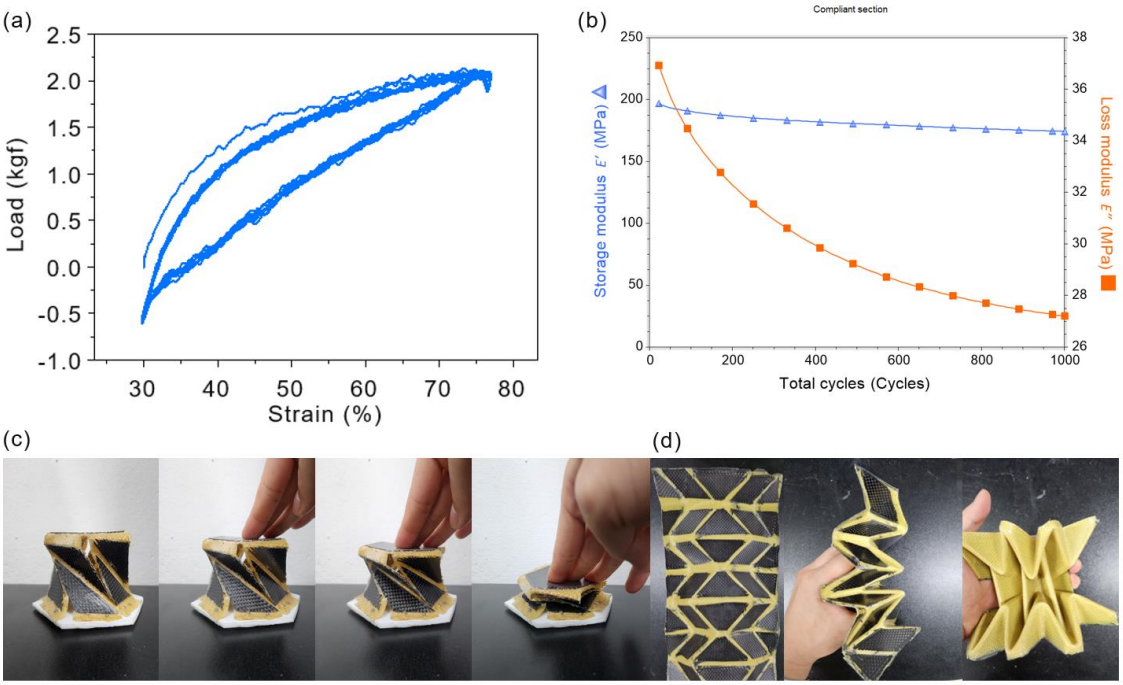

Figure 9: (a) Cyclic load–strain response of a Kresling tube under 30–80% axial strain. (b) DMA single-cantilever test results of the compliant section over 1,000 cycles at 1,000% strain. (c) Sequential compression and expansion images of the fabricated Kresling tube. (d) Tachi–Miura polyhedron structure fabricated via dual-resin dosing process.

Figure 9 presents the cyclic performance and structural versatility of the dual-matrix composite system. Figure 9(a) shows the cyclic deployment test of a Kresling tube under axial strain ranging from 30% to 80%. After initial cycle conditioning, the load–strain curves demonstrated minimal hysteresis over 10 cycles, confirming outstanding mechanical repeatability and resilience of the integrated composite structure.

To further evaluate durability under extreme deformation, DMA single-cantilever mode tests were performed on the compliant composite section under 1,000 cycles at 1,000% strain. As shown in Figure 9(b), the storage modulus retained over 90% of its initial value, while a gradual decrease in loss modulus was observed, indicating viscoelastic stabilization and sustained energy-dissipation capability of the compliant matrix during repeated folding cycles, validating its suitability for repeated folding and actuation.

Figure 9(c) displays sequential images of the fabricated Kresling tube undergoing manual compression and expansion, visually demonstrating its reversible deformation and structural robustness. In addition, Figure 9(d) showcases a Tachi–Miura polyhedron structure manufactured using the same dual-resin dosing process, highlighting the fabrication speed and geometric versatility of the method. The ability to produce complex foldable geometries such as Tachi–Miura patterns extends the applicability of this technique to broader categories of deployable and morphing structures in soft robotics and aerospace systems.

4 CONCLUSIONS

This work introduces a dual-resin composite approach that integrates stiff and compliant epoxy matrices to engineer spatially tunable mechanical properties within a single laminate architecture. Through detailed thermal and rheological characterization, we optimized a processing window that

supports simultaneous impregnation and curing of both matrix systems. The successful application of a programmable resin-dosing process allowed for precise deposition of low-viscosity, selectively cured epoxies into designed fiber regions without interfacial delamination or phase separation. Mechanical testing demonstrated that the stiff regions provide structural rigidity suitable for maintaining defined creases during deployment, while compliant regions support reversible folding and recoverable deformation. Notably, the compliant epoxy significantly enhanced impact toughness, even when combined with brittle carbon fibers, highlighting the dominant role of matrix properties in energy absorption. Temperature-dependent DMA and long-cycle durability tests confirmed excellent thermo-mechanical stability of both regions under realistic operating conditions. Furthermore, this architecture enabled the fabrication of advanced deployable structures such as Kresling tubes and Tachi–Miura polyhedra, which exhibited robust actuation over repeated deformation. The combined advantages of low processing complexity, mechanical programmability, and long-term durability position this dual-resin strategy as a promising platform for next-generation soft robotics, deployable aerospace components, and impact-resilient morphing systems.

- Objective: develop laminate design that satisfies both stress and manufacturing requirements
- Bi-level strategy selected due to complexity and runtime of software involved
  - Lower level: HyperX and CAPP iterate with VCP to optimize for stress and manufacturing respectively
  - Upper level: global iterations to converge the solution

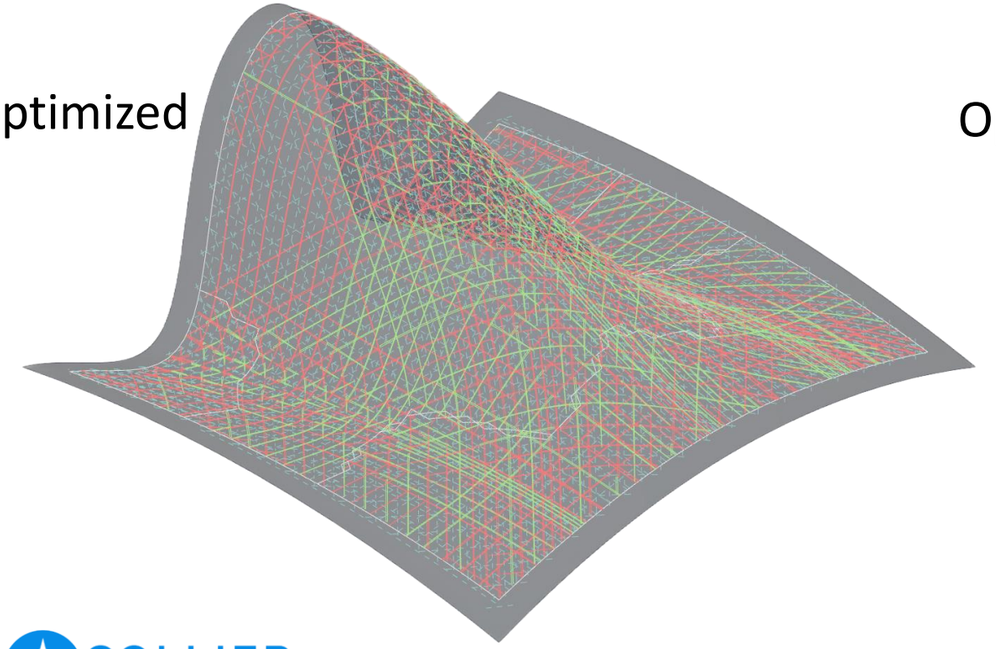
HyperX AFP Defect/Feature Handling

- Effect of defect testing/simulation is best left up to the manufacturer due to considerations specific to their material, manufacturing, etc
- Instead of implementing a specific analysis approach, create a framework to allow defects/features of any type from any source to be mapped to the user's FEM and analyzed with user-specific criteria

© Copyright 2024 Collier Aerospace Corporation. Confidential Information.

- Developed a command-line user interface (CLUI) for headless communication with DFM partner software applications
- Established stable protocol and optimized data handling for HyperX-CAPP-VCP communication
- Implemented customizable settings and an expanded GUI with enhanced capabilities
- Integrated margin-of-safety data within optimization process



HyperX MoS data is visualized per element on the mesh, with blue indicating highest margins and red indicating lowest margins

CAPP 1.0.0 Screenshots (CLUI/GUI)

- CAPP optimizes manufacturability by assessing features such as tow overlap/gaps and excess steering radius
- Optimization at two levels
  - Ply level: maximize manufacturability per individual ply
  - Laminate level: minimize stacking of defects through the laminate thickness
- Both approaches move defects away from areas of critical margin of safety

Un-optimized

Optimized

Laps and gaps spread out to minimize stacking-through thickness

Applied Mechanics Department,
Indian Institute of Technology Delhi, India

Wind turbine blade: Damages

Types of Wind Turbine Blade Damage:
Surface Damage:

- Leading edge erosion due to rain, hail, and debris impact.
- Microcracks in the surface and coatings.
- Lightning strike damage.

Structural Damage:

- Cracks and splits in the blade structure.
- Physical impact such as bird.
- Delamination (separation of layers).
- Bonding failures between different blade components.
- Broken or kinked fibers within the blade.

Average downtime per repair varies based on the type of repair and location.

- Minor damage, typical downtimes range from 2 to 7 days,
- Major structural repairs can cause 10 to 30 days

A wind turbine blade that has undergone leading edge erosion [*]

Structural damage in wind turbine blade [cotech]

[*] Mishnaevsky Jr, L., 2019. Repair of wind turbine blades: Review of methods and related computational mechanics problems. Renewable energy, 140, pp.828-839

Introduction to the problem

If damaged wind turbine blades are not repaired catastrophic failure may occur.

Surface and sub-surface structural damage → scarf repair technique

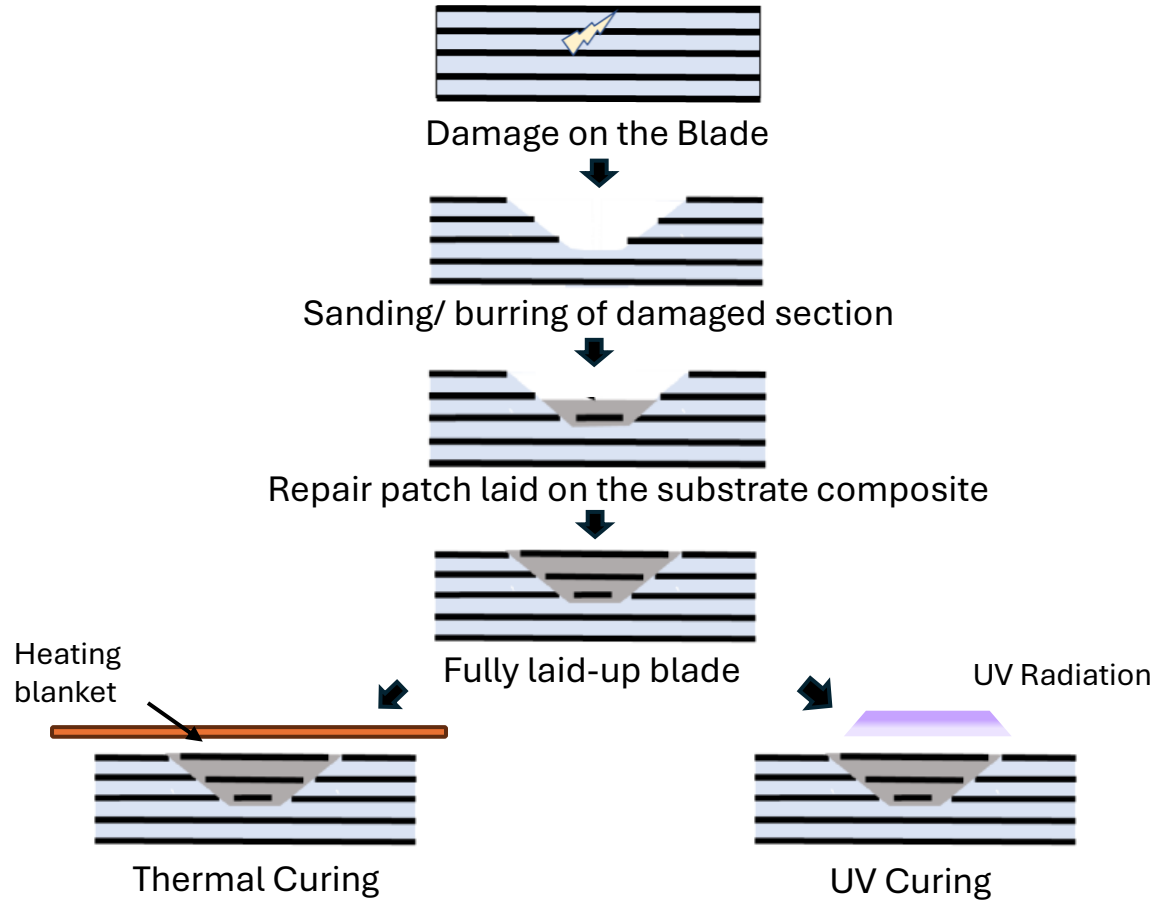

Fig: Schematic depicting scarf patch repair techniques

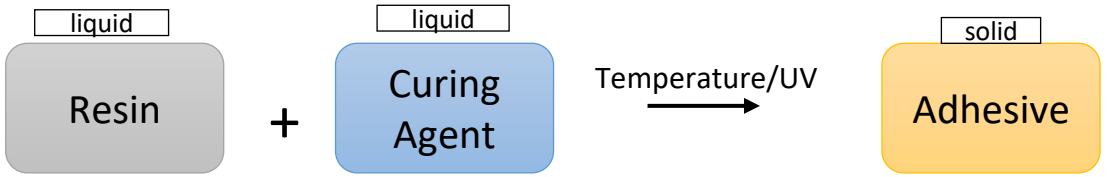

Fig: Repair on actual wind turbine blade *

[*] Cotech blade repair group and Gurit wind energy group

Curing

Curing is a chemical process that produces the toughening or hardening of a polymer material by cross-linking of polymer chains.

- Chemical Shrinkage due to the curing process.
- Thermal strain due to change in temperature.
- Void Size Evolution

→ Residual Stresses

UV Curing

- UV curing completes in minutes vs hours for thermal curing.
- Uses photoinitiators activated by UV light.
- Safer and eliminates need for heating blankets.
- Reduces blade downtime and labor costs.

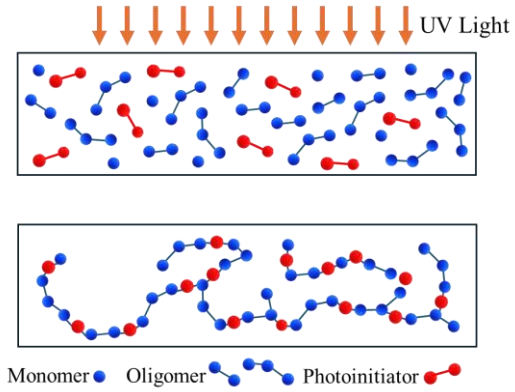

Fig: Cross-linking of the UV cured resin

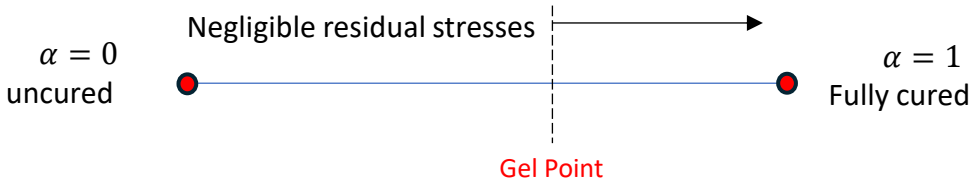
Cure Kinetics model



The cure process is modelled using an autocatalytic model according to Kamal and Sourour [*]

$$\frac{d\alpha}{dt} = (k_1 + k_2\alpha^m)(1-\alpha)^n$$

$$k_i = k_{0_i} exp\left(-\frac{E_{a_i}}{RT}\right)$$

α is the degree of cure,
$d\alpha/dt$ is the rate of cure,
m and n are model coefficients
E_{ai} are the activation energies (i = 1,2)
R is the universal gas constant
T is the absolute temperature.

Gel Point: The point at which the system stops flowing – rapid and sudden increase in viscosity

Equilibrium equation

$$\nabla . \boldsymbol{\sigma} + \boldsymbol{b} = 0$$

Heat transfer equation

$$\nabla \cdot \left(k\, \nabla T(v,t)\right) + \dot{q} + \varphi = \rho C \frac{\partial T(v,t)}{\partial t}$$

$$\dot{q} = v_r \rho_r \Delta H_r \frac{d\alpha}{dt}$$

$k\ is$ the thermal conductivities,
ρ is the density

C is the specific heat of the adhesive.
φ Mechanical energy dissipation

v_r is the resin volume fraction,
ρ_r is the density of the resin
ΔH_r is the polymerization enthalpy of resin

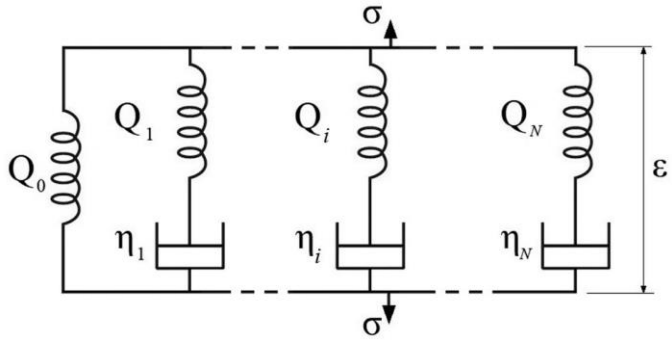
Stresses

$$\boldsymbol{\sigma} = \boldsymbol{Q}\,(\boldsymbol{\epsilon}_{total} - \boldsymbol{\epsilon}_{thermal} - \boldsymbol{\epsilon}_{chemical})$$

Q is the stiffness matrix

Thermal and chemical strain

$$\Delta\epsilon_{thermal} = (CTE)\Delta T \qquad \Delta\epsilon_{chemical} = (CCS)\Delta\alpha$$



$(CTE)_i$ coefficient of thermal expansion
$(CCS)_i$ coefficient of chemical shrinkage

[*] Mortensen, U.A., Andersen, T.L. and Mikkelsen, L.P., 2018, July. Pragmatic approach to cure profile enhancement for improved fatigue performance of thermoset matrix composites. In IOP Conference Series: Materials Science and Engineering (Vol. 388, No. 1, p. 012014). IOP Publishing

Material model: Viscoelastic with cure and temperature dependency

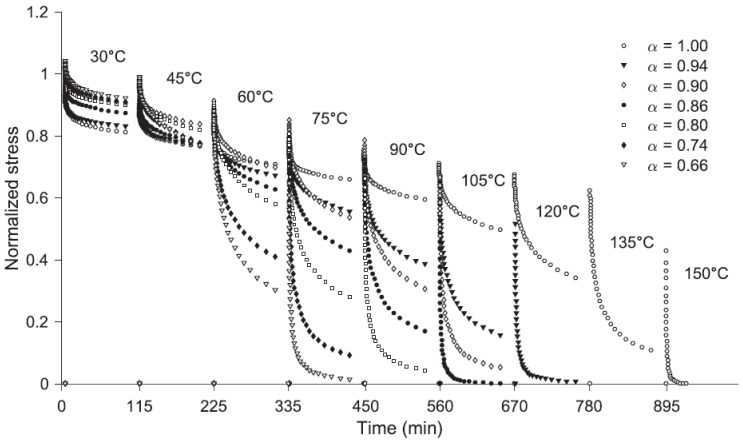
The stresses in an orthotropic composite are given as:

$$\boldsymbol{\sigma_{ij}(t)} = \left(\boldsymbol{Q_{ij}}\right)_{\infty} \boldsymbol{\epsilon} + \sum_{\boldsymbol{p=1}}^{\boldsymbol{N}} \left(\boldsymbol{Q_{ij}}\right)_{\boldsymbol{p}} \exp\left(-\frac{\boldsymbol{t}}{\boldsymbol{\tau_p}}\right) \boldsymbol{\epsilon_j}$$

$\boldsymbol{Q}_{\infty}$ is the long-term (orthotropic) stiffness matrix, $\boldsymbol{Q_p} = w_p \boldsymbol{Q}_{\infty}$ is the stiffness matrix associated with the p^{th} prony element, w_p and τ_p are the prony constants.

Degree of cure dependency

$$\tau_p(\alpha) = 10^{\left[\log\left(\tau_p(\alpha_r)\right) + (f(\alpha) - (\alpha - \alpha_r)\log(\lambda_p))\right]}$$



$$f(\alpha) = 9.1347\alpha^2 + 0.6089\alpha + 9.3694$$

$$\lambda_p = \frac{\tau_{peak}}{\tau_p(\alpha_r)}$$

Temperature dependency

$$a_T = 10^{\left[-a_1 \exp\left(\frac{1}{\alpha - 1}\right) - a_2\right][T - T_r]}$$

$$\xi^t = \int_0^t \frac{ds}{a_T(\alpha, T)} \;;\; \xi^s = \int_0^s \frac{ds}{a_T(\alpha, T)} \;;\; \xi^{\Delta t} = \int_t^{t+\Delta t} \frac{ds}{a_T(\alpha, T)}$$

[*] Sebastian Blanco, Hangil You, Tomas Webbe Kerekes, and Gun Jin Yun. Cure-induced residual stress buildup and distortions of cfrp laminates with stochastic thermo-chemical and viscoelastic models: Experimental verifications. Mechanics of Advanced Materials and Structures, 29(19):2740–2756, 2022

Objective

- To model the entire repair process numerically.
- To estimate the residual stresses at the end of the repair process UV curing using hybrid analytical-numerical modeling.
- To compare the results with the conventional technique (i.e. Thermal curing) different temperature cycles.
- Influence of void defects on the development of residual stresses.
- Investigate the post-repair mechanical behavior of UV-cured tensile coupon samples through both numerical simulations and experimental testing.

Residual stress analysis

The numerical analysis of the scarf model is executed on ABAQUS standard. A coupled temperature-displacement problem is solved to predict the residual stresses developed during the curing process.

Geometry configuration

Patch: 100 *100 mm ; 6 plies (each of thick 0.5 mm); 3° scarf angle

Adhesive layer: 0.1mm thickness

Substrate composite: 16 plies (each of thick 0.5 mm)

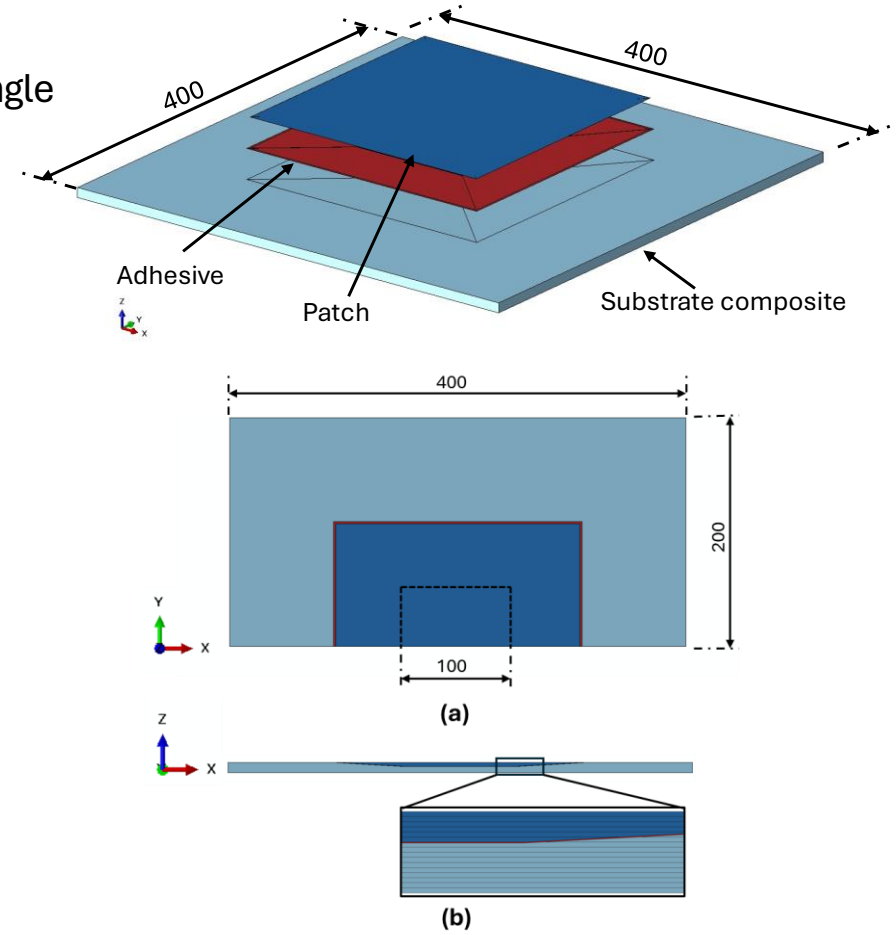


Fig: (a) The geometry of the half model.
(b) A cross-sectional view of the model.

Model :

- Heat generation during curing
- Cure and temperature dependent viscoelastic model:
  - Resin (epoxy) exhibits viscoelastic behavior
  - Pronounced at low degree of cure and high temperature

To reduce the computational time, half model is used

Subroutines used:

Material model → UMAT

Thermal + chemical strains → UEXPAN

Heat generation due to the curing process → HETVAL

UV light field → USFLD

Thermal Curing

- **Magnitude**: Residual stresses typically range between 15–25 MPa.
- **Location of Maximum Stress**: Near the interface between the substrate composite and the repair patch.
- **Repair Integrity**: These stresses worsen debonding at the interface during post-repair loading, potentially reducing long-term durability of the repair.

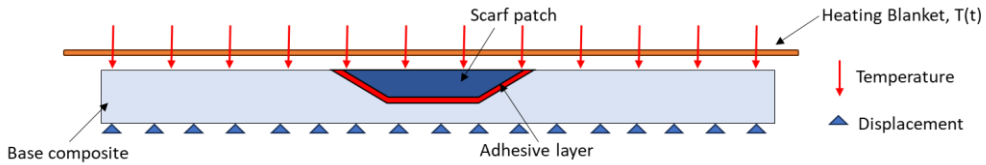

Fig: Schematic of the boundary conditions applied

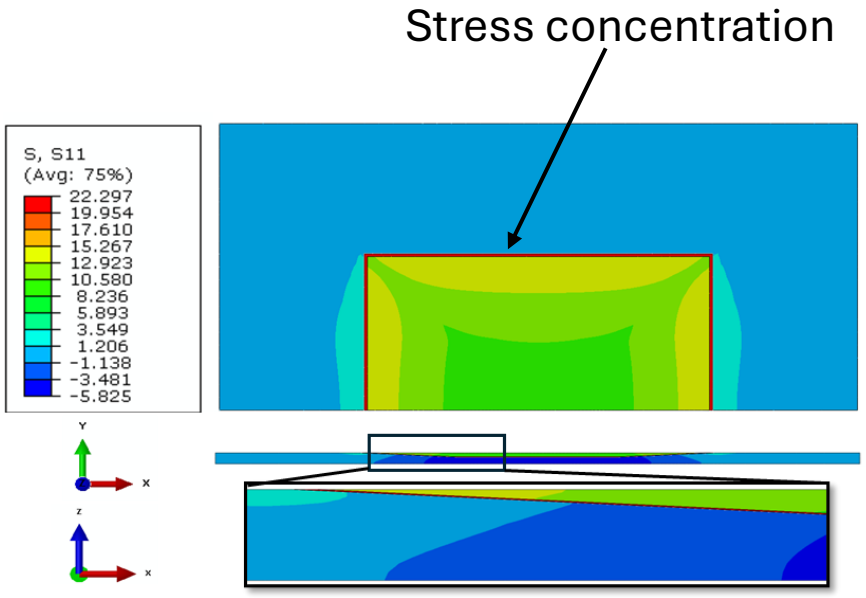

Fig: In-plane stress contours for single ramp 100°C

UV Cure Kinetics model

UV cure kinetics model *

$$\frac{d\alpha(v,t)}{dt} = \varphi I^{p}(v,t)\beta^{q}\exp\left(\frac{-E}{RT_{\text{abs}}(v,t)}\right)\alpha^{m}(v,t)\left(1-\alpha(v,t)\right)^{n}$$

ϕ pre-exponential factor of rate constant

- UV lamp consists of a series of UV LEDs arranged linearly,
- Adhesive (Gurit Renuvo MPS) is applied between substrate and patch.
- UV Light Source: Wavelength 395 nm (UV-A).
- UV lamp travels at a maximum of 20 mm/sec – for 20 passes and 300 mm/sec for the next 20 passes.
- Maximum light intensity of 300 mW/cm^2

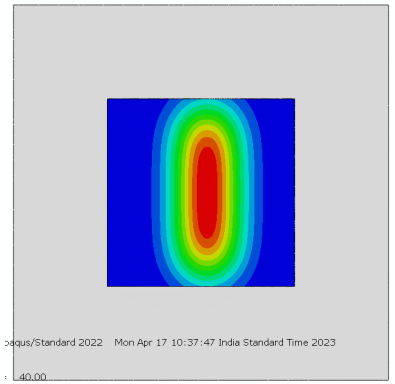

Fig: UV curing on wind turbine blade. [Gurit]

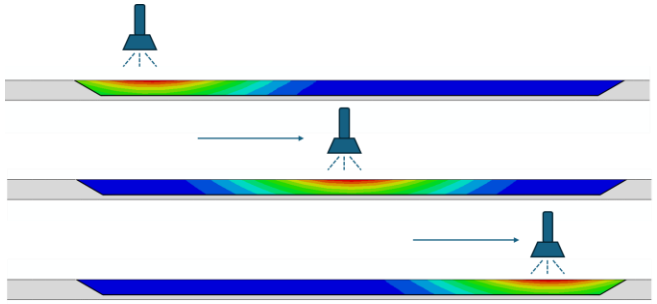

Fig: Movement of UV lamp.

Property	Patch (UV-cured Prepreg)	Adhesive (UV-cured resin)
E_{11}	41 MPa	4 MPa
$E_{22} = E_{33}$	13 MPa	4 MPa
ρ	1800 Kg/m^3	1200 Kg/m^3

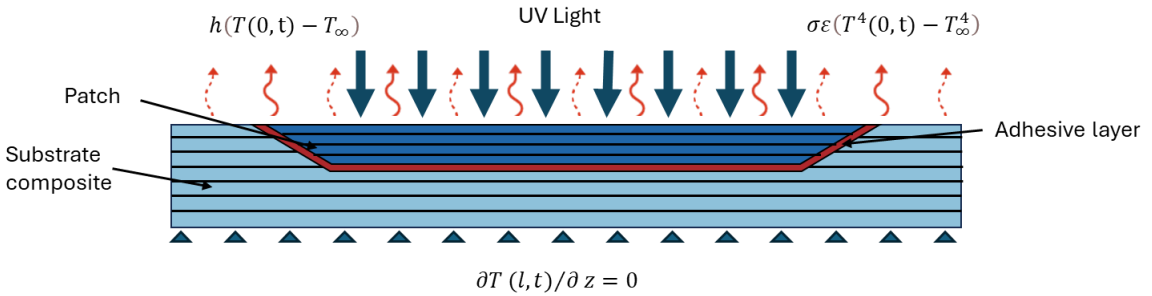

Fig: Boundary conditions applied to the scarf patch repair model.

Results

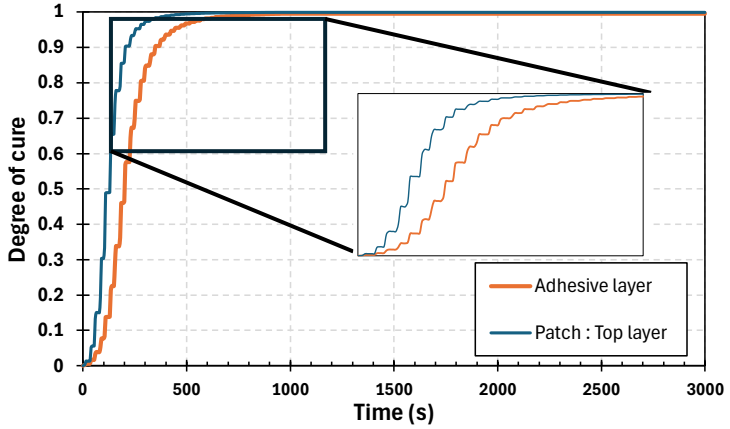

Fig: Degree of cure

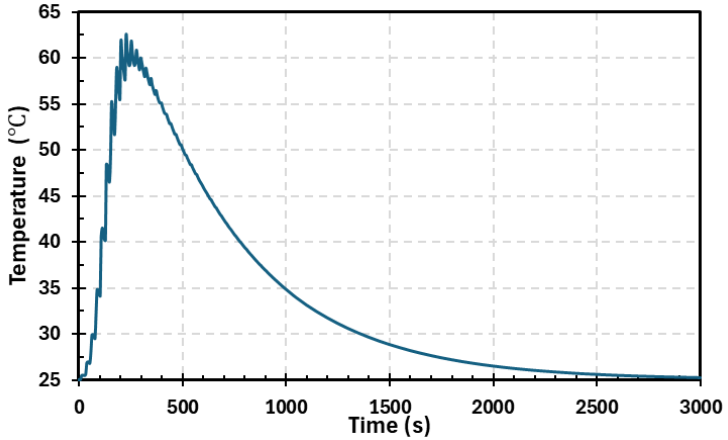

Fig: Temperature rise at a node in top layer of patch

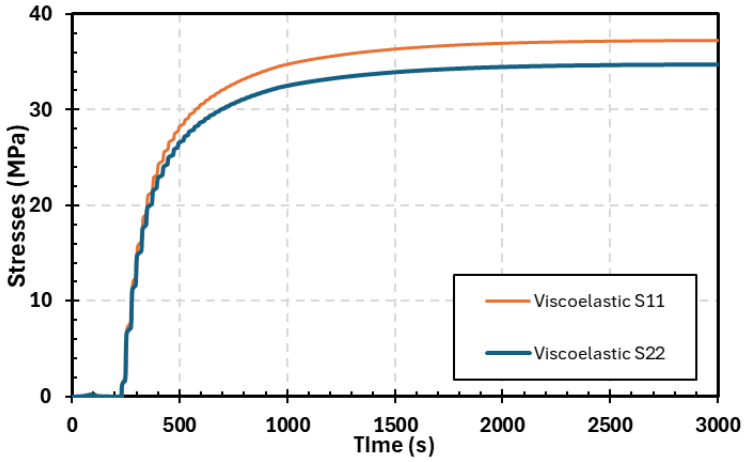

Fig: Stress at the center in the adhesive layer

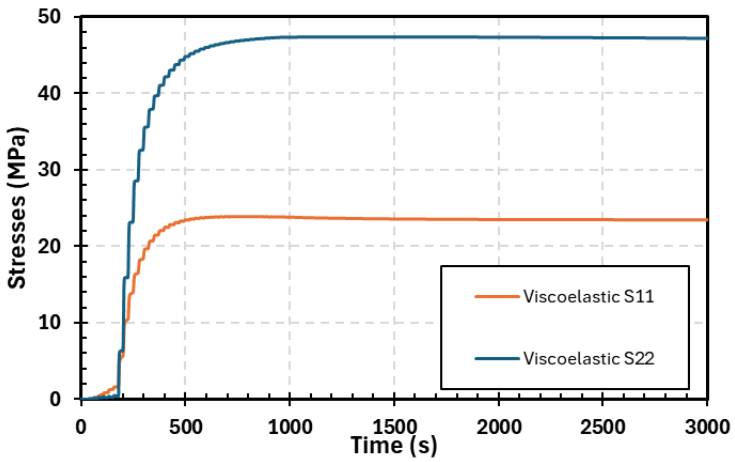

Fig: Stress at the center in the patch

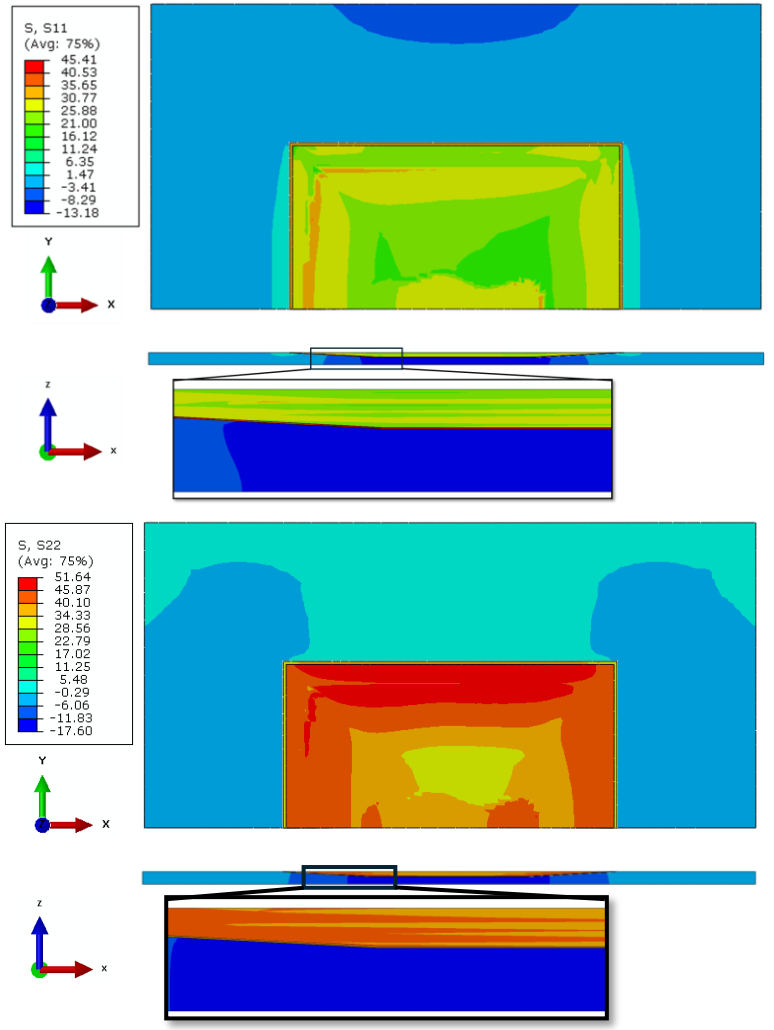

Fig: In-plane stress contours

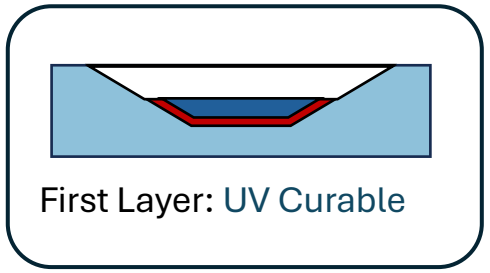
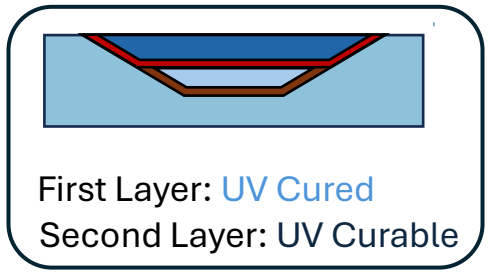
Results

- Unlike thermal curing, UV curing produces non-uniform residual stress fields.
- Residual stresses range from 45–55 MPa, nearly double that of thermal curing. (due to high chemical shrinkage coefficient)
- Stresses are concentrated at the interface between the substrate and patch, increasing the risk of debonding.



Limitation:

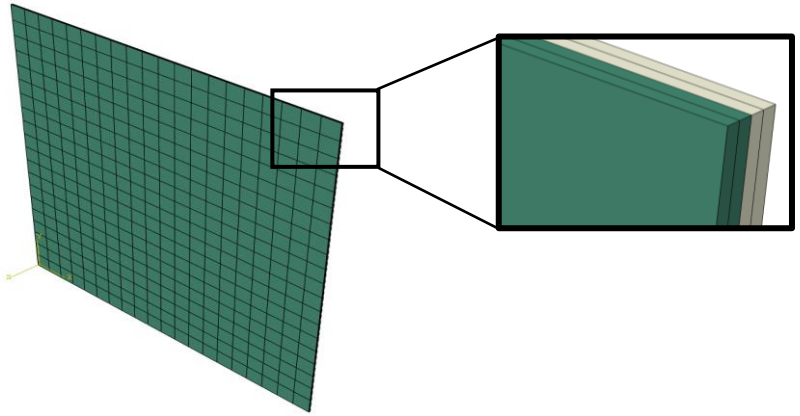
Can be used only for thin laminates because of limited light penetration



Multi-Stage Repair of Thick Laminates

Thick laminate can be cured in a number of stages.

Model 1: First Layer Curing



Model 2: Second Layer Curing

To repair thick laminates, multi-stage repair is investigated, which shows a 13% reduction in residual stresses compared to single-stage repair.

Compare simulation results with experimental measurements

Max deflections: 4.11 mm and 3.21 mm

Experimental Warpage:

Laminate fabricated using RENUVO UV-cured prepreg

Measured via dial gauge

Max deflections: 4.3 mm and 3.1 mm

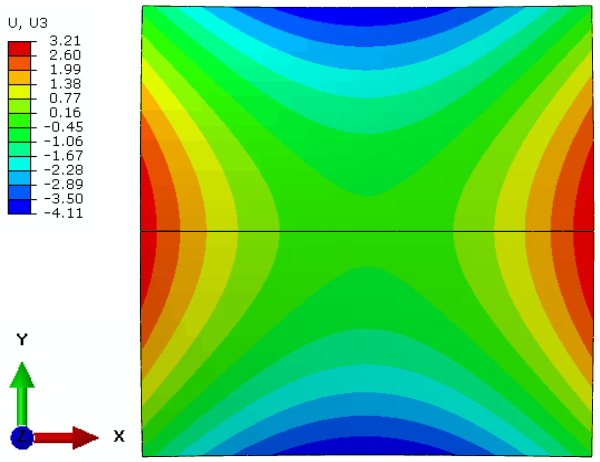

Fig.: Maximum out-of-plane displacement (z-direction) predicted by the numerical model

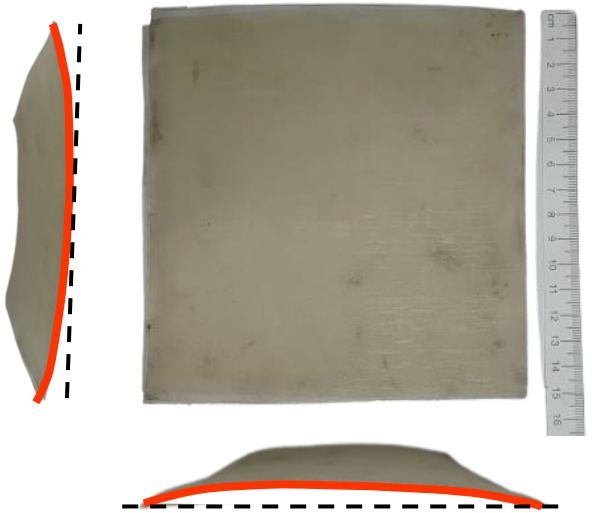

Fig.: Experimentally observed warpage in the UV-cured laminate

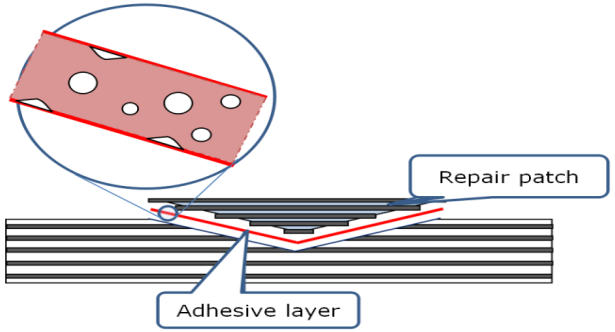


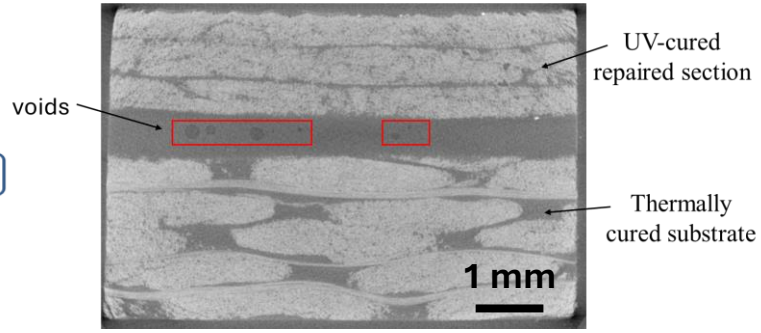
Voids and Effects

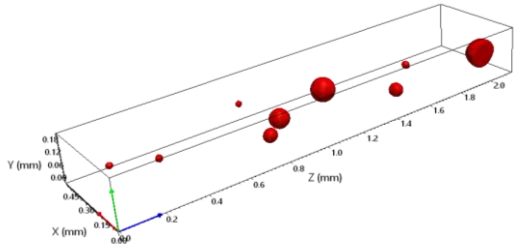
Causes

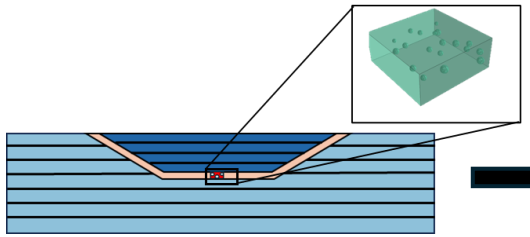
- Air entrapment during resin flow (primary cause)
- Gas is created due to chemical reactions during curing
- Nucleation of dissolved gases in the resin.

Effects

- Voids reduce mechanical properties, especially strength and fatigue resistance
- Voids at the interface can lead to:
  - Reduced strength
  - Premature debonding under mechanical loads







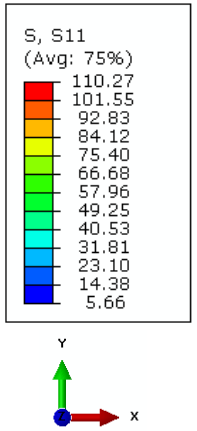


Fig: Micro-CT scan of the repaired sample

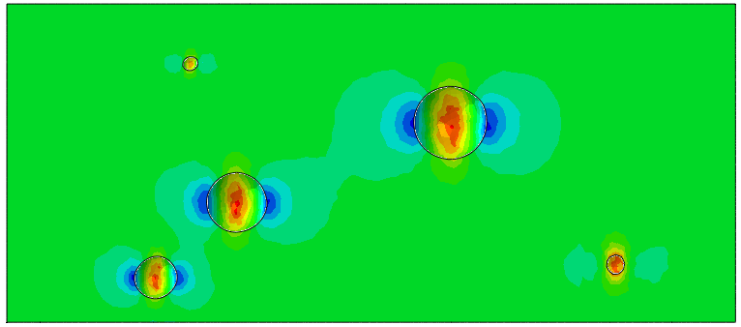
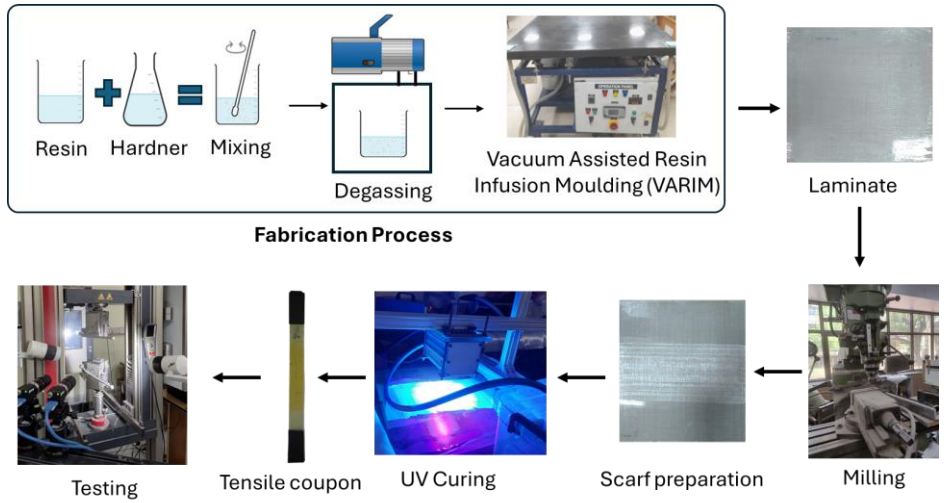


Void distribution

Sub modelling Technique

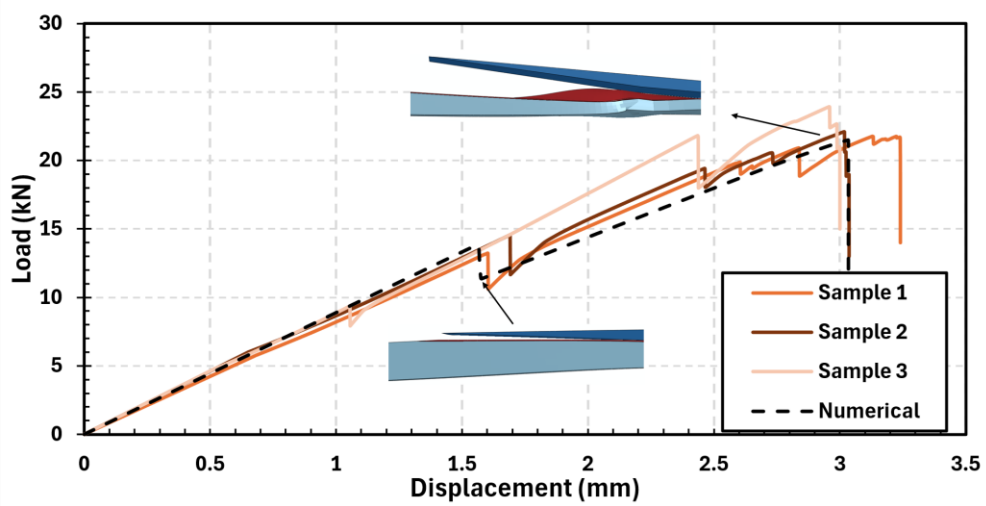


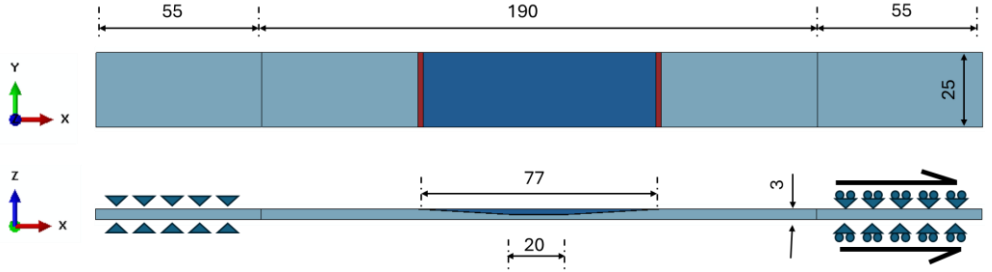
Stresses concentration near the voids.

Paul, D., Varshney, A., Mahajan, P., & Mishnaevsky Jr, L. (2023). Post-repair residual stresses and microstructural defects in wind turbine blades: Computational modelling. *International Journal of Adhesion and Adhesives*, *123*, 103356.

Post-repair mechanical behaviour of the repaired samples

Experimental





Initial Damage: Debonding at the interface

Damage Propagation: This leads to the separation of the patch from the substrate.

Final Failure: The substrate composite fails in the region with reduced cross-sectional area due to load redistribution.

Numerical

Thermally repaired composite samples exhibit **higher strength** compared to **UV-cured repairs.**

Conclusion

- A hybrid analytical-numerical model is proposed to estimate residual stresses for a given set of cure parameters and repair patch geometry.
- The numerical analysis is performed in ABAQUS using user subroutines (UMAT, UEXPAN, HETVAL, and USDFLD).
- Analysis findings:

  -Residual stresses heavily depend on the temperature cycle used (single-ramp vs. two-ramp)

  -Voids within the adhesive cause stress concentrations up to 2 to 2.5 times the average stresses.

  -Maximum stresses occur at the interface between the repair patch and the base composite.

  -Residual stresses induced by UV curing are higher compared to thermal curing.

Thank You!

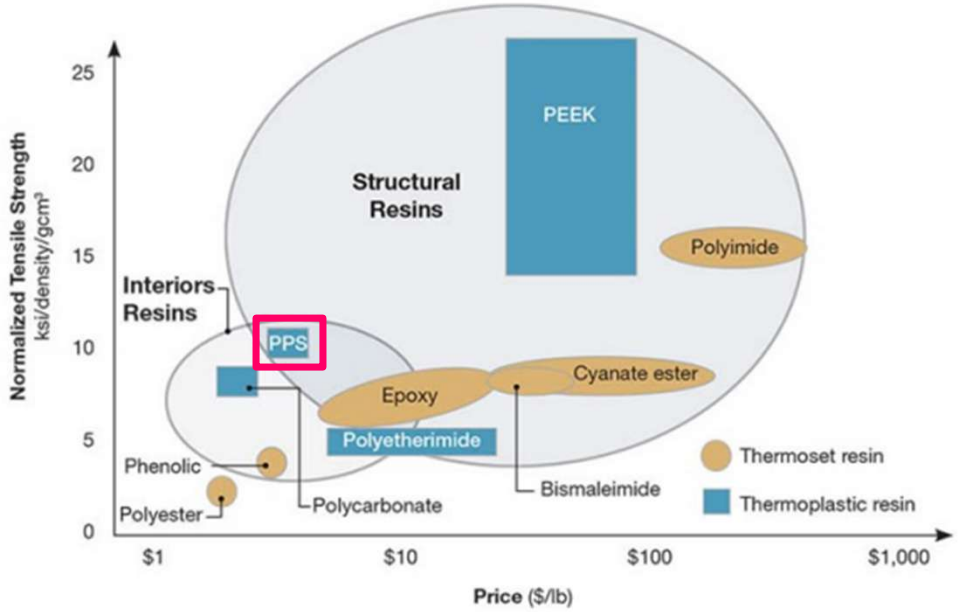
Effect of Cooling Rate on Mode II Fatigue Crack Growth Behavior in Carbon Fiber Reinforced Polyphenylene Sulfide

Yu Zusho[1], Sota Oshima[1,2], Ryo Higuchi[1],
Tomohiro Yokozeki[1], Takahira Aoki[1]



1. The University of Tokyo
2. Tokyo University of Agriculture and Technology

BACKGROUND

Carbon fiber reinforced thermoplastics (CFRTP)

Attention given to cycle time, material storage, toughness, recyclability, etc.

Aerospace applications → PPS, PAEK family (PEEK, PEKK, etc.)

[1] Tenney et al. NASA/CR–2011-217076 (2011)

Polyphenylene Sulfide (PPS)

-Crystalline

-High specific strength and toughness

-Relatively inexpensive

-Excellent thermal stability

-Excellent moisture and chemical resistance

BACKGROUND

CF/PPS application in aircraft

Excerpt from [2] Table A-II Flying structural parts made of thermoplastic composites (TPC).

Description	Manufacturer	Manufacturing Process	Date	Notes
Airbus 340 wing leading edge access panels	GKN Fokker	Co-consolidated.	2002	
Airbus A350 brackets	GKN Fokker	Stamp formed clips and cleats bolted to skins and frames.	2002	The Airbus 350-XWB has **over 8,000** TPC brackets.
Boeing 787 brackets	Dahar		2014	Over 10,000 per aircraft.
Fokker 50 main landing gear doors	GKN Fokker	Assembled with Resistive welding.		
Leonardo (AgustaWestland) AW169 helicopter horizontal tail leading edge	GKN Fokker	Two omega sections butted between flat skins to produce a full span torsion box.	2018	JEC 2013 innovation award. 15% lighter than previous design.
Airbus 340-600 ribs and angle brackets	GKN Fokker			Used on keel beam and ailerons.

CF/PPS has **high demand** in terms of high-rate production and weight reduction.

[2] Krueger et al. NASA/TM–20240005376 (2024)

BACKGROUND

CFRTP manufacturing: Hot press molding

Material placed in mold → Heating & Pressing → Cooling (Consolidation)

- High molding temperature

Crystallinity changes depending on **cooling rate**

→ Large mismatch in thermal expansion between the base material and the fibers

- In the case of crystalline resin: Thermal shrinkage + Volumetric shrinkage due to crystallization

→ Large thermal residual stress

Cooling rate → **Crystallinity** → **Mechanical Properties, Fracture Behavior**

Purpose Elucidation of cooling rate dependence of basic properties in CF/PPS composite materials

Our Previous study: Evaluation of Thermal, Mechanical, and Fracture Properties of PPS and CF/PPS

Today's Content

Mode II Fatigue Fracture Characterization of CF/PPS

(ENF Fatigue Test, Fracture Surface Observation)

EXPERIMENTAL METHOD

- CFRTP Specimen

  CF/PPS unidirectional prepreg sheet (TenCate Cetex® TC1100, Toray)

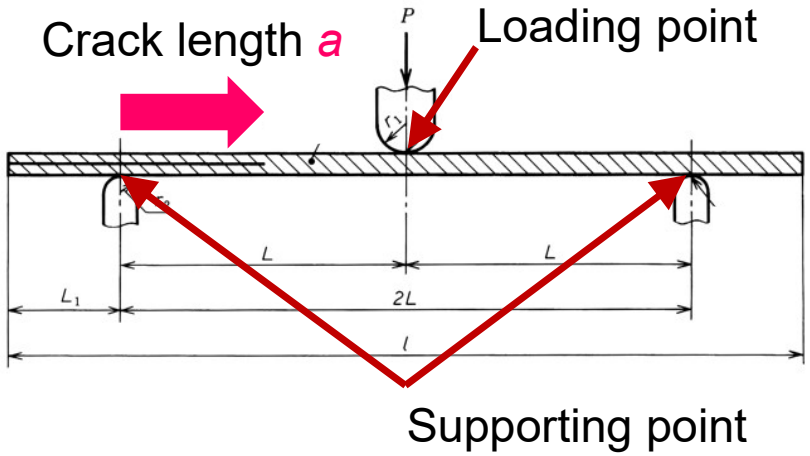
  (Carbon fiber; AS4, Vf = 59 vol%)

  → CF/PPS laminate $[0_{12}//0_{12}]$

  - Hot press molding: 325 ºC, 20 min
  - Cooling rate during consolidation: **1, 5, 10 ºC/min**

- Characterization of mode II fatigue crack propagation

  → End-notched flexure (ENF) fatigue test



EXPERIMENTAL METHOD

- Preliminary experiments for parameter setting

  Static loading while changing initial crack position a

  → Calculation compliance C at each crack position a

  → Relationship between crack length a - compliance C

$$(2h)^3 B C = \beta_0 + a^3 \beta_1$$ (h: thickness, B: width β0, β1: constant)

For fatigue test, setting crack length a and energy release rate G_{max} and determine P_{max}

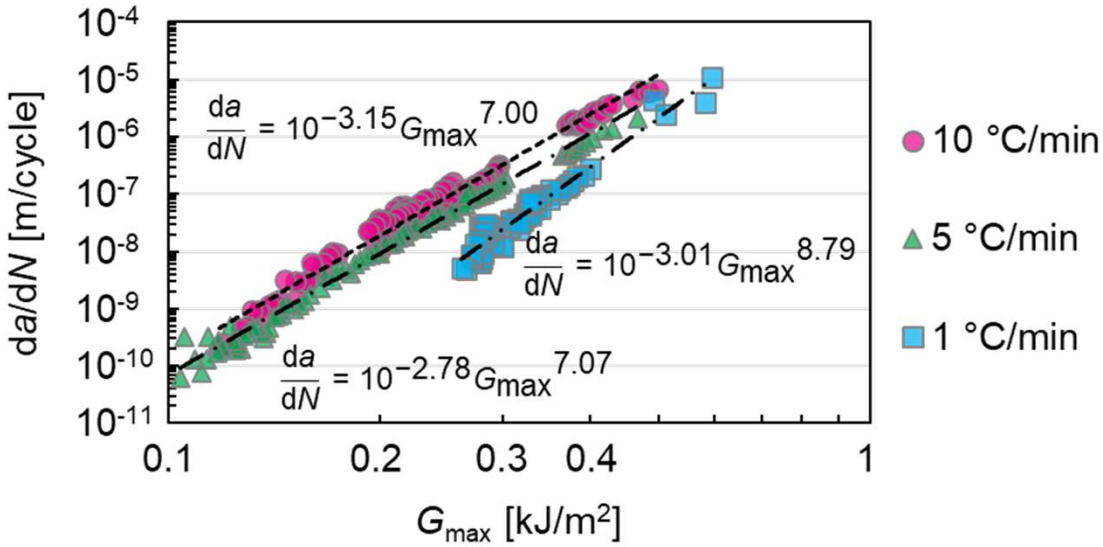
$$G_{max} = \frac{P^2}{2B}\frac{\partial C}{\partial a} = \frac{P_{max}^{\ 2}}{2B^2}\frac{3a^2}{(2h)^3}\beta_1$$ (Modified Compliance Calibration Method)

EXPERIMENTAL METHOD

- Fatigue test
  - Fatigue testing machine: Electropuls E10000 (Instron)
  - Load ratio: R = 0.1 (P_{max} / P_{min})
  - Frequency: 10 Hz
  - Sampling interval: 5 ms (20 points / wave)
  - Load gradation test method (× 0.99, 5 to 10 times / test)

Calculation of compliance C for each cycle, and crack length a corresponding to C

→ Calculation of G_{max} for each cycle



→ Setting ΔN at which the average R^2 value of G_{max} is greater than 0.90

→ Ploting fatigue crack propagation characteristics ($da/dN - G_{max}$ diagram)

$$G_{max} = \frac{P^2}{2B}\frac{\partial C}{\partial a} = \frac{P_{max}^{\ 2}}{2B^2}\frac{3a^2}{(2h)^3}\beta_1$$ (Modified Compliance Calibration Method)

RESULTS AND DISCUSSION

Fatigue crack propagation characteristics (da/dN − G_{max} diagram)

- Cooling rate 10, 5 ºC/min (G_{max} = 0.1～0.5 kJ/m^2)

  Proportional relationship between da/dN and G_{max} on both logarithmic graphs (Paris law)

  → Behavior following the Paris law until around da/dN = **10^{-10}** m/cycle

  → Fatigue crack growth threshold is not clear.

RESULTS AND DISCUSSION

Fatigue crack propagation characteristics (da/dN − G_{max} diagram)

- Cooling rate 1 ºC/min (G_{max} = 0.3～0.6 kJ/m^2)

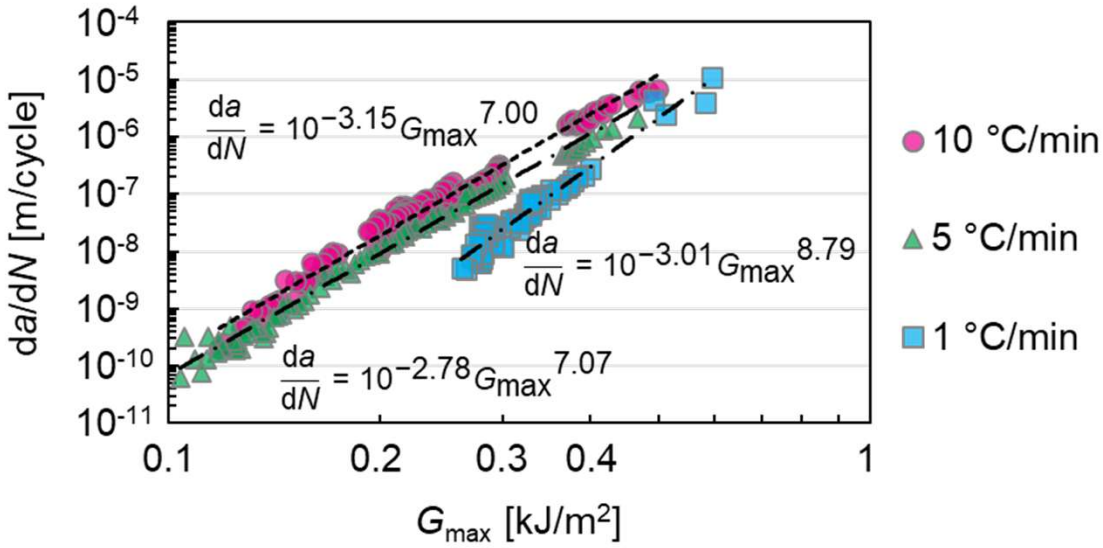
  Proportional relationship between da/dN and G_{max} on both logarithmic graphs (Paris law)

  Fatigue crack growth stops at around G_{max} = 0.26 kJ/m^2 → Fatigue crack growth threshold

  1 ºC/min is particularly variable (Large crystal size → Fracture might dominate local properties)

RESULTS AND DISCUSSION

(Crystallinity, Static fracture toughness test) Oshima et al. *Composites Part A* 164 (2023)



- Lower cooling rate → **Higher crystallinity** and **lower fracture toughness**

  (Reasonable results considering the properties of thermoplastic resins)

- G_{IIC}: **Equivalent at 5 and 10 ºC/min**, lower and more variable at 1 ºC/min

RESULTS AND DISCUSSION

Fatigue crack propagation characteristics (da/dN − G_{max} diagram)

- Plot value and slope: **Equivalent at 5 and 10 ºC/min**, lower and more variable at 1 ºC/min

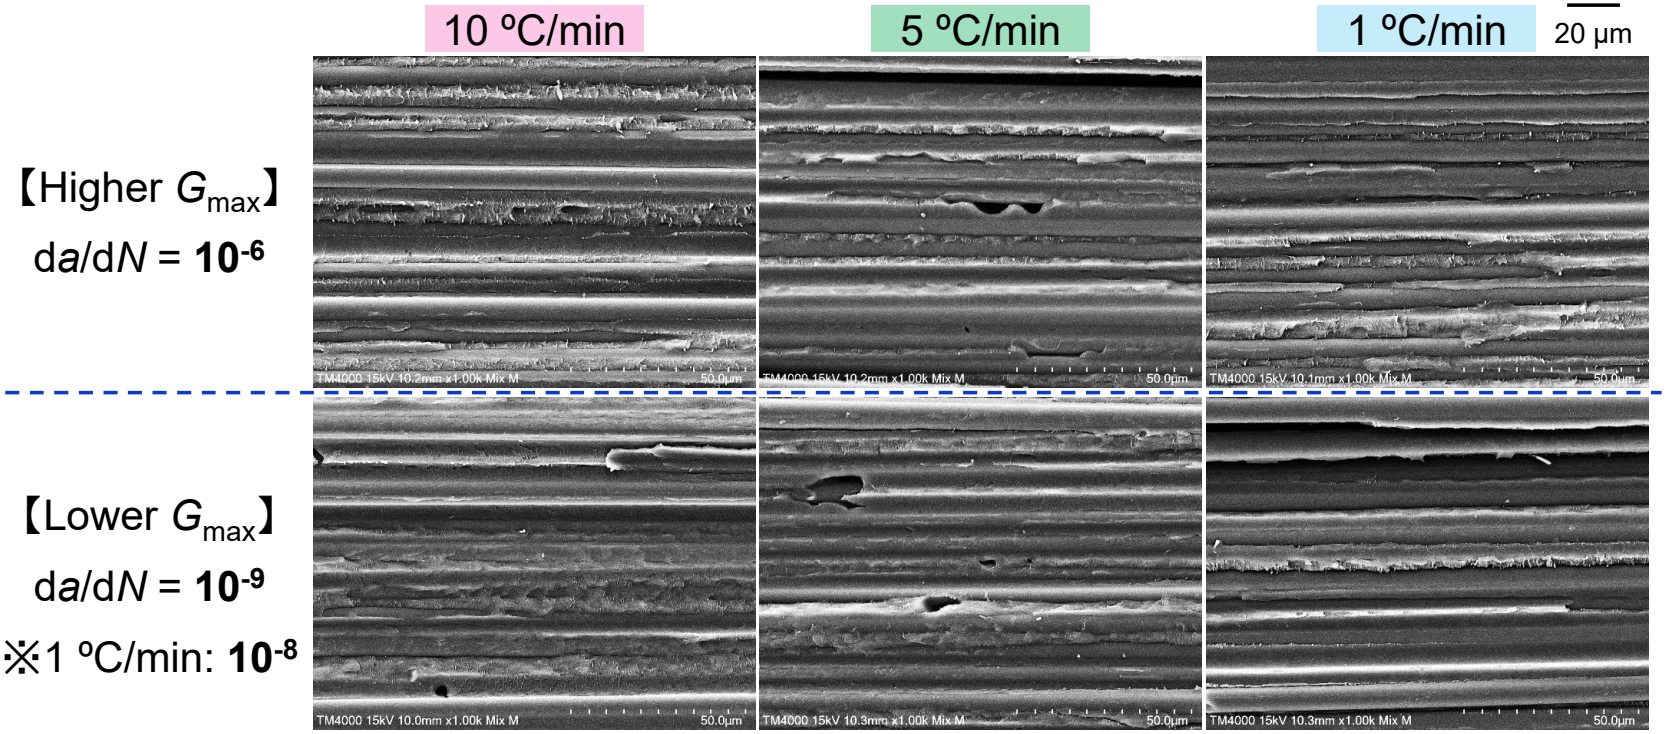
  → **Trends consistent with static test results**

- **Lower cooling rate → Crack propagation rate (da/dN) decreased**

(**The large slope at 1 ºC/min** corresponds to the **low toughness** in the static test region (higer G_{max}))

RESULTS AND DISCUSSION

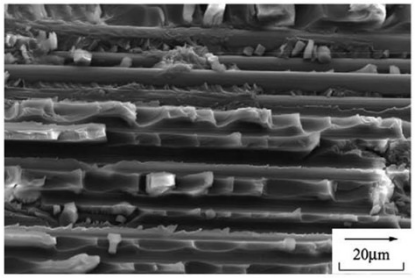
Fatigue crack propagation characteristics (da/dN − G_{max} diagram)



This suggests a possible transition in fracture mode between 5 ºC/min and 1 ºC/min.

→ The region of **significant change in crystallization behavior**

(→ Discussed later in fracture surface observation)

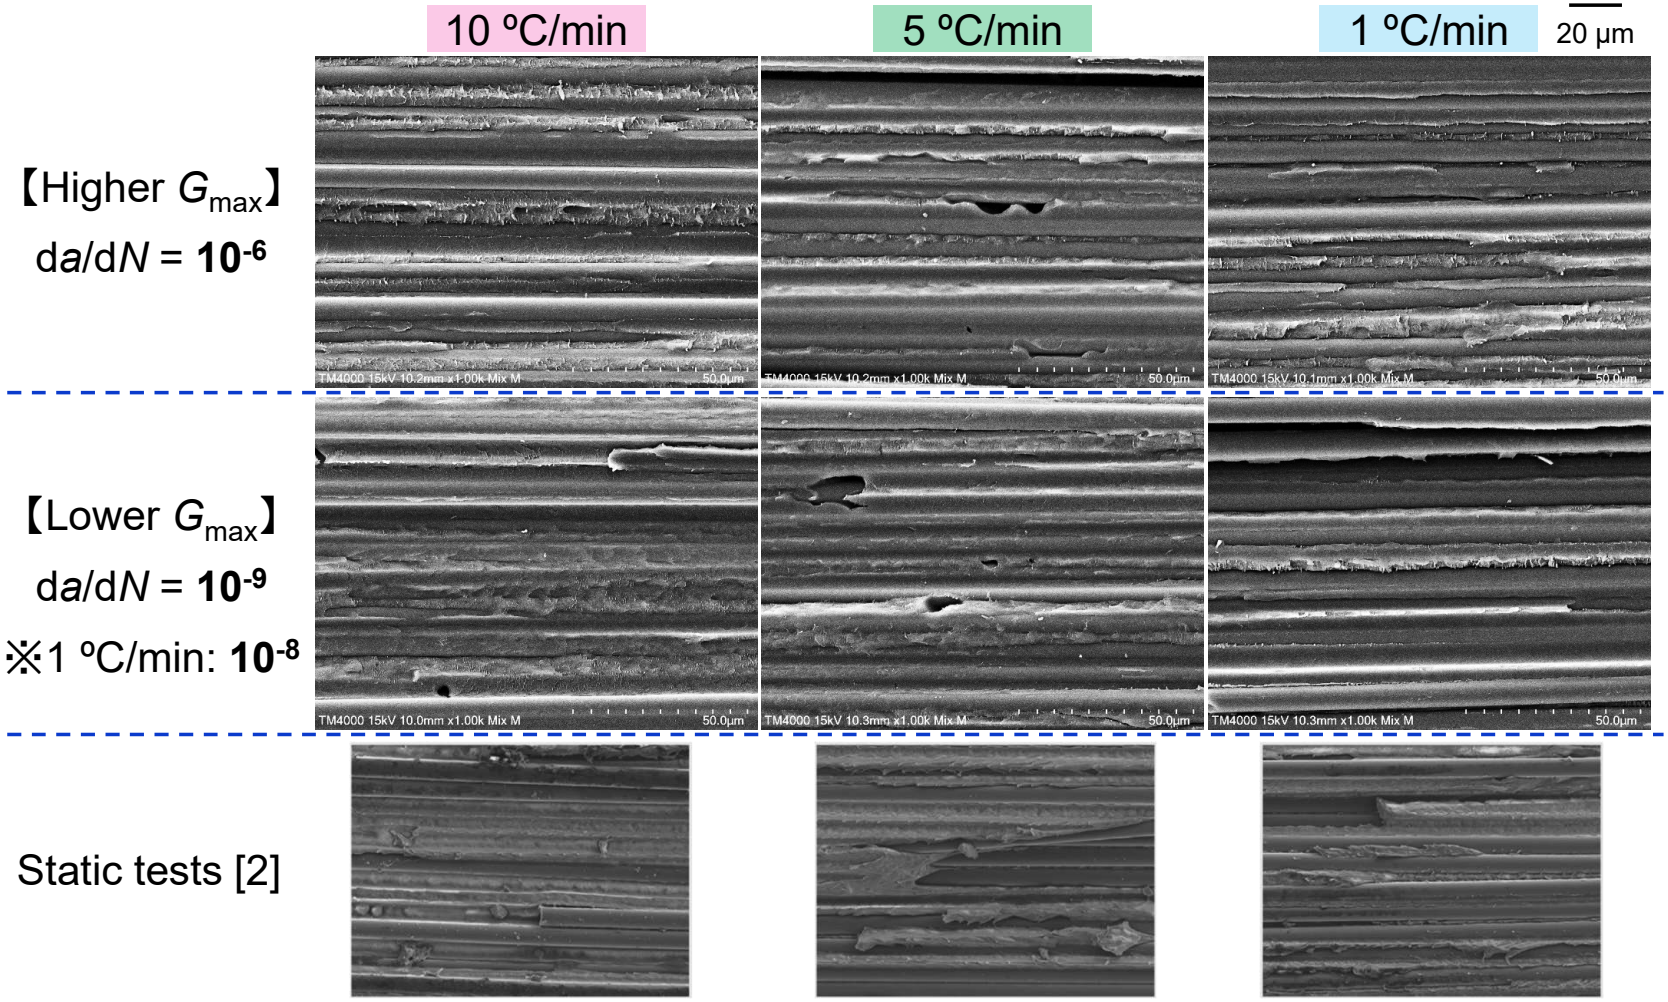


RESULTS AND DISCUSSION

Fracture Surface (SEM Image)

CF/Epoxy [3]

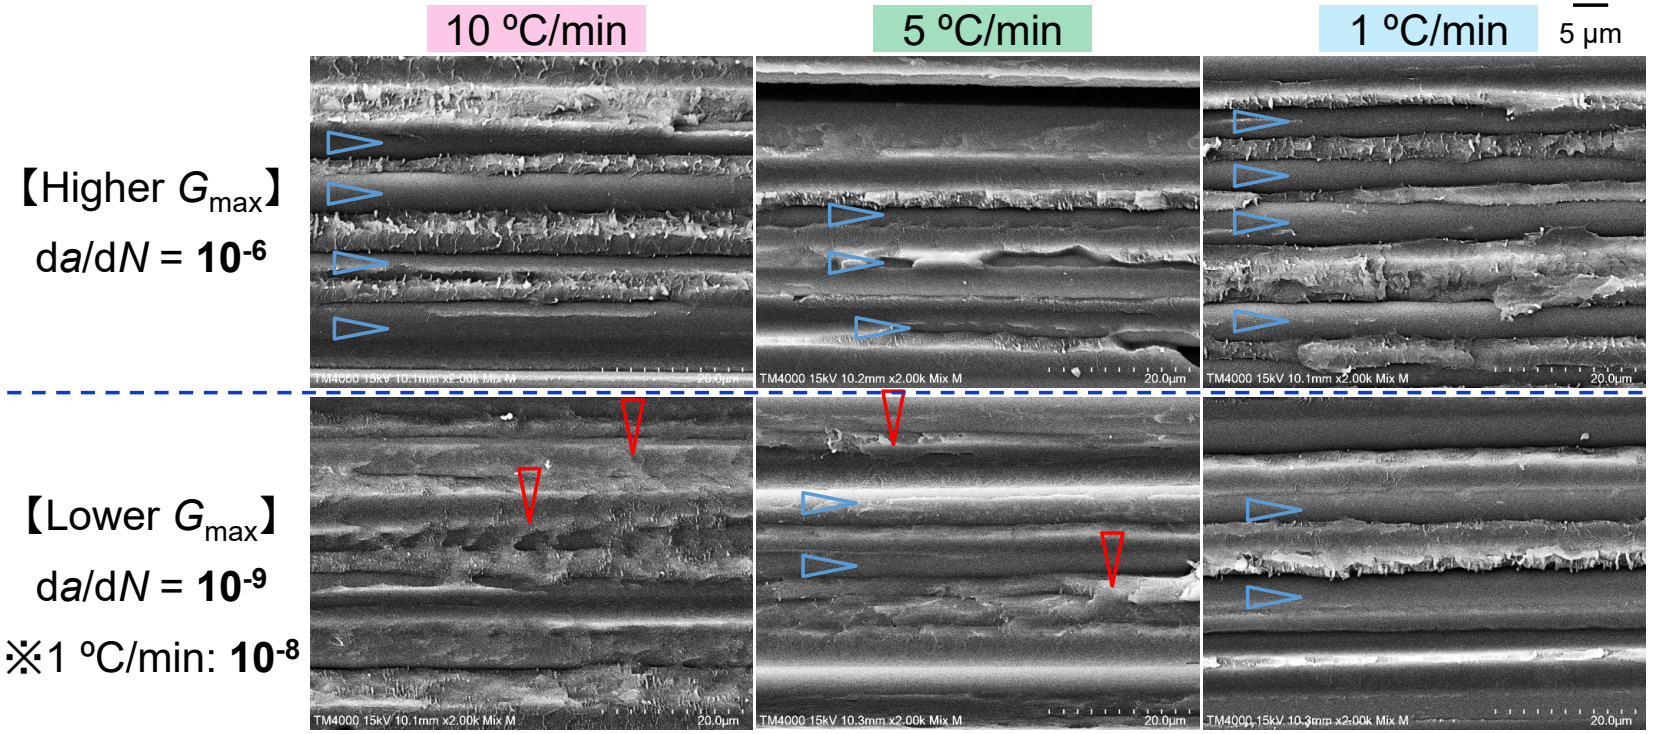
da/dN = **10^{-7}**



- **Ductile fracture of PPS matrix** observed throughout
  (Brittle fracture of epoxy: hackle pattern)
- Small effect of cooling rate on fracture morphology

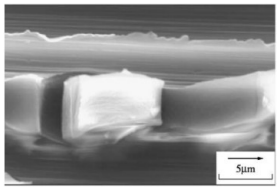
[3] Hojo et al. *Int J Fatigue* 28 (2006)

RESULTS AND DISCUSSION



Fracture Surface (SEM Image)

[2] Oshima et al. (2023)



RESULTS AND DISCUSSION

Fracture Surface (SEM Image)_Enlarged View

CF/Epoxy [3]

da/dN = **10^{-7}**

- Higher G_{max} Exposed carbon fiber ▷ (low interface strength)
- Lower G_{max} Resin elongated significantly ▽ in 10, 5 ºC/min

Influence of cooling rate appears at lower G_{max}

[3] Hojo et al. *Int J Fatigue* 28 (2006)

RESULTS AND DISCUSSION

Comparison with another polymer matrix

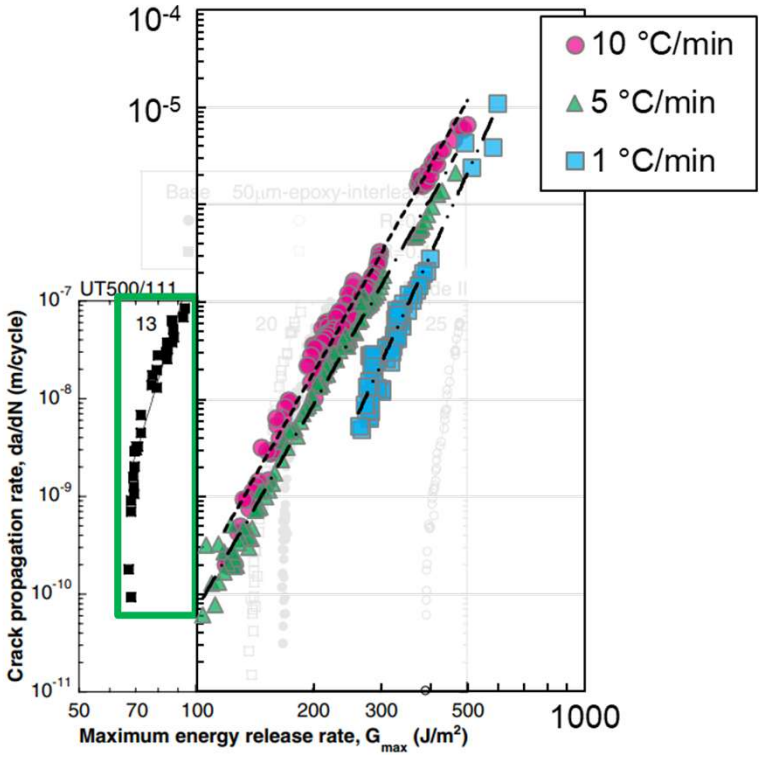


Fig. 14. Relation between crack propagation rate and maximum energy release rate under mode II loading for base and 50 μm-epoxy-interleaved laminates.

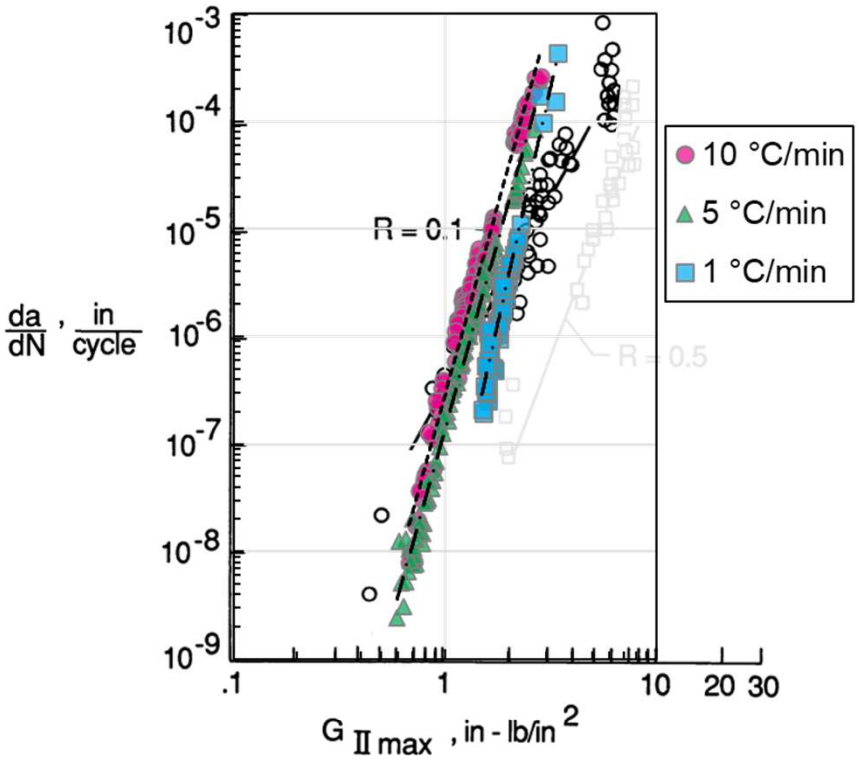
[3] Hojo et al. *Int J Fatigue* 28 (2006)



Compare with conventional **CF/Epoxy [3]** ...

- CF/PPS: Lower d*a*/d*N* and Higher G_{max}

→ CF/PPS has higher resistance to fatigue crack propagation than CF/Epoxy

RESULTS AND DISCUSSION

Comparison with another polymer matrix

[4] Martin et al. *NASA TECHNICAL MEMORANDUM* 100577 (1988)

Compare with **CF/PEEK [4]** …

- Value: Close to CF/PEEK
- Slope: CF/PEEK < CF/PPS (easier crack propagation)

→ **CF/PPS is inferior to CF/PEEK fatigue resistance**

∵ Interface properties, trans-crystal formation

Prospects of CF/PPS

Improvement of performance

by modifying fiber-base material interface

e.g. resin modification, CF surface treatment, molding process improvement, etc.

CONCLUSION

Influence of Cooling Rate on Fatigue Damage Mechanisms in CF/PPS Composites

- ✓ **Lower cooling rate → Lower crack growth rate**

  Cooling rate 10, 5 ºC/min → No clear fatigue crack growth threshold

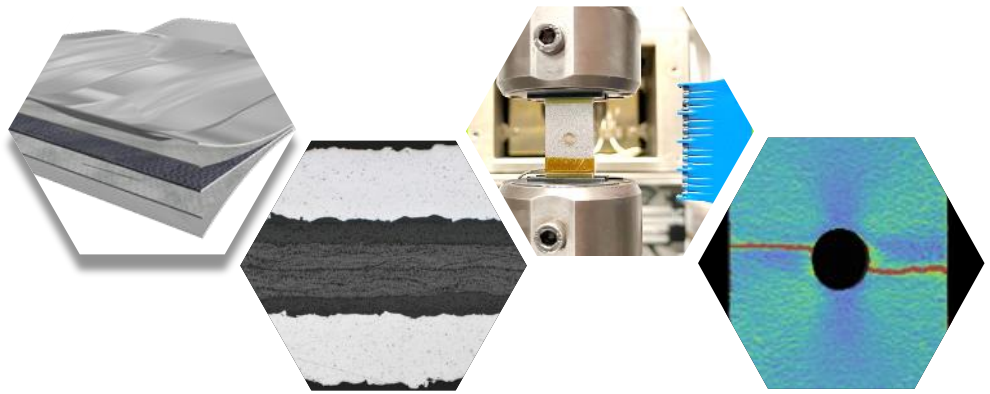
  Cooling rate 1 ºC/min → Fatigue crack growth threshold around G_{max} = 0.26 kJ/m^2

- ✓ Fracture surface → Ductile fracture of PPS matrix

  Influence of cooling rate on fracture morphology appears at lower G_{max}

- ✓ Resistance to fatigue crack propagation

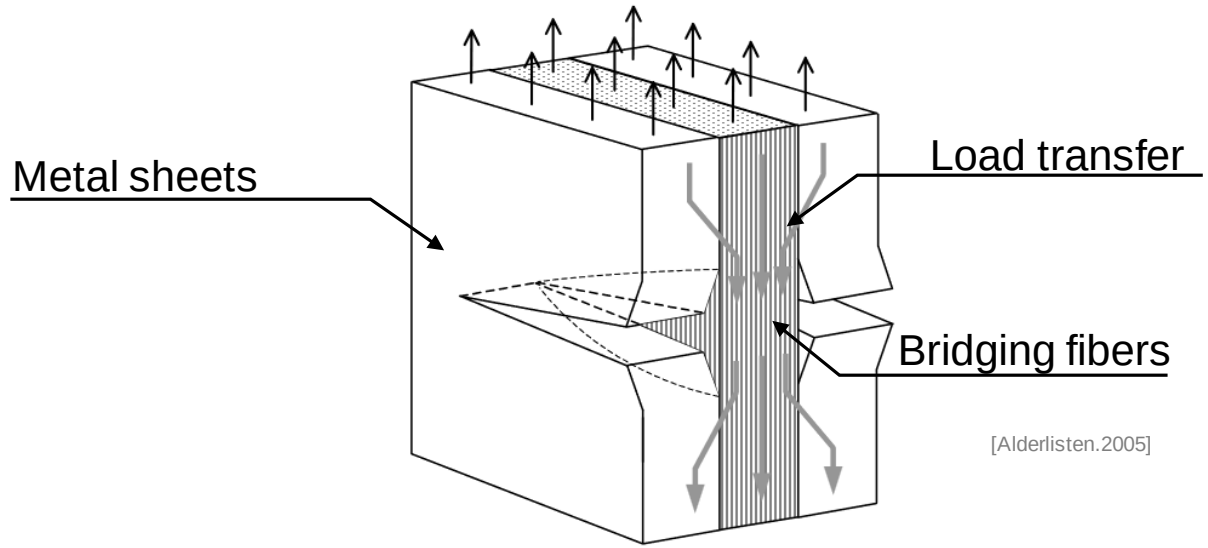
  CF/Epoxy << CF/PPS < CF/PEEK



Leibniz-Institut für Verbundwerkstoffe

Modified Curing Cycles and Accompanying Polymer and Adhesion Changes in Fiber Metal Laminates

A. Baumann[1], S. Mrzljak[2], F. Walther[2], J. Hausmann[1]
[1]Leibniz Institut für Verbundwerkstoffe GmbH, Kaiserslautern
[2]Chair of Materials Test Engineering (WPT), TU Dortmund University

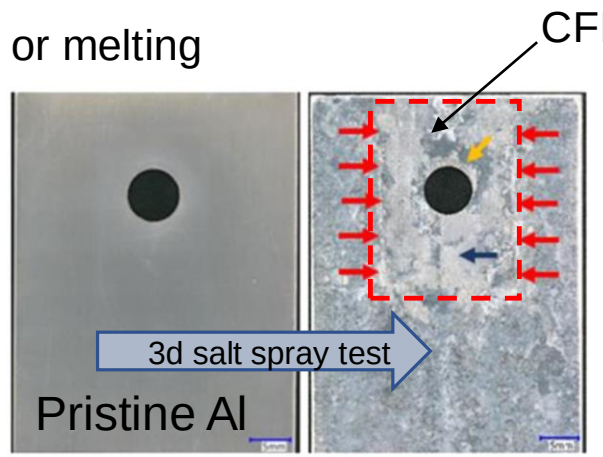


Chapter

1. Motivation
2. State of the art
3. Materials and methods
4. Modified curing cycle results
5. Adhesion between epoxy and metal sheets
6. Alternative approach
7. Conclusion & outlook

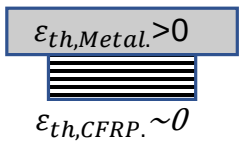
Fiber-metal laminates (FML) can improve:

- Damage tolerance
- Fatigue performance
  - Especially if carbon fibers are used
- Bearing strength
  - Especially if steel sheets are used

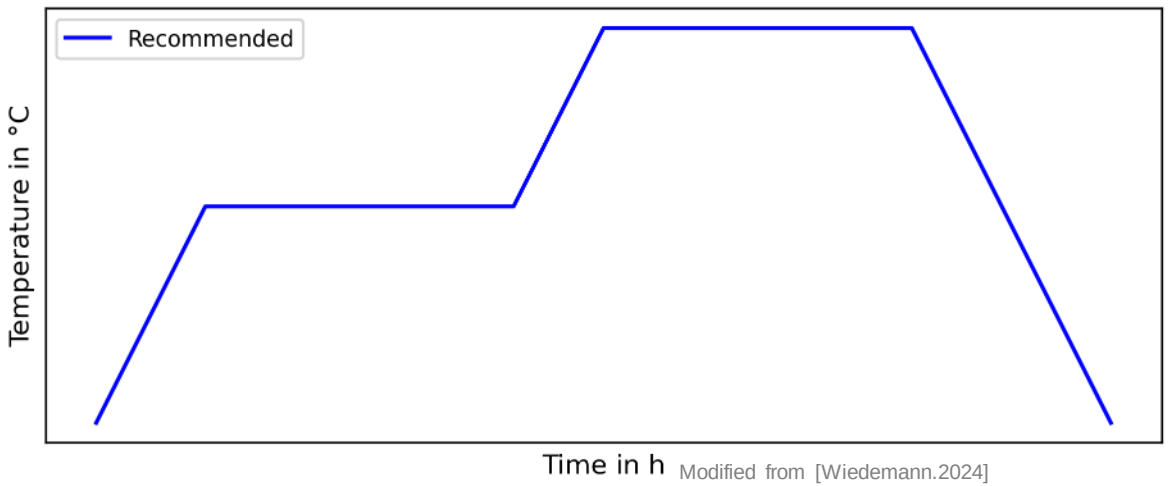


[Alderlisten.2005]

Problems associated with FML:

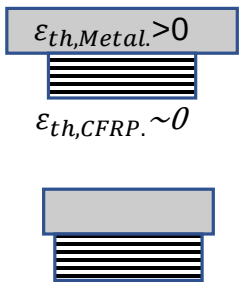


- Corrosion
- Surface treatment and adhesion
- Thermal residual stresses induced during the thermal cycle of polymer cure or melting

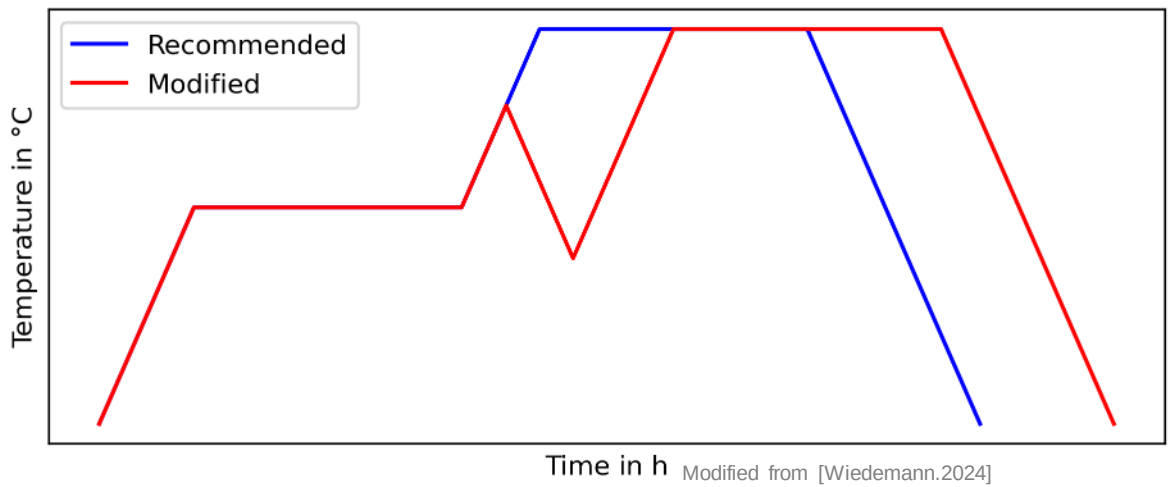


[Dammulla.2023]

Conventional curing cycle:



Modified from [Wiedemann.2024]

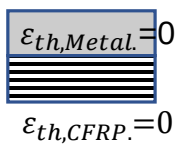


Replace

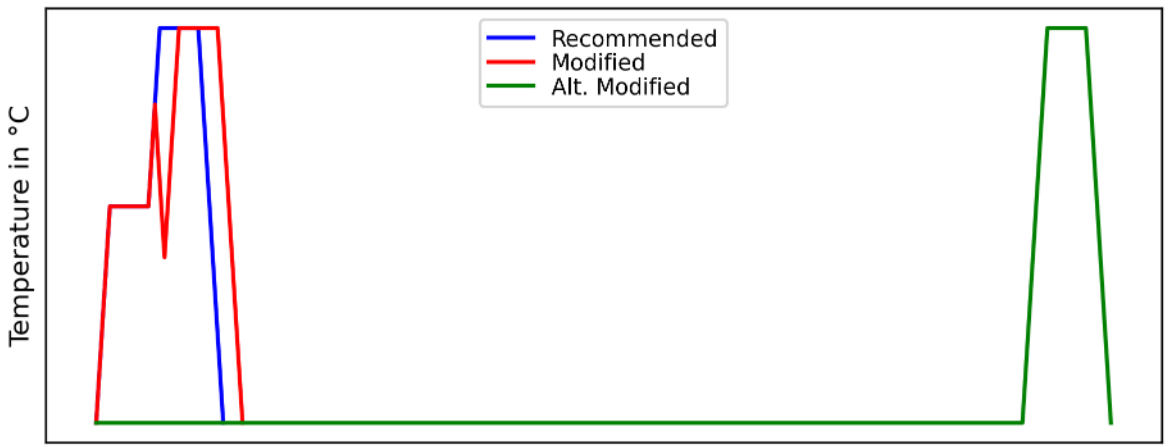
The modified curing cycle → lower Δϑ between curing and operation :

Modified from [Wiedemann.2024]

Increased fatigue life

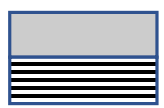


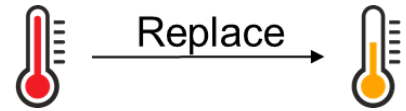
→Solidification at a lower temperature



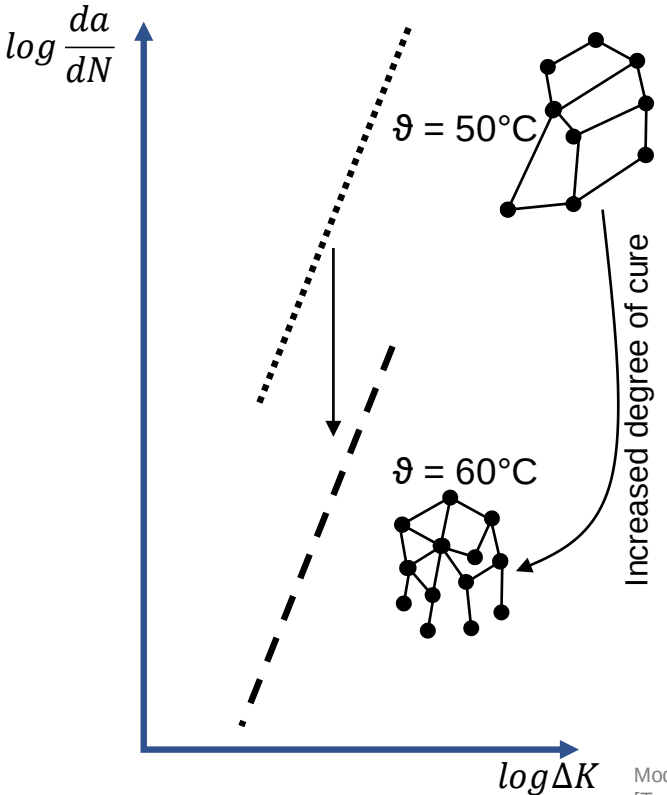
Replace

The modified curing cycle → lower Δϑ between curing and operation :



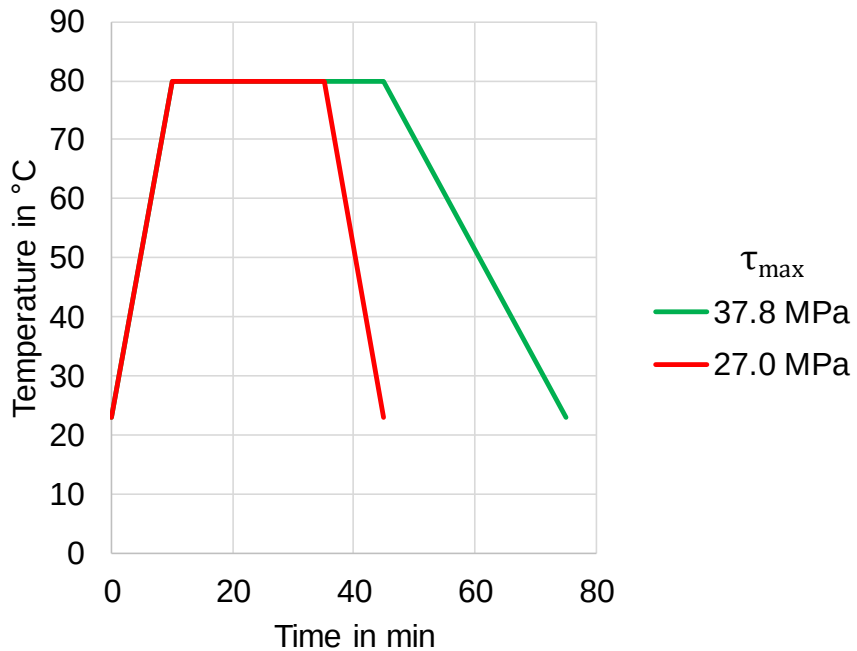


Modified from [Wiedemann.2024]



Further increase in fatigue life?

→Solidification at the lowest temperature possible.



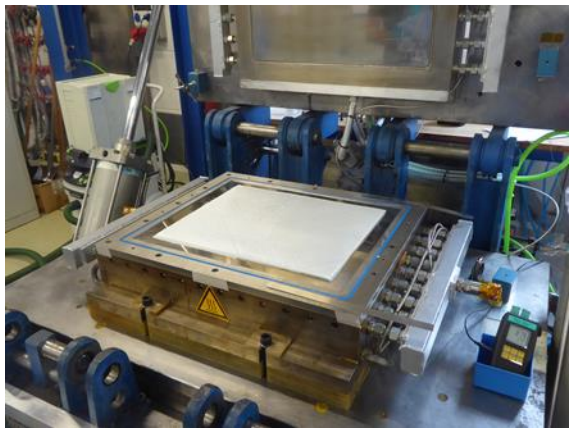
Effect of cure on fatigue crack resistance

Modified from [Trappe.2012]

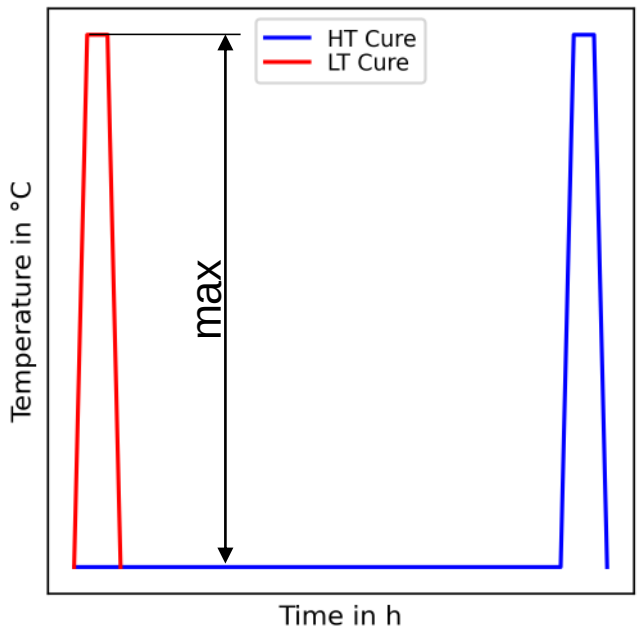
→Decreased fatigue crack propagation rate by increased curing temperature (identical curing time)

Effect of cure on adhesion (lap shear strength)

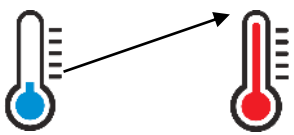
[Kotynia.2017]



→Curing cycle affects the resulting lap shear strength



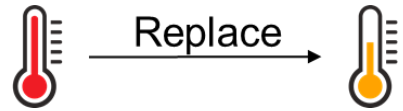
Replace



Polymer
SR 1660 / SD 7820

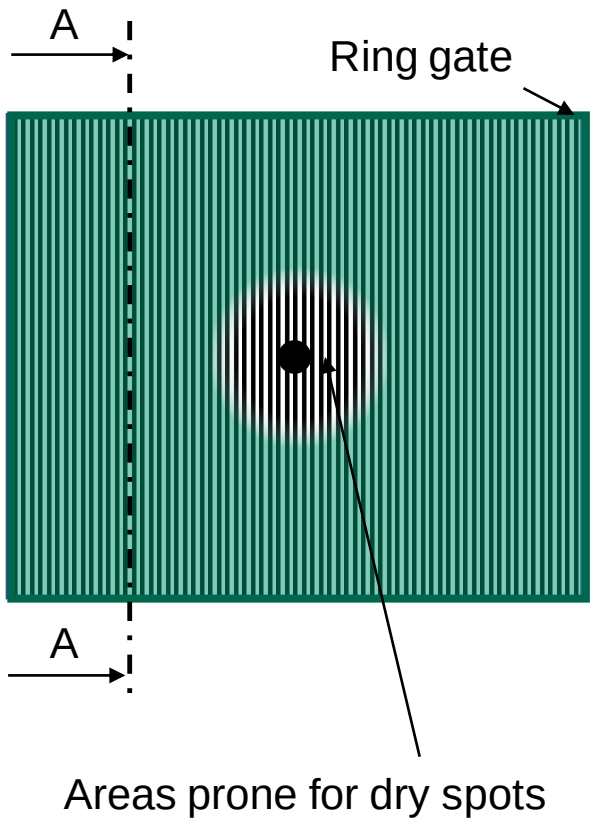
Carbon fiber non-crimp fabric

Stainless spring steel
1.4310 t ~ 0.1-0.3 mm



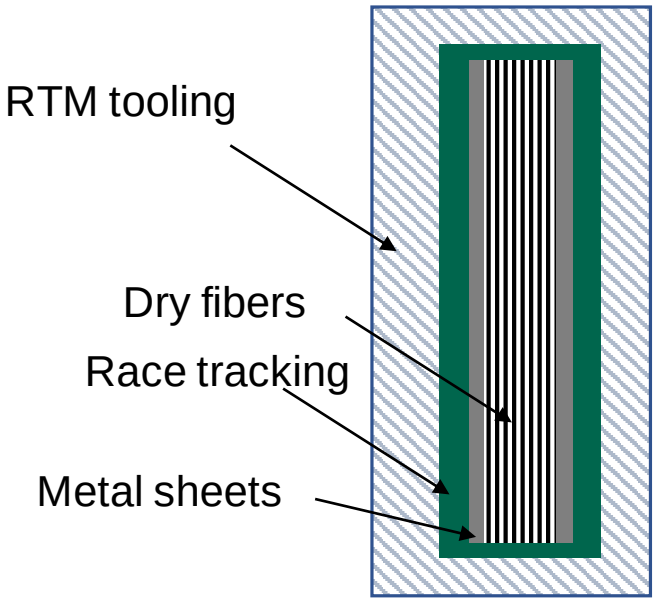
RTM process choices:

A. Non-stationary



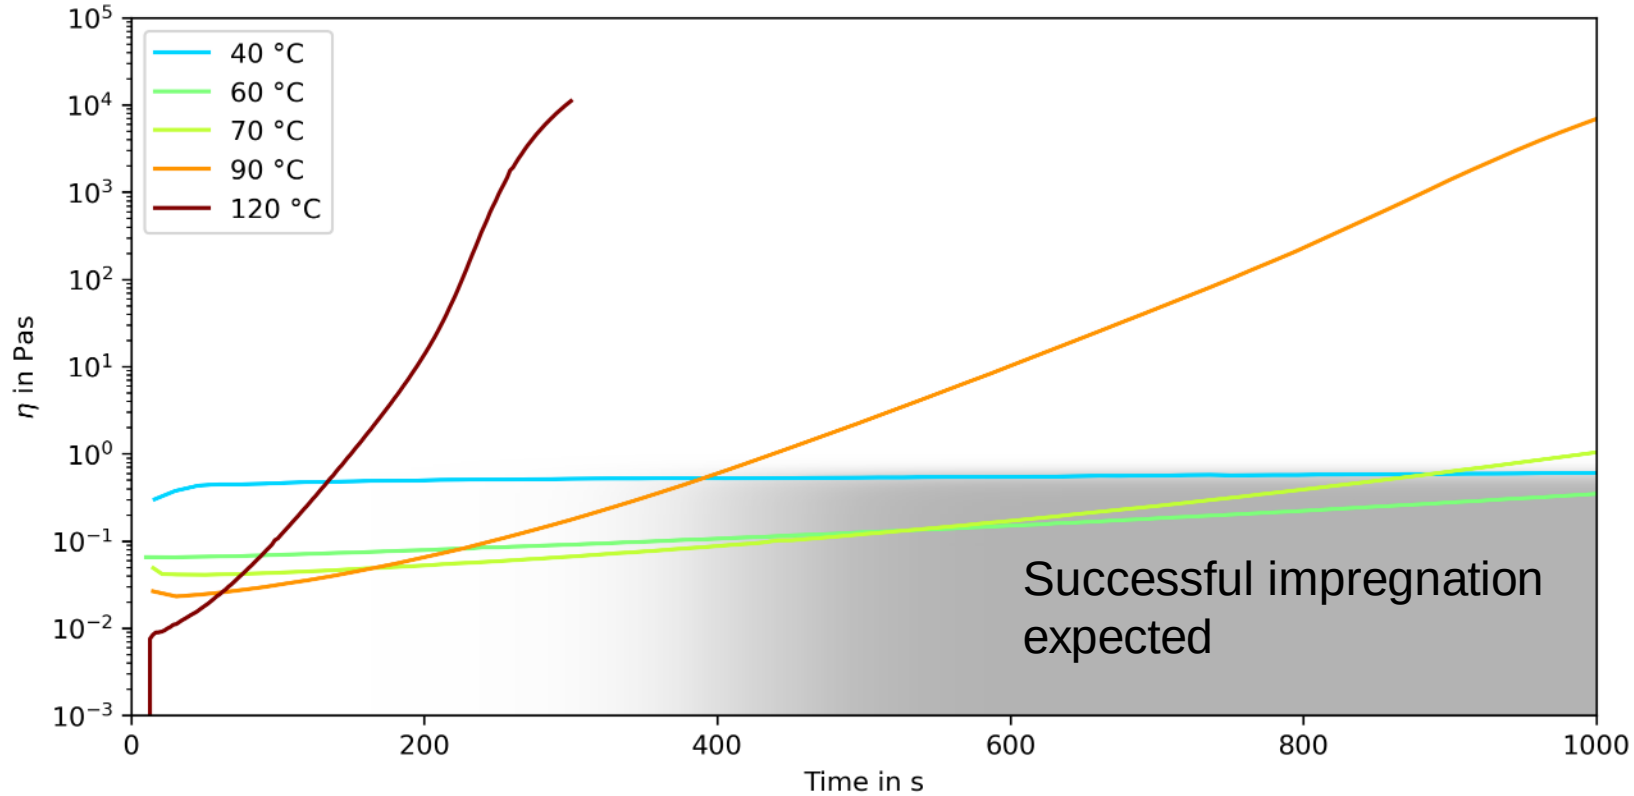
Cold tooling and heating ramp → good impregnation but maximum heating rate will define curing temperature, i.e. residual stresses

B. Isothermal



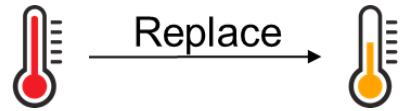
Preheated tooling and slightly heated resin → resin takes on tooling temperature immediately

Imperfect impregnation, due to maximized curing temperature for isothermal process (B)

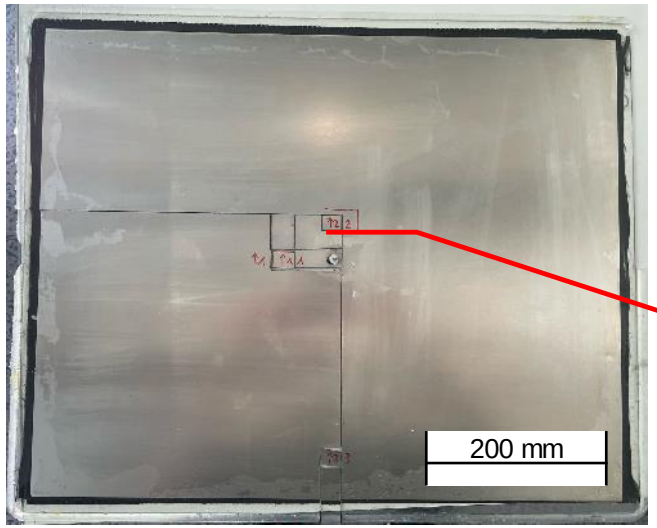


Race tracking around the metal sheets

A-A

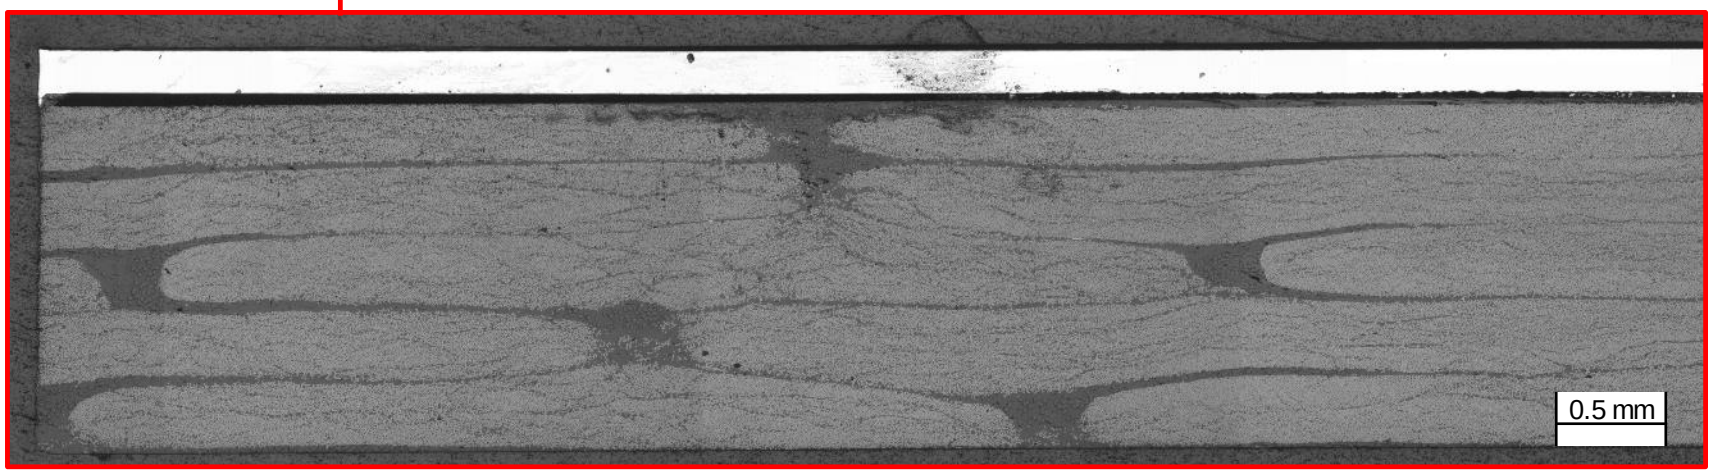


Replace



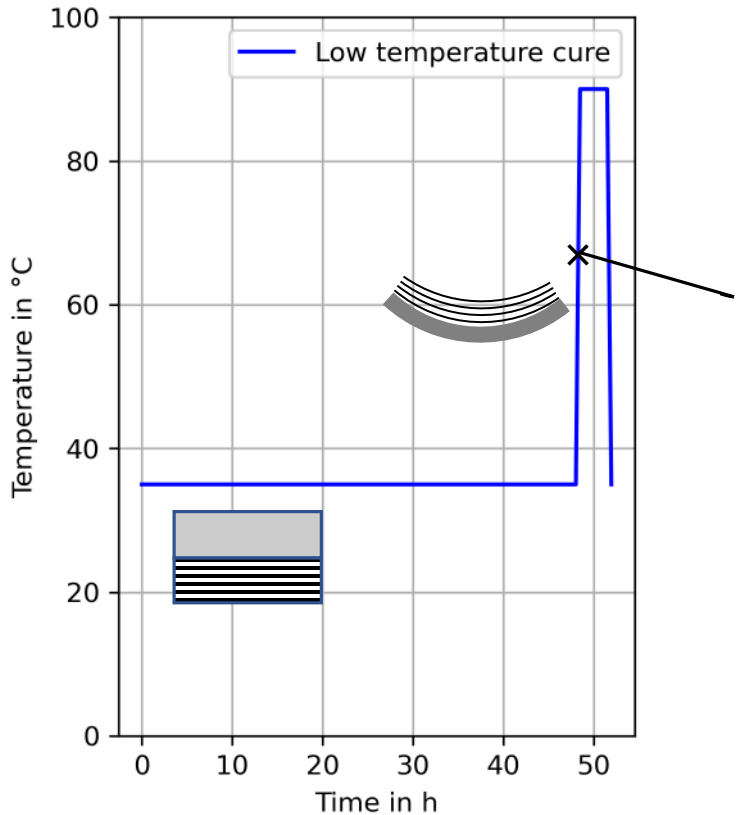
B. Isothermal process

Definition:



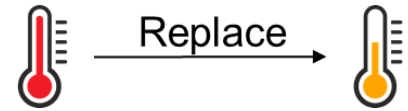
- Low temperature cure: 48h@35°C + Post-cure
- High temperature cure: 3h@90°C

QC of manufactured plates

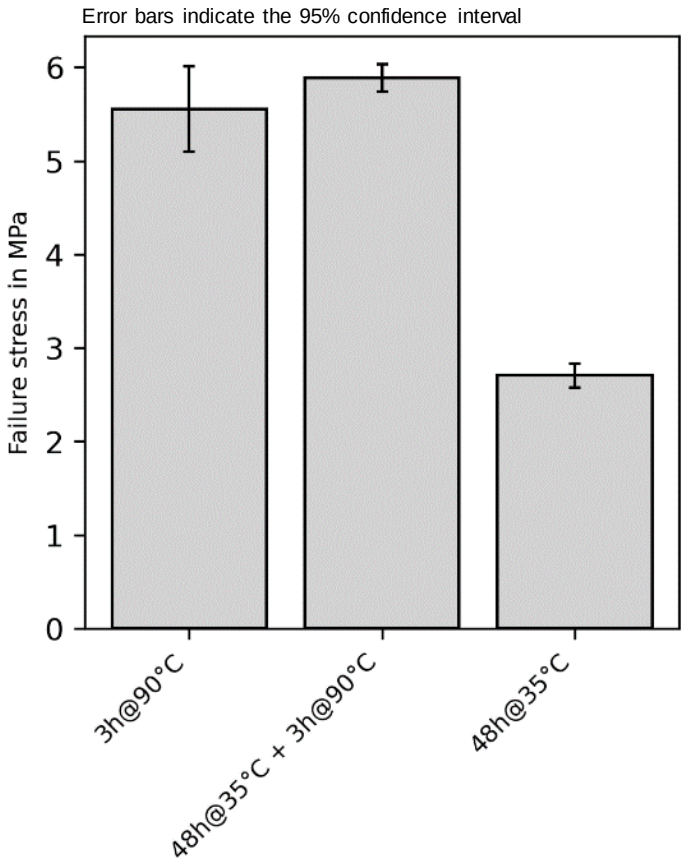


- No race tracking evident
- Fully impregnated at 90°C

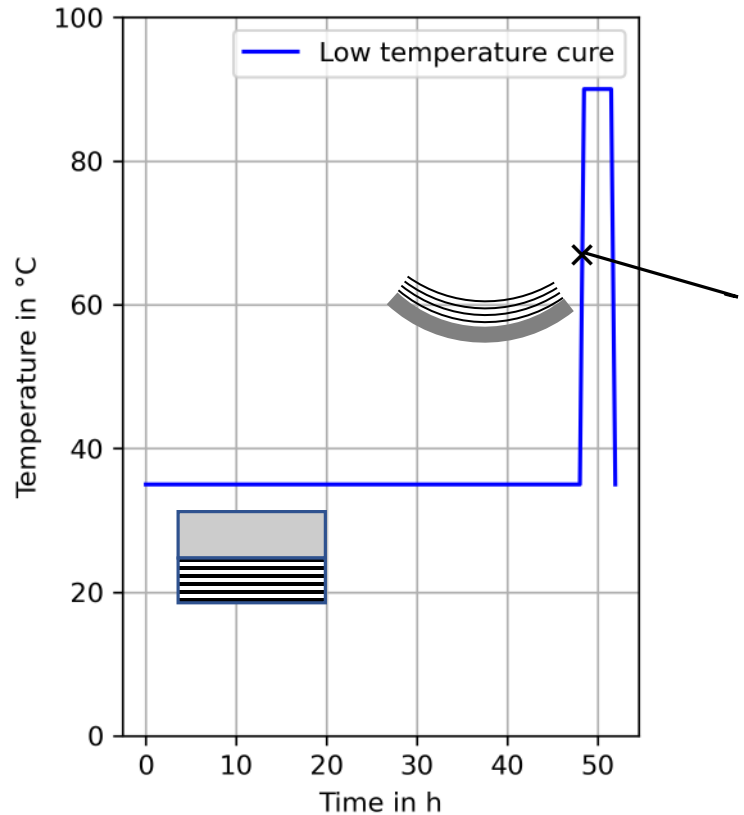
Replace



Seemingly no adhesion possible with various surface treatments

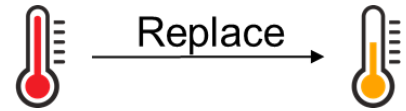


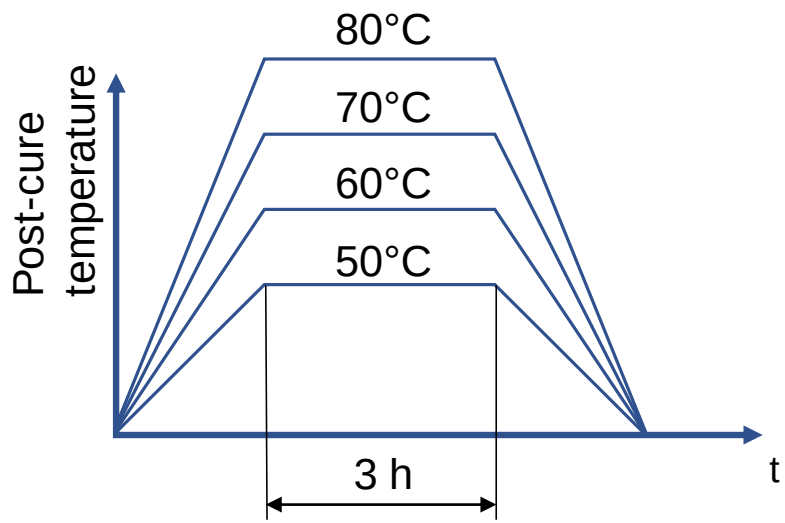
Potential adhesive failure during post-cure



5 Adhesion between epoxy and metal sheets
A function of cure and post-cure

Lap shear specimens produced by adhesively connecting metal to metal possible, however lap shear strength depends on the curing and post-curing cycle

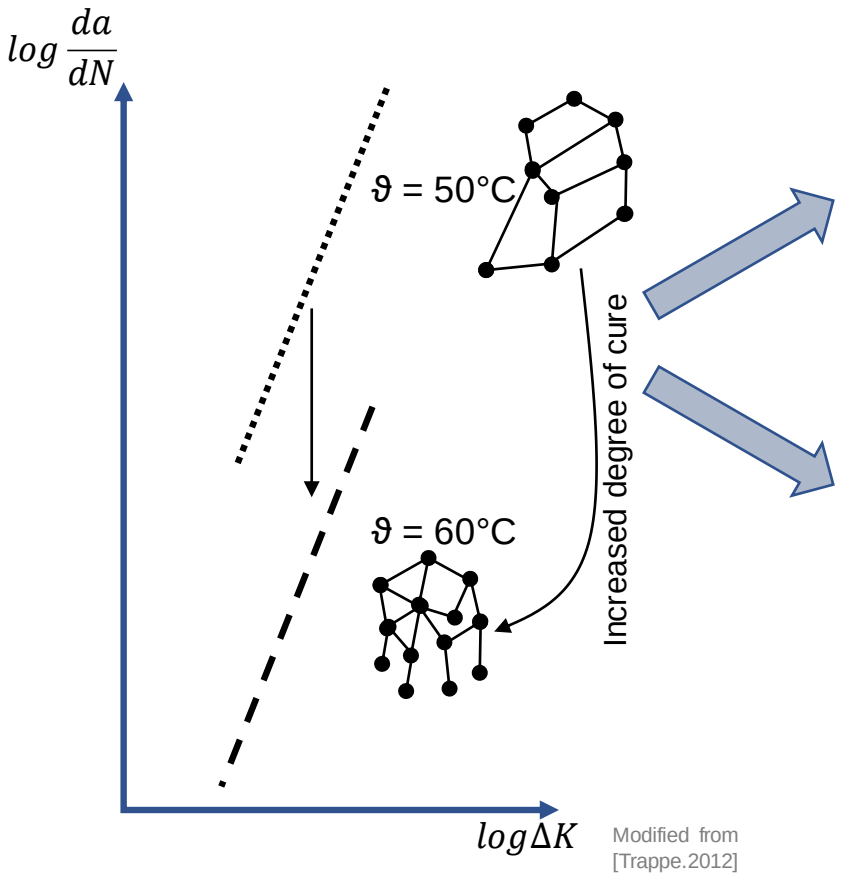




Potential adhesive failure during post-cure

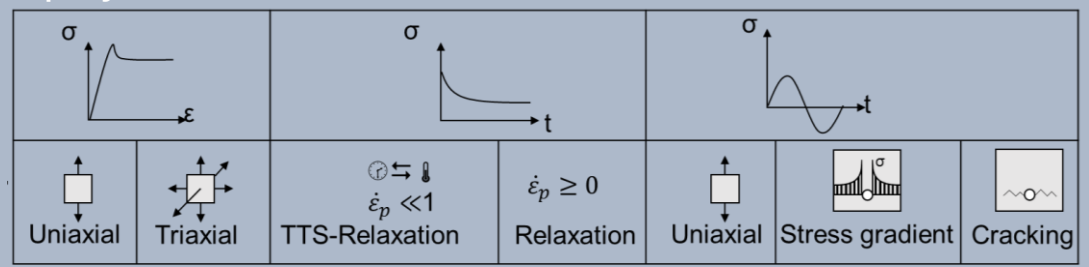
Conclusion: Thermal stresses during the post-cure treatment might exceed the bond strength.

Countermeasures:



- Reduced thickness of the metal sheets (0.3 mm → 0.12 mm)
- Suitable surface treatment (DLR Braunschweig / Germany)
- Slow heating rate during post-cure ramp

Investigation of adhesive strength in a conventional lap shear setting so far unsuccessful from a testing point of view but sufficient adhesive strength was achieved across at all post-curing stages



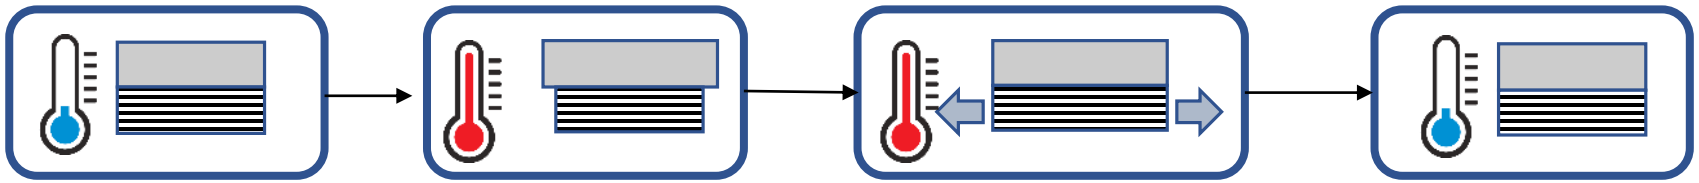
Result: Yielding of the metal sheets before bond failure for a sufficiently large overlap

Effect of cure on fatigue crack resistance and fracture toughness

Modified from [Trappe.2012]

Neat polymer characterization

[Baumann.2025]



Change of residual stresses in FML without alterations in the curing cycle

$$\Delta\varepsilon_{th}(\theta)+\Delta\varepsilon_{el} = \frac{\sigma_{res}}{E} = \min_{\theta} \Delta\varepsilon_{th}(\theta)$$

High-temperature cure

Low-temperature cure

Mechanical pre-strain $\Delta\varepsilon_{th}(\theta)+\Delta\varepsilon_{el}$

Strategy:

What if we could adjust the elongation of the carbon fibers to the thermal expansion of the metal sheets by applying a mechanical strain before and during cure?

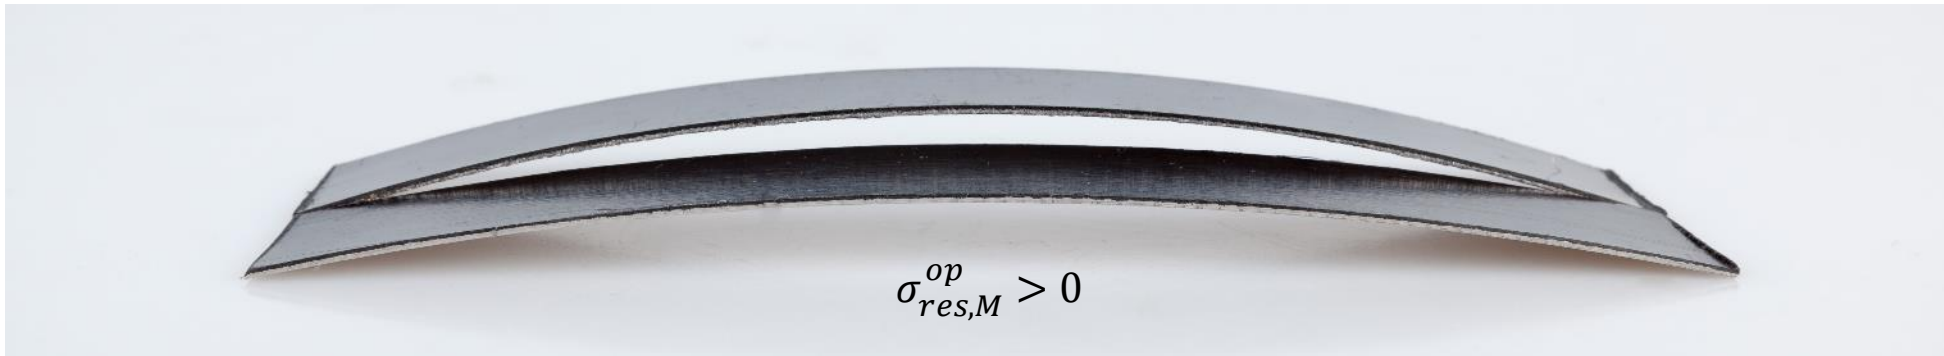
Mechanical pre-strain of the carbon fibers will be released during cool down of the high temperature cured laminate

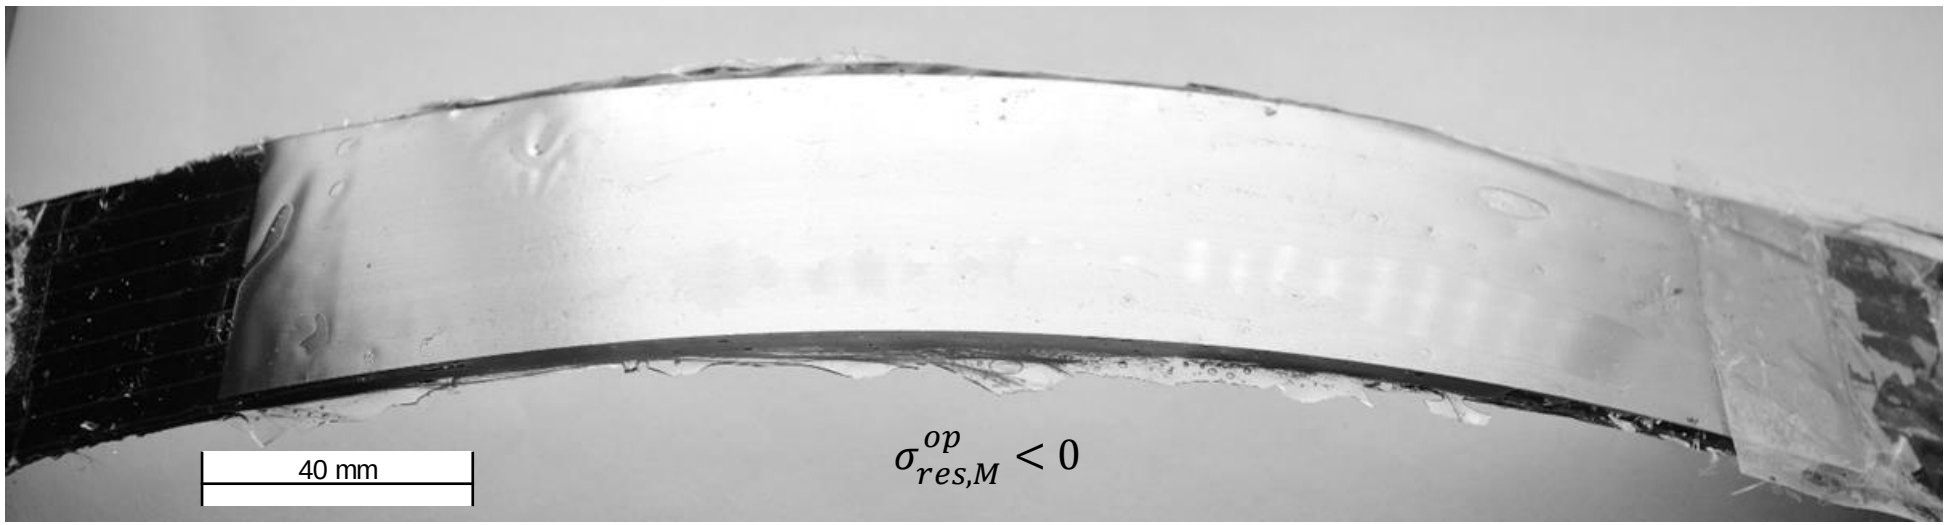
Impregnation

CF pre-stressed

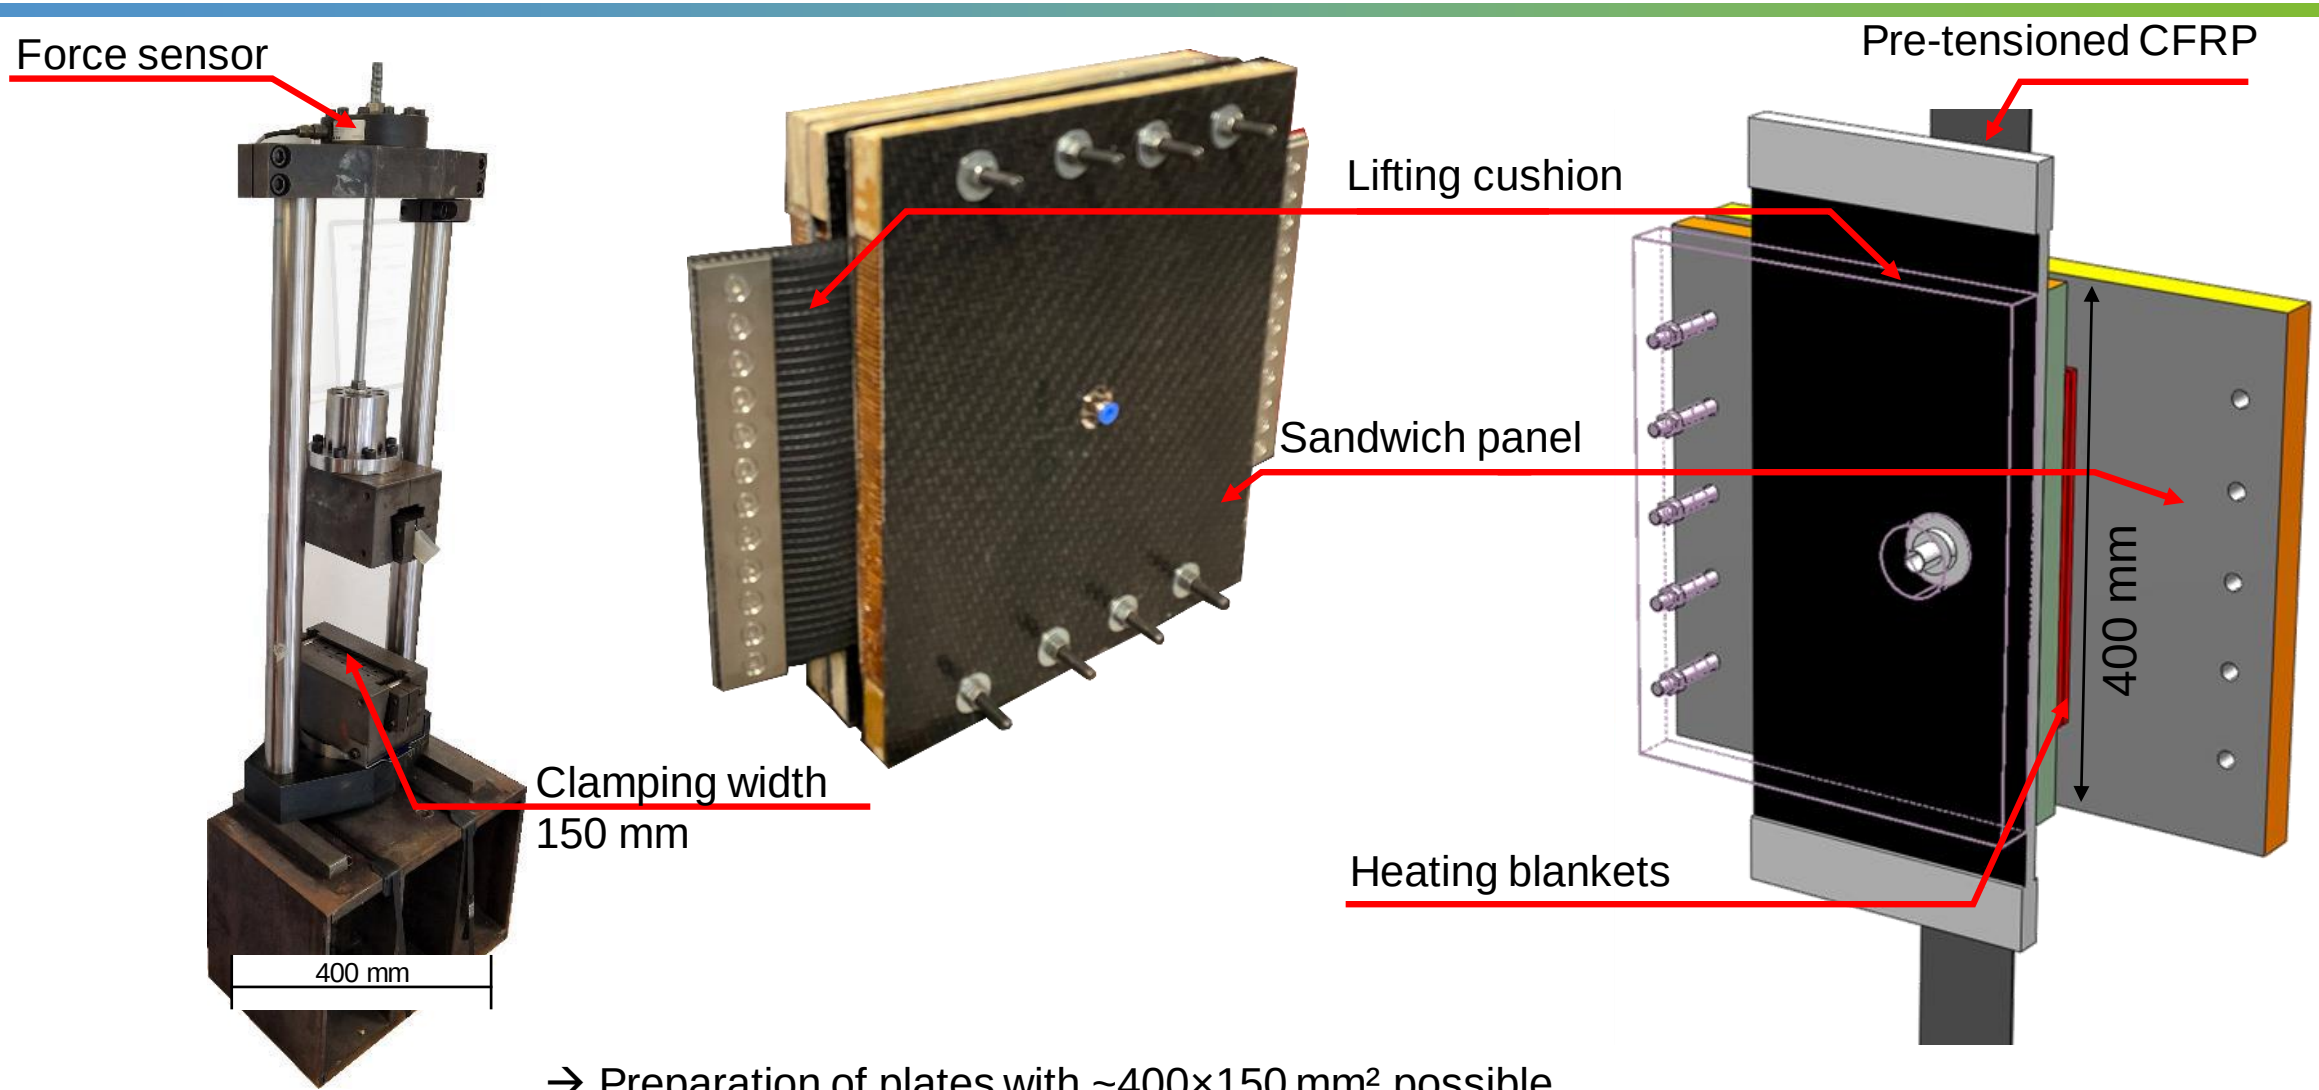
Cured with elongated CF

Ends were impregnated and cured in preliminary step





Compensation



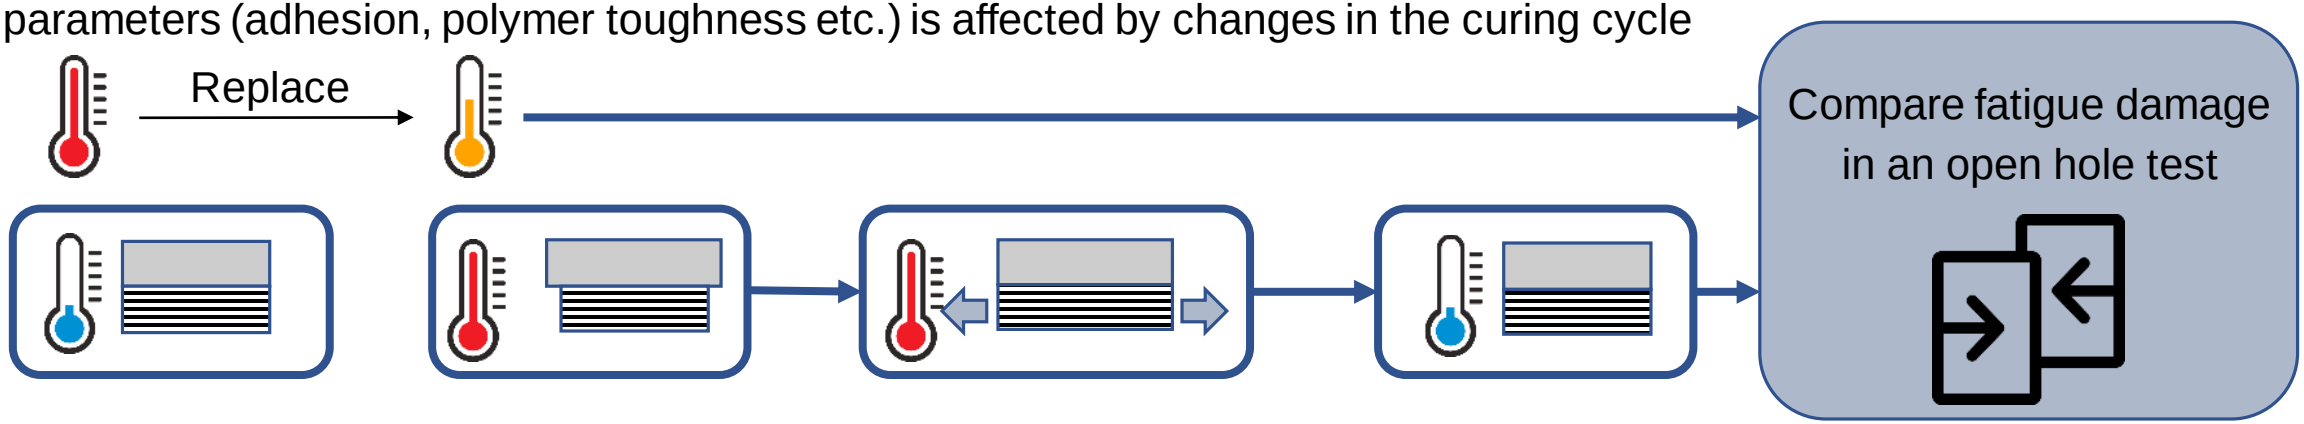
Thermal residual stresses

High temperature cure with mechanically strained CFRP during cure

6 Alternative Approach
New Manufacturing Set-up for Larger Plates

→ Preparation of plates with ~400×150 mm² possible

Current working hypothesis:



Adhesion of the metal sheets develops as a function of post curing treatment and can become critical if:

- The interface needs to transfer high shear loads, e.g. as a result of thermal stresses during post-curing
- Can be different as a result of the used surface treatment

→ More understanding and additional shear or peel tests are needed to fully understand the active mechanisms

Strategy to identify changes in the polymer or adhesive properties:

Comparison of modified curing cycle with mechanically modified residual stresses can c.p. show if any of the relevant parameters (adhesion, polymer toughness etc.) is affected by changes in the curing cycle

In addition to post-cure straining to induce residual stresses as result of plastically deformed metal sheets

Background of PEMFC and GDL

❖ PEMFC (Proton Exchange Membrane Fuel Cell)

- **Electric energy and water (H_2O)** are generated via the **electrochemical reaction** between hydrogen (H_2) and oxygen (O_2).
- Due to **fast startup** and **low operating temperature (80–120 °C)**, PEMFCs are gaining attention in mobility applications.
- A PEMFC unit cell consists of (1) **B**ipolar **P**lates, (2) **G**as **D**iffusion **L**ayers, (3) Membrane, and (4) **C**atalyst **L**ayers.

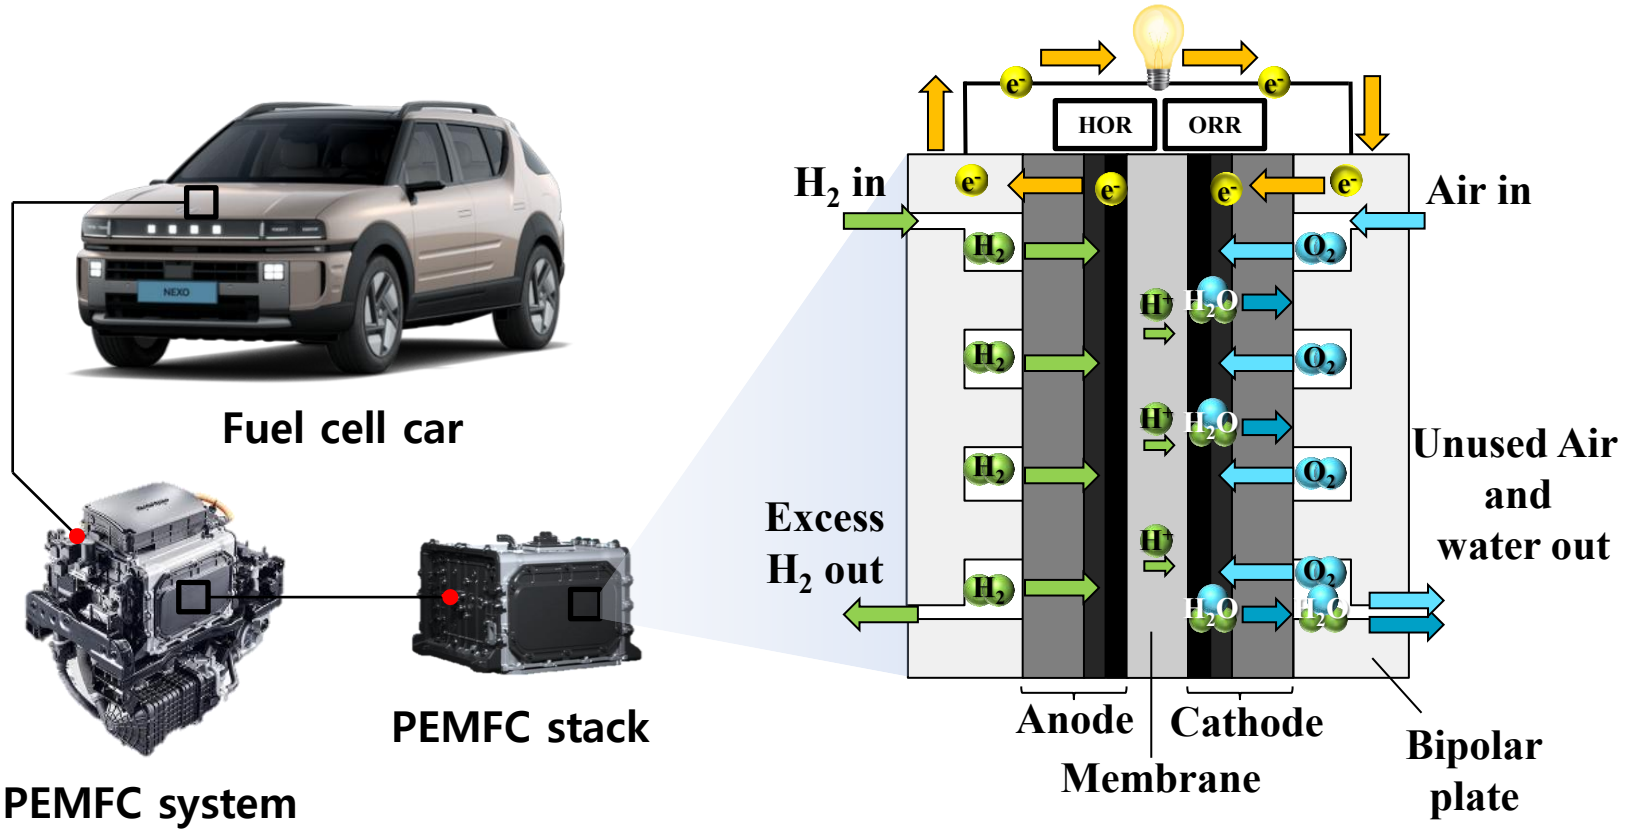

Figure. Schematic image of PEMFC unit cell

Electrochemical Reactions in PEMFC

Hydrogen oxidation reaction in Anode :

$$H_2 \rightarrow 2H^+ + 2e^-$$

Oxygen reduction reaction in Cathode :

$$0.5O_2 + 2H^+ + 2e^- \rightarrow H_2O$$

Overall Cell Reaction :

$$H_2 + 0.5O_2 \rightarrow H_2O$$

Background of PEMFC and GDL

❖ GDL (Gas Diffusion Layer)

- **GDL** consists of **GDB** (Gas Diffusion Backing layer) coated with **MPL** (Micro Porous Layer).
  - ✓ GDL serves **1) uniform diffusion of reactant gases, 2) conduction of generated electrons and heat, 3) removal pathway for produced water**.
- **GDB** : **Carbon paper composed of carbon fiber layers is typically used**, providing structural support to GDL
- **MPL** : Mainly composed of carbon black-based slurry; **it reduces contact resistance with catalyst layer and prevents catalyst loss.**

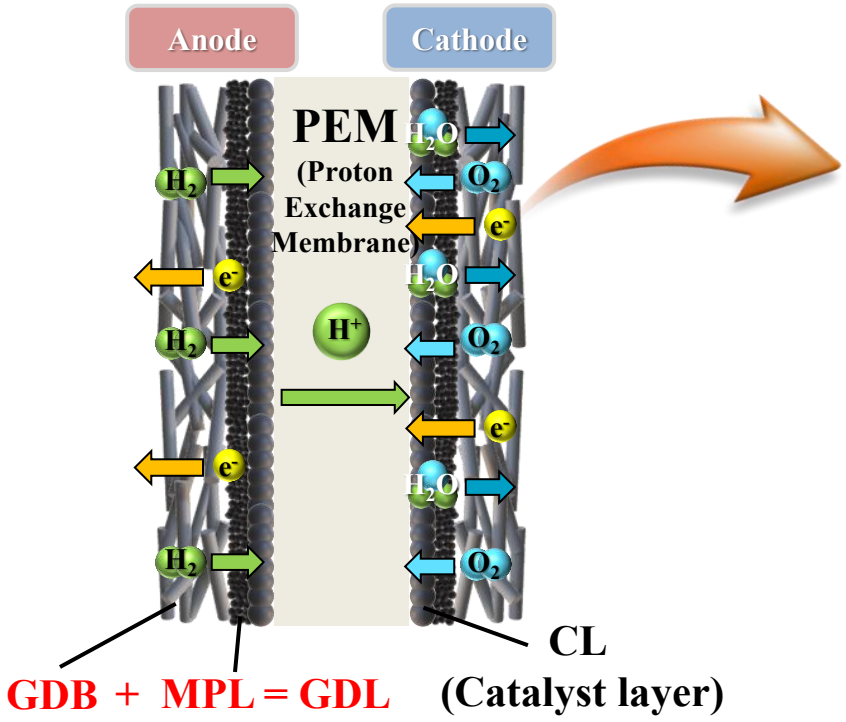

Figure. Illustration of gas diffusion layer

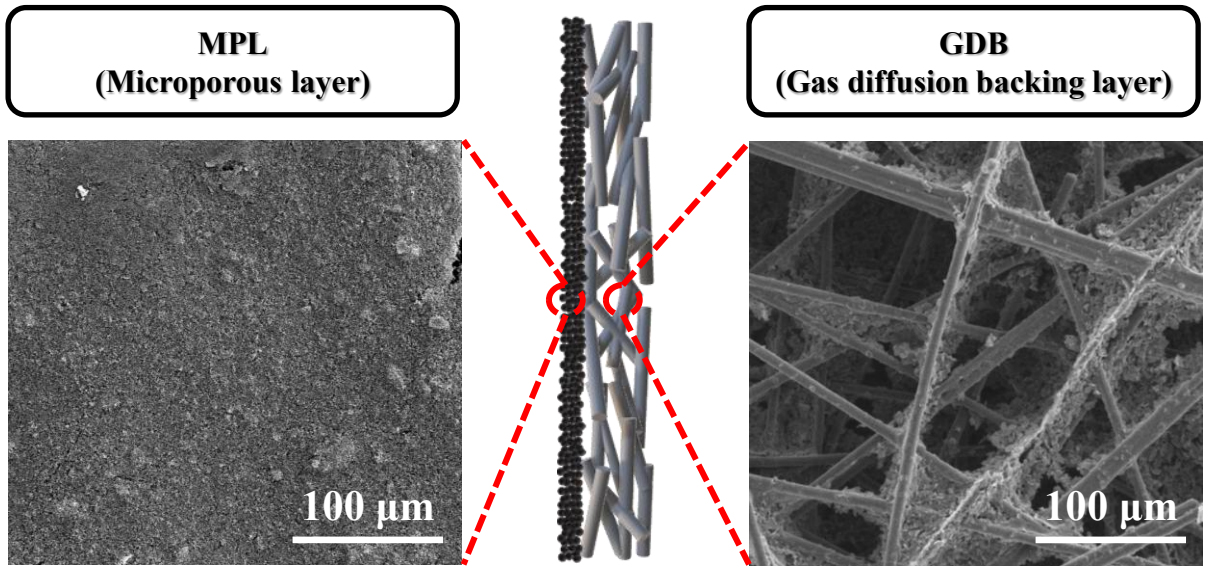

Figure. Images of GDB and MPL

Background of PEMFC and GDL

❖ Voltage losses in PEMFC

- During operation, PEMFCs exhibit **lower voltages than the theoretical value due to various losses.**
- These losses are typically categorized by the current density regions in which they have the greatest impact.
- Minimizing these losses requires **improving the material properties and performance of individual cell components.**

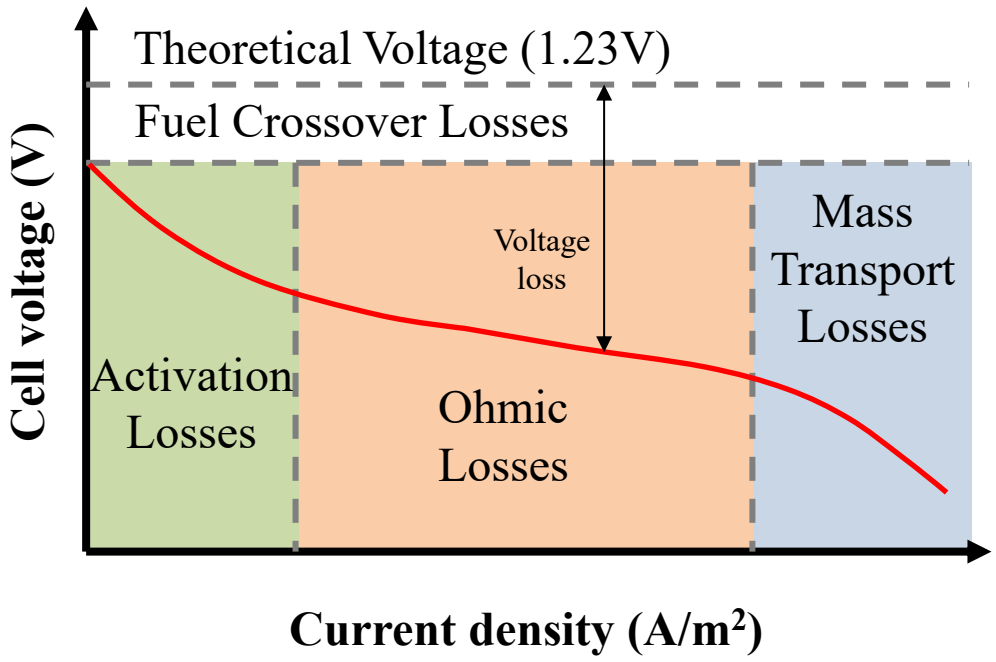

Figure. Various types of losses that occur during PEMFC operation

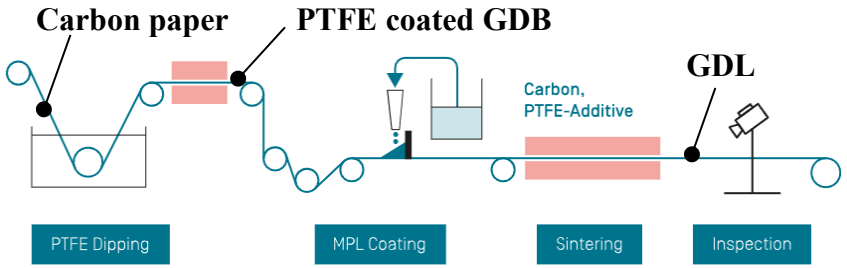
Table. Classification of major losses in PEMFC



Loss type	Loss mechanism
Fuel crossover loss	Losses caused by hydrogen diffusing through the membrane without reacting, reducing efficiency and open circuit voltage.
Activation loss	Losses caused by the activation energy barrier of the electrochemical reactions,particularly due to the slow kinetics of the oxygen reduction reaction (ORR).
Ohmic loss	Losses caused by resistance to ion flow in the membrane and electron flow in cell components, reducing cell voltage.
Mass transport loss	Losses caused by insufficient gas supply or water accumulation that blocks the pores of the gas diffusion layer, limiting reactant transport at high current densities.

Background of PEMFC and GDL

❖ Hydrophobic coating on GDB (Gas Diffusion Backing layer)

- Commercial carbon paper based GDBs are coated with **hydrophobic** agents such as **fluoropolymers, primarily PTFE.**
- This treatment prevents **water condensation and pore blockage**, thereby reducing **mass transport loss** in PEMFC.

✓ However, **fluoropolymers** are **electrically insulating** and significantly reduce the **through-plane electrical conductivity** of the GDB.

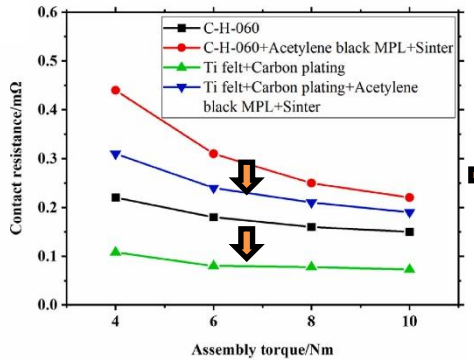
Figure. Reduction in through-plane electrical conductivity of GDL due to PTFE coating

Challenges in Balancing Conductivity and Hydrophobicity in GDLs



❖ Studies on enhancing electrical conductivity of GDBs

- Various approaches have been used to enhance GDB conductivity via **structure, materials, and coatings.**
- **Metal-based GDBs and conductive coatings** still require **hydrophobic coatings for water management**, which **offset conductivity gains.**

✓ Therefore, it is essential to address the **fundamental issue of conductivity loss caused by hydrophobic coatings** themselves.

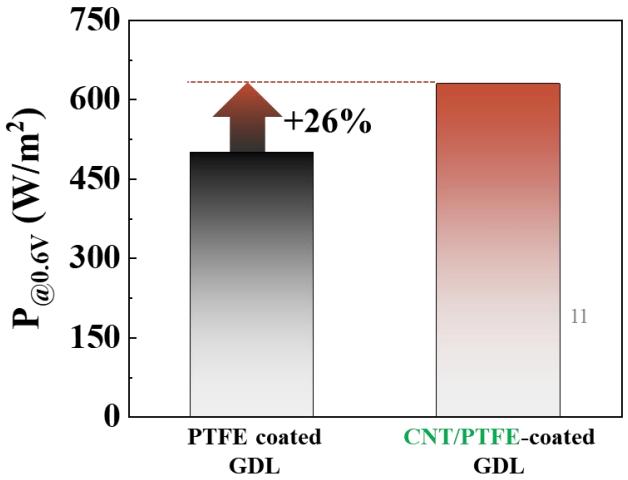
Research objectives



❖ Conductive and highly-hydrophobic coating on GDB for enhanced PEMFC performance

- **CNT/PTFE conductive-hydrophobic nanocomposite coating** on carbon paper (CP-GDBs)
  - Enhanced electrical conductivity, lower contact resistance, PTFE coating-level hydrophobicity, and improved PEMFC performance
- Analysis of **GDB and GDL property variations according to CNT/PTFE ratio** in the coating
  - Characterization: SEM, contact angle, conductivity, compressibility, and cell performance testing

➢ **New coating improves conductivity over PTFE, contributing to PEMFC performance enhancement**

PTFE-coated GDL　　CNT/PTFE-coated GDL

Enhanced PEMFC power (at RH 50%)

03. Results and discussion

1. Characterization of CNT/PTFE nanocomposite
2. Characterization of CP-GDBs
3. Characterization of CP-GDLs
4. PEMFC unit cell performance

Characterization of CNT/PTFE nanocomposite

❖ Dispersion of CNT/PTFE Nanocomposite (CxxPyy)

- To evaluate the dispersion of the CNT/PTFE nanocomposite, a film was formed by removing the water from the dispersion.
- **No noticeable agglomeration of CNT or PTFE** was observed at the microscale.
- **The small variation in electrical conductivity of the film** also indicated **uniform dispersion** of the nanocomposite.

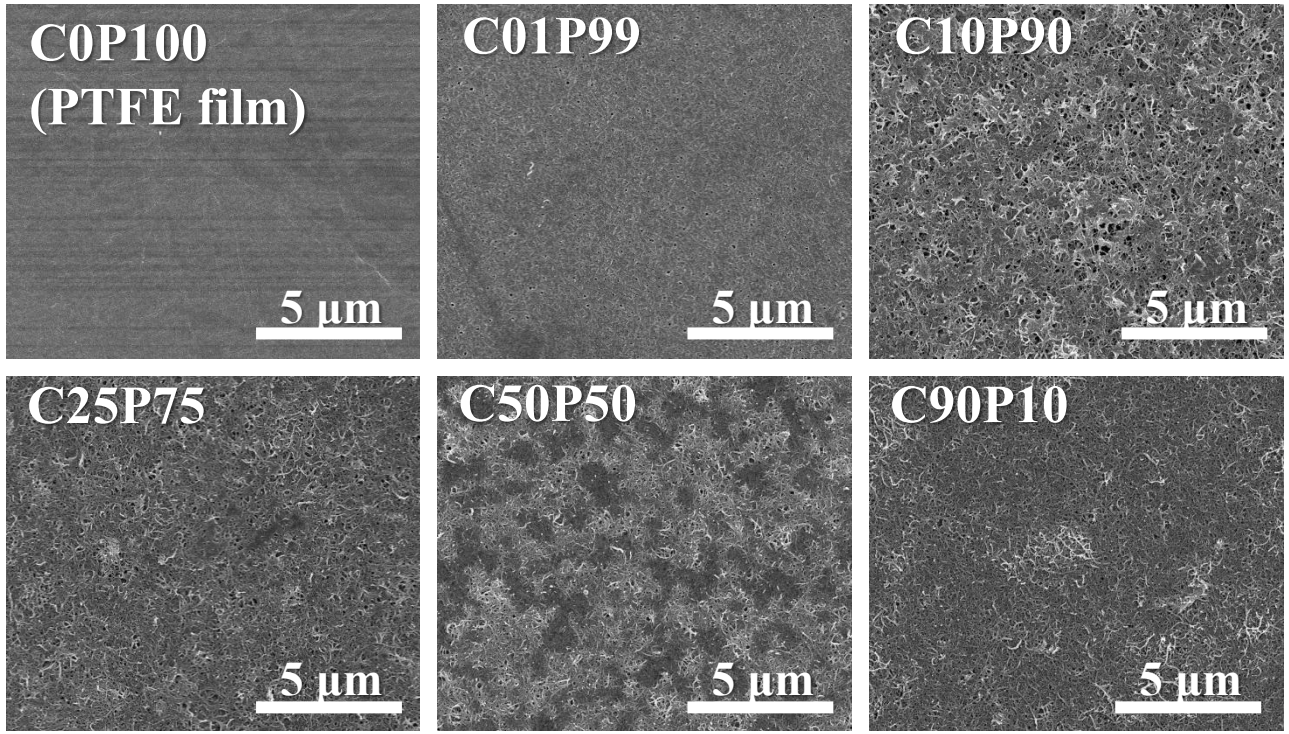

Figure. Microstructure images by CNT/PTFE nanocomposite

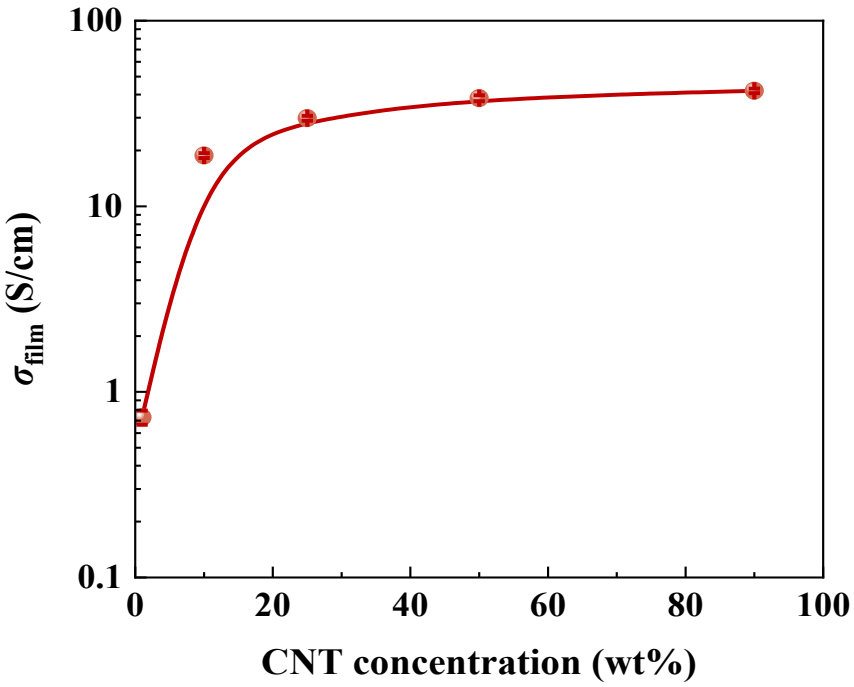

Figure. Electrical conductivity of CNT/PTFE nanocomposite film

Characterization of CP-GDBs

❖ Surface morphology of CP-GDBs (CxxPyyB)

- SEM images reveal **CNT/PTFE nanocomposite microstructures** forming **film-like layers between carbon fibers**.
- As **CNT ratio in the nanocomposite increases, denser CNT networks** are formed while **PTFE content decreases.**
- **No CNT agglomeration** observed at the microscale, indicating **uniform dispersion of the nanocomposite.**

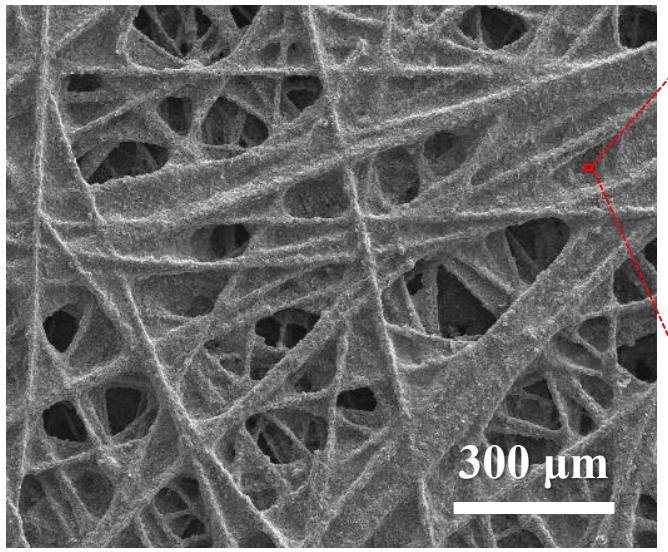

Figure. Magnified region (example)

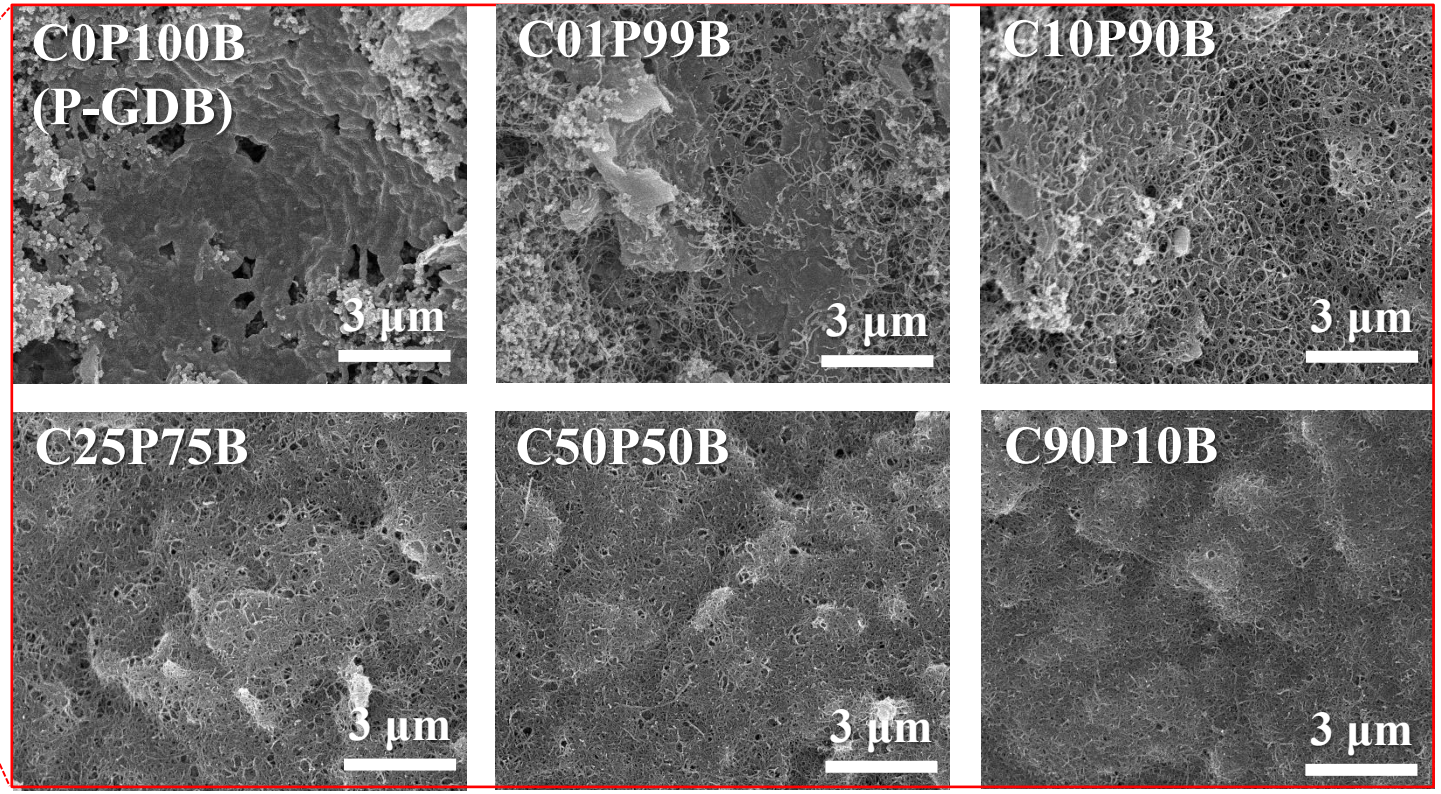

Figure. Microstructure images by CNT/PTFE composition in nanocomposite

Characterization of CP-GDBs

❖ Hydrophobicity of CP-GDBs (CxxPyyB)

- **CNT/PTFE coating** imparted hydrophobicity **comparable to that of conventional PTFE-coated GDB (C0P100B, P-GDB),** with a contact angle around 140º.
- **C90P10B exhibited hydrophobicity similar to pristine carbon paper** due to the **low PTFE content in the coating.**

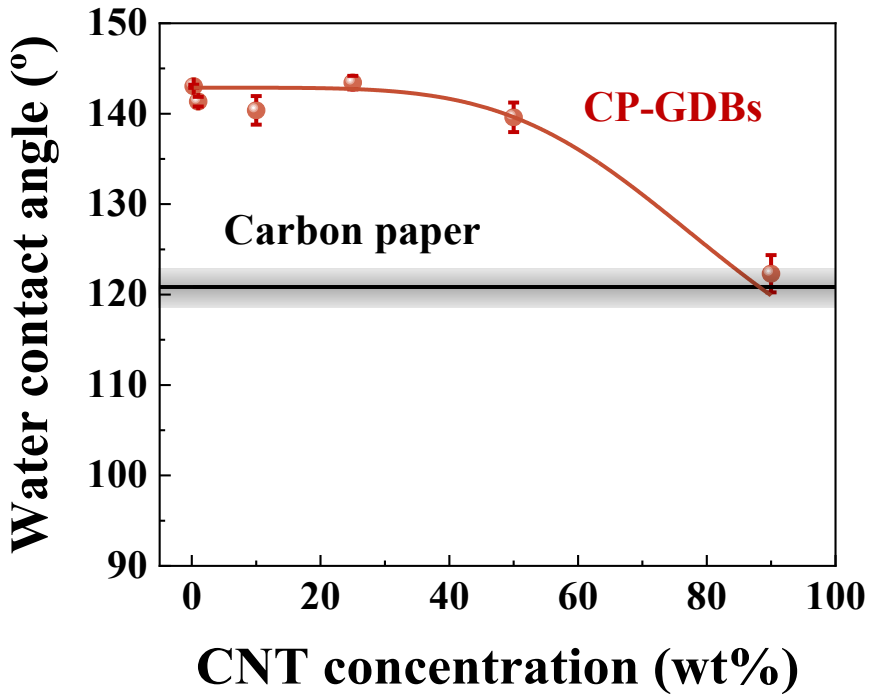

Figure. Contact angle of CP-GDBs according to CNT-to-PTFE ratio in the nanocomposite

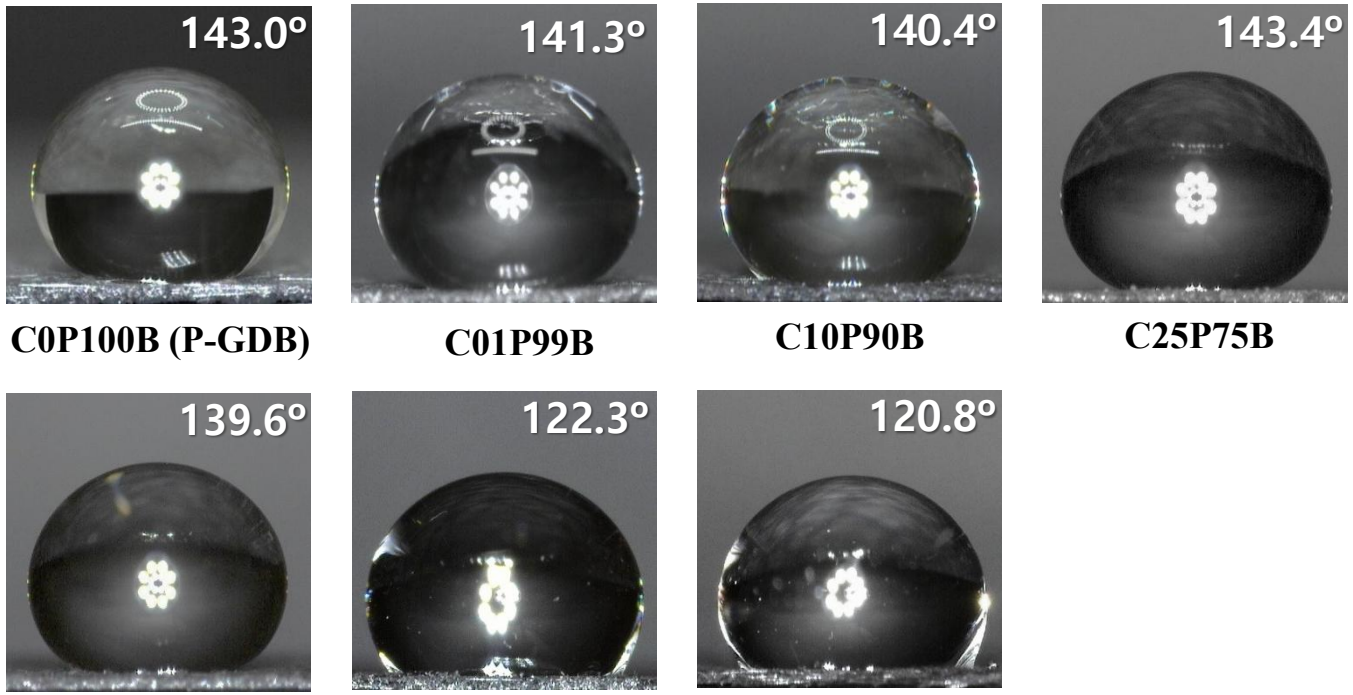

Figure. Water droplet images during contact angle measurement

Characterization of CP-GDBs

❖ Electrical conductivity of CP-GDBs (CxxPyyB) in TP* and IP** directions

- **TP electrical conductivity** was significantly **improved by CNT/PTFE coating compared to conventional PTFE-coated GDB (P-GDB).**
  - ➢ Increased from **4.85 S/cm (P-GDB) to 6.98 S/cm (C90P10B)**, representing a **44% enhancement.**
- **IP electrical conductivity remained nearly constant**, regardless of the coating composition.

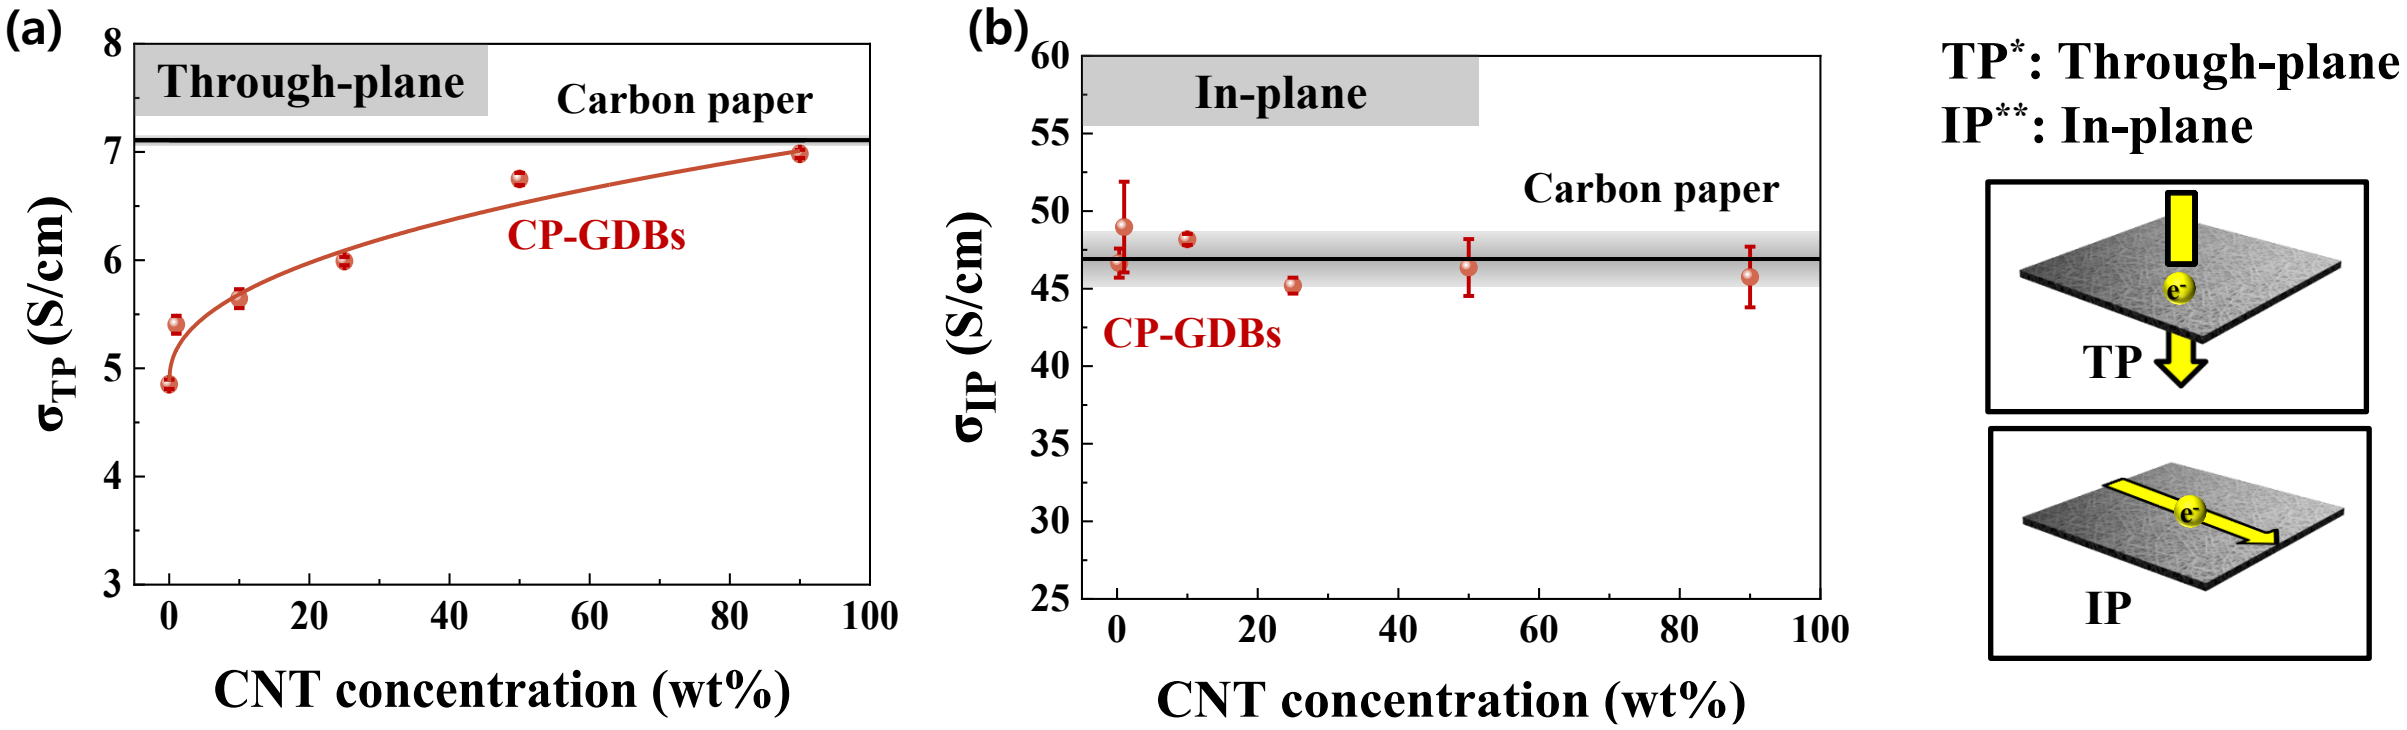

Figure. (a) TP and (b) IP electrical conductivity according to CNT-to-PTFE ratio of the coating

Characterization of CP-GDBs

IP*: In-plane
TP**: Through-plane

❖ Cause of electrical conductivity trends in CP-GDBs (CxxPyyB) in TP* and IP** directions

- **TP direction** : **In P-GDB (C0P100B), insulating PTFE blocks point contacts** between carbon fiber layers, **while CNT/PTFE coatings form additional inter-fiber conductive paths**, enhancing TP electrical conductivity.
- **IP direction : IP electrical conductivity** is **governed by continuous carbon fibers**, so coating has minimal effect.

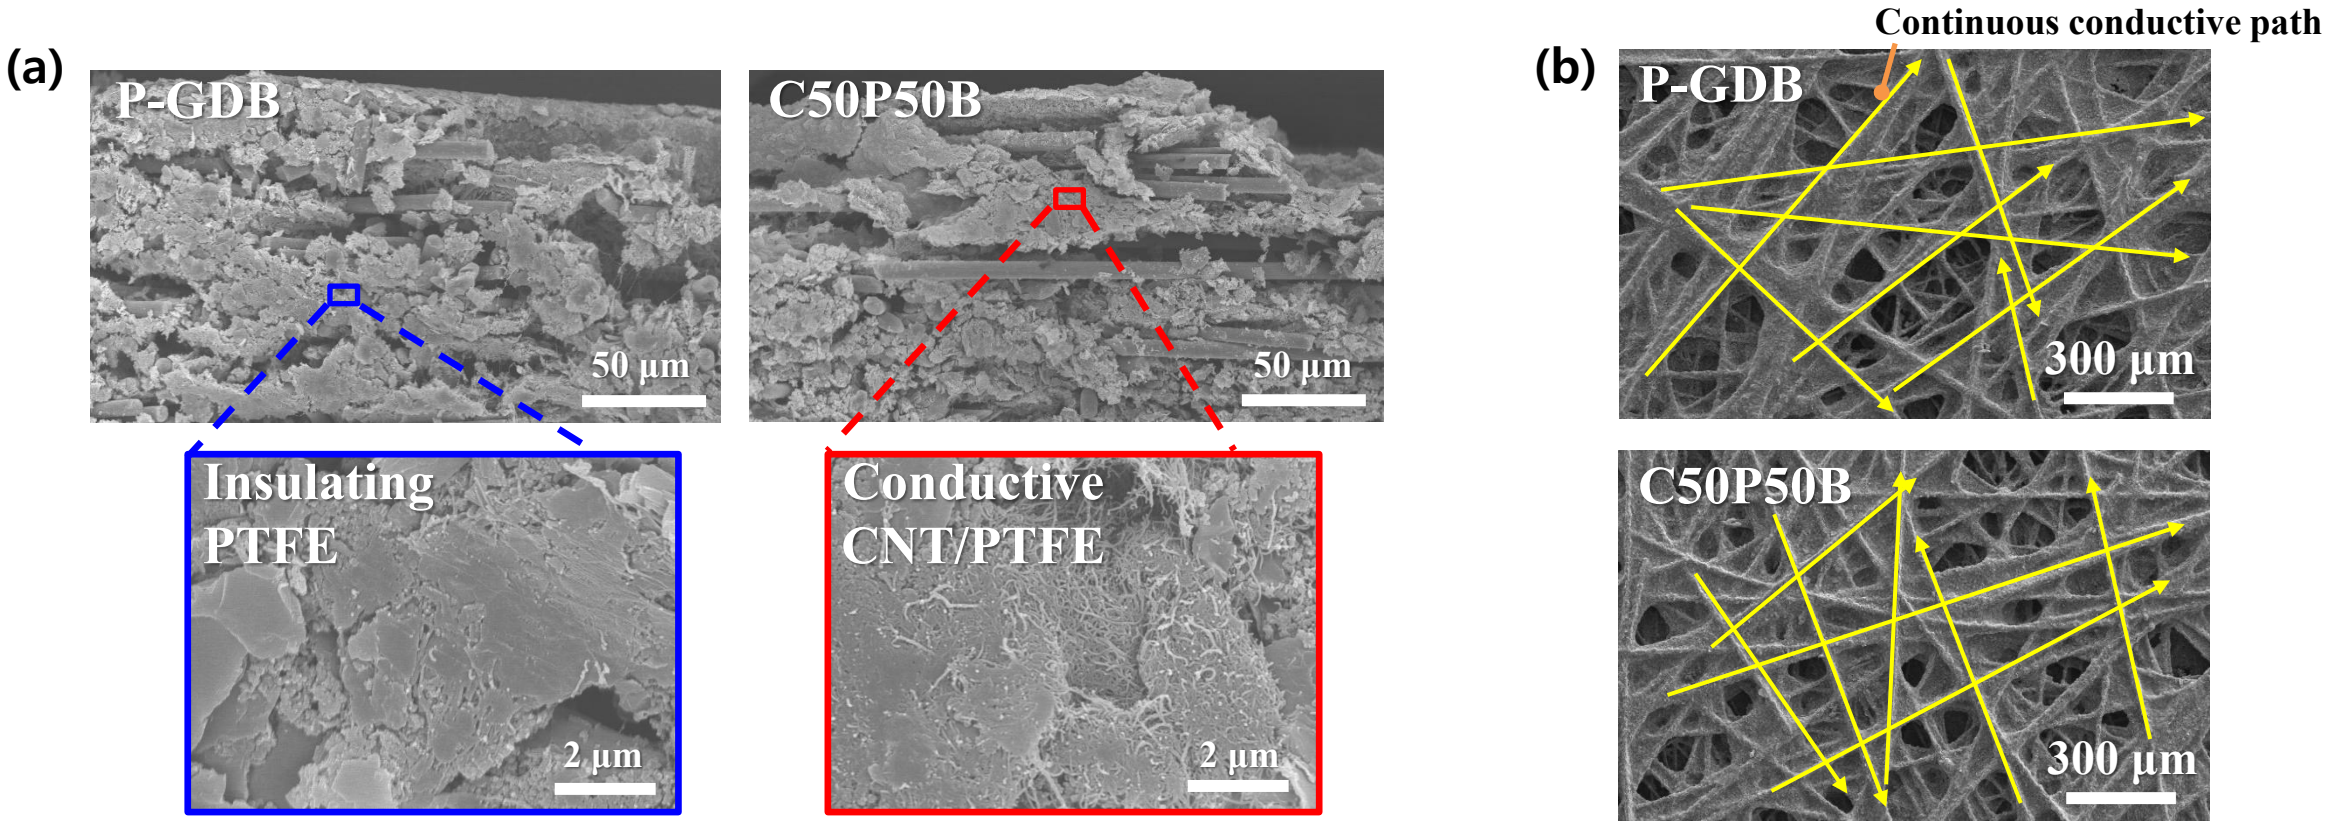

Figure. (a) Cross-sectional SEM images of P-GDB and CP-GDBs, (b) surface SEM images of P-GDB and CP-GDBs

Characterization of CP-GDBs

❖ Mechanical properties of CP-GDBs (CxxPyyB)

- Compressive properties were evaluated for various CNT-to-PTFE ratios in the coating.
- As the proportion of PTFE (serving as a binder of GDB) decreased, **compressibility increased** and **stiffness decreased.**
- Mechanical property trend: **P-GDB > C01P99B ≒ C10P90B ≒ C25P75B ≒ C50P50B > C90P10B**

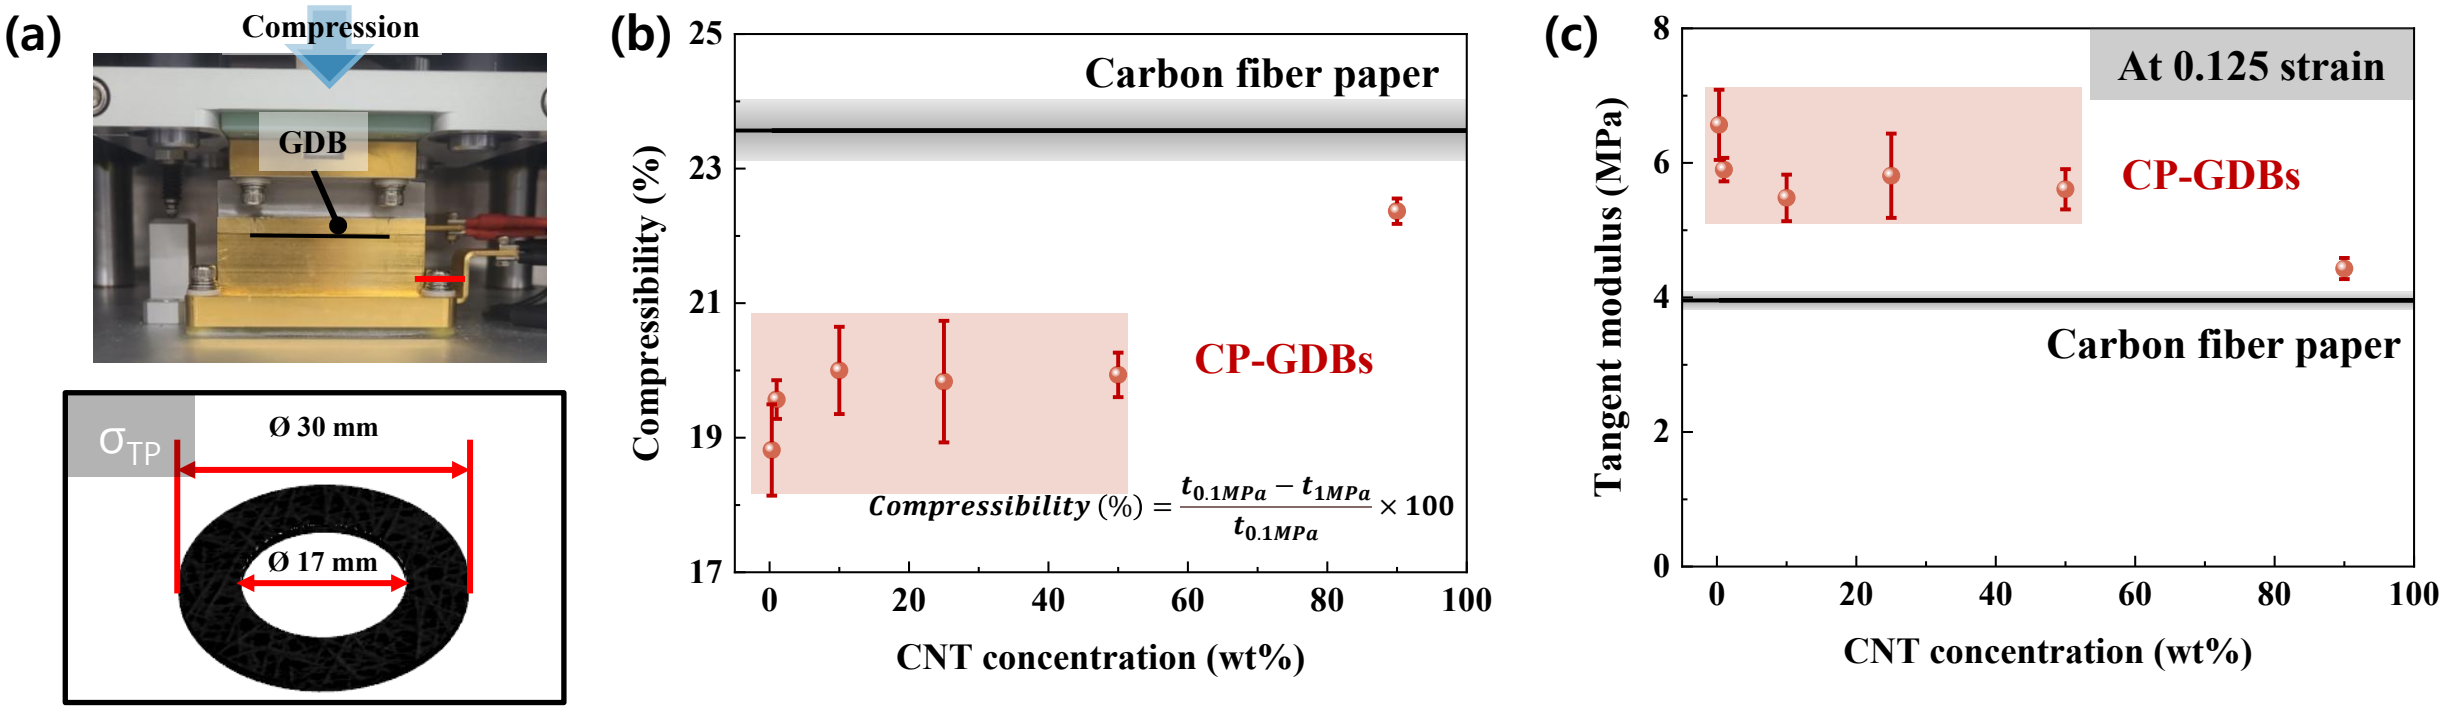

Figure. (a) Compression test setup and specimen dimensions, (b) compressibility by CNT-to-PTFE ratio in the coating, and (c) tangent modulus at 0.125 strain

Characterization of CP-GDLs

❖ Reduced contact resistance between CP-GDBs and MPL (in CP-GDLs, CxxPyyL)

- CP-GDBs exhibited **more than 50% lower contact resistance with MPL** compared to P-GDB.

