Bending tests on 16 0-plies specimens have been performed at ONERA Châtillon, but only at ambient temperature. The specimens measured 130 mm x 30 mm x 4.2 mm. Three specimens were tested. Different measurement techniques were used to improve understanding of the physical mechanisms involved and to obtain global and local information, as reported in Fig. 7a: (i) a LVDT sensor; (ii) acoustic emission to detect damage events during loading (no acoustic events were detected prior to final failure); (iii) strain gauges bonded to the upper and lower faces of the unnotched specimens to measure strain; and (iv) stereo digital image correlation (using the Vic3D system) on the two faces of the specimen painted with black-and-white speckles to measure in-plane strains on the outer surfaces, as shown in Fig. 6b, (v) post-mortem micrographs to study the failure pattern of the specimens. The distribution of fibre failure in tension and compression through the thickness can easily be observed in the post-mortem pictures since the grey colours correspond to different failure mechanisms. The evolution of the mid-plane during the tests is also clearly visible. Furthermore, failure occurs far from the jaws and can be considered a valid compressive fibre failure mode. The strain at failure on the compression face, measured with DIC and a strain gauge at ambient temperature, is -1.6%, with a covariance of 2.9%. This has been added to Fig. 6 (blue point) and should be considered instead of the test results at 20 °C and 45 °C obtained using four-point bending device. The evolution of the strain at failure appears to be linear again, with a -50% decrease in strain at failure for compression with a pivot test at ambient temperature compared to that measured in four-point bending tests at 165°C.

3.3 Analysis of the bending tests with the micromechanical model

The micromechanical model was applied to estimate the longitudinal compressive strength of bending tests carried out at different temperatures. The strain at failure was estimated by considering the elastic nonlinear behaviour mentioned in Section 2.2 and previously identified. It should be noted that the effective thickness considers the evolution of the middle plane during the bending test due to the hardening observed in longitudinal tension and the softening observed in longitudinal compression. Fig. 8 shows a comparison of the predicted and measured strain at failure obtained from the bending test. Initially, the predicted evolution of the failure strain appears slightly nonlinear and is consistent with the experimental data.

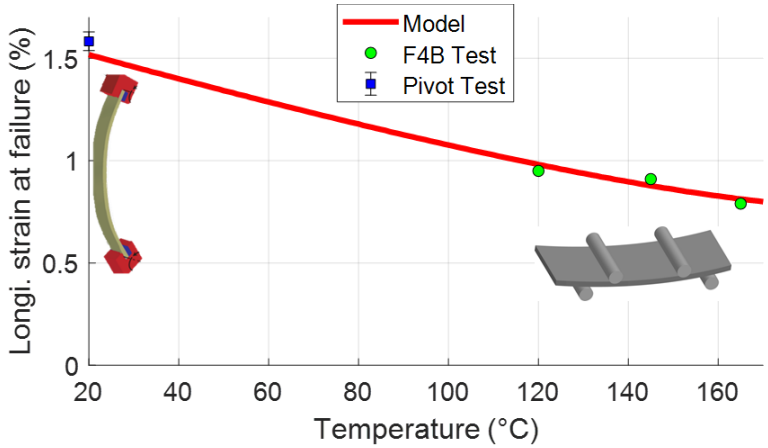

Figure 8: Predicted and measured evolution of the longitudinal strain at failure as a function of the temperature considering bending tests

The same identification has been used for the micromechanical model in order to predict the evolution of the longitudinal compressive strength (or longitudinal strain at failure) when 0-ply is subjected to compression or bending at different temperatures. The results obtained are promising.

4 CONCLUSIONS

This study determined the longitudinal compressive strength of T700GC/M21 unidirectional carbon/epoxy plies by performing compression and bending tests at different temperatures (from ambient to 145 °C) and analysing the results using an original micromechanical approach.

The longitudinal compressive strength was determined from the results of standardised compression tests on sixteen 0-plies at different temperatures. The longitudinal compressive strength and the associated strain at failure decreased linearly with temperature, dropping by -40% at 120°C. Furthermore, four-point bending tests were carried out on 8 0-plies at different temperatures. The longitudinal strain was measured using digital image correlation to observe the specimen through a large window into the furnace. Once again, the evolution of the measured strain at failure is almost linear as a function of temperature, dropping by -50% at 145°C.

The micromechanical model proposed by Grandidier was used to determine the apparent longitudinal compressive strength of the ply. This model takes into account the nonlinearity of the matrix and was calibrated at different temperatures through the analysis of tensile tests on $[\pm 45]_s$ laminates, and the nonlinear behaviour in the fibre direction. Analysis of the various tests using the current failure approach has demonstrated consistency between the test data obtained at different temperatures, which is encouraging.

ACKNOWLEDGEMENTS

The authors would like to express their sincere gratitude to DGA-TA for funding this experimental and numerical study.

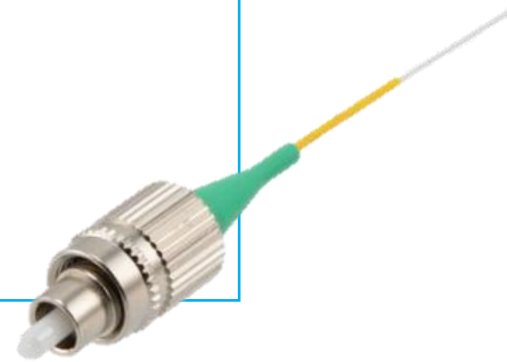
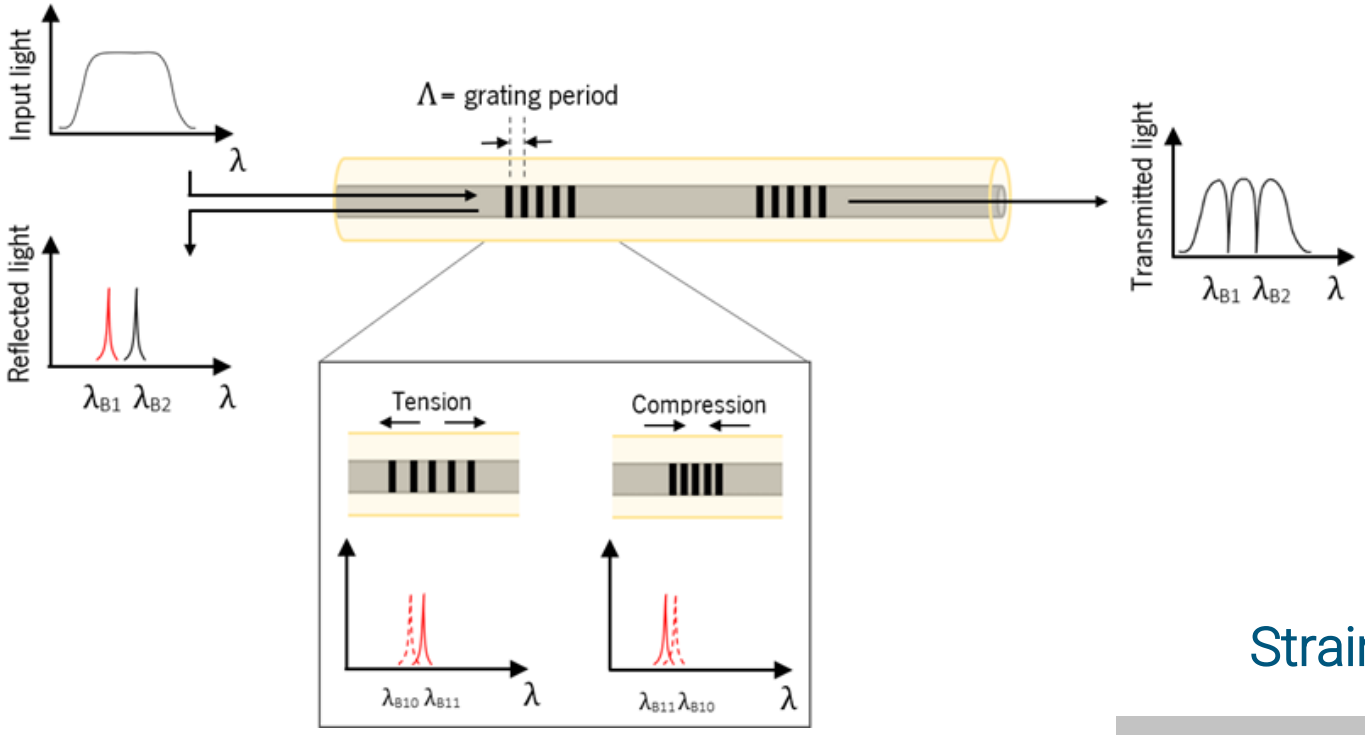
Embedded Sensorization:

A Smart Solution for Composite Health Monitoring



Optical Fiber Sensors:
Fibre Bragg Grating (FBG) sensors

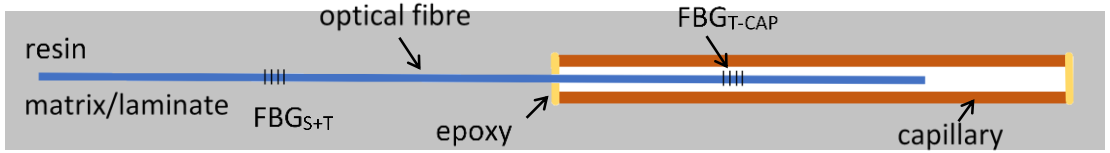
Advantages



+ compatibility with composites fabrication
+ reduced cabling as several FBG sensors can be multiplexed in the same OF
+ high sensitivity
+ ability to monitor the fabrication process and curing
+ capability of impact damage detection
+ localized strain measurement
+ immunity to electromagnetic interference
+ Durability

Disadvantages

- expensive optoelectronic interrogation system
- fragility
- localized strain measurement



Fibre Gragg Grating (FBG) sensors

Fatigue Testing

Specimen	Number of endured cycles in fatigue test
1	16 281
2	8 234

Comparison of strain measured in $FBG_{L\text{-}CD}$ and $FBG_{L\text{-}C1}$ sensors, bonded to the liner, on the different SCBA tank specimens

Conclusions

Winding Process: Heating of the wound setup promoted expansion of the liner (tank 1);

Curing: it is possible that full curing conversion is not achieved by the end of the isothermal period, as strain is still slightly decreasing;

Autofrettage:

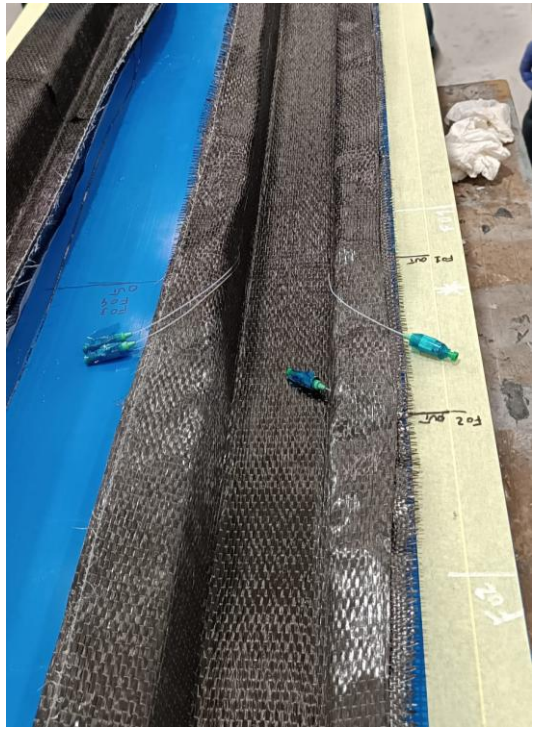
- The residual strain measured by the FBG sensors confirm that plasticity is successfully imposed on the liner;
- It is possible that tank 1 has suffered higher plasticity in the *autofrettage* process (increased volumetry);

Fatigue Testing:

- FBG sensors in the liner show higher amplitude deformation in SCBA tank 2 (non-heated), which may explain the much faster failure of this specimen;
- The lower strain amplitudes measured in FBG sensors in OF_{LINER} of tank 1 could be linked with the increase of liner's volumetry (plastic deformation) and the consequent higher compression loading induced from the composite (elastic behavior) on the liner;
- Heating of the wound setup during winding, may have contributed to improved fatigue strength due to two factors:

  (1) the initial expansion of the liner makes the composite to be wound at a larger radius, closer to the final one after autofrettage, causing less fibre breakage after curing and autofrettage;

  (2) the higher temperature increases resin viscosity promoting improved consolidation of the composite.

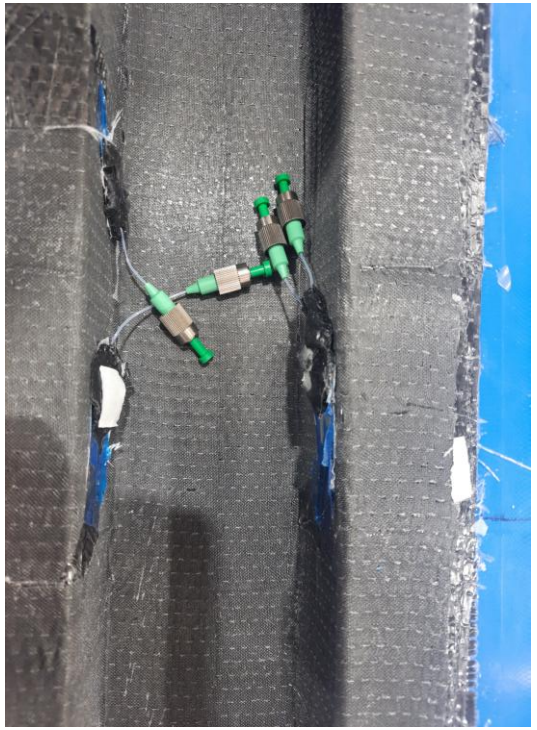


CASE STUDY 2

Monitoring of a UAV's spar

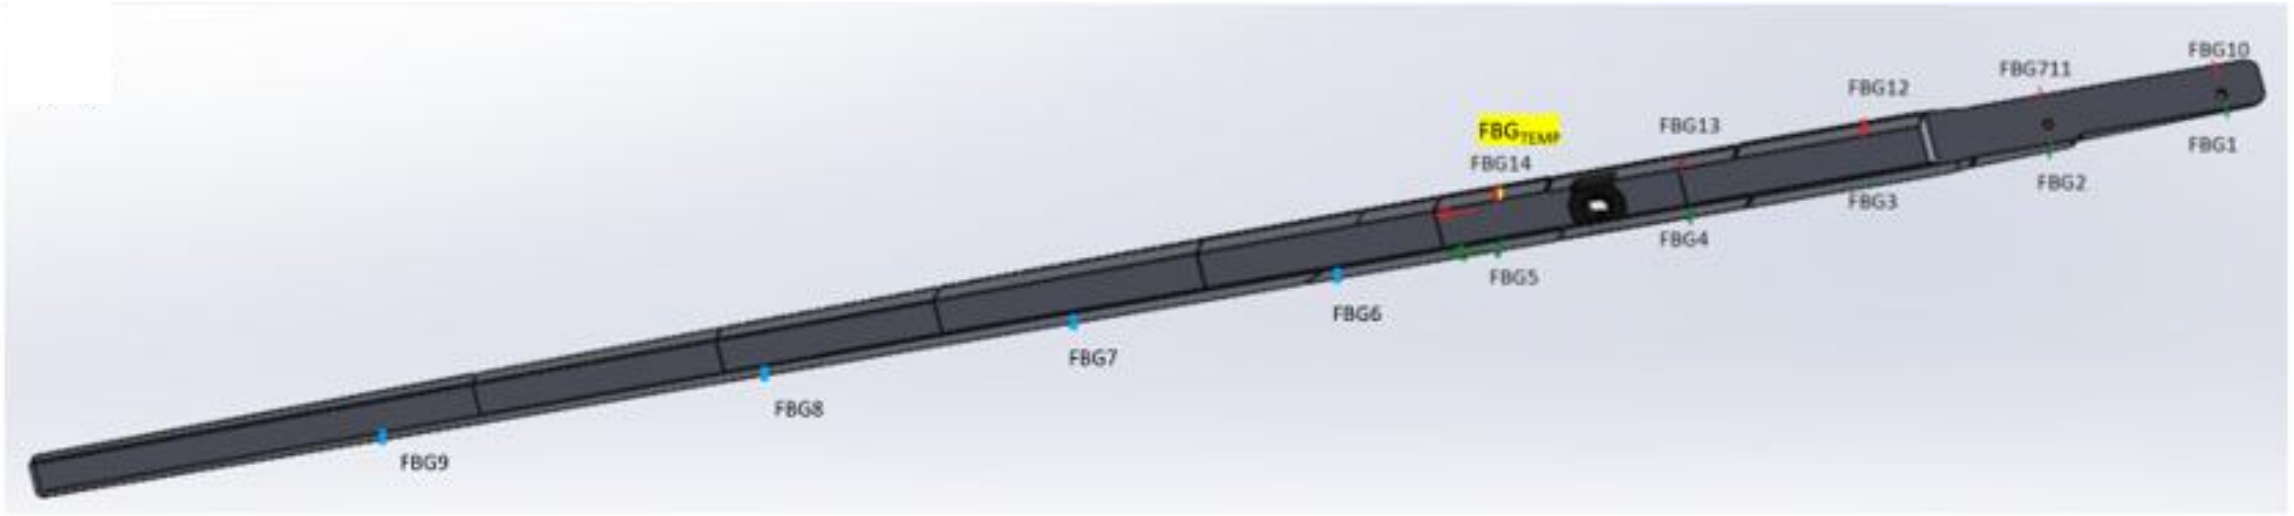
Objectives

- Monitor the manufacturing process
- Monitor the structural health condition of the spar, through static and flight testing
- Determine the Remaining Useful Life of the Structure

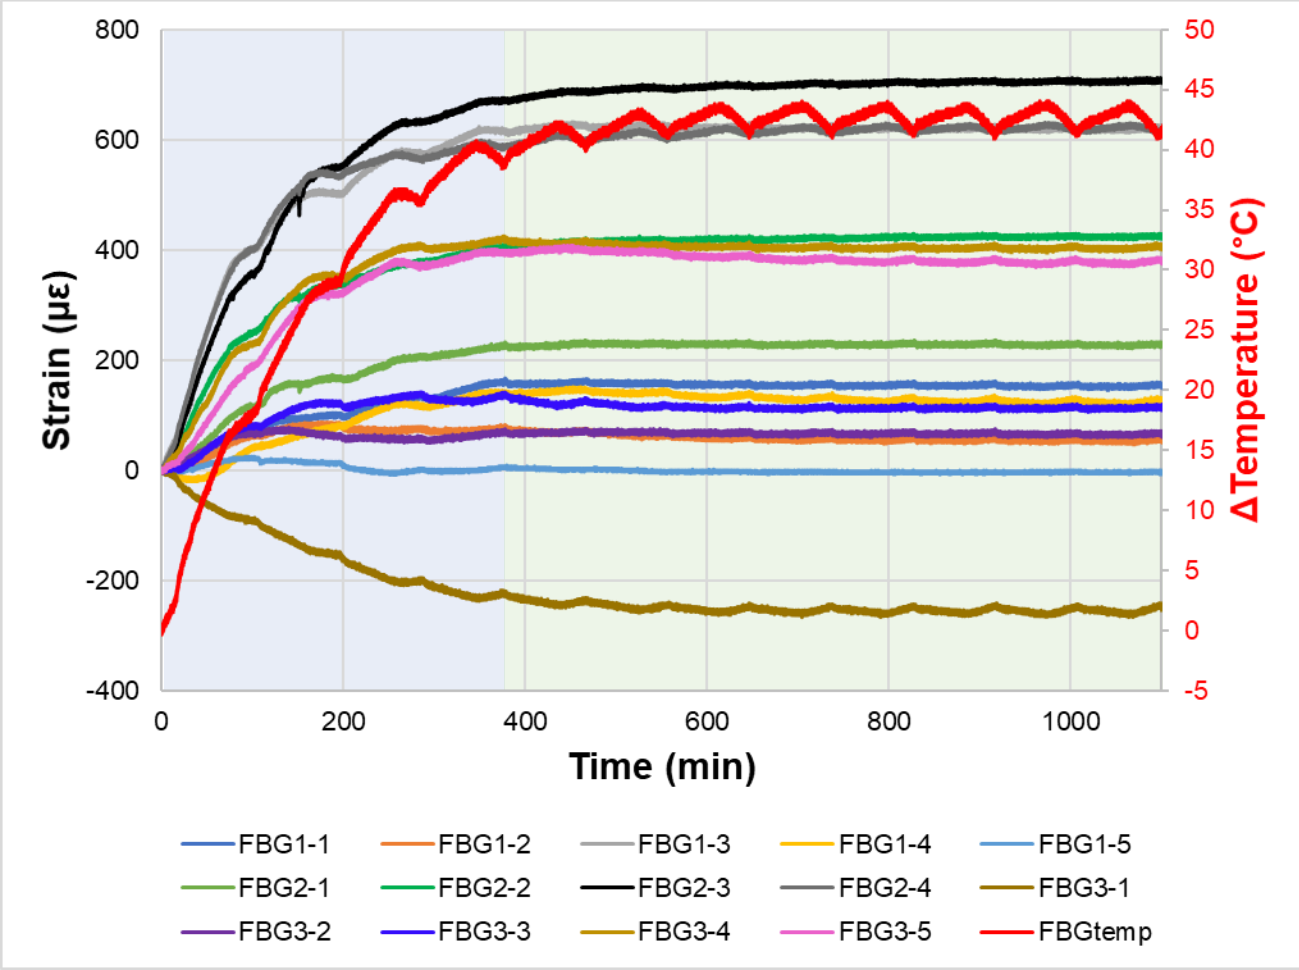


Optical Sensors Integration

Placement of Optical Fiber Sensors during Manufacturing

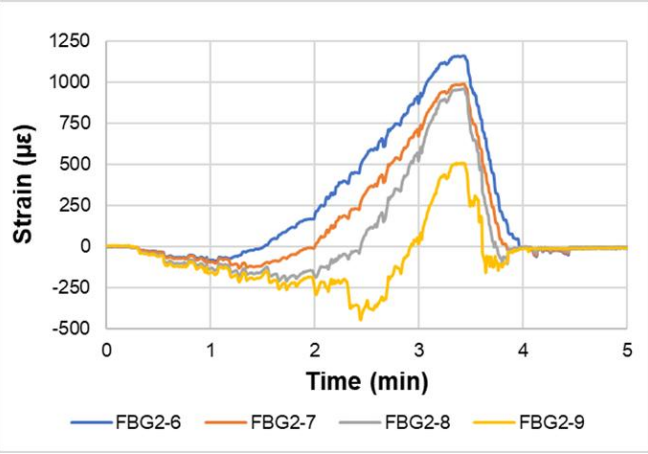


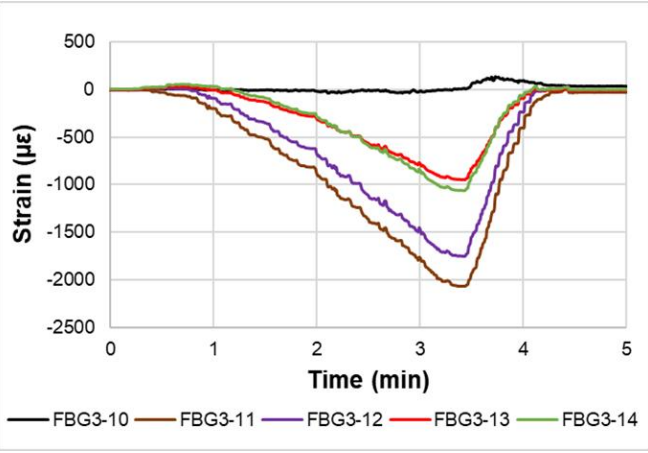
Vacuum Bag sealed



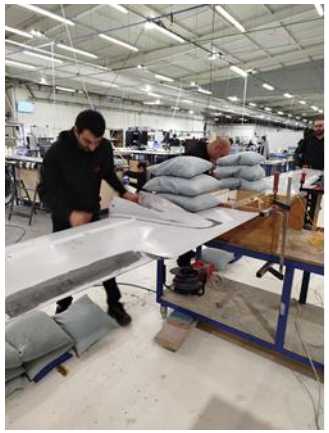
Demolded piece after curing

Optical Sensors Integration



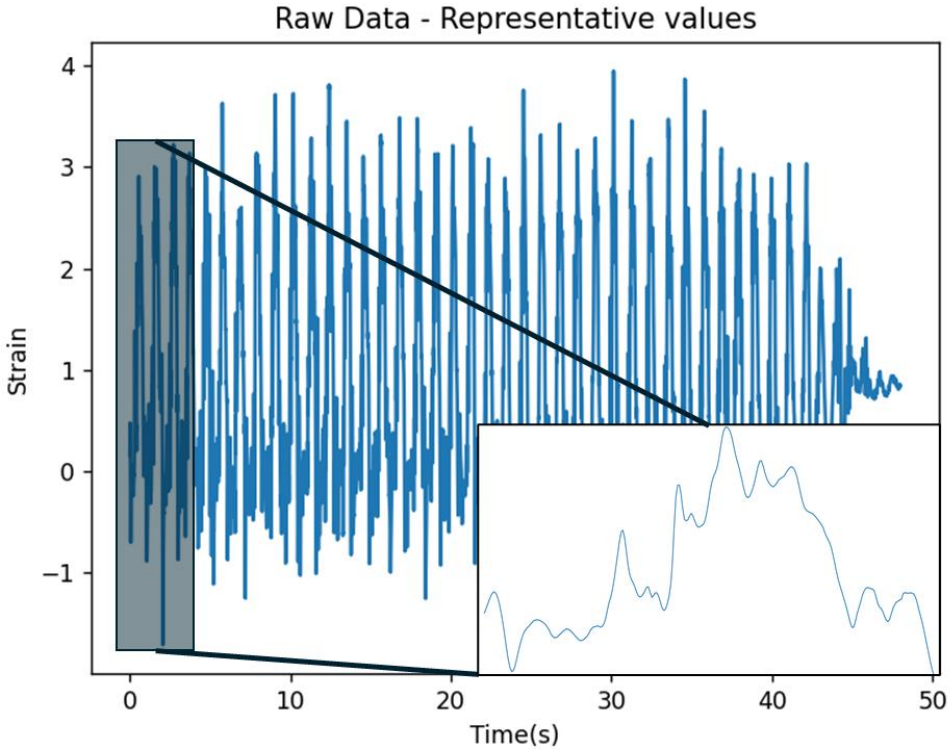


Cure Monitoring



Static Test Monitoring

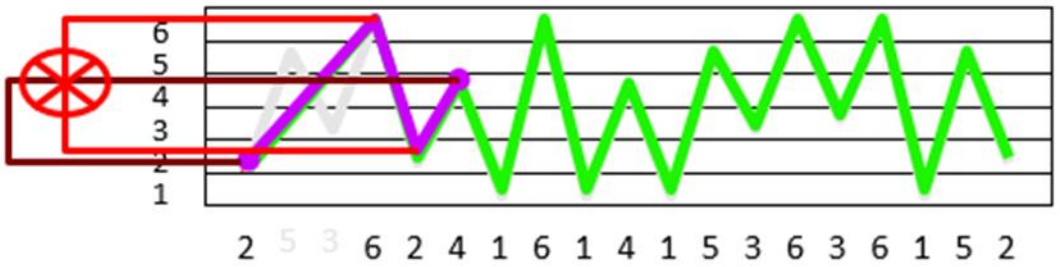
Strain change during Static Loading test



Maximum strain measured during test and residual strain after static test

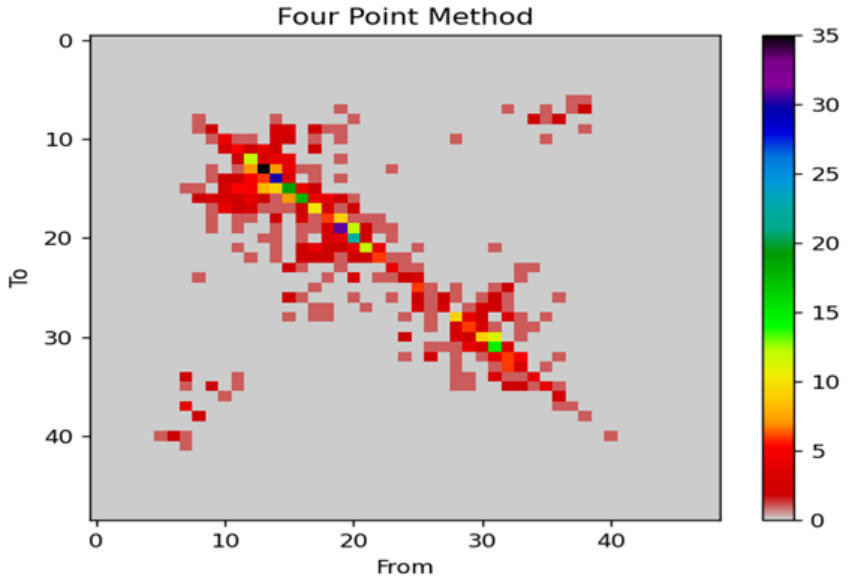
Sensor	Max. strain (με)	Residual strain (με)
FBG2-6	1159.4	-10.9
FBG2-7	989.9	-7.7
FBG2-8	958.3	-4.8
FBG2-9	504.7	-12.6
FBG3-14	-1068.4	-4.3
FBG3-13	-952.3	-4.3
FBG3-12	-1757.2	-4.7
FBG3-11	-2072.7	-23.8
FBG3-10	132.1	36.7

Prediction of the Remaining Useful Life



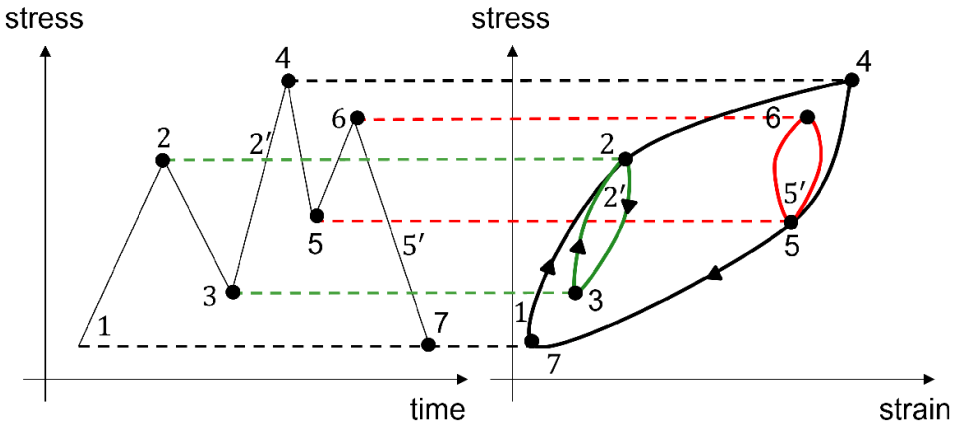
Strain Analysis of Real-World Irregular Loads

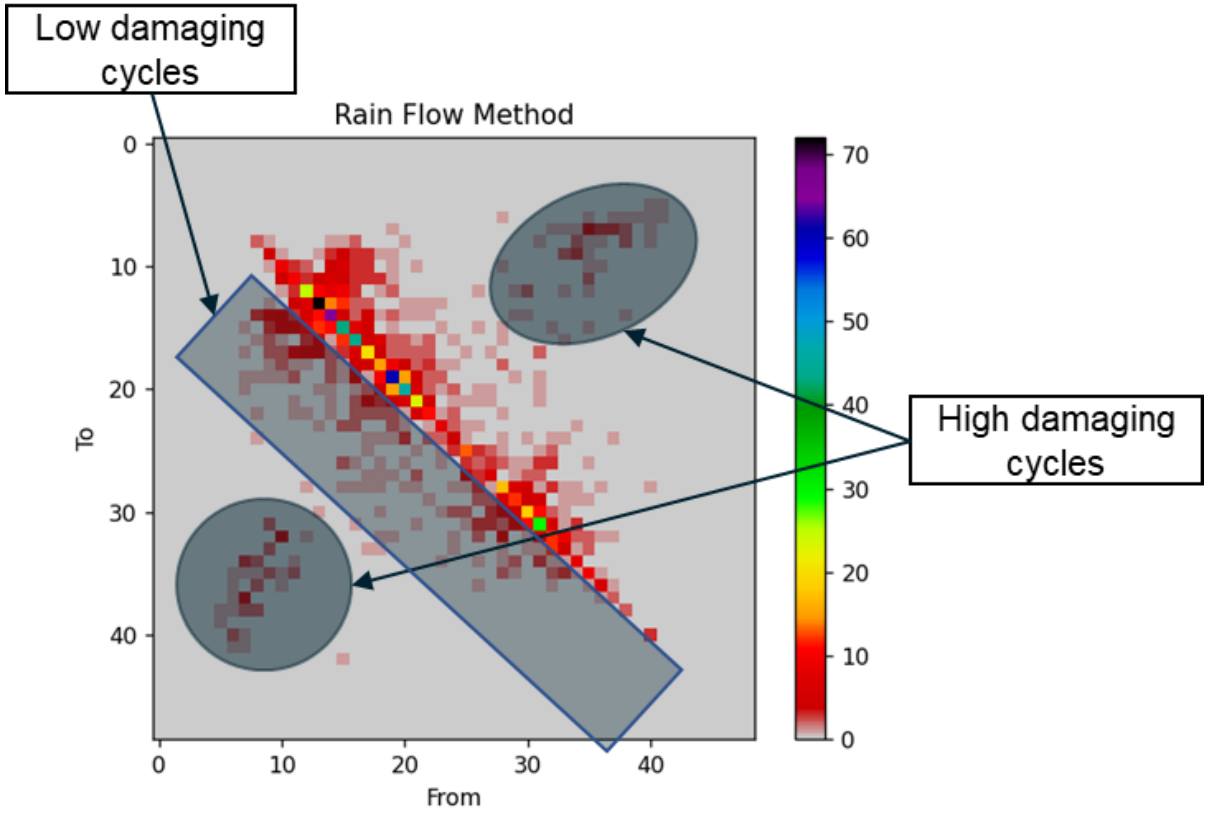
- Real-world strain transient data exhibit irregular behavior over time, making it difficult to count the number of cycles and the life span of that part
- Some methods and algorithms must be implemented to analyze this irregular data;
- Two of them are the Four-Point Method and the RainFlow method



Prediction of the Remaining Useful Life

Four-Point counting Method





The Four-Point Method is a simple algorithm to rapidly assess the incurred cycles across the transient data and indirectly acknowledge the part's fatigue life

Prediction of the Remaining Useful Life

RainFlow counting Method

The Rainflow method is a more robust approach to cycle counting and fatigue assessment;

It extracts the hysteresis cycles and is more precise to extract the damage caused by the “accumulation” of fatigue

Conclusions and Future Work

- The localized strain data allowed to verify the correct curing of the part
- The FBG sensors were able to accurately measure strain during static testing
- The application of cycle counting methods will give important in-situ information about the parts' lifespan, even extending their longevity. Furthermore, the information can be used to predict the most efficient way to plan maintenance operations, reducing the operational costs. Algorithms for the prediction of the Remaining Useful Life of the spar will be developed
- The same spar will be subjected to flight test, with sensing data being acquired in real-time

ABSTRACT

Design of lightweight (weight-minimized) composite structures that can meet stiffness, strength, and manufacturing constraints is challenging and time-consuming. Numerous constraints from wearable medical devices such as orthotics and exoskeletons, have geometric constraints from the user's anatomy determining their fit, comfort, and safety during wear. This paper presents a generative design methodology to create composite wearables customized to the user's anatomy. Design automation begins with a 3D scan of the relevant anatomy as input and produces 3D printable composite structure components. Through constrained optimization, the design process is accelerated by establishing the structural geometry, reinforcement fiber insertion paths, and manufacturing process plans. The methodology is illustrated on a patient-customized active ankle orthosis design. The geometric constraints are derived from a lower limb scan, and a patient-customized contact surface was generated and the fit is evaluated based on curvature and smoothness metrics. The surface is thickened to create a 3D structure, and the fiber reinforcement paths are determined based on the strength, stiffness, and limitations of additive manufacturing machinery. Considerations from the composite Process–Structure–Property–Performance (PSPP) relationships allow the considerations void and defect introduction by the 3D printing process. The insertion of generative design, automation, and optimization techniques reduced the scan to a real part cycle from several days to about 18 hours. The paper presents treadmill walk testing results from 15 healthy subjects.

1 INTRODUCTION

The development of personalized wearable medical devices, particularly orthotics and exoskeletons, represents a significant challenge in the intersection of biomechanics, materials science, and manufacturing technology. Traditional approaches to designing these devices often rely on manual processes that are time-intensive, costly, and may not fully optimize the mechanical properties required for individual users. The emergence of generative design methodologies, combined with advances in composite manufacturing and 3D printing technologies, offers unprecedented opportunities to create patient-specific devices that maximize performance while minimizing weight and production time [6].

Composite materials have gained prominence in wearable device applications due to their exceptional strength-to-weight ratio, design flexibility, and ability to be tailored for specific loading conditions [1,2]. However, the design of composite structures for wearable applications presents unique challenges,

including complex geometric constraints imposed by human anatomy, the need for comfortable user interfaces, and manufacturing limitations inherent in additive manufacturing processes. Additive Manufacturing (AM) has revolutionized the fabrication of composite structures by enabling complex geometries and customized fiber architectures. Fused filament fabrication (FFF) with continuous fiber reinforcement has emerged as a leading technique for producing high-performance composite components [3, 5]. Carbon fiber-reinforced polymers (CFRPs) and glass fiber-reinforced polymers (GFRPs) have demonstrated superior mechanical properties compared to traditional metallic materials, making them particularly attractive for lightweight wearable applications [7]. The biocompatibility and corrosion resistance of certain composite systems have further expanded their adoption in direct-contact medical applications [2]. Recent advances have enabled the development of patient-specific orthotic devices with tailored mechanical properties, achieving a weight reduction of up to 40% while maintaining equivalent stiffness characteristics compared to conventional materials [16].

The Process–Structure–Property–Performance (PSPP) framework provides a systematic approach to understanding the relationships between manufacturing parameters, resulting microstructure, material properties, and ultimate device performance. This framework becomes particularly critical when designing composite structures using additive manufacturing, where process-induced defects and anisotropic properties significantly influence the final product characteristics [6,8].

The Taguchi method, developed by Genichi Taguchi, provides a systematic approach to experimental design that maximizes information extraction while minimizing the number of required experiments [9]. This methodology is particularly valuable in composite design applications where computational analysis can be expensive and time-consuming for complex geometries [12]. The method employs orthogonal arrays to systematically explore the design space and identify optimal parameter combinations through statistical analysis of variance (ANOVA) [10].

This paper presents a comprehensive generative design methodology that integrates anatomical scanning, constrained optimization, and composite manufacturing considerations to create patient-customized wearable devices. The methodology is demonstrated through the design and testing of an ankle orthosis, showcasing the potential for significant reductions in design cycle time while maintaining or improving device performance. Taguchi method enables efficient exploration of geometric parameters while maintaining statistical rigor in the analysis of mechanical performance metrics [11].

2 METHODOLOGY

2.1 Generative Design Framework

The proposed generative design methodology follows a systematic approach that begins with the acquisition of anatomical data and progresses through geometric modeling, optimization, and manufacturing planning. The framework consists of three primary phases: anatomical scanning and constraint definition, surface generation and parametric modeling, and peridynamics-based structural analysis.

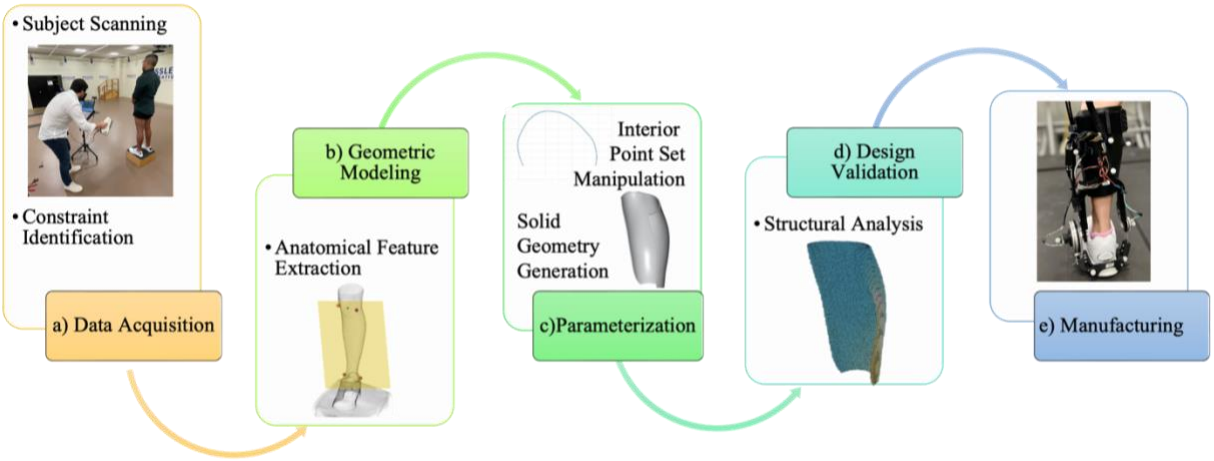

Figure 1: Geometric Design Pipeline.

The anatomical scanning phase, Figure 1a), utilizes high-resolution 3D scanning technology to capture the precise geometry of the relevant body segments. For the ankle orthosis application, this includes detailed scanning of the lower limb from the knee to the foot, capturing critical anatomical landmarks and surface variations that influence device fit and comfort. The scanning data is processed to remove noise and artifacts while preserving essential geometric features.

Constraint identification involves establishing geometric, mechanical, and manufacturing boundaries that guide the optimization process. Geometric constraints are derived directly from the anatomical scan data Figure 1(b), ensuring that the final device maintains appropriate clearances and contact areas. Mechanical constraints include minimum stiffness requirements, maximum stress limitations, and fatigue considerations based on anticipated loading conditions. Manufacturing constraints include limitations imposed by the additive manufacturing process, including minimum feature sizes, support requirements, and fiber placement capabilities.

Patient-customized contact surfaces are generated using advanced surface modelling techniques that balance conformity to the anatomical geometry with mechanical performance requirements. This step produces a solid geometry and is depicted in Figure 1(c) within the design pipeline. The surface generation process utilizes surface reconstruction algorithms, such as the Poisson Reconstruction Algorithm [17], which create smooth, continuous surfaces while maintaining proximity to the scanned anatomy.

2.2 Parametric Design Space Definition

A parameterization step follows the surface reconstruction to produce a solid geometry— the definition of key variables that control the geometric characteristics of the orthotic shank. The solid geometry is generated by converting a 2D surface mesh into a 3D solid by slicing it horizontally at various heights to extract contour points. These raw contour points are fitted with NURBS curves to create parameterized cross-sections. Afterward, new points are generated by extending perpendicular vectors from each point according to the specified thickness value. The process concludes by connecting the inner and outer curve endpoints with smooth arcs, resulting in continuous, watertight slices that form the final 3D solid structure. The structural analysis is performed on two parameters that control the shape of the contours: the thickness value and the profiling values.

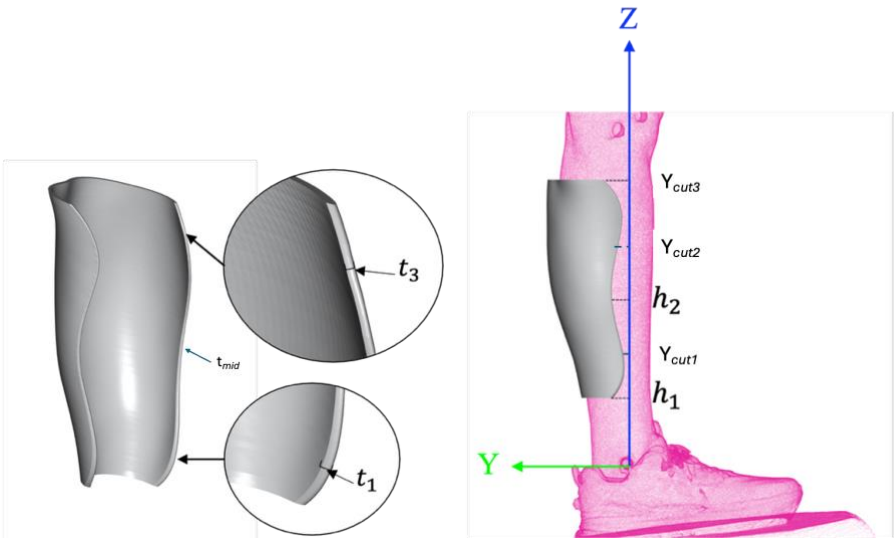

Figure 3: Variables corresponding to the thickness and profile of the shank. Geometry is parametrically varied by adjusting four variables, t_{mid}, Y_{cut1}, Y_{cut2}, and Y_{cut3}.

2.3 Taguchi L9 Orthogonal Array Design

The complete design space was systematically explored using Taguchi L9 fractional factorial analysis methodology. The full factorial design space encompasses 81 possible combinations, but the L9 array reduces this to nine strategically selected configurations that provide comprehensive coverage of the parameter space. We selected four variables to control the geometry of the shank as shown in Table 1.

Variable	Level1 (mm)	Level 2 (mm)	Level 3 (mm)
t_{mid}	3	4	5
Y_{cut1}	5	10	20
Y_{cut2}	15	20	25
Y_{cut3}	20	30	40

Table 1: Fractional Factorial (L9) Design Space.

Run	t_{mid} (mm)	Y_{cut1} (mm)	Y_{cut2} (mm)	Y_{cut3} (mm)
1	3	5	15	20
2	3	10	20	30
3	3	20	25	40
4	4	5	20	40
5	4	10	25	20
6	4	20	15	30
7	5	5	25	30
8	5	10	15	40
9	5	20	20	20

Table 2: Taguchi L9 Orthogonal Array.

2.3 Peridynamics-Based Structural Analysis

The structural analysis framework employs peridynamics theory to evaluate the mechanical behavior of composite shank designs under physiological loading conditions. Peridynamics provides a non-local continuum mechanics formulation that is particularly well-suited for analyzing composite materials with complex microstructures and potential damage mechanisms [13].

The peridynamics formulation replaces the classical partial differential equations of continuum mechanics with integro-differential equations, allowing for natural treatment of discontinuities such as cracks, delaminations, and material interfaces [14]. This approach is particularly advantageous for composite structures where traditional finite element methods may encounter difficulties in capturing damage initiation and propagation.

The implementation utilizes a mesh-free discretization approach, where the material domain is represented by a collection of material points, each interacting with neighbouring points within a defined horizon. The interactions between material points are governed by pairwise force functions that encode the material's constitutive behavior, including elastic response, damage initiation criteria, and failure mechanisms [15].

2.5 Taguchi Analysis Methodology

The Taguchi analysis methodology systematically evaluates the mechanical performance metrics obtained from peridynamics simulations. The analysis focuses on maximum stress, reaction forces, deformation, damage evolution, and fatigue as key performance indicators.

The analysis employs Signal-to-Noise (S/N) ratios to quantify the robustness of each design configuration [19]. For mechanical properties where smaller values are preferred, like stress and deformation, the ratio used is defined as:

$$\text{S/N} = -10log_{10}(\frac{1}{n}\sum y^2) \quad (1)$$

For properties where larger values are preferred, like load capacity, the "larger-is-better" S/N ratio is used:

$$\text{S/N} = -10log_{10}(\frac{1}{n}\sum \frac{1}{y^2}) \quad (2)$$

Analysis of Variance (ANOVA) is conducted to determine the relative contribution of each design parameter to the overall performance metrics, allowing us to identify the most influential parameters and optimal design configurations [20].

3 RESULTS AND DISCUSSION

3.1 Design Cycle Time Reduction

The implementation of the generative design methodology resulted in a dramatic reduction in design cycle time from the initial anatomical scan to the production of a functional composite device. Traditional manual design approaches typically required several days of skilled designer time, involving iterative modeling, analysis, and refinement cycles. The automated generative design process reduced this timeline to approximately 10 hours, representing a significant improvement in design efficiency.

The print direction received specific attention to match the anatomical complexity of the shank orthosis and to fulfil the mechanical requirements of dynamic gait loading. The orthosis in Batch 1,

Figure 4 left, is placed in the upright printing position as a single continuous piece to maintain the natural curvature and medial-lateral asymmetry of the patient's limb. The orientation of the print ensured that the layer lines followed the main loading direction because this direction is crucial for resisting torque during the gait cycle. To comply with the Bambu X1 printer's maximum Z-height of 256 mm, the generative design algorithm set the maximum length of the shank component to 250 mm. The upright configuration proved biomechanically superior; however, it required extensive support structures, which exceeded print stability limits due to the high aspect ratio.

The design of Batch 2, Figure 4, on the right, consisted of multiple parts arranged flat on the print bed to decrease the build height and enhance print reliability. The flat printing orientation reduced the likelihood of warping and resulted in improved surface quality throughout curved sections. The printing process utilized a 0.6 mm nozzle, combined with a 0.18 mm layer height, to achieve both mechanical strength and surface resolution. The orthosis features a 100% concentric infill pattern to enhance strength, adhering to the part contours and creating uniform torsional resistance. The chosen infill pattern minimized the chance of interlayer delamination and internal voids, which are essential for maintaining orthotic structural integrity when subjected to cyclic gait loading. The approach combines anatomical geometry with mechanical requirements to support both performance and manufacturability in patient-customized wearable devices.

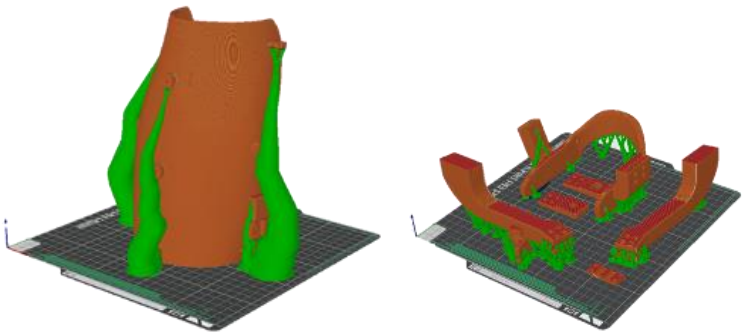

Figure 4: Printing batches in parallel allows for compliance with the machining time constraint.

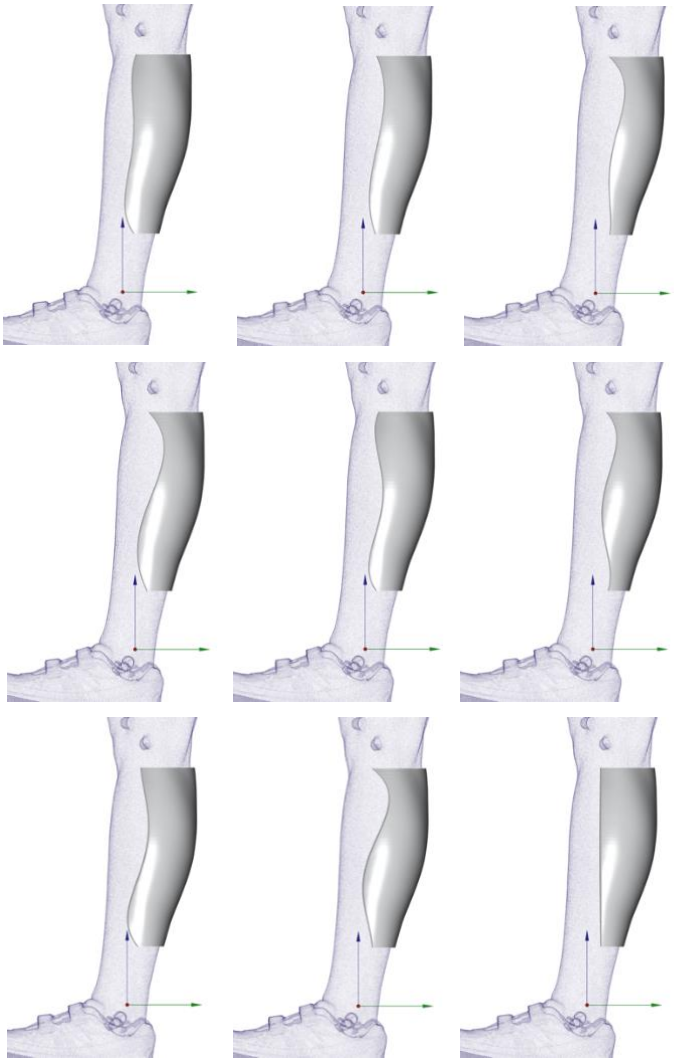
The time reduction was achieved through several key innovations, including automated surface generation algorithms, parallel optimization processing, and integrated manufacturing planning. The automated surface generation eliminated the need for manual surface modeling, while the parallel optimization approach allowed simultaneous evaluation of multiple design candidates. The integrated manufacturing planning ensured that manufacturability constraints were considered throughout the optimization process, eliminating the need for post-optimization design modifications.

3.2 Peridynamics Simulation Results

A comprehensive peridynamics analysis was conducted on all nine shank configurations from the L9 orthogonal array presented in Figure 5. The simulations were performed under a 2mm deflection scenario representative of the loading conditions resulting from the Series of Elastic Actuators (SEA) system. The analysis setup is shown in Figure 6. The left side represents the arrangement of particles for that shank, while the picture on the right illustrates the boundary conditions, represented by the points at the top, and the points at the bottom indicate the area subject to a deflection of 2 mm. Table 3 contains the mechanical properties data for each of the L9 configurations.



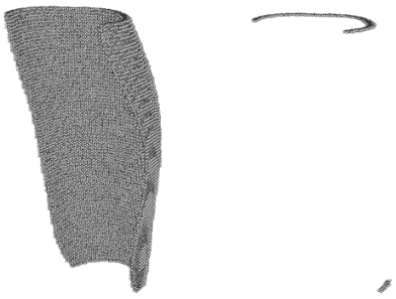


Figure 5: Profiles of the shanks analyzed with fractional factorial analysis.

(a) (b)

Figure 6: Point mesh used for the analysis and the locations where boundary conditions are applied (a) Point Mesh (b) Top surface is constrained, and bottom surface is pushed in to reflect the forces from the compliant actuator

Run	Mises Stress (MPa)	Max Displacement Magnitude (mm)	Reaction Force (N)
1	-1.85	7.9	4603
2	-1.40	6.2	2964
3	-1.00	7.2	2614
4	-1.05	8.7	2536
5	-1.05	8.2	4654
6	-0.70	7.1	3415
7	-0.67	5.5	3354
8	-0.41	6.2	2184
9	-0.64	11.2	2532

Table 3: Results from the simulations with factors from the Taguchi L9 array

3.3 Taguchi Analysis of Mechanical Properties

The Taguchi analysis reveals the relative importance of each design parameter in determining the stiffness performance of the orthotic shank designs. The study examines the sensitivity of mechanical properties to parameter variations and identifies optimal parameter combinations.

The main effect plots in Figure 7 illustrate how the response variable changes across different levels of each factor. The thickness level (T_{mid}) behavior suggests an optimal mid-range value. The variable Ycut3 exhibits the steepest and most consistent decline, which aligns with the ANOVA results indicating that this factor had the largest effect size.

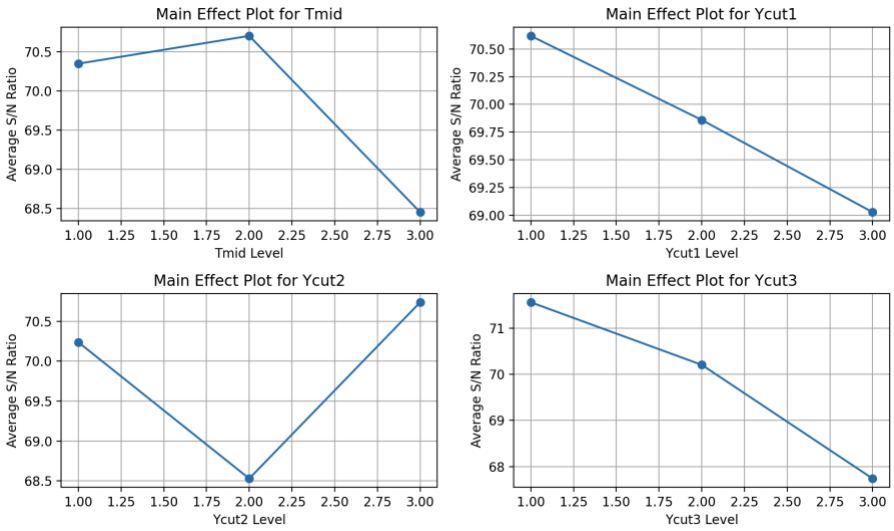

Figure 7: Effect tables for each level.

Source of Variation	Sum of Squares	Degrees of Freedom	F-Statistic	P-Value	Contribution (%)
t_{mid}	1,229,146	2	1.924	0.342	18.996
Y_{cut2}	1,288,155	2	2.016	0.332	19.908
Y_{cut3}	3,314,373	2	5.188	0.162	51.222
Residual	638,909	2	-	-	9.874

Table 4: ANOVA Table

Key findings from these results, presented in Table 4, show that $\boldsymbol{Y_{cut3}}$ shows the strongest effect, explaining 51.2% of the total variance with a large effect size. The low residual variance (9.9%) suggests that the model accounts for most of the systematic variation.

4 CONCLUSIONS AND FUTURE WORK

This paper has presented a comprehensive generative design methodology for creating patient-customized composite wearable devices. The methodology successfully integrates anatomical scanning, constrained optimization, and additive manufacturing considerations to produce high-performance devices with significantly reduced design cycle times. In addition, we present a systematic approach for analyzing composite orthotic shank designs using Taguchi's experimental design methodology combined with peridynamics-based structural analysis. The methodology successfully reduces the computational burden while maintaining statistical rigor in evaluating mechanical performance.

The key contributions of this work include the development of an automated surface generation algorithm that creates patient-specific contact surfaces, a multi-objective optimization framework that simultaneously considers mechanical performance and manufacturing constraints. The significant reduction in design cycle time from days to hours represents a major advancement in the practical implementation of personalized wearable devices.

The Taguchi method proves particularly effective for composite design applications where computational analysis can be expensive and time-consuming. The approach enables the identification of optimal design parameters while providing insights into parameter sensitivity and robust design practices.

Future work will focus on extending the methodology to other types of wearable devices. The integration of artificial intelligence techniques into the optimization framework represents another promising area for future development, potentially allowing for further reductions in design cycle time and improvements in optimization convergence. And the development of predictive models for mechanical performance based on Taguchi results.

Keywords: Green composites, Biopolymers, Natural fibers, Life cycle assessment, Environmental sustainability

ABSTRACT

The increasing urgency to address environmental challenges and reduce the environmental footprint of industrial processes has led to significant interest in the development of sustainable composite materials, commonly referred to as green composites or biocomposites. These materials usually consist of a bio-based or biodegradable polymer matrix reinforced with natural fibers.

In principle, biocomposites combine environmental benefits — such as reduced greenhouse gas emissions, lower energy consumption and better disposal options — with promising mechanical properties and low weight.

However, the concept of "sustainability" in the context of green composites is multidimensional and encompasses not only the origin of the material and biodegradability, but also metrics of life cycle assessment, durability, resource renewability and socio-economic impact. A holistic assessment of these aspects is essential to avoid the risk of greenwashing and to ensure the true environmental benefits of these new materials.

In this work, a representative case study from the literature is presented to highlight the importance of critically assessing the environmental impact of supposedly green materials such as biocomposites. The aim is to emphasize the crucial role of LCA analysis as an additional tool to characterize newly proposed materials.

1 INTRODUCTION

In recent decades, the transition to sustainable materials and production systems has become an urgent global priority. This change is driven by the growing awareness of environmental degradation, climate change, resource depletion and the unsustainable nature of many conventional production processes. In this context, green composites and especially biocomposites have emerged as one of the most promising material families to support a circular economy with low environmental impact. In the broadest sense, biocomposites are composite materials in which either the matrix, the reinforcement or both are derived from renewable, natural or biodegradable sources [1].

Biocomposites usually consist of natural fibers (such as flax, jute, hemp, sisal or agricultural residues) embedded in a polymer matrix that is either biodegradable (e.g. PLA, PHB) or bio-based (e.g. bio-polyethylene, bio-epoxy resins). These materials represent an attractive and increasingly feasible alternative to conventional composite materials based on synthetic fibers and petroleum-based resins. Their attractiveness lies not only in their use of renewable raw materials, but also in their potential to lower carbon emissions, reduce energy consumption during manufacture and improve end-of-life options, including composting and recyclability [2,3].

The environmental motivation for the development of biocomposites stems from their potential to mitigate various impacts associated with conventional composites. For example, life cycle assessment (LCA) studies have shown that natural fibers can reduce the global warming potential (GWP) of composites by 20–50% compared to synthetic alternatives [4]. This is mainly due to carbon sequestration during plant growth and the lower embodied energy of natural fibers. In addition, many bio-based polymers are derived from agricultural waste streams or non-food biomass, which underlines their sustainability and reduces competition with food resources.

Economically, biocomposites offer the opportunity to utilize local biomass resources, especially in rural or developing regions, thus promoting green value chains and decentralized production systems. The growing market demand for sustainable solutions, particularly in the automotive, packaging, consumer goods and construction industries, has created further incentives for research and innovation in this area.

Despite these advantages, the development and introduction of green composites still faces a number of technical and systemic challenges. First, natural fibers exhibit variations in their mechanical properties due to different growing conditions, harvesting and processing techniques. This inconsistency can affect the predictability and repeatability of composite performance [5]. In addition, natural fibers are hydrophilic, which can lead to poor interfacial bonding with hydrophobic matrices and moisture absorption, reducing long-term durability, especially in humid environments [6].

Another limitation concerns the trade-offs in mechanical properties: while biocomposites are lightweight and often sufficiently strong for semi-structural applications, they may not achieve the stiffness, heat resistance or impact strength of high-performance synthetic composites such as carbon or glass fiber systems. Advanced fiber treatments (e.g. silanization, acetylation) and matrix modifications (e.g. compatibilizers, nanofillers) are currently being explored to address these issues, but they may result in environmental impacts or higher costs, negating some of the original sustainability benefits.

It is crucial to emphasize that sustainability in materials science is not a topic that is limited to a single variable. It must be evaluated through a holistic and multi-criteria lens. While bio-based origin and biodegradability are important, they alone are not enough to claim true environmental sustainability. Factors such as durability, toxicity, ethics in the supply chain, renewal rate and overall life cycle performance must also be considered. Indeed, some bio-based polymers require high energy inputs or generate significant emissions during synthesis, necessitating a careful LCA comparison with petrochemical alternatives [7]. Furthermore, end-of-life scenarios remain a complex issue. While certain biocomposites are marketed as biodegradable, actual degradation rates vary widely depending on conditions, and industrial composting facilities may be required for effective degradation. In parallel, thermoplastic-based biocomposites can be recycled, but the separation of fibers and matrix remains a technical challenge. As a result, many green composites are still incinerated or landfilled unless they are specifically designed for the circular economy [8].

Overall, the future of biocomposites lies in the balance between performance, sustainability and scalability. From a system perspective, there is a growing need for standardization, certification systems and eco-labels that can validate the sustainability claims of green composites. This includes harmonized methods for life cycle assessment, toxicity screening and biodegradability testing. Such frameworks are essential to avoid the pitfalls of greenwashing and to inform both consumers and industrial users about the real benefits and limitations of these materials.

2 CASE STUDY

In a recent review by Suarez et al. the aspects related to sustainability of polymer composites were assessed, with the goal of highlighting if natural-based composites are actually sustainable [9]. The authors concluded that “there is a wide number of publications dealing with the use of natural fibers or natural, biodegradable or biobased matrices, which claims to be producing a more sustainable or more environmentally friendly material than those based on fuel, although very few of them have performed environmental analysis to really demonstrate this point”. Although the number of studies using LCA analyzes to quantify the environmental impact of biocomposites together with their technical performance is increasing, much remains to be done to understand the relationship between materials, processing and performance, both in terms of final application and environmental impact. As a representative case study in this direction, the work done by Filippone and co-workers [10] is considered in the following. In particular, the environmental implications due to the presence of the lignocellulosic microfibers were assessed by using unfilled PLA as benchmark. A “cradle-to-gate” life cycle analysis was carried out, considering the following three processes: a) production of the microfibers; b) production of the PLA; c) manufacturing of the bio-pellets (Fig. 1).

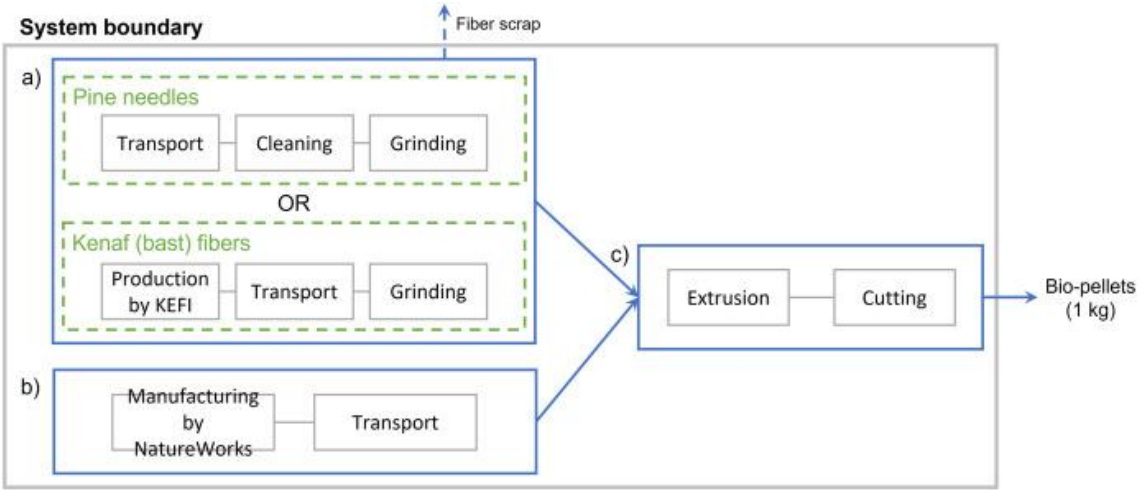

Figure 1: System boundary (*cradle-to-gate* life cycle). The process is divided into three sub-processes: a) production of the microfibers; b) production of the PLA; c) manufacturing of the bio-pellets. Taken from [10].

Moreover, since the origin of natural fibers has a strong effect on their environmental impact, two types of fibers are considered in the study, namely kenaf and pine needles microfibers, in order to compare cultivated and naturally grown feedstocks. Original fibers and microfibers obtain after the grinding process are shown in Fig. 2.

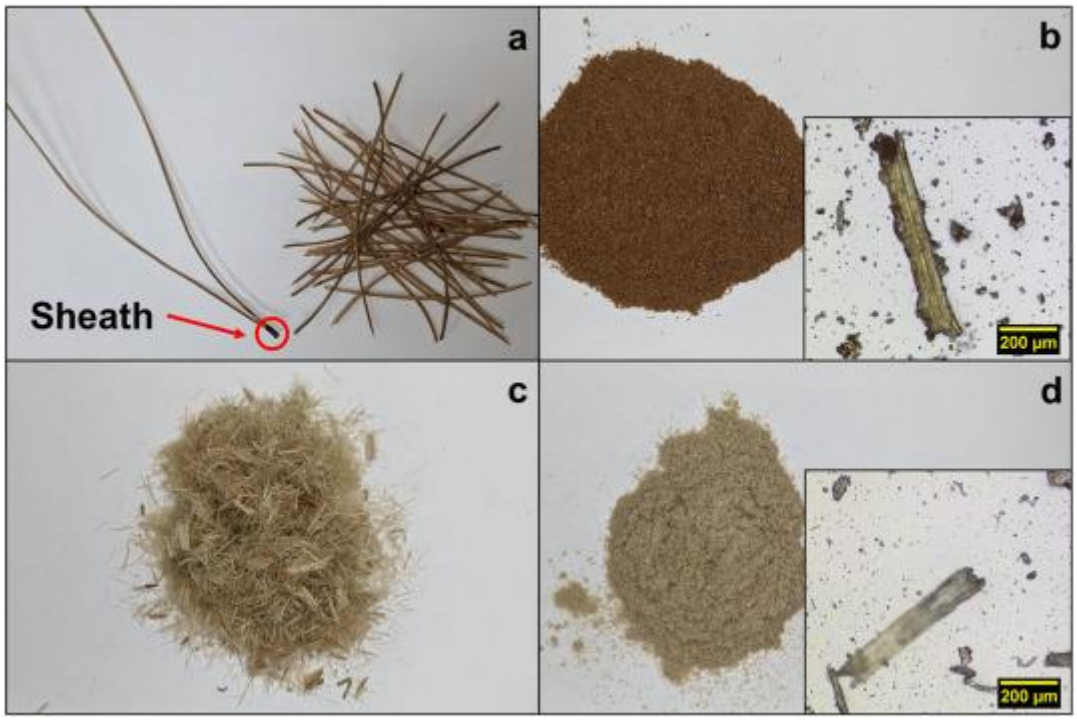

Figure 2: Pine needles and kenaf fibers before (a, c) and after (b, d) the grinding process. The arrow in a) indicates the fascicle sheath. Magnifications in b) and d) show the microfibers obtained after grinding that were used for producing the green composites. Taken from [10].

Interestingly, the LCA analysis revealed that fibers obtained from naturally grown raw material are only slightly better than cultivated ones in terms of environmental impacts. The main advantages of using natural raw materials concern the indicators for human toxicity and ecotoxicity. This is mainly

due to the impact of the washing and drying phases of the pine needles. Greater advantages of naturally grown raw materials are expected in the event of an industrial scale-up of fiber production. More importantly, the environmental impact of composites resulting from the combination of the effects of polymer and fillers and the contribution of the melt mixing process is much lower than that of pure PLA. The higher the fiber content, the greater the benefits (Fig. 3). The reason for this is that the fibers represent a negligible environmental impact compared to the polymer matrix. Therefore, replacing "high impact" PLA with "low impact" natural fibers is always preferable.

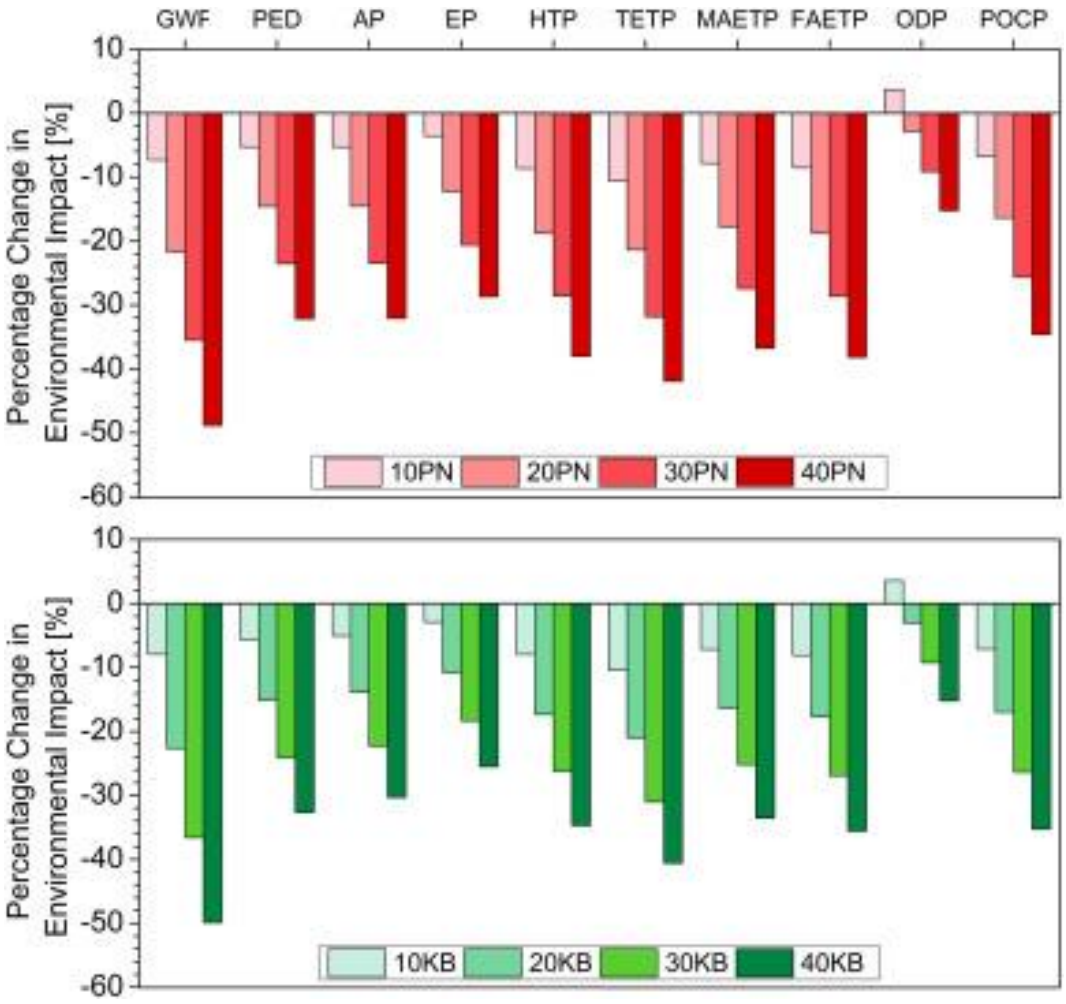

Figure 3: Percentage change in the environmental impacts of *x*PN and *x*KB bio-pellets with respect to pure PLA pellets (*x* indicates the percentage volume fraction of microfibers in the composite). Taken from [10].

In addition to the benefits arising from the improved environmental fingerprint, the selected fibers are also expected to improve the performance of the tested materials to a certain extent. This has an indirect impact on the overall sustainability of the composites, as improved performance potentially enables material savings [11]. For this reason, the mechanical performance of the composite samples was estimated and converted into weight reductions (Fig. 4).

A stiffness-limited design of a panel proves that the use of green composites instead of pure PLA leads to material savings of up to 8% (at 30% of the KB). By optimizing the formulation, e.g. by using surface-treated natural fibers to improve the polymer-fiber interaction, a much greater weight reduction could be achieved. In the latter case, a functionality-based LCA would be also necessary to assess whether this material saving outweighs the environmental impact of the fiber treatment.

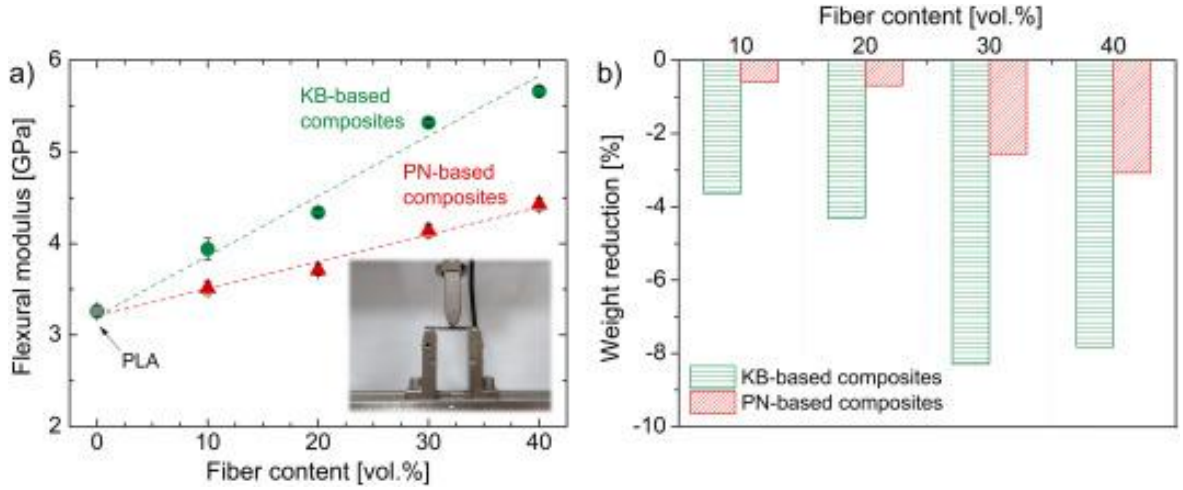

Figure 4: a) Flexural modulus of green composite samples as function of the fiber content. The testing setup for 3-point bending measurements is shown in the inset (dashed lines are guides for the eye). b) Percentage weight reduction achievable using green composites at different fiber content to realize a rectangular panel at fixed bending stiffness. Taken from [10].

3 CONCLUSIONS

In summary, green composites are a rapidly developing area with great potential to support the transition to sustainable and circular material systems. Their environmental attractiveness is obvious, but scientific rigor and holistic assessment are essential to ensure that their development leads to real environmental and social benefits. Collaboration between materials scientists, environmental engineers, industrial designers and policy makers will be crucial to overcome the current barriers and make biocomposites mainstream across all industries.

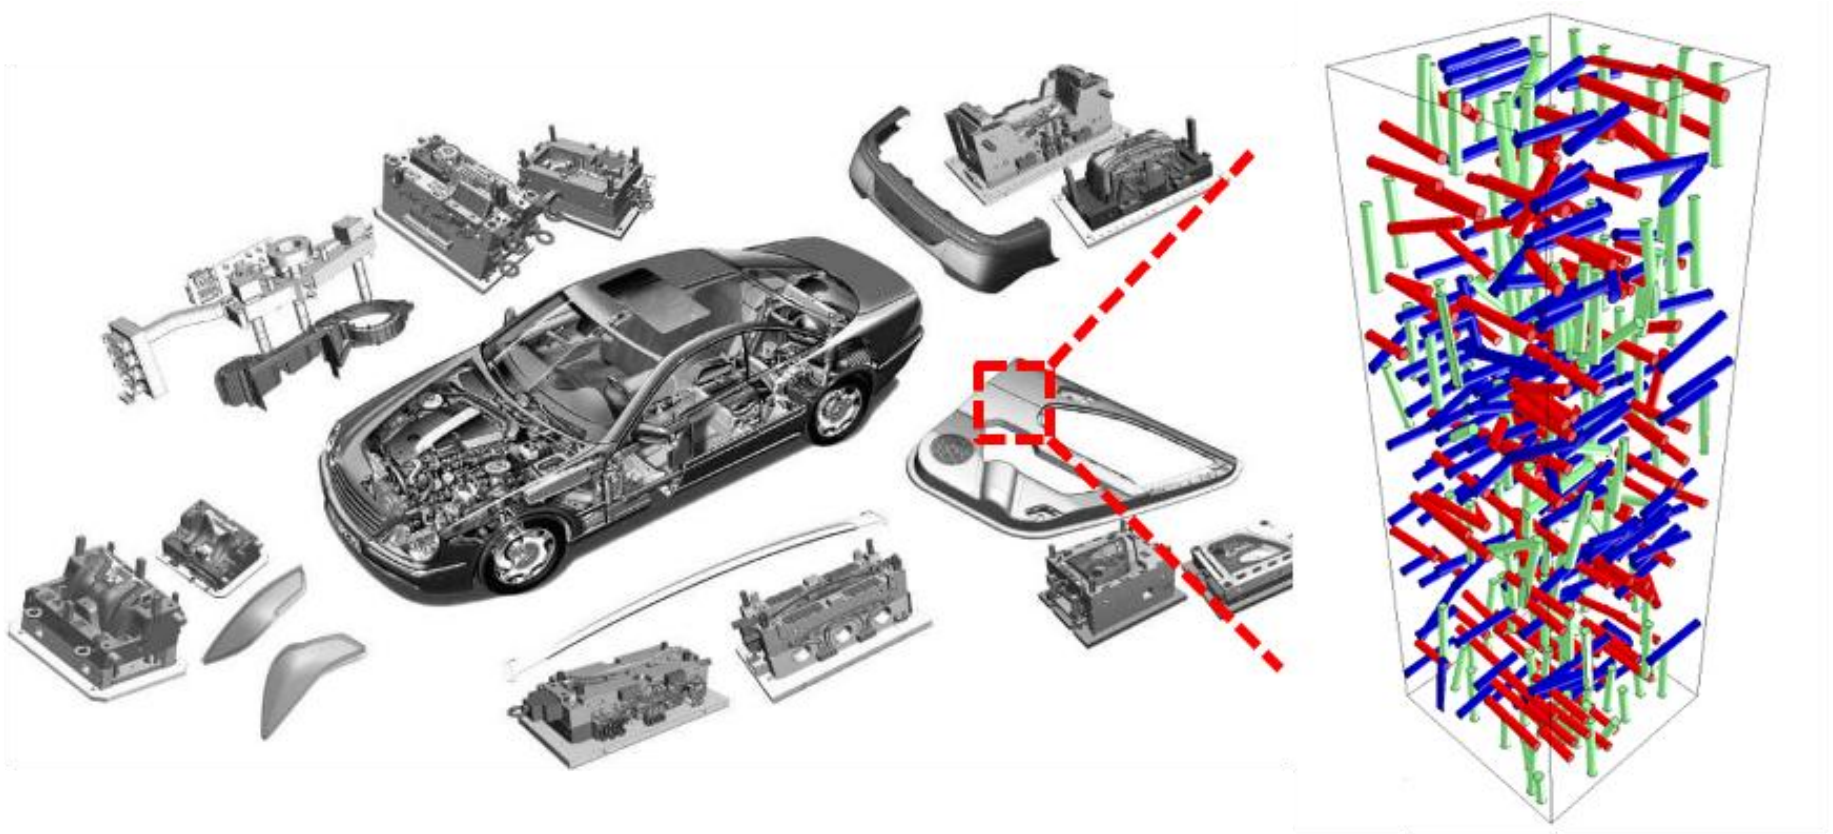
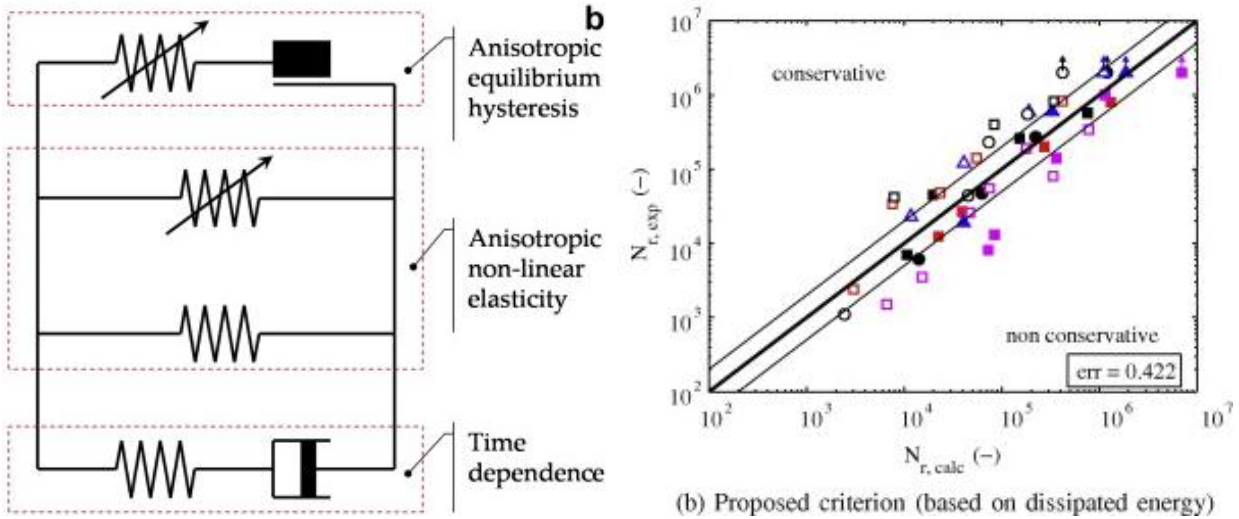
Computational Mechanics 61 (2018) ***729-750***



Anisotropic dependence on mechanical behavior

Composites: Part A 73 (2015) 166–175

- Tensile behavior of SFRP has strong dependence on local anisotropy induced by injection molding process.
- Mechanical behavior prediction method maintaining high accuracy and low computation cost is necessary for properly using SFRP in industrial field.

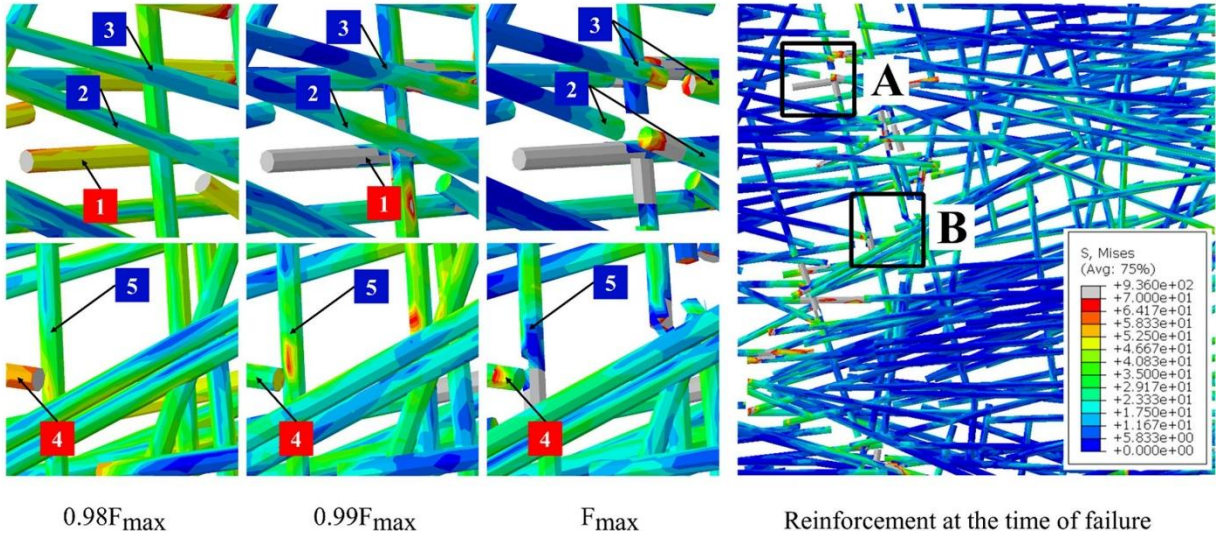


Prediction of the static failure behavior of SFRP Parts

How can we predict the mechanical failure behavior of this anisotropic composite?

Mechanical models for SFRPs

Phenomenological models



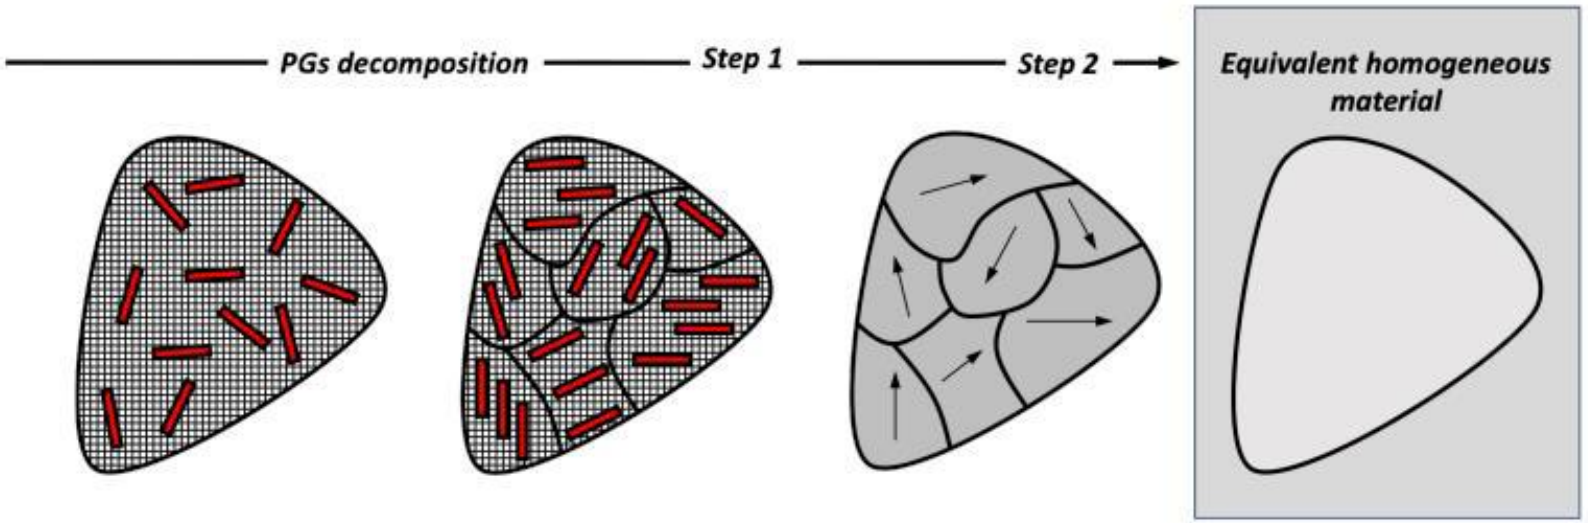
(b) Proposed criterion (based on dissipated energy)

European Journal of Mechanics-A/Solids 29(6) (2010) 1065-1077

International Journal of Fatigue 136 (2020) 105571

- Require labor-intensive experiments to characterize the fatigue properties considering the properties of constituents (fiber volume fraction, aspect ratio or orientation tensor).
- → **Difficult for modeling SFRP parts** that have significantly different mechanical properties due to varying the **local fiber orientation**.

Micromechanical models



$0.98F_{max}$ $0.99F_{max}$ F_{max} Reinforcement at the time of failure

International Journal of Fatigue 160 (2022) 106880

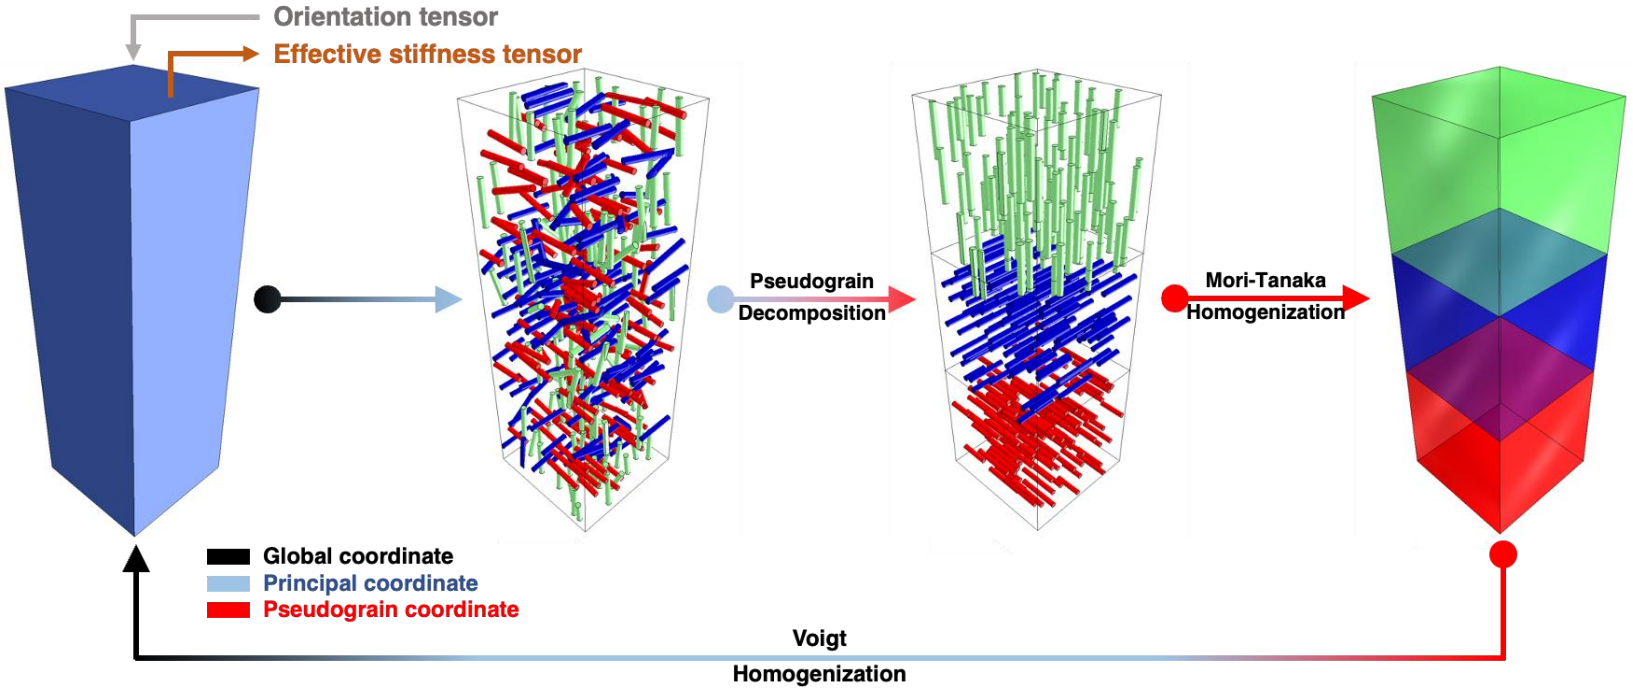
- Describe the fatigue failure of SFRPs considering individual constituents (fiber, matrix, and interface).
- → **Time-intensive** because stress calculation of all fibers, matrix and interfaces is enormous.

Two-step homogenization for SFRPs

1. **Pseudograin decomposition**: Gommers (1998), Weber (1999), Ogierman (2017)
2. **1st Homogenization**: Mori-Tanaka (1973)

$$\langle C \rangle_\Omega = [(1 - v_i)C_m + v_i C_i : A^\varepsilon] : [(1 - v_i)I + v_i A^\varepsilon]^{-1}$$
$$A^\varepsilon{}_{MT} = [I + S : (C_m{}^{-1} : C_i - I)]^{-1}$$

3. **2nd homogenization**: Voigt (1889)



$$\langle C \rangle_\Omega = [(1 - v_i)C_m + v_i C_i]$$

Thesis Ecole Polytechnique de Louvain *61* (2019)

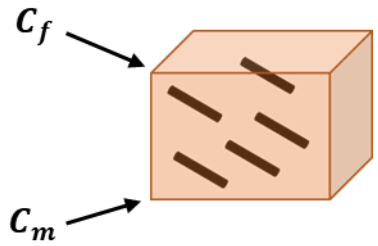
- **Two step homogenization method** was suggested to predict the mechanical behavior of SFRPs considering the **local orientation** and **computational cost**.
- Two-step homogenization is composed of following procedures.
  - Pseudograin decomposition: Gommers (1998), Weber (1999), Ogierman (2017)
  - 1st Homogenization: Mori-Tanaka (1973), Miller (2013)
  - 2nd Homogenization: Voigt (1889)
- DIGIMAT software allowed static failure prediction by using two-step homogenization, but failure behavior prediction showed high dependence on **user-defined failed weight fraction of entire pseudograin.**

We decided to develop ABAQUS user material subroutine (UMAT)

Based on two-step homogenization framework utilizing pseudograin approach.

Fiber - elastic

$\langle \Delta\varepsilon_f \rangle$



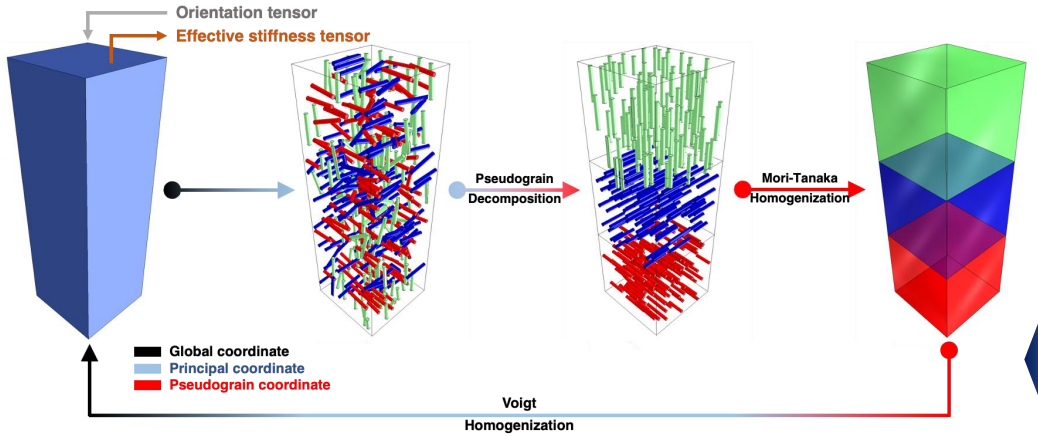
$$\langle \Delta\varepsilon_f \rangle = B : [v_f B + v_m I]^{-1} : \langle \Delta\varepsilon \rangle$$

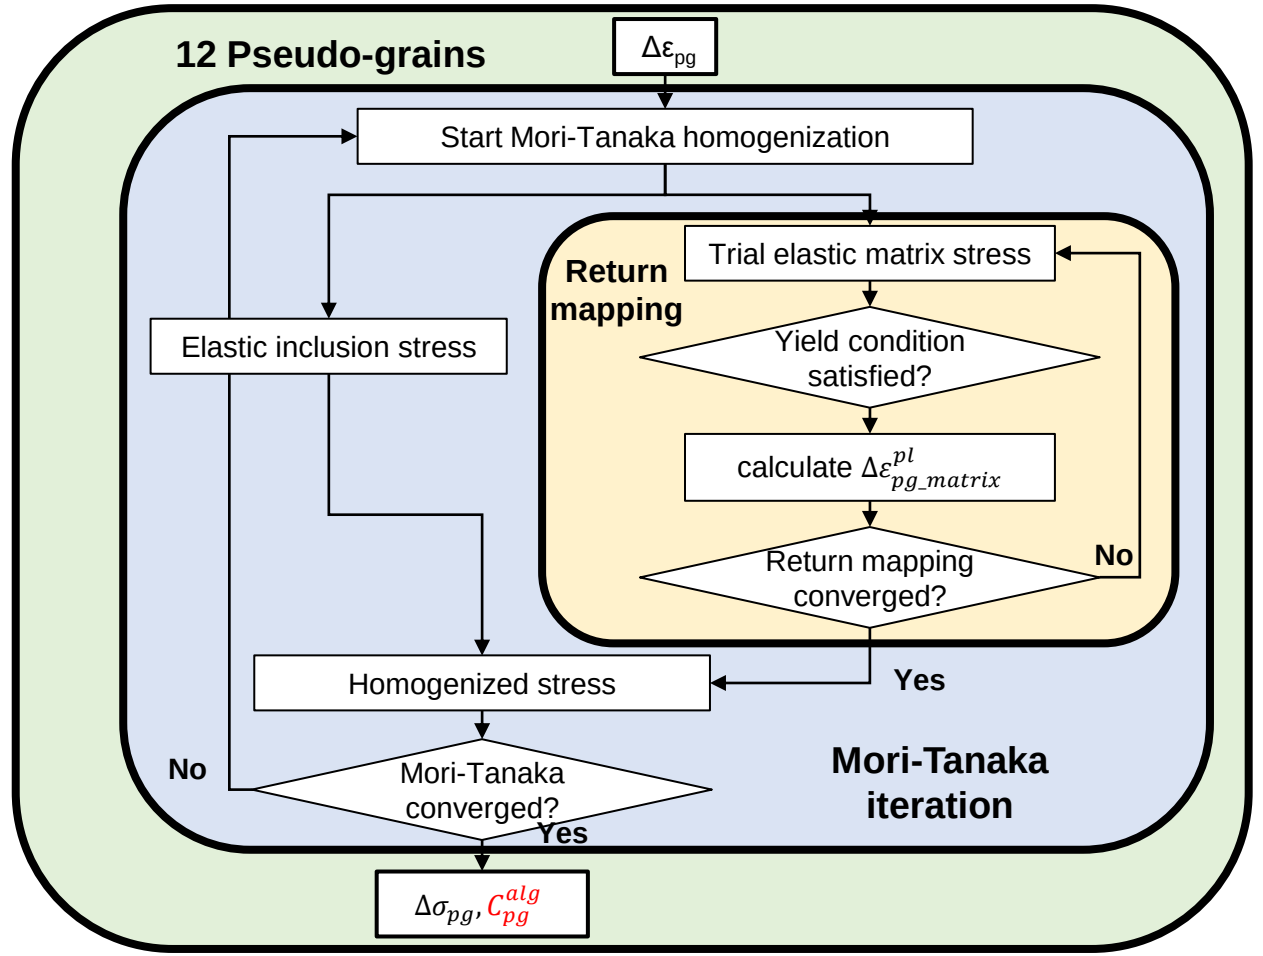
Matrix – viscoelastic viscoplastic

$\langle \Delta\varepsilon_m \rangle$

$$\langle \Delta\varepsilon_m \rangle = [v_f B + v_m I]^{-1} : \langle \Delta\varepsilon \rangle$$

Mori-Tanaka 1st homogenization



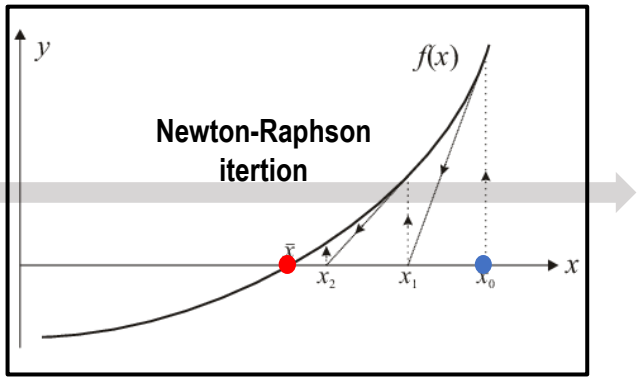


$$C_{PG} = [v_m C_m + v_f C_f : B^{\varepsilon}] : [v_f B + v_m I]^{-1}$$

$$\Delta\sigma_{PG} = C_{PG} : \Delta\varepsilon_{PG}$$

What are the main obstacles to achieve our goal?

Nested loop structure in 2-step homogenization algorithm

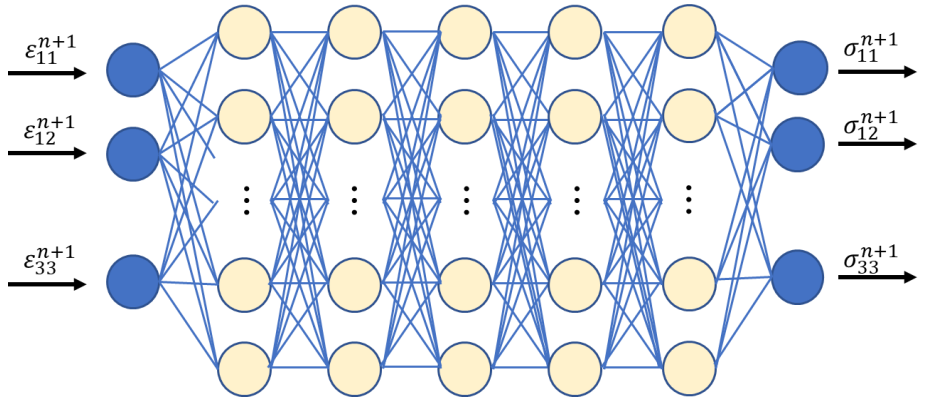


- ✓ 2-step homogenization using the pseudograin approach involves nested loops for calculation.

- → **The excessive number of iterations leads to increased computational time and lower vectorization efficiency.**

Comput. Methods Appl. Mech. Eng. 283 (2015) 1032–1060.

ANN-based constitutive equation

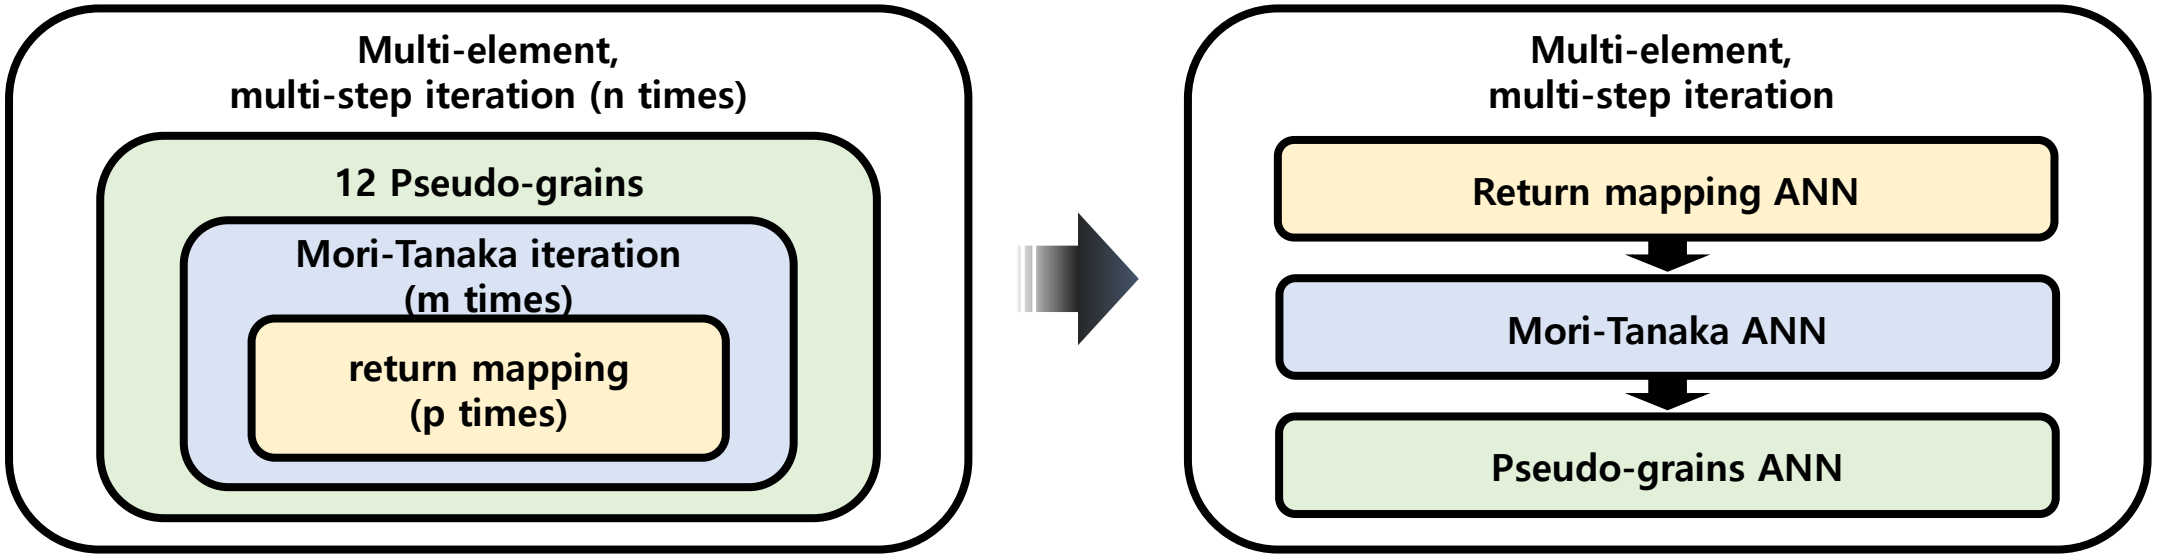


$\Delta\varepsilon$

$\Delta\sigma$
C^{alg}

Conventional constitutive equation

- ✓ Need to fully capture and understand the constitutive behavior of materials
- ✓ Iterative calculations to model non-linear plastic deformation

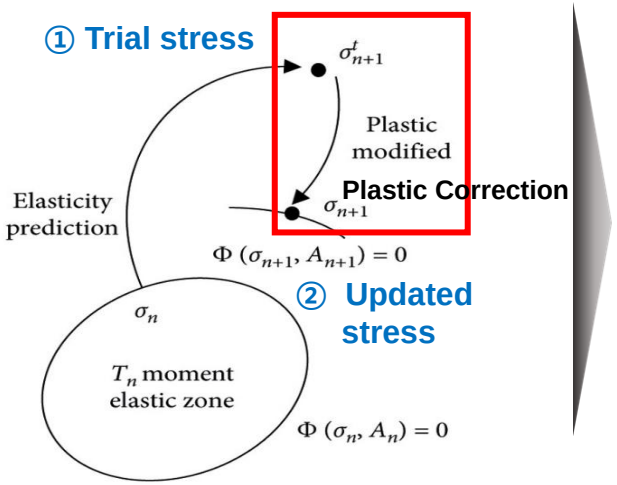


Artificial neural network (ANN)

- ✓ Highly nonlinear regression method predicting response without explicit function expressions
- ✓ Reduces the number of iterations and enhance vectorization efficiency

Comput. Methods Appl. Mech. Eng. 283 (2015) 1032–1060.

Initial approach: Modular ANN Architecture



Modularize each loop instead of creating multiple loops all at once.

1. Easy to focus on each system's physics, making pattern recognition and learning more effective.
2. Easy to modify each model when system changes occur, such as material changes.

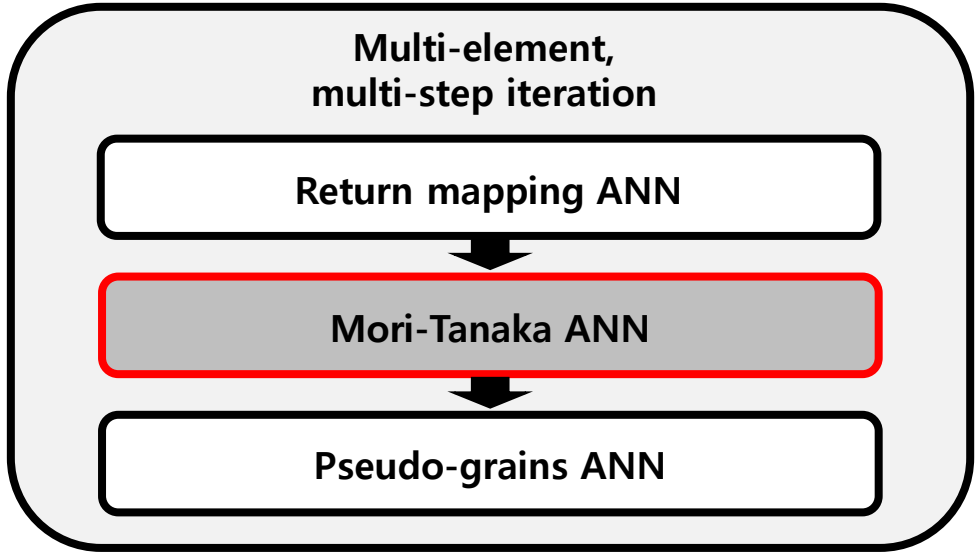
Deviatoric corrected stress (scalar)
Flow stress

Trial **Corrected**

Modular ANN (1): return mapping

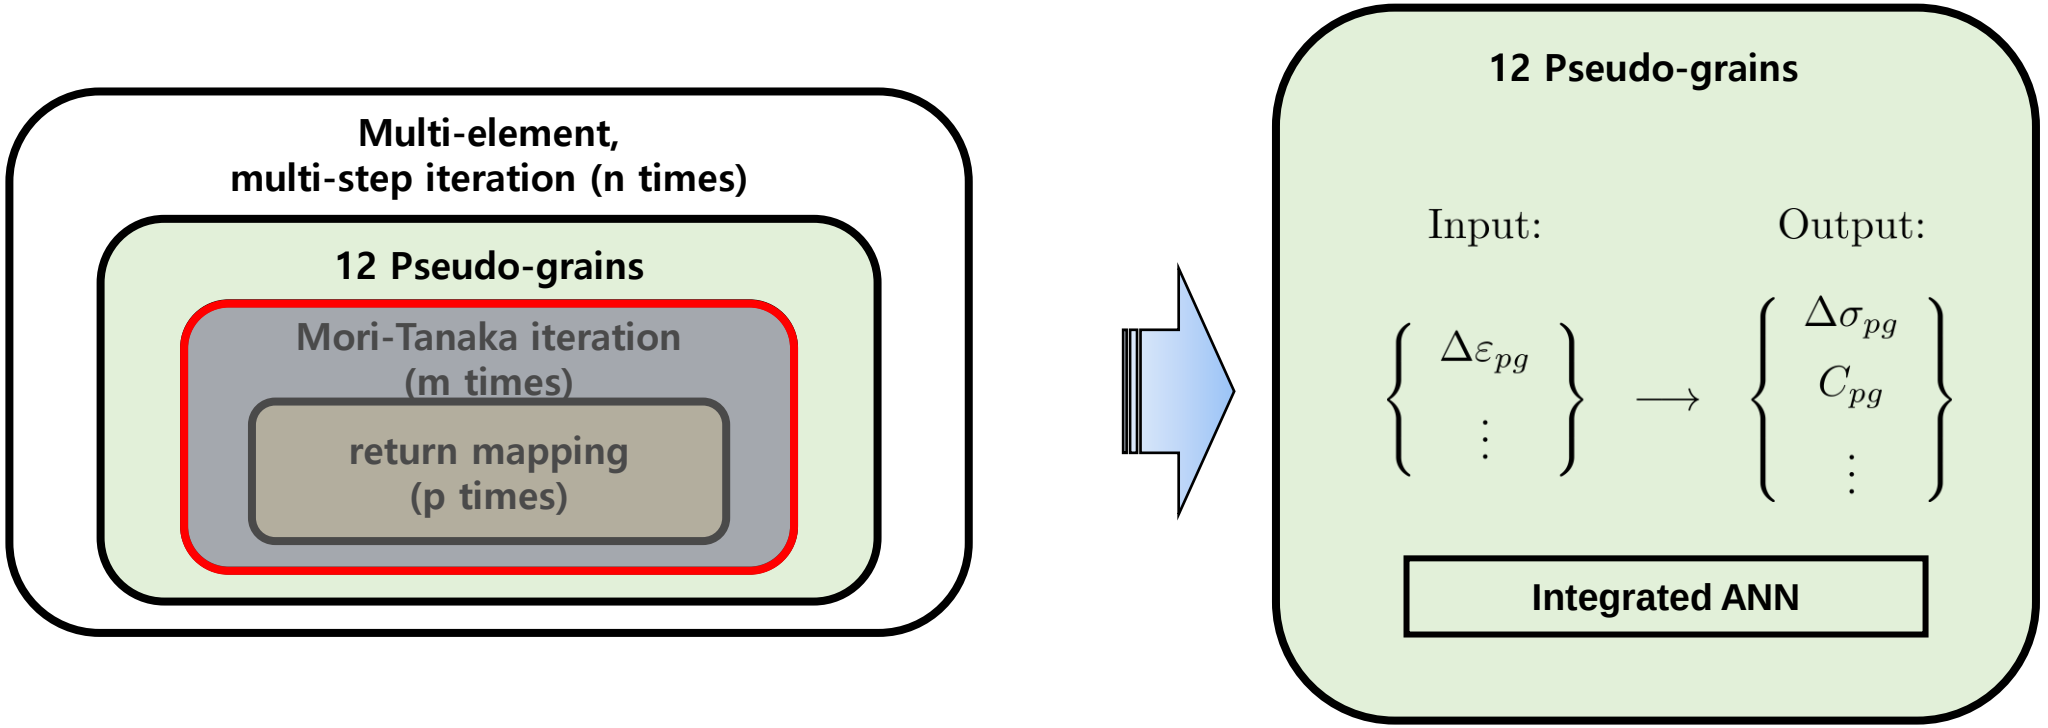


CPU calculation time for each algorithm

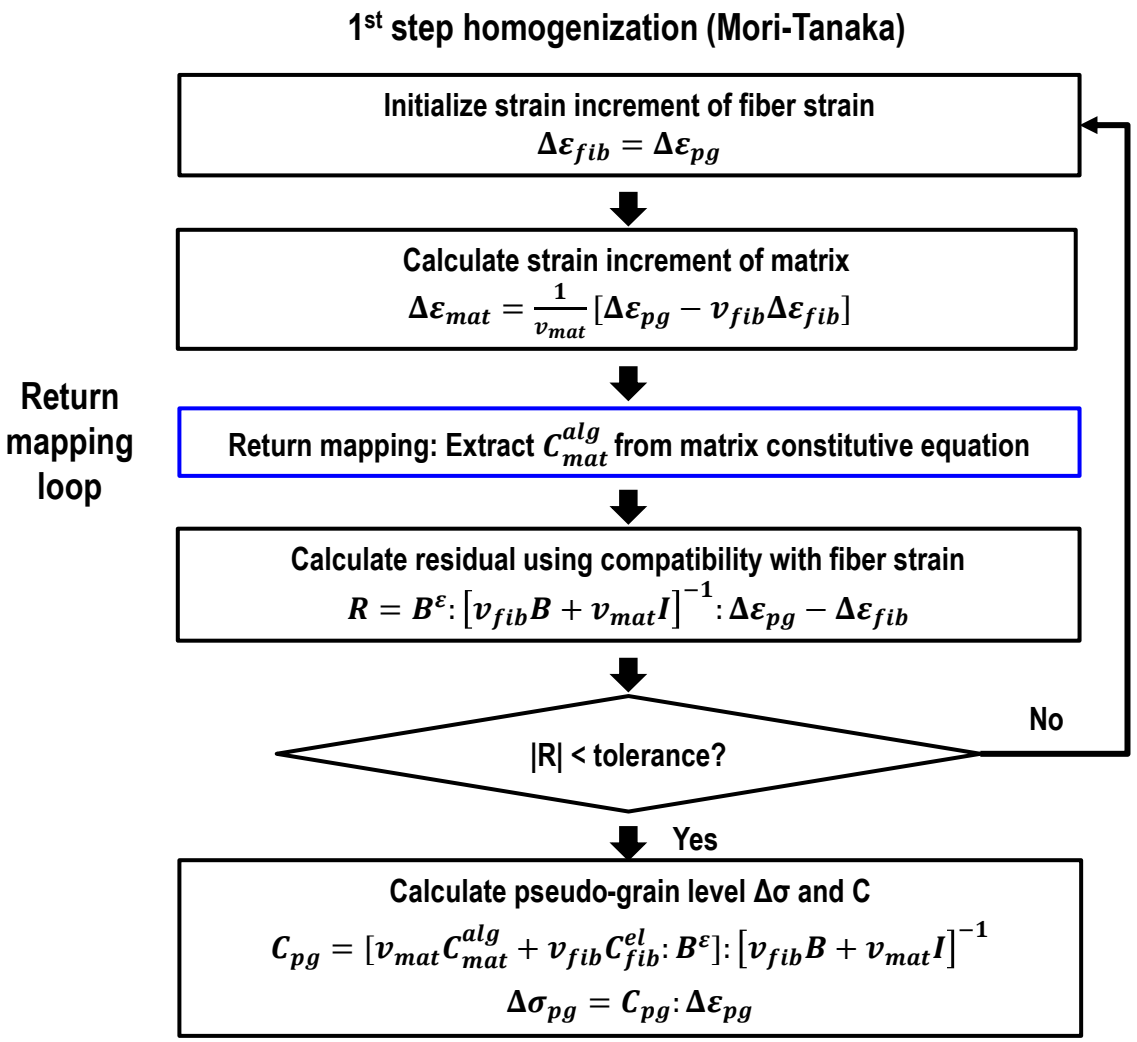
	Return mapping	ANN	Reduction rate
1000 elements	111 sec	108 sec	**3 %**
loop only	2.9 msec	1.6 msec	55 %

✓ Specimen level simulation showed both methods achieve high accuracy.

✓ The ANN model achieved a 55% reduction at the loop level, but only about 3% across the full 1000-element analysis.



Modular ANN (2): Mori-Tanaka homogenization ANN



- ✓ Error accumulation occurs due to the consecutive use of two neural networks.
- ✓ Since accurate prediction requires the output of one ANN as input for the other, using the first ANN's output as input was challenging.

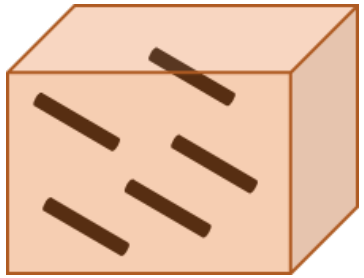
Alternative strategy: Integrated ANN

✓ Instead of sequentially connecting neural networks, a single integrated neural network that can simultaneously represent both systems is needed.

Mori-Tanaka iteration loop

- To estimate the macroscopic behavior of pseudo grain, the Mori–Tanaka homogenization method is used.
- Repeat until convergence:
  a. Decompose pseudo grain strain into matrix and fiber strain
  b. Update plastic matrix stress and elastic fiber stress
  c. Update average stiffness and recompute matrix strain
  d. Check convergence of matrix and fiber strain
- As a result, pseudo-grain level stiffness and stress are computed analytically.

Problem when using Integrated ANN



What we need is…

$\Delta\varepsilon_{pg}$

$\Delta\sigma_{pg}$ or C_{pg}^{alg}

Stress increment

Consistent tangent stiffness

Pseudo-grain

$$\Delta\sigma_{pg} = C_{pg}^{alg}\Delta\varepsilon_{pg}$$

Input:

$$\left\{\begin{array}{l}\Delta\varepsilon_{pg,11}\\ \Delta\varepsilon_{pg,22}\\ \Delta\varepsilon_{pg,33}\\ \vdots\end{array}\right\}$$

9+α inputs

$\longrightarrow$

Output:

$$\left\{\begin{array}{l}\Delta\sigma_{pg,11}\\ \Delta\sigma_{pg,22}\\ \vdots\\ C_{pg,11}\\ C_{pg,12}\\ \vdots\end{array}\right\}$$

9 outputs

36 outputs

- ✓ The ANN is designed to approximate Mori–Tanaka homogenization by mapping pseudo-grain strain to stress increment and tangent stiffness.
- ✓ However, directly using full 3D stress and stiffness tensors as ANN outputs makes the network excessively large and computationally inefficient.

→ **Need to reduce input and output features**

Strategy for integrated ANN (1): output feature

$$\left\{ \begin{matrix} \Delta\varepsilon_{mat} \\ \Delta\varepsilon_{fib} \end{matrix} \right\} \quad V_{mat}\Delta\varepsilon_{mat} + (1 - V_{mat})\Delta\varepsilon_{fib} = \Delta\varepsilon_{pg}$$

$$\left\{ \ \Delta\varepsilon_{fib} \ \right\} \quad B^{\varepsilon} : [V_{fib}B^{\varepsilon} + V_{mat}I]^{-1} : \Delta\varepsilon_{pg} = \Delta\varepsilon_{fib}$$

$$B^{\varepsilon} = \left[I + S : \left((C_{mat}^{iso})^{-1} : C_{fib} - I \right) \right]^{-1}$$

$$\left\{ \ C^{iso} \ \right\} \quad C^{\mathrm{iso}} \equiv 3\kappa^{ve} I^{\mathrm{vol}} + 2\mu^{reg} I^{\mathrm{dev}}$$

$$\left\{ \ \mu_{reg} \ \right\} \quad \mu^{\mathrm{reg}}(t_{n+1}) = \mu^{vep}(t_{n+1}) + (\mu^{\mathrm{reg}}(t_n) - \mu^{vep}(t_{n+1})) \exp\left(-\frac{h_{vep}}{h_v - h_{vep}} \right)$$

$$\mu^{vep} = \mu^{ve} \left(1 - \frac{3\mu^{ve}}{3\mu^{ve} + \frac{dR}{dp}(\bar{\varepsilon}^{p})} \right)$$

Regularized shear moduli

Knowing the matrix's **effective plastic strain ($\bar{\varepsilon}^{p}_{mat}$)** allows determination of $\Delta\varepsilon_{mat}$ and $\Delta\varepsilon_{fib}$.

Calculate matrix's stress and stiffness

$$\boldsymbol{\sigma}_{mat} = \mathbf{C} : \Delta\boldsymbol{\varepsilon}_{mat} - 2\mu\Delta\bar{\varepsilon}^{p}\mathbf{N}^{\mathrm{trial}}$$

$$\mathbf{C}_{mat}^{\mathrm{alg}} = \widetilde{\mathbf{E}} - \frac{(2\widetilde{G})^2}{h_v}\mathbf{N}\otimes\mathbf{N} - \left(2\widetilde{G}\right)^2 \frac{\sigma_{eq}\Delta\bar{\varepsilon}^{p}}{\sigma_{eq}+3\widetilde{G}\Delta\bar{\varepsilon}^{p}}\frac{\partial\mathbf{N}}{\partial\sigma}$$

- C_{pg} using rule of mixture
- Damaged stiffness and stress

∴ **The ANN requires only $\bar{\varepsilon}^{p}_{mat}$ as output.**

Strategy for integrated ANN (2): input features

Prior effective plastic strain of matrix

✓ Need to monitor the degree of plastic strain.

→ Use the effective plastic strain from the previous increment.

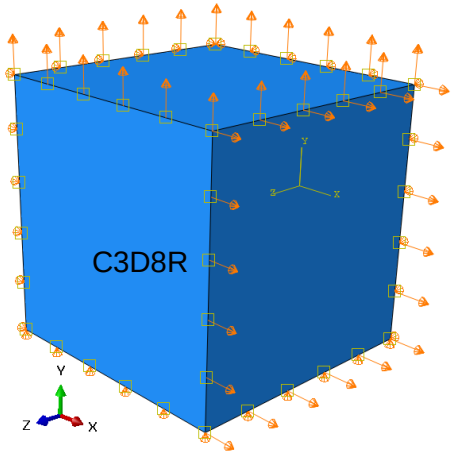
$$\bar{\varepsilon}^{p} = \sqrt{\frac{2}{3}\,\varepsilon_{ij}^{p}\,\varepsilon_{ij}^{p}}$$

Von-Mises pseudo-grain effective strain

✓ Need to provide scalar input for yield evaluation and plastic strain increment

→ Use von Mises equivalent strain derived from pseudo-grain level strain

$$\widehat{\varepsilon} = \sqrt{\frac{2}{3}\,\varepsilon_{\mathrm{dev}} : \varepsilon_{\mathrm{dev}}}$$



$$= \sqrt{\frac{2}{3}\left[(\varepsilon_{xx}-\varepsilon_{yy})^2 + (\varepsilon_{yy}-\varepsilon_{zz})^2 + (\varepsilon_{zz}-\varepsilon_{xx})^2 + 6(\varepsilon_{xy}^2+\varepsilon_{yz}^2+\varepsilon_{zx}^2)\right]}$$

Final ANN structure

$$(\bar{\varepsilon}_{mat}^{p,n}) = f_{\text{ANN-2}}\left(\widehat{\varepsilon}_{pg}, \bar{\varepsilon}_{mat}^{p,n-1}\right)$$

→ Two scalar values are used as input to predict one scalar output.

Dataset for integrated ANN (1)

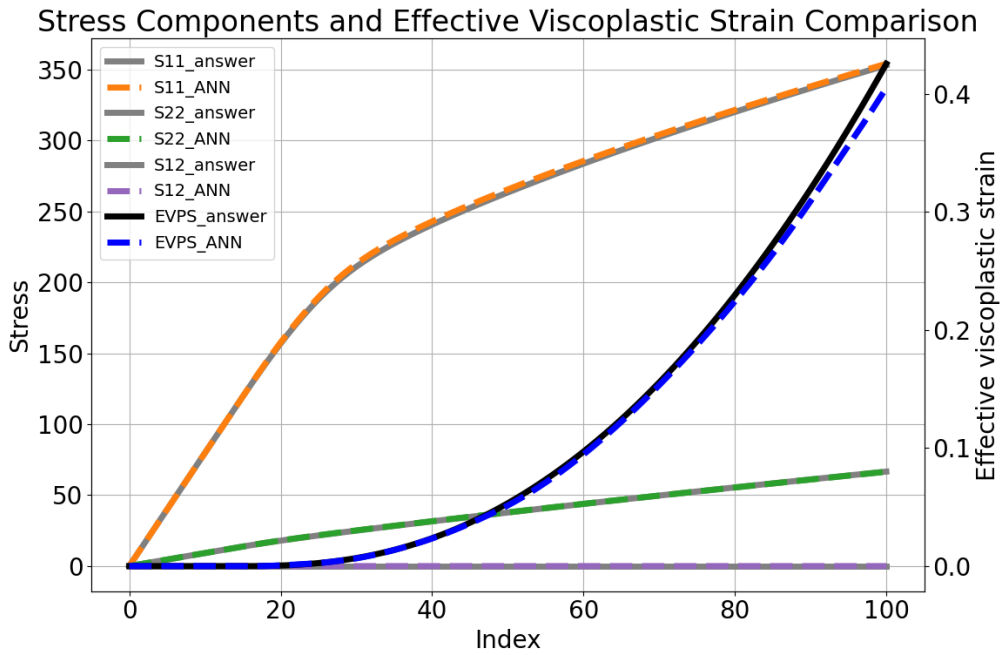
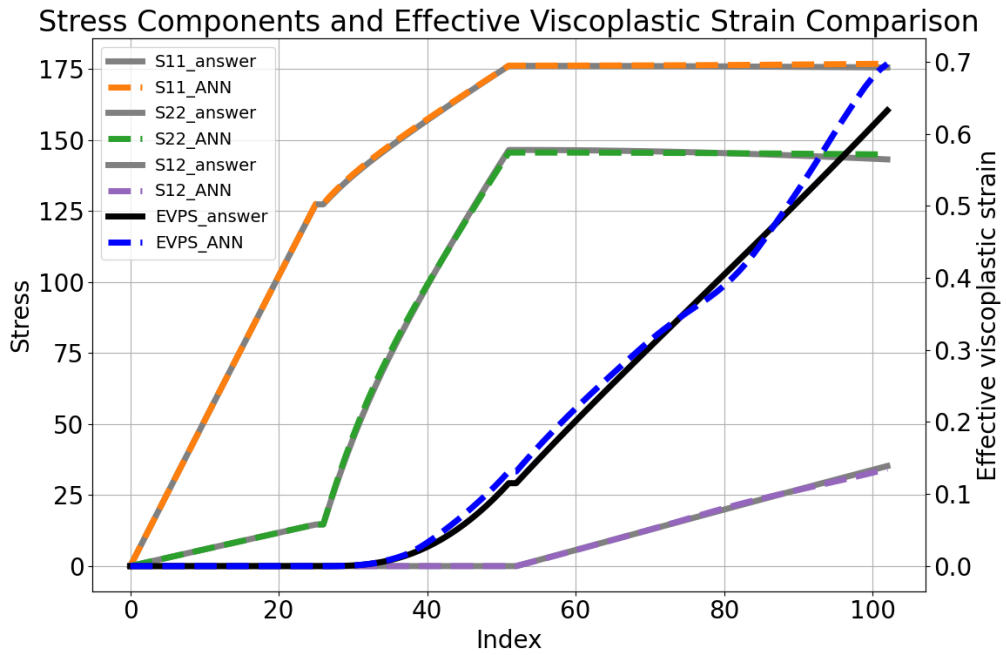
Test results (loading path #18~19)

→ 23-direction strain not included in training was used.



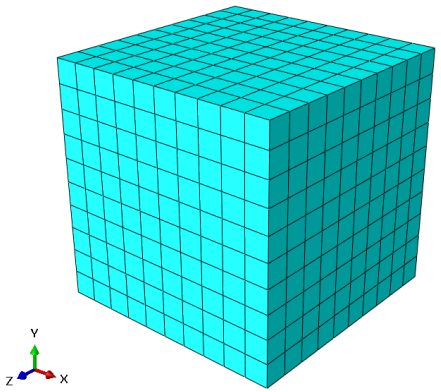
- ✓ The neural network shows high accuracy within the training range.
- ✓ The use of effective strain enables accurate predictions even when shear components not included in training are applied.

ABAQUS User Subroutine(UMAT) implementation results



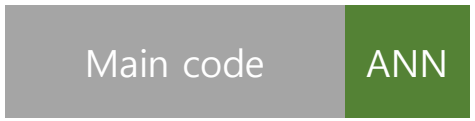
Loading beyond the training range

$$\{\varepsilon_{11}, \varepsilon_{22}, \varepsilon_{33}, \varepsilon_{12}, \varepsilon_{13}, \varepsilon_{23}\} = \{0.05,\ 0,\ \text{free},\ \varepsilon_3,\ 0,\ 0\}$$



Non-proportional loading

→ The loading path was altered through multiple steps

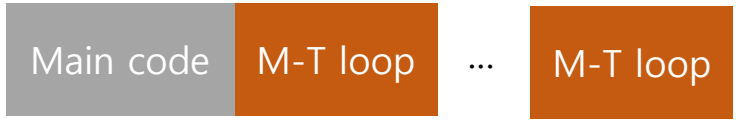


- ✓ The trained neural network was implemented and tested using an ABAQUS user-defined subroutine (UMAT).
- ✓ The model performs well beyond the training domain, effectively handling even non-proportional loading cases.

Calculation time comparison (1): multi-element test

Single pseudo grain test (1000 elements)

63 sec



68 sec

7.5% reduction

12 pseudo grain test (1000 elements)

120 sec

179 sec

33% reduction

- ✓ Computational time was reduced by employing neural networks, especially in cases involving 12 pseudo-grains.
- ✓ This reduction is expected to become more significant as the number of elements increases.

Concluding remarks

Non-iterative artificial neural network constitutive model

- ANN-based constitutive model to predict the properties of polymer matrix and combined fiber composite materials was developed.
- The proposed ANN successfully approximates Mori–Tanaka homogenization with high accuracy, even under loading conditions beyond the training domain.
- By reducing computational cost, the ANN demonstrates strong potential for integration into large-scale finite element simulations.

Thank you very much for your attention

Keywords: Bamboo fibre, Microstructure, Deep-Learning Geometrical Analysis, Tension Strain Mapping, vector fields.

ABSTRACT

Bamboo technical fibre is a structurally graded natural composite material consisting of tubular elementary fibres bonded by a middle lamella. Its hierarchical design exhibits localized distortions of unknown configuration. We applied a deep learning-based geometrical analysis to extract the spatial distribution of fibre hierarchies in the cross-section, correlating this with tensile strain maps in the longitudinal direction. The lumen fraction, representing the percentage of the total technical fibre cross-sectional area occupied by lumens, averaged 7 to 13%. In the middle part of the cross-section, the middle lamella had an average thickness of 0.48 μm, while the elementary fibres averaged 13.79 μm in diameter and their lumens averaged 2.7 μm in diameter. Using vector fields derived from gradient cubic approximations, we evaluated the positional distribution of elementary fibres on the cross-section and contrasted this with micro-tensile strain maps. This analysis categorized fibre failure origins as asymmetric defibrillation and cell wall cracking, identifying key parameters for physics-informed models.

1 INTRODUCTION

One of the main challenges in understanding the structural behaviour of technical bamboo fibres lies in establishing a clear relationship between their mechanical response and their complex microstructure present in the cross section. These fibres, composed of tubular elementary units bonded together by the middle lamella, form a hierarchical natural composite that features unique polygonal cell wall morphologies with internal lumens. At both the technical (fibre bundle) and elementary fibre levels, bamboo displays significant microstructural variability including distortions, surface irregularities, and cross-sectional asymmetries that have largely remained underexplored [1].

The area fraction of each anatomical phase (elementary fibre wall, lumen, and middle lamella) plays a role in defining the fibber's load-bearing capacity, as it dictates the effective cross-sectional area available for stress transfer. Such geometrical complexity results in non-uniform stiffness distributions, which may govern how damage initiates and propagates for samples without pre-existent defects. Specifically, the spatial variation in fibre cross-section is proposed as a design signature potentially linked to flexural loads experienced during the plant's growth. However, quantifying this link has been

limited by challenges in resolving these microstructures using conventional imaging. Bamboo has gained considerable attention as a natural, sustainable alternative for reinforcing composite materials due to its high strength to weight ratio, functional grading, and unique fibre architecture. Among the most studied species, Guadua angustifolia exhibit complex hierarchical structures, where tubular elementary fibres are bound by middle lamellae and contain central lumens. These microstructural features influence the fiber's mechanical properties, including tensile strength and stiffness, which can reach up to 800 MPa and 43 GPa, respectively [1].

Several studies have explored the mechanical behaviour of bamboo under varying loading conditions. For example, Hu et al. [2] demonstrated that strain rate sensitivity significantly affects bamboo's failure mechanisms, including fibre buckling, delamination, and intercellular cracking. Likewise, Wang et al. [3] highlighted the asymmetric bending behaviour of bamboo, driven by its gradient fiber distribution, and showed how failure initiates preferentially in parenchyma-rich zones. These investigations confirm that mechanical behaviour in bamboo is intimately tied to its internal architecture, but they often lack quantitative links between microstructure and local strain behaviour.

While scanning electron microscopy (SEM) and micro-computed tomography (μCT) have been used to visualize damage modes and structural defects, they often fall short in segmenting distinct anatomical phases such as lumen, middle lamella, and fibre wall at the resolution needed for geometric modelling. Osorio et al. [4] conducted detailed microscopy-based studies of bamboo fibres and confirmed that variations in fiber diameter, layering patterns, and microfibrillar angles play a critical role in determining stiffness and failure. However, quantitative segmentation of these regions and their influence on strain maps remain largely unaddressed. Recent approaches have proposed nature-inspired geometrical models to replicate bamboo's toughness in synthetic structures, validating that geometry particularly gradient patterns and void distributions can drastically alter fracture behavior [5]. Yet, within the bamboo research community, there is a critical gap; the lack of computational tools to decode the spatial distribution of microstructural phases and correlate them directly with strain localization and damage asymmetry.

Despite the potential of micro-computed tomography (μCT) to visualize complex vascular and fibrous networks in natural composites, its limited poor contrast at biological interfaces presents challenges for identifying key anatomical features, such as the middle lamella in bamboo. Recent studies have explored combining μCT with deep learning to improve interpretability. For example, Badran et al. Badran et.al [6] validated the use of deep learning for segmenting low-contrast CT images of fiber-reinforced composites yet emphasized the difficulty of capturing fine features below the voxel size threshold. Similarly, deep learning-based approaches have shown promise for automating structural defect segmentation and microstructure labelling in polymer and natural composites, but their success depends heavily on high quality annotations and the amount of available domain specific training data [7, 8]. These challenges underscore the need for complementary imaging strategies. In this context, optical microscopy paired with deep learning segmentation offers a high-resolution, label-specific approach for analysing microstructural features like lumen expansion and fibre wall gradients essential for quantifying the architectural parameters that drive bamboo fibre behaviour.

However, traditional image analysis techniques such as thresholding, edge detection, and clustering are often inadequate for capturing the complex and inhomogeneous microstructures of natural fibers like bamboo [9]. To address these challenges, advanced convolutional neural networks (CNNs) have been developed to enable precise semantic segmentation of hierarchical fiber structures. For instance, the CA-DeepLabv3+ model proposed by Lv et al. achieved a mean pixel accuracy of 95.2% and mean Intersection over Union (mIoU) of 90.7% across a range of natural fiber types, thanks to its attention-enhanced feature extraction and multi-scale segmentation capabilities [10]. Such architecture enables pixel-wise differentiation of critical regions such as lumens, fiber walls, and bonding interfaces. These tools offer a pathway to quantify geometrical gradients and interphase distributions, which are essential to link fiber architecture with mechanical response.

In this context, our study introduces a deep learning-based segmentation framework combined with micro-scale strain mapping to resolve the spatial hierarchy of bamboo fibre microstructures. By distinguishing lumen, middle lamella, and elementary fibre areas, and analysing their expansion gradients, we demonstrate how microstructural geometry modulates strain propagation and damage modes. This work provides novel insight into the cooperative behaviour of elementary fibres, providing quantitative geometrical links with strain and failure evolution, offering offers a foundation for bio-inspired design strategies in fibre reinforced materials.

2 MATERIALS AND METHODS GENERAL SPECIFICATIONS

Single bamboo fibers were embedded in Clarocit cold-curing resin (Struers) by manually mixing 20 g of powder with 12 g of liquid hardener. The mixture was poured into silicon rubber molds initially filled halfway to position the fiber centrally before topping off to fully encapsulate it. After curing for 30 minutes and stabilizing for 24 hours at room temperature. Sectioning was performed perpendicular to the fiber's axis with the initial cutting pitch of 3 mm using a fast-trimming device for locating the fiber in the resin. Transverse finer sections were prepared using a Leica UltraCut MZ6 ultramicrotome equipped with a DIATOME Histo diamond knife (HI-14910), with cutting pitch progressively reduced from 700 nm to 250 nm. Final cuts were made at 250 nm with a holder oscillation speed of 10 mm/s to ensure flat surfaces and minimal artifact generation (see **Figure 1a** and **1b)**.

Following sectioning, optical micrographs were acquired using an Olympus microscope at magnifications of 20×, 50×, and 100×. These scales were selected to first locate the fiber and then capture detailed regions of interest, such as lumens, middle lamella, and fiber walls. Images were recorded at a resolution of 2053 × 1086 pixels, enabling high-fidelity input for subsequent deep learning segmentation and morphological analysis with the deep learning root painter model database trained with 1500 images.

Bamboo fibers were tested under single fiber tensile testing with a loading rate of 0.2 mm/min using FAVIMAT single fiber tensile testing equipment. The sample preparation protocol consisted of embedding the fiber to test in epoxy (28% hardener) resin blocks at each side to use them as supports avoiding damage by conventional gripping or slippage. Gage length of 15 mm was defined for the tensile tests with a total span length of 55 mm, which means that 20 mm of fiber is embedded in the resin block at each side. The protocol was designed to load the fiber from adhesive gripping from the resin with the fiber and create a homogeneous force distribution in the cross section to facilitate the damage initiation occurs in a track between the gauge length.

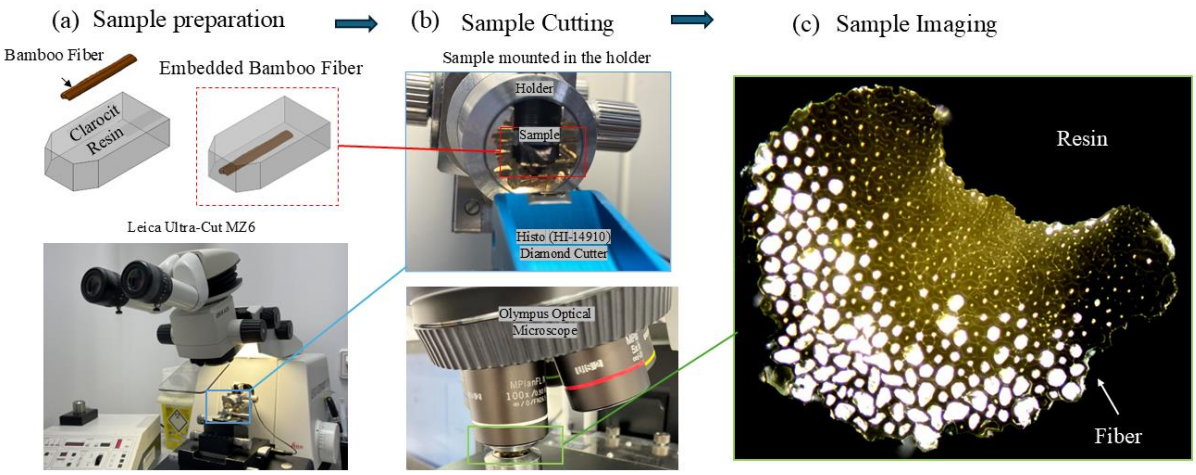

Figure 1. a) Fiber Sample preparation. b) Fiber Cutting by Ultramicrotomy. c) Fiber cross Section Imaging.

3 RESULTS AND DISCUSSION

Using Root Painter deep learning segmentation tool, we successfully resolved the three primary anatomical phases in cross-sections of bamboo technical fibres: elementary fibre walls, middle lamella, and lumens. Quantitative analysis revealed that elementary fibre walls constituted approximately 78% of the technical fibre cross-sectional area, while the middle lamella and lumens accounted for 12.9 % and 8.20%, respectively for the tested sample 1, see **Figure 2a** and **2b** (Sample1). Within an analysed area of 8214 μm² in the fibre cross-section (1033 × 541 sampled pixels), 25 lumen areas were calculated and sorted from minimum to maximum to determine the rate of change of lumen size within this area, based on a linear fitting with a growth rate of 0.2 per lumen.

To sample a larger portion of the cross-section, a deeper analysis of the segmented images was performed to investigate the localised expansion and shrinkage patterns governing the area distributions and, consequently, the fibre's hierarchical organisation (see **Figure 2c**). Using the equations presented in Section 5, the scattered values (X, Y, and lumen area magnitudes) were interpolated onto a regular grid via 2D cubic interpolation, yielding a continuous vector field contour map shown in Figure 3d.

The contour-streamline map reveals a distinct pattern of peripheral intensification and central stability in pore-area ratio. Along both the left and right borders, broad bands of high gradient ($\|\nabla A\| \gtrsim 20$) indicate pronounced expansion fronts pushing outward, likely reflecting material inhomogeneities. In contrast, the central plateau (around X ≈ 100–150 μm, Y ≈ 40–80 μm) remains cool and uniform ($\|\nabla A\| \lesssim 10$), indicating regions where pore sizes change minimally, suggesting a stable microstructure in the fibre core.

Superimposed hotspots of rapid expansion such as those near (X,Y) ≈ (230,15) and (30,105) highlight localized abrupt changes area flux intensity, which may correspond to defects or transitional microdomains (see **Figure 2c** and **d**). Streamlines coherently trace these flows, converging at local maxima (possible lumens coalescence) and diverging from local minima (lumen collapse zones). Quantitatively segmenting regions above a chosen gradient threshold could enable measurement of their spatial extent providing objective metrics for comparing specimens or assessing fibre conditions.

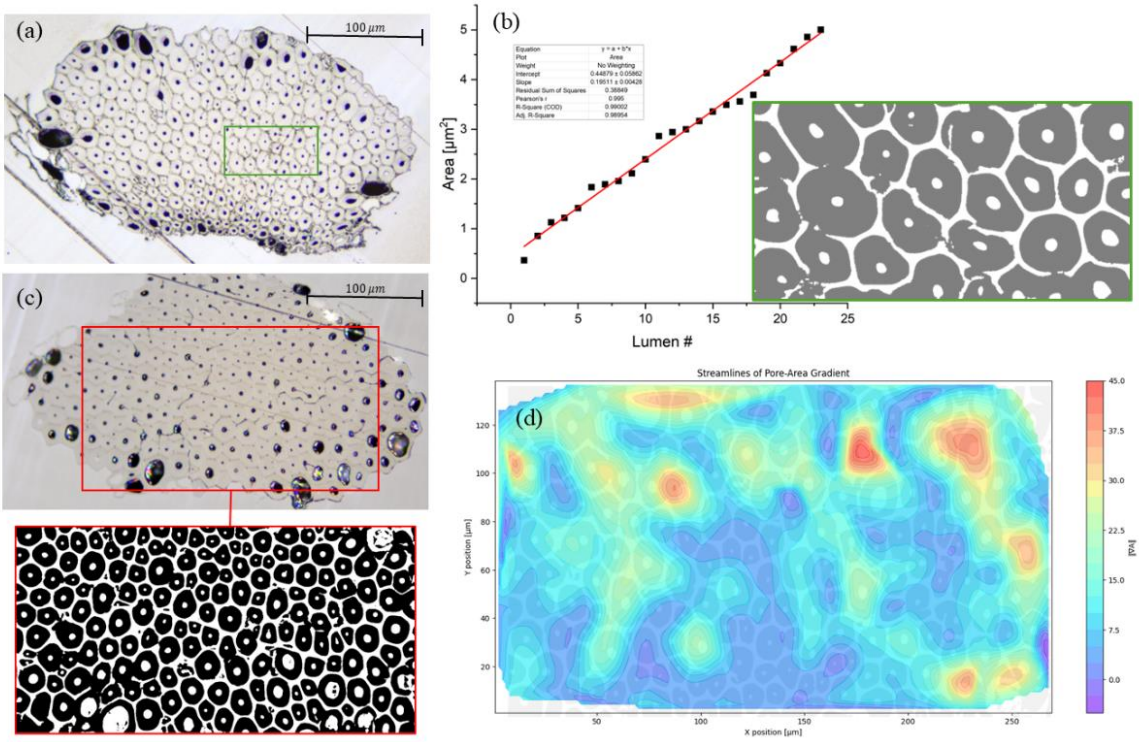

Figure 3. (a) (b) Calculation of the Lumen expansion variation with a linear approximation applied on a lumen count on 8-bit image segmented by the deep learning approach. (c)(d) calculation of the vector field of lumen area variation

For the samples tested under tension, strain maps were calculated for two bamboo fibres. The resulting strain fields exhibited distinct oscillatory waveforms up to the point of failure, with varying percentages of strain initiation. In Sample 1, over approximately 1600 µm of fibre length, strain began to localise at around 10% of the total elongation. The characteristic damage pattern in this sample was a combination of defibrillation and partial cell wall breakage, occurring with less depth compared to Sample 2 (see **Figure 3a** and **3b**).

In contrast, Sample 2 was examined laterally, with the observation direction perpendicular to the minor width of the fibre cross section. In this case, over a 3700 µm fibre length, more pronounced oscillations were observed, with strain concentration peaking at around 40% elongation. The failure mechanism in this sample was more strongly influenced by central defibrillation, where interfacial shear stress appeared to be the dominant factor. Notably, Sample 2 also exhibited greater elongation before failure compared to Sample 1 (see **Figure 3c** and **3d**).

These patterns suggested alternating regions of higher and lower strain intensity corresponding to variations in local phase composition demonstrated in the vector fields of the cross section. Particularly, higher lumen area regions versus lower lumen area regions. Such observations support the hypothesis of mechanical cooperation among elementary fibres, where load sharing occurs along complex and asymmetric paths, likely driven by the internal geometry.

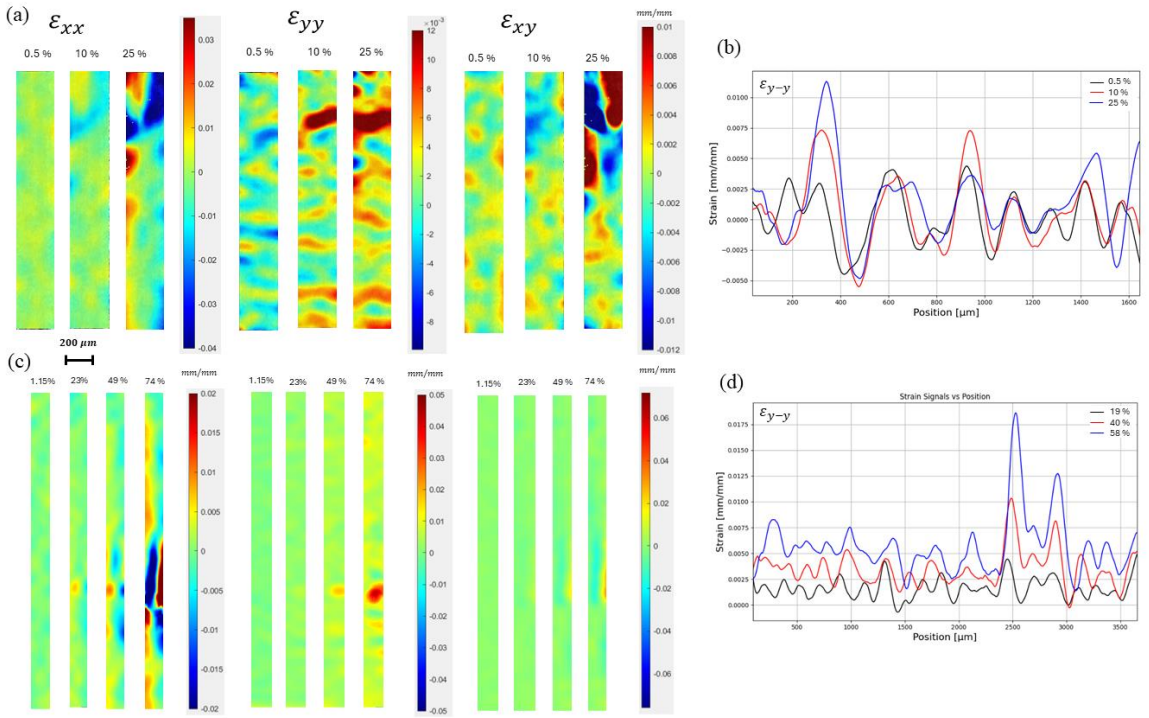

Figure 3. Strain maps applied on two bamboo fibers tested by tensile loading and strain oscillation functions. (a)(b). Sample 1. (c)(d). Sample 2

The oscillatory strain response observed along the central path of the bamboo fibre cross section is strongly indicative of an underlying structural heterogeneity presented in the cross sections studied by segmentation and gradients. Given the known anatomical features of bamboo alternating regions of vascular bundles, the higher strain amplitudes are likely associated with larger lumen fibres, while the lower amplitudes reflect more densely packed, small-lumen fibres. This interpretation is supported by the consistent periodicity and amplitude increase across different levels of applied strain, suggesting a

stable and load-sensitive mechanical differentiation and fibre cooperation. As for example, amplitude difference between the first two peaks of the strain signals was 22% in amplitude difference considering between 200 to 800 μm of fibre range at 25% of total fibre elongation in Y direction.

By analyzing the spatial strain oscillations within the 200–800 μm region, an oscillatory waveform pattern was observed in the strain signal extracted from the strain map, indicating energy dissipation along the length of the technical fiber. This behavior supports the hypothesis that internal geometry driven stiffness gradients contribute to a functionally graded mechanical response. The observed spatial damping suggests that elementary fibers cooperate mechanically, alternating in stiffness and compliance to distribute load and manage localized stress. This cooperative behavior delays failure initiation and governs the asymmetric damage evolution characteristic of bamboo technical fibers. Moreover, this difference in peak amplitude values reflect cooperative load sharing among elementary fibres. Notably, damage initiation and propagation are shown to be spatially dependent on fibre geometry and stiffness gradients. These findings support the hypothesis that microstructural geometry is a governing design parameter influencing not only failure modes (e.g., clean breakage, defibrillation, or mixed failure) but also energy dissipation and mechanical resilience.

4 EQUATIONS

To quantify the growth and shrinkage rates of the lumen size in area distributions sampling the gradient map obtained for the geometry the following equation was used:

$$\|\nabla A(x,y)\| = \sqrt{\left(\frac{\partial A}{\partial x}\right)^2 + \left(\frac{\partial A}{\partial y}\right)^2}\,, \tag{1}$$

where $(\partial A/\partial A)$ is the partial derivative of the area in x and y direction. The expansion rate provides information regarding the geometrical features linked to dominant regions of the microstructure which can be attributed to structural changes and density variations. We point out that these regions can be extracted as indicators of stress transfer and elementary fiber cooperation. See table 1

Engineering constant	Units	Values
Rate	[μm²/ μm]	0.90
Peak rate	[μm²/ μm]	5.85
Median rate	[μm²/ μm]	0.71
Percentiles	[%]	[0.02417066 0.06871499 0.14725231]

Table 1: rates of change of lumen area size.

6 CONCLUSIONS

This study confirms that bamboo technical fibres behave as functionally graded materials, exhibiting vector fields that can be interpreted as geometrical signatures for understanding how stress is distributed and transferred axially. Fibres that demonstrated greater elongation before failure such as the second sample in the strain map showed damage initiation at approximately 20% of total elongation, compared to earlier onset in Sample 1. Microstructural geometry, including lumen expansion and phase area distribution, governs both mechanical performance and damage behaviour.

Through deep learning–based segmentation and microscale strain mapping, we identified localised regions of rapid expansion particularly around coordinates (230, 15) and (30, 105), that indicate concentrated flux activity within the lumen areas, potentially corresponding to transitional microstructural domains. The flow streamlines exhibit organised patterns, converging at areas of

maximum flux, suggestive of void coalescence, and diverging from minima, which may represent zones of maximum lumen size.

The resulting strain fields reflect cooperative mechanical behaviour, with oscillatory patterns linked to variations in material density and phase distribution. This internal structural organisation leads to asymmetric damage evolution, with clear implications for predicting failure modes. These insights suggest that geometrical characteristics can serve as predictive design parameters in composites based on bamboo, supporting quality control, process optimisation, and performance modelling.

The quantified phase proportions highlight the dominant structural role of the fibre walls in bearing load, while the middle lamella governs inter-fibre bonding and stress transfer, and the lumens influence local stress distribution and contribute to damage initiation pathways. Together, these three components define the hierarchical architecture that underpins the fibre's mechanical performance and failure behaviour. Ongoing work aims to further validate the presence of alternating regions of stiffness and compliance that enable load sharing, delay failure initiation, and govern the asymmetric damage patterns observed in bamboo technical fibres.

ACKNOWLEDGEMENTS

The authors would like to express their gratitude to the Luxembourg National Research Fund (FNR) for supporting the SusPoCo (Sustainable Polymer Composites) project under grant agreement PRIDE21/167482260.

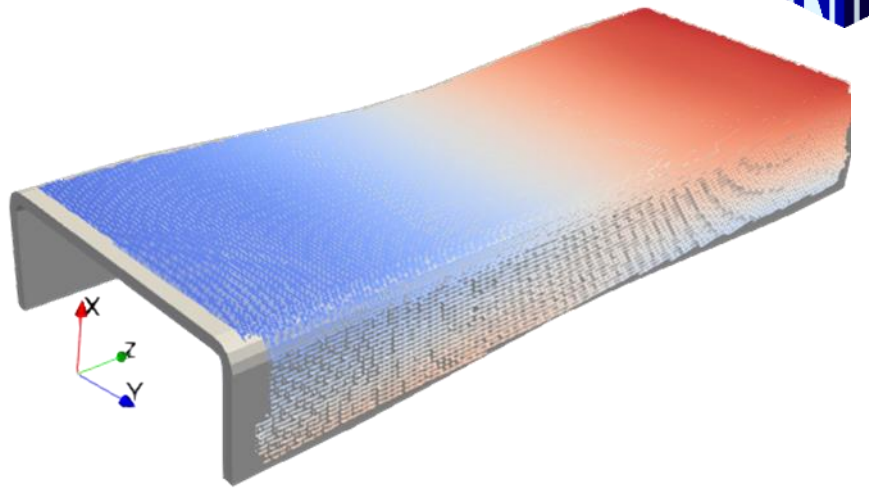
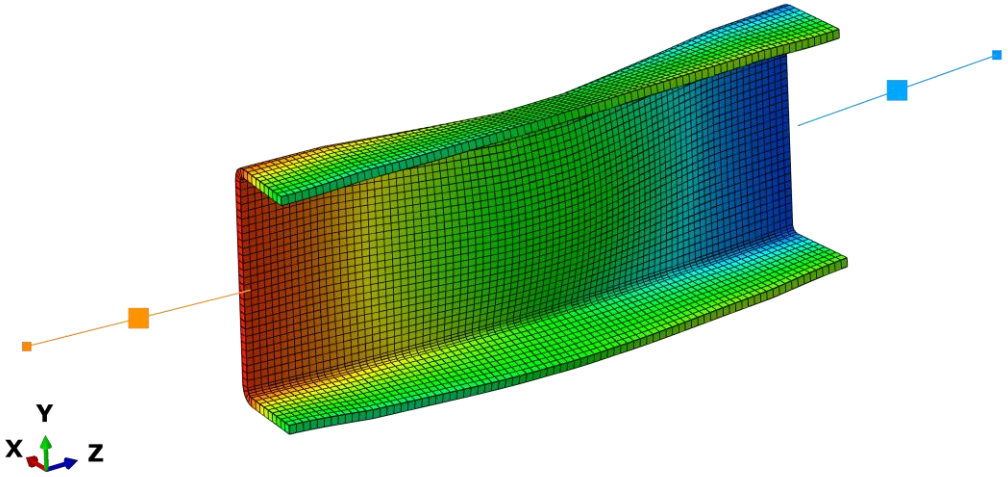
AI Empowering Composites
24th International Conference on Composite Materials (ICCM 24)
Baltimore, Maryland, USA, 4th-8th August 2025

Bayesian inference

- All predictions are subject to uncertainty:
  - Manufacturing uncertainty.
  - How accurate are models?
  - Are tests representative of reality? Noisy measurements?
  - Unknown quantities e.g. internal defects/features, damage.
- **Bayesian inference** helps us quantify and reduce this uncertainty by using new data to learn about uncertain quantities

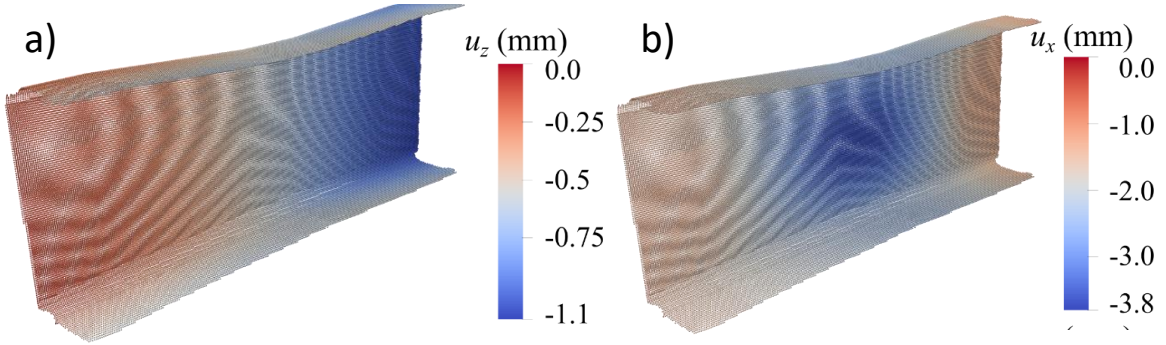




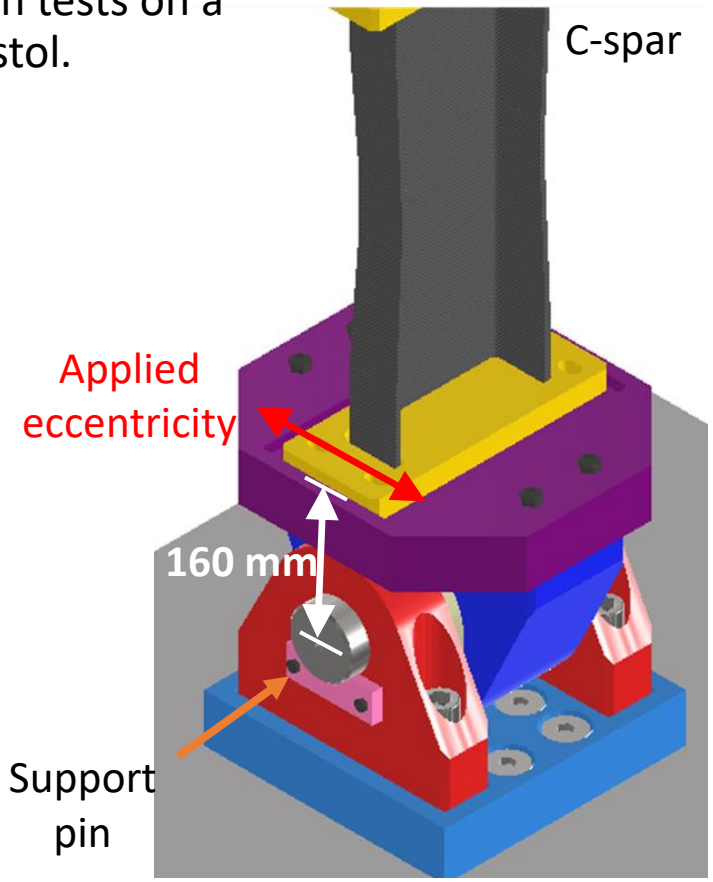
Bayesian model calibration

- Bayesian model calibration uses **model outputs** and **experimental data** to inform predictions.
- Can account for uncertainties in model inputs, model physics, and in the test data.
- Example case study using:
  - Stereo DIC from Compression tests on a C-spar.
  - ABAQUS model with material, boundary condition, and geometric uncertainty.
  - Main challenge is handling large quantities of data spanning both **time and space**.

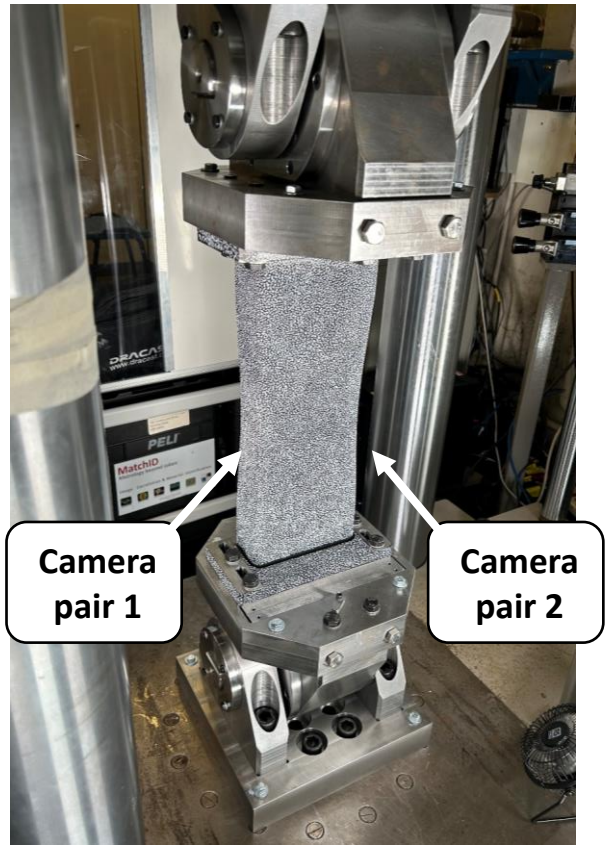
Can we use the DIC to verify the accuracy of the model despite the uncertain inputs?



Longitudinal displacement from DIC at 200kN



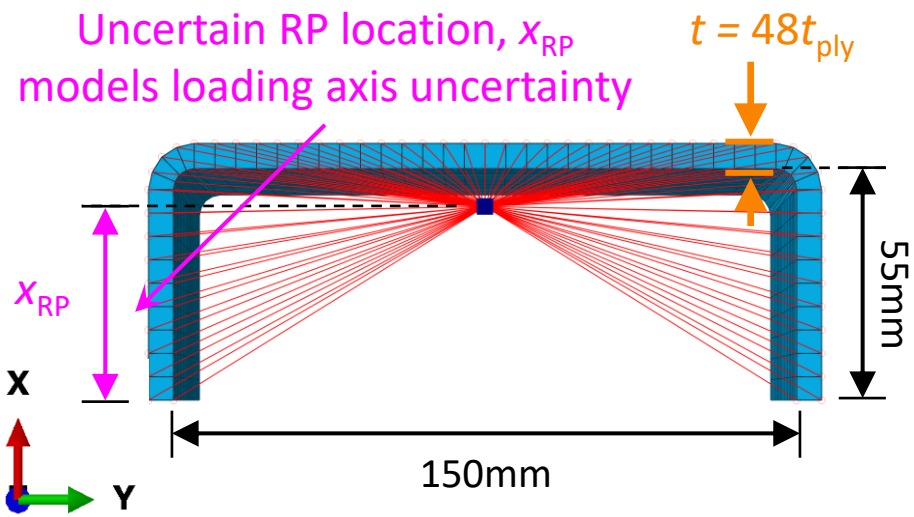
Longitudinal displacement from ABAQUS at 200kN

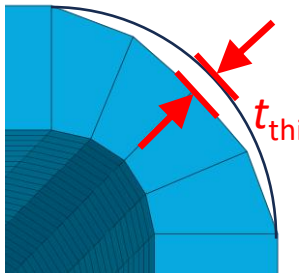


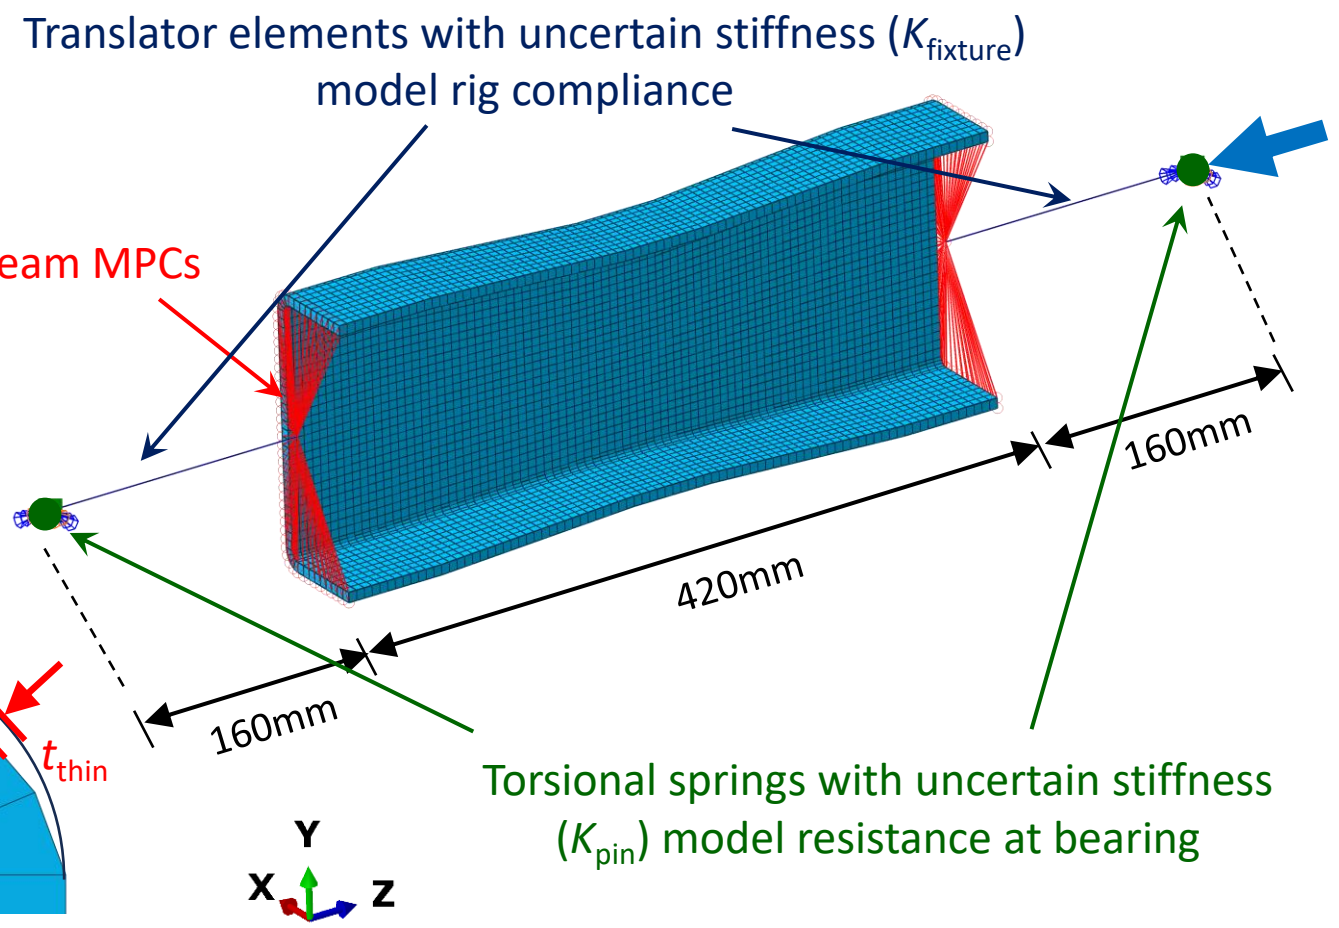
Experimental data

- Stereo DIC captured using MatchID, from compression tests on a composite C-spar undertaken at the University of Bristol.
- 48 plies of IM7/8552, QI layup.
- +4mm eccentric loading relative to neutral axis.
- Separate datasets from two camera pairs, each focussed on one flange + the web.
- Limit analysis to longitudinal and out-of-plane displacement, maximum load 150 kN.

DIC showing a) Longitudinal and b) out-of-plane displacement at 150 kN





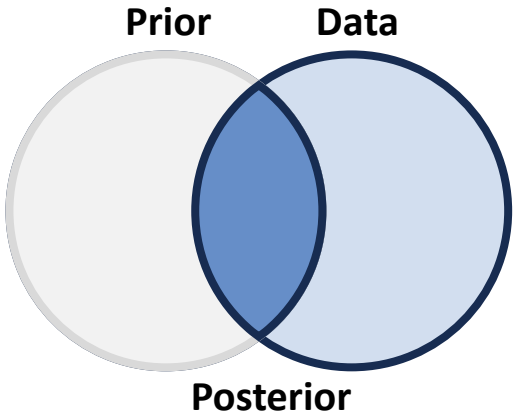


Experimental configuration showing rig design and camera pair focus

ABAQUS model and uncertainties

- Modelled with 4536 SC8R continuum shell elements (9354 nodes).
- Simply supported at reference nodes.
- Uncertainty in illustrated boundary conditions.
- Geometric uncertainty in ply thickness (t_{ply}) and corner thinning (t_{thin}).
- Uncertainty in E_{11}, E_{22} and G_{12}.

Calibration methodology



- Following Higdon et al.[1], method for calibrating models with vector-valued output:

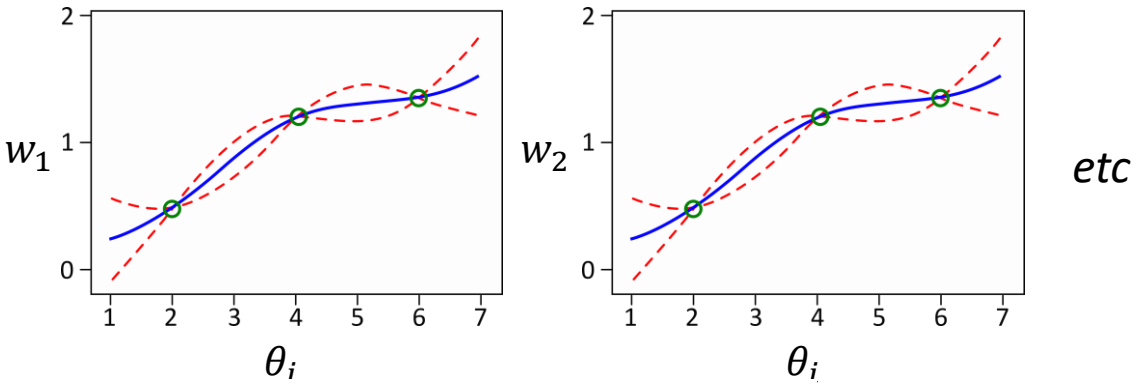
$$\boldsymbol{y} = \boldsymbol{\eta}(\boldsymbol{\theta}^*) + \boldsymbol{\varepsilon}$$

DIC point cloud **Abaqus model** **Error**

$\boldsymbol{\theta}^*$ = uncertain inputs we want to learn about:

E_{11}, E_{22}, G_{12}, t_{ply}, x_{RP}, $K_{fixture}$, t_{thin}, K_{spring}

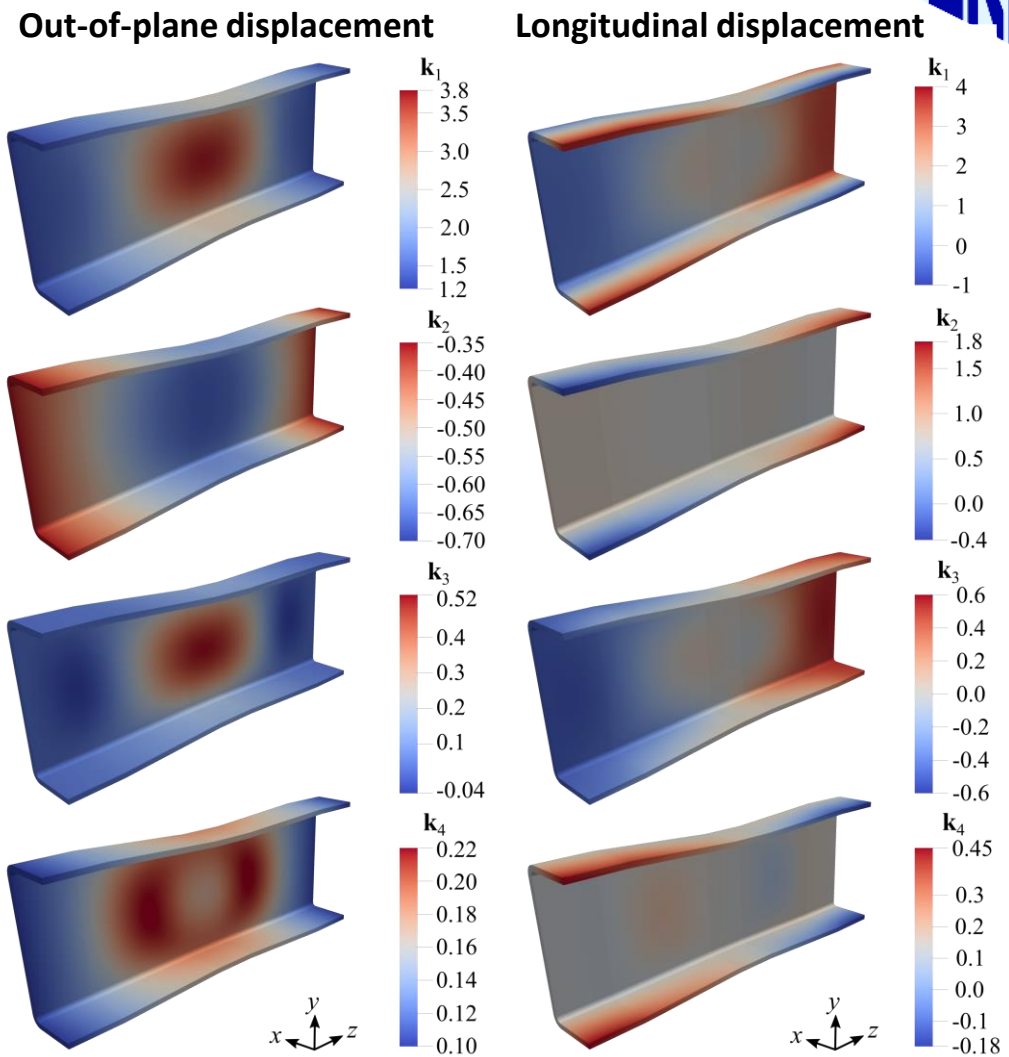
- An inverse problem:
  - $\boldsymbol{y}$ is known, $\boldsymbol{\theta}^*$, hyperparameters for $\boldsymbol{\eta}$, and magnitude of error $\boldsymbol{\varepsilon}$ are uncertain.
- Solve by:
  1) Specify **prior distributions** for uncertain parameters from coupon data, parametric studies & engineering judgement.
  2) Feed in **data**: combined dataset of DIC, plus 100 Latin Hypercube Samples of ABAQUS model output.
  3) Sample from the **posterior distribution** using Hamiltonian Monte Carlo (No-U-Turn Sampler, NUTS) in Stan[2].



[1] *D. Higdon et al, "Computer model calibration using high-dimensional output", Journal of the American Statistical Association, 2008*
[2] *Stan modeling language users guide and reference manual, Version 2.26.1, https://mc-stan.org*

Output decomposition

- Total of **299,328** model output values from each of the 100 training samples, and **1,227,163** DIC displacements.
- Decompose into first p = 7 principal components of model output using SVD:

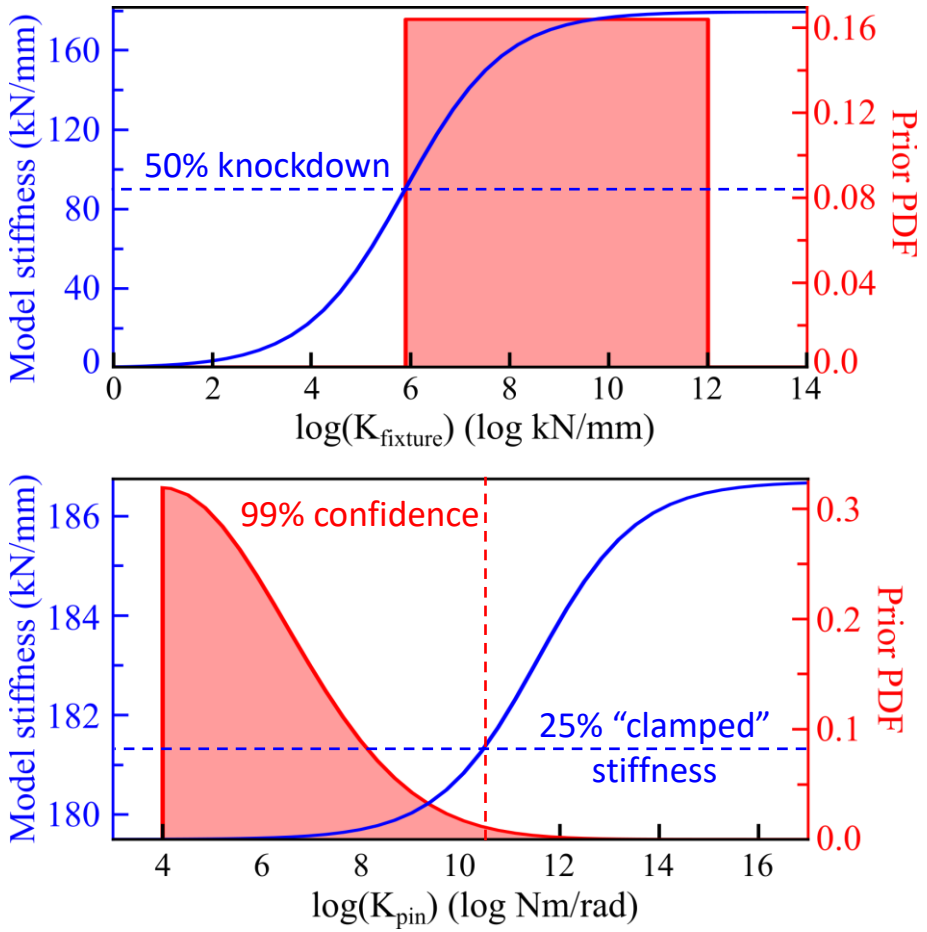


$$\boldsymbol{\eta}(\boldsymbol{\theta}^*) \approx \sum_{i=1}^{p} \boldsymbol{\phi}_i(\boldsymbol{x}, t)\, w_i(\boldsymbol{\theta}^*)$$

- Basis vectors $\boldsymbol{\phi}_i$ capture spatial & temporal dependency.
- Gaussian process emulators for coefficients w_i capture dependency on uncertain model inputs.

Gaussian process emulator illustration

etc



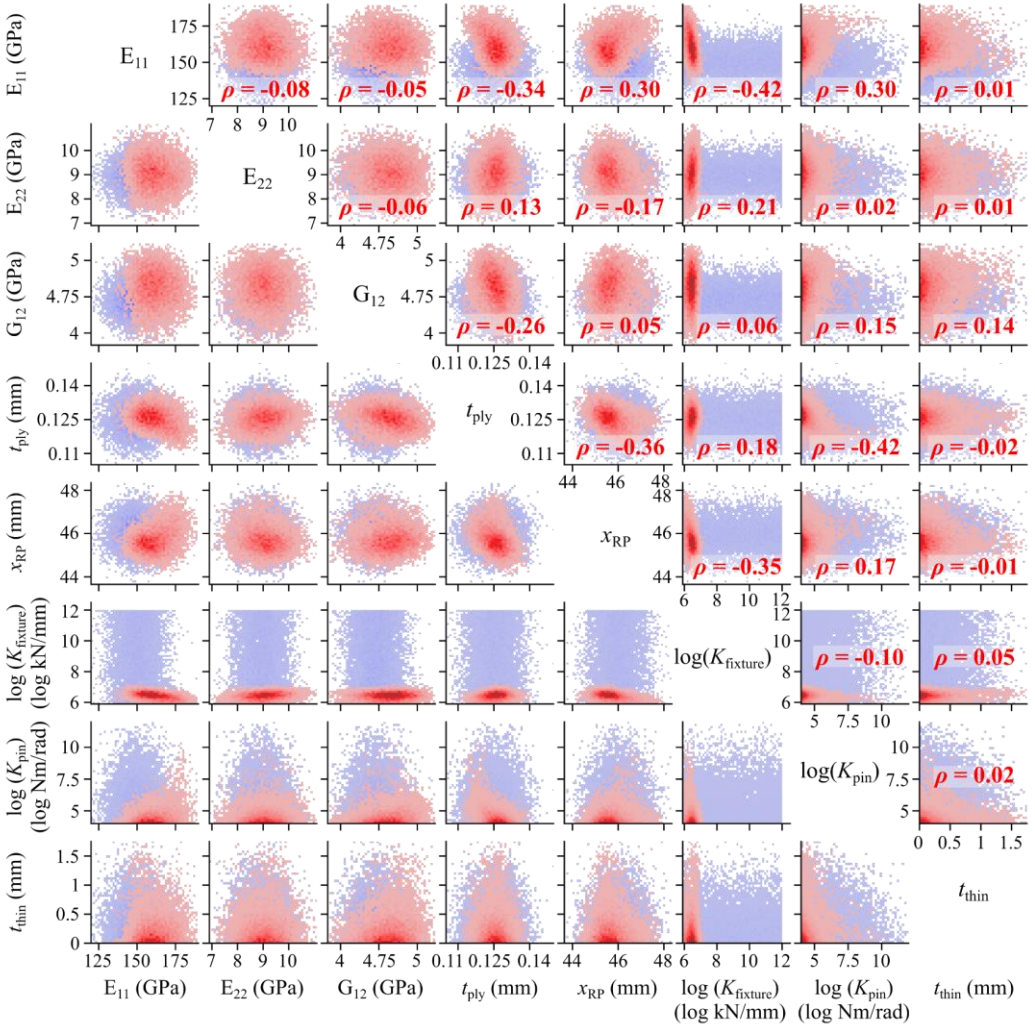
First 4 principal components at 150kN

Prior distributions

What do I **believe** about the uncertain inputs before the test?
Not a measure of variability.

Prior parameters: mean and standard deviation for Gaussian and Half-normal, upper and lower bounds for uniform

	Distribution	Parameter 1	Parameter 2
E_{11} (GPa)[3]	Gaussian	150.0	9.0
E_{22} (GPa)[4]	Gaussian	8.96	0.538
G_{12} (GPa)[4]	Gaussian	4.69	0.281
t_{ply} (mm)	Gaussian	0.125	0.00625
x_{RP} (mm)	Gaussian	46.0	0.667
$\log(K_{fixture})$	Uniform	5.9	12.0
$\log(K_{pin})$	Half-normal	4.0	2.5
t_{thin} (mm)	Half-normal	0.0	0.51



Initial mode force-displacement gradient at reference node vs $\log(K_{fixture})$ and $\log(K_{rig})$, overlaid with prior distributions

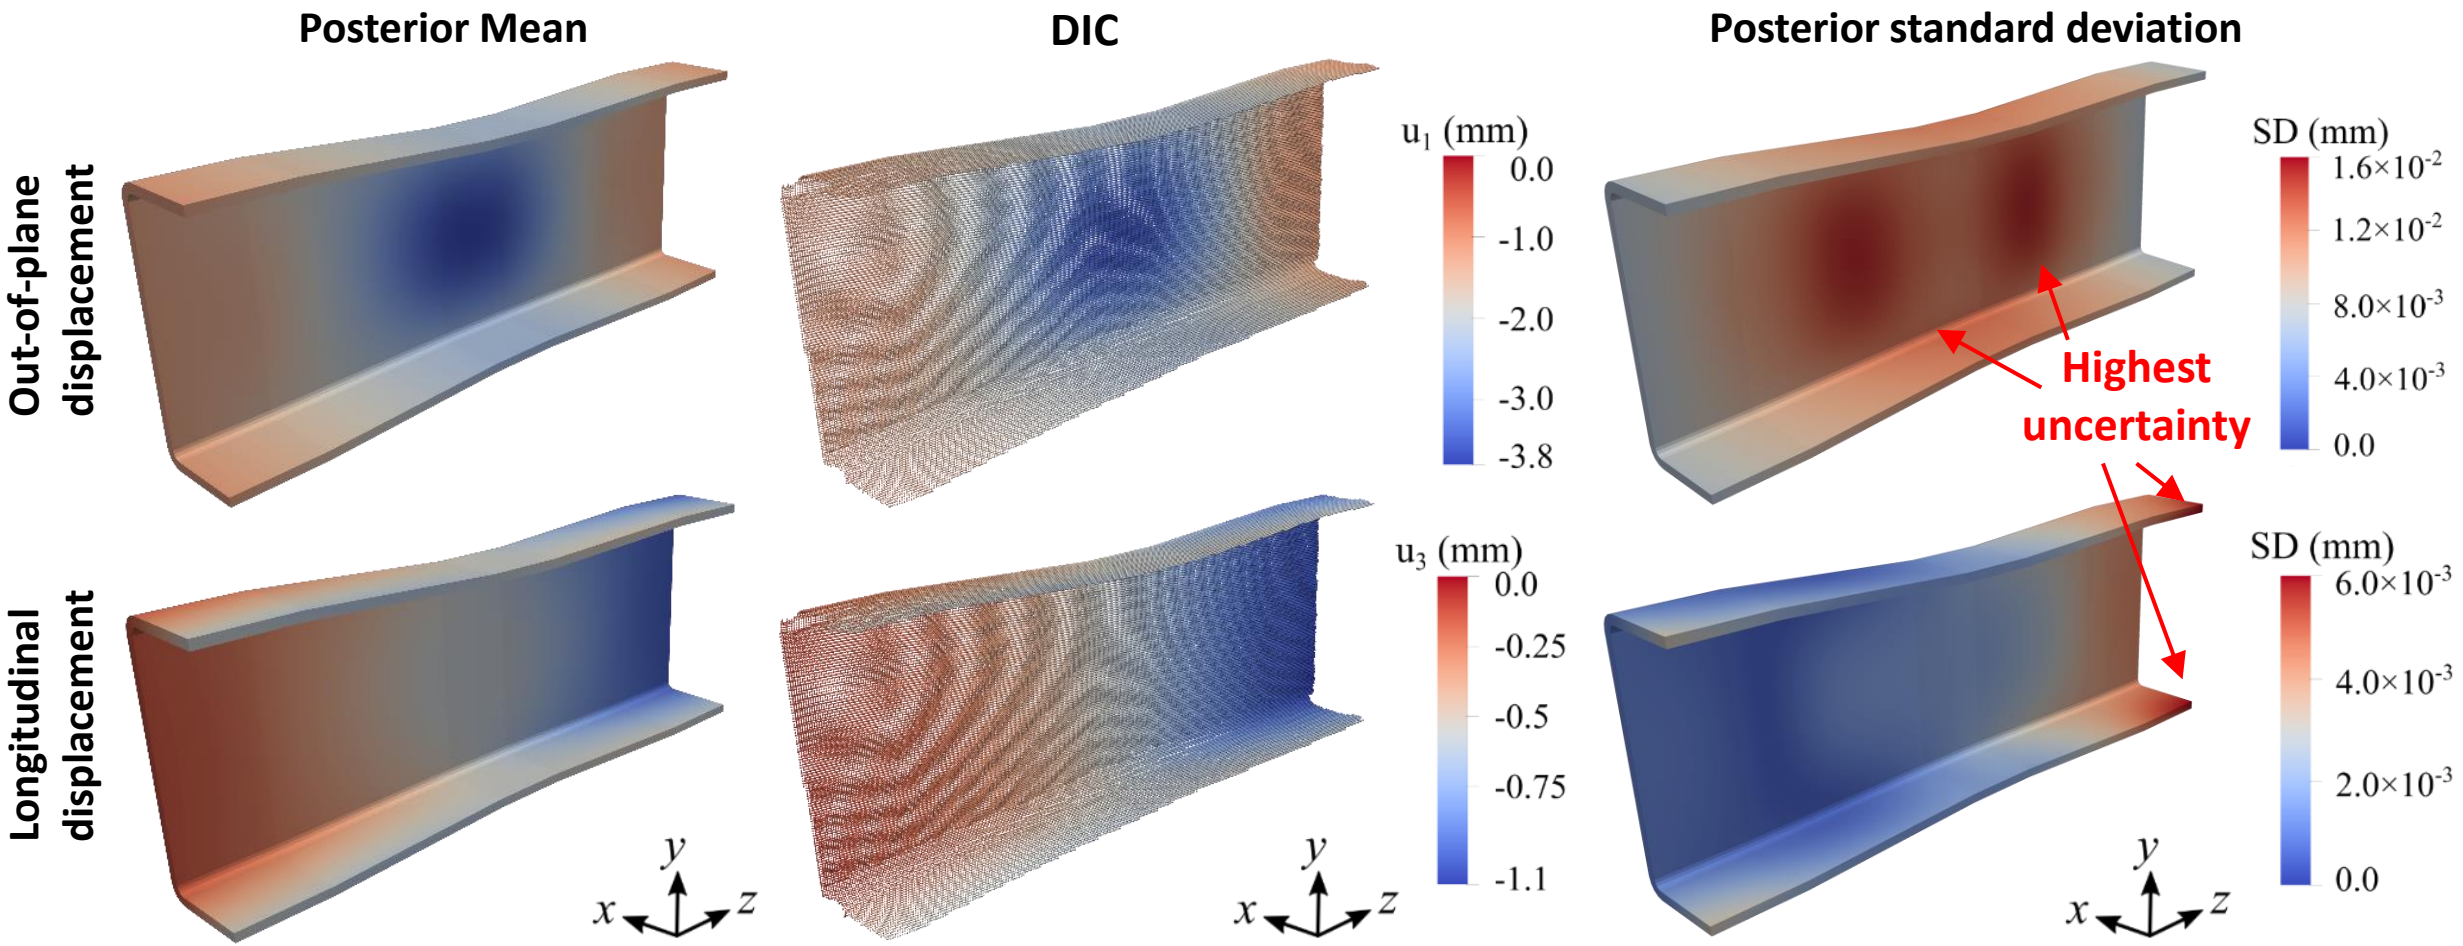
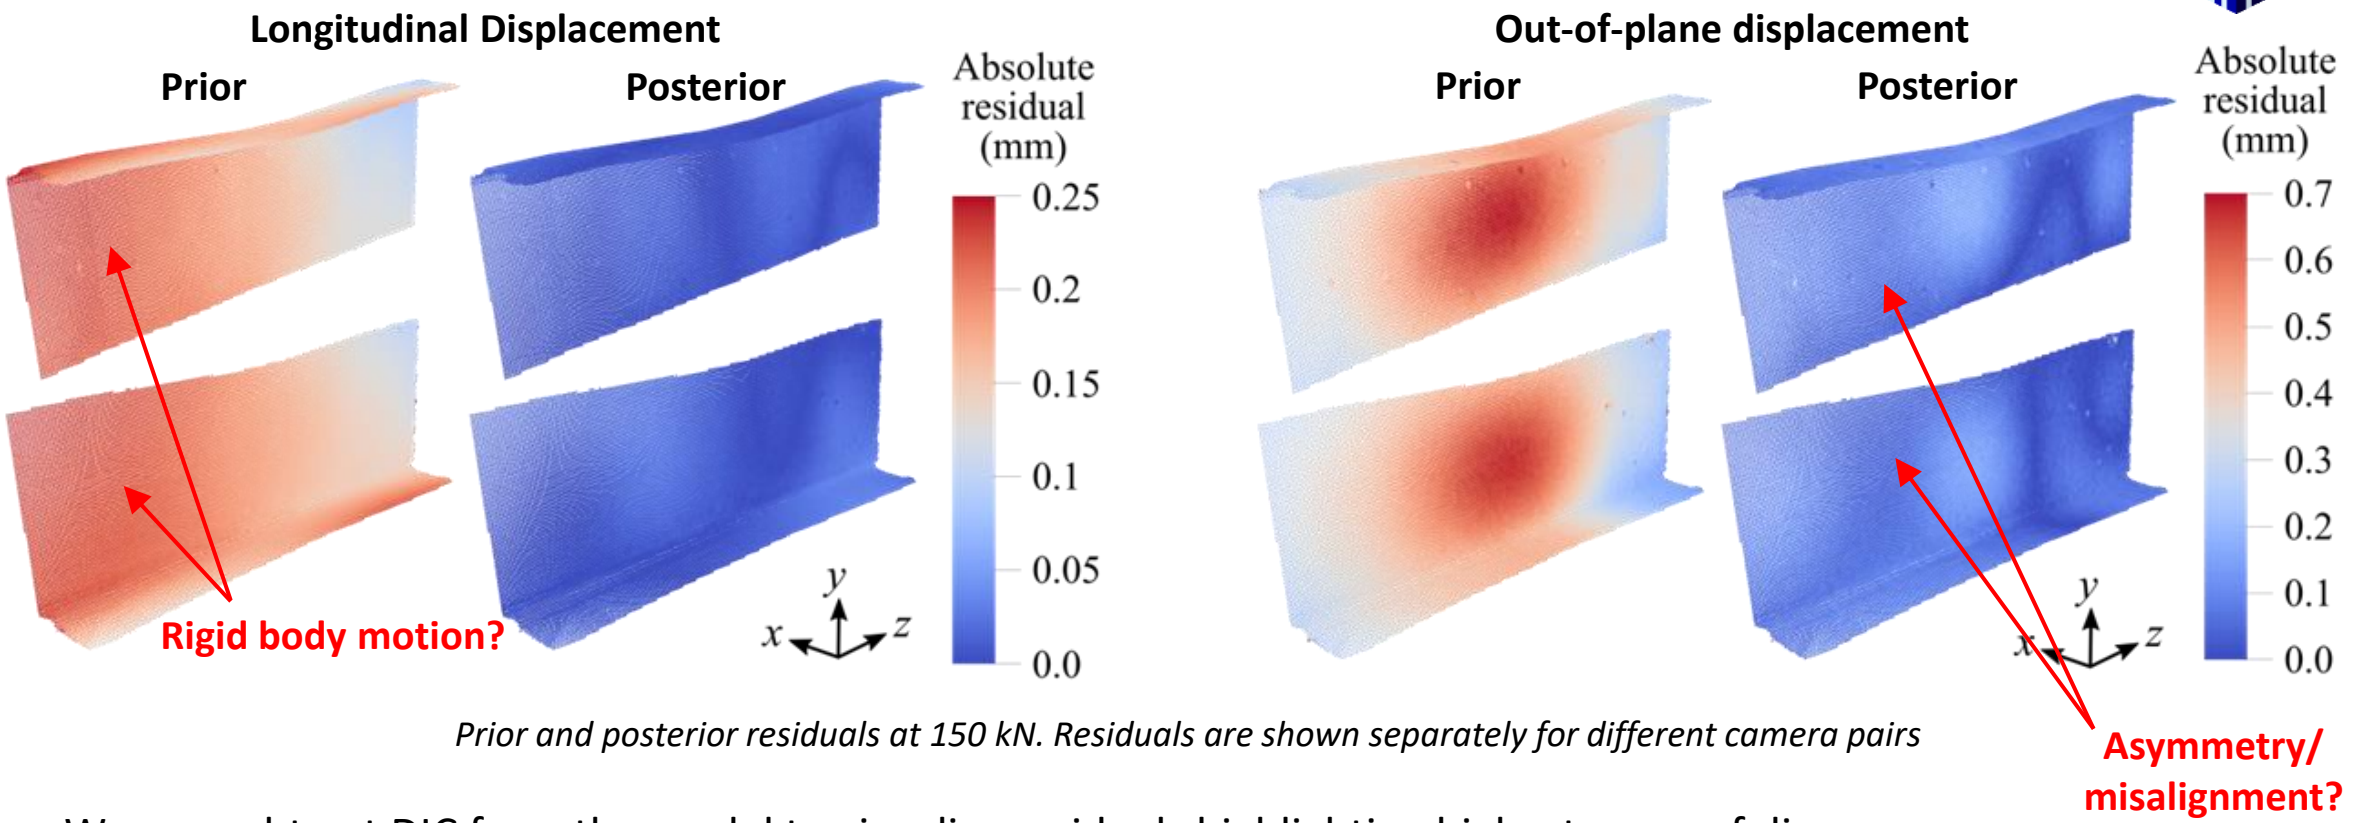
Results: Posterior distributions

Prior & posterior heatmaps

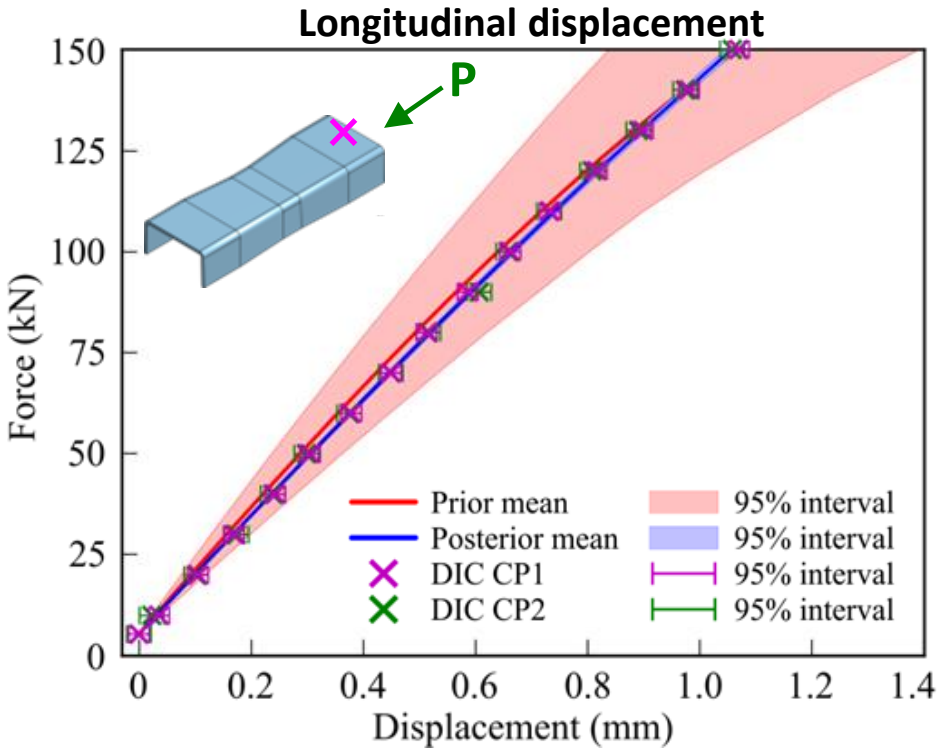


- Differences between blue and red show reductions in uncertainty
- Strong correlations indicate inputs have complementary or antagonistic effects

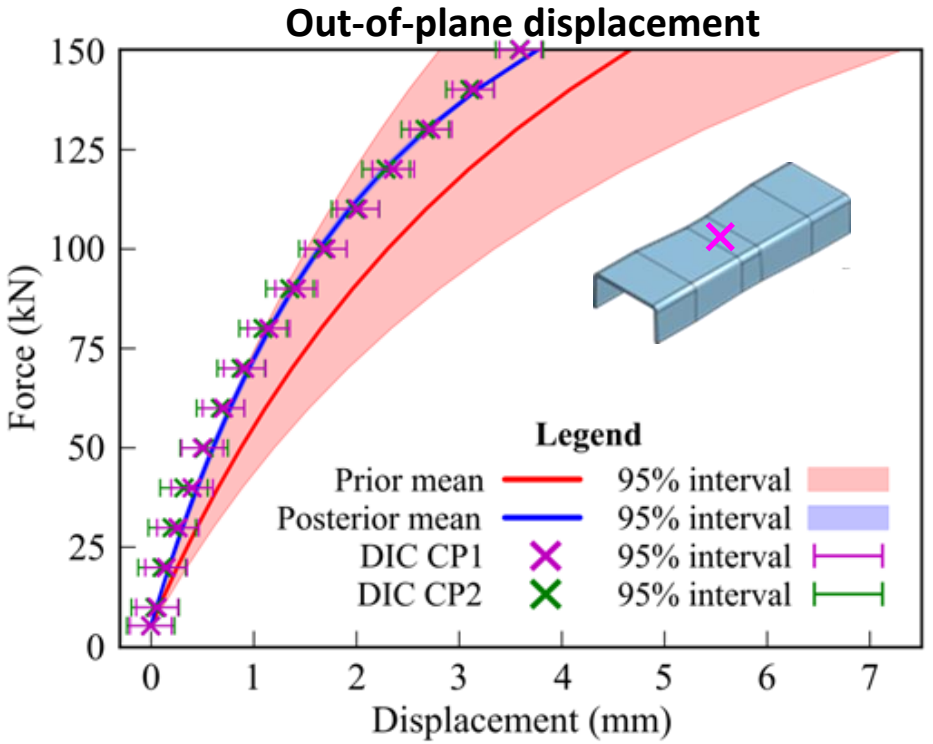


Posterior Predictions

- Run posterior samples back through model to get posterior prediction given “true” input values



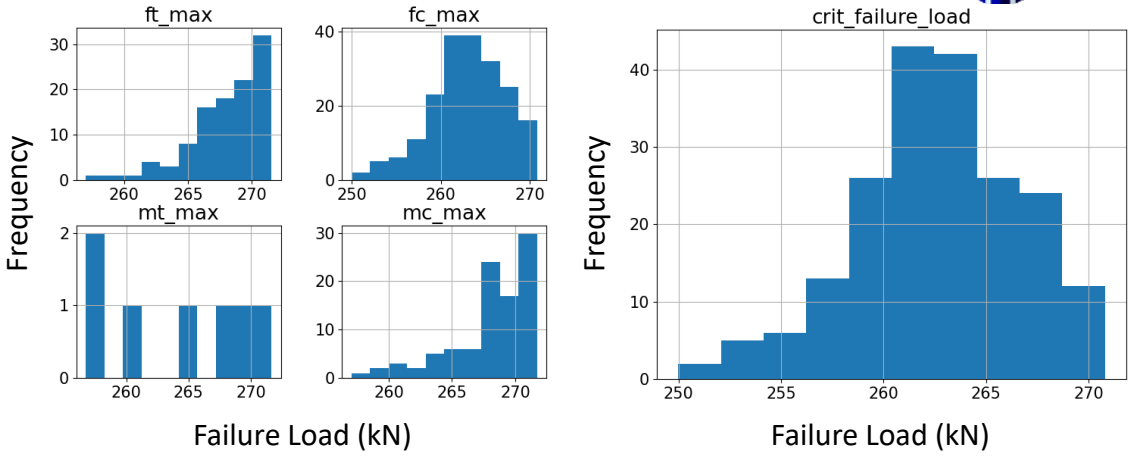
Prior & posterior residuals



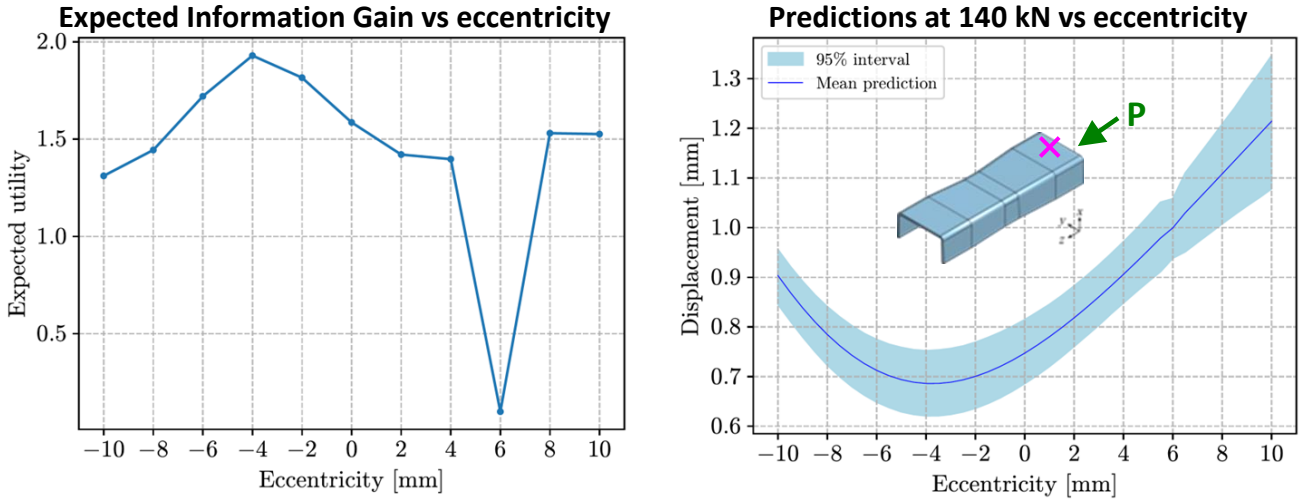
Prior and posterior residuals at 150 kN. Residuals are shown separately for different camera pairs

- We can subtract DIC from the model to visualise residuals highlighting highest areas of discrepancy.
- "Prior" residuals taken relative to model output using deterministic input values.
- Posterior residuals taken relative to posterior predictive mean.