✓ The **3D conductive CNT network** in the CNT/PTFE coating of CP-GDBs **entangles with the MPL**, increasing the conductive interface.

- **Contact resistance (R_{cont}) between CP-GDBs and MPL** was indirectly **estimated as R_{GDL}-R_{GDB}=R_{cont}+R_{MPL}.**
  - ➢ Since MPL was coated with the same composition and thickness, R_{MPL} was assumed to be constant.

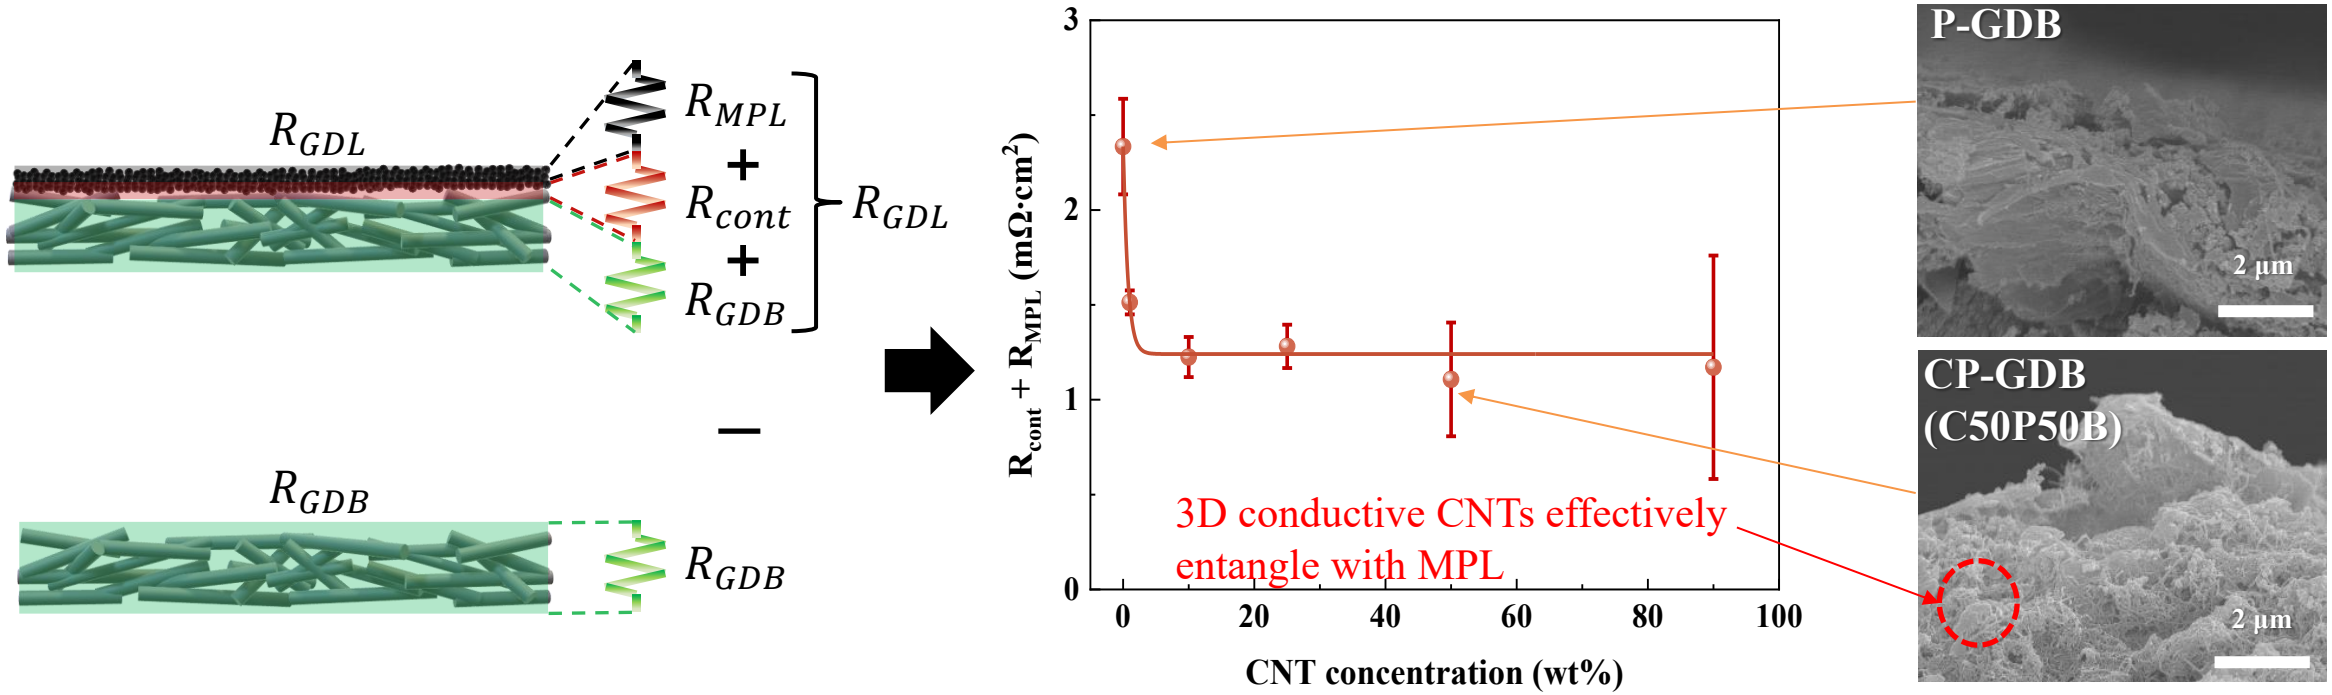

Figure. Contact resistance between CP-GDBs and MPL in CP-GDLs

PEMFC unit cell performance

❖ Fuel cell performance (I-V, I-P curve) evaluation: relative humidity(RH) 50% and 100% conditions

- Under both low and high humidity conditions, **CP-GDLs showed superior performance compared to P-GDL (C0P100L).**
- **Performance increased with higher CNT-to-PTFE ratio in the coating**, reaching up to a 26% improvement.
  - ➢ **CNT/PTFE coating enhanced the electrical conductivity** of the GDB, leading to **reduced cell ohmic loss.**
- Despite higher conductivity, **C90P10L exhibited lower performance to C50P50L** due to its **relatively lower hydrophobicity.**

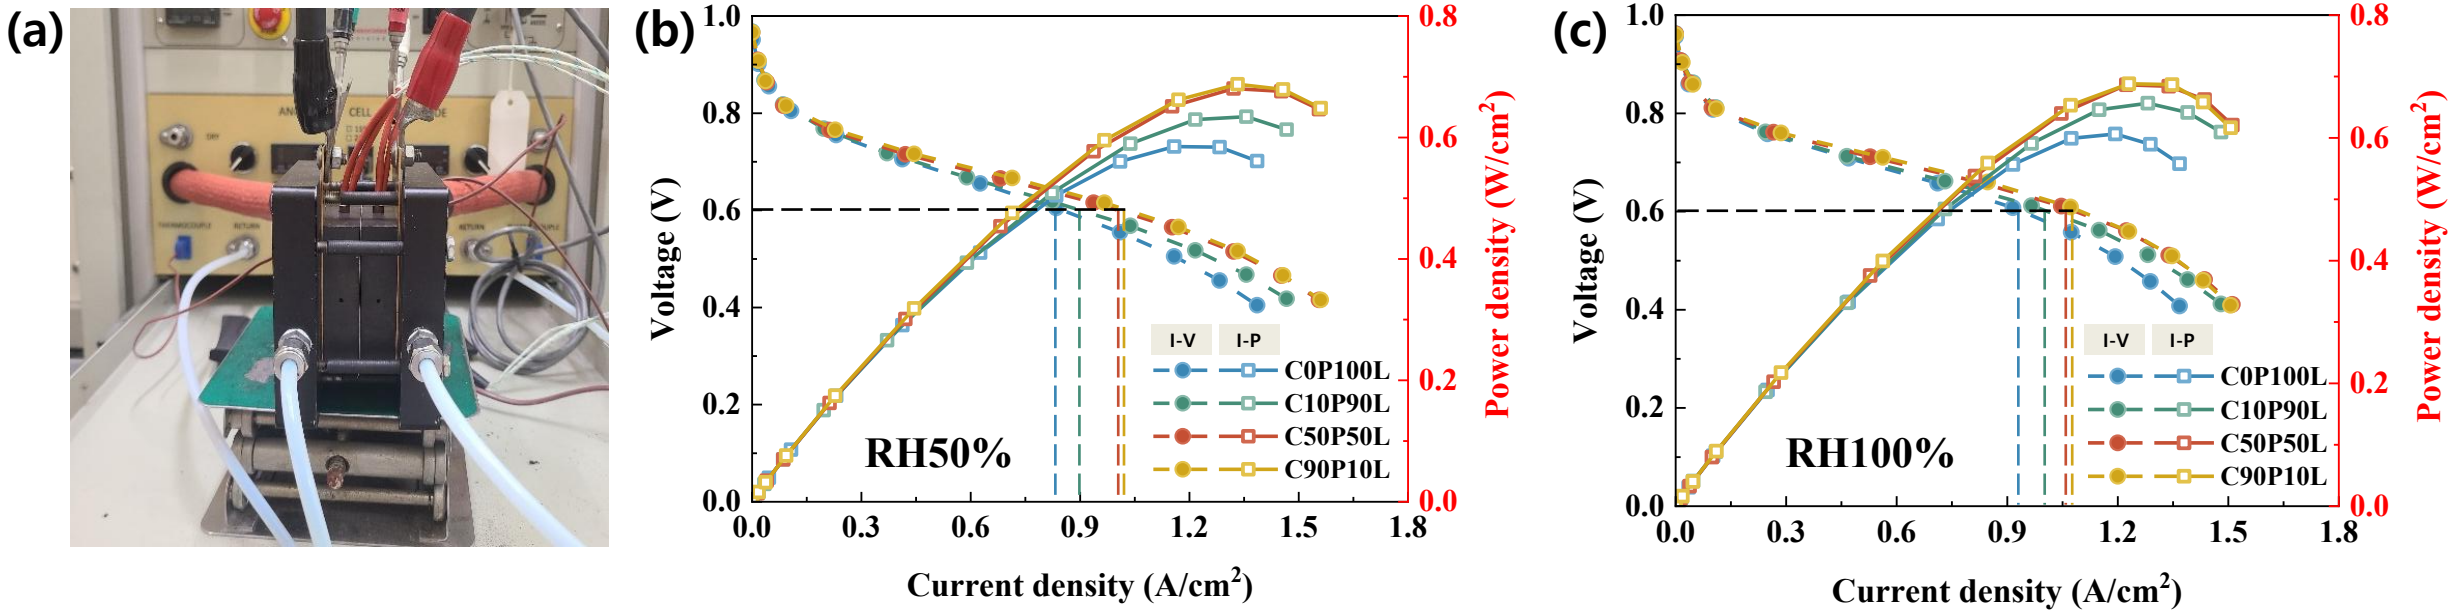

Figure. (a) Device setup for fuel cell performance test; I-V and I-P curves with CP-GDLs applied as cathode GDL, (b) Performance curves at RH 50%, and (c) performance curves at RH 100%. (I-V curve: dotted line, I-P curve: solid line

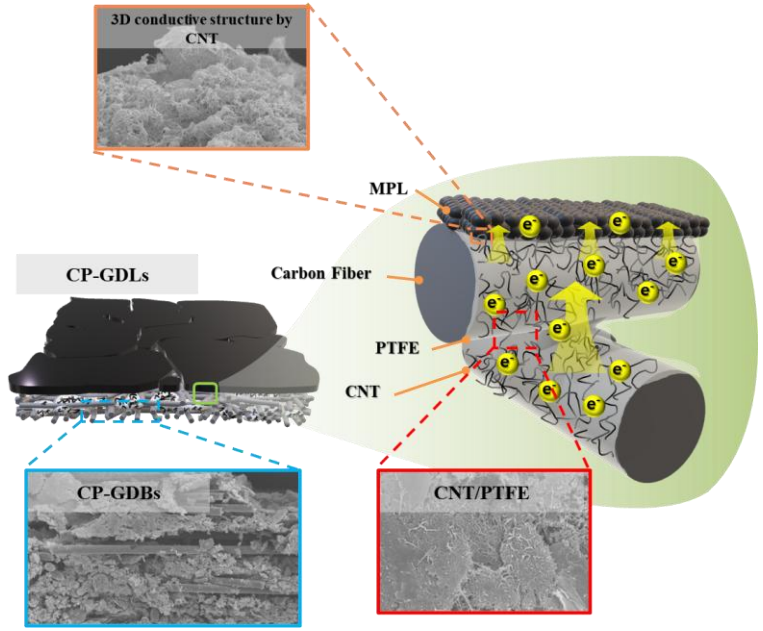
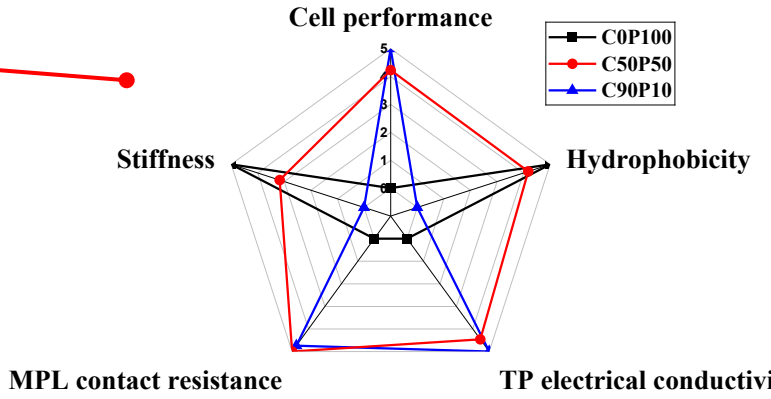


04. Conclusion

Conclusion



❖ Conductive-hydrophobic coating of GDB via CNT/PTFE

- Conclusion

- CNT/PTFE conductive-hydrophobic coating on GDB:
  - ✓ **Enhanced electrical conductivity**
  - ✓ **Improved unit cell performance (reduced ohmic loss)**
  - ✓ **Provided hydrophobicity**
  - ✓ **Maintained compressive stiffness**

- Property variation by CNT/PTFE ratio
  - ✓ GDB properties are tunable according to the CNT-to-PTFE ratio in the coating.

- Optimal composition by condition
  - ✓ Under general operating conditions, C50P50 is optimal (balanced properties).
  - ✓ Under low-humidity conditions, C90P10 is optimal due to maximized conductivity.

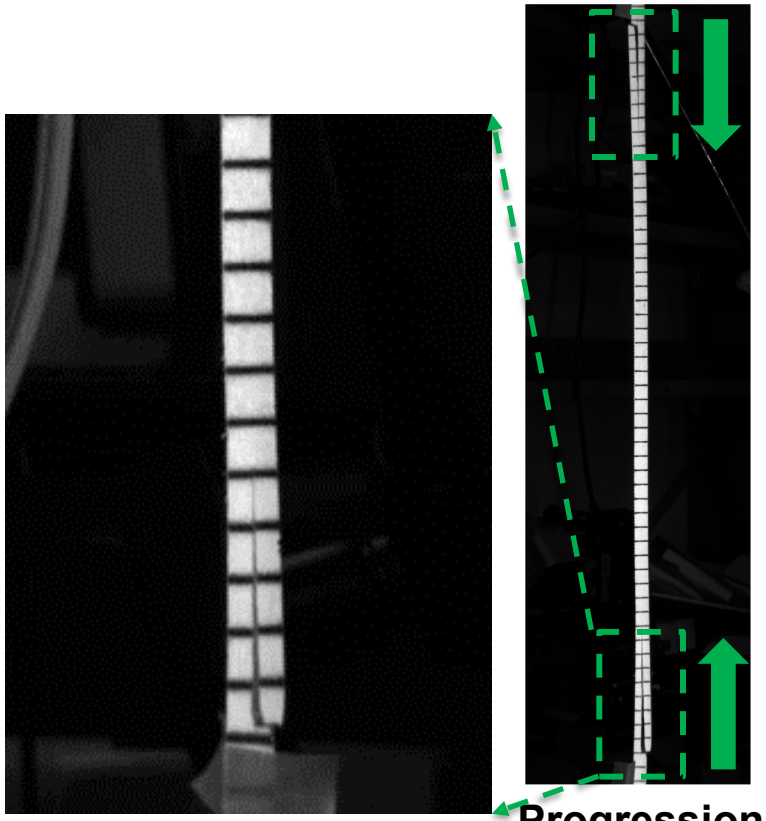
Development of a Height-Tapered Double Cantilever Beam Test Method for Mode I Interlaminar Fatigue Testing

Shagata Das
PhD Candidate
Department of Civil and Environmental Engineering | Center for Composite Materials



ICCM24

University of Delaware

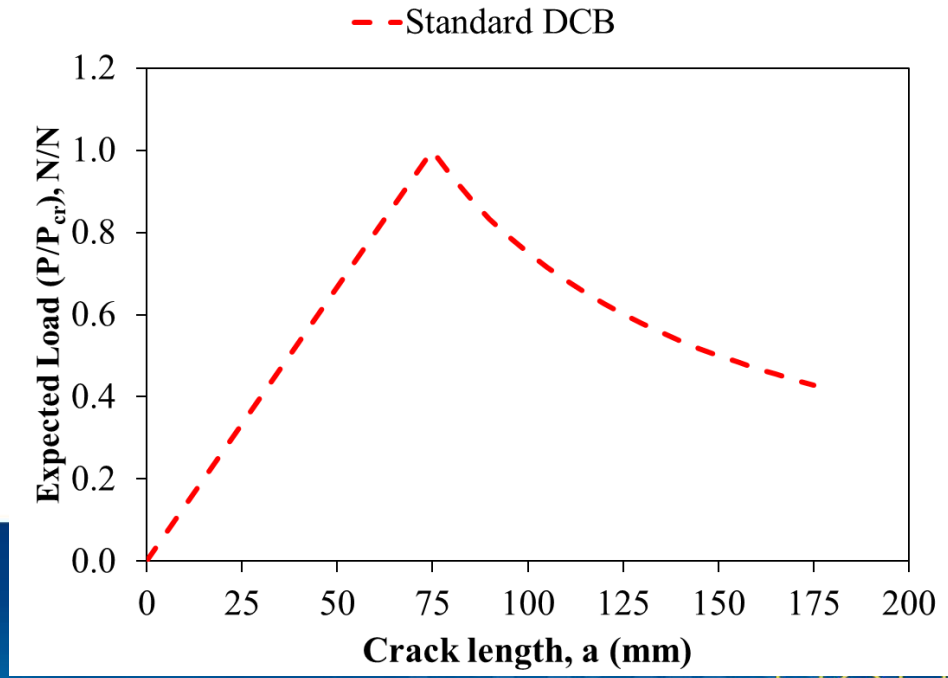
Motivation

Importance of Delamination and Mode I Failure in Composite Laminates

- Delamination is one of the most critical failure modes in laminated composite structures.
- It is often visually undetectable, making it highly dangerous and difficult to monitor.
- Leads to a significant reduction in both stiffness and strength.
- Fatigue-induced delamination is: Hard to detect; Irreversible; performance degradation or even catastrophic failure
- Design Philosophies in Practice:
  - No-Delamination Growth Principle (Conservative approach)
  - **Damage Tolerance Philosophy** (widely recommended): Emphasizes understanding failure mechanisms; Requires accurate prediction and monitoring tools
- In 2009, the Federal Aviation Administration (FAA) introduced **'slow growth' approach** to the certification of composites
- Among delamination modes, Mode I (opening mode) is often most critical.
- Dominates early-stage crack initiation in fatigue

Single Step Lap Joint Failure: Combination of Mode-I and Mode-II Loading

Challenges in Traditional Mode-I Fatigue Testing Methods



- Traditional Mode-I fatigue testing methods - based on constant load range (ΔP) or displacement range (Δd) - fail to maintain constant ΔG
- Under load control, ΔG increases with crack growth, leading to instability (da/dN → ∞)

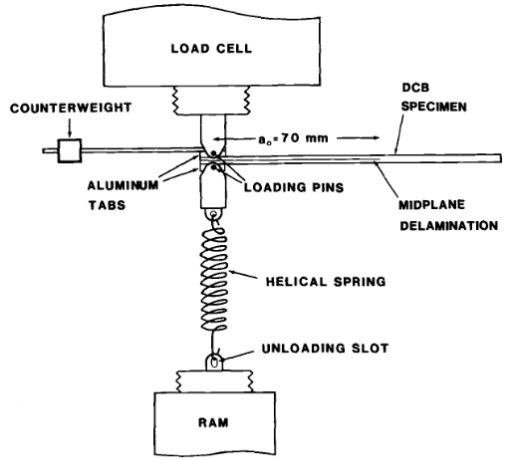
$$\Delta G = \frac{(P_{max}^2 - P_{min}^2)a^2}{bEI}$$

- Conversely, under displacement control, ΔG decreases with increasing crack length, resulting in crack arrest (da/dN → 0)

$$\Delta G = \frac{9EI}{4ba^4}(\delta_{max}^2 - \delta_{min}^2)$$

G-controlled Mode I Fatigue Testing

Russell & Street, 1988: *A Constant ΔG Test for Measuring Mode I Interlaminar Fatigue Crack Growth Rates*



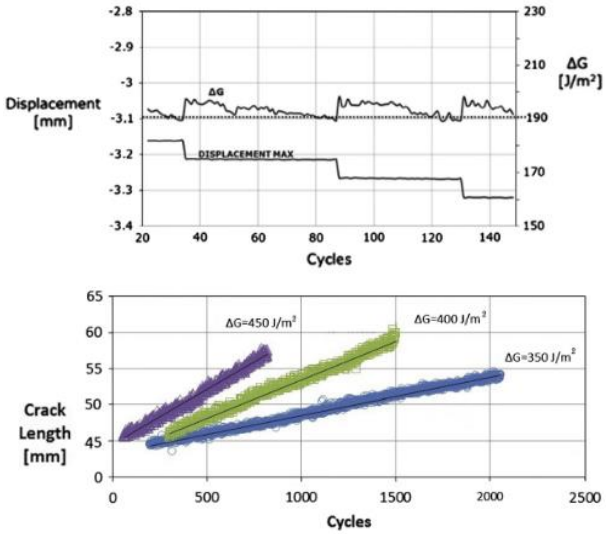


FIG. 1—*Experimental arrangement for constant ΔG interlaminar fatigue.*

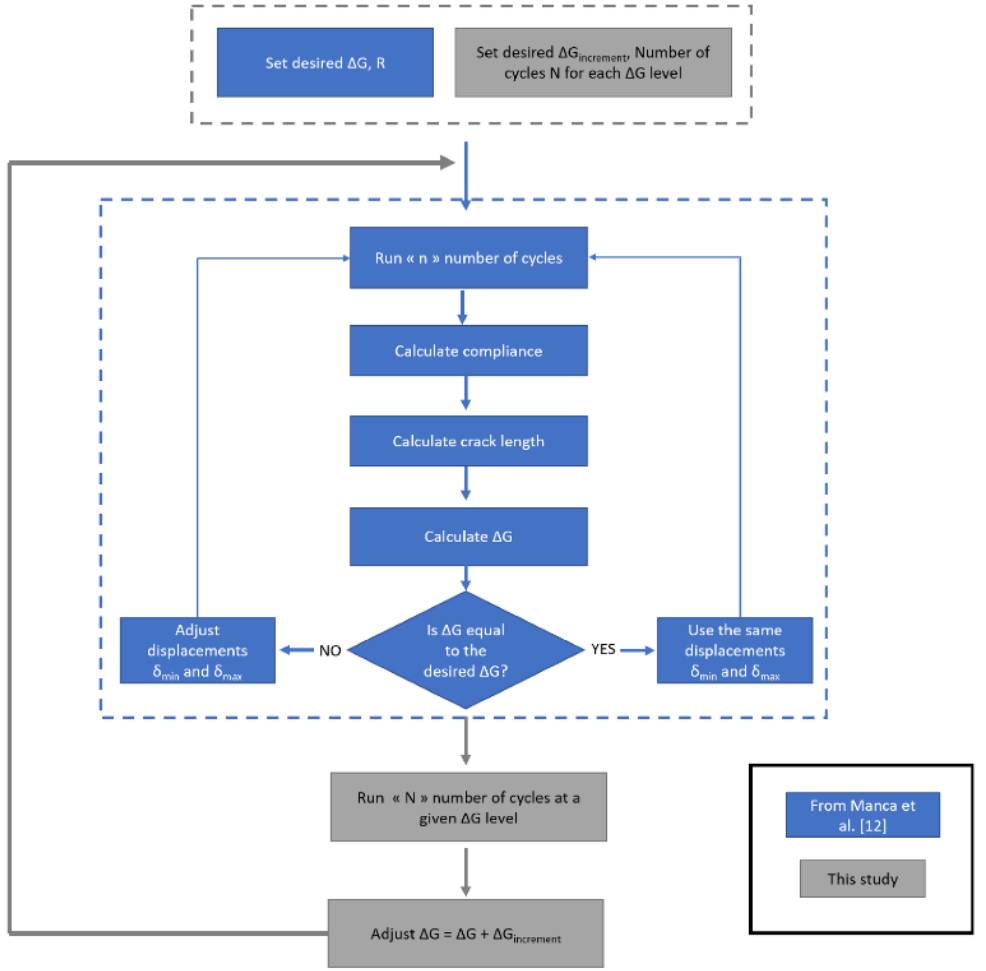
- Double Cantilever Beam (DCB) specimen loaded in series with a linear elastic spring.
- Spring mechanism provides optimum control of energy release rate (ΔG) during fatigue crack propagation.
- Displacement-controlled cyclic loading.

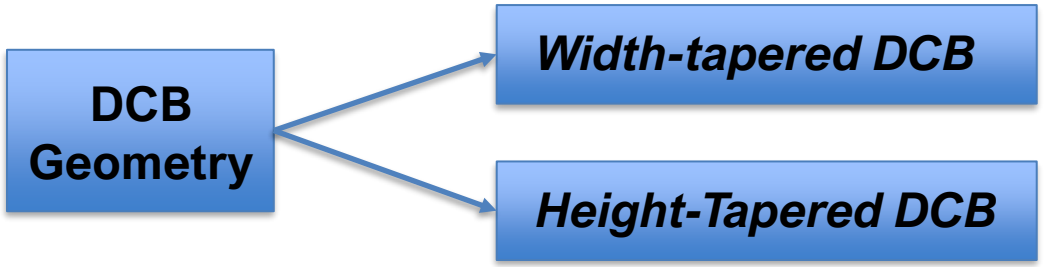


Manca et al., 2015: *G-control fatigue testing for cyclic crack propagation in composite structures*

- **Computer-controlled G-control testing** methodology
- Displacement-controlled fatigue

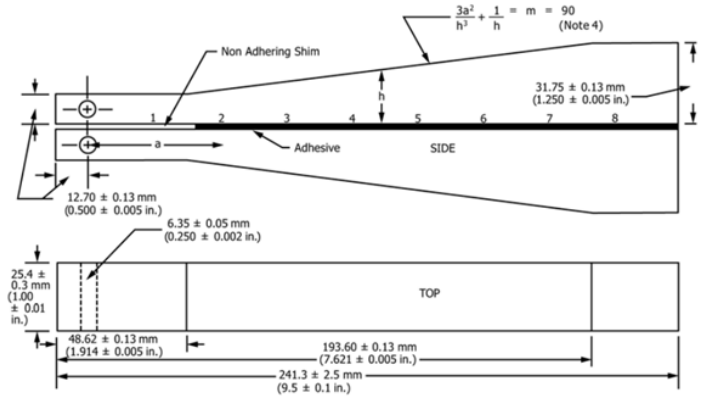
$$\Delta G = \frac{9EI}{4ba^4}\delta_{max}^2(1-R^2)$$

Arhant et al., 2021: *Fatigue crack growth properties of carbon-polyamide 6 thermoplastic composites using a multi-ΔG control method*

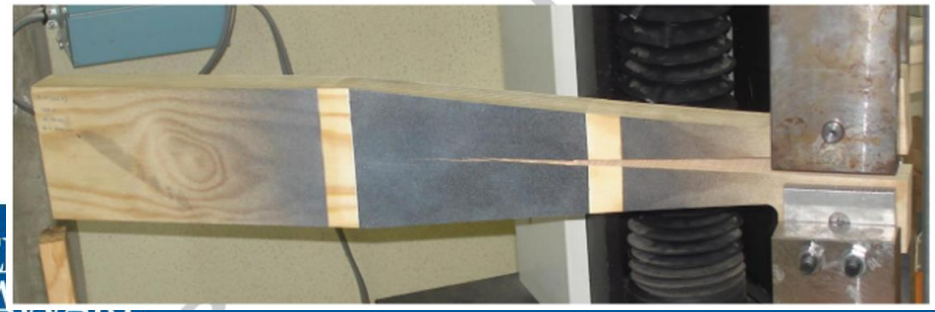


G-controlled Mode I Fatigue Testing

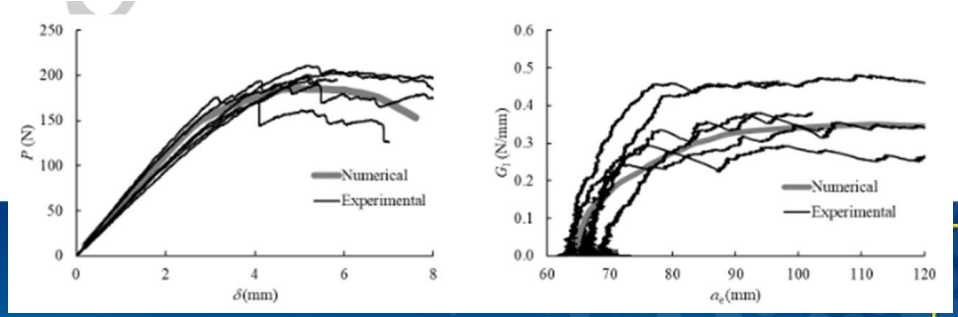
Research Gaps



1. *Frequent adjustment of displacement in the standard DCB fatigue testing to keep ΔG constant*
2. *Even small increments in crack length can cause significant changes in ΔG*
3. *Lack of Consideration for R-Curve Effects; difficult to understand the R-curve effect with standard DCB*
4. *The influence of R-curve behavior on the accuracy and reliability of Paris law fitting remains poorly understood.*

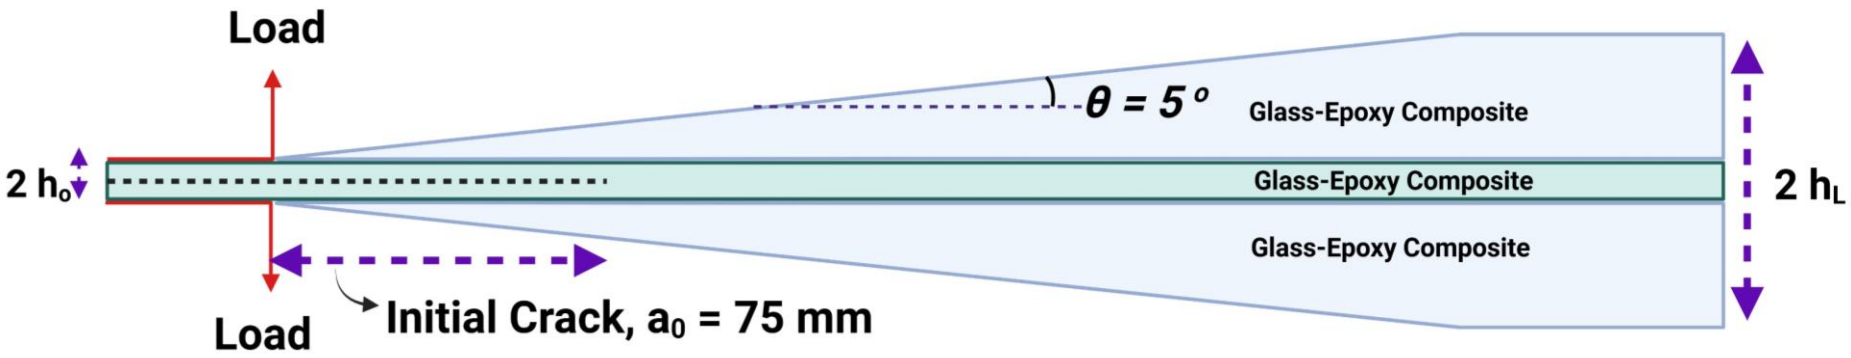


Geometry-Based G-controlled Mode I Quasi-Static Testing



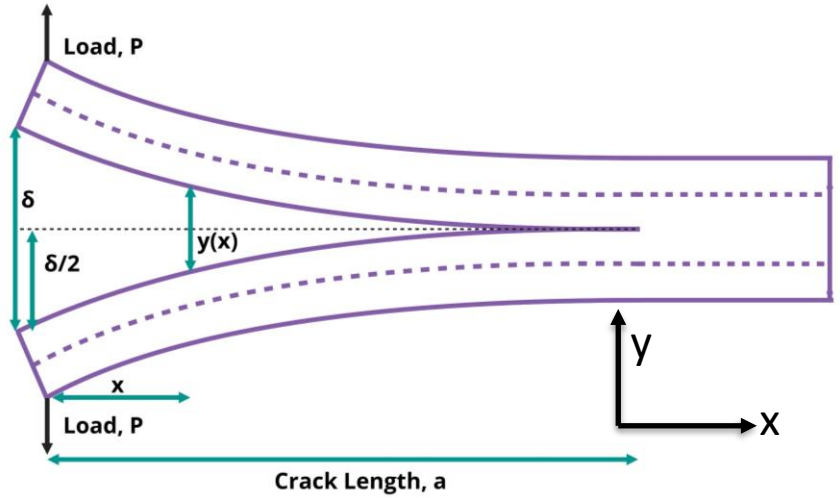
- Achieve constant ΔG during crack growth by altering the geometry of standard DCB
- ASTM Standard Available for HTDCB of Adhesively Bonded Metal Joints
- No standard available to perform ***fatigue HTDCB testing***
- **No comprehensive guidance exists** for designing HTDCB specimens specifically for fatigue testing of composite materials
- Prior studies focused exclusively on **Quasi-static behavior of adhesively bonded metal–metal or Wood**, with no application to composite laminates.

ASTM D3433: Standard Test Method for Fracture Strength in Cleavage of Adhesives in Bonded Metal Joints



Objective of This Study

- Designing Height-Tapered DCB (HTDCB) specimen to **maintain a constant energy release rate (G) and load (P)** during **quasi-static** delamination testing
- HTDCB configuration effectively maintains a **constant G during fatigue loading** conditions
- Ensure **stable crack growth** throughout fatigue testing
- Obtain **sufficient crack length** to accurately calculate fatigue crack growth rate (da/dN)



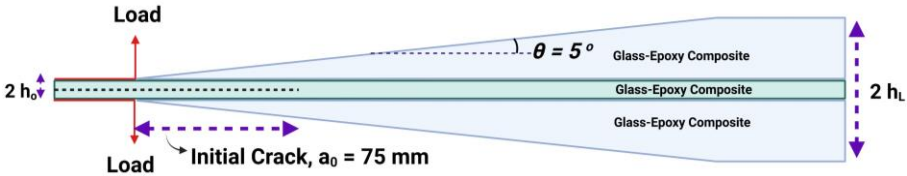
Design of HTDCB for Mode I Fatigue Testing of Composites

- **Shear flexible Timoshenko beam** is described through the following two differential equations:

$$Moment, \mathrm{M}(x) = \mathrm{EI}\frac{d\emptyset_z(x)}{dx} = Px$$

$$Shear\ force, \mathrm{V}(x) = k_s AG\ (\frac{dy}{dx} - \emptyset_z(x)) = -P$$

For classical Euler–Bernoulli formulation, $k_s AG = \infty$; shear-rigid beam

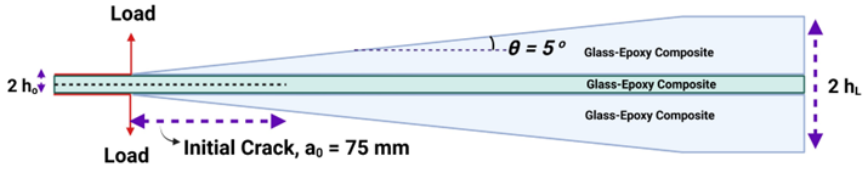


Here, P = Load, E = Flexural modulus, I = Moment of inertia, k_s = Shear correction factor, A = cross-sectional area, $\emptyset_z(x) = cross - sectional\ rotation$, y = deflection

$$\frac{d\emptyset_z(x)}{dx} = \frac{Px}{EI}$$

$$\frac{dy}{dx} = -\frac{P}{k_s AG} + \emptyset_z(x)$$

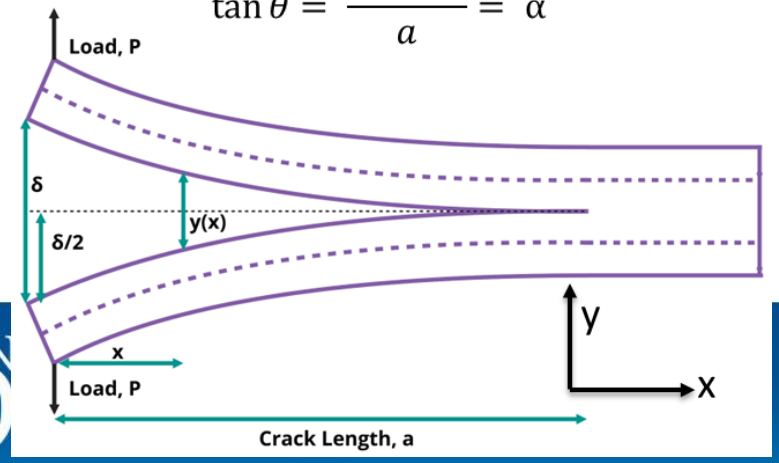
Deflection equation, y(x), was obtained by solving the two equations with the applied boundary conditions, $\emptyset_z(a) = 0\ and\ y(a) = 0$



$$h_L = h_o + \alpha a$$

$$\tan\theta = \frac{h_L - h_o}{a} = \alpha$$

$$k = \frac{\alpha}{h_o}$$



Design of HTDCB for Mode I Fatigue Testing of Composites

- **Timoshenko Beam Theory**, deflection, and compliance equations were analytically derived, accounting for both **flexural and shear effects**
- **Linear elastic fracture mechanics**-based strain energy release rate (**SERR**) equation (G) was derived
- **Validated** against **ASTM D3433-99** for metal joints (Poisson's ratio = 1/3)

$$h_L = h_o + \alpha a \qquad k = \frac{\alpha}{h_o}$$

$$\tan\theta = \frac{h_L - h_o}{a} = \alpha$$

- $\boldsymbol{Deflection\ at\ loading\ point, y(x=0) = \delta}$

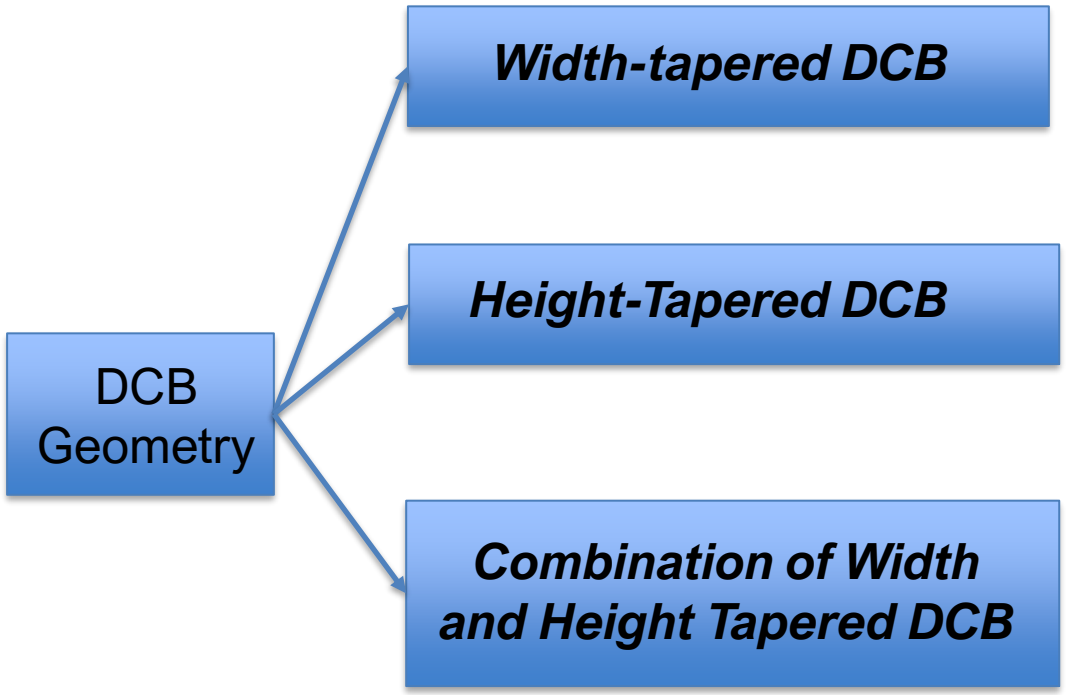
$$Deflection, \delta = \frac{Pa(-2-3ka)}{EI_o k^2(1+ka)^2} + \frac{2P\log(1+ka)}{EI_o k^3} + \frac{2P}{A_o G}\frac{log(1+ka)}{k}$$

$$C = \frac{\delta}{P}$$

$$Compliance, C = \frac{a(-2-3ka)}{EI_o k^2(1+ka)^2} + \frac{2\log(1+ka)}{EI_o k^3} + \frac{2}{A_o G}\frac{log(1+ka)}{k}$$

$$G_I = \frac{P^2}{2b}\frac{dC}{da}$$

$$SERR, G_I = \frac{12P^2a^2}{Eb^2{h_o}^3(1+ka)^3} + \frac{P^2}{k_s G b^2 h_o (1+ka)}$$



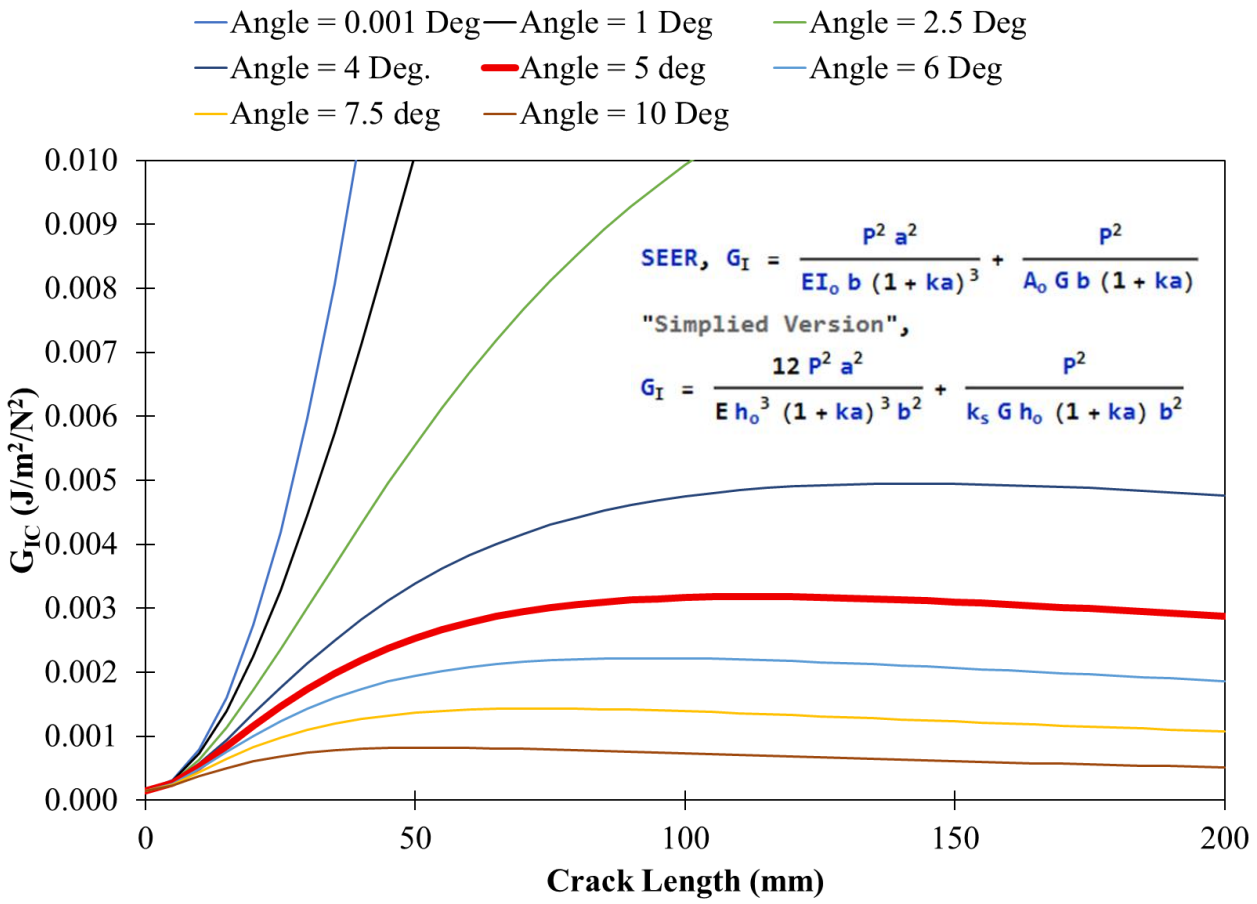
Rearranging Equation

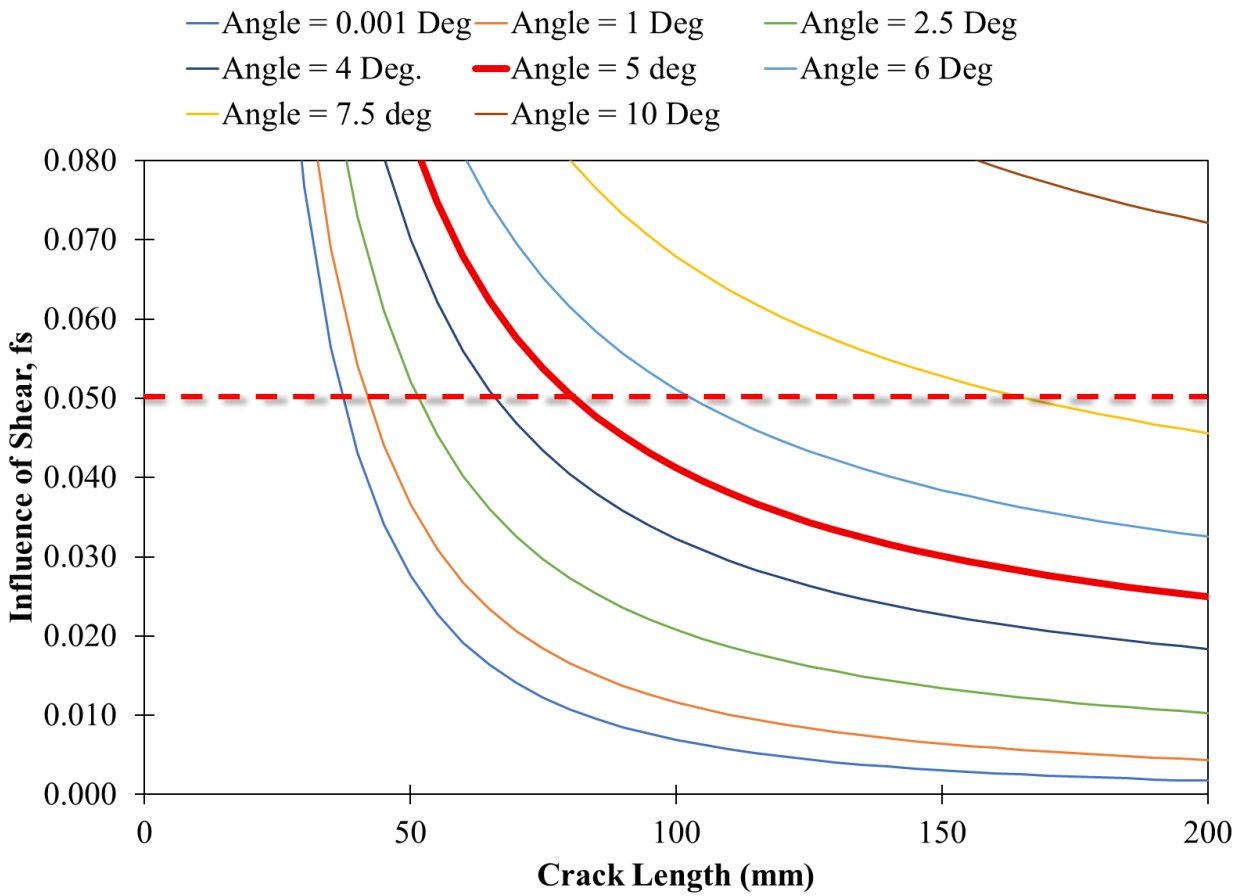
$$G_I = \frac{4P^2}{Eb^2}\left[\frac{3a^2}{{h_L}^3} + \frac{3E}{8Gh_L}\right]; \textit{Equation similar to ASTM D3433}$$

$$G_I = \frac{4P^2}{Eb^2}\left[\frac{3a^2}{{h_L}^3} + \frac{1}{h_L}\right]; \textit{ASTM D3433 Equation}$$

Geometry-Based Approaches to Maintain Constant ΔG During Mode-I Fatigue Testing

- Three approaches available to achieve constant ΔG during crack growth by altering the geometry of standard DCB



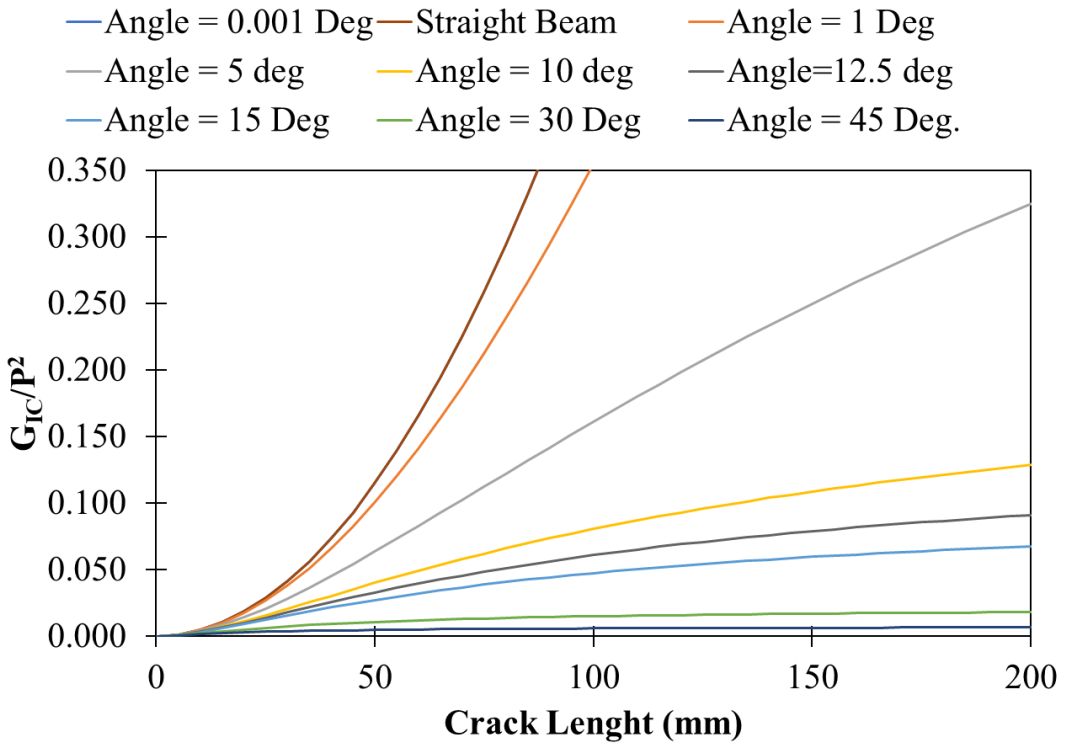


$$SERR, G_I = \frac{12P^2a^2}{Eb^2(1+k_2a)^2{h_o}^3} + \frac{P^2}{k_sGb^2(1+k_2a)^2h_o}$$

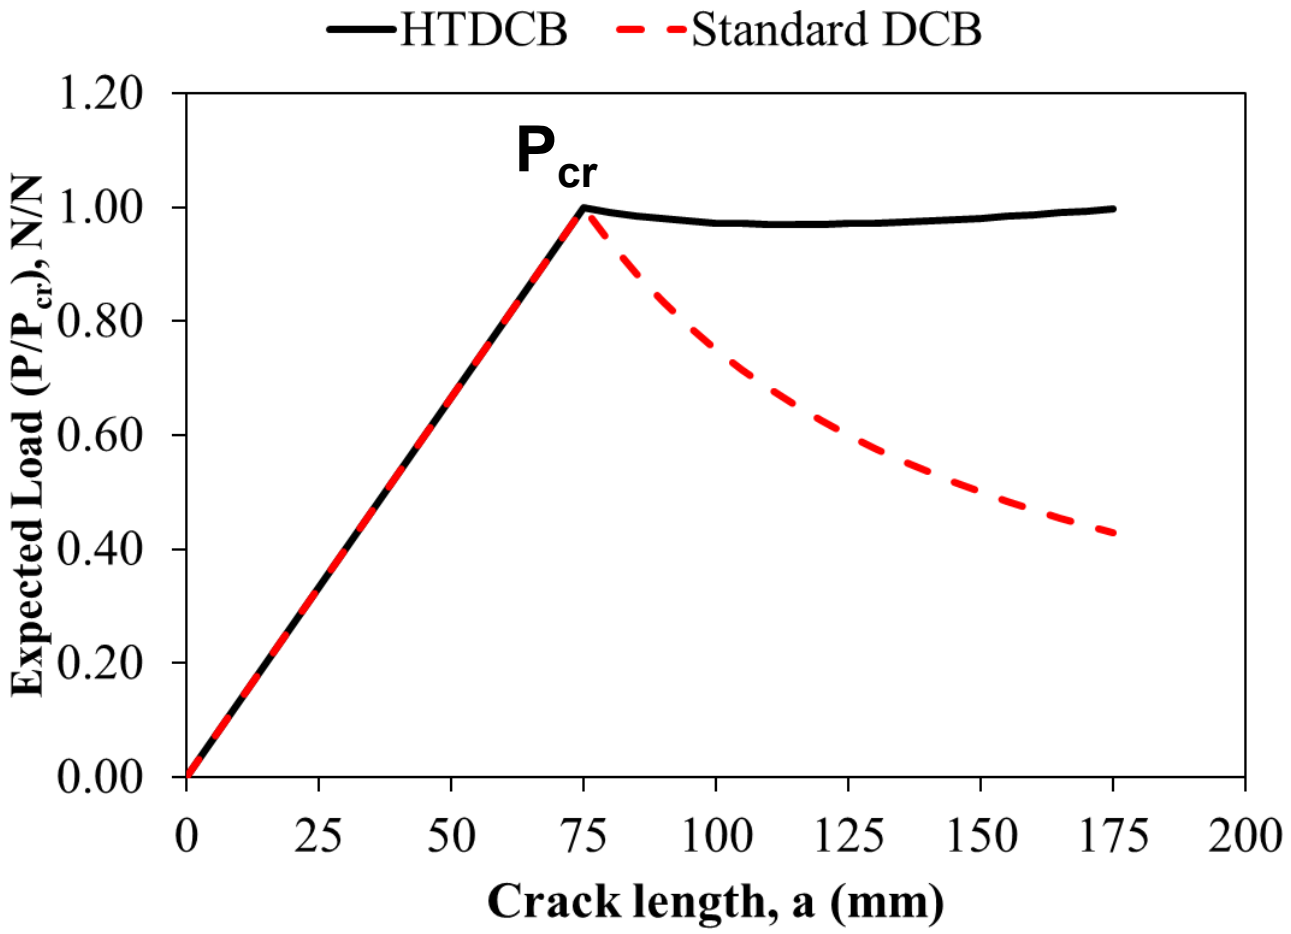
$$SERR, G_I = \frac{12P^2a^2}{Eb^2{h_o}^3(1+k_1a)^3} + \frac{P^2}{k_sGb^2h_o\,(1+k_1a)}$$

$$SERR, G_I = \frac{12P^2a^2}{Eb^2(1+k_2a)^2{h_o}^3(1+k_1a)^3} + \frac{P^2}{k_sGb^2(1+k_2a)^2h_o\,(1+k_1a)}$$

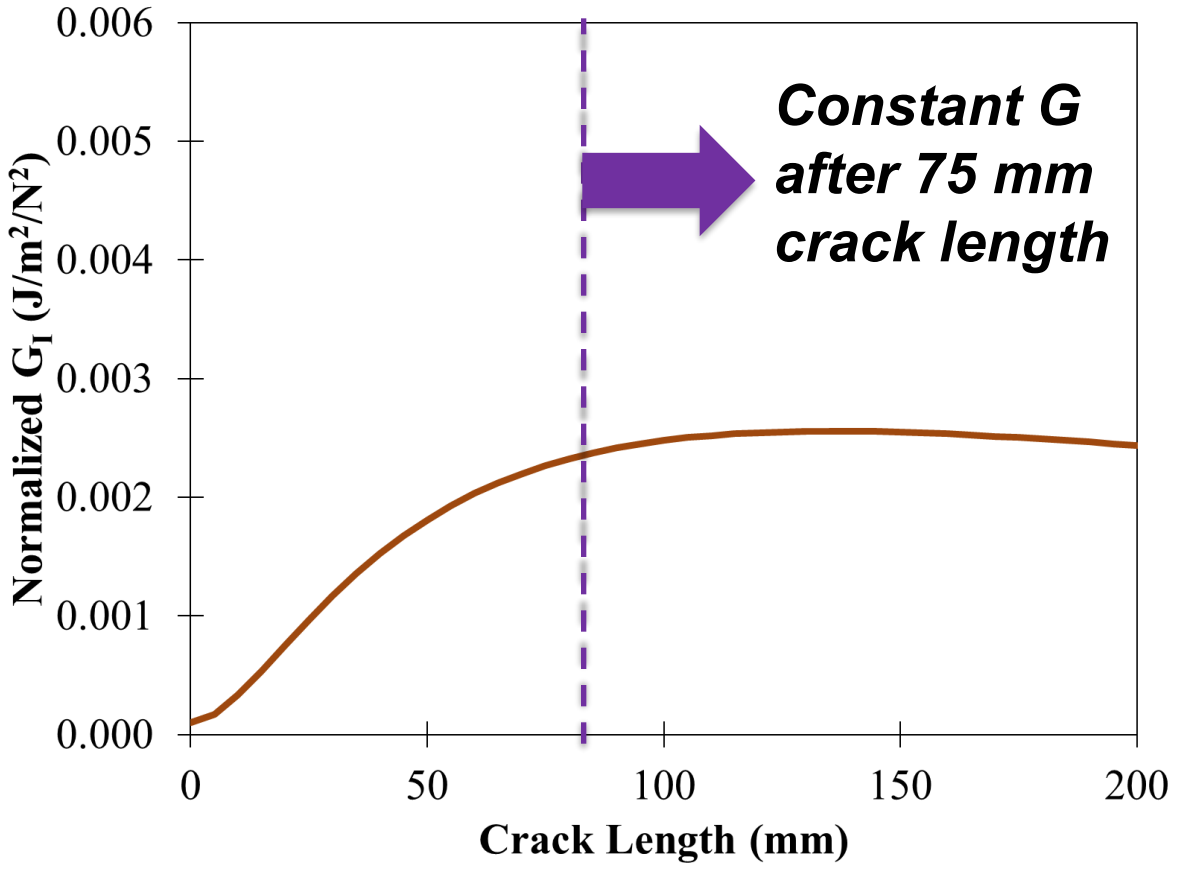
Parametric Study Varying Tapered Angle of HTDCB



- **Parametric analysis** varying the tapered angle (α) from 0° to 10° identified a **5° taper with an initial crack length of 75 mm**

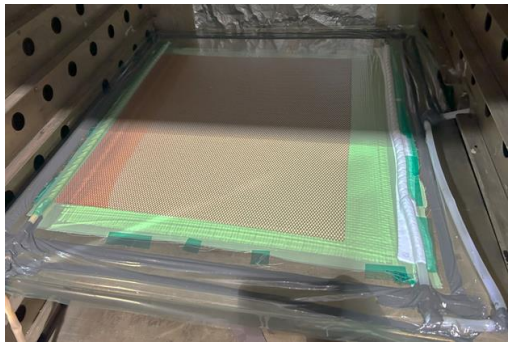


Parametric Study Varying Tapered Angle of WTDCB

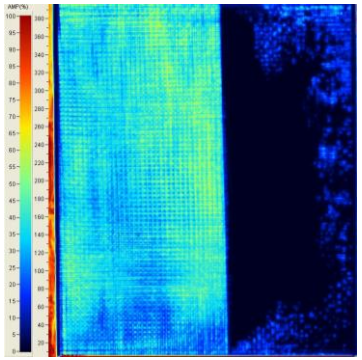


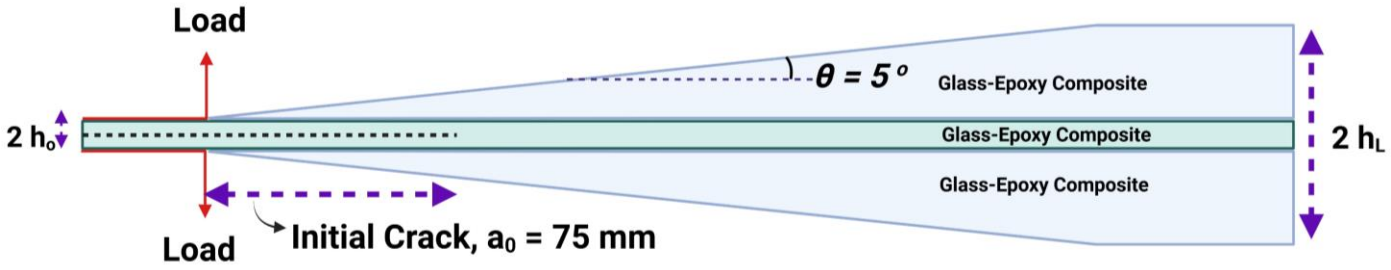
- Performed parametric analysis on Width-Tapered DCB (WTDCB) specimens by varying the taper angle from 0° to 45°
- Found that a taper angle of **at least 45°** is necessary to maintain a constant G with an initial crack length of **~80 mm**
- Such large taper angles lead to a **beam-to-plate transition**, complicating specimen geometry and testing
- Consequently, the **HTDCB configuration** was selected for further investigation

HTDCB Geometry to Maintain Constant ΔG During Mode-I Fatigue Testing



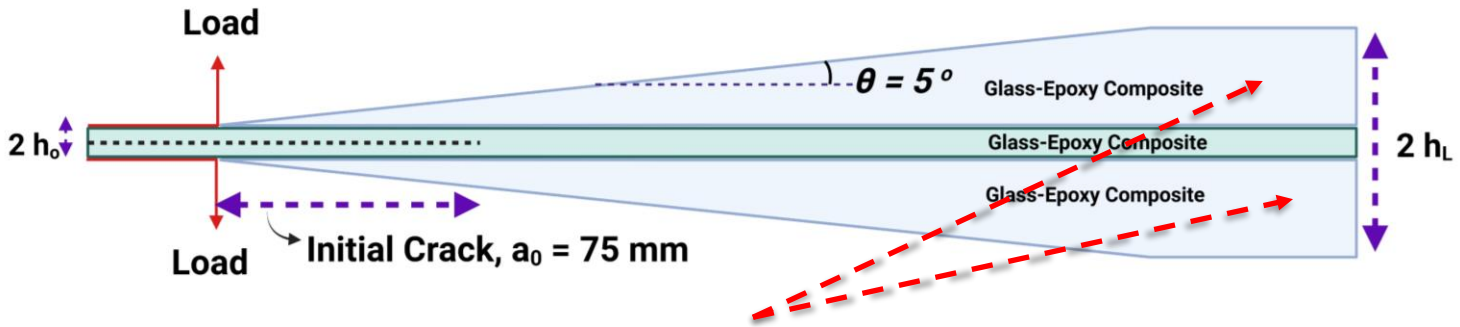
Analytical equation indicates ΔG remains independent of crack growth during fatigue testing

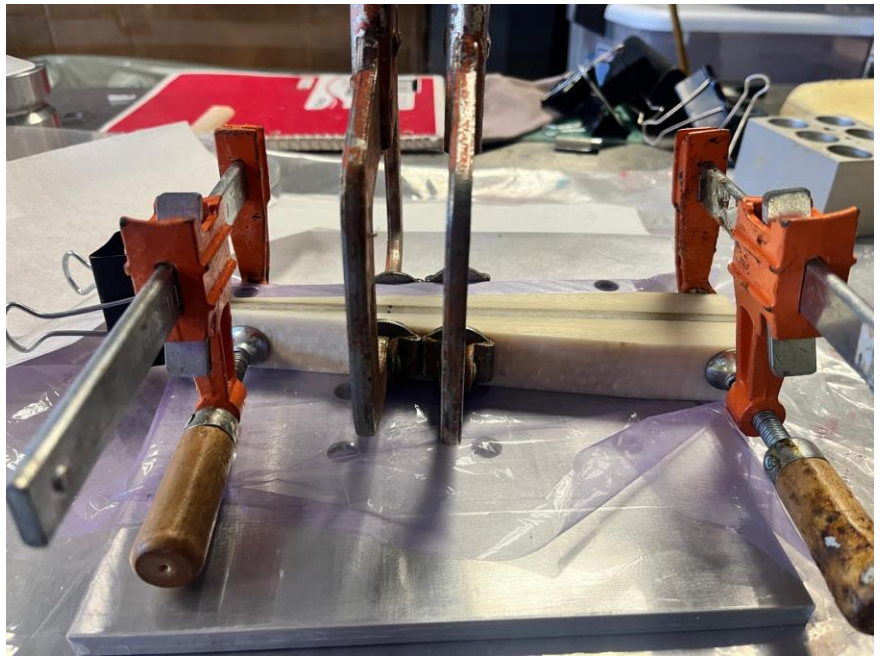




Materials and Methodology

- 463 S-glass Plain Weave Fabric
- RDL-RDC-Epoxy Resin
- Vacuum Assisted Resin Transfer Molding (VARTM) at 60 ℃
- Curing: 80℃ for 2.5 hrs and 121℃ for 4 hrs
- Flexural Modulus: ~ 20 GPa
- Shear Modulus: ~ 2.5 Gpa
- **16-layer PW-RDL-RDC composite** with a pre-crack length of 100 mm at the mid-plane using a Teflon film

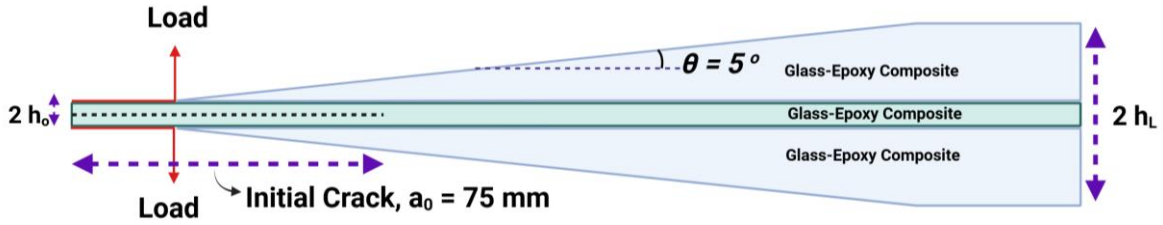


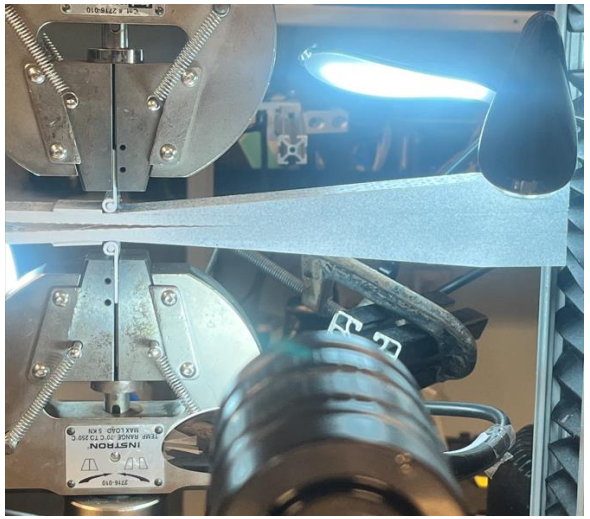


$2h_0 = 10\ mm$ **(Thickness of 16-layer PW-RDL-RDC composite)**

Materials and Methodology

- **24-layer PW-RDL-RDC** composite used to fabricate the tapered geometry
- Tapered section machined from a 19 mm-thick panel using CNC milling or waterjet cutting
- Bonded to the pre-cracked composite panel using LOCTITE EA 9309.3NA AERO epoxy adhesive
- Final cure performed at 80 ℃ for 2 hours



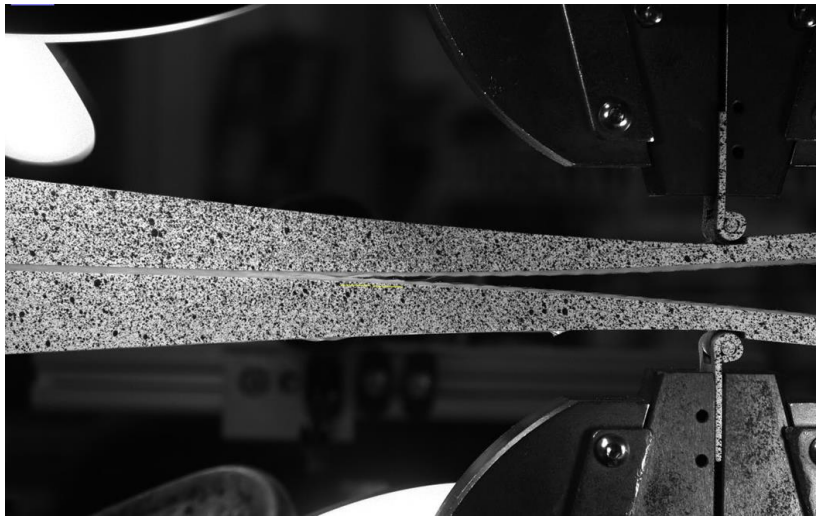


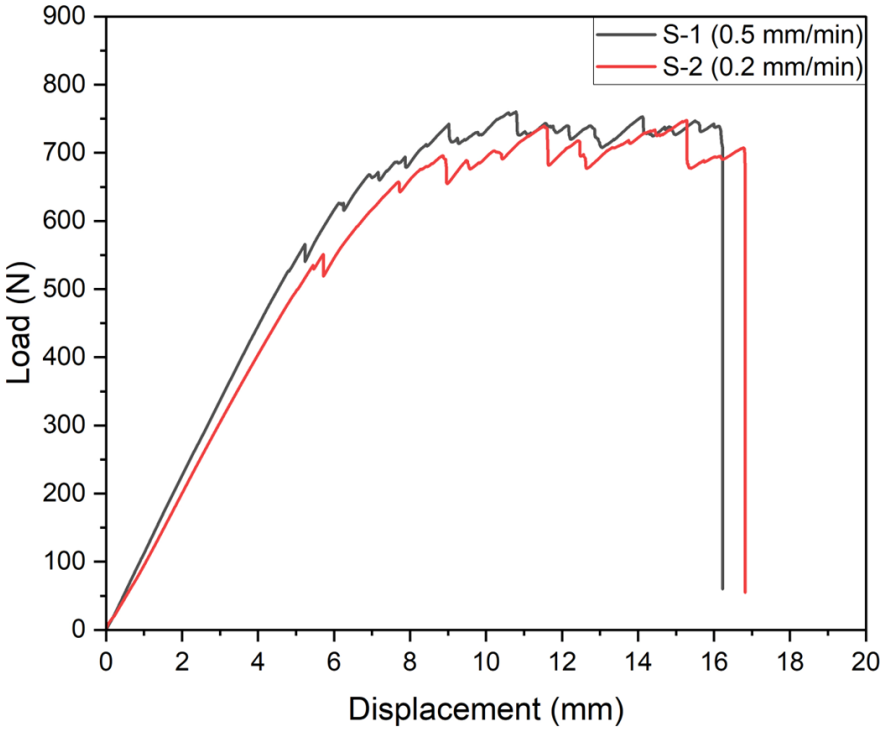
Tapered sections bonded symmetrically on top and bottom of the pre-cracked panel

Fixture used for bonding the tapered section to the composite panel

HTDCB Quasi-Static Testing

HTDCB Test Setup





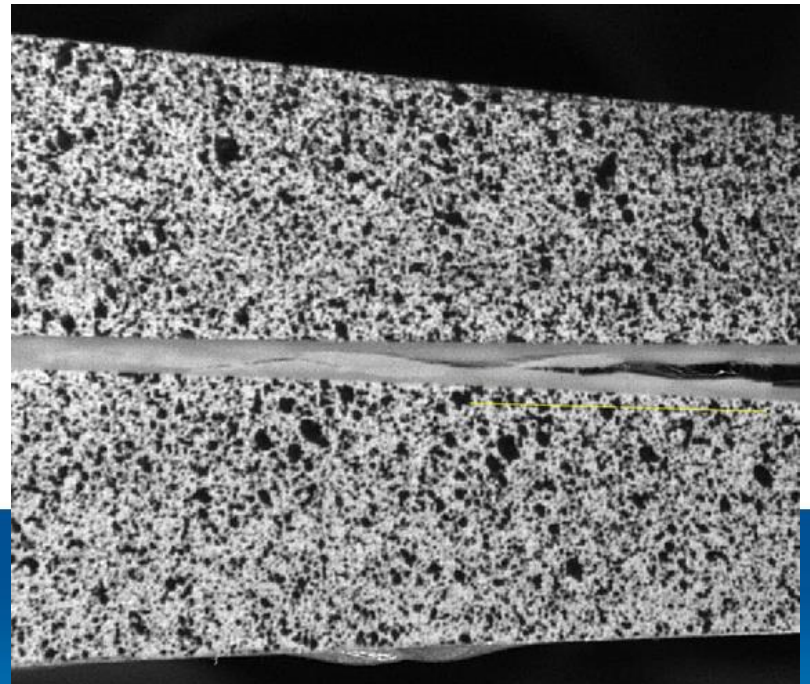


Image processing software, Fiji ImageJ, used to measure the crack propagation distance

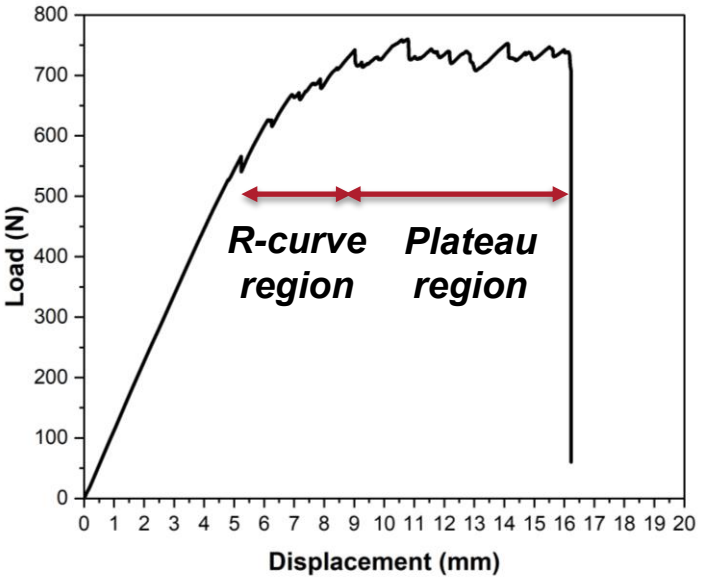
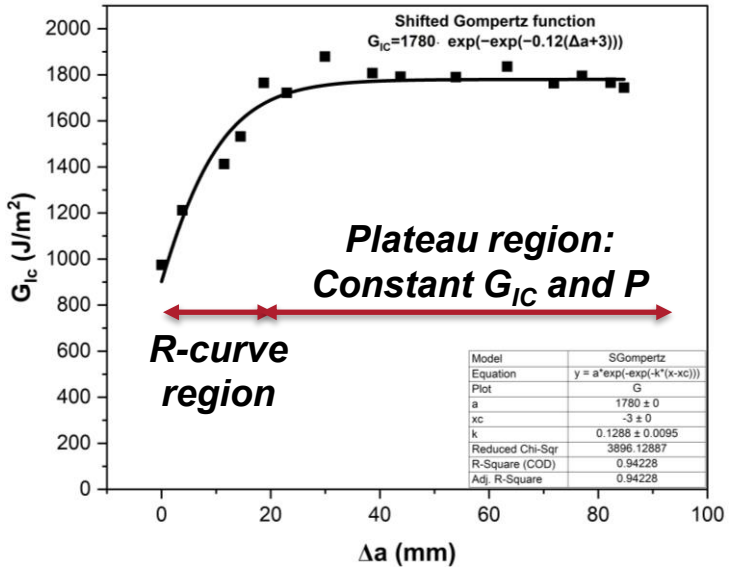
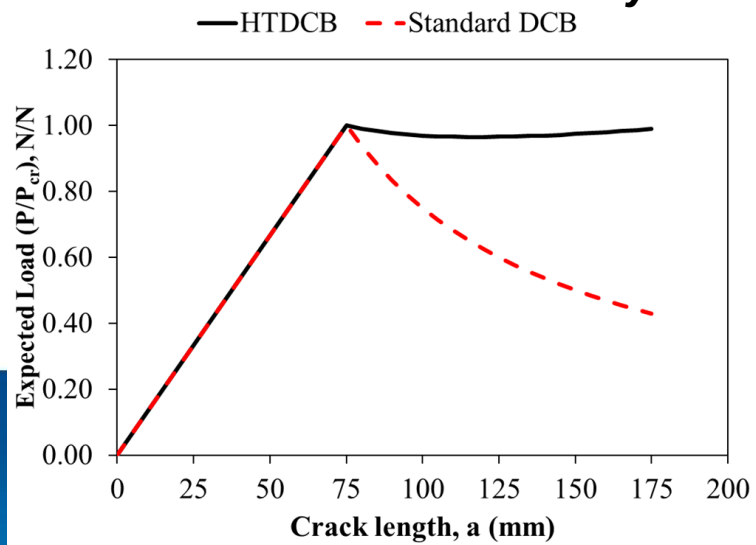


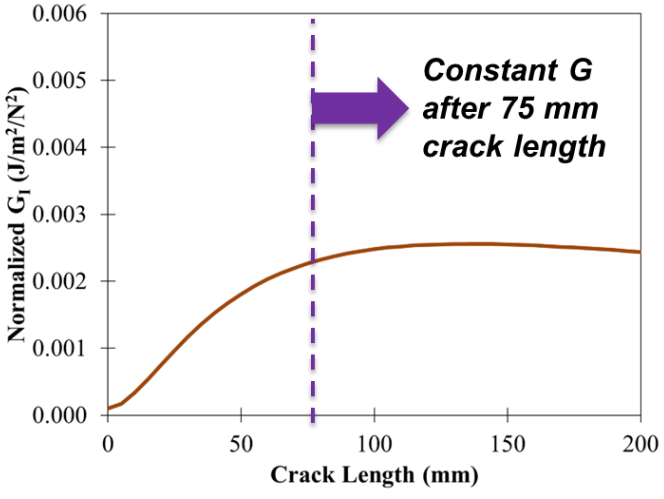
- Quasi-static tests were conducted at two displacement rates (**0.2 mm/min and 0.5 mm/min**) to assess rate effects.
- No rate dependence was observed within this range.



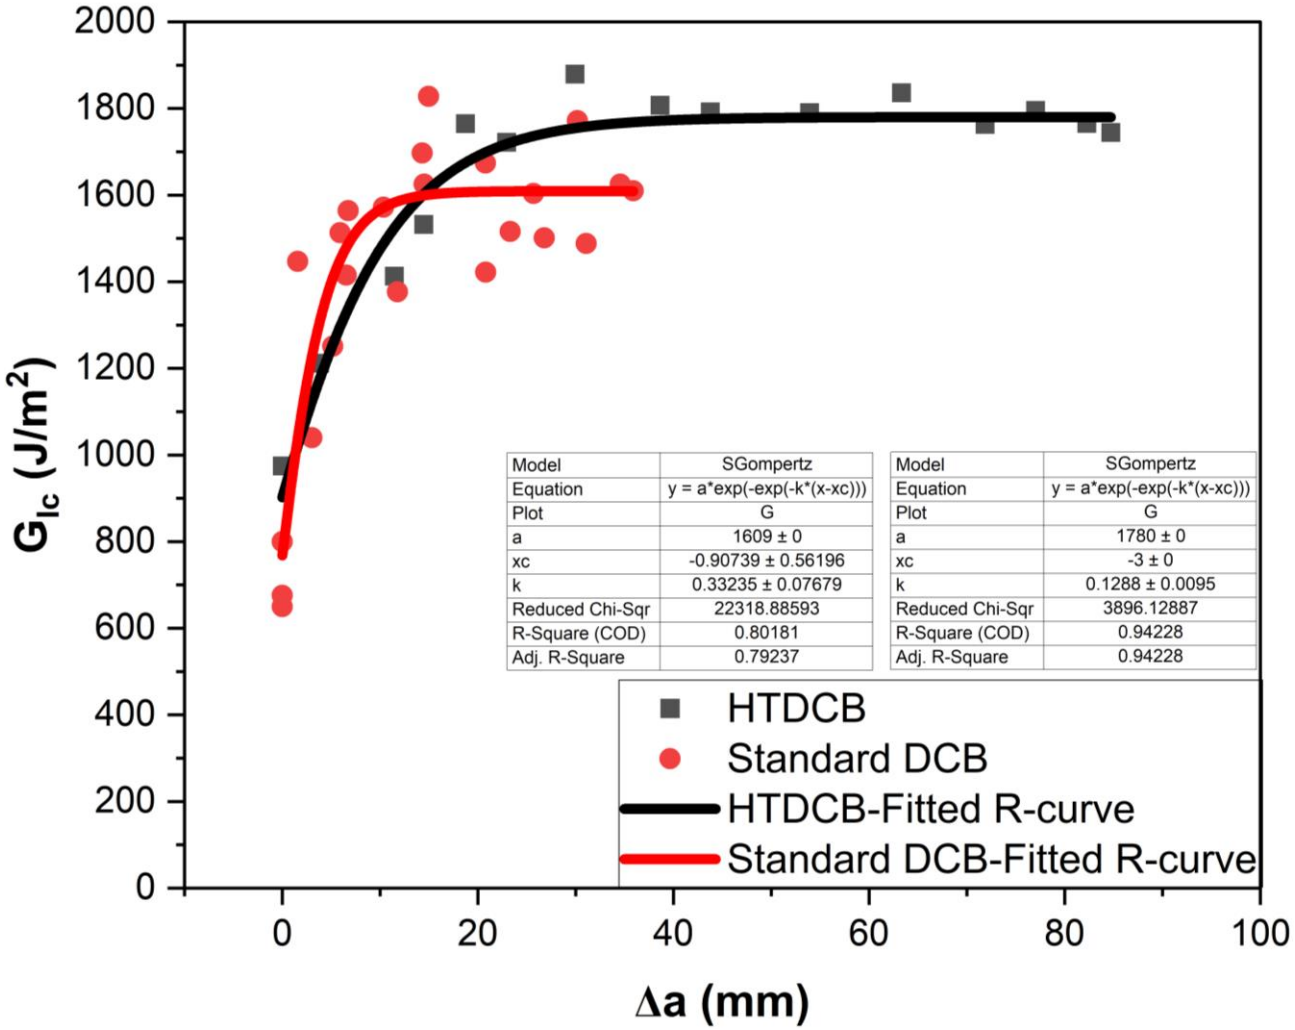
HTDCB Quasi-Static Test Result

- **Load increases** during the **initial ~20 mm** of crack growth, indicating **R-curve behavior**.
- **Load stabilizes** once fracture toughness reaches the **plateau region**.
- Design equation was developed assuming **constant fracture toughness**.
- R-curve behavior attributed to mechanisms such as **fiber bridging, tow-to-tow delamination, and secondary cracking**.





Experimental Results



Analytical Prediction

HTDCB vs Standard DCB Quasi-Static Test Result

- Fracture toughness (G_{IC}) vs crack growth (Δa) compared
- HTDCB demonstrated **R-curve behavior comparable** to Standard DCB tests for the PW-RDL-RDC composites
- Welch's t-test on **$G_{Plateau}$ values**
- p-value: 0.57
- p-value > 0.05, **no statistically significant difference** in the mean fracture toughness at the 95% confidence level

Model	SGompertz

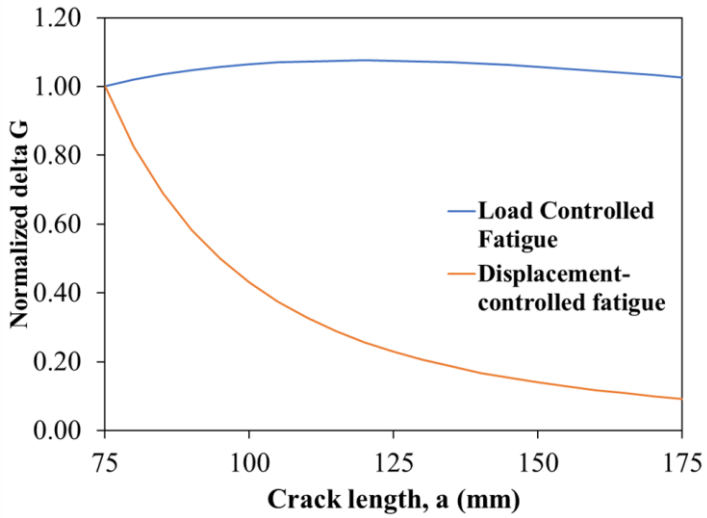
Fatigue Testing of HTDCB

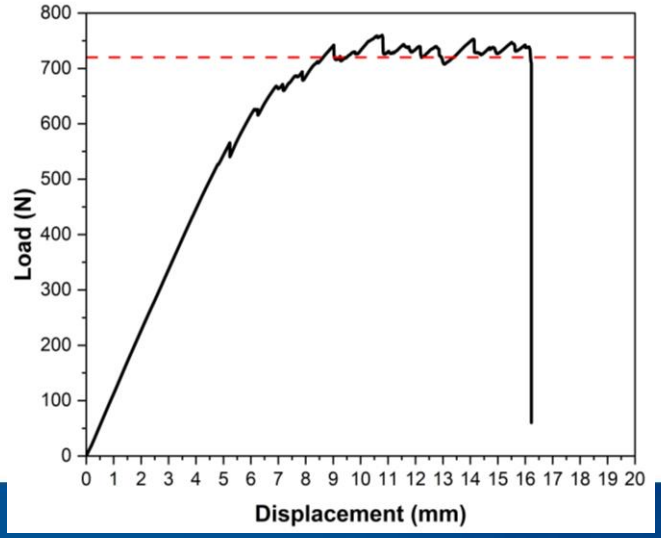
Loading-controlled vs Displacement-controlled Fatigue



Fracture toughness equation for HTDCB

"Simplied Version",

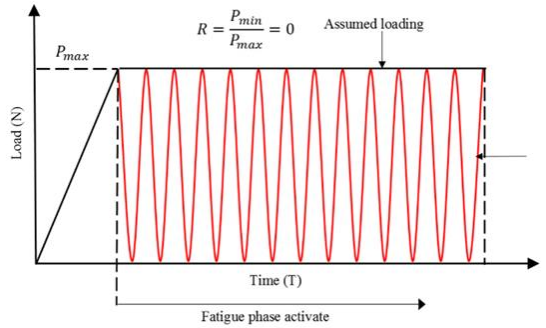
Load-controlled fatigue ⇒ $$G_I = \frac{12\,P^2\,a^2}{E\,h_o^3\,(1+ka)^3\,b^2} + \frac{P^2}{k_s\,G\,h_o\,(1+ka)\,b^2}$$



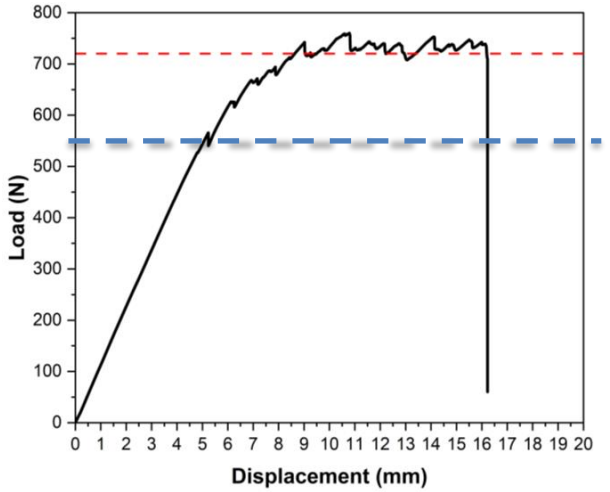
Compliance, $C = \frac{\delta}{P}$

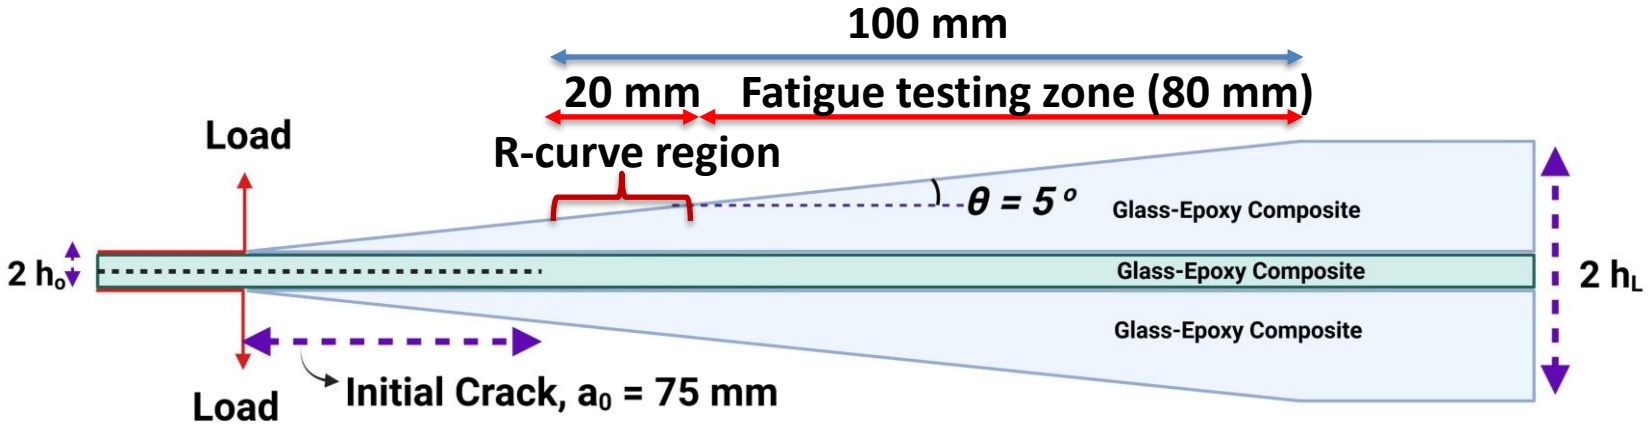
Displacement-controlled fatigue ⇒ $$G_I = \frac{12\left(\frac{\delta}{C}\right)^2 a^2}{E\,h_o^3\,(1+ka)^3\,b^2} + \frac{\left(\frac{\delta}{C}\right)^2}{k_s\,G\,h_o\,(1+ka)\,b^2}$$

1. To be conservative, **90% $G_{plateau}$**
2. **A-basis allowable** = Mean of plateau load – 3 * Standard deviation = **720 N**



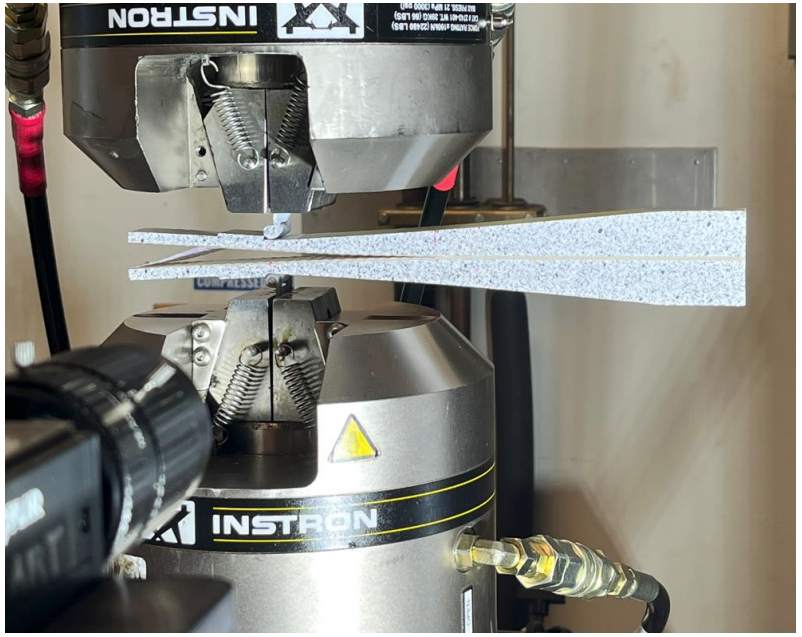
P_{max}	720 N	δ_{max}	8.0 mm
P_{min}	72 N	δ_{min}	0.8 mm



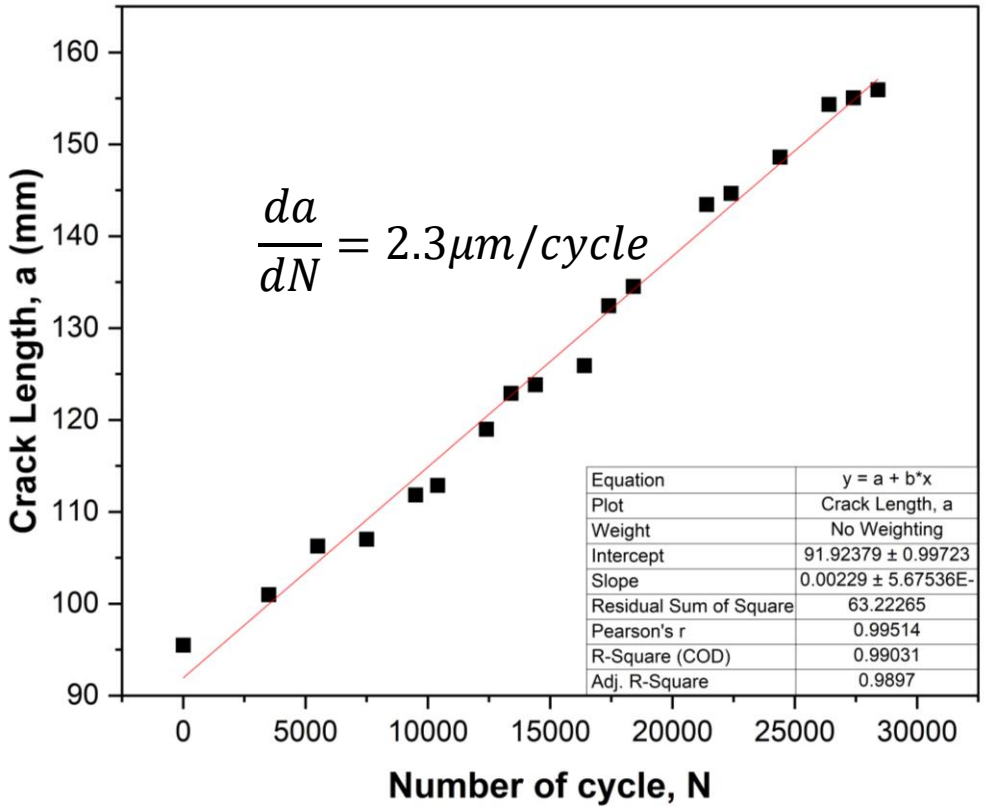


- **ΔG remains constant** under **load-controlled fatigue**, whereas it **decreases** progressively under **displacement-controlled fatigue**.
- HTDCB **fatigue testing** should be conducted under **force control** to maintain a constant ΔG during crack growth.

HTDCB Fatigue Testing: Proof of Concept



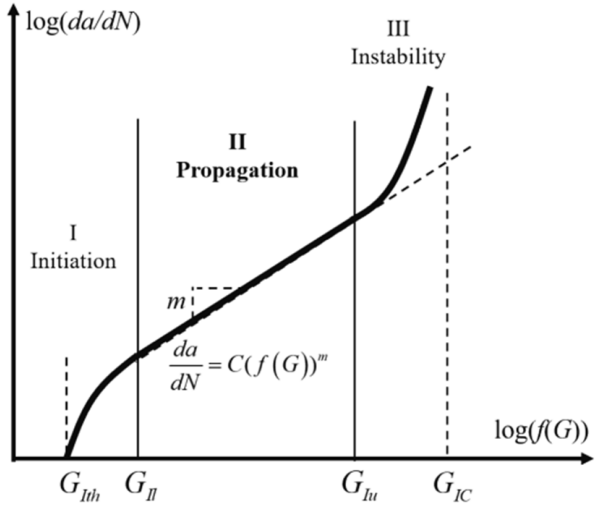
- Load-controlled fatigue
- Load ranges: 55 N to 550 N
- Fatigue frequency = 1 Hz
- delta $G/G_{plateau}$ = 65%
- *65% of $G_{plateau}$ (A basis allowable) = 1080 J/m^2*
- Crack was propagated quasi-statically until the crack tip reached the plateau region



HTDCB Fatigue Testing: Proof of Concept

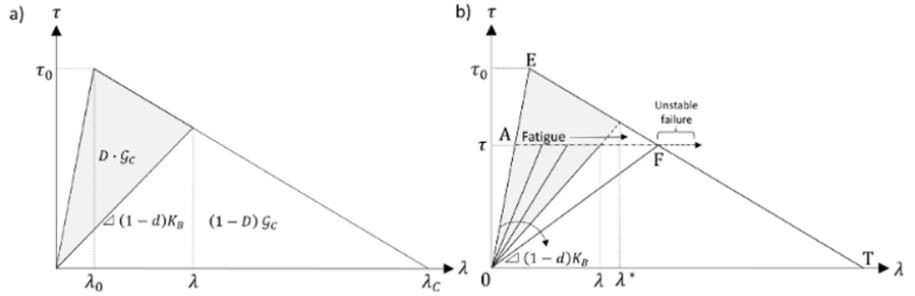
Mode-I Fatigue Test Instrumentation

- Stable fatigue crack growth



Conclusion

- **Deflection and compliance equations** were derived using **Timoshenko Beam Theory**, incorporating both **flexural and shear effects**.
- **LEFM-based SERR equation (G)** was derived and validated against ASTM D3433-99 for metal joints.
- **Parametric analysis** identified a **5° taper angle with a 75 mm** initial crack length as optimal among the 0°–10° range.
- Quasi-static testing of HTDCB showed **R-curve behavior** comparable to Standard DCB for PW-RDL-RDC composites.
- **Load increased** during the **R-curve region** and **plateaued** after reaching **stable fracture toughness**.
- R-curve behavior resulted from mechanisms including **fiber bridging, tow-to-tow delamination, and secondary cracking**.
- **Stable fatigue crack growth** was achieved at 65% of G_{IC}
- HTDCB configuration ensured **ΔG remains independent of crack growth** during fatigue testing.



Ongoing Work

- Establish a Fatigue Delamination Model for Mode I Fatigue of Plain Weave S-glass Epoxy
- Growth of delamination damage in composite laminates is conventionally described by a Paris-law type of relation given below:

$$\frac{da}{dN} = C\left(\frac{\Delta G}{G_C(a)}\right)^m$$

- Validation of Fatigue Delamination Model using Standard DCB Specimen
- Establish a Cohesive Zone Model (CZM) based on Fatigue Delamination Model (or Paris Law) for Mode I Fatigue of Plain Weave S-glass Epoxy Composite
- This approach can potentially be applied for characterizing Mode II and mixed-mode (I/II) fatigue delamination behavior

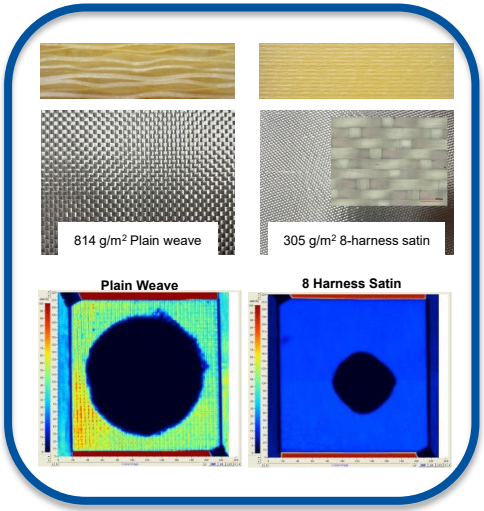
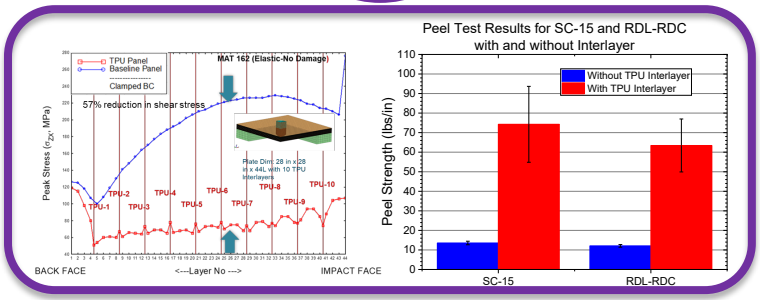
Design Goal	Attribute	Design Outcome
Durability	Resistance to Damage	High Delamination Resistance
Damage Tolerance	Retention of Functional Performance after Damage	High Retention of Original Stiffness after Impact Damage



Impact Damage Energy Absorption



Improving Energy Dissipation

Objective

Improve durability and damage tolerance GFRP

Improve durability and damage tolerance protective-structural parts against low velocity impact (LVI)

Role of fracture toughness

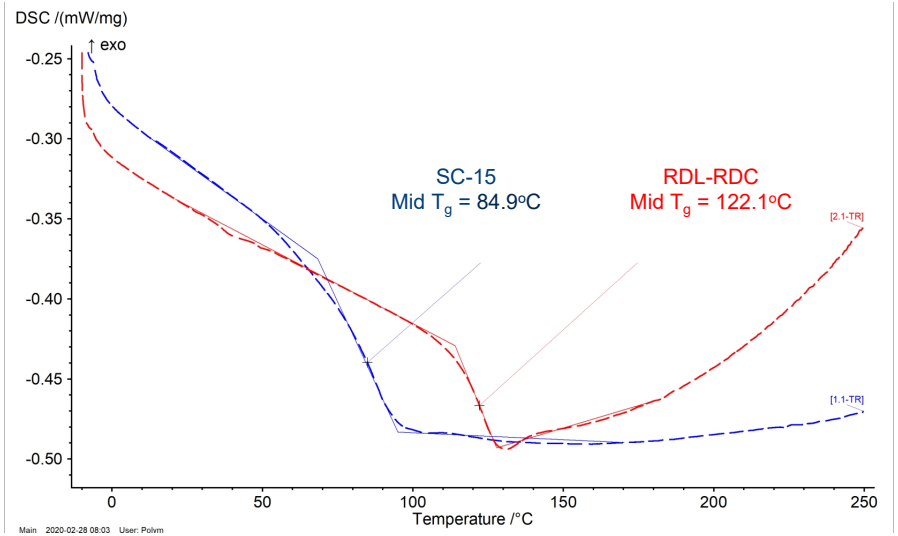
Understand the role of fracture toughness on the LVI performance

Role of fabric architecture

Understand the role of fabric architecture and nesting on fracture toughness and impact performance

Role of sizing and fiber/matrix interface

Understand the role of fiber/matrix interface on fracture toughness and impact performance



Material Systems: Resin Systems

SC-15 Epoxy (Baseline)

- Long standing baseline, being replaced due to issues with high temperature performance (T_g = 85°C)
- Two part infusible toughened epoxy resin system

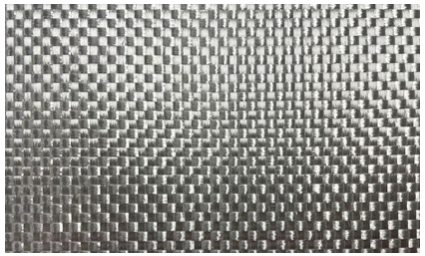
RDL-RDC Epoxy

- SC-15 replacement by Huntsman with superior high temperature performance (T_g = 122°C)
- Similar to SC-15, an infusible two part toughened
- Similar or better mechanical strengths with S-2 Glass

The Army's wet T_g requirement requires a change in the matrix system

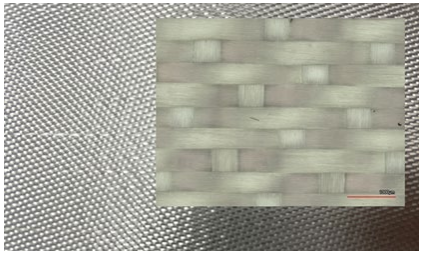
Material System: Fabric Architecture

S-2 Glass



- High strength aluminosilicate glass used for protective-structural applications in the US Army vehicles

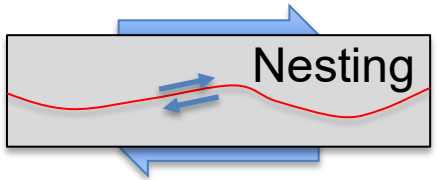
Fabric Weave Architecture



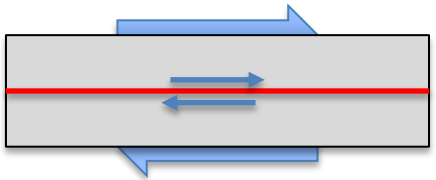
- Coarse plain weave historically used for protective-structural
- A light weight 8-harness satin weave, approximately 37% areal weight of the plain weave

Sizing

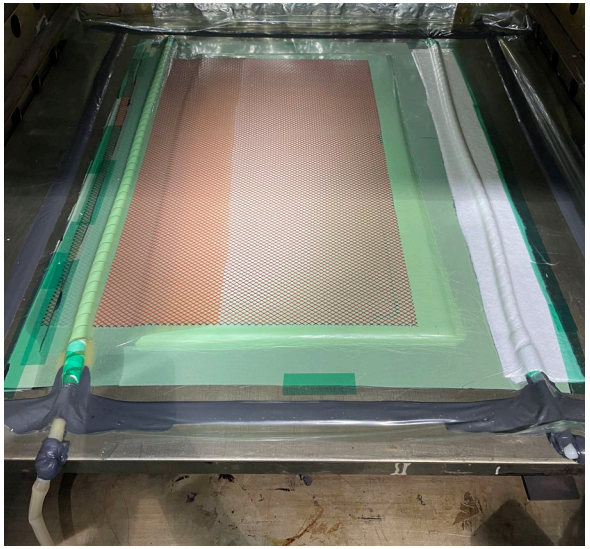
- 463 sizing system historically used for this application
- 933 sizing marketed as a damage tolerant sizing system



814 g/m^2 Plain weave
8 plies for a 5 mm thick sample



305 g/m^2 8-harness satin
20 plies for a 5 mm thick sample



Material System Combinations Evaluated

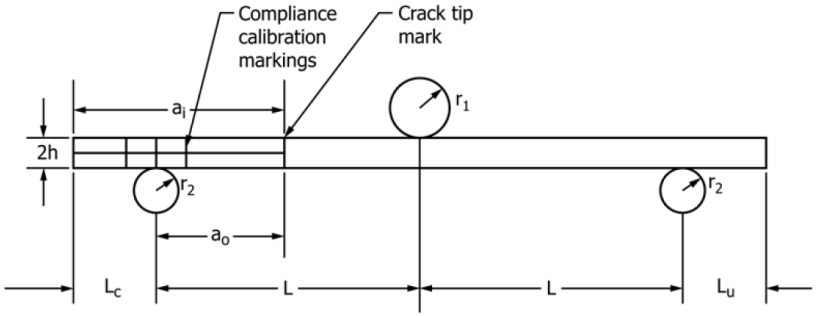
Sample Fabrication

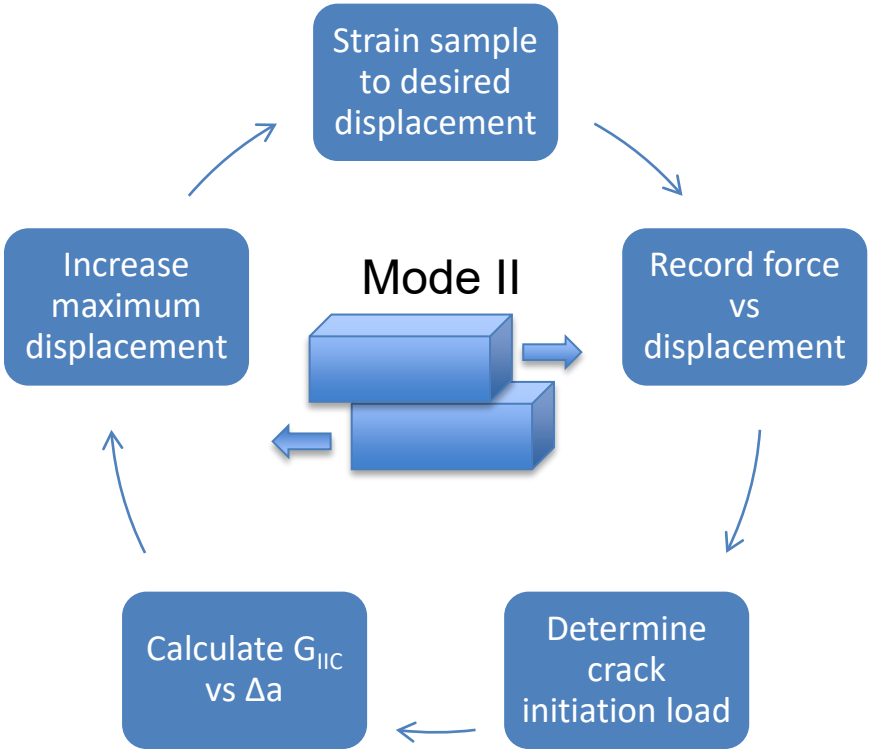
System Combinations

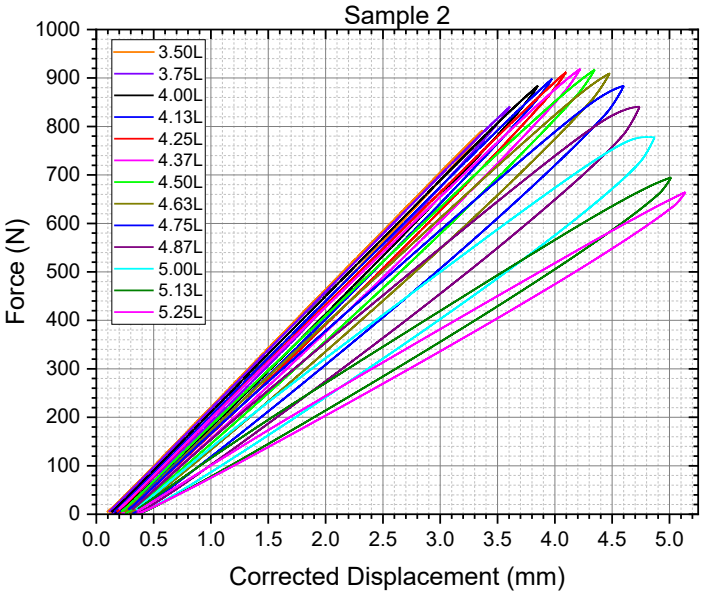
	Plain Weave (24 oz/yd^2)	8-Harness Satin (9 oz/yd^2)
AGY 463 Sizing	SC-15 and RDL-RDC	N/A
AGY 933 Sizing	SC-15 and RDL-RDC	SC-15 and RDL-RDC

Evaluating Mode II Fracture Toughness

End Notched Flexure (ENF) Test







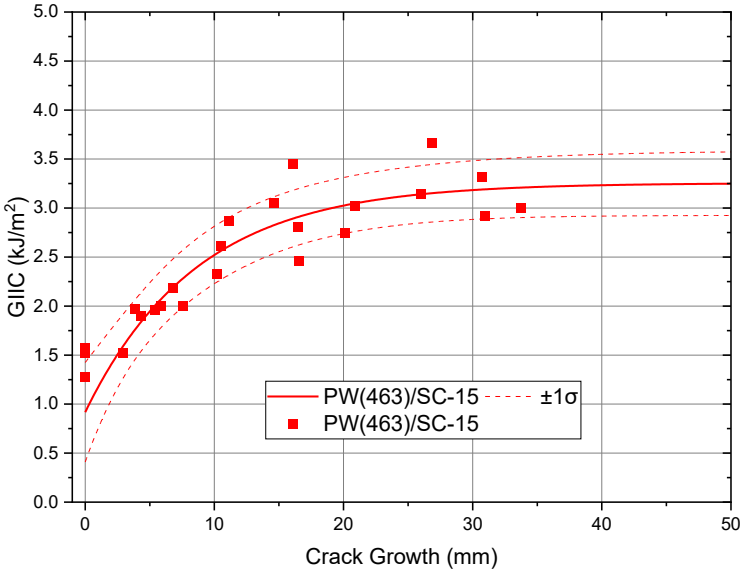


FIG. 2 ENF Specimen, Fixture, and Dimensions

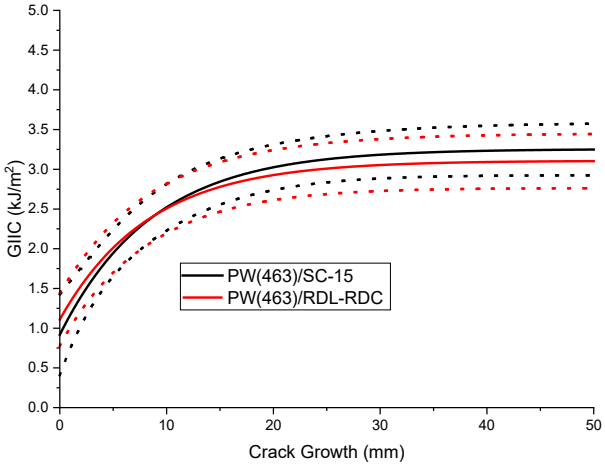
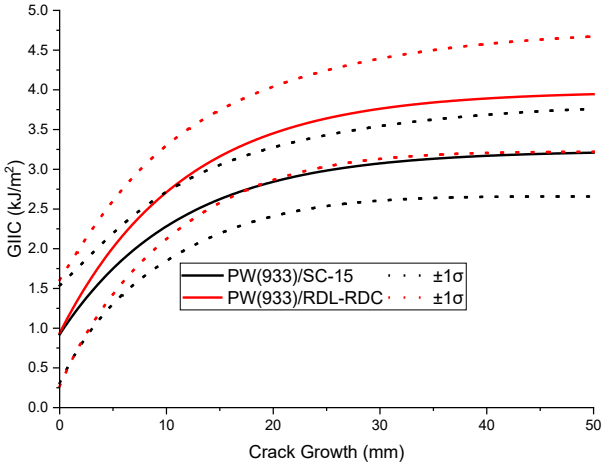
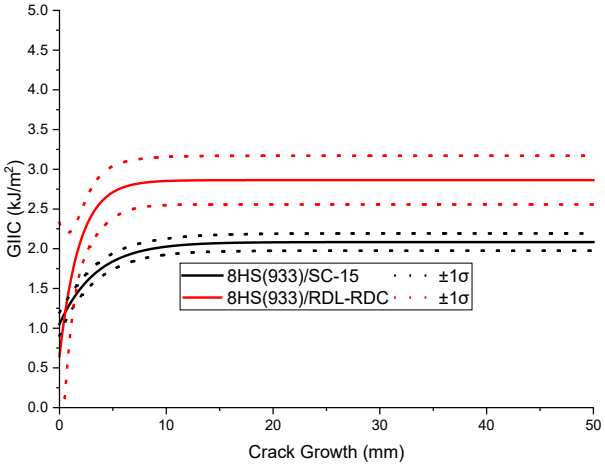
$$G_{IIC}^{SH} = \frac{9P^2a^2}{16E_f w^2 h^3}\left(1 + 0.2\left(\frac{E_f}{G_{13}}\right)\left(\frac{h}{a}\right)^2\right)$$



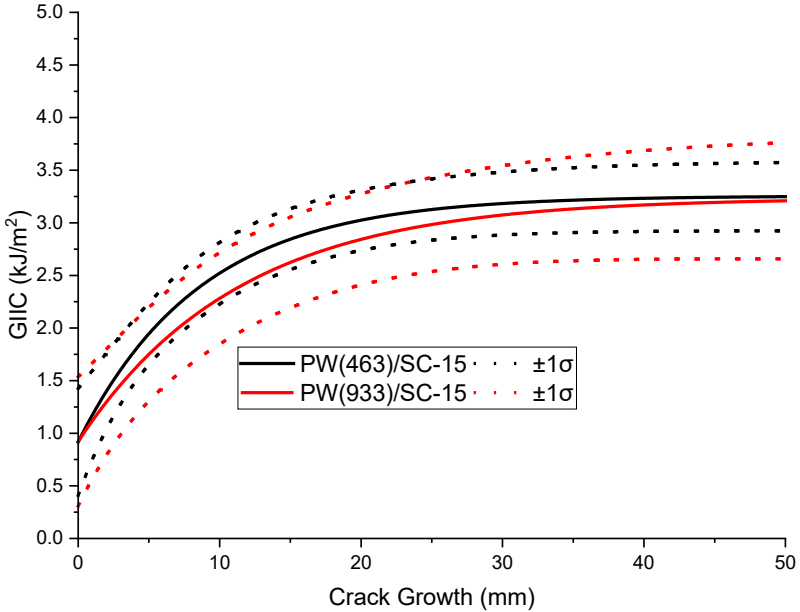
ENF Testing

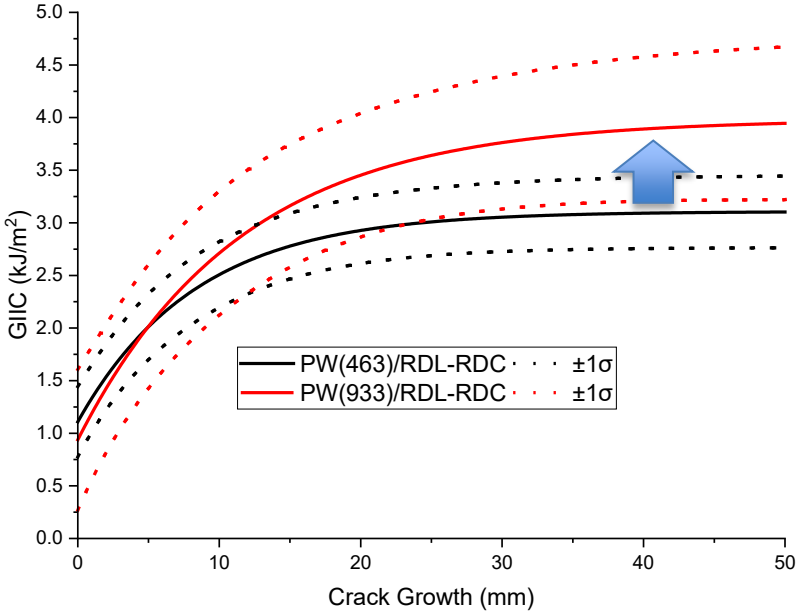




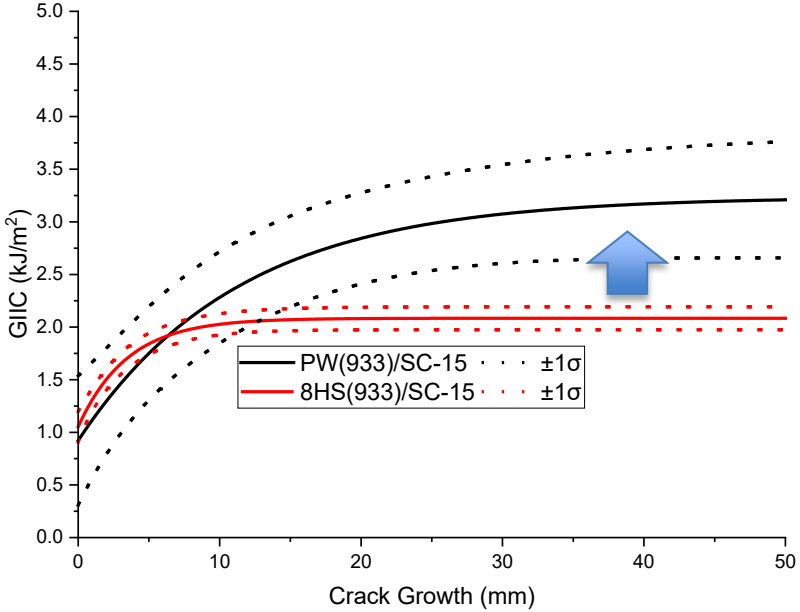
$$G_{IIC}^{SH} = \frac{9P^2a^2}{16E_f w^2 h^3}\left(1 + 0.2\left(\frac{E_f}{G_{13}}\right)\left(\frac{h}{a}\right)^2\right)$$

Effect of the Resin

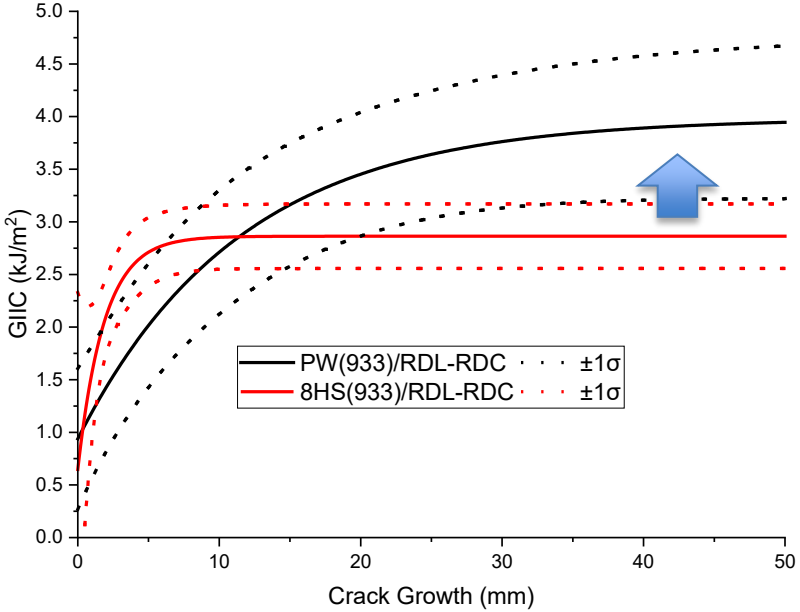




PW(463) shows resin insensitivity, while RDL-RDC shows improved fracture toughness over SC-15 with 933 sizing; however, the plain weave architecture seems to be creating a larger spread in the data



Effect of the Fiber Sizing



SC-15 shows sizing insensitivity while RDL-RDC seems to show a modest increase in fracture toughness due to the sizing

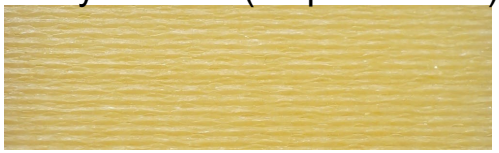
Effect of the Fabric Architecture

The fabric architecture shows an increase in fracture toughness due to the nesting, requiring more energy to fracture

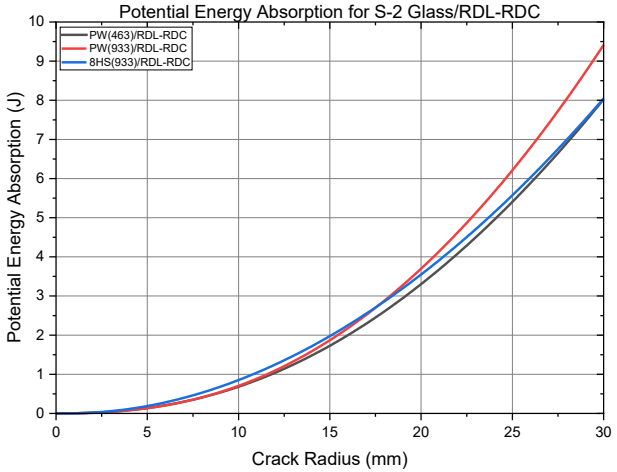
Higher Fracture Toughness vs Increasing Interfaces

24 oz/yd^2 PW

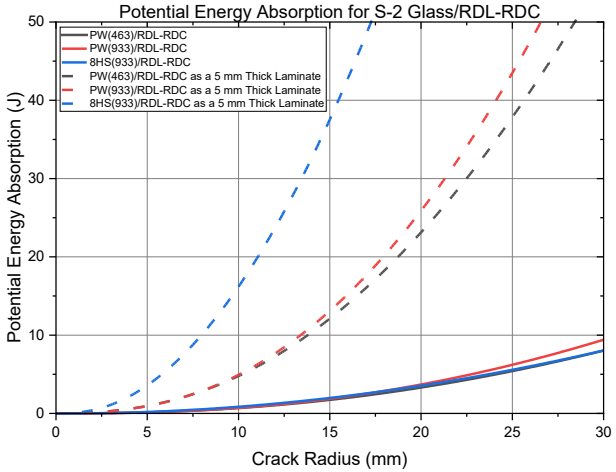
- Higher fracture toughness at larger crack lengths
- Mechanical interlocking of tows for increased energy absorption through



9 oz/yd^2 8HS

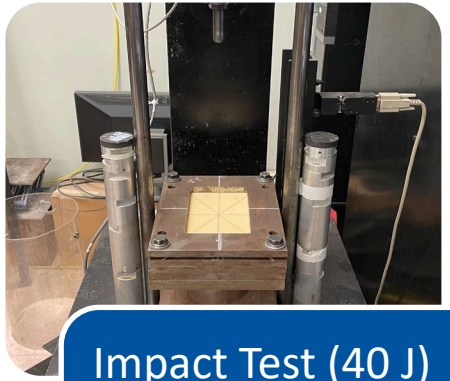


- x2.7 more interlaminar interfaces to potentially fracture

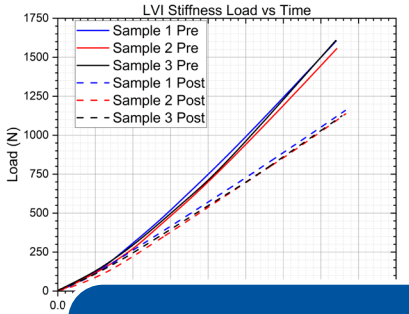


24 oz/yd^2 Plain Weave (8 plies/5 mm)

9 oz/yd2 8-HS (20 plies/5 mm)



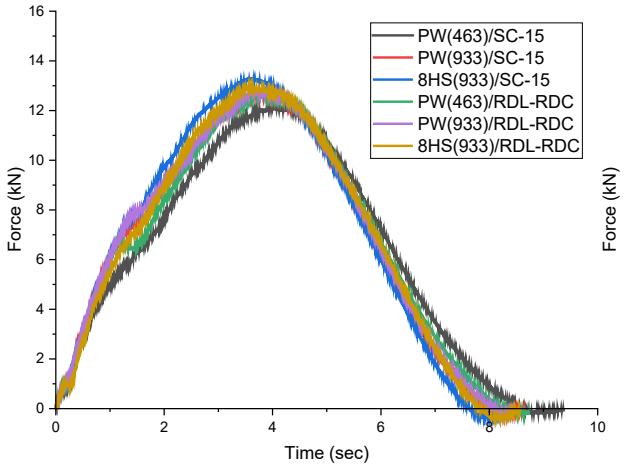
Low Velocity Impact Test



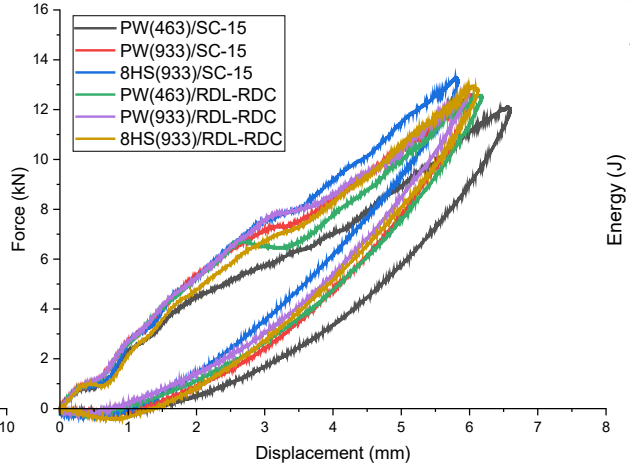
Initial Stiffness

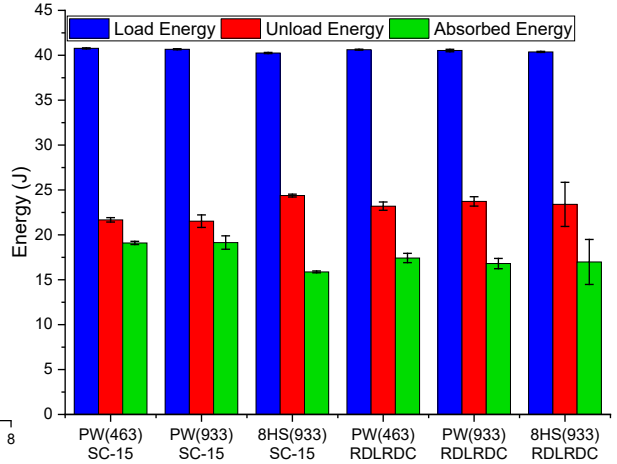
- Bolts tighten to 75 lbf-in
- Loaded to 0.8 mm
- Subtract machine compliance

Impact Test (40 J)



- Mass: 13.7 kg
- Height: 0.3 m
- Velocity: 2.4 m/s
- Impactor Geometry: 12 mm hemispherical tup

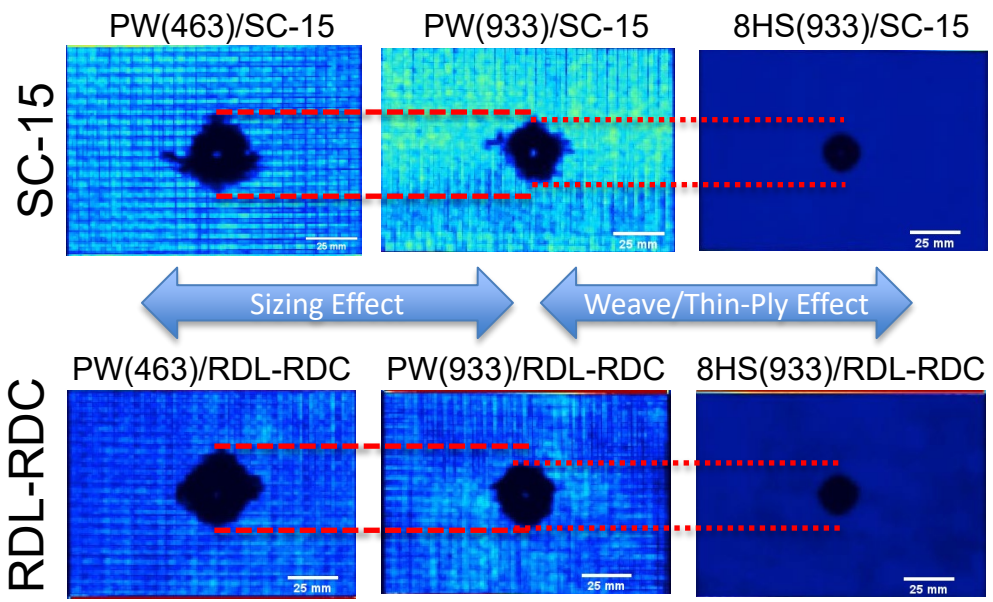


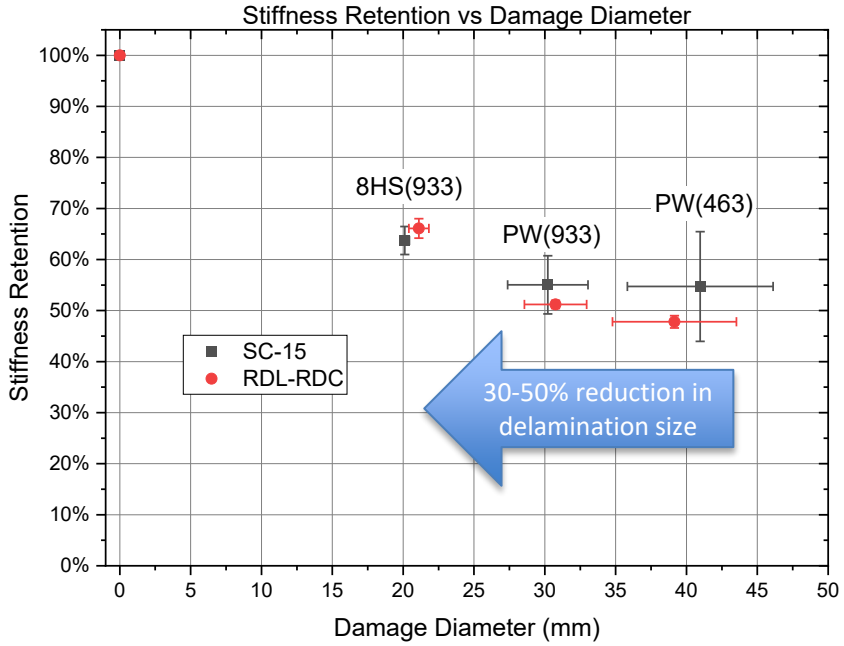


Post Impact Stiffness

- Bolts tighten to 75 lbf-in
- Loaded to 0.8 mm
- Subtract machine compliance

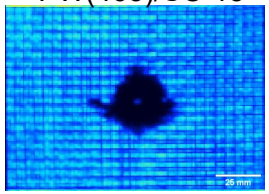
LVI Impact Energy

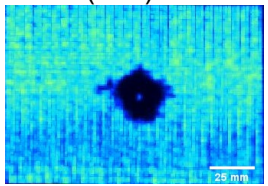




- The force vs time and displacement show similar responses
- The absorbed energy shows RDL-RDC generally absorbs less energy, thus less damage is expected

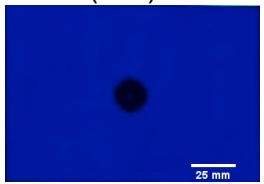
LVI Damage and Property Retention



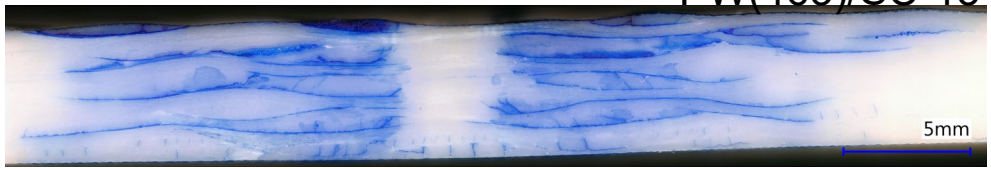


S-2 Glass/SC-15 LVI Samples Sectioned

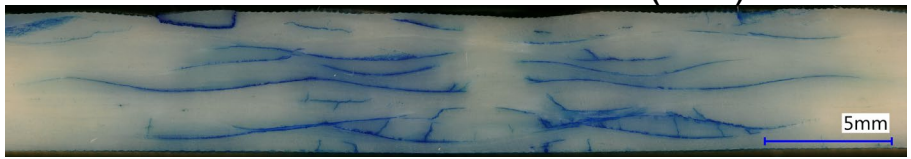
- PW shows ~7 primary cracks
- Crack branching and tow cracking observed
- 8HS shows only nine interlaminar interface fractures (19 interfaces are present) and some back face damage due to tension failure



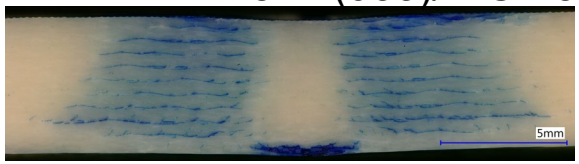
PW(463)/SC-15



PW(933)/SC-15

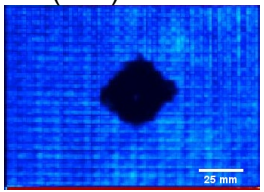


8HS(933)/SC-15

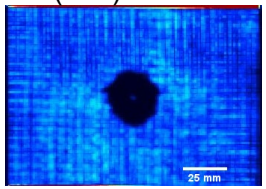


PW(463)/SC-15

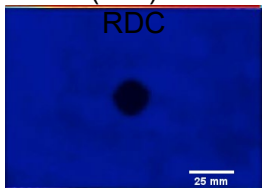
PW(933)/ SC-15



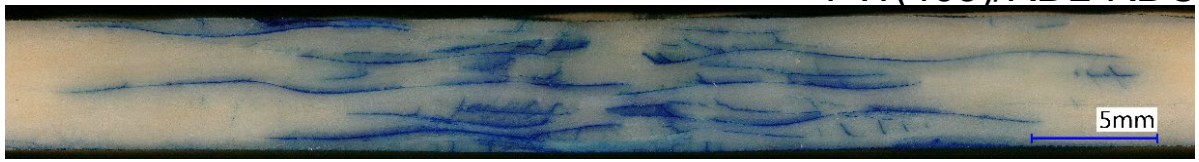
8HS(933)/ SC-15



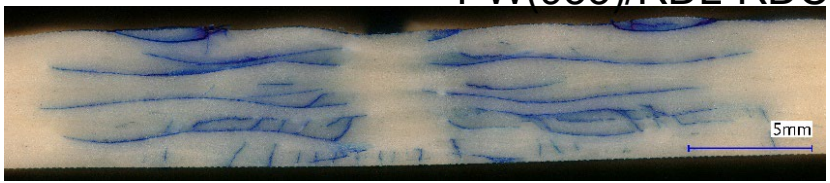
S-2 Glass/RDL-RDC LVI Samples Sectioned



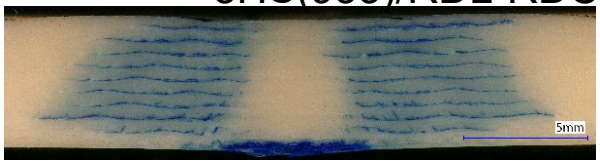
PW(463)/RDL-RDC



PW(933)/RDL-RDC

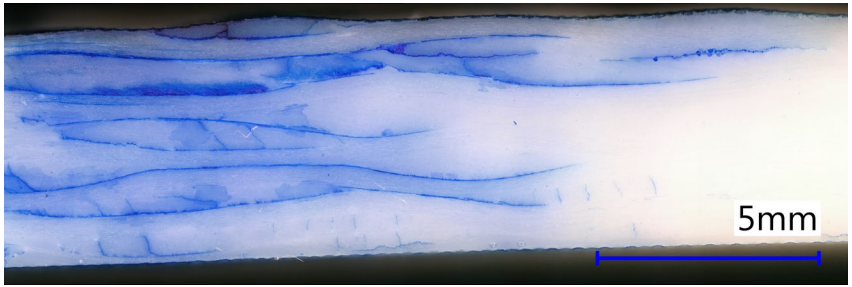


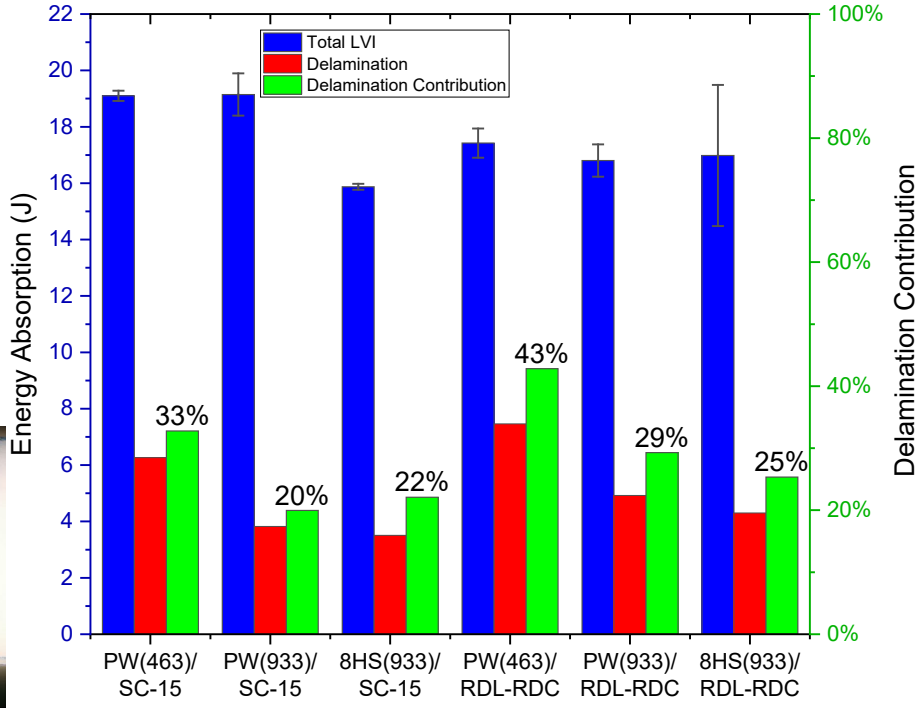
8HS(933)/RDL-RDC



PW(463)/RDL-RDC

PW(933)/RDL-RDC





8HS(933)/RDL-RDC

Main Crack Measurements and Analysis

- Energy absorption from the primary crack only captures <50% of the absorbed energy
- The effects of tow cracking, crack branching, fiber breaking, strain rate effects, and other damage modes are unaccounted for

Key Findings on

Fracture Toughness

- Sizing alone shows a slight improvement in mode II fracture toughness for one of the epoxy systems
- The fabric architecture and mechanical interlocking due to fabric nesting show significant contributions to fracture toughness

Damage Tolerance and Durability

- Modest increases in fracture toughness show a reduction in damage
- Increasing interlaminar interfaces reduces the damage area more significantly than the increase in fracture toughness

Key Findings on

- Evaluation of the sectioned laminates shows that the main interlaminar cracks account for less than half of the energy absorbed; further evaluation is necessary to determine other sources of energy absorption
  - Tow cracking, crack branching, fiber breaking, etc
- 8HS(933)/RDL-RDC showed a 50% reduction in delamination diameter, indicating improvement in durability and more than 33% improvement in damage tolerance while meeting the wet T_g requirements previously not met by the PW(463)/SC-15 system

Path Forward

- Improved fracture area analysis needs to be developed for a better understanding of the damage extent
- The strain-rate effect on the fracture toughness of these systems needs to be understood to capture the fracture energy release rates better for an LVI event
- Fracture surface analysis to understand the damage mode and compare to the ENF testing to gain insights into some key differences in damage evolution and identify potential mechanisms not captured in ENF present in LVI experiments
- Incorporation of a compliant thermoplastic interlayer may be able to absorb and allow for the flexture during impact, preventing or restricting delamination and retaining higher property retention

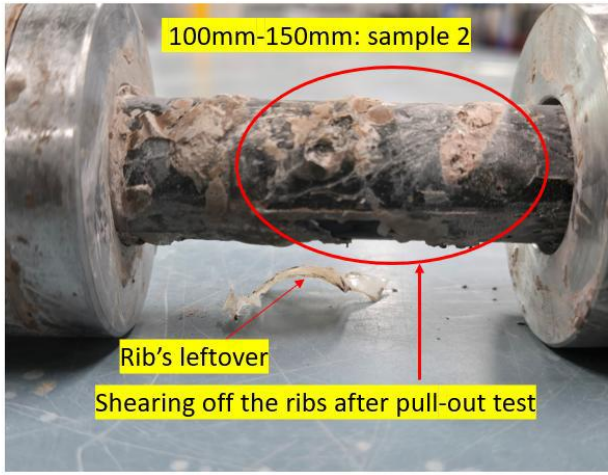
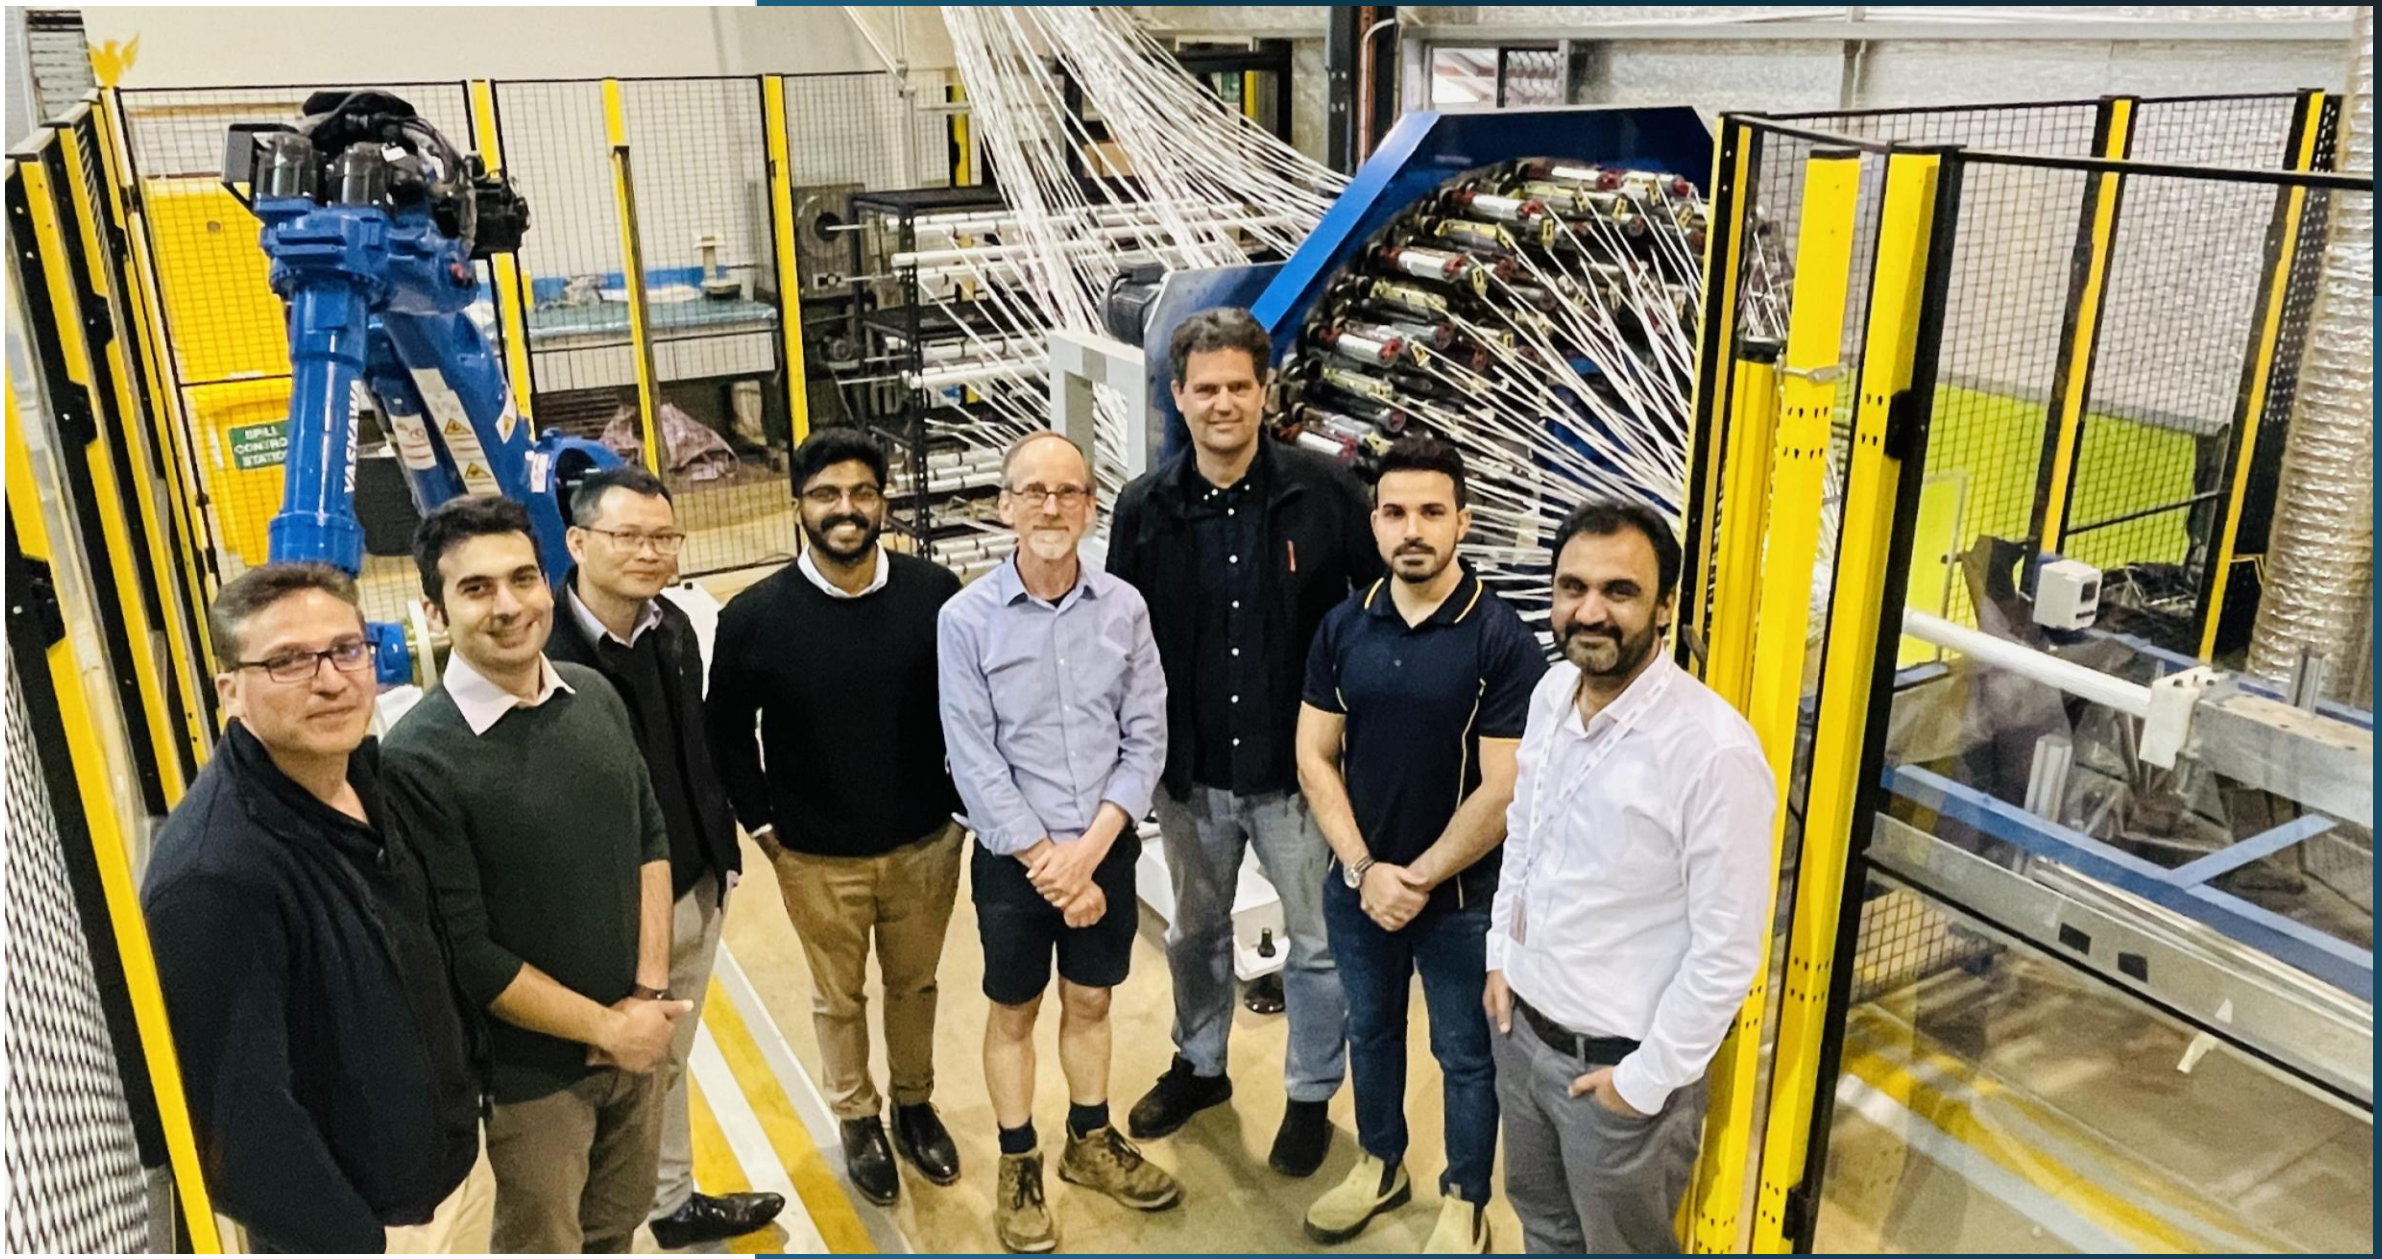
Damage Analysis during Pull-out testing





Summary

- ✓ The testing results shows that Braided Carbon FRP composites Rebar (Carbolt) as viable alternative or complement to the traditional Steel rock bolts.
- ✓ Although, prototype demonstrated strengths, yet there are further refinement to achieve full commercial viability.
- ✓ In terms of single shear strength, the braided CFRP composite Rebar was lower than M24 Steel rock bolt but remained superior to that of glass fibre rebar. The use of braided carbon fibre contributed to the higher normalized single shear strength, improving load bearing capacity, and energy absorption.
- ✓ The braided CFRP composite rebar performed well in tensile strength when its specific strength was normalized for cross-sectional area. The results suggests that with further optimization of the carbon fibre content, the braided CFRP composite rebar could match or exceed the tensile strength of steel rockbolt.
- ✓ Overall the results suggest that the braided CFRP composite rebar has significant potential as a corrosion-resistant, light weight, alternative to steel rock bolts.

YASKAWA

Acknowledgements

I would like to express my sincere gratitude to the following organizations for their invaluable support and contributions to this research:

- **Centre for Future Materials** (CFM), University of Southern Queensland – for providing the state-of-the-art facilities, technical guidance, and a collaborative research environment throughout the project.
- **Mining3** – for their industry partnership, strategic direction, and ongoing encouragement that made this applied research impactful and relevant to real-world challenges.
- **CSIRO** – for their scientific collaboration, expertise, and support in advancing the technical scope of the research.

Their collective contributions have been instrumental in the successful completion and presentation of this work. I am truly grateful for the opportunity to be part of this collaboration.

Thank You!

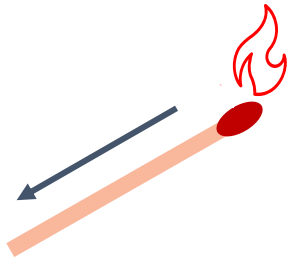
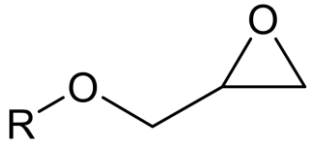
Optimization of Cationic Frontal Polymerization Experiments: An Analysis of Compositions, Reproducibility, and Materials



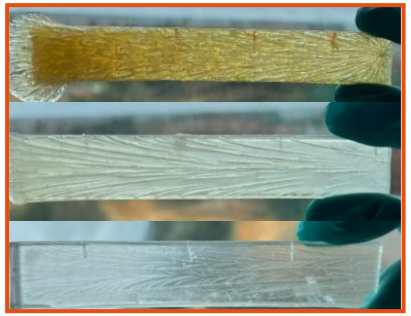
Brecklyn Groce

VUB SUME SUSTAINABLE MATERIALS ENGINEERING RESEARCH GROUP



ICCM24
24TH INTERNATIONAL CONFERENCE ON COMPOSITE MATERIALS

OVERVIEW OF THIS TALK

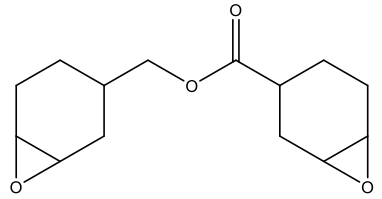


- Frontal polymerization

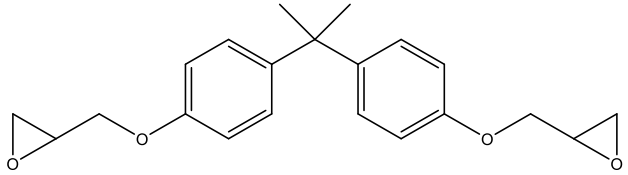
- Radical-induced cationic frontal polymerization

- Motivation, experimental design/optimization
  - Data collection, formulation chemistry, mold design

WHAT IS FRONTAL POLYMERIZATION?



- Propagating localized reaction zone
- Vital: greater rate of heat production than heat loss
- One-pot formulations
- Cure on-demand
- Long pot lives
- Fast curing



Acrylate (free-radical) FP initiated via UV light

Pojman, J. A. Frontal Polymerization, In: *Polymer Science: A Comprehensive Reference*, K. Matyjaszewski, M.Möller, Eds., Elsevier BV, Amsterdam, **2012**, *4*, 957 - 980.

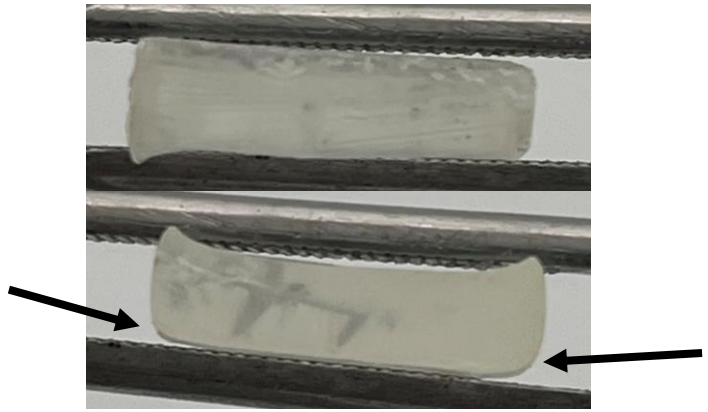
DESIGN OF MOLDS

- Silicone mold (heat resistant up to 294 °C)
  - Can adapt to many different needs
  - Rapidly generate molds for studies of boundary conditions

DESIGN OF MOLDS

- Also possible: creation of wooden mold
  - Adaptable as well
  - Basswood, as shown here
  - Differences in thermal properties

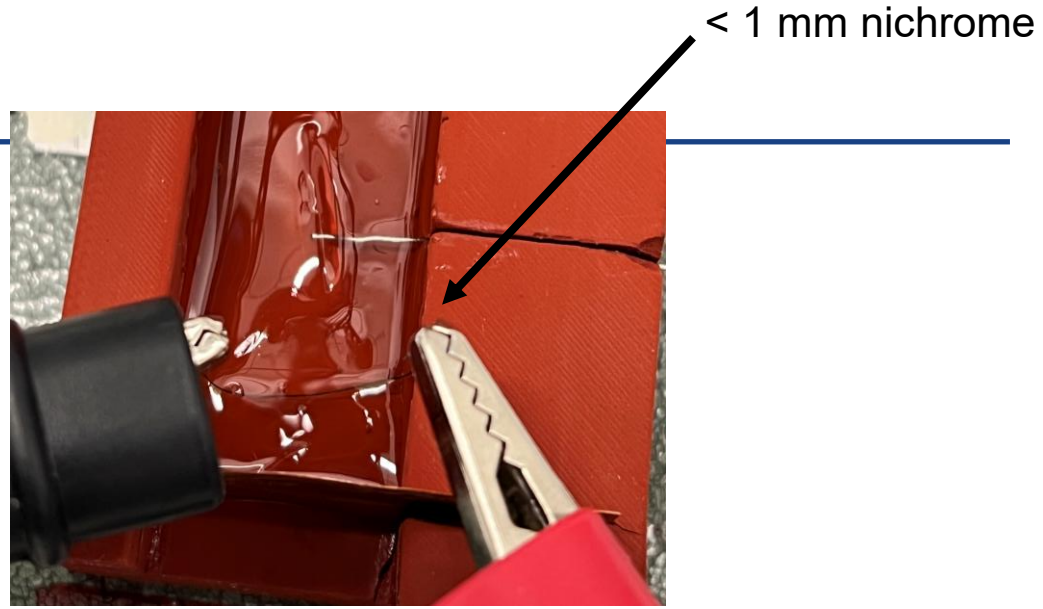


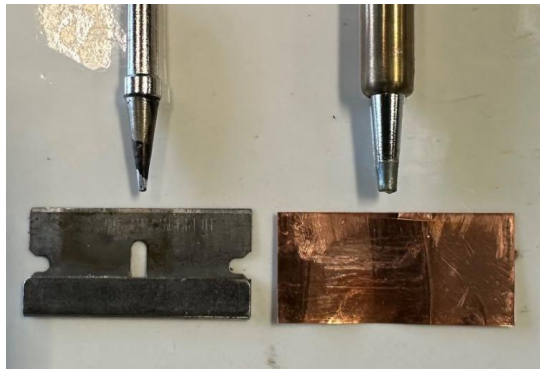
Propagating front in wooden mold

DESIGN OF MOLDS: EFFECT ON FP

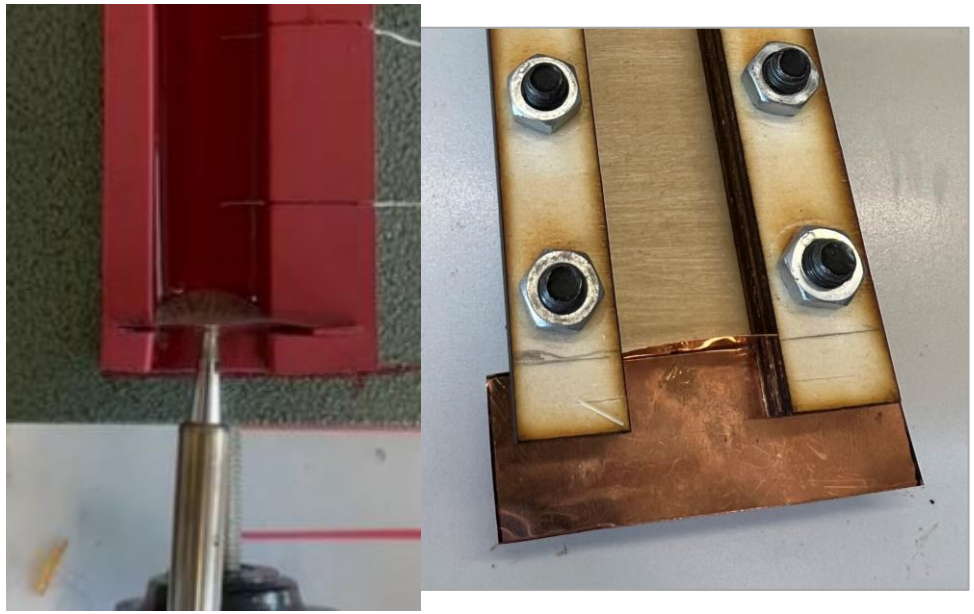
- Wooden mold: little uncured material left
- Silicone mold: much more uncured material remaining

Top: polymer after FP in wooden mold
Bottom: polymer after FP in silicone mold





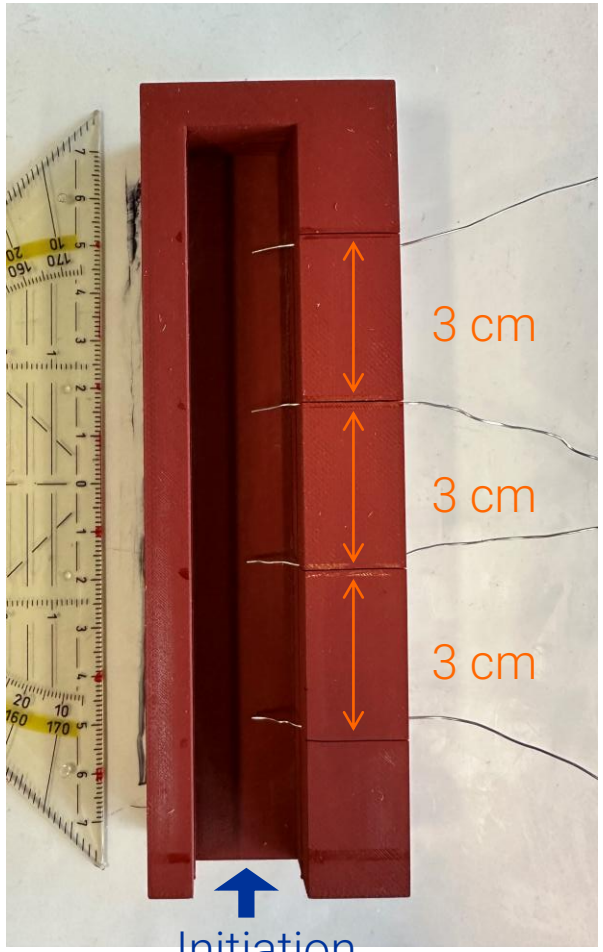
After FP polymer removed

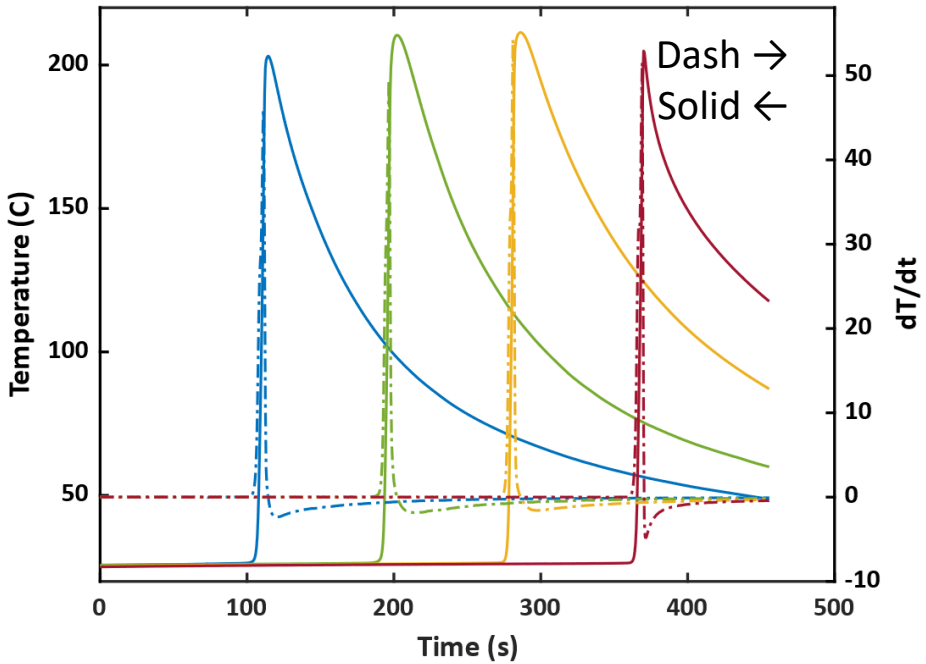


INITIATION OF FRONTS

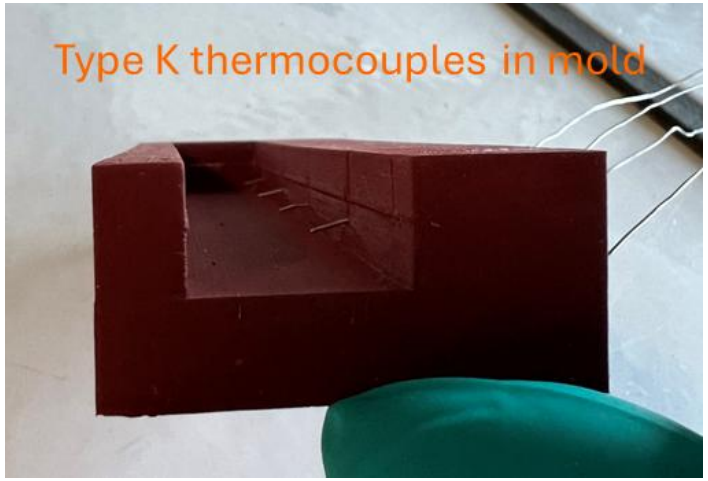
- RICFP initiated with heat for our case
  - Decompose radical initiator → acid generation from IOC decomposition
  - w/ direct contact → found that initiation temp has little effect on velocity
    - Also results in longer time to stable front

Insert metal plate to initiate the front from side



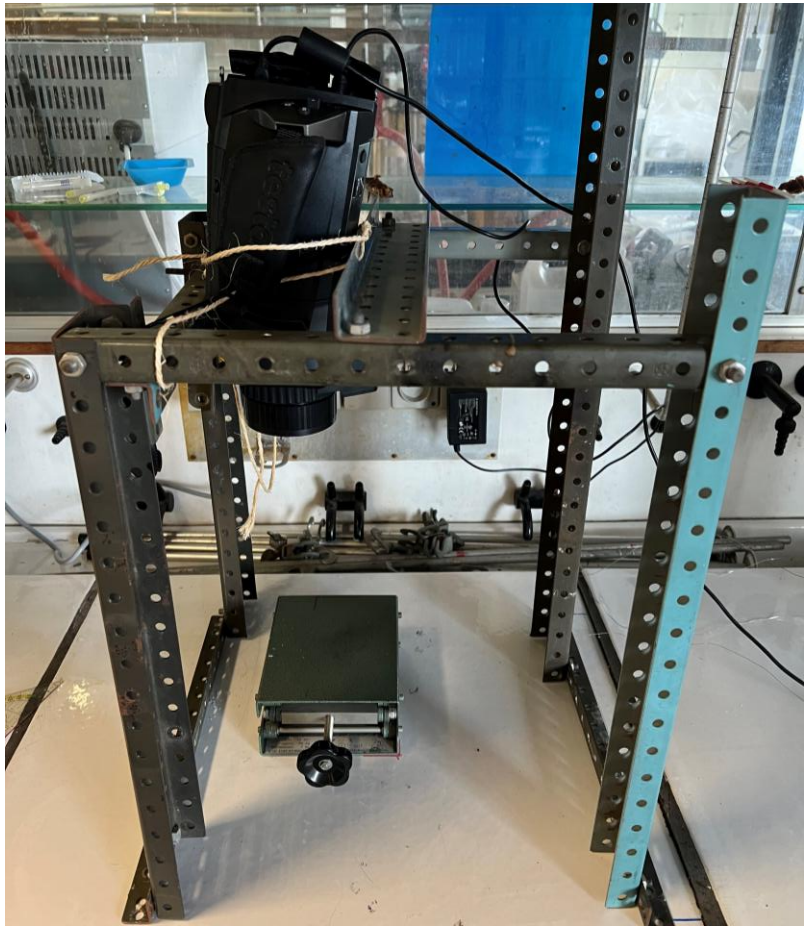


Resistive nichrome wire w/ direct current



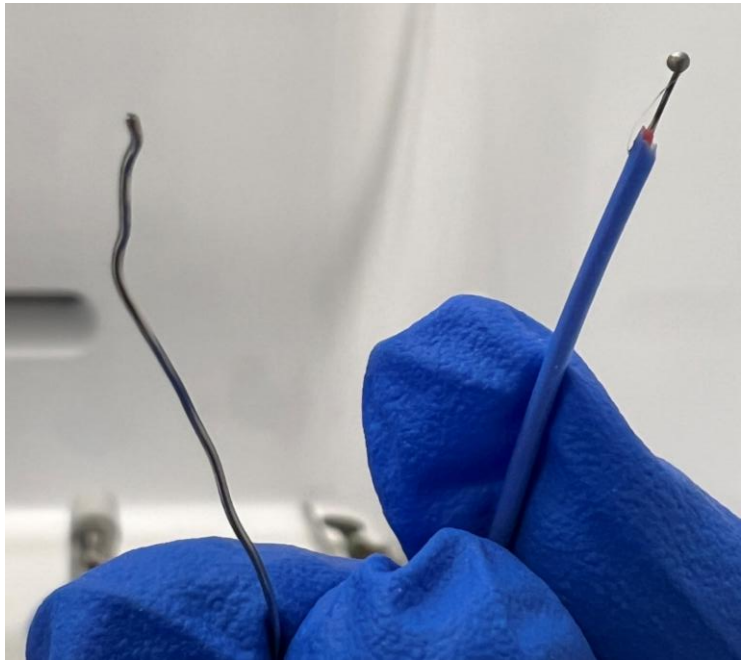
OBSERVATION OF FRONTS: THERMOCOUPLES

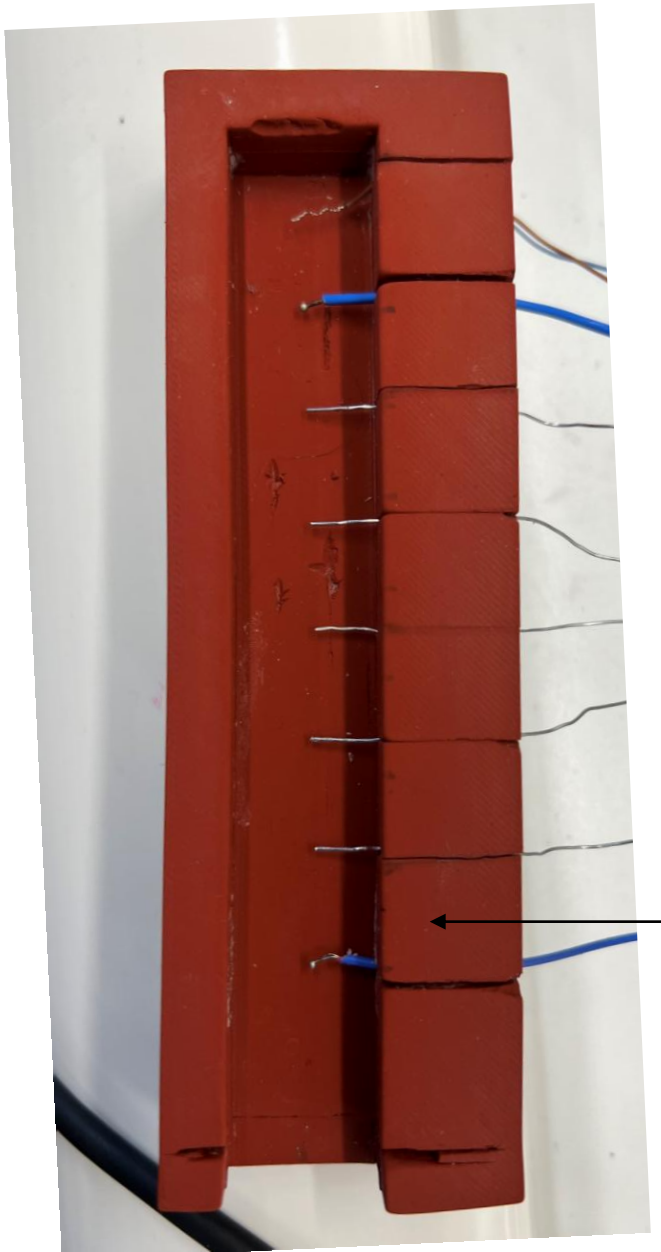
- Insert thermocouples into resin
- Calculate velocity based on max dT/dt



Example plot temperature extracted by thermocouples

OBSERVATION OF FRONTS: IR CAMERAS

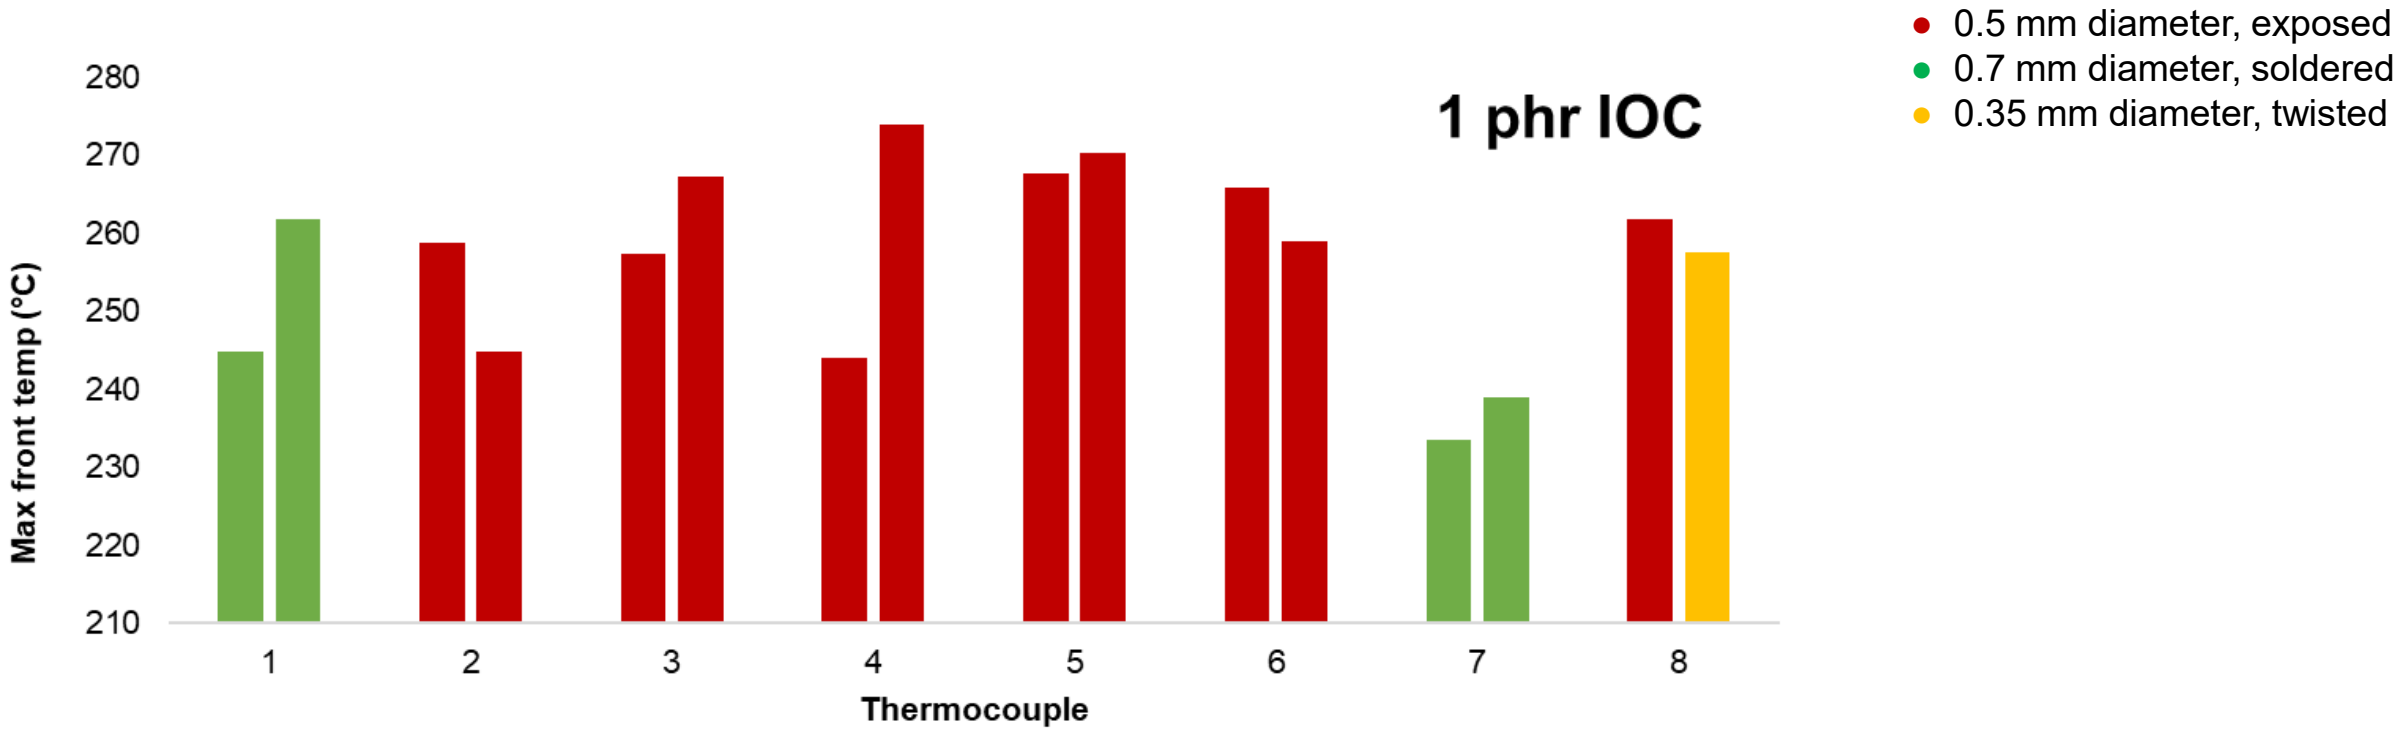




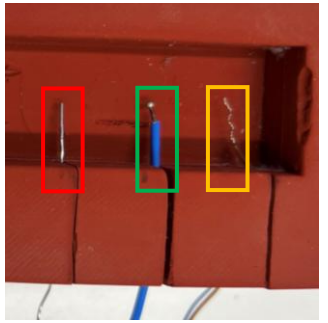
Left: Testo IR camera
Right: FLIR mobile IR camera
Equivalent formulations

OBSERVATION OF FRONTS: THERMOCOUPLE EFFECTS

- 8 thermocouples max (all type K)
  - 3 different brands:
    - 0.5 mm diameter, exposed wire type
    - 0.7 mm diameter, soldered tip
    - 0.35 mm diameter, twisted wire



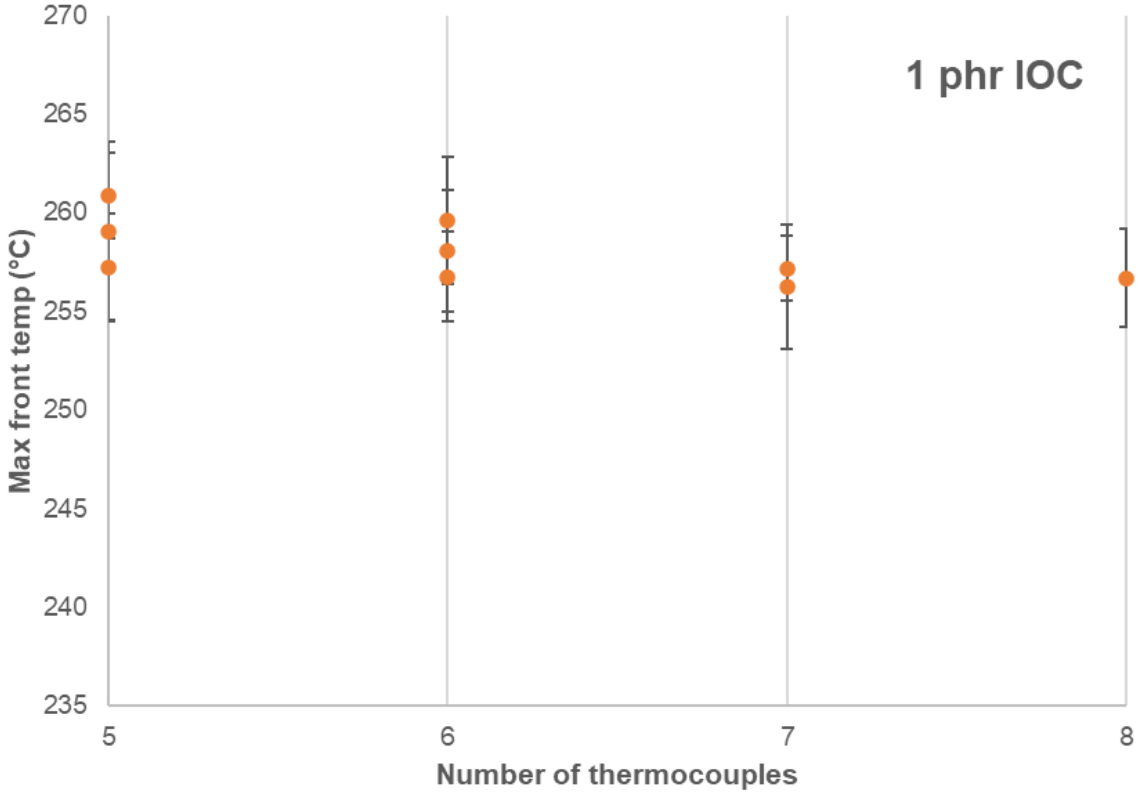
THERMOCOUPLE EFFECTS



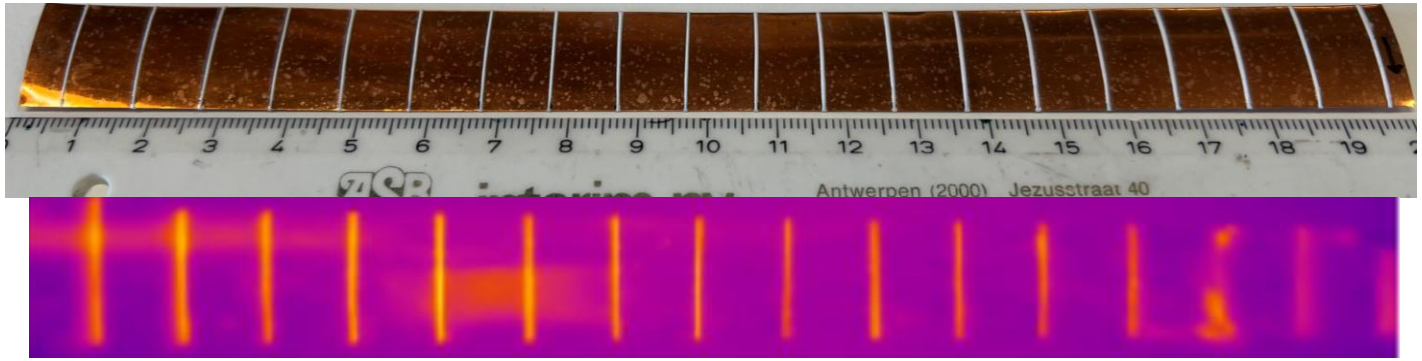
(approx. position of TCs)