Force-Displacement Trends



Prior and posterior force-displacement trends at fixed point X on spar surface



- Significant reduction in prediction uncertainty. Discrepancies attributed to observation error.
- Stiffer material response due to increased E_{11} better fits both longitudinal and out-of-plane DIC.
- Higher error inferred for out-of-plane displacement

Conclusions and outlook

- Demonstrated a powerful statistical toolkit for comparing FE models against DIC, while accounting for uncertainty in model inputs and test data.
- Overcame challenge of calibrating full-field model output using high volumes of data.
- Useful for validating virtual tests.
- Uncertainty in boundary conditions very important.
- Shift in modulus also noteworthy. Using a homogeneous linear value across structure in may be overly simplistic.
- Future work will extend further into nonlinear regime and consider failure.
- Long term aim to decide most informative future experiments via Bayesian Design of Experiments.

Preliminary uncertainty quantification study using Hashin failure criteria

Preliminary Design of Experiments using displacement at fixed location on spar

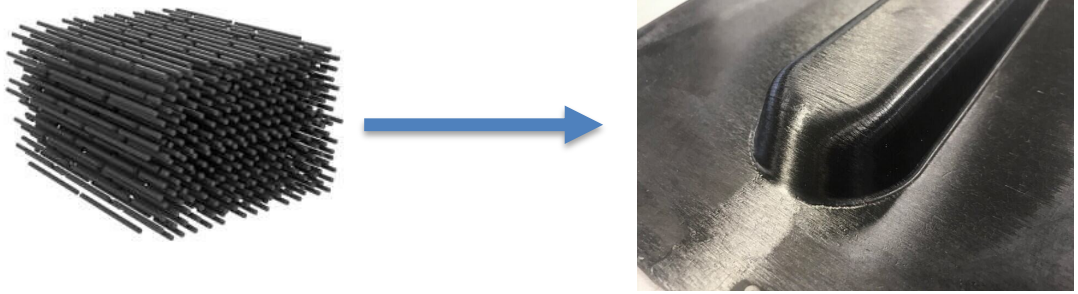
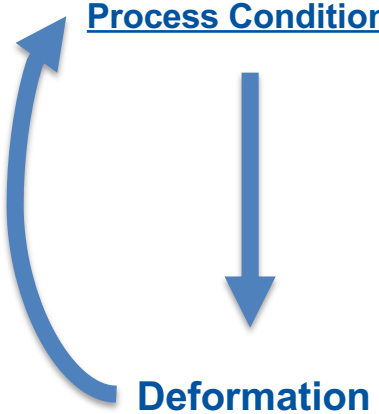
Characterization and Modeling of Deformation Mechanisms of Aligned Discontinuous Fiber Prepreg during Thermoforming

Aidan Ford, Andrew Stack, Tom Cender, Suresh Advani



DISTRIBUTION STATEMENT A. Approved for public release: distribution unlimited. AFRL-2025-3663

TuFF: Tailored universal Feedstock for Forming



- **Chopped fibers are aligned** by water flow onto a film
- Films of aligned fiber are prepregged with resin
- Prepreg can be used in **thermoforming process**
  - **Allows for stretch** during forming
  - Final properties comparable to continuous UD prepreg

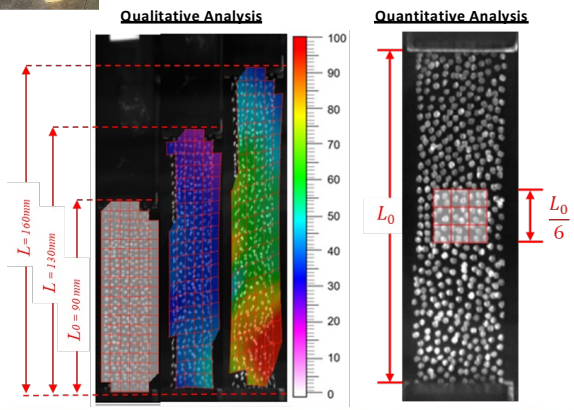
DISTRIBUTION STATEMENT A. Approved for public release: distribution unlimited AFRL-2025-3663.

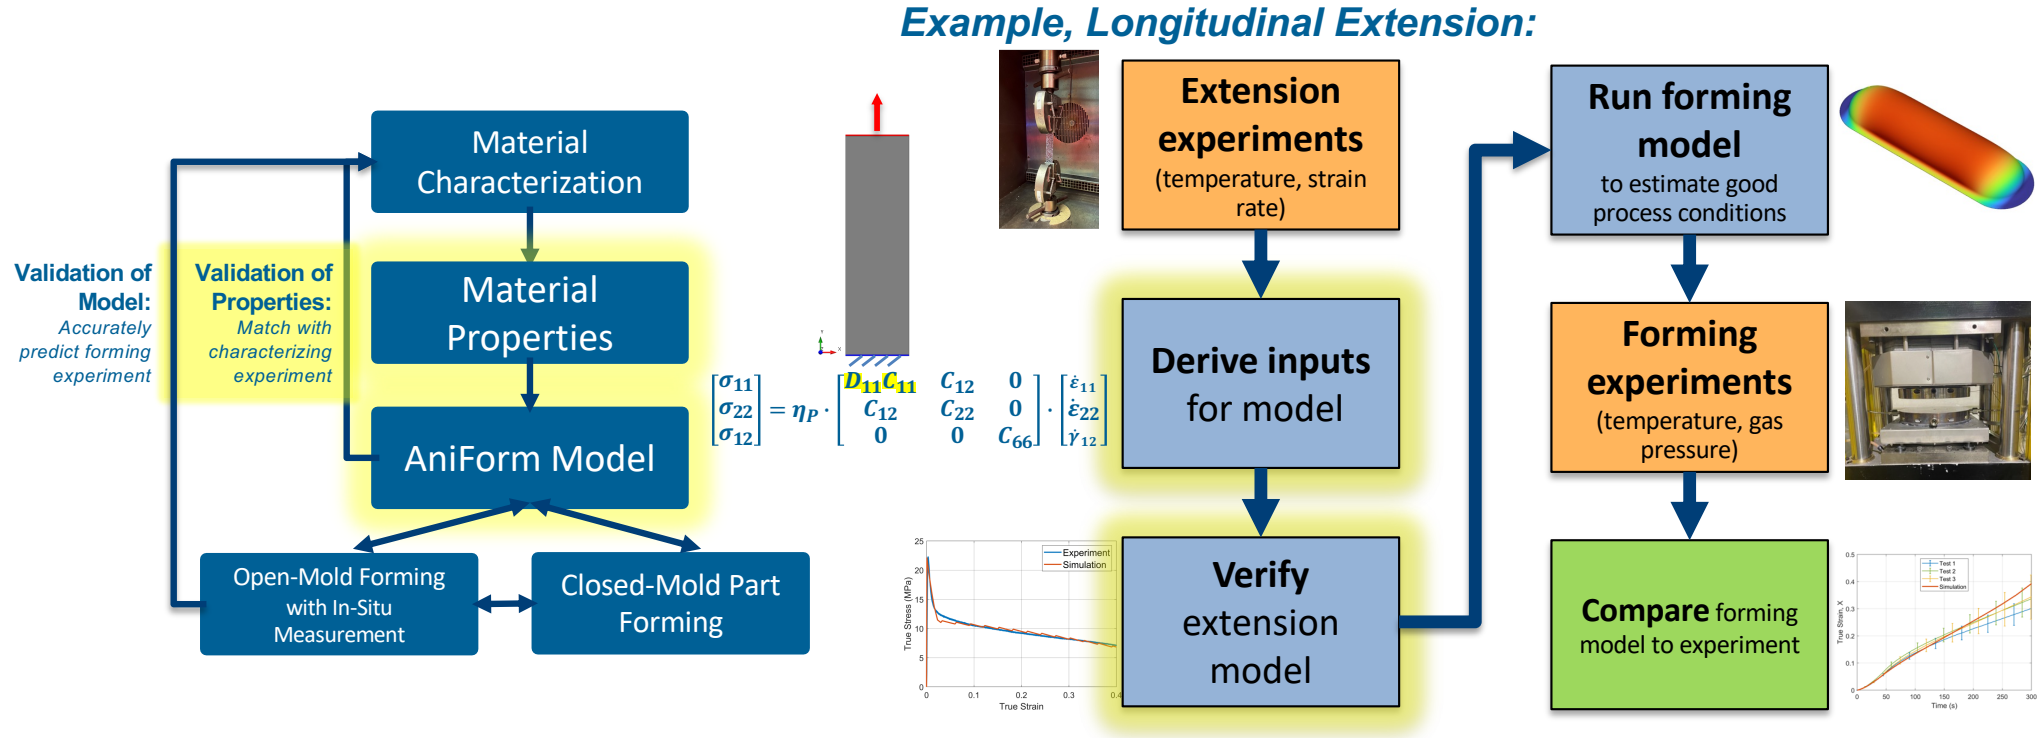
Axial Extension Experiments:
Setup and Data Measurement

- **Axial extension tests** characterize TuFF in a primary deformation mechanism
- Goal:
  - **Measure** strain + stress as a function of strain rate + temperature
- Procedure:
  - Stretch a 25.4 × 90 mm sample at known strain rates (s^{-1}) and temperatures (^oC)
  - Extension at constant strain rate



Test setup: a sample is gripped and stretched inside an environment chamber

Data analysis: Digital image correlation (DIC) tracks local strains over time.



Force is measured by a load cell to calculate stress (not shown)

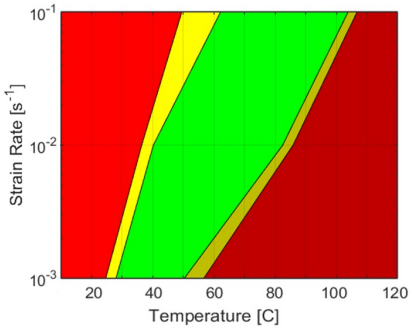
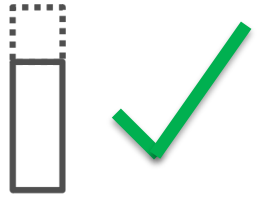
Conclusions

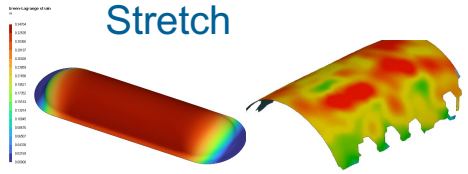
Extensional properties predicts stretch in forming



- **Validated model** to predict **longitudinal extensior** in forming.
- Simple equation + properties works:



Longitudinal Extension:
- Constant strain rate, impulsively started
- Single ply
- No transverse pressure



Forming:
- Gas pressure-driven
- Multi-ply with bladder
- Transverse pressure

- Suggests continuum-scale viscosity behaves in the same manner for single ply extension and multi-ply blanks in bead forming

Stretch

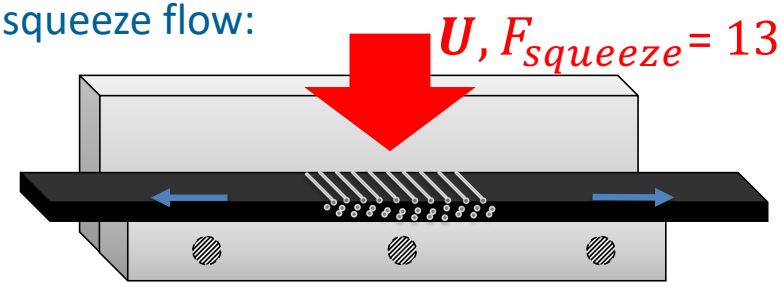
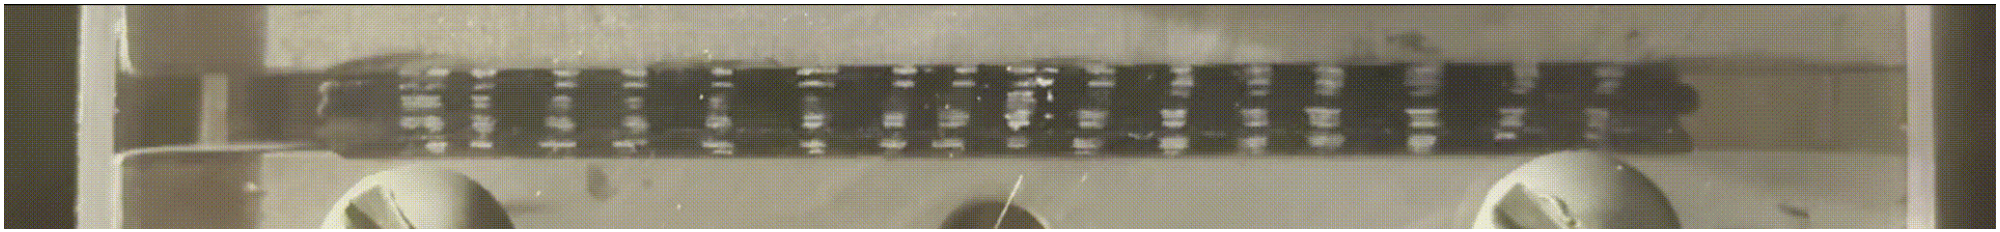
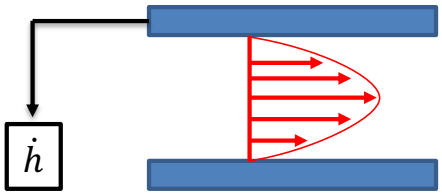
Squeeze Flow Experiment to Determine C_{66}



Consolidate sample:



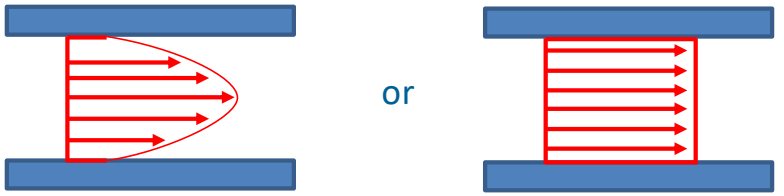
Drive squeeze flow:



Squeeze flow creates a **shearing deformation** in the sample which allows C_{66} to be characterized

DISTRIBUTION STATEMENT A. Approved for public release: distribution unlimited. AFRL-2025-3653.

Squeeze Flow Visualization with Markers



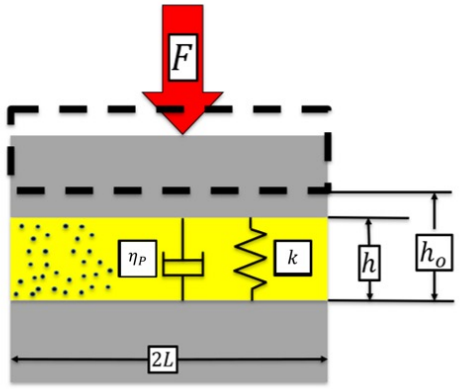
- Initial **parabolic** flow -> no slip boundary condition at **TuFF-tool** interface
- Analytical solution for force available from dimensions, viscosity (η), and closing rate ($\dot{h}$)

$$F = \frac{4\,L^3 W \eta \dot{h}}{h^3}$$

- Transition to plug or partial slip flow → evidence of **interfacial slip** developing at the TuFF-tool interface in later stages of the test

DISTRIBUTION STATEMENT A. Approved for public release: distribution unlimited. AFRL-2025-3653.

Model Formulation



- TuFF prepreg in squeeze flow is not only a viscous reaction, acts like a **spring and damper** system when squeezed:

Viscous Resin Force:

$$F_{Resin} = \frac{4L^3 W \dot{h} \eta_P C_{66}}{h^3}$$

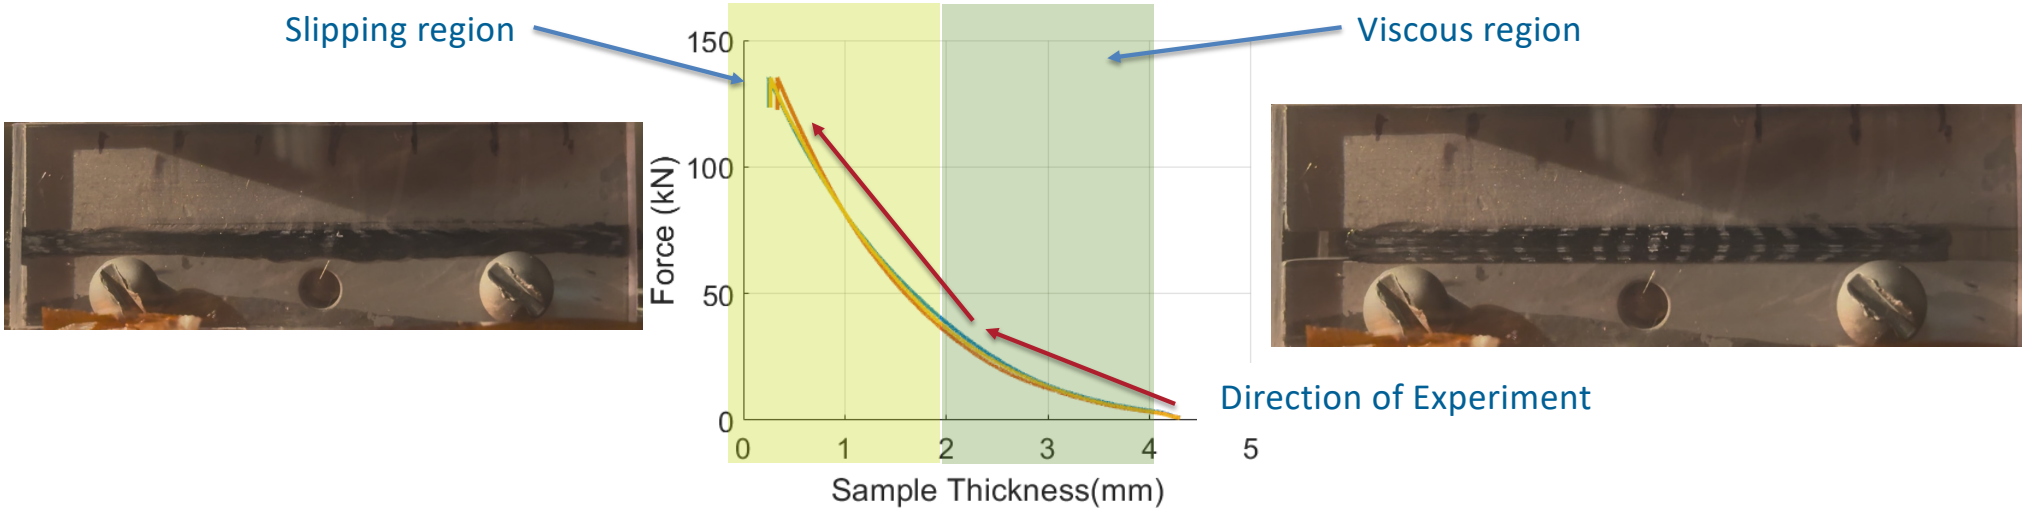
Spring Fiber Force:

$$F_{Fiber} = \sum_{i=1}^{n} k_i \, (h_o - h)^i$$

- The addition of these two reaction forces will describe the no slip portion of the experiment

$$F_{Sample} = F_{Resin} + F_{Fibers}$$

- h_o has been selected to be the displacement where the force begins to increase at $h = 4.68mm$

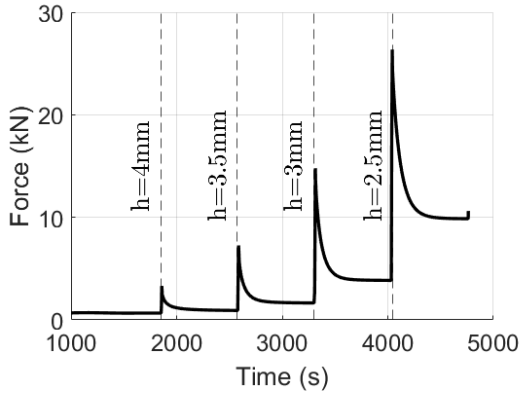


UNIVERSITY OF DELAWARE CENTER FOR COMPOSITE MATERIALS AFRL
DISTRIBUTION STATEMENT A. Approved for public release: distribution unlimited. AFRL-2025-3653.

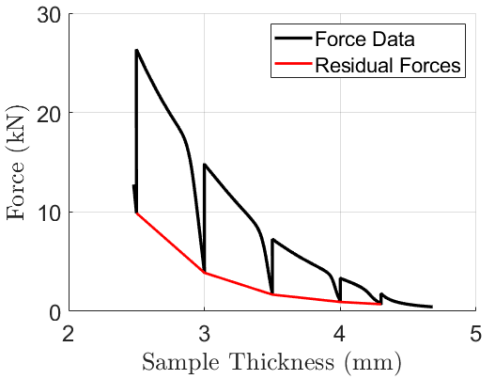
Results and Future Work

DISTRIBUTION STATEMENT A. Approved for public release: distribution unlimited. AFRL-2025-3653.

Squeeze Flow Experimental Results

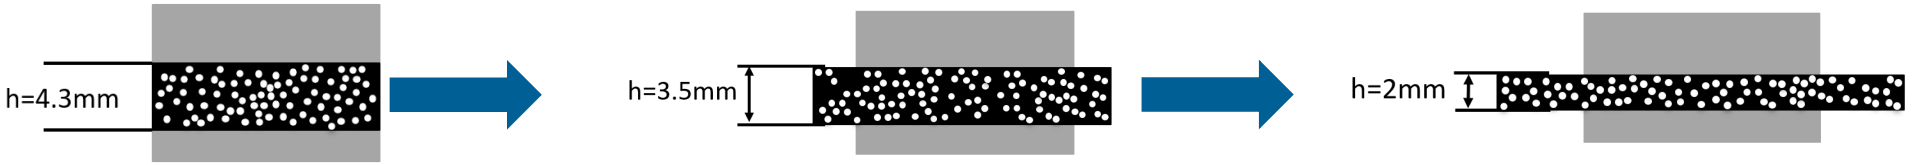


- Squeeze flow experiments produce repeatable results



DISTRIBUTION STATEMENT A. Approved for public release: distribution unlimited. AFRL-2025-3653.

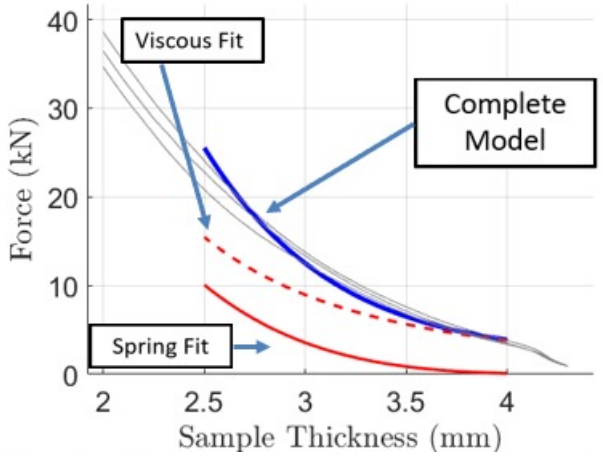
Modeling The Spring Response



- To fully describe spring response, sample squeezed to consecutive displacements
- Fiber spring response tracked

Fiber Response:

$$F_{Fibers} = 0.44(4.68 - h)^4$$



DISTRIBUTION STATEMENT A. Approved for public release: distribution unlimited. AFRL-2025-3653.

Fitted Parameters

- By isolating the viscous response to squeeze flow, C_{66} can be found using least squares optimization.
- For characterization to be correct, C_{66} remain constant at different dimensions and closure rates

$$F = \frac{4L^3 W \dot{h} \eta_P C_{66}}{h^3} + k_4 (h_o - h)^4$$

Parameters:
C_{66}: 17853
k_4: 0.44

- Prepreg viscosity is 18000 time larger than the polymer viscosity

UNIVERSITY OF DELAWARE CENTER FOR COMPOSITE MATERIALS AFRL
DISTRIBUTION STATEMENT A. Approved for public release: distribution unlimited. AFRL-2025-3653.

Summary

- A model was formulated to characterize the transvers viscosity of TuFF prepreg.
- Squeeze flow experiments were conducted in a 2”x1” fixture, all fibers were aligned in the direction perpendicular to flow.
- Three consistent experiments were performed and the viscosity was found to be 1e4 times larger than the polymer viscosity.
- Same methodology will be used to find viscosity using 4”x1” fixture.
- The characterized value will be used in Aniform.

$$\begin{bmatrix}\sigma_{11}\\ \sigma_{22}\\ \sigma_{12}\end{bmatrix} = \eta_P \cdot \begin{bmatrix}D_{11}C_{11} & C_{12} & 0\\ C_{12} & C_{22} & 0\\ 0 & 0 & C_{66}\end{bmatrix} \cdot \begin{bmatrix}\dot{\varepsilon}_{11}\\ \dot{\varepsilon}_{22}\\ \dot{\gamma}_{12}\end{bmatrix}$$

Proposed Solution

Stage Resin

Pre-form blank

Final Form + Cure

Benefits:

1. Reduces TuFF/977-3 porosity issues:
   a. Vent volatiles with oven-vacuum (no pressure and no bleed)
   b. Reduces resin bleed during cure (higher visc. and shorter time to gel)
2. Reduces risk:
   a. Inspect after preforming (visual)
   b. Splitting the forming process: deep draw vs detailed feature
3. Reduces cycle time:
   a. Stamping press at constant temp.
   b. Parallel processes

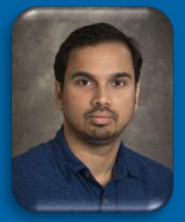
"Tensile Behavior and Stress Relaxation of Uncured Prepreg of Aligned Discontinuous Fiber Materials"



Objectives

- Characterize tensile behavior of uncured TuFF under uniaxial loading.
- Develop and validate a continuum constitutive model.
- Enable forming process simulations for TuFF prepreg.
- Approach
  - Perform room temperature tensile tests over wide range of strain rates.
  - Analyze recorded video for strain measurement.
  - Formulate and validate constitutive expressions.
  - Implement model in commercial forming software.
  - Validate forming simulations with experimental results.

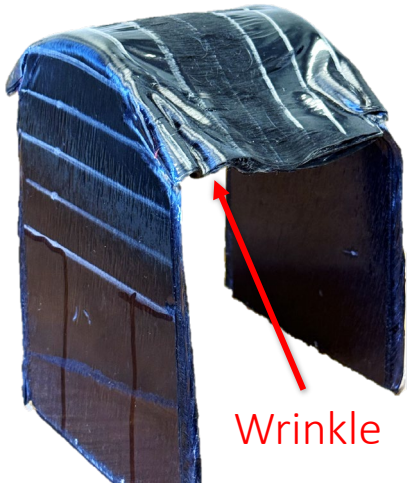
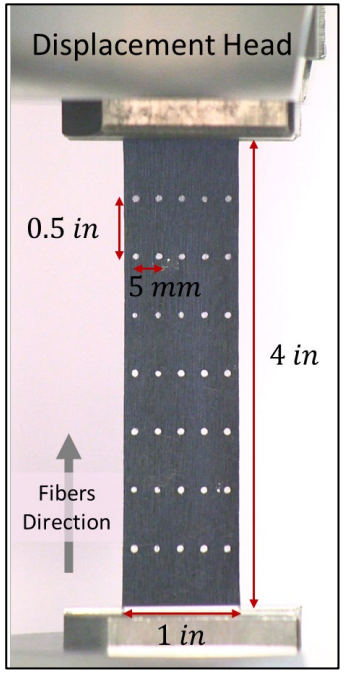
NASA ULI UNIVERSITY LEADERSHIP INITIATIVE

Introduction

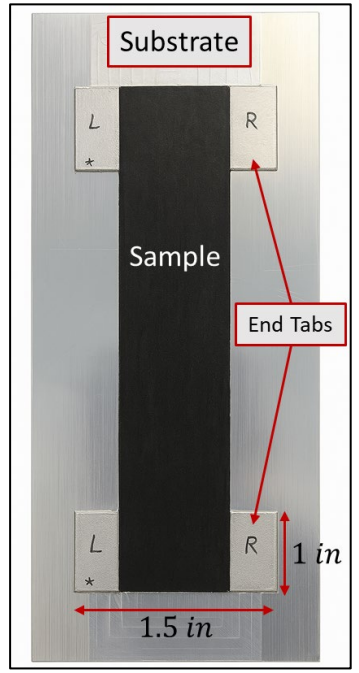


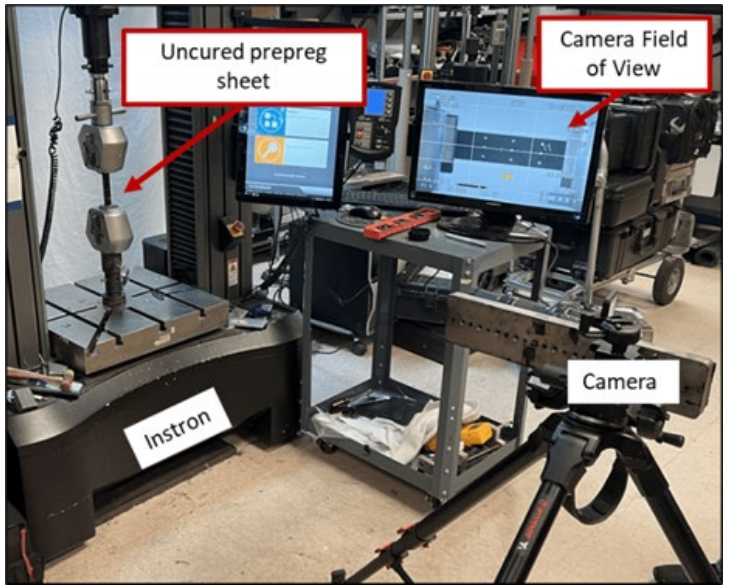
- Forming of Fiber-Reinforced Composites
  - Continuous fibers offer strength, but poor formability.
  - Aligned Discontinuous Fiber (ADF) composites (like TuFF) balance formability and performance.

- TuFF Forming Opportunities and Challenges
  - **Significant** fiber-direction stretchability (e.g. local maximum strain 42%)
  - **Lack of constitutive models** capturing anisotropic mechanical behavior of uncured prepreg.



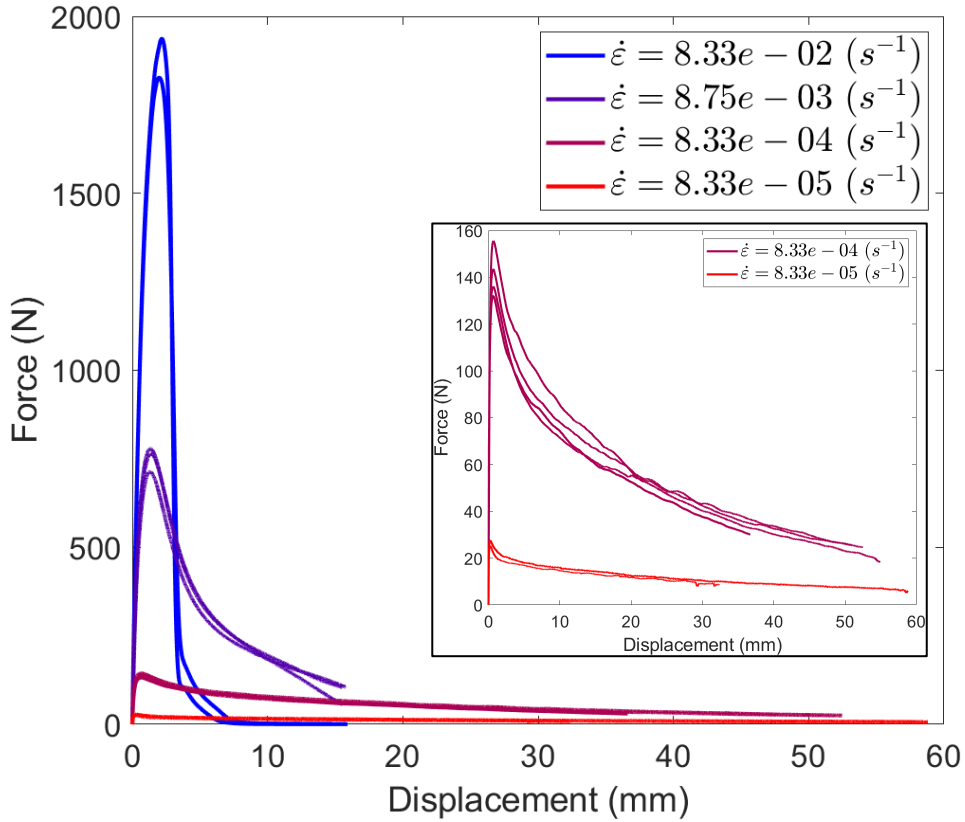
- Methodology:
  - **I.** **Design** experimental framework for tensile testing of uncured TuFF prepreg.
  - **II.** **Characterize** strain-rate dependent viscous response in fiber direction.
  - **III.** **Develop** continuum constitutive model using normalized master curve.
  - **IV.** **Implement** model in composite forming simulation software.





Experimental Procedure

- Materials and Conditions
  - Prepreg: 3mm IM7 carbon fiber with Axiom (Ax-2201FR) thermoset resin.
  - Volume fraction: 40%
  - Areal Weight: 120gsm
  - Specimens: 4” gauge length x 1” width x 0.25mm Thickness.
  - Room temperature conditioning.
- Sample Preparation
  - Utilized mirror-finished aluminum fixture for end-tab bonding.
  - Applied a dot-grid pattern on specimens surface using an acrylic stencil.
- Experimental Setup
  - Captured force and cross-head displacement via Instron (2kN load cell - 1000Hz)
  - Recorded deformation by HD digital video camera (24 fps)

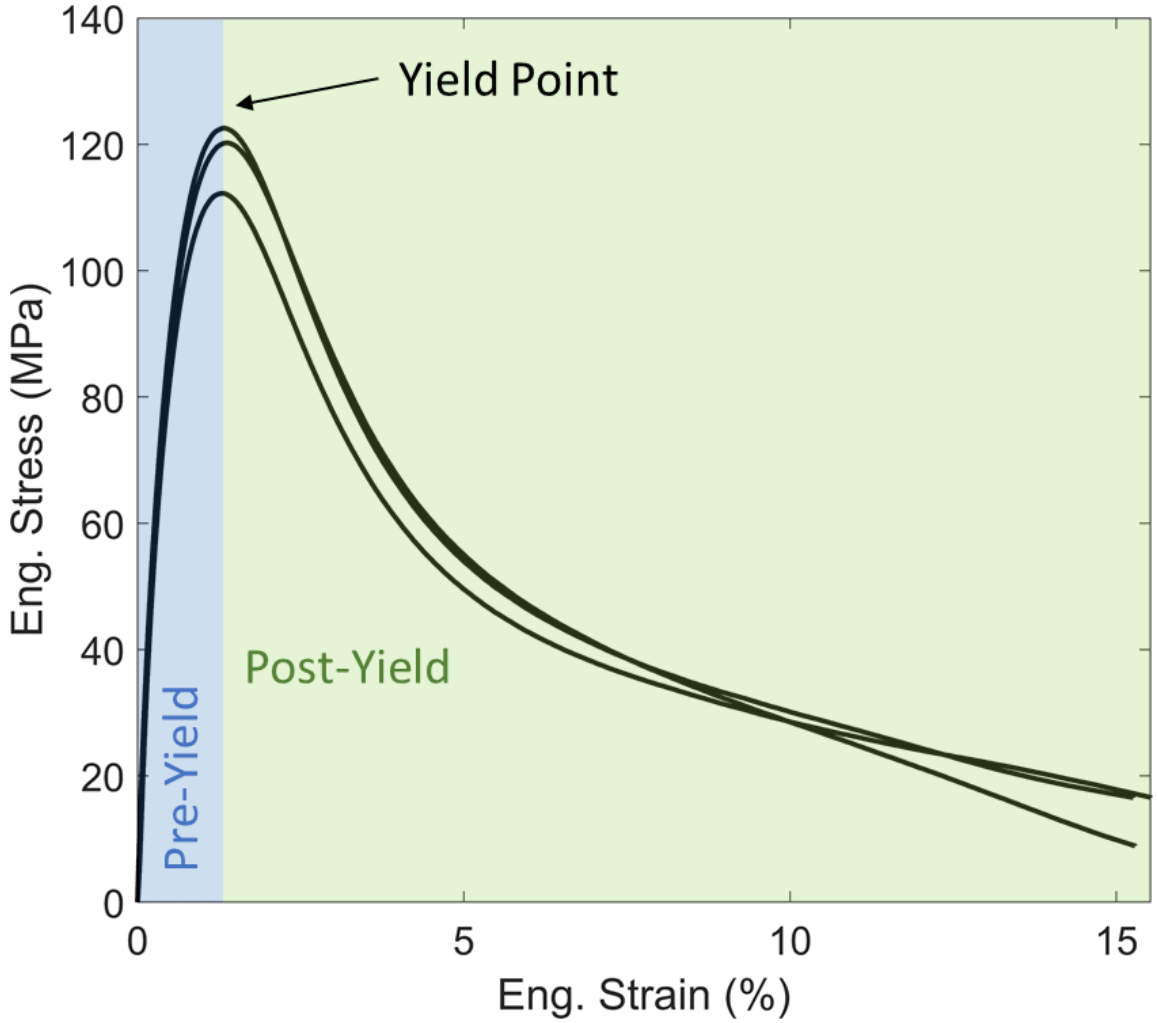


Experimental Procedure – Uniaxial Tensile in Fiber Direction

- Preliminary Data
  - Uniaxial tensile test at **constant strain rates** (x3/x5 replicates per strain rate).
  - Strain rates (displacement velocity) spanning three orders of magnitude (displacement velocities:0.02 to 20 $^{in}/_{min}$).

Displacement Rate (inch/min)	Strain Rate (1/s)	Yield Stress (MPa)		Yield Strain (%)	
		Mean	Standard Deviation	Mean	Standard Deviation
0.02	8.33e-05	4.16	0.19	0.23	0.025
0.2	8.33e-04	21.60	0.92	0.61	0.007
2.1	8.75e-03	118.36	5.41	1.33	0.031
20	8.33e-02	296.29	12.23	2.05	0.134

- Reliable Experimental Data
  1. High experimental repeatability (< 5%).
  2. Low material variability.
- Similar Normalized Response.



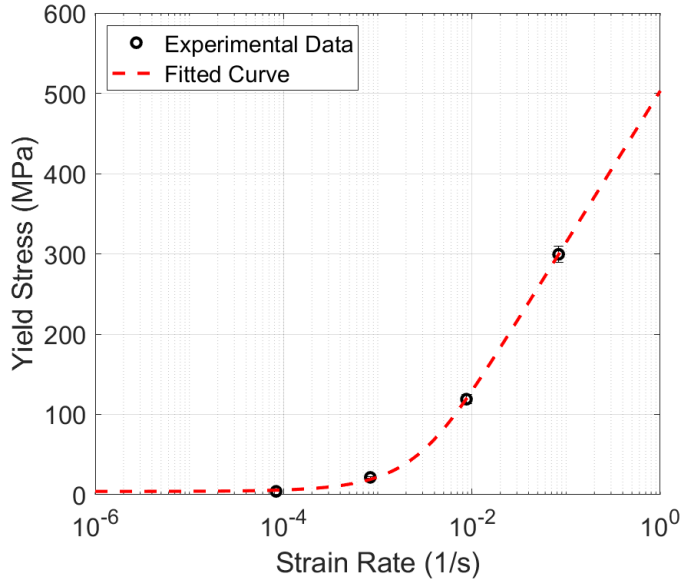
Constitutive Model Formulation – Approach

- Approach

1. Convert *Force-Displacement* to *Eng. Stress-Strain*.

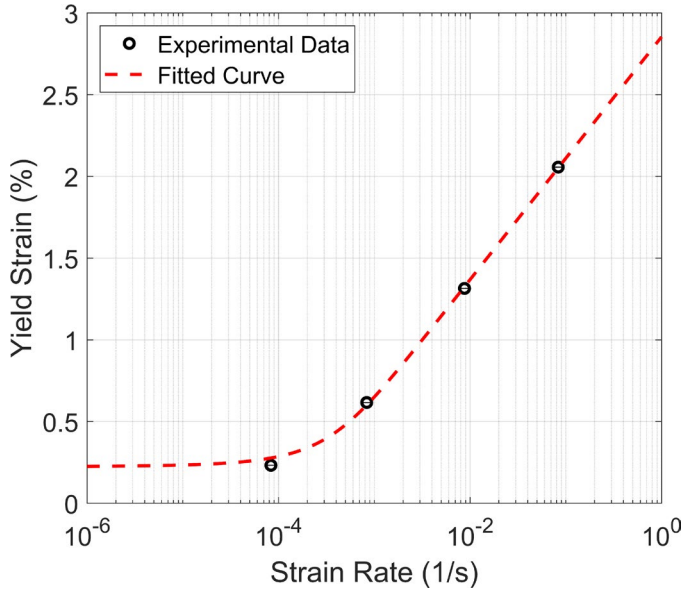
2. Split material response in two distinct regions:
   a) Pre-Yield (Region I)
   b) Post-Yield (Region II)

3. Propose Individual rate-dependent models for Pre-Yield and Post-Yield regions with smooth transition at yield.



Constitutive Model Formulation – Constant Strain Rate Loading

- Yield Stress (σ_0) increase with increasing Strain Rate ($\dot{\varepsilon}$)
- Implemented Model (Eyring Yielding model):

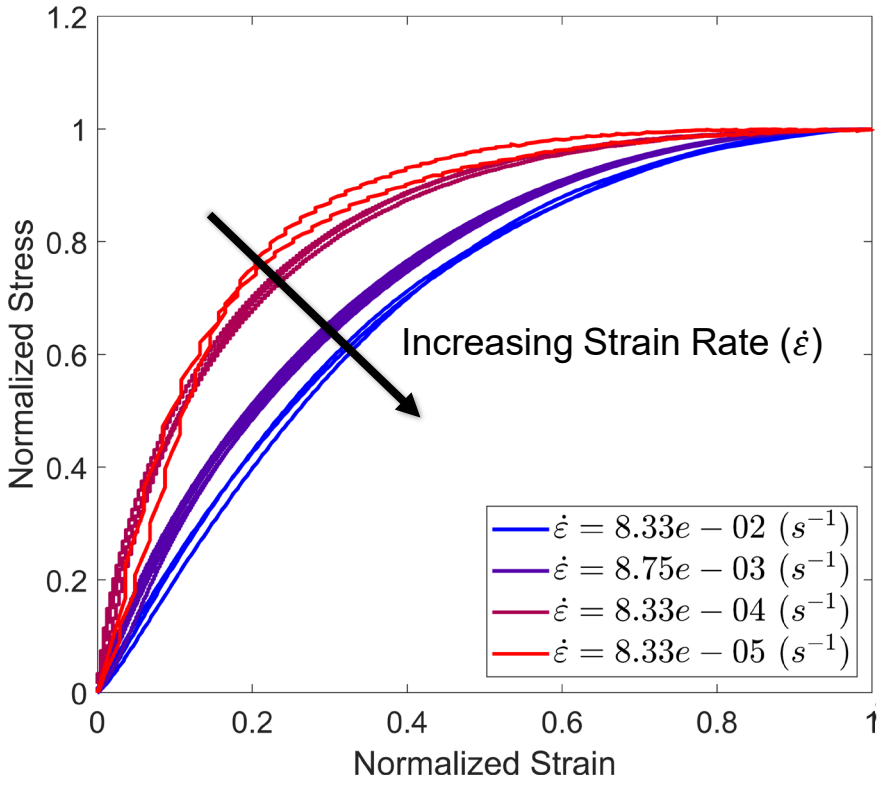


$$\sigma_{0(\dot{\varepsilon})} = A.\ln\left(\frac{\dot{\varepsilon}}{C_1}\right) + B.\sinh^{-1}\left(\frac{\dot{\varepsilon}}{C_2}\right) + D$$

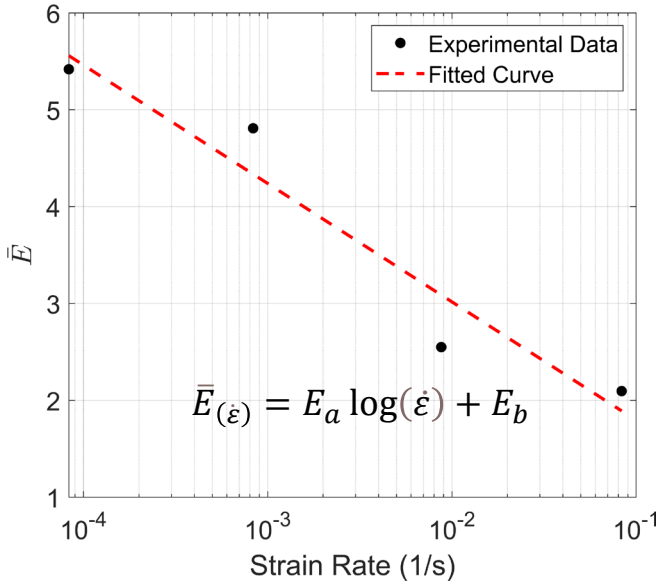
- Assumptions:
  - Plateau at very low strain rates (half the yield stress). $D = \frac{\dot{\varepsilon}_{min}}{2}$
  - Keep yield stress positive at very low strain rates. $C_1 = \dot{\varepsilon}_{min}$

- Similar procedure for Yield Strain (ε_0)

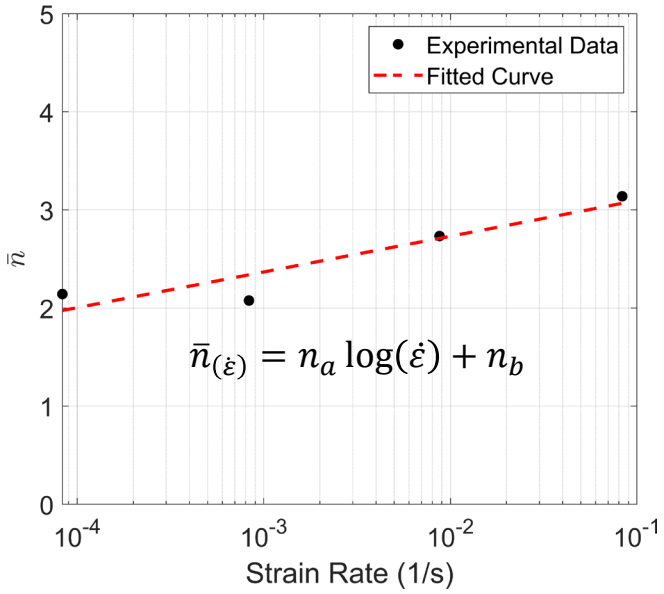
Yield Stress	Yield Strain
$\sigma_{0(\dot{\varepsilon})} = A\ln\left(\frac{\dot{\varepsilon}}{C_1}\right) + B\sinh^{-1}\left(\frac{\dot{\varepsilon}}{C_2}\right) + D$	$\varepsilon_{0(\dot{\varepsilon})} = a\ln\left(\frac{\dot{\varepsilon}}{c_1}\right) + b\sinh^{-1}\left(\frac{\dot{\varepsilon}}{c_2}\right) + d$
$A = 8.50\ \mathrm{e} - 03$	$a = 6.65e - 06$
$B = 5.93e + 01$	$b = 2.92e - 03$
$C_1 = 8.33e - 05$	$c_1 = 8.33e - 05$
$C_2 = 2.50e - 03$	$c_2 = 2.97e - 04$
$D = 2.08$	$d = 1.20e - 03$



Constitutive Model Formulation – Constant Strain Rate Loading



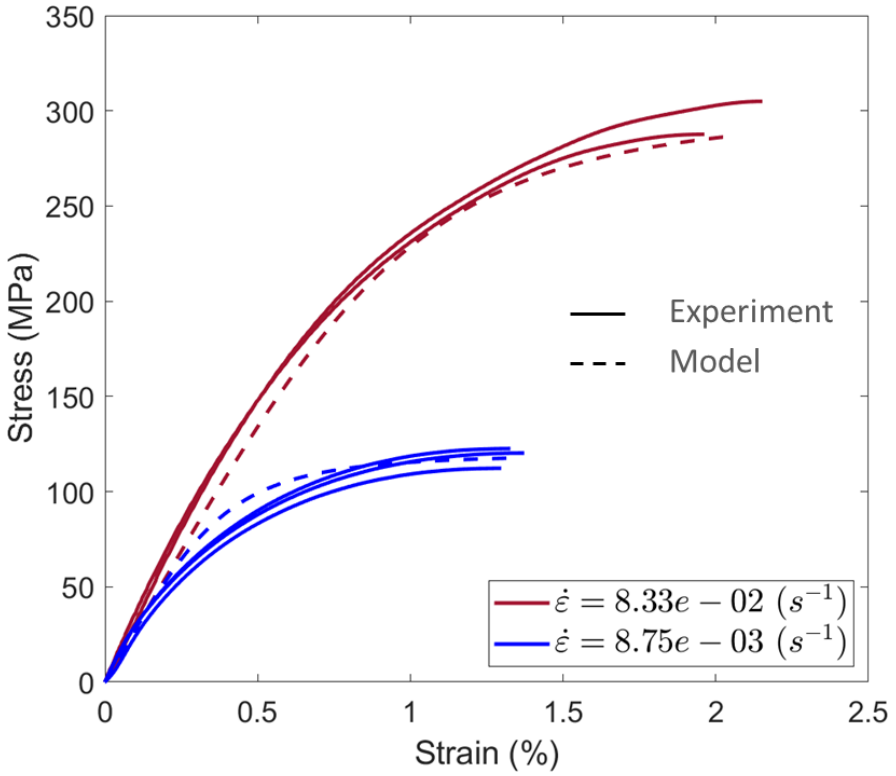
- Pre-Yield (Region I) Modeling: Non-linear Hardening
  - Normalized Stress ($\bar{\sigma}$) – Normalized Strain ($\bar{\varepsilon}$) (with respect to *Yield Stress* and *Yield Strain)*.

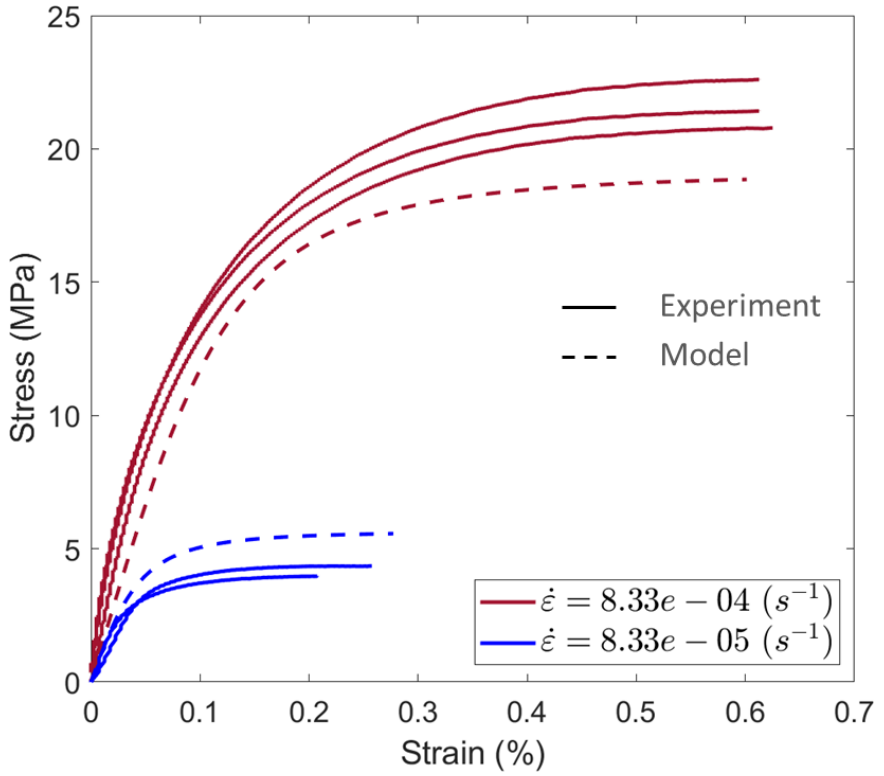


- Implemented Model :

$$\bar{\sigma}_{(\bar{\varepsilon},\ \dot{\varepsilon})} = \frac{\bar{E}_{(\dot{\varepsilon})} . \bar{\varepsilon}}{\left(1 + \left(\bar{E}_{(\dot{\varepsilon})} . \bar{\varepsilon}\right)^{\bar{n}_{(\dot{\varepsilon})}}\right)^{\frac{1}{\bar{n}_{(\dot{\varepsilon})}}}}$$

- Fitting Parameters:
  - $\bar{E}_{(\dot{\varepsilon})}$: Initial Slope (Initial Normalized Stiffness)
  - $\bar{n}_{(\dot{\varepsilon})}$: Asymptotic Plateau shape



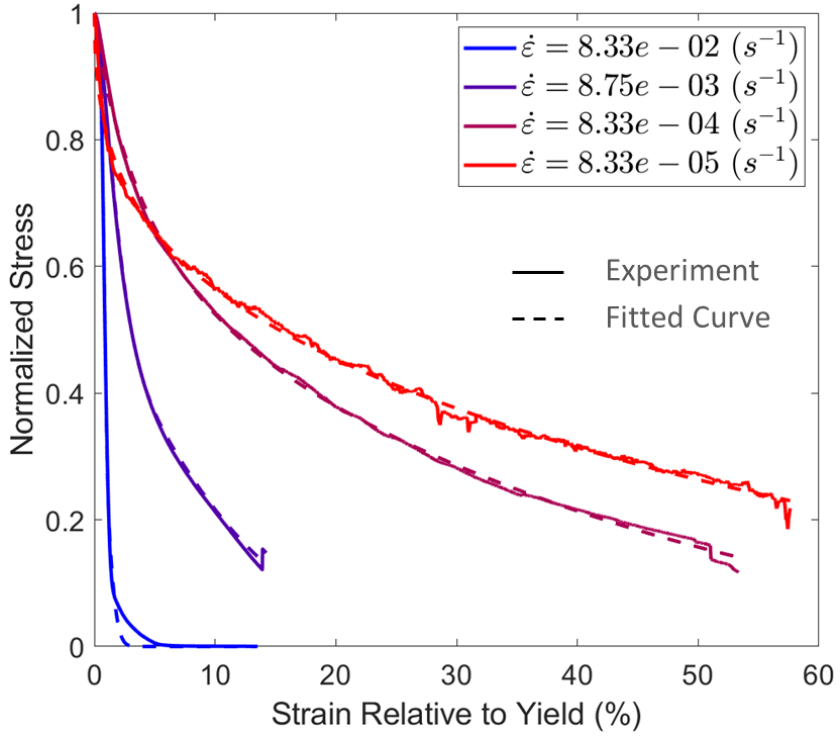


Constitutive Model Formulation – Constant Strain Rate Loading

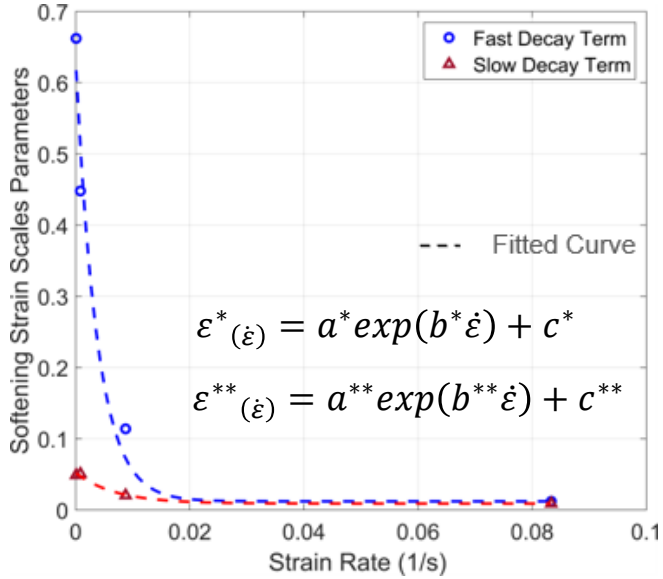
- Pre-Yield (Region I) Model Validation
  - Denormalizing the model prediction (normalized stress - strain) by multiplying them to yield stress and yield strain.

$$\sigma_{(\bar{\varepsilon},\ \dot{\varepsilon})} = \sigma_{0(\dot{\varepsilon})} \cdot \frac{\bar{E}_{(\dot{\varepsilon})} \cdot \bar{\varepsilon}}{\left(1 + \left(\bar{E}_{(\dot{\varepsilon})} \cdot \bar{\varepsilon}\right)^{\bar{n}_{(\dot{\varepsilon})}}\right)^{\frac{1}{\bar{n}_{(\dot{\varepsilon})}}}}$$

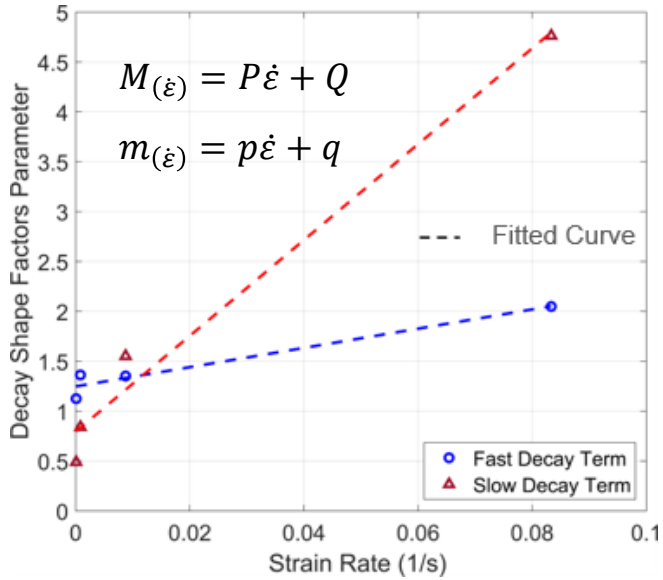
- High Strain Rate Data



- Low Strain Rate Data



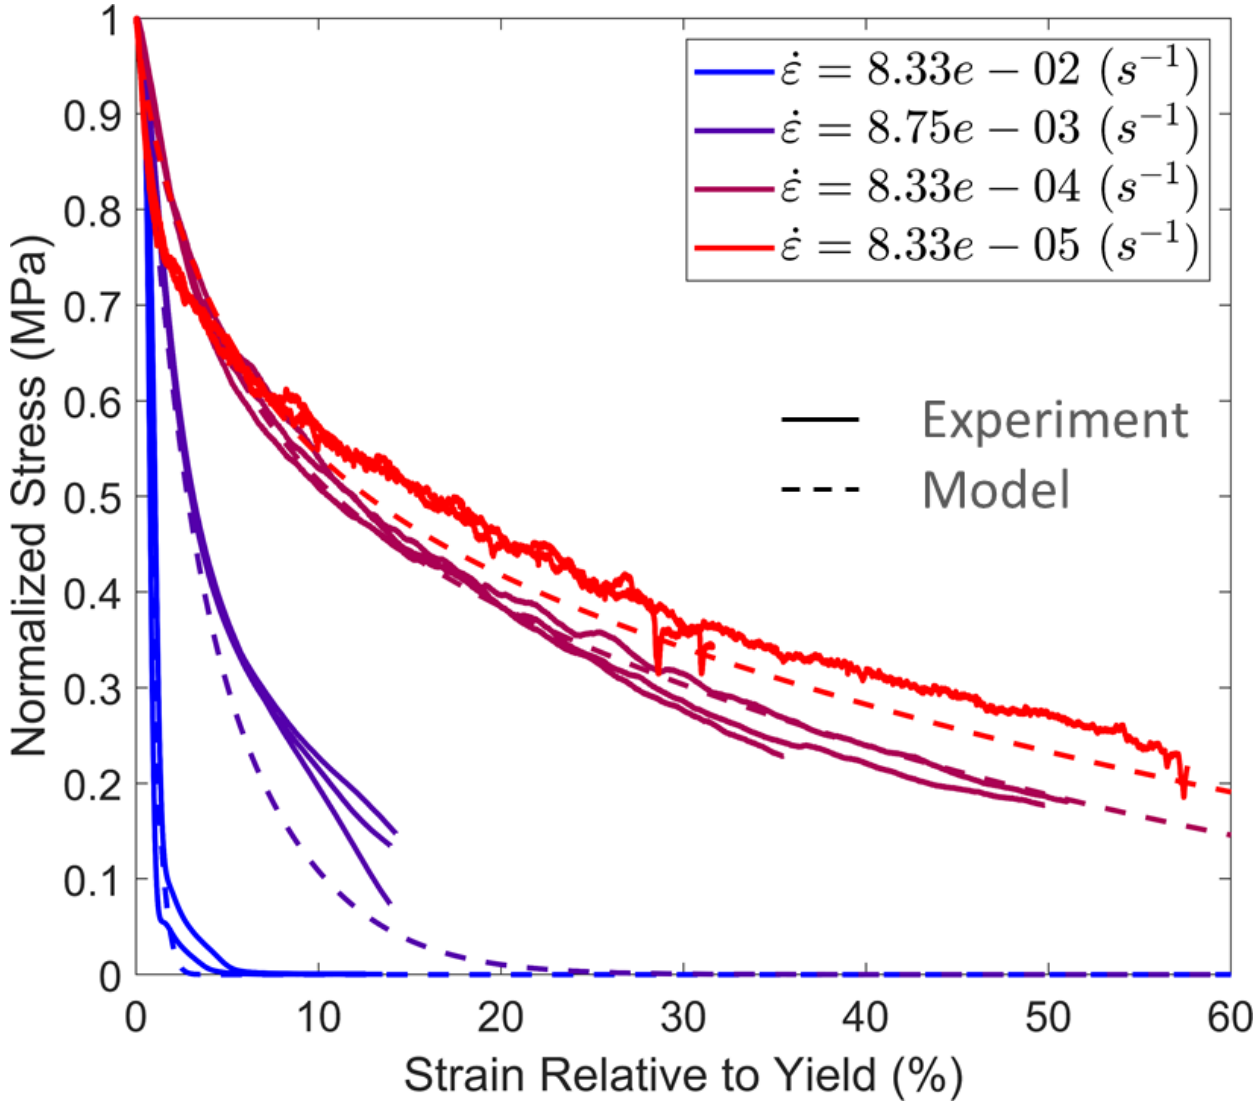
Constitutive Model Formulation – Constant Strain Rate Loading



- Post-Yield (Region II) Modeling: Exponential Softening
  - Normalized Stress ($\bar{\sigma}$) – Relative Strain ($\varepsilon - \varepsilon_0$)
- Implemented Model :

$$\bar{\sigma}(\varepsilon, \dot{\varepsilon}) = \frac{1}{2}\left(\exp\left[-\left(\frac{\varepsilon - \varepsilon_0}{\varepsilon^*_{(\dot{\varepsilon})}} \right)^{m_{(\dot{\varepsilon})}} \right] + \exp\left[-\left(\frac{\varepsilon - \varepsilon_0}{\varepsilon^{**}_{(\dot{\varepsilon})}} \right)^{M_{(\dot{\varepsilon})}} \right] \right)$$

- Fitting Parameters:
  - $\varepsilon^*_{(\dot{\varepsilon})}$ / $\varepsilon^{**}_{(\dot{\varepsilon})}$: Decay Coefficient
  - $m_{(\dot{\varepsilon})}$ / $M_{(\dot{\varepsilon})}$: Softening Strain Scales



Constitutive Model Formulation – Constant Strain Rate Loading

- Post-Yield (Region II) Model Validation

1. Stress decays exponentially toward zero in the post-yield regime (desirable for implementation in forming simulations).
2. Prediction error is comparable to variation across replicates.
3. Stress can get de-normalized with respect to yield stress.

Constitutive Model Formulation – Constant Strain Rate Loading

- Characterized Models

- Yield Stress (σ_0) and Strain (ε_0)

$$\sigma_{0(\dot{\varepsilon})} = A.\ln\left(\frac{\dot{\varepsilon}}{C_1}\right) + B.\sinh^{-1}\left(\frac{\dot{\varepsilon}}{C_2}\right) + D$$

$$\varepsilon_{0(\dot{\varepsilon})} = a.\ln\left(\frac{\dot{\varepsilon}}{c_1}\right) + b.\sinh^{-1}\left(\frac{\dot{\varepsilon}}{c_2}\right) + d$$

- Pre-Yield Non-linear Hardening

$$\sigma(\varepsilon,\dot{\varepsilon}) = \sigma_{0(\dot{\varepsilon})}.\frac{\bar{E}_{(\dot{\varepsilon})}.\bar{\varepsilon}}{\left(1 + \left(\bar{E}_{(\dot{\varepsilon})}.\bar{\varepsilon}\right)^{\bar{n}_{(\dot{\varepsilon})}}\right)^{\frac{1}{\bar{n}_{(\dot{\varepsilon})}}}}$$

$$\bar{E}_{(\dot{\varepsilon})} = E_a \log(\dot{\varepsilon}) + E_b$$

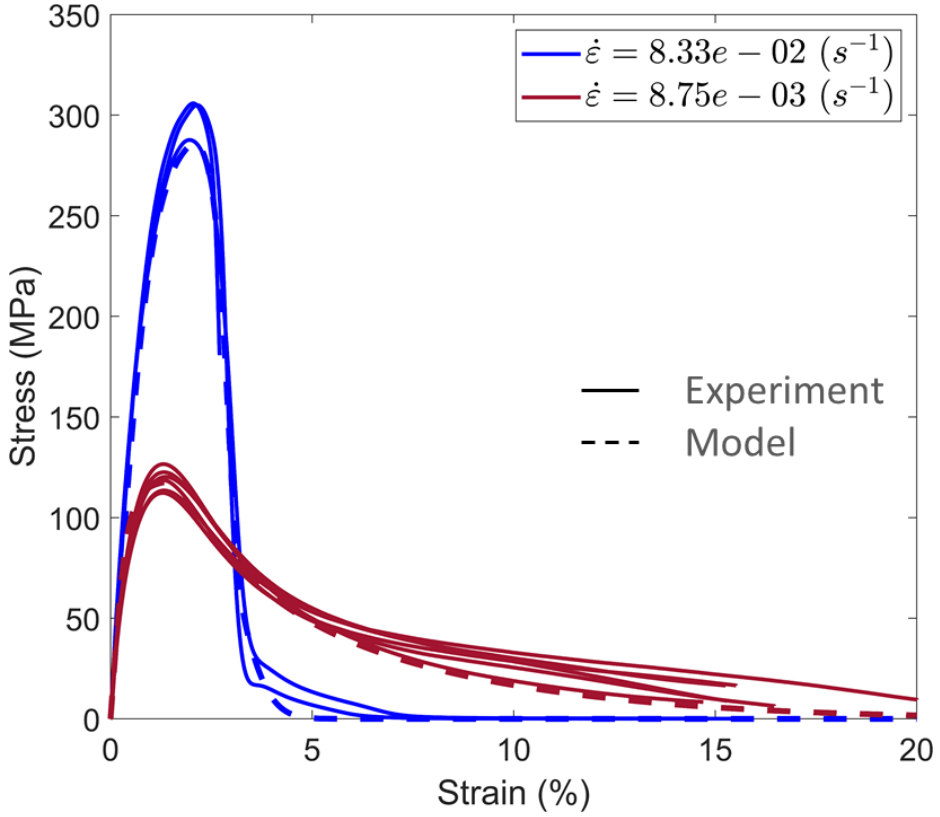
$$\bar{n}_{(\dot{\varepsilon})} = n_a \log(\dot{\varepsilon}) + n_b$$

$$\bar{\varepsilon} = \frac{\varepsilon}{\varepsilon_{0(\dot{\varepsilon})}}$$

- Post-Yield Softening

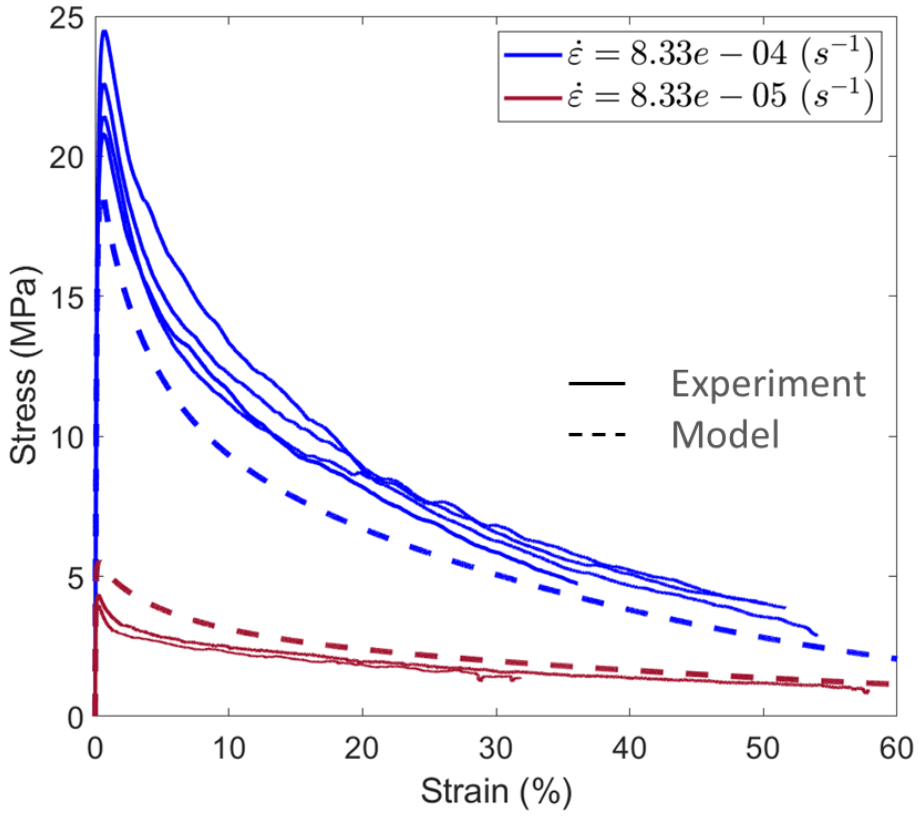
$$\sigma(\varepsilon,\dot{\varepsilon}) = \frac{\sigma_{0(\dot{\varepsilon})}}{2}\left(\exp\left[-\left(\frac{\varepsilon-\varepsilon_0}{\varepsilon^*_{(\dot{\varepsilon})}}\right)^{m_{(\dot{\varepsilon})}}\right] + \exp\left[-\left(\frac{\varepsilon-\varepsilon_0}{\varepsilon^{**}_{(\dot{\varepsilon})}}\right)^{M_{(\dot{\varepsilon})}}\right]\right)$$

$$\varepsilon^*_{(\dot{\varepsilon})} = a^* exp(b^*\dot{\varepsilon}) + c^*$$



$$\varepsilon^{**}_{(\dot{\varepsilon})} = a^{**} exp(b^{**}\dot{\varepsilon}) + c^{**}$$

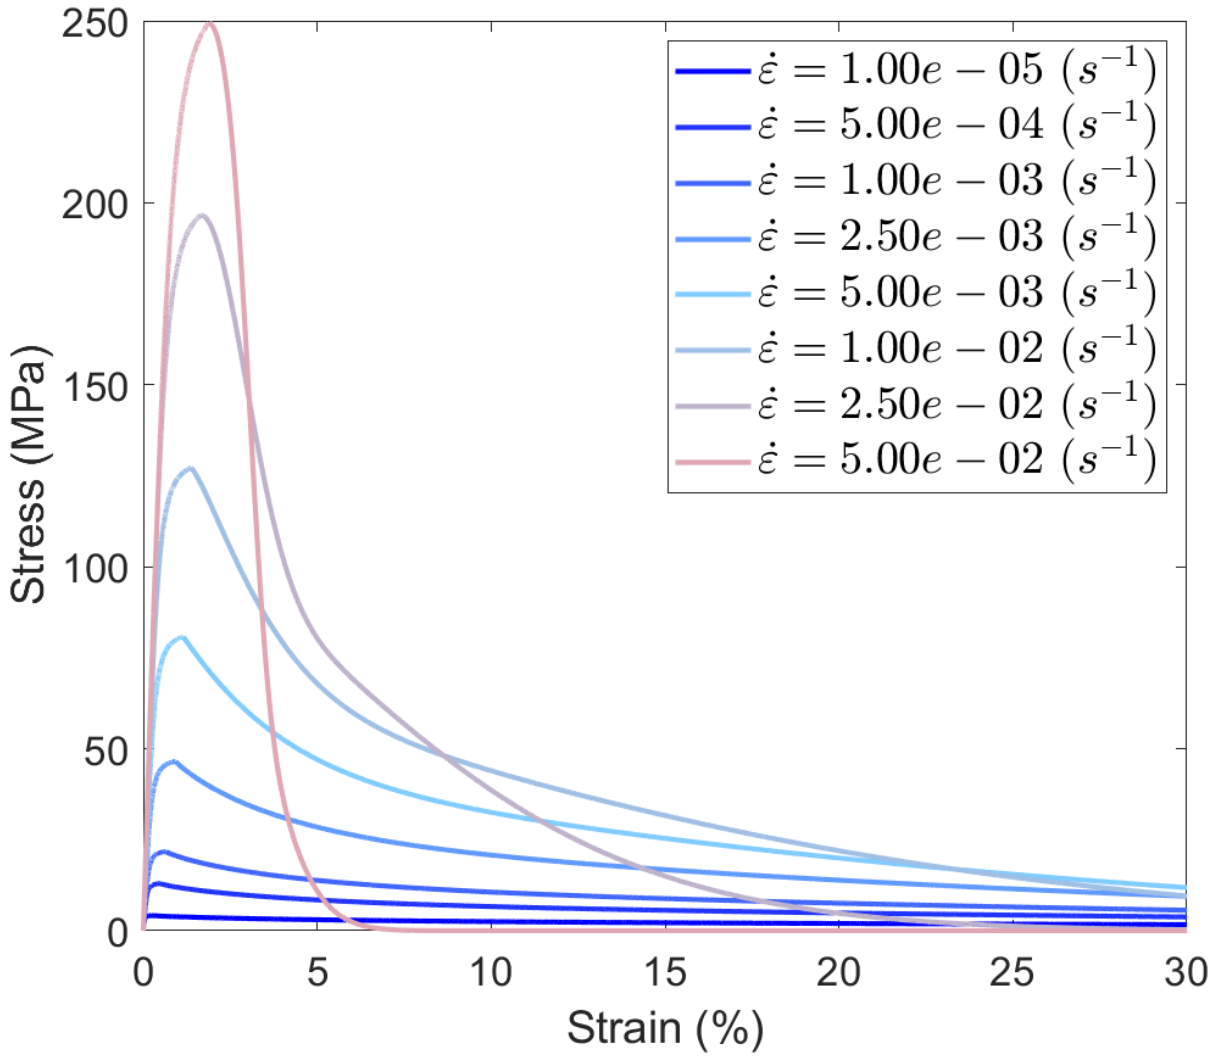
$$M_{(\dot{\varepsilon})} = P\dot{\varepsilon} + Q$$



$$m_{(\dot{\varepsilon})} = p\dot{\varepsilon} + q$$

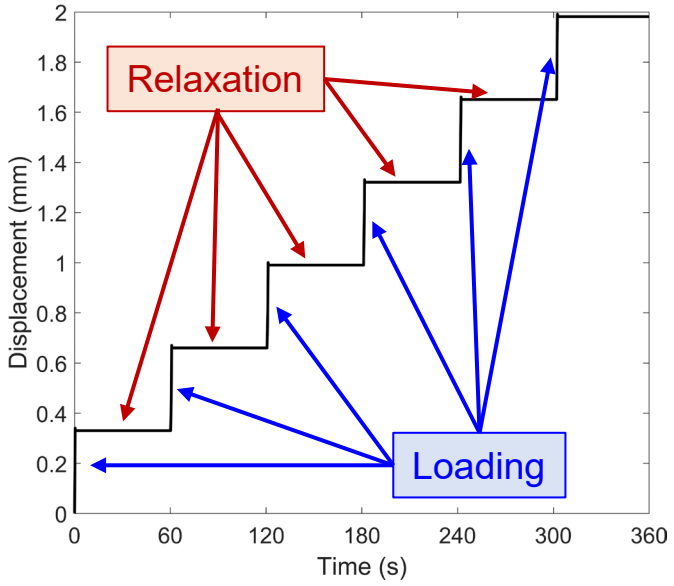
Constitutive Model Formulation – Constant Strain Rate Loading

- Material response validation across 3 orders of strain rate magnitude (22 fitting parameters).

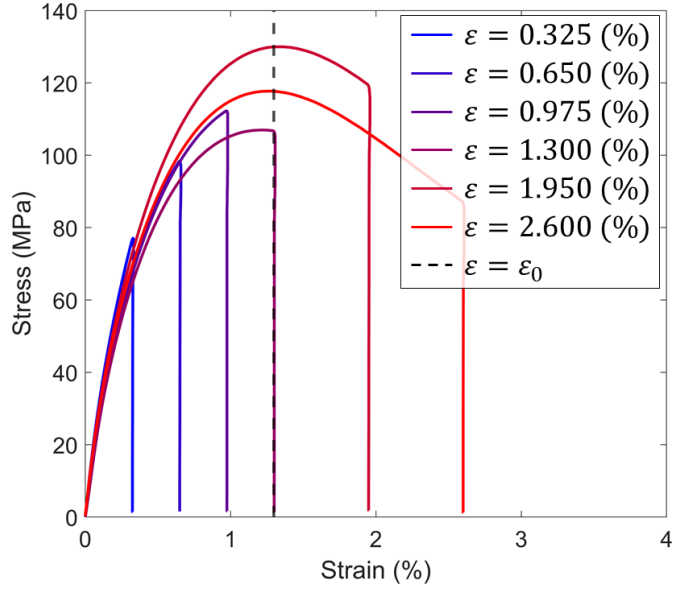


- High Strain Rate Data

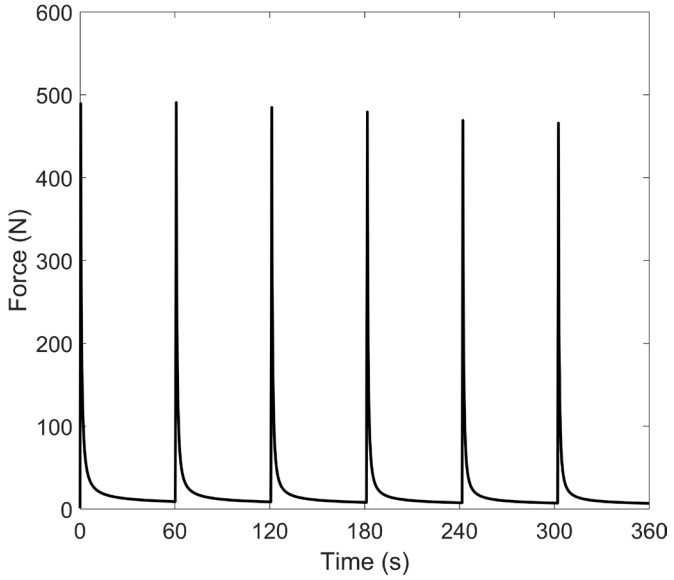
- Low Strain Rate Data

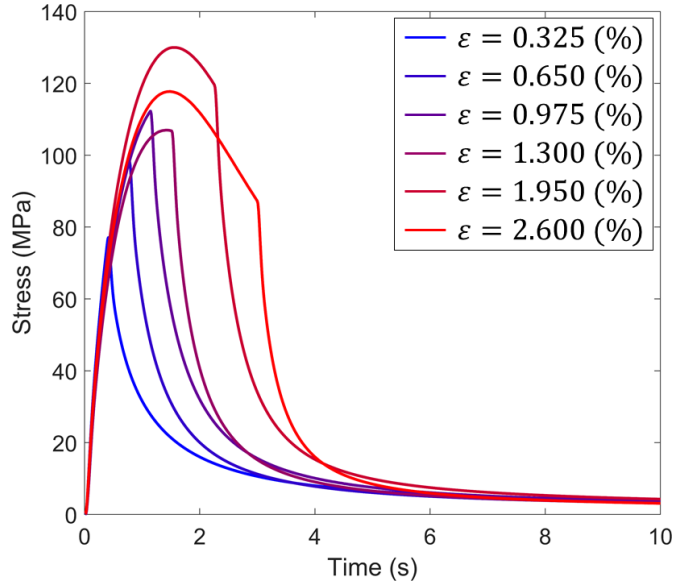


Constitutive Model Formulation – Constant Strain Rate Loading



- Strain Rate Dependent Constitutive Tensile Behavior (Family of curves)
  - Predicted curves covering strain rates from very low to very high levels
  - Lower Strain Rates:
    i. Lower yield stress,
    ii. Earlier yielding at smaller strains,
    iii. Gradual softening.
  - Higher Strain Rate:
    i. Higher yield stress,
    ii. Larger strain before yielding,
    iii. Sharp stress decay after yield.
  - Tabular inputs for ABAQUS explicit solver

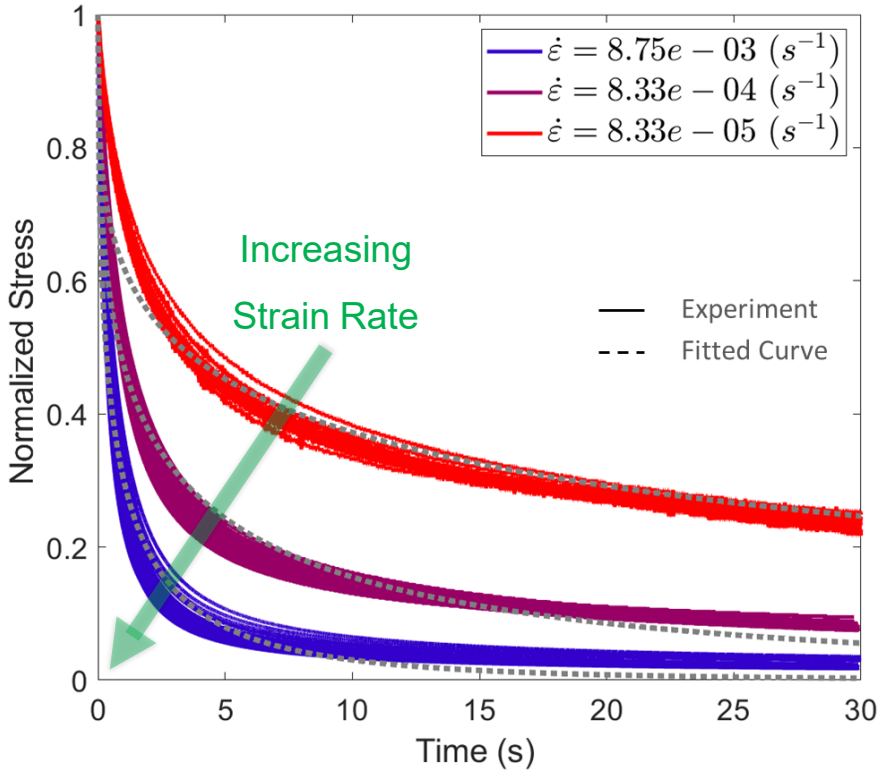




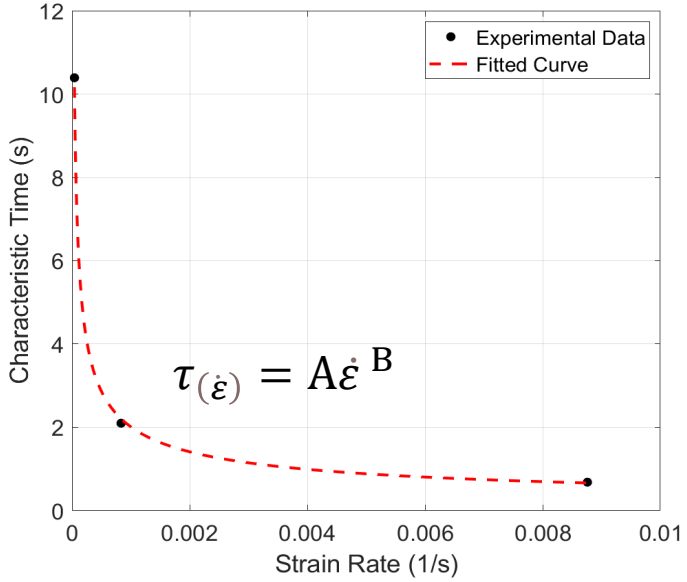
Constitutive Model Formulation – Stress Relaxation

- Experimental Procedure and Data
  - **Loading at constant strain** rate, followed by **stress relaxation** hold at defined strain levels.
  - **Strain levels** : $\left[\frac{1}{4}, \frac{1}{2}, \frac{3}{4}, 1, \frac{5}{4}, \frac{6}{4}\right] * \varepsilon_0$
  - Each test includes 6 sequential loading –relaxation cycles.
  - The first Loading-Relaxation cycle results.
  - Stress decay curves isolated for relaxation model fitting.

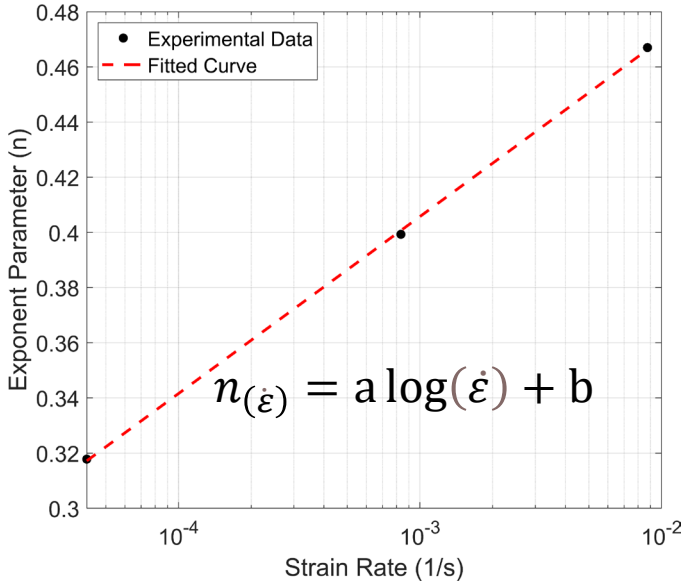
Constitutive Model Formulation – Stress Relaxation



- Stress Decay Model
  - Fully viscous response.
  - Dependency on the strain rate of the prior loading interval.
  - No significant strain dependency.



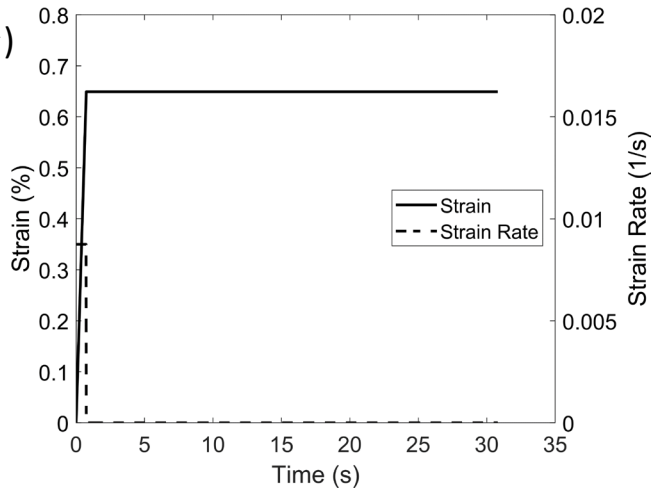
- Implemented Model :

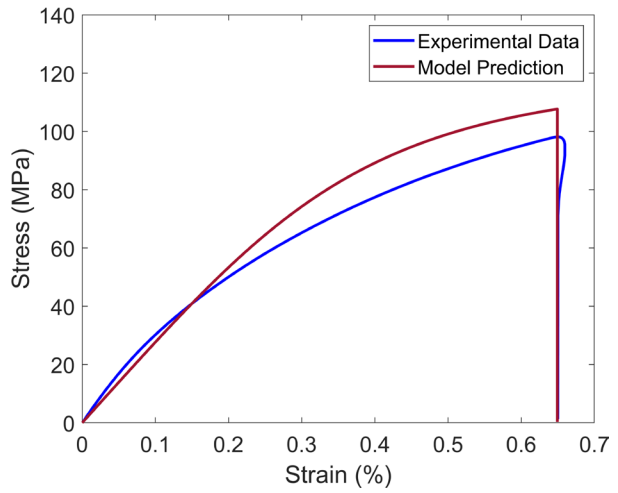


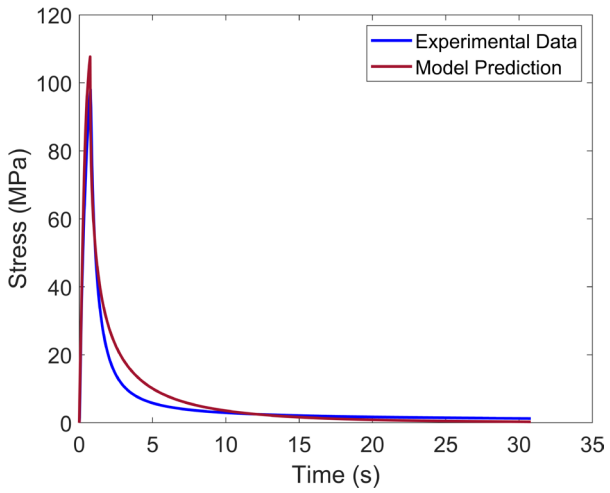
$$\bar{\sigma}(t,\dot{\varepsilon}) = \exp\left[-\left(\frac{t}{\tau_{(\dot{\varepsilon})}}\right)^{n_{(\dot{\varepsilon})}}\right]$$

- Parameters:
  - $\tau_{(\dot{\varepsilon})}$: Characteristic Time
  - $n_{(\dot{\varepsilon})}$: Exponent Parameter

- Stress Relaxation Time scales: 1-10 seconds

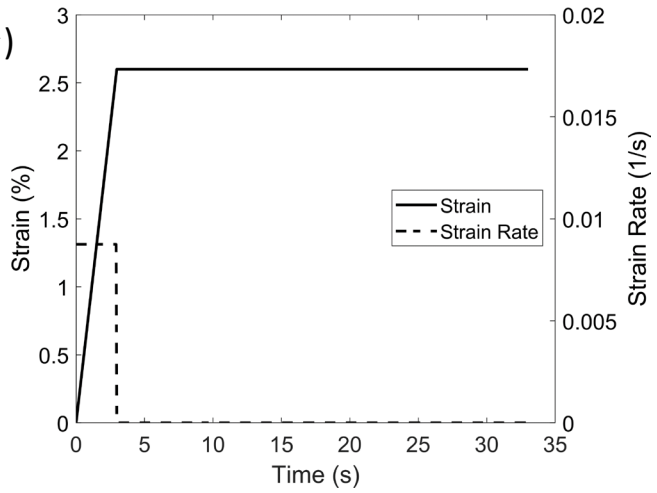




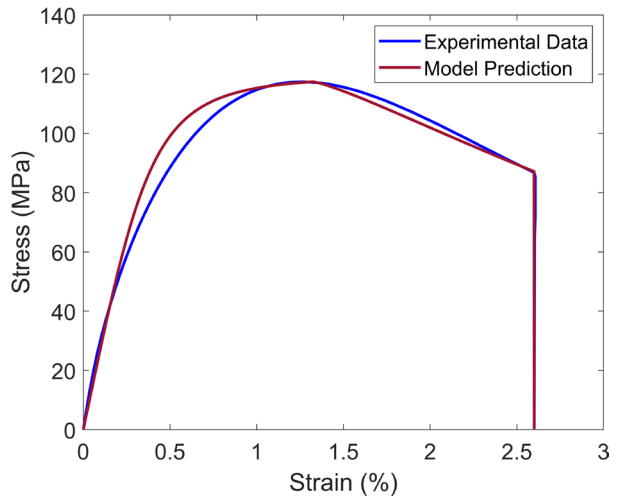


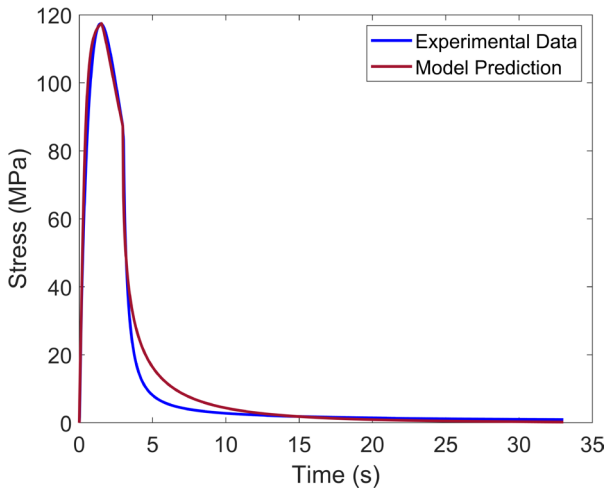
Constitutive Model Formulation – Stress Relaxation

- Stress Relaxation Model Validation



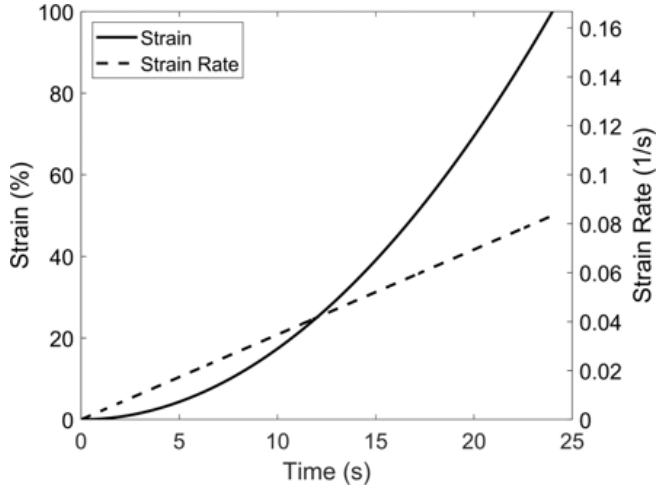
- Constant strain rate (8.75e-5 s^{-1})
- Up to 0.64% strain.
- 30s of stress decay



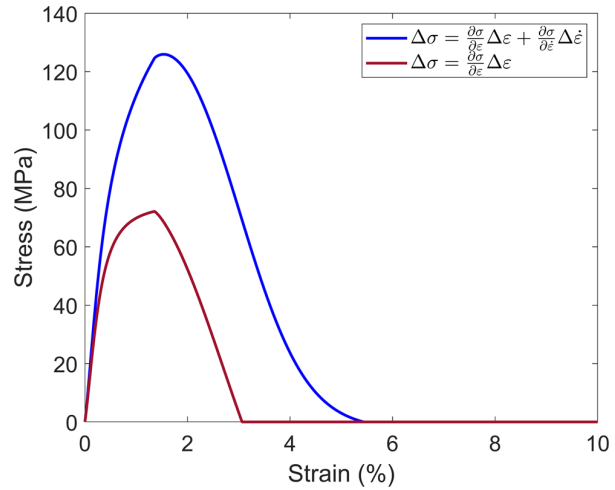


- Constant strain rate (8.75e-5 s^{-1})
- Up to 2.6% strain.
- 30s of stress decay

Constitutive Model Formulation – Incremental Formulation



- Incremental Formulation for Software Implementation



$$\sigma^{new} = \sigma^{old} + \Delta\sigma$$

- Stress increment formulations:

$$\Delta\sigma = \frac{\partial\sigma}{\partial\varepsilon}\Delta\varepsilon + \frac{\partial\sigma}{\partial\dot{\varepsilon}}\Delta\dot{\varepsilon}$$

- Chain rule differentiation

Pre-Yield

$$\sigma(\varepsilon,\dot{\varepsilon}) = \sigma_{0(\dot{\varepsilon})}.\frac{\bar{E}_{(\dot{\varepsilon})}.\bar{\varepsilon}}{\left(1+\left(\bar{E}_{(\dot{\varepsilon})}.\bar{\varepsilon}\right)^{\bar{n}_{(\dot{\varepsilon})}}\right)^{\frac{1}{\bar{n}_{(\dot{\varepsilon})}}}}$$

Post-Yield

$$\sigma(\varepsilon,\dot{\varepsilon}) = \frac{\sigma_{0(\dot{\varepsilon})}}{2}\left(\exp\left[-\left(\frac{\varepsilon-\varepsilon_0}{\varepsilon^*_{(\dot{\varepsilon})}}\right)^{m_{(\dot{\varepsilon})}}\right] + \exp\left[-\left(\frac{\varepsilon-\varepsilon_0}{\varepsilon^{**}_{(\dot{\varepsilon})}}\right)^{M_{(\dot{\varepsilon})}}\right]\right)$$

Stress Relaxation

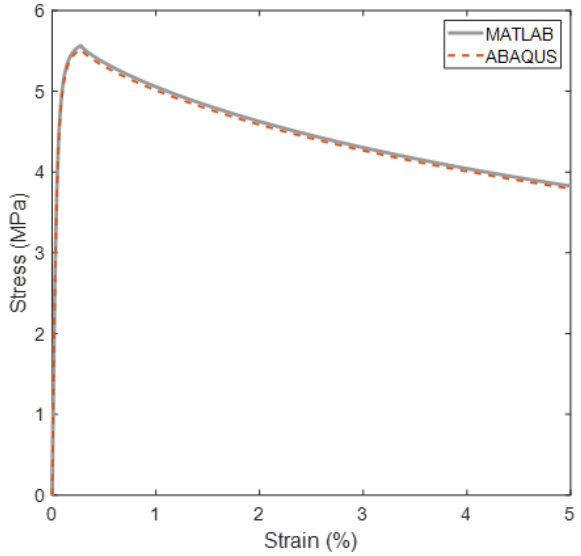
$$\sigma(t,\dot{\varepsilon}) = \sigma_{0(\dot{\varepsilon})}.\exp\left[-\left(\frac{t}{\tau_{(\dot{\varepsilon})}}\right)^{n_{(\dot{\varepsilon})}}\right]$$

CAD/CAM Software Implementation

- Constitutive Model in Fiber Direction
  - Pre-Yield

$$\sigma(\varepsilon,\dot{\varepsilon}) = \sigma_{0(\dot{\varepsilon})}\cdot\frac{\bar{E}_{(\dot{\varepsilon})}\,.\,\bar{\varepsilon}}{\left(1+\left(\bar{E}_{(\dot{\varepsilon})}\,.\,\bar{\varepsilon}\right)^{\bar{n}_{(\dot{\varepsilon})}}\right)^{\frac{1}{\bar{n}_{(\dot{\varepsilon})}}}}$$

  - Post-Yield

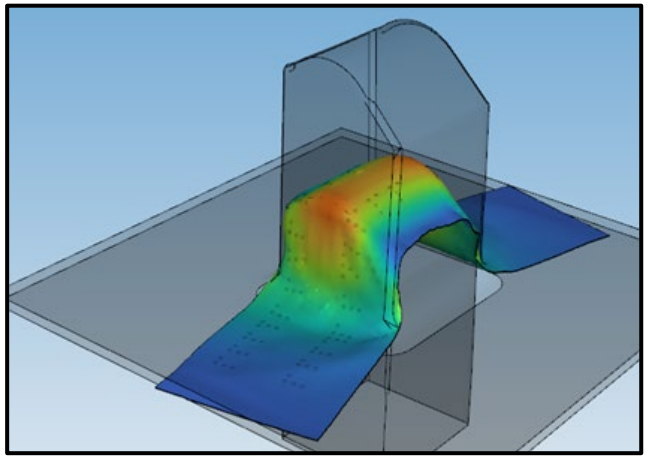


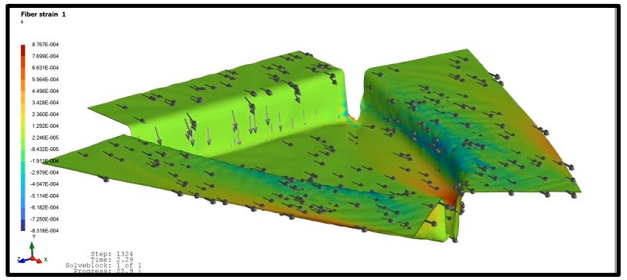
$$\sigma(\varepsilon,\dot{\varepsilon}) = \frac{\sigma_{0(\dot{\varepsilon})}}{2}\left(\exp\left[-\left(\frac{\varepsilon-\varepsilon_0}{\varepsilon^{*}_{(\dot{\varepsilon})}}\right)^{m_{(\dot{\varepsilon})}}\right]+\exp\left[-\left(\frac{\varepsilon-\varepsilon_0}{\varepsilon^{**}_{(\dot{\varepsilon})}}\right)^{M_{(\dot{\varepsilon})}}\right]\right)$$

SIMULIA ABAQUS

Explicit Implementation

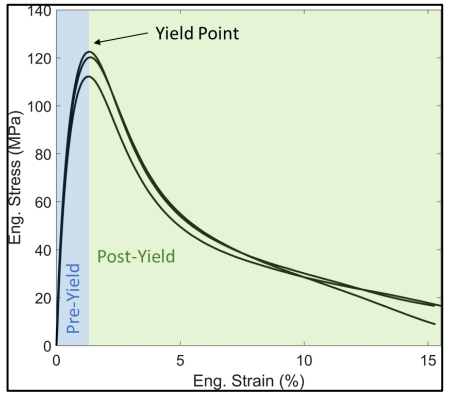
(Tabular inputs by family curves)



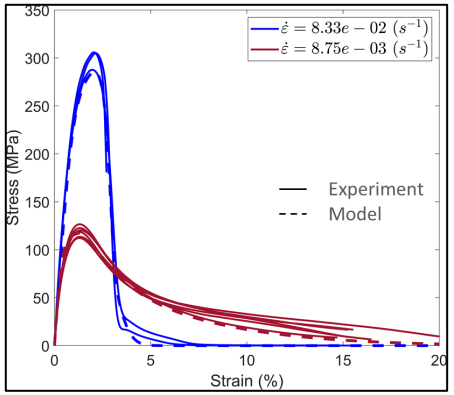


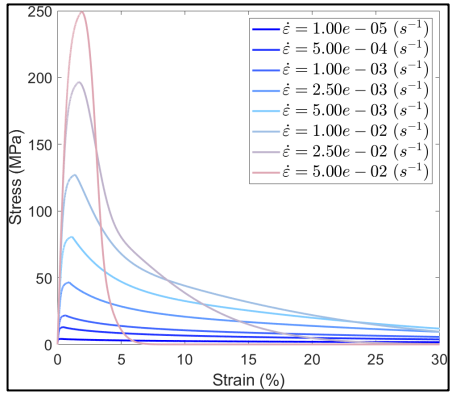
ANIFORM VIRTUAL FORMING

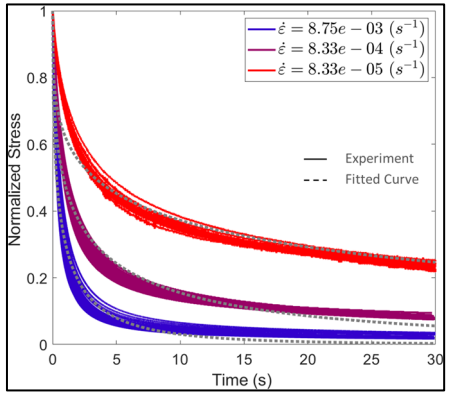
Implicit Implementation



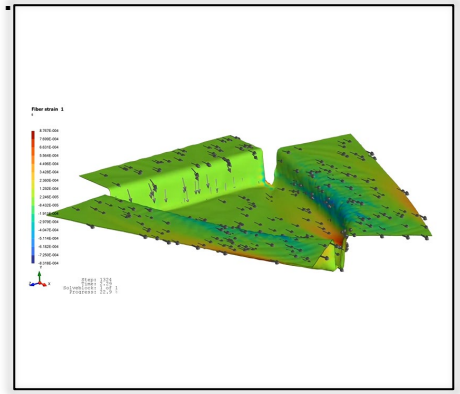
(Incremental Formulation)



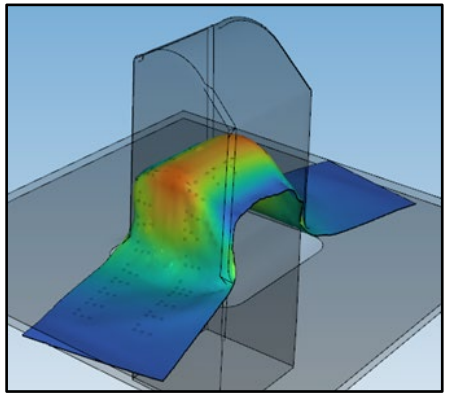




Conclusions



- Developed an **experimental and analysis methodology** for characterization of uncured highly aligned discontinuous fiber prepreg at room temperature.
- Demonstrated normalized stress-strain curves **collapse onto a master curve**.
- Formulated a **strain-rate-dependent anisotropic model** capturing:
  - i. Pre-yield non-linear hardening,
  - ii. Post-yield exponential softening, and
  - iii. Exponential stress decay during relaxation.
- **Validated** model predictions against experimental results.
- Generated a **family of rate-dependent input curves** for forming simulations.
- Formulated Constitutive model in **incremental form** for software implementation.
- Implemented the constitutive model in CAM/CAD software (**AniForm / Abaqus**).
- **Simulated complex** part geometries using Axiom TuFF model.



Future Directions

- Expand mechanical characterization to additional in-plane loading conditions
  i. Transverse direction (90° to fiber alignment),
  ii. In-plane shear,
  iii. Off-axis loading scenarios,

  that enables a more complete anisotropic material model.

- Investigate thickness deformation (thinning response).

- Characterize temperature-dependent behavior at elevated temperatures.
  - Supports non-isothermal forming simulations.

Conclusions

Current:

- Experimental investigations of continuous and discontinuous composites.
- Alignment and packing efficiency analysis.
- Mechanical performance vs aspect ratio investigations with analytical models, experimental validations and interpretations.

Future Scope:

- Mechanical performance vs aspect ratio curve with fibers ranging lower and higher end of S-curve.
- Mixing of multiple fiber lengths at higher and lower end to investigate the mechanical behaviors.

Long term goals:

- Enabling closed loop recycling for sustainable manufacturing.
- High performance short fiber composites.

Keywords: Carbon Fiber Composites, Laminates, Prepreg, Defects, Discontinuous Fibers

ABSTRACT

Stretch broken carbon fiber (SBCF) offers enhanced formability over traditional continuous carbon fiber (CCF) while retaining comparable mechanical properties. Leveraging this advantage, SBCF has the potential to reduce the formation and severity of common laminate defects such as wrinkling and bridging. This study introduces and applies volumetric methods for quantifying these defects with improved accuracy and resolution. Two SBCF and two CCF quasi-isotropic laminates were manufactured in a curved c-channel geometry and analyzed using 3D scan data and updated image processing methods. Results showed that the Montana State University (MSU)-developed SBCF laminates outperformed their CCF counterparts in terms of bridging behavior, exhibiting significantly lower average bridging volume and variability across both inner and outer radii of the channel. In contrast, both material systems yielded comparable wrinkling based on the defect scoring method discussed herein. However, there were differences observed in the wrinkling behavior between CCF and SBCF laminates with similar scores. While CCF laminates exhibited a higher frequency of and more broadly located wrinkles, SBCF laminates showed fewer wrinkles of larger average magnitude, particularly in non-critical regions. These findings reinforce SBCF as a promising material system for complex forming applications and highlight the need for further optimization to reduce wrinkling, particularly when occurring in critical regions.

INTRODUCTION

Carbon fiber (CF) composites are widely employed in performance-driven industries such as aerospace, automotive, and sporting goods due to their high tensile strength-to-weight ratio and design flexibility. These properties make them particularly desirable for structural applications where being lightweight and stiffness are critical material considerations. Fiber-reinforced composites are generally categorized into two groups: continuous fiber and discontinuous fiber systems. Continuous carbon fibers (CCF) are commonly used in pre-impregnated (prepreg) laminates for specific, efficiency focused applications. However, the limited maximum strain and inability for fibers within a CF tow to stretch and displace with respect to other fibers, can present significant challenges during the layup of complex geometries. Defects such as bridging and wrinkling are likely to occur in these geometries, limiting application due to manufacturability and performance [5, 6, 8].

Aligned, discontinuous fiber systems, such as stretch broken carbon fiber (SBCF), have been proposed as a more formable alternative for complex laminate geometries. SBCF laminates offer an improved ability to conform to complex geometries, making it a promising candidate for next-generation composite structures. Researchers at Montana State University (MSU) [1-3,7,10] have made significant

progress in developing an SBCF prepreg system and are actively evaluating its forming behavior in geometrically challenging applications, using CCF laminates as a performance benchmark.

This study focuses on two critical laminate defects: wrinkling and bridging [4]. By quantifying these defects across both SBCF and CCF material systems within a specified complex geometry, the curved c-channel, this work aims to assess the formability of MSU SBCF material, identify successful forming strategies, and evaluate metrics related to the material's potential for use in industrial composite component manufacturing.

METHODOLOGY

Laminate Manufacturing

Six laminates were manufactured for this study; three of which were continuous unidirectional Syensqo Hexcel 12k IM7 CYCOM® 977-3 carbon fiber prepreg [12]. The remaining three laminates were made with unidirectional MSU SBCF carbon fiber prepreg. This SBCF prepreg was made in conjunction with the University of Southern Mississippi using MSU stretch broken Hexcel 12k IM7 fibers and CYCOM® 977-3 resin system [11-12]. All laminates, CCF and SBCF, were eight-ply, quasi-isotropic, $[45/0/-45/90]_S$ to maintain consistency with laminates evaluated in previous MSU SBCF program studies [1]. The laminates for this study were formed into a curved c-channel geometry, Figure 1, following the layup method used in previous studies, also with the purpose of maintaining consistency [1]. This method is described briefly below.

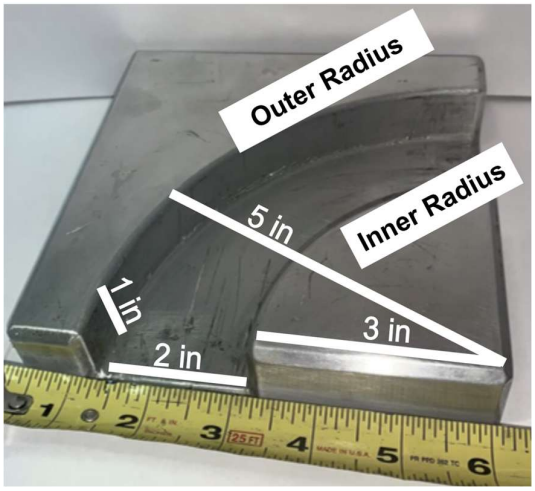

Figure 1: Curved c-channel aluminum mold used for previous program laminates in [1].

During manufacturing, 9-inch square plies were laid up in pairs and formed to the mold starting in the corner where the radii are centered. The plies were then worked across the surface of the mold, down the inner radius face, across the bottom of the channel, up the outer radius face, and onto the larger flat area towards the diagonal corner of the start. The newest curved c-channel mold, the mold for these studies, has been expanded by 1.5 inches in length and width from the mold used in previous studies to accommodate grit strips to secure material edges during forming. During the layup, plies were formed by hand using 200°F [93.3°C] via heat gun to increase the pliability of the two-ply sub-laminate. Once initially placed, the same heat and force was then applied to the pair of plies to enhance forming and smooth out wrinkles that may have formed. A silicon intensifier was placed onto the laminate after the layup was completed. Figure 2 shows the completed layup with the grit strips and intensifier. The laminate was then vacuum bagged and debulked for 20 minutes before curing in an autoclave. The autoclave recipe for all laminates in this study follows the current recipe for curing MSU SBCF parts: the autoclave is initially ramped to 200°F [93.3°C] for 30 minutes before a 4-hour dwell at 250°F [121°C]. This cure cycle has been developed from forming evaluations of SBCF parts during autoclave

curing in previous program studies [1-2]. During the autoclave cure, the grit strips mitigate slipping on the ply-mold interface. After curing completed, the laminate was demolded and trimmed to a 6 inch by 6-inch square. Sharp edges were then sanded away for handling.

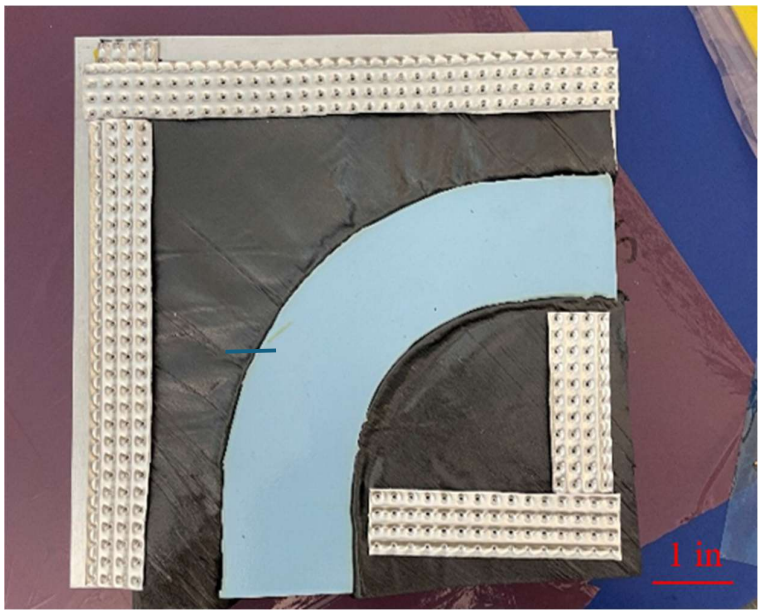

Figure 2: Complete curved c-channel layup ready for bag.

Wrinkling Analysis

After the laminate was cured, trimmed, and sanded, it was scanned in 3-dimensions using a Keyence VL-800 Series 3D scanner. The scan produces a point cloud with about 300,000 points and an STL mesh of the scanned laminate. Once scanning was completed, the rectangular footprint (boxed in Figure 3) of each observable wrinkle was directly measured and recorded with dial calipers for later use. The critical area–the main channel and circled in Figure 3 – is where wrinkles would be most concerning. The non critical area outside of the circle is of lesser, but substantial, concern.

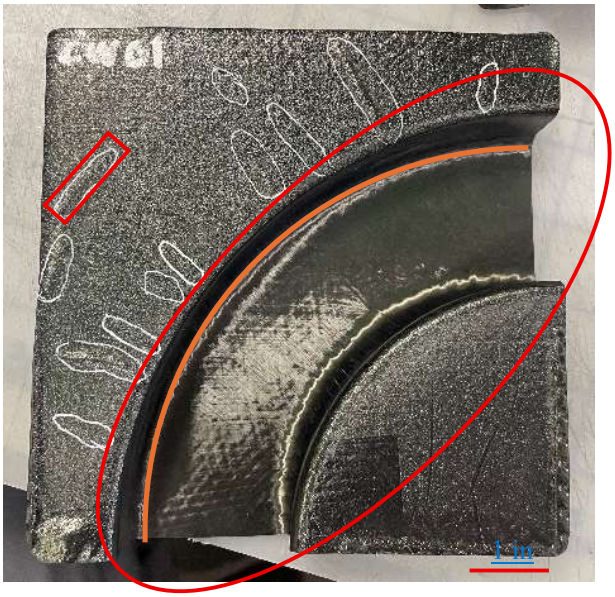

Figure 3: Curved c-channel laminate after complete wrinkle measurement.

3D scans of laminates were analyzed using CloudCompare. A reference mesh of the as-designed, ideal laminate is imported into the software as is the STL mesh of the scanned laminate. These two meshes are then scaled and aligned. Using CloudCompare's cloud to mesh (C2M) comparison tool, the distance between the reference mesh and various groups of points in the scanned mesh–usually around 50,000 groups–can be calculated. This analysis yields a displacement mapping of the scanned laminate onto the original, highlighting where the greatest distances between the two are. An example of results from this process is shown in Figure 6 below. Wrinkles are easily visible; they can be easily identified, isolated, and labeled for individual analysis. Using a Gaussian distribution tool in CloudCompare, the Gaussian mean distance of each wrinkle from the reference was determined and recorded. This mean was then multiplied across the rectangular footprint of each wrinkle to determine a volumetric approximation of the wrinkle size.

With the 3D scans, all laminate wrinkles were analyzed to create a more complete understanding of SBCF wrinkling during forming. Therefore, wrinkles can be analyzed both in the critical area, circled in Figure 3, as done in prior studies and in the submitted conference abstract, as well as more broadly across the parts. This full-part analysis allows for a more complete understanding and quantification of wrinkling frequency, magnitude, and location during forming. Additionally, it is important to note that the techniques of the MSU SBCF Parts and Structures Manufacturing group have progressed to where wrinkling rarely occurs on critical surfaces. Wrinkles on the critical area and noncritical areas of each laminate are denoted separately for further analysis.

Bridging Analysis

After the wrinkling analysis was complete, each laminate is cut every 15° from 0° to 90°, as depicted in Figure 4. Section faces were sanded for imaging at the inner and outer radii to obtain the cross-sectional area for bridging measurements and calculations.

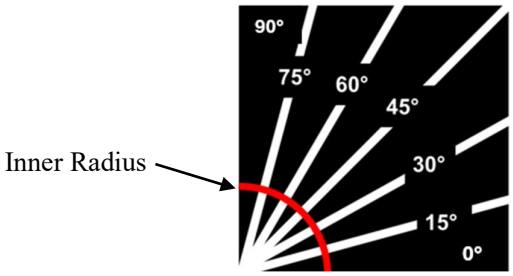

Figure 4: Sectioned curved c-channel showing the slices made for the bridging analysis.

Figure 5 depicts the cross section of both the inner and outer radii of Figure 1, as both have the same cross-sectional geometry and a fillet of 0.125 in radius. Using ImageJ, measurements of the distance, L_x and L_y, between the laminate-mold contact point and the perpendicular mold surface were collected from images. The lengths measured were used to calculate the cross-sectional area of the bridging space. L_x and L_y were first used to find the area of the red rectangle, Figure 5, and then used to find the area of the ellipse formed by the laminate. The area of the ellipse was then subtracted from the areas of the rectangle and fillet. The result of this calculation is the area of space generated from bridging, measured in square inches. This area was then extended over a fraction of the length of the curve perpendicular to the cross section in such that each area possesses equal length relative to all other calculated areas for a given radius. For example, if there are twelve faces, that of Figure 4, created along a radius of curvature with an arc length –such as the orange arc of Figure 3– of six inches, the cross-sectional area of each face is extrapolated over 0.5 inches of the total six inches. This analysis assumes that the surface created when the laminate was cut is an adequate representation of bridging for the surrounding area of the radius through this extreme region of the geometry.

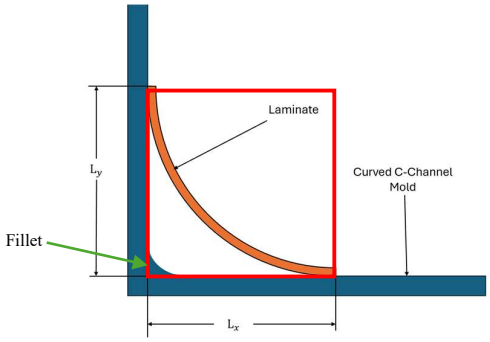

Figure 5: Curved c-channel cross-section and location of measurements to calculate bridging volume.

Table 1: Variables for Calculating Bridging Volume

Variable	Definition
r_f	Fillet radius, 0.25 in.
i	Cross-sectional face being measured, ND*.
L_{yi}	Vertical length from point of tangency to perpendicular mold surface at i, in.
L_{xi}	Horizontal length from point of tangency to perpendicular mold surface at i, in.
A_e	Cross-sectional Ellipse area, in.^{2}
A_R	Cross-sectional Rectangle area, in.^{2}
A_B	Cross-sectional Bridging area, in.^{2}
l_{ARC}	Length of curvature of concern, in.
N	Total number of cross-sectional faces created, ND*.
V_B	Volume of Bridging, in.^{3}

*ND: Non-dimensional

Equation 1, below, describes the summation of small sections of volumes for each face created when cutting the laminate at the specified angles shown in Figure 4. These volumes are generated by multiplying the cross-sectional area of bridging (blue boxed term in Equation 1) by a fraction of the area's guide curve (orange boxed term in Equation 1). The terms in the blue box of Equation 1 represent the subtraction of the ellipse's area from the red rectangle's area plus the small cross-sectional area of the fillet, Figure 5. The term boxed in orange, below, describes a fraction of the cross-sectional area's guide curve. The outer and inner radii are the guide curves of this geometry. The length of the arc, l_{ARC}, is simply the total length of the outer or inner radius, depending on the radius of curvature. Multiplying the blue and orange terms of Equation 1 generates the volumetric measurement of bridging in cubic inches.

$$\sum_{n=0}^{N}\left[\left((L_y \cdot L_x) - \frac{\pi \cdot L_{yi} \cdot L_{xi}}{4} + ({r_f}^2 - \frac{\pi * {r_f}^2}{4})\right) * \left[\frac{l_{ARC}}{N}\right]\right] = V_B \qquad (1)$$

Cutting a curved c-channel laminate, as previously discussed, creates twelve cross-sectional faces: one at 0°, another at 90°, and two at every remaining cut site. Thus, in Equations 1 and 2, the inner and outer radii lengths were sectioned into twelfths for the purpose of these equations. These equations were used to extrapolate the cross-sectional area along a portion of the extreme radius such that each volume was equal in the length it spans. The summation of these twelve volume approximations formed a 3D model of the total volume created by bridging for the geometry under inspection (variables are listed in Table 1).

Equation 2 is a simplified version of Equation 1. It uses the same variables but establishes a constant that represents subtracting one-quarter of an ellipse from a rectangle whose sides are equal to the major and minor axes of the ellipse. This constant, in the purple box of Equation 2, assumes that the laminate maintains a smooth, elliptical cross-sectional profile. Equation 2 also introduces the constant

cross-sectional area of the fillet in square inches, the green box, since the fillet is of a known, constant value. Equation 2 was used to determine the total bridging volume estimate.

$$\sum_{n=0}^{N}\left[\left(\left(L_{yi}L_{xi}\right)*\left(1-\frac{\pi}{4}\right)+0.00353\right)*\frac{l_{ARC}}{N}\right]=V_B \qquad (2)$$

It is important to note that equations 1 and 2 are specific to calculations for this geometry and represent the application of this quantification process to the curved c-channel. The principles of this method can be applied to any concave laminate of interest where bridging may occur. In future work, similar calculations will be extended for use in other geometries. The key feature of this approach is that a model of the space created by bridging can be established using cross-sectional measurements to define bridging and extrapolated over an appropriate perpendicular arc length. This calculation is repeated at each face created from cutting, and the resulting volumes are summed to form a comprehensive volumetric bridging model of the laminate.

NOMENCLATURE

Table 2: Sample Laminate Labelling

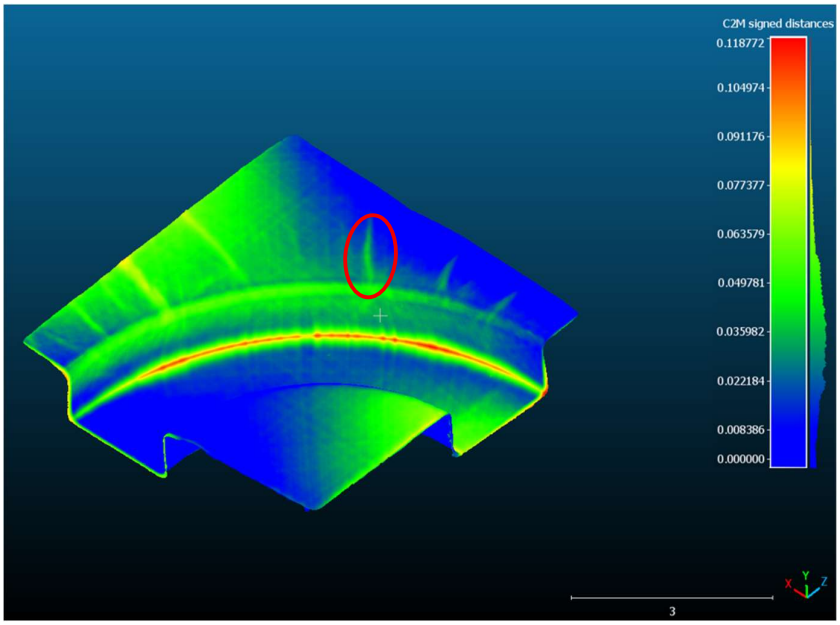
Sample Number	Continuous Fiber (CF)	Stretch Broken Carbon Fiber (SBCF)
1	CF01	SBCF01
2	CF02	SBCF02
3	CF03	SBCF03

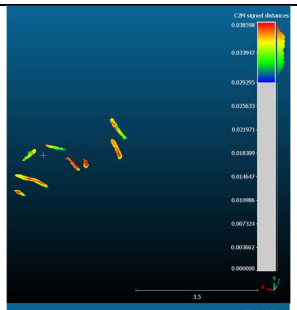
RESULTS

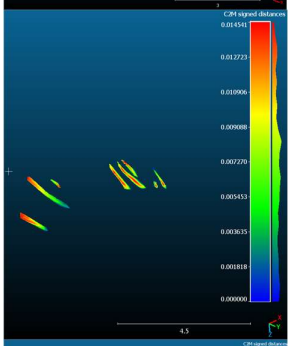
Due to a layup error, laminate SBCF01 was found to be asymmetric and was therefore excluded from further wrinkling analysis in this study. The nonconformity rendered its scans unusable for 3D wrinkle characterization. To maintain balanced sample sizes between SBCF and CCF groups, wrinkling data for CF02 are also withheld.

Wrinkling Analysis Results

The greatest number of wrinkles was observed in CF01, which exhibited twelve distinct wrinkles. All the other laminates presented eight wrinkles each. Wrinkles were primarily located in non-critical regions of the laminate geometry, with the exception of a single critical-region wrinkle observed in CF03. SBCF01 and SBCF03 exhibited larger average wrinkle volumes than either of the continuous fiber laminates: 0.00589 in^3 and 0.00711 in^3, respectively. In comparison, CF01 and CF03 had average wrinkle volumes of 0.00221 in^3 and 0.00309 in^3, respectively. The stretch-broken fiber laminates also demonstrated greater variability in wrinkle size, with standard deviations of 0.00745 in^3 in SBCF02 and 0.006013 in^3 in SBCF03.







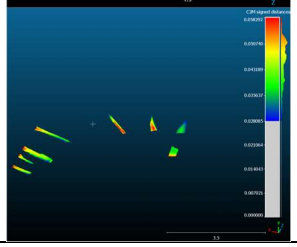


Figure 6: Complete CloudCompare C2M analysis of SBCF03. Both scales display inches, which may marginally deviate through a scaling factor.

Figure 6 depicts a completed CloudCompare C2M (Cloud-to-Mesh) analysis used to quantify wrinkle geometry. This analysis was similarly performed for CF01, CF02, and SBCF02, isolated wrinkles are displayed in Table 3. In Figure 6, wrinkle locations correspond to areas of maximum deviation from the nominal surface geometry. Areas near 0 in of deformation are shown in blue while areas of high deformation approaching 0.01188 in are shown in red. Green, yellow, and orange areas depict increasing distances from the designed part, respectively. Wrinkles were shown highlighted and easily observed as green and yellow areas of Figure 6. All eight wrinkles in SBCF03 were located on the large, non-critical zone of the part, a trend observed across most laminates in the study. Notably, SBCF02 exhibited both the largest and smallest wrinkles by volume, measured at 0.228 in^3 and 0.0005 in^3, respectively. This range underscores the variability in wrinkle severity found in stretch broken laminates compared to their continuous fiber counterparts.

Table 3 below shows the isolated wrinkles of each laminate after the initial alignment is completed. These wrinkles are located mainly on the top flange as previously discussed and can dramatically vary in size. Many of the wrinkles are either aligned with the fiber axis of the +45° plies or the corner where layup begins. Color scales for these wrinkles also widely vary as they are typically one of the largest deformations in a laminate and can have varying prominence, meaning that the height of the wrinkle itself varies with respect to the height of the surface it propagates on.

Table 3: Images of isolated wrinkles of all analyzed laminates

CF01	
CF03	
SBCF02	
SBCF03	

*Laminate scales are in inches and marginally deviate from designed laminate part through a scaling factor.

Bridging Analysis Results

CF02 exhibited the highest average bridging volume along both the inner and outer radii, measured at 0.01182 in^3 and 0.00916 in^3, respectively. The variance of CF02 was also larger than all other laminates: 5.81130E-05 in^6 at the inner radius and 2.15772E-05 in^6 at the outer radius. SBCF02 showed the lowest average bridging volumes across both regions, 0.00230 in^3 (inner) and 0.00381 in^3(outer), and also exhibited the lowest variance: 3.75586E-07 in^6 (inner) and 3.99120E-07 in^6 (outer). At both radii, SBCF01 displayed average bridging comparable to CF01–the best CF laminate in terms of bridging–but performed the worst among SBCF laminates with average bridging at the inner radius of 0.00643 in^3 and 0.00584 in^3 at the outer radius. SBCF02 and SBCF03 showed low bridging with maximum average bridging at either radius of 0.00381 in^3 and 0.00412 in^3, respectively.

.

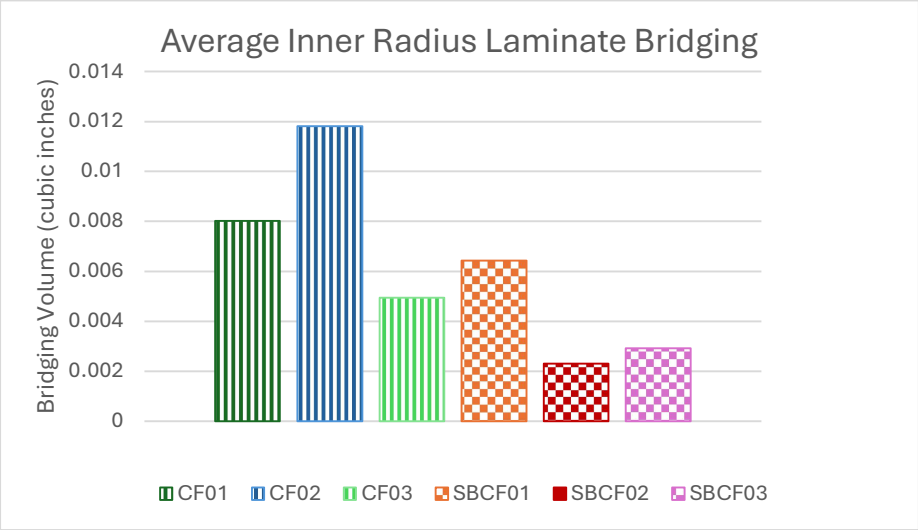

Figure 7: Average inner radius bridging volume of all laminates.

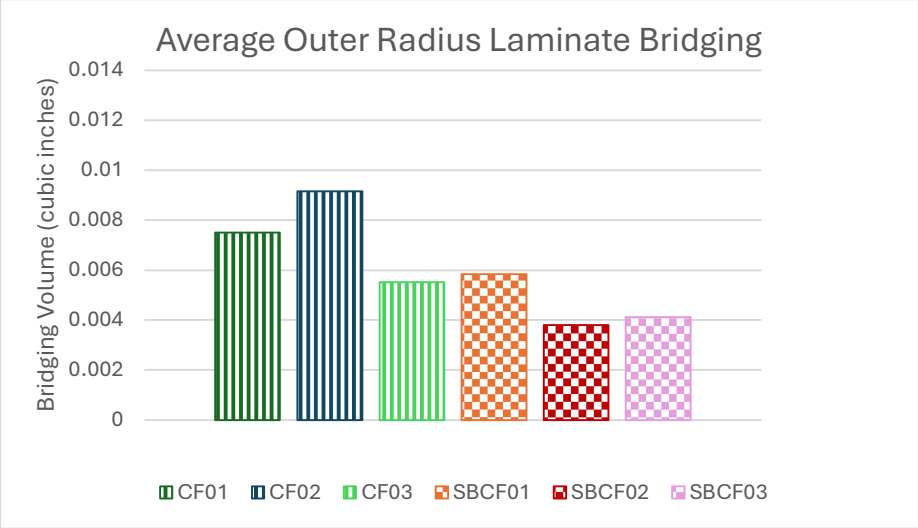

Figure 8: Average outer radius bridging volume of all laminates.

The x-axes of Figure 9 and Figure 10 correspond with the cuts shown in Figure 4, not ply fiber angle. All laminates exhibit a local peak in bridging volume near the 45° face cuts, Figure 4, with this effect more pronounced in the continuous fiber laminates. In addition to having the highest average bridging volumes, CF02 also shows both the highest and lowest bridging occurrences at the outer radius, indicating a broader spread in localized bridging severity. Similar to the average bridging behavior, the forming of SBCF01 is comparable to that of the CF laminates but is much greater than other SBCF laminates, especially at extreme geometry. In contrast, SBCF02 and SBCF03 laminates demonstrate the most consistent bridging behavior across both radii while maintaining low bridging volumes, as shown in Figure 9 and Figure 10. At the inner radius, continuous fiber laminates demonstrate poor forming to the concave radius as the curve of the channel becomes more aggressive; but bridging decreases at the 0° and 90° cuts. Conversely, SBCF laminates exhibit low amounts of bridging across the curve with fluctuations throughout.

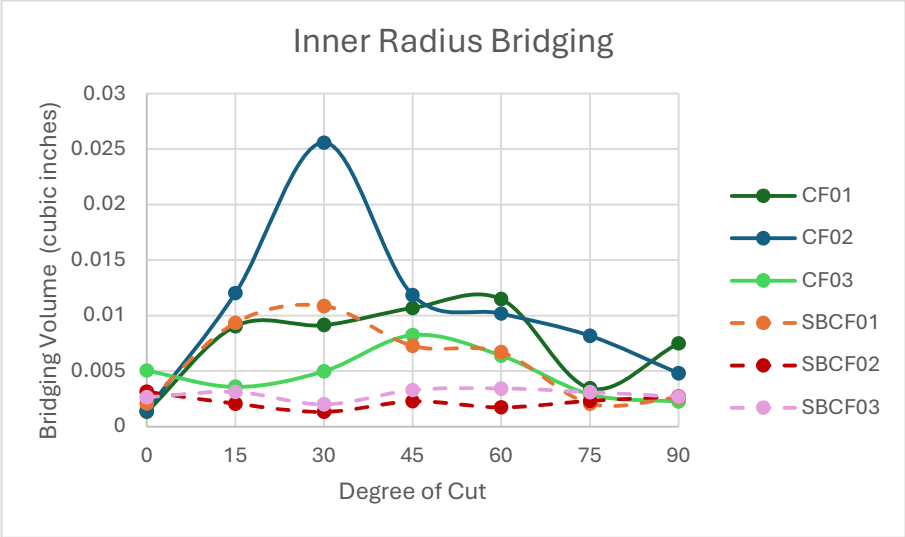

Figure 9: Inner radius bridging volume mapping.

Similar to their behavior at the inner radius, continuous fiber laminates at the outer radius of the curved c-channel exhibited greater bridging towards the extreme portions of the curve, with better conformity before and after this section of geometry. The stretch broken laminates outer bridging performance was also comparable to their bridging performance at the inner radius, again with SBCF01 as an outlier. SBCF03 had a lower range of bridging volume throughout the laminate with stronger local fluctuations at the most aggressive portions of the geometry. Notably, SBCF02 demonstrated outstanding bridging performance, maintaining a low, nearly constant bridging volume around the curvature.

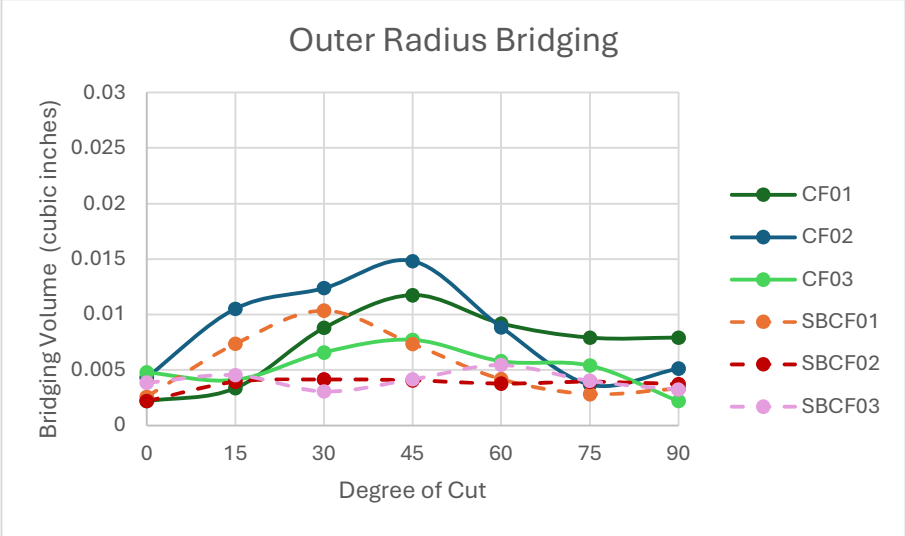

Figure 10: Outer radius bridging volume mapping.

DISCUSSION

Wrinkling Analysis Discussion

The higher variability of wrinkle magnitude and comparable wrinkle propagation in SBCF laminates compared to CCF laminates indicates that SBCF may also be more sensitive to local

disturbances during layup and curing given that the current MSU SBCF laminate manufacturing practices are under continual development, and current practices may still allow small process inconsistencies to manifest as wrinkles and other defects. The consistent wrinkle locations of this study loosely align with wrinkling from previous studies, despite more refined manufacturing processes [1]. The larger non-critical flange regions are more susceptible to wrinkling, likely due to the layup technique and residual forming forces induced during layup and curing. Wrinkling at this flange emphasizes the consideration placed on tooling design and layup practices, such as tension control when working with this material.

The present wrinkling analysis between CCF and SBCF materials does not clearly indicate which material is better suited to avoiding laminate wrinkling. The consistent presence of wrinkles in both materials highlights residual challenges in achieving defect-free forming. The wrinkling behavior of CCF laminates may be within the expected bounds for unidirectional laminates of this geometry, but the ceiling for formability for SBCF laminates is much higher than demonstrated in this study. As optimal SBCF laminate manufacturing practices such as tooling design, vacuum bag configuration, layup technique, and strategic intensifier use continue to be identified and refined, it is probable that SBCF part conformity will improve, especially for this geometry.

Bridging Analysis Discussion

As the laminates form to the mold geometry during forming, the 0° and 90° plies are primarily subjected to transverse in-plane tension, particularly near the extreme regions of curvature where stress concentrations are highest. The ±45° plies behave differently under deformation: the +45° plies experience in-plane longitudinal tension, while the -45° plies are subjected to in-plane orthogonal tension. At both the inner and outer radii, CCF tend to bridge as they span the concave geometry, constrained by their high tensile stiffness and limited ability to stretch. In contrast, the SBCF laminates demonstrate improved conformity in these regions. This increased geometric conformity is attributed to the shorter, discontinuous but aligned fiber segments that characterize SBCF materials, which allow for higher effective stretch ratio without theoretically significantly sacrificing composite properties. The reduced fiber lengths in SBCF laminates not only improve formability but also significantly lower the likelihood of bridging in concave regions.

While Figure 9 and Figure 10 may initially suggest that bridging is more severe at the outer radius than the inner, this comparison is misleading due to differences in arc length between the two regions. The outer radius spans a longer arc (7.854 in) than the inner radius (4.712 in), which inherently increases the calculated bridging volume at the outer radius (Equation 2), regardless of actual bridging severity. This difference allows for the direct comparison of a specific radii between laminates but not between the inner and outer radii of a given laminate.

In addition, the use of a silicon intensifier during autoclave processing has become a critical feature of MSU's SBCF laminate manufacturing approach. In this study, it played an important role in enhancing forming quality by reducing bridging and alleviating layup "touch" time. Bridging has been a challenge for previous SBCF programs due to fiber length [9]; however, the MSU SBCF laminates significantly outperformed the continuous fiber laminates in terms of bridging behavior in the c-channel geometry of this study. The results of this study have direct implications for manufacturing curved composite components where conformability, labor efficiency, and defect tolerance are critical, such as an aerospace stiffener design or automotive reinforcements.

CONCLUSION

Forming an eight-ply quasi-isotropic prepreg laminate into a curved c-channel geometry provided valuable insights into the layup, forming, and curing procedures and preliminary defect behavior of MSU's SBCF material system in complex structures. Using CCF laminates as a control enabled direct benchmarking of bridging and wrinkling performance under identical geometric and process constraints.

The CCF laminates exhibited significant bridging, particularly in regions of high curvature, along with wrinkling defects in both critical and non-critical areas. In contrast, two of the SBCF laminates demonstrated improved bridging performance, with reduced defect volume and variability across the inner and outer radii. However, SBCF laminates also showed comparable, yet slightly higher average wrinkle volumes compared to their continuous fiber counterparts, despite similar wrinkle counts. None of the wrinkles in SBCF laminates were in critical regions. While no definitive material preference can be established from this study alone, the findings suggest that with further refinement in processing techniques, SBCF materials have strong potential for use in complex-forming applications, especially where bridging is a limiting defect.

Additionally, this work provides valuable insights regarding the effectiveness of these new quantification methods. The bridging system worked as intended without any unforeseen challenges. The wrinkling system, however, was particularly challenged in the analysis of laminates with high macroscopic deviation from the designed laminate, such as SBCF01. This challenge will be overcome as the wrinkling analysis process is refined, and knowledge gaps will be filled accordingly.

FUTURE WORK

Subsequent studies will focus on expanding the defect characterization framework by employing next-generation metrics similar to those used for bridging and wrinkling in this study. Particular attention will be given to understanding the behavior of SBCF materials in concave radii, where corner thickening is observed; furthermore, the mechanisms and mitigation strategies for this phenomenon are outside the scope of the present study, they will be addressed in future work. Understanding, quantifying, and potentially mitigating this effect will be essential for enabling the broader adoption of SBCF laminates in geometrically complex structural components, including the curved c-channel. Another future focus will be to expand the types of complex geometries that are evaluated for forming complex structures using this rigorous defect quantification scheme. As the production of MSU SBCF output increases in volume and quality, as outlined in [3], a growing catalog of laminate quality evaluations will guide the optimization of MSU SBCF applications and manufacturing techniques.

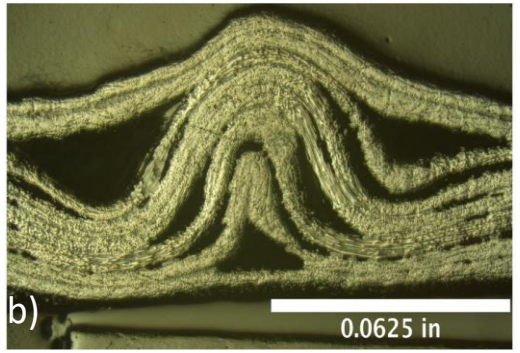
Interply Friction Characterization of Continuous and Stretch Broken Carbon Fiber (SBCF) Composites during Forming

Presenter: Tasnia Javin Nur

PhD Candidate, Material Science

Montana State University, Bozeman, MT

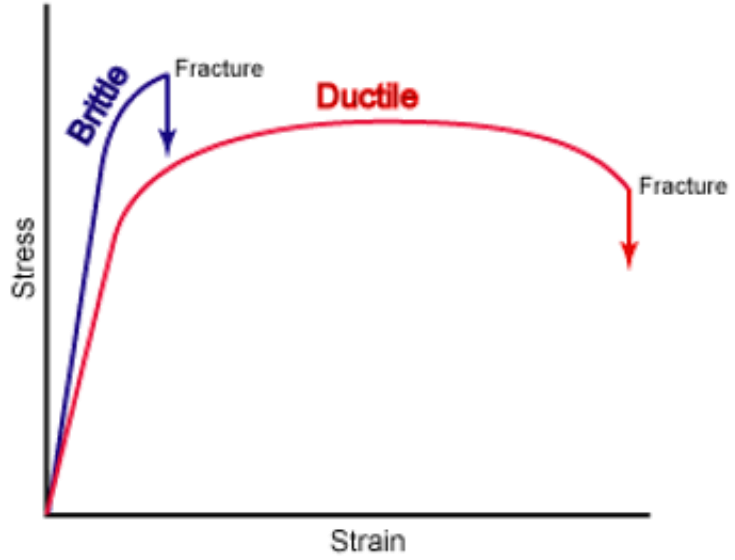


Outline

- Challenges in composite forming
- Introduction to stretch broken carbon fiber (SBCF)
- Relevance of friction during forming
- Interply friction characterization
  - Test materials
  - Test method
  - Test matrix
- Results and discussion
- Future work and conclusion

Challenges during Composite Forming

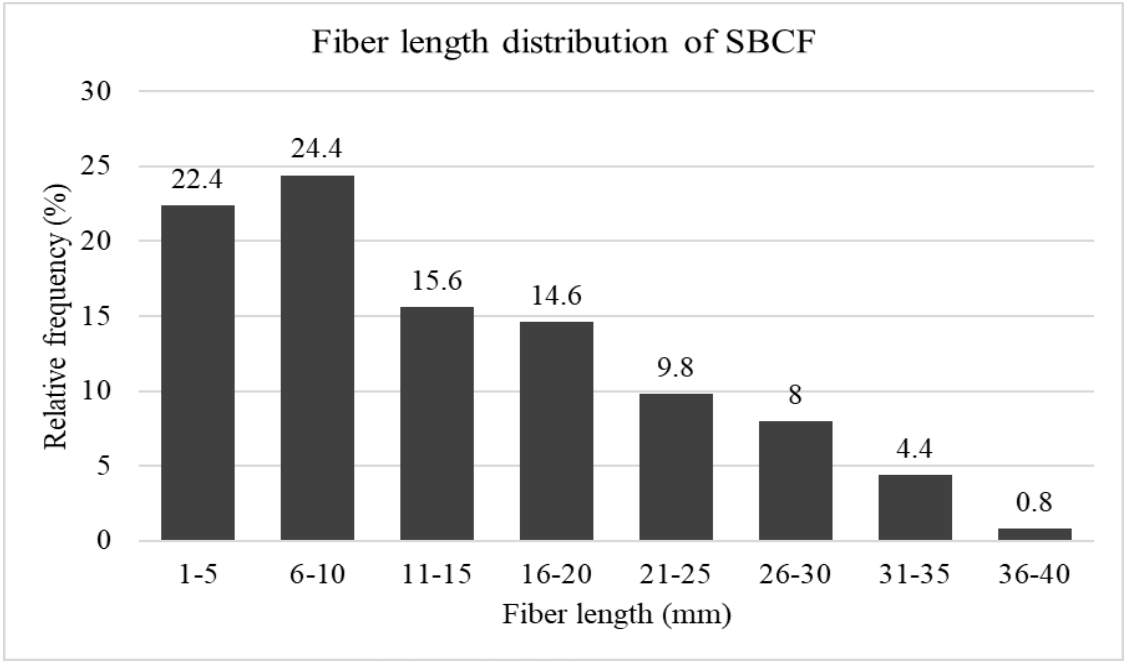
- Conventional CFRP composites made of continuous fibers –
  - -high axial stiffness
  - -low strain-to-failure
- Poor drapability and limited formability over double-curved or complex geometries
- Leads to forming defects: wrinkling, buckling, bridging, misalignment
- Limits large-scale adoption of CFRPs as replacement for metals in aerospace structures

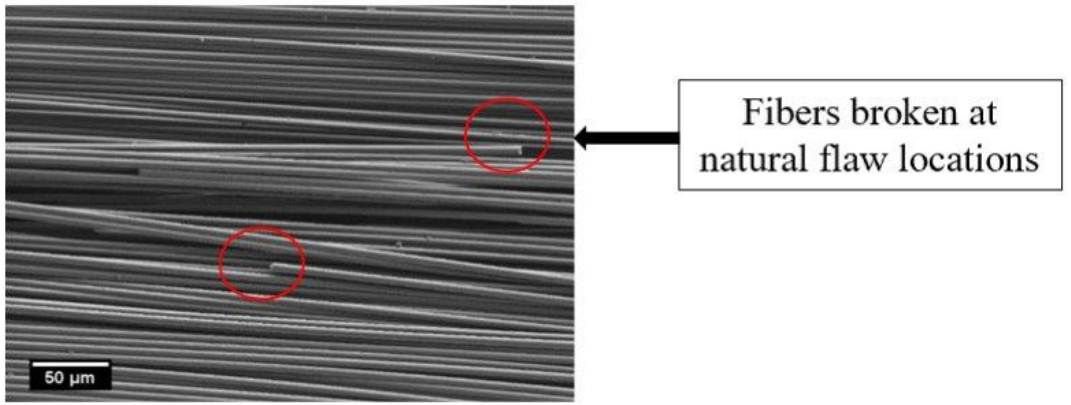


Forming defects : (a,b) Ply wrinkling and fiber buckling (c) Bridging

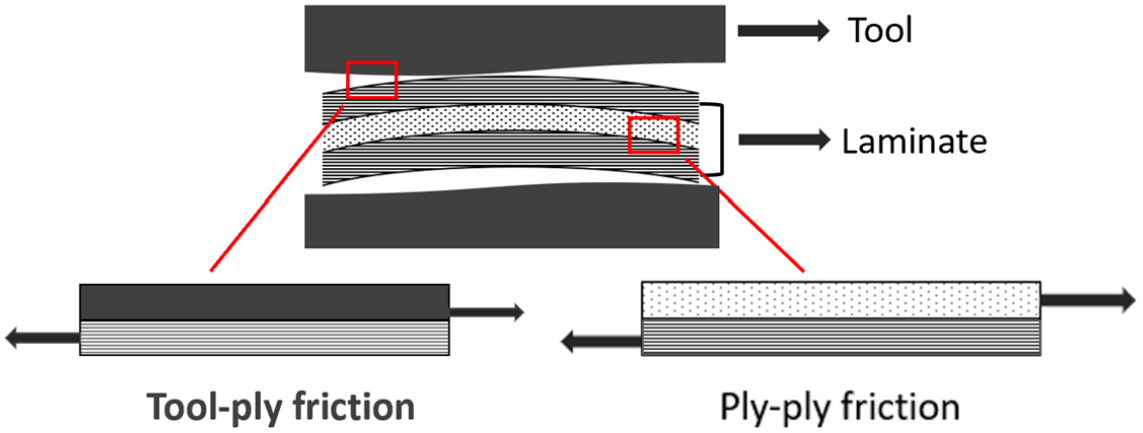
Stretch Broken Carbon Fiber (SBCF)

Metal-like formability in carbon fiber composites without compromising stiffness or strength





Stretch Broken Carbon Fiber (SBCF)



- Discontinuous, aligned short fibers with variable lengths (1- 40 mm)
- Continuous carbon fiber tows broken in tension, with breaks occurring at natural flaws
- Forming facilitated by axial stretching of the fibers when impregnated with resin (pseudo-ductility)
- Tensile strength retained through local shear load transfer

Relevance of Friction during Composite Forming

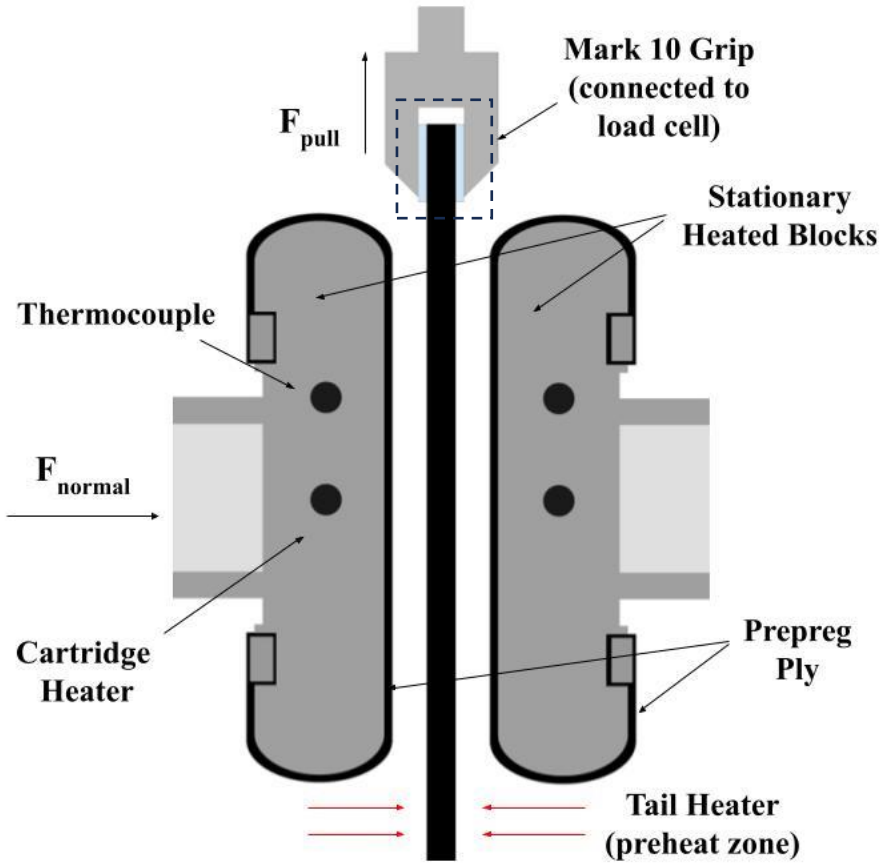
- Interply shear and slippage are essential deformation mechanisms for forming laminates into complex geometries
- Slippage is governed by interply friction, involves relative movement between adjacent uncured plies
- High frictional resistance limits interply shear, leading to forming defects
- SBCF introduces stretch deformation mode, reduces influence of friction and shear

Interply Friction Characterization: Materials

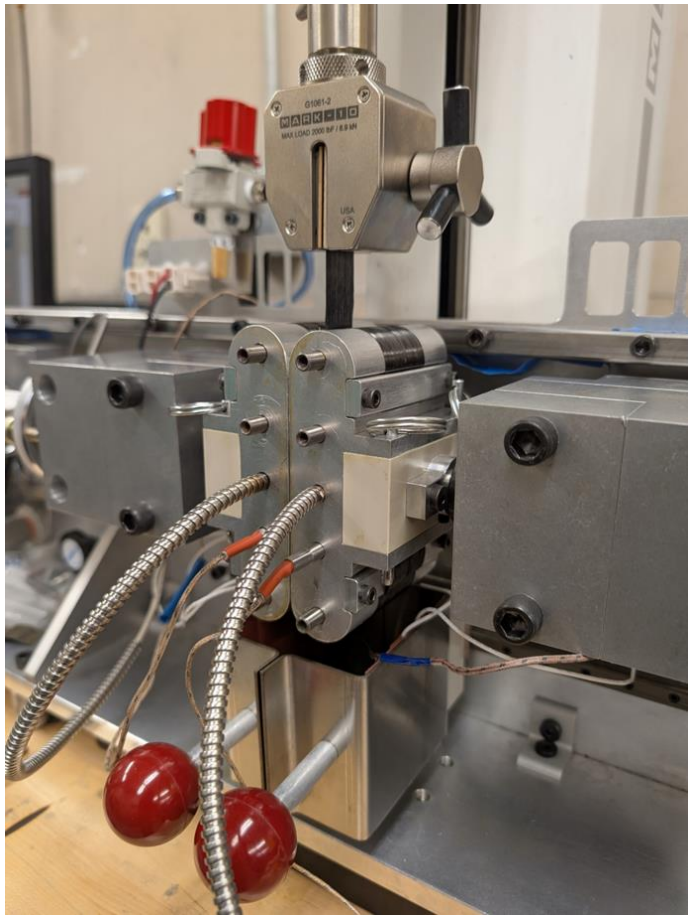
Two carbon/epoxy prepregs :

- **Stretch broken carbon fiber (SBCF) prepregs** –

MSU Hexcel IM7 SBCF fibers impregnated with CYCOM® 977-3 resin in collaboration with USM (RC=37.5 %, FAW=139.6 gsm, Water Pickup (%) = 0.53)



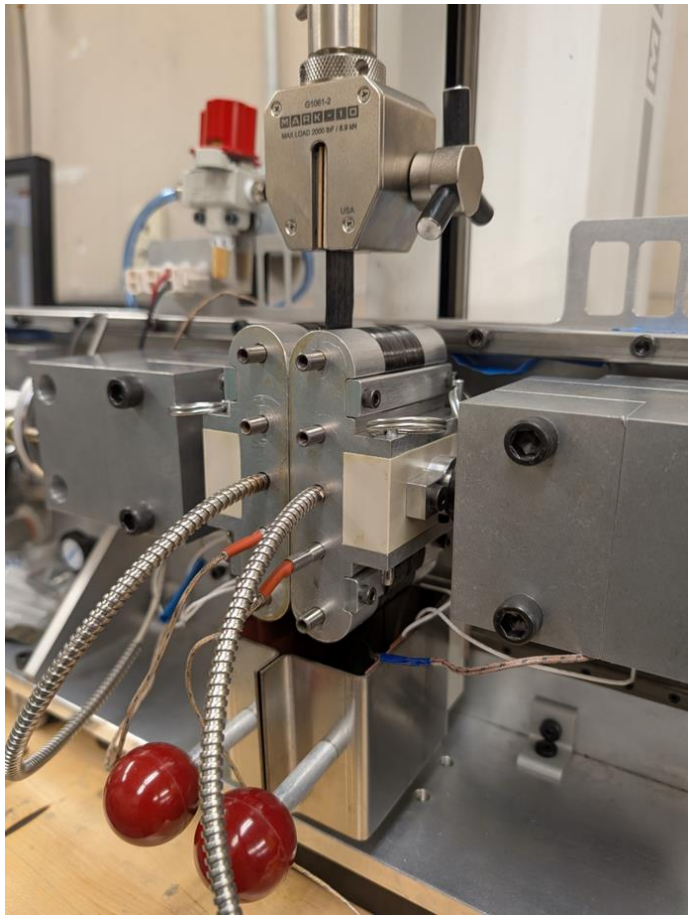
- **Continuous carbon fiber (CCF) prepregs** –



Syensqo Hexcel 12k IM7 continuous fiber impregnated with CYCOM® 977-3 resin (RC = 32.7, FAW= 137.9 gsm, Water Pickup (%) = 0.57)

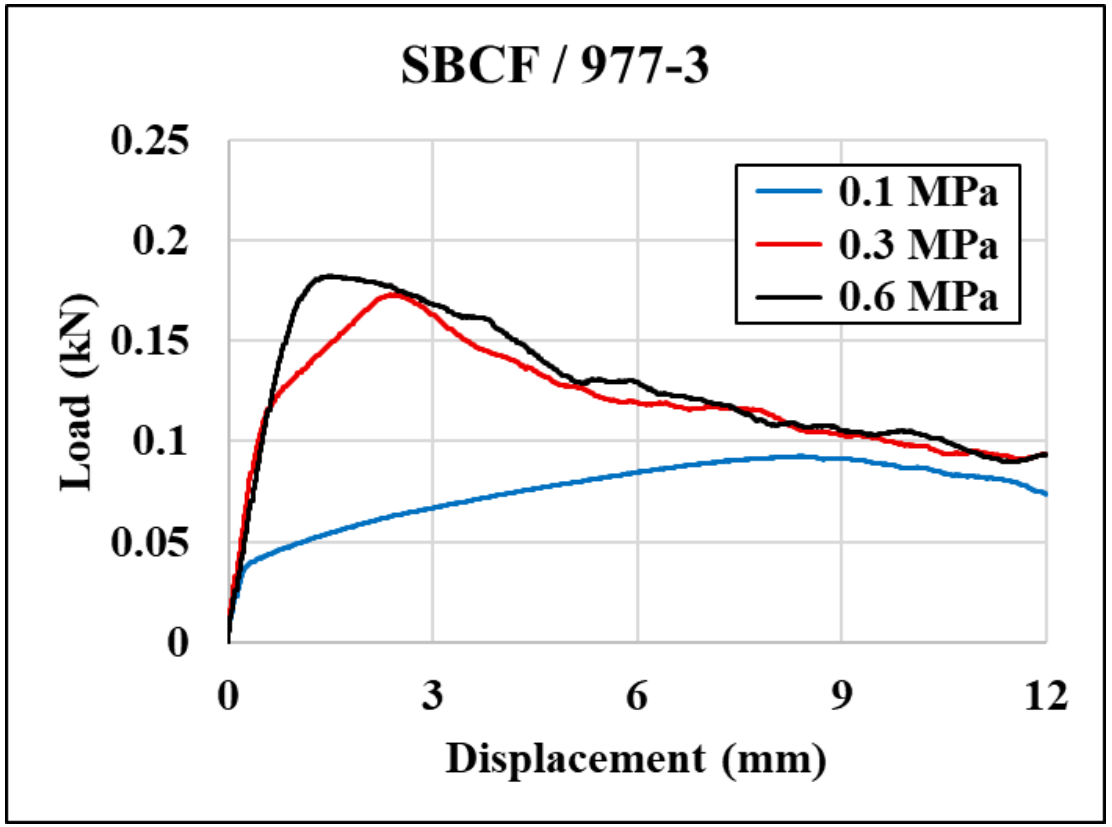
Novel stretch-breaking process developed at MSU

Interply Friction Characterization: Pull-through Test Method



Test configuration and test matrix

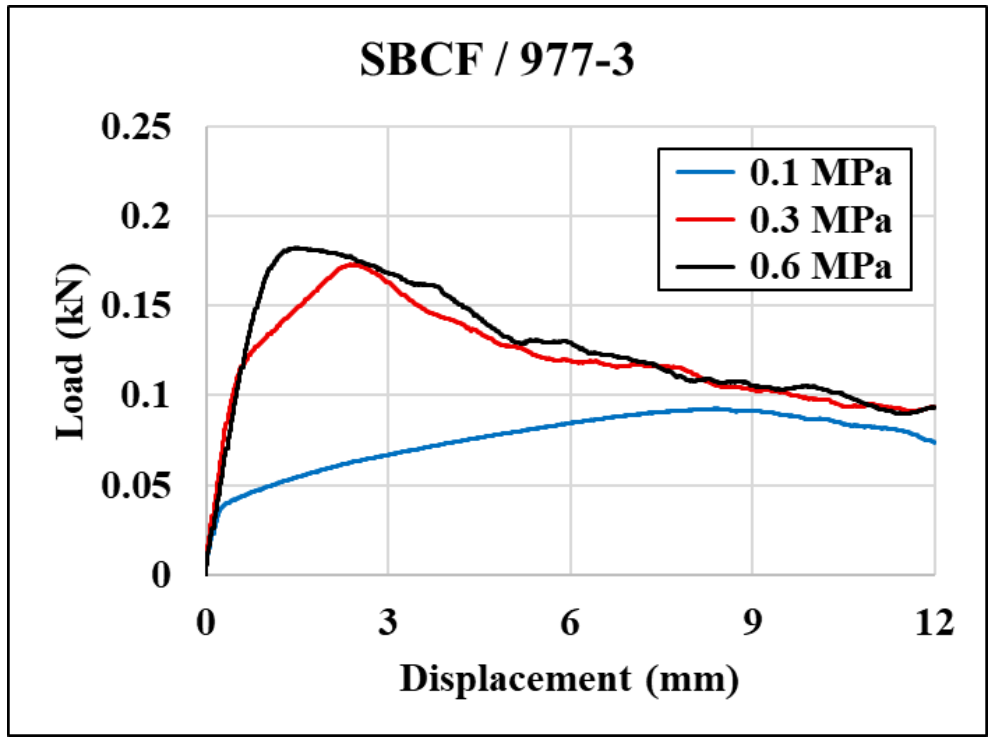
	Clamping block	Central specimen	Clamping block
SBCF test	0° CCF	$[0]_{12}$=All 0° SBCFs	0° CCF
CCF test	0° CCF	$[0]_{12}$=All 0° CCFs	0° CCF

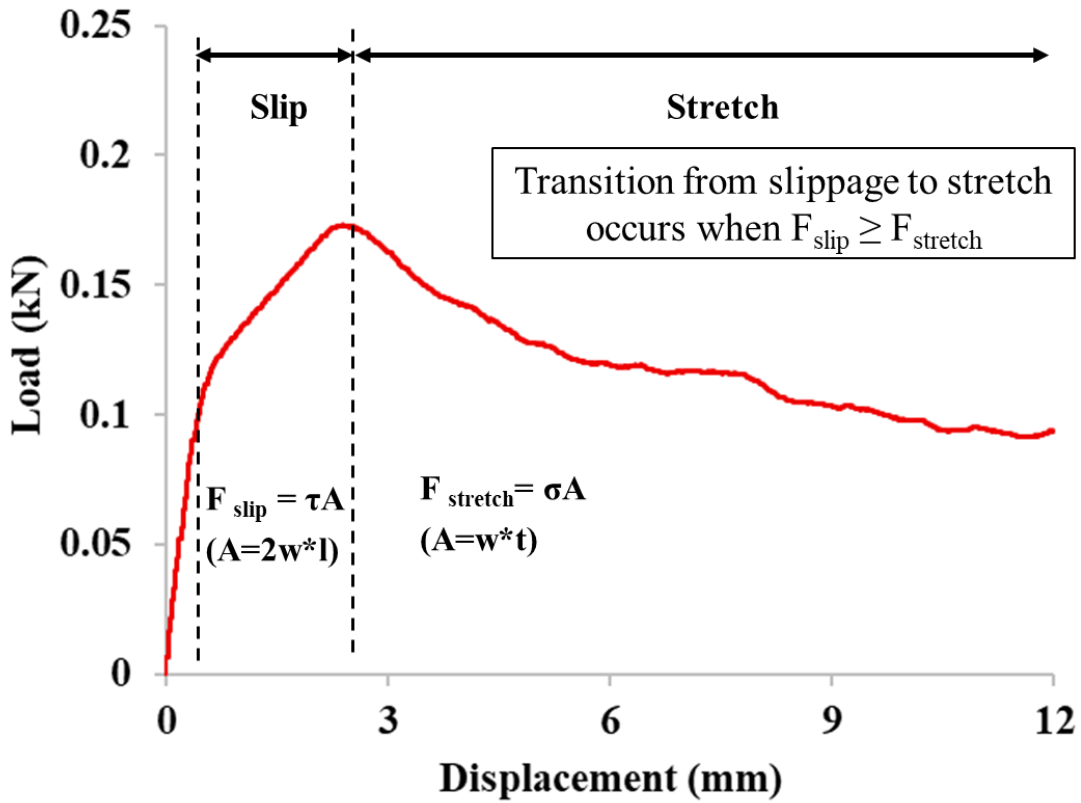


Test *	Temperature (°C)	Normal pressure (MPa)	Pulling rate (mm/min)
1	121	0.1	1
2	121	0.3	1
3	121	0.6	1

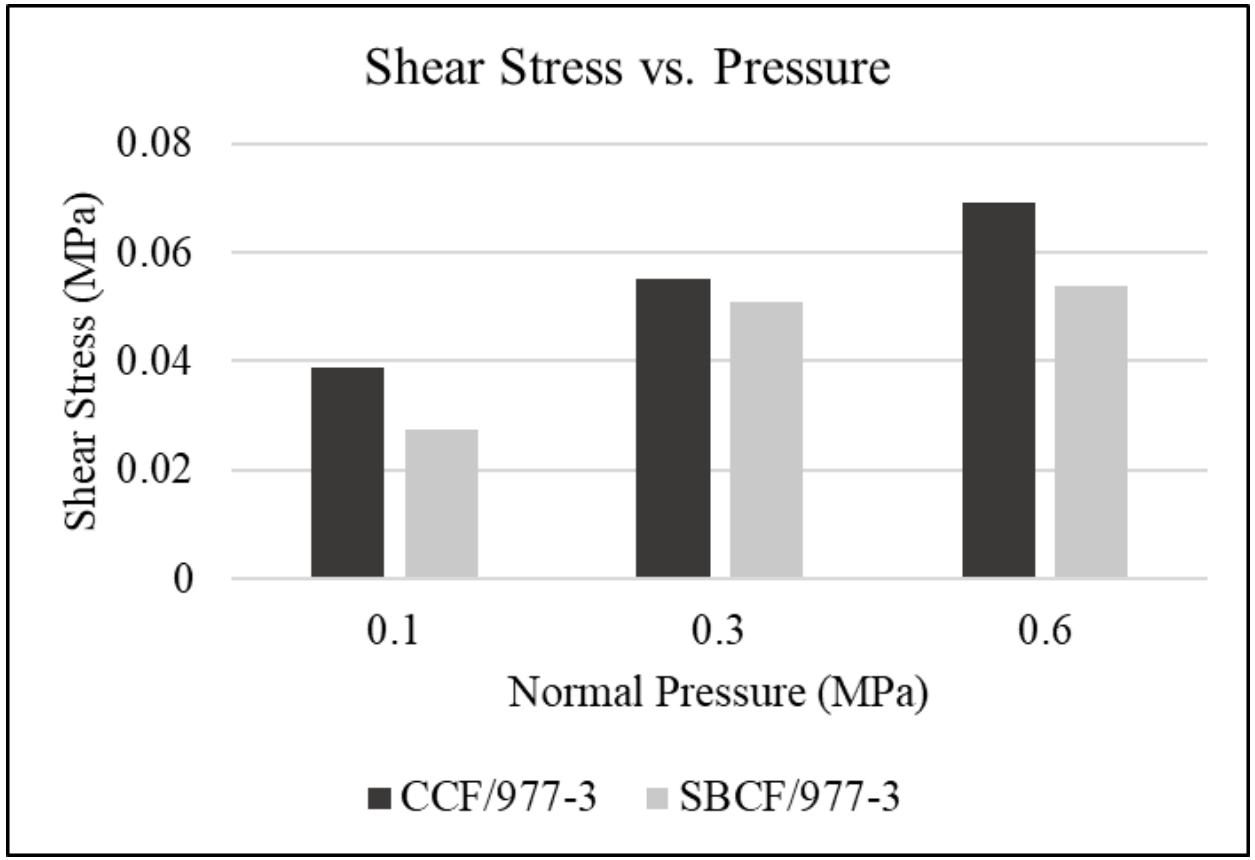
*Each test corresponds to three replicates and results are averaged for three tested samples

Results : CCF vs SBCF





Load due to frictional resistance increases with displacement and normal pressure



Load relaxation for each test after frictional resistance reached a threshold value

Results: continued

Results: continued

Shear stress, $\tau = F/A$

F = max load from load displacement curve (in N)

A = area = (w * l) * 2 =3386 mm^2

Conclusion

- Differences in the material deformation behavior between CCF and SBCF laminates during interply friction testing -

➢For CCF laminates -

  - primarily frictional interply shear, higher normal pressure increases resistance

➢For SBCF laminates -

  - axial stretching at the onset of high interply frictional resistance

- Unique SBCF deformation behavior can help mitigate excessive shear stress generation

Future work

- Continue testing to study effect of temperature and ply orientation
- Determine threshold between stretch and slippage response under various forming conditions

Keywords: HiPerDiF, aligned discontinuous carbon fibre preforms, Rapid fibre alignment assessment (RFAA), electrospun material, PLA

ABSTRACT

Aligned short fibre composites have demonstrated exceptional tensile strength, stiffness, and load-bearing capabilities, as evidenced by both theoretical and experimental [1, 2] studies over the past decade, establishing them as a promising material for future advanced applications. Additionally, they provide an opportunity to better utilise recycled fibres, further promoting sustainability in composite materials. Short fiber alignment techniques, such as HiPerDiF [2] and TuFF [3], produce dry preforms that must be combined with a resin system. The most effective method to fabricate composites with aligned fibres involves stacking epoxy resin films with aligned fibre preforms, followed by compression using autoclave vacuum bag moulding. Another approach has been to use resin infusion processes with infusible epoxy resin or thermoplastic (Elium®) resin systems. Though they have shown great success in proving superior mechanical properties, challenges remain: 1) thermoset resin systems are difficult to recycle, and 2) there is limited understanding of how the resin combining process affects the structural integrity of aligned fibre assemblies during fabrication. This study therefore investigates the role of matrix material and its microstructure in composites fabricated with aligned carbon fibres by comparing two distinct matrices: electrospun thermoplastic polymer and conventionally fabricated polymer films. The electrospun polymer matrix features a fine, partially aligned fiber architecture and a high surface area, enhancing fiber-matrix impregnation unlike conventional polymer films. Both composite configurations are fabricated with aligned carbon fibres and subjected to mechanical testing, including tensile properties, to evaluate their performance. This paper highlights the potential of leveraging advanced matrix fabrication techniques to maximise the mechanical advantages offered by aligned carbon fibres, paving the way for lightweight, high-performance composite materials suitable for engineering and aerospace applications.

1 INTRODUCTION

Highly aligned discontinuous fibre composites have drawn attention not only for their comparable stiffness and strength to continuous fibre composites [4], but also for their formability and recyclability. Several methods have been developed to produce such composites, e.g., HiPerDiF [5], rotating drum [6] and TuFF [7].

Studies show that the mechanical performance of the composite increases with greater fibre alignment [2, 5, 8]. In addition to improved mechanical properties, manufacturing complex parts with aligned discontinuous fibre is easier, as the fibres can adjust their position during forming, preventing buckling and wrinkling [7, 9]. Also, aligned discontinuous fibre composites possess some level of ductility, making them a suitable choice for applications that require pseudo-ductile materials [10]. Most importantly, the greatest protentional of aligned discontinuous fibre composites is their ability to

support recyclability. Fibres reclaimed after their lifecycle in applications can be used to produce new aligned discontinuous fibre composites. In this way, recycled fibres are utilised in higher-value materials, supporting a circular economy and reducing landfill waste [4]. Case studies and application prototypes, such as flexi wings on formula 1 car, tennis rackets, provide good examples of this potential [11].

However, to take full advantage of the recyclability of aligned discontinuous fibre composites, thermoplastic type polymer is preferred over thermoset type polymer [12]. Thermoplastics, however, have higher melt viscosities, which lead to insufficient impregnation of the fibre bundles [13]. Poor impregnation results in inefficient load transfer between the fibres and matrix [14], reducing the overall strength of the composite.

One approach to improving impregnation is to use the electrospun form of thermoplastic polymers. Electrospun thermoplastic polymer sheets have higher porosity and surface area than conventional films, which can enhance impregnation [15]. Using electrospun polymer sheets in aligned short fibre composites offers additional benefits beyond improved impregnation. One such benefit is that electrospun sheets exhibit a unique structure, with nano/micro-fibres partially aligned in a single direction. This, combined with their porosity, could help retain fibre alignment during compression moulding. Moreover, this is particularly beneficial when using HiPerDiF or TuFF processes to produce aligned fibre preforms, as these methods may leave a small amount of moisture after fibre alignment. The porous structure of electrospun sheets can help remove this moisture effectively.

This study attempts to use electrospun thermoplastic polymer material as a matrix in manufacturing aligned short carbon fibre composites, in order to compare them with conventional aligned short carbon fibre composites. Aligned short carbon fibres are combined with two types of PLA material: i) Conventional PLA film and ii) Electrospun PLA film, to form composites whose tensile properties are then compared.

2 ALIGNED SHORT CARBON FIBRES

An experimental setup was developed to prepare aligned carbon fibre preforms. This setup is based on the principle of HiPerDiF method [2], which uses a sudden change in momentum of a fibre-water suspension onto a plate to align the fibres. The fibre alignment head consists of thin parallel plates that capture the fibre-water suspension jets. Below the head is a moving conveyor belt, which collects the aligned fibres and allows the water drain out, resulting in an aligned fibre preform on the belt. This setup is of smaller size than HiPerDiF and can generate a preform of around 5 mm in width. 3 mm length of carbon fibres (Tenax-A HT C124- 3 mm [16]) were used in this study which resulted in an aspect ratio of around 428. To assess the alignment of fibres in a preform, the Rapid Fibre Alignment Assessment (RFAA) method was adopted [17, 18]. To apply this method (See Figure 1), a section of preform was first imaged. The whole image was then sectioned into equally spaced, same-sized 'Region Of Interest (ROI)'. This code was applied to each ROI individually. Based on the defined formula, the image in each ROI was transformed in the x and y directions, and the transformed image was then subtracted from the original image. The resultant pixel density in x and y directions after subtraction indicated the fibre alignment in each ROI.

This method is quicker and effective [18, 19]. The RFAA method was applied to five images of the dry preforms before they were combining with the resin matrix, and the mean fibre alignment was found to be $\pm$ 8 deg.

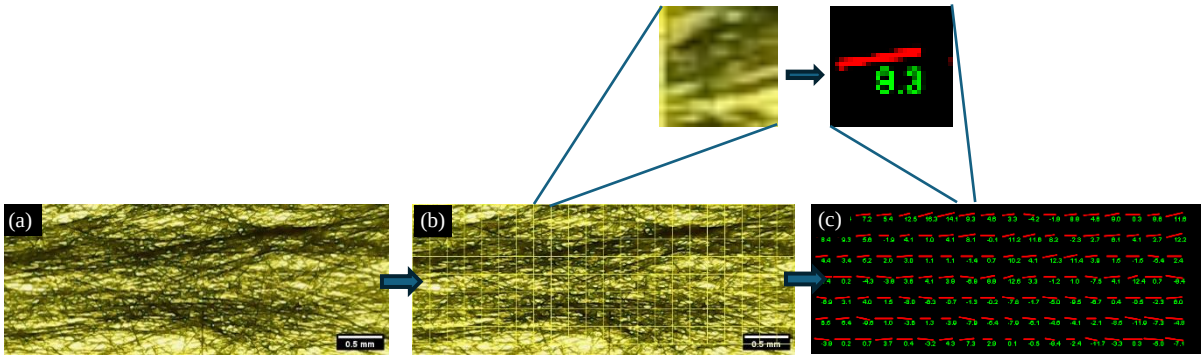

Figure 1: (a) Aligned fibres image, (b) Segmented into small region of interest (ROI), and (c) Applied RFAA method to assess alignment in each ROI

3 PLA MATERIAL AS MATRIX

The conventional PLA film was obtained from Goodfellow, Cambridge UK (product: ME34-FM-000100). This film has a thickness of 0.05 mm, with a tensile strength of 53 MPa and a tensile modulus of 3.5 GPa. For electrospun PLA, granules were acquired from the same manufacturer and have similar mechanical properties. These granules were then dissolved in chloroform and dimethylformamide, and stirred for 4 hours at 50° C to produce a PLA solution. This solution was then fed through a syringe, where it was stretched and deposited as a porous film (containing PLA micro-fibers) onto a collector, similar to a typical electrospinning process [20], except that a roller type collector was used instead of a flat one. Since the roller rotates at a constant speed, the deposited micro-fibers are aligned in the direction of rotation. A voltage of 25 kV was applied between the syringe and the collector, and with the collector rotating at 3500 RPM, a 20 µm thick, porous film containing PLA micro-fibers was formed.

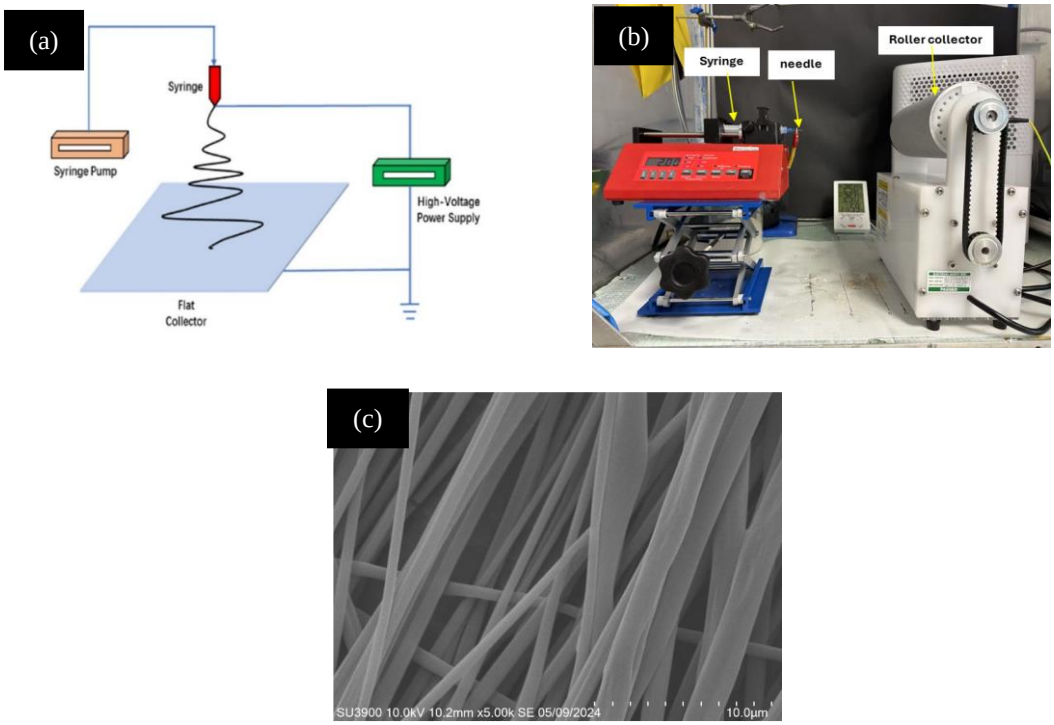

Figure 2. (a)Typical Electrospinning set-up, (b) Electrospinning setup with roller collector and (c) micro-fibres of PLA in electrospun film.

4 TENSILE TEST SAMPLE PREPARATION

Two sets of samples were prepared: one using conventional PLA film and the other using electrospun PLA sheets, and tensile tests were performed in accordance with ASTM D3039 standards. In both cases, the same number of dry aligned carbon fibre preform layers (eight in total) was used. To achieve a consistent fibre volume fraction of approximately 23%, the preforms were stacked differently according to the stacking sequence as follows:

For conventional PLA - ***P*** + aligned carbon fibre – ***f*** :

$$[P/f_4]_s$$

For electrospun PLA - ***EP*** + aligned carbon fibre – ***f*** :

$$[EP_5/[f/EP]_4/EP/[EP/f]_4/EP_5]$$

These stacked layers were subjected to compression moulding by vacuum bagging and then placed in an oven. The pressure and temperature were set to 1 bar and 200° C, respectively. The samples measured 5 mm in width, 150 mm in length and 0.2 mm in thickness. Conventional PLA required 30 mins at 200°C to form composites, while electrospun PLA formed composites in 20 mins at the same temperature (see Figure 3).

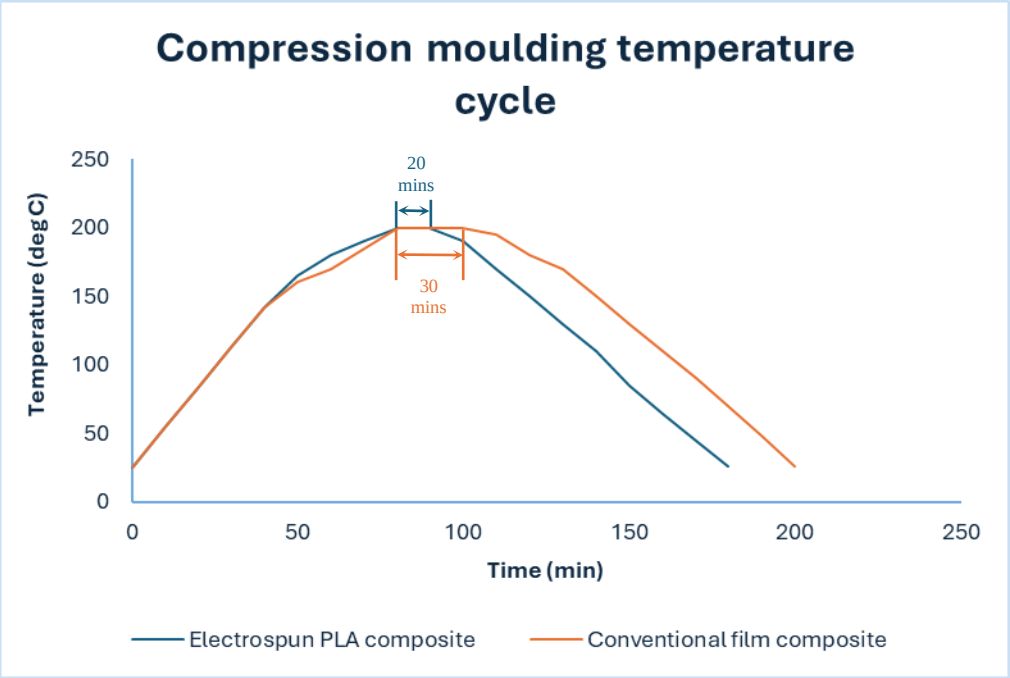

Figure 3: Heating cycle for electrospun and conventional PLA composites (Note: Constant vacuum applied.)

5 RESULTS AND DISCUSSION

Three specimens were tested in each sample set using a tensile testing machine (Instron D5967, 30 kN load cell). The results are shown in Figure 4. The use of electrospun PLA as a matrix resulted in a meaningful increase in mechanical properties compared to conventional PLA film. The tensile strength increased from 285 MPa to 337 MPa, an improvement of approximately 18%. Likewise, the tensile

modulus rose from 17.6 GPa to 19 GPa, reflecting an increase of about 8.0%. These results show that electrospun PLA can contribute to enhancing the mechanical performance of aligned short fibre composites. This can be attribute to more uniform and thermal behaviour of electrospun film. Due to its fine fibre structure, it heats and melts evenly and quickly. Also, it's higher surface area due to fine fibre structure helps it to flow more effectively between fibre bundles without affecting fibre alignment, resulting in good impregnation. In contrast, the conventional PLA film with its lower thermal responsiveness results in incomplete impregnation and its lower surface area may disrupt fibre alignment.

.

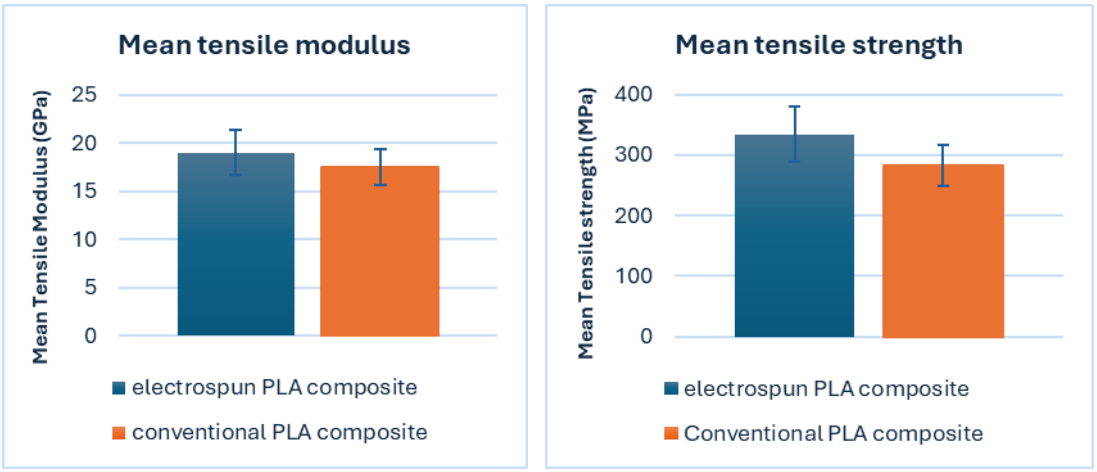

Figure 4. Tensile strength and modulus between electrospun and conventional PLA composites with aligned discontinuous carbon fibres.

6 CONCLUSION AND FUTURE WORKS

In this study, a simple comparison was made between the tensile properties of composites manufactured from two different forms of PLA. The conventional PLA film and electrospun PLA film were compression moulded with aligned short carbon fibres for 30 mins and 20 mins respectively, at 200° C. The results show that the electrospun PLA composite achieved higher tensile modulus and tensile strength than the conventional PLA composite, despite requiring less processing time. Therefore, using the electrospun form of the thermoplastic matrix material could be a potential solution for improving the sustainability of carbon fibre composites. This is largely attributed to its better impregnation capability, which leads to fewer defects during processing. The fine fibre structure and porosity of the electrospun PLA allow the matrix to flow more efficiently between the carbon fibre bundles, reducing voids and enhancing composite quality with shorter moulding times.

However, further research is needed to fully understand the effects of the moulding process on fibre alignment. The high viscosity of melted PLA can disrupt the alignment and structure of the carbon fibre preforms during processing. This disruption is expected to be less significant when using electrospun PLA, due to its porous structure and fine fibre morphology, which promote more uniform melting and better flow. Ongoing studies aim to investigate how these characteristics influence fibre alignment during composite fabrication.

ACKNOWLEDGEMENTS

We would like to thank Lineat for providing their technical expertise. We would also like to thank Mr. Jeff Boston, Mr. Gary Barter, Mr. Angus Tillotson and team from workshop, 3D printing lab and biomechanics lab in mechanical engineering dept., University of Bath for their help in building experimental setup and testing.

IS THERE A HYBRID EFFECT IN TENSILE AND COMPRESSIVE FAILURE OF CARBON FIBRE COMPOSITES?

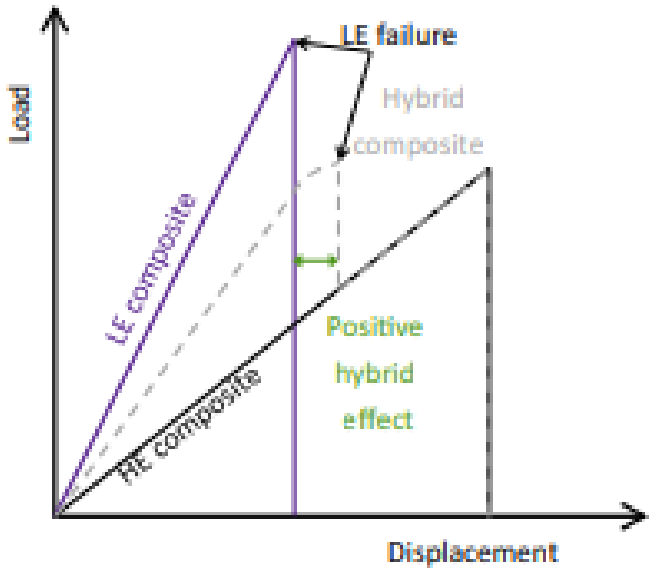
Michael R. Wisnom

Bristol Composite Institute, University of Bristol

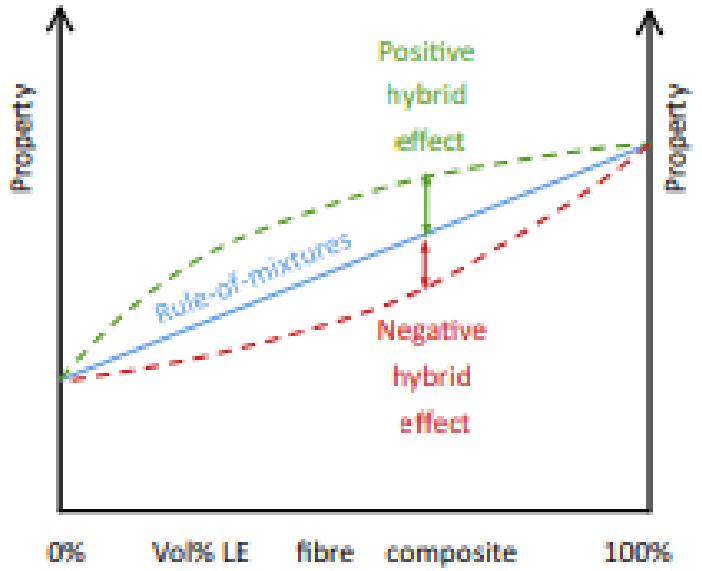
Next Generation Fibre-Reinforced Composites

IMPERIAL

The Composites Centre
for research, modelling, testing and training in advanced composites



University of BRISTOL
Bristol Composites Institute

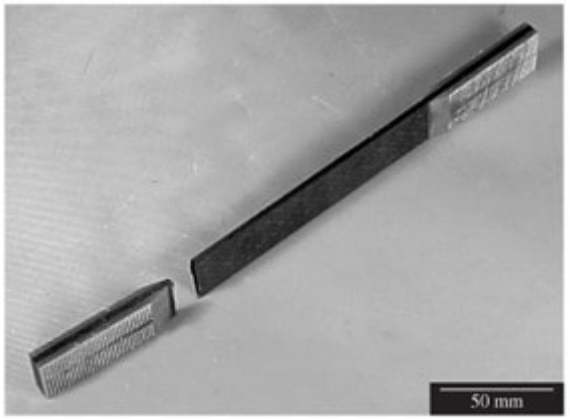


UK Research and Innovation

Engineering and Physical Sciences Research Council

HYBRID EFFECT

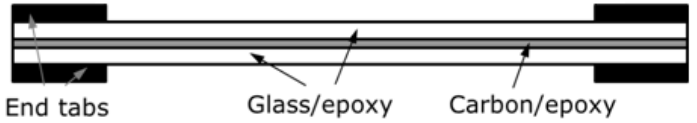
- Can be defined as an increase in failure strain in a hybrid composite compared with when tested on its own
- Reports of hybrid effects from the early days of composites generated much debate, e.g. Hayashi, 1972



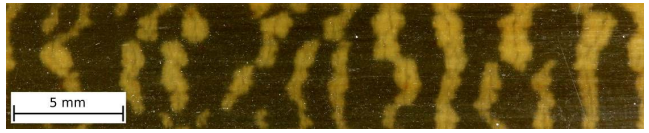
- Low extension (LE) fibre e.g. carbon
- High extension (HE) fibre e.g. glass
- Deviation from Rule of Mixtures

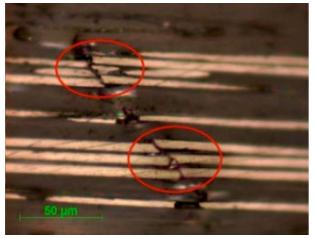
Swolfs, 2014

NEED FOR A GOOD BASELINE



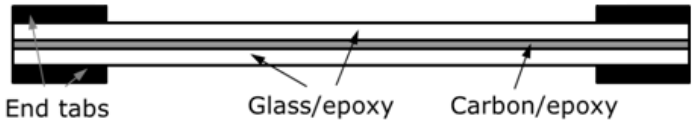
- Testing of composites is very challenging
- Failures often occur prematurely at grips
- Compression testing is particularly difficult
- Makes it hard to accurately compare strengths
- Reliable baseline failure strains are crucial for proper assessment of hybrid effects

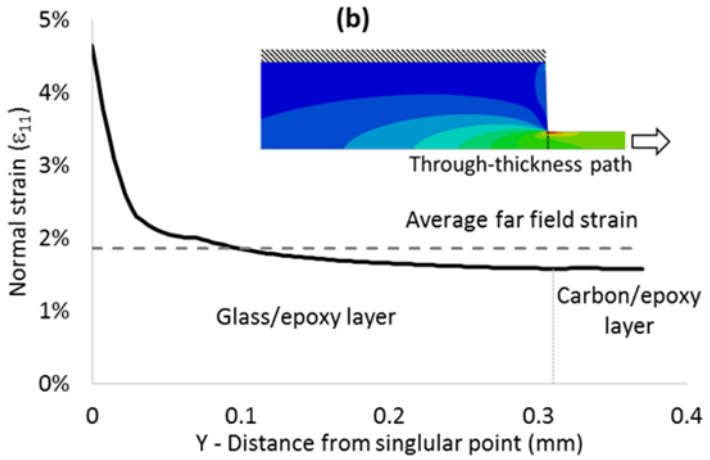


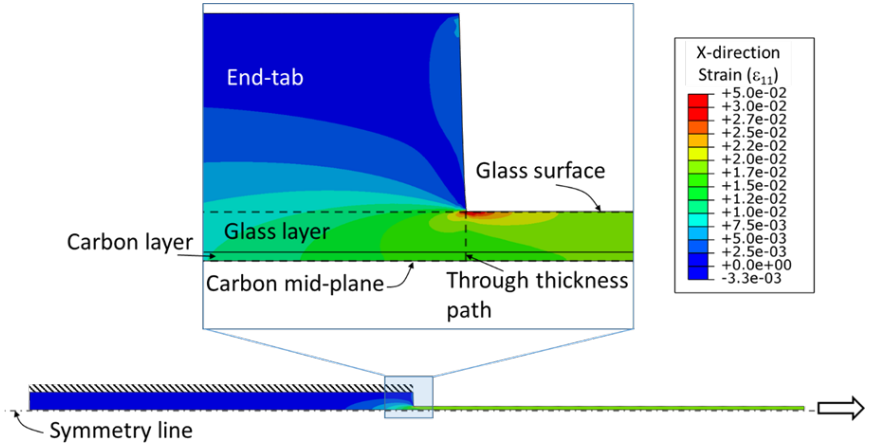


OUTLINE

- Obtaining a good baseline
- Hybrid effects in tension
  - UD glass/carbon
  - UD high modulus/high strength carbon
  - QI glass/carbon
- Hybrid effects in compression
  - UD high strength carbon / S-glass
  - UD high modulus/high strength carbon

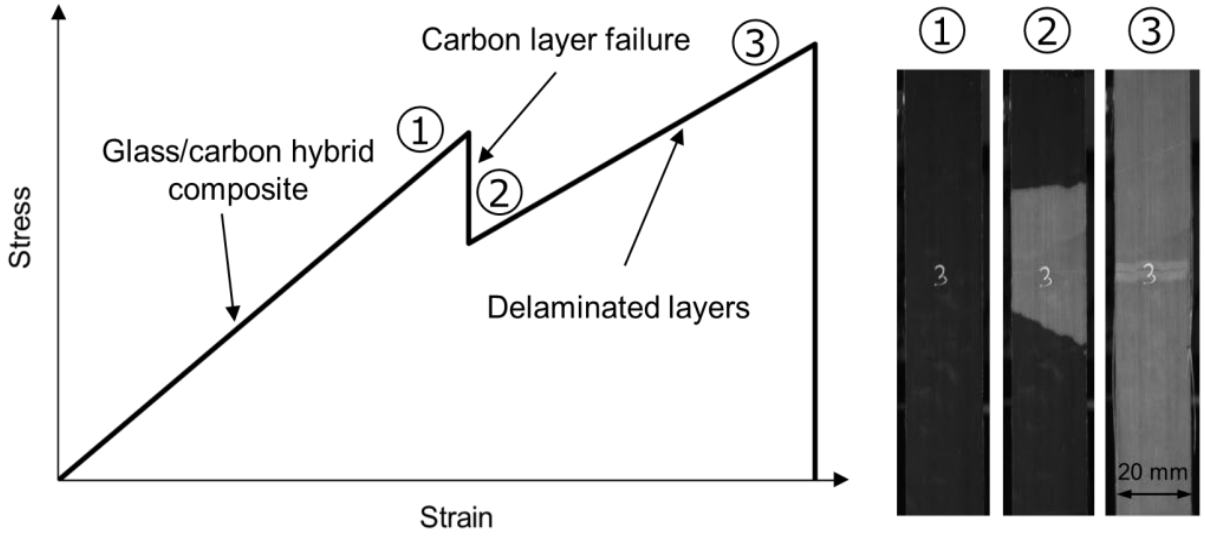


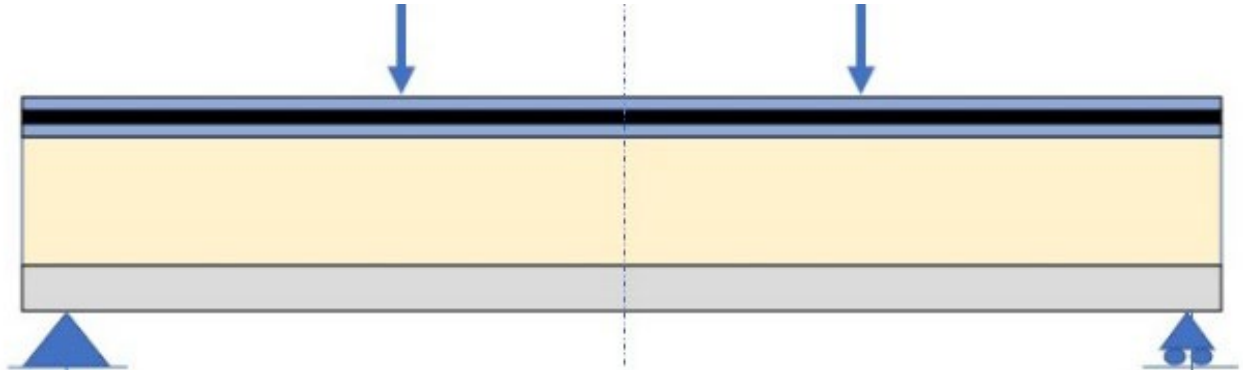




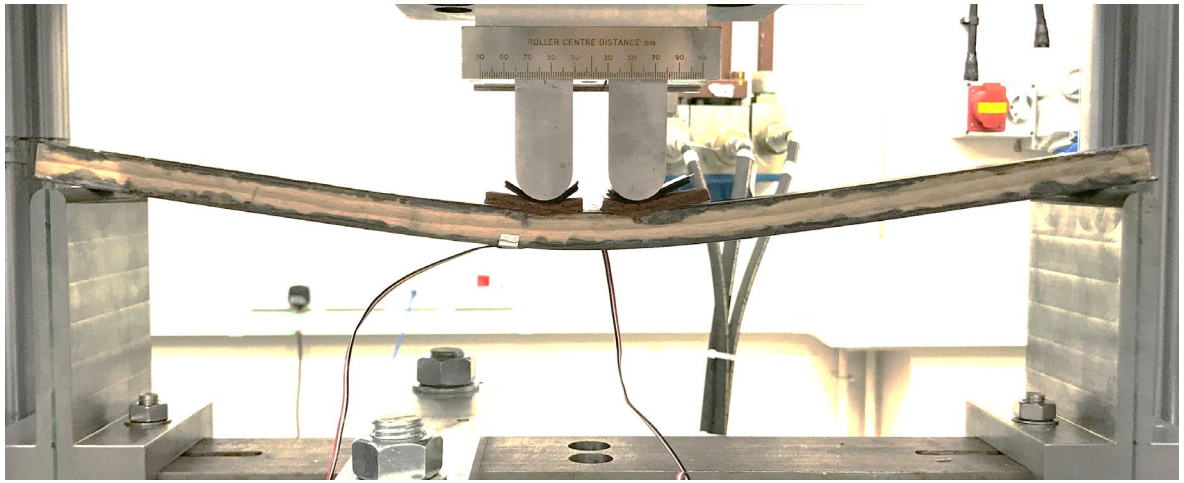
AN ACCURATE SIMPLE TENSILE TEST

- Sandwich specimen eliminates stress concentration
- Strain in carbon LOWER at tab
- Eliminates grip failures





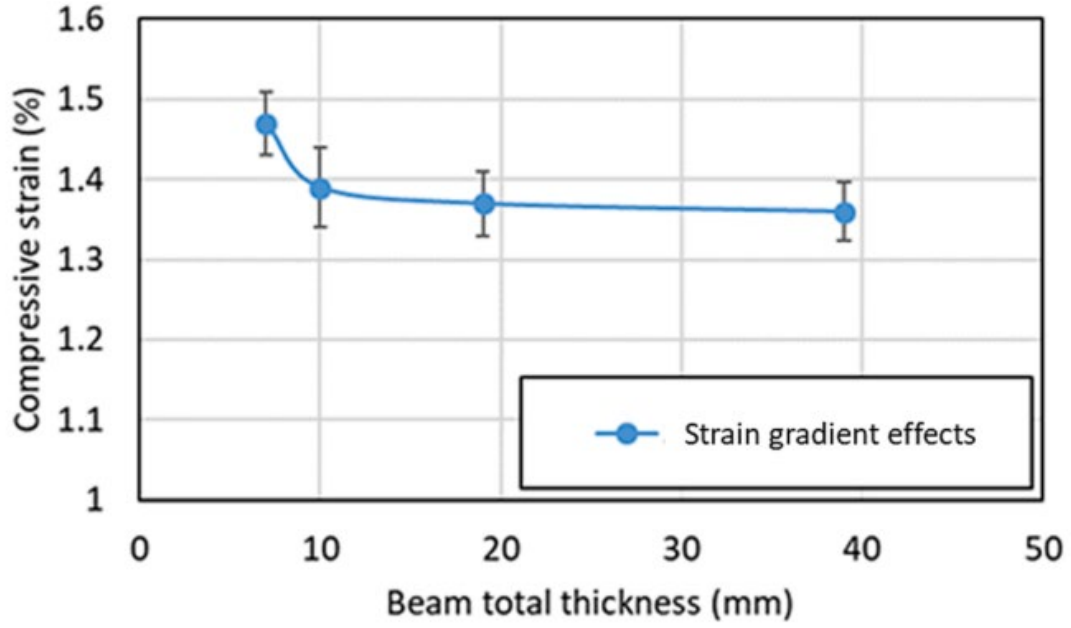
Czél, Jalalvand, Wisnom, 2016



CONSISTENT TENSILE FAILURES

- Gauge section failure followed by delamination
- Much higher failure strain, lower variability
- E.g. 1.86% vs. 1.5% strain for TR30 carbon/epoxy
- Gauge section failure even without end-tabs

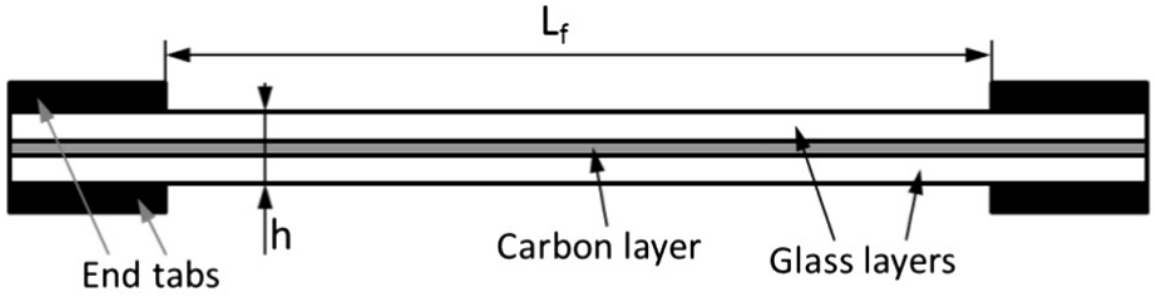
SANDWICH BEAM COMPRESSION TEST



Wu & Wisnom, 2023

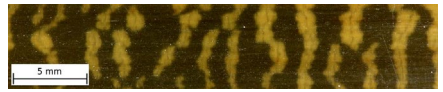
- Four-point bending
- Hybrid compression skin
- Carbon tension skin
- Wood or PMMA core
- Large rollers avoid local failures
- Strain gradient effect?