- No significant difference in front stability

THERMOCOUPLE EFFECTS: FRONT TEMPERATURE



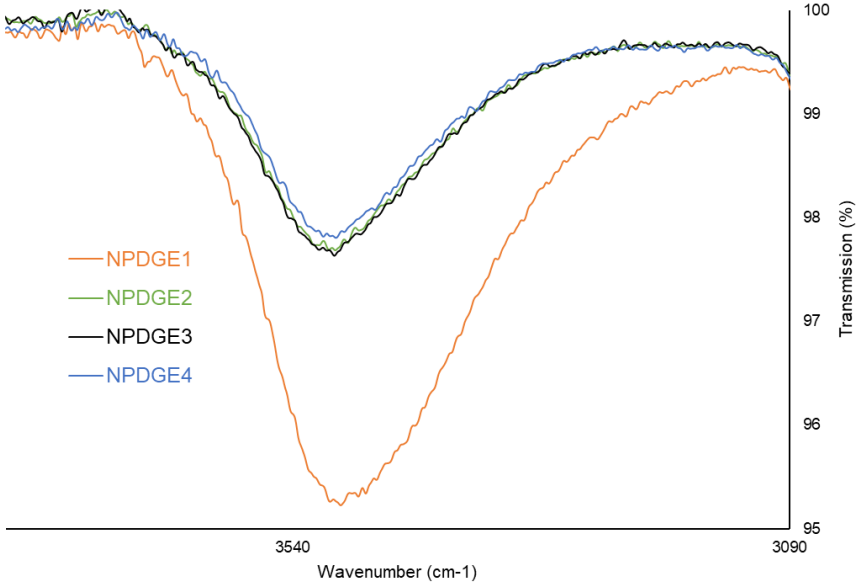
THERMOCOUPLE EFFECTS: NUMBER OF THERMOCOUPLES



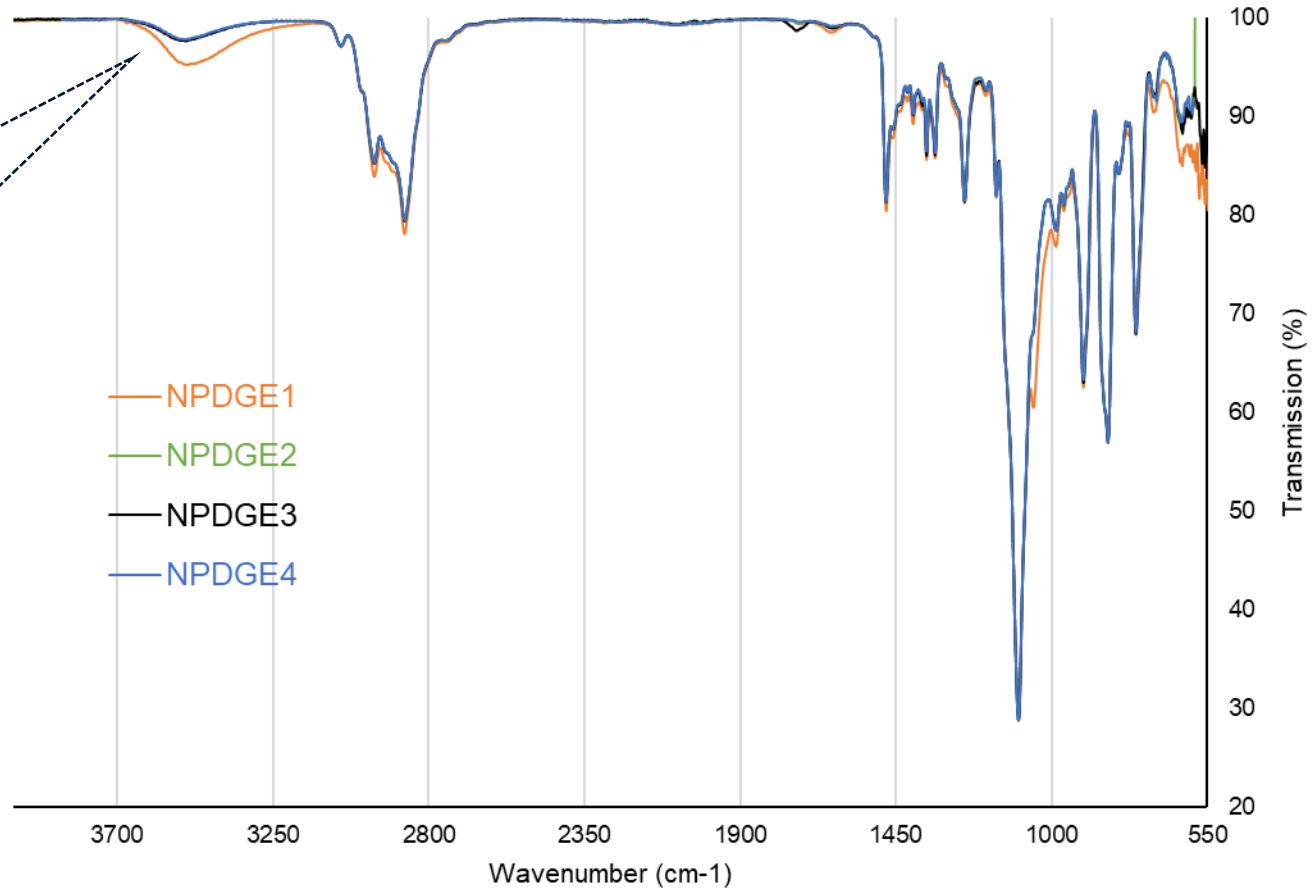
1 phr IOC, 1 phr TPED, NPDGE			
# thermocouples	TCs used	Front velocity (cm/min)	Front temperature (C)
8	12345678	5.40 ± 0.08	256.7 ± 2.5
7	1234567	5.36 ± 0.12	256.3 ± 3.1
	2345678	5.43 ± 0.03	257.2 ± 1.6
6	123456	5.31 ± 0.08	259.6 ± 3.2
	234567	5.39 ± 0.07	256.8 ± 2.3
	345678	5.50 ± 0.08	258.1 ± 3.1
5	23456	5.32 ± 0.00	260.9 ± 2.2
	12345	5.40 ± 0.05	259.0 ± 4.5
	45678	5.51 ± 0.14	257.3 ± 2.7

- After 4, within same range for velocities

OBSERVATION OF FRONTS: IR CAMERA



- Problem with IR camera: no length scale
  - Cannot calculate velocity based on observed position of the front
- Heat up using heat gun, polyester tape heats faster than copper



- Larger difference higher concentration IOC samples
- Provides data for front velocity at the boundary

FUTURE WORKS AND CHALLENGES: PURIFICATION

- Another issue with front reproducibility: monomer purity
- 4 bottles of NPDGE

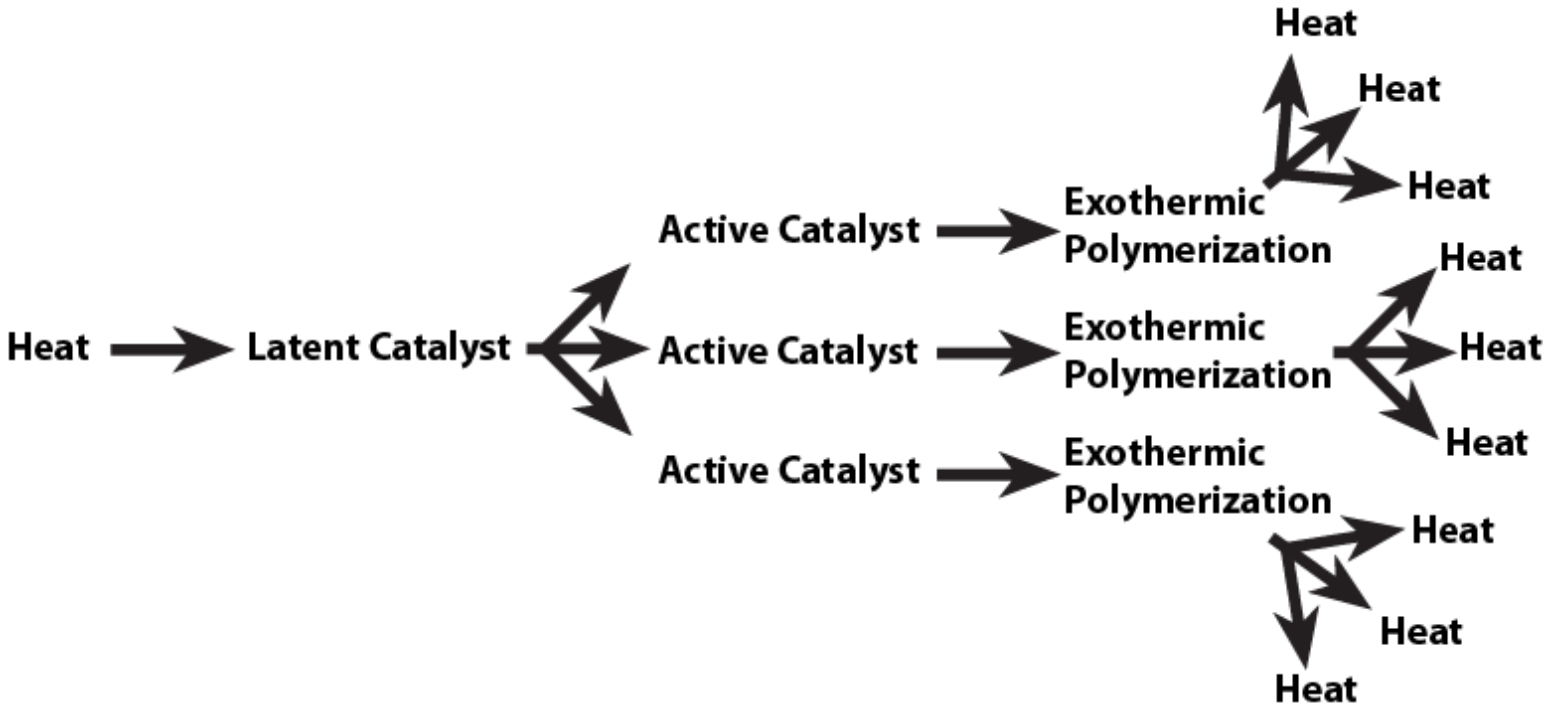
Challenges in Composite Manufacturing

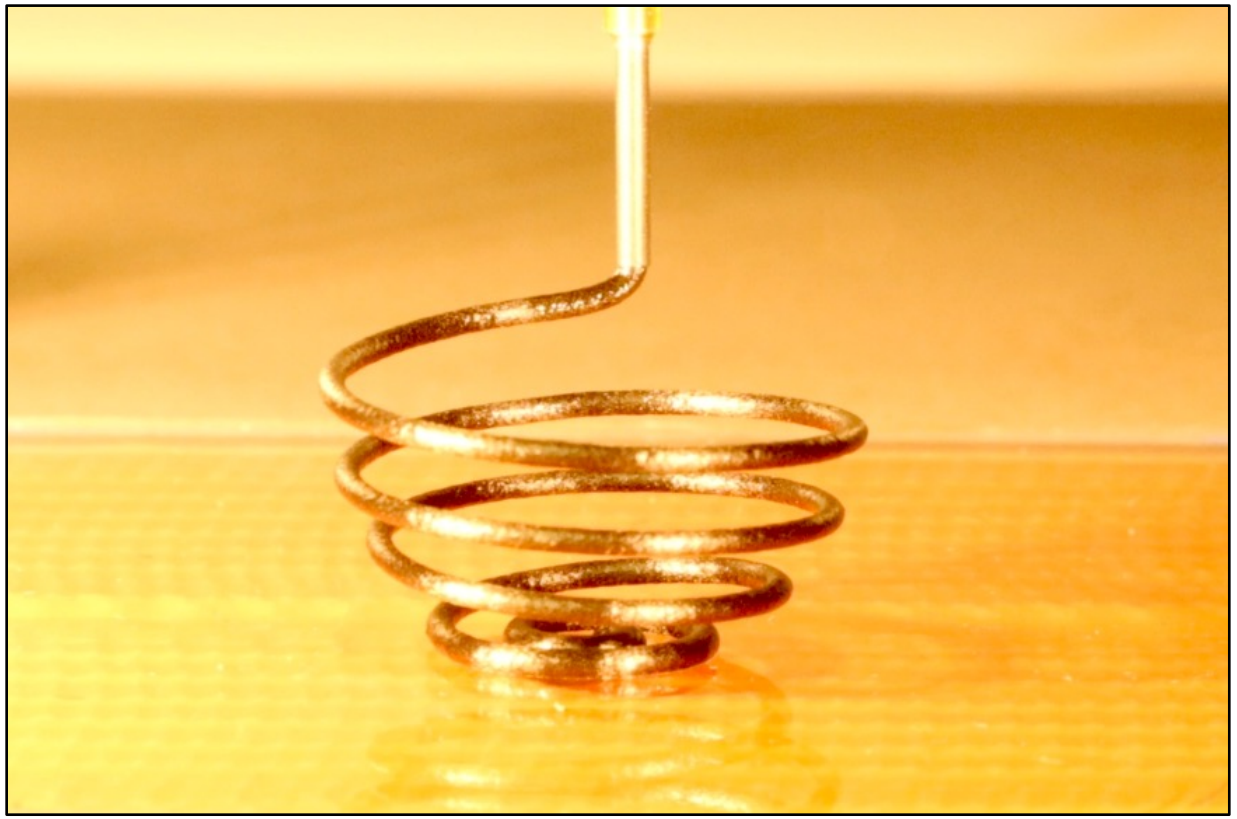


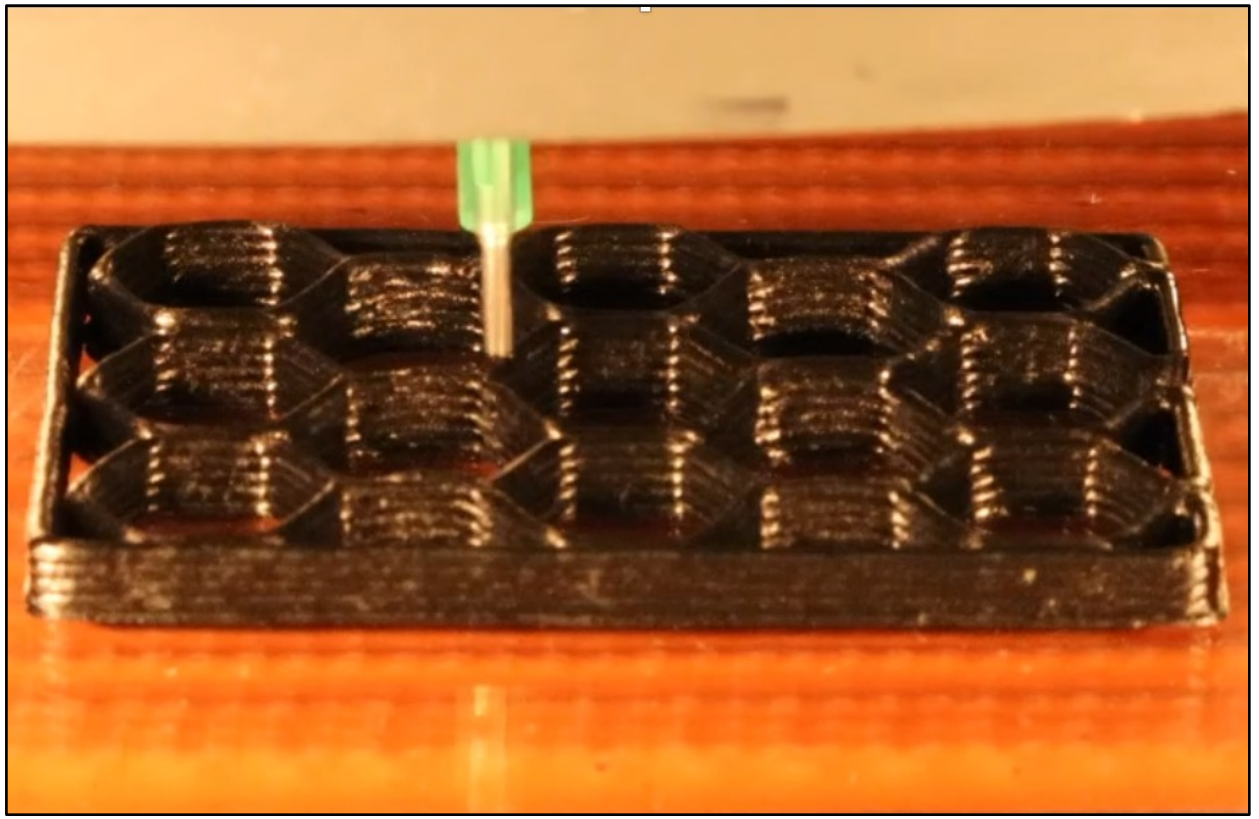
Boeing autoclave

Heated mold for manufacturing a wind blade

Frontal Polymerization (FP)

Self-propagative exothermic reaction wave driven by heat of polymerization





Robertson, Yourdkhani et al., *Nature*, 2018

3D Printing via Frontal Polymerization

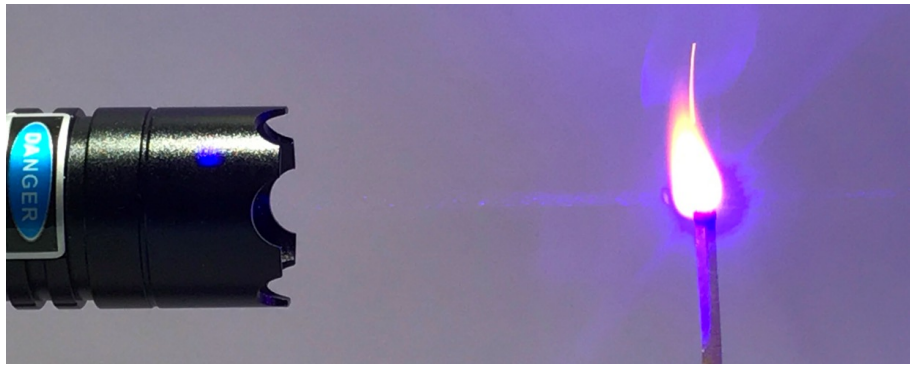
- Rapid curing of thermoset composites during 3D printing processes
- Freeform and layer-by-layer printing enabled by synchronized and asynchronized frontal curing

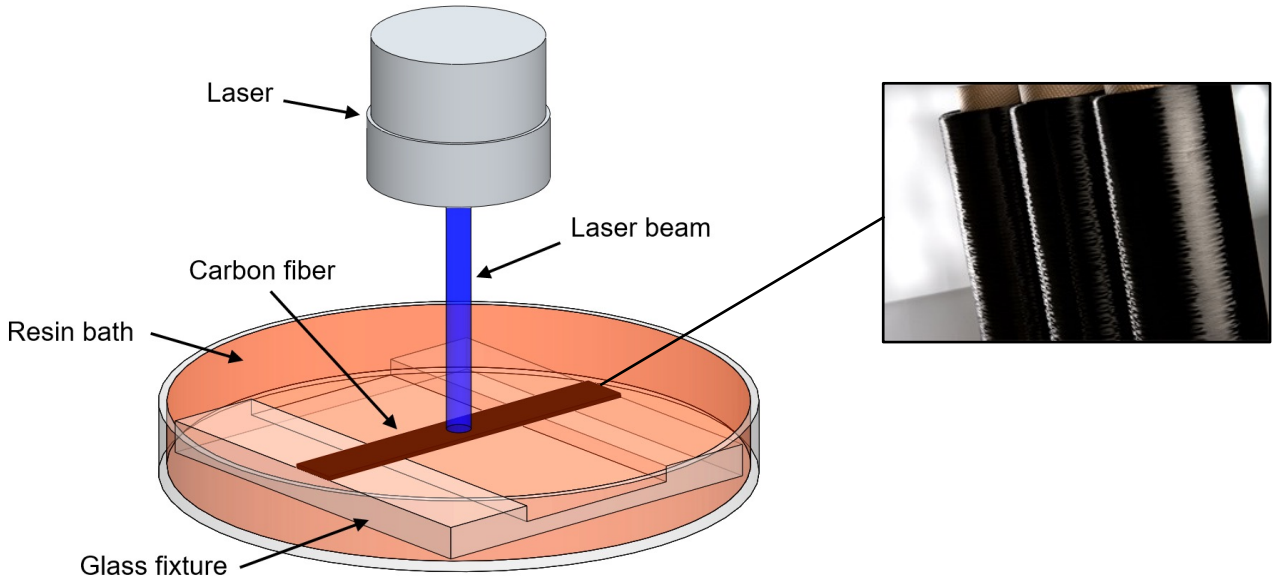
Ziaee et al., *ACS Applied Materials & Interfaces*, 2022

Activation of Frontal Reaction

Frontal polymerization is typically activated using thermal contact methods

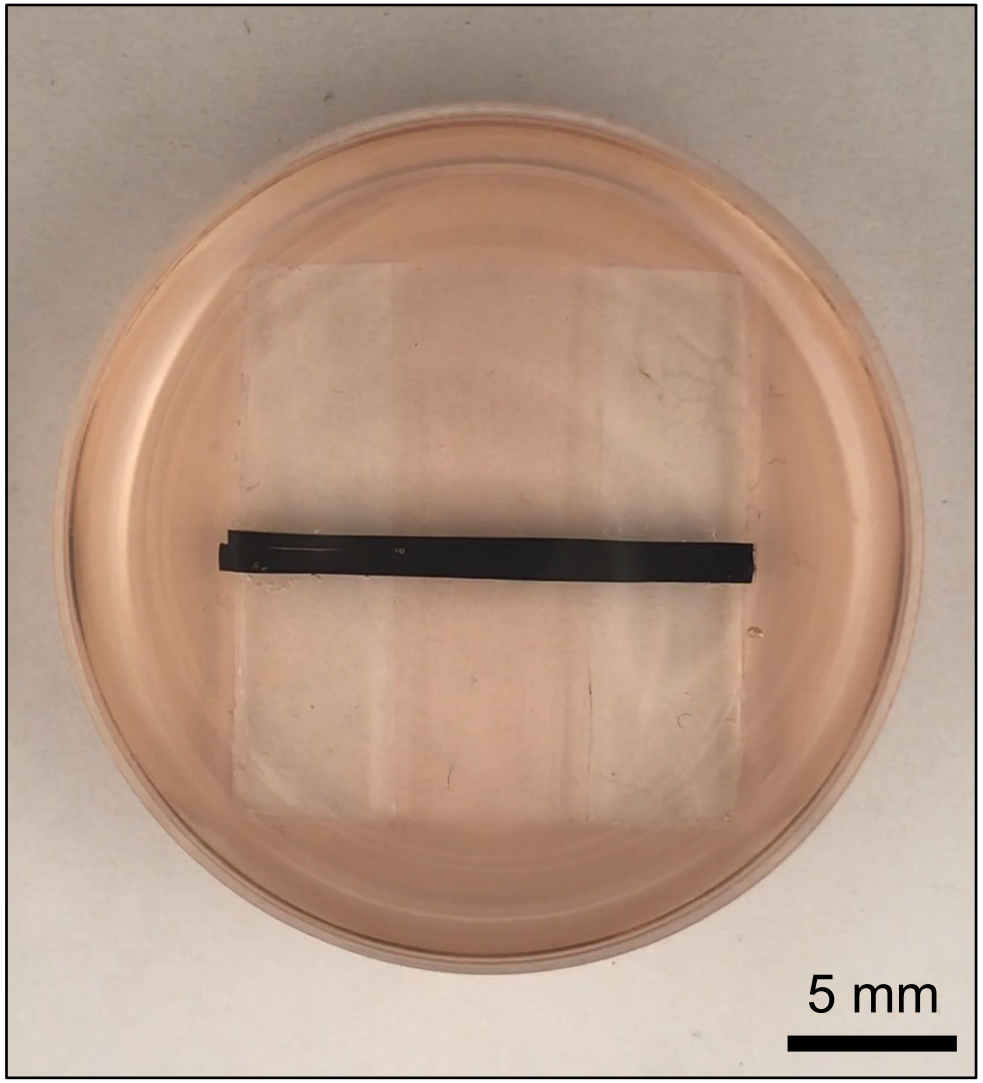
- Long activation times (few seconds to minutes)
- Local variation in material properties or damage to material





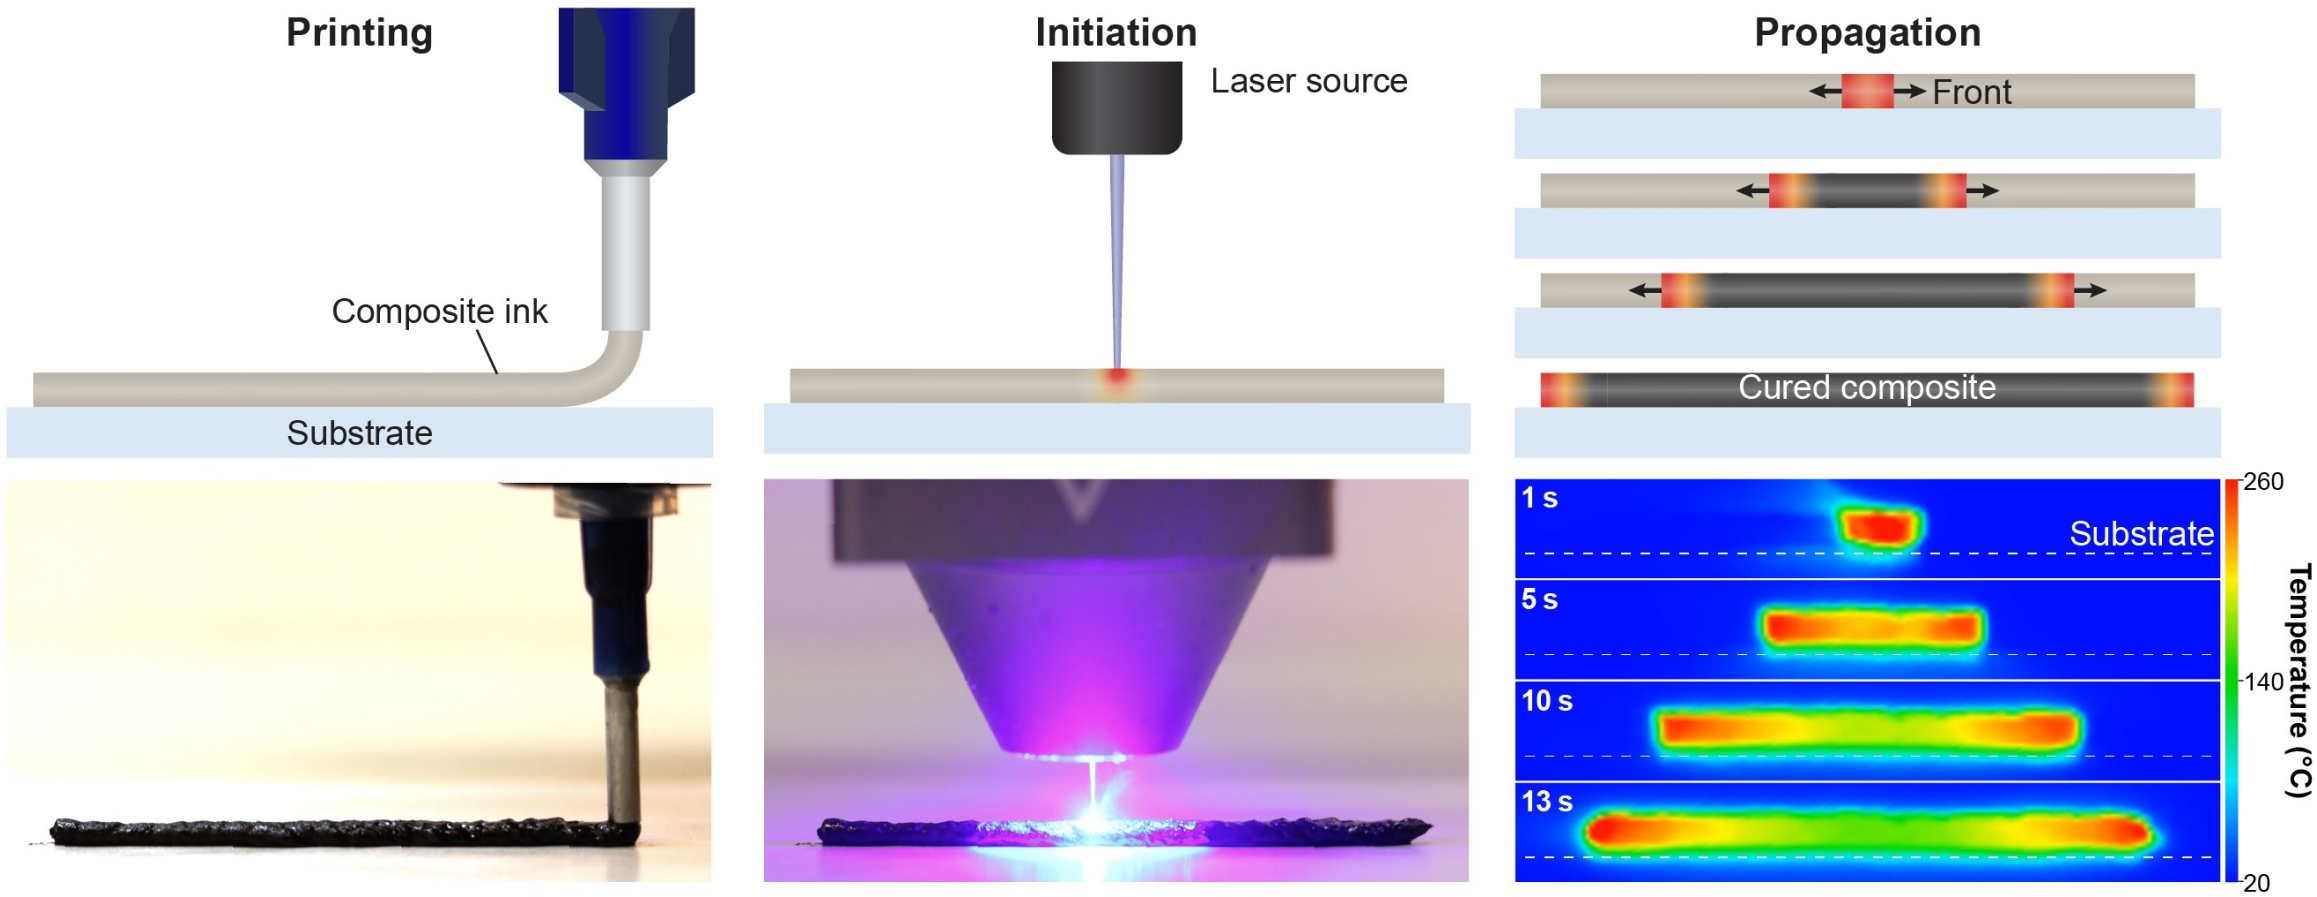
Activate frontal polymerization remotely

Photothermal Activation



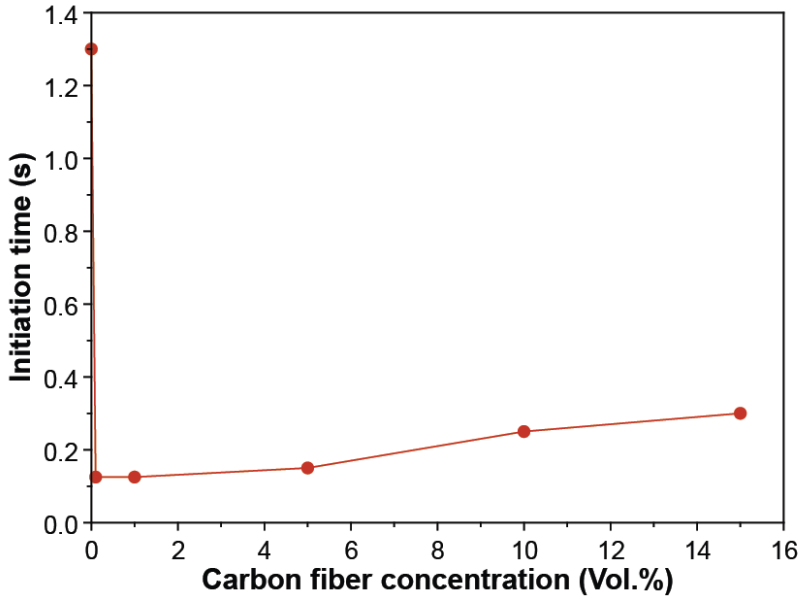
- Photothermal activation offers
  - Remote initiation
  - Precise control of energy input

- Exploit high absorptivity of carbon fibers
  - Blue laser light source (wavelength = 450 nm)

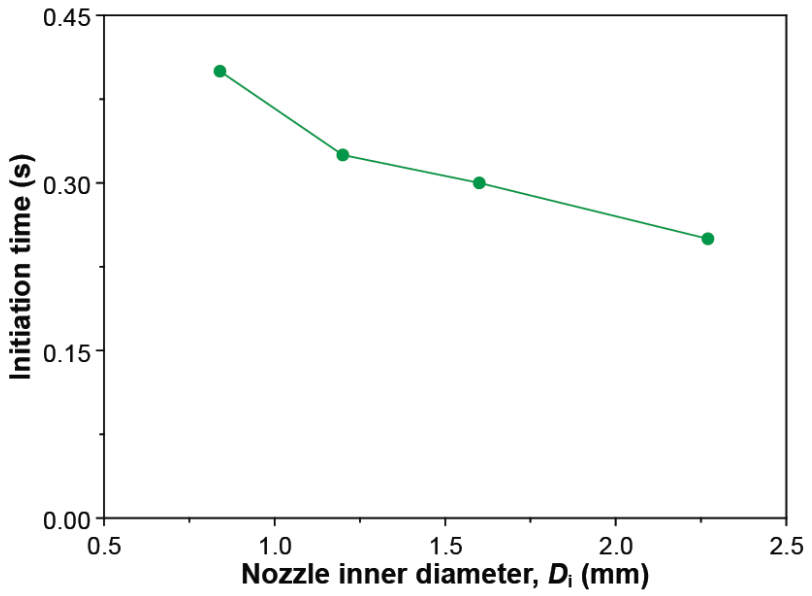


Rapid Initiation of Frontal Reaction

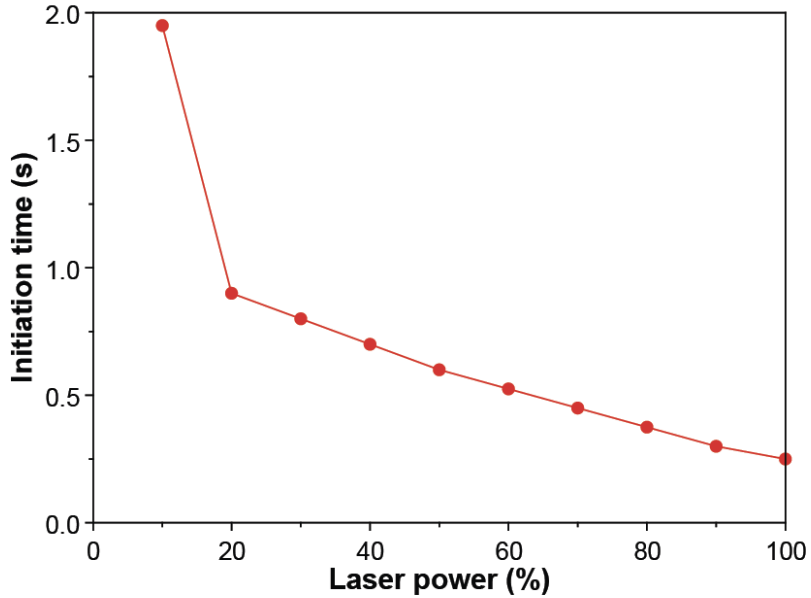
- Frontal activation within 200 ms



FP Initiation During Composite Printing

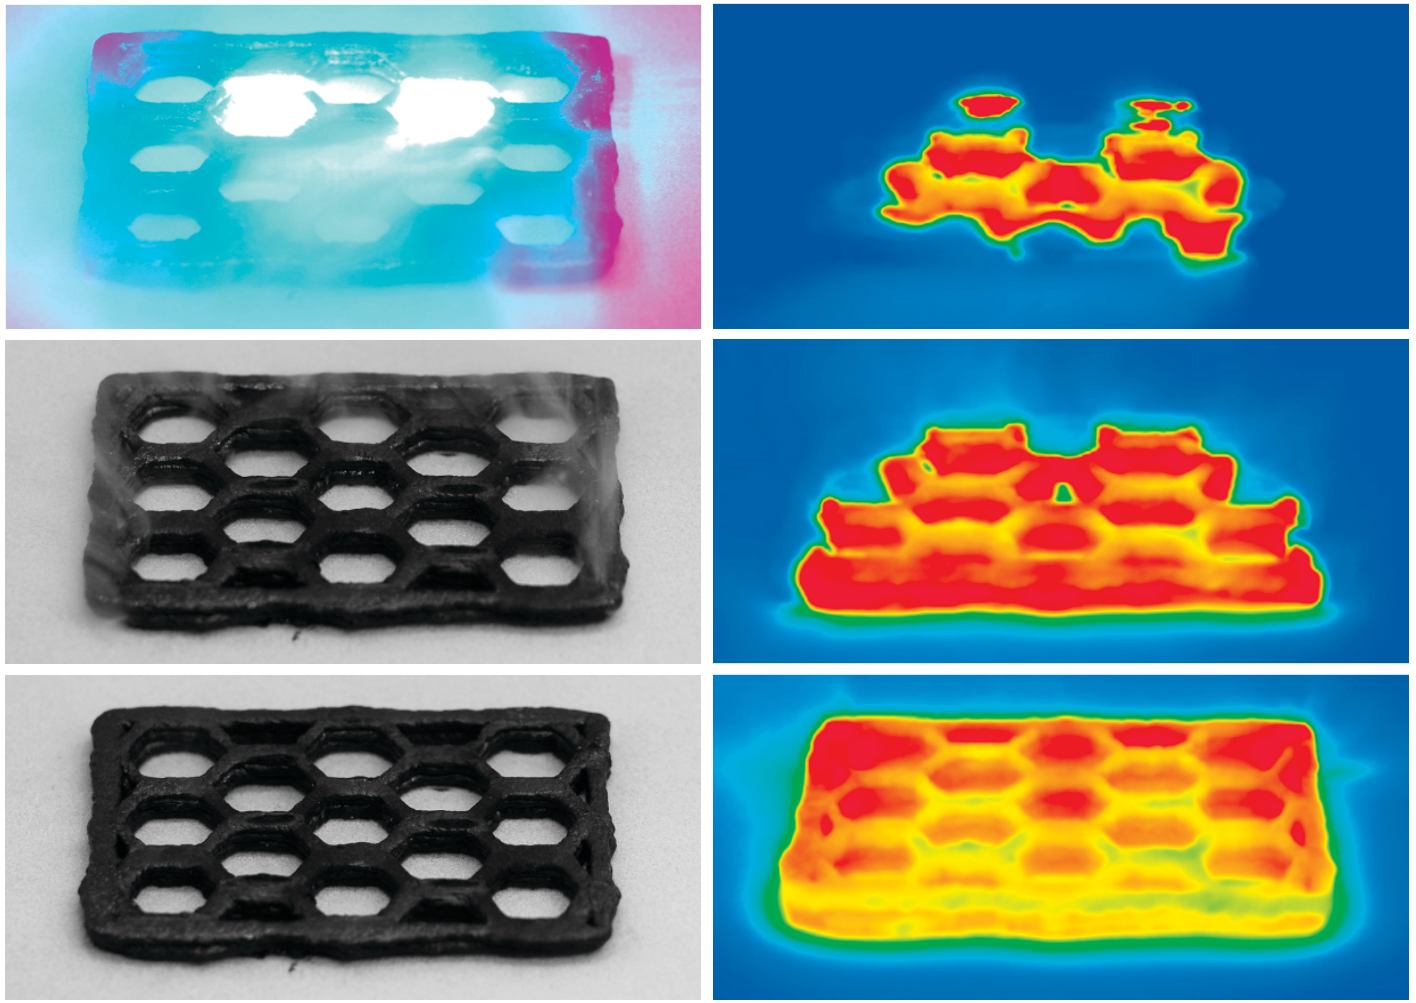


Rapid, remote initiation of frontal polymerization during direct ink writing (DIW) of carbon fiber composites



Effect of Material and Processing Parameters

Initiation time of FP can be tuned by varying the material and processing parameters



FP initiation in < 1s using various concentrations of milled carbon fibers

Multipoint Initiation

Overall cure time can be reduced by applying multiple laser pulses

Conclusions

- Low-power laser enables rapid, remote initiation of FP during DIW of thermoset composites
- Reliable initiation achieved with as little as 0.1 vol% carbon fiber for photothermal conversion
- Automated laser integration allows multipoint initiation, significantly reducing layer cure times
- Compatible with diverse FP resin systems and fiber reinforcements
- Supports spatially controlled, on-demand curing for manufacturing freeform, unsupported, and complex multi-layer structures

Prof. Stephen Tsai and Aidan Hawkins (Hawaii, 2023)

5th August 2024

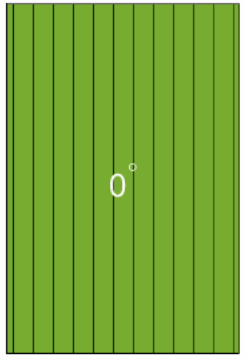
Introduction

QUEEN'S UNIVERSITY BELFAST
SCHOOL OF MECHANICAL AND AEROSPACE ENGINEERING
SPIRIT AEROSYSTEMS

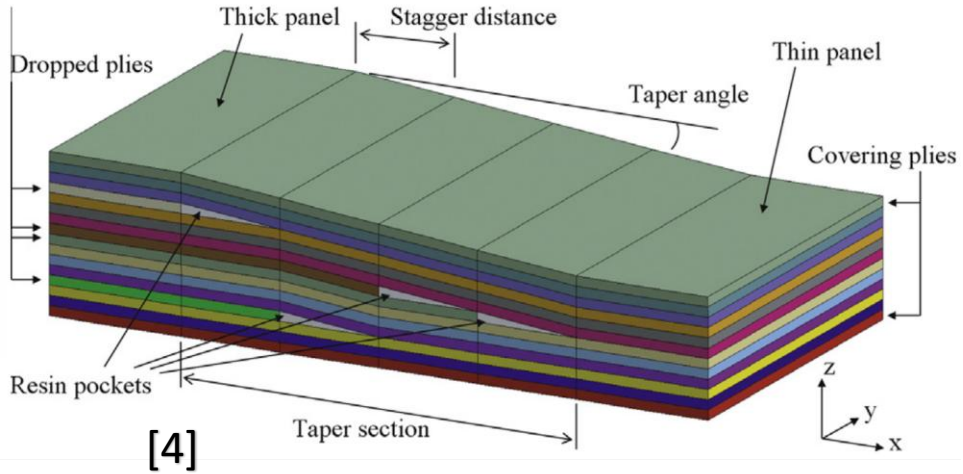
Traditional Quad Laminates

Collection of 0°, ±45° & 90° plies

Same principle since the 1960s



- Large number of stacking sequence permutations



(>1 Million for a 32 ply laminate)

- Layup constrained by 30+ legacy rules [3]

……

→ Stacking sequence optimisation is virtually impossible

[4]

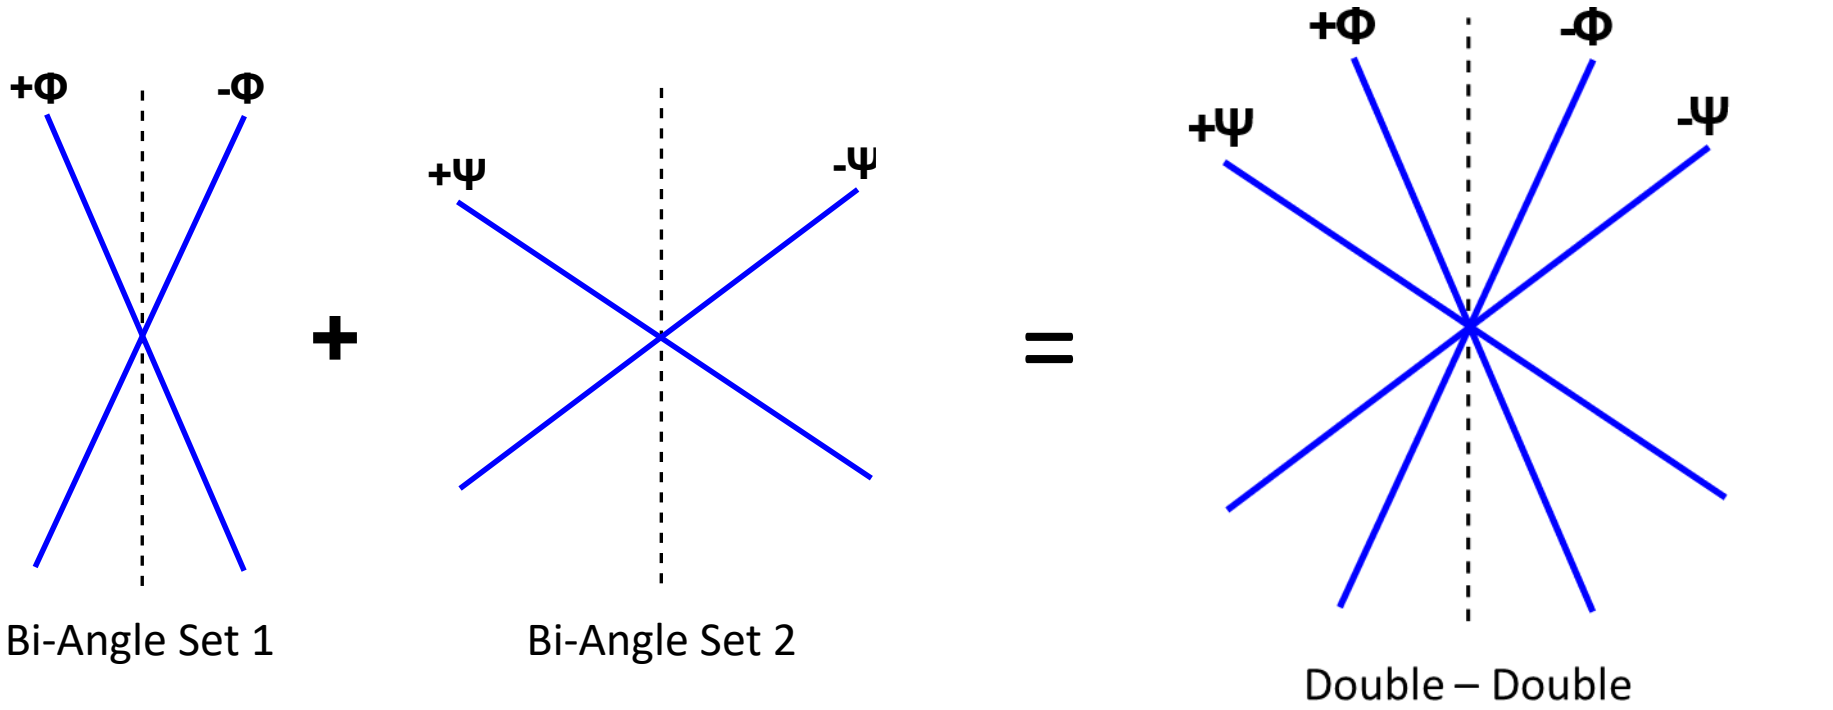
→ Internal discontinuities

→ Resin pockets

→ Ply wrinkles

→ More difficult to detect defects

[3] J. A. Bailie, R. P. Ley, and A. Pasricha. A Summary of Composite Laminate Guidelines. 1997.
[4] Irisarri, F.-X. *et al.* (2014) 'Optimal design of laminated composite structures with ply drops using stacking sequence tables'



Double-Double Laminates

QUEEN'S UNIVERSITY BELFAST

Proposed by Prof. Stephen Tsai in 2017 [5].

Removes the design limitations imposed by quad laminates

Simplify the design and manufacturing of composite laminates

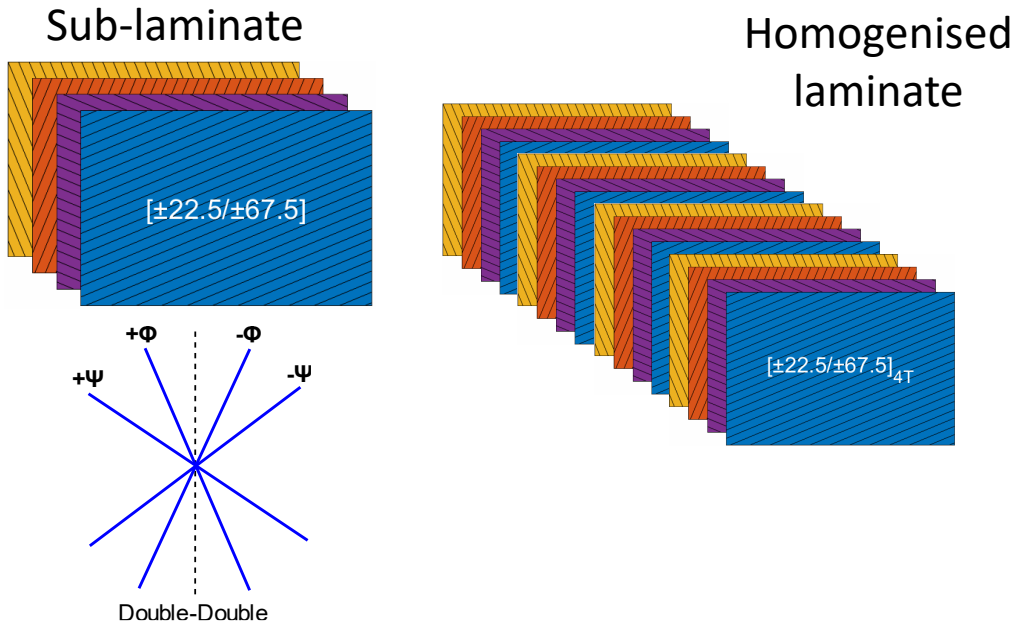
Sub-laminate



Homogenised laminate

Homogenisation of Double-Double Laminates

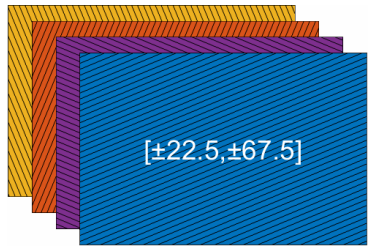
QUEEN'S UNIVERSITY BELFAST
SCHOOL OF MECHANICAL AND AEROSPACE ENGINEERING
SPIRIT AEROSYSTEMS

Homogenisation of DD Laminates

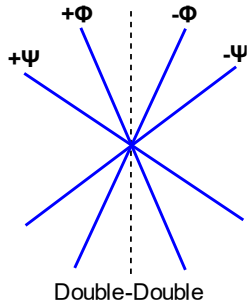
How many sub-laminate repeats are needed to meet the homogenisation criteria [8]?

$$|D^{Tr*} - A^{Tr*}| < 0.02 \quad \& \quad B^{Tr*} < 0.02$$

Thickness normalised terms based on Master Ply values

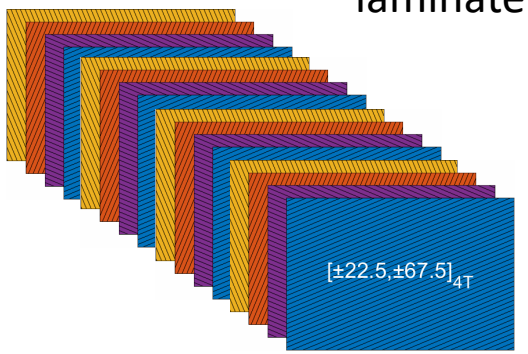


What sequence of angles within the sub-laminate minimises the required repeats?



[±Φ/±Ψ], [+Φ/-Ψ/-Φ/+Ψ], [+Φ/-Ψ /+Ψ /-Φ]……

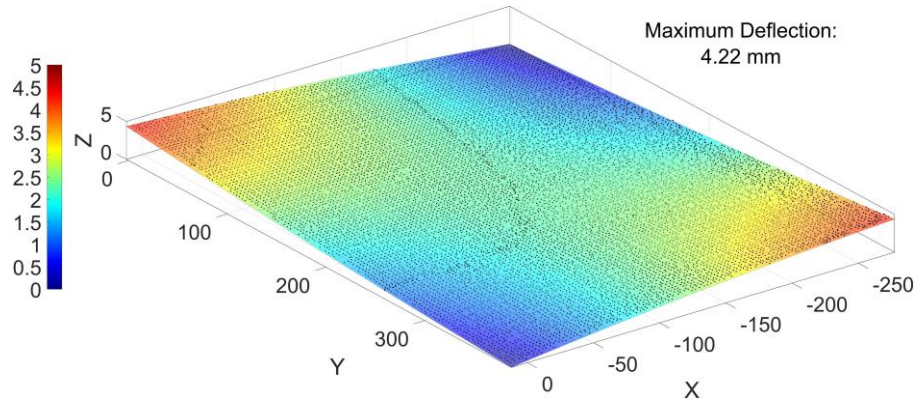
[8] Vermes, B. *et al.* (2021) 'Application of the Tsai's modulus and double-double concepts to the definition of a new affordable design approach for composite laminates', *Composite Structures*, 259, p. 113246.



Homogenisation of DD Laminates

Sub-laminate

Homogenised laminate

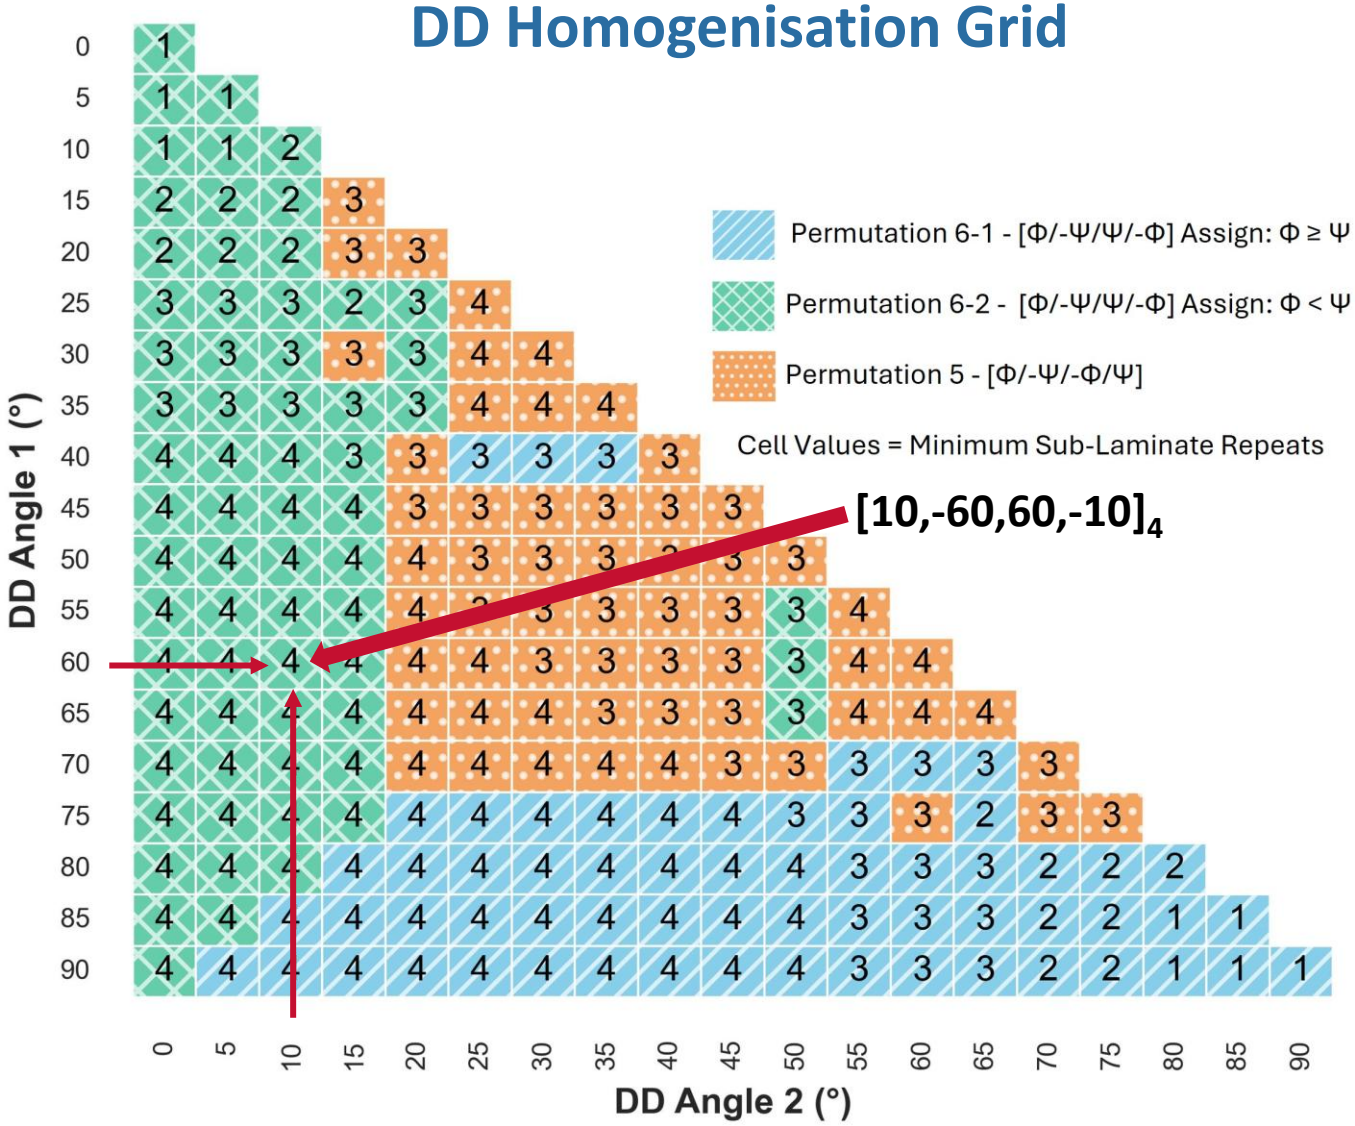


Sub-laminate repeats to satisfy original homogenisation criteria [8]

$$|D^{Tr*} - A^{Tr*}| < 0.02 \quad \& \quad B^{Tr*} < 0.02$$

Sequence of angles minimising the required repeats?

[±Φ/±Ψ], [+Φ/-Ψ/-Φ/+Ψ], [+Φ/-Ψ /+Ψ /-Φ]……

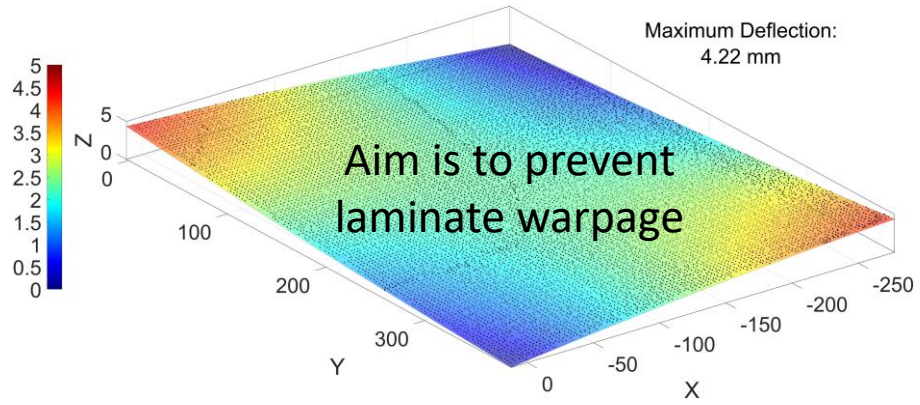


Aim is to prevent laminate warpage

[8] Vermes, B. *et al.* (2021) 'Application of the Tsai's modulus and double-double concepts to the definition of a new affordable design approach for composite laminates', *Composite Structures*, 259, p. 113246.

Homogenisation of DD Laminates

DD Homogenisation Grid

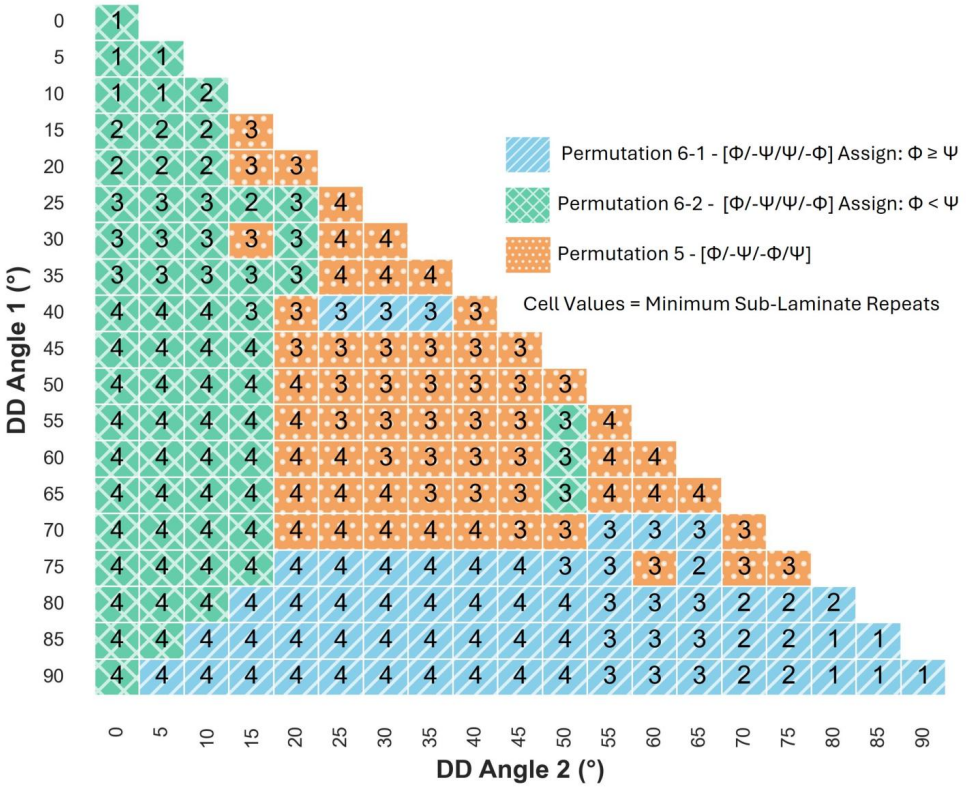


Sub-laminate repeats to satisfy original homogenisation criteria [8]

$$|D^{Tr*} - A^{Tr*}| < 0.02 \quad \& \quad B^{Tr*} < 0.02$$

Sequence of angles minimising the required repeats?

[±Φ/±Ψ], [+Φ/-Ψ/-Φ/+Ψ], [+Φ/-Ψ /+Ψ /-Φ]……



[8] Vermes, B. *et al.* (2021) 'Application of the Tsai's modulus and double-double concepts to the definition of a new affordable design approach for composite laminates', *Composite Structures*, 259, p. 113246.

Experimental Homogenisation Results

QUEEN'S UNIVERSITY BELFAST

Original homogenisation criteria [8]

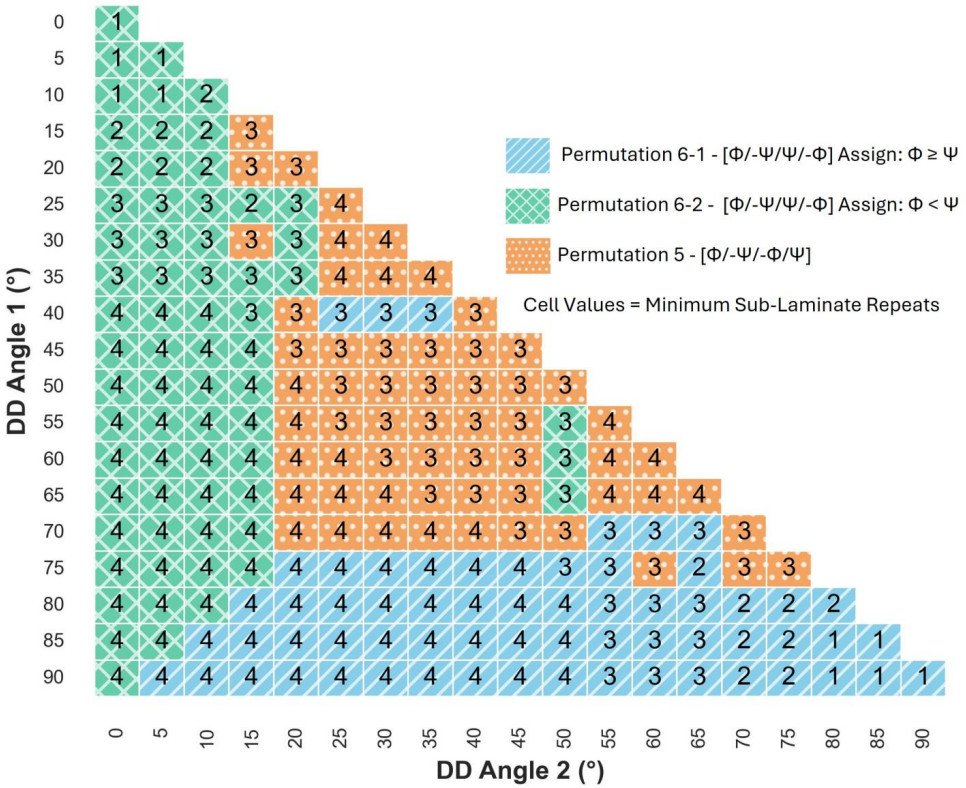
$$|D^{Tr*} - A^{Tr*}| < 0.02 \quad \& \quad B^{Tr*} < 0.02$$

Manufactured Panels IM7 977-2 Prepreg

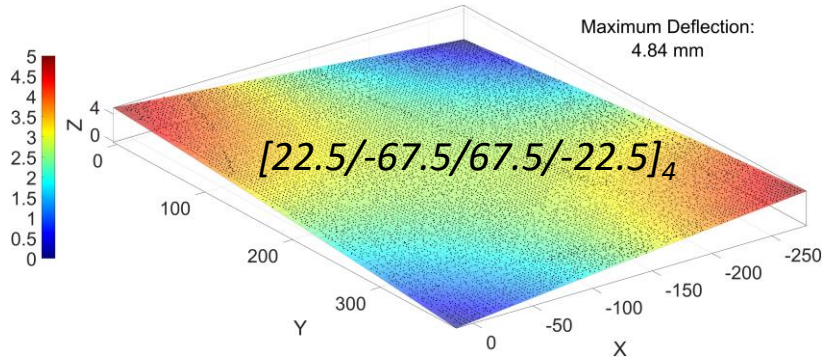
$[22.5/-67.5/-22.5/67.5]_4$

$[22.5/-67.5/67.5/-22.5]_4$

$[9, -47, -9, 47]_5$

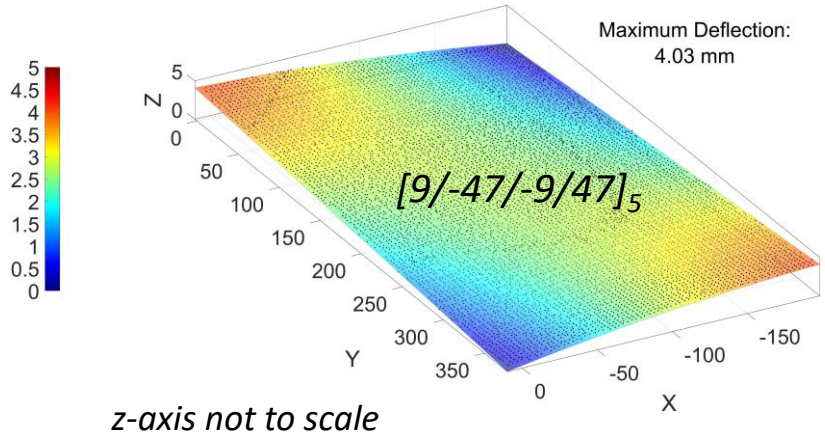


[8] Vermes, B. *et al.* (2021) 'Application of the Tsai's modulus and double-double concepts to the definition of a new affordable design approach for composite laminates', *Composite Structures*, 259, p. 113246.



Experimental Homogenisation Results

QUEEN'S UNIVERSITY BELFAST



Original homogenisation criteria [8]

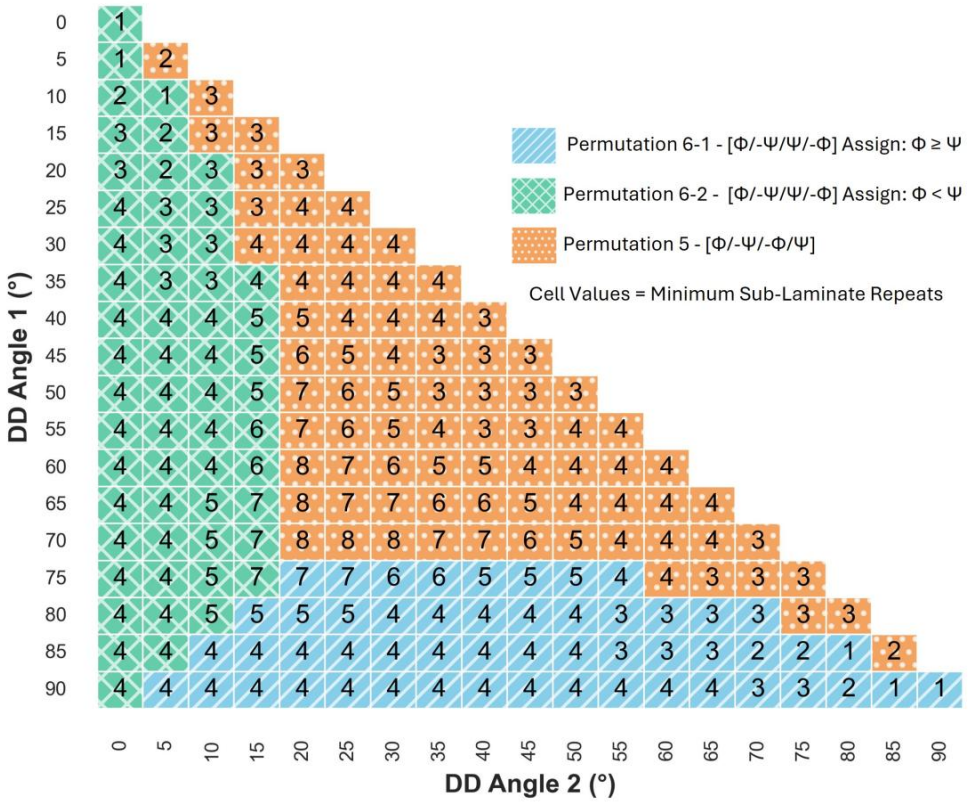
$$|D^{Tr*} - A^{Tr*}| < 0.02 \quad \& \quad B^{Tr*} < 0.02$$

Point cloud data from surface scanning

z-axis not to scale

Panels exhibited warpage

Conclusion:



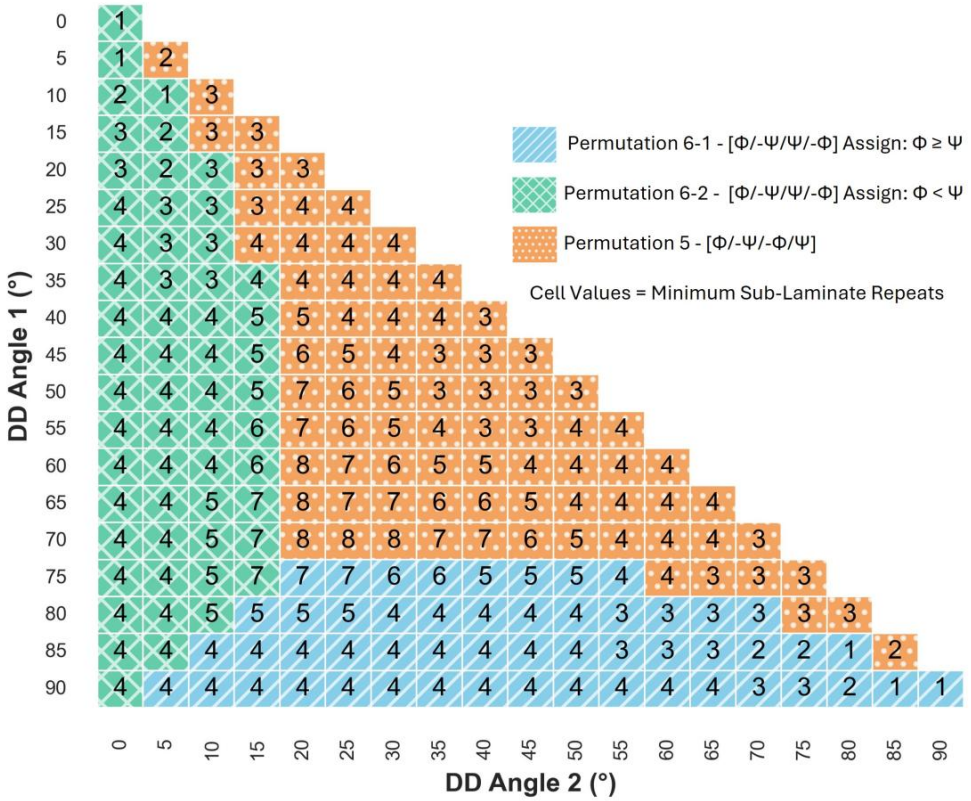
The "arbitrary" 2% homogenisation criteria [8] is not sufficient to prevent warpage

[8] Vermes, B. *et al.* (2021) 'Application of the Tsai's modulus and double-double concepts to the definition of a new affordable design approach for composite laminates', *Composite Structures*, 259, p. 113246.

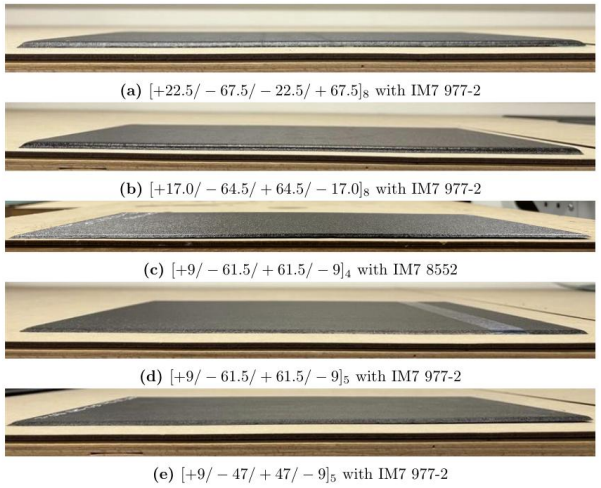
Updated Homogenisation Criteria

Proposing updated homogenisation criteria:

$$|D^{Tr*} - A^{Tr*}| < 0.02 \quad \& \quad B^{Tr*} < 0.01$$



Updated Homogenisation Criteria

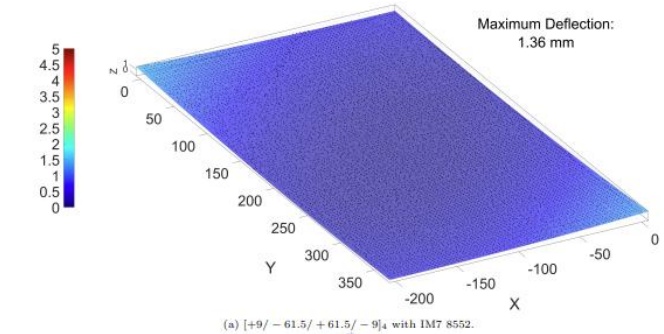


QUEEN'S UNIVERSITY BELFAST

Proposing updated homogenisation criteria:

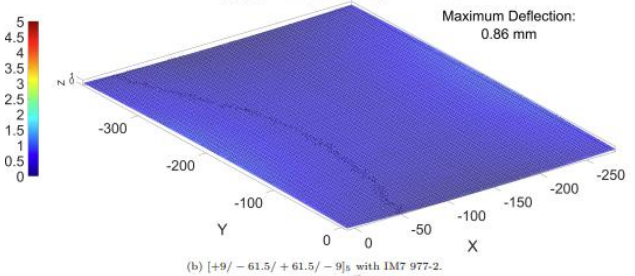
$$|D^{Tr*} - A^{Tr*}| < 0.02 \quad \& \quad B^{Tr*} < 0.01$$

Laminates manufactured meeting these criteria, have shown very minimal to negligible warpage



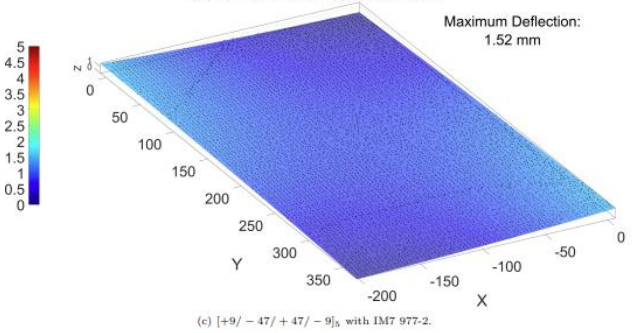
(a) $[+22.5/-67.5/-22.5/+67.5]_8$ with IM7 977-2

(b) $[+17.0/-64.5/+64.5/-17.0]_8$ with IM7 977-2



(c) $[+9/-61.5/+61.5/-9]_4$ with IM7 8552

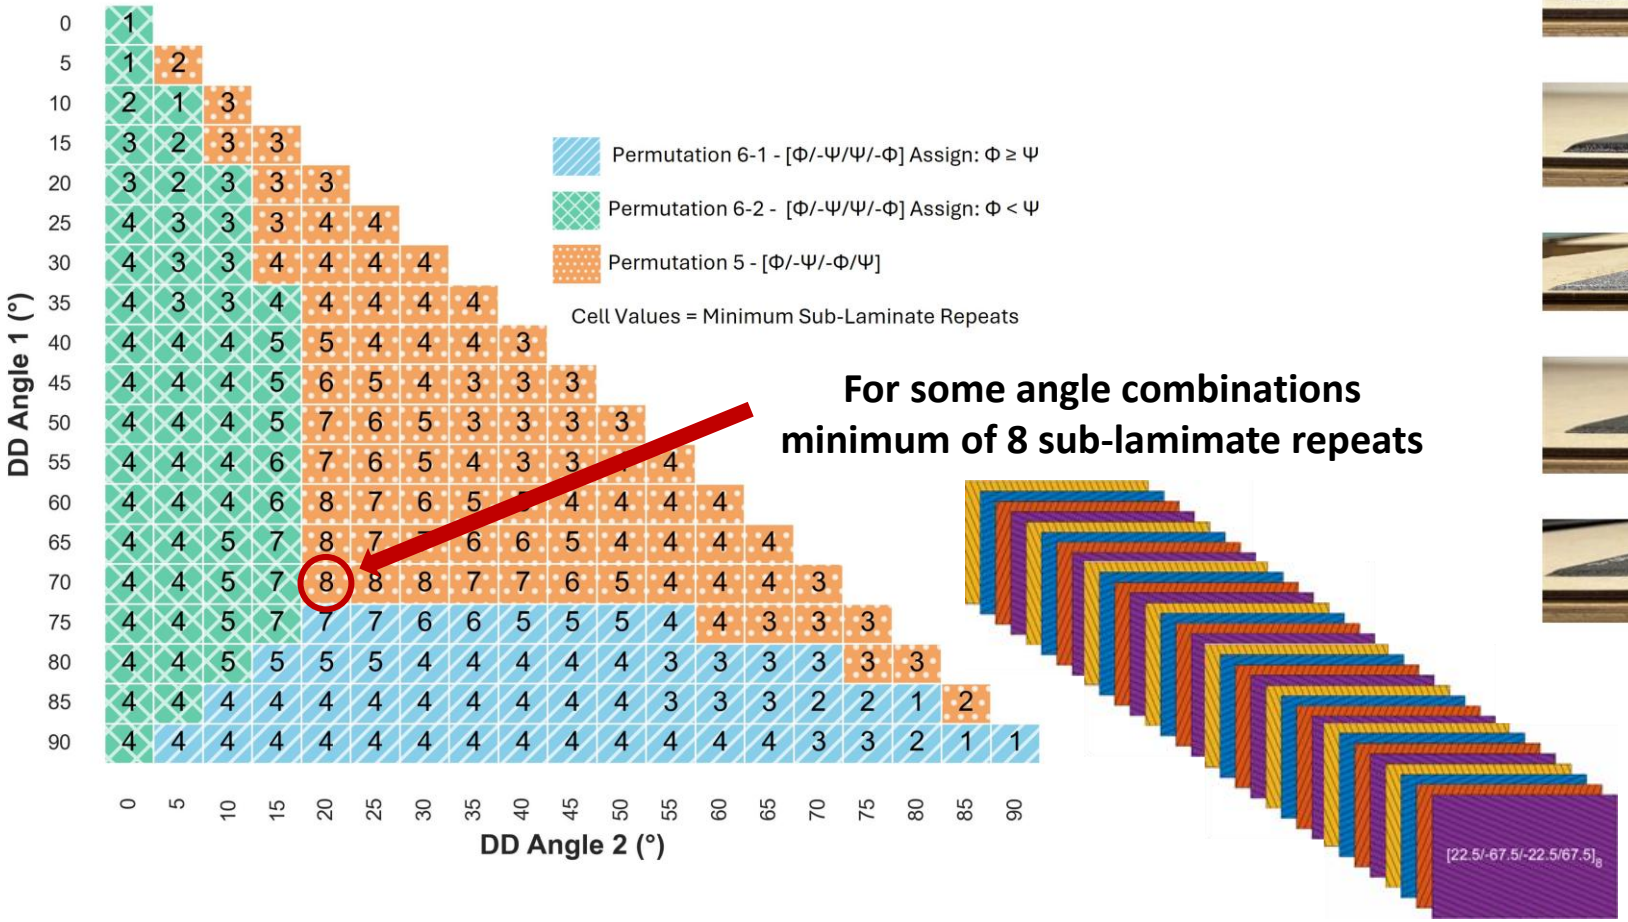
(d) $[+9/-61.5/+61.5/-9]_5$ with IM7 977-2



(e) $[+9/-47/+47/-9]_5$ with IM7 977-2

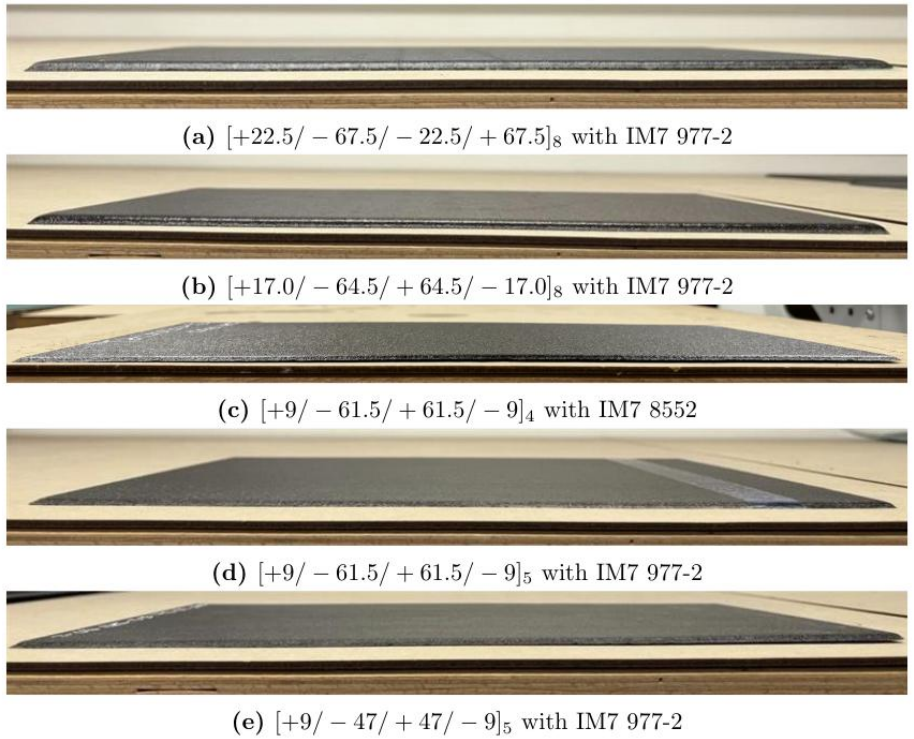
(a) $[+9/-61.5/+61.5/-9]_4$ with IM7 8552.

(b) $[+9/-61.5/+61.5/-9]_5$ with IM7 977-2.



(c) $[+9/-47/+47/-9]_5$ with IM7 977-2.

Updated Homogenisation Criteria



Proposing updated homogenisation criteria:

$$|D^{Tr*} - A^{Tr*}| < 0.02 \quad \& \quad B^{Tr*} < 0.01$$

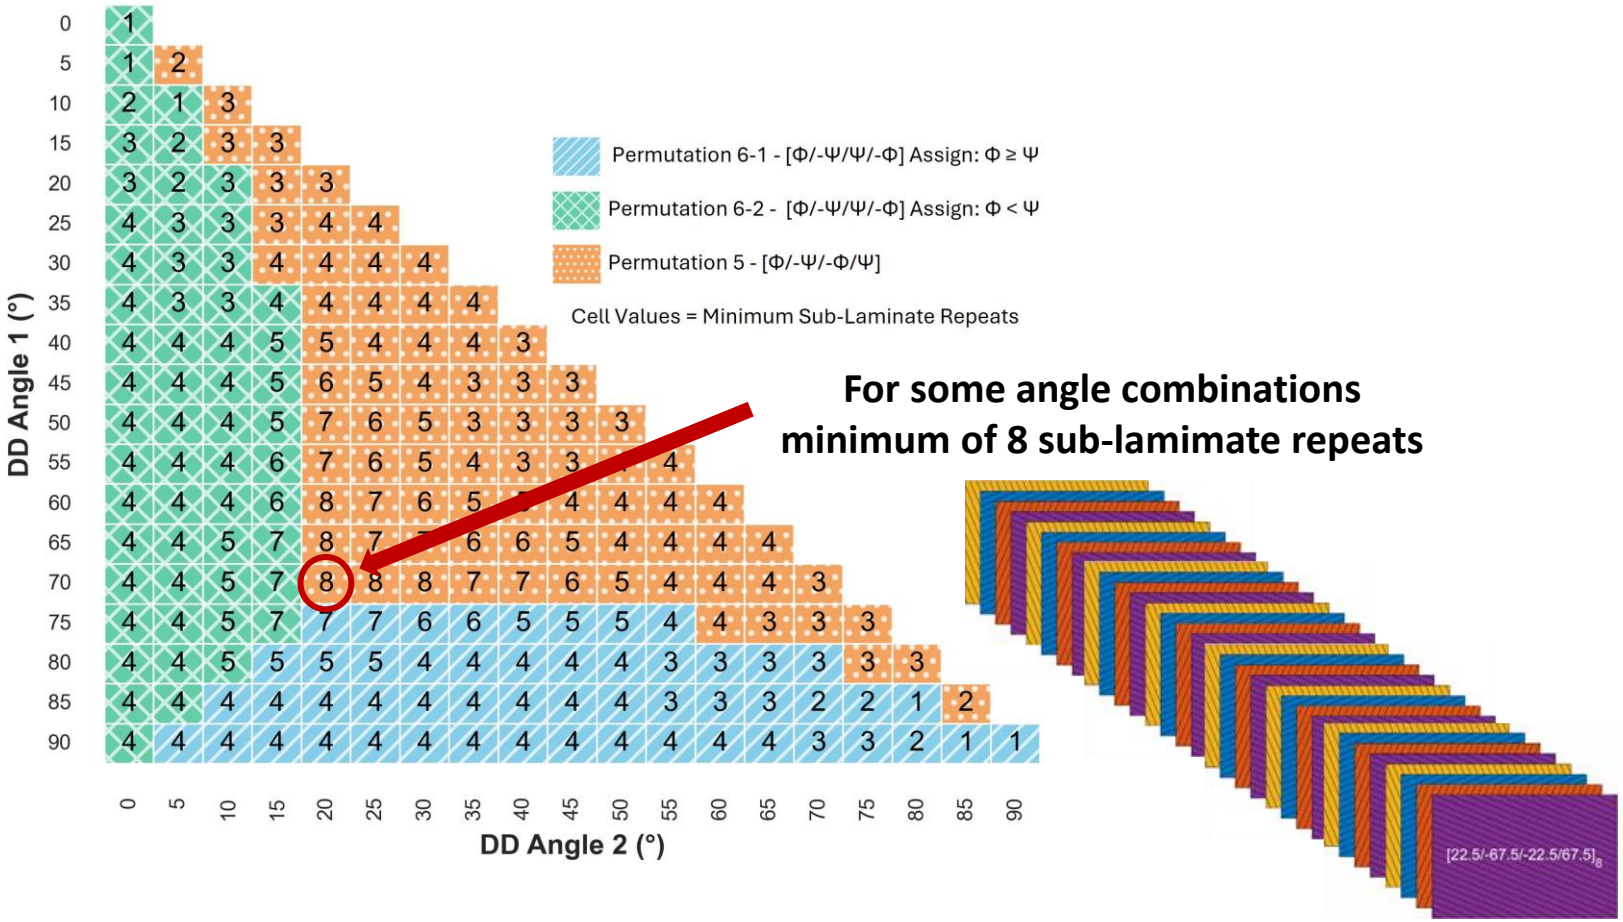
For some angle combinations minimum of 8 sub-lamimate repeats

Minimal to zero warpage

(a) $[+22.5/-67.5/-22.5/+67.5]_8$ with IM7 977-2

(b) $[+17.0/-64.5/+64.5/-17.0]_8$ with IM7 977-2

(c) $[+9/-61.5/+61.5/-9]_4$ with IM7 8552



(d) $[+9/-61.5/+61.5/-9]_5$ with IM7 977-2

(e) $[+9/-47/+47/-9]_5$ with IM7 977-2

Updated Homogenisation Criteria

Proposing updated homogenisation criteria:

$$|D^{Tr*} - A^{Tr*}| < 0.02 \quad \& \quad B^{Tr*} < 0.01$$

For some angle combinations minimum of 8 sub-lamimate repeats

Abstract

This study deals with the low velocity impact and post-impact behavior of Double-Double laminates. Impact on composite structures is one of the most common and critical sources of damage. The brittleness of composite materials makes them more vulnerable to such type of loading (matrix cracking, fibre breakage, delamination). The recent Double-Double method developed by S.Tsai [1] offers new perspectives for design optimization and manufacturing. Double-Double method seems to allow a better freedom and a possible better optimization in a laminate choice. The work presented aims to understand and quantify the key damage mechanisms in these structures, as well as to compare impact and post impact response to traditional laminates, with a view to a potential replacement and weight saving. For this, drop-weight impact tests and compression after impact tests have been carried out.

Keywords: Low velocity impact, Compression after impact, Double-Double laminates, damage tolerance

1. Introduction

Impact is one of the most common and most penalizing sources of damage for composite structures. Indeed, the brittleness, heterogeneity and lamination make them more vulnerable to this effect. Impact have to be studied for laminate structures especially in the field of aeronautics as it can be critical: bird collision, hail, tool falls during maintenance [2].

The impact damages commonly observed are intralaminar matrix cracks, delaminations and fibers breakage [3,4]. The mechanisms that control the initiation and propagation of theses damages are strongly influenced by the architecture of the composites. The first damage that appears is matrix cracking, then delamination is initiated which are very penalizing for the compressive strength of the laminates [5,6].

As failure mechanisms are difficult to represent with simple models, in industry, conservative empirical models and charts have been implemented.

The Double-Double method developed by Stephen W. Tsai [1] & al. is an innovative concept of lamination. It consists of a stack of structures called “building blocks” comprising 4 angles $[\pm\varphi/\pm\psi]$ [1], [7], [8]. These angles are defined according to the desired mechanical properties and can be between 0° and 90°.

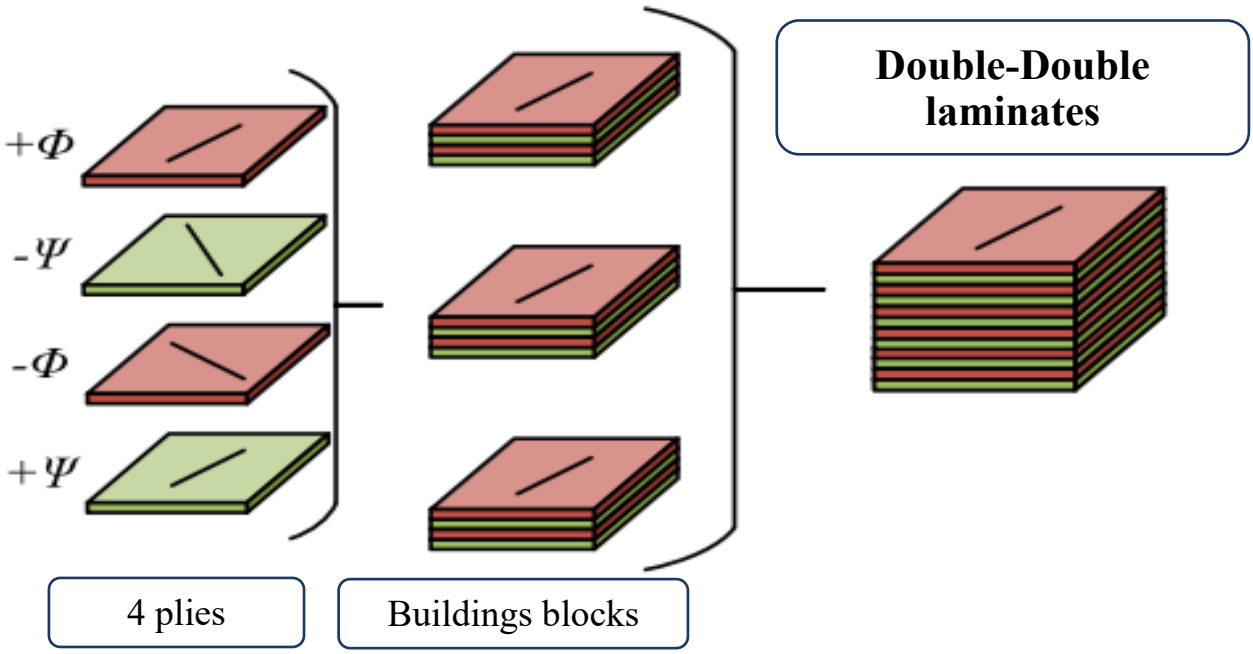

Figure 1 General principle of double-double method [12]

This method was developed to provide more freedom in the sizing and to bypass the restrictive lamination rules for manufacturers. Better optimization for composite seems possible.

Double-Double laminates are different than traditional ones (interface numbers, mismatch angle, homogenization…). Because of these properties, impact and compression after impact behavior may be different from traditional laminate behavior and challenge the principles of impact sizing.

There are a few studies that focus on the impact tolerance of Double-Double composites [9],[10],[11].

The research is still in its early stages, and no study has reached a definitive conclusion. A deeper understanding of the damage mechanisms in this type of laminate is needed.

The objective of this paper is to compare the response to low-velocity impact and post-impact of a Double-Double laminate and a traditional laminate. To do so, a traditional oriented laminate was chosen as the basis of the study named QUAD in this paper, the chosen Double-Double laminate has the same elastic properties in the plane and similar flexural properties as the reference laminate. So, the differences in stratification of the Double-Double method (angle between 0 and 90, homogenization, inter-ply angle, numbers of interface, etc...) compared to the traditional method are really studied. These two configurations were tested under low-speed impact for energies of 9J, 16J and 25J. Some specimens were analyzed using Tomography. Finally, these two configurations were tested under compression (Compression After Impact) in order to fully evaluate the impact tolerances of these two configurations. The tests were carried out according to ASTM D7136/D7136M and ASTM D7137/7137M standards.

2. Material and Methodology

2.1. Material and Stacking sequence design.

In this work, the material used was Toray 2510 Prepreg, P707AG-15 Fiber T700G. The

unidirectional propriety are summarized in Table 1. The base line Quad laminate was selected not according to the ASTM D7136. The QUAD stacking sequence is $\mathbf{[45/0_2/-45/90_2/45/0_3/-45/90]_s}$ resulting of a total thickness of 3.65 mm.

The configuration of the Double-Double laminate was made so that the in plane and flexion elastic properties are nearly the same as the QUAD laminate properties. For the comparison study it is important to have the same membrane stiffness for in plane load, whereas in impact test bending stiffness is more relevant.

The classic laminate theory (CLT) describes the behavior of laminate with the matrix $[\boldsymbol{A}, \boldsymbol{B}, \boldsymbol{D}]$:

$$\begin{bmatrix} \boldsymbol{A} & \boldsymbol{B} \\ \boldsymbol{B} & \boldsymbol{D} \end{bmatrix}$$

With;

A: in-plane stiffness matrix

B: membrane-bending coupling matrix

D: Bending stiffness matrix

It was arbitrary decided to have a perfect match for the in-plan properties and nearly the same for bending properties.

A way to achieve that is to use the laminates parameters. Tsai and Pagano [13] demonstrate that matrix A, B and D are a combination of materials parameters and laminates parameters. These lamination parameters depend only on the stacking sequence of the laminate (orientation and positioning of the plies)

In-plane laminates parameters $\boldsymbol{\xi^1_{A,Quad}, \xi^2_{A,Quad}}$ were evaluated for the QUAD laminate and the angles of Double-Double were calculated with this:

Quad stacking sequence $\longrightarrow (\boldsymbol{\xi^1_{A,Quad}, \xi^2_{A,Quad}})$

$(\boldsymbol{\xi^1_{A,Quad}, \xi^2_{A,Quad}}) \longrightarrow (\boldsymbol{\xi^1_{A,DD}, \xi^2_{A,DD}})$

$(\boldsymbol{\xi^1_{A,DD}, \xi^2_{A,DD}}) \longrightarrow \boldsymbol{\varphi \; and \; \psi}$

The Double-Double laminate for this specimen based on the extensional stiffness matrix was $\mathbf{[7/-64/64/-7]_{6T}}$. For these specimens, a perfect match was achieved with the [A] matrix and [D] matrix were quite similar. The A, B and D matrix are summarized in table 2.

Concerning the bending stiffness, the difference between the maximum of the matrix coefficient $\boldsymbol{D_{11}}$ is less than $\mathbf{2}\%$. Moreover, according to Christoforou [14] the response of FRP under low velocity impact is a function of the equivalent bending stiffness $\mathbf{D_{eq}} = \sqrt{\frac{\mathbf{A+1}}{\mathbf{2}}\mathbf{D_{11}D_{22}}}$, where $\mathbf{A} = \frac{\mathbf{D_{12}+2D_{16}}}{\sqrt{\mathbf{D_{11}D_{22}}}}$. The difference in equivalent bending stiffness between the laminates is less than 3%. It can be considered that Double-Double and Quad specimen have nearly the same elastics properties.

Engineering constant		Identification
E_1	[GPa]	125
E_2	[GPa]	8.41
ν_{12}	–	0.31
G_{12}	[GPa]	4.23
ρ	[kg.m^{-3}]	1 517
Ply thick-ness	[mm]	0.152

Table 1 Materials properties

The absence of mirror symmetry does not allow to obtain a zero-coupling matrix B. Mechanical couplings and thermal warping may exist. Homogenization makes it possible to overcome these problems. The repetition of building block makes it possible to obtain a "homogeneous" distribution of plies in the thickness of the laminate. Homogenization allows Double-Double laminates to behave like a homogeneous orthotropic material — meaning no mechanical coupling, no thermal

Matrix A, B and D for the Quad laminate:

$$A = \begin{bmatrix} 247 & 43.7 & 0 \\ 43.7 & 175 & 0 \\ 0 & 0 & 49{,}5 \end{bmatrix} \times 10^6 \quad D = \begin{bmatrix} 283 & 57.3 & 18.1 \\ 57.3 & 167 & 18.1 \\ 18.1 & 18.1 & 63.8 \end{bmatrix} \quad and \; B = [0]_{3,3}$$

Matrix A, B and D for the Double-Double laminate:

$$A = \begin{bmatrix} 247 & 43.7 & 0 \\ 43.7 & 175 & 0 \\ 0 & 0 & 49.5 \end{bmatrix} \times 10^6 \quad D = \begin{bmatrix} 278 & 47.8 & 0 \\ 47.8 & 191 & 0 \\ 0 & 0 & 54.3 \end{bmatrix} \quad and \; B = \begin{bmatrix} 0 & 0 & -4820 \\ 0 & 0 & 4820 \\ -4820 & 4810 & 0 \end{bmatrix}$$

Table 2 Matrix A $(Pa.m)$,B $(Pa.m^2)$ and D $(Pa.m^3)$

warping. While perfect homogenization is never truly achieved, increasing the repetition of building block brings the laminate closer to this ideal behavior. For this reason, a homogenization criterion has been defined [1]. When this criterion is met, the laminate is generally expected to exhibit no warping during curing, no excessive residual stresses, and no membrane-flexural coupling.

Homogenization criterion [1]:

$$|A^* - D^*| < 2\% \; Tsai$$
$$and$$
$$|B^*| < 2\% \; Tsai$$

With $A^* = \frac{A}{h}$; $B^* = \frac{2B}{h^2}$; $D^* = \frac{12D}{h^3}$ and

h the laminate thickness

The criterion is validated by the Double-Double laminate.

The two laminates therefore exhibit similar macroscopic elastic behavior in theory. However, from a mesoscopic perspective, the ply orientations differ between them, leading to a different distribution of both in-plane and out-of-plane stresses. Additionally, the number of interfaces and the inter-ply angles vary between the two stacking sequences.

Specimen	Quad	Double-Double
Number of interface	14	23
Inter-angle ply	Always 45°	Variable 72°, 53° *et* 14°

Table 3 Laminates configurations

2.2. Drop-weight and compression after impacts test

2.2.1. Drop-weight

Specimen were tested for low-velocity impact using a drop-weight device with a mass of 2 kg and an hemispheric impactor with a diameter of 16 mm for impact speeds between 3 and 5 m/s. The specimen dimensions are 150 x 100 mm. These low-velocity impacts are characteristic of so-called "classic" incidents in the workshop, such as tools falling onto parts or collisions during transport. The specimens were placed over a flat support fixture base with a 125 x 75 mm rectangular frame, which allowed the impactor to contact through the specimen without interferences.

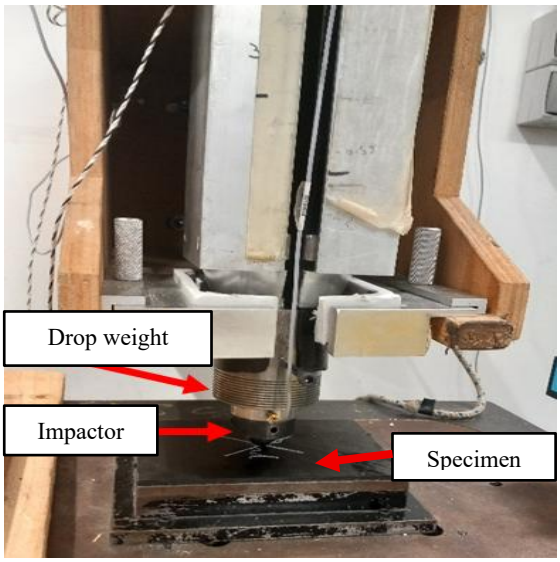

Figure 2 Impact test setup

Impact energies of 9 J, 16 J, and 25 J were applied, corresponding respectively to impact velocities of 3 m/s, 4 m/s, and 5 m/s. For each energy level, two specimens per configuration were tested.

2.2.2. Compression after impact test

The Compression After Impact (CAI) tests were performed using a Hydraulic test machine (Schenk PCS 450 kN) and a 250 kN load cell. To prevent global buckling, anti-buckling devices were implemented. Digital image correlation was employed to identify the buckling mode and monitor strain evolution.

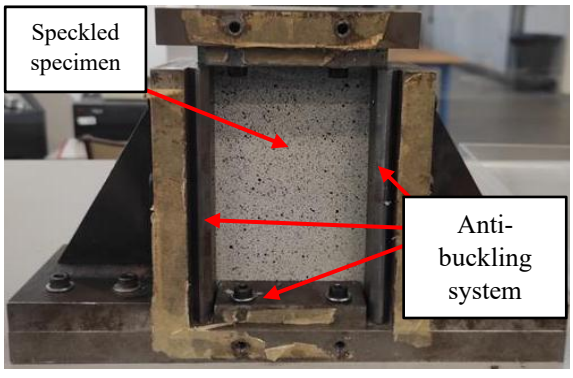

Figure 3 CAI test apparatus

3. Results

At 3 m/s, the damage induced is not significant enough to observe clear differences in either the impact response or the compression after impact performance. For the highest speed (5m/s), the samples are fully perforated so the difference in behavior between QUAD and Double-Double laminate is not relevant.

Fig 4 shows a comparison between the response of the two stacking sequences at $4\,m.s^{-1}$ $(E = 16J)$. It can first be observed that both laminates exhibit similar elastic behavior, which confirms the relevance of the selected stacking sequence. However, the energy dissipated by the Quad laminates is significantly higher than that dissipated by the Double-Double laminates. The first noticeable drop in stiffness — indicative of the onset of severe damage — does not occur at the same load level. The Quad laminates show a gradual reduction in stiffness starting around 3 kN, whereas the Double-Double laminates experience a more abrupt drop later, at approximately 3.8 kN, suggesting a delayed but more sudden damage initiation.

To complete this study, X-ray computed tomography (CT) scans were performed. Figure 5 shows the total delaminated area for both stacking configurations. The Quad laminates exhibit approximately twice the delaminated area ($\mathbf{15\,400\ mm^2}$) compared to the Double-Double laminates ($\mathbf{8000\ mm^2}$), suggesting that the Quad laminates sustained more severe damage during impact.

The delamination shape in the Quad laminates corresponds to the typical patterns observed in this type of test. In contrast, the Double-Double laminates display more circular delamination zones, likely due to their distinct ±45° inter-ply angles. Interestingly, while the Double-Double laminates present a greater number of delaminated interfaces, these are smaller in size. Conversely, the Quad laminates exhibit fewer delaminated interfaces, but the damage is more severe at each one.

This suggests that the Double-Double stacking sequence may distribute impact energy more effectively across multiple interfaces, leading to smaller, more controlled delaminations.

Figure 6 presents the results of the compression-after-impact (CAI) tests. As expected, both laminates exhibit similar elastic behavior. However, the failure load is significantly higher for the Double-Double laminates, reaching 50 kN compared to 33 kN for the Quad laminates. This corresponds to failure stresses of 137 MPa and 90 MPa, respectively. This difference in residual strength can be attributed to the extensive delamination observed in the Quad laminates. The large delaminated areas result in the formation of several thinner sub-laminates, which are more prone to local buckling and thus offer lower post-impact compressive resistance.

Additionally, the failure modes differ notably: the Double-Double laminates exhibit a more abrupt, brittle failure, whereas the Quad laminates show a more progressive failure behavior.

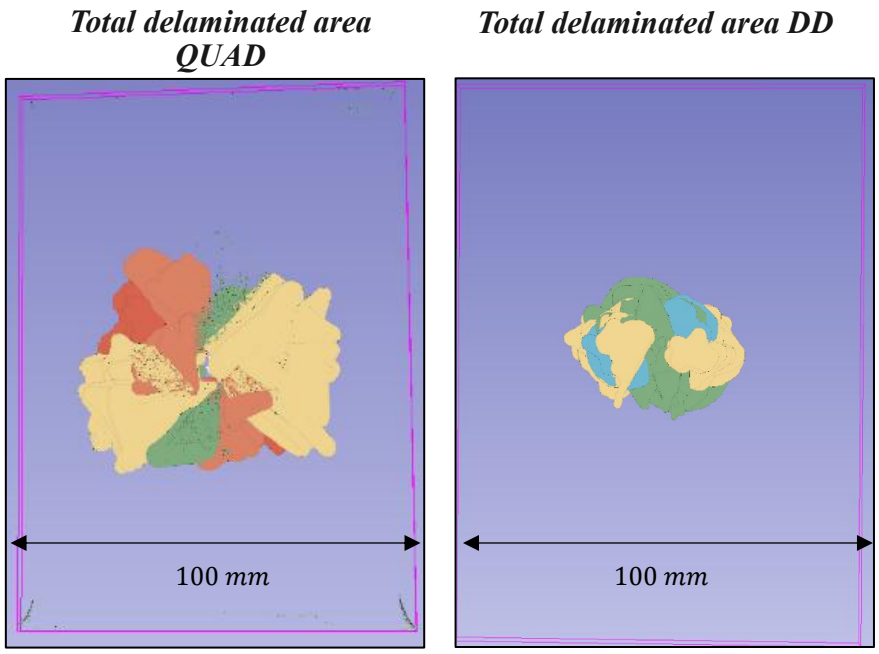

Figure 5 Delaminated surfaces after impact at 4 m/s on a Double-Double laminate (left) & Quad (right)

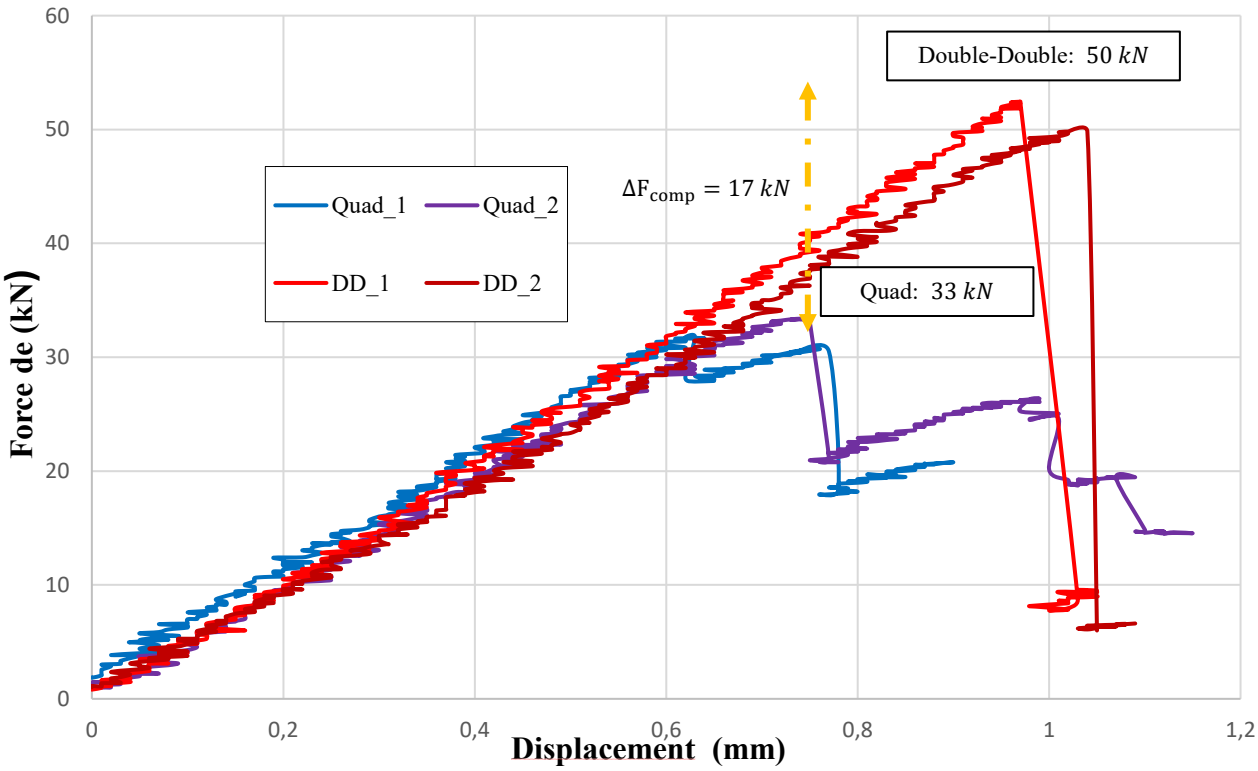

Figure 6 CAI results with LVI at 4 m/s for Quad & Double-Double laminate

4. Conclusion & perspectives

In this study, the response of a Double-Double laminate was analyzed and compared to that of a traditional Quad laminate with equivalent elastic properties. The selected Double-Double configuration appears to exhibit better damage tolerance than its Quad counterpart. However, caution is warranted: only one Double-Double configuration was studied, and the Quad laminate used for comparison may not have had the most optimized ply dispersion, as the primary objective was to comply with all the traditional design constraints.

Beyond the number of interfaces, other factors may contribute to the improved performance of the Double-Double laminate—such as a more favorable distribution of transverse shear stresses, the absence of bending-twisting coupling, or differing interfacial properties. Further investigation is necessary to better understand the damage mechanisms involved. Digital image correlation will be used to analyze both global and local buckling behavior of the specimens.

Since Double-Double laminates represent a broad class of layups, no general conclusions can be drawn based on the study of a single configuration. Future work will involve exploring other Double-Double configurations with varied angles and stacking sequences.

In addition to impact and compression-after-impact tests, quasi-static tests will be conducted to further understand the damage evolution in this type of laminate. To complement the experimental work, a numerical campaign will be carried out using the semi-continuous model developed at the Clément Ader Institute of Toulouse [15].

ABSTRACT

In this work we investigated the fundamental mechanisms behind fuzzball formation in Automated Fiber Placement (AFP), leveraging an Electroimpact AFP 4.0 cell. The goal was to develop a deeper understanding of the sources of imperfections that degrade the mechanical performance of composite components fabricated via AFP. To this end, we achieved direct observation of fuzzball formation by integrating an optical microscope into the AFP end effector. These observations revealed that most fuzz accumulation occurs in the feeding channel section. To further study the phenomenon, we developed a dedicated AFP workbench that allows for controlled material feeding under variable prepreg tension. Using this setup, we examined fuzzball formation under different prepreg tensions and feed rates in a static environment with constant temperature and humidity. These tests enabled real-time visualization of the fuzzball growth process. We then performed a quantitative analysis of the initiation and steady state growth phases. Our measurements showed that fuzzball growth rate scales with a power-law function of growth duration, feed rate, and prepreg tension. Additionally, we extended our investigation to full AFP operations, focusing on the effects of path curvature. By applying the same quantitative evaluation method, we found that fuzzballs grow more rapidly as the radius of curvature decreases. This curvature effect was further characterized in terms of the contact angle between the feeding channel and a prepreg tape, revealing a strong correlation with fuzzball formation.

1 INTRODUCTION

In modern aircrafts such as the Boeing 787 and Airbus A350, carbon fiber composite materials are integral to critical structural components, comprising approximately 50% of the total weight of the aircraft [1]. For manufacturing, initially hand layup was the predominant fabrication method, however, to address the limitations, automated processes such as Automated Tape Laying (ATL) and Automated Fiber Placement (AFP) were soon introduced.

A 2008 Airbus report [2, 3], based on data from Spirit AeroSystems [4], indicated that the actual laydown rate for the Boeing 787 was only 8.6 kg per hour—just 20% of Boeing's original estimate of 45.4 kg per hour [3, 5]. This discrepancy arises because composite layup involves more than just material deposition; it also requires extensive rework to correct imperfections. Boeing's analysis of the 787 fuselage barrel production at its South Carolina facility [6, 7] revealed that machine layup accounted for only 24% of the total floor-to-floor cycle time, whereas inspection and rework contributed to 63% (Figure 1a). Similarly, a 2014 report from Electroimpact [8, 9], a world-leader in AFP technology development, showed that, during part fabrication, 32% of time was dedicated to inspection and repair, 14% to process errors, and only 30% to machine layup (Figure 1b). Additionally, at the Defense Manufacturing Conference 2014, USA, Maass reported 55% of floor-to-floor time is consumed for 37%

inspection and 18% rework (Figure 1c). Consequently, more than half of AFP build time is spent on imperfection repair. This issue strongly motivates research into defect reduction and its impact on mechanical properties.

Harik et al. [11] classified AFP imperfections into 14 categories, with tow gaps/overlaps and wrinkles identified as common defects. Among these defect types, Foreign Object Debris (FOD) represents a unique anomaly [11]. FOD refers to unintended objects that become embedded in a part during layup, such as glove fragments, washers, backing films [12], or foil [10, 13]. These contaminants can degrade component performance by inducing wrinkles and other structural defects [14]. One of the specific FOD, i.e. fuzzball (Figure 2), consists of accumulated composite material—either carbon fiber or resin—that collects on the AFP machine head and is dropped on the part under fabrication, introducing excessive material volume into laminates [11]. Benson and Arnold [15] investigated fuzzball formation during the tape slitting process for AFP using Bismaleimide (BMI) prepregs. Their findings revealed that fiber fragments accumulate on machine components when fibers rub against surfaces in the material path process. The study examined five different BMI materials, all of which produced unacceptable amounts of fuzz despite considerable efforts by material vendors to reduce fuzz generation.

Although several studies on fuzzball formation have been published, quantitative investigations remain limited. This is likely due to the difficulty of evaluating fuzzball formation under standardized conditions, given variations in AFP machines, material properties, layup path designs, material feed rates, prepreg tension, and environmental factors such as temperature and humidity. To enhance AFP composite manufacturing efficiency and ensure component reliability, this research aims to establish a quantitative evaluation framework for fuzzball formation. Specifically, this study focuses on developing a controlled workbench for fuzzball formation analysis, conducting in-situ observations of fuzzball growth during AFP operations, and assessing the dependence of fuzzball growth rates on manufacturing conditions.

2 MATERIALS AND METHODS

2.1 Materials and AFP system

For this study, we used a 1/4” unidirectional prepreg slit tape (P2362W-19L:T800S-24K/3900-2C) supplied by Toray Industries Inc. [16]. The prepreg material, featuring a fiber areal weight of 192 g/m2 and a resin content of 35.5 wt%, was stored in a freezer at a temperature of -18.6 ◦C (-1.4 ◦F) before use. Before each test, the bobbins were allowed to reach room temperature inside a vacuum bag for 24 h. For all tests performed in this study, room temperature and humidity ranged between 17.9 and 24.5◦C and 20 and 53% respectively. The experimental work presented in this report was carried out on an Electroimpact AFP 4.0 cell installed at the Advanced Composites Center (ACC) [17], at the University of Washington (Figure 3).

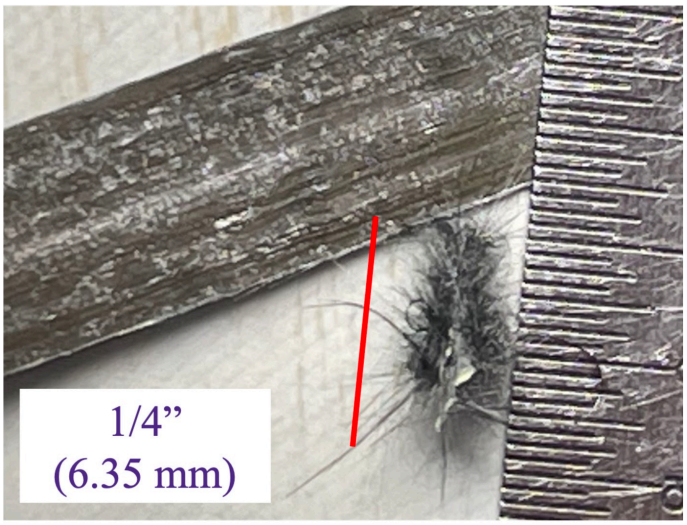

Figure 2: A fuzzball formed on a curved path operation. The scale bar corresponds to 1/4” (6.35 mm).

2.2 Workbench study

The end-effector is composed of multiple components (Figure 4). Through a series of test runs, we determined that the majority of fuzz accumulation occurs at the feeding channel of the AFP end effector module components (Figure 4h, Figure 5). To investigate the fundamental effects of prepreg tension and feed rates, we employed an external module – referred to as the AFP workbench (Figure 6a) to feed prepregs out of the AFP head.

A USB digital microscope (AF7915MZTL by Dino-Lite [18]) was mounted to observe the feeding channel directly. Since fuzz formation is driven by contact between material and fixtures, we intentionally introduced lateral contact between the prepreg tape and the edge of the feeding channel module outlet. In all experiments, the prepreg ran parallel to the outlet edge while being fed straight through the system, as shown in Figure 4f. Feed rate and prepreg tension were varied independently. Feed rates ranged between 2.52 and 10.1 in/s; 8.4 in/s representing our standard feed rate for qualified flat straight layups. Prepreg tension was maintained between 0 and 3.42 lbs, of the upper limit for our AFP system. Notably, no thermal input was applied during workbench tests, as heating typically occurs only during material deposition onto the tool surface (Figure 6d). Our analysis focused on the following observable operation parameters: (1) material feed rate, (2) prepreg tension, (3) layup path radius.

2.3 AFP operation study

We investigated whether the fuzzball formation model on the workbench study can be applied to realistic AFP operation in the same manner. To compare the results, we laid prepregs up on a flat coupon table in the AFP cell. For this case we used the laser heating system because otherwise the laid prepregs frequently get peeled off the tool table, although the fuzzball formation spot on the feeding channel is not exposed directly to the laser. We fed prepregs at the feed rates close to the workbench cases. We also fed at 1.67 in/s, but it showed no apparent fuzzball. To be consistent with regular AFP operations, we followed the basic operation program, at which condition the prepreg tension is linearly decided by the material feed rate (Figure 6c). We also changed the layup path radius to several values: 51.5”, 62.0”, 70.0”, 80.0”, and 89.7” (Figure 7). This range was tested because with radii less than 51.5” path radius, we frequently see out-of-plane prepreg deformation on the flat table. On the other hand, if it exceeds 89.7”, we hardly see fuzzballs. Due to the difficulty of microscope mounting, we instead used a short focal lens camera mounted on the laser heating module (Figure 6b).

3 RESULT AND DISCUSSION

3.1 Fuzzball formation observation

In the workbench study, we captured the fuzzball formation process and examined its structural evolution (Figure 8). A fuzzball formation begins with the appearance of a white accumulation composed of prepreg matrix material that has been ground or scattered due to mechanical feeding. Shortly thereafter, chopped black fibers become embedded in the resin and are twisted together by the motion of the advancing prepreg tape. This interaction forms a spheroidal mass of resin and fibers that elongate over time. As growth continues, the spheroid begins to twist into a tangled, thread-like structure – commonly referred to as a fuzzball. The fuzzball grows in size and complexity by continuously

absorbing additional resin and chopped fibers. Eventually, it becomes large enough to be caught by the material flow and is pulled away, detaching from the feeding channel. Based on these observations, we categorized the fuzzball growth process into four distinct phases: 1) Initiation: rapid formation and growth of a spheroidal structure, 2) Stable Growth: semi-constant growth while retaining a spheroidal shape, 3) Unstable Growth: transition to an irregular, non-spheroidal morphology, and finally 4) Detachment: separation of the fuzzball from the material flow. In the following sections, we focus primarily on the behavior observed during Stages 1 and 2 (Initiation and Stable Growth), which precede the onset of morphological instability.

In the workbench study, we captured the fuzzball formation process and observed its structure (Figure 8). A fuzzball starts to form with white accumulation. This white part is made of prepreg matrix ground/scattered by the feeding. Then, black chopped fibers are involved in the initial resin, being twisted by the flowing prepreg thread. It forms a spheroidal object of resin and fibers, and that quickly begins to elongate. Next it starts to be twisted again into a tangled thread ball, or a fuzzball. As it keeps growing, the object gets longer and bigger absorbing more resin and chopped fibers, and finally that fuzzball is hooked by material flow and then detached.

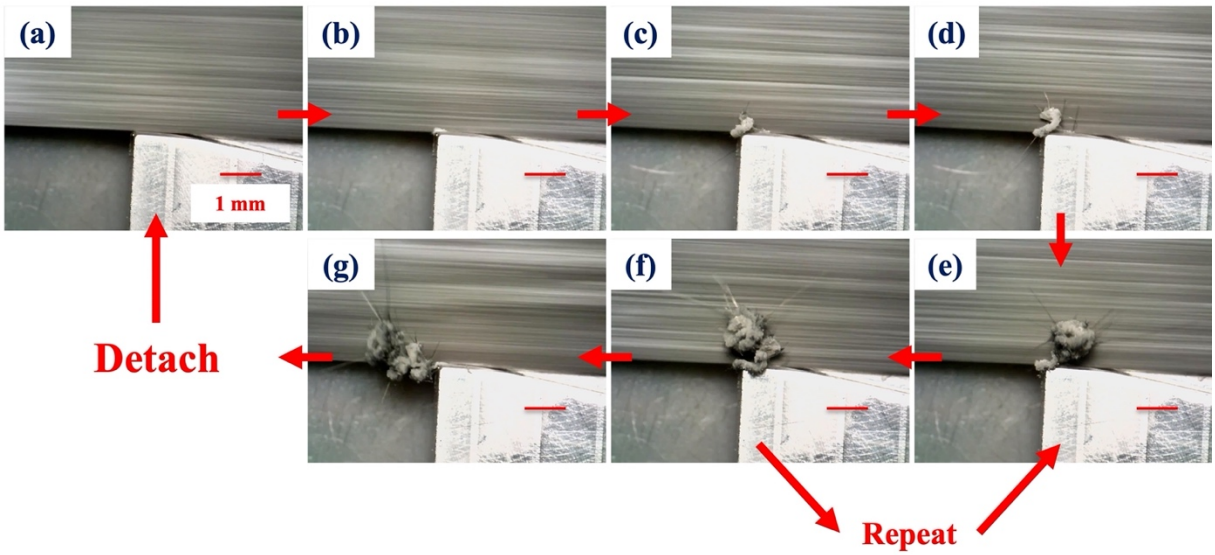

Figure 8: Fuzzball growth cycle. (a) Feeding starts. (b) Initiation (A fuzzball seed is formed.) (c) Stable growth in a spheroid form. (d) Starting to be twisted. (Unstable growth starts in a non−spheroidal form.) (e) Keep growing unstably. (f) Twisted again and grow until (g) it gets large enough to be hooked by the prepreg, and then detached.

3.2 Workbench study result

To quantitatively analyze the fuzzball growth process, we plotted the fuzzball major and minor axis lengths against the corresponding amount of fed prepreg material (Figure 9). The results suggest that the amount of material fed is not the primary factor determining fuzzball size. In contrast, Figure 10b shows the aspect ratio between the major and minor axes remains nearly constant throughout growth. This ratio follows a normal distribution with a mean value of approximately 5. Assuming the fuzzball can be approximated as a prolate spheroid with a constant aspect ratio s, the minor axis length l_{minor} is constantly proportional to the major axis length l_{major}, as expressed in Equation (1). Consequently, the fuzzball volume can be approximated using the standard formula for the volume of a prolate spheroid, as shown in Equation (2).

$$l_{major} = s\, l_{minor} \tag{1}$$

$$Fuzzball\ Volume = \frac{4\,\pi l_{major}^3}{3\,s^2} \tag{2}$$

The underlying assumption of our analysis is that the rate of fuzzball volume growth is proportional to Q, the volume of material removed per unit time as Equation (3):

$$\frac{d}{dt}\left(\frac{4\,\pi l_{major}^3}{3\,s^2}\right) = C_{Env.Mat.}\,Q \tag{3}$$

This relationship includes a proportionality coefficient, $C_{Env.Mat.}$, which accounts for environmental conditions (e.g. temperature and humidity). In this study, $C_{Env.Mat.}$ is assumed to be constant under the controlled test conditions. To quantify growth, we measured the fuzzball size starting from the point of initiation—defined as the moment when the fuzzball length first begins to increase from zero as (4):

$$l_{major} = \left(\frac{C_{Env.Mat.}\,Q}{\frac{4}{3}\pi s^{-2}}\right)^{\frac{1}{3}} t^{\frac{1}{3}} \tag{4}$$

$$\because\ l_{major}(t=0) = 0$$

To normalize the effect of prepreg tension on fuzzball growth, we draw upon principles from Metal Cutting Theory. This theory suggests that the depth of cut a is proportional to the product of powers of cutting speed and cutting force [20]. In the context of our study, these variables correspond to the feed rate and prepreg tension, respectively (Figure 11) This relationship is expressed as follows:

$$\frac{d}{dt}l_{major} = \left(\frac{C_{Env.Mat.}\,Q}{\frac{4}{3}\pi s^{-2}}\right)^{\frac{1}{3}} \frac{1}{3}\,t^{-\frac{2}{3}} \tag{5}$$

$$a = C_{CT}\,V^{a_V}\left(\frac{P}{b}\right)^{a_P}(1-\sin(\alpha))^{a_\alpha} \tag{6}$$

where b represents the width of cut—equivalent to the thickness of the prepreg tape in our setup—and C_{CT} is a proportionality constant. Additionally, α denotes the rake angle (i.e. the angle between the material and the cutting surface), and a_α is its associated exponent. In the workbench tests, α is assumed to be constant.

Following this framework, the material removal rate per unit time (Q) can be expressed as the product of cutting speed, width of cut, and depth of cut as in (7):

$$Q = V\,b\,a \tag{7}$$

By substituting Equations (6) and (7) into the earlier expression for fuzzball growth rate, Eq. (5), the following growth model can be derived as (8):

$$\begin{aligned}\frac{d}{dt}l_{major} &= C_{L.M.}P^{(\frac{a_P}{3})}V^{\frac{(a_V+1)}{3}}t^{a_t}\,(1-\sin(\alpha))^{(\frac{a_\alpha}{3})}\\ &\equiv C_{L.M.}\,P^{A_P}V^{A_V}t^{a_t}\,(1-\sin(\alpha))^{A_\alpha}\\ \because\ C_{L.M.} &= \frac{1}{3}\left(\frac{C_{Env.Mat.}\,b^{(1-a_P)}C_{CT}}{\frac{4}{3}\pi s^{-2}}\right)^{\frac{1}{3}}\end{aligned} \tag{8}$$

According to this equation model, $a_t = -\frac{2}{3}$, $A_V = 1$ and $A_P = 0.59$ are determined. We plot the growth rate/$V^{A_V}P^{A_P}$ to t^{a_t} (Figure 12). It organizes the manufacturing condition effects of material feed rate and prepreg tension normalized with the growth duration in fuzzball stable growth.

3.3 AFP Operation Study Result

We investigated fuzzball growth behavior during AFP operations along curved paths with constant radii of curvature. The major axis growth rate was normalized using the same parameters defined in the workbench study specifically A_V, A_P and a_t. We plot the normalized growth rate to that in Figure 13 and measured the slopes of each subplot. The slope comparison to path radius is in Figure 14 (Left). The workbench experiments correspond to straight-path feeding, which translates to a path radius greater than 89.7". Notably, we did not observe any fuzzball formation when the path radius exceeded this value. To incorporate curvature effects into the cutting model, we attempted to relate the rake angle α and its exponent A_α to the path radius, as path curvature influences the prepreg's position within the feeding channel and thus alters the effective rake angle. However, due to the small range of observed α, it was not possible to obtain direct quantitative measurements. To address this, we defined the rake angle α parametrically as a function of path radius R, using a characteristic length l_{sp}:

$$\alpha = \frac{\pi}{2} - \arctan\left(\frac{l_{sp}}{R}\right) \tag{9}$$

This formulation satisfies two key constraints: (1) the variation in rake angle is minimal and visually negligible across cases, and (2) following the definition of rake angle [20], $\alpha = \frac{\pi}{2}$ corresponds to zero depth of cut, as the blade becomes parallel to the material surface. The parameter l_{sp} was determined in Figure 14 (Right), however, we found that any value less than approximately 0.3" yielded a good fit to the experimental data. Therefore, we selected the prepreg width of 1/4" as a representative length for l_{sp}. Additionally, we enforced the boundary condition that no fuzzball growth occurs in straight path layups (i.e. as $R \to \infty$). Based on these considerations, we determined the rake angle exponent to be $A_\alpha = 0.25$.

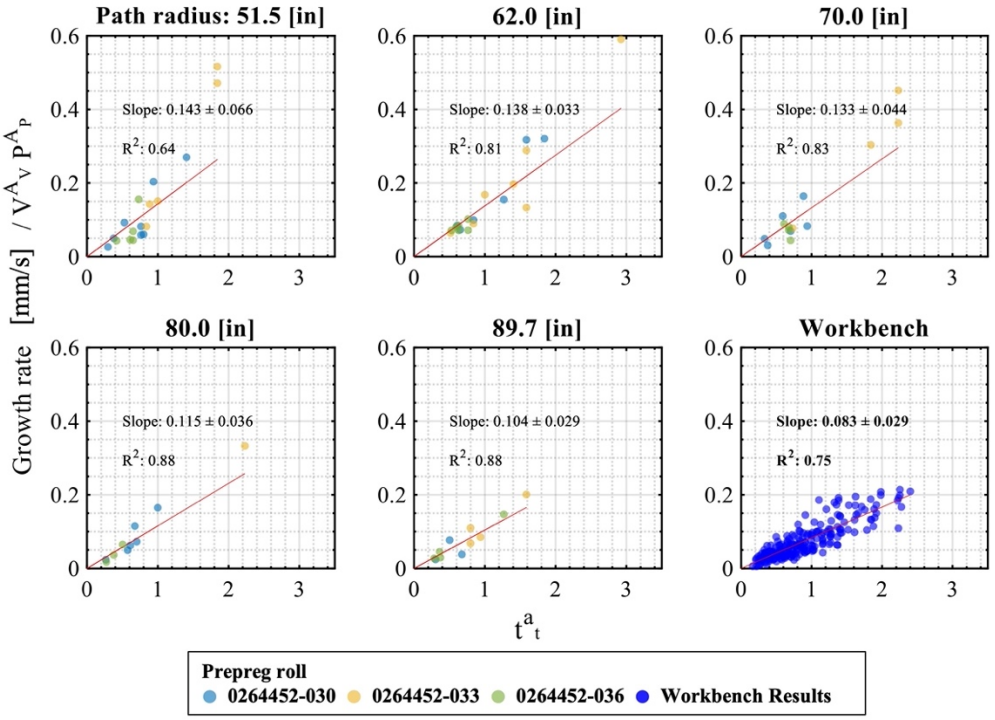

Figure 13: Major axis growth rate/$V^{A_V} P^{A_P}$ to t^{a_t} for curved-path AFP operations and workbench comparison. The workbench plot represents its data for all prepregs.

4 CONCLUSIONS

This study investigated the fundamental mechanisms of fuzzball formation during Automated Fiber Placement (AFP) operations. Using a microscope, we directly observed fuzzball formation both in controlled workbench experiments and during actual AFP operation. In the workbench study, we quantified the fuzzball size and growth duration under various feed rates and prepreg tension levels. The results, interpreted through the framework of Metal Cutting Theory, revealed that the fuzzball growth rate is proportional to the product of power functions of growth duration, feed rate, and prepreg tension. In the AFP operation study, we extended this evaluation method to examine the influence of path curvature. The results quantitatively demonstrated that increased curvature (i.e. smaller path radius) leads to faster fuzzball growth. Through this combined analysis, we evaluated how key manufacturing parameters—prepreg tension, feed rate, and path curvature affect fuzzball growth rate. This framework

offers a basis for quantitatively predicting fuzzball formation behavior, and it can be extended to incorporate material-specific and environmental effects. Such predictive capabilities are critical for improving the producibility and reliability of composite components fabricated in AFP. Future work will focus on extending this study to the effects of temperature and humidity leveraging the new upgraded AFP cell at the UW Advanced Composites Center (ACC). Furthermore, computational work leveraging quasibrittle fracture mechanisms [21] frameworks such as the microplane model [22, 23] and the Discrete Model for Composites (DM4C) [24, 25, 26] is ongoing to be able to predict some of the constants identified in this work.

ACKNOWLEDGEMENTS

The authors gratefully acknowledge the generous support from ES3 Inc. and the University of Washington Advanced Composites Center (ACC), which made the experimental work presented in this study possible. We also extend our sincere thanks to Toray Industries for providing the prepreg material used in this research, through the UW ACC–Toray technical partnership.

24th International Conference on Composite Materials

August 4-8, 2025, Baltimore, MD, USA

Outline

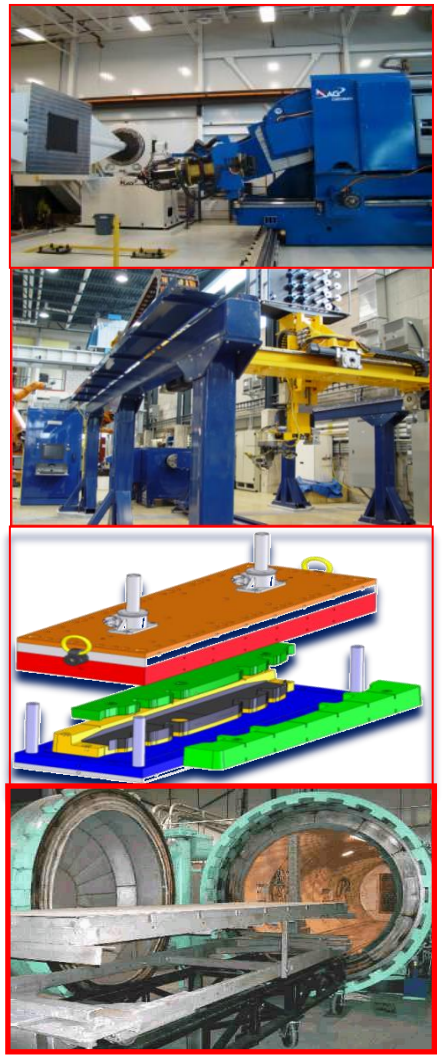
- Introduction
  - Why Automated Fiber Placement (AFP)?
- AFP Activities at NRC Aerospace
- Key Stages in AFP Process Development
- Our Approaches to Optimize AFP Manufacturing Process
- Case Study
- Summary

Introduction

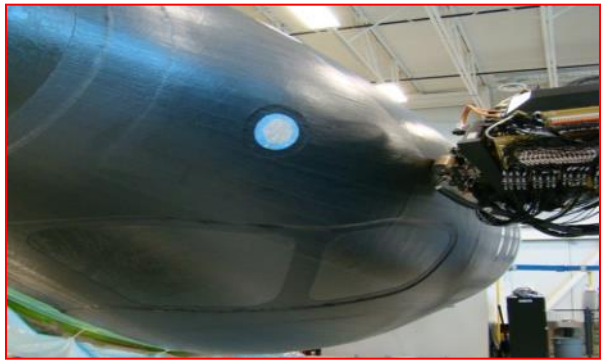
What is AFP?:

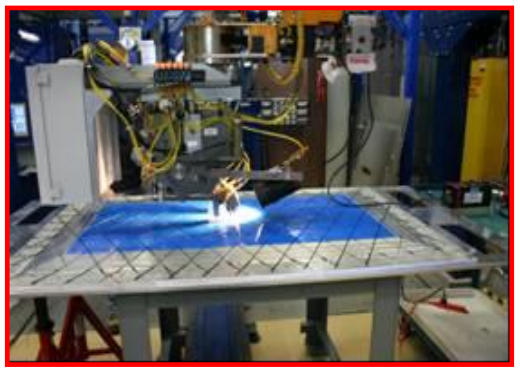
- Automated Fiber Placement (AFP) is a manufacturing process that uses computer controlled AFP machines to make composite structures by laying down composite slit tape layer by layer precisely.

Why AFP?:

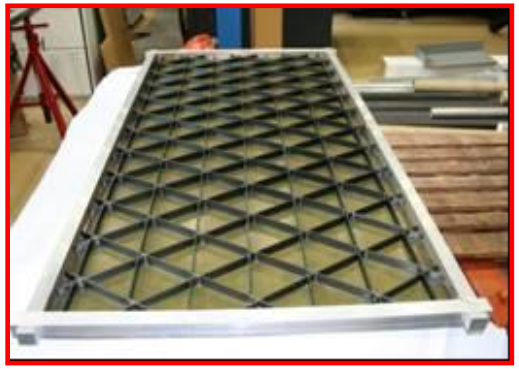


- Large structures with complex shapes
- Consistent quality
- Faster and efficient
- Less waste and cost
- High precision and quality





Manufacturing fuselage panels for the A350 XWB (Picture © Premium Aerotec GmbH.)



Composites Research at NRC Aerospace

- Composites manufacturing
  - Automated fibre placement
  - Liquid composite moulding
  - Thermoplastic composite joining and manufacturing
  - Autoclave processing
  - Compression moulding
  - Low-cost tooling
- Process modeling and simulation
- Composites joining and repair
- Structure design and stress analysis
- Material characterization and mechanical testing

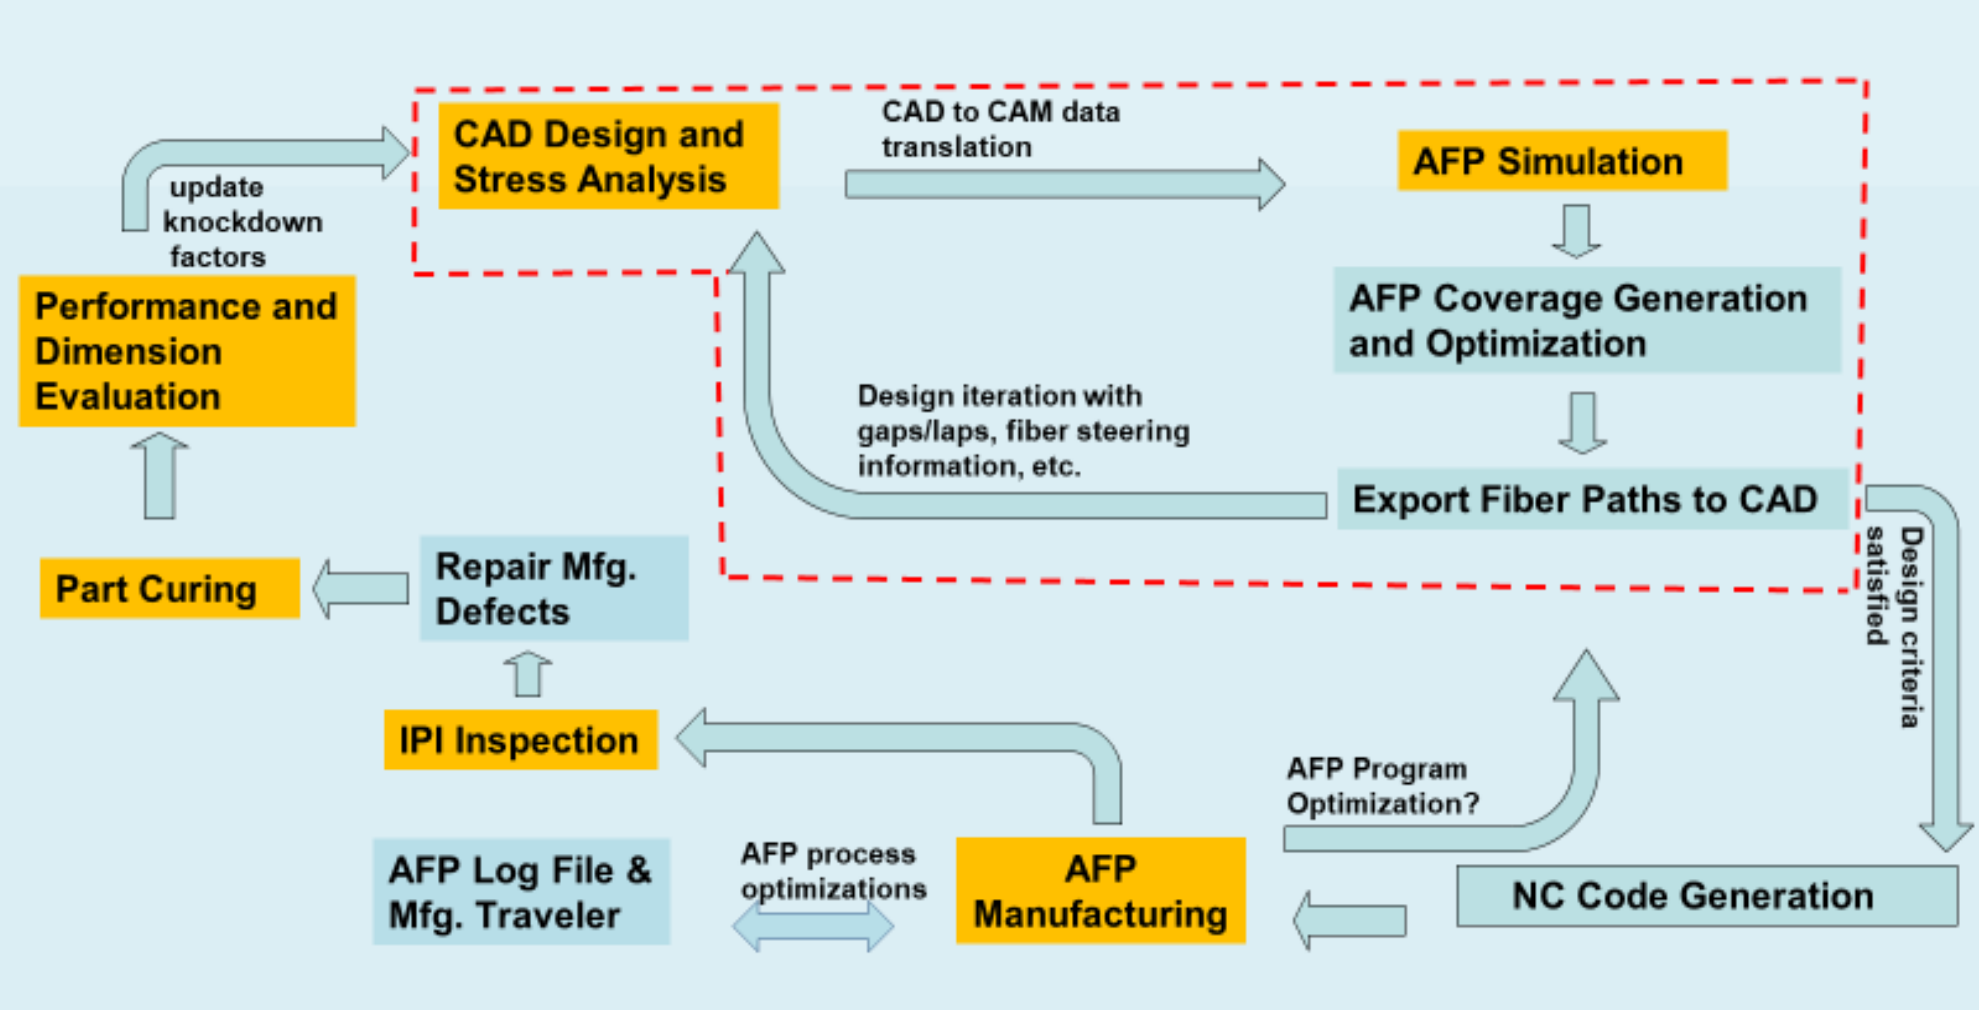
Process modelling and simulation

Key Stages in Automated Fiber Placement Process

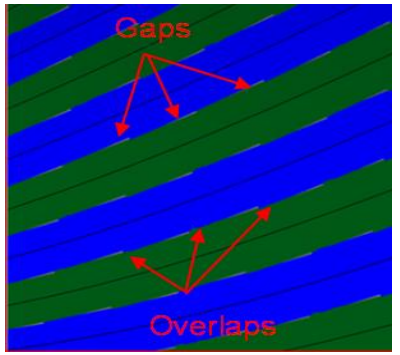


- Part Design
- AFP Simulation and Programming
- AFP Manufacturing
- Inspection and Quality Control
- Part Curing
- Testing and Evaluation

Our strategy: Optimize the AFP process by optimizing each individual stage

The challenge: Each stage is linked to the others. Optimizing any stage depends on iterative data transfer and feedback within a closed-loop workflow

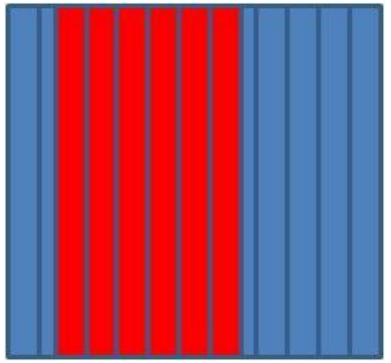
Closed-Loop Workflow of Automated Fibre Placement Process



AFP Simulation

Main Tasks of AFP Simulation

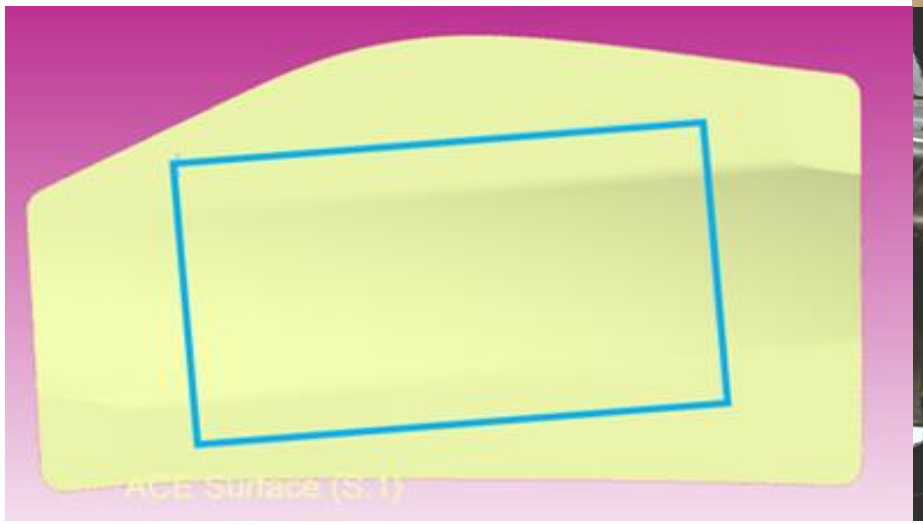
- Tooling validation and process feasibility study
- Ply coverage generation and optimization
- Defects prediction, e.g. gaps/laps and fiber steering, etc.
- AFP programming and virtual commissioning
- Productivity and cost analysis



Important Parameters for AFP Simulation

- Mesh size
- Surface update
- Tow count and tow thickness
- Coverage method, start point and layup directions
- Fiber orientation
- Stagger offset
- Gap/overlap ratios
- ……

0%·Overlap → → 100%·Overlap¶

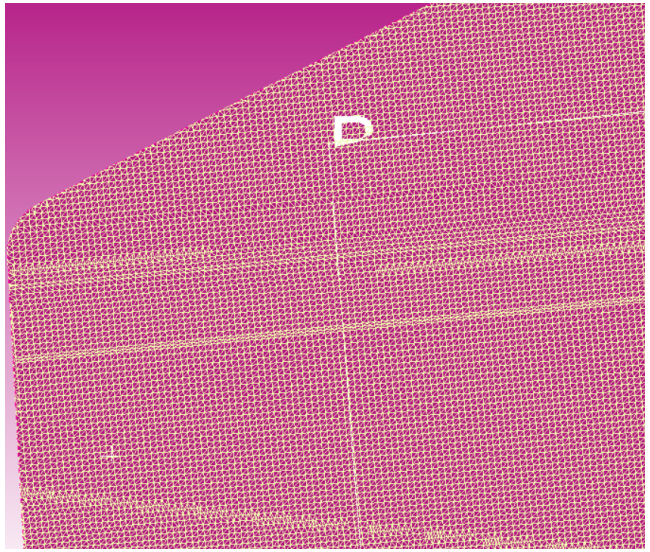


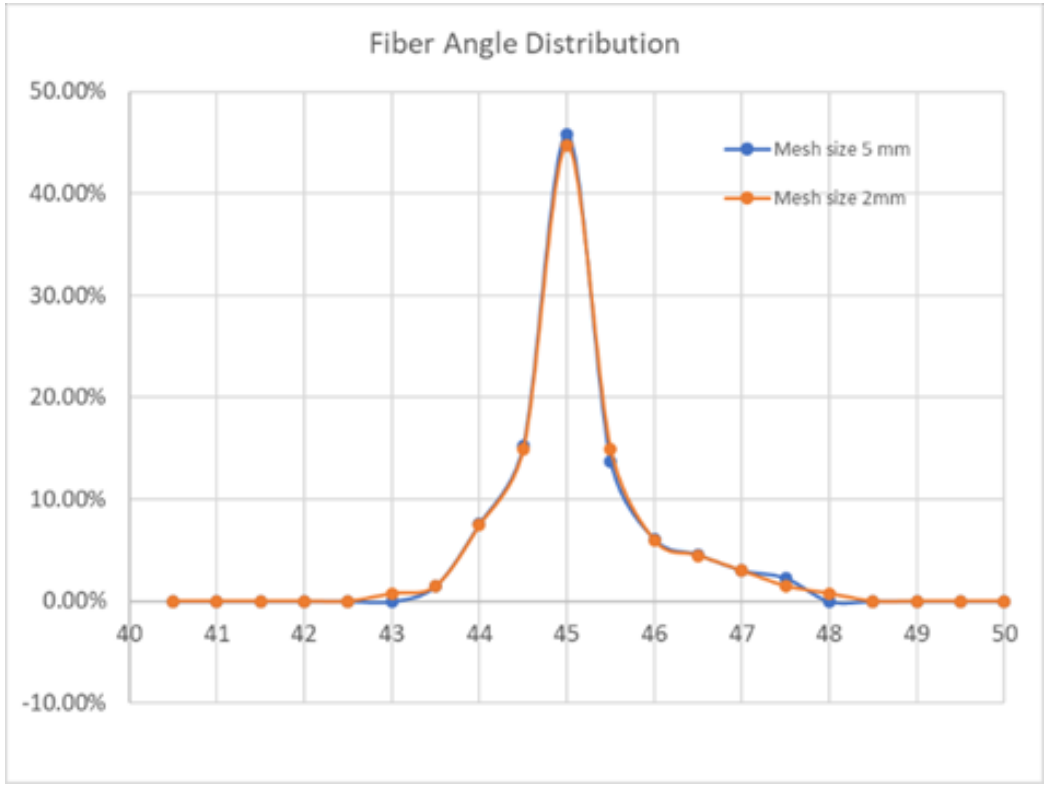
Fiber stagger

Case Study: Fiber Placement of A Curved Composite Panel

Part Info:

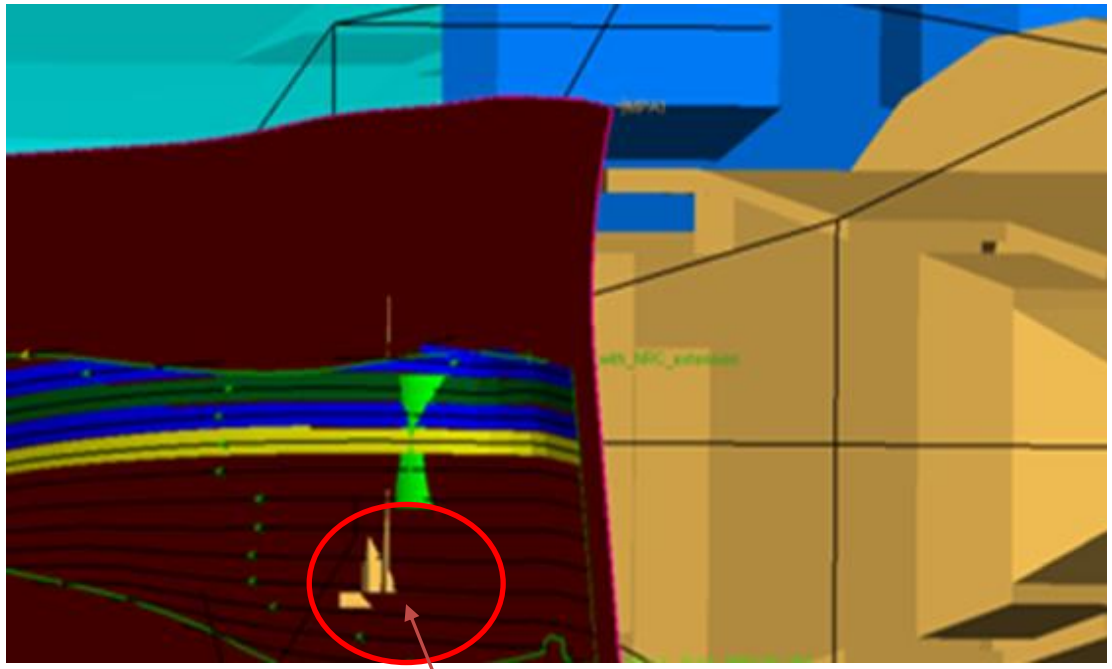
- Panel size: 15.5 x 27 inches
- Material: Carbon fiber/epoxy
- Layup sequence: [45/0/-45/0]s

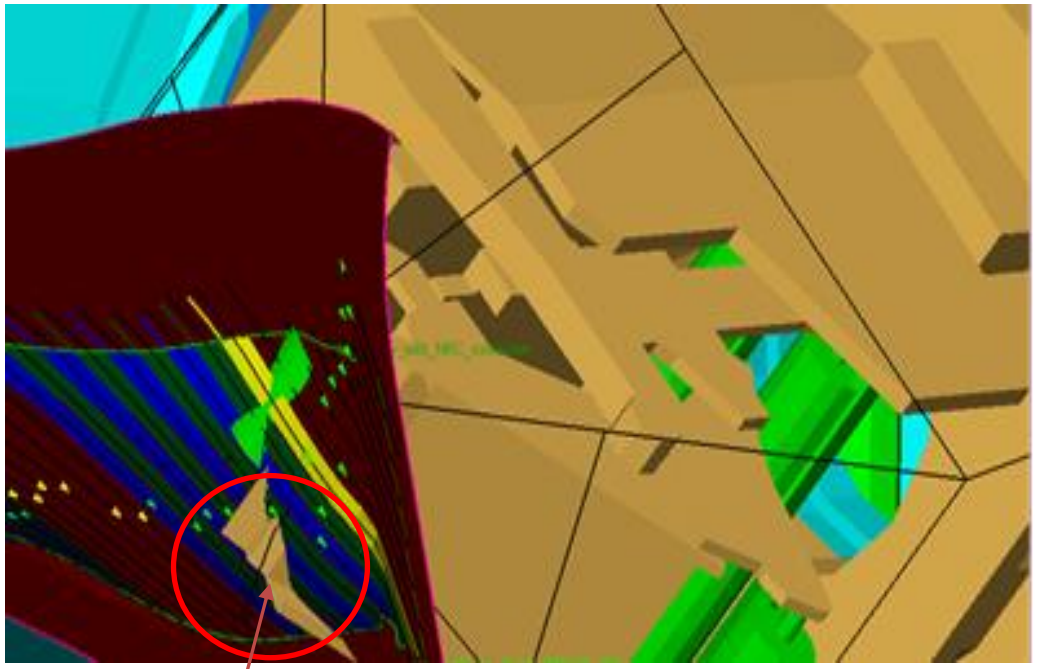




AFP Simulation: Surface Meshing

Common question:
Is the mesh size good enough for this part?

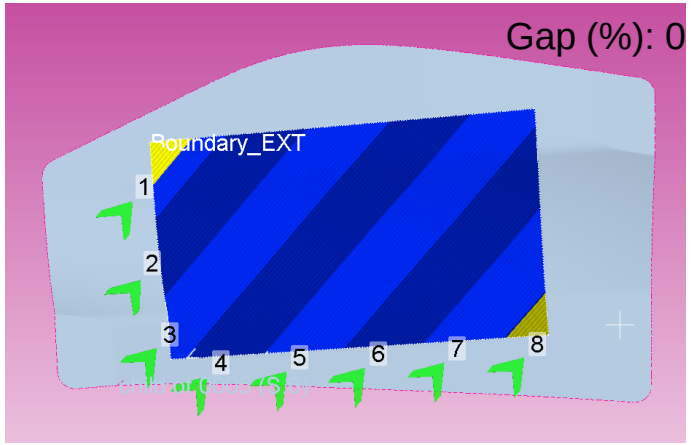




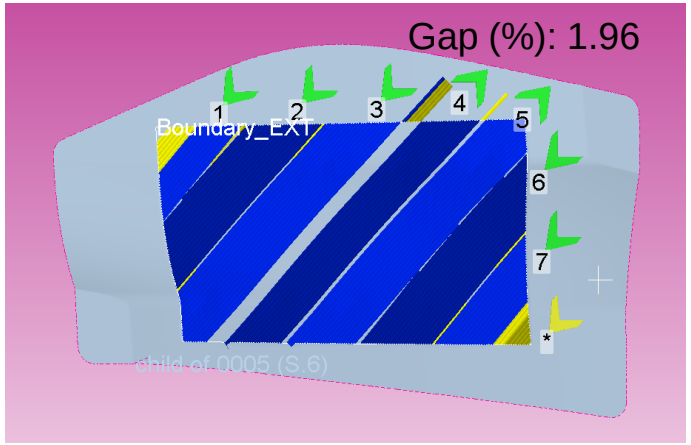
- Finer mesh improves path accuracy on complex surface
- Mesh size depends on geometry, part size, and computer capability
- For example, for this curved panel, reducing mesh from 5 mm to 2 mm increased ply time by 2.5×

Mesh Strategy: Balancing simulation accuracy and computational time is key

AFP Simulation: Tooling Validation and Process Feasibility Study

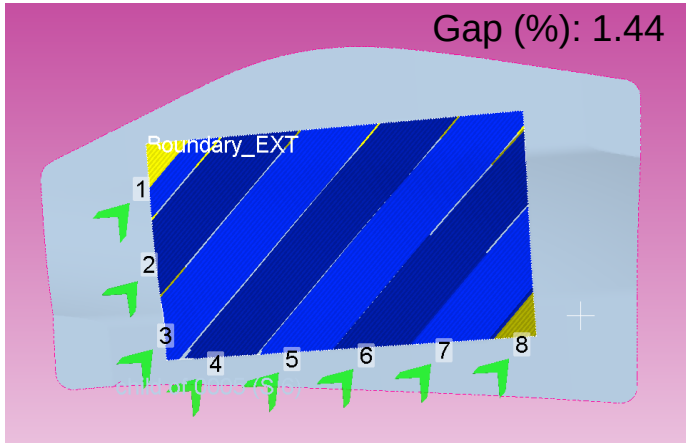


Collision in 0° ply

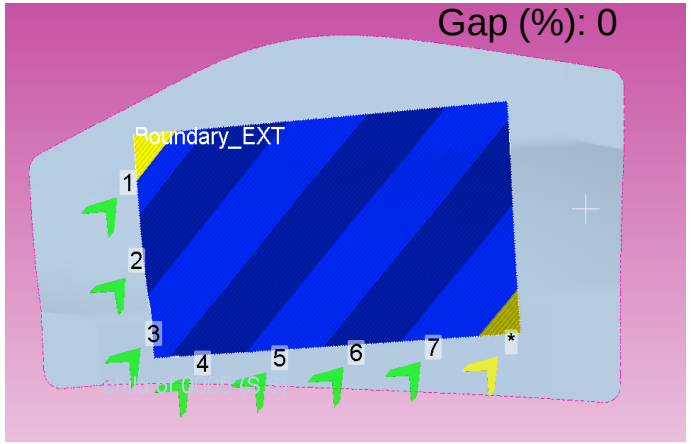


Collision in 45° ply

AFP Simulation: Identifying potential collisions (*illustrative example, not from this project*)



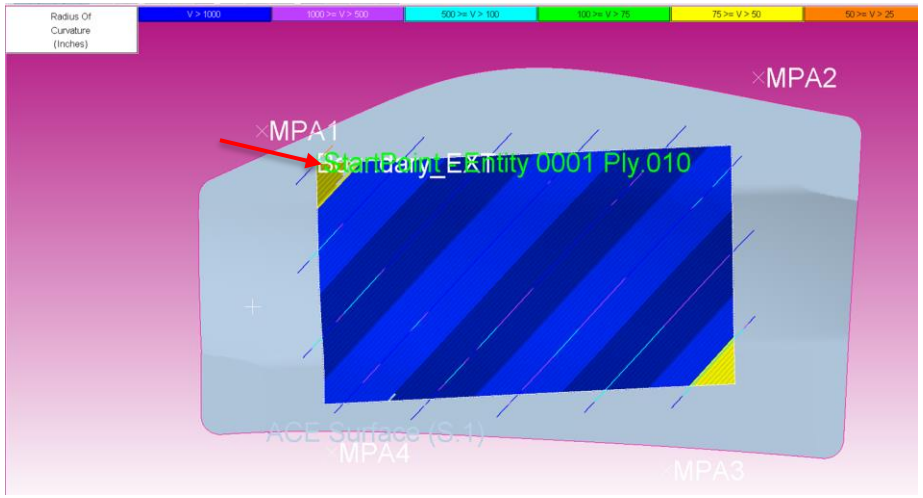
AFP Simulation: Coverage Method Selection

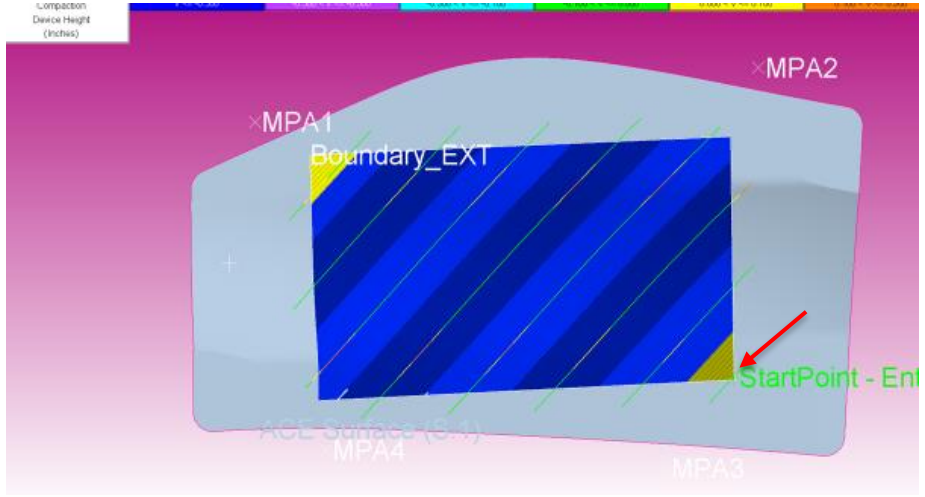


Parallel Limited (3° dev. allowed)

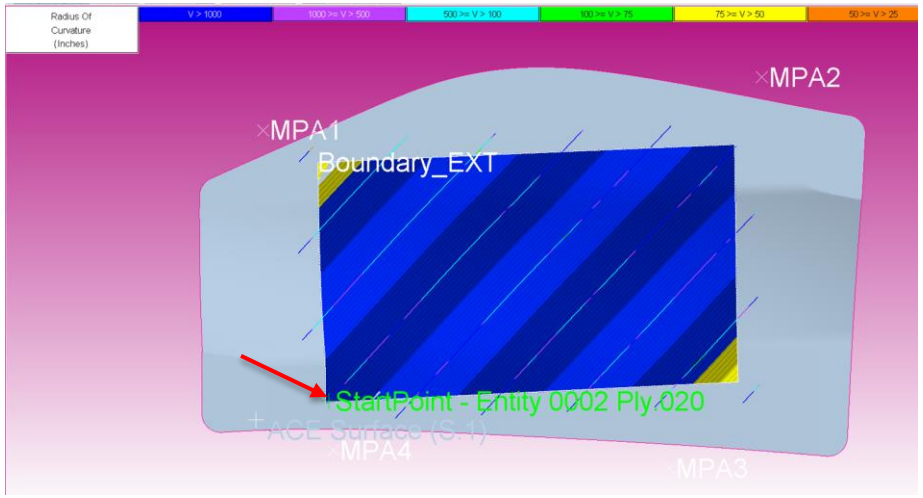
Natural Path

Fixed Angle

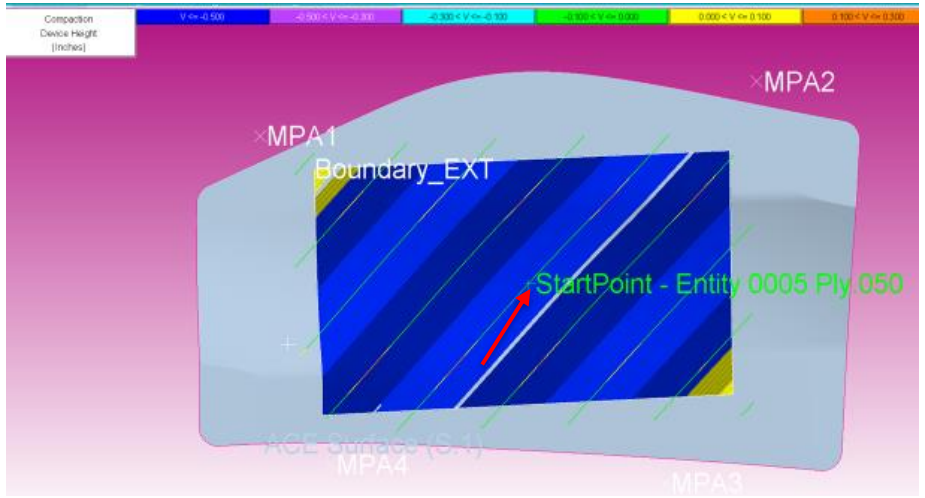




Fixed Parallel

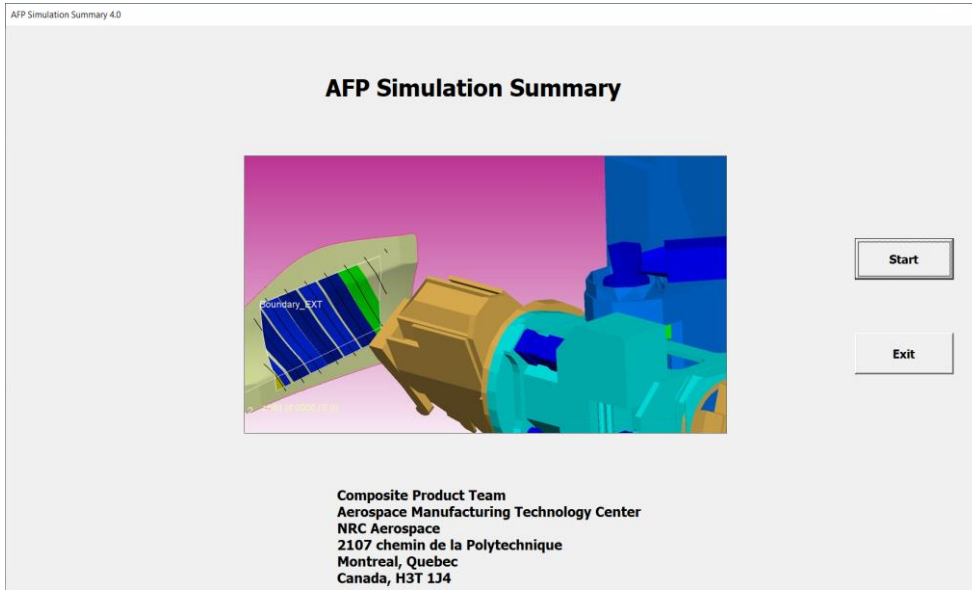


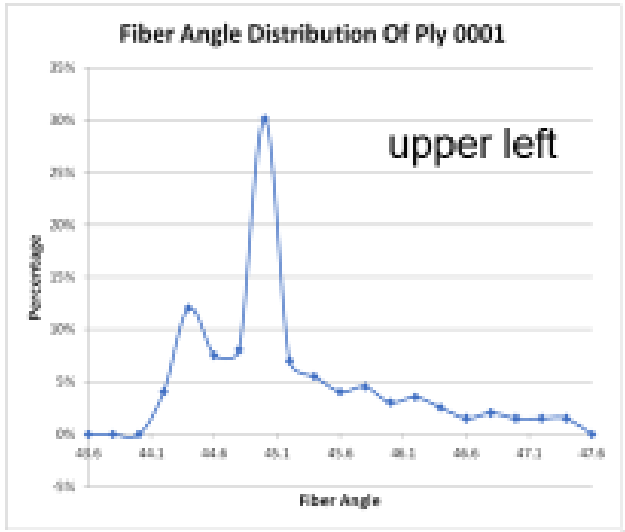
Coverage Method Selection Strategies:



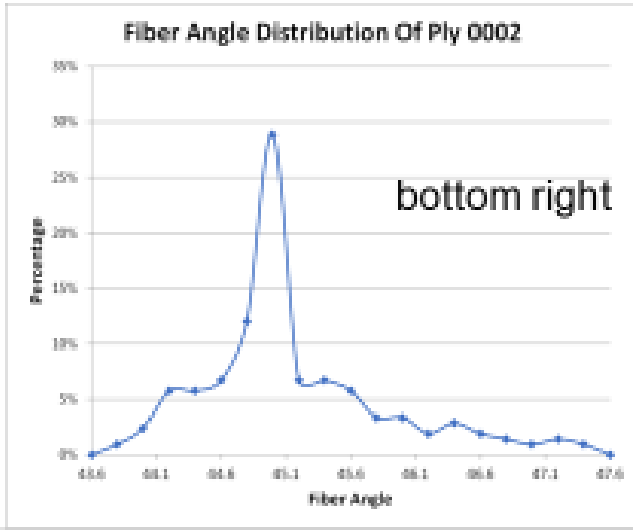
- Design requirements
- Part geometry
- Part application

AFP Simulation: Influence of Start Point Location

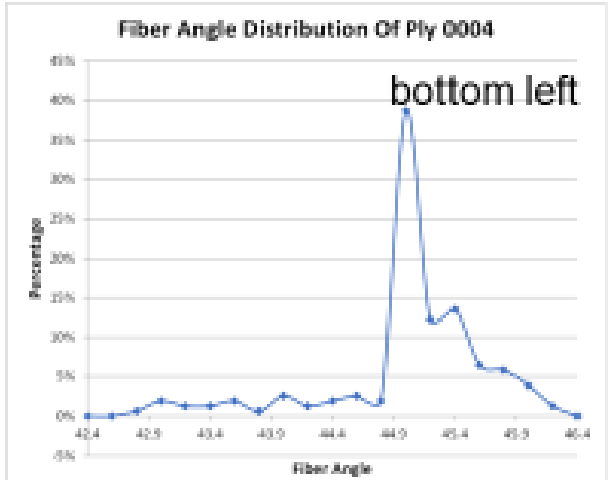




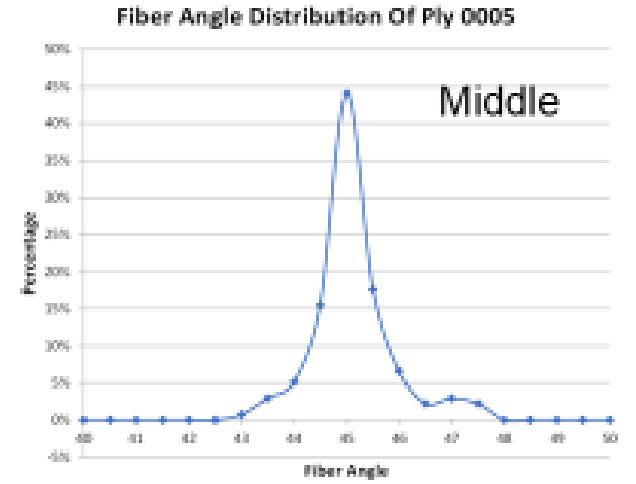
Start Point:



- The start point acts as the origin for coverage generation
- It is one of the most critical parameters in AFP simulation



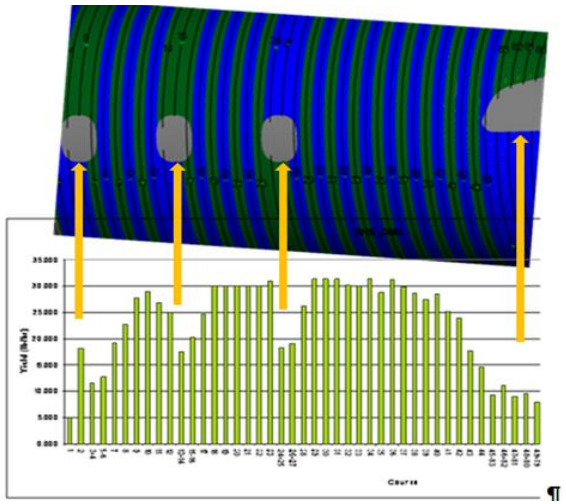
AFP Simulation: Influence of Start Point Location



A proprietary program developed at NRC, *AFP Simulation Summary,* was used to analyze AFP simulation data

AFP Simulation Summary

AFP Programming Parameters	Summaries	Notes
ACE V2 Version	V2.R2.72n (Coverage); V2.R2.72o (Program)	
Project Description	Influence of start point	Project #: TBD
Date of Documentation (Y/M/D)	2025-06-25	
AFP Part Name	StartPoint: Middle	
ACE Program Name	CurvedTool_Fiber Path Analysis	
Ply Number #	Ply 0005	BDY Name: Boundary_EXT
Path Orientation (ACE Axis System)	45	FAD <= 3°: 100.00 (%); FAD <= 5°: 100.00 (%)
Average Tool Misalignment (in)	0.03386	Tool misalignment is moderate
Ply Layup on Surface #	5	
Tow Count	32	
Course Count in this Ply	9	
Coverage Method	Fixed Parallel	
Coverage Start Point (Design Coordinate)	X=3.491, Y=1.19, Z=4.445	
Coverage Step Size (in)	0.25	
Gap in the Ply %	0	
Overlap in the Ply %	0	
Min Ply Roller Sag (in)	-0.028	
Max Ply Roller Crown (in)	0.257	No compaction issues expected
Minimum Tow Length Used for the Ply Coverage (in)	0.00	Warning: Patches are needed for short fiber paths
The Ply's Minimum Radius of Curvature (in)	27.37	Warning: Medium risk of fiber wrinkles
Head Clearance DiatanceX (in)	40.00	
Collision Avoidance Enable	TRUE	
Predicted Material Usage of the Ply (lb)	0.132	
Predicted Ply Cycle Time (h:m:s) [On Surface]	00:01:59 [00:00:48]	
Predicted Material Yield (lbs/hour)	3.979	AFP down time is not included in the caculation

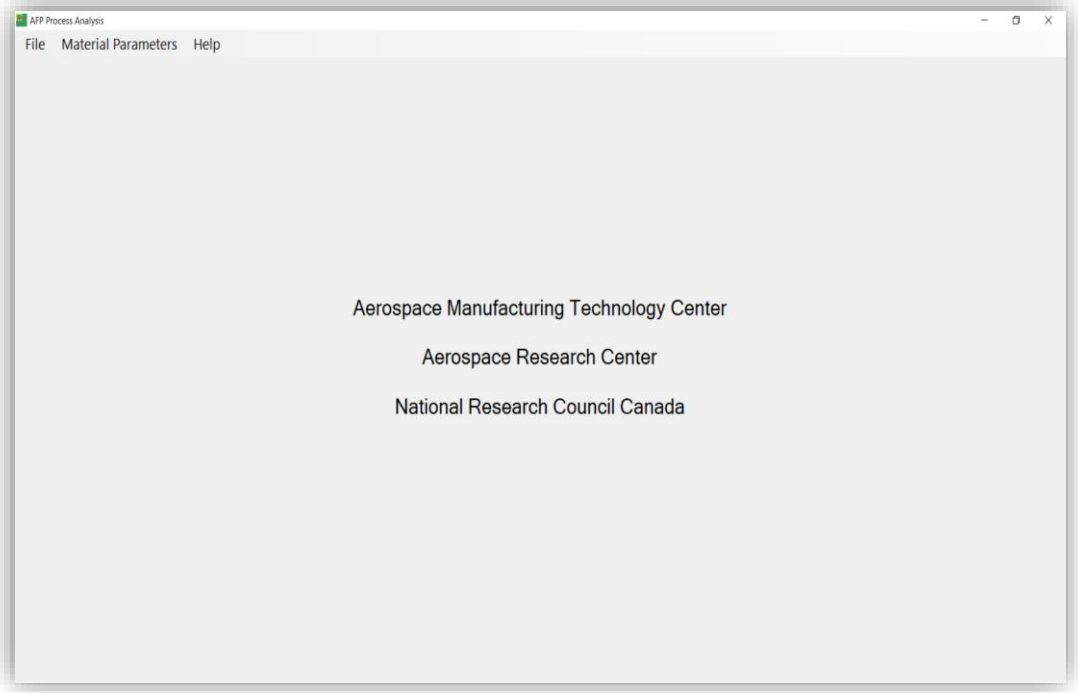


*** The warnings in this table are based on AFP simulation results. The final results of AFP process will be also influenced by various other manufacturing parameters**

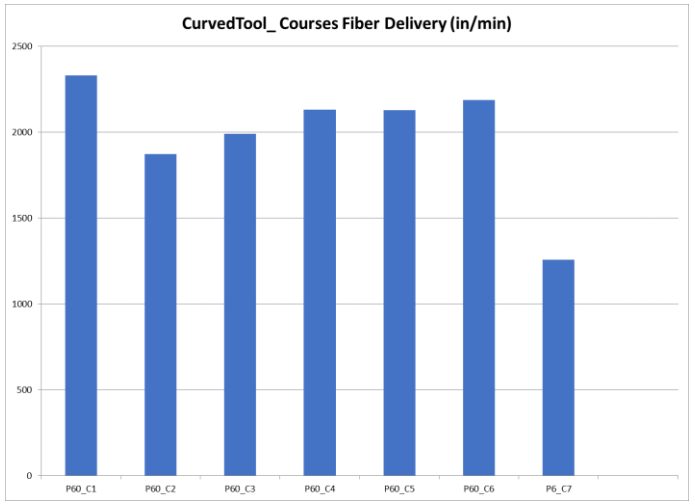
This Table is generated by the *AFP Simulation Summary* program

AFP Manufacturing: Parameters and Strategies

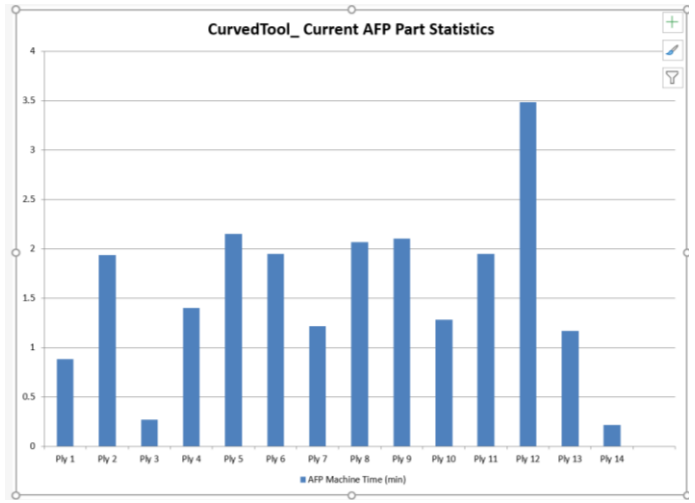
Important Parameters for AFP Manufacturing



- Compaction force
- Fiber tension
- Heating temperature
- Humidity level
- Layup speed
- Material tackiness
- Substrate temperature
- …..



Strategies to Improve AFP Productivity and Quality



- Establish standard work instructions for AFP setup and operation
- Use virtual simulation to pre-validate layup strategy
- Perform dry-run of the AFP program - fully or only in critical areas for large parts
- Maximize layup speed
- Use large material spools to reduce load time
- Enable automated in-line inspection to reduce downtime
- Adjust parameters based on material & environment conditions
- Avoid small cutouts, tight radii, and complex geometries in design
- Favor long continuous fiber courses during path planning
- Optimize layup sequence and fiber direction
- Minimize off-surface movements of the AFP head
- Schedule regular head maintenance — don’t wait for failure

AFP Manufacturing: Data Tracking and Analysis

A proprietary program developed at NRC, *AFP Process Analysis,* was used to analyse AFP manufacturing process

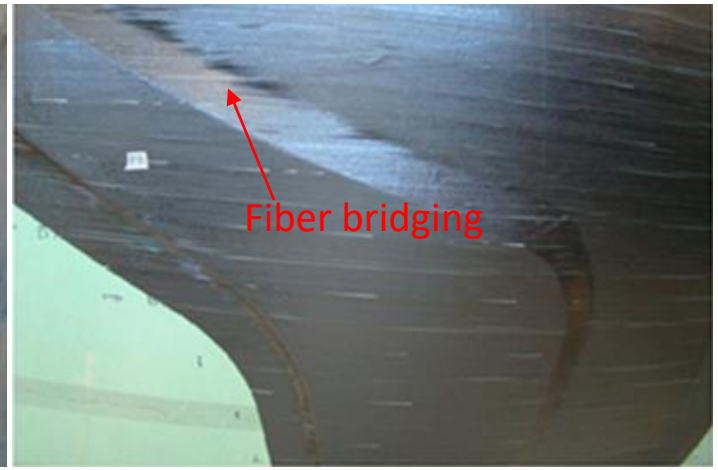
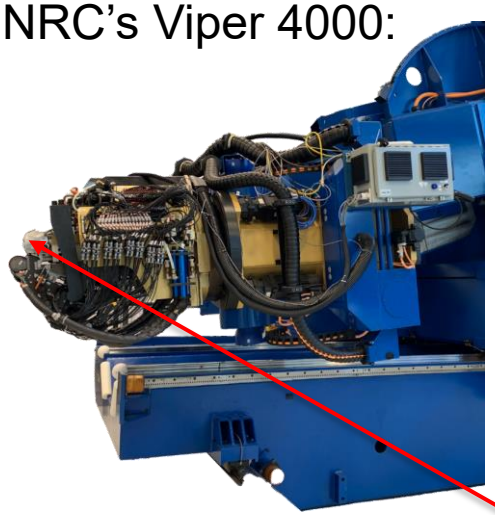
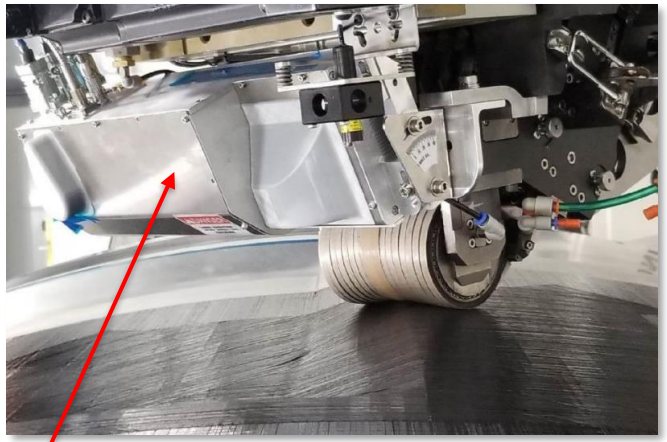
Quality Assurance



Typical AFP Manufacturing Defects

- Gaps/overlaps
- Fiber bridging
- Wrinkles
- Fiber fuzz
- Missing tow
- Twisted tow
- Foreign Object/debris (FOD)





In-Process Inspection

- Conducts real-time inspection
- Operates without interfering with the AFP process
- Identifies the type, dimensions and location of the defects
- Provides warnings for the oversized defects that need rework
- Documents the inspection results automatically
- Creates digital data tracking and travelers
- Largely increases the efficiency of the AFP process

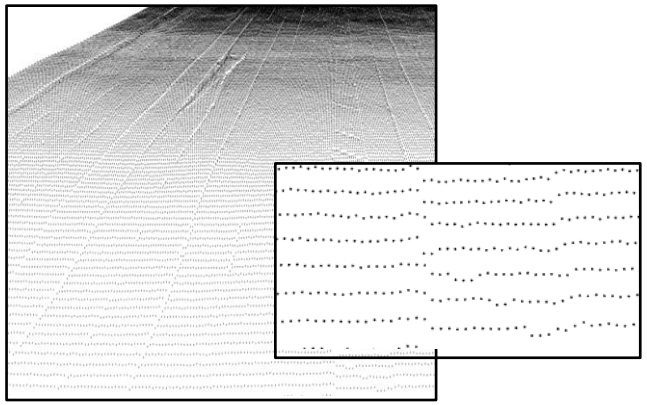
In-Line Inspection System: Examples of Defect Detection

In-process measurements:

High resolution 3D located point cloud



Ply 60, approx. 9.7 mm thick ply stack

Summary

- AFP process can be categorized into six key stages: CAD design, AFP simulation and programming, AFP manufacturing, inspection and quality control, part curing, testing and evaluation
- Closed-loop data flow is essential in AFP process — each AFP stage influences and depends on the others
- AFP process optimization relies on continuous feedback between stages to ensure better outcome
- NRC is actively developing software tools and sensors to collect, track, and analyze AFP simulation and process data
- These capabilities have enabled NRC to successfully develop hundreds of composite structures with partners across sectors
- We will continue refining this approach — using ply-by-ply AFP simulation studies to guide design decisions and ensure consistent, high-quality outcomes

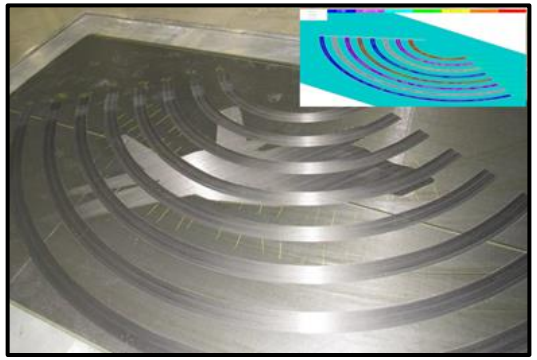
SMART ROLLER: AN ESSENTIAL TOOL FOR AUTOMATED FIBER PLACEMENT

C. Picciotto*, X. Yin, A. Poursartip, J. Madden, and A. Clare

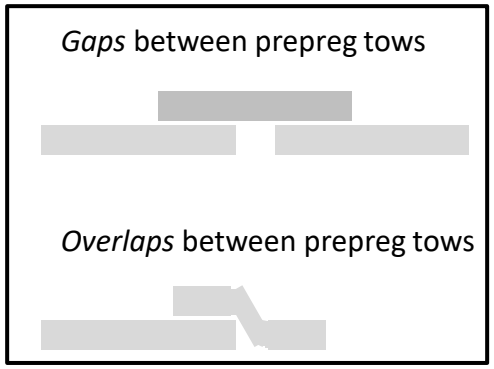
Composites Research Network, Department of Materials Engineering, The University of British Columbia, Vancouver, Canada

Keywords: Lay-up (automated), prepreg

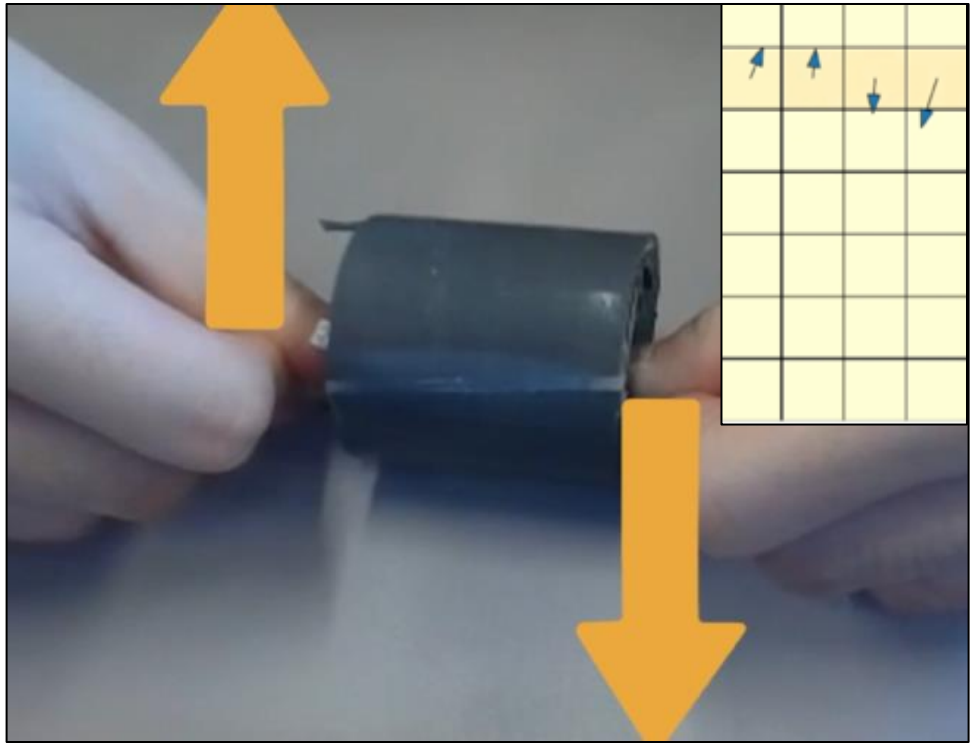


Background: In-situ measurements at the nipping point of an Automated Fiber Placement (AFP) process

- In AFP, measuring and controlling the local compaction pressure (as opposed to globally applied compaction force) is crucial to understanding the process at the nip point
- Various examples with a significant pressure gradient at the nip point:



Complex tool geometry



Tow steering

- In-situ measurements provide insight into the local conditions that control the process

Smart Roller measuring shear and local pressure at the contact surface, giving AFP machines tactility at the nip point of the process.