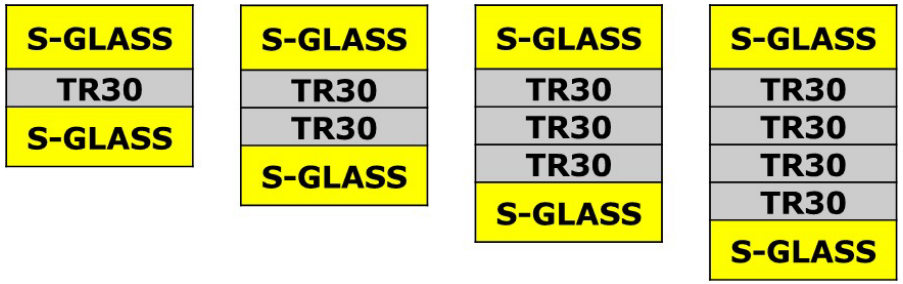
VALIDATION OF TEST



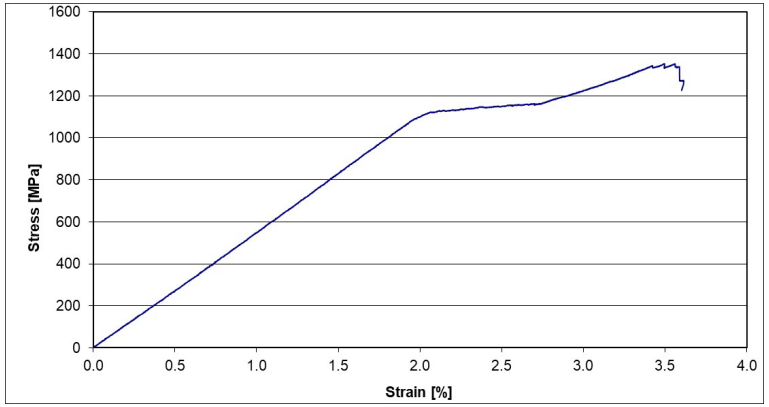
- IM7/8552 carbon/epoxy skins, t = 0.5 mm
- Little effect of strain gradient above 10 mm thickness
- 1.36% strain - 14% higher than 1.19% in direct compression

(Thomson et al, 2019)



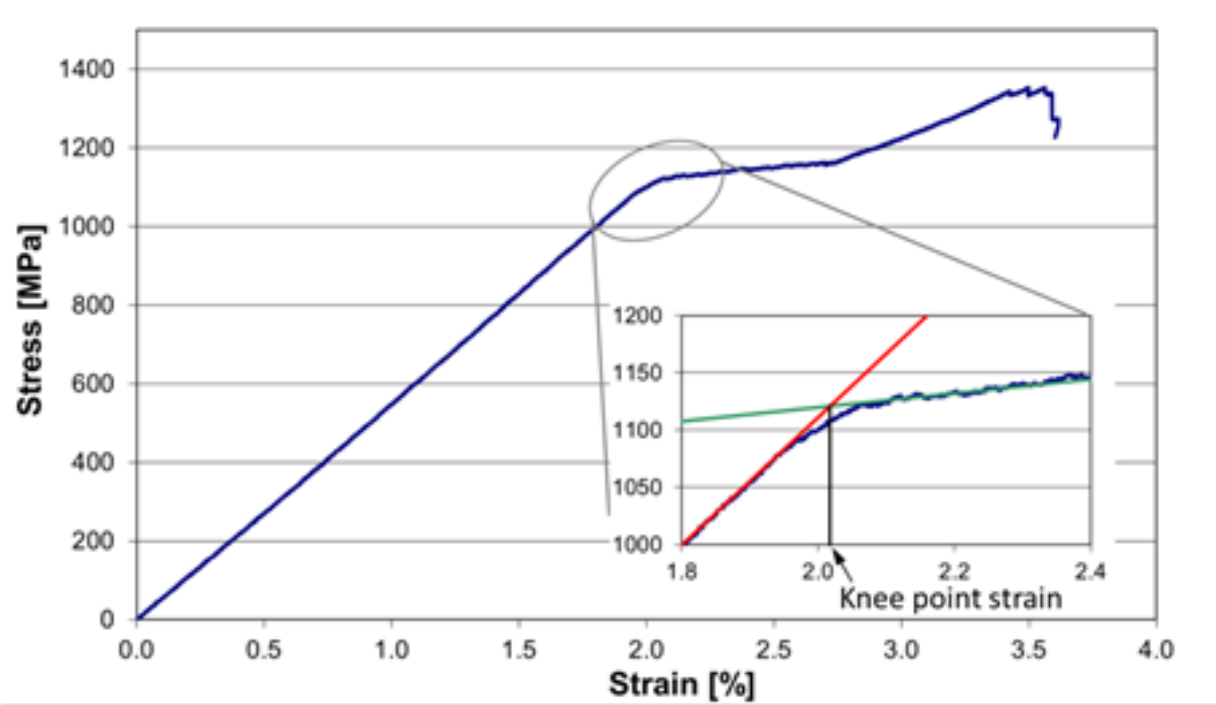


Wu & Wisnom, 2023



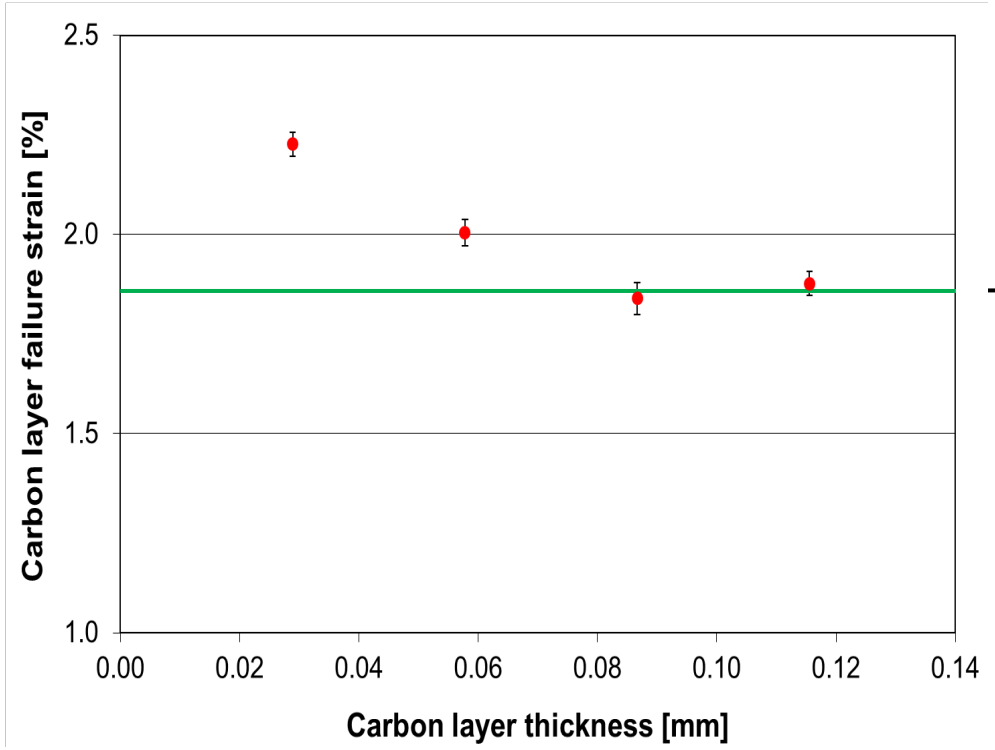
HYBRID TENSION TESTS

- Skyflex TR30 high strength carbon/epoxy (0.029 mm)
- Hexcel S2 glass/epoxy plies (0.155 mm) either side

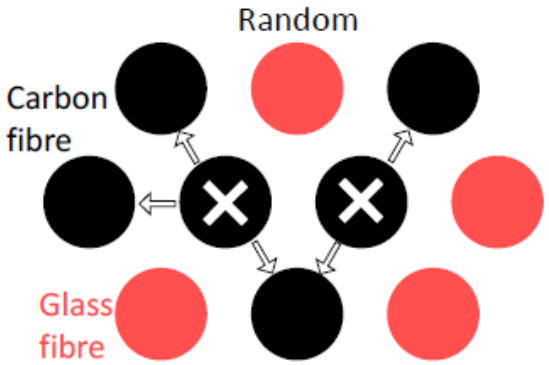


- 3 and 4 ply specimens delaminated with clear load drop
- 1 and 2 ply specimens exhibited pseudo-ductile behaviour

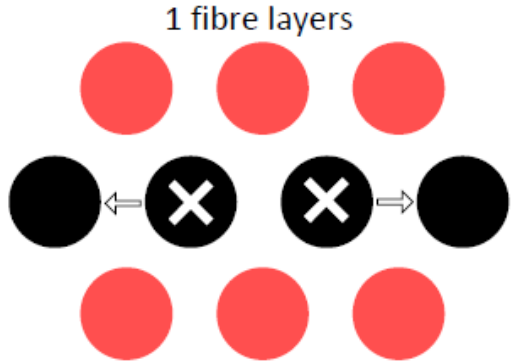
Wisnom et al, 2016



DEFINITION OF FAILURE STRAIN

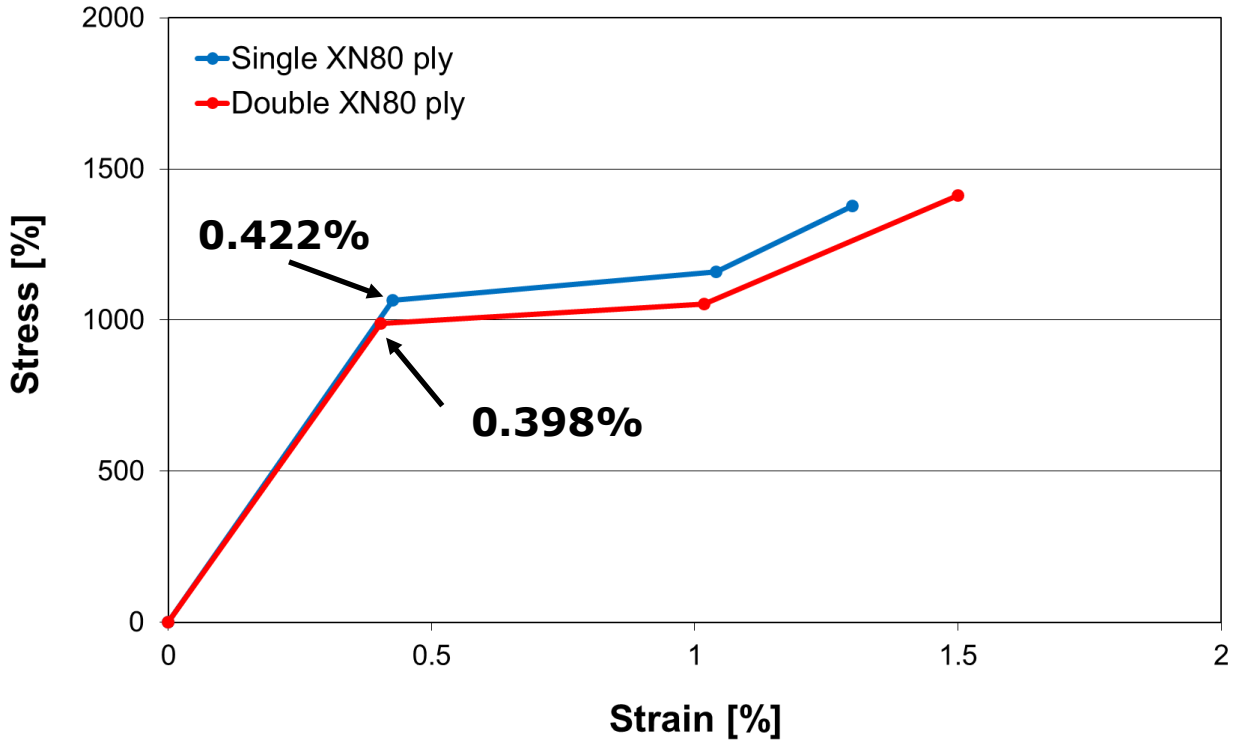


- Thick specimens: strain at load drop
- Thin specimens: knee point in stress-strain curve
- Corresponds to point of establishment of ply fragmentation
- All results corrected for thermal strains



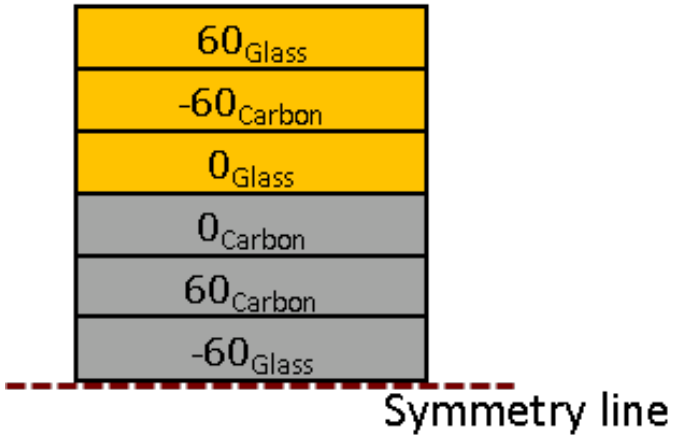
HYBRID EFFECT IN GLASS / CARBON

- 3 and 4 carbon plies similar, close to expected fibre strain
- 1.86% baseline cf 1.5% with conventional test
- 20% increase in strain to 2.2% for single ply case
- Due to restriction on forming critical cluster

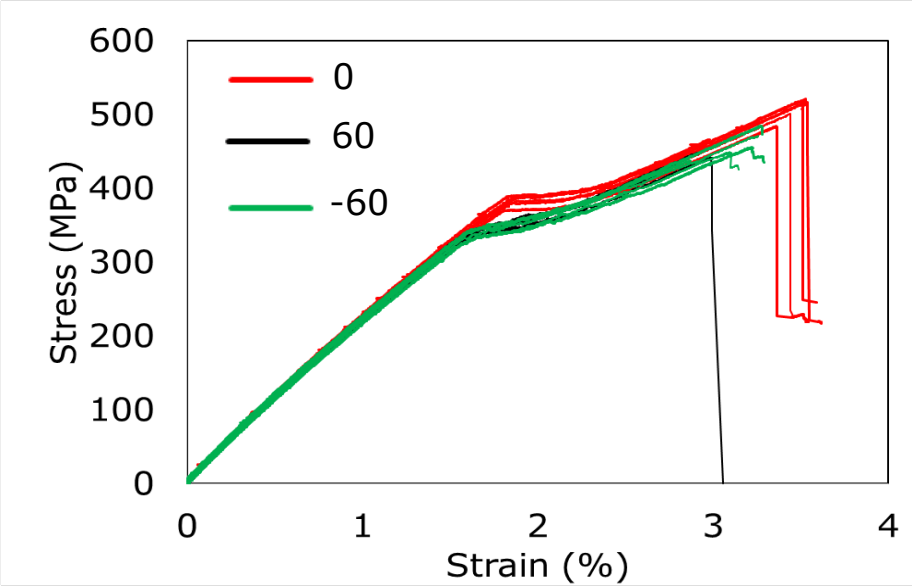


Wisnom et al, 2016

HYBRID EFFECT IN ALL CARBON LAMINATES



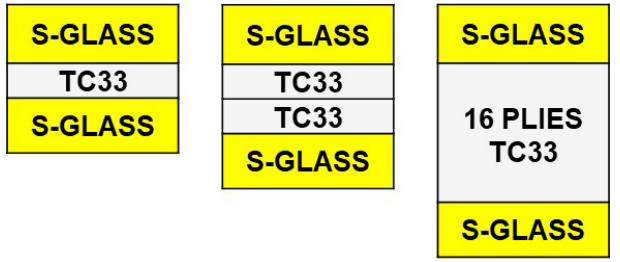
- Carbon /carbon hybrids also show hybrid effect
- Ultra high modulus XN80 (0.047 mm ply t)
- T1000 intermediate modulus (0.032 mm ply t)
- $[T1000_2/XN80_2/T1000_2]$ versus $[T1000_1/XN80_1/T1000_1]_2$
- ~30% higher than datasheet laminate failure strain of 0.31%
- 6% increase in knee point strain for single XN80 ply



Czél, Jalalvand, Wisnom, Czigány 2017

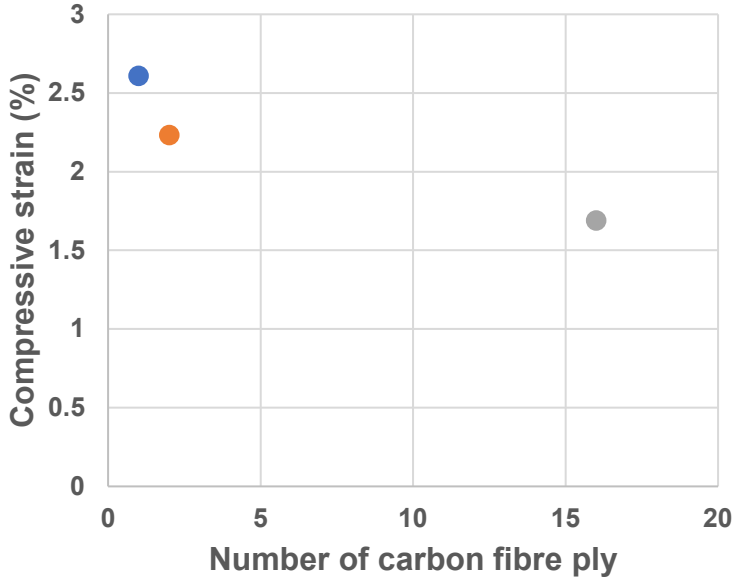
QUASI-ISOTROPIC PSEUDO-DUCTILE HYBRIDS

- $[\underline{QI}_{G60}/\underline{QI}_{C60}]_s$ tested in 0, 60 and -60 directions
- 13% higher strain when loaded in 0° direction
- Due to higher stiffness of adjacent 0° glass ply
- Can be correlated with stress concentrations in adjacent plies (**Idarraga et al, 2025**)

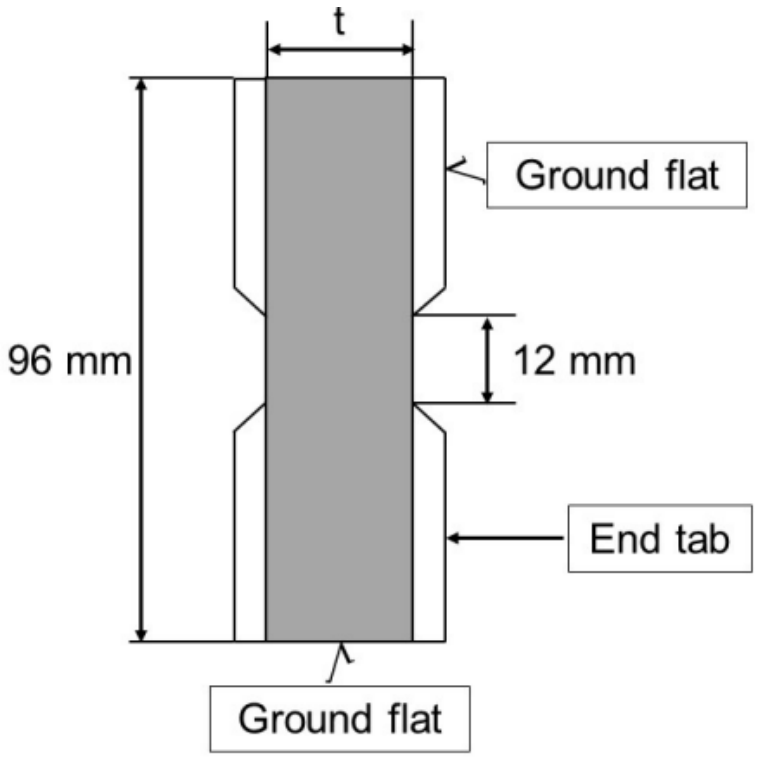


Fotouhi, Jalalvand, Wisnom, 2017

COMPRESSIVE FAILURE OF CARBON/GLASS HYBRIDS



- High strength TC33 carbon, 95 GPa, 0.03 mm
- S-glass, 45 GPa, 0.155 mm ply thickness
- Tested in 4-point bending
- Sudden failures with kink bands
- Large hybrid effect - 54% increase in strain
- Similar stresses – instability more related to stress than strain



Specimen configuration	Compressive failure strain (%) CV(%)	Laminate failure stress (MPa)
SG/TC33$_1$/SG	2.609 (8)	1271
SG/TC33$_2$/SG	2.234 (8)	1232
SG/TC33$_{16}$/SG	1.691 (6)	1121

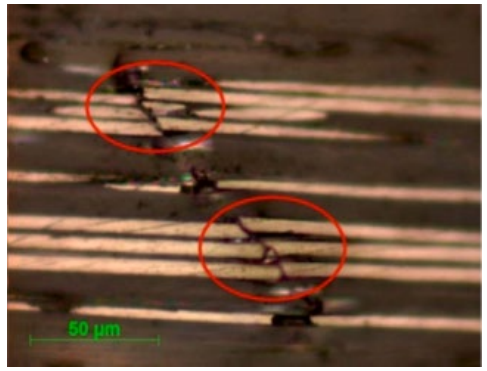
Tongloet, 2025

HIGH MODULUS CARBON / GLASS HYBRIDS

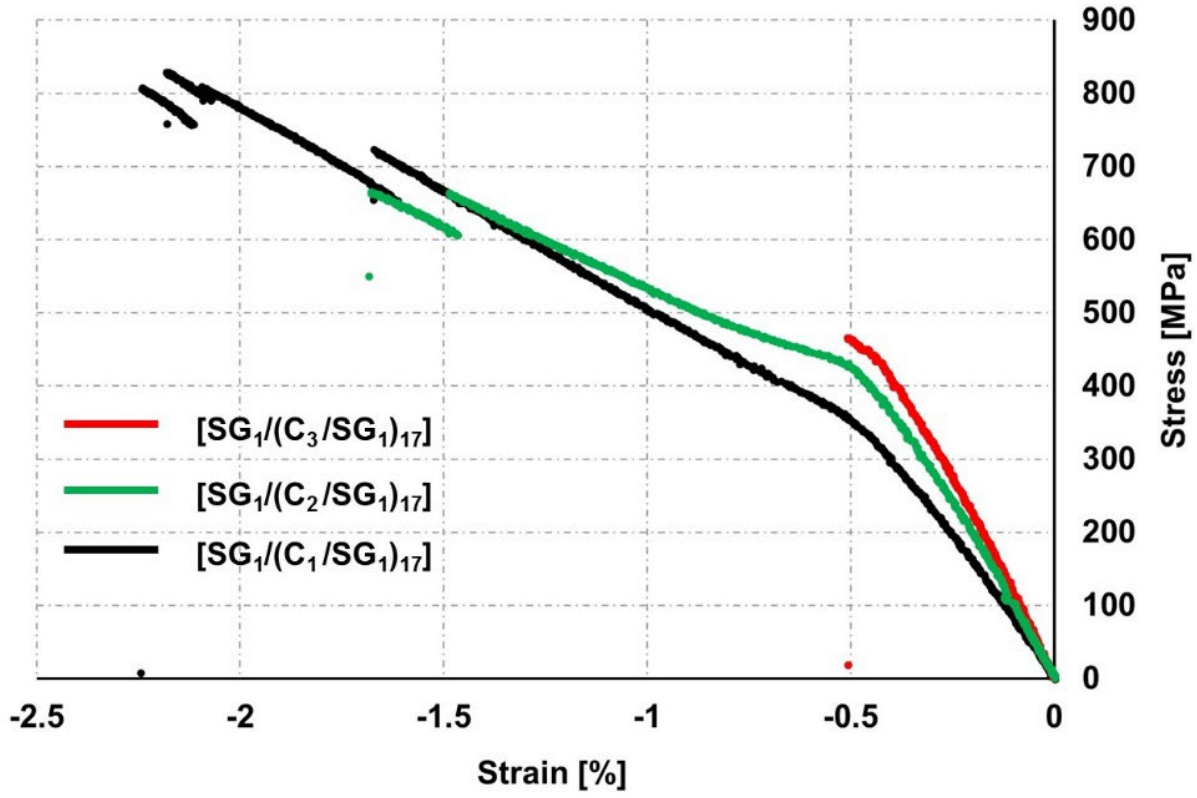
Direct compression

Suwarta et al., 2025

- M55J high modulus PAN, ply t=0.03 mm, 240 GPa
- S-glass, t=0.155 mm, 45 GPa
- 17 repeats with single glass ply between each carbon sublaminate
- Thickness 3.31 to 4.35 mm



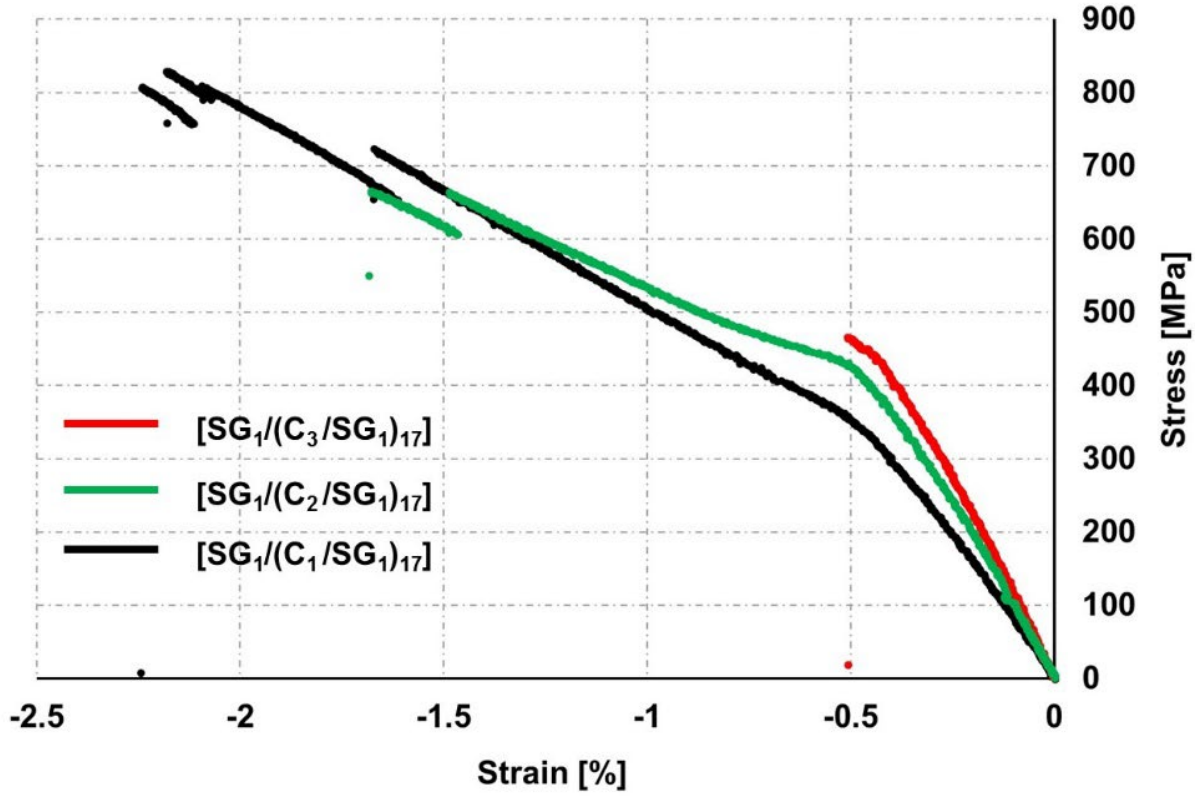
Layup 1
S-glass
M55J
S-glass



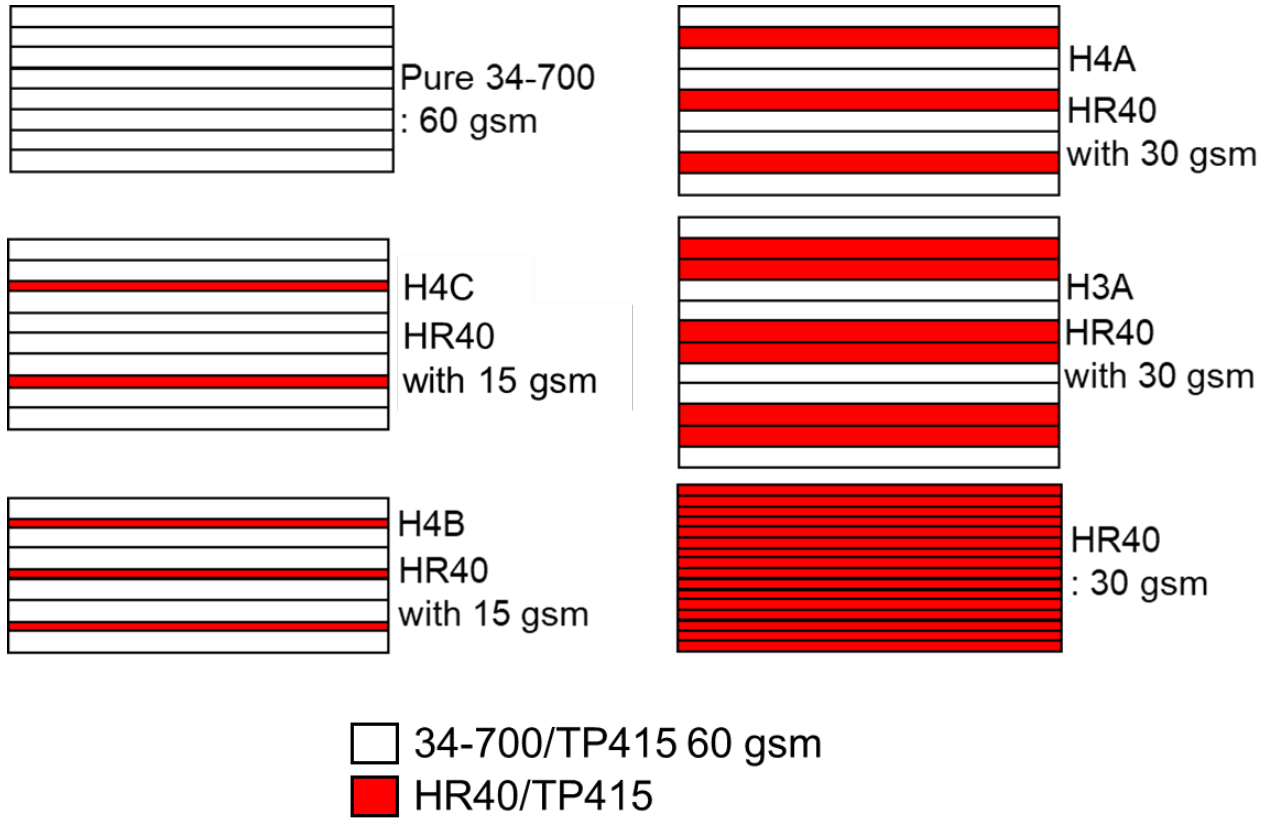
Layup 2
S-glass
M55J
M55J
S-glass

Layup 3
S-glass
M55J
M55J
M55J
S-glass

S-GLASS / HIGH MODULUS CARBON HYBRID EFFECT

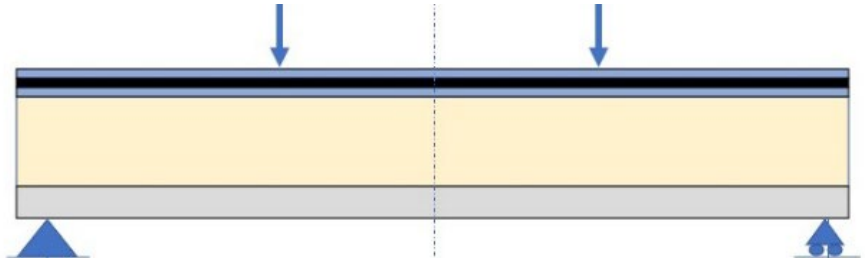


- Pseudo-ductile response with fragmentation
- Controlled by fibre failure not shear instability
- Final failure by delamination
- Knee point at 0.5% for all cases
- No hybrid effect?



S-GLASS / HIGH MODULUS CARBON HYBRID EFFECT

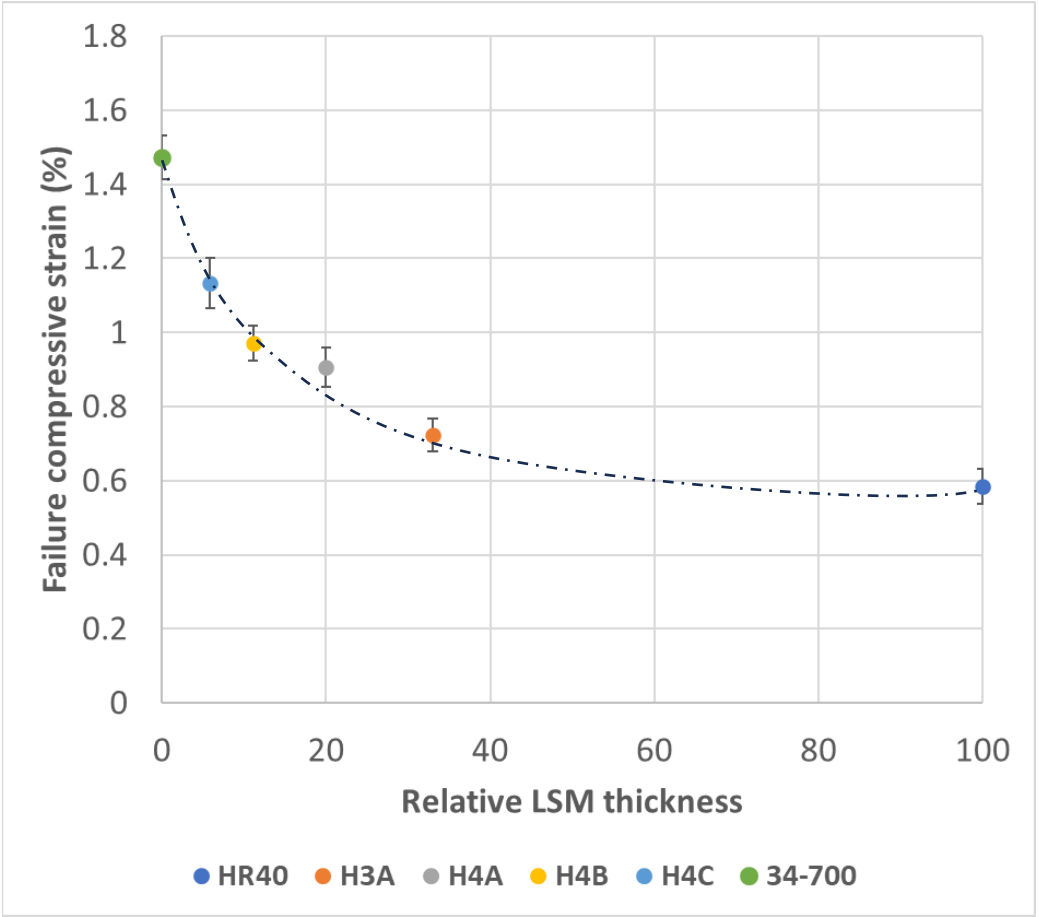
- Knee point at ~0.5% for all cases
- But failure strain of monolithic M55J composite reported ~0.31% **(Montagnier & Hochard, 2004)**
- Hybrid effect – fibre failure is delayed by support from Glass
- But fragmentation still occurs at similar strains



HIGH MODULUS / HIGH STRENGTH CARBON HYBRIDS

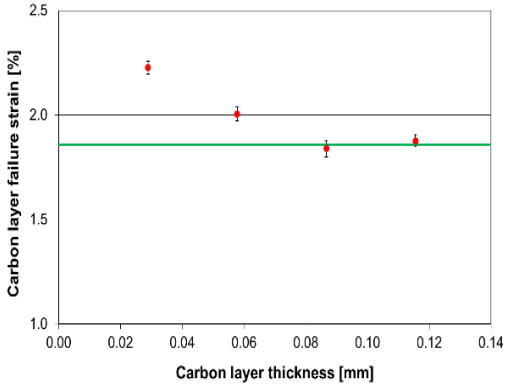
Unidirectional laminates

Fibre type	Fibre tensile modulus (GPa)
34-700	234
HR40	390

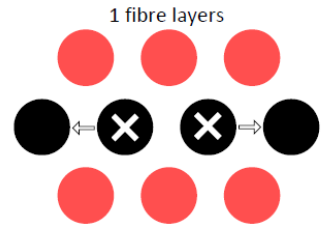


Sandwich 4 point bending test

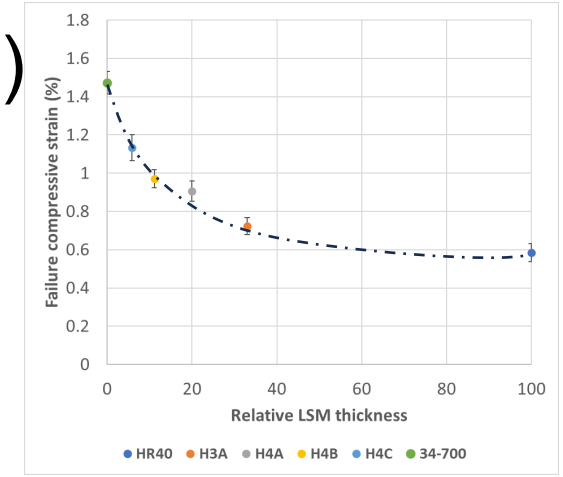
Tongloet et al, 2025

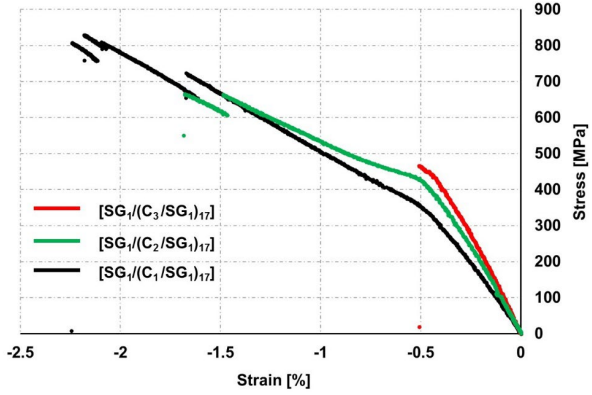


HIGH MODULUS / HIGH STRENGTH CARBON HYBRIDS



- No fragmentation or pseudo-ductility
- All failures show kink bands
- HR40 failure strain nearly doubled
- Due to support from 34-700
- Hybrid effect
- Fibre failure initiates by instability
- Before fibre fracture, failure transitions to composite instability





IS THERE A HYBRID EFFECT?

- Yes - significant effects in tension and compression
- But - need good baseline for valid comparison
- Tension – up to 20% increase in strain for thin plies
- Due to restriction in forming critical cluster
- Compression – large increases in failure strain when failure by composite shear instability (Std. Mod. C/G)
- Fibre failure instability delayed (HM C) but similar fragmentation strain
- Hybrid effects in compression due to support against instability

BUILDING ON PREVIOUS WORK

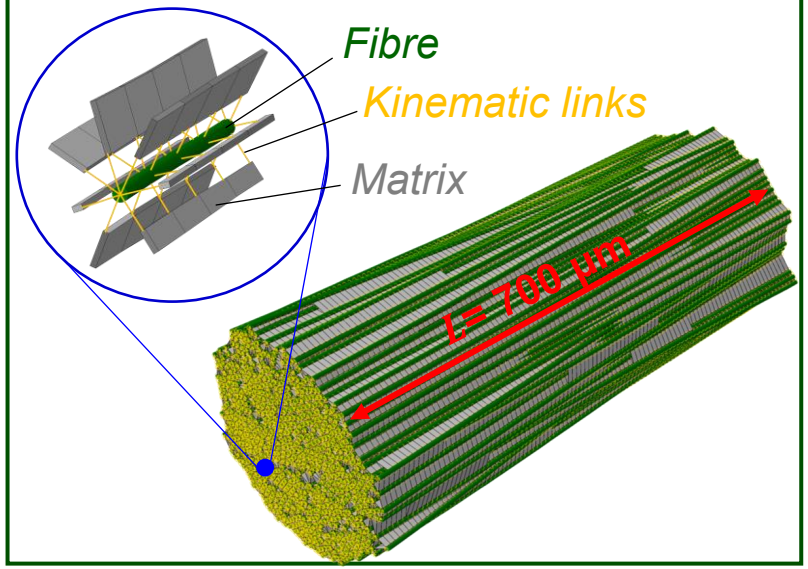
ECCM21: "*FE-Simulation of real microstructures: 1000 fibres, 1 mm long*"

12 hours

In-depth analysis of fibre imperfections and compressive failure mechanisms.

LAYOUT

Aims



Why the need of 3D micromechanical FE-Models.

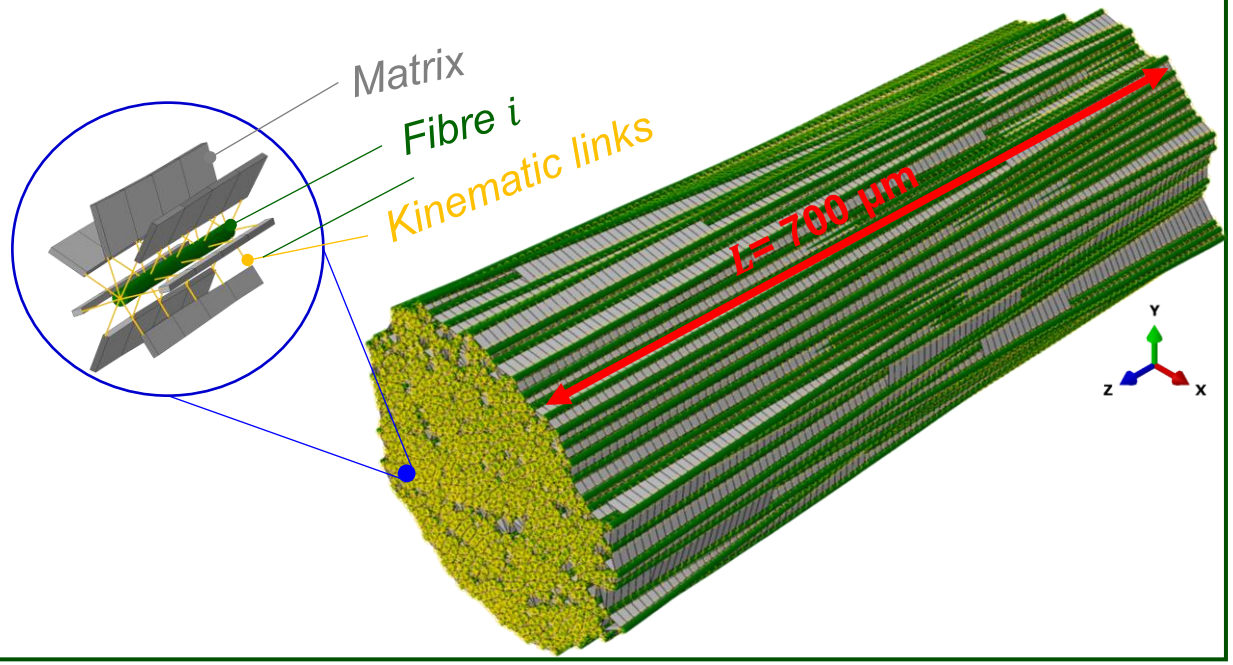
Importance of simulating real microstructures:

- *Why average metrics are not enough.*

Demonstration

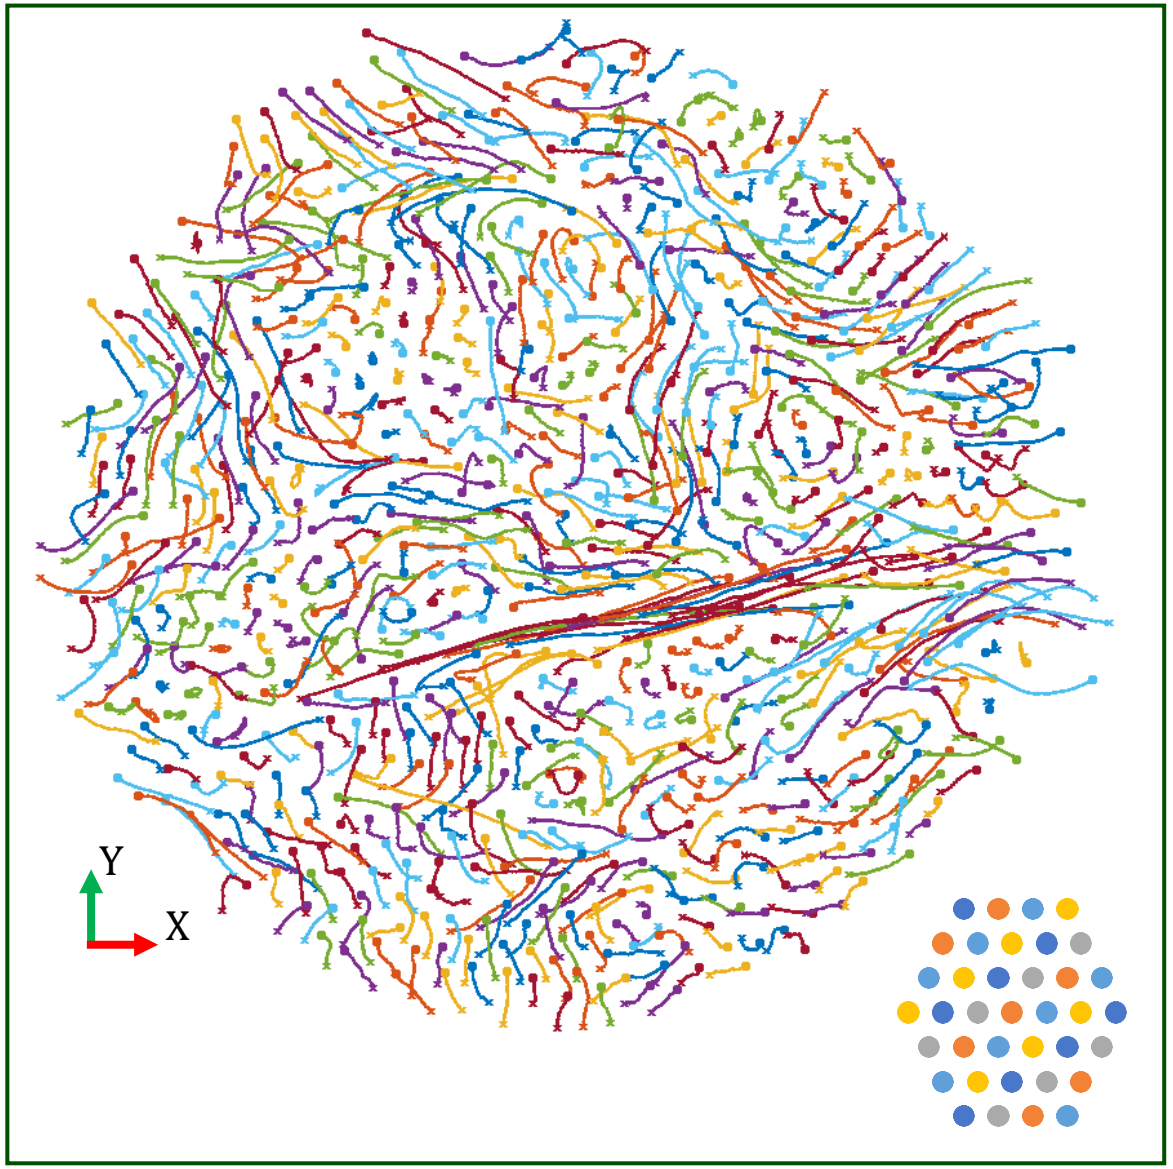
SB FE-simulations on a LARGE CFRP microstructure with our most accurate and computationally-efficient model.

Opportunities



An in-depth analysis of compressive failure mechanisms of real FRP microstructures.

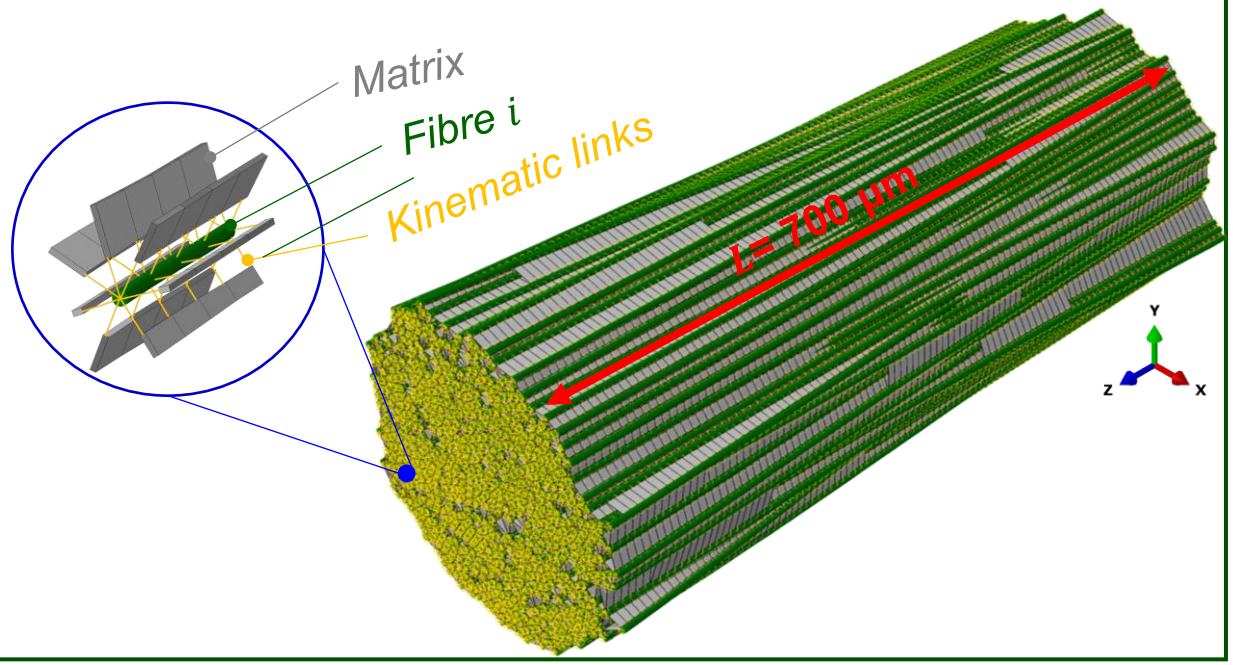
Analysis of coupled torsion-kinking behaviour of RVE.



Bonus study: Effect of real microstructures with similar average fibre imperfections.

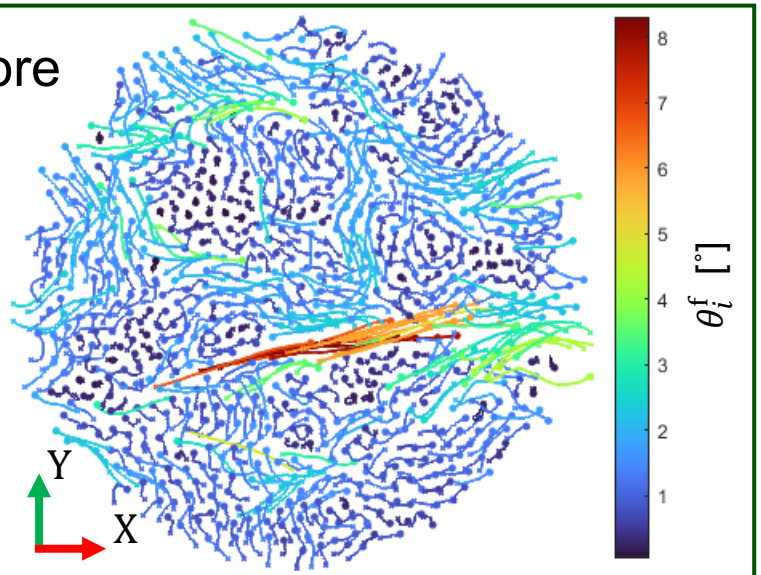
Analysis of real CFRP imperfections

800 CF paths from μCT (Emerson *et al.* 2017).



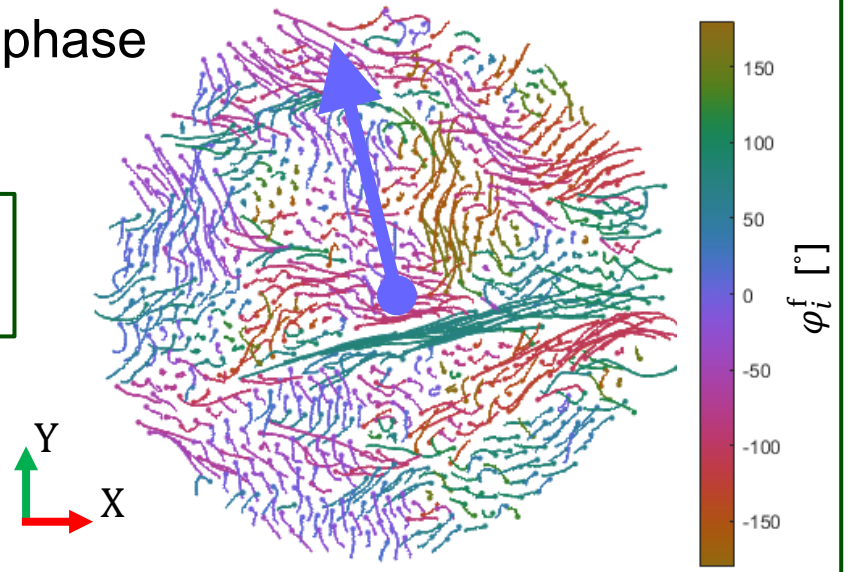
ANALYSIS OF REAL CFRP IMPERFECTIONS

800 CF paths from μCT (Emerson *et al.* 2017).



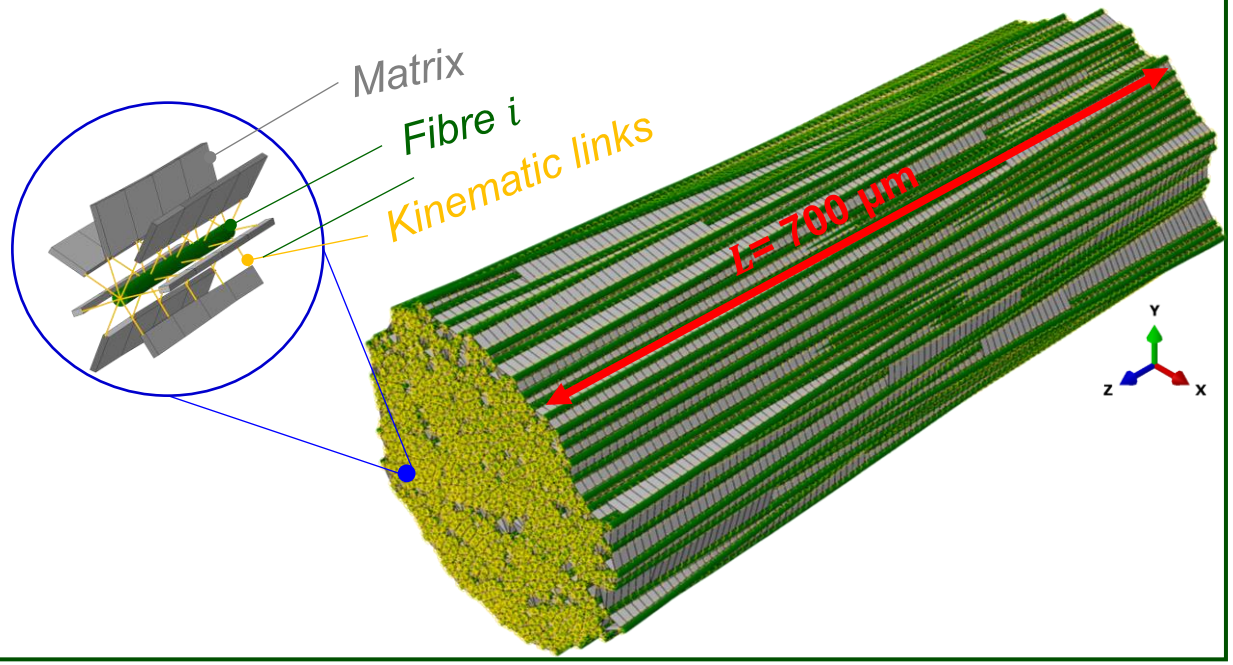
The misalignment angle of a given fibre i is defined by its:

i. Magnitude, $\boldsymbol{\theta_i^f}$
ii. Planar orientation, phase angle, $\boldsymbol{\varphi_i^f}$



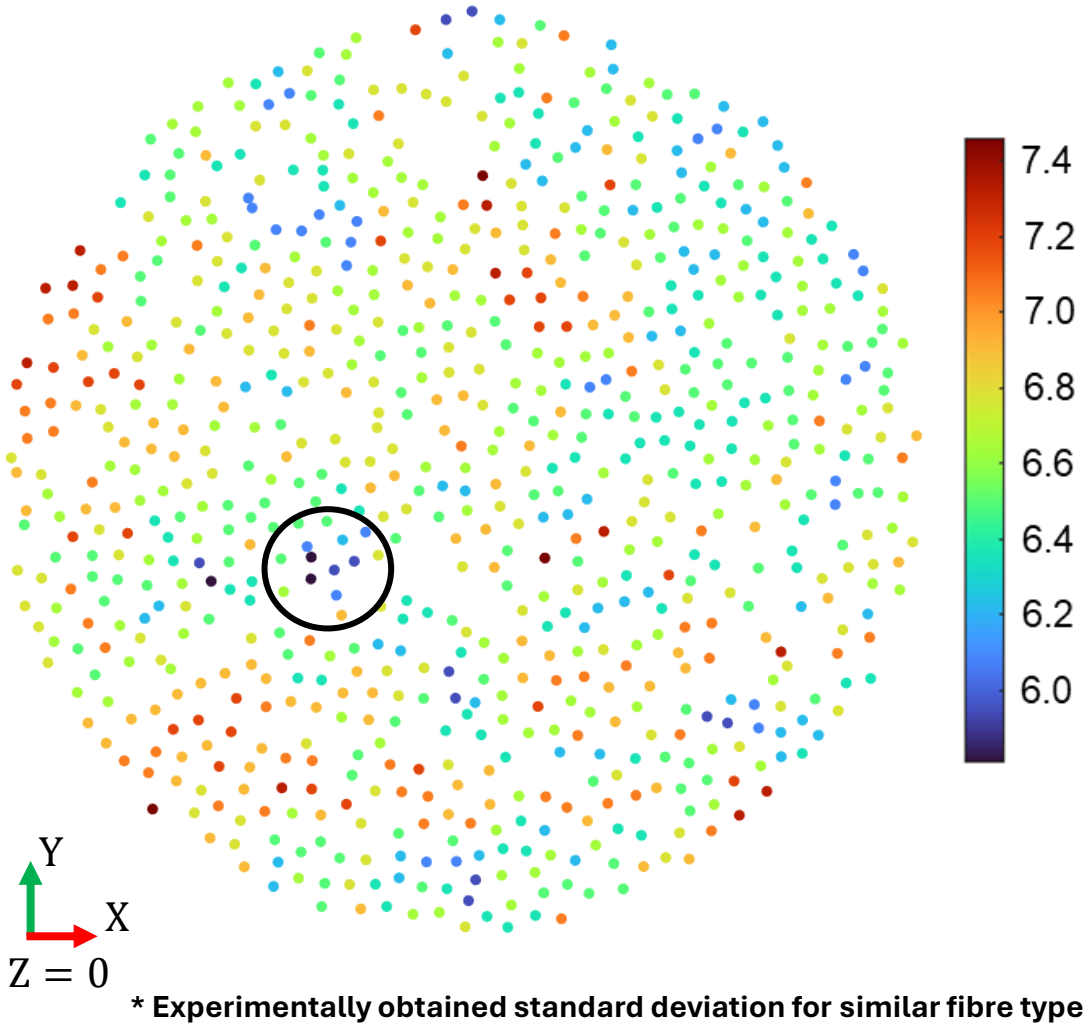
Magnitude of fibre misalignment angle, $\boldsymbol{\theta_i^f}$

$\overline{\boldsymbol{\theta^f}}$**=1.39** $\pm$ **1.03°**



Global fibre phase angle, $\boldsymbol{\varphi_i^f}$

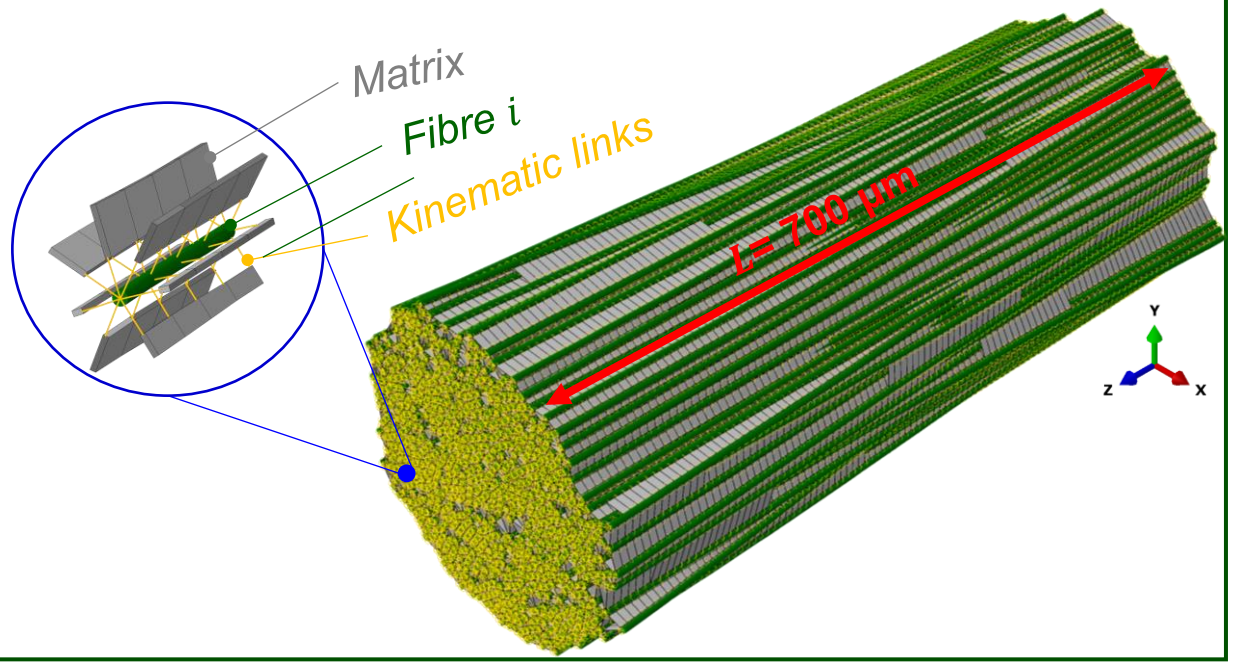
$\overline{\boldsymbol{\varphi^f}}$**=-14.7°**
IQD=138.9°



ANALYSIS OF REAL CFRP IMPERFECTIONS

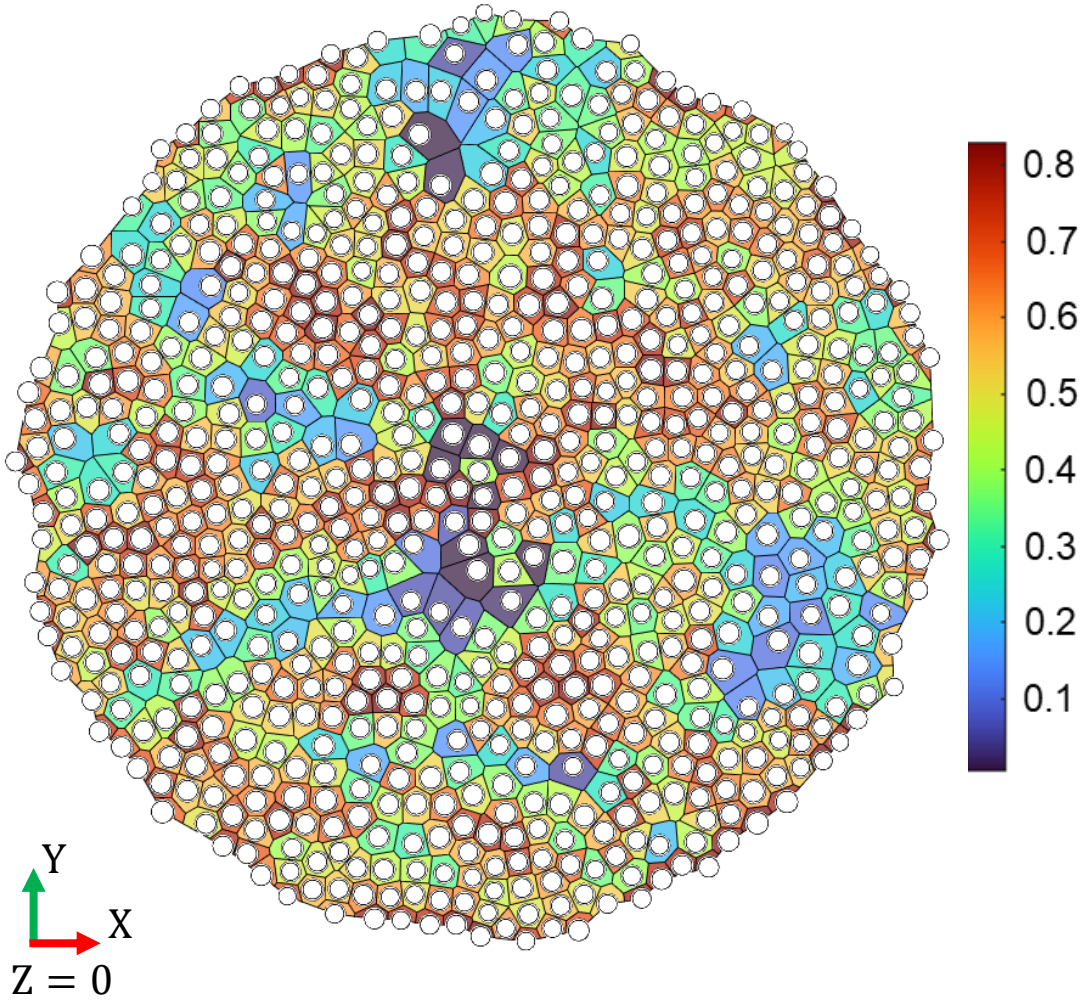
800 CF paths from μCT (Emerson *et al.* 2017)

- A distribution of fibre diameters is assumed due to lack of available tracking data;
- A normal distribution with: $\overline{\emptyset^f}$=6.6 ± 0.3 μm*



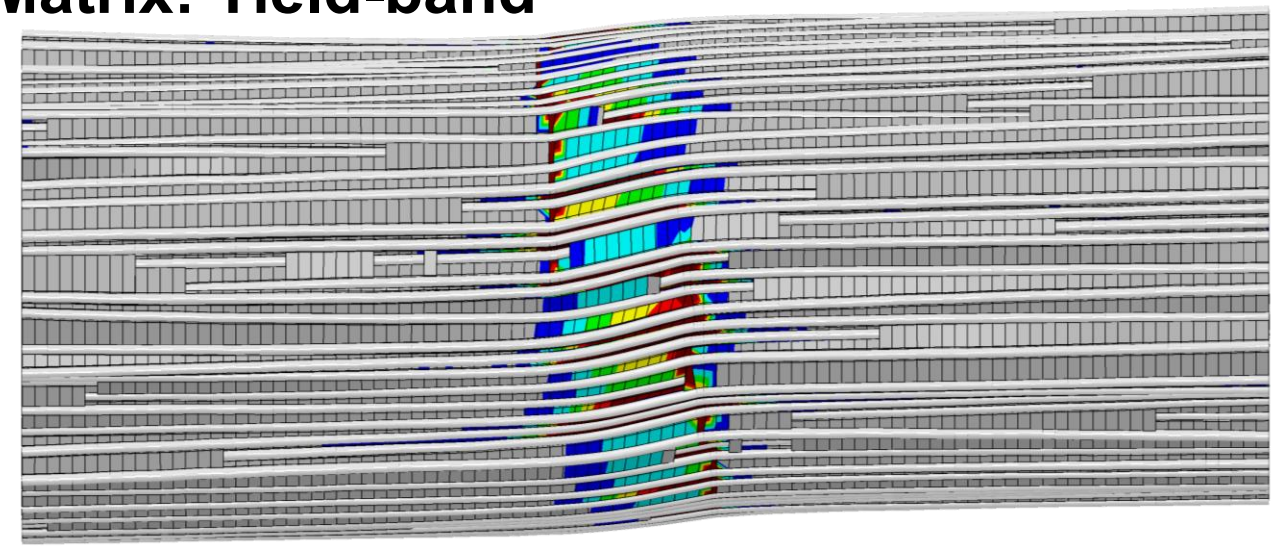
Distribution of fibres diameter, $\emptyset^f$ [μm]

* Experimentally obtained standard deviation for similar fibre type (Mesquita *et al.* 2021)

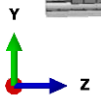


Analysis of real CFRP imperfections

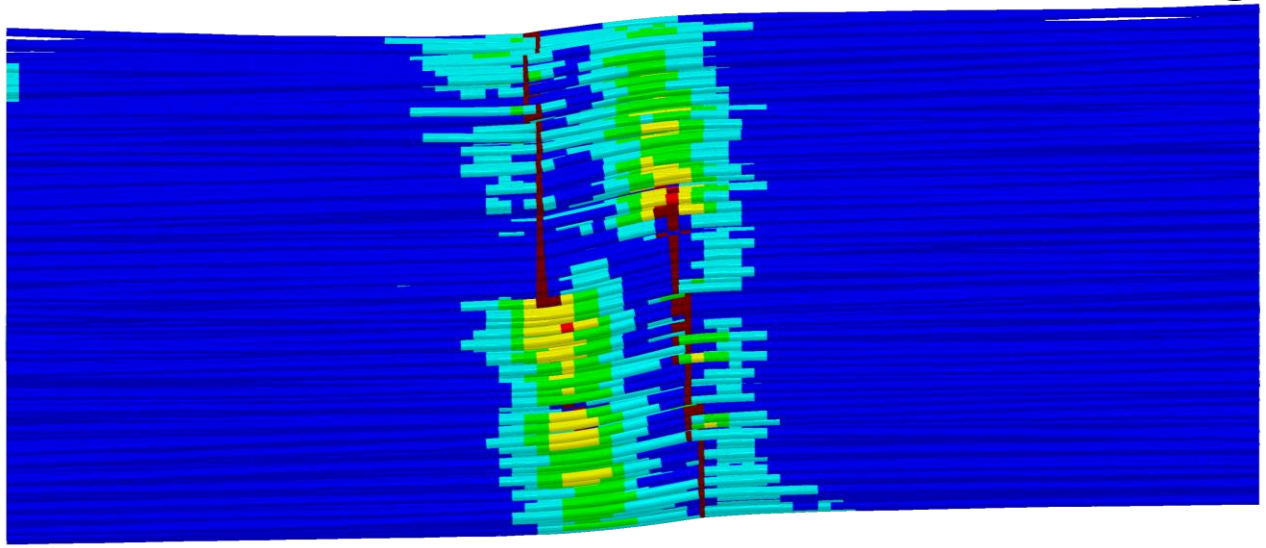
800 CF paths from µCT (Emerson *et al.* 2017)



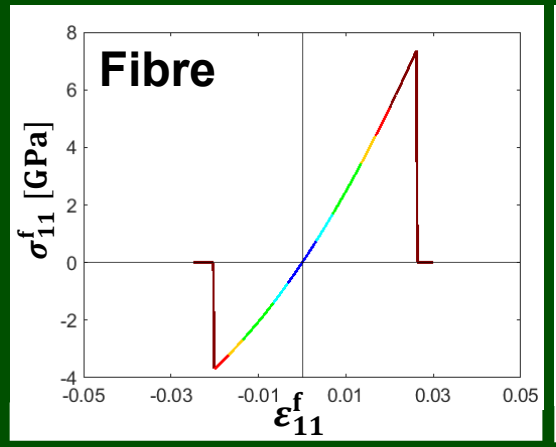
- The local fibre volume fraction of the RVE ($\mathbf{V^f}$) is calculated employing the Voronoi Network for each Z section;
- A large variation in $\mathbf{V^f}$ is observed → $\overline{\mathbf{V^f}}$**=49.2 ± 8.4 %**



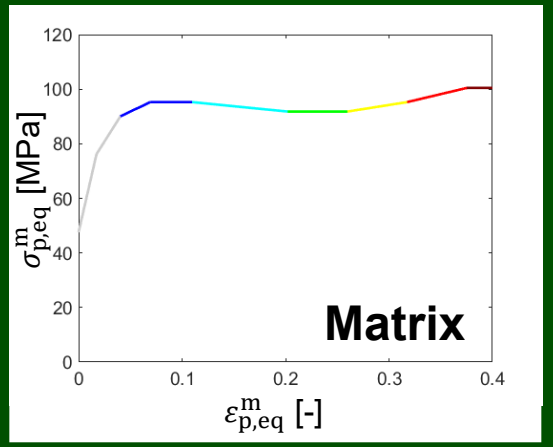
Local fibre volume fraction, $\mathbf{V^f}$

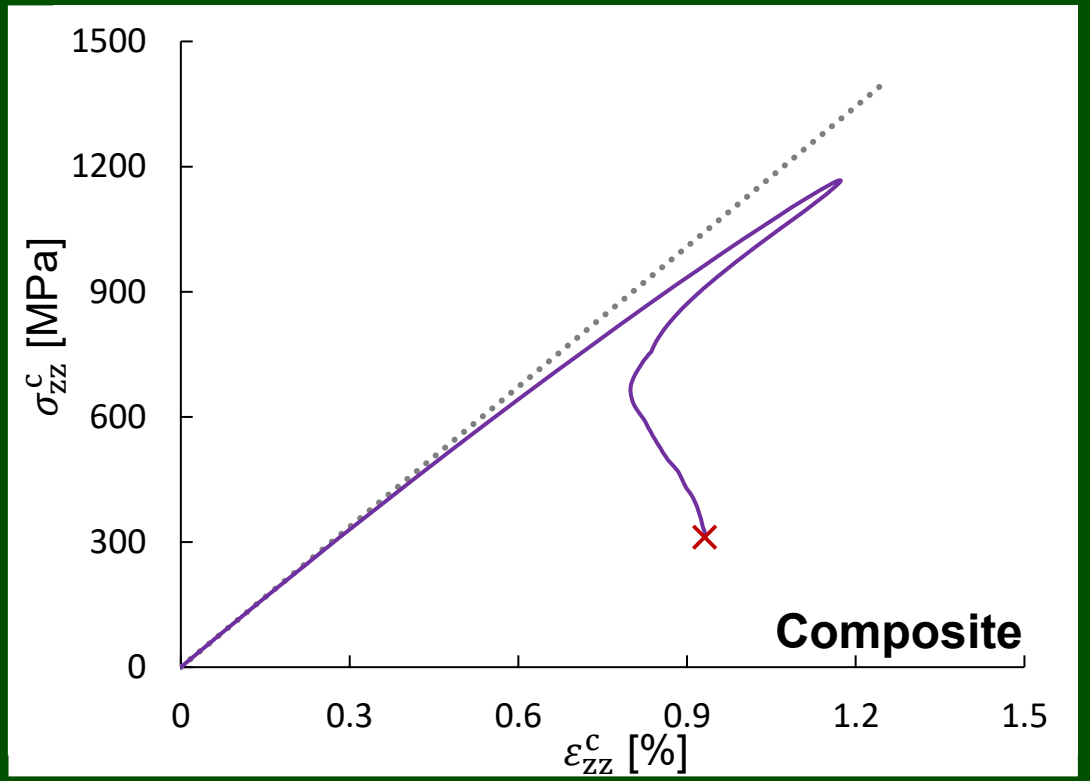


SIMULATING REAL CFRP-RVEs

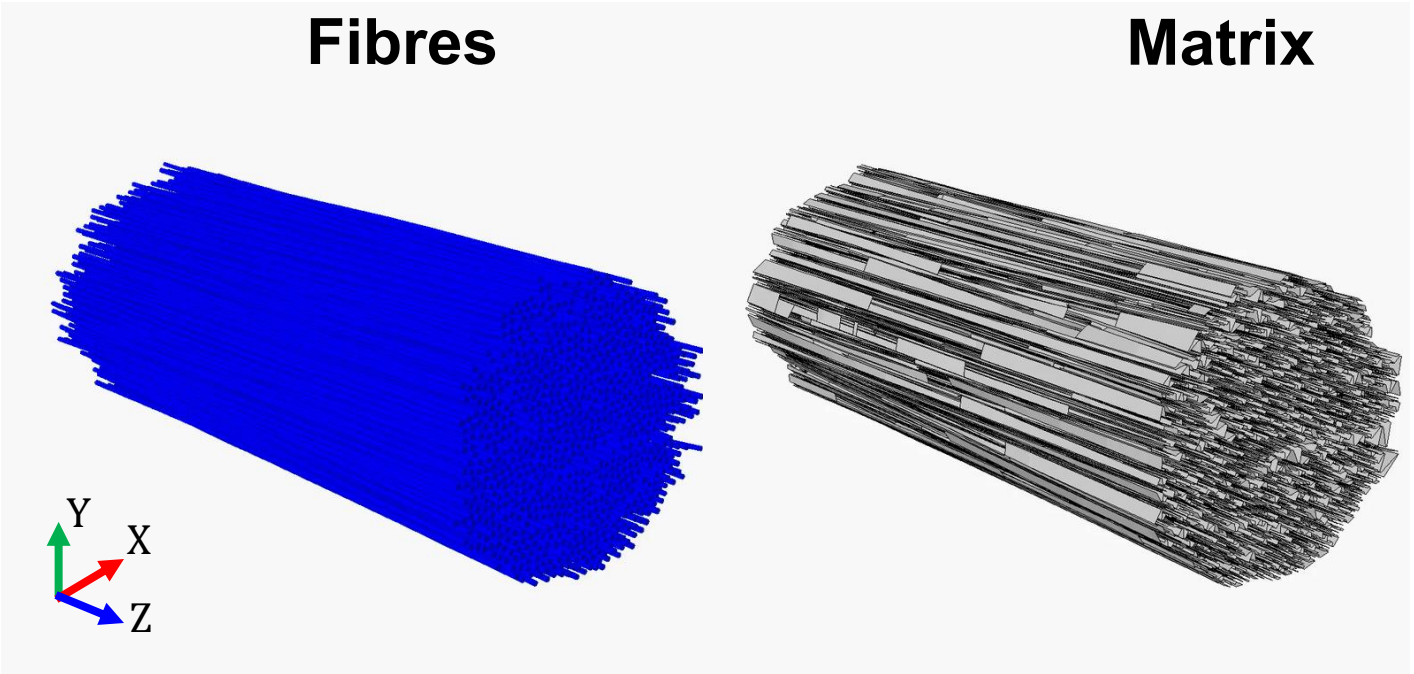


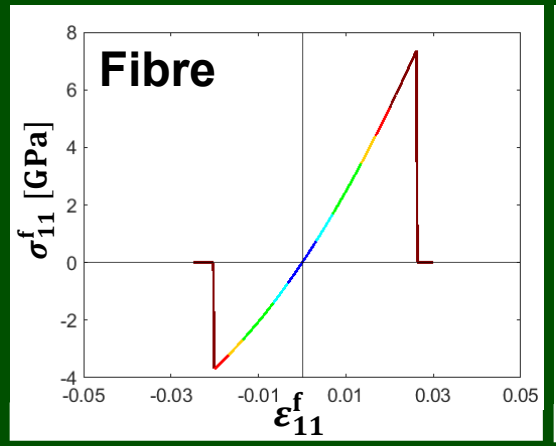
Matrix: Yield-band

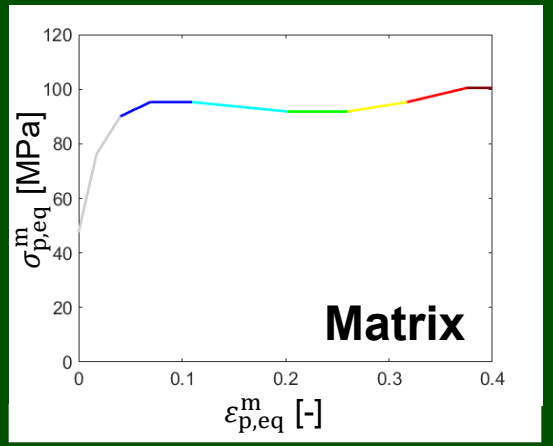


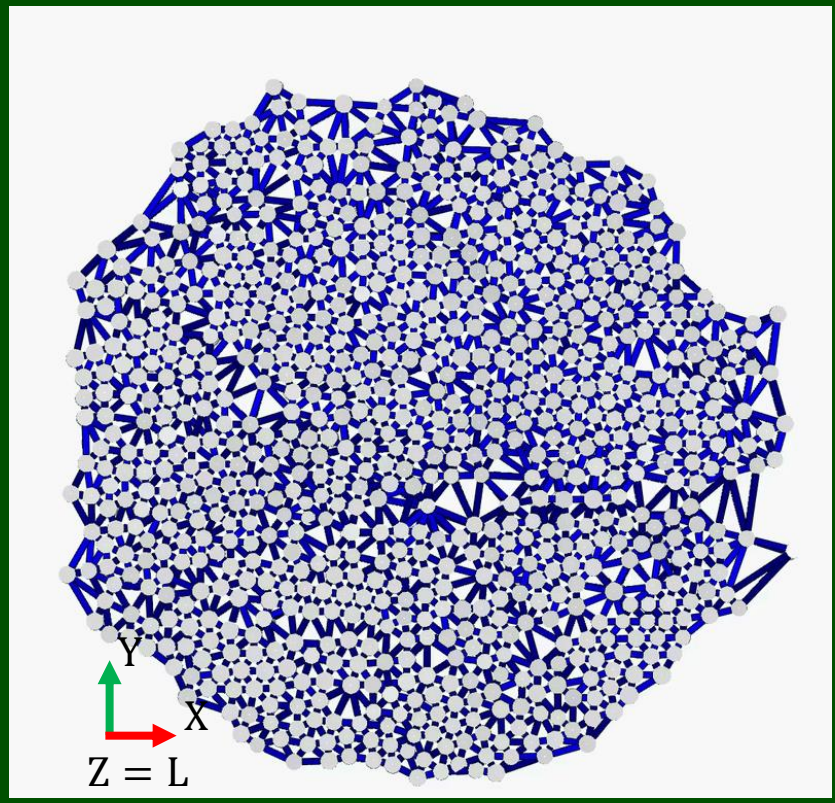


Fibres: Fibre kinking



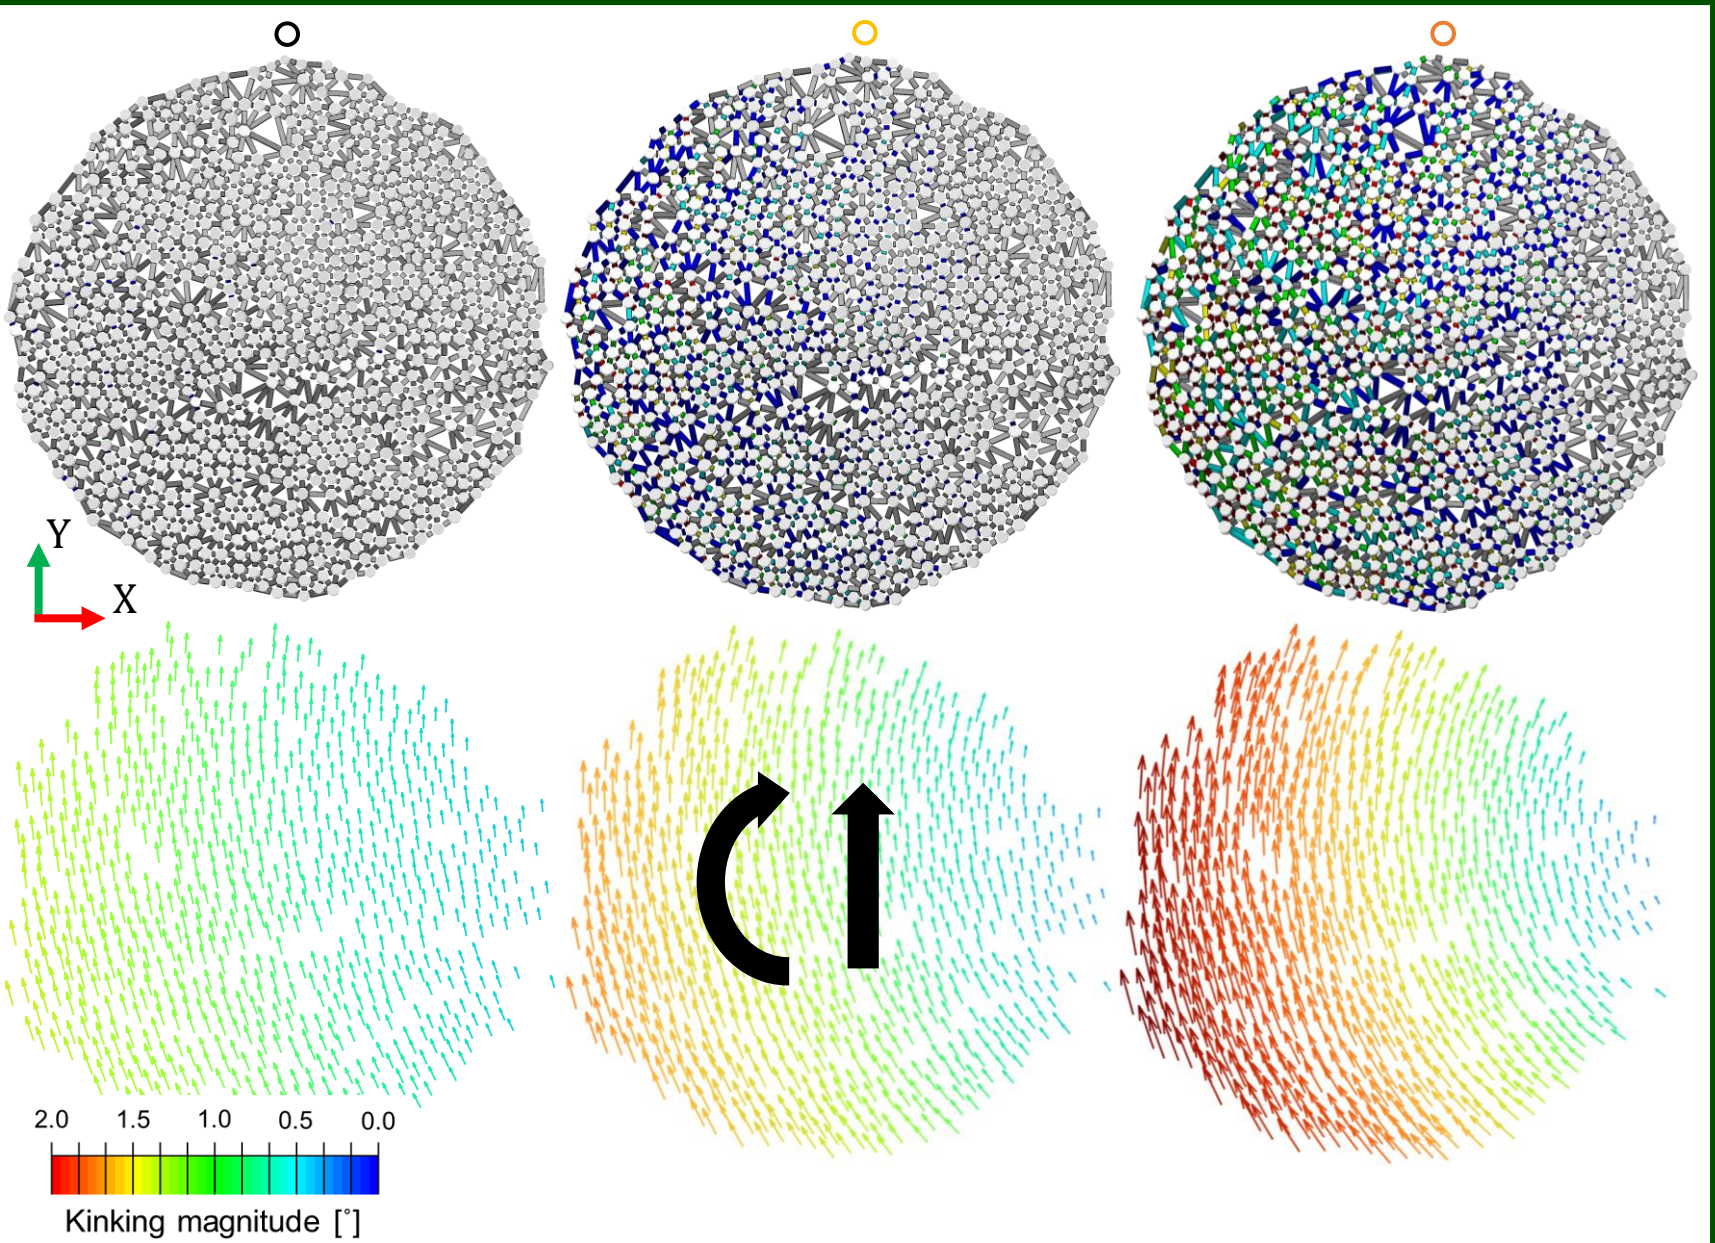


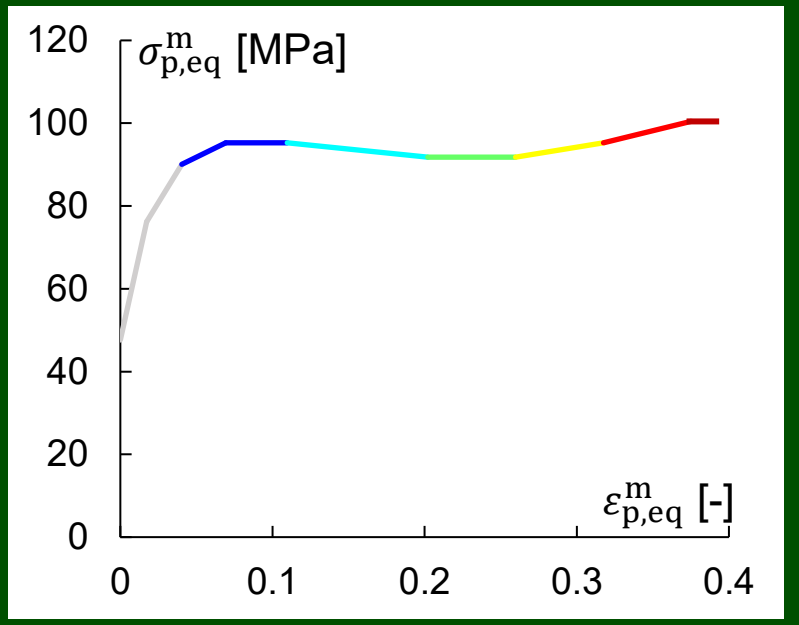


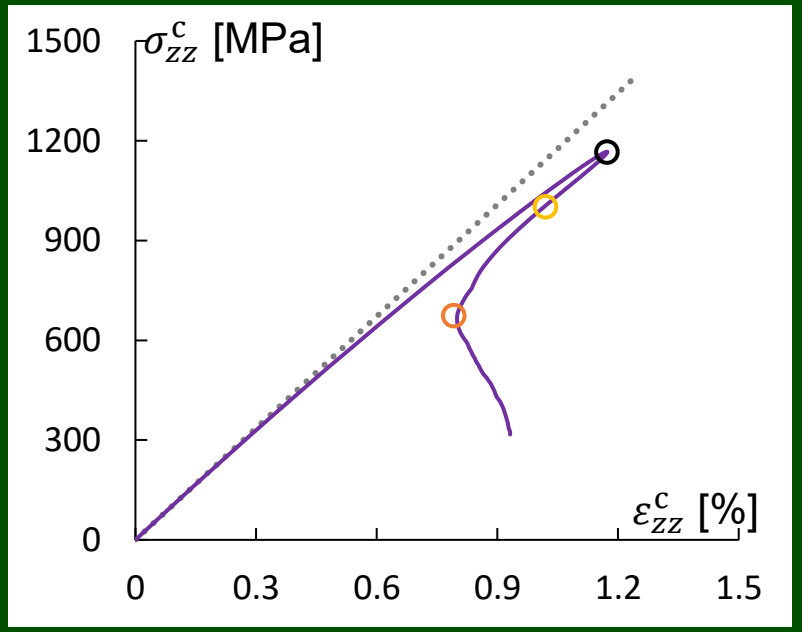


SIMULATING REAL CFRP-RVES

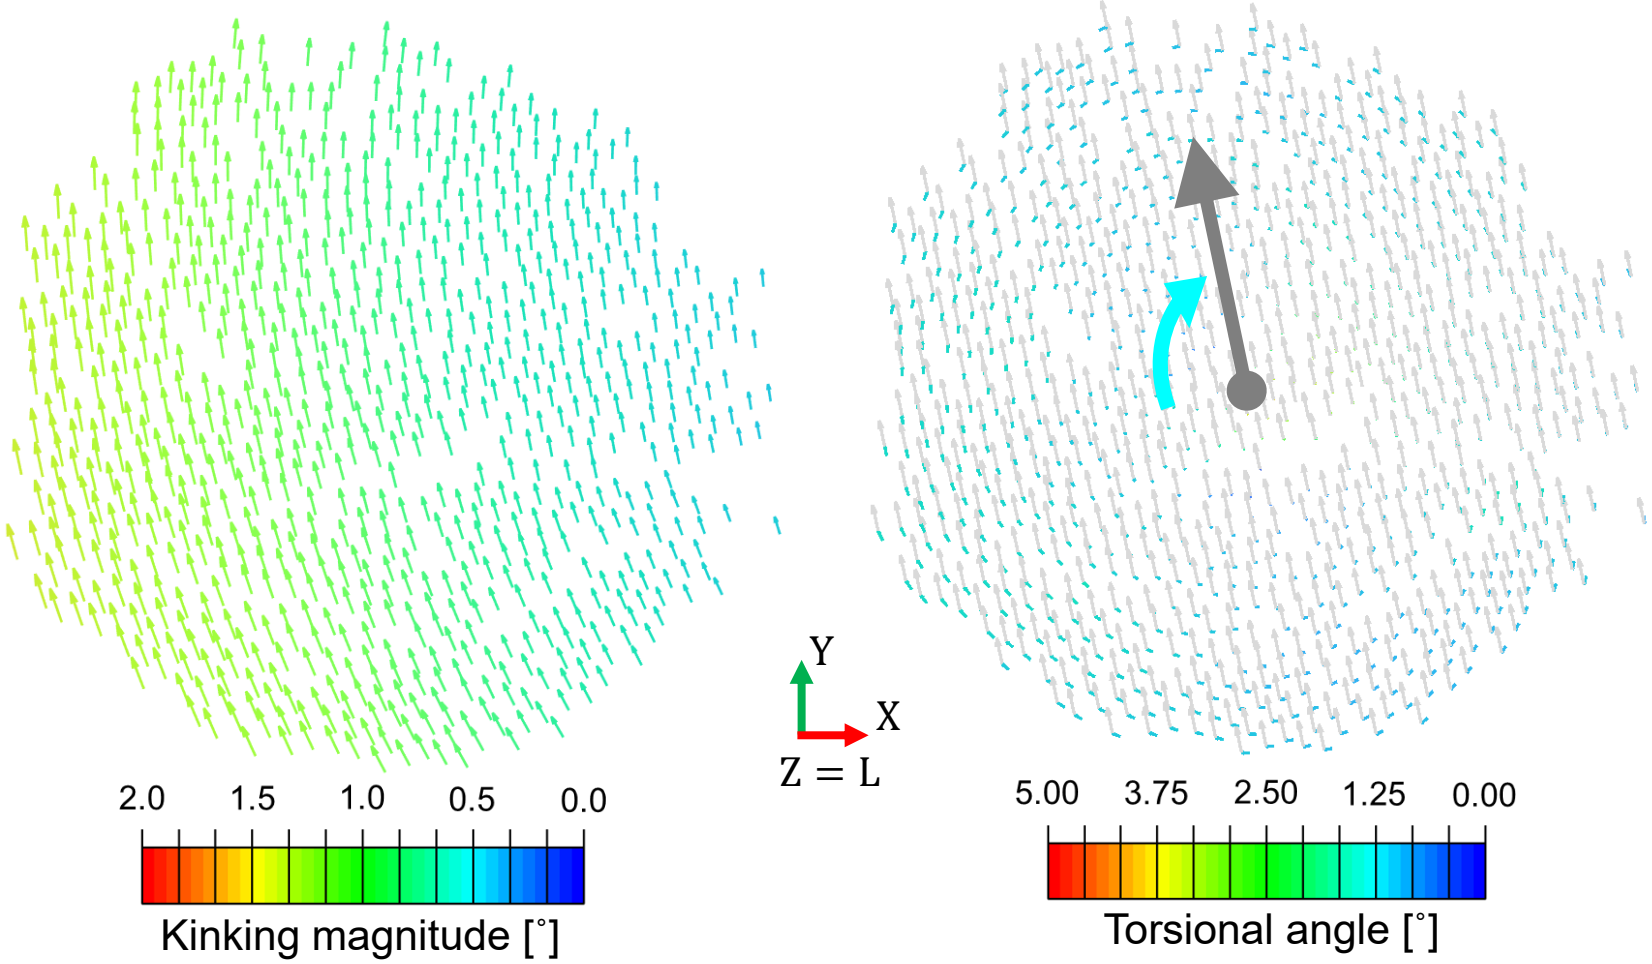
- A 3D torsional deformation occurs and becomes more pronounced during matrix yielding.
- The direction of torsion is not constant.

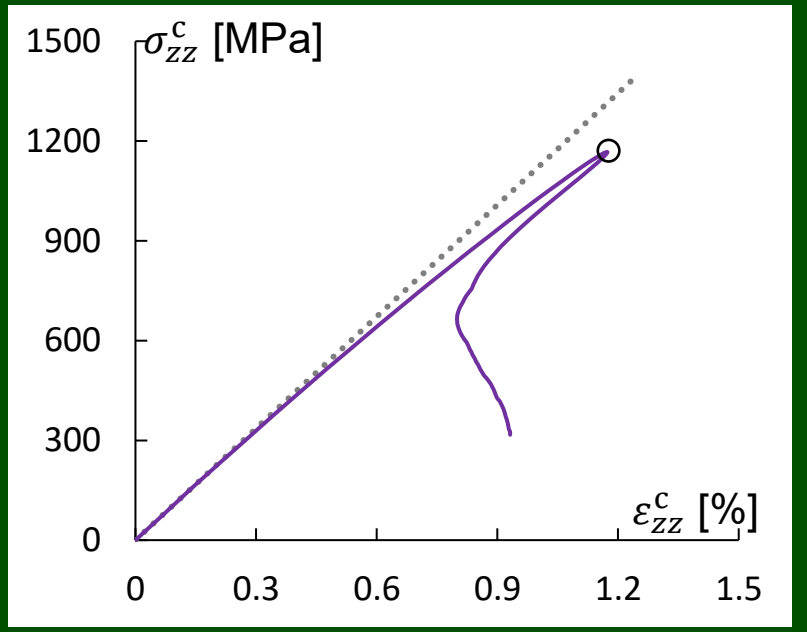






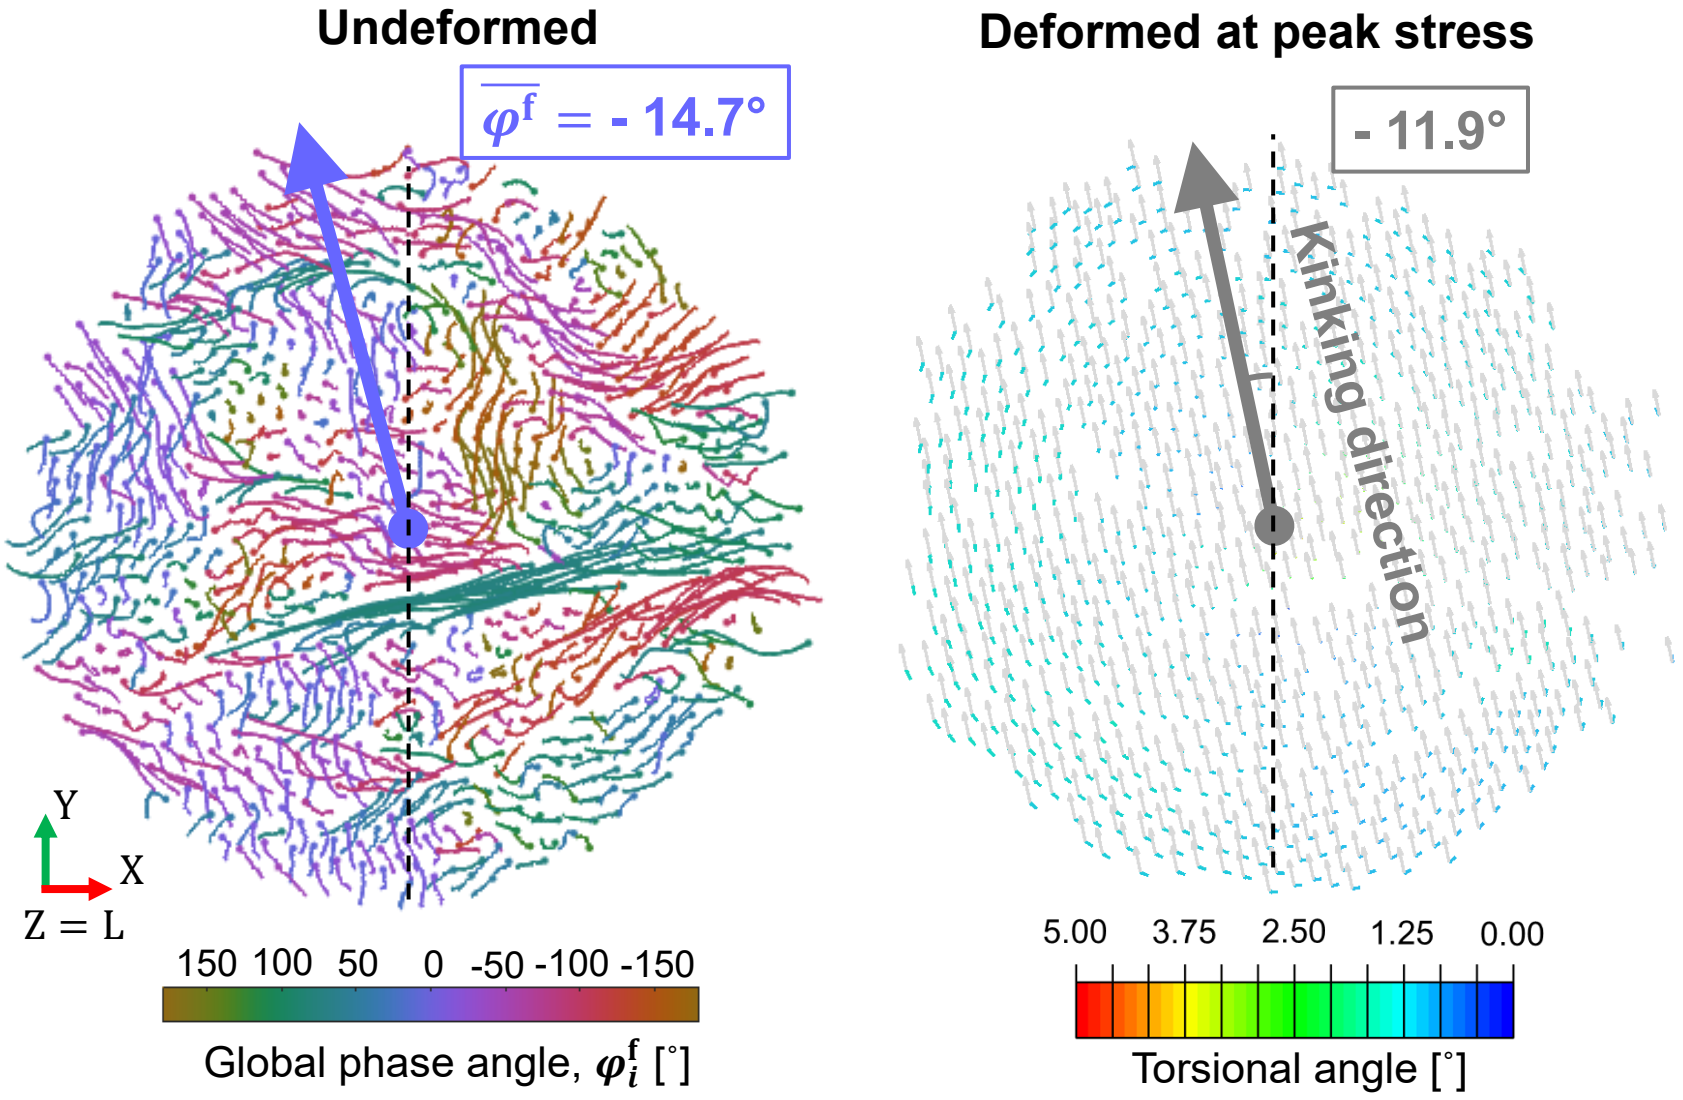
FRAME BY FRAME ANALYSIS

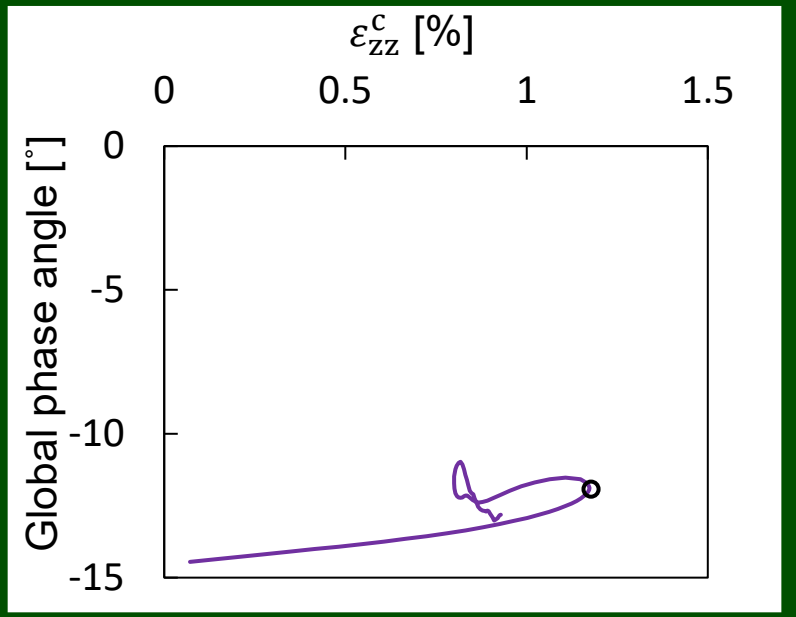




FIBRE MOTION – PEAK GLOBAL STRESS

Fibre motion can be decoupled to kinking and torsional motion
A small (~1.25˚) but perfect circular motion is observed.



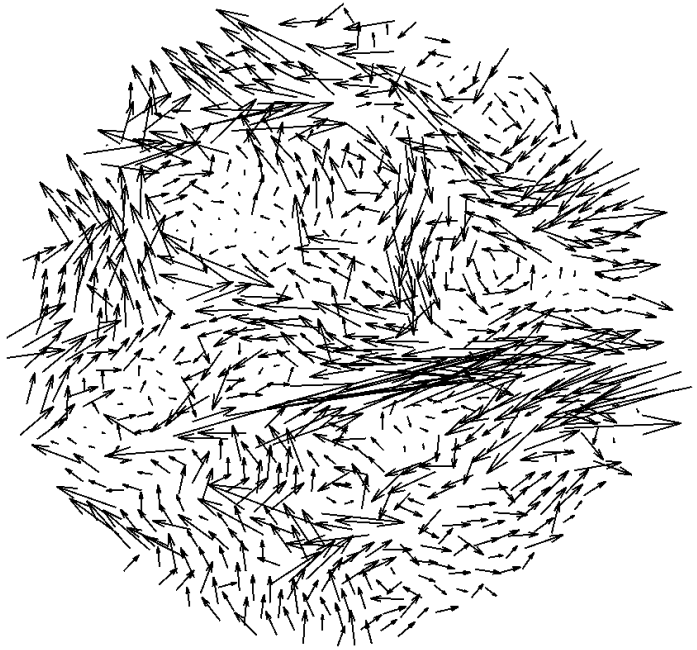


Key questions:

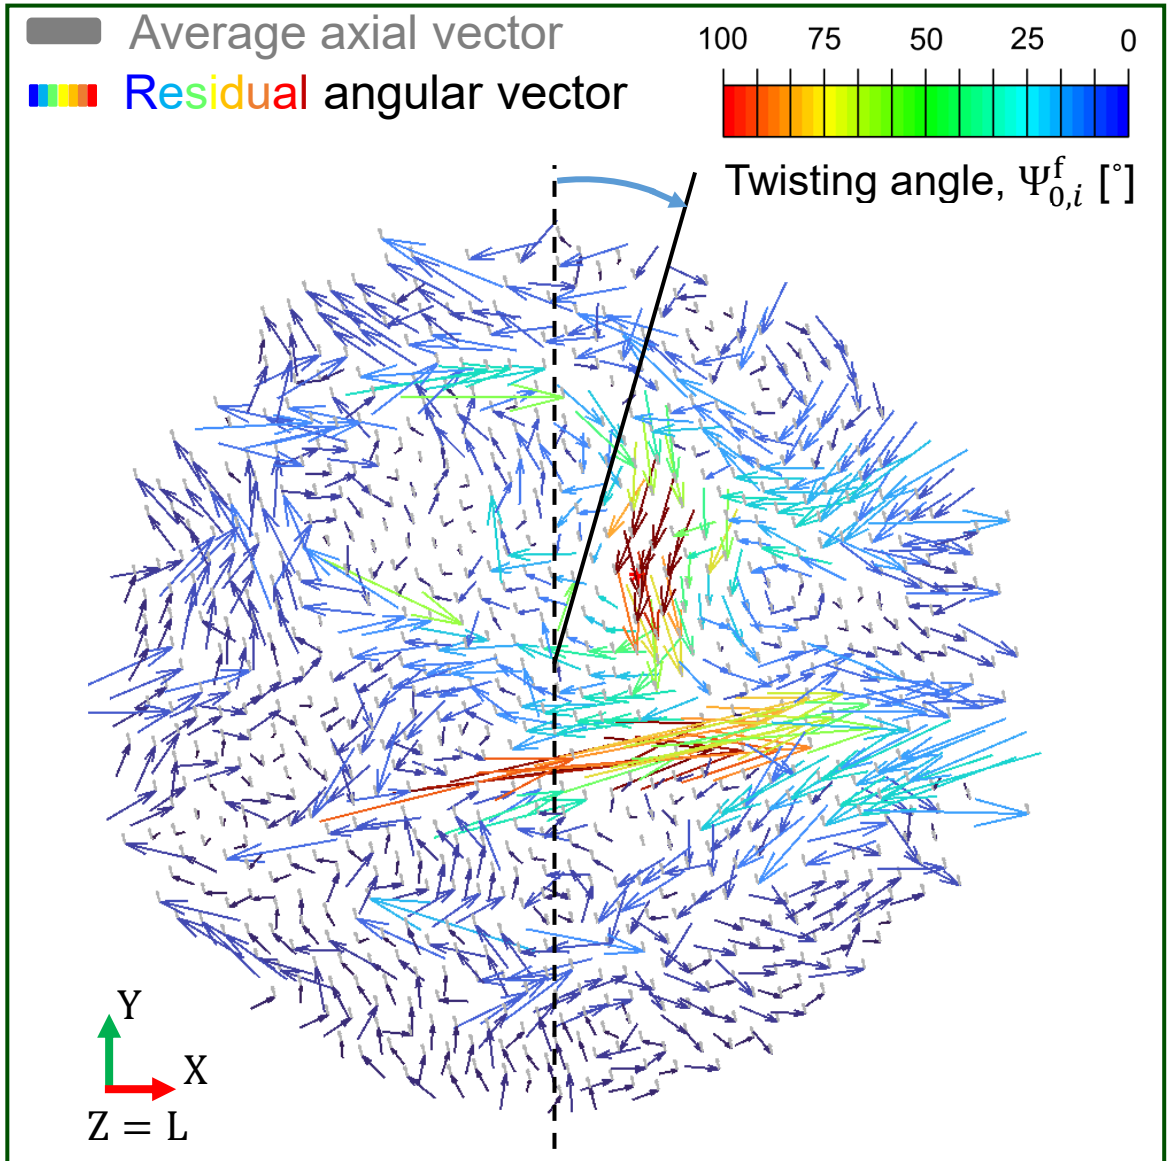
"What drives the torsional deformation?"

"Why is this even important?"

FIBRE TWISTING – PEAK GLOBAL STRESS



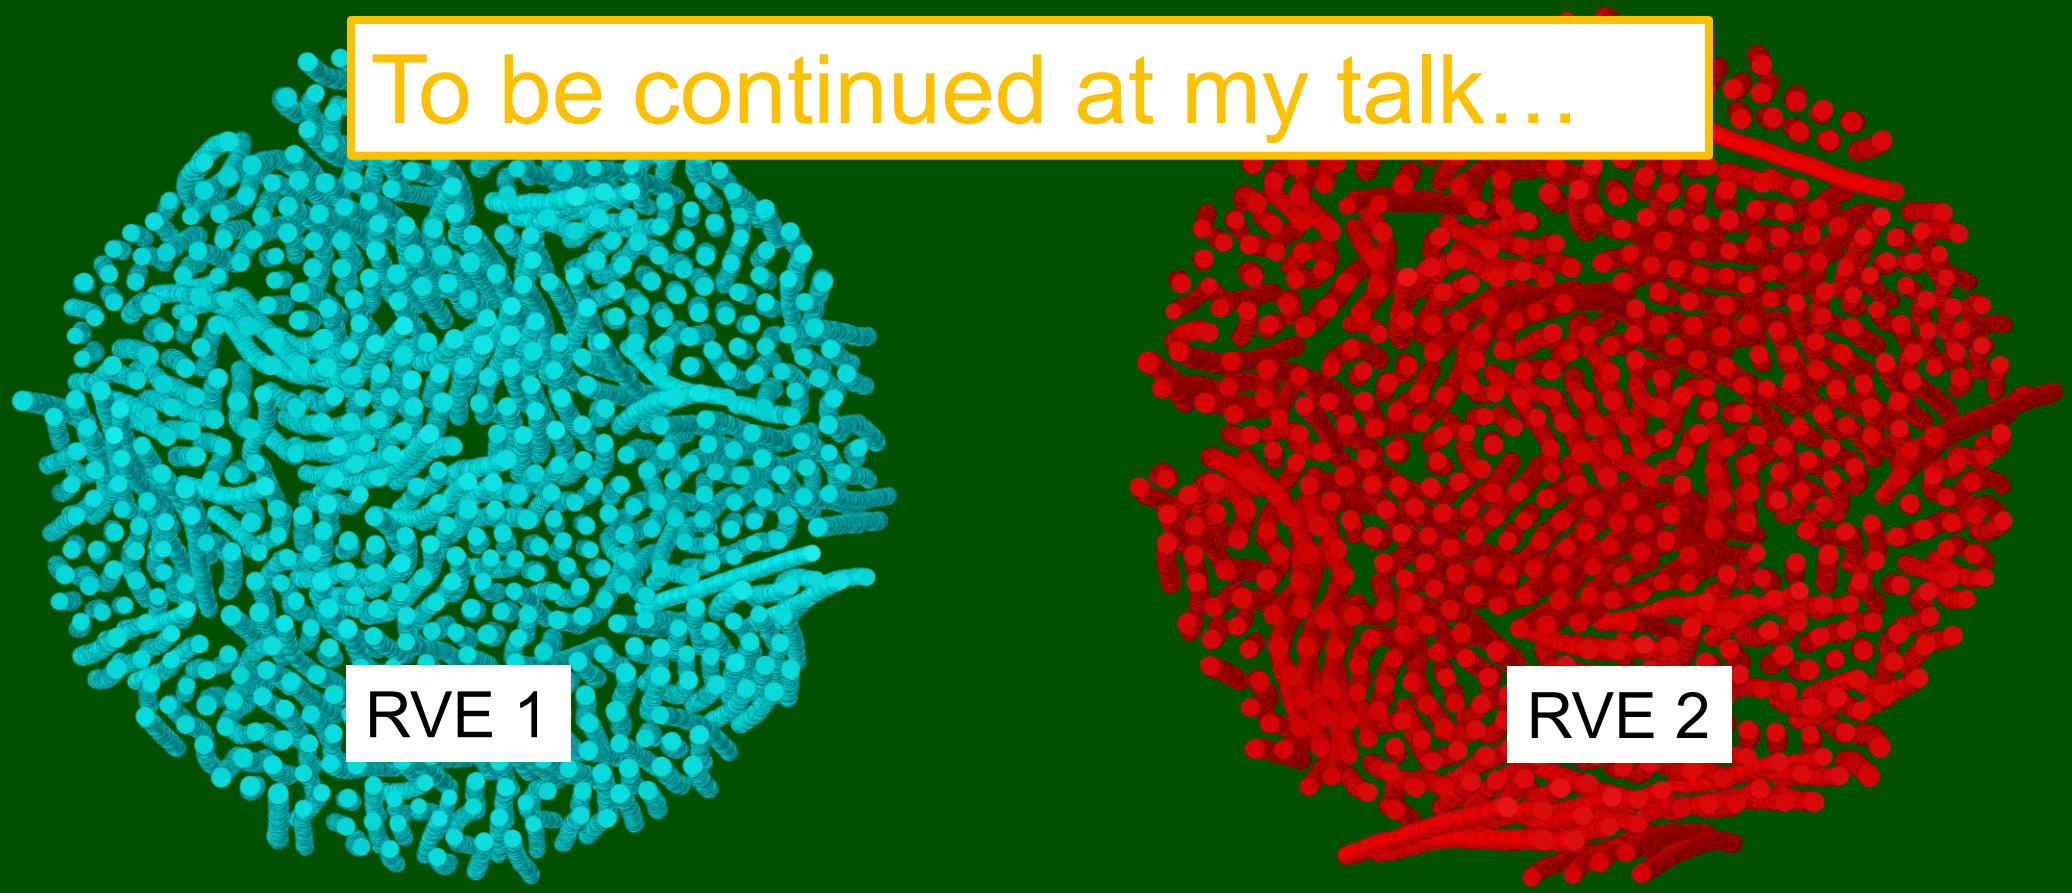
Torsional deformation potentially occurs because of the initial twist of fibre architecture!



ASSESSMENT OF FIBRE TWISTING

Decouple the mean misalignment from mean twisting of fibres.

The average twisting angle of the initial fibre architecture:



$$\overline{\Psi_0^{\mathrm{f}}} = 16.4\ °$$

Case study: Effect of real fibre imperfections

Compressive failure in RVEs with similar microstructural features

To be continued at my talk…

RVEs with 600 fibres and L =450 μm but in different region in the CT specimen

ABSTRACT

Biological materials are often reinforced by irregular structures that provide outstanding mechanical properties, ranging from high stiffness-to-weight ratios to excellent energy absorption. Unfortunately, replicating the complex design of non-periodic biological structures in synthetic materials still proves a significant design and fabrication challenge. In this context, the recent development of virtual growth algorithms, a tile-based material design tool, can pave the way to a new class of bioinspired architected materials, with superior structural properties. The algorithms can independently tailor the global topology and the local geometry of the generated structures, allowing precise control over the final mechanical properties of the generated materials. Using the algorithm, polymer composites can be designed and then fabricated by additive manufacturing, achieving control over global mechanical properties, like strength and rigidity, as well as local mechanisms of fracture nucleation and propagation, and of fracture energy dissipation. Furthermore, VGAs can be used for bioinspired materials design, by converting complex non-periodic biological structures into a network of building blocks and rules that determine their relative connectivity. Rather than creating an exact replica of the biological material, the method generates synthetic polymer composites with equivalent global- and local descriptors to the biological material, allowing for the emergence of analogous structure-to-property relationships. The method is demonstrated using the pericarp of an orange, a biological material known for its high energy-absorbing capabilities and its gradual rigidity variations. Starting from high resolution micrographs of the biological material, design guidelines for the creation of materials inspired by the orange pericarp can be extracted. Using additive manufacturing, orange-inspired polymer composites can be fabricated and tested under quasi-static and dynamic compressive loading. While the quasi-static results reveal spatially varying mechanical properties, dynamic loading experiments highlight the local mechanisms of deformation responsible for the dissipation of impact energy.

1 INTRODUCTION

Over the process of evolution, nature has generated a multitude of materials that display excellent mechanical properties, ranging from high rigidity, load-bearing capacity, resistance against the initiation and propagation of fractures, and resistance against unpredictable impacts. Using readily available resources, nature achieves these properties by fine-tuning the internal architecture of the materials, arranging reinforcing elements, such as particles, rods, and platelets, in complex and often hierarchical assemblies. Bone and mother-of-pearl are examples of such hierarchically reinforced materials, whose mechanical properties exceed those of their constituents. Nacre, another name for mother-of-pearl, is the inner lining of pen, oysters and abalone shells, and is composed of 95% of calcium carbonate platelets, in the form of aragonite. Despite aragonite is a brittle constituent, nacre displays a fracture resistance that is two orders of magnitude higher than its monolithic equivalent. This remarkable improvement in fracture resistance is due to the internal arrangement of the platelets, organized in a highly regular and periodic, brick-and-mortar configuration [1]. This structure can deflect incoming cracks on long and tortuous trajectories, dissipating enormous amounts of fracture energy. Over the last decades, efforts have targeted the reproduction, at the laboratory scale, of brick-and-mortar architectures, leveraging

freeze casting,[2], [3] magnetic alignment,[4], [5], [6] and gravitational sedimentation,[7], [8], [9] as means to control the alignment of large aspect ratio reinforcing elements in high-volume fraction nacre-inspired composites. Replicating the internal architecture of biological nacre in synthetic composites, using high-performance ceramics, like alumina or glass, has enabled the design and manufacturing of composites which display a combination of strength, stiffness, and toughness, properties that are often mutually exclusive in manmade materials.[10] Similarly to nacre, the club of the mantis shrimp and cortical bone[11], [12], [13] are other examples of materials that display periodic internal architectures, with their reinforcing elements arranged in Bouligand or in concentric lamellar domains, respectively.

Periodic bioinspired materials have been widely studied and replicated in the laboratories, due to their ease of manufacturing, through particle-assembly methods or additive manufacturing. However, nature does not always resort to highly periodic structures for its structural materials. Trabecular bone[14], [15] and the citrus fruit pericarp[16] are examples of biological structural materials that display a highly irregular, non-periodic internal architecture. Trabecular bone, also called spongy bone, constitutes the highly porous internal portion of our bones. It is formed by trabecular struts and plates, and despite its mechanical properties are highly dependent on its mineral and collagen content, it is critical to transfer stresses to cortical (or compact) bone and to carry loads, while maintaining an overall low weight.[17] Fruit pericarps are instead formidable impact absorbers. When the fruits fall from the tree, citrus fruit pericarps protect the pulp and the seeds, efficiently absorbing impact energy and leaving the fruit intact. Taking inspiration from irregular biological structural materials and replicating their complex structures using higher-performance engineering constituents is extremely relevant, from safety critical applications, where preventing damage from impacts with objects is paramount, to soft robotics and smart skins, where damage avoidance is critical for object manipulation and human-robot interactions.

Unfortunately, replicating the internal structure of an irregular biological material is complex. High-fidelity replication requires microcomputed tomography[18], [19] or investment casting.[20] Stochastic processes, like foaming,[21], [22] prove limited, because they are often unable to imitate the complex internal structure of the biological material, as well as its structural logic. In this context, computational approaches, like tile-based assembly methods and virtual growth algorithms, VGAs, can provide the level of control that is necessary to replicate the irregular arrangement of domains across lengthscales and their spatially varying density, critical aspects when replicating the internal architecture of biological materials.

In this work, I will highlight a VGA-based material design method that recently emerged as a promising platform to replicate non-periodic biological materials and to generate non-periodic reinforcing materials architectures. Starting from the pericarp of an orange, its irregular structure is discretized into a network of tiles, connected through a precise set of connectivity rules, allowing the generation of countless equivalent irregular architectures that display analogous topology, the connectivity between adjacent tiles, and geometry, the shape of the generated domains or mesostructures. The generated materials are then fabricated using additive manufacturing and tested in quasi-static and dynamic compression, with the goal of determining their architecture-to-properties relationship, along with the role of the tiles or of their assembly into mesostructures, on the global and local mechanical response of the materials.

2 METHODS AND RESULTS

2.1 Tile-based Material Generation: Virtual Growth Algorithms

Virtual Growth Algorithms (VGAs) are a powerful platform for materials design and generation that gained significant traction for their ability to develop non-periodic structures and networks through local growth processes, that have been recently exploited for the generation of reinforcing networks in composites and lattices. Introduced by Liu and co-authors, VGAs are graph-based and rely on the assembly of simplified building blocks, or tiles.[23] The assembly of the tiles occurs stochastically over a predefined grid or mesh, following a precise set of connectivity or adjacency rules, paramount to determine the tile-to-tile connections that are allowed or not. The final structure that is generated depends on the geometry and connectivity of the tiles, as well as on their availability and relative connectivity

(Figure 1). These are all inputs that are provided by the user. As a result, VGAs are extremely powerful as they allow to decouple the topology of the network, or its connectivity, and its geometry, emerging from the shape of the chosen tiles. The VGAs developed by Liu and co-authors implemented a *WaveFunctionCollapse* algorithm.[24] The structure gets formed iteratively; the algorithm evaluates eligible sites for growth and selects the location with the minimal nodal entropy for the next tile assignment. For each location, the nodal entropy depends on the total number of tiles that satisfies the connectivity rules. As the structure gets formed, structural features, also called mesostructures, emerge. Preventing the formation of mesostructures that are disconnected from the rest of the network is paramount, and connections that can lead to closed-loops are often forbidden.

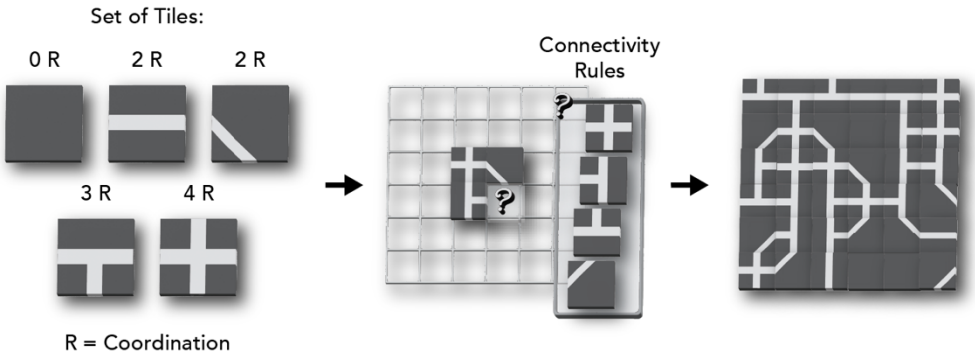

Figure 1: Sketch depicting the virtual growth algorithm and its working principle. Figure adapted from Magrini et al.[25] and Fox et al.[26]

2.2 Bioinspired Materials Generation

2-dimensional cross-sectional microscopy images of the pericarp of an orange were retrieved. The detailed procedure to cut and stain the biological tissues for histological imaging has been carefully reported by Fox and co-authors.[26] Orange pericarps display a density gradient, as they are composed by two primary regions. The external region, called flavedo, is rigid and highly interconnected. The internal region, called albedo, contains large intercellular spaces, that due to their high compressibility are responsible for the great energy absorbing capability of the pericarp (Figure 2).[27], [28]

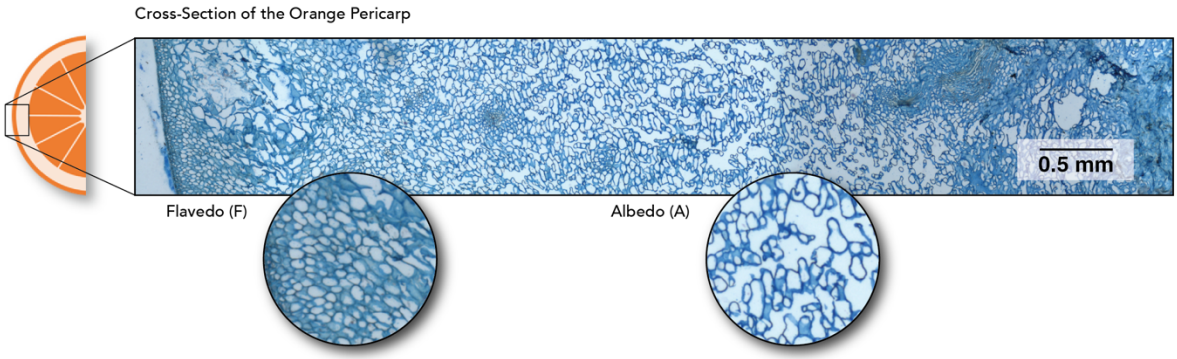

Figure 2: The orange pericarp (cross-sectional view). Microscopy image credits: M. Antonini.

Leveraging the image processing software Fiji,[29] the histological cross-section of the pericarp is first converted into a skeleton,[30] a line with a single pixel thickness. The skeleton is then subdivided into a collection of irregular tiles, using a regular grid. The size of the grid elements is chosen to ensure that no more than one node per element is included (Figure 3a). Despite each tile extracted from the biological material is irregular and different from the neighbouring ones, a conversion must be carried out, with the goal of simplifying the extracted tile into one of the five pre-selected VGA-tiles. This

conversion is performed by analyzing the perimeter of the irregular tiles, and assigning a value to each intersection of the branches with the external perimeter. Using binary code values, 1, 10, 100 and 1000, representing left, top, right and bottom respectively, it is possible to uniquely assign a simplified VGA-tile equivalent to each irregular element extracted from the starting image. Each simplified VGA-tile is defined by its coordination number, the number of connections it forms, and its orientation (Figure 3b).

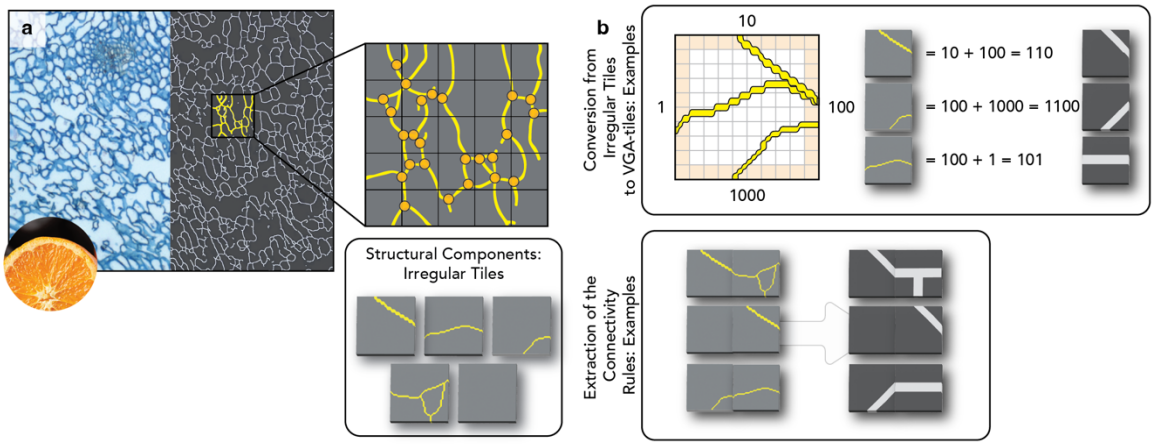

Figure 3: The conversion method. a) Image processing to extract the irregular tiles from the skeletonized image. b) Conversion in simplified VGA-tiles and relative connectivity rules (examples). Figure adapted from Fox et al.[26]

Once all grid elements have been converted into simplified VGA-tiles, the connections between VGA-tiles are analysed, with the goal of determining the connectivity rules that allow the reconstruction of the orange peel. As expected, the composition, intended as the frequency of each simplified VGA-tile, as well as the rules that determine the connectivity between the tiles, both depend on the region of the pericarp that is studied. For example, the flavedo region of the pericarp features a higher frequency of 3- and 4-coordinated tiles than the albedo region. This is representative of the higher density and interconnectivity of the external layer of the pericarp. On the other hand, the albedo region features a higher frequency of empty tiles, due to the presence of larger intercellular spaces in the inner portion of the peel (Figure 4a). Analogous conclusions can be drawn from the extracted connectivity rules. The flavedo-inspired portion features a higher frequency of 3-to-3 coordinated tiles and 3-to-2 coordinated tiles connections than the albedo-inspired portion, while the empty-to-empty tile connections are more representative in the albedo than in the flavedo (Figure 4b).

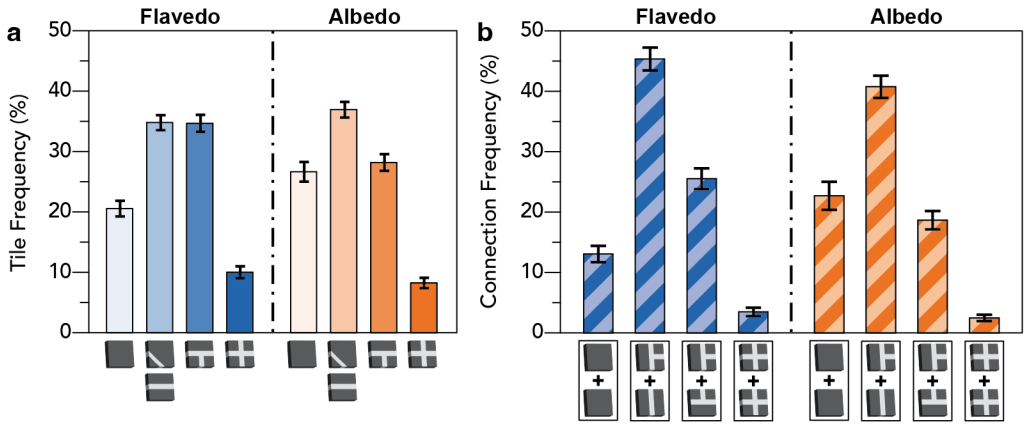

Figure 4: Extracting tile composition and connectivity rules from the orange pericarp. a) Tile frequency. b) Examples of the connectivity rules. Figure adapted from Fox et al.[26]

2.3 Material Fabrication

With the tile frequencies and connectivity rules extracted from the flavedo and albedo portions of the pericarp, the virtual growth algorithm is used to reconstruct flavedo-inspired (F) VGA-samples and albedo-inspired (A) VGA-samples, with a size of 50-by-50 tiles. As the flavedo accounts for 10-20% of the overall peel thickness, and the albedo for the remaining 80-90%, the generated structures are then combined, recreating the full-pericarp (P) VGA-samples (Figure 5). To carry out the mechanical characterization of the structures, samples with a height of 2.5 cm, width of 2.5 cm and thickness of 1.0 cm were manufactured using a polyjet printer (Stratasys Objet500 Connex3), using two commercially available photoresins, Stratasys VeroWhite Polyjet Resin (VW) and Stratasys TangoBlack Polyjet Resin (TB). VW, a stiff viscoelastic polymer, is used for the reinforcing network, while TB, a soft elastomeric polymer, is used for the matrix, filling the gaps within the network. Accounting for the limitation of the polyjet printer, a tile size of 0.5 mm by 0.5 mm was chosen, with individual network struts of 0.1 mm. In this study, contrary to the biological material, generating a two-phase material was preferred, leading to polymer-composite specimens suitable for mechanical testing and for mapping of strains through 2D digital image correlation (DIC). The mechanical properties of the resins used in this study fall within the ranges reported in literature. [31], [32]

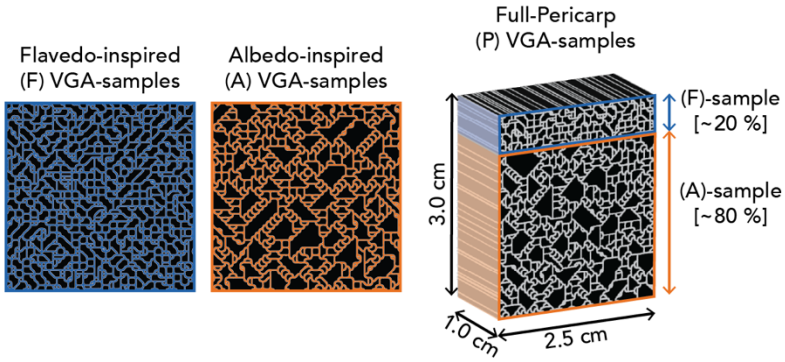

Figure 5: VGA-generated samples: (F), (A), and (P). Flavedo-, Albedo-, and full-Pericarp inspired samples. Figure adapted from Fox et al.[26]

2.4 Quasi-static Mechanical Testing: Compression

Quasi-static mechanical testing was carried out using a universal testing machine (UTS) (Instron E3000, Instron, USA), with a 5kN load cell equipped with flat compression plates, at a rate of 1mm/min and up to a 10% compressive strain. Three set of samples have been tested: flavedo-inspired (F) VGA-samples, albedo-inspired (A) VGA-samples, and full-pericarp (P) VGA-samples. From the stress-strain curves, the modulus of elasticity was extracted. As one could expect from their biological counterparts, the F-samples proved 116% stiffer than the A-samples, while P-samples displayed intermediate values (Figure 6).

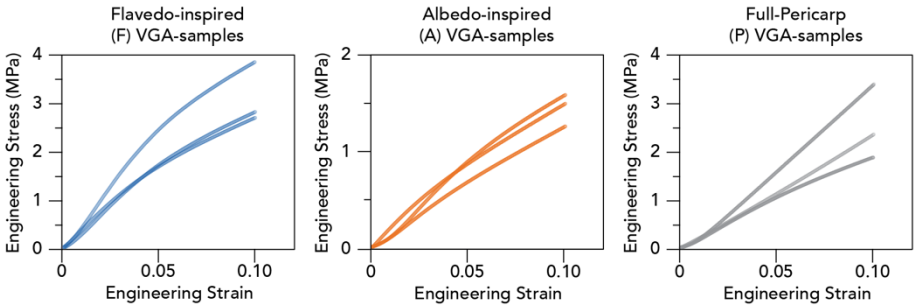

Figure 6: Stress-strain curves recorded on flavedo-inspired (F) VGA-samples (left), albedo-inspired (A) VGA-samples (middle) and full-pericarp (P) VGA-samples (right). Adapted from Fox et al.[26]

To determine the role of local mesostructures (the local domains formed by adjacent VGA-tiles) during compression loading, 2D DIC was performed to track the strain field. The composites were spray painted using a flat white paint and speckled with flat black paint, generating a speckle size of 0.1 to 0.3 mm. Commercially available DIC software (VIC 2D, Correlated Solutions, USA) was used to reconstruct the Lagrangian strain field (subset size 35, step size 2). Through DIC it was possible to elucidate the strain distribution during compressive loading. Up to 10% global compressive strain, F-samples displayed uniform strain fields, without exceeding 15% strain at the local scale (Figure 7a). This is due to the extensive presence of stretching-dominated mesostructures, formed by high-coordination tiles (3- and 4-coordinated tiles). On the contrary, A-samples displayed highly localized strain field, with mesostructures reaching up to 30% local strain, at an applied 10% global compressive strain (Figure 7b). This was observed in large and highly compressible mesostructures, composed of consecutive low-coordination tiles (2-coordinated tiles and empty tiles). These mesostructures often featured concave edges and 2-coordinated tiles arranged diagonally in series, which can rotate, during deformation, around 3-coordinated nodes.

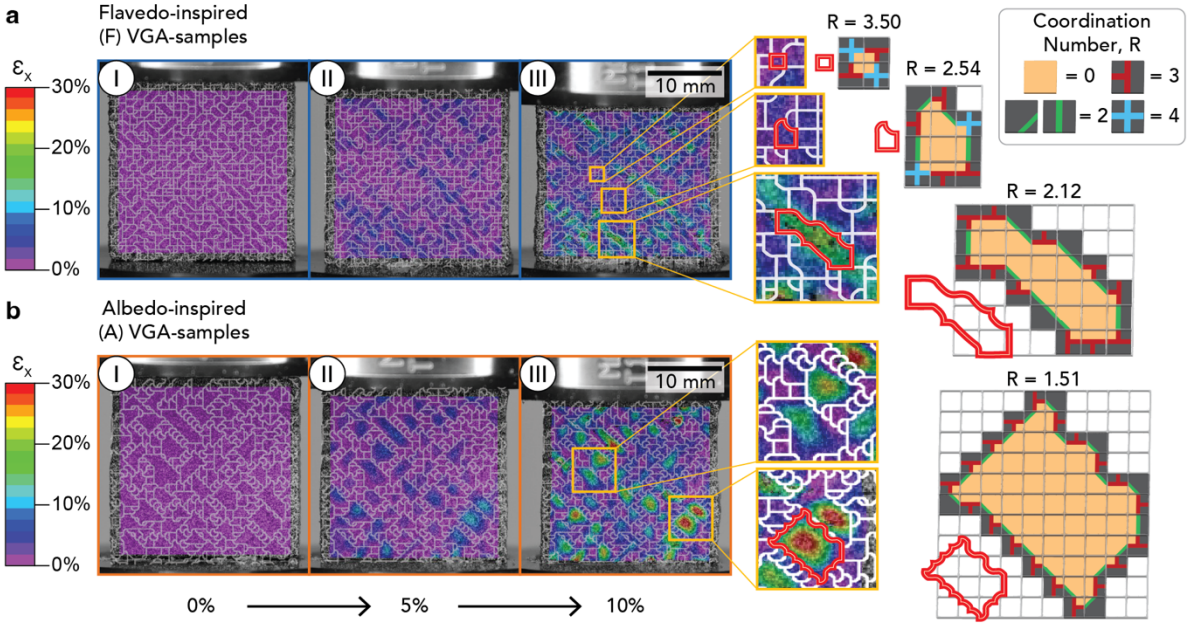

Figure 7: Compression tests. 2D DIC recorded at 0%, 5% and 10% global strain on flavedo-inspired (F) VGA-samples (a) and albedo-inspired (A) VGA-samples (b). Figure adapted from Fox et al.[26]

2.5 Dynamic Mechanical Testing: Compression

Finally, the energy absorption capabilities of the samples were characterized using drop tower tests conducted at a strain rate of ~100 s^{-1}. For the purpose, a drop tower of 3 m height and 2.7 cm inner diameter and a cylindrical striker of 10 cm height, 2.5 cm diameter and a 400 g mass were chosen. The experiments were recorded using a high-speed camera (Phantom v1610, Vision Research, AMETEK, USA), triggered by a photodiode mounted in proximity of the tower's lower opening, set to an acquisition rate of 50k fps at a resolution of 512 pixel by 512 pixel (Figure 8a). Analysing the recorded videos with the image processing software Fiji,[29] the time in contact between the striker and the sample, along with the coefficient of restitution (*e*), defined as the ratio between the velocity of the striker before and after the impact with the sample, were extracted (Figure 8b and 8c). The results were compared to periodic honeycomb (H) and graded honeycomb (gH) samples having the same volume fraction of reinforcing phase. Among all the conducted tests, the flavedo-inspired (F) VGA-samples displayed the highest *e* and the shortest time in contact with the striker. On the other hand, the full-pericarp (P) VGA-samples, similarly to the albedo-inspired (A) VGA-samples, displayed a 7.5% and 10% lower *e* than the H- and gH-samples respectively. In parallel to a lower coefficient of restitution,

(P)- and (A) VGA-samples display a 16% and 25% longer time in contact with the striker with respect to H- and gH-samples, respectively. Such a striking difference in energy absorption performance is due to the reinforcing architecture of the materials. There is indeed a correlation between the mesostructures size and shape, and the deformation they are subjected to during compressive loading. For example, the presence of large, concave mesostructures formed by low coordination tile assemblies, often observed in the albedo-inspired (A) VGA-samples (and therefore in the full-pericarp (P) VGA-samples), leads to less constrained strut bending and buckling. These mechanisms of deformation, already observed in the quasi-static compression loading tests, are analogous to what is observed in the biological material counterpart, where large and compressible intercellular spaces in the orange albedo are responsible of dissipating most of the energy caused by unpredictable impacts, like when the fruit falls from the tree.

3 CONCLUSIONS

In summary, using computer-aided tile-based material design methods, it is possible to extract the topology and the geometry of irregular biological materials, like the pericarp of an orange, and recreate their structure-to-properties relationship in bioinspired equivalents. The bioinspired structures are fabricated using multi-material additive manufacturing and tested in quasi-static and dynamic compression. Using DIC and image analysis, it is possible to analyze the mechanisms of deformation that occur at the local scale, correlate them to the global mechanical performance of the materials and to the mesostructures that emerge during sample generation.

ABSTRACT

In classic discontinuous silica-epoxy nanocomposites, strong matrix-reinforcement interactions may enhance toughness by introducing new energy absorption mechanisms. These silica-epoxy interactions are mediated either directly through inherent silica silanol groups or *via* tethering of reactive amine or epoxide groups. Recently, bicontinuous silica-epoxy nanocomposites have been formed by backfilling monolithic silica aerogel with epoxy resin. The continuous reinforcement network provides long-range load transfer, inherently uniform silica distribution, and synergistic interlocking effects. When preparing these nanocomposites, the silica aerogel is typically hydrophobised to prevent moisture absorption which can lead to shrinkage or cracking prior to backfilling. However, the aggressive reagents used (typically trimethylchlorosilane,TMCS) give almost complete conversion of silanol groups, leading to an inert surface which forms only very weak interactions with epoxy resin. Under shear loading, this poor interface leads to brittle failure at relatively low strain. Mild hydrophobisation agents such as dimethyldimethoxysilane (DMDMS), instead give incomplete conversion of silanols to yield a "part-methylated" surface which, while providing some hydrophobic character, forms a stronger silica-epoxy interface. Furthermore, as it does not form acidic byproducts, which would otherwise catalyse ring opening, DMDMS may be used alongside (3-glycidyloxypropyl)trimethoxysilane (GPTMS) to give a "part methylated + epoxidated" surface. Across a broad range of silica aerogel densities, both surface types give significantly lower moisture content ("part methylated" ≈ 2.6 wt.%, "part methylated + epoxidated" ≈ 1.4 wt.%) when compared with unmodified silica aerogel (≈ 9.8 wt.%). These values are greater than those of TMCS-methylated silica aerogel, however, in contrast to unmodified silica aerogel, uncracked monoliths are formed in all cases.

1 INTRODUCTION

For unidirectional carbon fibre composites (UD CFRPs), conventional polymer matrices provide insufficient shear support against fibre micro-buckling in compression. Consequently, the compressive strength of UD CFRPs is typically less than 60% of their tensile strength. Commercial nanosilica reinforcements improve matrix shear strength and modulus leading to enhanced fibre composite compressive strength [1]. These nanocomposite matrices typically contain dispersed discontinuous nanofillers with no direct load transfer within the reinforcement phase. Furthermore, above very modest loadings (6 SiO_x vol.%) nanofiller agglomeration leads to decreased compressive performance in unidirectional fibre composites. Bicontinuous nanocomposites feature a macroscopically continuous reinforcement which interlocks with the matrix phase to give synergistic mechanical property enhancement [2]. Silica-epoxy bicontinuous nanocomposites have been formed with loadings of up to 10 SiO_x vol.% by backfilling a continuous silica reinforcement (silica aerogel) with epoxy resin [3]. These novel materials display distinct super-linear power law loading-property relationships owing to fractal branching of the silica network. In contrast, the equivalent trends for discontinuous nanocomposites are distinctly linear or sub-linear [4-6]. At present, modulus enhancement in silica-epoxy bicontinuous nanocomposites is curtailed by low reinforcement loadings and a weak matrix-reinforcement interface. To aid aerogel processing (decreased network shrinkage and moisture absorption), reinforcement networks were previously formed with fully-methylated surfaces. However, this functionalisation precludes covalent bonding at the matrix-reinforcement interface. In particulate systems, specimens with inert interfaces have significantly worse strength, stiffness and toughness *vs*. otherwise-equivalent specimens with covalently-bound interfaces [7]. Commercial discontinuous nanosilica reinforcements feature reactive surface silanol groups for improved toughness through strong covalent bonding with the epoxy resin matrix [8, 9]. Here, novel part-methylated silica aerogel surface chemistries are developed to balance the processing benefits of methylation with the superior mechanical properties of reactive surfaces.Two new surface types are introduced: “part-methylated” and “part-methylated + epoxidated” (Figure 1). The former features reactive silanol groups while the latter has silanols and additional tethered epoxide groups. Both surfaces were partially methylated with dimethyldimethoxysilane (DMDMS), a mild methylating agent. Unlike trimethylchlorosilane (TMCS) – a classic methylating agent for silica aerogel, DMDMS produces no acidic byproducts and is therefore well-suited for co-functionalisation in the presence of acid-sensitive epoxide groups. Synthesis of the silica skeleton is described in [10]. To confirm compatibility with a range of silica content, the tetramethylorthosilicate (TMOS) volume fraction in the sol-gel precursor was varied for measurement of aerogel physical properties relevant to epoxy backfilling.

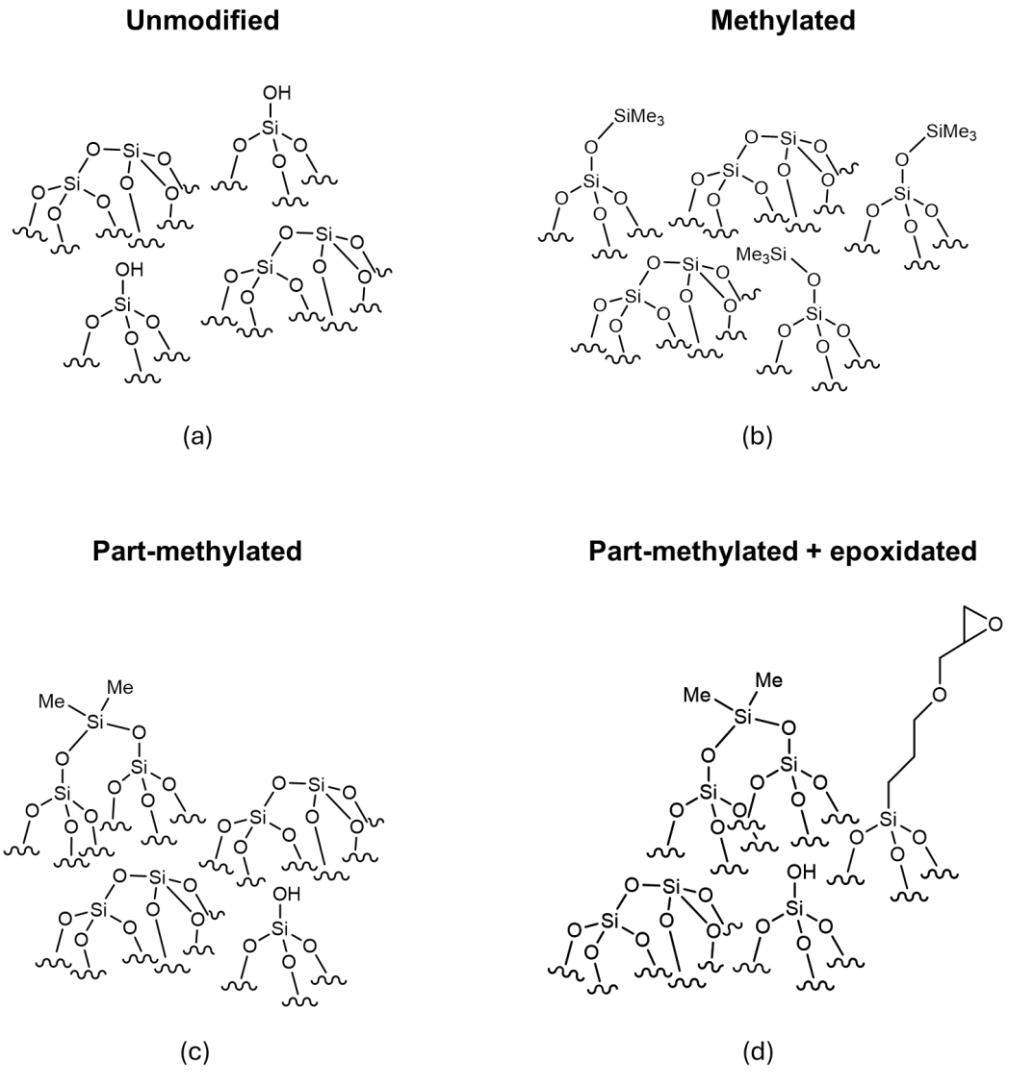

Figure 1. Chemical structures of silica aerogel surfaces discussed in this paper.

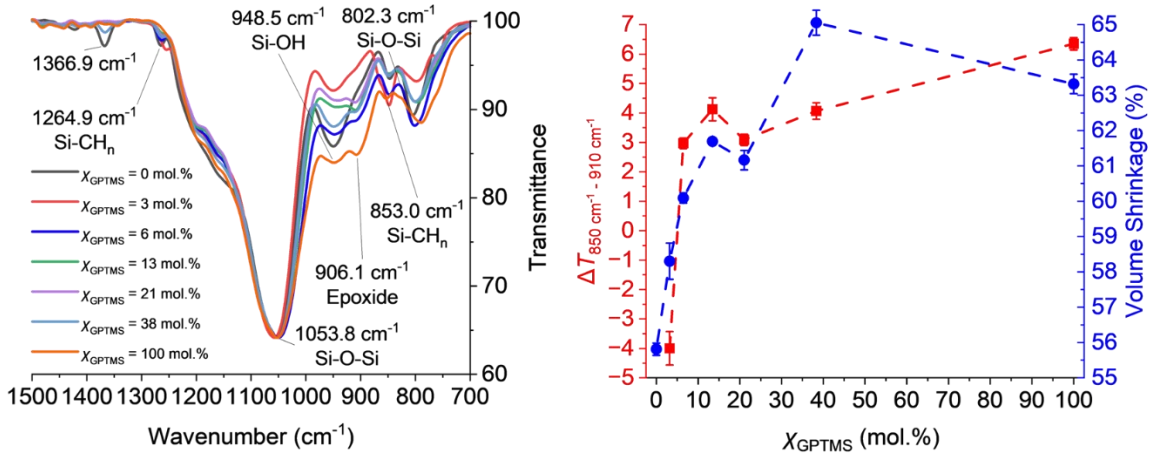
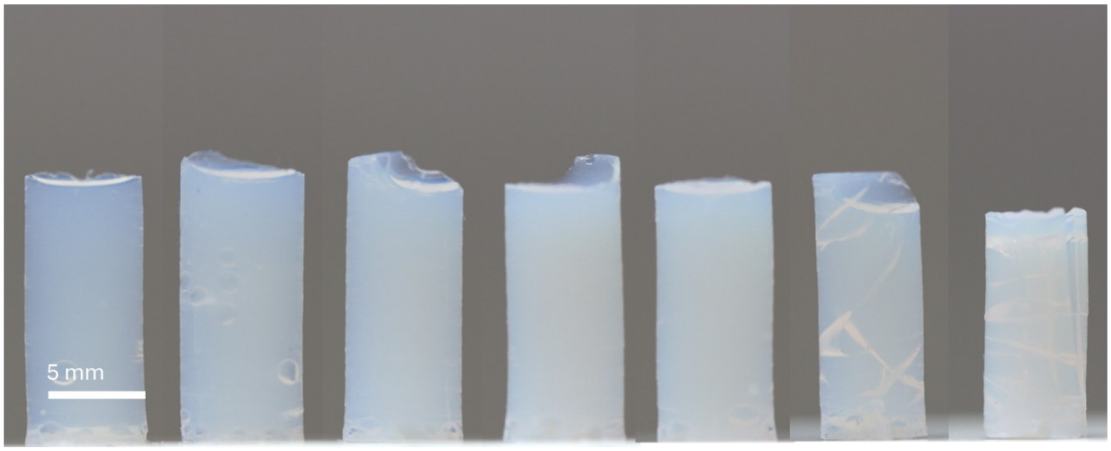
2 SURFACE MODIFICATION METHODS



Part-methylated and part-methylated + epoxidated silica aerogel monoliths were formed by functionalisation of TMOS-derived wet silica gel monoliths. Cylindrical monoliths (d = 6 mm, l = 15 mm) were prepared by stirring the appropriate mixture of TMOS, water and ethanol (TMOS volume fraction, φ_{TMOS} = 0.23) for 3 h at 25 °C before transfer of the liquid sol to high density polyethylene moulds [3]. After gelation, samples were aged in the supernatant for 4 days at room temperature to consolidate the silica network through increased inter-particle crosslinking. After demoulding, samples were transferred to ethanol prior to functionalisation. After functionalisation, samples were exchanged first into ethanol and then acetone before drying. Samples were dried from supercritical CO_2 to minimise the capillary forces that drive pore collapse and overall sample shrinkage. Infra-red spectroscopy was used to identify surface-bound groups. All IR spectra are normalised to the transmittance of the largest Si-O-Si (siloxane) signal (1050 cm^{-1} – 1080 cm^{-1}) at an arbitrary transmittance (T) value of T = 64.2. This signal has been chosen as it represents the bulk amorphous silica (SiO_x) only and hence will not change as a result of new siloxane linkages formed during surface modification [11]. Consequently, by



using the same feedstock aerogel, intensities of all other relevant signals may be compared semi-quantitatively between candidate surfaces to contrast relative loadings of various surface groups.

Table 1. IR signals relevant to the functionalisation of silica aerogel surfaces [11].

Bond	Si-O-H	Si-C-H	Si-O-Si	Si-O-C-H	Epoxide
Wavenumber [cm^{-1}]	3300 – 3500 (*O-H stretch*)	2975 (*C-H stretch*)	1080 (*stretch*)	2855 (*C-H stretch*)	910 *(asymm. Stretch)*
	950 (*Si-O stretch*)	1250 (*Si-C-H bend*)	800 (*bend*)		
		840 (*Si-C stretch*)	455 (*rocking*)		
		755 (*Si-C stretch*)			

To achieve a part-methylated + epoxidated surface, a simultaneous functionalisation reaction was trialled using the mild methylating agent DMDMS. This reagent replaces TMCS which was found to catalyse epoxide ring opening by releasing HCl during grafting [12]. Functionalisation solutions were prepared by first, separately hydrolysing GPTMS and DMDMS (1 $mol.dm^{-3}$) in an ethnanol-water mixture (n_{water}/n_{silane} = 1.33). Solutions were then combined in various volume ratios to vary the relative silane concentrations. The mole fraction of GPTMS out of the total number of moles of silane (χ_{GPTMS}) is used when discussing the effect of functionalisation solution on aerogel properties. Functionalisation was performed by immersing wet silica gel monoliths in functionalisation solution for 48 h at 65 °C. 50 mL of functionalisation solution was used for every 4 mL of wet silica gel. Samples were then exchanged to acetone *via* ethanol and dried by critical point drying (CPD). Relative intensity (decreased transmittance) of the 910 cm^{-1} (epoxide) signal increases with increasing χ_{GPTMS} (Figure 2 (a)). This relative intensity is quantified as the difference in transmittance between the Si-alkyl (850 cm^{-1}) and epoxide (910 cm^{-1}) signals ($\Delta T_{850\ cm^{-1} - 910\ cm^{-1}}$) (b)). A greater value of $\Delta T_{850\ cm^{-1} - 910\ cm^{-1}}$ indicates a greater degree of GPTMS grafting relative to methylating agent (DMDMS) grafting. The systematic change in relative intensity of these two signals with functionalisation solution composition shows that both 3-(glycidyloxypropyl)silyl (GPS) and dimethylsilyl (DMS) residues are bound to the surface. A constant ratio would indicate that only GPS residues were bound. $\Delta T_{850\ cm^{-1} - 910\ cm^{-1}}$ increases sharply with GPTMS content before levelling off. This gradient decrease commences between χ_{GPTMS} = 6 mol.% and χ_{GPTMS} = 13 mol.%. DMDMS should bind to the surface more rapidly than GPTMS due to its smaller steric bulk. At χ_{GPTMS} = 38 mol.% $\Delta T_{850\ cm^{-1} - 910\ cm^{-1}}$ approaches the value seen for the χ_{GPTMS} = 100 mol.% sample, hence, in this range of GPTMS content, GPS residues dominate the grafting. This dominance may result from the ability of a single GPS residue to prevent binding of DMDMS at a relatively large number of neighbouring silanol sites due to the large steric bulk (relatively large radius of gyration) of its longer chain. The trend in specimen shrinkage with χ_{GPTMS} approximately follow the $\Delta T_{850\ cm^{-1} - 910\ cm^{-1}}$ trend (Figure 2 (b)). Uncracked monoliths were formed with functionalisation solutions containing up to and including χ_{GPTMS} = 21 mol.% (Figure 2 (c)). Beyond this value, the capillary pressures associated with moisture absorption caused specimen disintegration. The χ_{GPTMS} = 6 mol.% functionalisation solution composition was selected for further study due to its relatively high $\Delta T_{850\ cm^{-1} - 910\ cm^{-1}}$ and relatively low shrinkage. Silica aerogel formed with a DMDMS-only functionalisation solution is also a suitable candidate reinforcement as it produces uncracked "part-methylated" monoliths bearing reactive silanol groups.

(c)

Figure 2. (a) Overlaid IR spectra for silica aerogel monoliths formed after treatment with functionalisation solutions containing varying ratios of DMDMS and GPTMS. (b) Volume shrinkage and difference in transmittance ($\Delta T_{850\ cm^{-1}-910\ cm^{-1}}$) between IR signals at 850 cm-1 and 910 cm-1 plotted against χ_{GPTMS} for silica aerogel monoliths formed after treatment with functionalisation solutions containing varying ratios of DMDMS and GPTMS. (c) Silica aerogel monoliths formed after treatment with functionalisation solutions containing varying ratios of DMDMS and GPTMS. For (b) bars show one standard error.

3 PHYSICAL PROPERTIES OF FUNCTIONALISED AEROGEL

This section investigates the application of part-methylated and part-methylated + epoxidated functionalised surfaces to silica aerogel of varying silica content and provides a detailed discussion of physical properties. Silica content was controlled by varying sol-gel precursor TMOS volume fraction (φ_{TMOS}) in the range of $0.15 > \varphi_{TMOS} > 0.41$. For each φ_{TMOS} value, four surface types (methylated, unmodified, part-methylated, and part-methylated + epoxidated) were prepared from a single batch of monolithic wet silica gel. Therefore, prior to functionalisation, the primary structure should be identical for each surface type at a given φ_{TMOS}. . Thermogravimetric analysis (TGA) is used to quantify the moisture content of these mildly-hydrophilic aerogels to determine how this content varies between

different surface functionality and pore characteristics. This moisture content is also used to renormalise mass-dependent properties to the actual silica aerogel mass after moisture removal. Mass loss from silica aerogel is also given by renormalisation of the mass loss at 150 °C, which is the temperature at which removal of physisorbed water is observed to be complete. However, these TGA data give only a semi-quantitative measure of the quantity of surface-bound groups for two reasons: Firstly, the Si atoms of surface-bound residue remain bound to the silica surface as Si-O bonds are not broken in this temperature range and consequently only the organic components are removed (as methane or methanol in the case of TMS or DMS residues) [13]. Secondly, above 200 °C silanol groups will undergo condensation to form new siloxane linkages resulting in loss of water which increases the overall mass loss. Consequently, TGA dry mass loss values are compared only in terms of their relative magnitudes for each surface type at a given φ_{TMOS} [14]. The various samples synthesised for this study are identified by their φ_{TMOS} and surface type (Figure 1). Surface-bound groups are identified by the following names: TMS (from TMCS), silanol (Si-OH), methoxy (residual methoxy groups in unmodified silica aerogel), DMS (from DMDMS), and GPS (from GPTMS). The structures of these surface-bound groups are shown in Figure 3.

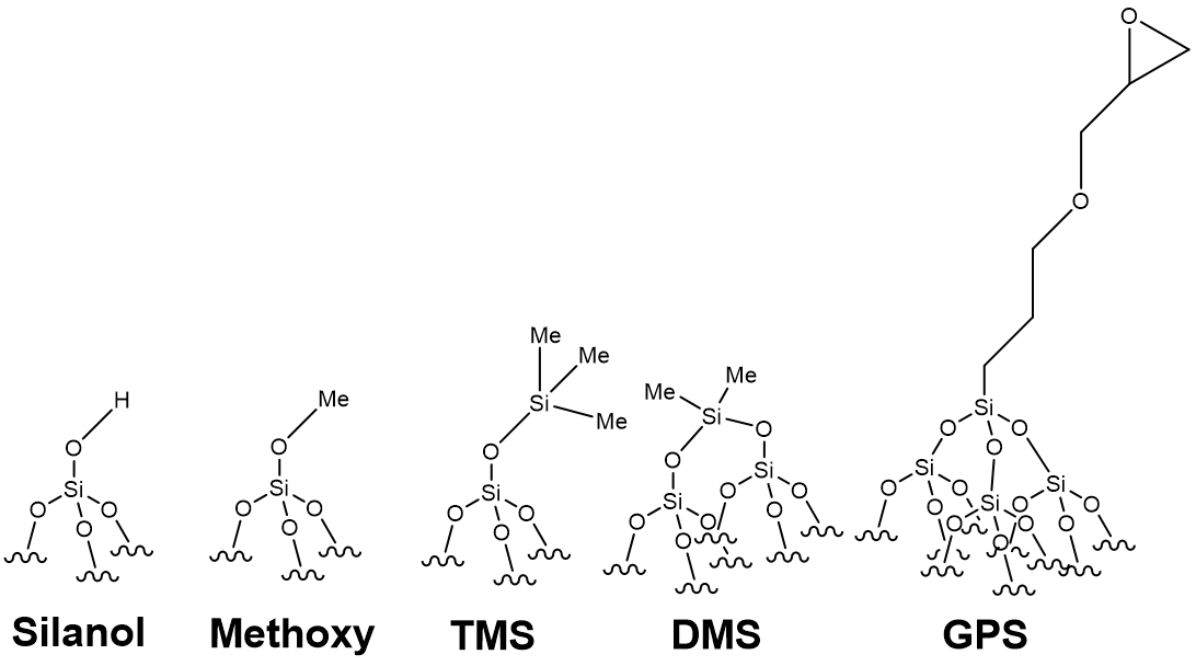


Figure 3. Chemical structures of surface-bound groups. TMS = trimethylsilyl, DMS = dimethylsilyl, GPS = (3-glycidyloxypropyl)silyl.

Density and porosity

Envelope densities were measured by mass and volume measurement due to the incompatibility of hydrophilic porous materials with Archimedes' density measurement in water. However, due to the high precision of the balance and callipers used, repeat measurement yielded low uncertainties. For each surface type, envelope density generally increases with increasing φ_{TMOS}. Methylated aerogel shows a reasonably-linear envelope density trend and is a good match for the TMOS-water aerogel reported previously [3]. The trends for the other three surfaces are far less linear and are shifted to higher densities relative to the methylated surface due to greater volume shrinkage (Figure 4 (b)). Although the shrinkage of the unmodified aerogel (at any φ_{TMOS}) is greater than that of the part methylated + epoxidated aerogel, the unmodified aerogel has the lower envelope density. This difference is due to the significantly greater relative surface-bound mass fraction of the part-methylated + epoxidated aerogel due to the large

molecular mass of the GPS chains. The skeletal densities of methylated silica aerogel agree with TMOS-water aerogel reported previously for $\varphi_{TMOS} > 0.2$ [3]. These skeletal densities are significantly lower than the density of amorphous silica (2.3 $g.cm^{-3}$) due to the contribution of the low-density TMS surface coating [15]. However, at lower values of φ_{TMOS}, the skeletal density increases sharply. This increase is indicative of a lower contribution of the low density TMS surface to the overall skeletal density. This lower contribution results from the decreased specific surface area of the particles due to the significantly slower gelation kinetics at lower [TMOS] (lower φ_{TMOS}) which leads to a smaller TMS volume fraction. From literature, the surface loading of these alkoxy groups is approximately 3.5 nm^{-2} [14, 16]. Skeletal densities of unmodified silica aerogel are an excellent match for literature values for neutral unmodified TMOS aerogel (1.8 $g.cm^{-3}$ – 1.9 $g.cm^{-3}$) [17]. Despite the lack of intentional surface modification, this skeletal density is still lower than the density of amorphous silica (2.3 $g.cm^{-3}$) due to the presence of residual surface alkoxy groups resulting from incomplete precursor hydrolysis. From literature, alkoxy surface loading is approximately 2.4 nm^{-2} [14]. In surface-modified silica aerogels, these methoxy groups are displaced during grafting reactions. The skeletal densities of part-methylated, and part-methylated + epoxidated silica aerogel are intermediate between the unmodified and methylated silica aerogels. These relative skeletal densities imply that the surface-bound loading of these samples fall between the surface-bound loadings of unmodified and methylated aerogel. The greater molar volume of the GPS residues vs. DMS residues cancels out their greater mass leading to no net change in skeletal density vs. the part-methylated surface (Figure 4 (c)).

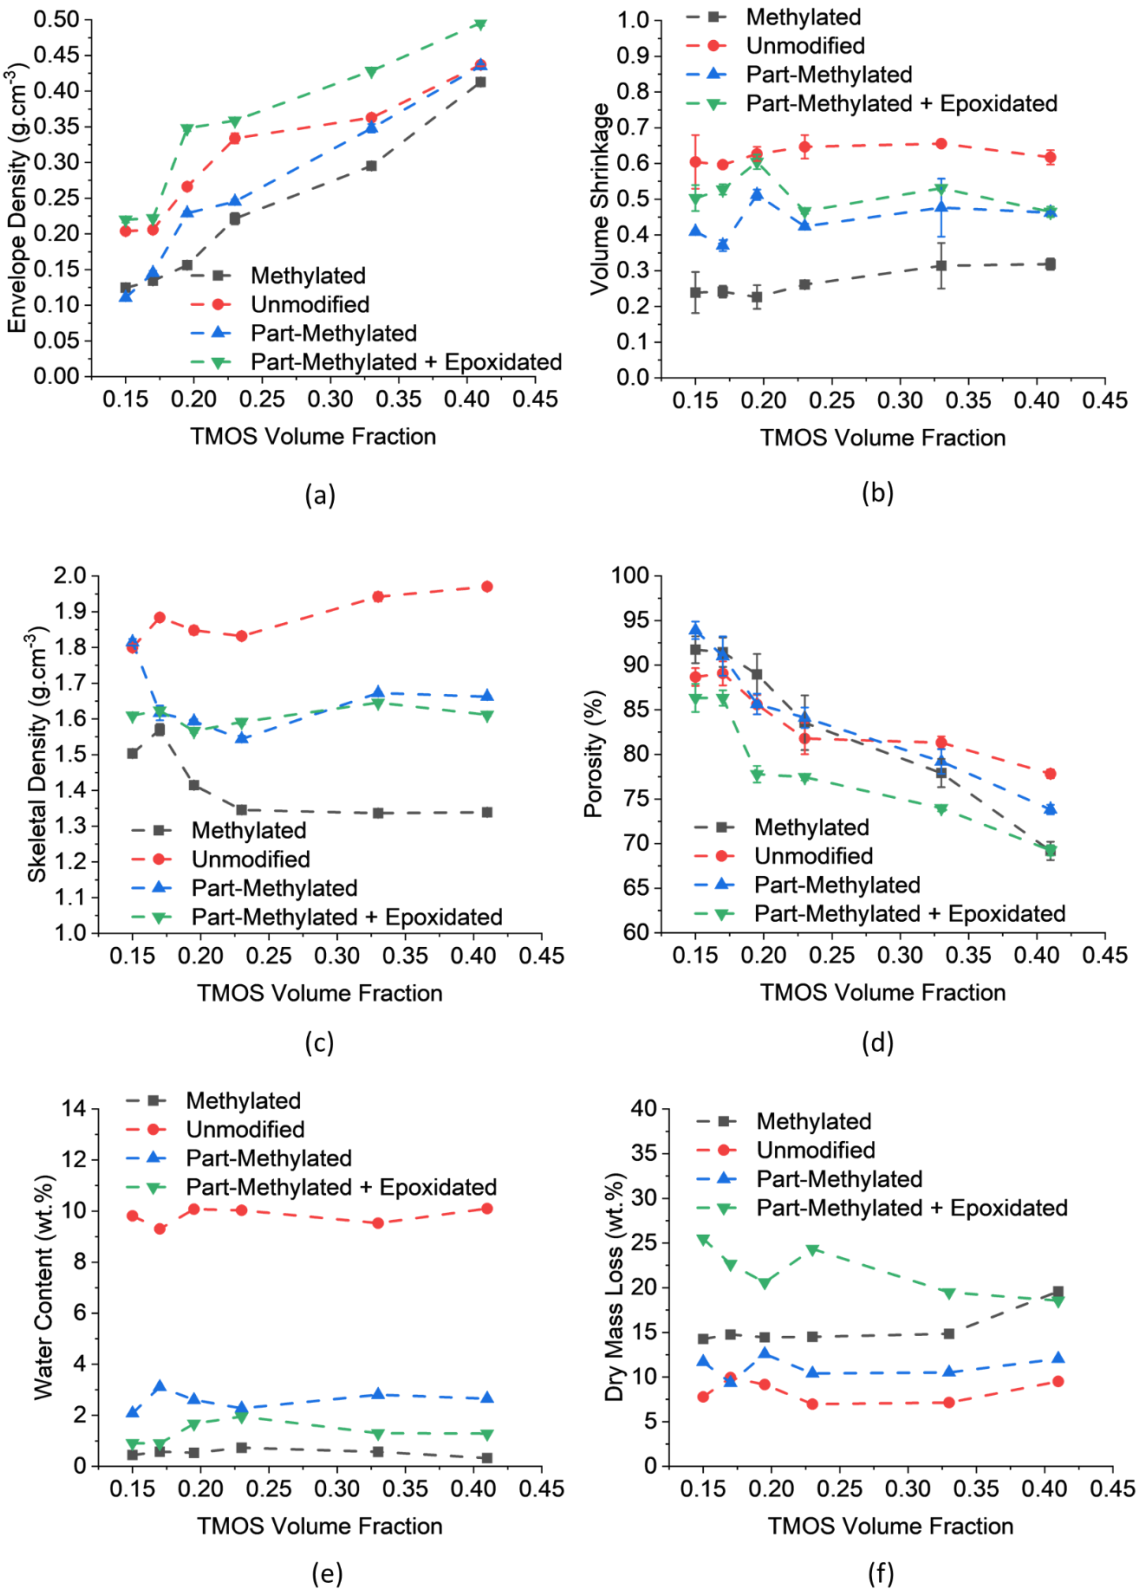

Figure 4 (a) Envelope density (Archimedes method), (b) volume shrinkage, (c) skeletal density (AccuPyc), (d) porosity (calculated from envelope and skeletal densities), (e) water content (TGA), and (f) Mass loss (TGA) of dry silica aerogel monoliths with various surface types plotted against aerogel precursor TMOS volume fraction. Bars show one standard error.

Thermogravimetric analysis

The water content of aerogel monoliths was measured by TGA (Figure 4 (e)). This water content is calculated from the mass loss at the first TGA first derivative minimum. This minimum occurs in the range of 100 °C – 150 °C. Water content is lowest (≈ 0.5 wt.%) for methylated specimens and highest for unmodified specimens (≈ 9.8 wt.%) reflecting their respective superhydrophobicity and hydrophilicity (Figure 5). Accordingly, the water content of the part-methylated aerogel is intermediate of these values (≈ 2.6 wt.%). Interestingly, the water content of part-methylated + epoxidated aerogels is consistently around half that of their part-methylated counterparts (≈ 1.4 wt.%). Decreased water absorbance indicates that binding of GPS residues has a net hydrophobising effect on the aerogel surface which is likely due to the replacement of three highly hydrophilic silanol groups with a single less hydrophilic epoxide group during tripodal binding of GPS. This finding helps justify the choice of GPTMS over hydrophilic (3-aminopropyl)triethoxysilane (APTES) as a linking group. This water content is similar to that reported for GPTMS-functionalised particulate nanosilica (0.7 wt.% – 1.1 wt.%) [18]. Methylated specimens formed from precursors with $\varphi_{TMOS} = 0.15$ to $\varphi_{TMOS} = 0.33$ have similar TGA first derivative profiles with a large mass loss event centred at 360 °C which overlaps with a secondary mass loss event centred at 480 °C (Figure 5 (a)). Decomposition of silica-bound TMS residues is known to produce methane and methanol by methyl displacement in this temperature range [13]. For $\varphi_{TMOS} = 0.41$, the positions of maxima are shifted slightly. However, most organic decomposition still occurs in the range of 300 °C – 600 °C. For $\varphi_{TMOS} = 0.33$ and $\varphi_{TMOS} = 0.41$ a third mass loss event is seen at 730 °C. $\varphi_{TMOS} = 0.17$ is the only sample which has an additional mass loss event at 640 °C. These higher temperature decomposition events are the result of Si-C homolysis. It is not understood why these further events are only seen for these three specimens. The mass loss at 200 °C is due to condensation of surface silanol groups and the resulting water loss. This condensation is most significant for higher φ_{TMOS} values where the lower porosity likely generates a greater number of silanol groups inaccessible to TMS modification which are, therefore, available for condensation prior to TMS decomposition [12]. Unmodified specimens begin to lose additional mass immediately after drying (≈ 150 °C) (Figure 5 (b)). This mass loss is due to condensation of the large concentration of silanol groups. A second, broad peak in the TGA first derivative commences at 400 °C due to loss of surface-bound methoxy groups through a hydrolysis mechanism facilitated by moisture generated from silanol condensation. A similar mass loss profile is seen in literature for unmodified TMOS-derived silica aerogel specimens [19]. The TGA first derivative profile of part-methylated silica shows several distinguishable overlapping signals (Figure 5 (c)). Decomposition of dry aerogel again commences at a lower temperature than observed for methylated silica aerogel (≈ 200 °C vs. 350 °C) due to silanol condensation. Loss of methane and methanol follow at higher temperatures as seen for methylated aerogel. The TGA first derivative profiles of $\varphi_{TMOS} = 0.33$, and $\varphi_{TMOS} = 0.41$ differ from the other samples in the form of a smoother broad peak ($\varphi_{TMOS} = 0.33$ and $\varphi_{TMOS} = 0.41$) which again replicates the behaviour seen for methylated silica aerogel. This broader peak may result from a greater degree of mass loss through silanol condensation resulting from a lower degree of surface functionalisation due to a greater proportion of very small pores in the higher density aerogel. The sharp signal seen for $\varphi_{TMOS} = 0.20$ at 650 °C may be due to contamination. The TGA first derivative profile of part-methylated + epoxidated silica aerogel is more like that of methylated silica aerogel than the other surfaces with both showing a large maximum at approximately 350 °C (Figure 5 (d)). The distinct shoulder preceding this peak (starting at 150 °C) may be due to significant loss of condensation products (water) resulting from the self-polymerisation of surface-bound epoxide (GPS residues) in addition to the previously described silanol condensation. Again, $\varphi_{TMOS} = 0.33$ and $\varphi_{TMOS} = 0.41$ show a smoother peak likely due to greater surface silanol concentrations.

CONCLUSIONS

Two new silica aerogel surface types were synthesised and characterised: part-methylated, and part-methylated + epoxidated. These surfaces enable the formation of moisture-stable, high-density, silica aerogel monoliths with amphiphilic reactive interfaces. The simultaneous independent binding of dimethylsilyl (DMS) and (3-glycidyloxypropyl)silyl (GPS) residues in part-methylated + epoxidated silica aerogel has been confirmed by IR analysis. This bi-functionalisation forms silica aerogel with a surface featuring DMS, GPS and silanol groups. The GPS and silanol groups act as reactive sites and DMS groups provide hydrophobic character for decreased moisture uptake. The shrinkage of part-methylated + epoxidated silica aerogel monoliths was found to decrease with increased proportion of DMS binding relative to GPS binding. A suitable GPTMS/DMDMS ratio (χ_{GPTMS} = 6 mol.%) was chosen to trade-off shrinkage against GPS loading. Part-methylated and part-methylated + epoxidated surfaces were found to be mildly hydrophilic by thermogravimetric analysis (TGA). However, moisture uptake was far less than that of the equivalent unmodified silica aerogel. These reinforcement networks are therefore suitable for backfilling with epoxy resin to form bicontinuous nanocomposites, which may themselves be applied as nanostructured matrices for fibre-reinforced composites.

The concept of cure-induced wrinkles

Wind turbine blade composite consists of fibres embedded in polymer ”resin”.

- The polymer will have to polymerise to give the blade its mechanical properties.
  - This process is referred to as **curing**.
  - Performed at elevated temperatures
- **Temperature gradients** occur during **heating** or **exothermal heat release** from the resin.
- The temperature gradients results in varying build-up of resin stiffness.
- This allows the fibres to buckle, driven by variations in thermal expansion and chemical shrinkage of the resin.
- This results in the phenomenon called ***”Cure-induced wrinkles”.***

ABSTRACT

Automated Fiber Placement (AFP) enables high-speed, precise deposition of fiber-reinforced composites, making it ideal for complex, high-performance structures. Understanding the transient thermal behavior of thermoplastic composites during AFP is critical, as it affects bonding, residual stress, and final properties. This study presents a systematic experimental characterization of thermal evolution and resulting crystallinity in CF/LM-PAEK composites exposed to a moving Xenon-arc flash lamp. A robotic setup was developed to map the lamp's irradiance profile, and infrared thermography was used to capture surface temperature during heating. Differential Scanning Calorimetry (DSC) measured crystallinity across varying process conditions. Results show that temperature and crystallization are governed by radiant exposure, thermal diffusivity, cooling rates, and process parameters such as power and speed. These insights support improved AFP thermal control and process optimization.

1 INTRODUCTION

Carbon fiber reinforced polymer (CFRP) composites are widely used in aerospace applications due to their high strength-to-weight ratio. Traditional methods like hand layup are labor-intensive and inefficient [1], whereas Automated Fiber Placement (AFP) enables scalable manufacturing by robotically depositing pre-impregnated CFRP tows with improved precision [2, 3]. Both thermoset and thermoplastic CFRPs can be manufactured via AFP. Thermosets require curing post-laydown, while thermoplastics offer the advantage of in-situ consolidation, eliminating autoclave requirements and shortening cycle times [4–6]. However, controlling crystallinity and achieving strong interlaminar bonding in thermoplastics is challenging due to rapid thermal cycles.

In AFP of thermoplastics, tows must be rapidly heated to 320°C–350°C [7] to allow polymer chain mobility and subsequent crystallization, forming lamellae and spherulites that determine mechanical performance [8, 9]. Studies indicate that rapid cooling reduces crystallinity, while prolonged heating enhances it [10]. Thus, uniform and efficient heating becomes essential. Various non-contact heating systems have been examined, including Hot Gas Torch (HGT) [11–13], induction heating [14–16], and Near-Infrared (NIR) lasers [17–19]. A newer alternative is Xenon-arc flash lamp heating [20–22], which delivers high-energy broadband UV–IR pulses.

Heating strategies strongly affect temperature gradients and resulting microstructure. Tafreshi et al. [12] showed that while HGT effectively heats the surface, inner plies remain under-heated. Similarly, Shafaq et al. [23] linked cooling rate variations to crystallinity fluctuations. Laser heating improves interlaminar bonding but has limited penetration, causing lower crystallinity in core plies [24]. Xenon-arc flash lamps, emitting diffuse radiation unlike lasers' collimated beams, may enable better thermal penetration and uniformity [25]. However, few studies to date explore their behavior and process optimization in AFP.

Challenges in Xenon-arc flash AFP heating include energy distribution control, consistent material exposure, and understanding crystallization effects. Heating effectiveness is governed by the radiative heat flux and the temperature evolution rate in the laydown zone [7]. While prior studies have used thermocouples [26], fiber Bragg gratings [27], and IR thermography [28, 29] to map AFP thermal profiles, limited data exists on Xenon-arc systems. Danezis et al. [30] developed a 3D optical ray-tracing model to simulate lamp behavior, highlighting the complexity of diffuse source modeling.

This study focuses on the thermal characteristics of Xenon-arc flash heating in AFP. It aims to isolate key parameters—irradiance, exposure time, and thermal response—and quantify their effects on surface temperature and crystallization. A spatially resolved irradiance field is characterized and linked to temperature evolution and crystallinity, as measured by Differential Scanning Calorimetry (DSC). Experiments are conducted using a KUKA robotic AFP platform, a Xenon-arc flash lamp as the heating source, and LM-PAEK carbon fiber tows as the material system [31]. The results aim to bridge critical gaps in understanding AFP thermal behavior and to optimize Xenon-arc based heating strategies for next-generation thermoplastic composites.

2 EXPERIMENTS

2.1 Flux Measurement

A measurement setup was developed to characterize irradiance (Ee) near the Xenon-arc flash lamp of a humm3 heating system [20]. The lamp, enclosed in a 26 mm × 70 mm cavity, was mounted vertically, and irradiance was measured using a water-cooled Gordon gauge heat flux sensor (Hukseflux) mounted on a six-axis robotic arm. The sensor, with a 4.3 mm port and up to 1 MW/m² measurement capacity, recorded data at 200 Hz using a DI-245 system (Dataq). Irradiance output was controlled by adjusting pulse width (tp), while keeping voltage (200 V) and frequency (90 Hz) constant. Based on the relation P=Ie ω tpV, with Ie=230 A, pulse widths of 0.3 ms, 1 ms, and 1.7 ms yielded power outputs of 1240 W, 4132 W, and 7025 W, respectively.

A KUKA robotic arm, programmed using Grasshopper UI in Rhino 7, was used to move a heat flux sensor through a 3D grid above the Xenon-arc flash lamp. At each grid point, the sensor held position for four seconds to record voltage, which was averaged and converted to irradiance. Measurements were taken from 36 mm to 12 mm vertically (Z-axis), and across a 52 mm × 36 mm area in the horizontal plane (X–Y), with 4 mm step sizes. Due to housing constraints, data below 12 mm was linearly extrapolated.

Three power levels (1240 W, 4132 W, and 7025 W) were tested. A full 3D irradiance field was mapped at 4132 W using 1078 measured and 462 extrapolated points, covering one quadrant and mirrored to form the full field. Radial Basis interpolation in Python was used to generate the 3D irradiance map, which was then scaled linearly for the other two power levels. This enabled development of a power-based scaling law for estimating irradiance fields between 1240 W and 7025 W.

2.2 Thermal Measurement

Following irradiance field characterization, a new setup was implemented to measure the surface temperature profile on a CF/LM-PAEK panel (VICTREX AE™ 250 UDT) as the Xenon-arc flash lamp moved across it. A FLIR A655sc infrared camera operating in the 7.5–14 µm spectral range at 60 Hz captured real-time thermal data during lamp traversal at various speeds (Figure 1).

The setup included a four-rod frame supporting a panel made of ten evenly spaced CF/LM-PAEK tows, secured using double-sided tape. The lamp, mounted on the robot arm, moved along a path aligned with the center of the panel and tows, ensuring radiation incidence was normal to the surface. The fiber direction matched the direction of lamp motion. The IR camera was positioned to monitor the full temperature field, while a flux sensor placed beneath the panel verified irradiance during lamp motion. The robot's path was carefully calibrated to ensure accurate tracking over the panel.

The interpolated irradiance field guided the selection of a 28 mm lamp height for the moving lamp experiments—sufficient to avoid blocking the thermal camera's view. The robotic arm was programmed to traverse a path beyond the lamp's irradiance footprint, ensuring full coverage over the CF/LM-PAEK tows (Figure 1).

Twelve tests were conducted in two phases. The first phase studied how varying speeds affected surface temperature evolution. For lamp powers of 2066 W, 4132 W, and 7025 W, speeds of 200, 300, and 400 mm/s were tested (nine experiments). The second phase aimed to reach the optimal crystallization temperature range (320–340 °C). Speeds were adjusted accordingly: 35 mm/s (2066 W), 130 mm/s (4132 W), and 210 mm/s (7025 W), with additional runs at 100 mm/s and 500 mm/s (4132 W).

Each test followed a consistent procedure: the lamp was set to simmer mode, IR recording began, then after five seconds, the lamp switched to flash mode and the robot initiated motion. The FLIR camera recorded the full heating and cooling cycle, while the flux sensor captured irradiance over time to validate the empirical irradiance model. A new panel was used for each test and preserved for post-experiment material characterization.

2.3 Material Characterization

After the moving lamp experiments, the irradiated CF/LM-PAEK tows within a panel were sectioned to measure the degree of crystallization corresponding to their distance from the lamp, the lamp power, and the lamp speed across the tow. The tows which exceeded the glass transition (Tg) temperature of 150 ◦C were considered for Differential Scanning Calorimetry (DSC) and further analysis. Certain experiments were excluded from mate- rial analysis, since the panel never exceed the Tg. These experiments were: 200 mm/s, 300 mm/s, and 400 mm/s for a power of 2066 W and 500 mm/s for a power of 4132 W .

For each measurement, a hole puncher was used to cut out a disc in the center of an irradiated tow. For the DSC measurements, temperature sweep was set from 40 ◦C to 360 ◦C at a rate of 10 ◦C/m. For all experiments, only tows 1-3 were chosen, since these crossed the Tg threshold. A total of 33 samples were analyzed using DSC including the three as-received pristine (unheated) samples and three oven-baked samples. The pristine samples represented the lower benchmark of CF/LM-PAEK tape crystallinity. On the other hand, the oven-baked samples represented the upper benchmark of crystallinity through a slow heating and cooling process, allowing for increased spherulite growth [33]. Specifically, the oven-baked samples were heated to 310 ◦C and held at 280 ◦C for 60 minutes. The samples were then cooled at a rate of 18 ◦C/min to room temperature. Crystallinity in each sample was estimated using the following standard procedure [10]:

Bulk crystallization is a result of multiple factors during the experiments, but is most influenced by the resulting temperature-time profile during the cooling phase. The temperature data from the IR camera for each experiment was converted to a multidimensional array. Each pixel at any location on the tows exhibited a heating and cooling phase, and is easily extracted for analysis.

3 SUMMARY OF RESULTS

3.1 Irradiance Field Characterization

A 3D irradiance field around the Xenon-arc flash lamp (at 4132 W) was generated using Radial Basis Function interpolation (Figure 2). The irradiance profile revealed a conical decay from the lamp center, dropping from ~0.7 MW/m² near the origin to ~0.2 MW/m² at 20 mm. While the spatial shape remained consistent across power levels, magnitudes scaled with a third-order polynomial function accounting for voltage, frequency, and pulse width. This enables prediction of transient irradiance at any speed or location on the panel.

3.2 Transient Irradiance and Radiant Exposure

As the lamp traverses the panel, the irradiance on a point varies over time. Radiant exposure (He) is computed by integrating irradiance over exposure time. Experimental validation with a flux sensor confirmed strong correlation with the predicted irradiance. Increasing lamp speed narrows the irradiance profile and reduces peak irradiance. Multiple combinations of power and speed can yield the same radiant exposure (Figure 3).

3.3 Temperature Evolution Across the Panel

IR camera measurements show that the surface temperature lags behind the peak irradiance due to thermal diffusion (Figure 4). At high speeds and powers (e.g., 7025 W at 400 mm/s), the temperature front moves slower than the lamp, with increasing lag. Table 1 summarizes this lag, showing temperature front speeds are typically 30–67% of the lamp speed, decreasing with higher lamp power.

3.4 Linking Temperature, Radiant Exposure, and Speed

Bubble plots (Figure 5) reveal that even with equal radiant exposure, different power-speed combinations yield different peak temperatures due to location effects and thermal inertia. Tow 1 (closest to the lamp center) did not always show the highest temperature, likely due to dynamic heat accumulation and loss mechanisms. There is no one-to-one mapping between radiant exposure and peak temperature—thermal response is a function of power, speed, and thermal transport properties.

3.5 Crystallinity Trends

DSC analysis showed only slight increases in crystallinity across samples compared to the as-received material. The highest crystallinity (5.45%) was obtained at 7025 W and 200 mm/s. Most experimental runs yielded crystallinity in the 2.4–3.3% range, similar or slightly above baseline. Oven-baked samples reached much higher crystallinity (18.8%) due to longer controlled cooling. Key factors influencing crystallinity were maximum temperature and cooling duration. However, given the short exposure and rapid cooling inherent to AFP, significant increases in crystallinity are limited without further thermal management (Figure 6).

4 CONCLUSIONS

This study developed a systematic method to quantify the thermal history and resulting crystallinity of CF/LM-PAEK composite tape heated by a Xenon-arc flash lamp. A robotic test setup was used to map the 3D irradiance field and then simulate a moving heat source over a stationary panel. The resulting transient temperature behavior was captured using infrared thermography, and the crystallinity outcomes were analyzed via DSC.

Key findings include:

- A complete irradiance field model was created using robotic measurements, RBF interpolation, and a power-based scaling law, enabling prediction under any lamp setting.
- A clear thermal lag was observed between lamp motion and temperature front, which increases with speed.
- Radiant exposure depends on lamp power, position, and speed; different parameter combinations can result in the same exposure.
- Peak material temperature correlates with radiant exposure and spatial position, not just power and speed, making simple process control insufficient.
- DSC results showed that rapid cooling under the Xenon-arc leads to crystallinity levels significantly lower than those achieved via slow cooling, even when peak temperatures exceeded the melt point.

Overall, the study underscores the need for precise thermal control in AFP of thermoplastics. The experimental framework established here lays the foundation for predictive modeling of thermal behavior and microstructure evolution in advanced manufacturing of CF/LM-PAEK composites.

ACKNOWLEDGEMENT

The Automated Fiber Placement (AFP) system was developed through the University of Texas System's Science and Technology Acquisition and Retention (STAR) program and PD Start-up funding. Authors are grateful to Dr. Rassel Raihan for use of DSC system.

Keywords: Composite Materials, Thermoplastics, Fiber Waviness

ABSTRACT

In recent years, carbon fiber-reinforced thermoplastics (CFRTPs) have been increasingly applied, particularly in the aerospace field, due to their high productivity and recyclability. However, various molding defects caused by complex molding behaviors and high processing temperatures have hindered their application to critical structural components. Among these, in-plane fiber waviness on the surface of component surfaces is known to reduce longitudinal strength and induce complex damage propagation behavior. While numerous studies have investigated the geometric characteristics of fiber waviness and its influence on mechanical performance, the effects of process-induced phenomena during molding, especially crystallization behavior in thermoplastics, remain largely unexplored. This study aims to develop a numerical analysis framework that captures the entire process, from molding to mechanical performance of fiber waviness, incorporating the effects of the crystallization behavior of thermoplastics during the forming process. The validity of the proposed method is assessed through comparison with experiments, enabling a comprehensive evaluation of residual stresses and their influence on the mechanical performance of CFRTPs with fiber waviness.

1 INTRODUCTION

In recent years, as the application of carbon fiber-reinforced plastic (CFRP) components in aerospace structures has advanced, there has been a growing demand not only for their excellent mechanical properties but also for additional functional innovations, such as recyclability or manufacturing productivity. In response, significant efforts have been directed toward the development of carbon fiber-reinforced thermoplastics (CFRTPs), which use thermoplastic matrices that solidify upon cooling and can be re-melted upon heating. Owing to these characteristics, CFRTPs have attracted considerable attention as recyclable and highly productive materials. However, the high flowability of thermoplastic resins and the elevated processing temperature required during molding pose challenges, resulting in various manufacturing defects that continue to hinder the widespread application of CFRTPs to structural components.

Among these defects, fiber waviness caused by misalignment of fiber orientation is one of the most critical issues [1]. In CFRTP laminates, fiber waviness typically occurs in the in-plane direction of the surface, inducing inhomogeneous stress fields that lead to a reduction in mechanical strength and the emergence of complex fracture modes. These issues are further compounded by the relatively high processing temperatures and crystallization behavior characteristics of thermoplastic matrices, which are known to generate substantial residual strain during molding and cooling [2]. Notably, CFRTPs employed in structural components primarily utilize semicrystalline thermoplastic resins as their matrix

materials, which exhibit distinct crystallization behavior that significantly influences the development of residual strain. While the influence of fiber waviness on mechanical properties has been widely investigated through various numerical analysis methods [3-5], the potential impact of process-induced residual strains on fiber waviness and structure strength has raised increasing concern. Nevertheless, only a limited number of studies have incorporated the effects of molding-induced residual strain into numerical simulations.

Numerous experimental studies have explored the mechanisms of fiber waviness formation in CFRP laminates [6]. Among the various types of fiber waviness, in-plane fiber waviness occurring on the laminate surfaces is known to result from the interaction of multiple factors. Kugler et al. [7] identified key factors, such as tool plate/part coefficient of thermal expansion (CTE) mismatch, temporal temperature gradients, and spatial temperature gradients through comparative investigations of amorphous CFRTPs. Krämer et al. [8] conducted real-time observations of crystalline CFRTPs and revealed the effects of molding conditions on fiber waviness formation. However, the influence of the parameters of molding conditions on fiber waviness formation and the effects on the mechanical properties of CFRTP laminates remain unclear.

This study proposes a numerical analysis framework to investigate the effects of molding conditions on in-plane fiber waviness in CFRTP laminates, with a particular focus on geometric characteristics and mechanical behavior. By comparing numerical simulation results with experimental data, the validity of the proposed approach is evaluated, and the influence of residual stresses generated around the fiber waviness on component strength is examined. This research establishes a link between molding conditions and the structural performance of CFRTP components, thereby contributing to the advancement of forming technologies for CFRTPs.

2 EXPERIMENT

MCCP1223 (CF/PA6 based unidirectional prepreg, Maruhachi Co.) is used as the material in this study. To intentionally induce in-plane fiber waviness through longitudinal compression during molding, A5052 aluminum molds with intentionally poor release agent coverage near the edges are employed, as illustrated in Figure 1. The release agent failure localizes the constraint during the cooling process, promoting localized compressive stress and fiber buckling (see Figure 1). A unidirectional 6-ply laminate (0° stacking) of 200 × 200 mm is prepared, with a total thickness of approximately 1 mm. The laminate is heated and pressed at 280 °C and 1 MPa for 15 minutes.

Three different cooling conditions were applied: Slow cooling (in the hot press), Medium cooling (at room temperature), and Fast cooling (using water). Two laminates were molded under each condition. The average cooling rate between 250 °C and 200 °C was defined as the representative cooling rate: Slow (0.02 K/s), Medium (2.06 K/s), and Fast (24.30 K/s).

After molding, the geometric shape of the fiber waviness is measured using an optical microscope (see Figure 2). Furthermore, mechanical performance is evaluated using four-point bending tests (according to JIS K7074) and tensile tests (according to JIS K7165), with ten specimens tested for each cooling condition (n = 10). Load–displacement curves are used to determine the mechanical strength of the specimens, and the failure modes are identified through post-fracture observations of the tested specimens.

3 NUMERICAL ANALYSIS METHOD

3.1 Molding analysis

According to Kugler et al. [7], the primary mechanisms responsible for fiber waviness formation in amorphous CFRTPs include tool plate/part CTE mismatch, temporal temperature gradients, and spatial temperature gradients. Furthermore, in a study on crystalline CFRTPs, Krämer et al. [8] reported that fiber waviness forms during the cooling process within the temperature range between the processing temperature $T_{\max}$ and the crystallization temperature T_c, referred to as the waviness formation temperature interval $\Delta T_w = T_{\max} - T_c$. It was also found that the width of this interval ΔT_w significantly affects the severity of the fiber waviness. Since both the waviness formation temperature interval ΔT_w and the crystallization behavior of thermoplastics are highly dependent on the cooling rate, this study treats the cooling rate as a key molding parameter and investigates its influence on the mechanical characteristics of fiber waviness.

Considering the above findings and the molding characteristics of crystalline thermoplastics, the fiber waviness formation process can be modeled in the following three stages:

(i) Molten phase (Processing temperature $T_{\max}$ to crystallization temperature T_c):
This stage is governed by the fluidity of the thermoplastic matrix.

(ii) Solidification phase (Crystallization temperature T_c to glass transition temperature T_g):
The solidification of the matrix and the generation of residual stresses are considered.

(iii) Solid phase (Glass transition temperature T_g to room temperature T_r):
The matrix is assumed to behave as a fully elastic material.

(i) Molten phase (Processing temperature $T_{\max}$ ~ crystallization temperature T_c)

Above the crystallization temperature T_c, thermoplastics exhibit fluid-like behavior. Therefore, axial compressive stress acting on the fibers due to differential thermal shrinkage between mold and laminate is considered the primary cause of fiber waviness formation. Based on this assumption, the difference in shrinkage between the mold and the laminate during the cooling process is presumed to correspond to the amount of longitudinal shrinkage caused by the formation of fiber waviness.

The difference in thermal strain between the fiber and the mold ε_t can be expressed as:

$$\varepsilon_t = -(\alpha_t - \alpha_f)\Delta T_w, \tag{1}$$

where α_t and α_f are the CTE of mold and fiber. Based on the experimental observations, the geometric shape of fiber waviness is fitted to be sinusoidal as:

$$Y(x,y,z) = 2A_0(z)\cos^2(\pi y/2U)\cos^2(\pi x/\lambda) \tag{2}$$

$$A_0(z) = \begin{cases} A_0^{\max} z \text{ (under compression)} \\ A_0^{\max} \text{ (under tensile)} \end{cases} \tag{3}$$

where x, y: in-plane fiber direction and transverse direction, respectively; z: out-of-plane direction. $A_0^{\max}$: maximum amplitude; λ: wavelength; U: width of the waviness region (Figure 3). The strain caused by the fiber waviness ε_w is then given by:

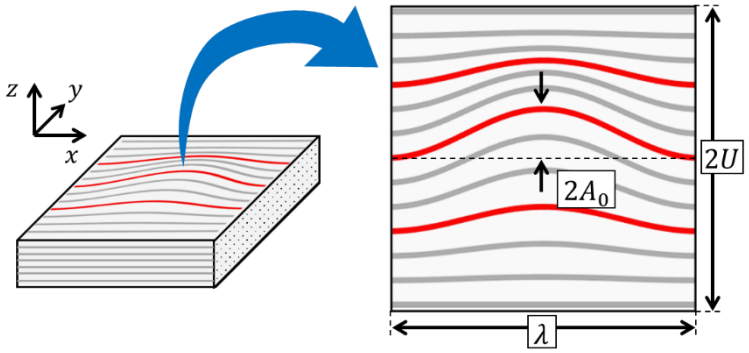

Figure 3: Geometry of fiber waviness

$$\varepsilon_{\mathrm{w}} = \ln\left(\lambda \Big/ \int_{-\lambda/2}^{-\lambda/2} \sqrt{1 + \left(\partial Y/\partial x|_{y=0}\right)^2}\, dx\right). \tag{4}$$

Since fiber waviness is generated locally in CFRTP laminates, the relationship between ε_{t} and ε_{w} can be described using the length subjected to axial fiber compression L_{t} and the length of the waviness region L_{w}:

$$L_{\mathrm{t}}\varepsilon_{\mathrm{t}} = L_{\mathrm{w}}\varepsilon_{\mathrm{w}}. \tag{5}$$

From Equations (1) to (5), the crystallization temperature T_{c} can be associated with the resulting geometric shape of the fiber waviness. Since T_{c} is significantly affected by the cooling rate, this establishes a direct relationship between the cooling rate and the geometric characteristics of fiber waviness. The stiffness of the thermoplastics is sufficiently low, and thus, the residual stress generated during this process is assumed to be negligible.

(ii) Solidification phase (Crystallization temperature T_{c} to glass transition temperature T_{g}):

Below the crystallization temperature T_{c}, it becomes necessary to consider the residual stresses generated during the cooling process due to the increase in matrix stiffness. In thermoplastics, shrinkage during the cooling process can be broadly classified into two categories: thermal shrinkage, caused by reduced molecular mobility with decreasing temperature, and crystallization shrinkage, resulting from the formation of crystalline structures. An incremental linear elasticity (ILE) model [9,10], which employs representative material properties in segments, introduced, is introduced to implement these effects of thermal shrinkage in numerical analysis.

Crystallization kinetics are modeled using the Ziabicki–Nakamura equation [11,12], a non-isothermal crystallization model:

$$\tilde{\theta}(t) = 1 - \exp\left[-\left(\int_0^t K(T)dt\right)^n\right], \tag{6}$$

$$K(T) = K_{\max} \exp\left[\frac{-4\ln 2\,(T-\bar{T})^2}{D^2}\right], \tag{7}$$

where $\tilde{\theta}(t)$: the relative degree of crystallinity with respect to the maximum degree of crystallinity at time t, $K(T)$: the crystallization rate constant at temperature T, n: the Avrami index representing the fractal dimension of the crystals, and $K_{\max}, \bar{T}, D$: fitting parameters in the Gaussian approximation of the crystallization rate.

In this study, it is assumed that the mechanical properties of the thermoplastic matrix are proportional to its degree of crystallinity. The total shrinkage strain is considered to consist of two components: thermal shrinkage, which is proportional to the temperature change, and crystallization shrinkage, which is proportional to the degree of crystallinity. The magnitude of the crystallization shrinkage strain is estimated based on the warpage deformation in asymmetric laminates with a [0/90/90] stacking sequence, according to reference [13].

(iii) Solid phase (Glass transition temperature T_g to room temperature T_r)

Since no further crystallization is assumed to occur below the glass transition temperature T_g, the mechanical properties of the matrix are considered constant. Therefore, only the effects of thermal shrinkage are considered in this process. Finally, the demolding process is modeled by imposing a stress-free boundary condition on the model.

3.2 Strength analysis

Around the fiber waviness, complex damage behavior can arise due to the combined effects of the geometric shape of the fiber waviness and applied load conditions. To investigate this phenomenon, a high-fidelity numerical approach is introduced, in which fiber- and matrix-dominated damage mechanisms are modeled separately.

In fiber-dominated damage, it is well known that distinct failure mechanisms occur under longitudinal compressive and tensile loading. Under compressive loading, inhomogeneous shear stress fields arising from the initial fiber misalignment trigger the shear yielding of the matrix, leading to the formation of kink bands. In this study, the LaRC03 failure criterion [14], which accounts for fiber misalignment, is introduced for the onset of kink band. In addition, the physical based model (PBM) [15,16] is implemented to represent energy dissipation due to matrix plastic deformation. Under tensile loading, brittle damage associated with fiber fracture progresses, with failure initiation occurring randomly. This introduces a size effect, which is addressed in this study using the Weibull failure criterion [17].

In matrix-dominated damage, it is essential to capture displacement discontinuities caused by matrix cracking. In CFRP laminates, matrix cracks typically propagate along the fiber direction and can exhibit complex geometries. To efficiently model this cracking behavior, this study employs the extended finite element method (XFEM) [18,19], which allows for the representation of displacement discontinuities independently of the mesh geometry. Furthermore, to capture the plastic zone around the crack tip, a cohesive zone model (CZM) [20] is incorporated in conjunction with XFEM.

4 RESULTS AND DISCUSSION

4.1 Simulation conditions

Numerical simulations are performed under three different cooling conditions: Slow (0.02 K/s), Medium (2.06 K/s), and Fast (24.30 K/s), in accordance with the experimental setup. The influence of cooling conditions on the geometric shape of the fiber waviness and its mechanical effects are investigated.

The dimensions of the finite element model are shown in Figure 4. Since fiber waviness forms continuously on the surface of the component, a representative volume element (RVE) with periodic boundary conditions is used as the analysis domain. In the four-point bending analysis, macroscopic curvature is applied, and the analysis is terminated when a 5% load drop is observed. In the tensile test simulation, macroscopic in-plane strain is applied, and the analysis is terminated when the Weibull failure criterion is satisfied. Structural strength is evaluated based on the surface stress of the RVE at the termination point of each analysis.

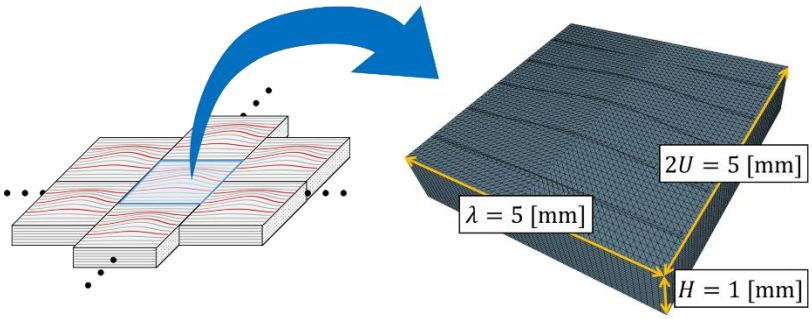

Figure 4: Finite element model and its dimensions

4.2 Experimental and simulation results

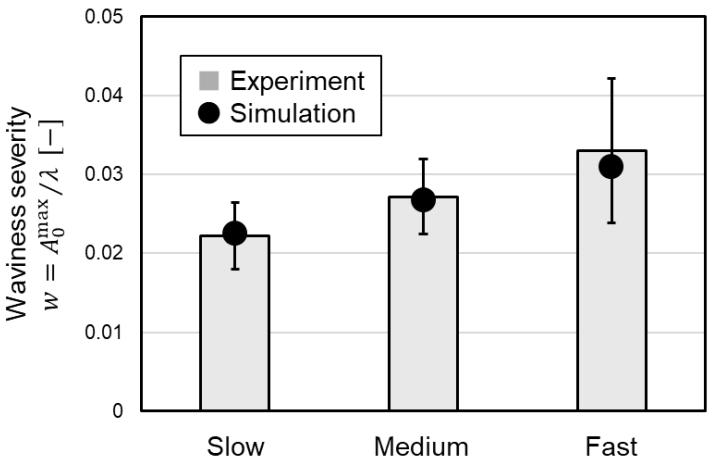
The effect of the cooling rate on the geometric characteristics of fiber waviness is shown in Figure 5. The vertical axis represents the severity of waviness, which is commonly used as a geometric metric of fiber waviness and is defined as:

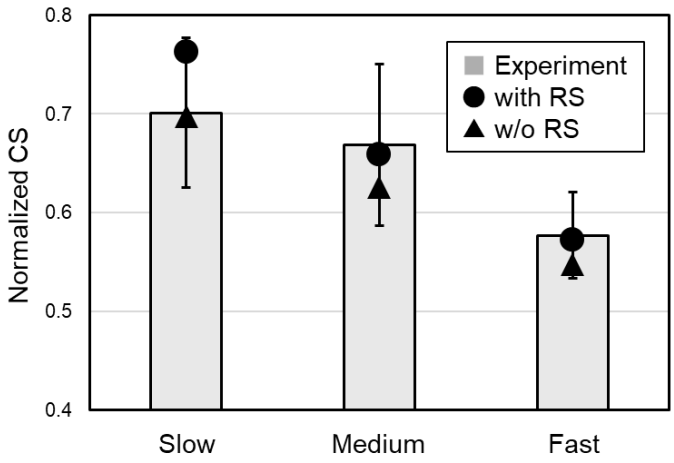
$$w = A_0^{\max}/\lambda. \tag{8}$$

The simulation results show reasonable agreement with experimental data. These results indicate that the severity of fiber waviness increases with higher cooling rates. This is because higher cooling rates lead to lower crystallization temperature, thereby widening the waviness formation temperature interval ΔT_{w} in which fiber waviness forms. However, it should be noted that the Fast cooling condition exceeds the validated range of the cooling rate range of the DSC device (DSC 8500, Perkin Elmer Co.) used in the measurements of crystallization temperature, and further investigation is required.

Figure 6 presents both experimental and numerical results for the dependence of compressive and tensile strength on cooling rate. The vertical axis indicates the normalized strength obtained by dividing the measured or simulated strength by the reference strength of a specimen without fiber waviness. The numerical results show good agreement with the experimental data. Additionally, simulation results without residual stresses are included in Figure 6 to assess the effect of residual stresses on the mechanical behavior associated with fiber waviness. These results indicate that residual stresses generated around the fiber waviness region contribute to an increase in compressive strength while causing a reduction in tensile strength.

In the next section, the effects of the residual stress fields induced around the fiber waviness on the mechanical properties and the underlying mechanisms are discussed.





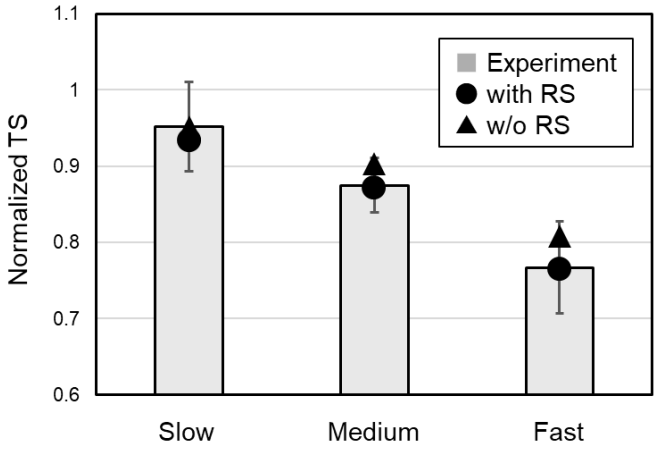


Figure 5: Cooling rate-dependent waviness geometry

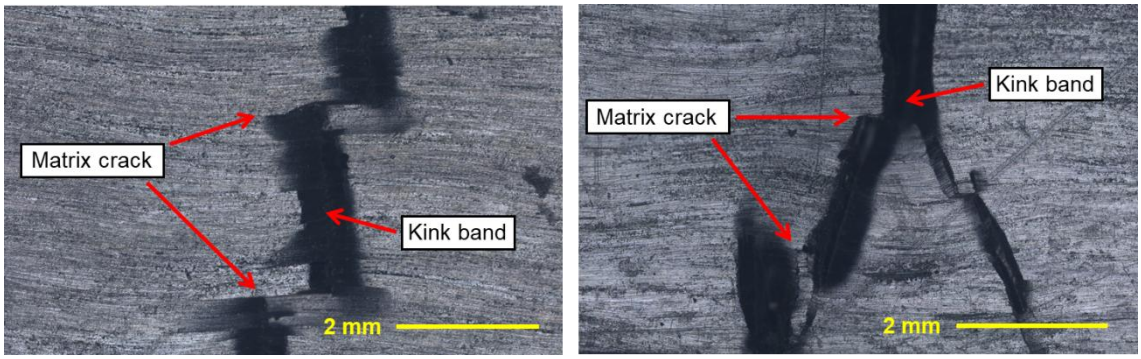
(a) Compressive strength

(b) Tensile strength

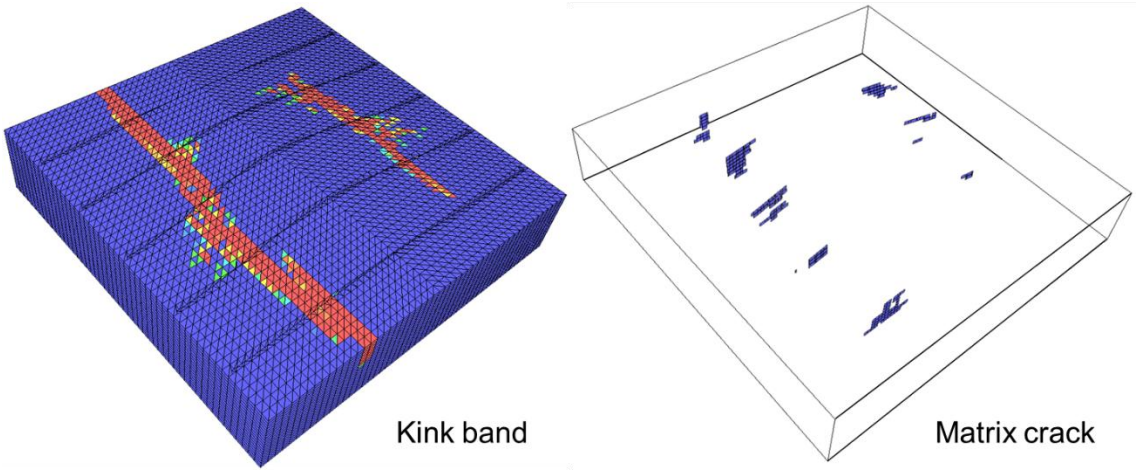
Figure 6: Cooling rate-dependent structural strength



4.3 Discussion

The residual stresses around the fiber waviness contribute to an increase in compressive strength while leading to a reduction in tensile strength. This behavior is closely related to the dominant damage mechanisms occurring near the fiber waviness.

Under compressive loading, kink bands and matrix cracks are initiated around the fiber waviness due to localized shear stress, ultimately resulting in failure (Figure 7). In contrast, under tensile loading, matrix cracking caused by localized shear stress induces stress concentration, which subsequently leads to fiber breakage (Figure 8). As shown in Figure 9 and Figure 10, the residual shear stress field generated by fiber waviness acts in the opposite direction to the shear stress field induced under compressive loading but in the same direction as that induced under tensile loading. This observation suggests that the residual stress field helps to suppress damage under compressive loading while it facilitates damage initiation under tensile loading.



Among the three cooling conditions, the residual shear stress field is found to be most pronounced under the slow cooling condition. Although both the geometric nonlinearity of fiber waviness and the magnitude of matrix shrinkage during cooling contribute to the development of the residual shear stress field, the results indicate that matrix shrinkage has a more dominant influence.

Considering the residual stresses, the simulation results for the Medium and Fast cooling conditions show good agreement with the experimental data. However, this is not the case for the Slow condition. The proposed analysis approach does not account for time-dependent effects in the resin, such as the relaxation of residual stresses. Therefore, the development of numerical methods capable of capturing these effects is needed in future work.

5 CONCLUSION

In this study, a numerical analysis framework is developed to investigate the relationship between molding conditions, specifically cooling rate, and the geometric and mechanical characteristics of in-plane fiber waviness in CFRTP laminates. The proposed method incorporates a process-dependent residual stress formulation based on the crystallization behavior of semicrystalline thermoplastics and evaluates its influence on mechanical performance through comparison with experimental data.

The results demonstrated that higher cooling rates lead to more severe fiber waviness due to a wider waviness formation temperature interval associated with a lower crystallization temperature. The severity of fiber waviness is found to significantly affect both compressive and tensile strength, and the proposed simulation framework showed good agreement with experimental results under Medium and Fast cooling conditions.

Residual stresses generated around the fiber waviness region are shown to enhance compressive strength by offsetting the externally applied shear stress field, while they promoted failure under tensile loading due to reinforcement of the local stress field. These mechanisms were validated by both experimental observations and simulation results.

However, discrepancies between simulation and experiment under the Slow cooling condition highlight the limitations of the current framework, which does not account for time-dependent effects such as residual stress relaxation during slow cooling. Future work should focus on incorporating viscoelastic behavior and long-term stress relaxation models into the process simulation in order to further improve the accuracy and predictive capability of fiber waviness modeling in CFRTPs.

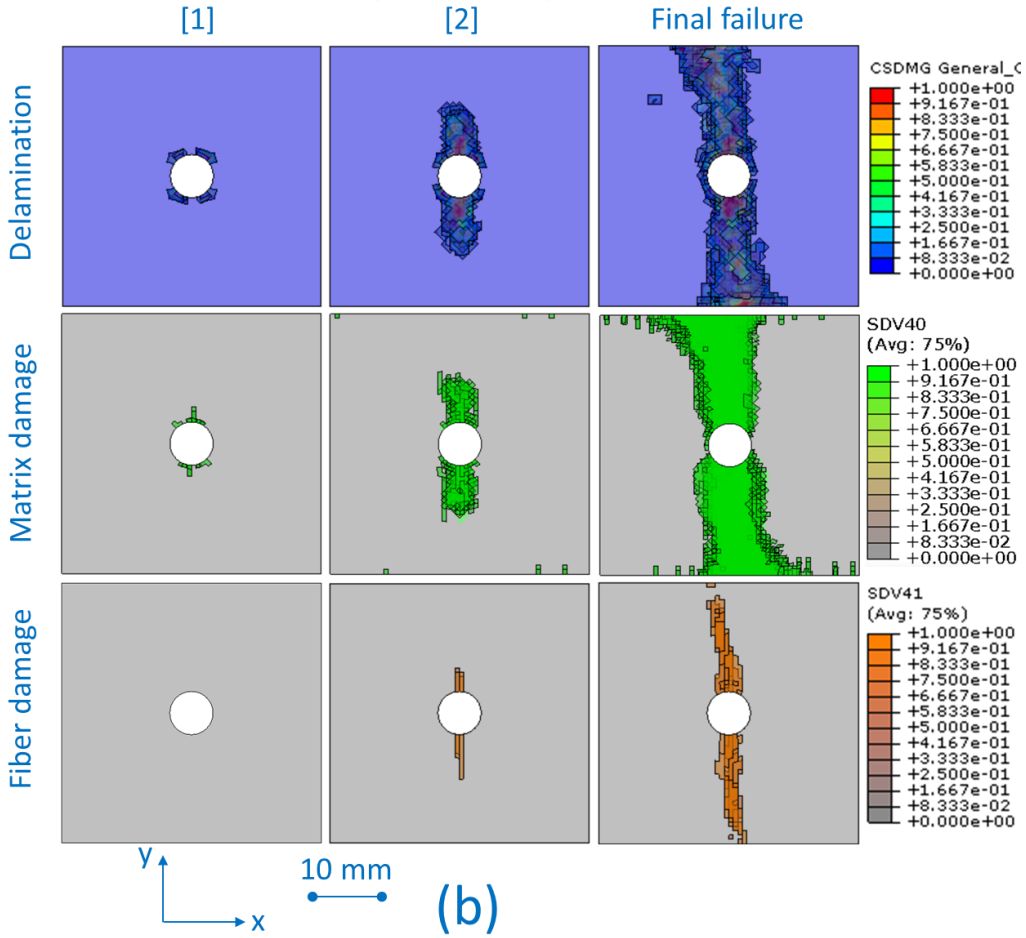
https://featips.com/2022/09/29/implicit-vs-explicit-analysis/

	Implicit PDFA (Backward Euler)	Explicit PDFA (Forward Euler)
Stable time increment size	Large	Small, proper mass scaling may be used
Analysis Accuracy	High	High only when sufficiently small time increment is used
Analysis Efficiency	High	Low
Analysis Robustness	Low	High, more suitable for damage propagation analysis
Abaqus subroutine implementation	Request Jacobian, stress, and state variable updates	Request stress, and state variable updates

1. Accuracy, Efficiency, and Robustness in PDFA



Load-displacement

(a)

Damage development

(b)

- Most of the OHT loading history (**Stage I**) is without damage initiation or propagation.
- At **stage II**, minimal matrix damage and delamination start to happen.
- At **stage III**, extensive damage of all the three modes keep growing, leading to the final catastrophic failure.
- **Most of the OHT analyses are done with explicit PDFA**. Some implicit PDFA may be conducted but most likely convergent until the beginning of **stage III** -- **no extensive damage propagation could be effectively predicted by implicit PDFA**.

1. Accuracy, Efficiency, and Robustness in PDFA

Commercial Software (e.g. Abaqus)

Implicit (fast)

Pristine to minimal damage

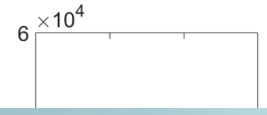
Damage analysis model (e.g. EST)

Load-displacement **Damage development**

[1] [2] Final failure

- Fast implicit PDFA analysis only applicable to Stage I and partially Stage II.

1. Accuracy, Efficiency, and Robustness in PDFA



Commercial Software (e.g. Abaqus)

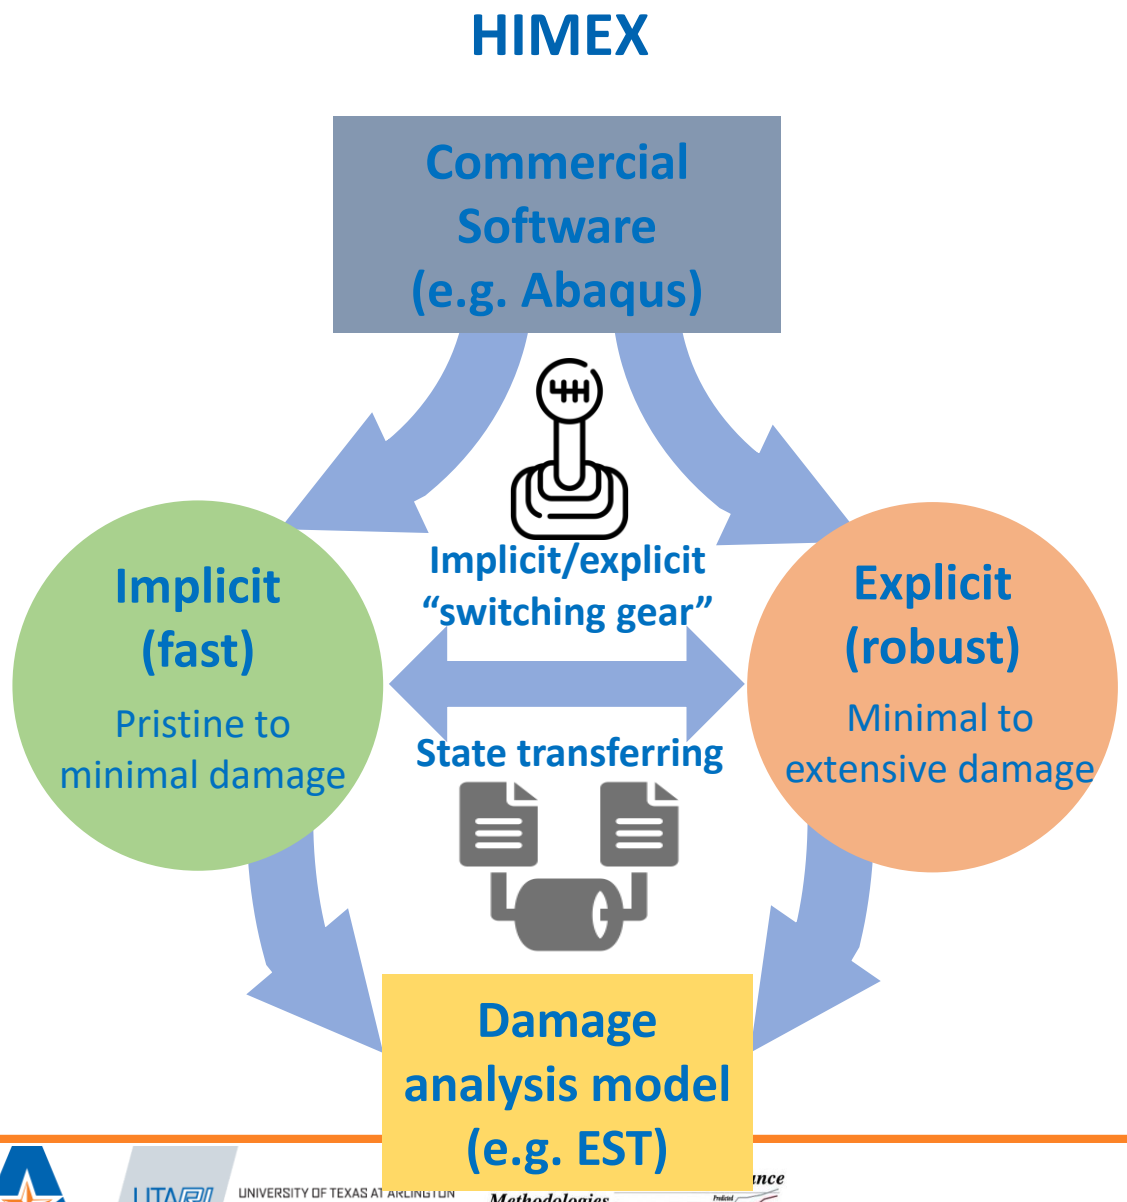
Explicit (robust)

Minimal to extensive damage

Damage analysis model (e.g. EST)

Load-displacement

Damage development

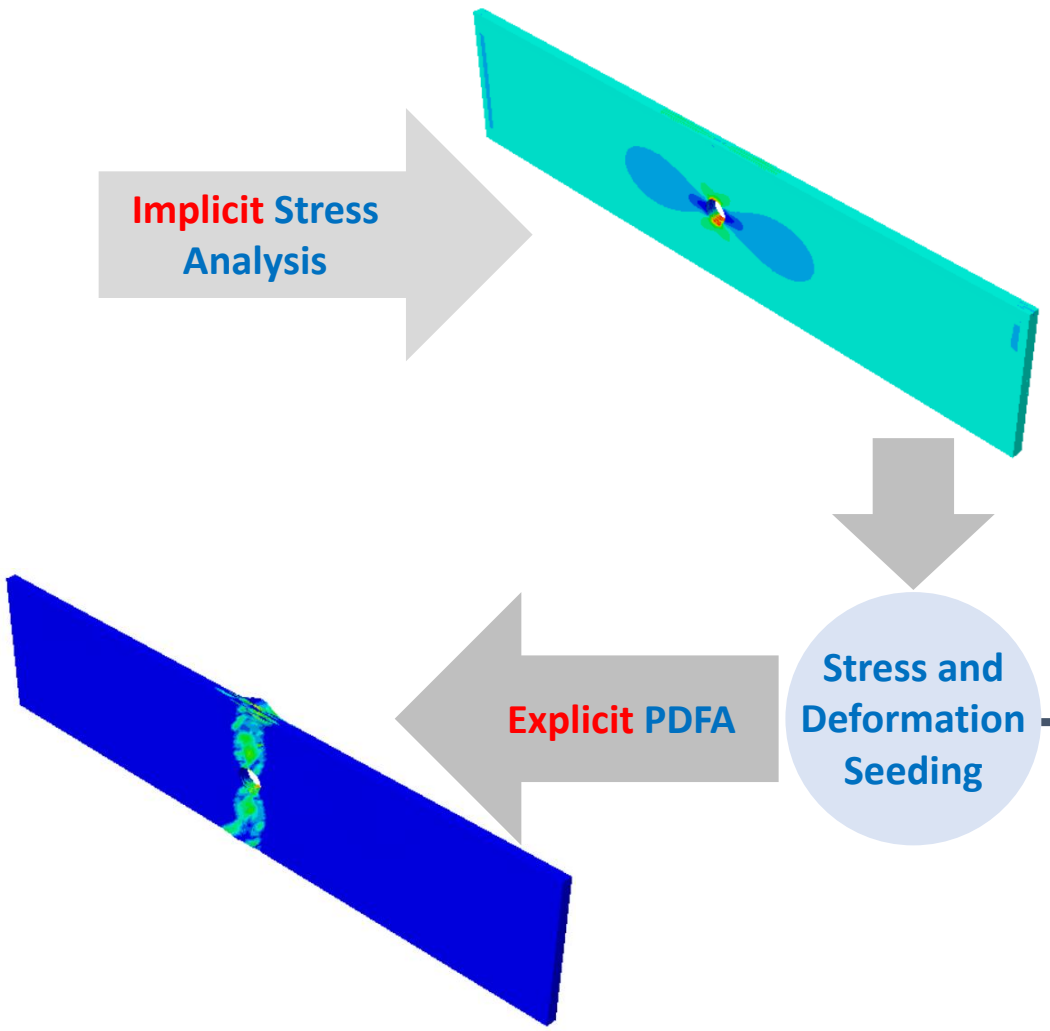


Analogy: Driving on a rugged uphill road with low gears

- **Rugged:** High numerical difficulty (e.g., damage propagation)
- **Low gears**: Slow and robust **explicit solver**

- Robust explicit PDFA applies to all the stages, but **not necessary for stage I**.

1. Accuracy, Efficiency, and Robustness in PDFA



- Many PDFA analysis cases (e.g., OHT/OHC, single-edge notched tension, compression after impact, etc.,) are initially and majorly with no or minimal damage initiation and propagation, followed by drastic/catastrophic damage propagation.
- Elastic implicit stress analysis is applicable to the undamaged stage for high efficiency. When damage is about to happen, explicit PDFA is activated to predict damage evolution and structural failure.
- The key questions are **how and when to transfer from implicit analysis to explicit analysis**.

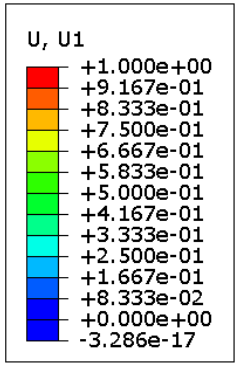
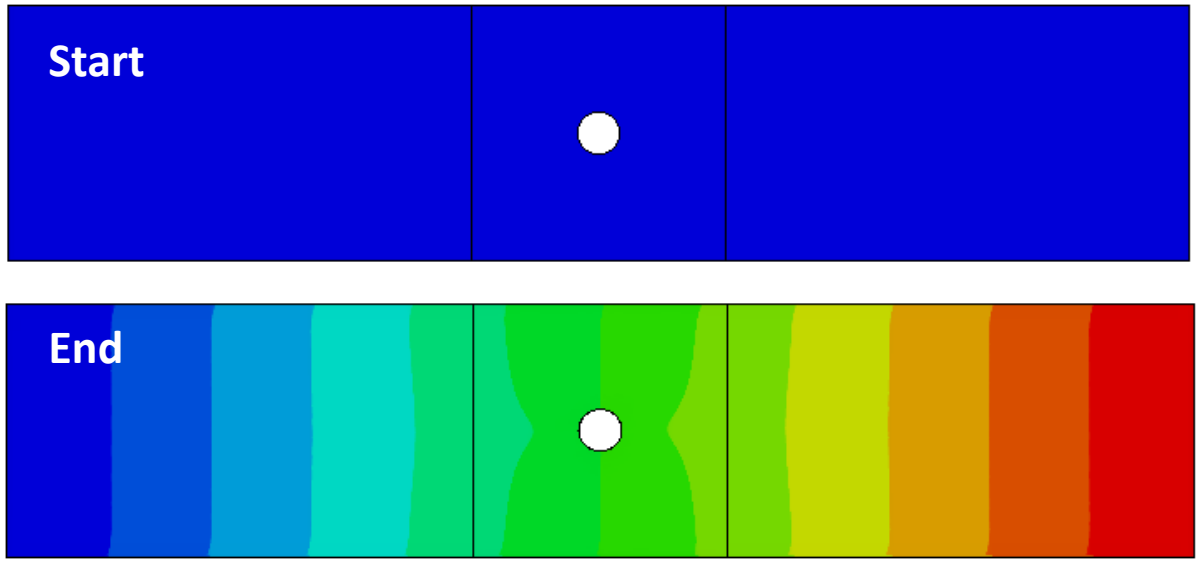
5. Conclusions and Vision



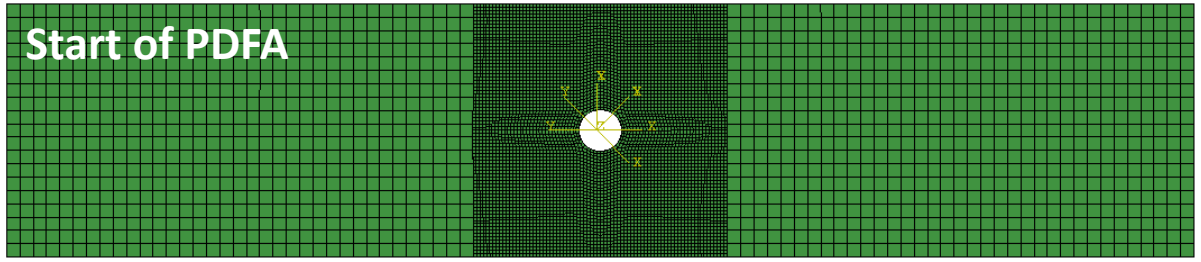
2. HIMEX: Hybrid Implicit-Explicit PDFA



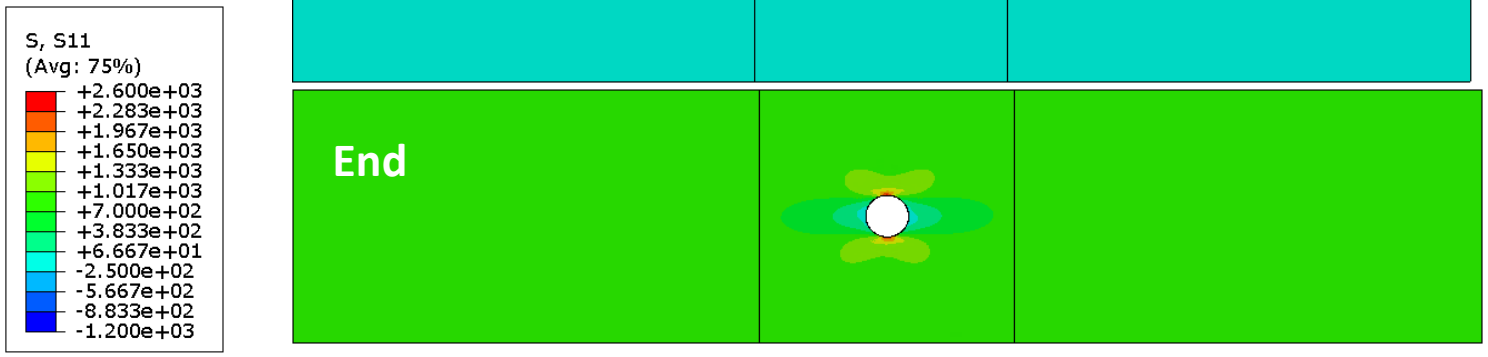
- Implicit stress analysis → state transferring → explicit PDFA.
- For most quasi-static testing of composites, **only one** "switching gear" is needed. Therefore, HIMEX may not be applied to impact or fatigue analyses yet.
- Deformed **geometry**, full-field **strains**, and **stresses** are to be transferred from the implicit stress analysis to the explicit PDFA.

2. HIMEX: Hybrid Implicit-Explicit PDFA: Deformation Transferring

Implicit Stress Analysis

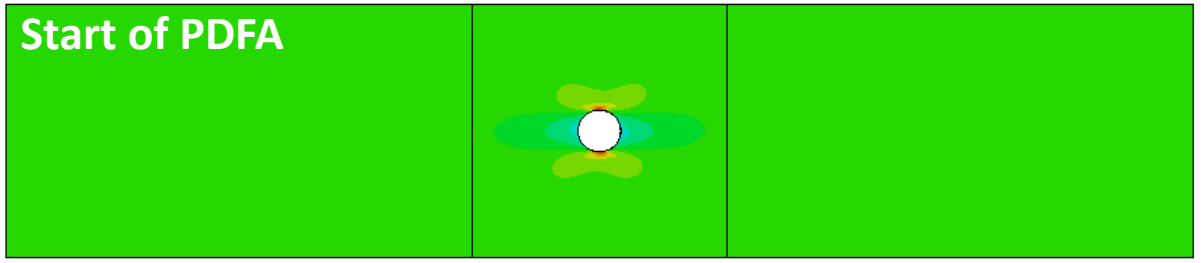


Explicit PDFA: starting with a deformed mesh



Deformed mesh imported from the end of the implicit analysis

- Implicit stress analysis is the first step of HIMEX.
- Deformation transferring is ensured by **importing nodal coordinates of the deformed mesh** at the end of the implicit analysis to the explicit PDFA mesh.
- Deformation interpolation can be achieved **between different meshes**, enhancing the flexibility of HIMEX.
- Explicit PDFA starts with a deformed mesh and **pre-existing stresses and strains** need to be imported.
- A **semi-automated Python script** has been developed to facilitate fast deformation transferring.



2. HIMEX: Hybrid Implicit-Explicit PDFA: Stress and Strain Transferring

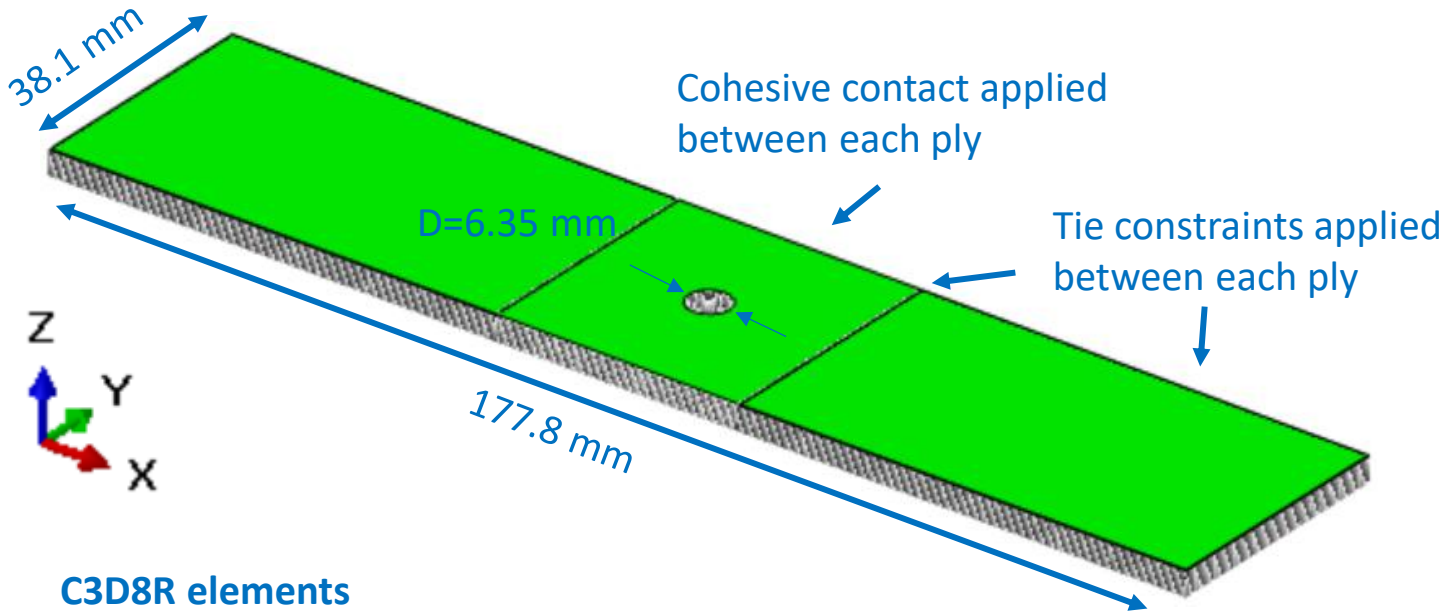
Implicit Stress Analysis

Explicit PDFA: starting with pre-existing stresses and strains

Stress states imported from the end of the implicit analysis

- Stress transferring is ensured by **importing stresses from the integration points** of the implicit mesh to the corresponding **integration points** of the explicit mesh.
- Strain transferring is ensured by calculating the pre-existing strains of the PDFA model by:

$$\{\epsilon^{pre}\} = [S]\{\sigma^{pre}\}.$$



where, $[S]$ is the elastic **compliance matrix**.

- A **semi-automated Python script** has been developed to facilitate fast **stress transferring**.
- The PDFA model enhanced Schapery theory (**EST**) **has been modified** to facilitate fast **strain transferring**.

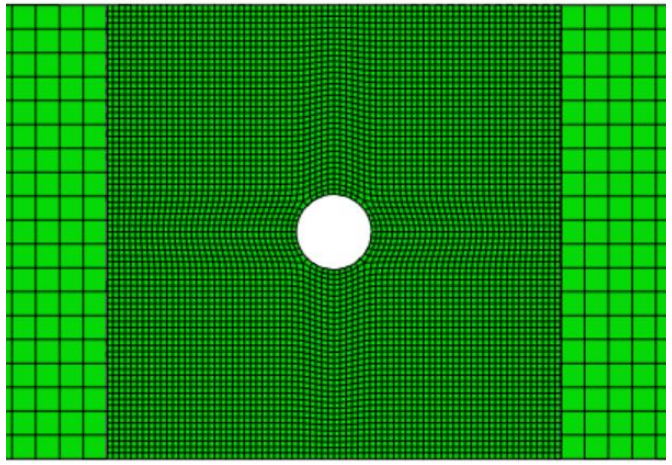
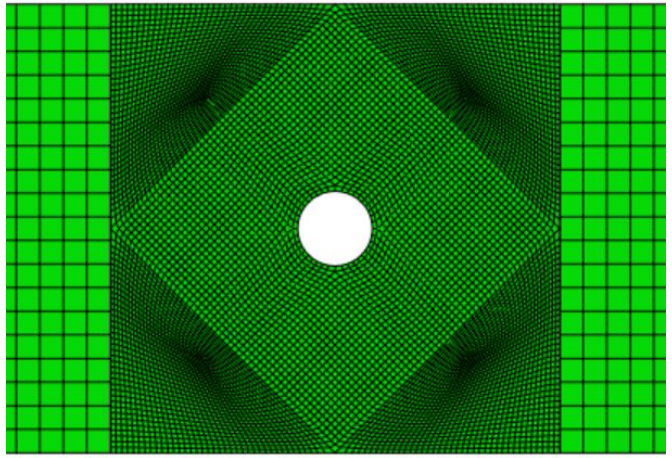
5. Conclusions and Vision

3. Application Example: OHT – Model and Mesh



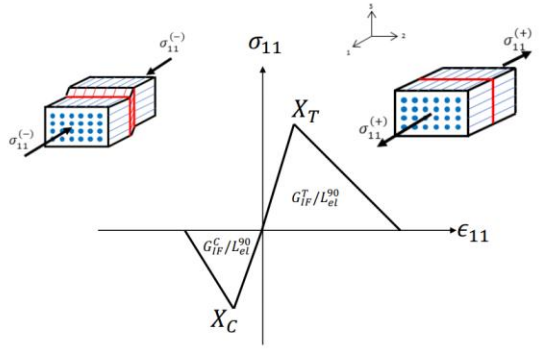
C3D8R elements
HIMEX Analysis
Mass scaling target time increment 1e-5 s



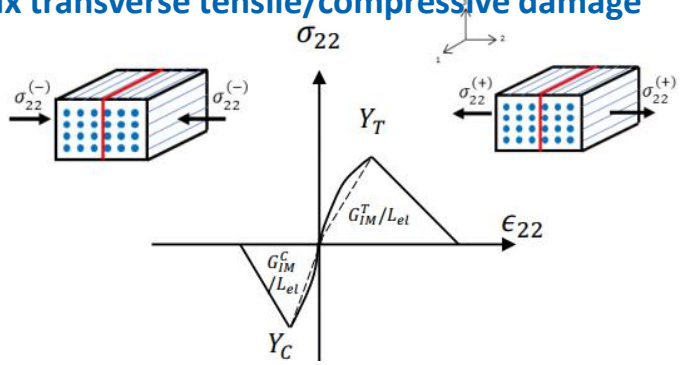
Virtual extensometers

0°- or 90°-ply mesh

45°- or -45°-ply mesh

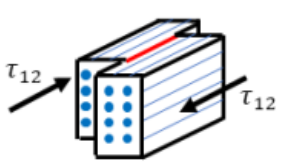


Fine: 0.5 ~ 0.6 mm, Coarse: 2 mm

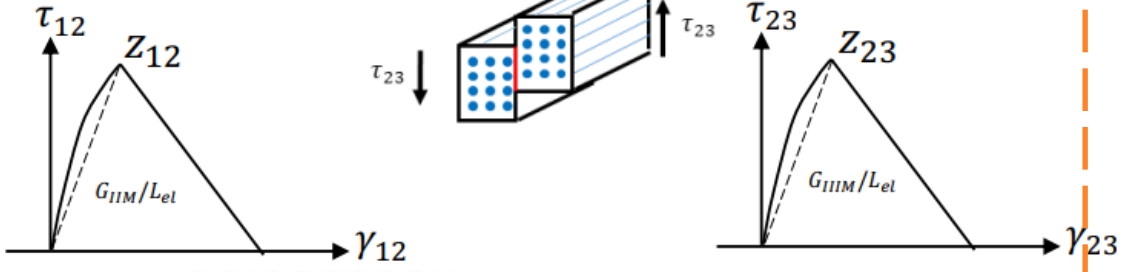


3. Application Example: OHT – PDFA Model EST

Damage modes of 3D EST

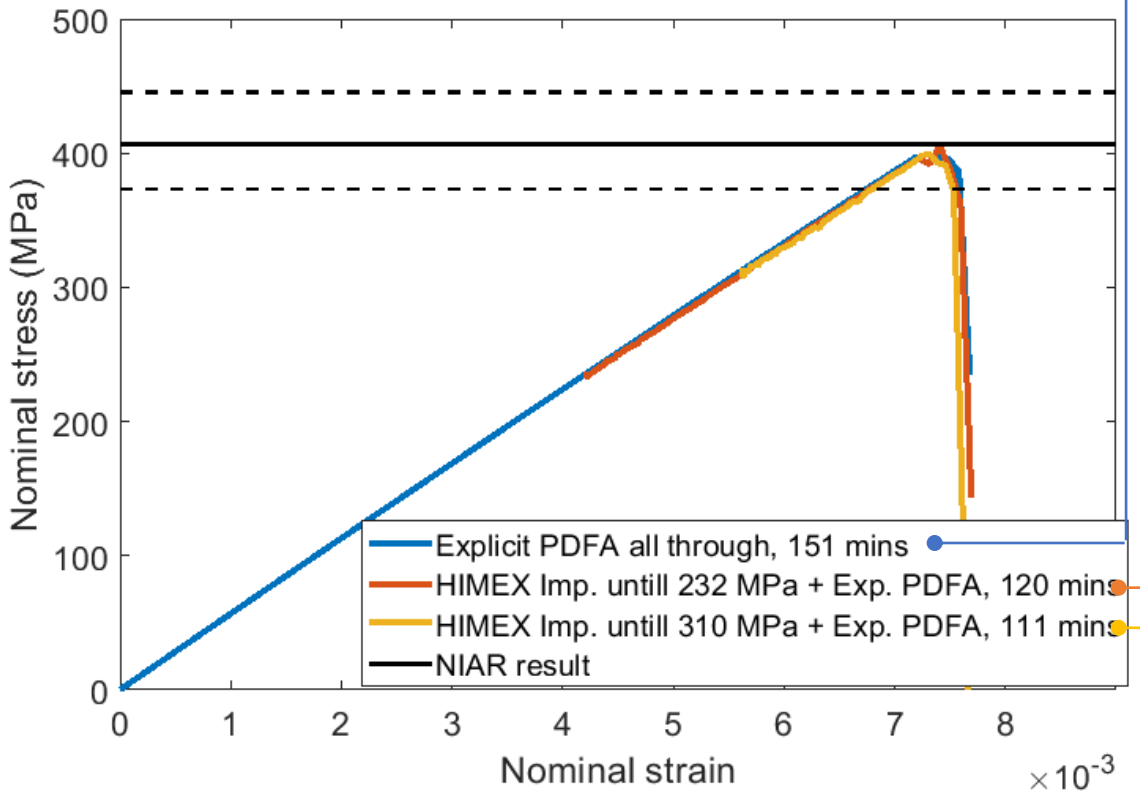


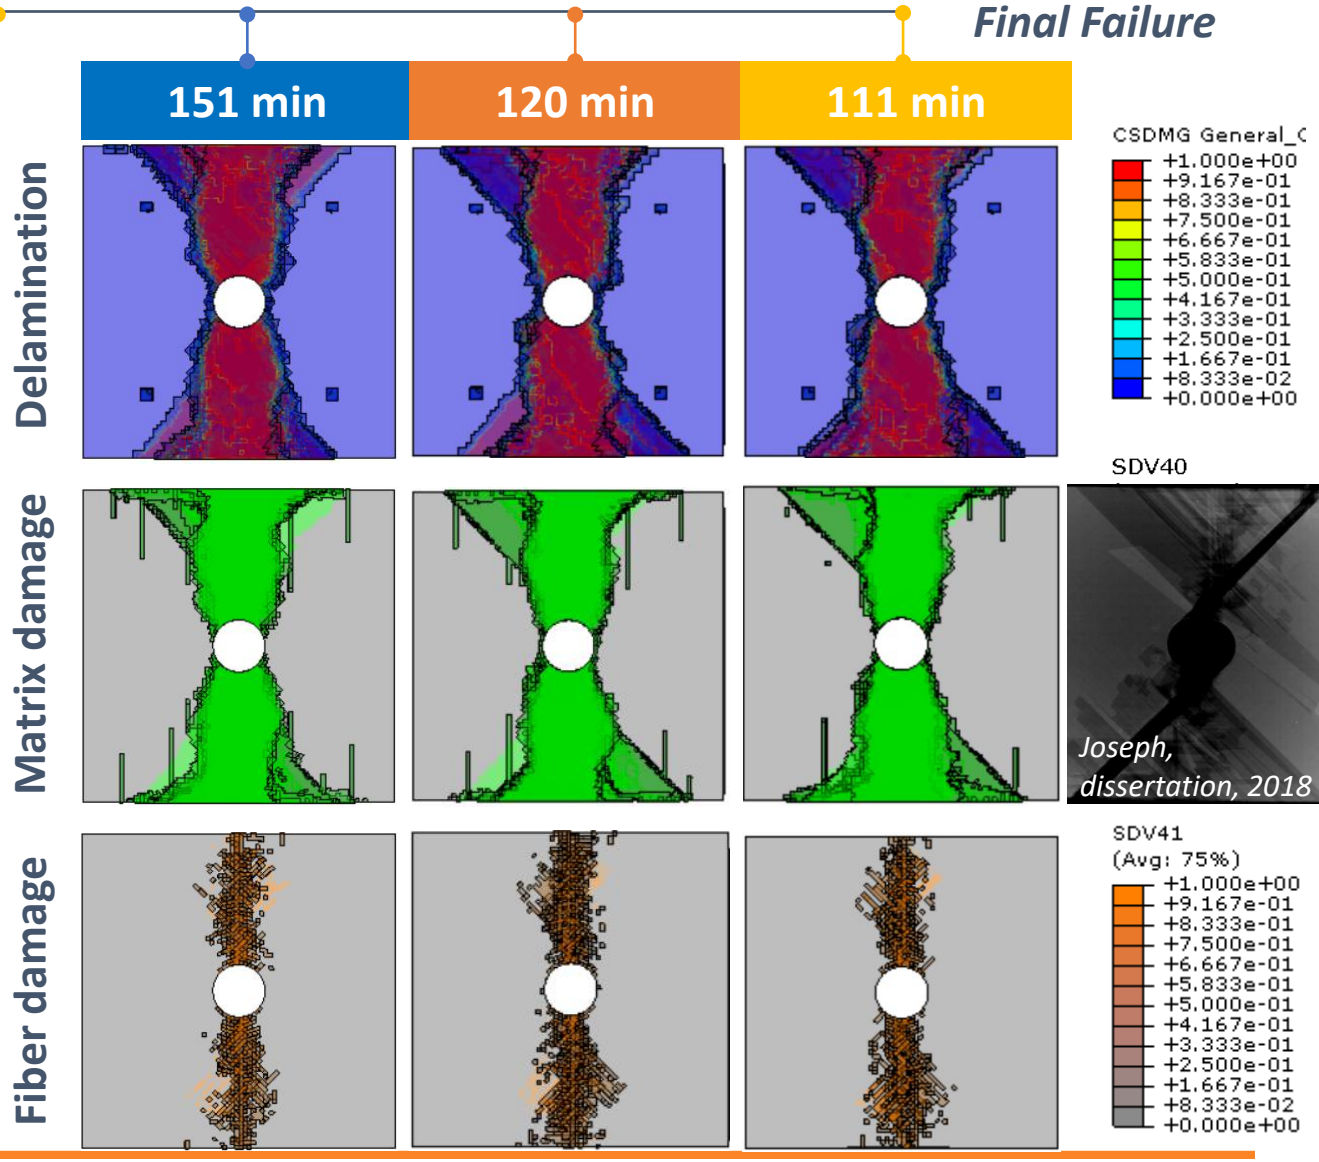
Fiber tensile/compressive damage



Matrix transverse tensile/compressive damage

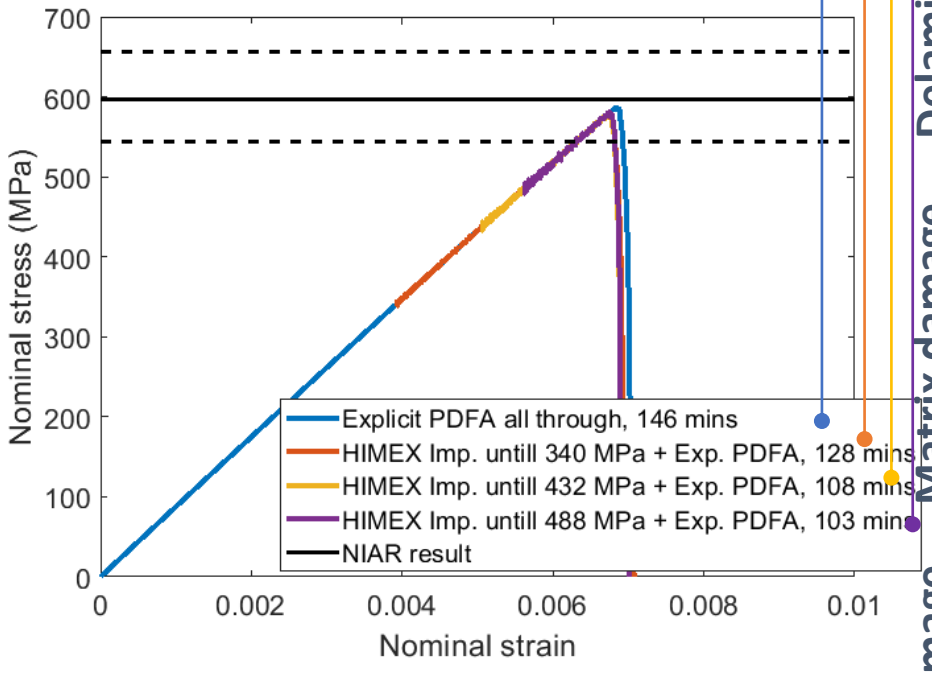
Matrix in-plane shear damage



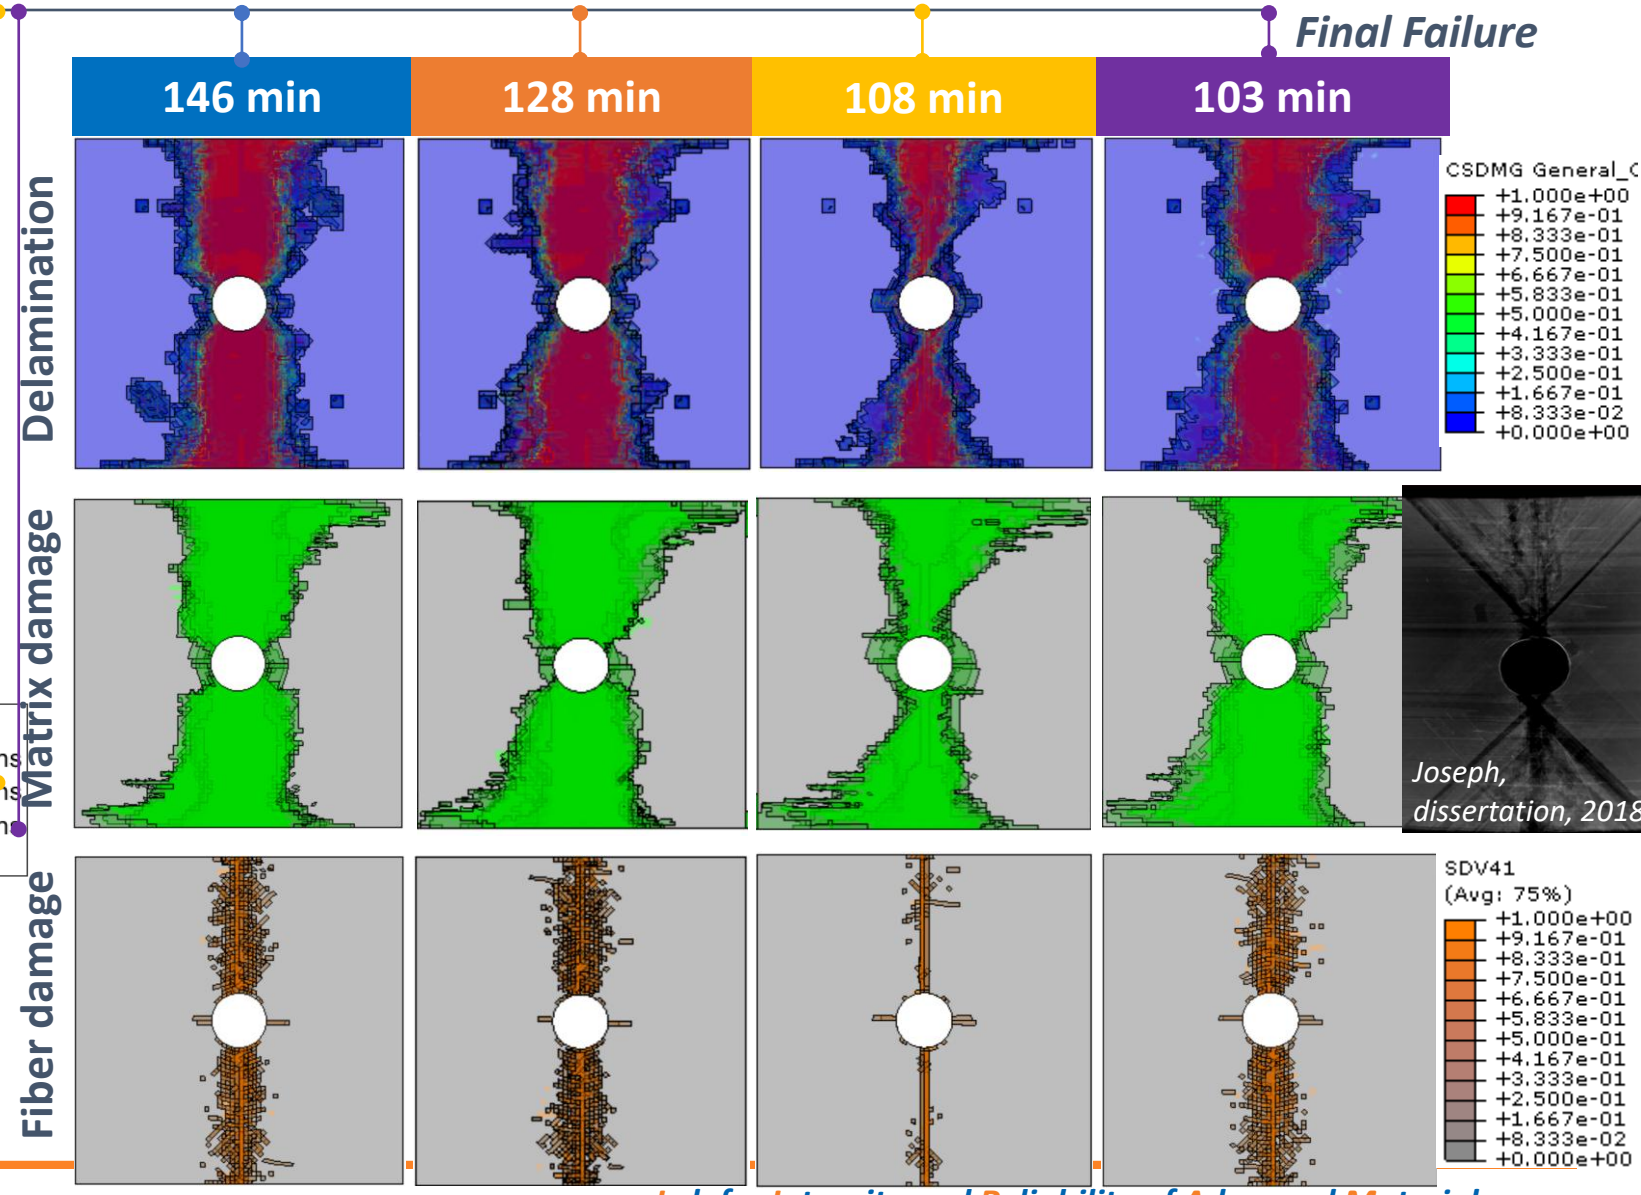


Matrix transverse shear damage

- Enhanced Schapery Theory (**EST**) combines Schapery Theory (**ST**) (Schapery, 1989) and the Bazant-Oh Crack Band (**CB**) (Bazant, 1983) model to analyze the intra-ply damage and failure of a lamina
- Implemented with Abaqus VUMAT.

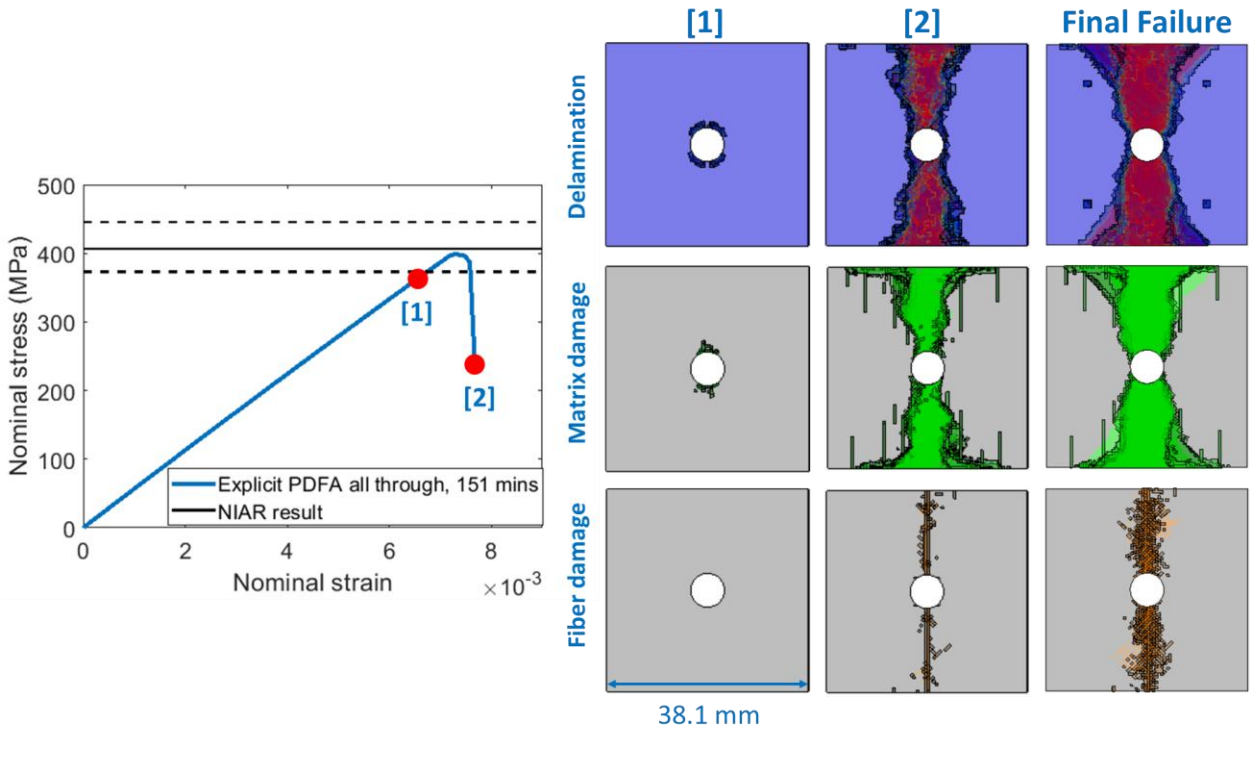


3. Application Example: OHT Results [25/50/25] Layup

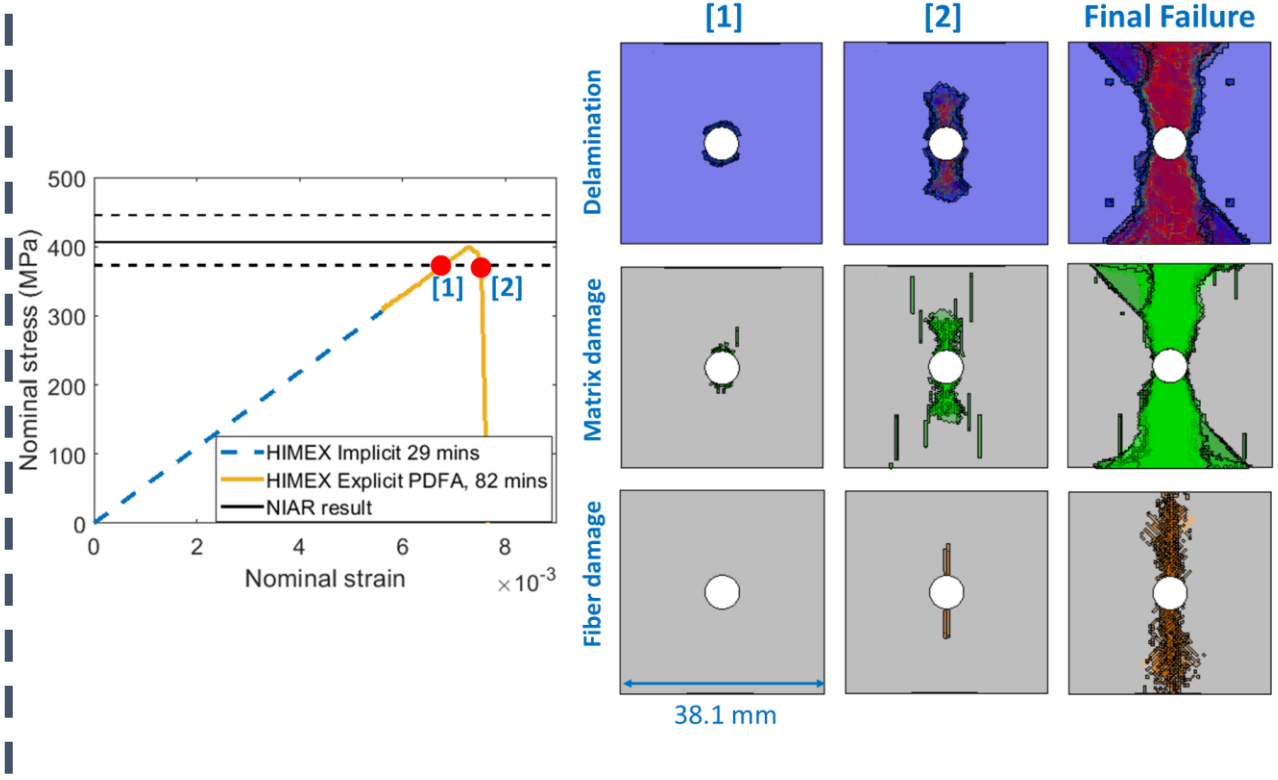


- Max time saving: 26.5%
- No accuracy loss.

3. Application Example: OHT Results [50/40/10] Layup



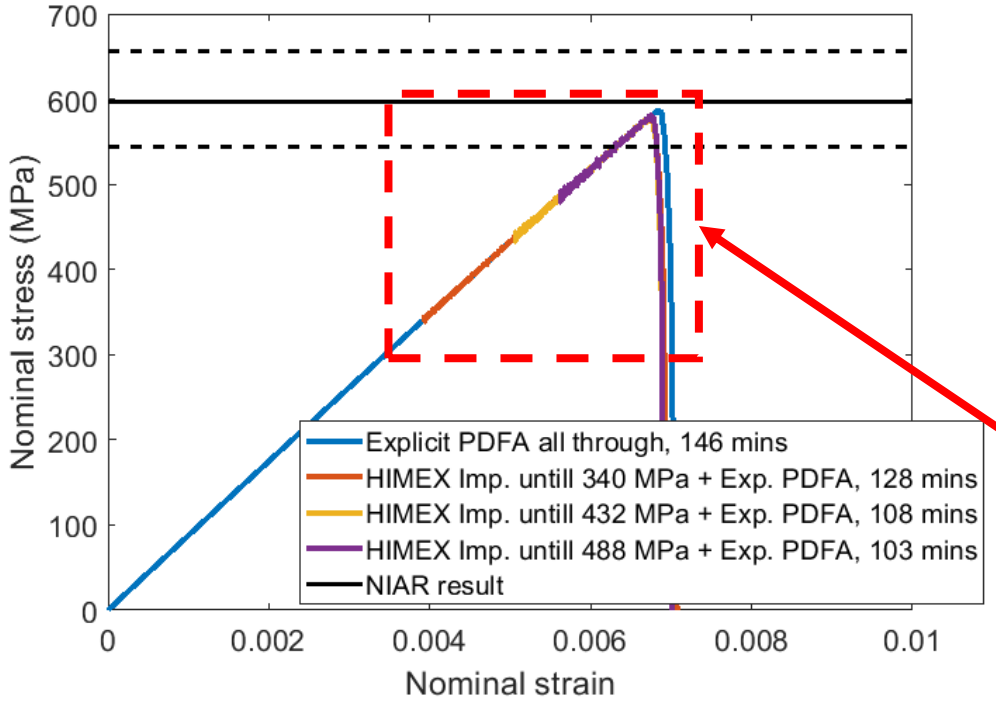
- Max time saving: 29.5%
- No accuracy loss.

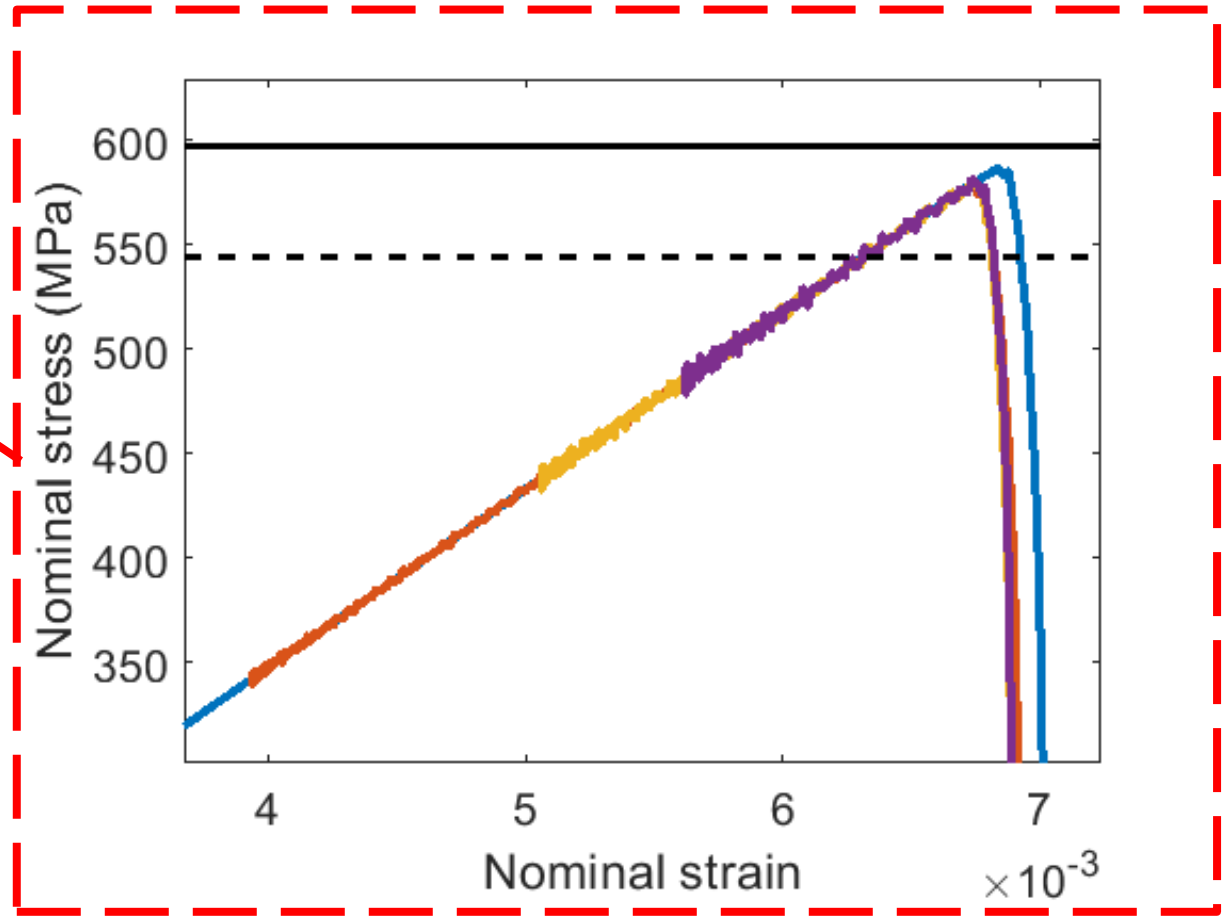


3. Application Example: OHT Results: Damage History of the [25/50/25] Layup

Explicit PDFA All Through: 151 mins

HIMEX: Implicit analysis (29 mins) + Explicit PDFA (82 mins)



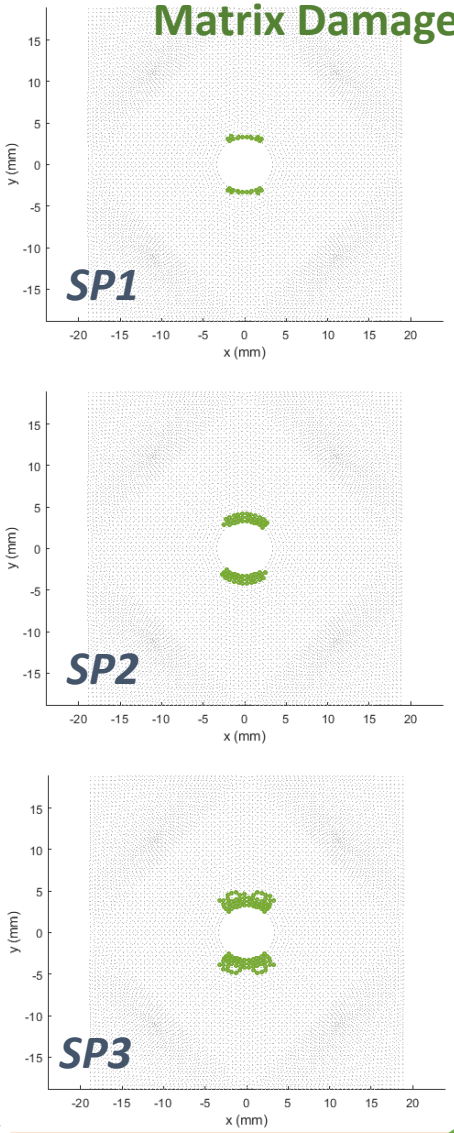


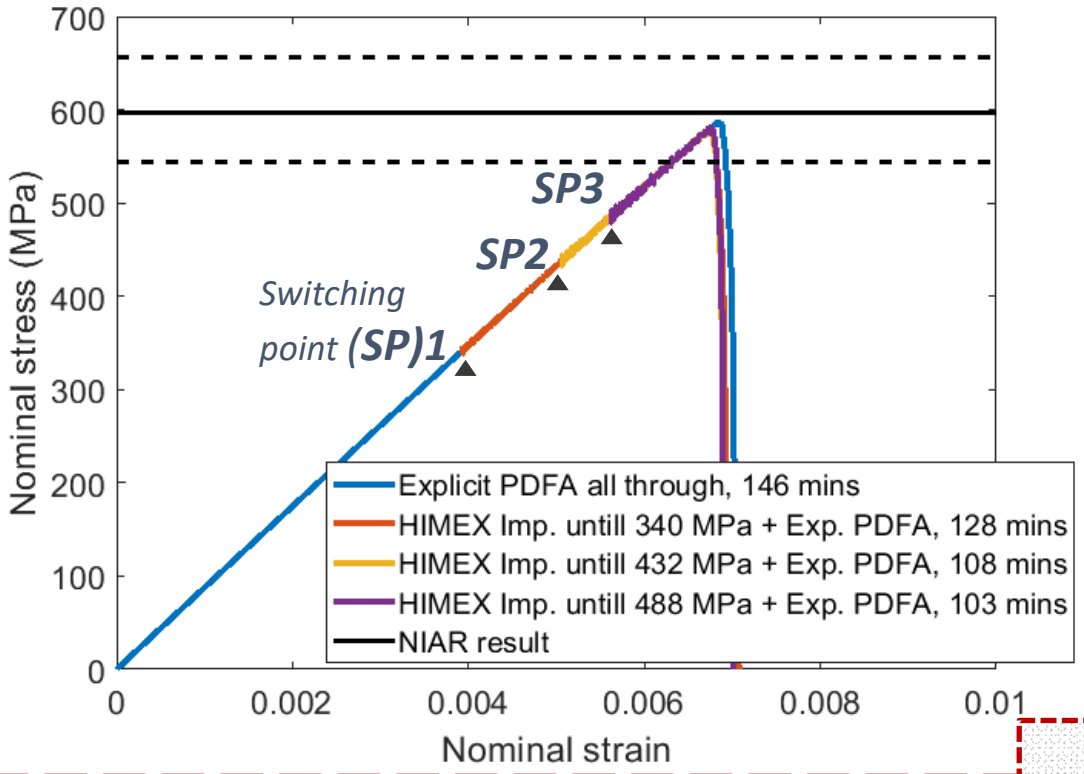
- The predicted damage development histories are highly similar.
- Snapshots of damage taken at slightly different time due to the mismatch of starting points.

Content

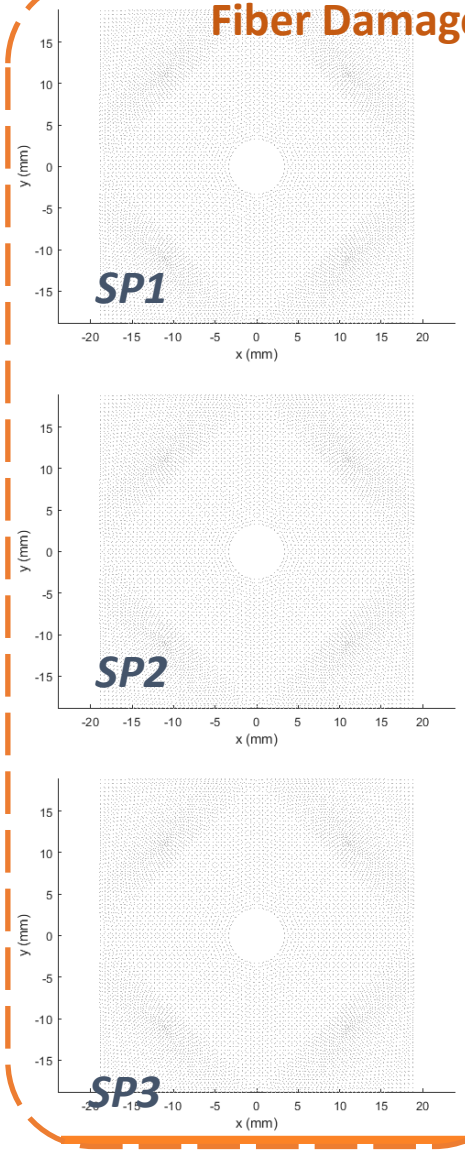
1. Numerical Accuracy, Efficiency, and Robustness in Progressive Damage and Failure Analysis (PDFA)
2. HIMEX: **H**ybrid **Im**plicit-**Ex**plicit PDFA
3. Application Examples: Open-hole Tension
4. Discussions
5. Conclusions and Vision

4. Discussions: Numerical Oscillations induced by HIMEX



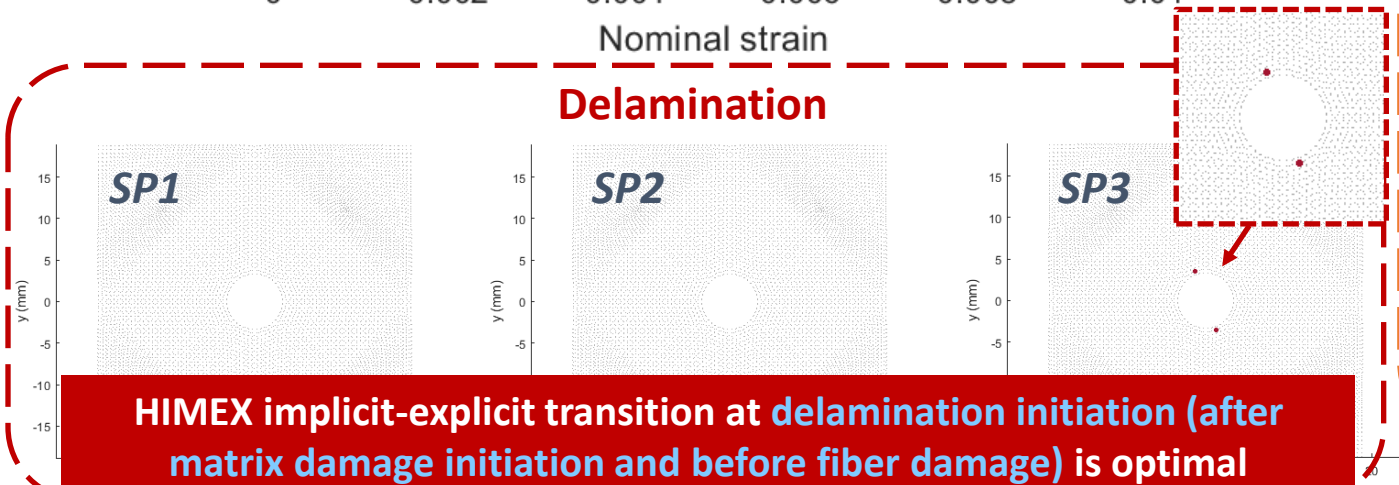


- After the implicit-explicit transitioning, **numerical oscillations** are seen. The later the transition, the higher the oscillations.
- The numerical oscillations are likely to be induced by 1) **precision** of stress and strain transferring. 2) **damage initiates** shortly after transition, and 3) exact **force equilibrium** is inherently **not ensured** in explicit analysis.



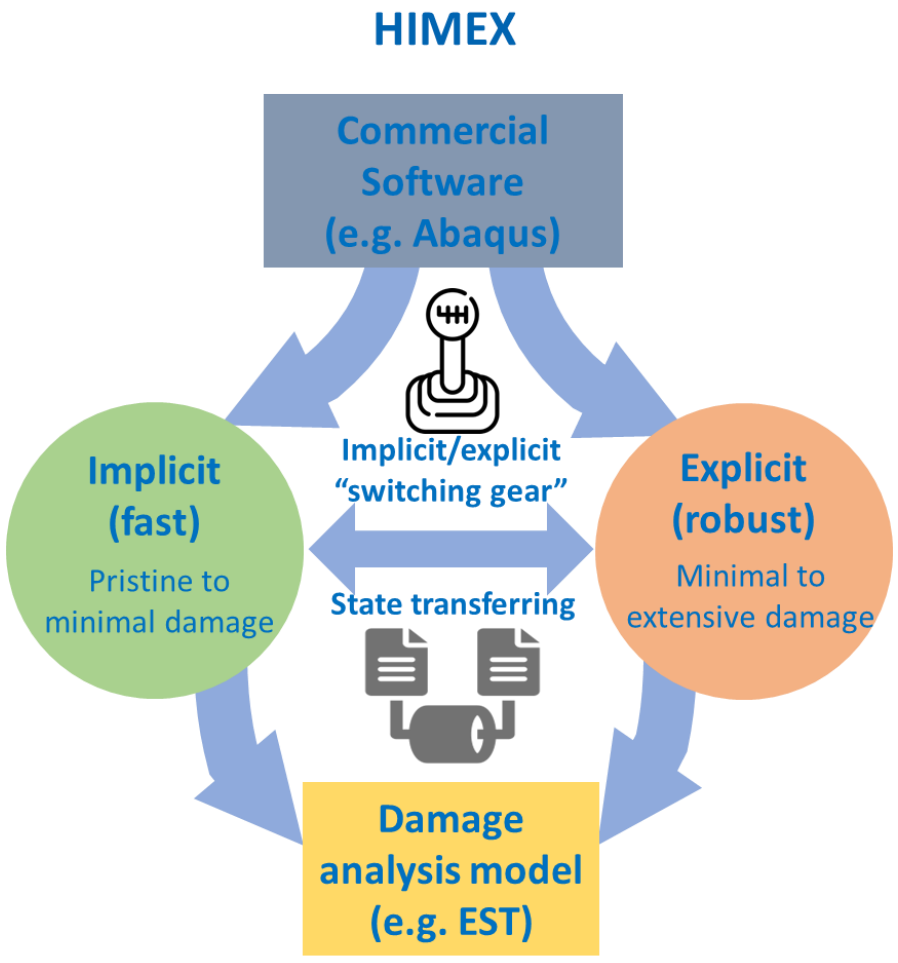
4. Discussions: When to "Switch Gears" in HIMEX

Matrix Damage



Fiber Damage

Delamination



HIMEX implicit-explicit transition at delamination initiation (after matrix damage initiation and before fiber damage) is optimal

Content

1. Numerical Accuracy, Efficiency, and Robustness in Progressive Damage and Failure Analysis (PDFA)
2. HIMEX: **H**ybrid **Im**plicit-**Ex**plicit PDFA
3. Application Examples: Open-hole Tension
4. Discussions
5. Conclusions and Vision

5. Conclusions

- A new **h**ybrid **im**plicit-**ex**plicit (**HIMEX**) PDFA framework has been developed to accelerate the PDFA. HIMEX leverages the advantages of both the implicit (high efficiency) and explicit (robustness) algorithms.
- Demonstrated by the OHT application cases, HIMEX **saves the computation time up to 29.5% without compromising accuracy**.
- HIMEX is **transferrable across analysis software packages and PDFA subroutines**, generally applicable to quasi-static damage analysis of composites (e.g., OHT/OHC, SENT, SLP, DCB/ENF/MMB, etc.)
- Future directions include applying HIMEX to more complex cases (e.g., postbuckling and CAI) and developing HIMEX with **multiple explicit-implicit transitioning** for fatigue analysis.

Thank you, Question?

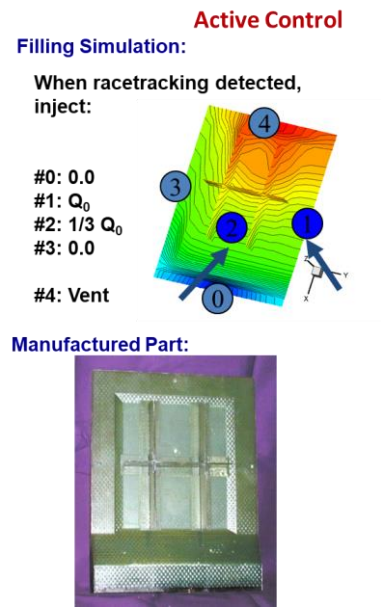
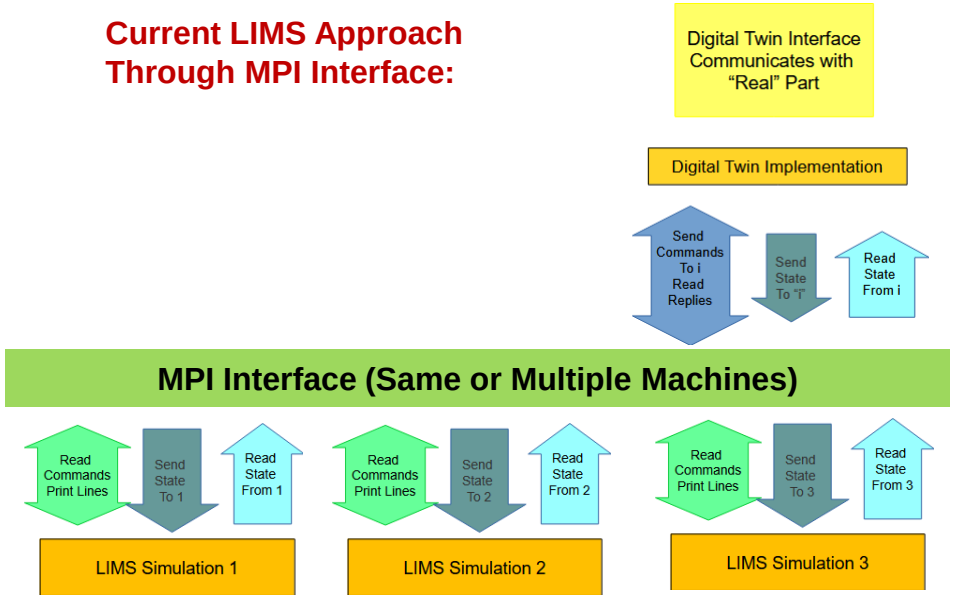
Process Control and Sensing



To Use Simulation for Digital Twin It Must Allow Control of Model Process

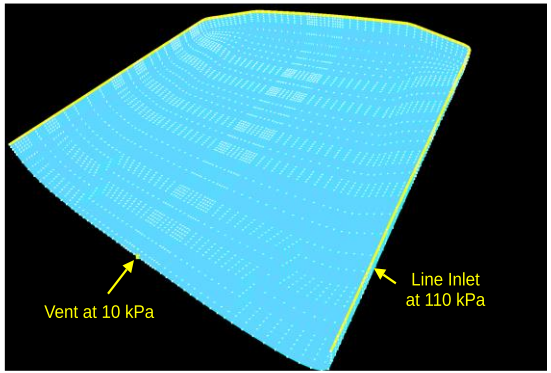
- Simulation of Sensor Action Needed!
- Implementation of Control Elements (Say, Additional Gates) Needed

Simulation Capability Available for Digital Twin Development

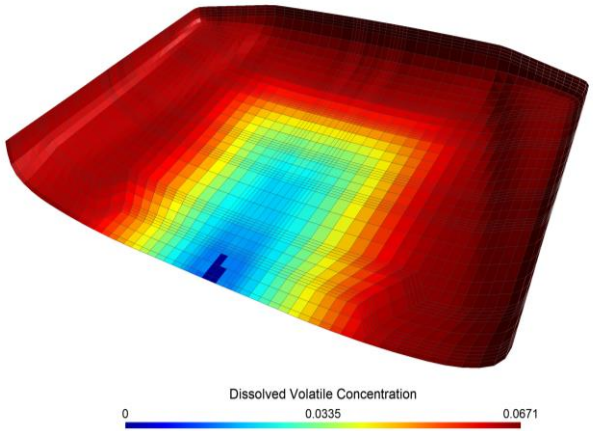


- Most Liquid Composite Molding Processes Can Be Satisfactorily Modeled
  - Performance is *Very* Acceptable even for Large Number of Possibilities
  - Variations of LCM Processing Have Been Addressed
  - Modeling Extra Distribution Hardware (Tubing, Distribution Media) Has Been Fully Resolved
- Process Variability Has Been Addressed. Disturbances Based on Part Geometry Have Been Successfully Generated
- Control Actions Can Be Designed and Modelled
  - Approaches Vary, Generic Recipe Still Ahead (Space for ML Here)
  - Actual Implementation Remains Task for Digital Twin Development

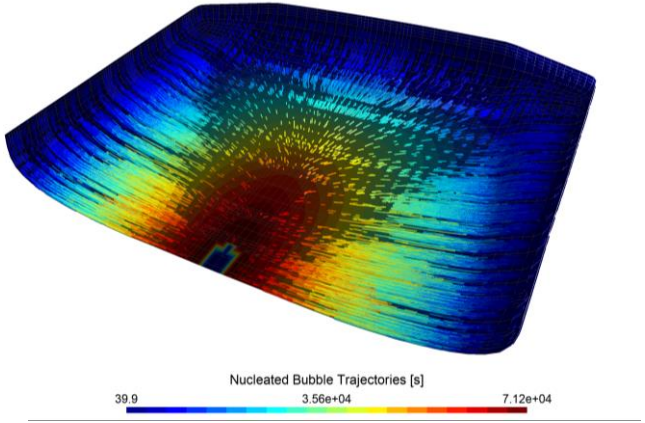
Communication Between Simulation and Outside World



What Is Needed to Use Simulation On-Line Within Digital Twin



- Simulation Flexibility to Change Settings Mid-Way of Run
- Mechanism for Digital Twin Code to Send Commands to Simulation
  - Change the State of Parameters As Needed (Determined from Physical Realm)
  - Modify Simulation State on the Fly Including Injection Control Option(s)
- Mechanism to Transfer Simulation Data Between Executed Programs
  - This Can Be Used to Chain Other Models "In" as Needed (Volatiles, Heat….)
  - It Can Facilitate Parallelization



Current LIMS Approach Through MPI Interface:

MPI Connectivity and Coupling LIMS Simulation with Additional Process Physics Models (Volatile Transport)

Properly Resolved Communication (In This Case over MPI) Broadens the Process Model Applicability

Conclusions

- The Construction of Digital Twin for LCM Requires Process Modeling
  - Either Directly or to Train AI
- Process Model Must Handle The Usual Trappings of LCM Processes (Most Do)
- Process Model Must Simulate Process Variability (Most Do)
  - To use On-line Modeling, The Model Parameters Must Be Accessible *During* the Simulation (LIMS Allows This)
- Process Model Must Simulate Control Action (Some Do)
  - To use On-line Modeling, The Controls Must Be Accessible *During* the Simulation (LIMS Allows This)
- Important Features for Actually Using Simulation are Inter-Process Communication and Computational Performance

Keywords: Computational modeling, Finite element analysis FEA, Filament winding

ABSTRACT

The coreless filament winding (CFW) is a novel robot assisted manufacturing process, where impregnated fiber bundles are wound around sleeves in a defined chronological order. Unlike conventional winding, there is no mandrel available to define the resulting shape. Instead the fiber-fiber and fiber-sleeve interaction, influenced by winding sequence and prestress, is forming the final fiber architecture. Depending on the load case of the subsequent area of application, a precise knowledge on the cross-section of the resulting fiber structure is required for a reliable structural evaluation. In order to enable virtual modeling of the forming process, an expansion-based multifilament method is presented. The values for influencing parameters, such as filament diameter, static coefficient of friction, Young's modulus, pretension and penalty stiffness require a balanced interaction and therefore need to be optimised to experimental results during an optimization loop. To evaluate the deviation between simulation results and experimental data, the area and maximal dimensions in a cross-section of a specimen is used.

1 INTRODUCTION

The coreless filament winding technique is a novel robot assisted manufacturing process, where pre-impregnated tows are wound around sleeves in a predefined pattern without a mould resulting in shell-like truss or lattice structures. The flexibility in shape design and its potential for lightweight construction make the process suitable not only for the architectural sector, but also as topology-optimized fiber-reinforced connecting elements or satellite structures. For this highly interconnected structure a sufficient fiber-fiber interaction is required to ensure a reduced buckling length for each free-spanning fiber segment between two fiber connection points [1]. The non-cured, impregnated fibers exhibit no bending resistance during fabrication so that each newly added fiber segment deforms the previous ones [2]. This deformation significantly influences the final shape of the structure and introduces tension in the previously wound fibers. The final structural architecture thus results from fiber-fiber and fiber-sleeve-interaction during the process as well as sleeve point positioning and orientation [3]. A precise cross-section is required to reduce over-dimensioning and material waste. Due to compaction of the fibers during the process and the typically large number of tow crossing points in coreless wound structures, analytical calculation of fiber architecture and bundle cross-sections of

complex structures is challenging. To obtain detailed data prior to fabrication and virtually replicate manufacturing as basis for structural and process optimization, a process simulation workflow has been developed by Hügle et al. using an explicit finite element approach [4]. The finite element approach is able to capture the elastic deformation and friction but requires a long computation time, thus limiting the applicability for large structures. Furthermore, it indicates that modeling of fiber deformation must be included in the simulation for a realistic prediction of fiber architecture and cross-sections. Modeling of a realistic tow shape is a wide-ranging research topic during the generation of unit cell models in woven composite simulation. Here, single and multifilament relaxation models have been used to simulate the fiber-fiber-interaction that form the resulting structure on a sub mesoscale model as reviewed by Wielhorski et al [5]. The approach has been continued by Jones [6] to model the influence of winding sequence and pin configuration on a mandrel for a wound truss structure. In this work the multifilament approach is extended to predict the fiber architecture and cross-sectional yarn deformation of a coreless-wound structure. As a mandrel is not used for this manufacturing technology, an expansion-based approach is applied, which requires a parameter fitting to experimental data to obtain information on realistic fiber bundle deformation.

2 METHODOLGY

In the following section the fundamentals for the methodology of the simulation approach will be explained. Afterwards the implemented procedure to evaluate selected cross-sections of a simulation result and quantify the deviation to experimental results are described. The methods are then implemented in an optimization loop with the software tool LS-Opt to identify values for the following parameters: virtual fiber diameter, static coefficient of friction, Young's modulus, internal loading and penalty stiffness.

2.1 MODELING APROACH

The software used for the expansive modeling approach is the solver SimTex, developed by the Bristol Composites Institute. This explicit finite element solver was originally created for digital element simulation with an implementation of fast contact algorithms to reduce computation time for textile forming processes. The digital element method uses chains of artificial beam elements with a reduced stiffness matrix that are connected with joints [7]. This enables a reduced computational effort under usage of non-physically related material data. During multifilament textile forming processes, an initial single tow and respective fiber path, that represents an initial geometry of the fiber architecture, is transferred into arrays of multiple virtual fibers that interact with each other to form the deformed tow shape. This multifilament cross-section is derived by a division of the single virtual filament of the initial fiber path into multiple virtual filaments with a smaller diameter. By varying the number n_{virt_fibers} of virtual fibers per tow that represent it in the simulation and the diameter of this fibers d_{virt_fibers}, a realistic virtual textile architecture and cross-sectional shape can be modelled.

In the modeling approach, a single virtual filament fiber path out of a process simulation by Hügle et al. is transferred in an overlapping multi-filament cross-section (Fig. 1 a)) by scaling of the tow cross-section. In Fig. 1 c) a comparison of different amounts of virtual fibers for a circular virtual tow is displayed, where a single virtual fiber represents several physical fibers. This virtual tow is subsequently expanding due to penalty stiffness in the contact among the individual overlapping virtual filaments (Fig. 1 b)). The initial contact space between the filaments is defined by the dimensions of the mesoscopic fiber path out of the process simulation, where the initial dimension needs to be larger than the scaled virtual tow cross-section, but not too large to enable a sufficient interaction of the virtual filaments. To address this issue an additional internal loading and thus axial shrinking of the elements is applied to control the expansion and fiber interaction in SimTex. This expanding approach enables modeling of large cross-sectional deformations as they occur at intersections of fibers or at sleeves as shown in Fig. 3.

In the virtual filament approach by Jones, the diameter of the virtual filaments is dimensioned to preserve the total area of all physical fibers. The resulting calculated cross-section is then scaled to enable an expansion of the virtual tow. The methodology is also part of a pre-processor for SimTex. As the coreless winding uses pre-impregnated fiber bundles, this approach is extended to preserve the

theoretical wet yarn cross-section A_{wet} for a defined fiber volume ratio FVR, presuming that the total area of the real roving (including resin and neglecting pores) corresponds to the total area of the virtual roving.

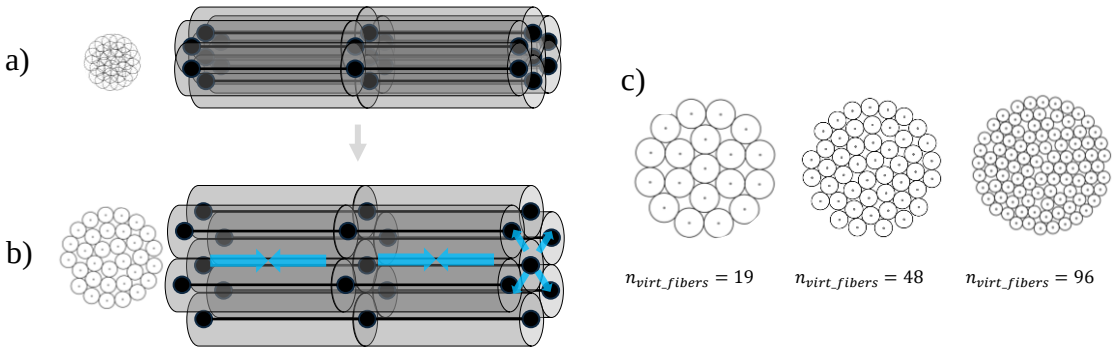

Figure 1: Schematic representation of the simulation approach: Initial overlapping virtual filaments (a) of a virtual tow that expand due to contact forces among the filaments controlled by additional internal contraction loading to a final expanded stage (b). Cross section of a circular virtual tow consisting of an increased number of virtual fibers and their respective centroid points (c).

Assuming a complete expansion of the virtual fiber bundle, the required diameter d_{virt_fibers} of a virtual filament in the impregnated modeling approach can be calculated by additional scaling. As the sum of cross-sectional areas of the finite number of virtual elements A_{virt_fibers} is not able to fill the circular cross-sectional wet tow area A_{wet} without free space, the packing density p_d of the virtual fiber bundle needs to be considered. the following equation (Eq. 1) must be satisfied:

$$A_{virt_Fil} = p_d \cdot A_{wet} \tag{1}$$

The value of the fiber volume ratio (FVR) of the wet tow can be calculated according to Eq. 2 using the physical diameter d_{fiber} and number of filaments n_{fibers}:

$$A_{wet} = \frac{n_{fibers} \cdot \pi \cdot \left(\frac{d_{fiber}}{2}\right)^2}{FVR} \tag{2}$$

Considering a FVR of one, the same formula applies for A_{virt_Fil} and thus the diameter of a virtual filament d_{virt_fibers} can be calculated:

$$d_{virt_fibers} = d_{fibers} \sqrt{\frac{p_d \cdot n_{fibers}}{n_{virt_fibers} \cdot FVR}} \tag{3}$$

As shown in Fig. 2, the packing density of the cross-section can change during usage of different numbers of virtual filaments. The packing density of a centroid configuration can be calculated by dividing the total area of all virtual fibers by the resulting diameter d_{virt_tow} of the resulting virtual tow during a pre-calculation with $p_d = 1$ according to Eq. 4.

$$p_d = \frac{n_{virt_fibers} \cdot \ {d_{virt_fibers}}^2}{{d_{virt_tow}}^2} \tag{4}$$

The resulting unscaled cross-section of a virtual tow with 48 virtual fibers and the respective theoretical diameter of the impregnated wet yarn cross-section for the experimental data used in this study with a radius of $1.704\ mm$ is shown in Fig. 3 a). A scaling factor of 0.5 enables a reasonable fiber interaction during expansion and usage of the process simulation results with a bundle thickness of $2.5\ mm$ thickness without overlapping of individual fiber layers resulting in intertwined virtual fibers. A scaled

cross-section with a target scale factor of 0.5 and a resulting radius of 0.961 *mm* is illustrated in Fig. 3 b). The actual scale factor for this input data is 0.564 as the scaling is applied to the centroids of the fibers neglecting the influence of fiber bundle dimensions.

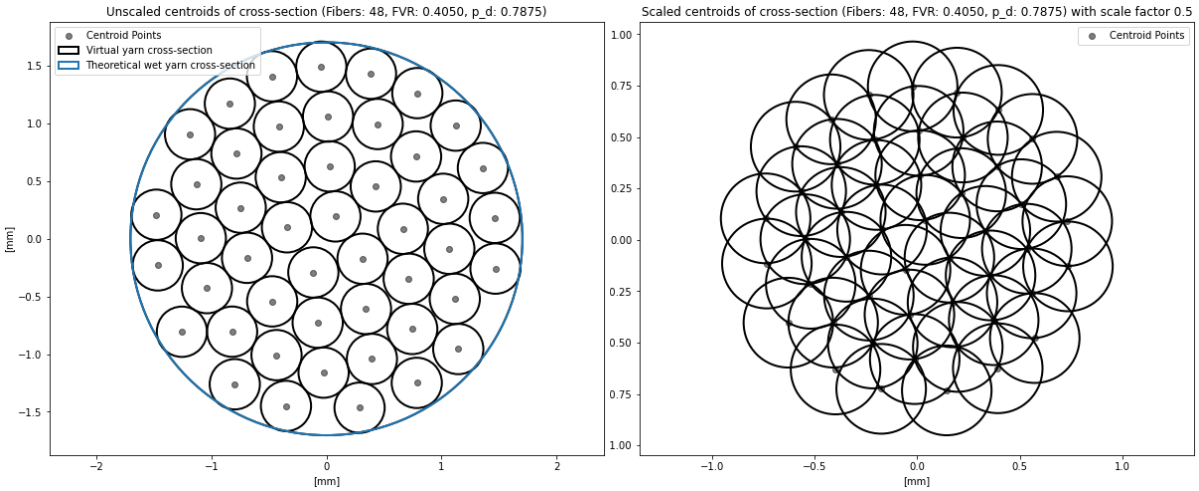

Figure 2: a) Unscaled cross-section of a virtual tow with 48 virtual fibers and the respective theoretical wet yarn cross-section. B) Scaled virtual tow with a target scale factor of 0.5.

In Fig. 3 shows a simulation model for the analyzed structure and the result after an interaction of the multiple fibers (Fig. 3 b)). The model of the sleeve (detail in Fig. 3 a)) is discretized with triangular *Tri*-elements, that are only used as rigid contact surface and are fixed in their translational and rotational degrees of freedom. The virtual fiber elements are modeled in SimTex as spherocylindrical *Line*-elements. These are defined by a discretization of the initial fiber path into elements of a user defined length. A high amount of virtual fibers with a resulting small diameter will result in a large aspect ratio (element length over diameter) and may cause penetrations at contact areas with a high curvature. To prevent these penetrations, the user-defined length is reduced when setting up the model to ensure an aspect ratio of 4 according to empirical results from Jones. The ends of the fiber path are fixed in fiber direction, but free to move in the cross-sectional plane perpendicular to it, allowing the filaments to move freely in crossing areas or at contact areas with anchors. The end of the yarn must be positioned so that the fibers are pulled towards the sleeve under tensile load. To define this boundary condition, a local coordinate system at each end point is used. As this local coordinate system is depending on fiber path and its discretization, the adjoining elements are used to define the new local x-axis with its direction pointing outward. The new local y-axis is defined with a rotation of the global coordinate system using the Gram-Schmidt orthogonalization method and the z-axis as a cross-product of these two axis vectors.

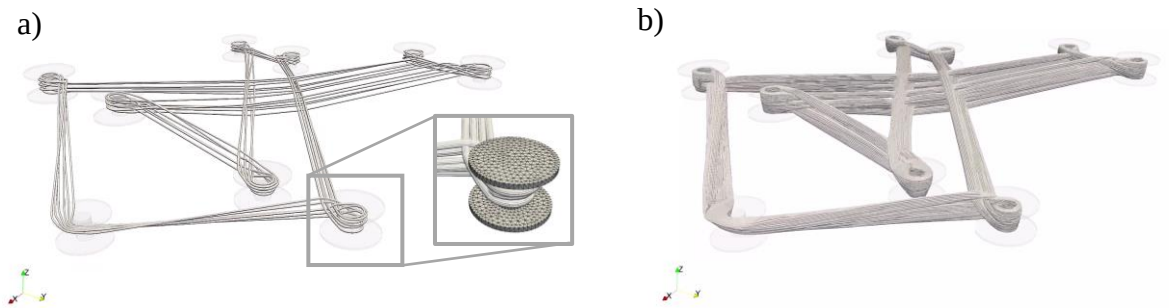

Figure 3: a) Initial configuration of the overlapping virtual fibers with a fiber path extracted out of a previous simulation of the winding process. The detail shows the discretization of the sleeve model. b) SimTex simulation result after interaction of the virtual fibers with each other.

2.2 APPROACH FOR GEOMETRIC ANALYSIS

To enable a comparison of the simulation results with experimental data, a fast but representative approach for the geometrical evaluation of a cross-sectional shape out of a point cloud is required. A convex hull is not sufficient for the irregular convex and non-convex shaped cross-section of those structures. Green et al [8] used a modified version of the convex hull with a finite search radius for a yarn cross-section, showing good agreement with a curved yarn cross-section. The approach is controlled by the local search radius during the construction of a polygon line. A varying average point distance in the data set is disadvantageous and requires an iterative increasing of the search length if no point is found. The same might apply for an alpha-shape, the generalization of a convex hull that calculates the boundary of a point cloud by removing edges from an initial Delaunay triangulation based on an alpha parameter that controls the degree of detail. Balangé et al [9] suggested a convex hull for a limited number of points and a B-spline based approach for the envelope of a more complex cross-section. As the B-spline approach reduces usage for further analysis, a segmented convex hull approach is used in this paper to evaluate a cross-sectional area at a point selected for analysis.

While an exact match between the simulation points and an experimentally determined point cloud cannot be guaranteed, a point cluster is initially extracted using a cylindrical search volume defined by a start and endpoint and a radius. These points are then projected onto a plane with two-dimensional coordinate system defined by a rotation of the global coordinate system with the Gram-Schmidt orthogonalization, so that the new x-axis matches the cylinder axis. The origin of this projection coordinate system is defined as the first point. The vertical axis is the rotated z-axis (coordinates defined as v) and the horizontal axis is defined as the inverted rotated y-axis (coordinates defined as h).

To calculate the cross-sectional envelope, the centroid (v_c, h_c) of the projected points is calculated and used as center for a segmentation of the points into a user-defined number of subsections defined by their angular range. For each subsection an individual convex hull is calculated and all hulls are then combined to a single hull curve, where duplicate points are removed and the area of the subsegments hulls are added up to calculate the area of the combined cross-section.

To define the segments based on angular values, Eq. 5 is used to calculate the angle of each projected point with coordinates (v_i, h_i) relative to the centroid and additionally converted in a value range of $[0,\ 2\pi]$.

$$\theta_i = \operatorname{atan}^2(h_i - h_c, v_i - v_c) \tag{5}$$

Starting from the first segment (with lower boundary $\theta = 0$) the points in this segment are extracted on the border angle θ_{start} and θ_{end} of this segment and a convex hull is calculated for the points. In addition to the number of sections the shape of each segment hull and thus the accuracy of the approach is highly depending on the point of the transition boundary between the sections. In the absence of a point on the boundary, an artificial point must be created to prevent an indentation between two segments, which could significantly impact the results. A search area with a defined threshold is used to identify a point with the maximal distance to the centroid point in each of the neighbouring sections of a border. If no point is found in a section, the threshold is iteratively increased with a threshold delta until a maximum number of iterations is reached. To define the distance of this boundary point to the centroid, the mean value of both distances in the neighbouring segments are used. If the maximum distance of the current segment is more than 1.5 times smaller than that of the adjacent segment, this smaller value is used. This avoids an overprediction of the segments hull, if a small sized segment is neighbouring a larger one.

Since the usability of the approach depends on the density of the point distribution, two approaches are used to identify the border points. For a high-density distribution, a rectangular shaped search area with the angular boundary line as center line is applied. Points with the greatest distance from the centroid can be effectively identified, even when the distribution follows a grid-like configuration as it can occur with the previous mentioned approach. As the threshold and the delta of the iteration needs to be as low as possible to avoid an overprediction of the hulls, the rectangular approach is more time consuming for a low point distribution. With an angular based and thus circular search area, the coverage expands proportionally with increasing distance from the centroid. While the search area can be rapidly expanded, the likelihood of selecting suboptimal points increases in the presence of large spatial

discontinuities within the search region. The centroid and the calculated points on the boundary line are then added to the point cloud of the segment. An individual convex hull is calculated for the subsection, where the segment area A_{seg} of the segments convex hull polygon can be calculated according to Bronstein et al. [10] with Eq. 6.

$$A_{seg} = \frac{1}{2}\sum_{j=0}^{n}(h_i v_{i+1} - h_{i+1} v_i) \tag{6}$$

The result for the segment area and the convex hull points without the centroid can then be added to data defining the full hull envelope. This procedure is executed in an anti-clockwise direction until the initial segment reached, completing the loop. If during calculation a segment is reached that contains less than the required three points to calculate a convex hull its angular range is merged with the next segment. Fig. 4 shows a comparison of a convex hull (Fig. 4 a)) to the segmented hull approach with a low segment number of 12 (Fig. 4 b)) and the respective boundary points. With the convex hull the shape and area of 156.8 mm^2 are overpredicted, whereas the segmented approach results in a better prediction with an area of 138.6 mm^2. Increasing the number of segments to 360 further improves the accuracy of the calculation to an area of 134.2 mm^2. To avoid artifacts and indentations resulting from isolated internal points, the threshold parameter needs to be increased to ensure that smaller segments are integrated into larger ones.

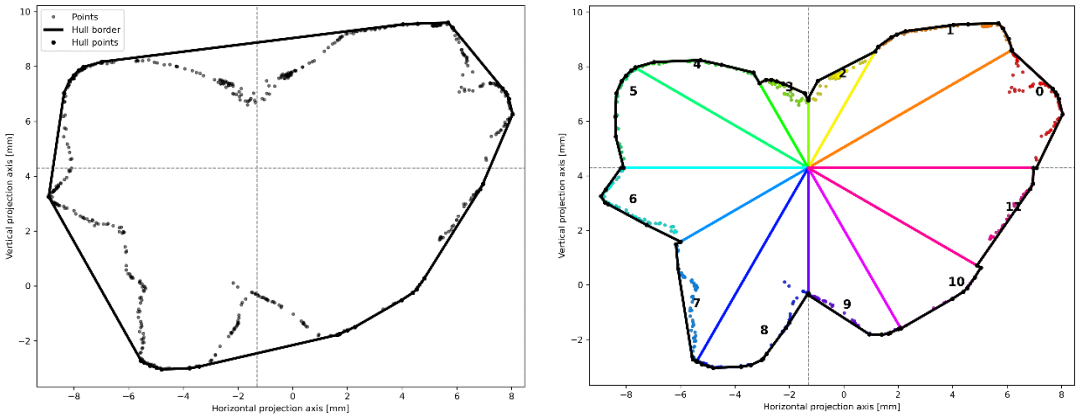

Figure 4: a) Projected points with a hull border resulting out of convex hull that is overpredicting the shape of specimen cross-section. b) Hull using the segmented approach with a low number of 12 segments enabling a more precise calculation of the envelope curve.

Analogous to the method proposed by Jones, the fiber volume ratio of the calculated cross-section can be estimated by dividing the amount n_{Fil} of physical filaments d_{fiber} within the cross-section by the summed area A_{Env} of the hull envelope curve representing the deformed cross-sectional boundary, as defined in Equation 7.

$$FVR = p_d \frac{n_{Fil} \cdot \pi \cdot \left(\frac{d_{fiber}}{2}\right)^2}{A_{\mathrm{Env}}} \tag{7}$$

Since the cross-sectional area alone is insufficient to fully characterize the shape or quantify deviation, additional geometric parameters are required. In this paper, the moments of inertia I_{hh}, I_{vv} and I_{hv} in the two-dimensional coordinate system are used. As the points that define the envelope of the hull curve is a closed polynomial with already anti-clockwise sorted points, a mathematical approach by Steger [11] based on the Gaussian trapezoidal formula is used (Eq. 8 to 11).

$$I_{hh} = \frac{1}{12}\sum_{i=1}^{n-1}\left(v_i^2 + v_i v_{i+1} + v_{i+1}^2\right) \cdot a_i \tag{8}$$

$$I_{vv} = \frac{1}{12}\sum_{i=1}^{n-1}\left(h_i^2 + h_i h_{i+1} + h_{i+1}^2\right) \cdot a_i \tag{9}$$

$$I_{hv} = -\frac{1}{24}\sum_{i=1}^{n-1}\left(h_i v_{i+1} + 2h_i v_i + 2h_{i+1} v_{i+1} + h_{i+1} v_i\right) \cdot a_i \tag{10}$$

$$a_i = h_i v_{i+1} - h_{i+1} v_i \tag{11}$$

As an alternative approach, the maximal dimension $d_{\max_h}$ in horizontal and $d_{\max_v}$ in vertical direction in the cross-sections coordinate system are calculated for the hull points of the cross-section according to Eq. 12 and 13.

$$d_{\max_h} = h_{max} - v_{min} \tag{12}$$

$$d_{\max_v} = v_{max} - v_{min} \tag{13}$$

This approach enables fast and, in most cases, a stable estimation of irregular cross-sectional areas without requirement for iterations. However, local variations in the computed area may arise due to the choice of the number of segments and the method used to determine points along the boundary between segments, as well as the corresponding threshold value. As the centroid of all points is used as the center for the circular segmentation, concave regions with slender overhangs encompassing multiple circular segments simultaneously, or cross-sections with a predominantly rectangular geometry cannot be accurately represented using this method. To address such cases and use more circular input data for the approach, an additional grid-based subdivision before the aforementioned approach needs to be implemented. This requires an additional consideration of the additional grid boundaries and sorting of edge points along the outer hull curve.

2.3 OPTIMIZATION APPROACH

The framework for the scripted implementation of the optimization problem of parameter identification for the expansion process is based on a LS-Opt workflow. The software is a multiparameter, multi-objective optimization platform for highly user specific approaches. Although it was originally created for LS-Dyna it supports any scriptable software and FE-solver. The flowchart in Fig. 6 shows the optimization strategy and workflow.

A successive response surface method was utilized for the optimization problem. In this approach, the solver selects D-Optimal points from the initial design space, evaluates the corresponding responses, and constructs a polynomial metamodel to estimate optimal design points. These design points are used to generate a solver input file for the SimTex simulation via an implementation of the methods in subsection 2.1 in a Python script. The results of each simulation are then post-processed using BetaCAE Meta, a software tool tightly integrated into LS-OPT, providing a user-friendly Python interface for post-processing. To address the challenges posed by highly nonlinear response surfaces, sequential domain reduction is employed. This technique refines the design space iteratively, improving convergence towards optimal solutions. For the expansion simulation the following parameters were identified as influential and were included in the optimization process.

Percentage strain via fiber modulus and internal loading: A combination of the Young's modulus of the fiber and internal contraction loading applies a direct nodal load. This induces up to 0.25 % elastic strain, acting effectively as a global tensile force. With increased nodal loading, the force equilibrium shifts toward a more compact cross-sectional configuration.

Fiber volume ratio: This parameter scales the combined surface area of virtual fibers and affects the cross-sectional area of bar elements during preprocessing.

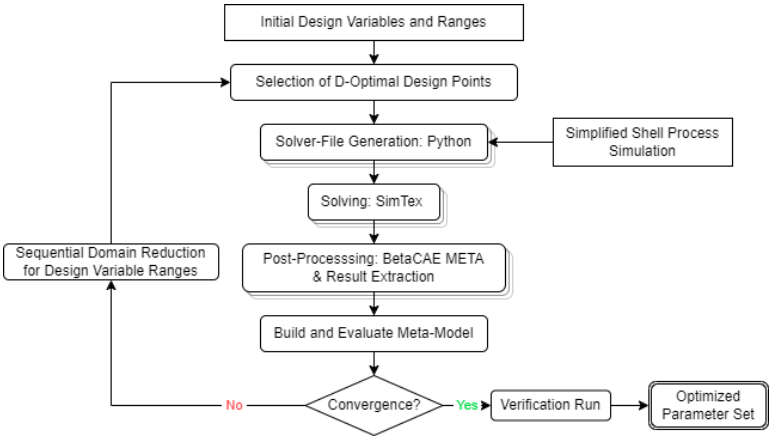

Figure 5: Flowchart of the optimization workflow.

Contact stiffness between fibers: It determines the degree of overlap at contact areas between fibers, particularly at termination time or converged nodal force equilibrium. This parameter scales and balances the cross-sectional area for locations of different interacting nodal forces.

Contact properties: This includes parameters such as contact thickness and penalty stiffness. These values are crucial for defining realistic interactions and avoid interpenetrations.

Friction parameters for fiber-fiber and sleeve-fiber interaction: The friction affects the deformation behavior and shape of fiber cross sections under tension by influencing sliding and sticking between contact surfaces.

Fiber density: The density of the fibers acts as a mass scaling factor to adjust the time step size and maintain contact stability, especially for the sleeve regions with high tension and contact forces. This compensates for current limitations in the SimTex solver's capabilities.

Simulation time: The simulation time is set as a fixed parameter for all simulations. Kinetic energy convergence is not used as a termination criterion, as local fiber movements introduce oscillations that reduce numerical performance without significantly enhancing accuracy. As a result, the optimized parameter sets are only representative for the selected simulation run time.

Furthermore, the accuracy of the optimization, regarding cross-sectional shapes and the position of their center of gravity highly depends on an accurate base model. The primary goal is to derive realistic approximations of cross sections to support subsequent structural analyses. The target function used for optimization is the mean square root error calculated from a set of identifying metrics for multiple cross sections. The selected cross sections represent key structural interaction mechanisms: the interaction between sleeve and fiber, the interaction between mostly parallel fibers and at the intersection points of multiple crossing tows.

Each cross section with additional points added to discretize the contact area during analysis is characterized by its surface area and the maximum extents $d_{\max_h}$ and $d_{\max_v}$ (Eq. 12 and 13) within the projection plane. These geometric descriptors are sufficient for identifying and comparing structural responses across design variants. While more detailed metrics, such as moments of inertia (Eq. 8 to 1), can be more descriptive especially for subsequent evaluation of mechanical performance. Specifically, these values inherently scale with the square of the distance from a reference point, which must itself be accurately defined and matched between datasets. This dependency adds numerical weighting that can reduce the convergence rate of the optimization algorithm by overemphasizing deviations in geometry relative to location. Consistency in cross section analysis between reference and simulation data is achieved by using identical extraction methods respectively. This alignment ensures that the evaluated parameters reflect true physical variations rather than differences arising from analysis methodology.

3 EXPERIMENTAL DATA GENERATION

In order to validate simulation results, different sizes of robotically wound specimen are used. The basis for the optimization of parameters is a small model with two anchors of 200 mm distance and an

intersection of the fibers in the middle of the anchors. For an evaluation of the approach a middle-sized model with four anchors and a dimension of $320\ mm\ x\ 160\ mm$ is used. Both of the specimen consist of a fiber bundle out of two fibers of type Teijin Carbon Tenax-E STS40 F13 48K with a filament diameter of $0.007\ mm$. The fibers are impregnated with the resin MGS LR 135 and the curing agent combination MGS LH 138 / LH287 with a fiber volume ratio of $40\ \%$. The structures were impregnated in an inline impregnation process within the winding head, so that the influence of different resin viscosities is negligible. For both specimen, six layers of fibers are used, resulting in a total number of 12 fiber bundles at fiber intersection points. The specimens where scanned with a terrestrial laser scanner (TLS) of type Trimble X7 with a 3D Point accuracy of $2.4\ mm$ at a distance of $10\ m$. A target-based registration and a Statistical Outlier Removal (SOR) filter in CloudCompare was applied to the data to remove isolated points. To increase the point density for evaluation, especially during the optimization approach, the specimen where additionally scanned with a structured light 3D scanning (ATOS III Rev. 02 800) with a measurement volume of $560\ mm\ x\ 420\ mm\ x\ 420\ mm$ (CP40/MV560) with a measuring point distance of $0.176\ mm$. Target points on the specimen mounting device and scanning spray was used during the measurements. The data was processed, referenced and cropped with the associated manufacturer software GOM Inspect. As the specimen do consist of an irregular and curved surface, three tilting angles of the sample holder and multiple repositions around the rotation axis were used for a high coverage ratio during this scanning. Nevertheless, areas around the sleeve and in the area between sleeve and intersection point in the middle of the structure cannot be fully captured using this approach. However, a comparison of the two measurement methods in Fig. 6 b) shows a more precise capturing of the specimen for the structured light scanning. The measured points of the TLS are more distributed, but a scanning of large structures in a short time as a higher field of view is available and fewer scanning positions are required. As the sleeve positions were taught manually during production, a deviation of the sleeve positions measured in the teach-in and the specimen mounting devices in the lower millimetre range cannot be avoided. In order to use the scanned data for a comparison between experiment and simulation, the sleeve positions were manually adjusted to the point clouds in CloudCompare.

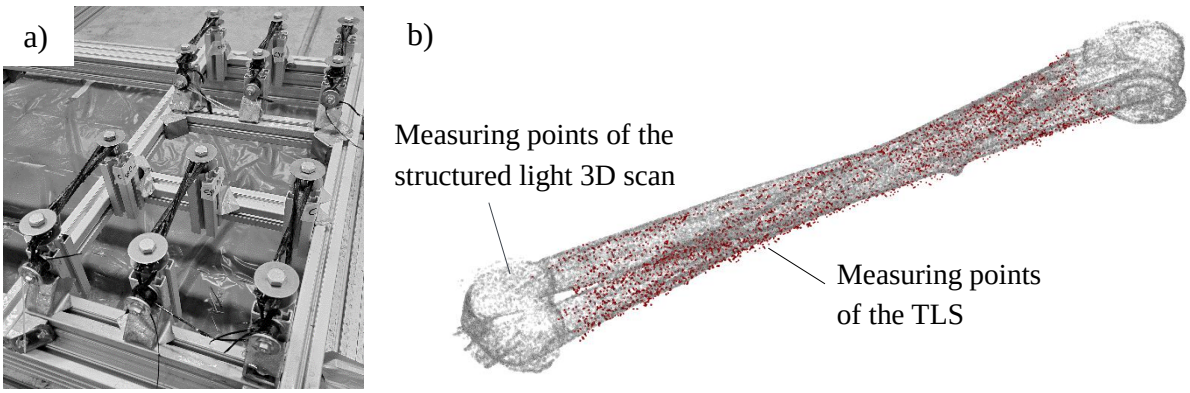

Figure 6: a) Result of the winding process for the small specimen used for optimization. b) Comparison of scanning results: The TLS measuring points (red) are more distributed compared to the structured light 3D scan, but enable a measurement of larger structures.

4 RESULTS

The discrete simulation effects and respective displacements are shown in Fig. 7. The initial virtual tow with overlapping elements (Fig. 7 a)) is expanding due to contact (Fig. 7 b)) without internal loading with limited displacements. With a global tension force, applied as internal loading, without fiber-fiber friction a high level of compaction of the tow can be achieved (Fig. 7 c)). The fiber deformation is significantly influenced by the parameter set used and the results are depending on time of evaluation. It should be noted that numerical optimization approaches furthermore always directly depend on a representative model, and accurate results extraction. The simulation results are evaluated after a runtime of 2.25 s with an increased stabilizing damping factor of 0.4 during the first second of the simulation.

After this a damping value of 0.05 is used. A cross-section (Fig. 7 d)) at the intersection in the middle of the specimen (point 1) and at one fiber strand (point 2) are used for optimization. The optimized results for 32 fibers model provide a parameter set of inputs (Table 1) that show good accuracy for deviation of area (< 5.5 % for point 1 and < 1 % for point 2) and maximal dimensions simultaneously (vertical and horizontal deviation < 10.0 % for point 1 and < 13.0 % for point 2). A usage of 16 fibers increases the area deviation for point 1 and dimension deviation for point 2 by 1.5 %. However, the moments of inertia are overestimated by up to 30%.

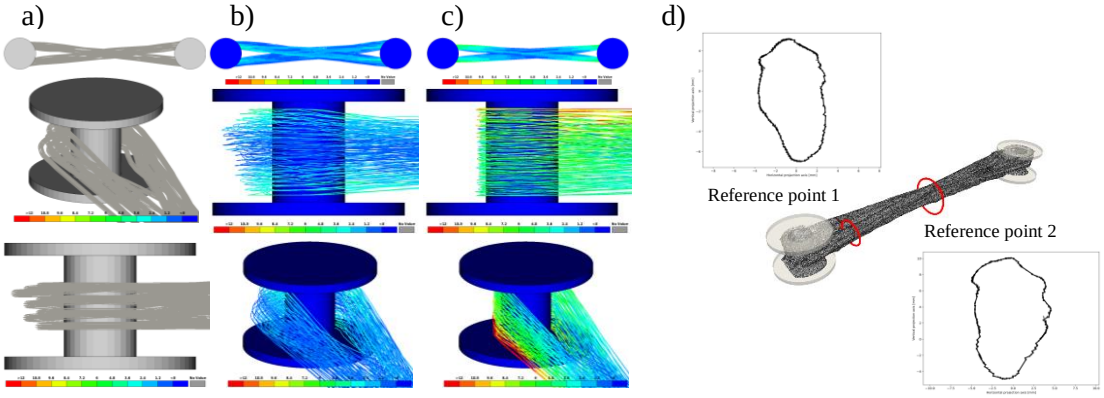

Figure 7: Discrete simulation effects and displacements: a) Initial model setup. b) Expansion of filaments due to contact resolution without fiber-fiber friction. c) Applied global tension force as internal loading. d) Optimization reference points and respective cross-sections.

The optimized parameter set for the non-physical digital element simulation shows that FVR is comparable to target values during manufacturing and that the scale factor (s) for the cross-section matches initial suggestions. The friction values for fiber-fiber friction μ_{FF} are nearly identical for both numbers of virtual fibers, with a slightly increased value for 16 fibers virtual to endure the shape of the expanding cross-section. The fiber stiffness E_{Fiber} and density ρ_{fiber} are adjusted to enable a fast computation as anticipated during a digital element simulation, but still enable an enhanced dynamic response and stiffness of the fibers during the simulation. The penalty stiffness for the sleeve-fiber contact $E_{Penalty_SF}$ is higher than that of the inter-fiber contacts $E_{Penalty_FF}$ to reduce interpenetrations at the sleeve. A sleeve thickness h_{sleeve} of $2.0\ mm$ is additionally prescribed to meet this requirement. The optimized value for the number of virtual fibers indicates that a relatively small number of virtual fibers is sufficient for a low aerial deviation, which is also advantageous for larger structures.

Parameter	Description		Optimum for 16 fibers	Optimum for 32 fibers
FVR	Fiber Volume Ratio	–	0.38	0.38
n_{virt_fibers}	Number of virtual fibers	–	16	32
l_{fiber}	Length of fiber element	[mm]	2.0	2.0
h_{sleeve}	Thickness of sleeve	[mm]	2.0	2.0
s	Scale factor	–	0.53	0.53
μ_{FF}	Inter-Fiber friction	–	0.11	0.08
μ_{SF}	Sleeve-Fiber friction	–	0.26	0.26
$E_{Penalty_FF}$	Inter-Fiber penalty stiffness	[MPa]	1197.59	1225.7
$E_{Penalty_SF}$	Sleeve-Fiber penalty stiffness	[MPa]	15000.00	15000.00
E_{fiber}	Young's modulus of fiber	[MPa]	96857.0	98279.4
E_{sleeve}	Young's modulus of sleeve	[MPa]	50000.0	50000.0
ρ_{fiber}	Density of fiber	$\left[\frac{t}{mm^3}\right]$	0.01	0.01
ρ_{sleeve}	Density of sleeve	$\left[\frac{t}{mm^3}\right]$	0.5	0.5
IL_{fiber}	Fiber internal loading	[N]	-0.1	-0.1

Table 1: Optimized values for 16 and 32 virtual fibers.

To examine the transferability of the optimized parameters to larger structures, the methodology and the optimized values for 16 fibers were evaluated for a model with four sleeves. In Fig. 9 the respective results of geometry and a cross-section (A-B) for process simulation (Fig. 9 a)), multifilament approach (Fig. 9 b)) and scanned data (Fig. 9 c)) are shown. As the process simulation uses a two-dimensional modeling approach the volume defined by the contact is replicated with artificial nodes. The results show, that the cross-sectional shape at the intersection point in the middle of the structure (A-B) cannot be fully captured using this approach. In addition, the clustered distribution of the virtual fibers implies an insufficient influence of the internal contraction force so that the initial distance of the fiber path out of the process simulation cannot be compensated. Since such a clustering of the elements limits the application of the segmented hull, an evaluation is carried out with a single segment as a normal convex hull. The calculated area of 266.0 mm^2 for the multifilament approaches has a smaller deviation to the scan data (187.7 mm^2) compared to the initial result of the process simulation (316.8 mm^2). The vertical dimension is overestimated by 20 % and the horizontal dimension by 39 % resulting in a large deviation in the moment of inertia. Nevertheless, the multifilament approach shows comparable fiber alignment to the scan data at the fiber junction area at the sleeves (Fig. 9, blue frame). In addition to a longer simulation duration that may cause penetrations at the sleeves, additional consideration of the internal loading as an optimization parameter and a reduction of the yarn geometry of the process simulation could reduce the deviations.

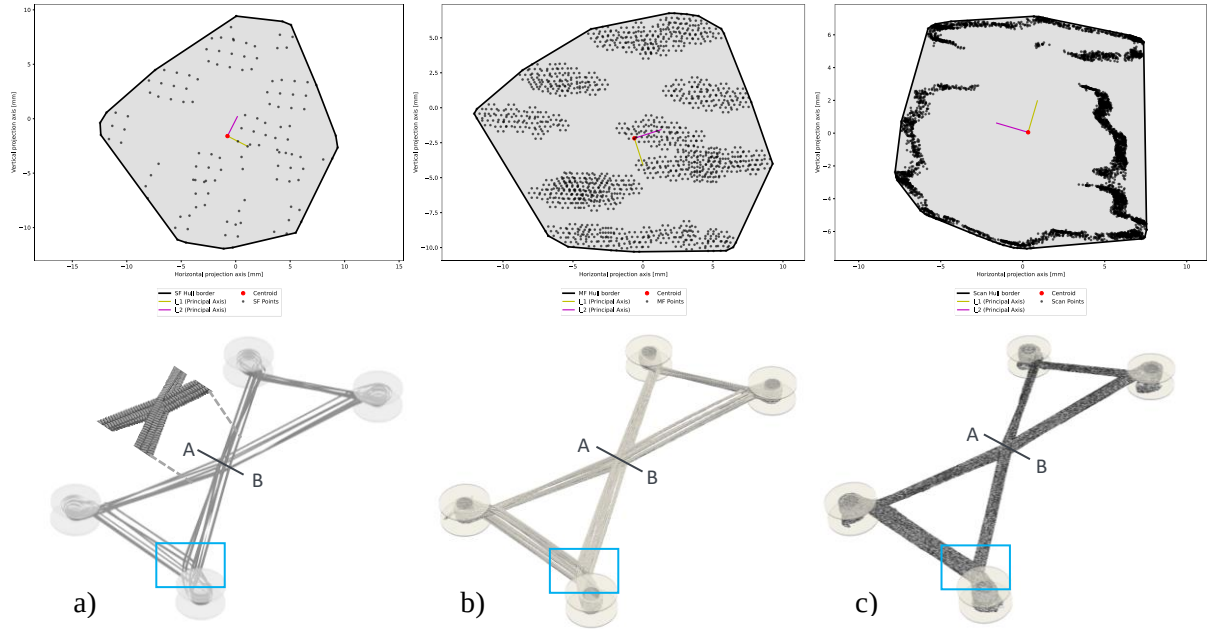

Figure 9: Comparison of modeling and simulation models and a respective cross-section showing convex hull and principal moments of inertia (A-B): a) Simulation result of the process simulation and respective point cloud to replicate the contact volume. b) Result multifilament approach using optimized values for 16 fibers. c) Scanned structure with additional (unscanned) sleeve geometry.

5 CONCLUSION AND OUTLOOK

The presented work employs a multifilament and parameter optimization approach in the solver SimTex to improve the prediction of final fiber architecture and enables the simulation of complex bundle deformations during the coreless winding process. The paper describes relations between design variables and respective interactions and provides an optimized parameter set that is showing good accuracy in area estimation to a real-world equivalent used during optimization. It showed that a relative low number of filaments can be sufficient for a reasonable prediction of a cross-sectional area, thus reducing the computational expenditure. However, to enhance the stability of the optimization, the area has a greater influence than the maximal dimensions of a cross-section. As the shape is not considered

sufficiently this further reduces a transferability of the optimized parameter results to a larger structure. In further optimizations, an equal weighting of the parameters should be considered to improve the predictive capabilities for the shape of a cross-section. Furthermore, a more representative basis model should be used and interrelations of fiber bundle modelling during process simulation and multifilament simulation results need to be studied to improve the transferability to more complex simulation models.

In a continuation of the work, the proposed simulation chain can be used to generate discretised geometrical data for a simplified but fast beam model. Using the local center of mass and moments of inertia, the mechanical behaviour of a structure could be predicted with reasonable accuracy. A complete simulation chain can thus be used to virtually validate or optimize a structural design on a high detail level.

ABSTRACT

End of life strategies for wind turbine blades become increasingly important, as an ever-growing number of wind turbines reaches its decommissioning date. Various types of recycling i. e. mechanical, thermal and chemical, are currently the subject of research.

The goal of this study is, to assess the suitability of recycled glass fibre reinforced polymers (rGFRP) from wind turbine blade as a raw material for truck trailer floor panels. In order to achieve weight-wise competitive material properties with the currently used plywood, rGFRP is used in a sandwich part, as both skin and core material. A static simulation and a linear buckling analysis of established and rare core types have been conducted to compare these options regarding stiffness, mechanical stresses and susceptibility for buckling. Compared to the currently used plywood, rGFRP sandwich parts show significantly higher stiffness. However, stresses exceeding the tensile strength of rGFRP in the skins occur, highlighting the need to either further improve the recycled material or to add virgin GFRP. Equally high stresses in the core have to be investigated further, as stress concentrations occur on sharp edges and corners in the core geometries. Preliminary analysis of buckling behaviour indicates that buckling is not an issue for the used wall thickness at the expected loads.

1. INTRODUCTION

Wind turbines are essential for producing clean and renewable energy. With the rapid growth of the wind energy industry, the extensive use of composite materials in wind turbine blades is posing significant environmental challenges [1]. To fulfill the design criteria of durability and high strength to weight ratio, wind turbine blades are manufactured from non-biodegradable materials such as glass fibers and thermoset polymers like epoxy resin. An exceeding number of turbines reach their end-of-life, necessitating the need for comprehensive recycling and reuse strategies. As of right now, wind turbine blades at their end of life are either burnt or stored at landfills [2]. These strategies however, lead to a waste of resources and could also be legally prohibited in the future. For example, WindEurope, a leading non-profit association that represents and promotes the wind energy industry across Europe, proposed a landfill ban for wind turbine blades in Europe from 2025 onwards [3]. Of the currently known recycling methods [4], mechanical recycling is still the only economically and ecologically sensible process according to literature [5].

The goal of this study is to evaluate the suitability of mechanically recycled glass fiber reinforced polymer (rGFRP) as a raw material for truck trailer floor panels. Plywood, with a density of 680 kg/m³, is currently used in truck trailer floors. With a density of more than 1500 kg/m³ and similar tensile strength as plywood, the use of rGFRP only makes sense if used as a sandwich part. To determine the ideal core geometry, different core geometries were virtually tested regarding the stresses that occur and their sensitivity towards buckling using Finite Element Analysis.

2. MATERIAL

The starting point for this study was unsorted shredded wind turbine blade material. Besides glass fibre reinforced polymer (GFRP), this material contained metals such as copper (likely from lightning rod) and lead (likely from balancing weights) among other things. While no lead was found after further refinement, the copper could only be partially removed by the available metal separator using eddy currents.

Plates of shredded material mixed with virgin epoxy resin were manufactured by a press process, curing the material at 80 °C for 90 minutes. Density was measured using the immersion method according to ISO 1183-1:2019. To determine E1 and E2 for rGFRP, uniaxial tensile tests in accordance with ISO 527-4 were carried out. The Poisson ratio was measured by applying strain gauges. Samples with a size of 100 x 10 mm were cut out in 0°, 45° and 90° to the length axis of the panel. These angles are not corresponding to any fibre direction. No significant difference was found, which is why isotropic in-plane behaviour was assumed. Tests in thickness direction were not carried out and isotropic behaviour was assumed. A simulation was carried out to estimate the effect of that assumption.

Three different grain sizes were investigated (0-0.355 mm, 0.355-1.4 mm, 1.4 mm-2.8 mm). The middle fraction (0.355-1.4 mm) showed a slightly weaker mechanical performance in bending and tensile tests than the finest grain size but was available in a larger quantity and therefore selected for further steps in the project. Different epoxy resins were investigated of which KR 44.39 showed the best performance in tensile tests. The weight percentage of the shredded material is approximately 60%, resulting in a fibre volume ratio of approximately 30%.

A comparison between the values of rGFRP and the currently used plywood are given in Table 1. The values for plywood are from the “Finnish plywood-27 mm birch” entry in the Altair ESA-Comp database.

Table 1 Important mechanical quantities of rGFRP and plywood

Property		rGFRP	Plywood
E_1	[GPa]	10.03±0.4	7.67
E_2	[GPa]	10.03±0.4	7.21
E_3	[GPa]	10.03±0.4	3
σ_{1t}	[MPa]	53.1±3.3	38.7
σ_{2t}	[MPa]	53.1±3.3	36.3
ν_{12}	–	0.3	0.05
ρ	[kg/m³]	1540±10	680

rGFRP is the raw material for both, the skins and the core.

3. PROBLEM DESCRIPTION AND DESIGN CONSTRAINTS

The planned application for the material is as floor panel in a truck trailer. The truck trailer substructure consists of a steel frame (*Figure 1*) and floor panels screwed onto the steel frame. The largest unsupported span of a panel in the truck trailer has dimensions of 1600 mm x 500 mm. The total height of the floor panels is limited to 28 mm.

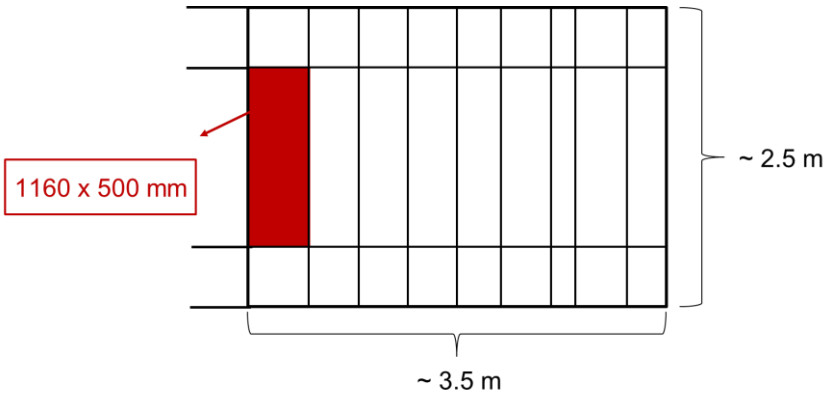

Figure 1 Schematic top view of truck trailer steel frame segment: steel beams (black lines) and panels (white spaces in between), of which the largest unsupported span is highlighted in red

The critical load case is a forklift with a weight of 3600 kg per wheel standing at the weakest point, which is usually the center of the panel, for 5 minutes. The contact area of a wheel based on dimensioning guidelines for plywood panels is 180 x 80 mm. The load applied on the contact area amounts to a pressure of 2.45 MPa.

From a manufacturing perspective, project partners agreed to focus predominantly on core patterns that are easy to manufacture while using a pressing process.

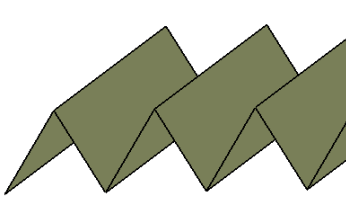
The grain size of the shredded material of 1.4 mm determines the theoretical lower limit for the thickness of a pressed structure.

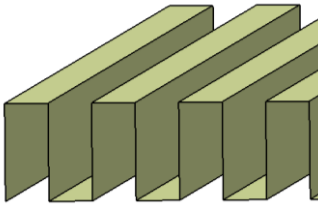
The weight of the sandwich panel should be equal to or less than the weight of the plywood panel. Furthermore, the stiffness of the panel should be equal to or higher than the stiffness of the plywood panel.

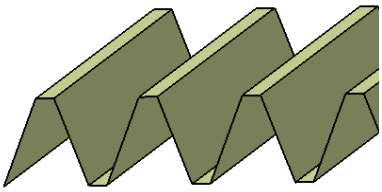
4. INVESTIGATED CORE TYPES

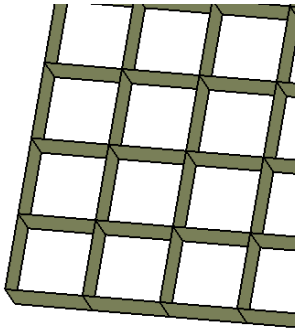
In the current analysis, sandwich parts consisting of 4 mm thick skins and a core with a height of 20 mm have been investigated. The only factor, that has been varied was the core geometry.

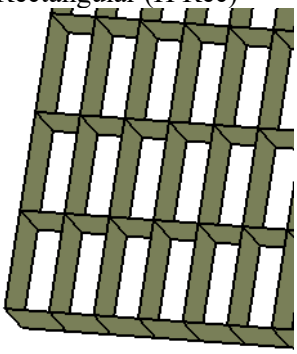
The investigated core types can be divided into four groups: Corrugated, honeycombs, Miura-ori foldcore geometries and generalized Resch pattern foldcore geometries. Corrugated and honeycombs are well-established core types. Honeycombs are difficult to manufacture using a pressing process due to their vertical elements. They were nevertheless included as benchmark, as literature indicates great bending, compression and shear properties [8]–[10]. Miura-ori cores and cores inspired by generalized Resch pattern geometries represent rare core types but have also been investigated in the literature [11], [12]. For an overview of all investigated core geometries, see Table 2.

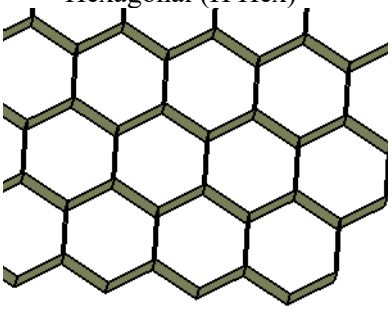


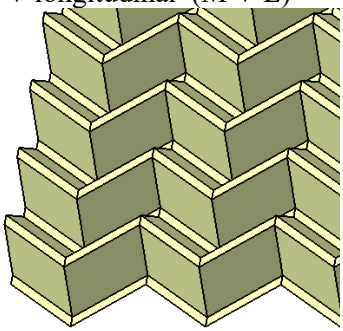


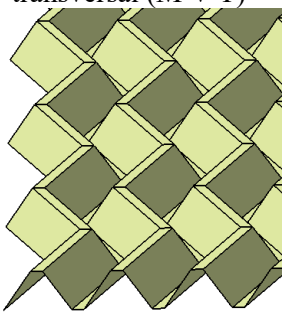


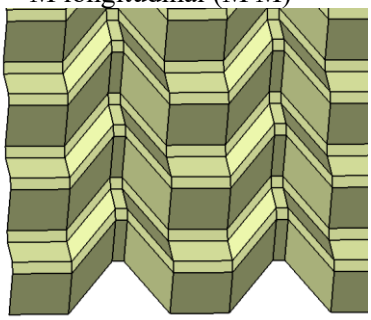


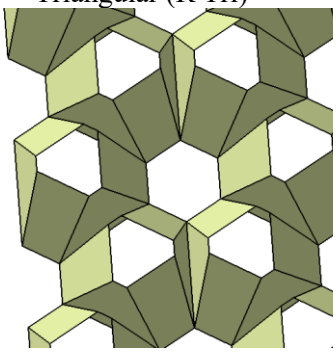


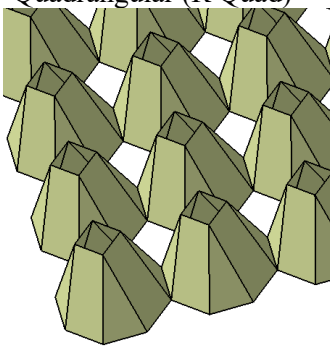


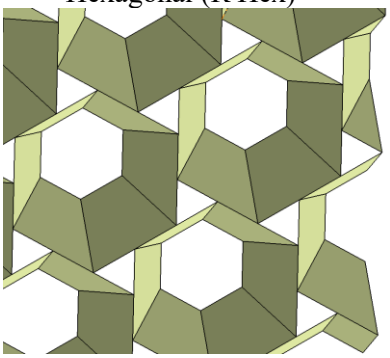












A wall thickness of 2 mm was chosen for all geometries. Dimensions of the cores were chosen so that the volume filling degree was between 18-22%. By that, equivalent weight with the plywood panel was achieved.

5. SIMULATION SETUP

For virtual testing, a geometrically non-linear static simulation and a linear buckling analysis (LBA) were set up using the Finite Element software Abaqus CAE 2020. The goal of the static simulation was to determine the stresses and displacements in skins and core when the forklift stands in the center of the panel. Therefore, a load of 2.45 MPa (see Section 3) was used. A static simulation of the plywood panel was carried out for comparison. In the LBA, an initial value of 1 was used, which is common in literature. The analysis then solves for eigenvalues which will give you the factor by which the initial load has to be multiplied to reach the buckling loads. In either case, the load was distributed evenly over the entire contact area. For the static simulations, a symmetry condition was used, allowing to calculate only half of the geometry. For the buckling simulations, the entire model had to be calculated.

As core cell dimensions (i. e. 20 mm square honeycomb cell length) are in the same order of magnitude as the overall sandwich thickness (28 mm), the cores were not homogenized but simulated as discrete structures, allowing a visualization of local effects to some extent.

Table 2 Investigated core geometries; length-direction is roughly horizontal and width direction roughly vertical

Core Type			
Corrugated	Triangular (C Tri)	Rectangular (C Rec)	Trapezoidal (C Trap)
			
Honeycombs	Square (H Square)	Rectangular (H Rec)	Hexagonal (H Hex)
			
Miura-ori	V longitudinal (M V L)	V transversal (M V T)	M longitudinal (M M)
			
Resch	Triangular (R Tri)	Quadrangular (R Quad)	Hexagonal (R Hex)
			

For both simulations, “Tie”-contacts, simulating perfect bonding, were defined between the core top and bottom surfaces and the respective skin surfaces. For the LBA, movement in z-direction was prohibited (U3 = 0) on all 4 edges, modelling the rigid connection via screws onto the trailer. On one side, in plane-movement was additionally constrained (U1, U2 = 0). For the static simulation, the boundary condition of one edge with prohibited movement in z-direction war replaced by the symmetry condition (U2=UR!=UR3=0).

For the skins, quadratic shell elements (S8R) and for the core quadratic solid elements (C3D20R for corrugated and honeycomb cores, C3D10 for Miura-ori and Resch cores) were used. A 2 mm mesh was specified for the load area for the skins, while a 5 mm mesh was used outside of the load area. For the core, this general criterion was used as well – however for all Miura-ori or Resch cores at least two elements were assigned over any dimension (thickness, width and length) in the load area. For corrugated and honeycomb cores, there are at least three elements.

Mesh convergence studies were carried out for each core geometry groups i. e. corrugated cores, honeycombs, etc. for both, the static simulation and the LBA.

6. RESULTS

6.1. Static simulation

6.1.1. Estimation of thickness property influence

A simulation of a H-Rec sandwich with E1, E2 of the rGFRP and 5 MPa for E3 (approximately half of E1, E2) was set up to determine the effect of assumption of isotropic material behaviour. The other properties to describe the material behaviour (G_{12} = 3.03 GPa, G_{13} = G_{23} = 2.5 GPa, ν_{13} = ν_{23} = 0.3) were taken from the “7781 Glass Fabric / MGS418” entry in the Altair ESA-Comp database – a typical glass fibre fabric in epoxy matrix. The simulation showed a slight increase of 8.3% in displacement compared to isotropic properties, indicating that thickness properties only slightly influence the displacement results.

6.1.2. Displacement

Several plots were derived from the results of the static simulation. One of the key takeaways is that all investigated core geometries have a significantly smaller displacement (max. 13.7 mm) than the plywood panel (16.5 mm, Figure 2). With the exception of the corrugated rectangular core, a clear trend by core type can be established: Miura-ori cores and Resch pattern cores are less stiff under bending (11.5-11.8 mm). Corrugated and honeycomb cores have lower displacements (10.9-11.2 mm), with the lowest values experienced by the corrugated trapezoidal and the rectangular honeycomb cores.

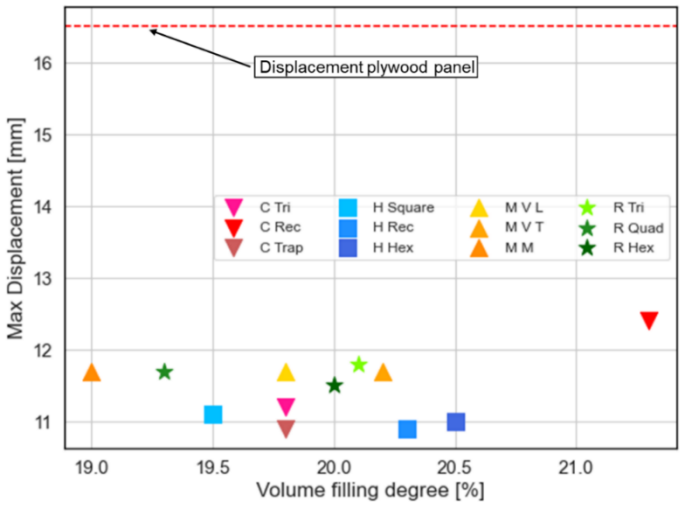


Figure 2 Maximum displacement in static simulation of different core types as a function of volume filling degree

The lower displacement of the rectangular honeycomb compared to the square honeycomb can be explained by its tighter spaces between the beam elements in the width direction. This feature was specifically put in place to increase stiffness. When the length to width ratio exceeds factor of 2, stresses occur predominantly in width direction, as that direction is much stiffer. Therefore, stiffening in the width direction improves the stiffness more than stiffening in the length direction. This is also the reason why corrugated cores are as stiff as honeycomb cores in this example and Miura-ori and Resch pattern cores are less stiff.

6.1.3. Skin stresses

The maximum tension stresses in skins for the different core geometries can be seen in Figure 3. For this analysis, stress maxima at the edges where boundary conditions were applied, were ignored. Overall, skin stresses are quite similar for all cores. A similar trend as in Figure 2 can be seen: stiff cores lead to less stress in the skins. For all core geometries, the maximum stress exceeds the ultimate tensile strength of GFRP by a significant margin. Figure 3 could have also been plotted for compression stresses, which show a very similar trend to the tensile stresses.

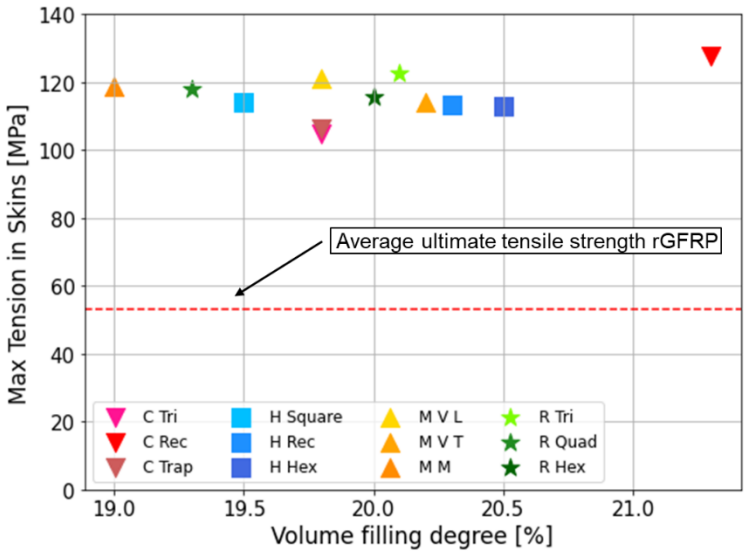

Figure 3 Maximum tension in skins in static simulation of different core types as a function of volume filling degree

6.1.4. Core stresses

Core stresses were evaluated as well and were in the same order of magnitude as the skin stresses and higher (peak stresses between 90 MPa and 300 MPa). However, a sensible evaluation is challenging: While Mesh convergence studies converge for skin stresses and displacements, they linearly increase or even slightly diverge for core stresses due to stress concentrations on corners and edges (i. e. Figure 4, Figure 5).

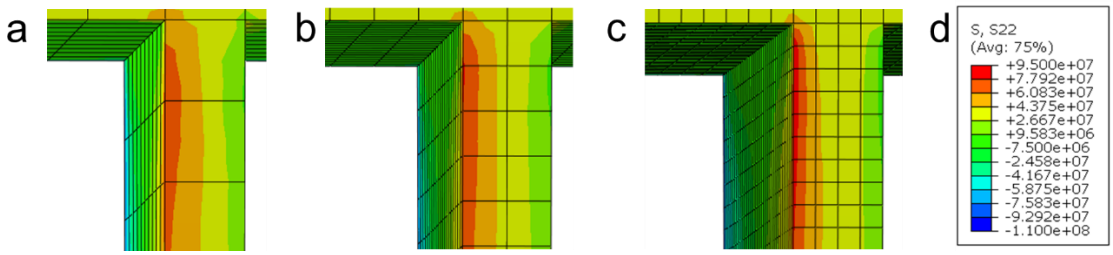

Figure 4 Edge of load area of square honeycomb with 1 (a), 2 (b) and 4 elements (c) over the width resulting in 74,7 MPa, 80,3 MPa and 91,7 MPa peak stress respectively; d: scale for all three simulations

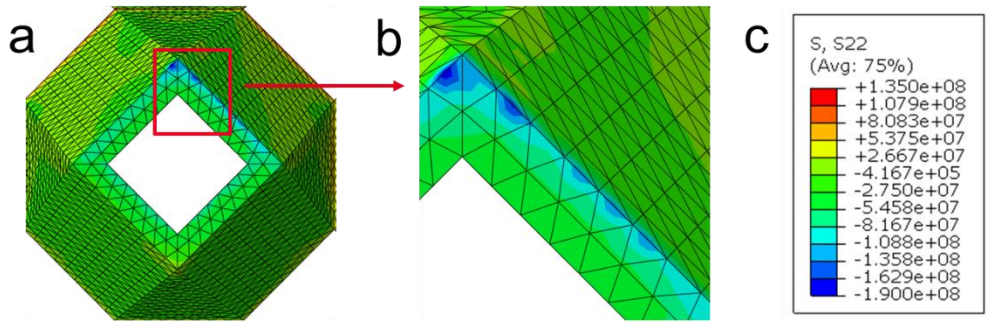

Figure 5 Stress concentrations in quadratic Resch pattern in load area (a, b) with the corresponding scale (c)

Further investigations will take place to accurately evaluate the core stresses.

6.2. LBA

By employing an LBA, a preliminary investigation of the buckling load for each core geometry has been established. None of the core geometries failed at loads less than twice the currently used static load (Figure 6).

Further investigation by using a non-linear buckling analysis would be necessary to accurately determine the exact buckling loads. However, given the magnitude of the normal skin and core stresses in the static simulation, focus will be placed on evaluating the core stresses and improving static performance.

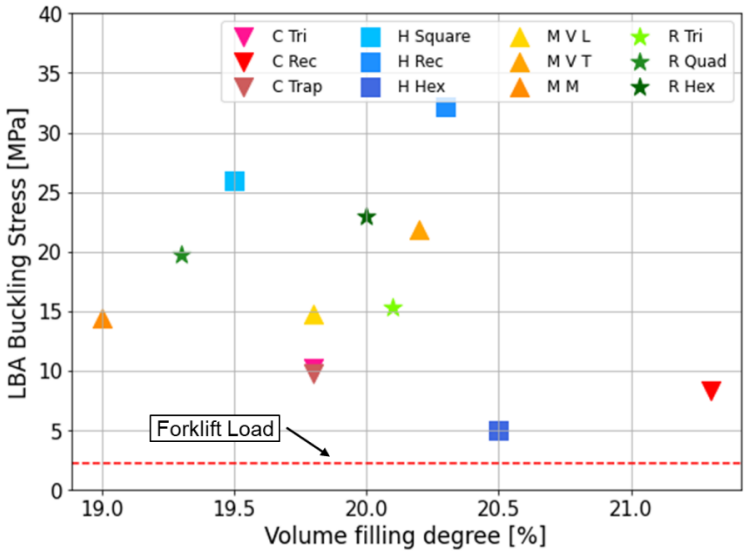

Figure 6 LBA buckling stress of different core types as a function of volume filling degree

7. CONCLUSION AND OUTLOOK

A geometrically non-linear static simulation and a linear buckling analysis (LBA) were set up for sandwich parts differing in employed core geometry (different corrugated cores, honeycomb cores, Miura-ori cores and generalized Resch pattern cores). To evaluate their suitability for truck trailer floor panels, the results of the static simulation were compared to the simulation of the currently used plywood floor panel. All investigated core geometries showed significantly increased stiffness than the plywood panel. For all geometries, the skin stresses exceeded 100 MPa. Given the tensile strength of

rGFRP of 55 MPa, additional reinforcement or the use of virgin GFRP as skins is needed. Stresses in the core were in the same magnitude as the stresses in the skins. They need to be further investigated as stress concentrations occur on edges and at corners in the load area (global-local submodelling techniques). As a possible alternative, rGFRP foam cores, consisting of epoxy resin, blowing agents and shredded blade material, will be investigated. The LBA indicates that no core geometry is susceptible to buckling.

All investigations have been carried out for the load case where the load is applied centrally onto the panel for maximum bending stress. However, shear stress is maximized with the load closer to the panel edge, decreasing the area where shear can be relieved. This load case has to be investigated as well to accurately determine the highest shear loads.

Introduction

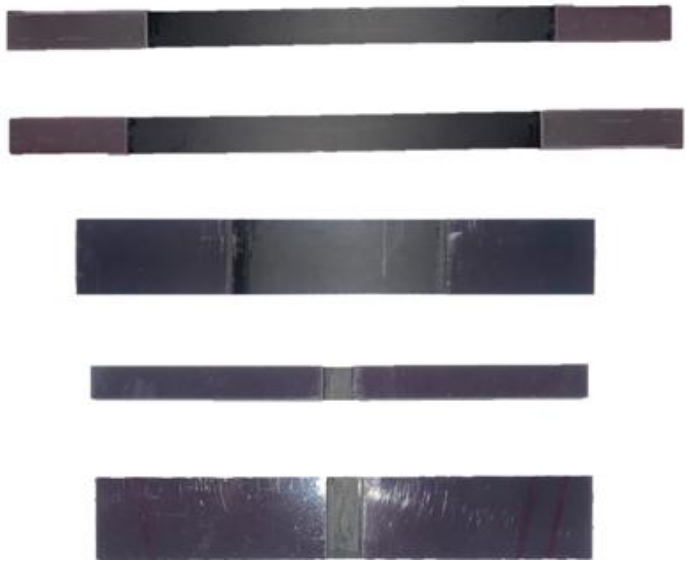
Background of the Study

< Composite materials trends>

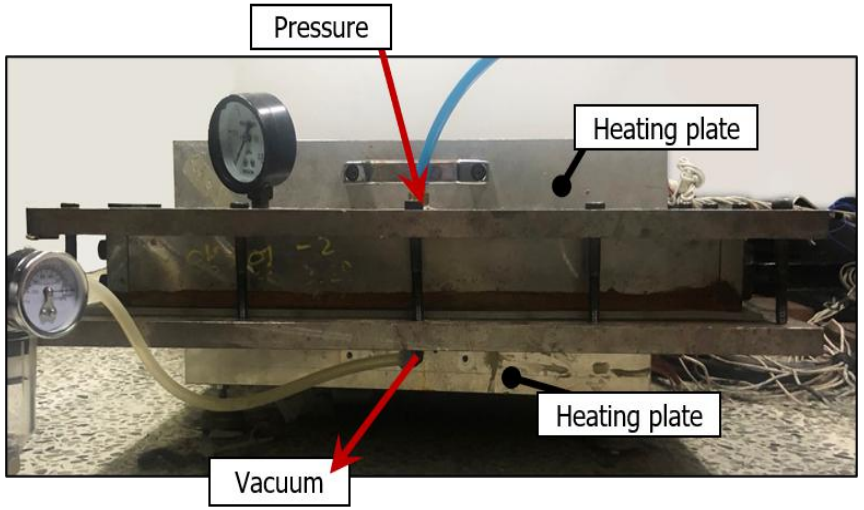
- Dissimilar material joints, which combine composite materials with metals, are widely used in aerospace and automotive industries due to their high specific strength, stiffness, and long fatigue life
- With the trend of replacing metal materials with composites, there is a growing need for research on composite-metal joints
- Since fatigue damage is one of the principal causes of joint failure, predicting the fatigue life of joints is essential

Introduction

Research Objectives



Propose a neural network-based method to predict fatigue life of dissimilar material joints with improved accuracy and reduced computational cost



- **Investigate fatigue behavior of bonded and hybrid joints with varying overlap lengths**
- **Predict fatigue life using neural networks trained on experimental data**
- **Bayesian regularized to prevent overfitting and enhance model generalization**
- **Compare neural network predictions with experimental S-N curves for validation**

YONSEI UNIVERSITY
DEPARTMENT OF MECHANICAL ENGINEERING
ISID Intelligent Structure & Integrated Design Lab

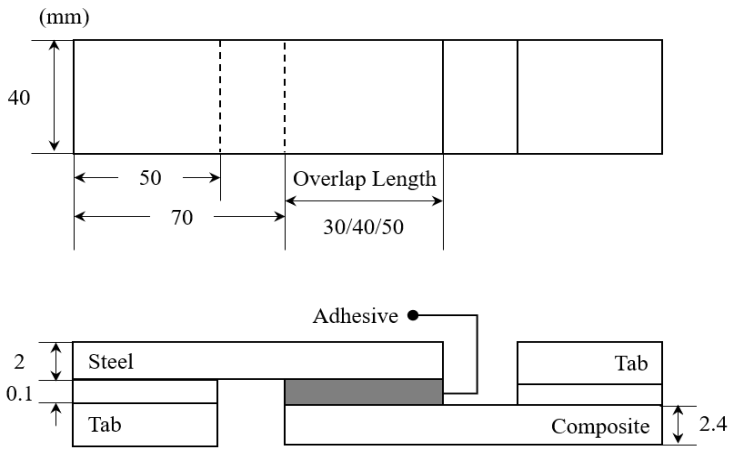
Materials and Methods

Specimen preparation & Experiment

<Specimen preparation >

- Composite specimens made by cutting unidirectional prepregs into 250 mm×250 mm
- Hand lay-up lamination $[0/90]_{5s}$, autoclave curing and machining
- Glass fiber reinforced plastic tabs, Specimen bonding surface treated with #400 silicon carbide paper and acetone degreasing, Tabs attached with EA9309.3NA adhesive
- SS400 steel specimens were prepared similarly, with a GFRP tab, acetone treatment, and Teroson EP 5016 adhesive bonding

Materials and Methods



Specimen preparation & Experiment

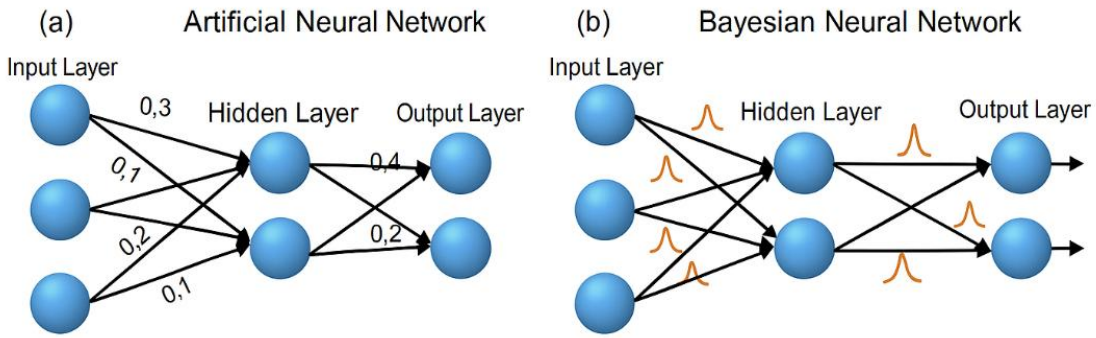
Tensile Test



- 6 tests per joint; average values used
- Universal Testing Machine at room temperature
- Displacement control: 0.2 mm/min
- Force–displacement curves obtained for reference

Fatigue Test

- Load levels selected from the elastic range of tensile results
- Bonded Joint: 65%, 60%, 57% of failure load
- Hybrid Joint: 60%, 55%, 50% of failure load (Hydraulic servo-type machine (SALT Co.))
- Load control, sinusoidal wave, 3 Hz frequency
- Tension–tension fatigue, R = 0.1, 6 tests per load level; F–N diagrams constructed

Materials and Methods

Bayesian Regularized Neural Network (BNN)

< Comparison of an artificial neural network (ANN) and a Bayesian Regularized Neural Network (BNN)>

Feature	Standard Neural Network (ANN)	Bayesian Regularized Neural Network (BRANN)
Goal	Minimize prediction error only	Minimize both prediction error and model compl exity
Loss function	E_D –> focuses only on data error	$\beta E_D + \alpha E_W$ –> balances error and weight size
Weight treatment	Single fixed optimal value	Treated as a probability distribution (uncertainty -aware)
Generalization	Higher risk of overfitting	Better generalization and robustness
Data requirement	Needs a large dataset to perform well	More stable with small or noisy datasets
Overfitting	Likely if regularization is weak	Actively avoids overfitting by penalizing complex ity

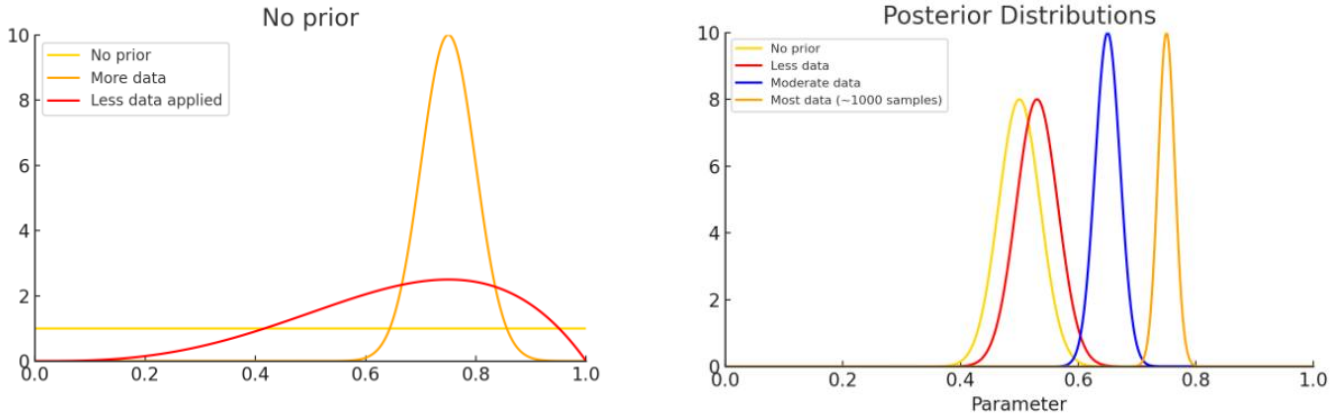
Materials and Methods

Loss function

- In general, neural networks aim to minimize the sum of squared errors E_D

$$E_D = \sum_{i=1}^{n} (t_i - a_i)^2$$

- t_i : the target value of the training data
- a_i : the predicted value produced by the neural network



- However, to reduce model complexity and prevent overfitting, a regularization term E_W , which represents the sum of squared network weights, is added. The objective function becomes:

$$F = \beta E_D + \alpha E_W$$

- α: the weighting factor for the weight magnitude term
- β : the weighting factor for the data error term

Materials and Methods

Bayes' theorem

- **Without prior knowledge:**
  Distribution narrows around 0.78 as more data are added, increasing confidence.

- **With a prior following a Normal distribution 0.5:**
  Estimate keeps a shape similar to the prior while progressively approaching the true value

➔ By applying such Bayesian prior probabilities to constrain the weights, this approach aims to prevent overfitting caused by excessively large weights

Materials and Methods

Bayesian regularization

$$P(\alpha, \beta \mid D, M) = \frac{P(D \mid \alpha, \beta, M) P(\alpha, \beta \mid M)}{P(D \mid M)}.$$

- w: the weight vector (connection strengths) of the neural network
- D: the training dataset
- M: the neural network architecture (model)
- α,β: hyperparameters used for regularization

1. $P(w|\alpha,M)$: the Gaussian prior distribution that encourages the weights to remain small

2. $P(D|w,\beta,M)$: the likelihood, representing how well the data fit given the current weights

➔ This formulation means that as more data are observed, the posterior becomes narrower, while a strong prior keeps the estimate close to the prior beliefs

➔ In other words, it balances data fit and prior constraints to prevent excessively large weights (model complexity) and reduce overfitting

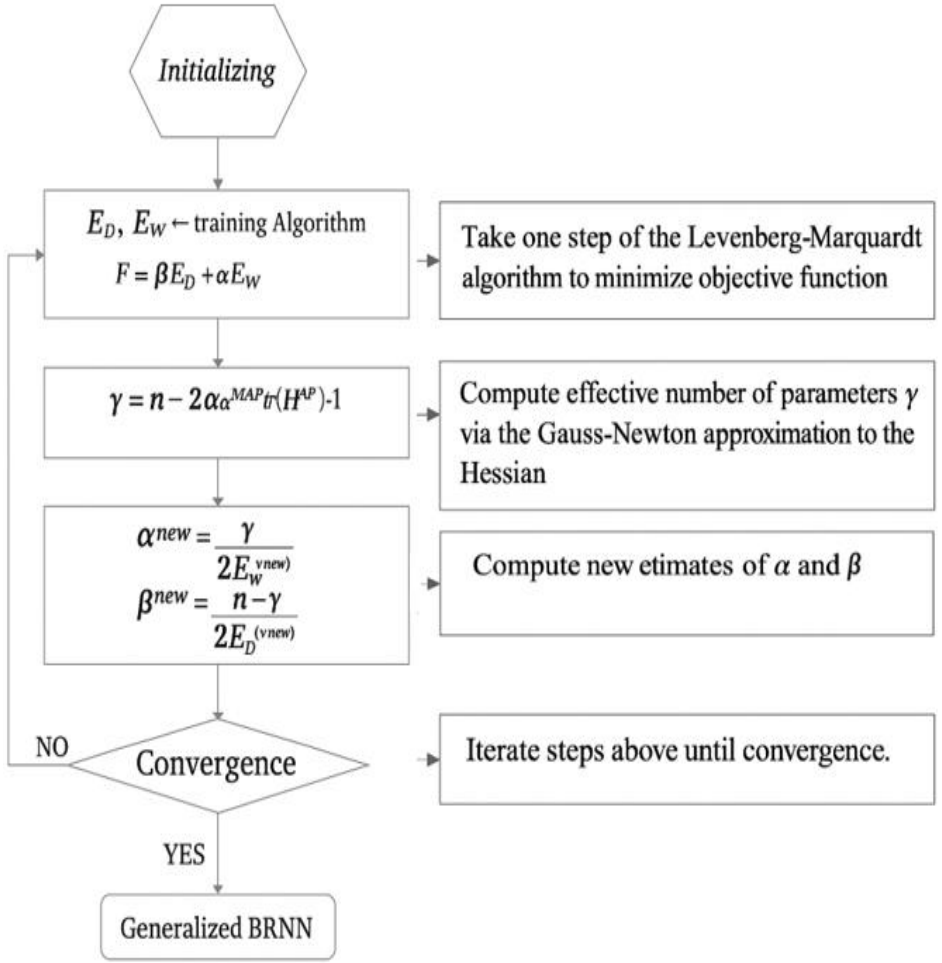
Materials and Methods

Flow chart for Bayesian optimization of regularization parameters

Error Term Calculation

- The objective function combines data error and weight decay error from training data.

Application of the Levenberg–Marquardt Algorithm



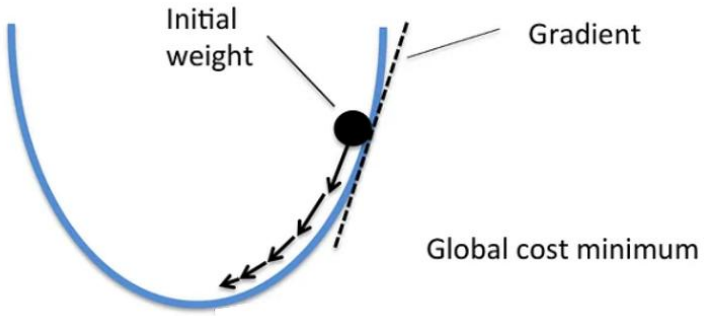
- The algorithm updates the weights in the direction that minimizes the objective function.

Effective Number of Parameters γ

- The Gauss–Newton approximation is used to compute the model complexity γ

Updating α and β

- Using the newly calculated γ, update the regularization parameters α and β.



Convergence Check

- **YES** → Training complete → **Generalized BRANN model** is formed
- **NO** → Repeat the above steps

Materials and Methods

Levenberg-Marquardt

- **A hybrid between Gradient Descent and the Gauss–Newton method**

  Minimize $F = \beta E_D + \alpha E_W$

- **Weight Update Rule:** $w_{new} = w_{old} - (J^T J + \lambda I)^{-1} J^T e$

- J: **Jacobian matrix (partial derivatives of the error function with respect to weights)**
- e: **Error vector (e.g.,** $e = y - f(x,w)$**e=y−f(x,w))**
- λ: **Damping factor (adjusts between gradient descent and Gauss–Newton behavior)**

If λ **is large → behaves like gradient descent (slow but stable)**
If λ **is small → behaves like Gauss–Newton (faster but potentially unstable)**

Materials and Methods

Gauss–Newton Approximation & Parameter Update

This is the stage where the model complexity (γ) is estimated, and the regularization parameters (α and β) are updated accordingly

- **Estimating the Effective Number of Parameters (γ)**
- **γ quantifies how complex the model is**
- **The computed value of γ is used in the regularization parameter update step:**

$$\gamma = n - 2\alpha^{MAP} tr(H^{MAP})^{-1}$$

- **n: Total number of parameters**
- **$(H^{MAP})^{-1}$: Approximate inverse Hessian matrix at the MAP estimate**

$$\alpha^{new} = \frac{\gamma}{2E_w(w^{new})}$$

$$\beta^{new} = \frac{n-\gamma}{2E_D(w^{new})}$$

YONSEI UNIVERSITY
DEPARTMENT OF MECHANICAL ENGINEERING
ISID Intelligent Structure & Integrated Design Lab

Materials and Methods

BRANN-Based Fatigue Life Prediction

Levenberg–Marquardt Algorithm

- Minimizes the objective function:

$$F = \beta E_D + \alpha E_W$$

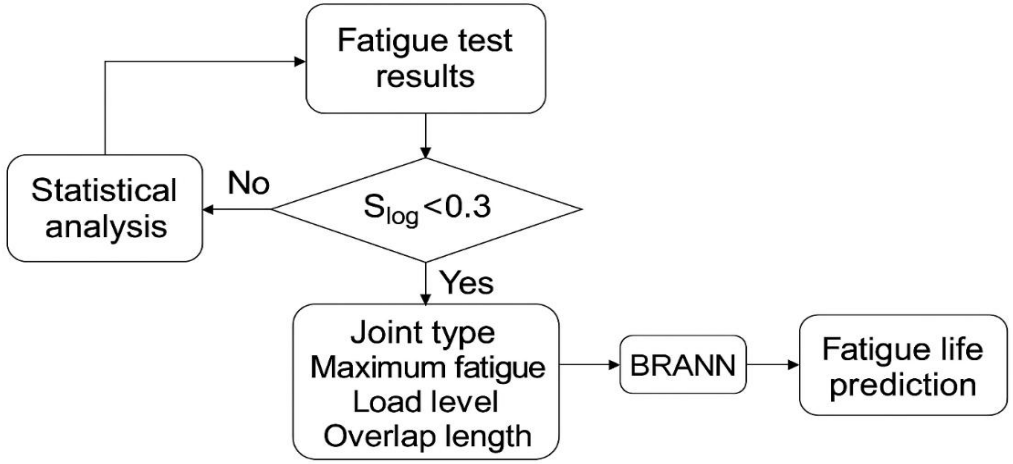
- Efficiently finds weights that balance accuracy and smoothness
- Enables fast convergence and stable learning even with small datasets

BRANN uses this algorithm to update weights while preserving generalization

Gauss–Newton Approximation & Parameter Update

- Approximates the Hessian matrix using the Gauss–Newton method
- Repeats until convergence

→ well-regularized, generalized BRANN model



$$\alpha^{new} = \frac{\gamma}{2E_w(w^{new})}$$

$$\beta^{new} = \frac{n-\gamma}{2E_D(w^{new})}$$

This Bayesian framework allows BRANN to prevent overfitting automatically

Materials and Methods

Fatigue life prediction methodology

< Fatigue life prediction methodology>

- Fatigue test results are obtained from experimental data.
- Statistical analysis is performed to check the data quality
- If the logarithmic standard deviation S_{log}<0.3S, the data is considered reliable
- Input features such as joint type, maximum fatigue, load level, and overlap length are selected
- These inputs are fed into the BRANN model to predict fatigue life

Summary & Future Works

Summary

- Proposed a fatigue life prediction method for dissimilar material joints using a neural network
- Constructed experimental F-N data for bonded and hybrid joints with varying overlap lengths
- Trained a Bayesian Regularized Neural Network (BRANN) using fatigue data from 30, 40, and 50mm overlaps
- Predicted fatigue life for unseen overlap lengths (25, 35, 45, 55 mm) using the trained model
- Prediction accuracy was validated at 35 mm and 45 mm overlaps, showing good agreement with experiments

Future Works

- Expand training dataset to cover more diverse joint configurations and loading conditions
- Apply model to multi-axial fatigue cases and real structural joint geometries

ABSTRACT

Metamaterials have attracted interest in both academia and industry due to their outstanding properties across various fields, such as mechanical, thermal, electromagnetic and acoustic. Those properties are realised by underlying architectures of metamaterials. Controlling the micro-architecture in a multiscale metamaterial opens the possibility for multifunctional applications relevant to diverse sectors including aerospace, automotive, biomedical and sports.

Innovative metamaterial designs have been effectively derived from approaches such as inverse homogenisation and dehomogenisation, which have evolved from traditional density-based topology optimisation. Alternatives to these approaches, leveraging machine learning-based inverse generation strategies have also been developed. Our recent work has proposed a two-step metamaterial designing approach that combined topology optimisation and machine learning.

This study advances the proposed two-step approach by extending the geometry space to include 3D unit lattice cells and accommodating material anisotropy, specifically orthotropy in this study, opening the opportunity to utilise fibre-reinforced additive manufacturing. Numerical evaluation using finite element analysis confirmed that the optimal structures performed better than their uniformly designed counterparts, while the difference was marginal in isotropic materials due to the difference in boundary conditions applied in optimisation and numerical validation. The 3D extension was achieved by applying two types of unit lattice cells: truss-based BCC and plate-based BCC. The numerical evaluation showed that the plate-based BCC lattice structure outperformed the truss-based BCC, indicating the effectiveness of plate-based metamaterials.

This study aims to accelerate the development in the field of composite metamaterials by presenting the validated computational ML-based inverse design framework, considering practical fabrication and use cases. Future work will include the extension to other objective functions incorporating buckling, vibration, thermal etc. along with experimental validations.

1 INTRODUCTION

Metamaterials (MMs) are intentionally designed architectures that exhibit effective properties surpassing those of their constituent materials. These properties range from electromagnetic to acoustic, thermal and mechanical characteristics, attracting researchers in various fields such as aerospace, automotive, biomedical and sports. [1] The properties of MMs are realised by their underlying micro-architectures, also known as unit lattice cells. Designing these lattice cells enables MMs to exhibit outstanding behaviours not found in nature.

A variety of lattice cell structures have been proposed as micro-architectures for MMs, such as truss-based, surface-based and plate-based lattices. Truss-based lattices are the most widely studied due to their geometric simplicity. Representative examples include Body-Centred Cubic (BCC) and Face-Centred Cubic (FCC) lattices, which are typically bending-dominated and thus relatively compliant at low volume fractions. Plate-based lattices, introduced by Berger et al. [2], are characterized by interconnected flat panels. Plate-based lattices have attracted interest because of their ability to approach the Hashin–Shtrikman (HS) bound, the theoretical limit of the elastic moduli in accordance with the volume fractions of isotropic lattices. Several research group have designed mechanical MMs utilising plate-based lattices. [3], [4]

Numerous approaches have been developed to effectively design the MMs' micro-architectures. For example, inverse homogenisation was proposed by utilising a density-based topology optimisation (TO) to minimise the error between the predefined target properties and the effective properties calculated by numerical homogenisation. [5] Dehomogenisation has been developed to concurrently optimise the macro and micro-architecture of MMs by parameterising pre-defined micro-architectures and applying homogenisation-based TO. [6], [7] As an alternative to these TO-based approaches, optimisation leveraging machine learning (ML) has gained interest as a computationally efficient approach. [8] Our recent study [9] has proposed a two-step designing approach for realising multi-scale architecture, i.e., lattice structure, by combining TO and ML. Various 2D lattice geometries considering isotropic material properties were explored. The lattice geometries were parameterised and optimised by a ML-based inverse generator to map architectures based on specified target properties.

This study advances on the proposed TO and ML-based lattice optimisation approach by extending the geometry space to include 3D unit lattice cells and considering material anisotropy, opening the opportunity to utilise fibre-reinforced additive manufacturing (FRAM). A FRAM material is simplified as a transversely isotropic, i.e., orthotropic, material in this study. The 3D lattice optimisation considers two types of 3D unit lattice cells: truss-based BCC and plate-based BCC. Finite element analysis (FEA) for a three-point bending (3PB) test is conducted to numerically evaluate the performance of the optimised lattice structures.

This study aims to accelerate the development in the field of composite metamaterials by presenting the validated computational ML-based inverse design framework, considering practical fabrication and use cases.

2 METHODOLOGY

2.1 TO and ML-based lattice optimisation

As described in Jier and Panesar (2022)[9], the lattice generation approach consists of two steps: 1) optimise mechanical property for each unit cell from density and stress distribution obtained by low resolution TO; 2) generate lattice unit cell to realise the optimal mechanical property using the ML-based inverse generator.

This study considered the Messerschmitt-Bölkow-Blohm (MBB)-beam problem shown in Fig. 1. The objective of the lattice optimisation is to minimise the mechanical compliance $\boldsymbol{C}$ (a measure of the inverse of stiffness) defined as:

$$\boldsymbol{C} = \frac{1}{2}\boldsymbol{U}^T\boldsymbol{K}\boldsymbol{U} \tag{1}$$

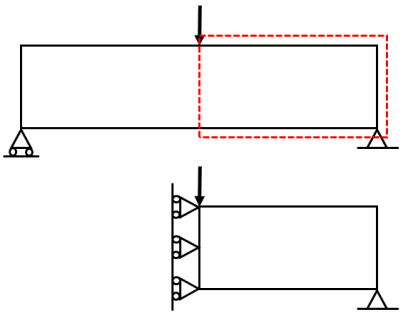
where $\boldsymbol{K}$ is the global stiffness matrix and $\boldsymbol{U}$ is the global displacement vector. The optimisation starts with density-based low resolution TO described in Eqs. 2.

$$\begin{aligned} &\min_{\boldsymbol{\rho}} \boldsymbol{C} \\ &s.t.: \sum_{i=1}^{N} V_i\rho_i - V_f \leq 0 \\ &\boldsymbol{K}\boldsymbol{U} = \boldsymbol{F} \\ &0 \leq \rho_i \leq 1 \end{aligned} \tag{2}$$

where N is the number of elements in the design domain, V_i is the elemental volume, ρ_i is the elemental density ($\rho_i = 1$ means that the element is filled with material while $\rho_i = 0$ means void), V_f is the volume fraction and $\boldsymbol{F}$ is the global load vector. V_f was set to be as 0.5 in this study. Solid Isotropic Material Penalisation (SIMP) method is applied to calculate the elastic properties, i.e., Young's modulus, in each element by interpolating with the value of density ρ_i:

$$E(\rho_i) = E_{min} + E_0 {\rho_i}^p \tag{3}$$

where E_{min} is the minimal value that the elemental Young's modulus can take ($E_{min} = 1.0 \times 10^{-9}$ in this study) and p is the penalisation factor in SIMP. In this study, p was set to be 2.6 in 2D cases based on the precious study [9] and 3 in 3D cases as a generalised value. As an example for the lattice optimisation, an optimal lattice structure having 20×10 unit cells (as Fig. 2b) is derived from the low resolution TO in 20×10 elements (as Fig. 2a).



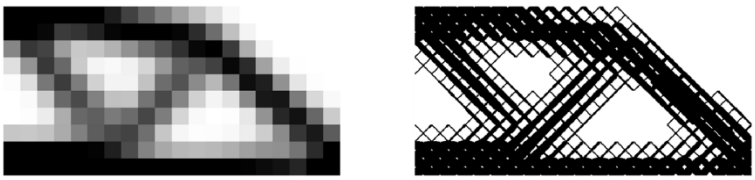


Figure 1: The MBB-beam problem

(a) (b)

Figure 2: Examples of (a) low resolution TO and (b) lattice structure for MBB-beam problem

2.1.1 Optimisation of mechanical property

This study applied elastic stiffness tensor $\boldsymbol{D}$ as a mechanical property to be optimised in the first step. Elastic stiffness tensor $\boldsymbol{D}$ represents the relationship between strain ε and stress σ as described in 2D and 3D in Eqs.4 and 5, respectively. The tensor in 2D and 3D has 6 and 21 independent entries because of its symmetry as shown in Eq. 6.

$$\begin{bmatrix}\sigma_{11}\\ \sigma_{22}\\ \sigma_{12}\end{bmatrix} = \begin{bmatrix}D_{1111} & D_{1122} & D_{1112}\\ D_{2211} & D_{2222} & D_{2212}\\ D_{1211} & D_{1222} & D_{1212}\end{bmatrix}\begin{bmatrix}\varepsilon_{11}\\ \varepsilon_{22}\\ \varepsilon_{12}\end{bmatrix} \tag{4}$$

$$\begin{bmatrix}\sigma_{11}\\ \sigma_{22}\\ \sigma_{33}\\ \sigma_{12}\\ \sigma_{23}\\ \sigma_{31}\end{bmatrix} = \begin{bmatrix}D_{1111} & D_{1122} & D_{1133} & D_{1112} & D_{1123} & D_{1131}\\ D_{2211} & D_{2222} & D_{2233} & D_{2212} & D_{2223} & D_{2231}\\ D_{3311} & D_{3322} & D_{3333} & D_{3312} & D_{3323} & D_{3331}\\ D_{1211} & D_{1222} & D_{1233} & D_{1212} & D_{1223} & D_{1231}\\ D_{2311} & D_{2322} & D_{2333} & D_{2312} & D_{2323} & D_{2331}\\ D_{3111} & D_{3122} & D_{3133} & D_{3112} & D_{3123} & D_{3131}\end{bmatrix}\begin{bmatrix}\varepsilon_{11}\\ \varepsilon_{22}\\ \varepsilon_{33}\\ \varepsilon_{12}\\ \varepsilon_{23}\\ \varepsilon_{31}\end{bmatrix} \tag{5}$$

$$D_{ijkl} = D_{klij} \tag{6}$$

The elastic stiffness tensor $\boldsymbol{D}$ in each low-resolution element is optimised based on the minimisation problem as in Eq. 7 so that the elemental mechanical compliance c_e be minimised.

$$\min_{\boldsymbol{D_e}} c_e = \frac{1}{2}\boldsymbol{\sigma}^T \boldsymbol{D_e}^{-1}\boldsymbol{\sigma} \qquad (7)$$
$$s.t.: P(\boldsymbol{D_e}, vf_e) \geq \epsilon$$
$$|vf_e - \rho_e(SIMP)| \leq \delta$$

where $\boldsymbol{D_e}$ is the elemental elastic tensor to be optimised, $\boldsymbol{\sigma}$ is stress derived from the result of the low resolution TO, $P(\boldsymbol{D_e}, vf_e)$ is the probability of the combination of the values of $\boldsymbol{D_e}$ and the lattice cell volume fraction vf_e, which are constrained by the elemental density from the low resolution TO ($\rho_e(SIMP)$). ϵ and δ is the predefined limit of the probability and the volume fraction error.

2.1.2 Inverse generator for multi-scale lattice

This study advanced the previous study [9], which considered 2D truss-based BCC lattices, by extending unit cell types into 3D truss-based and plate-based BCC lattices. Each cell type was parameterised as shown in Fig. 3. 2D unit cells had 4 representative parameters, $a_1 - a_4$, while 3D unit cells had 8, $a_1 - a_8$. Based on the unit cell structure, a corresponding mechanical property, an effective elastic tensor $\boldsymbol{D}$ described in 2.1.1, was calculated by applying numerical homogenization [10], [11]

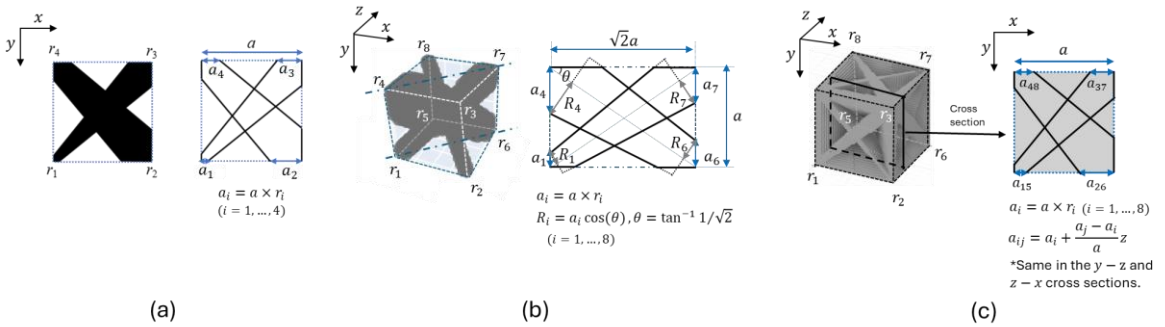

Figure 3: Unit cells parameterisation for (a)2D truss-based BCC, (b)3D truss-based BCC and (c)3D plate-based BCC

Based on the optimisation results of mechanical properties in 2.1.1, a corresponding structure of the lattice unit cell is obtained. This lattice unit cell generation is realised by a pretrained ML-based inverse generator. This study applied multi-layer perceptron (MLP) as a model utilised in the inverse generator. The input of the inverse generator is independent components of $\boldsymbol{D_e}$ (6 components in 2D and 21 components in 3D) and the volume fraction vf_e. The output is a set of unit cell parameters ($r_1 - r_4$ in 2D and $r_1 - r_8$ in 3D). In the training processes, 5000 randomly generated sets of unit cell parameters along with computed volume fractions and numerically homogenised elastic tensors $\boldsymbol{D}$ were applied as a training or testing data.

2.2 Materials and numerical validation

This study considered two materials, Nylon (Polyamide 6) and a short fibre-reinforced nylon called Onyx. The mechanical properties described in Table 1 were defined based on the datasheets by *Markforged Inc.* [12]. Onyx was assumed as isotropic material in 3D lattices as orthotropy in 3D was out of scope in this study.

The 2D lattice unit cell considering orthotropic material was divided into 4 regions, described as i-iv in fig. 5. Each region was assumed to have material properties specified in Table 2 by considering short fibre orientation in the printing process.

	2D lattice		3D lattices
Material type	Isotropic	Orthotropic	Isotropic
Mechanical properties used on optimisation process	$\rho = 1.1$ kg/m^3 $E = 1.7$ GPa $\nu = 0.3$	$\rho = 1.2$ kg/m^3 $E_{11} = 2.4$ GPa, $E_{22} = 1.7$ GPa $\nu = 0.3$, $G_{12} = E_{11}/2(1+\nu)$	$\rho = 1.2$ kg/m^3 $E = 2.4$ GPa $\nu = 0.3$
Corresponding materials	Nylon (PA 6)	Onyx (PA with short CF)	Onyx (PA with short CF)

Table 1: Material properties

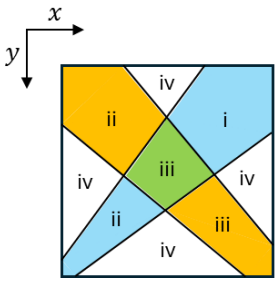

Figure 5: Assumption of material distribution in 2D unit cell with orthotropic material

Region in Figure 5	i	ii	iii	iv
Material type	Orthotropic	Orthotropic	Isotropic	Void
Fibre orientation (direction of E_{11})	45 deg	-45 deg	-	-
Mechanical properties	$\rho = 1.2$ kg/m^3 $E_{11} = 2.4$ GPa $E_{22} = 1.7$ GPa $\nu = 0.3$ $G_{xy} = E_{11}/2(1+\nu)$		$\rho = 1.2$ kg/m^3 $E = 1.7$ GPa $\nu = 0.3$	$\rho = 0$ kg/m^3 $E = 0$ GPa

Table 2: Material properties in 2D unit cell with orthotropic material

Three-point bending (3PB) tests, which corresponds to the half MBB-beam problem, were simulated using finite element analysis (FEA) with *Abaqus CAE* based on the ASTM D7264/D7264M – 15 standard (Fig.4(b) [13]). All lattice structures were set to have the same size of $120 \times 30 \times 10mm$ as shown in Fig. 4(a). Flat plates with the thickness of 2mm were added where the specimens contacted the loading nose and the supports (middle of the top surface and the left and the right corner of the bottom surface). This is to smoothly load the specimens throughout the test as the contacting points change during the 3PB test. In this study, both materials, Nylon and Onyx were set as isotropic in the FEA validation for simplicity, though orthotropy in validation is to be considered in the future work.

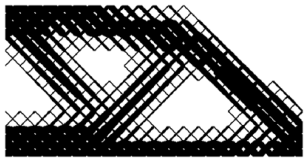
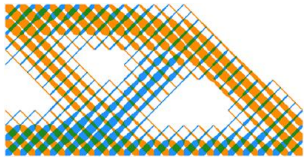
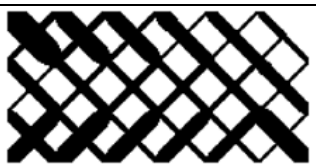
3 RESULTS AND DISCUSSIONS

3.1 2D truss-based metamaterials

The application of the TO and ML-based lattice optimisation to 2D truss-based BCC using isotropic and orthotropic materials is detailed in Table 3. This table includes structural performance, i.e., mechanical compliance and mass, which is the volume fraction multiplied by material density. The number of unit cells were varied by changing the mesh resolution of low resolution TO.







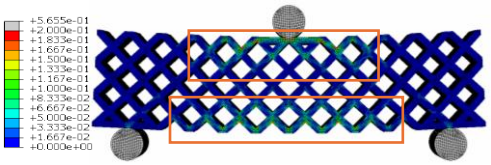
Low resolution	Cell size	Material type	Lattice design	Compliance	Mass ($V_f \times \rho$)
20×10	30×30	Isotropic (Nylon)		59.8	$0.52 \times 1.1 = 0.57$
		Orthotropic (Onyx)		40.3	$0.46 \times 1.2 = 0.55$
8×4	30×30	Isotropic (Nylon)		202.6	$0.50 \times 1.1 = 0.55$
		Orthotropic (Onyx)		78.2	$0.48 \times 1.2 = 0.58$
6×3	30×30	Isotropic (Nylon)		319.7	$0.50 \times 1.1 = 0.55$
		Orthotropic (Onyx)		110.9	$0.48 \times 1.2 = 0.58$

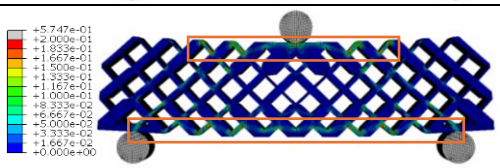
Table 3: Optimisation results with isotropic and orthotropic materials in 2D truss-based BCC

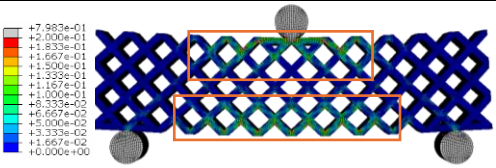
The optimal structures having 6×3 lattice unit cells in Table 3 along with the uniform counterparts were extruded into the 2.5D structures as shown in the Fig.4(a) and numerically evaluated using FEA corresponding to the 3PB test, which are summarised in Table 4. The uniform counterparts had more widely distributed region having higher strain energy above the average while the optimal structures had higher values in specific regions (orange rectangles in the strain energy distribution in Table 4). This results in lower total strain energy, i.e., mechanical compliance, calculated by integrating the elemental strain energies. A stress-based constraint is needed to reduce stress in higher strain energy region in the optimal structures.

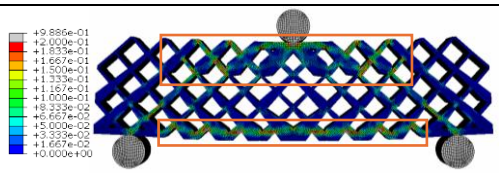
The specific stiffnesses, defined as a measure of the flexural stiffness of the structures, were higher in the optimal structures than in the uniform counterparts whereas the difference with Nylon was marginal. One of the reasons is considered to be a difference in boundary conditions used in the

optimisation (half MBB beam) and the FEA. Spatial positions of the supports were at the corner in the half MBB beam (Fig. 1) while at 10mm from the corners in the FEA (Fig. 4(b)). The assumption of the interaction between the lattice structures and the load / supports were also different; the half MBB beam applied fixed boundary condition while the FEA applied contact boundary condition. More investigation is needed for the boundary condition.







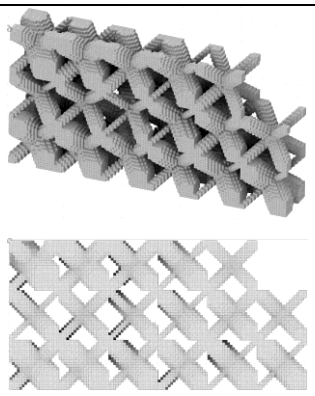


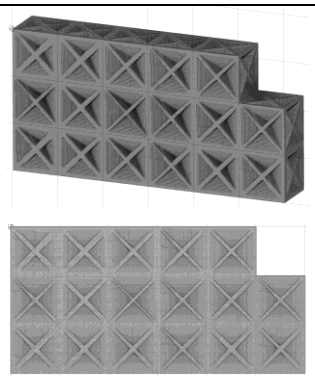
Material	Structure	Strain energy distribution at displacement 2mm	Specific stiffness N/mm (Load / displacement/ V_f)
Nylon	Uniform (benchmark)		162.5
	Optimal		165.1
Onyx	Uniform (benchmark)		229.4
	Optimal		335.6

Table 4: Maximum principal strain distribution of each structure

3.2 3D truss and plate-based metamaterials

Optimisation results with 3D lattices are summarised in Table 5. Unlike the truss-based BCC, plate-based BCC had less thickness variant structure because of its high surface area. Nevertheless, the thicker plates were seen in the cells connected to the load i.e., top left corner, and the support, i.e., bottom right corner. This was the same tendency as the 2D lattices in Table 3. The specific stiffness calculated from the FEA result was higher in the plate-based BCC than in the truss-based BCC, confirming the efficiency of the plate-based lattices in the same volume fraction. This result complies to the experimental work conducted by Tancogne-Dejean et al. [14], where the normalised Young's moduli of plate-based lattices surpassed those of truss-based lattices.





Low resolution	Cell type	Cell size	Lattice design	Specific stiffness N/mm (Load / displacement/ V_f)
$6 \times 3 \times 1$	Truss-based BCC	$30 \times 30 \times 30$		143.9
	Plate-based BCC	$50 \times 50 \times 50$		671.4

Table 5: Lattice optimisation results in 3D truss-based and lattice-based BCC

4 CONCLUSIONS

The TO and ML-based lattice optimisation approach was advanced to consider orthotropic material properties and 3D lattice structures. The optimal structures in both orthotropic and isotropic materials were numerically evaluated by computing 3PB test using FEA. The results showed that the optimal lattice structures were stiffer, i.e., had better performance, than their uniform counterparts while the difference was marginal in isotropic materials, possibly due to the difference in boundary conditions. The optimal structures had smaller regions having higher strain energy, resulting in the lower total strain energy, i.e., mechanical compliance.

The 3D lattice optimisation results considering truss-based BCC and plate-based BCC lattices showed a tendency for the graded lattice structures similar to those in 2D cases. The optimal plate-based BCC lattice structure had less-graded structures than the truss-based BCC due to its high surface area. The plate-based BCC lattice outperformed the truss-based BCC lattice, indicating the effectiveness of applying plate-based lattices in the proposed lattice optimisation approach.

This study presented a numerically validated TO and ML-based MM design framework to accelerate the development in the field of composite MMs. Future works will include the extension to other objective functions incorporating buckling, vibration, thermal etc. along with experimental validations.

Keywords: Wind turbine blades, Composite material, Mechanical recycling, 3D printing, Computed Tomography

ABSTRACT

The rapid growth of the wind energy sector is expected to generate a significant amount of end-of-life (EoL) fiber-reinforced polymer (FRP) waste as wind turbines reach their 20–25-year lifespan. By 2050, Europe is expected to accumulate around 7.6 million tons of FRP from decommissioned wind turbine blades (WTBs). Among the different disposal strategies, mechanical recycling is the most discussed due to its sustainability. This research investigates the reuse of mechanically recycled glass fiber reinforced polymers (GFRP) in 3D printing, specifically in the production of reinforced acrylonitrile butadiene styrene (ABS) pellets. Tensile samples with different fiber content are produced using a fused granulate fabrication (FGF) 3D printer and analyzed by X-ray micro-computed tomography (µCT) and mechanical testing. The findings demonstrate the viability of incorporating recycled WTB materials into engineering thermoplastic composites, thereby enhancing their mechanical properties. Further research is needed to maximize the recycled content while meeting the performance criteria for demanding applications.

1 INTRODUCTION

The rapid expansion of the wind energy sector is expected to lead to a significant amount of end-of-life (EoL) fiber reinforced polymer (FRP) material stream in the coming years. This challenge arises as wind turbines blades (WTBs), which are primarily made of FRPs [1], reach the end of their initial 20 - 25 year life cycle [2]. According to Lahuerta *et al.* [3], approximately 7.6 million tons of FRP EoL WTB material mass will be generated in Europe by 2050. For Germany a total mass of EoL WTB of 689 kt is estimated [4].

Various strategies have been proposed and implemented in response to this impending material stream. The concept of different ‘R's’ to manage EoL WTB materials, emphasizing reduction, reuse, recycling, recovery, and redesign [5]. According to Lund and Madsen [6], mechanical recycling is the most frequently discussed ‘R’-strategy in the literature for the management of EoL WTB materials. The recycling process includes a series of mechanical operations, such as cutting, shredding, grinding or crushing the WTB. These operations are intended to reduce the size of the resin and fibers or to separate them for further processing or direct use in secondary products [7]. Studies, such as those by Delvere *et al.* [8], have concluded that mechanical recycling is currently the most sustainable recycling technology for FRP WTBs, based on comprehensive sustainability criteria.

Mamanpush *et al.* [9] demonstrated the feasibility and potential of mechanically recycled WTB materials in the production of high-performance composites. For instance, recycled glass fiber reinforced polymers (rGFRPs) have been used in noise barriers [10], as a filler in concrete [11], and in sheet molding compounds [12]. Recent advancements have also explored the use of mechanically recycled fibers in 3D printing materials. In [13] it is demonstrated that recycled FRP could replace virgin fibers in additive manufacturing while maintaining mechanical integrity. Furthermore, several studies

by Rahimizadeh *et al*. ([14-17]) have investigated the integration of rGFRP materials with polylactic acid (PLA) in 3D printing, showing improvements in strength and modulus compared to neat PLA samples, despite some reductions in tensile strength and failure strain.

Building on recent advancements in the field of composite mechanical recycling, this research investigates the reuse of mechanically recycled GFRP materials in 3D-printing applications. The focus is on the optimized production of reinforced acrylonitrile butadiene styrene (ABS) composites incorporating rGFRP. Employing a pellet-based approach using fused granular fabrication (FGF) instead of filament-based fused deposition modeling (FDM) simplifies the printing process by reducing feedstock quality requirements. Furthermore, FGF and large-format additive manufacturing enable the direct reuse of recycled fiber-reinforced polymer (rFRP) granulate, making them highly effective for industrial-scale recycling and the scalable integration of composite EoL material into new large-scale applications [18, 19]. This approach aims to increase recyclate incorporation while ensuring the mechanical integrity required for technical-grade applications.

2 MATERIALS AND METHODS

2.1 EoL WTB Material

For the present study, EoL WTB segments from an E40/6 wind turbine (Enercon, Germany) are selected as the source material. These segments are obtained through perpendicular cuts along the WTB length (see Figure 1a). The spar caps are cut out of the WTB segment through the utilization of a panel saw equipped with a diamond-tipped circular blade. The selection of these components is driven by their high glass fiber volume content and structural homogeneity, especially in comparison to the shear web and sandwich regions (see Figure 1b). The resulting spar cap material (see Figure 1c), which serves as the feedstock for subsequent mechanical size reduction, is composed of unidirectional glass fiber laminates embedded in an epoxy matrix. The glass fiber volume content of the spar cap material in an E40/6 WTB is estimated at approximately 57 % (calculated with a calcination process using a glass fiber density of 2.48 g*cm^{-3} (measured with a pycnometer) and a matrix density of 1.2 g*cm^{-3} [20]).

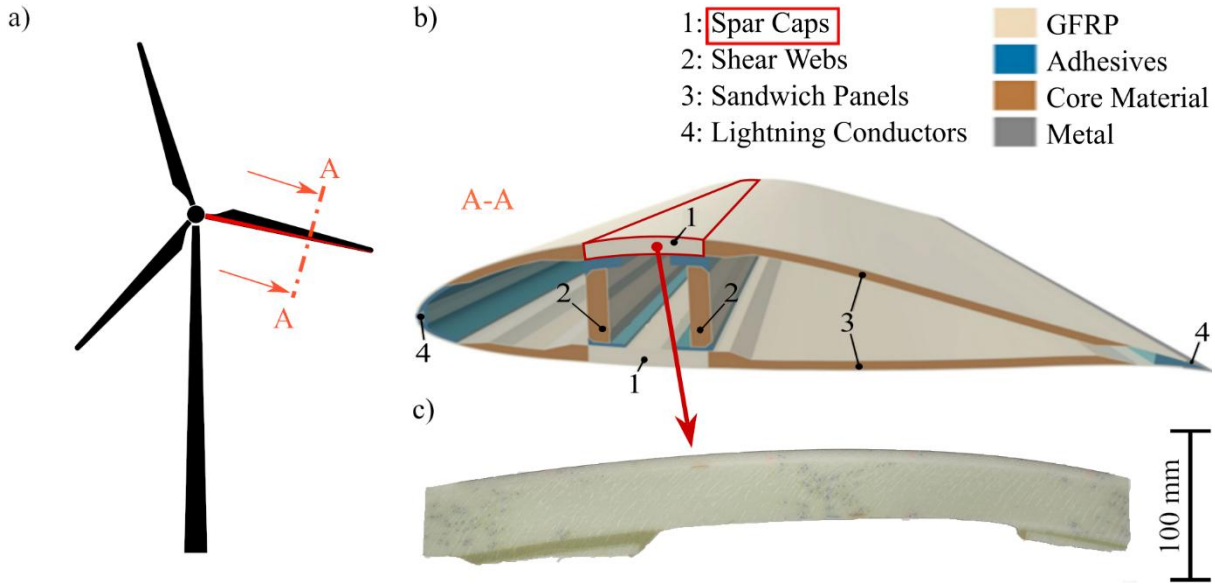

Figure 1: (a) Cutting section perpendicular to the length of the wind turbine blade (WTB); (b) Schematic cross-section of an E40/6 WTB (based on [21]); (c) Spar cap material used in this study for the shredding process.

2.2 Shredding and Sieving Process

To enable further processing, the previously prepared material is shredded using the GP20 Hybrid granulation system (3devo B.V., Utrecht, Netherlands), which combines a twin-shaft shredder and a rotary mill. The shredder features two counter-rotating shafts, each with seven blades bearing three teeth, while the milling stage includes a rotary cutter with three edges and a 3.4 mm sieve. The material is processed three times to ensure consistent fiber shortening and homogenization. The mixture is then dry-sieved using a sieve shaker (AS 200 Control, Retsch GmbH, Haan, Germany) with mesh sizes of 250 µm, 100 µm, and 63 µm. In the following, remaining material on the sieves (see Figure 2) is referred to as the "oversize fraction" (OF) in combination with the corresponding mesh size, e.g. OF>100. The OF>250 was further milled using a laboratory cutting mill (MF 10 basic Cutting Mill, IKA-Werke GmbH & Co. KG, Staufen, Germany) fitted with a 2 mm sieve to increase yield in the desired size ranges. For subsequent processing the OF>100 and OF>63 are selected.

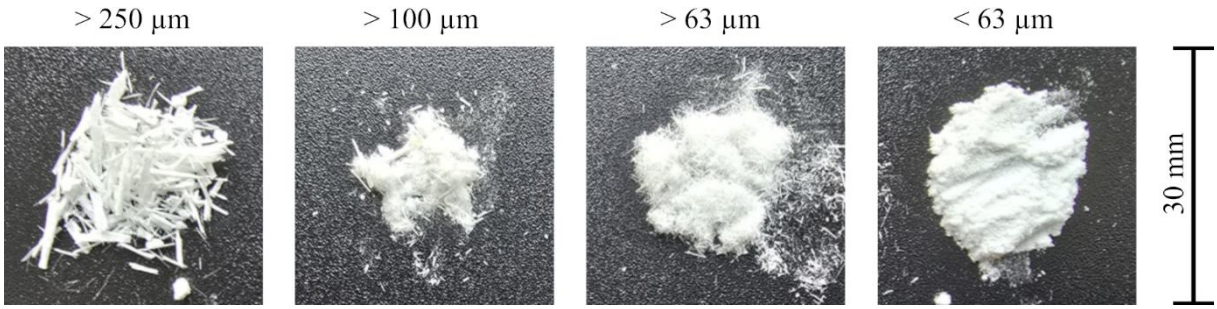

Figure 2: Comparison of the oversize fractions.

2.3 Compounding and 3D-Printing

The OF>100 and OF>63 are compounded with virgin ABS (vABS) powder (Magnum™ 3513, INEOS Styrolution, Germany) with two different weight ratios. This results in five material variants: Neat vABS and four rGFRP compounds. ABS-rGF10/100 and ABS-rGF20/100 containing 10 wt% and 20 wt% rGFRP from the OF>100, respectively, as well as ABS-rGF10/63 and ABS-rGF20/63 containing 10 wt% and 20 wt% rGFRP from the OF>63 (Figure 3).