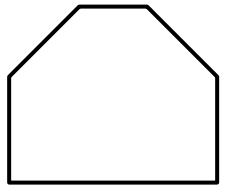
Custom Smart Rollers

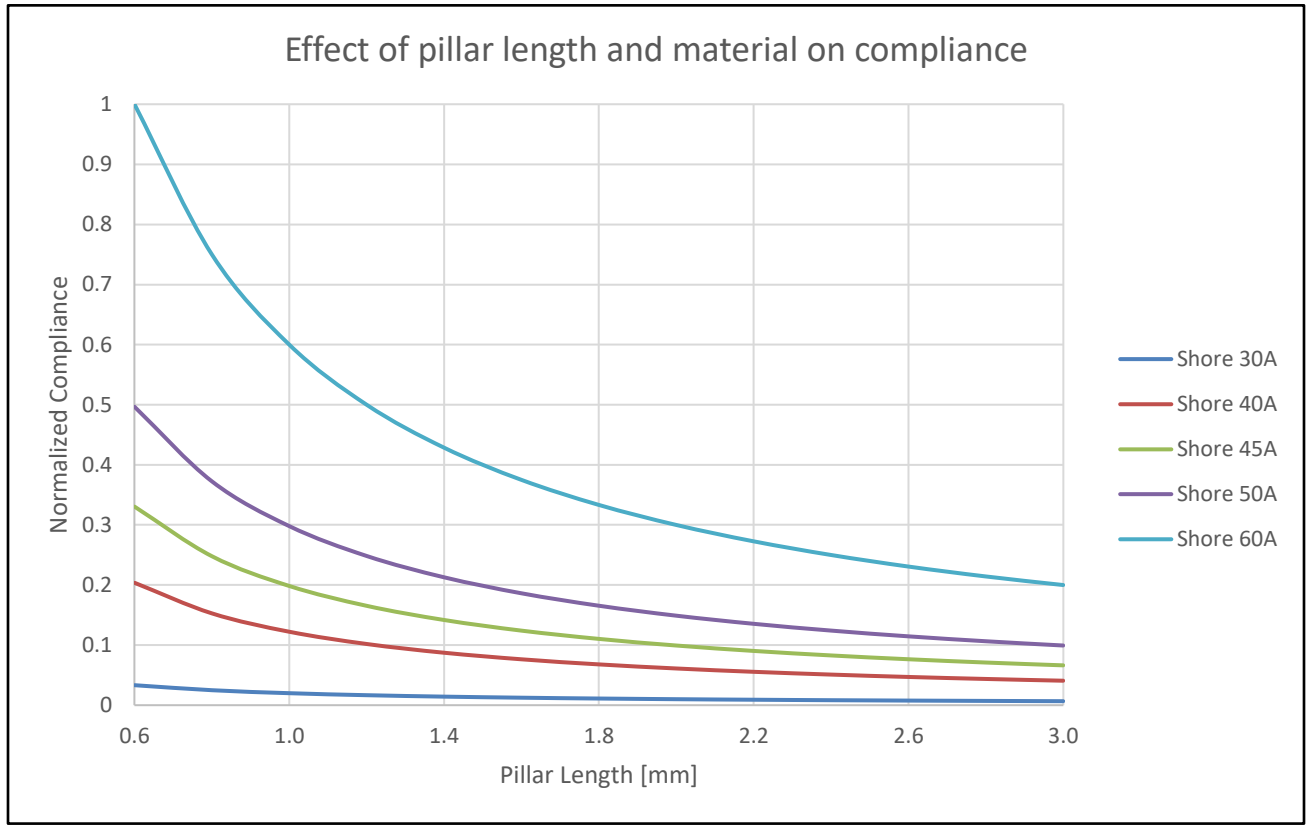
Composites Research Network

© CRN UBC (2025) -- DO NOT REPRODUCE WITHOUT WRITTEN PERMISSION



Custom Compliance

Simple compliance model outputs:



- Material (shore hardness)
- Pillar length (tire thickness)

Other customizations:

- Roller diameter
- Pillar geometry
  - Shape/size
  - Spacing

These parameters feed into the parametric mold to fabricate custom smart rollers

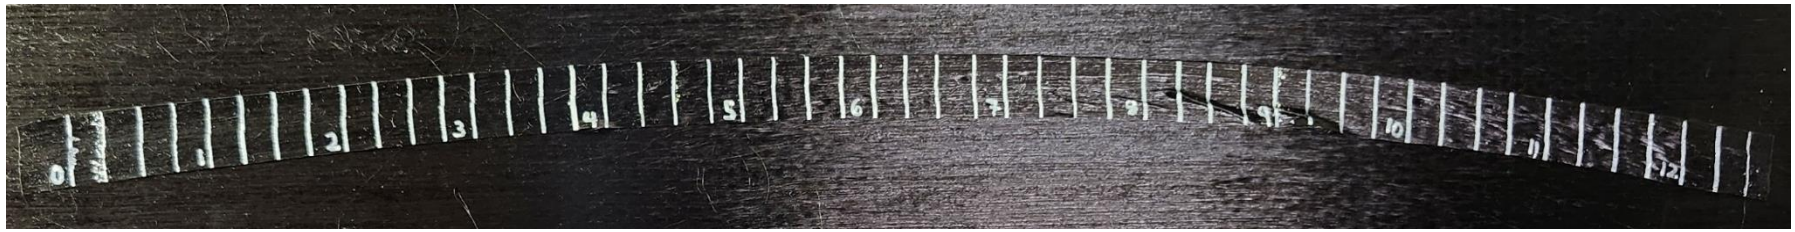
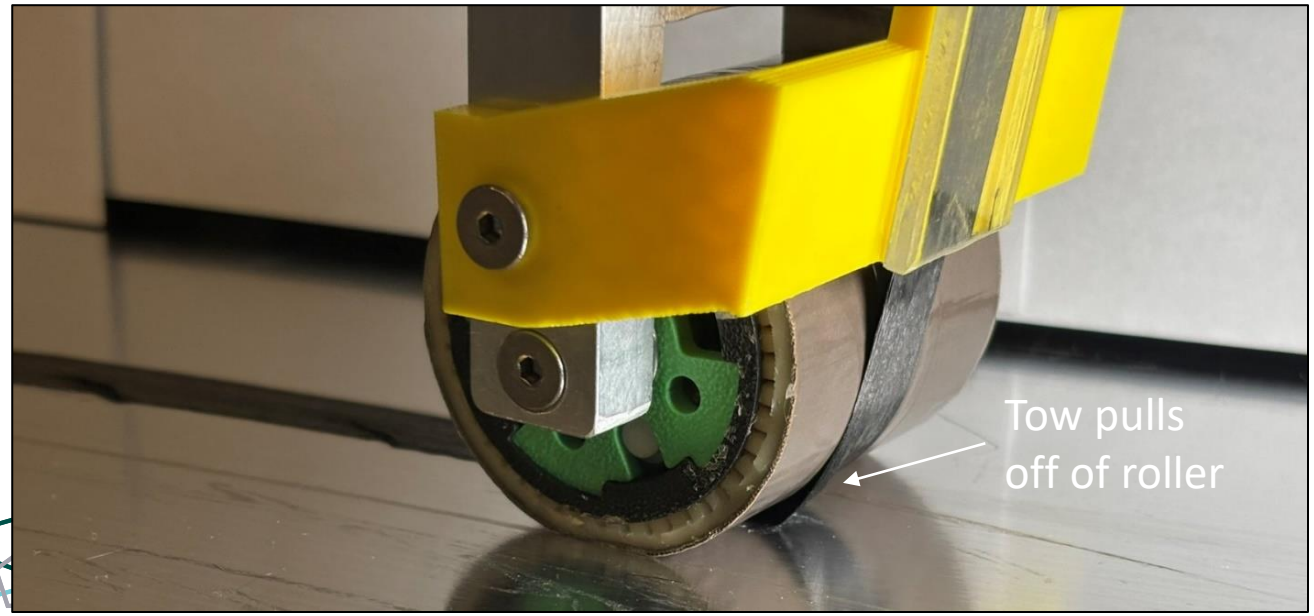
Aligning Smart Roller data in deposition with tow tension during peel

© CRN UBC (2025) -- DO NOT REPRODUCE WITHOUT WRITTEN PERMISSION

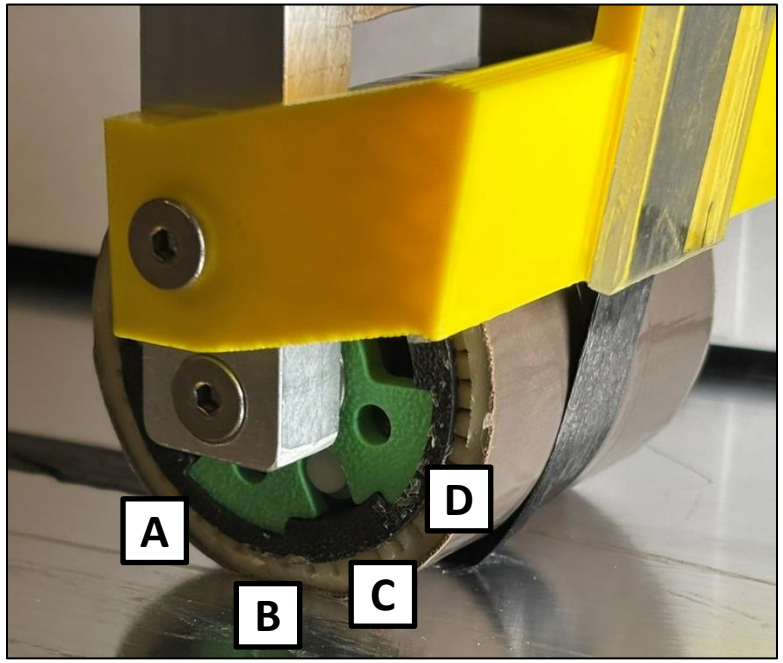


Depositing a curve and measuring the twist in the tow



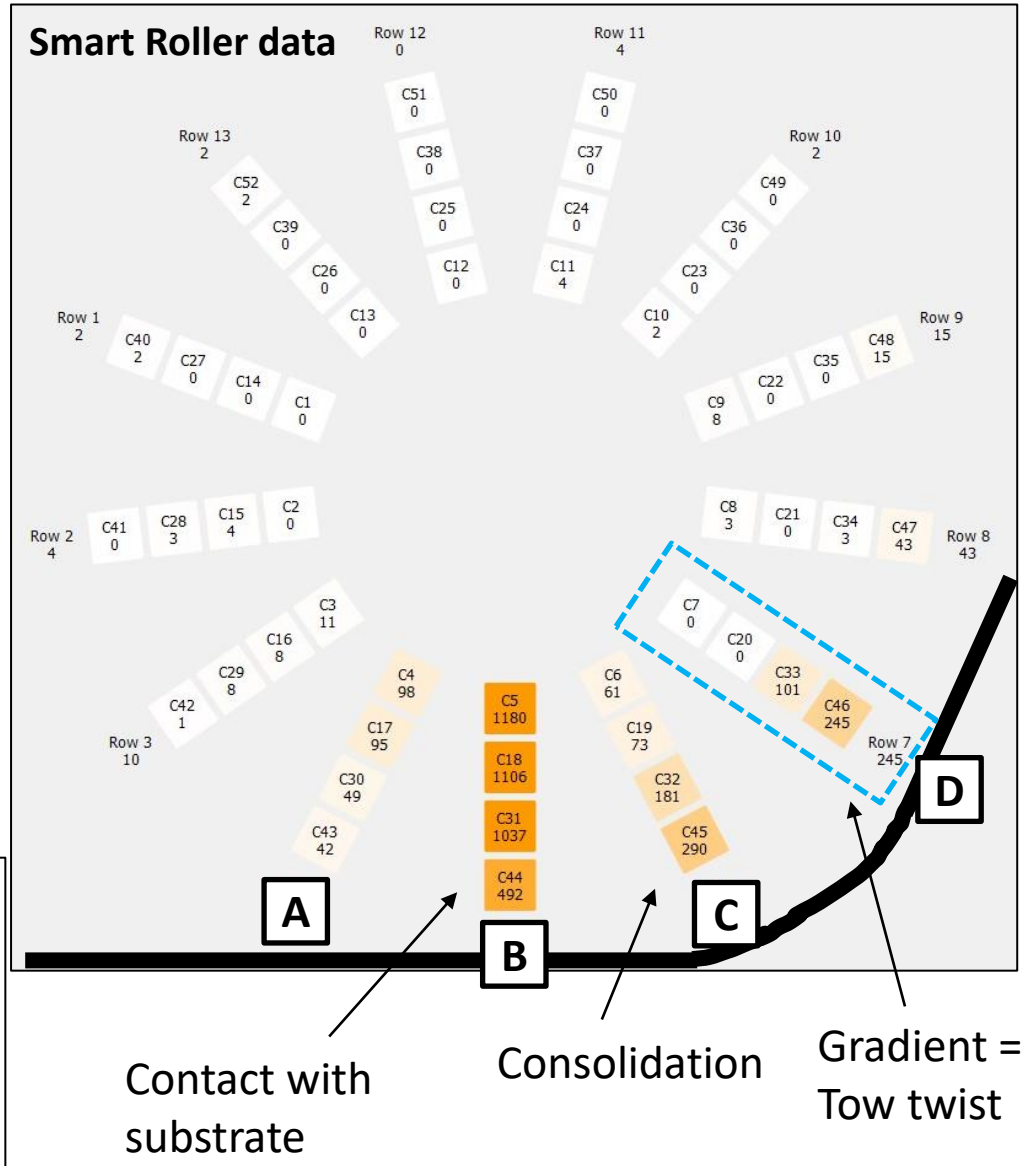
400 mm radius

750 Mm radius



Deposit curves of various radii to measure the twist in the tow before deposition. A tighter radius leads to more wrinkle formation, and the Smart Roller can predict wrinkle formation by measuring the pressure gradient across a twisted tow.

© CRN UBC (2025) -- DO NOT REPRODUCE WITHOUT WRITTEN PERMISSION

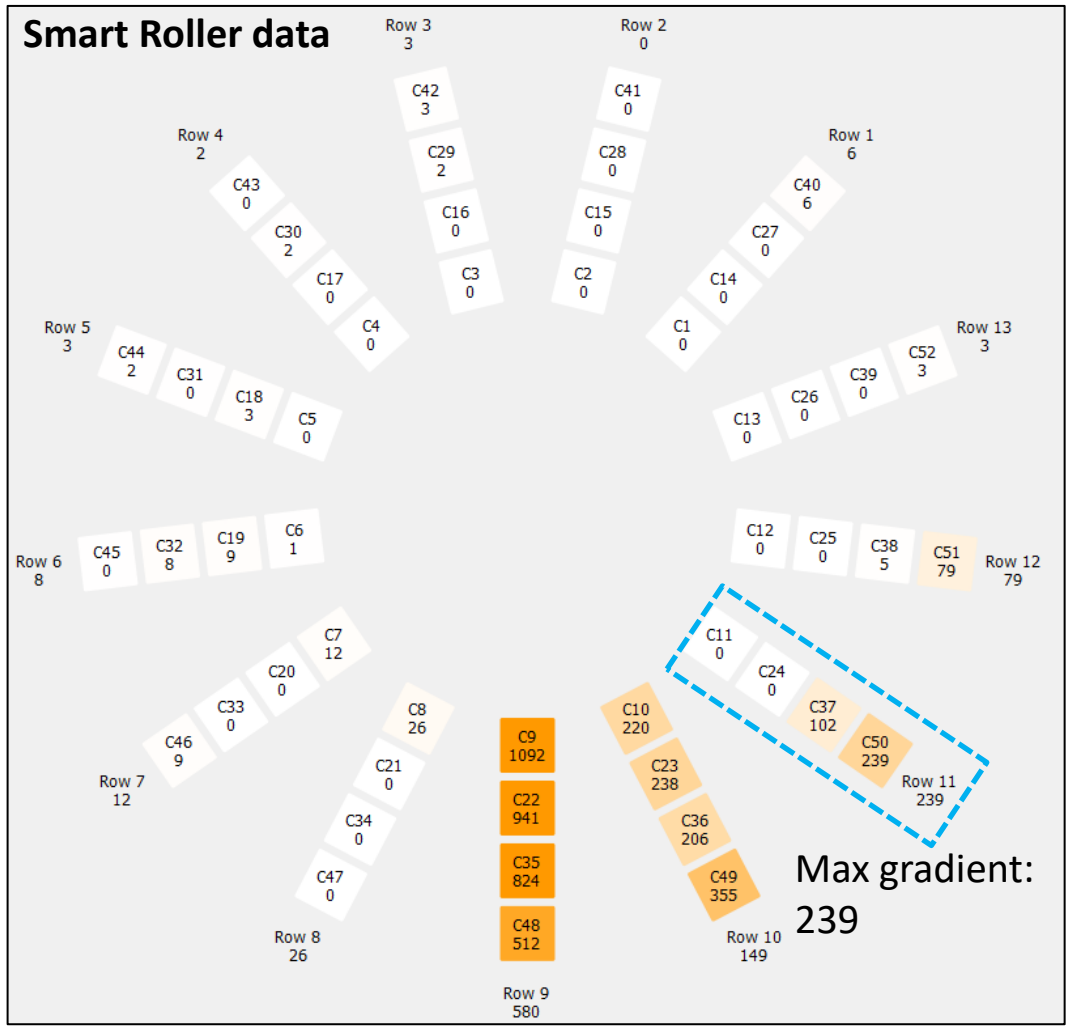


Interpreting Smart Roller data

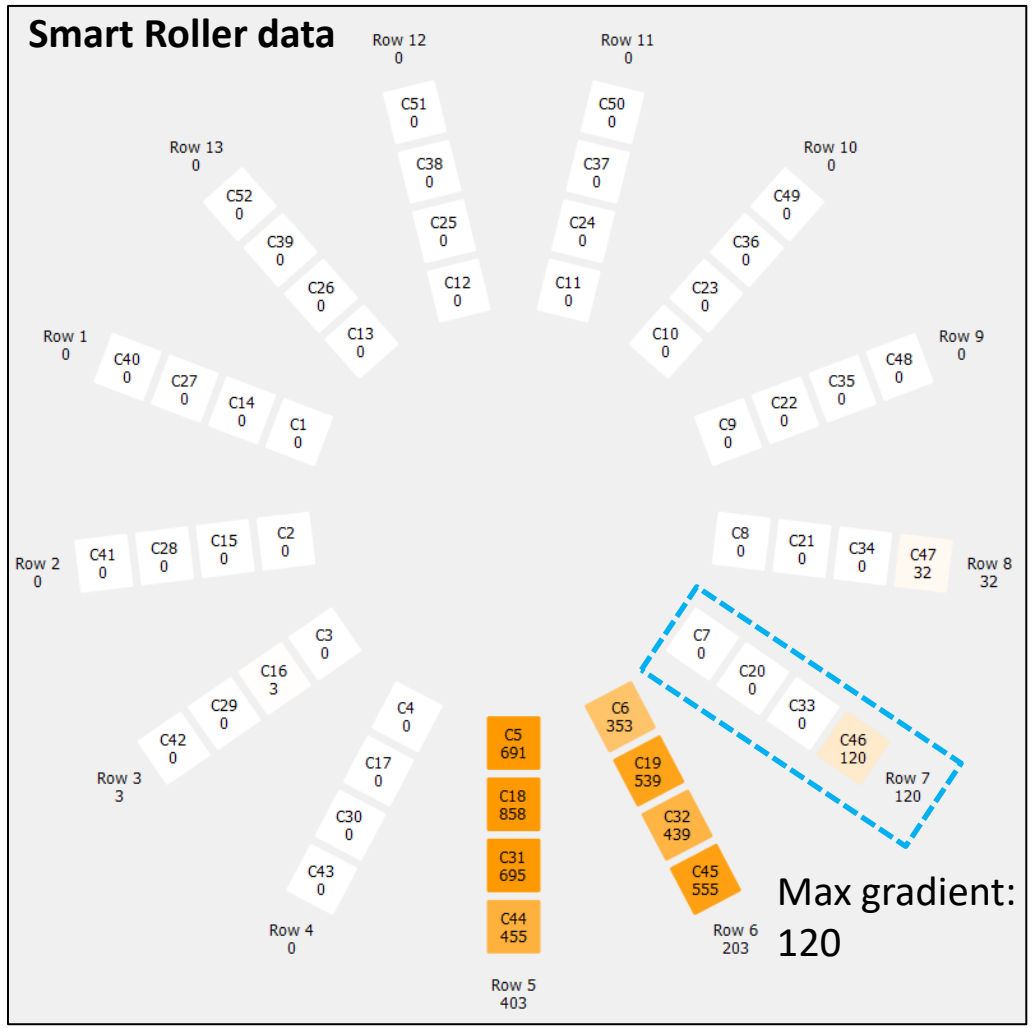
Smart Roller on µAFP

Each square represents one local pressure-sensing “taxel”. There are 4 taxels across the width of one ½” tow, and 13 rows of taxels around the circumference.

Each spoke in the visualization is one row of taxels across the width of the tow, with the taxels on the outer radius of the heatmap corresponding to the outer radius of the deposited path.



Location D on the heatmap corresponds to the location on the compaction roller where the carbon tow twists before consolidation. The twist can be measured by looking at the gradient in pressure from the taxels on the outer radius to the ones on the inner radius, at this location.



Composites Research Network

Smart Roller Data for straight path

The next step for this experiment is to threshold the Smart Roller data so it can trigger an alert when it detects an abnormality (i.e. torsion in the tow, gaps/laps, or low tack).

Composites Research Network

© CRN UBC (2025) -- DO NOT REPRODUCE WITHOUT WRITTEN PERMISSION

Summary and Future Work

1. The Smart Roller is made with custom dimensions, compliance, and sensor arrangement to match the mechanical performance of a standard compaction roller and add pressure/shear force sensing capability.
2. The sensors on the Smart Roller are characterized to convert a displacement measurement to an accurate local pressure/shear value.
3. The Smart Roller can detect certain gaps, overlaps, low tack regions, and tow torsion before consolidation.

Next…

- Use the Smart Roller as a real-time alert system by creating models that interpret the data and predict potential defects.
- Install the Smart Roller on a full-sized AFP machine to validate on a machine other than our in-house tabletop AFP.
- Make a Smart Roller version for higher temperatures (AFP with thermoplastics).

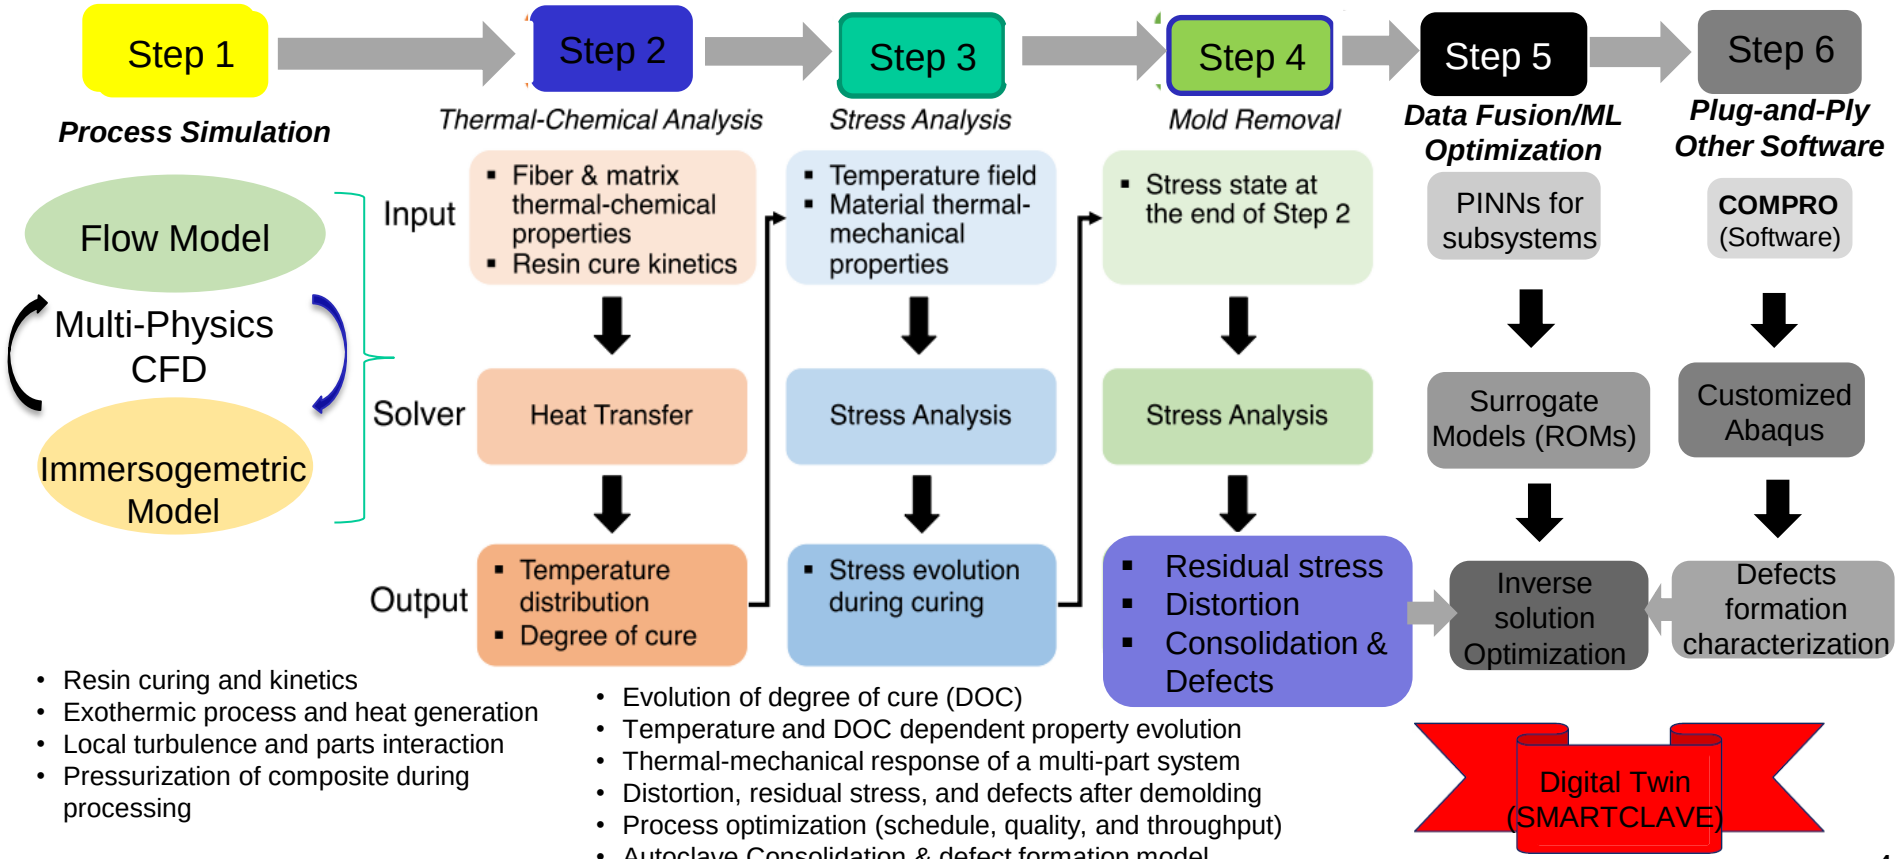
Acknowledgement

This work is funded by Naval Air Warfare Center (NAVAIR), Aircraft Division under the Contract of N68335-23-C-0116.

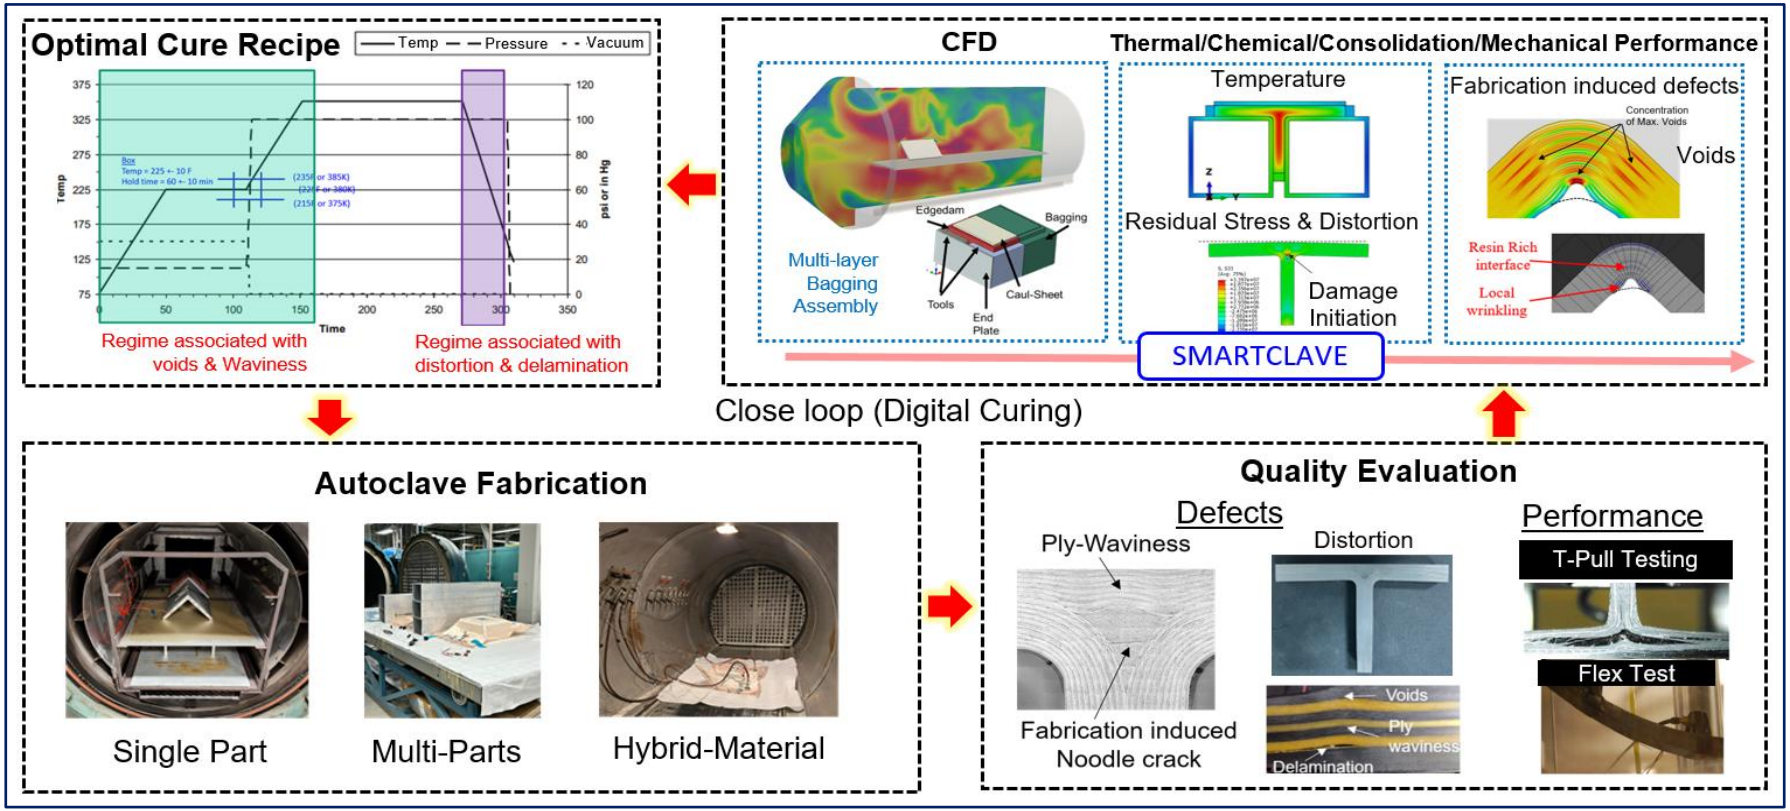
Motivation



- Autoclave time is the bottleneck in manufacturing lines increasing overall production time and cost
- Optimization of the autoclave process by simultaneously curing multiple parts without deviating from the recommended cure cycle can significantly reduce scrap rate and also the overall production time and cost
- GEM and the team propose to deliver a high-fidelity multi-physics predictive simulation toolkit (SMARTCLAVE) that can optimize the autoclave process condition to balance the throughput and quality of cured-composite parts

NAVAIR Public Release SPR# 2025-0404. Distribution Statement A - Approved for public release; Distribution is unlimited.

Overview of Technical Approach



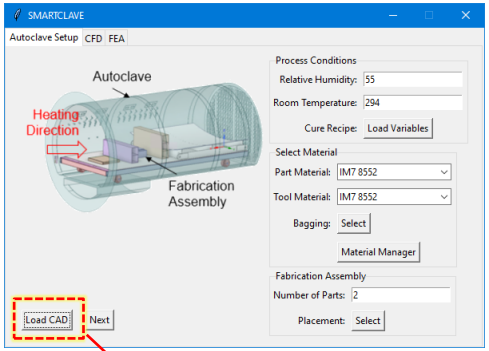
- Resin curing and kinetics
- Exothermic process and heat generation
- Local turbulence and parts interaction
- Pressurization of composite during processing

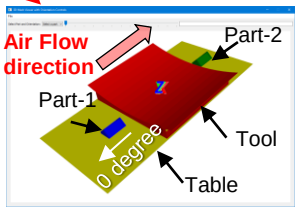
- Evolution of degree of cure (DOC)
- Temperature and DOC dependent property evolution
- Thermal-mechanical response of a multi-part system
- Distortion, residual stress, and defects after demolding
- Process optimization (schedule, quality, and throughput)
- Autoclave Consolidation & defect formation model

Digital Twin (SMARTCLAVE)

NAVAIR Public Release SPR# 2025-0404. Distribution Statement A - Approved for public release; Distribution is unlimited.

Summary of SMARTCLAVE Capability



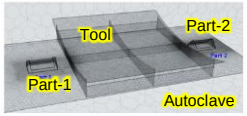


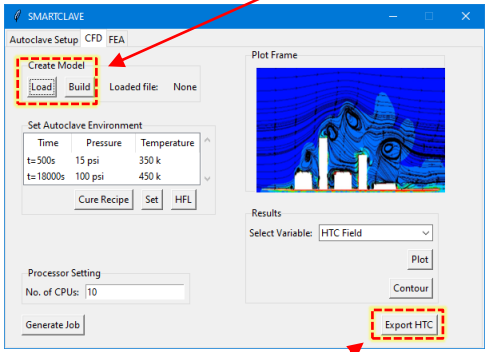
GEM's SMARTCLAVE GUI

Step 1: Autoclave setup

User Inputs:

- CAD model
- Autoclave Parts (i.e., bagging assembly & table)
- Material system
- Part placement

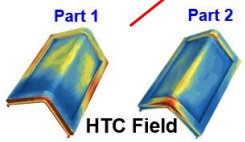




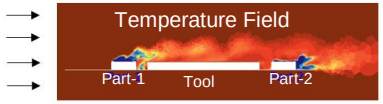
3D interactive interface
(load CAD & adjust placement)

Step 2: Heat Transfer Coefficient

User Inputs:

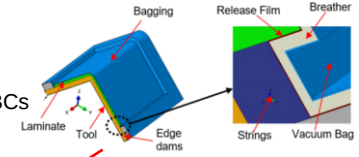


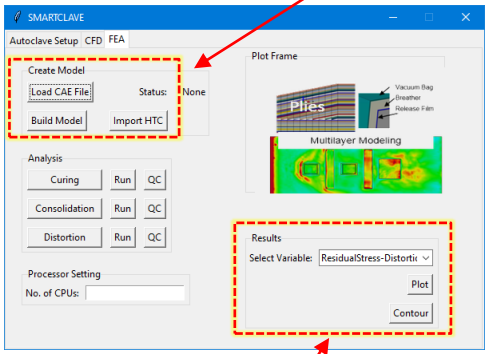
- Model file with Mesh & BCs
- Time step



Outputs:

- Flow Field
- HTC Field

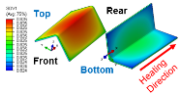


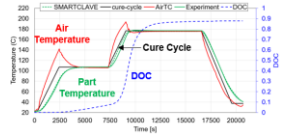


Step 3: Temperature, Consolidation & Residual stress

User Inputs:

- Model file with Mesh, layup & BCs
- Time step





Outputs:

- Temperature
- Degree of Cure
- Residual stress & Distortion
- Consolidation (thickness change + fiber volume fraction)
- Fabrication induced defects such as ply-waviness, voids & delamination zone

Conclusions

- Developed a multiphysics CFD modeling approach to capture flow, temperature, and multiple parts interaction in an autoclave
- Developed the customized Abaqus model for thermo-chemo-mechanical prediction using local CFD-driven boundary condition
- Efficient generation of HTC field from CFD results without using exhaustive calibration autoclave runs
- Validated the performance prediction using the measured spring-in angles
- Established a digital twin autoclave for the rational selection of the processing parameters to balance the parts load out and the quality

NAVAIR Public Release SPR# 2025-0404. Distribution Statement A - Approved for public release; Distribution is unlimited.

Keywords: Digital Twin, Machine learning, Production planning, Scenario based optimization, Uncertainty

ABSTRACT

Various composite material production systems are inherently complex and labour-intensive, relying heavily on skilled human workers for critical tasks. This human dependency introduces significant uncertainty into production planning, with fluctuations in worker availability, process durations, and quality-related rework impacting system stability and efficiency. Traditional planning methods often fail to adapt to these dynamic conditions, highlighting the need for a more flexible and predictive approach. This study presents a novel framework that integrates Digital Twin (DT) and Machine Learning (ML) to optimize workforce allocation and production planning in composite manufacturing environments. A discrete-event simulation-based DT was developed to replicate system behaviour under varying operational conditions. An ML algorithm was used to forecast key performance indicators (KPIs), while a Reinforcement Learning (RL) algorithm was employed to optimize resource allocation across multiple uncertainty scenarios. The framework was applied to a real composite production line, yielding a 34% reduction in worker cost and a 16% decrease in time in system, without compromising throughput. The results demonstrate the effectiveness of the proposed approach in supporting resilient, data-driven decision-making for human-centric composite manufacturing systems.

1 INTRODUCTION

Global competition and increasing customer demands compel modern production, assembly, and logistics systems to become more efficient, responsive, and adaptive. These complex systems involve dynamic interactions between numerous components, making their behaviour difficult to predict using traditional analytical methods alone. To evaluate potential improvements and validate operational strategies, simulation-based approaches are often required to capture the evolving behaviour of such systems [1,2].

In parallel, the rise of Industry 4.0—driven by the integration of digital technologies such as the Internet of Things (IoT), Artificial Intelligence (AI), Machine Learning (ML), and cloud computing—has transformed how industrial systems are designed and managed. One of the most prominent concepts emerging from this digital transformation is the Digital Twin (DT) [3].

A Digital Twin is a virtual representation of a physical asset, process, or system that enables real-time monitoring, predictive analysis, and informed decision-making. DTs have found widespread application in manufacturing, where they support functions such as production control, asset management, and predictive maintenance. Recent studies have explored various aspects of DT development, including their architecture, lifecycle integration, software platforms, and industrial impact [4].

This study focuses on the development and application of a Digital Twin framework within a composite manufacturing system (CMS)—a production environment known for its high complexity, process variability, and dependence on human labour. In such systems, production planning is especially

challenging due to uncertainties in worker availability, process durations, and output quality. These uncertainties can lead to shifting bottlenecks, reduced throughput, and inefficient resource utilization—limitations that are often not addressed adequately by static or one-off optimization methods.

1.1 Objective

This research investigates the integration of AI-driven Digital Twin technologies into composite production systems, with a particular focus on proactive production planning (PP) under uncertainty. The objective is to enable scenario-based optimization through RL, allowing the system to simulate and evaluate a wide range of possible future states and operational conditions. By incorporating these insights, the production plan can be dynamically adjusted to improve system-level Key Performance Indicators (KPIs).

The key contributions of this study are:

Assessment of Digital Twin modeling approaches and software platforms for CMS, including evaluation of features such as real-time connectivity, 3D visualization, and implementation cost.

Proposal of a reinforcement learning-based scenario analysis framework to address planning uncertainties related to human resource variability and production quality.

Application of the proposed framework to a real-world composite production case study, demonstrating its effectiveness in generating optimized and resilient production plans.

This work contributes to the growing body of knowledge on AI-enhanced Digital Twin systems and their potential to improve decision-making in complex, uncertainty-prone manufacturing environments.

2 DIGITAL TWIN

DT technology has garnered significant interest across academia and industry for its ability to support smart manufacturing within the broader Industry 4.0 paradigm. A DT is a dynamic virtual representation of a physical asset or system, enabling real-time monitoring, simulation, and optimization through the integration of physical and digital environments.

The concept of the DT was initially proposed by Dr. Michael Grieves in 2003, comprising three key elements: the physical product, the virtual product, and the data connections between them. NASA's implementation of a DT for the International Space Station in 2012 marked a major milestone, demonstrating the potential of DTs to improve system design, monitoring, and maintenance. Their definition emphasized high-fidelity, multi-physics simulations informed by real-time data and predictive models [5].

Advances in AI, IoT, and cloud computing have accelerated DT adoption, enabling applications in real-time control, predictive analytics, and lifecycle management [3].

2.1 Digital Twin Architecture

Early DT architectures were limited to three elements—physical, virtual, and connection—but Tao et al. expanded this to a more comprehensive five-dimensional model including data and service layers [6]. These components collectively support the DT ecosystem:

- Physical Part: The real-world asset or system
- Virtual Part: The digital counterpart
- Connection: Real-time communication between the two
- Data: Collected via IoT and manufacturing systems
- Service: The computational intelligence for decision-making
- Modern manufacturing generates massive volumes of heterogeneous data from sensors, supply chains, and user interactions. Managing and integrating these datasets is foundational to effective DT implementation.

2.2 Modeling Approaches for Digital Twin

Modeling is critical for DT development as it determines the system’s semantics, structure, and behavior. A variety of modeling approaches have been proposed [7-11]:

- UML and SysML: Useful for system-level design and stakeholder communication but limited in execution semantics.
- Object-Oriented Modeling: Widely used in DTs for encapsulating state and behavior but requires additional tools for simulation.
- Petri Nets and Colored Petri Nets (CPN): Effective for modeling discrete event systems and concurrency, though limited in visualization.
- Functional Mock-up Units (FMUs): Promote interoperability between simulation tools via standard interfaces.
- Ontologies: Structure heterogeneous data and improve semantic integration in DTs across lifecycles.
- Knowledge Graphs: Enhance data connectivity and inferencing capabilities by organizing relationships and attributes.
- AutomationML: Supports data exchange between manufacturing tools and preserves engineering semantics.

Despite this variety, a lack of standardized, reusable, and holistic DT development methodologies remains a key limitation. Current implementations often omit key parameters (e.g., input/output configurations) and offer little support for integration across the full system lifecycle.

2.3 Digital Twin Applications in Manufacturing

DT applications are most prevalent in manufacturing, covering multiple stages of the product lifecycle—from design to retirement. Applications include [3]:

- Design: Virtual prototyping, simulation, and optimization
- Manufacturing: Production control, resource allocation, workpiece quality prediction, and real-time monitoring
- Service: Predictive maintenance, diagnostics, and system health monitoring
- End-of-life: Dismantling, reuse, and recycling planning

In the manufacturing stage, DTs enable real-time data collection from machines and human operators, which can be used to compute and optimize Key Performance Indicators (KPIs). These KPIs serve as the basis for evaluating system performance and guiding continuous improvement initiatives.

The benefits of DT adoption include improved production efficiency, fault prediction, optimized scheduling, and enhanced decision-making.

2.4 Software Platforms for Digital Twin Implementation

Various software platforms support DT development, each with strengths tailored to different use cases. These platforms fall into four categories [11-16]:

- Discrete Event Simulation (DES) Tools: General-purpose simulation platforms (e.g., Arena, AnyLogic) using historical data and system logic modeling.
- Manufacturing Simulation Software: Tools with domain-specific capabilities, real-time data integration, and enhanced visualization (e.g., Siemens Plant Simulation, FlexSim).
- IoT Platforms: Focused on live system monitoring with cloud integration and real-time dashboards (e.g., Azure Digital Twins, AWS IoT TwinMaker).
- Other Tools: Specialized software not fitting above categories, often including AR/VR or 3D modeling (e.g., Unity, Dassault 3DEXPERIENCE).
-

Software capabilities are often compared across features such as:

- Real-time data integration (API/IoT) [17]
- Cloud deployment
- AI/ML support
- Customizability
- 3D visualization
- Licensing and cost

Selection of the appropriate platform depends on the system's complexity, real-time requirements, and long-term integration goals. Table 1 demonstrates the available software with their modelling approaches and their pros and cons in the context of developing DT for manufacturing systems.

Table 1 Comparison of Available software's

Software	Category	Modelling Scope	Pros	Cons
Simio MathWorks(MATLAB ,Simulink) Anylogic Flexsim Simul8	Discrete Event Simulation (DES)	Mainly behaviour modelling, and basic physical modelling	Well-suited for design and experimentation. Focus on system level and general flow. Abstract level of detail. In most cases, based on historical data. Easier to develop and implement. In most cases, cheaper than other types.	Limited support for real-time data. Limited level of detail Limited features for modelling complex systems
Ansys Twin Builder Siemens Tecnomatix Dassault DELMIA	Manufacturing Simulation	Behaviour, physical, and geometric Simulation based	Can be used to simulate running factories or design new ones. High level of detail. A wider range of features related to the manufacturing industry. Ability to simulate real-world conditions. Support real-time data and historical data.	More complex to develop. In most cases, more expensive than DES.
AWS IoT TwinMaker Azure Digital Twins Siemens Mindsphere PTC ThingWorx	IoT Platform	Data Driven	Best suited for running factories that do not require simulation. Real-time data from sensors and IoT devices. Cloud-based. Usually for monitoring and control.	More complex to develop and use. Limited simulation features
Unity	Animation	Physical, and geometric. Simulation-Based	An interactive environment. - Cross-platform support (a wide range of platforms including Augmented Reality/Virtual Reality devices).	More complex to develop. Not focused on simulation.

3. MODELING AND MANAGING UNCERTAINTY IN DIGITAL TWIN SYSTEMS

Composite material manufacturing systems are inherently uncertain, due in part to their dependence on human labor and variable curing or quality conditions [17]. DTs, while powerful, must be integrated with robust uncertainty modeling techniques to remain effective under real-world conditions.

- Uncertainty in DT systems can be broadly categorized as:

- Stochastic Uncertainty [18]: Inherent randomness in system parameters such as worker arrival times and task durations. Modelled using probabilistic distributions.
- Epistemic Uncertainty [19]: Incomplete knowledge of system behaviour or input conditions. Addressed using Bayesian inference methods.

Aleatory Uncertainty: Intrinsic variability that is irreducible [20] (e.g., raw material inconsistencies).

4. FRAMEWORK

This study presents an integrated framework that combines DT and RL to optimize production planning (PP) in a composite manufacturing system (CMS). The framework is designed to handle uncertainties—particularly in human resource availability—through scenario-based learning and optimization.

The approach consists of the following key steps:

Development of a DT using Discrete Event Simulation (DES) to simulate CMS operations.

Integration of RL to model and predict uncertain parameters, such as workforce availability and task durations.

Scenario generation using ML/RL based on historical and predicted uncertainties.

Simulation of production outcomes under different scenarios to assess their impact on key performance indicators (KPIs).

Optimization of production plans and worker allocation policies using RL, aiming to improve KPIs such as throughput, cycle time, and resource utilization.

The framework was implemented and validated on a real-world composite production line. KPIs such as production output, bottleneck reduction, and worker utilization were prioritized. All DT and RL components were developed in MathWorks and cross-validated using a Simio-based DT model to ensure robustness and accuracy.

4.1 Digital Twin Development

The DT serves as a virtual replica of the production line, enabling real-time simulation and analysis [21]. It provides insight into several KPIs, including Production throughput, Bottleneck identification, Cycle time and Worker utilization.

The DT was modeled using Discrete Event Simulation (DES) to capture dynamic system behavior and task sequences. Each production station, task duration, and resource dependency were modelled with high granularity, enabling assessment of operational performance under various conditions.

A significant innovation in this research was the dual-platform validation of the DT. While the main model was developed in MathWorks, it was independently validated using a Simio-based DT. This addresses a known challenge in DT research—lack of standard validation methods—and strengthens confidence in the simulation accuracy and results.

4.2 Scenario Analysis

Scenario analysis was used to evaluate how uncertainty in parameters related to human resource affects system-wide KPIs. The DT enabled dynamic simulation of task sequences, human-machine interaction, and queue formation between stations. The key KPIs analyzed include:

Resource utilization

Queue length minimization

Production volume maximization

The scenario analysis methodology included the following components:

Historical data integration: Real production and workforce data can be used to model variability in task durations and attendance patterns.

ML-based forecasting: An ML model can be trained on historical data to predict future workforce availability and its downstream effects on production.

Scenario generation and simulation:

A range of scenarios can be created based on predicted workforce variability. These scenarios can be simulated within the DT to assess their effects on system KPIs.

This process enabled the system to evaluate not only likely but also unseen edge-case scenarios, facilitating resilient production planning.

4.3 Optimization Using Reinforcement Learning

To optimize production planning, particularly worker allocation across stations, the framework employed a Reinforcement Learning (RL) algorithm. This model was trained in the DT environment, which allowed it to:

- Learn from simulated feedback in a risk-free setting
- Adaptively adjust policies to meet changing operational conditions
- Optimize KPIs under uncertainty
- The RL model's objective function is targeted: Maximizing throughput, minimizing total worker cost, and Reducing time in system for each product on average.

By leveraging DT for safe experimentation and RL for adaptive decision-making, the framework supports data-driven, scenario-aware, and resilient production planning.

5. CASE STUDY

To validate the proposed framework, a real-world composite manufacturing system (CMS) was modeled. Due to confidentiality agreements, the name of the partner company is withheld. The production system consists of seven interconnected stations, each historically staffed with dedicated operators using a static, manually scheduled workforce assignment.

The developed Digital twin in MathWorks and Simio are shown in Fig. 1 and Fig. 2 respectively.

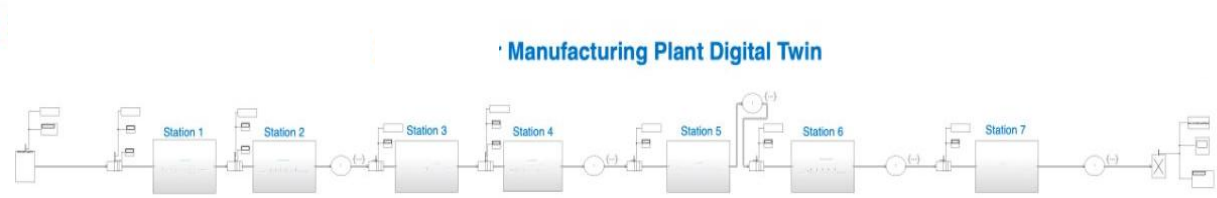

Figure 1. Developed Digital twin in MathWorks

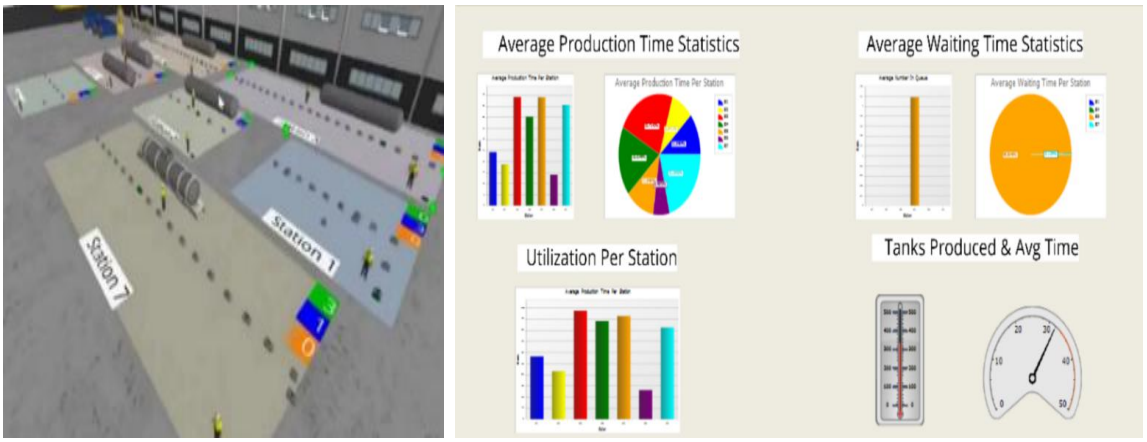

Figure 1. a) Developed Digital twin in Simio b) Developed Dashboard in Simio for Digital Twin

A new category of flexible, multi-skilled shop-floor workers was introduced. These workers are capable of operating across multiple stations, albeit at a higher wage. The key objective was to determine an optimal workforce allocation strategy that balances throughput (T), total worker cost (C), and time in system (TIS). These KPIs were prioritized based on the factory's operational strategy: throughput (60%), worker cost (30%), and TIS (10%).

5.1 Human Resource Uncertainty and Modelling Enhancements

The subjected CMS faces operational uncertainty primarily due to two factors:

- Variability in human resource availability (e.g., sick leave, absenteeism)
- Quality-induced rework which reintroduces components back into the production flow

These uncertainties significantly impact production schedules and system stability. To address this, the Digital Twin (DT) was enhanced with features that simulate the effects of rework and human resource fluctuations. This new version extended the previously developed model by adding:

- Dynamic modeling of worker types and availability
- Simulation of 81 interdependent processes, both sequential and parallel
- Time variability per task and resource-based processing times
- Movement and behavior of workers and products
- Modeling of station capacity constraints
- Automatic dynamic allocation of workers
- Full 3D visual animation
- A live KPI dashboard and WIP (work-in-progress) metrics

These enhancements allowed for robust scenario generation and simulation across a broad range of operational conditions.

5.2 Scenario Analysis Using Machine Learning

A data-driven scenario analysis was conducted to quantify the impact of human resource uncertainty on system performance and identify optimal worker allocation strategies.

Applied Methodology:

- Historical data on worker attendance and production variability in ERP was used to train the ML model.
- An ML model was developed to predict system performance under varying worker availability and process durations.
- The Digital Twin simulated hundreds of production scenarios incorporating predicted variations.
- Scenario results informed the reinforcement learning optimization process.

This enabled a nuanced understanding of how shifts in workforce capacity influenced production bottlenecks, queue lengths, and throughput.

5.3 Reinforcement Learning-Based Optimization

The optimization process used a Reinforcement Learning (RL) framework. The framework included:

- Simulation Dataset Generation: A year's worth of possible worker availability combinations (~11,250 scenarios) was generated using the DT.
- ML-Based Performance Prediction: The ML model forecasted KPIs based on simulated outcomes.
- RL Agent Optimization: The RL agent iteratively adjusted worker allocations.

Rewards were calculated using the weighted objective function based on throughput, worker cost and time in the system for each product.

Through multiple training episodes, the agent learned to maximize throughput while minimizing costs and delays.

5.4 Key Outcomes and Impact

The integration of DT with RL enabled a robust, data-driven framework for resilient workforce planning in a high-variability environment. Compared to baseline operations:

- Worker costs were reduced by 34%
- System time was reduced by 16%
- No negative impact on throughput, despite labor constraints

These findings demonstrate the potential of combining simulation, predictive modeling, and reinforcement learning to achieve adaptive, cost-effective, and scalable production strategies in human-intensive manufacturing systems.

The case study also confirmed the feasibility of conducting advanced optimization in a risk-free virtual environment, with actionable insights ready to be applied to real operations. Future work will extend this framework to include additional constraints (e.g., maintenance schedules, product customization) and explore real-time decision-making integrations.

6. CONCLUSION

This paper presented a scenario-driven optimization framework that integrates Digital Twin (DT), Machine Learning (ML), and Reinforcement Learning (RL) to enhance production planning in a human-intensive composite manufacturing system. The proposed approach addressed key uncertainties related to human resource availability and process variability, which are common challenges in such manufacturing environments.

A DT model, developed and validated across two platforms, was used to simulate dynamic operations and generate realistic production scenarios. A ML model predicted performance metrics under varying conditions, enabling the RL agent to explore and optimize worker allocation strategies efficiently.

The framework was validated through a real-world case study, demonstrating significant reductions in total worker cost (34%) and time in system (16%), while maintaining maximum achievable throughput under existing capacity constraints. These results highlight the value of integrating data-driven decision-making tools within virtual environments for resilient and efficient production planning.

Future work will focus on extending this framework to real-time decision support and incorporating additional production constraints, further improving its applicability in dynamic and complex manufacturing settings.

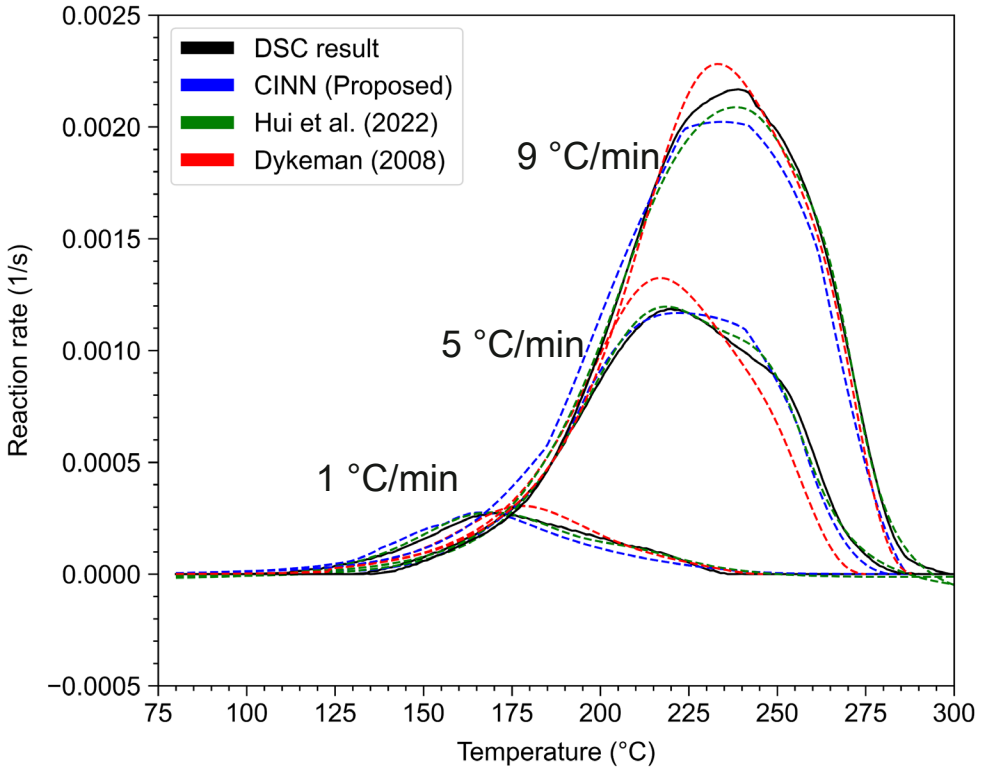
60	140	5.56E-05	10	0.002061476

Georgia Tech

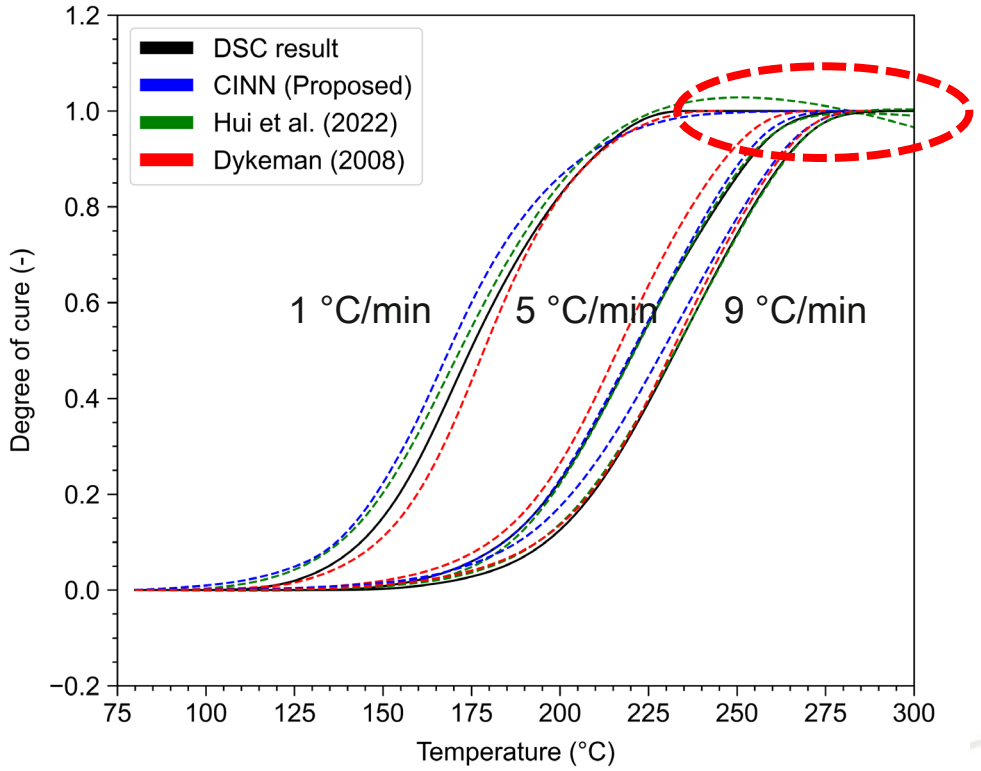
Experimental Setup

- Material: Toray T830H 6K/3900-2D carbon fiber prepreg
- Sample mass: 11 ~ 15 mg
- Pan & lid: T-zero Hermetic

DSC: Q2000 (TA Instruments)



Oven: HAFO 1602

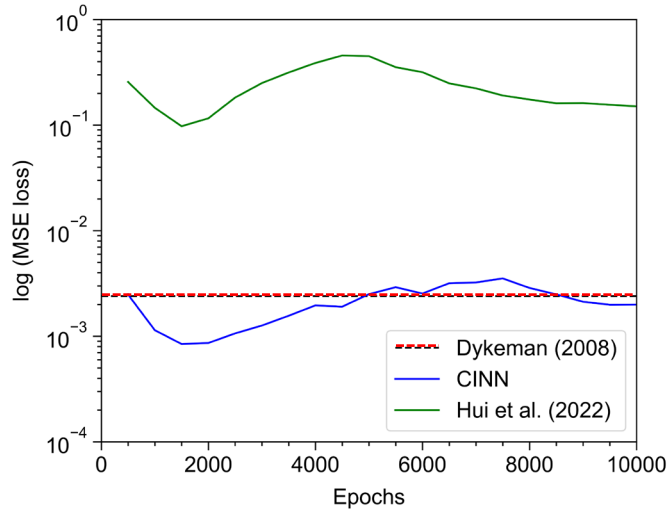


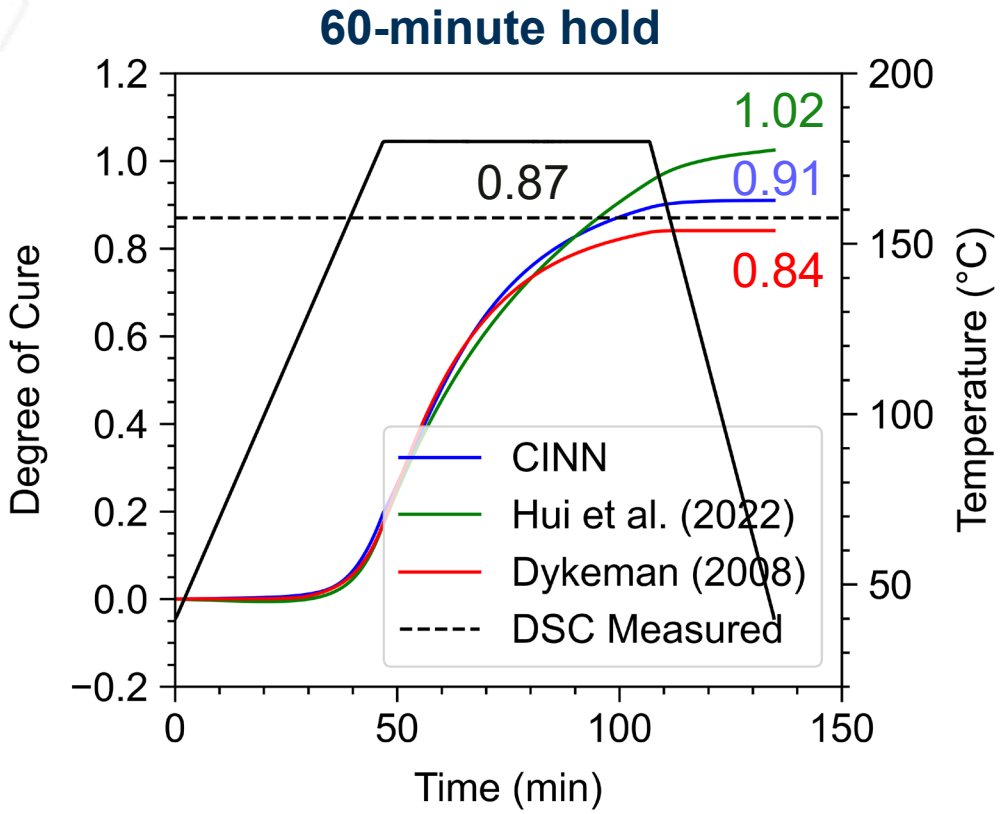
Georgia Tech

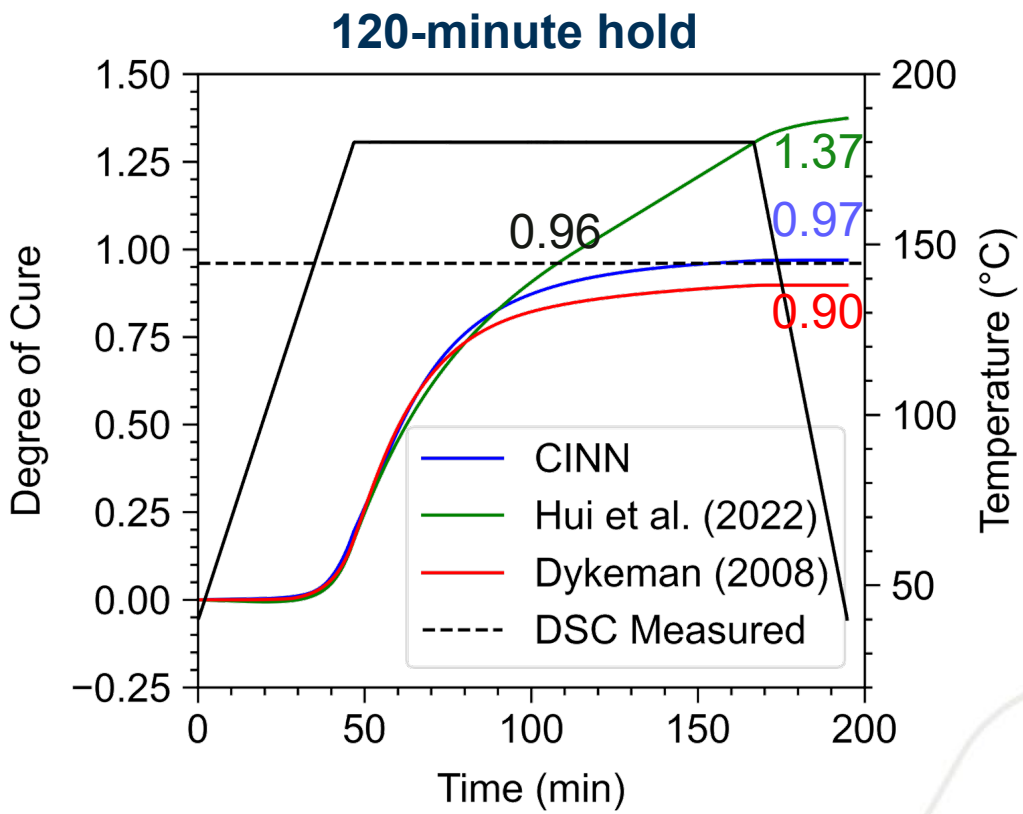
Training Accuracy

Goodness of the fit to the trained curve

- Closely matches DSC curve, but Hui's model shows a negative reaction rate



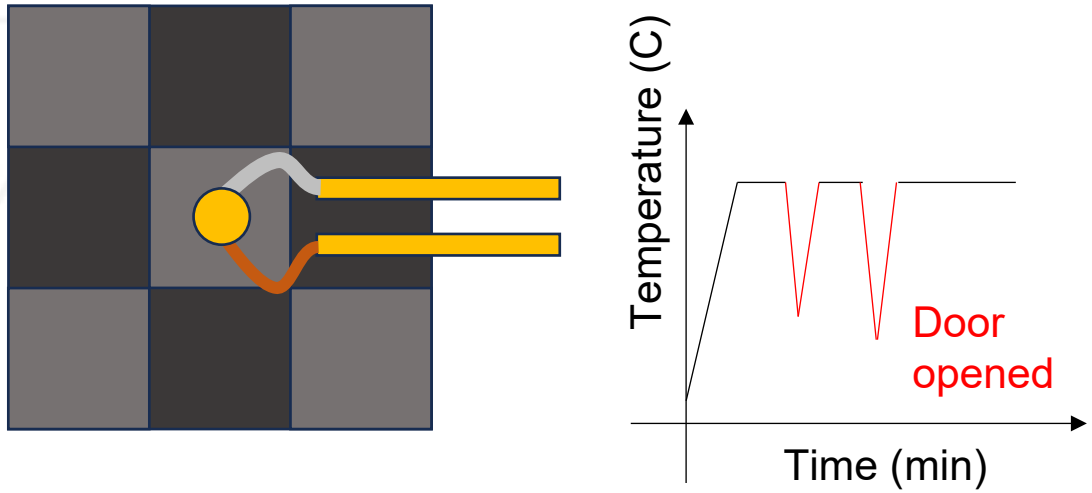


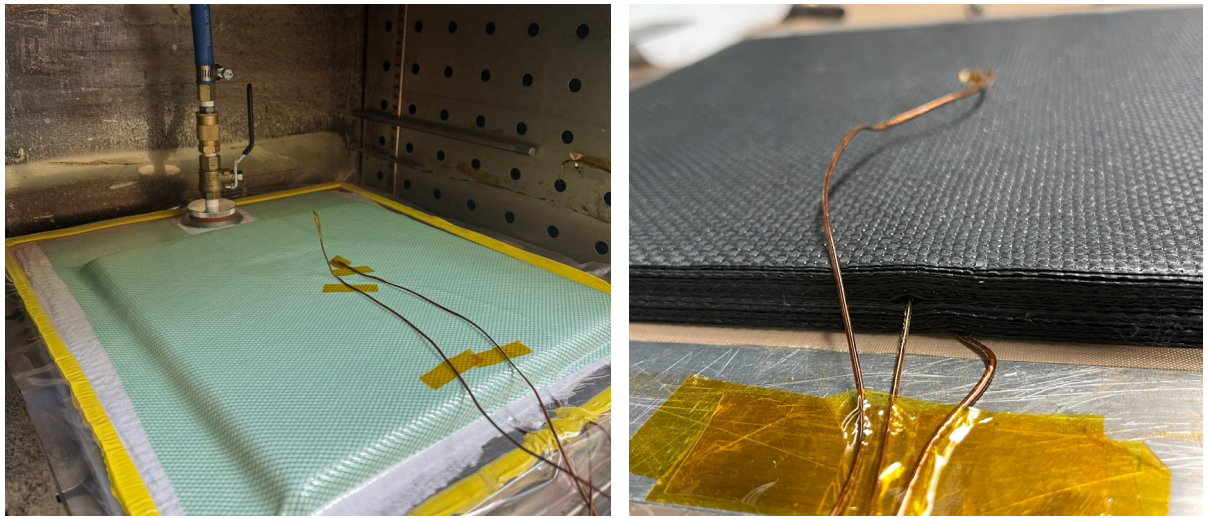


Validation Accuracy

Both models show minimum error at 1500 epochs

- 60-minute hold : 4.9% relative error (CINN)
- 120-minute hold: 0.9% relative error (CINN)

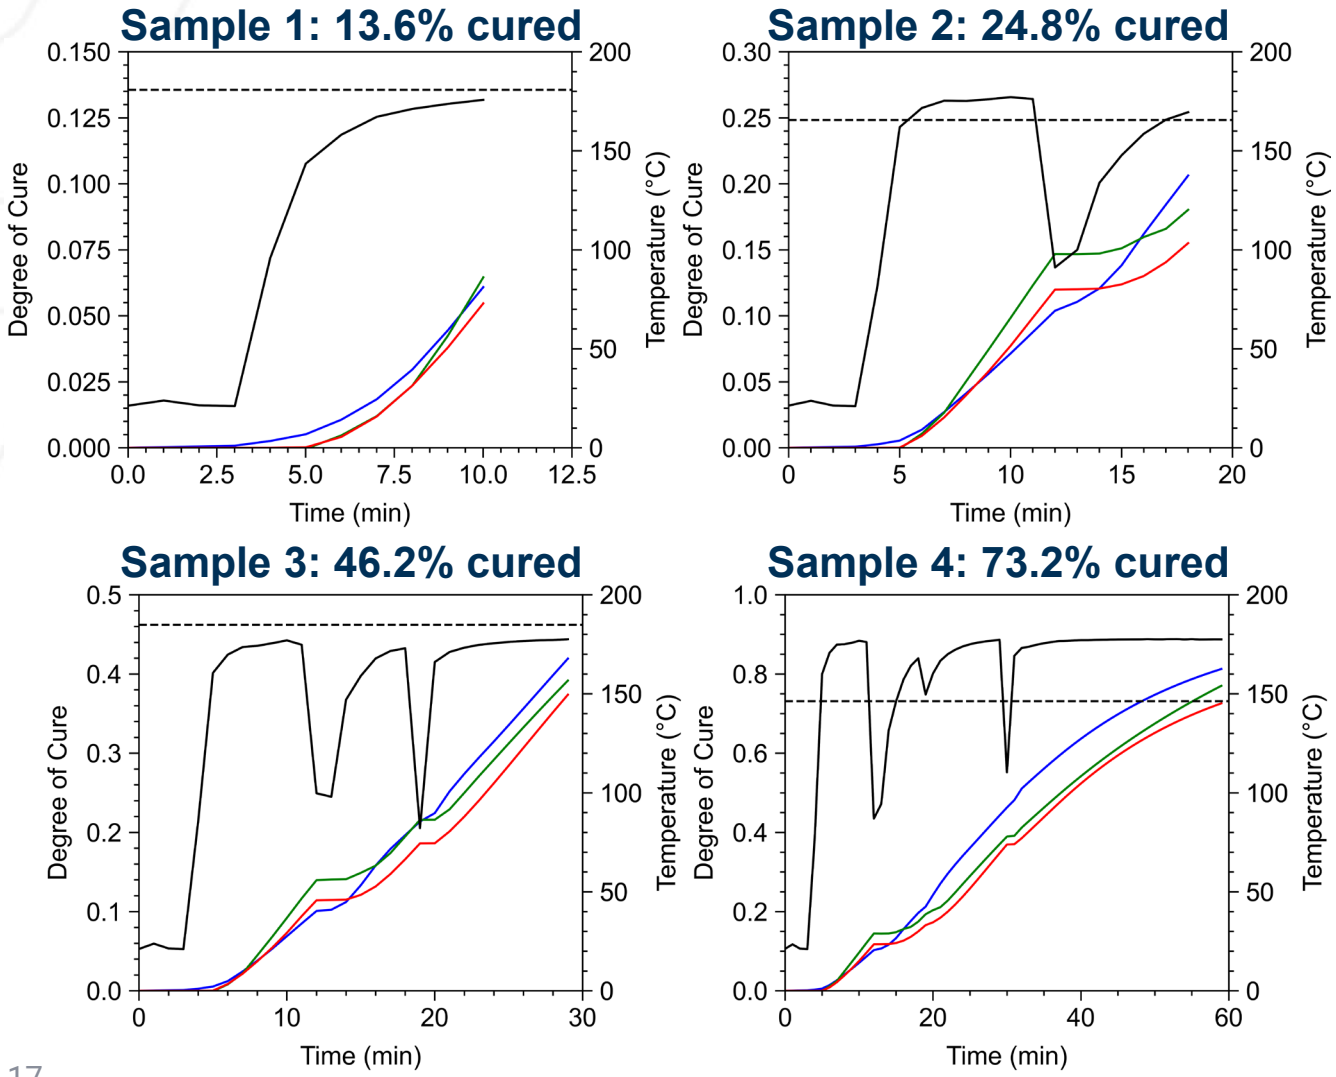




Robustness Tests

Thermal disturbance

- 4 Samples
- Each of a part size: 12 mm x 12 mm x 0.25 mm
- Cure cycle: Varies



Fabrication

- Part size: 300 mm x 300 mm x 12.5 mm
- Cure cycle: MRCC (3 hours hold)

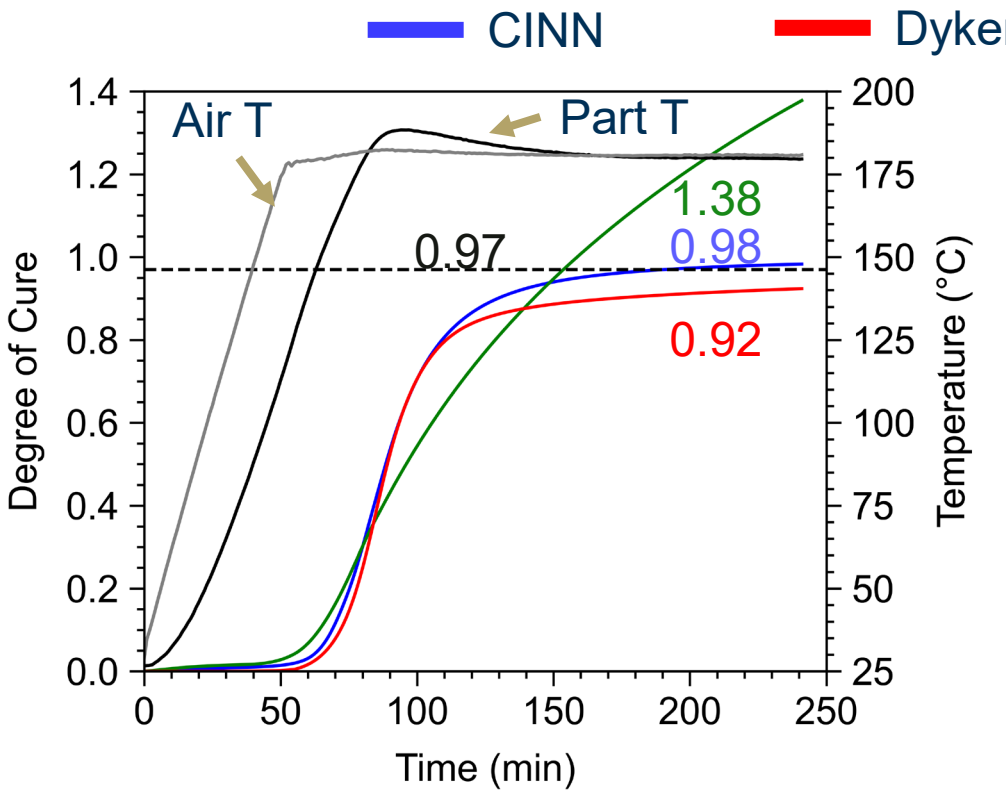
Georgia Tech

Thermal Disturbance Test

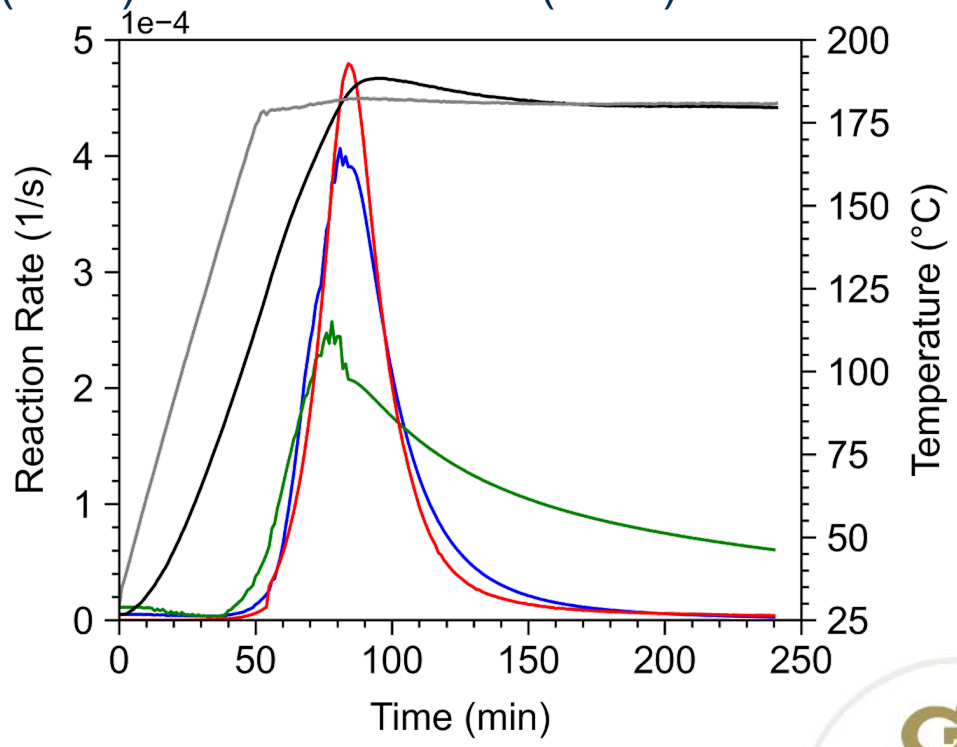
Measured

CINN

Dykeman (2008)



Hui et al. (2022)



All models match well

Georgia Tech

Fabrication Test

- CINN showed similar trend, even outperforming the Dykeman's model
- Hui's model starts to deviate as temperature reaches peak and hold
  → Overestimates heating rate

Georgia Tech

Conclusion

- Chemistry-induced neural network model (CINN) showed not only high accuracy but also numerical stability and chemical validity.
- Scenario based selected model showed consistent performance.

Future Plans

- Test using different resin systems for generalizability
- Elaborate model selection method

Georgia Tech

Appendix: Dykeman's Model (Dykeman, 2008)

Total Model:

$$\dot{\alpha} = K_{1eff}(1-\alpha)^{n_1} + K_{2eff}\alpha^{m_2}(1-\alpha)^{n_2} + K_{3eff}\alpha^{m_3}(1-\alpha)^{n_3} \qquad 5.19$$

Chemical Reaction:

$$\dot{\alpha} = K_1(1-\alpha)^{n_1} + K_2\alpha^{m_2}(1-\alpha)^{n_2} + K_3\alpha^{m_3}(1-\alpha)^{n_3}$$

Primary-Amine and Epoxy:

If $T < 124^{o}C$ and $\alpha < 0.035$, Then $A_1 = 34378*\mathrm{Ln}(\alpha) + 229563$ /sec and $E_1 = 73300$ J/mol;

If $A_1 < 50000$ /sec, Then $A_1 = 50000$ /sec.

End If.

Else, If $T < 124^{o}C$ and $\alpha > 0.035$, Then $A_1 = 113881$ /sec and $E_1 = 73300$ J/mol;

Else, If $T > 124^{o}C$, Then $A_1 = 14240$ /sec and $E_1 = 66435$ J/mol.

End If.

Secondary-Amine and Epoxy: $A_2 = 473684$ /sec, $E_2 = 73063$ J/mol

Etherification: $A_3 = 1.5E9$ /sec, $E_3 = 115624$ J/mol

Reaction Orders:

$m_1 = 0$, $n_1 = 1$

$m_2 = 1$, $n_2 = 2.5$

$m_3 = 2.91$, $n_3 = 0.83$

Georgia Tech

Appendix: Dykeman's Model (cont.)

Tg-α:

$$Tg = \frac{\lambda\alpha(Tg_\infty - Tg_0)}{1-(1-\lambda)\alpha} + Tg_0 + \frac{D}{1+\exp[-F(\alpha-\alpha_{critical})]}$$

λ (copolymer) = 0.8, Tg_0 = 8.8°C, Tg_∞ (copolymer) = 200°C, D = 35, F = 25

Tg_∞ (epoxy) ≥ 222°C

$\alpha_{critical}$:

If dT/dt < 0.0001 K/sec, Then $\alpha_{critical} = (0.0025/K)*T - 0.3329$;

Else, $\alpha_{critical} = (0.0025/K)*T - (0.00017K/\sec)/\dot{T} - 0.3329$.

End If.

If $\alpha_{critical} < 0.675$, Then $\alpha_{critical} = 0.675$.

End If.

If $\alpha_{critical} > 1$, Then $\alpha_{critical} = 1$.

End If.

Diffusion:

Primary and secondary amine reactions with epoxide:

$$k_{d1,2} = A_{d1,2}\exp\left(-\frac{E_{d1,2}}{RT} - \frac{b_{1,2}}{f_v}\right)$$

$A_{d1,2}$ = 4E12 /sec, $E_{d1,2}$ = 60 kJ/mol, $b_{1,2}$ = 0.52, and $f_v = a_f$(T-Tg) + f_g, a_f = 0.00008 /°C, f_g = 0.025

If T-Tg <-50 K, Then $K_{d1,2}$ = 1E-99 /sec

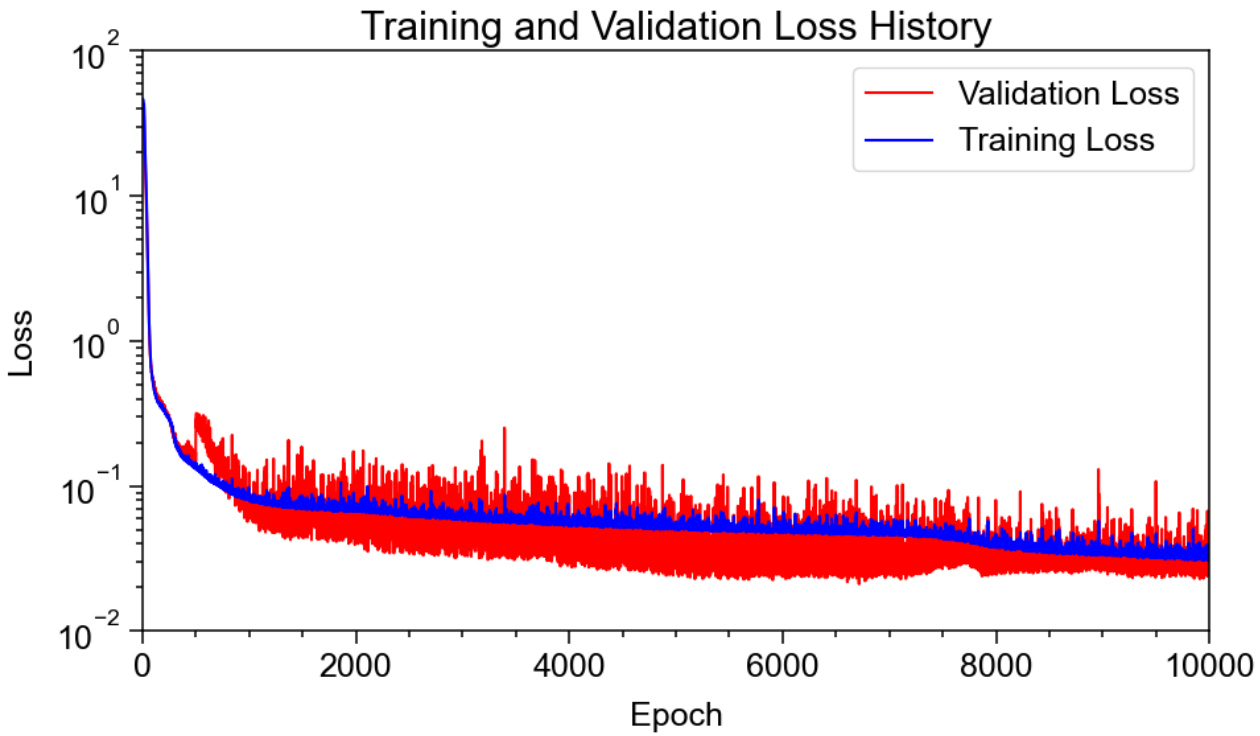
End If.

Etherification:

$$k_{d3} = A_{d3}\exp\left(-\frac{b_3}{f_v}\right)$$

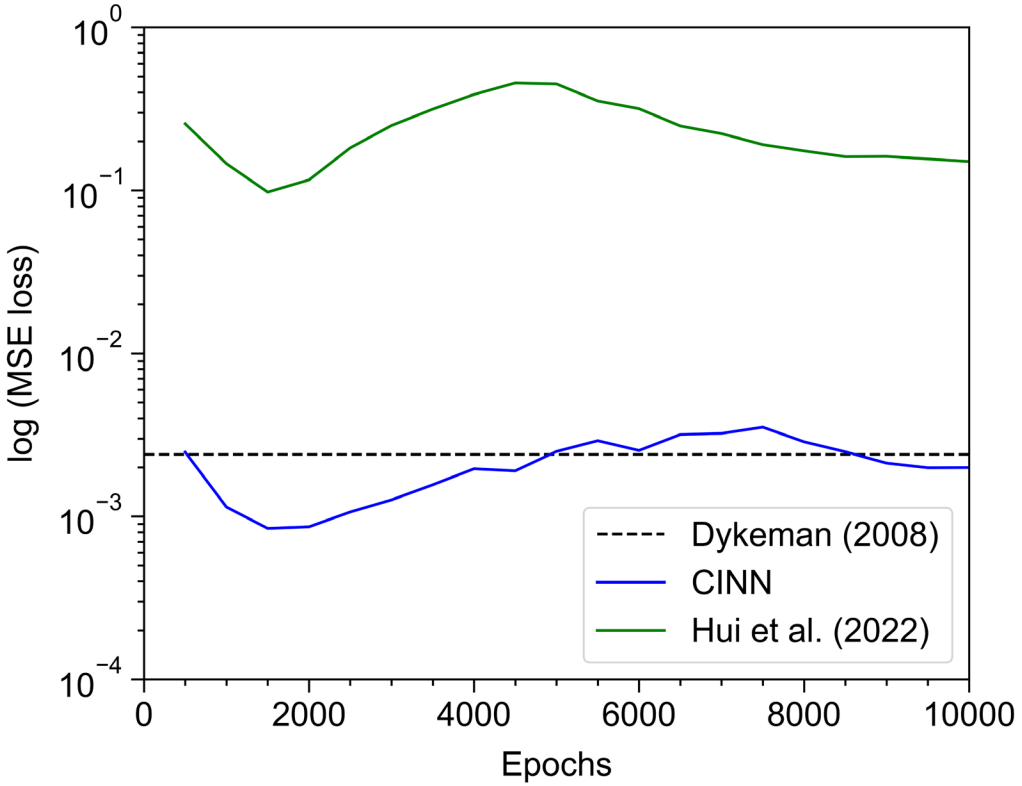
A_{d3} = 1.5E9 /sec, b_3 = 0.7, and $f_v = a_f$(T-Tg) + f_g, a_f = 0.00008 /°C, f_g = 0.025

If T-Tg <-50 K, Then K_{d3} = 1E-99 /sec



End If.

$k_{d,1-2}$ and $k_{d,3}$ are added to k_1 , k_2 and k_3 chemical by the Rabinowitch equation:



$$\frac{1}{K_e} = \frac{1}{K_c} + \frac{1}{K_d}$$

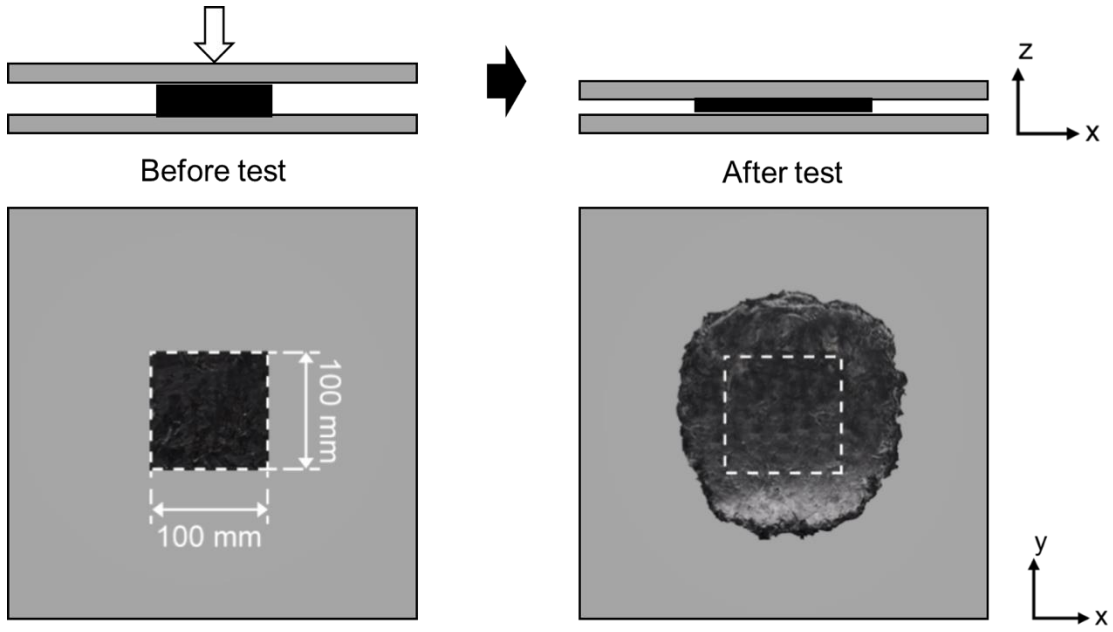
The First European Benchmark Exercise on Squeeze Flow Testing of High-performance Carbon Fibre Sheet Moulding Compounds

Connie Qian, Miro Duhovic, Dominic Schommer, Florian Gortner, Andreas Gebhard, Thomas Neumeyer, Marcel Olma, Louis Schreyer, Luise Kärger, Martin Hohberg, Hao Yuan, Anna Julia Imbsweiler, Sepehr Simaafrookhteh, Jan Ivens, Stepan V. Lomov, Gerben Bieleman, Wouter Grouve, Francois Mahé, Christophe Binetruy, Andreas Kapshammer, Zoltan Major, Dmitry S. Ivanov, Jonathan P.-H. Belnoue, Anatoly Koptelov, Jakub Jakimow, Dimitra Ramantani, Yvonne Aitomaki, Steven Nothhelfer, Nicole Stoess

Content

- Background and motivation
- Participants and facilities
- Experimental methodology
- Data collection
- Conclusions

High-performance SMC



- Long fibres (length>10mm, typically 25mm)
- High fibre content (volume fraction >30%)
  - ➢ Formation of “fibre network”
  - ➢ Suspension theory no longer applies
- Rapid cure resin system
- High-rate compression moulding processes
- High compression forces and pressures (>100 bar)
- High variabilities caused by the manufacturing (compounding) process

CT image of a compression moulded CF-SMC sample
(25mm fibre length, 47% wt, scanned area approximately 35mm x 25mm)

The squeeze flow test

- Squeeze flows – flows in which a material is compressed between two parallel plates
- Increasing popularity for SMC flow characterization
  - ➢ Similar to compression moulding
  - ➢ Easy to setup with existing load frames/presses
  - ➢ Wide range of strain rates
  - ➢ Internal material deformation is ensured
  - ➢ High variabilities, inhomogeneous (and anisotropic) flow due to the nature of the material
  - ➢ Lacking standarised test setup and procedure

Schematic illustration of the SMC squeeze flow test

Scope of the benchmark

Anticipated outcomes:

- Understanding the sources of variabilities -> improve the reliability and repeatability
- Moving towards the development of a testing standard

Anticipated impact:

For academia

- Robust and reliable experimental approach
- Downstream research e.g. process simulation development

For industry

- Quality assurance testing
- Improved process robustness
- Material selection

Benchmark Overview

- 14 research institutes, 10 testing facilities, 7 countries
- 500kg material donation from Polynt Composites
- 5-day testing campaign, up to 120 samples total per participant
- 3 months from material manufacturing to the completion of testing campaign

Total materials donated by Polynt Composites

Facilities overview

Institute	Platen size [mm]	Testing machine	Heating method	Force limit [kN]
ECN & HESAM	220	Static frame	Heated platens	100
IVW	345	Hydraulic press	Heated platens	6500
JKU	Ø200	Hydraulic frame	Heated platens	50

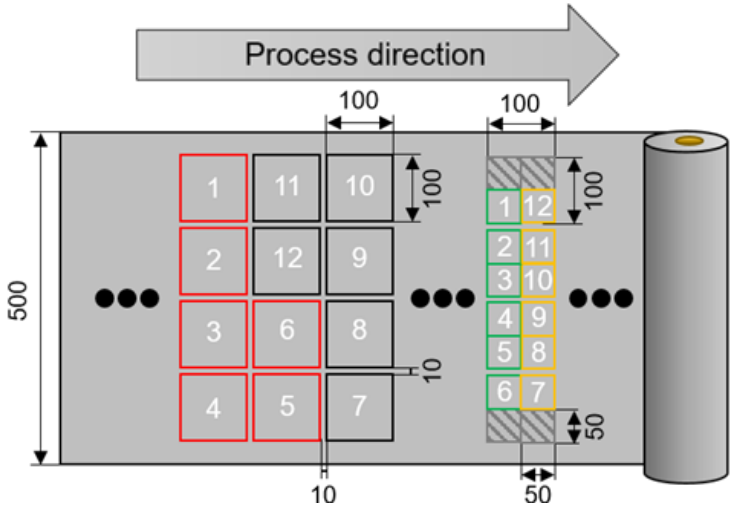
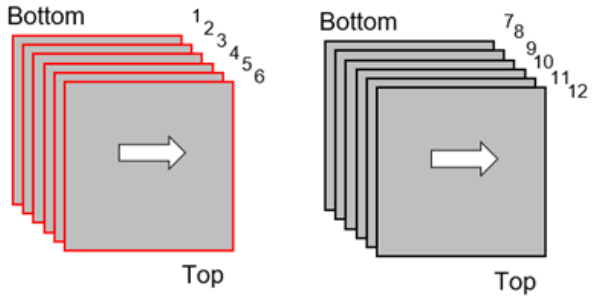
Materials



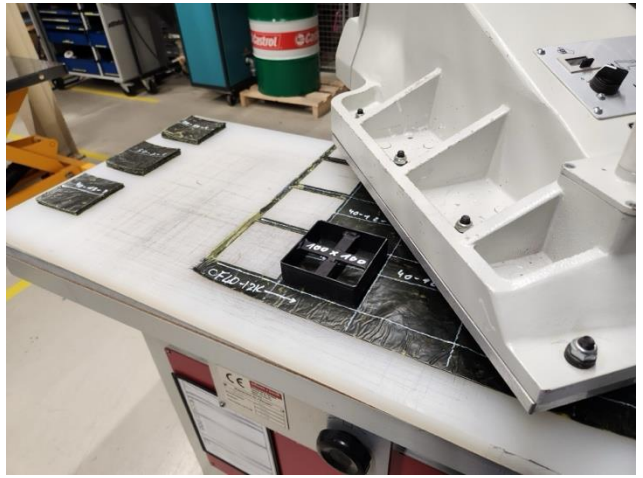
- Carbon fibre SMCs (C-SMC), **5** different specifications
- Identical vinylester resin system
- Recommended processing temperature **125-140°C**
- Recommended cure time **35s / mm part thickness**
- Shelf life **3 months** at room temperature or 6 months frozen
- Materials received by IVW and redistributed to all testing facilities

Product code	**Fibre tow size**	**Fibre length [mm]**	**Fibre weight fraction [%]**	**Target areal weight [g/m²]**
24 CF50-50K*	50K	25.4	50	1800
24 CF50-12K**,***	12K	25.4	50	1800
24 CF50-3K**	3K	25.4	50	1800
24 CF40-12K***	12K	25.4	40	1800
24 CF60-12K***	12K	25.4	60	1800



*Baseline material – Polynt's best selling C-SMC
** Effects of fibre tow size
*** Effects of fibre content

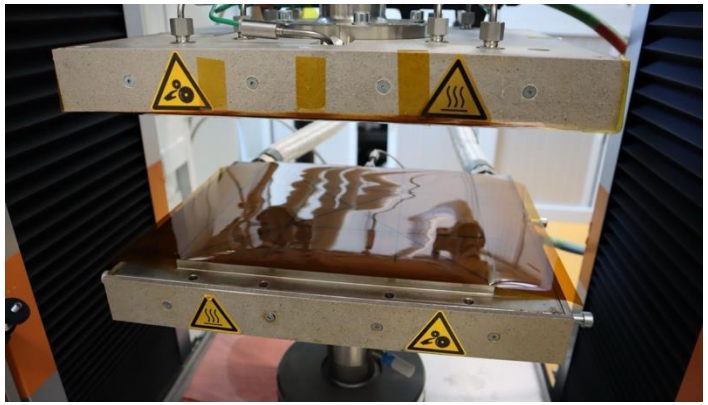
Sample preparation



- Square samples of 100mm and 50mm edge length
- Platen size ≥ 220mm -> both sample sizes
- Platen size < 220mm -> 50mm sample only
- 6 plies
- Fixed cutting plan and stacking sequence
  - ➢ Material tracing through UUIDs
- Strictly controlled sample preparation time (minimise exposure to air)

Cutting plan

Stacking sequence

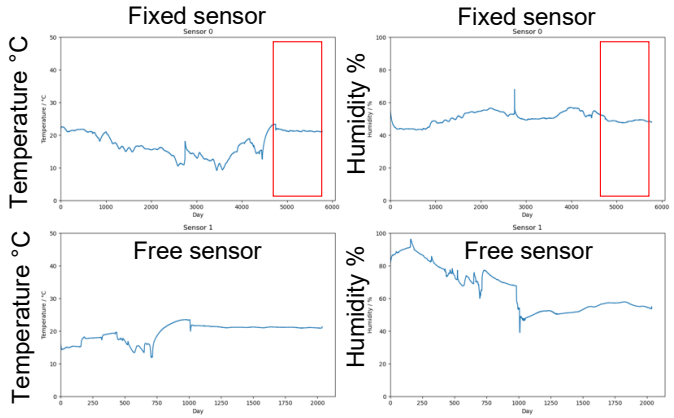


Clicker press

Manual cutting

Testing procedure

- Mould temperature 140°C
- Closing speed 0.5 mm/s
- Initial cavity height 11mm
- Final cavity heights 7, 5, and 3mm
- 10s sample loading time
- 210s minimum cure time
- Platens lined with Kapton films coated with release agent
- 6 repeats per testing configuration
- Fully randomised testing plan
  - ➢ Testing parameters alternated in blocks
  - ➢ Randomised material order within blocks



Kapton film lining

Flow front development

Force-displacement curves

Conclusions

Summary of the benchmark

- C-SMCs of 5 different specifications have been tested at 10 research facilities
- A well-defined testing procedure has been implemented to minimise the variabilities caused by testing conditions
- A comprehensive range of testing data and information has been collected
- Data analysis is being conducted to assess the variabilities in the testing results, and their potential causes

Potential next steps

- Follow-on benchmark exercise on squeeze flow modelling
- Development of an ATSM standard for high-performance SMC squeeze flow testing
- Collaborate projects on developing further SMC flow characterisation and flow simulation techniques
- Collaborate projects on improving quality controls of existing C-SMC products

Rapid Curing of Composites by Filament Winding Technique

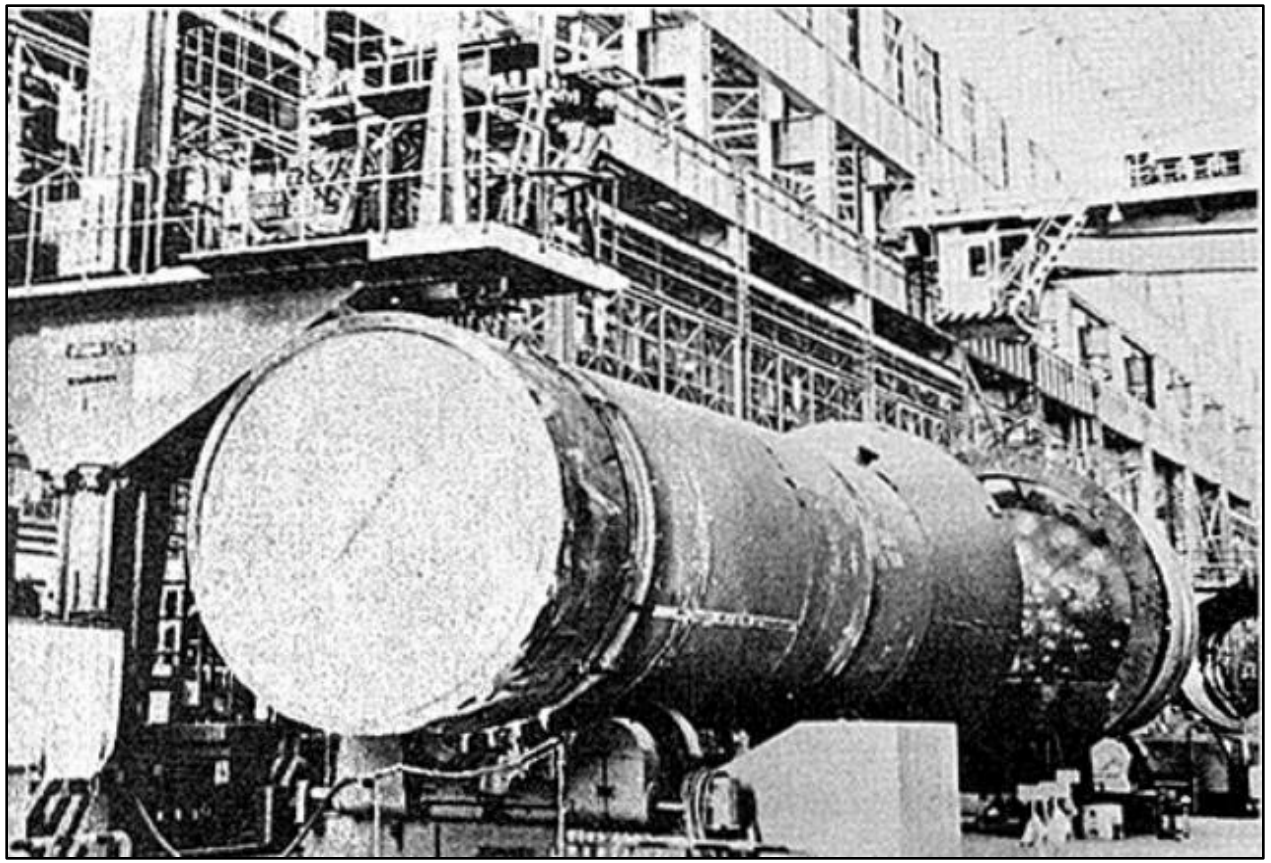
Soroush Dashtizad, Mahdi Baniasadi, Walter Jordan, Carter Dojan, Mostafa Yourdkhani

School of Manufacturing Systems and Networks

Arizona State University

August 5th, 2025

Arizona State University

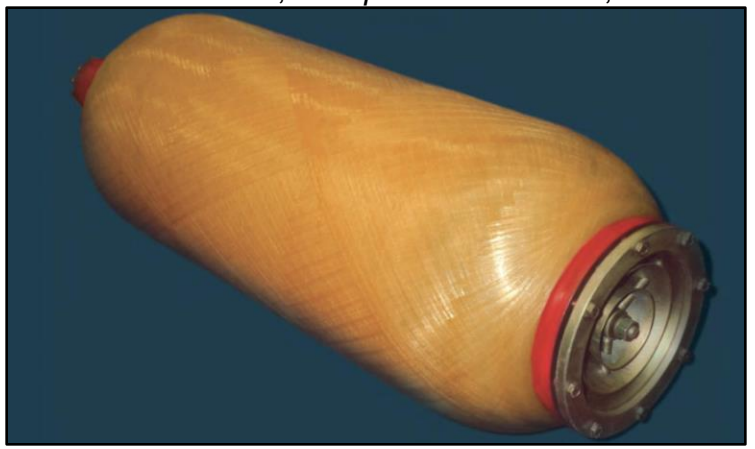


ICCM24

Outline

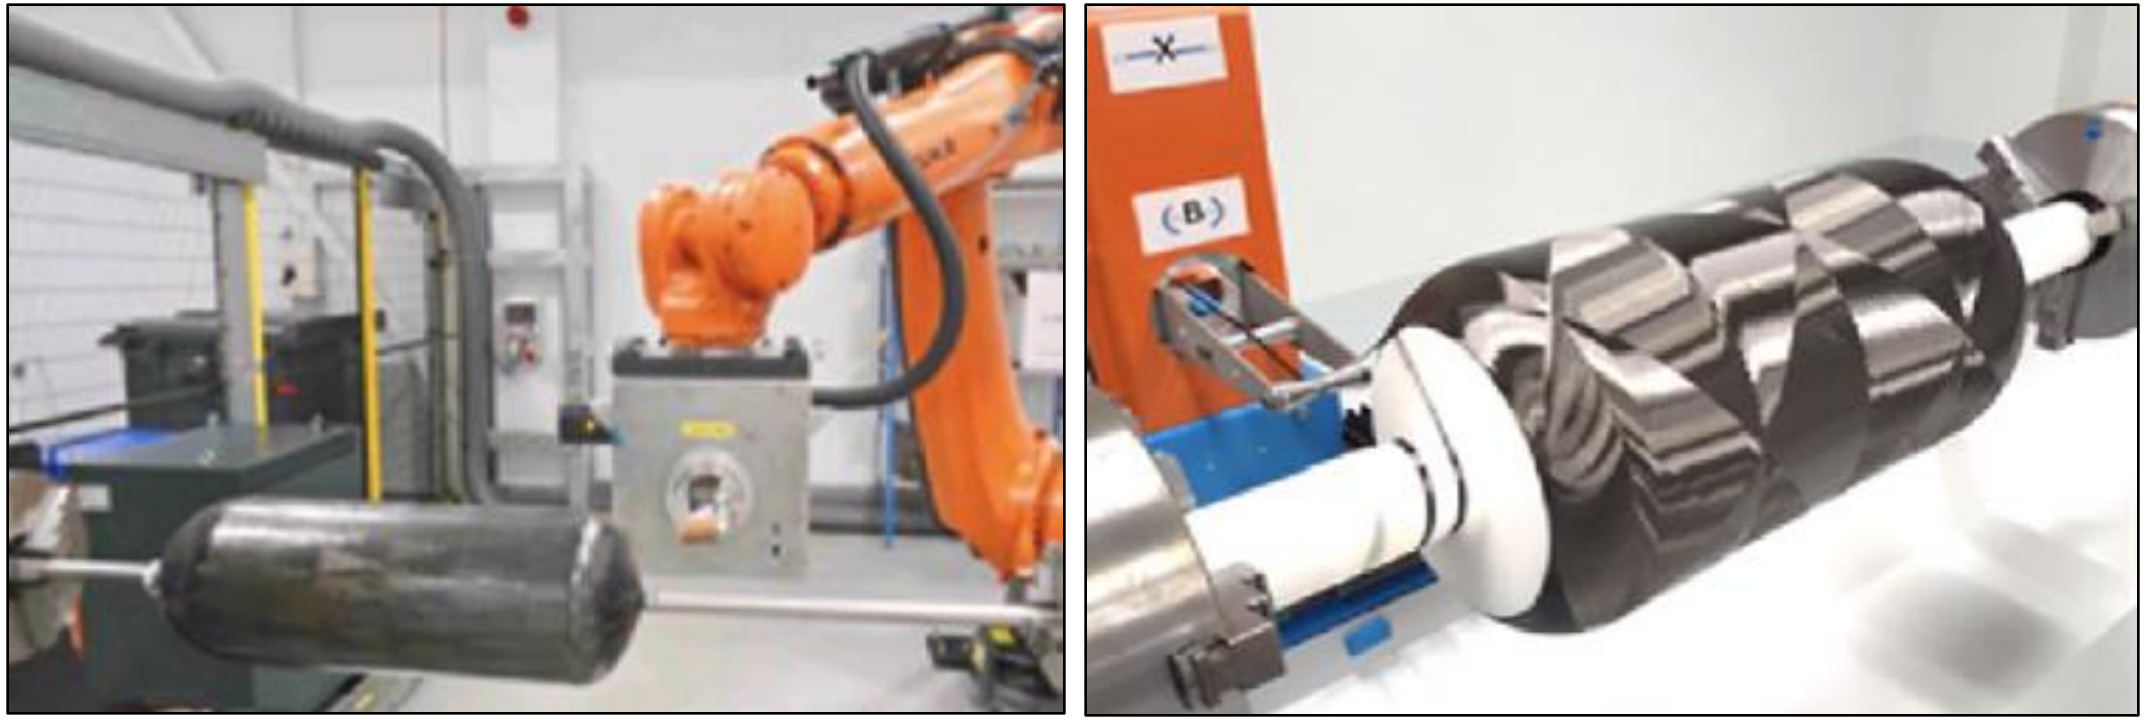
- Challenges with current filament winding approaches
- Frontal polymerization
- Frontal curing of composites during filament winding
- Experimental methods
- Understanding the underlying processing science
- Conclusions

Pressure Vessel



Composites are increasingly replacing metals in pressure vessel applications due to their superior strength-to-weight ratio and corrosion resistance

Ando et al., *Journal of Pressure Vessel Technology*, 1974

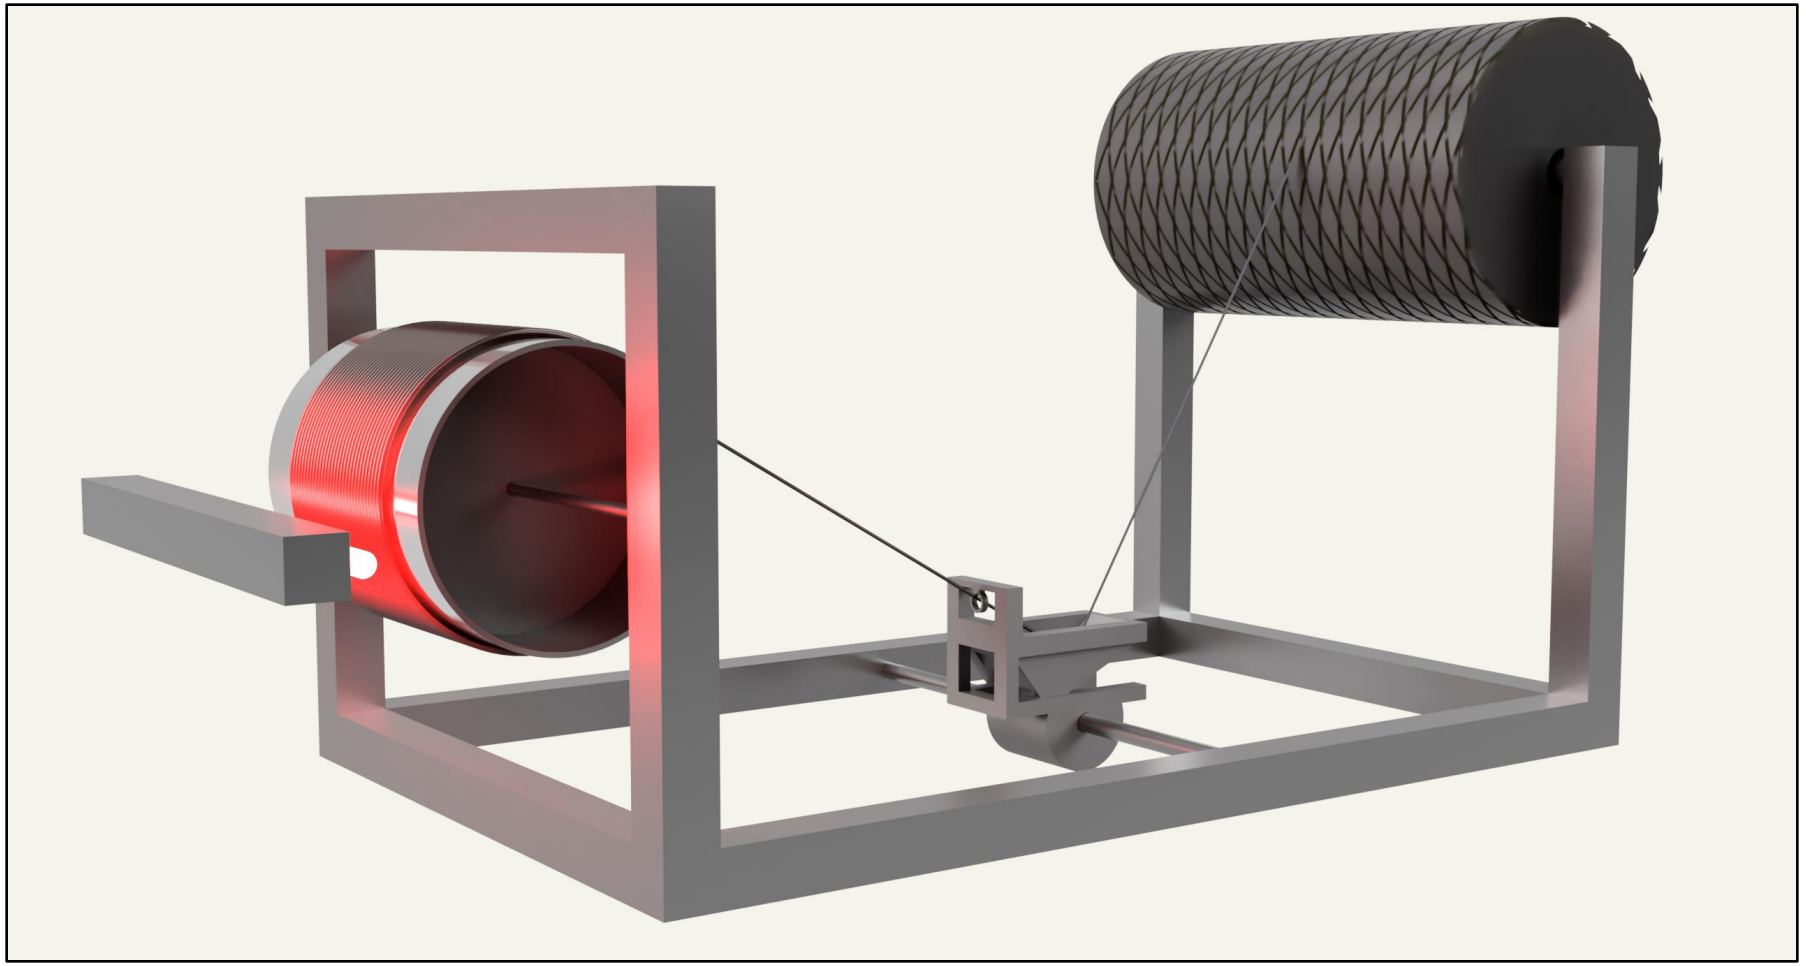


Blachut et al., *Composite Structures*, 2023

Vasiliev et al., *Composite Pressure Vessels*, 2009

Filament Winding

Filament winding is widely used for manufacturing composite pressure vessels

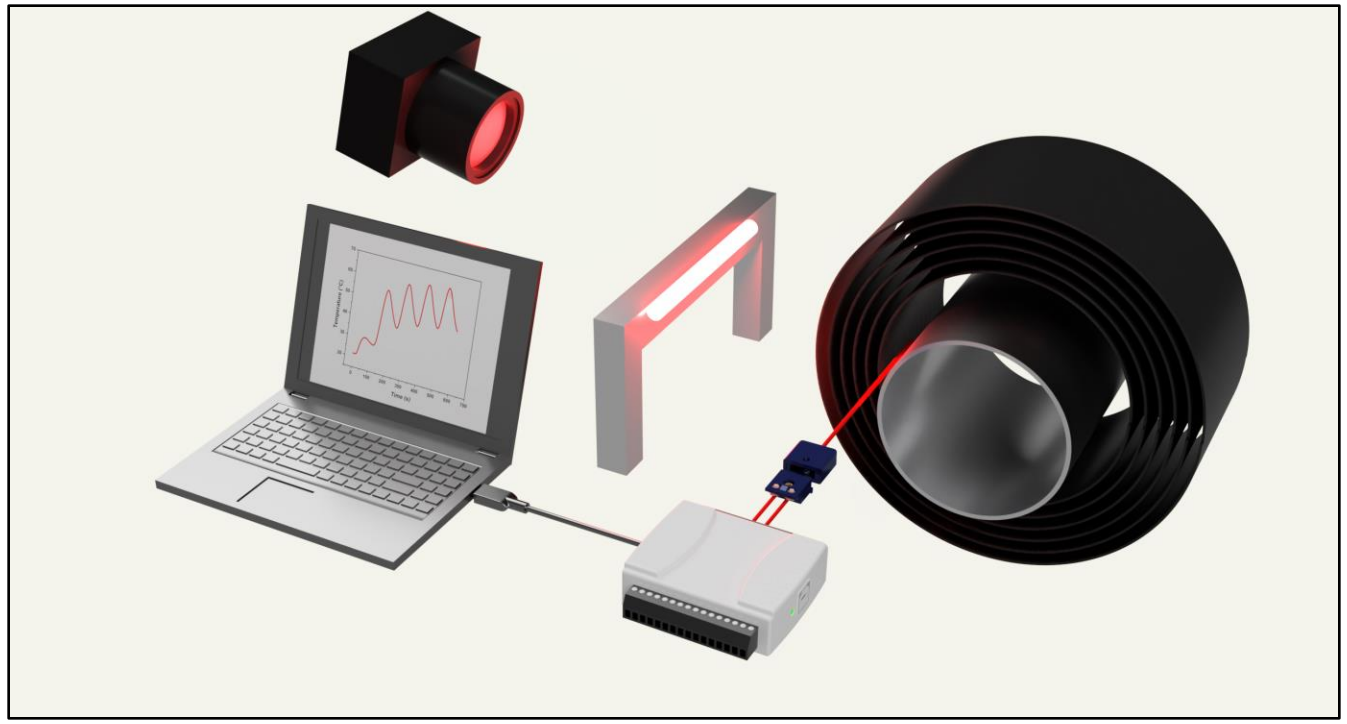


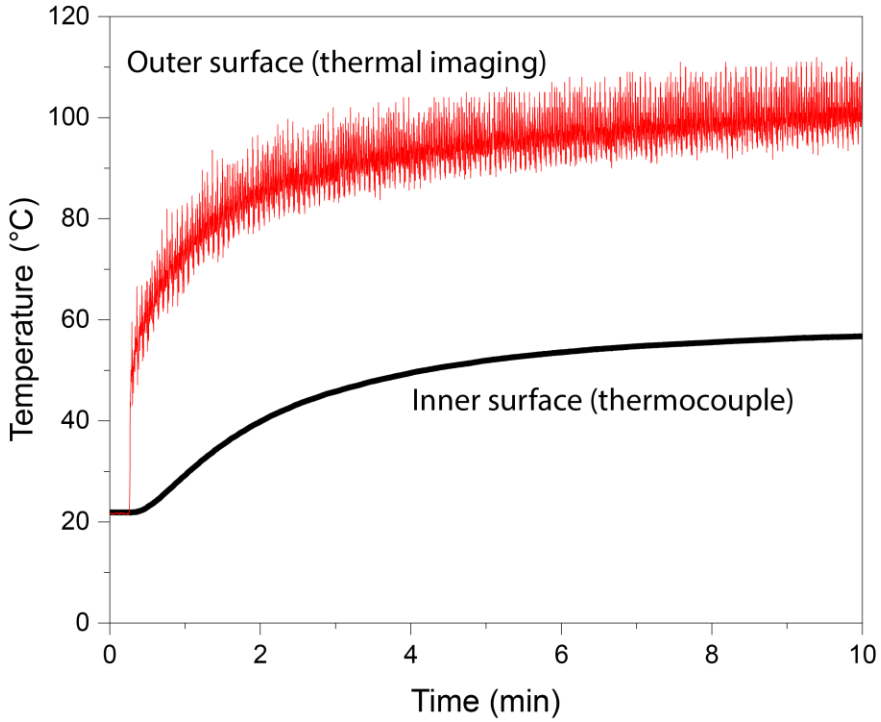
Ma et al., *International Journal of Hydrogen Energy* , 2024

- Fibers are wound on a mandrel using wet or prepreg techniques to tailor mechanical properties
- Conventional curing remains slow and energy-intensive, requiring hours of heating even with optimized processes

Filament Winding with *In-Situ* Curing

Rapid, one-step composite manufacturing enabled by in-situ frontal curing during filament winding

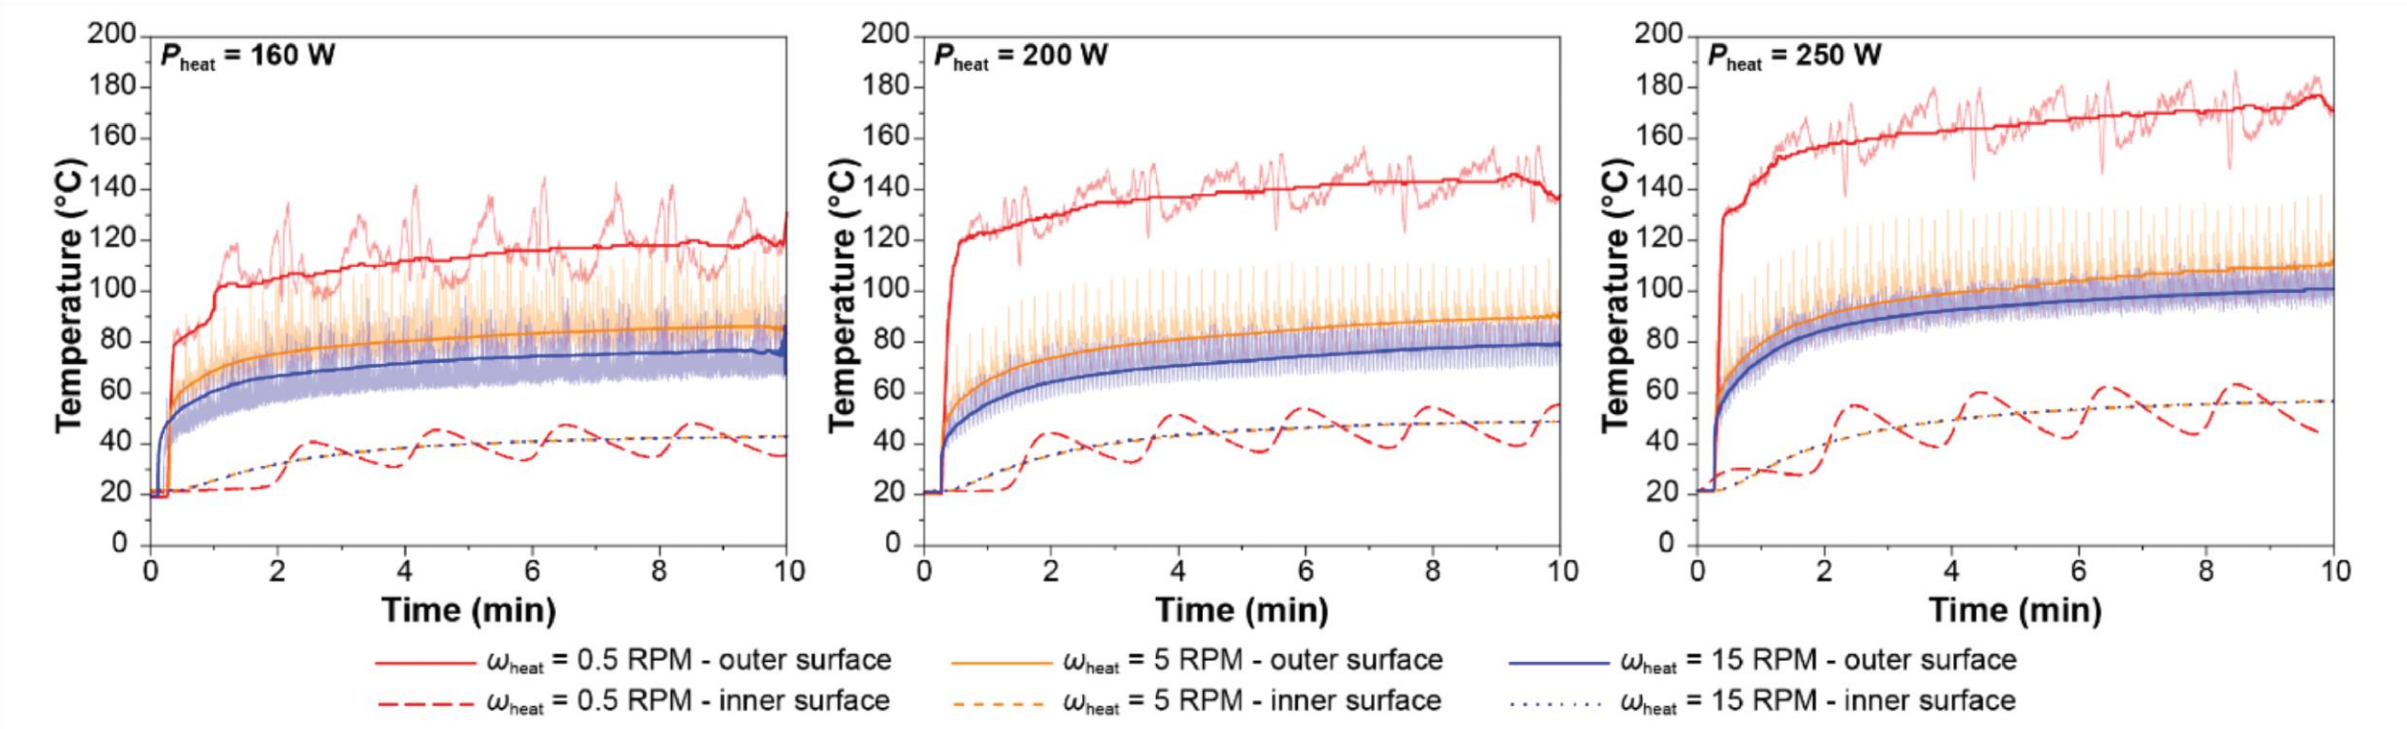




Materials

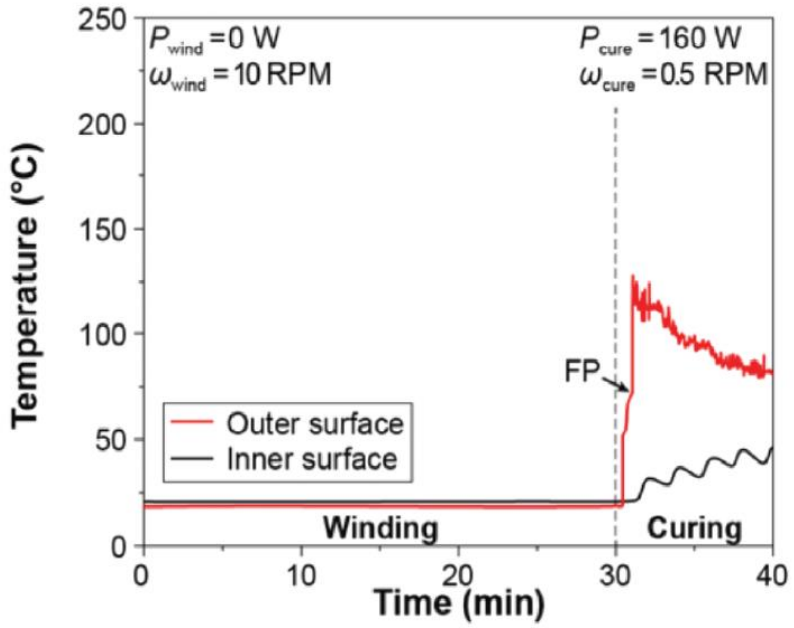
- Carbon fiber tow
- Dicyclopentadiene (DCPD)
- Second generation grubbs' (GC2)
- Tributyl phosphate (TBP)
- Phenyl cyclohexane (PCH)

Thermal Profile Measurement Setup

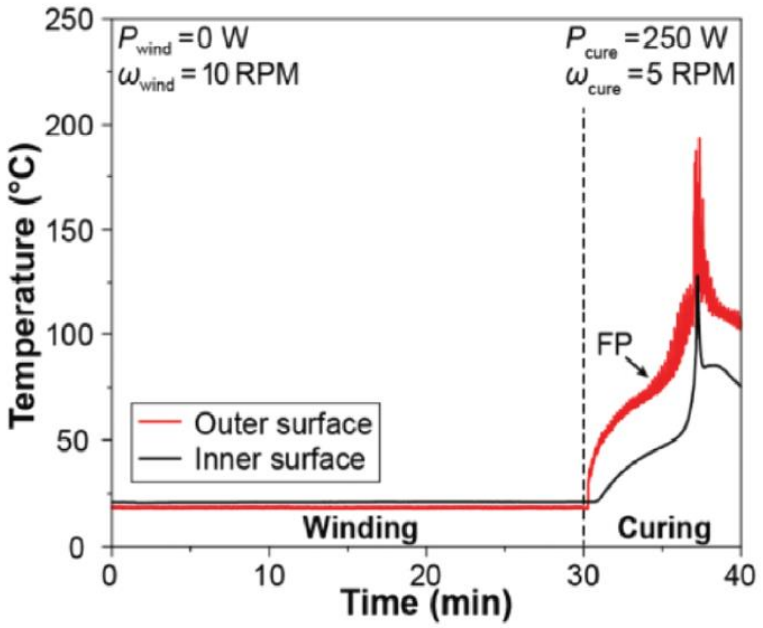


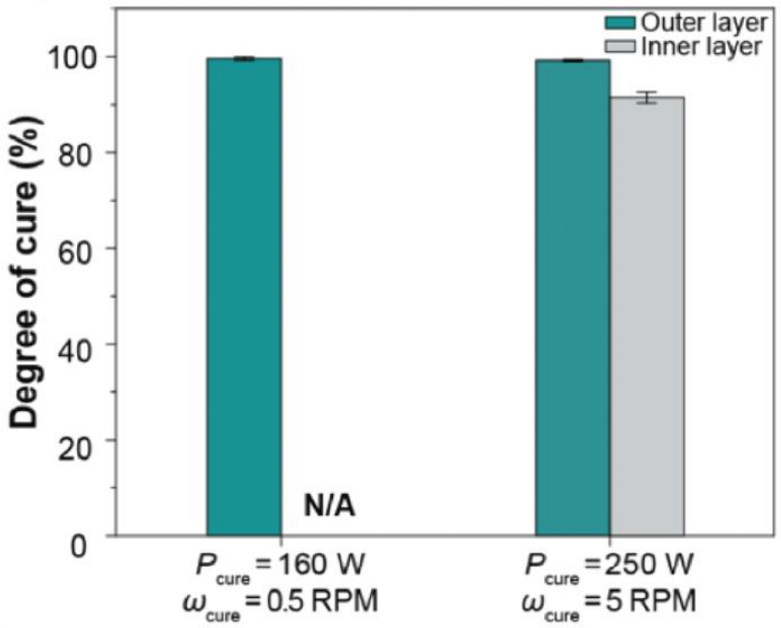
- Outer surface temperature measured using a thermal camera
- Inner surface temperature measured using a thermocouple

Dry Fiber Winding



Dry fiber winding is used to study the effect of input power and mandrel rotation on photothermal performance of carbon fiber tows

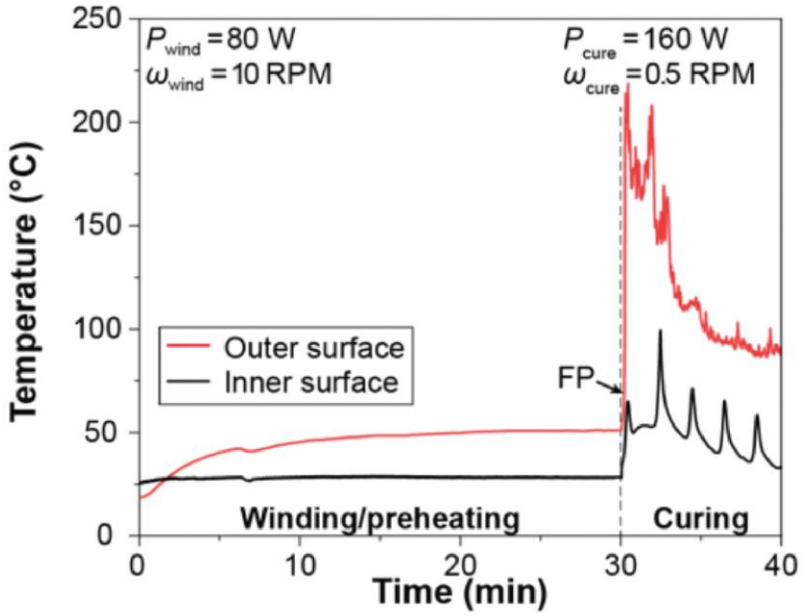


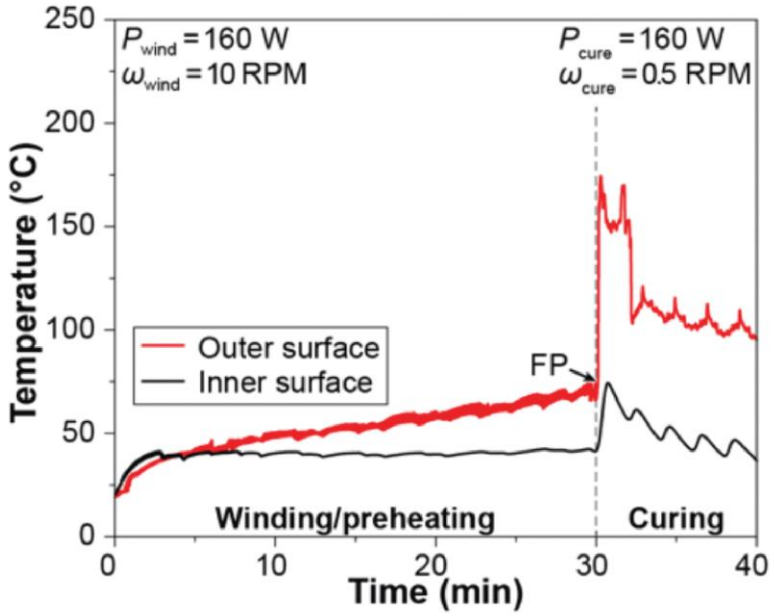


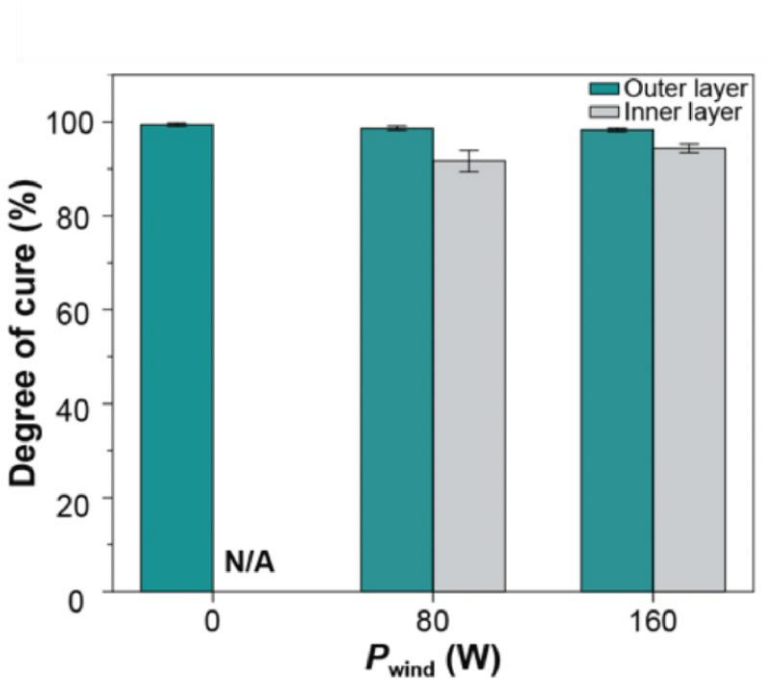
Higher mandrel speeds improve uniformity but lower the average temperature

Wet Winding

Based on the results of dry fiber winding, two processing conditions are selected for wet winding studies







- Low-power curing starts FP but leaves inner layers uncured
- High-power curing enables full cure but causes uneven through-thickness curing

Wet Winding with Preheating

Preheating during the winding step to increase the initial temperature of the material and its reactivity

Preheating enables more uniform curing and faster initiation of frontal polymerization

Conclusions

- A new approach is developed for rapid, energy-efficient, *in-situ* curing of composites during filament winding using IR-assisted frontal polymerization
- Photothermal-assisted frontal polymerization enables on-mandrel curing of composite parts within minutes
- Varying IR power and mandrel rotation speed affects front propagation dynamics and cure quality
- Preheating during winding enhances front initiation and sustained propagation throughout the composite
- Controlled IR input results in uniform curing, while excessive heating leads to surface defects

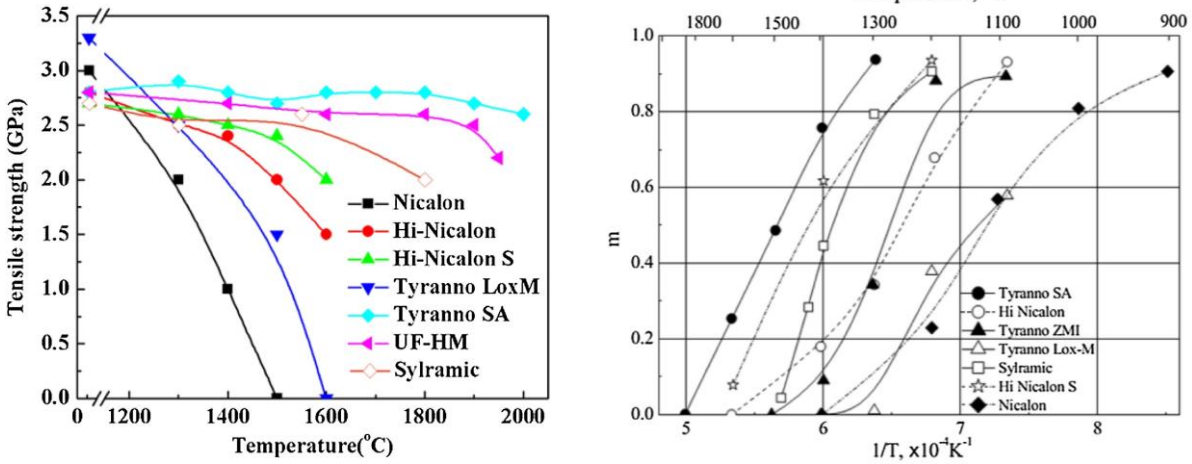
Need for 3-Dimensional SiC_f/SiC composite

SiC/SiC complex three-dimensional structure

Materials Science and Engineering 678 (2019) 012043

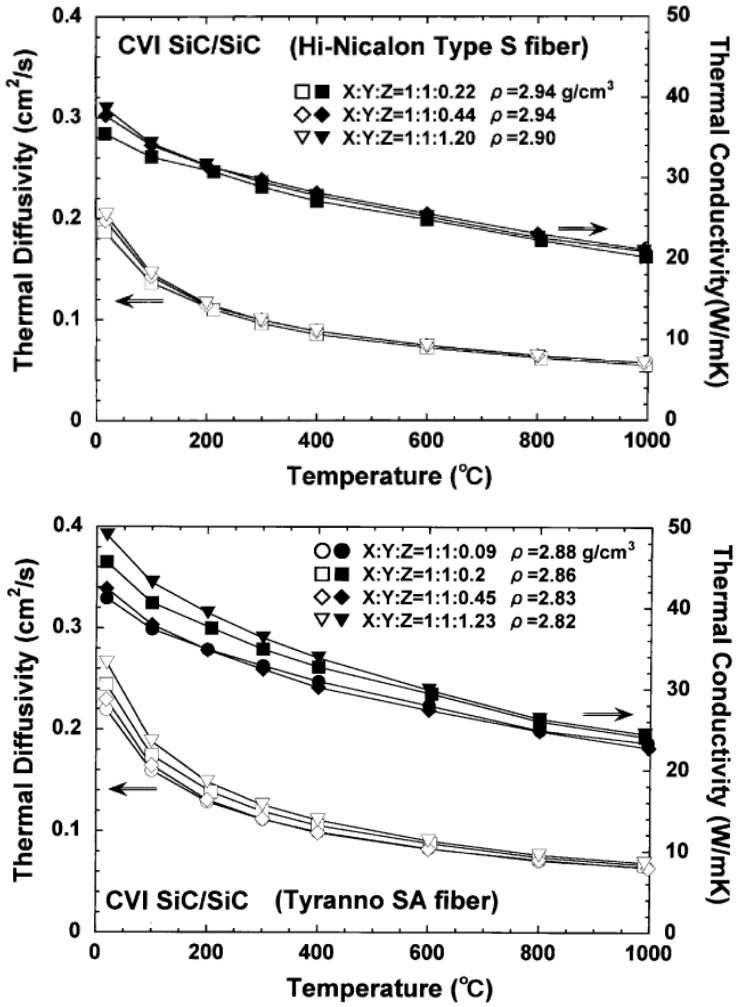
Examples of three-dimensional woven structures



Journal of the European Ceramic Society 44 (2024) 116739

- SiC_f/SiC composites are prized in aerospace for their superior oxidation resistance
- Although **3D weaving** is essential for fabricating **complex structures**, process challenges mean composites are implemented in 2D or 2.5D architectures

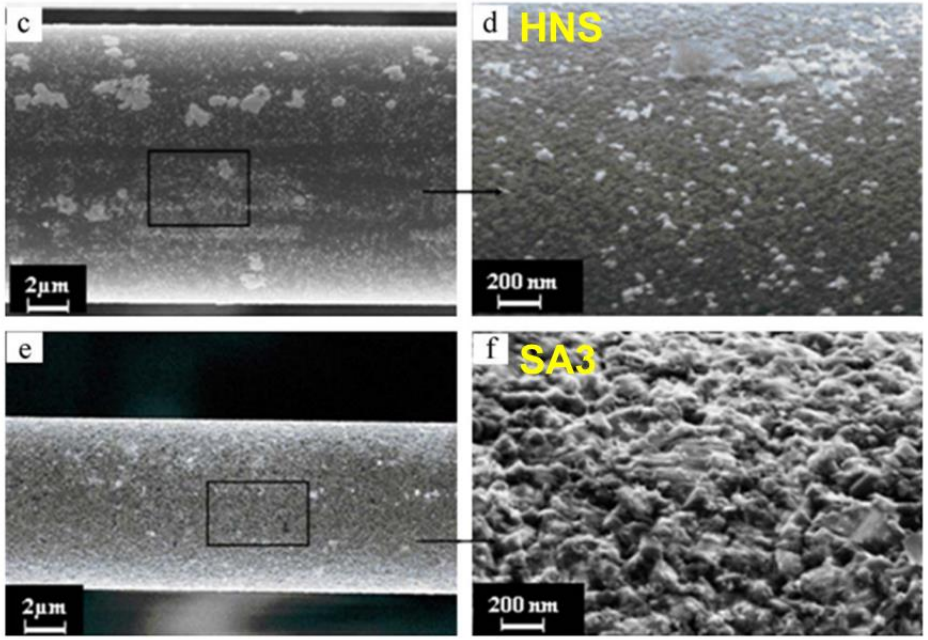
High-Temperature stability of Tyranno SA fiber



Tensile strength and creep resistance at high T

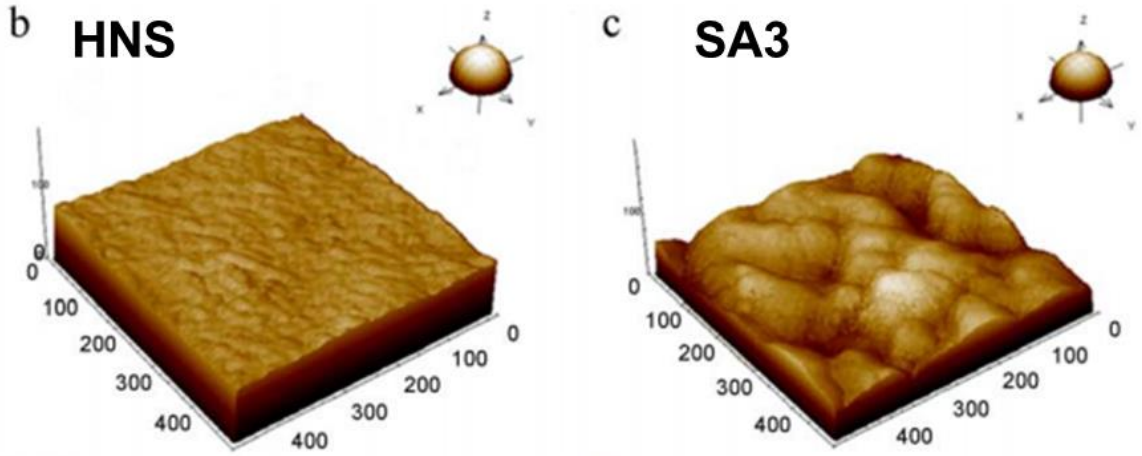
Journal of Materials Science & Technology 35 (2019) 2743–2750

- Tyranno SA fiber maintains higher tensile strength and creep stability at high temperatures compared to other fibers
- Its thermal conductivity is higher than other fibers, making it advantageous in fields like nuclear energy where thermal diffusion is crucial



Change in composite thermal conductivity at high T

Journal of Nuclear Materials 329–333 (2004) 497–501

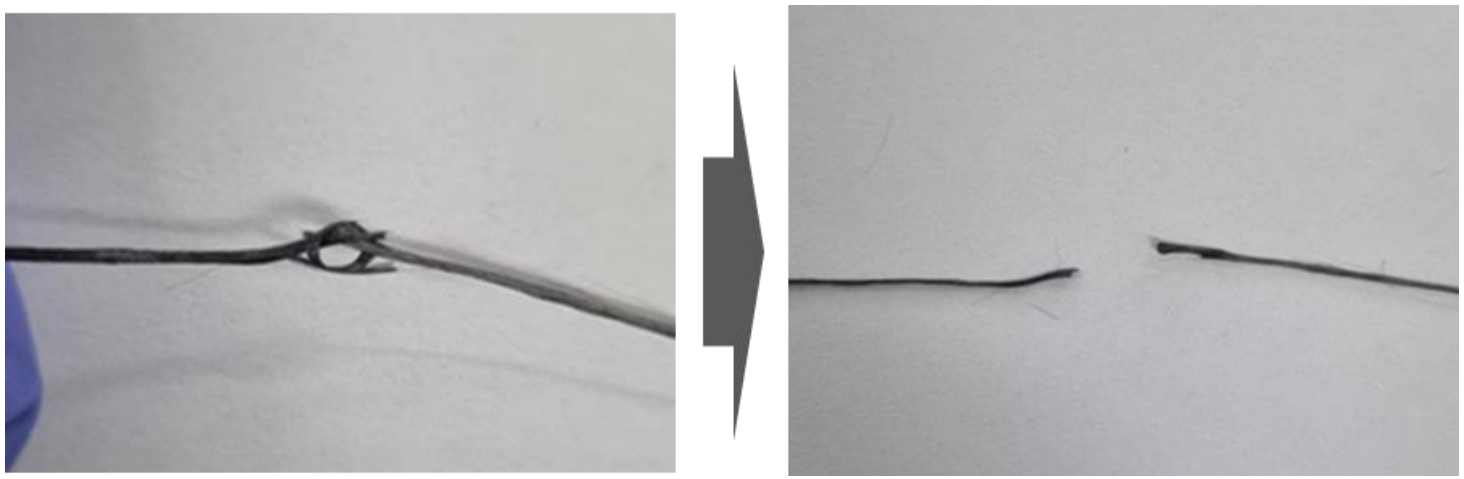


SiC fibers susceptible to friction

Comparison of Scanning Electron Microscopy (SEM) images of SiC fibers

Journal of the European Ceramic Society 32 (2012) 547–557

Comparison of Atomic Force Microscopy (AFM) images of SiC fibers



Journal of the European Ceramic Society 32 (2012) 547–557

- Tyranno fibers are produced at higher temperatures than other fibers, resulting in **greater crystallinity** and thus **superior thermal properties**
- However, this causes the fiber surface to be extremely **rough**, resulting in severe **abrasion damage** and increased fiber brittleness

Low flexibility of SiC fibers

Low flexibility of SiC fibers (UBE-SA3)

- SiC fibers have **high brittleness**, resulting in much **lower fracture strain** compared to carbon fibers, which are commonly used in weaving

T700G Rev. 5: Updated April 13, 2018

Research strategy - Covering

3D depiction of covering tow

Covering process method

Polymers 2024, 16(17), 2476

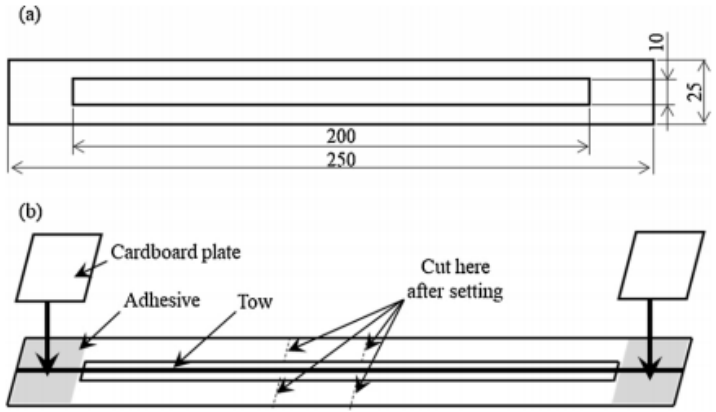
- Goal of the covering process is to enhance the mechanical properties of the tow, including bending strength, and increase friction resistance
- SA3 tow was covered with PET, and SA4 tow was covered with PLA. In the case of SA3, an inner core was added beneath the covering, and both were compared together

Research objective

- To examine the strengthening effect at the tow level when covering is applied
- To assess the effect of covering in the weaving process and understand its impact on the material properties at the composite level

Index

I. Introduction



II. Methodology

III. Results & Discussion

IV. Conclusions

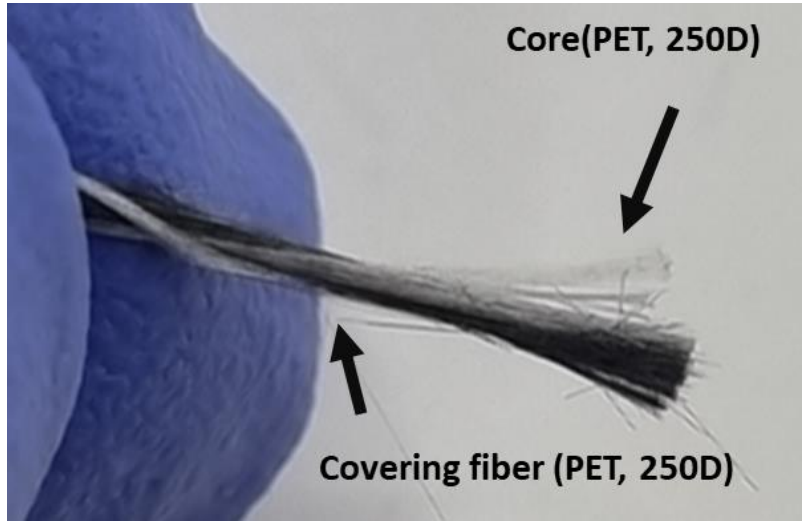
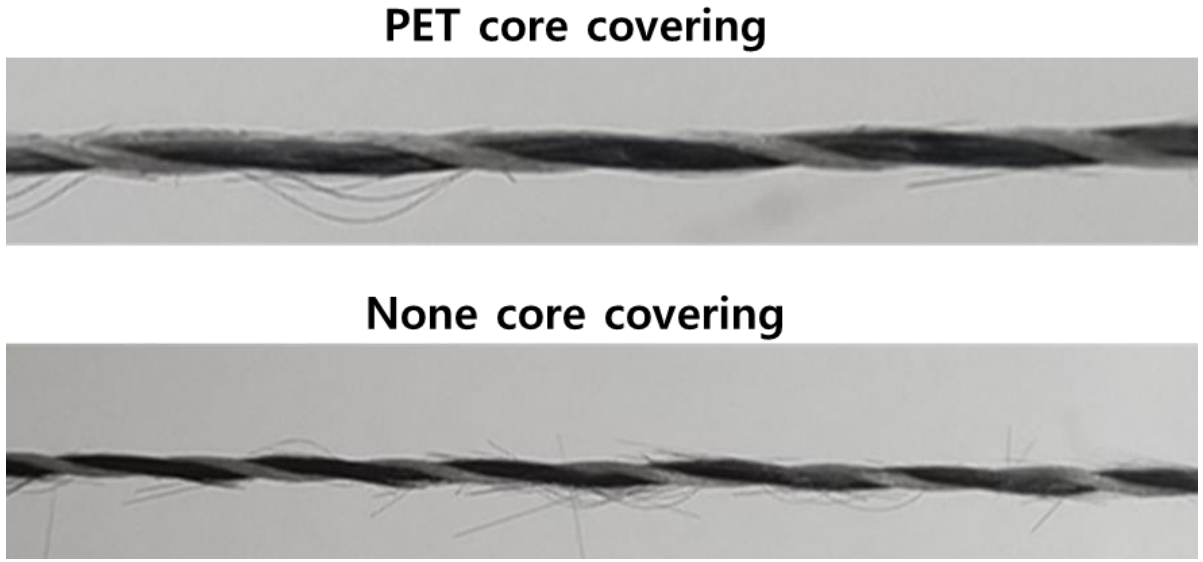
Index



I. Introduction

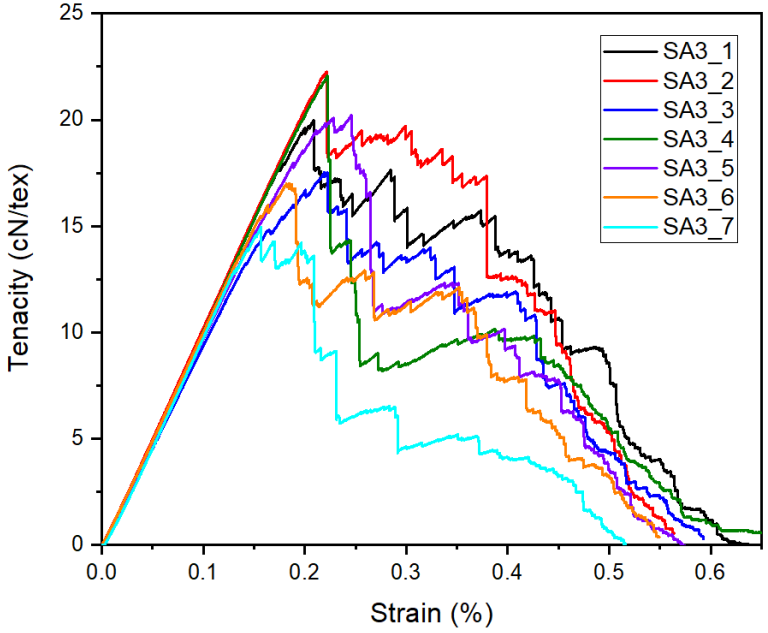


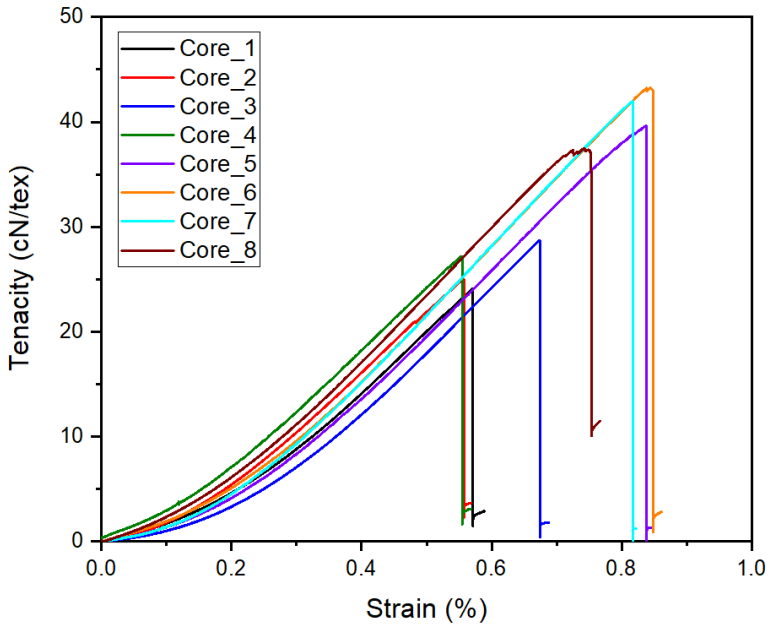
II. Methodology

III. Results & Discussion

IV. Conclusions

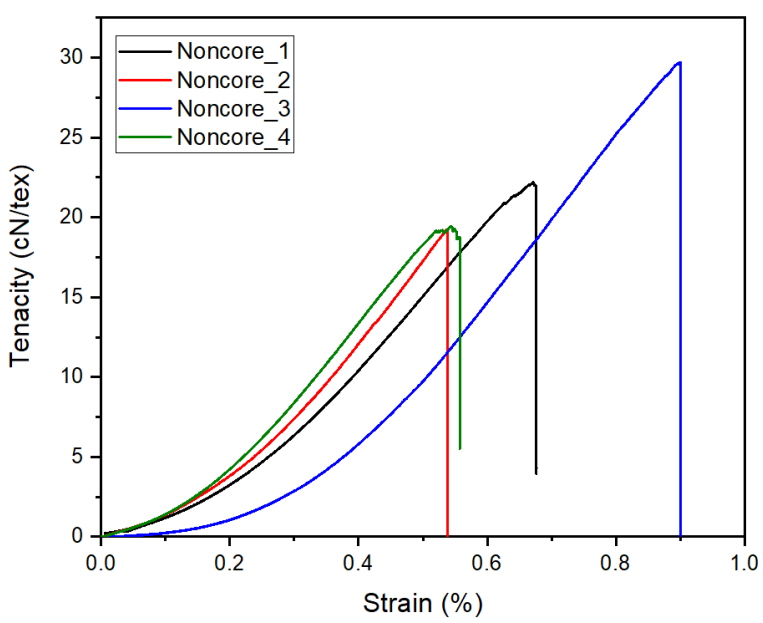
Morphological analysis of covered SiC tow





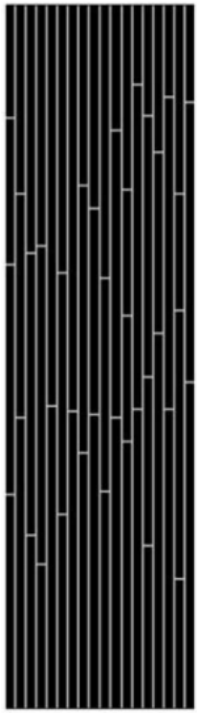
- Both covered samples were processed successfully with minimal damage
- Friction during the process caused slight fly debris
- The sample without a core showed more damage due to increased frictional impact

Tensile test results – SA3

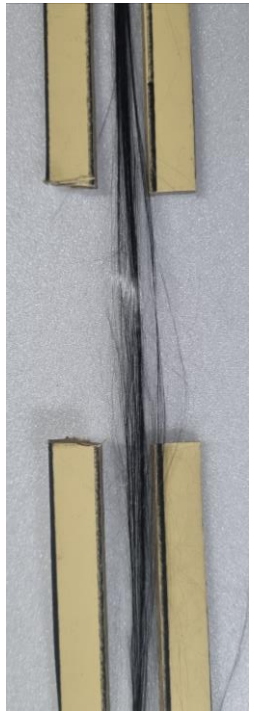


Pure Tyranno SA3

PET core and PET covering

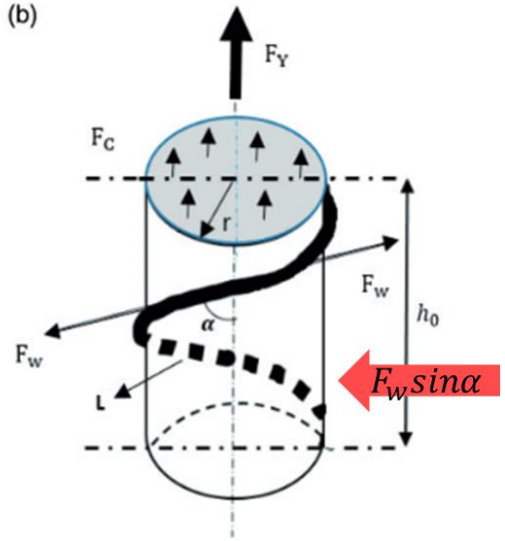


Noncore and PET covering



- After covering, both tensile strength and strain significantly increased
- Failure morphology changed from irregular stress reduction to sudden failure

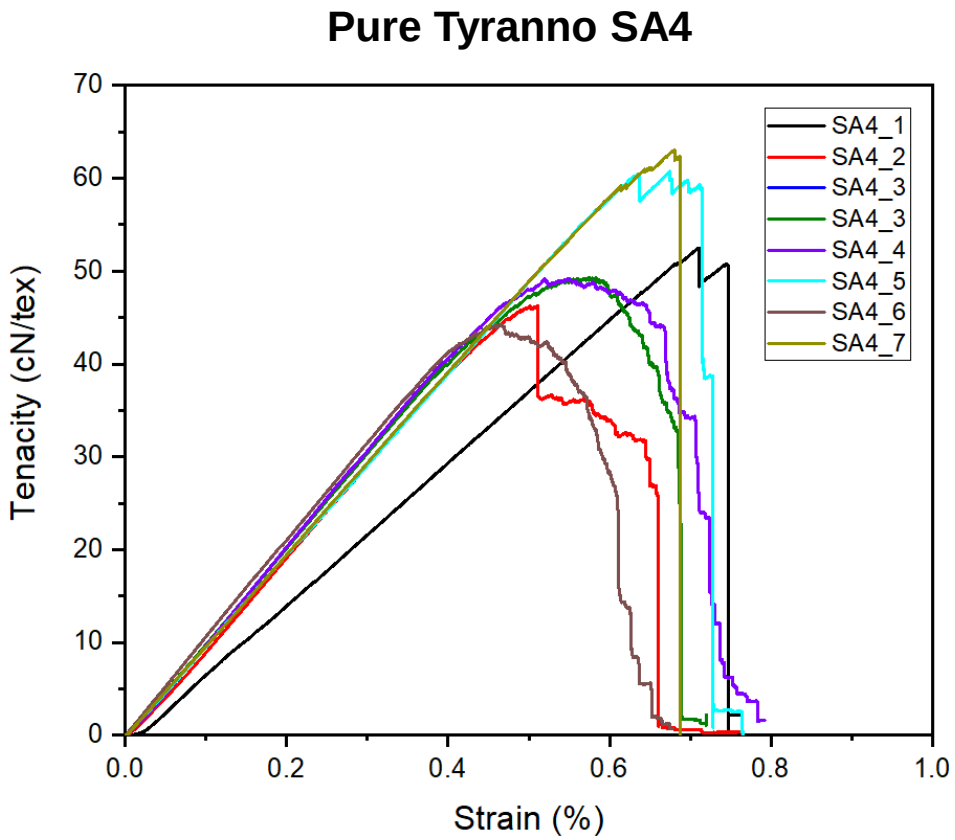
Mechanism of property enhancement through covering

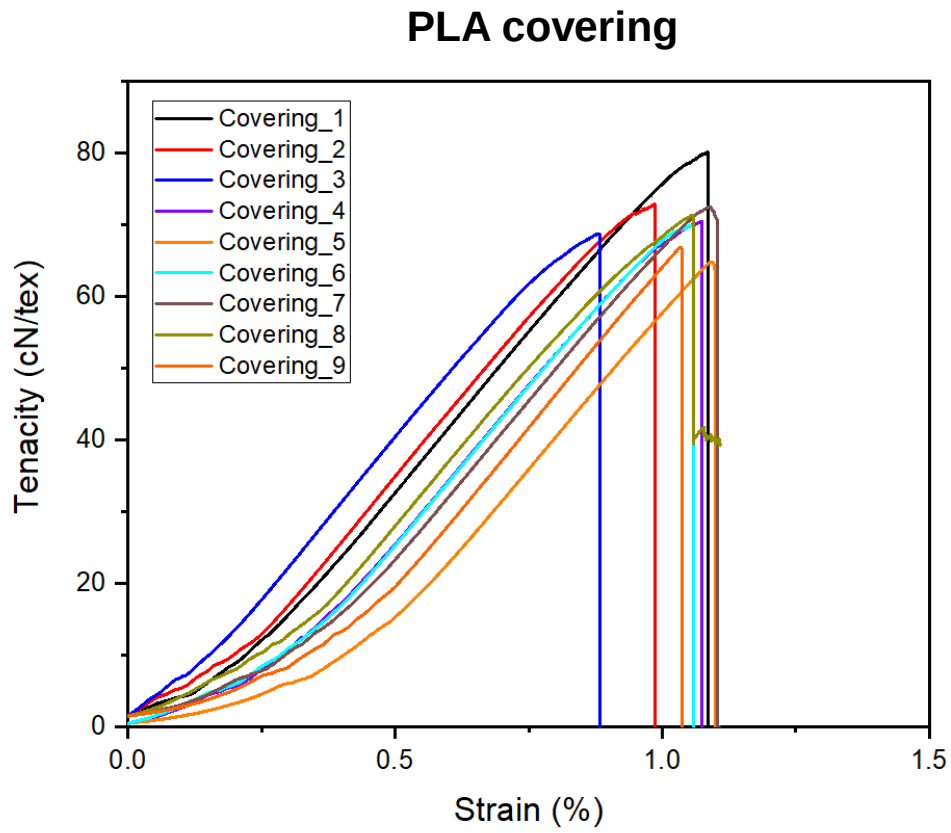


Slip failure of SiC ceramic tow

Composites Part A 146 (2021) 106426)

Transverse compressive stress due to covering and simultaneously failure after covering

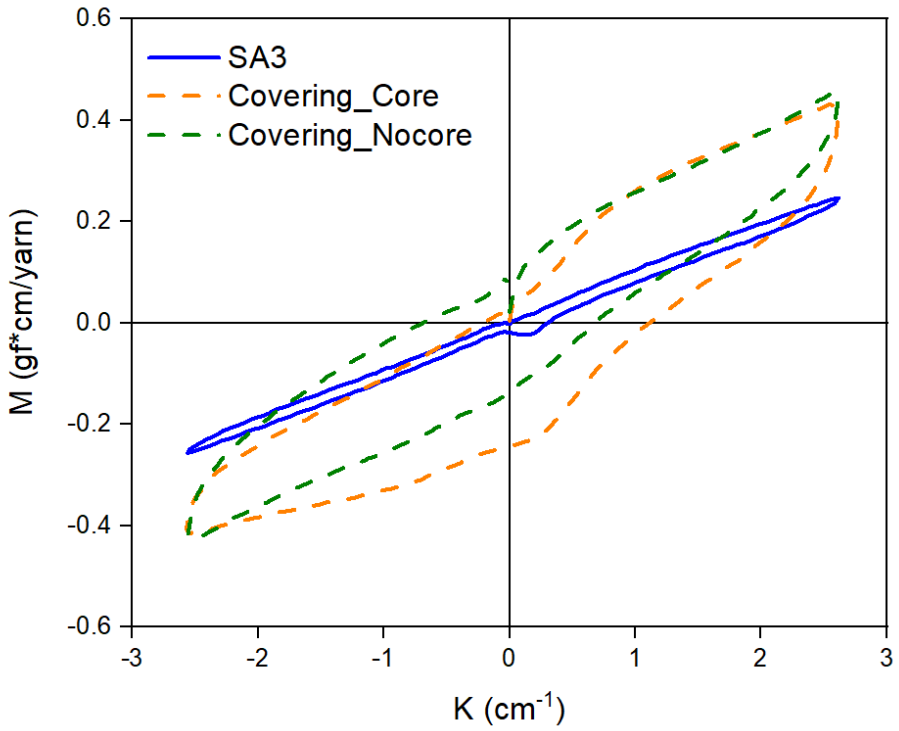


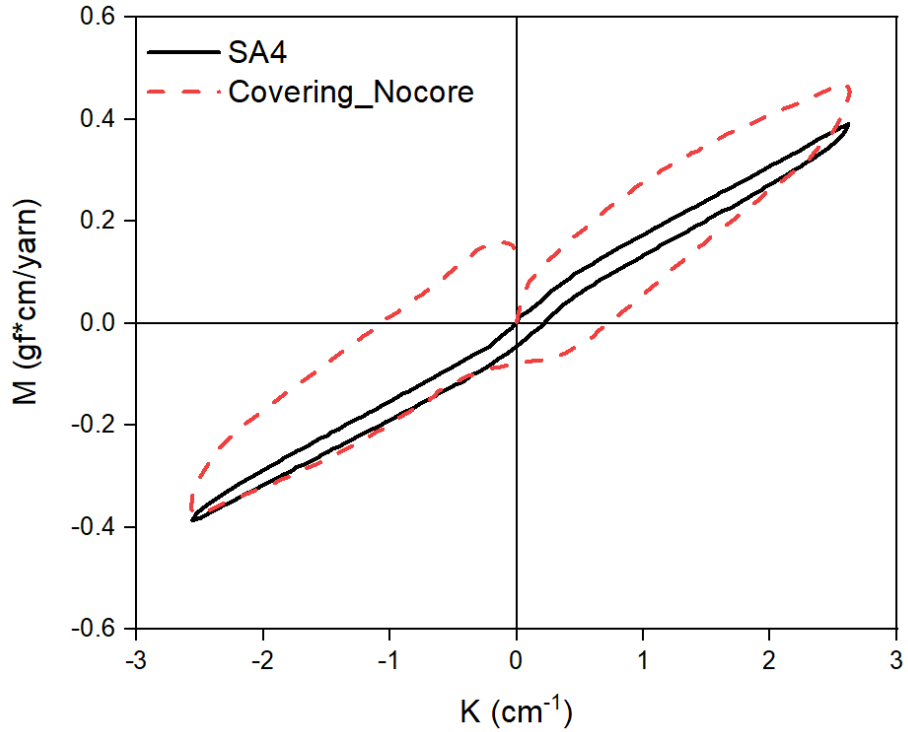


Journal of Industrial Textiles 47(8)

- In the uncovered tow, the fibers are held together only by weak physical bonds, so slip dominates the failure behavior
- Once a covering is applied, however, transverse compressive stresses promote efficient stress transfer between fibers, making fiber fracture the primary failure mode

Tensile test results – SA4

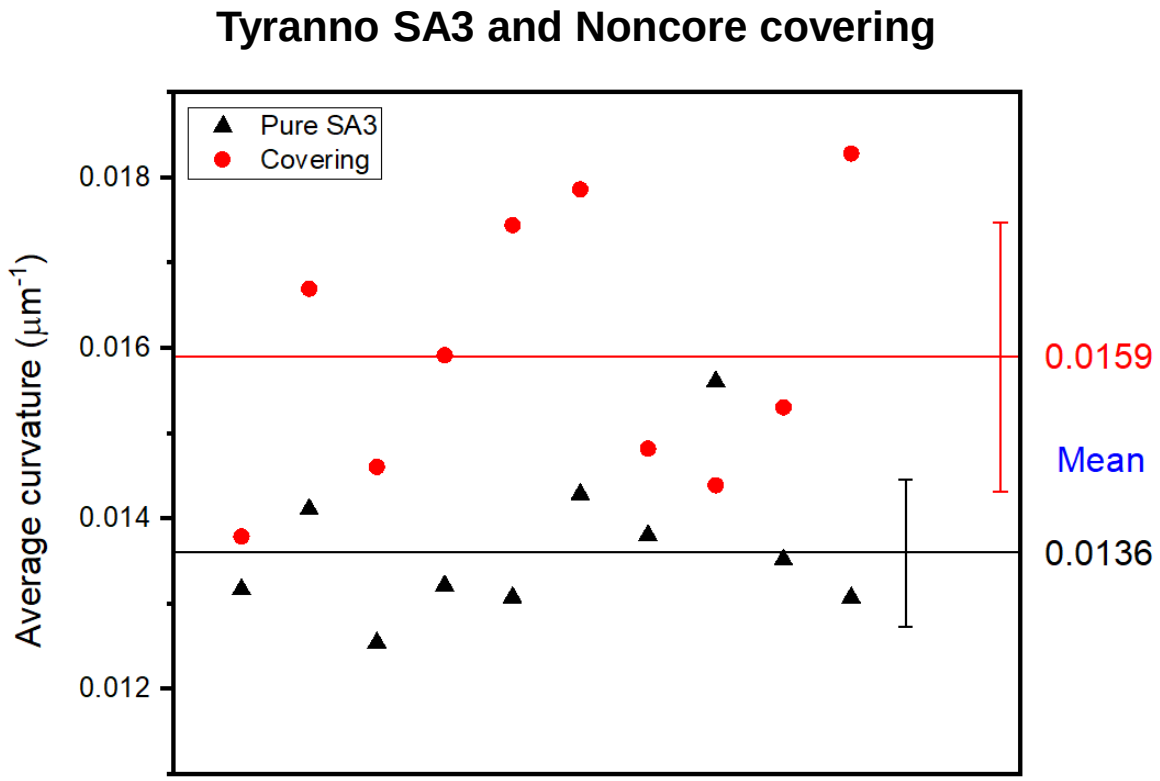




- SA4 exhibits more **uniform fiber properties** and superior sizing compared to SA3, resulting in significantly **less tow slip**
- Nevertheless, when **covered**, it demonstrates a **strengthening effect**, with both stress and strain increasing by approximately 25%

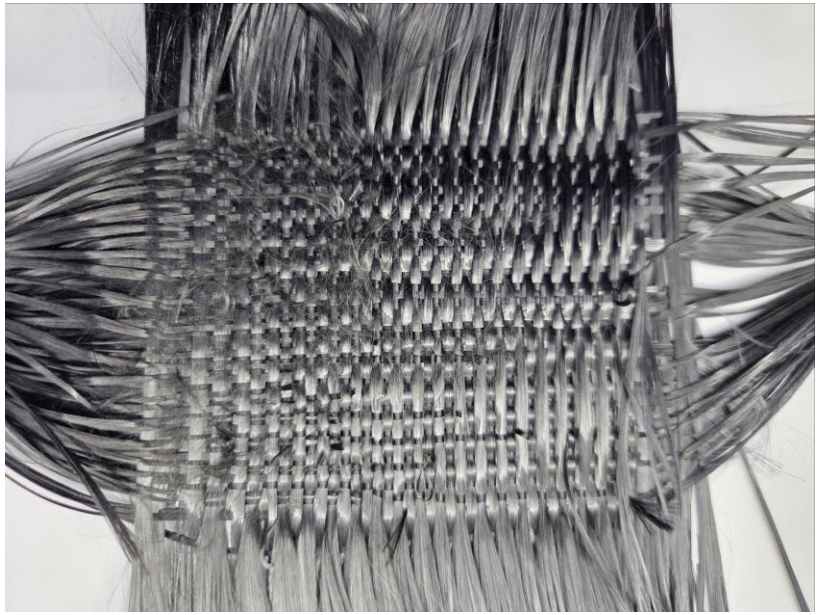
Increase in bending resistance

Tyranno SA3 and PET covering



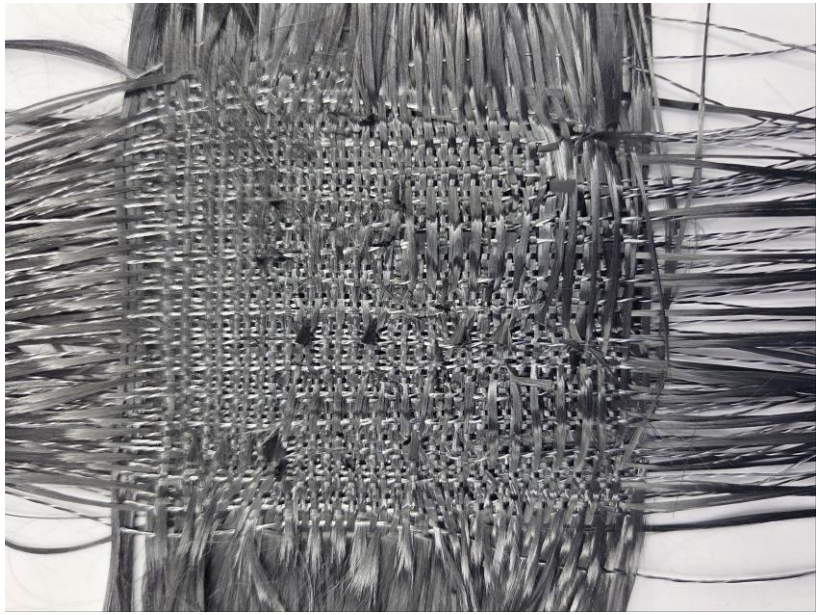
Tyranno SA4 and PLA covering

- Following covering, the added thickness of the covering yarn enhances bending resistance
- And the inclusion of low-elasticity polymer fibers leads to greater energy dissipation, thereby increasing hysteresis



Increase in maximum curvature

- By facilitating the redistribution of stresses that occur during bending and thereby delaying failure, the maximum curvature increases
- A high maximum curvature enables the fabrication of complex structures in 3D weaving



Enhanced weavability resulting from covering

Tyranno SA3 woven

SA3	Held 1 Z-binder	Held 2 Fixed warp	Held 3 Fixed warp	Held 4 Z-binder	Held 5 Fixed warp	Held 6 Fixed warp	Held 7 Fixed warp	Held 8 Z-binder
Remaining tows	5/15	0/15	12/15	0/15	14/15	11/15	13/15	9/15

Tyranno SA3 and covering woven

PET cover	Held 1 Fixed warp	Held 2 Z-binder	Held 3 Fixed warp	Held 4 Z-binder	Held 5 Fixed warp	Held 6 Z-binder	Held 7 Fixed warp	Held 8 Z-binder
Remaining tows	15/15	9/15	15/15	0/15	15/15	9/15	15/15	3/15

- Pure SA3 suffered significant friction-induced damage over roughly 10 cm of weaving, whereas the covering tow used as the fixed warp incurred zero losses

Index

II. Research object and strategy

III. Methodology

IV. Conclusions

Conclusions

I. As aerospace activities intensify, research into SiC 3D-woven ceramic composites capable of fabricating complex structures is essential

II. However, because SiC fibers are inherently brittle and have poor weavability, fiber reinforcement processes are required

III. Applying a polymer-fiber covering to the SiC tow resulted in increases in various tow-scale properties

IV. Friction-induced damage and failure during the weaving process were greatly reduced, and composite-scale property changes will be measured subsequently

Thank you

ABSTRACT

The determination of the percolation threshold (Φ_c) in particulate and short-fiber composites is essential for understanding mechanical behavior, transport properties, and degradation, especially in biocomposites with hydrolysable matrices. In such systems, percolating fiber networks promote water and degradation agent penetration, potentially accelerating biodegradation. Conventional methods to determine Φ_c (e.g. theoretical models or conductivity-based techniques) are unsuitable for biocomposites containing non-conductive, variable natural fibers. Here we summarize the results of two studies in which (i) a simple rheological protocol is proposed to accurately determine Φ_c in poly(lactic acid) biocomposites reinforced with short hemp or kenaf fibers, and (ii) the relevance of Φ_c for biodegradation purposes is thoroughly examined for the hemp-based composites.

Regarding the first point, the proposed method for the assessment of Φ_c relies on the linear viscoelastic "two-phase model" originally developed for nanocomposites but general enough to be extended to microcomposites despite the non-Brownian nature of microfibers. Rheological estimates of Φ_c were compared with values obtained via dielectric spectroscopy, which is a more complex and time-consuming method requiring water equilibration of the samples over several weeks. Regarding the second point, changes in molecular weight under two environmental conditions (water and mature compost) were studied in hemp-based composites below and above Φ_c. The results highlighted non-linear behavior in relation to filler content and showed contrasting degradation patterns between aqueous and soil-like media due to the effect of the crystallinity forming during degradation.

Overall, besides providing valuable guidance for the development of environmentally sustainable PLA-based materials with improved end-of-life performance, this study demonstrates that rheological analysis is a fast, accurate, and effective method to determine Φ_c, even in highly inhomogeneous and anisotropic materials like natural fiber biocomposites. Compared to other experimental techniques (e.g. dielectric spectroscopy), rheology offers shorter testing times and easier sample preparation, making it a promising standard method for characterizing percolation behavior in sustainable, fiber-reinforced biocomposites.

1 INTRODUCTION

Biodegradable polymer composites reinforced with natural fibers have attracted growing interest due to their eco-friendly nature and potential to replace conventional plastics. Among them, polylactic acid (PLA) is a widely used bio-based polyester derived from renewable sources such as corn starch or sugarcane. However, PLA biodegradation in natural environments can be unacceptably slow. This process involves abiotic hydrolysis of ester bonds followed by microbial assimilation of the resulting low-molecular-weight fragments. Since only chains with a molecular weight below 10–20 kDa can be mineralized by microorganisms, the rate-limiting step is the initial hydrolytic cleavage.

One strategy to accelerate PLA degradation is incorporating lignocellulosic fillers, which promote water diffusion through their hygroscopic hemicellulose content. Their swelling in moist environments can also induce matrix-filler debonding, creating capillaries that enhance water ingress. However, the overall impact of natural fibers on PLA degradation is complex and influenced by filler properties such as chemical composition, geometry, and content. In particular, the fiber volume fraction plays a crucial role, especially when it exceeds the percolation threshold (Φ_c). The latter is the critical point at which fibers form a continuous network that facilitates the transport of water and pro-degradative agents into the composite's core.

Beyond biodegradation, the identification of Φ_c is fundamental due to the abrupt changes it causes in key material properties, such as mechanical strength, rheological behavior, and diffusivity. Nevertheless, accurately determining Φ_c in green composites is challenging. Theoretical models often rely on unrealistic assumptions, while many experimental techniques are unsuitable due to the non-conductive and variable nature of natural fibers.

In this context, we present the results of two studies [1, 2] carried out on PLA-based composites filled with short fibers from hemp and kenaf, focusing on how fiber content and morphology affect degradation and percolation behavior. Two complementary experimental techniques—dielectric spectroscopy and rheological analysis—were used to identify Φ_c. While dielectric spectroscopy requires lengthy water equilibration, rheology offers a faster, simpler, and equally accurate alternative. By applying a linear viscoelastic two-phase model originally developed for nanocomposites, we isolated the fiber contribution and precisely determined Φ_c, which was around 10% for hemp and 20% for kenaf. Moreover, degradation kinetics in water and compost environments were monitored for the hemp-based composites to highlight the relevance of Φ_c for biodegradation purposes. Our results indicate that filler content has non-monotonic effects, with significant differences between conditions. These findings underline the importance of understanding the interplay between percolation, crystallinity, and filler structure to design more sustainable PLA-based materials with controlled end-of-life behavior.

2 EXPERIMENTAL

2.1. Materials

PLA pellets (Luminy® LX175, density: 1.24 g cm^{-3}, MFI: 6 g/10 min at 210 °C/2.16 kg) were obtained from Corbion. Hemp shives and kenaf bast fibers were sourced from Equilibrium S.r.l. (Nibionno, Italy) and Kenaf Eco Fibers Italia (Guastalla, Italy), respectively. Prior to compounding, fibers were ground using a Retsch cutting mill with a 0.25 mm sieve. Images of the fibers before and after milling (Fig. 1) show a mix of micrometer-scale fibers and finer debris, likely generated during grinding. The ground fibers used in our composites can be assimilated to short, capped cylinders. The hemp fibers are slightly shorter than the kenaf ones (volume average length: 376±181 μm for hemp, 461±213 μm for kenaf) [1]. The distribution of the aspect ratio (length-to-diameter ratio) of the fibers after milling is also shown in Fig. 1.

2.2. Melt Compounding and Sample Preparation

PLA and fibers were compounded using a Brabender Pantograph EC batch mixer. Samples were prepared at fiber volume fractions (Φ) of 5, 10, 15, 20, 25, 30, and 35%. Prior to mixing, PLA pellets were vacuum-dried at 85 °C overnight, and fibers were conditioned at 25°C and 80% relative humidity. Compounding was carried out at 180 °C and 60 rpm for 6 min. The mixture was then dried again at 85°C under vacuum and compression molded into 100×100×3 mm^3 plates using a Lab Tech Engineering hydraulic press. Molding involved a preheating phase at 180°C without pressure (5 min), compression at ~150 bar (4 min), and cooling under pressure to room temperature. The molded plates were then cut

into 30×30×3 mm^3 specimens for rheological tests. Regarding the samples for the degradation tests in water and soil, the material, sandwiched between two Teflon sheets, was placed in the mold preheated at 180°C and softened for 5 minutes without pressure. Then the pressure was increased to ~15 MPa and kept constant for 4 min. Finally, the mold was cooled to ~40°C under constant pressure. The resulting plates were cut into rectangular specimens (30×10×3 mm^3) using a circular saw.

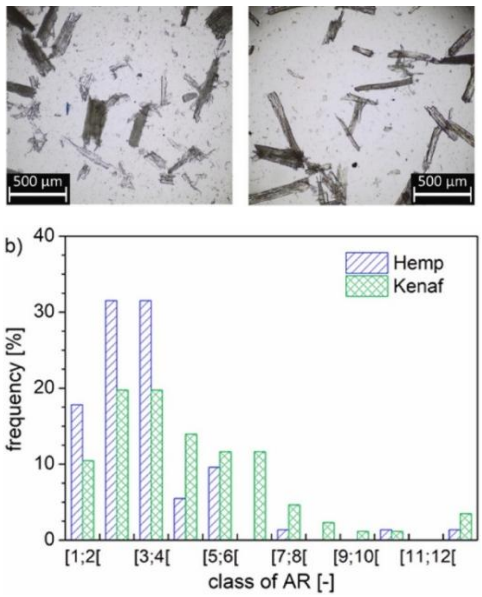

Figure 1: Upper row: hemp (a–c) and kenaf (a′–c′) fibers before (a, a′) and after (b, b′, c, c′) grinding. Lower row: distribution of the aspect ratio (AR; length-to-diameter ratio) of the fibers. Images taken from [1].

2.3. Characterization Techniques

Fiber size and aspect ratio were determined via image analysis from optical micrographs obtained with an Olympus BX53M microscope. Approximately 100 particles were analyzed per fiber type. For improved visualization, fibers were suspended in diluted poly(vinyl alcohol) (PVA) solution before deposition on glass slides.

Sample microstructure was examined using scanning electron microscopy (SEM, Leica 420, Wetzlar, Germany). Samples were cryo-fractured at ca. -80°C and gold-coated before imaging.

Rheological measurements were conducted on a TA Instruments AR-G2 rheometer with parallel plate geometry (25 mm diameter). Specimens were dried at 80 °C under vacuum before testing. All tests were performed using a 2 mm plate gap, with samples taken from consistent positions on the plates to minimize orientation effects from compression molding. Small-amplitude oscillatory shear (SAOS) tests were conducted at 180 °C in nitrogen. The elastic (G′) and viscous (G″) moduli were collected in a frequency range between ω=0.06 and ω=600 rad/s. Strain amplitudes were set between 0.2% and 2%, ensuring linear viscoelastic behavior and reliable stress measurements.

For the degradation tests in water, the specimens were immersed in test tubes containing 50 mL of water (pH≈7.5) and kept at 45°C with gentle stirring in a shaking incubator (Bormarc Shaker SKI 4). Before subsequent characterization, the samples were collected at fixed time intervals and carefully dried until reaching a constant weight. The specimens for the degradation tests in soil were buried in mature green compost (water holding capacity 80%, moisture content 55%, pH=6.6) and kept in an incubator (Bormarc Shaker SKI 4) at 55°C and 20% RH. The samples were collected at fixed times and subjected to the following analyses.

Size exclusion chromatography (SEC) was performed with a Waters 590 chromatographic system equipped with HSPgel HR3 and HR4 columns and a refractive index detector. Tetrahydrofuran (THF) was used as the mobile phase at a flow rate of 0.3 mL/min. The weight-average molecular weight (Mw) and the polydispersity index (M_w/M_n) were determined based on a calibration curve generated with polystyrene standards ranging from 0.370 to 100 kg/mol.

3 RESULTS

3.1. Assessment of the percolation threshold – The two-phase model

Unlike nanoparticles, which undergo Brownian motion even in highly viscous polymer melts and tend to form fractal aggregates that percolate at very low filler loadings (Φ_c~1%), the fibers employed in this study are too big do exhibit Brownian behavior In similar cases, percolation theory can be applied to estimate Φ_c by using the concept of excluded volume, V_{ex}, defined as the region around a filler particle within which the center of another particle cannot enter [3]. However, theoretical calculations suffer from the wideness of the aspect ratio distribution, which reflects in wide ranges of possible Φ_c. Further uncertainty stems from the variability of the orientation of the fibers, which affects V_{ex}. As a result, the Φ_c for the hemp fibers was estimated to range between 5.2 vol.% (perpendicular orientation) and 20.8 vol.% (parallel orientation). The range of Φ_c for the kenaf fibers was 4.3-17.2 vol.% (parallel).

To assess the values of Φ_c with much higher accuracy, experimental methods must be used. Unfortunately, when dealing with very flexible and non-conductive natural fibers dispersed in viscoelastic polymer matrices, the experimental detection of Φ_c is anything but simple. Here we propose to resort to rheology, which is a well-established characterization technique in the field of polymeric materials. In particular, we exploit the prediction ability of a simple two-phase model that we derived to describe the linear viscoelasticity of polymer nanocomposites [4, 5, 6]. Since the two-phase model only works for samples at $\Phi>\Phi_c$, and being the $G'(\omega)$ curves of these samples scalable on a single master curve by means of only two shift factors with a precise physical meaning, the Φ_c can be easily computed. In brief, the vertical shift factors for the building of the master curve represent the precise values of the elasticity of the networks of nanoparticles, G'_0. The percolation theory predicts that the latter scale with the volume fraction as $G'_0 \sim (\Phi-\Phi_c)^\nu$, where ν is a critical exponent that depends on the stress bearing mechanism. Fitting this law to the experimental values of the vertical shift factors for the building of the master curve eventually returns the Φ_c of the system. This simple procedure is made robust because of the deterministic feature of the shift factors, which makes the scaling of a G' curve of a sample at $\Phi<\Phi_c$ not possible.

When trying to extend such an approach to natural fibers, many differences emerge (see Figure 2).

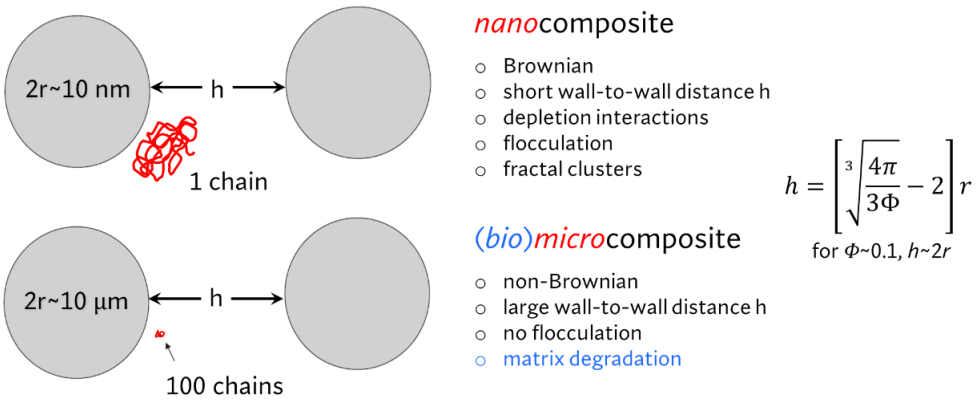

Figure 2: differences between nano- and microcomposites. The relationship between wall-to-wall interparticle distance h and particle volume fraction Φ is shown on the left-hand side.

The non-Brownian feature of micron-sized particles prevents them from moving and rearranging in the host medium due to thermal energy, eventually flocculating in the host matrix at very low particle volume fractions. Percolation at low Φ is also disfavored by the relatively long wall-to-wall distance (h) between contiguous particles. Nonetheless, the basic principle underlying the two-phase model, i.e. the coexistence of two well-distinct populations of dynamical species (the particle network and the host polymer matrix) remain valid. As a result, we expect that the previous procedure to compute Φ_c can be used also for the biocomposites under investigation.

The master curves built for the hemp- and kenaf-based composites are shown in Figure 3.a and b. The critical scaling of the network elasticity with $\Phi-\Phi_c$ is reported in Figure 3.c.