Dry mixing is followed by homogenization in a low-speed laboratory mixer until visual uniformity in fiber distribution and color is achieved. According to the specifications outlined in the Magnum™ 3513 datasheet, all materials are dried at a temperature of 80 °C for a duration of four hours in a convection oven. This procedure is conducted to remove residual moisture and prevent pore formation and surface defects caused by vapor expansion during extrusion.

The resulting compounds, along with vABS as reference, are extruded into continuous filaments using a Filament Maker ONE Composer 450 single-screw extruder (3devo, Netherlands). Parameters are chosen according to 3devo extrusion report for Magnum™ 3513 (heat zones h4-h1: 215, 225, 235, 245 °C with 2 mm nozzle diameter). The filaments are pelletized using an open-source pelletizer, printed out of vABS to minimize contamination.

Tensile samples are manufactured using a FGF 3D printer (Tumaker NX300 Modular, Tumaker S.L., Irun, Spain), equipped with a pellet extruder comprising two independently controlled heating zones and a 0.8 mm diameter hardened steel nozzle to mitigate abrasive wear from the rGFRP feedstocks. Tensile sample dimensions follow ISO 527-4 (Type 2) and are 250 × 25 × 2 mm (L × W × T). They are printed sequentially on a heated build plate set to 100 °C, with cooling fans deactivated. Slicing is performed using Simplify3D (Simplify3D LLC, Cincinnati, USA), applying a layer height of 0.2 mm, no outer perimeters, no top or bottom layers, and a 100 % infill with aligned pattern oriented parallel to the tensile load direction. Extrusion multipliers are calibrated individually for each compound to ensure closed layers and dimensional accuracy. Values range from 100 % for vABS to 118 % for ABS-rGF20/100. To provide an overview of the processing of the 3D-printed tensile samples, the procedure is summarized schematically in Figure 3.

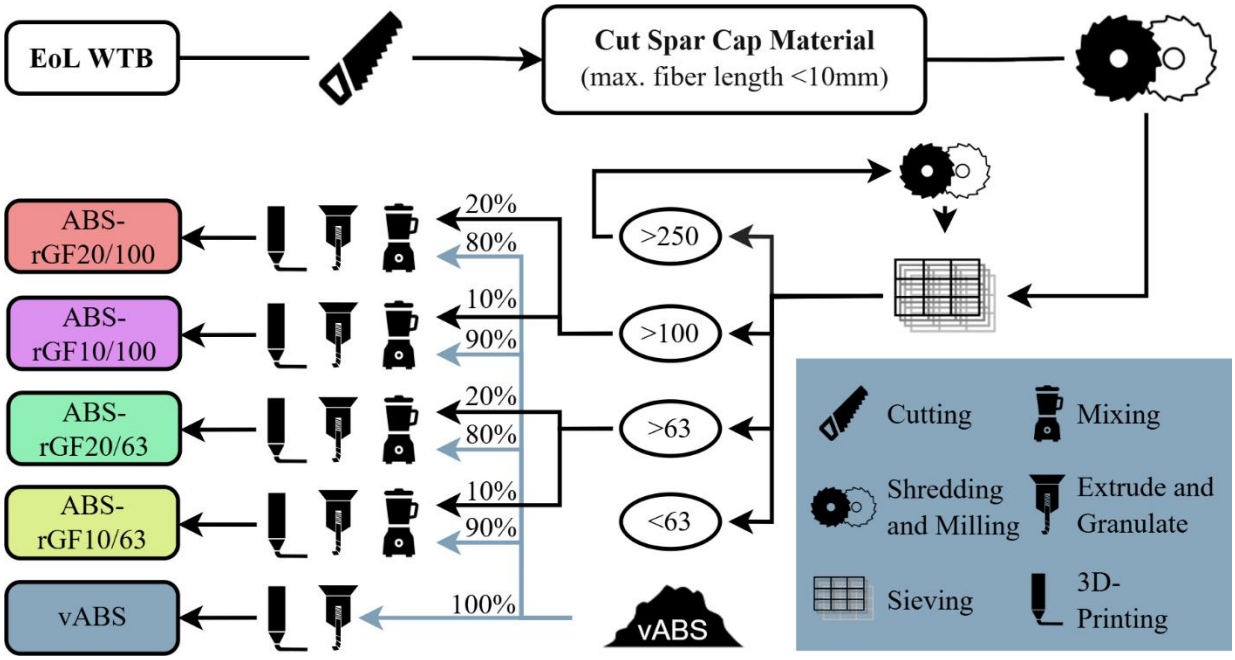

Figure 3: Schematic representation of the processing route from EoL WTB to 3D-printed tensile samples.

2.4 Material Characterization of recyclates and tensile samples

In order to characterize the EoL WTB recyclates, the fiber mass and volume content of each OF is determined through calcination tests according to ISO 1172 and ISO 1183-1 (glass fiber density of 2.48 g*cm^{-3} and matrix density of 1.2 g*cm^{-3}). Particle size and shape are analyzed using the dynamic image analysis system QICPIC with the LIXELL wet dispersion module (Sympatec GmbH, Clausthal-Zellerfeld, Germany), following ISO 9276 and ISO 13322-2. Samples are dispersed in distilled water, homogenized by stirring, and treated with surfactant. Each sample is measured three times from two independent subsamples to ensure repeatability. Size distributions are evaluated as volume-based density $q_3^*(x)$. Calcinated fiber samples (OF>63 and OF>100) are described by fiber length (LEFI) and fiber diameter (DIFI). Particle shape is assessed via elongation and straightness. Volume is calculated using a cylindrical mode. Characterization of vABS is estimated by equal projected circle diameter (EQPC).

To characterize the tensile samples, X-ray micro-computed tomography (µCT) is conducted on one randomly chosen printed rGFRP sample per compound using a high-resolution system (Phoenix Nanotom M, Waygate Technologies GmbH, Wunstorf, Germany) to evaluate internal structure, porosity and fiber volume content. Scans are performed using *datos|x* software. Image processing and volumetric analysis are carried out using *VGSTUDIO MAX 2023.1* (Volume Graphics GmbH, Heidelberg, Germany). Fiber volume content and porosity are quantified via manual segmentation of a selected region of interest (ROI), located within the interior of the sample to exclude surface effects and ensure that surface roughness does not affect the measurements. Segmentation was based on the gray value histogram using the ISO50 threshold method, in accordance with the general guidelines of ISO 15708-3. The applied scan parameters are listed in Table 1.

Mechanical testing of the printed samples (n=20 for each variant) is conducted in accordance with ISO 527-1. Prior to testing, samples are conditioned under standard laboratory climate (23 °C, 50 % relative humidity). A universal testing machine (Zwick Roell Z050, ZwickRoell GmbH & Co. KG, Germany) is used to determine tensile strength, Young's modulus, strain at break and tensile stress at break.

Table 1: Parameters used for µCT-scans.

Parameter	Unit	Value
Tube voltage	kV	100
Tube current	µA	110
Focus-detector-distance (FDD)	mm	290
Focus-object-distance (FOD)	mm	7.5
Voxel size	µm	2.6
Number of projections	-	2500
Binning	-	1
Averaging	-	3

3 RESULTS

3.1 Characterization of recyclates

The mean fiber mass content of the OF>63 and OF>100 are 76.03 wt% and 78.36 wt%, respectively. This corresponds to fiber volume content of approximately 60.54 % and 63.67 %. The distribution curves of OF>63 and OF>100 are shown in Figure 4.

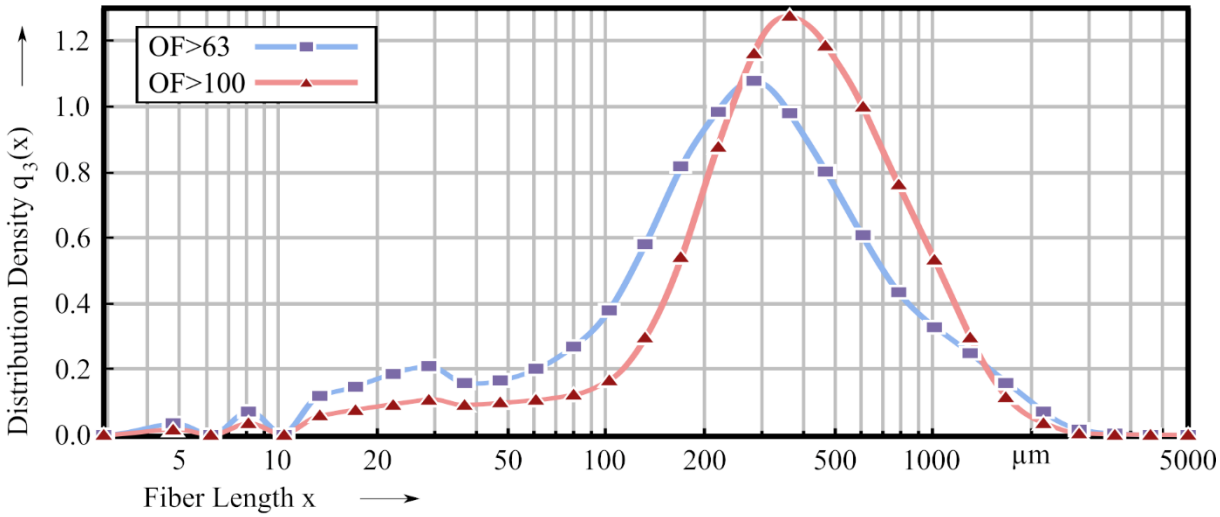

Figure 4: Fiber length distribution density curves of the OF>63 and OF>100.

Both curves show right-skewed profiles with a broad spread of fiber lengths. OF>63 exhibits a wider distribution in the lower length range, with a gradual rise and a long tail extending toward higher lengths. The cumulative curve increases more steadily, indicating a relatively even spread of shorter and medium-length fibers. In contrast, OF>100 shows a steeper rise in the cumulative curve at longer lengths, reflecting a larger proportion of long fibers. Its density curve is shifted to the right, with a more pronounced peak at longer fiber lengths compared to OF>63.

The vABS sample shows a median EQPC of 147 µm. OF>63 fibers range (Figure 4) from 40 to 852 µm in length (x_{50}=263 µm), while OF>100 fibers are longer overall, ranging from 106 to 926 µm (x_{50}=371 µm). The shift toward higher fiber lengths in OF>100 is also reflected in the cumulative distribution. Fiber diameters are similar in both samples, with median values of approximately 22 µm. This indicates a higher proportion of long fibers in OF>100 compared to OF>63. The key parameters are summarized in Table 2.

Table 2: Key parameters for all analyzed materials.

Variant	Value	Unit	X_{10}	X_{50}	X_{90}
vABS	EQPC	µm	45.76	147.42	345.56
OF>63	LEFI	µm	40.46	262.55	851.81
	DIFI	µm	15.59	22.01	28.07
OF>100	LEFI	µm	105.56	371.01	925.58
	DIFI	µm	17.18	22.42	28.31

3.2 Characterization of tensile samples

The µCT analysis shows clear differences in internal structure, porosity and fiber volume content among the different compounds used for the tensile samples (see Figure 5).

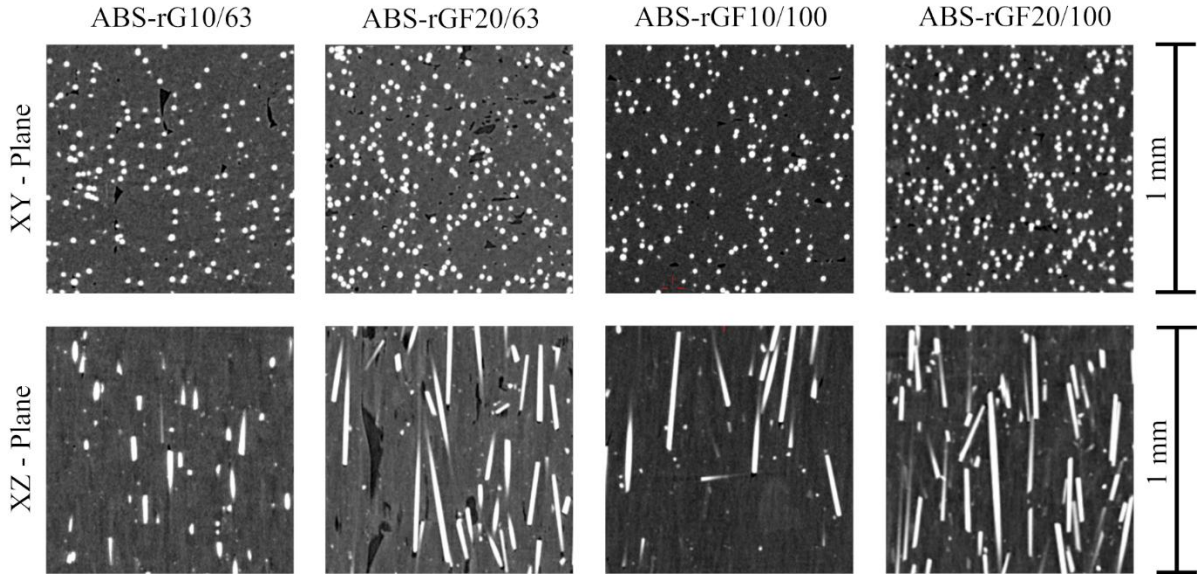

Figure 5: Cut out of cross-sections from the ROI in XY- and XZ-plane from the tensile samples of each compound.

For ABS-10rGF/63 and ABS-10rGF/100, the fiber volume content is approximately 5 vol%. ABS-20rGF/63 and ABS-20rGF/100 variants show an increased amount of approximately 9 vol%. A generally homogeneous fiber distribution is visible, with occasional fiber agglomerations. A preferred fiber orientation corresponding to the 3D printing paths is observed. Porosity within the ROIs ranges from 0.62 vol% to 1.58 vol%. The fiber volume content and porosity are summarized in Table 3.

Table 3: µCT-based quantification of fiber volume content and porosity in tensile samples of different compounds using ISO50 threshold values.

Parameter	Value	ABS-10rGF/63	ABS-20rGF/63	ABS-10rGF/100	ABS-20rGF/100
Fiber volume content	%	5.04	9.26	5.01	9.04
Porosity	%	1.04	1.58	0.62	0.91

The tensile tests results show improvements in stiffness and strength for all tested rGFRP samples compared to the vABS. Fracture occurs perpendicular to the loading axis in all variants (see Figure 6a). While vABS exhibits a distinct yield point, stress plateau, and extensive post-yield deformation, all rGFRP samples show a steeper slope with nearly linear elastic behavior up to failure with lower strain, lacking a visible yield point, except ABS-rGF10/63 (see Figure 6b and 6e). This finding suggests a shift in failure behavior due to the reinforcement with chopped fibers coming from EoL WTB spar cap material. An increase in mechanical properties from 10 wt% to 20 wt% compounds is observed. The greatest improvements in mechanical properties are observed for ABS-rGF20/63 with an increase of 101 % in Young's modulus and 27 % in tensile strength in comparison to vABS (see Figure 6c and Figure 6d). Tensile strain at failure reduces among all rGFRP compounds. Values decreased by 79 to 89 % compared to the reference. The increase in Young's modulus and tensile strength by increasing the fiber mass content from 10 wt% to 20 wt% is greater for OF>63 than for OF>100. Furthermore, the greatest dispersion was observed for ABS r20GF/100.

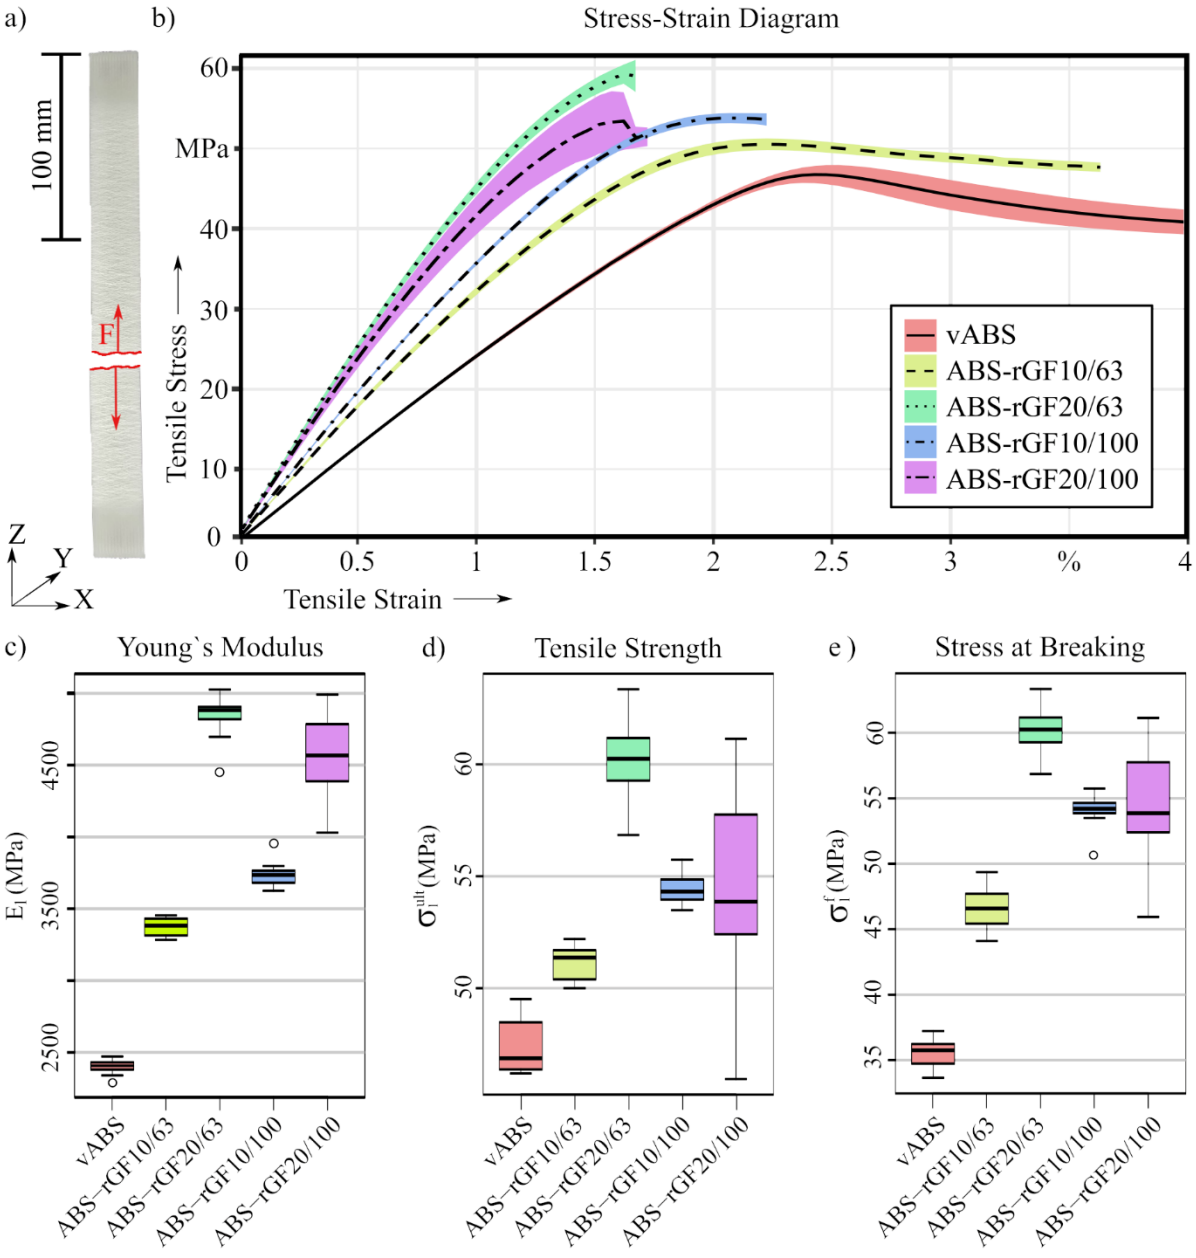

Figure 6: Mechanical testing of vABS and rGFRP samples: (a) tensile sample after testing; (b) mean stress–strain curves; (c) Young's modulus; (d) ultimate tensile strength; (e) stress at break.

The tensile test results are summarized in Table 4, which lists the engineering constants with mean values and standard deviations.

Table 4: Tensile test results: Youngs-Modulus (E_1), tensile strength (σ_1^{ult}), stress at break (σ_1^f) and strain at break (ε_1^f).

Engineering constant	Unit	vABS	ABS-rGF10/63	ABS-rGF20/63	ABS-rGF10/100	ABS-rGF20/100
E_1	MPa	2402±42	3367±61.4	4839±142	3734±74.3	4587±237
σ_1^{ult}	MPa	47.4±1.16	51.1±0.74	60.2±1.72	54.4±0.64	54.6±3.61
σ_1^f	MPa	35.6±1.57	46.6±1.57	60.2±1.72	54.2±1.02	54.6±3.62
ε_1^f	%	30.9±10	6.3±0.79	3.3±0.14	3.9±0.21	3.4±0.26

4 DISCUSSION

The incorporation of 10 wt% rGFRP into printed samples resulted in an enhancement in stiffness and strength, without compromising printability for either OF. The low porosity values and homogeneously distributed fibers in µCT scans provide further evidence to support these findings. The use of vABS powder in the compounding process facilitates generally homogeneous fiber distribution, thereby ensuring consistent processing and mechanical behavior.

Conversely, combinations of elevated recyclate content and coarser sieve fractions (OF>100) result in increased variability in mechanical properties and diminished surface quality. This phenomenon is likely attributable to impaired flow and printability, particularly when employing a 0.8 mm nozzle. Local printing defects and material inhomogeneities, including fiber agglomerations, have been identified as additional contributing factors to the observed deviations. These findings underscore the necessity of optimizing print parameters.

The measured fiber volume content of the rGFRP indicates that only small amounts of matrix material are lost during the mechanical recycling. In comparison to the initial spar cap material with approximately 57 vol%, the OF>63 and OF>100 show an increase of about 6.2 % and 11.7 %, respectively.

Fiber length and distribution have been identified as pivotal factors influencing both mechanical performance and processing behavior. The successful integration of short, mechanically recycled GFRP, which is often considered low-value residue, demonstrates its potential for use in circular material flows. The purely mechanical preparation route avoids pyrolysis or chemical treatment, thereby simplifying material recovery and enabling direct reuse in thermoplastic matrices.

The present study focuses on ABS in powder form and GFRP derived from EoL WTB spar cap material. While the method is applicable to other thermoplastics and WTB sections, components such as shear webs or sandwiches generally exhibit lower fiber content and higher levels of contaminants (e.g., balsa wood, polyurethane foam). These materials may necessitate supplementary separation or pretreatment procedures, such as air classification or density-based sorting, to yield recyclates suitable for further utilization. Furthermore, the mechanical test data and µCT-based structural information may serve as a valuable basis for developing numerical simulation models of rGFRP-based components. These models have the potential to facilitate design optimization and material performance prediction in the field of additive manufacturing. In order to further validate these findings, it will be necessary to characterize additional parameters in subsequent studies. These additional parameters may include, but are not limited to, local fiber orientation, orientation distribution, and fiber-matrix interface quality.

5 CONCLUSIONS

The present study demonstrates the feasibility of mechanically recycled GFRP materials from EoL WTB spar caps into thermoplastic composites suitable for large-scale additive manufacturing. The applied process chain, which is entirely dependent on mechanical recycling steps such as cutting, shredding, milling, and sieving, enables the production of high-fiber-content recyclates. These recyclates are successfully compounded with ABS powder and processed via FGF.

These findings indicate that energy- and resource-intensive recycling methods, such as pyrolysis, are not necessary to produce compatible feedstocks for thermoplastic matrices. This contributes to the expansion of existing recycling strategies for WTBs beyond the practices of downcycling or incineration, thereby facilitating more circular material flows in accordance with established R-strategies. The developed process chain provides a scalable and transferable framework for the further utilization of fiber-rich WTB residues. To achieve the optimal utilization of this material, future research should prioritize increasing the recycled content while maintaining the processability and performance of the material.

ACKNOWLEDGEMENTS AND FUNDING

Our thanks go to Sebastian Blanke from the chemistry laboratory at MNZ, HTWK Leipzig, for his invaluable technical support. We also gratefully acknowledge Sympatec GmbH for conducting the fiber length and particle size analyses. Furthermore, we thank Enercon GmbH, Magdeburg, for kindly providing end-of-life wind turbine blades used in this study.

The study has been performed within the HORIZON-CL4-2021-RESILIENCE-01 project "European recycling and circularity in large composite components (EuReComp)", call "A Digitized, Resource-Efficient and Resilient Industry 2021", HORIZON Research and Innovation Actions, Contract Number 101058089. Views and opinions expressed are however those of the author(s) only and do not necessarily reflect those of the European Union or HADEA. Neither the European Union nor HADEA can be held responsible for them. This research was supported by the Deutsche Forschungsgemeinschaft (DFG), which funded the acquisition of the X-ray CT system.

Research background

Increase in Utilization of Composites in Aerospace Structure

- Due to the need for **lightweight structures** in the aerospace industry, demand for composites has significantly increased.
- For instance, the **Boeing 787** uses **composite materials** about 50% of its weight. [1]
- Furthermore, **1st and 2nd stage forward fuselage** and **payload fairing** of **Nuri (Korea Space Launch Vehicle-Ⅱ).** use **composite material** to reduce the weight of launch vehicle.

<Use of composite materials in Boeing 787 [1]>

<Use of composite materials in Nuri>

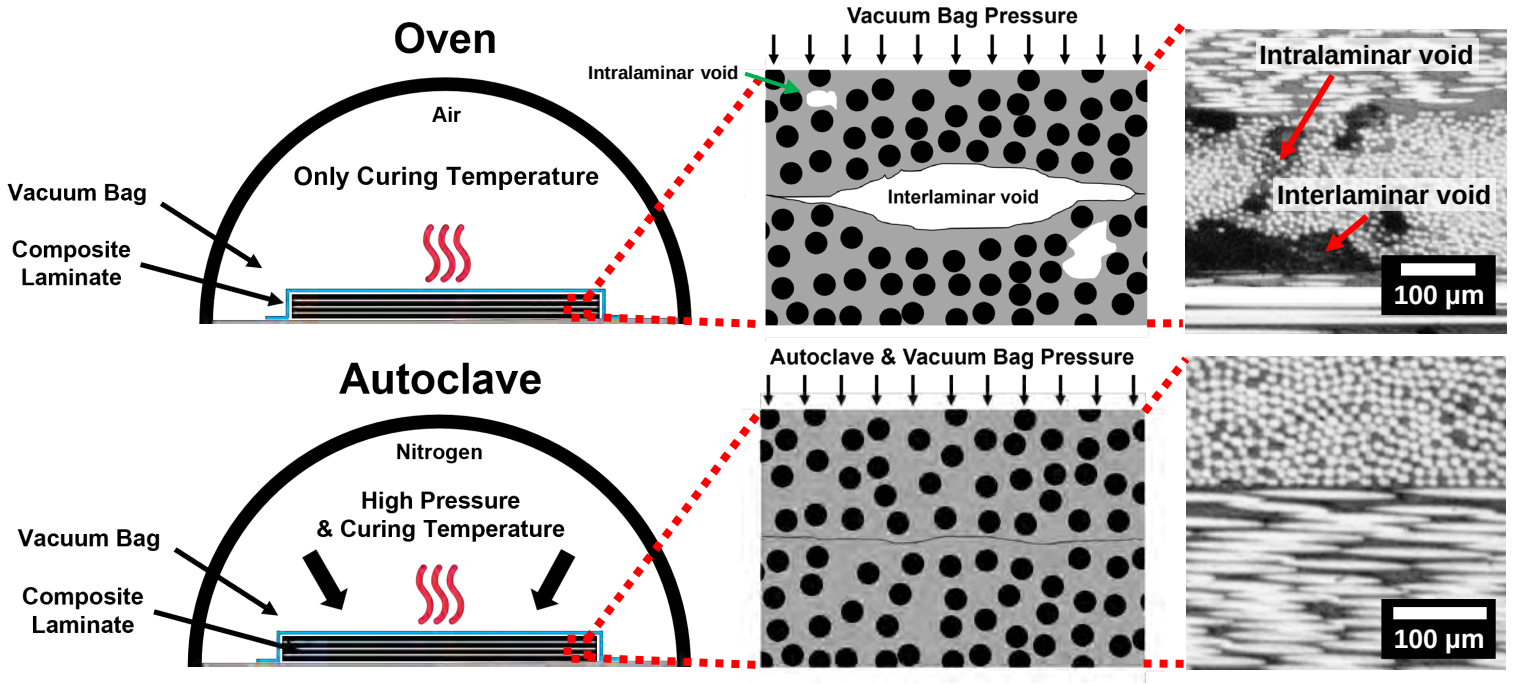
Composite Application in Aerospace Industry: Composite Overwrapped Pressure Vessel (COPV)

- By changing the **material from metal to composites** in a pressure vessel, approximately **70% weight reduction** can be achieved. [2]
- Space launch companies and research institutions are continuously conducting research to replace **metal fuel tanks in launch vehicles with COPVs**.

<Composite LOX tank for launch vehicle>



<Schematic of COPV for different types>

Void Defects Occur Due to Low Pressure in COPV Manufacturing Processes

- Aerospace composites are manufactured using the **autoclave process** for **high quality structure.** [3]
- However, **autoclave process** cannot be used for **COPV manufacturing**, due to the high cost and **external pressure** applied in **radial direction.**
- Due to a manufacturing process restrictions, COPVs have a **high void content,** approximately 3 to 9%. [4]

Influence of Void Content in Mechanical Properties and Gas Permeability of Composite

- **Void defects** that occur during the oven curing process **significantly reduce the mechanical strength.** [5-6]
- **Enclosed damage (e.g., void defect)** in composite can **increase gas permeability.** [7]

<Relationship between mechanical properties and void content [6]>

<Relationship between helium permeability and enclosed damaged in CFRP laminate [7]>

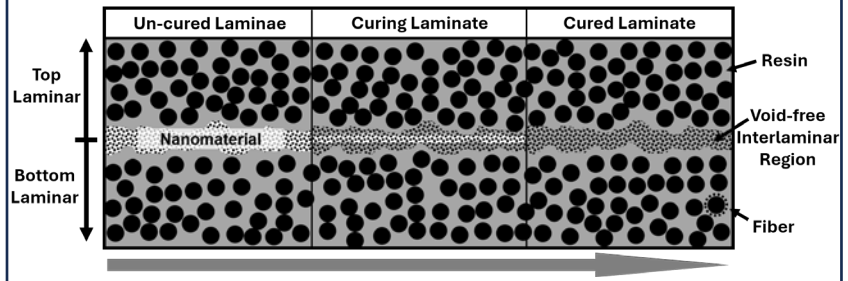
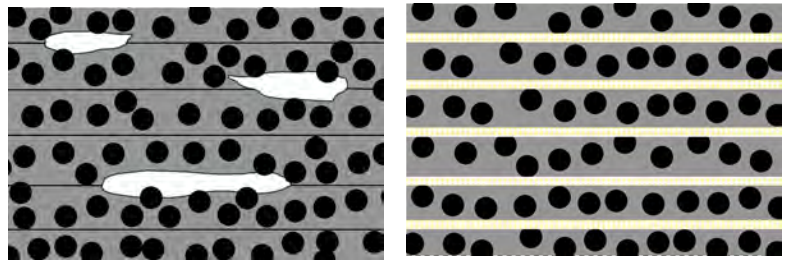
Objective and Approach

Research Approach



Nanomaterial architectures in composite interlaminar region

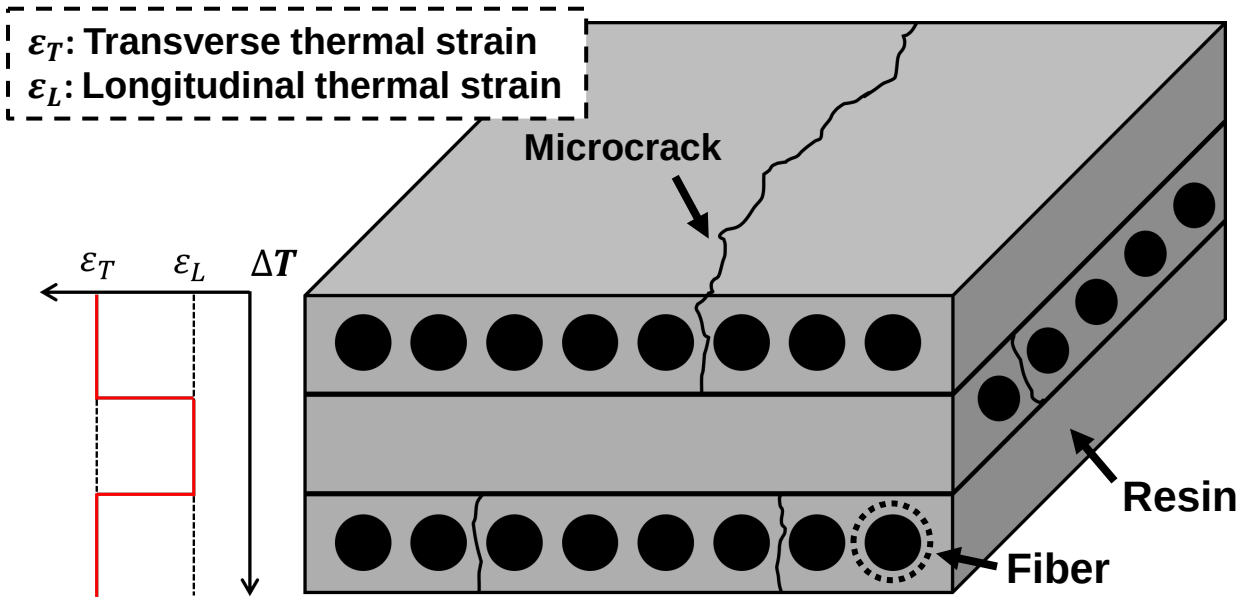
#1. Nano-structured interlaminar toughening as a CTE mismatch buffer



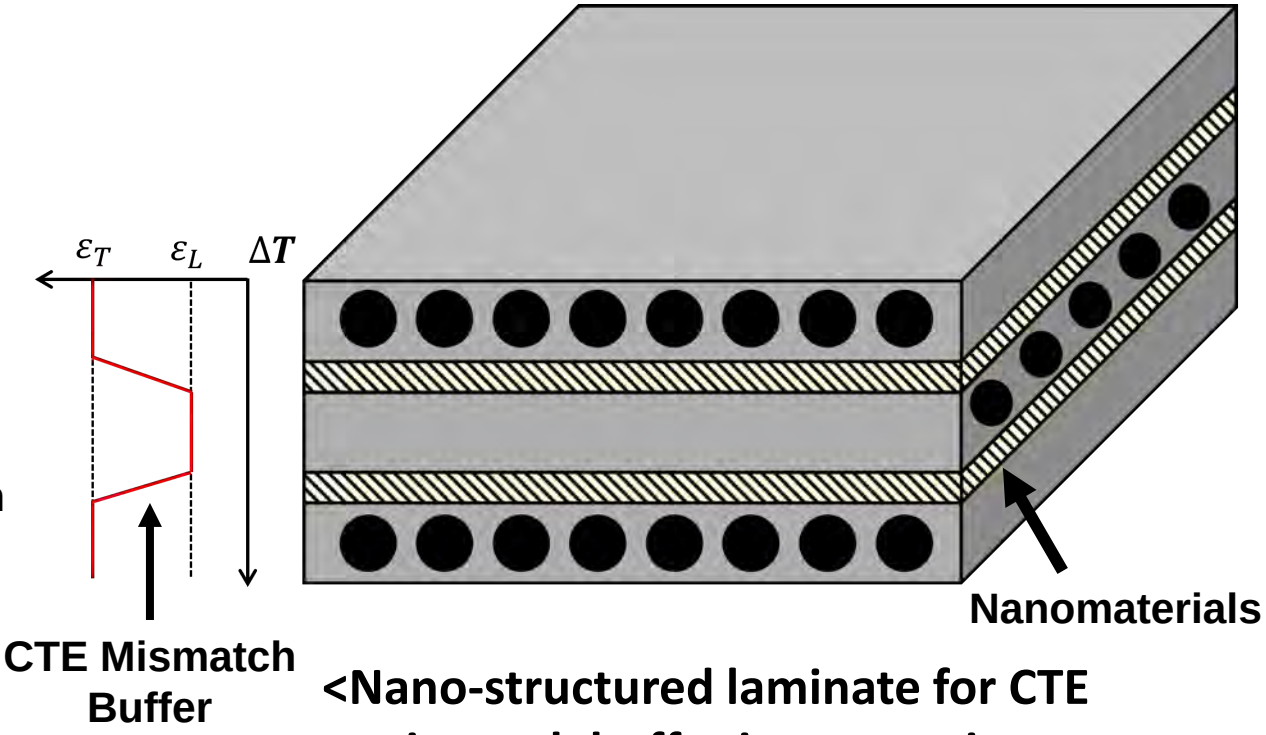
- Prohibit microcrack and delamination due to thermal cycling

#2. Capillary-enhanced void-free manufacturing

- Void defect-free next-generation composite production process



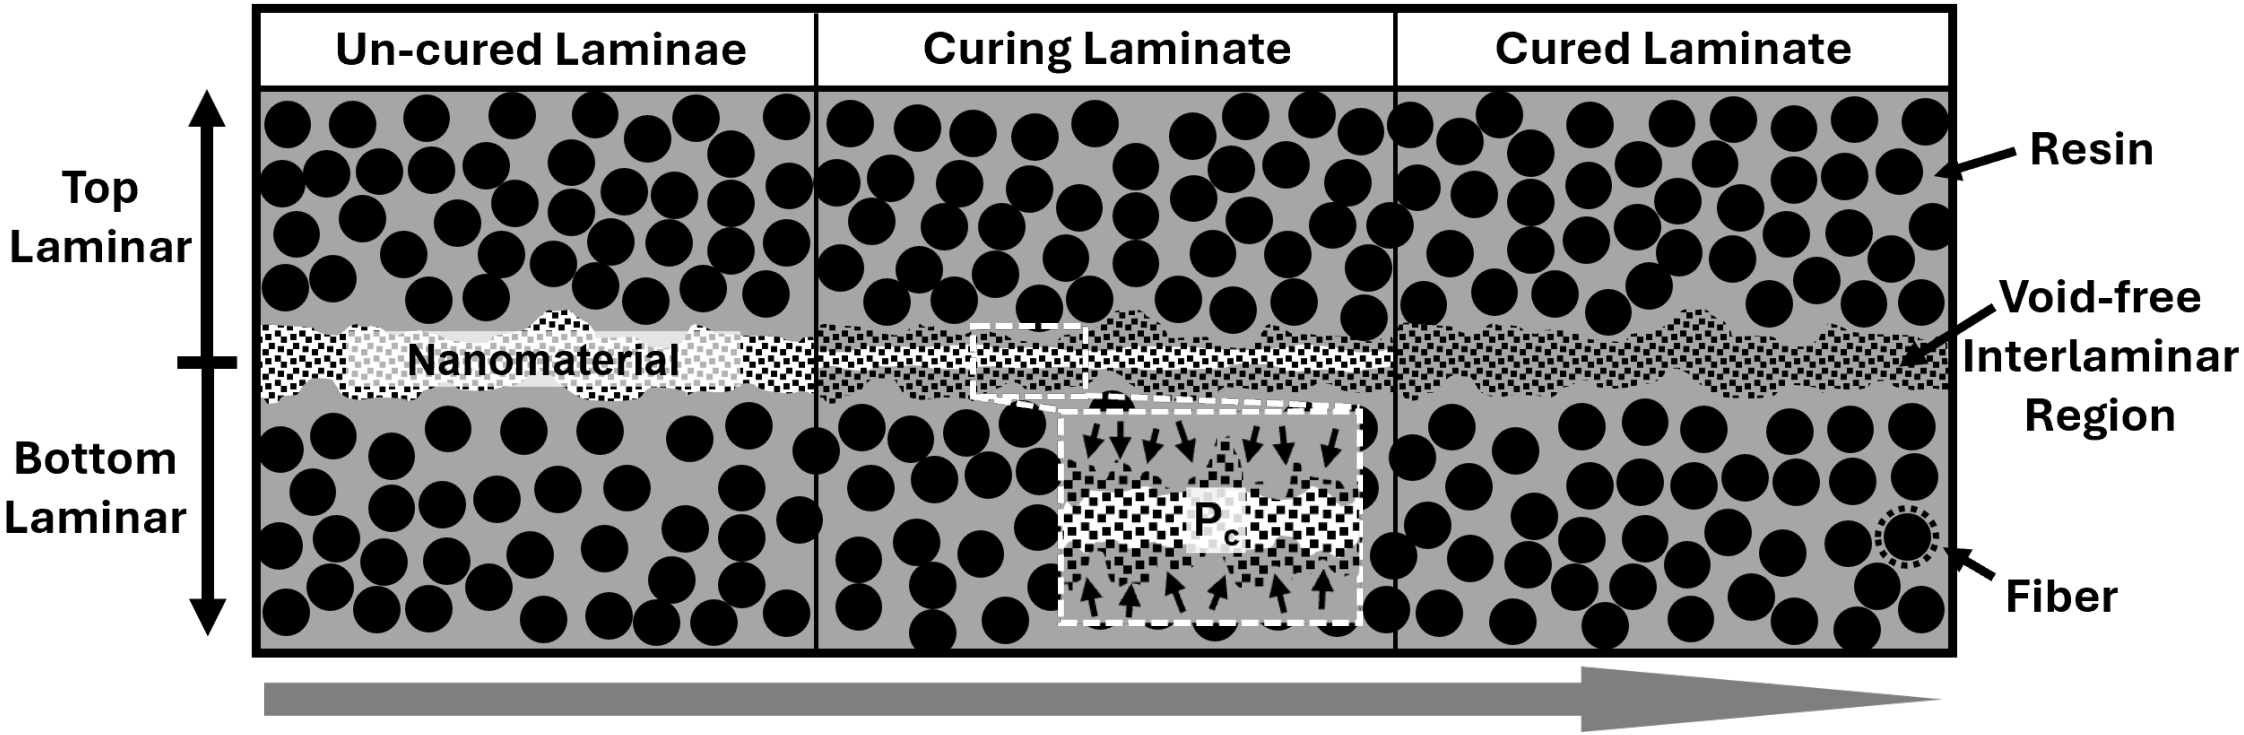
#3. Nanomaterials act as a gas permeation barrier



- Nanomaterials perform as a thin yet multi-layered permeation barrier

Nano-Structured Interlaminar Toughening as a CTE Mismatch Buffer

- High-toughness nanomaterials are layered between composite laminate layers and co-cured.
- The **high-toughness nanomaterials** act as a **CTE mismatch buffer** in the laminate, preventing microcracks and delamination.

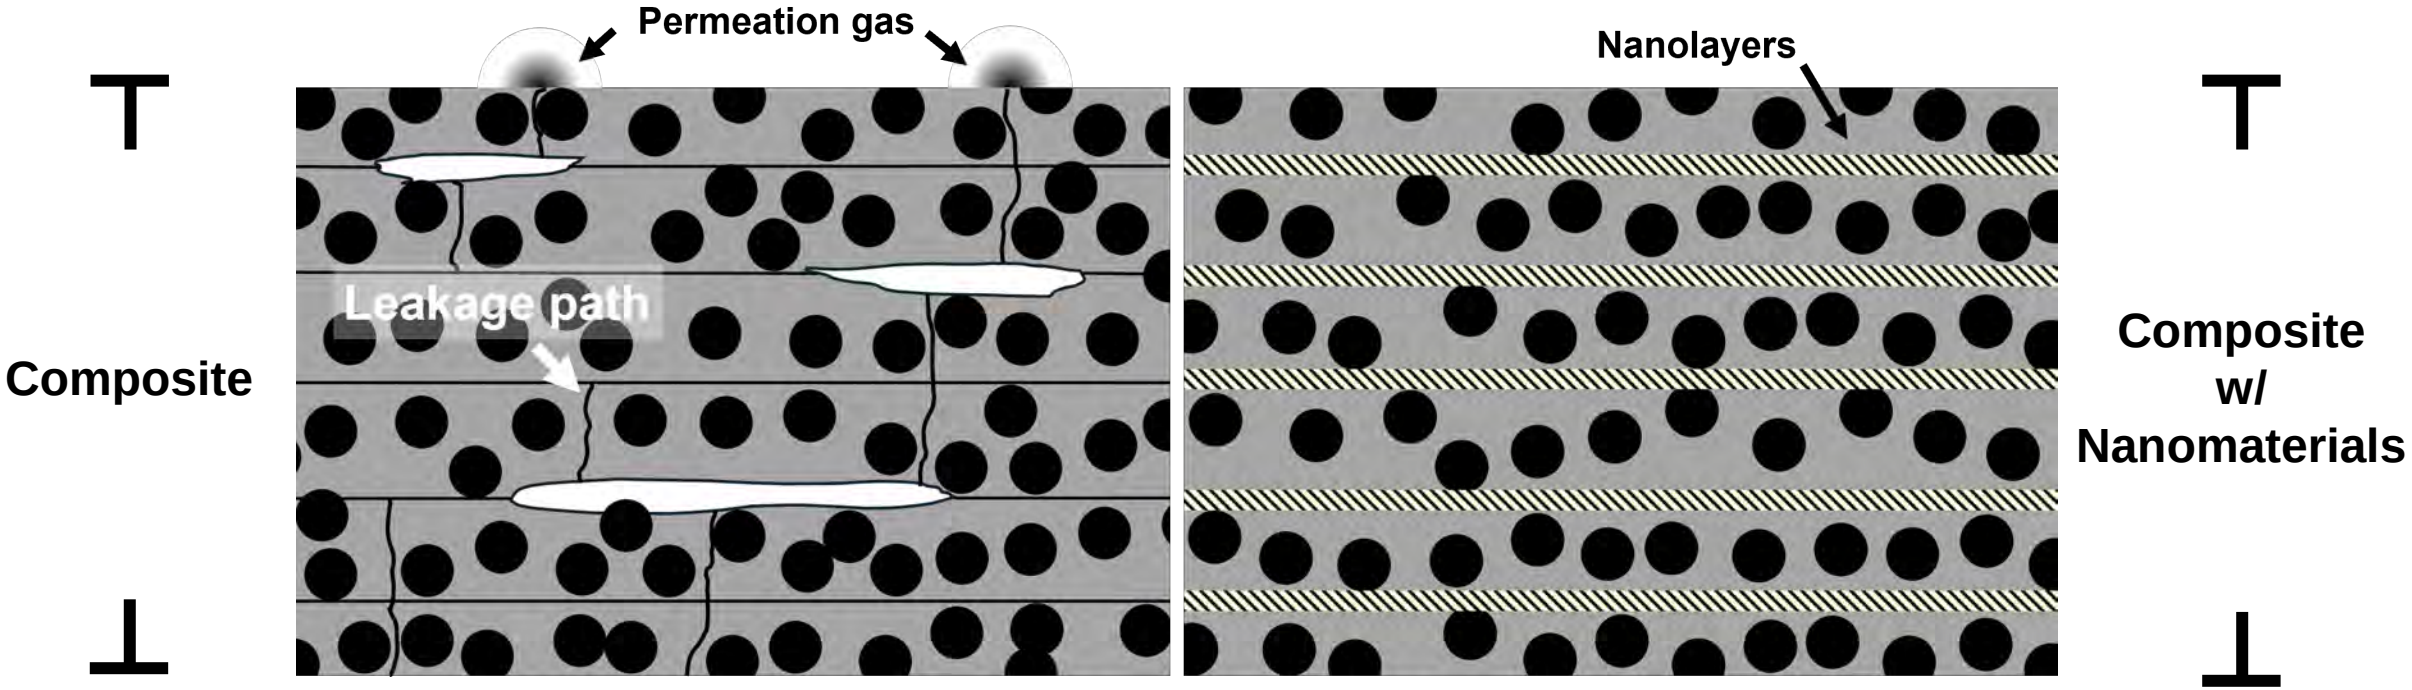


<Microcracks, delamination in composite induced by thermal cycling>

<Nano-structured laminate for CTE mismatch buffer in composite>

Capillary-Enhanced Void-Free Manufacturing

- Due to limitations in the manufacturing process, void defects occur between laminate interfaces.
- By utilizing the **capillary action of nanostructures**, it is possible to **provide additional pressure** to the composite without using an autoclave. [14]

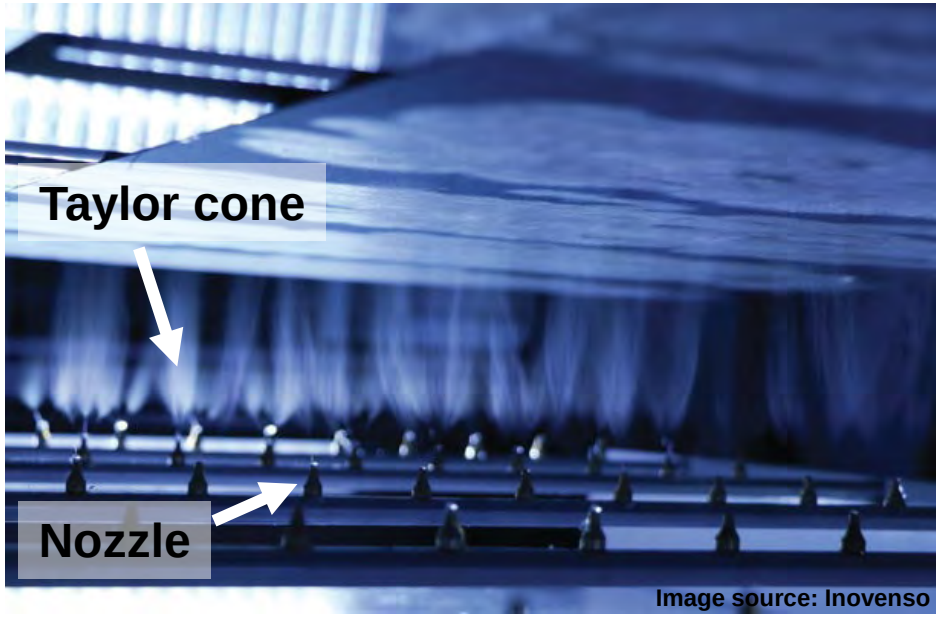


<Capillary pressure can act as additional pressure for reducing void contents>

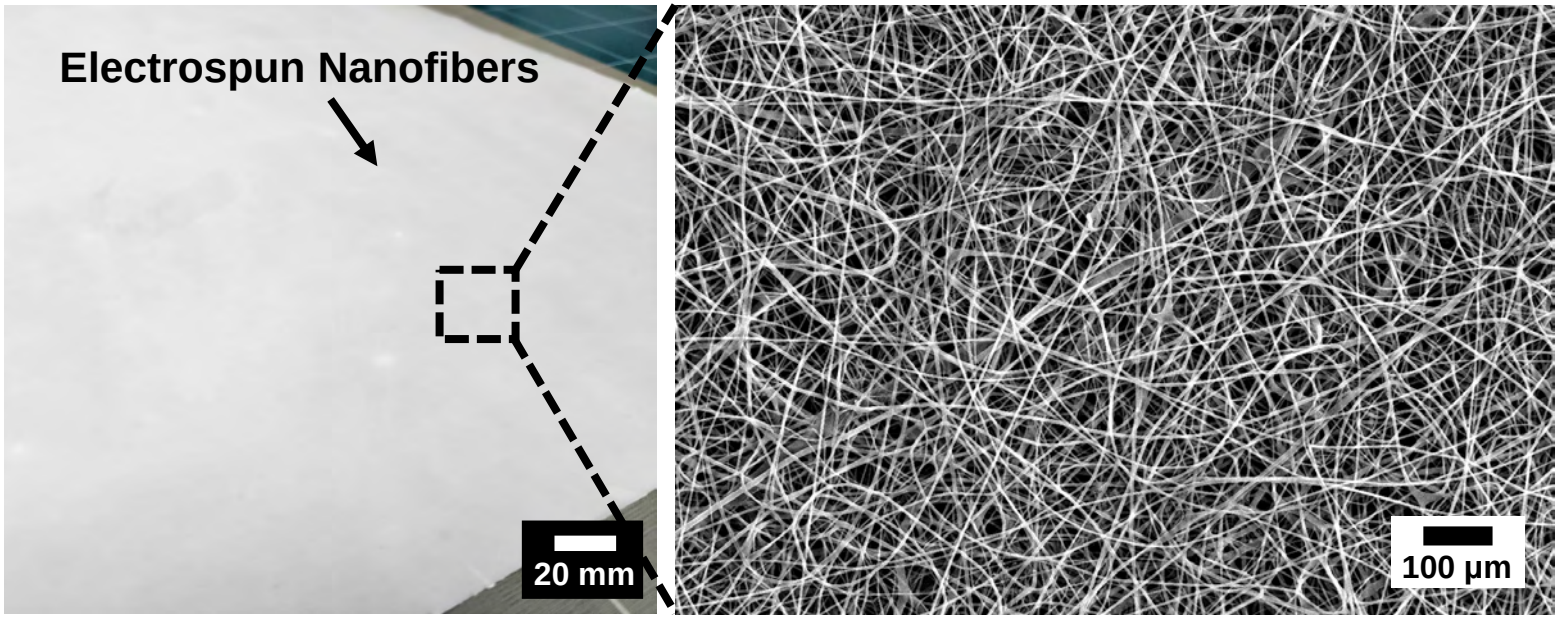
[14] Lee, J., et al. (2020). Advanced Materials Interfaces.

Nanomaterials as a Gas Permeation Barrier

- **Void defects** in the composite act as **gas leakage paths**, permanently increasing the **steady state leak rate**.
- Further, microcracks and delamination caused by thermal cycling hinder the use of composite as a gas permeation barrier.
- **Nanomaterials** layered between the composite laminate serve as a **gas permeation barrier**.



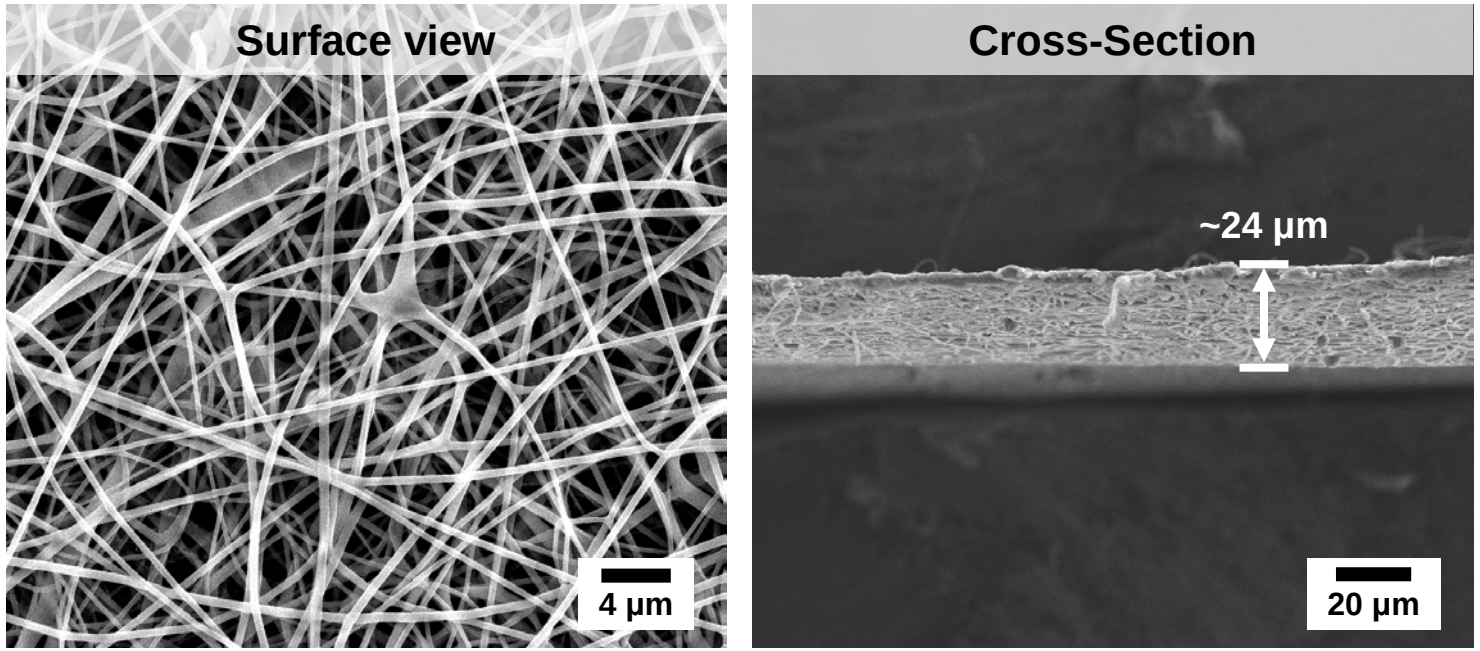
<Nano-structured laminate for a gas permeation barrier>



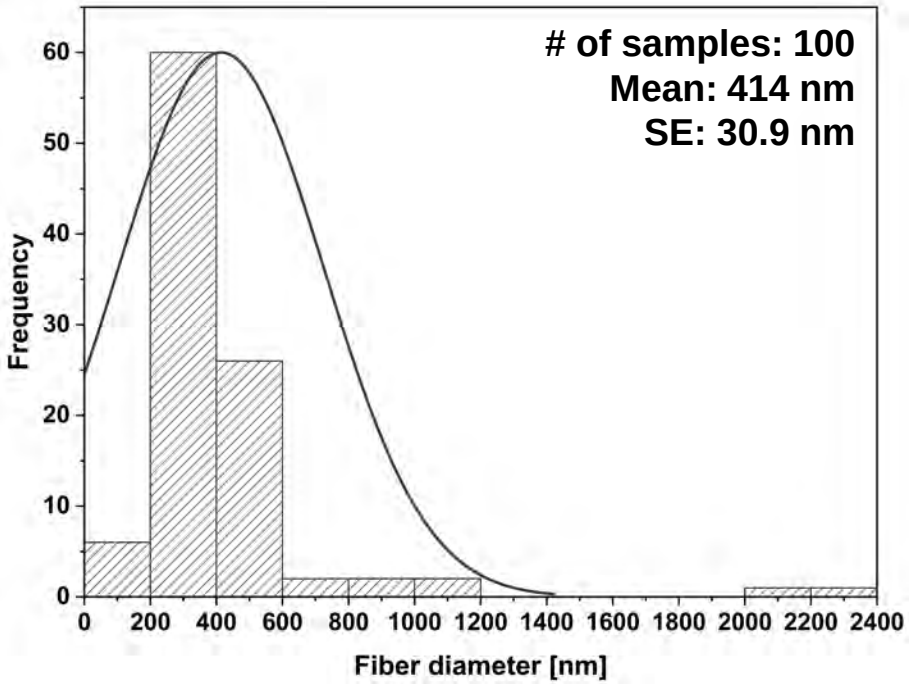
Fabrication and Process

Synthesis Process of Nanofibers: Electrospinning

- **Electrospinning** is used as a method for synthesizing polymer nanomaterials (**high productivity**, **low cost**).
- **High voltage** is applied to create an **electric field;** the **polymer** dissolved in the solvent is emitted through a nozzle.
- The solvent **evaporates** before reaching the substrate, forming **polymer fibers** with **nanoscale structures.**



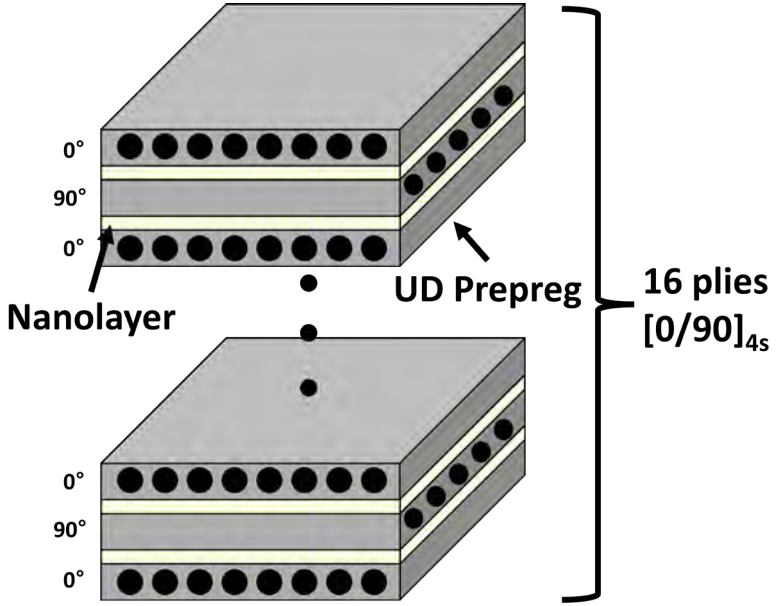
<Electrospinning process>



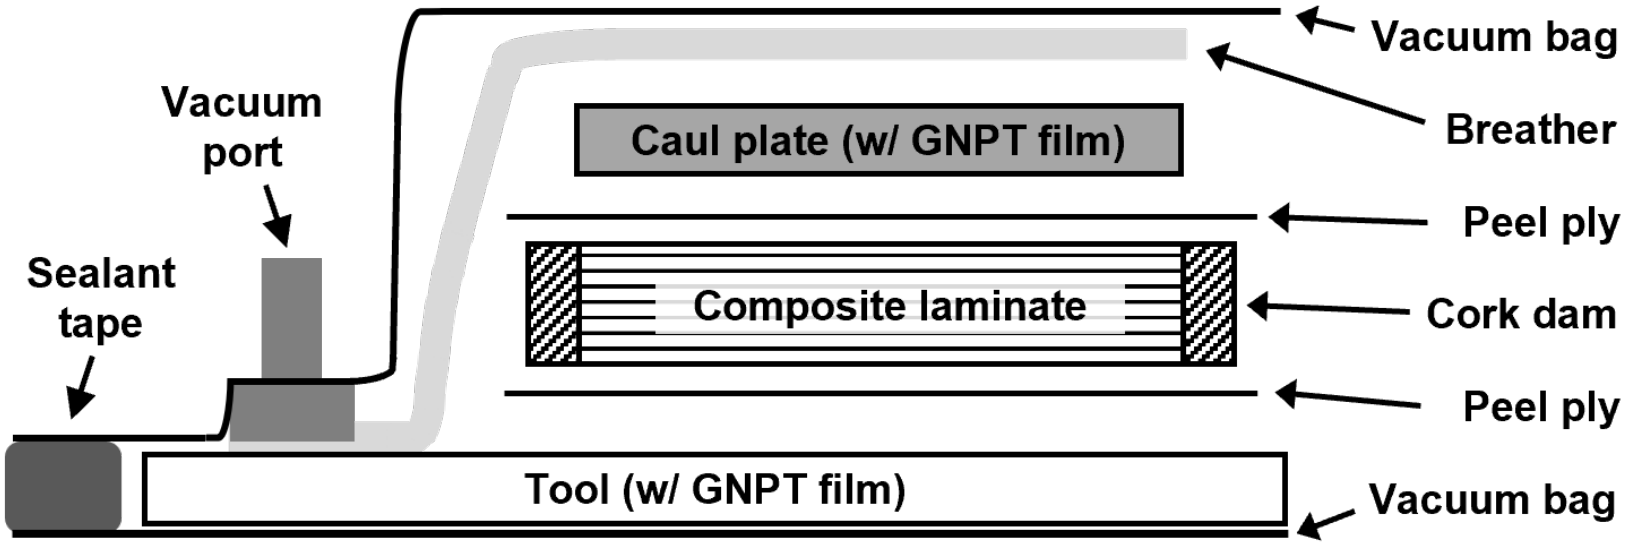
<Morphology of electrospun nanofibers>

SEM Images of Electrospun Nanofibers

- **Nanolayers** used in this study were Nanolayr® electrospun PA6 (XLB).
- **Nanofibers** have **smooth surface** without any beading, as observed through Scanning Electron Microscope (SEM).
- **Cross-sectional SEM images** showed that the **thickness** of the **nanolayer** was ~**24 µm** per layer for **4.5 gsm**.
- **Average fiber diameter** was **414 nm (SE = 30.9 nm),** based on manual measurement.



<SEM image of nanolayers (4.5 gsm)>

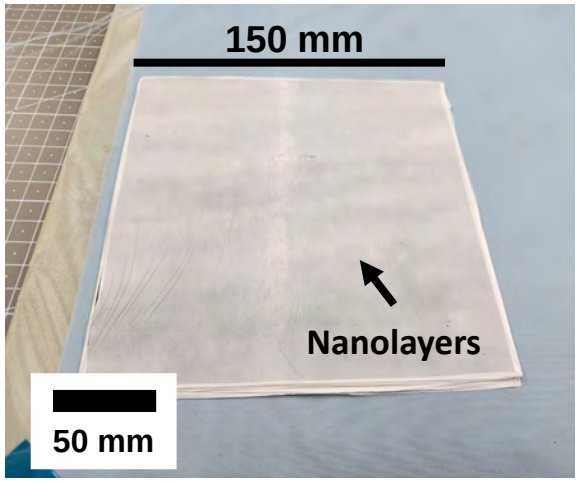


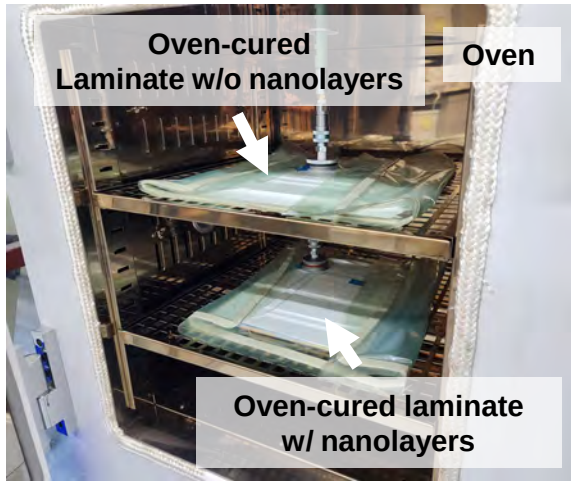
<Histogram of nanofibers diameter>

Fabrication, Curing Process of Composite Laminates with Electrospinning Nanolayers

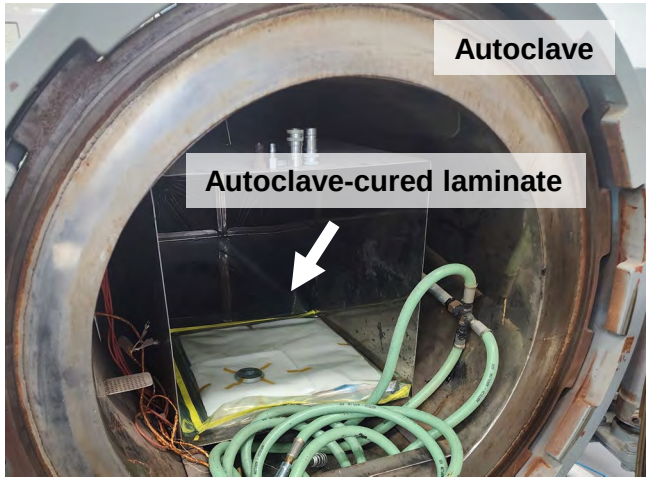
- Considering the mechanism of microcracks and delamination due to CTE mismatch, the laminate **lay-up** is selected as **cross-ply $[0/90]_{4s}$** to evaluate the **worst-case scenario**. [15]
- **Nanolayers** are **transferred** between **all the laminae** (SK chemicals T700/H18 UD prepreg, USN-125B).
- Vacuum bagging is a commonly used method, and the surface film varies depending on the type of experiment.

<Lay-up of laminate with nanolayers>

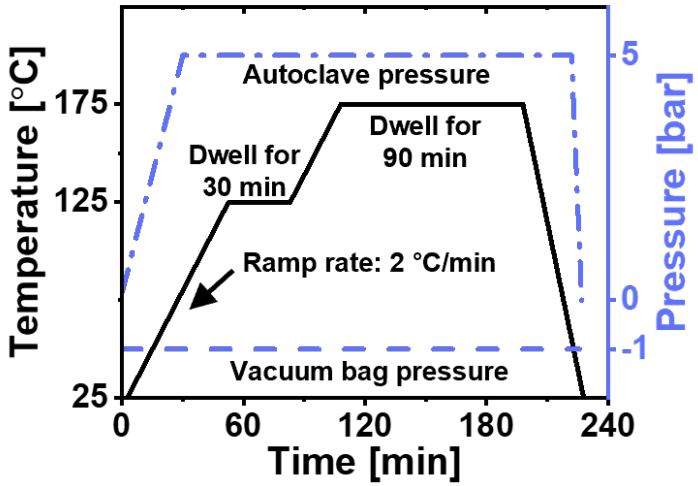




<Vacuum bagging of the composite laminate>

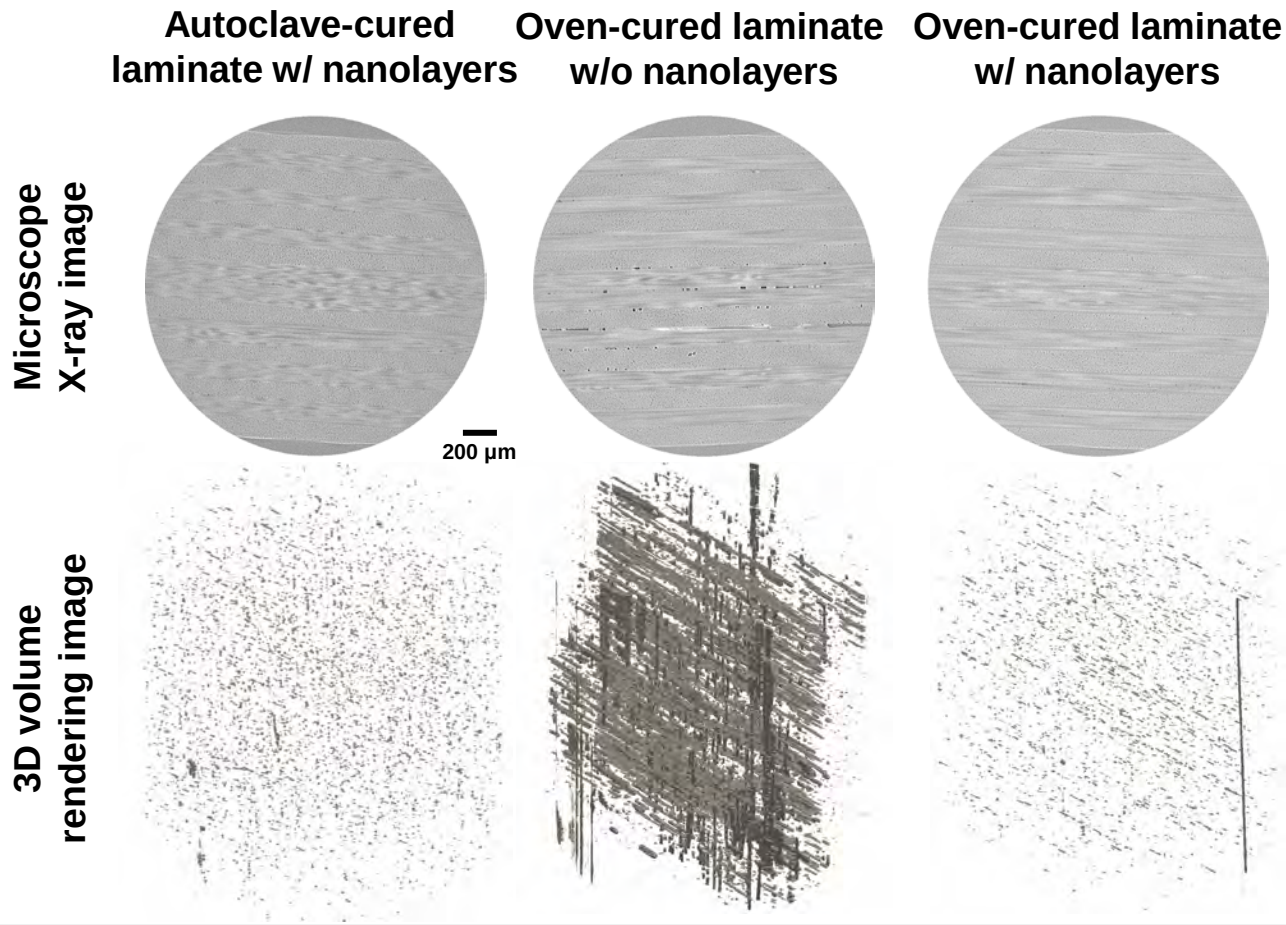


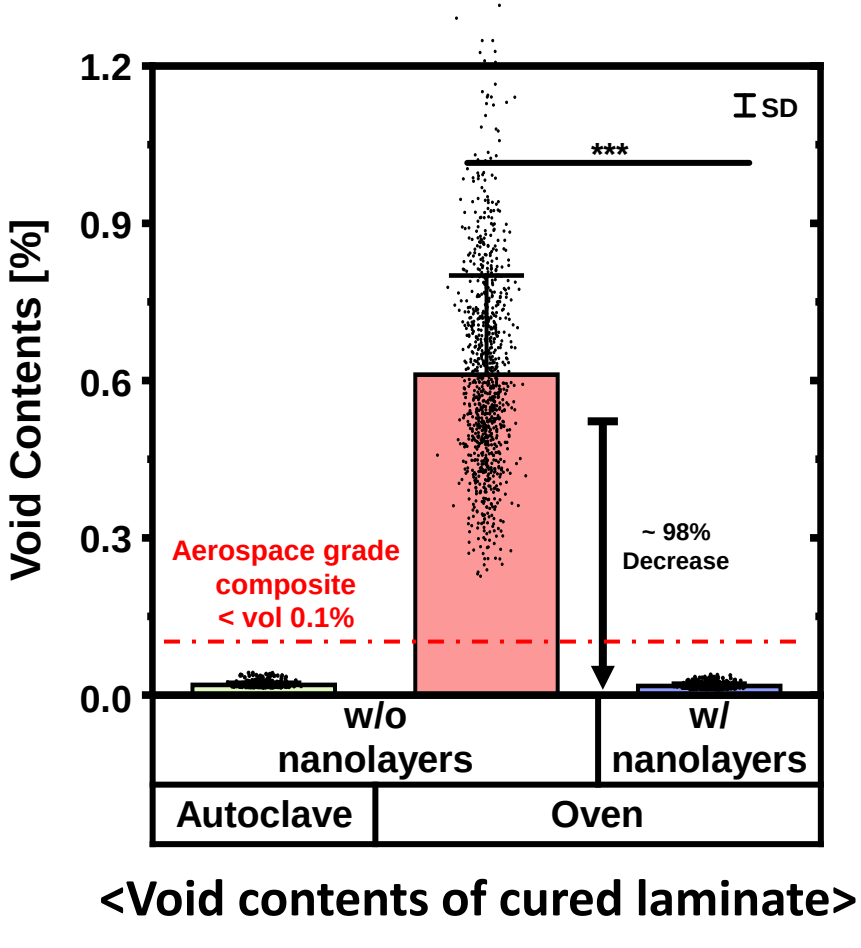
[15] Meng, Jinxin, et al. Composites Science and Technology (2022)



Fabrication, Curing Process of Composite Laminates with Electrospinning Nanolayers

- Nanolayers are cut slightly larger than the prepreg to cover all surfaces of the composite.
- Curing is performed in an **oven** and **autoclave** according to the **Manufacturer Recommended Cure Cycle** (MRCC) of the prepreg resin.
- Oven-cured laminate w/o nanolayer and oven-cured laminate w/ nanolayers are cured simultaneously in oven
- **Autoclave-cured laminates** are cured using the same cure cycle as oven-cured laminates, under an applied pressure of **5 bar** (nominal cured thickness: 1.92 mm).



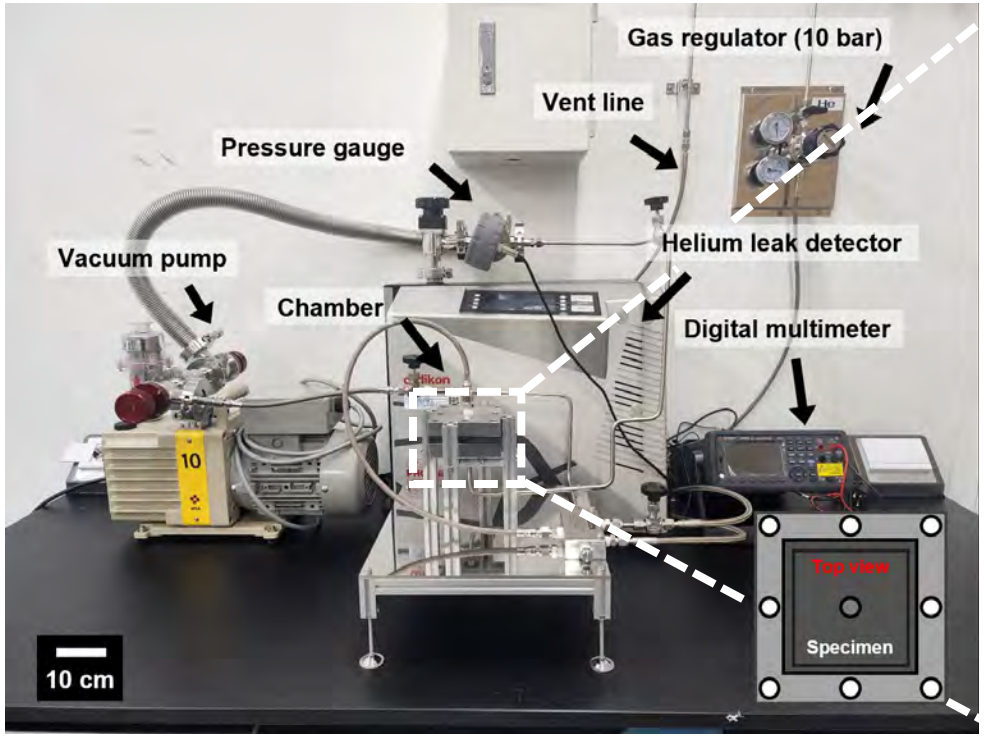


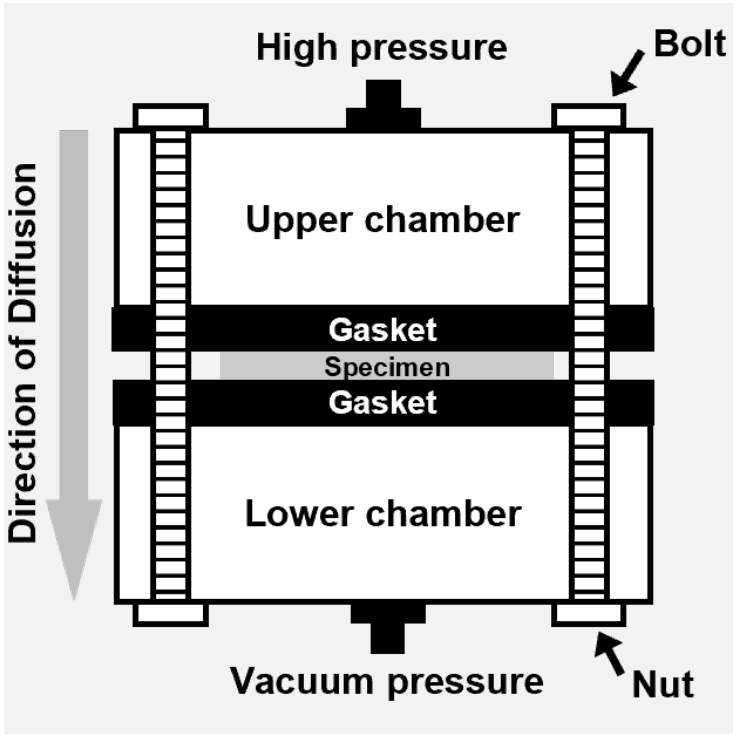
<Fabrication, curing process, and cure cycle of composite laminate>

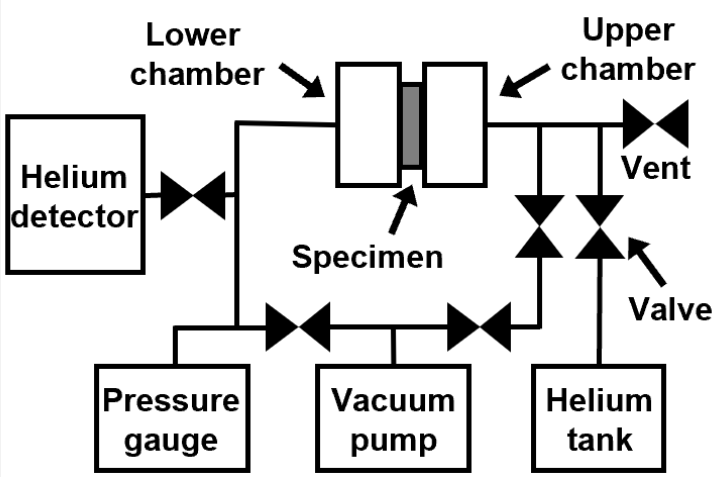
Result and Discussion

Void Analysis: Void Contents & 3D Rendering

- The **oven-cured laminate w/ nanolayers** was found to have approximately **98% fewer voids** compared to the oven-cured laminate w/o nanolayers (same as autoclave-cured laminate w/o nanolayers).



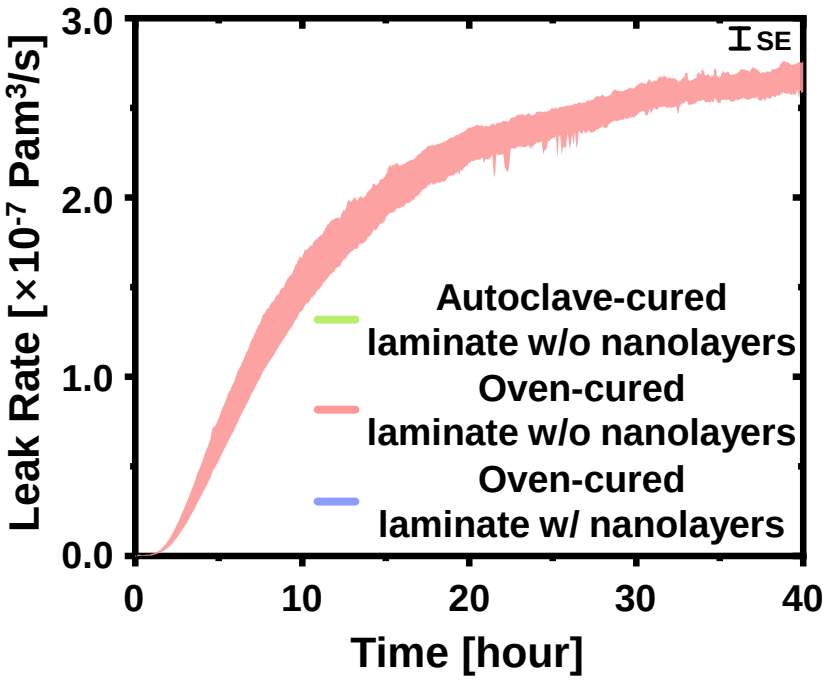




<Void contents of cured laminate>

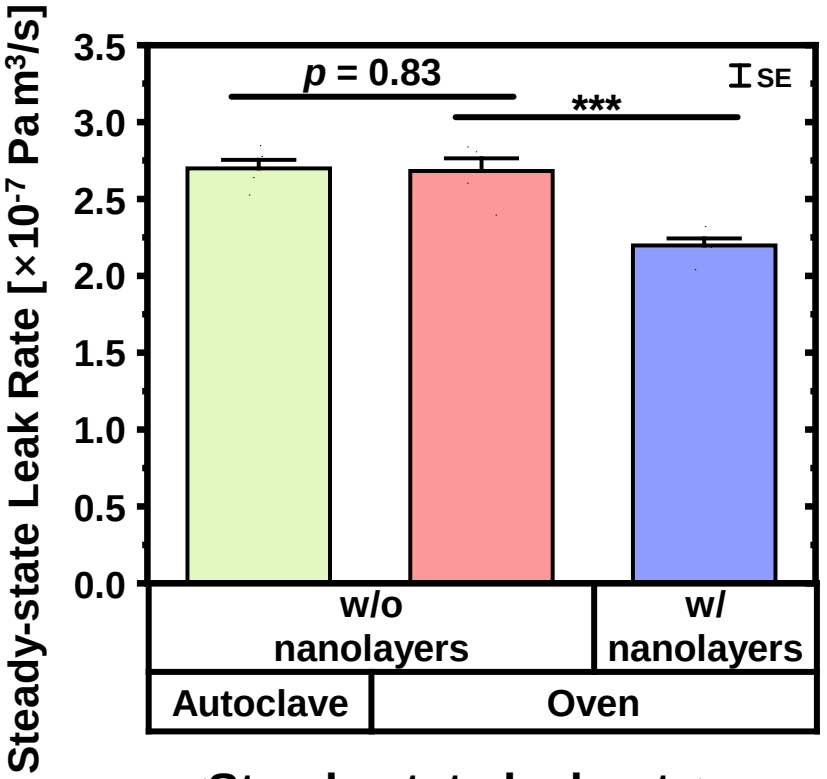
Apparatus of Gas Permeability Test

- **Concentration gradient** between the upper and lower chambers induce **diffusion** in the **out-of-plane direction** of the specimen.
- The **permeation gas** is **helium** (10 bar), which has a **small molecular size** and **high diffusion rate**. [16]



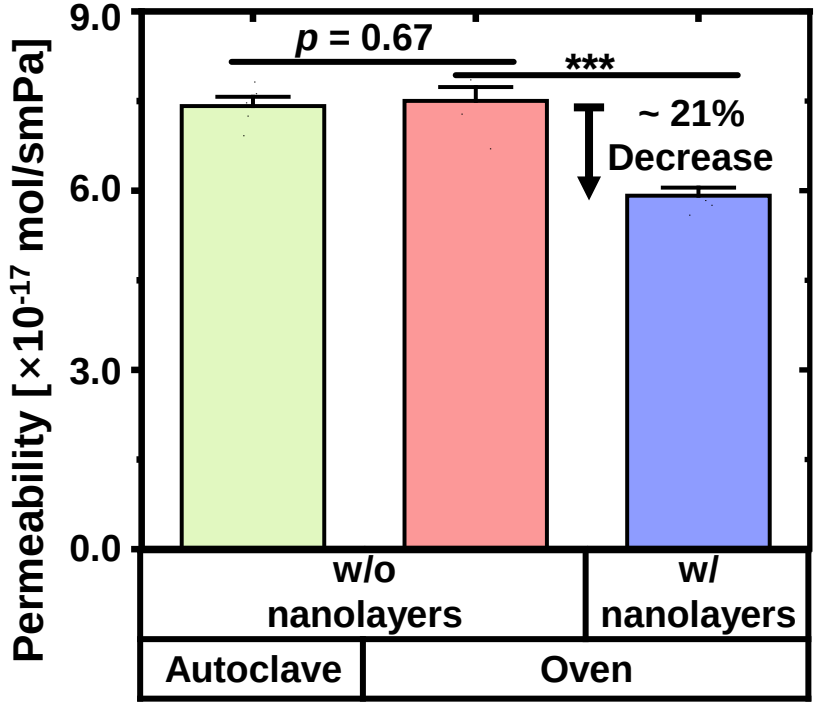
<Schematic of apparatus for helium gas permeability testing>

<Apparatus for helium gas permeability measurement of composite laminate>



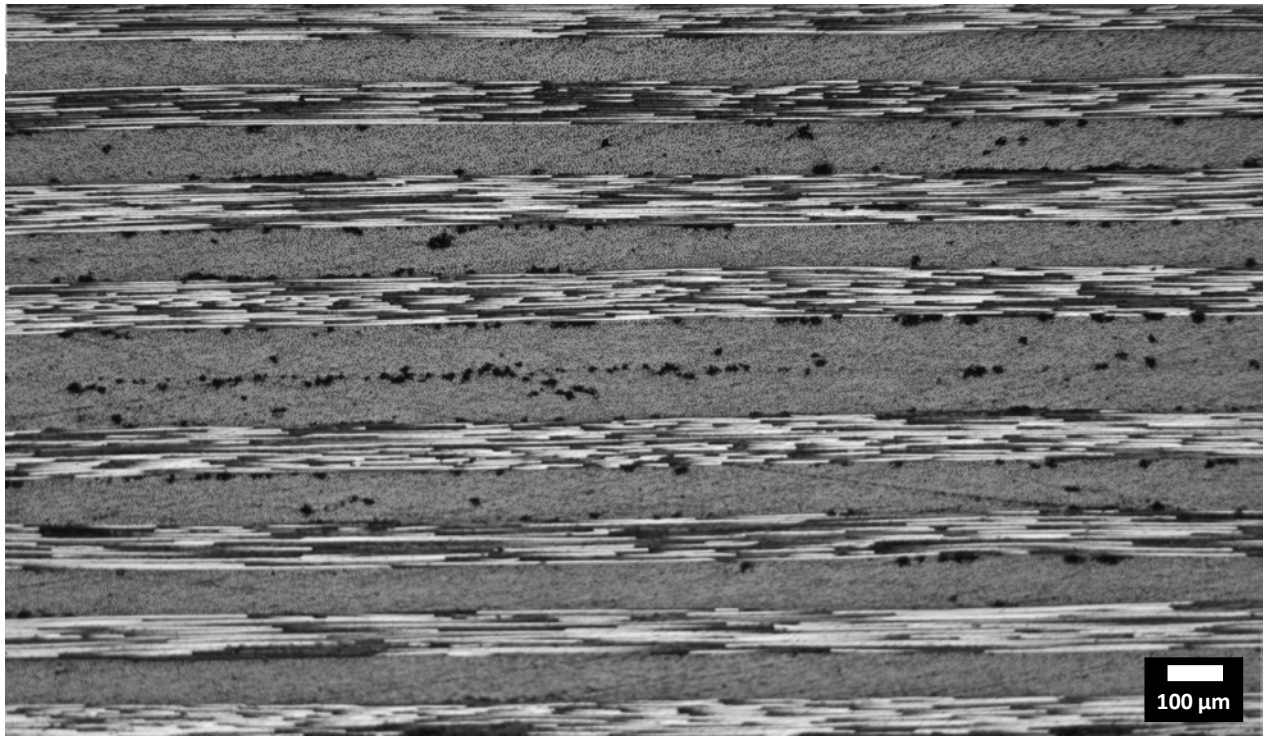
[16] Choi, Sukjoo, et al. Composites Part B: Engineering (2008)

Results of Gas Permeability Test

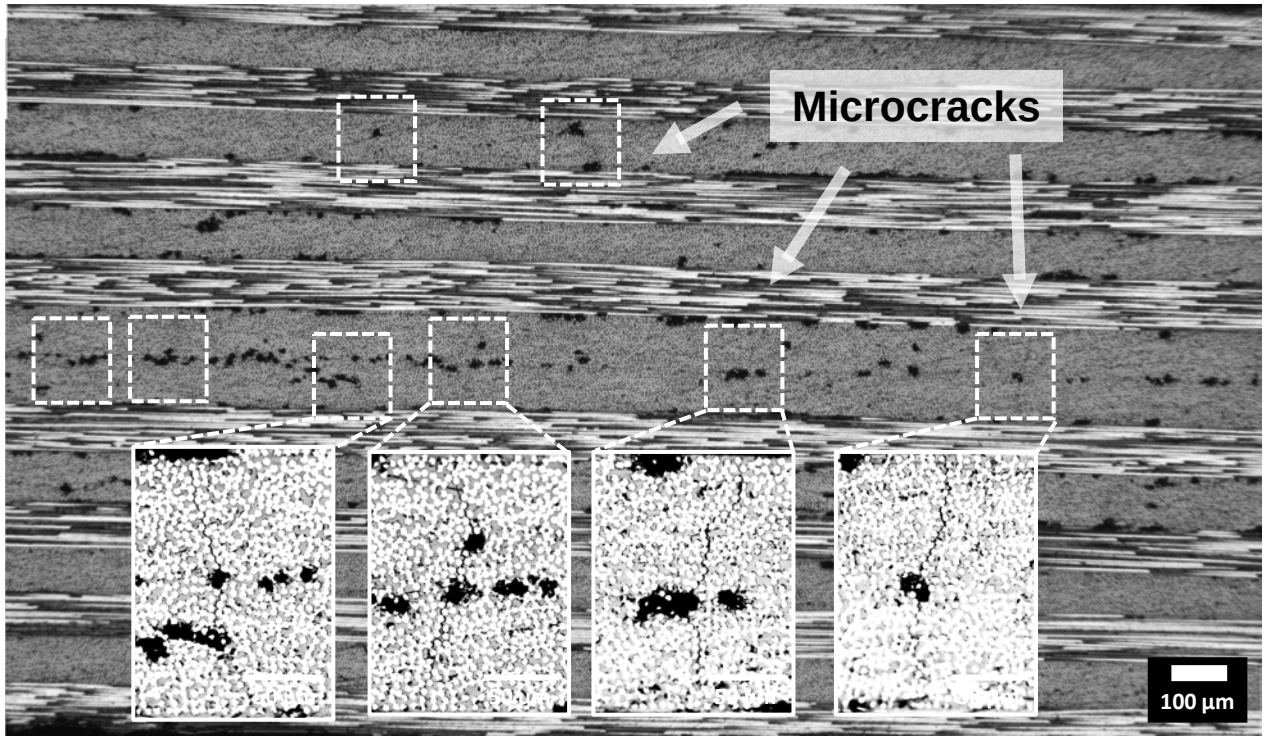


- There are **no significant difference of steady state leak rate** in **autoclave-cured** and **oven-cured laminate.**
- The **gas permeability** was calculated to remove the influence of **thickness**, **temperature**, **concentration**, and **area**.
- The **gas permeability** of **oven-cured laminate w/ nanolayers was 21% reduction** compared to the w/o nanolayer.

<Leak rate-time curve>



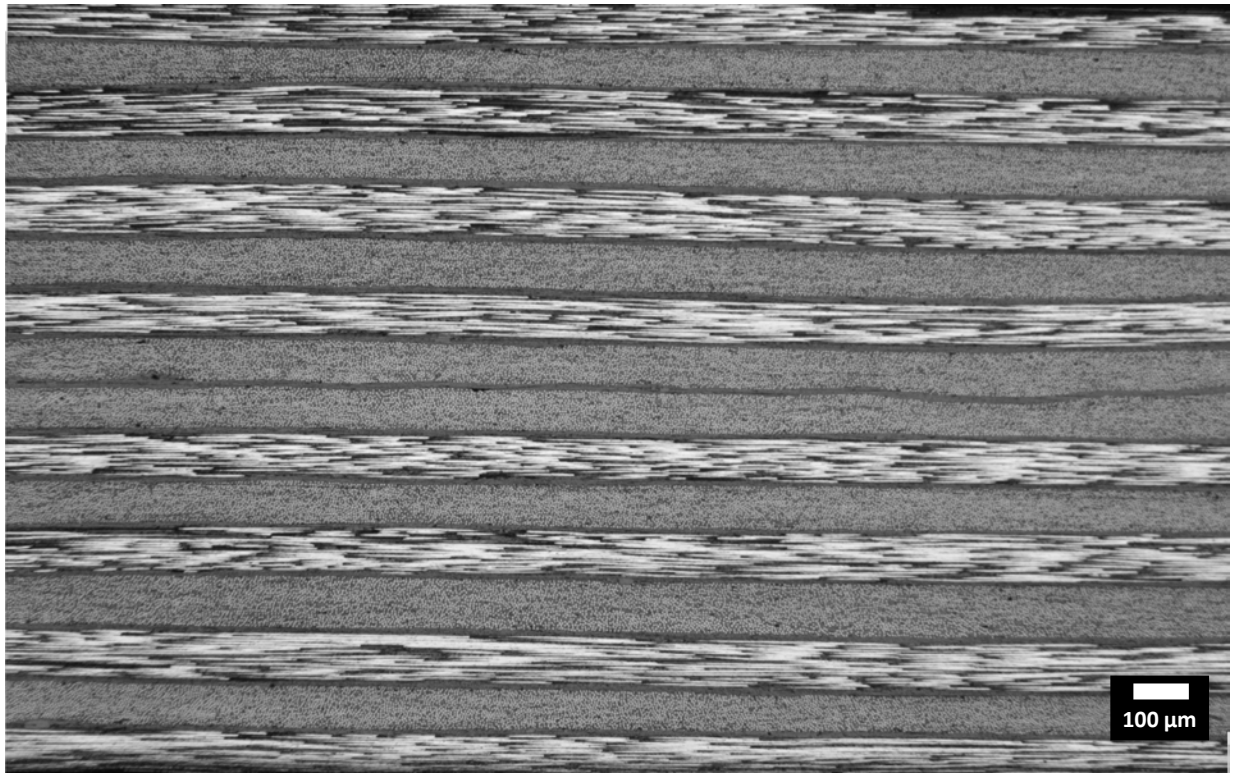
<Steady state leak rate>



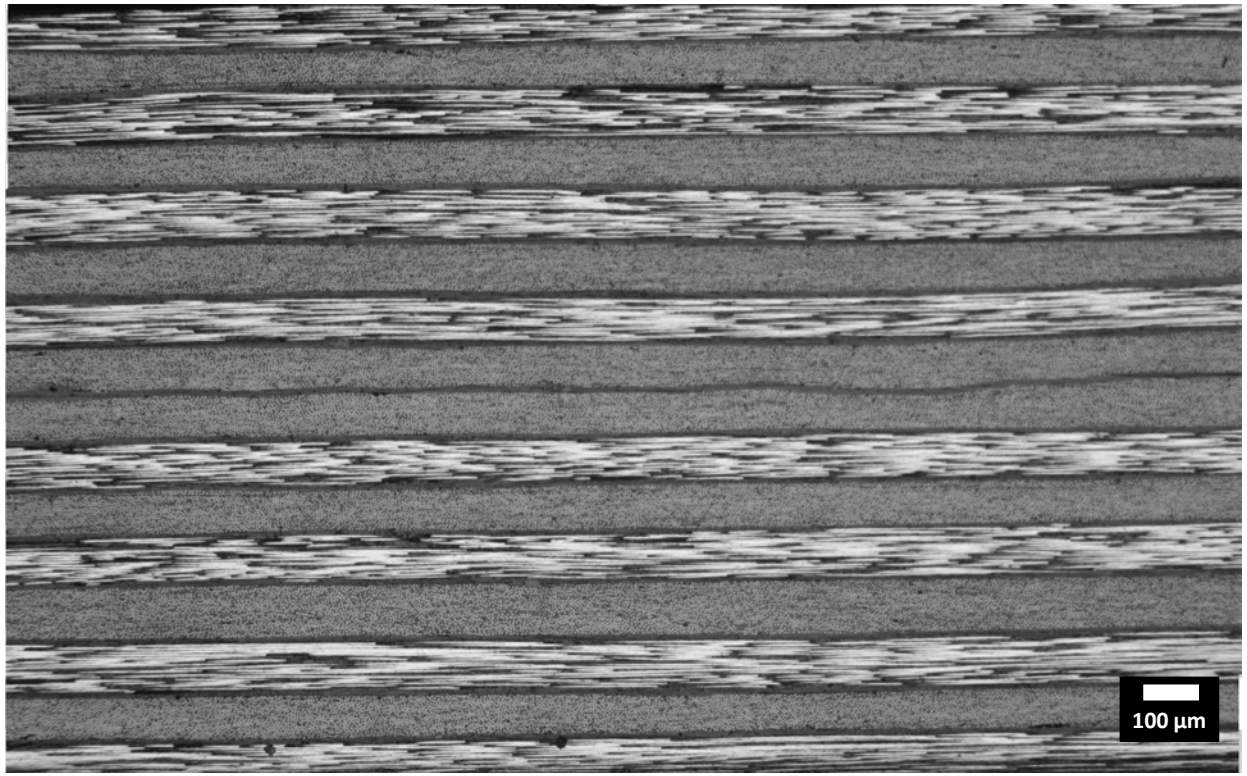
<Helium gas permeability>

Microcrack in Oven-cured Laminate w/o Nanolayers

- The cryogenic cycling test oven-cured laminate was performed for **300 cycles** from room temperature to cryogenic temperature (-196 °C).
- The **microcracks** were **observed** in **oven-cured laminate w/o nanolayers** after 300 cryogenic cycling.



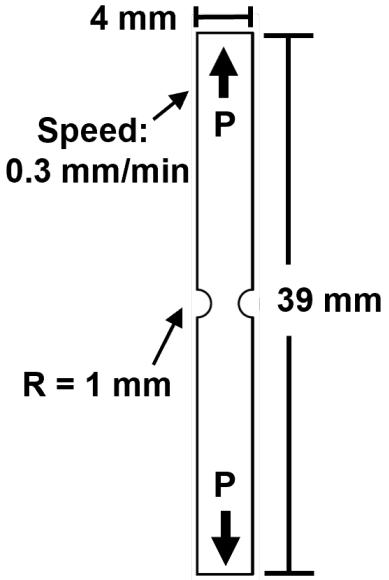
<# of cycles: 0>



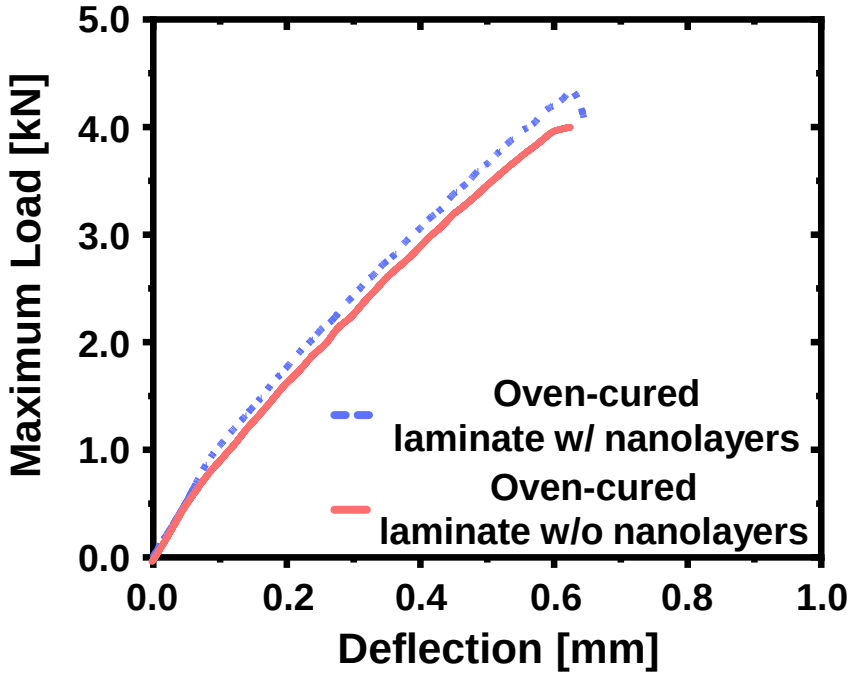
<# of cycles: 300>

Microcrack in Oven-cured Laminate w/ Nanolayers

- The cryogenic cycling test oven-cured laminate was performed for **300 cycles** from room temperature to cryogenic temperature (-196 ˚C).
- The **microcrack** was **not observed** in **oven-cured laminate w/ nanolayers** after 300 cryogenic cycling.

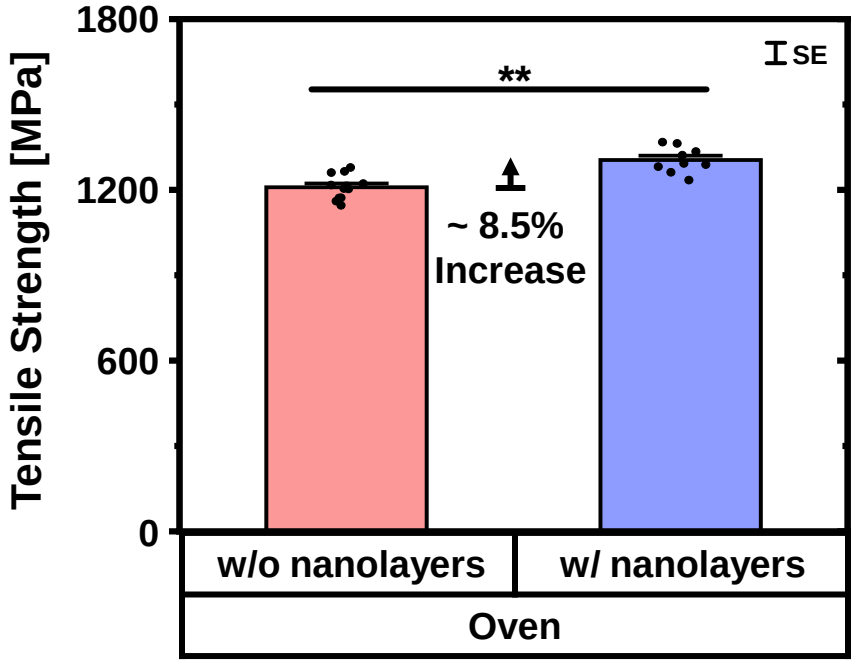


<# of cycles: 0>



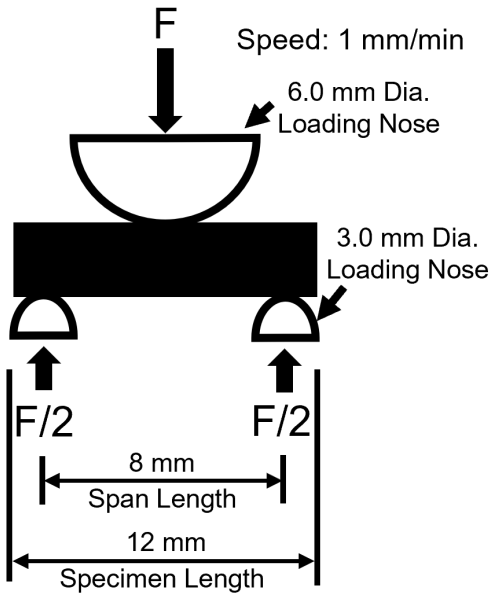
<# of cycles: 300>

Results of Double-Edge Notched Tensile Test

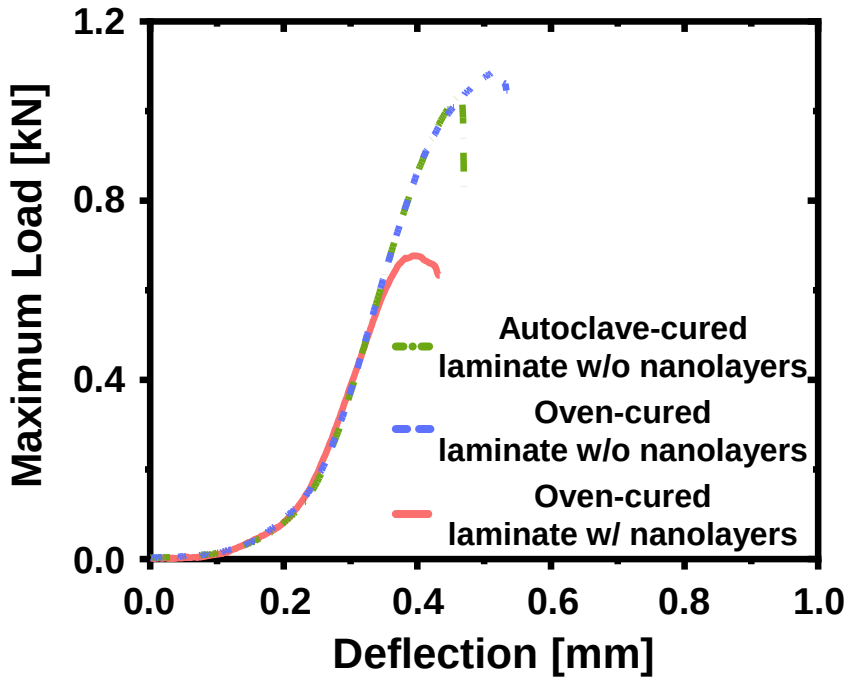


- Double-Edge Notched Tensile specimens (**cross-ply, $[0/90]_{4s}$**) are machined using a **water jet**.
- The tensile test was conducted using a hydraulic Instron 1350. **Pilot test** results confirmed that **failure occurred** at the **exact center** of the **specimen**.
- The **laminate with nanolayers** can **withstand higher tensile loads** compared to the baseline laminate.

<Schematic of DENT test>

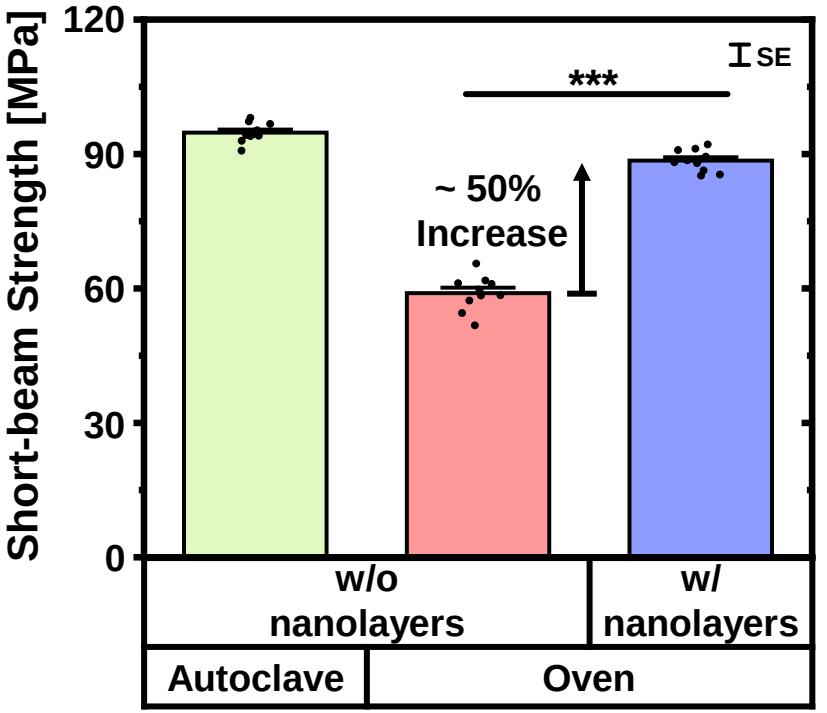


<Load-deflection curve>



<Ultimate Tensile Strength>

Results of Short-beam Shear Test



- **Short-beam Shear Test** was conducted based on **ASTM D2344** for measurement of **bending** and **shear failure.**
- The composite lay-up consists of **18 unidirectional** (**UD**) **prepregs** (100 mm x 100 mm).
- The **short-beam strength** of the oven-cured laminate w/ nanolayers is significantly **higher** than oven-cured laminate w/o nanolayers (but, slightly lower than the autoclave-cured laminate w/o nanolayers).

<Schematic of Short-beam shear test>

<Load-deflection curve>

<Short-beam strength>

Conclusion

- We investigated the effects of layering **electrospun nanofiber** at the interfaces of composite laminates.
- Due to nanolayer's conformable morphology and the **capillary action** resulting from the small fiber diameter, nanolayers effectively **reduce voids** in a vacuum-bag-only process.
- Nanolayers **reduce the gas permeability** of the composites, serving as an effective permeation barrier.
- Integration of **nanolayers** in laminate can provides a significant effect on **microcracks prevention**.
- The incorporation of nanolayers **enhances** both the **ultimate tensile strength** and **short beam strength** of the composites.

ABSTRACT

The two most common numerical methods to predict delaminations in composite laminates are the Cohesive Zone Model (CZM) and the Virtual Crack Closure Technique (VCCT). The available literature on the topic has shown comparable performance for CZM and VCCT, but is limited to the comparison of global descriptors, like the load-displacement curve. A local comparison is thus still lacking, especially for large and curved delamination fronts, for which more significant differences are expected. This work thus aims to compare the predictions of CZM and VCCT considering the local calculations of the strain energy release rate G and its components. To address this, we simulated the response of a special reinforced end-notch flexure specimen featuring a curved delamination front. A reference CZM simulation was first performed; since G is not an immediate output of cohesive elements, a J-integral formulation was implemented in this simulation. Delamination fronts were then extracted at different damage levels and then mapped in VCCT simulations. A smoothing algorithm was successfully adopted to compensate the discontinuities due to the discontinuous nature of VCCT. The comparison showed that both methods predicted similar trends in G and its mode I, mode II, and mode III components, but significant differences were observed in absolute values. Overall, this work presents a comparison methodology for the comparison of VCCT and CZM predictions, overcoming the previous limitations of both approaches.

1 INTRODUCTION

Delaminations is a critical failure mode of composite laminates. Predicting it is thus crucial in the safe design of composite structures. The two most commonly adopted numerical approaches for this task are the Cohesive Zone Model (CZM) and the Virtual Crack Closure Technique (VCCT) [1-2]. The former relies on the use of cohesive elements, that are special purpose elements whose constitutive law is in the form of a traction-separation law. Through a damage variable, CZM can model the fracture process zone ahead of the delamination front. Conversely, VCCT is a linear elastic fracture mechanics approach, and does not model any process zone.

Several work in the literature compare the performance of both approaches and under different loading conditions, including static and fatigue loading [1-4]. However, this comparison is often performed at a global scale using global descriptors, most commonly the load-displacement curve. While this allows a first comparison, it provides only limited insights into the capabilities of the two approaches. Moreover, it prevents an understanding of the causes of any possible discrepancy. A more accurate and deep analysis would compare the calculations of the strain energy release rate G at the delamination front, and how G is decomposed in the different modes of fractures. However, this was so far prevented for the following causes:

1. G is not a direct output of the CZM [5-7];
2. The CZM does not make a distinction between mode II and mode III [5-7];

3. The VCCT is often affected by discontinuities and concentrations of G for large and curved crack fronts [8].

This work presents a procedure to overcome these limitations and compare the local readings of G and its components by the CZM and the VCCT. The first two limitations above are overcome by adopting a J-integral formulation of the cohesive elements. The third limitation is addressed by adopting a smoothing algorithm for the description of the delamination front. A large partially reinforced End-Notched Flexure (ENF) specimen was used as study case, since it features large and curved delamination fronts.

2 MATERIALS AND METHODS

2.1 Numerical case-study

Abaqus 2024 was used in all the numerical simulations [9]. Figure 1a shows the partially reinforced ENF specimen considered, which was previously introduced in [6]. It is composed by two 140 mm x 60 mm x 1.5 mm composite plates, featuring an initial 40 mm delamination. Two reinforcing arms, of dimensions 85 mm x 25 mm x 1.5 mm, are bonded on both the top and bottom sides of the ENF: these promote a curved delamination front that evolves during loading.

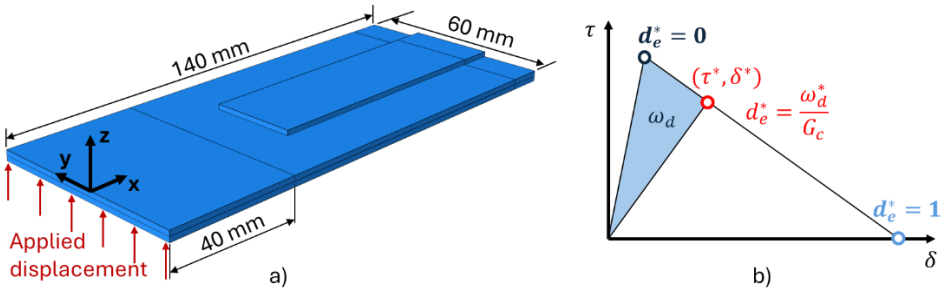

Figure 1: a) The ENF model adopted in this work; b) a triangular traction-separation law.

A vertical displacement is imposed in the front edge of the specimen. Following [6], the material properties of both laminates (large arms and reinforcing arms) and those of the interface are reported in Table 1. In the table, G_{Ic}, G_{IIc} and G_{IIIc} are the mode I, mode II and mode III fracture toughnesses, respectively, while η is the BK law exponent [10]. Note that these toughnesses are used only in the CZM simulations, while the VCCT simulations employ virtually infinite toughnesses (see Section 2.2). For the CZM simulations, bilinear traction-separation laws are considered and described by the stiffnesses K_I, K_{II} and K_{III} and the maximum stresses τ_I, τ_{II} and τ_{III} in mode I, mode II and mode III, respectively. Note that these stresses are adopted to cause an extended process zone: although less realistic, this would better highlight the main differences between VCCT and CZM and facilitate the extraction of the different delamination fronts.

Table 1: Laminate and interface property adopted [6].

Laminate elastic properties					
E_{11} (GPa)	$E_{22} = E_{33}$ (GPa)	$G_{12} = G_{13}$ (GPa)	G_{23} (GPa)	$\nu_{12} = \nu_{13}$ (-)	ν_{23} (-)
154	8.5	4.2	3.036	0.35	0.4
Interface properties for all simulations			**Traction-separation law parameters**		
G_{Ic} (kJ/m^2)	$G_{IIc} = G_{IIIc}$ (kJ/m^2)	η (-)	τ_I (MPa)	$\tau_{II} = \tau_{III}$ (MPa)	$K_I = K_{II} = K_{III}$ (N/mm^3)
0.3	3	2	35	35	10^5

The mesh size in the area of the delamination front was always kept equal to 1 mm or below; in the other regions it was increased for computational efficiency, but it was never higher than 5 mm. For the CZM simulations, solid C3D8I elements were used for all laminates, with three elements in the thickness direction; zero-thickness cohesive elements were used via an UEL subroutine developed in [7]. For the

VCCT simulations, continuum shell SC8R were used for all laminates, with one element in the thickness direction; the standard VCCT interaction of Abaqus was considered [9].

2.2 Adopted approach

A meaningful comparison of the CZM and VCCT readings of G would require the same delamination front and the same imposed displacement. To this end, a first reference CZM simulation was performed with a maximum applied displacement of 30 mm. This simulation was performed considering the initial delaminated 40 mm. As mentioned in Section 1, G is not a direct output of the CZM and a decomposition between mode II and mode III cannot be obtained. Therefore, the J-integral approach developed and implemented in [7] is adopted for the CZM simulation: through the identification of the delamination growth direction, this approach can compute all three G components in a simulation featuring cohesive elements.

The reference CZM simulation thus allows to identify a process zone, defined as:

$$0 < d_e = \frac{\omega_d}{G_c} < 1 \tag{1}$$

where d_e is the energy damage and ω_d is the dissipated energy (both quantities are defined in the traction-separation law reported in Figure 1b). In [7], the iso-damage lines were considered as perpendicular to the delamination growth direction. Therefore, in this work, these are extracted from the CZM process zone and used as delamination fronts for the VCCT simulations. In particular, for specific increments of the CZM simulation, five delamination fronts are extracted corresponding to a damage variable d_e equal to 0, 0.25, 0.5, 0.75 and1.

These delamination fronts are thus described via the nodes whose damage variable d_e is closer to these values. This, however, causes a discontinuous description of the delamination front, since the mesh is not conformal to the shape of the front. As a result, strain energy release rate concentrations arise in corner nodes; moreover, in these nodes, the directions of mode II and mode III propagation cannot be distinguished [6-7]. This is issue is even more critical for the ELS considered in this work, since it is characterised by a very large and curved crack front [8]. Therefore, the coordinates of the nodes composing the delamination front were smoothed using a moving average algorithm with window size of 15. The smoothed coordinates are then mapped to a the VCCT simulation to create the delamination front. Finally, the VCCT simulations can be run with the smoothed delamination front extracted from the CZM simulation: note that, for these simulations, an infinite fracture toughness is considered to prevent propagation and allow the readings of G. A simple schematic of the procedure is reported in Figure 2.

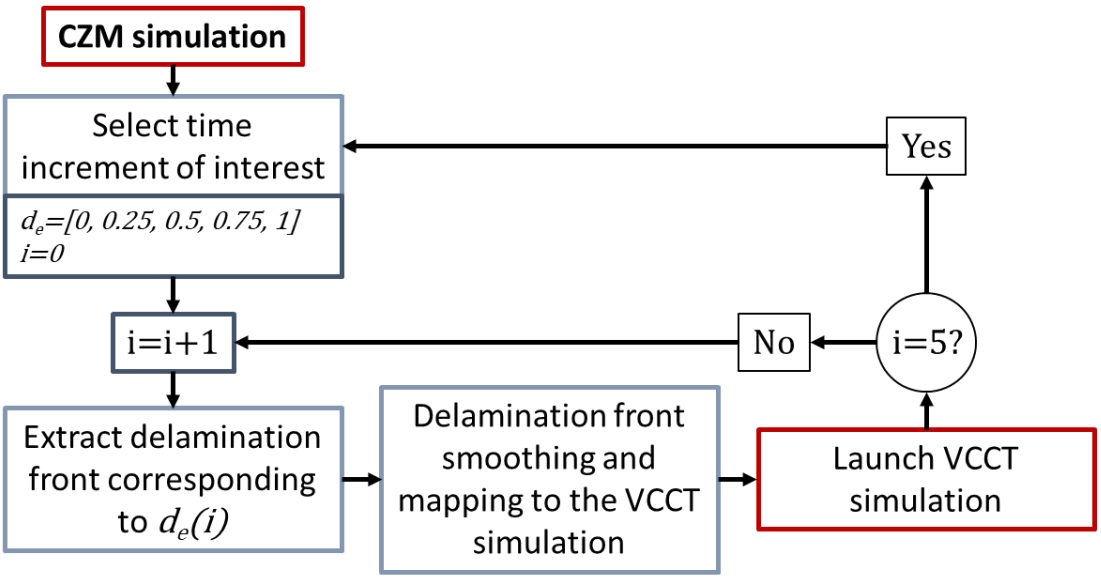

Figure 2: the adopted comparative procedure.

3 RESULTS AND DISCUSSION

Figure 3a shows the load-displacement curve obtained from the CZM simulation. As shown, we have selected two increments on this curve for the present analysis, corresponding to specific values of applied displacement and resulting load. These were selected to ensure the delamination front propagated enough to allow a meaningful comparison. The delamination fronts extracted for both points are reported in Figure 3b and Figure 3c. The delamination fronts of the Figure 3b increment are close to the beginning of the reinforcing arm: the fronts are relatively straight, with some curves starting to form towards lower values of damage. Conversely, the delamination fronts relative to Figure 3c are well developed below the reinforcing arm, being significantly more curved.

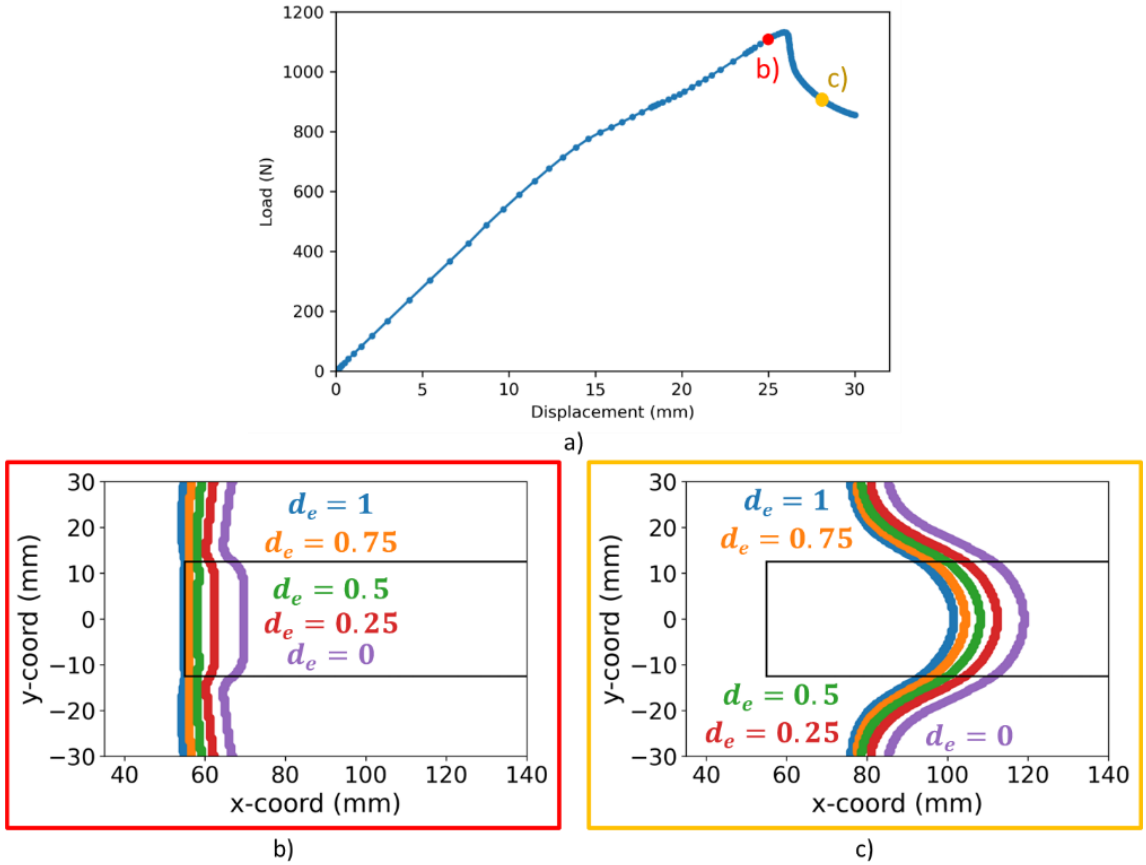

Figure 3: a) load displacement curve of the simulated ELS and b-c) delamination fronts at different increments of the CZM simulation.

The calculated strain energy release rate components by both the VCCT and the CZM (through the implemented J-integral formulation) are reported in Figure 4 and Figure 5 for the delamination fronts reported in Figure 3a and Figure 3b, respectively. Overall, the two techniques seem to lead to similar trends but generally different results.

Regarding Figure 4, the discrepancies between the different fronts appear significant. In particular, the VCCT calculates very high values of the strain energy release rate, especially for the fronts with the higher damage. This higher discrepancy can be explained by the fact that the higher damage fronts are located below the front edge of the reinforcing arms (see Figure 3b). One of the fundamental assumptions of the VCCT is that the propagation of the front is self-similar. The sudden thickness variation cause by the presence of the reinforcing arms makes this assumption not applicable, since the crack propagation is locally altered by the increased thickness and thus stiffness. Indeed, for the lower damage fronts, this effect seems mitigated. This is interesting, since these fronts are more curved than the higher damage ones (see Figure 3b): the thickness variation thus seems to have a stronger effect than the curvature of the delamination fronts.

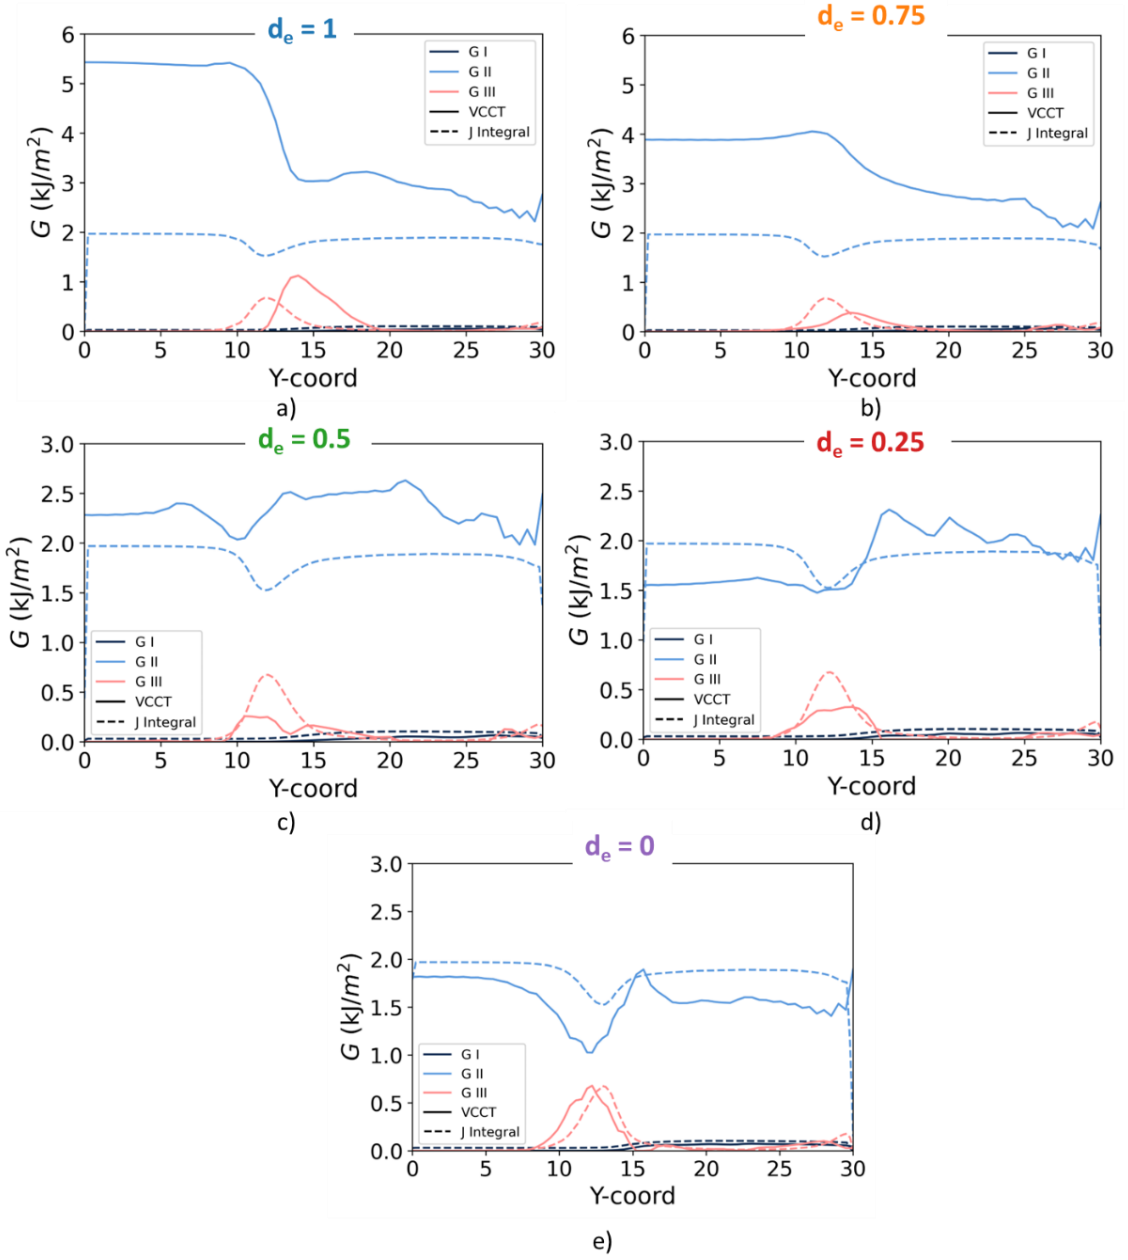

Figure 4: a-e) The calculated components of the strain energy release rate by both the VCCT and the CZM for the five delamination fronts of Figure 3b.

Figure 5 shows, instead, a much closer agreement between the two tested methods. In this case, VCCT and CZM show more similar results for the higher damage fronts. In all cases, the highest discrepancy is observed for the GIII peak in correspondence of about 15 mm of the y-coordinate. Considering the mode III direction, thus parallel to the delamination front, this is also a location of thickness variation still due to the presence of a reinforcing arms' bounding edge (see Figure 3c). Both this discrepancy and the general better agreement seem to confirm that the reinforcing arms affect the accuracy of the VCCT.

In all cases, discrepancies are always observed in at least one of the components of G. Moreover, the discrepancies between the methods seem to be independent between each other, which implies that the total strain energy release rate G_{tot}, the sum of the components, is also calculated differently. Therefore, the discrepancies are not due different decomposition in the modes of fracture.

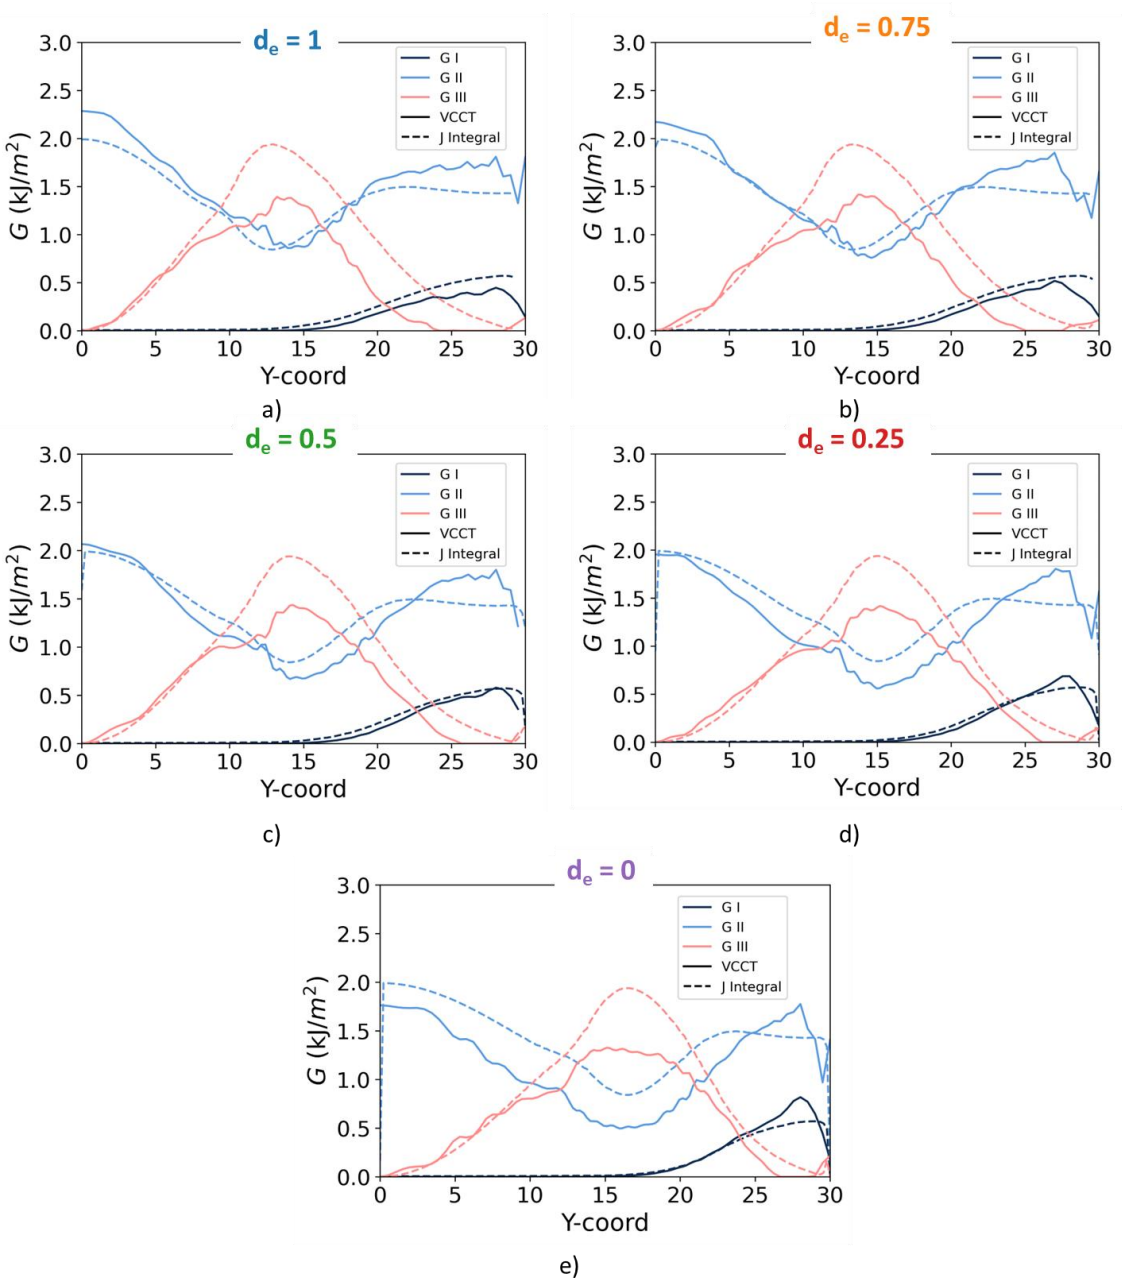

Figure 5: a-e) The calculated components of the strain energy release rate by both the VCCT and the CZM for the five delamination fronts of Figure 3c.

4 CONCLUSIONS AND FUTURE WORKS

This work presented a comparative analysis on the strain energy release rate (G) calculation by the VCCT and the CZM. The two techniques were already compared earlier, but always at a global level, while in this work their local capabilities are investigated. The considered study-case is a reinforced ENF specimen, which causes large and curved delamination fronts.

A specific procedure was thus developed. First, a CZM simulation is run using a J-integral algorithm to compute G at the delamination front from the cohesive elements. For two simulation increments, five delamination fronts were extracted corresponding to damages equal to 0, 0.25, 0.5, 0.75 and 1. These fronts are then smoothed with a moving average algorithm, as their discontinuous nature would prevent correct readings from the VCCT. The smoothed coordinates of the fronts are then mapped onto a new simulation to be run with the VCCT.

All the tested delamination fronts highlighted some level of discrepancy. In particular, the thickness variations caused by the reinforcing arms seemed to be the main source of inaccuracy from the VCCT: indeed, such thickness variations violate the VCCT assumption of a self-similar crack propagation. Conversely, the curvature of the delamination fronts does not seem to cause significant discrepancies: this further confirms the importance of the smoothing algorithm that allows a mesh conformal to the delamination front.

The work investigated mainly two increments of the ENF specimen, which is mainly loaded in mode II and mode III. Further investigations are planned, involving more increments of the ENF as well as the study of a reinforced Double Cantilever Beam (DCB) specimen. The reinforced DCB would allow a mode I comparison, thus extending the scope of this work, but also give a more informed feedback, since experimental results are available for the reinforced DCB. Moreover, the comparison presented in this work is performed considering an extended process zone to better distinguish the different fronts. Considering that the process zone is a key difference between VCCT and CZM, performing this comparison with more realistic process zones is an important future planned work.

ABSTRACT

We have developed a chemical recycling method for carbon fiber reinforced plastics (CFRP) using nitric acid decomposition. While carbon fiber (CF) recycling has been widely studied, reports focusing on the chemical recycling of the resin matrix in CFRP remain limited. In this study, we targeted the resin fraction of epoxy-based prepreg CFRP and successfully decomposed it under mild conditions (3 hours at 80 °C) using nitric acid. This process enabled the efficient separation and recovery of carbon fiber with minimal damage, while also allowing for the isolation of decomposed resin fragments.

Characterization of the resin decomposition products revealed the formation of nitro-containing aromatic compounds. Subsequent catalytic hydrogenation of these nitroaromatics yielded amine-functionalized compounds, which were evaluated as potential curing agents for new epoxy resins. The resulting recycled amines demonstrated reactivity comparable to conventional amine hardeners, indicating their applicability as a value-added recycled product. This approach not only contributes to the full recycling of CFRP components but also provides a pathway to upcycle the resin fraction into functional intermediates for polymer synthesis.

Our work highlights a viable strategy for the holistic recycling of thermoset-based CFRPs, addressing the sustainability challenges associated with composite materials. Further research is underway to optimize the reaction parameters, improve product yields, and evaluate the performance of resins cured with the recycled amines in real applications. This study represents a significant step toward establishing a closed-loop material cycle for CFRPs.

1 INTRODUCTION

Carbon fiber reinforced plastics (CFRPs) are composite materials that combine high-strength carbon fiber with a thermosetting polymer matrix, typically based on epoxy resins. Owing to their superior mechanical properties, low weight, and excellent corrosion resistance, CFRPs are widely adopted in high-performance applications such as aerospace structures, automotive parts, wind turbine blades, and sporting goods. While the production of CFRPs is energy-intensive, their lightweight nature allows for significant energy savings during service, particularly in transportation applications, resulting in reduced fuel consumption and carbon dioxide emissions [1]. From a life cycle assessment (LCA) perspective, CFRPs are thus considered environmentally favorable materials [2]. However, the end-of-life (EoL) treatment of CFRPs presents a major sustainability challenge. The difficulty of recycling thermosetting resins, which cannot be remelted or reshaped, has led to widespread incineration or landfilling of CFRP waste, undermining efforts toward resource circulation and environmental conservation [3].

To address these issues, several CFRP recycling techniques have been investigated, including mechanical shredding, pyrolysis, and chemical solvolysis [4-8]. Mechanical recycling involves cutting or grinding CFRP into short-fiber-reinforced fillers. Although this method is relatively simple and low-cost, it significantly degrades fiber properties and limits the reuse of recovered materials to low-performance applications [9]. Pyrolysis processes, which decompose the resin at high temperatures (typically 450–700 °C) in an inert atmosphere, can recover carbon fiber with moderate structural preservation. However, these methods suffer from high energy demand, degradation of fiberurfaces, and emission of volatile organic compounds[6]. Chemical recycling approaches, such as solvolysis, utilize

solvents to depolymerize the matrix resin, offering greater selectivity. Yet, these techniques often face limitations in scalability, solvent recovery, and economic feasibility [7].

A critical limitation of these conventional strategies is their emphasis on recovering carbon fiber while neglecting the thermoset resin fraction. In most cases, the resin is either thermally evaporate or discarded as waste, despite comprising 30–40% of the CFRP mass [8]. This practice not only results in material loss but also generates environmental concerns related to emissions and residues [9]. The limited research on resin recycling can be attributed to technical challenges such as the crosslinked nature of thermoset networks, low intrinsic value of the resin relative to fiber, and the historical focus on maximizing fiber performance [10]. However, for CFRP recycling to align with the principles of a circular economy, it is essential to develop approaches that recover and valorize both components of the composite.

In this study, we present a nitric acid-based chemical recycling method that simultaneously enables the recovery of high-quality carbon fiber and the upcycling of resin decomposition products into functional curing agents. Nitric acid has been previously studied for its ability to depolymerize epoxy model compounds and introduce nitro groups into aromatic moieties under controlled conditions [11-12]. Compared to pyrolysis and solvolysis, nitric acid decomposition offers milder operating conditions, better selectivity, and the potential for downstream chemical transformation of the degraded resin.

To enhance the practicality and efficiency of the proposed method, we selected CFRP prepreg waste as the feedstock material. Prepregs are composed of partially cured epoxy resins and carbon fiber, and they represent a common form of production scrap in composite manufacturing [12]. One key advantage of using prepreg over fully cured CFRP is that partially crosslinked matrices are more susceptible to chemical cleavage, enabling faster and more efficient decomposition. While fully cured CFRP components exhibit dense three-dimensional crosslinking, prepregs retain unreacted or semi-reacted functional groups, reducing the energy, uptimes and reagent requirements for matrix breakdown. In our laboratory, we confirmed that the recovered fiber retained their morphology and mechanical integrity, with some batches even showing improved tensile properties compared to virgin carbon fiber so far [13]

In our experiments, CFRP prepreg samples were treated with concentrated nitric acid at 80 °C for 3 hours. This condition was sufficient to dissolve the matrix and release the embedded carbon fiber with minimal structural damage.

Chemical analysis of the liquid-phase degradation products revealed the formation of nitroaromatic intermediates, derived from the nitration of the epoxy resin's aromatic backbone [14]. These compounds were subsequently subjected to catalytic hydrogenation using palladium on carbon ($Pd(OAc)_2$) under mild conditions (r.t.), yielding amine-functionalized compounds. These recycled amines were then evaluated as potential curing agents for new epoxy systems. Reactivity tests demonstrated comparable performance to commercial hardeners such as polyetheramines, indicating the feasibility of reintroducing the resin-derived products into composite manufacturing workflows.

The novelty of this study lies in the integrated approach that targets both the fiber and resin fractions of CFRP, transforming waste materials into reusable and functional components. By choosing prepreg as a feedstock, the process circumvents some of the chemical intractability associated with fully cured CFRP, thus improving decomposition kinetics and reaction control. Moreover, the nitric acid-based pathway offers a promising route to closed-loop CFRP recycling, combining environmental responsibility with industrial utility.

In contrast to traditional methods that focus solely on carbon fiber preservation, our approach demonstrates the possibility of full-component CFRP valorization under mild and scalable conditions. The dual recovery strategy not only addresses the technical gap in thermoset resin recycling but also contributes to the reduction of emissions and waste associated with CFRP disposal. From an economic standpoint, the ability to obtain both high-quality fiber and value-added resin-derived products enhances the overall material efficiency of the recycling process.

In conclusion, this work establishes a new paradigm in CFRP recycling by leveraging the reactivity of prepreg-based waste and utilizing nitric acid chemistry to achieve simultaneous fiber recovery and resin upcycling. Through the formation of amine curing agents from nitro intermediates, we provide a rare example of thermoset polymer circularity. Ongoing work is focused on optimizing reaction parameters, improving product separation, and scaling up the process for broader industrial application.

The findings presented here lay the foundation for a holistic, sustainable approach to CFRP waste management.

2 EXPERIMENTAL SECTION

2.1 Materials

In this study, the recycle target is Prepreg offcuts derived from actual CFRP manufacturing processes, but in practice new Prepreg were used as raw materials. The material used was TORAYCA® T800SC/3900-2B (Toray Industries, Inc.), consisting of T800SC carbon fiber fabric pre-impregnated with an epoxy-based matrix resin. The precise formulation of the epoxy resin was not disclosed by the manufacturer.

All chemical reagents were purchased from Kanto Chemical Co., Inc. (Tokyo, Japan), and used as received without further purification.

2.2 Nitric acid decomposition

A custom-made 500mL separable flask with fins was used (Figure 1) as decomposition reactor vessel. 10g of prepreg sheet (40mm x 40mm x 0.1mm) was placed in the flask and immersed in 200g of 7.5M nitric acid.

The separable flask was attached to a rotary evaporator, and the reaction temperature was set to 80 °C, and the flask was rotated and stirred at 60rpm for 180 minutes at a constant temperature. After that, the CF and resin decomposition products were removed with tweezers. The CF and resin decomposition products were then washed with 400mL of ion-exchanged water and 300mL of ethyl acetate. The ethyl acetate was evaporated, and 1.6g of resin decomposition products were collected.

On the other hand, to recover the resin digest dissolved in nitric acid, the HNO_3 solution was subjected to liquid-liquid extraction with 200 mL of ethyl acetate. This procedure was repeated three times. The ethyl acetate phase was neutralized with 1 M $NaHCO_3$ aqueous solution before being evaporated to obtain the resin digest, and the ethyl acetate was washed with 200 mL of pure water to remove the salt. Resin decomposition products obtained weighed 1.5 g.

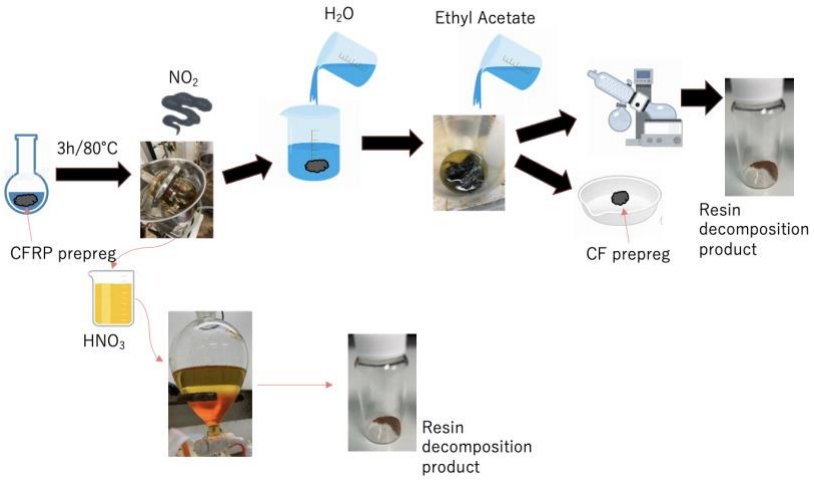

Fig. 1. Carbon fiber decomposition process using nitric acid in the modified separable flask.

2.3 Hydrogenation reaction of resin decomposition

The resin decomposition product (0.5 g) was dissolved in THF (3 mL) at room temperature. Then, the catalyst Palladium (II) acetate (0.5 mmol, 11 mg) and KF (2 mmol, 116 mg) were dissolved in 2 mL of water, and the hydrogenation agent polymethylhydrosiloxane (PMHS) (4 mmol, 0.24 mL) was mixed and stirred for 30 min. After that, the reaction product (approximately 0.2 g) was obtained by filtration through Celite. The obtained reaction product was analyzed by FT-IR to confirm the progress of the

reaction.

2.4 Analytical methods

A thermogravimetric analysis (TGA) was conducted using DTG-60 (Shimadzu) to investigate the amount of the residual resin on the recovered carbon fiber. Fourier transform infrared (FT-IR) spectroscopy was carried out using FTIR-8300 (Shimadzu) to evaluate the functional groups in the decomposed products. Molecular weight distribution was measured using Size Exclusion Chromatography(SEC) (PU-980, JASCO Corporation, Tokyo, Japan). Tetrahydrofuran (THF) was used as mobile phase of SEC analysis.

3 RESULTS AND DISCUSSION

3.1 Optimization of Nitric Acid Decomposition Conditions

To investigate the decomposition behavior of CFRP prepreg under, we employed a custom-built 500 mL separable flask mounted on a rotary evaporator platform, rotated at 60 rpm to ensure gentle agitation and uniform exposure to the acid. Prepreg sheets were immersed in 38 mass% nitric acid at 80 °C for varying durations (5 min to 8 h). The residual resin mass was measured after each time point to evaluate decomposition progress.

As shown in Figure 2, the resin mass began to decrease rapidly within the first hour, reaching a plateau at 3 h, where more than 45% of the matrix resin had decomposed. Beyond this point, no significant change in mass was observed up to 8 h. Therefore, 3 h was adopted as the optimal decomposition time for further processing.

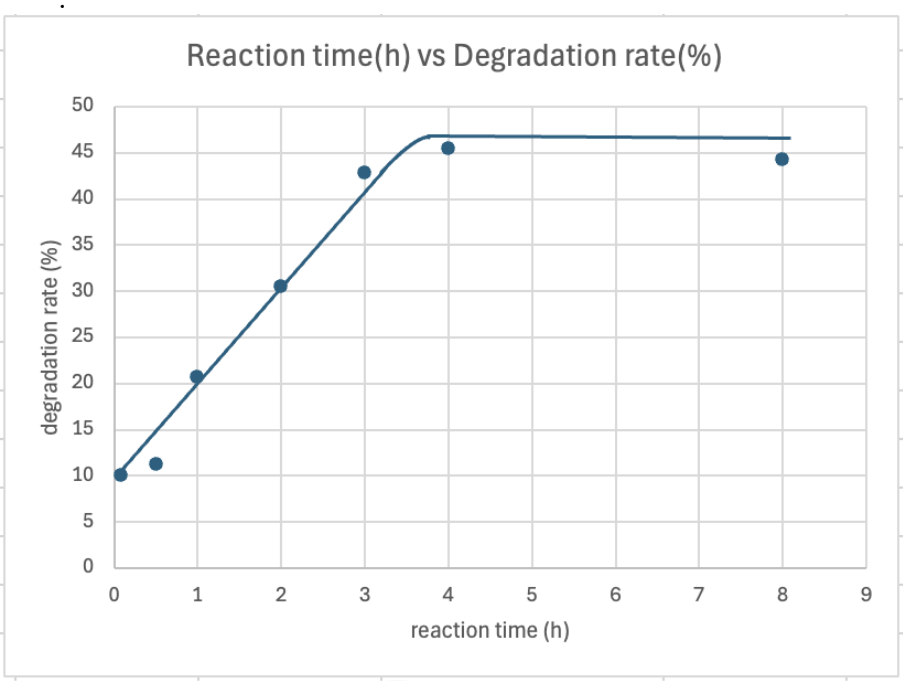

Figure 2: Reaction time(min) vs Degradation rate(%)

To clarify the material flow during the decomposition process, a mass balance summary is provided in Figure 3, which includes input prepreg mass, recovered carbon fiber, and decomposed resin yields. In the optimized 3 h reaction, 10.0 g of prepreg yielded 6.5g of carbon fiber and 3.5 g of organic decomposition products, with the remainder attributed to gaseous losses and trace residues.

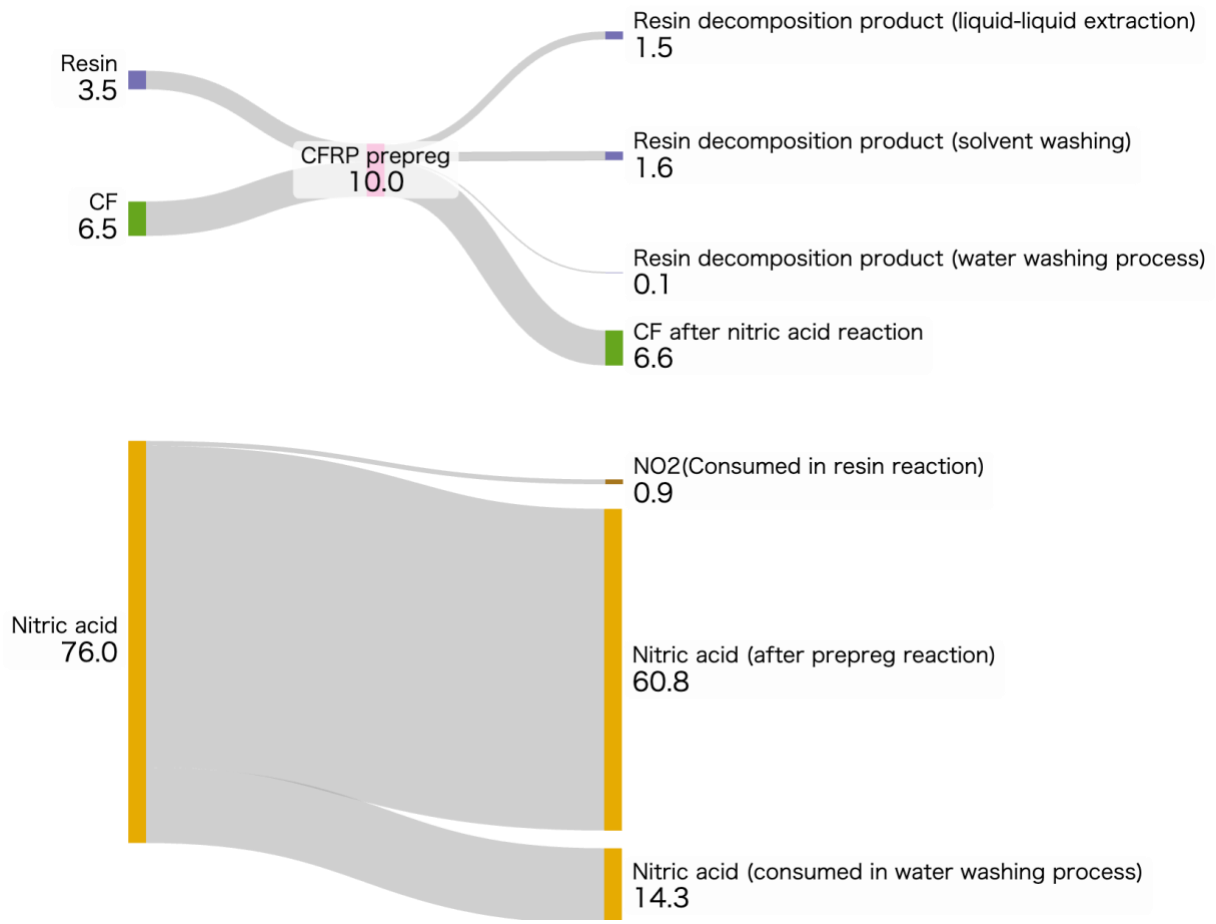

Figure.3 A mass balance summary

3.2 Structural Analysis of Decomposed Resin

Visual observation during the reaction revealed a distinct color change from pale yellow to deep orange, indicating oxidative nitration. FT-IR spectra of the isolated resin decomposition products (Figure 4) exhibited characteristic nitro group peaks at 1550 cm^{-1} (asymmetric stretch) and 1330 cm^{-1} (symmetric stretch), consistent with aromatic nitration. This suggests that the nitric acid preferentially attacked the aromatic backbone of the epoxy network.

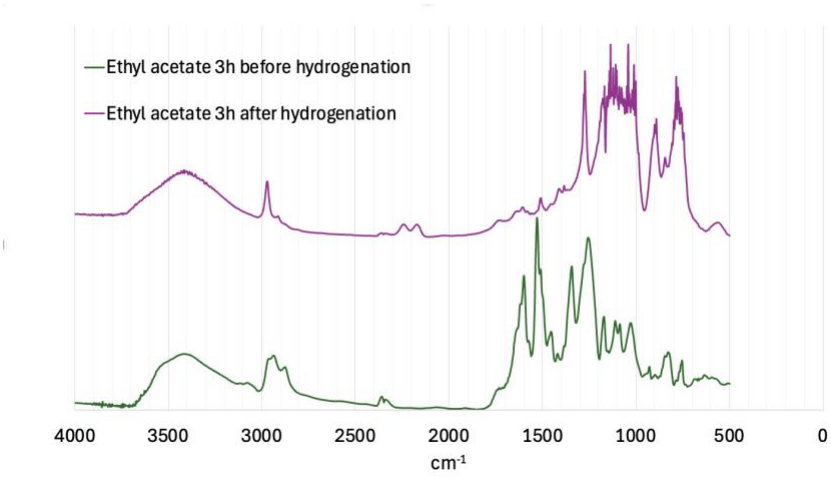

Figure 4: FT-IR of CFRP prepreg and decomposed resin

Molecular weight changes were evaluated using size exclusion chromatography (SEC). The number-average molecular weight (Mw) decreased from 1830 g/mol (original resin) to 1050 g/mol (decomposed resin) after 3 h of treatment.

3.3 Amination and Amine Value Determination

The nitrated resin was subsequently subjected to catalytic hydrogenation using $Pd(OAc)_2$ in THF to obtain amine-functionalized compounds. The reaction product was a black solid with a recovery rate of 62.3 mass%, based on the mass of nitrated intermediates. FT-IR analysis after reduction showed

The disappearance of the peaks at around 1550 cm-1 and 1330 cm-1 due to the nitro group confirmed that the hydrogenation reaction had progressed. (Figure 5).

Amine value titration was conducted in methanol using perchloric acid titrant and crystal violet as the indicator (ASTM D2073-modified method). The resulting amine value was 138 mg KOH/g, corresponding to an amine equivalent weight of 406 g/mol. These results indicate that the recycled amine mixture has sufficient nucleophilicity and basicity for potential use as an epoxy curing agent.

3.4 Application as Epoxy Resin Curing Agent

To test its applicability, the recycled amine was mixed with JER 828 epoxy resin at an equivalent stoichiometric ratio and cured at 60 °C for 1 h followed by 150 °C for 11 h. The resulting cured resin exhibited good crosslinking without surface defects. Mechanical testing revealed a flexural strength of 51 MPa, compared to 62 MPa for the control system cured with commercial Jeffamine D-230. Although approximately 20% lower in strength, the recycled system achieved sufficient hardness and structural integrity, demonstrating practical potential, especially for secondary applications where ultra-high strength is not required.

4 CONCLUSIONS

This study demonstrates that nitric acid decomposition is an effective and scalable method for simultaneous recovery of both carbon fiber and epoxy resin-derived intermediates from CFRP prepreg. The moderate operating conditions (80 °C, 3 h, mild rotation) facilitate high resin decomposition rates while preserving fiber morphology. Subsequent conversion of nitrated oligomers into amine compounds enables their reuse as curing agents, achieving a closed-loop recycling pathway.

The resin recovery and the amine functionality of the final product confirm the feasibility of upcycling CFRP matrices into chemically useful forms. Although the mechanical performance of the recycled resin is modestly lower than that of virgin materials, this can be improved through purification, formulation optimization, or blending strategies. Future work will explore continuous processing configurations and lifecycle analysis to assess environmental and economic advantages of this approach.

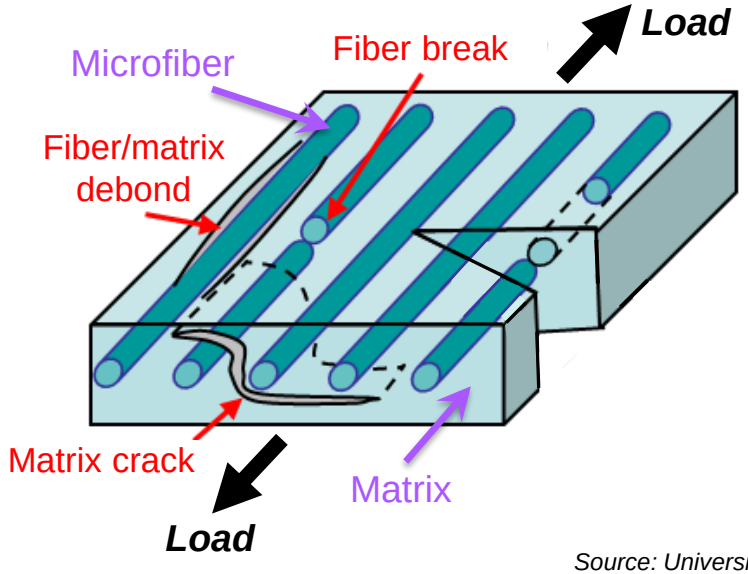
Overview

- Motivation and Background
- Approach and Results
- Conclusions and Future Work

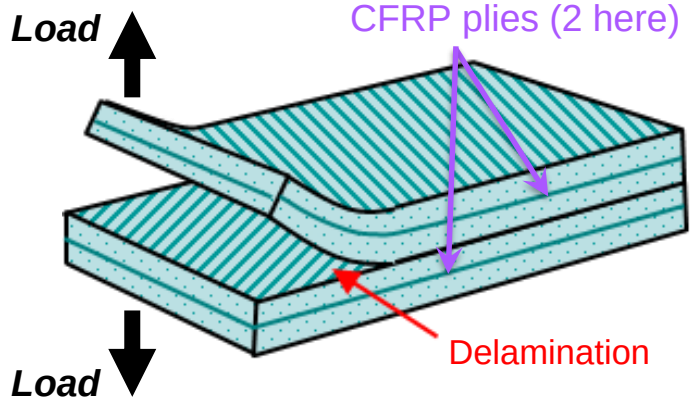
NAVAIR Public Release SPR# 2025-0376. Distribution Statement A - Approved for public release; Distribution is unlimited.

Carbon Fiber Reinforced Polymers (CFRPs) Exhibit Complex Micro/Mesoscale Failure Modes under Mechanical Loading

- Consider general loadings of a **single CFRP unidirectional ply**:



Source: Composites World

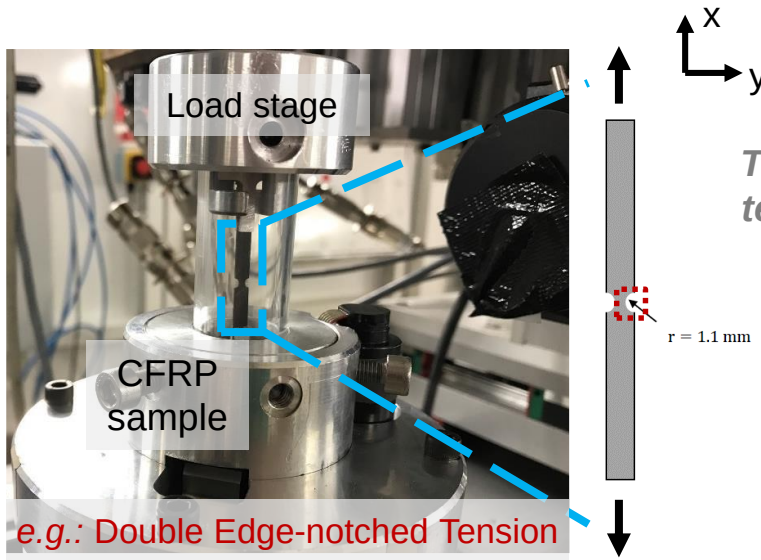


Intra-ply (single ply) damage modes

Failure via multiple damage modes

Inter-ply (ply-ply) damage modes

Source: University of Liège (adapted)



NAVAIR Public Release SPR# 2025-0376. Distribution Statement A - Approved for public release; Distribution is unlimited.

Progressive Damage Characterization Underpins CFRP Strength/Toughness Understanding but is Limited

Characterizing progressive damage requires imaging of several material features:

- constituent morphology *(micro-/meso-structure)*
- manufacturing defects & damage precursors
- multi-scale damage *(micro-, meso-, macro-)*

e.g.: Double Edge-notched Tension

Traditional techniques

1. **Exterior:** Microscopy (optical, **scanning electron**)
   - High-resolution, but only 2D
   - Can be destructive to expose interior

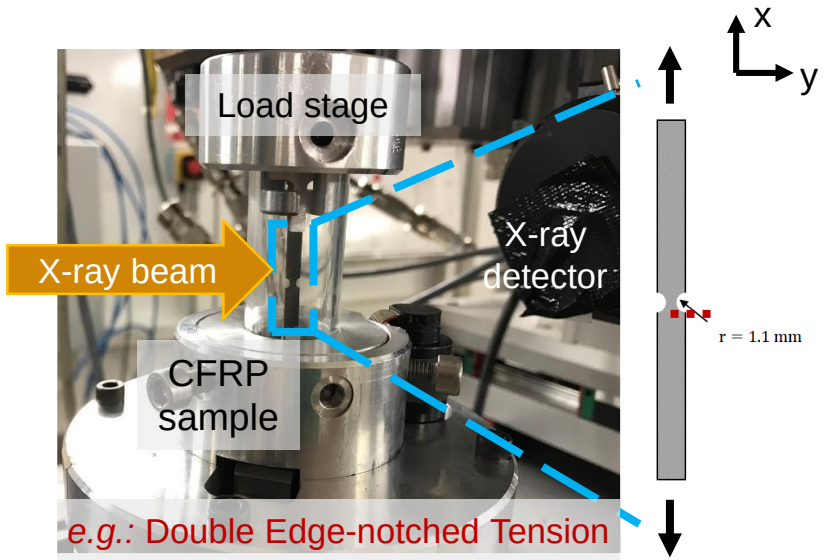
Scanning electron microscopy (SEM)

e.g. **Nanostitch** effects on damage *[Lewis et al. 2016]*

2. **Interior:** **Ultrasound** (**C-scan**, tomography), 2D X-ray
   - C-scan: low-resolution, "quasi-3D", underwater
   - Step-wise *ex situ* with cyclic imaging/reloading

C-scan

e.g. **Ply thickness** effects on damage *[Amacher et al. 2014]*

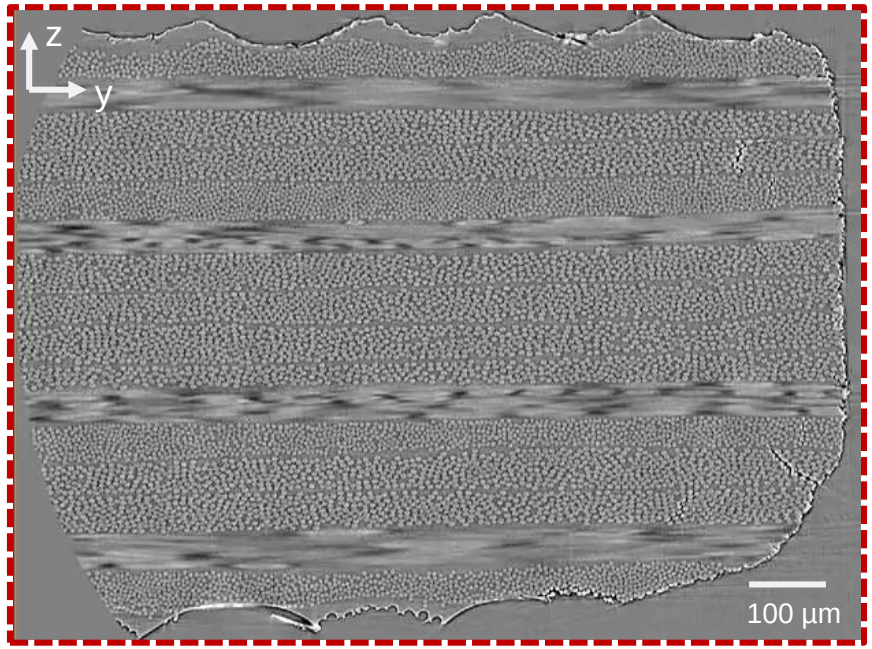


Challenge: How can we characterize 3D micro-failure behavior?

NAVAIR Public Release SPR# 2025-0376. Distribution Statement A - Approved for public release; Distribution is unlimited.

Modern Progressive Damage Characterization:
X-ray µCT Reveals 3D Material Interior

Characterizing progressive damage requires imaging of several material features:

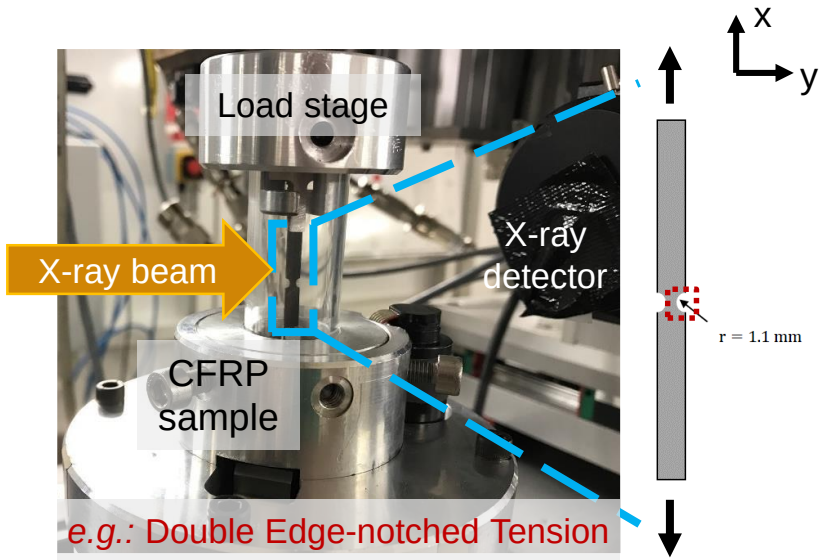


- constituent morphology *(micro-/meso-structure)*
- manufacturing defects & damage precursors
- multi-scale damage *(micro-, meso-, macro-)*

Challenge: How can we characterize 3D micro-failure behavior?

X-ray Micro-computed Tomography (µCT) → Nondestructive high-resolution imaging of material interior

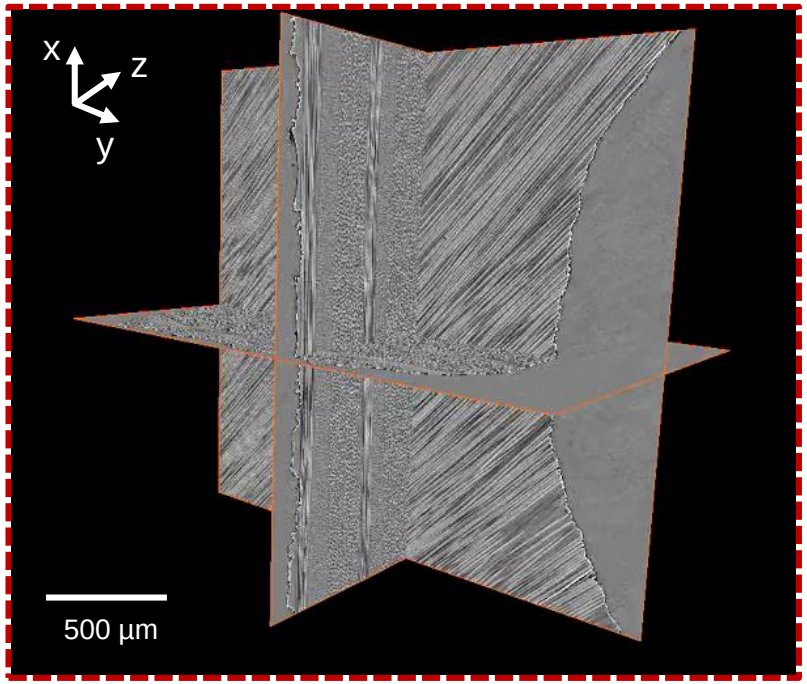
2D Virtual Cross-sections



NAVAIR Public Release SPR# 2025-0376. Distribution Statement A - Approved for public release; Distribution is unlimited.

Modern Progressive Damage Characterization:
X-ray µCT Reveals 3D Material Interior

Characterizing progressive damage requires imaging of several material features:

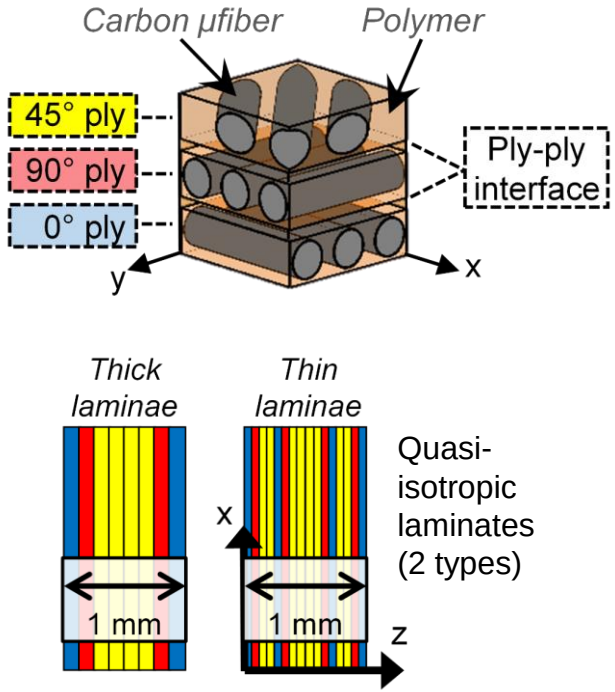


- constituent morphology *(micro-/meso-structure)*
- manufacturing defects & damage precursors
- multi-scale damage *(micro-, meso-, macro-)*

Challenge: How can we characterize 3D micro-failure behavior?

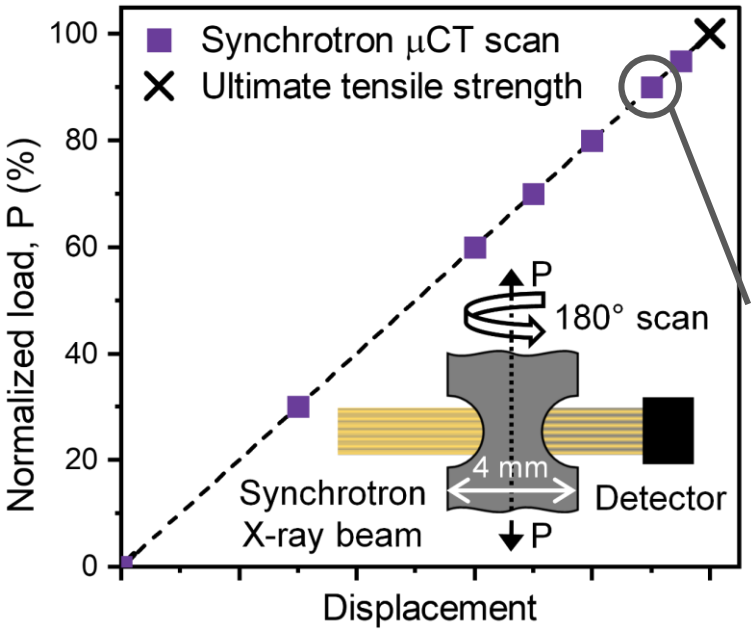
X-ray Micro-computed Tomography (µCT) → Nondestructive high-resolution imaging of material interior

Mutually ⊥ 2D Cross-sections



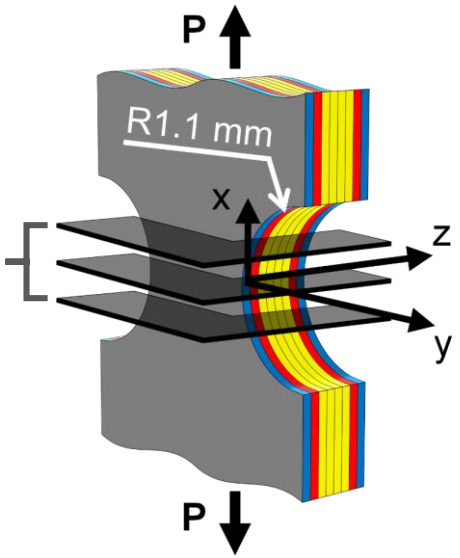
NAVAIR Public Release SPR# 2025-0376. Distribution Statement A - Approved for public release; Distribution is unlimited.

Multiclass 3D Microdamage Characterization in Heterogeneous Materials



- What is the current segmentation problem and why is it hard (**no rule-based feasible solutions**)?

Heterogeneous materials → **μCT-based *in situ* visualization** → **BIG data**



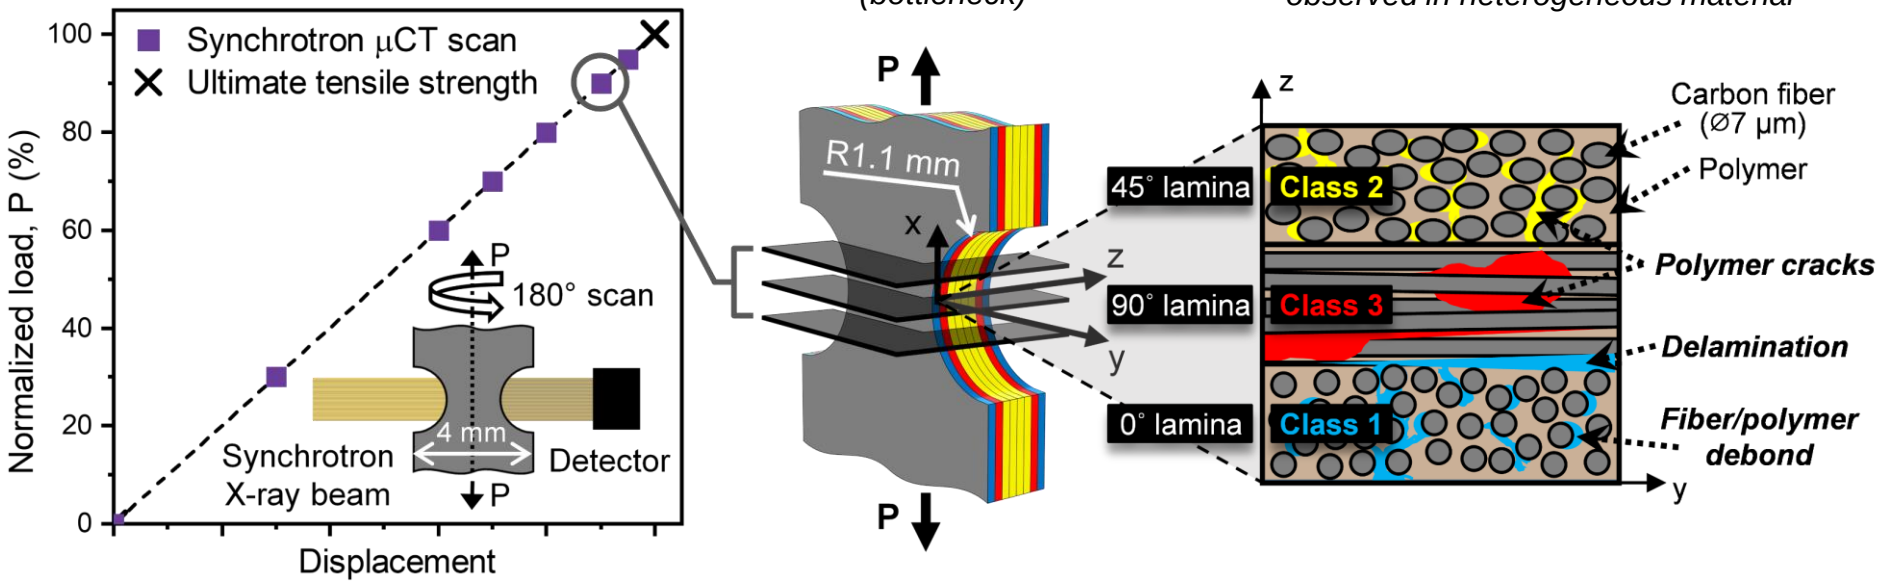
Advanced composites

3D damage progression (artifact prone)

Stack of virtual cross-sections (bottleneck)

NAVAIR Public Release SPR# 2025-0376. Distribution Statement A - Approved for public release; Distribution is unlimited.

Multiclass 3D Microdamage Characterization in Heterogeneous Materials

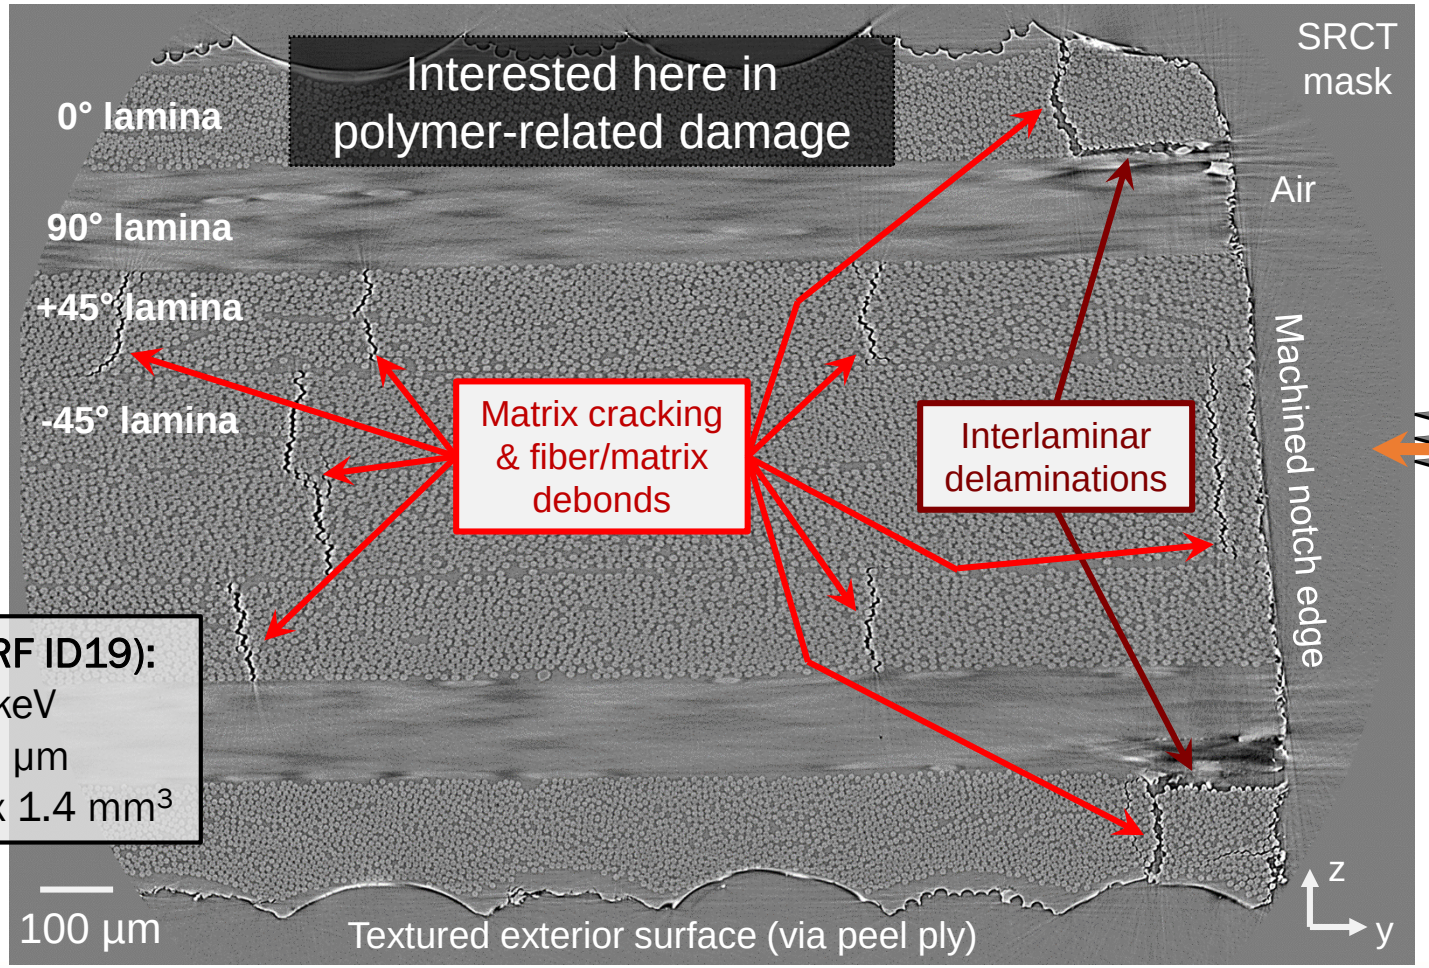


- What is the current segmentation problem and why is it hard (**no rule-based feasible solutions**)?

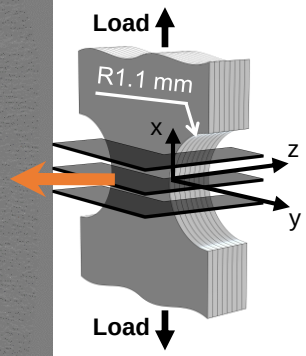
μCT-based *in situ* visualization → **BIG data** → **Sparse, complex damage**

3D progressive damage (artifact prone)

Stack of virtual cross-sections (bottleneck)



*Multiclass, interacting **polymer-related microdamage** nondestructively observed in heterogeneous material*



NAVAIR Public Release SPR# 2025-0376. Distribution Statement A - Approved for public release; Distribution is unlimited.

Modern Progressive Damage Characterization:
How to achieve objective analysis of X-ray µCT data?

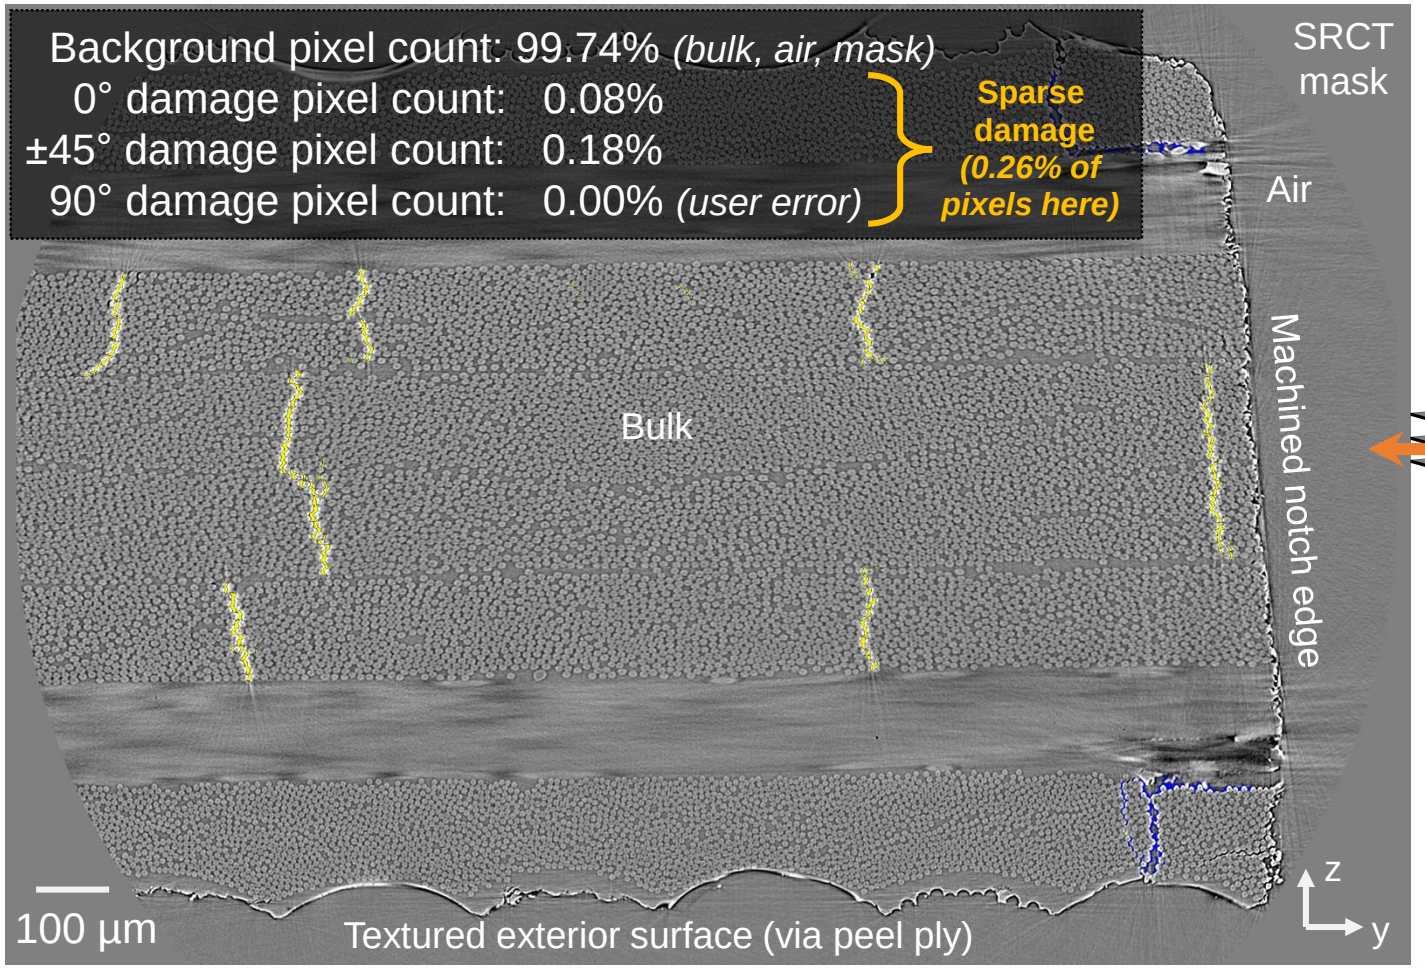
- Consider an artifact-prone raw (unsegmented) tomogram, following minimal pre-processing:

SRCT parameters (ESRF ID19):

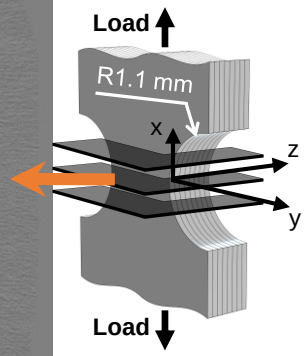
X-ray energy:	20 keV
Voxel (vx) size:	0.65 µm
Field-of-view:	1.6 x 1.6 x 1.4 mm^3

NAVAIR Public Release SPR# 2025-0376. Distribution Statement A - Approved for public release; Distribution is unlimited.

Modern Progressive Damage Characterization:
How to achieve objective analysis of X-ray µCT data?



- **Semi-auto human segmentation** of multiclass matrix damage (general state-of-the-art method*):

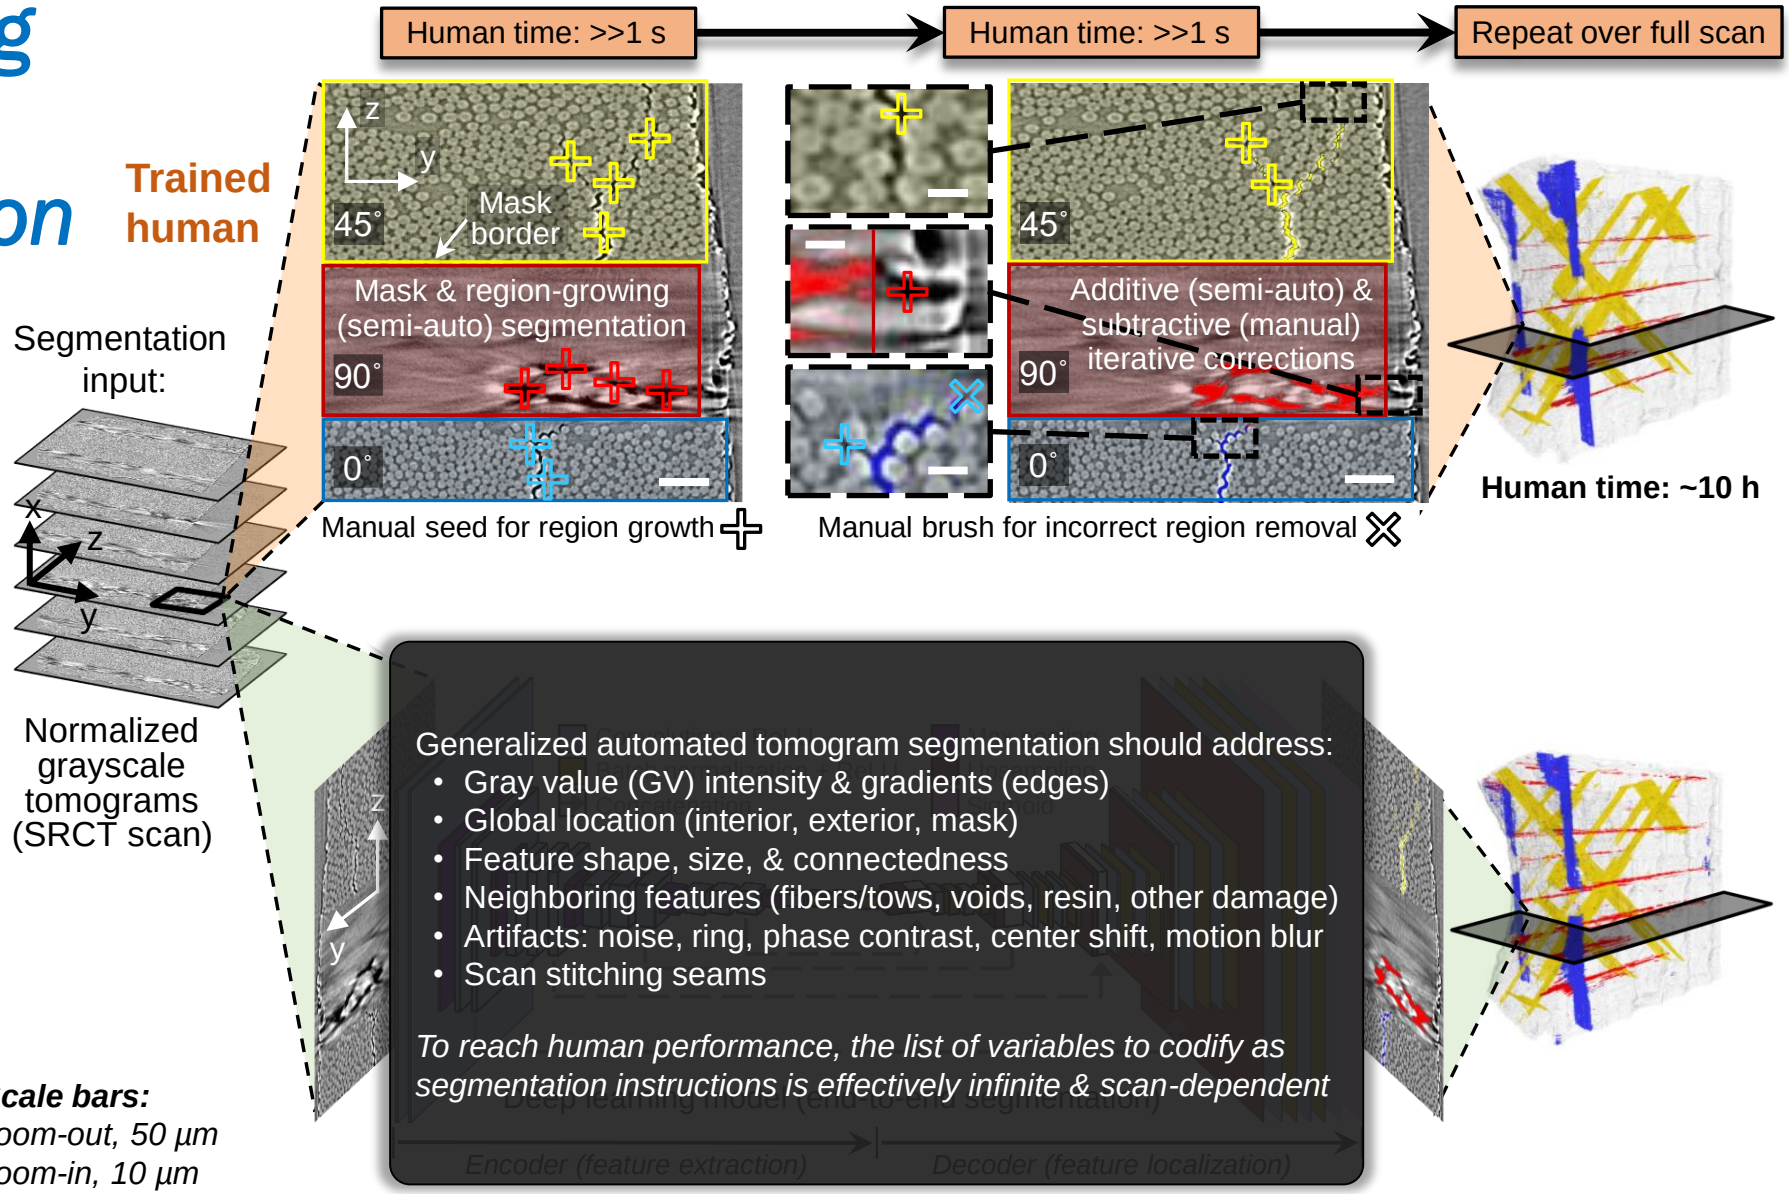


Class imbalance challenge

Background pixel count: 99.74% *(bulk, air, mask)*
0° damage pixel count: 0.08%
±45° damage pixel count: 0.18%
90° damage pixel count: 0.00% *(user error)*

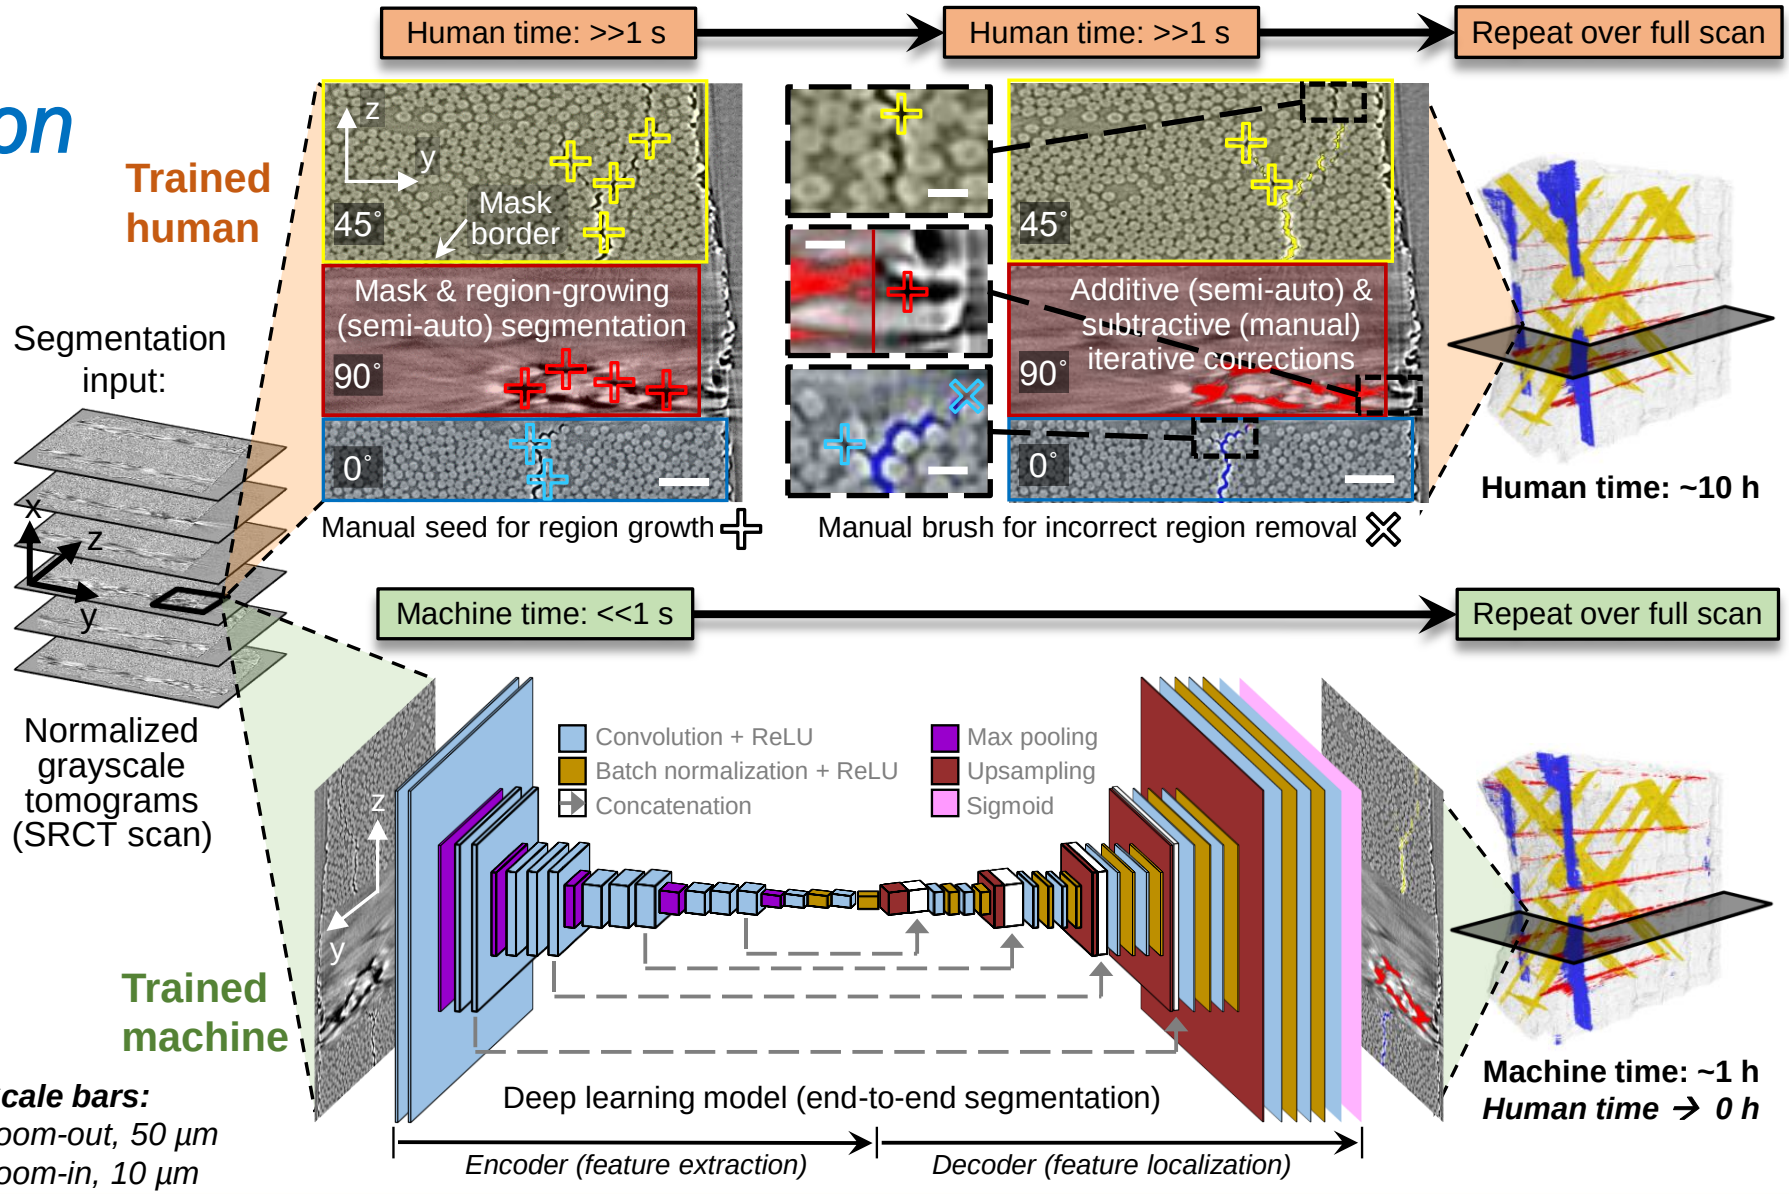
Sparse damage *(0.26% of pixels here)*

Matrix damage
- 0° ply
- ±45° ply
- 90° ply



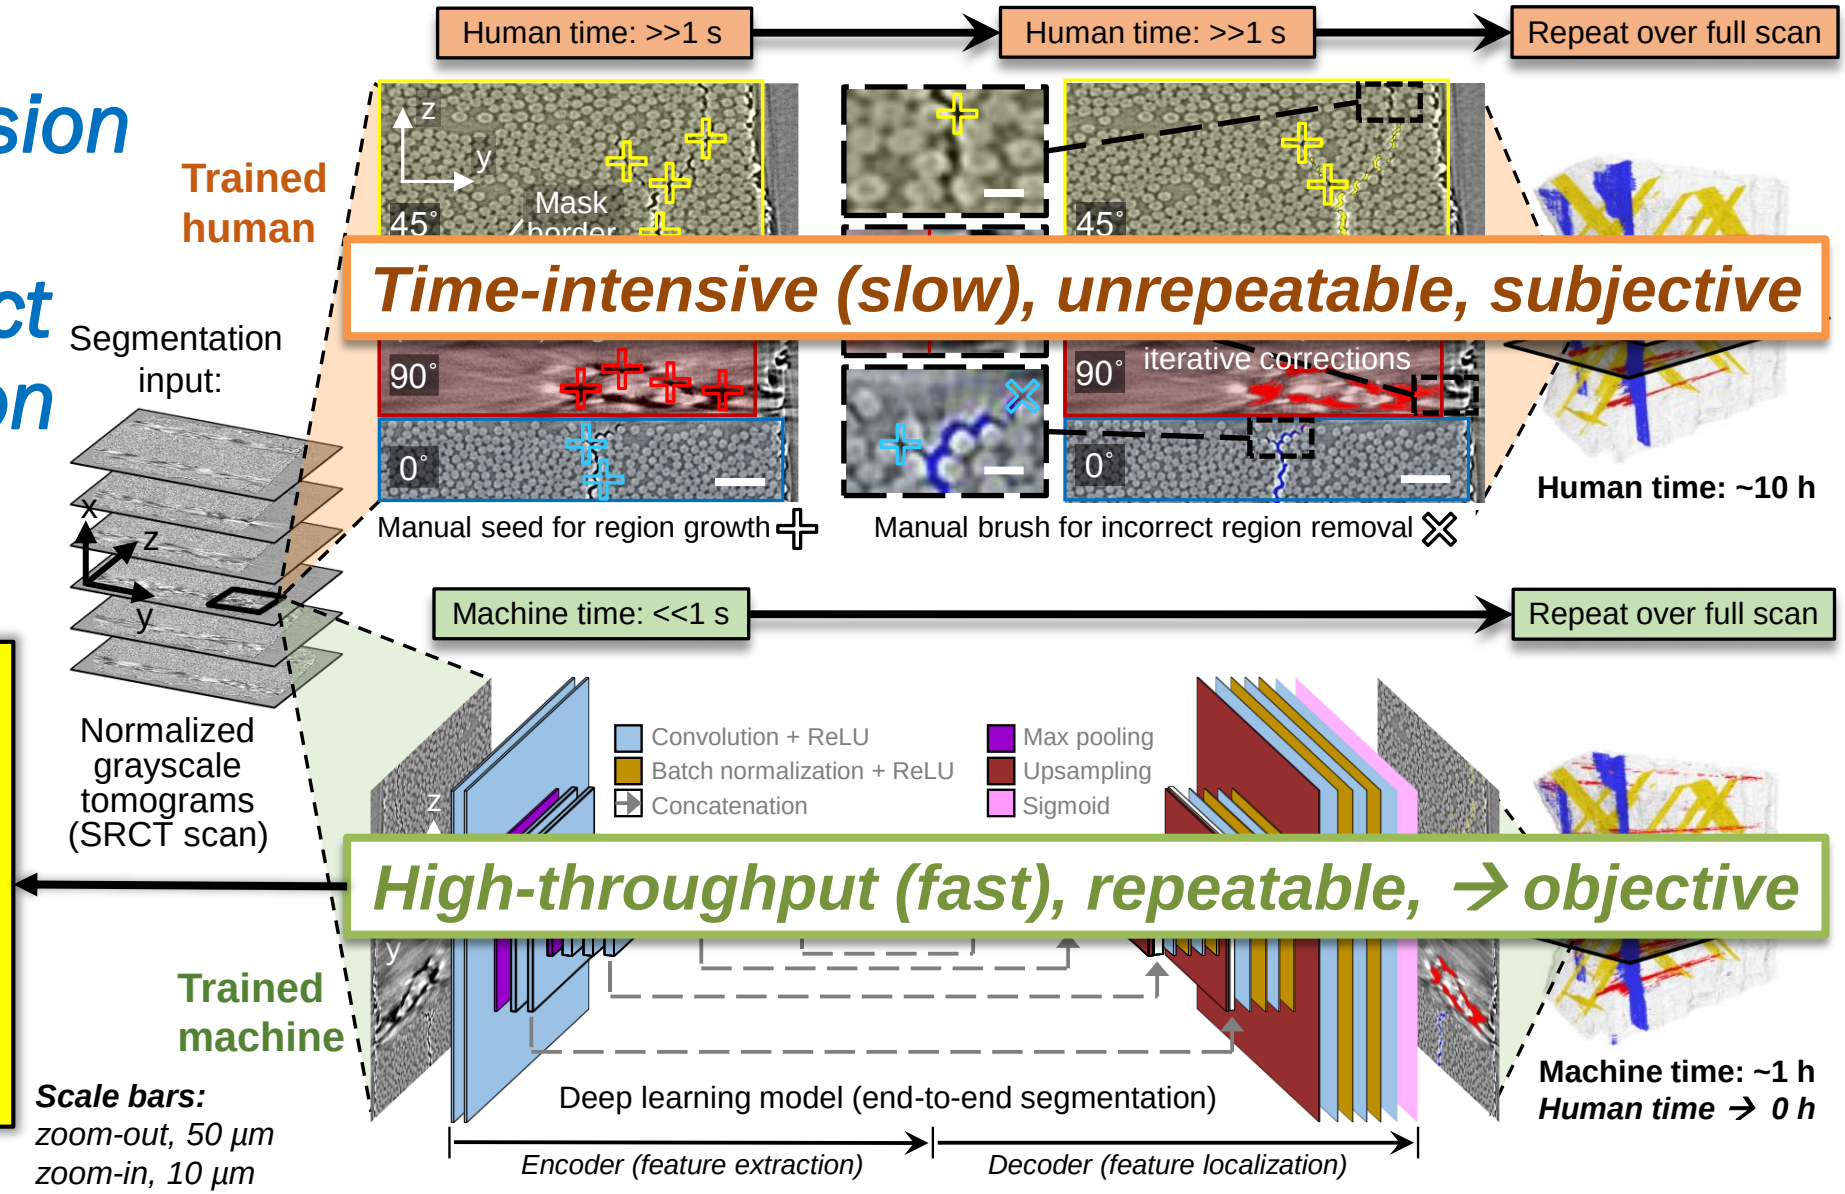
*Approx. 10 h per scan segmentation

NAVAIR Public Release SPR# 2025-0376. Distribution Statement A - Approved for public release; Distribution is unlimited.



Deep Learning (DL)-based computer vision for complex, sparse defect segmentation (1/2)

Scale bars:
zoom-out, 50 µm
zoom-in, 10 µm

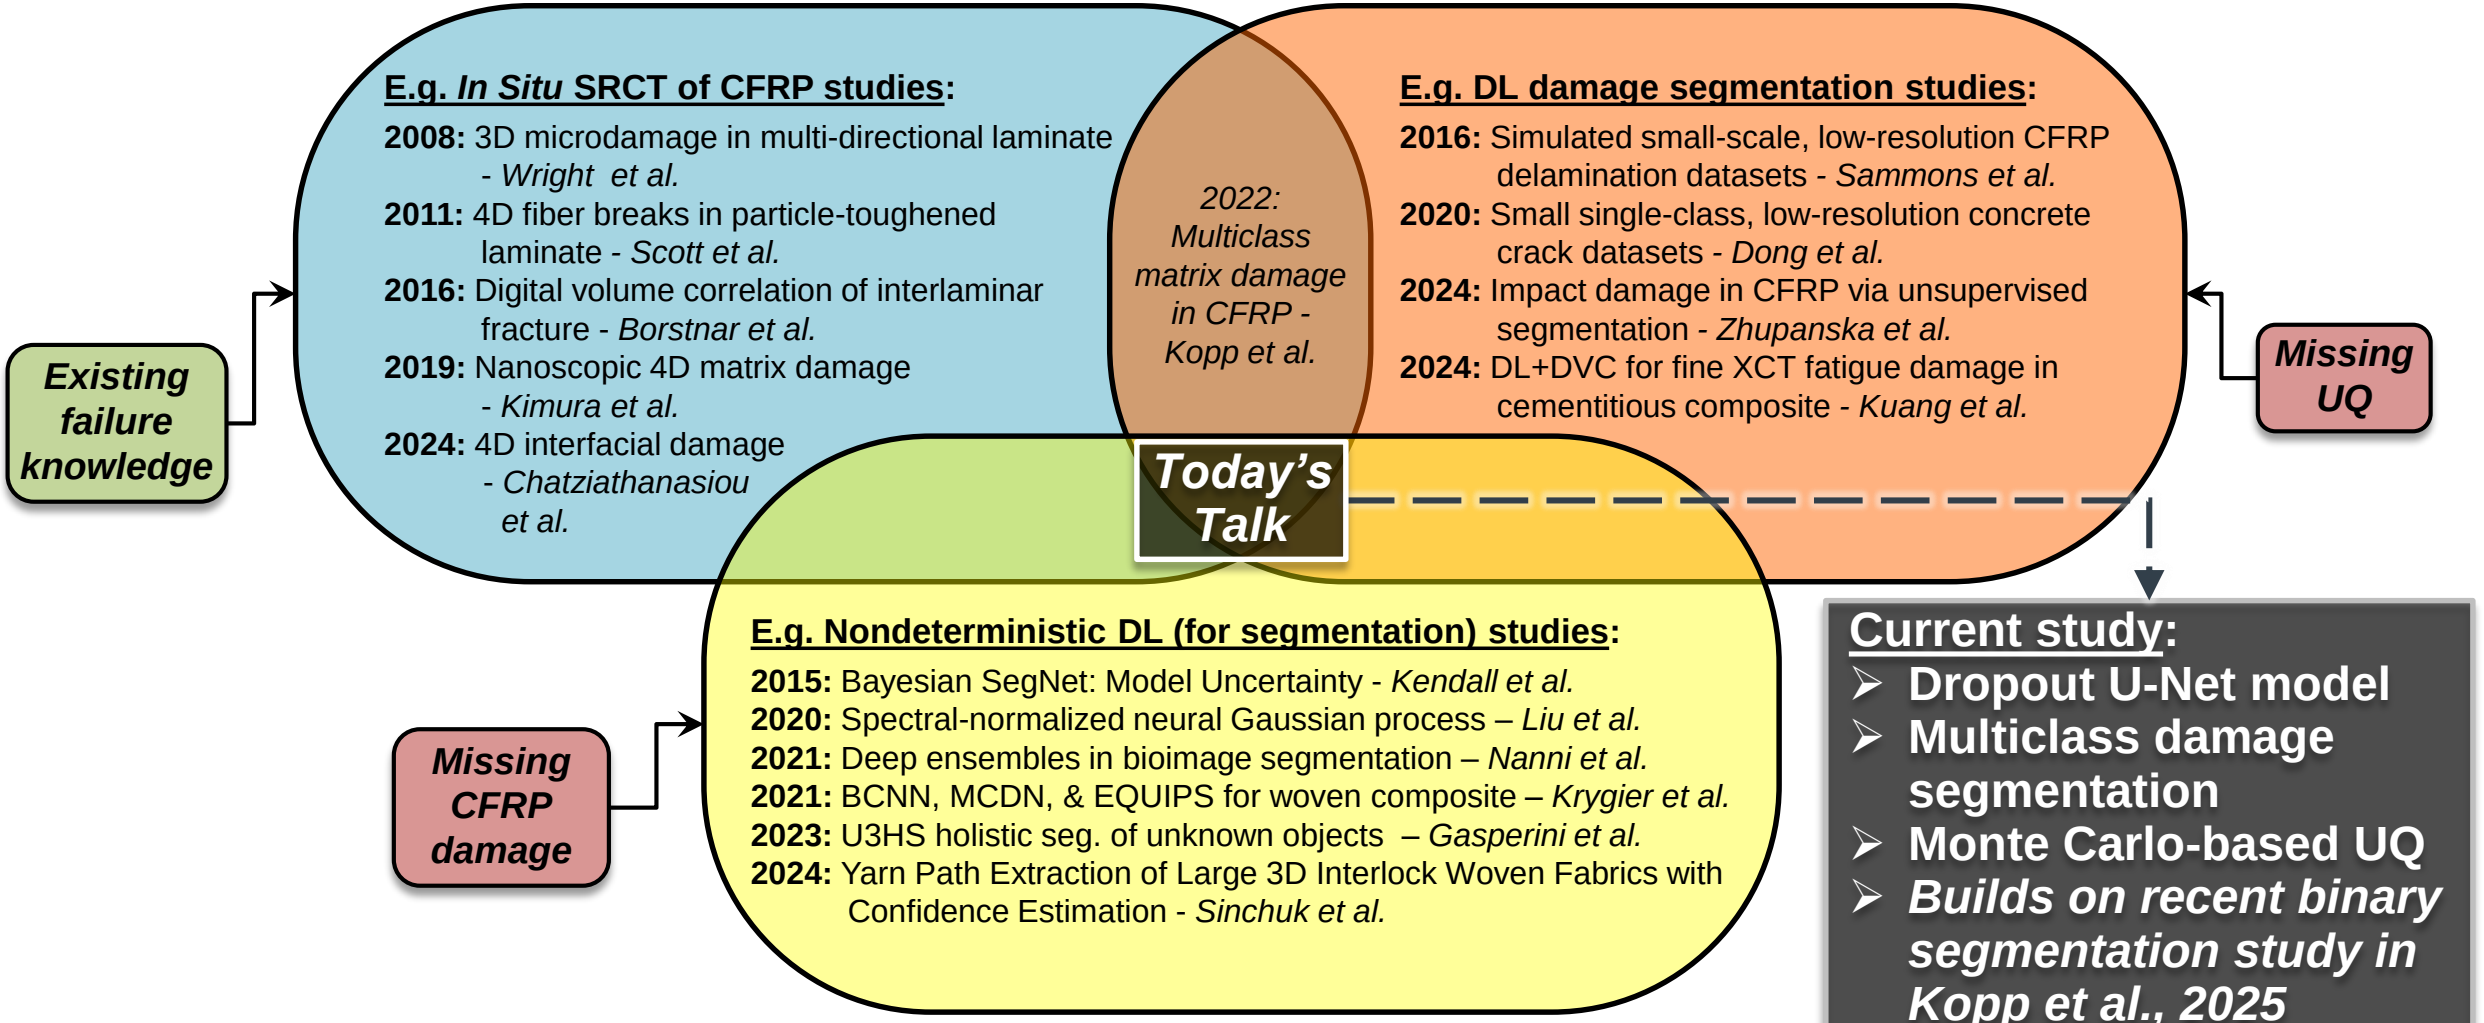


NAVAIR Public Release SPR# 2025-0376. Distribution Statement A - Approved for public release; Distribution is unlimited.

DL-based computer vision for complex, sparse defect segmentation (2/2)

NAVAIR Public Release SPR# 2025-0376. Distribution Statement A - Approved for public release; Distribution is unlimited.

DL-based computer vision for complex, sparse defect segmentation (2/2)



However, broader body of related literature still focused on deterministic methods.

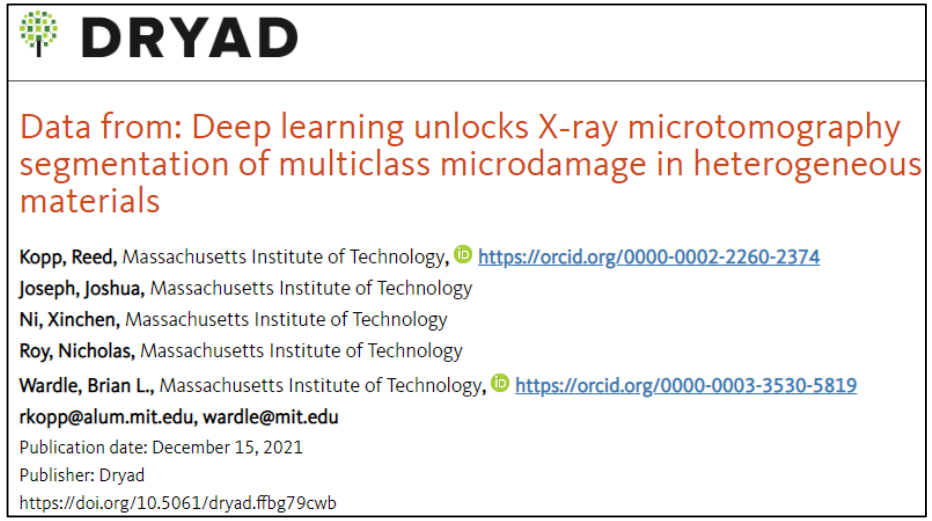
Scale bars:
zoom-out, 50 µm
zoom-in, 10 µm

NAVAIR Public Release SPR# 2025-0376. Distribution Statement A - Approved for public release; Distribution is unlimited.

Study Goals at the Intersection of Advances in Composites Damage and Computer Vision for Materials XCT Segmentation

NAVAIR Public Release SPR# 2025-0376. Distribution Statement A - Approved for public release; Distribution is unlimited.

Paper and Public Data Leveraged for Current Study



➢Relevant Literature – Advanced Materials:

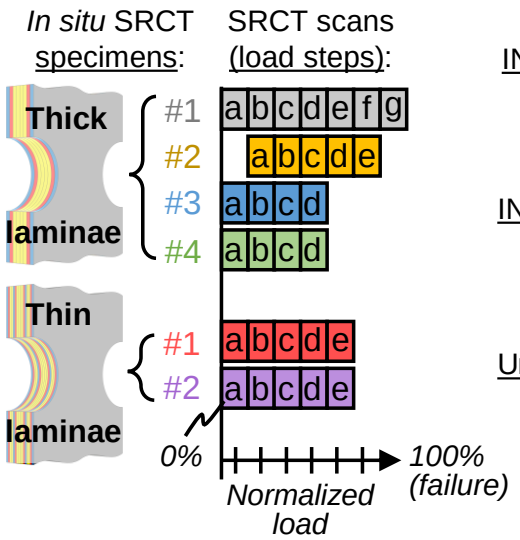
  - ***200+ GB of raw & labeled SRCT tomograms***

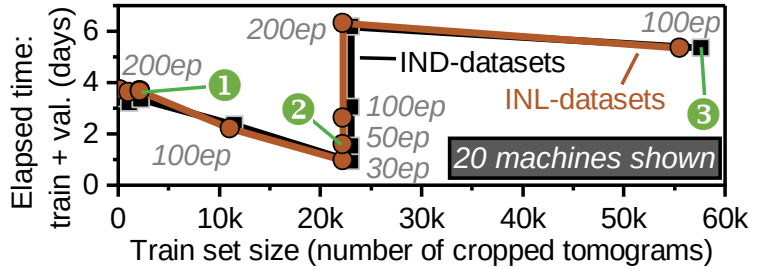


NAVAIR Public Release SPR# 2025-0376. Distribution Statement A - Approved for public release; Distribution is unlimited.

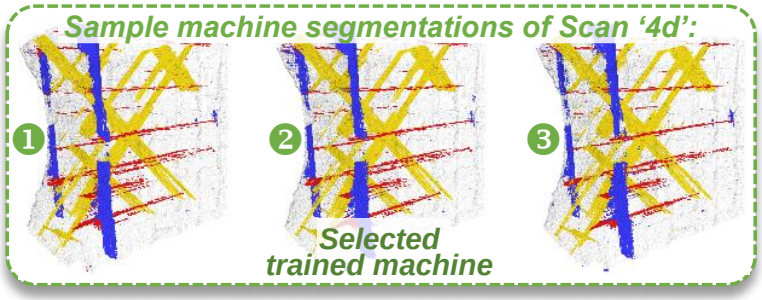
Kopp et al. 2022: Dataset Preparation & Key Variables

Summary of key details and variables studied in deep learning machine development:

Establishing trained machine



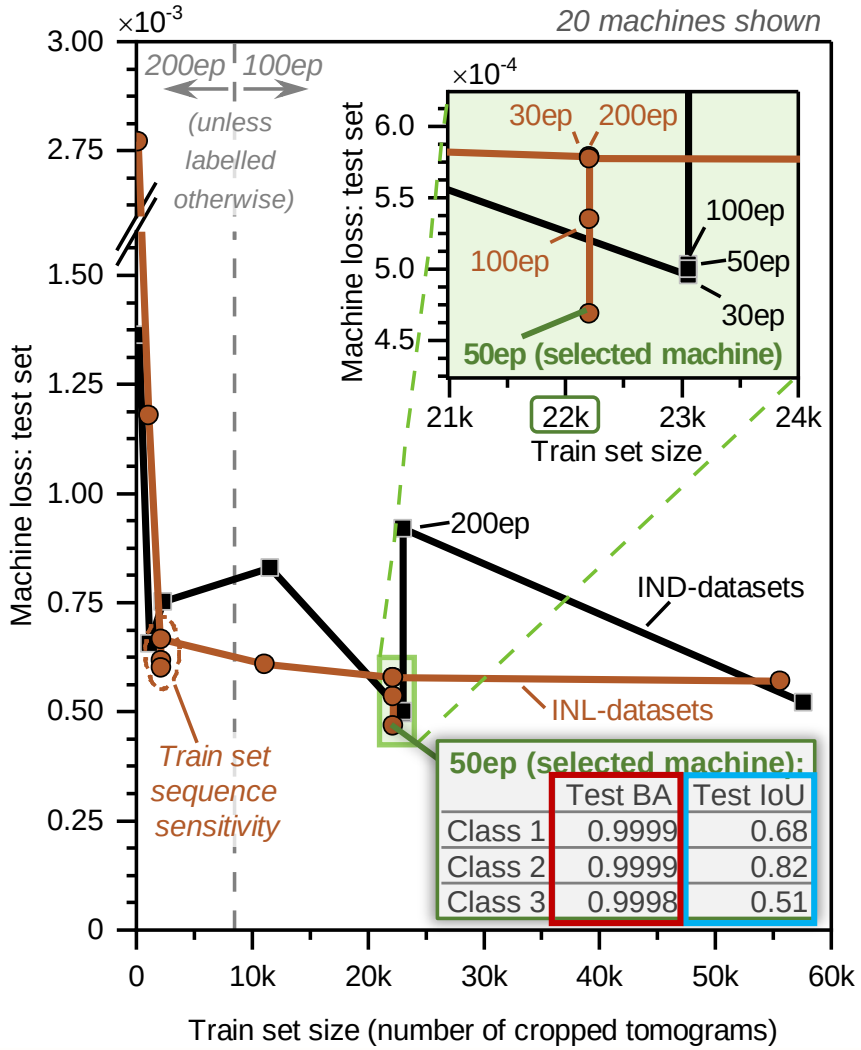
Human segmentation database *(~65,000 SRCT tomograms)*[1] → **SRCT scan composition of datasets** *(cropped tomograms sampled from scans)* → **Hyperparametric study and machine downselection** *(effects of train set composition/size/sequence, epochs)*



IND-datasets: *independent specimens*
Train: a b c d e a b c d e
Validation: a b c d e f g a b c d

INL-datasets: *interleaved specimens*
Train: a c e b d f a c b d
Validation: b d a c e g b d a c e

Universal dataset (same for IND & INL):
Test: a b c d a b c d e



Matrix damage:
0˚ laminae | ±45˚ laminae | 90˚ laminae

[1]*Ni*, Kopp* et al. 2021*

NAVAIR Public Release SPR# 2025-0376. Distribution Statement A - Approved for public release; Distribution is unlimited.

Kopp et al. 2022: Model Testing Comparison & Hyperparameter Selection

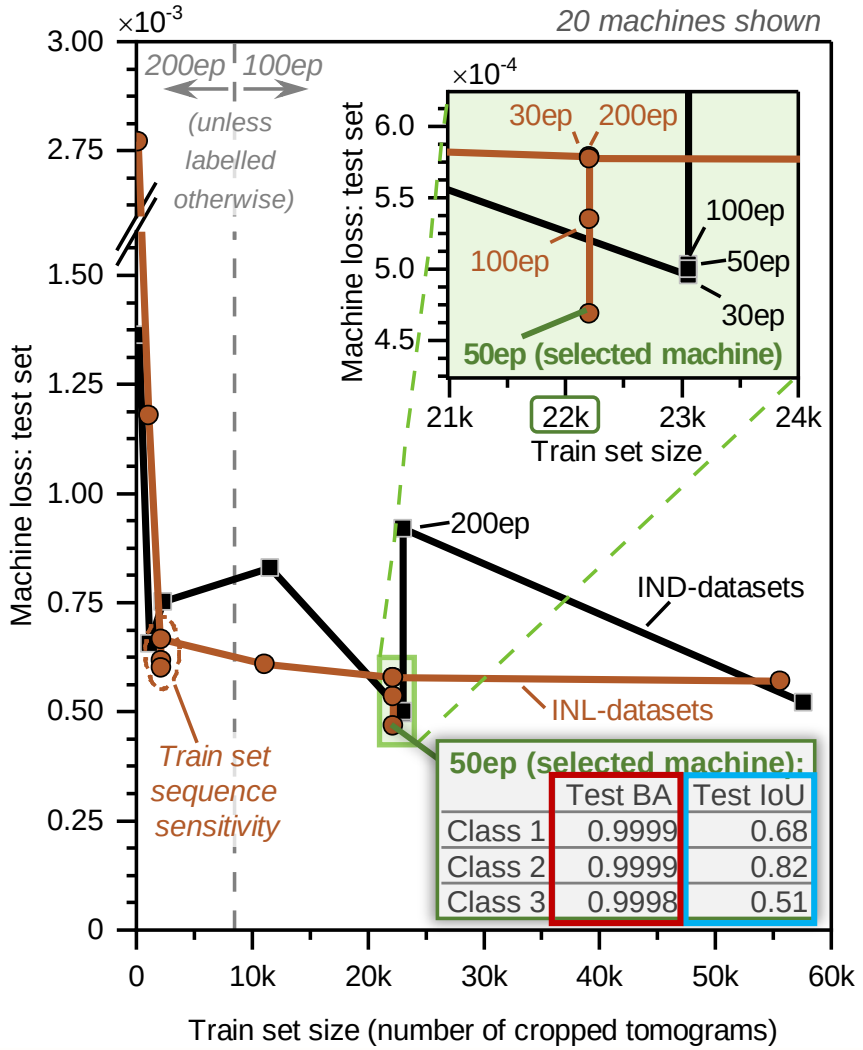
$$\text{IoU Score} = \frac{\text{Intersection Set}}{\text{Union Set}} =$$

$$\text{IoU Score} = \frac{\text{True Pos.}}{\text{True Pos.} + \text{False Pos.} + \text{False Neg.}}$$

→ *dominated by positive damage performance*

Needle: *Damage*

Haystack: *Bulk, air, mask*



$$\textbf{Binary accuracy} = \frac{\text{True Pos.} + \text{True Neg.}}{\text{All Pixels}}$$

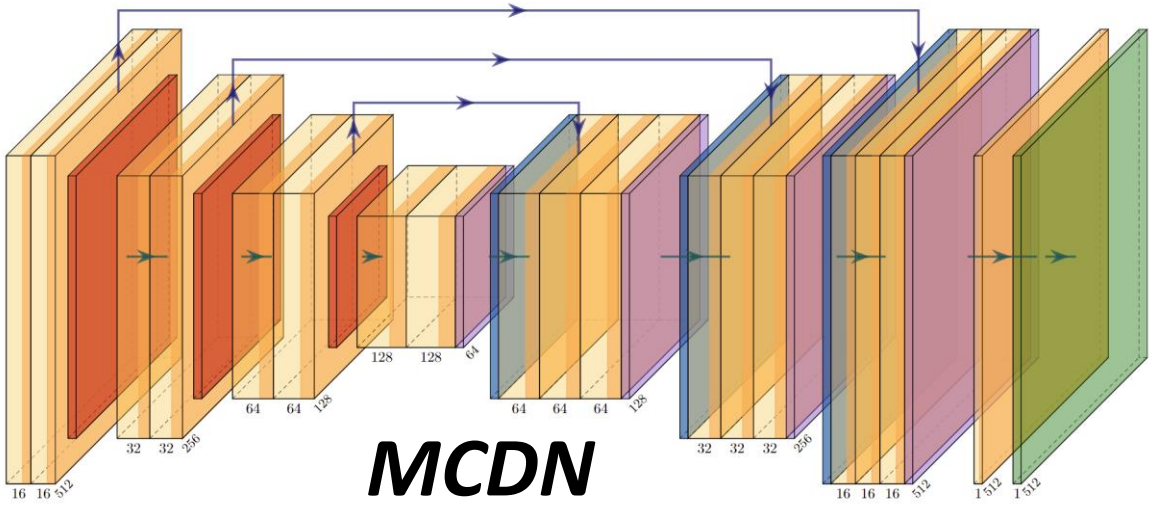
Matrix damage:		
0˚ laminae *(Class 1)*	±45˚ laminae *(Class 2)*	90˚ laminae *(Class 3)*

NAVAIR Public Release SPR# 2025-0376. Distribution Statement A - Approved for public release; Distribution is unlimited.

Kopp et al. 2022: Model Testing Comparison & Hyperparameter Selection

Downselection of machine based on:

- **20 different machines**
- **12 different datasets** *(patch size: 512 x 512)*
  - 6 different training set sizes (“1” [sm] – “6” [lg])
  - 2 different scan set splits evaluated (INL vs. IND)
- **4 different epoch # cases**
- 3 different random train seeds (sequence)
- **2 different loss functions (binary vs. categorical cross entropy)**
- 53 different scan/machine inferences
- 19 different 3D visualizations with inferred data



Performance elbow point occurs around 2,000 train patches

Matrix damage:		
0˚ laminae *(Class 1)*	±45˚ laminae *(Class 2)*	90˚ laminae *(Class 3)*

NAVAIR Public Release SPR# 2025-0376. Distribution Statement A - Approved for public release; Distribution is unlimited.

DL Model Architecture: U-Net-based Monte Carlo Dropout Network (MCDN)

- **MCDN model architecture (based on Krygier et al., 2021]) was the primary motivation** of the current study of key hyperparameter effects on nondeterministic segmentation predictions
  - *~10X fewer parameters than model in Kopp et al. 2022*
- **MCDN spatial dropout layers** enable user definition of their spatial dropout factor/magnitude *(i.e., the fraction of neural network nodes that are eliminated in each forward pass)*
- **Observations from Kopp et al., 2025 (AIAA SciTech): Increasing the dropout factor generally increased the prediction variability and thus capacity for UQ, though often at the cost of predictive accuracy**

Customizable DL model architecture* of the Monte Carlo U-Net dropout network (MCDN).

Layers are colored as follows:

Yellow: Conv2d + RELU *Blue: Upsample*
Orange: Max pooling *Green: Sigmoid*
Purple: Spatial dropout

**Configuration shown here has a depth of 3 and 16 initial channels*

NAVAIR Public Release SPR# 2025-0376. Distribution Statement A - Approved for public release; Distribution is unlimited.

Nondeterministic Segmentation Development on Public Multiclass Matrix Microdamage XCT Data (1/5)

Summary of multiclass dataset targets *used to develop DL segmentation of matrix microdamage.*

- Optimal sizing of training and validation datasets based on prior deterministic work by [Kopp, 2022]

Similar to [Kopp, 2022]

Dataset case	Dataset split	Number of scans	Patch width	Patch height	Patch depth	Target number of patches per scan	Target maximum voxel count per scan	Target maximum number of patches	Target patch class sampling split: E/0°/45°/90°

Key DL configurations to study hyperparameter effects

Primary DL hyperparameters assessed in the current study:

- Train set size (patch count)
- Loss weighting
- Data augmentation
- Batch size
- U-Net architecture and size
- Patch dimensions
- MC dropout magnitude *(focus)*

Additionally, an initial study was done to verify general reproduction of Kopp et al. 2022 results with the current methods (not shown here)

Model case	Dataset case	MCDN dropout factor	U-Net depth, initial channels	U-Net parameter count	Loss weighting	Data augmentation	Epochs	Batch size	Initial learning rate	Pretrained model case

NAVAIR Public Release SPR# 2025-0376. Distribution Statement A - Approved for public release; Distribution is unlimited.

Key DL results to assess hyperparameter effects (1/5)

Hyperparameters of interest here:

- Train set patch qty. (*"Dataset case"*): *2K ("1"), 20K ("2")*
- Loss weighting: *None, slight, inverse class vol.*
- Data augmentation: *None, flip/rotate*

- *Suggested practice: Larger train sets, no loss weighting, and flip/rotate data augmentation*

Patch size for these cases: 512 x 512

Model case	Dataset case	MCDN dropout factor	U-Net depth, initial channels	U-Net parameter count	Loss weighting	Data augmentation	Epochs	Batch size	Initial learning rate
1-2.1	1	0.1	4, 16	2.2E+06	None	90° rotate, flip	100	16	1E-03
1-4	1	0.1	4, 16	2.2E+06	None	None	100	16	1E-03
2-1	2	0.1	4, 16	2.2E+06	None	90° rotate, flip	100	16	1E-03
2-2	2	0.1	4, 16	2.2E+06	0.1, 0.3, 0.3, 0.3	90° rotate, flip	100	16	1E-03
2-3	2	0.1	4, 16	2.2E+06	Class vol. inverse	90° rotate, flip	100	16	1E-03

Training & validation, save based on min. train loss

NAVAIR Public Release SPR# 2025-0376. Distribution Statement A - Approved for public release; Distribution is unlimited.

Key DL results to assess hyperparameter effects (2/5)

Hyperparameters of interest here:

- Mini-batch size: *2, 4, 8, 16*
- *Note: For current GPU, full VRAM for 4 to 8 3D patches; larger batches use shared memory*

- *Suggested practice: Larger mini-batch sizes improve generalizability and validation set convergence*

Patch size for these cases: 128 x 128

	Validation		2.13E-03	1.00	0.67	0.77	0.55	
2-5	Training	92	1.15E-03	1.00	0.73	0.84	0.68	17.1
	Validation		1.97E-03	1.00	0.68	0.78	0.59	

Patch size for these cases: 512 x 512

NAVAIR Public Release SPR# 2025-0376. Distribution Statement A - Approved for public release; Distribution is unlimited.

Key DL results to assess hyperparameter effects (4/5)

Hyperparameters of interest here:

- Patch dimensions (*"Dataset case"*): *512x512 ("2"), 256x256 ("3"), 128x128 ("4"), 512x512x8 ("5"), 256x256x32 ("6"), 128x128x128 ("7")*
- *Suggested practice: Larger 2D patches appear to lead to higher-performance models, albeit at increased runtime*

Key DL results to assess hyperparameter effects (5/5)

Hyperparameters of interest here:

- Dropout factor magnitude:
  0.0 (deterministic), 0.1, 0.3, 0.5, 0.7, 0.9

- *Suggested practice: Lower MC dropout magnitude improves accuracy and convergence*

Patch size for these cases: 512 x 512

Conclusions:

- Established **suggested practices for developing MCDN models** based on: Train set size, loss weighting, data augmentation, batch size, U-Net architecture/size, patch dimensions, and MC dropout magnitude.
- MCDN models including a **relatively high dropout factor of up to 0.7 can relatively effectively learn** the sparse multiclass segmentation task with useful levels of uncertainty/confidence *(here, IQR used as a simple first-pass)* and without any appreciable increase in training times.
- Highest uncertainty is unsurprisingly typically observed at the borders of classes.
- The qualitative results suggest an **inverse relationship between segmentation predictive accuracy (decreased) and UQ capacity (increased) when the dropout factor is increased**.
- Additionally, the **models correct many ground truth errors**, albeit at the expense of metric scores that assume label set perfection.

Future/Ongoing Work:

- Develop and assess alternative 2D/3D nondeterministic model architectures and multiclass uncertainty approaches
- Explore uncertainty-guided DL-segmentation model fine-tuning and active learning

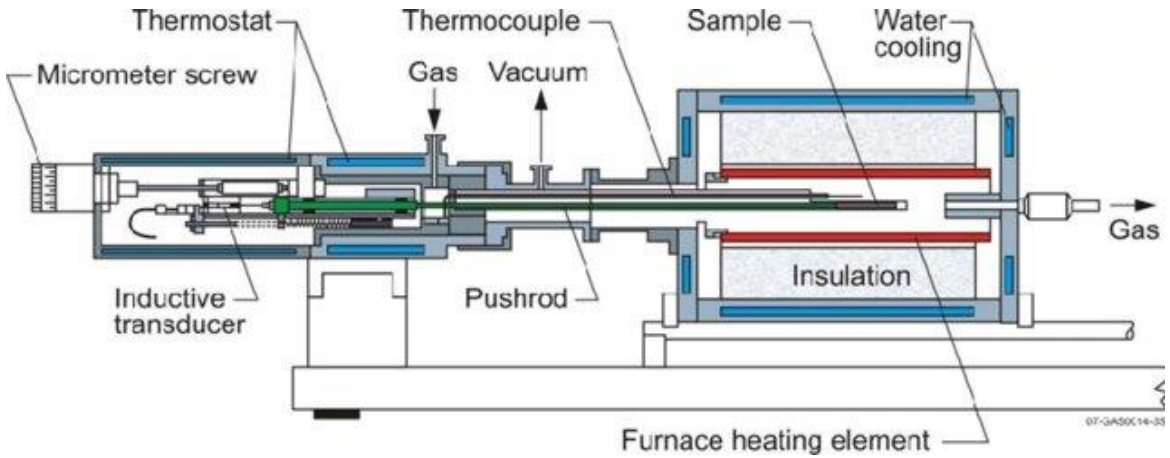
A new approach for quantifying the transverse coefficient of thermal expansion in PAN-based carbon fibres at low temperatures via X-ray Diffraction.

Jiraphant Srisuriyachot[a], Wadwan Singhapong[a], Paloma Rodriguez Santana[a], Carl Sangan[a], Chris Bowen[a], Igor P. Dolbnya[b], Richard Butler[a] and Alexander J. G. Lunt[a]



[a] Materials and Structures Research Centre, University of Bath, Bath, UK
[b] Diamond Light Source Ltd, Harwell Science and Innovation Campus, Didcot, UK

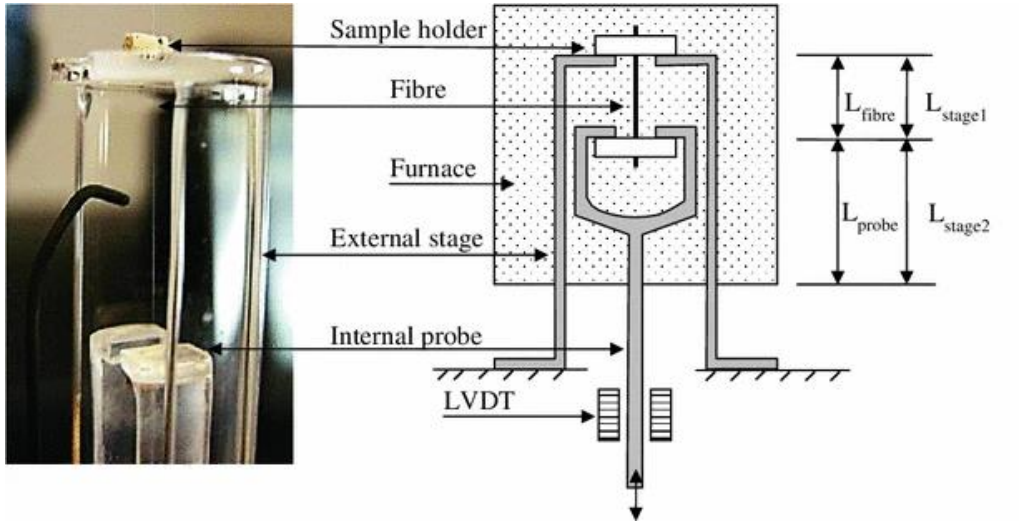
24th International Conference on Composite Materials (ICCM 24)

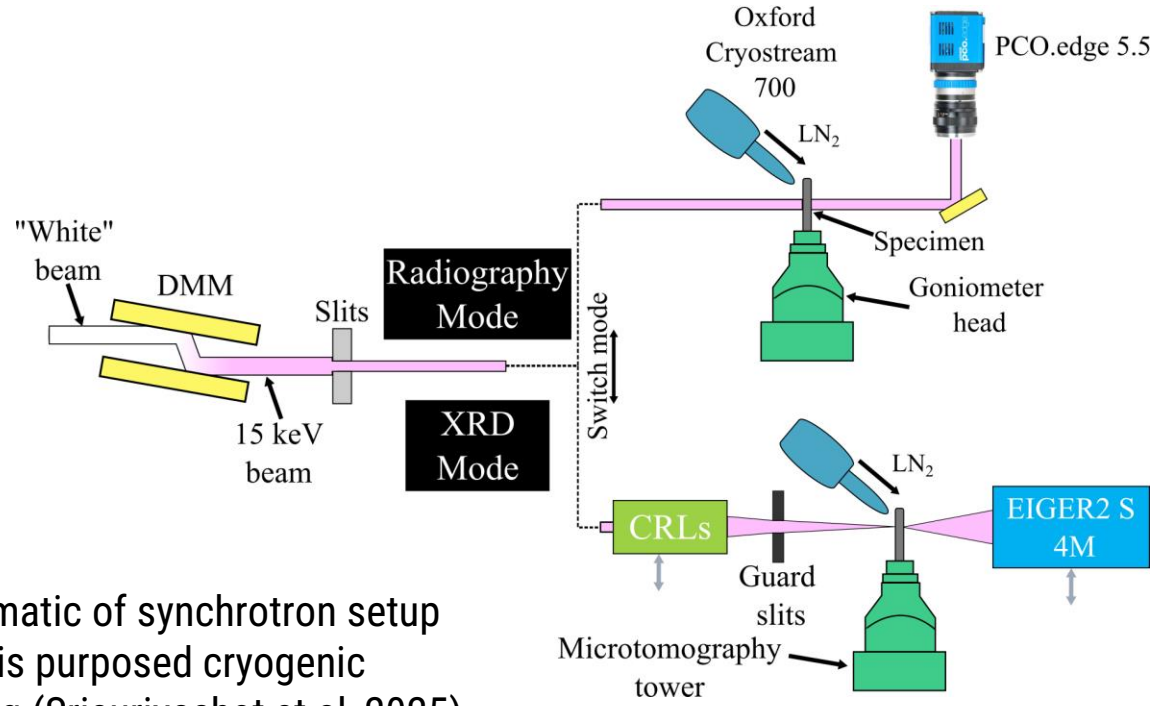
Baltimore, 4th -8th August 2025

Background

- Thermal expansion mismatch between fibre and matrix
  - Leads to micro-cracking resulting in tank hydrogen leakage
- Conventional thermal analysis method such as dilatometer to measure thermal expansion coefficient
  - Not accurate in the transverse direction of the fibres (5-7 micron)

Schematic of conventional dilatometer in horizontal configuration (Joshya et al, 2008).





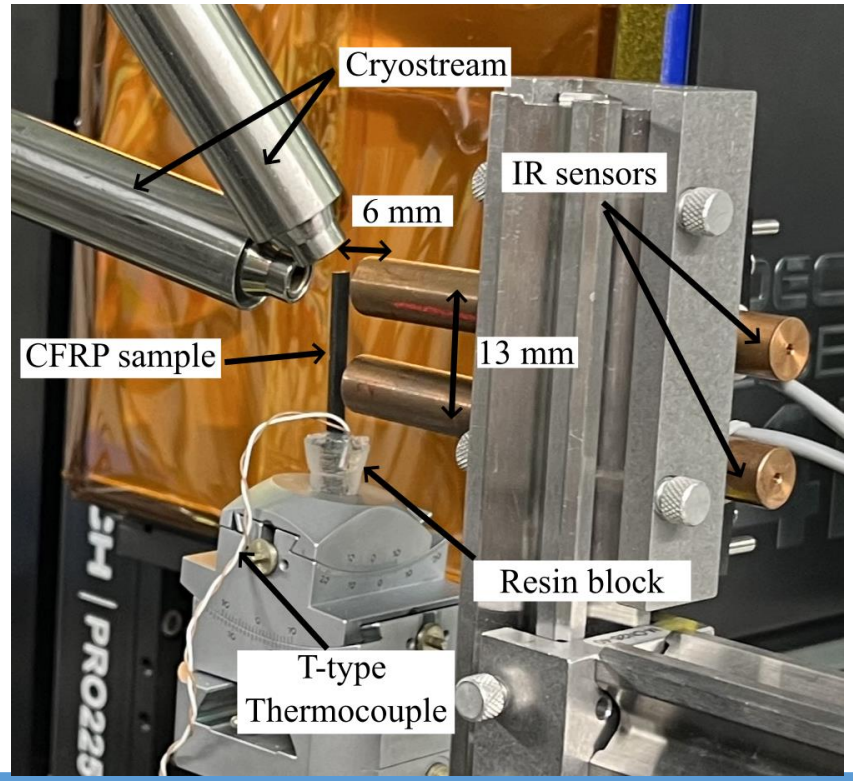


Illustration of the TMA set-up for the fibre/film sample (Yang and Thomason, 2013).

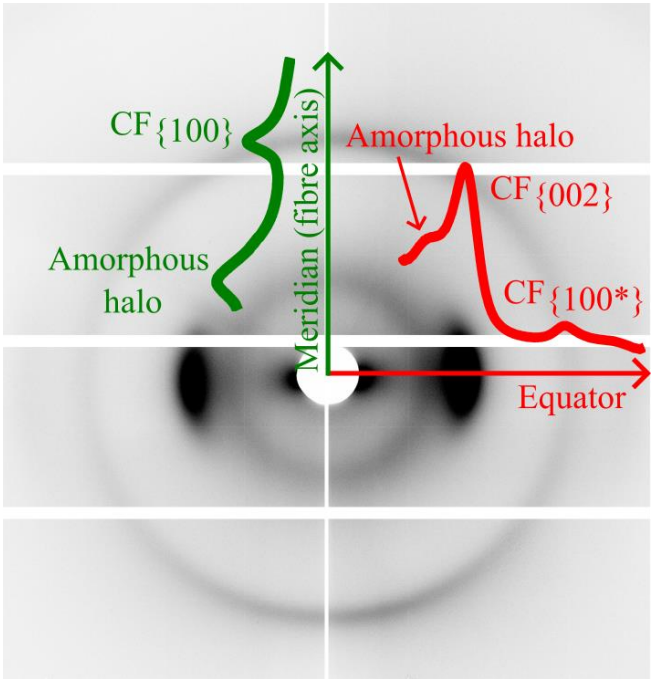
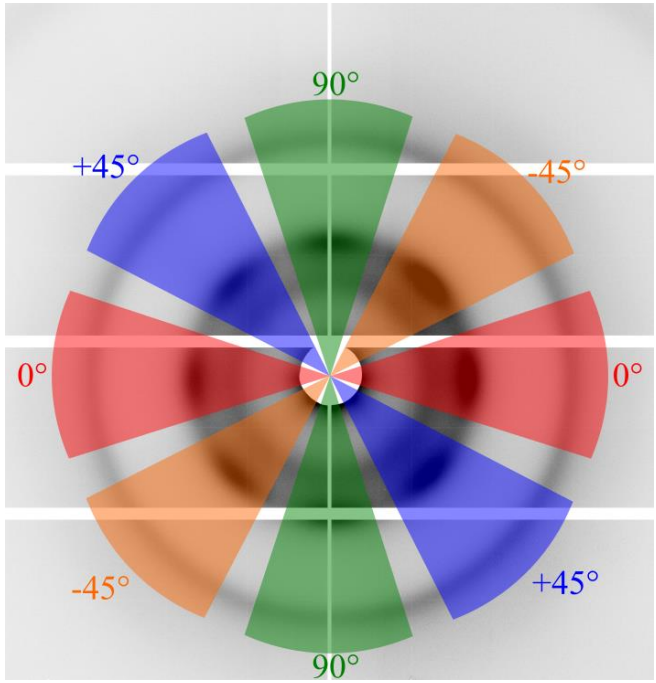
Methodology

- Synchrotron experimental setup (X-ray diffraction (XRD) and radiography)
- Dual cryostream to cool sample (open environment)
- Infrared sensors to measure temperature

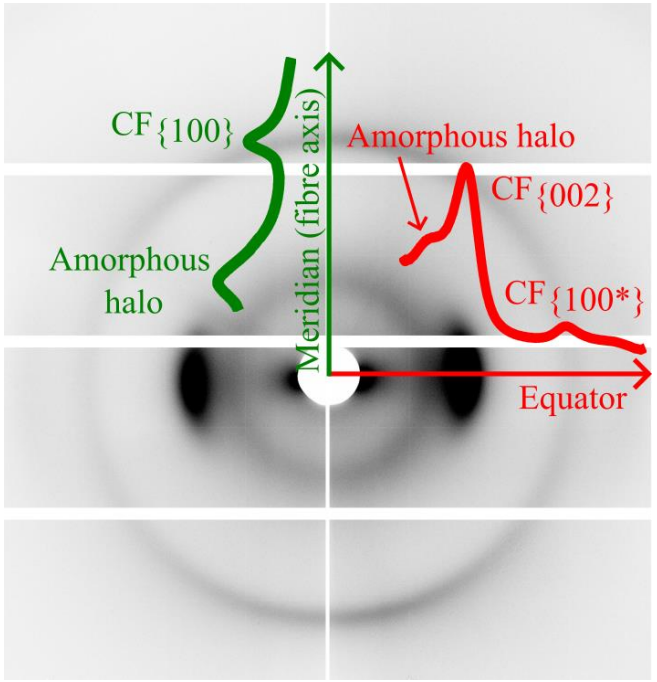


Schematic of synchrotron setup for this purposed cryogenic testing (Srisuriyachot et al, 2025).

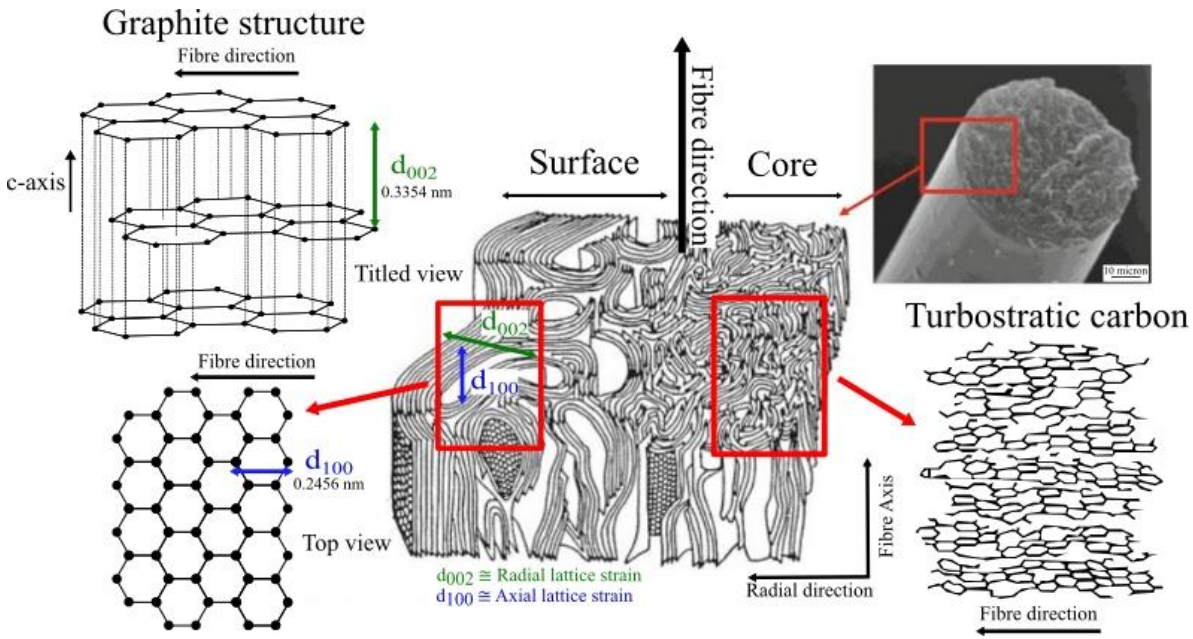


Methodology

- Example of X-ray diffraction pattern of Unidirectional (UD) and Quasi-isotropic (QI) CFRP



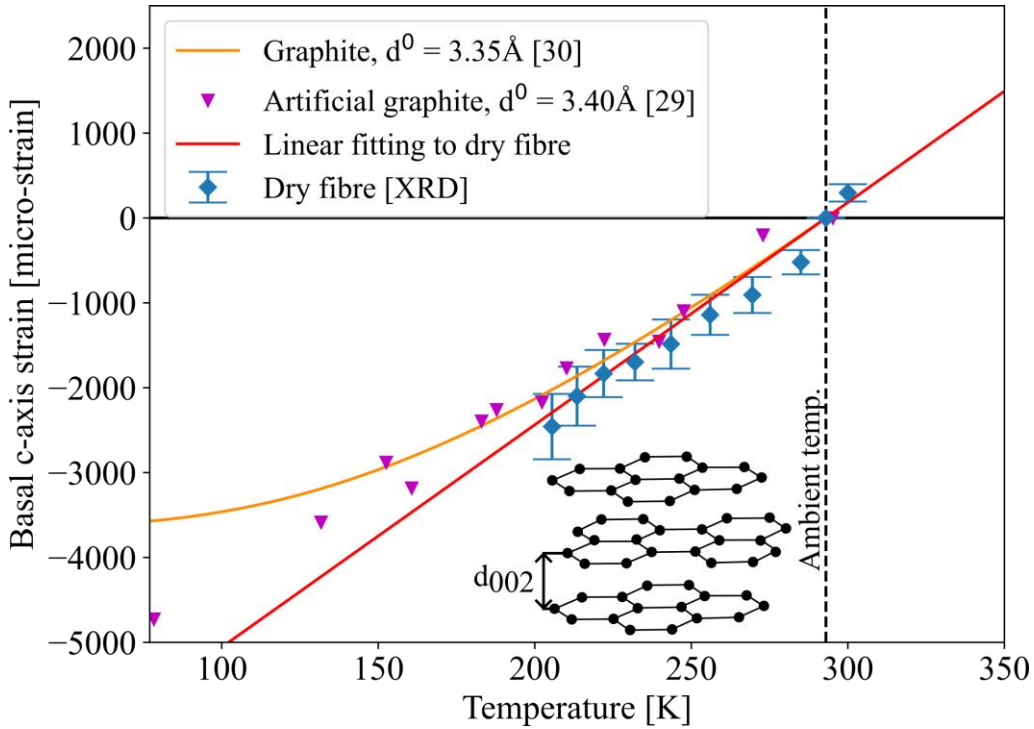
XRD pattern of UD shows the two primary PAN-based fibre lattice planes; {002} and {100}.

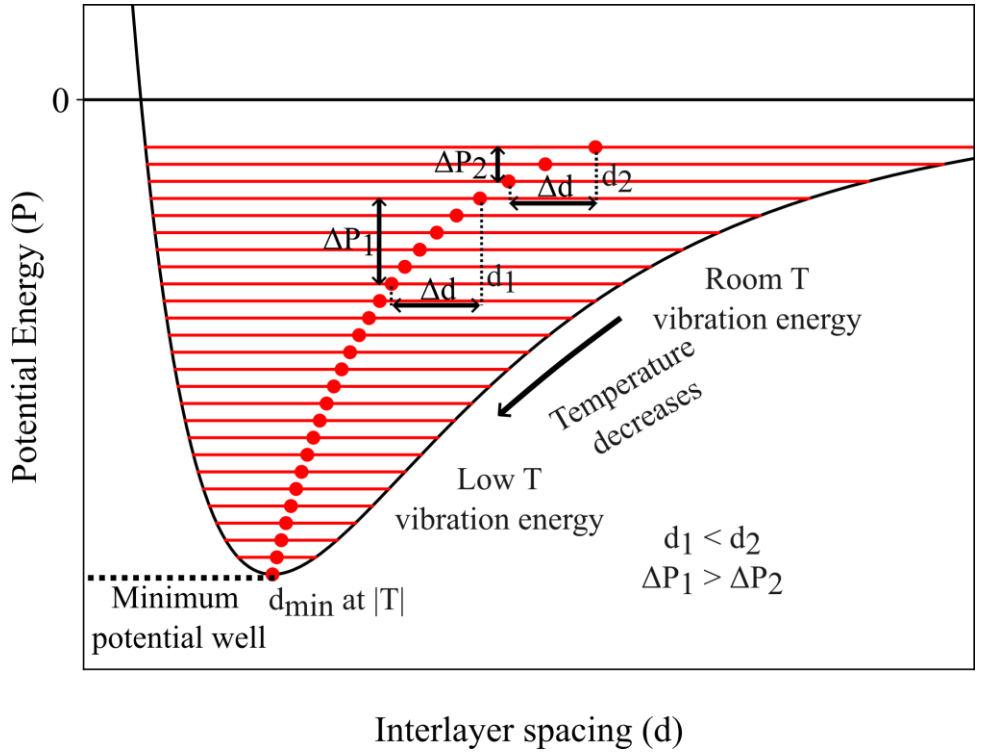


XRD pattern of QI shows the superposition of the fibre lattice planes in 0, 90 and 45/-45-degree plies.

Methodology

- Microstructure of PAN-based carbon fibres
- Measurement of the change in transverse/radial direction of fibre



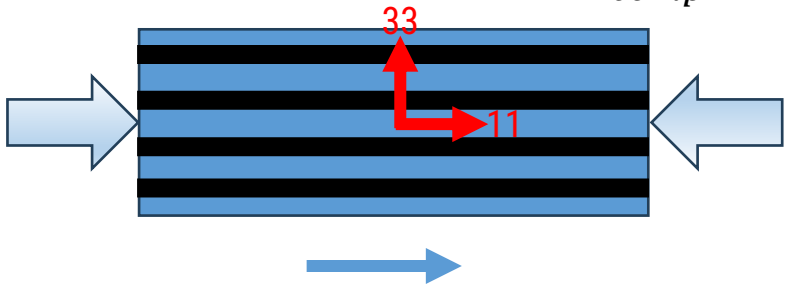


The relationship between the XRD pattern and microstructure of the PAN-based carbon fibres. Δ{002} ≈ Radial lattice strain and Δ{100} ≈ Axial lattice strain (Srisuriyachot et al., 2022).

Experimental results

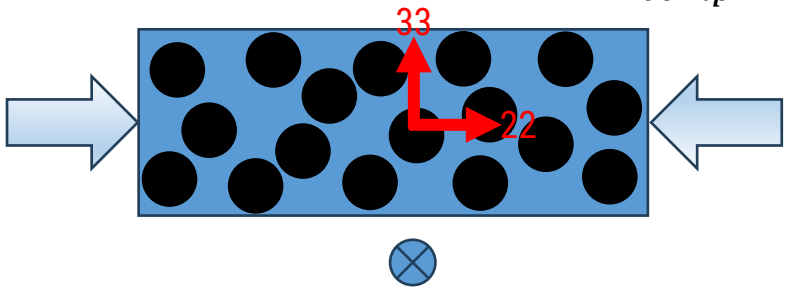
- Plots of measured fibre lattice strain vs. graphite

Thermal strain in dry fibre closely matches interlayer spacing changes in natural and artificial graphite up to the measured temperature.



The rate of change of the lattice strain is varies depending on the initial d-spacing. A larger d-spacing will require less energy to deform the same Δd. The smaller d-spacing is starting to plateau earlier.

Experimental results



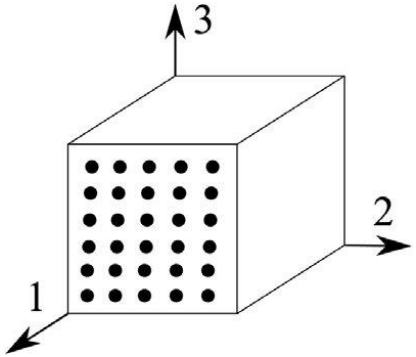
- Indirect measurement to obtain coefficient of thermal expansions from three configurations

0° composite laminate → α_{comp}^{11}

Fibre direction

90° composite laminate → α_{comp}^{22}

Fibre direction



Pure resin matrix → α_m

Isotropic

Experimental results

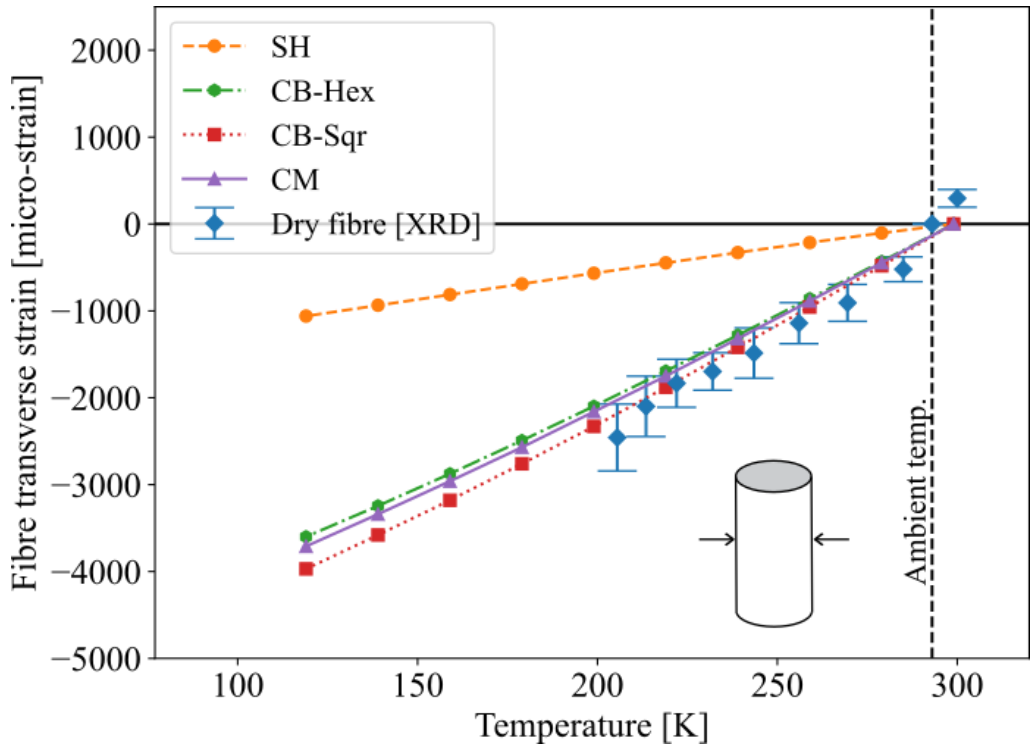
- Analytical models to workout transverse CTE of fibres

Schapery model (SH)

$$\alpha_{f_{SH}}^{22} = \frac{\alpha_{comp}^{22} - (1+\nu_m)\alpha_m V_m + \alpha_{comp}^{11}(\nu_m V_m + \nu_f^{12} V_f)}{(1-\nu_f^{12})V_f}$$

Chamberlain model (CB)

$$\alpha_{f_{CB}}^{22} = \alpha_m + \frac{(\alpha_{comp}^{22} - \alpha_m)\left[\nu_m(F-1+V_m) + \left(F+V_f\right) + (E_m/E_f^{11})(1-\nu_f^{12})(F-1+V_m)\right]}{2V_f}$$



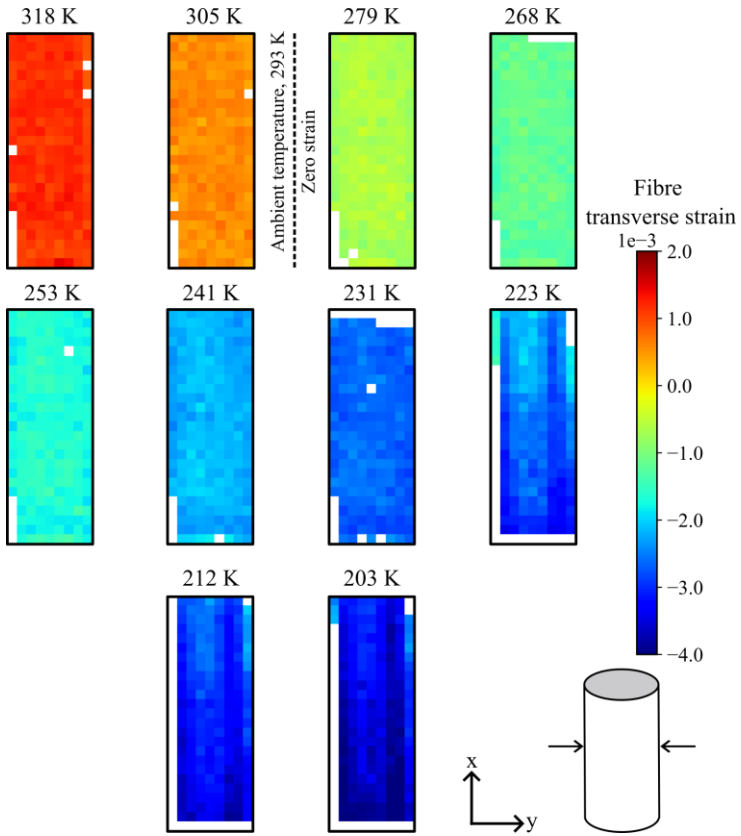
Chamis model (CM)

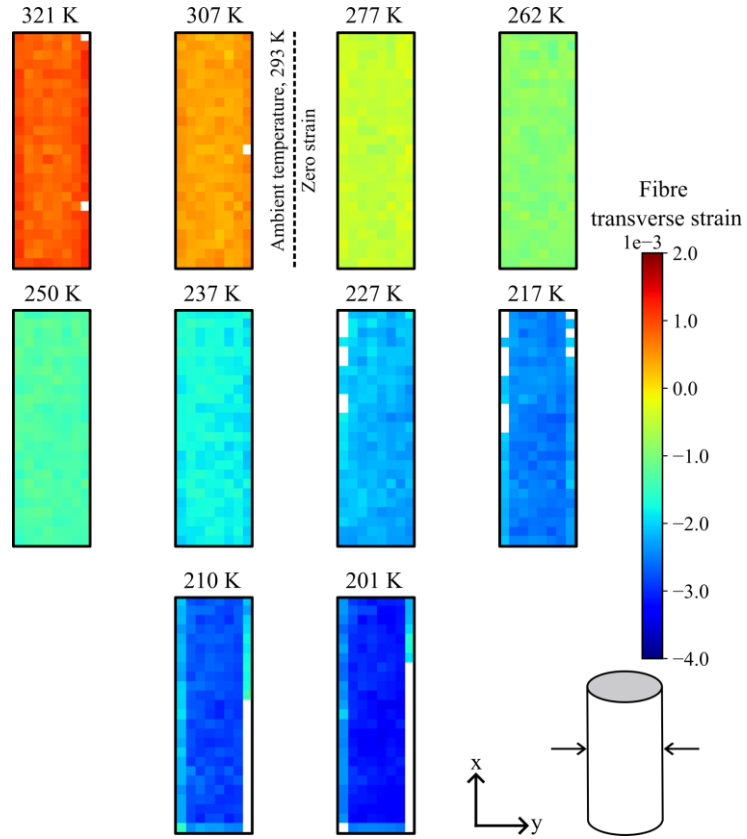
$$\alpha_{f_{CM}}^{22} = \frac{\alpha_{comp}^{22} - \alpha_m(1-\sqrt{V_f})(1+V_f\nu_m\frac{E_f^{11}}{E_m})}{\sqrt{V_f}}$$

comp: composite
f: fibre
m: matrix
F: fibre packing factor

Experimental results

- Plots of measured fibre lattice strain vs. indirect measurement



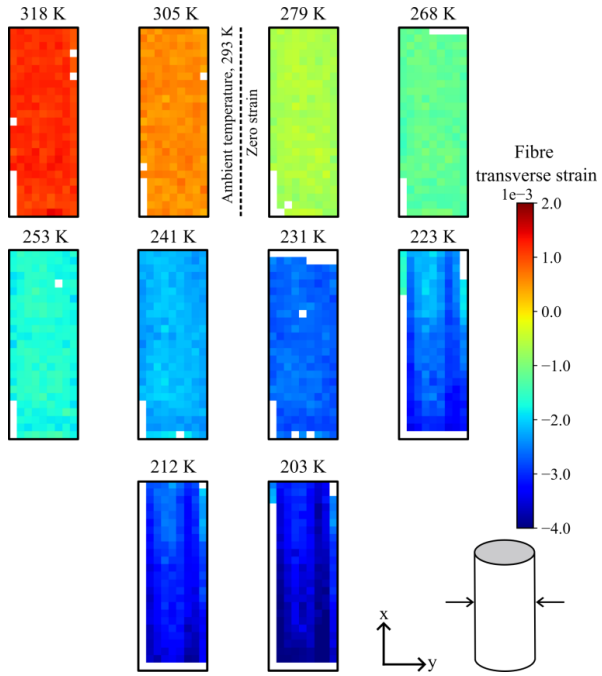


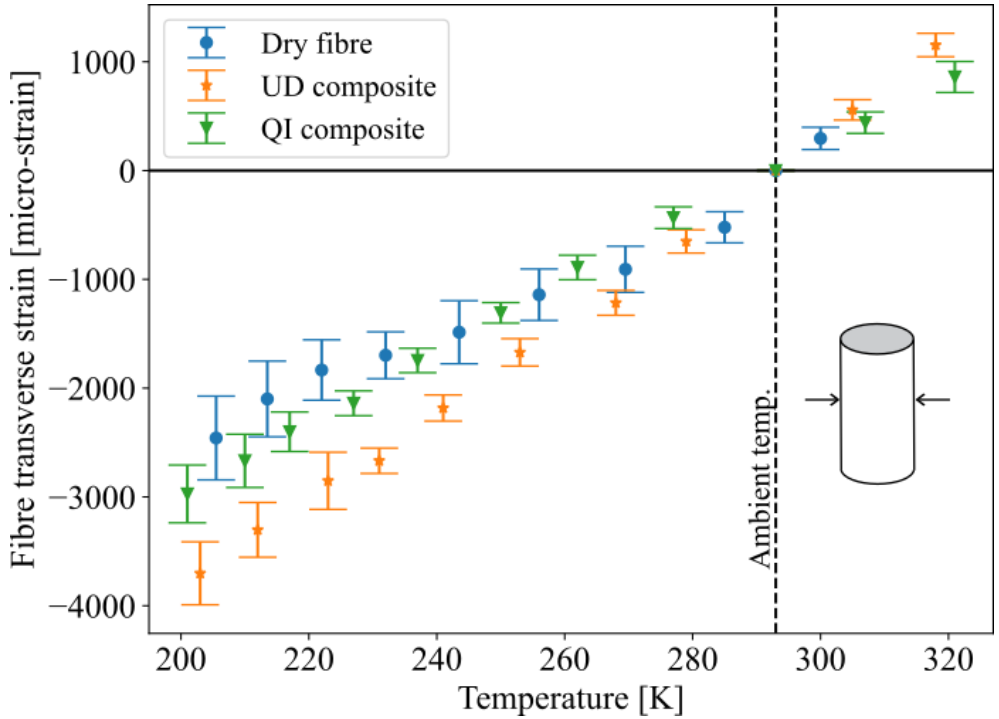
- Comparison of thermally induced dry fibre lattice strain with bulk CTE, highlighting variability due to model dependent assumptions (Gaitonde and Lowson, 1991).
- SH showed the most discrepancies but matched the reported α_f^{22} ($5.2 \times 10^{-6}\ K^{-1}$) at elevated temperature.
- This suggests macroscopic α_f^{22} $\neq$ microscopic α_f^{22} ($26.2 \times 10^{-6}\ K^{-1}$), likely due to crystalline relaxation from defects (micropores, microcracks, crimps) reducing bulk expansion to ~30% of crystallite deformation.

Experimental results

- 2D fibre lattice strain mapping
- Deconvolution of fibre lattice strain at different fibre orientation

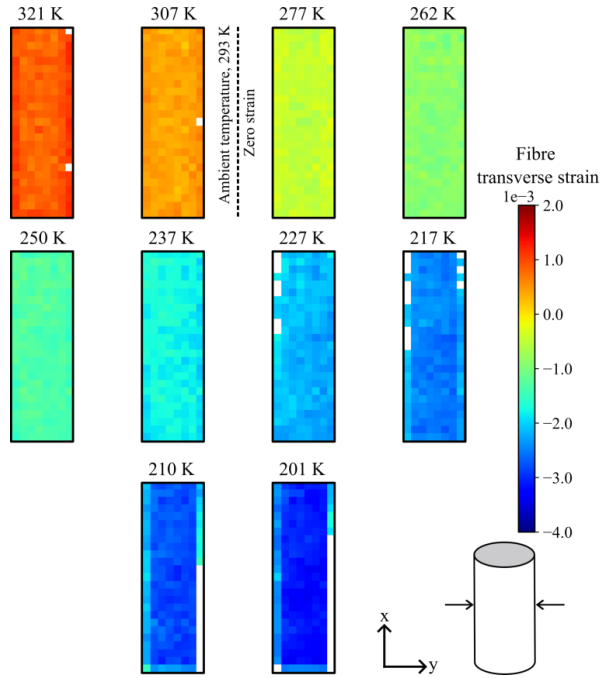
UD laminate





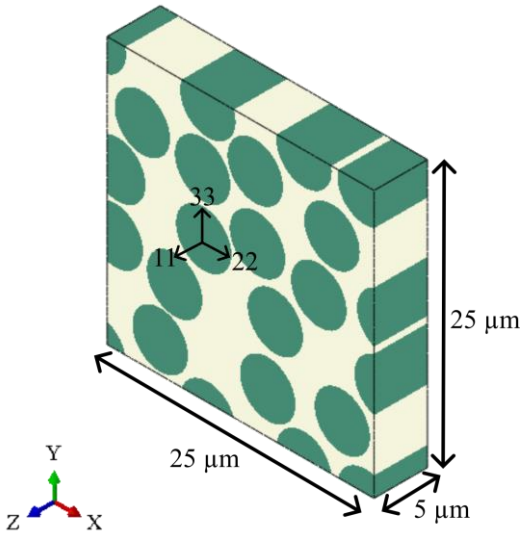
QI laminate

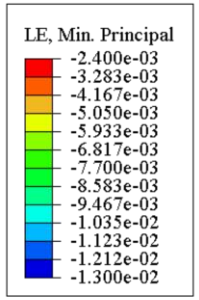
Experimental results



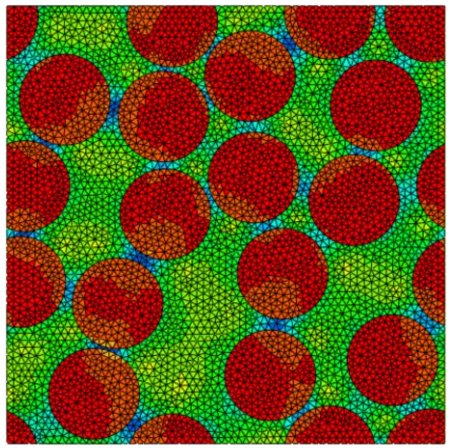
- The average lattice strain was determined and plot against each other
- Thermal induced strain: UD > QI > Dry fibre due to the existing of resin matrix and ply orientation

UD laminate

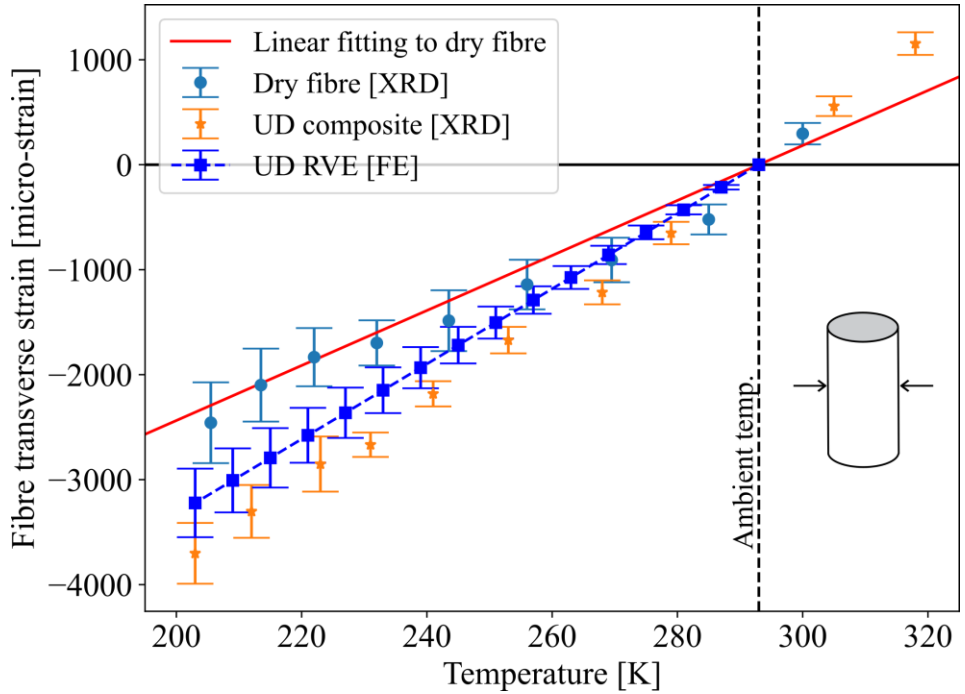




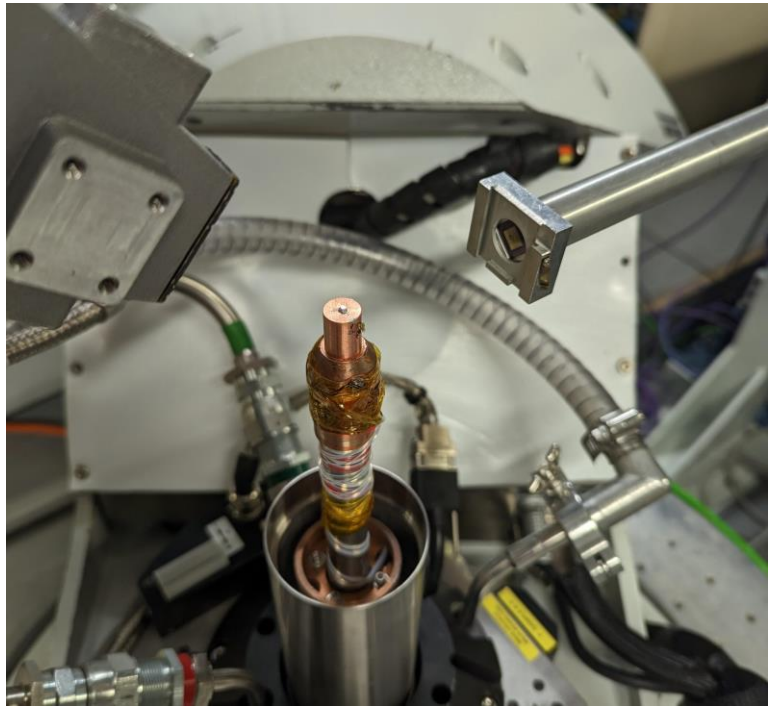
QI laminate

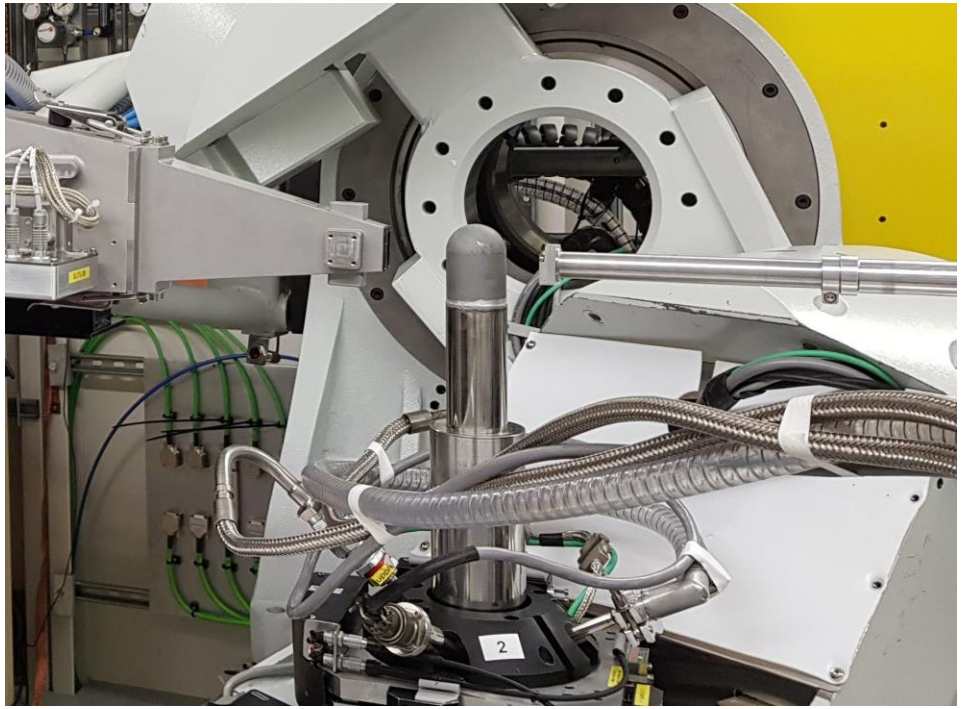


Finite element results



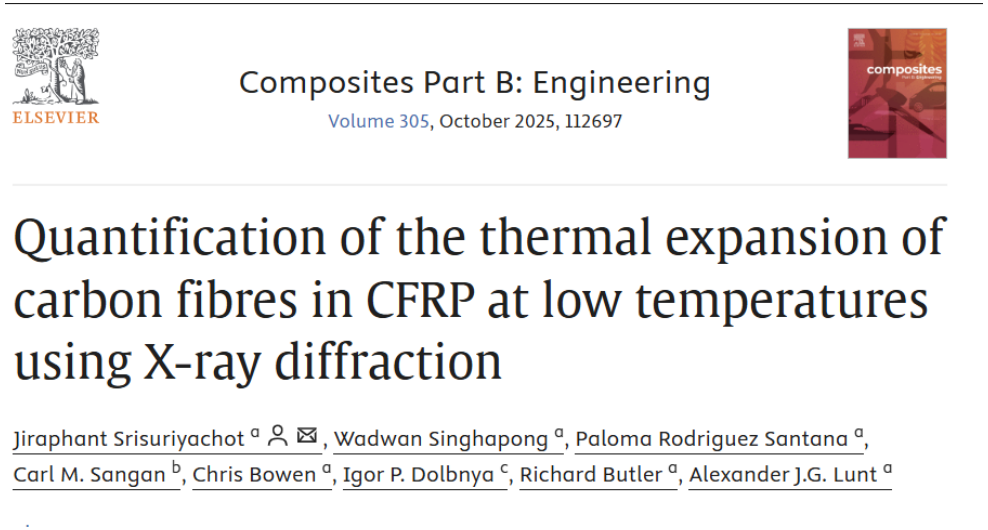
- Thermal induced strain in fibre compared with microscale FE model
- ~13% error between experimental and FE model at ~200 K





Future work

- Develop a cryostat that is compatible with a beamline in order to reach 20 K or even lower
- Different stacking and fibre volume fraction to fully understand the effect of the fibre orientation



Beryllium dome, I16
Diamond Light Source, UK

Conclusion

- Measurement directly on fibre lattice strain in the transverse direction
- Fibre lattice strain ≠ Fibre strain → crystalline relaxation
- Deconvolution of fibre lattice strain at different fibre orientation
- Understanding the impact of the existing of resin and stacking sequence
- Accepted by Composites Part B: Engineering

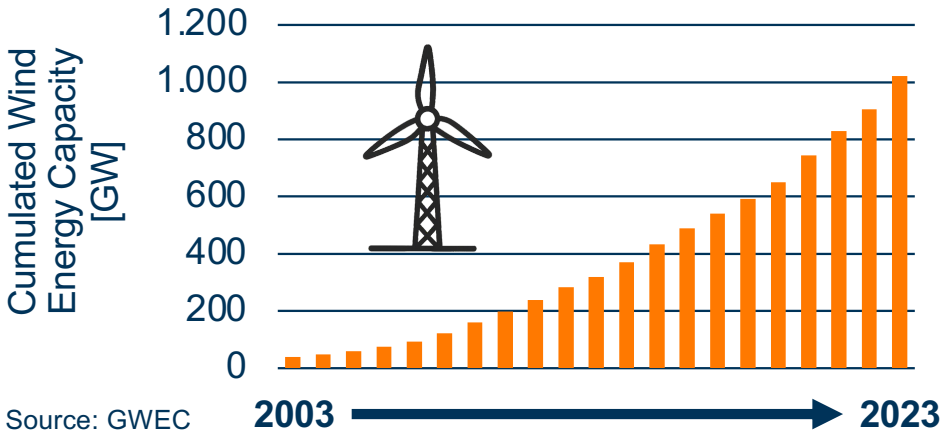
Detection of Progressing Material Defects with FMCW Radar Signals



24th International Conference on Composite Materials
Baltimore, August 6, 2025

Florian Puch; Benedikt Neitzel; Maximilian Lang; Marton Steierlein; Felix Hellmann; Thomas Dallmann

Diese/r Präsentation/ Bericht ist durch Mitarbeiter des Fachgebietes Kunststofftechnik der TU Ilmenau erstellt. Die Verwendung, Verteilung, Zitierung und Vervielfältigung – auch auszugsweise – zum Zwecke der Weitergabe an Dritte ist nur mit vorheriger schriftlicher Zustimmung der Autoren gestattet.

Motivation

- A significant increase of wind energy capacity and increasing wind turbine blade sizes can be observed.
- As highly complex composite materials wind turbine blades are prone to a variety of defects.
- Non-destructive testing (NDT) is used for structural health monitoring (SHM) and can extend the service life of wind turbine blades

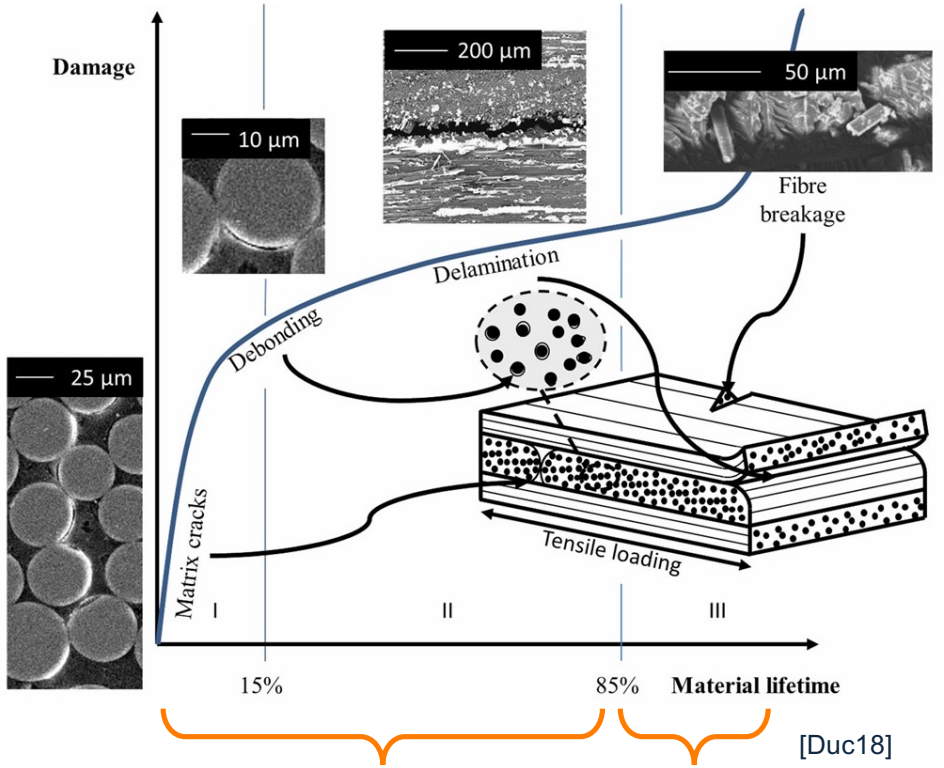
→ **This feasibility study shall explore, if radar can potentially used as NDT method for in field SHM.**

Evolution of damage in composite materials

Matrix cracks:

- Force transmission to fibers is impaired

Debonding:



- Detachment of the matrix from the fiber at the fiber-matrix interface
- Loss of adhesion, fiber cannot absorb load in this area

Delamination:

- Detachment of layers in the fiber composite component
- Complete loss of shear strength between the detached layers

Fiber breakage:

- Tearing of the fiber, can no longer absorb forces
- Accelerates all other failure mechanisms

[Duc18]

KTI The SPIRIT of science TECHNISCHE UNIVERSITÄT ILMENAU

Non-destructive testing (NDT) of composite structures

Detection of internal and surface defects

- Identification of manufacturing errors and incipient damage
- After manufacturing and during operational phase (SHM)

✓ Confirmation of structural integrity

✓ Prevention of catastrophic failures

✓ Assessment of aging, fatigue and failure

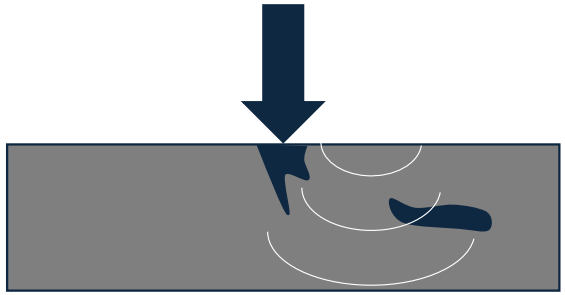
✓ Condition-based maintenance reduces costs

  ✓ Minimized downtime

  ✓ Avoidance of unnecessary replacements

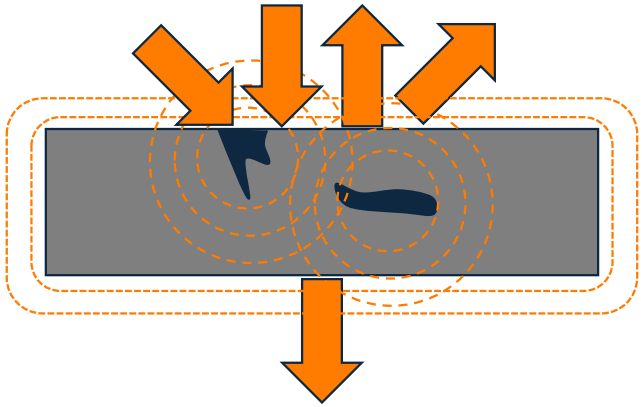
🧠 Challenging in-situ implementation

🧠 High data volumes need to be interpreted



🧠 Material and geometry complexity need to be accounted for

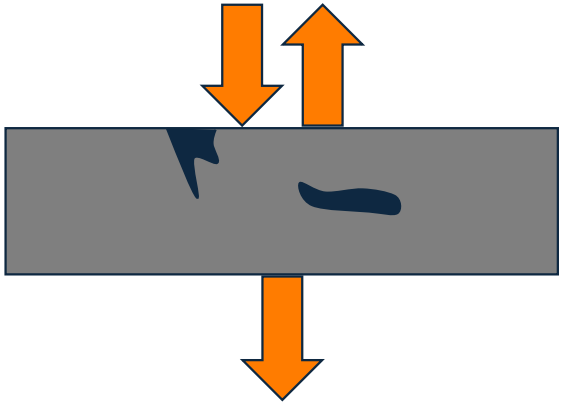
→ Extension of lifespan and reduction of waste and costs



KTI The SPIRIT of science TECHNISCHE UNIVERSITÄT ILMENAU

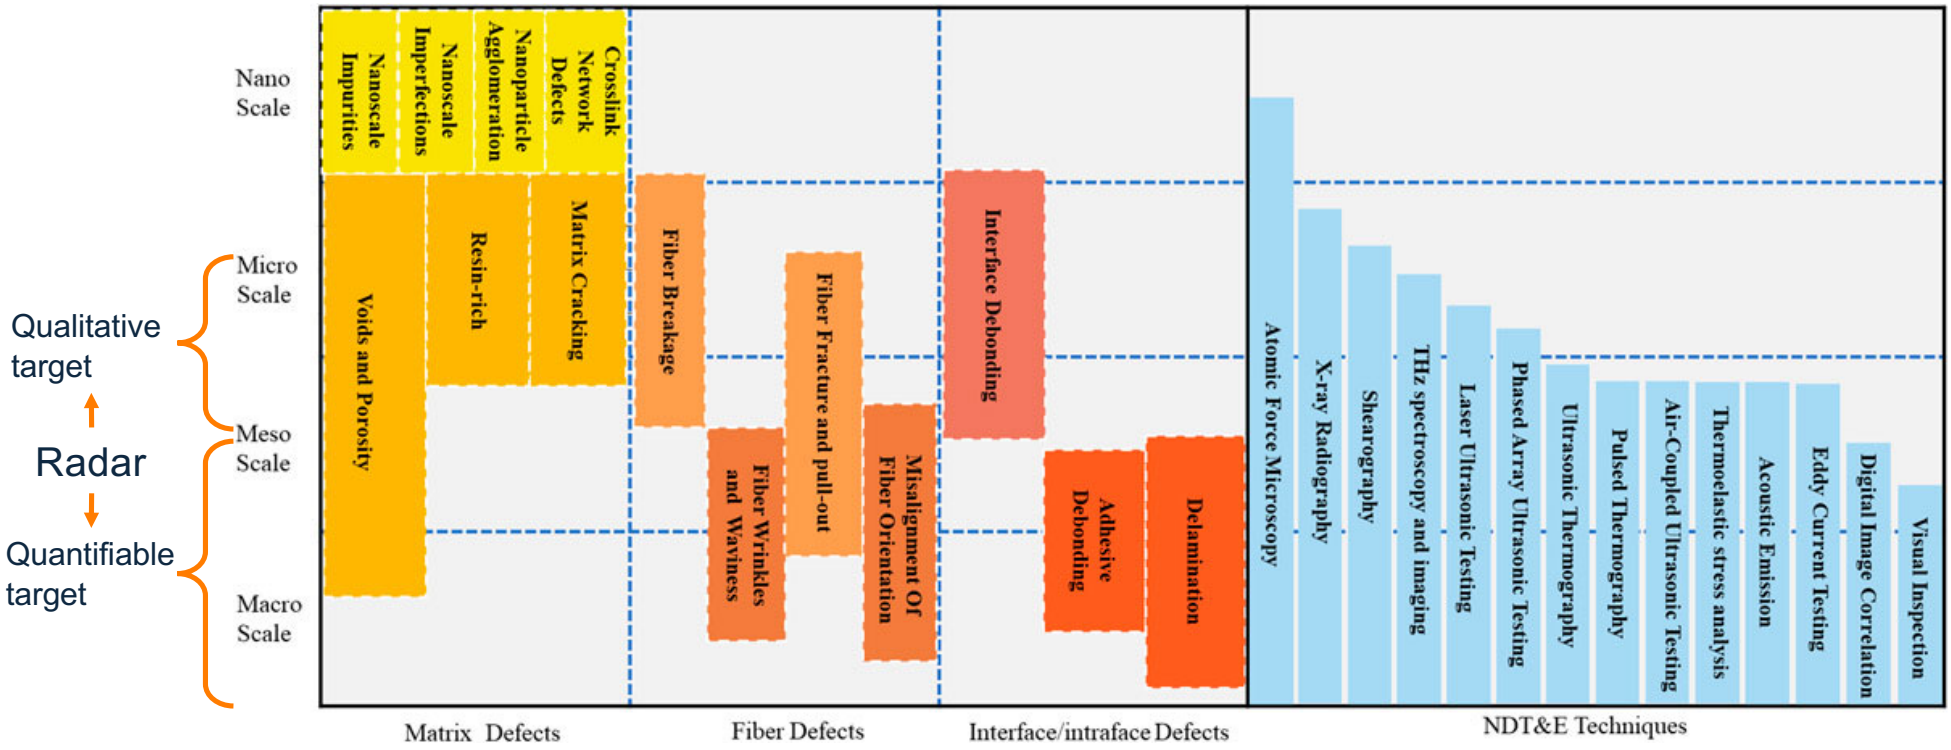
Non-destructive testing methods

Active or passive excitation



Response

- Visual inspection
- Infrared thermography
- Magnetic particle testing
- Eddy current testing
- Acoustic emission testing
- Ultrasonic testing



Reflection / transmission

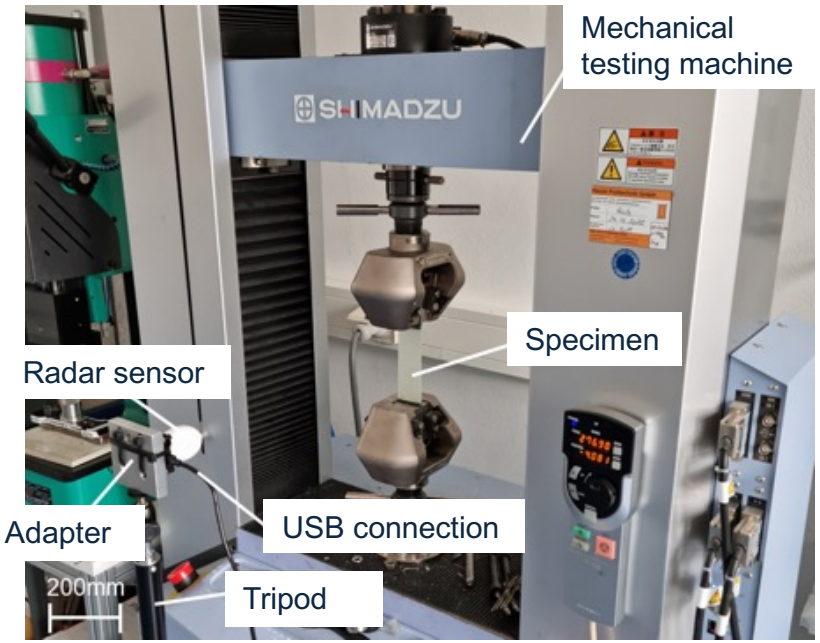
Overview of NDT-methods



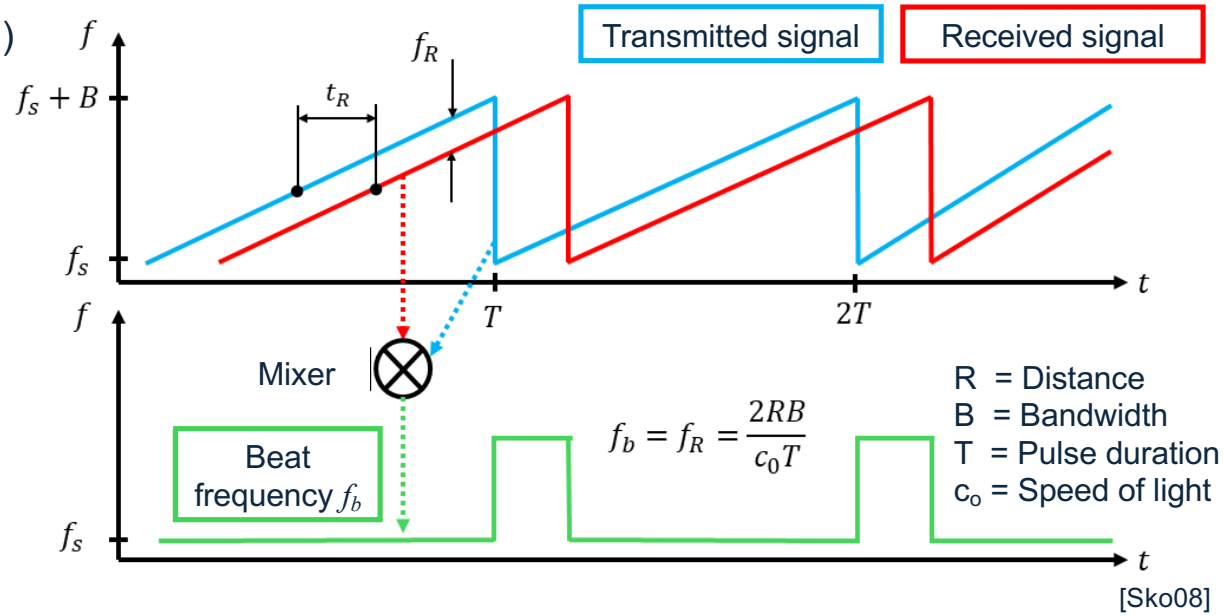
[Che22]

KTI The SPIRIT of science TECHNISCHE UNIVERSITÄT ILMENAU

Experimental setup

- Tensile test according to DIN EN ISO 527-4
- Change in the amplitude of the echo is observed
- Parameter settings for clear amplitude allocation
- Frequency spectrum defined as 75-85 GHz
- Bandwidth of 10 GHz

KTI The SPIRIT of science TECHNISCHE UNIVERSITÄT ILMENAU

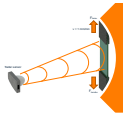


Frequency modulated continuous wave (FCMW) radar

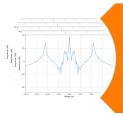
Radar in general:

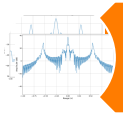
- Electromagnetic waves in the range from 100 MHz to 100 GHz (microwave radiation)
- Transmitter sends a signal, receiver receives the echo
- Echo is analyzed to obtain information about direction, distance and relative speed to the object

FMCW radar:



- Frequency of the signal changes continuously
- Distance determination by determining the frequency difference between the transmitted and received signal





[Sko08]

Sample with delamination

KTI The SPIRIT of science TECHNISCHE UNIVERSITÄT ILMENAU

Summary

- NDT and SHM are essential methods to detect failures and to increase service life of composite parts.
- An initial study on a contactless method using FCMW radar was presented.
- The measurement uncertainty of the presented method was determined.
- First results indicate that the measurement method using FCMW radar may be suitable to detect (larger) failures in glass fiber reinforced composite parts.
- Further investigations are necessary.

Presentation outline

- Transverse matrix cracking in cross-ply laminates
- Experimental setup
- Results
- Conclusions and outlook

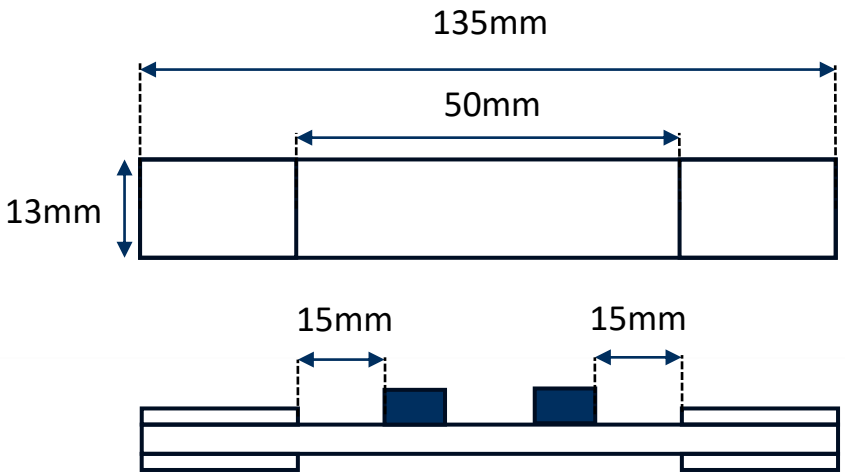
*spyros.spyridonidis@bristol.ac.uk

Transverse Cracking

Transverse Cracks schematic (1)

- The first damage mode under most of the thermomechanical loading cases
  - Immediate sequencies in thermomechanical properties and precursor for further damage types.

Aim



Experimentally observation of the damage evolution using in-situ microscopy and acoustic emission under quasi-static loading

Conclusions and Outlook

Conclusions

- Oblique, and c-shaped cracks were observed along the formation of straight cracks, without necessary interaction of other cracks.

- The nature of nature of matrix cracking is stochastic not only in terms of spatial distribution but also regarding the number of cracks

- Matrix cracking initiation and progression was captured from both experimental techniques, using microscopy data to validate acoustic emission data

Future Work

Acoustic Emission:

- Implement a classifier with the labeled acoustic emission data from matrix cracking

Microscopy

- Training the crack detection model with a wider dataset to increase the accuracy
- Check the sensitivity of the set-up, with quasi-isotropic layup configuration.

BACKGROUND

- Non-Destructive Testing (NDT) techniques are used for assessing the manufacturing quality of complex parts and for monitoring the life cycle of installed components.
  - Minimize downtime by allowing analysis to be conducted on-site via non-destructive means.
- Non-Destructive Testing (NDT) Techniques
  - Visual Testing
    - Primarily used for detecting macroscopic irregularities.
  - Computed Tomography:
    - Captures internal attenuated X-rays and converts them into electronic signals.
    - Suitable for evaluation of micro-cracks or defects such as voids and pores..
  - Ultrasonic Testing
    - Waves interact with the material (phase-array, c-scan, air-coupled, and laser).
    - For detection of fiber misalignment, localizing porosity, and delamination [Ref. 1.0].
  - Acoustic Emissions
    - Surface vibrations are captured by AE sensor and ultimately digitalized.
    - Most effective method for internal faults and damage type detection in CFRP.
    - AE signals affected by many factors (specimen, waveguide transfer function, sensors transfer function, etc.).
    - Features such as Risetime, Frequency, Energy, and CWT have been studied as the most suitable features for analysis as they carry information about AE source type [Ref. 7.0].

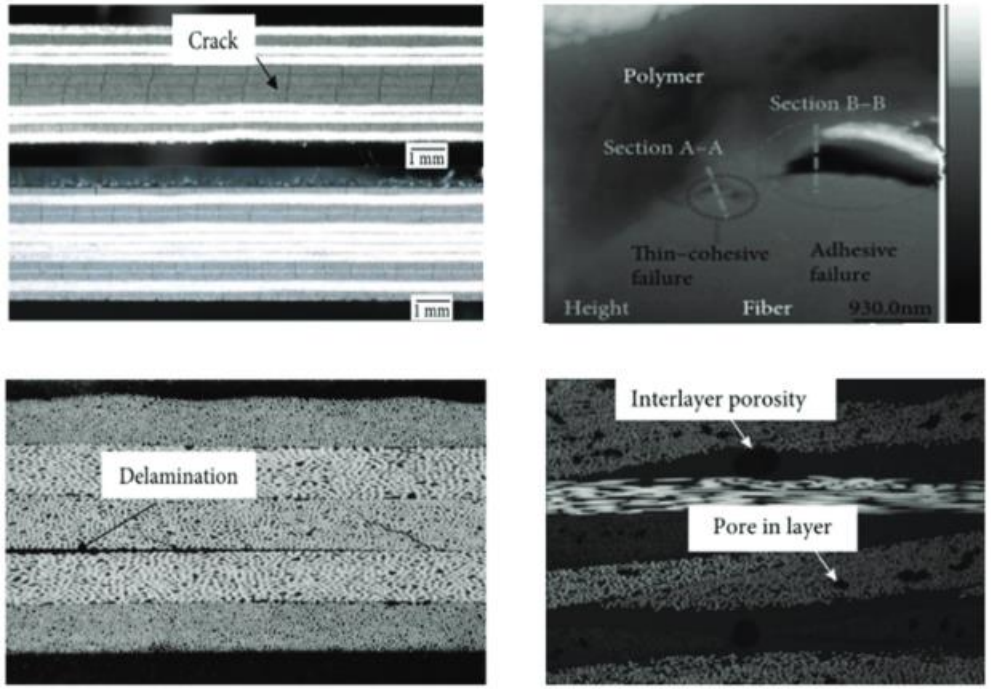

Figure 1. Common Type of Defects Analyzed in CFRP Through NDT Techniques [Ref. 1.0].

HSU-NIELSEN AE SOURCE

- Yields a consistent, replicable, burst acoustic signal if pencil lead is broken at the same angle and position each time.
- Excites a broad range of frequencies.
- Analyzed AE Features: Amplitude, Rise Time, and Energy.
  - Peak Detection Window of 200 µs.

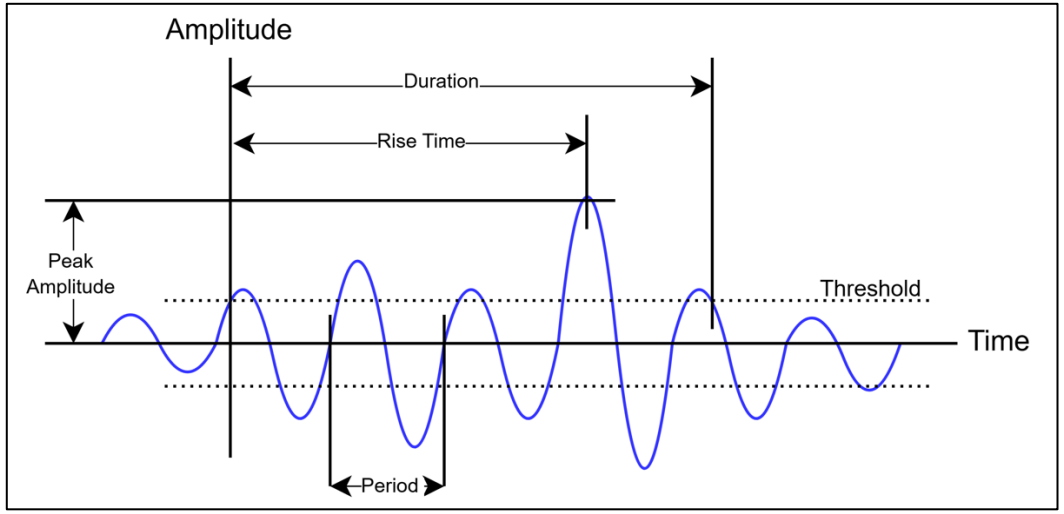

Figure 2. Acoustic Emission Features.

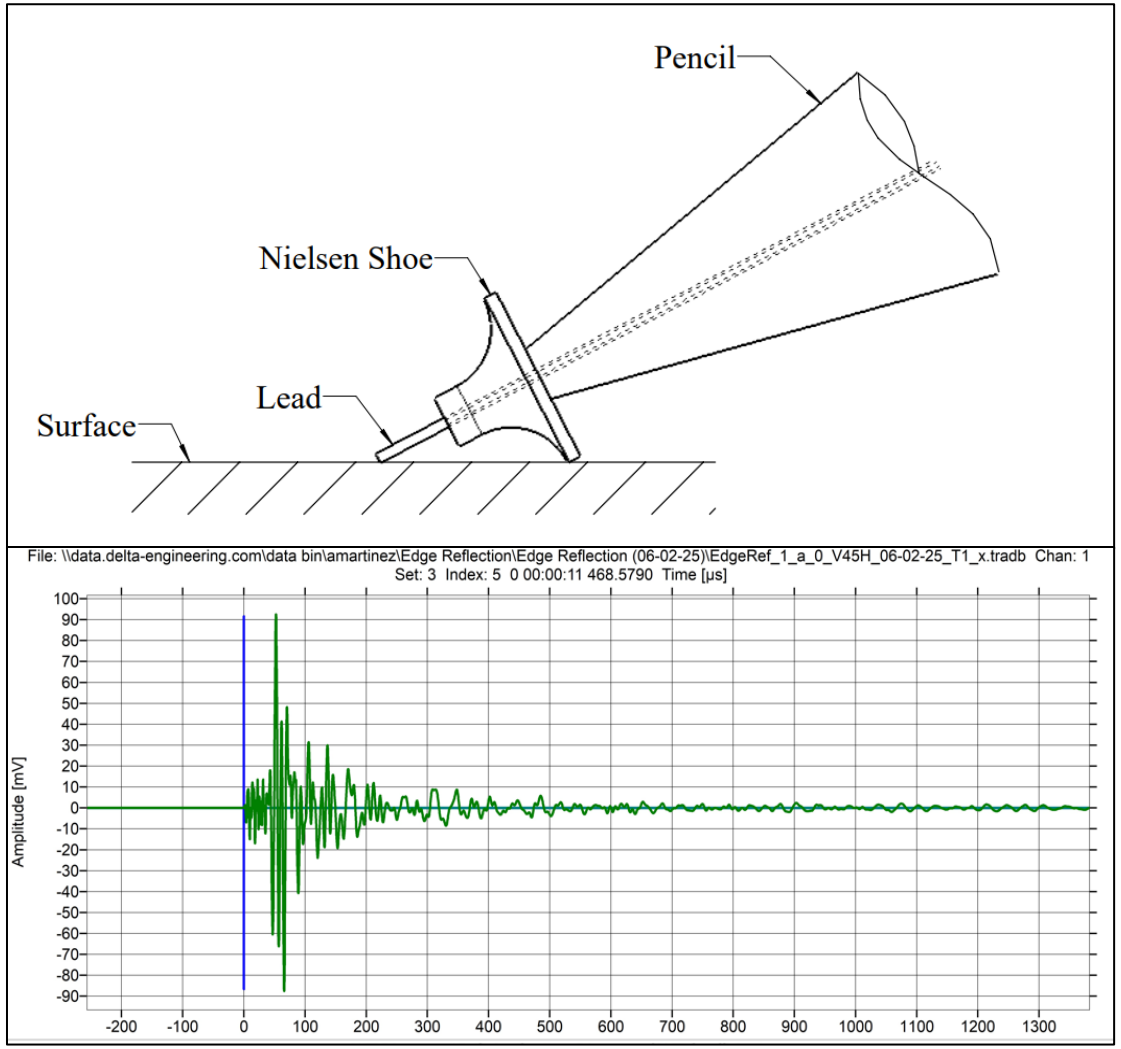

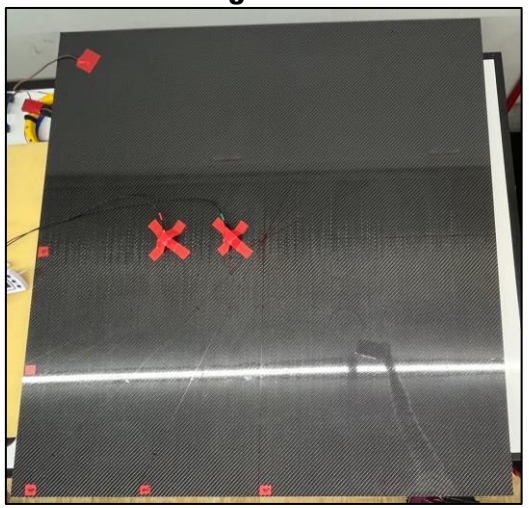

Figure 3. Hsu-Nielsen Pencil Lead Break (PLB) Technique.

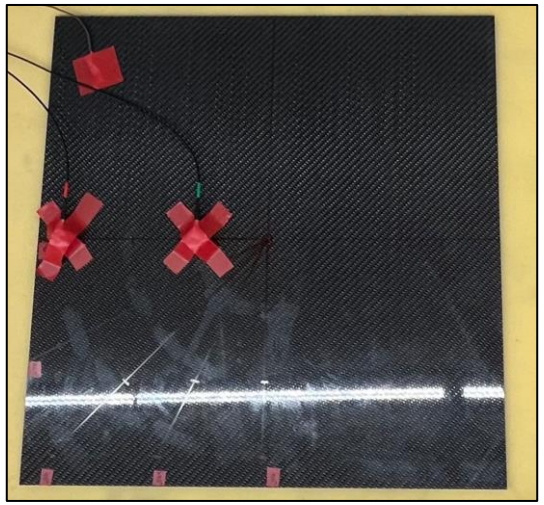
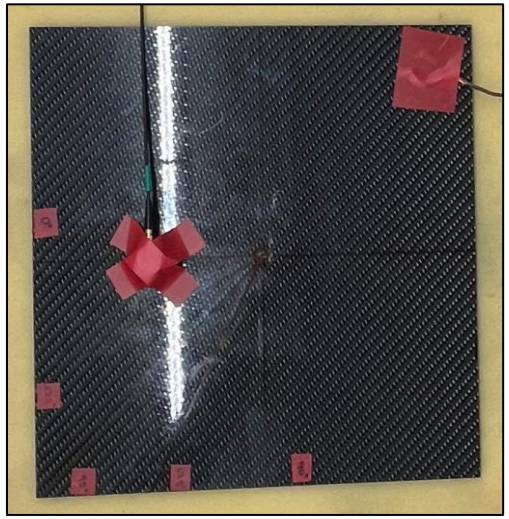
TEST SETUP - OVERVIEW



- ISO Conditions: 20°C, ~1.01 MPa.
- Performed 2 sets of 30 PLBs across three panels (6 plies of 12k twill weave carbon fiber).
  - Sensors were positioned at 8.7 cm and 26.2 cm.
  - Only one sensor was used for the smallest panel.
- Tested five angles: 0°, 22.5°, 45°, 67.5°, 90° for all panels.

Large Panel



Dimensions = 122.2 cm x 122.2 cm x 4 mm.

Medium Panel

Dimensions = 58.7 cm x 58.7 cm x 4 mm.

Small Panel

Dimensions = 34.5 cm x 34.5 cm x 4 mm.

CONCLUSIONS AND RECOMMENDATIONS

CONCLUSIONS:

- The risetime is significantly affected by interference patterns between the primary waveform and the reflection.
- Amplitude was generally consistent during all tests performed for the different orientation angles and panel sizes.
- There was a large data spread for energy values at a 0° orientation angle compared to 22.5° and 45°. The highest energy magnitude was at 0° whereas the lowest magnitude was at 22.5°. The energy of a signal which is dependent on the duration and amplitude is significantly affected by reflections.
- Changes in waveform shapes indicate the presence of low and high frequency edge reflections. Interference and attenuation of a signal throughout the visualized plots can affect the AE features discussed above.
- When edge reflections are of concern, features such as energy may be better assessed for just the beginning of the signal.

RECOMMENDATIONS:

- Implementation of sensor mounts is highly recommended to keep PLB-to-Sensors and Sensor-to-Sensor distances consistent.
- Preliminary analysis of reflection arrival times is required to evaluate how risetime and energy are affected during post-processing.
- It is recommended to conduct testing on areas free from nearby bonded or fastened structure (ex. center of skin panel).

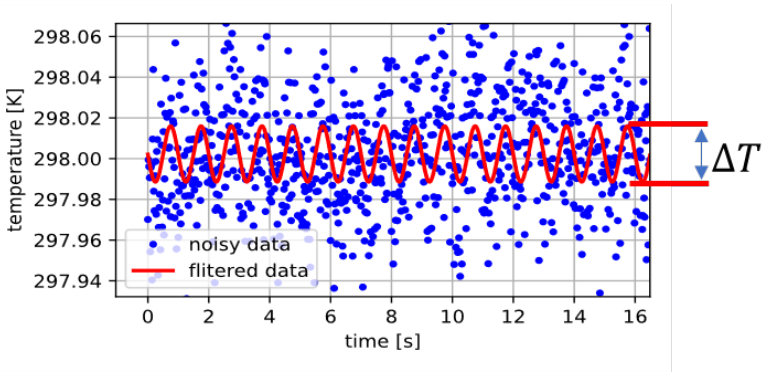
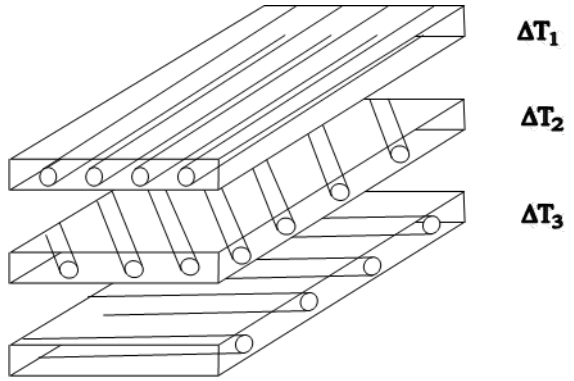
DIC

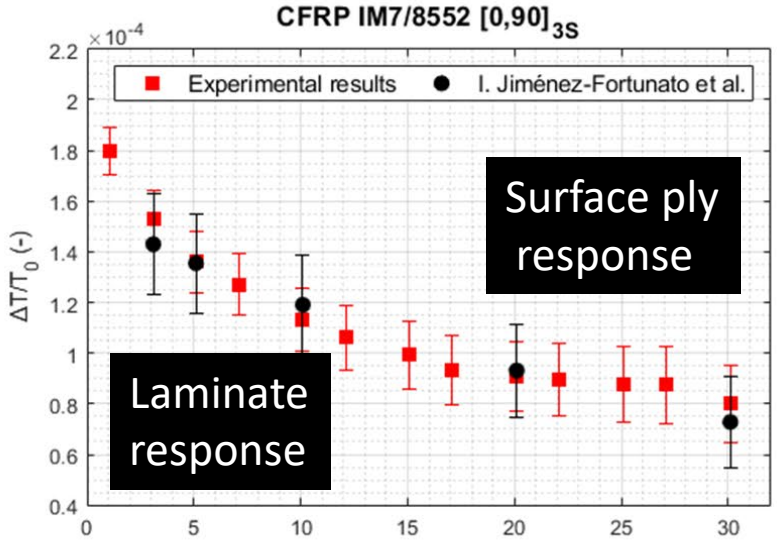




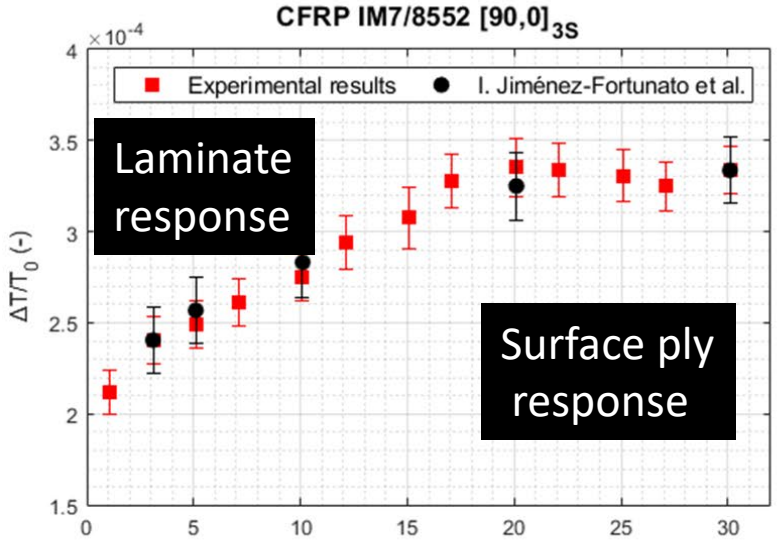
IR, TSA

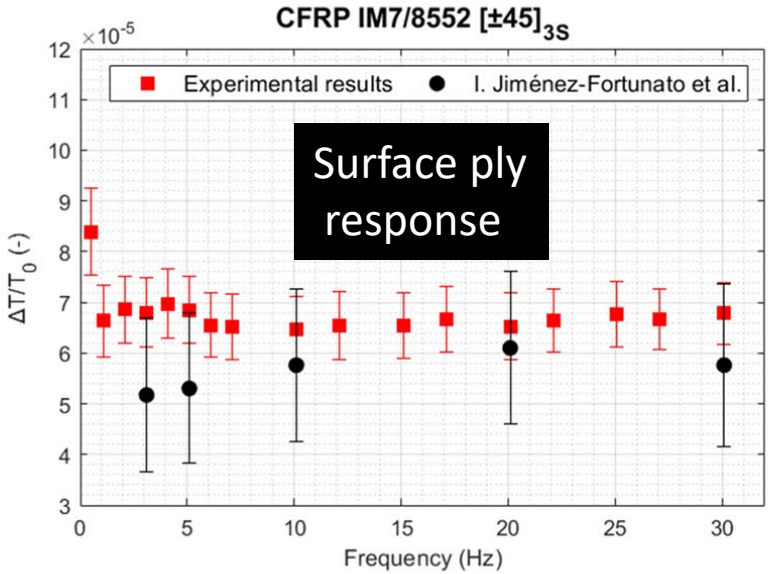
Thermoelastic stress analysis (TSA)

- TSA relies on the measurement of a small temperature change from a specimen subject to cyclic loading:



$$\Delta T = -T_o \frac{1}{\rho \cdot c_p}(\alpha_1 \Delta\sigma_1 + \alpha_2 \Delta\sigma_2)$$





- Assumption is temperature change occurs under adiabatic conditions
- In CFRP laminates heat conduction occurs as a result of the degree of anisotropy (thermal and mechanical) and high thermal conductivity
- Increasing the strain rate (loading frequency) reduces thermal diffusion but is limited in large structural testing and high loading rate induce viscoelastic heating

ABSTRACT

Non-Destructive Testing (NDT) techniques have distinct advantages and limitations, making their selection highly dependent on factors such as the material being tested, the part geometry, the expected defects, or the experimental conditions. To address their limitations, researchers and industry professionals have widely explored ways to optimise existing NDT techniques. A promising direction is Data Fusion, extensively explored in Structural Health Monitoring (SHM), which combines data from multiple inspection techniques to enhance defect detection and material characterisation.

In this study, a Data Fusion methodology is implemented to combine quantitative results from InfraRed Thermographic (IRT) inspection and Lamb Waves inspection, an advanced Ultrasonic Testing (UT) technique adapted to relatively thin structures such as plates. IRT enables rapid, non-contact detection of surface and near-surface defects through heat propagation analysis. In this work, thermal diffusivities are calculated from cooling curves extracted from thermal maps. Lamb Waves are generated and measured using a fully non-contact system; their interaction with internal defects is quantified using RMS energy values, which provide insights into subsurface damage.

However, Lamb Wave propagation in anisotropic, layered composites remains challenging, with possible misdetections. Multiple CFRP samples of varying geometries and thicknesses (1.6 mm to 6.4 mm), with artificial and impact-induced delaminations, were tested. Results showed that while each method has detection limitations, their fusion offers enhanced characterisation. This is especially valuable for complex defects such as lightning-induced delaminations or deep-layer damage.

By combining IRT's surface sensitivity and Lamb Waves' subsurface reach, the fusion approach improves not only detection but also the characterisation of damage mechanisms, crucial for composite materials with complex architectures. Future work will focus on improving individual techniques, such as refining signal processing algorithms for Lamb Waves inspection, and extending the investigated dataset to a wider range of composite structures and defects.

1 INTRODUCTION

The increasing use of Carbon Fibres Reinforced Plastics (CFRP) materials in aerospace, automotive and energy sectors has led to growing demands for highly reliable and efficient Non-Destructive Testing (NDT) techniques. Due to the complex, anisotropic and layered nature of these materials, detecting and characterising internal defects such as delaminations remains a major challenge. To address this issue, industries and researchers have been widely investigating the performance of NDT methods to improve their efficiency and accuracy and obtained major advances over the last decades. For example, the introduction of X-Ray Computed Tomography (XRCT) has transformed Radiographic Testing (RT) capabilities by supplying 3D volumetric imagery methods. The development of Phased Array Ultrasonic Testing (PAUT) or non-contact systems based on guided waves revolutionised classic Ultrasonic Testing (UT) abilities [1–3].

However, the limitations inherent to each of these methods often persist, particularly as they often come from the application cases or the CFRP materials. In this context, Data Fusion has emerged as a promising approach in the field of Structural Health Monitoring (SHM). By combining data from different inspection techniques, Data Fusion aims to provide a more comprehensive and robust understanding of structural integrity. This integration can take various forms, from simple visual overlays to more advanced mathematical or statistical models that merge complementary parameters. The goal is not only to increase detection reliability, but also to enrich the interpretation of damage features by leveraging the distinct sensitivities of each technique [4–10].

This study explores the application of Data Fusion to InfraRed Thermography (IRT) and Ultrasonic Lamb Waves inspection, two NDT methods based on different physical principles. While IRT offers rapid detection of shallow discontinuities by analysing thermal response on the surface [2,11], Lamb Wave inspection enables the detection of internal defects by analysing the interaction of propagating guided ultrasonic waves with material discontinuities [12,13]. While these two techniques are particularly well-suited to thin-walled CFRP plate inspection, each of them remains subjected to physical and practical limitations when applied individually. IRT is inherently limited in depth penetration due to the thermal diffusion nature of heat propagation, and its sensitivity decreases with increasing material thickness or with defects located deep beneath the surface. Conversely, Lamb Wave inspection suffers from complex propagation behaviour in anisotropic and heterogeneous materials such as CFRPs, often leading to ambiguous or incomplete defect characterisation. Wave mode conversion, dispersion, and scattering can significantly affect signal interpretation, especially in the presence of geometrical complexity or stiffness variations [12,13].

The present work proposes a quantitative fusion approach applied to CFRP samples with known delamination features. Thermal diffusivities are extracted from IRT cooling curves, while Root Mean Square (RMS) energy values are calculated from Lamb Wave measurements to assess internal damage. The study includes a variety of sample configurations, incorporating different layups, thicknesses, and delamination types. Particular attention is paid to lightning-strike-induced delaminations, which represent a challenging case due to complex damage morphology and depth.

The paper is organised as follows: Section 2 presents the experimental samples structure and their manufacturing process, particularly the insertion of defects. Section 3 describes the experimental, data acquisition and data extraction process for the two NDT methods used in the study: IRT and UT. Section 4 details the Data Fusion methodology. The results of the study are presented and discussed in Section 5. Finally, Section 6 concludes the study and proposes directions for future work.

2 EXPERIMENTAL SAMPLES

Three types of CFRP samples were investigated in this study, as shown in Fig. 1.
The stiffened plates LW50S and LW75S are 450 × 450 mm² CF/epoxy laminates (T800S/3900-2B, autoclave-cured at 180 °C) with a quasi-isotropic 8-ply lay-up [45/0/–45/90]s. A central stiffened area (100 × 450 mm²) was created by adding eight plies with a [-45/0/45/0]s lay-up. Artificial delaminations were introduced by inserting a Teflon film between the base and stiffened zones, with widths of 50 mm and 75 mm for LW50S and LW75S, respectively.
The flat plates LW16 and LW32, also 450 × 450 mm² and made from the same CF/epoxy system, consist of 16 and 32 plies with lay-ups $[45/0/–45/90]_{2s}$ and $[45/0/–45/90]_{4s}$, respectively. LW16 contains Teflon-based delaminations of various sizes (10 to 50 mm), while LW32 includes delaminations at different depths (from 8 to 24 plies).
Finally, LS1 and LS2 are 150 × 150 mm² plates made of plain weave carbon fabric and a conductive Polyaniline/Phenol (PDPD) resin, as described in [14], with a $[0/90]_{10}$ lay-up. Artificial lightning strike tests were performed using −100 kA peak current pulses, leading to surface swelling in circular areas of about 30 mm diameter. These damaged zones are later segmented into three subregions based on thermographic imaging: a black ring, a white ring, and a grey centre.

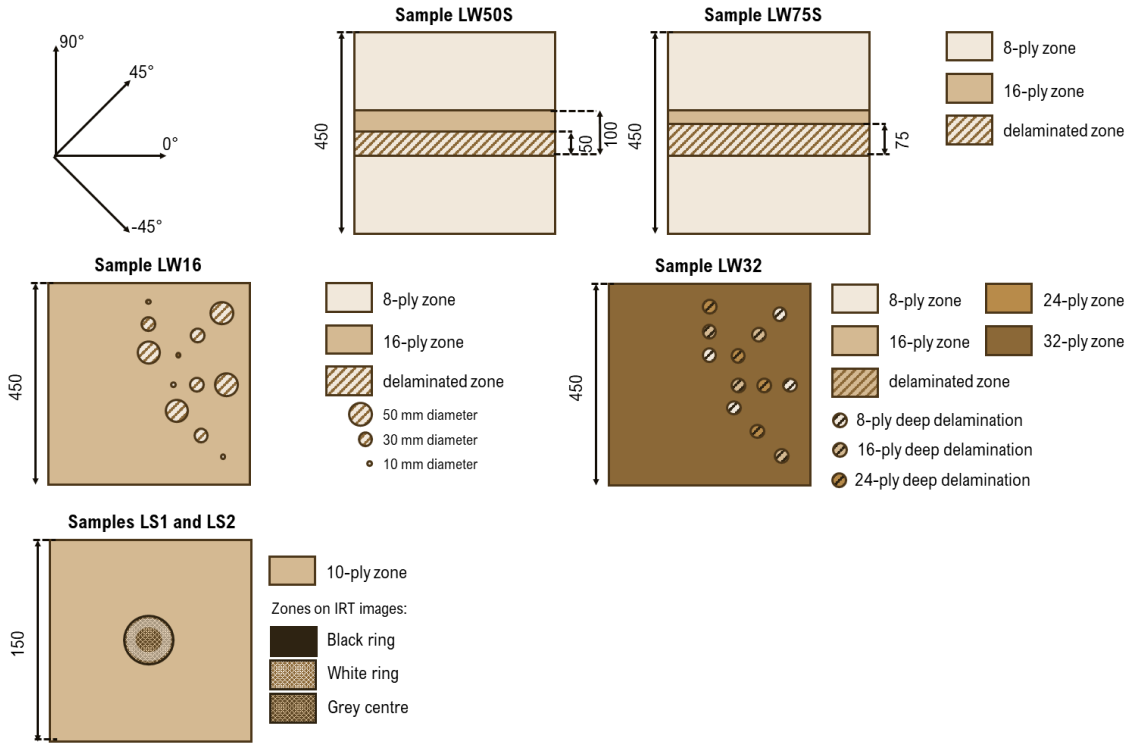

Fig. 1: Experimental samples' configuration representation (top view)

3 NON-DESTRUCTIVE TESTING

3.1 InfraRed Thermography (IRT)

3.1.1 Experimental system

The InfraRed Thermography system used in this study is the Active Pulse Thermography setup from Echotherm Thermal Wave Imaging [15]. It consists of a hood enclosing the inspected area, equipped with a high-energy flash lamp and a FLIR SC4000 infrared camera, connected via an umbilical cable to a mobile control unit containing the flash power source, a sample support, and a computer running MOSAIQ 4.2 analysis software.

For the inspection, the sample is positioned on the dedicated support and the hood is placed directly above it to ensure consistent illumination and thermal capture. Due to their large surface area, samples LW50S, LW75S, LW16 and LW32 were inspected in four successive scans (upper left, upper right, lower left, and lower right). A flash pulse of 30 ms is emitted for each scan, after which surface temperature evolution is recorded for a duration T_{shot} at 300 frames per second by the infrared camera. The acquired thermographic data are then post-processed to generate Thermographic Signal Reconstruction (TSR) cartographies.
In this study, log–log cooling curves were extracted at selected points across the sample surfaces from these TSR maps in order to estimate the thermal diffusivity α.

3.1.2 Data extraction

To evaluate the thermal behaviour of the CFRP samples, thermal diffusivity α was selected as the key parameter, as it reflects the material's ability to conduct heat relative to its capacity to store it. For each sample, log–log cooling curves were extracted from TSR cartographies at selected measurement points, allowing the determination of α based on the breaking time T_{break}, based on the relation:

$$\alpha = \frac{t^2}{\exp(T_{break})} \quad (1)$$

With t the thickness of the material and T_{break} the breaking time of the cooling curve, as shown in the Fig. 2.
The measurement points are selected for each sample depending on their configuration, in order to compare thermal behaviour in different zones such as delaminated zones and healthy zones, or zones of different thicknesses. On the stiffened samples (LW50S and LW75S), measurement points were positioned in zones of varying thickness (8-ply, 16-ply) and above the artificial delamination, with twelve and ten points respectively. For the small delamination plates (LW16 and LW32), sixteen points were selected across healthy areas and Teflon-inserted defect zones. Finally, on the lightning-strike-damaged samples (LS1 and LS2), the analysis focused on four distinct zones identified from the TSR images and represented in Fig.1: the healthy background, a peripheral "black ring", an intermediate "white ring", and a central "grey zone."
Fig. 2 shows an example of IRT results obtained from this method for LW75S sample, with a) the localisation of measurement points (different colours and shapes representing different zones of interest), b) the log-log curves extracted from each of these measurement point with an example of determination of T_{break} and c) the thermal diffusivities obtained from equation (1) using the measured T_{break}. In all cases, thermal diffusivity values were calculated with associated uncertainties, using a recording duration T_{shot} = 9.3 s and a frame rate of 300 fps. This localised quantification of α enables the identification of material heterogeneities and delamination-affected areas, offering a more informative characterisation than surface temperature mapping alone. Fig. 3 shows the thermal diffusivities calculated for all measurement points of each sample, along with a localisation of these points.

3.2 Lamb Waves

3.2.1 Experimental system

This study uses a fully non-contact system to extract Lamb Wave propagation data from the experimental samples. The excitation is performed using a Laser Induced Plasma Shock Wave (LIPSW) setup, based on a SURELITE III-10 Nd:YAG laser (5 ns pulse, 1064 nm wavelength, 9.5 mm beam diameter, 850 mJ energy), focused through a plano-convex lens. At a standoff distance d = 10 mm from the surface, a plasma is generated and the associated shock waves, encountering the surface, are the source of Lamb Waves propagation along the experimental plate. The response is measured using a

Scanning Laser Doppler Vibrometer (SLDV). For samples LW50S, LW75S, LW16 and LW32, a Polytec PSV-500 system (He-Ne laser, 0–20 m/s velocity range) was used, while the new-generation Polytec Q-tec system was employed for LS1 and LS2. The experimental setup used in this study has been widely described in [13].

3.2.2 Data extraction

Lamb Wave propagation was measured over predefined zones on each sample using point-by-point acquisition with the SLDV system. For the stiffened samples (LW50S and LW75S), a 200 × 200 mm² central area was scanned with a 2 mm spatial step in both directions, resulting in 10,201 points, each recorded over 0.8 ms at 2.56 MHz. The resulting data formed a matrix of 10,201 columns (measurement points) by 2048 rows (time samples). For the flat plates (LW16 and LW32), the scanned area was extended to 400 × 400 mm² to cover nearly the entire surface, using the same 2 mm spatial resolution. Each point was recorded over 1.6 ms at 3.125 MHz, resulting in matrices of 40,401 points × 5000 time samples. For the lightning strike samples (LS1 and LS2), the scanned area was set to 140 × 140 mm², again with 2 mm resolution. Signals were recorded for 1 ms at 3.125 MHz, yielding matrices of 5041 columns × 3125 rows.
To quantify the signal energy at each point, the Root Mean Square (RMS) value was computed using the standard formula:

$$RMS = \sqrt{\frac{1}{n}\sum_{i=1}^{n} {S_i}^2} \tag{2}$$

Where S_i is the signal amplitude at time step i, and n is the total number of time samples.
The RMS values represent the average energy of the Lamb Wave signal at each surface point. High RMS values may indicate energy concentration due to reflections, scattering from defects, or local changes in wave amplitude, potentially linked to delaminations or thickness variations. Conversely, low RMS values suggest attenuation or limited interaction with structural features. These values are mapped across the scanned areas to generate RMS cartographies, shown in Fig. 4.

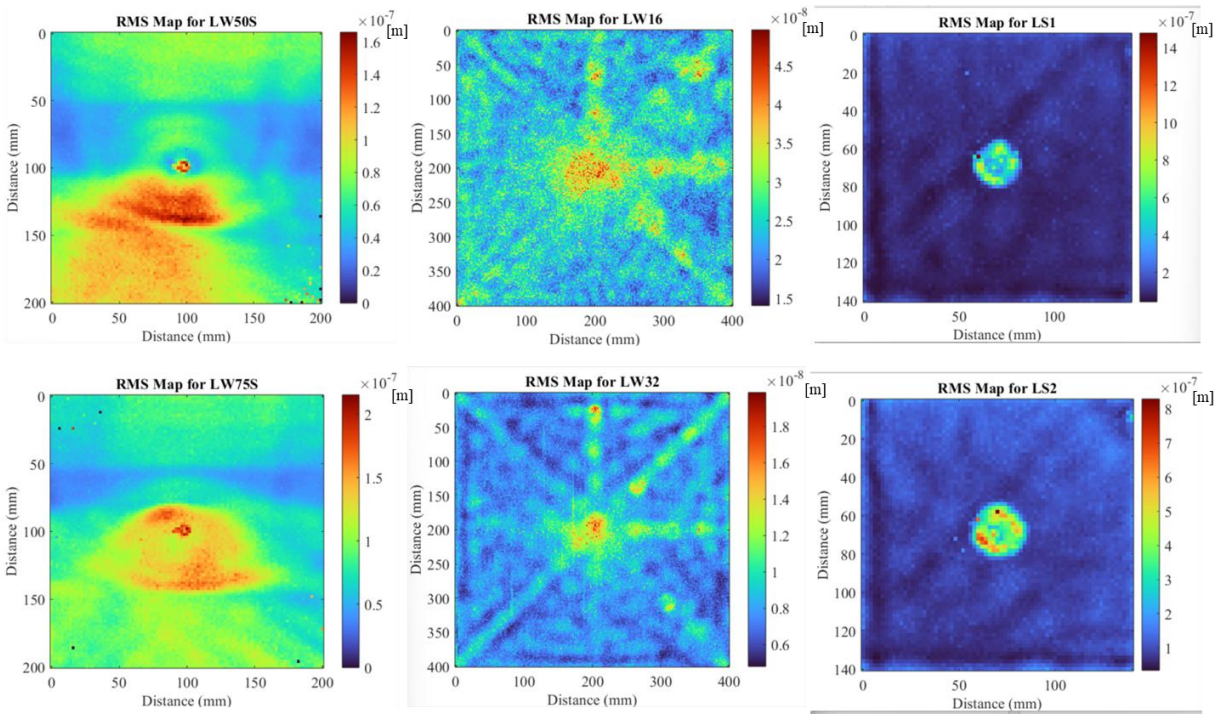

Fig. 4: RMS cartographies obtained for all experimental samples

4 DATA FUSION

Data fusion is a powerful approach for integrating multiple sources of information to enhance the reliability and interpretability of defect detection. In this study, a feature-level fusion strategy is used, inspired by similar approaches in Structural Health Monitoring (SHM) . The goal is to combine the quantitative outputs from InfraRed Thermography (thermal diffusivity α) and Lamb Wave inspection (RMS energy) to enable a richer characterisation of the inspected CFRP samples [4–10].
The method consists of plotting the thermal diffusivity values (obtained from IRT) against the RMS values (extracted from Lamb Wave measurements) in 2D scatter plots, with each point representing a measurement location on the sample. This bivariate representation allows the emergence of clusters corresponding to different zones or damage types. In contrast to a single-parameter analysis, the combined view enhances the separation between structural states that may not be distinguishable using one method alone. This is particularly useful when one modality provides ambiguous information due to physical limitations (e.g., depth sensitivity in IRT or propagation noise in Lamb Waves).
The results of the data fusion process are presented and discussed in the following section.

5 RESULTS AND DISCUSSION

The data fusion results are shown in Fig. 5 for LW50S, LW75S, LW16 and LW32, and in Fig. 6 for LS1 and LS2. In LW50S and LW75S, measurement points were grouped into three zones: i) 8-ply healthy areas, ii) 16-ply healthy areas, and iii) delaminated areas in the stiffened region.
Thermal diffusivity was calculated point-by-point from IRT data, while RMS values were averaged per zone due to the smaller acquisition area of Lamb Wave scans. Fig. 5 shows a clear separation of these three groups. Interestingly, the 8-ply zones split into two clusters depending on their position relative to the wave excitation point. This difference, captured only by Lamb Waves, illustrates that signal amplitude is influenced not only by the local structure but also by the path of propagation through the delamination.
In LW16 and LW32, 16 points were analysed across healthy and defective areas with varying defect sizes (10–50 mm) and depths (8–24 plies). As shown in Fig. 5, the fusion reveals only a weak separation between healthy and damaged zones. The Lamb Waves data show a slight drop in RMS for delaminated regions, but no clear differentiation is observed across different defect sizes or depths. This highlights a limitation of both methods when applied to small or subtle delaminations.
The damage in LS1 and LS2 exhibits a visible surface deformation and distinct thermal patterns in IRT. Based on the thermographic images, four zones were identified: healthy background, black ring, white ring, and grey centre. Using the same zone segmentation, the scatter plot in Fig. 6 shows that fusion enables a clearer distinction between zones than either method alone. For example, Lamb Waves can separate the grey centre from the healthy background, while IRT alone could not, likely due to thickness variations. Conversely, IRT captures distinct behaviour in the black ring, which is poorly resolved by Lamb Waves due to its narrow geometry and possible interference effects.
IRT provides information about surface-level heat diffusion, while Lamb Waves probe internal mechanical properties through guided wave propagation. In the stiffened and lightning-strike samples, the combination of both offers complementary insights:

(i) IRT resolves thickness variations and localised heating effects,
(ii) Lamb Waves highlight stiffness reductions due to delaminations.

In contrast, both methods struggle with small artificial delaminations, where signal changes are less pronounced and easily masked by measurement noise or geometric variability.
The apparent increase in thermal diffusivity in thicker areas, despite α being theoretically independent of thickness, is likely due to heat conduction through the metal support base. As thickness increases, thermal losses to the base decrease, leading to artificially higher α values. This phenomenon is especially visible in LW50S and LW75S and must be considered when interpreting thermal data.
In the lightning strike samples, the extreme energy conditions cause local material transformations such as carbonisation, porosity or microcracking which significantly alter both thermal and mechanical responses. This explains the high diffusivity observed in the black ring and the strong Lamb Wave scattering in the central defect.

Finally, the study demonstrates that the data fusion approach effectively compensates for the limitations of each method, providing a more nuanced picture of the internal damage, particularly in complex or multi-zone configurations.

6 CONCLUSION

In this study, the combination of InfraRed Thermography (IRT) and Ultrasonic Lamb Wave inspection through a data fusion approach for the characterisation of delaminations in CFRP composites has been investigated. Each technique, based on distinct physical principles, offers valuable yet partial insight into the material's condition: IRT is sensitive to surface and near-surface thermal behaviour, while Lamb Waves provide information related to internal mechanical changes. However, both face limitations when used independently, particularly in cases involving complex geometries, variable thicknesses, or subtle defect signatures.

By jointly analysing thermal diffusivity (from IRT) and RMS energy (from Lamb Waves) through feature-level fusion, the proposed method enabled a more comprehensive interpretation of damage patterns. The results demonstrated a clear benefit for samples with complex internal structures, especially stiffened panels and lightning-strike-induced damage, where single-method inspections either failed to differentiate certain zones or produced ambiguous data.

In contrast, the fusion method was less effective for small artificial delaminations, where both techniques showed limited sensitivity to variations in size or depth. These results suggest that the approach remains dependent on the physical detectability of the defect by at least one modality, and that further improvements are needed in signal acquisition and processing to enhance sensitivity to fine-scale

damage.
Beyond the immediate results, this study highlights the potential of multimodal NDT as a step towards more quantitative and integrated material characterisation. Moving beyond binary “healthy/defect” classifications, data fusion offers a promising avenue for future inspection strategies in complex composite structures, with applications in both quality control and structural health monitoring. Further work will aim to refine the methodology, explore alternative fusion strategies, and extend the study to more complex configurations and real-world defect scenarios.

ACKNOWLEDGEMENTS

The current research project has been funded by the Japan Society for the Promotion of Science under the Grant-in-Aid for Scientific Research programs (Grant No. JP22H01692). The authors acknowledge Mr. Tonegawa Shota, Mr. Mita Masakatsu and Mr. Suyama Mamoru from the Shibaura Institute of Technology for their great support in the realisation of Lamb Waves experiments, and Mr. Yu Zhou and Mr. Kamiyama Shintaro for their important expertise regarding the Lightning Strike experiments.

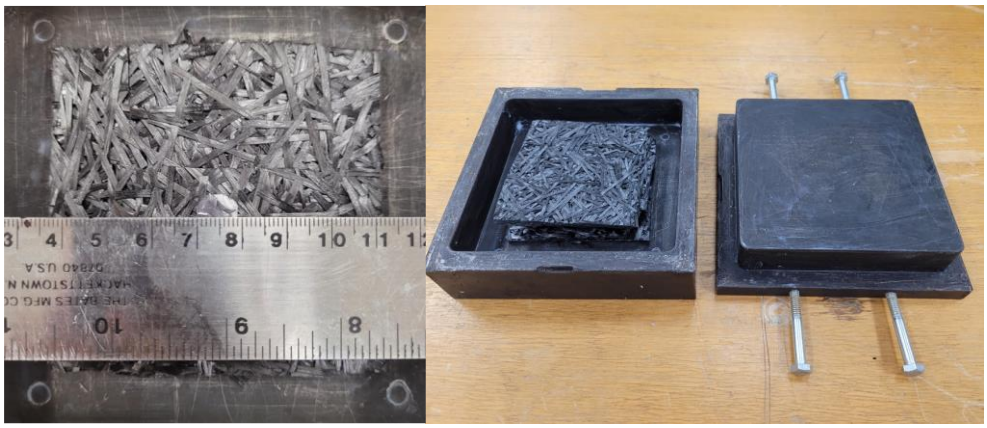
Keywords: Discontinuous Long Fiber Composites, Non-Destructive Testing, Probability of Detection, Infrared Thermography

ABSTRACT

The inspection of discontinuous long fibre-reinforced plastic composites (DLFRPCs) presents significant challenges due to the stochastic nature of their meso-structure, particularly in detecting subsurface defects that may compromise performance in critical applications. Traditional non-destructive testing (NDT) methods struggle with the variability introduced by randomly oriented fibre strands, necessitating more advanced techniques to ensure reliable detection across varying defect depths and sizes. This study investigates the use of transient infrared thermography (T-IRT), employing halogen lamp heating, to detect subsurface voids and inclusions in DLFRPCs. T-IRT offers rapid full-field inspection and the ability to highlight thermal gradients associated with defects, making it well-suited for heterogeneous materials. Compression-molded plates (5×5 inches, 2.5 mm thick) composed of 0.25×2-inch unidirectional prepreg platelets were used. The orientation and placement of individual platelets resulted in non-uniform thermal responses, complicating defect detection and precluding the definition of a representative "sound" region. To address this, artificial defects in the form of flat-bottom holes (FBHs) were introduced at controlled depths and diameters. A pre/post scan approach was developed to calculate corrected thermal contrast at each FBH location, isolating defect-related signals from background variability. Defect detection was defined by a contrast threshold, and binary outcomes were analyzed using logistic regression within a hit/miss Probability of Detection (POD) framework. POD curves were generated to evaluate the influence of defect size on detectability. The results show that increasing defect diameter correlates with higher detection probability, as expected. However, the transition in detection is more gradual than in typical CFRP inspections, and confidence bounds are broader, attributed to the stochastic mesostructure of the DLFRPCs and associated signal variability. The pre/post scan method enabled robust contrast evaluation without relying on reference sound areas, a key contribution for defect quantification in complex materials. The findings demonstrate the feasibility of T-IRT combined with statistical POD for characterizing subsurface damage in DLFRPCs. This approach provides a foundation for optimizing inspection protocols and supports broader application of thermography in automotive and aerospace composite evaluation.



1 INTRODUCTION

Non-Destructive Testing (NDT) techniques are important for quality assurance and structural health monitoring in advanced composite materials [1]. Among these, Infrared Thermography (IRT) offers significant advantages due to its rapid, contactless inspection capability, particularly for identifying subsurface anomalies [2]. When applied in a transient mode, Transient Infrared Thermography (T-IRT), the method captures thermal diffusion responses following controlled heating, enabling the detection of internal features such as voids, delaminations, or inclusions. Discontinuous Long Fibre Reinforced Composites (DLFRPCs), such as platelet-molded carbon fibre systems, present unique challenges for NDT. Their highly stochastic mesostructure, characterized by randomly distributed and oriented fibre bundles, leads to significant variability in thermal behavior. This complicates defect detection and reduces the reliability of traditional contrast-based evaluation methods that rely on reference regions with uniform properties. To address these challenges, there is a need to quantify the detection performance of T-IRT in LDFCs using robust statistical frameworks. Probability of Detection (POD) analysis is the standard method to quantify the reliability of NDT techniques. Two common approaches exist: the continuous response method, ($\hat{a}$ vs. a) [3] ,and the binary classification method, hit/miss [4], which is used for this work.

This work presents a comprehensive POD analysis for simulated defects in compression-molded long discontinuous fibre composites inspected via T-IRT. A rigorous methodology is adopted, including the manufacturing of defect-free plates, precise machining of flat-bottom holes (FBHs) as artificial defects, execution of front-side transient thermography using halogen lamp excitation, and advanced signal processing through Thermal Signal Reconstruction (TSR) and a custom signal-to-noise ratio (SNR) classification approach. Detection reliability is quantified using a hit/miss POD framework, where a binary classification threshold is applied to matched pre- and post-drilling thermographic responses. Statistical confidence bounds are established using a logistic regression model and the delta method. The results provide new insights into the capabilities and limitations of T-IRT for inspecting LDFCs and offer practical guidance for improving defect detectability in materials with inherently random mesostructure.

2 MATERIAL SYSTEM AND PLATE MANUFACTURING

The composite plates used in this study were manufactured from XForge™ VZ TDS, a long discontinuous carbon fiber reinforced epoxy prepreg supplied by DowAksa. This material is designed for isothermal compression molding at 150°C with rapid cure cycles under 3 minutes for parts under 9.5 mm thickness. The randomly distributed platelets give rise to a highly stochastic meso-structure. Plate fabrication was carried out at Old Dominion University (ODU) under controlled conditions (see Fig. 1a). Each plate was initially molded within a 5 × 5-inch (127 × 127 mm) aluminum tool (see Fig. 1b). After curing, the plates were trimmed to final dimensions of 4 × 4 inches (101.6 × 101.6 mm) to remove edge effects and ensure dimensional uniformity. The nominal thickness of all plates was 2.5 mm, with an actual measured mean of 2.579 mm and a standard deviation s = 0.119 mm. These results confirm good geometric consistency, which is important for reliable thermographic and statistical analysis, especially considering the mold charging process is non-trivial due to the semi-preg format of the material, which requires careful manual placement. Once an optimized process was established, all subsequent plates were subjected to both IRT and UTPA prior to further processing. Only plates confirmed to be free of internal defects via UTPA were retained for testing. A total of eleven defect-free plates were selected based on these criteria. Following inspection, artificial defects were introduced in the form of Flat-Bottom Holes (FBHs), precisely machined into the back surface of each plate. These FBHs serve as controlled defect simulants with known geometries, enabling the quantification of detection capability through thermographic contrast analysis.

3 DEFECT SIMULATION USING FLAT BOTTOM HOLES (FBHS)

In POD studies, artificial defects are introduced to replicate damage modes such as delaminations or voids commonly observed in impacted or poorly consolidated composites [5]. In this work, artificial defects were implemented using Flat-Bottom Holes, selected over other options such as Teflon inserts. While Teflon inserts are often used to simulate delaminations in traditional composite laminates, they proved unsuitable for DLFRPCs manufactured via hot press compression molding. During pressing, inserts tend to shift from their intended positions due to resin and fiber flow and are distorted as they become entangled within the disordered fiber bundles. This results in unpredictable geometries and locations, conditions that are incompatible with quantitative and repeatable defect detection studies.

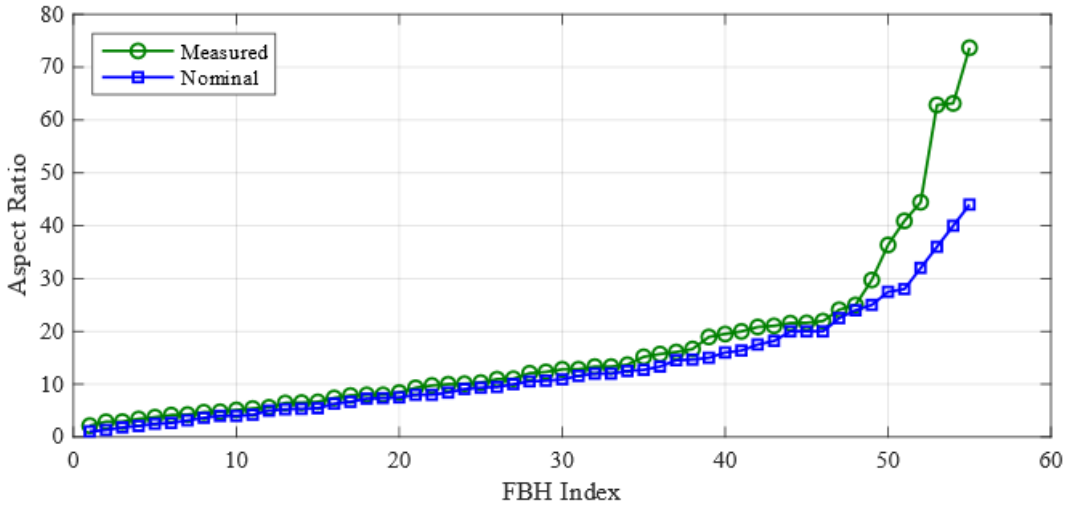

Figure 2. Flat bottom hole (FBH) index versus aspect ratio for the 55 simulated defects used in this study. This image show comparison between measured and nominal values.

In contrast, FBHs can be machined post-curing using precision CNC milling, allowing tight control over defect diameter, depth, and location. This ensures high geometric accuracy and repeatability across samples, making FBHs a reliable and reproducible defect type for thermographic POD evaluation. Due to machining tolerances inherent to the milling process, small variations in FBH depth were expected and confirmed. The

shallowest FBH in each plate (closest to the inspection surface) was designed to maintain a minimum remaining wall thickness of 0.5 mm to prevent breakthrough. Considering potential depth errors of up to ±0.3 mm from the milling setup, this safety margin was necessary. The actual measured depths of these shallowest FBHs ranged from 0.15 mm to 0.45 mm, with a mean value of 0.348 mm and a standard deviation of 0.104 mm. A total of 55 FBHs (Fig. 2) were distributed across 11 plates, consistent with the minimum recommendations outlined in MIL-HDBK-1823A and ASTM E2862. The FBH diameters range from 2 mm to 22 mm, in 2 mm increments, with five depth levels per plate. Each plate contains a unique diameter and five FBHs positioned at nominal depths of 0.5 mm, 0.8 mm, 1.1 mm, 1.5 mm, and 1.9 mm from the front (inspection) surface. This configuration covers a realistic range of subsurface defect scenarios, from easily detectable shallow defects to more challenging deeper ones that may be partially masked by backwall reflections. FBHs were drilled under constant feed and speed conditions using a precision CNC machine to minimize heat-affected zones (see Fig. 3). All dimensions were subsequently verified using a caliper. For example, Plate 001 contains FBHs ranging from 0.15 mm to 0.69 mm in depth, while Plate 011 includes defects from 0.35 mm to 1.82 mm, paired with a 22 mm diameter. Overall, the controlled and fully characterized FBH dataset developed in this study provides a rigorous foundation for assessing the detection performance of the T-IRT system and for quantifying POD in relation to defect geometry and depth.

4 EXPERIMENTAL SETUP FOR TRANSIENT INFRARED THERMOGRAPHY

Each plate was inspected using a Transient Infrared Thermography setup configured for front-side heating and observation. The DLFRPC material under investigation, presents unique challenges for thermographic evaluation. First, there is limited prior literature on applying IRT to such materials, and second, their inherent local fibre orientation variability introduces significant spatial non-uniformity in thermal behaviour. This makes conventional approaches in POD, where the thermal response over a defect is compared with a neighbouring sound area, unsuitable. Due to the randomness of the fibre orientation distribution (FOD), "sound" zones [6] may exhibit vastly different transient responses depending on local conductivity and heat flow patterns. This limitation is illustrated in Figure 4, which shows two distinct regions on the same plate with different thermal decay curves despite both being defect-free.

To overcome this, a differential inspection approach was implemented. Each plate was scanned twice using T-IRT: once immediately after trimming (baseline condition), and once after FBH drilling. During both

scans, all boundary and measurement conditions were kept constant, including ambient temperature, lamp intensity and position, camera distance, and sample alignment. To further minimize experimental error, four defect-free reference areas on each plate were used to calculate the average first temporal derivative of the thermal signal before and after FBH drilling. This allowed for minor residual normalization and correction, ensuring that contrast changes were attributable to the presence of the artificial defects rather than material variability or setup drift. The final evaluation of detectability was based on the ratio of thermal responses between the same area *before* and *after* - FBH drilling. This comparative metric captures local thermal contrast due to the artificial defect while compensating for the spatial variability inherent in the DLFRPCs.

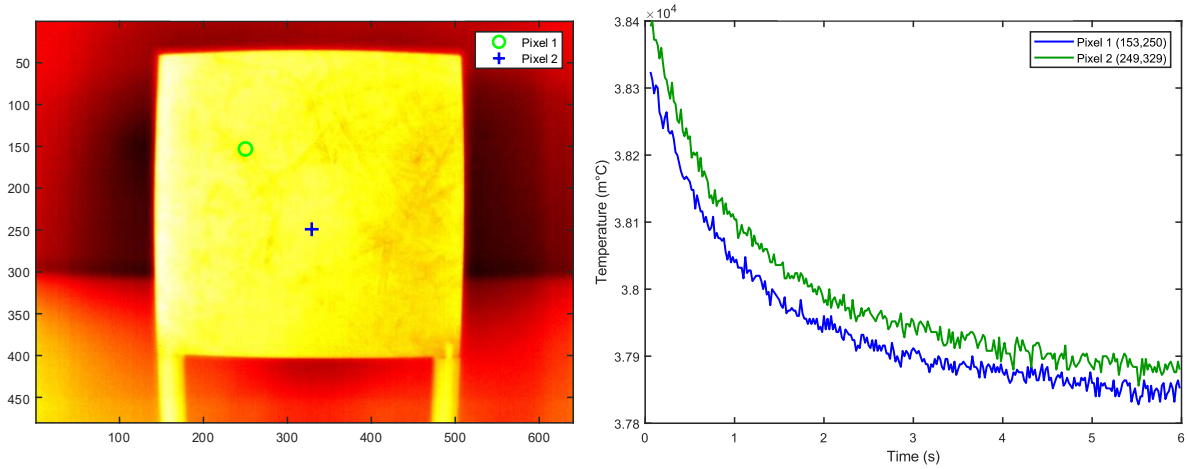

Figure 4. Left: Analyzed pixel locations. Right: Temperature profile of the analyzed pixels.

To enable reproducible and precise alignment between pre- and post-defect scans, a customized 3D-printed fixture was developed to hold the infrared (IR) camera, halogen lamps, and specimen in fixed relative positions (Fig. 5). The fixture allows the specimen to be inserted and removed while preserving a fixed geometry between all components. The plate is held in position on a height-calibrated platform to ensure repeatable distance and centering relative to the optical axis of the camera and illumination sources. The inspection was conducted in Dr. Kravchenko's laboratory at the University of British Columbia using a C-CheckIR system developed by Automation Technology (see Fig. 5). The setup included an IRS x640 NDT uncooled infrared camera equipped with a 12 mm wide lens, providing a thermal sensitivity of 75 mK and a spatial resolution of 640 × 480 pixels. For heating, two 850 W dimmable halogen lamps were used, controlled by an IRX-Box, which synchronized the entire system, including the IR-NDT Transient & Pulse Software Evaluation Module. One of the challenges in T-IRT is interpreting noisy thermal data. To create the final thermal image and improve signal-to-noise ratio and extract meaningful features such as contrast and defect depth, Thermal Signal Reconstruction (TSR) was used. This method computes temperature derivatives with respect to time and was implemented using custom MATLAB scripts based on [7,8].

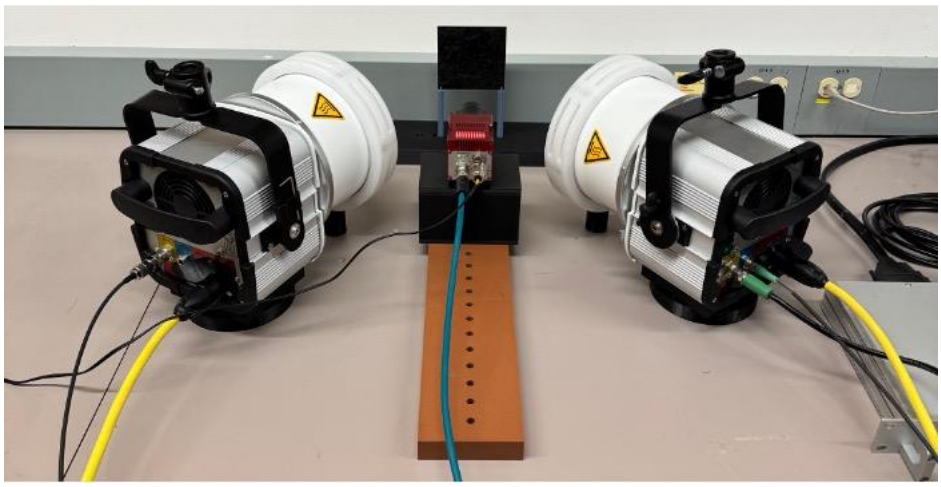

Figure 5. IRT setup

5 STATISTICAL POD ANALYSIS

In POD analysis, two main approaches are typically used: a continuous model based on response data (â vs. a), and a binary hit/miss model [5,9]. Both aim to quantify the likelihood of detecting a defect as a function of size or other damage parameters. The response-based method assumes normally distributed variability in measured signals and derives the POD curve using a cumulative distribution function above a decision threshold. Detailed derivations and assumptions are available in the referenced standards and literature [10]. In this study, the hit/miss approach was selected due to the variability in thermal signal response caused by the stochastic nature of the composite material. A defect was classified as detected when the corrected local thermal contrast exceeded a defined threshold. The resulting binary outcomes were analyzed using logistic regression, and confidence bounds were computed using the delta method. This section describes the model selection, parameter estimation, and interpretation of results based on this approach.

5.1 Hit/Miss model selection

The hit/miss analysis is a statistical method used when the inspection output is binary, meaning the result for each flaw is either a hit (detected) or a miss (not detected). This approach is especially relevant when the NDT system provides a yes/no decision instead of a continuous signal.

Ordinary linear models assume continuous and unbounded outcomes, with normally distributed residuals. However, hit/miss data are discrete and bounded between 0 and 1. For such data, the residuals follow a binomial distribution, making ordinary least squares inappropriate. Generalized Linear Models (GLMs) resolve this by using a suitable link function to transform the binary outcome into a form compatible with linear modeling.

In hit/miss analysis, a flaw is classified as detected if the signal exceeds the threshold; otherwise, it is missed. This approach is particularly robust when response measurements are not reliably quantifiable, which may occur in materials such as DLFRPCs with complex, stochastic microstructures.

Several link functions are available to model PoD as a function of flaw size a:

Logit (log-odds)
$$POD(a) = \frac{1}{1 + exp(-Xf)} \quad (1)$$

Probit (log-normal)		$POD(a) = \Phi(Xf)$	(2)
Complementary (cloglog)	log-log	$POD(a) = 1 - exp\big(-exp(Xf)\big)$	(3)
Log-log		$POD(a) = exp\big(-exp(-Xf)\big)$	(4)

Where $Xf = \beta_0 + \beta_1 \cdot \ln(a)$ is a linear function of the explanatory variable. $\Phi(\cdot)$ denotes the standard cumulative distribution function.

The choice of link function impacts the shape of the PoD curve and the estimated $a_{90/95}$. Symmetric links (logit and probit) are preferred for symmetric data, while skewed data may be better modeled with cloglog (left-skewed) or log-log (right-skewed) links. In practice, logit and probit yield similar results for well-behaved data.

To estimate the parameters of the POD model, Maximum Likelihood Estimation (MLE) was used to fit a logistic regression to the binary hit/miss data. The model relates the probability of detection to flaw size, and the log-likelihood function was optimized to determine the intercept and slope. A key performance metric is $a_{90/95}$, defined as the smallest flaw size detectable with 90% probability at 95% confidence. Confidence intervals were computed using the delta method, which propagates uncertainty from the fitted model parameters to the POD curve through partial derivatives and the variance–covariance matrix. The $a_{90/95}$ was obtained by solving for the lower 95% bound of the POD curve at 90% probability. This approach follows the procedure outlined in the ASM Handbook [10] and remains widely adopted for its efficiency and robustness. Alternative methods such as Bayesian inference or bootstrapping may be used in cases with limited data or non-ideal model assumptions.

5.2 Defect Classification and POD Curve Interpretation

To select an appropriate detection threshold ϕ_{dec} and classify defects for hit/miss POD analysis, a custom signal-to-noise ratio approach was developed. This method compares thermal contrast at the same physical location before and after FBH insertion. The objective is to isolate the defect-related signal while minimizing the impact of stochastic background variation and environmental factors (e.g., ambient temperature, lamp distance, humidity).

The local thermal contrast change at the defect site is computed as:

$$\Delta\phi = \phi_{post} - \phi_{pre}$$

where ϕ_{post} and ϕ_{pre} represent thermal contrast in the same region of interest (ROI) in the post- and pre-drilling scans, respectively. To compensate for global changes in experimental conditions, the average contrast change in unaffected reference regions $\Delta\phi_{ref}$ is subtracted:

$$\Delta\phi_{corrected} = \Delta\phi - \Delta\phi_{ref}$$

A defect is marked as detected if the corrected contrast change exceeds the detection threshold:

$$\Delta\phi_{corrected} \geq \phi_{dec}$$

A threshold $\phi_{dec} = 1.2$ was selected based on values commonly used in thermographic NDT studies (typically ranging from 1.2 to 1.5 for TSR and phase-based metrics [5,11]) and was empirically validated to balance sensitivity and false positive rate.

This approach enables robust defect classification without relying on assumptions of spatial uniformity or Gaussian noise distribution. It is particularly suitable for composites like DLFRPC, where random fiber

orientation and local mesostructure variation can compromise traditional referencing methods. By leveraging spatially aligned pre/post scan data, this method provides a consistent basis for classification under realistic noise conditions.

5.3 POD Analysis and Results

The resulting POD curve from the hit/miss classification is shown in Figure 6. The model demonstrates the expected increase in detection probability with increasing FBH size. However, the curve exhibits a relatively shallow slope and wide confidence bound, indicating variability in thermal contrast response for defects of similar size. This behaviour is attributed to the stochastic mesostructure of DLFRPCs, where local fibre orientation, platelet overlap, and resin-rich zones lead to non-uniform heat flow. These effects introduce background fluctuations that degrade defect signal repeatability and widen the statistical uncertainty of detection.

The estimated 90% detection threshold (a_{90}) was reached at an FBH ratio of approximately 22, indicating that defects of this size were detected with high probability under the current inspection conditions. However, the 90% detection at 95% statistical confidence ($a_{90/95}$) was not achieved within the tested flaw size range. This outcome highlights a key limitation in applying classical POD assumptions to random-fiber composites: material heterogeneity imposes a fundamental constraint on statistical detectability. This limitation arises not from deficiencies in the inspection method, but from inherent variability in the composite's mesostructure.

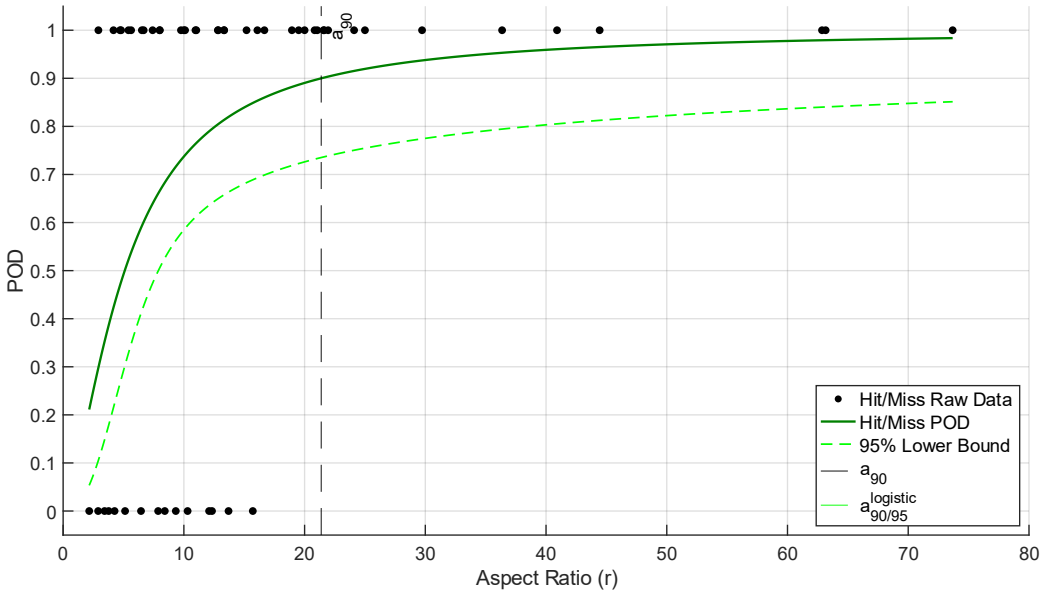

Figure 6. POD curve from the hit/miss classification.

Despite these challenges, the study demonstrates that robust thermographic POD analysis is feasible when adapted methodologies are employed. The pre/post scan approach with SNR-based classification provides a reliable framework for inspection in non-uniform composites.

6 CONCLUSIONS

A DLFRPC specimen containing 55 Flat Bottom Holes distributed across 11 plates was inspected using Transient Infrared Thermography. To address the lack of thermally uniform regions, a common limitation in randomly structured composites, a pre/post scan methodology was implemented. This approach enabled isolation of defect signals through differential thermal contrast, making it suitable for materials with significant background variability. Defect classification was performed using a custom signal-to-noise metric and hit/miss POD analysis was conducted using a detection threshold of 1.2.

The resulting POD curve exhibited a gradual increase in detection probability with flaw size, as expected. The 90% detection threshold (a_{90}) was reached at an estimated FBH aspect ratio of 22. However, the 90% detection at 95% statistical confidence ($a_{90/95}$) was not achieved within the tested range. This result highlights a key limitation when applying conventional POD models to composites with random internal architecture. In such materials, the assumption of consistent defect detectability breaks down due to the influence of local mesostructure, not shortcomings in the inspection technique itself.

"The relatively shallow slope and wide confidence intervals of the POD curve reflect the stochastic variability in thermal response caused by factors such as random fibre orientation, platelet misalignment, and non-uniform resin distribution. These features affect heat diffusion paths and result in inconsistent thermal contrast at defect sites, differing from those observed in CFRP studies [5,9,10,12].

Despite these challenges, the study demonstrates that reliable thermographic POD assessment is achievable for DLFRPCs when adapted analysis strategies are used. The integration of spatially aligned pre/post scans and contrast-based SNR metrics offers a robust framework for flaw classification in the presence of complex background noise. These findings establish a basis for developing standardized inspection protocols in stochastic composite materials.

Future improvements may include multimodal inspection strategies, such as combining thermography with ultrasonic or X-ray methods, to reduce uncertainty and improve detection confidence.

ABSTRACT

This study investigates the manufacturing and testing of conformable carbon fiber-reinforced polymer tanks with integrated continuous fiber-reinforced tension struts for hydrogen storage applications. Two demonstrator tanks were manufactured using 3D-printed core structures combined with wet filament winding and hand lay-up processes. While the concept demonstrated mechanical integrity under hydrostatic loading, leakage at the interface between the CFRP and aluminum boss, as well as poor laminate compaction in flat regions, revealed existing challenges. The manual forming of the strut ends was time-consuming and resulted in high variability in joint strength. These results highlight the potential of strut reinforcement while emphasizing the need for improved laminate compaction and enhanced strut–wall connection to enable practical applications of conformable composite tanks.

1 MOTIVATION AND BACKGROUND

As climate change progresses, sustainable mobility is becoming increasingly important. In the passenger car sector, battery electric vehicles (BEVs) have become the dominant form of locally emission-free mobility [1–3]. Nevertheless, some manufacturers are additionally pursuing hydrogen-powered fuel cell electric vehicles (FCEVs) to provide an alternative to BEVs [4, 5]. Due to the low production volumes, these vehicles are expensive, which represents a key barrier to broader consumer adoption [3, 6]. A cost-reduction approach is to use the same vehicle architecture for both BEVs and FCEVs. To use the skateboard platform, which is common for BEVs, in FCEVs, the hydrogen storage system must be integrated into a flat installation space in the vehicle underbody [7, 8]. Hydrogen pressure vessels on the market have a cylindrical geometry and are therefore not well suited to this installation space [7].

One approach to using the volume more efficiently for hydrogen storage is to use conformable tanks, which are adapted to the cuboid design space [7]. However, pressure vessels that deviate from a cylindrical or spherical geometry are subject to high bending forces in the vessel walls [11]. This makes it necessary to integrate reinforcing elements such as struts or ribs to counteract these forces. Several approaches for conformable composite tanks can be found in literature [7, 8, 11–13]. A major challenge is the connection of the reinforcing elements (struts, ribs, etc.) to the tank wall, as very high forces have to be transmitted in this area [11, 14].

This work presents a manufacturing process for conformable CFRP tanks with inner tension-strut reinforcement. The main aim is to investigate the feasibility of the presented concept through the development, fabrication, and testing of two tank demonstrators.

2 CONCEPT AND DESIGN

This chapter outlines the overall concept for a conformable CFRP tank with tension-strut-reinforcement, including the design of the winding core and boss elements, the integration strategy for the struts, the composite layup definition, and the materials for demonstrator manufacturing.

2.1 Manufacturing concept

The basic manufacturing concept was presented in a previous contribution at ECCM20 [15] and is briefly summarized here for completeness.

The concept consists of four main steps, as shown in Figure 1. In the first step, a winding core with integrated continuous fiber-reinforced struts is prepared. The struts, which have a thermoplastic (TP) matrix, are positioned such that both ends protrude beyond the surface of the core. In the second step, the tank wall is formed using the wet winding process. During the deposition of the impregnated fibers on the winding core, the ends of the struts pierce the rovings, resulting in a semi-finished product with an uncured composite laminate in which the end sections of the struts protrude from the outer surface of the laminate. In the third manufacturing step, the end portions of the TP-CFRP struts are formed into a flat geometry using heat. In the final step, an outer composite laminate is formed using the filament winding process to cover the reshaped ends of the struts.

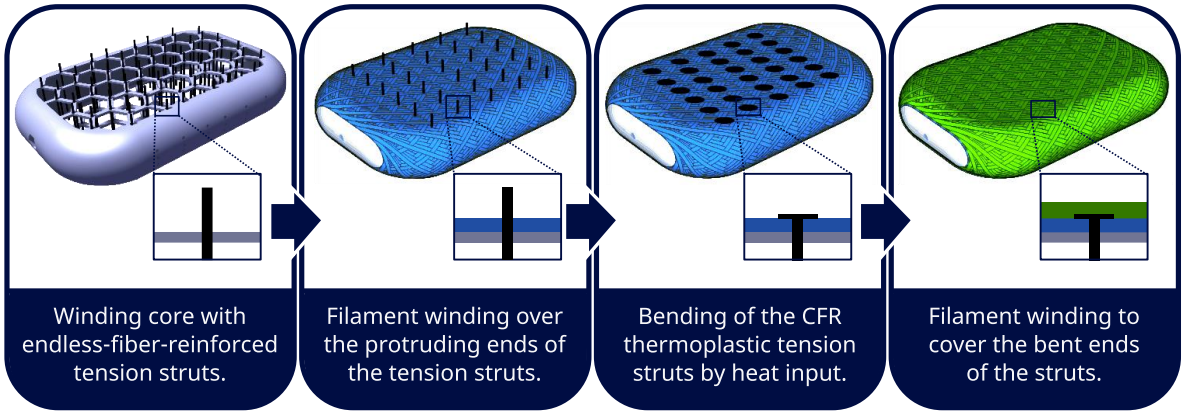

Figure 1: Overview of the manufacturing steps for the conformable CFRP tank with integrated tension struts [15].

The presented manufacturing concept demonstrates promising potential for the fabrication of conformable CFRP tanks with integrated tension struts. Compared to designs based on steel, the CFRP approach offers superior lightweight potential [14, 16]. Furthermore, the use of filament winding, a well-established process in pressure vessel manufacturing, supports scalability, as suitable equipment is already widely available in industry. An important aspect of the concept is the strut integration strategy, which is intended to allow efficient load transfer from the struts into the laminate along the fiber direction. In the configuration shown in Figure 1, a 3D-printed skeleton structure serves as a winding core. However, the concept is equally applicable to Type IV tanks, where a polymer liner with channels for the struts could fulfill this role. As such liners are currently not commercially available, the demonstrators presented in this study utilize a 3D-printed skeleton structure.

2.2 Design of winding core and boss element

The winding core for the demonstrators was designed using Catia V5 and is depicted in Figure 2. The core features a hexagonal structure, designed for 3D-printing without the need for additional support material between the hexagons. It includes holes at the intersection points for the struts, as well as

recesses to enable adhesive application during strut insertion. The core dimensions are 426 mm × 290 mm × 80 mm. The strut spacing was defined as a parameter, allowing the number of struts to be easily varied during the tank design process. Additionally, the winding core includes a recessed area for bonding the boss element, ensuring its precise positioning during assembly.

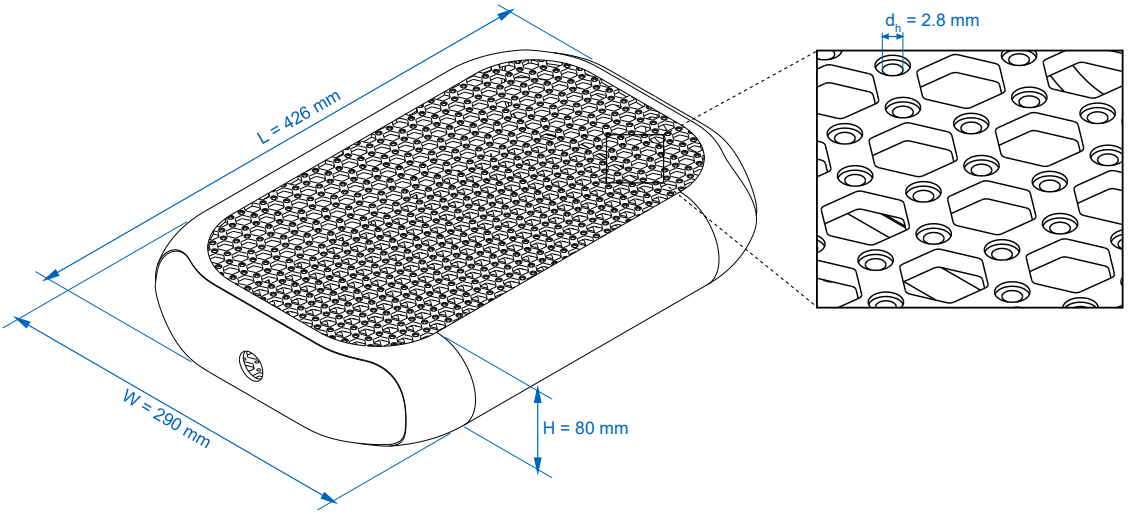

Figure 2: CAD design of the winding core.

The boss element and key dimensions are shown in Figure 3. It should be noted that the structural design of the boss was not focus of this project. Therefore, only an approximate design was created without detailed analyses, such as stiffness evaluation.

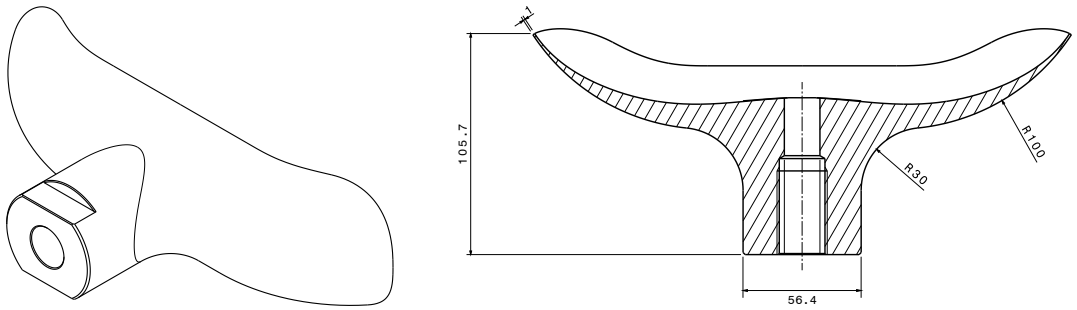

Figure 3: Boss element for conformable tank demonstrators and main dimensions in mm.

2.3 Strut integration and anchoring strategy

Comprehensive investigations to improve the strut connection were carried out. The general approach is shown in Figure 4. Parts of these investigations have been published in Gleis et al. [17]. As these investigations are not the focus of this publication, they are not discussed in further detail. From preliminary studies, a length of 4 mm for the reshaped strut end, combined with the application of thickened resin after bending of the struts was found to provide good connection strength between the struts and the tank wall.

For the building of the demonstrators, the thermal forming of the strut heads was conducted manually using a modified soldering iron. A conservative value of 1.5 kN was assumed for the transferable load between each strut and the tank wall for the definition of the strut spacing. This assumption accounts for the differing conditions during demonstrator manufacturing, which are less controlled compared to the laboratory environment during the parameter study.

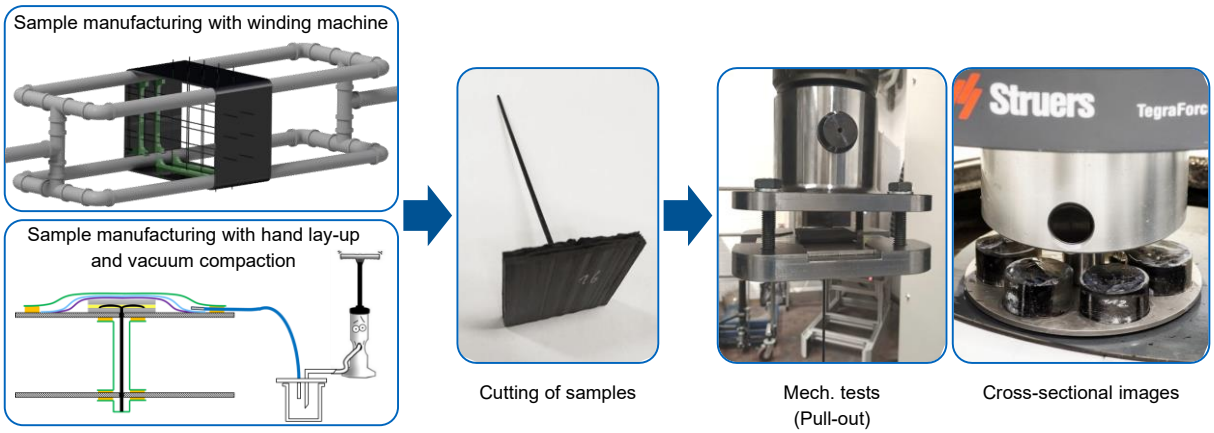

Figure 4: Approach for improving the connection between the struts and the laminate of the tank wall.

2.4 Composite layup and strut configuration

For the fabrication of the demonstrator tanks, design parameters such as the number of composite layers, the stacking sequence and the number and spacing of the struts had to be determined. It should be noted that detailed structural design was not the focus of this work. The following procedure was used as a pragmatic approach to define the key design parameters. A burst pressure of 100 bar was defined as the design target. Since the objective of the project was to investigate the strut integration concept at demonstrator level, the design parameters were selected so that the laminate of the tank wall was oversized and the strut spacing served as the critical design parameter. The aim was to ensure that during burst testing, failure would occur at the strut connection rather than in the laminate.

Strut spacing

A simplified one-eighth model of the tank was simulated in Abaqus to define a reasonable strut spacing for the demonstrator. The strut spacing was adapted in the model to achieve a maximum stress of 361 MPa in the struts in fiber direction. With the strut diameter of 2.3 mm, this corresponds to the value of 1.5 kN assumed in Section 2.3 for the pull-out strength of the strut-wall connection and resulted in a strut spacing of 12 mm in the simulation. Since the struts are arranged in a square pattern in the Abaqus model and hexagonally in the core structure of the demonstrators (due to 3D-printing constraints), the spacing was adjusted to achieve a comparable reinforcement density, resulting in 10 mm spacing distance.

Composite Layup

As current winding software cannot generate winding paths for non-rotationally symmetric geometries such as the conformable tank demonstrators, a combined approach of filament winding and hand layup was employed for the tank wall. Layers oriented at 0° and 90° were realized through circumferential winding, while ±45° layers, as well as patches on the corners and sides of the demonstrators, were applied by hand layup. A schematic illustration of the composite layup approach and the used patches is shown in Figure 5.

The number of layers was set at a total of 16, with four repetitions of the sequence 0°/90°/+45°/-45°. Before placing each 0° layer, the corners of the tank were reinforced by hand lamination, and before each 90° layer, the side patches were applied. For the 0° layers, a manufacturing aid (shown in Figure 6, right) was used to wind over the boss elements.

As described above, the aim was to over-dimension the tank wall deliberately so that failure in the burst test occurs at the strut connection and not in the laminate. To verify the selected layup, the Abaqus model mentioned above was used to simulate the tank wall with 16 layers according to the specified orientations. The maximum stress in the fiber direction and the maximum shear stress were evaluated for each layer to ensure that these values were within a non-critical range for CFRP.

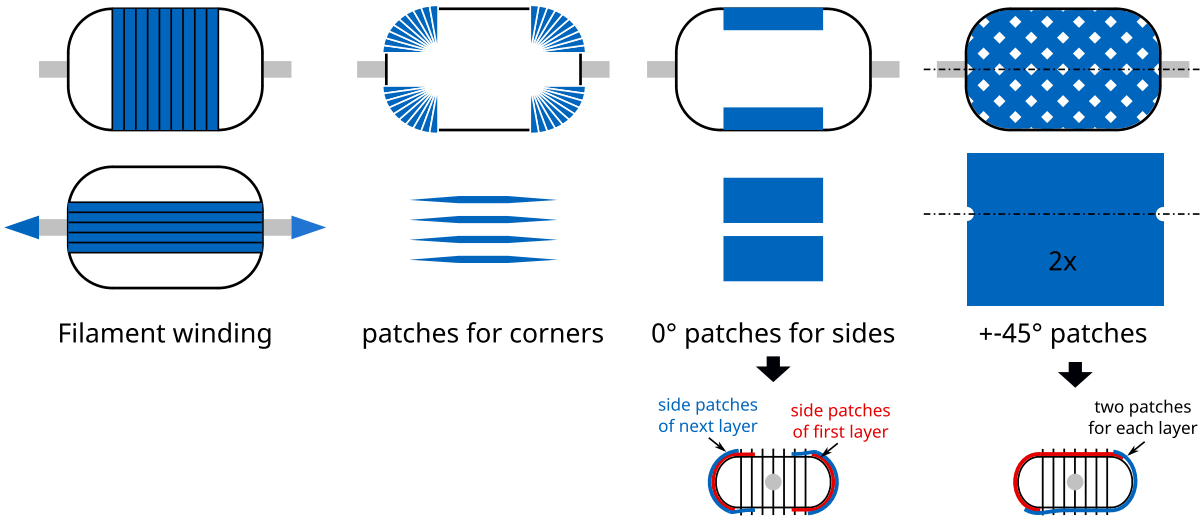

Figure 5: Schematic illustration of the layup strategy combining filament winding and hand layup for the conformable tank wall.

2.5 Materials

All the materials used for the manufacturing of the demonstrators, their specific designations, and the relevant manufacturing steps are listed in Table 1. Figure 6 shows the prepared fiber patches on the left. The conical strut caps and the 0° winding aid (middle and right) were 3D-printed using SLA resin. Two different resin systems were used for the two demonstrators, which required different 3D-printing filaments. For the demonstrator manufactured with the Araldite LY1135-1/917/960 resin system, PA6-CF was selected for the core structure due to its higher thermal resistance.

Material	Trade name	Manufacturing steps
Carbon fiber roving	Toray T700S-24K-50C	Filament winding of 90° and 0° layers
UD Non-crimp fabric (NCF)	SGL Sigratex® C U170-0/ST-E214/10g	Hand laminated edge and side patches
±45° NCF	Saertex ±45° 256 g/m²	Patches for hand laminating of ±45° layers
Struts	SGL CF/PA6 struts (prototype material)	Reinforcing strut with carbon fiber d = 2.3 mm used for both demonstrators
Resin system for 1st demonstrator	SikaBiresin® CR80/CH10	Wet winding and hand lamination of 1st demonstrator
Resin system for 2nd demonstrator	Huntsman Araldite LY1135-1/917/960-1	Wet winding and hand lamination of 2nd demonstrator
3D-printing filament PETG	Polymaker PolyLite PETG	3D-printing of core structure for first demonstrator
3D-printing filament CF-PA11	Polymaker PolyMide PA6-CF	3D-printing of core structure for second demonstrator
SLA printing resin	Anycubic standard resin	Printing of manufacturing aid for 0° layers and strut caps
Adhesive	Scotch-Weld™ DP 490	Assembly of core structure, fixation of the struts in the core structure
Thixotropic agent	Evonik AEROSIL® 380	Viscosity increase of neat resin applied after strut forming
2K Silicone	SilikonFabrik SF00 - RTV2	Implementation of silicone layer into the 2nd demonstrator as an attempt to seal it

3 MANUFACTURING OF THE DEMONSTRATORS

This chapter describes the manufacturing process of the demonstrator tanks, including the preparation of the winding cores with integrated struts, the combined filament winding and hand lay-up process, the anchoring of the strut ends, and the vacuum-assisted curing procedure.

3.1 Preparation of winding cores

The core structure of the demonstrators is fabricated in four individual segments using a fused deposition modeling (FDM) process on a Prusa i3 MK3S+ printer. After printing, the segments are assembled using a 2K epoxy adhesive (Scotch-WeldTM DP 490). Two different filament materials were used for the core structures of the two demonstrators: PETG and PA6-CF. The choice was based on the requirements of the respective resin systems, which necessitate different curing temperatures. PA6-CF offers a higher heat deflection temperature, while PETG is easier to process during printing. Figure 7 shows the printing process for a single segment and the four segments prior to assembly.

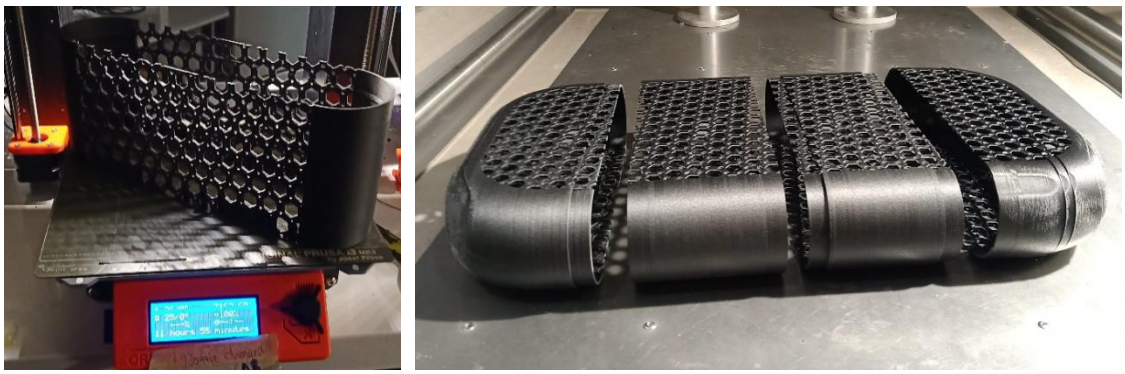

Figure 7: 3D-printing of a core segment (left) and the four segments prior to adhesive assembly (right).

The aluminum boss elements were adhesively bonded to the core structure using the aforementioned adhesive. As structural reinforcements, continuous fiber-reinforced tension struts were integrated into the conformable tank demonstrators. Prior to their insertion into the core structure, the struts were dried, cleaned with isopropanol, and trimmed to a uniform length. Each strut was individually bonded to the core structure using the DP490 adhesive, as shown in Figure 8. To facilitate piercing of the strut ends through the fiber layers during filament winding and hand lamination, conical strut caps with pointed ends were manually attached (Figure 8, right). The preparation of the core structure was very time-consuming due to the significant manual labor involved, such as the adhesive joining of 564 struts.

Figure 8: Insertion of continuous fiber-reinforced tension struts into the core structure with adhesive (left) and attachment of conical strut caps (right).

3.2 Filament winding and hand lay-up process

A total of 16 layers, consisting of four repetitions of the sequence 0°/90°/+45°/−45°, was applied. Before each 0° layer, the tank's corners were reinforced by hand lamination and before each 90° layer, the side patches were placed. After the first 0° and 90° layers, an intermediate curing step was implemented to prevent deformation of the 3D-printed core under thermal and mechanical process loads e.g. during strut forming.

For the circumferential layers in 0° and 90° direction, the wet filament winding process, shown in Figure 9, was applied. The fiber tension during winding was set to 10 N, and the winding paths were generated using CADWIND. As a workaround for the non-rotationally symmetric geometry of the conformable tank, cylindrical mandrels were modeled in CADWIND with equivalent circumferences to the core geometry in the respective 0° and 90° winding directions. The bandwidth was defined as 5.5 mm in the winding software. To enable winding in the 0° direction despite the presence of the boss element, a custom manufacturing aid was employed, as shown in Figure 9.

During winding, several practical challenges arose. In some cases, strut caps detached from the ends of the tension struts and had to be manually removed from the laminate, requiring an interruption of the winding process. Furthermore, due to the presence of the protruding strut ends, the rovings occasionally failed to deposit fully onto the surface of the mandrel and had to be manually pushed down. Winding across the boss element in the 0° direction using the manufacturing aid caused local deviations from the intended fiber alignment along the tank's longitudinal axis. Filament winding was chosen for these layers because it enables full 0° wrapping of the boss element and, compared to hand lamination, reduces the risk of layer detachment and shifting after placement.

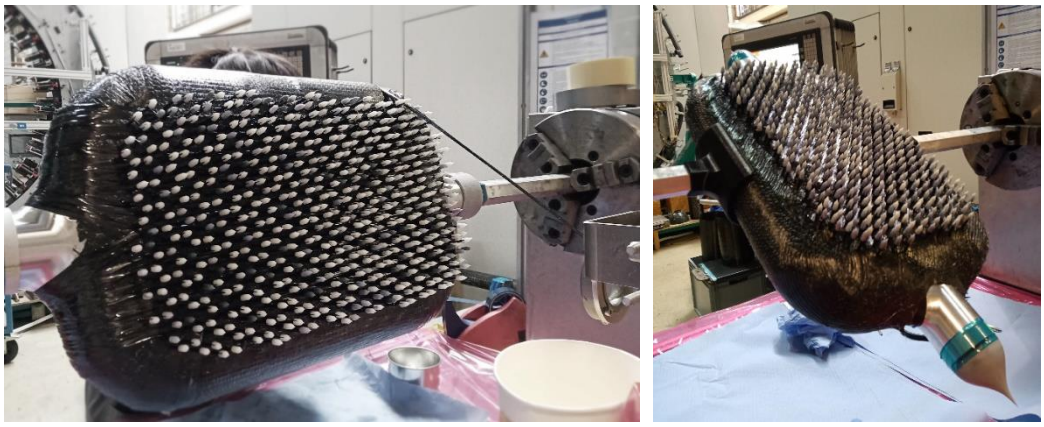

Figure 9: Wet filament winding setup for circumferential layers: 90° (left) and 0° (right). A custom manufacturing aid was used in 0° to enable fiber deposition across the boss element.

The application of the prepared fiber patches by hand lamination is shown in Figure 10. For each ±45° NCF layer, two patches were applied: one on the top and one on the bottom of the tank, overlapping

along the curved sides. A brush was used to push the ±45° NCF down onto the mandrel surface along the struts. The patches applied along the sides of the demonstrators (see Figure 10, middle) are oriented in the 0° direction and were positioned so that the strut rows adjacent to the curved sides pierced each patch alternately from the top and bottom. To cover each of the four corners of the tank, six patches (shown in Figure 6) were placed side-by-side, as illustrated on the right in Figure 10. During the layup process, several issues arose due to insufficient fixation of the fiber patches. The lack of tension complicated accurate positioning, leading to patch movement and wrinkle formation during vacuum compaction.

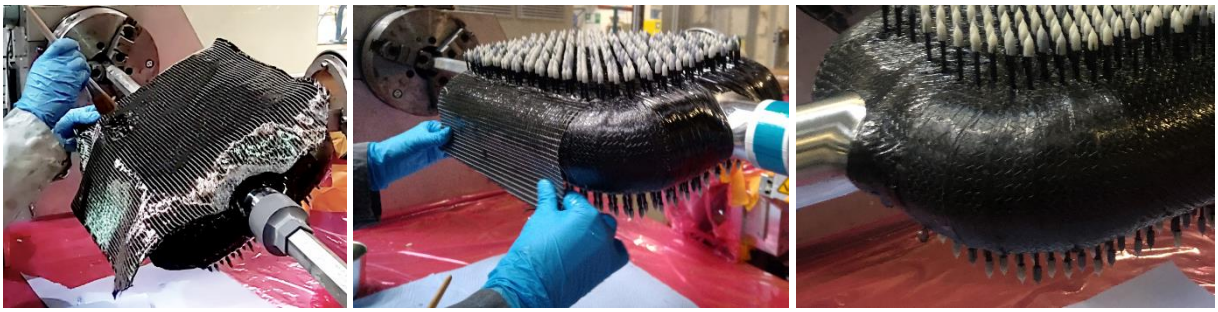

Figure 10: Hand lamination process of ±45° NCF layers (left), 0° patches along the sides (middle), and coverage of the curved shoulders (left).

3.3 Anchoring of strut ends

The thermal forming of the strut ends was performed after the 12th layer. The struts, including the caps, were first trimmed with pliers, leaving 4 mm protruding. The remaining ends were flattened directly on the uncured laminate using a soldering iron with a flat tip. The intermediate state, with some strut ends already formed and the remaining ones trimmed, is shown in Figure 11 (left). Due to the high number of struts and the limited ability to form them in parallel at this early development stage, the manual forming process was very time-consuming. Approximately four hours were required for two people to complete the thermal forming on one demonstrator. To improve the mechanical performance of the strut–laminate interface, a layer of neat epoxy resin, shown in Figure 11 (right), mixed with 4 wt-% thixotropic agent (Aerosil 380) was applied. A 90° layer was immediately wound over the area to prevent resin runoff. The remaining layers were then applied according to the defined sequence.

Figure 11: Trimmed and formed strut ends (left) and resin application with thixotropic agent (right).

3.4 Vacuum-assisted curing process

To prepare the vacuum setup, a perforated release film was stretched over the wet laminate, followed by the application of breather fabric and vacuum film. Curing was performed under a vacuum of 400 mbar (absolute pressure). Cure cycles were resin-dependent: CR80-10 was cured for 10 hours at room temperature, while Araldite LY 1135-1/917/960 was cured for 4 hours at 80°C, followed by 6 hours at 120°C. The vacuum setup and the final demonstrators after curing are shown in Figure 12.

Figure 12: Vacuum setup (left) and final demonstrators after curing (right).

4 TESTING AND EVALUATION OF THE DEMONSTRATORS

4.1 Hydrostatic burst testing and leakage analysis

Hydrostatic burst tests were conducted on both demonstrators but had to be terminated early due to premature leakage. The tank manufactured with CR80-10 resin exhibited leakage at 80 bar, while the one using Araldite LY 1135-1/917/960 showed leakage at 30 bar. A follow-up test with compressed air and leak detection spray was performed to locate the leaks. In both cases, leakage occurred at the interface between the composite structure and the boss elements (see Figure 13, right). Figure 13 (left) shows one of the demonstrators in the burst test chamber.

Figure 13: Left: Demonstrator in hydrostatic burst chamber. Middle and right: Leak detection at the composite–boss interface using compressed air and leak detection spray.

4.2 Mass and volume

The two demonstrators had masses of 5.86 kg (Demonstrator 1, CR80-10) and 6.35 kg (Demonstrator 2, Araldite 1135/917/960) and an internal volume of 7.7 L. Assuming a design pressure of 100 bar and a safety factor of 2, this corresponds to a theoretical hydrogen capacity of 32 g, resulting in a gravimetric efficiency of 0.50-0.55%. In a dissertation by Ruf [16], a gravimetric efficiency of 5.9% was reported for a conformable tension-strut-reinforced Type IV tank. However, this value is based on simulation results and does not represent a demonstrator at technical scale. The low gravimetric efficiency observed here is partly due to the deliberate overdimensioning of the tank wall and manufacturing challenges leading to a relatively low fiber volume content. This result further highlights the early development stage and low technology readiness level (TRL) of the presented concept.

4.3 Supplementary inspection of laminate and strut connections

To gain further insight into the manufacturing process and investigate the demonstrators in more detail, both tanks were cut into quarters and samples were taken for microscopy and mechanical testing of the strut connections. Cross-sectional images revealed very high porosity and low fiber volume content, especially in the flat sections where the struts are integrated. In the boss area, the composite laminate detached from the aluminum surface during cutting, confirming insufficient bonding at the interface. A neat resin layer was observed on the tank side that faced downward during curing, likely due to gravity-induced flow. The effect was more distinct in the demonstrator manufactured with the

Araldite LY1135-1/917/960 resin system, as can be seen in Figure 14, middle. A cross-sectional image, as well as cut sections from both demonstrators are shown in Figure 14.

Figure 14: Cut sections of demonstrators made with CR80-10 (left) and Araldite 1135/917/960 (middle), and a microscopy image of a strut–laminate interface (right).

Mechanical pull-out tests were performed on a total of 57 samples taken from different sections of each demonstrator to investigate the strength of the joint between the strut and the tank wall. The tests showed an average pull-out force of 1.7 kN for both tanks. However, as already observed in previous studies of the strut connection [17], the results showed considerable scatter (±0.4 kN), which is a known challenge for this concept.

5 DISCUSSION AND LESSONS LEARNED

The demonstrators provided valuable insights into the performance and manufacturability of the strut-reinforced conformable tank concept. Key aspects are summarized below.

Promising outcomes:

The integration of struts into the tank wall was successful in principle. The strut-wall connection withstood the forces expected from coupon-level testing and did not show mechanical failure during hydrostatic loading. In one of the demonstrators, no rupture occurred at 80% of the design pressure (i.e. 80 bar), indicating sufficient mechanical integrity of the strut anchorage. The test was aborted due to leakage, not structural failure.

Identified challenges:

A critical issue was leakage at the interface between the composite structure and the aluminum boss element. The lack of adhesive bonding and the mismatch in thermal expansion between aluminum and CFRP likely contributed to poor bonding, particularly during curing and cool-down of the demonstrator manufactured with the resin system Araldite 1135/917/960. Leakage occurred in both demonstrators: the one cured at 120 °C leaked at 30 bar, and the room-temperature cured one at 80 bar. This suggests that thermal effects may intensify the problem but are not the sole cause. The boss design further limited bonding strength due to the narrow contact area in the center. Local detachment of the laminate from the boss during cutting confirmed insufficient adhesion at the CFRP-boss interface.

Another major challenge was the laminate quality in the flat sections where the struts were integrated. Microscopy revealed severe porosity, attributed to inadequate compaction during winding. In filament winding, compaction relies on fiber tension combined with a convex surface. On flat surfaces, fiber tension does not result in compaction pressure. The presence of the protruding struts prevented the use of compaction rollers and intermediate vacuum consolidation steps. For future investigations, the struts could be inserted after winding to enable better compaction through suitable consolidation methods. However, inserting the struts after laminating introduces additional challenges. Besides the poor compaction, a resin layer was observed on the side of the tank that was positioned at the bottom during curing, which could in the future be prevented by rotating the tank during the curing process (compare Figure 14, middle).

The thermal forming of the strut ends was performed manually and lacked process control, resulting in significant scatter in the measured pull-out strength values. Additionally, the forming process, along

with steps such as inserting and bonding the struts to the winding core and trimming them prior to forming, proved to be highly labor-intensive and time-consuming when carried out manually.

Interpretation and concept evaluation:

From a structural standpoint, the strut-wall connection does not fully utilize the material potential. While the used PA6/CF struts have an average tensile strength of 986 MPa [17], corresponding to 4.1 kN, the strut-wall connection in the demonstrators reached only 1.7 kN on average, resulting in a connection efficiency of 41%. According to calculations by Gleis et al. [17], a 700 bar tank with 100% connection efficiency would require a strut spacing of 5.49 mm. This spacing poses significant manufacturing challenges but remains theoretically feasible given the 4 mm formed strut length used in the demonstrators. However, for the concept to achieve practical viability, the connection strength must be significantly increased. Under more controlled laboratory conditions, 2.1 kN has already been achieved, though further improvements are necessary.

From a manufacturing perspective, the current process is highly complex and involves numerous additional steps compared to the production of conventional cylindrical Type IV tanks. While some of these steps, such as strut bonding, trimming, and forming, could be automated and parallelized (e.g. using a heated press tool for simultaneous forming), the overall production effort and associated costs are high. The cost-effectiveness of these additional manufacturing steps relative to the reported 5-10% increase in volumetric efficiency for cuboid packaging spaces, as indicated by Ruf [16], needs to be further assessed.

6 SUMMARY AND OUTLOOK

This work presents the development and manufacturing of conformable CFRP tank demonstrators reinforced with continuous fiber-reinforced tension struts. While the integration of struts was successfully demonstrated, key challenges remain in improving compaction in laminate regions without curvature, as well as achieving a reliable interface between the CFRP and the aluminum boss. The two demonstrators showed leakage before burst at 30 and 80 bar, respectively. The manual and labor-intensive forming process of the strut ends shows that this approach is significantly more complex and time-consuming compared to the manufacturing of conventional cylindrical tanks. Future efforts will focus on increasing the strut-wall connection strength, enhancing compaction e.g. through a modified process sequence, and generating concepts for scalable, cost-effective production techniques.

Khalifa University

Background

Hydrogen as a clean energy carrier:

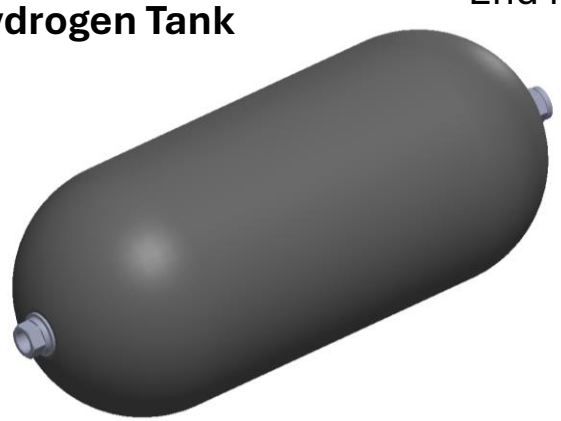
- High specific energy (~3x gasoline by weight) and environmentally friendly
- Challenges in storage due to low volumetric energy density in gaseous form

Hydrogen storage solutions:

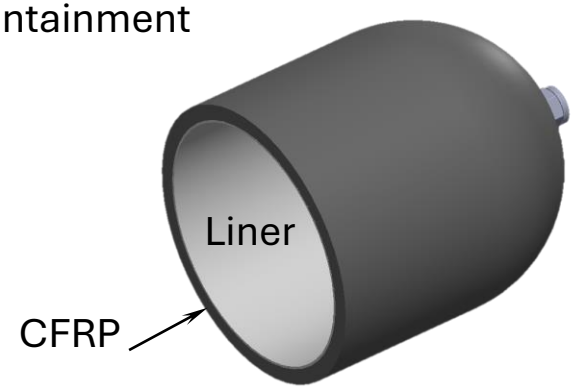
- Commonly stored as compressed gas at 700–900 bar in composite pressure vessels
- Type IV vessels: polymer liner with carbon fiber overwrap for lightweight, strength, and gas containment

Polymer liner challenges:

- Critical barrier against hydrogen permeation.
- Subject to degradation from pressure cycles, temperature changes, and mechanical stress



Medium-Density Polyethylene (MDPE):



- Widely used liner material due to ductility, chemical resistance, and ease of fabrication
- Limitation: relatively high hydrogen permeability affecting long-term storage

Graphene Nanoplatelets (GNPs) as additives:

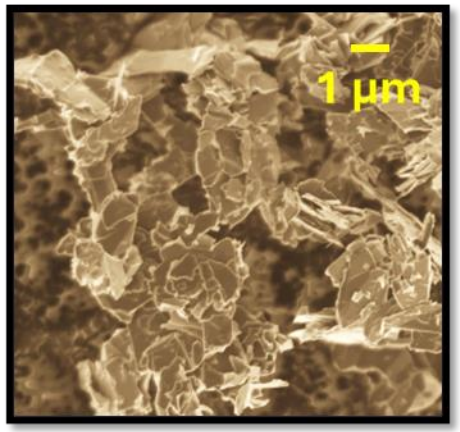
- High aspect ratio and impermeability create tortuous paths reducing gas diffusion
- Improve mechanical strength, stiffness, and impact resistance

Type IV Hydrogen Tank

Filament winding process

Objective of the Work

To systematically investigate the effect of incorporating graphene nanoplatelets (GNPs) at 0.05–1 wt.% on medium-density polyethylene (MDPE) used as a liner material in Type IV hydrogen storage tanks.