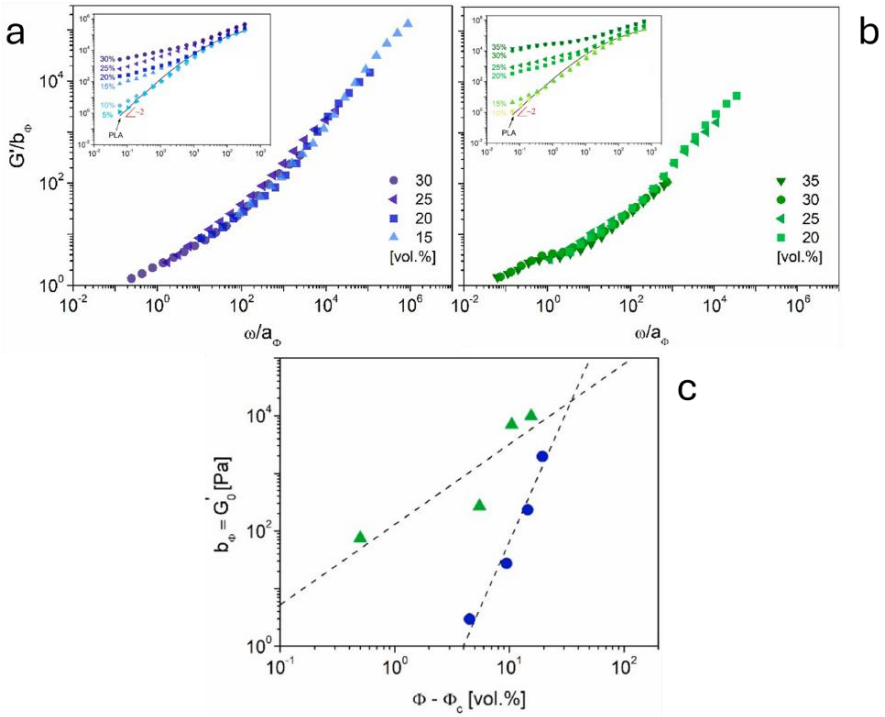

Figure 3: a and b) Master curves of G′ for hemp- (a) and kenaf-based composites (b) at Φ≥15 vol% and Φ≥20 vol%, respectively. The inserts show the G′ curves of samples at different Φ before the scaling. c) Critical scaling of the network elasticity for hemp- (circles) and kenaf-based (triangles) composites. The dashed lines are the best fitting curves. R^2=0.9780 (hemp) and 0.9311 (kenaf). Images readapted from [1].

The above procedure led to Φ_c=10.1 and 19.5 vol% for the hemp- and kenaf-based composite, respectively. These values were confirmed by means of broadband dielectric spectroscopy, which was carried out by using an ARES rheometer equipped with a dielectric analysis tool connected to an Agilent E4980A LCR meter. This method exploits the high sensitivity of the complex permittivity (ε*) to the water contained in the fibers, which makes it possible to correlate Φ_c to a discontinuity in the (di)electric response [7, 8, 9]. In this way we obtained Φ_c=10.1 and 18.5 vol% for the hemp- and kenaf-based composite, in excellent agreement with the linear viscoelasticity results. It is worth mentioning that a much more laborious and time-consuming procedure was needed in the case of dielectric tests because of the need of a very long (ca. 1 month) conditioning step before the measurements [1].

3.2. Effect of the percolation threshold of the degradation kinetics of PLA-hemp biocomposites

Once the percolation threshold has been estimated with accuracy, its role in dictating the degradation kinetics of hydrolysable matrices was investigated. The results of degradation tests in freshwater and mature compost are summarized in Table 1, where the evolution of M_w and M_n assessed by SEC is reported as a function of time for samples at different Φ.

After 50 days of immersion in freshwater, a clear inverse relationship emerges between fiber content and molecular weight: as the fiber loading increases, M_w decreases. This means that the formulation with the highest fiber fraction shows the most pronounced reduction in molecular weight (over 40%). Interestingly, even though the fiber network becomes more interconnected beyond the percolation threshold (Φ_c=10.1%), no abrupt changes in the degradation trend are observed.

The PLA exhibits a significantly faster degradation rate in soil, which is expected due to the elevated temperature and microbial activity typical of composting conditions. Regarding the influence of fibers, an acceleration in the degradation kinetics is observed after 10 days. An effect of the percolation threshold is noticed, even if a substantial acceleration is only observed from Φ=15vol%, that is well above Φ_c. What is more interesting is that the trend reverses at longer burial times, when the fibers surprisingly appear to inhibit degradation.

	Φ [vol.%]	0	5	10	15	20	25	30
as prepared samples (reference)	M_w [kDa]	113.9		110.3		100.8		113.6

	M_w/M_n	1.7	1.7	1.7	1.7	1.7	1.8	1.8
after 20 days in soil	M_w [kDa]	24.8	41	53.6	56.3	71.8	63.4	70.3
	M_w/M_n	1.8	1.8	1.7	1.7	1.5	1.7	1.6

Table 1: Average molecular weight and polydispersity indices of PLA composites in different environments.

The reduction in molecular weight is known to be autocatalytic, with the degradation process accelerating once the molecular weight drops below a critical threshold (M_c), beyond which oligomeric chains begin to solubilize into the surrounding medium [10]. According to Stloukal *et al.*, this threshold is approximately 20 kDa for PLA in soil [11]. As shown in Table 1, pure PLA reaches this value within around 20 days, whereas composites with increasing fiber content require more time. Nonetheless, degradation remains relatively fast, with composites approaching M_c between 20 and 40 days. After 40 days, size exclusion chromatography (SEC) reveals the presence of three distinct chain populations: low (~2 kDa), intermediate (~5 kDa), and high (>10 kDa) molecular weights. It is important to note that SEC measurements at extended burial times may underestimate degradation due to the loss of water-soluble oligomers, which are no longer present in the solid phase. Despite this limitation, the data indicate that fiber incorporation slows degradation, particularly at higher loadings. To understand this behavior, which contrasts with observations in freshwater, one must consider the relationship between molecular weight evolution and the crystallinity of the samples during composting. A thorough DSC characterization (DSC Q2000, TA Instruments) demonstrated that the reduced degradation rate observed in composites with high Φ can be attributed to the protective influence of fiber-induced crystallinity, which hinders water penetration and shields the amorphous regions from hydrolytic attack [2]. In essence, within mature compost, the fibers initially facilitate water uptake during the early stages of burial. This effect, which seems to be favored at fiber contents well above Φ_c, vanishes over time. As burial progresses, the crystallinity promoted by the fibers becomes dominant, ultimately slowing down the overall degradation process.

4 CONCLUSIONS

The percolation threshold of PLA-based composites reinforced with short hemp shives or kenaf bast fibers (average length <500 μm) was evaluated by applying and validating a model originally conceived to depict the linear viscoelasticity of polymer nanocomposites. Despite the substantial differences with biocomposites, the physics underlying the two-phase model keeps working, the only difference being the higher filler contents needed for percolation in this class of composites based on micron-sized reinforcing fibers. The two-phase model led to Φ_c values of ~10.1 vol% for hemp and 19.5 vol% for kenaf composites. Dielectric spectroscopy supported these findings, though it required more complex sample preparation. Regarding the relevance of the percolation threshold on the degradation kinetics, the impact of short hemp fibers on PLA degradation in freshwater and mature compost was evaluated using SEC analyses, with fiber content ranging from 5 to 30 vol%, surpassing the percolation threshold. A contrasting behavior was observed: in freshwater, fibers accelerated degradation by promoting hydrolysis and enabling water infiltration, even affecting crystalline regions. In compost, degradation

was generally faster due to the biotic environment and higher temperature (~55 °C). While fibers initially enhanced hydrolysis and surface erosion, over time, the fiber-induced crystallinity slowed PLA degradation compared to the neat polymer. Additionally, the fibers slightly improved the flexural modulus of the composites, potentially enabling material savings and enhancing sustainability throughout their life cycle.

Keywords: Agricultural wastes, Biodegradable polymers, Green Composites, Mechanical Properties, Thermal Properties

ABSTRACT

The increasing accumulation of post-consumer plastic waste, particularly from single-use packaging, has intensified global concerns regarding environmental sustainability. Currently, plastic packaging constitutes nearly half of all plastic waste generated worldwide, highlighting the urgent need for sustainable alternatives. In response, the plastics industry is undergoing a transition from petroleum-based polymers to biodegradable, compostable, and biobased materials. However, the adoption of biodegradable polymers remains limited by their lower mechanical strength, durability, and processing performance compared to conventional plastics. To address these limitations, the use of green composites represents a promising solution, offering not only materials with enhanced performance but also cost-effective. This study explores the use of natural fillers to improve the properties of biodegradable polymers such as polybutylene succinate (PBS) and polybutylene adipate terephthalate (PBAT). Agricultural by-products such as rice straw and wheat straw were used as reinforcement at loadings up to 30 wt.%. Mechanical (tensile, flexural) tests and thermal (TGA, DSC) analyses were conducted on both neat polymers and composite formulations to evaluate performance improvements. Results show that incorporating 30 wt.% wheat straw significantly promoted the mechanical properties of both polymers. For PBS-based composites, tensile strength increased by approximately 16.5%, with >400% rise in tensile modulus. PBAT-based composites demonstrated even greater enhancements, including a 42.9% increase in tensile strength and a significant improvement in Young's modulus compared to pure PBAT.

1 INTRODUCTION

The extensive use of petroleum-based polymers, such as polyethylene (PE), polypropylene (PP), and polyvinyl chloride (PVC), has resulted in their accumulation in the environment. These materials are adopted in different sectors from packaging and automotive components to medical devices and construction. However, their environmental persistence has emerged as one of the most pressing challenges of our century [1]. Due to their chemical inertness, high hydrophobicity, and mechanical durability, these polymers resist degradation in natural environments, leading to their long-term accumulation in terrestrial and marine ecosystems. This buildup, often termed "white pollution," results not only in visual alteration but also in profound ecological consequences, including harm to wildlife, soil fertility degradation, and microplastic contamination of food chains [2].

To address this environmental issue, researchers and industries have turned to biodegradable polymers as more sustainable alternatives. Biodegradable plastics such as poly(lactic acid) (PLA), polyhydroxyalkanoates (PHAs) like polyhydroxybutyrate-co-valerate (PHBV), poly(butylene adipate-co-terephthalate) (PBAT), and poly(butylene succinate) (PBS) offer the potential to reduce long-term environmental impact by breaking down into non-toxic by-products (CO_2 and H_2O) under biodegradation or composting conditions. These materials, derived from renewable or partially renewable sources, have gained attention not only for their ecological compatibility but also for their potential to support circular economy models and reduce dependence on fossil resources [3].

PBS and PBAT are examples of biodegradable aliphatic polyesters: PBS is synthesized through the polycondensation of succinic acid and 1,4-butanediol and is known for its high thermal resistance, good ductility and compatibility with conventional polymer processing techniques, including injection molding and extrusion [4]. These properties make PBS a suitable candidate for various applications, especially in food packaging, mulching films, and disposable items. PBAT, an aliphatic-aromatic copolyester composed of 1,4-butanediol, adipic acid, and terephthalic acid, possesses high ductility and impact resistance. It is often used in films, bags, and packaging applications that require high elongation at break. However, PBAT is derived from fossil-fuel sources and suffers from relatively low mechanical strength, which can limit its adoption [5].

Despite the intrinsic ecological benefits of PBS and PBAT, their widespread commercial adoption faces several obstacles. These include the relatively high production costs and low durability [6].

To address these shortcomings, in particular performance and cost, one promising strategy is the incorporation of fillers into biodegradable polymer matrices to enhance tensile strength, thermal stability, stiffness, and impact resistance. Natural fillers derived from renewable agricultural by-products represent an interesting solution due to their low cost, availability, renewability, and intrinsic biodegradability. Among these there are lignocellulosic residues, such as straw, husks and plant fibers. These materials are rich in cellulose and lignin, making them suitable for reinforcement purposes when properly processed and introduced into polymer matrices [7]. These wastes are often discarded, underutilized, or burned contributing to environmental degradation and greenhouse gas emissions. Their addition into biodegradable polymers not only provides an effective waste management strategy but also adds value to agricultural by-products by transforming them into functional eco-friendly materials. This dual benefit aligns with global sustainability goals and supports rural economies [8]. In this context, wheat and rice straws represent examples of lignocellulosic agricultural residues that can serve as reinforcing materials: their potential has been mainly explored in polylactic acid (PLA)-based composites, especially when used as fibers. Results in literature have demonstrated that the addition of these fibers can significantly enhance the tensile and flexural properties of PLA matrix when fibers are adequately processed. Common strategies to improve fiber-matrix adhesion include chemical modifications such as alkaline treatment, silane modification, and grafting with compatibilizers. These treatments alter the fiber surface by removing impurities, increasing surface roughness, and introducing reactive functional groups that promote interfacial bonding with the polymer matrix.

Feng et al. [9] demonstrated that the addition of 30 wt.% of NaOH and silane-treated rice straw fibers into a PLA/PBAT blend enhanced its mechanical properties, resulting in a tensile strength of 12 MPa and a flexural strength of 18 MPa. Similarly, Beniwal et al. [10] used PLA-grafted rice straw fibers to improve dispersion and adhesion within PLA matrix, leading to enhanced mechanical performance and biodegradability. In the case of wheat straw, Liao et al. [2] introduced the 30 wt.% of fibers treated with alkaline and hydrogen peroxide into PLA and observed improved tensile strength and modulus. They also explored the effects of adding PBS to the formulation. Berthet et al. [11] investigated the role of fiber size and surface characteristics by adding wheat straw fibers into PHBV matrix, observing changes in thermal stability and mechanical behavior depending on fiber content and processing conditions.

The biodegradability attitude of the polymer is maintained in the presence of such natural fillers. Pradhan et al. [12] observed that PLA filled with 30 wt.% of wheat straw maintains its compostable nature. Furthermore, these bio-based fillers can impart tunable properties to composites, such as improved water vapor permeability due to their inherent hydrophilicity [11] and contribute to economic sustainability with potential cost reductions of up to 30%.

While most of the works previously summarized focused on PLA-based systems and waste fibers, this study examines the effect of as-received wheat and rice straw incorporated into PBS and PBAT

matrices, without specific particle size selection or chemical modification, to assess their intrinsic reinforcement capabilities, aiming for more environmentally and economically sustainable manufacturing operations. The mechanical properties of the materials were evaluated under quasi-static conditions through tensile and flexural tests. In addition, the thermal characteristics of the composites were analyzed by thermogravimetric analysis (TGA) and differential scanning calorimetry (DSC), while morphological analysis by scanning electron microscopy (SEM) was useful to point out the interfacial features that influence composite performance.

2 MATERIALS AND METHODS

Rice straw (RS) was provided by Azienda Riso Milano (Italy) and wheat straw (WS) by Agriturismo Cascina Scanna (Italy). Both straws were washed with tap water and oven-dried at 80 °C for 24 hours. As a final step, the materials were ground using a knife mill and sieved through a 1 mm mesh sieve.

PBS and PBAT maleic anhydride (MA) grafted granules were purchased from Auser Polimeri (Italy). The polymers have a density equal to 1.26 g/cm³ (ISO 1183) and melt mass flow rate of 8 g/10 min and 4 g/10 min, respectively (measured at 190 °C and 2.16 kg, ISO 1133). The MA content is ≤0.1%.

The composite materials were prepared using a two-stage process involving extrusion (co-rotating twin-screw extruder, Thermo Scientific Process 11, Thermo Fisher Scientific) and injection molding (Haake MiniJet IIPro, Thermo Fisher Scientific). During melt compounding, the following temperature profile from feeder to die was adopted: 145 °C—155 °C—155 °C—160 °C—170 °C—170 °C—165 °C—165 °C. The screw speed was set at 150 rpm. During the injection, a pressure of 450 bar was maintained for 10 s and a post-injection was operated at 150 bar for 10 s. The mold was maintained at 50 °C while the loading cylinder was kept at 165 °C. Prior to extrusion, the pellets and fillers were dried at 80 °C overnight.

The particle size distribution (PSD) of WS and RS was analyzed using a Microtrac Sync laser diffraction particle size analyzer (Verder Scientific S.r.l., Bergamo, Italy). Measurements were conducted in dry mode, applying a dispersion pressure of 100 kPa and a suction pressure of 70 kPa. The PSD of the fillers is reported as percentile values: D10, D50, and D90. D10 represents the particle diameter below which 10% of the sample (by mass or volume) is finer; D50 corresponds to the median particle size, where 50% of the sample is finer; and D90 denotes the diameter below which 90% of the particles are finer.

Tensile and flexural properties of both neat polymers and composite samples were evaluated using a Zwick/Roell Z010 universal testing machine. Tensile tests were performed under displacement control at a crosshead speed of 10 mm/min and ambient temperature, following the ISO 527-2 standard (specimen type 1BA, gauge length $l_0 = 30$ mm). Three-point bending tests were conducted in accordance with ISO 178, using specimens with dimensions of 80 × 10 × 4 mm, a crosshead speed of 5 mm/min, and a span-to-thickness ratio of 16:1. Each test was carried out with a minimum of five replications.

Thermogravimetric (TGA) analysis was carried out according to ISO 11358 by heating the samples (around 20 mg) from room temperature to 800 °C under nitrogen atmosphere (50 mL/min) and with a heating rate of 10 °C/min (TG209 F1 Libra instrument by Netzsch). Differential scanning calorimetry (DSC) analysis was performed according to ISO 11357 with a nitrogen flow of 60 mL/min (DSC 214 Polyma by Netzsch). Specimens (around 10 mg) were analyzed with a temperature program from −100 °C to 200 °C with a heating/cooling/heating rate of 10 °C/min. Results for melting and crystallization temperatures, as well as the degree of crystallinity (X_c, Equation 1), are reported as the mean values of three repetitions:

$$X_c\ (\%) = \Delta H_m / [\Delta H_m^{\,0} \cdot w_c] \cdot 100 \quad (1)$$

where the subscript "c" specifies the polymer (PBS or PBAT), ΔH_m is its measured enthalpy of melting in J/g, $\Delta H_m^{\,0}$ the enthalpy of melting of fully crystalline polymer equal to 110.3 J/g for PBS [13] and 114.0 J/g for PBAT [14]. w is the polymer mass fraction in the composite.

3 RESULTS

From a thermal perspective, the addition of both fillers into the polymer matrices, in agreement with

findings reported in the literature [15,16], affects the thermal stability of the final composites. This is primarily attributed to the degradation of the hemicellulose components present in the straw-based fillers, which typically decompose at lower temperatures compared to the degradation temperatures of the neat polymer matrices. TGA data supports this observation: the onset of thermal degradation, defined as the temperature at which 5% weight loss occurs ($T_{5\%}$), decreased by 17.0% and 20.0% for PBS matrix composites reinforced with WS and RS, respectively. While for PBAT matrix composites, both fillers induced a comparable reduction of approximately 27.0%. Such values are calculated with respect to the $T_{5\%}$ of the neat polymers, observed at 341.1 °C for PBS and 362.2 °C for PBAT.

From DSC analyses no significant variations in the characteristic thermal transition temperatures such as glass transition, melting and crystallization were observed with the addition of both fillers. However, differences were in the degree of crystallinity of the polymer matrices (calculated according to Equation 1). Neat PBS exhibited a superior degree of crystallinity (61.5%) compared to PBAT (10.0%) while, in presence of WS and RS, the crystallinity of PBS decreased by 14.7% and 2.0% with WS and RS, respectively. For PBAT, the reduction was 5.4% and 4.4% for WS and RS, respectively. These findings indicate that no nucleating effect occurs for either type of filler [17].

Formulations	Tensile strength [MPa]	Flexural strength [MPa]	Young's Modulus [GPa]	Flexural Modulus [GPa]
PBS	33.8 (±1.0)	44.1 (±1.4)	0.7 (±0.1)	0.9 (±0.1)
PBS_30WS	40.5 (±1.5)	64.3 (±1.2)	3.7 (±0.6)	2.9 (±0.2)
PBS_30RS	38.1 (±1.3)	60.3 (±2.3)	2.7 (±0.4)	1.9 (±0.3)
PBAT	11.0 (±3.6)	5.8 (±0.2)	0.1 (±0.1)	0.1 (±0.1)
PBAT_30WS	15.7 (±0.3)	27.2 (±1.0)	1.0 (±0.1)	1.0 (±0.2)
PBAT_30RS	14.5 (±0.4)	24.1 (±0.6)	0.9 (±0.2)	0.7 (±0.1)

Table 1: Quasi-static mechanical properties of polymers and composites.

Table 1 summarizes the results of mechanical characterization, including strength and modulus values under both tensile and flexural loading conditions. Although the materials investigated are grafted polymer formulations, the overall mechanical performances of the neat polymers are consistent with values reported in the literature for both PBS [18] and PBAT [19], also in agreement with their degrees of crystallinity [20], as previously discussed in the DSC results.

The introduction of rigid lignocellulosic fillers led to a significant increase in stiffness, both in tension and in bending. This behavior is typical of composites reinforced with natural fillers [21,22] and, as comparison, the enhancement observed with the addition of 30 wt.% of WS was greater than that recorded for composites with 30 wt.% of RS, in both polymer matrices.

Percentile values	WS Size [µm]	RS Size [µm]
D10	29.4	69.6
D50	181.5	286.8
D90	256.4	464.7

Table 2: Particle size distribution of WS and RS.

This difference can reasonably be attributed to heterogeneities in particle morphology (shape and size) between the two fillers. This is demonstrated by SEM micrographs (Figure 1a–b), where it is possible to notice in both fillers a high morphological heterogeneity, and from results in Table 2 where are summarized the particle size distributions by their cumulative percentiles. WS exhibits a finer

dimension compared to RS, which likely facilitates better distribution of the filler into the matrix and promotes a better load transmission at the interface due to a larger surface area. This interpretation is supported by findings from Berthet et al. [12], who reported that stiffness enhancements are more pronounced when the specific surface area of the filler increases, even in the presence of limited interfacial adhesion. Although the fracture surface micrographs (Figure 1c–f) display signs of fiber pull-out and visible gaps between the matrix and the filler, typically associated with limited interfacial adhesion between the hydrophobic polymer matrices and the hydrophilic lignocellulosic reinforcements [23,24], the overall interfacial bonding is not significantly compromised (Figure 1c), owing to the MA-grafted nature of both polymers.

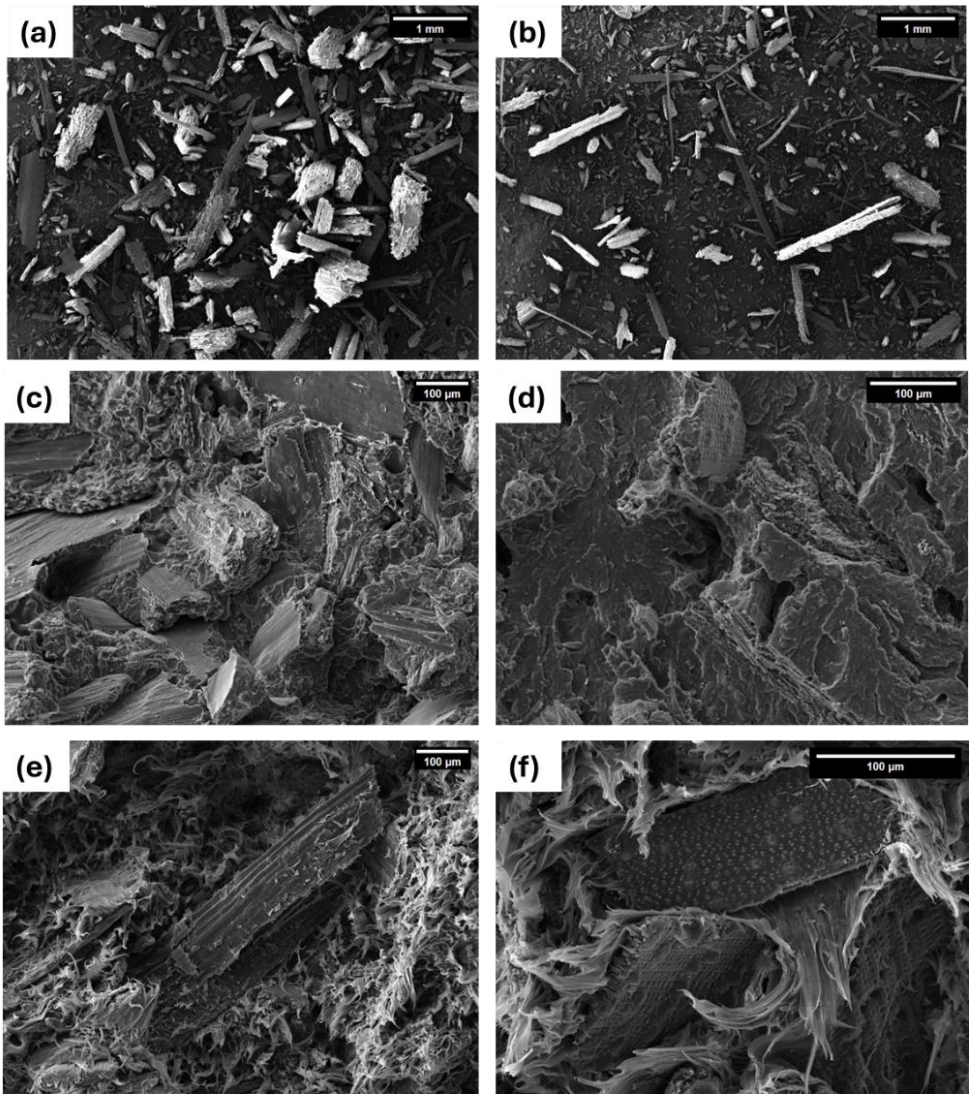

Figure 1: SEM micrographs of (a) WS and (b) RS fillers, and fracture surfaces of composites: (c) PBS_30WS, (d) PBS_30RS, (e) PBAT_30WS and (f) PBAT_30RS.

Interestingly, for both types of fillers, the tensile and flexural strengths also increased, albeit to a lesser extent than the moduli. This trend is consistent with observations by Kumar et al. [16] who measured a superior tensile strength in PBS with 30 wt.% of untreated sisal fibers composites than the neat polymer of about 15.8%. In general, a possible explanation for this behavior lies in the combined effect of chemical anchoring (promoted by the presence of MA) and mechanical interlocking effect, wherein the surface roughness of the lignocellulosic particles acts as anchoring points within the matrix,

thereby improving load transfer at the interface [25]. The enhancements observed in tensile and flexural strengths were superior in the PBAT based formulations compared to those with PBS matrix and this is because of the higher ductility of PBAT than PBS (with the highest deformation at maximum tensile strength of 86.1% ± 5.2% compared to 16.6% ± 1.5%), which allows for a more effective mechanical interlocking.

4 CONCLUSIONS

This study investigated the thermal and mechanical behavior of biodegradable polymer composites based on PBS and PBAT matrices reinforced with lignocellulosic by-products, specifically wheat straw (WS) and rice straw (RS). TGA results demonstrated a reduction in the onset degradation temperature upon filler addition, primarily due to the early decomposition of hemicellulose components present in both straws. DSC analysis revealed no significant changes in the characteristic thermal transitions; however, a reduction in crystallinity was observed for both matrices, with PBS showing a more substantial decrease. This suggests the absence of a nucleating effect. The addition of straw fillers significantly improved the stiffness of both polymers under tensile and flexural conditions, with WS proving more effective than RS. This enhancement is attributed to the finer morphology and higher surface area of WS, which facilitates more efficient stress transfer. Despite the limited interfacial adhesion between the hydrophilic fillers and the hydrophobic matrices, the mechanical interlocking effect contributed to strength improvements, particularly in the PBAT based composites.

Overall, the results confirm the potential of such agricultural by-products such as cost-effective and sustainable reinforcing agents in biodegradable polymer systems. However, further optimization, especially at the interface level, is essential to fully exploit their reinforcing capabilities.

ABSTRACT

Thermoset polymers such as phenolic resins are commonly used as precursors for the ceramic matrix in carbon fiber-reinforced composites due to their high carbon yield in pyrolysis, and desirable thermal properties. Although the initial carbon content is inherent to the polymer, factors such as volatile release and pore structure evolution depend on reaction rates and phase transformations, both of which are strongly influenced by processing conditions. To better understand these complex correlations, it is essential to investigate and characterize the underlying kinetics of transformation, and their impact on property evolution during processing. Experimental data is typically used to establish these governing kinetics; however, accurate characterization remains challenging due to noisy and limited data, as well as the complexity and multiplicity of the reactions involved.

This paper presents a framework that combines machine learning and sparse regression with traditional model-based kinetic analysis to extract governing equations for the pyrolysis of a phenolic thermoset composite. The proposed approach follows three main steps: (1) estimation of activation energies and pre-exponential factors for a multistage process using traditional model-free analysis of thermogravimetric data; (2) prediction of reaction kinetics using a neural network with customized activation functions; and (3) model optimization using LASSO regularization to enforce sparsity, select key features, and reduce overfitting. This combined method improves interpretability and results in a simplified kinetic model that highlights dominant reaction mechanisms.

Applied to dynamic TGA data, the framework achieved strong predictive performance and produced interpretable kinetic expressions. Preliminary results from the in-house Python implementation demonstrate its potential as a promising alternative to traditional kinetic analysis, accurately capturing the kinetics of complex, multistage reactions, with reduced testing. By combining machine learning with sparse regression, this method enhances parameter estimation while offering a scalable and interpretable approach applicable across a range of thermal decomposition processes.

1 INTRODUCTION

Over the past decades, fiber-reinforced composite materials have become increasingly popular across various industries due to their exceptional properties, including high specific strength and stiffness, and resistance to corrosion [1,2]. In particular, ceramic matrix composites are increasingly used in aerospace applications due to their unique combination of high thermal resistance, high strength, and low weight. Thermoset polymers like phenolic resins, for example, form three-dimensional networks through covalent bonding during curing. These crosslinked structures not only provide high thermo-mechanical properties but also exhibit desirable char-forming behavior during thermal decomposition, making them particularly well-suited for applications involving high-temperature exposure, such as ceramic-matrix composite manufacturing, where pyrolysis kinetics plays a critical role in determining the final material properties [3–6]. As a result, considerable effort has been devoted to understanding how processing conditions affect the underlying chemical reactions and, in turn, the resulting material behavior.

In recent years, advanced machine learning models, have emerged as valuable tools for studying high dimensional datasets to uncover underlying patterns, including the effect of processing conditions on material properties [7–9]. These data-driven methods are increasingly employed to uncover complex patterns in material behavior that are difficult to capture through traditional approaches. While conventional physics-based methods remain central to materials science, they often rely on simplifying assumptions, limiting their predictive capabilities in nonlinear, multistage processes [10]. As a result, there is growing interest in hybrid frameworks that integrate physical principles with machine learning to address these challenges, as well as improve generalization and enhance interpretability in complex systems [10].

Despite these advancements, significant challenges remain. For instance, qualification and certification of fiber-reinforced composite structures for aerospace applications still relies on extensive testing campaigns [8]. In the context of reaction kinetics, where understanding the rate and mechanism of chemical reactions under varying conditions is essential, this task is further hindered by the complexity and multiplicity of the reactions involved [5,11]. These limitations underscore the need for efficient, interpretable modeling approaches that can reduce experimental demands while still capturing the essential features of material behavior.

This work introduces a novel, theory-guided machine learning framework for analyzing the high-temperature pyrolysis stage in phenolic-based ceramic-matrix composites manufacturing. The proposed approach, NN-LASSO, integrates sparse regression, neural networks, and established kinetic theories to derive physics-based kinetic expressions from experimental data. The approach builds on the foundation of the Sparse Identification of Nonlinear Dynamics (SINDy) method, extending its applicability to thermo-kinetic systems where overlapping mechanisms and limited data can hinder traditional modeling strategies [10,12]. Experimental data from thermogravimetric analysis (TGA) is used to estimate kinetic parameters through the Friedman isoconversional analysis. These parameters, along with the extent of conversion, are used as inputs to train a neural network with custom activation functions representing candidate reaction mechanisms. Lasso regularization is then applied to enforce sparsity and improve model interpretability.

Preliminary results demonstrate the proposed framework's potential as a scalable alternative to traditional kinetic analysis. By integrating machine learning with sparse regression, the method enables improved parameter estimation while maintaining physical interpretability across multistage, nonlinear reaction systems.

2 MATERIALS AND METHODS

2.1 Data Collection & Transformation

Experimental data used in this study was obtained from TGA tests conducted on cured carbon/phenolic composite samples. The composite was fabricated using a proprietary prepreg and processed into panels with a thickness of 0.64 cm (¼"), and a quasi-isotropic layup of $[(0/90)/(\pm 45)]_{8S}$. Lay-up and bagging were carried out according to the manufacturer's recommended procedures, and the laminates were cured in an autoclave following the manufacturer's recommended pressure and temperature cycles. Microstructural evaluation and density measurements showed results consistent with literature data for similar systems [5]. Samples were sectioned from the cured laminates and used for pyrolysis analysis via TGA. The test specimens had nominal dimensions of 0.2 × 0.1 × 0.64 cm and weighed between 8–10 mg. All samples were obtained from the same composite batches and stored under consistent conditions to minimize variability [11].

TGA tests were performed using a TA Instruments TGA 550 under a nitrogen flow rate of 20 mL/min. Samples were placed in open platinum pans within a sealed chamber. Weight loss and weight loss rate were recorded throughout the pyrolysis process to assess thermal stability and extract kinetic information. Each run was conducted from room temperature up to 1000°C, followed by a 20-minute

isothermal hold before cooling. This temperature range was selected based on prior work establishing that the pyrolysis process in phenolic resins is typically complete by 800°C [13].

For data analysis, the extent of conversion, or degree of pyrolysis (α), was calculated from TGA results using normalized weight loss:

$$\alpha = (m_i - m_t)/(m_i - m_f) \tag{1}$$

where m_i is the initial mass, m_t is the mass at time t, and m_f is the final residual mass for each test [11,14,15].

For solid-state degradation reactions, the reaction rate is typically expressed as a function of the extent of conversion (α), rather than concentration. The general form of the rate equation:

$$\frac{d\alpha}{dt} = k(T)f(\alpha) \tag{2}$$

here $f(\alpha)$ describes the reaction mechanism and $k(T)$is the temperature-dependent rate constant. According to the general form of the Arrhenius equation, the temperature dependency is commonly expressed as:

$$k(T) = Aexp\left(-\frac{R}{RT}\right) \tag{3}$$

where A and E represent the pre-exponential factor and the activation energy, respectively [10,19]. The substitution of Eq. 3 in Eq. 2 gives:

$$\frac{d\alpha}{dt} = Aexp\left(-\frac{E}{RT}\right)f(\alpha) \tag{4}$$

This rate expression is widely used in model-free and model-fitting approaches in thermal analysis [16]. In this study, the Friedman method was used to extract activation energies and pre-exponential factors from the TGA data [16,17]. These parameters, along with the calculated conversions, were used as inputs for the NN-LASSO framework.

2.2 NN-LASSO Framework for Kinetic Modeling

The NN-LASSO framework was developed to identify kinetic models from experimental data by combining neural networks, Lasso-based feature selection, and established pyrolysis kinetic theories. It builds upon the principles of the Sparse Identification of Nonlinear Dynamics (SINDy) method, which assumes that the temporal evolution of dynamic physical systems can be approximated by a sparce summation of nonlinear basis functions [10,12]. In this work, the governing reaction rate is expressed in the form:

$$\frac{d\alpha}{dt} = \sum_{i=1}^{n} \omega_i f_i(\alpha) \tag{5}$$

where $f_i(\alpha)$ are functions representing potential reaction mechanisms, and ω_i are trainable weights. The goal is to select a minimal subset of physics-based features that balances physical interpretability with sufficient accuracy in capturing the observed kinetics.

The experimental TGA data was first segmented into distinct temperature regions based on the observed weight-loss trends, with each segment corresponding to a different pyrolysis stage [11]. Activation energies and pre-exponential factors for each stage were calculated using the Friedman method and used as inputs to the model. A feature library was built from kinetic expressions commonly used to describe solid-state reactions, including functions of the form:

$$f(\alpha) = \alpha^m(1-\alpha)^n \tag{6}$$

$$f(\alpha) = \alpha^m \tag{7}$$

$$f(\alpha) = (1-\alpha)^n \tag{8}$$

$$f(\alpha) = ((1+\alpha)^n - 1)^p \tag{9}$$

Each function was implemented as a custom activation layer within the neural network, parameterized by $m, n,$ and $p,$ and constrained to remain within realistic kinetic ranges during training. Lasso regularization was then applied to the output layer to enforce sparsity by minimizing the L1 norm of the weights, driving non-essential terms to zero [18]. This promotes interpretability and reduces overfitting, resulting in a simplified expression composed of the most relevant kinetic mechanism. The Lasso penalty term is defined by:

$$\phi(\boldsymbol{w}) = \|\boldsymbol{w}\|_1 \tag{10}$$

where $\boldsymbol{w} = (\omega_1, \omega_2, \dots, \omega_n)^n$ is the vector of trainable weights assigned to each feature in the output layer [18].

To optimize performance, a hyperparameter search was performed across regularization strengths, learning rates, batch sizes, and feature combinations. Multiple models were trained using randomly selected subsets of candidate functions. The final model was chosen based on its ability to match experimental trends while maintaining a minimal, interpretable form. **Fig. 1** presents a schematic of the three main steps of the framework.

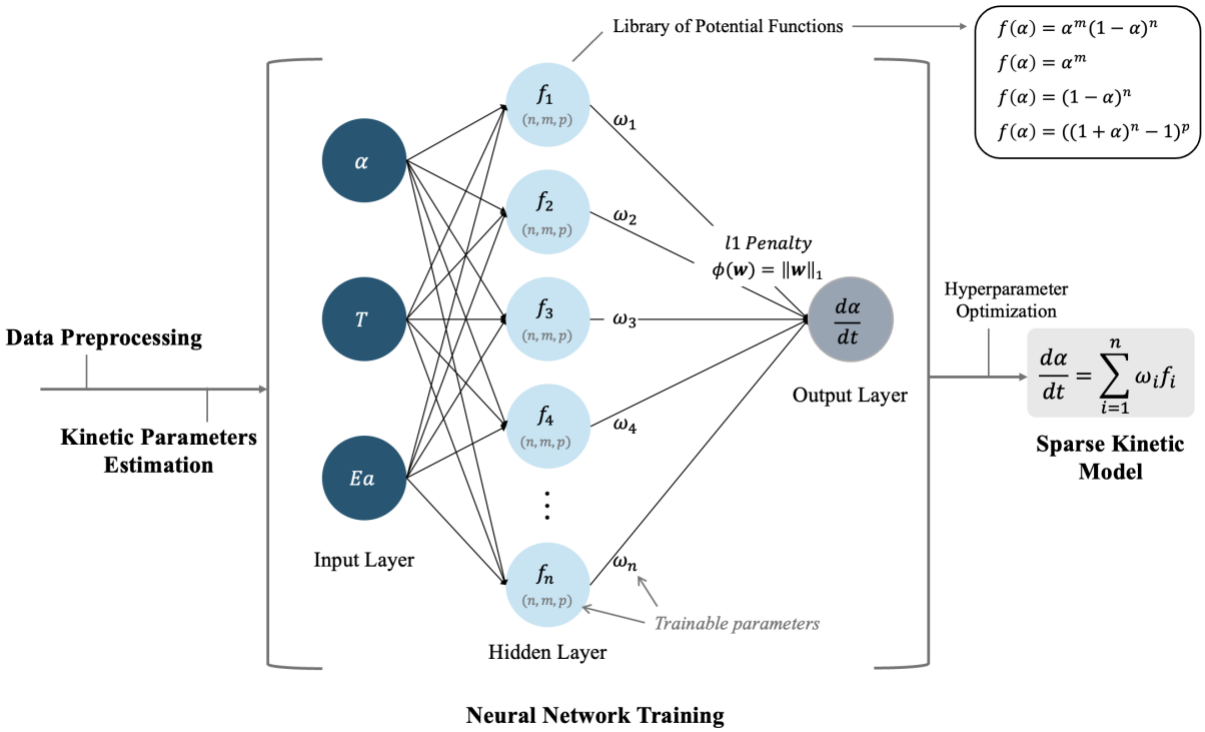

Figure 1: Schematic of the proposed approach for kinetics modeling from experimental data using the NN-Lasso framework.

The framework was validated by comparing predicted reaction rates against experimental TGA results across dynamic and complex temperature cycles.

3 RESULTS

Based on TGA test data and reported results in the literature, three distinct temperature regions with peak degradation rates near 350°C, 550°C, and 600°C were identified for the studied material (**Fig.2**a) [11]. These correspond to crosslinking and chain scission reactions (300-440°C), followed by char formation and oxidation reactions (400-800°C) [13,15]. To focus on thermal degradation behavior, weigth loss below 225°C, associated with polymerization and dewatering during curing, was excluded

from the analysis [19]. As summarized in **Table 1**, average activation energies of 195.5, 104.8, and 136.4 kJ/mol were calculated for these stages using Friedman's isoconversional method (**Fig.2**b) [11,20].

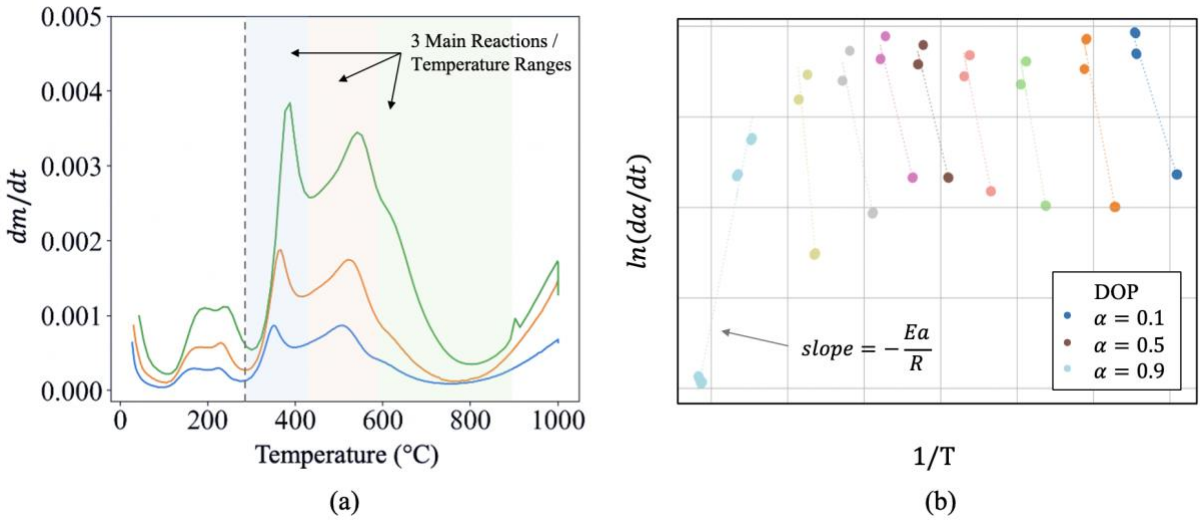

Figure 2: TGA derivative weight loss curves showing main degradation regions (a), and activation energy estimation using Friedman's analysis at various degrees of conversion (b).

Stage	Temperature Range (°C)	$\boldsymbol{Ea}$ $\boldsymbol{(k/mol)}$
1	300-430	195.5
2	430-600	104.8
3	600-900	136.4

Table 1: Kinetic parameters using Friedman analysis for different temperature ranges.

Following previous studies [21,22], the pyrolysis was modeled as a three-stage mechanism, with the rate expressions defined as:

$$\frac{d\alpha_1}{dt} = A_1\, exp\left(-\frac{E_{a,1}}{RT}\right) f(1-\alpha_1)^{n_1} \tag{11}$$

$$\frac{d\alpha_2}{dt} = A_2\, exp\left(-\frac{E_{a,2}}{RT}\right) f(\alpha_1-\alpha_2)^{n_2} \tag{12}$$

$$\frac{d\alpha_3}{dt} = A_3\, exp\left(-\frac{E_{a,3}}{RT}\right) f(\alpha_2-\alpha_3)^{n_3} \tag{13}$$

The overall conversion is expressed as:

$$\alpha(t) = w_1\alpha_1(t) + w_2\alpha_2(t) + w_3\alpha_3(t) \tag{14}$$

with $w_1 + w_2 + w_3 = 1$ and $0 < \alpha(t) < 1$.

To evaluate the NN-LASSO framework under different conditions, two models were trained using TGA data collected at heating rates of 2°C/min and 5°C/min. Training was performed over dynamic temperature cycles ranging from 225°C to 900°C. The mathematical expressions for the resulting kinetic models derived from the training process are presented in Eq. 28 and 29, respectively.

$$\frac{d\alpha}{dt} = 0.0016 * \exp\left(-\frac{E}{RT}\right) x^{0.84} + 0.7 * \exp\left(-\frac{E}{RT}\right) x^4(1-x)^2 + 0.13 * \exp\left(-\frac{E}{RT}\right) x^{0.7}(1-x)^4 \tag{15}$$

$$\frac{d\alpha}{dt} = 0.0223 * \exp\left(-\frac{E}{RT}\right) x^{0.62}(1-x)^5 + 1.32 * \exp\left(-\frac{E}{RT}\right) x^5(1-x)^{3.7} + 0.24 * \exp\left(-\frac{E}{RT}\right) ((1+x)^4 - 1))^5 \tag{16}$$

As shown in **Fig. 3** the predicted conversion rate curves closely matched experimental TGA results. The model trained on 2°C/min data achieved a R^2 value of 0.9703, while the 5°C/min model achieved R^2 = 0.9634. Although both models accurately captured the underlying kinetics, the differences in selected mechanisms and reaction orders across heating rates highlight the sensitivity of pyrolysis behavior to thermal conditions. These variations highlight the complexity of the pyrolysis process and the need for adaptable kinetic modeling approaches to accurately describe thermal degradation under different processing conditions.

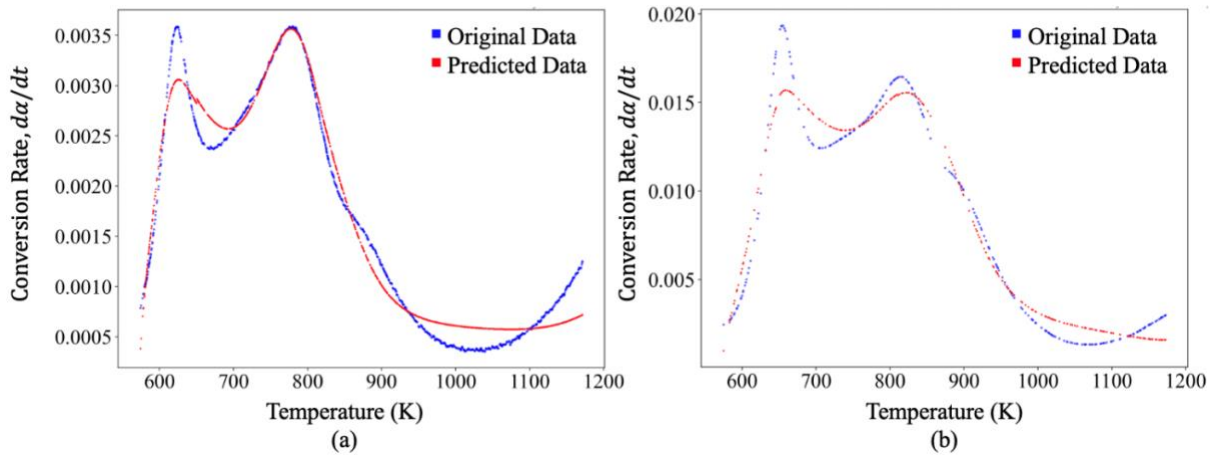

Figure 3: Comparison of the conversion rate (dα/dt) curve predicted for a 2°C/min (a) and a 5 °C/min (b) dynamic cycle with that obtained from experimental results.

To further evaluate model performance under complex processing conditions, the NN-LASSO framework was trained on TGA data collected from a multi-step cycle, which included multiple heating ramps and isothermal holds (5°C/min to 550°C, followed by a 1-hour isothermal hold, and then 2°C/min to 1000°C). The model achieved an R^2 value of 0.9433. However, results shown in **Fig 4**.b reveal that the model struggled to accurately follow material behavior during the isothermal hold, suggesting that the current framework may benefit from incorporating additional variables or modifying the base equations.

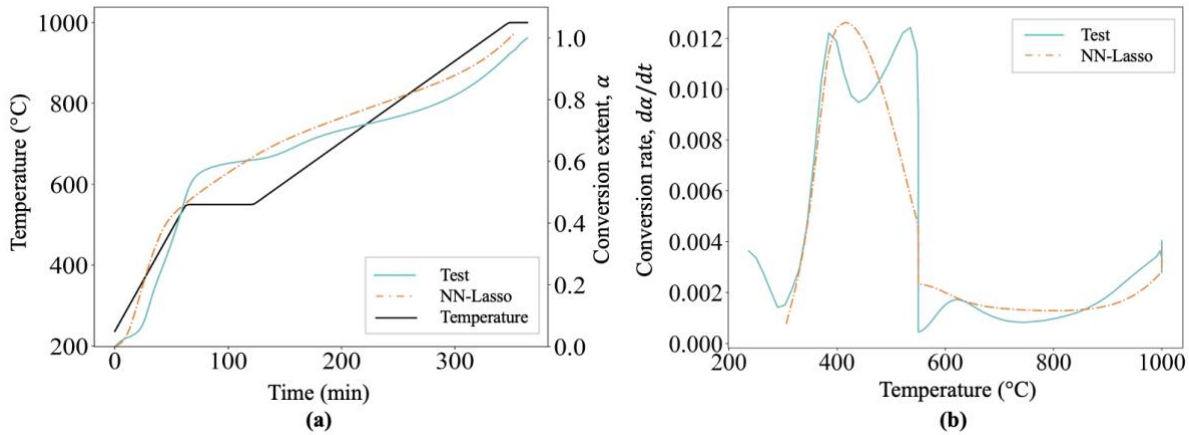

Figure 4: Comparison of the (a) conversion extent (α), and (b) conversion rate (dα/dt) curve predicted for a complex temperature cycle with that obtained from experimental results.

4 CONCLUSIONS

Accurate kinetic modeling of ceramic-matrix composites manufacturing remains a significant challenge, particularly during high-temperature processes like the pyrolysis stage. Predicting material behavior requires understanding the rate and mechanism of chemical reactions under varying thermal conditions, but this is often hindered by the complexity of multistage reactions and the limited, noisy nature of experimental data. These challenges highlight the need for efficient, interpretable modeling approaches that can capture the underlying kinetics while reducing experimental efforts.

Applied to the pyrolysis stage of ceramic-matrix composite manufacturing, the proposed machine learning-based framework demonstrated reliable performance in capturing overall reaction behavior using limited experimental data. By enforcing sparsity, the approach identified physics-based kinetic expressions, that are adaptable across different processing conditions.

While the balance between predictive accuracy and physical interpretability makes the NN-LASSO framework a promising tool for kinetic modeling, developing a single model that generalizes across all manufacturing scenarios remains a challenge. Incorporating physics-based constraints, could be a potential direction to address this challenge and support the development of a more robust machine learning framework. Future work will also focus on extending the application of this framework to other reaction kinetics and various thermally driven material transformations.

ABSTRACT

This paper investigates shape memory characteristics, negative Poisson's ratio (NPR) and thermal stability of re-entrant (RE) structures made from polyurethane (PU)/halloysite nanotube (HNT) nanocomposites via fused deposition modelling (FDM). The addition of 10 wt% HNTs within PU matrices enhanced shape fixity ratio of PU/HNT nanocomposites by 12% despite a slight drop in both shape recovery ratio (9%) and NPR (60%), along with prolonged recovery time up to 45%. This result clearly indicated their promising commercial potential as a shape-memory shock absorber in the future. Furthermore, the incorporation of HNTs improved thermal stability of PU/HNT nanocomposites, which was shown by their relatively high thermal decomposition temperatures. It could be associated with barrier effect of HNTs to postpone the degradation of PU hard segments. Additionally, an entrapping mechanism of HNT lumens made a significant contribution in thermal stability improvement of 3D printed nanocomposite structures. Finally, the presence of HNTs also elevated glass transition temperature T_g, melting temperature T_m, crystallisation temperature T_c and the degree of crystallinity χ_c due to much better covalent bonding, microphase separation and nucleating effect of such nanoparticles in addition to mobility restriction of PU molecules.

1 INTRODUCTION

Re-entrant (RE) structures have drawn great attention due to their light-weight and high-strength characteristics, resulting in a high stiffness/strength to mass ratio. Besides, such desired structures also possess unique material behaviour, namely negative Poisson's ratio (NPR), which allows them to exhibit transverse expansion under uniaxial tension and transverse contraction when subjected to uniaxial compression [1]. Lakes [2] mentioned that RE structures with remarkable shear stiffness for the first time, motivated many researchers to create and develop various auxetic structures over many decades.

It is tedious work to manufacture RE structures using conventional manufacturing methods such as injection moulding and melt extrusion owing to their typical lattice structures constructed from simple unit cells with significantly high porosity [3]. This critical issue can be overcome with the aid of 3D printing technology to achieve free-form fabrication. When RE structures are made from shape-memory polyurethane (PU), resulting structures reveal great potential as shock absorbers in possession of shape memory behaviour, enabling them to recover after deformation by using external stimuli such as heat, light, electrical and magnetic fields. Nevertheless, PU possesses typical drawbacks associated with its

mechanical strength [4]. Therefore, such a material requires the reinforcements like fibres and nanoparticles. Among nanoparticles like carbon nanotubes (CNTs), montmorillonites (MMTs) and halloysite nanotubes (HNTs), HNTs have typical advantages since they are classified as a non-toxic material and become abundantly available in nature as low-cost additives to improve mechanical properties [5].

This study presents a comprehensive investigation with respect to the effect of different HNT content (i.e. 0, 2, 4, 6, 8 and 10 wt%) on shape memory behaviour of PU/HNT nanocomposites via fused deposition modelling (FDM). Besides, thermal stability of 3D printed RE structures was also evaluated. Initial nanocomposite samples were prepared via mixing and solution casting processes. They were then examined in compression and shape memory tests, thermogravimetric analysis (TGA) and differential scanning calorimetry (DSC) to determine corresponding Poisson's ratio (PR), shape memory behaviour and thermal stability of 3D printed nanocomposites.

2 MATERIAL AND METHODS

Polyurethane (PU) MM 4520 [6] manufactured by SMP Technologies, Tokyo, Japan, was used as primary polymeric material in this study. Meanwhile, HNT particles were supplied by Imerys Ceramics Kaeo, New Zealand [7]. Dimethylformamide (DMF) [8] was employed as a chemical solvent to dissolve PU pellets for better HNT dispersion. DMF was supplied by Chem-Supply Pty Ltd., SA, Australia. The properties of PU and HNTs are listed in Tables 1 and 2 respectively.

Physical properties		Mechanical properties		Thermal properties	
Melt viscosity (Pa·s at 215°C)	3310	Young's modulus (MPa)	729	Glass transition temperature (˚C)	45
		Tensile strength at break (MPa)	41.4		
		Ultimate elongation (%)	600		
		Shore D hardness	72		

Table 1: PU MM-4520 properties [6].

Property	Value
Moisture content (%)	3.0
Specific gravity	2.55
pH (aqueous slurry at 20% solids)	3.5 – 4.5
Surface area [Brunauer-Emmett-Teller (BET)] (m^2/g)	25
Linear shrinkage (dried at 110°C) (%)	3.8
Modulus of rupture (dried at 110°C) (MPa)	2.9

Table 2: HNT properties [7].

To prepare nanocomposite samples, PU pellets and HNT particles were dried in a vacuum oven at 80°C for 4 and 8 h accordingly [6,9] in order to minimise adverse moisture effect, as depicted in Fig. 1. HNT particles were then dispersed in DMF with a mix ratio of 1:30 [10] using an ultrasonicating bath at the frequency of 25 kHz, power intensity of 90% and sonication time of 1 h [11]. Meanwhile, PU pellets were dissolved in DMF (mix ratio: 1:8) [10]. Before mixing with PU pellets, DMF was heated in a magnetic stirrer at 300°C with the rotor speed of 700 rpm. At this temperature, PU pellets were gradually added into the beaker until such materials were fully dissolved to prevent sedimentation issue.

Afterwards, HNT/DMF mixture was added into PU/DMF under stirring and heating processes for approximately 30 min. PU/HNT/DMF mixture was then cast onto a glass container, and then heated again in an oven at 100°C for 24 h to remove the solvent. Finally, prepared nanocomposite films were stored in a desiccator containing silicon gels before further material testing and characterisation. It is worth mentioning that nanocomposite film preparation in this study followed the same procedure previously mentioned elsewhere [13, 14].

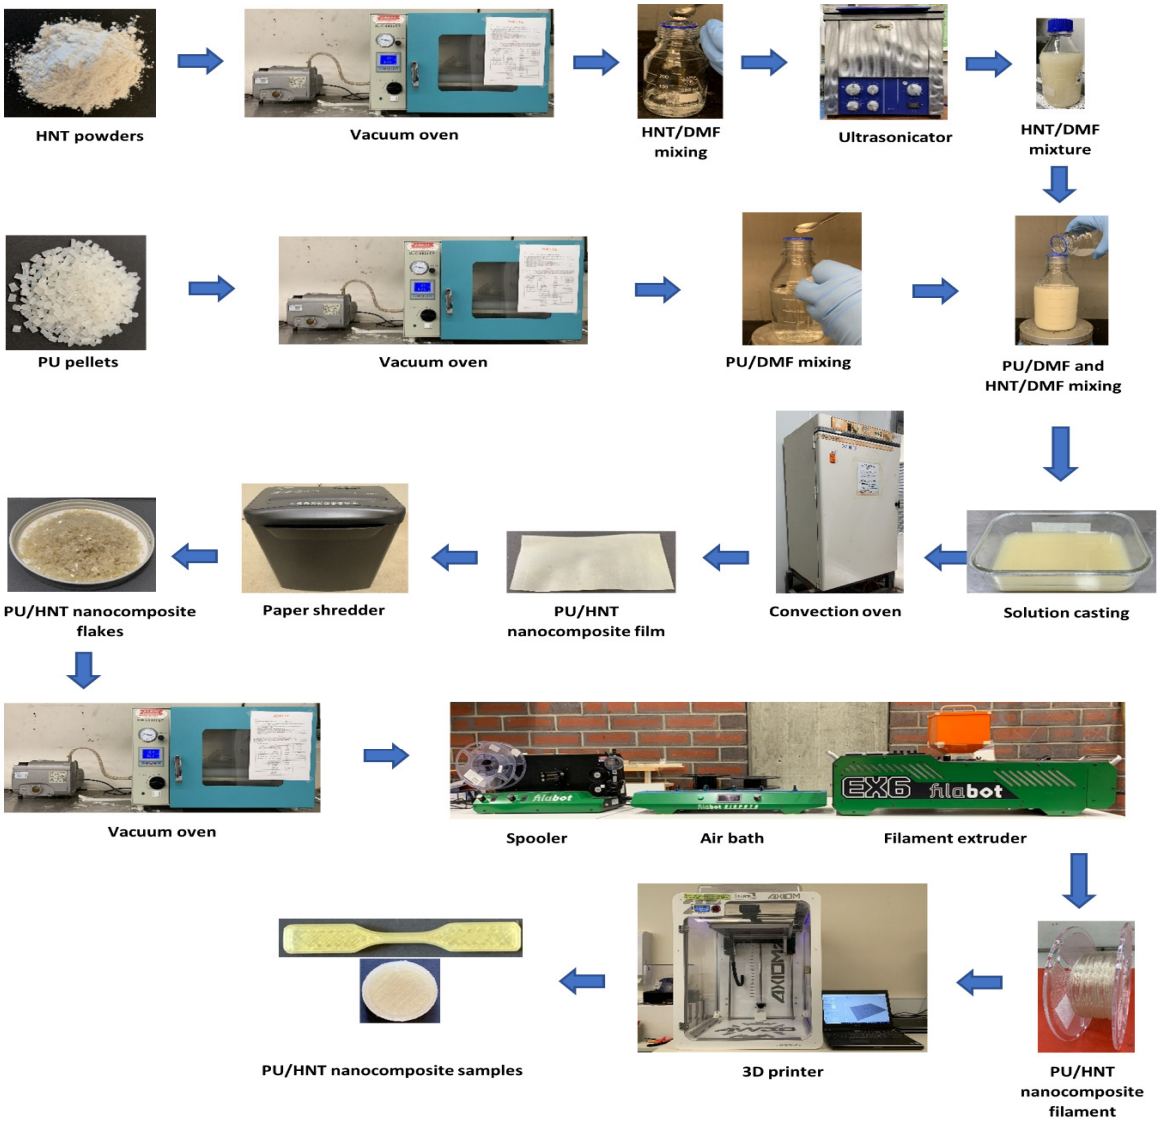

Figure 1: Flow chart of manufacturing PU/HNT nanocomposite films, filaments and samples [12].

The extrusion process was carried out using a single screw filament extruder, Filabot EX6 (Screw diameter: 16 mm and L/D ratio: 24) , supplied by Filabot company, VT, USA. Such an extruder has four temperature chambers consisting of feed, back, middle and front zones with specific temperatures controlled at 45, 165, 165 and 165˚C respectively. On the other hand, screw speed of filament extruder was set to 50 rpm to produce nanocomposite filaments.

Prior to an extrusion process, PU/HNT nanocomposite films were shredded and further chopped into small flakes with the thickness of 0.45 ± 0.1 mm, the width of 3.00 ± 0.1 mm and the length of 4.30 ± 0.5 mm. Processed flakes were then dried using a vacuum oven at a controlled temperature of 80°C for 4 h to reduce moisture content. After the extrusion process, nanocomposite filaments were spooled and further stored in airtight containers with silica gels in order to dry prepared filaments. Filament fabrication from virgin PU pellets also followed this procedure with the exception of no shredding and chopping. Processing parameters for filament extrusion are presented in Table 3.

Finally, nanocomposite samples were manufactured by employing a FDM printer Axiom 20 integrated with a built-in software APEX supplied by Airwolf 3D company, USA. The samples were created at various HNT contents according to Table 4. Meanwhile, the settings of selected 3D printing parameters and other fixed 3D printing parameters are listed in Tables 5 and 6.

Parameter	Setting
Front temperature (T_{front}) (°C)	165
Middle temperature (T_{mid}) (°C)	165
Back temperature (T_{back}) (°C)	165
Feed temperature (T_{feed}) (°C)	45
Extrusion speed (rpm)	50

Table 3: Settings of filament extrusion parameters.

Factor	Level					
HNT content (wt%)	0	2	4	6	8	10
Nozzle temperature (˚C)	210		220		230	
Print speed (mm/s)	10		20		30	
Infill density (%)	40		70		100	
Layer height (mm)	0.2		0.3		0.4

Table 6: Fixed 3D printing parameters for PU/HNT nanocomposites.

Compression tests at the first step were carried out to assess the influence of HNT content on Poisson's ratio (PR) of 3D printed samples. Re-entrant (RE) structures were employed in this study for compression tests, which were made from both neat PU and PU/HNT nanocomposites. RE structures, as illustrated in Fig 2(a), have the length of vertical strut (l) of 20 mm, the length of inclined strut (s) of 12 mm and the height (h) of 20 mm. On the other hand, the width (w), the cell thickness (t) and the angle of inclined strut (θ) of this structure are 20 mm, 2 mm and 40º accordingly. Compression tests were

performed with the load-cell capacity of 10 kN to conduct uniaxial quasi-static tests at room temperature in the in-plane *y* direction depicted in Fig. 2(b). Under the tests, RE structures were set on the fixed platen on the universal testing machine, and three structure samples were assessed for test reproducibility at each HNT content.

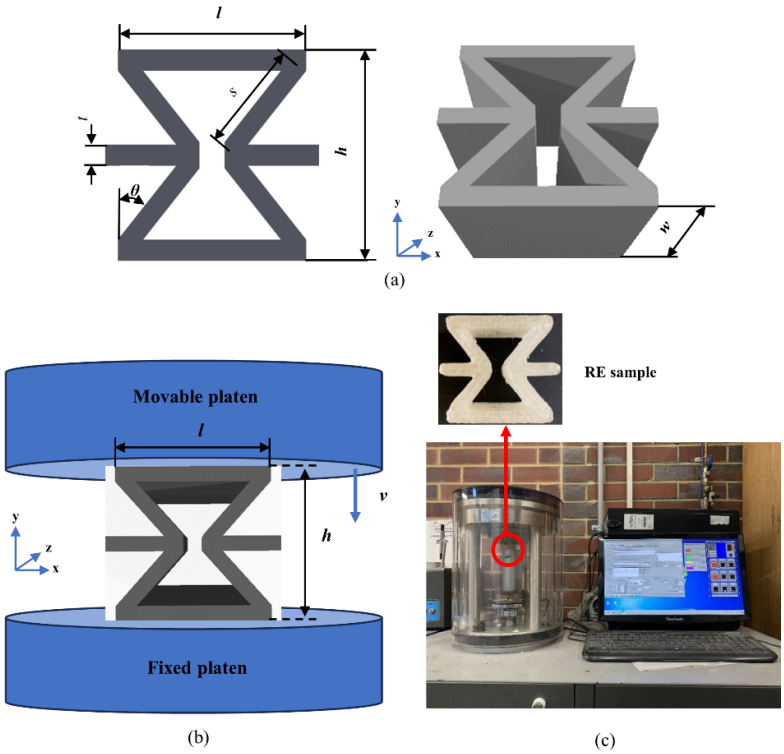

Figure 2: (a) A RE structure and its dimensions (in mm), (b) a schematic diagram of typical compression test for RE structure and (c) compression test for the investigation of shape memory behaviour of RE structure.

The crosshead speed of movable platen travelling downwards was set to 0.5 mm/min according to ASTM C365 standard. The test ended when a densification phenomenon was reached. Nominal stress σ and normal strain ε were determined based on equations (1) and (2) as follows

$$\sigma = \frac{F}{l \times w} \tag{1}$$

$$\varepsilon = \frac{\Delta h}{h} \tag{2}$$

where F and Δh are the applied load and the change of displacement between movable and fixed platens. The built-in software of the universal testing machine was used to automatically record such displacement along with time and force throughout compression tests.

PR in this study can be defined as the negative ratio of lateral strain to axial strain. The axial strain was calculated based on the platen displacement in the *y*-axis. On the other hand, a digital camera Fujifilm X-T3 manufactured by Fujifilm Corporation, Tokyo, Japan, was used to capture RE structure displacement in the *x*-axis. The resulting data were employed to determine the lateral displacement in the *x*-axis with the aid of DaVinci Resolve 18 and ImageJ 153 software. The values of axial strain ε and lateral strain ε_L were determined using equations (2) and (3). In addition, l and Δl denote initial length and the change of the length. Meanwhile, PR was calculated using equation (4) [15].

$$\varepsilon_L = \frac{\Delta l}{l} \tag{3}$$

$$PR = -\frac{\varepsilon_L}{\varepsilon} \quad (4)$$

Compression tests at the second test step to evaluate shape memory behaviour of RE structures were conducted at 50˚C using an asphalt mixture performance tester (AMPT) with the load cell of 15 kN depicted in Fig. 2(c). This device is equipped with an oven, enabling it to perform compression at elevated temperatures. The compression process was ended immediately after Δh reached 8 mm where Δh of 5 mm was considered as the onset densification of RE structures. The oven employed at the first test step was also applied to evaluate shape memory behaviour of RE nanocomposite structures at the second test step. The oven heating temperature was set to 80˚C for fast recovery and twisting effect.

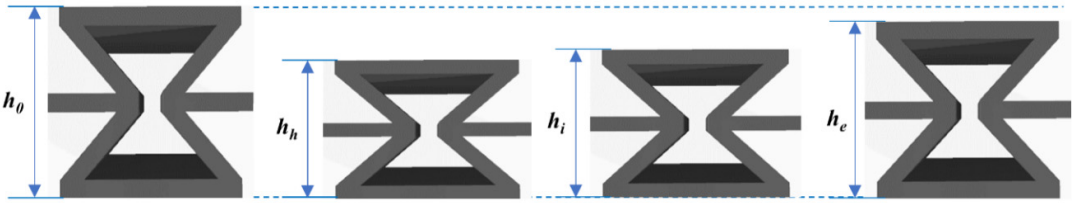

Figure 3: Compression tests for shape memory behaviour of RE structures

Fig. 3 exhibits different heights of RE unit-cell samples, namely the height before compression h_o, the height after compression h_h, the height after load removal h_i and the height after recovery h_e. Equations (5)-(9) can be applied to determine shape fixity ratio R_f, shape recovery ratio R_r, the amount of deformation after load removal ε_u, maximum strain ε_m and the amount of reversible strain ε_p.

$$R_f = \frac{\varepsilon_u}{\varepsilon_m} \times 100\% \quad (5)$$

$$R_r = \frac{\varepsilon_m - \varepsilon_p}{\varepsilon_m} \times 100\% \quad (6)$$

$$\varepsilon_m = \frac{h_o - h_h}{h_o} \quad (7)$$

$$\varepsilon_u = \frac{h_o - h_i}{h_o} \quad (8)$$

$$\varepsilon_p = \frac{h_o - h_e}{h_o} \quad (9)$$

A thermogravimetric analyser (TGA) SDT 2960, supplied by TA Instruments, USA, was used to investigate thermal stability of neat PU and PU/HNT nanocomposites based on sample weight-loss method. A cooling system with cryofill liquid nitrogen was utilised to determine the weight loss of material samples. About 20 mg TGA samples were heated from 25 to 900°C with the heating rate of 10°C/min [13]. Conversely, a differential scanning calorimeter Discovery DSC 25, supplied by Texas Instruments, USA, was in operation to evaluate glass transition temperature (T_g), crystallisation temperature (T_c) and melting temperature (T_m) of neat PU and PU/HNT nanocomposites. About 4 mg DSC samples were placed in aluminium pans, then heated from -50 ˚C to 240˚C with the heating rate of 20˚C/min. To eradicate thermal history, an isothermal condition was kept at 240˚C for 5 min. DSC samples were then cooled from 240˚C to –50˚C with the same cooling rate of 20˚C/min again. Heating-cooling processes were replicated for the second time. T_g and T_m were then detected from the first heating while T_c was determined from the second heating.

3 RESULTS AND DISCUSSION

3.1 Effect of HNT Content on NPR

The addition of HNTs within PU matrices tended to restrict the mobility of polymeric chains, thus resulting in much higher stiffness. The presence of siloxane and aluminol groups on HNT surfaces

induced hydrogen bonding with PU molecular chains, which further reduced their mobility. Moreover, when HNT content was increased up to 10 wt%, it could reduce engineering strain specifically with respect to lateral strain. This is attributed to the limited effect on the movement of polymeric chains, thereby resulting in a decrease in NPR by approximately 60% (Fig. 4). RE structures made from PU/HNT nanocomposites had an auxetic behaviour due to their unique forms, which allowed them to encounter transverse contraction under uniaxial compression [16]. Once compression strain reached 10%, the curve section of the strut in the middle region of RE structure touched each other, which was followed by a decrease in lateral strain. It was evidently observed that all curves had a consistent trend from initial sharp rise to nearly the plateaus, which was in good agreement with Park et al. [17] to investigate the efficacy of chondrocyte proliferation for PU auxetic scaffolds in compressive tests, which was especially applicable to articular cartilage in tissue engineering. Overall, PR versus compressive strain curves of PU/HNT nanocomposites appeared to be in good accordance with Alomarah et al. [18] where PR values were calculated based on lateral engineering strain and axial engineering strain for RE structures under compressive loading in the *x*-direction.

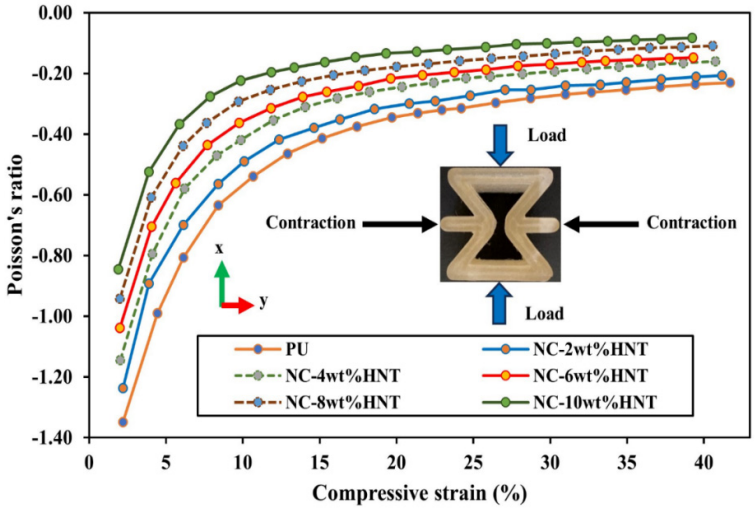

Figure 4: Effect of HNT content on NPRs of PU and PU/HNT nanocomposite samples.

3.2 Effect of HNT content on shape memory behaviour

In relation to shape memory behaviour, the presence of HNTs induced three different effects on 3D printed nanocomposite samples. The first effect was associated with the improved ability of PU/HNT nanocomposite samples to be programmed, which enhanced their shape fixity ratio. The inclusion of 10 wt% HNTs could enhance the shape fixity ratio of nanocomposite samples up to 12%, as opposed to that of virgin PU according to Fig. 5(a). This phenomenon might be related to strain-induced crystallisation effect [17]. The incorporation of rigid nanofillers such as HNTs increased soft-segment crystallinity. Furthermore, the strain distribution in PU matrices in the vicinity of HNTs became greater under deformation. It could be induced by significant modulus difference between the matrices and the fillers [19]. Strain localisation promoted strain-induced crystallisation caused by higher crystallisation to limit the relaxation process of deformed polymeric chains. The increase of HNT content was detected to further enhance strain-induced crystallisation, as indicated by shorter h_i along with higher R_f.

The second effect was related to HNTs to prevent PU matrices from regaining their original form, leading to the reduction of shape recovery ratio. In particular, when PU was incorporated with 10 wt% HNTs, shape recovery ratio of resulting nanocomposite samples slightly declined to 9%. Final effect could be associated with the contribution of existing HNTs to hinder PU molecules from shape recovery, and further prolong the recovery time by 45% with the addition of 10 wt% HNTs in their nanocomposites according to Fig. 5(b).

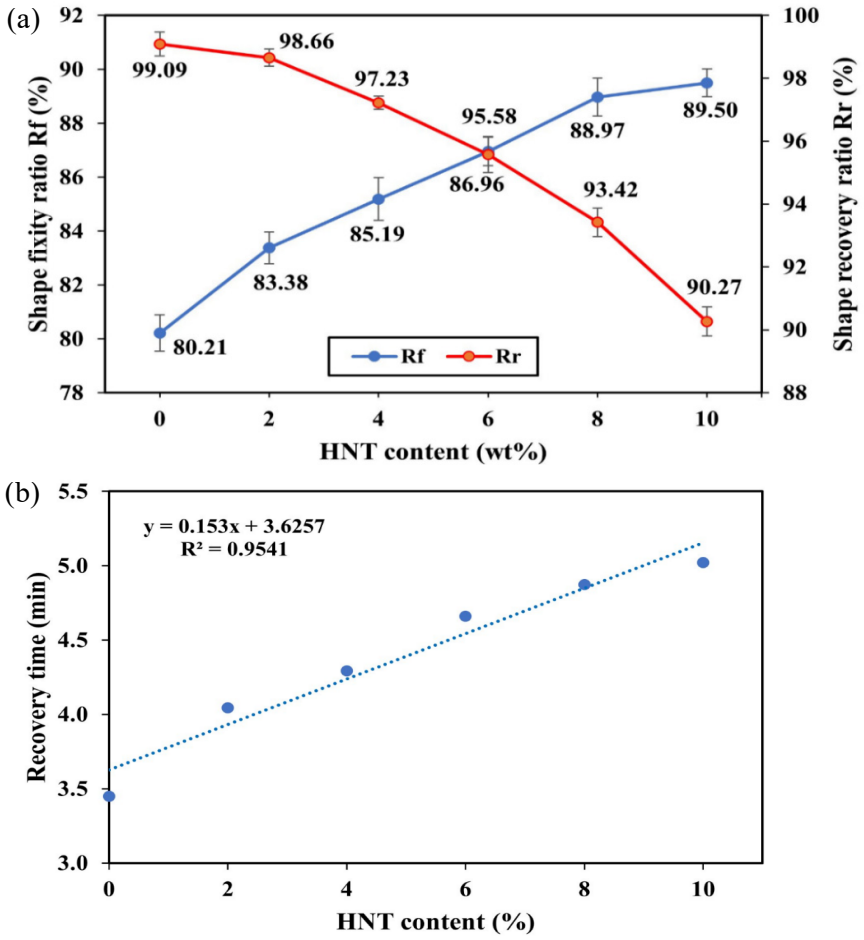

Figure 5: (a) Shape fixity and shape recovery ratios and (b) recovery time of PU/HNT nanocomposites

3.3 Effect of HNT content on thermal stability

Thermal stability for PU/HNT nanocomposites was shown in their TGA thermograms in Fig. 6(a). Four decomposition temperatures, represented by T_{d1}, T_{d2}, T_{d3} and T_{d4}, were associated with hard segment degradation of PU matrices into isocyanate and alcohol along with a clear sign of process complexity [20]. As for T_{d1} and T_{d2}, they were related not only to hard-segment dissociation of PU/HNT nanocomposites [21], but also to a bond disentangle of water molecules in empty tubular lumens of HNTs [22]. T_{d3} and T_{d4} were referred to as the thermal decomposition of PU soft segments [23] and carbon degradation accordingly.

Four TGA peaks appeared for neat PU at the temperature ranges of 41-348˚C, 348-387°C, 387-460°C and 663-788°C. Conversely, four temperature ranges were also identified at 28-358˚C, 358-391˚C, 391-465˚C and 664-782˚C with respect to four corresponding TGA peaks of PU/HNT nanocomposites reinforced with 2 wt% HNTs. The addition of HNTs to PU matrices increased T_{d1}, T_{d2}, T_{d3} and T_{d4} to higher temperature levels when compared with those of neat PU, as indicated in Fig. 6(b). This tendency could be caused by barrier effect of HNTs to postpone the dissociation of PU hard segments, resulting in the increase of T_d [23]. Moreover, an entrapping mechanism of HNT lumens for degradation products of polymers increased thermal stability and significantly delayed mass transport [24]. When HNT content was beyond 2 wt%, the decomposition temperatures of nanocomposite samples slightly decreased, in particular for T_{d3} and T_{d4} of PU/HNT nanocomposites at HNT contents of 4, 6, 8 and 10 wt% shown in Table 7. It might be ascribed to inhibited hydrogen bonding between hard segment domains of PU matrices and embedded HNTs to hinder the retention of thermal stability for polymer

nanocomposites [21]. Generally speaking, T_{d1}, T_{d2}, T_{d3} and T_{d4} of nanocomposite samples were higher than those of neat PU. It implied that the presence of HNTs within PU matrices tended to improve thermal stability of resulting PU/HNT nanocomposites.

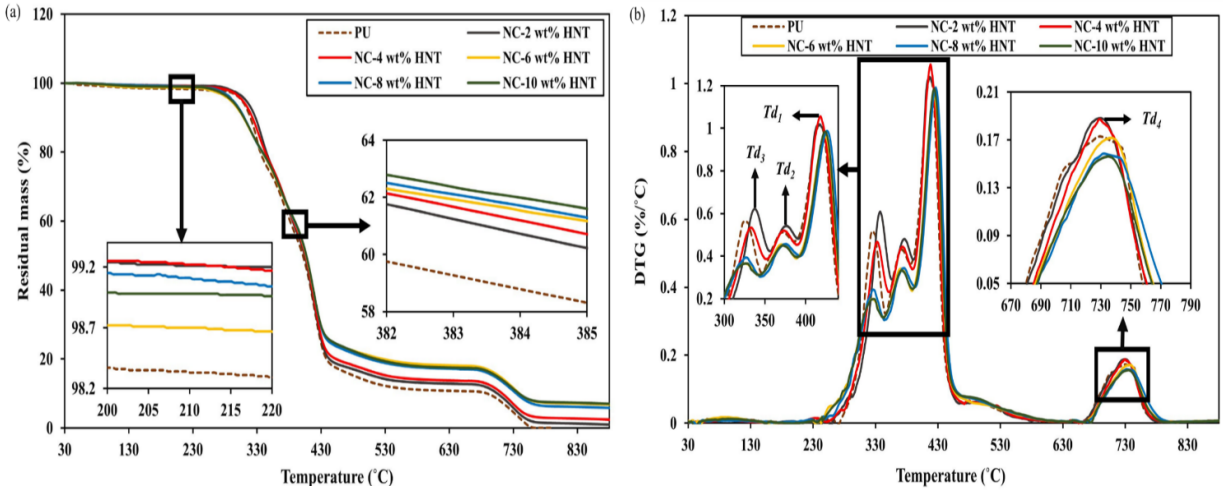

Figure 6**:** TGA thermograms for PU and PU/HNT nanocomposites: (a) TGA curves and (b) DTG curves. Note T_d refers to the decomposition temperature.

Material type	Sample batch	T_{d1} (°C)	DTG (%/°C)	T_{d2} (°C)	DTG (%/°C)	T_{d3} (°C)	DTG (%/°C)	T_{d4} (°C)	DTG (%/°C)
Neat PU	PU	325.31	0.5661	371.19	0.5118	416.85	1.021	730.08	0.1732
2 wt% HNTs	NC-2 wt% HNT	337.59	0.6223	376.4	0.5418	417.49	1.017	730.15	0.1882
4 wt% HNTs	NC-4 wt% HNT	333.04	0.5336	373.41	0.5196	418.13	1.056	729.12	0.1873

DTG stands for derivative thermogravimetry, which is a technique that plots the derivative of the TGA curve and represents the rate of mass change with respect to temperature or time.

Table 7: TGA data summary of PU and PU/HNT nanocomposite samples.

3.4 DSC thermal analysis

DSC thermograms for nanocomposite samples at various HNT contents were displayed in Fig. 7, while their thermal parameters were presented in Table 8. As mentioned earlier, PU molecules comprise hard and soft segments. T_g is connected to hard segments because of covalent bonding of NCO and OH groups to influence the mobility of polymeric chains [25]. The presence of HNTs may promote covalent bonding despite the limitation to chain mobility of PU molecules, resulting in the increase of T_g [26]. The addition of HNT content up to 4 wt% within PU matrices increased T_g to be 42.56°C, as opposed to 40.96°C for neat PU according to Fig. 7(a) and Table 8. When HNT content was increased, urethane stability was disturbed, inducing a further drop in T_g [21]. The incorporation of HNTs within PU matrices generated microphase separation due to specific transformation into hard segments by embedding such nanoparticles [26]. The addition of small amounts of HNTs at approximately 2 wt% in nanocomposites enhanced melting temperature up to 166.16°C when compared with that of neat PU at 161.32°C. Beyond this content level, the purification of soft segments prevailed, which was followed by the extraction of hard segments from the mixture. Accordingly, T_m shifted to the lower temperature level shown in Table 8, which was supported by previous work carried out by Razzaq et al. [27].

The inclusion of HNTs in nanocomposites yielded a higher χ_c owing to typical nucleating effect of HNTs [26]. When HNT content was increased to 6 wt%, χ_c of nanocomposite samples was improved by 55% relative to that of neat PU, as shown in Table 8. A further increase in HNT content from 6 to 10 wt% yielded a reduction in the growth rate of nuclei in the crystallisation process. It was evidenced by approximately 10% increase in χ_c. Additionally, the incorporation of HNTs also shifted DSC peaks with respect to the crystallisation temperatures of hard and soft segments, which were represented by $T_{c,HS}$ and $T_{c,SS}$, as demonstrated in Fig. 8(b) and Table 8. A higher T_c was proven to increase microphase separation, thus leading to pure soft segments and better shape fixity [26, 28].

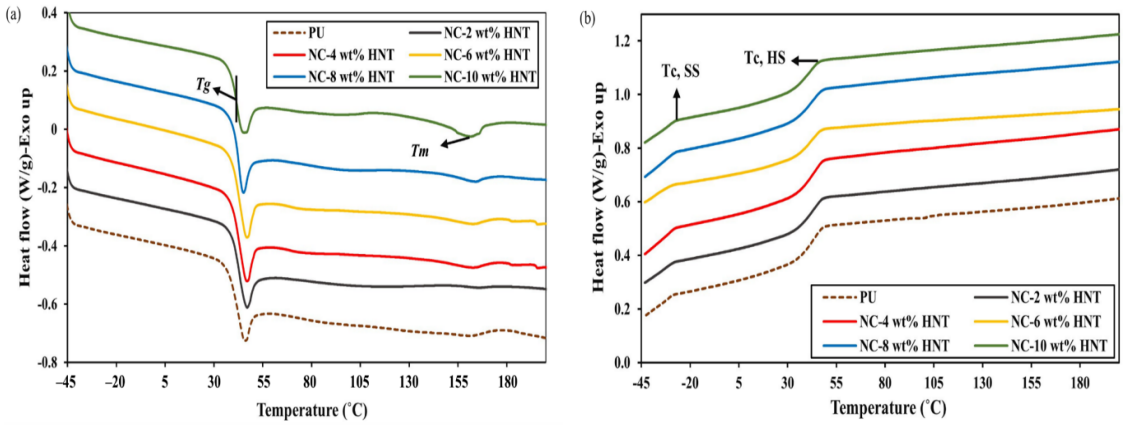

Figure 7: DSC thermograms of nanocomposite samples at various HNT contents: (a) heating process and (b) cooling process.

Material type	Sample batch	T_g (°C)	$T_{c,SS}$ (°C)	$T_{c,HS}$ (°C)	T_m (°C)	ΔH_m (J/g)	ΔH_c (J/g)	χ_c (%)
Neat PU	PU	40.96	–31.05	47.66	161.32	4.34	0.37	2.84
2 wt% HNT	NC-2 wt% HNT	42.44	–30.12	48.44	166.16	4.26	0.34	2.85
4 wt% HNT	NC-4 wt% HNT	42.56	–29.88	49.36	163.32	5.18	0.64	3.38
6 wt% HNT	NC-6 wt% HNT	42.35	–28.56	49.43	163.04	6.23	0.43	4.41
8 wt% HNT	NC-8 wt% HNT	41.57	–28.07	48.42	164.03	6.43	0.49	4.61
10 wt% HNT	NC-10 wt% HNT	41.28	–27.24	48.04	161.78	6.68	0.53	4.89

ΔH_m and ΔH_c denote the heat of fusion and heat of crystallization of neat PU and PU/HNT nanocomposites respectively.

Table 8: DSC thermal properties for neat PU and PU/HNT nanocomposites.

4 CONCLUSIONS

This study presented holistic evaluation of HNT addition on NPR, shape memory behaviour and thermal stability of 3D printed PU/HNT nanocomposites. In general, the presence of HNTs in PU matrices could promote shape fixity ratio of PU/HNT nanocomposites despite slight drop in both shape recovery ratio and NPR, along with prolonged recovery time. The presence of 10 wt% HNTs within PU matrices improved shape fixity ratio of PU/HNT nanocomposites up to 12% though a slight decrease occurred in shape recovery ratio (9%) and NPR (60%), along with prolonged recovery time by 45%. They might have great commercial potential as a shape-memory shock absorber in the future.

The inclusion of HNTs enhanced thermal stability of PU/HNT nanocomposites, which was indicative of their relatively high decomposition temperatures. It could be associated with thermal barrier effect of HNTs to postpone the degradation of PU hard segments. Furthermore, an entrapping mechanism of HNT lumens played a significant role in increasing thermal stability of nanocomposite samples. Finally, the incorporation of HNTs also elevated T_g, T_m, T_c and χ_c due to much better covalent bonding, microphase separation and nucleating effect of HNTs in addition to evident mobility restriction of PU molecules.

04. Conclusion

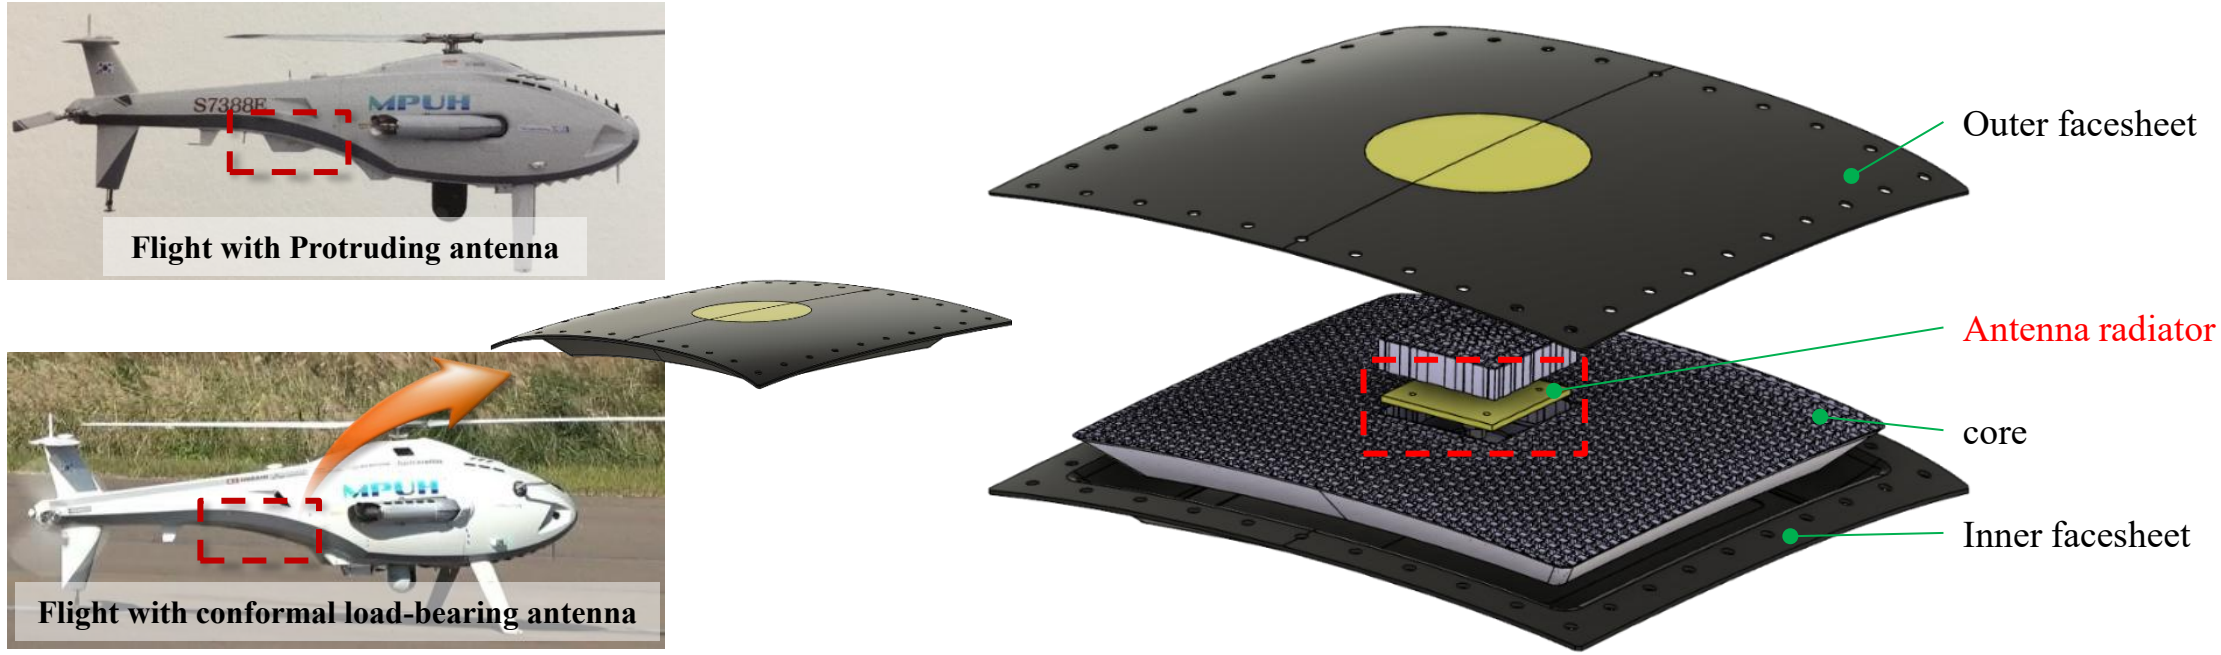
01. Introduction

1. Research background
2. Research purpose

Research background

❖ CLAS (Conformal Load-bearing Antenna Structure)

- **What is Conformal Load-bearing Antenna Structure (CLAS) ?**
  - Next-generation antenna integrated into the aircraft's Outer Mold Line (OML)
  - Replaces protruding antennas for improved aerodynamics
- Composed of multiple parts, including an antenna radiator for signal transmission and reception



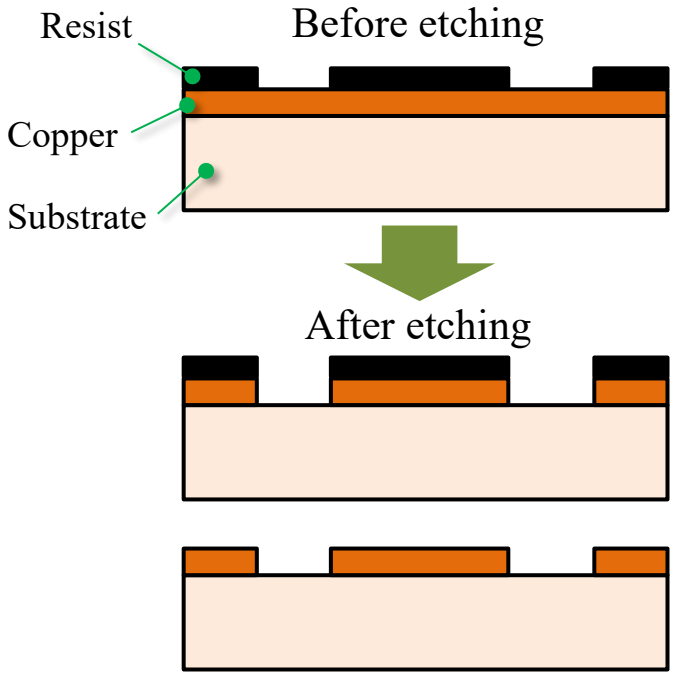


Fig. 1. Schematic of Conformal load bearing antenna structure (CLAS).

Research background

❖ Antenna radiator and limitations of conventional antenna fabrication

- Traditional antenna fabrication is limited by substrate type and shape
- **CLAS often follows curved aircraft surfaces (OML), requiring non-flat substrates**

  → Growing need for antennas on curved or complex geometries
- Direct Ink Writing (DIW) offers a flexible solution for conformal antenna fabrication

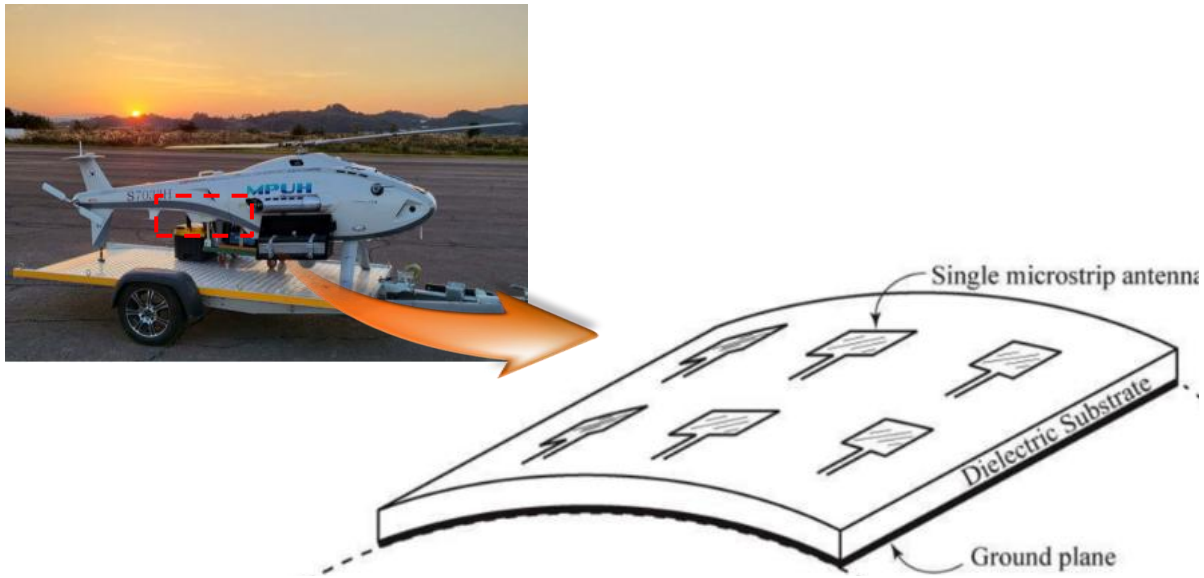

Fig. 2. Copper etching microstrip antenna.

Research background

❖ DIW (Direct Ink Writing) Process [1-7]

- **What is Direct Ink Writing (DIW)?**
  - A type of 3D printing that directly deposits ink onto a substrate
- Enables multifunctional structures using application-specific materials
- Compatible with various substrate shapes, including flat and curved surfaces

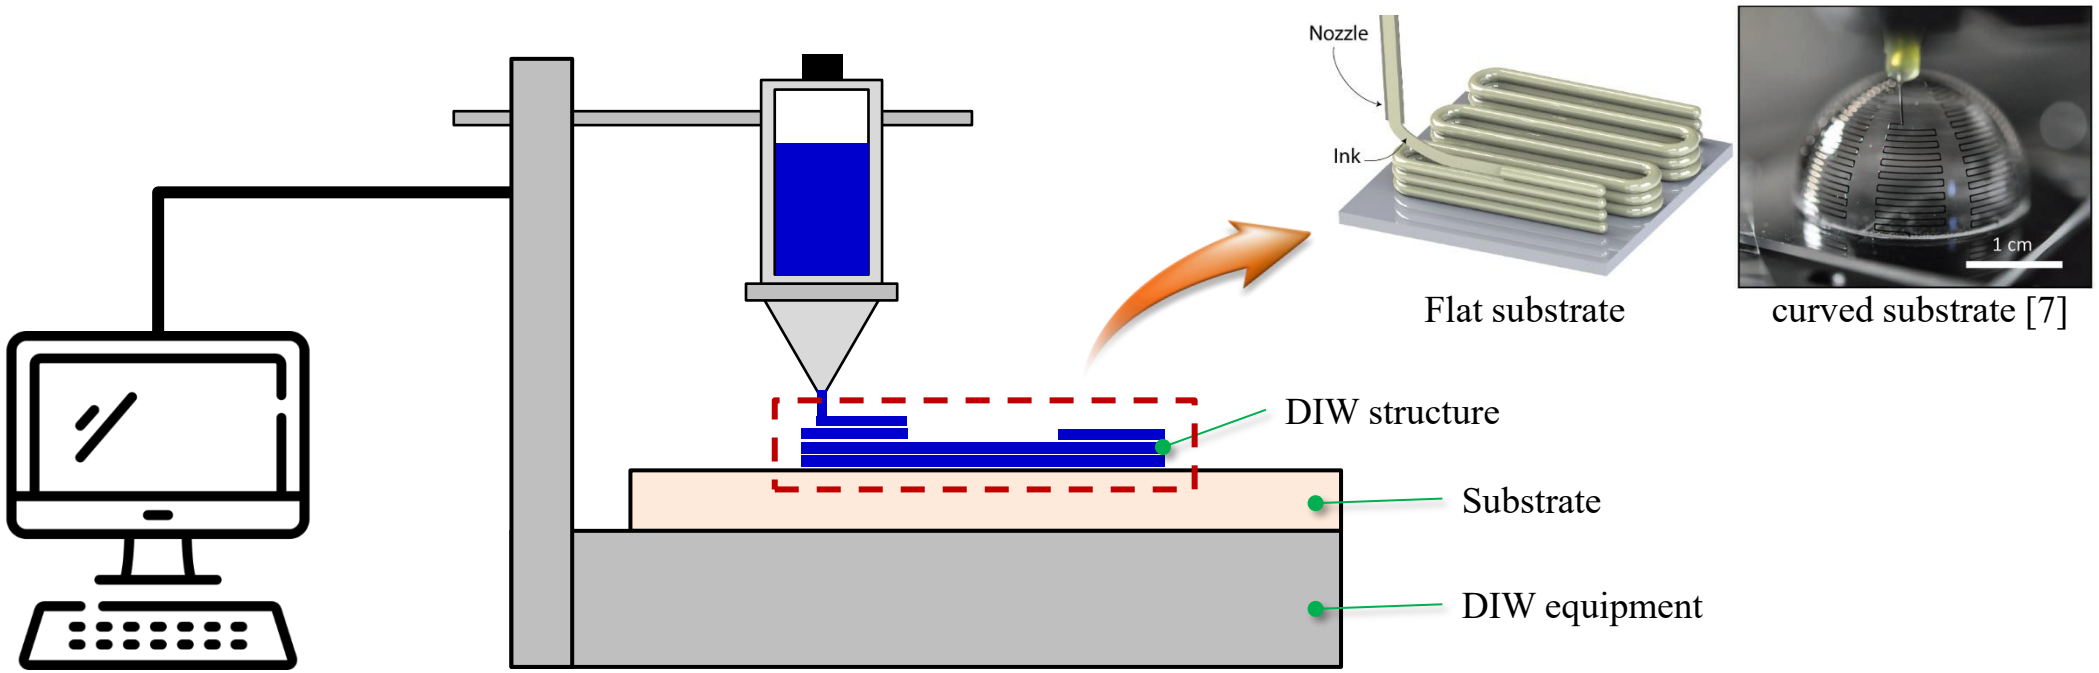

Fig. 3. Schematic of Direct ink writing (DIW) fabrication process.

Research background

❖ Research trends in DIW process

➢ Skylar-Scott et al., PNAS, 2016

- Demonstrated laser-assisted DIW
- Using Silver nanoparticle ink
- Enabled 3D printing without separate sintering

➢ Asrar Alam et al., J. Energy Storage, 2022

- Developed Ag/TiO_2 nanoparticle composite ink
- Electrode material for high-performance supercapacitors
- Cured at 60 °C for 24 hours without sintering

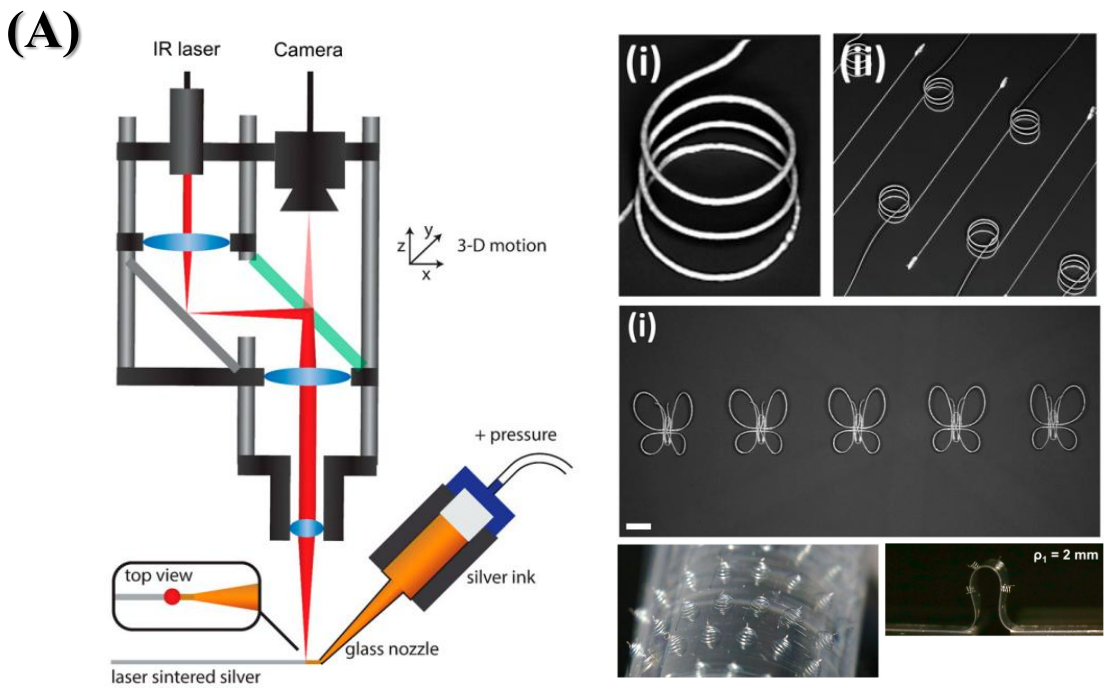

Fig. 4. DIW fabrication process research trends: (A) 2016, PNAS, (B) 2022, J Energy storage.

Research purpose

❖ Study on CLAS with DIW antenna radiator

- **Design requirements for printed antenna radiator patterns**
  - Targeting resonant frequency and bandwidth suitable for structural reliability and operational conditions
- Development and performance evaluation of DIW-based antennas for integration
- Investigation of printed antenna implementation in conformal load-bearing structures

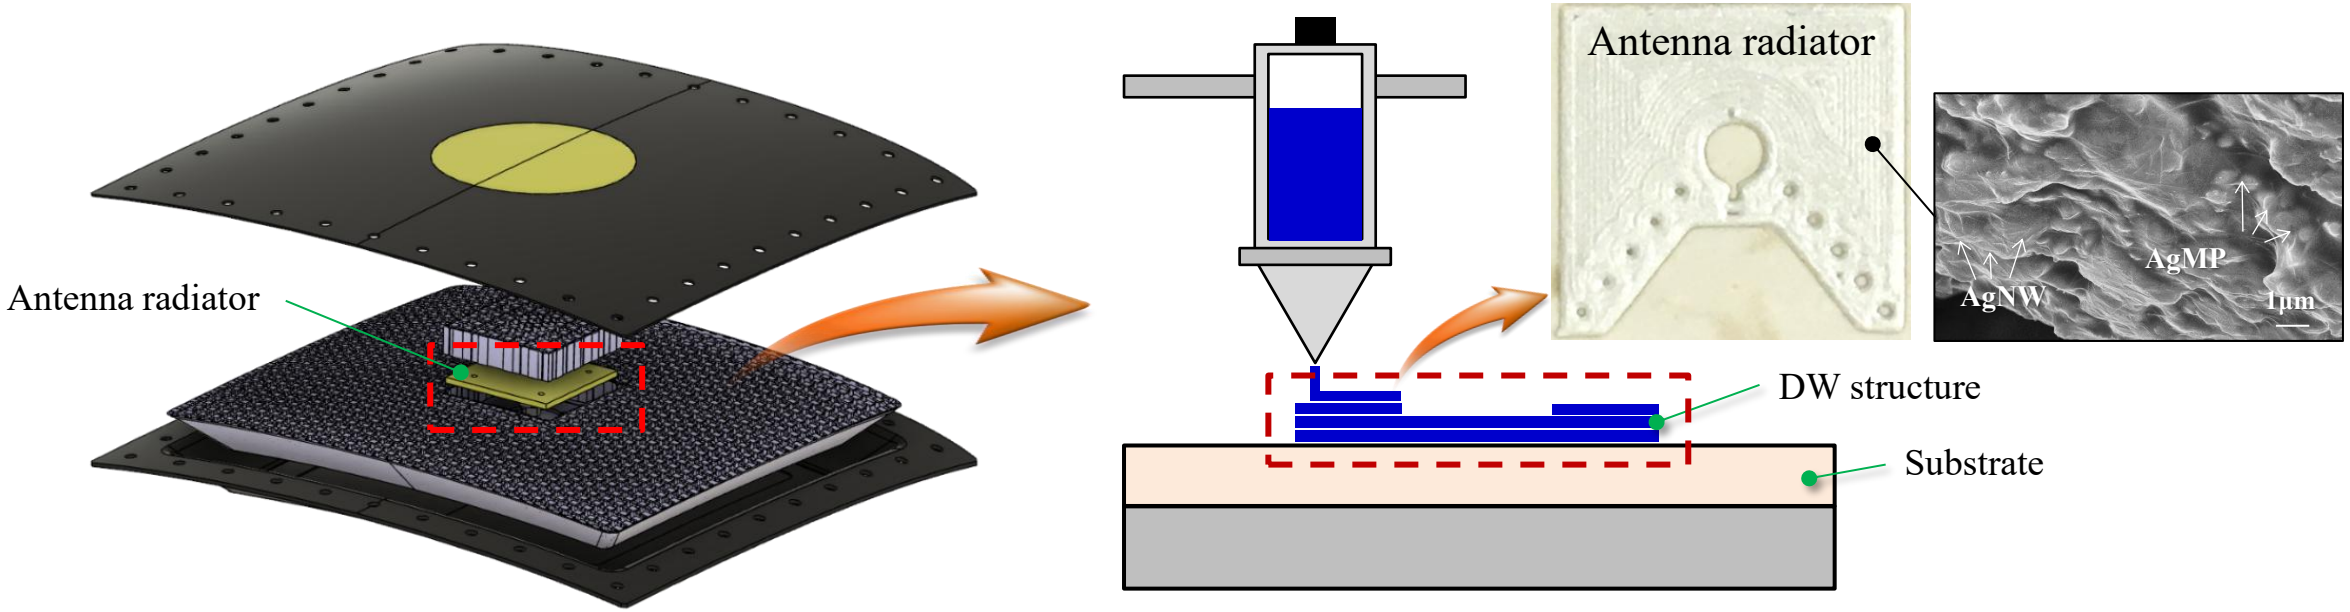

Fig. 5. Research purpsose.

02. DIW antenna radiator fabrication and evaluation

1. Development of Materials and Process
2. Fabrication and evaluation of DIW antenna

Development of DIW Materials and Process

❖ Selection of materials for DIW antenna radiator

- Silver Microparticle Paste (AgMP, ACH35001LV, Protavic Korea)

  → Ensures strong adhesion to substrate

- Silver Nanowires (AgNW, C3NW02, C3nano, USA)

  → Enhances electrical conductivity of printed patterns

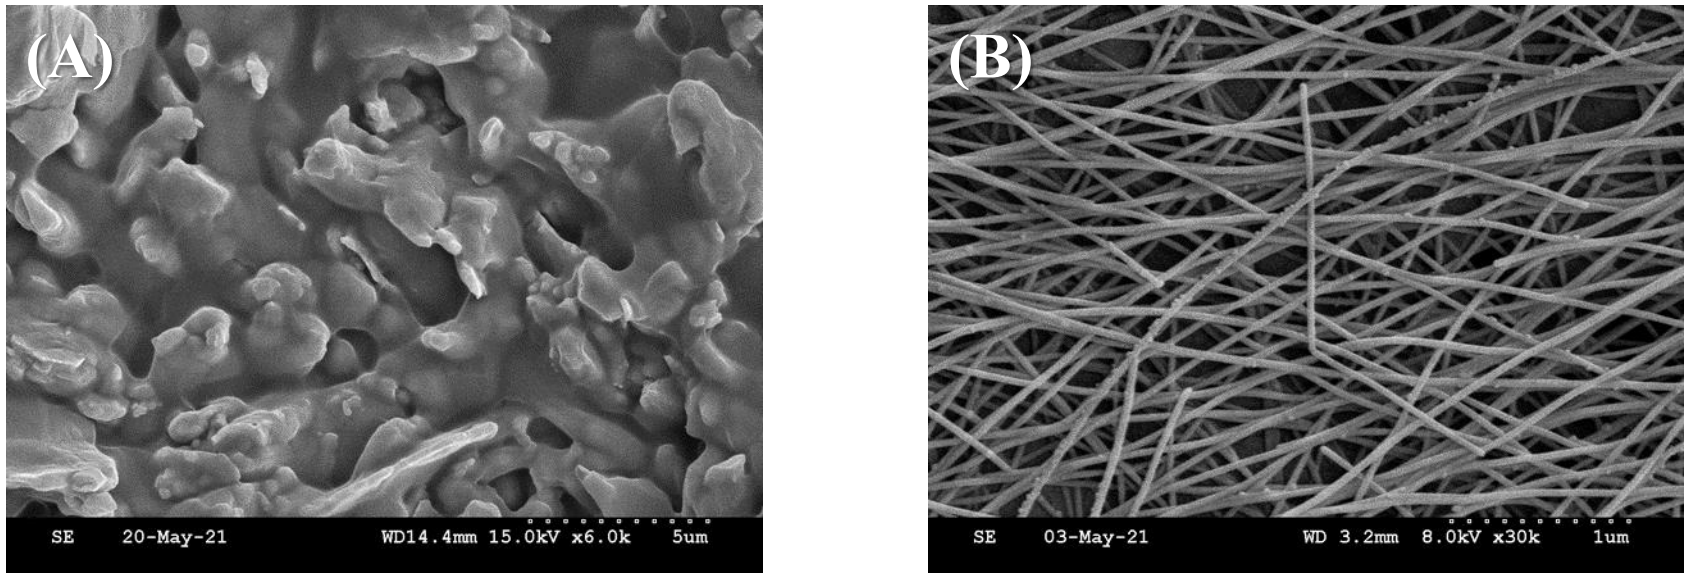

Fig. 6. SEM image of DIW composition materials: (A) AgMP, (B) AgNW.

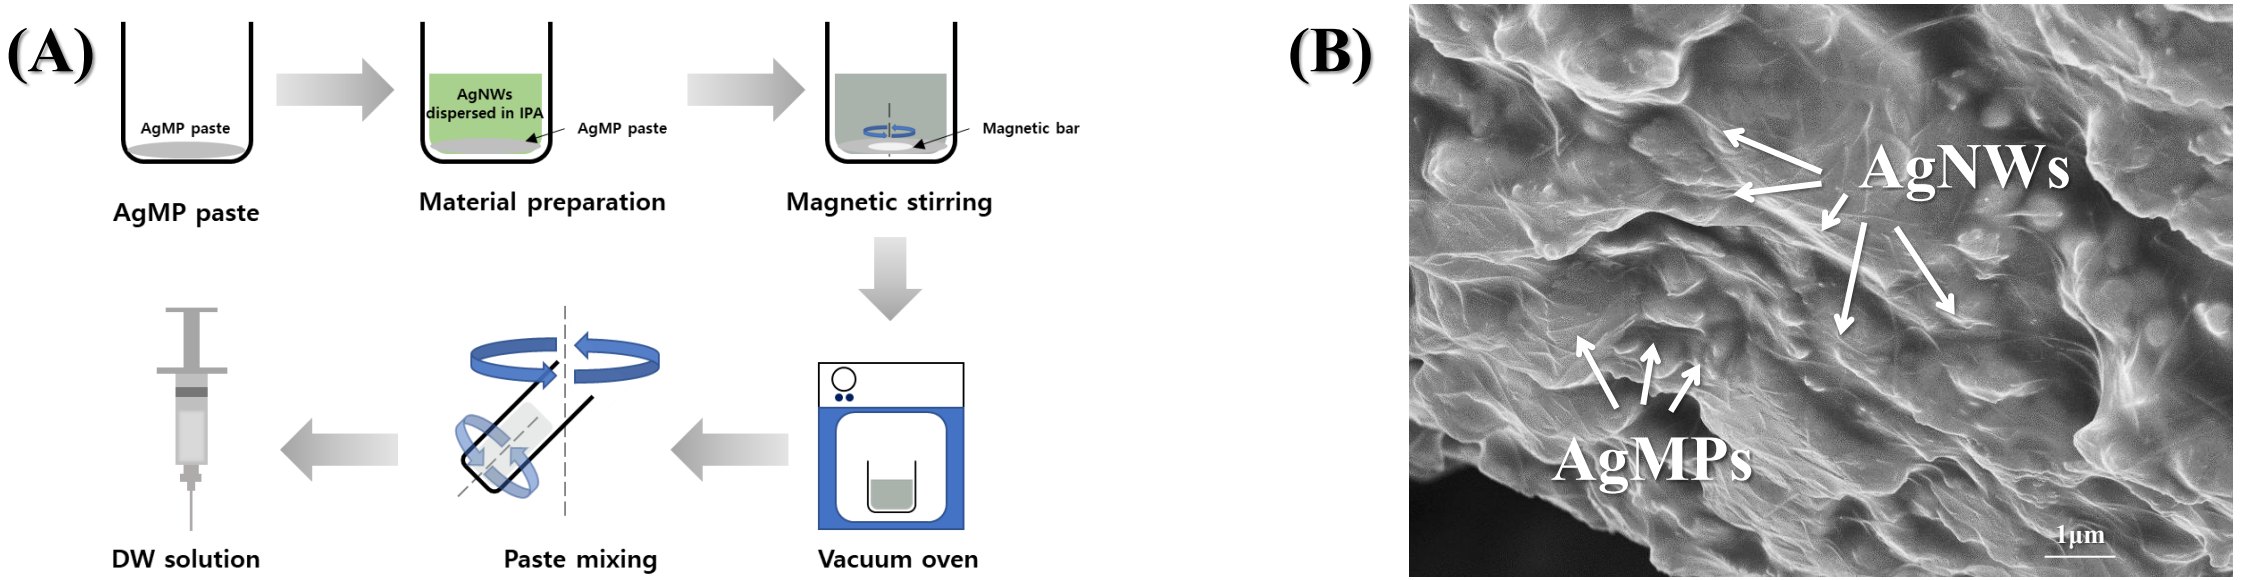
Development of Materials and Process

❖ Development of DIW antenna radiator material

- **Development and Application of DIW Material Fabrication Method Based on IPA Content Control**
  - AgNP paste and AgNW solution were mixed for 45 minutes
  - IPA was evaporated using a vacuum oven
  - After vacuum processing, a paste mixer was used to uniformly disperse AgMP and AgNW
- The material containing **1.2 wt%$_{AgNW}$ (σ_{elec}= 4.16 (±0.38)×10^{5}S/m)** was used.



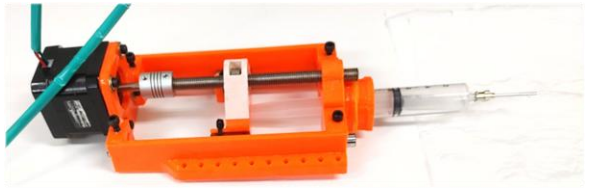


Fig. 7. (A) DIW material manufacturing technique based on IPA content control method, (B) SEM image of DIW material.

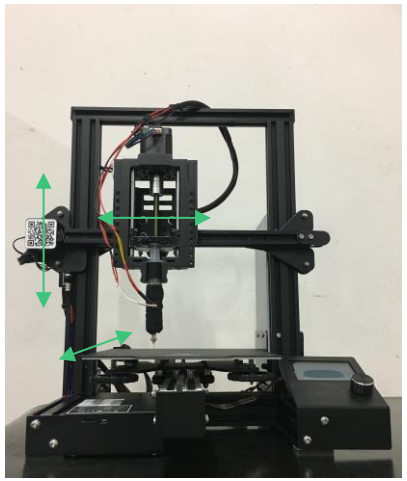
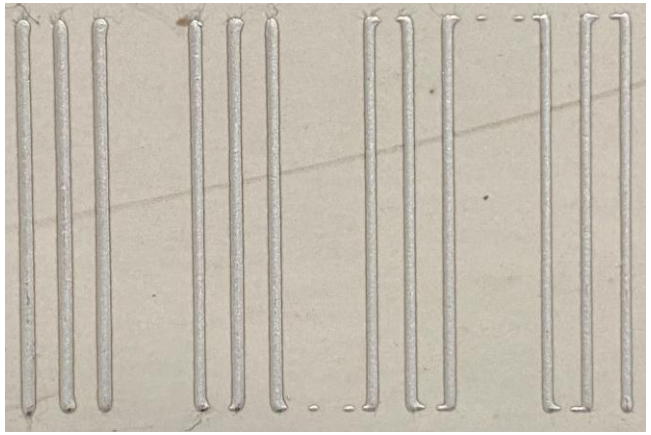


Development of Materials and Process

❖ Development of DIW antenna radiator manufacturing process



- Viscosity of DIW paste was tested using a trial extrusion setup
- Extruder mounted on Ender-3 Pro (Creality, China) for 3-axis DIW printing (Fig. A)
- Controlled via display panel and G-code
- Verified stable and consistent print quality (Fig. B)

(A)

(B)

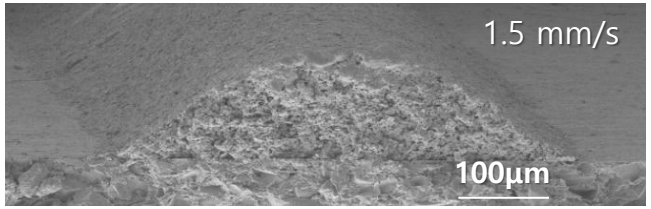


Fig. 8. (A) Extruder for testing and DIW equipment, (B) image of DIW line.

Fabrication and evaluation of DIW antenna

❖ DIW Antenna Pattern Design and Fabrication

- Designed for resonance frequency (f_R) of 5.03 GHz based on copper conductivity
- **DIW antenna pattern fabrication procedure**
  - Antenna pattern fabricated using DIW equipment and cured in an oven
  - Feed line soldered and antenna connector attached

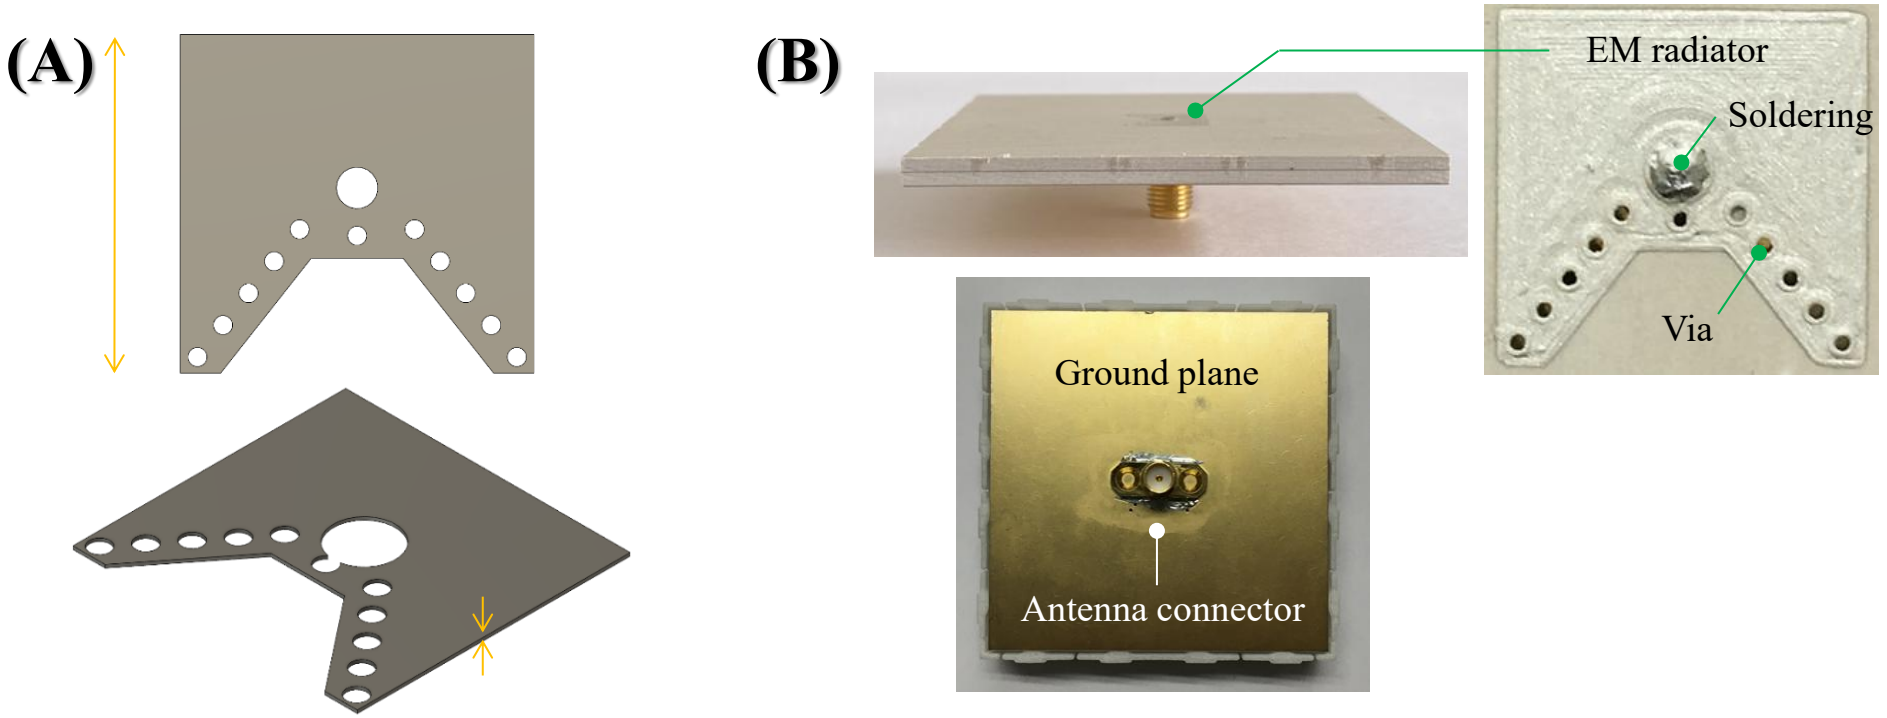

Fig. 9. (A) CAD Modeling of EM radiator, (B) manufactured DIW antenna pattern.

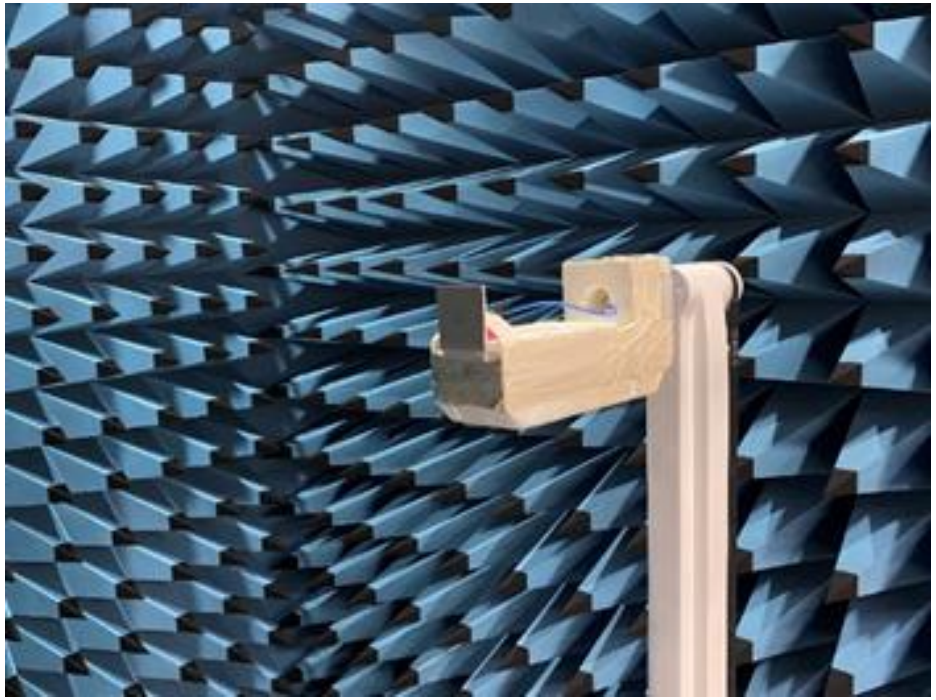
Fabrication and evaluation of DIW antenna

❖ Performance evaluation of DIW antenna radiator

- Antennas were fabricated using both copper etching and direct ink writing (DIW)
- Performance was evaluated in an anechoic chamber



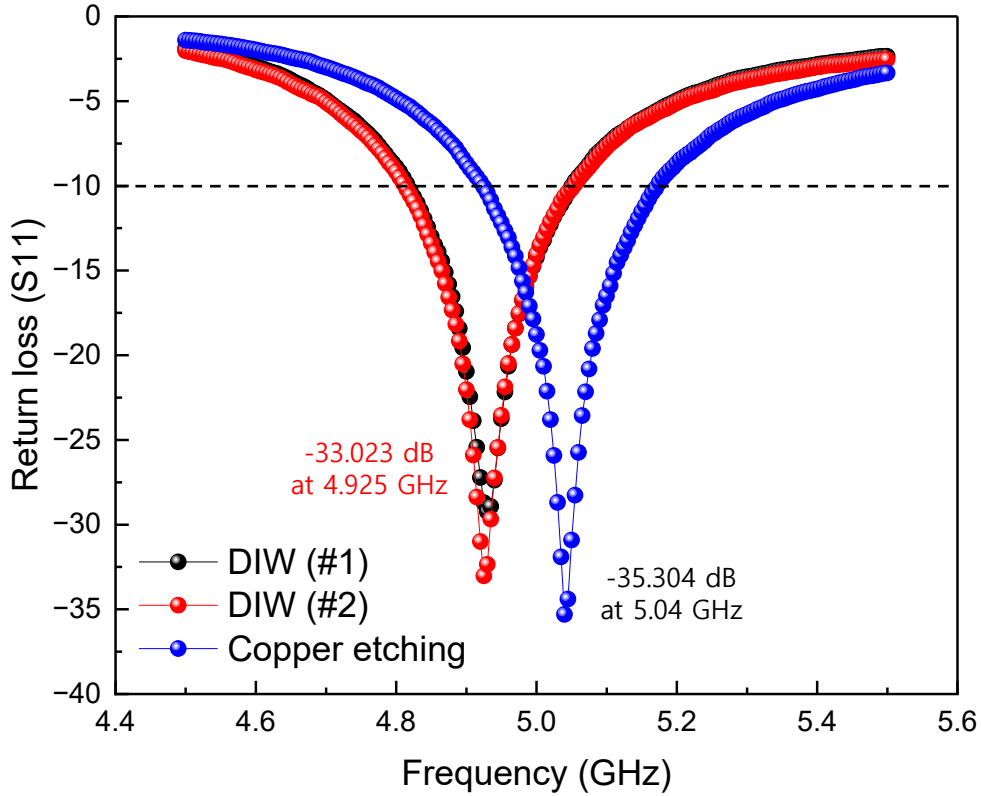


Fig. 10. Performance test of antenna fabricated DIW process on anechoic chamber.

Fabrication and evaluation of DIW antenna

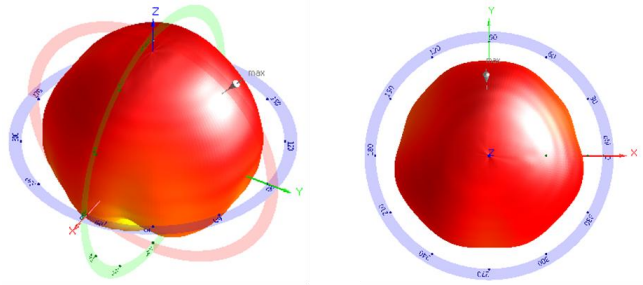
❖ Comparison of Antenna Return Loss Performance

	Resonance frequency(f_R)	Reflection loss (RL)	Bandwidth (BW)
Copper etching antenna	5.04 GHz	-35.304 dB	248 MHz
DIW antenna	**4.925 GHz**	**-33.023 dB**	**241 MHz**

Except for the resonant frequency shift,

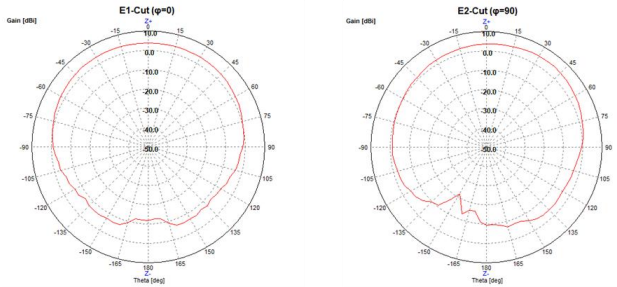
the DIW and copper-etched antennas show nearly identical performance across the frequency band

Fig. 11. Return loss of EM radiator fabricated by copper etching and DIW.



Fabrication and evaluation of DIW antenna

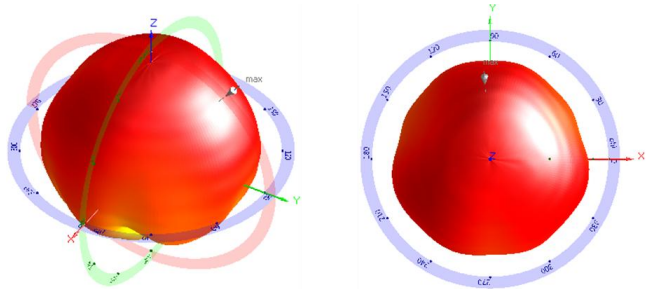
❖ Comparison of antenna gain patterns



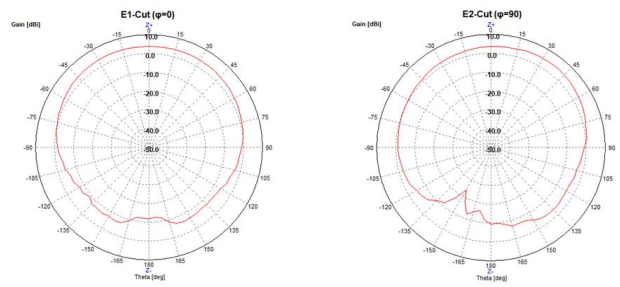
- Copper-etched and DIW antennas showed no significant difference in radiation pattern and peak gain.

→ **The DIW method demonstrated both structural flexibility and stable electrical performance.**

(A)



3D gain pattern



2D gain pattern

Gain (dBi)			Half power (3dB) beam width	
Maximum	φ = 0° Elevation Plane	φ = 90° Elevation Plane	φ = 0° Elevation Plane	φ = 90° Elevation Plane
+4.65	+3.79	+4.65	144.3°	111.8°

(B)

3D gain pattern

2D gain pattern

Gain (dBi)			Half power (3dB) beam width	
Maximum	φ = 0° Elevation Plane	φ = 90° Elevation Plane	φ = 0° Elevation Plane	φ = 90° Elevation Plane
+4.68	+3.80	+4.68	145.5°	111.2°

Fig. 12. 2D and 3D gain patterns of EM radiator: (A) copper etching antenna, (B) DIW antenna

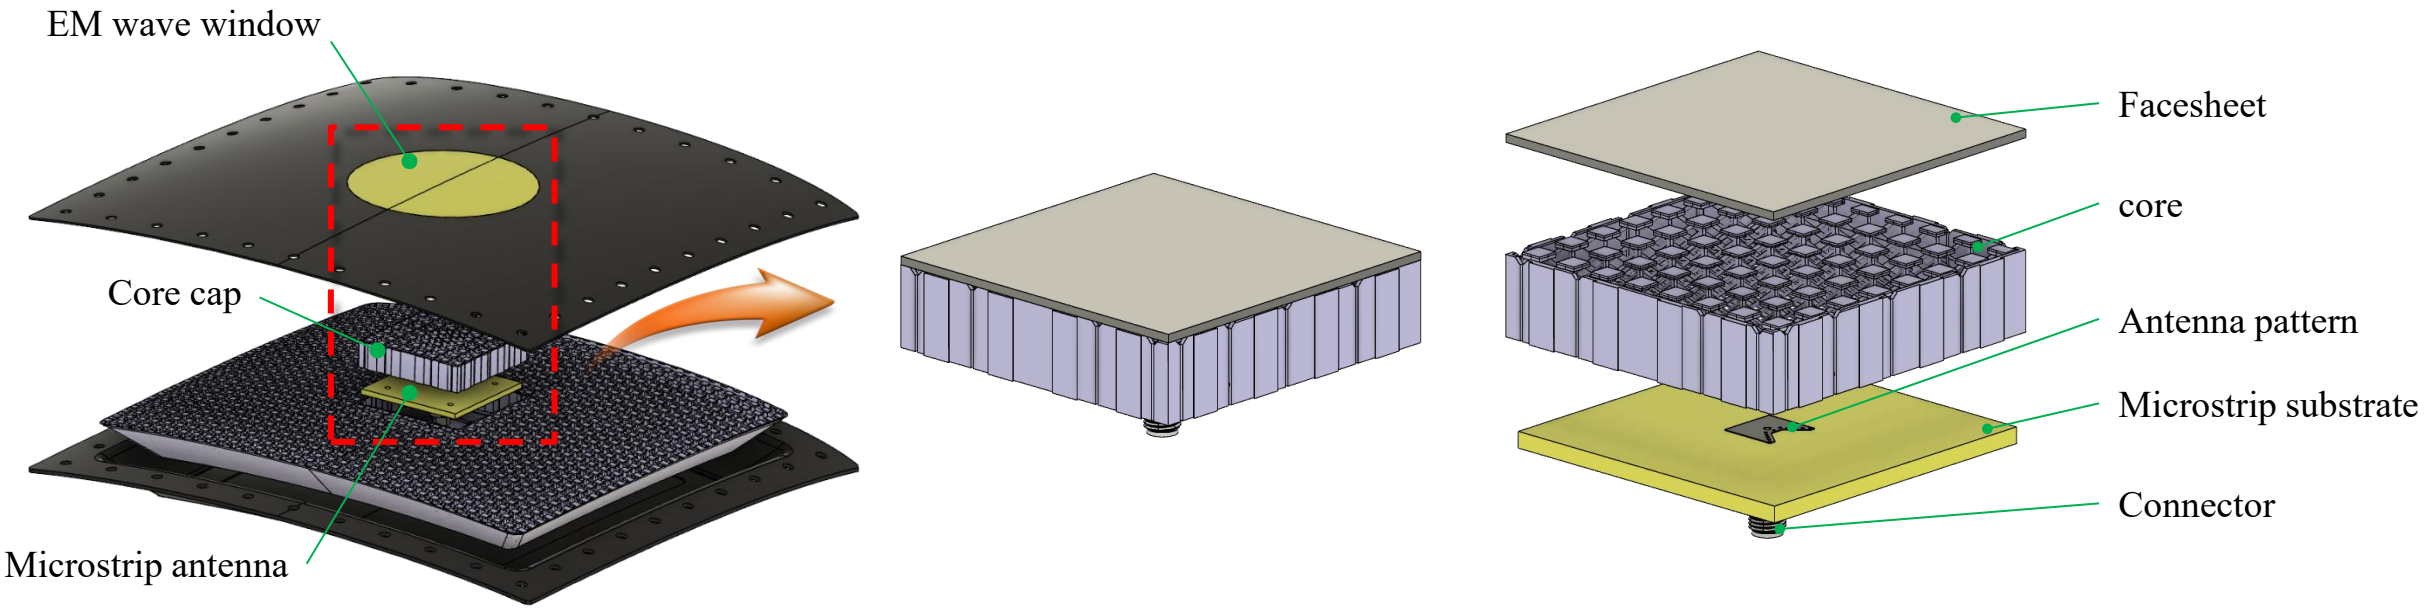
03. Integration into CLAS

1. Fabrication and Evaluation of MAS
2. Integration of DIW antenna into CLAS

Fabrication and Evaluation of MAS

❖ Design of MAS (Multifunctional Antenna Structure)

- Designed and fabricated a Multifunctional Antenna Structure (MAS)
- Structure composed of facesheet, core, and DIW antenna radiator
- Investigated effects of dielectric loading



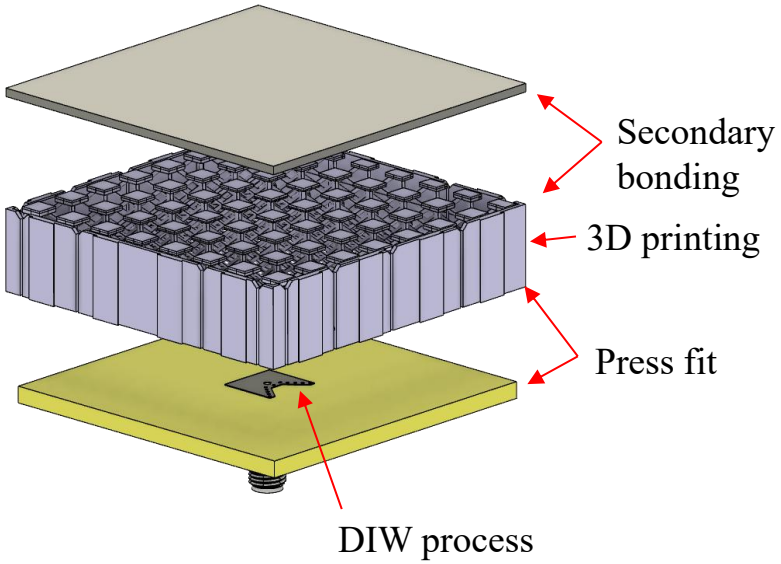


Fig. 13. Schematic of multifunctional antenna structure (MAS).

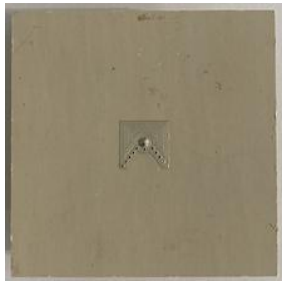
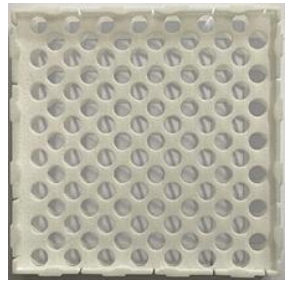
Fabrication and Evaluation of MAS

❖ Components and fabrication of MAS

- Facesheet : RT/duroid®6002 (Rogers corporation, USA)
- Sandwich core : Duraform ProX PA (3D system, USA) (Selective laser sintering, SLS)
- Adhesive film : AF 163-2K (3MTM, Scotch-WeldTM, USA)





- Top view -

- Side view -

- Bottom view -

- core (Top) -

- Microstrip antenna -

- core (Bottom) -

- Microstrip antenna (Side view) -

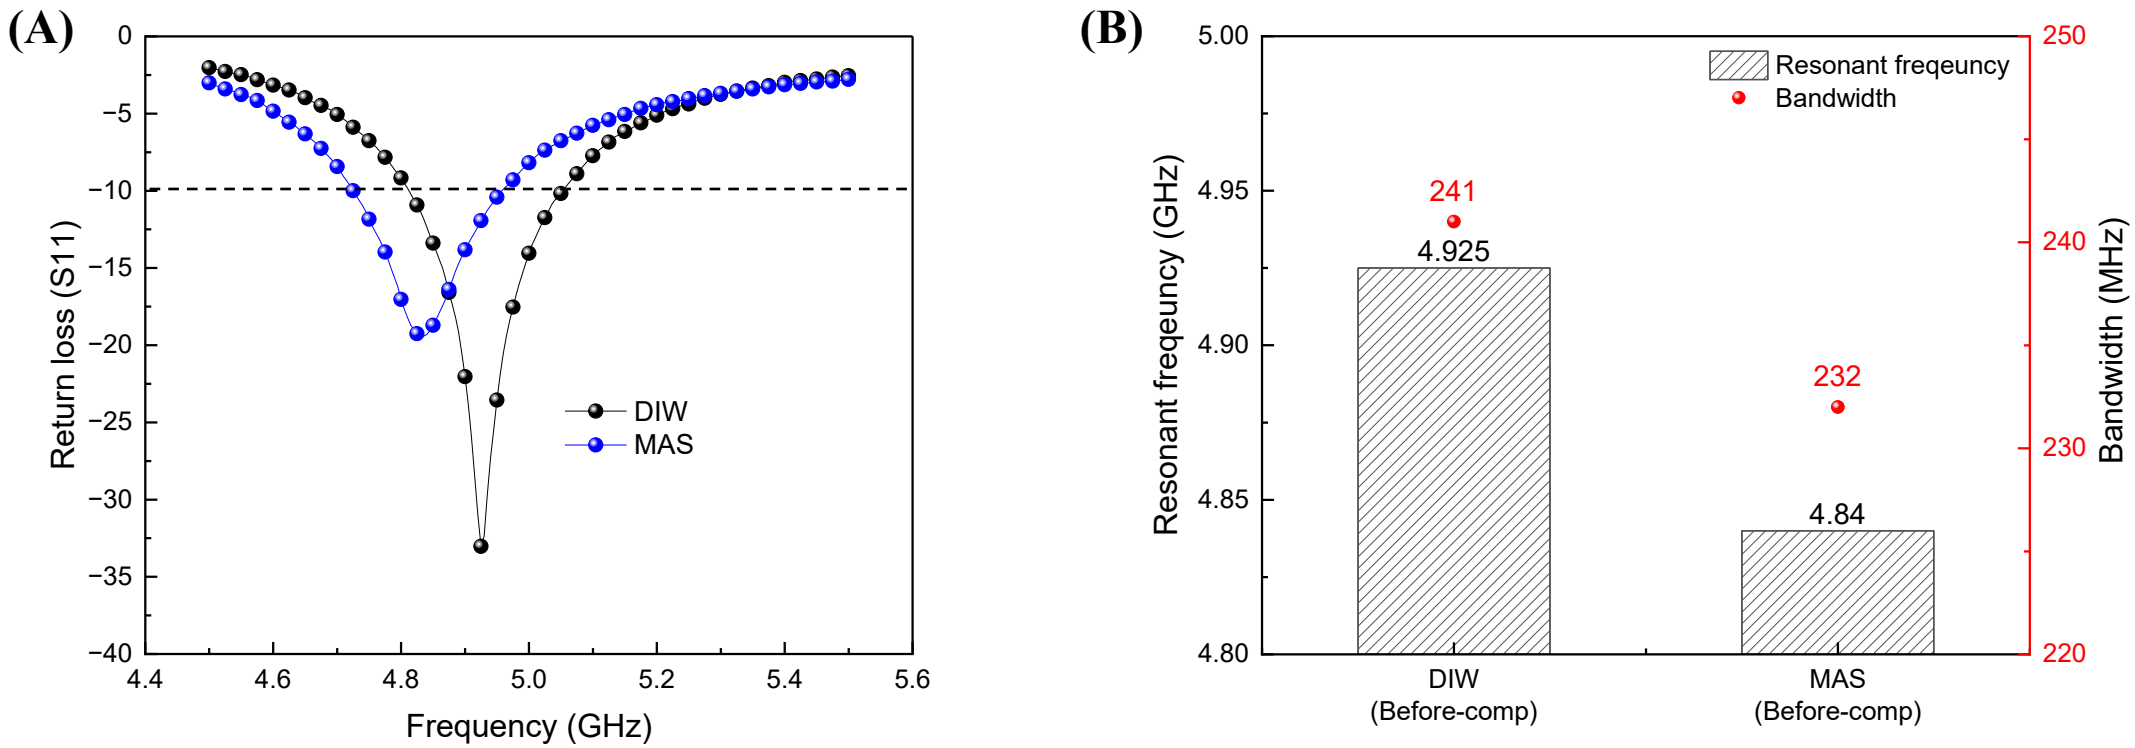
Fig. 14. Components and fabrication of multifunctional antenna structure (MAS).

Fabrication and Evaluation of MAS

❖ Comparison of antenna performance evaluation

	Resonance frequency(f_R)	Reflection loss (RL)	Bandwidth (BW)
DIW	4.925 GHz	-33.02 dB	241 MHz
MAS	4.840 GHz	-20.51 dB	232 MHz

DIW → MAS
f_R = 4.925 GHz → 4.840 GHz
※ Effect of Dielectric loading



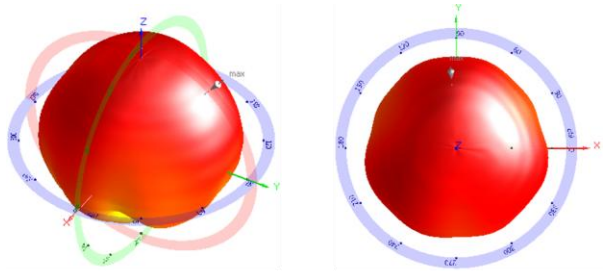


Fig. 15. Antenna performance results: (A) return loss, (B) resonant frequency and bandwidth.

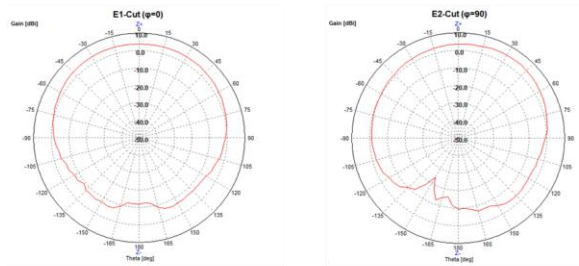
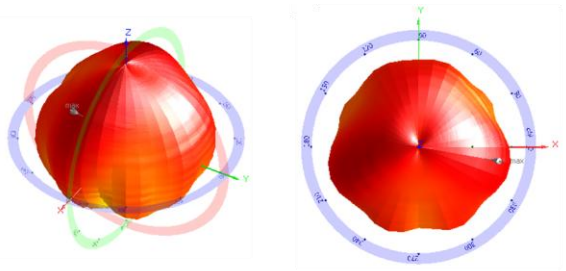
Fabrication and Evaluation of MAS



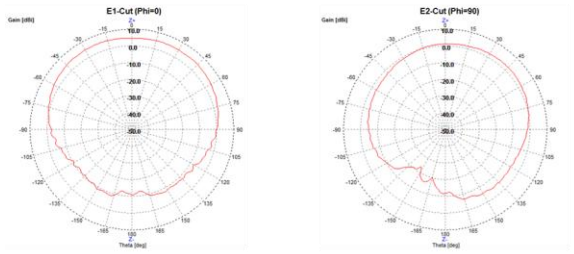
❖ Comparison of antenna performance evaluation

- Gain pattern and beamwidth remained similar with and without MAS integration
- A shift in resonant frequency was observed due to dielectric loading
- With frequency adjustment, the antenna can be used in CLAS with comparable performance

(A)



3D gain pattern



2D gain pattern

Gain (dBi)			Half power (3dB) beam width	
Maximum	φ = 0° Elevation Plane	φ = 90° Elevation Plane	φ = 0° Elevation Plane	φ = 90° Elevation Plane
+4.68	+3.80	+4.68	145.5°	111.2°

(B)

3D gain pattern

2D gain pattern

Gain (dBi)			Half power (3dB) beam width	
Maximum	φ = 0° Elevation Plane	φ = 90° Elevation Plane	φ = 0° Elevation Plane	φ = 90° Elevation Plane
+4.95	+4.95	+2.38	145.1°	107.1°

Fig. 16. 2D and 3D gain patterns of EM radiator (A) DIW antenna, (B) MAS.

Integration of DIW antenna into CLAS

❖ Fabrication of CLAS with DIW antenna radiator

- Antenna-integrated structure fabricated using a directly printed radiator
- Structure composed of Outer facesheet, Core, Antenna radiator, Inner facesheet
- Verified feasibility of applying the printed radiator to the integrated structure

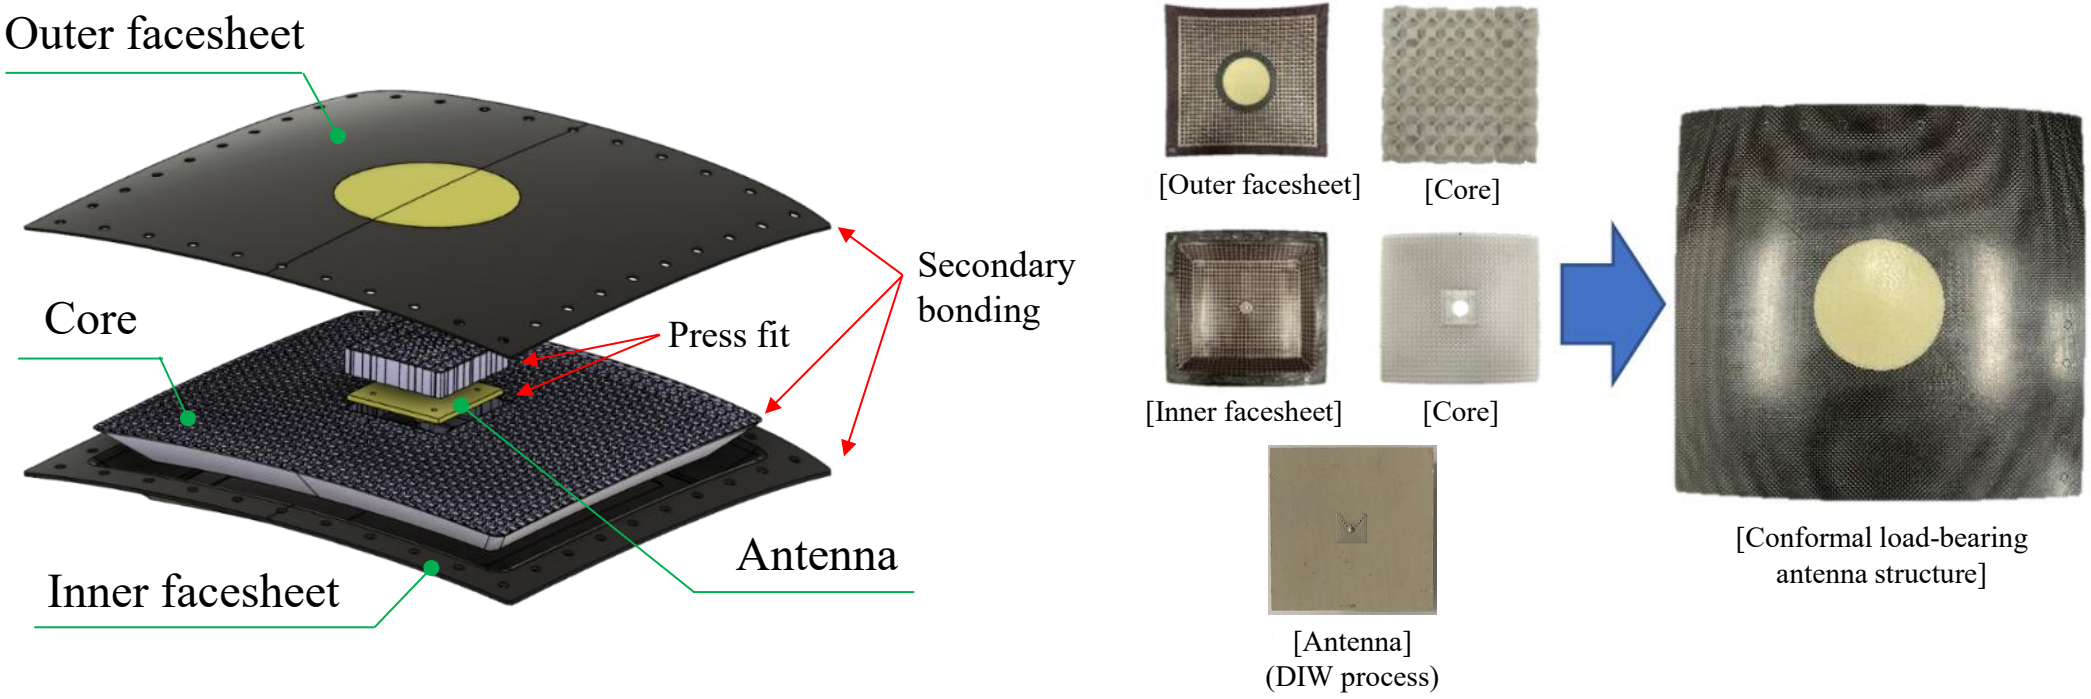


Fig. 17. Fabricated DIW process antenna applied CLAS.

Integration of DIW antenna into CLAS

❖ Fabrication of CLAS with DIW antenna radiator

5.3 GHz	f_R	RL	BW
DIW	5.035 GHz	-44.58 dB	250 MHz
CLAS	4.83 GHz	-29.01 dB	315 MHz

5.4 GHz	f_R	RL	BW
DIW	5.275 GHz	-35.42 dB	290 MHz
CLAS	5.1 GHz	-16.31 dB	290 MHz

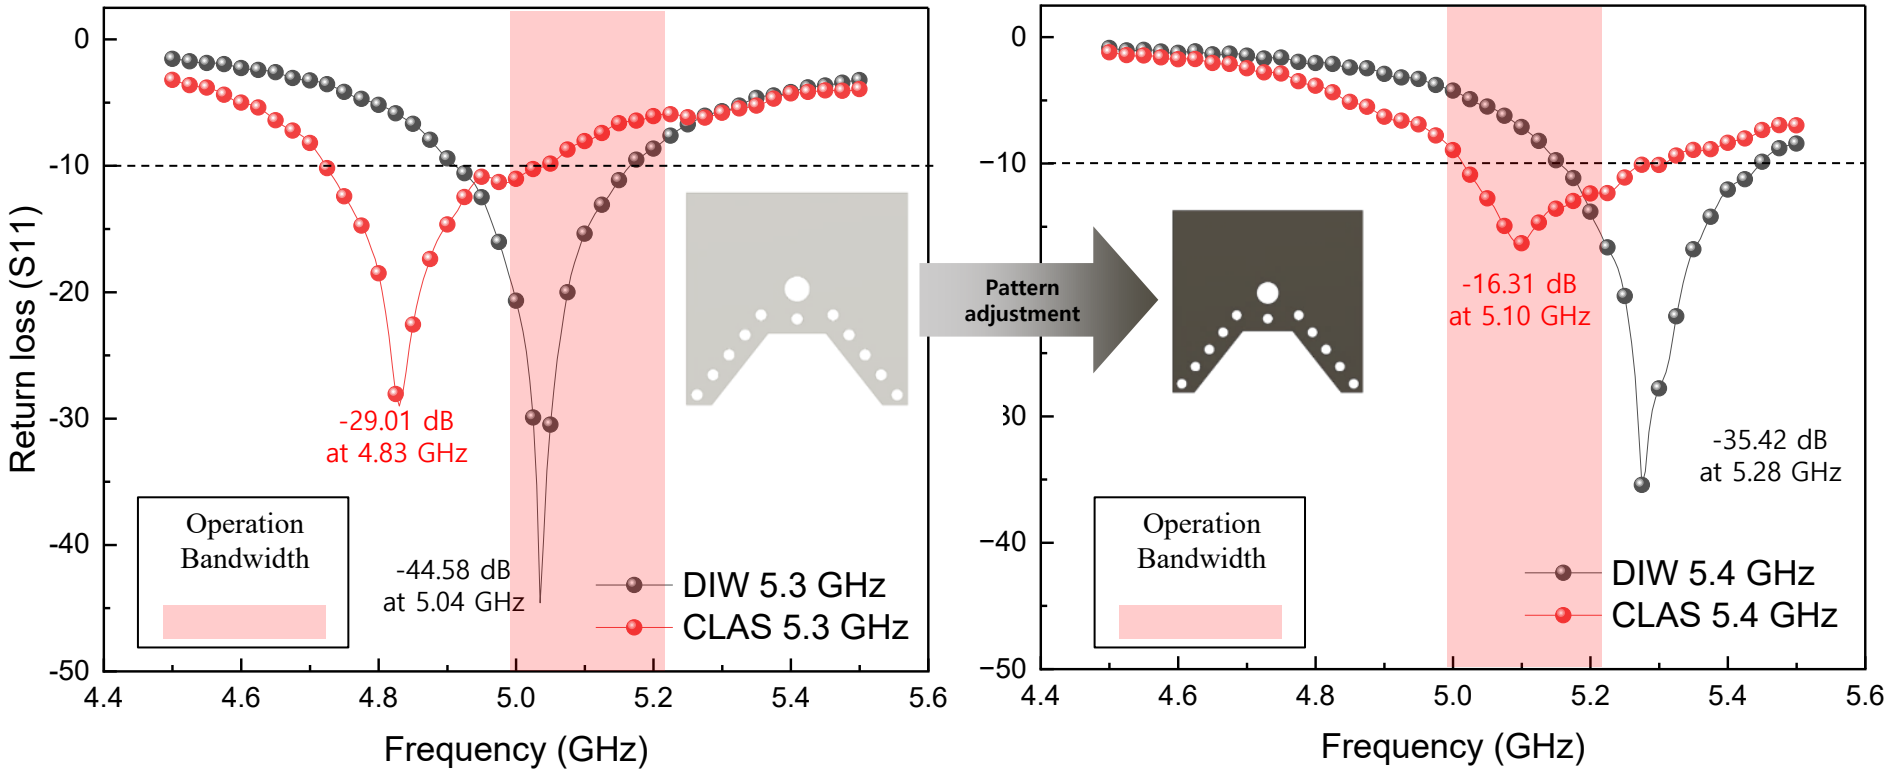

Fig. 18. Antenna performance results according to DIW antenna pattern adjustment

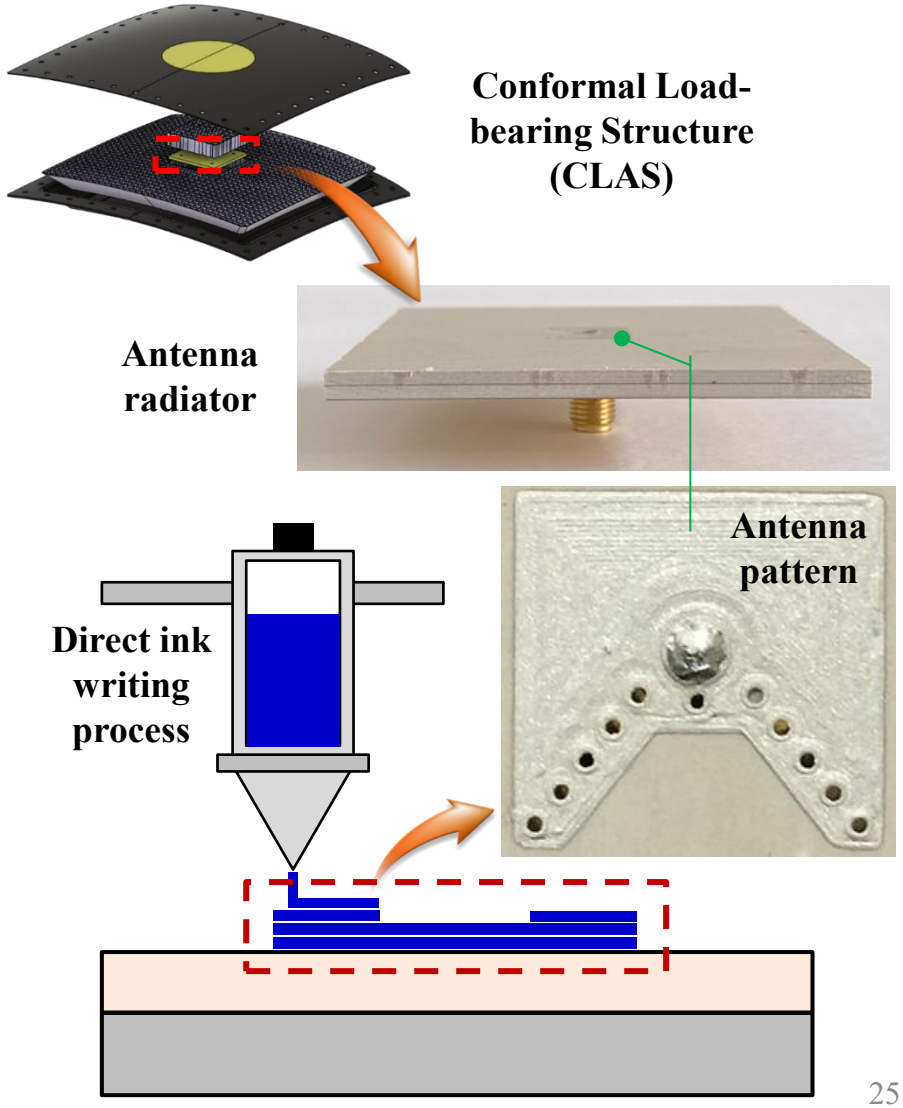

04. Conclusion

Conclusion

❖ Direct Ink Writing antenna radiator for Conformal Load-bearing Antenna Structure

- **DIW Antenna Fabrication and Application to CLAS**
  - ✓ Developed a high-conductivity nanocomposite material for DIW antennas
  - ✓ Established a DIW fabrication process for antenna patterning
  - ✓ Verified the effect of dielectric loading (resonant frequency shift)
  - ✓ Achieved CLAS performance within the target frequency band
  - ✓ Confirmed the feasibility of applying DIW antennas to CLAS

➢ **This approach enables lightweight, conformal, and multifunctional antenna integration for future aerospace systems**

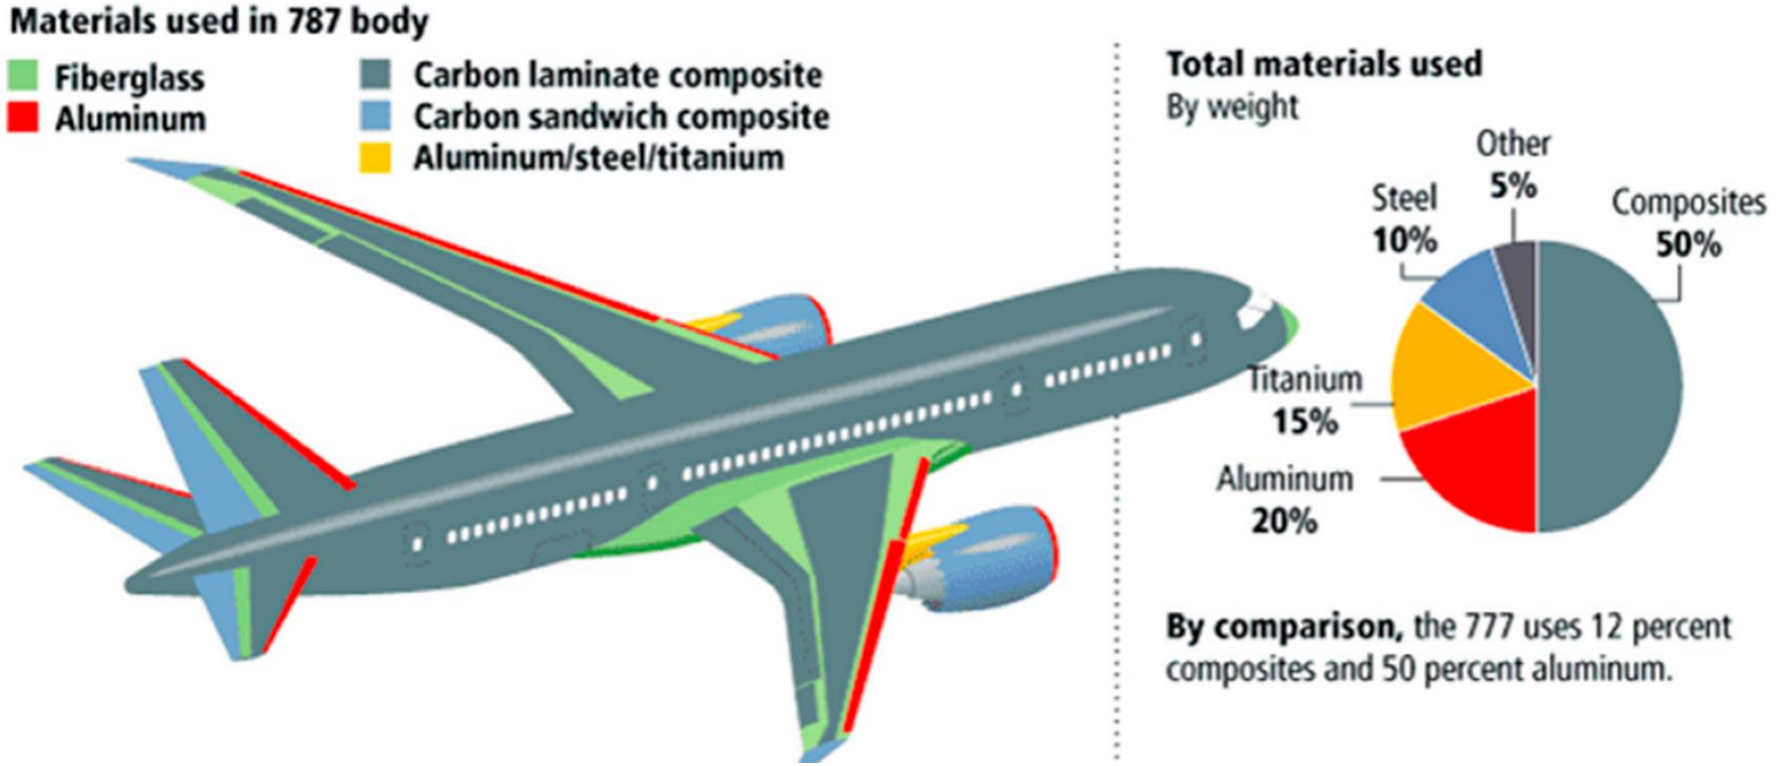
PEEK-Based Polymer Electrolyte with Tailored Morphology for Structural Battery Composites

Mia Carrola, Amir Asadi, Ahmad Amiri, Zhenning Yu, Hilmar Koerner

24th International Conference on Composite Materials



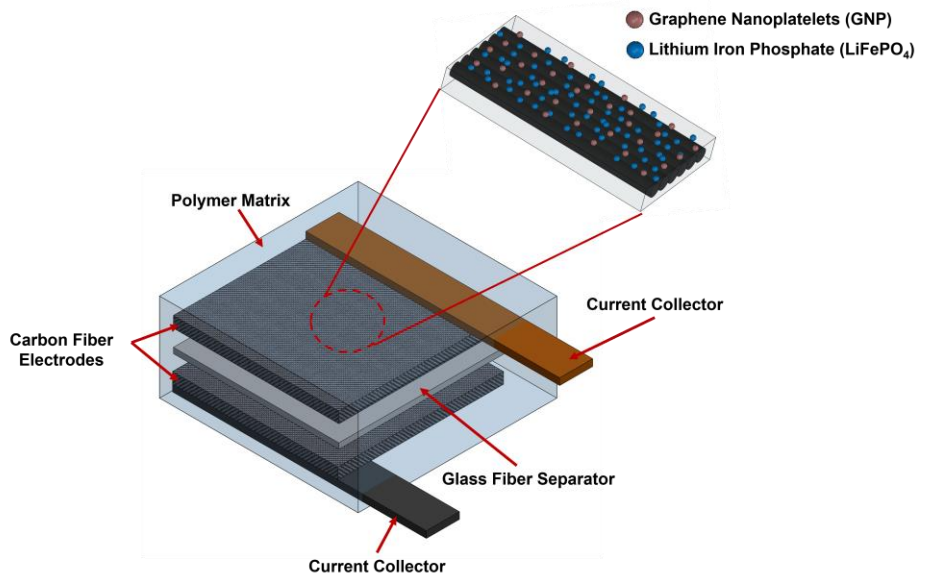
Baltimore, Maryland August 2025

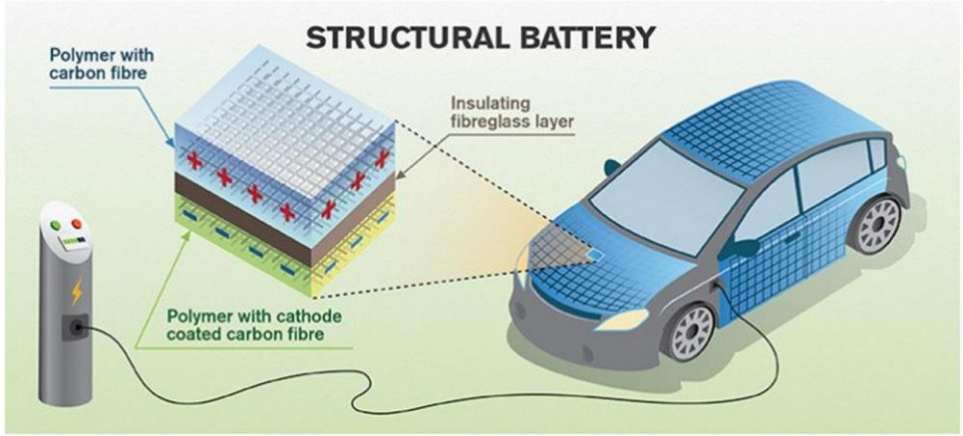
Introduction to Structural Battery Composites

- 1915: First all-metal aircraft
- 1930s: Transition from steel to aluminum
- 1950s: Integration of exotic metals
- 1970s–80s: Fiberglass takes off
- 1990s - Present: Carbon fiber increases in popularity

Parveez, Bisma, et al. "Scientific advancements in composite materials for aircraft applications: a review." *Polymers* 14.22 (2022): 5007.

Introduction to Structural Battery Composites



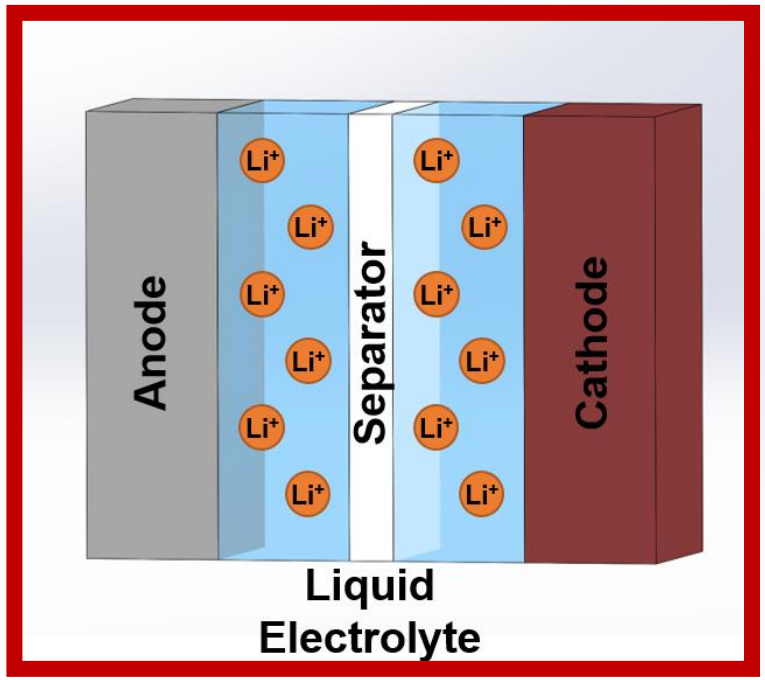


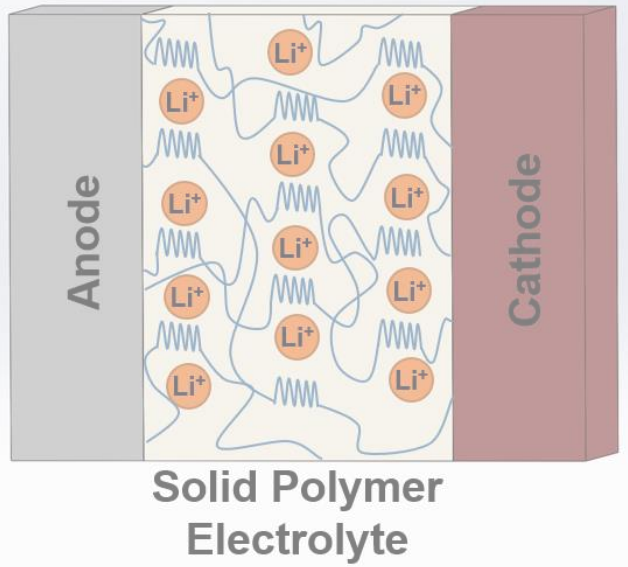
How can we enable the future of composites?

Airbus, Aviation's material evolution, 2017

Introduction to Structural Battery Composites

- Carbon Fiber:
  - Stiffness and Strength
  - Electrode
  - Current Collector
- Polymer Matrix:
  - Binder and Load Transfer
  - Solid Electrolyte



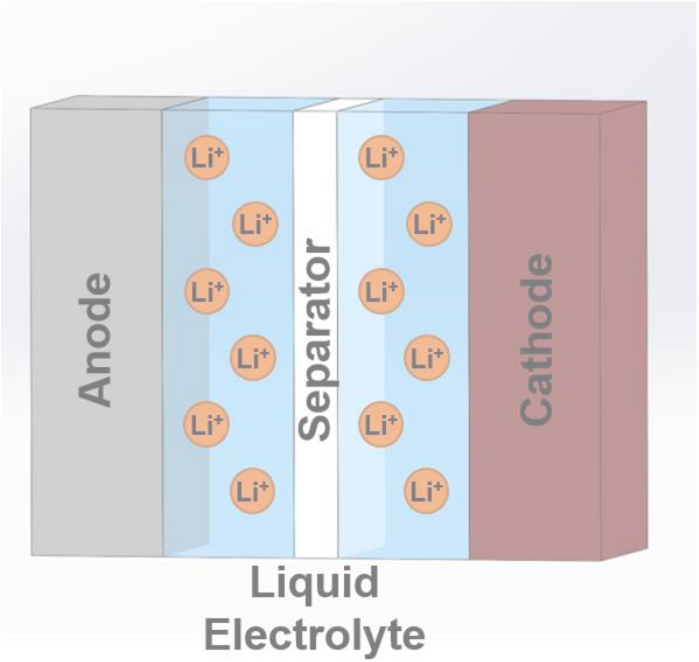


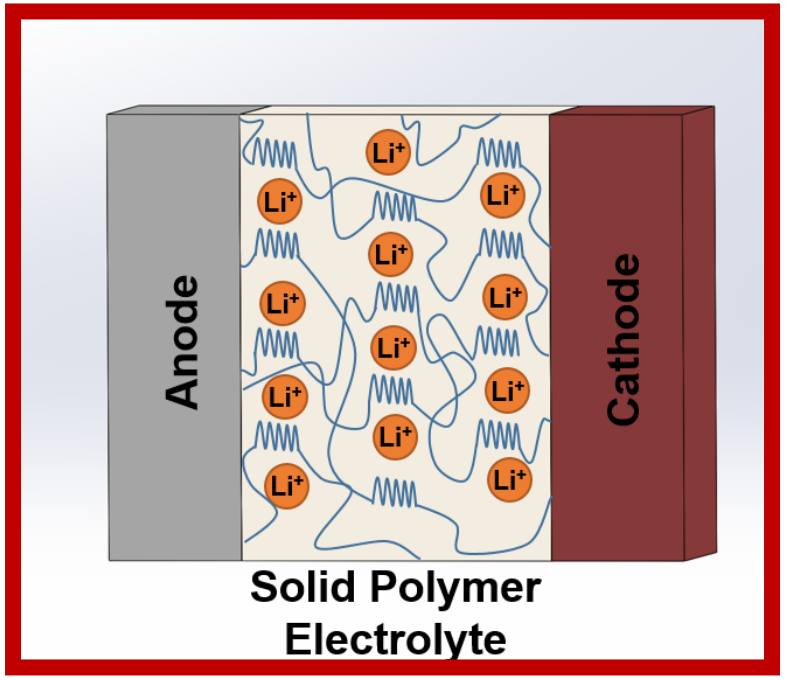
Leif E Asp *et al* 2019 *Funct. Compos. Struct.* **1** 042001

Current State of Electrolytes

Liquid Electrolyte:

- Ionic Conductivity: 10^{-2} S/cm
- Lithium salt solubility
- Ideal wettability & viscosity
- Wide electrochemical stability window



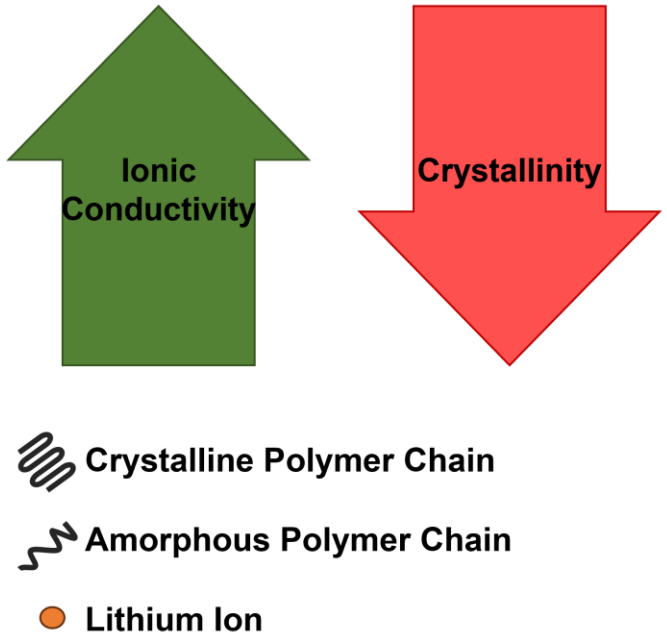


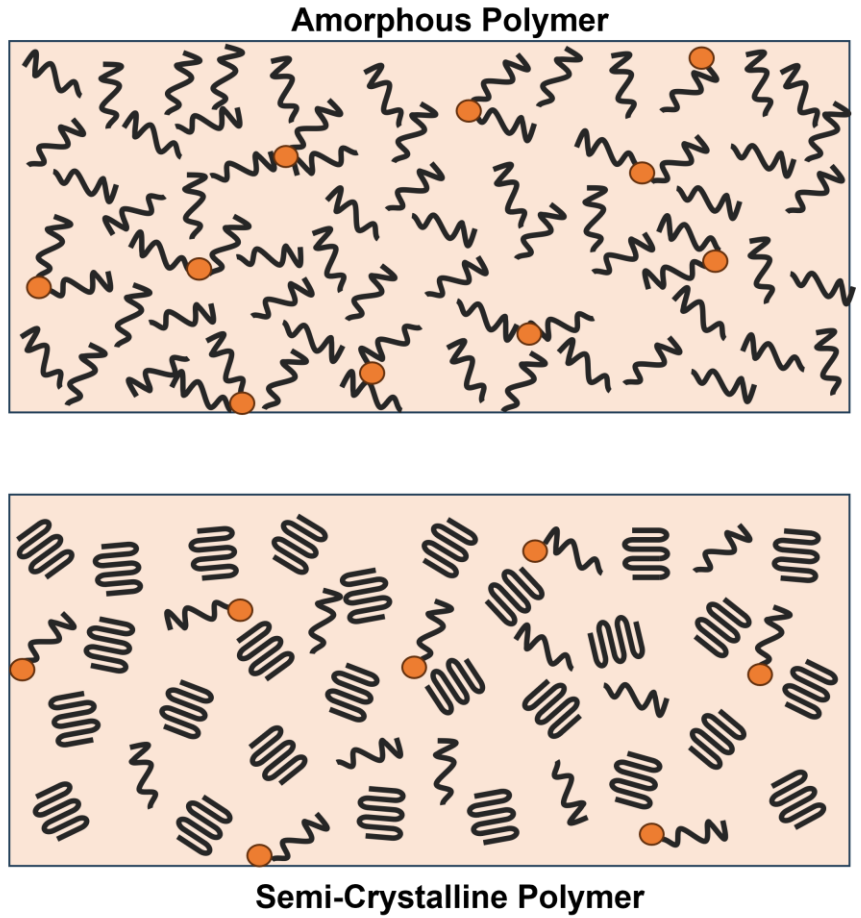
Xu, Kang. "Nonaqueous liquid electrolytes for lithium-based rechargeable batteries." *Chemical reviews* 104.10 (2004): 4303-4418.

Current State of Electrolytes

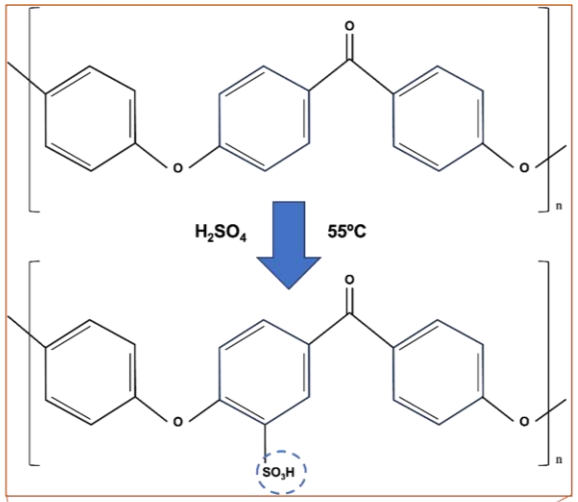
Solid Polymer Electrolyte (SPE):

- Ionic Conductivity: 10^{-6} S/cm
- No leakage
- Superior thermal stability
- Preventative for lithium dendrite growth



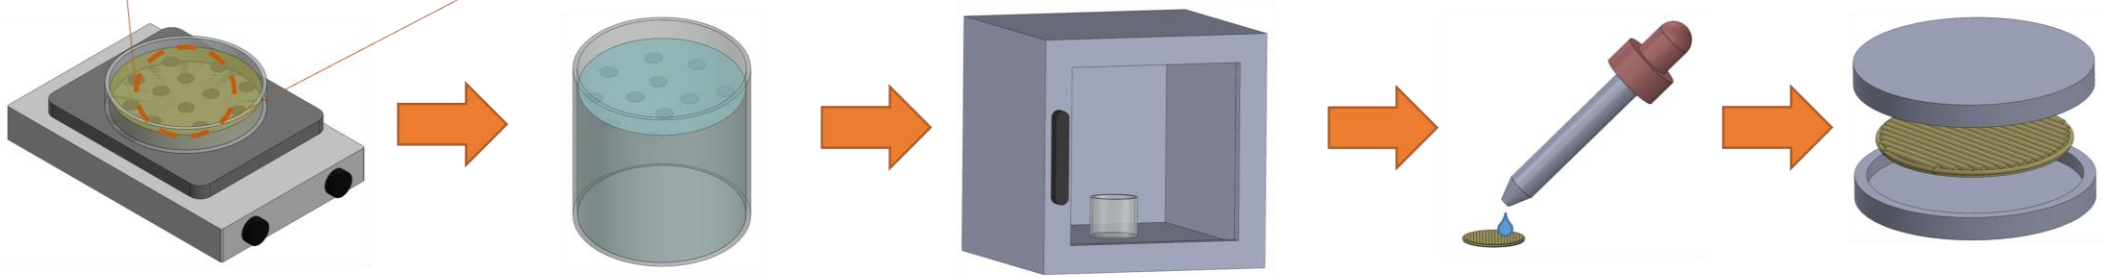


Yue, Liping, et al. "All solid-state polymer electrolytes for high-performance lithium ion batteries." *Energy Storage Materials* 5 (2016): 139-164.