To evaluate the impact of GNP addition on:

- Mechanical properties (tensile, flexural, and impact resistance)
- Thermal stability and crystallization behavior
- Gas barrier performance against gas permeation

To analyze the microstructure, filler dispersion, and polymer-filler interactions using advanced techniques such as Raman spectroscopy and 2D mapping.

To establish correlations between nanocomposite structure and macroscopic performance, providing guidance for optimizing liner materials in next-generation hydrogen storage systems.

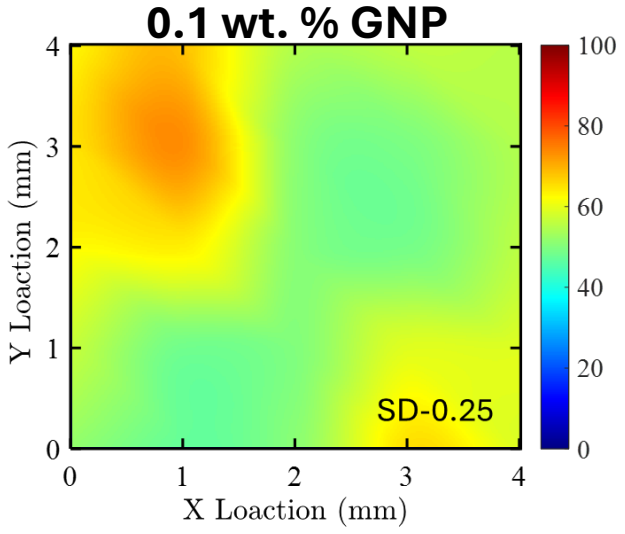
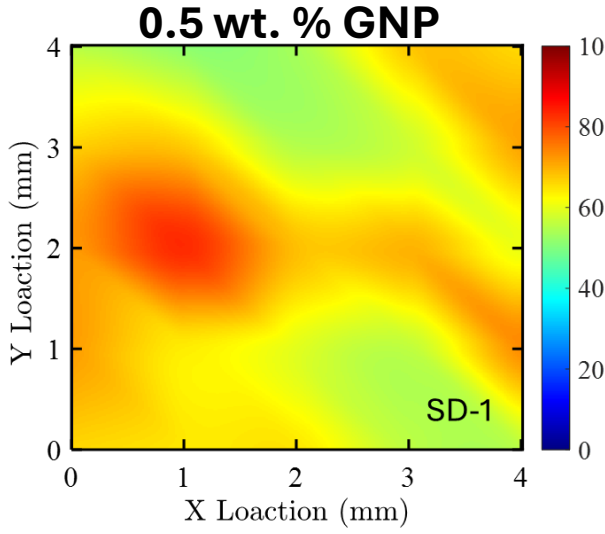
Raman Mapping Analysis of GNP Dispersion in MDPE Composites

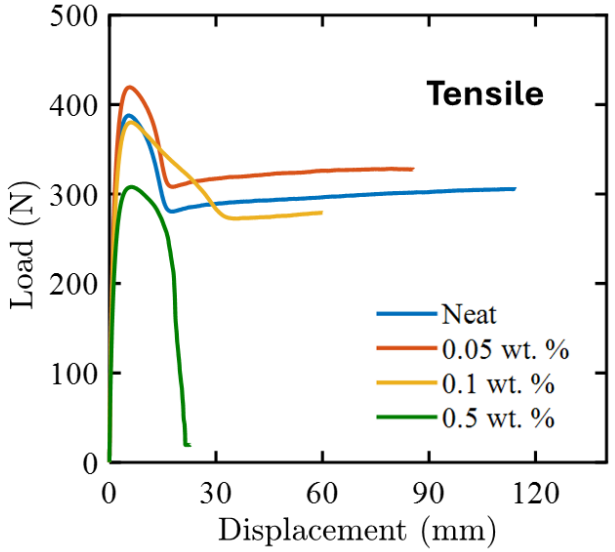


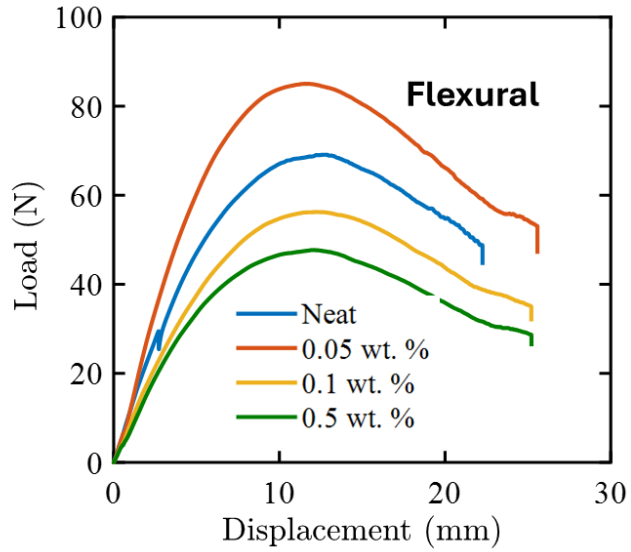
Confirmation of GNP Incorporation: **G-band (1580 cm^{-1}), D-band (1350 cm^{-1}) & 2D-band (2700 cm^{-1}).**



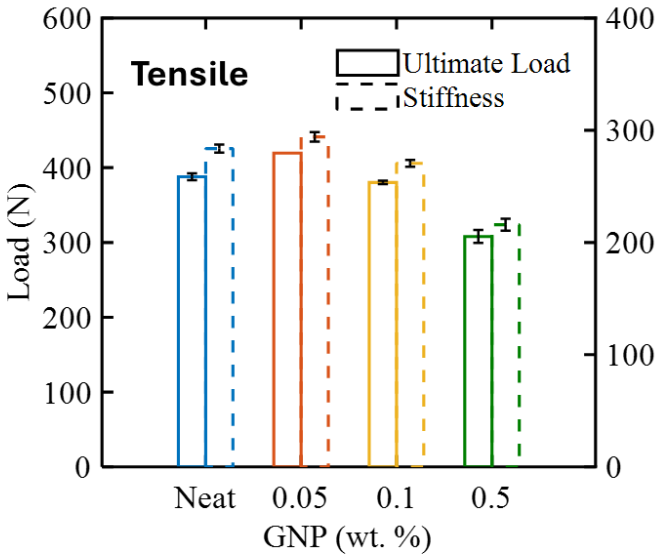
Control Comparison: Neat MDPE shows **no graphitic peaks**, validating GNP-specific signal origin.

Final Takeaway: Optimal GNP loading **(0.05–0.1 wt.%)** ensures structural integrity and **uniform dispersion** in MDPE composites.

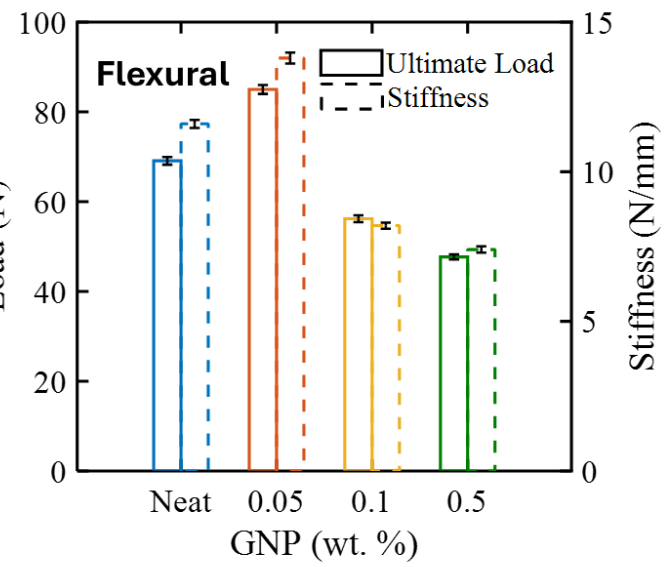




جامعة خليفة
Khalifa University

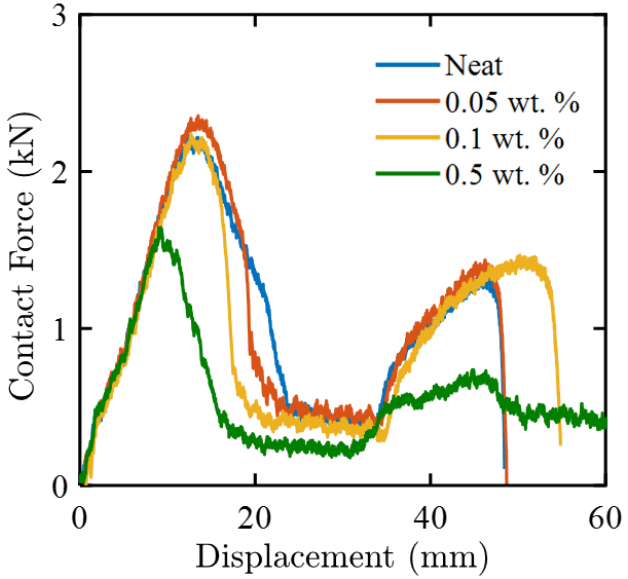


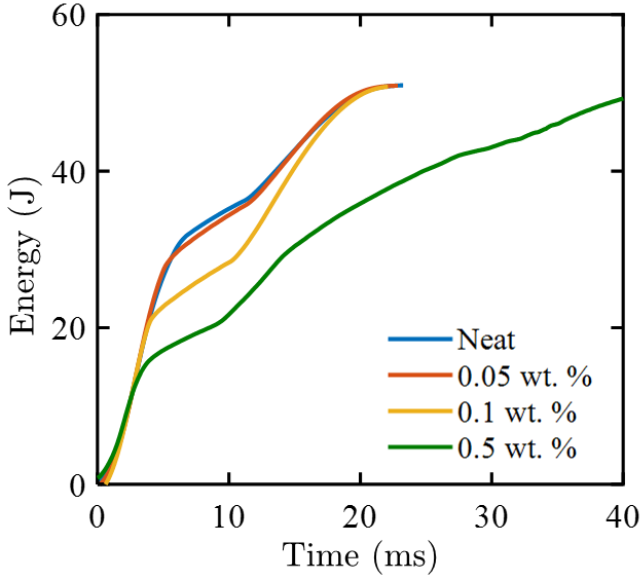
RiC2D

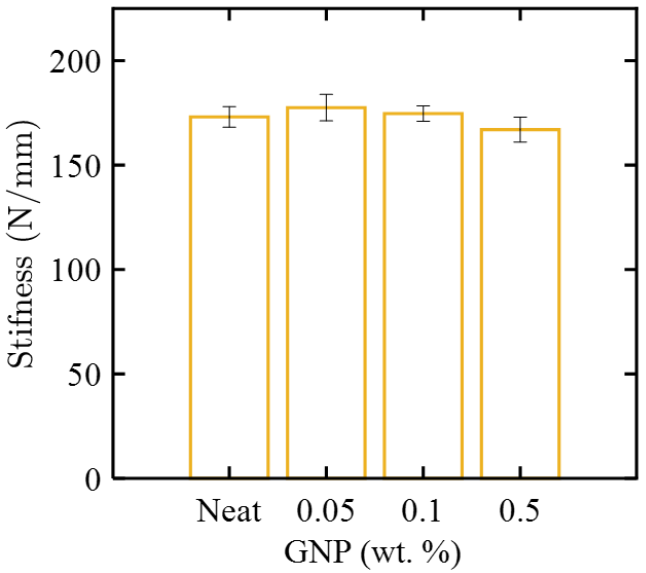


Quasi-Static Mechanical Properties

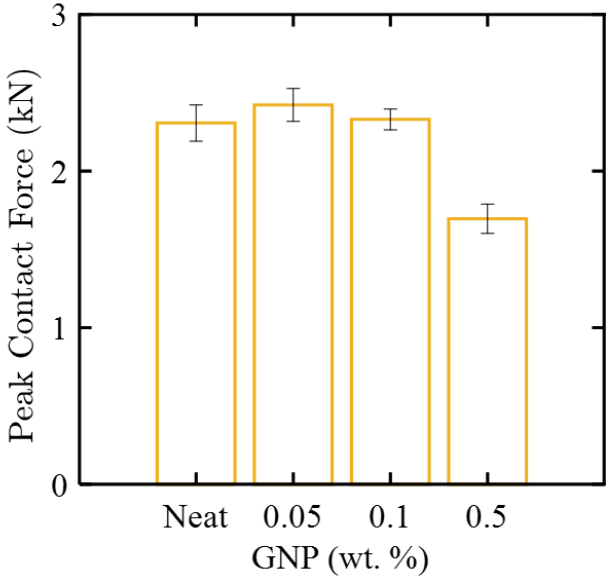
- **0.05 wt.% GNP** raised **tensile load by 8.1% and stiffness by 3.7% vs.** neat MDPE.
- Higher GNP content **(>0.1 wt.%)** led to **agglomeration** and reduced strength.
- **Tensile ductility fell** by **80.2%** from 114.4 mm to 22.7 mm at 0.5 wt.% GNP.
- **Flexural load** rose 23% and stiffness 19% at 0.05 wt.% GNP vs. neat MDPE.





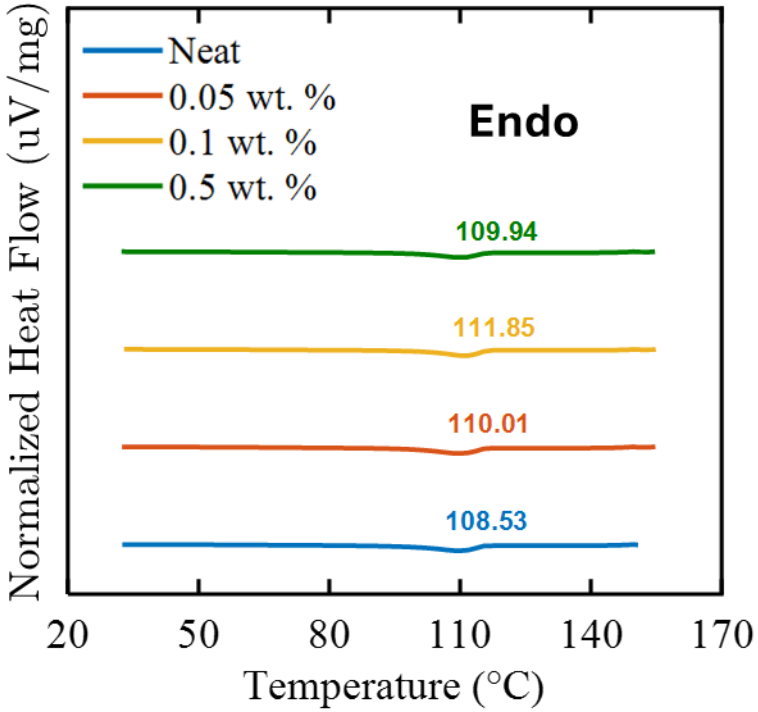


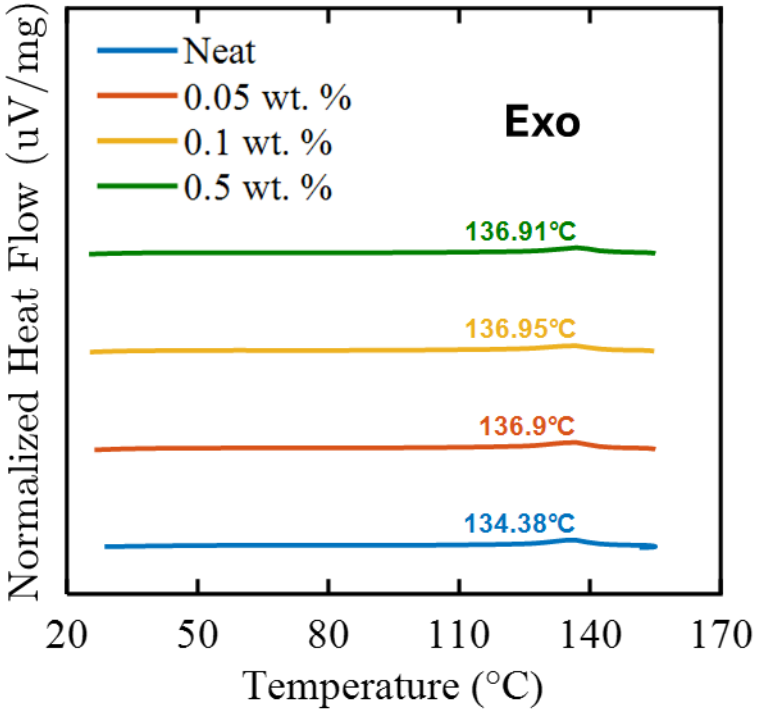
Quasi-static test	Samples Shape	Samples Dimensions (mm)	Loading Speed (mm/min)
Tension	Dog-bone	33 (gauge length) × 6.35 × 3.5	5
3-Point Flexural	Rectangular	127 ×12.7 × 3.5	5



Dynamic Energy Absorption Characteristics

- Impact trends a**lign with quasi-static results,** optimal at 0.05 wt.%.
- **Neat MDPE** absorbed **30.76 J**; GNP helps only when well dispersed.
- **0.05 wt.% GNP** improved **peak force (+5%) and energy absorption (+3.6%).**
- 0.05 wt.% GNP enhances energy dissipation mechanisms.
- **1 wt.% GNP** caused **26.5% drop** in peak force due to filler agglomeration.

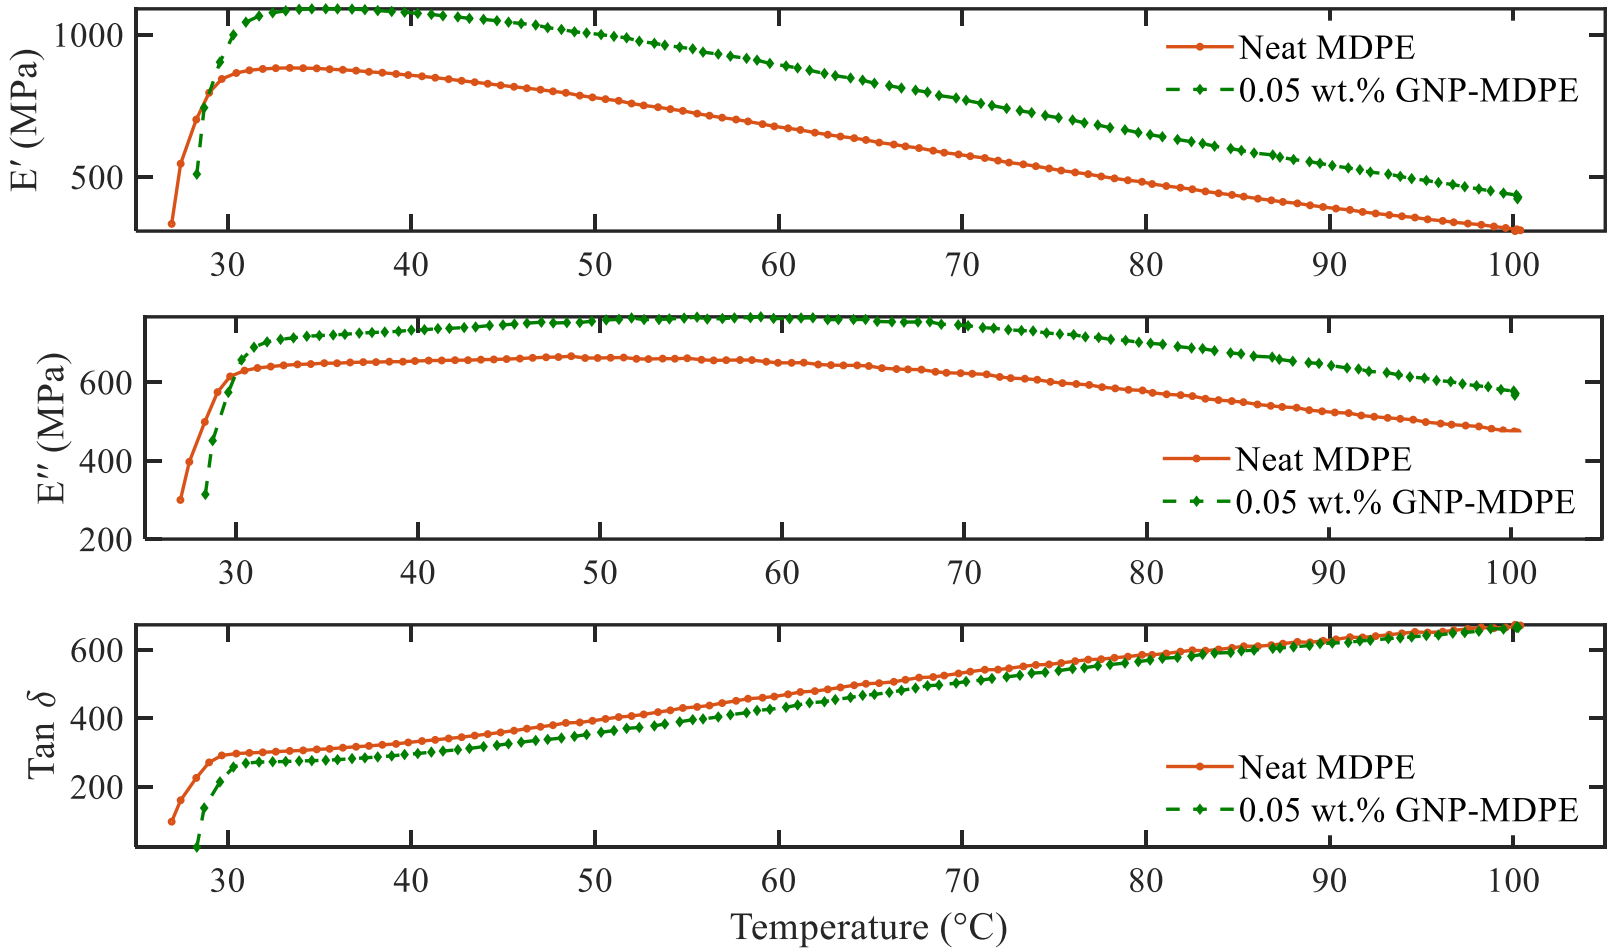




- Striker: 12.7 mm hemispherical steel
- 5.45 kg mass
- Impact energy: 50 J
- Specimen size: 60 × 60 mm^2

Thermal Analysis

- **0.05 wt.% GNP** raised melting temp **(Tm) by 1.4%;** 0.1 wt.% raised it by 3.1%.
- Tm dropped slightly at 0.5 wt.% GNP, likely due to nanoparticle agglomeration.
- Crystallization temp **(Tc)** increased from **134.4 °C to ~136.9 °C** for all GNP loads.



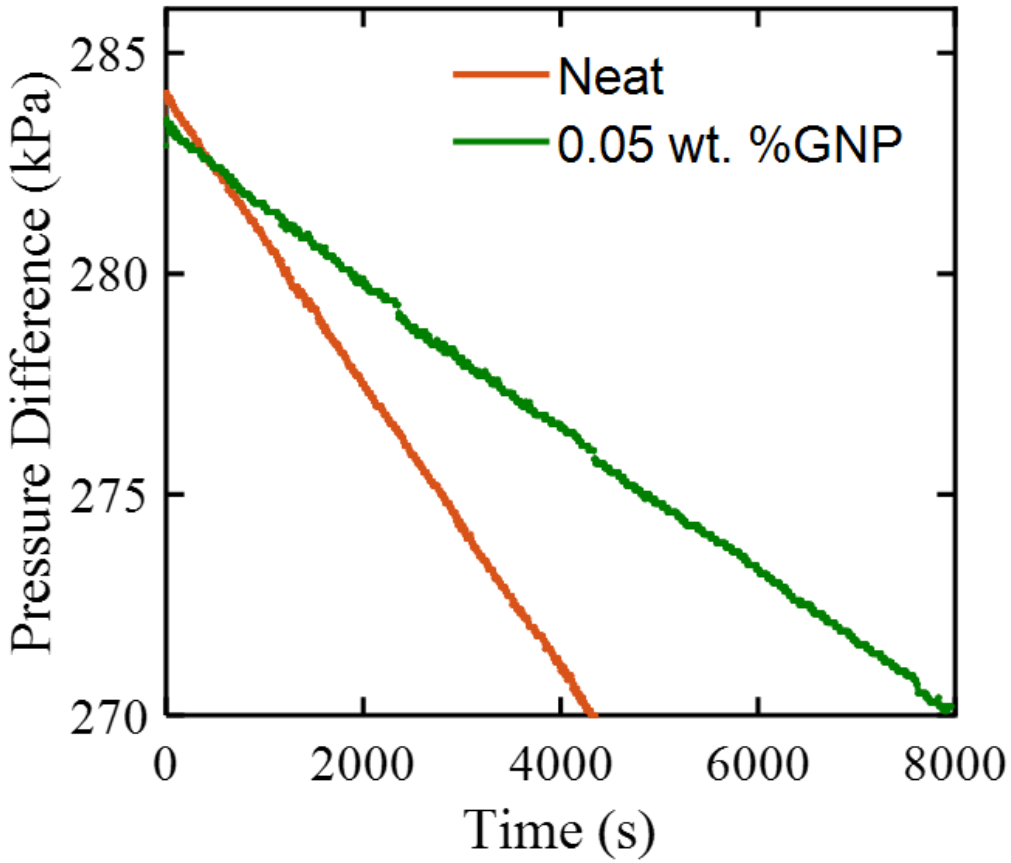
- Rise in Tc confirms GNPs act as nucleation sites during polymer cooling.
- Higher GNP loadings didn't further increase Tc, suggesting nucleation saturation.
- **Dual effect:** GNPs raise Tc via nucleation, and Tm via chain mobility restriction.
- Improved thermal transitions support **better stability** in hydrogen tank liners.

- DSC Sample mass: ~10 mg
- Heating range: 30 °C to 150 °C
- Heating/cooling rate: 10 °C/min
- Atmosphere: Nitrogen
- Cooling range: 150 °C to 30 °C

جامعة خليفة Khalifa University RiC2D

Thermomechanical Stability and Energy Dissipation Characteristics

- GNP-reinforced MDPE maintained **higher stiffness** across entire temp range.
- Loss modulus peaked ~140 MPa with GNP, 22% higher than neat MDPE (~115 MPa).
- Slightly lower tan δ (0.216 vs. 0.218) suggests restricted chain mobility.
- **GNPs enhance toughness** without sacrificing stiffness or damping.
- DMA **confirms strong GNP–matrix interaction** and good nanoparticle dispersion.
- Even 0.05 wt.% GNP **boosts thermal-mechanical stability** significantly.



- Test mode: 3-point bending (25 mm span); Heating rate: 5 °C/min
- Specimen size: 30 × 12.5 × 3.5 mm^3; Frequency: 1 Hz
- Temperature range: –40 °C to 100 °C

Khalifa University جامعة خليفة

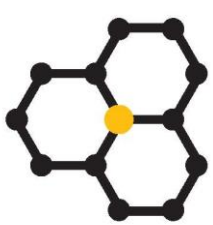
RiC2D

Gas Permeability test

- **0.05 wt.% GNP** significantly reduced gas permeability in MDPE sheets. GNP/MDPE showed slower pressure drop, indicating **lower gas diffusion rate**.
- GNPs create **tortuous pathways**, hindering gas molecule movement.
- Barrier effect stems from GNP's high aspect ratio and impermeability.
- Low filler loading still provides stable, **long-lasting diffusion resistance.**
- Enhanced gas resistance achieved **without sacrificing processability**.
- **Ideal for hydrogen tanks** where long-term barrier integrity is essential.

- Test gas: Helium
- Temperature: Room temperature (~25 °C)
- Pressure: Constant 10 bar
- Sample thickness: 0.5 mm

Conclusion



- The addition of GNPs significantly improved MDPE's multifunctional properties, with 0.05 wt.% identified as the optimal concentration. At this level:
  - Tensile strength and stiffness increased by 8.1% and 3.7%,
  - Flexural load and stiffness improved by 23% and 19%,
  - Low-velocity impact tests showed a 5.0% rise in peak contact force and 3.6% higher absorbed energy, indicating better dynamic load resistance.
- Raman spectroscopy and 2D mapping confirmed uniform dispersion at 0.05 wt.% (standard deviation = 0.05), while higher loadings caused agglomeration and reduced performance.
- Thermal analysis revealed: Increased melting point (from 108.5 °C to 111.9 °C)~2.5 °C rise in crystallization temperature due to nucleation
- DMA showed:15.5% increase in storage modulus21.7% increase in loss modulus, indicating improved stiffness and damping
- Helium permeability tests confirmed enhanced gas barrier performance due to well-dispersed GNPs.

These results establish low-GNP MDPE nanocomposites as strong candidates for Type IV hydrogen storage liners, combining mechanical strength, thermal stability, and impermeability.

CMH-17
COMPOSITE MATERIALS HANDBOOK

Composite Materials Handbook (CMH-17): An Introduction and Overview

Teresa Vohsen
Wichita State University
National Institute of Aviation Research
Presenting at ICCM24 in Baltimore, MD

Outline

- What is CMH-17?
  - Organization and Operating Structure
  - Our Members and our work
  - Goals
- What does CMH-17 Offer You?
  - Upcoming releases: Vol. 2, 3, 5, 6, and 7
  - Statistics Software
  - Education, Training, and Knowledge Sharing
- How can you get involved?

What is CMH-17?

CMH-17
COMPOSITE MATERIALS HANDBOOK

- CMH-17 stands for the Composite Material Handbook, which is supported by a Composite Material Handbook *Organization*
- The Handbook itself consists of 6 volumes published by SAE, with a 7th in work on non-metallic additive manufacturing
  - The six volumes were originally MIL-HDBK-17 (Vol 1-5) and MIL-HDBK-23 (Vol 6)
  - The FAA took over management near the turn of the century and renamed the organization in 2005
- CMH-17 operates as a volunteer organization comprised of international participants from industry, government, and academia

Key Information about CMH-17

- Aviation authorities rely on CMH-17 to supplement formal guidance:
  - Strong focus on safety, certification efficiency and workforce education
  - Rich record of lessons learned and best practices

- Although funded by the FAA, handbook content is primarily written by industry and reflects priorities of both regulators and industry members:
  - In this unique organization competitors collaborate to document common engineering, manufacturing, and maintenance guidelines and protocols for complex subjects, including those applied to ensure aircraft safety and efficient product certification, which otherwise are typically kept as proprietary practice

Working with CMH-17

Our Members' Experience:

- FAA funded, chaired, and steered organization focused on safety and collaboration
- International networking with technical experts
- Collaboration across companies
- A level playing field for all membership regardless of industry segment
- Unparalleled learning opportunities with tutorials on Certification, Bonded Processes, our Statistics Software, and more

Our Organization Experiences:

- Industry consensus on content like other SDO products
- Thriving technical community of experts
- Over 20 active Working Groups and 15 active Task Groups
- Opportunities for connection, growth, and modernization based on participant feedback
- Peer-reviewed, and balloted content on industry best practices
- Biannual joint coordination meetings to deepen connections and knowledge transfer

CMH-17 Goals

CMH-17
COMPOSITE MATERIALS HANDBOOK

The handbook has three goals/purposes:

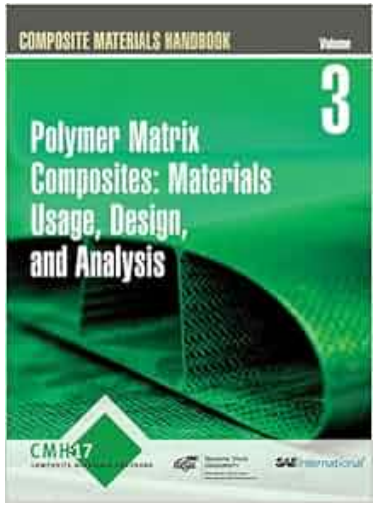
1. Provide material data
   - PMC, MMC, CMC, Sandwich Structure, and Non-Metallic AM
   - Physical and mechanical properties
   - Tied to a single material specification AND a single process specification (published elsewhere, but publicly available)
2. Describe how to generate material data
   - Material and process control
   - Test matrices and testing methodologies
   - Statistical methods
3. Describe how to use material data
   - Proven methodologies, engineering solutions, best practices, lessons learned, and case studies for the design, analysis, certification, manufacture, and field support of parts and structures made from advanced materials

- Includes significant information for aerospace applications, with benefit to other applications
- Constitutes overview of advanced composite and additive materials technology and engineering
- Volumes are continuously being updated to reflect advances in industry best practices

What's in the Handbook?

CMH-17
COMPOSITE MATERIALS HANDBOOK

Testing Procedures
Process Controls
Spacecraft Applications



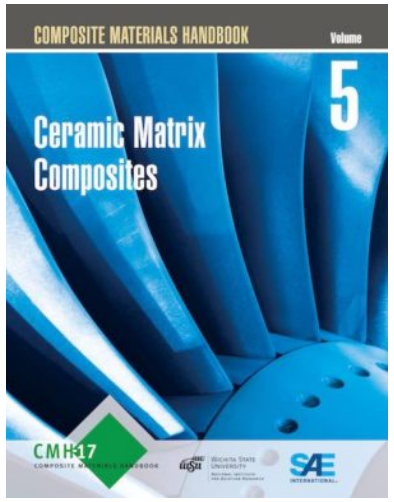
Bonded Processes
Sustain-ability
Material Qualification
Design Tools
Damage Tolerance
Engine Applications
Statistical Material Data
Structural Substantiation
Support-ability
Building Block Approach
Integrated Product Teams
Analysis Methods
Case Studies
Quality and Inspection
Disbond Analysis

Active Items

WHAT DOES CMH-17 OFFER YOU?

Volume 3: PMC Materials Usage, Design, and Analysis

Revision H – planned release Oct 2025



- Volume 3 provides methodologies and lessons learned for the design, analysis, manufacture, and field support of fiber-reinforced PMC structures.
- Also provides guidance on material and process specifications and procedures for utilization of the data presented in Volume 2.
- Information is an extensive compilation of the current knowledge and experiences of the engineers and scientists from industry, government, and academia who actively apply composites to products.

- Rev H has more than doubled in content (990 Rev G pages to over 2000 pages)
  - New content on Building Block Approaches, Damage Tolerance, Structural Bonding, Design, Sustainability and Supportability, Crashworthiness, Engine and Space Applications
  - The tremendous advancement could only be achieved through collaboration and buy-in from all members

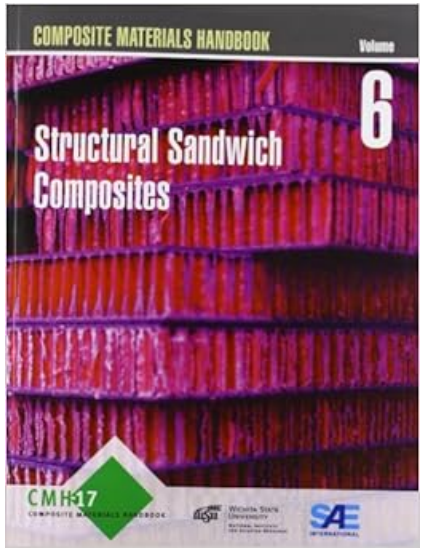
Volume 5: Ceramic Matrix Composites

Revision B – planned release Dec 2025

- Volume 5 contains CMC material system properties for which data meeting the specific requirements of the handbook are available.
- Also provides selected guidance on other technical topics related to SiC/SiC and Ox/Ox composites:
  - Material selection of constituents and external coatings
  - Material specifications, processing and quality control
  - Characterization, testing, and data reduction
  - Design and analysis
- Revision B has increased content by about 25% from Rev A
  - New content on Environmental Barrier Coatings, Engine Applications, new Data Sets, increased information on melt infiltrated (MI) SiC/SiC, Attachments, and Testing Methodologies.

Volume 2: PMC Material Properties

Revision J – planned release Spring 2026



- Volume 2 contains reviewed and approved material property data for polymer matrix composites.
  - Data is arranged in categories by reinforcement class and matrix class. Within a category, the data is in chronological order (based on when data was submitted).
  - Data is also divided by full data documentation (including public material specifications) and older partial documentation data
  - Volume 2 Annex contains data with export control restrictions

- Revision J will include new approved data sets

Volume 6: Structural Sandwich Composites

Revision A – planned release Spring 2027

- Volume 6 provides information on the design, analysis, and fabrication of composite sandwich structures
- Includes typical design values for sandwich constituent materials (core, adhesives).
- MIL-HDBK-23 information was incorporated into initial release of Volume 6.
- Revision A will include an increased emphasis on damage tolerance and damage arrestment features as primary design considerations in structural sandwich designs.
  - Volume is being reorganized and expanded from 7 into 12 chapters
  - Will document industry best practices in a range of aircraft applications from cabin interior structures to primary structural components, covering structural design and analysis, material and process controls, manufacturing implementation and maintenance practices
  - Will provide newly developed methods for assessing damage in sandwich structures for maintenance and repair.

Volume 7: Non-Metallic Additively Manufactured Materials – planned release Fall 2026

CMH-17
COMPOSITE MATERIALS HANDBOOK

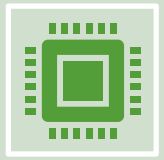
VOLUME 7
1 CMH-17 AM Introduction And Guidelines
2 Characterization Considerations
3 Evaluation of Feedstock
4 Processing and Manufacturing
5 Quality Control of Production Materials And Processes
6 Material Testing & Characterization For Submission Of Data to CMH-17
7 Property Testing of Additively Manufactured Materials
8 Statistical Methods
9 Evaluation of AM Parts
10 Element Level Testing
11 Design and Analysis
12 Maintainability And Supportability
13 Applications, Case Histories, and Lessons Learned
14 AM Property Data

Volume 7 will be a new volume covering non-metallic AM materials.

Provide knowledge necessary to efficiently design, certify, manufacture, and maintain non-metallic AM parts in aerospace applications

CMH-17 Statistics Software

CMH-17 COMPOSITE MATERIALS HANDBOOK



CMH-17 defines procedures for statistical analysis for composite testing data

Statistical methods included in CMH-17 are available in software form for purchase

Software generates A- and B-basis values and test statistics for material equivalency and acceptance testing (modified coefficient of variation (MOD CV)).

A Python based software is in development to replace the existing Excel based software

New software has finished beta testing and statistical equivalency testing

User Interface is in development

New Software and Tutorial planned for May 2026

Involvement to Influence Content Development and Learning Opportunities

CMH-17
COMPOSITE MATERIALS HANDBOOK

- Our semi-annual meetings are an excellent networking opportunity
- In attendance are subject matter experts (SMEs) from the FAA, EASA, DoD, NASA, the worldwide aerospace industry, and academia
  - Spring meetings are in person at various sites in continental US and fall meetings are virtual
  - Meetings include “all-hands” coordination sessions, a technical forum, and working and task group meetings
  - May include mini-tutorials, FAA-sponsored research reviews, panel sessions, local industry tours
  - Offer optional 6-hour tutorials during our spring in-person meetings
- We plan to aggressively increase our training offerings, both in-person and virtually, to help explain handbook content and share best practices, particularly for the newly revised volumes.
  - Will include opportunities for Q&A with organizational SME

WE'RE WORKING ON A LOT!

A NOVEL SLEEVE ASSEMBLY METHOD FOR SPM MOTORS USING CFRP WITH ATYPICAL LAYUP

Kazunori Takagaki, Ichiya Takahashi, Masami Kume, Tatsuya Koyama and Hiroki Kobayashi[1]

[1] Composite & Ceramic Material Section, Materials & Processing Technology Department,
Advanced Technology R&D Center, Mitsubishi Electric Corporation
8-1-1, Tsukaguchi-Honmachi, Amagasaki City, Hyogo 661-8661, Japan
Email: Takagaki.Kazunori@ak.MitsubishiElectric.co.jp
web page: https://www.mitsubishielectric.com/en/

Keywords: Carbon fibre, Polymer-matrix composites (PMCs), Anisotropy, Mechanical properties, Laminate mechanics

ABSTRACT

Motor is one of the most important components for industry. Some of surface permanent magnet (SPM) motors have sleeves made of carbon fibre reinforced plastics (CFRPs) to prevent magnets from separating during operation. Though the CFRP sleeve is conventionally assembled by press fitting, this process is cost intensive. Therefore, this research aimed to propose a novel sleeve assembly method for the SPM motors to reduce the cost and the press-fit pressure. For the purpose, a theoretical analysis based on the classical lamination theory was carried out and the concept of 'anomalous Poisson's effect' was proposed. This is the coupling effect of an anisotropic material, inducing normal strain by shear force. The optimized layup was determined to maximize the tension in the circumferential direction after assembly. A CFRP cylinder was then fabricated to experimentally validate the theoretical result. Torsion test was carried out on the cylinder, successfully confirming the validity of the anomalous Poisson's effect. In addition, a concept was proposed to prevent interaction between the cylinder and core during assembly.

1 INTRODUCTION

Motor is one of the most important components for industry. It is a key element for electric vehicles, factory automation and so on. Since motors consume more than 40% of global electricity consumption [1], improving their performance is a crucial issue for addressing global warming as well as for cost reduction.

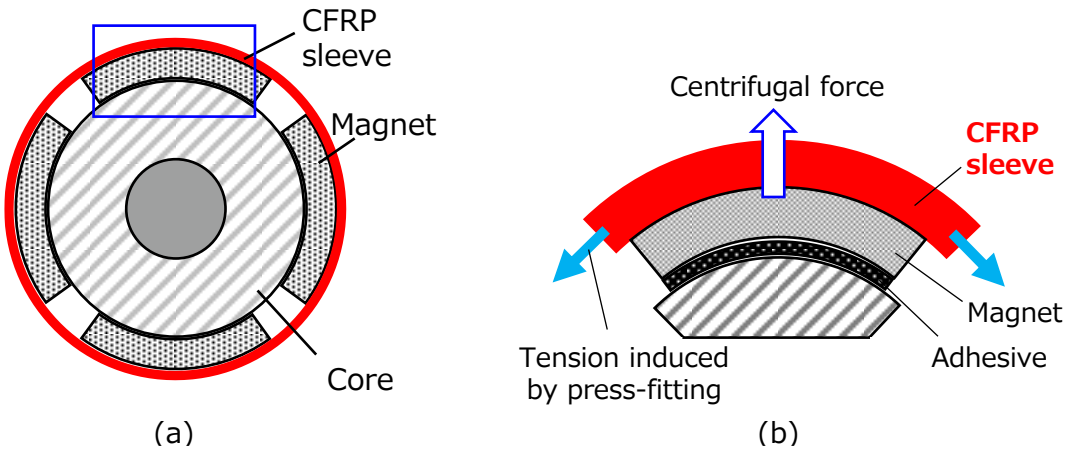

Figure 1: Schematic of rotor of SPM motor with CFRP cylinder.
(a) Cross sectional view of whole structure. (b) Enlarged view of blue line in (a).
Core and magnets are press-fitted, inducing tension in CFRP. It prevents the magnet from leaving from the core under centrifugal force.

Surface permanent magnet (SPM) motors have magnets mounted on the rotor cores and are highly efficient. Figure 1 depicts schematic of a SPM motor. SPM motors with high-speed rotation use sleeves to prevent the magnets separating from the cores under the centrifugal force. Since high strength materials are desirable for the sleeve, carbon fibre reinforce plastic (CFRP) has been adopted for some of SPM motors. A CFRP cylinder is assembled onto the core by press-fitting, making the motor manufacturing process uneconomical. This research proposes a novel sleeve assembly process with CFRP having an atypical stacking sequence to reduce the cost and the press-fit pressure.

2 CONCEPT AND THEORETICAL ANALYSIS

2.1 Basic Concept

Figure 2 illustrates the schematic of the conventional and proposed assembly processes. As shown in Figure 2 (a), the conventional method utilizes a CFRP with fibres mainly aligned in the circumferential (0^o) direction. A core and magnets are press-fitted into a CFRP, inducing tension due to the change in the circumferential length of the CFRP. Meanwhile, the basic concept of the assembly process proposed in this research is to use a CFRP cylinder which expands in the radial direction when it is subjected to torsion. Torque generally do not affect diameters of cylinders made of isotropic materials (e.g., metals and polymers), and the same is true for even CFRP with a harmonic layup. The torsion-diameter coupling, however, is achieved by activating the coupling effect of an anisotropic material. Based on the analogy to the Poisson's effect, the phenomenon is called 'anomalous Poisson's effect' in this research. The middle image in Figure 2 (b) depicts the expanded CFRP under torque. After inserting the core and magnet into the expanded CFRP, the torque is released, and more preferably CFRP is twisted in the opposite direction to induce tension as shown in the bottom figure. This assembly method tightly holds the magnets in place while eliminating press-fitting process. The layup of the CFRP is discussed in the following section.

2.2 Theoretical analysis

For simplicity, CFRP with two fibre direction ($[\theta_1/\theta_2]_{2S}$) was considered in this research. Figure 3 illustrates the coordinate system used in this research. According to the classical lamination theory (CLT), resultant force is written as

$$\begin{Bmatrix} \boldsymbol{N} \\ \boldsymbol{M} \end{Bmatrix} = \begin{bmatrix} \boldsymbol{A} & \boldsymbol{B} \\ \boldsymbol{B} & \boldsymbol{D} \end{bmatrix} \begin{Bmatrix} \boldsymbol{\varepsilon}^0 \\ \boldsymbol{\kappa} \end{Bmatrix} \tag{1}$$

where $\{\boldsymbol{N}\}$ and $\{\boldsymbol{M}\}$ are force and moment resultant with three dimensions, $[\boldsymbol{A}]$, $[\boldsymbol{B}]$,and $[\boldsymbol{D}]$ are 3x3 stiffness matrices, and $\{\boldsymbol{\varepsilon}^0\}$ and $\{\boldsymbol{\kappa}\}$ are neutral plane strains and curvatures with three dimensions. For specific derivation and values, see a reference [2] for example. This research deals with symmetric laminates and therefore does not consider bending moment. Thus, $[\boldsymbol{B}]$ and $[\boldsymbol{D}]$ matrices are ignored as

$$\begin{Bmatrix} N_x \\ N_y \\ N_{xy} \end{Bmatrix} = \begin{bmatrix} A_{11} & A_{12} & A_{16} \\ A_{12} & A_{22} & A_{26} \\ A_{16} & A_{26} & A_{66} \end{bmatrix} \begin{Bmatrix} \varepsilon_x^0 \\ \varepsilon_y^0 \\ \gamma_{xy}^0 \end{Bmatrix} \tag{2}$$

where ε^0 and γ^0 are normal and shear strains at the neutral plane. The subscripts *x* and *y* represent the directions of a laminate. Assuming that only torque is applied to the cylinder, shear force N_{xy} is solely induced and eq. (2) is transformed as

$$\begin{Bmatrix} \varepsilon_x \\ \varepsilon_y \\ \gamma_{xy} \end{Bmatrix} = \begin{bmatrix} [A]^{-1}{}_{11} & [A]^{-1}{}_{12} & [A]^{-1}{}_{16} \\ [A]^{-1}{}_{12} & [A]^{-1}{}_{22} & [A]^{-1}{}_{26} \\ [A]^{-1}{}_{16} & [A]^{-1}{}_{26} & [A]^{-1}{}_{66} \end{bmatrix} \begin{Bmatrix} 0 \\ 0 \\ N_{xy} \end{Bmatrix} = \begin{Bmatrix} [A]^{-1}{}_{16} \\ [A]^{-1}{}_{26} \\ [A]^{-1}{}_{66} \end{Bmatrix} N_{xy} \tag{3}$$

where $[A]^{-1}{}_{ij}$ indicates the $[i, j]$ component of the inverse matrix of the in-plane stiffness matrix $[\boldsymbol{A}]$.

Although several failure criteria exist [3], the maximum strain theory was adopted in this research due to its simplicity. Based on the theory, the maximum allowable shear force is shown as

$$N_{xy\,\max} = \min\left(\frac{Y_1^-}{{\varepsilon_1}^1}, \frac{Y_1^+}{{\varepsilon_1}^1}, \frac{Y_2^-}{{\varepsilon_2}^1}, \frac{Y_2^+}{{\varepsilon_2}^1}, \frac{Y_{12}}{|{\gamma_{12}}^1|}, \frac{Y_1^-}{{\varepsilon_1}^2}, \frac{Y_1^+}{{\varepsilon_1}^2}, \frac{Y_2^-}{{\varepsilon_2}^2}, \frac{Y_2^+}{{\varepsilon_2}^2}, \frac{Y_{12}}{|{\gamma_{12}}^2|}\right) \quad (4)$$

where ε and γ represent the normal and shear strains induced by unit shear force $N_{xy} = 1$, and Y is the maximum allowable strain. The superscripts on the strains represent the fibre directions of the layup ($[\theta_1/\theta_2]_{2S}$), and the superscripts of Y show tension, +, and compression, -. The subscripts 1 and 2 represent fibre and transverse directions, respectively. Each value used in this research is shown in Table 1. Note that all the strains in eq. (4) are the strains in the fibre and transverse direction of each ply. From eqs. (3) and (4), the maximum strain induced by the shear force, $\varepsilon_{x\,max}$, is written as

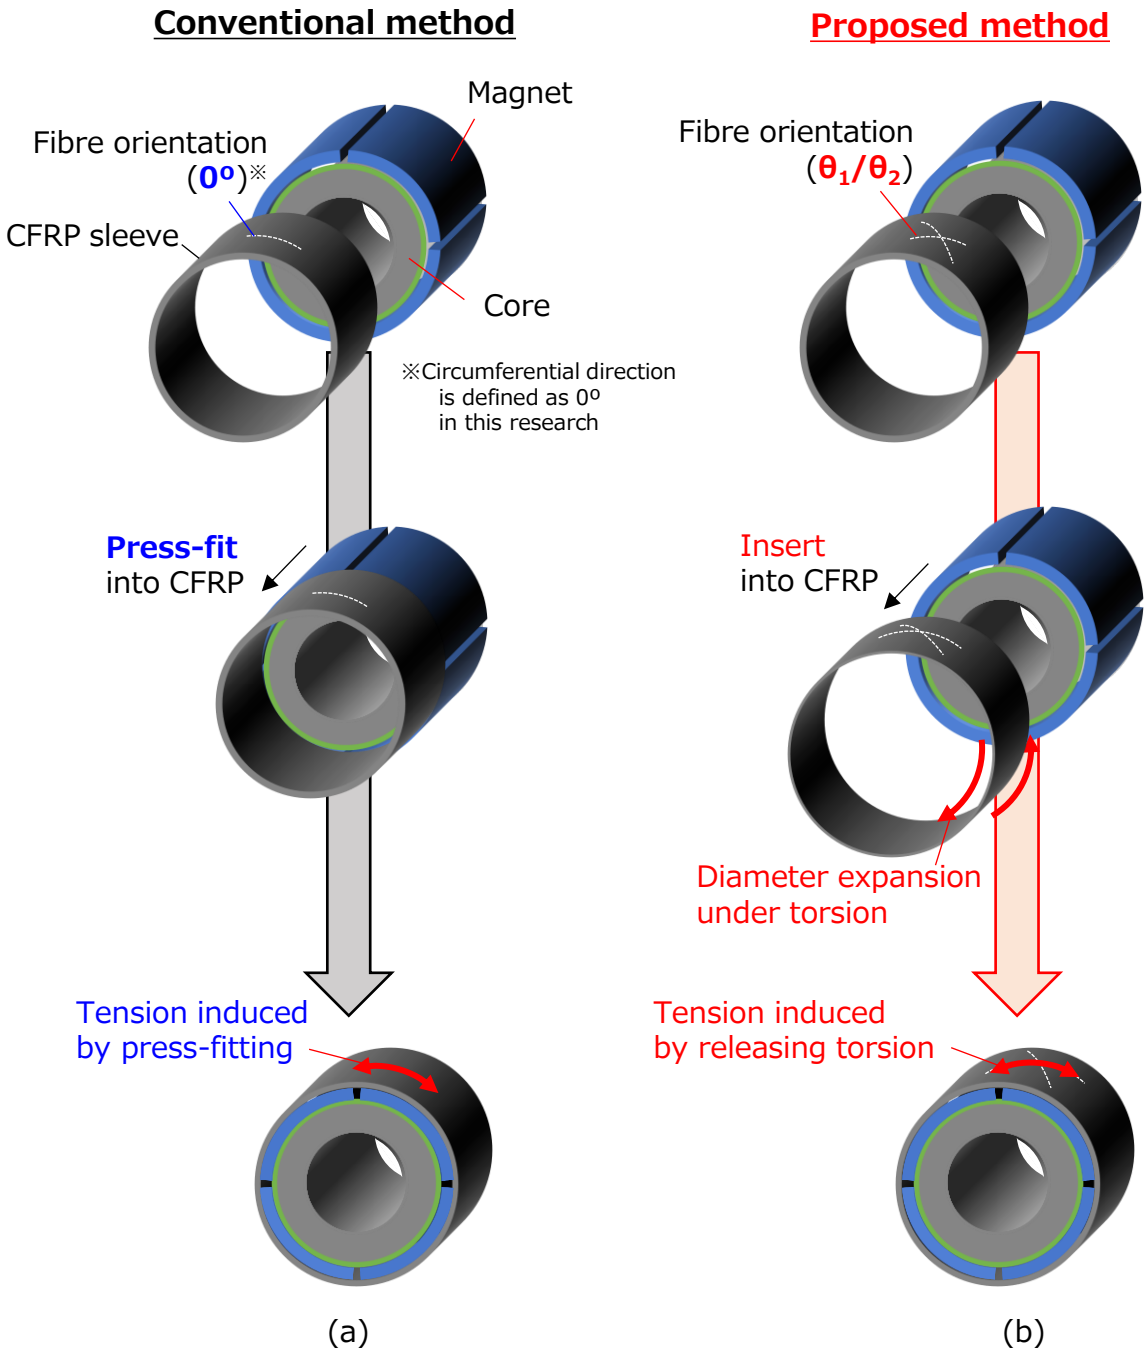

Figure 2 Assembly process of CFRP cylinder. (a) conventional press-fit method, (b) proposed method using CFRP cylinder with atypical layup.

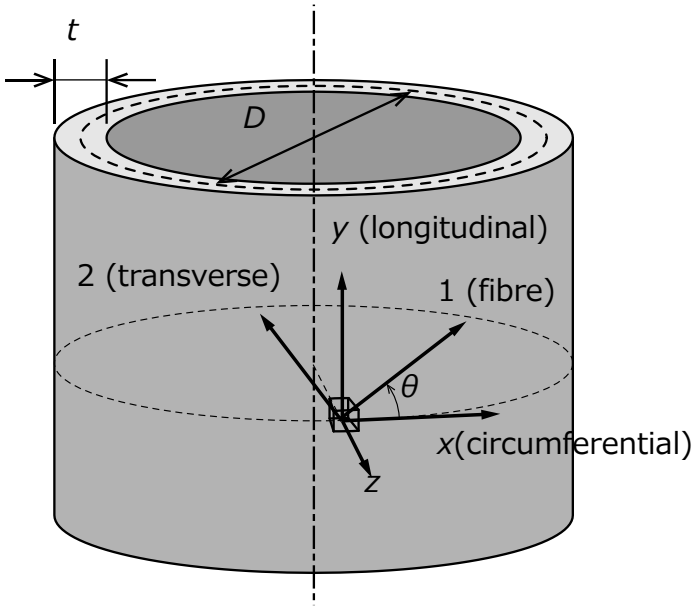

Figure 3 Coordinate system on CFRP cylinder.

$$\varepsilon_{x\,max} = [A]^{-1}{}_{16} \cdot N_{xy\,\max} \tag{5}$$

Assuming that the *x* direction corresponds to the circumferential direction of the cylinder, the maximum strain in the circumferential direction is calculated by eq. (5).

Then the tension in the circumferential direction after releasing torque is calculated, which corresponds to the bottom image in Figure 2 (b). Assuming that the forces in the longitudinal and shear direction would be negligible after releasing torque, only the circumferential force, N_x in eq. (2) exists and eq. (2) reduces to

$$\begin{Bmatrix} \varepsilon_x \\ \varepsilon_y \\ \gamma_{xy} \end{Bmatrix} = \begin{bmatrix} [A]^{-1}{}_{11} & [A]^{-1}{}_{12} & [A]^{-1}{}_{16} \\ [A]^{-1}{}_{12} & [A]^{-1}{}_{22} & [A]^{-1}{}_{26} \\ [A]^{-1}{}_{16} & [A]^{-1}{}_{26} & [A]^{-1}{}_{66} \end{bmatrix} \begin{Bmatrix} N_x \\ 0 \\ 0 \end{Bmatrix} \tag{6}$$

Assuming no gap between the expanded cylinder and the core, $\varepsilon_{x\,max}$ in eq. (5) corresponds to ε_x in eq. (6), leading to the circumferential force, N_x, after releasing torque as

$$N_x = \frac{\varepsilon_{x\,max}}{[A]^{-1}{}_{11}} = \frac{[A]^{-1}{}_{16}}{[A]^{-1}{}_{11}} \cdot N_{xy\,max} \tag{7}$$

The circumferential stress is obtained by dividing the circumferential force in eq. (7) by thickness of the cylinder, *t*, as

$$\sigma_x = \frac{N_x}{t} \tag{8}$$

Calculations were carried out for all sets of two fibre directions, θ_1 and θ_2, with 1° increments from 0° to 90°.

2.3 Analysis Results

Figure 4 shows the strain, ε_x, calculated by eq. (3) with unit shear force (i.e., N_{xy}=1). The strain, ε_x, corresponds to the circumferential strain in the cylinder case. The horizontal and vertical axes represent fibre directions, θ_1 and θ_2, respectively. The map has symmetrical contour, and several areas have high strain value above 30 με. Meanwhile, strain is not induced with harmonic layups (i.e., $\theta_2 = -\theta_1$ line in the figure), verifying the calculation.

Figure 5 (a) shows the maximum strain calculated by eq. (5). The maximum strain above 1.2% is

achievable. Note that thought the areas with strain above 1.2% matches to the high strain area in Figure 4, the maximum strain are relatively low at the high strain area at the top right and bottom left in Figure 4. This would be because different criterions in eq. (4) were applied in different areas. Figure 5 (b) shows the stress after releasing torque calculated by eq. (8). The highest stress value is above 350 MPa at the vicinity of $\theta_1 = \theta_2 = 0°$ where the fibres wound in the circumferential direction of the cylinder.

Figure 6 replots the relationship between the maximum strain (Eq. (5)) and stress after releasing torque (Eq. (8)). Each point represents a set of two fibre directions, θ_1 and θ_2. Though the maximum strain exceeds 1.2% with some layups, the stress remains relatively low, below 200 MPa. The main purpose of this research is to achieve high tension (i.e., circumferential stress) to prevent the magnets from separating from the cores. Therefore, the layup circled in red in Figure 6 was chosen for the following experiment since the highest stress is expected. Note that though the maximum strain is 0.43%, which is about one third of the highest value with another layup (above 1.2%), the diameter expands by approximately 430 μm for a cylinder with a diameter of 100 mm, for example. Since the typical fitting tolerance between a cylinder and a column is about 100 μm, 430 μm is enough for insertion.

Table 1 Material properties used for theoretical analysis.

		Unit	Value
Elastic Property	Fiber direction, E_1	GPa	156
	Transverse direction, E_2	GPa	8.87

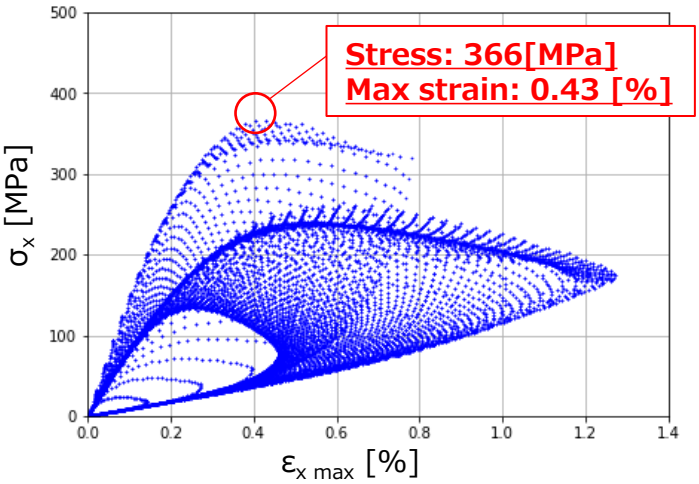

Figure 6 Maximum stress as a function of maximum strain.

3 EXPERIMENTAL VALIDATION

3.1 Materials and Method

A CFRP cylinder having the designed layup was fabricated. The manufacturing method was sheet winding using prepreg with PAN-based carbon fibre. Considering thickness and fibre direction of the laminate, prepregs were cut into rectangular shapes. The prepregs were then wound around a steel carbon mandrel. Whole the prepregs and mandrel were covered with a breather and a vacuum bagging film. The sample was vacuumed and cured in an autoclave at a gauge pressure of 0.6 MPa. The cure process included 1°C/min heating and 170°C holding for 4 hours. Shape measurement of the cured cylinder verified that the cylinder was fabricated with the designed diameter and almost perfect circle in the cross-section.

The cylinder was then mounted on a torsion testing machine. Figure 7 (a) shows a photograph of the testing machine and the mounted cylinder. Four triaxial strain gauges were attached to the specimen, with two orthogonal axes of each gauge aligned with the coordinate axes shown in Figure 3. The gauges were positioned at the longitudinal centre of the specimen, corresponding to the four cardinal directions on its cross section. Figure 7 (b) illustrates a schematic of the cross-sectional view of the test setting. Test fixtures were used to connect the cylinder and testing equipment. The fixtures and the cylinder were adhesively jointed, and the fixtures and the testing equipment were pin-connected. Torsion was applied to the cylinder at a rotational speed of 0.5 deg/min until torque dropped. Strains measured by the attached strain gauges and torque were concurrently recorded every 0.1 second.

3.2 Experimental Results and Discussion

Figure 8 shows the measured strains as a function of applied torque. Figure 8 (a) is the result of strain measured by the gauges attached in 45° direction. The four values are almost consistent, confirming that the torque was appropriately applied. The circumferential strain (Figure 8 (b)) increased almost linearly with torque. The average value of the slope was 663 με/kNm, which is well consistent with the theoretical value (743 με/kNm), experimentally proving the anomalous Poisson's effect proposed in this research. The variations of the measured strains would be caused by variations during mounting on the test equipment. Figure 8 (c) depicts the longitudinal strain. The longitudinal strains at the SG1 and SG3 have different trend from that of the SG2 and SG4, which implies a bending moment was present during mounting.

Meanwhile, the maximum torque was about 0.7 kNm, which is less than half of the expected value. Sample observation after the test revealed that the drop in torque is likely to be caused by an adhesive

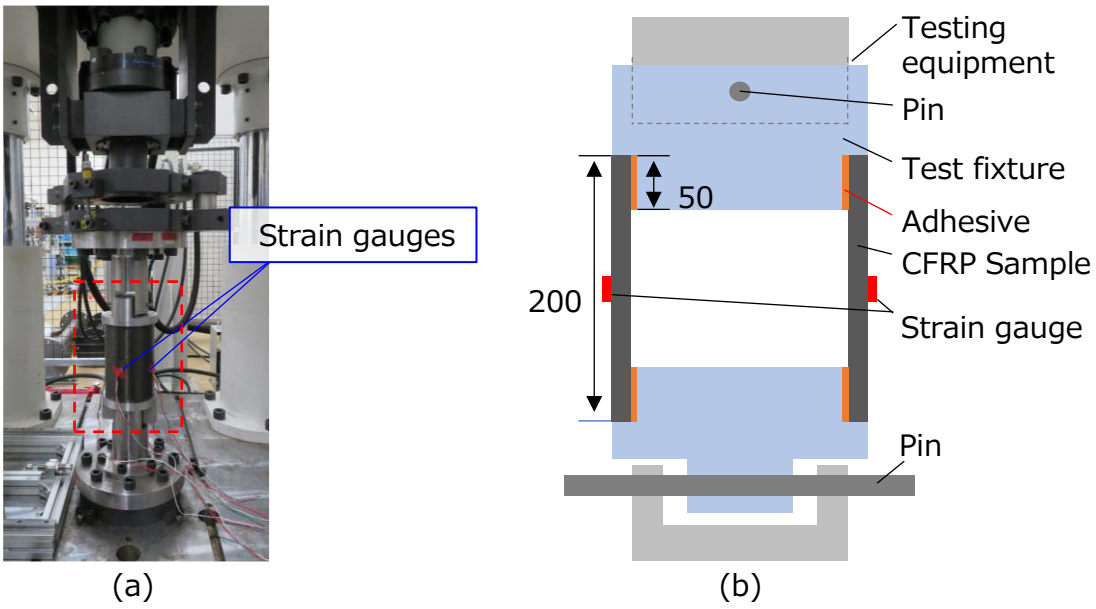

Figure 7 Test setup. (a) Photograph of setup, (b) Schematic of dotted red line in Figure (a).

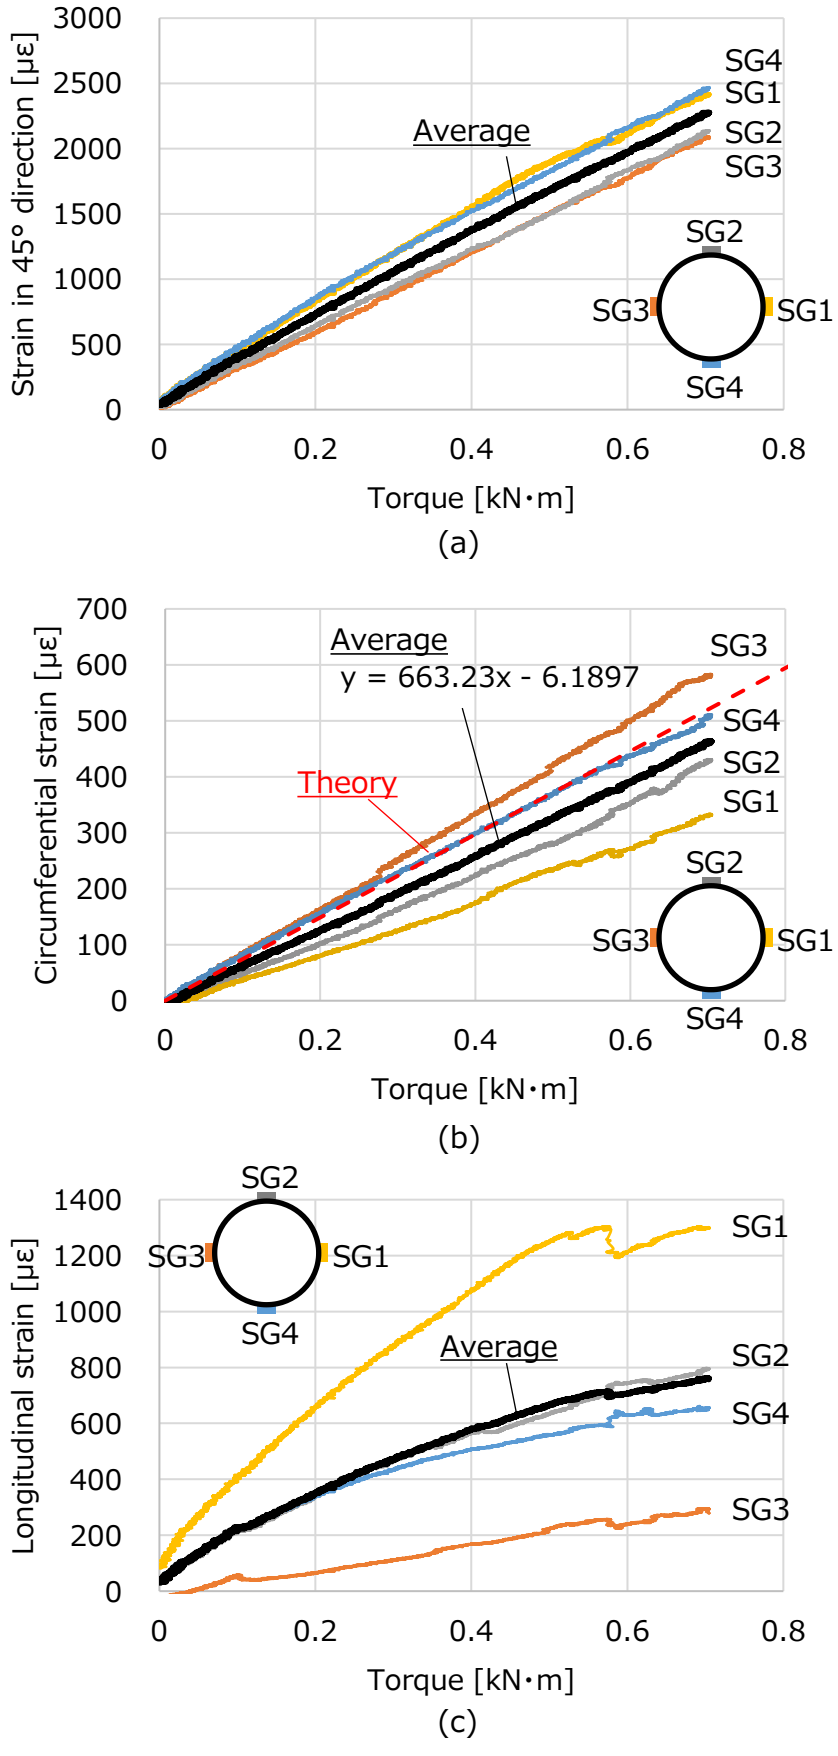

Figure 8 Measured strains as a function of torque. (a) 45°, (b) Circumferential, (c) Longitudinal.

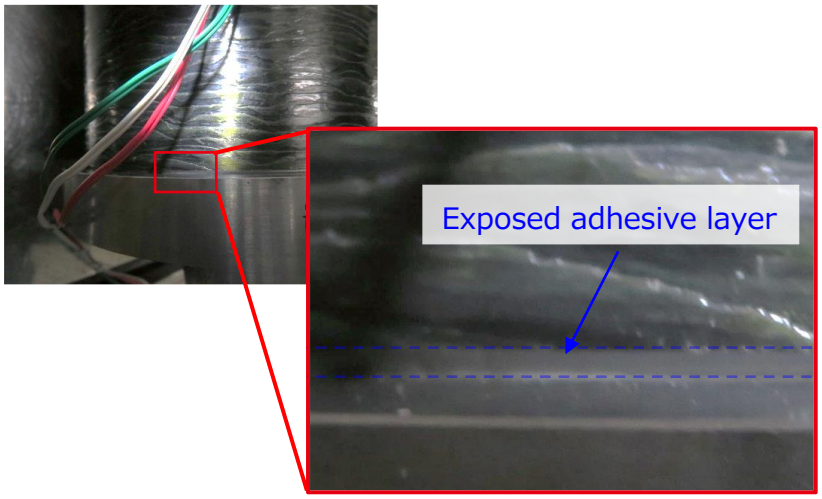

Figure 9 Photograph of edge area of CFRP cylinder after test.

failure between the test fixture and the cylinder, because no damage was observed in the cylinder (Figure 9). Though the bonding length was determined considering adhesive strength and applied torque, defects in the adhesion would have resulted in the failure. Mechanical joint is preferable to avoid process uncertainties commonly found in adhesive joints. However, with uniform cross section, the mechanically attached rigid fixture constrains deformation in the circumferential direction, preventing core insertion (Figure 10 (a)). Therefore, this research suggests a solution concept. This includes a CFRP cylinder with a tapered section where the grip fixture is attached (Figure 10 (b)). Although the attached area, similar to the uniform cross section, barely deforms, there is sufficient clearance between the core and the cylinder owing to the taper angle. Consequently, the core can be successfully inserted into the straight section of the cylinder without interaction. Future work will evaluate the validity of this proposed method.

4 CONCLUSION

This research aimed to propose a novel sleeve assembly method for SPM motors to reduce the cost and the press-fit pressure. The basic concept of the method is to use anisotropy of a CFRP and realize the ‘anomalous Poisson’s effect’. The effect induces normal strain by shear force. Theoretical analysis for the effect was carried out based on the classical lamination theory. The result led to a layup to maximize tension after the assembly while keeping enough clearance between the cylinder and core during assembly. Then a CFRP cylinder with the layup was fabricated to validate the theoretical analysis result and anomalous Poisson’s effect. Torsion test was conducted with the cylinder and the circumferential strain increased with torque, successfully confirming the anomalous Poisson’s effect. Furthermore, the strain increment with unit torque was 663 με/kNm, which is consistent with the theoretical value (743 με/kNm). Additionally, a cylinder design with a tapered section was proposed to prevent the interaction between test fixture and the core during insertion, which was an issue found in the experiment. Future work will evaluate the validity of this method.

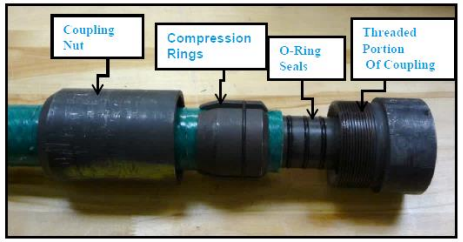
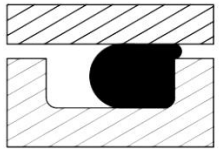
Transforming natural gas delivery system in SG



- Hydrogen transmission and receiving infrastructure is not ready in Singapore. The solution of hydrogen fuel distribution from filling stations or tanks are absent.
- Augmentation of the network such as additional pipelines and larger pipe configurations, would be required to ensure that supply can continue meeting required hydrogen energy demand of end-users.
- One possibility for rapidly expanding the hydrogen delivery infrastructure is to adapt part of the natural gas delivery.
- Both metal and fiber-reinforced composite pipelines are currently used in the gas transmission network in SG. But metal pipeline systems are not suitable for hydrogen due to hydrogen embrittlement.

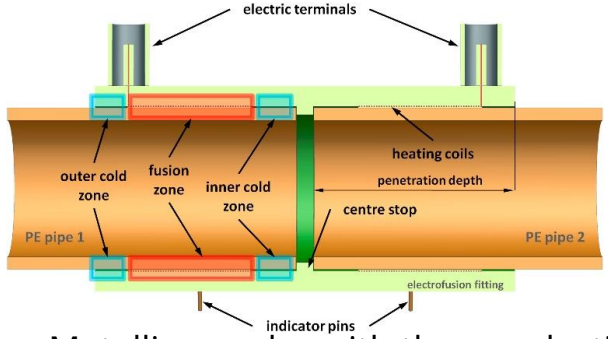


Background: Review of Existing Pipeline System

Pipeline system	Applications	Materials	Operating pressure	Distribution pressure	Remarks
U.S. Natural Gas (NG) Pipeline [1]	Electric power production and split between residential and commercial uses	Carbon steel, API 5L A, B, X42 and X46	42 – 84 bar (OD 4 inch to 48 inch)	less than 17.2 bar (OD 0.5 inch to 8 inch)	
SG Town Gas (TG)	for industrial, eating houses and residential	Carbon steel X60 05 X65 grade	3 barg	0.5 barg and 0.02 barg	The pipes are internally coated with 75 micron epoxy and 2.5mm, 3-layer Polyethene coating. Welded
SG NG pipeline [2]	for power stations and industrial uses	Carbon steel for operation and PE for distribution	28 and 40 barg	3-6 barg	The Design Pressure is 50 barg and Test Pressure is 62.5 barg.
Strohm thermoplastic composite pipe (TCP)	Suitable for CO2 and Hydrogen transport	Carbon – PVDF Carbon – PA12 Fiberglass - HDPE	Failure at max 689 bar		Grades with different temp limit, 65, 80 and 121 °C.
SoluForce TCP	Hydrogen transmission	Not released	42 bar (OD 4-6 inch)		Flexible pipe system with nonmetal fitting

Current Technology for Pipe Connectivity and Limitations

Metallic coupler with mechanical joints

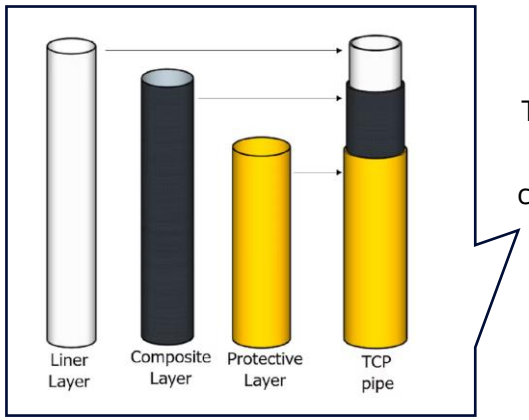


Compression of O-Ring seals

Failure of O-Ring seals

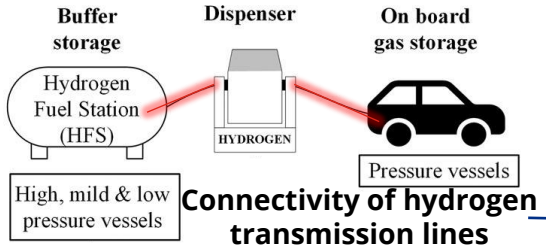
- A metallic joint with elastomer O-ring seals.
- Lack of durability in H_2.
- O-ring sealing fail during fatigue testing of the structural layer at all pressure levels for hydrogen pipes.

Polymer Electrofusion Coupler



Leakage / Crack at fusion interface

- Metallic coupler with thermoplastic liner, being used in current NG and geothermal pipeline system
- Limited to a very low-pressure pipe system, energy-intensive
- Once the fusion process is completed, the joint is considered permanent and unrepairable



Growing trend of using fibre reinforced thermoplastic (FRTP) composite pipes

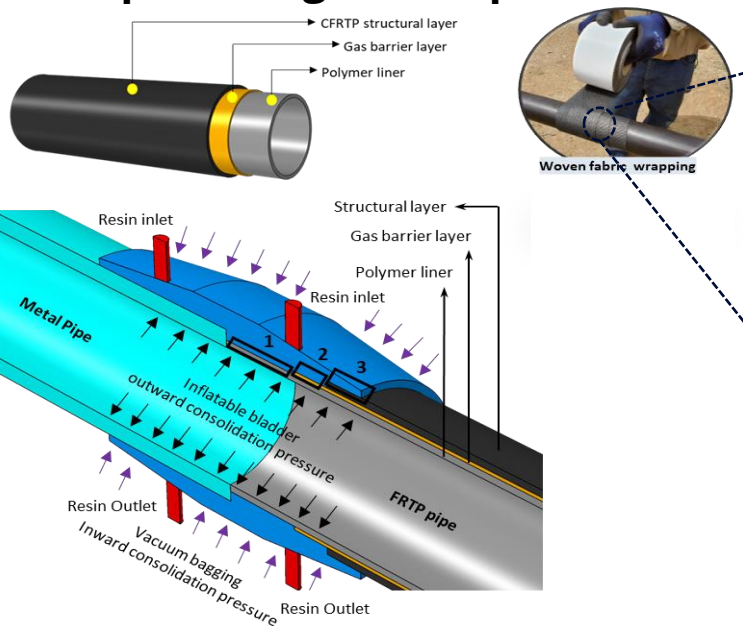
Multi-layer composite pipeline

- **Metal to FRTP pipe**
- **FRTP to FRTP pipe**

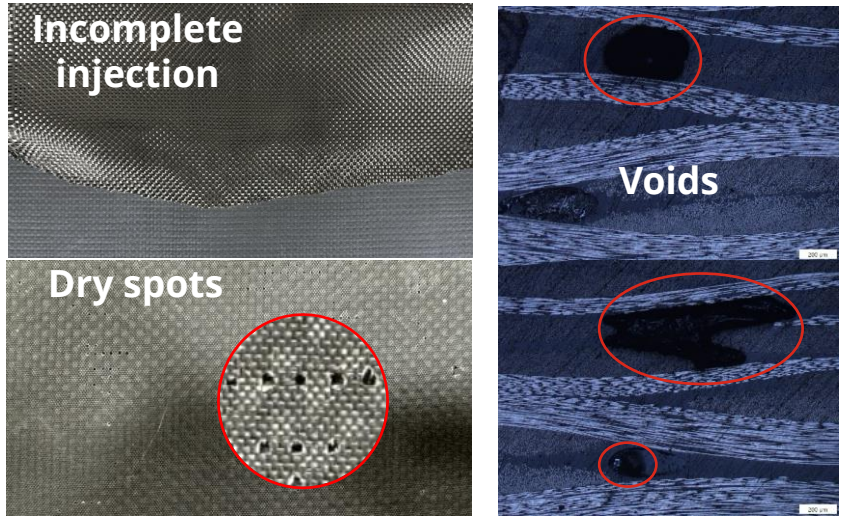
Connectivity of hydrogen transmission lines

Requirements for pipe connectivity

- Sufficient interlayer bonding
- Minimised hydrogen leakage
- Strong durability under thermocycles
- Safe, reliable and cost-effective



We want FRTP composite couplers !

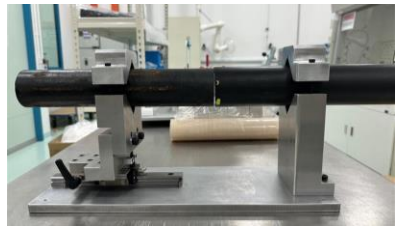


- *Weldable*
- *Impermeable*
- *Energy-efficient*
- *Recyclable*
- *Durable*

FRTP Couplers: from Concept Design to Prototyping

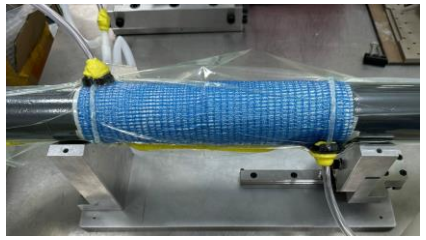
Aims at development of a fiber reinforced thermoplastic (FRTP) composite coupler for joining metal and thermoplastic composite pipelines, synergizing robust bonding and pressure resistance

Coupler design concept

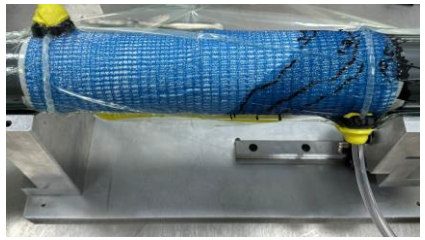


Defects in composites part fabricated by resin infusion

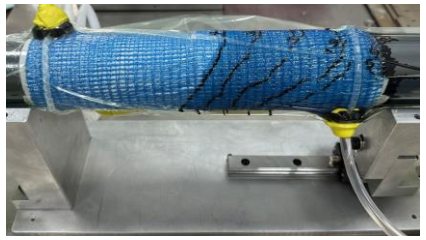
Research Scopes



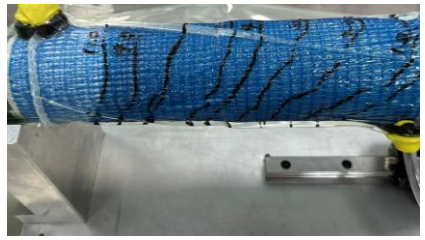
- **In-situ polymerization technology** with infusible resins to achieve the minimised defects.
- Composite coupler formalization: tubular shape, irregular shape, etc..
- **Enhancing material compatibility regarding multiple interface bonding** between the coupler and the metal or FRTP pipelines.
- Advanced simulation techniques for **coupler layup design** and **optimization**.



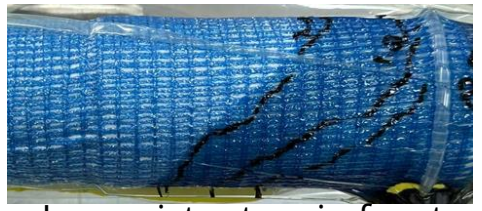
Preliminary Study on Composite Coupler



❑ Composite coupler connecting carbon steel pipe and PE pipe

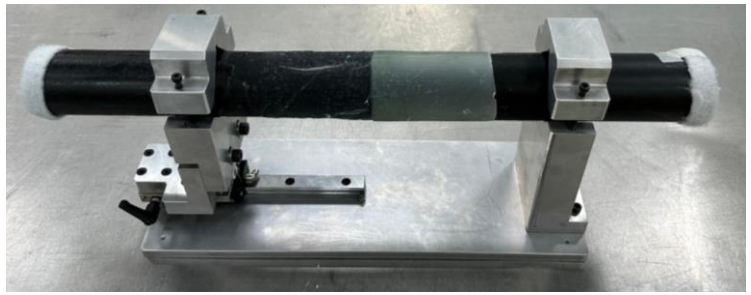


Pipe assembly fixture



Resin infusion process of the coupler

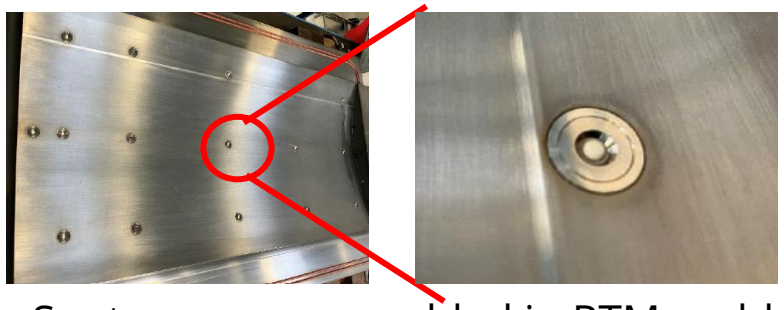
Some difficulties identified:



- Poor resin penetration and inconsistent flow front.
- Wrinkle and distortion of fabrics after curing
- Non-uniform interface stress transfer between dissimilar materials

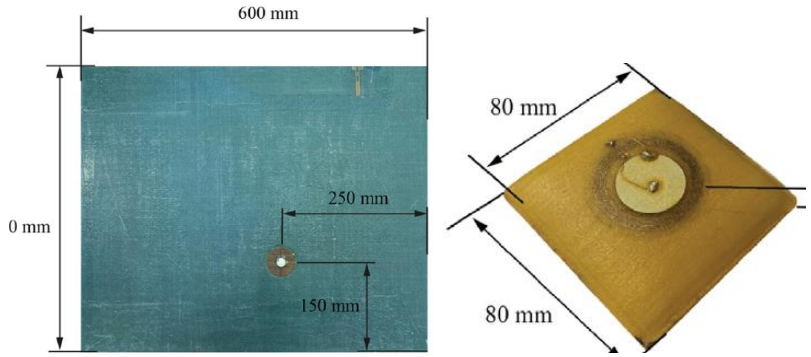
Inconsistent resin front

Fabric wrinkle



Proof-of-concept: composite coupler

Solution: It's important to develop **process monitoring system** and **physics-based process simulation model** to improve composite coupler quality.

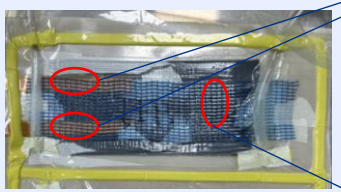


Development of in-situ polymerization monitoring system

❑ Current solutions

Spot sensors assembled in RTM mold [1]

- Numerous sensors are required to cover whole area, increasing tooling **complexity** and **cost**

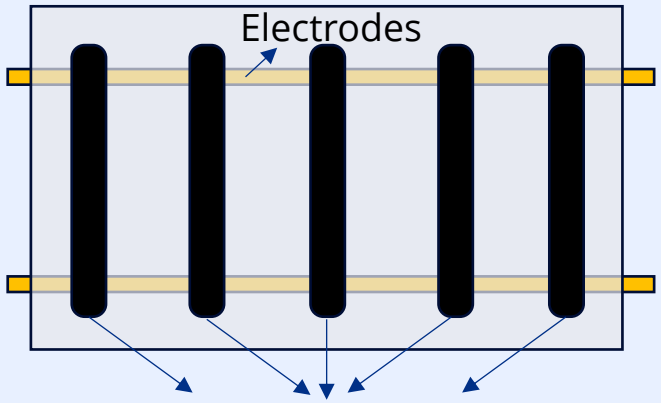


Inductively coupled sensor [2]

- Sensor **interference** with the base due to poor material compatibility, reducing structural integrity.

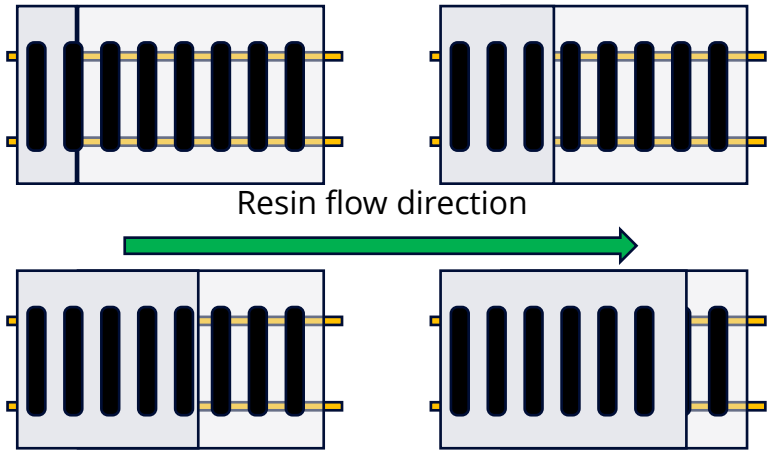
❑ **Distributed resistance sensor** for resin-infusion monitoring

Methodology:

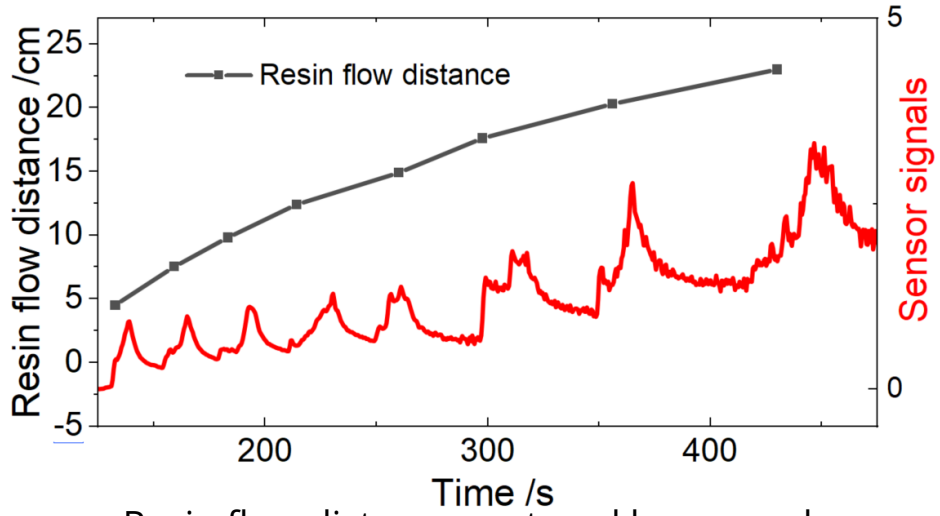


Electrodes printed on glass fiber via direct ink writing (DIW) with high conductive silver ink

Resistors printed on glass fiber via direct ink writing (DIW) with low conductive carbon ink



- Ultra-thin
- No foreign materials (carbon-based sensors used)
- Minimized influence on resin flow

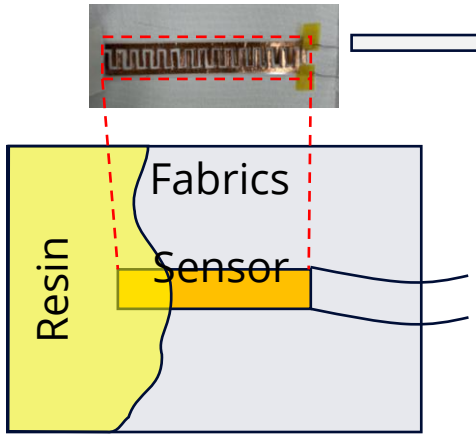


[1] Pantelelis, Nikos, et al. "Advanced Process Monitoring and Control for CFRP RTM in Aerospace without compromises." SAMPE 2024 (2024).
[2] Chilles, James S., et al. "Monitoring cure and detecting damage in composites with inductively coupled embedded sensors." Composites Science and Technology 134 (2016): 81-88.

Development of in-situ polymerization monitoring system

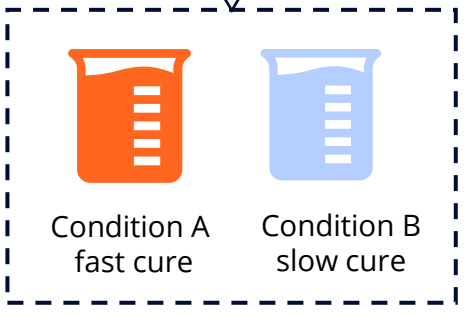
❑ Resin front position captured by the distributed resistance sensor

Working principle:
The resistance change when resin immerse the resistors



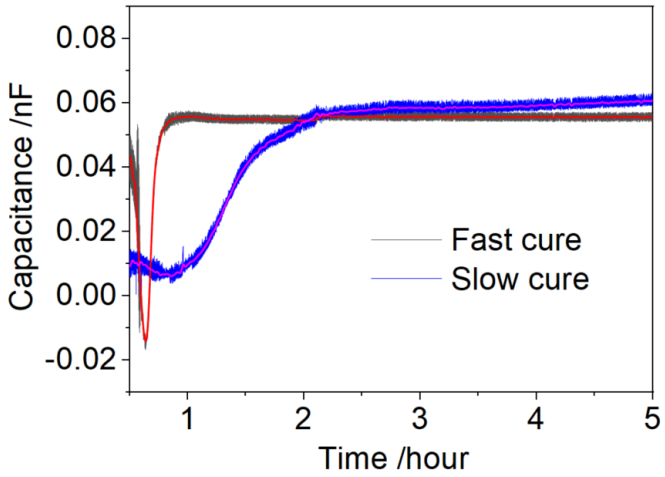
Resin flow distance captured by manual observation and distributed sensors

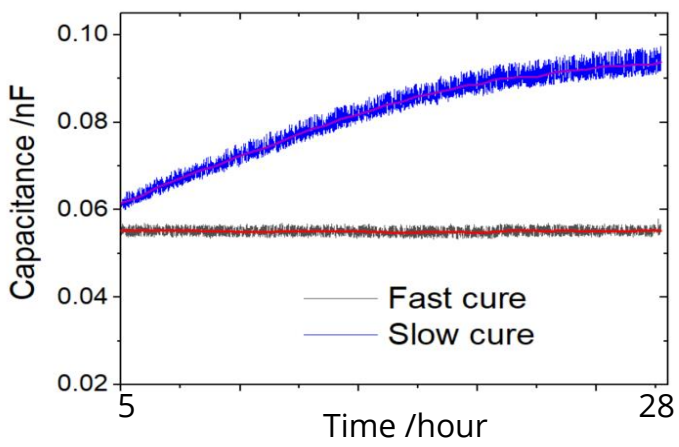
- Distributed resistance sensors accurately reflect the resin front positions, showing great agreement with physical flow observation.
- The resin front captured by the sensor is for the bottom layer, lagging behind that from the top layer observed. The difference is caused by uneven flow through the fabrics thickness.
- The developed sensor can be used to continuously monitor the resin front distribution.
- More effective than commercial piezoelectric and piezoresistive sensors.



Development of in-situ polymerization monitoring system

❑ Capacitance sensor for curing status monitoring

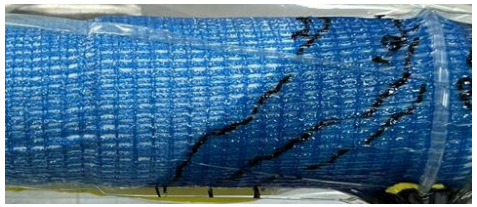




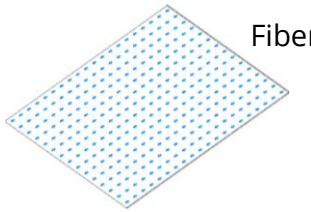
Interdigitated capacitance sensor

Embed sensors into the resin curing

Temperature is controlled to manipulate curing speed

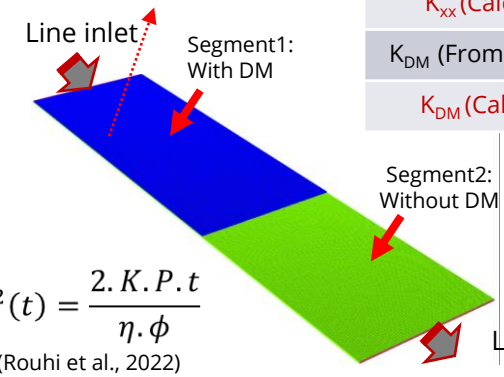


The capacitance signal of fast cure resin convergence soon, while the slow cure resin takes longer



- Two curing status were monitored, and their curing characteristics are captured by sensors
- The capacitance during the curing decrease first then increase
- Curing status can be further correlated to the capacitance signals

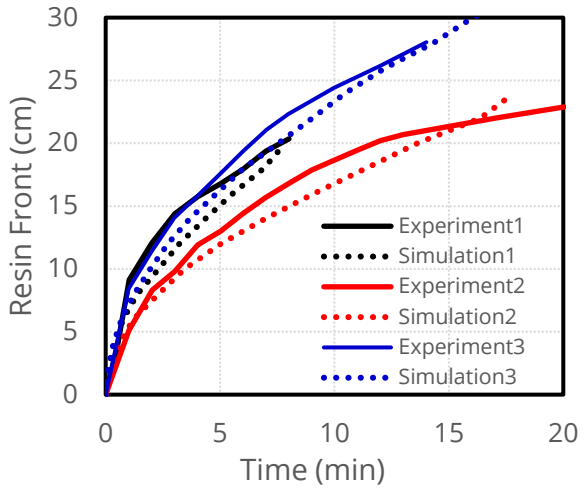
Infusion Process Analysis (Moldex3D)

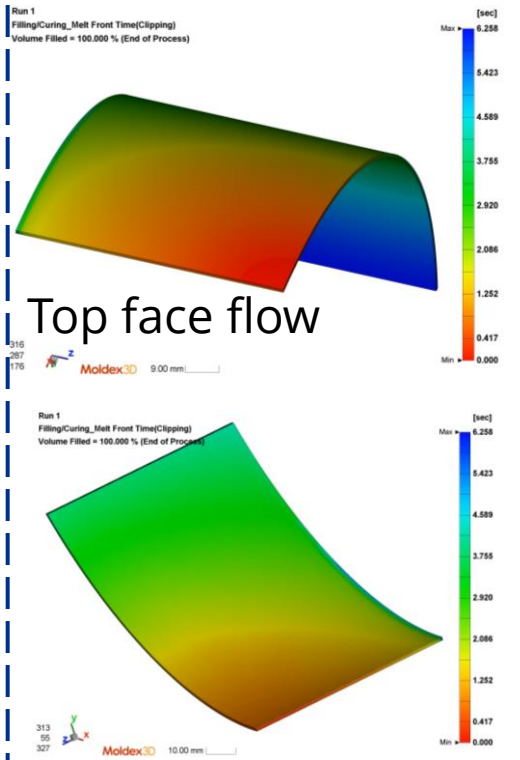


Flow complexity and the needs of process simulations

- ❑ The placement of inlet and outlet is needed to be optimised for infusion over a tubular shape. Process simulation model was hence developed.
- ❑ It is challenging to evaluate effects of fibre layup orientation, peel plies and distribution media, while a homogenous flow model lacks of accuracy.
- ❑ Flow inconsistency at top and bottom layers were captured, yet to be further validated with experiments.

Fiber layup stacking sequence defined



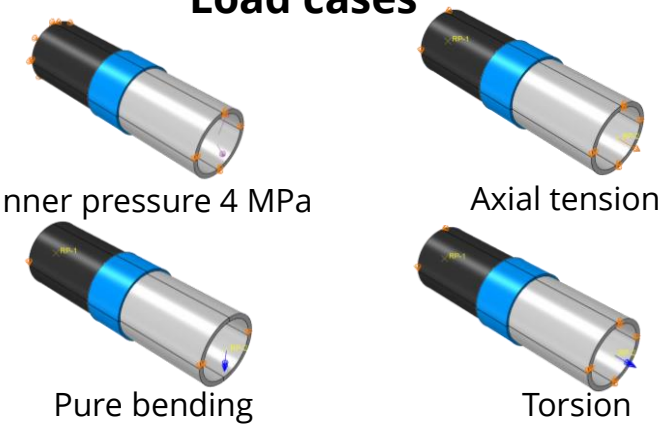


$$L^2(t) = \frac{2.K.P.t}{\eta.\phi}$$

(Rouhi et al., 2022)

Parameters	Values
K_{xx} (From Literature)	1.743×10^{-11} m^2
K_{xx} (Calculated)	1.211×10^{-10} m^2
K_{DM} (From Literature)	1.94×10^{-8} m^2
K_{DM} (Calculated)	1.038×10^{-8} m^2

Explicit numerical flow simulation models with and without distribution media (DM)

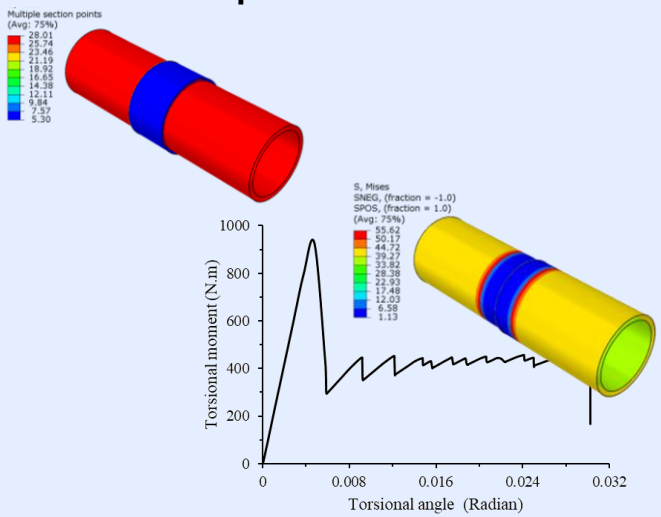


- Tubular shape model showed different flow front time between top and bottom surfaces indicated the through-thickness flow penetration

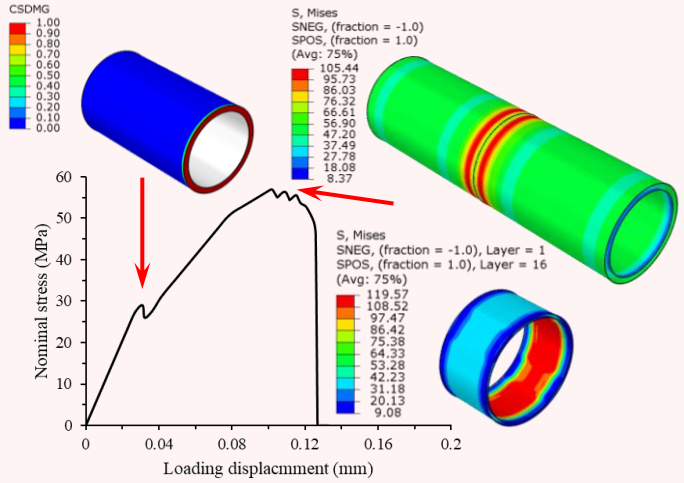
- Flat sample studies concluded that mesh sensitivity was insignificant regarding number of elements across the thickness of both the distribution media and laminates.
- We verified that back calculated permeability values ***K*** are needed instead of citing input permeability values from literatures.
- More studies are on-going to add more detailed settings regarding K values for peel ply and porosity ϕ.

Numerical Design for Composite Couplers

- Direct end-to-end joining with composite coupler
  - Adhesive bonding between the coupler and the pipes
  - Coupler with plain weave composite
- Finite-element progressive failure modelling
  - Cohesive interaction between the coupler and the pipes
  - Cohesive interaction at the two ends of the pipes

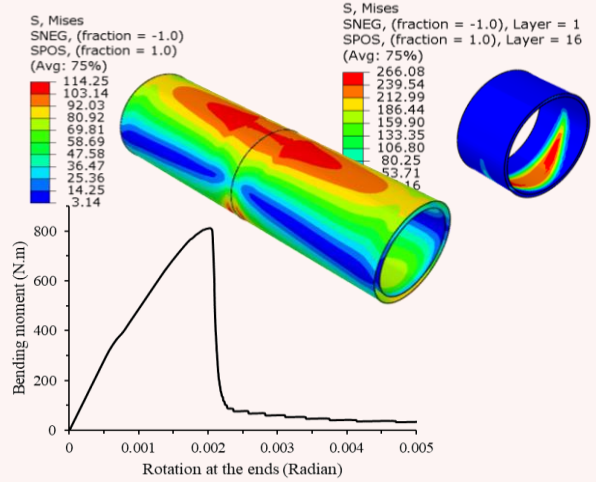


Load cases



Bending and **axial tension** are identified as two critical loading cases.

- Delamination between the coupler and pipes happens in these two cases.
- Both the bonding strength and the composite lay-up need to be considered in the coupler design



Composite coupler is not easy to fail under inner pressure and torsion

Critical Load Cases

Axial tension

Bending

Summary And Future Work

Summary

- The development of FRTP coupler is of great significance to ensure a reliable connectivity for hydrogen transmission pipeline.
- The in-situ polymerization monitoring system was developed, including distributed resistance sensors for resin front monitoring, and a interdigitated capacitance sensor for resin polymerization monitoring.
- Critical loading cases of composite coupler were identified and process simulation models were established.

Future work:

- To develop optimal coupler structural design considering the critical loading cases.
- To improve the in-situ polymerization quality for coupler by simulation-assisted process optimization.
- To study the interface behaviour between composite coupler and heterogeneous materials.

Fabricated Space Structure

Summary

- Frontal polymerized composites can enable in-space manufacturing of structural beams and tubes/longerons
  - ✓ Low processing energy
  - ✓ Rapid cure
  - ✓ Low volume and weight processing equipment
- Encapsulation of prepreg facilitates infusion, improved stability, low off-gassing, and processing
- Infusion leads to lower voids and higher flexural stiffness
- In-space manufacturing of thermoset composites is feasible

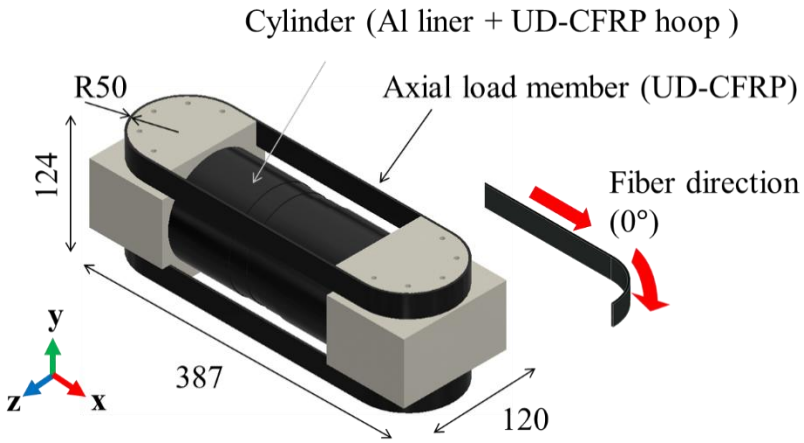
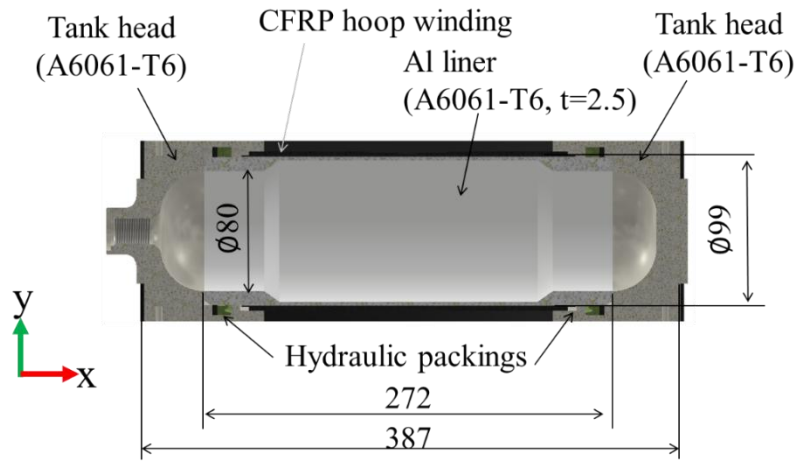
ABSTRACT

Cost reduction of CFRP hydrogen tanks is important to promote the practical use of fuel cell vehicles. In this study, in order to achieve a significant reduction in the amount of carbon fiber used, a "multi-load path structure" is proposed in which the axial and circumferential loads acting on the tank are shared by different members: CFRP overwrapped cylinder and belt shaped load members. For the purpose of technically verifying the structural concept, stress analysis, design and prototyping were carried out for a tank structure that uses two belt-shaped axial load members, and a structural strength evaluation was carried out by burst tests. As a result, it was demonstrated that it is possible to realize a tank structure that has a burst pressure almost as designed.



1 INTRODUCTION

Type-IV 70 MPa class high-pressure hydrogen tanks, in which carbon fiber is wound around a polymer liner by the filament winding (FW) method, have been applied to commercially available fuel cell vehicles (FCVs) [1, 2]. In order to expand the use of FCVs, in addition to reducing the cost and improving the productivity of hydrogen tanks, it is necessary to improve the packaging capability of the tanks to automobiles. To improve the packaging capability of the tanks, the concept of a " multiple tank module" has been proposed [3]. In the tanks made by FW method, low-angle helical winding must be applied to form the dome section, but there is a tendency for excess carbon fiber to be generated in the cylinder section. This tendency is more pronounced in small-diameter, long tanks, and simply combining the FW tanks will result in increased costs and reduced weight efficiency due to the increased amount of carbon fiber used. In order to commercialize a tank module with multiple small-diameter, long tanks, it is necessary to significantly reduce the amount of carbon fiber used.



Therefore, this study aims to achieve a significant reduction in the amount of carbon fiber used by applying a "multi-load path structure" in which the axial load and circumferential load acting on the tank are borne by different members. In this structure, the "axial load member" that bears the axial load and the "CFRP overwrapped cylinder" that bears the hoop load are manufactured separately, and then assembled into an integrated tank. It is possible to design the tank so that most of the carbon fibers reach their breaking strain at the same internal pressure when the tank bursts. Therefore, in the case of a small-diameter, long tank, it is possible to reduce the amount of carbon fiber used by more than 30 % compared to a FW tank. In addition, the axial member and cylinder have simple shapes, so productivity is also excellent. If a small-diameter, long tank with a multi-load path structure is realized, it is possible to significantly reduce the cost increase associated with connecting tanks and realize a tank structure with

excellent packaging capabilities at low cost. A similar concept to the multi-load path structure in this study was proposed in a German patent publication [4, 5], but no design considerations or technical demonstrations using tanks have been reported within the scope of the authors' investigation.

In this paper, we report on the results of stress analysis, design, and prototype fabrication of a tank structure that uses two belt-shaped axial load members, as well as the results of a structural strength evaluation conducted by a burst test, with the aim of technically demonstrating the multi-load path structure concept.

2. STRESS ANALYSES AND DESIGN

2. 1 BASIC CONCEPT OF TANK STRUCTURE

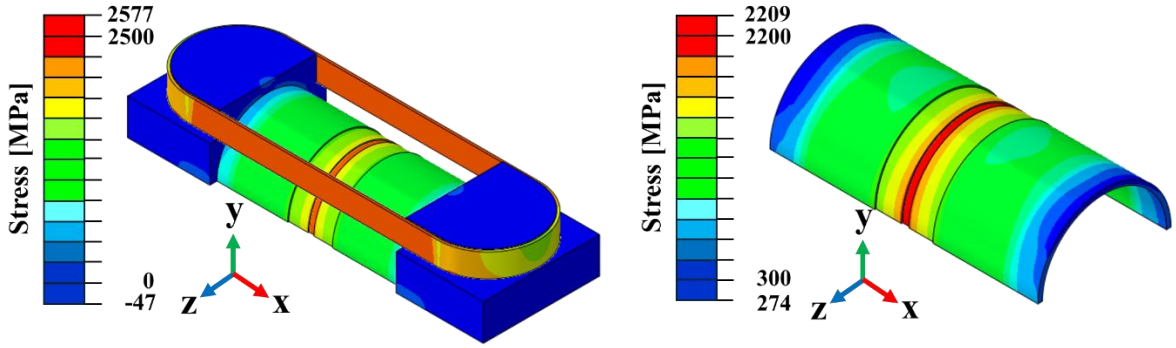
The basic structure and cross-section of the tank used in this study are presented in Fig. 1(a) and (b). The external appearance is similar to the basic structure illustrated in the references [4, 5], but the detailed structure is significantly different. The components are an aluminum alloy (A6061-T6) liner (outer diameter φ 99 × length 272 × thickness 2.5-9.5 mm), a hoop CFRP layer (CF/Epoxy, thickness

1.6-3.6 mm), an aluminum alloy (A6061-T6) tank head, and two CFRP belt-shaped axial load members (width 25, thickness 2.4, curvature of the arc section 50 mm). The circumferential stress (hoop stress) in the cylinder due to internal pressure is mainly borne by the CFRP hoop layer overwrapped around the Al liner. The axial load acting on the cylinder is borne by two UD-CFRP belt-like axial load members. The tank head (A6061-T6) has a structure in which the dome and boss are integrated. The belt-like axial load members are made of unidirectional CFRP (CF/Epoxy) and are fitted around the top and bottom of the tank head. A high-pressure packing (NOK, Japan) is used as a water tight seal between the outer circumference of the liner and the inner circumference of the tank head.

In this structure, there is a small clearance between the axial load member and the tank head because of mechanical assembling. Therefore, even if an axial load member is applied to a Type III tank that uses a typical dome-cylinder integrated aluminum alloy liner, an axial load will also act directly on the cylinder due to the internal pressure load. In this case, since CFRP is not applied in the axial direction of the cylinder, there is a concern that the cylinder will break in the axial direction at low pressure. Therefore, it is important structural feature that the domes on both sides of the aluminum liner are eliminated, making it a cylindrical liner so that the internal pressure acts directly on the inside of the dome of the tank head.

2. 2 STRESS ANALYES OF TANK STRUCTURE

A commercial code, ABAQUS/ Standard 2023 (Dassault Systems), was used for the finite element analysis (FEA). The material of the liner and tank head was an aluminum alloy (A6061-T6), and the hoop layer and axial load members were made of unidirectional CFRP (T800/Epoxy, Mizuno Technics, Japan). The mechanical properties of the CFRP used in the analysis are shown in Table 1. The stress-strain curve of the aluminum alloy (A6061-T6) was based on literature values [6], and an elastic-plastic model according to the associated flow rule was applied.



A half model as shown in Fig. 2(a) was used for the FEA in consideration of symmetry, and an internal pressure of 100 MPa was applied to the inner wall of the tank. 10-node tetrahedral two-dimensional elements (C3D10) were used to the tank head and the dome part of the liner, and 8-node hexahedral reduced integration elements (C3D8R) were applied to the axial member, cylinder, and circular head of the liner.

Table 1 Material Properties of CFRP (T800S/Epoxy)

Properties		Values
Elastic moduli [GPa]	E_L	168.0
	$E_T = E_Z$	10.0
Shear moduli [GPa]	$G_{LT} = G_{LZ}$	6.06
	G_{TZ}	5.0
Poisson's ratio [-]	$\nu_{LT} = \nu_{LZ}$	0.31
	ν_{TZ}	0.45
Tensile strength [MPa]		3290
Failure strain [%]		1.96

2. 3 STRESS ANALYSIS RESULTS

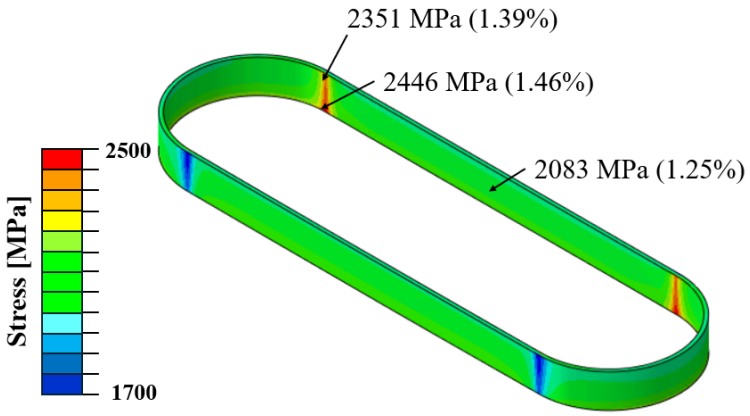
Figures 2(a) and (b) show contour plots of the maximum principal stress in the entire tank and in the cylinder section at an internal pressure of 100 MPa, respectively. As per the design concept, it can be seen that the axial load is mainly carried by the two belt-shaped axial load members, while the circumferential load is carried by the CFRP hoop layer of the cylinder. The circumferential tensile stress is high in the central part of the cylinder, but this is because the CFRP hoop layer is thin (1.6 mm) around here. At an internal pressure of 100 MPa, the axial strain in the general part of the axial load member was 1.25 %, and the strain in the hoop direction in the cylinder CFRP layer was 1.19 %.

(a) Tank assembly (b) Cylinder

Fig.2 Contour plot of max principal stress at the internal pressure of 100 MPa

Fig. 3 shows the maximum principal stress distribution in the axial member when the internal pressure is 100 MPa. The axial stress in the general part of the axial member is 2083 MPa (strain 1.25 %), while the maximum principal stress around the straight line-arc boundary is 2446 MPa (strain 1.47%), which is about 17 % higher. This is because in this area, bending load is superimposed on the tensile load. In addition, watching the straight line-circular arc boundary of the axial load member in Fig. 3, the maximum principal stress is about 4% higher in the lower part (2446 MPa) than in the upper part (2351 MPa). In other words, the axial member has stress distribution in the width direction as well. Fig. 4(a) shows the distribution of the von Mises stress of the tank head when the internal pressure is 100 MPa, and Fig. 4(b) shows the deformation diagram and contour diagram of the z-direction (lateral) displacement. The z-direction displacement is about 0.12 mm larger in the lower part of the tank head compared to the upper part at the contact part of the axial member. In other words, it can be understood that the bending deformation of the tank head causes uneven load distribution on the axial member, and the tensile stress is high in the lower part of the axial member.

In the tank designed this time, it was predicted that the axial load member would break at an internal pressure lower than that of the hoop layer. In addition, based on the tensile strength of UD-CFRP (3290 MPa), it was predicted that the pressure at which the axial load member would break would be approximately 133 MPa.



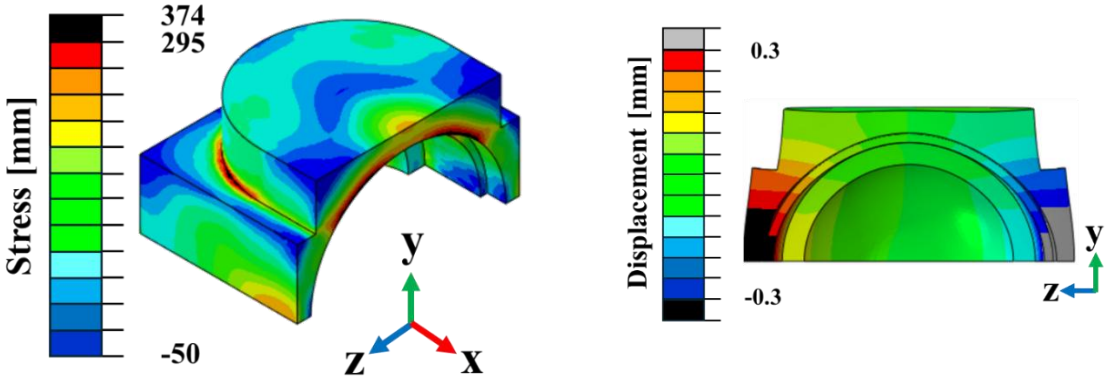


Fig.3 Contour plot of maximum principal stress of axial load member at the internal pressure of 100 MPa.

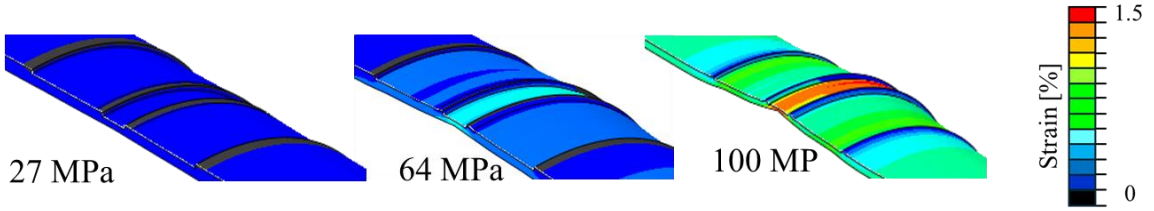
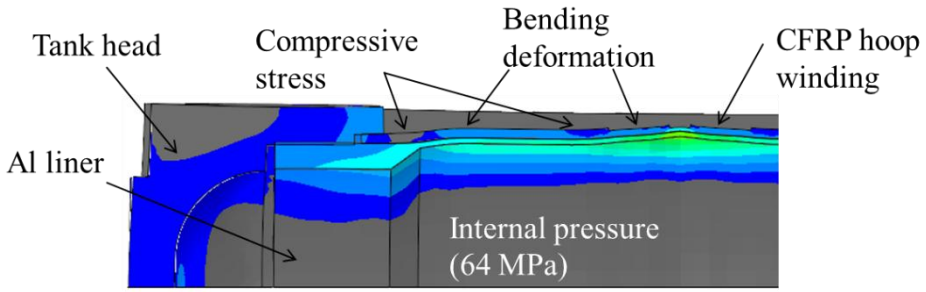


(a) Mises stress



(b) Displacement of Z direction (Magnification 20 times)

Fig.4 Contour plot of Mises stress and z-displacement of tank head at the internal pressure of 100 MPa.

Fig. 5(a) presents the longitudinal strain in the cylinder surface at internal pressures of 27 MPa, 64 MPa, and 100 MPa, respectively. Axial compressive strain appears in the cylinder at the boundary between the cylinder and the tank head. Fig. 5(b) shows the deformation diagram of the tank cross section at an internal pressure of 64 MPa. At the boundary where the longitudinal out-of-plane stiffness differs, out-of-plane bending deformation of the cylinder occurs due to the internal pressure, which can be seen to cause localized compressive strain. For the same reason, localized compressive strain is also observed at each end of the pad-up of the cylinder. Localized out-of-plane deformation also appears in the center of the cylinder, where the hoop thickness is thin, due to the difference in bending stiffness before and after it.

3. EVALUATION OF TANK PROTOTYPES THROUGH BURST TESTS

3.1. TANK PROTOTYPE

The CFRP hoop layer was formed by wrapping CF/Epoxy Towpreg in the hoop direction around a cylindrical liner made of Al alloy (A6061-T6) using the FW method. The belt-shaped axial force member was also produced by FW forming of Towpreg. The cylinder liner and tank head were produced by machining from Al alloy (A6061-T6) blocks using an NC milling cutter. A photograph of the appearance after assembly is shown in Fig. 6.

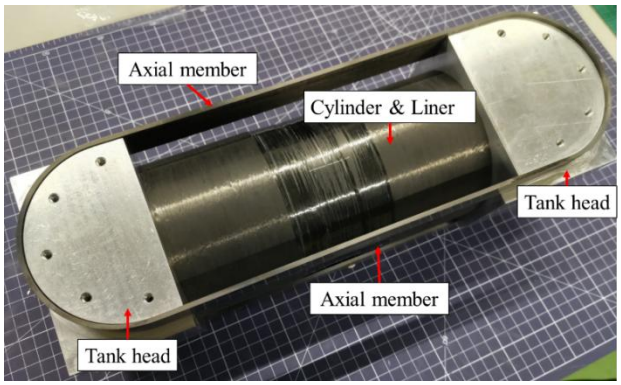

Fig.6 Photograph of a tank prototype

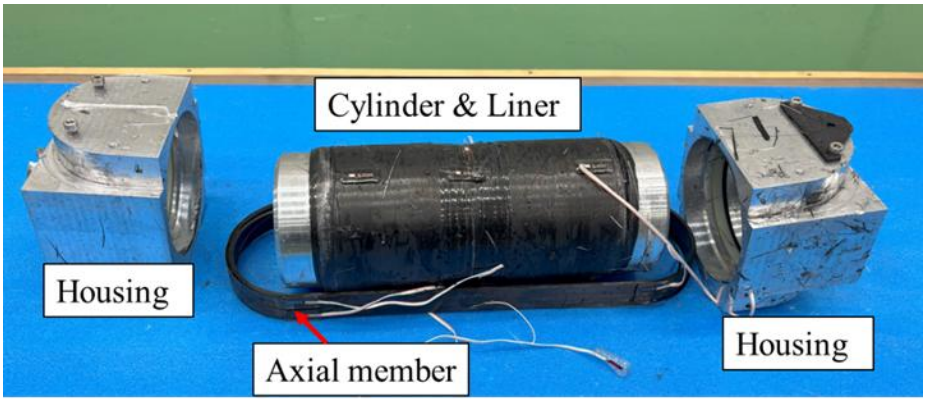
3.2. BURST TEST PROCEDURE

A water pressure burst test was carried out in accordance with ISO19881, with a target pressure rise rate of 0.3 MPa. Multiple strain gauges (WFCA-6-11-10LDBTB-F, Tokyo Sokki, Japan) were attached to the surfaces of the cylinder and axial load member, and strain at each part during pressurization was measured with a data logger (EDX-10, Kyowa Denki, Japan). Strain was measured in the hoop direction and axial direction of the cylinder, and in the axial direction at the center of the axial load member and above and below the straight line-arc boundary. In addition, damage and burst behavior of the tank during the test was photographed using a camera (Hero 10, GoPro, USA) installed in the chamber.

3.3. EXPERIMENTAL RESULTS AND DISCUSSIONS

Figure 7 presents the external appearance after the burst. The burst pressure was 99.8 MPa, and the fractured origin was the fiber break of the axial member. The burst pressure was about 75 % of the burst pressure (133 MPa) predicted by the FEA described above. Figure 8 shows photos captured at internal pressures of 0, 72 MPa, and 99.8 MPa from the video taken during the burst test. When the internal pressure exceeded about 50 MPa, audible sounds were heard due to the occurrence and progression of damage in the CFRP. In addition, at an internal pressure of 72 MPa, as shown in Figure 8 (b), separation between fibers (splitting) and partial fiber breakage were confirmed starting from the straight-line-arc boundary of the axial member. This coincides with the location where tensile stress concentration was confirmed in the axial load member in Figure 3. From this damage boundary, many audible sounds were heard due to the occurrence and progression of damage in the CFRP axial load member. As shown in Fig. 8(c), localized splitting and fiber breakage of the axial load member were also observed at another straight-line-arc boundary just before the rupture.



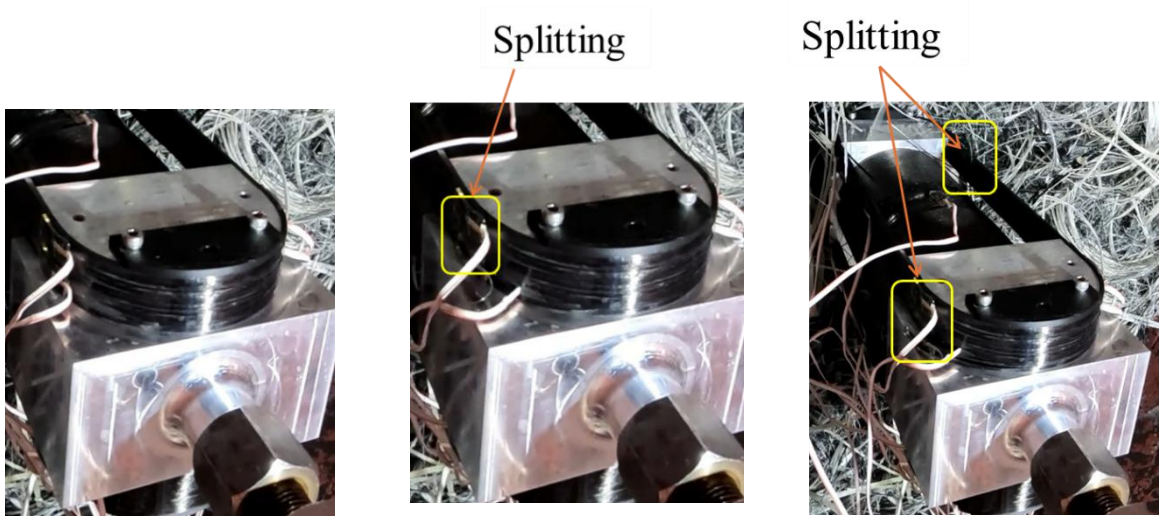


Fig.7 Photographs after burst testing (Burst pressure 99.8 MPa)

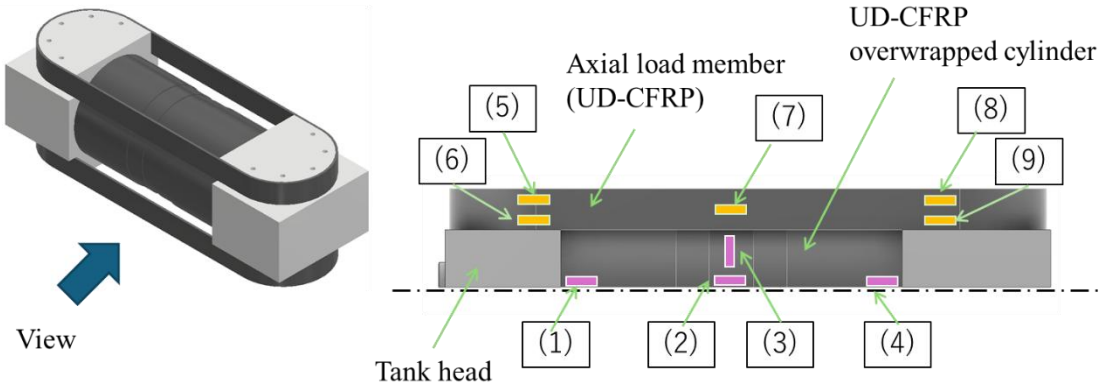
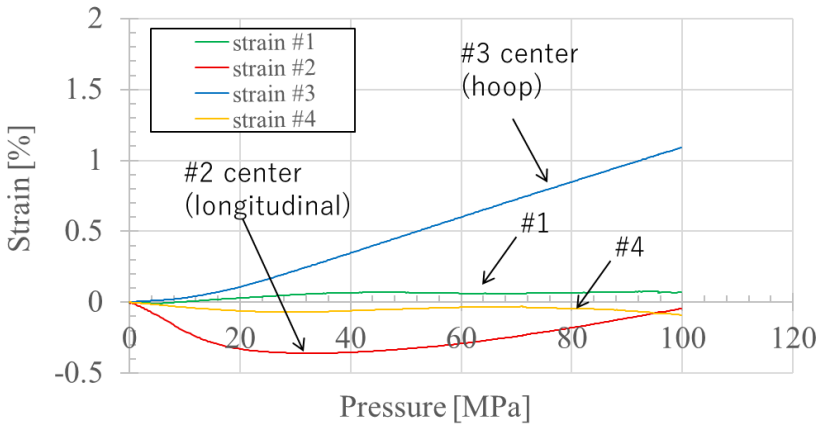
(a) 0 MPa (b) 72 MPa (c) 99.8 MPa

Fig.8 Captured images showing the splitting of axial load member.

The attachment positions of the strain gauges (#1-9) on the tank are shown in Fig. 9, and the strain measurement results for the cylinder and axial load member are presented in Fig. 10(a) and (b), respectively. The axial and hoop direction strains of the cylinder hoop layer roughly matched the FEA results. However, the experimental value for the axial strain (strain #2) at the center of the cylinder was much higher compressive strain. This is thought to be due to an error in the attachment position of the strain gauges.

Looking at the axial strain (strain #7) at the center of the axial force member shown in Fig. 10(b), a sudden increase in strain, namely “strain jumping”, can be seen at internal pressures of around 63 MPa, 72 MPa, and 91 MPa. As is clear from the images taken during the burst testing (Fig. 8(b)), local splitting and fiber breakage occurred in the axial load member at the straight-line-arc boundary when the internal pressure was 72 MPa, and this is presumed to be the cause of the strain jump in the axial load member. As mentioned above, bending deformation at the point where the axial member of the tank head is fitted causes a non-uniform stress distribution in the width direction of the axial member, as shown in Fig. 3(a) (b). As a result, in-plane and out-of-plane shear stresses occur in the axial member, and it is believed that splitting occurred due to in-plane interlaminar shear failure.





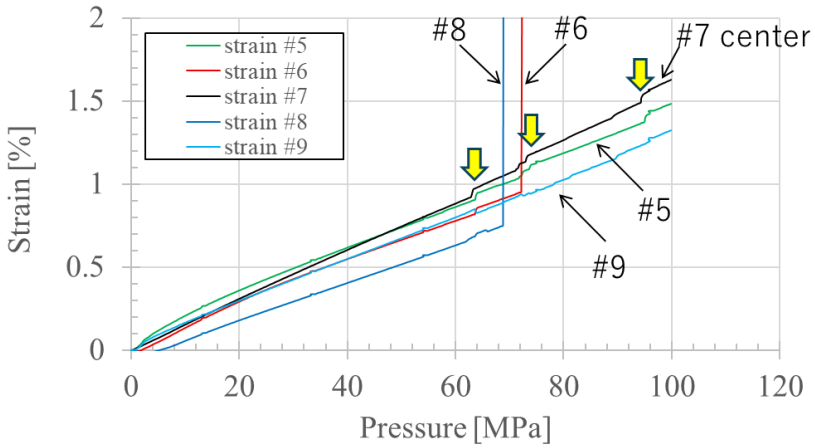


Fig. 9 Strain gauge installation position

(a) Cylinder

(b) Axial load member

Fig. 10 Strain versus internal pressure

The maximum strain at the time of fracture at the center of the axial member (Strain #7) was 1.63 %. This is approximately 17 % smaller than the fracture strain (1.96 %) of UD-CFRP shown in Table 1. The FEA results show that the maximum strain at the straight-arc boundary is approximately

17 % larger than the strain in the general part of the axial member. Taking these effects into account, when the strain in the general part of the axial member is 1.63 %, the strain at the straight-arc boundary is expected to be approximately 1.9 %. This is 97 % of the fracture strain (1.96 %) of CFRP, which is an appropriate value for the fracture strain of an axial member.

The above suggests that it is important to consider the prevention of splitting due to non-uniform load distribution (shear stress) in the plane and the reduction of stress concentration at the straight-arc boundary when designing axial members.

4. CONCLUSIONS

In this study, with the aim of technically verifying the multi-load path structure concept, we carried out stress analysis, design, prototyping, and evaluation of a tank structure that uses two belt-shaped axial force members and CFRP overwrapped cylinder. It was also investigated the burst behavior and the damage progressive behaviors. As a result, it was verified through analysis and experiments that it is possible to realize a tank structure with a burst pressure roughly as designed by designing a structure in which the internal tank pressure acts directly on the dome part of the tank head. Observation results during the burst test showed that localized splitting and fiber breakage occurred in the axial load members prior to the burst. It was suggested that further increases in burst pressure could be effectively achieved by making the stress acting on the axial load members uniform and by suppressing splitting of the axial load members.

ACKNOWLEDGEMENT

These results were obtained as a result of work commissioned by the New Energy and Industrial Technology Development Organization (NEDO).

MATERIAL BEHAVIOR OF PREPREGS IN AUTOMATED ROBOTIC SHEET-LAYUP: A COMPARATIVE STUDY

Moritz Lennartz[1], Liang Yu[1] and Thomas Gries[1]

[1]Institut für Textiltechnik der RWTH Aachen University
Otto-Blumenthal-Str. 1, 52074 Aachen, Germany

Keywords: Robotics, Prepreg, Layup, Laminates

ABSTRACT

A novel approach to the automated production of complex fiber-reinforced components, while retaining process flexibility, is robotic layup of prepreg sheets. By optimizing path planning for robot trajectory generation and employing specially developed end-effectors, the goal is to achieve error-free placement and forming of the prepreg sheets.

Research to date has focused primarily on the development of a suitable overall system consisting of one or more robots with effector tools. Initial proof-of-concept studies have already been carried out with this overall system. Nevertheless, material behavior and its interaction with the robot-based draping process and the mold geometry were often neglected. However, especially with complex, multi-curved molds, different material properties in combination with different process parameters, such as the layup sequence, lead to a very different end quality. These interactions between material, process and mold geometry must be taken into account when developing suitable robot operations.

This paper, therefore, presents a comprehensive analysis of the behavior of various prepreg materials during robotic sheet layup. The study investigates how different material properties of prepregs influence draping quality by applying different draping strategies to various complex molds. This research is the first to demonstrate the impact of material and process parameters on the fully automated, robotic layup of prepreg sheets.

The results show that various material parameters influence the quality of robot-assisted draping. However, the choice of a layup strategy for the prepreg sheets is more decisive for a good quality. An optimized draping strategy with suitable end effectors can ensure error-free forming of the prepreg sheets with almost all common prepreg materials, even on more complex molds.

1 INTRODUCTION

Fiber reinforced plastics (FRP) have undergone remarkable development in recent years and have established themselves as key materials in many industries. Their versatility, combined with increasing demands for efficiency, sustainability, and performance, has significantly enhanced their relevance. While composite parts have traditionally been used primarily in aerospace and high-performance motorsports, advancements in manufacturing technology, falling raw material prices, and improved availability have extended their application into the automotive industry, construction, and the energy sector. [1 – 3]

The excellent mechanical properties of FRPs largely depend on the fibre materials used and their precise alignment within the component (direction-dependent behavior, known as anisotropy). However, this increases manufacturing complexity, as FRPs must be built up layer by layer. The current state-of-the-art for high performance application is the prepreg process, in which a pre-impregnated textile semi-finished product is manually formed into a near-net-shape geometry and then cured into a finished component in an autoclave process. [4,5]

Forming the flexible, sticky textile layers into the desired three-dimensional shape is time-consuming, error-prone, and—due to the material's specific properties—currently only very limitedly automatable. This forming process (known as draping) requires a sensitive understanding of the material and considerable experience to avoid defects such as wrinkles and voids. Despite this, 30% of continuous

fibre-reinforced components in aerospace are manufactured through draping, with automation implemented in only 5% of those cases. [6]

Experienced and well-trained specialists can process up to 1.15 kg of material per hour. Their sensorimotor skills, cognitive flexibility, and low machine and tooling costs also enable rapid product changeovers. [7] At the same time, manual production leads to high material waste, end-product defects, and - especially in Western countries - high labor costs, making the process uneconomical. Furthermore, unattractive working conditions, which often cause health issues such as wrist or back pain and allergies, are contributing to an increasing shortage of skilled workers. [8]

A promising strategy to reduce manual processes and improve reproducibility is the automation of production. This can save up to 90% of the working time per component and increase material efficiency from around 40% to as much as 95% compared to manual production. Large companies in the aerospace and automotive industries are already using fully automated processes for manufacturing FRP components. [8, 9]

Current automation in the form of Automated Fiber Placement or Automated Tape Laying requires very high investment costs and is also limited to simple component shapes, such as shell geometries. The process also requires long set-up times, which further limits flexibility. For this reason, research has been conducted for some time into a robot-based lay-up process that takes the manual prepreg lay-up process as a model and enables prepreg lay-up and with specialized end effectors and defined trajectories. So far, the focus has been on the development of suitable hardware for draping and holding the prepreg as well as the implementation for individual component shapes. However, for an error-free robot-based prepreg layup, the material properties and different layup strategies must also be taken into account, as these have a significant influence on the layup process. [10 – 12]

For this reason, a material study is presented in which a total of four different materials were tested on four different molds. The focus of the study was to investigate the extent to which individual material properties and different draping strategies influence the quality of the final result.

2 RELATED WORK

2.1 Robot based prepreg layup

The prepreg layup is defined according to [13] as the spherical forming of planar reinforcement textiles into near-net-shape component geometries. The transformation of the textiles takes place under the influence of external forces. This forming process has a significant impact on the mechanical and optical properties of the final component. The draping result is determined by the process, the material, and the component geometry [14,15]. Various draping strategies are used to drape the textiles.

Robot-assisted draping is a promising approach for automating the prepreg layup process in the production of fiber-reinforced components. To achieve the goal of near-complete automation, an intelligent robot-assisted manufacturing system is employed, which automates the draping process, thereby ensuring consistent quality, increased productivity, and reduced labor costs. [11,12,16]

Such a system typically consists of a hybrid robot cell with multiple robot arms or a single robot arm in combination with a holding fixture. These components work closely together to grasp, position, and apply the material to a mold. Specialized end effectors are used, which form the prepreg onto the mold contour with appropriate force and precision using rollers. To avoid defects such as wrinkles or air inclusions, controlled tension during draping is required. This is achieved through the use of robots with integrated force control or a dedicated holding fixture. [11,12,16]

2.2 Draping Defects and Their Influencing Parameters

Regardless of whether a manual or robot-based draping process is used, draping effects occur during the forming of reinforcement textiles. These effects alter the fiber orientation compared to the target position and should therefore be minimized, as they—like previously mentioned—negatively impact the optical and mechanical properties of the final component [17]. A variety of draping defects are distinguished, typically classified into two-dimensional and three-dimensional defects. Two-dimensional defects include fiber undulations and gaps, while three-dimensional defects comprise wrinkles and loops. In general, the frequency and severity of draping effects correlate with the geometric

complexity of the component in automated forming processes [17,18]

The occurrence of draping defects is primarily influenced by the component geometry, the type of process, and the textile properties. Such defects are more likely to occur on component geometries featuring high aspect ratios, small radii, sharp angles, and strong curvatures. From a process perspective, draping defects are mainly promoted by relative movements between the tool and the textile, foreign particles, or excessive applied forces. However, the textile used has the most significant influence on the occurrence or prevention of draping defects. Key textile parameters include the type of textile, weave pattern, areal weight, roving material, and laminate structure. [18]

The emergence of draping defects is linked to various physical effects, with the so-called Trellis effect being predominant. The Trellis effect describes the shearing of a woven fabric. Shearing occurs when external tensile forces act on the rovings in directions other than the principal fiber orientation. As the degree of shear increases, friction between the intersecting rovings rises, requiring greater force to continue shearing. The shear force can increase until a material-specific critical shear angle is reached. Beyond this angle, the shear can no longer be accommodated within the plane of the fabric. Shearing beyond the critical angle inevitably leads to draping defects, which must be avoided. The extent of draping effects is highly dependent on the choice of textile semi-finished product and its drapability. Textiles that allow higher shear with lower shear resistance generally enable better forming quality. [18]

3 METHOD AND EXPERIMENTAL DESIGN

The aim of this study is to investigate the influence of different prepreg materials and different layup strategies on the draping quality in a robot-based sheet layup process. However, the study does not solely focus on the drapability of various materials or layup strategies; rather, it places particular emphasis on analyzing the interdependencies between process parameter, layup strategy, the geometry of the mold, and the type of textile reinforcement. Accordingly, the material study is structured using a two-stage approach.

3.1 Examination of drapability with regard to the material parameters

Initially, four materials were examined on two different mold geometries. To do this, a preliminary selection of ten commonly available prepreg materials from the market was made. From these ten materials, four were selected for testing. The selection focused on the main influencing factors, namely the type of weave, fabric weight, and weave pattern. Additionally, the materials were chosen in such a way that non-investigated factors—such as the matrix type—remained consistent across all selected materials. Table 1 presents the tested materials along with their respective parameters.

Material	Prepreg variant	Type of binding	Grammage
Nr 1	Roving	Plain weave	200 gsm
Nr. 2	Roving	Twill weave	200 gsm
Nr. 3	Roving	Twill weave	410 gsm
Nr. 4	Towpreg	Plain weave	76 gsm

Table 1: Tested Materials

The focus of this experiment was to investigate the drapability of the materials with respect to their inherent properties, without a detailed analysis of the influences from the robot's draping strategy or the mold geometry. For this reason, an ideal strategy for the robot-based draping was defined by an expert. The selected molds feature relatively simple geometries to ensure that process- and geometry-related parameters do not overshadow the textile properties. The following figure shows the two molds along with the draping strategy applied by the robot.

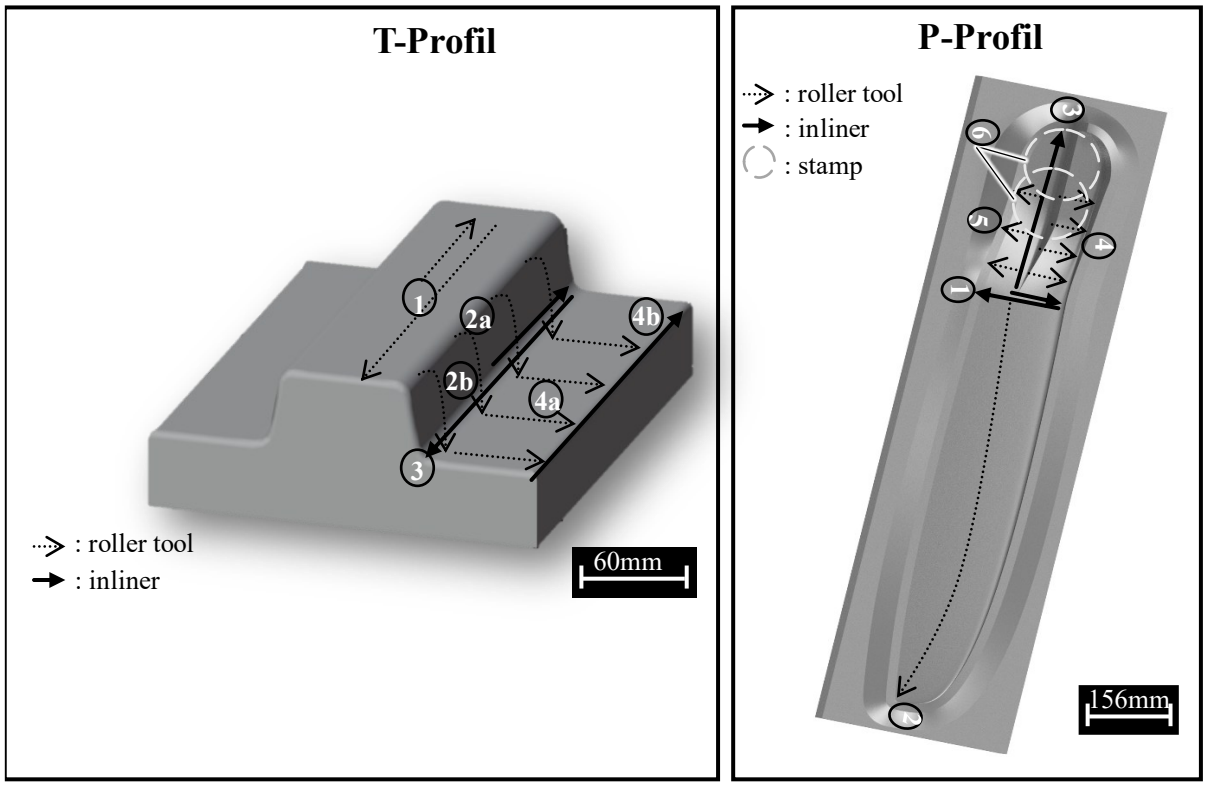

Figure 1: Used molds and corresponding trajectories

For the implementation of the draping strategies, a Universal Robot UR5e was used, featuring a payload capacity of 5 kg and a reach of 850 mm. In addition, custom-developed end effectors were employed—some designed for universal use across a wide range of geometric features, and others specifically engineered for one of the component geometries presented in this study. An integrated impedance controller was used to enable simultaneous position and force control. The initial positioning on a specific geometry element of the corresponding mold was carried out manually to ensure precise alignment. To allow for fully automated draping, an automatic tool changer was also utilized. Figure 2 shows the end effectors used as well as the complete robotic cell employed for the tests.

The evaluation of the layup quality was carried out using the method developed by Schöfer [15]. This assessment methodology enables a quantitative evaluation of quality by relating the severity of defects (Gi), the frequency and size of defects (Ai), and the distance of each defect from the component's symmetry axis (ai) to the total component area (Ages) and the maximum possible distance from the symmetry axis (amax). Based on these parameters a defect index (FI) can be calculated using the following formula, where a defect index of 0 represents perfect quality:

$$FI = 100 * \sum_{i}^{k} G_i * \left(\frac{A_i}{A_{ges}} * \left(1 - \frac{a_i}{a_{max}} \right) \right) \quad (1)$$

This method allows for a direct comparison between the individual materials. To eliminate process-related uncertainties, each trial was performed five times. In addition to the qualitative evaluation of the layup, process efficiency was also examined by measuring the cycle time.

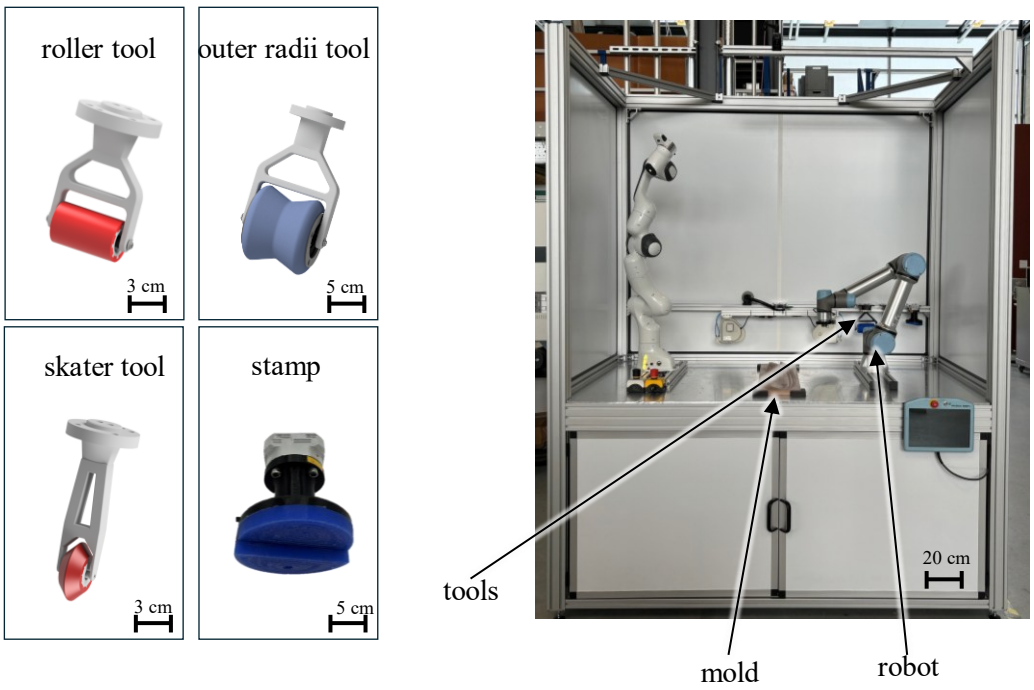

Figure 2: robot tools and used setup for the study

3.2 Investigation of drapability with respect to draping strategy and form complexity

Based on the results from the first part of the material study, the best-performing material was selected for the second part of the investigation. This material was then subjected to further testing with varying process parameters by applying different layup strategies on significantly more complex mold geometries. The two molds from the first part of the study were reused, along with two additional molds featuring considerably higher geometric complexity. The two new geometries are characterized by inward-facing corners that require very high textile shear in order to achieve a defect-free layup. However, the level of shear remains below the critical shear angle, meaning both geometries are still suitable for flawless draping.

The focus of this part of the study was to examine the extent to which different robot layup strategies and the complexity of the mold geometry influence the final layup quality. For each of the four tested geometries, three distinct layup strategies were developed by an expert and implemented by the robot in the same manner as in the first part of the study. The evaluation of quality was again performed using the Schöfer method [15]. The following Figure 3 illustrates the draping strategies applied to the four component geometries.

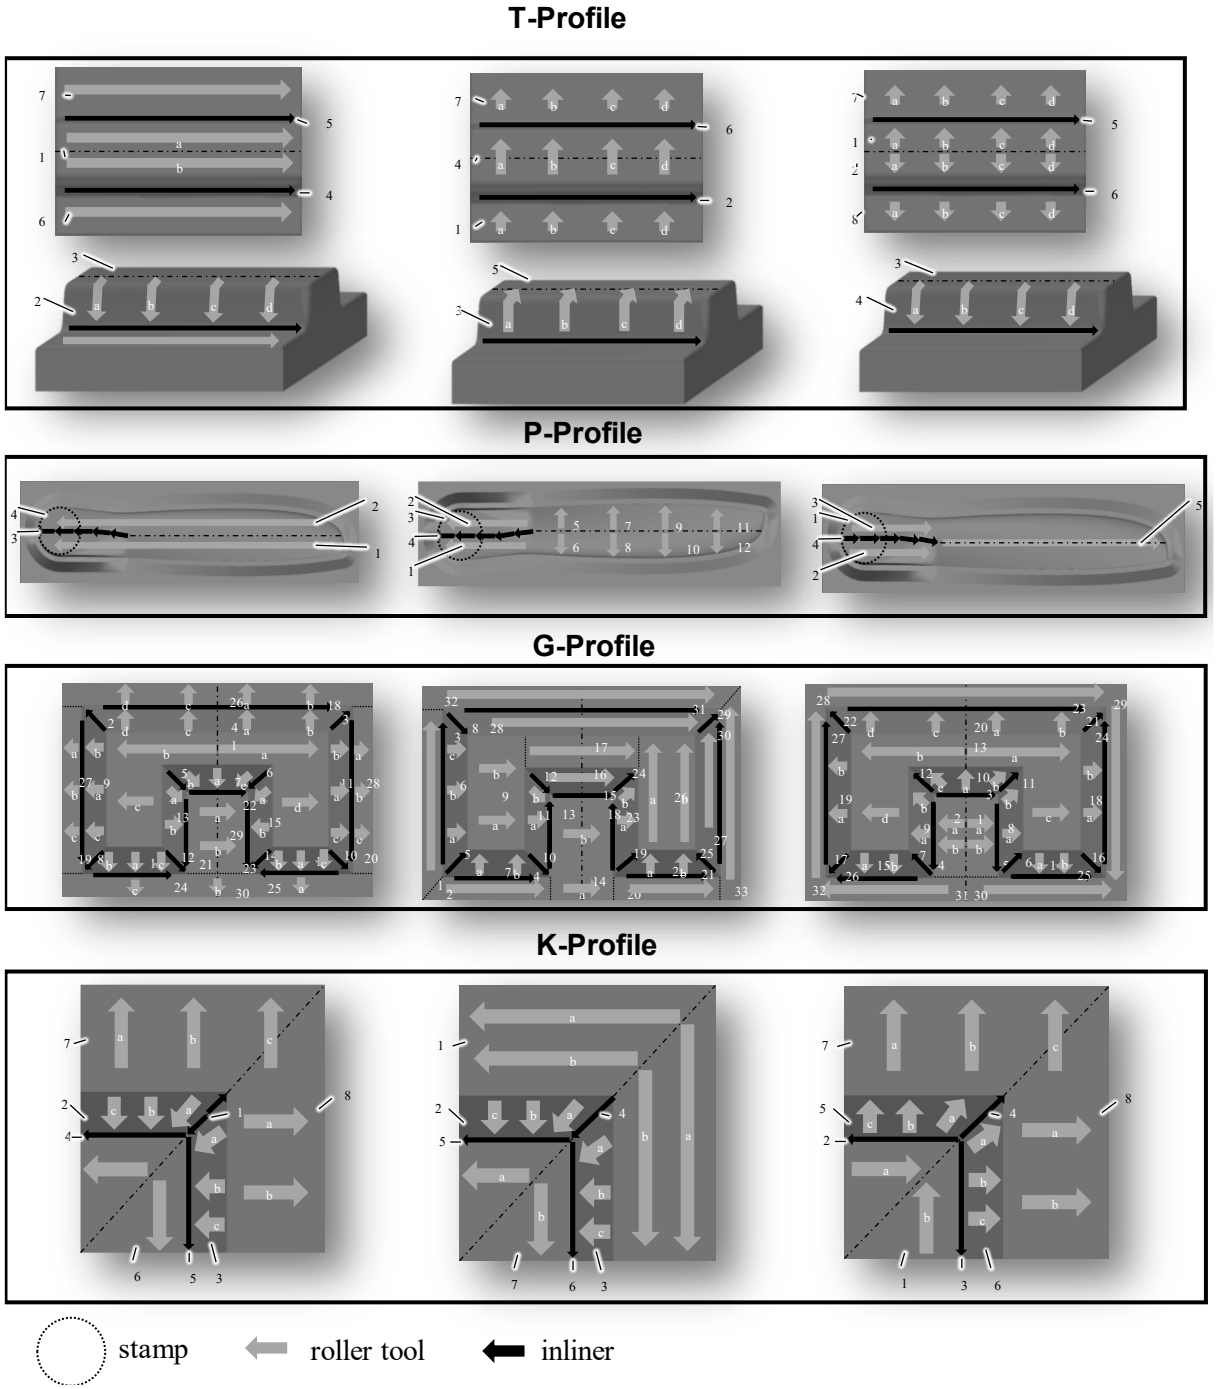

Figure 3: Layup strategies

The aim of this part of the study was to investigate the interaction between the material and various draping strategies. For this section, three identical trials were carried out for each case to eliminate process-related uncertainties.

4 EXPERIMENTAL RESULTS

The results of the study are presented below. The results are divided into several parts. Firstly, the results of the first part of the study are presented. In particular, the individual material parameters and their effects are discussed. The second part of the evaluation then examines the interactions between the material and various draping strategies.

4.1 Results of the material influence parameters on the quality of the robot-based prepreg layup

To determine the influence of material parameters, a fractional factorial experimental design was chosen, as shown in the following table. In the first test series, a roving prepreg was compared with a towpreg. Both materials feature a plain weave and have an areal weight of 200 gsm and 76 gsm, respectively. The second test series examines the influence of the weave type by comparing two roving prepregs, each with an areal weight of 200 gsm—one with a plain weave and the other with a twill weave. The third key influence parameter, the material weight, was investigated using two prepregs with a twill weave and areal weights of 200 gsm and 410 gsm.

Test series	Prepreg variant	Type of binding	Grammage
Nr 1	**Roving**	Plain weave	200 gsm
	Towpreg	Plain weave	76 gsm
Nr. 2	Roving	**Twill weave**	200 gsm
	Roving	**Plain weave**	200 gsm
Nr. 3	Roving	Twill weave	**200 gsm**
	Roving	Twill weave	**410 gsm**

Table 2: Material parameters tested in the first part of the study

First, the T-profile was draped and evaluated according to the experimental plan shown in table 2. Table 3 presents the average defect indices from all five trials. In terms of defect types, almost exclusively wrinkles occurred during the draping. No gaps or loops were observed, and fiber undulations were rare to non-existent. The table shows that neither the weave type nor the areal weight leads to a significant difference in the draping quality. Only the towpreg exhibited noticeably poorer quality.

This indicates that, for simple geometries that do not require textile shearing, the robot is able to handle and process both plain and twill weave fabrics equally well. The prepreg weight also plays a minor role in the robotic process. The end-effectors are capable of manipulating both lightweight and heavyweight prepregs. However, the towpreg cannot be processed satisfactorily by the robot. The towpreg used in this study is very tightly woven and thus extremely resistant to deformation. In addition, it allows almost no air permeability between the crossover points, of which there are very few due to the inherent characteristics of towpreg. As a result of the high inter-fiber friction and lack of permeability, the robot's end-effectors are unable to adequately conform the prepreg even to simple geometries.

According to the experimental plan from Table 2, the same tests were also carried out on the drone propeller blade shown in Figure 1. Here, similar results in draping quality were observed as with the T-profile. Wrinkles again appeared most frequently, while no gaps or loops and only minimal fiber undulations were present. The average defect index increased significantly for all four materials compared to the T-profile (see Table 2). This is due to the considerably more complex geometry. In particular, the root area of the propeller blade with its very tight radius, requires textile shearing, which the robot's end-effectors can only apply to a limited extent.

Nevertheless, even for this mold, the influence of weight and weave type on the robot-based prepreg layup remains minor. In contrast, draping using a towpreg is significantly worse than with a roving prepreg. As previously explained, this is primarily due to the weave structure and high inter-fiber friction of the towpreg material.

Material	Mean error index T-profil	Mean error index P-profil
Nr 1	0,64	4,19
Nr. 2	0,65	4,83
Nr. 3	0,0	4,28
Nr. 4	3,11	18,74

Table 3: Mean error index of the tested materials

In addition to evaluating draping quality using the Schöfer method [15], the study also analyzed where most defects occurred within the component geometries. For the T-profile, only a few defects were observed, and these could not be assigned to any specific region. Except for the towpreg, the observed defects were primarily due to process uncertainties in the robotic draping process, which could likely be eliminated through iterative process refinement.

For the propeller shape, defects—consistent with previous observations—were concentrated mainly in the root area of the blade. This is primarily due to insufficient textile shearing, which is required to conform the material to the tight radii in that region.

In summary, different material parameters have only a limited influence on the draping quality in robot-based prepreg layup when applied to simple geometries. Only the towpreg proved unsuitable for robotic draping due to its structural characteristics. However, the experiments also clearly showed that the most critical factors influencing the final draping quality are the complexity of the mold geometry and the robotic draping process itself. For this reason, the second part of the study focuses on investigating the interaction between form geometry, robotic strategy, and material behavior.

4.2 Influence of draping strategy and form complexity on robot-based prepreg layup

To investigate the interaction between the material, the robot process, and the form geometry, the molds and robot strategies described in Chapter 3.2 were used. Since the total test space with four molds, three robot strategies, and four materials would have resulted in 48 combinations that each needed to be tested at least three times, we decided to test only one material. This decision was based on previous results, which showed that material parameters have a less decisive impact on achieving good quality in robot-based draping. The chosen material was a twill weave with a weight of 200 gsm, as it is the most common material on the market and can be used in nearly all applications.

Initially, the T-profile and the propeller profile were draped again by the robot using the respective end effectors. Table 4 shows the average error index of the three identical trials for each case along with the standard deviation. Analysis of the results shows that the draping strategy has a significant influence on the final quality. Using strategies similar to those from the first part of the study (see Chapter 4.1), very good results with error indices of 0.308 and 2.584 were achieved. The two other strategies for the T-profile and the P-profile resulted in higher but still acceptable error indices. These results demonstrate that the choice of draping strategy also has a decisive impact on draping quality, even for simple form geometries. In particular, the choice of the starting point is crucial. If it is not optimally selected, there is a risk during robot-based draping that the textile can no longer adapt to the form because it is already fixed at too many points, which prevents any movement.

However, not only the choice of a suitable draping strategy is important for good draping quality. For all three strategies and both components, errors appear consistently in specific regions. As already observed in the first part of the study, errors on the propeller profile mainly occur in the complex root area (see Figure 4). For the T-profile, errors are also visible in more complex regions such as vertical surfaces and inner radii

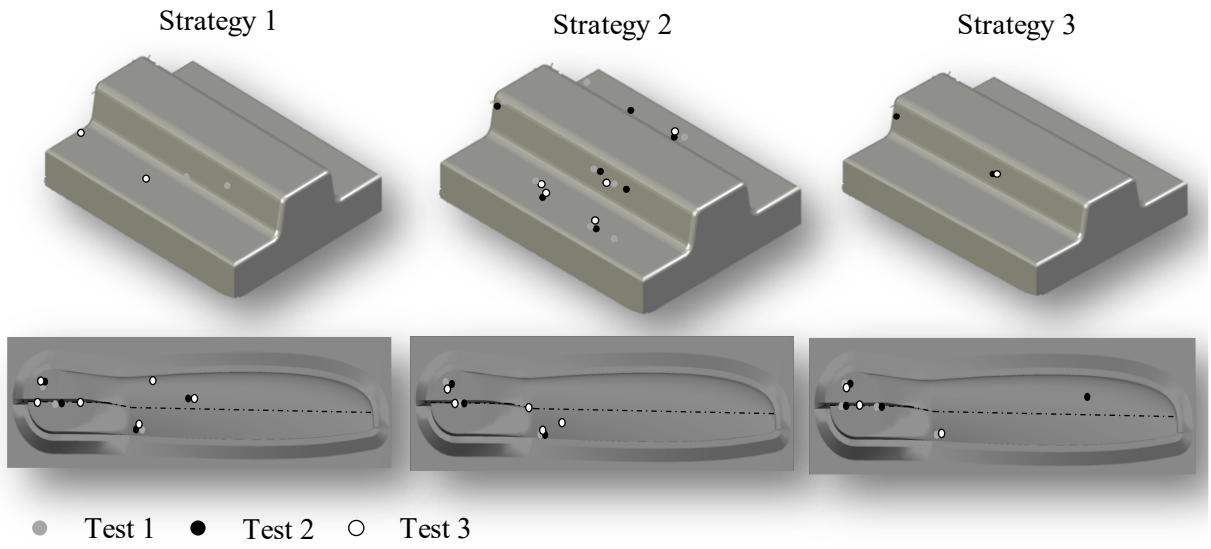

Figure 4: Regions, where erros occurred during the layup process

These two experiments have shown that, with the current draping process, less complex mold geometries can be draped with a very good result, when using an appropriate draping strategy. To analyze the interaction between draping strategy, material, and complex form geometries in more detail, the two additional shapes (see Chapter 3.2) were draped and analyzed in a subsequent step using three different strategies and one material (twill weave, 200 gsm).

With an error index ranging from 1.07 to 19.43 for the K-profile and from 7.71 to 51.154 (see Table 4), the quality for both molds is significantly lower due to the high form complexity. Furthermore, the quality, expressed by the error index, varies much more between the individual strategies for these two components than for the previously tested parts. This indicates a strong interaction between the chosen draping strategy and the form complexity. Critical influences on quality include the selection of the starting point and the sequence of the individual draping paths. It is crucial that the textile can be sheared by the end effectors for as long as possible. Additionally, strategies in which the draping movements proceed toward the outer edges of the part lead to better results than those where the movements go toward the center of the component. In the following figure the results of the three draping strategies for the k-profile are shown.

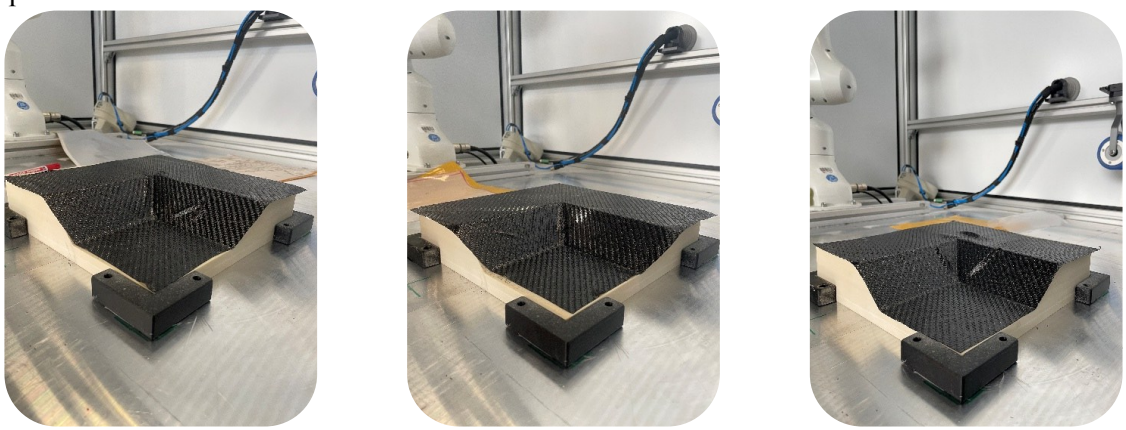

Figure 5: Draping results for the k-profile

Figure 6 assigns the errors to specific regions of the components. It is evident that the errors primarily occur where high textile shear takes place. For the K-profile, this is especially the case at the ramps, where the folds arise due to the strong shear required at the inner edge. For the G-profile, the errors are

distributed across the entire mold, but here too, it can be seen that the errors mainly occur in areas where significant textile shear occurs.

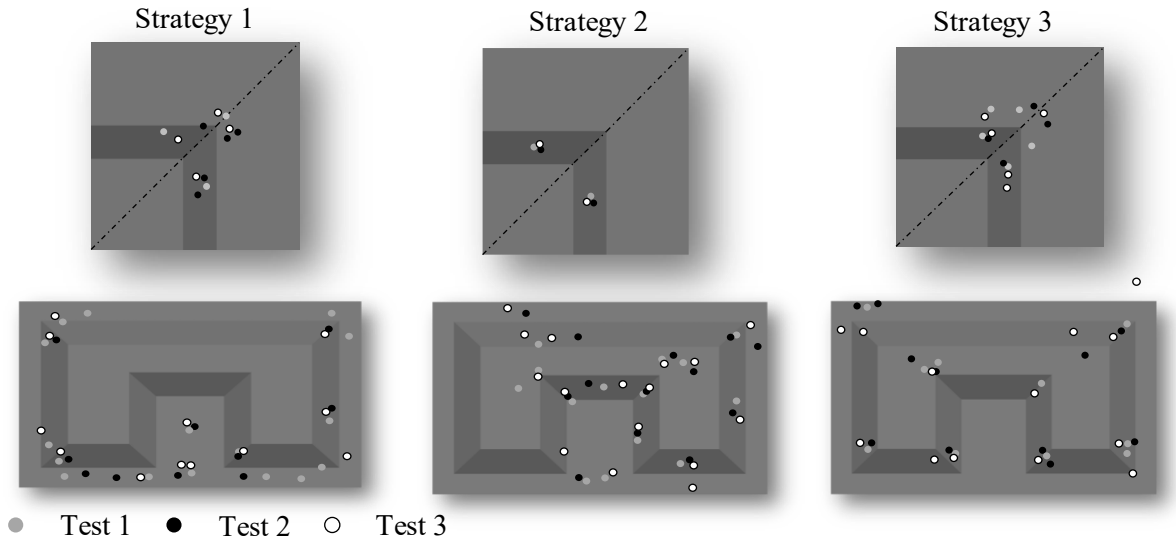

Figure 5: Regions, where erros occurred during the layup process

The experiments on the K-profile and G-profile have shown that there is a very strong interaction between the draping strategy and the form complexity. It is even more important than with simple geometries to choose the appropriate draping strategy. In particular, selecting the correct starting point, determining the proper sequence of individual draping movements, and defining the direction of these movements are crucial for achieving good results.

Test series	Mean error index	Standard deviation
T-Profil 1	1,794	1,559
T-Profil 2	4,775	0,279
T-Profil 3	0,308	0,154
P-Profil 1	7,606	8,809
P-Profil 2	5,183	1,202
P-Profil 3	2,584	0,705
G-Profil 1	51,154	1
G-Profil 2	16,066	3,729
G-Profil 3	7,707	3
K-Profil 1	12,460	11,878
K-Profil 2	4,269	2,895
K-Profil 3	19,426	5,166

Table 4: Material parameters tested in the first part of the study

5 CONCLUSION

In this study, the robot-assisted layup process of prepregs was analyzed with regard to the influence of different material parameters, the selected draping strategy, and the complexity of the part geometry. In the first part of the study, various material parameters and their impact on layup quality were evaluated. The second part focused specifically on investigating the extent to which the choice of draping strategy and the complexity of the part affect the final layup quality. A total of 40 trials were conducted

to test three material parameters on two shapes, and 36 trials were performed to evaluate three draping strategies on four different geometries.

It was found that material parameters such as weave type and areal weight have no significant impact on the quality of the final product. This indicates that all common prepreg materials can be used in a robot-based layup process.

The trials involving different draping strategies on geometries of varying complexity showed that selecting a well-suited draping strategy is crucial. In particular, the starting point and the sequence of individual draping steps must be defined with care. Furthermore, it is not only necessary for the end effectors to enable the forming of the textile, but also to actively induce textile shearing during the process so that even complex part geometries can be draped without defects.

Future research should therefore focus on the development of suitable draping strategies that can be applied to a wide range of part geometries. In this context, the analysis of manual draping motions and their abstraction and transfer to robotic processes can be especially helpful. In addition, a holding mechanism should be developed that enables targeted shearing of the prepreg during the process, thus improving the ability to prevent wrinkle formation in robotic layups.

AN INVESTIGATION OF THERMOPLASTIC TAPE-TO-TAPE BONDING USING XENON FLASH LAMP HEATING

Professor David Williams[1]

Keywords: Thermoplastics, Xenon flash lamp, Tape bonding, Peel strength, Welding

ABSTRACT

This research was undertaken to investigate factors affecting the tape-to-tape bond strength of thermoplastic composite tapes in the Automated Fibre Placement (AFP) process using a xenon flash lamp as the heat source. Two variants of flash lamp were studied with different spectral outputs.

The effect of exposure to the broadband output of the flash lamp on the polymer chemistry of representative thermoplastic tapes was investigated by analysing exposed tape samples. Particular focus was given to the potential for the UV wavelengths within the spectrum to photodegrade the long polymer chains into lower molecular weights, reducing their ability to form strong tape-to-tape bonds. Three spectroscopy techniques were used: Fourier-Transform Infrared Spectroscopy (FTIR); Raman Spectroscopy; and X-Ray Photoelectron Spectroscopy (XPS). The study included carbon fibre tapes with polyaryl ether ketone (CF-PAEK) and polyamide 6 (CF-PA6) matrices. From these spectroscopy studies, no clear evidence was found that exposure to flash lamp energy causes photodegradation of the polymers.

The study then investigated how the spectral output of the flash lamp affected the peel strength of the tapes through peel testing of bonded tape pairs and imaging of the peeled surfaces. Tapes were bonded (welded) by a novel process, using the flash lamp's ability to heat and apply compaction force onto the tapes simultaneously. The peeled surfaces revealed the failure mechanism of the polymer at the interface via Scanning Electron Microscopy (SEM), which in all cases showed ductile failure of discrete polymer regions and not overall brittle failure. The difference between low and high peel strengths was observed to be related to the number of discrete areas of polymer that undergo plastic deformation during the peel.

1 INTRODUCTION

Research into efficient manufacturing processes using high-temperature thermoplastic composites has been ongoing for many years ([1], [2]), but their adoption for applications in the aerospace and automotive industries has been relatively slow, in spite of their clear advantages over thermoset composites through enhanced material properties, faster manufacture and their potential to be recycled. One of the reasons for this delay in adoption has been the challenges inherent in fast, automated tape lay-up processes such as AFP or Filament Winding (FW) to achieve full, in-situ consolidation in a single manufacturing step. These fast processes typically produce partial bonding of the composite tapes, which then necessitates a secondary (slow) heating step in order to reach the desired lay-up quality. These processes also typically induce very fast cooling rates in the processed materials, which limits the level of crystallinity that can be recovered in semi-crystalline thermoplastic polymers, resulting in lower mechanical properties of the part ([2]).

There is a compelling need to understand the tape-to-tape bonding process more closely, especially when using high-power heat sources such as lasers and xenon flash lamps. With a deeper understanding of the behaviour of the thermoplastic polymers during the heating and cooling phases, it may be possible to adapt current automated manufacturing processes to achieve higher tape-to-tape bond strengths and higher quality parts. This paper investigates aspects of xenon flash lamp heating that affect the bond strength of thermoplastic tapes during AFP.

Xenon Flash Lamp Heating

The xenon flash lamp heating system consists of a xenon-filled flash lamp (a quartz glass tube with metallic electrodes), within which an energetic plasma is created in short duration pulses that emit photons from the lower ultraviolet (UV) wavelengths to the higher infrared (IR) wavelengths. The lamp is housed within a larger diameter quartz glass flow tube to allow an annular flow of deionised water to pass the lamp for cooling purposes.

The material of the lamp (or flow tube) can either be clear fused quartz (CFQ), which causes no attenuation across the spectrum, or cerium doped quartz (CDQ), which attenuates the majority of the energy within the UV spectral region. Typical spectral outputs of the CFQ and CDQ variants are shown in **Figure 1**, differing only in wavelengths below 400nm.

The flash lamp and flow tube are contained within a small, T-shaped head with a shaped reflector behind and an aperture in front of the lamp to guide the energy into a solid quartz light guide (**Figure 2**). The light guide acts to guide the diffuse flash lamp energy to the target by means of total internal reflection. The output face of the light guide can be kept as a flat surface or shaped with planar facets to create a desired heating profile ([3], [4]). The output from the light guide is thus high-energy, pulsed, broadband and diffuse.

Three pulse parameters: pulse voltage (typically 150-250V); pulse frequency (number of pulses per second – typically 60-100 Hz); and pulse duration (typically 2-5ms) are varied to modulate the average output power of the system. The maximum average power of the system used in this study was 6kW, with an instantaneous, in-pulse power of up to 85 kW. In the typical AFP usage, where the flash lamp moves on a robotic arm, pulses superimpose as the lamp passes across a moving target, resulting in an approximately constant surface temperature.

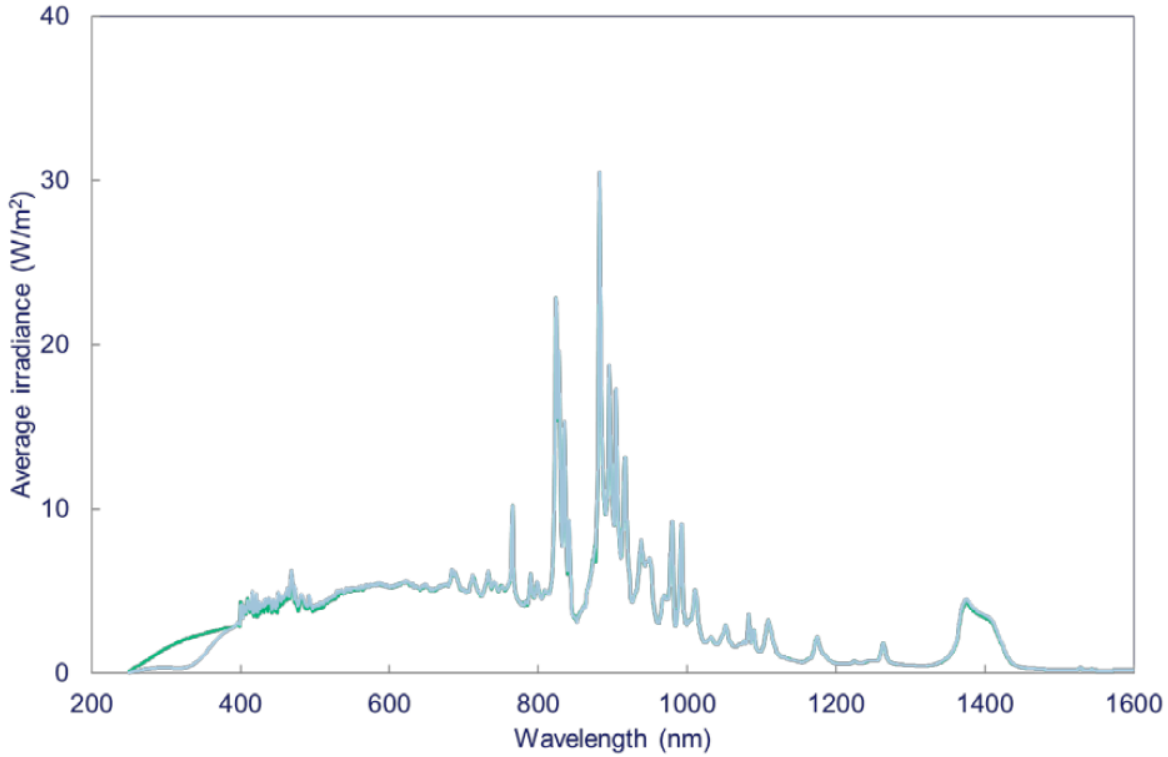

Figure 1: Spectral output of flashlamp with CFQ and CDQ flow tubes. The spectral outputs are identical above 400nm, but below 400nm most of the UV energy is removed by the CDQ case.

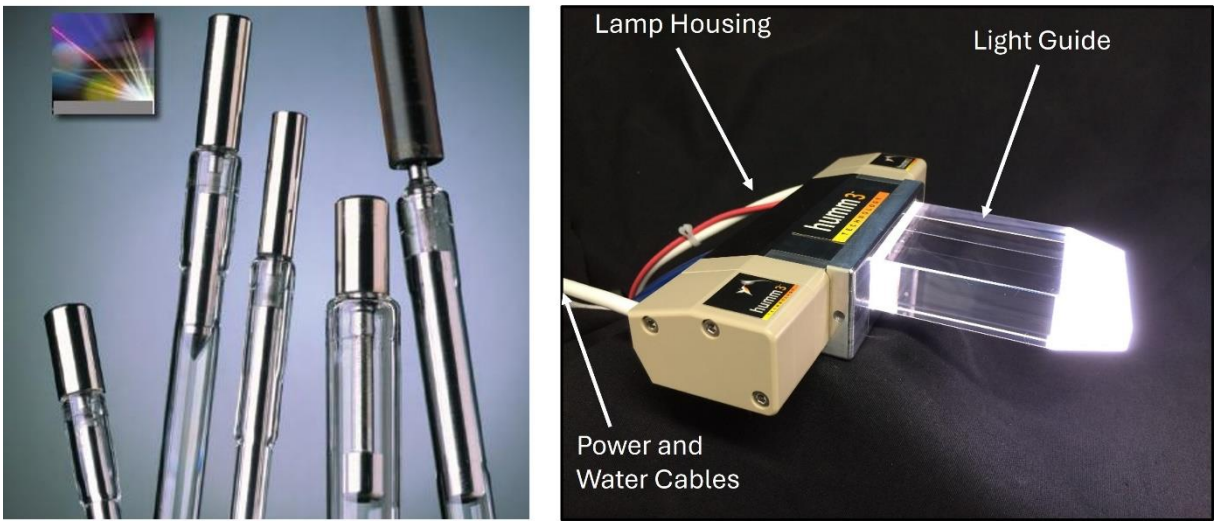

Figure 2: Image showing typical xenon flash lamps (left) and the flash lamp system head (right)

The motivation for this project arose from the results of previous unpublished work carried out at the National Composites Centre (NCC), UK, on AFP of CF-PAEK tapes using the flash lamp. The CFQ and CDQ variants of the system were compared as heat sources on a Coriolis AFP robotic system under nominally identical conditions. It was found that the CDQ variant produced tape pairs with a significantly higher bond strength than the CFQ variant, even though speed, compaction pressure and nip point temperature were matched. It was hypothesised that the additional UV content in the CFQ spectral output may have caused the lower tape-to-tape bond strengths. This motivated the current study to look for changes to the polymer surface chemistry caused by flash lamp irradiation.

It is generally well understood that polymers are sensitive to UV exposure, and can suffer degradation effects such as photooxidative aging, which may result in the breakage (scission) of polymer chains and a reduction in average molecular weight ([5]). However, the main body of literature has looked at long-term UV aging, for example by sun exposure, rather than the short exposure times (fractions of a second) typical of AFP processing.

As a result, this project has tested the hypothesis that changes to the polymer chemistry of the tape surfaces due to exposure to the broadband flash lamp radiation cause a reduction in bond strength. As a first step in this investigation, several spectroscopy techniques were deployed to look for changes to the polymer chemistry due to flash lamp exposure.

2 FLASH LAMP TAPE EXPOSURE METHOD

In the AFP process, each discrete area of the incoming tape is exposed to flash lamp energy for a short time as it passes through the heated zone, before reaching the AFP nip point and being compacted onto the substrate by the roller ([3], [4]). Under typical AFP conditions, the tapes are estimated to be within the heated zone for 0.5s to 1s, depending on the lay-up speed and dimensions of the heated zone. In order to replicate this tape exposure and investigate any changes to the tapes caused by the flash lamp heating, samples of the tape materials were exposed to flash lamp radiation on a moving linear stage without further processing. The exposure rig is shown in **Figure 3** showing the flash lamp light guide directed vertically downwards, heating the tape as it passes on the linear stage. The offset distance between light guide and tape was 20mm.

Tape surface temperatures were maintained at approximately the melting points of the polymers (220°C for PA6 and 300°C for PAEK) by modulating the tape speed at constant flash lamp pulse parameters of 175 Volts, 60 Hertz and 2 milliseconds. A thermal camera was used to monitor tape temperatures during the exposure. Tape speeds of 50mm/s were used for CF-PA6 samples and 40mm/s for CF-PAEK samples. The CFQ variant of the flash lamp system was used to create exposed tape samples for spectroscopic testing. Exposed samples were compared with unexposed (control) samples. All tapes were 1/4” wide.

Additional exposed samples were created using the same configuration but with the CDQ flash lamp variant. These samples were used in the subsequent testing of the strength of bonded tape pairs, described in section 4.

3 SPECTROSCOPY RESULTS

FTIR Spectroscopy Results

Fourier-transform infrared spectroscopy (FTIR) is a chemical analysis technique that applies infrared light to a sample to gain insights into its chemical structure. The FTIR analyses described here were conducted at the NCC. In these analyses, an attenuated total reflectance (ATR) sampling head was used attached to an Agilent Exoscan 4100 FTIR. Spectra were taken between wavenumbers of 600 cm^{-1} and 4000 cm^{-1}. For each material, the control (unexposed) and CFQ-exposed samples were compared. The tapes were held onto the ATR sampling head with a clamp and spectra were taken at three points along the surface of each tape.

Polymer chemistry changes to the tape surfaces were expected to be evidenced by changes to spectral peak positions and heights, or the appearance of additional peaks. Representative results are shown in **Figures 4** and **5**. A typical FTIR spectrum is shown in **Figure 4** for a control sample of the CF-PA6 material**.** The peaks have been annotated with their corresponding chemical bonds within the thermoplastic resin.

Figure 5 shows a comparison of nine FTIR spectra from control and CFQ samples of CF-PAEK tapes. No clear changes to peak positions, heights or numbers are observed.

It is worth noting here that carbon fibre is highly infrared absorbent across the full wavenumber range. Slight changes in the resin-to-fibre ratio on the tape surface will alter the baseline height of each graph. This effect is known as baseline drift. The slight peak height differences seen in **Figure 5** are attributed to this baseline drift rather than any chemical changes.

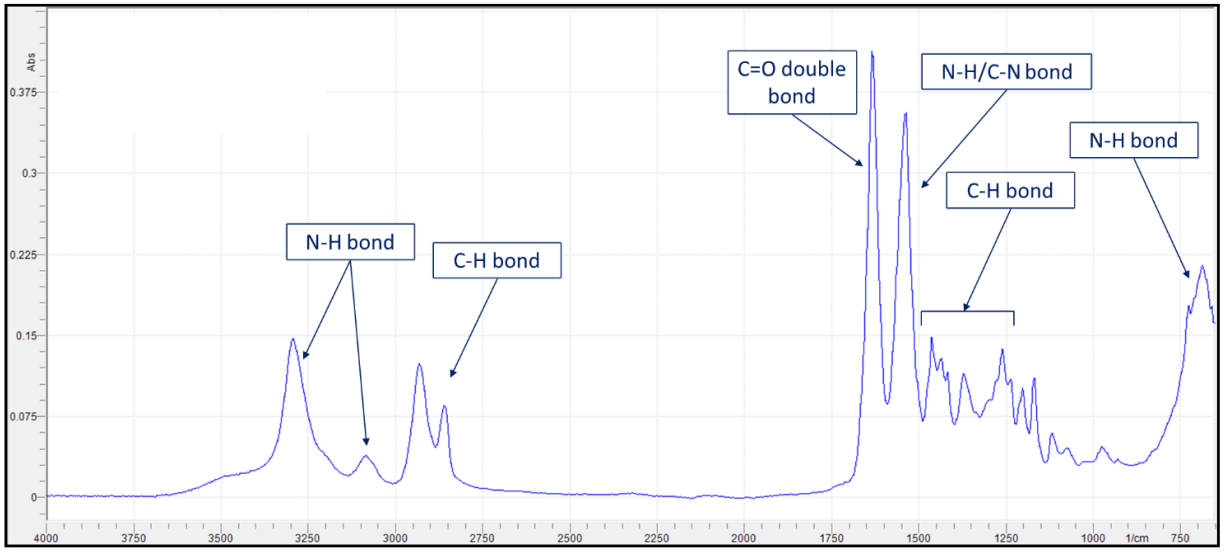

Figure 4: FTIR spectrum of unprocessed CF-PA6 tape, 650-4000cm^{-1}.

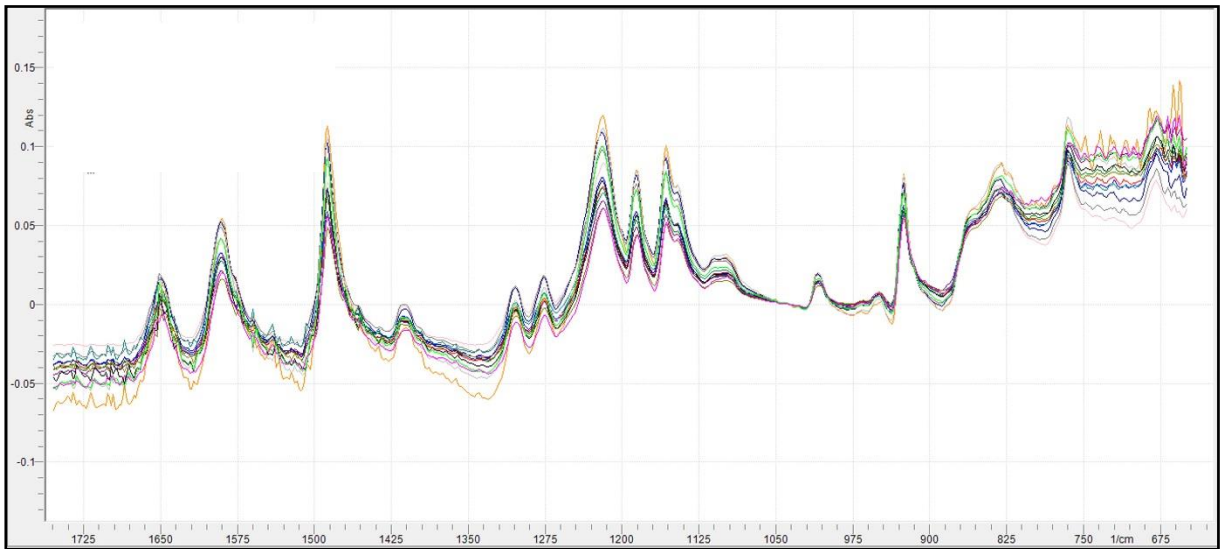

Figure 5: FTIR spectrum of control and CFQ LM-PAEK tapes, 650-1750cm^{-1}

The results shown in Figure **5** are typical of all other FTIR analyses conducted in this project. No changes to spectral peaks were observed in the case of the CF-PA6 samples. It can be concluded that no evidence of chemical degradation was observed by FTIR spectroscopy when the CF-PAEK and CF-PA6 materials were exposed to flash lamp radiation.

Raman Spectroscopy Results

Raman spectroscopy was chosen as an alternative chemical analysis technique for composite materials that typically applies high-intensity laser light to a sample to gain insights into the chemical structure. It was deployed in this project as a complementary technique to FTIR to look for evidence of chemical degradation. The Raman analysis was conducted at the University of Bristol. For all the samples tested, significant baseline drift was observed, which affected the ability to interpret results. One possible explanation of this baseline drift is the autofluorescence of exposed carbon fibres at the surface. The Raman and FTIR spectra of a control CF-PA6 tape sample are overlayed in **Figure 6**. The Raman trace is in black and the equivalent FTIR trace is in red. The peaks in the Raman trace are poorly defined and the baseline drift masks the lower intensity peaks between 1000-1750 cm^{-1}. The fluorescence

was even more pronounced for the CF-PAEK material samples tested, so that only the most intense peaks could be seen. This meant that no comparison between samples could be made as it was not possible to assess whether peak heights were changing or if new peaks were appearing.

Within the budgetary and time constraints of this project, it was not possible to improve this method. For this reason, Raman spectroscopy was discounted from the rest of the study.

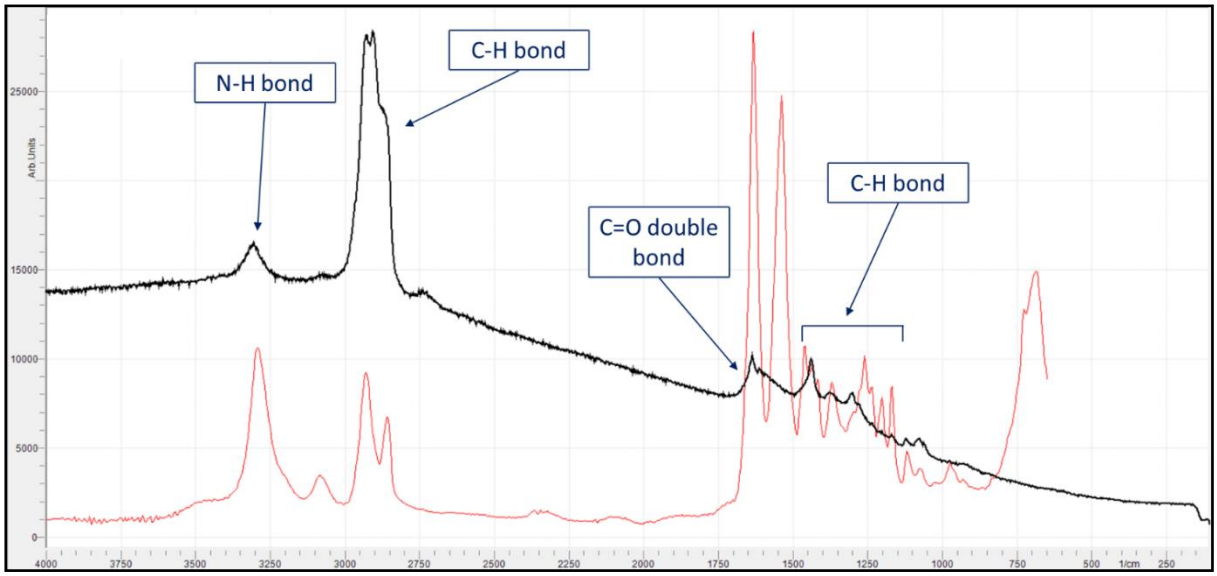

Figure 6: Black trace – Raman spectrum of control CF-PA6 tape. Red trace - FTIR spectrum of control CF-PA6 tape.

X-Ray Photoelectron Spectroscopy Tests

The results from FTIR and Raman spectroscopy did not show any clear evidence for polymer degradation of the composite sample surfaces. However, both techniques assess a relatively thick (several micron) surface layer of the material. It was thought that the high energy pulses from the xenon flash lamp may not penetrate into the material to this depth, and thus these two spectroscopy techniques may not be able to distinguish surface effects from the unaffected bulk material. As an alternative technique, X-ray photoelectron spectroscopy (XPS) was explored.

XPS is a spectroscopic technique that applies x-rays to the surface of a sample and measures the kinetic energy of the electrons that are emitted from the surface. It provides information about the chemical elements present in the sample and is a very surface-sensitive techniques that is only influenced by the top 10 nm of the material ([6]).

The XPS tests were carried out by Harwell XPS, at the EPSRC National Facility for XPS in Oxfordshire, UK. Technical details of the XPS set up and analysis are not provided here (but can be supplied by contacting the author). The samples tested were the control, CDQ and CFQ samples of each of the CF-PA6 and CF-PAEK tapes. Five repeats were carried out for each sample type, and particular interest was paid to any change in the oxygen percentage calculated, as this could be an indication of oxidative degradation of the polymer.

Composite materials are, by their nature, more difficult to assess than single material systems, especially as the ratio of resin and fibre on the surface of the material may vary with surface location and change during processing. If the ratio of resin to fibre changes, then the elemental ratios will vary. This appears to be the case for the CF-PA6 samples analysed here. As shown in

Figure **7** (left graph), the carbon percentage for the CF-PA6 tapes increased from 79.5% in the control samples to 81% for the CDQ samples and 83% for the CFQ samples. This may suggest an increase in fibre on the surface of the CDQ and CFQ samples as the carbon fibre contains solely carbon atoms compared to the polyamide resin which contains carbon, nitrogen and oxygen. A corresponding drop in nitrogen and oxygen percentage (Figure **7**, middle and right graphs) was observed. If oxidative degradation of the polymer had occurred, then an increase in the percentage of oxygen on the tape

surface would be expected. However, any increase in oxygen percentage from oxidative degradation may be masked by changes to the resin to fibre ratio. Hence it was not possible to make a firm conclusion that there was evidence of oxidative degradation. It should be noted that the standard deviation on all results (shown as black vertical bars in the figure) was large and therefore further testing would be required to determine whether these results were statistically significant.

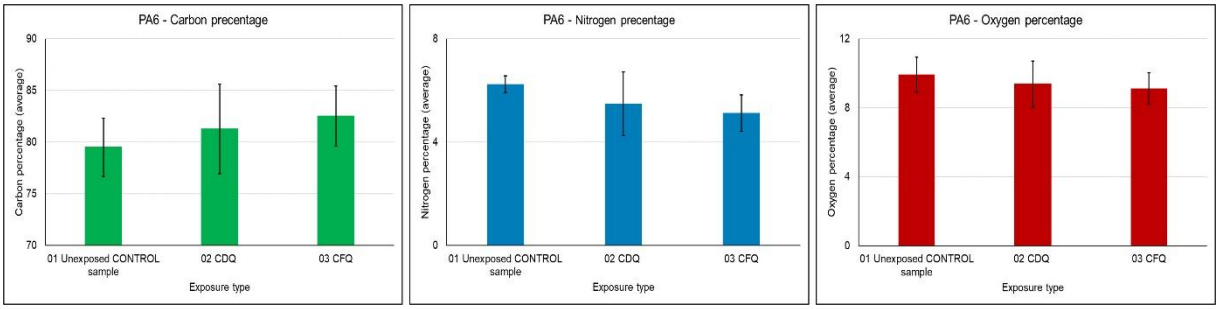

Figure 7: XPS results for the CF-PA6 samples. Carbon percentage is shown on the left, nitrogen percentage is shown in the middle and oxygen percentage is shown on the right. Each graph shows results for the control, CDQ and CFQ cases.

As with the CF-PA6 samples, there was a change in the carbon and oxygen percentage for the CF-PAEK tapes, however the opposite trend was observed. The CDQ and CFQ samples had a lower carbon percentage and higher oxygen percentage, as shown in **Figure 8**. These results are more consistent with the pattern to be expected from oxidative degradation. However, these results could also be explained by an increase in the resin to fibre ratio on the surfaces of the CDQ and CFQ samples. Again, it should be noted that the standard deviation on all these results was large and therefore further testing would be required to draw more confident conclusions.

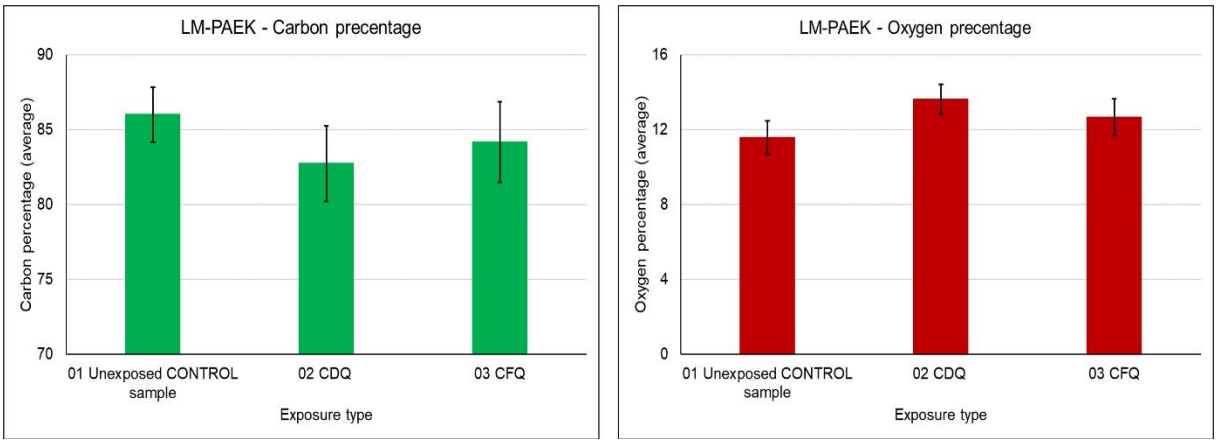

Figure 8: XPS results for the CF-PAEK samples. Carbon percentage is shown on the left and oxygen percentage is shown on the right. Each graph shows results for the control, CDQ and CFQ cases.

Conclusions from Spectroscopy

Three spectroscopy techniques, FTIR, Raman and XPS, were applied to control, CFQ-exposed and CDQ-exposed samples of CF-PA6 and CF-PAEK materials. The complementary tests did not find conclusive evidence that exposure to flash lamp radiation causes chemical degradation of the material surfaces. Of the techniques, XPS showed most promise for further work, possibly combined with similar tests on neat resin to remove the effects of the carbon fibres at the surface.

4 ALTERNATIVE FLASH LAMP TAPE BONDING METHOD

The complexity of the AFP process, with its many interacting parameters, such as compaction force, tape feed accuracy, tool temperature, first ply contact with tool, position of thermal camera and many others make repeatable tests and accurate thermal measurements difficult to achieve. Through reassessing the AFP results on thermoplastic tapes at the NCC, the results of which motivated this project, it became clear that a simpler, more laboratory-scale method of bonding tape pairs would facilitate easier assessment of the effects of single parameters on the bond strength. To this end, a new tape bonding technique was developed, and is described here for the first time, which takes advantage of the flash lamp system's unique ability to apply radiant heat and compaction pressure simultaneously. Under static conditions, it is possible to apply pressure through the quartz light guide at the same time as heating via irradiation through the light guide, creating a precise weld between tapes. The light guide itself does not heat up during the process and is therefore relatively easy to remove from the bonded tapes after processing.

The new method of tape bonding includes the following steps. The previously exposed surfaces of tape pairs are placed in contact, one on top of the other, and covered with a piece of Kapton film, before the quartz light guide is pressed onto the top surface with a known force (**Figure 9**, left). The flash lamp is then used to heat the samples for a given short duration while maintaining the compaction force, to allow the tapes to melt through their thickness and be bonded (welded) together.

In order to bond tape pairs for this project, flash lamp pulse parameters of 200 Volts, 60 Hz, and 1.5 ms, with a heating time of 1 second, were used in all cases. A compressive force of 200 N was applied by tightening a scissor-jack beneath the samples and pressing them onto the light guide of the statically mounted flash lamp head, force being measured on a set of scales beneath (**Figure 9**, right). The compressive force was maintained for 60 seconds after the heating, and a delay of 180 seconds between tests was used to allow the base plate to cool to ambient temperature between tests. Using this method, a 55mm long central section of the tape pairs was bonded (the longer dimension of the rectangular output face of the light guide). A separate project has assessed the ability of this method to bond (weld) multiple layers of thermoplastic material in one short-duration heating step, and results will be published in subsequent papers.

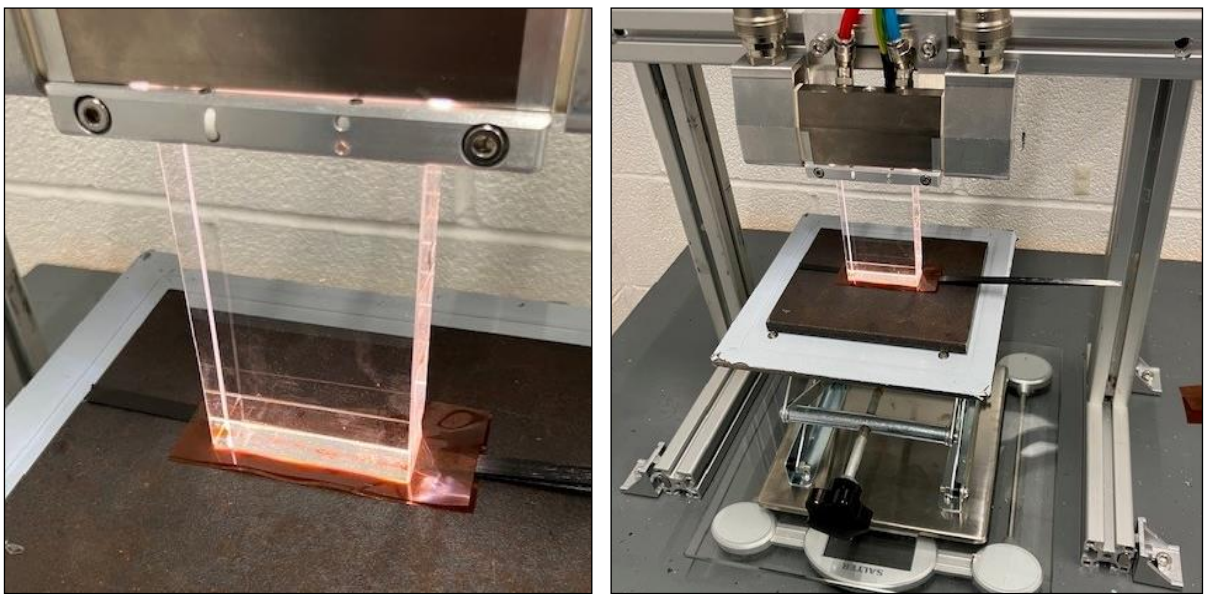

Figure 9: Xenon flash lamp system welding two CF-PAEK tapes under the quartz light guide. Left image: tape pair and Kapton film under the light guide. Right image: the scissor jack and scales.

Measuring Bond Strength of Tape Pairs

Several methods exist in the literature for measuring bond strength of welded thermoplastic interfaces. Standard tests, such as the lap shear test or double cantilever beam (DCB) test, work on thick, rigid specimens of multiple plies. These tests cannot be applied to the thin, flexible tape pairs being considered in this project. Alternatively, several different types of peel testing have been used to characterise the bonding of flexible tapes. T-peel tests, wedge peel tests and floating roller peel tests have been used in the literature ([7], [8]), however T-peel tests are prone to snapping of the tapes prior to interface failure when assessing strongly bonded samples, and wedge peel test results are complicated by the friction between the tapes and the wedge itself. The floating roller peel test ([9]), used throughout this project, provides direct measurement of the bond strength between two flexible tapes along the entire bond surface.

Figure 10 shows the floating roller peel test configuration.