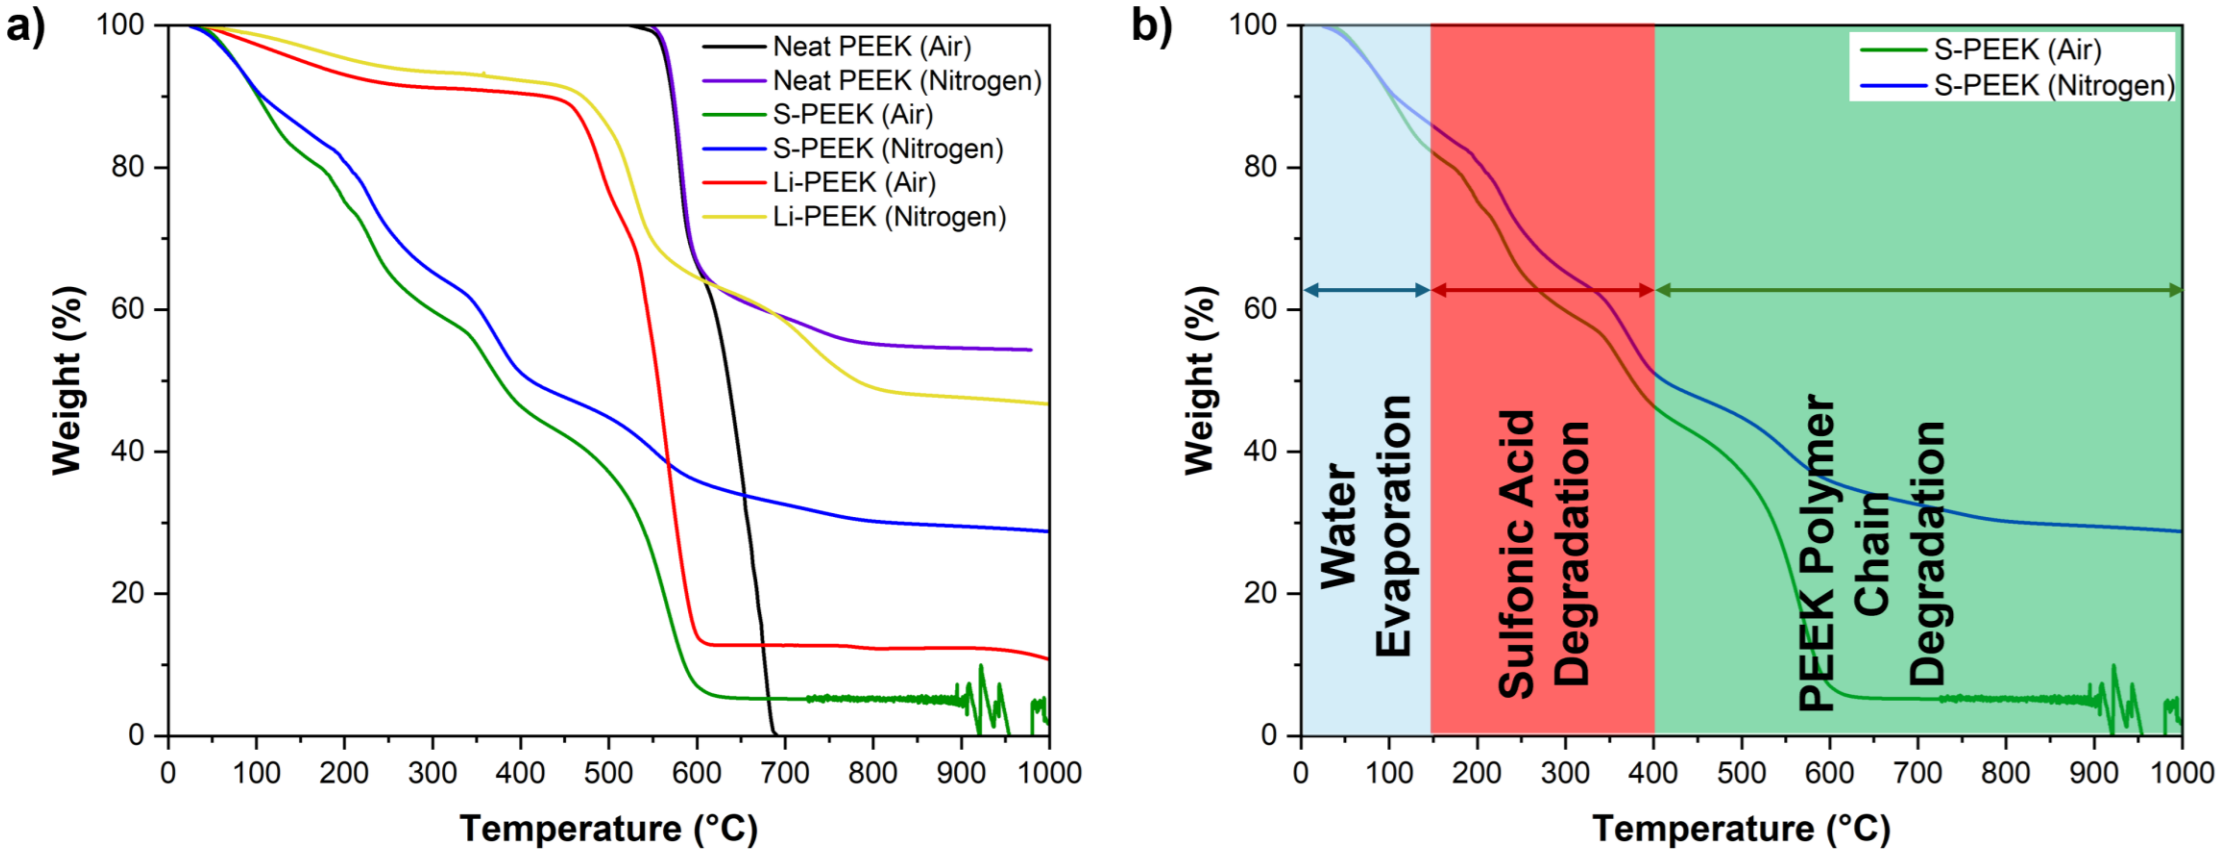


Solid Polymer Electrolyte Morphology Dependence

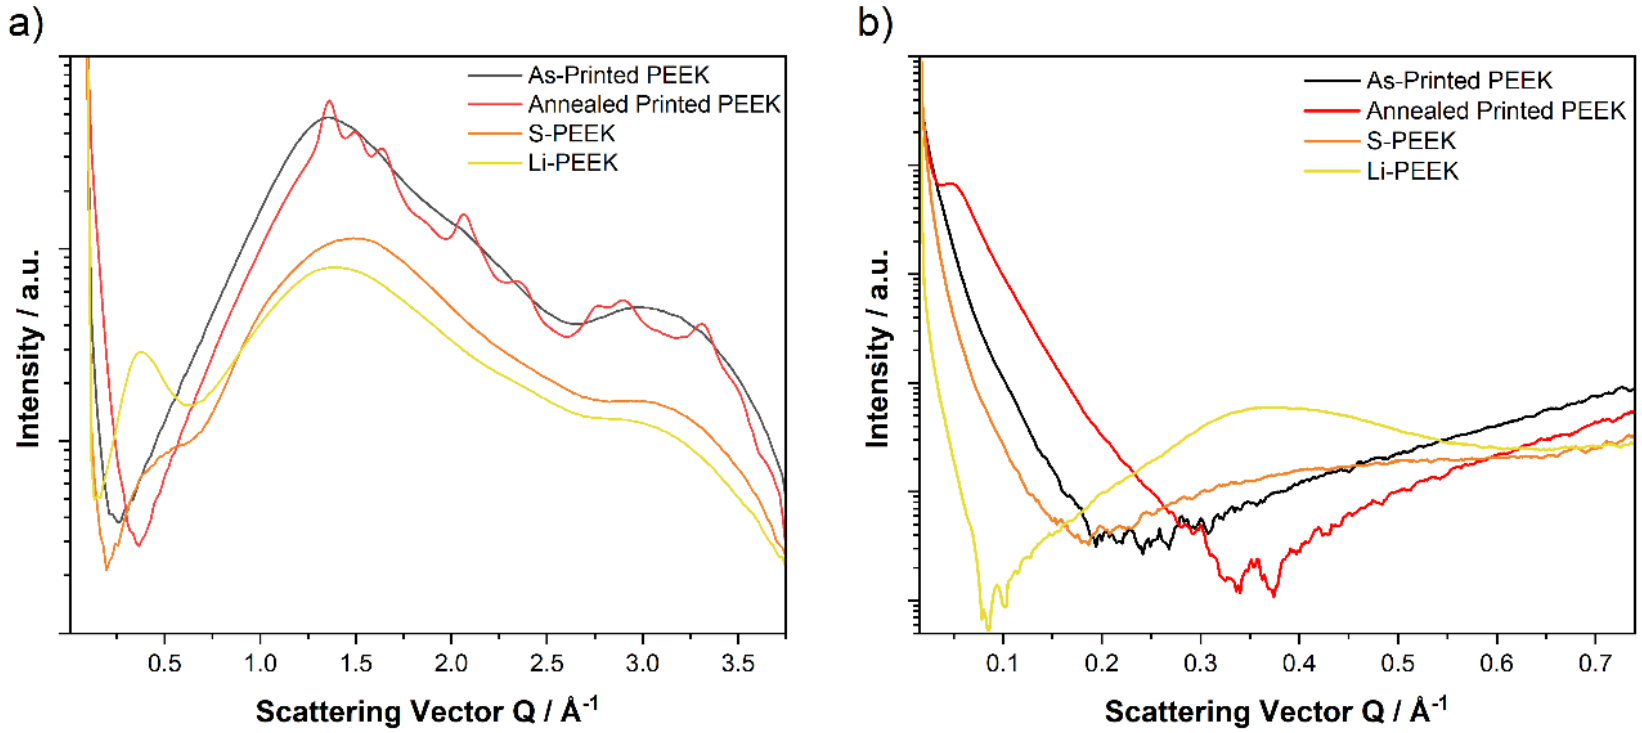
- Structure-Properties relationship
- Crystallites act as a barrier for lithium-ion transport
  - Inverse relationship with ionic conductivity



Functionalization of PEEK

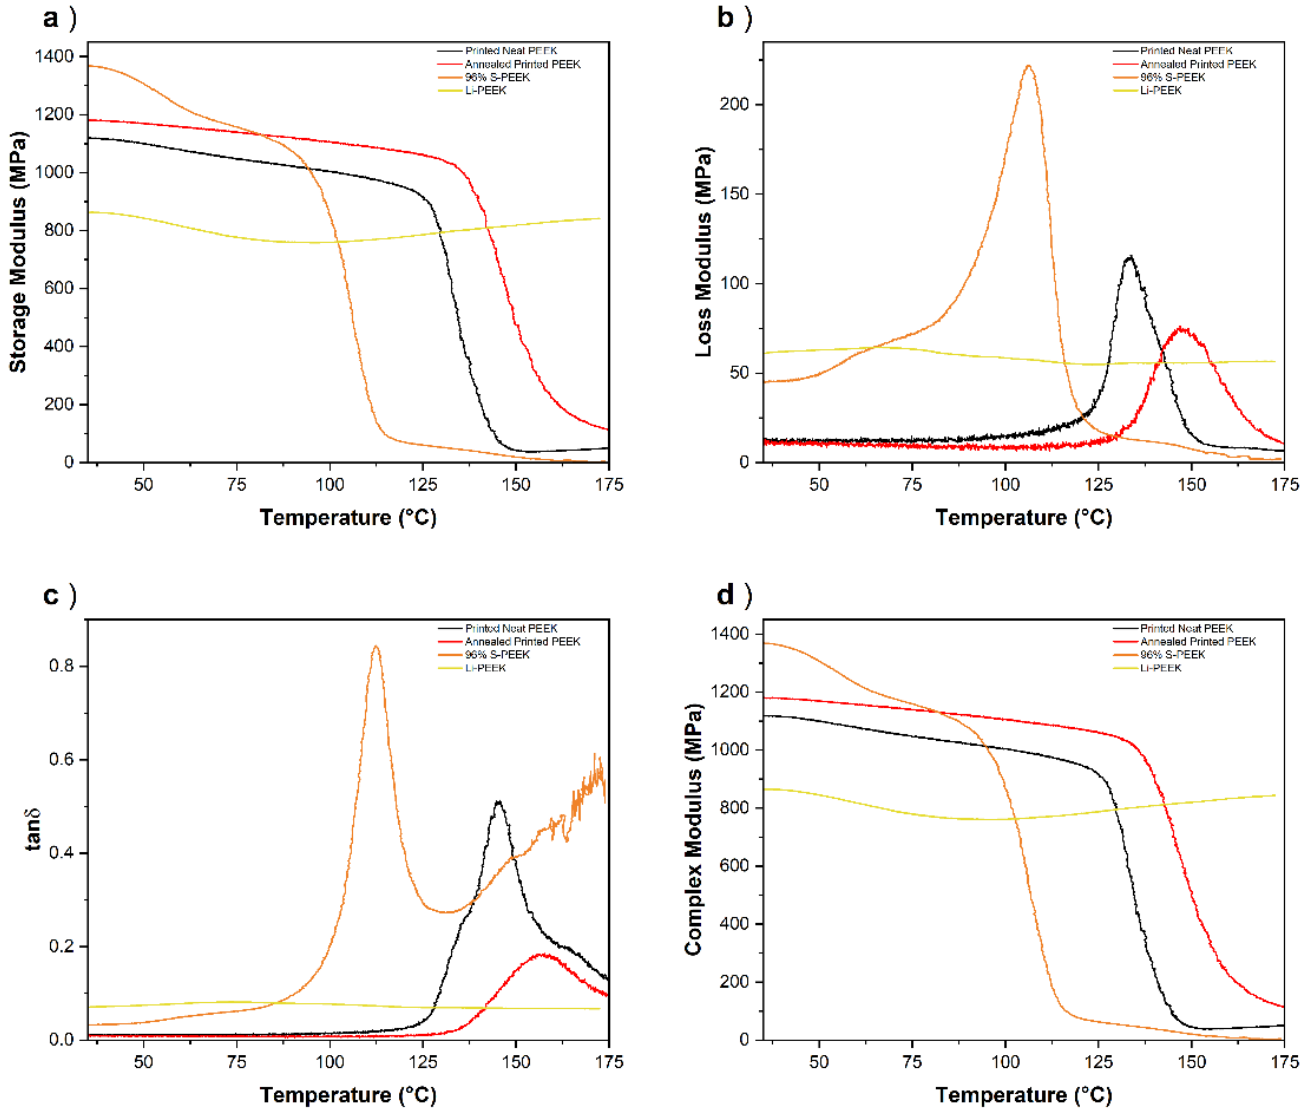


- Sulfonic acid groups on the PEEK backbone enables morphological changes
  - Can be further functionalized with lithiation treatment



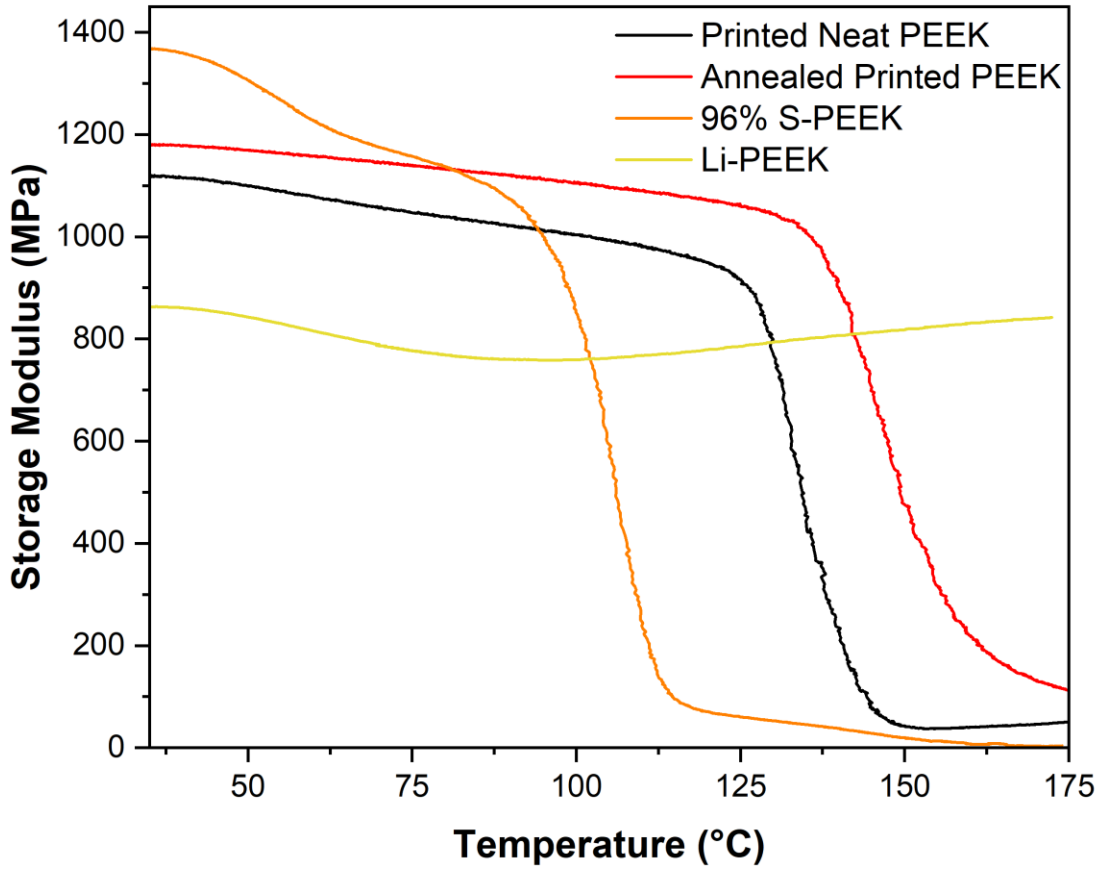
Sulfonate Polymer in H_2SO_4 → Rinse in DI Water → Dry in Vacuum Oven → Add Lithium Salt Solution → Assemble into Coin Cell Battery

Thermal Stability of Functionalized PEEK



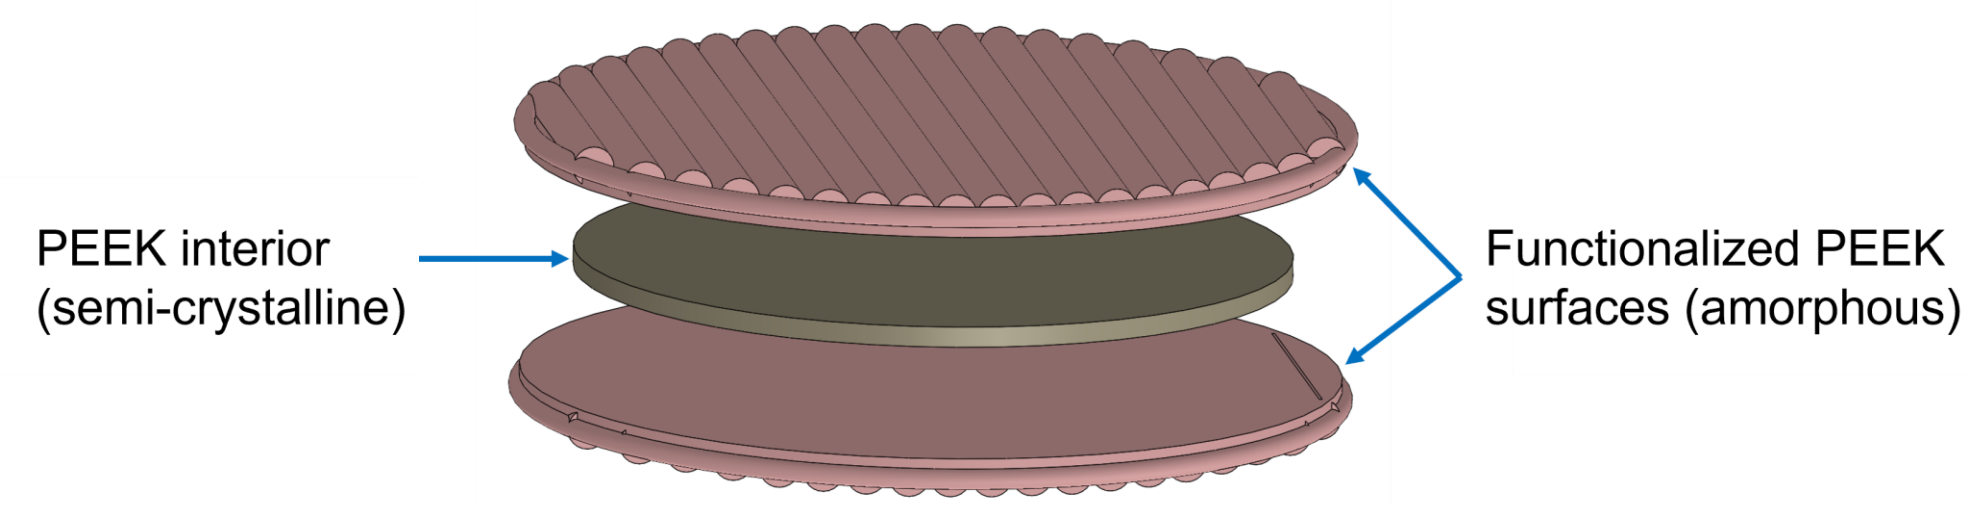
Morphology of Functionalized PEEK

- Lithiated PEEK displays ionomer peak, suggesting ionic conductivity
  - Sulfonated PEEK shows similar behavior



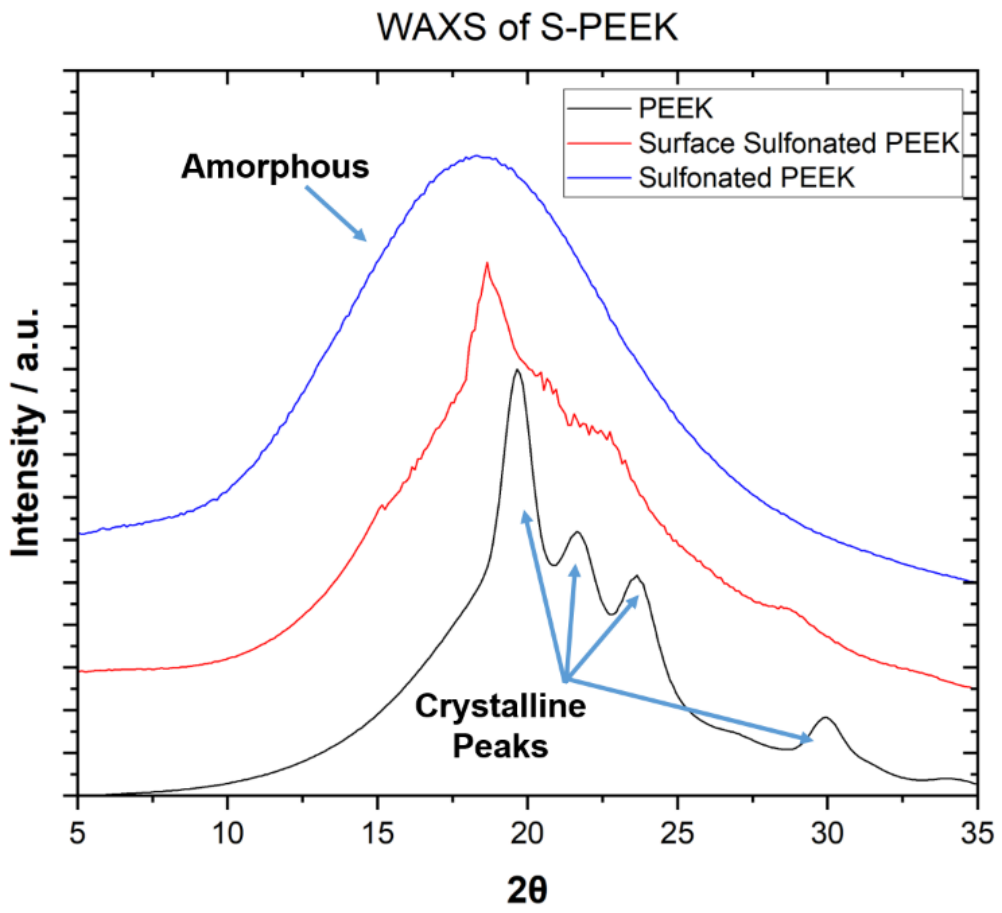
Thermomechanical Properties

- Sulfonated PEEK has highest storage modulus at ambient temperatures
- Lithiated PEEK has lowest storage modulus
  - Consistent at elevated temperatures



Thermomechanical Properties

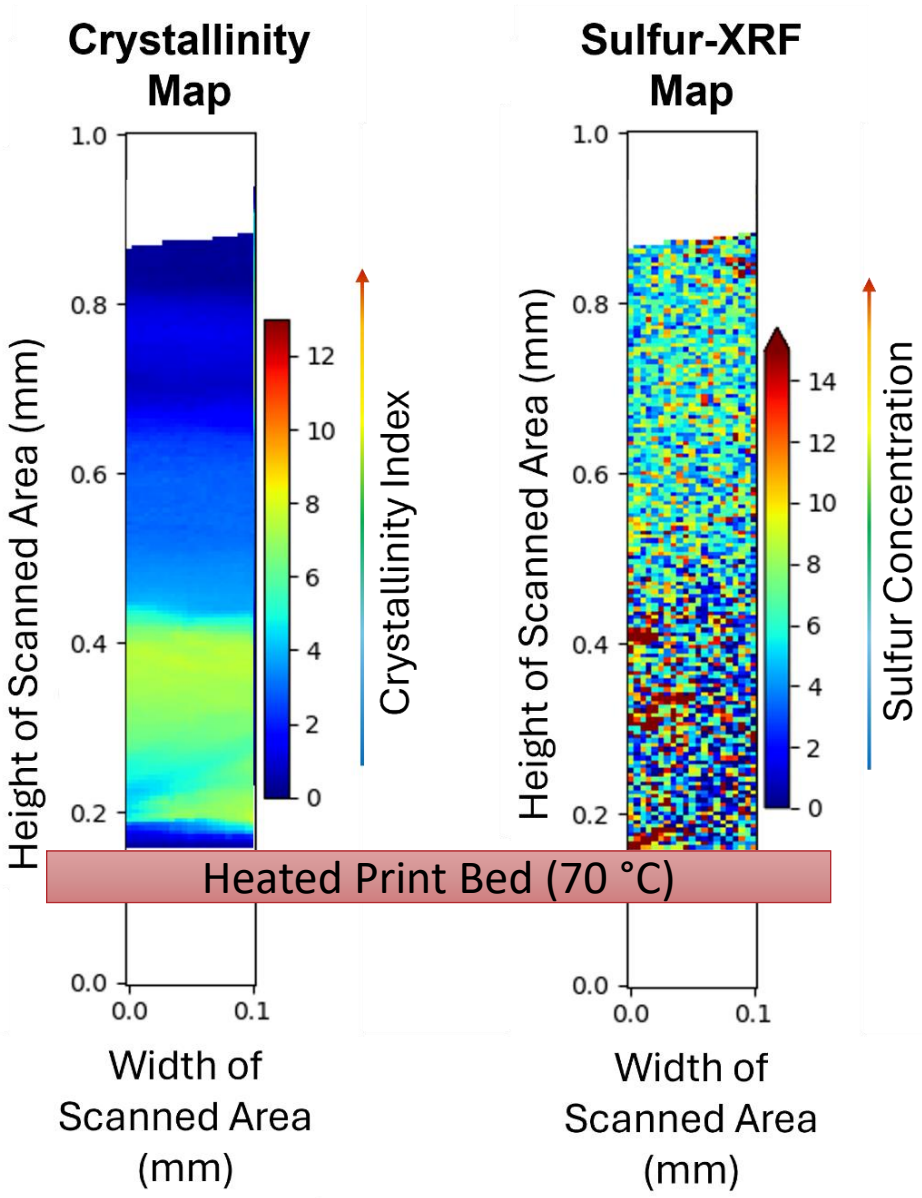
How can we optimize the mechanical properties at temperature without compromising ionic conductivity?



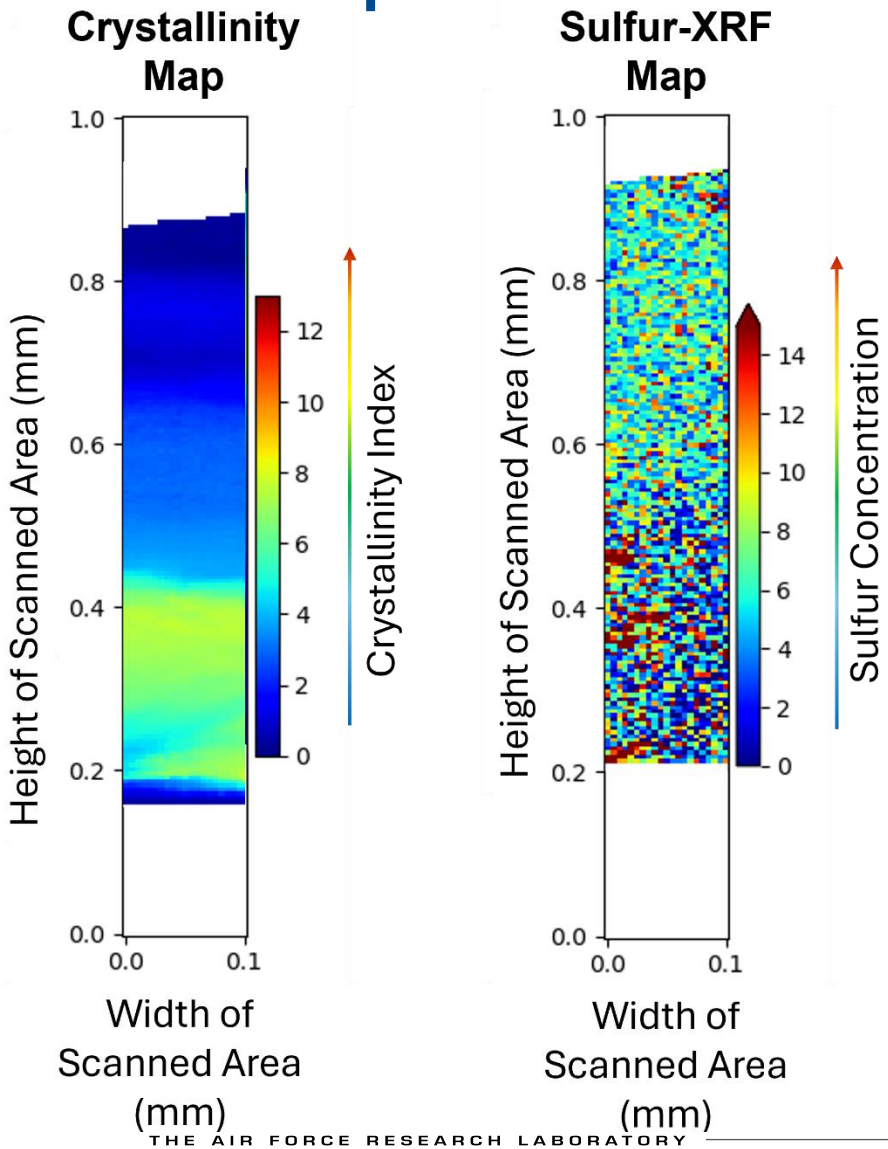
Tailoring Morphological Properties

- Instead of fully functionalizing PEEK, selectively sulfonating the surfaces can allow for amorphous exterior and semi-crystalline interior
  - Balances the mechanical properties and ionic conductivity

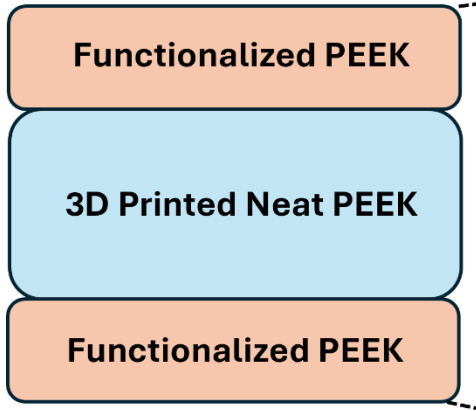
Evaluating Dual Phase Functionalized Structure



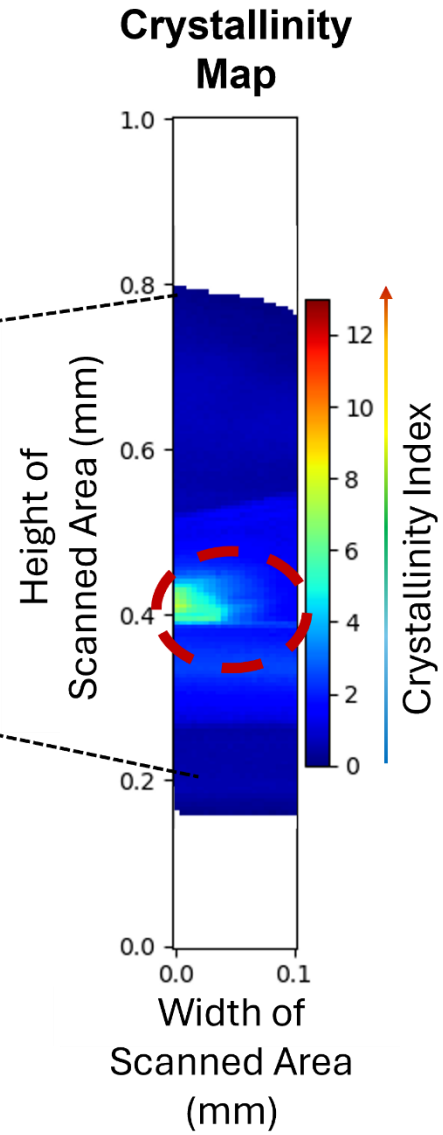
- Surface sulfonation provides both amorphous and semi-crystalline structure simultaneously
- Confirms the balancing of properties of ionic conductivity and structure



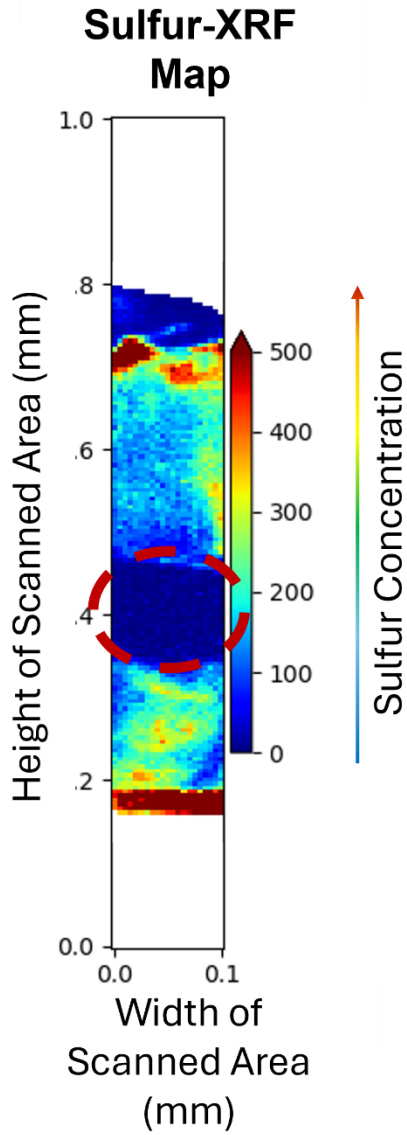
Mapping PEEK Morphology



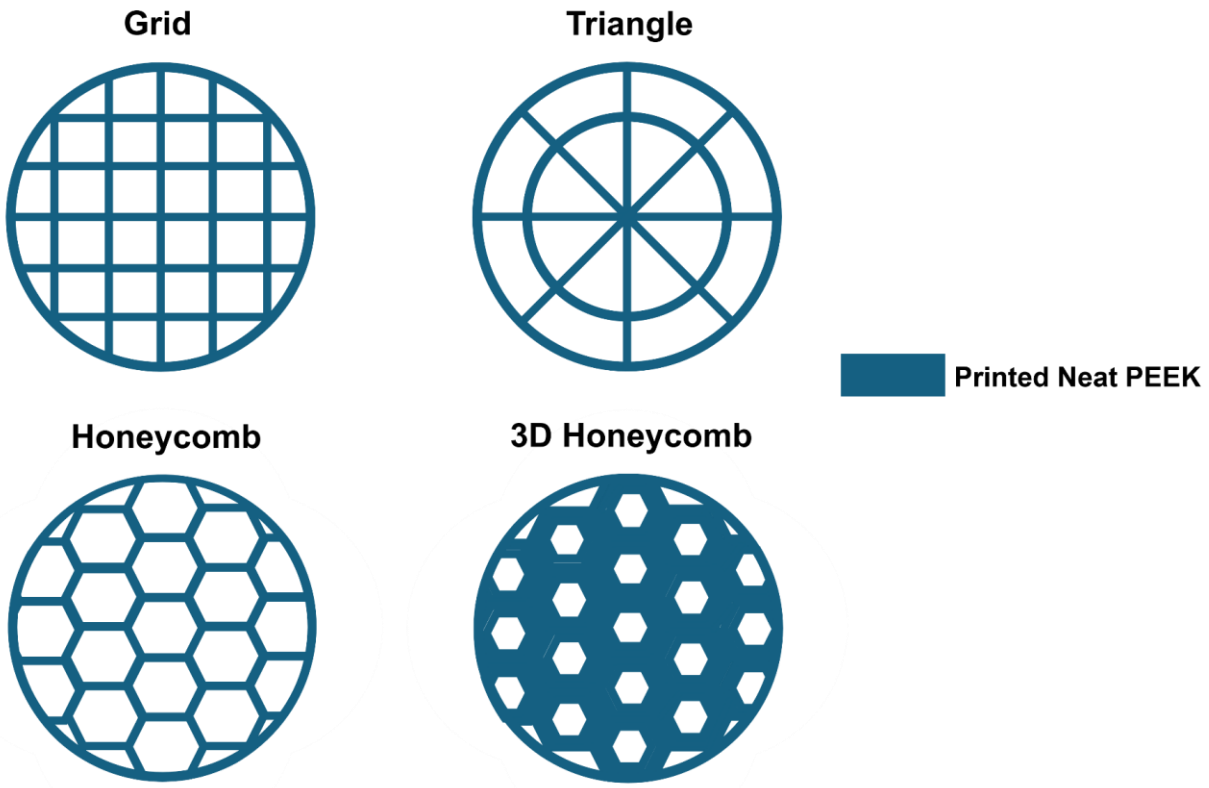
Crystallinity Behavior of Printed PEEK

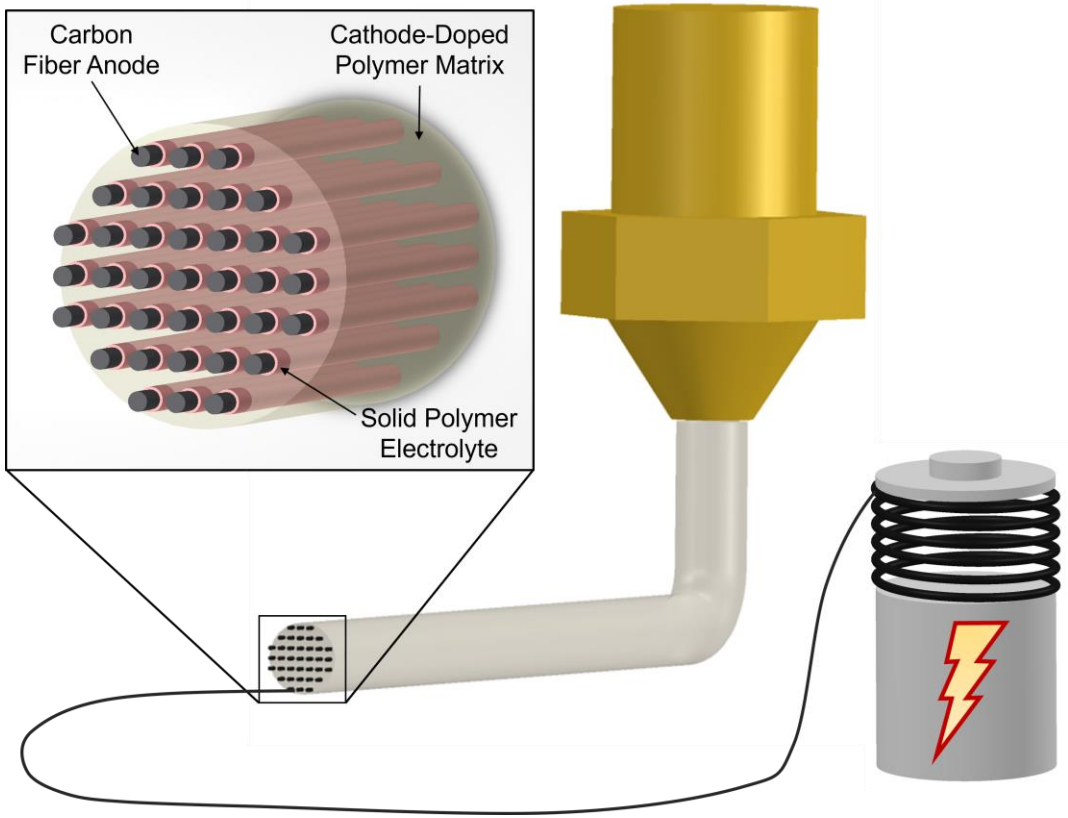


- Highest crystallinity is found closest to the print bed
- Crystallinity decreases with increased thermal gradient from supercooling
- No sulfur present in the material



Mapping PEEK Morphology





Enabling Additive Manufacturing

- Printed PEEK mesh to maintain mechanical properties
- Functionalized PEEK infill to provide ionic conductivity

Conclusions & Future Work

- Functionalization of PEEK can provide ionic conductivity to enable its use as a solid polymer electrolyte
- Additive manufacturing allows for selective enabling of crystalline and amorphous morphologies for optimized solid polymer electrolyte

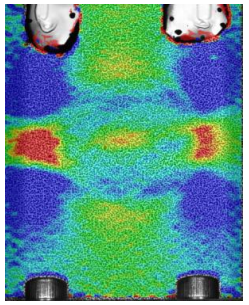
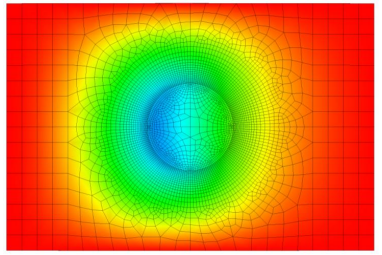
Conclusions

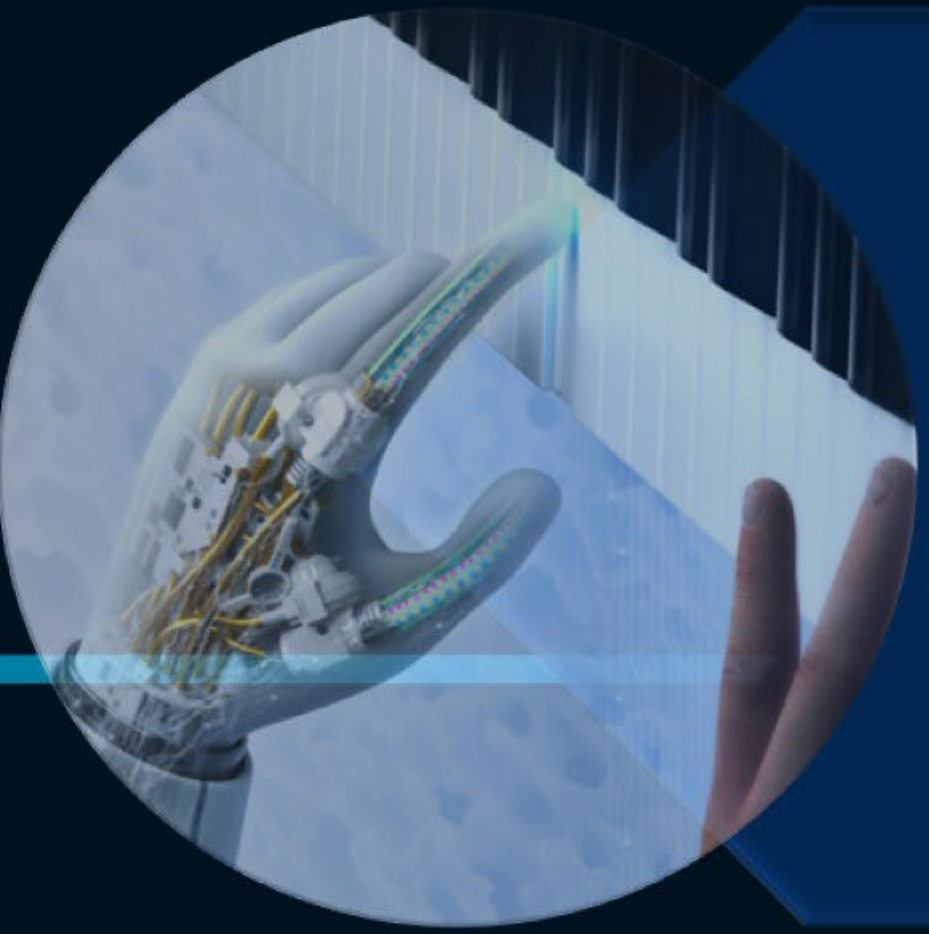


- Composite laminates with embedded SSC and PTFE defects were tested under compression with high repeatability (CV 1.84–2.64%).
- SSC specimens were ~10% stronger than PTFE, indicating a structural contribution from the SSC materials.
- Ultrasonic testing showed better sound transmission through SSC regions, confirming improved integrity.
- Sub-critical damage initiated earlier in SSC (60% failure load) than PTFE (85%), involving delamination and local instability.
- Final failure mode included translaminar fracture in both configurations.
- Non-linear BSAM analysis aligned better with experiments than linear analysis but still overpredicted failure by >25%.



PUBLIC RELEASE

Further work .....



- Apply newer versions of analysis software to improve prediction accuracy.
- Conduct more in-depth post-test examinations using X-ray micro-computed tomography (XmCT).
- Perform synchrotron experiments to observe SSC failure modes in greater detail.
- Investigate the structural contribution of SSC materials through high-resolution imaging and in situ testing.
- Refine modelling techniques based on insights from experimental characterisation

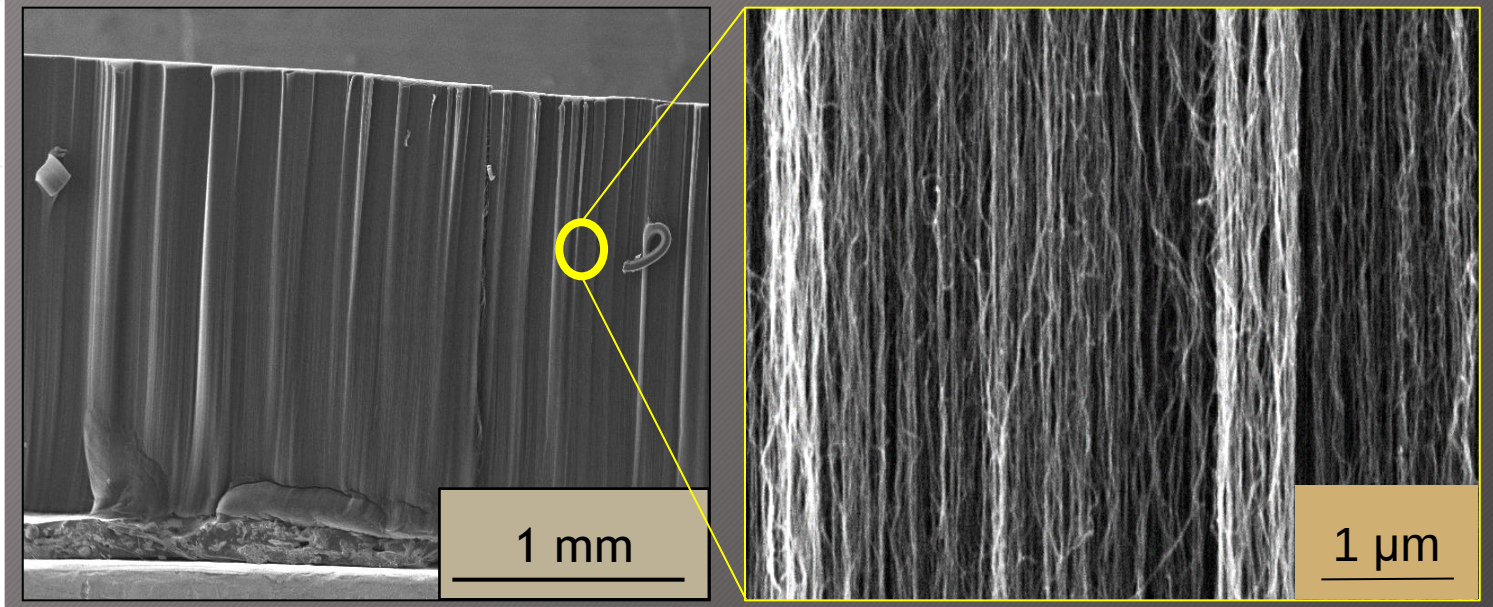
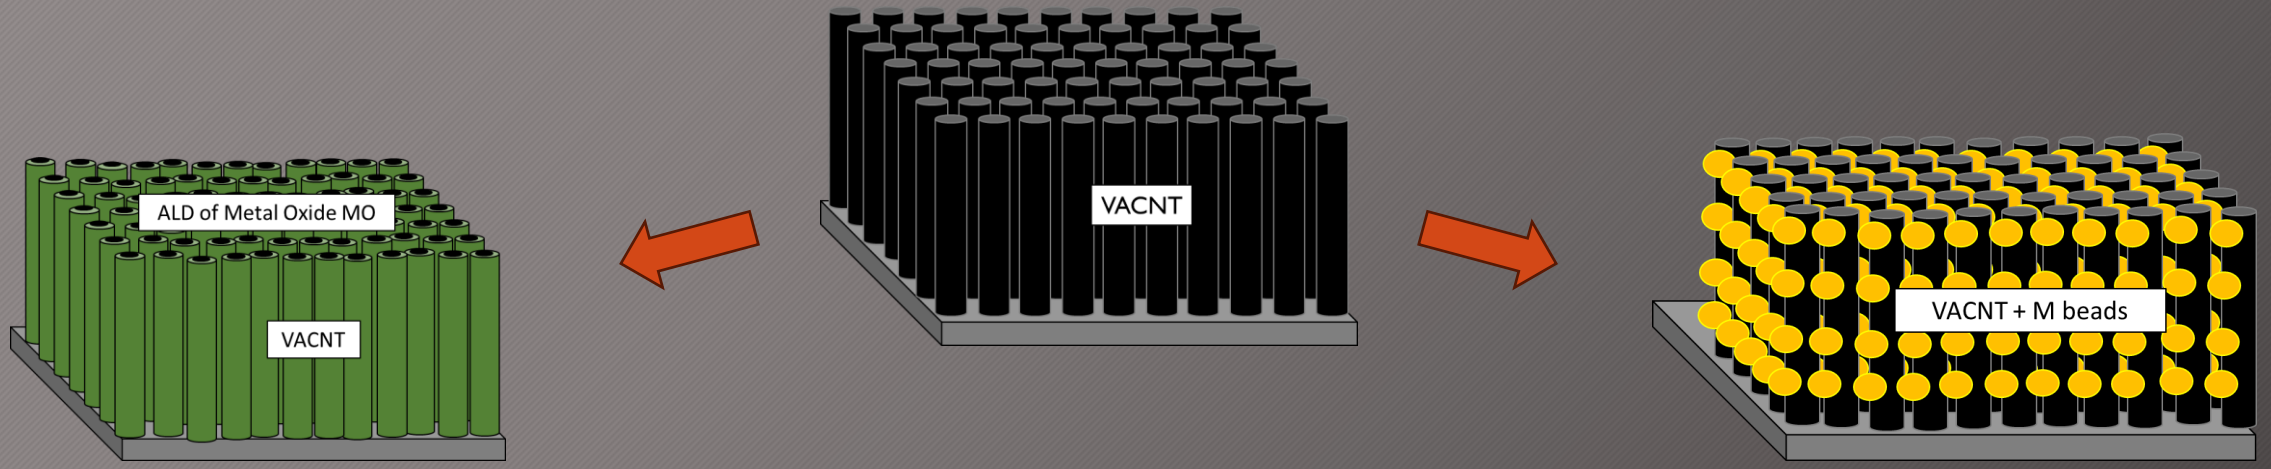
Tailoring the Chemistry and Morphology of Vertically Aligned Carbon Nanotubes Forests, Implications for Smart Electrodes

Lev Rovinsky
PhD Student
CSI Group



Vertically Aligned Carbon Nanotubes (VA-CNT)

- Showcasing the outstanding properties of CNT has been cumbersome.
- VACNT architecture bypasses 2/3 ‘typical’ CNT challenges.
- Key challenge: The delicate structure complicates solving the third

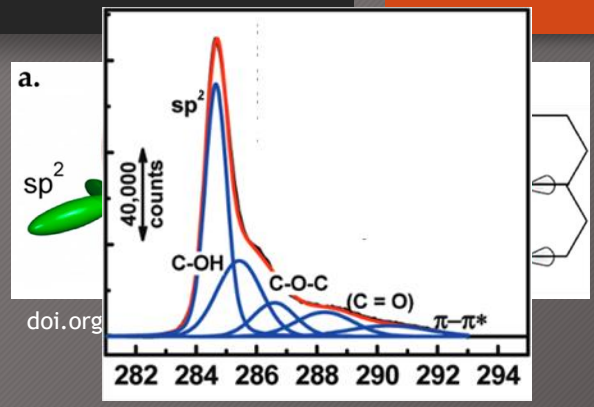


Property	Single-walled carbon nanotube	Double-walled carbon nanotube	Multiwalled carbon nanotube
Tensile strength (GPa)	50–100	23–63	10–60
Elastic modulus (TPa)	1	–	0.3–1
Elongation at break (%)	5.8	28	–
Density (g/cm^3)	1.3–1.5	1.5	1.8–2.0
Electric conductivity (S/m)	10^6	10^6	10^6
Thermal conductivity at room temperature (W/m K)	6000	3000	2000

https://doi.org/10.1016/j.compositesb.2017.08.020

Motivation: VACNT-Hybrids

- VACNT are very porous architectures (99vol% air), with immense surface-to-volume ratio
- For example: If a carbon nanotube has 10nm diameter and 2 mm length, aspect ratio will be ~10^6. In typical VACNT (1 cm^2 Si-die) there are **~10^9 CNT**.
- Such conditions are 'prime real-estate' for secondary phases!



Strategy

1. Protection of CNT Chemistry.
   - Introduction of novel ‘chemical’ success criteria (proof: XPS).
   - On top of existing ‘structural’ criteria (proof: Raman).

2. Retention of VACNT Architecture
   - Morphological analysis (proof: SEM)'
   - Avoiding ‘capillary forces’ of wet methods.

3. Fabrication of VACNT-Hybrid
   - Dry methods, such as sputtering and atomic layer deposition (ALD)

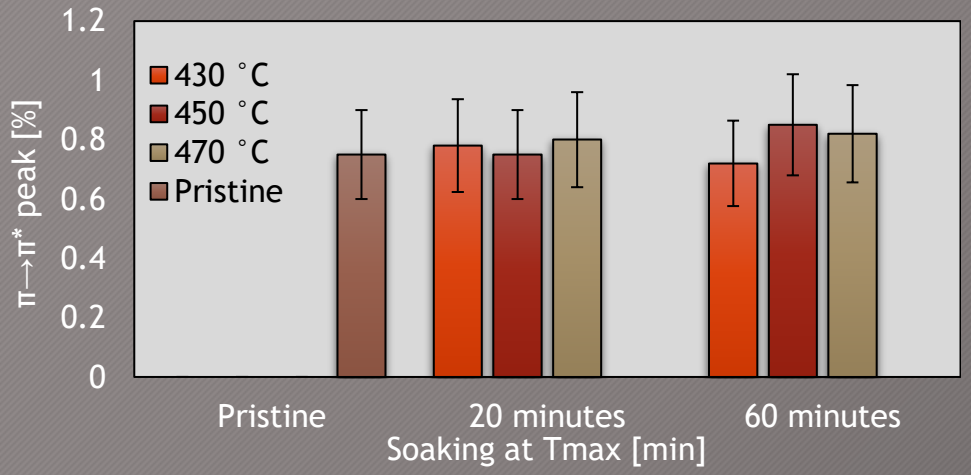
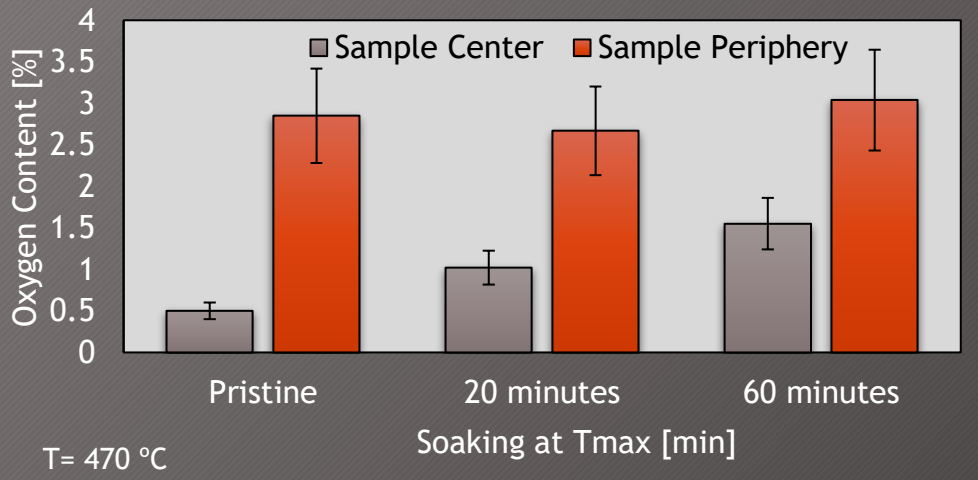
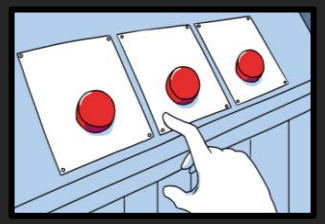
Table 5. - Oxygen content and "π-π*" for VACNT arrays, for pristine and plasma-treated samples, at two different gas ratios, after 2.5 minutes of treatment.

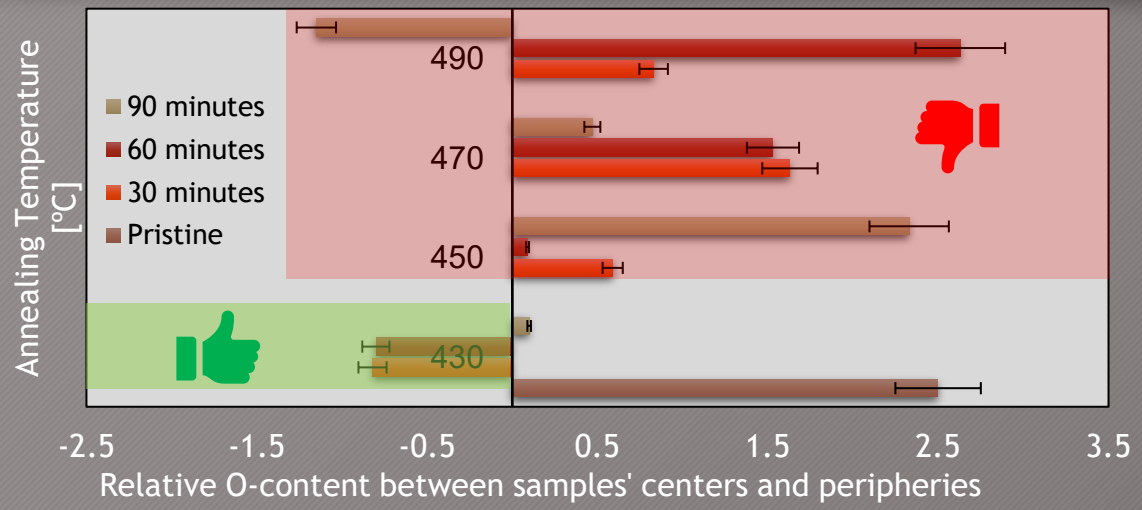
	Pristine	O_2/Ar (3:3)	O_2/Ar (4:2)
Oxygen Center	0.50 (±.05)	8.47 (± 0.8)	1.66 (± 0.16)
Oxygen Periphery	2.85 (± 0.3)	15.55 (± 1.5)	19.93 (± 2)
"π-π*" Center	0.98 (± 0.1)	0.71 (± 0.07)	0.98 (± 0.1)
"π-π*" Periphery	0.91 (± 09)	0.59 (± 0.06)	0.47 (± 0.05)

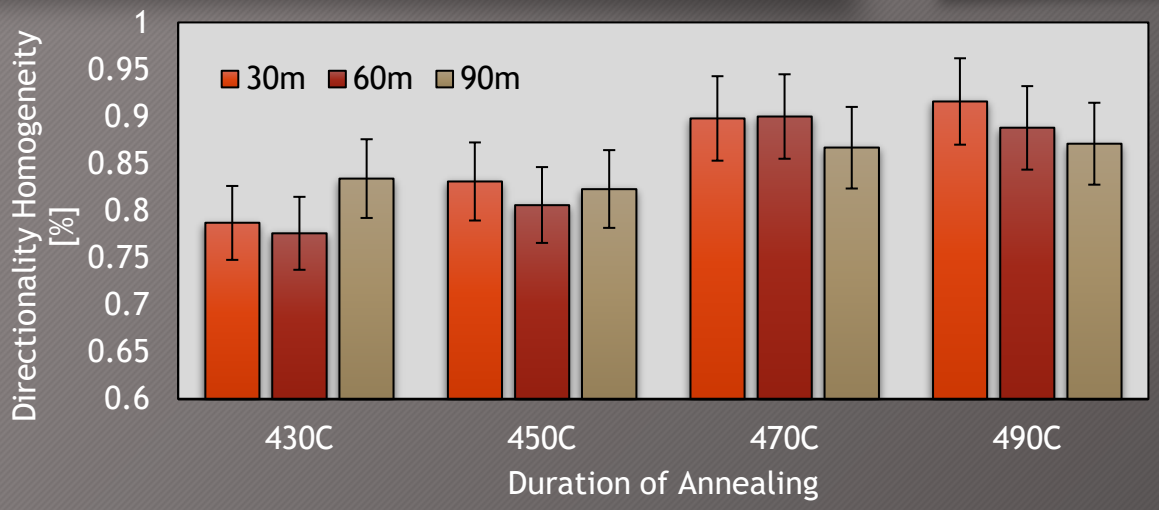


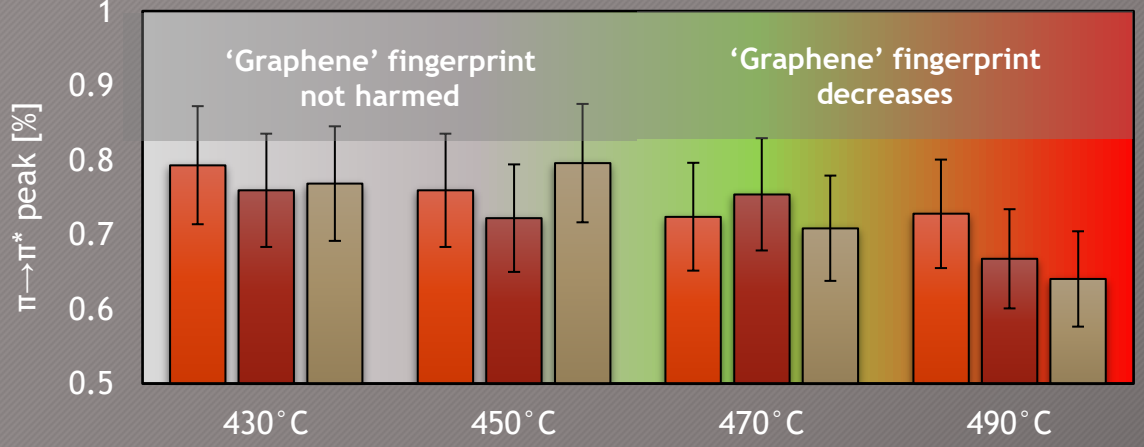


Annealing atmosphere, choice 1 - Air

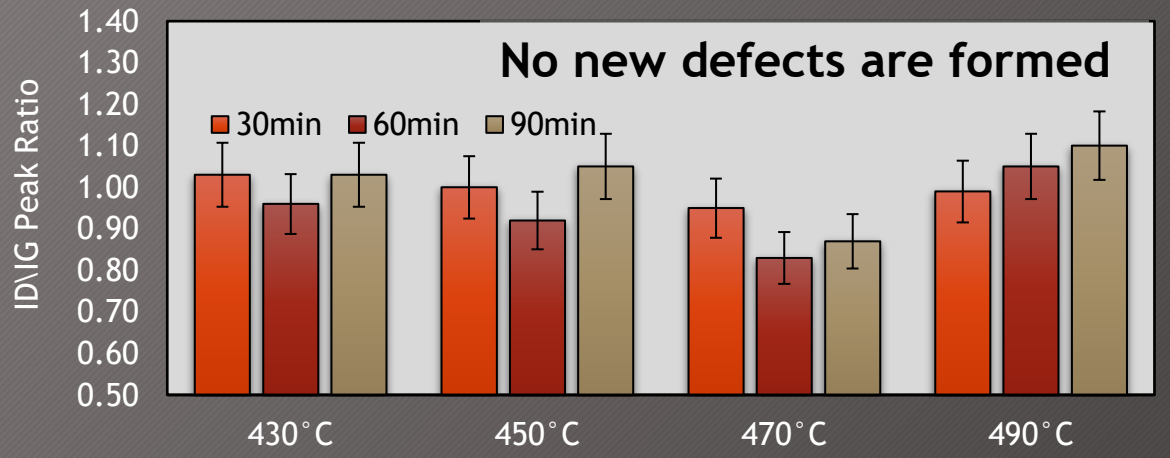








T= 470 °C



Annealing atmosphere, choice 2 – Ar (Shir's and Ella's BSc project)

Summary (To take home)

- The electronic structure of MWCNT is conserved in post-treated VACNT, with clear validation criteria.
- VACNT high-interface hybrid structures are naturally inhomogeneous, and require a tailored surface treatment to ensure homogeneity.
- Lowering the fabrication temperature of VACNT-metal hybrids makes them more approachable for various applications (e.g. energy harvesting or bio-medical)

QUASI-DISTRIBUTED PRESSURE SENSORS EMBEDDED INTO SURFACE MATERIALS ON COMPOSITE LAMINATES

ABSTRACT

In this study, upcoated and buffered optical fibres with Fibre Bragg Gratings (FBGs) have been used as quasi-distributed pressure sensors that can be embedded into surface materials for composite structures. The main goal has been to develop compact and robust sensors/sensor materials that measure pressures from 10 to 200 kPa.
The sensor used for this experiment was FBGs inscribed in 125µm optical fiber having either Polyimide (PI) or Acrylate (Ac) as original coating. The wavelength shift of an FBG can be related to strain, and its sensitivity is approximately 1.2 pm/µstrain. To make the FBG sensitive to pressure, the optical fibers with FBGs were coated with a soft up-coating layer of silicone and a stiffer buffer material. The total outer diameter was 1 mm. Four buffered fibre cables were manufactured with combinations of the two original coating materials and two different buffer materials that were either Polyamide (PA) or Polyetheretherketone (PEEK).
The buffered optical fibres were embedded into a couple of different types of surface materials on top of pre-cured 4 mm carbon fibre /epoxy (CFRP) laminates. The surface material was either a syntactic foam material with a 0.1 mm glass fibre/epoxy cover layer or 10 epoxy film layers (36 gsm Hexel 6376 resin) with a 0.1 mm glass fibre/epoxy cover layer. The pressure response of the inbuilt optical fibres was tested in an Instron Machine in the load range of 10 to 200 kPa.
The best combination for pressure sensitivity was either to use an optical fibre with PI coating and PEEK buffer or an optical fibre with Ac coating and PA buffer combined with the syntactic foam surface cover material.

1 INTRODUCTION

Fibre Bragg Gratings (FBGs) are sensitive to external parameters, such as strain and temperature. Their high multiplexing capabilities allows the manufacturing of extremely dense sensing arrays in a single optical fibre, enabling highly localized measurements over a distributed area and making them attractive for structural health monitoring.
Extensive research and development have been performed using FBGs as pressure sensors in a variety of harsh environment applications such as thermoelectric power plant combustion chamber [1] (Rosolem et al) and filament wound pressure tanks [2] (Kang et al). Since FBG-based solutions are intrinsically poorly sensitive to external pressure, it is necessary to convert external pressure to

fibre elongation, more conveniently measured with FBGs and thus increasing the pressure sensitivity of these devices. Thus, the performance analysis of pressure sensors using different types of fibre Rodriguez et al [3] and packaging designs such as flexible diaphragm [4] (Liang et al), polymers [5] (Zhang et al) and bourdon tubes [6] (Huang et al) was addressed in several studies, achieving pressure sensitivities up to 280 nm⁄MPa Sebastian et al [7].
In the aeronautics scenario, Chehura et al [8], demonstrated FBG-based pressure sensors effectively applied to measure pressure on aircraft wings. When compared to traditional pressure sensors, FBG-based technique enables a much higher density of measurement points, thus providing a higher level of details of the wing model under load. The research summarized above shows that FBG sensors can meet the requirements on distributed pressure sensors. However, the FBGs used have a diameter ≥2mm which is too large to effectively be built into composite wing structures. Commercially are also Fabry-Perot sensors available, which measure the pressure in the end of the fibre. However, this type of sensor only allows point measurements. The FBGs presented in earlier studies are added to the surface of the component, thereby vulnerable to surface loads. Older types of sensors integrated into composites have in some cases reduced the mechanical performance of the material since having large radie, around 3 mm or larger.

Wing surface pressure monitoring on an aircraft with traditional technology will employ hundreds of electrically connected sensors on the wing. This is a bulky, complex and costly solution and, therefore, only used in on ground wind tunnel tests today. For measurements during service, there is no existing pressure monitoring system today. In this scenario, optical fibre solutions based on Fibre-Bragg Gratings (FBGs) [3,7,8] are advantageous due to their capability to be seamlessly embedded into lightweight aircraft composite parts, multipoint sensing possibility and immunity to electromagnetic interferences.

In this study optical fibres with FBGs have been used for creating quasi-distributed pressure sensors that can be embedded into surface materials for composite structures.
To enhance the pressure sensitivity, FEM (Finite Element Method) was used to identify the best combination of materials for the coating, upcoating and buffer.
The main goal has been to develop compact and robust sensors/sensor materials that measure pressures from 10 to 200 kPa.

2 EXPERIMENTAL

The FEM study showed that the highest sensitivity could be achieved with a thicker layer of a soft material between the fiber optics diameter (125μm) and the external buffer diameter (limited to 1mm in this study). Several materials were studied for the fiber coating, upcoating and buffering. The combination of the different materials and dimensions were evaluated and the most promising combinations were fabricated for tests.
The sensor used for this experiment was FBGs inscribed in 125μm optical fiber having either Polyimide (PI) or Acrylate (Ac) as original coating. The wavelength shift of an FBG can be related to strain, and its sensitivity is approximately 1.2 pm/μstrain. To make the FBG sensitive for pressure the optical fibers were coated with a soft up-coating layer of Silicone and a stiffer buffer material (see figure 1). The total outer diameter was 1 mm. Four different types of fibres were manufactured with combinations of the two original coating materials and two different buffer materials that were either Polyamide (PA) or Polyetheretherketone (PEEK) (see table 1). The Central Wave length (CW) for each FBG is presented in table 1.

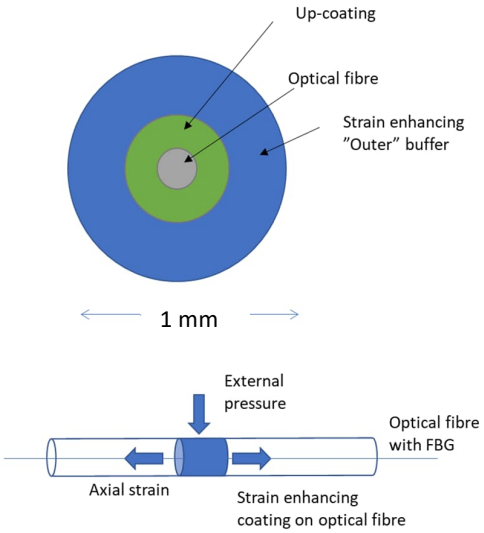

Figure 1: Principle of the pressure-sensitive fibre-optic sensor: the combination of upcoating the fibre and a buffer material changes external pressure to an axial strain. , enhancing the sensitivity to pressure.

Identification	Original Coating	Up-Coating	Buffer	Surface material	Central wave length (CW) [nm]
AC-SI-PEEK-1	Acrylate	Silicone	PEEK	Amspand	1534.79
AC-SI-Nylon-1	Acrylate	Silicone	Polyamide	Amspand	1554.4
PI-SI-PEEK-1	Polyimide	Silicone	PEEK	Amspand	1544.4
PI-SI-Nylon-1	Polyimide	Silicone	Polyamide	Amspand	1539.596
AC-SI-PEEK-2	Acrylate	Silicone	PEEK	Epoxy	1539.5
AC-SI-Nylon-2	Acrylate	Silicone	Polyamide	Epoxy	1549.315
PI-SI-PEEK-2	Polyimide	Silicone	PEEK	Only tested alone	1549.058
PI-SI-Nylon-2	Polyimide	Silicone	Polyamide	Epoxy	1534.38

Table 1: Test samples configuration coating, buffer and composite surface material.

The pressure sensitivity of the coated optical fibres was first measured for the fibres alone in a pressure chamber. In the next test step, the coated optical fibres were built into a couple of different types of surface materials on top of pre-cured 4 mm carbon fibre /epoxy (CFRP) laminates. The CFRP was built up of 7 layers of Hexcel prepreg M49/HS/600 gsm. The surface material was either a syntactic foam material (Amspand) with a 0.1 mm glass fibre/epoxy cover layer (Delta DT120/823) or 10 epoxy film layers (36 gsm Hexcel 6376 resin) with a 0.1 mm glass fibre/epoxy cover layer (see figure 2).

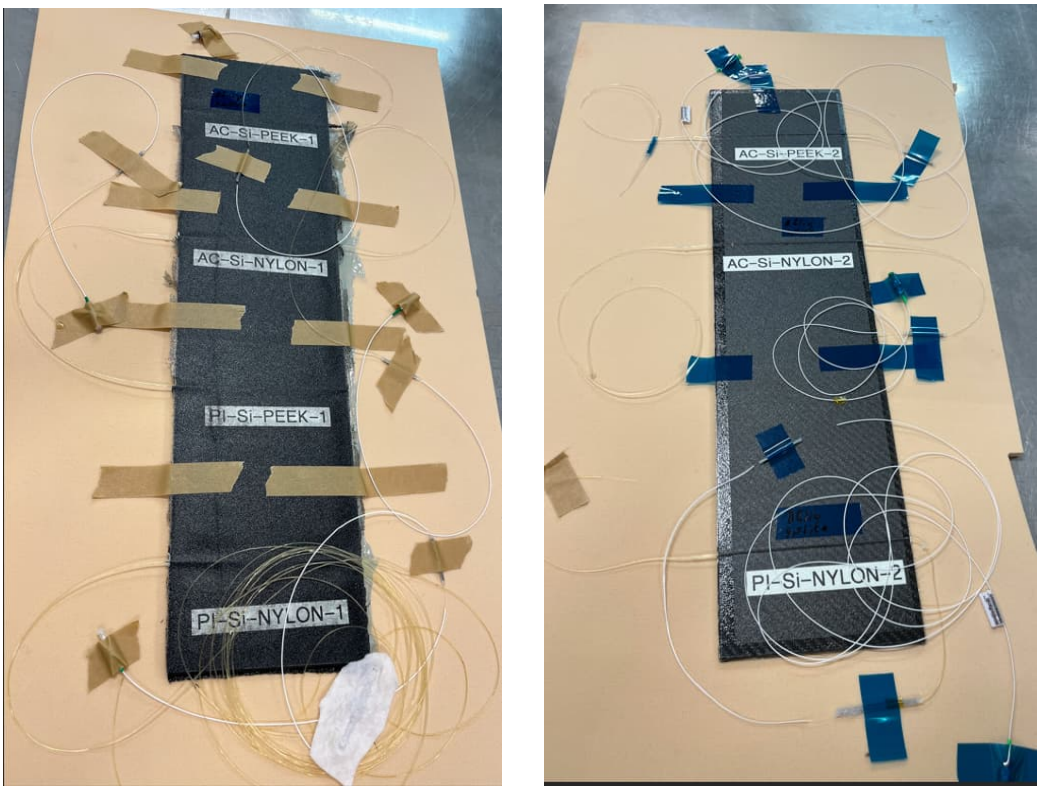

Figure 2: Fibre optics build into a) Amspand surface material b) Epoxy surface material.

The pressure response of the inbuilt optical fibres was tested in an Instron Machine (see figure 3) in load steps of 20, 40, 60, 80, 100, 200 kPa. Each load step contained a one minute hold. The pressure was calculated from the machine compression force and the pressure area.

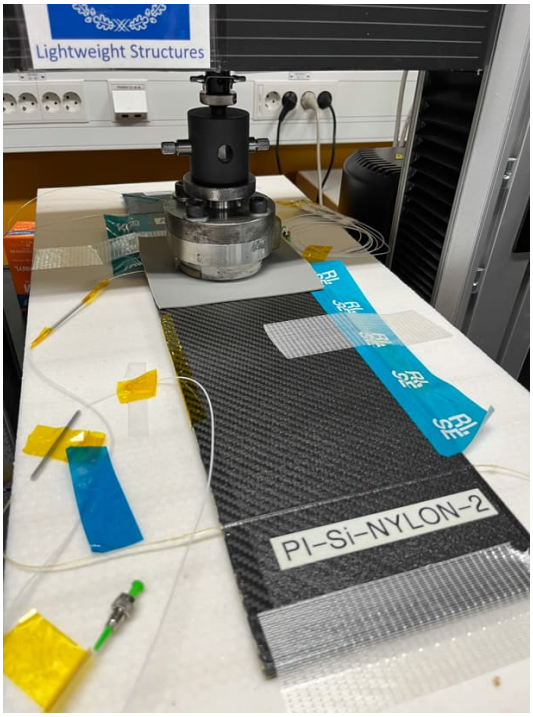

Figure 3: Test set-up in the Instron Machine.

3 RESULTS

The test in the pressure chamber of the single FBG fibres showed hysteresis during the measurements. However, the best results were obtained with the PI coated fiber with PEEK buffer. When the fibres were built into surface material on the top of CFRP laminates, and tested in the Instron Machine, the effect of the hysteresis was less pronounced. The best combination for pressure sensitivity was either to use an optical fibre with PI coating and PEEK buffer or an optical fibre with Ac coating and PA buffer, combined with the syntactic foam (Amspand) surface cover material (see figure 4).

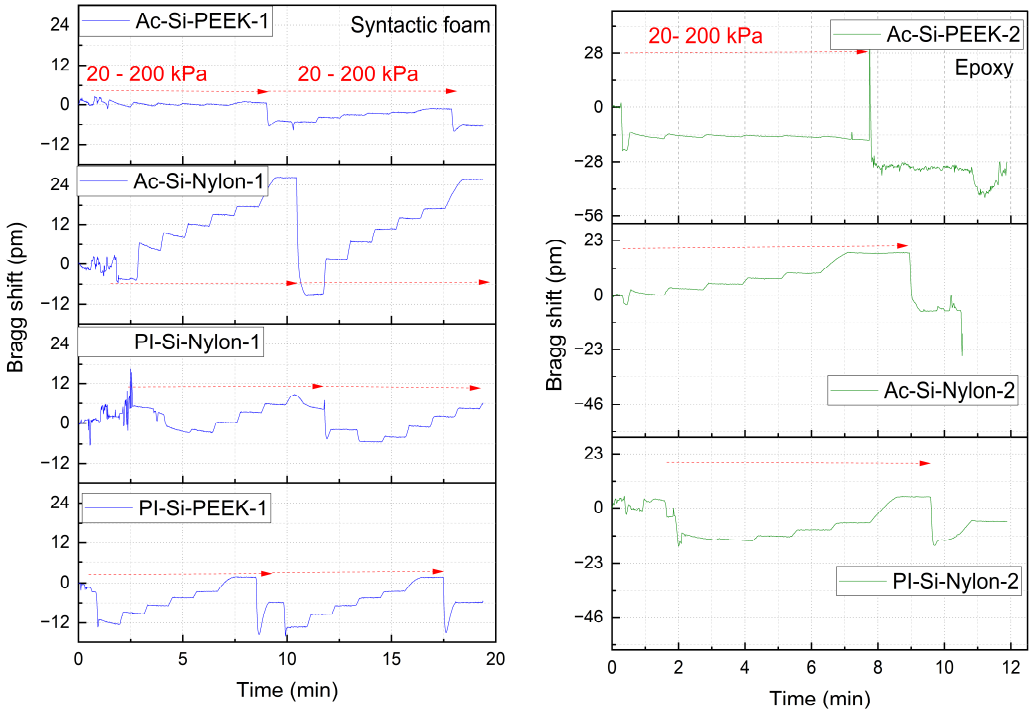

Figure 4: Results from pressure test. 1 was built into Amspand surface material and 2 was built into epoxy surface material.

3 DISCUSSIONS

the test results with the unembedded up-coated and buffered optical fibres did show hysteresis, while the laminates with embedded up-coated and buffered optical fibres, in the syntactic foam (Amspand) did not. This is not in line with a previous study that showed hysteresis when using the Amspand as a buffer material instead of PEEK or Polyamide (PA) in stand-alone measurements with the fibres. However, in the laminate configuration with optical fibres embedded into the surface material on CFRP laminate a 0.1 mm glass fibre/epoxy cover layer was also used on top of the surface material. This glass layer might have a faster recovery due to its stiffness and that might have helped the hysteresis effect to be less pronounced. The measurements of the laminates with the epoxy surface material did show less pressure response compared to the laminates with the Amspand surface material. This is not a surprise

since the epoxy material is much stiffer than the Amspand material.

9 CONCLUSIONS

The aim of this study was to use optical fibres with FBGs for quasi-distributed pressure sensors that could be embedded into surface materials for composite structures. The main goal was to develop compact and robust sensors/sensor materials that measure pressures from 10 to 200 kPa. The study showed that the best combination for pressure sensitivity was either to use an optical fibre with Polyimide coating and Polyetheretherketone buffer or an optical fibre with Acrylate coating and Polyamide buffer, combined with the syntactic foam (Amspand) surface cover material topped with a 0.1 mm glass fibre/epoxy cover layer. The study also showed that the embedded sensors was sensitive for pressure in the required pressure range.

ABSTRACT

In this paper, a graphene-coating on glass fiber weave has been evaluated as a multifunctional sensing material based on previous work performed by the authors on embedded vertically aligned carbon nanotube forests. First, the graphene-coating has been assessed as a resistive cure-monitoring sensor when embedded in thermosetting glass fiber/epoxy laminate to monitor its production. The graphene-coating showed similar results to the resistive cure monitoring of carbon nanotubes. However, the graphene-coating diverges in its resistive signature upon reaching cure temperature, showing a continuous resistance decrease in this phase, suggesting a sensitivity to cure-induced shrinkage of the epoxy, not seen in the carbon nanotube sensor. Later, in the cured state, the embedded graphene-coating functions as an excellent temperature sensor, possessing a negative thermoresistive effect. However, as a strain sensor, the graphene-coating does not perform as well as the embedded carbon nanotube sensor, possessing an initial drift in resistance upon its first load cycle and additional drift during constant strain conditions, and when unloaded.

1. INTRODUCTION

Fiber-reinforced composites (FRPCs) have seen increased use within the aerospace, automotive and wind turbine sectors due to their high specific modulus and strength. Together with their increased implementation, the interest in monitoring FRPC structures has increased. This includes monitoring the production of the components, performing cure monitoring, and later structural health monitoring (SHM) during their operational lifetime. To perform SHM, the possibility of monitoring strain, temperature, pressure, and more, experienced by the component is of interest.

FRPCs have the possibility to embed sensors in their structure, obtaining multifunctionality. However, when embedding a sensor into the composite structure, the sensor's size is critical to not interfere with, or deteriorate, the mechanical structure. Preferably, the embedded sensor should be mechanically non-intrusive and possess the ability to perform in-situ online cure monitoring during production of the component for quality and process control. Thereafter, in the cured state, the sensor should be used for other types of sensing, i.e. for structural health monitoring (SHM).

In parallel, new sensitive resistive sensors have been envisioned using carbon nanotubes (CNTs) and graphene-based sensors. Research using CNT-based sensors for strain [1–4] and temperature [3,5] sensing, and cure monitoring [4,6,7] has been published. Similarly, graphene-based sensors have been

studied for strain [8–13] and temperature [8,13–15] sensing and cure monitoring [6,13,16]. In these papers, using CNTs and/or graphene, the sensors have been achieved through modification of the matrix with fillers [1,5,8], fiber-coatings [4,6,13,16], vertically aligned CNT (VACNT) forests [3,7], CNT buckypapers [2], and graphene films [10–12,14,15]. Although much work has been done on graphene-based sensors, limited work exists where graphene-based sensors have been embedded into FRPCs for sensing [6,9,13,16].

In this paper, a graphene-based sensor is embedded into glass fiber/epoxy laminate and evaluated as a resistive sensor. The sensor is compared to previous work conducted by our group studying VACNT forests as embedded resistive sensors. This paper presents initial results on the sensing capabilities of the graphene-based as a 1) cure-monitoring, 2) temperature and 3) strain sensor.

2. Method

2.1 Material

In this work, the glass fiber/epoxy prepreg used was HexPly6376-G-120 from Hexcel. The HexPly6376-G-120 has a fiber volume fraction of 42 %, the weave being a 4-harness satin weave, HexForce 120. In addition, the HexPly 6376 (36g/m^2) epoxy adhesive film was used.

Two materials were used for resistive sensing. First, VACNT forests were used, grown on stainless steel substrate provided by N12 Technologies and used as received. The VACNT forest has been studied in previous work, determining the individual CNTs to contain 7±2 walls and an outer diameter of 8±2 nm. In the same work, the volume fraction of CNTs in the VACNT forest was determined to be 0.4 %; please see [3] for more details. Secondly, a graphene-coated glass fiber weave, delivered by Grafren AB, was used. See section 2.3 for more details on the graphene-coated glass fiber weave.

A copper-nickel-coated non-woven carbon fiber veil from Technical Fibre Products Ltd (Carbon 20444A, 8g/m^2) was used to establish contact with the resistive sensors.

2.2 Deposition of VACNT Forests

To embed the VACNT forest into laminates they were deposited on a prepreg surface. A vacuum bag and a heating plate were used to perform the deposition of the VACNT forest. The substrates with the VACNT forest were placed on the prepreg surface with the VACNT forest facing the prepreg surface. The prepreg was placed inside a vacuum bag, on top of a heating plate, and heated to 55°C. Upon reaching 55°C, vacuum was applied, pressing the substrate and VACNT forest into the prepreg's surface. Vacuum was held for a few seconds. Thereafter, the vacuum bag was opened and the substrates removed, leaving behind the VACNT forest deposited on the prepreg surface.

2.3 Graphene-Coated Glass Fiber Weave

Electrically conductive inks with functionalized graphene (fG) were prepared according to Grafren's patented method [17]. Graphene fG ink was a graphene containing water dispersion with high electrical conductivity (up to 10 Ω/m^2 for 1 µm thick coating). As the dispersion was water-based and free of adhesives, it could be applied to most surfaces. E-glass mats (Hexcel 7781 glass fiber weave) were tested and verified for application with this type of fG ink. The prepared ink was applied to the surface of the glass fiber using Grafren's method [18]. Each individual fiber was covered with nano-flakes of conductive graphene. After several successive surface treatment steps, a complete electrically conductive skin of flexible fG sheets was created. The flake had a nano-sized thickness and a surface spread of 1–3 µm. These overlapped with each other and developed strong bonds between the functional groups in the adjacent flakes. The surface layer thickness achieved allowed high heat and electrical conductivity in the plane and out of the plane. This surface layer will from now on be referred to as the graphene-coating.

2.4 Sample Preparation

Samples with VACNT forests and graphene-coated glass fiber were prepared. The dimensions of all samples were 30x200 in-plane. The VACNT forest samples were 20 plies in thickness, with the VACNT forest being deposited on both prepreg surfaces facing each other in the midplane. During the lay-up, contacts of Carbon 20444A veil were placed in each, exiting the sample, to permit connectivity. In a similar way, the graphene-coated glass fiber weave was placed in the midplane, with 10 plies of HexPly6376-G-120 prepregs on each side. An extra layer of HexPly6376 epoxy adhesive film was added to one of the 10-ply stacks to aid with the wetting of the graphene-coated glass fiber weave. Contacts of Carbon 20444A veil were added and then subsequently cured, see 2.5. Three samples of each type were manufactured and studied in this work.

2.5 Cure Monitoring

The curing of the samples was performed using a vacuum-bag-only method inside an oven. The used cure cycle consisted of the following steps: 30 min at 30°C, followed by a temperature increase to 180°C, using a 2°C/min heat-up. Thereafter, the temperature was kept at 180°C for 2 hours and thereafter cooling down in the oven to room temperature. Full vacuum was applied during the whole curing cycle. A SP-50 Biologic Potentiostat, applying 10 V voltage, recording the current at 1 Hz, was used to monitor the resistive behavior of the embedded VACNT forests. Metallic interconnects were used to bridge the tacky tape and vacuum bag to connect the sample to the potentiostat. Two K-type thermocouples together with a NI9212 module from National Instruments via LabVIEW were used to register the temperature during the curing. The first thermocouple was placed in the oven, monitoring its temperature, the second was embedded in the mid-plane of a separate laminate of equal material and thickness as the samples, to measure the temperature at the placement of the resistive sensors.

2.6 Temperature Sensing

After curing, the samples were exposed to a temperature cycle to study their thermoresistive response. The test was performed using a ACS FM340C climate chamber. The climate chamber was programmed to decrease from 30°C to -70°C at 2°C/min and maintain -70°C during 15 min. Thereafter, the temperature increased 2°C/min to 150°C and was then maintained for 15 min. Lastly, the temperature decreased 2°C/min to 0°C. The resistance and temperature data were recorded as described in section 2.5.

2.7 Strain Sensing

The manufactured samples' piezoresistive response was evaluated performing quasi-static tensile testing together with continuous measurement of the sample's resistance. An Instron 4505 electromechanical tensile test machine was used for tensile testing together with a surface-mounted extensiometer to measure the sample-strain. The samples were loaded 100 N/s, up until 0.5 % strain was reached, staying in the elastic region of the sample. The 0.5 % strain was maintained for 30 seconds, then unloaded with the same speed. This cycle was repeated for each sample 5 times. To perform resistive measurements, the SP-50 Biologic Potentiostat was used to record the current at a constant 10 V voltage using a sampling rate of 10 Hz.

3. Results and Discussion

In this work, the focus is evaluating the performance of the graphene-coating as a multifunctional sensor. This evaluation is based on previous work performed by the authors on VACNT forests for the same applications, namely, cure monitoring [7], and strain and temperature sensor [3].

3.1 Curing

To evaluate the cure monitoring capability of the graphene-coating, a previously established procedure for assessing the VACNT forest's capability has been used. The cure cycle has been divided into phases, based on the cure cycle's temperature. First, phase I is the initial 30 minutes under vacuum at 30°C. Phase II is the heat-up to curing temperature, which has been divided into two parts in [7] due to the significant resistive shift. The third phase corresponds to the time spent at the curing temperature.

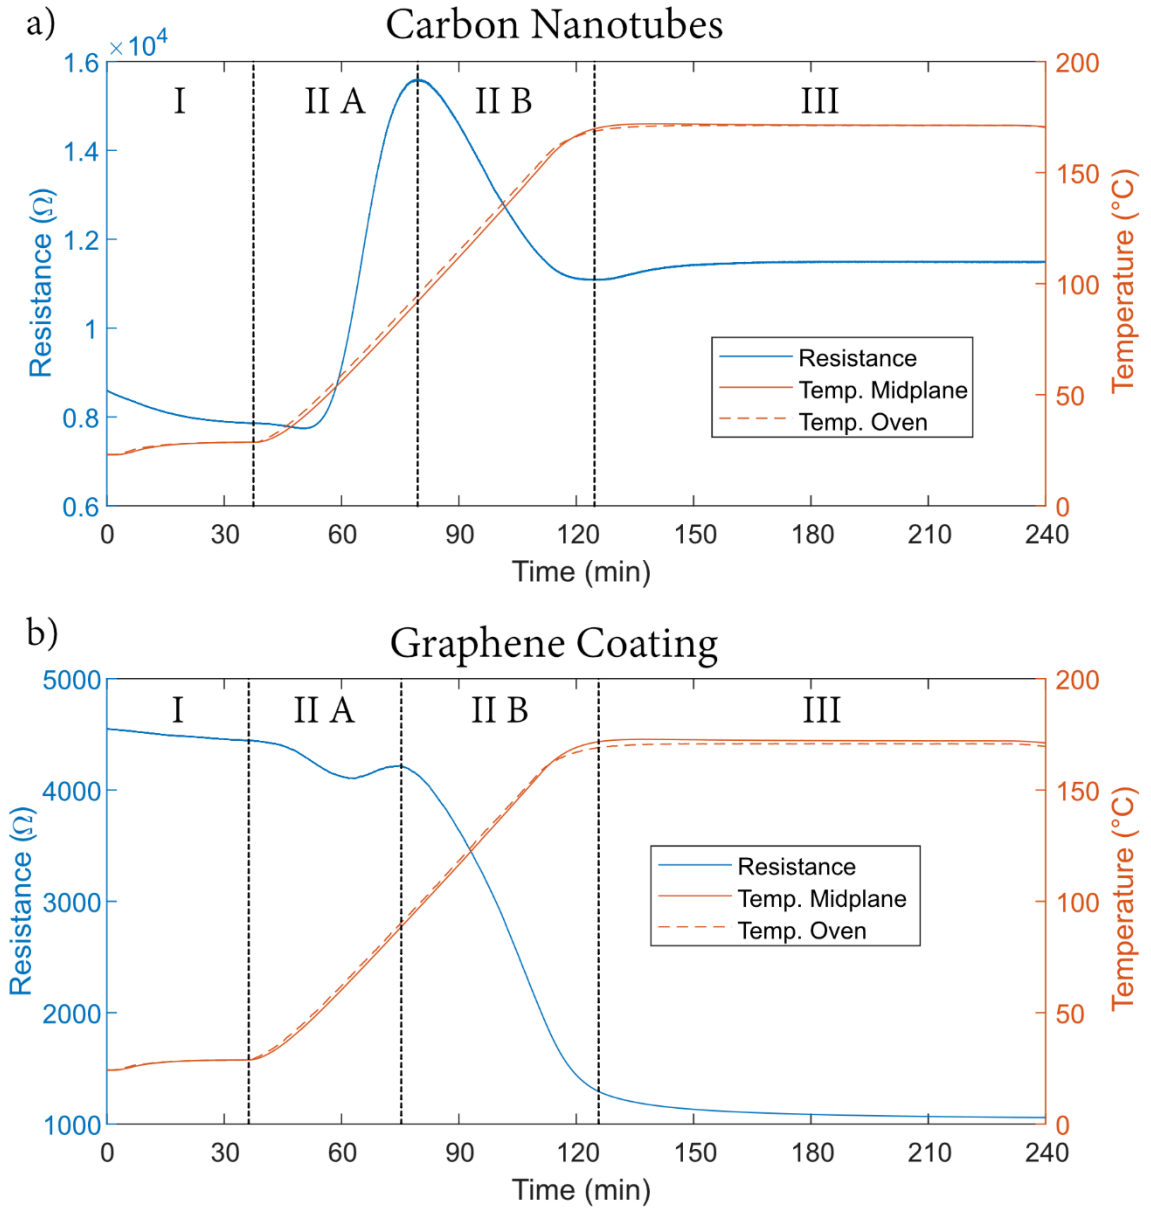

Figure 1: Resisitive cure monitoring of a) embedded CNTs b) graphene-coated glass fibers.

The decreasing resistance in phase I in Fig. 1a is caused by the consolidation of the laminate, the two VACNT forests in the midplane getting into better contact with each other, in addition to the slight increase of temperature to 30°C, both contributing to a lower resistance. In Fig. 1b, a small resistance decrease is also observed. Here, no significant impact of the consolidation is expected on the graphene coated on the glass fiber weave. Rather the slight resistance decrease is believed to be caused by the slight temperature increase, graphene having a negative thermoresisitive effect [13]. In phase II A, Fig 1a, as the heat-up commences, there is first a slight decrease in resistance. This is, again, caused by the

temperature increase, before the viscosity of the prepreg's epoxy is lowered enough to fill the interspace between the embedded CNTs, causing the dramatic resistance increase seen later in phase IIA in Fig. 1a. In Fig. 1b, there is also an initial resistance decrease, which is also reasonably caused by the temperature increase. However, the resistance decrease is lasting into higher temperatures using the graphene-coating than the embedded CNTs. At around 62 min, the resistance turns around and increase slightly until reaching 90°C. We believe this is also caused by the partial infiltration of the epoxy into the graphene-coating. However, the graphene structure's epoxy infiltration is not expected to be as significant as for CNTs, only achieving partial infiltration as presented in [6], explaining the relatively low resistance increase observed in Fig. 1b compared to in Fig. 1a. Later, in phase II B, the resistance decrease in Fig. 1a was determined to be caused by the thermoresisitve effect, decreasing as the temperature increased. The cure-induced shrinkage measured in [7] was concluded not to affect the resistive behavior directly. This is due to the resistive behavior observed in phase III, where the resistance increases, rather than decreases. A resistance decrease would have been expected if the embedded CNTs were significantly affected by the cure-induced shrinkage, resulting in a shorter inter-CNT distance. However, in Fig. 1b, the resistance decreases continuously. Initially, this is reasonably caused also by the thermoresistive effect, until approaching the cure temperature and phase III. Observing the resistance evolution over phase III for the graphene-coating, we observe a continuous resistance decrease over the whole phase, even though the temperature is stable. This may indicate a sensitivity to cure-induced shrinkage, which becomes more pronounced from 160° C, up until ca 15 minutes into the curing temperature, after that, it continues over its whole duration, but at a slower rate. Even though the epoxy infiltration is expected to be less significant in the graphene-coating than the embedded CNTs, the shrinkage of this epoxy is believed to still affect the resistive behavior. Similar observations have been made in [6].

3.2 Temperature Sensing

The thermoresistive response of representative samples of a) embedded CNTs and b) graphene-coated glass fiber weave is presented in Fig. 2 below.

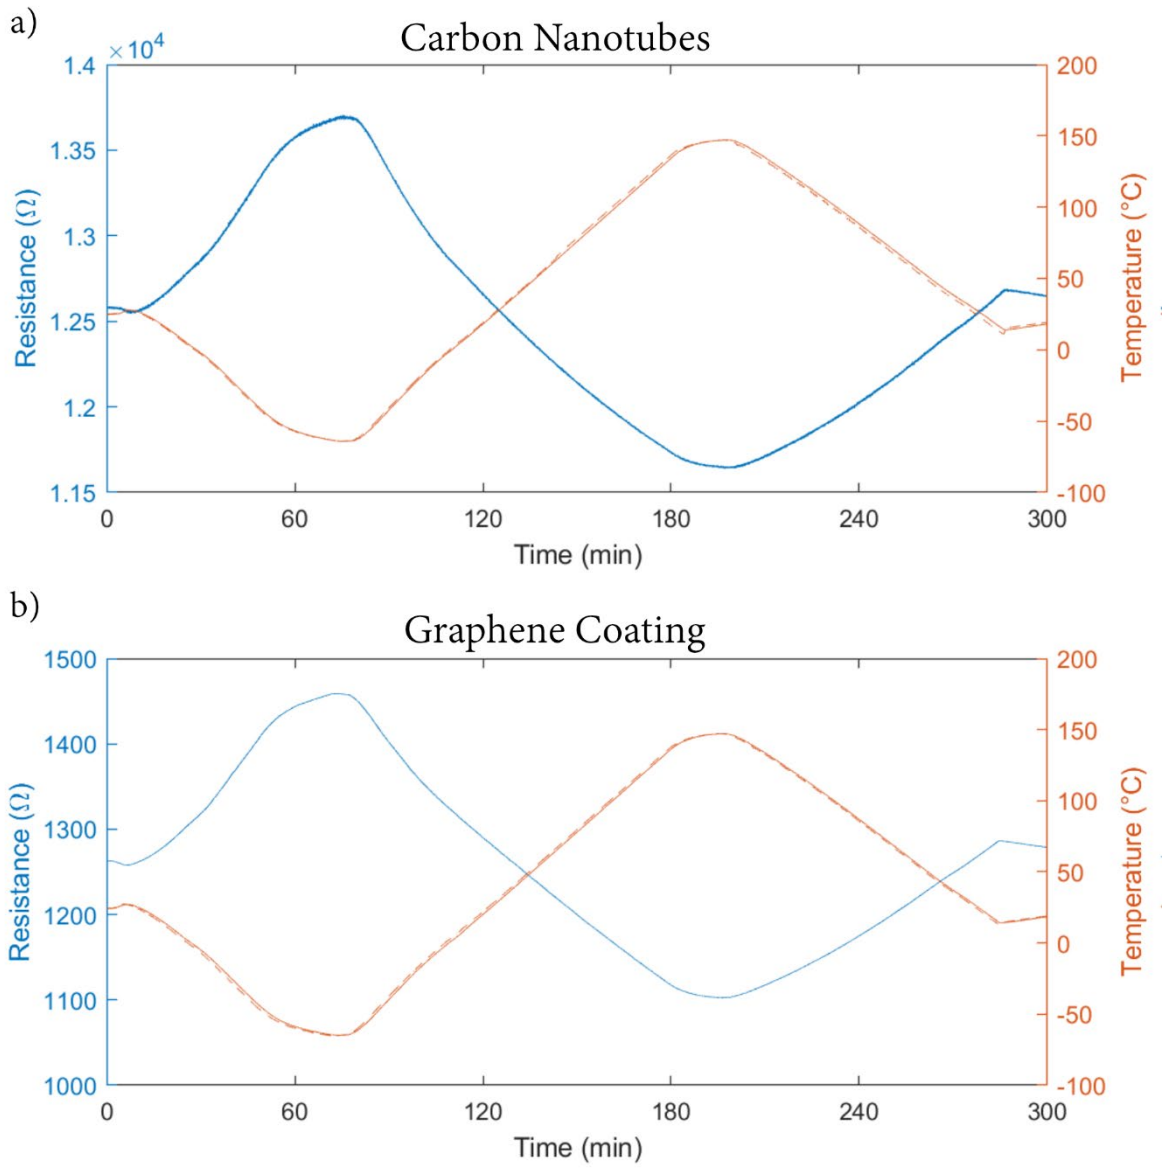

Figure 2: Thermoresisitve response between -70°C and 150°C for a) embedded CNTs and b) graphene-coating.

In both figures, it is obvious that the studied sensors have a significant resistive sensitivity to changes in temperature. The resistive signatures of the two sensors are close to identical, both having a negative thermoresistive effect, i.e. resistance decreasing as a response to a temperature increase.

3.3 Strain Sensing

The piezoresistive response of the two studied sensors is presented in Fig. 3. Fig. 3a presents the resistive changes observed for an embedded VACNT sensor, and Fig. 3b the resistive changes for the graphene-coated glass fiber weave.

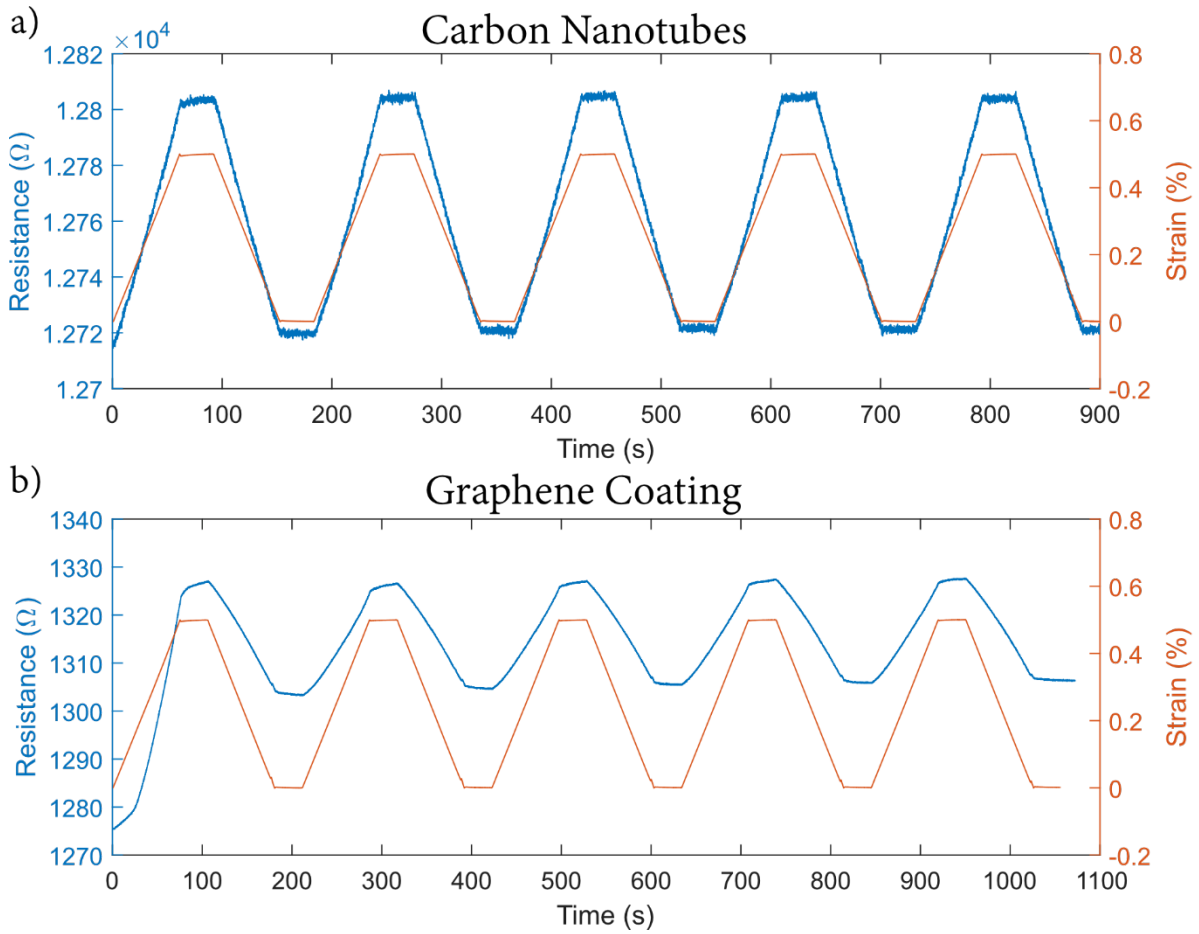

Figure 3: Resistive strain sensing of a) embedded CNTs and b) graphene coating.

First studying Fig. 3a, a linear piezoresistive response to the strain is observed. The resistance is stable during the holds at 0.5 % strain, and when off-loaded, no resistance drifting is observed. This pattern is repeated over the five repetitions. Our previous work [3], showed that the piezoresistive effect of individual CNTs collectively produce the observed piezoresistive response seen here. Looking at the piezoresistive response of the graphene-coated glass fiber weave, Fig. 3b, a large resistance shift is observed in the first load-cycle, the sample's resistance not returning to its original value once off-loaded. However, the following load-cycles are repetitive, indicating the initial behavior to be a one-time occurrence, at least for this specific load-cycle. No explanation for this resistive behavior of the graphene-coating samples is presented in this work, requiring further studies. During the 0.5 % strain holds, the graphene-coating shows a resistance drift, the resistance increasing over time. This is similarly observed when off-loaded, the resistance decreasing slightly. Again, to determine why this resistive behavior is present more work is required. However, the authors suspect the nature of the epoxy infiltration into the graphene-coating on the glass fiber weave to be a cause of this, and plan to investigate this further in future work, and also the adherence of the graphene-coating to the individual glass fibers.

5. Conclusions

In this paper, the suitability of a graphene-coating on glass fiber weave as a multifunctional sensor is evaluated and compared to previous work performed by the authors on embedded VACNT forests. The graphene-coating has been evaluated as a cure-monitoring sensor when embedded in thermosetting glass fiber/epoxy laminate to monitor its production. The graphene-coating showed similar results to the cure monitoring of CNTs, the resistance being sensitive to its surrounding temperature and also believed to respond to partial epoxy infiltration of its structure. However, the graphene-coating diverges from the CNT sensor when kept at cure temperature, showing a continuous resistance decrease in this phase. This

possibly indicates a sensitivity to cure-induced shrinkage of the epoxy, which infiltrated the graphene structure earlier in the cure cycle. Later, in the cured state, the embedded graphene-coating functions as an excellent temperature sensor, possessing a negative thermoresistive effect. However, as a strain sensor, the graphene-coating does not perform as well as the compared-to embedded CNT sensor, possessing an initial drift in resistance upon its first load cycle and additional drift during constant strain conditions at 0.5 % strain, and when unloaded.

ACKNOWLEDGEMENTS

The authors would like to express their gratitude to Erik Khranovskyy and Mykhailo Zhybak at Grafren AB for developing and delivering the studied graphene-coating within the 2DTech project, and also the Swedish Governmental Agency for Innovation Systems, Vinnova, funding the 2DTech project.

ABSTRACT

Fiber reinforced composite materials are currently essential for several engineering applications that need to combine high mechanical properties with very low structural weight. However, due to their heterogeneous composition, the failure mechanisms in composites are still very unpredictable, unlike that happens with steel or aluminum [1]. This leads to the need of applying real-time monitoring techniques in composites, through the incorporations of appropriated sensors into them, in order to ensure their safely work in service. This work presents a new layer concept to be embedded within carbon fiber reinforced polymer (CFRP) composite laminated structures, capable of real-time monitoring of their strain status. It contains strain gauges (SG) that can measure the evolution of strains in the internal laminae of structural composites and an electric circuit directly printed on its surface to transmit the data obtained to an acquisition system for further processing and analysis. Bulk CFRP/epoxy samples and equivalent ones containing embedded sensing film and regular polyimide films are submitted to interlaminar shear strength and tensile testing. With the former, it was possible to assess eventual effects on the adhesion between the layers of the composite, while the latter were used to evaluate the influence of the embedded film on the mechanical properties. Moreover, by placing an equivalent surface mounted SG, it was possible to directly compare strain data from the surface and the interior of the composite, thereby serving as validation method for the sensing circuit. The experiments carried out demonstrated that the proposed embedded sensing film allowed indeed accurately monitoring the internal strains developed within composites. Additionally, it was observed that the inserted embedded monitoring layers did not affect significantly the adhesion and mechanical properties of the CFRP composites, unlike what happened with the embedded polyimide layers.

1 INTRODUCTION

The application of composite materials has seen a significant increase in recent decades in several engineering fields, continuously replacing traditional metals such as steel or aluminum. Due to their high strength-to-weight ratio, achieved by combining high mechanical properties fibers with matrices capable of ensuring an efficient stress distribution, the production of parts and structures with high mechanical properties at low structural weights is achieved by multiple manufacturing techniques. In comparison to metals, this means that the mechanical performance is either equal or improved at more reduced fuel consumption and CO_2 emissions as well [2].

One of the issues of composites is the difficulty in predicting their mechanical performance and failure mechanisms at the loading conditions they need withstand by design, because of their inherent heterogenic and anisotropic nature. In addition, polymer matrix composites are sometimes brittle, which makes even more difficult predicting their in-service failure due to the high number of mechanisms involved in this process. It is of particular concern in aeronautic and aerospace applications that composites are also prone to barely visible impact damage (BVID), in which certain low-velocity

impacts caused by relatively small masses, can lead to delamination, fissures or even cracks in the composite laminate [1].
An increasing number of research has been carried out concerning these issues using structural health monitoring (SHM) solutions. Among them, the most auspicious monitoring concepts use built-in structural diagnostic systems containing a sensing network, integrated hardware and software to read and analyze the collected data in real-time during the service life of the composite structure. This is the main idea behind the use of "Embeddable monitoring layers" (EML), which are essentially thin flexible layers with sensing networks for being embedded, as additional layer between structural composite laminae, which are capable of monitoring and transmitting in real-time data regarding the current state of the host structure. When working with composites it is advisable to have such sensors embedded within their inner structure, as it is closer to internal damage sources, which are easier to detect due to the enhanced sensitivity caused from the stronger coupling with the structure [1, 3, 4]. Other advantages include the shielding from environmental factors [5], monitoring throughout the entire lifespan of the structure [6], noise reduction [7], less complexity due to the removal of wiring [8] and surface profile integrity preservation, which is extremely important in aeronautic applications, as aerodynamic efficiency is one of the critical design constrains [9].
It is also worth noting that embedding monitoring devices or sensing films increase the overall complexity of the manufacturing process of composites, mostly regarding difficulties in adhesion and incompatibility between the materials that are being embedded and the surrounding structural layers of the composite. When not properly addressed, the final part or structure could be more susceptible to the occurrence of geometrical defects, namely delamination or increased number of voids in the composite, which affect negatively the overall mechanical performance of the composite structure [10, 11].
This paper presents the development and validation of a new concept for EML to be inserted within CRFP laminated structures, for strain monitoring purposes. The novelty lies in the substrate of the film itself, which is a cured thin strip of epoxy resin, equal to that of the matrix of the composite, to prevent issues with delamination [12] in the interface between the EML and the adjacent structural layers. The experimental work was focused on the development of the EML by using vacuum bag infusion (VBI). Tensile tests are then carried out on bulk CFRP samples and the equivalent ones containing embedded EMLs and regular polyimide (PI) films, in order to verify the performance of the sensing circuit and to evaluate the influence of the inserted sensing films on the mechanical performance of composites. Another group of samples was submitted to ILSS tests to assess the overall adhesion properties. Comparisons are traced out between EML and PI films, as the latter is a very popular substrate used in the design of flexible sensing circuits, and has been embedded in composite materials for monitoring purposes [6, 13, 14].

2 EXPERIMENTAL PROCEDURE

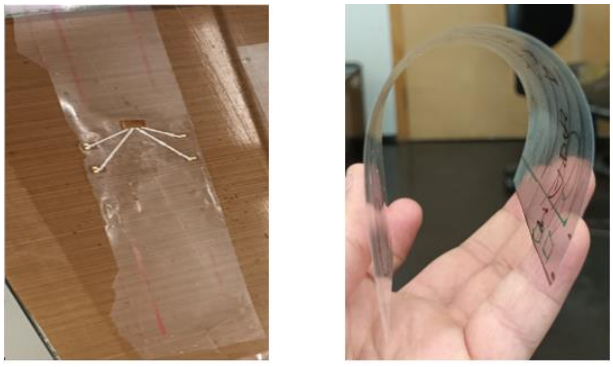
2.1 Materials and methods used for manufacturing the embeddable monitoring layers (EML)

The development of a new EML for internal strain monitoring to apply in polymer reinforced composite materials is presented. Its substrate is meant to be equal to that of the matrix of the composite laminate in which it is going to be inserted into, to achieve compatibility between the matrix of the composite and the EML itself. In this experimental work, the following epoxy resin is used for both of the aforementioned ends:

- Sicomin SR Infugreen 810 resin mixed, at mass fraction of 29%, with the SD4771 hardener.

The EML substrate is obtained by VBI, under the following procedure:

- After mixing the resin with the hardener, it should be impregnated, under vacuum, to the interior of a sealed bag that contains the mold of the film, as shown in Figure 1;
- The mold is composed of two glass plates, with Teflon layers to facilitate demolding, that are vacuum sealed inside a bag, with no observable air leaks. The resin flows between the two glasses, due to the prior application of layers of thin tape on one of the glasses. This ensures that



there is a cavity between the glasses from which the resin can slowly flow and form the film with the desired thickness. For this set of experiments, two layers of 50 µm non-absorbent tape were placed on the edges of a single glass in order to later obtain thin epoxy resin films with 100 µm of thickness;

- The resin fully cures after two days at room temperature. However, at this point, the epoxy resin is very brittle, and there is a serious risk of shattering the film when separating glass. Thus, the separation process needs to take place before the resin is completely cured. Multiple tests with the resin demonstrated that the glasses should be separated approximately 30 hours after resin impregnation. These values are of course completely dependent on the type of resin or matrix that is being utilized to fabricate the films;
- Upon separation, the thin epoxy film is sticked on the glass that contains the reference tape.

Figure 1 - VBI arrangement to manufacture the thin epoxy resin

The sensing circuit used in this work was designed for strain monitoring. It consists on a single bi-directional SG (Omega, model SGT-4/350-XY41 – with 350 Ω base resistance, 2.09 gauge factor and 30000 µm maximum strain), 4 manually screen printed silver ink (Dyoctec, model DM-SIP-2004) conductive tracks used to transmit strain data and 4 soldering terminals (HBM, model 1-LS4-G), from which it is possible to relay the strain data to an acquisition system capable for post-processing and analysis. The circuits can be directly mounted in the epoxy substrate, and since the Ag ink needs to undergo curing at temperatures between 80 and 150 °C, the latter must still be attached to the glass, otherwise, the thin epoxy structure deforms irreversibly. Finally, the film can be detached from the glass plate, thus finalizing the manufacturing of the EML, as shown in Figure 2 a). The main characteristics of the film are its transparency, its low thickness, which was set at 100 µm, and its high flexibility, as can be seen in Figure 2 b).

a) b)

Figure 2 - Epoxy substrate EML: a) view with SG sensing circuit; b) EML flexibility

2.2 Manufacture of CFRP samples

The EML was embedded in composite laminates and the manufactured samples were submitted to tensile and ILSS tests. In both experiments three groups of CFRP samples were compared: G1 containing

bulk CFRP samples with no embedded films, G2 including CFPR with embedded EML and G3 having CFRP samples with embedded a PI sensing films.
For both tests, the following sequences for each group of samples were adopted:

- G1 Tensile test (G1-T) sample configuration – $[0]_{3s}$
- G2 Tensile test (G2-T) sample configuration – [0/0/0/EML/ISO/0/0/0/]
- G3 Tensile test (G3-T) sample configuration – [0/0/0/PI/ISO/0/0/0]
- G1-ILSS sample configuration – $[0]_{4s}$
- G2-ILSS sample configuration – [0/0/0/0/EML/ISO/0/0/0/0]
- G3-ILSS sample configuration – [0/0/0/0/PI/ISO/0/0/0/0]

The CFRP laminates were manufactured through VBI, in which each individual layer is stacked on a mold that is subsequently vacuum sealed, and then impregnated with epoxy resin and left to cure for approximately two days at room temperature. The structural layers were obtained from unidirectional carbon fiber fabric 350 UT from Rebelco, with areal weight of 350 g/m^2, and for the specimens that contain PI sensing films, Kapton variant model 300 MT from DuPont, with 0.075 mm of thickness is used. To safeguard the electric circuit from adjacent conductive carbon layers, an additional thin strip of epoxy resin (reference ISO), obtained from the same procedure that is described in section 2.1, is placed on top of the circuit.

The tensile test samples were prepared accordingly ASTM D3039/D3039M standard, while the ones for ILSS ones followed the procedure of ISO 14130:1997 standard. However, to ensure that the internal strain data is being collected from the samples with EML and PI sensing films that are submitted to tensile testing, it was necessary to slightly increase their width. To avoid deformation on these films during the manufacturing process, the width of the structural layers that are placed beneath should likewise be the same. Figure 3 presents a manufactured stacked laminate prior to the addition of the sensing system. As ILSS testing is only conducted to verify the adhesion properties of the laminates, even if these contain embedded sensing films, the data will not be recorded, and all layers, both structural and sensitive, will have the same dimensions. Overall, 60 test specimens were manufactured, belonging 10 to each of the six groups. The dimensions of all manufactured samples are presented in Table 1.

Figure 3 - Stacking sequence used for manufacture of CFRP tensile test specimens with EML

Table 1 - Dimensions for ILSS and tensile test subjects

Sample group	Length (mm)	Width (mm)	Thickness (mm)
G1-T	250	25	2.44 ± 0.0583
G2-T			2.49 ± 0.0772
G3-T			2.46 ± 0.0756
G1-ILSS	27.5 ± 0.5	13.75 ± 0.25	2.75 ± 0.05
G2-ILSS	30.5 ± 0.5	15.25 ± 0.25	3.05 ± 0.05
G3-ILSS	28.2 ± 0.4	14.4 ± 0.2	2.82 ± 0.04

All the samples submitted to tensile tests will contain a single conventional SG (equal to the ones present in EML and PI sensing films) mounted on their surfaces. By comparing the obtained strain data between G1-T, G2-T and G3-T it is possible to assess the effect of the embedded resin layers and PI layers,

present in G2-T and G3-T respectively, on the tensile properties of the CFRP samples. On the other hand, the comparison between internal strains and external strains can be used to validate the sensing performance of EML. Representative ILSS and tensile test specimens are shown in Figure 4.

a) b) c) d)

Figure 4 – Examples of final test samples: a) CFRP specimen with EML for tensile test; b) CFRP specimen with embedded PI film for tensile test; c) Bulk CFRP samples for ILSS tests; d) CFRP samples with EML for ILSS testing

3 RESULTS AND DISCUSSION

3.1 Results and discussion

Composite specimens belonging to groups G1-T, G2-T and G3-T, each representative of a specific condition, were submitted to tensile testing in a MTS Criterion model 45 universal testing machine at a crosshead velocity of 2 mm/min, using a load cell of 250 kN, and 180 mm as initial distance between grips. The SGs used in this work contain two grids, allowing the simultaneous measurement of both longitudinal and transversal displacements and the determination of the Poisson´s ratio (ν_{12}), alongside the Young´s modulus of the composite in the longitudinal (E1) and transverse directions of the fibers, depending on the orientation of the fabric layers of the samples used in the tensile tests.

3.1.1 EML internal circuit validation

To validate the EML strain monitoring mechanism, the respective internal data was compared with the corresponding one obtained from surface SG. Figure 5, for sample reference G2-T3, shows the stress/strain curves (Figure 5 a)), derived from longitudinal strain data, and transversal strains (Figure 5 b)), respectively.

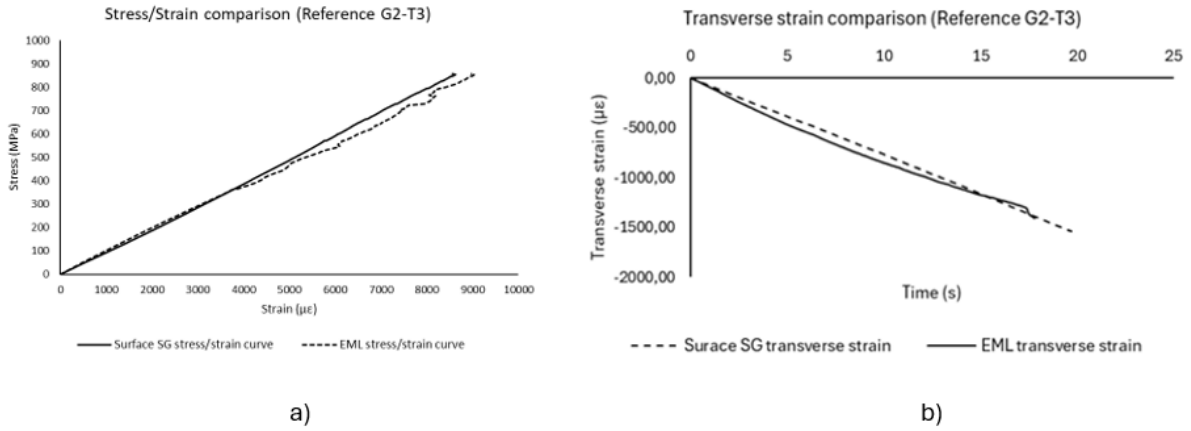


Figure 5 - Comparison between EML mechanism and conventional surface SG during tensile test on sample referenced G2-T3: a) Stress/Strain curve; b) Transversal strain

As can be observed in Figure 5 a), the evolution of stress during the tensile tests is extremely alike considering strain data of both EL and conventional SG sensing methods. The slight differences that are observed starting from 4000 με can be attributed to the fact that both SGs are measuring strains in different surfaces, with the internal SG from the EML measuring the deformation of the embedded epoxy substrate, while the external one is monitoring directly on the carbon surface. Other factors, such as the different location of the sensors in the laminate, potential contamination of the internal tracks with the impregnated epoxy, eventual deformations imposed on the printed ink during the tensile test and the different conductors that are used (metal cables for the conventional surface SG and conductive silver ink for the embedded SG), which may have different associated electrical resistivity, can potentially contribute to the small observed deviations between both sensors. When comparing the linearity of both data sets with the Pearson correlation coefficient, a matching of ≈ 99.83% is obtained indicating very good match. E_1 was calculated in accordance with ASTM D3039/D3039M in which its value corresponds to the slope of the stress/strain curve between strains of 1000 με and 3000 με. For the G2-T3, the measured E_1 from the surface was 96.72 GPa, while the one calculated with data from EML was 95.43, amounting to a final error of 1.3% between the two sensing mechanisms. Overall, considering all the CFRP samples, the average longitudinal moduli measured with EML was 97.6 GPa ± 4,74, while in the surface a mean value of 100 GPa ± 0.105 was determined, with a very small corresponding error of 4.21 ± 2.66, attesting for rather satisfactory performance of the internal strain monitoring mechanism.
Likewise, transverse strains could also be measured with a certain degree of precision with EML, as can be observed in Figure 5 b). These values are negative, since the samples under tensile test tend to shrink, alongside the respective internal and external mounted SGs. Using transverse strains between 1000 με and 3000 με it is possible to calculate ν_{12} with the data from the EML and the surface mounted SG, obtaining, respectively, 0.34 ± 0.0396 and 0.29 ± 0.0425, which translates to an error of approximately 14.7%. This larger error is expected since strain in the transverse direction is more dependent on the behavior of the matrix, which is more susceptible to variability due to matrix cracking or fiber-matrix. Furthermore, considering that the SGs are placed in different locations and measuring strains in different surfaces, with the one from EML being mounted on a flexible epoxy layer, a higher deviation between the external and internal transverse strain may not be fully unexpected and could explain the slight higher deviation of ν_{12} in relation with E_1.

3.1.2 Tensile properties of CFRP laminates with EML

Upon verifying the performance of embedded SG sensing circuits in CFRP composites laminates, it was necessary to verify just how does EML affects the mechanical behavior of the host structural composite. This comparison was made by studying thirty CFRP laminated samples, distributed equally across three different conditions (G1-T, G2-T and G3-T), with all of them containing a surface mounted bi-axial SG for the determination of E_1 and ν_{12}. The results from the tensile tests are presented in Table 2.

Table 2 - Final values of E_1, ν_{12} and ultimate tensile strength for different CFRP tensile test sampling groups.

CFRP sample group	E_1 (GPa)	ν_{12}	Ultimate tensile strength (MPa)
G1-T	105 ± 3.98	0.301 ± 0.0398	925 ± 60.4
G2-T	99.1 ± 4.83	0.311 ± 0.0525	875 ± 8.85
G3-T	96.8 ± 3.08	0.312 ± 0.0650	808 ± 54.5

The insertion of both EML and monitoring PI films has seemingly minimal effect on E_1 and ν_{12} values. When comparing the average E_1 obtained from samples belonging to G2-T and G3-T groups with the control group G1-T, the modulus decreases, respectively, 5.62% and 7.81%. Comparing G1-T with G2-T and G3-T regarding the obtained average values for ν_{12}, it can be attested that the latter increases 3.32% and 3.65%, respectively. The differences between the analyzed groups of CFRP laminates seem to be more noticeable when analyzing the ultimate tensile strength, where, in comparison with the control group G1-T, samples from G2-T showed a reduction in this parameter of approximately 5.41%, whereas the ones belonging to G3-T exhibited a decrease around 12.65%. Since the substrate of the monitoring technique is the only testing parameter that is different across the three types of samples, it can seemingly be attested that while the monitoring technique itself may exert reduction of the mechanical properties of CFRP composites, these effects may be dampened with the application of the epoxy layer substrate corresponding to the material used as the matrix.

The results demonstrated in Table 2 can be better understood through the visualization of representative stress/strain curves in Figure 6, where, once again, it seems that the introduction of the embedded monitoring layer in CFRP laminates does not significantly affect E_1 and ν_{12}, as the slopes for all three curves, calculated for strains between 1000 με and 3000 με, is nearly coincident.

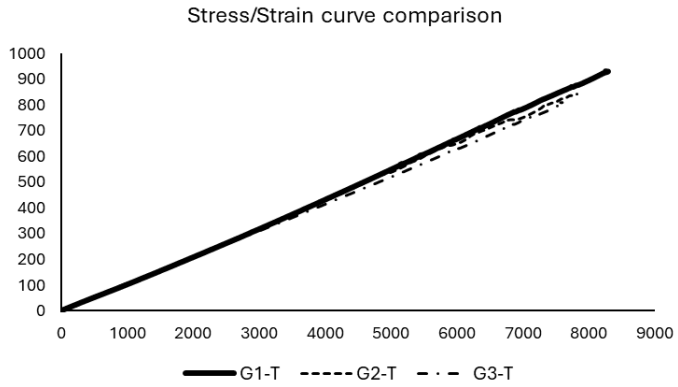

Figure 6 - Comparison of Stress/Strain curves obtained for the different CFRP sampling groups

Slightly higher differences are observed as the tensile samples approach their respective ultimate tensile strength, where it is possible that the inclusion of the SG monitoring circuits could be the main factor in the reduction of this parameter in CFRP laminates belonging to both groups G2-T and G3-T. The advantage in using the proposed epoxy substrate for the EML, regarding the mechanical properties, could be the usage of the thin epoxy film itself, where the latter can sustain slightly higher tensile stress, with the average maximum stress obtained for G2-T being approximately 7.65% higher than the one observed in G3-T CFRP samples.

3.2 Interlaminar shear strength test

One important aspect that must be assessed when inserting the EML inside CFRP laminates, is the effect it may have on the adhesion with the remaining structural plies of the host composite. To that end, ILSS tests were also conducted on CFRP laminated specimens, split between G1-ILSS, G2-ILSS and G3-ILSS, in agreement with ISO 14130:1997 standard. Adhesion can be evaluated with this test, as specimens with small support span lengths are submitted to three-point bending. The apparent interlaminar shear strength (τ) is calculated using (1), where *F* is the failure load in N, *b* the width of the composite in mm and *h* is the thickness of the composite in mm.

$$\tau = \frac{3}{4} \times \frac{F}{bh} \quad (1)$$

The samples are submitted to three point bending at a testing velocity of 1 mm/min, with pre-load of 10 kN, in the universal testing machine Shimadzu Autograph AGX.
Before calculating τ, it is necessary to evaluate the failure mode of the samples. To properly assess the adhesion, the samples have to fail either from single shear or multiple shear, which represent the occurrence of delamination (Figure 7). Four samples of the G1-ILSS group, however, exhibited compression failure, thus rendering their respective results unusable, according to IS0 14130:1997 standard. As all specimens from G2-ILSS and G3-ILSS, which contain respectively the EML and the PI sensing film, presented either single shear or multiple instances of shear, a potential indicator that the embedded monitoring devices could affect adhesion. The calculated results for τ are shown, for each of the tested conditions, in Table 3.

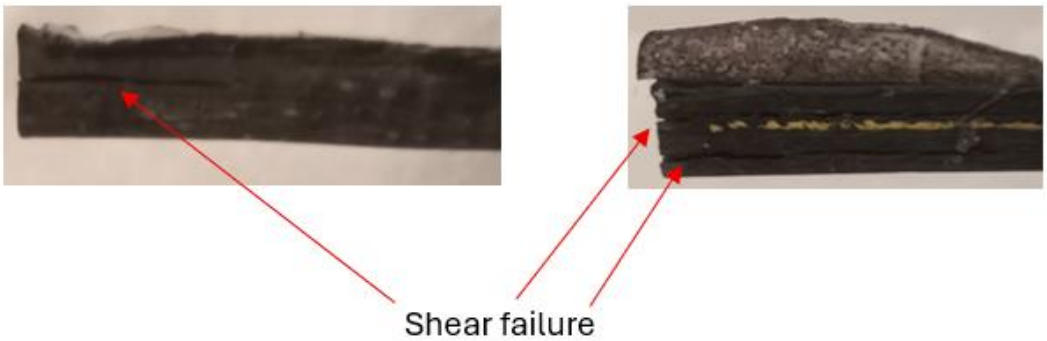

Figure 7 - Single shear and multiple shear failure observed in CFRP samples after ILSS test

Table 3 – Calculated values for τ

CFRP sample group	T (MPa)
G1-ILSS	38.2 ± 2.64
G2-ILSS	37.9 ± 1.12
G3-ILSS	19.5 ± 1.75

From the values obtained for τ, it can be attested that the adhesion properties of composites with embedded monitoring mechanisms are heavily reliant on the substrate of the embedded film. This is due to the fact that the G1-ILSS and G2-ILSS have extremely similar values for τ, with the insertion of EML reducing this value, in average, by approximately 0.785%, whereas the embedment of PI sensing films decreased τ nearly in half by 48.9%. The near coincidence in the results observed for G1-ILSS and G2-ILSS in addition to the extremely large reduction of τ calculated for G3-ILSS seem to indicate that the circuit itself might not affect the adhesion of the overall adhesion of the composite, since it is presented only in G2-ILSS. As such, the main factor that can alter τ could most likely be the substrate used for the

embedded sensing devices, where the PI is vastly outperformed by the thin epoxy film. This is explained by the high mechanical and chemical compatibility of the epoxy that was utilized in the production of EML, which is equal to the resin used for the matrix of the composite.

For a better evaluation of the results shown in Table 3, τ was plotted in relation to the displacement as shown in Figure 8, considering representative ILSS samples from each of the conditions that were studied. There seems to be a good agreement with the values calculated for τ, as the curve for the G3-ILSS is well below the ones from G1-ILSS and G2-ILSS, once more alluding that the PI film could severely affect the interlaminar adhesion of the composite. While this issue with PI can be potentially solved or mitigated with surface treatments, in accordance with the results obtained from the ILSS tests, the epoxy substrate of the EML has seemingly residual effect on the adhesion properties of the host composite, without needing surface treatment.

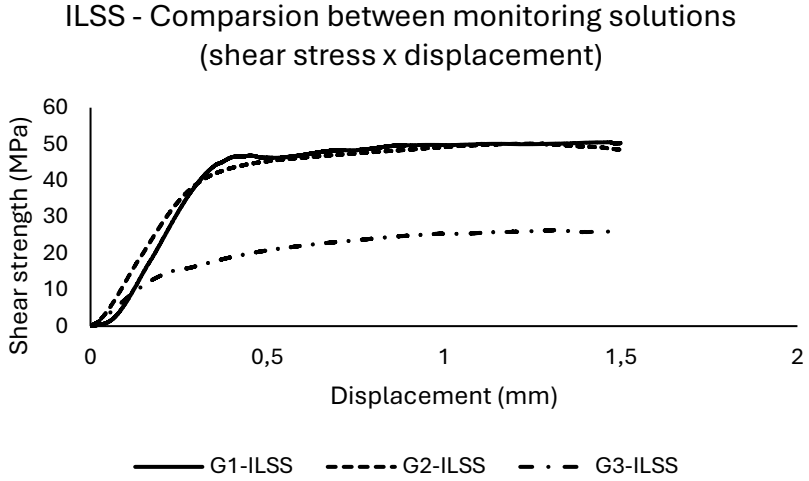

Figure 8 - Plot of τ in relation to the displacement for representative samples.

4 CONCLUSIONS

In this paper, the design, validation and effects of a new proposed EML for real-time monitoring of composite laminated structures was presented. The sensing mechanism was obtained by developing a reliable and repeatable variant of the typical VBI technique that is commonly applied for the production of high-end composite materials. Using that same process, it is possible to create multifunctional composites with EML. Regarding the performance of the internal sensors in measuring strains, it could be observed, from the conduction of tensile tests, that the EML sensing approach was able to precisely measure both transversal and longitudinal strains. Moreover, from the same tests, it was possible to determine that EML and the more common PI sensing films have low effect on the mechanical properties of the CFPR composites, with E_1 decreasing 5.62% in G2-T specimens and 7.81% in G3-T specimens.
The main differences were observed when assessing the influence of the embedded mechanisms in the adhesion of the composite, where it was possible to observe, even before analyzing the data from the tests, that the insertion of the layers could prompt the occurrence of delamination. However, from the analysis of τ, it was possible to verify that the EML outperformed the PI sensing film in preservation of the adhesion properties, where samples from G2-ILSS presented reduction in τ inferior to 1%, whereas in samples from G3-ILSS, this increase was almost 50%.
More studies are still needed to evaluate the effect that the developed EMLs can have on composite materials under bending and impact testing. Additionally, the EML concept needs to be studied with other sensors, such as piezoelectric ones for real-time monitoring of vibrations or impact events, to ensure it can be applied in a wide range of scenarios.

INFLUENCE OF LAMINATE SURFACE RESIN DEPTH ON THE INTERFACE STRENGTH OF OVERMOULDED COMPOSITES

ABSTRACT

A systematic study was performed to investigate the influence of surface resin depth on the interfacial strength of overmoulded composites using both experimental and simulation methods. Discontinuous fibre reinforced polyetheretherketone (PEEK) was injected over a unidirectional (UD) laminate to manufacture lap-shear specimens, varying both the surface resin depth present on the laminate insert and the weight fraction of discontinuous fibres filling the injected polymer. The surface resin depth was modified from a standard quasi-isotropic laminate with limited surface resin content with inclusion of a film of two different polymers. This included both polyaryletherketone (LMPAEK) and polyetherimide (PEI) film of thickness 40µm. In both cases the films were added to the laminate surface during the consolidation of the laminate. Mechanical tests showed an increase in lap-shear strength when a thin film was present on the specimen surface. A similar improvement in bond strength was achieved for both LMPAEK and PEI surface film layers. A counterpart numerical modelling process was developed to understand the heat transfer process occurring during overmoulding. The primary finding of the simulation was that a reduction in local thermal diffusivity at the interface (such as achieved through a resin-rich layer at the interface) can be used to increase the interface temperature. The results of this study are important for the manufacture of overmoulded composites as both the technical findings and the simulation process presented can be used in the design process to improve interface strength.

1 INTRODUCTION

Composite injection overmoulding is performed by combining injection moulding with the use of continuous fibre reinforced thermoplastic composites (also referred to as the insert or substrate throughout this text) by placement within a mould tool prior to the injection stage. As the molten polymer is injected into the mould, contact with the surface of the insert allows a bond to form and consolidate under pressure, heat, and time. Composite injection overmoulding can reduce the costs associated with the manufacture of complex composite structures. This is the case, as incorporating injection moulding for features can significantly reduce processing times and increase automation. The superior strength of continuous fibre reinforcement can be attained for load-bearing components by incorporation of a composite insert [1]. However, achieving a desired interface strength may be an issue as the formation of a strong bond at the interface is required for maintaining structural integrity in load-bearing applications. The interface strength is dependent on the material and processing conditions which include (but are not limited to) interface temperature, crystallinity, thermodynamic compatibility, and local flow velocity [2-5].

2 METHODOLOGY

During this study a systematic approach was undertaken to understand the relationship between the resin present on the surface of a composite laminate and the interface strength of overmoulded composites. This involved the manufacture and testing of overmoulded single lap-shear specimens alongside the development of a complimentary overmoulding process simulation to understand the heat transfer process (Fig. 1).

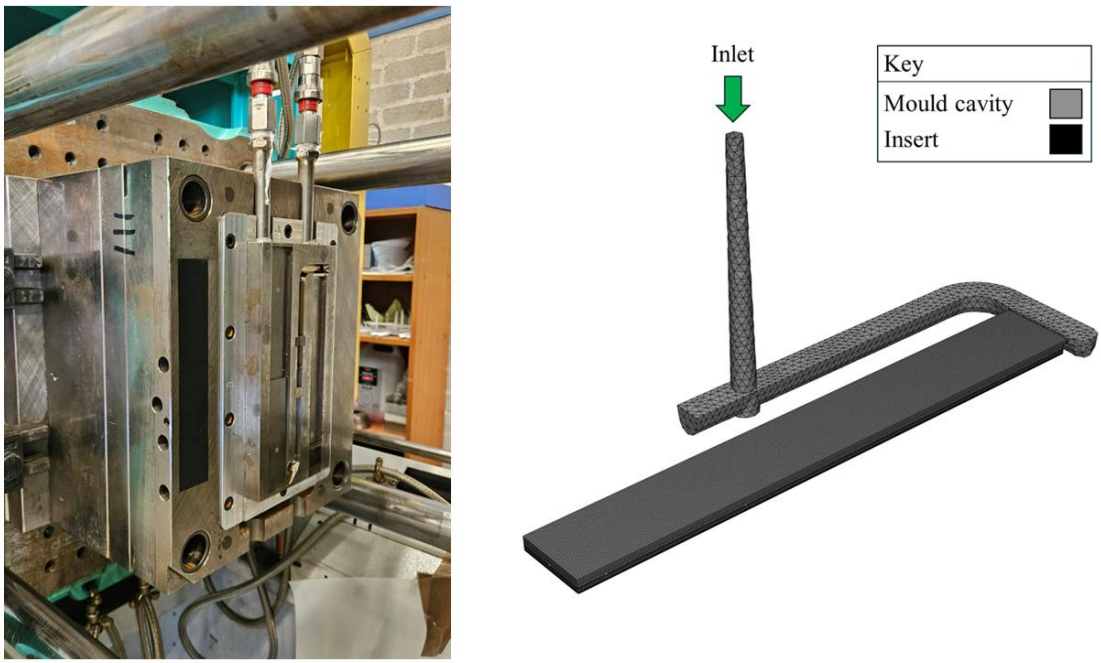

Figure 1: Overmoulding mould used for the manufacture of overmoulded coupons (left) and simulation grid of counterpart process simulation.

2.1 Overmoulding single lap-shear specimens

Rectangular coupons were prepared using quasi-isotropic Toray Cetex TC1225 composite reinforced with T300 carbon fibres. The matrix of the TC1225 composite is a proprietary blend of thermoplastic polymers from the polyaryletherketone (PAEK) family which are selected to reduce its melting point in order to improve processing, particularly for thermal bonding scenarios and is referred to by its suppliers as low-melt PAEK (LMPAEK). To make a comparison between the bond properties of laminates which had a higher surface resin fraction, additional LMPAEK laminates were obtained from Toray which included an additional preconsolidated film on the surface. One side of the surface-resin modified LMPAEK composite was consolidate with an additional LMPAEK film while the other side had a polyethylenimine (PEI) film. This allowed inserts to be flipped to vary whether insert/injected melt interface was on the LMPAEK or PEI side of the laminate. Two different grades of injected material were used to manufacture overmoulded lap-shear specimens. These were two different grades of polyetheretherketone (PEEK) which contained different concentrations of discontinuous reinforced carbon fibres. The two grades of material were Evonik's Vestakeep 2000 CF30 (30wt% carbon) and Vestakeep 4000 CF10 (10wt% carbon) and are abbreviated as V2000 CF30, and V4000 CF10 throughout this work. These two grades of material contain PEEK of a different range of molecular

weights, with V2000 being lower than V4000. PEEK is a polymer within the greater PAEK family and as such highly compatible with both PEI and LMPAEK.

Overmoulding was performed using an Arburg Allrounder 520 S injection moulding machine. The mould block was cooled by pressurised water and produced rectangular coupons of dimensions 144 x 20 mm. Lap-shear specimens were manufactured from the overmoulded bi-material specimens by milling a channel on either side of the specimen, allowing a one-inch overlap about its centre.

2.1 Simulation of the overmoulding process

The overmoulding process was simulated using the Volume of Fluid (VoF) method in the simulation package Ansys Fluent. The following continuity equation is solved for each phase of index i. The continuous phase is denoted by the subscript 1 [6]:

$$\frac{1}{\rho_1}\left[\frac{\delta}{\delta t}(\alpha_i\rho_i) + \nabla\cdot(\alpha_i\rho_i\vec{u})\right] = S_{\rho,i} \tag{1}$$

where ρ is density, t is time in seconds, α is the volume fraction, $\vec{u}$ is the velocity vector. $S_{\rho,i}$ is a density sink term used to return the air pressure to ambient within an enclosed mould. The momentum conservation equation is calculated for a shared velocity field with volume-averaged properties [6]:

$$\frac{\delta}{\delta t}(\rho\vec{u}) + \nabla\cdot(\rho\vec{u}\vec{u}) = -\nabla p + \nabla\cdot\bar{\bar{\tau}} + S_{mo,i} \tag{2}$$

where p is pressure, $\bar{\bar{\tau}}$ is the stress vector and $S_{mo,i}$ is the component i of the momentum source term to balance the momentum equation based on the extracted air. The energy equation is calculated for a shared field:

$$\frac{\delta}{\delta t}(\rho E) + \nabla\cdot\left(\vec{u}(\rho E + p)\right) = \nabla\cdot\left(k\nabla T + (\bar{\bar{\tau}}\cdot\vec{u})\right) + S_E \tag{3}$$

E is the energy contained within a cell, k is thermal conductivity, T is temperature. S_E balances the energy equation for the extracted continuous phase for the shared energy field, similar way to S_{mo}.

Separate material properties are implemented for the composite substrate and the polymer film layer at the insert surface, allowing their relative influence on the heat transfer process to be captured. Figure 2 shows the layers of material used in the insert region of the simulation of heat transfer during the overmoulding process.

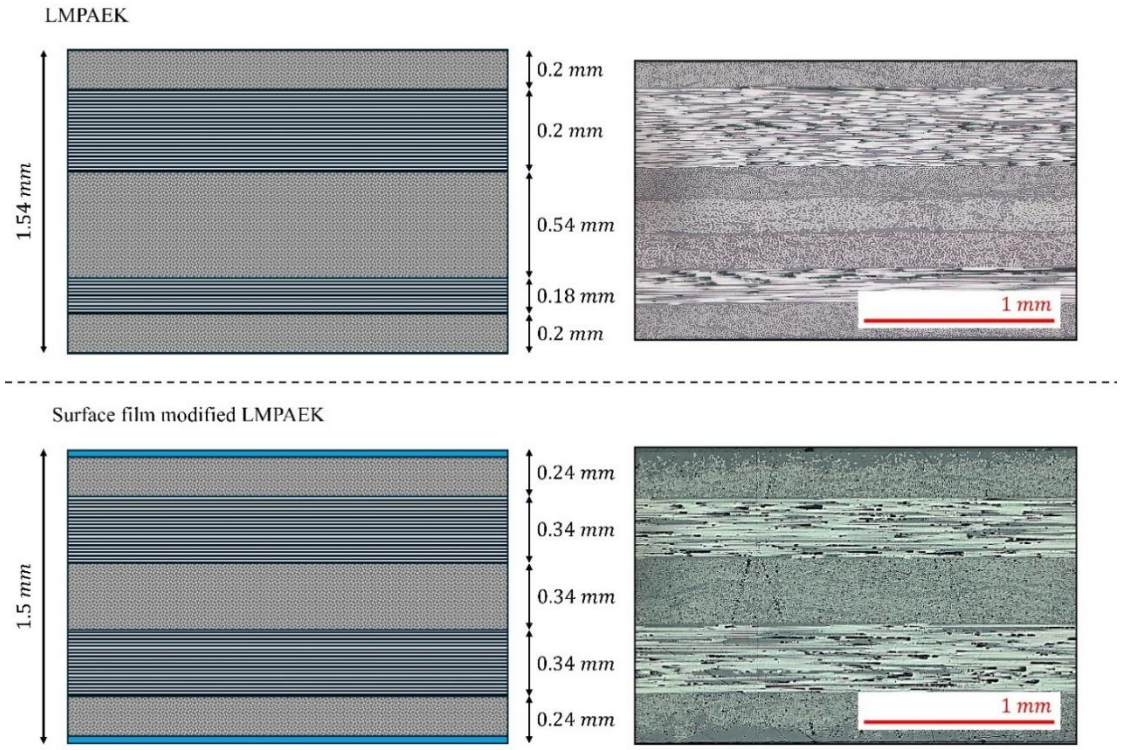

Figure 2: Diagram of the composite thermal domain (left) are shown next to micrographs (right) used to determine dimensions. Images are extracted such that the flow direction is normal to the plane of observation.

For solid composite regions an estimation of specific heat capacity, density, and thermal conductivity was required to compute the heat flux. The rule of mixtures in either the series (Voigt Model) or parallel form (Reuss Model) were used in each of the layers of the composite insert, considering their orientation. As there is a continuous path of fibres to transfer heat, the thermal conductivity in the fibre direction was calculated through the Voigt model (Eq. 4) in addition to all scalar material properties. In the transverse directions, the fibre material is discontinuous and insulated by the matrix material. In this case, the homogenised thermal conductivity is typically closer to its theoretical minimum and the Reuss Model (Eq. 5) offers a better estimation [7].

The Voigt model was implemented for thermal conductivity in the longitudinal direction of the fibres as well as for all scalar properties:

$$P_c = P_f V_f + P_m(1 - V_f) \tag{4}$$

where P represents a generic material property. The subscript c denotes the property relating to the composite whereas f and m relate to its fibre and matrix constituents, respectively. V_f is the fibre volume fraction. The rule of mixtures was applied in the parallel form (Reuss model) to model thermal conductivity in the transverse and vertical directions relative to fibre alignment:

$$\frac{1}{P_C} = \frac{1}{P_f} V_f + \frac{1}{P_m}(1 - V_f) \tag{5}$$

The thermal properties of carbon fibre were extracted from the Toray T300 datasheet. Polymer thermal properties were sourced from the Moldflow database.

3 RESULTS & DISCUSSION

The results of the single lap-shear tests are displayed in Table 1 where they are referred to by their injected material and, where applicable, the presence of a surface film layer is denoted by the brackets. For both injected PEEK grades, the lap-shear strength is improved considerably with the consolidated surface film when compared to the unmodified laminate. Generally, the mean values of lap-shear strength are higher for the 30% carbon fibre loaded injected PEEK overall. However, considerable variation in results are noted for some material configurations, notably the V2000 CF30 (unmodified) and V4000 CF10 with LMPAEK film. However, the material configurations with a PEI film interface generally defies this rule as the lap-shear strength is marginally higher at the lower injected melt fibre concentration. The PEI film also performs marginally better than the LMPAEK surface film, with both higher lap-shear strength and low standard deviation for both injected melt configurations.

Specimen	Lap-shear strength (MPa)
V2000 CF30	9.7 ∓ 4.5
V2000 CF30 (PEI)	16.8 ∓ 0.9
V2000 CF30 (LMPAEK)	15.2 ∓ 0.2
V4000 CF10	7.9 ∓ 1.4
V4000 CF10 (PEI)	18.6 ∓ 0.7
V4000 CF10 (LMPAEK)	14.4 ∓ 2.4

Table 1: Interface strength as measured by single lap-shear tests for all specimen configurations.

The strength of thermally bonded thermoplastic interfaces is known to be closely related to the temperature of the interface and welding time. A spatial dependence on temperature is observed in Figure 3 which occurs due to the variation in time of contact of the injected melt flow with the substrate. In all configurations a significantly higher interface temperature is observed in a localised region near the injection gate due to longer contact time.

The interface temperature after the pressure/velocity switch-over is substantially higher for all configurations when comparing the those with an applied surface film to those which have no film present on the surface. The primary mechanism responsible for this is the increase in the ability of the PEEK melt to transfer heat to the interface (thermal effusivity) at higher carbon fibre concentrations due to an increase in thermal conductivity. Since the time for bonding of thermoplastic polymers through ‘interdiffusion’ is closely related to temperature and time, and is the primary mechanism responsible for interface formation, an increase in interface temperature is likely to be the primary cause of the increase in lap-shear strength in all film configurations results when compared to the unmodified laminate with low surface resin depth present. A higher CF concentration within the injected polymer also results in a comparably higher interface temperature due to an increased thermal effusivity of the phase which allows heat to be exchanged more easily from the injected melt to the interface.

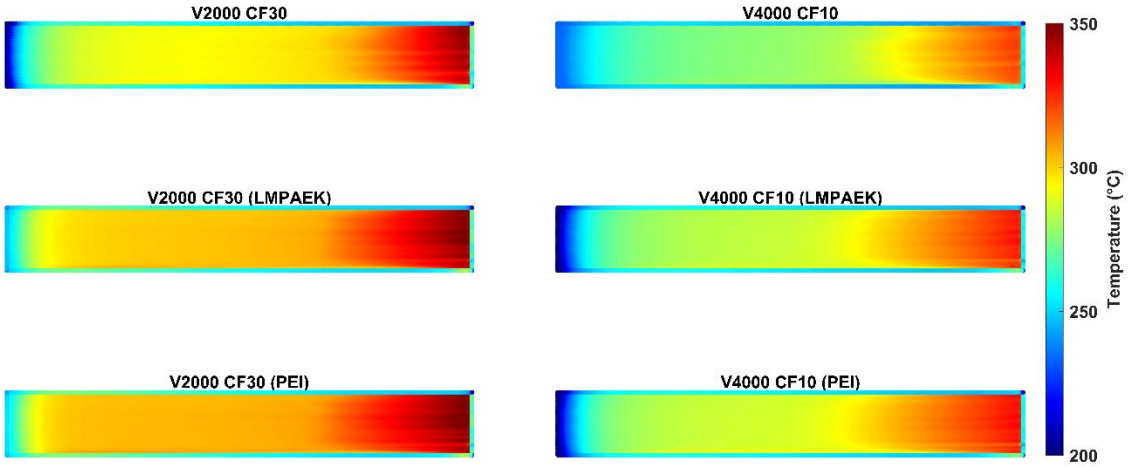

Figure 3: Contours of interface temperature during simulation of the overmoulding process, recorded at the pressure-velocity switch-over.

4 CONCLUSIONS

Overall, it was demonstrated that the interface strength can be improved through the modification of the local thermal diffusivity in the vicinity of the interface. In the case of unidirectional fibre reinforcement, a high volume fraction of carbon fibres may provide useful mechanical properties but at the cost of a high thermal diffusivity. A high thermal diffusivity can prevent the development of a strong interface by increasing the energy flux through the insert and away from the interface where a high temperature promotes the formation of a strong bond. Through a relatively minor surface modification, the local diffusivity at the interface is improved, resulting in the development of a strong bond. Modification of the surface resin depth in this case improves the interfacial bond strength without altering the laminate reinforcement. The results of this study are useful for the design of overmoulded structures. This is especially the case for those which require a high volume fraction of carbon fibres such as in load-bearing structures. The simulation process developed is also useful for this purpose and could be used to optimise the surface resin depth of the composite for both insert composite strength and interface strength of the overmoulded composite.

ACKNOWLEDGEMENTS

The authors gratefully acknowledge the contributions of the following industry and institutional partners: Collins Aerospace UK, and the Polymer Processing Research Centre (PPRC) at Queen's University Belfast (currently part of Advanced Manufacturing Innovation Centre (AMIC)) for their expertise in the design and manufacture of overmoulded composite components. This work was supported by funding from the Department for the Economy (DfE), and the Engineering and Physical Sciences Research Council (EPSRC) under the OVERCOMP project (EP/X041360/1).

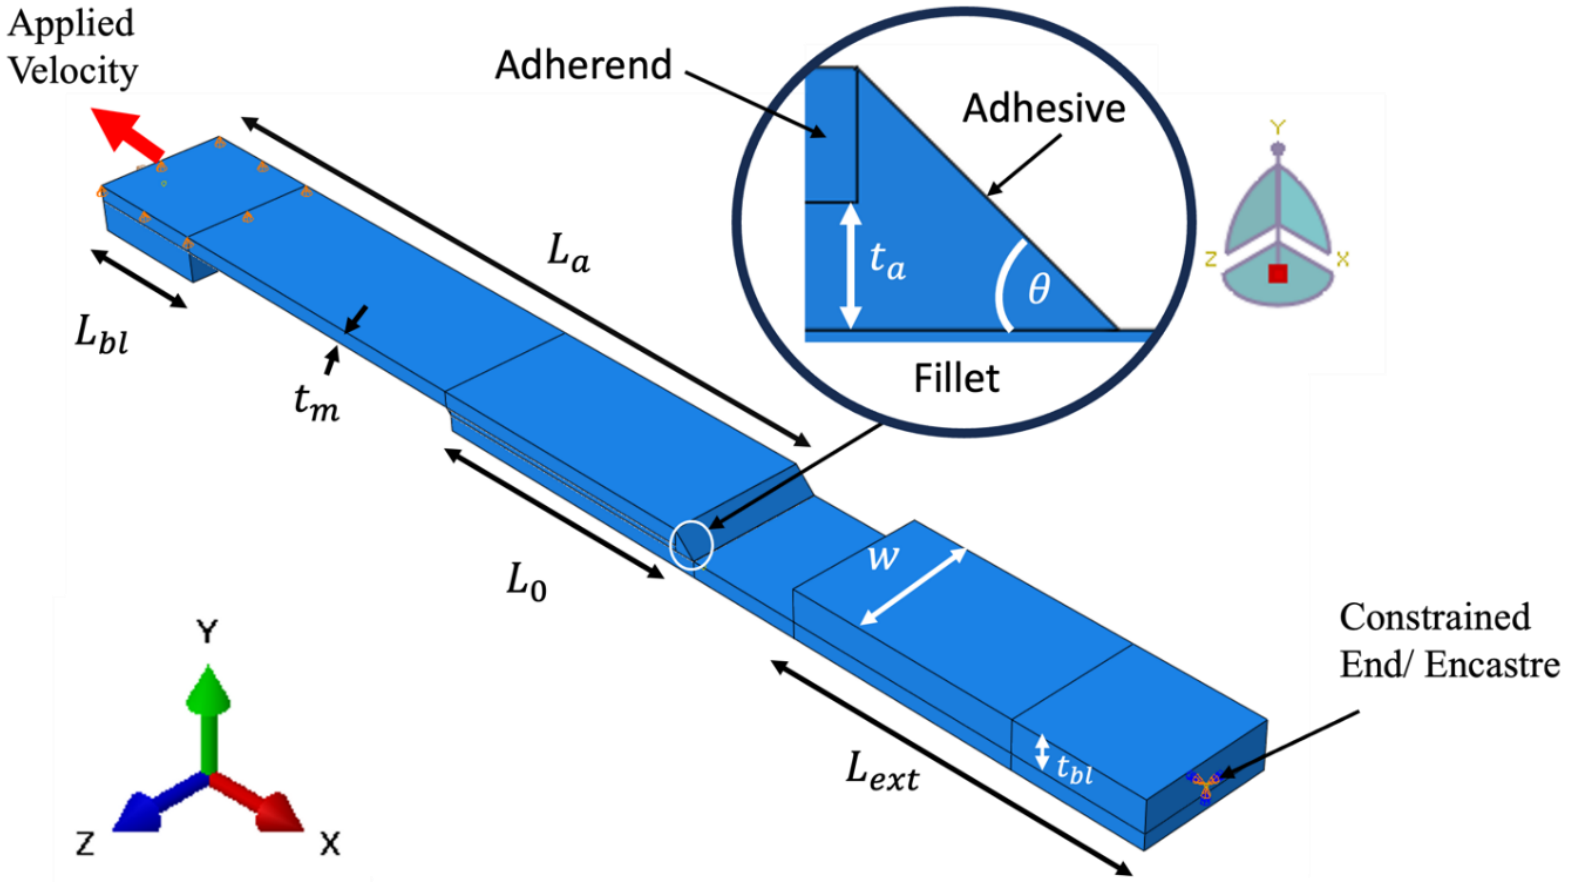
SwRI Overview

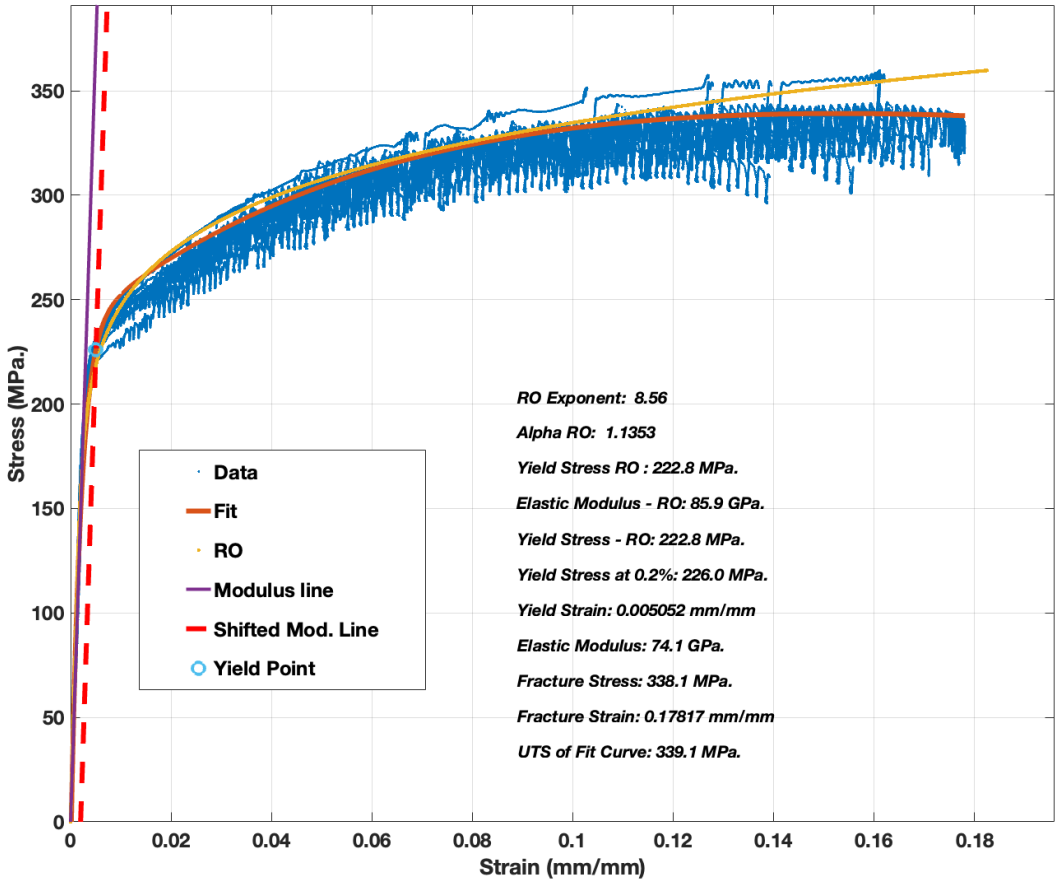
- Founded in 1947
- Nonprofit organization
- More than 3,100 employees
- More than 1,500 acres / 6.1 km2 facility in San Antonio, TX
- More than 2.5 million ft^2 / 232,000 m^2 of laboratories, workshops & offices
- More than 1,500 patents
- 52 R&D 100 awards
- Deep sea to deep space



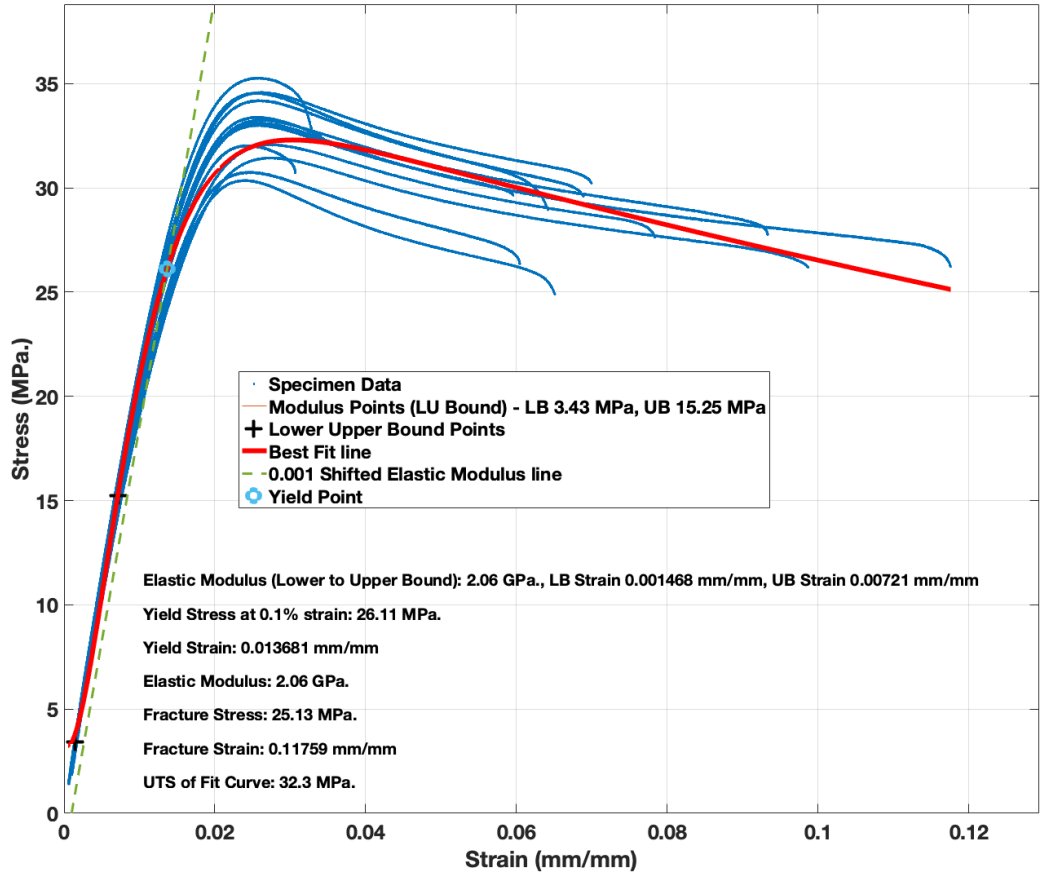
Motivation

- **Bonded composite** structures are increasingly favored for their potential to reduce weight and improve structural efficiency
- Complex behavior of adhesive joints under varying load conditions necessitates **predictive modeling** approaches that can accurately simulate failure mechanisms
- This study applies the **Ductile Damage Evolution Material** (DDEM) model to single lap shear joints to predict strength and time to failure under shear loading

Previous Research: Simulation

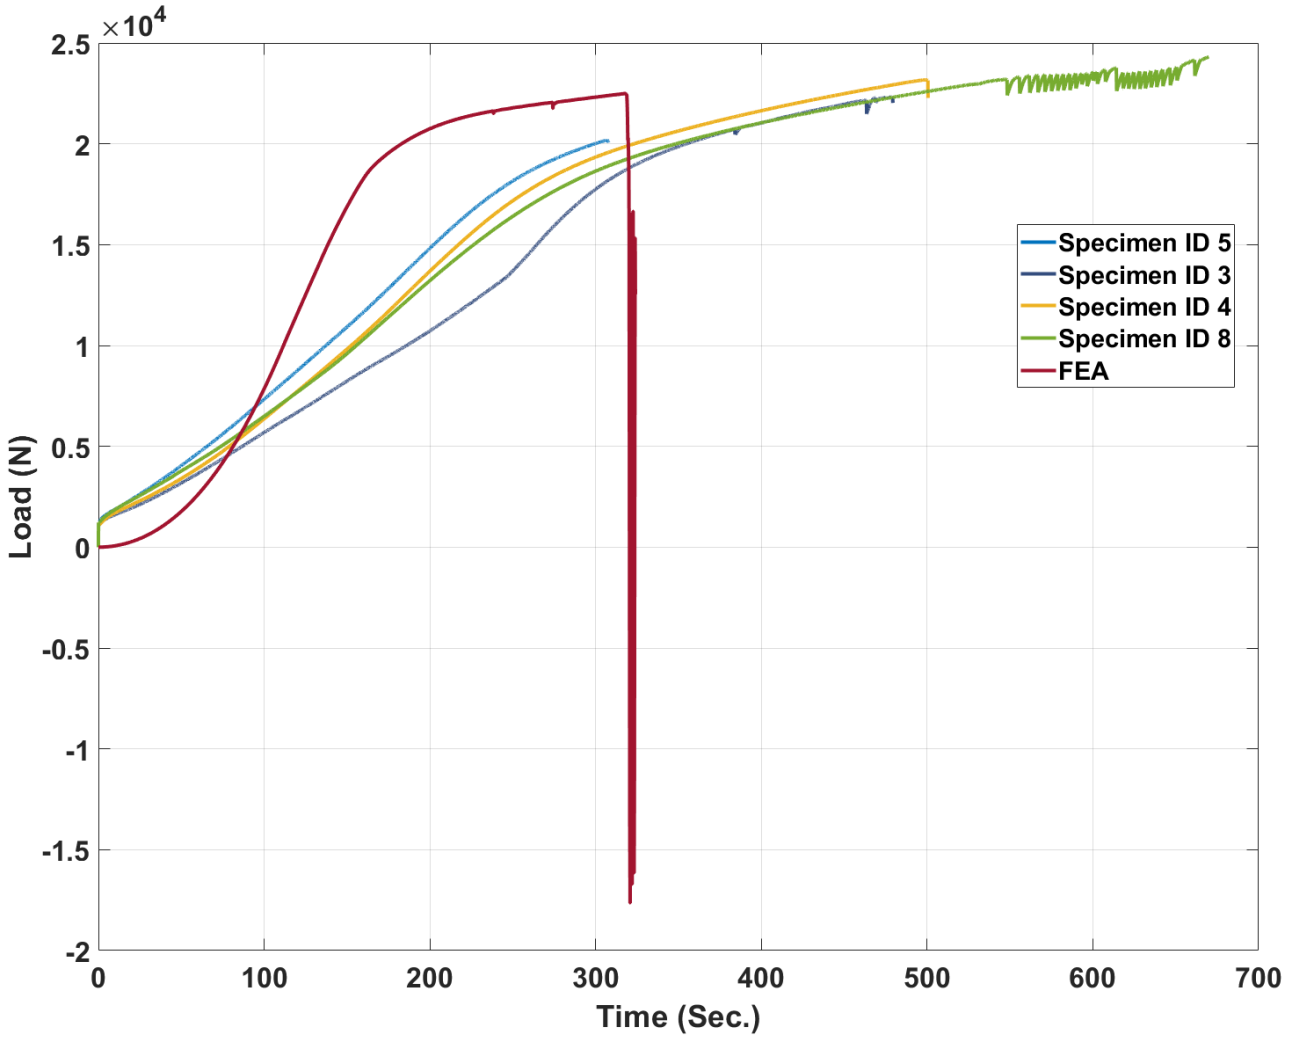


- Single Lap Shear Joint (SLSJ)

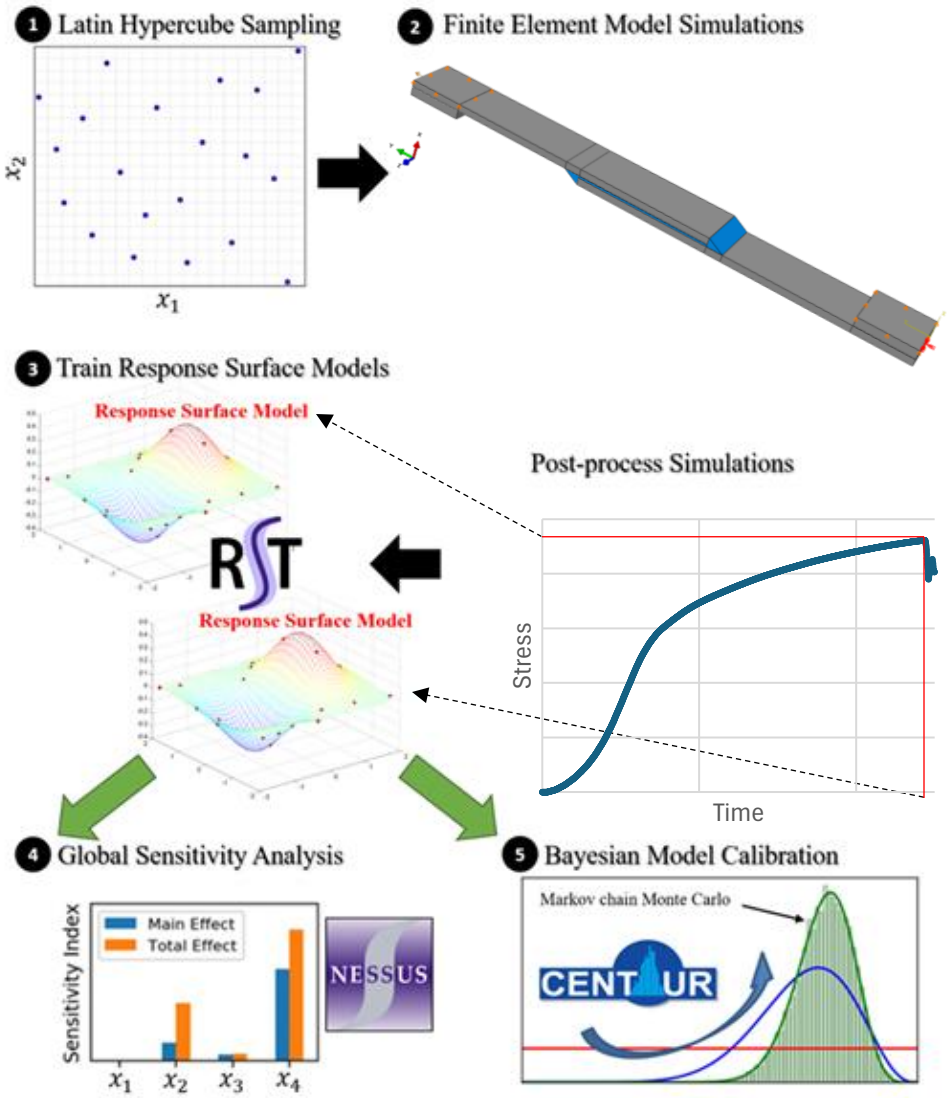


Single Lap Shear Joint Dimensions	
Parameter	**Value (mm)**
t_m	3.18
t_a	1.00
t_b	4.18
L_O	61.10
L_a	150.00
L_{bl}	25.40
L_{ext}	60.00
w	25.40
θ	45°

Previous Research: Material Characterization



- Adherend and adhesive tensile tests

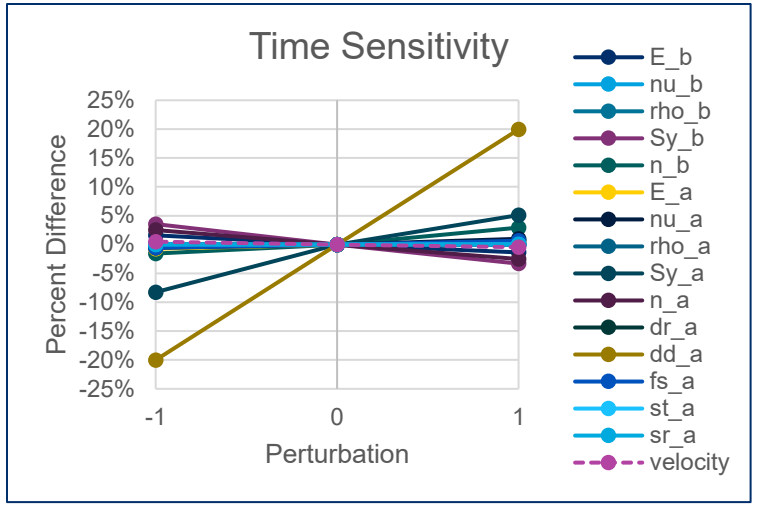


Previous Research: Experimental Results

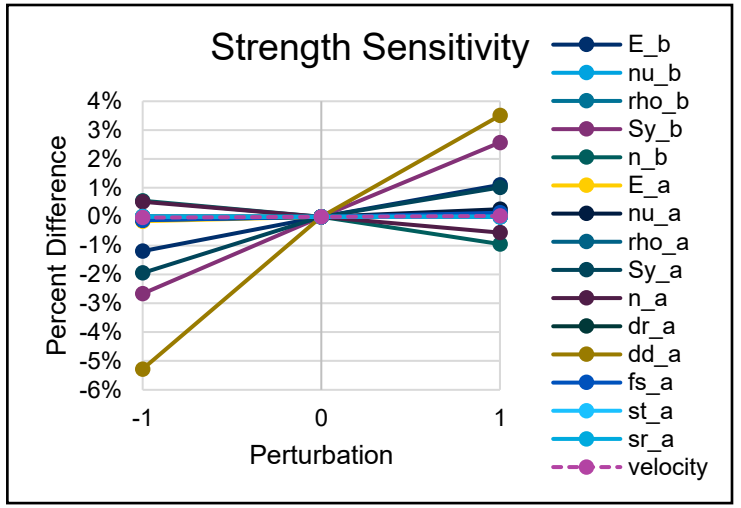
- SLSJ Strength
- Time-to-failure
- Simulation prediction
  - Pretty good strength
  - Terrible time-to-failure
- Initial conclusion was to investigate the effect of the adherend response

VVUQ Approach

- Parameterize model
- Establish PIRT
- Identify sensitive parameters
- Build surrogate model
- Global Sensitivity Analysis
- Bayesian Model Calibration



PIRT



- Phenomena (Parameter) Identification Ranking Table
- Engineering judgement
- Quantify parameter uncertainties

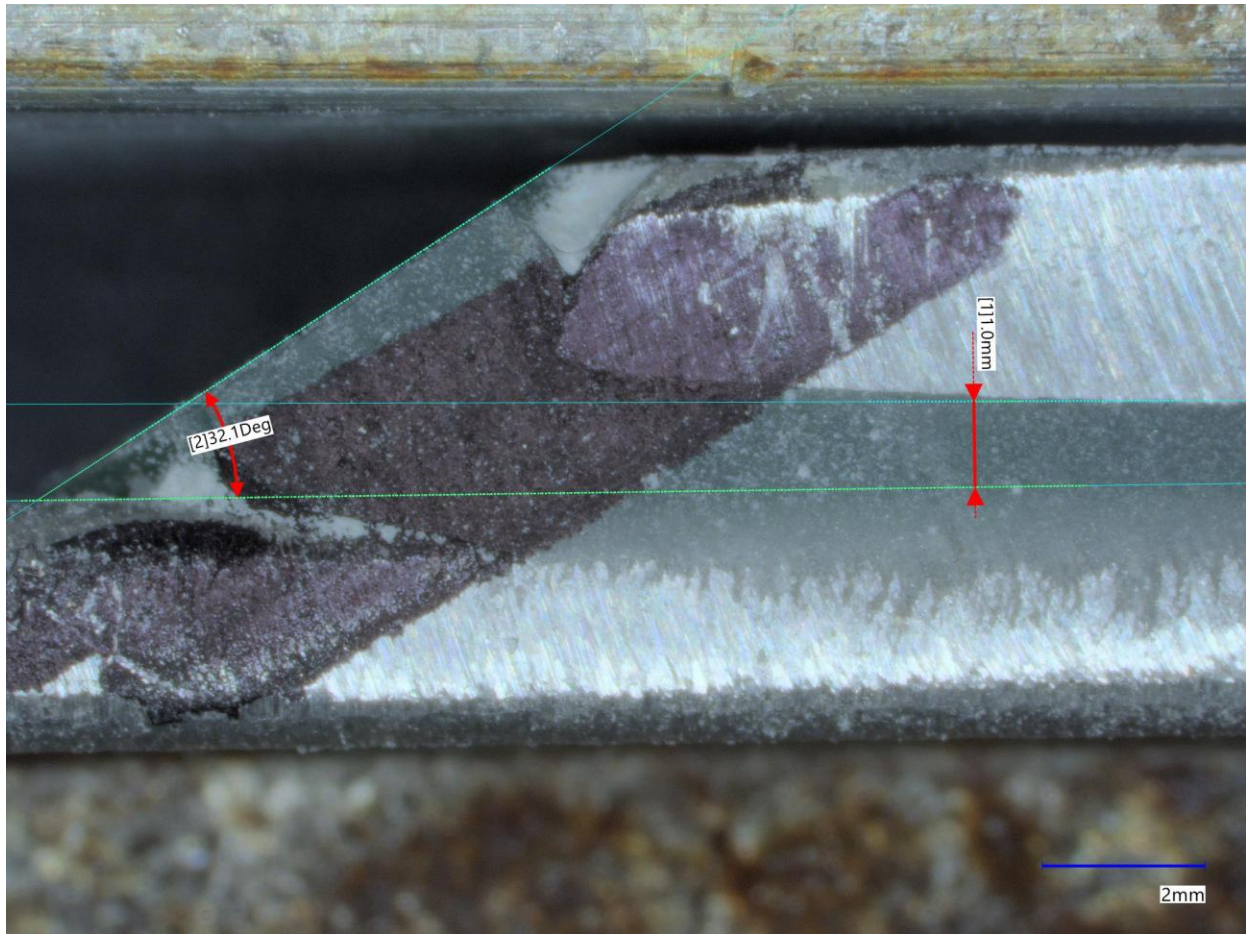
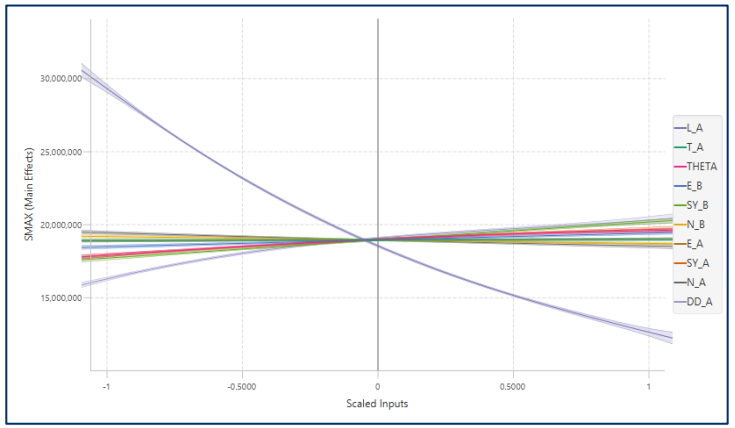
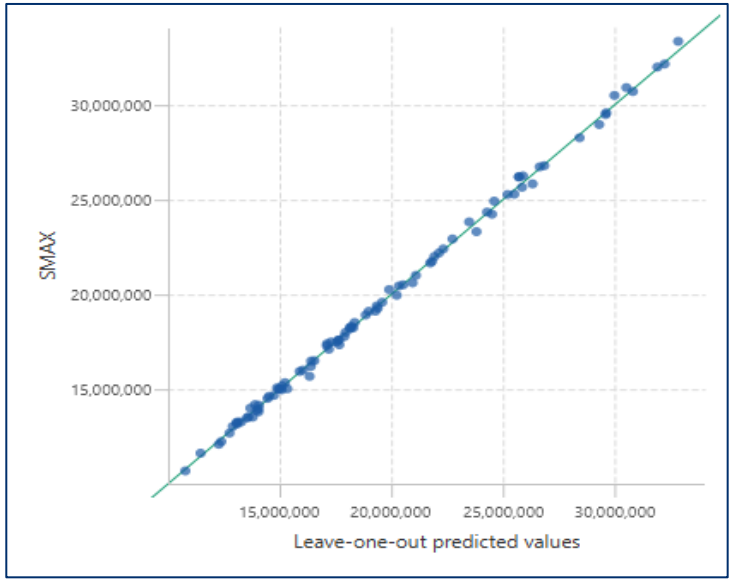
Deterministic Sensitivity Study

- Central differencing of nominal parameters with a standard deviation of 1*σ
- Used to identify highest sensitivities
- Down select parameters for next steps
- Adhesive angle identified

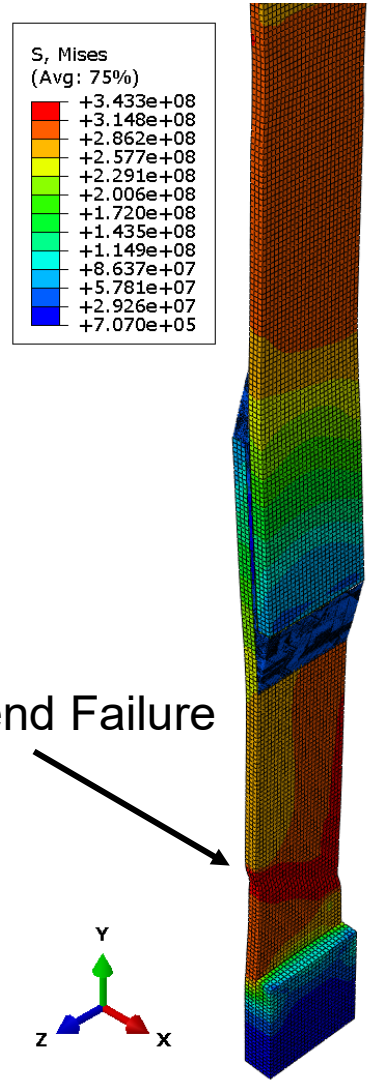




Adhesive Angle Measurement

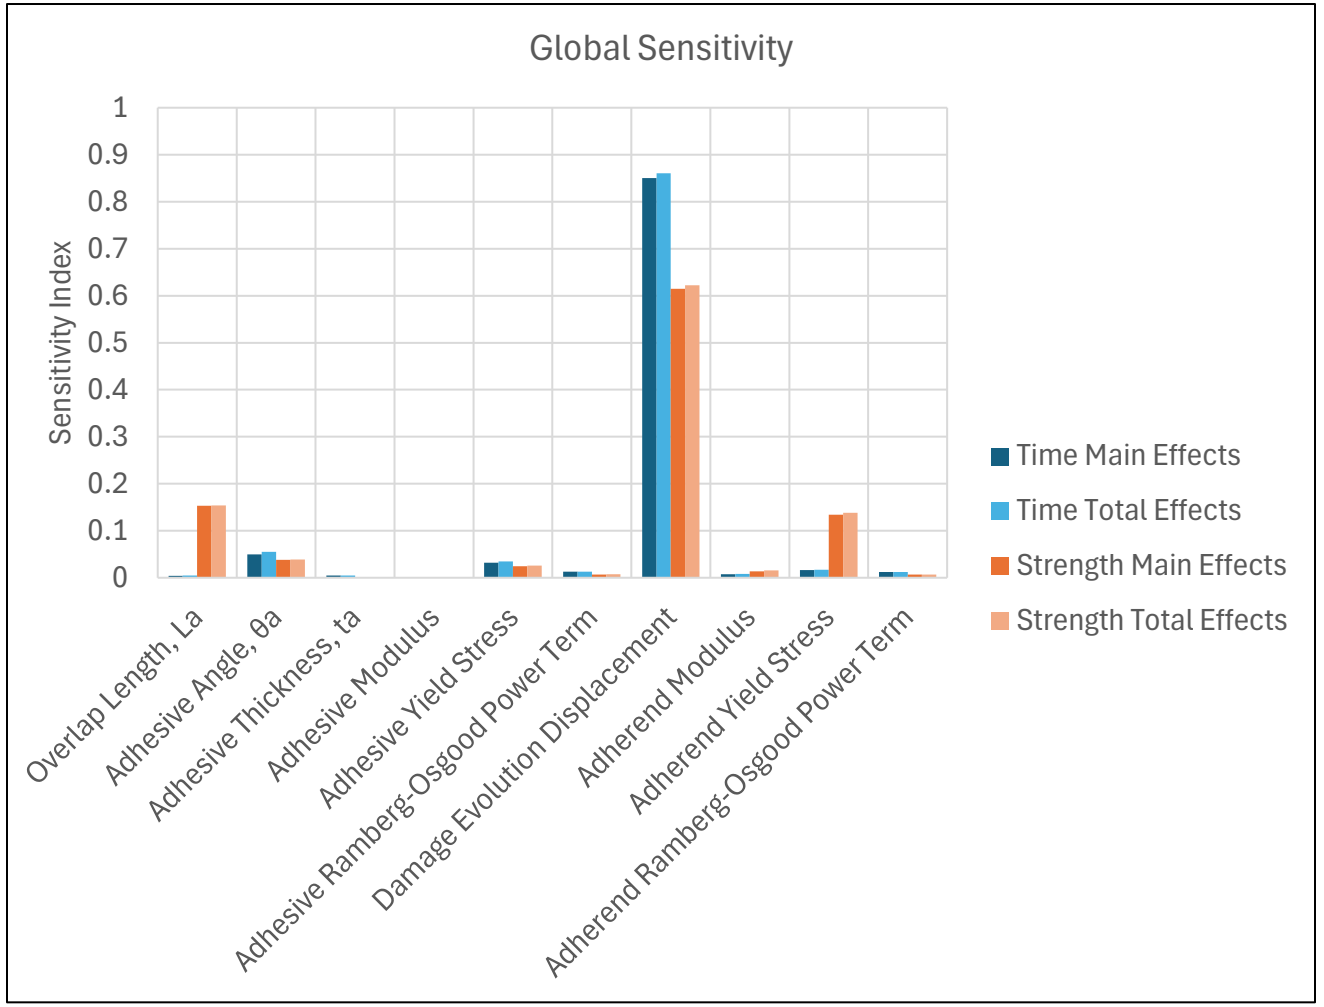


- Using an optical microscope, the adhesive fillet angles were measured
- Previous assumption was 45 degrees
- Angle was measured closer to 30 degrees



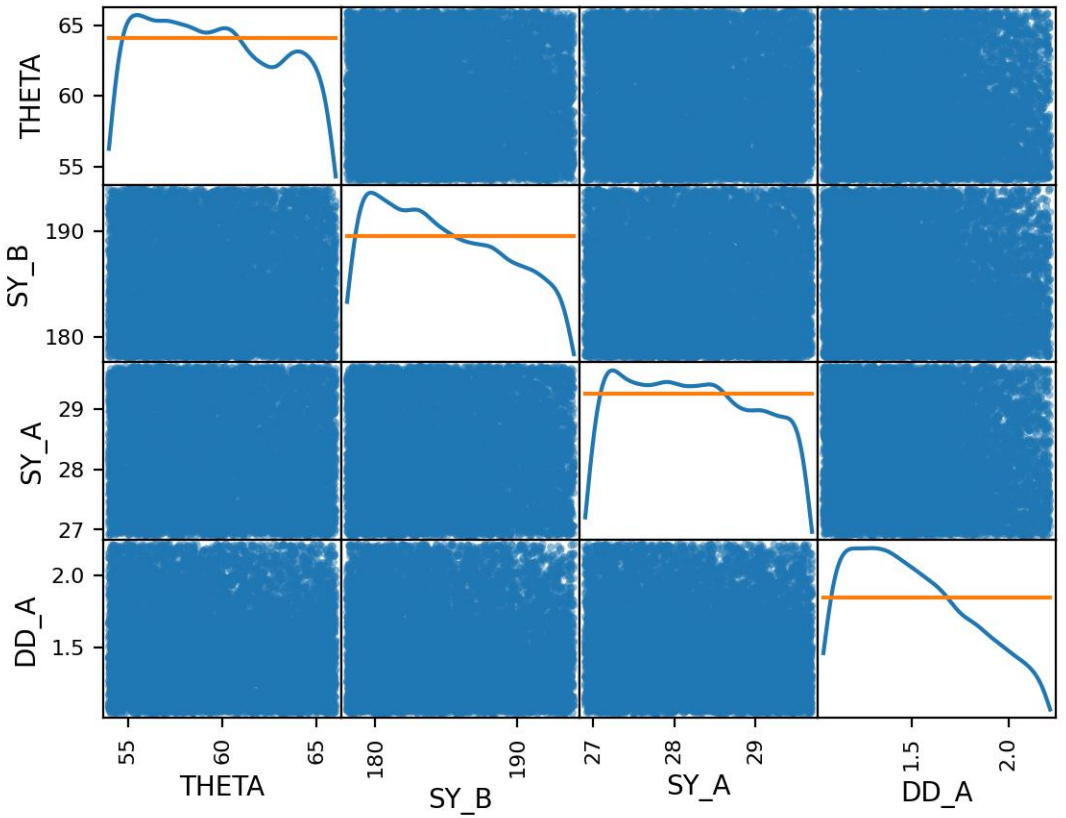
Surrogate Model

- Response Surface created using NESSUS RST
- Latin Hypercube Sampling (LHS) used to generate domain of inputs
- Uniform distribution +/- 3σ
- Typically use 10*variables simulations
- 5% of simulations failed in the adherend, removed from training data
- Gaussian Process Model
- LOO cross-validation



Global Sensitivity Analysis

- Monte Carlo: 100,000 samples
- Sobol indices
- Time-to-failure effects
  - Damage Evolution
  - Adhesive Angle
  - Adhesive Yield Stress
- SLSJ Strength
  - Damage Evolution
  - Overlap Length
  - Adherend Yield Stress



Bayesian Calibration

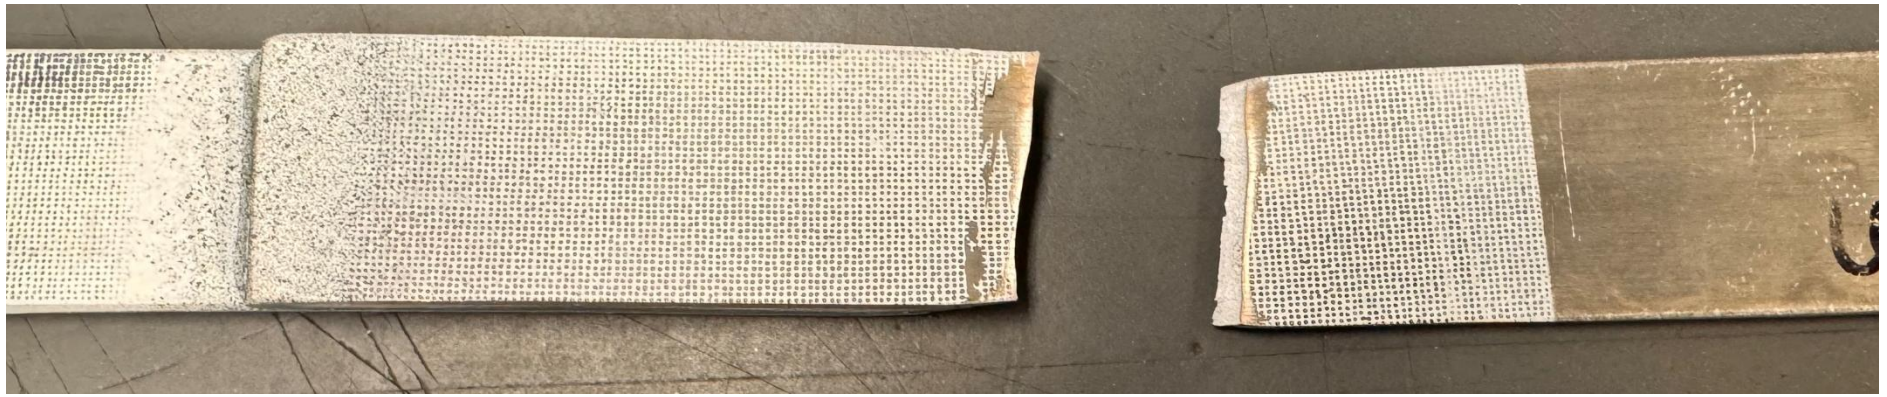
- Goals
  - Obtain a set of likely model parameters that predicts the two responses of the SLSJ model
  - Capture uncertainty in calibration parameters due to limited data
- Down-selected calibration parameters based on sensitivity analysis
- Used uniform prior distributions
- Likelihood function:

$$L(\theta) = L_{SLSJ,S_{max}}(\theta) \cdot L_{SLSJ,T_{failure}}(\theta)$$

$$L_{SLSJ,S_{max}}(\theta) = \prod NormPDF(GP_{SLSJ,Smax}(\theta) - SLSJ_{S_{max},i}, \sigma_{SLSJ,Smax})$$

- Strength & time-to-failure within 5% of the test data

Validation Testing



- Overlap length (30, 60, 75)
- Fillet angle (30, 45, 60)
- FEM accuracy:
  - 7% for strength
  - 17% for time
- NESSUS surrogate model
  - 12% for strength
  - 19% for time

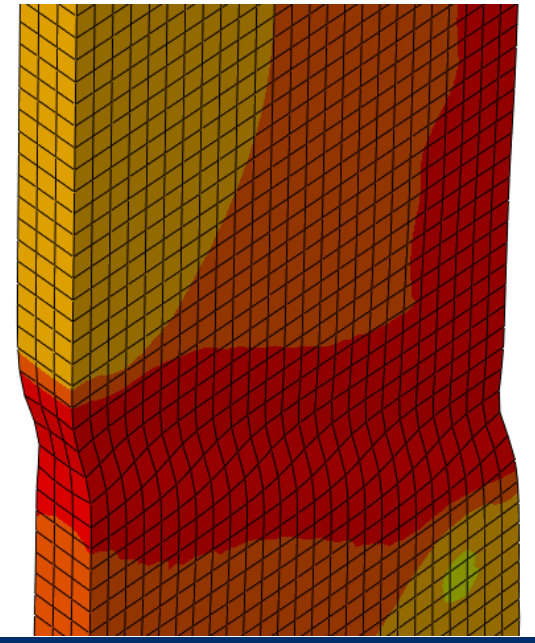
Adherend Failure

- Failure observed during validation testing in the adherend, close to the finite element model prediction



Adhesive Failure

Adherend Failure

Summary & Conclusions

- VVUQ approach provided a framework to assess major sources of variability in the test and finite element models
- Variability in the fillet angle was major source of error in the initial models
- Discrete Damage Evolution Model remains highest source of uncertainty
- The surrogate model provided similar accuracy as compared to the finite element model
- Model captured adherend failure, which was then observed during validation testing

Future Work

- Double Lap Shear Joint (DLSJ) – currently running LHS to create surrogate models (4x longer simulation time than SLSJ)
- Investigate SLSJ validation testing DIC to obtain velocity ramp rate for simulation
- Deep dive sub model / coupon testing of Discrete Damage Evolution Model inputs
- Investigate adherend failure

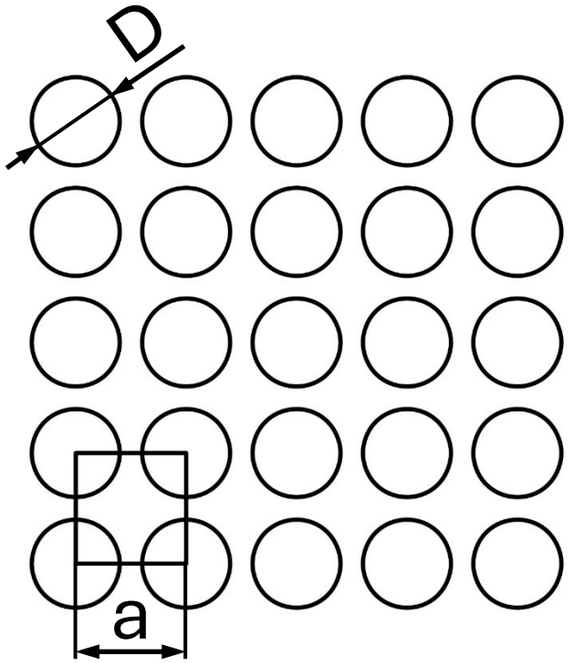
Introduction

- Laminated composite materials are prone to delamination, which plays a key role in their design
- Film interleaving with tough materials that bond well to the composite plies is an established approach to improve delamination resistance
- Precisely controlled reduction of the fracture toughness is useful to direct delamination damage accumulation to a chosen interface within a laminate
- Perforation patterns for release film interleaves were designed, and their geometry was analysed optically
- Tensile tests on novel central cut layer coupons were executed to obtain the mode II fracture toughness (G_{IIC}) of the interfaces

Materials



Fibre type	Manufacturer	Diameter	Elastic modulus	Strain to failure	Tensile strength	Density
		[μm]	[GPa]	[%]	[GPa]	[kg/m³]

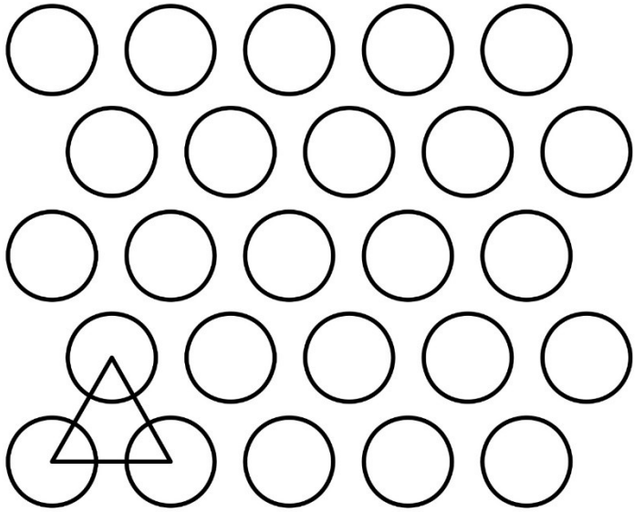
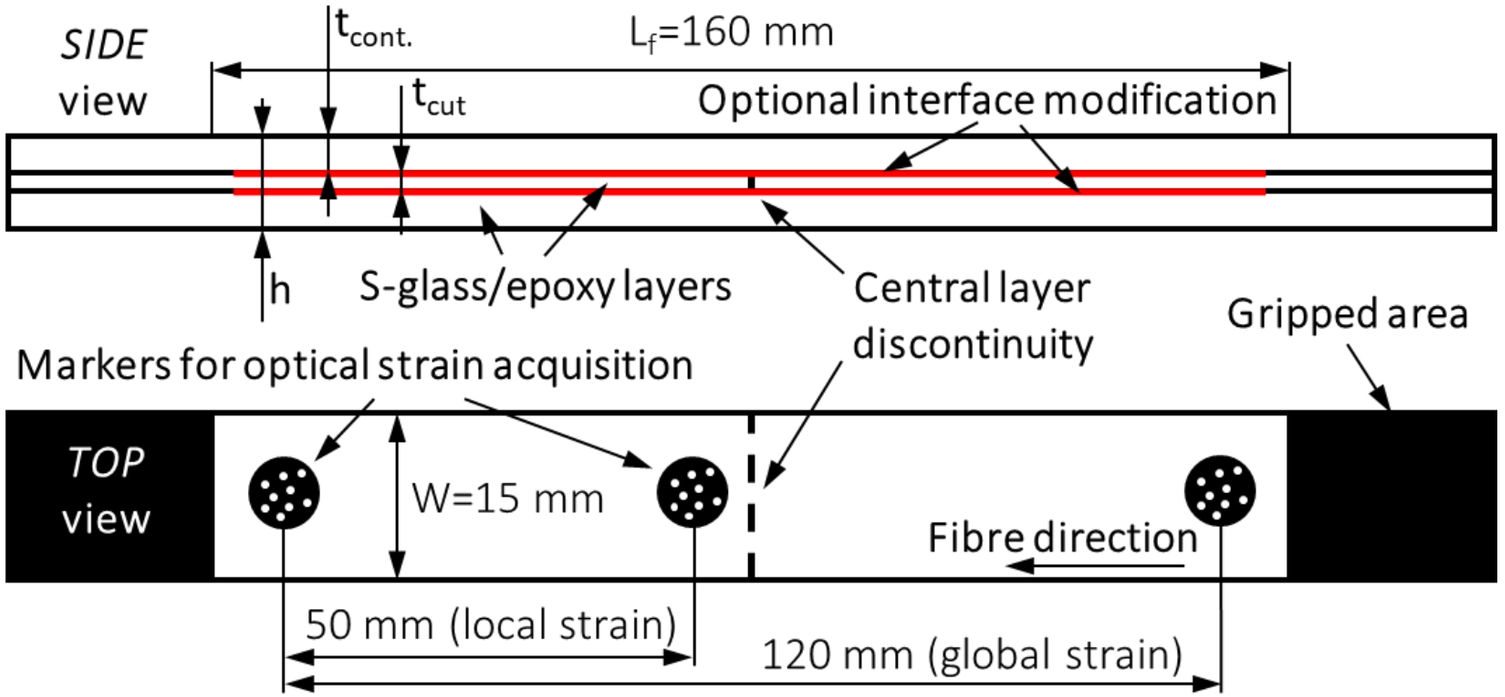
Perforation pattern design



Quadratic pattern

Quadratic pattern rotated by 45°

Hexagonal pattern



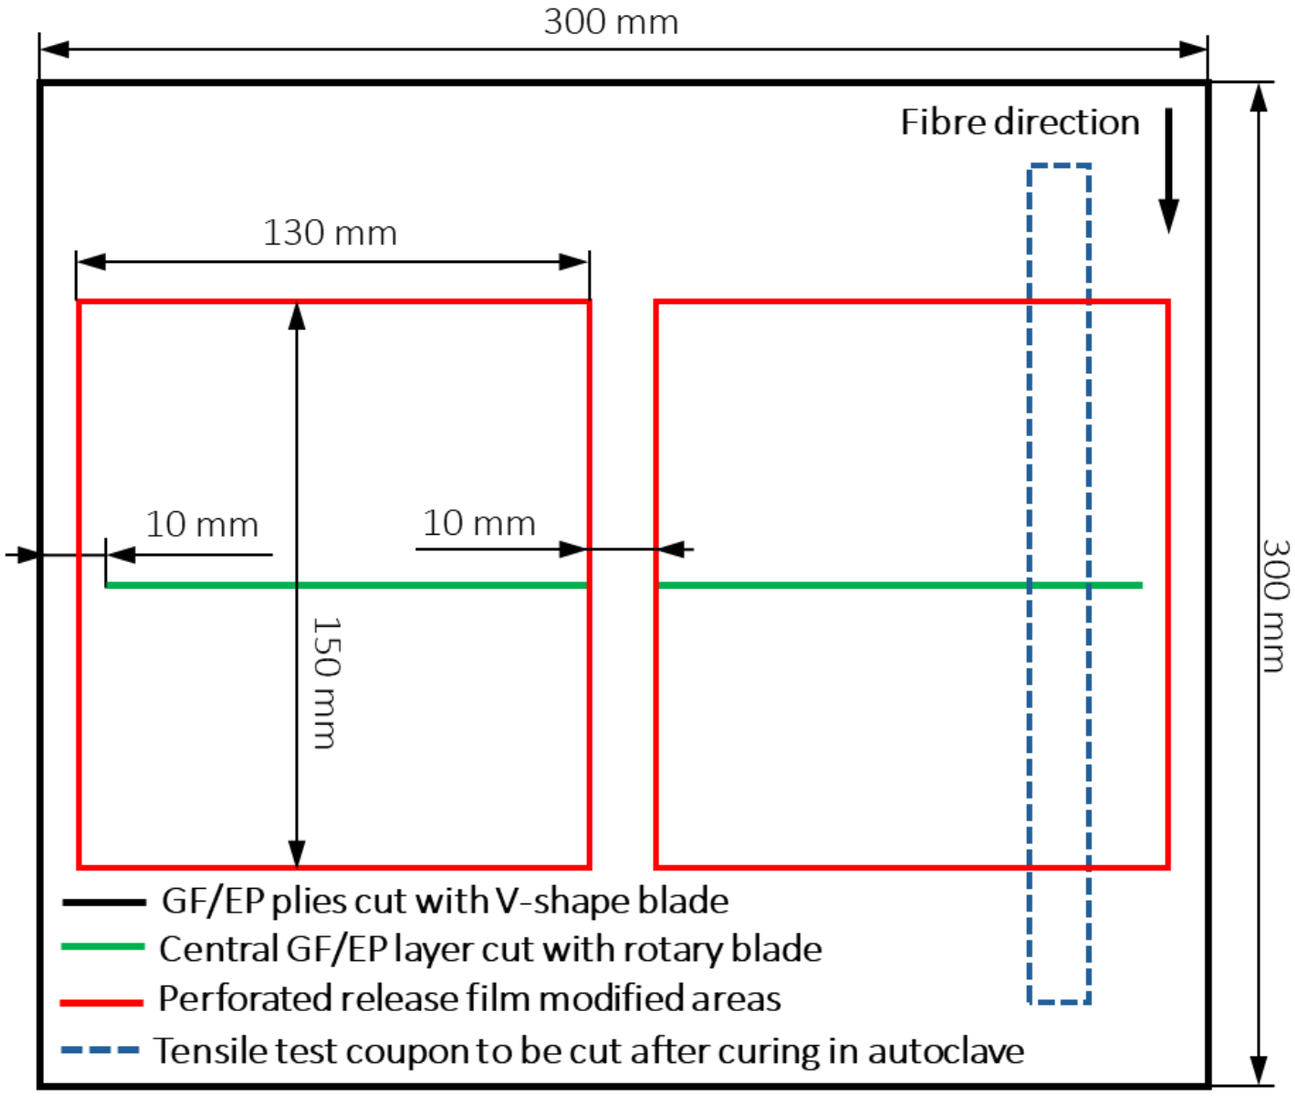
Definition of interlaminar contact area ratio:

$$ICAR = \frac{A_{PERF}}{A_{TOT}} = \frac{D^2\pi}{4a^2}$$

Centre offset for quadratic pattern:

$$a = \sqrt{\frac{\frac{D^2\pi}{4}}{ICAR}} = \sqrt{\frac{D^2\pi}{4(ICAR)}}$$

Coupon design

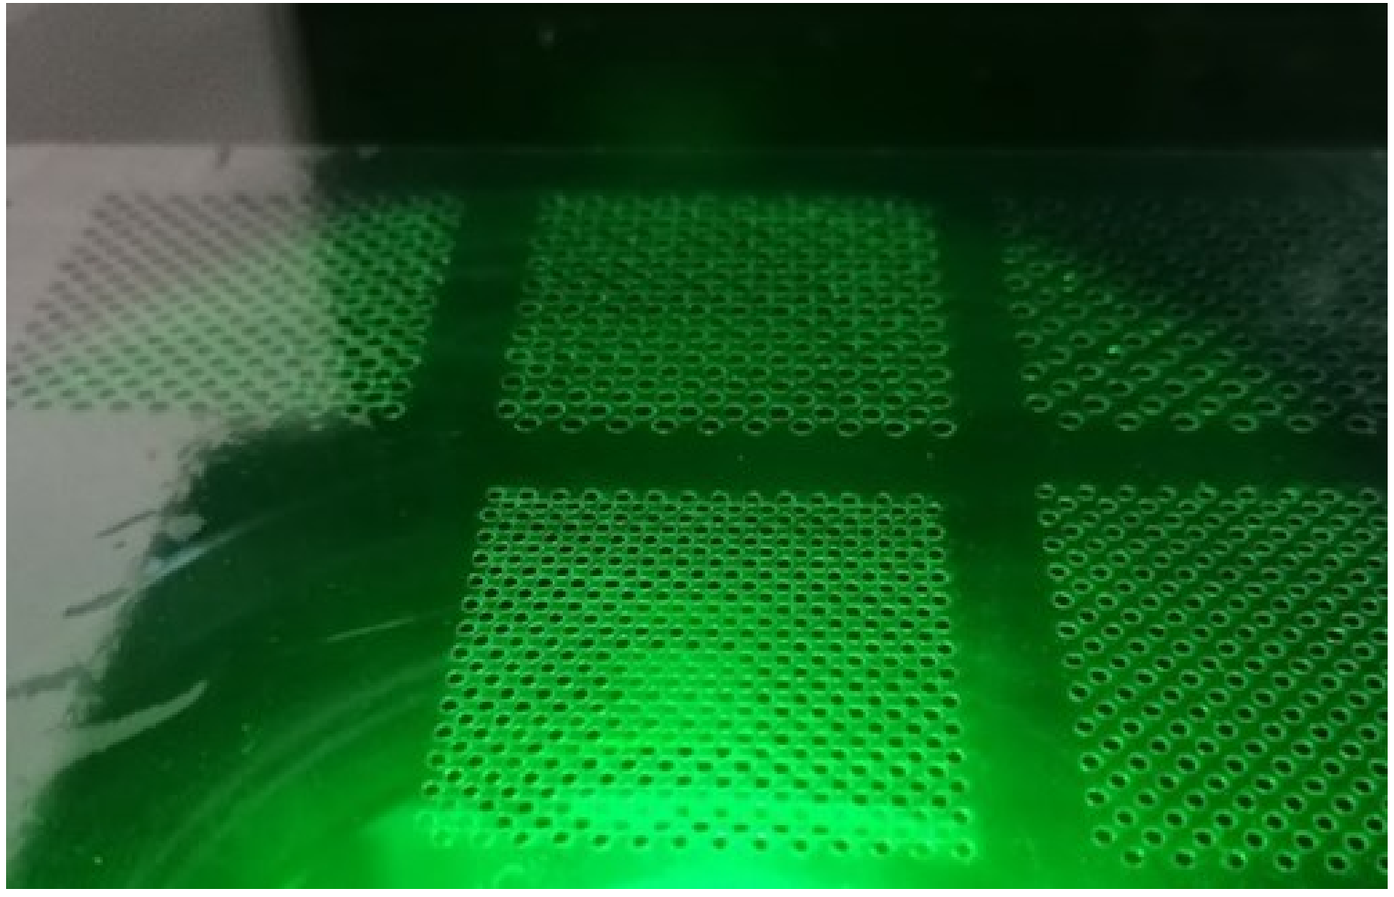


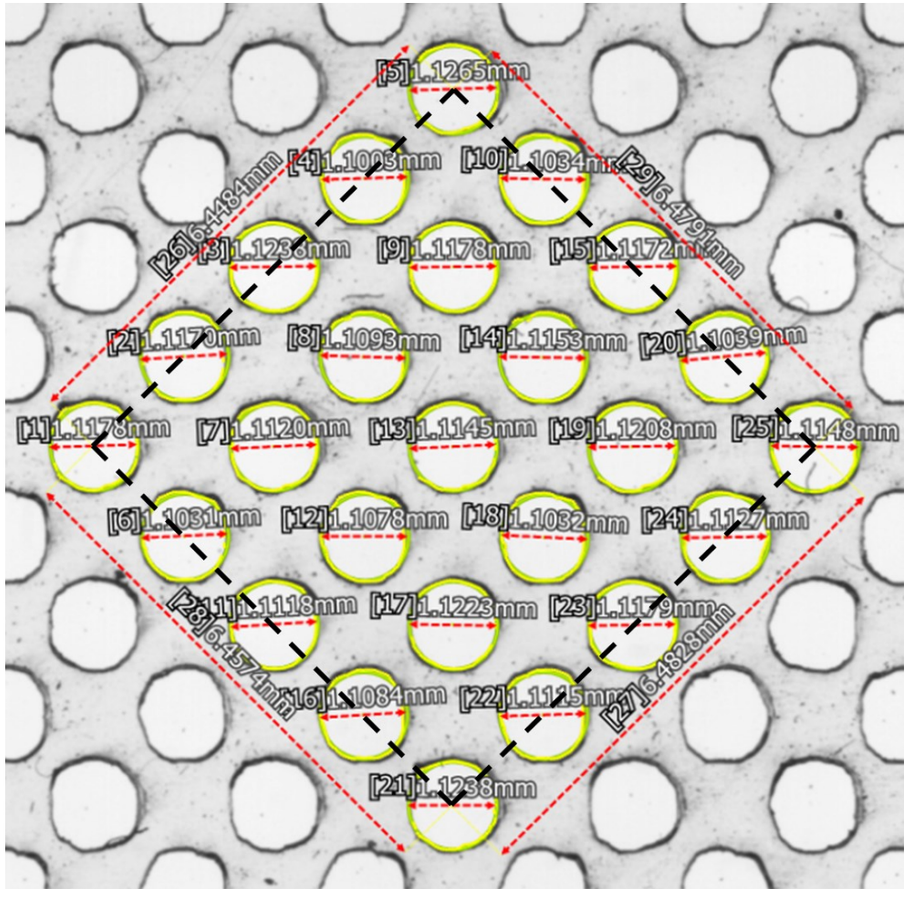
Design criteria for delamination:

$$G_{II} = \frac{E\varepsilon^2 h t_{cut}}{4(h - t_{cut})}$$

$$t_{cont} > \frac{\varepsilon_{del} E t_{cut}}{2E\left(\varepsilon_{b\,GF/EP} - \varepsilon_{del}\right)}$$

Laminate assembly, interleaf positioning





- Patterns were cut with a Versa Laser VLS2.30 type cutting/engraving CO_2 laser with a 10.6 µm wavelength and 30 W maximum power
- Perforated release films were interleaved between prepreg layers manually
- The central ply blocks of the laminates were cut manually with a rotary blade

*Compared to the average G_{IIC} of the flattened baseline series.

Conclusions

- Perforation patterns were systematically designed for geometrical characterisation and interface modification.
- **Six** laser-cut perforation **patterns** were **analysed** optically, the **actual perforation diameters were larger** than the nominal values regardless of the nominal diameter.
- The laser-cutting-induced increase in the perforation diameters resulted in a **difference between** the **nominal and actual interlaminar contact area ratios (ICAR)**. The differences in the ICAR values showed a monotonic increase with the total perforation length.
- Unidirectional composite tensile test coupons having one-third of their plies cut in the central layer were suitable for G_{IIC} assessment.
- The $\boldsymbol{G_{IIC}}$ of the modified laminates **showed a strong linear trend with increasing ICAR**, which enables the control of composite layer interface properties.
- The **maximum reduction of $\boldsymbol{G_{IIC}}$ was up to 50%** with the applied perforation patterns, but the test campaign results indicate that the full range may be covered.
- Baseline laminates with flattened interfaces showed slightly lower G_{IIC} values than the pristine ones.
- The **perforation pattern with the highest ICAR (0.56) increased the $\boldsymbol{G_{IIC}}$ of the laminate by 10%**. This offers scope for limited, but well-controlled increase of G_{IIC}.

ABSTRACT

The accurate prediction of fatigue delamination growth and critical damage size remains an open challenge in enabling the Slow-Growth design and damage-tolerance substantiation in composite aircraft structures. Delamination is especially important due to difficult detectability and the high sensitivity of laminated composites to this failure mode. This work presents a preliminary experimental characterization of the fatigue-driven delamination in a thick, pre-damaged L-shaped composite specimen. To support and interpret these results, a cohesive zone-based finite element (FE) fatigue modelling framework was first verified on standard Mode I (DCB), Mode II (ENF), and Mixed-Mode (MMB) specimens, using experimental data from the literature. The framework was then applied to simulate the fatigue behaviour of the L-shaped specimen. Finally, the variation of energy release rate with crack-growth was investigated to explain the observed failure modes, highlighting the strong sensitivity of delamination growth to initial loading conditions.

1 INTRODUCTION

Laminated composite structures are inherently susceptible to out-of-plane loading, with delamination initiating at stress levels significantly lower than those required for in-plane failure. Low-velocity impacts frequently induce internal delaminations that may not be externally visible but compromise structural performance. Delamination disrupts interlaminar stress transfer, inhibiting load redistribution mechanisms between plies and reduces sustainable load in compression. The FAA Advisory Circular AC 20-107A [1] addresses damage tolerance in composite structures, particularly for Category 2 barely visible impact damages, which may reduce residual strength below the Ultimate Load (UL) but never below Limit Load (LL). Three substantiation approaches are identified: (i) no-growth, where damage is stable over inspection intervals; (ii) arrested-growth, where propagation halts before reaching a critical size; and (iii) slow-growth, allowing controlled propagation, which is monitored via scheduled inspections. Slow-growth design leads to greater structural efficiency than no-growth but requires predictive models for both residual strength and fatigue crack growth [2]. Consequently, finite element (FE) models used for a slow-growth design of composite structures must reliably predict (i) residual static strength in the presence of damage, and (ii) delamination growth under cyclic loading.

Existing models for static delamination strength are well-established while, in contrast, fatigue modelling remains an active research area. Traditional FE-based fatigue models [3], [4], [5], [6], [7], [8], typically rely on Paris-law parameters and fracture mechanics inputs, which pose significant experimental and computational demands. Recently, a simplified S-N-based framework for the FE simulation of fatigue loading of structures has been proposed [9], [10], [11], using a two-step Simple Cyclic Loading (SCL) method based on a monotonic preload followed by a constant-amplitude fatigue step that activates the fatigue damage accumulation. Different versions of such functions have been proposed. The most recent version of fatigue damage accumulation function, presented in [10], is empirical in nature, and it is calibrated via Paris rate data and two fitting parameters for each

delamination mode, I and II. While initial calibrations in the literature are manual (trial and error), an automated procedure is also possible [12].

The studies presented in the literature are typically focused on the development and validation of fatigue damage accumulation functions at the coupon levels, considering different propagation modes and levels of severity. This work investigates the crack growth in thick L-shaped laminates containing a pre-existing delamination (at a critical interface) under fatigue loading. Specimens were tested under a tensile opening configuration, which induces an interlaminar tensile stress state in the curved zone of the specimens that promotes crack growth. Despite the large amount of research work on the inelastic quasi-static response of L-shaped and curved structural elements, studies on their fatigue behavior are rare. An accurate analysis and comparison between quasi-static and fatigue failure modes is presented in [14,15] for unidirectional and cross-ply L-shaped laminates without pre-damage. In the present research activity, attention is focused on the analysis of crack growth regimes and rate. Moreover, the predictive capabilities of a modelling approach based on fatigue damage accumulation laws are presented, outlining the potential and the challenges for the application of these methods to the prediction of growth rates in structural elements.

2 EXPERIMENTS ON L-SHAPED COMPOSITE LAMINATES

Fatigue tests were conducted on pre-delaminated, L-shaped, thick-laminate specimens with a width of 20 mm, promoting an interlaminar mode I crack propagation by applying loads at the ends of the arms. The geometry, shown in Figure 1-(a), is representative of curved laminates that are typically prone to delamination in aeronautical composite structures. In particular, the experimental activity aims to support broader efforts in characterizing slow-growth fatigue behaviour in thick curved composite elements of rotorcraft structures. In Figure 1-(b), the experimental setup is presented. Loads were applied through hinged grips clamping the first 30 mm of each leg. Fatigue tests were conducted in displacement control with a displacement ratio $R = 0.1$ and a frequency of 5 Hz. Maximum and minimum forces and the cycle count were recorded throughout the test.

All specimens were manufactured from AS4/8552 unidirectional (UD) prepreg, with the layup $[0]_{48}$ using the manufacturer-recommended cure cycle. The nominal cured ply thickness is 0.13 mm [13], resulting in a total nominal laminate thickness of 6.24 mm. The material elastic properties and the most significant interlaminar properties for the presented activity are reported in Table 1, where G_{Ic} is the critical energy release rate for mode I, and $\sigma_{c0\ is}$ the interlaminar tensile strength.

Table 1: AS4/8552 elastic and interlaminar properties [13] and [14]

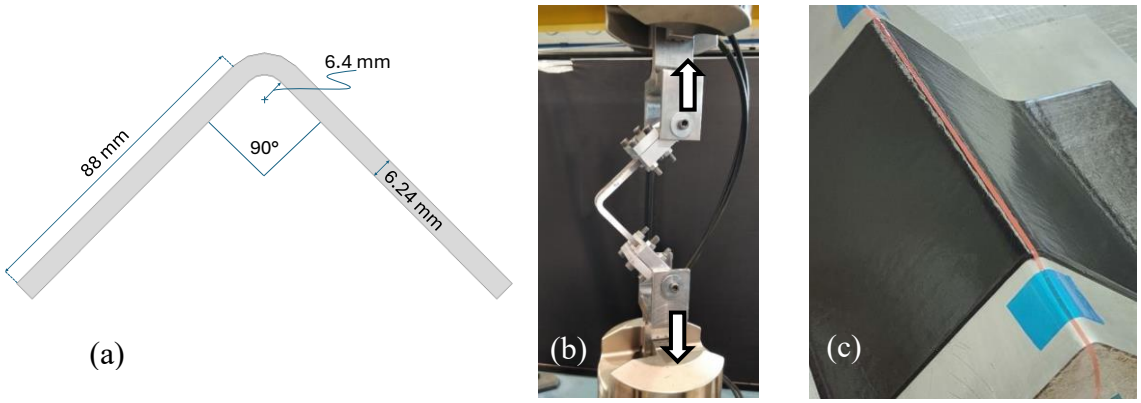

Figure 1: Specimen dimensions (a), test set-up (b), and pre-delamination placement (c)

All the specimens were manufactured with a 2-mm long artificial delamination induced with a Teflon film placed at the centre of the curved region, at one-third through the thickness (between the 16th and 17th plies). This location corresponds to the region of maximum interlaminar tensile stress for the considered load condition [15]. (Figure 1-(c)).

Before fatigue testing, two static tests were conducted to evaluate the way in which damage progresses (Figure 2). In both tests, the initial linear-elastic phase in which the defect did not propagate was followed by a sudden load drop (Figure 2-(a)). The drop corresponds to an unstable growth from the pre-delamination through the whole curved region (Figure 2-(c)). Further loading extended the crack into the specimen legs (Figure 2-(d)), which is reflected in the reduction of the secant stiffness in the force–displacement curves.

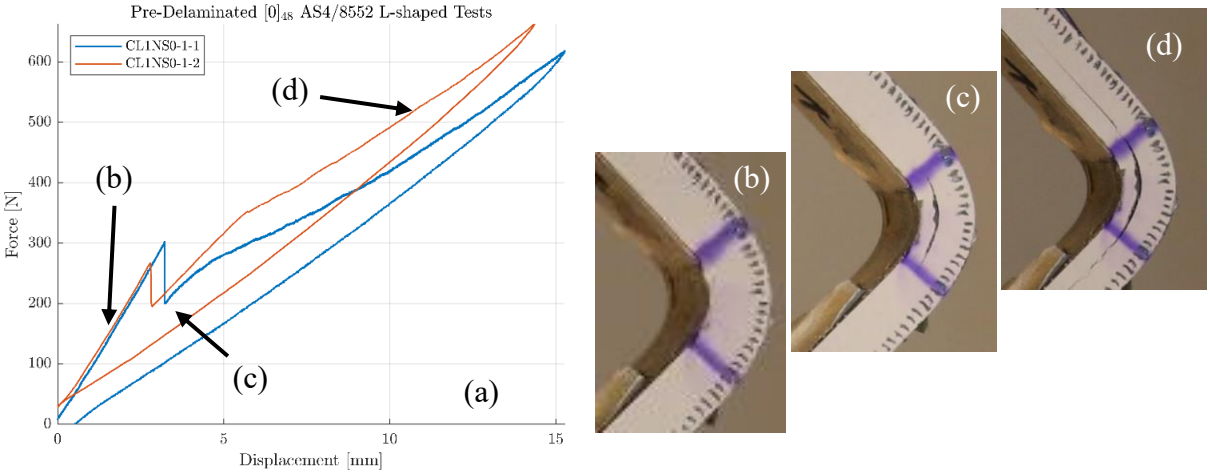

Figure 2: Static tests on L-shaped specimens

Fatigue tests were performed on five specimens in displacement control. Initial test severities were derived from the static tests (Figure 2), as a function of the displacement at the onset of unstable delamination propagation. Assuming an initial linear elastic response, fatigue loading levels were selected to correspond to a target load severity (defined in terms of strain energy release rate), scaled from the critical propagation value δ_{crit} (at delamination onset under static loading), using the relation:

$$\frac{G_{max}}{G_{crit}} = Severity = \frac{\delta^2_{max}}{\delta^2_{crit}} \quad (1)$$

where δ_{max} is the maximum applied displacement in fatigue. The Irwin-Kies equation, $G = \frac{P^2}{2B}\frac{dC}{da}$, was used, where P is the applied load, C the specimen compliance, B the specimen width, and a the crack length. Table 2 summarizes the nominal load-levels decided for the fatigue test, the corresponding maximum displacements, and the corresponding G-severities (all with a displacement ratio R=0.1). Two specimens were tested at high severity levels (0.90 and 0.75) and three specimens were tested with a nominal severity of about 0.60. The effective displacement and force levels were adjusted considering the response of each specimen and the discrepancies with the nominal levels are also due the presence of mechanical plays and contact tolerances in the test setup. Regarding the codes used to identify specimens, the first number indicates the specific production batch they were cut from, and the second is a number specific to each.

Table 2: Specimens tested under fatigue loading, the initial test severity and the test maximum displacement (R = 0.1)

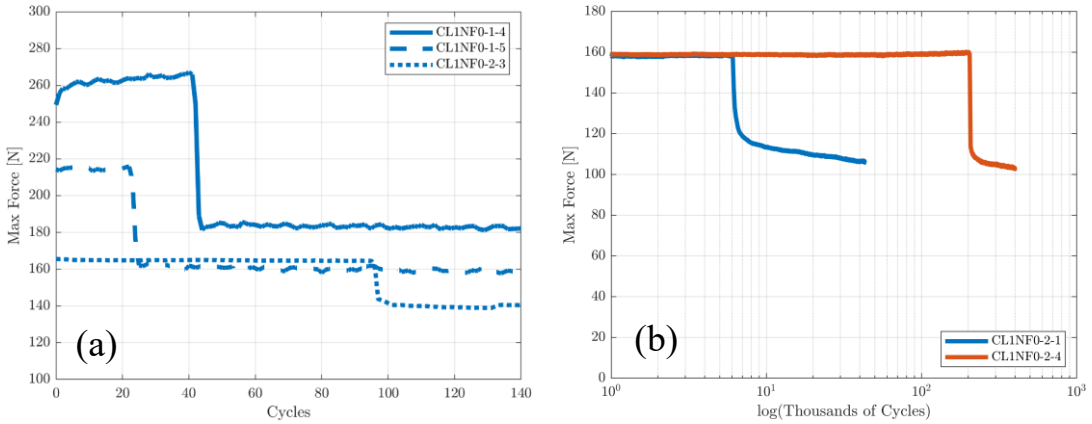

Figure 3: Max force during L-shaped fatigue tests: (a) Highest severity tests, (b) CL1NF0-2-1 and CL1NF0-2-4

The two specimens CL1NF0-1-4 and CL1NF0-1-5, tested at the highest severity, underwent a rapid delamination propagation within very few cycles (41 and 22 load cycles, respectively). The rapid drop of the force shown in Figure 3-(a) is a consequence of the rapid crack growth, which accelerated abruptly from the Teflon insert (initial defect length of 2 mm) along the curved region. Crack growth rate was significantly reduced after a specific load, which was 189 N for specimen CL1NF0-1-4 and 162 N for CL1NF0-1-5. The load drop was obtained in 3 cycles for CL1NF0-1-4, as well as for CL1NF0-1-5 (about 0.5 s)

The three specimens tested at the lowest severities (in the range 0.55 to 0.62) provided different responses. The trend of force vs. cycles for the specimen CL1NF-2-3 (effective severity 0.62) is plotted with those of the highest severities tests in Figure 3-(a), since it exhibited a similar rapid crack propagation just after 95 load cycles, with a force drop from 164 N to 141 N, in 6 cycles (about 1 s). Considering the test at 0.55 severity level (blue curve in CL1NF0-2-1, Figure 3-(b)), the number of cycles required to reach the region of rapid force drop increased to approximately 6000 cycles, and the rapid force drop went on until about 140 N after 40 cycles (about 6.5 s). The subsequent test was conducted at the same nominal load level (red curve in CL1NF0-2-4, Figure 3-(b)). It obtained the same qualitative response, with an initial stable force level followed by a rapid growth of the crack, but the onset of the rapid crack propagation required about 204,000 cycles. The rapid force drop arrested at about 139 N after 83 cycles (about 14 s).

During fatigue testing, damage accumulates at the pre-existing delamination tip until a critical threshold is reached, triggering a rapid crack propagation across the curved region, which corresponds to the load drop that was observed in the different tests. The load drop is not instantaneous, as in the unstable propagations that occurred in quasi-static tests, and its velocity tends to decrease if severity is reduced. Prior to this event, load fluctuations were minimal, indicating negligible crack growth. The initial rapid growth is arrested at different load levels. Thereafter, the load decreases gradually as the

delamination extends into the specimen legs. This behaviour highlights the existence of a threshold for the onset of the accelerated crack propagation phase and a transition from such phase to a slow crack propagation activated after a certain propagation length. The number of cycles required for these transitions vary from a few cycles to tens or hundreds of thousands of cycles, with maximum values that were obtained only in the tests with the lower severity levels.

In the quasi-static tests, the initial crack undergoes an initial unstable propagation. The propagation regime then changes to a stable slow-growth regime when the crack, approximately, reaches the end of the curved zones. Assuming a constant crack resistance for the material, such response is indicative of a strong variation of the Energy Release Rate (ERR) available to promote crack propagation with the crack length. In the fatigue tests, despite the quantitative differences in the number of cycles required to activate fast crack propagation, the qualitive responses are very similar for all the five tests. Although the propagations observed in the fatigue testing were not instantaneous, the occurrence of two regimes in the fatigue crack growth is evident in all the fatigue tests performed. The interpretation of these phenomena requires an analysis of the ERR variation, which is accomplished in the next section by applying the Irwin-Kies equation, linking the compliance of the specimens to the crack propagation. The simulations of these type of propagation with the fatigue damage accumulation laws validated for characterization specimens, like DCB and ENF, is particularly challenging due to the expected gradients in ERR and the presence of unstable propagation regimes in the quasi-static tests. The large scatter exhibited by the specimens tested at a nominal severity around 0.60 should be investigated, although such variability in fatigue test results is consistent with literature on similar specimens [16], [17], which emphasizes the need to model the statistical distributions of interfacial properties in fatigue analyses more than static ones.

3 NUMERICAL COMPLIANCE AND ENERGY RELEASE RATE EVOLUTION WITH CRACK LENGTH

The evaluation of the ERR for different crack lengths was performed via semi-analytical assessment based on the Irwin-Kies equation:

$$G = \frac{F^2}{2B}\frac{dC}{da} \tag{3}$$

This relation links applied load F, the specimen compliance C (or, better said, the effect of specimen geometry characteristics as a function of crack-length a) to the strain energy release rate G, the energy available for crack growth. A finite element model of the specimen was developed in Abaqus Standard [18] to numerically evaluate the compliance as a function of crack length.

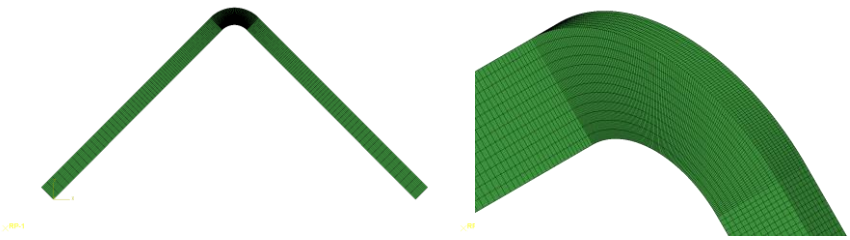

Figure 4: FE model of the angular specimen

The model is a 2-mm-wide strip of the specimen, meshed with laminated continuum shell elements (SC8R). Each shell comprises 4 plies A layer of zero-thickness cohesive elements (*COH3D8*) – containing a pre-crack at the centre of the curved region – was inserted between the 16th and 17th plies (i.e., between the 4th and 5th continuum shell layers). A total of 8 elements was used across the width. The mesh is coarse at the extremities of the legs and becomes finer in the curved region, where elements are approximately 0.1 mm long. Material properties are those reported Table 1. Loading was simulated by applying opening displacements to rigid bodies including the last 30 mm of each leg. Such boundary conditions were applied to the reference nodes of the rigid bodies, positioned in correspondence of the

hinges. Free rotations were allowed around the grip hinge axis, which replicates experimental boundary conditions. An implicit static analysis procedure was used, allowing for non-linear geometrical effects. Damage in cohesive elements was inhibited since the objective of these analyses was simply to evaluate the compliance at different crack lengths. A series of analyses was performed by removing cohesive elements in 0.2 mm increments to represent the development of an ideal crack from 1 mm to 13.4 mm (i.e., until the end of the curved region). The crack was symmetrically extended at both crack-tips. The compliances obtained in each analysis were interpolated with a polynomial, proving the result reported in Figure 5-(a) and then derived. By applying Eq. 3, the variation of the ERR with the crack length a was evaluated, as reported in Figure 5-(b), considering the load corresponding to an opening of 2 mm.

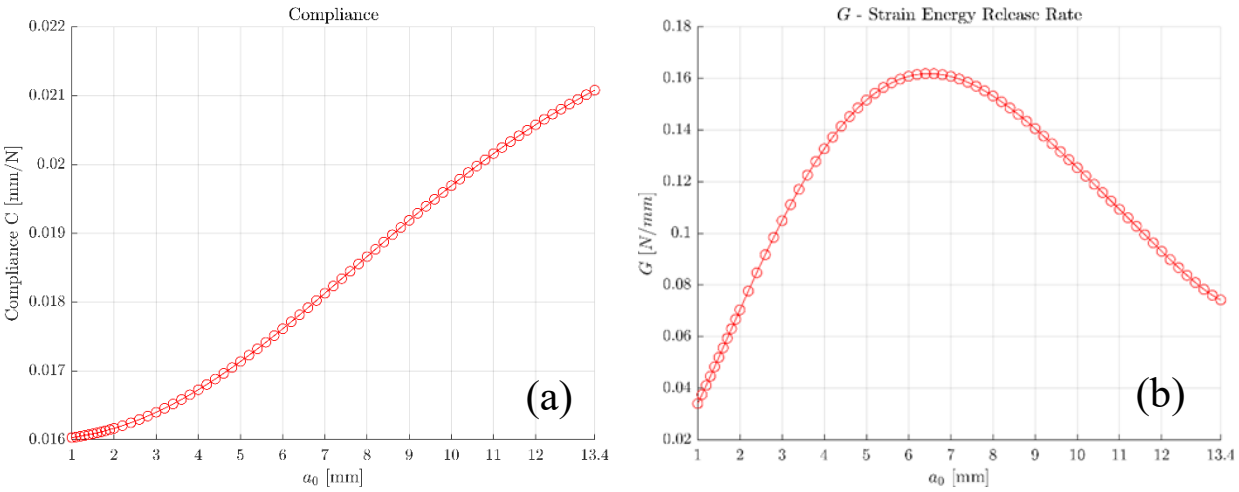

Figure 5: Numerical Compliance (a) and Energy Release Rate (b) of the L-shaped specimen as a function of crack length

Assuming a constant crack resistance, the sign of the derivative of the ERR curve, dG/da, determines the crack propagation regime: unstable if $dG/da > 0$ and stable if $dG/da < 0$. According to Figure 5-(b), the existence of a transition between unstable and stable regimes is evidenced at a = 6.4 mm. These results are consistent with those reported in [19], [20], where a similar approach was used to calculate G and the stability of delamination propagation in L-shaped laminates. Despite the differences in specimen geometry and loading conditions, the existence of a threshold for unstable-to-stable crack growth transition was found beyond a certain crack length (a = 6.55 mm in [18]).

This approach does not consider the presence of any fracture process zone (FPZ) at the crack tip. An estimate for the length can be evaluated using the formulation in [21]:

$$l_{pz}^{ss} = \gamma \frac{E' G_c}{\sigma_c^2} \text{ where } E' = \frac{E_{22}}{Q}, Q = \frac{1}{2}\sqrt{2\left[\sqrt{\frac{E_{22}}{E_{11}}} - \nu_{21}\right] + \frac{E_{22}}{G_{12}}} \tag{4}$$

which, using the values for γ reported in [22] ($\gamma = 0.73$) and [23] ($\gamma = 1.00$) and the material properties in Table 1, yields 0.16 mm and 0.22 mm as upper and lower bounds for the FPZ length. Although the process zone can be considered small, these values could affect the evaluation of the compliance as a function of the crack length used to obtain the results in Figure 5.

The experimental results can be interpreted by using the results of the semi-analytical procedure presented above. Since the tests were performed at fixed opening, the evolution of force and the relation between the compliance and the crack length in Figure 5-(a) can be used to estimate the crack length during the fatigue tests. The results, for the specimens tested with the lowest severity levels are similar. For CL1NF0-2-3, where rapid propagation was triggered after 95 cycles, the rapid crack growth was arrested at a force level that is compatible with a crack length of 7.5 mm. For the specimens CL1NF0-

2-1 and CL1NF0-2-4, the estimated crack lengths at the end of the rapid crack growth is of 6.7 mm and 7.2 mm. All these values are slightly beyond the maximum in the ERR-*a* curve, indicating the phase of rapid propagation ends when the crack enters the region of stable crack growth. For the specimens tested at the highest severity levels (CL1NF0-1-4 and CL1NF0-1-5), the estimation provides values larger than 13 mm. Such results can be explained by considering that the elastic energy stored in the specimens promoted a propagation of the crack into the region of stable propagation.

4 NUMERICAL SIMULATIONS

4.1 Static failure modelling

The same finite element model developed for the evaluation of the compliance with crack growth, was used to perform quasi-static simulation through a fully non-linear analysis, adopting an explicit time integration scheme with Simulia Abaqus/Explicit. The explicit solver can capture unstable propagation phenomena and transition to stable regimes without the convergence difficulties that are common with implicit codes. The model retains the continuum shell (SC8R) representation of the specimen, including the zero-thickness cohesive interface elements (COH3D8) positioned between the 16th and 17th interfaces, where the defect was located. The model was subjected to an opening displacement at the reference points coupled to the specimen legs. Quasi-static conditions were ensured by imposing a smoothly varying opening time history, and by checking that reaction forces read at the two reference points were identical. A user-defined Cohesive Zone Model (CZM) was used to characterize the fracture process. The CZM in [24], originally conceptualized for static fracture, was implemented in a VUMAT subroutine for COH3D8/COH2D4 cohesive elements in Abaqus/Explicit. The model is characterized by an initial linear elastic response (of penalty stiffness K_p). Damage initiates at the cohesive strength σ_0 (at the displacement δ_0) and progresses, gradually reducing the stress carrying capability according to a linear softening law, until a displacement δ_f, where the work spent in the damage process equals the prescribed interface toughness. The critical ERR and strengths used in the analyses are reported in Table 1 [14]. A quadratic strength criterion for damage initiation and the B-K model for damage progression were selected for mixed-mode propagation. The penalty stiffness was set at 1.25E+05 N/mm^3, following the formulation in [25].

The simulated force-displacement response in the analysis of the L-shaped specimen is presented in Figure 6, together with the corresponding experimental curves of the two specimens tested. The model accurately captures the linear elastic stiffness of the specimen during initial loading, as well as the predicted load at the onset of unstable delamination propagation from the pre-crack, which matches closely with the experimental failure loads.

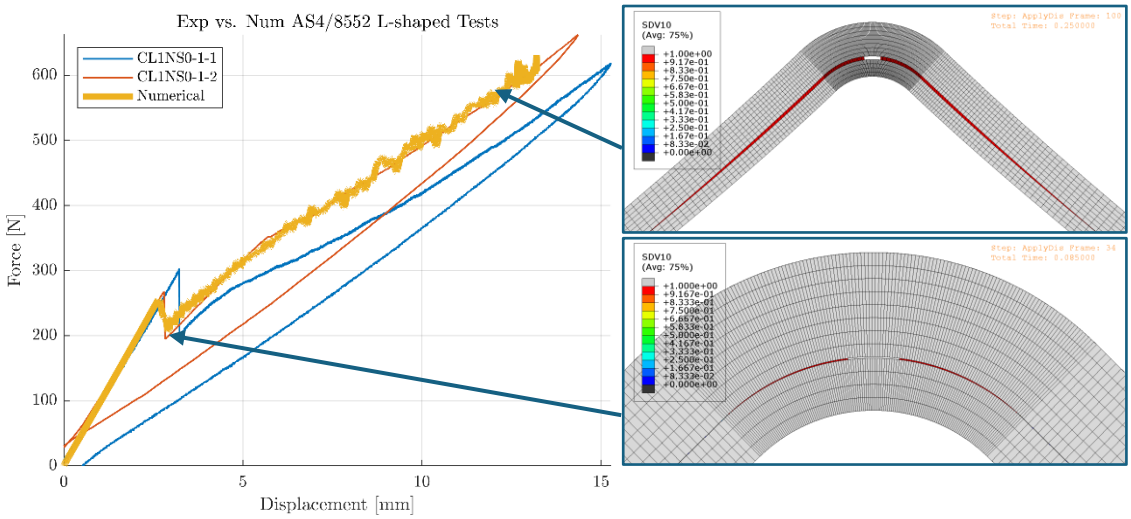

Figure 6: Numerical vs Experimental tests on L-shaped specimen

The sudden load drop that accompanies unstable delamination growth through the curved region was also captured by the simulation, as well as the response during the stable propagation of the crack along the legs of the specimens. This successful correlation of the static force-displacement response (including stiffness, first failure load, load drop, and crack stable propagation) provides confidence in the capability of the modelling approach to reliably model the loads required to propagate the initial delamination in quasi-static simulations, both for stable and unstable propagation regimes.

4.2 Modelling of fatigue damage accumulation and crack growth

Examples of cycle-by-cycle FE fatigue simulations exist in the literature but are only practical for Low and Ultra-Low Cycle Fatigue (LCF, ULCF) situations, which involve very few cycles with large plastic strains (such as seismic loading of steel structures [26]). For High Cycle Fatigue (HCF) applications, involving millions of cycles, simulating every cycle is computationally prohibitive. Therefore, simplified strategies are necessary for the practical FE simulation of structures under fatigue. A common class of simulation approaches is that of the "envelope load" methods [27]. They consist in the modelling of only the maximum (and/or minimum) loads in a fatigue load block, while relying on the CZM constitutive law to capture damage accumulation due to fatigue. Among the possible methods, the Simplified Cyclic Loading (SCL) is the one adopted here: it involves the quasi-static loading up to the block maximum load, after which fatigue damage accumulation is activated and continued, either until a specified cycle count or the (static) structural failure. A fatigue damage accumulation law can be easily integrated in the VUMAT subroutine previously used for quasi-static simulations. The fatigue model used here is based on Dávila's approach [9], [10], [11], using the SCL method and the suggested damage accumulation function, calibrated by fitting two parameters to the Paris data for mode I and II. The model applied is an updated version of the original approach proposed in [9] (CF18). It is based on the evaluation of a damage norm D. At each step in the simulation, the new values of the quasi-static and fatigue damage variables are evaluated independently of each other, and the larger of the two is selected as the one to be passed on to the next time increment. The typical response of a bi-linear cohesive zone element is shown in Figure 7-(a), showing the fatigue damage progression on a single cohesive element under a constant maximum stress. Load is applied quasi-statically from $\sigma = 0$ to $\sigma = \sigma_{max}$, and then kept constant while fatigue damage accumulates. As fatigue damage is accumulated, the damage norm degrades the penalty stiffness and λ increases. The traction-displacement state at the material point evolves along the path denoted as "Fatigue" in Figure 7-(a), until the softening branch of the static cohesive law is reached, at a displacement jump λ^*, at which point, the cohesive response is dominated by static tearing, which goes on until full separation of the cohesive interface.

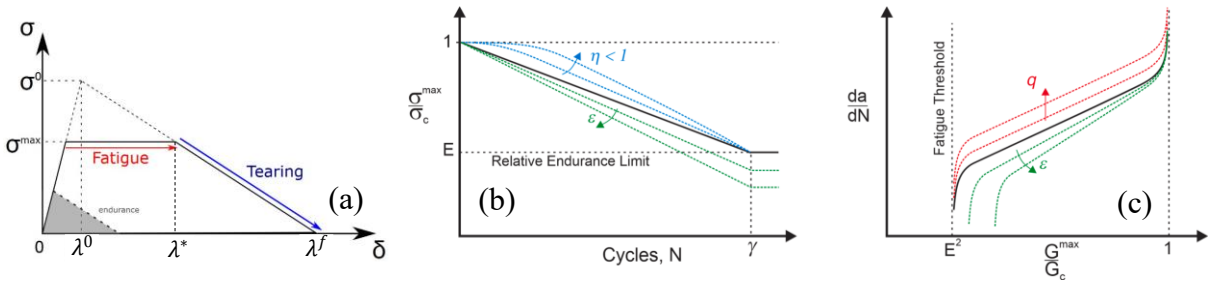

Figure 7: Fatigue damage accumulation law: (a) single element response in fatigue simulation, (b) effects of parameters η and ε in the S-N curve, and (c) effect of parameters q and ε in the Paris Curve

The CF22 fatigue damage accumulation law proposed in [11] is used herein within a VUMAT for explicit simulations. CF22 expresses the rate of change of the damage norm, D, with load cycles, N:

$$\frac{dD}{dN} = \frac{(1-D)^{-q}}{\gamma\, E^{\beta}(\beta+q+1)} \left(\frac{\lambda}{\lambda^*}\right)^{\beta} \tag{5}$$

where λ/λ^* is the ratio of current cohesive displacement jump λ to the corresponding static fracture displacement λ^* at the current residual fracture toughness; q is a fitting parameter to be calibrated, while

β, E and γ are parameters with a precise physical meaning in the S-N curve of the material. E is the infinite-life endurance threshold normalized with the static strength, i.e., the maximum allowable stress amplitude below which fatigue life is infinite, and γ is the number of cycles corresponding to this endurance limit. The threshold E is differentiated for the two opening modes, depends on the stress-ratio, and is interpolated between Mode I and Mode II endurance thresholds:

$$E = E_I + B(E_{II} - E_I) \text{ where: } E_I = \frac{2\varepsilon}{\varepsilon+1+R(\varepsilon-1)}, E_{II} = min\left(0.999,\ \phi\left(\left(\frac{2}{1-R}\right)^{\varpi}\right)\right) \quad (6)$$

here, ε and ϕ are the relative endurance values at fully reversed loading ($R = -1$) for Mode I and II, respectively; ϖ is a parameter controlling the variation of E_{II} as a function of R, and B is the mode mixity. The parameters β and q in Equation 5 are expressed as follows:

$$\beta = \frac{\eta \log(\gamma)}{\log(E)}, q = q_I + B(q_{II} - q_I) \quad (7)$$

where η is the brittleness parameter, and q_I and q_{II} parameters that allow the fitting of Paris crack growth rates in Mode I and II. The effect of the model parameters in the S-N curve and in the growth rate vs. severity plots are represented in Figure 7-(b) and Figure 7-(c), respectively. The calibration of the fatigue damage accumulation law for the AS4/8552 unidirectional (UD) prepreg was obtained via a trial-and-error procedure in [11]. Since the material is the same as used for the L-shaped specimens described in Section 2, the same calibration was adopted for the simulation of the fatigue tests.

In the explicit time integration scheme, each time step corresponds to a number of cycles ΔN. By discretizing the expression in Equation 5, the current value of the fatigue damage norm can be evaluated, as in Equation 8.

$$\frac{\Delta D}{\Delta N} = \frac{(1-D_{k-1})^{-q}}{\gamma E^{\beta}(\beta+q+1)}\left(\frac{\lambda}{\lambda^*}\right)^{\beta} \rightarrow D_k = D_{k-1} + \frac{(1-D_{k-1})^{-q}}{\gamma E^{\beta}(\beta+q+1)}\left(\frac{\lambda_k}{\lambda^*_k}\right)^{\beta}\Delta N \quad (8)$$

The fictitious frequency that links simulation time with cycle is selected to keep ΔD small enough at each integration step to avoid the numerical instabilities associated with excessive damage increments, but large enough to avoid a waste of computational power.

4.3 Simulation of the L-shaped specimen under fatigue loading

This section presents the results of simulations of the fatigue tests on the L-shaped laminated specimen. Figure 8 shows fatigue simulation results for specimens CL1NF0-1-5, tested at an initial severity of 0.70, and CL1NF0-2-1, at an initial severity of 0.55. Specimen CL1NF0-1-4 reaches the onset of unstable propagation during the quasi-static loading phase, so its fatigue simulation was not possible.

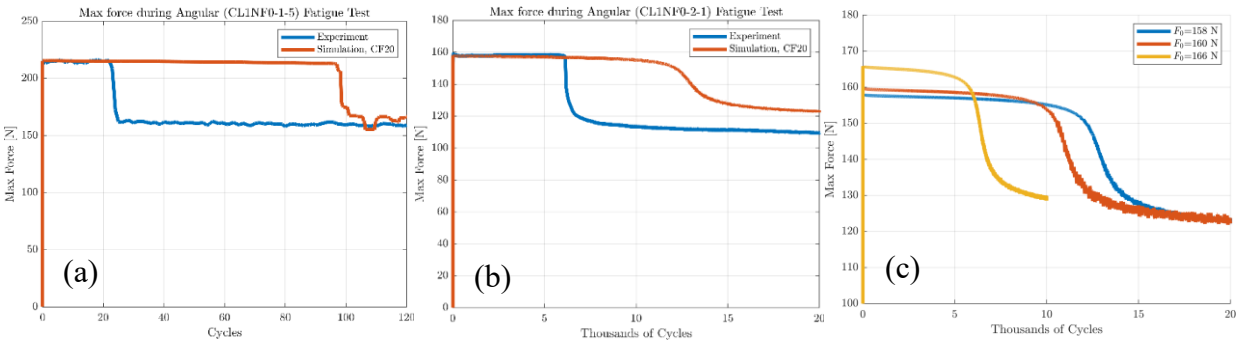

Figure 8: FE simulations compared with experimental fatigue tests on L-shaped specimens

The FE analyses show the onset of a rapid crack propagation after few cycles in CL1NF0-1-5 (96 cycles against 22 cycles in the test) and the need of thousands of cycles to activate the same phenomenon

in CL1NF0-2-1, where the model predicts the threshold at approximately 12,000 cycles, about twice the observed 6100 cycles. Considering the scatter of the experimental tests, the results are promising. In the CL1NF0-1-5 simulation, the crack growth is almost instantaneous and is arrested at a force level that matches the experimental level. In the simulation of CL1NF0-2-1, conducted at a severity of 0.55, the rate of the force reduction, related to the crack growth rate, is lower in the simulation than in the test. Moreover, the total crack propagation in the fast phase of the growth is lower than the experimental one, as indicated by the higher force level.

Despite these discrepancies, the qualitative aspects of the response are captured in both cases. Considering noticeable experimental variation of the response for the three tests performed at severity levels of 0.55, 0.57, and 0.62, two additional simulations were performed by applying slightly different openings, corresponding to 158 N and 166 N. The results are compared in Figure 8-(c) with the simulation performed at 160 N, already presented in Figure 8-(b). As can be seen, small variations in the applied load produce a large variation in the number of cycles required to activate the rapid growth propagation from 6000 to 12,500 cycles.

5 CONCLUSIONS

In this work, a study of delamination propagation under quasi-static and cyclic loading in L-shaped specimens was presented. Different regimes of propagation were found in quasi-static tests, in agreement with the results obtained with a semi-analytical evaluation of the ERR, through the application of an Irwin-Kies analysis. In the fatigue tests, very different quantitative responses were obtained by varying different severity levels, although three phases could be identified in all the experiments: a first phase of nucleation, without crack growth, a second phase of rapid crack growth, at a rate increasing with the severity, and a third phase of slow growth of the crack.

The availability of the ERR vs. crack length curve obtained through the semi-analytical procedure made possible an interpretation of the results. The energy available for crack opening increases with a significant gradient from the pre-cracked conditions until a crack length of about 6.4 mm (from 0.06 kJ/m2 to 0.16 kJ/m2 for an opening of 2 mm). This means the severity imposed at the beginning of the tests increases rapidly as the crack grows, promoting a very fast propagation phase. Interestingly, the experimental results indicate that this phase of rapid crack propagation ends after the maximum of the ERR curve, when severity starts decreasing with crack length.

The application of a cohesive-based approach within FE explicit simulation was able to capture the response in quasi-static tests. A fatigue damage accumulation law available in literature was described, implemented in a user-defined material subroutine and applied to model the fatigue tests. The three phases of the fatigue responses were qualitatively reproduced, with quantitative discrepancies that can be difficult to interpret, considering the limited number of experiments and the relevancy of typical scattering in fatigue propagation of delamination documented in the literature. The application of explicit time integration schemes made possible the identification of different propagation regimes with a good level of reliability. Results are promising for the possible application of the proposed approach in the presence of large variation of ERR with crack advancement, which can induce significantly different crack propagation rates in real-world damage scenarios.

Problem Statement and Approach

Overall Goal

- ✓ Optimize the process, to achieve a complete polymerization at the highest production speed
- ✓ Necessity of a fine and predictive model to support process control

Complex thermal behavior

- ➢ Strong thermo-kinetic coupling due to the complex polymerization of the Elium resin.
- ➢ Development of a numerical model of the pultrusion process by coupling heat transfer equations with the polymerization kinetics of the resin.
- ➢ Influence of Elium's specific kinetic behavior on the thermal regime during pultrusion.
- ➢ Evolution of material properties as a function of both temperature and degree of conversion.

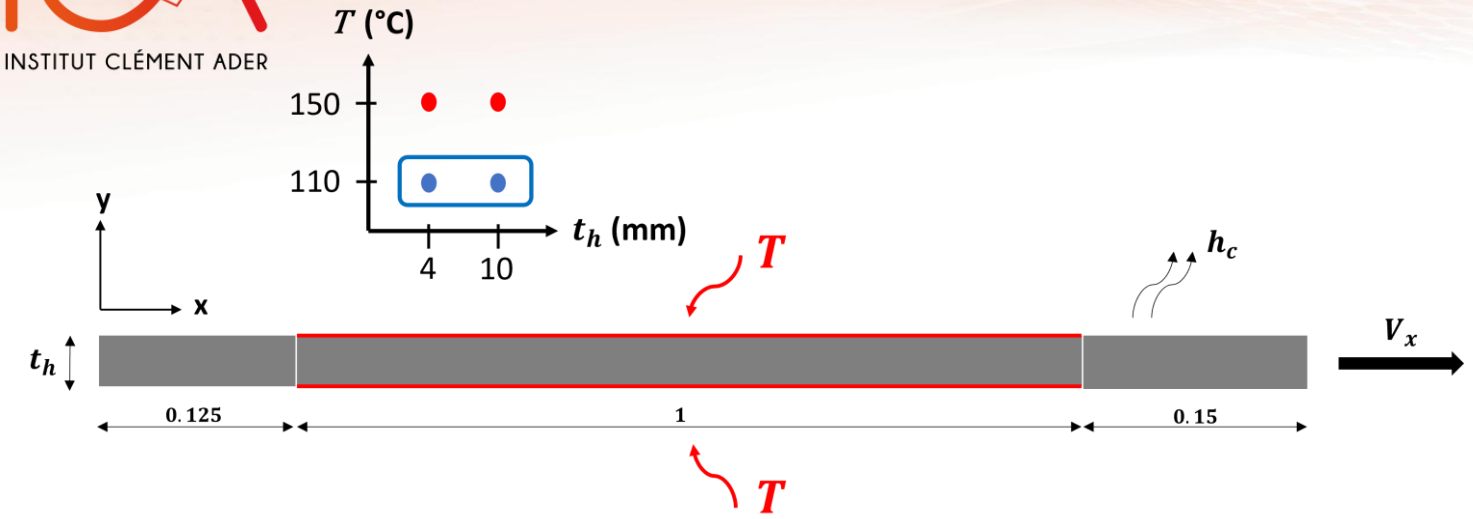
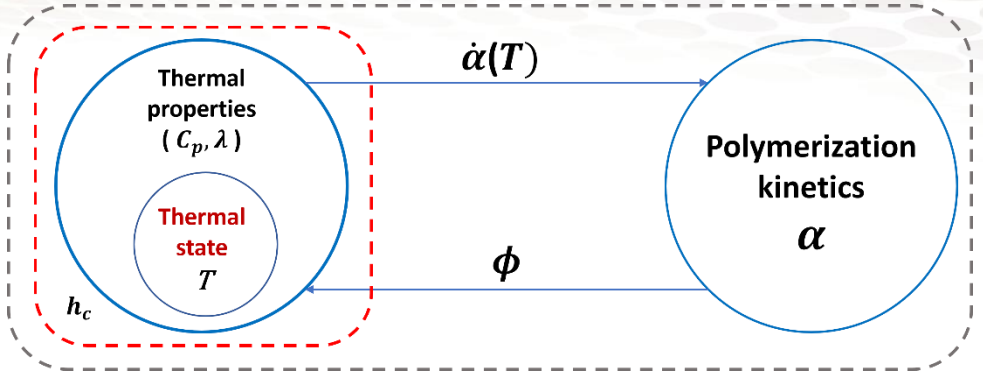
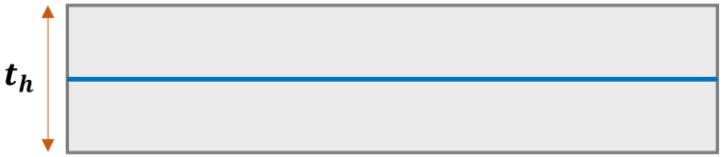
- **Validation of the kinetic model using COMSOL**



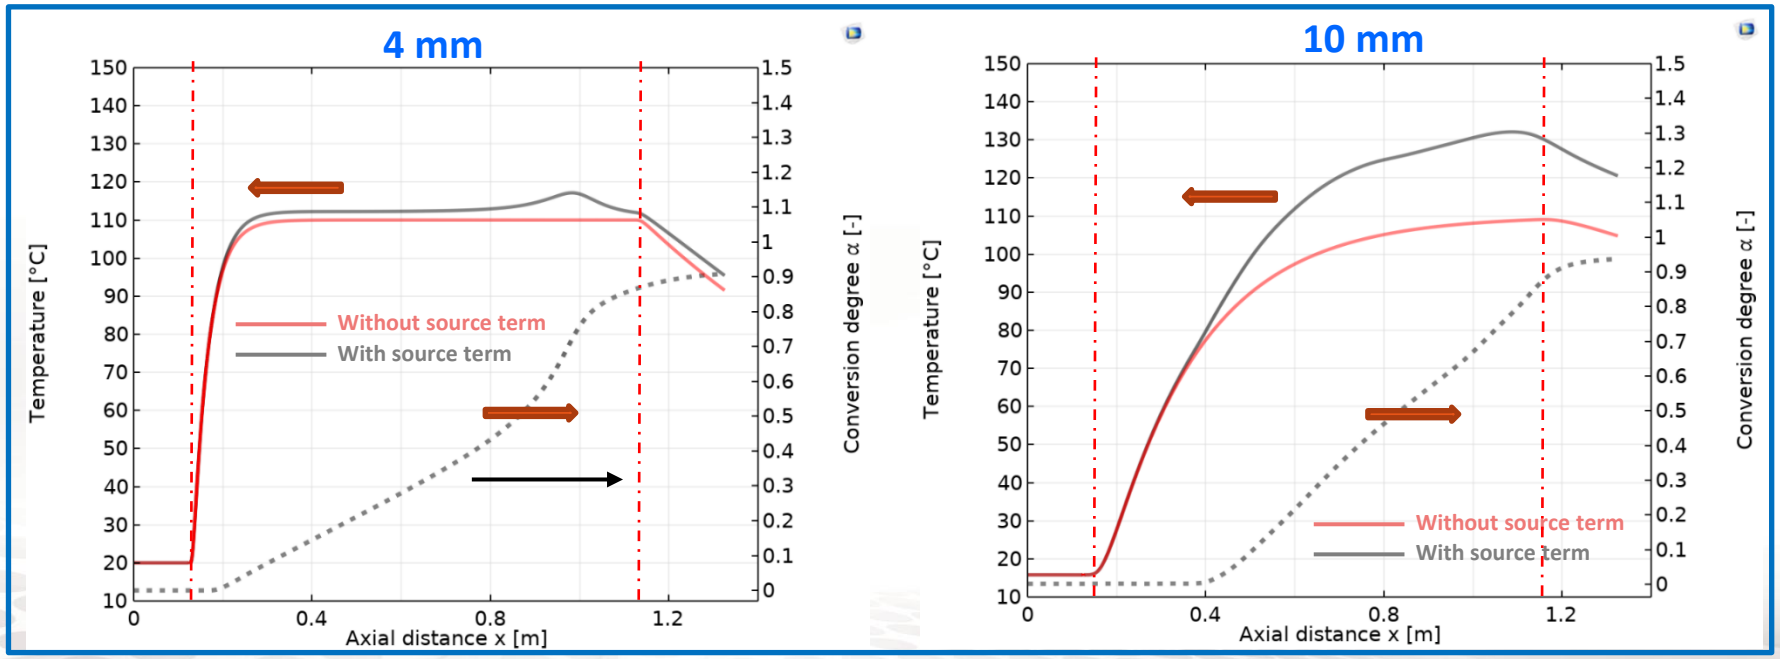
Assumptions:



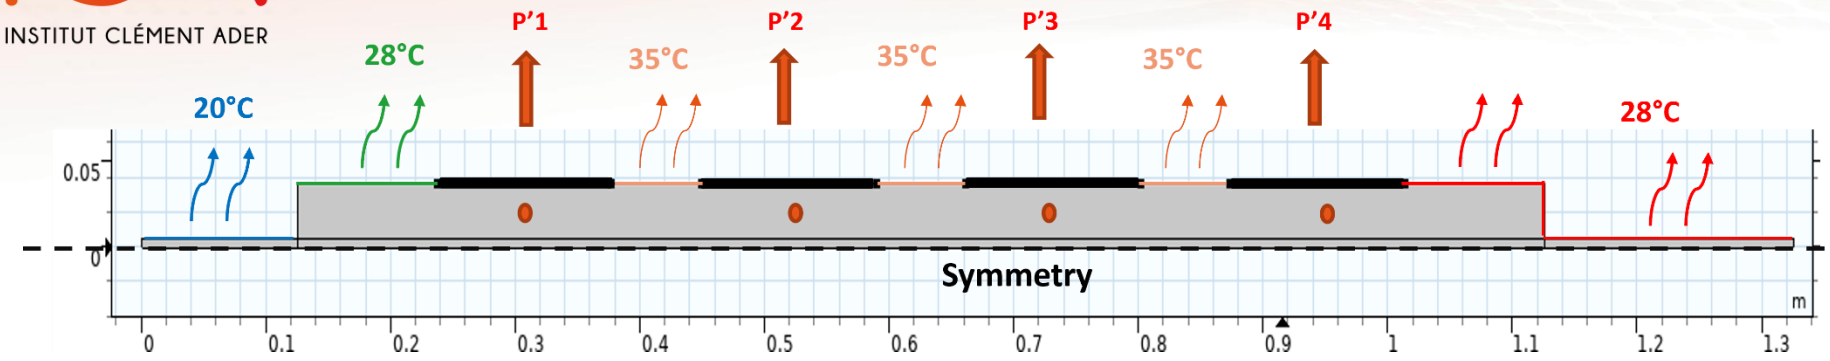
- **Thermal study under adiabatic conditions using COMSOL Multiphysics.**

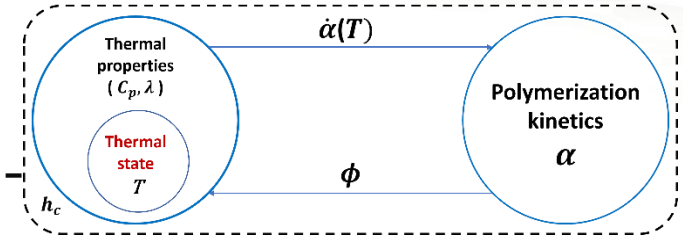


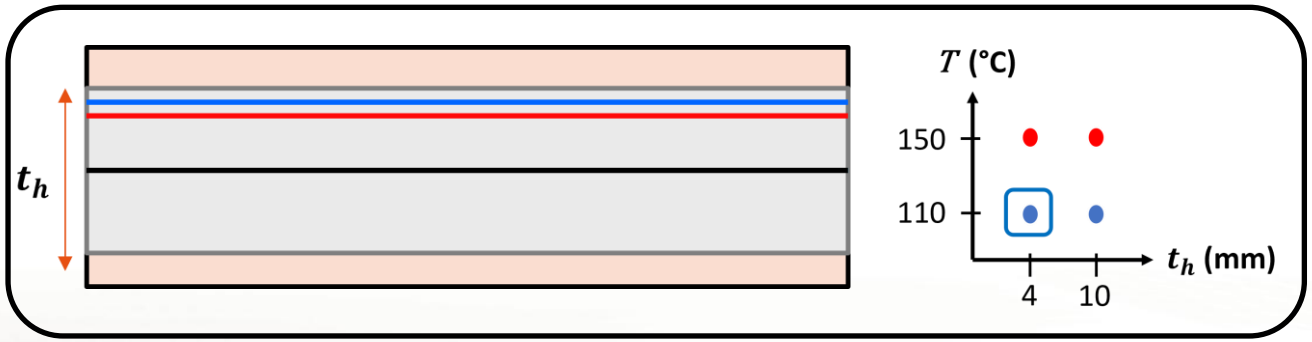
- **Validation of the results obtained in COMSOL with the actual experimental data**



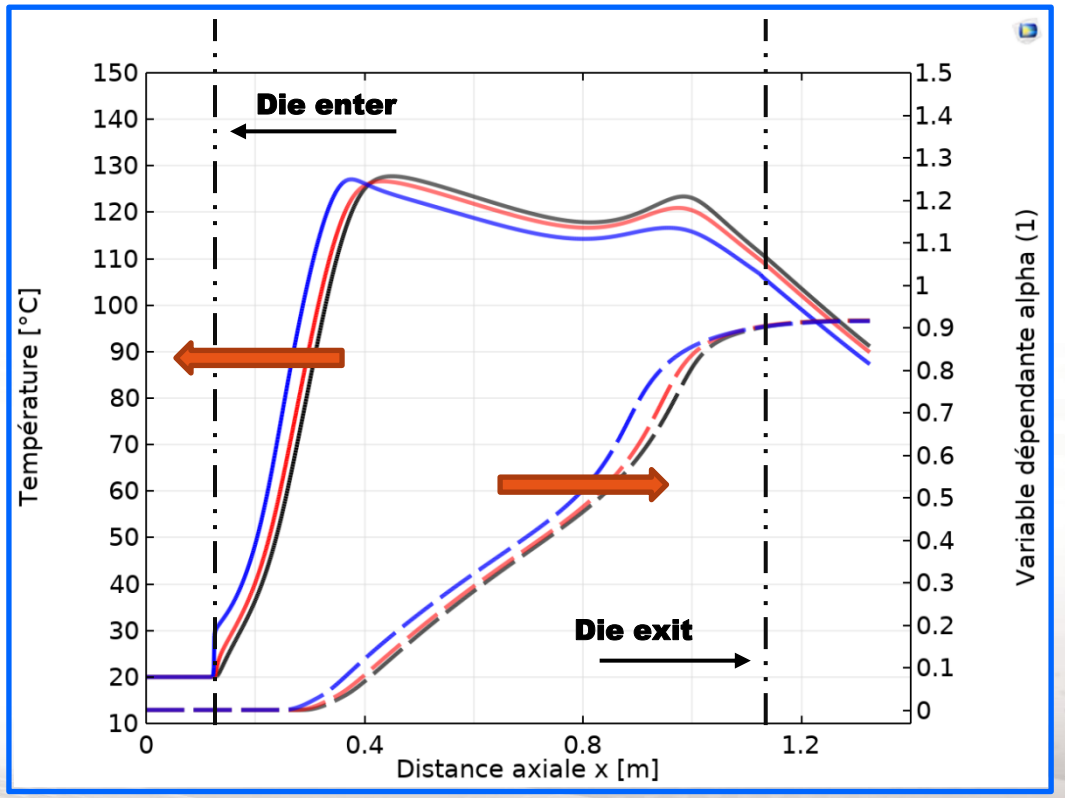
Influence of the source term at 110°C





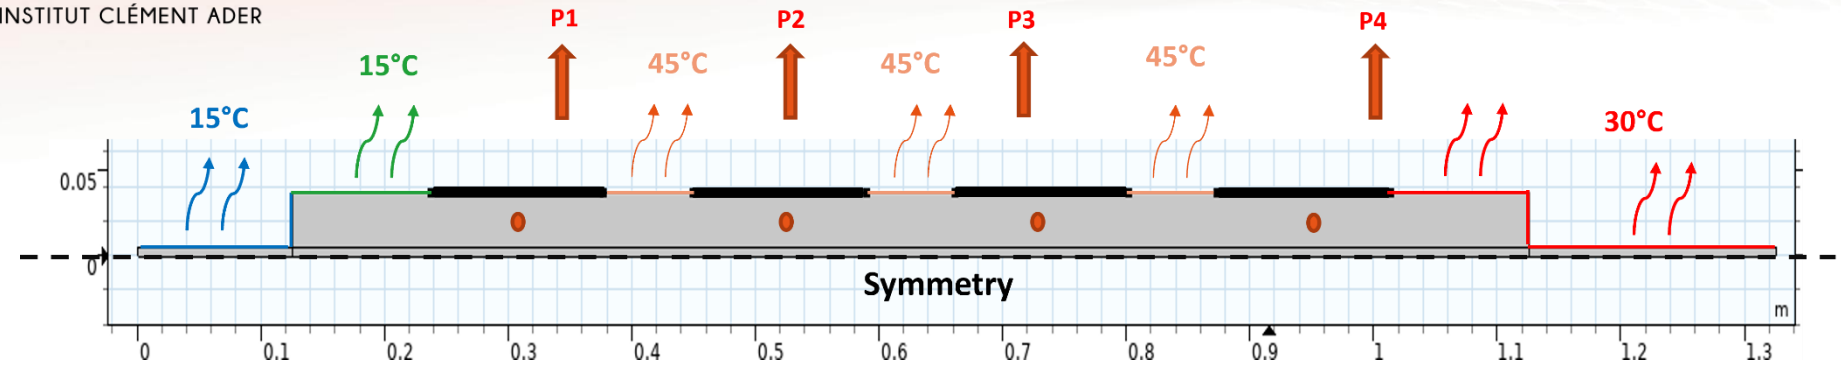


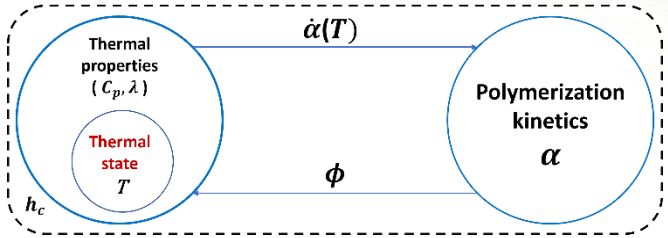
Conclusion

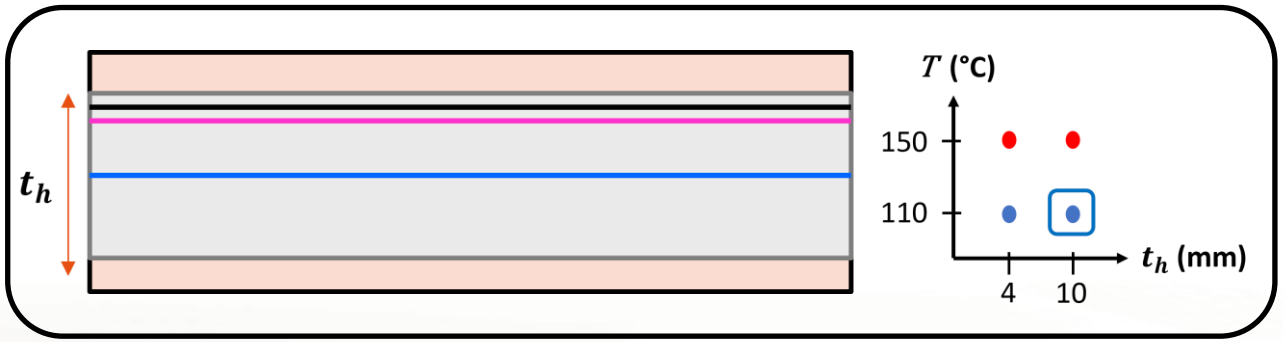


- A temperature rise due to the exothermic heat generated by polymerization.
- With a source term, the temperature exceeds the applied temperature

System setup in COMSOL



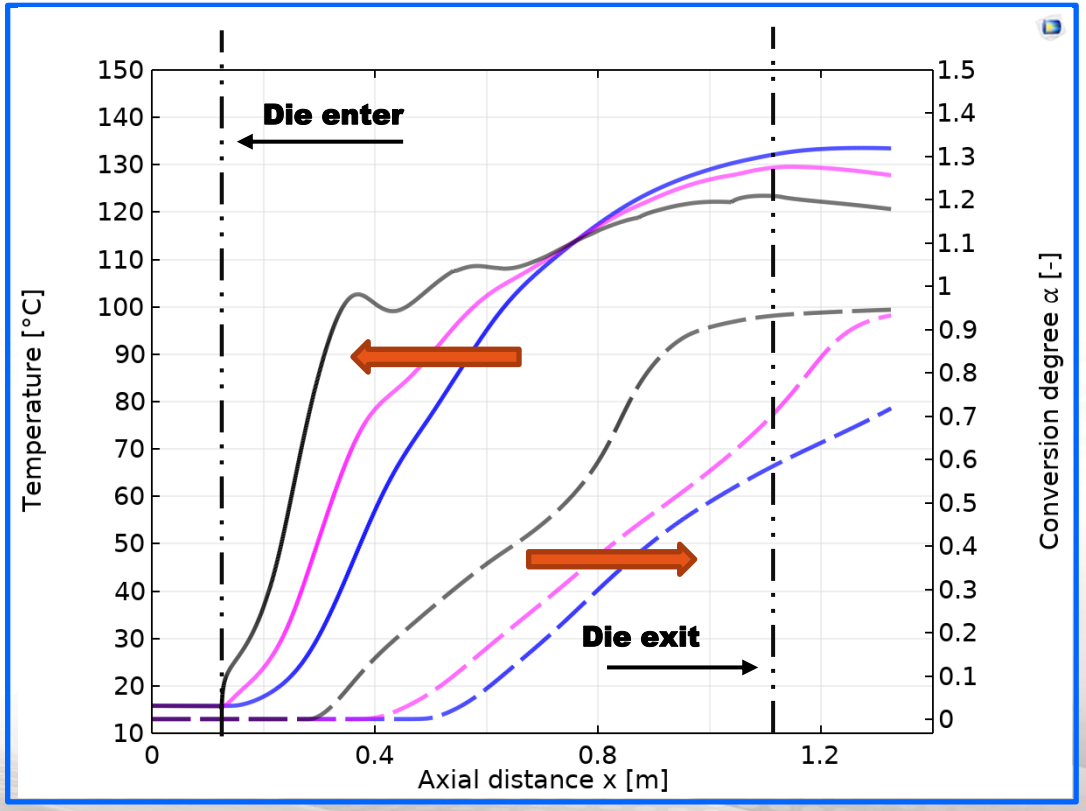




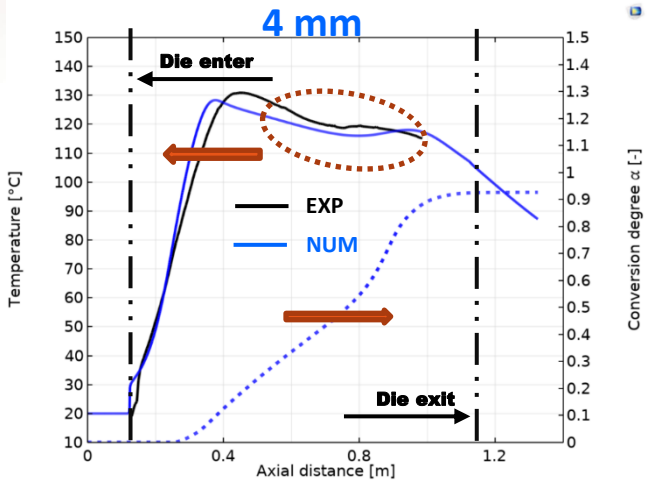
Conclusion

- Polymerization starts at the surface due to the high thermal conductivity of the die.
- Temperature and polymerization are delayed at the core.
- Homogeneous heat transfer.

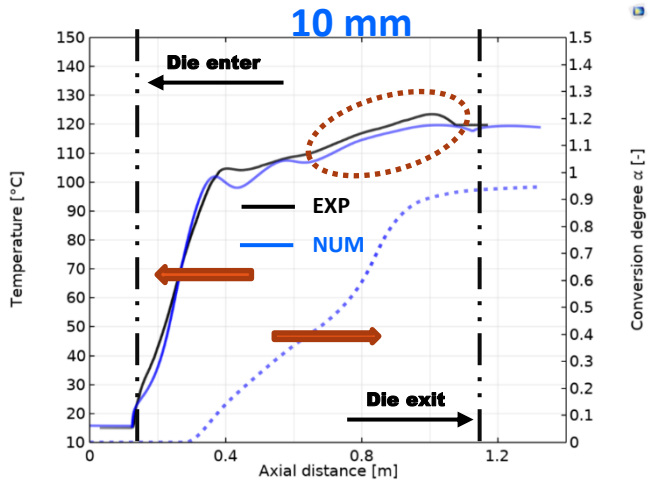
System setup in COMSOL

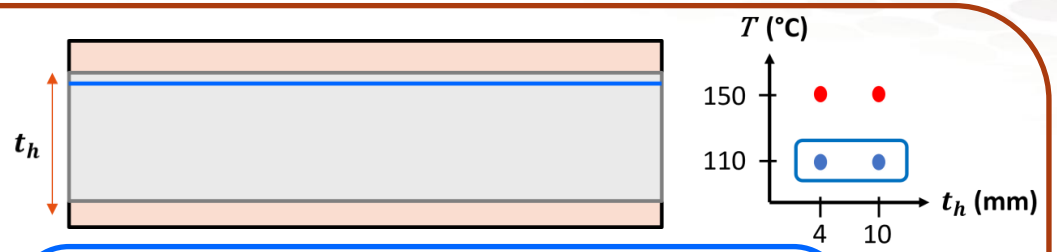


Conclusion



- Polymerization starts at the surface due to the high thermal conductivity of the die.
- Temperature and polymerization are delayed at the core.

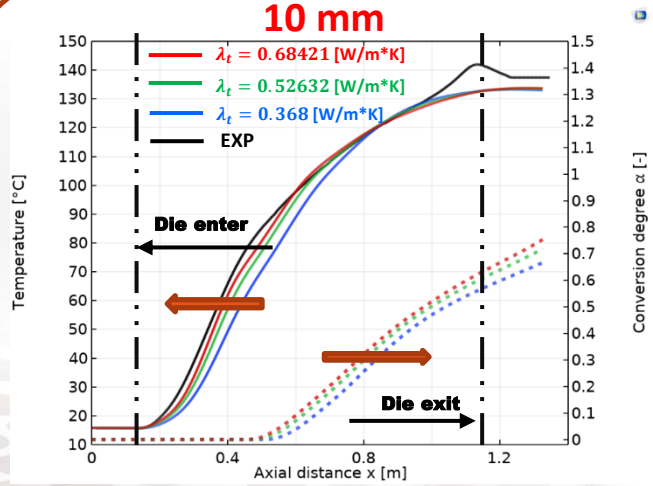




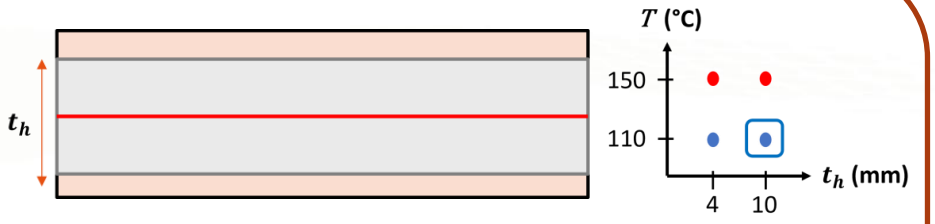
Intermediate conclusion

INSTITUT CLÉMENT ADER

Surface analysis



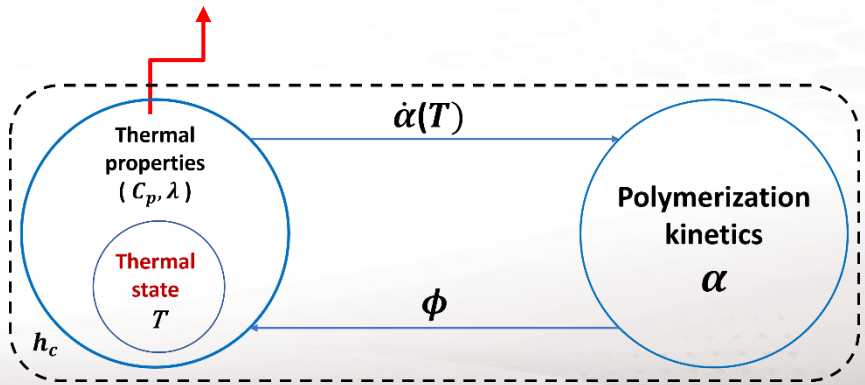
Relevant thermo-kinetic coupling



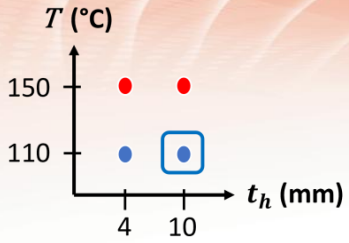
- Allows to capture the thermal evolution

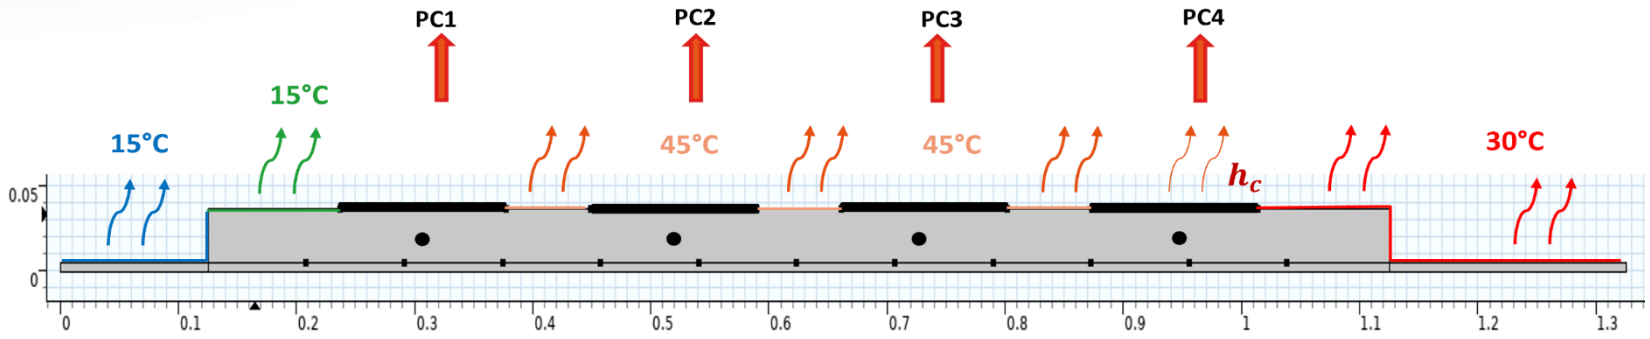
But !!

- Slight shift in temperature at the surface !
- Problem for the thick part such as Rail !
  - **Thermal contact resistance ?**

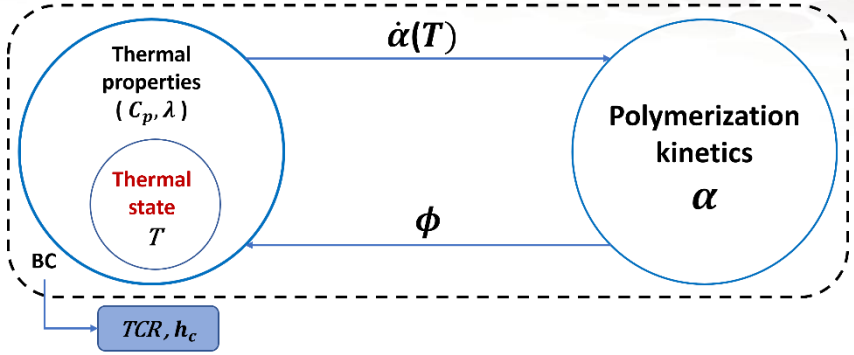


Core analysis

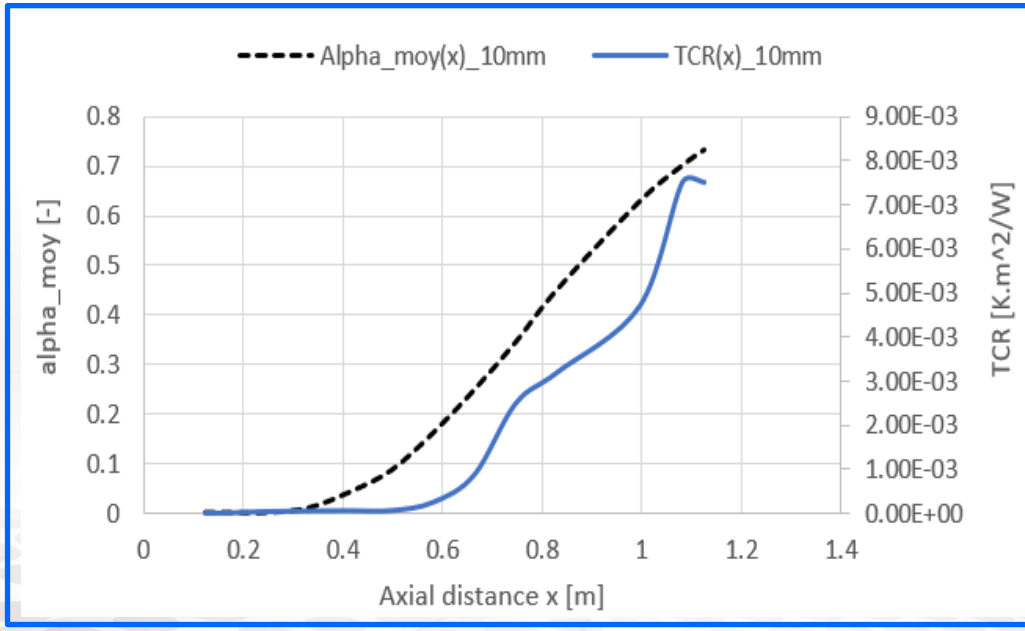


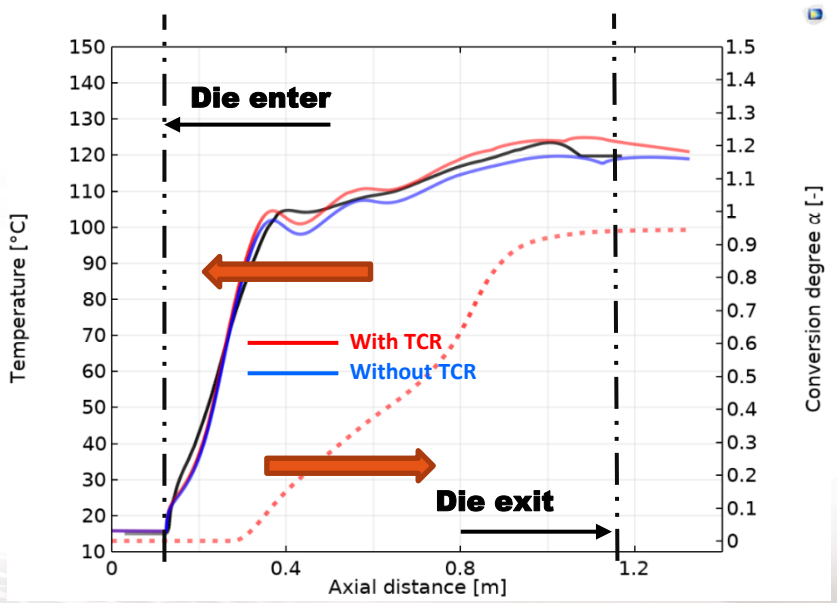


- A delay at the core is observed compared to experimental data
- **Can porosity affect thermal conductivity ?**

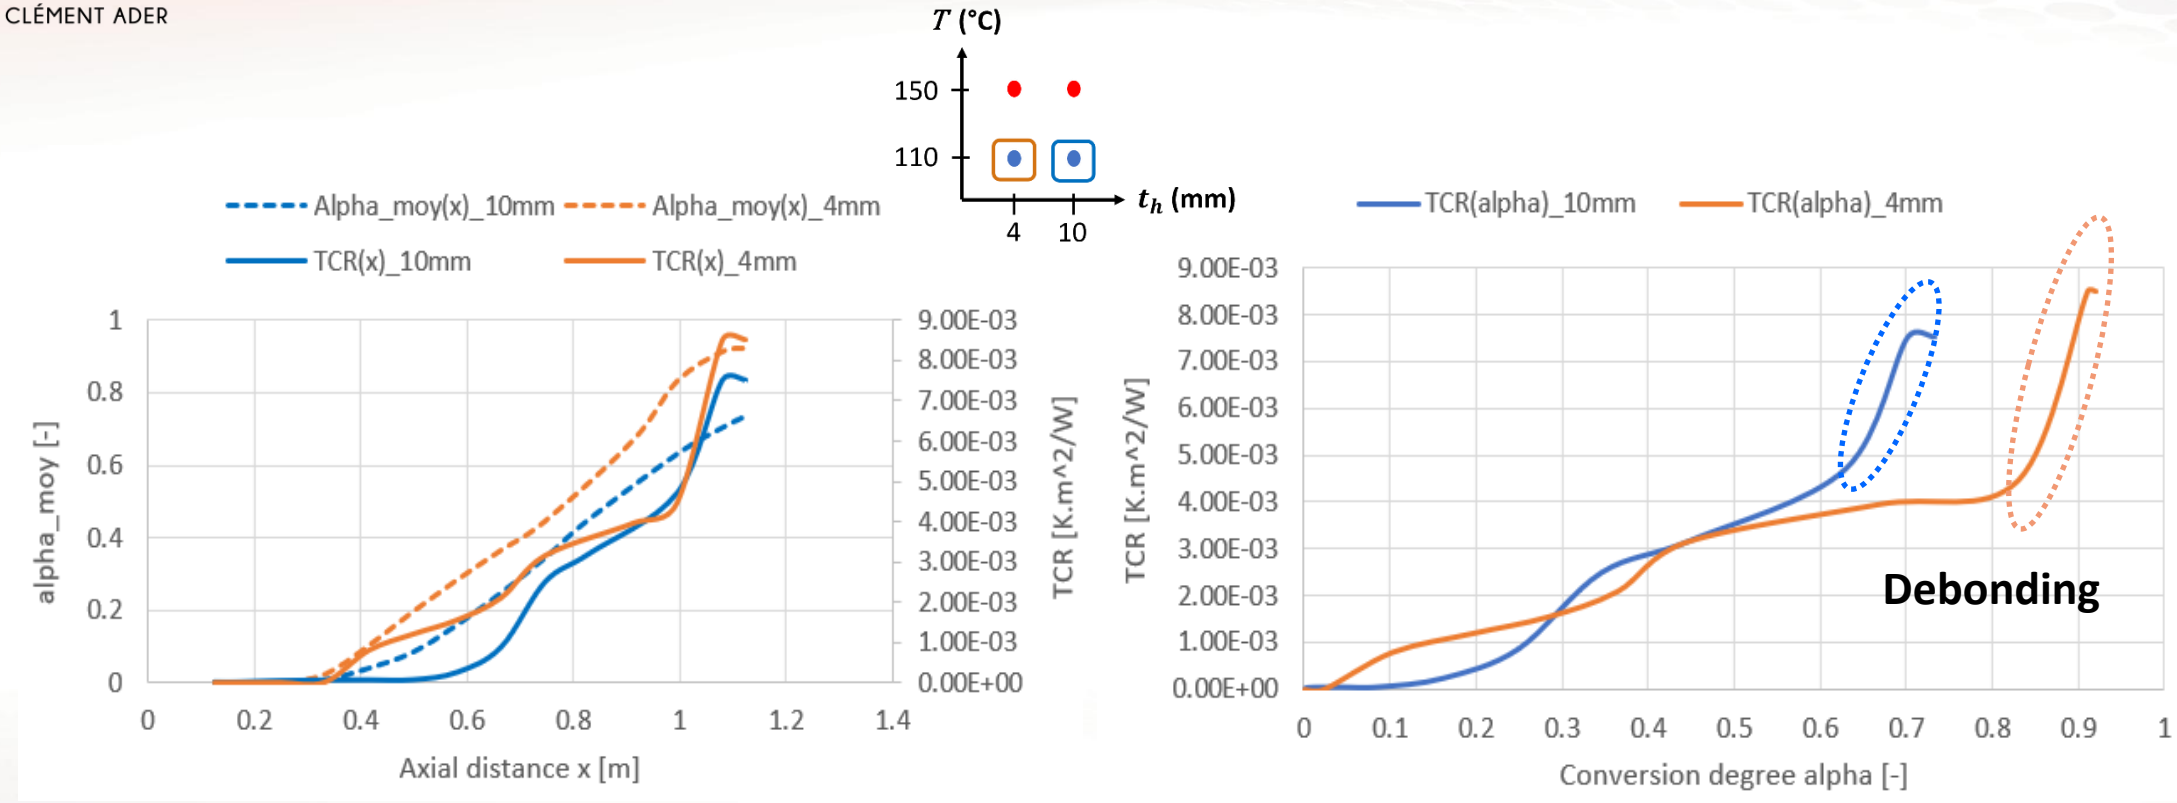


TCR ??





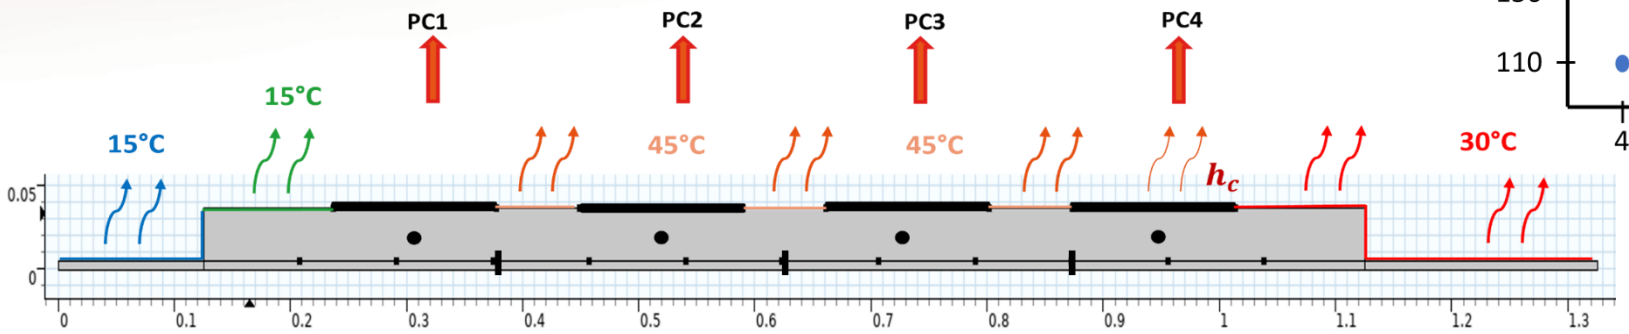
Thermal Optimization of TCR

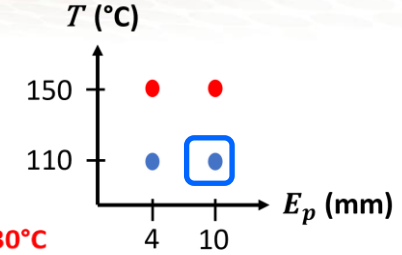


Conclusion

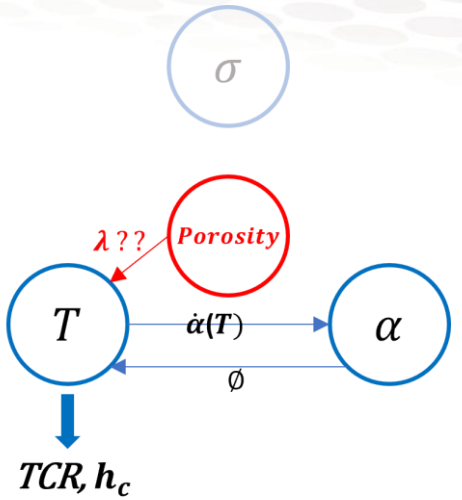
- The surface thermal profile shows better agreement with the experimental one with TCR
- Proportional relationship between TCR and the polymerization rate

Evolution of TCR as a function of conversion degree

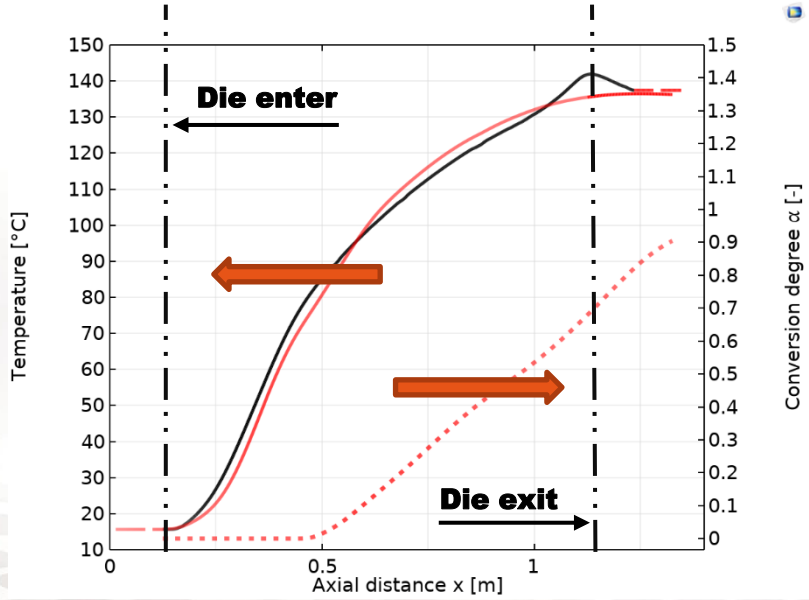




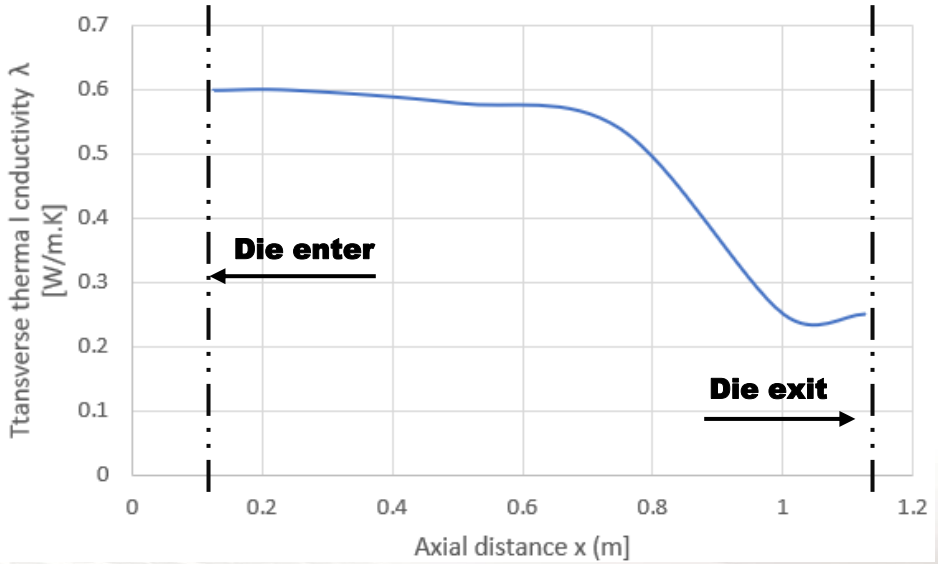
A linear relationship between shrinkage and alpha *(literature)*



$$\alpha_{moy} = \frac{\sum_i \alpha_i}{thickness}$$

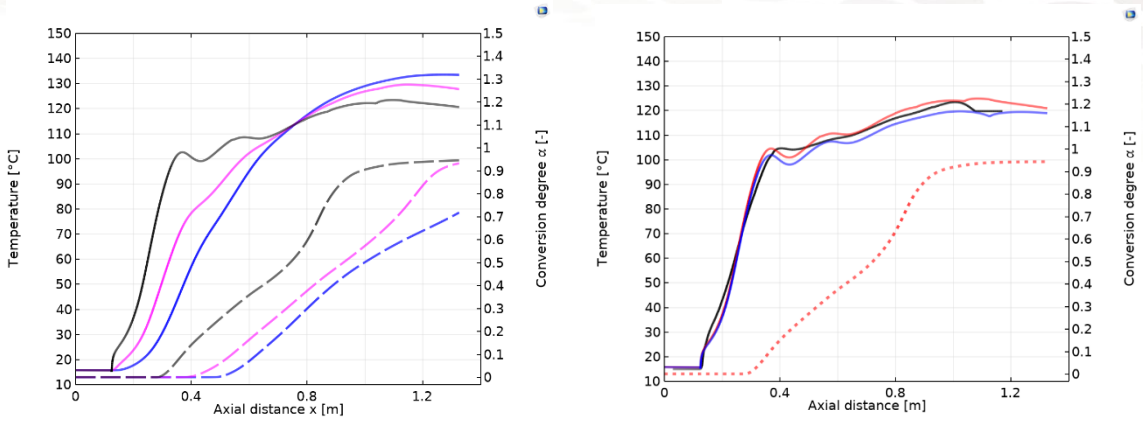


- **Relationship between TCR and chemical shrinkage ?**
- **Sudden increase in TCR due to material debonding ?? possible link with mechanical effects ?**



Optimization of transverse thermal conductivity

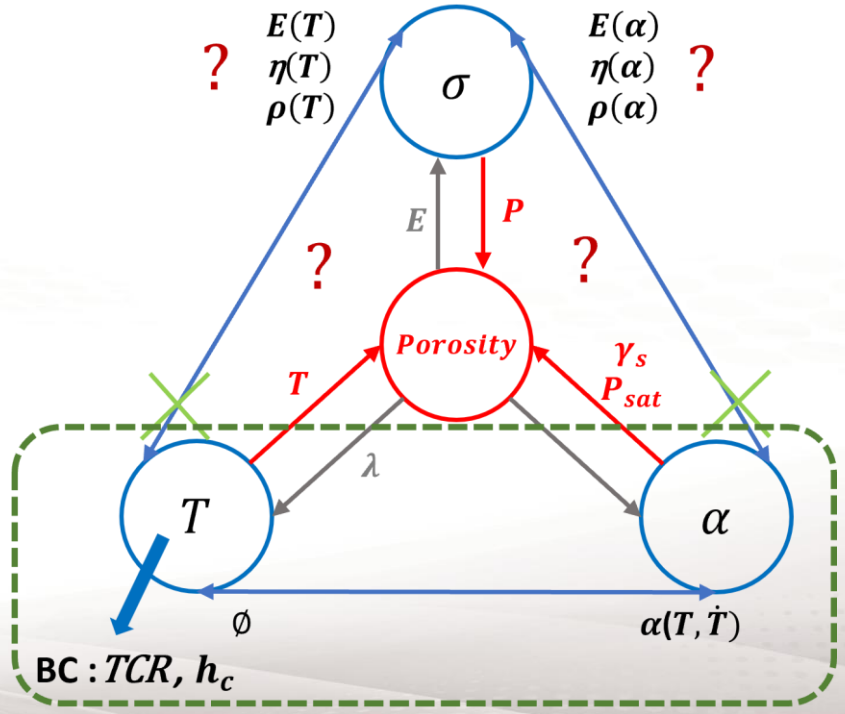
Conclusion



- **Thermal conductivity decreases along the die as the reaction progresses.**
- **Relation with porosity?**
- The central thermal profile shows better agreement with experimental one.

Conclusions and Perspectives

INSTITUT CLÉMENT ADER



Conclusion

- Implementation of thermo-kinetic coupling between the thermal behavior and the polymerization kinetics of the Elium resin.
- Comparison with experimental results shows a good phenomenological representation of exothermic effects and heat transfer.
- Representation of a possible effect of TCR and λ.

Perspectives

- **Consideration of additional physical phenomena :** TCR (α, T) as a function of chemical shrinkage, thermal conductivity as a function of porosity.
- **Development of a model**, that explains the presence of porosity at the core of the material by coupling physico-chemical phenomena with the mechanical behavior of the composite.
- Numerical thermal application in the case of the **pultruded rail**.

Keywords: Elium® thermoplastic composites, Process-induced residual stresses, CHILE model

ABSTRACT

The adoption of Elium® acrylic thermoplastic composites in wind energy and marine applications offers significant sustainability advantages through end-of-life recyclability. Process-induced residual stresses during room-temperature polymerisation remain a critical manufacturing challenge, however, with large through-thickness temperature gradients developing during processing of thick-section composites. While viscoelastic models can predict these stresses, they require extensive material characterisation that is particularly challenging for the rapidly-evolving properties of room-temperature reactive thermoplastics. This paper presents the application of the Cure Hardening Instantaneously Linear Elastic (CHILE) model to reactive thermoplastic composites, offering computational efficiency without sacrificing accuracy. The CHILE framework is implemented through coupled thermal-chemical-mechanical finite element analysis in ABAQUS, incorporating autocatalytic polymerisation kinetics, conversion-dependent material properties and a critical gelation criterion ($\alpha = 0.4$) that governs the transition from liquid to solid behaviour. Simulations of thick UD E-glass/Elium® laminates demonstrate the model's capability to predict temperature profiles, through-thickness gradients, and resulting thermal and chemical residual stress distributions. Comparative analysis of forced convection at an elevated temperature (30°C) reveals that elevated-temperature processing can reduce spring-back by 33% and peak tensile stresses by up to 65%, despite fundamentally reversing the warpage mode from U-shape to Ω-shape through altered thermal-chemical shrinkage coupling during polymerisation. These findings provide manufacturers with an efficient tool for process optimisation and establish a framework for sustainable composite manufacturing. Future work will explore adaptive temperature control strategies to minimise residual stress formation, and a quantitative comparison of stress calculations using CHILE and full viscoelastic formulations.

1 INTRODUCTION

The International Energy Agency's Renewables 2024 Outlook [1] projects that the world will install more than 5.5 TW of new renewable power between 2024 and 2030, propelled by a doubling of annual wind-capacity additions. This will raise the amount of electricity from clean sources to about 46% of global electricity by the decade's end. Wind and marine renewable energy systems are positioned to play a critical role in this transition, requiring robust infrastructure capable of withstanding harsh operational environments for 20-25 year service lives [2]. The sustainability of these technologies remains limited, however, by the predominance of thermoset composite materials, which are difficult to recycle at end-of-life and contribute to growing composite waste streams, estimated at 62,000 tonnes annually, predominantly arising from wind turbines blades [3].

Elium® resin, a liquid methyl methacrylate infusible thermoplastic, offers a transformative solution by enabling room-temperature processing with the recyclability advantages of thermoplastics [4]. This resin system has been successfully demonstrated in full-scale renewable energy applications, including the TIGER project's 18-meter tidal turbine blades and the ZEBRA project's 62-meter recyclable wind turbine blade manufactured by Arkema and LM Wind Power [5], seen in Figure 1. These demonstrators have validated Elium®'s mechanical performance while highlighting manufacturing challenges that must be addressed for widespread adoption.

Figure 1 The world's then-largest recyclable Elium® wind blade, constructed as part of the ZEBRA project in 2022 – it has since been surpassed in length by a 77-metre blade manufactured by the same consortium [5].

Wind and tidal-turbine blades are designed to survive up to 10^8–10^9 variable-amplitude fatigue cycles over a 20-year life (IEC 61400-5), and recent full-scale tests at the University of Edinburgh's FastBlade facility confirm that tidal energy blades experience highly complex cyclic loads, enduring an entire lifetime's loading when exercised at 18–20 Hz for an equivalent 20 years [6]. Process-induced residual stresses significantly impact fatigue performance by superimposing on service loads, essentially acting as an internal mean load that accelerates fatigue damage in composites [7]. On wind-blade-grade glass/epoxy laminates, lowering residual stresses by 50 % triples the cycles to failure, while a 75% reduction extends life by roughly an order of magnitude, confirming residual-stress magnitude as a dominant lever in composite fatigue durability [8].

In reactive thermoplastic systems like Elium®, residual stresses arise from two coupled mechanisms during polymerisation. Chemical shrinkage, which in the case of Elium® is reported to result in a 13% volumetric reduction, according to Bamane et al. [9], occurs as polymer chains form and densify. Simultaneously, the exothermic polymerisation reaction generates temperature rises of up to 100°C in thick sections. This leads to thermal stresses due to global temperature gradients, as well as thermal expansion coefficient mismatches between the matrix and fibre phases [10]. The interaction between these mechanisms, combined with the material's transition from liquid to solid state during polymerisation, creates complex stress fields that vary significantly through component thickness.

Skin-core residual-stress and temperature gradients are a hallmark of thick composite laminates. Bogetti and Gillespie showed that the complex stress gradients which arise are sensitive to various factors including resin properties, laminate thickness, and processing history [13]. They showed that in cases where outside-to-inside curing arises, the laminate skins can be locked into compression while the solidifying core is put in tension; with the resulting stresses being sufficient to induce transverse cracking in some cases. In terms of wind and tidal turbine blades, Maguire et al. simulated the oven-curing of thick blade sections and showed that the use of low-exotherm resins and modified processing cycles can reduce thermal and cure gradients during critical periods (e.g. during gelation) [11]. In Elium® parts the exotherm peaks at the mid-plane [12], so polymerisation typically proceeds inside-out; the core

contracts first and is later restrained by the belatedly polymerised skins, giving the opposite stress sign (tensile centre, compressive outer plies). This effect creates a need for tailored polymerisation and temperature profiles to avoid warpage and residual-stress build-up.

Three primary modelling approaches exist for predicting process-induced residual stresses. Linear elastic models, while computationally efficient, cannot capture the evolving material state during polymerisation. Viscoelastic models provide the highest fidelity by tracking the complete stress history through polymerisation, as demonstrated in the seminal works of Bogetti and Gillespie [13] and White and Hahn [14]. However, the Cure Hardening Instantaneously Linear Elastic (CHILE) approach, introduced by Johnston et al. [15], has become widely adopted in process modelling of composites as it offers a compromise by assuming instantaneously elastic behaviour only after gelation while maintaining computational efficiency. While CHILE models typically overestimate residual stresses because they neglect matrix stress-relaxation [16], they provide a conservative, worst-case assessment that serves as an acceptable first-order approximation of material behaviour.

The application of viscoelastic models to Elium® composites faces unique challenges. Unlike high-temperature epoxy systems where reactions can be arrested by cooling, Elium® polymerises at room temperature, making it impossible to "freeze" intermediate conversion states for property characterisation. The rapid evolution from low-viscosity liquid (μ = 0.1 Pa·s) to solid polymer (E = 3.2 GPa) occurs within hours, requiring extensive time-dependent testing that is both technically challenging and computationally intensive to implement. With respect to the latter, full viscoelastic analyses typically require 20-50 times more computational resources than equivalent CHILE/pseudo-viscoelastic simulations, while offering moderate accuracy improvements for final residual stress predictions ([17], [18]). Nonetheless, no such comparative studies have been produced yet for Elium® room-temperature processing resins in particular, as of the current time of writing of this paper.

This paper presents the implementation of a CHILE framework specifically adapted for reactive thermoplastic composites, as a step towards addressing the critical need for efficient residual stress management in sustainable composite manufacturing. By capturing the essential physics of polymerisation-induced stresses while maintaining computational tractability, this approach enables practical process optimisation for next-generation recyclable composite structures.

2 CHILE MODEL FORMULATION AND THEORETICAL FRAMEWORK

The Cure Hardening Instantaneously Linear Elastic (CHILE) model offers a computationally efficient framework for predicting process-induced residual stresses while capturing the essential physics of polymerisation. The key distinction from viscoelastic models is that CHILE assumes the material responds purely elastically to each strain increment after gelation, using only the instantaneous modulus at the current conversion state. In contrast, viscoelastic models account for the entire loading history through hereditary integrals, where stresses depend on when strains were applied relative to the evolving relaxation modulus. The CHILE framework decomposes the total strain increment into three components:

$$d\varepsilon_{ij}^{\text{total}} = d\varepsilon_{ij}^{\text{elastic}} + d\varepsilon_{ij}^{\text{thermal}} + d\varepsilon_{ij}^{\text{chemical}} \quad (1)$$

where the thermal and chemical strains evolve continuously throughout polymerisation according to:

$$d\varepsilon^{\text{thermal}} = \alpha_{\text{CTE}}(T, \alpha) \cdot dT \quad (2)$$

$$d\varepsilon^{\text{chemical}} = \beta_{\text{CS}} \cdot d\alpha \quad (3)$$

Here, α represents the degree of conversion ($0 \leq \alpha \leq 1$), α_{CTE} is the coefficient of thermal expansion, and β_{CS} is the chemical shrinkage coefficient. The polymerisation kinetics follow an autocatalytic model with diffusion control:

$$\frac{d\alpha}{dt} = (k_1 + k_2\alpha^m)(1-\alpha)^n \cdot f_d(\alpha, T) \tag{4}$$

where k_1 and k_2 are temperature-dependent rate constants following Arrhenius relationships, m and n are reaction exponents, and $f_d(\alpha, T)$ represents diffusion limitations at high conversion, and is dependent on the degree of conversion and the temperature.

A critical aspect of CHILE residual stress calculation models is the gelation criterion. As liquid resin cannot sustain mechanical stress, the material accommodates all thermal and chemical strains through viscous flow prior to gelation. After the physical-gel point, these accumulated strains instantaneously generate elastic stresses based on the evolving stiffness tensor $C_{ijkl}(\alpha)$. The stiffness matrix is constructed using a given fibre-volume fraction and micromechanics, based on the evolving tensile modulus E (Figure 2), shear modulus G and Poisson's ratio ν of the resin. In the case of Elium® 191 XO/SA, where $\alpha_{\mathrm{gel}} \approx 0.4$ [9], the following holds true:

$$\sigma_{ij} = \begin{cases} 0 & \text{if } \alpha < 0.4 \\ C_{ijkl}(\alpha) \cdot \varepsilon_{ij}^{\mathrm{elastic}} & \text{if } \alpha \geq 0.4 \end{cases} \tag{5}$$

The CHILE model assumes that: (i) the material behaves as a nearly incompressible liquid before gelation, (ii) the transition to solid behaviour occurs instantaneously at the gel point (an approximation of this assumption was used for numerical stability), (iii) smooth transition to post-gelation behaviour is linear elastic with polymerisation-dependent properties, and (iv) no stress relaxation occurs after gelation. These assumptions, while simplifying the complex viscoelastic behaviour of polymerising systems, capture the dominant mechanisms of residual stress formation.

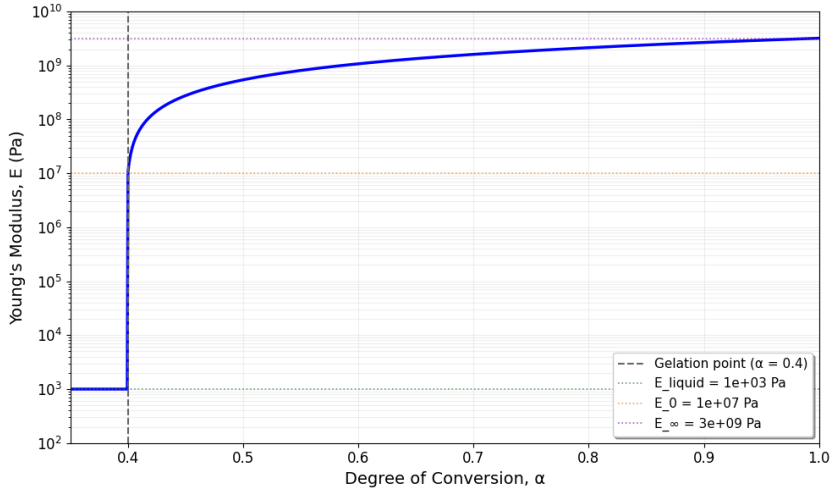

Figure 2 Evolution of resin's Young's Modulus in the CHILE formulation

3 NUMERICAL IMPLEMENTATION AND MATERIAL MODELLING

3.1 ABAQUS/Standard FEA simulation

The coupled thermal-chemical-mechanical analysis was implemented in ABAQUS/Standard using user-defined subroutines to capture the thermo-chemo-mechanical behaviour of Elium® polymerisation. The finite element model employs C3D8T coupled temperature-displacement elements, which provide simultaneous solution of heat transfer and mechanical equilibrium equations essential for capturing

process-induced residual stresses. The laminate geometry (200 mm by 200 mm, with an equivalent thickness of 60 plies, or 52.95 mm) was discretised with a structured mesh refined through the thickness. The mesh consists of over 70,000 nodes and 65,000 elements. The mesh was determined to be sufficient in calculating accurate residual stress and deformation results for this simulation. A two-step approach was used to reflect the polymerisation/consolidation phase, and the instantaneous tool-removal stage. Step 1 simulated the 24-hour polymerisation using coupled temperature-displacement analysis with automatic time incrementation (initial = 100s, minimum = 0.05s, maximum = 200s). The maximum temperature change per increment was limited to 2°C to ensure accurate capture of the exothermic peak. Step 2 modelled the tool removal as a static step, releasing the substrate constraint to reveal final part distortion.

The bottom surface (substrate interface) was constrained in the through-thickness z-direction to prevent rigid body motion while allowing in-plane deformation during the consolidation phase on a one-sided tool. Three reference nodes were constrained to prevent numerical singularities: a central node fixed in all directions, a second node constrained in x and z, and a third node constrained only in z-direction. These three nodes remain active in the second step of tool removal to permit free warpage of the laminate while still suppressing rigid-body modes, thereby capturing the true redistribution of residual stresses without numerical drift. Thermal boundary conditions specified natural convective heat transfer ($h = 10\ \mathrm{W/m^2 \cdot K}$) on the top surface with remaining surfaces insulated, representing typical open-mould processing. At this point, no thermal resistances have been implemented to represent the thermal effect of the tool (heat sink), in order to produce a first-order assessment of residual stress formation.

Four main ABAQUS user subroutines implemented the CHILE framework. USDFLD solved the autocatalytic kinetics using fourth-order Runge-Kutta integration, updating the degree of conversion field variable. HETVAL calculated internal heat generation from the polymerisation rate and heat of reaction. UEXPAN defined thermal and chemical strain increments based on composite micromechanics. UMAT implemented the gelation-dependent stiffness matrix, transitioning from liquid (E = 1 kPa) to the commencement of solid-like behaviour at α = 0.40. A flowchart overview of the model can be found in Figure 3.

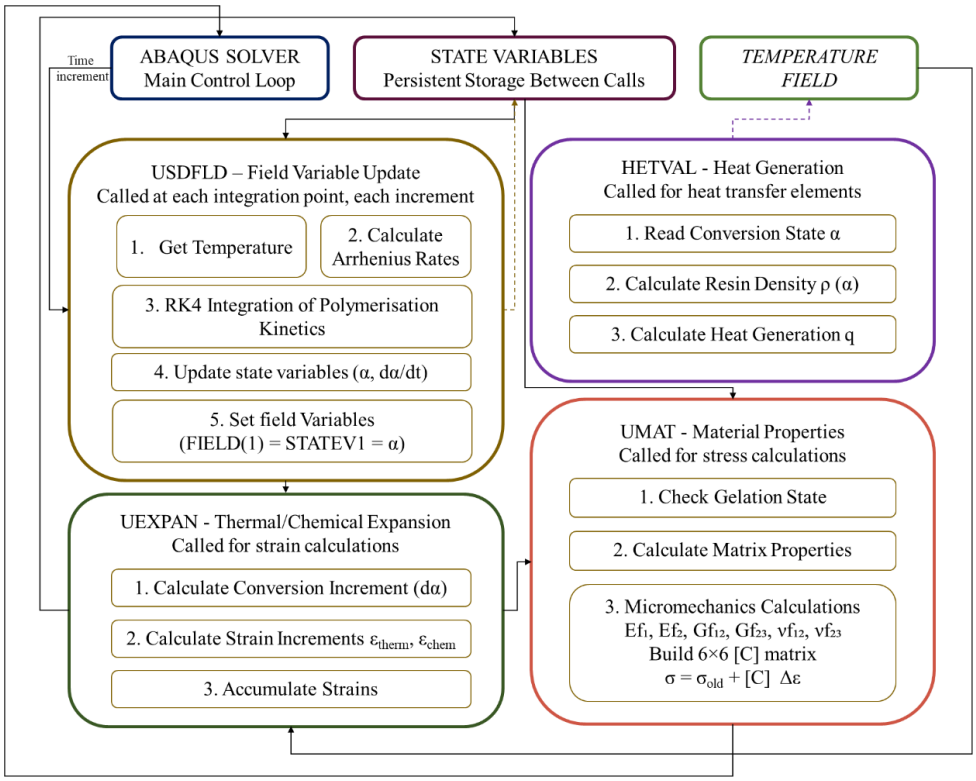

Figure 3 CHILE residual stress numerical scheme flowchart – key interactions.

Numerical stability was ensured through multiple strategies, including clamping degree of conversion between 0 and 0.999999, implementing overflow protection in exponential calculations, and checking for near-singular stiffness matrices.

3.2 Elium® 191 XO/SA Material Model

Elium® material properties were derived from resin molecular dynamics simulations by Bamane et al. [9]. The autocatalytic polymerisation kinetics were derived from best-fit DSC curves and incorporate both chemical reaction and diffusion limitations, seen in Table 1.

Table 1 Polymerisation kinetics.

Property	Symbol	Value	Unit
Fibre volume fraction	V_f	0.52	–
Heat of reaction	ΔH	253	kJ/kg
Pre-exponential factor 1	A_1	4.18	1/s
Pre-exponential factor 2	A_2	2.42×10^5	1/s
Activation energy 1	E_1	26.5	kJ/mol
Activation energy 2	E_2	41.8	kJ/mol
Autocatalytic exponent	m	2.86	–
Diffusion exponent	n	2.02	–
Gelation point	α_{gel}	0.40	–

Composite properties were calculated using micromechanics, with equivalent chemical shrinkage of -0.19% longitudinal strain and -0.37% transverse strain, reflecting fibre constraint effects, and equivalent coefficients of thermal expansion of 6.1 × 10^{-6} K^{-1} in the fibre direction and 25 × 10^{-6} K^{-1} in both transverse directions.

4 NUMERICAL RESULTS

4.1 Thick Laminate Case Study 1: Unidirectional Laminate

The through-thickness thermal profile of the laminate (Figure 4) shows lower temperature change ΔT from ambient (20°C) at the top surface, which is closest to the convective boundary. On the contrary, the bottom of the laminate reaches the highest temperature from ambient (82°C), as it is located furthest away from the convective boundary, resulting in through-thickness thermal gradients of approximately 30°C.

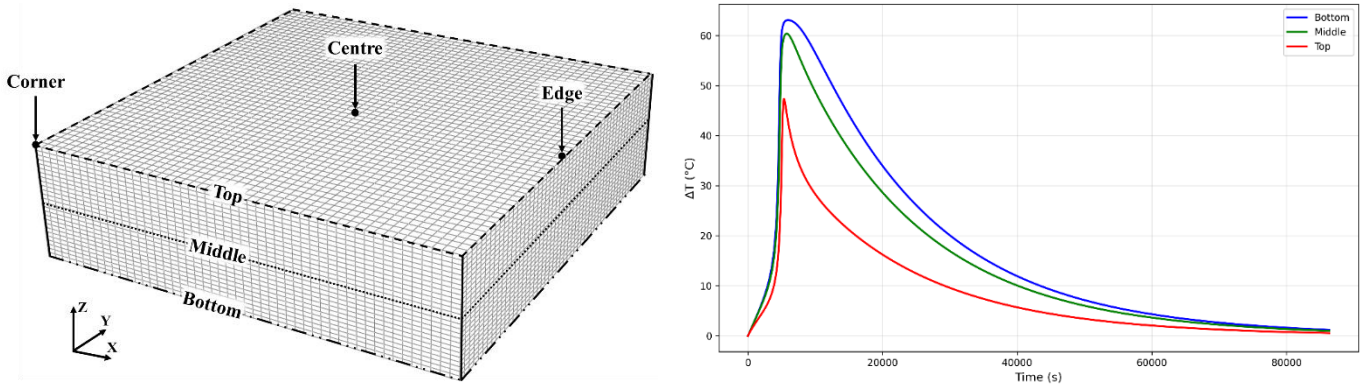

Figure 4 Left: Schematic of mesh and laminate location definitions. Right: Relative temperature increase from ambient 20°C, at the centre of a 52.95mm GF/Elium® laminate.

Similarly, the degrees of conversion were tracked, with a slight lag in the polymerisation of the top of the laminate being observed as a result of the convective heat loss boundary condition (Figure 5).

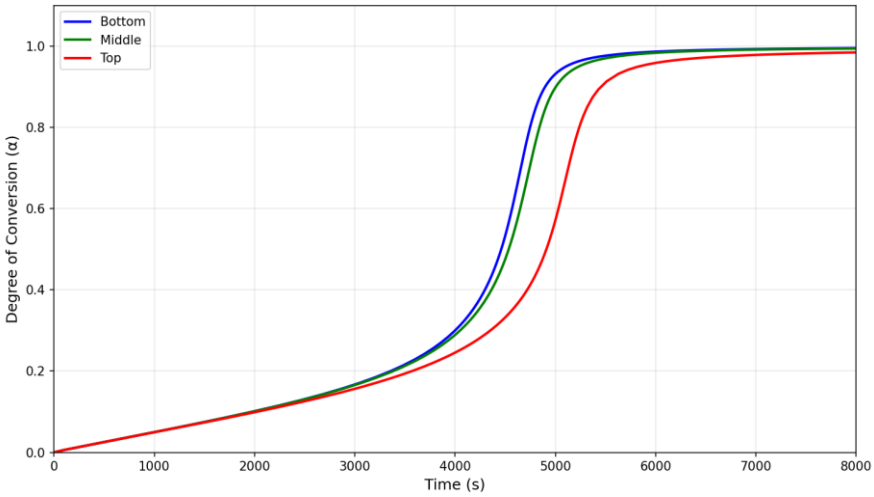

Figure 5 Through-thickness degrees of conversion at the centre of the laminate.

Following the removal of the tool, the unidirectional laminate experiences cylindrical bending as a result of the thermal and chemical stresses that developed during polymerisation. Displacement results are shown in metres in Figure 6. Owing to its omission of viscoelastic relaxation, the CHILE formulation would typically overpredict the deformation observed experimentally.

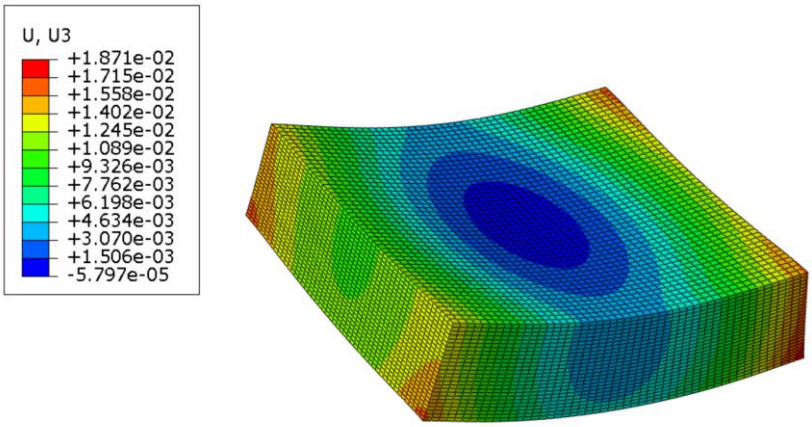

Figure 6 Cylindrical warpage of the 60-ply unidirectional GF/Elium® unidirectional laminate.

Chemical and thermal strains were also tracked (Figure 7), with results shown for the 1-direction - along the fibres. The maximum chemical strain (-0.00191) significantly dominates the maximum thermal strain (0.00038), showing that residual stress formation in the case of Elium® is a phenomenon largely driven by chemical shrinkage, and additionally due to the low temperature increase of the laminate from ambient (approximately 60°C relative temperature increase).

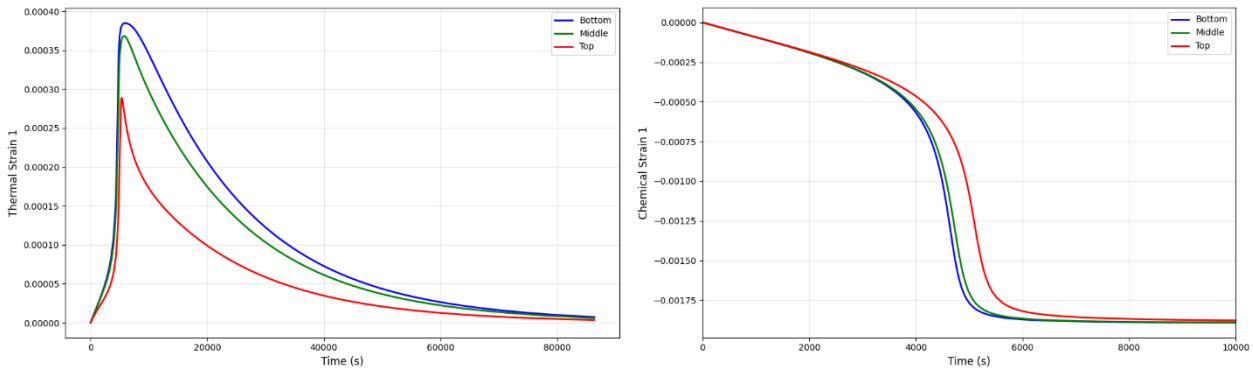

Figure 7 Thermal (left) and chemical (right) Strains during consolidation stage.

While strains occur from the beginning of the polymerisation, stresses do not become locked-in prior to gelation. Once the gelation condition is triggered (α = 0.4), chemical strains initially cause compression and subsequently the rate of thermal expansion surpasses the rate of chemical shrinkage, resulting in a bounce-back effect. Subsequently, as the exothermic reaction accelerates, and the rate of conversion increases, therefore resulting in a rapid increase of chemical stress. Afterwards, the laminate enters a cool-down phase, during which chemical stresses remain compressive, but in addition, thermal stresses become compressive as well ($\Delta T < 0$).

The fibre-direction stress (S11) evolution (Figure 8) during the polymerisation process exhibits significant spatial variation and magnitude differences across the composite laminate. At the geometric centre (left), substantial residual stresses develop, with the top layer reaching approximately 12.5 MPa of tensile stress, and the bottom layer developing compressive stresses of -5 MPa, while the middle layer remains at a much lower compressive stress state. This through-thickness gradient indicates significant bending moments induced by polymerisation shrinkage and thermal effects, and specifically the sequential polymerisation process: the middle and bottom layers polymerise and shrink first, then act as rigid constraints preventing the top layer from freely shrinking during its later polymerisation, forcing it into tension while the bottom layer experiences compression from the tool constraint. As seen later in section 4.3, upon tool removal, this asymmetric stress distribution creates a bending moment that causes the part to warp and the stress states to invert, with the previously compressed bottom surface transitioning to tension and the top surface stress transitioning to compression.

The corner region (right) demonstrates more complex transient behaviour, with the middle and bottom layers initially developing tensile stresses up to 0.12 MPa, followed by an asymptotic stress equilibrium toward 0.05MPa, while the top layer momentarily oscillates between tensile and compressive stresses before remaining at a very small compressive state throughout the end of consolidation. The marked difference in stress magnitudes between centre (±2.5-12.5 MPa) and corner (±0.12 MPa) locations reveals that the centre experiences substantially higher residual stresses, likely due to greater constraint from surrounding material, whereas the corner's proximity to free edges allows for stress relief through deformation.

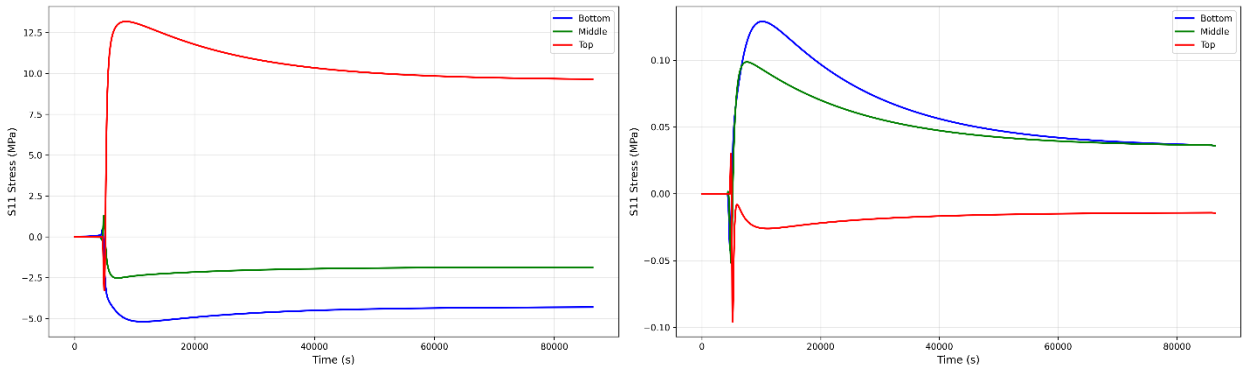

Figure 8 S11 stresses during consolidation stage at the centre (left) and a corner (right) of the laminate - stresses remain at zero pre-gelation as prescribed.

4.2 Thick Laminate Case Study 2: Elevated Temperature

To model the effect of oven heating at 30°C, an additional subroutine was employed to impose a forced convection to the top surface during the temperature rise in the centre of the laminate due to the exotherm. The aim was to gain further insight into residual stress mitigation strategies by reducing the skin-core effect present in Elium® laminates, where the core polymerises first due to heat not dissipating as effectively as the surfaces exposed to convection, therefore initiating premature shrinkage of the core earlier than the edges. The main differences implemented in the simulation are (a) longer consolidation time at room temperature following the forced convection phase, to allow for full cool-down prior to tool removal and (b) a supplementary FILM subroutine whereby the laminate top surface is exposed to forced convection condition with $h = 30\ \mathrm{W/m^2 \cdot K}$ at a pre-heated oven with a temperature of 30°C.

This heated condition is implemented until the temperature at centre of the laminate peaks (to promote concurrent polymerisation initiation at the middle and top of the laminate) and instantaneously removed and replaced by the natural convection at ambient temperature previously discussed.

The implementation of elevated temperature processing with controlled forced convection demonstrated significant mitigation of the skin-core thermal gradient characteristic of thick GF/Elium® laminate polymerisation, as seen in Figure 9. Application of 30°C forced convection until peak exotherm, followed by natural convection cooling, essentially broadens (resulting in a slight bimodality due to lagged heat transfer from inner-layer exotherm) and lowers the temperature profile at the top of the laminate (top). The result is higher through-thickness temperature gradients compare to the ambient case study. Nevertheless, the modified thermal profile promoted synchronised polymerisation initiation across the laminate thickness (bottom left), significantly reducing the temporal conversion gradient observed under ambient conditions (bottom right).

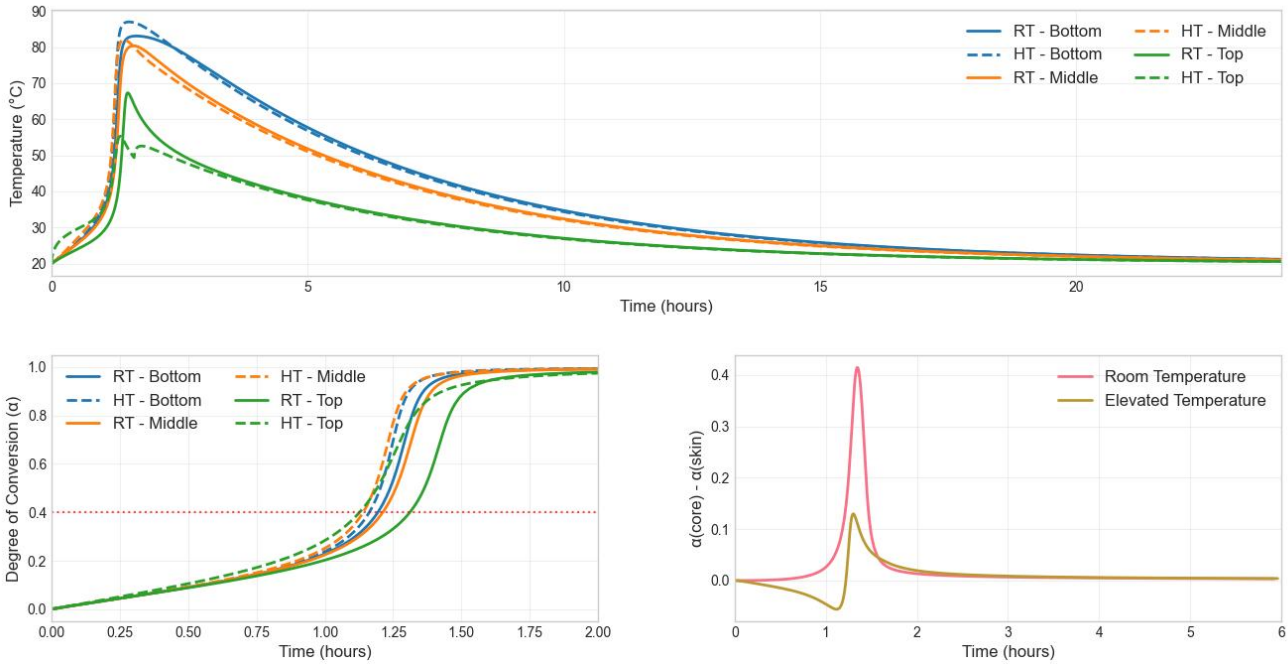

Figure 9 Comparison of ambient and elevated temperature processing case studies in terms of (top) temperature, (bottom left) degree of conversion, and (bottom right) skin-core temporal difference in degree of conversion.

4.3 Comparison of Case Studies: Post Tool-Removal

Following tool removal in both cases, the addition of forced convection fundamentally altered the residual stress state, manifesting as an inversion of the warpage mode from concave (U-shaped) to convex (Ω-shaped) curvature. The individual through-thickness stress states can be found in Figure 10. In absolute terms, there are reductions in final stresses in σ_{11}, σ_{22}, and σ_{23}, while σ_{33} and σ_{13} have remained essentially constant. A comparative summary of the worst-cases across all locations (centre and edges) of key parameters can be found in Table 2.

Investigating the edge effects, it becomes clear that there is significantly higher in-plane difference in the elevated temperature case, where the edge-to-centre stress ratio surpasses 500 for τ_{23}, as seen in Figure 11. This extreme stress concentration at edges in the elevated temperature case likely results from the more severe thermal gradients creating differential shrinkage patterns that are accommodated through interlaminar shear at the free boundaries, where the absence of constraint allows stress singularities to develop more prominently than in the room temperature case.

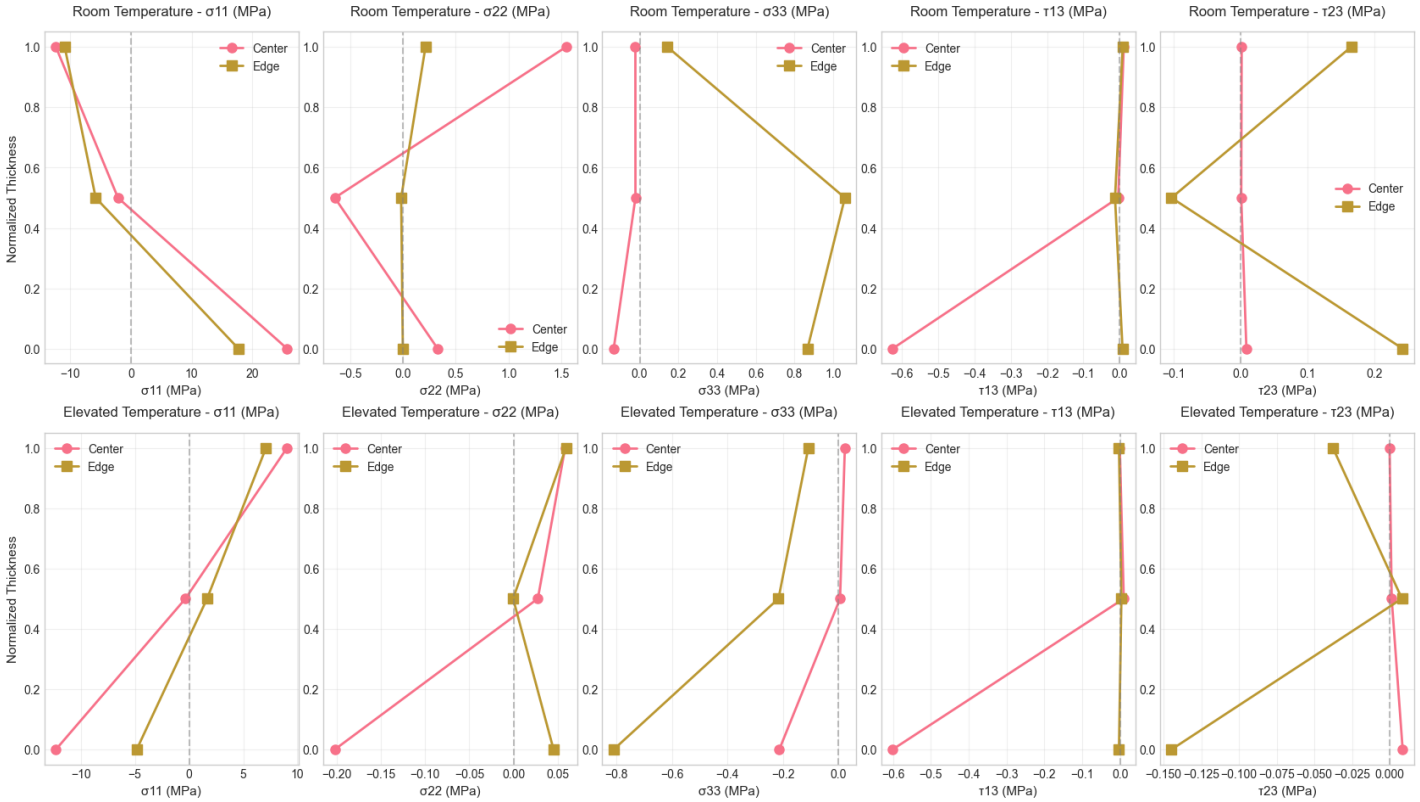

Figure 10 Through-thickness worst-cases stress states in ambient (top row) and forced convection (bottom row) cases.

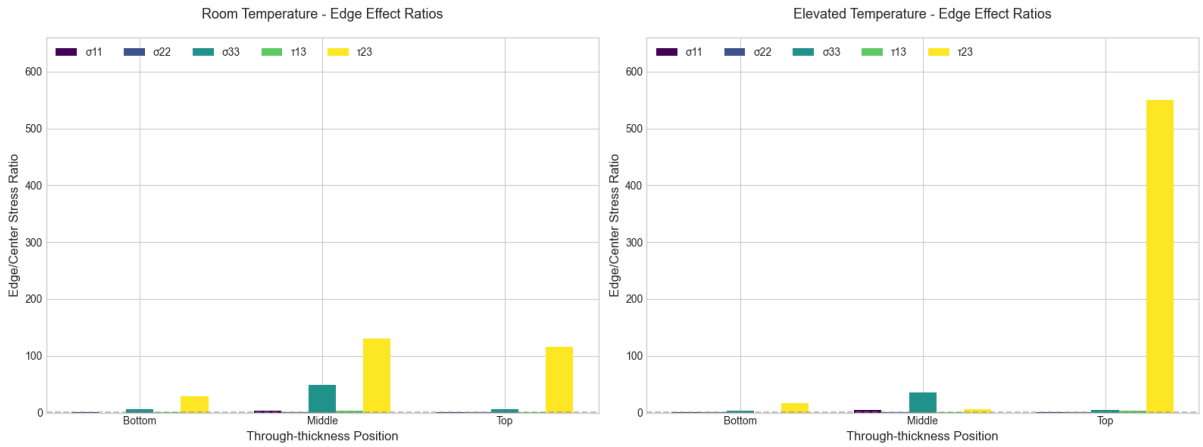

Figure 11 Summary of edge/centre stress ratios for room temperature (left) and elevated temperature (right) cases.

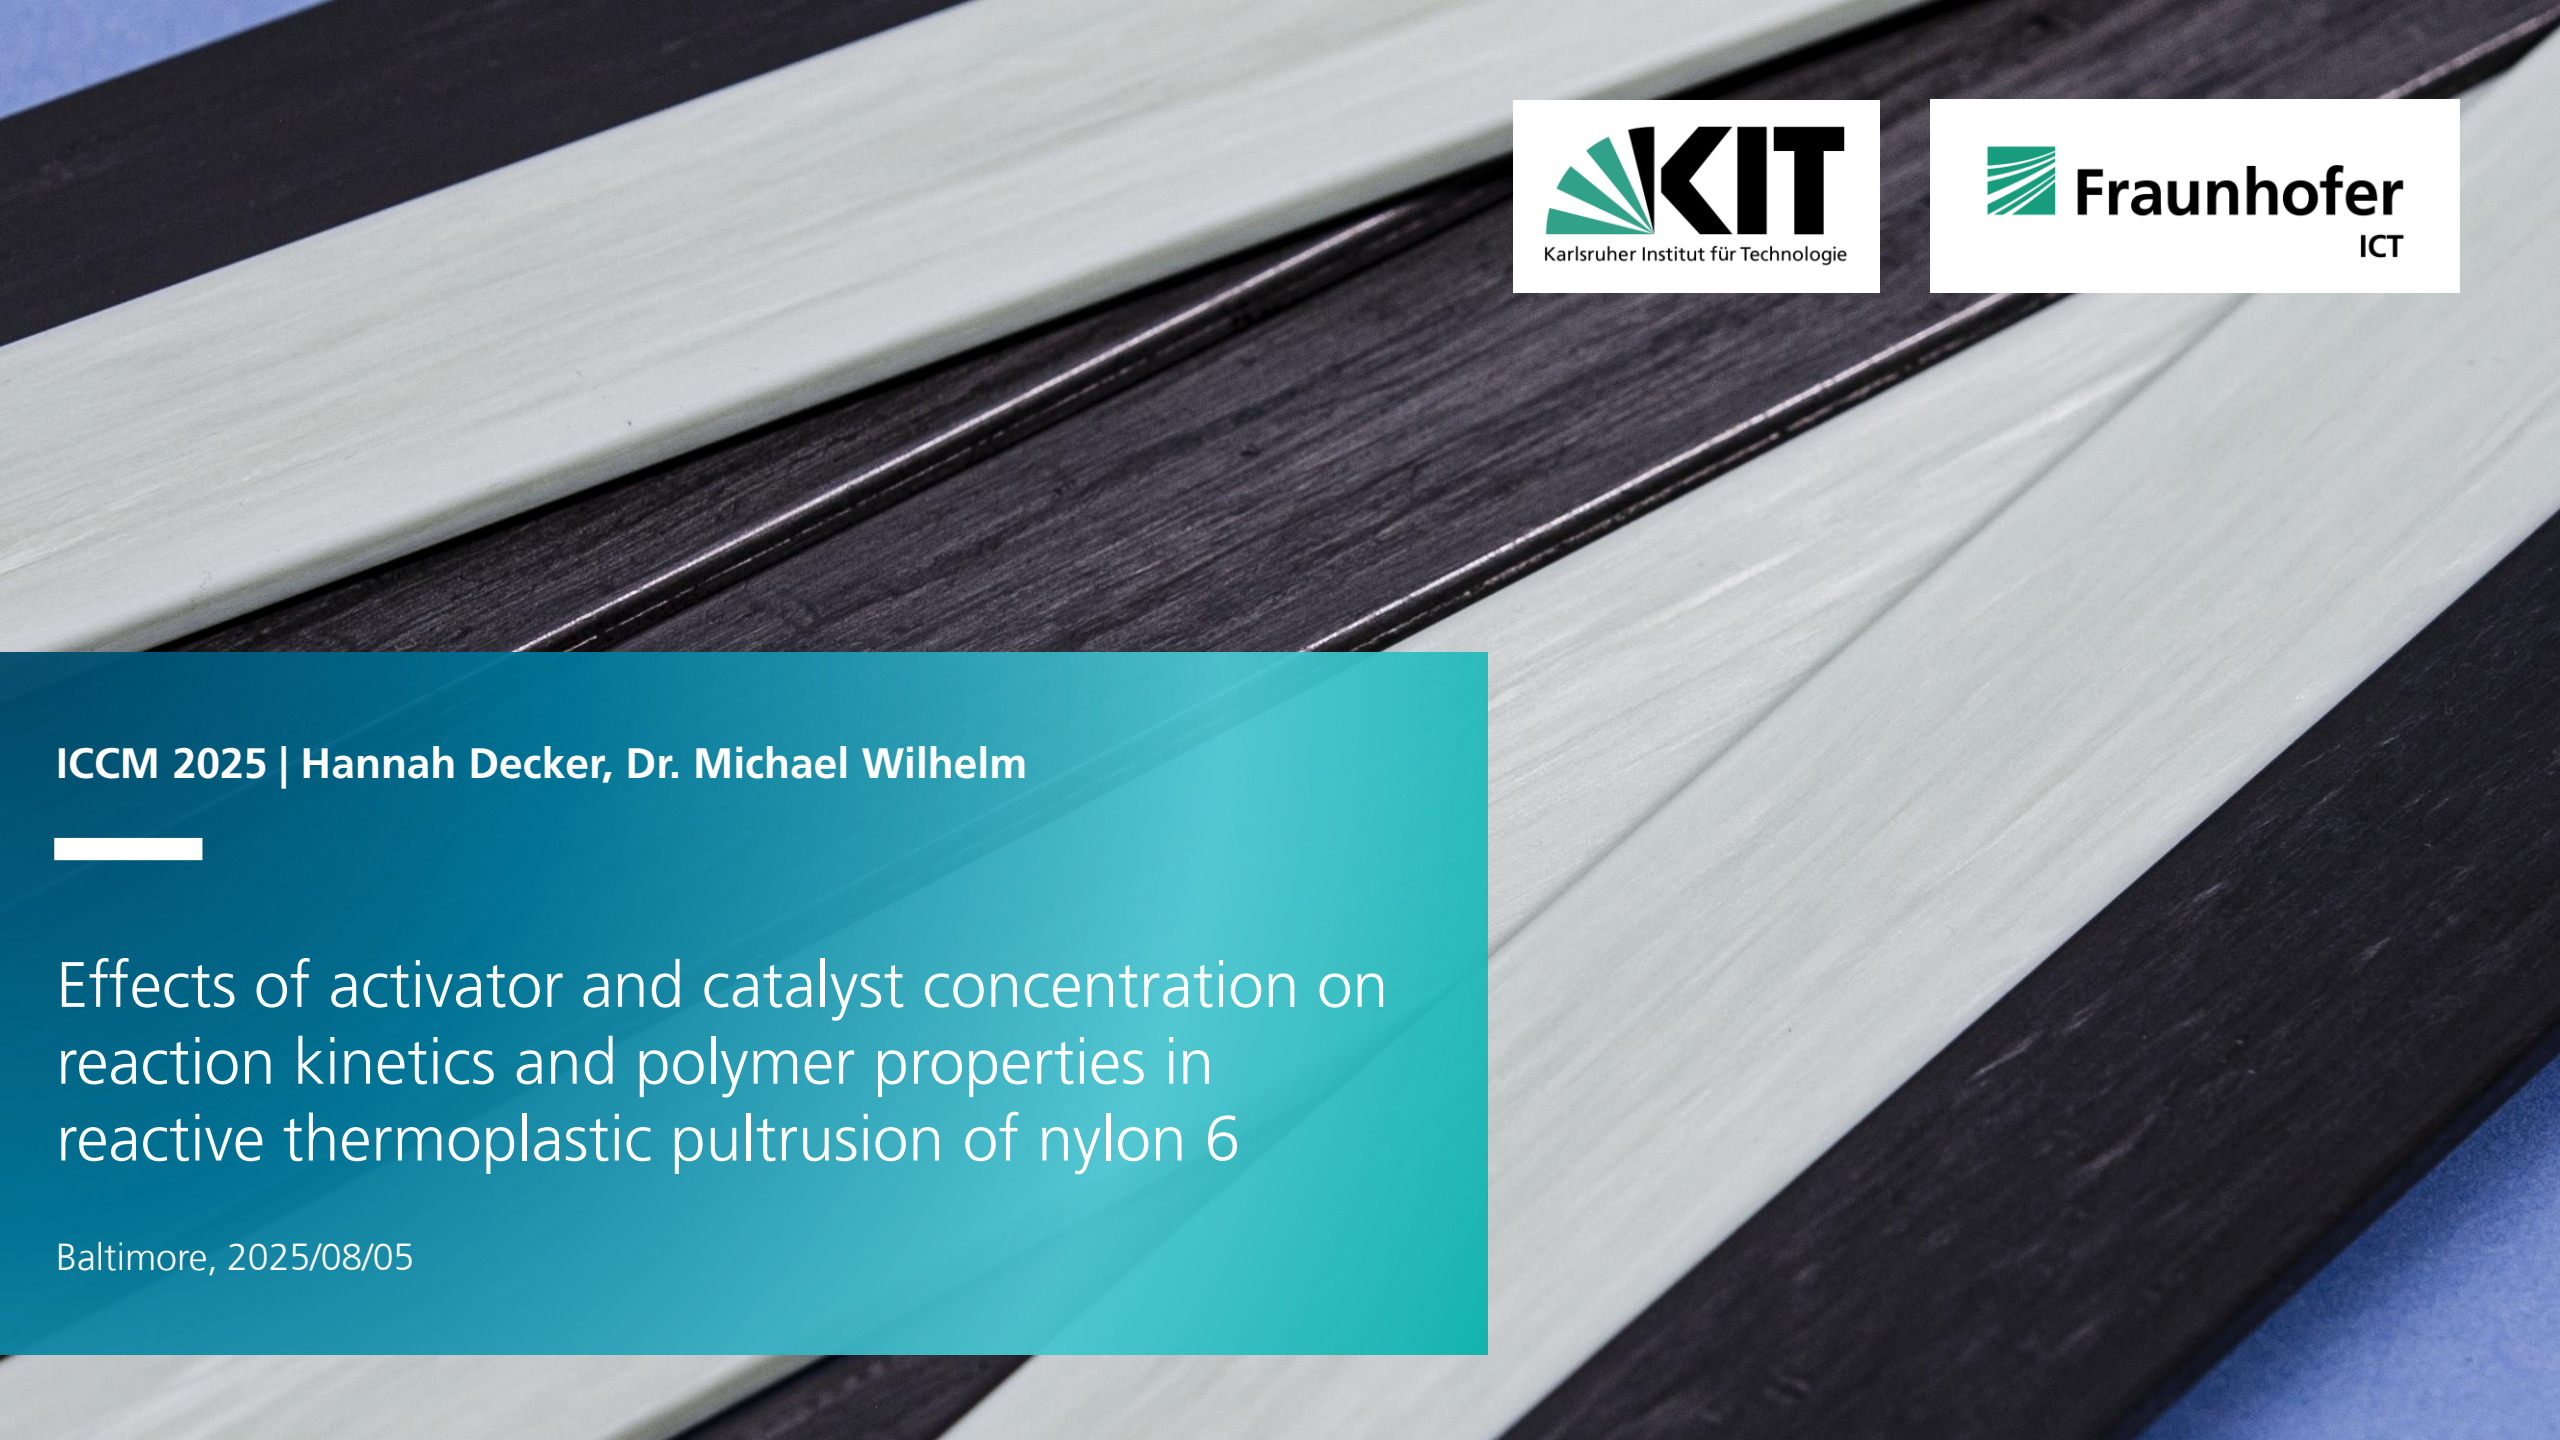
As seen in Table 2, the elevated temperature processing strategy achieved a 33% reduction in spring-back displacement (13.4 mm to 9.0 mm) despite generating 4.7% higher peak temperatures during the exothermic polymerisation of the thick UD Elium® laminate. Additionally, the fibre-direction stress (σ11) range (maximum tensile stress minus maximum compressive stress) reduced from 38.2 MPa to 21.3 MPa with a 65% reduction in peak tension (25.8MPa reduced to 9MPa), and the through-thickness normal stress (σ33) shifted from predominantly tensile (+1.06 MPa) to compressive (-0.81 MPa). The transverse stress (σ22) demonstrated a significant reduction, with the stress range decreasing from 2.1 MPa (room temperature) to 0.3 MPa (elevated temperature), representing an 86% reduction driven primarily by a 93% decrease in peak tensile stress (1.5 MPa to 0.1 MPa) while compressive stresses remained minimal in both cases. The interlaminar shear stress τ23 showed a 40% reduction, indicating improved mitigation of edge effects, while maintaining similar compressive stress magnitudes in both cases (~12.4 MPa). Despite these improvements, the 9.0 mm residual warpage in the elevated

temperature case still represents unacceptable dimensional instability for practical applications. Nonetheless, these findings indicate that relatively modest thermal control interventions during the polymerisation phase can substantially influence the development of manufacturing-induced residual stresses in thick thermoplastic structures.

Table 2 Summary of key comparative results between worst-case room temperature and elevated temperature processing, across all locations (centre and edges).

Parameter	Room Temperature (20°C)	Elevated Temperature (30°C)	Change (%)
Peak Temperature (°C)	83.1	87.0	+4.7
Final σ11 Compression (MPa)	-12.4	-12.3	-0.8
Final σ11 Tension (MPa)	25.8	9.0	-65.1
Final σ22 Compression (MPa)	-0.6	-0.2	-66.7
Final σ22 Tension (MPa)	1.5	0.1	-93.3
Final σ33 Compression (MPa)	-0.13	-0.81	+523.1
Final σ33 Tension (MPa)	1.06	0.02	-98.1
Final τ13 Shear (MPa)	0.625	0.601	-3.8
Final τ23 Shear (MPa)	0.242	0.145	-40.1
Max Spring-back (mm)	13.4	9.0	-32.8
Final Curvature Direction	U-shape (bottom tension)	Ո-shape (bottom compression)	—

5 CONCLUSIONS



This study demonstrated the application of the CHILE framework for predicting process-induced residual stresses in thick Elium® thermoplastic composites, providing manufacturers with a computationally efficient tool for process optimisation. The model captures the coupling between exothermic polymerisation, chemical shrinkage, and mechanical response, revealing that chemical shrinkage dominates thermal effects in driving residual stress formation. Comparative analysis of ambient versus elevated temperature processing revealed that modest thermal interventions can achieve 33% spring-back reduction and 65% decrease in peak tensile stresses, though the resulting 9 mm warpage remains unacceptable for industrial applications. Critically, the complete reversal of the warpage mode (U-shape to Ո-shape) demonstrates the extreme process sensitivity of thick unidirectional laminates, highlighting fundamental manufacturability challenges that cannot be overcome through process optimisation alone. The dramatic edge stress concentrations, particularly the 500-fold increase in τ_{23} for elevated temperature processing, underscore the three-dimensional nature of residual stress development in thick sections to reduce risk of delamination. As CHILE inherently overestimates residual stresses by neglecting viscoelastic relaxation, future implementation of full viscoelastic models may reveal lower stress magnitudes and reduced warpage predictions. Nevertheless, the severe dimensional instability and edge effects observed even in these conservative estimates suggest that achieving manufacturability in thick Elium® wind and tidal energy structures will require careful consideration of both layup architecture and processing strategies.

Motivation

Die length and pull-off speed: influence on the polymerization time

In-situ pultrusion line with caprolactam

The polymerization time is determined by the pull-off speed and die length

Matrix dwell time in die

Polymerization times for economical in-situ pultrusion: < 36 s

© Fraunhofer ICT

State of research

Previous ratio regulations

Concentrations of Brüggolen C10 (NaCL) as catalyst and Brüggolen C20P (HDCL) as activator used in T-RTM

[A] : [C] in wt.-%	[A] : [C] in mol.-%	Relative ratio [A] : [C]	Source, year
3,0 : 4,5		1 : 1,5	Thomassey et al. [1], 2017
1,0 : 2,0 - 2,5 : 5,0		1 : 2	Wendel et al. [2], 2018
1,0 : 2,5 - 3,0 : 4,5		1 : 2,5 - 1 : 1,5	Choi et al. [3], 2019
3,2 : 3,2		1 : 1	Osváth et al. [4], 2020
	0,6 : 1,2	1 : 2	Murray et al. [5], 2021
3,0 : 3,0		1 : 1	Semperger et al. [6], 2022
1,5 : 2,2 - 4,0 : 6,0		1 : 1,5	Lagarinhos et al. [7], 2022

No standardized formulation for activator and catalyst concentration or ratio can be defined.

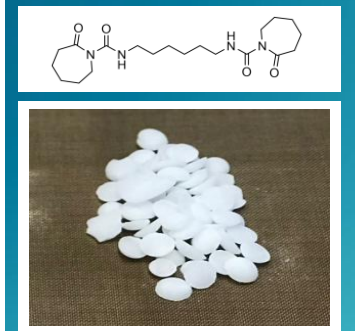
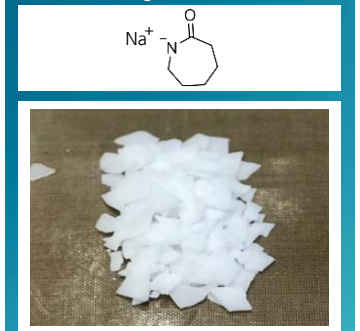
Formulation development

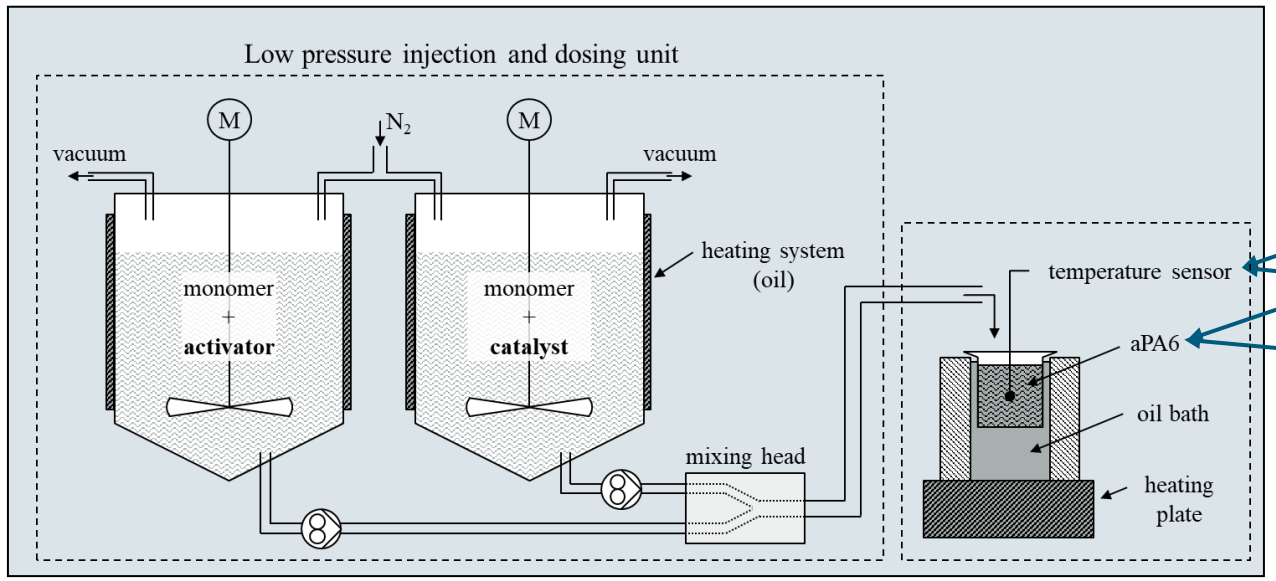
Investigation of polymerization kinetics

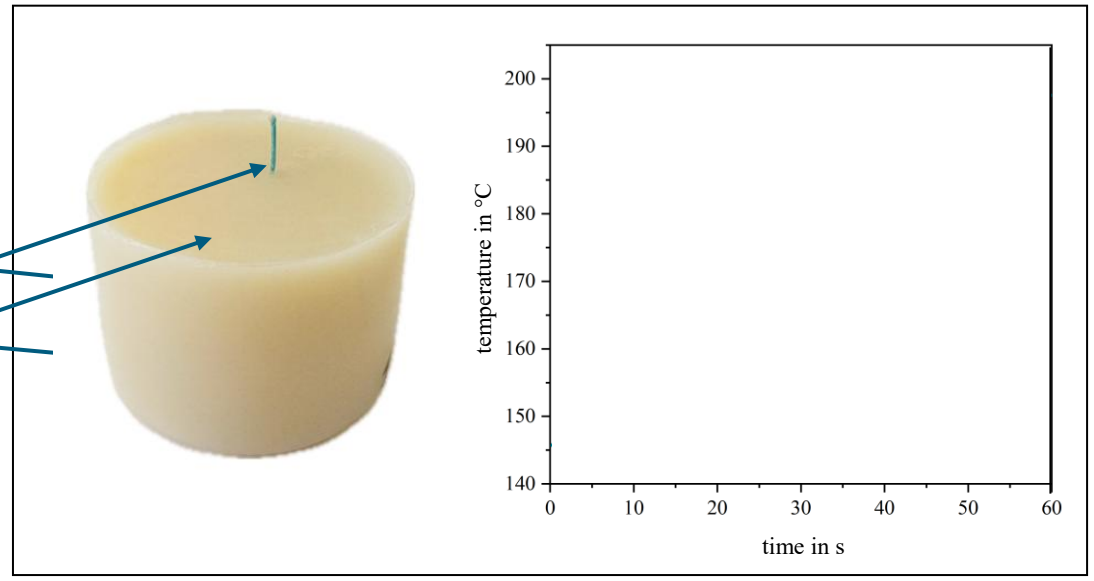


Semi-adiabatic beaker tests



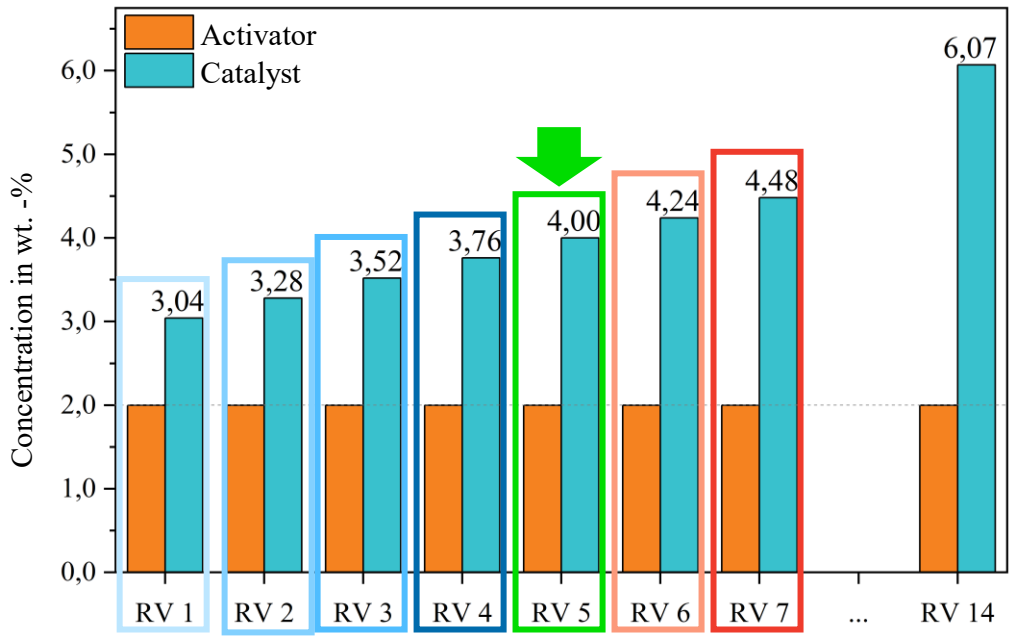
Monomer (ε-CL)



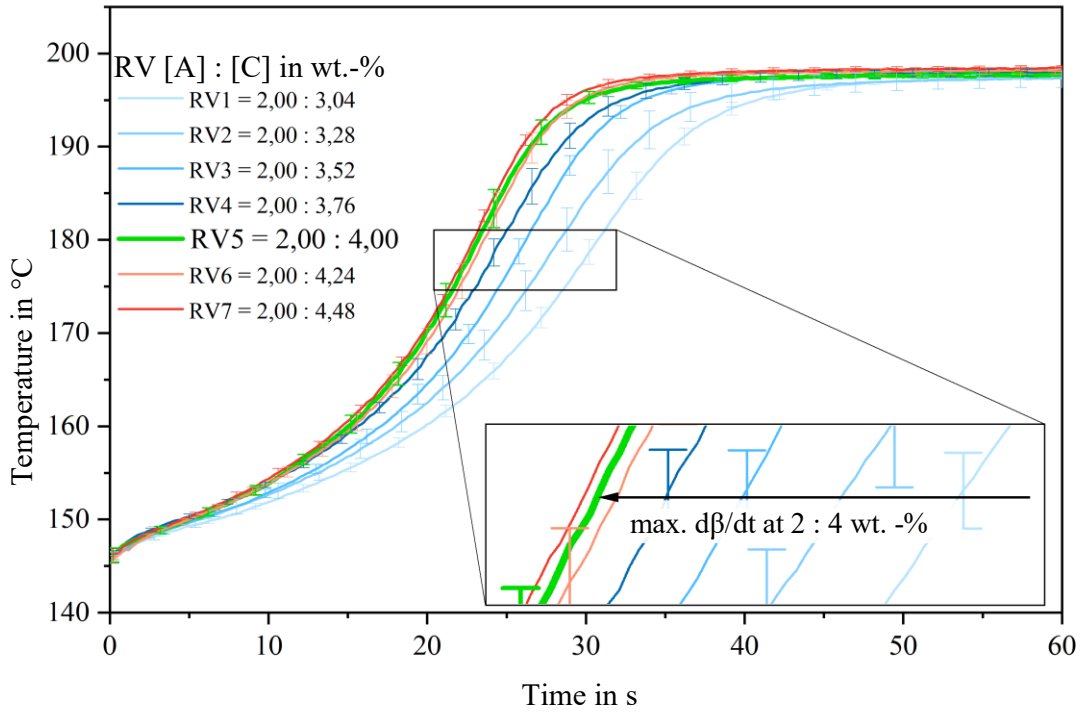


Activator (HDCL)

Catalyst (NaCL)



© Fraunhofer ICT



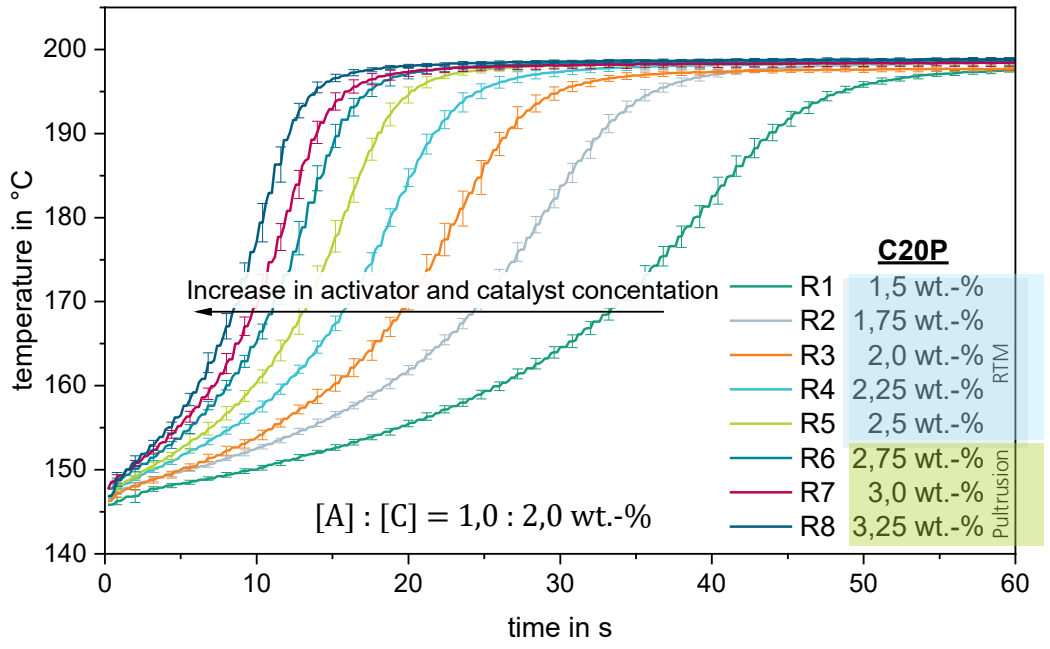
Formulation development

Determination of a suitable relative mixing ratio for the in-situ Pultrusion

Relative mixing ratio from activator to catalyst

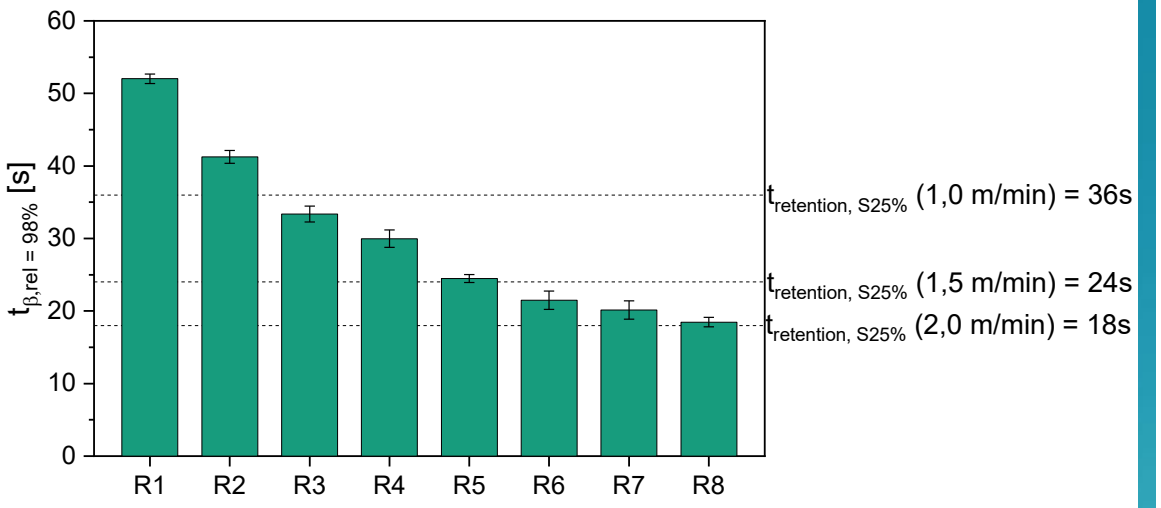
Ratio dependent polymerization kinetics

→ $(\text{max. } d\beta/dt)_{\text{min. Cat}} = [A] : [C] = 1{,}0 : 2{,}0$ wt.-%



Gradual increase of the catalyst concentration

© Fraunhofer ICT



Formulation development

Determination of suitable total concentrations

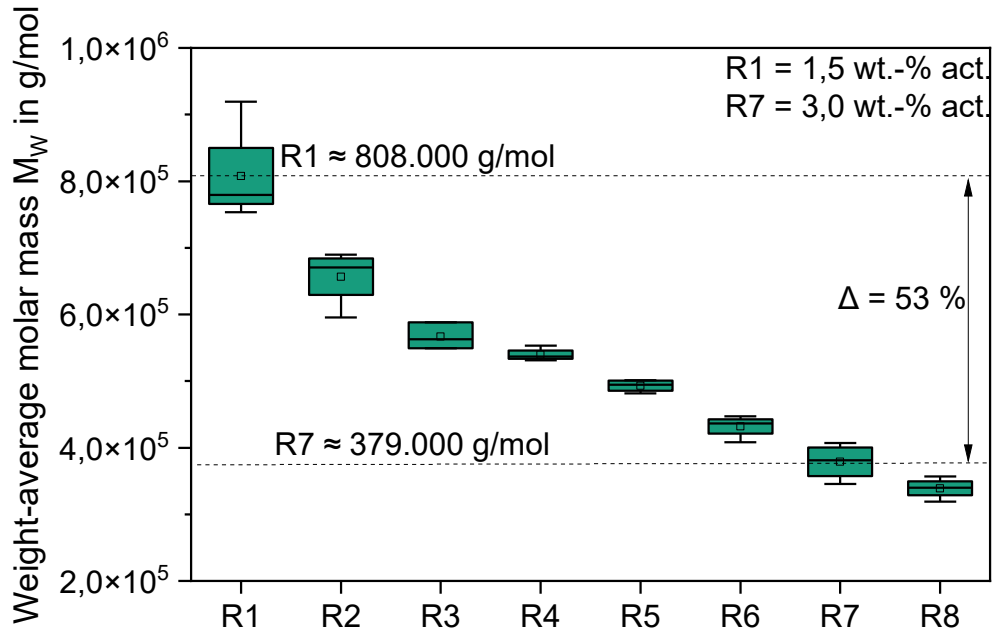
Concentration-dependent polymerization kinetics

Polymerization time required for 98 % conversion

$$t_{ß,rel=98\,\%} = \left(T_{max,Rx} - T_{0,Rx}\right) * 98\,\%$$

With increasing total concentrations of Act./Cat., the polymerization rate increases disproportionately

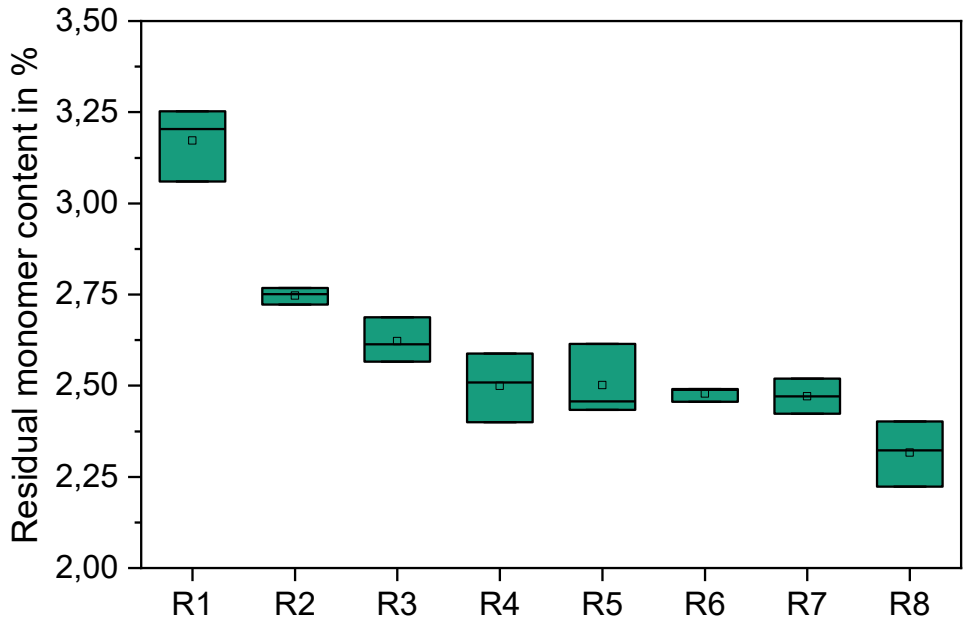
Formulations **≥ R6** suitable for pull-off speeds up to **1.5 m/min**



© Fraunhofer ICT

Fraunhofer ICT

Formulation development



Influence of the activator and catalyst concentration on polymer properties

Influence on the weight-average molar mass

Approx. linear reduction of molar masses through increased proportion of activator and catalyst

Influence on the residual monomer content

Constant low residual monomer content at relevant formulations (**≥ R6**)

© Fraunhofer ICT

Conclusion

Semi-adiabatic beaker tests are a valid method for investigating the influence of activator and catalyst concentration on kinetics and properties

The catalyst concentration can be limited to a minimum at an optimum ratio of [A] : [C] = 1.0 : 2.0 wt.% for max. reaction rate, high polymer properties and less side reactions.

From an activator concentration of 2.75 wt.% and a corresponding catalyst concentration of 5.5 wt.%, economical pultrusion is possible at a pull-off speed of ≥1.5 m/min

Increasing the activator and catalyst concentration even further showed no significant negative influence on the investigated polymer properties

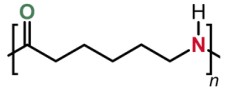
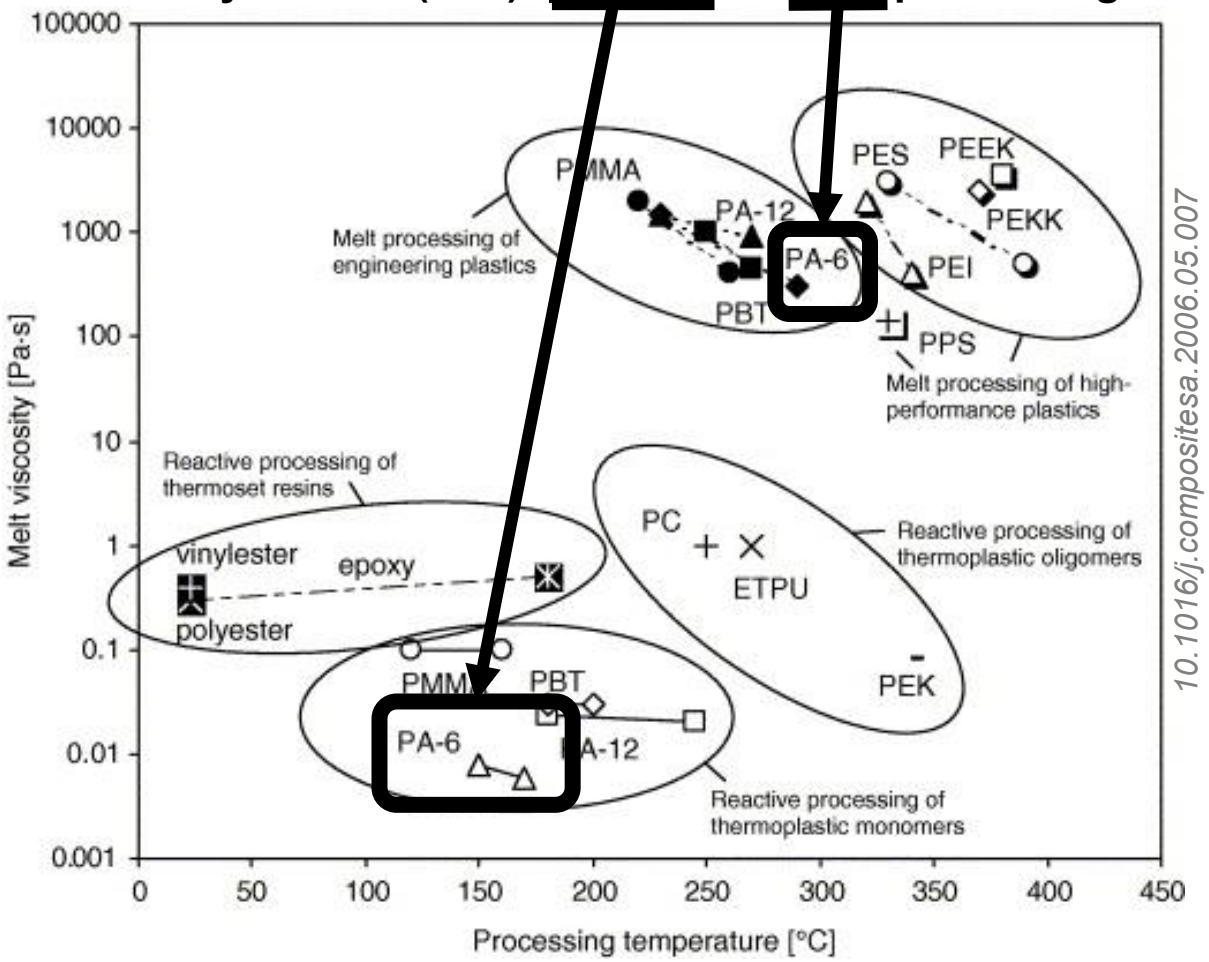
Baltimore (MD, USA) - August 5, 2025

giulia.fredi@unitn.it



Thermoplastic composites: traditional and reactive processing

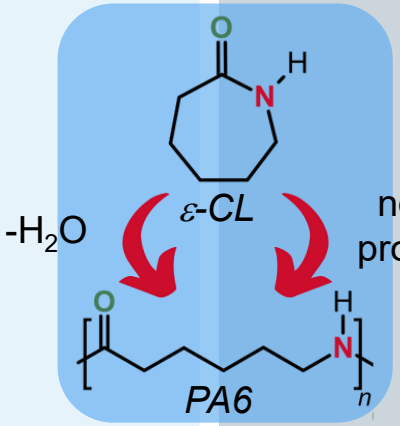
Thermoplastic composites



- shorter thermal cycles → increased production rate
- «infinite» shelf life
- post-thermoformability and recyclability
- High viscosity
- High-temperature processing

- **low-viscosity** precursors
- complete fiber **impregnation**
- **shorter and less complex** production cycles

Polyamide 6 (PA6): reactive vs. melt processing



10.1016/j.compositesa.2006.05.007

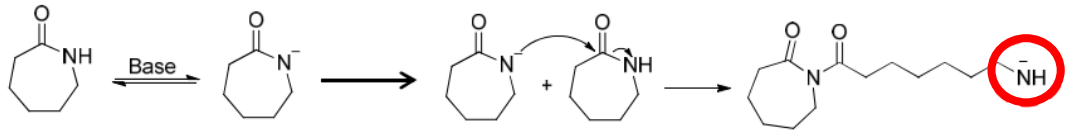
PA6: hydrolytic vs. anionic polymerization

Hydrolytic polymerization

- T = 250 °C (> T_c)
- Hours-Days

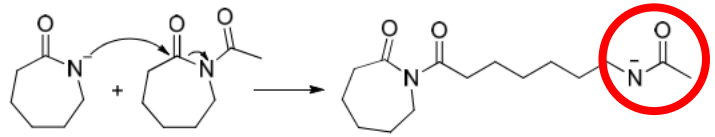
- Mw = 30 kg/mol
- Conv. > 90%
- X_c = 20-30 %
- E = 2-3 GPa

Anionic (ring-opening) polymerization



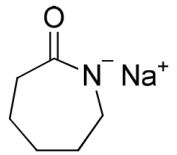
- T = 140-170 °C (< T_c)
- Seconds-minutes

no by-products → *suitable for reactive processing*

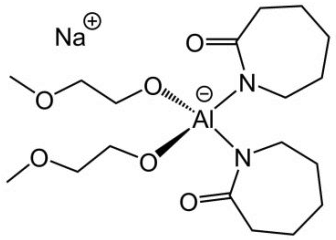


- Mw = 500 kg/mol
- Conv. >99%
- X_c = 40-50 %
- E = 3-4 GPa

extremely moisture-sensitive

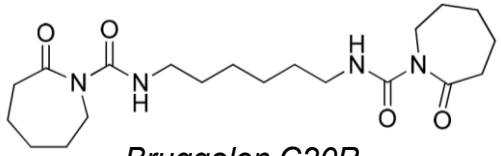


Initiation



Initiation with an activator (faster)

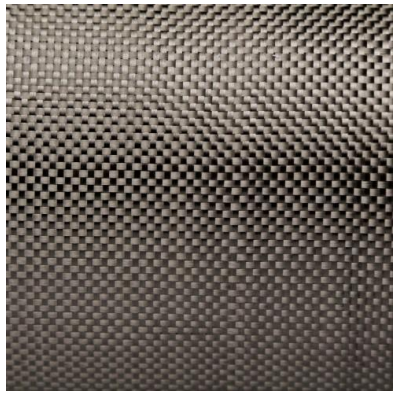
Common initiators:



Bruggolen C10

Dilactamate

Common activator:



Bruggolen C20P

Aim of the work

Prepare and characterize aPA6-matrix composites with two types of continuous reinforcement:

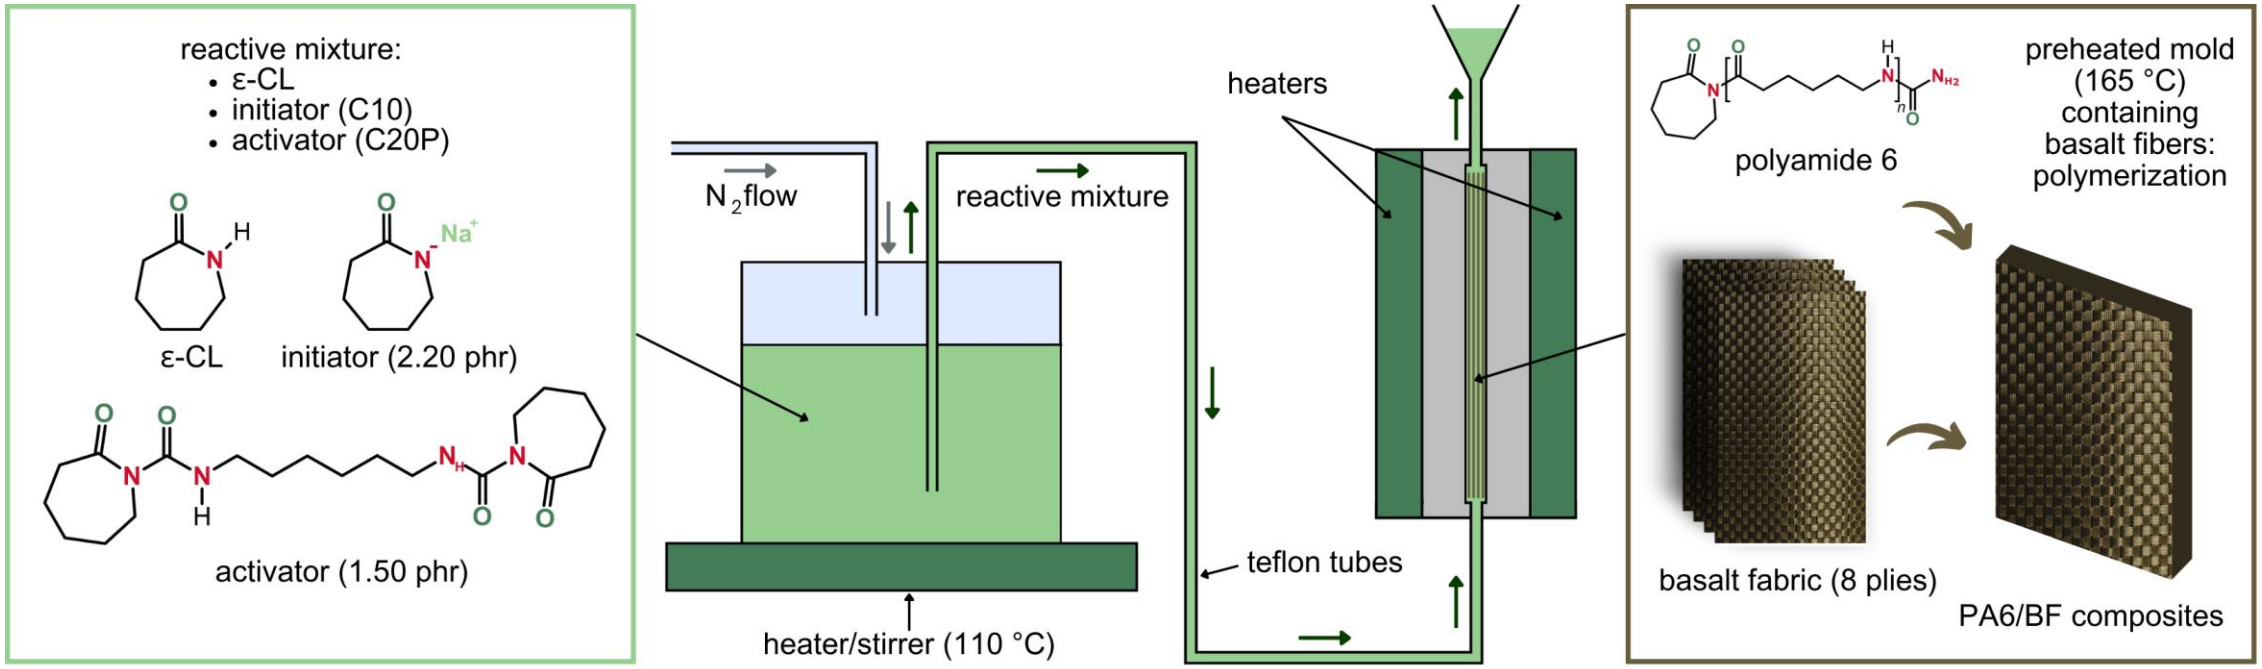
1. Basalt fiber fabric

BAS220P (Basaltex NV)
- 220 g/m^2
- Plain
- (3-glycidyloxypropyl)trimethoxysilane sizing
- 3 types of surface state

2. Flax fiber fabric

Flax fabric Flaxdry BL200 (Eco-Technilin)
- 200 g/m^2
- Twill
- Twisted yarns
- 3 types of surface state

Outline

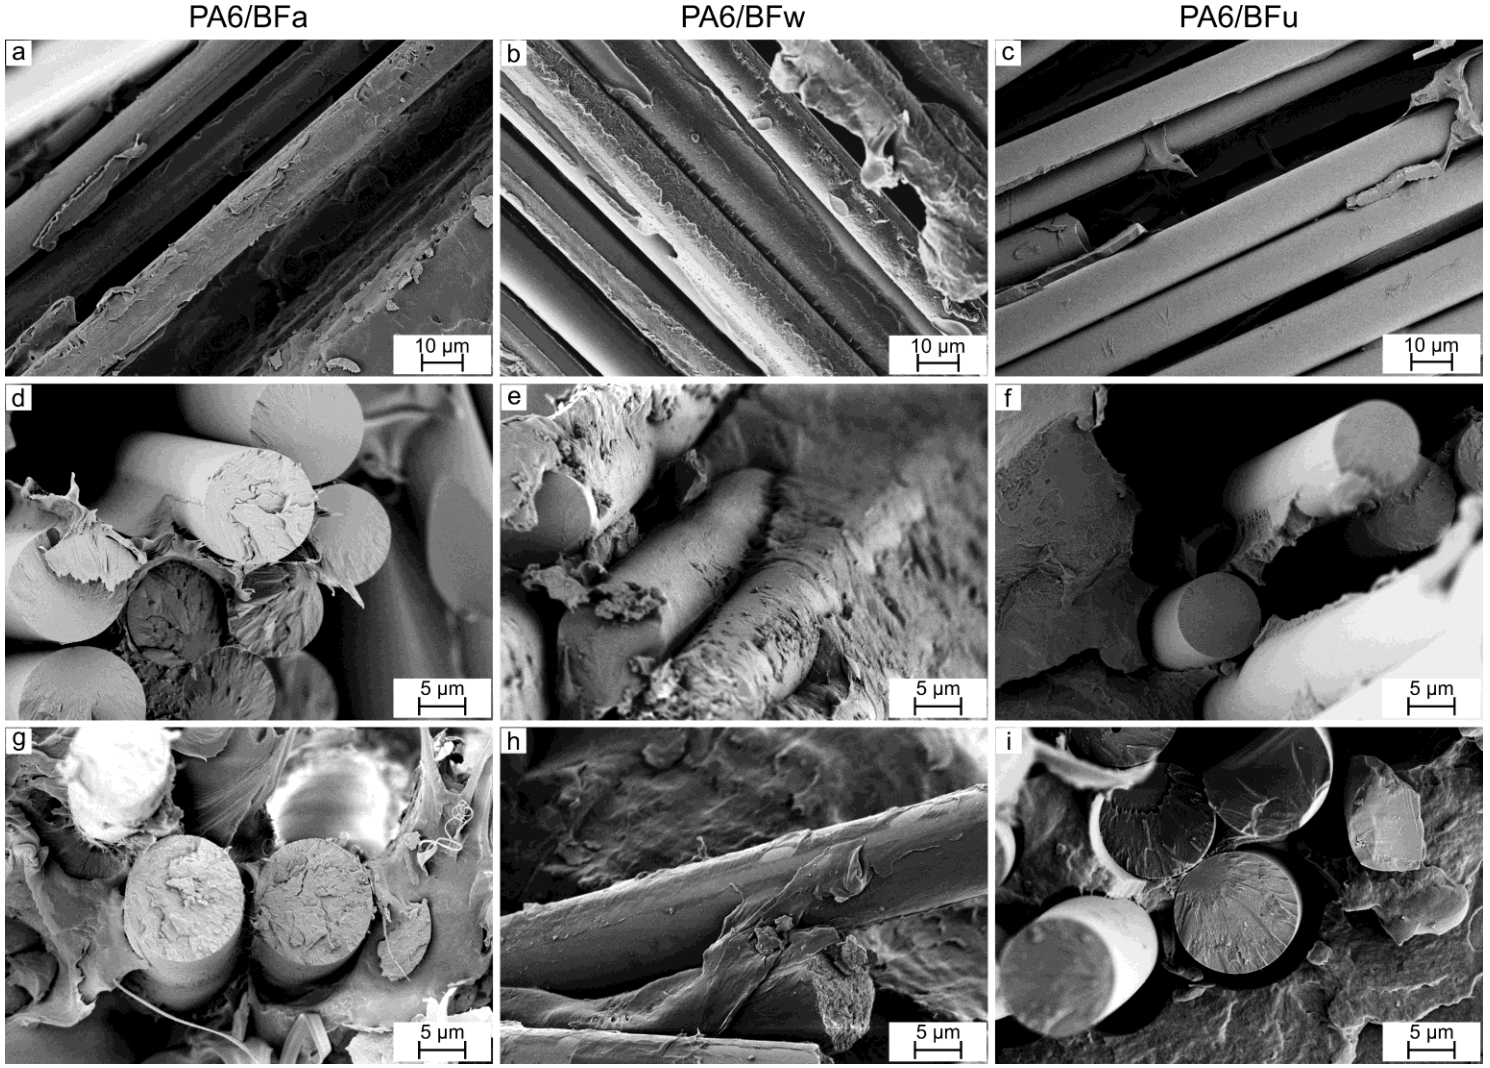


PA6/BF
- Monomer conversion
- Mechanical properties
- Fiber/matrix adhesion

PA6/FF
- Why plant fibers + anionic PA6?
- Fiber surface state
- Monomer conversion
- Mechanical properties

PA6/basalt fiber composites

Preparation of PA6/BF laminates via tRTM



Reactive in situ activated polymerization – Thermoplastic resin transfer molding

Sample	Reinforcement	Monomer conversion (%)	ϑ_v (vol%)	ϑ_f (vol%)
PA6/BFa	As-received BF	97.2	6.6	28.2
PA6/BFw	BF washed with ethanol	97.7	1.4	31.5
PA6/BFu	Thermally desized BF (400 °C – 4 h)	98.7	3.4	32.4

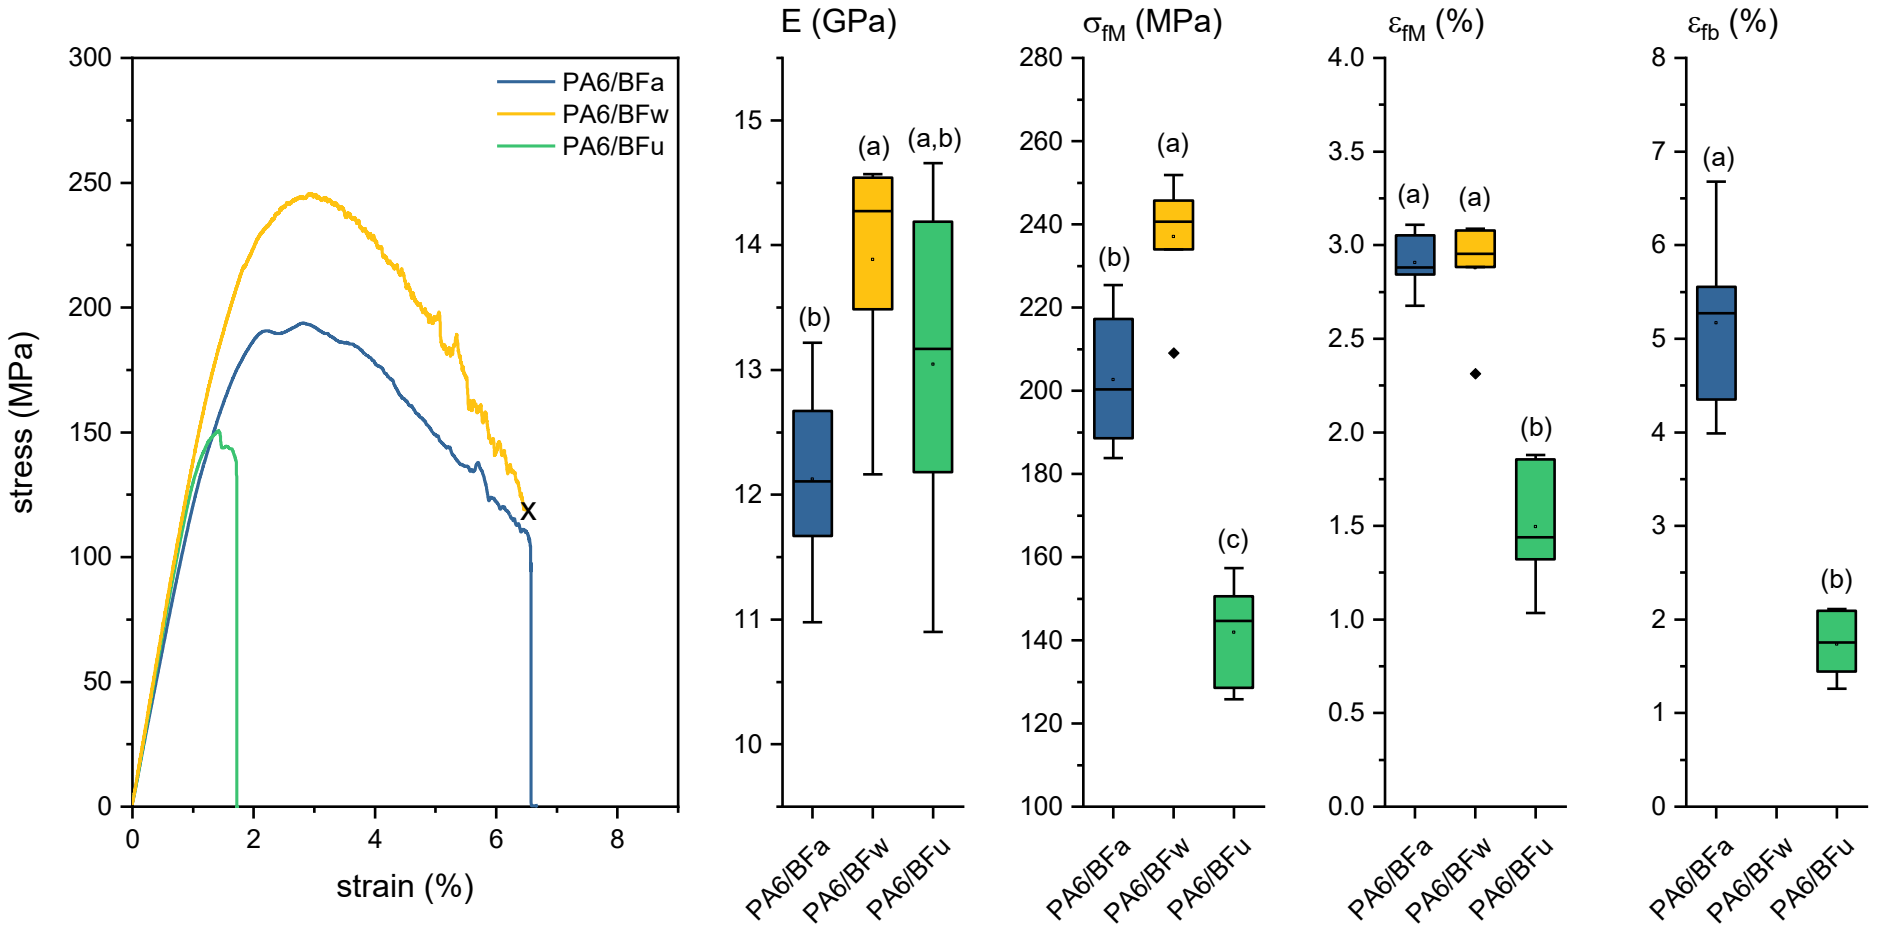
Valentini,… and Fredi, Composites A 2025, 190, 108681, 10.1016/j.compositesa.2024.108681

PA6/BF: microstructure

PA6/BFa and PA6/BFw:

- Matrix residues on the fibers
- Matrix deformation
- (slight) improvement with washing

→ good fiber/matrix adhesion



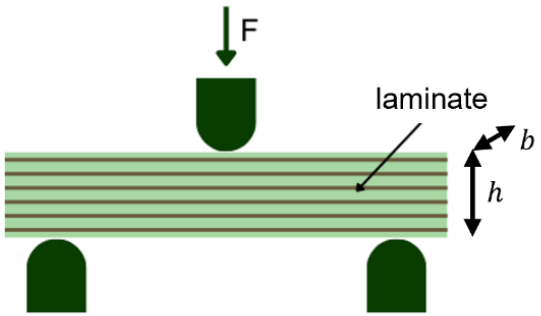
PA6/BFu:

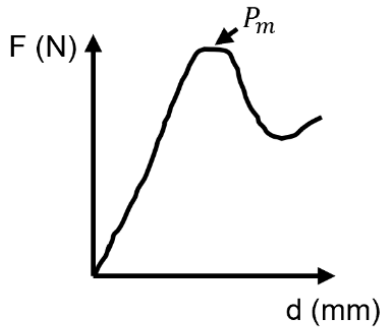
- Clean fibers and grooves

→ scarce fiber/matrix adhesion

Valentini,… and Fredi, Composites A 2025, 190, 108681, 10.1016/j.compositesa.2024.108681

3-point bending test



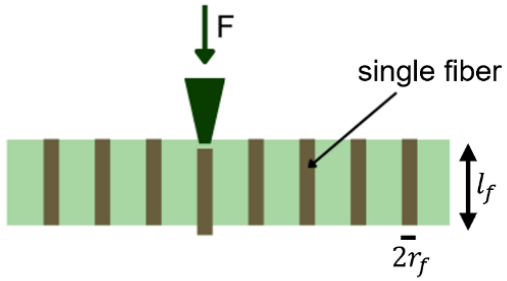


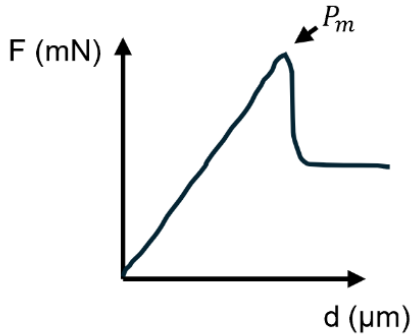
- Ethanol washing significantly increases the stiffness and strength
- Desizing decreases the mechanical properties
- TT at 400 °C may decrease the BF strength but not the stiffness
- Theoretical stiffness (mixture rule):
  - PA6/BFa: 13.0 GPa
  - PA6/BFw: 14.2 GPa
  - PA6/BFu: 14.5 GPa

Valentini,… and Fredi, Composites A 2025, 190, 108681, 10.1016/j.compositesa.2024.108681

Interfacial adhesion: three tests

Short beam shear (SBS) test

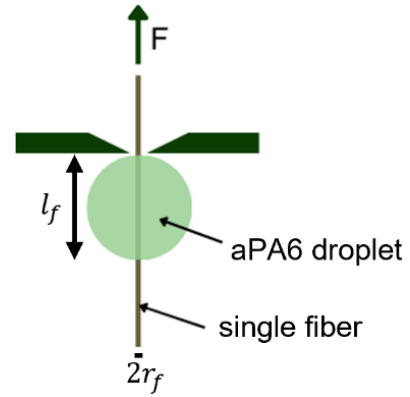


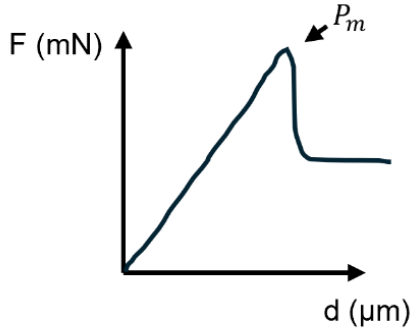


$$ILSS = F^{SBS} = \frac{3P_m}{4bh}$$

- 3-p bending with a short specimen
- Maximization of shear streses
- Delamination promoted

Single fiber push out (SFPO) test

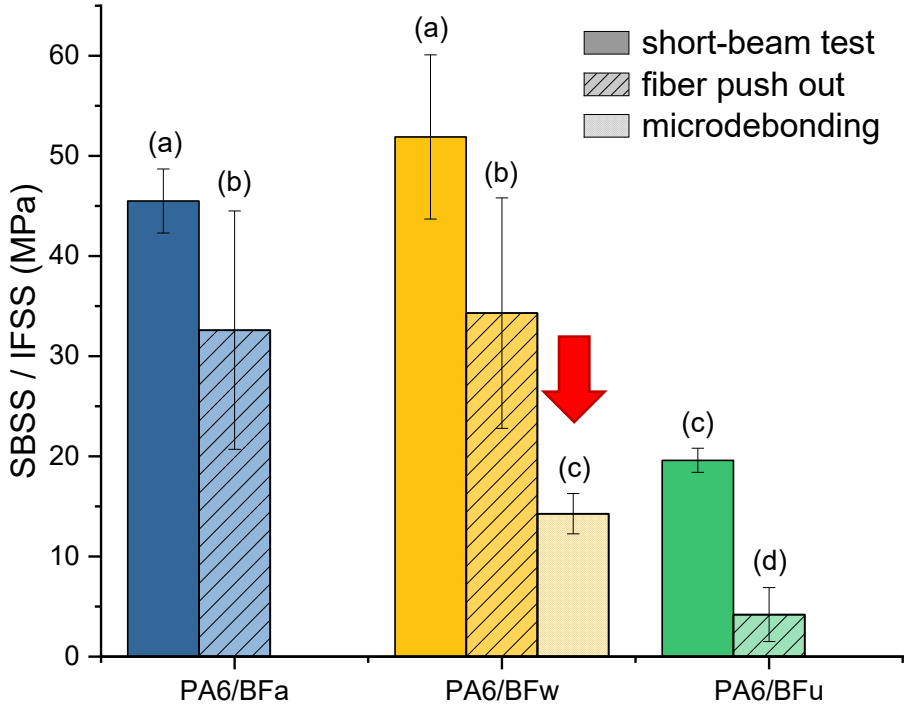




$$IFSS = F^{SFPO} = \frac{P_m}{2\pi r_f l_f}$$

- Thin (tens of μm) specimen
- Fiber is pushed out of the matrix

Microbond (MD) test

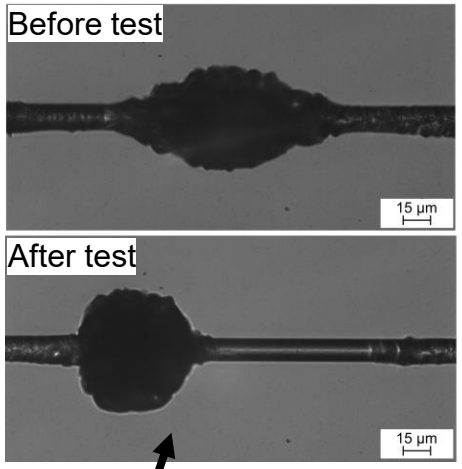


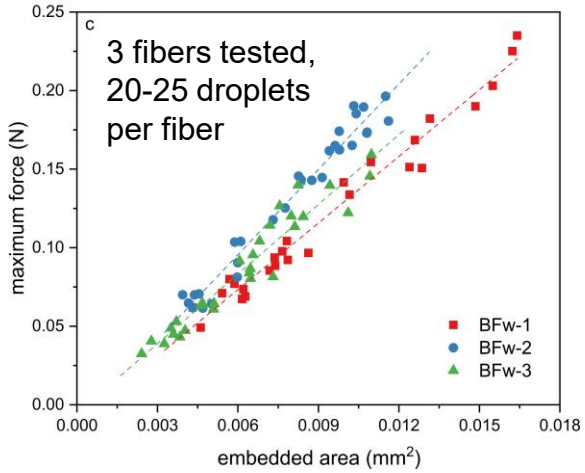
$$IFSS = F^{MD} = \frac{P_m}{2\pi r_f l_f}$$

- Droplets of matrix on the fiber
- Fiber is drawn out of the droplet

Valentini,… and Fredi, Composites A 2025, 190, 108681, 10.1016/j.compositesa.2024.108681

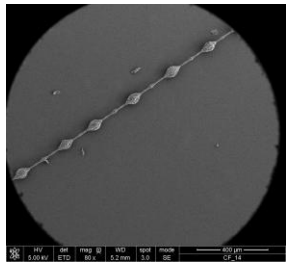
Interfacial adhesion



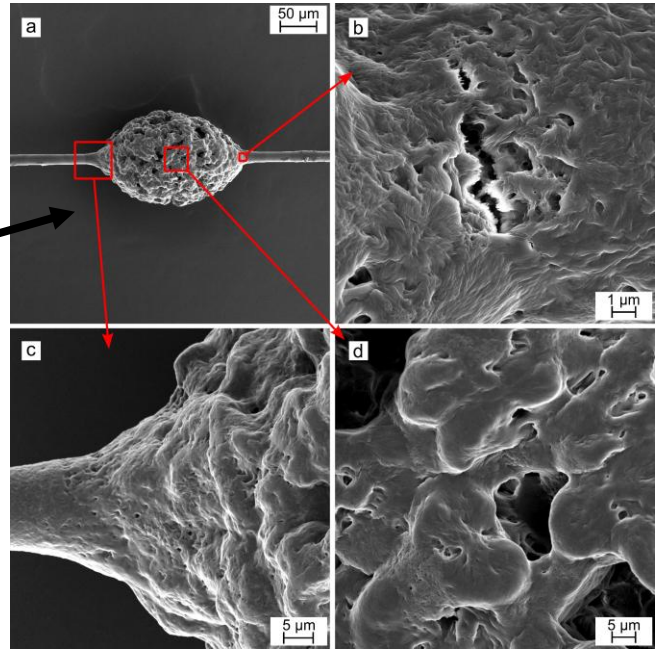


Short beam vs push out:

- Dispersion is higher with a micro-scale test but trends are similar:
  - PA6/BFw: washing increases adhesion
  - PA6/BFu: desizing decreases adhesion



Microdebonding:



- Lower adhesion

- **Ductile** droplets: residual monomer
- **Porous** droplets: overestimation of the interfacial area

Valentini,… and Fredi, Composites A 2025, 190, 108681, 10.1016/j.compositesa.2024.108681

PA6/BF: conclusions

- **Fiber surface treatment critically determines fiber-matrix adhesion** (simple treatment effective with a sensitive polymerization reaction), **while the bulk matrix properties are not affected**

- **Ethanol washing** emerged as the most effective treatment, increasing short-beam shear strength by 14% compared to as-received fibers (51.9 ± 8.2 MPa vs 45.5 ± 3.2 MPa)
- Thermal desizing at 400°C significantly impaired interfacial bonding, reducing interfacial shear strength by ~50% (19.6 ± 1.2 MPa)

- **Multi-technique characterization** (short-beam shear, fiber push-out, microdebonding) provided complementary insights into interfacial behavior at different scales, but **the microdebonding test presents challenges that are unique of this matrix system**

aPA6/flax fiber composites

Lignocellulosic reinforcements: industrial applications

Key Benefits
(vs. glass)

- **High specific properties**
- Cost-effective production
- Bio-based
- Biodegradable
- Other functional properties (e.g., vibration-damping)

Automotive Industry
- Hemp, jute, flax, sisal fibers
- Seat cushions, interior panels, front grills

Transportation
- Aircraft interior components
- Boat hulls
- Pressure vessels (w/ thermosetting resins)

Construction & Building
- Wood-plastic composites for furniture & decking
- Hemp/lime concrete for soundproofing
- Recycled WPC in asphalt & concrete

Consumer & Sports Goods
- Musical instruments
- Sport equipment
- Packaging

pressure vessel

packaging

kenaf/PP inner-door panel

Sports-cycle frame

Mercedes Benz E-Class components

Lignocellulosic reinforcements in polymers: three main challenges

Challenge 1: Poor interfaces

Poor interfacial interaction with polymer matrices, for two main reasons:

1) **Hygroscopicity** and swelling (enhanced by fiber porosity)
2) **Hydrophilicity** and poor chemical compatibility with hydrophobic polymer matrices

Challenge 2: Poor stability

Poor thermal and environmental stability, so:

1) **Degradation during processing (T>200°C):** challenges with technical thermoplastics
2) **Degradation during use**: attack by microorganisms and fungi; flammability

Challenge 3: Property variability

Variability and challenges in measuring mechanical properties:

1) **Variable morphology** and irregular cross section
2) **Variability due to environmental conditions**

Bonus challenge
Decreased **durability** of durable composites (and of the biodegradable ones?)

Lignocellulosic reinforcements in polymers: poor thermal stability

Degradation during processing (T > 200°C)

- restricts manufacturing temperature
- limits the matrix selection to:

Thermosets
with curing temp.
below 200 °C

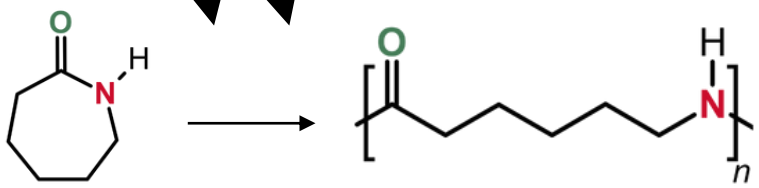
Low-melting-temperature thermoplastics
e.g., PE, PP, PLA

- Unfair competition with glass fibers
- Restricts broader industrial applications: **challenges with technical thermoplastics** like PET, PA, PEEK, etc.

https://doi.org/10.1016/j.jmrt.2024.04.085

Weight loss (%)	T (°C) at 5wt%	T (°C) at 25wt%	T (°C) at 50wt%	T (°C) at 75wt%
Hemp	105	329	341	458
Kenaf	64	313	341	371
Henequen	61	301	337	392
Flax	88	323	339	441
Glass	586	–	–	–

PA6/flax: aim of the work



Produce and characterize

polymer composites combining

lignocellulosic fibers and an

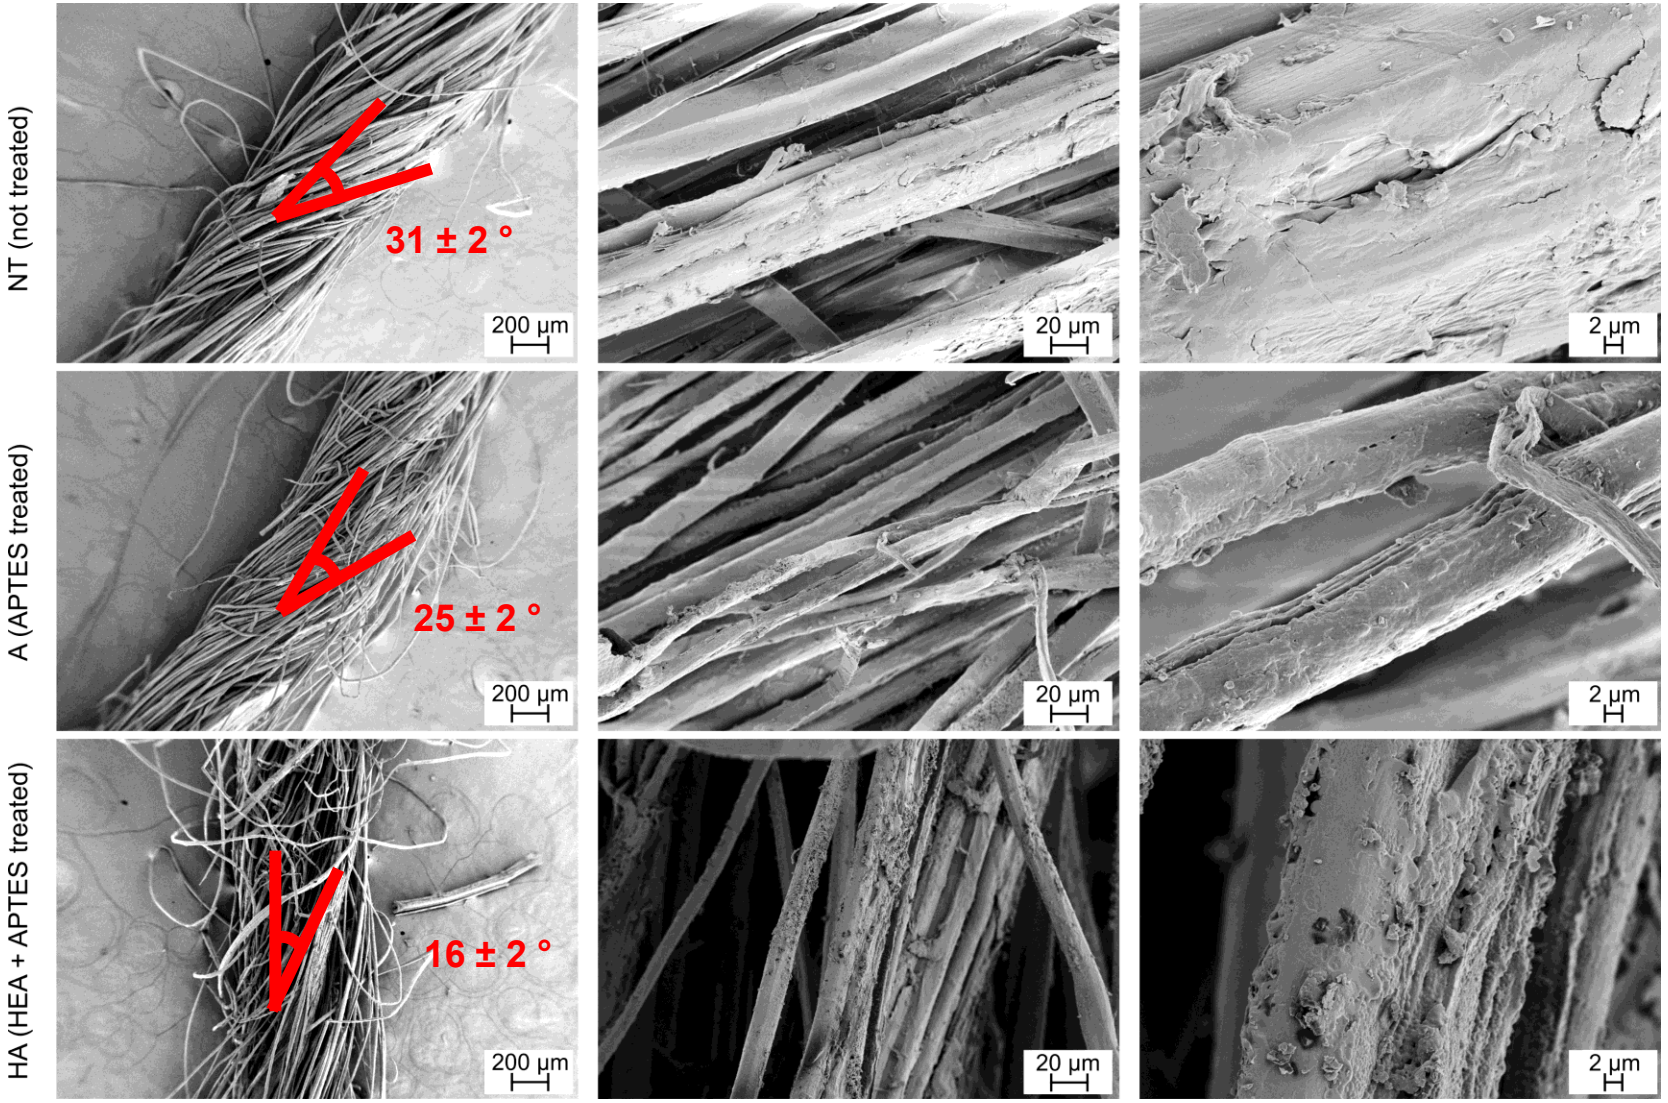
engineering polymer matrix (polyamide 6) exploiting

in situ reactive processing, which allows low precursor's viscosity and low processing temperatures

ε-caprolactam *PA6*

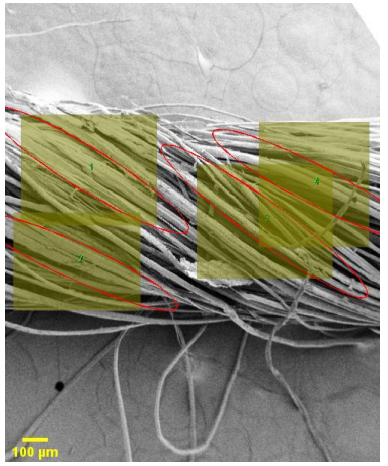
- Activated anionic ring-opening polymerization
- **Extremely sensitive to moisture and surface impurities** (initiator reacts with proton donating species and deactivates → lower degree of conversion)

Flax fabric Flaxdry BL200



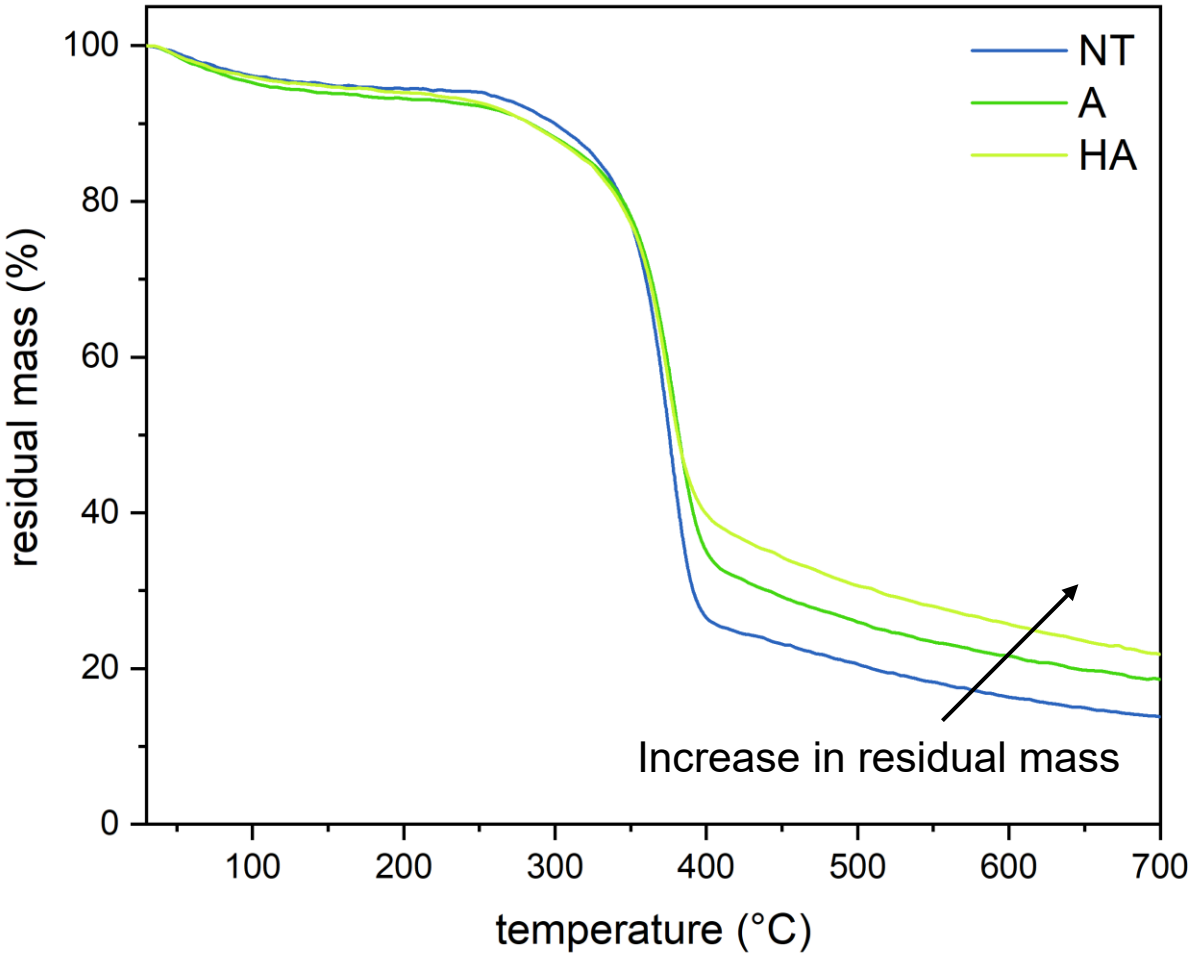
Three surface states:

- **NT**: not treated (as received)
- **A**: silanized with APTES (spray coated)
- **HA**: treated with hexane, ethanol, acetone (HEA) and then silanized with APTES



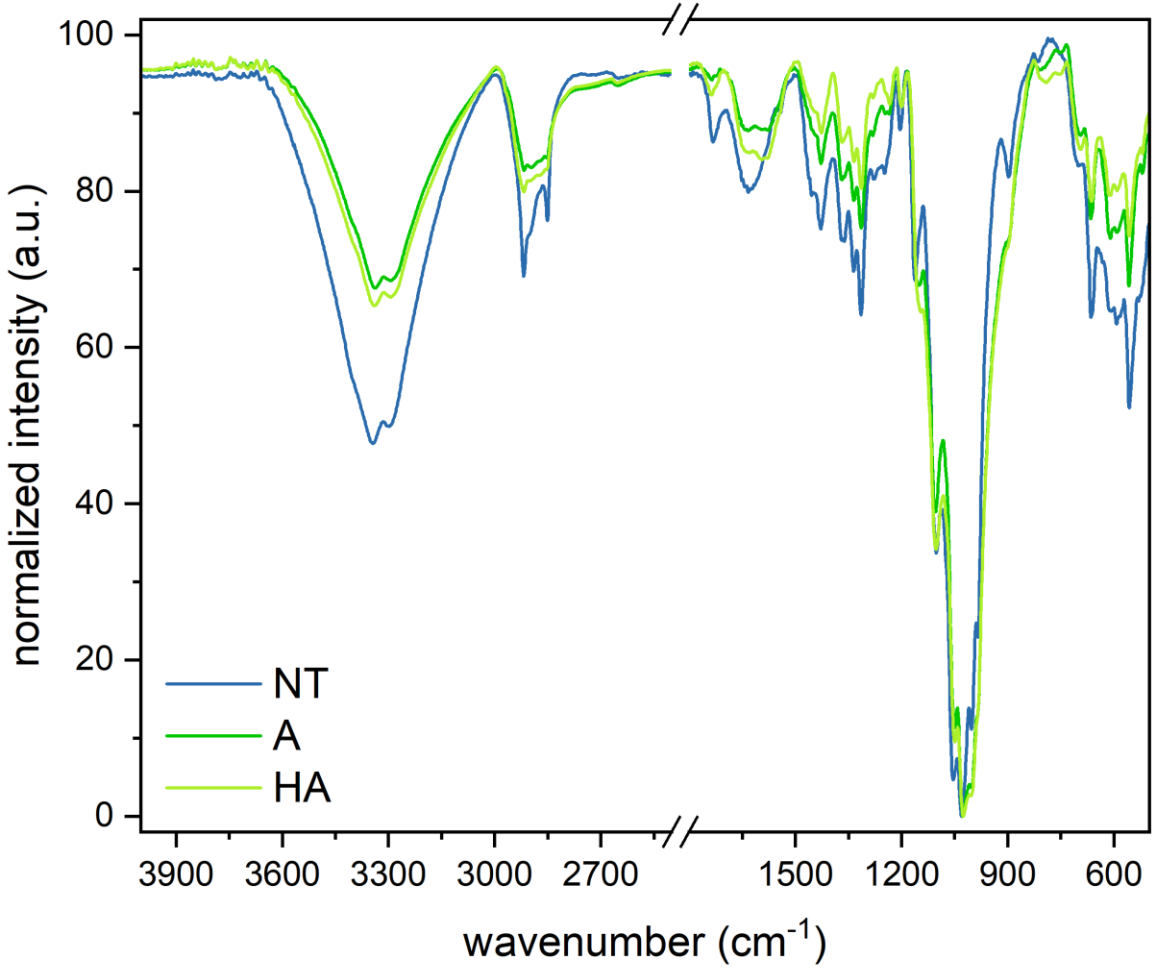
Increase degree of conversion and interfacial adhesion

Characterization of the fibers: microstructure

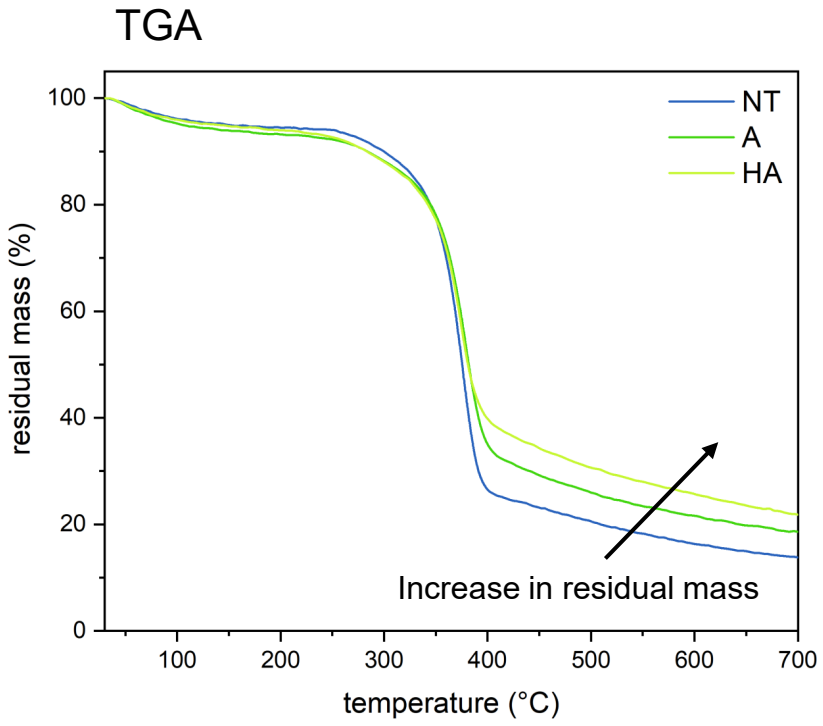


- Decrease in twist angle with both treatments
- No clear effects on the surface morphology

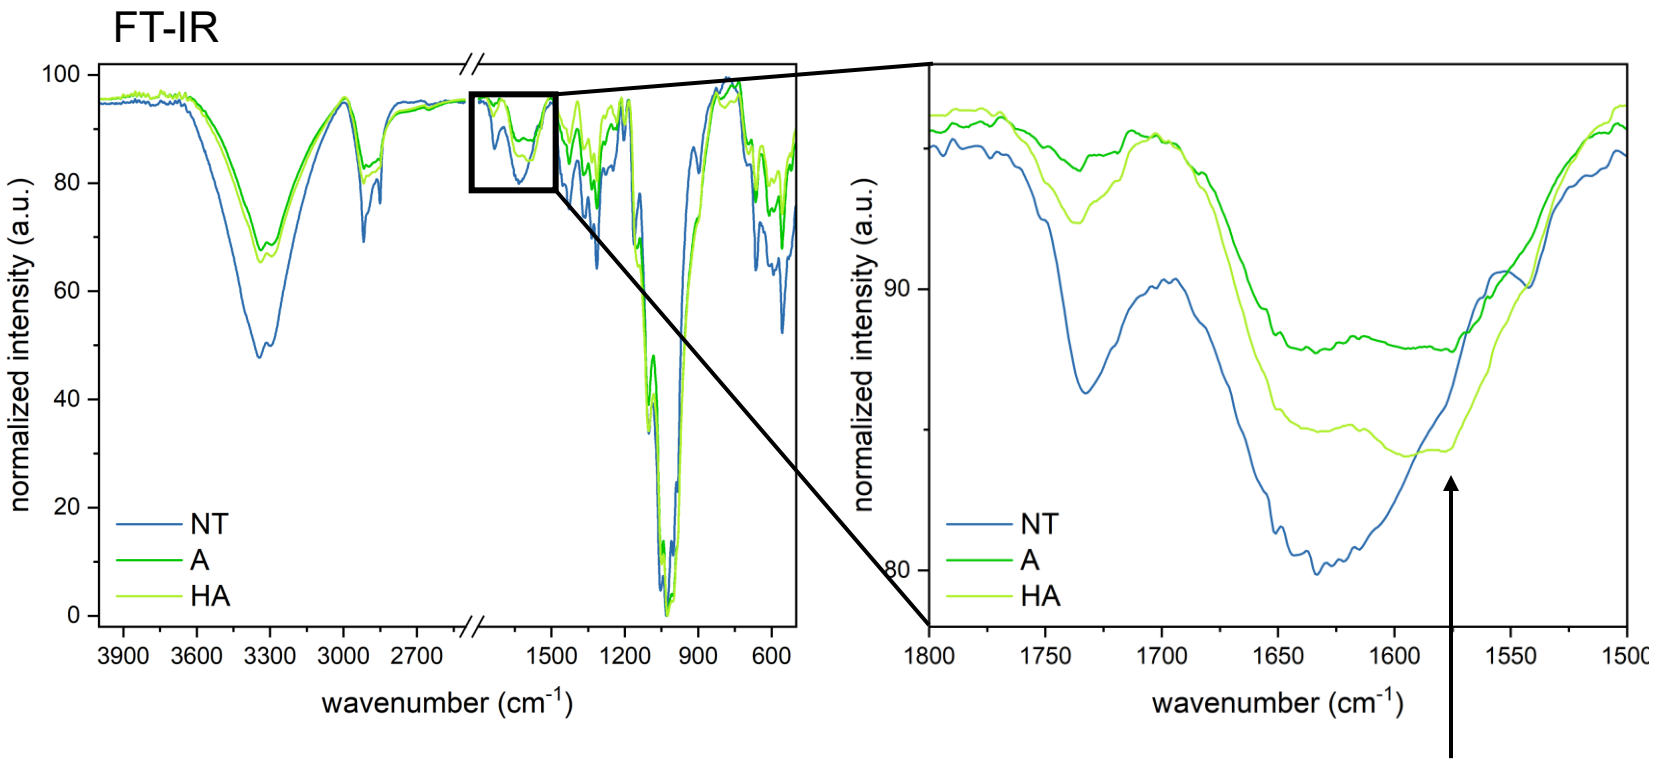
Twist angle (Orientation J – ImageJ)



Characterization of the fibers: silanization



TGA

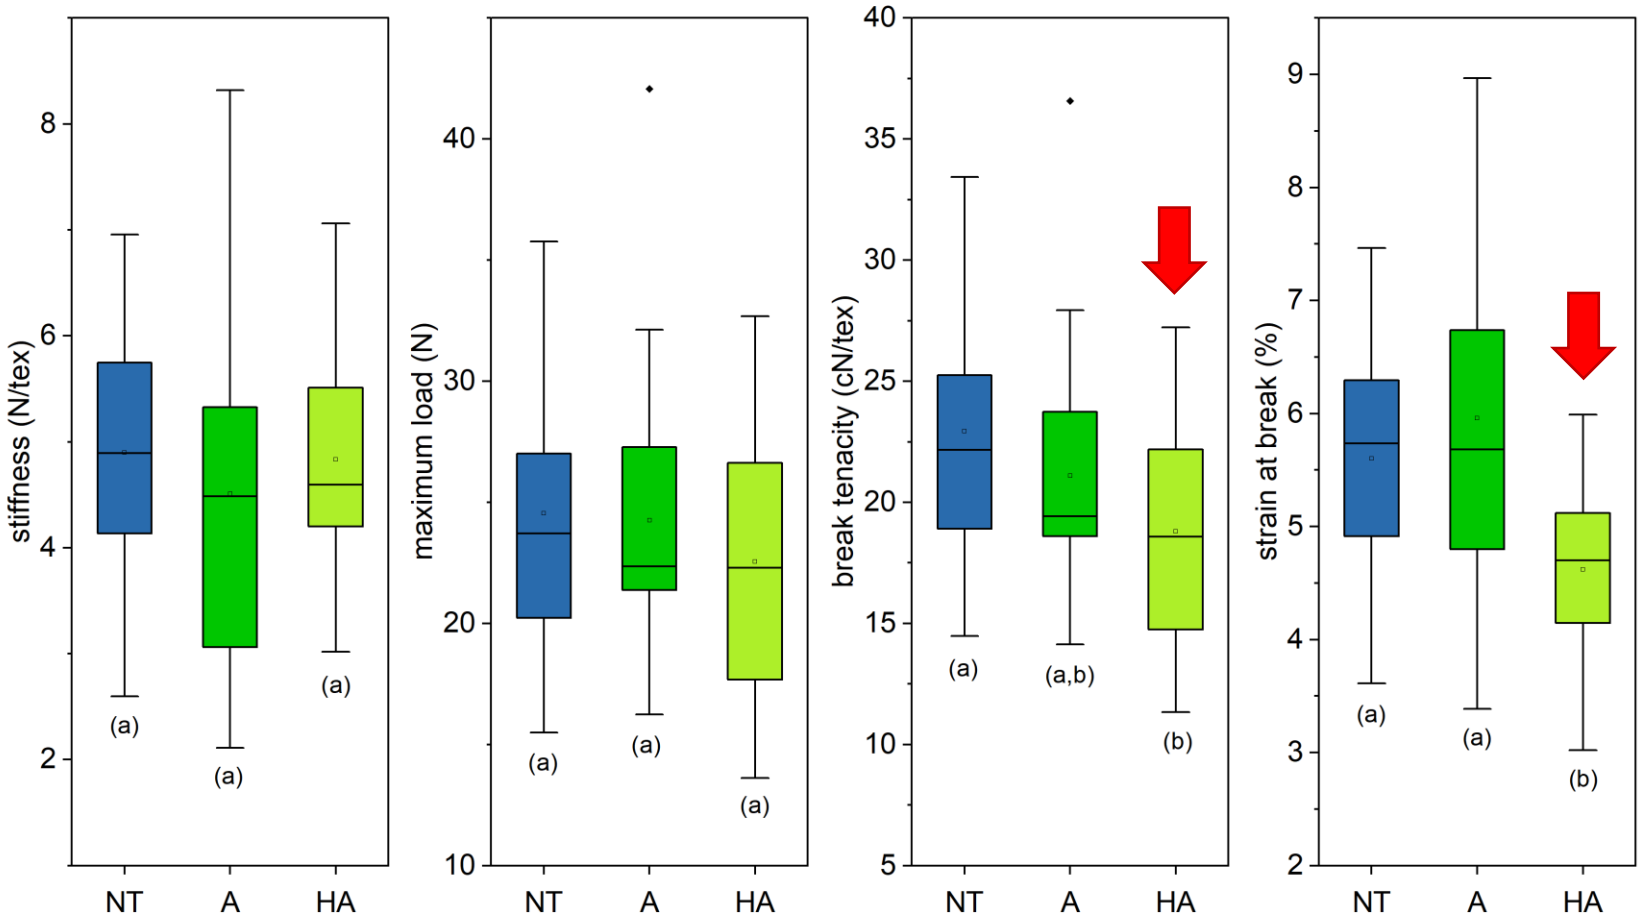


FT-IR

Characterization of the fibers: silanization

1590-1650 cm^{-1}: N-H bending

- Successful silanization
- Silanization seems more effective if preceded by HEA treatment

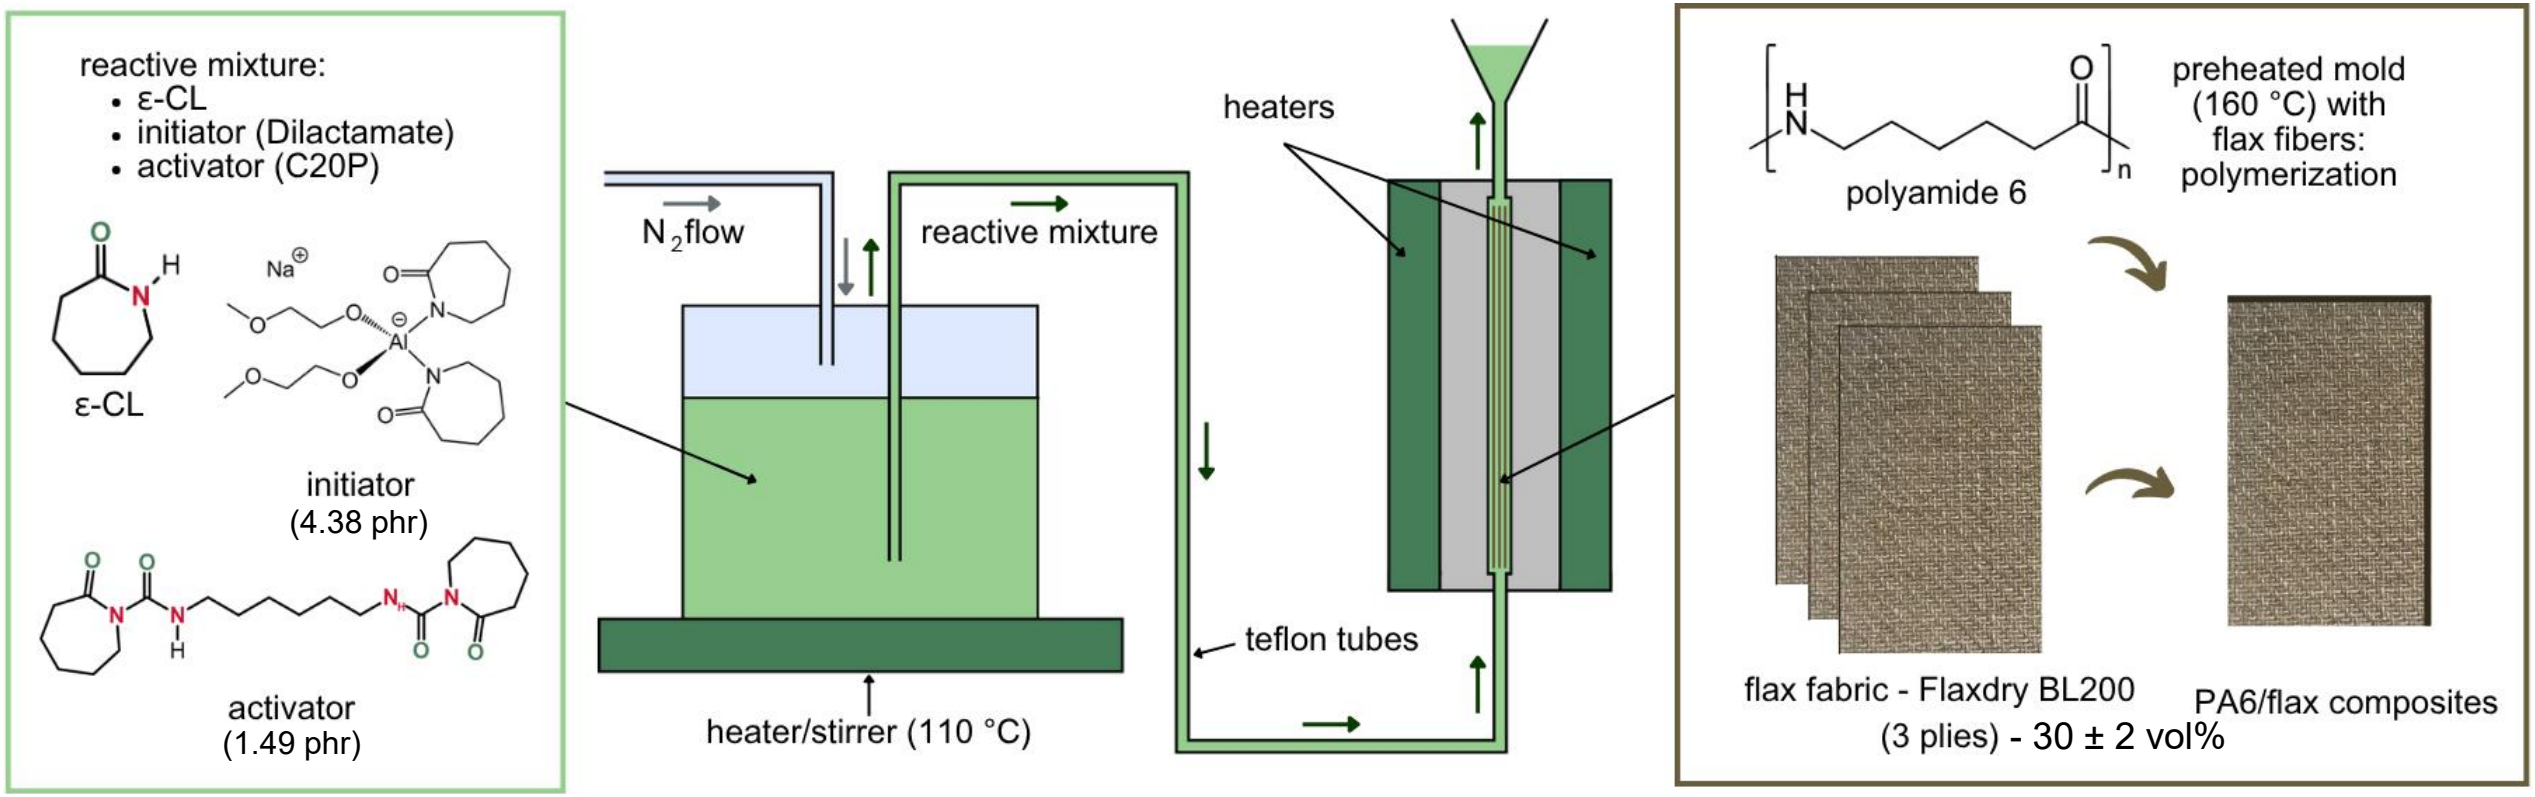


Characterization of the fibers: tensile tests

Tensile tests
- Single fibers
- Yarns →

- HA treatment **decreases the strain at break and the break tenacity**, but not the max load → increase in linear density

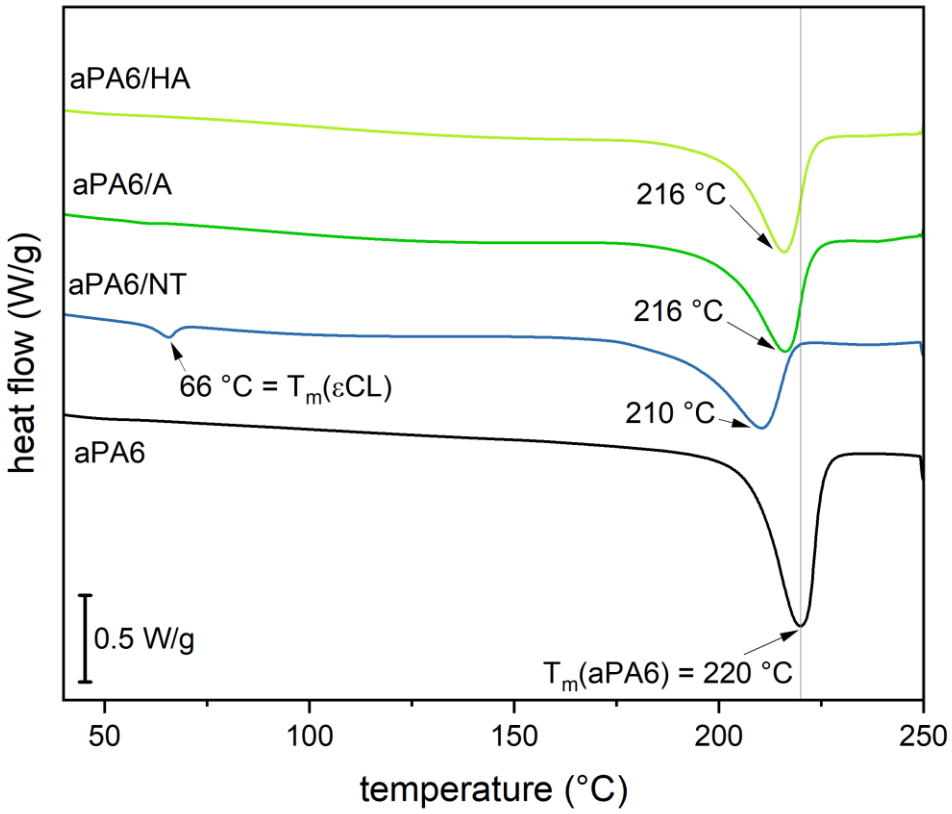
	Yarn (tex)	Staple (tex)
NT	107 ± 27	0.3483 ± 0.0007
A	115 ± 24	0.4248 ± 0.0007
HA	120 ± 34	0.4509 ± 0.0007



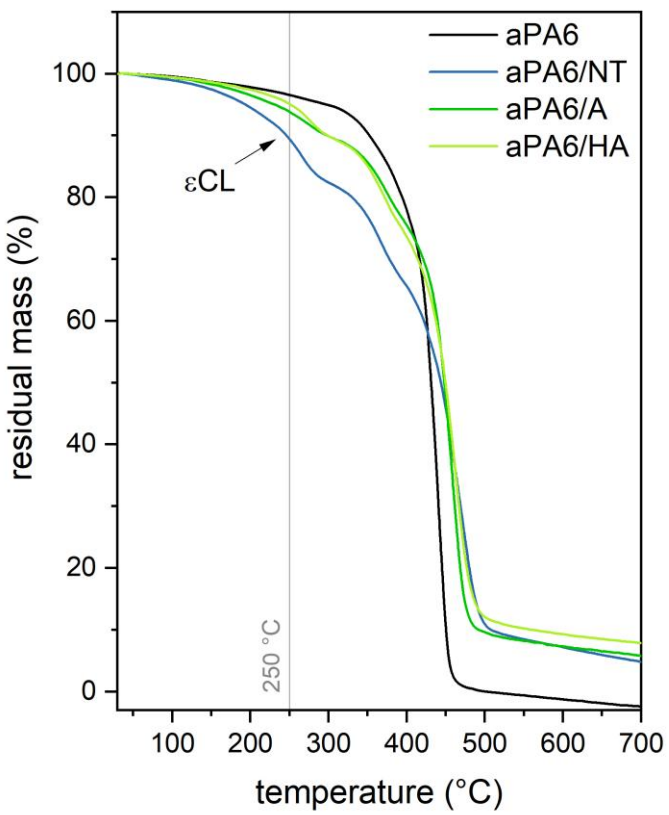
- the decrease is significant (for HA) but slight
- The **stiffness [N/tex]** is not significantly affected

One-way ANOVA and Tukey's HSD test at p = 0.05

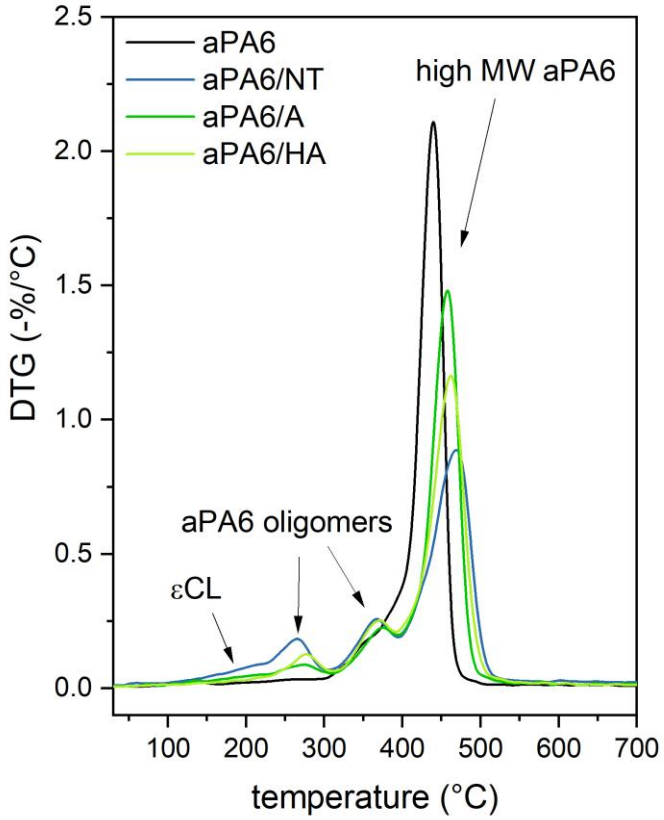
Preparation of PA6/flax laminates via tRTM



Reactive in situ activated polymerization – Thermoplastic resin transfer molding



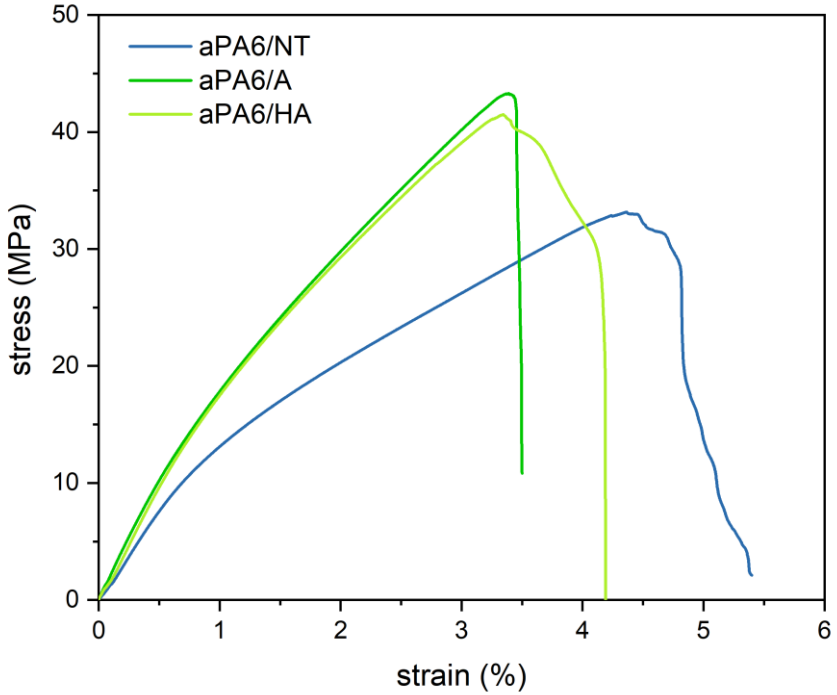
- Moisture-tolerant initiator (other initiators like NaCL perform worse)

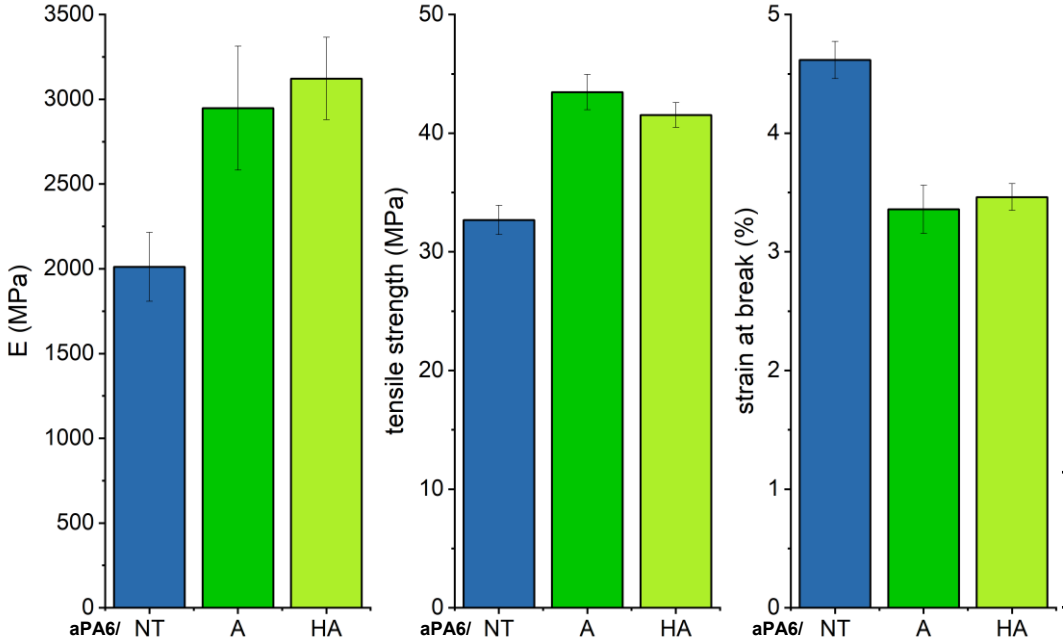


PA6/flax composites: monomer conversion

DSC (first heating scan)

TGA



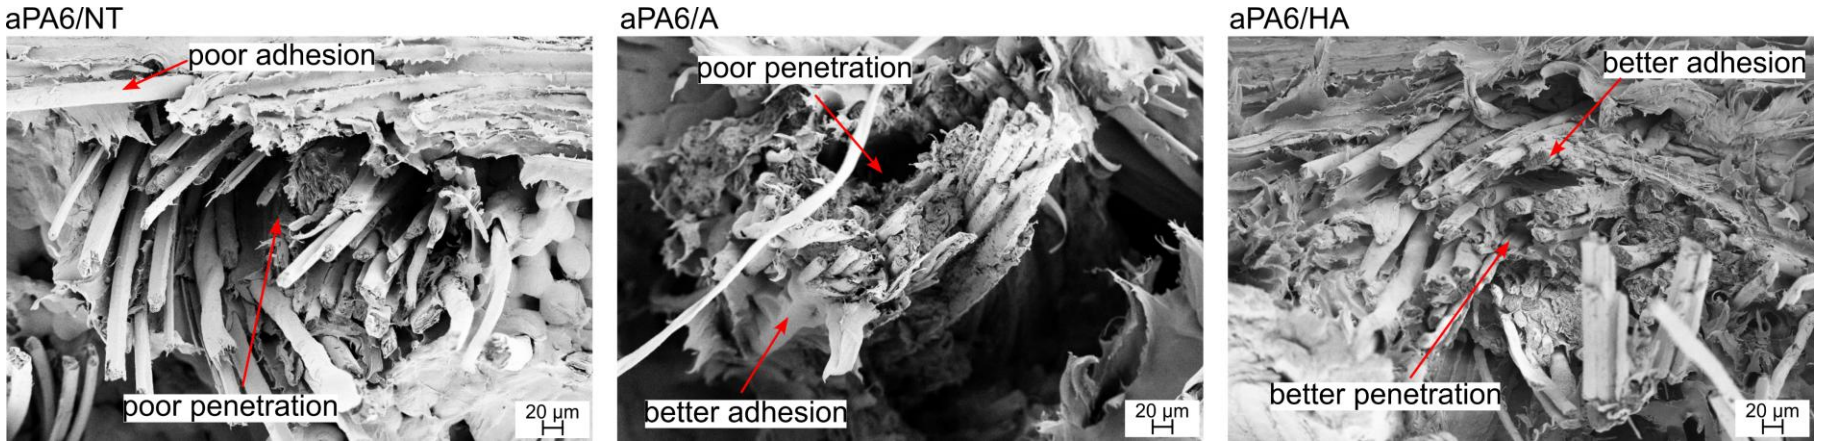


- aPA6 melting point decreases more with NT flax and less with A and HA flax
- Same trend for the conversion degree

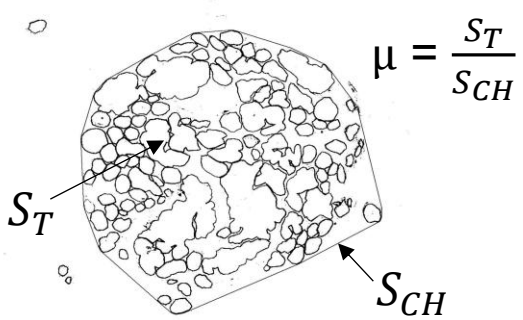
Degree of conversion (%)	
aPA6	97.6
aPA6/NT	89.5
aPA6/A	93.9
aPA6/HA	95.1

Better than literature data (DL is an effective initiator)

PA6/flax composites: tensile tests

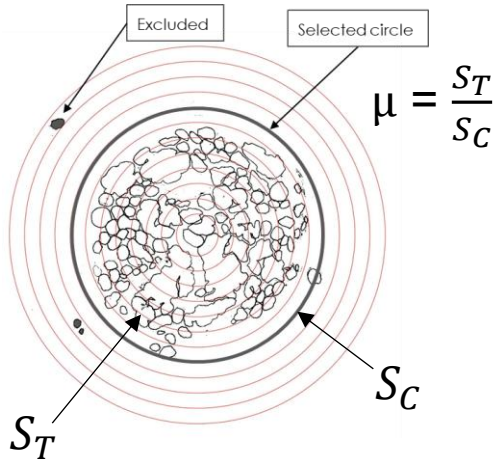


Unreinforced aPA6

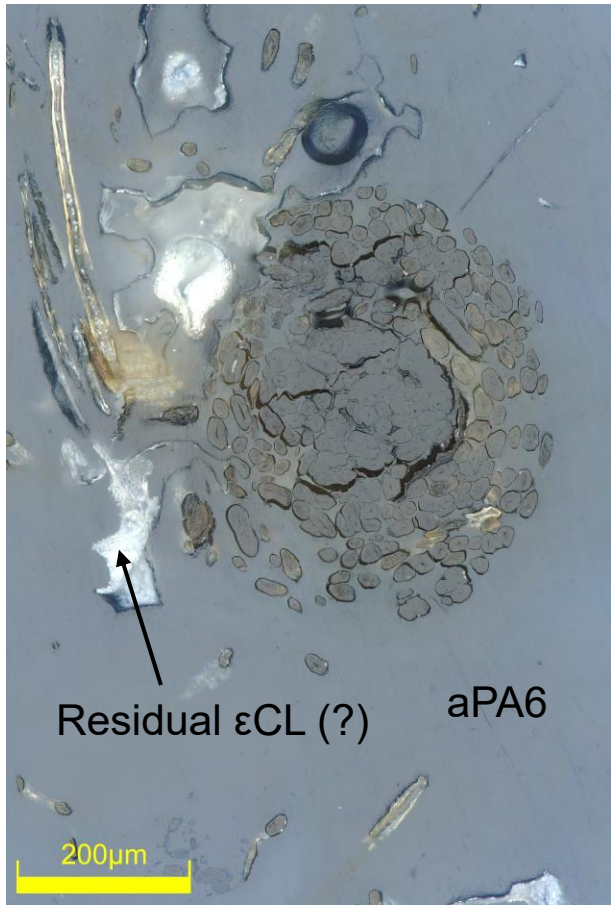


E (GPa)	2.8 ± 0.3
UTS (MPa)	60 ± 1
Strain at break (%)	63 ± 19

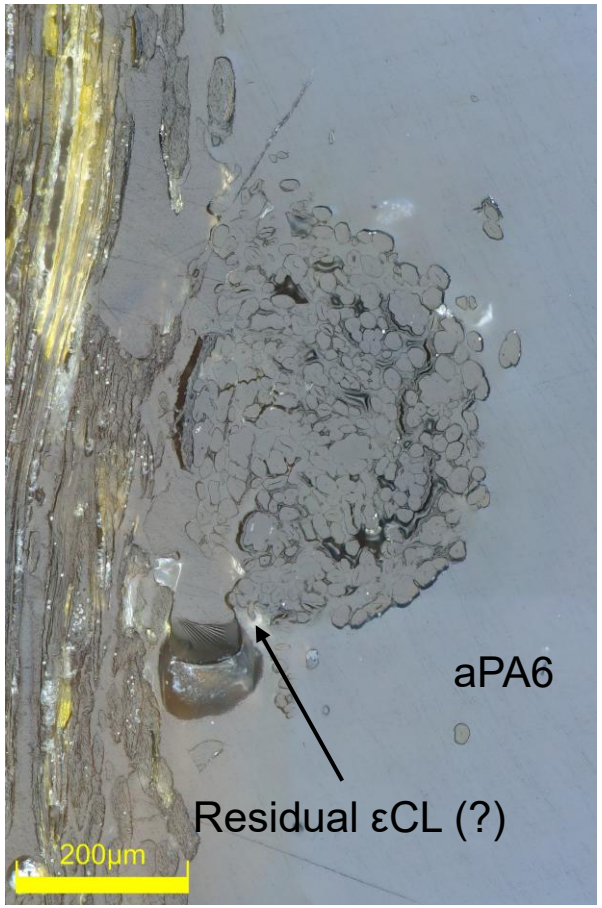
Tensile fracture surface



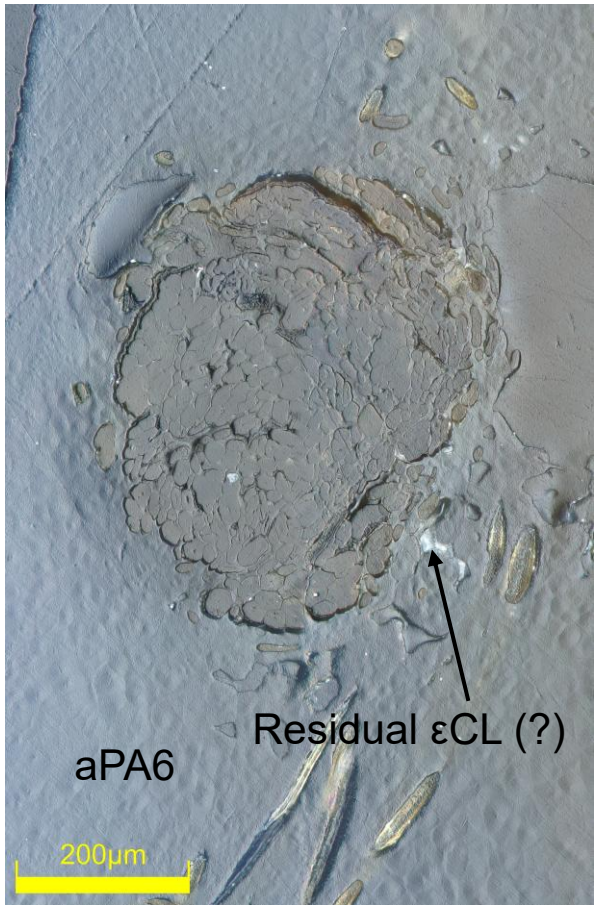
Matrix impregnation and packing factor (μ)



Convex hull



Concentric circles



aPA6/NT

aPA6/A

aPA6/HA

μ, convex hull method	0.62 ± 0.07	0.54 ± 0.05	0.64 ± 0.10
μ, concentric circles method	0.52 ± 0.08	0.42 ± 0.06	0.45 ± 0.07

Conclusions

- APTES silanization, especially if preceded by solvent treatment, **increases the monomer conversion, matrix penetration, interfacial adhesion and mechanical properties**
- The chosen initiator (Dilactamate) is suitable to reach **a high (89-95 %) degree of conversion** with a challenging reinforcement (moisture sensitivity of the anionic polymerization)
- The process and the surface treatment **has been proven effective** with a type of flax reinforcement (bidirectional highly twisted)

Current and future work

- Test the **impact** and **short-beam shear (SBS)** properties on the composites
- Explore **more environmentally sustainable surface treatments** (e.g., enzymatic treatment, collab. Univ. Ferrara, Italy)
- Look for **property maximization** with non-twisted UD fibers

FastBlade - World's First Regenerative Fatigue Test Facility

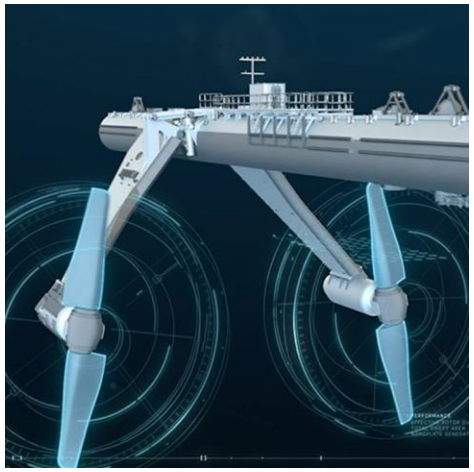
What We Do at FastBlade:

- Specialise in accelerated fatigue testing for tidal turbine blades
- Use advanced technology to simulate real-world conditions

- Develop novel tidal turbine blades and marine structures
- Aim to improve durability and performance of structures
- Collaborate on projects in renewable energy, aerospace, and other industries
- Work towards developing standards for the tidal sector

FastBlade - World's First Regenerative Fatigue Test Facility

THE UNIVERSITY of EDINBURGH

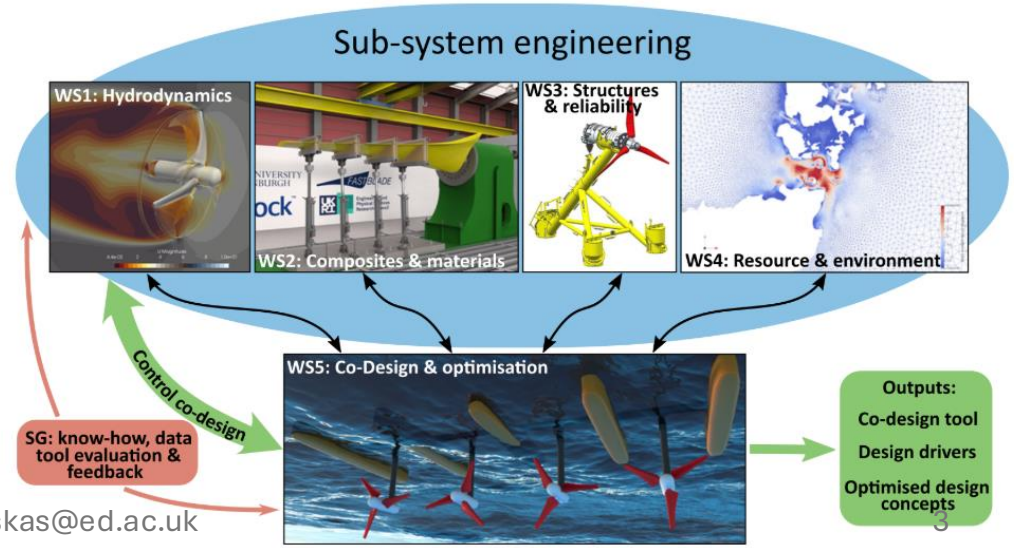


FASTBLADE

UKRI Engineering and Physical Sciences Research Council

Research projects:

- **MaxBlade** - Maximising tidal energy generation through blade scaling & advanced digital engineering



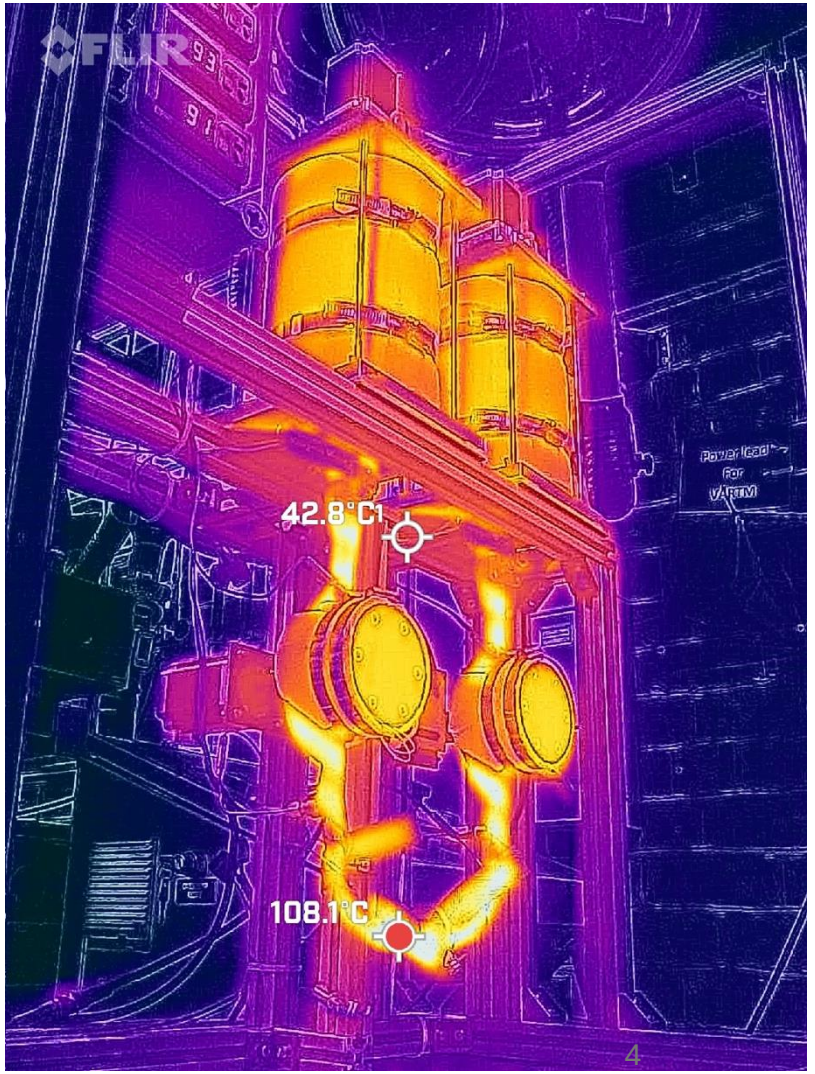
MAX BLADE

- **CoTide** - Developing and demonstrating holistic integrated tools and design processes for tidal stream energy

CoTide

Thermoplastic Infusion, In-Situ Polymerisation (TPIIP) and Double Diaphragm Forming (DDF) for Complex Parts at Scale

Fibre Reinforced Thermoplastic Composites (TPC):



- Favoured for recyclability over landfill or pyrolysis
- Enables development of secondary markets

Importance:

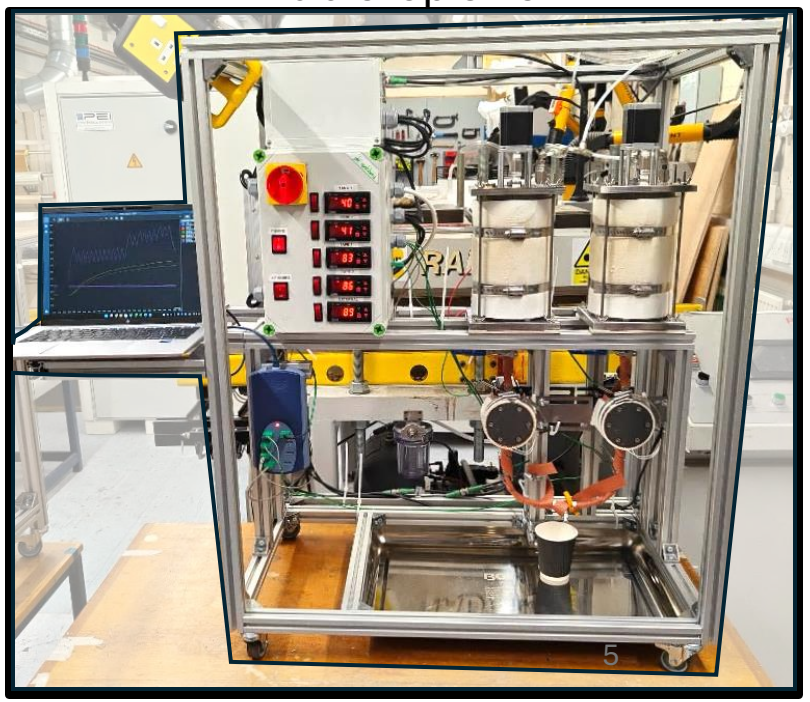
- Growing demand across sectors like renewable energy, automotive, and aerospace.

Benefits:

- Welding
- Thermoforming
- Recyclability

Objectives and Significance

Objective: Address barriers to adopting reactive thermoplastic resin transfer moulding (RTM) for glass fibre reinforced polyamide 6 composites.



Significance:

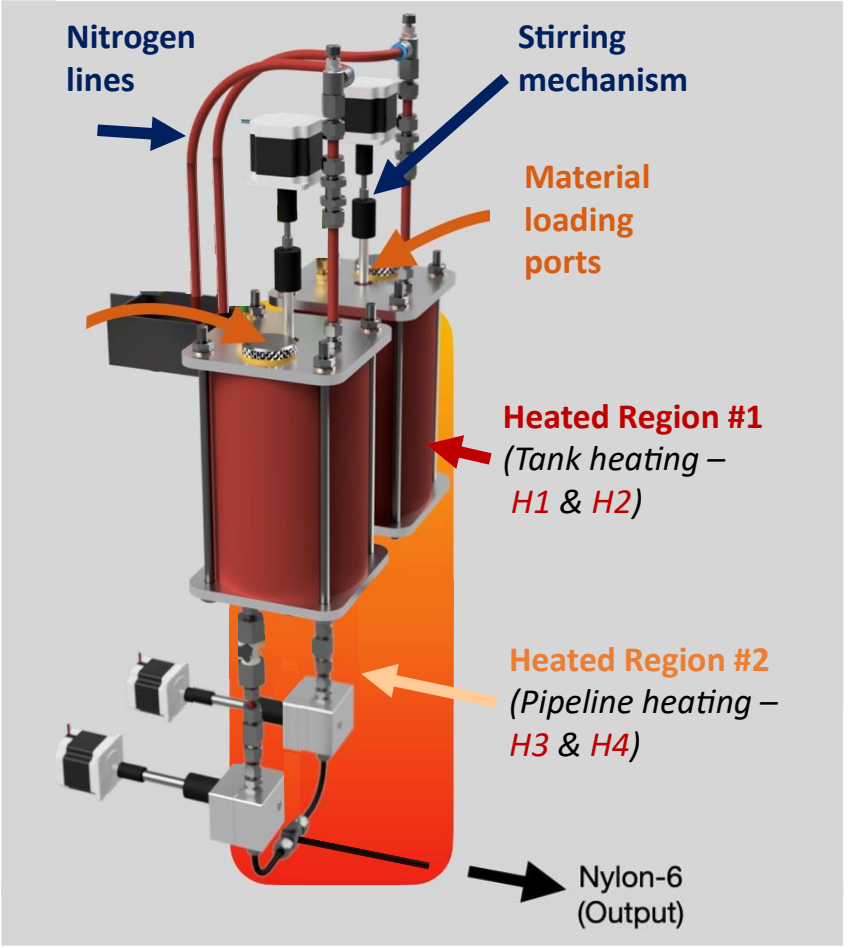
- Enables research and smaller-scale production using polyamide-6 (nylon-6) thermoplastic systems through reduced equipment costs
- Industrial-scale machines of a similar type are prohibitively expensive
- Offers insights into high-quality composite manufacturing and improved mechanical properties

Industrial scale

Tabletop size

Methodology Overview

Materials Used:



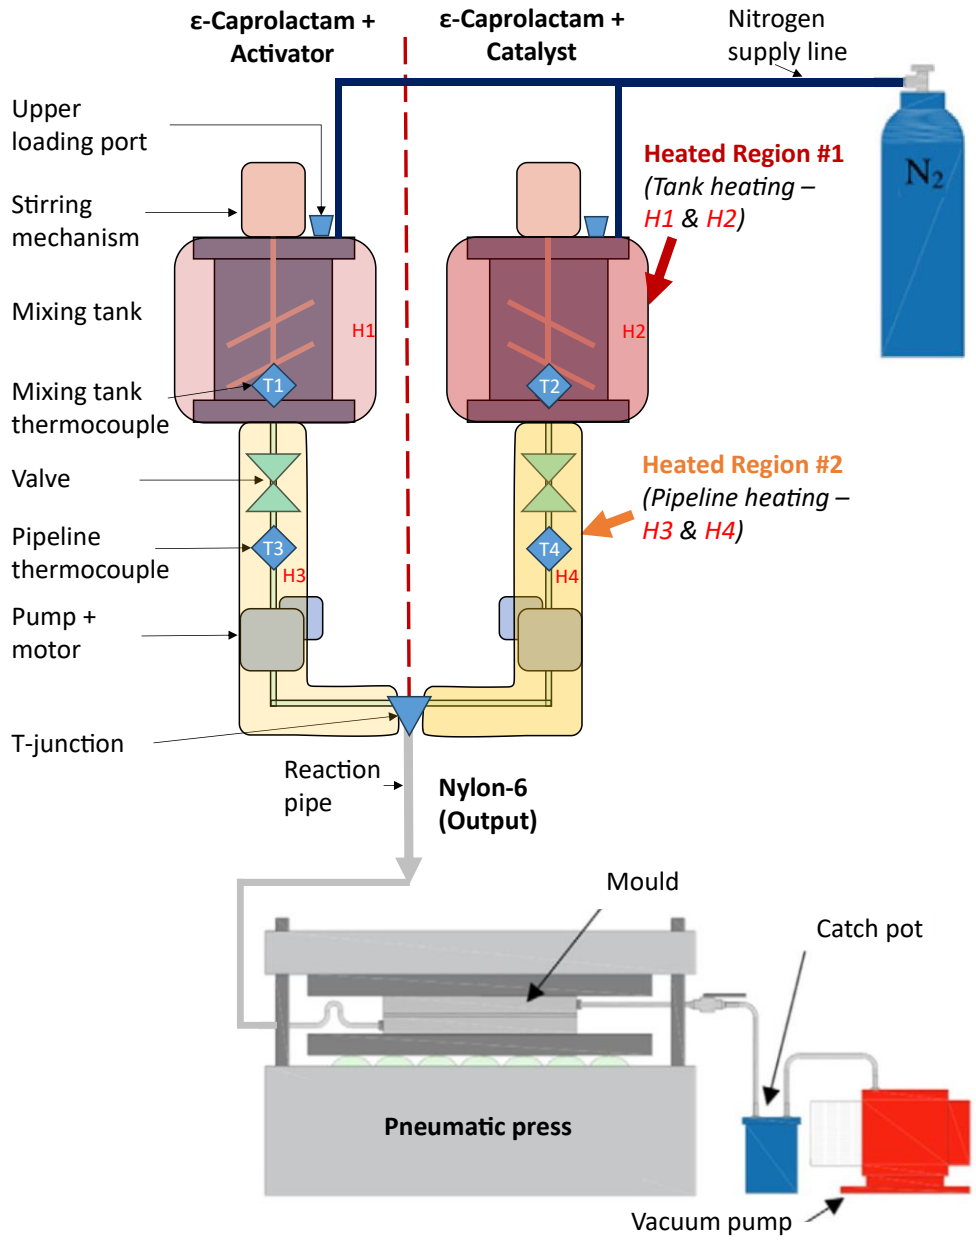
- Monomer: ε-caprolactam
- Catalyst: Sodium caprolactamate
- Initiator: Hexamethylene-1,6-dicarbamoylcaprolactam
- Reinforcement: Polyester stitched UD glass fibre NCF

Equipment:

- Custom TP-RTM machine with heated tanks, gear pumps, and a static mixing head.
- Pneumatic press and aluminium mould for composite formation.

Process:

- Components heated and injected under low pressure.
- Polymerisation occurs in situ, forming the composite.



Manufacturing Process

Steps:

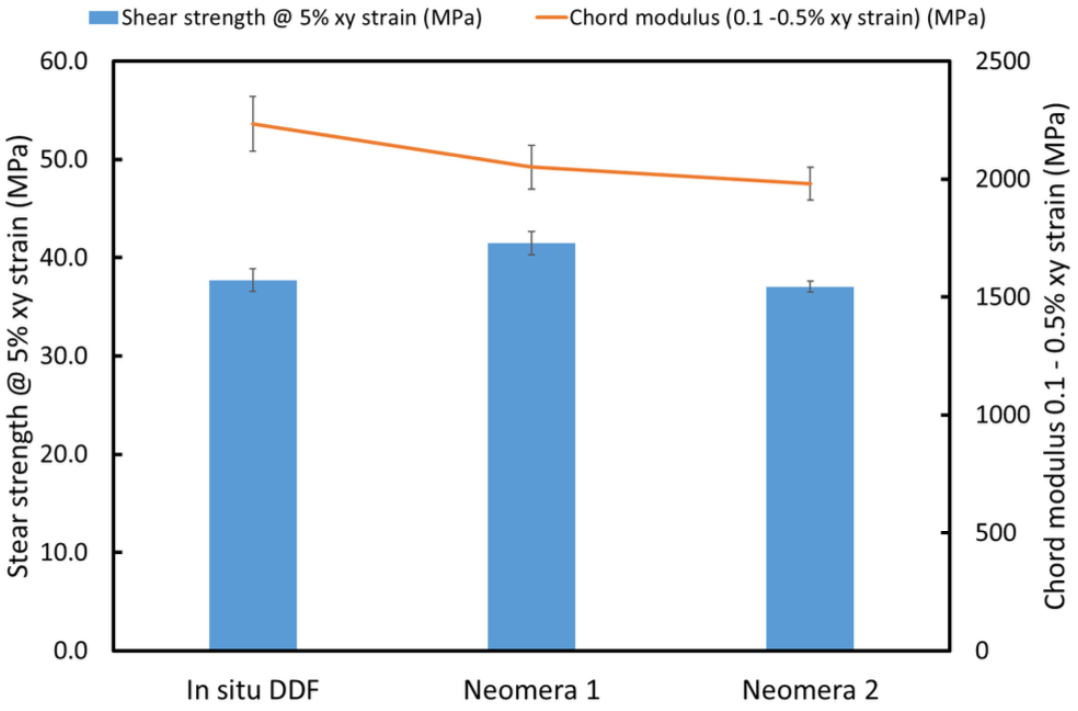
- Preparation: Drying of glass fibre fabric under vacuum.
- Injection: Low-viscosity monomers injected into the mould.
- Polymerisation: In-situ reaction forming polyamide 6 matrix.
- Cooling and Demoulding: Controlled cooling to ensure part quality.

Key Parameters:

- Injection pressure significantly lower than thermoset RTM.
- Temperature control critical for polymerisation and void reduction.

Polymerization and Manufacturing Process Overview

- After vacuum infusion, the reactant mixture polymerizes at 140–160 °C
- Benchmarked against Johns Manville's organosheet
- Successful infusion led to a manufacturing process using hot press tooling, demonstrating forming capabilities
- The "fill then form" process ensures even permeability before shaping, with polymerization below the 215 °C melt point allowing isothermal tool moulding



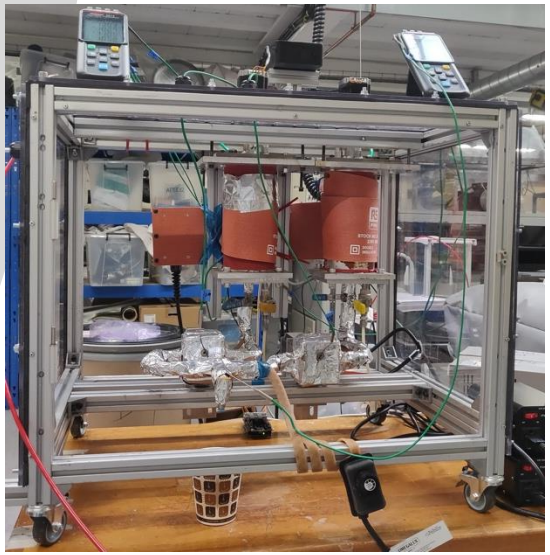


Figure 3: Results for in-plane shear testing comparing a flat panel produced using vacuum infusion between double diaphragms with two commercial organosheet panels (J. J. Murray *et al.*, Materials & Design, 2020).

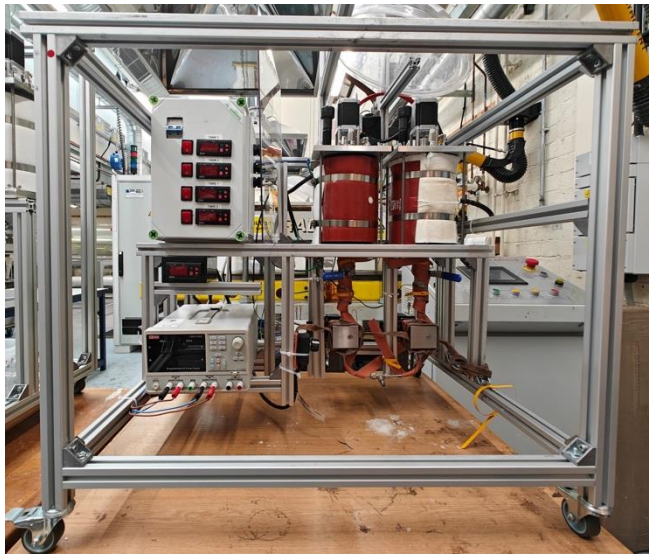
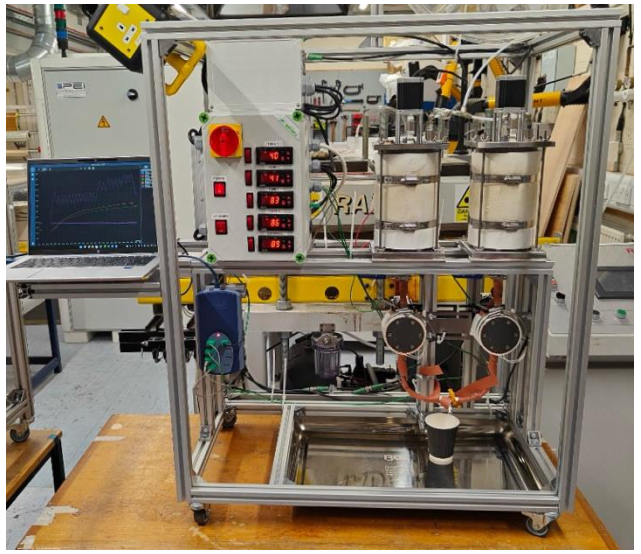


Increasing TRL levels

- Constantly increasing TRL levels
- Equipment version progression



- Research collaborators
- Industry partners

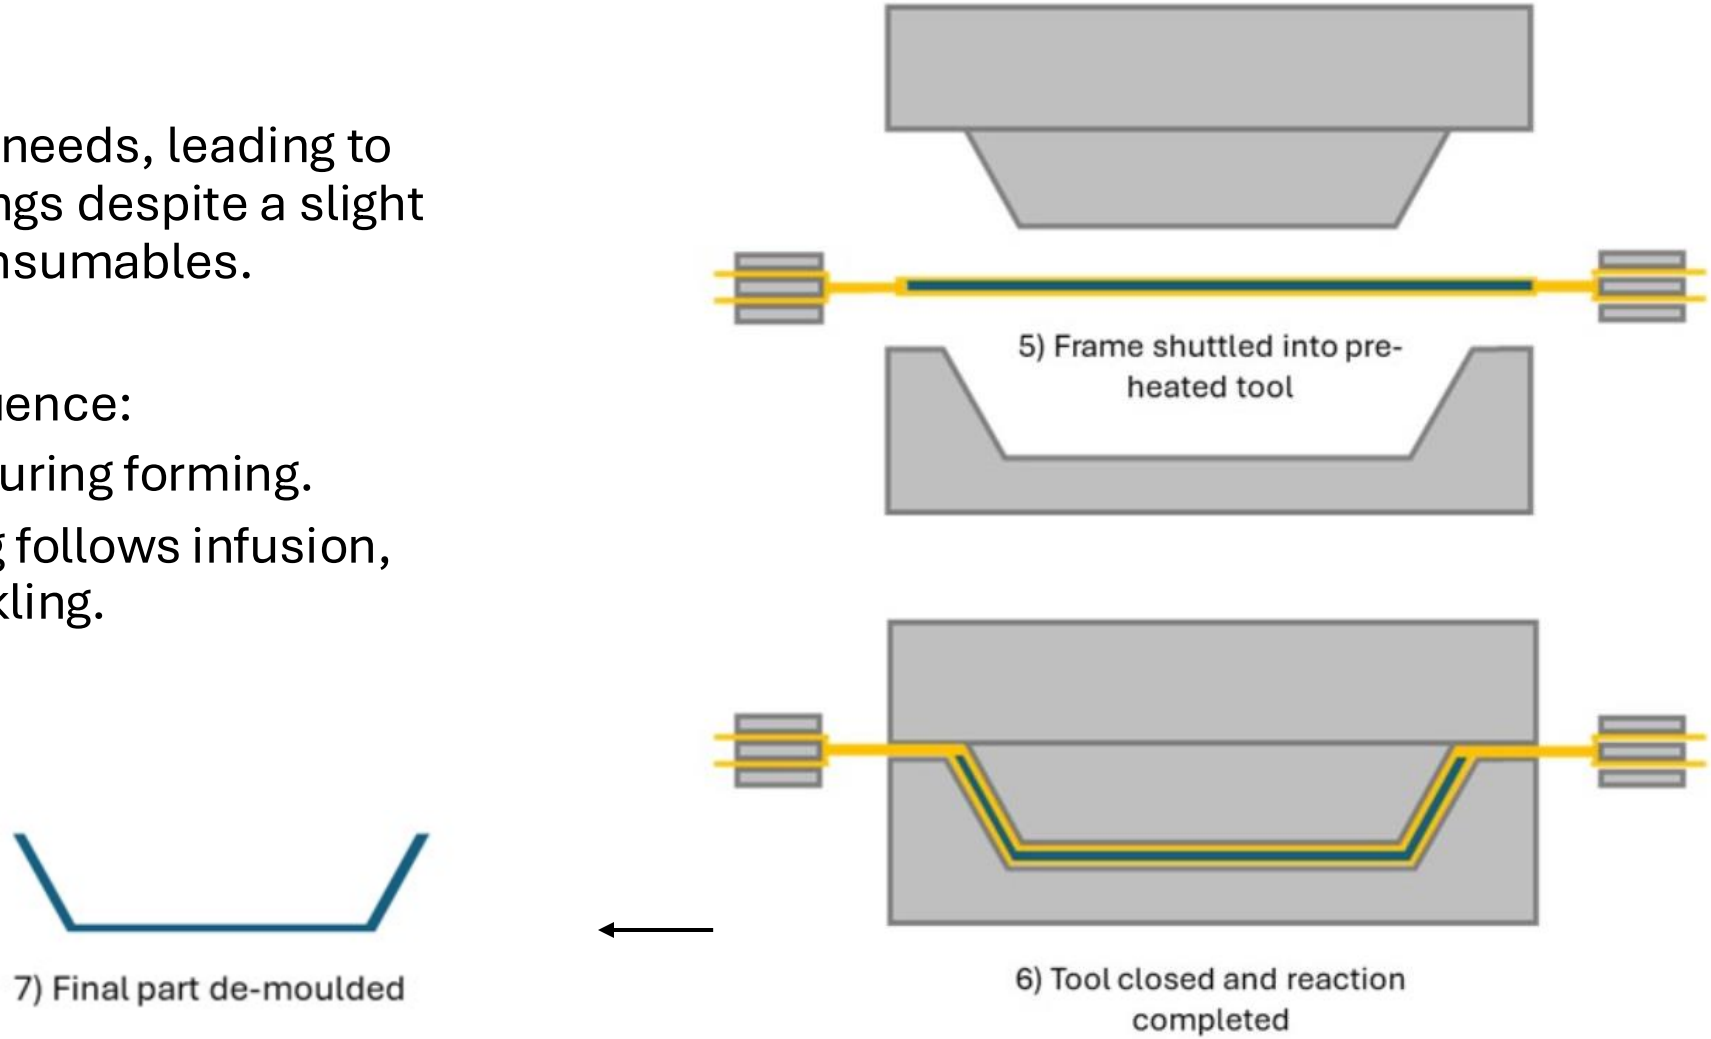
Benefits of DDF Process Variations

Dr Andrew Parsons - UoN

- Process Variations:
  - Immediate Part Formation:
    - Uses two tough, stretchable polymeric films.
    - Forms liquid thermoplastic composite blank before final polymerisation.
  - Flat Pre-Polymer Blank Production:
    - Creates a semi-polymerised oligomer resin system.
    - Can be reheated, formed, and polymerised in a press, stabilized against moisture.



Three-part frame with central vacuum channel

Benefits of DDF Process Variations

Dr Andrew Parsons - UoN

- Advantages and Efficiency:
  - Reduces metal tooling needs, leading to significant capital savings despite a slight increase in bagging consumables.
  - Fill-Form Process Sequence:
    - Lubricates fabric during forming.
    - Immediate forming follows infusion, reducing part wrinkling.

DDF Process: Current work and Challenges

Dr Andrew Parsons - UoN

- Process is temperature limited by available materials.
- Only Dahlar 9300Y, a high elongation fluoropolymer, meets mechanical and chemical demands.
- Bag strength is affected by temperature, risking pin-holing in high strain areas.
- Process is limited to a 145 °C ceiling for the tea tray tool.

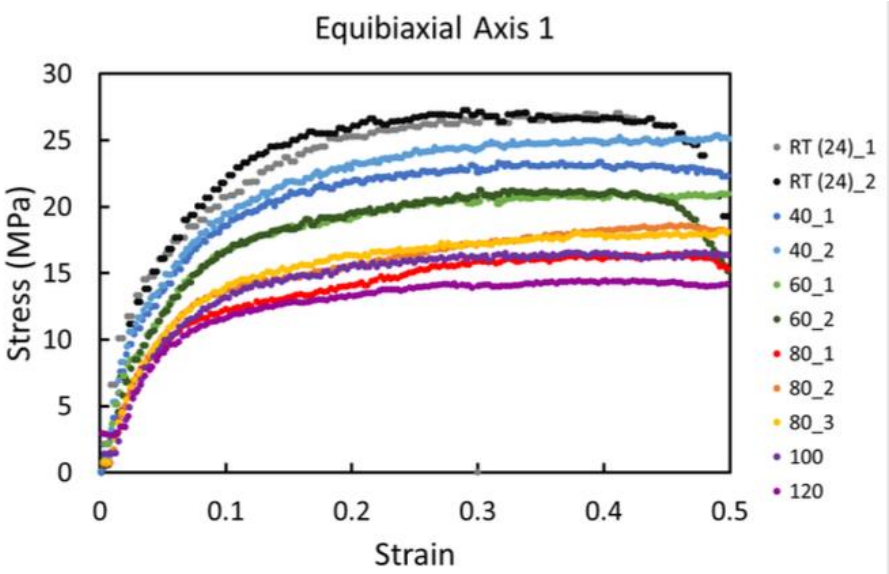


Figure 1: Temperature dependence of bagging in equibiaxial testing results.

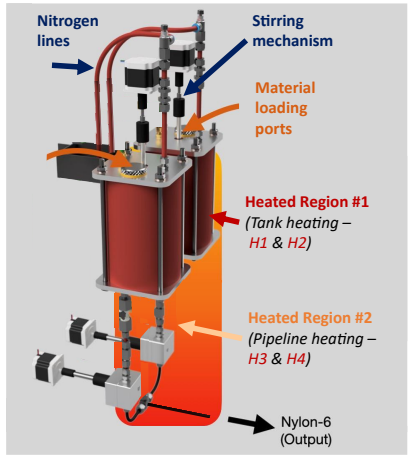

Figure 2: Pin-holing observed at regions of high strain.

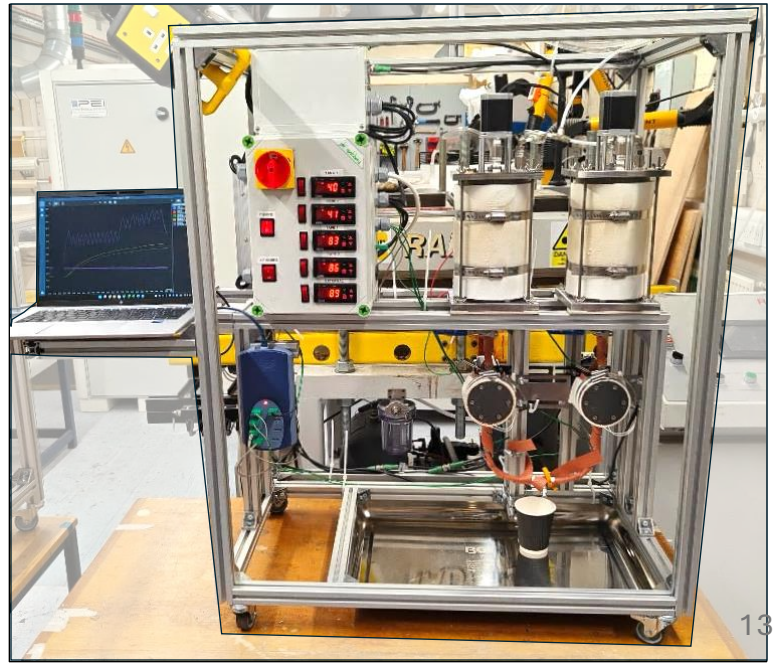
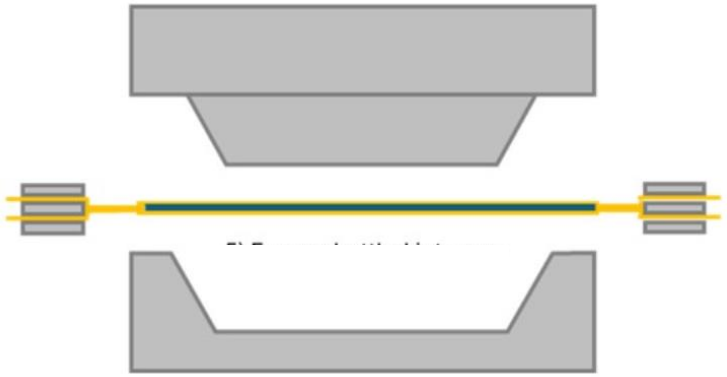


Summary: custom TP-RTM machine and the developed process



- Enables research which would not otherwise be possible due to high entry and operational costs
- Allows development work in thermoplastic (PA6), composite and other hybrid systems
- Project benefits from multidisciplinary expertise from a range of industrial partners and research institutions
- Happy to collaborate and develop custom solutions

Keywords: flexural tests, Timoshenko beam theory, relaxation data, temperature

Abstract

The importance of shearing deformation when utilizing flexural tests to determine the relaxation properties of CF/PEKK [1] composites as a function of temperature is discussed in the context of Timoshenko beam theory with the goal of understanding differences between the 0-degree and 90-degree test results. Relaxation data are presented for relaxation moduli developed with the conventional dynamical mechanical test system. The range in temperature examined was 30 – 350 ^{0}C.

1 INTRODUCTION

The use of the three-point bending test to develop quasi-static and viscoelastic stress relaxation properties of polymers is well documented in the literature [2-3]. Furthermore, dynamic mechanical analysis (DMA) test facilities required to carry out these experiments as a function of temperature typically utilize property characteristics restricted to isotropic materials when converting imposed flexural deformation or force to determine the flexural stress within the test specimen. Of course, the correct relationship between applied deflection and the resulting stresses in the specimen for both orthotropic and isotropic systems is well known as Timoshenko beam theory [4].

$$\delta_T = \frac{PL^3}{48EI} + \frac{PL}{4k_s GA} \tag{1}$$

Where E and G are the appropriate Young's and shearing moduli of the orthotropic or isotropic medium for the 0-degree test geometry. In the present case, the two test geometries are in the 1-3 plane (0-degree test) and 2-3 plane (90-degree test) planes, where the fiber direction is 1, and the thickness direction is 3. The properties in equation (1) for the 0-degree specimen are thereby, E_{11} and G_{13}. For the 90-degree test, the Young's modulus is E_{22} and the shearing modulus, G_{23}. The other variables in equation (1) are the applied central load, P, the specimen span, L, the beam moment of inertia, I, cross-sectional area, A, and shear correction factor, k_s. Flexural stress calculation as a function of the applied load, P is identical for both beams of isotropic and orthotropic media.

The flexural test is typically used with confidence in prediction of Young's modulus for isotropic materials systems. However, for highly orthotropic materials this approach can produce misleading results, as discussed in reference [3]. Table 1 illustrates the conventional approach in utilizing only the first term of equation (1) to predict Young's modulus for a CF/PEKK composite. As discussed in reference [3], the modulus data developed within the Q800 DMA System of TA Instruments and utilized in the present study can yield moduli data for thin specimens that can be as much as 10-20 Percent in error.

2 APPARENT REDUCTION IN YOUNG'S MODULUS, E_{11}

The E_{11} modulus experimental data for the 0-degree flexure test are shown in Table 1. Furthermore, the data sheet of reference [1] shows the tensile and compressive moduli of the composite to be 139.0 GPa and 127.0 GPa, respectively. Thus, the ambient test results of 126. 42 GPa is only 5 percent less than the average of tensile and compressive modulus values reported in reference [1].

Temp. ^{0}C	30	120	150	180	210	240	270	300	330
E_{11}, GPa	126.42	130.89	128.27	120.40	115.30	107.55	99.29	80.61	18.05

Table 1 Values of E_{11} determined from deflection, δ and force, P utilizing classical beam theory (only first term in equation (1))

The data in Table 1 imply that the Young's modulus, E_{11}, is reduced from 126.42 GPa at 30 ^{0}C to 18.05 GPa at 330 ^{0}C. Yet the modulus of carbon fiber does not change over this temperature range and the contribution of the matrix phase to the composite tensile modulus is of second-order. Hence, it must be concluded that utilizing the conventional approach to determine E_{11} temperature dependence of the CF/PEKK composite will not yield the desired results. The following discussion explores the causes for this inconsistency.

3 RELATIVE SHEARING DEFORMATION TO FLEXURAL DEFORMATION

Equation (1) illustrates the relationship between the total beam central deflection, δ_T and that due to both the flexural stress, δ_f and to the shearing stress, δ_s. The constant, k_s is an area correction factor, typically taken as 5/6 for beams of rectangular cross-section. The important message of equation (1) is that both flexural stress and shearing stress contribute to the beam deflection and that their relative contributions can be measured by the ratio of the two terms, as shown in equation (2). Furthermore, the ratio of the Young's modulus to the shearing modulus and the square of the ratio of the beam height to beam span are shown to determine the relative contributions of the two deformation modes.

$$\frac{\delta_s}{\delta_f} = \left(\frac{1}{k_s}\right)\left(\frac{E_{11}}{G_{13}}\right)\left(\frac{h}{L}\right)^2 \tag{2}$$

Equation (2) can be utilized to determine the beam aspect ratio (L/h) that minimizes the influence of shearing deformation upon beam deflection, but its use requires knowledge of both the material

shearing modulus and Young's modulus. For isotropic materials, the shearing modulus and Young's modulus are related by the Poisson's ratio, ν.

$$\frac{\delta_s}{\delta_f} = \frac{12(1+\nu)}{5}\left(\frac{h}{L}\right)^2 \approx 3\left(\frac{h}{L}\right)^2 \tag{3}$$

Thus, for isotropic materials in bending, the ratio of the shearing to flexural displacements is less than 0.002 for L/h = 45, (ν = 0.3). In the present study, the DMA span was set at L = 50 mm and for the beam height of 1.08 mm, the ratio was 0.001. This ratio is clearly acceptable for isotropic systems, but this may not be the case for orthotropic materials where the ratio of Young's modulus to shearing modulus can be quite large.

4 FLEXURAL TESTS FOR VISCOELASTIC RELAXATION

Dynamic mechanical analysis (DMA) test facilities are often utilized to measure viscoelastic stress relaxation of composite materials such as CF/PEKK. A typical DMA test facility is shown in Figure 1 where the load or displacement control actuator and the pin supports are shown. The beam loading condition in Figure 1 is for three-point bending. The span length shown is 50 mm, but the apparatus can be adjusted for span length of 25 mm, as well.

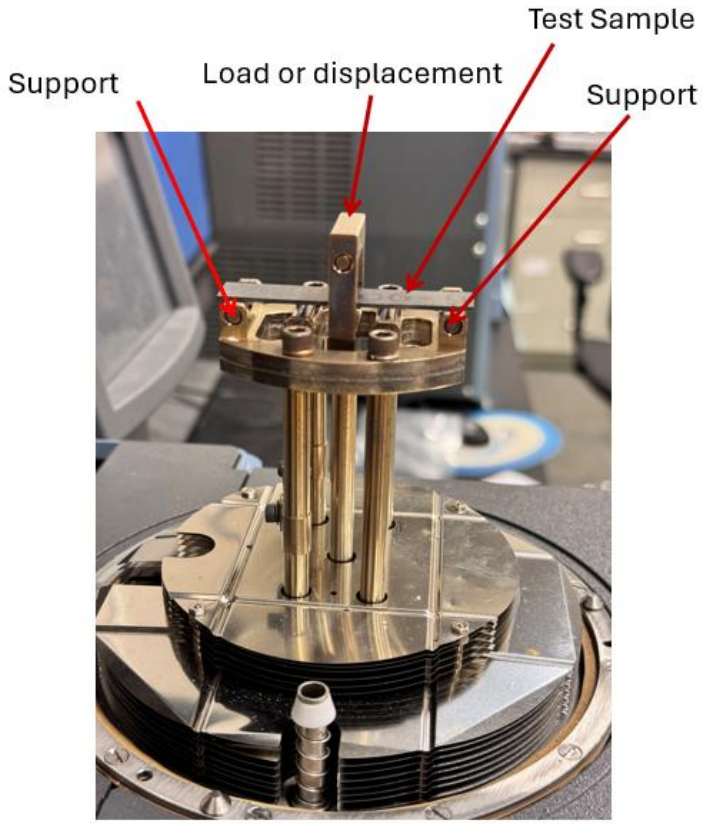

Figure1. Conventional DMA Test Facility for Three-point Flexure Tests

The DMA test facility allows for control of the time-temperature history of the test sample for harmonic or creep/relaxation loading conditions. Stress relaxation experiments are carried out by imposing a specified deflection at the mid-span of the beam and monitoring the reduction in the applied force with time. For isotropic materials, the relationship between beam deflection and flexural stress, utilizing Euler-Bernoulli beam theory, is well known and is correct for these materials for $L/h \geq 45$. However, as shown in the previous section, this is not true for highly orthotropic materials such as CF/PEKK in the 0-degree test geometry. Thus, issues with the role of shearing deformation in flexural testing under multiple temperature conditions are also present for viscoelastic stress relaxation. Furthermore, the relationship between total beam deflection and force involves both flexural and shearing deformation components in the viscoelastic case, just as it does in quasi-static testing.

The viscoelastic experimental results for the 0-degree composite beam composed of CF/PEKK is shown in Figure 2. The data presented in Figure 2 were determined by the conventional DMA system wherein a constant central displacement of 0.193 mm was imposed and the decay in force with time was recorded as a function of temperature.

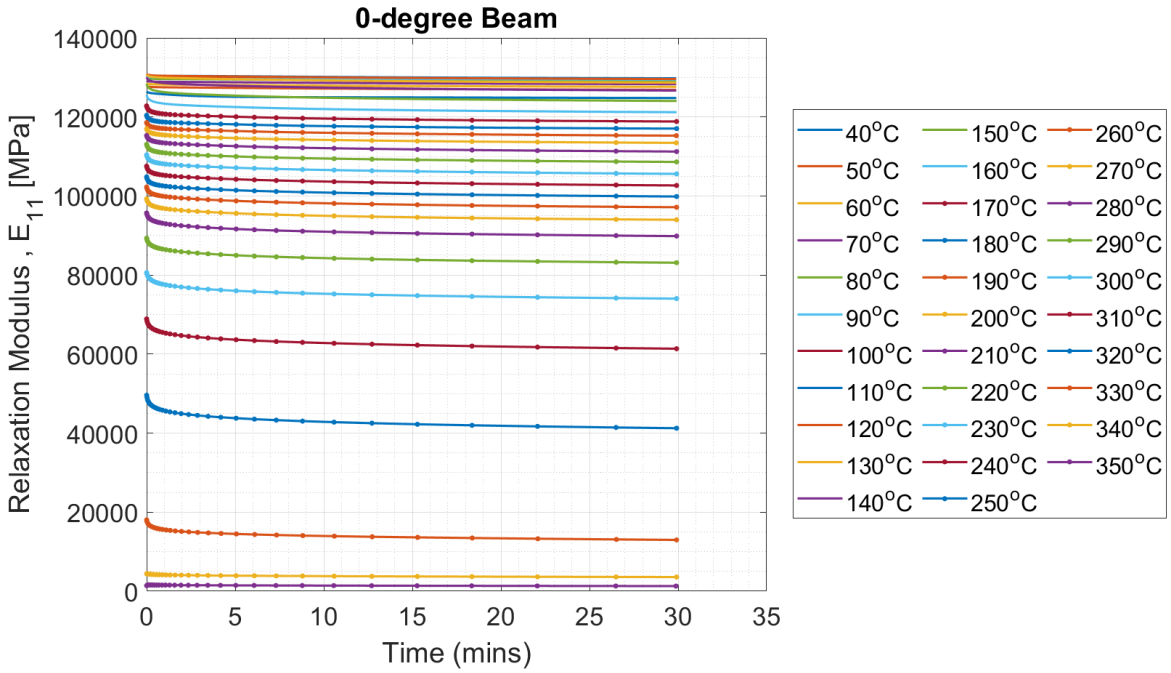

Figure 2. Apparent relaxation data for the 0-degree CF/PEKK composite beam in three-point bending

The dilemma presented in the foregoing discussion is that to separate the contributions of flexural and shearing deformations to determine beam total deformation requires knowledge of the very property that the test is designed to determine, namely E_{11} and G_{13}. Thus, a strategy must be

developed to quantify the relative contributions of the two deformation modes over the temperature range of interest. For the 0-degree specimen, test temperature provides the vehicle for this separation because the deformation due to shearing stress shows significant change with temperature, while the deformation due to flexural stress does not. This characteristic of the 0-degree specimen was illustrated earlier through equation (2). In Timoshenko beam theory [4], the two deformation modes are coupled in series and both support the same applied load, P, while contributing individually to the total deflection, δ_T. If the Young's modulus, E_{11} is taken as equal to the value measured at instantaneous, ambient conditions and to be independent of temperature, then deformation due to the flexural normal stress, δ_f can be calculated using Euler-Bernoulli beam theory (first term in equation 1) and subtracted from the total deflection to determine the deflection due to the shearing stress, δ_s.

Test data from the DMA in Figure 3 shows 90-degree modulus relaxation data taken for a CF/PEKK composite subjected to three-point bending of the 90-degree specimen over the temperature range of 40 ^{0}C to 300 ^{0}C. Hexagonal symmetry at the microscopic scale of the CF/PEKK implies that the 2-3 plane is a plane of transvers isotropy. Thus, the 90-degree flexure specimen satisfies minimization of the shearing contribution to lateral deflection at a specimen length to height ratio of 45. These results show that the relaxation modulus exhibits significant dependence upon temperature, falling from 9034 MPa at 30^{0}C to 273 MPa at 300 ^{0}C. Furthermore, significant relaxation in stress occurs in the first minute after application of the applied displacement.

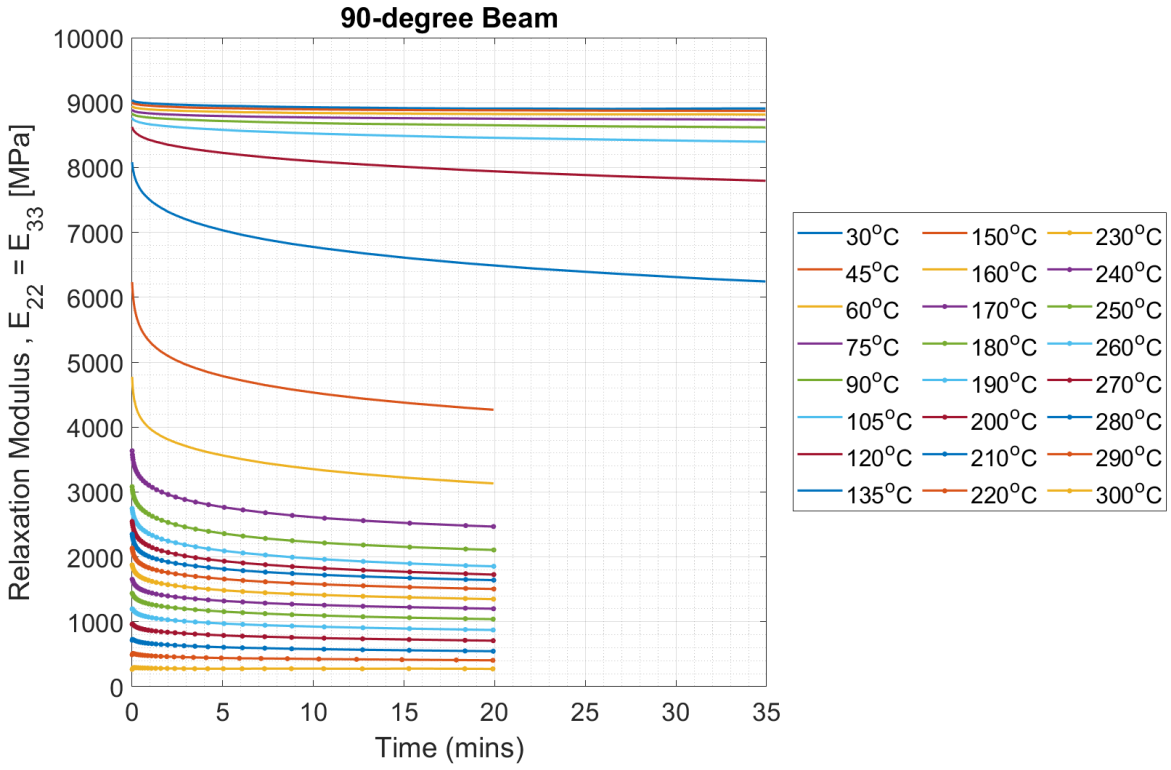

Figure 3 Relaxation of the transverse modulus, E_{22} from 30^{0}C to 300 ^{0}C

Given that the polymer matrix relaxation is largely responsible for relaxation of all matrix-dominated properties of the composite, the composite shearing modulus, G_{13} should exhibit quite similar behavior to E_{22}. Thereby, the authors chose to derive the relaxation properties in shear from the 90-degree data by fitting the form of the 90-degree relaxation data to the t = 0, T = 30 ^{0}C value for shearing modulus (5297 MPa) reported in the literature [5]. The resulting shearing modulus relaxation data for G_{13} are shown in Figure 4 where the primary relaxation occurs in the first 5 minutes at T $\geq$ 240 ^{0}C.

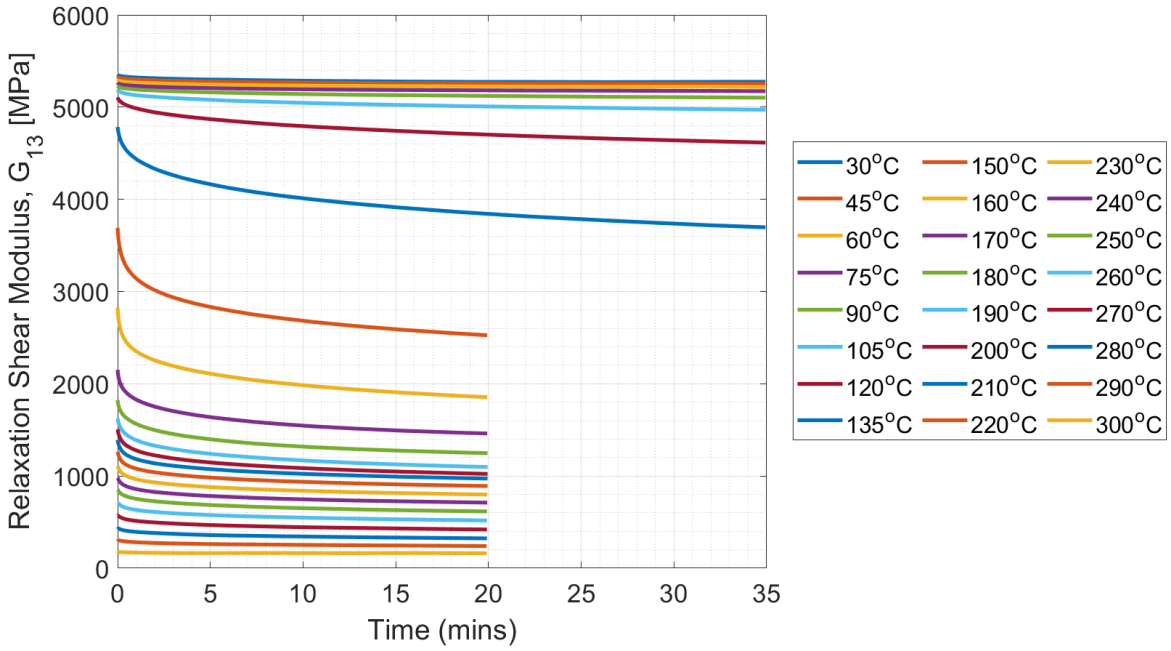

Figure 4 Relaxation data for the transverse shearing modulus, G_{13}

5 SHEAR MODULUS RELAXATION

Data for G_{13} presented in Table 2 were derived from the instantaneous values of the shearing modulus as a function of temperature shown in Figure 4. Experimental results and predictions (Equation 1) of the magnitude of the quasi-static, central force, P in three-point bending in the DMA Test system are presented for multiple temperatures and for a fixed displacement of 0.193 mm. The test specimen geometry was L = 50 mm, h = 1.08 mm and specimen width of 12.48 mm. If the Young's modulus, E_{11} is held constant at 126.42 GPa for the calculations and the shearing modulus is varied from 5297 MPa to 158 MPa, it is informative to examine the predicted force required to sustain the 0.193 mm in deflection as shown in Table 2. The close agreement between predictions and experiments for the magnitude of the force required to produce a deflection of 0.193 mm shows that the dominant contribution to the observed apparent relaxation of E_{11}, is actually due to relaxation of G_{13} and not relaxation of E_{11}.

^{0}C	G_{13}, GPa	E_{11}, GPa	$P^{Predicted}$, N	$P^{Experimental}$, N

Table 2 Predicted and experimental central force, P for three-point bending of the 0-degree test geometry at temperatures ranging from 60 – 300 ^{0}C for CF/PEKK composite

These results show that while the influence of temperature on deflection of the 0-degree beam would typically be expected to be due to a reduction of the Young's modulus, E_{11}, with temperature, the predictions of the force were carried out with equation (1) wherein E_{11} was held constant at 126.42 GPa. With temperature dependence of the shearing modulus, G_{13} utilized in the force predictions, good agreement between predicted force and observed force was demonstrated. This approach is counter to conventional interpretation of the use of the flexure test as a method to determine the temperature dependence of the Young's modulus. However, the general agreement between the predictions and experimental results demonstrate that when deflection is used as a measure of beam stiffness, there are two contributors to that stiffness and not one. Further, these results indicate that the major contributor to reduction in stiffness due to temperature in 0-degree flexure test is the shearing modulus, G_{13} and not E_{11}.

6 CONCLUSIONS

The first and primary conclusion of this work is that the 0-degree flexural test is inappropriate for the measurement of the time and temperature-dependent properties of the Young's modulus, E_{11}. Rather, this test yields data that reflects the time-dependent properties of the shearing modulus, G_{13}. Furthermore, extraction of G_{13} relaxation data from the 0-degree flexure sample test data, while plausible, is numerically difficult due to the form of equation (1) wherein G_{13} is in the denominator of the second term. This study also shows that the flexure test for the 90-degree fiber orientation geometry provides adequate data for the time dependent properties of the transvers Young's modulus, E_{22} so long as the beam aspect ratio, $L/h \geq 45$. Although the choice to derive the relaxation

data for the shearing modulus, G_{13} from that of the transverse Young's modulus, E_{22} is an approximation, it was shown to be useful in establishing the relationship between flexural deformation of the 0-degree sample and G_{13}, as witnessed by the agreement between predicted and observed relaxation force magnitudes. Finally, the difference between the tensile and compressive elastic modulus, E_{11} for the CF/PEKK materials system (139.0 GPa versus 127.0 GPa) was not considered in the present study, although results in reference [6] suggest the effect is of second order for CF/PEKK [1].

5. Conclusions

- A transition from brittle-like to ductile load response is found as the yarn angle increases.
- A mesoscale RVE model is developed to examine this transition as well as the progressive failure of woven thermoplastic composites.
- Large deformation with yarn rotation and fabric inter-locking effects are captured in large yarn angle RVEs.
- The failure mode changes from being dominated by fiber fracture in small yarn angle RVEs to being jointly dominated by fiber and matrix damage in large yarn angle RVEs.

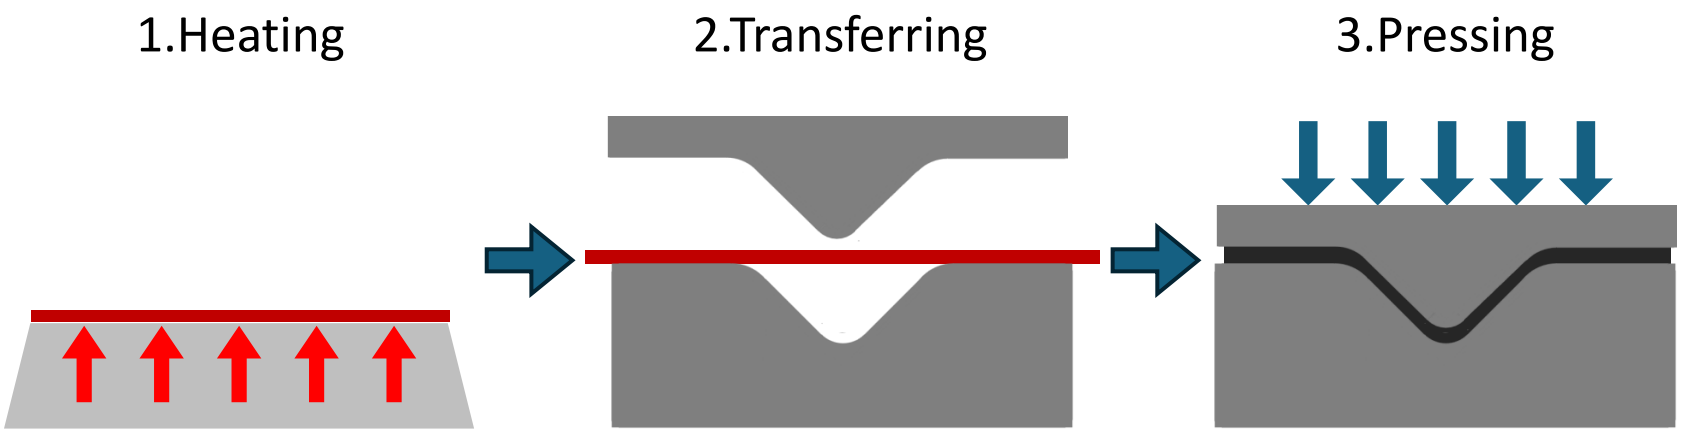
Tracking Ply Deformation during Thermoplastic Stamp Forming using Embedded Shape Sensor

K. Chikamori, S. Minakuchi*

The University of Tokyo

Background

Stamp forming process



Advantage

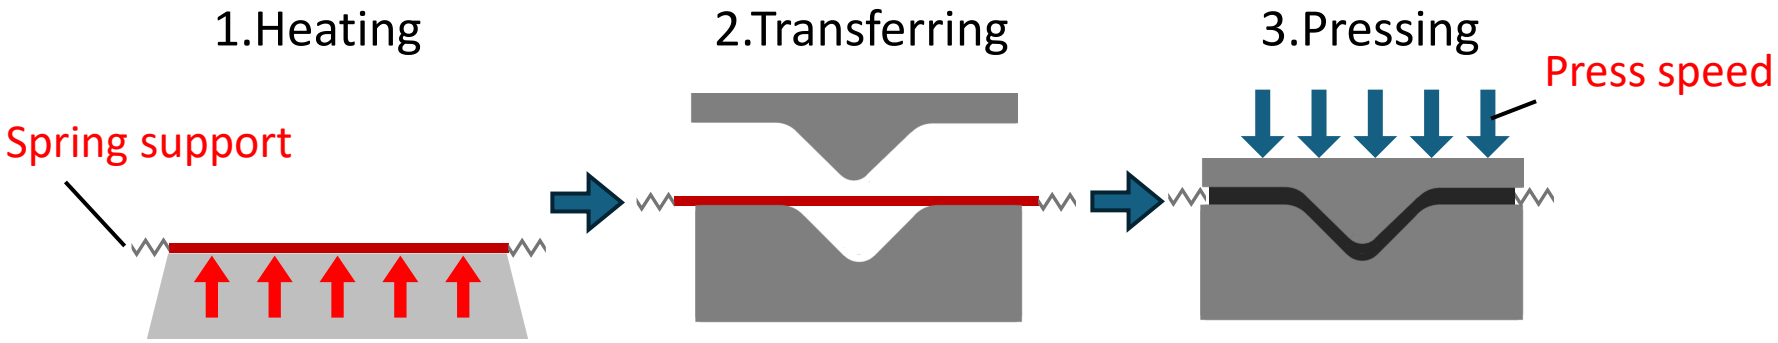
✓ High-rate ✓ High-quality ✓ Complex structures

Background

Depending on forming conditions, heated composite plate is not properly pressed against mold….

- ✓ Areas of wavy plies and inadequate pressurization occur
- ✓ Mechanical properties of manufactured parts are reduced.

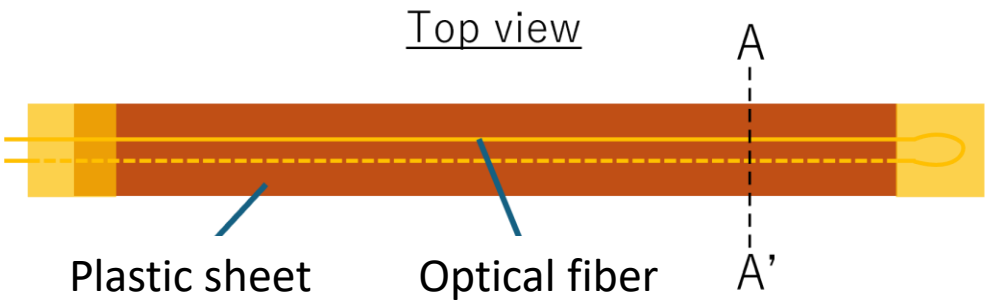
Now, forming conditions set by trial and error based on observations after forming



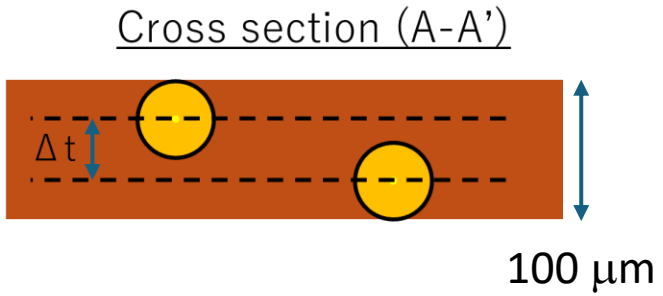
New in-situ measurement technology is needed to measure deformation of each ply during forming

Objective

- ✓ **Measure deformation of thermoplastic composites during stamp forming using shape sensor (originally for thermoset composites*)**
- ✓ **Investigate influence of forming parameters on deformation behavior**

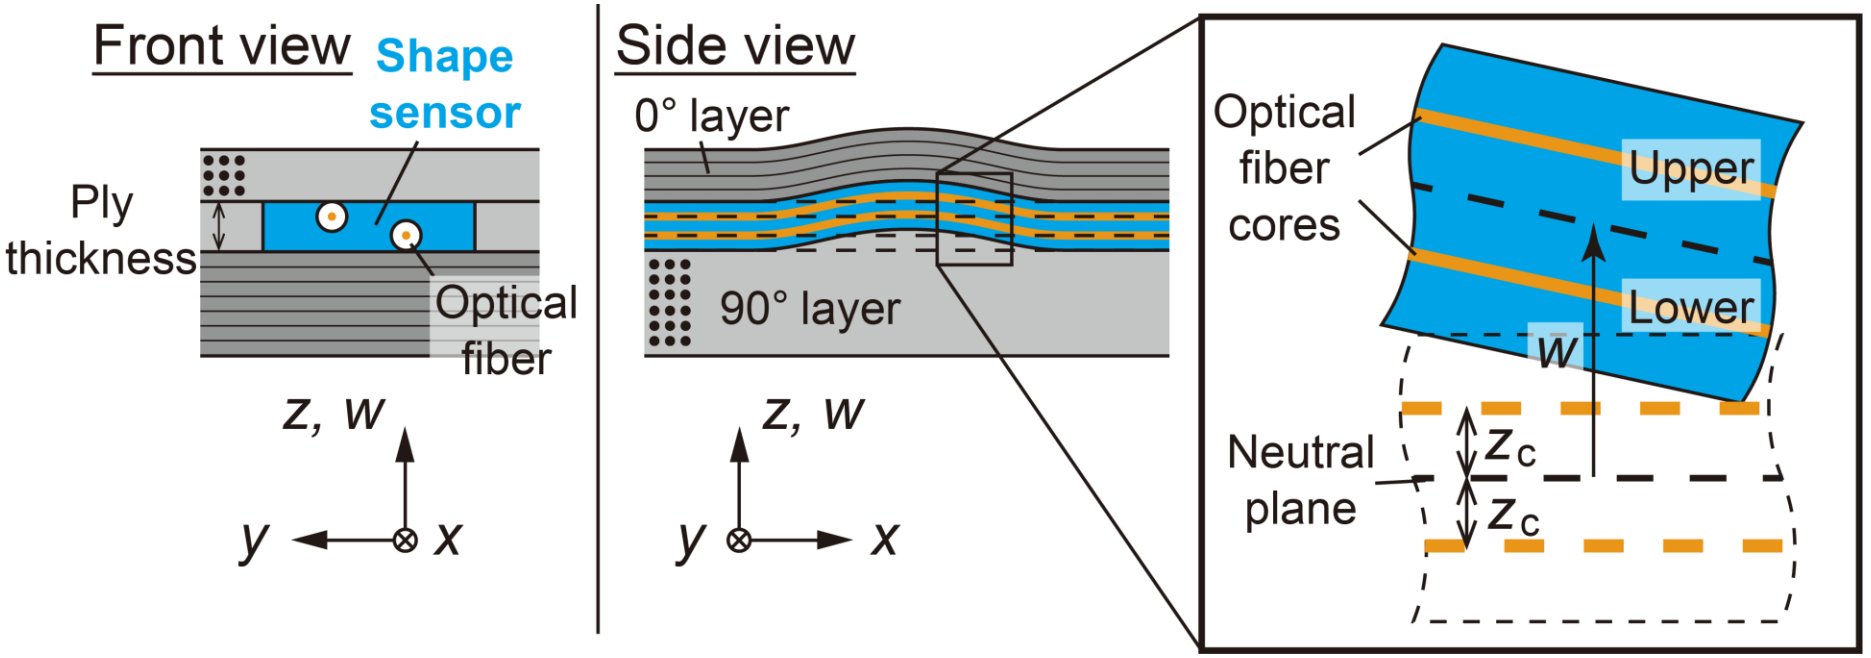


*S. Minakuchi, S. Niwa, N. Takeda. "Strip-Type Embeddable Shape Sensor Based on Fiber Optics for In Situ Composite Consolidation Monitoring" Sensors 22, no. 17: 6604 (2022)
*T. Tamagawa, Y. Mori, S. Minakuchi. "Consolidation mechanism of composite corners cured on convex and concave tools" Composites Part A: Applied Science and Manufacturing 169, 107500 (2023)



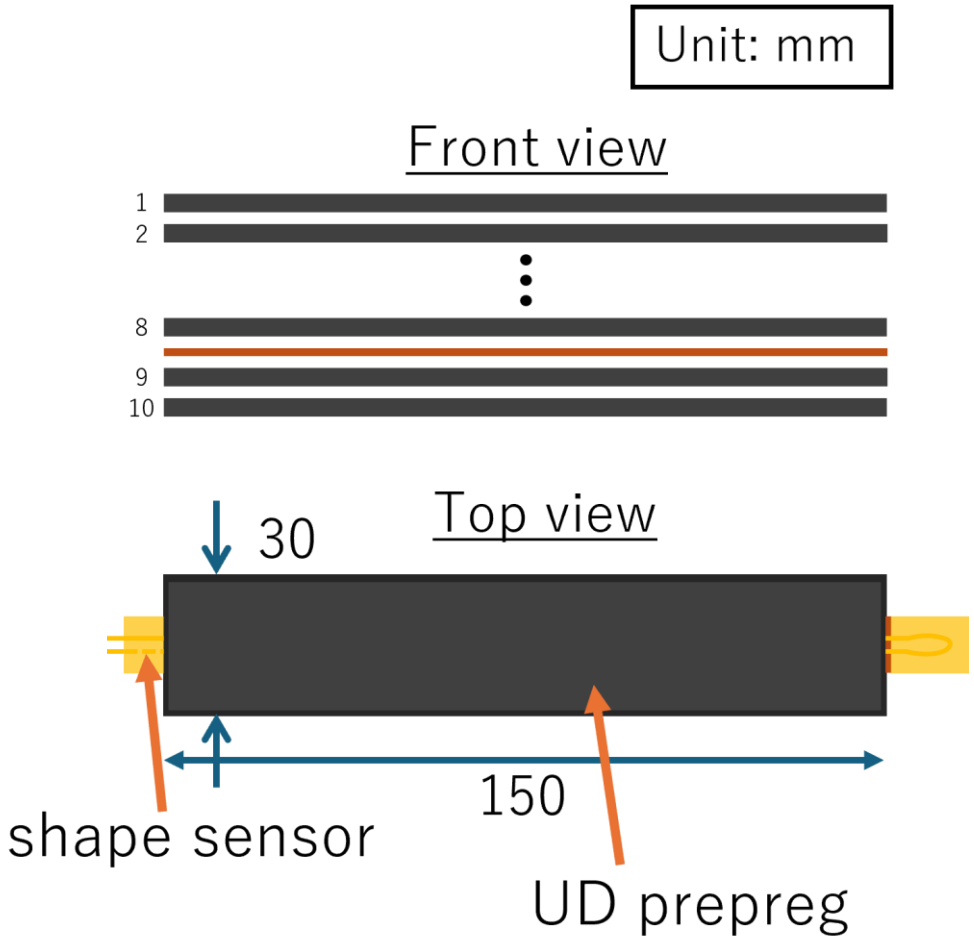
Forming parameters to be investigated

Strip-type shape sensor



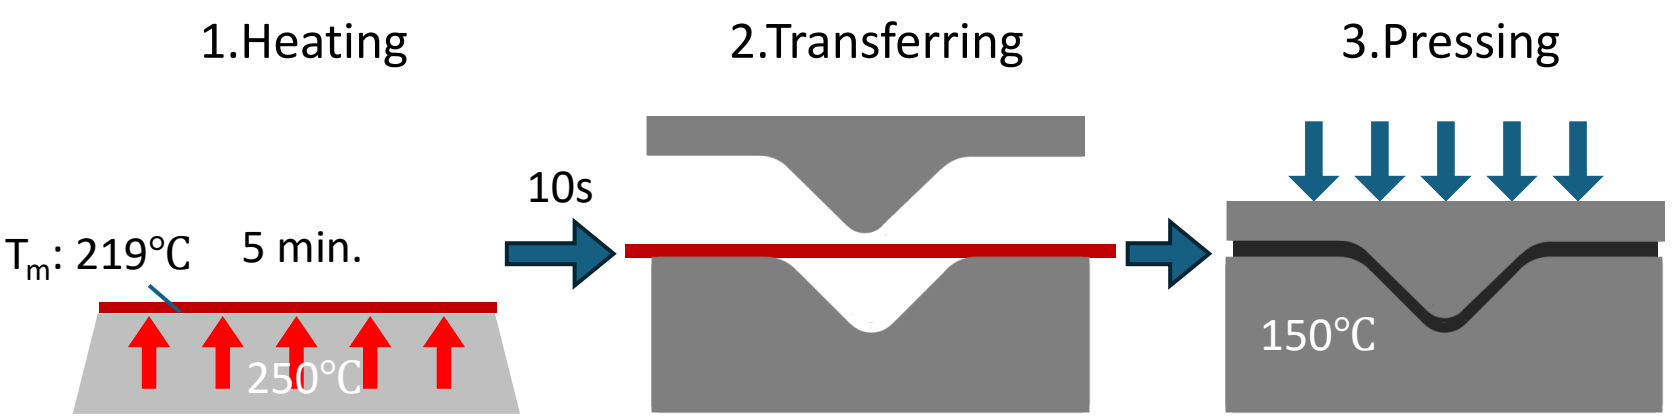
- ✓ Two optical fibers embedded in upper and lower surfaces of thin polyimide sheet
- ✓ When bended along sensor axis, different strain (bending strain) is induced in two optical fibers and sensor shape can be back-calculated
- ✓ Deformation can be measured by embedding in composite

Strip-type shape sensor



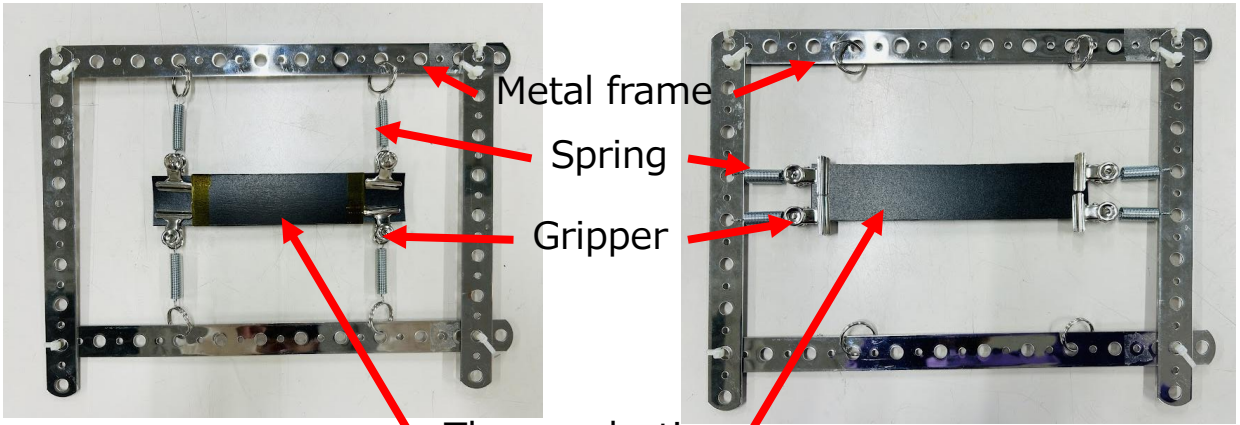
Curvature $\kappa = \dfrac{\varepsilon_{\text{lower}} - \varepsilon_{\text{upper}}}{2z_c}$,

- ✓ When this flexible sensor is embedded in composite part during lay-up, sensor deforms with surrounding plies
- ✓ By monitoring shape change of sensor, we can clarify dynamic deformation process during consolidation

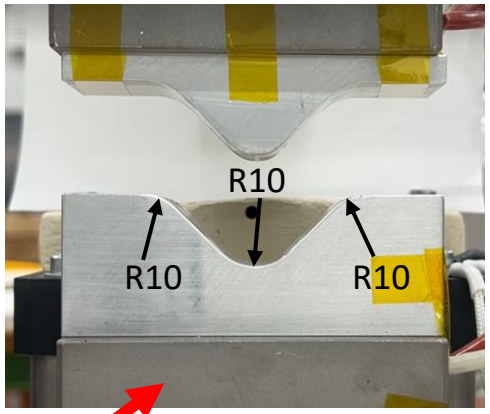


Material and specimen

UD prepreg

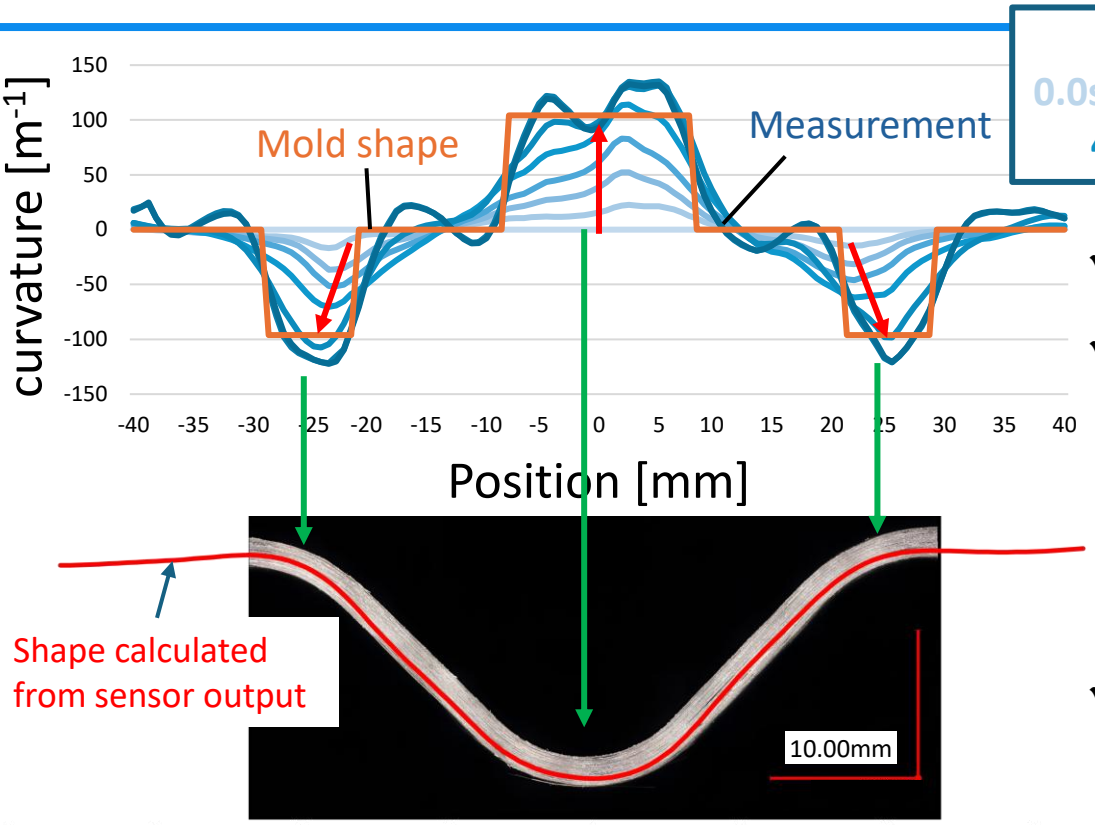


- ✓ CF/PA6 (T_m: 219℃)
- ✓ Thickness：200μm
- ✓ Stacking sequence：$[0_{10}]$



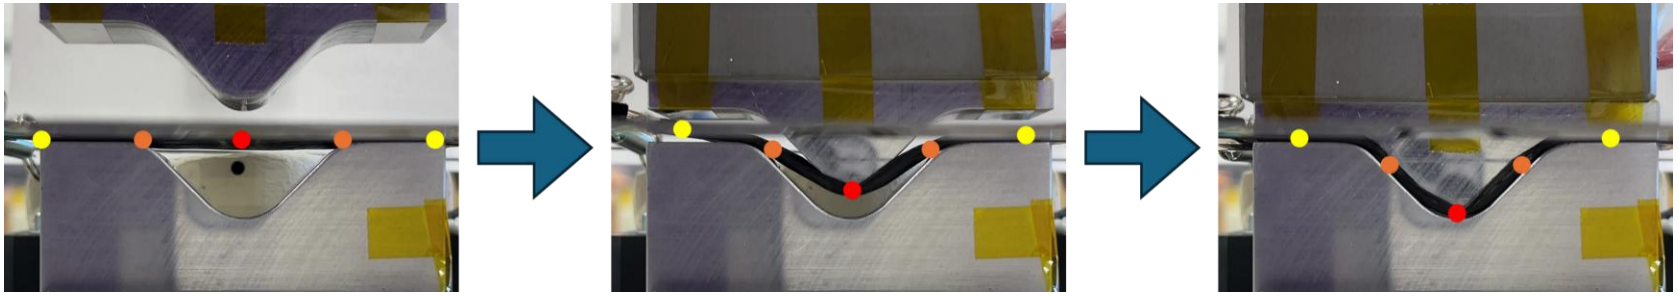
Stamp forming process

Spring support

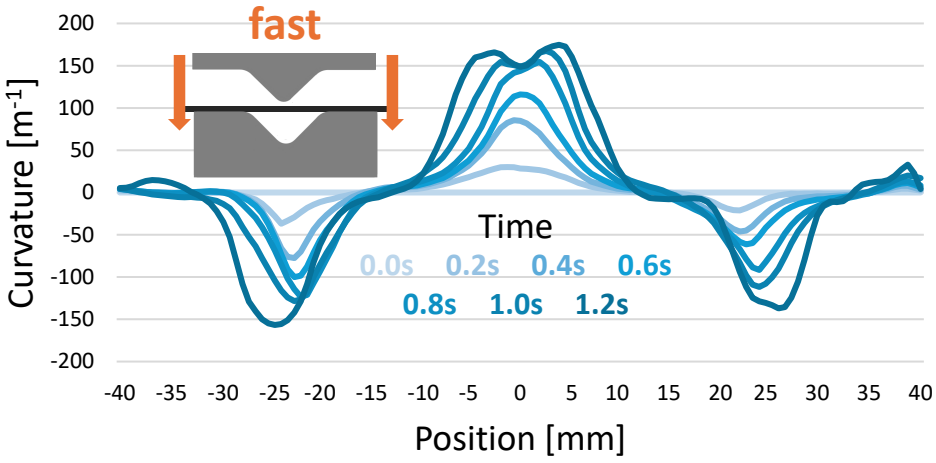


Mold

Measurement: sampling 10Hz, spatial resolution 0.65mm



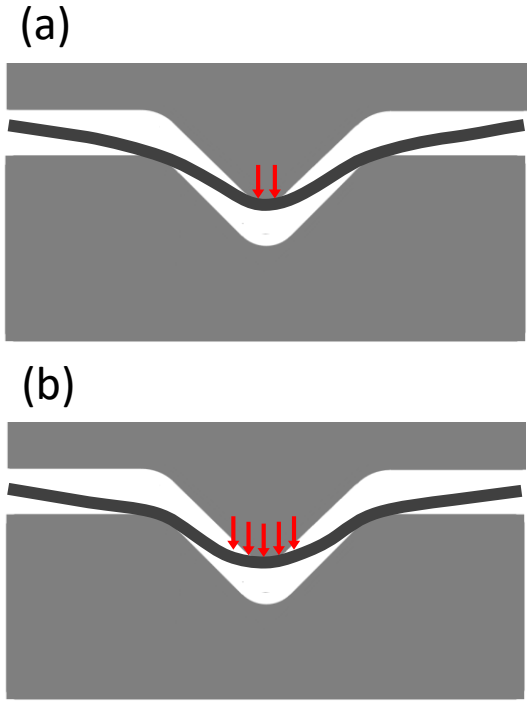
Result



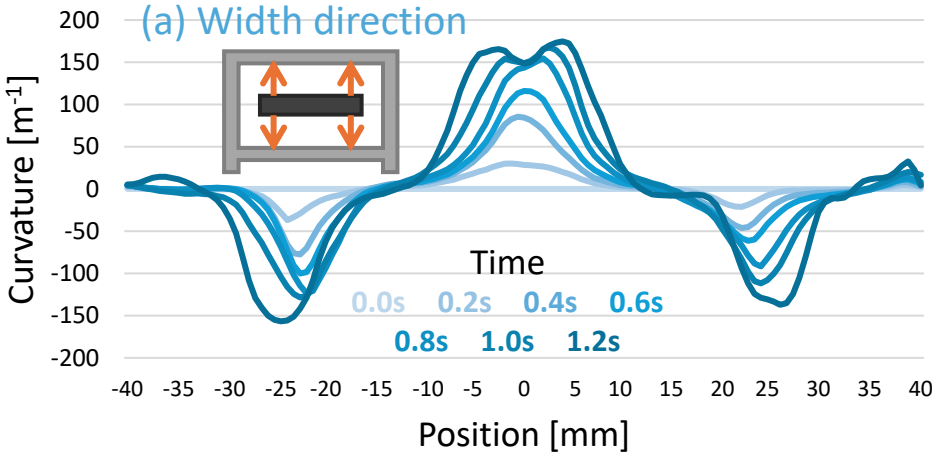
- ✓ Curvature increased in corners
- ✓ Left and right curvature peaks moved outward

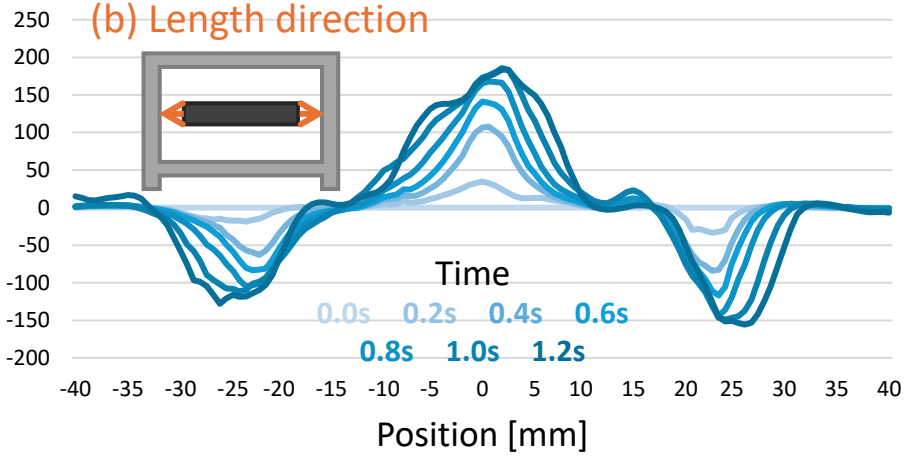
  >>Contact point with mold moved outward as forming progressed.
- ✓ Curvature did not match mold shape >> Ply distortion

Movement of contact points outward

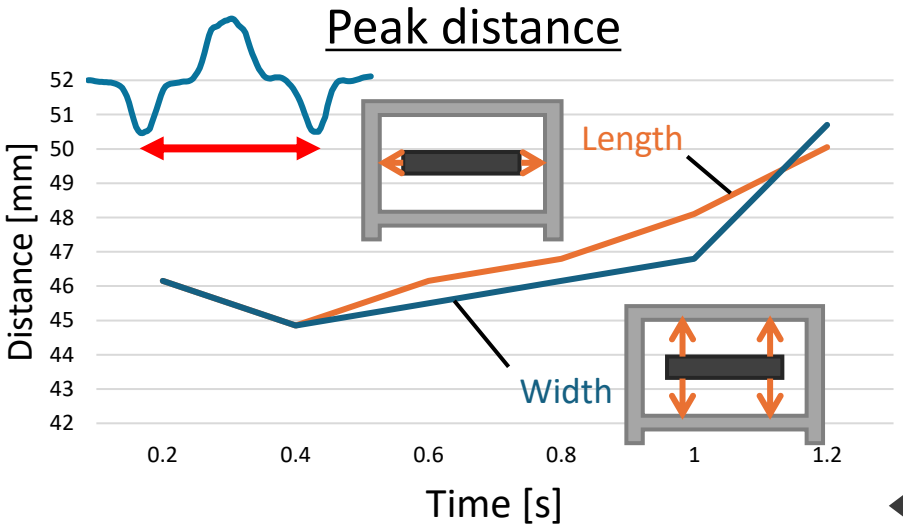


Effect of press speed

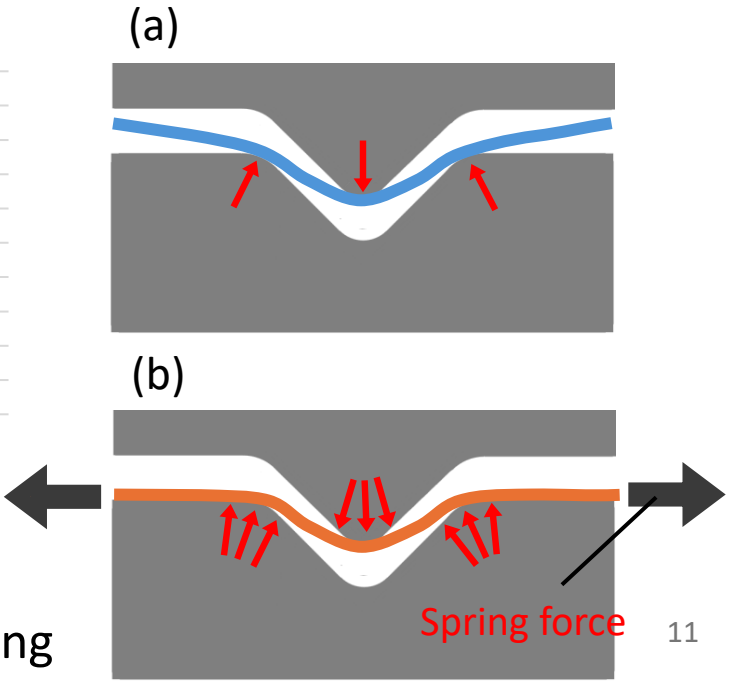




- ✓ When fast, curvature increased locally, and straight part remained unchanged (a)
- ✓ When slow, curvature increased over wide region, and straight part deformed once before returning to straight (b)



<u>Due to viscoelasticity of melted thermoplastic composite, deformation varied with press speed.</u>



Effect of spring support

Longitudinal spring force changed corner shape
and caused gradual forming

Conclusions

- ✓ In-situ deformation monitoring technique was developed for stamp forming
- ✓ Technology will be applied to stamp forming with closed molds with large-scale

ABSTRACT

In the design of aeronautical structures, determining the allowable values associated with failure criteria remains a key issue for the aeronautical industry, particularly the longitudinal compressive strength. Furthermore, this critical allowable value must be determined at various temperatures representative of flight conditions, or even in the event of a fire, which adds complexity to the multi-instrumented testing procedure and the associated analysis methods. This study has determined the longitudinal compressive strength of T700GC/M21 unidirectional carbon/epoxy plies by considering different classical and innovative tests performed at various temperatures (from ambient to 120 °C) and analysing them using an original hybrid failure approach.

1 INTRODUCTION

Composite materials, especially carbon fibre reinforced plastics (CFRP), are widely used in modern aircraft. Currently, design methods for laminated composite structures mainly rely on linear elastic structural analysis combined with failure criteria [1] defined at the scale of the unidirectional (UD) ply. Therefore, determining the design allowable — the ply strengths that take into account material scattering, as recommended in aeronautical standards [2]— is a major concern for designers. Determining the design allowable is a time-consuming and expensive process since many tests are required, especially at different temperatures representative of flight or fire conditions. To reduce costs and product lead times, fast and simple identification tests and analysis methods are required. Furthermore, identifying tests with low coefficients of variation (CV) would increase the A- and B-basis allowable [2], resulting in higher-performance designs. Among the in-plane strengths of a unidirectional ply, determining the longitudinal compressive strength of the ply currently remains a technical and scientific challenge.
This article analyses existing tests for determining the longitudinal compressive strength of unidirectional plies at different temperatures, from ambient temperature to 120°C. It considers classical compressive tests described in Section 2.1, but also classical and innovative bending tests in sections 3.1 and 3.2. An approach based on failure analysis has been developed to predict fibre kinking in composite laminates subjected to different loadings and temperatures in section 2.2. This approach considers the unidirectional ply as the elementary modelling entity, but some material parameters are updated using a micromechanical model. The model is applied to different test configurations performed at various temperatures in compression (section 2.3) and bending (section 3.3).

2 COMPRESSION TESTS ON UD PLY AT DIFFERENT TEMPERATURES

2.1 Presentation of compression test results on UD ply

The longitudinal compressive strength of carbon/epoxy T700GC/M21 unidirectional plies (aeronautical quality) with a weight area of 268 g/m² has been determined using classical compression tests on 16 0° laminates. All composite specimens were manufactured at ONERA using an autoclave, with a curing cycle corresponding to that recommended by the material provider.

The longitudinal compressive strength, associated with the onset of fibre kinking, is usually identified using standards based on uniaxial compressive tests on unidirectional 0° laminates. There are many standards regarding testing methods and fixtures in the literature. As initially proposed by [3] and subsequently refined in ASTM D3410/D3410M-16 [4], compressive force can be transferred to the specimen via shear at the wedge grip interfaces. This experimental device requires the use of tabbed specimens and complex, heavy fixtures. Alternatively, the EN2850 AECMA standard [5] recommends transmitting the compressive force into the specimen through end-loading [6], thus avoiding the use of additional tabs. [5] recommends transmitting the compressive force into the specimen through end-loading [6], thus avoiding the need for additional tabs. This method is currently the most commonly used in the aeronautical industry and corresponds to the ASTM D695-15 standard [7]. Finally, the ASTM D6641/D6641M standard [8] combines shear and end-loading to transmit the compressive force.

Since a higher compressive strength can be obtained using the latter method [9,10], the experimental device shown in Fig. 1 has been considered in the present study. It is associated with an Instron hydraulic testing machine with a maximum load capacity of 300 kN. Compression tests were performed at ONERA Lille with a loading rate of 1.5 mm/s. Longitudinal strain was measured using a QFLAB-3-11 strain gauge. The experimental device was introduced into a furnace, as illustrated in Fig. 1b. Compression tests have been carried out at four different temperatures: 20 °C, 80 °C, 100 °C and 120 °C. Three specimens were tested for each configuration of tests to estimate the scattering.

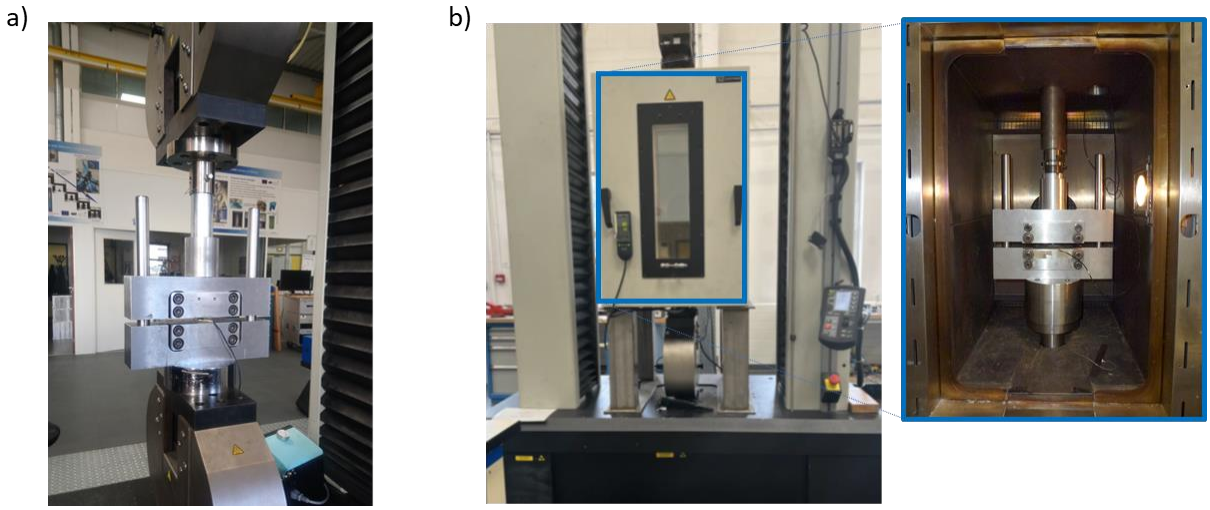

Figure 1: a) compression test device available at ONERA, b) compression test performed in a furnace.

Fig. 2a shows that the behaviour in the fibre direction appears to be insensitive to the applied temperature and exhibits slight nonlinearity up to failure. Experimental results have already demonstrated that this nonlinearity is due to the nonlinear elastic behaviour imposed by the carbon fibres [11,12], which is consistent with the observations performed in this study. Fig. 2b shows the evolution of the measured longitudinal compressive strength as a function of temperature. The evolution is almost linear and consequent (the strength is decreased by 40% at 120°C). It should be noted that the scatter of the measured strength increases with temperature. The failure patterns of the different specimens, as shown in Fig. 2b, are not located at the ends of the jaws, and the tests appear to be relevant for measuring the longitudinal compressive strength at different temperatures using the proposed experimental device.

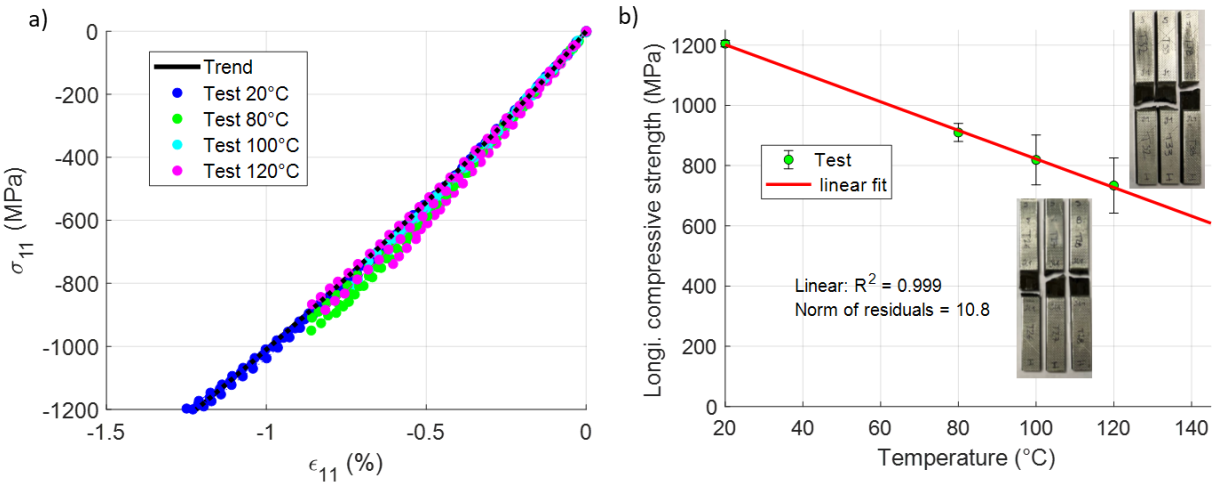

Figure 2: a) Longitudinal behavior and b) evolution of the longitudinal compressive strength of UD ply subjected to compression loading at different temperatures

2.2 Micromechanical model to predict the longitudinal compressive strength of a UD ply

A model defined at the micromechanical scale has been proposed by Grandidier [13,14]. This model is based on finite element simulations with enhanced elements to capture the fibre buckling embedded within the matrix. Based on this work, a simplified analytical model has been proposed by Grandidier [15] later in order to be used in design office to determine the longitudinal compressive strength, considering compressive loading or bending. The model accounting for the combined contributions of fibre micro-buckling [16] and the structural effect (stacking sequence, strain gradient) [17–19] was proposed to describe the mechanism of failure under compression or flexural loading [15]. The local failure mechanism accepted by the scientific community puts together a sequence of phenomena: under compression load a little fibre misalignment triggers fibre buckling, the matrix provides the assembly of the fibres but evolves to plasticity which amplifies therefore the instability, fibre failure appears successively by developing a kink band [16]. The main governing parameters of this mechanism are the nonlinearity of matrix properties and fibres initial undulation defects noted ϕ_0.
The most efficient models existing in the literature account quite well for these effects. Budiansky and Fleck [16] modelled the non-linear shear behaviour of UD (shear strain) vs. (shear stress) by using a Ramberg-Osgood (RO) description, reported in Eq. 1:

$$\frac{\gamma}{\gamma_{UD}^{y}} = \frac{\tau}{\tau_{UD}^{y}} + \frac{3}{7}\left(\frac{\tau}{\tau_{UD}^{y}}\right)^{n_{UD}} \tag{1}$$

It involves three material parameters (τ_{UD}^{y}, G_{UD}, n_{UD}) or (γ_{UD}^{y}, τ_{UD}^{y}, n_{UD}). G_{UD} is the in-plane shear modulus of the composite, τ_{UD}^{y} is a nominal shear yield stress for which the secant modulus is reduced to 70% of its initial value G_{UD}. γ_{UD}^{y} is defined as the elastic strain at the shear stress τ_{UD}^{y} so that $\tau_{UD}^{y} = G_{UD} \,.\, \gamma_{UD}^{y}$. The compressive strength, referred to as σ_{UD}^{stab}, and calculated using Budiansky and Fleck's model, is defined as the maximum stress applied on UD before the fibre instability, as reported in Eq. 2.

$$\sigma_{UD}^{stab} = \frac{1}{1 + n_{UD}\left(\frac{3}{7}\right)^{\frac{1}{n_{UD}}}\left(\frac{\phi_0/\gamma_{UD}^{y}}{n_{UD}-1}\right)^{\frac{n_{UD}-1}{n_{UD}}}} \tag{2}$$

The structural effect results in the increase of UD failure compressive strain and stress with respect to σ_{UD}^{stab}. It is due to several mechanisms that do not take place at the UD mesoscopic scale but rather at a larger, macroscopic scale (laminate).

Three factors are included in the structural effect, namely the deformation gradient through the thickness due to bending loadings, the thickness of UD ply and the stiffness of off-axis neighbouring plies. Experimental observations on the structural effect have been experimentally detailed and compared by Grandidier [15], ending with the proposal of an analytical model (reported in Eq. 3) to predict the stress due to structural application.

$$\sigma_{UD}^{struct} = 2r_{gf}\frac{\pi}{e_b}\sqrt{\frac{E_m E_f}{1-\nu_m^2}V_f(1-V_f)} \quad (3)$$

where r_{gf} is the gyration radius of fibre r_{gf}= *I/S* , with *I* the second moment of area of the fibre, and *S* the area of the fibre's cross section (it is equivalent to the fibre diameter divided by 4, in case of fibres are considered circular), E_m and ν_m are respectively the Young's modulus and the Poisson's ratio of the matrix, E_f the longitudinal elastic modulus of the fibre, V_f the volume fraction of fibres and e_b the characteristic thickness of UD involved in the instability mode (a fraction of the total thickness of UD), which is discussed below. For a UD layer subjected to bending, only the part in compression is considered for critical thickness (e_c). A reduced part of thickness is considered to contribute to compression failure due to the distribution of the strain and is considered equal to $e_b = 0.5\, e_c$ which permits correlation with experimental results considering the evolution of the middle plan during bending loading because the longitudinal behaviour in tension and in compression is different. For a UD layer subjected to compression, $e_b = \infty$ to deactivate the structural part in the model.

To summarize, the proposed model considers both the micro-buckling mechanism ($\sigma_{\mathrm{UD}}^{\mathrm{stab}}$) and the structural effect ($\sigma_{\mathrm{UD}}^{\mathrm{struct}}$). The estimated compressive strength is called critical, referred to as σ_{UD}^{crit}, is higher than σ_{UD}^{stab}, since it is defined in Eq. 4:

$$\sigma_{UD}^{crit} = \sigma_{UD}^{stab} + \sigma_{UD}^{struct} \quad (4)$$

2.3 Analysis of compression tests with an advanced micromechanical model

The micromechanical model proposed by Grandidier has been fully validated for the T700GC/M21 material. In order to use the model, however, several pieces of experimental data are required.

Firstly, the analysis of the microstructure has been performed to measure parameters related to the structural effect, such as the volume fraction of fibres and their radius, thanks to the analysis of CT scans. The distribution of fibre radii has been determined, yielding an average Weibull value of r_f=3.25µm and a fibre volume ratio of V_f =56%. In a previous study, the mechanical properties of the fibres and the matrix were determined using an inverse method based on the Mori-Tanaka approach. This method was used to obtain the relevant mechanical properties measured at the ply scale, based on tensile tests performed on 0-ply, 90-ply and [±45] laminates. The values identified were E_f=240GPa, E_m=3100MPa, and ν_m=0.3.

Then, the plasticity of the matrix, which is modelled using a Ramberg-Osgood law, requires the identification of three parameters ($\tau_{UD}^{y}, G_{UD}, n_{UD}$) at different temperatures. These parameters can be determined by inverse identification using tensile tests on a $[\pm 45]_s$ laminate tested at 20 °C, 70 °C and 120 °C at ONERA, as reported in Fig. 3 [20]. The tensile tests were performed at ONERA Lille in accordance with AITM1-002 [21], but with a displacement rate of 1 mm/s, which is consistent with the loading rate applied to the 0-ply compression tests. Longitudinal and transverse strain gauges were used to measure the in-plane shear strain in the tested specimens at different temperatures. The Ramberg-Osgood parameters for each temperature were identified independently using an automated identification method based on the simplex method [22] to calibrate the three parameters. It was observed that these three parameters evolve linearly as a function of temperature. Therefore, a first-order polynomial has been fitted to each of the three parameters to successfully describe the available experimental data at different temperatures, as shown in Fig. 3.

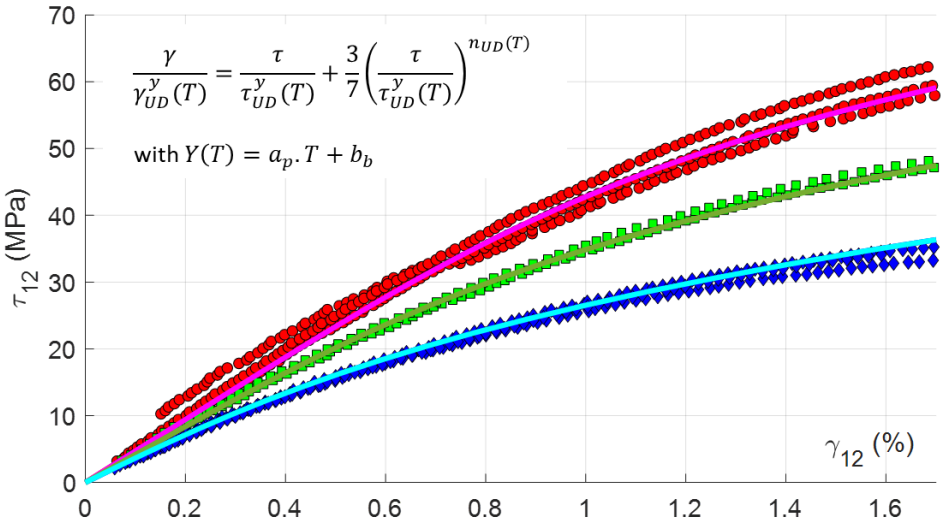

Figure 3: Tensile test on $[\pm 45]_s$ laminates at different temperatures and comparison with simulated Ramberg-Osgood model predictions

The final parameter to identify is the initial misalignment of the fibres, which causes them to kink within the composite material. This value was determined using inverse identification in conjunction with a tensile test on a specific laminate that failed in compression. The identified value is $\phi_0 = 2°$, which is consistent with data found in the literature [15,23].

Fig. 4a shows a successful comparison between experimental stress/strain curves at different temperatures and the predicted elastic nonlinear behaviour introduced in the OPFM model which is assumed to be insensitive to temperature. The details of the nonlinear elastic behaviour are given in [24]. Finally, Fig. 4b presents a comparison of the test results for 0 ply at different temperatures with the predictions of the identified micromechanical model. The evolution of strength with temperature is predicted very accurately from ambient temperature to 120°C. The decrease in strength with temperature is approximately -40% compared to ambient temperature, which is significant and must be considered in the design of composite structures.

3. BENDING TESTS ON UD PLY AT DIFFERENT TEMPERATURES

3.1 Presentation of four-point bending test results on UD ply at different temperatures

The longitudinal compressive strength of 268 g/m² carbon/epoxy T700GC/M21 unidirectional plies has also been determined using classical four-point bending tests on 0° laminates. Several authors have indeed proposed using bending tests to overcome the challenges associated with compressive testing of unidirectional laminates. For a carbon/epoxy unidirectional ply, the longitudinal compressive strength is much lower than the longitudinal tensile strength. Therefore, three-point bending tests [25,26] and four-point bending tests [27] are useful for identifying compressive strength in the fibre direction.

Therefore, four-point bending tests have been performed on specimens constituted with 8 0-plies at ONERA Châtillon using an electromechanical testing machine with a maximum loading capacity of 150kN. The specimens measured 120×10×2.23 mm. The loading rate was fixed at 1 mm/min. The distance between the support spans is 100 mm, and the distance between the loading spans is 30 mm. The span radius has been set to 5 mm. The experimental device was introduced into a furnace that allowed a temperature to be applied ranging from -100°C to 500°C. Furthermore, a large window in the furnace door enables measurement of the strain field on one of the specimen's free edges, where a black-and-white speckle pattern has been applied. This is achieved using digital image correlation with Vic2D software, with one camera focused between the loading span to observe the failure pattern and another observing the global view of the setup to control the boundary conditions. The experimental setup is described in Fig. 5. Four-point bending tests were performed at different temperatures: 20 °C, 45 °C, 120 °C, 145 °C and 165 °C. Only one specimen was tested for each temperature studied.

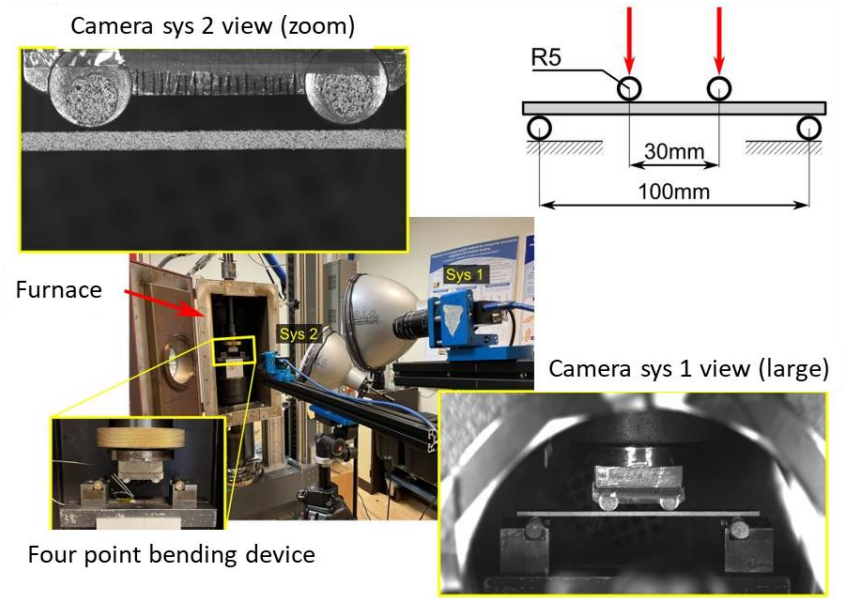

Figure 5: Four-point bending tests performed in a furnace at different temperatures, from ambient temperature to 165°C.

The failure pattern has been analysed at different temperatures. At temperatures above 100°C, failure of the specimen is more progressive, with compressive fibre failure occurring between the loading spans. The measured strains at failure for these high temperatures are reported in Fig. 6. A typical failure pattern is observed at 120 °C, and these results can be considered valid. Linear evolution of apparent longitudinal strain at failure as a function of temperature is observed. However, at 20°C and 45°C, failure occurs prematurely within the loading spans. These strains at failure, which are also reported in Fig. 6, are not considered valid for the purposes of the following analysis. It is well known that four-point bending test set-ups generate high stress concentrations under the rollers, which can lead to local indentation and premature specimen failure.

To avoid this, some authors introduced polymer pads between the rollers and the specimens [23]. However, this necessitates the characterisation of the additional material's mechanical behaviour. To overcome this difficulty, an alternative bending device has been developed, which is presented in the next section.

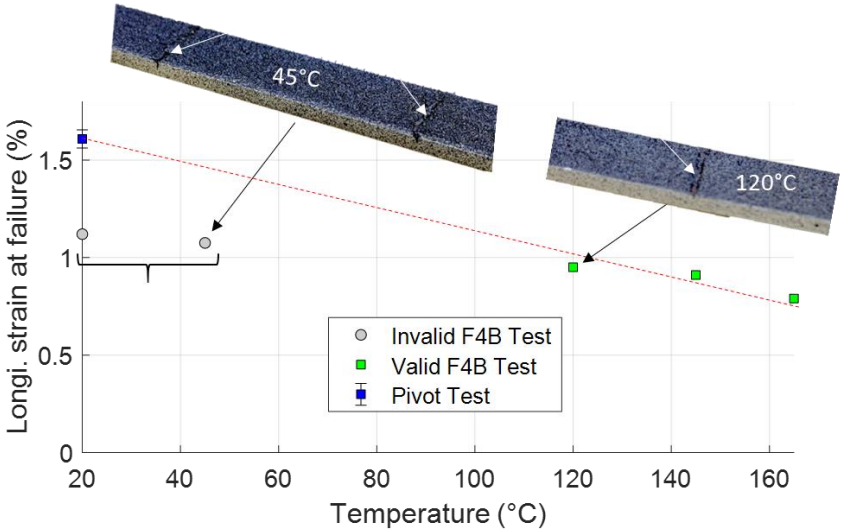

Figure 6: Evolution of the longitudinal strain at failure as a function of the temperature considering test results from four-point bending and compressive with pivot tests.

3.2 Presentation of compression with pivot test on UD ply at ambient temperature

The compression with pivots testing device [28] enables bending loading to be generated by offsetting the mid-plane of the laminate with respect to the rotation axes of the pivots. This is an alternative to existing bending testing devices [11,14,29–31]. This device avoids local stress concentrations close to the jaws and the indentation issues experienced with the aforementioned testing set-ups. Furthermore, it enables direct observation of compressive failure in the surface plies of the laminate. Due to the use of a bending loading mode, the failure mechanism can be observed in the gauge section, which is far from the jaws.

Figure 7a shows an original experimental compression device with pivots. The concept involves applying uniform compression to a laminate plate that is clamped between two jaws with pivots. The eccentricity of a given test relates to the offset of the plate's mid-surface and imposes the compression-to-bending ratio. This is controlled by inserting a couple of wedges adequately into the jaws of the tabs. In the present study, large eccentricities equal to half the total thickness of the specimen being tested are used to obtain a quasi-pure bending moment in the gauge length.

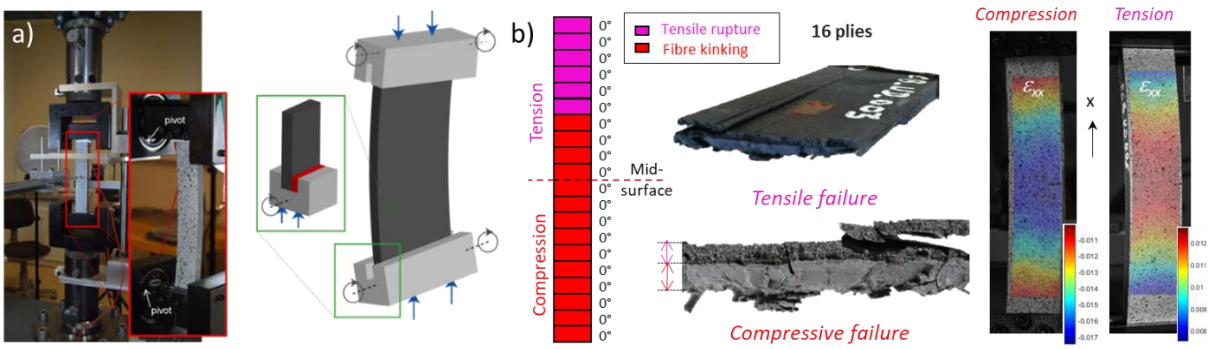

Figure 7: a) Presentation of the compression with pivots experimental device, b) Failure pattern of the 16 0-plies subjected to bending loading