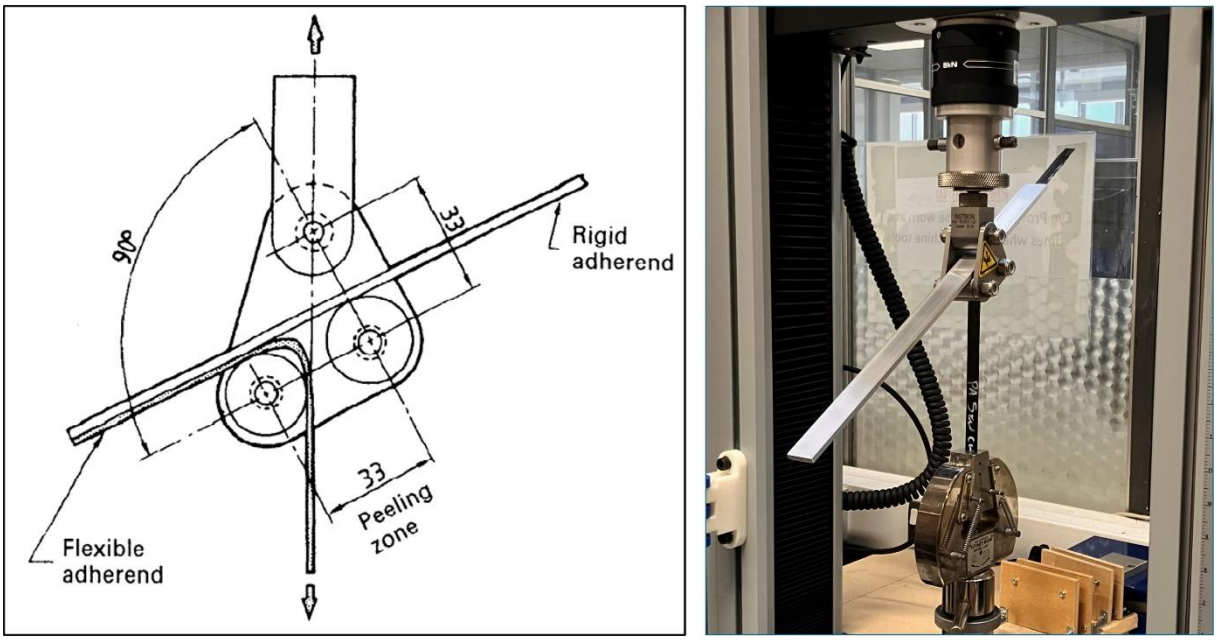

Figure 10: Floating roller peel test configuration. Left: schematic diagram from ASTM D3167−10. Right: picture of floating roller peel test in progress.

Bond Strength Results

Bonded tape pairs from the CDQ-exposed and the CFQ-exposed CF-PAEK material samples were compared with control samples that had not been exposed to flash lamp energy. A total of 10 bonded pairs were created for each category, and bond strengths were measured with the floating roller peel test.

Each tape pair was adhered to an aluminium metal backer using a strip of 3M double coated tape adhesive, 93015LE. The samples were left for at least 24 hours to allow for sufficient adhesive strength between the tape and the aluminium.

The peel tests were carried out on a Instron 5966 screw driven mechanical testing machine, fitted with a 10 kN load cell. The testing methodology was altered from that specified in D3167-10 as the length of bonded tape was only 55mm. The peel rate used was 150 mm/min.

The average force between 10 mm and 20 mm displacement was calculated for each tape pair, then the average of these values was taken over all the samples in each category to give a single number for peel strength of control, CDQ-exposed and CFQ-exposed tapes.

Figure 11 shows the results of the peel tests. The CDQ and CFQ-exposed tape samples, when bonded with the flash lamp welding method, showed a significant reduction in bond strength. There was an 86% reduction in the average force required to peel the tapes apart between the control and CDQ samples and a 98% reduction between the control and the CFQ samples. In general, these results are similar to results

from previous (unpublished) work where AFP was used to bond the tapes. Note that standard deviations, shown with vertical black bars, are high in each category, even though testing was repeated with care.

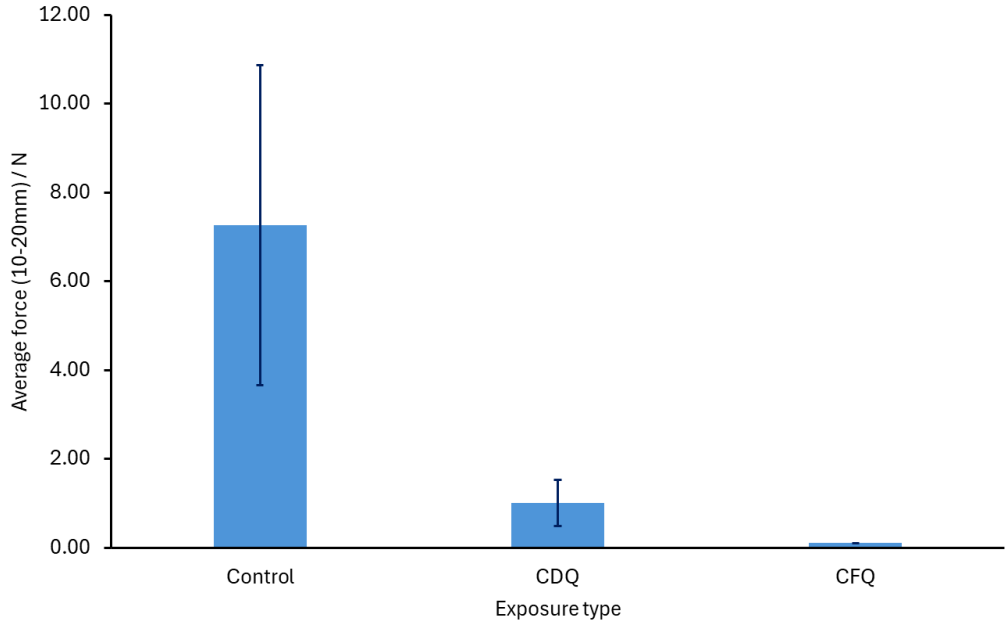

Figure 11: Peel test results from CF-PAEK control, CDQ-exposed, and CFQ-exposed tape pairs

Scanning Electron Microscopy of Peeled Surfaces

Scanning electron microscopy (SEM) images were taken of the peeled surfaces of representative tape pairs to investigate the cause of the different bond strengths seen in the peel tests described in the previous section. Images were taken on a Zeiss Evo MA25 scanning electron microscope. Tape samples were adhered to a 25mm stub using a carbon adhesive tab. The samples were positioned so that the two opposing faces of the bonded pair were next to each other with the peeled surfaces uppermost. The tape samples were coated with a 15nm layer of gold using a Quorum Q150T sputter coater. **Figure 12** shows SEMs of representative peeled surfaces for control, CDQ-exposed and CFQ-exposed samples.

The main observable difference between the control samples, which exhibited high peel strengths, and the CFQ-exposed samples, which exhibited low strengths, was the number of discrete regions of polymer that have failed in a ductile manner, seen in the top images of **Figure 12** as light-coloured ribbons of polymer projecting from the surface, but absent from the bottom images for CFQ-exposed samples. The CDQ-exposed samples exhibited some regions of ductile failure, as shown by the smaller number of ribbons of polymer in the middle image. This type of ductile failure was noted by Comer et. al. ([2]) in their study of PEEK polymer samples and attributed to plastic failure of regions of low crystallinity. The difference between low and high peel strengths was observed to be related to the number of discrete areas of polymer that undergo plastic deformation during the failure of the bond surface.

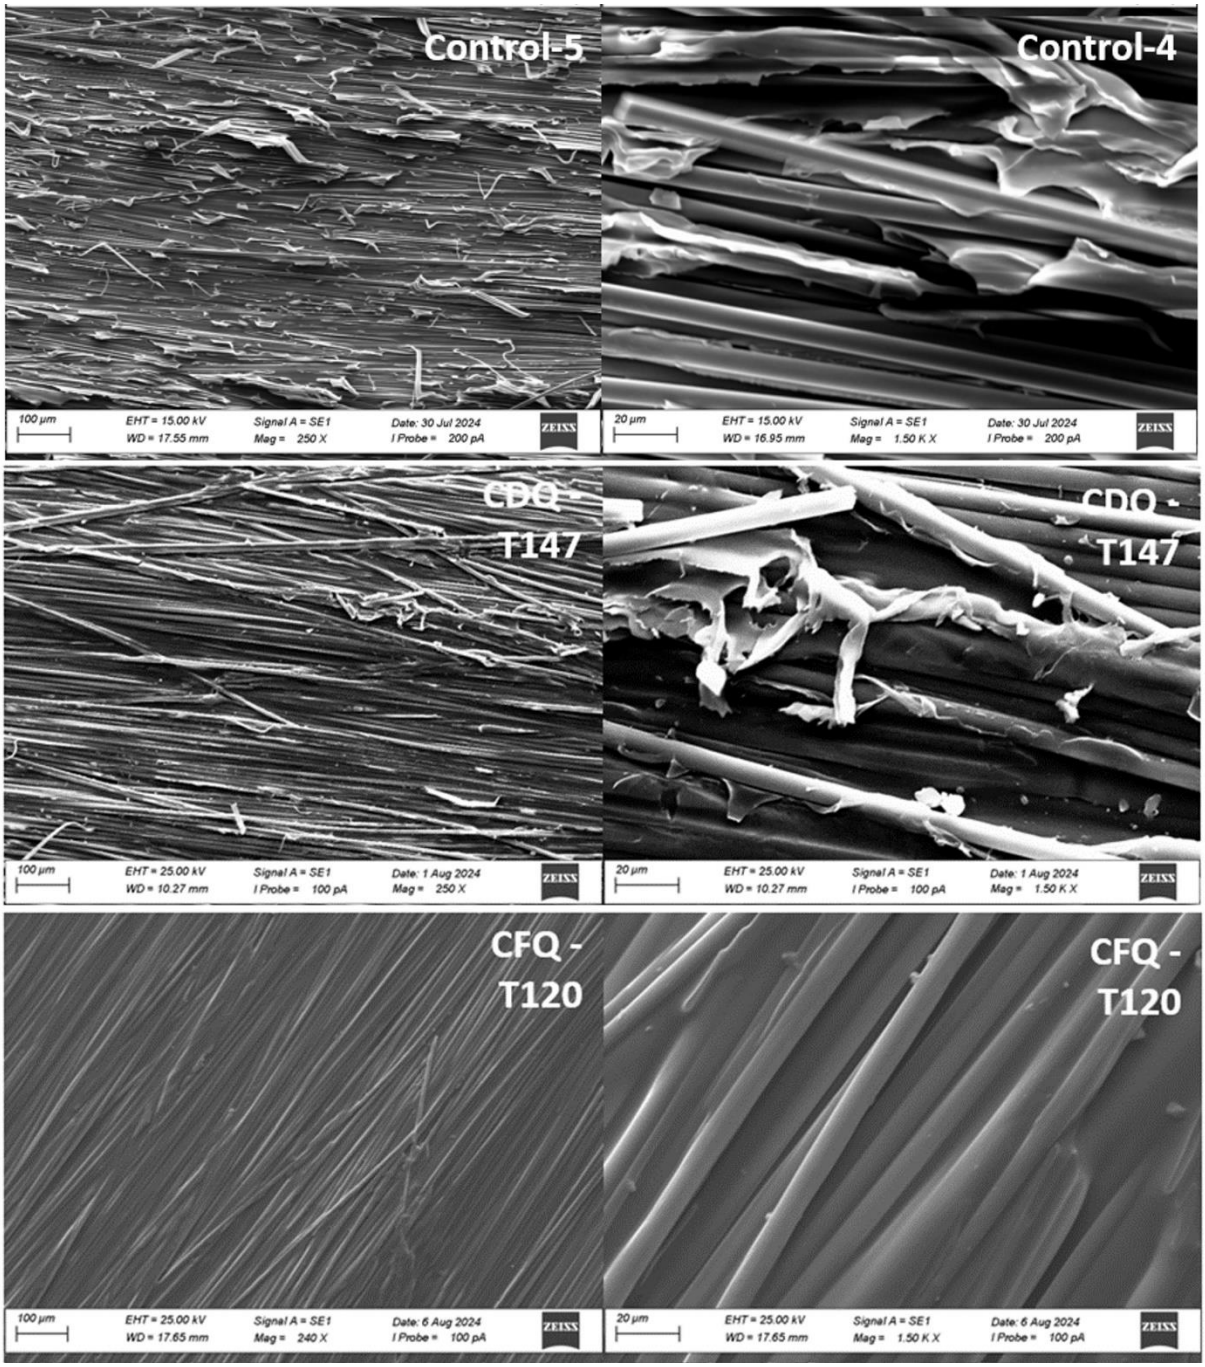

Figure 12: SEM images of peeled tape surfaces for control samples (top), CDQ-exposed samples (middle) and CFQ-exposed samples (bottom). Magnification is 250x (left) and 1500x (right).

Conclusions from Flash Lamp Bonding

Flash lamp bonding of tape pairs from control, CDQ-exposed and CFQ-exposed samples confirmed that exposure to flash lamp energy reduces bond strength. The spectroscopy analysis described in the previous section shows no clear evidence that the polymer surfaces are being chemically degraded by this short duration exposure to the flash lamp energy. An alternative explanation for this reduction in bond strength will form the subject of further work in this area.

5 DISCUSSION AND FURTHER WORK

In this project, no evidence was found that exposure to flash lamp energy caused chemical degradation to CF-PA6 and CF-PAEK tape samples. Further work will be carried out to establish which other factors, present during AFP processing, may detrimentally impact the bond strength between tapes. From the results described here, it appears that reduction in bond strength may not be caused by polymer aging due to UV exposure but by other factors associated with flash lamp heating.

ACKNOWLEDGEMENTS

The main body of this work was completed while the author was a consulting engineer at Excelitas Noblelight (formerly Heraeus Noblelight), Cambridge, UK.

The author wishes to express his gratitude to Martin Brown, Ross Kitson and colleagues at Excelitas Noblelight for supporting this work with funding, technical advice and access to the xenon flash lamp heating system.

The majority of the results shown here were generated through a project at the National Composites Centre funded by Excelitas Noblelight. The author acknowledges with thanks the important contributions of Tom Andrews and Keith Bean at the NCC to the project.

Keywords: Digital Twin, Asset Administration Shell, Life Cycle Assessment, Automated Tape Laying, Thermoforming

ABSTRACT

In the aviation sector, highest demands are placed on the mechanical properties, quality and traceability of all components. Complex manufacturing processes such as Automated Tape Laying (ATL) and subsequent thermoforming imply comprehensive quality inspections to meet strict air transport safety regulations. Utilizing these processes to produce parts fulfilling the harsh requirements needs exact process control and knowledge about every aspect of the process chain. Each processing step generates huge amounts of machine not currently stored in a common, centralized form. A digital twin describing the products along the chain is created to store and transmit this data in a standardized structure and common format as a necessary requirement for overarching process control and life cycle analysis (LCA). This is achieved by means of the Asset Administration Shell (AAS), a standardized approach to implement vendor-independent digital twins and to provide an interoperable meta-model to represent relevant information. Instances of the AAS contain data for all process steps, wherein several sub-models contain general data in standardized models in combination with a self-defined model leveraging classical laminate theory (CLT). Standardized models allow taking advantage of standards beyond the boundaries of composite specific process data, such as the Product Carbon Footprint (PCF) used in the calculation of the LCA. The composite specific model retains the relevant data for composites. Due to the integration in the AAS, all data is transformed into a common shape, ensuring all data to be useable. This integration of information can be shared across processes, applications and industries. The models along the process chain are presented in this contribution, providing subject for discussion.

1 MOTIVATION

In the aviation sector, highest demands are placed on all mechanical properties, quality and traceability of all components to meet strict air transport safety regulations. As a result of this, rigorous inventory recording and tracking for all used materials, components and assemblies up to final products is mandatory. A current challenge therefore is to digitalize the documentation of these processes and test results whilst adhering to existing standards and established concepts. In addition to safety, social and governance reasons, documentation of environmental impacts has become an additional requirement. In order to precisely compute the ecological footprint of the manufacturing of structural aerospace components, processes have become the focus of data collection. At the same time, this data is an valuable asset for controlling and predicting the quality of components along the whole processing chain.

2 INTRODUCTION

To support the digitalization of aerospace manufacturing and enable precise process control, as well as continuous Life Cycle Assessment (LCA), the processes of Automated Tape Laying (ATL) and Thermoforming (TF) were digitalized. This includes the comprehensive assessment of process parameters and results, which are essential for reducing environmental impact. The rejection of defective components significantly increases the overall environmental footprint of accepted parts, making quality improvement a critical objective. To represent realistic starting points in the industry, existing software systems were not replaced, but instead new capabilities were to be added.

The solution created in the scope of this work is thus designed with a non-monolithic architecture to ensure seamless integration with existing enterprise environments. Unlike tightly coupled solutions, this approach avoids interference with established Enterprise Resource Planning (ERP), Manufacturing Execution Systems (MES), and Supply Chain Management (SCM) systems, which already manage parts of the information necessary to describe the digital twin. Instead of replacing or altering internal digital twin implementations, these are extended through the Asset Administration Shell (AAS), as defined by the Industrial Digital Twin Association (IDTA), which functions as a standardized and shareable external representation. It is utilized, because it is an industry-neutral standard with broad applicability, and has strong potential for long-term market relevance. An additional benefit as depicted in Figure 1 is the improved control over shared and published data. The external layer created by the AAS (blue) enables interoperability while maintaining strict data sovereignty. Confidential and internal company data remain fully contained within the organization's secure network (grey). The AAS merely references selected data elements that are explicitly defined for external use through control of a firewall-layer (yellow), ensuring that sensitive information is neither exposed nor transferred. Only access-controlled links to designated non-sensitive attributes are instantiated, preserving the integrity and independence of internal systems. The physical manufacturing layer (orange) and the internal layer communicate as before without experiencing change. As a result, the solution supports a high degree of system independence and facilitates structured external collaboration without compromising internal security or operational workflows.

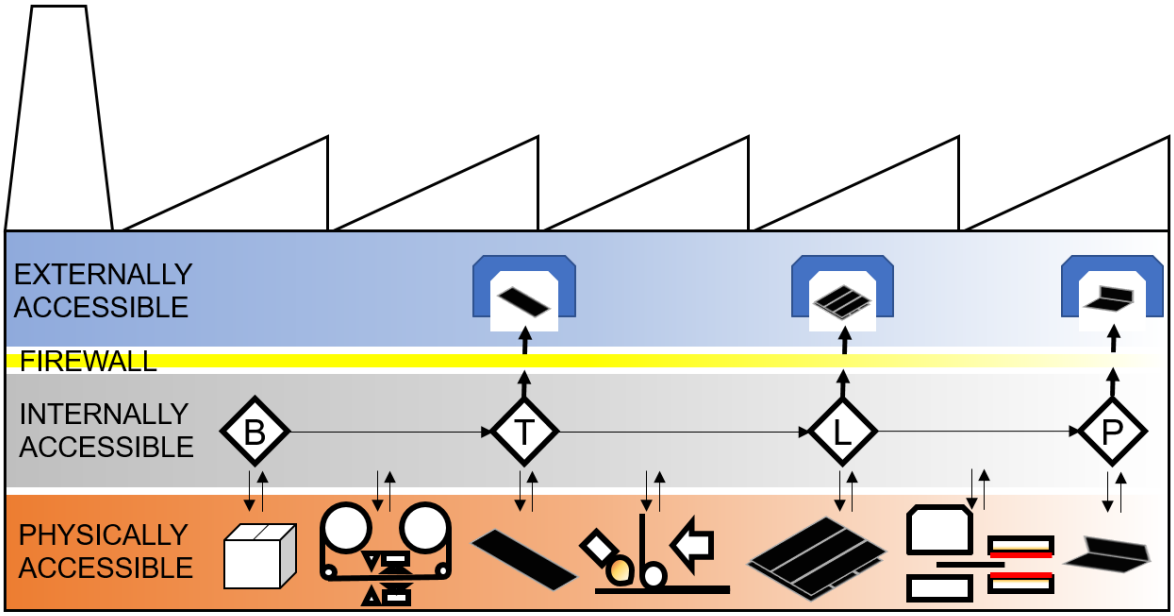

Figure 1: Representation of relationships between modelling layers in the internal and external solution as well as the physically accessible field level where data is produced and consumed for manufacturing

3 STATE OF THE ART

3.1 Life Cycle Assessment for Composite Manufacturing

One central driving aspect of the creation of the process-focused digitalization across industry is LCA, although it is closely followed by the aspect of process control. Accordingly, it is the most important subject meeting requirements and assess achievable results by the creation of the digital twin as in the European unions (EU) Battery Passport [1]. As it will likely become mandatory for a growing number of products, it is already a focus in many digitalization attempts and will remain so here.

LCA is an environmental evaluation tool for determining or predicting the potential effects associated with a product or a process that includes its entire life cycle. The conduction of LCA is standardized in DIN EN ISO 14040 (Principles and Framework) and DIN EN ISO 14044 (Requirements and Guidelines). As an iterative approach, its four phases, namely *Goal and Scope Definition*, *Life Cycle Inventory*, *Life Cycle Impact Assessment*, and *Interpretation* are interrelated and refined throughout the study. It is also a holistic approach, considering the entire life cycle of a product following a cradle-to-grave perspective, from raw material extraction to disposal and end-of-life treatment. An LCA study typically considers multiple impact categories (e.g. *Climate Change*, *Ozone Depletion*, *Human Toxicity*), whereas a Product Carbon Footprint (PCF) only assesses the climate change impact of greenhouse gas emissions. The choice of the evaluated impact categories must be documented during the *Goal and Scope Definition* phase. Incorporating multiple impact categories prevents burden shifting between environmental issues and represents a fundamental aspect of the holistic approach. During the *Life Cycle Inventory* (LCI) phase, all input and output flows relating to the unit processes of the product system under investigation are compiled and quantified. These include raw materials, energy, products (such as services, software or hardware), elementary flows (those extracted from or released into the environment) and waste. In the *Life Cycle Impact Assessment* (LCIA) phase, the results from the LCI are assigned to the different impact categories to which they contribute. A single flow can contribute to multiple impact categories.

LCA can be used as a predictive tool to estimate environmental impact under different scenarios. FERRARI ET AL. [2] applied the methodology to evaluate the environmental impacts of various production scenarios involving raw materials from different suppliers in the ceramic tile manufacturing process. In field of composites materials, raw materials account for a significant share of the environmental impact, particularly the production of carbon fibers. According to BENITEZ ET AL. [3], the impact of carbon fiber production on climate change under the conditions of the study (2019) was estimated at 69.12 kg CO_2-eq./kg, while PRENZEL ET AL. [4] reports a range from 13 to 34.1 kg CO_2-eq./kg. The wide range of results can be explained by various factors influencing the impact on climate change during carbon fiber production, such as the type of precursor used, the energy source for precursor and fiber production, the conversion rate from precursor to carbon fiber, and the geographical location of the plant [4,5]. The method applied by the LCA practitioner can additionally influence the results, for example through the choice of system boundaries, functional units or allocations [5]. Using LCA as a predictive tool enables the optimization of composite material manufacturing processes, with the dual objective of improving efficiency and minimizing environmental impacts. The rejection rate during the manufacturing process considerably influences the final LCA results, due to the high environmental cost of carbon fibers. According to LCA methodology, all material flows intended for disposal without recovery are categorized as waste flows in the LCI phase. Despite not contributing to the final product, their associated environmental burdens are included in the overall assessment.

In the context of this study, the environmental impact of the Automated Tape Laying (ATL) and thermoforming process chain is assessed with a focus on the *Climate Change* impact category. The emphasis is placed on the digitalization of manufacturing processes following a gate-to-gate approach. Transportation, use and retail, as well as end-of-life phases are out of the scope of this study. The impacts of raw materials are considered at the process level by monitoring the rejection rate, with the aim of optimizing each process step of the production chain and minimizing its environmental impact.

3.2 Digital Twins for Composite Manufacturing Processes

Whilst there have been several proposals for the definition of the term *Digital Twin*, the concept mostly is used to describe few commonalities. A digital twin is in general a virtual representation of an object or system designed not only to represent, but to reflect a physical object accurately. It spans the physicals object life cycle, updates in real time from corresponding data and provides insight into its condition and behavior.

Digital twins are mostly a concept for information provision and evaluation, which utilizes the communication capability of product systems and aggregates data from the entire product life cycle. In this way, they are a perfect fit for the continuous LCA alongside the process chain, providing current values in real time, but also quality centered process monitoring since state variables can be monitored in a central location in real time for every process and product.

Whilst the general concept of digital twins is easy to describe, fine details can make lots of differences especially considering the environment and planned usage as well as the framework and implementation. Whilst environment and usage are defined by the objective undertaken in this work, the framework to be used is subject of discussion and the implementation will be based around this decision. GIL ET AL. [6] provide a comparison and overview over different open-source digital twin frameworks, underlining the importance of AAS-based implementation as standardized solutions, whilst also pointing out the incompleteness of the frameworks.

In order to enable digital product representations that support LCA, interoperable and standardized information models are essential. The AAS plays a key role in realizing this requirement within the Industry 4.0 framework. It provides a digital representation of any physical or virtual asset, such as a machine, sensor or workpiece using an unified metamodel that allows structured data exchange across system boundaries [7].

The AAS consists of modular submodels, which cover a wide range of domains such as production planning, material properties, process capabilities, and more [8]. These submodels follow standardized structures, making data from heterogeneous systems interoperable. This makes the AAS a foundational technology for enabling cross-organizational collaboration and dynamic value chains, which are essential in modern, sustainable manufacturing scenarios [9–11].

AAS-based submodels are being successively standardized by the IDTA to ensure compatibility across industries and applications. However, in specific domains such as composite material products, standardized submodels for relevant data like material composition are not yet available. Importantly, the AAS framework supports the development of custom submodels, allowing domain-specific extensions to be added in a structured and interoperable manner [12]. This extensibility enables companies to integrate domain specific information models, still maintaining compatibility with the broader Industry 4.0 ecosystem.

3.3 The Process Chain

Since the subject of LCA and digital twins is closely related to future manufacturing of aerospace composite components, the process modelled in this work should reflect those attributes as well. Due to their specific benefits, a growing percentage of thermoplastic composites in aerospace applications can be observed in future aircrafts, used mainly in fuselage components. While many manufacturing processes are slow and costly, the thermoforming process has made it into regular production. This is due to high-rate capability, allowing the production of large panels, doors and frames [13].

Stamp forming of thermoplastic composite laminates is typically a two-step process: Fully impregnated laminates are heated in an oven to melt the matrix and to allow deformation and shearing of the laminate to fit to the later 3D-geometry. From the oven it is transferred quickly into a press, where it is stamp formed in a tool and cooled below melting point in a single step, producing the finished part within seconds. Due to the near-net-shape design of the laminate, only little machining of the part is needed, if the design of the component is optimized for thermoforming. [14, 15]

Both steps of the process – heating and thermoforming - are performed within the same equipment, a forming press with an integrated infrared oven (LZK-Uk-2600-SO, Langzauner GmbH Austria). Being equipped with a multitude of sensors, it is capable of tracking and recording all relevant processing parameters, such as pressures, positions and other states of the machine during the process. Additionally,

temperatures are monitored within the integrated infrared oven, individually controlling the 234 radiators for reproducible process conditions. Nonetheless, it also integrates a thermal camera to document temperature distribution during transfer from oven into the press during the short transfer time of approximately a second. All data is collected within an integrated process data logging system (LZ perfectDATA, Langzauner GmbH, Austria) and distributed over Message Queuing Telemetry Transport (MQTT).

To reduce the high cost and high waste of consolidated laminates, near-net-shape preforms can be manufactured in ATL with Unidirectional Reinforced Thermoplastic Tapes (UD-Tapes). A preform is a pre-consolidated laminate that is fully consolidated in the press. ATL allows load-path optimized tape placement and is suitable for high rate production of nearly flat structures such as skins and panels [16–18]. These flat tape preforms can be used as semi-finished parts for the subsequent stamp forming of three-dimensional components. Since there is a higher potential for process induced errors while placing individual tapes, there is a high demand for quality control [19,20].

The ATL machine used (F2-Compositor, ASH Automation Steeg & Hoffmeyer GmbH, Germany) is optimized for high speed deposition (up to 4 m/s) and can process UD-Tapes based on engineering as well as high performance thermoplastic polymers. To create adhesion of the individual layers, the polymer in the tape surface is molten by a hot gas torch, followed by rapid cooling under consolidation force provided by a consolidation roller. During production, it continuously and precisely measures all axis positions and temperatures, as well as material temperature and gas consumption.

It is also set up with a MQTT server with manufacturer-defined topics encompassing all aforementioned position, temperature and gas consumption data. Additionally it transmits status and further crucial process step data, thought to simplify correlation between measured data and planned program steps.

The tapes used for producing the preforms are usually commercial products supplied by different manufacturers all over the world. Therefore tapes as well as their raw materials like carbon fibers, matrices, precursors and other ingredients cannot be included explicitly into the in-house digitalized process chain. As a result, during LCA the environmental impact of tapes is computed using standardized data (e.g. datasheet or database values). However, in order to correlate information that is related to process quality, a custom built test bench is used to provide seamless quality information for every tape used in later processes [21]. The Tape-Quality-Bench (TQB) measures the precise cross section of the tested tape whilst also filming its surface using a polarization camera (VCXU-50MP, Baumer GmbH, Austria) for measuring fiber orientation close to the surface and check for defects and foreign objects.

4 CREATING THE INTERNAL SOLUTION: IIOT AND LIMS

Starting from the state as described before and an already in part created solution for a custom build Laboratory Information System (LIS), an example for the usage of a digital twin framework is created for the presented process. Here, internally developed software was combined with open-source code to create a solution that is able to be shared fully later on. The architecture and especially the workflow within this system is described to give a general overview about the internal use and capabilities and create a basis for the later following description of the externally shared AAS.

Data along the process chain is initially collected locally on the respective production machines—namely, the TQB, the F2-Compositor, and the Langzauner press—and subsequently transmitted to the internal Industrial Internet of Things (IIoT) infrastructure. To accommodate the heterogeneous nature of legacy and modern machine controls, and their varying data export capabilities, the IIoT system exposes multiple data ingestion interfaces, including MQTT brokers, Representational State Transfer Application Programming Interfaces (RESTful APIs) and Open Platform Communications Unified Architecture (OPC UA) endpoints. This multi-protocol support ensures seamless integration of both current and future manufacturing assets. All incoming data to the IIoT system must be timestamped upon ingestion. Where timestamps are not natively provided by the machines, edge devices append them, synchronized via Network Time Protocol (NTP) servers. This ensures the temporal consistency of otherwise independent data sources, which enables automated detection of stale or delayed data, and facilitates precise correlation of process data streams.

In cases where not all relevant data is natively available from the machine control, the IIoT compensates by logically integrating supplementary data sources. For example, although the F2-Compositor does not report the energy consumption of its auxiliary aggregates, this gap is filled by an external energy monitoring device (Shelly Pro 3EM, Shelly Group SE, Bulgaria), which independently measures and transmits the data via MQTT. Its measurements are published under a structured topic hierarchy, e.g., `F2Compositor/Energy/Auxiliaries`, enabling semantic classification of the data stream. Through topic-based filtering and stream parsing, the IIoT system aggregates disparate signals into unified datasets associated with logical assets. This approach ensures semantic coherence even when physical data sources are decoupled. Temporal alignment is achieved via the shared timestamping infrastructure.

While the IIoT layer provides the backbone for scalable ingestion and storage of raw process data, including sensor values, machine parameters, and energy metrics, it does not itself impose any domain-specific structure. Semantic enrichment and high-level data modeling are instead delegated to the LIS. This architectural separation ensures modularity and scalability, with the IIoT handling efficient data logistics, and the LIS capturing contextual and semantic relationships. The LIS organizes data within a hierarchical structure conceptualized as a forest, where each tree corresponds to a specific project. Root nodes are labeled with unique project identifiers, which can optionally link to external project management systems. Subordinate nodes represent physical or logical entities (e.g., materials, processes, parts) and are enriched with attributes and metadata. Each node is uniquely identified via a Universally Unique IDentifier (UUID). Nodes may be interlinked to express compositional, transformational, or inheritance-based relationships, thus capturing complex interdependencies within and between projects.

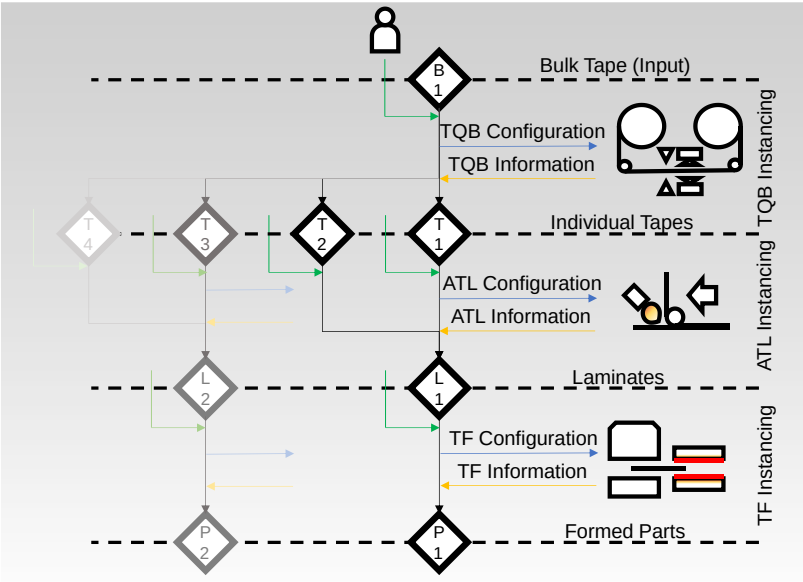

Figure 2: Representation of relationships between component instances along the manufacturing workflow in the internal solution

The manufacturing workflow, illustrated in Figure 2, begins with the thermoplastic tape, the smallest production unit. Bulk tape is initially registered in the LIS as a node containing general attributes such as type, manufacturer, mechanical properties, and nominal width as well as the PCF in form of a single numerical value. Individual spools derived from this bulk material are created as subordinate nodes. During initial quality assessment at the TQB, measured data is recorded and tagged with the associated spool's UUID, stored in the Influx time-series database of the IIoT system, resulting in a set of data which includes measured tape width and its cross-sectional height. At present, tape manufacturers do not provide machine-readable datasheets, digital product representations, or unique identifiers for individual spools. Consequently, UUIDs are generated internally by the LIS. These identifiers are physically linked to spools via QR codes, enabling consistent association between digital representations and physical items. Designed to digitally unify a set of discrete manufacturing processes

for fiber reinforced plastics, the system uses these QR codes to ensure end-to-end traceability. In addition, UUIDs serve as tags within the IIoT data streams, enabling seamless linkage between time-series data and LIS entities.

In the subsequent process step, spools are mounted on the F2-Compositor and identified via QR code scanning. This action associates the spool node with the current instance of the tape laying process and creates a new entity representing the manufactured preform. The resulting preform node automatically inherits attributes from the tape spool and is linked to process data that has been measured during its manufacturing by being linked to its parent node, which represents this manufacturing step. Users may augment these nodes with additional information such as program parameters, machine setup, manual observations, or process events, which are then available to downstream analyses. A persistent challenge in ATL processes is the correlation of process conditions with final part quality. While consolidation quality of the laminate has minimal impact, defects originating in the tape-laying step, such as wrinkled or flipped tows or foreign objects, can significantly impair quality. Although the F2-Compositor provides detailed process data, this alone has proven insufficient. Therefore, a laser line scanner (ScanCONTROL 3000-25/BL, Micro-Epsilon Messtechnik GmbH & Co. KG) is installed on the tape-laying head to capture the surface geometry of each layer. This sensor produces a continuous data stream, recorded as a time-series in the IIoT system and tagged to the corresponding laminate node in the LIS. This data can be evaluated either post-process or in real-time by subscribing to the F2-Compositor's MQTT data channels.

Finally, the laminate serves as the raw material in the thermoplastic stamp forming step. Each finished part is registered as a new node in the LIS, inheriting attributes from the laminate node and receiving its own UUID. Time-series data from this process is again captured in the Influx database. The exception is the thermal imaging data, acquired by an infrared camera. In contrast to the laser scanner, which generates continuous streams, the infrared system captures discrete images per part. These images are attached to the respective part node as singular or occasional multiple instances and are stored using MinIO (MinIO Inc., USA).

5 EXTERNAL SOLUTION: INTERFACING THROUGH AAS

The AAS is used to create external representations based on internally stored information. It is perfectly suited for this, because its modular and extensible structure allows for the integration of heterogeneously collected internal data, such as those originating from LIS, time-series databases or data processing and storage platforms, into a unified, semantically consistent model.

5.1 AAS Modeling using Standardized Submodels

AAS Structure and Infrastructure has a large degree of freedom in terms of information structure, especially in customized submodels. There are limitations of course, nesting of AAS and submodels is forbidden by the metamodel for example. In this way, the structure used in the internal implementation becomes impossible to reproduce. Instead, a new data model based on the AAS metamodel has to be created. Different implementations of the AAS can be used to achieve this easily, however there are no extensive and understandable guides for doing so yet. Also, for most cases there is currently no automated solution for checking the conformity to the metamodel or the used submodels.

In this way, defining the data structure is more difficult than it seems. Being compliant to other standards such as Concept Descriptions and SemanticIDs applies a large amount of implicit and explicit conventions, in addition to the constraints already applied by the metamodel. Handing this large amount of complexity correctly and creating fitting submodel structures is the most important aspect of the work, not only because it needs to be correct, but also because it needs to be widely applicable and understandable. In the following, an effort to structure the data created along the studied process chain is presented.

The starting point for defining the AAS from the finished part perspective is the relation between parts and resources. As stated before, nesting of AAS is not allowed. The alternative is to provide AAS with the information of either the parts containing them or alternatively the parts contained within. This is specified within the published submodel *IDTA 02011-1-1 Hierarchical Structures enabling Bills of Material*. Here, three model variants are allowed concerning the detail and way of relationship between

components. As thermoformed parts are not complete systems, the *full* type is not applicable, leaving the *one up* and *one down* modelling variants, where every component in an assembly hierarchy is linked to the ones it contains (*one down*) or the ones it is contained in (*one up*).

For our example, we define three types of AAS, representing different states of manufacturing. The first is the tapespool and instances of it, being contained within preforms, which is in turn the currently single component of a thermoformed part. Whilst fitting to our internal model closely, as the parts are used up as resources they are not components that could be recovered from the thermoformed part. However, there is the benefit of being able to export any of those three steps as AAS without the need to create a model not considered in our structure, allowing for more flexible process routes as to export every step in between. The relation is created using the inherited parent node in the internal representation at the end of the parts manufacturing process tracked in the LIS. There, an associated AAS is derived from the node, already created with the corresponding submodel for the parent node, creating a submodel entry node as well as the node defining the relationship.

The now existing AAS instance is automatically created with two more submodels containing meta-information. The first one is the *IDTA 02002-1-0 Submodel for Contact Information*. This submodel describes IVW in the form of attributes as well as a contact person. Since the presented process chain is within IVW's manufacturing department, the contact information is per default the head of the manufacturing department. The submodel element collections within Contact Information also include additional data such as an email address and telephone and fax numbers as well as typically available times of day in relation to coordinated universal time.

Similarly, general information for *IDTA 02006-3-0 Digital Nameplate for Industrial Equipment* is set for the country of origin, company logo and production date as well as address information. Additionally, depending on the type of node, the product type is set as tape, preform or part as well. Furthermore, the link to the real part is stored here. The node's UUID reflecting the marking on the real part is set as serial number.

Each AAS created in this study also incorporates the *IDTA 02023 Carbon Footprint* submodel, enabling a structured and standardized assessment of greenhouse gas emissions throughout the production process. The carbon footprint represented by the submodel encapsulates the relevant data for PCF calculation. Within the *ProductCarbonFootprint* collection, the scope and the methodology for the assessment are defined. The Submodel Element List (SML) *LifeCyclePhases* specifies the considered life cycle stages according to the ECLASS 15 value list *LifeCyclePhase*. In this study, phase *A3 - production* is selected, corresponding to a gate-to-gate approach since the internal focus is placed on the production phase of each process. The SML *PcfCalculationMethods* contain the standards applied to the calculation. In this study, the internal calculation node is aligned with the ISO 14040 and ISO 14044 standards with *Climate Change* as evaluated impact category. Quantitative results are stored as property *PcfCO2eq*, which holds the sum of greenhouse gas emissions as decimal in kilograms of CO_2-equivalent (kg CO_2-eq.). In this study, the reference unit of the product i.e. tapes, preforms, and thermoformed parts, is kilogram (kg). This layered and semantically enriched submodel structure supports transparent, traceable, and interoperable reporting of product carbon footprints.

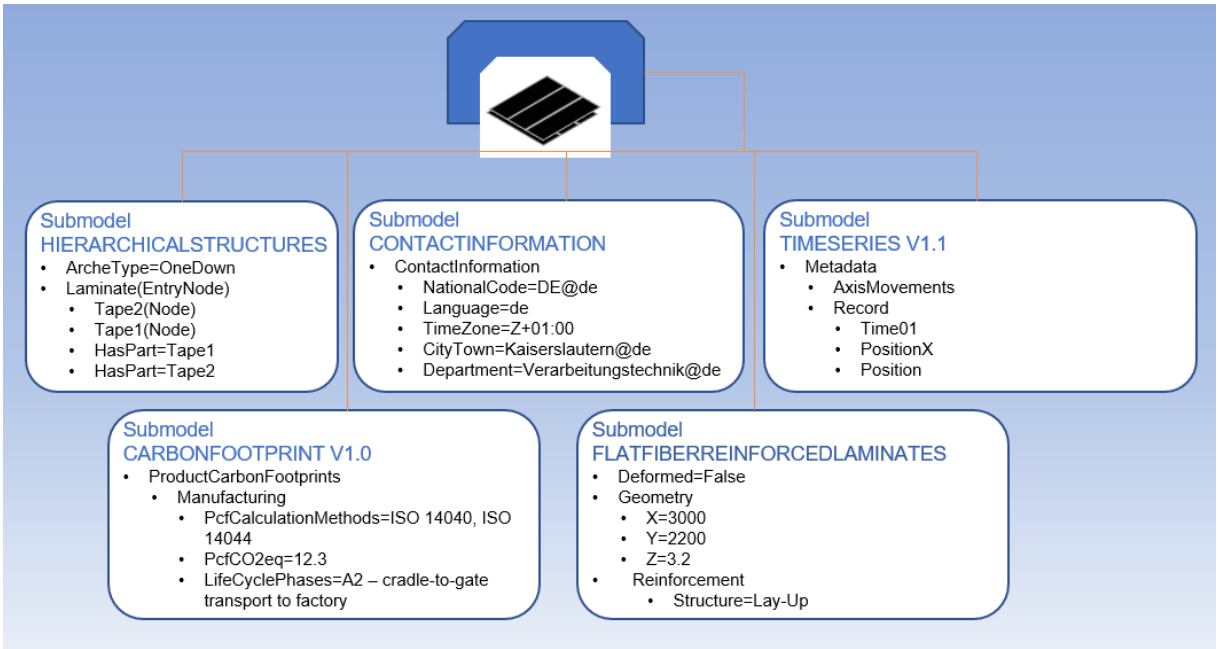

Figure 3: Representation of submodels within the external AAS-based solution as an example for the preform as used in the process chain presented here

In the calculation of the PCF, a large amount of time series data is already used and does not need to be included in the AAS. Most other data acquired for process control purposes is also time series data. Whilst it is mostly used for internal purposes, the *IDTA 02008-1-1 Time Series Data* submodel is included as well to potentially share it externally. The submodel offers many different ways to add data to it and even manipulate the data within, if used as an active model. Since the purpose and way of using the process data is not fully defined for the example yet, the data is strictly passively attached as internal data segments. This means, the selected data is saved directly within the AAS. For the proposed processes, these are width and height of the tape instance, position of the ATL axis as well as forces applied in the thermoforming process.

As the data is already included within the internal nodes representing the corresponding process steps, the data just hast to be exported to the AAS. This is also the step, where the control over process data export can be exercised. Because the data is already available as a link to influx database storage, every available data channel can be exported in the same way. Time series data corresponding to different measurement channels can be stored into individual segments of the time series submodel. The required timing information is taken directly from the Influx database in the form of Universal Coordinated Time (UTC) time stamps. Semantic data in the form of identifiers is taken from MQTT topics, including their respective data sources.

5.2 AAS Modelling of Composites and Composite Manufacturing

There are no implementations of composite-specific submodels or their processes yet. This means anybody is free to define data structures as preferred. This work uses Classical Laminate Theory (CLT) with the stacking rules for individual layers and mechanical characterization based on single layer-attributes as common ground. For this, a custom submodel *FlatFiberReinforcedLaminates*, as depicted in Figure 4 starts with the top level domain of macro-scale objects. Here, laminates and semi-finished laminates (preforms) are generally characterized as flat or deformed to conform to the needs of the thermoformed part. On the same level, the geometry of the full laminate is listed to describe strictly rectangular outlines in Cartesian notation. Here, actively calculated data for the laminates mechanical data based on the CLT calculations could be added in the future, generated from the single laminate layers. These are added as a submodel collection on this level of the model instead, integrating multiple layers as used in the stacking rules for laminate. Here, single layers are collected in a bottom to top order, named by their number of appearance within the laminate. Every single laminate is described by

their textile reinforcement structure, with lay-up as the only type used in this example. Additionally, the orientation angle of the layer is saved according to the rules of the laminate code as defined by NETTLES [22] and the height. Furthermore, the individual layers' mechanical attributes are added as an additional submodel. Here, the individual attributes as needed in the CLT are provided as properties. Further data such as areal weights and densities could be added, where available. Considering the use of thermoplastic matrices, an additional thermal submodel was set up to contain relevant thermal properties such as melting point and glass transition temperature. The original data sheet, where available is added to the layer model as well.

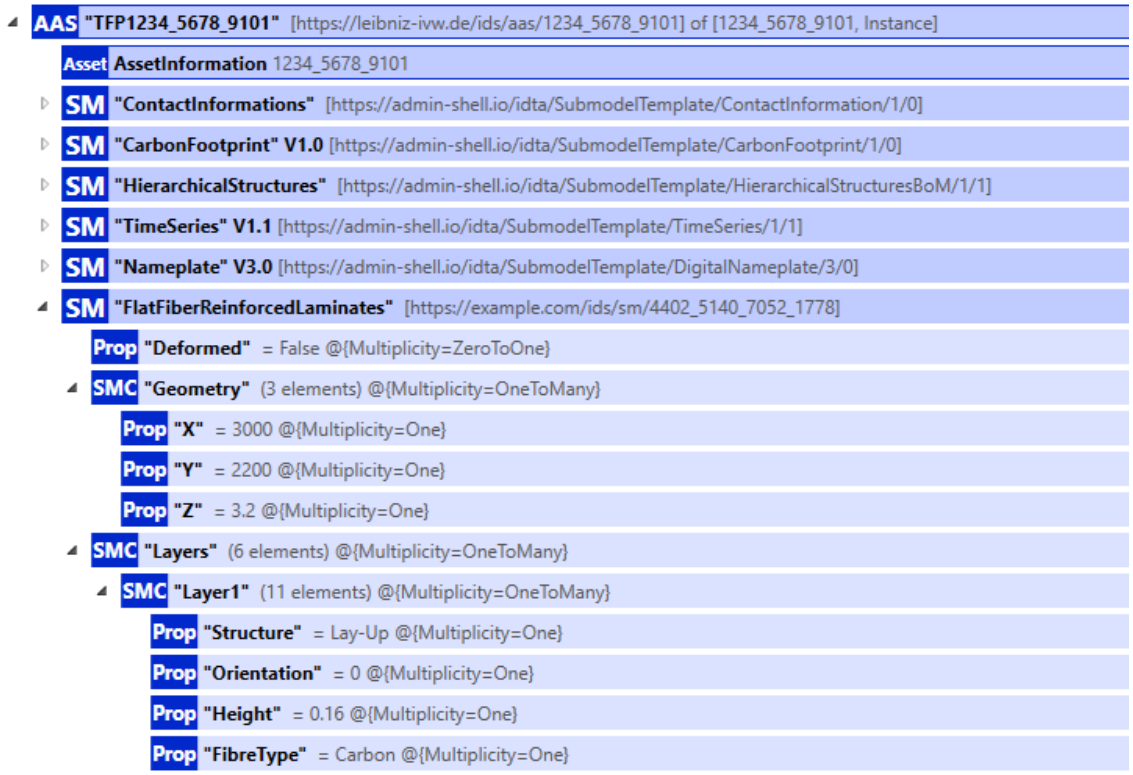

Figure 4: Depiction of an instance of a laminate shell within the AASX-Package Explorer

The presented model thus allows for the description of all states occurring within the demonstrated processing chain. Furthermore, the shared attributes between all states allows to copy or reference the submodel for process steps earlier in the process chain. In a possible next step, the matrices and fibers could be described as additional entities, resulting in a more detailed model.

6 SUMMARY AND CONCLUSION

In the presented work, digital twins for a process chain based around thermoplastic stamp forming of tape layed preforms were created. The process is a promising combination of fast production and high performance products with less emissions during the production chain compared to thermosets. For aerospace applications the process chain needs improved process control and life cycle analysis, which can be easily achieved using Digital Twin. An internal twin to collect, aggregate and store the data has been created based on a custom solution. From it, an external twin has been derived which contains the same information but in a standardized exchangeable form, using the AAS. For this external representation, different aspects of structuring data have been presented and discussed. The most basic element of the taxonomy is the representation of the tape spool, which contains only generic data, such as the manufacturer or fiber type. On the next level, tapes are aggregated into laminate layers, which in turn are aggregated into laminates, following the rules of CLT. Finally, after the thermoforming process steps, these laminates are transformed into deformed parts by adding the deformed tag.

The presented model is but an example to create such a combination of digital twins along a process chain. Through the direct integration of PCF relevant measuring devices, the groundwork for LCA has been laid. Additional feedback opportunities for linking part quality and process quality have been integrated as well. Still, the digitalized process chain lacks some components, especially to reach the goal of proper lifecycle assessment, as well as integrations into ERP, MES or SCM systems. It can however, already show the advantages of digital twins alongside a process chain in creating a clearer data structure and effectively reducing individual management effort for process data. The investigation of part quality influences across multiple process steps with data science methods can only be realized in a manner where process data is collected and managed in an automatic way, enabling this promising field of work.

Altogether, the presented work cannot represent a fully defined standard, but using standardized elements from the AAS is already a large step into the direction of a digital twin. Information as contained in the submodel for carbon footprint will likely find their way in to the product passport and will thus be enforced for businesses. As it will be a requirement to provide similar structures in the near future, we recommended to start working with the subject as soon as a standard fit for long term use has been defined. In our opinion, the AAS could be just the one that prevails, and whilst the product carbon footprint may be obligatory, additional benefits from the use of process data can be generated.

By expanding our approach down to the fiber and matrix levels as well as the machines and finally to other processes for composite manufacturing such as filament winding or sheet molding compound, we can further enhance our understanding of relevant process parameters that can be shared in standardized models. This is especially important for using LCA as a predicting tool, e.g. for selecting suitable and sustainable production techniques in the future.

ABSTRACT

This paper presents an active control scheme for the cure of advanced composites based on the combination of simulation with cure monitoring signals. The cure of composites is a time-intensive and energy-consuming process, often carried out under conservative conditions to satisfy process performance metrics and deal with variability. Utilisation of process simulation alongside online signals presents an opportunity to increase process efficiency, while also ensuring process robustness. An accurate cure simulation model is developed here based on detailed constitutive models, taking into consideration cure kinetics as well as the evolution of thermal properties during the cure. The development of a dielectric sensor compatible with carbon fibre reinforcement and a protocol for its calibration achieves direct and accurate measurement of the degree of cure in the curing component. This, accompanied by thermal monitoring signals, informs the simulation to predict the level of temperature overshoot online, taking into account the process history and the current state of the part. Incorporation of this information in an active control loop permits updating the thermal profile to minimise process duration, while ensuring temperature overshoot is kept below a limit. Implementation of the strategy in the curing of thick carbon fibre cable achieves a process time reduction of about 65%, demonstrating the clear cost and energy consumption benefits of the approach developed.

1 INTRODUCTION

The cure of thermosetting matrix fibre composites is a crucial stage of the manufacturing chain that plays a major role in component quality and overall manufacturing cost. In designing the cure process, manufacturers need to address often competing objectives of minimising process time, minimising tooling cost, ensuring temperature uniformity, and minimising exothermic effects, whilst satisfying constraints of adherence to process certification requirements and addressing variability challenges. Current industrial approaches address the overall problem by adopting conservative thermal profiles, usually comprising two or more isothermal segments, resulting in expensive and energy-consuming manufacturing, adversely affecting both part cost and overall sustainability.

The inefficiency of cure processing becomes more pronounced in thick parts. The exothermic character of the cure reaction, combined with the low thermal conductivity of curing composites in the thickness direction, makes temperature overshoots likely, forcing manufacturers to adopt even more conservative thermal profiles, often involving an initial long isothermal segment at low temperature to consume a significant part of the matrix reactivity under mild conditions. This increases the cost of processing significantly, often making the adoption of a composite solution for thick parts uneconomical.

Numerical optimisation methods have been put forward as a potential solution for addressing cure cost minimisation and maximisation of product quality. Optimisation approaches integrate, in their core, a method for mapping process variables (e.g., thermal profile variables, tooling properties, environmental variables) into process outcomes (maximum overshoot, process duration, cure uniformity, thermal gradients) through simulation [1] or data-based representations combined with models [2]. Optimisation schemes, such as gradient-based techniques [3], genetic algorithms [4], and neural networks [5, 6], are used to identify optimal process conditions and setups that can minimise process duration or cost, maximise quality/minimise defects, or achieve both in a multi-objective setting.

Numerical optimisation exploits regions of high sensitivity of the objectives to the design variables, often obtaining solutions that have a level of instability. In practical terms, this means processing carried out under optimal conditions can be potentially affected more by variability in the manufacturing environment and materials. The process of cure is subject to uncertainty due to variability in surface heat transfer coefficients, ambient conditions in the manufacturing environment, and the initial state of the curing matrix material [7, 8]. The utilisation of process monitoring provides a solution for resolving the uncertainty associated with composite manufacturing, with techniques based on optical, electric/dielectric, and ultrasonic sensing [9 -13] offering solutions for both the flow and cure stages of processing. In a recent development, temperature monitoring has been combined with modelling of the cure of carbon fibre composites to achieve online optimisation in an active control scheme, delivering significant simultaneous reduction in cure duration and temperature overshoot, with improvements matching those achieved using numerical optimisation, and without being affected by issues related to uncertainty [14].

The present work extends active control of cure with the utilisation of dielectric cure sensors. The method involves models for translating dielectric signals to an online estimation of degree of cure. This, alongside thermal signals and simulation of cure and its associated constitutive models, is used to predict an optimal temperature setting dynamically as the process evolves. The control scheme developed is applied to the cure of a thick carbon fibre cable to validate the development.

2 METHODS

2.1 Material characterisation

The material used is unidirectional (UD) carbon fibres prepreg with 12K tows and areal density of 385 g/m^2 with an epoxy resin mixed with hardener and accelerator (System A). The cured ply thickness of the prepreg is 0.358 mm.

Cure kinetics was characterised using differential scanning calorimetry (DSC) experiments in a DSC 250 Discovery (TA Instruments). Isothermal cure tests were carried at 120 and 110°C, following a 10°C/min ramp form ambient to the test temperature and then holding until completion of the reaction. Dynamic cure tests were performed at 2 and 10°C/min from ambient temperature to reaction completion. Isothermal heat flow signals were integrated using a horizontal baseline to calculate the degree of cure and its evolution. Integration of dynamic signals was carried out using a sigmoidal baseline. The fitting of the cure kinetics model to the experimental data to determine the values of cure kinetics parameters was performed using Solver of Microsoft Excel [15]. The evolution of the glass transition temperature as a function of the degree of was investigated using 10 samples partially cured from fully unreacted to complete reaction at 2 °C/min. The glass transition temperature of these samples was measured using the inflection point of the heat flow step at the transition in dynamic DSC tests at 10°C /min.

The evolution of specific heat capacity during the cure was measured using the DSC 250 Discovery (TA Instruments) in modulation mode. Two isothermal tests were carried out at 130 and 110°C and one dynamic at 1°C/min. In all experiments, a modulation amplitude of 1°C and modulation period of 60 s were used. Thermal conductivity in the thickness and fibre directions was measured using a Laser Flash Analyser (TA Instruments LFA Discovery 1200). Cured samples of the prepreg comprising 4 plies and 50 plies were utilised for the through thickness and fibre direction measurements. The specimen size was 10 mm × 10 mm in both cases. Prior to the measurement the specimens were sprayed with graphite to enhance optical absorption. A laser power of 1200 W was used, and measurements comprising 3 laser shots were performed in the temperature range of 20-160 °C at 40 °C intervals. The parameters of the

corresponding constitutive models for specific heat capacity and thermal conductivity through fitting to the experimental data using Solver of Microsoft Excel [15].

2.2 Manufacturing trials and process monitoring setup

A round cable with length of 2.8m consisting of wound UD prepreg plies, equivalent to 115 layers from centre to the surface consolidated by release film resulting in a diameter of 41 mm for the whole assembly was cured in an industrial oven. Two K-type thermocouples and two dielectric sensors were placed on the outer surface and in the centre of the cable. The setup of the experiment is illustrated in Figure 1.

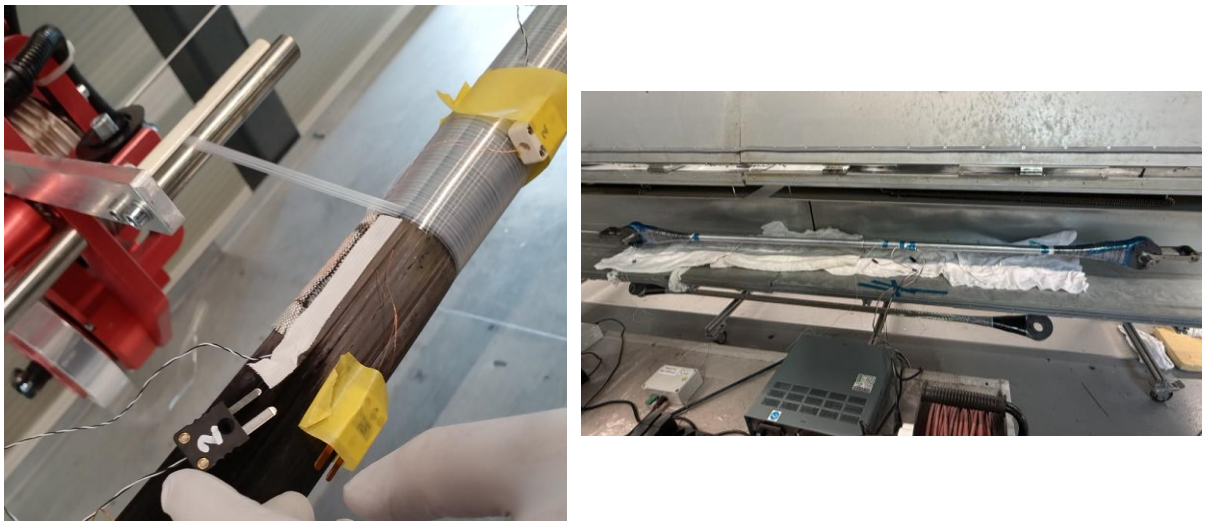

Figure 1: Trial setup: (left) wound cable with sensors and connectors; (right) curing setup.

The dielectric sensor used in the experiments is based on twisted insulated copper wires [13], which was weaved into a glass fibre cloth (Figure 2). Data acquisition for both dielectric sensors and thermocouples was carried out using a DETA-SCOPE from ADVISE-DETA [16]. Dielectric measurements were acquired in the frequency range of 1 Hz to 20 kHz. The capacitance (C) at 10 Hz was utilised to determine the degree of cure. Calibration experiments were carried out off-line using a thermal profile comprising isothermal segments at 110 and 150°C and 1°C/min ramps. Temperature signals were acquired and the cure kinetics model for the material of the study was used to calculate degree of cure (α) values to determine the coefficients b, c, and d of the calibration function:

$$\alpha = b + c\ logC + \frac{d}{T} \tag{1}$$

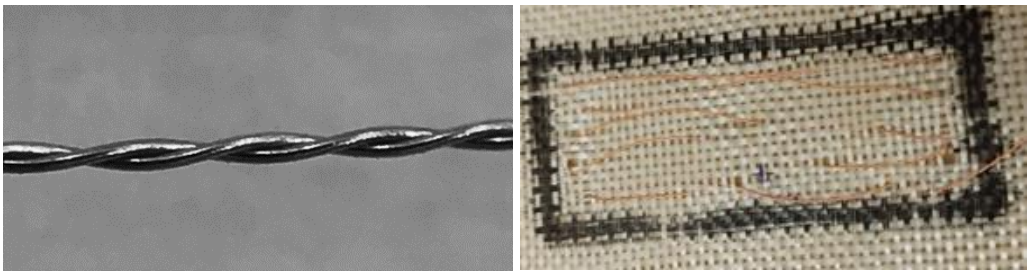

Figure 2: Sensor setup: (left) detail of sensing wire; (right) integration in woven cloth.

2.3 Cure simulation

Cure simulation was carried out using the Finite Element (FE) solver FLEXPD 7 [17]. The solver allows the definition of non-linear constitute models coupled with differential equations. The problem

solved corresponds to the representation of the cure of a circular cross-section cable in cylindrical coordinates expressed as:

$$\frac{1}{r}\frac{\partial}{\partial r}\left(K\frac{\partial T}{\partial r}\right) = \rho c_p \frac{\partial T}{\partial t} - (1-v_f)\rho_r H_{tot}\frac{d\alpha}{dt}, \qquad r \in [0, R_{cable}] \tag{2}$$

where ρ is the density of the composite, c_p is its specific heat capacity, T the temperature, α the degree of cure, K the thermal conductivity in the radial direction, v_f the fibre volume fraction, ρ_r the resin density, H_{tot} the total heat of the curing reaction, and R_{cable} the radius of the cable. The reaction rate is expressed as:

$$\frac{d\alpha}{dt} = \frac{A_1 e^{-E_1/RT}(1-\alpha)^{n_1} + A_2 e^{-E_2/RT}\alpha^m(1-\alpha)^{n_2}}{1 + e^{C_0[a-a_c-a_T T]}} \tag{3}$$

Here where m, n_1 and n_2 are reaction orders, $A_1$and A_2 are pre-exponential factors, E_1 and E_2 are activation energies and R is the universal gas constant. The denominator of Eq. 2 incorporates diffusion limitations in the cure kinetics model through a critical value of the degree of cure expressed as a function of temperature, where a_T, a_c are phenomenological parameters controlling the value of critical degree of cure as a function of temperature, and C_0 is a parameter controlling the breadth of the transition to diffusion-control. The specific heat capacity is a function of the degree of cure and temperature, implemented through the dependence of the instantaneous glass transition temperature on the degree of cure, expressed by:

$$c_p = A + \alpha G + \frac{B}{1 + e^{C_1(T_g - T + F)}} + T\left(D + \frac{H}{1 + e^{C_1(T_g - T + F)}}\right) \tag{4}$$

$$T_g = T_{go} + \frac{\lambda\alpha(T_{g\infty} - T_{go})}{1 - (1-\lambda)\alpha} \tag{5}$$

where A, B, D, F, G and H are fitting coefficients, C_1 is a parameter controlling the breadth of the glass transition, T_{go} and $T_{g\infty}$ are the glass transition temperatures of the uncured and fully cured material respectively and λ is a parameter controlling the convexity of the dependence of glass transition temperature on degree of cure. The thermal conductivity of the composite material is considered to be a linear function of temperature, with the corresponding constitutive model accounting for different conductivities in the fibre and transverse or thickness direction. In the case of the one-dimensional model of the cable, only the transverse conductivity is utilised in the solution.

Assuming uniform heating across around the cable, the heat transfer problem becomes one-dimensional in the radial direction. Symmetry implies a perfect insulation boundary condition at the cable centre. The nominal thermal profile was applied as a prescribed temperature boundary condition on the outer surface. Initial conditions are imposed at every model run following the monitored values of temperature and degree of cure at the model start, with an assumed distribution across the radial direction.

2.4 Active control scheme

The active control strategy reported in [14] was extended to incorporate cure monitoring data. A representation of the active control scheme is shown in Figure 3. The active control tool aims to determine in real time instantaneous temperatures that do not produce a high temperature overshoot while minimising the duration of the cure of the process. This is achieved by executing the simulation at every increment using existing monitoring data to define updated initial conditions.

The control system suggests a cure temperature higher than the current setpoint value, whilst considering the measured temperature and degree of cure on the cable surface and core as initial conditions in the cure simulation. The control system accepts the suggested temperature if - based on the results of the simulation - it does not produce an overshoot exceeding a predefined limit (set at 10°C here) before cure completion (Figure 4-left). If the new temperature is rejected, due to an unacceptably high overshoot (Figure 4-right), the suggested temperature is maintained at the current level and the

simulation is rerun to determine if the current temperature is acceptable. If the condition of overshoot below the limit is adhered to the temperature is maintained otherwise the temperature is lowered.

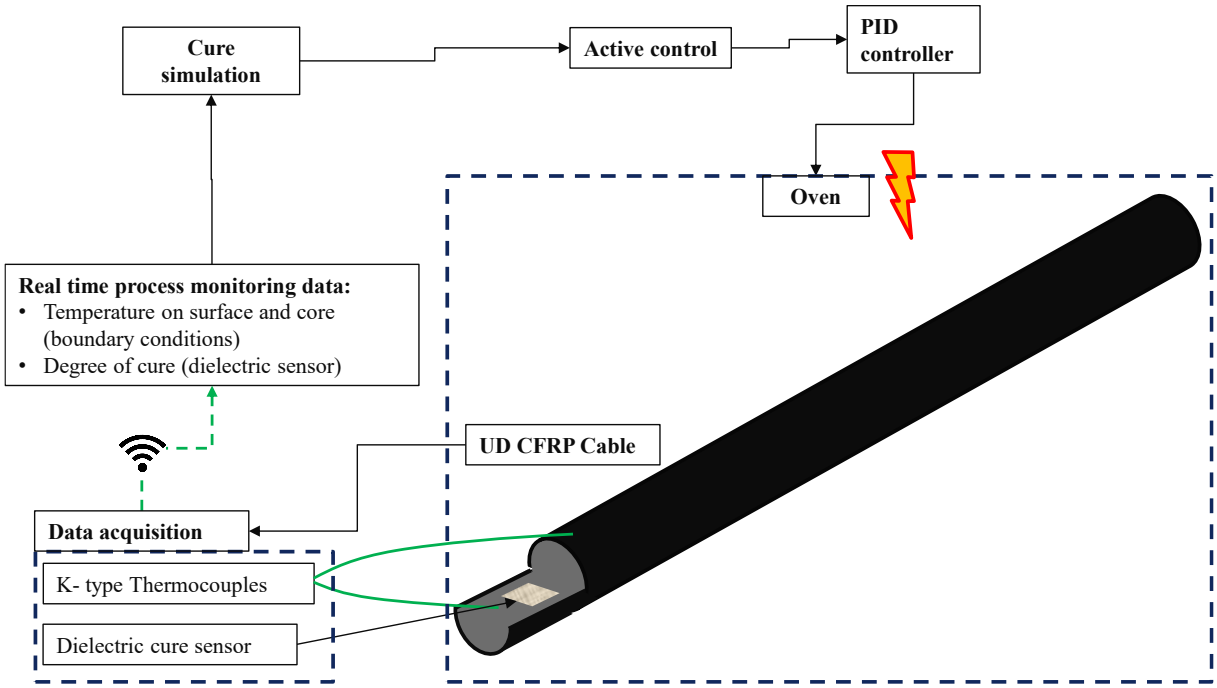

Figure 3: Integrated monitoring – modelling – control setup.

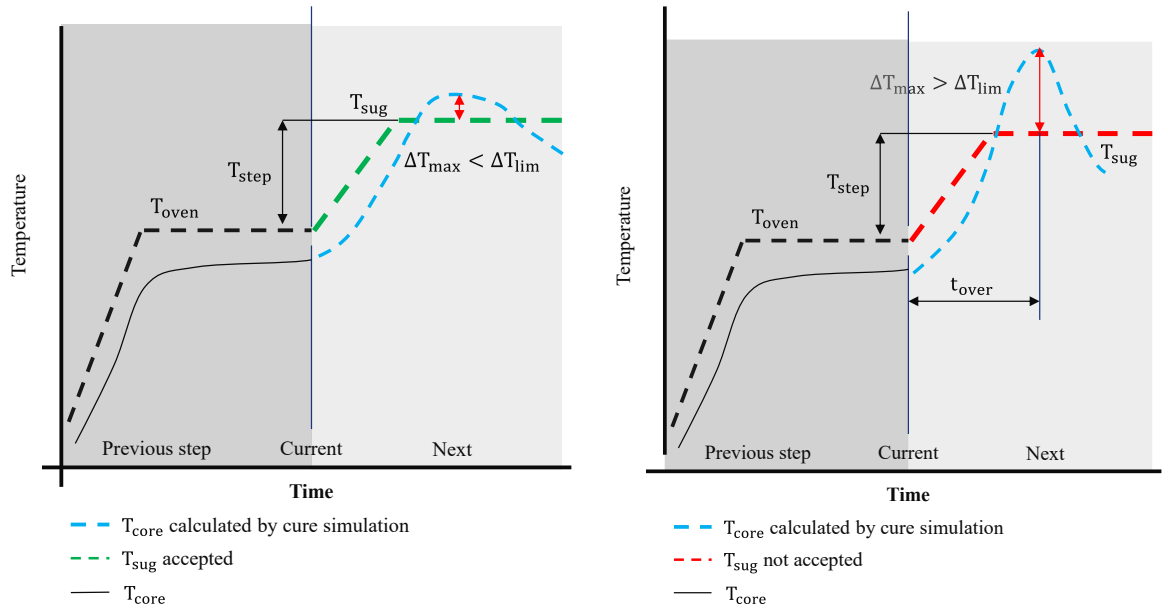

Figure 4: Examples of active control scenarios: (left) accepted increment in temperature as overshoot limit is not exceeded; (right) rejected increment due to overshoot greater than the limit occurring prior to cure completion.

3 RESULTS AND DISCUSSION

3.1 Constitutive models

Figure 5 illustrates the performed fitting of the cure kinetics model of Eq. 3. The model follows both dynamic and isothermal data closely with an average absolute error of 1.5E-5 for isothermal tests and 2.0E-4 for dynamic tests. The model reproduces successfully the autocatalytic character of the reaction at low degrees of cure and the dominance of nth reaction kinetics at high degrees of cure. The Di Benedetto equation fitting (Eq.5) matches experimental data closely with an average absolute error of 2.5°C. The fitting of Eq.4 to specific heat capacity data is presented in Figure 6-left. The model reproduces experimental data successfully including the transition region. The average error in specific heat capacity values is 0.006 J/g/°C. The linear fitting of thermal conductivity data is illustrated in Figure 6-right. As expected, the conductivity in the fibre direction is significantly greater than in the thickness/transverse direction. Overall, the constitutive models map well the evolution of properties and of reaction rate as a function of temperature and degree of cure, which provides the basis for an accurate heat transfer model of the cure.

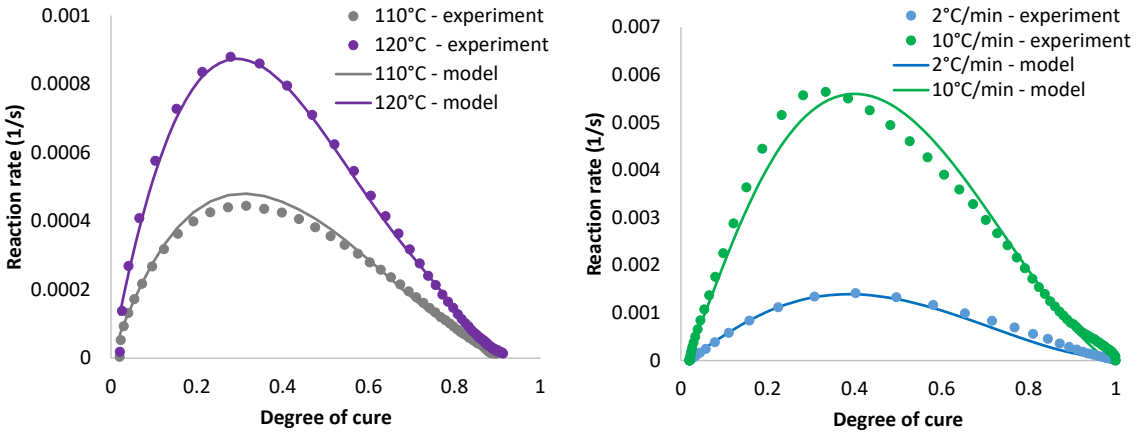

Figure 5: Cure kinetics model: (left) isothermal cure; (right) dynamic cure.

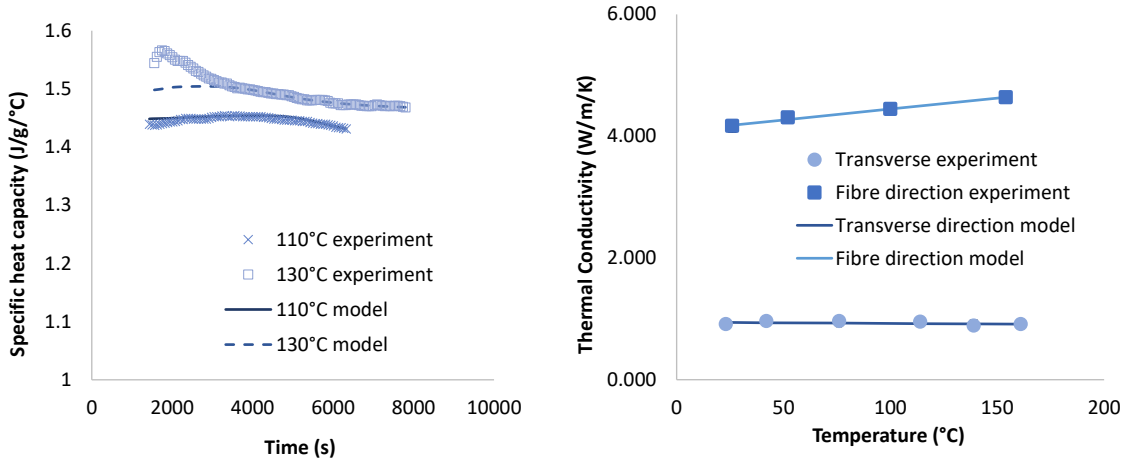

Figure 6: Constitutive models: (left) specific heat capacity; (right) thermal conductivity.

3.2 On line monitoring of the degree of cure

Figure 7 illustrates the accuracy of the use of Eq.1 for the determination of the degree of cure based on data of capacitance obtained by the dielectric sensing setup. The degree of cure based on the kinetics model reaches about 70% at the end of the first isothermal segment, progresses to about 90% at the end of the ramp, and reaches its maximum value of about 98% after 40 min at the high temperature isothermal segment. The fitting is accurate with some small deviations in the early stages of cure. The sensing data and calibration equation provide a very good direct estimate of the degree of cure even under non-isothermal conditions or when the conditions are nominally isothermal but there is significant deviation in temperature with time. The robustness of the degree of cure estimation is key for enabling its use in an active control loop.

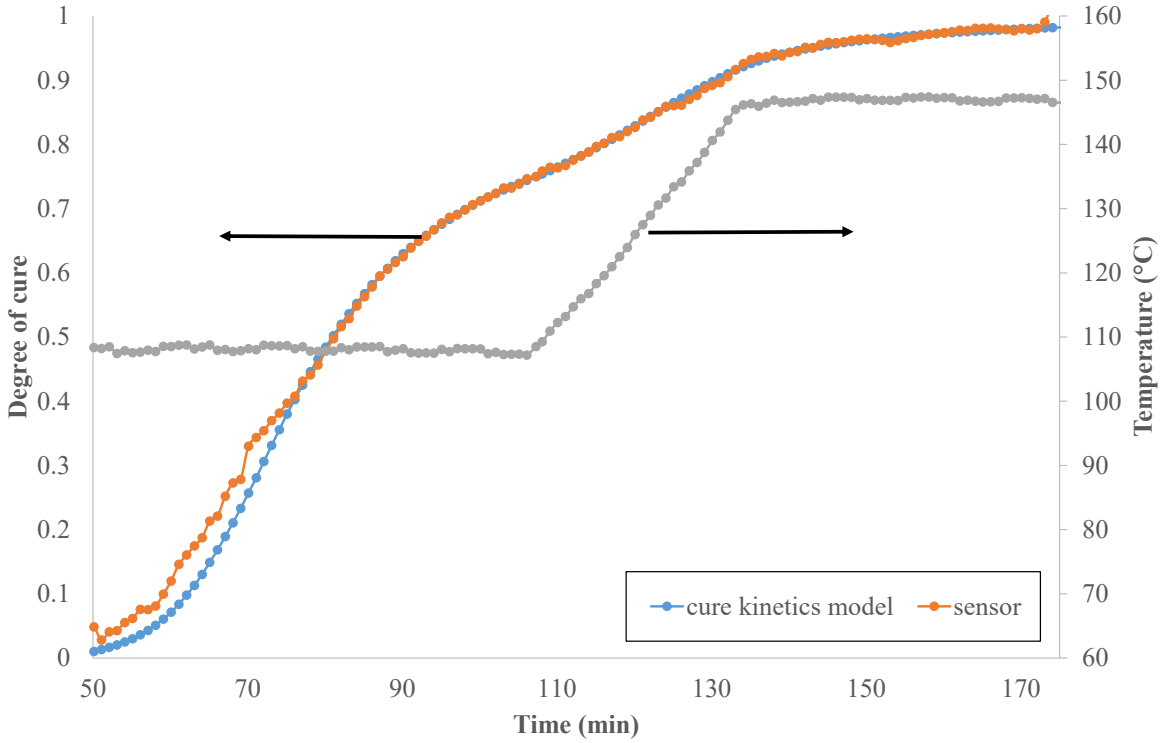

Figure 7: Validation of cure sensing functionality.

3.3 Active control trial

The results of the active control trial are illustrated in Figure 8. The degree of cure from the sensors is provided to the active control every 60 s. The initial temperature is 70°C, and the process is held at this temperature until the temperature sensors in the part approach 60°C. At this point, the active control algorithm starts increase the temperature gradually as predicted overshoots are well below the limit. This results in effective heating rate of about 1°C/min, translated to a lower but broadly uniform heating rate in the curing part. The prediction of overshoot becomes greater than the limit of 10°C when the part reaches about 90°C and the oven temperature is about 105°C. The oven temperature is stabilised at that level for about 60 min. After that time, the temperature in the part exceeds 100°C and the degree of cure reaches about 30%. At this point it is possible to increase the temperature without inducing an unacceptable overshoot, as a significant part of the reactivity of the resin has been consumed. The active control algorithm increases the temperature gradually at an average rate that approximates 1°C/min, up to about 150°C. The composite part follows at a similar rate as a result of the exothermicity of the reaction which progresses by about 50%. This is indicative of the capability of the active control system to use the heat of the curing reaction to benefit the efficiency of the process. A further 40 min at 150°C is required to complete the cure, after which colling down starts.

During the whole process, the temperature in the part is relatively uniform, with gradients kept below 10°C. The maximum overshoot observed is only 3.5°C occurring right after reaching the second isothermal segment of the profile. This shows the efficiency of the control, as the ramp stops just before an overshoot is manifested, ensuring the positive feedback of reaction exothermicity does not dominate the evolution of the thermal profile. The role of accurate sensing in this is paramount, as the strong non-linearity of exothermic effects would have easily created a risk if similar decisions for the oven temperature profile have been taken without accurate information of the state and temperature of the curing part. The degree of cure evolution is relatively uniform across the radius of the cable, with the different parts reaching the same level of cure within 10 min. The total cure time using the active control system is 2.6 h. This, compared to the 7 h duration of the nominal cure profile for the material used, represents an improvement of about 65%. This significant reduction is reflected in a corresponding improvement in both process costs and emissions. These are achieved whilst ensuring that part quality is equivalent to that obtained with the use of a conventional, slow cure profile.

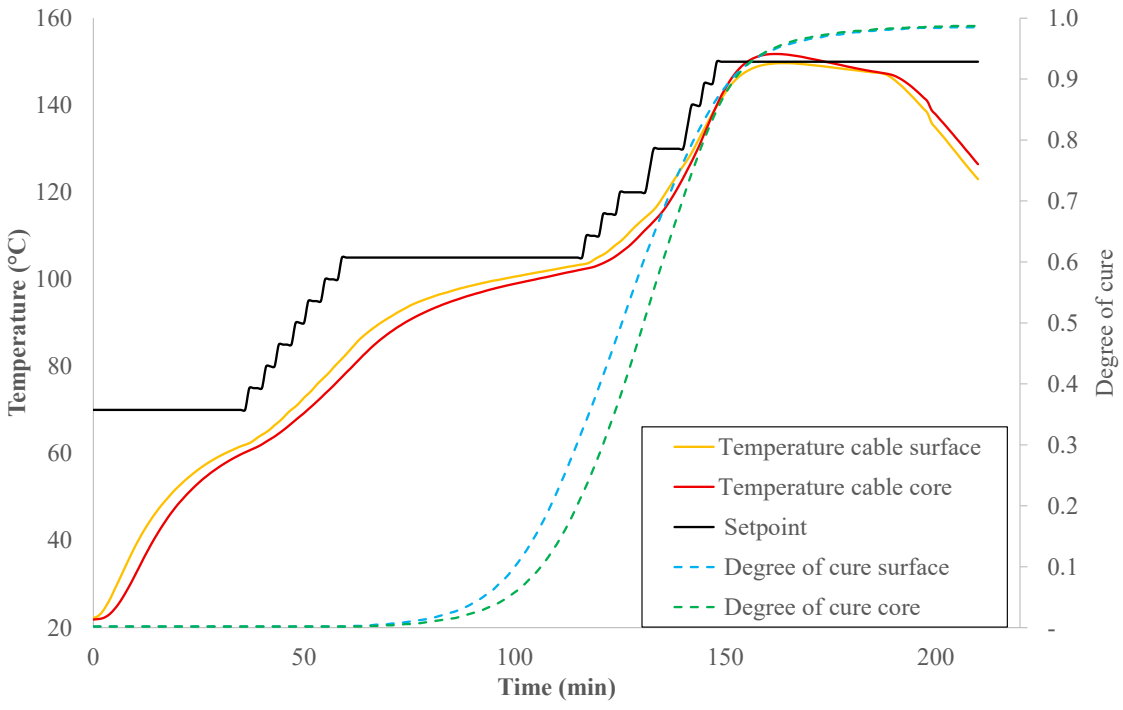

Figure 8: Demonstration of active control operation in curing of UD carbon fibre cable.

4 CONCLUSIONS

An active control strategy based on use of cure monitoring signals alongside simulation has been developed and implemented in this work. The demonstration of the system in the cure of a thick carbon fibre cable shows that the ability to inform the control algorithm with accurate thermal and cure signals allows the process to exploit the exothermicity of the curing reaction is a controlled manner. Achieving reduction in cure time by about 65%, whilst maintaining temperature uniformity and ensuring associated quality metrics are met, presents a major opportunity for decreasing costs and energy usage. This enhances the overall sustainability of composites.

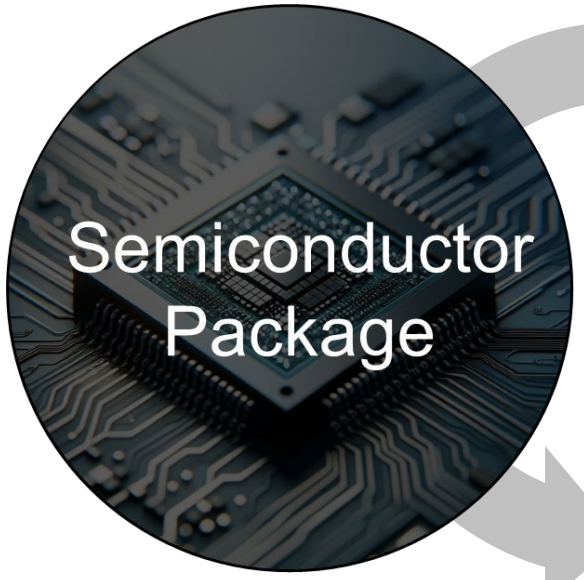
Flow analysis of the capillary-driven underfill process for the use of thermally conductive epoxy composites in semiconductor packaging

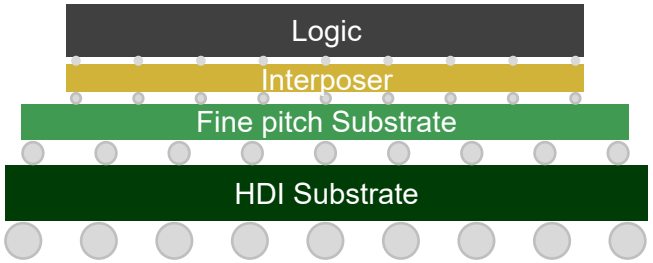


Jeeeun Lee
Gyumin Sim & Seong Su Kim

Mechanical Design Lab. with Advanced Materials
Department of Mechanical Engineering, Korea Advanced Institute of Science and Technology (KAIST), Republic of Korea

Semiconductor packaging

❖ What is a semiconductor package?

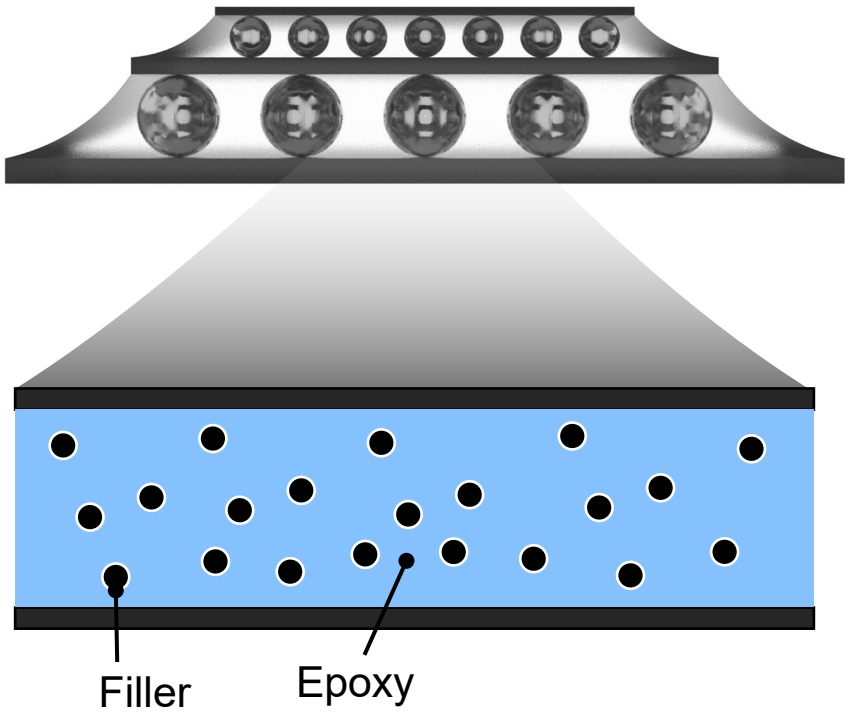


The semiconductor package is a protective casing that connects the chip to the board/other chips and can help with heat dissipation

• Conventional Package

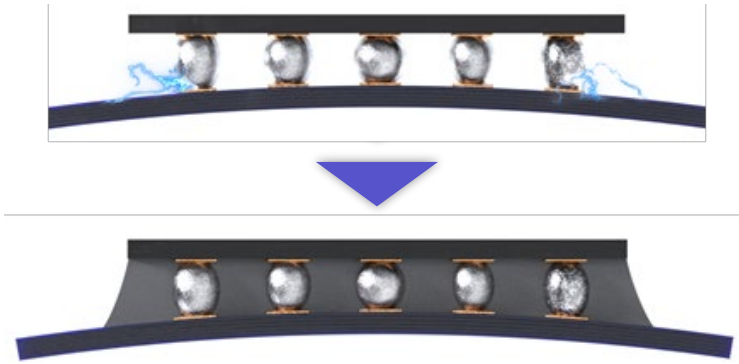
• Advanced Package

Thinner, stacked chips



Semiconductor packaging

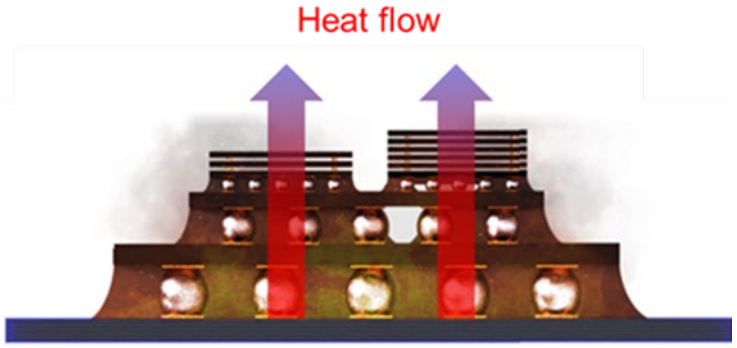
❖ Underfill Material



➢ Composite material of epoxy and filler material that goes between the chip and substrate, improving the reliability of electrical devices.

Underfill

Key effect of Underfill [1]

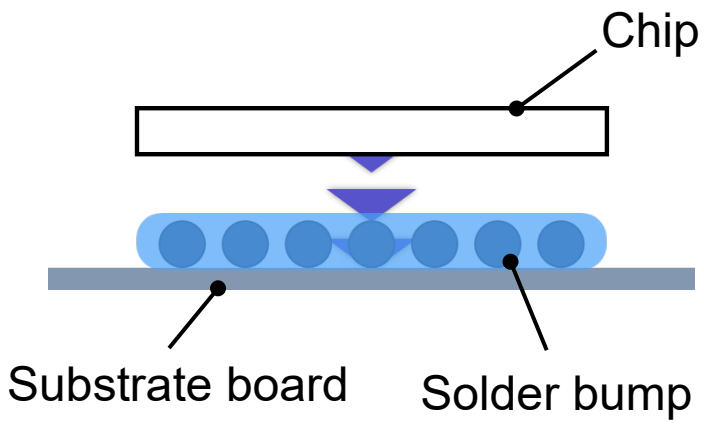


• Mechanical Protection

➢ Solder bump protection

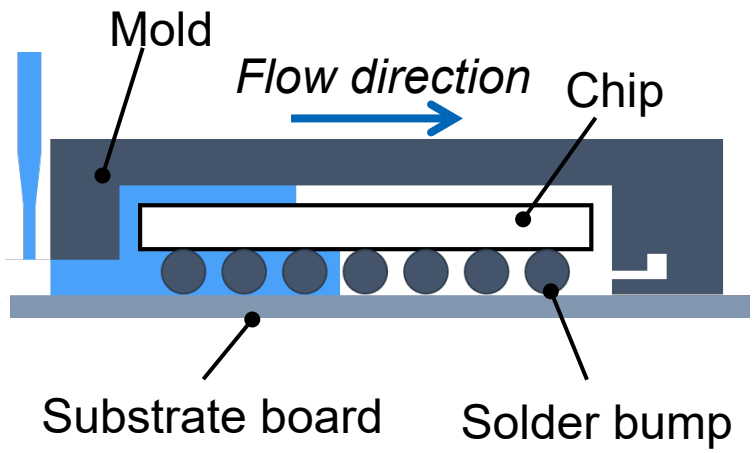
➢ Stress concentration mitigation

• Heat Dissipation



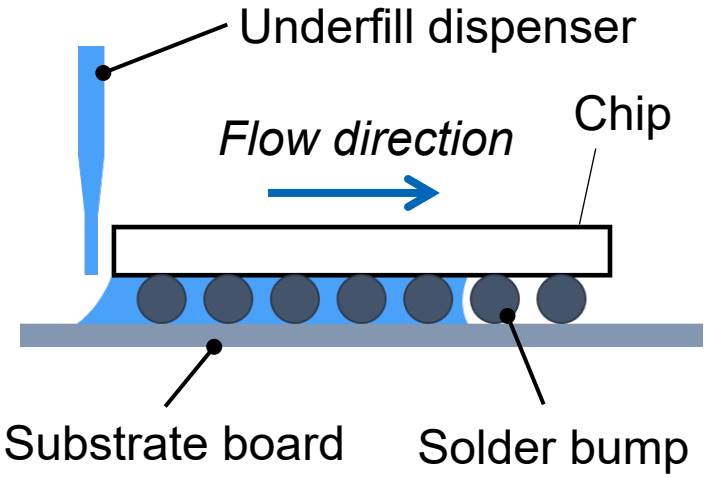
➢ Effective dissipation of heat generated by chip

Semiconductor packaging



❖ Types of Underfill Process[2,3]

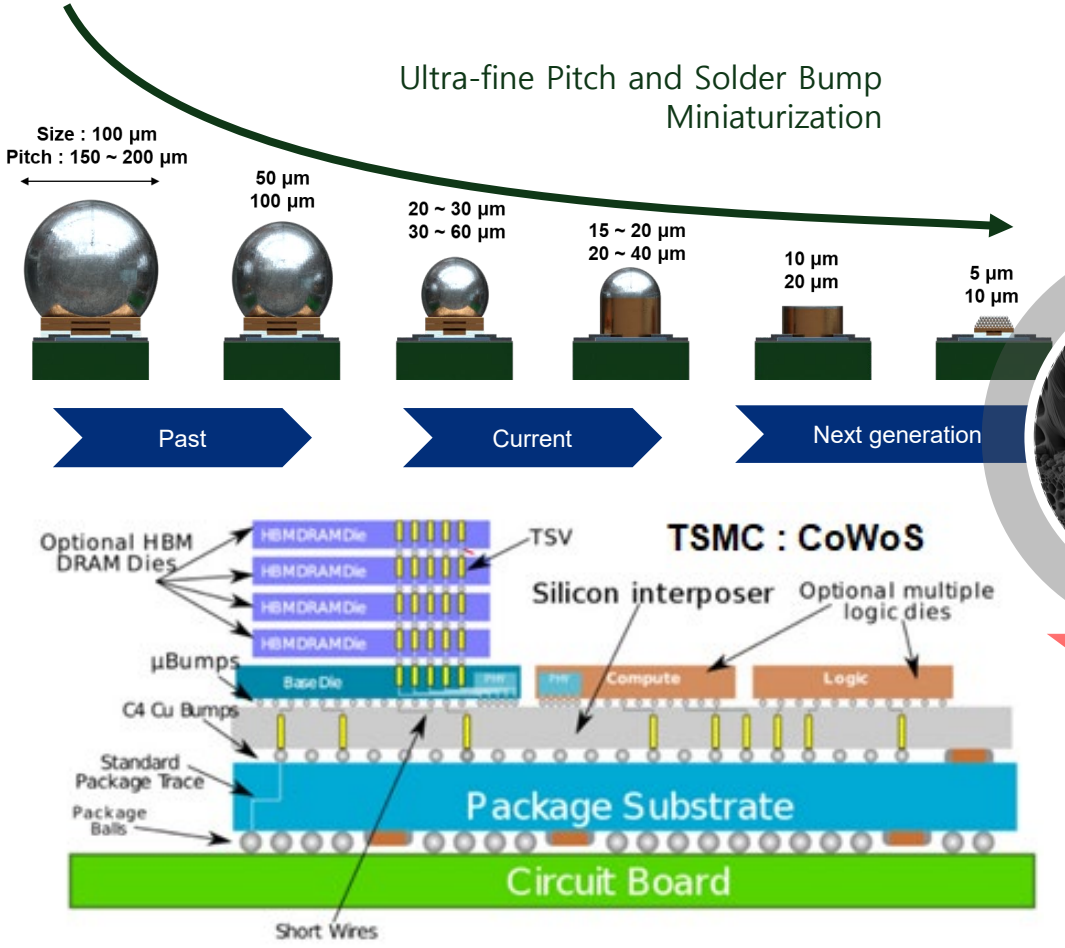
No Flow Underfill



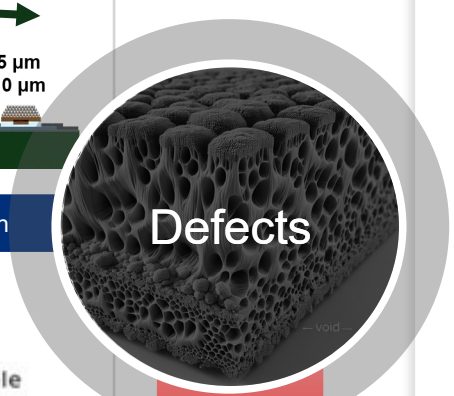
- Fast and simplified process
- High likelihood of void formation

Molded Underfill

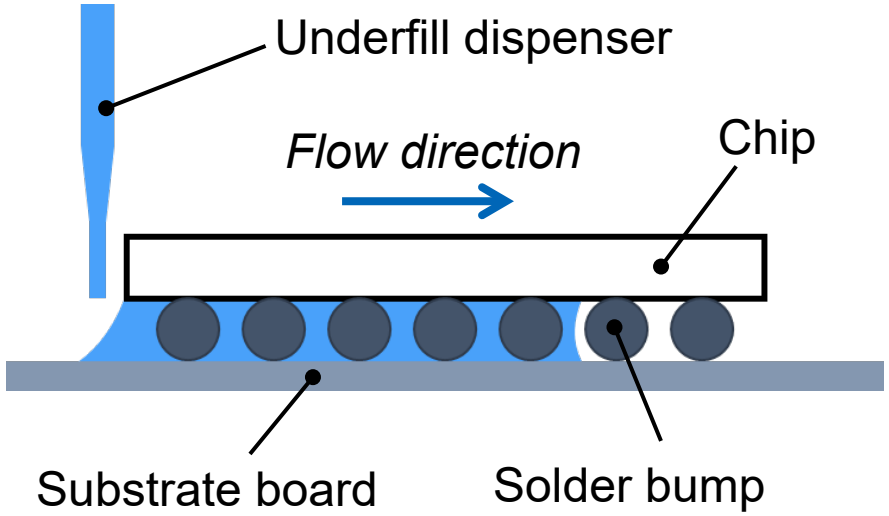
- Fast process time
- High cost
- High likelihood of void formation



Capillary Underfill

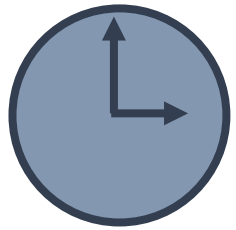


- Simplest process
- Cost-effectiveness
- Slow process time

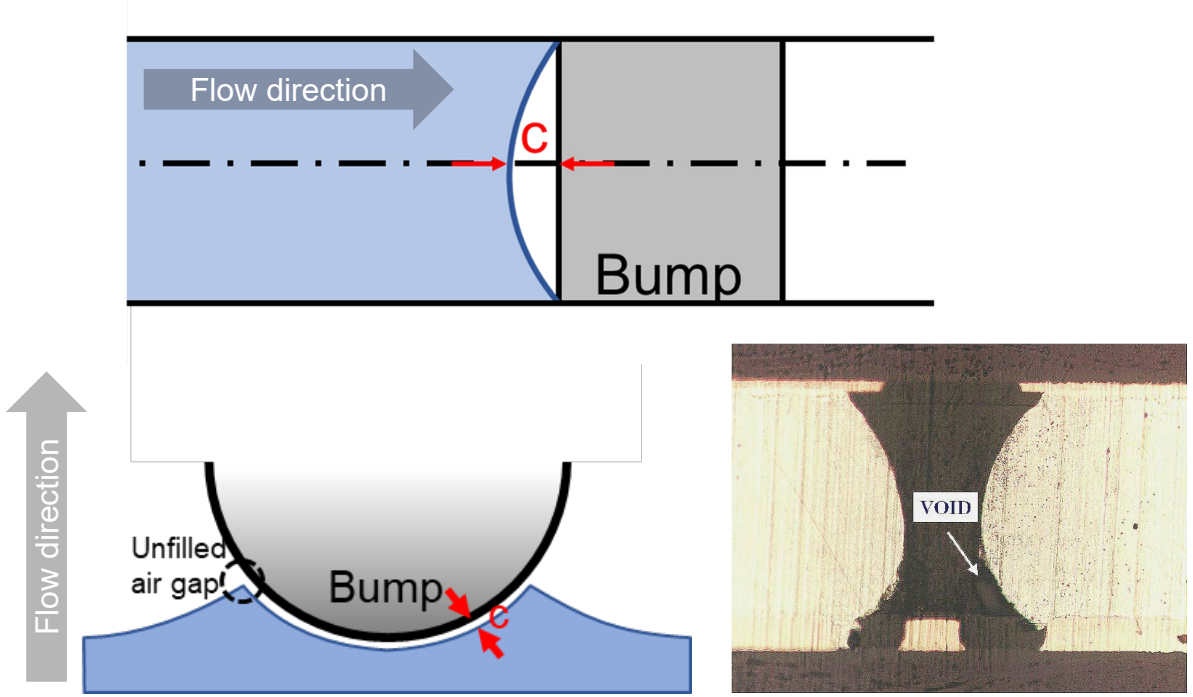


Semiconductor packaging

Advanced technology in semiconductor packaging

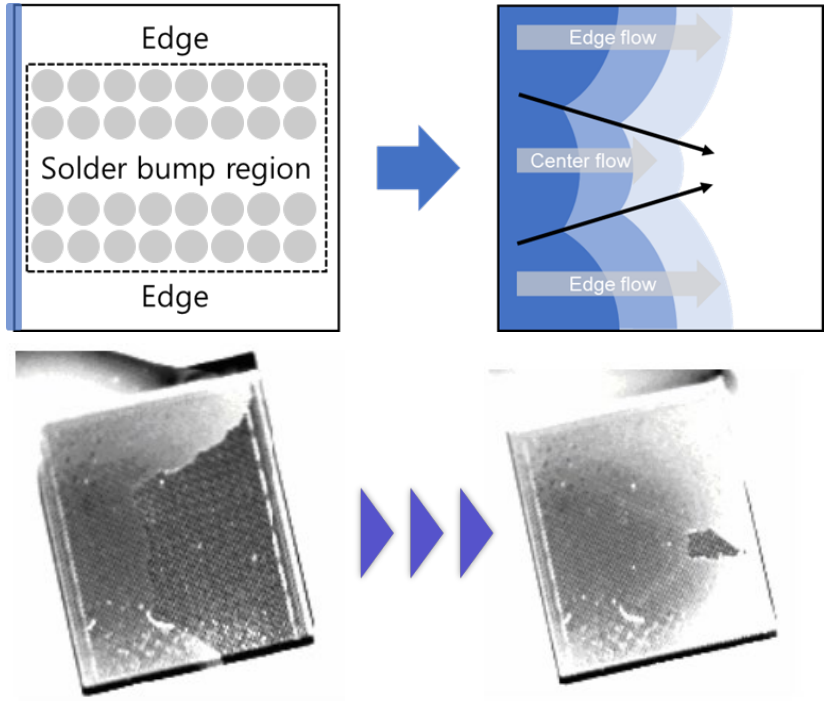


Requirements of the capillary underfill process



No void

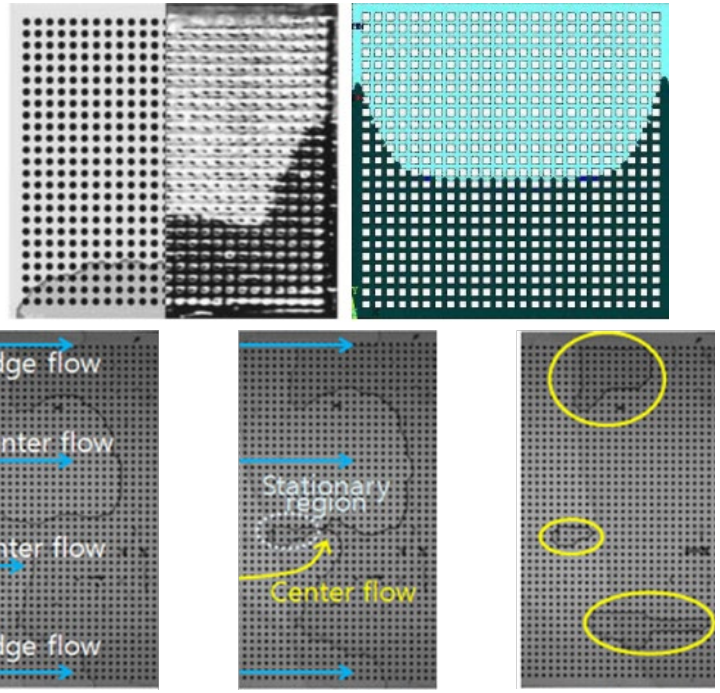
Reducing filling time



Void Formation

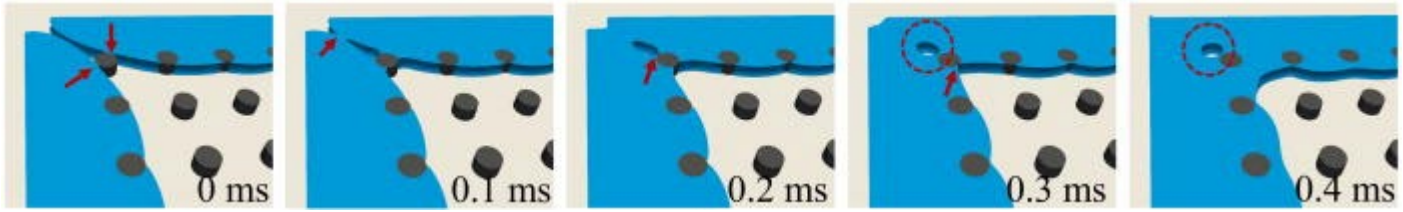
Micro-voids[4,5]

- Micro-voids formed by interaction between bumps and flow front



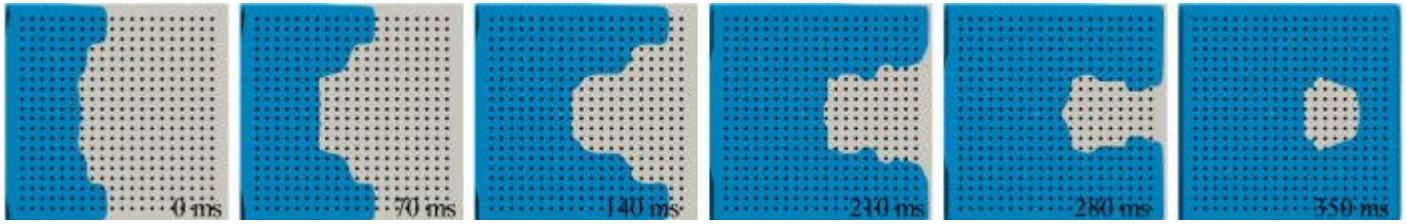
Macro-voids[6,7]

- Macro-voids formed by faster flow in the edge regions and subsequent flow front merging



Void formation

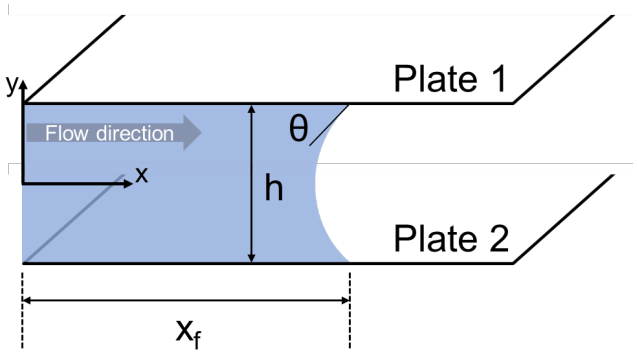
Race-tracking[7]



- Air entrapment due to flow difference between the edge and the center

Different dispensing types and contact angles[8]

Void formation by flow front merging



Void formation by variation in contact angles

- Void formation for different dispensing types
- Different wetting behavior (contact angles) due to flux residues

Analytic expressions of the filling time

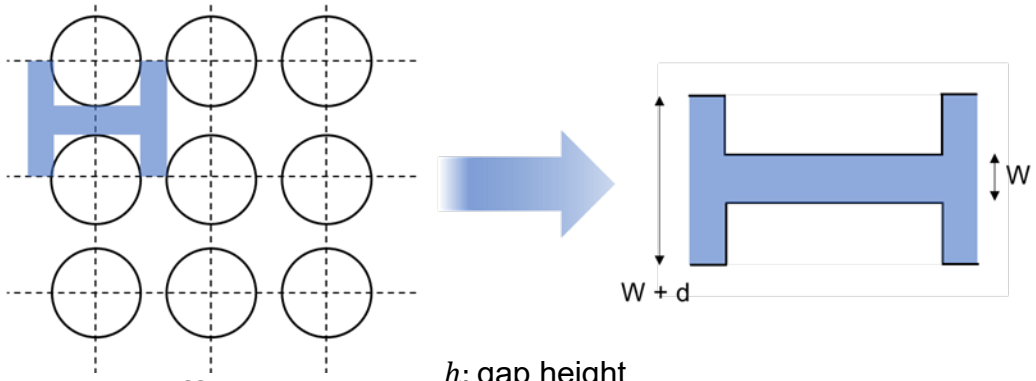
Capillary driven flow between two plates[9]

Assumptions

1. Incompressible
2. 2D fully-developed laminar
3. Gravity neglected

Plane Poiseuille flow

$$\frac{\partial p}{\partial x} = \mu \frac{\partial^2 u}{\partial y^2}$$



Young-Laplace equation for surface tension:

$$\Delta p_\sigma = \frac{2\sigma cos\theta}{h}$$

$$t_f = \frac{6\mu x_f^2}{\Delta p_\sigma h^2} = \frac{3\mu x_f^2}{h\sigma cos\theta}$$

t_f: filling time, x_f: flow distance

Capillary driven flow with solder bump[10]

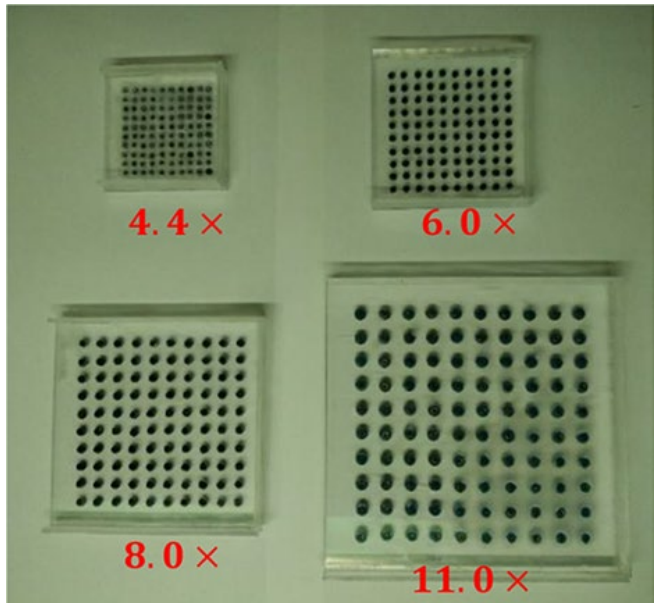
h: gap height

Pressure difference

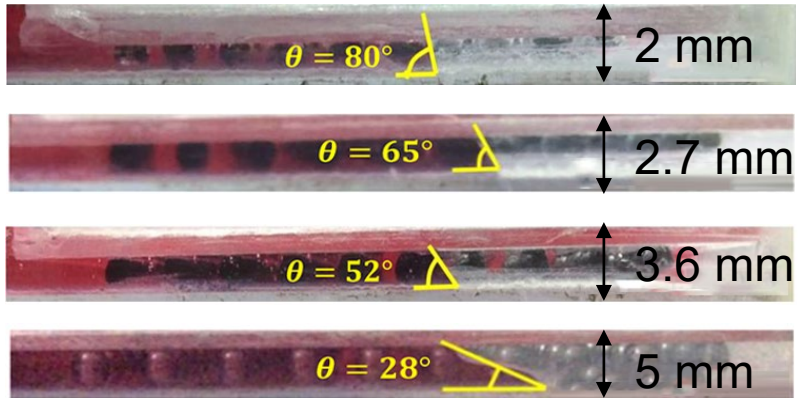
$$\Delta p = \Delta p_\sigma - \Delta p_j$$

Δp_σ: pressure due to surface tension;

$$\Delta p_\sigma = \frac{2\sigma cos\theta}{h}$$



Δp_j : pressure loss due to solder bump;

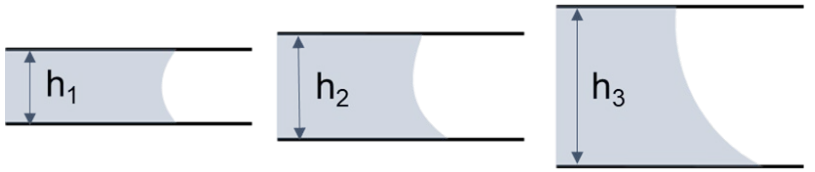


$$\Delta p_j = 2\sigma cos\theta \left[\left(\frac{1}{h} + \frac{1}{W}\right) - \left(\frac{1}{h} + \frac{1}{W+d}\right)\right]$$

$$t_f = \frac{3\mu W(W+d)}{h\sigma cos\theta(W^2 + dW - dh)} x_f^2$$

Experiments for flow front visualization

Scale-up experiments [11,12]



- ✓ Scale-up experiments to visualize flow front progression and calculate infiltration time
- ✓ The effects of gravity are ignored and flow similarity is not ensured

Effect of gravity[13,14]

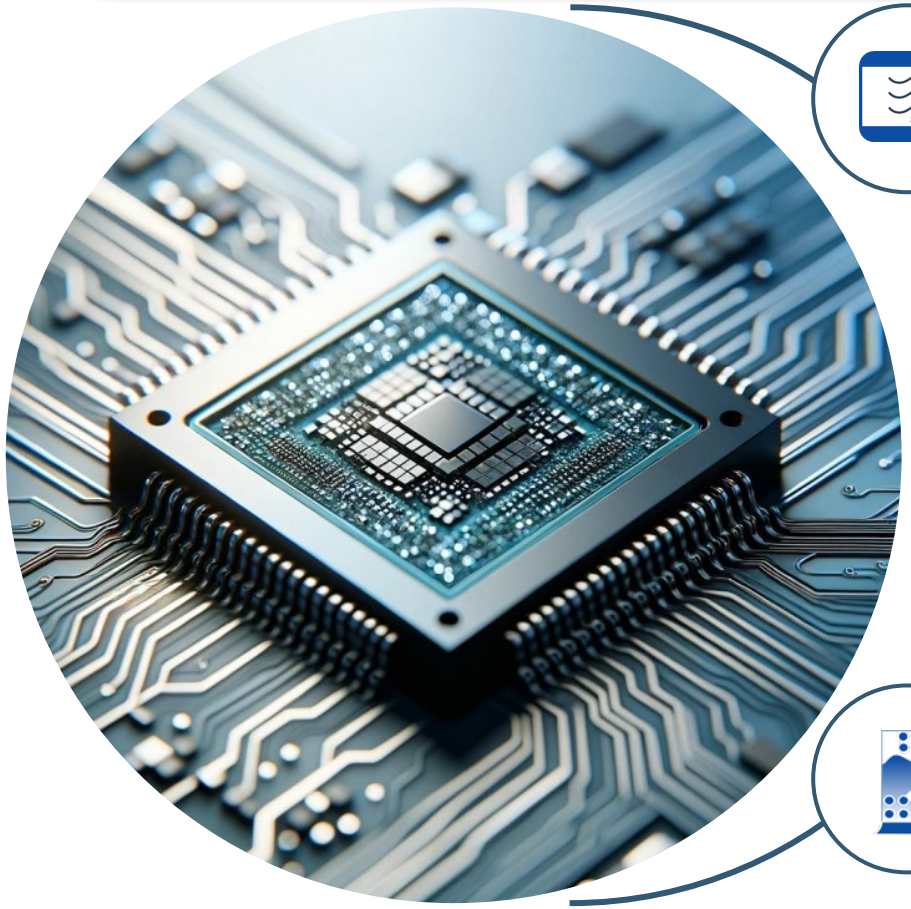
$$h_1 < h_2 < h_3$$

$$Bo = \frac{Gravity\ force}{Capillary\ force}$$

- ✓ The interface changes due to the effects of gravity
- ✓ The shape of the meniscus varies depending on the gap height
- ✓ **Bond number** is a key dimensionless number

Research motivation

❖ Overview



1. In the capillary underfill process, macro-voids develop due to the merging of **flow fronts advancing at different velocities**

2. Non-uniform flow between the edge and center are recognized as factors contributing to void formation, however, the **void formation mechanism has not been extensively studied**

3. Scaled-up experiments for visualizing flow and predicting infiltration time have been conducted, however, **gravity effects and flow similarity were not considered**

Research Objectives

- Investigate the void formation mechanism both numerically and experimentally
- Optimize the capillary underfill process to minimize the filling time and void formation

Flow simulation

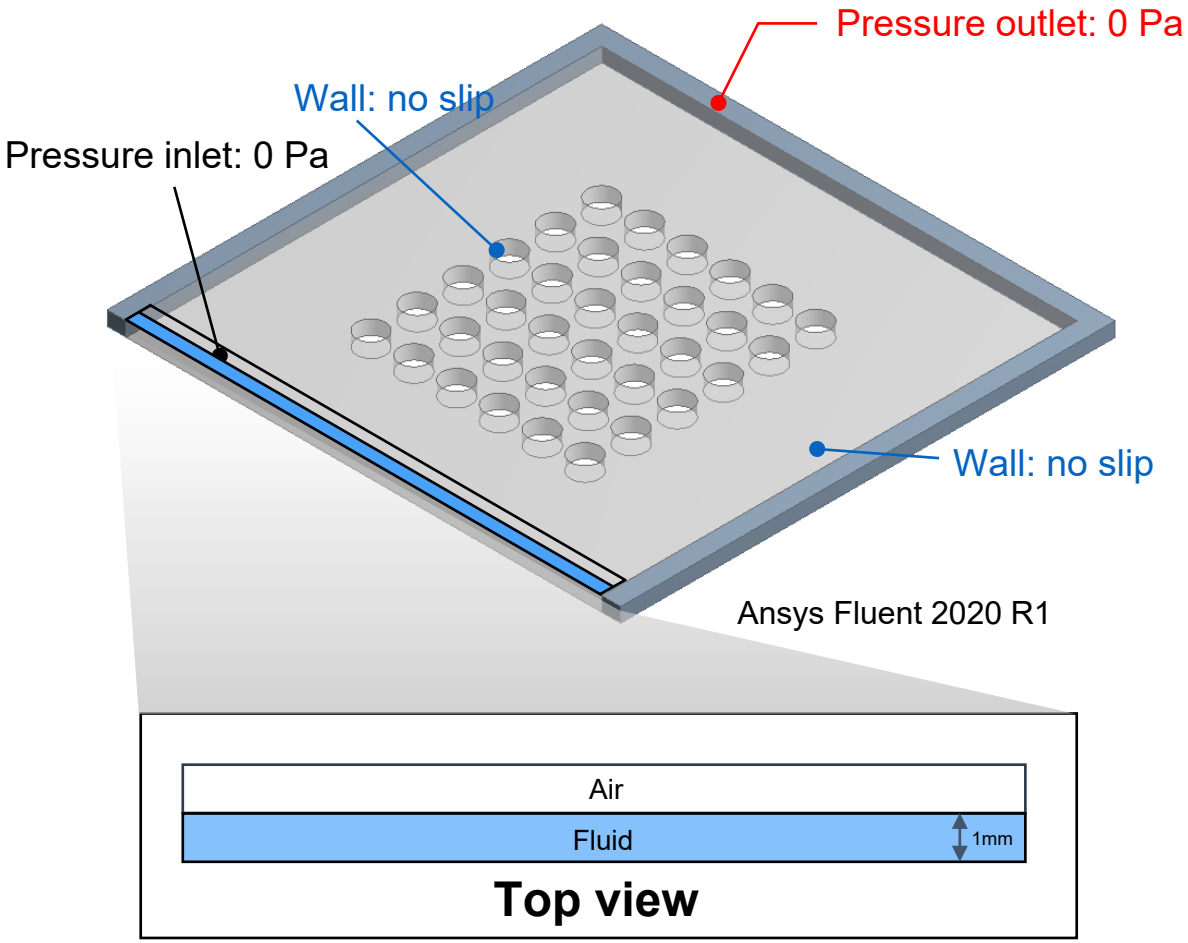
- Experimental validation
- Parametric study

Experiment

- Experimental design
- Flow front measurement

Flow analysis

- Velocity difference of edge and bumps
- Void formation mechanism



MODELLING & EXPERIMENTAL SETUP

- **Numerical simulation model**
- **Experiment design**

Void formation mechanism

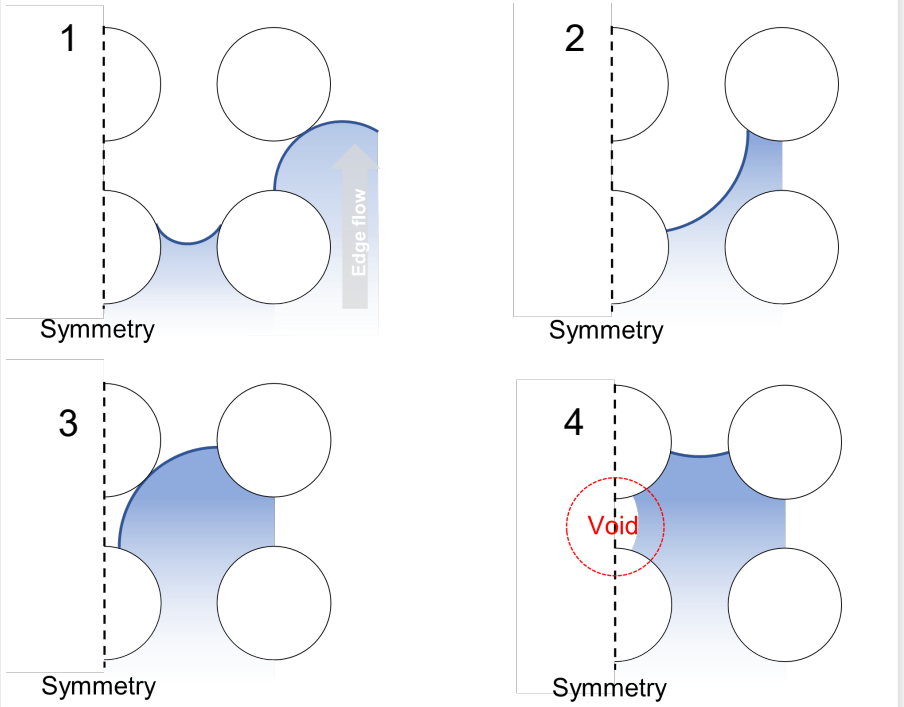
Bump pitch effect

- ✓ As the bump pitch decreases, the pressure drop across the bumps and the viscous drag increase ⇒ decreased flow velocity in bump region
- ✓ Difference between the flow in the edge and bump regions increases the amount of transverse flow.

Gap height effect

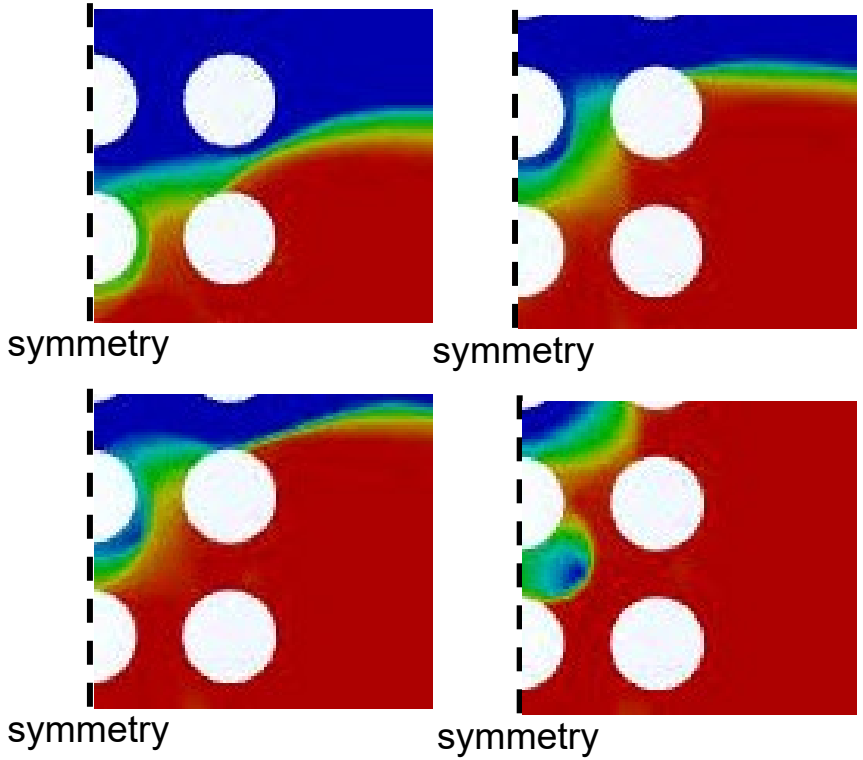
Flow direction

$$P_L = 2\sigma cos\theta \frac{1}{h}$$

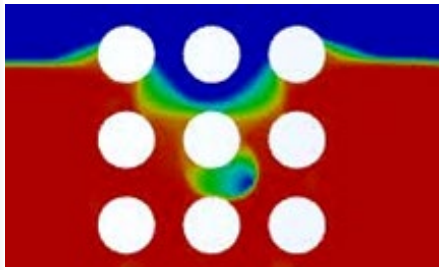


Transverse flow direction

$$P_T = 2\sigma cos\theta \left(\frac{1}{h} + \frac{1}{w}\right)$$



- ✓ As the gap height becomes larger, the effect of the transverse capillary force increases.



Void formation mechanism

CONCLUSIONS

Conclusions

- Scaled-up test bench was constructed for improved visualization of the flip chip capillary underfill process while maintaining flow similarity
- The primary cause for void formation is air entrapment due to the velocity difference between the edge and bump regions
- Flow in the solder bump region depends on both the viscous drag and pressure drop as the flow front passes through the solder bumps
- A parametric study showed that increasing gap height and decreasing bump pitch increase the likelihood of void formation

Future work

- Extend test bench to track filler particles during filling
- Simulation of the flow of the underfill material with filler particles
- ML-driven framework to predict filling patterns for complex bump arrangements and varying fluid properties

Analysis of the image-based evaluation of the permeability of carbon-carbon composites

T. Lavaggi, J. W. Gillespie Jr., P. Mulye,
C. Binetruy, S. Advani

UNIVERSITY OF DELAWARE

Project Overview

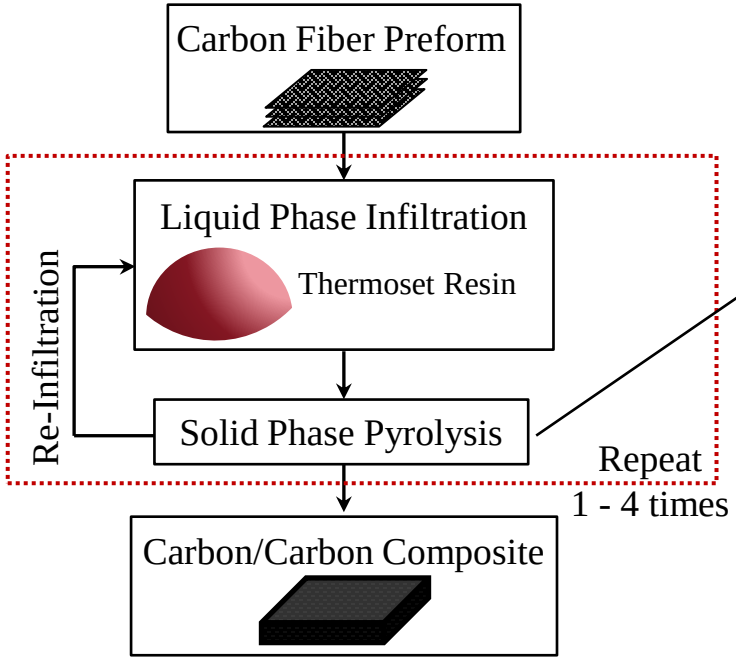
Project Goal

- Improvement of the densification process of carbon-carbon composites.

Focus of Today's Presentation

- Identification of the minimum dimensions of the statistical representative volume element of carbon-carbon composites for permeability characterization.

Outline



1. Introduction
    I. Densification process of carbon-carbon composites
    II. sRVE of carbon-carbon composites
2. Permeability of carbon-carbon composites as function of sample dimensions and inlet location
3. Image-based determination of the stochastic permeability
4. Numerical simulations for the prediction of the effective permeability
    I. Sample of 5 plies
    II. Sample of 33 plies
5. Conclusions

Densification of Carbon-Carbon Composites

Manufacturing of Carbon/Carbon Composites

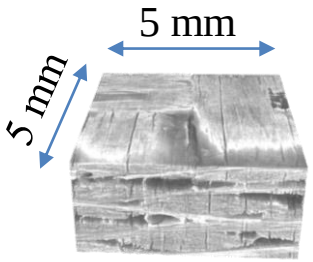
Densification Process

- Repetition Infiltration/Pyrolysis.
- Takes several months to complete.

Densification process: Muhammed et al. 2021 *J. Mater. Sci.* DOI 10.1007/s10853-021-06401-3

Improvement of Densification of Carbon-Carbon Composites

How to improve the process?



- Tailor pyrolysis schedule to control porosity development.
- Find re-infiltration parameters to reduce infiltration time.

Characterization of permeability of carbon-carbon composites (CCC)

- Key parameter for characterization of connected porosity.
- Describes how gas generated during pyrolysis evacuate porosity.
- Determines how resin permeates connected pores during re-infiltration.
- Necessary for numerical simulations to improve the densification process.

Necessary to identify the minimum size of the statistical representative volume element (sRVE)

- Macro-cracks dimensions can be comparable or larger than fabric RVE (25 mm^2).

Framework for the Identification of the sRVE

Image-Based Stokes and Stokes-Brinkman Solver PoroS

- Research software for the virtual characterization of porous materials developed at the Ecole Centrale de Nantes.
- PoroS 1.0: solves Stokes flows by finite element method (FEM) where the finite elements are the voxels (3D) or the pixels (2D) of CT images or digital twins.

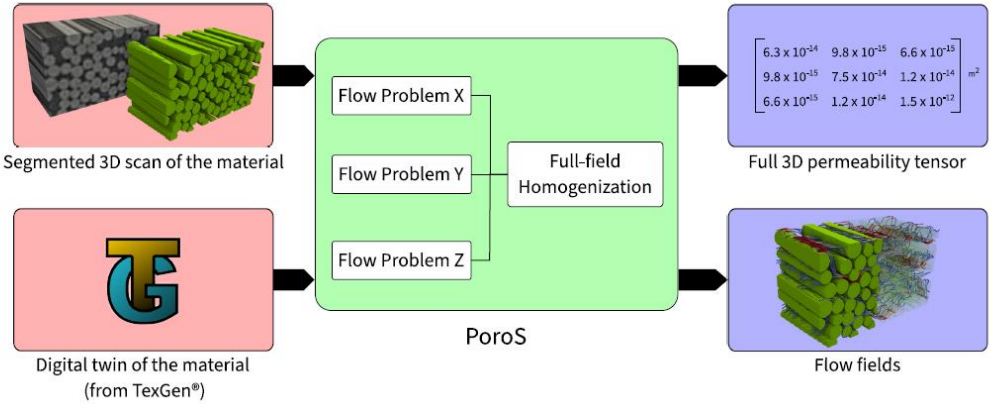

Figure: P. Mulye et al. 2024 *Materials* DOI 10.3390/ma17122873

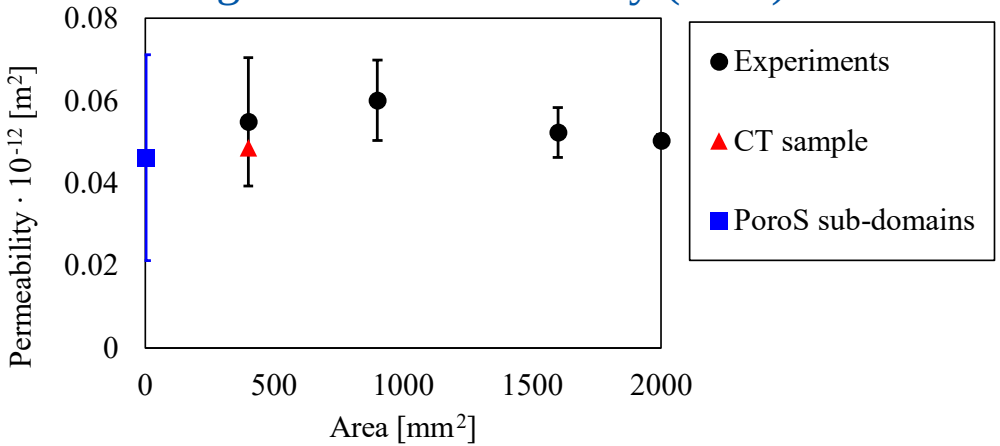

Image-Based Predicted Permeability of Carbon-Carbon Composites

- Voxel size: 6 µm.
- Geometry divided in 70 sub-domains.

- *PoroS* used to **predict the permeability tensors** of the 70 sub-domains.
- Permeability dependent on scale of experiment even for constant microstructure of CCC.

Comparison of Experiment and Image-Based Permeability (z-dir)

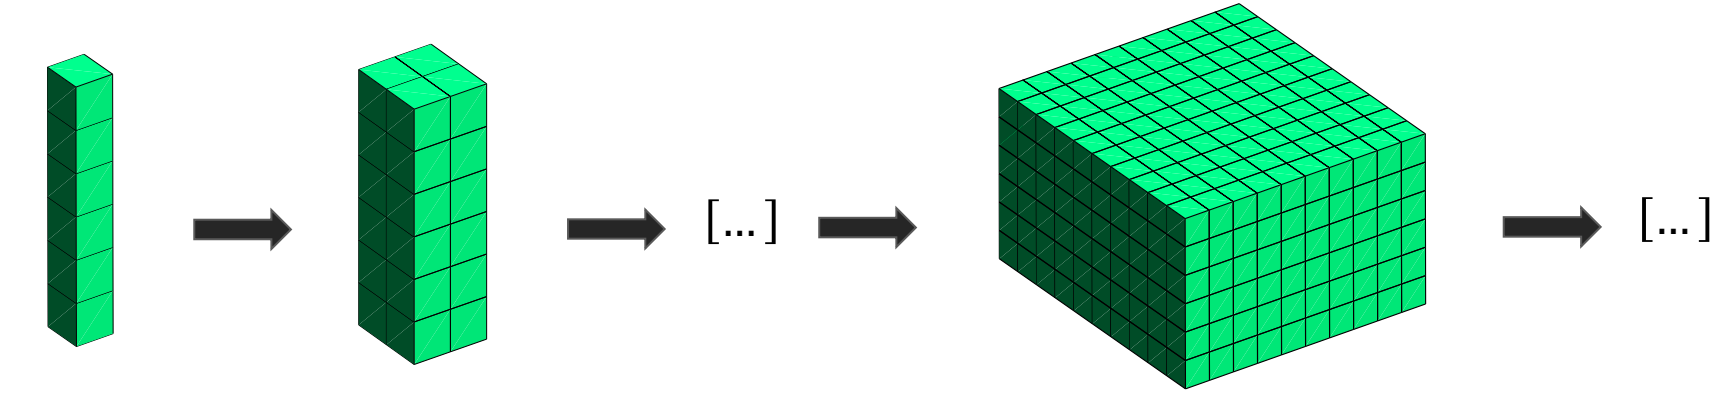
    II. sRVE of carbon-carbon composites
2. Permeability of carbon-carbon composites as function of sample dimensions and inlet location
3. Image-based determination of the stochastic permeability
4. Numerical simulations for the prediction of the effective permeability
    I. Sample of 5 plies
    II. Sample of 33 plies
5. Conclusions

Numerical Simulations: Model Generation of Sample of 5 Plies

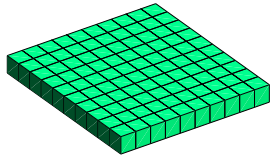


- Element dimensions equal to CT sub-domains dimensions.
- *Thickness* of sample of 5 plies equal to **1 sub-domain** in z-direction.
- Model in-plane dimensions increased from area of 3.5 mm^2 (1 element) to 35000 mm^2 (100 by 100 array of elements).

1 element 4 elements 100 elements

Numerical Simulations: Model Generation of Sample of 33 Plies

- Element dimensions equal to CT sub-domains dimensions.
- *Thickness* of sample of 33 plies equal to **6 sub-domains** in z-direction.
- Model in-plane dimensions increased from area of 3.5 mm^2 (1 element) to 35000 mm^2 (100 by 100 array of elements).



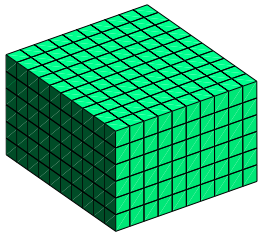
6 elements 24 elements 600 elements

Numerical Simulations: Evaluation of the Effective Permeability

Sample of 5 plies

- Flow assumed parallel for effective permeability K_{eff} in out-of-plane direction.

$$K_{eff} = \frac{1}{A}\sum_i K_i A_i$$

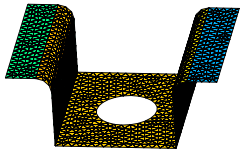


K_i: permeability of i^{th} element.
A_i: area of i^{th} element.
A: area of numerical model.

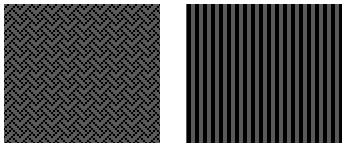
Sample of 33 plies

- Effective permeability K_{eff} evaluated with software Liquid Injection Molding Simulations (LIMS).

$$K_{eff} = \frac{qL\mu}{A\Delta P}$$



q: flowrate.
L: thickness of numerical model.
A: area of numerical model.
μ: viscosity of fluid.
ΔP: applied pressure difference.



Numerical Simulations: Liquid Injection Molding Simulations (LIMS)

- Research software developed at the Center for Composite Materials University of Delaware for the simulations of mold filling stage of liquid composite molding (LCM) processes.
- LIMS: models flow through porous media by finite element/control volume method.

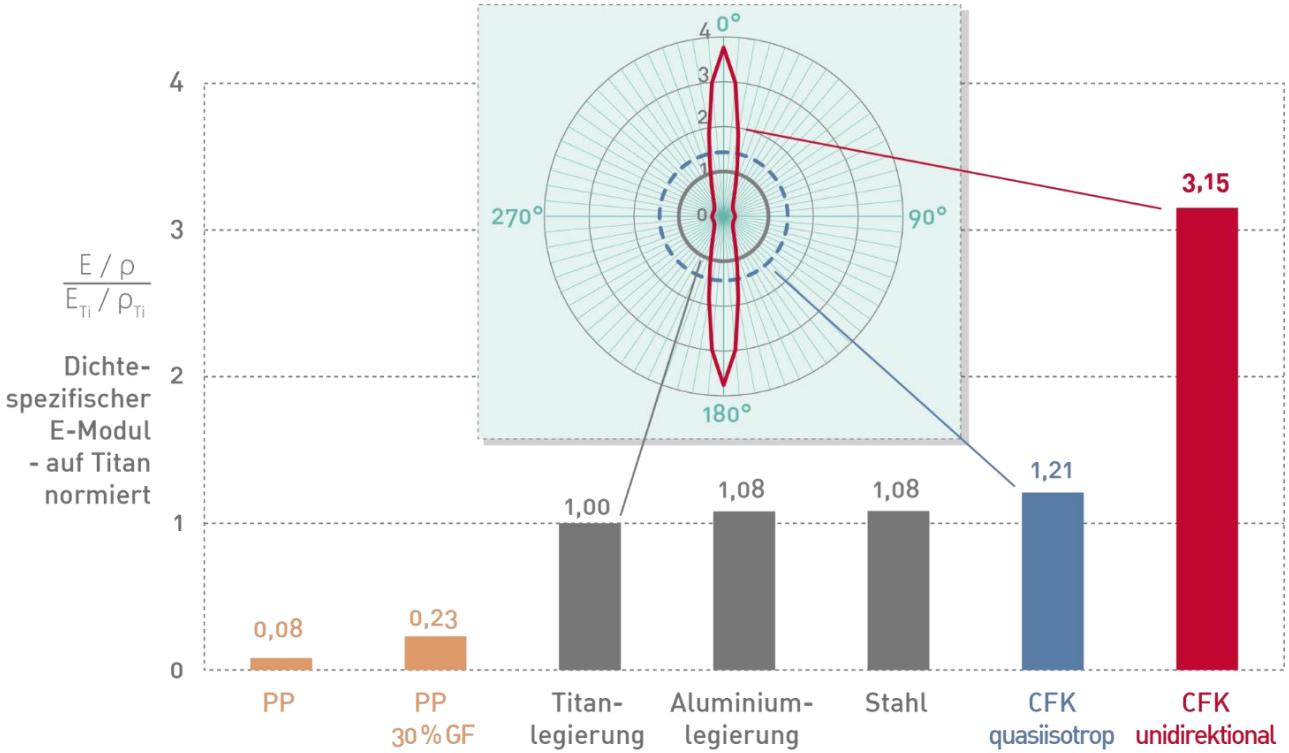
Monitoring RTM Infiltration Behavior of TFP Preforms Using Near-Net-Shaped Transparent Cavities

Cameron Welker[1], Lars Bittrich[1], Dennis Weitze[2], Sarah Schlegel[2], Luise Kärger[2], Tales Lisbôa[1], Axel Spickenheuer[1]

[1] Leibniz-Institut für Polymerforschung Dresden e. V.

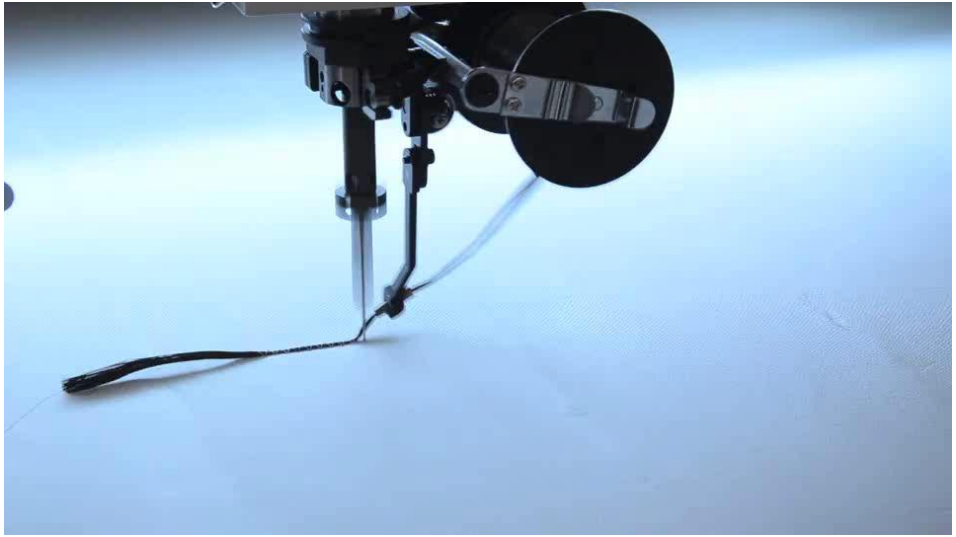


[2] Institute of Vehicle System Technology, Karlsruhe Institute of Technology

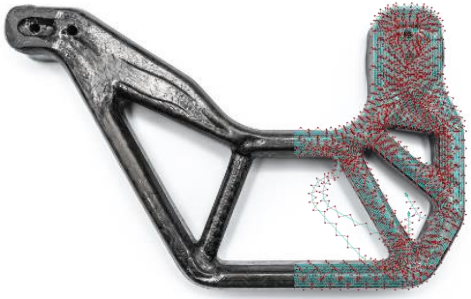
Agenda

- Tailored Fiber Placement (TFP)
- Challenges in mold design for RTM injections of TFP preforms
- Additive manufactured molds for RTM infiltration
- Accuracy of 3D-printed RTM molds
- Experimental results

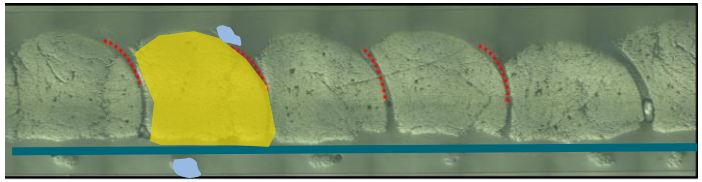
Properties of different materials



Normalized dense specific elastic modulus of different lightweight material



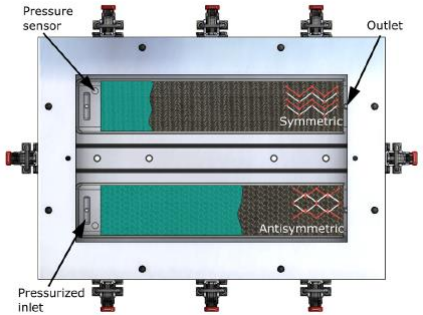
Tailored Fiber Placement (TFP)

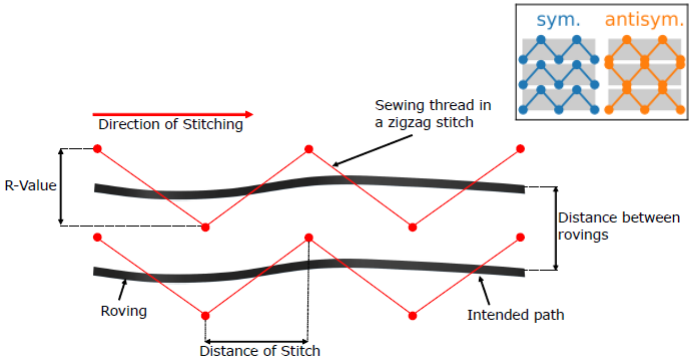


Process characteristics

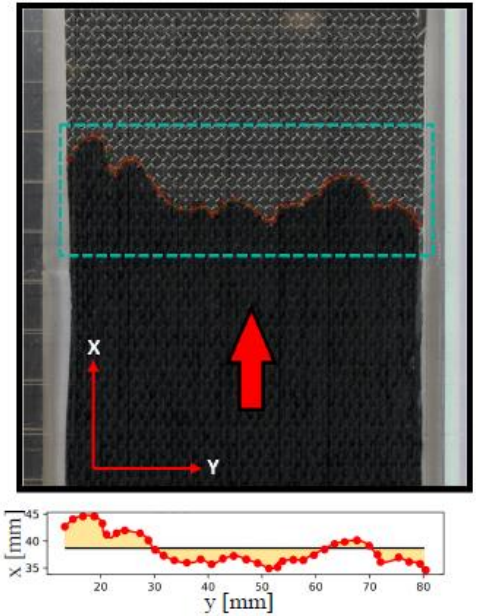
- Near-net-shape production of variable-axial textile preforms
- Almost ideal utilization of anisotropic material properties
- Placement radii up to 5 mm

Complex infiltration behavior





Roving Base material Stitching yarn



Tailored Fiber Placement (TFP)

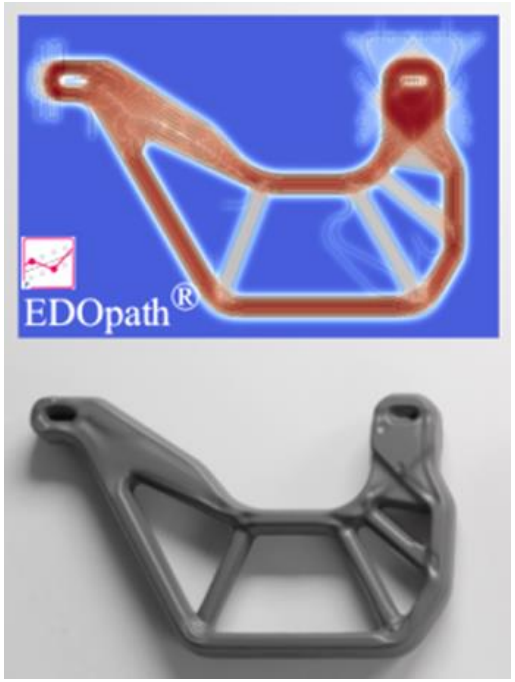
Process characteristics

- Preliminary studies about measurement of in-plane permeability
- Antisymmetric stitching pattern showed higher permeability
- CFD flow simulations of the experiments for predicting resin flow

Bittrich, L.; Seuffert, J.; Dietrich, S.; Uhlig, K.; Lisboa, T.d.V.; Kärger, L.; Spickenheuer, A. On the Resin Transfer Molding (RTM) Infiltration of Fiber-Reinforced Composites Made by Tailored Fiber Placement. *Polymers* **2022**, *14*, 4873. https://doi.org/10.3390/polym14224873

Tailored Fiber Placement (TFP)

Overcoming the challenges by numerically predict resin flow

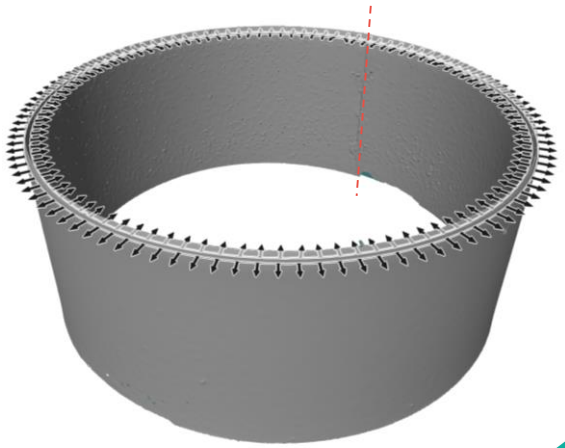


- Anisotropic material permeability needs to be evaluated by experiments
- Race-tracking needs to be avoided
- Experimental determination of out-of-plane permeability of TFP preforms is current subject of research

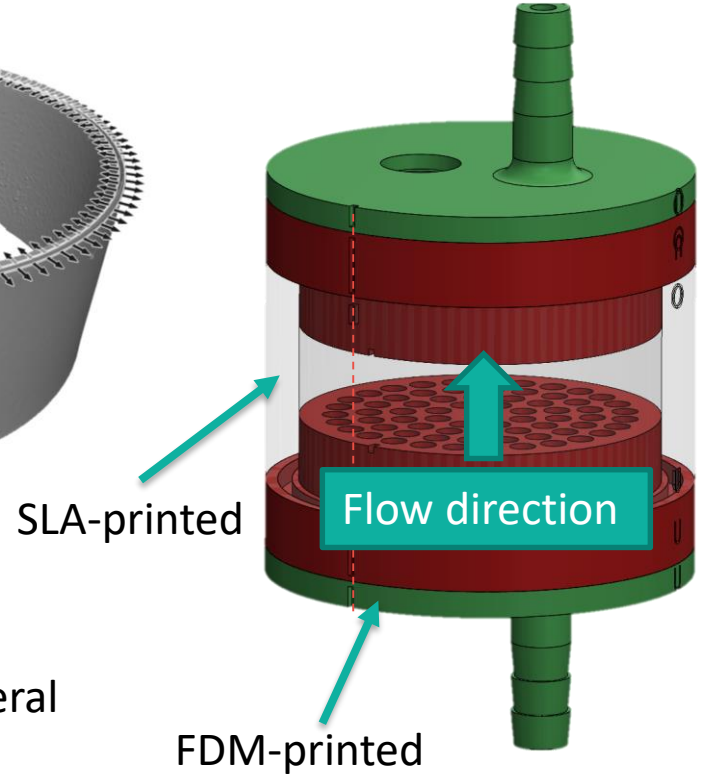
- ➢ Additive manufactured tools enable rapid change of cavity geometries and inlet/outlet locations
- ➢ Near-Net-Shaped cavities avoid race-tracking

(Transparent) molds for RTM injections

Comparison between different manufacturing technologies

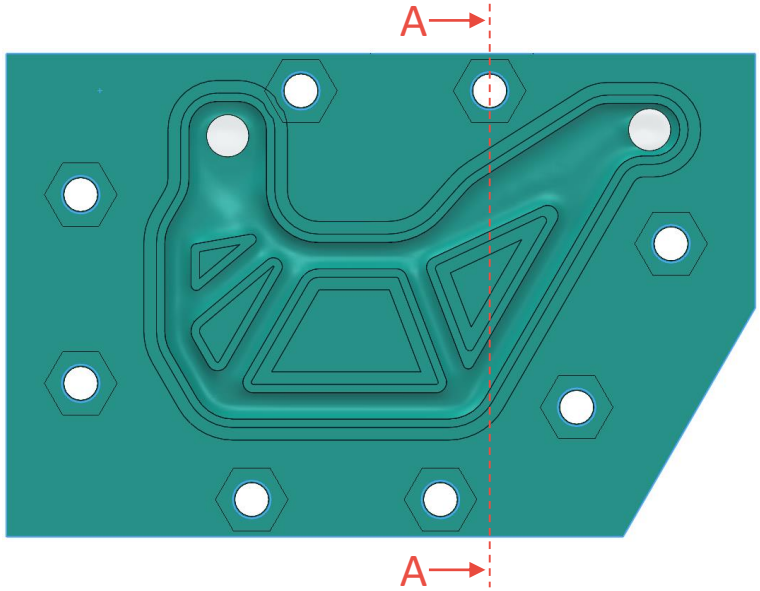


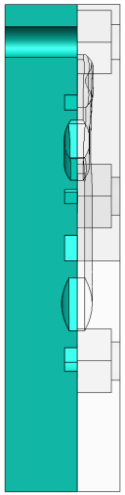
- Complex TFP surfaces often require 3D-Milling
  - Surface Quality
  - Structural stiffness
  - Time consuming process
  - costly
- 3D-printing (Fused Deposition Modeling) technology
  - Cheap process
  - Comparatively fast
  - Not really transparent
  - Surface quality
  - Not sealed (porosity)
- 3D-printing (Stereolithography) technology
  - Transparent parts
  - Sealed structure
  - Brittle structures

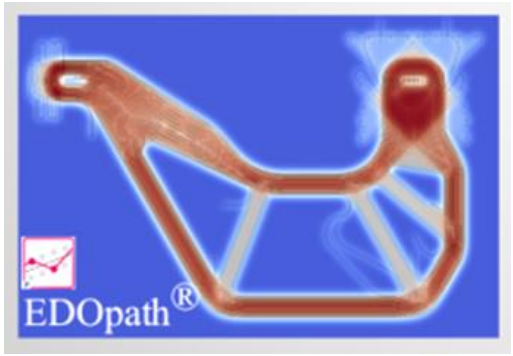


(Transparent) molds for RTM injections

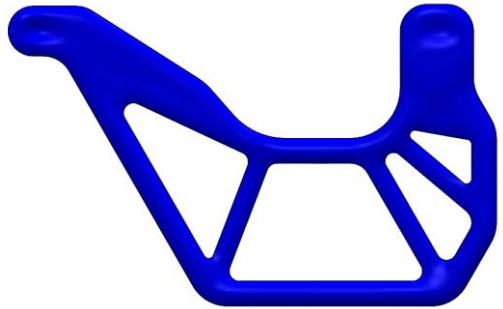
3D-printed approach





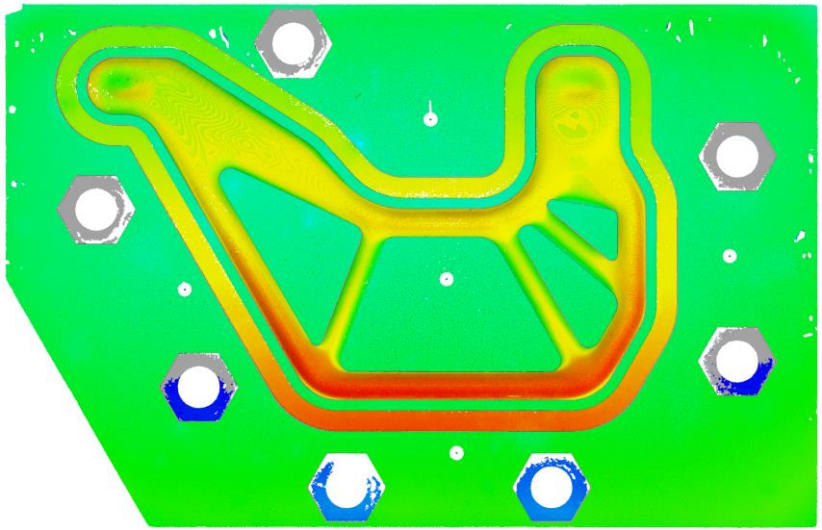


- 3D-Scan of fiber cutting tool
- Cross-section used as cavity cross section
- FDM print enables connection of various peripheral devices (pressure sensor etc.)

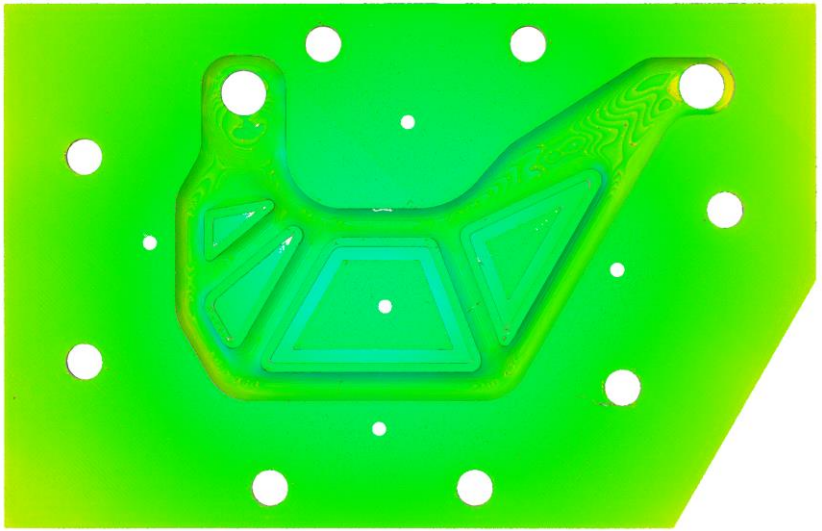


(Transparent) molds for RTM injections

3D-printed approach



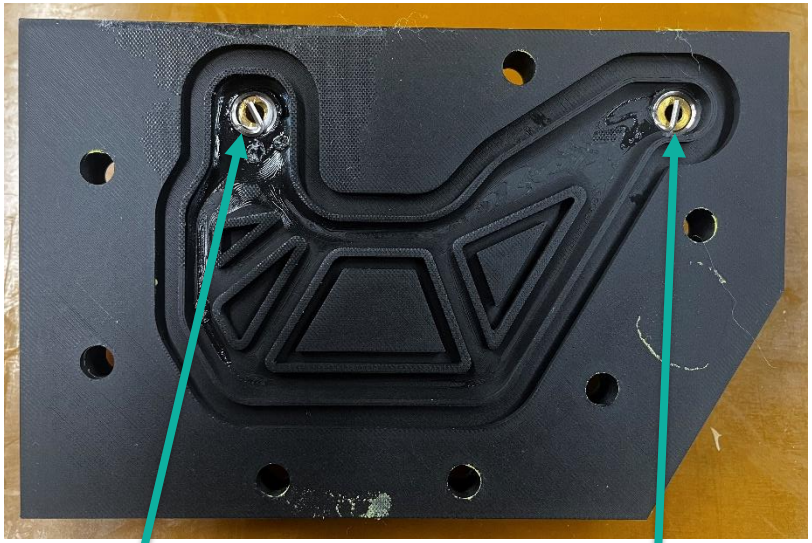
- Top part SLA printed (transparent)
- Bottom part FDM printed (non-transparent)



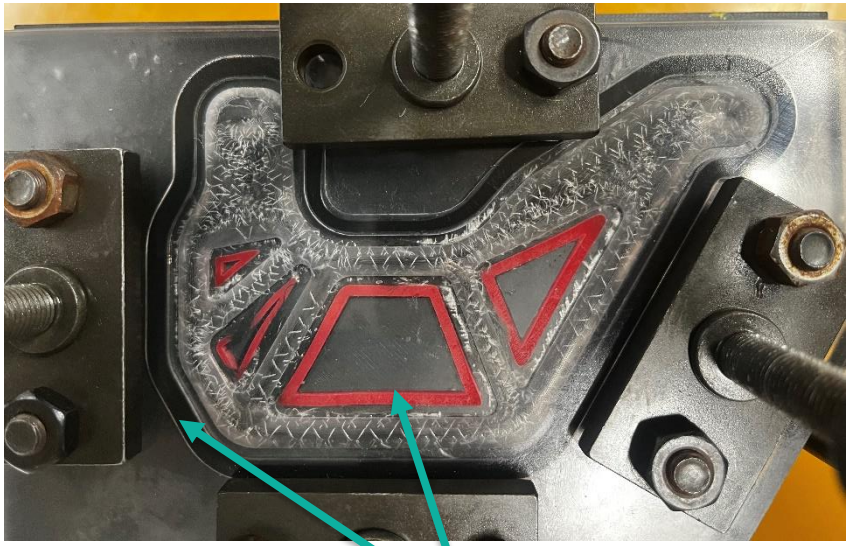
(Transparent) molds for RTM injections

3D-printed approach – Evaluation of accuracy

- Zeiss GOM Metrology GmbH ATOS Q, MF 170
- Deviation to CAD model by best-fit

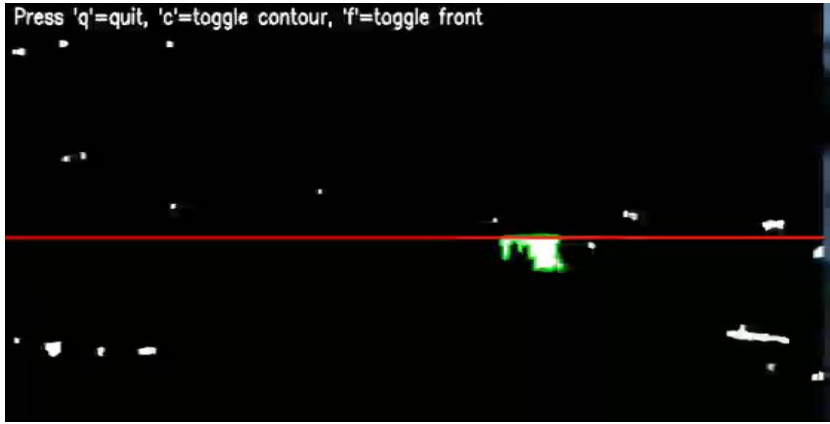


- SLA part after printing

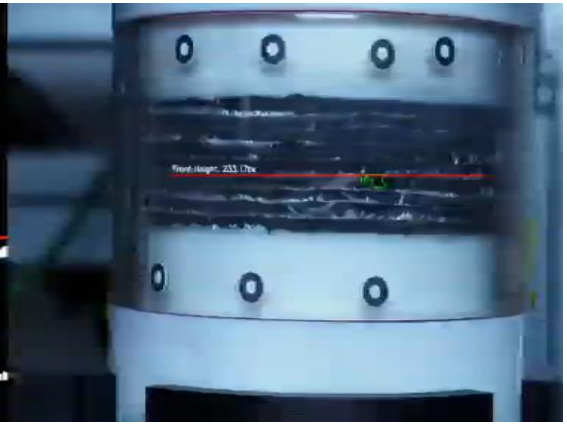


- FDM part after printing

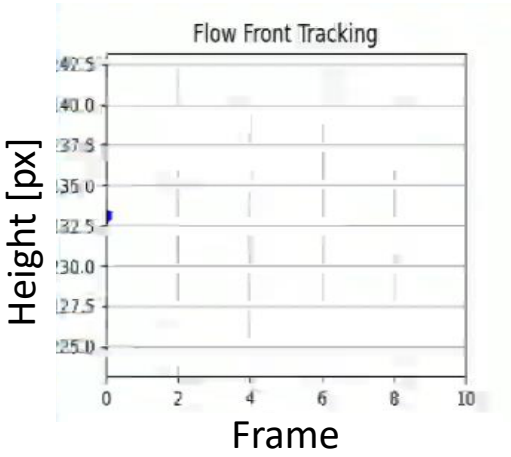
(Transparent) molds for RTM injections



3D-printed approach



- Top and bottom part pressed together by quick release clamps



Injection experiment
simple cavity

Thresholded video frame with contour detection

Original video frame

Flow front height (px) over time (frame)

- No race-tracking
- Flow front clearly visible through SLA printed cavity

Injection experiment
complex cavity

- Race tracking at borders
- Inner sealings not sufficient
- Flow front clearly visible through SLA printed cavity

Content

1 Introduction
- 1.1 RTM Process Overview
- 1.2 Particle Mixed Resin Flow

2 Methodology
- 2.1 Resin Flow Model
- 2.2 Particle Transport Models
- 2.3 Numerical Implementation
- 2.4 Particles and Permeability
- 2.5 Numerical Flow Domain

3 Results
- 3.1 Partially Coupled Model
- 3.2 Fully Coupled Model
- 3.3 Time Evolution of Particle Distribution
- 3.4 Time Evolution of Permeability
- 3.5 Influence of Particle Injection Conditions
- 3.6 Influence of Particle Size
- 3.7 Trials with Radial Flow

4 Summary and Outlook

1. Introduction

1.1. RTM Process Overview

- Resin Transfer Moulding (RTM) is a process used to manufacture Fibre Reinforced Polymers (FRP), which consists of 5 steps as shown in Fig. 1.

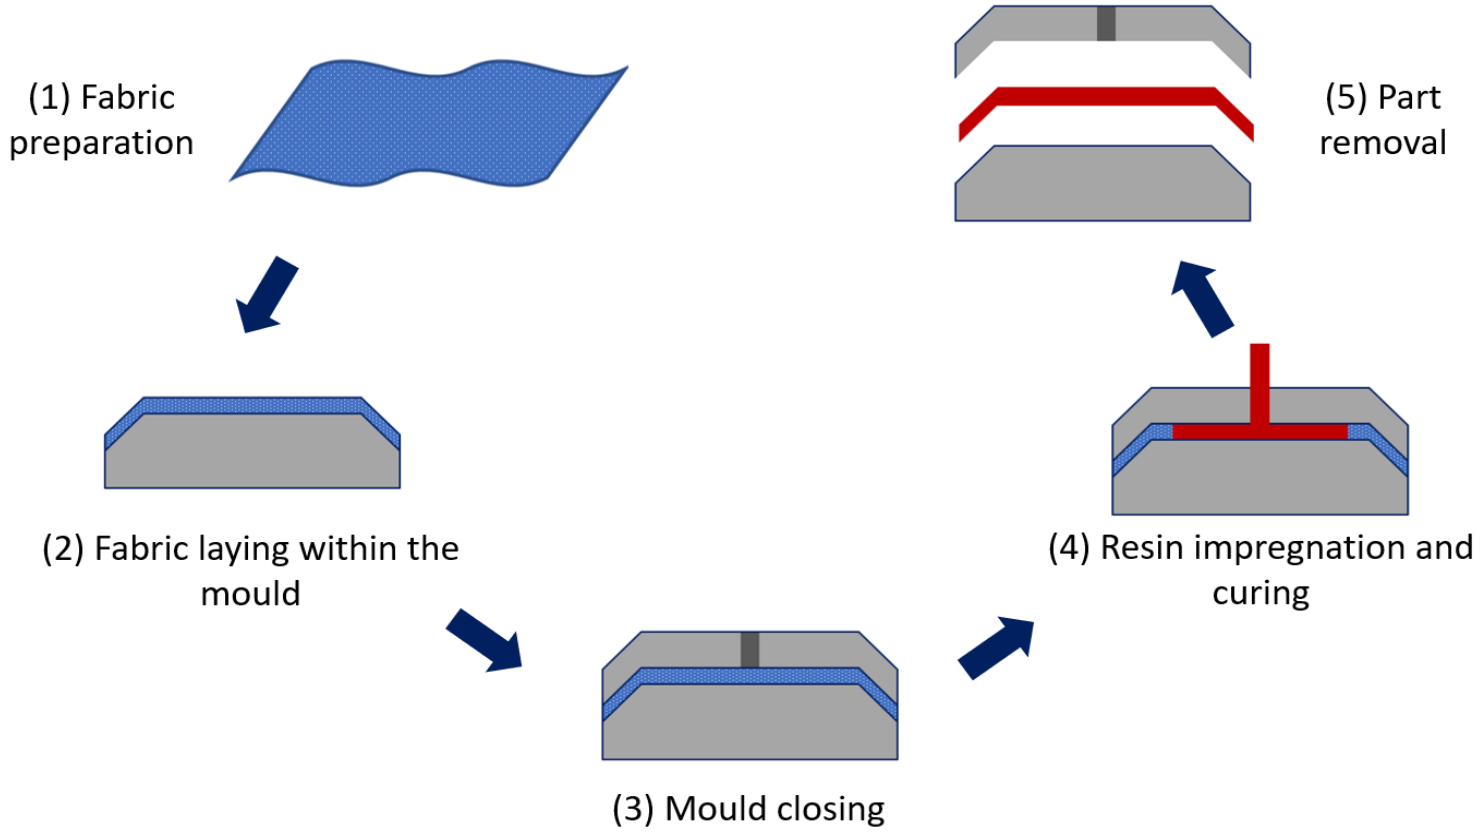

Figure 1: The Resin Transfer Moulding (RTM) process

1. Introduction

1.2. Particle Mixed Resin Flow

- Particles may be mixed with the resin to improve the properties of parts manufactured using RTM [1][2].

- The sizes of these particles can range from the micrometre scale to the nanometre scale, as shown in Fig. 2.

- Transport models and simulations can provide valuable information regarding the final particle distribution, permeability changes, and particle filtration [3].

- The presence of particles will affect the permeability of the flow channels, which in turn will affect the flow of particles [4][5].

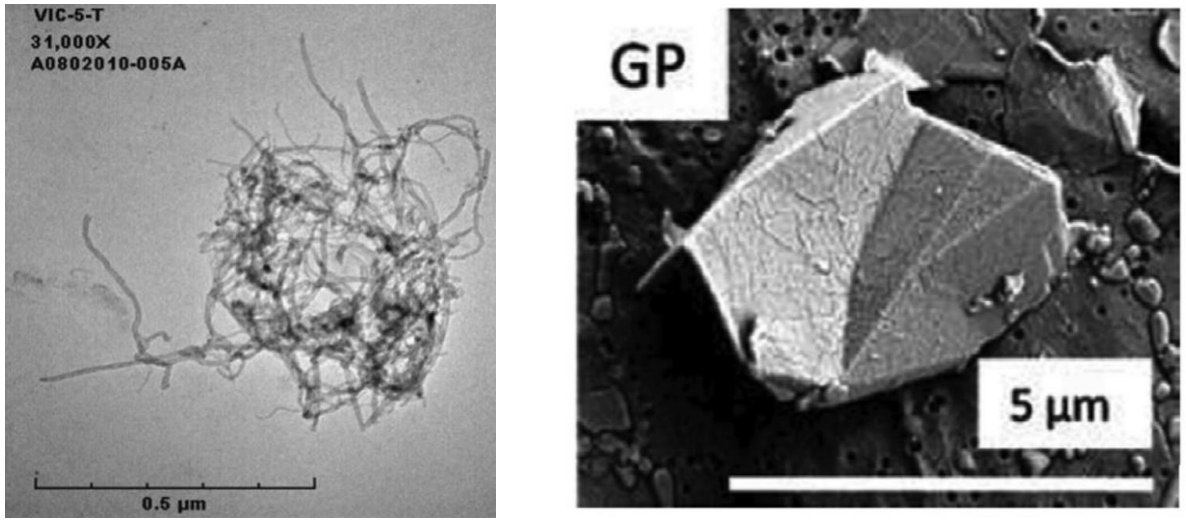

Figure 2: Different types of particles (a) Multi-Walled Carbon Nanotubes (b) Graphene Nanoplatelets [6]

2. Methodology

2.1. Resin Flow Model

- The resin flow through the reinforcement preform is modelled as a flow through a porous medium, governed by the mass conservation equation (Eq. 1) and the Darcy equation (Eq. 2).

$$\nabla \cdot \mathbf{u} = 0 \tag{1}$$

$$\mathbf{u} = -\frac{\mathbf{K}}{\mu}\nabla P \tag{2}$$

- Here, $\mathbf{u}$ is the volume-averaged resin velocity, $\mathbf{K}$ is the permeability tensor for the porous preform, μ is the resin viscosity, and P is the resin pressure.

- The above equations can be combined to obtain Eq. 3, which is then used to solve for the in-mould pressure distribution at each time step.

$$\nabla \cdot \left(\frac{\mathbf{K}}{\mu}\nabla P\right) = 0 \tag{3}$$

2. Methodology

2.2. Particle Transport Models

Partially Coupled Model

- In this approach, the preform permeability is assumed to be constant and unaffected by the presence of particles (Fig. 3a)

- After the pressure and velocity fields are solved, the particle locations are updated based on the resin flow, resulting in a passive transport.

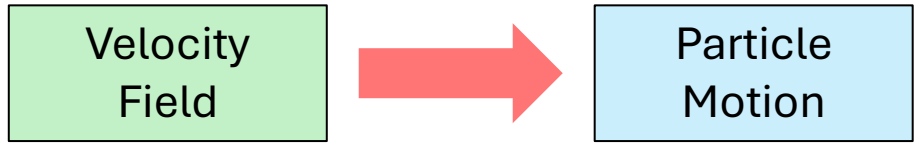

Figure 3a: Partially coupled model

Fully Coupled Model

- In this approach, the preform permeability is updated at each time step according to the presence of particles within an element (Fig. 3b)

- The new permeabilities of elements are calculated using the Gebart model by adjusting the porosity accordingly.

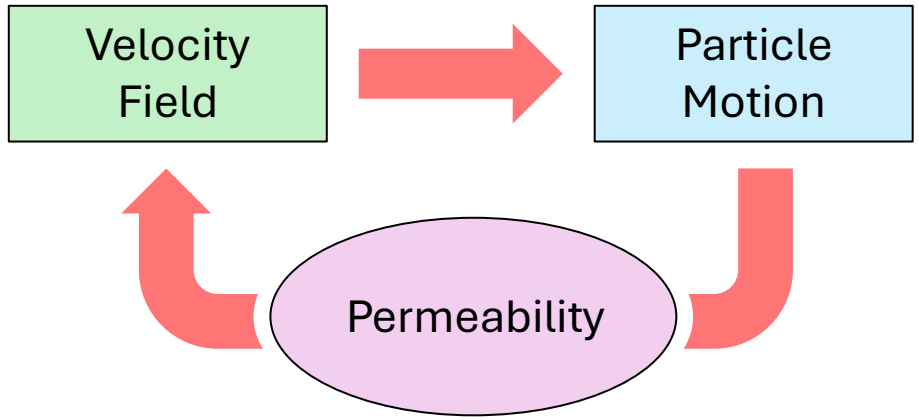

Figure 3b: Fully coupled model

2. Methodology

2.3. Numerical Implementation

- Resin pressure and velocity values are calculated using the Liquid Injection Moulding Simulation (LIMS) software developed at the University of Delaware.
- The particle transportation is implemented using a worker script that reads pressure and velocity data from LIMS and updates the particle location.
- This architecture is shown in Fig. 4 [7].
- At each time step, Eq. 3 is solved using the finite element method in LIMS.

$$\boldsymbol{\nabla} \cdot \left(\frac{\mathbf{K}}{\mu} \nabla P \right) = 0 \qquad (3)$$

- Data is communicated between LIMS and the worker script using Message Passing Interface (MPI).

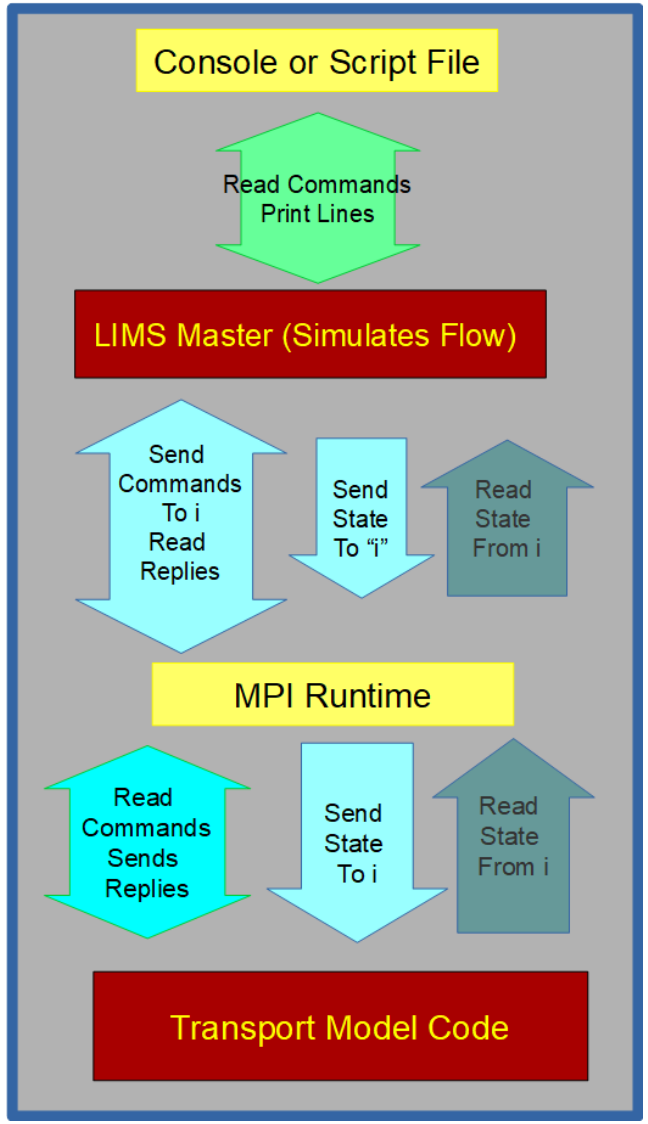

Figure 4:
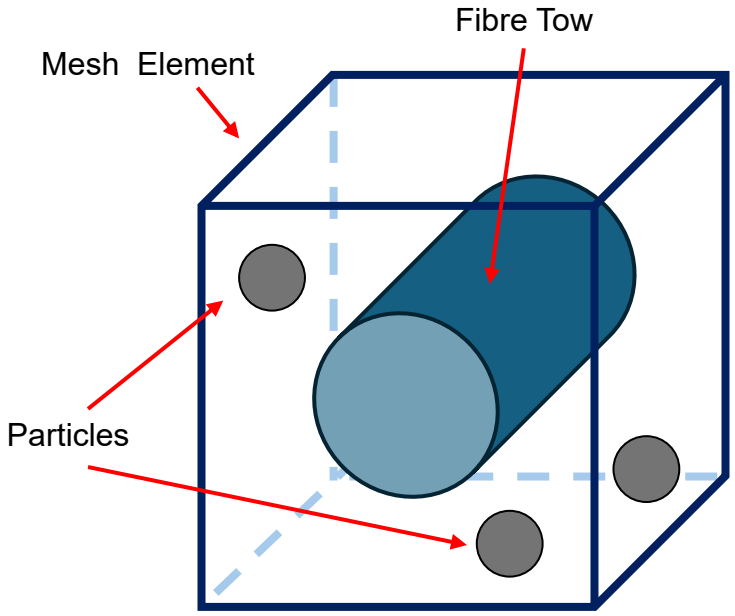
Simulation software architecture [7]

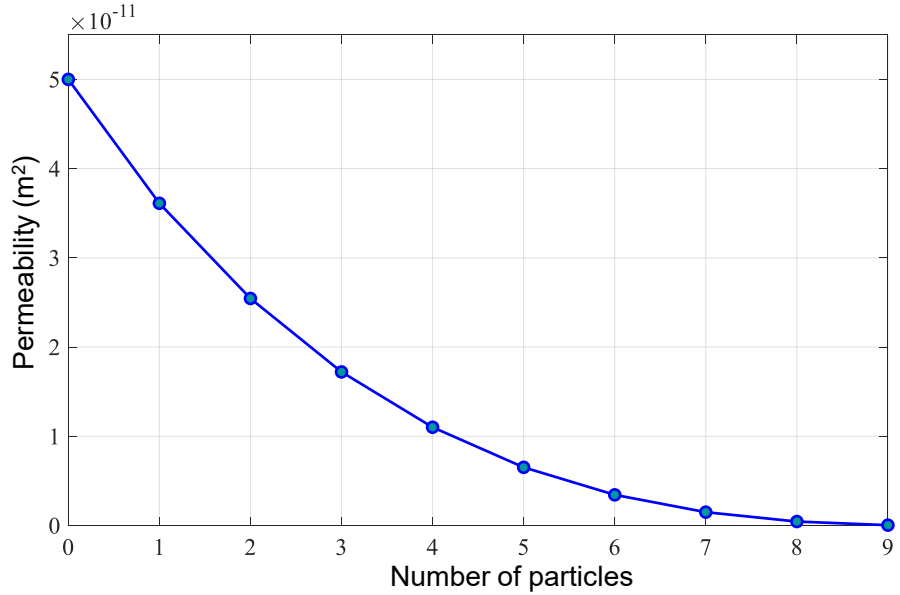
2. Methodology

2.4. Particles and Permeability



- In the fully coupled model, the new permeabilities of elements are calculated using the Gebart model for transverse permeability of cylinders in quadratic arrangement, given in Eq. 4 [8].

$$K_{\perp} = \frac{16}{9\pi\sqrt{2}}\left(\sqrt{\frac{V_{fmax}}{V_f}} - 1\right)^{5/2} R^2 \qquad (4)$$



- Here, V_{fmax} is the maximum volume fraction, V_f is the volume fraction, R is the fibre radius.

- The volume fraction is updated according to the number of particles within an element, as shown in Fig. 5a.

- As more particles enter the element, the permeability gradually reduces (Fig. 5b) and becomes zero beyond the maximum fraction.

(a)

(b)

Figure 5: (a) Contents within an element (b) Variation of permeability with the number of particles within an element

2. Methodology

2.5. Numerical Flow Domain

- The numerical domain is a 10cmx30cm rectangular mould, and the resin is injected under controlled pressure from a line gate, as shown in Fig. 6.

- Particles are introduced to the system from the inlet at different concentrations and pressures, and their motion is tracked.

- The numerical parameters are given in Table 1.

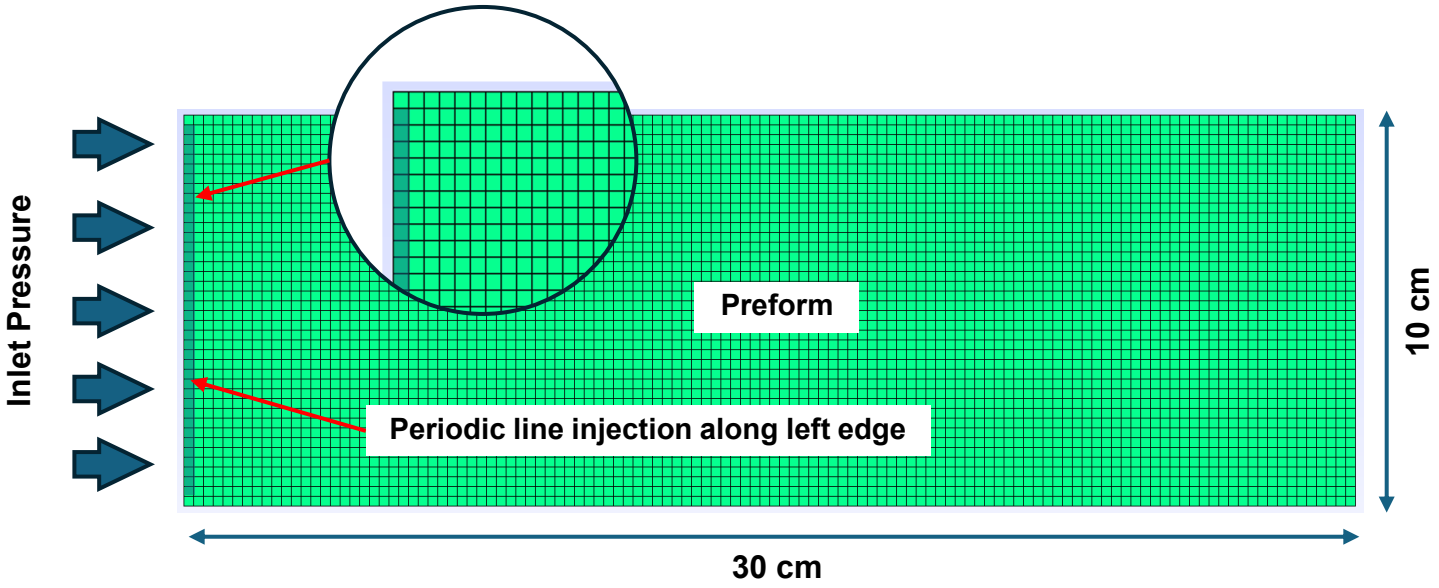


Figure 6: Numerical domain setup

Table 1: Flow simulation parameters

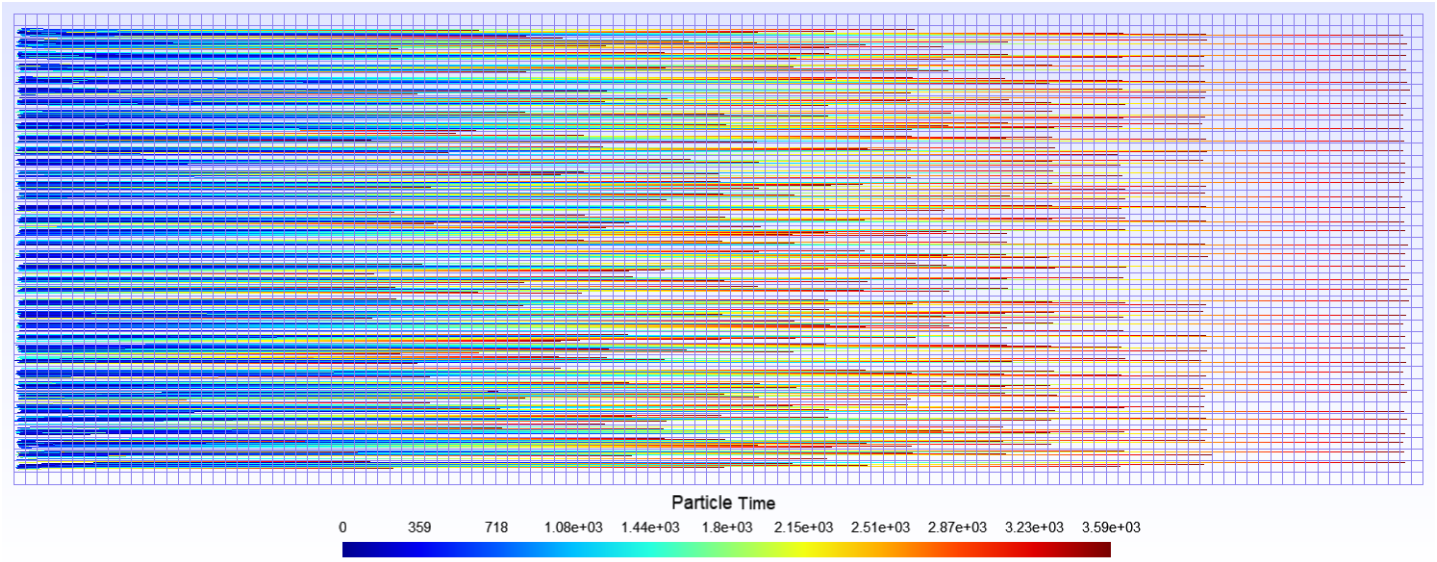
Parameter	Value
Preform permeability	5e-11 m^2
Resin viscosity	200 mPas
Injection pressure	25 kPa
Mould thickness	5 mm
Particle diameter	0.6 mm

3. Results

3.1. Partially Coupled Model

- During the simulation, 1710 particles were introduced into the system.
- Fig. 7a shows the path of motion of the particles.
- The particles move in straight lines due to being passively transported by the flow.
- Fig. 7b shows the distribution of the particles within the mould at fill time.
- The injection profile of the particles is preserved due to the absence of flow obstructions.

Figure 7a



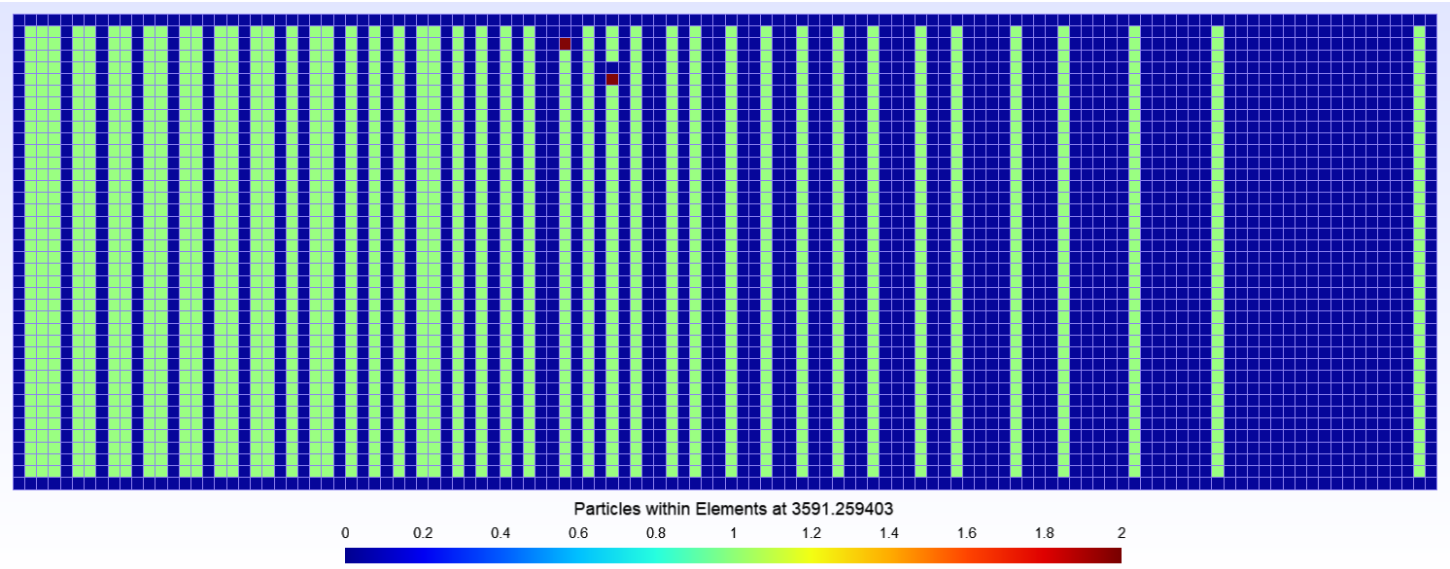


Figure 7b

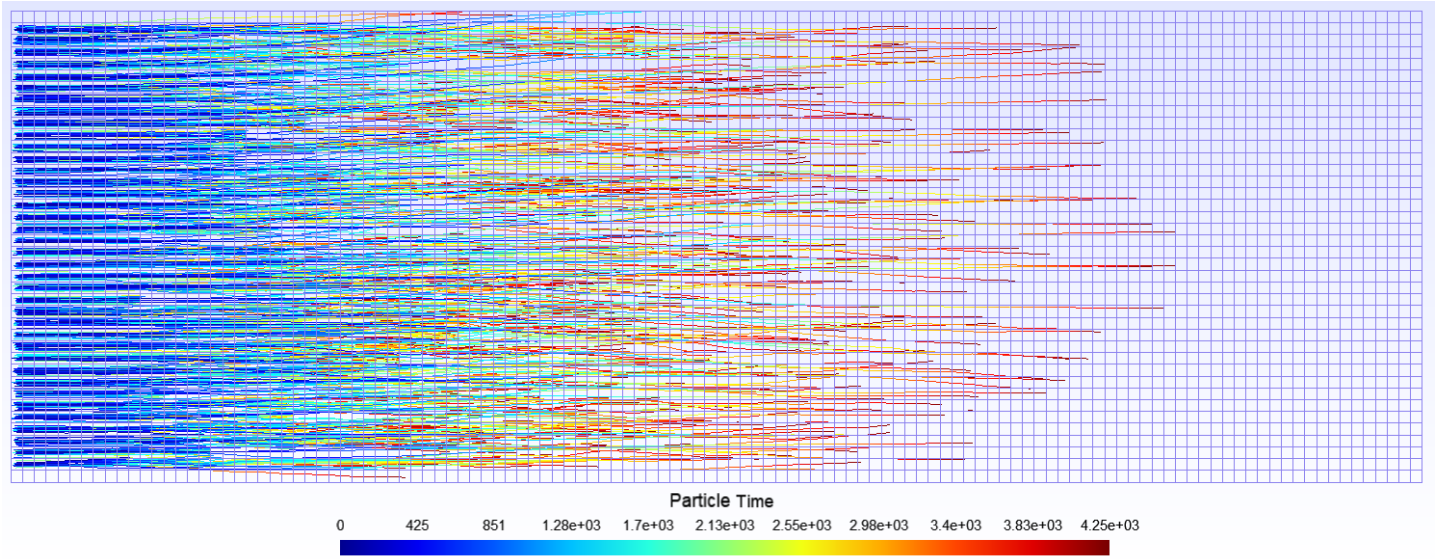
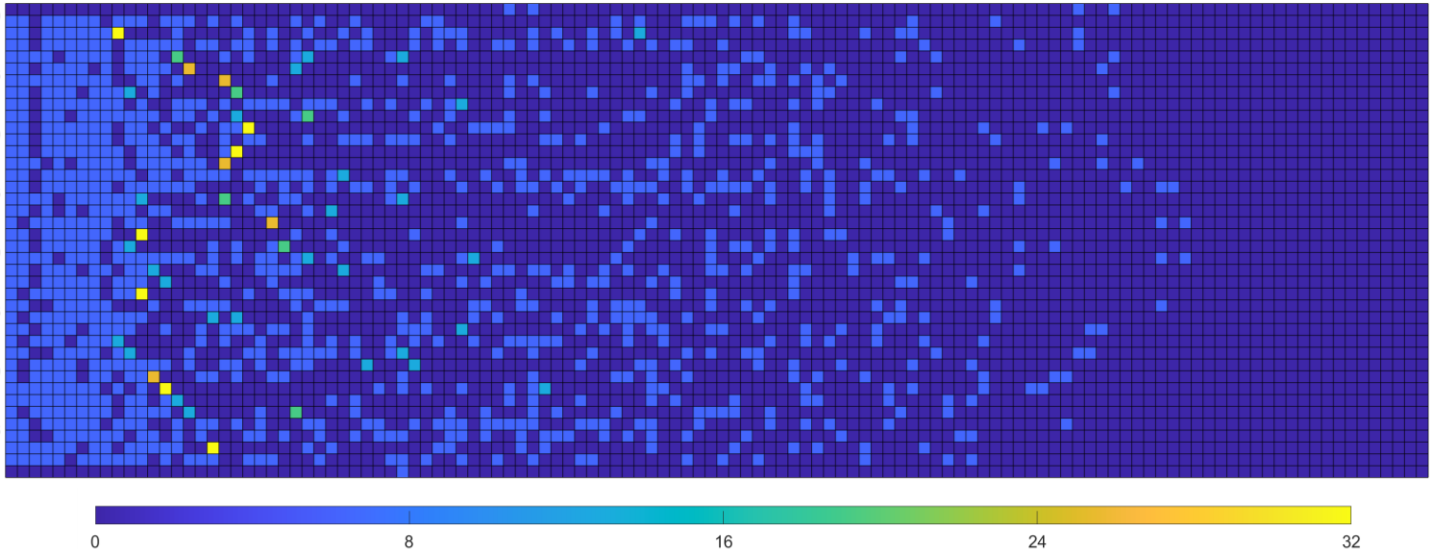
3. Results

3.2. Fully Coupled Model

- During the simulation, 2052 particles were introduced into the system.
- Fig. 8a shows the path of motion of the particles.
- Now, their flow paths are affected due to the local changes in permeability.
- Fig. 8b shows the distribution of the particles within the mould at fill time.
- Near the inlet, particles accumulate causing the permeability to reduce, leading to further accumulation.

Figure 8a





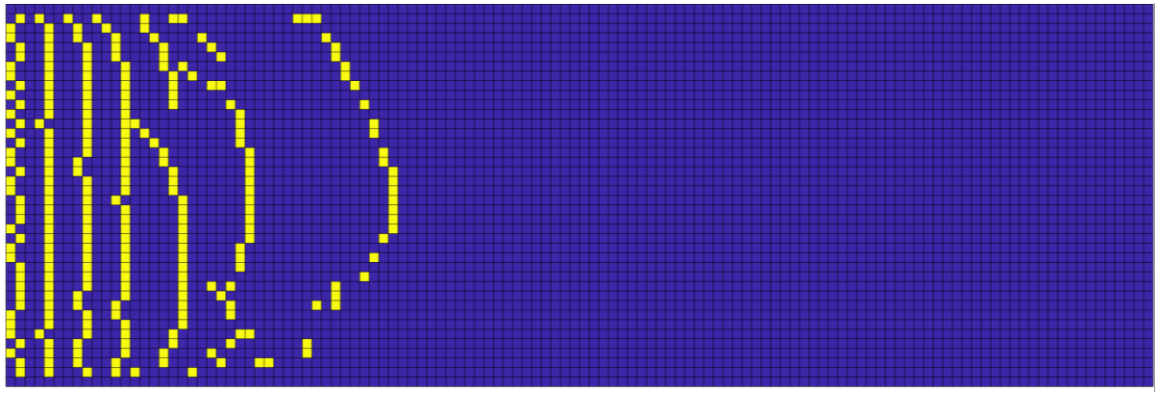


Figure 8b

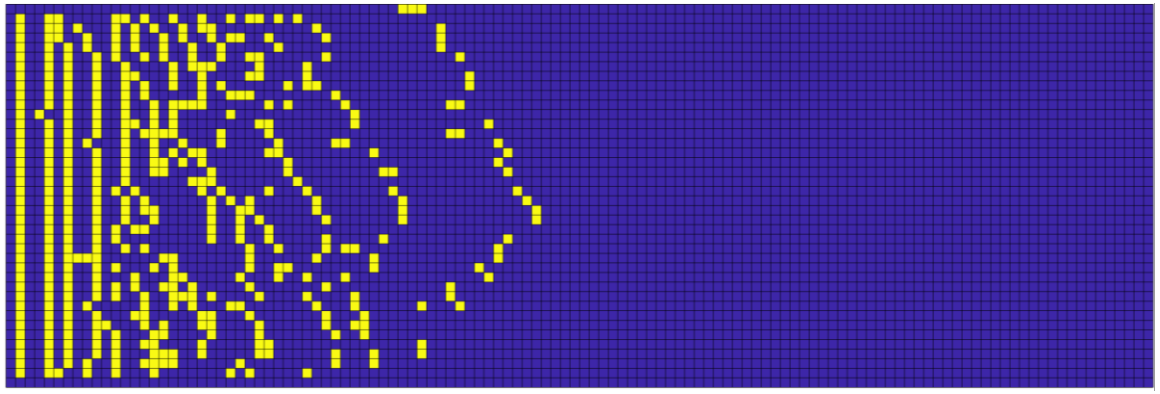
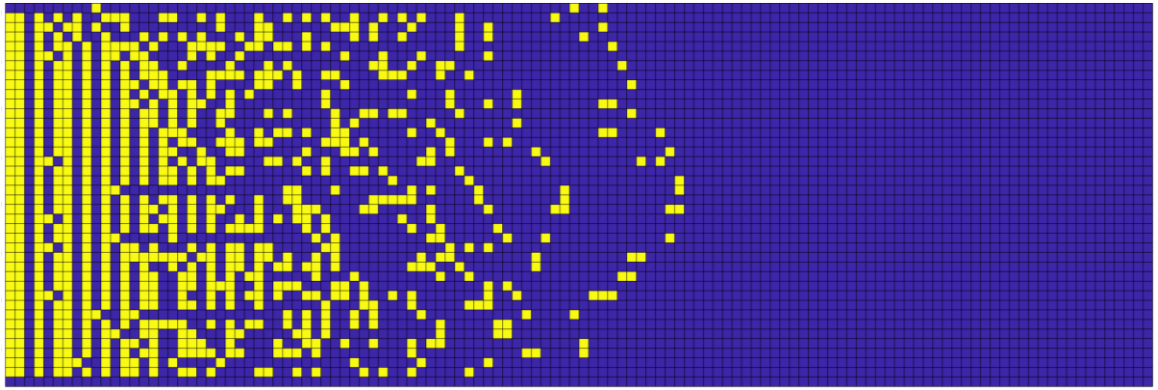
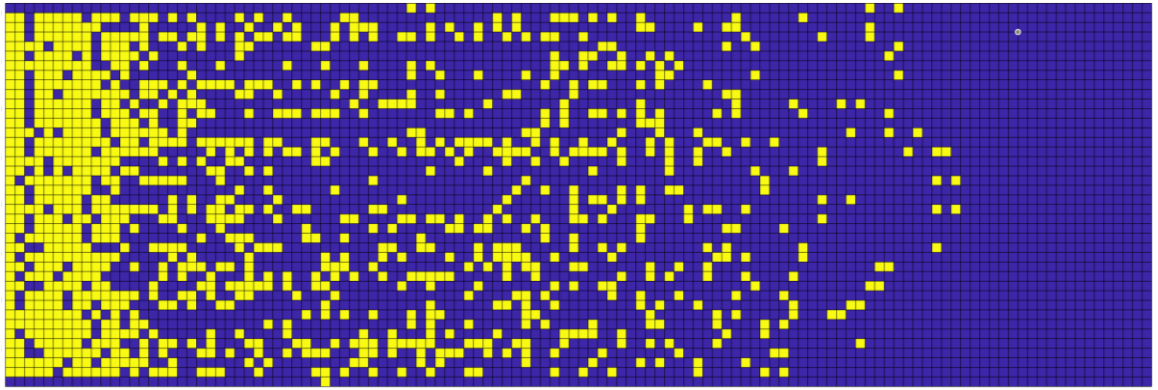


3. Results



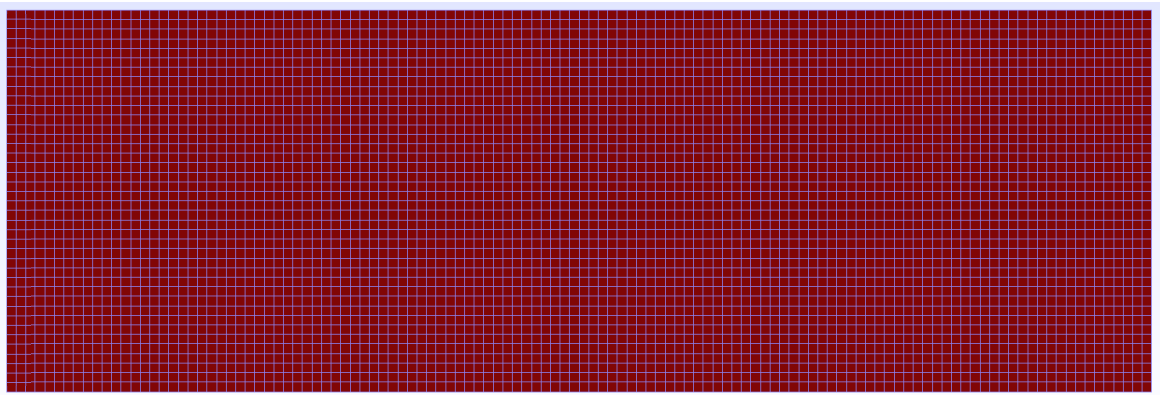
3.3. Time Evolution of Particle Distribution



(a) t = 100 s

(b) t = 500 s

(c) t = 2000 s



(d) Mould fill

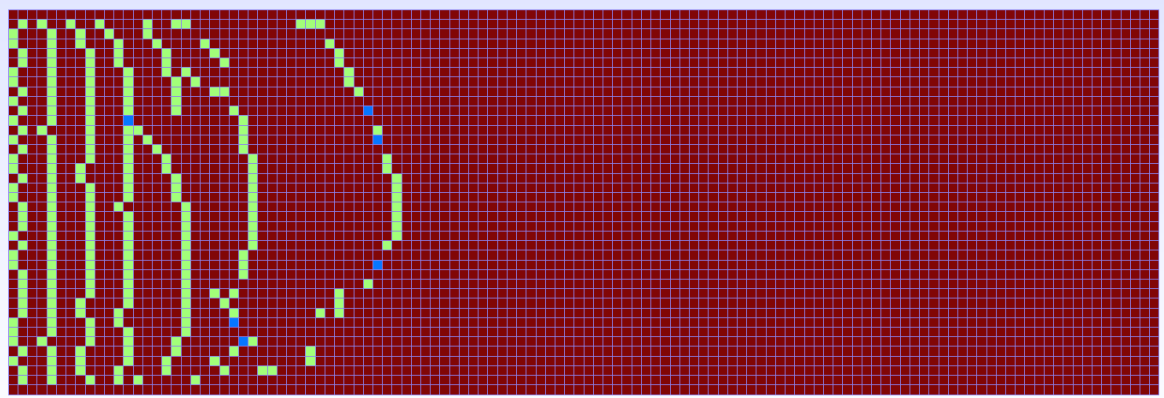


Figure 9: Evolution of the particle distribution with time

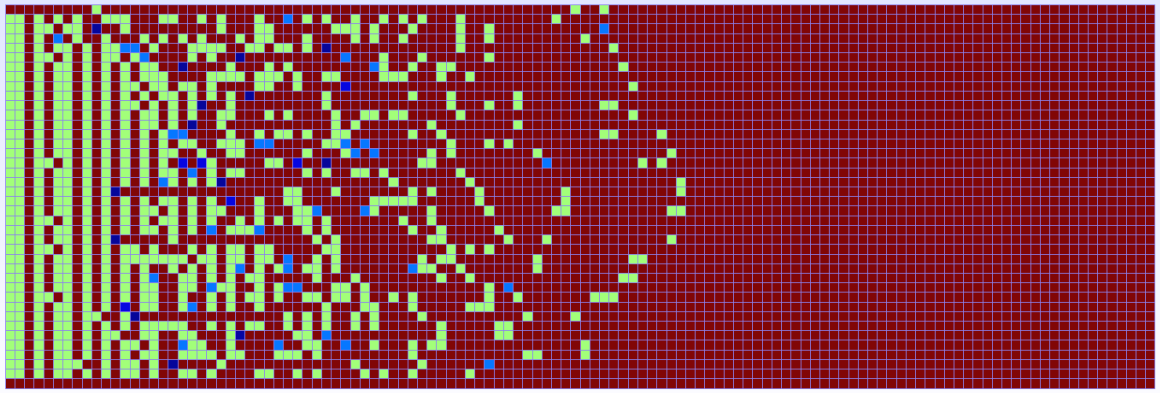
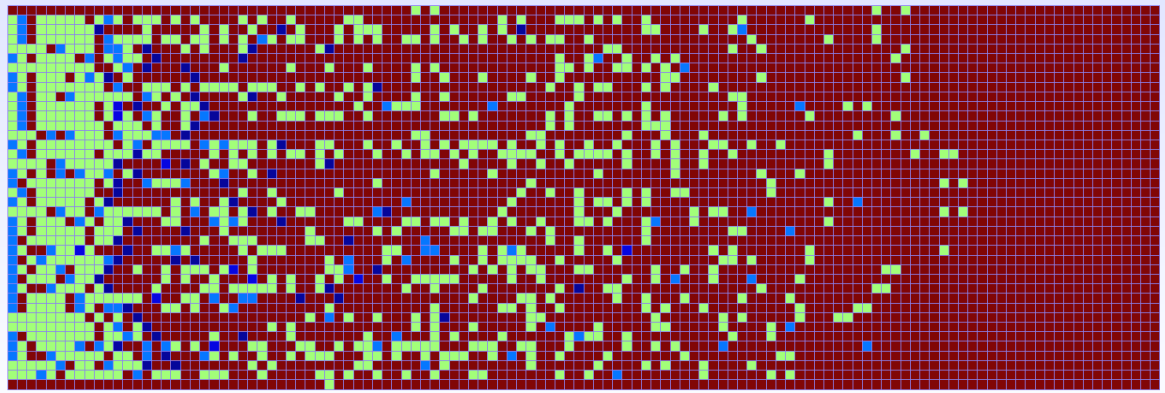
3. Results



3.4. Time Evolution of Permeability

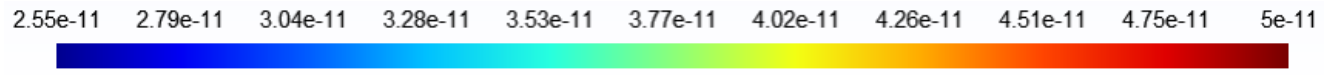


(a) t = 0 s

(b) t = 500 s

(c) t = 2000 s

(d) t = Mould fill



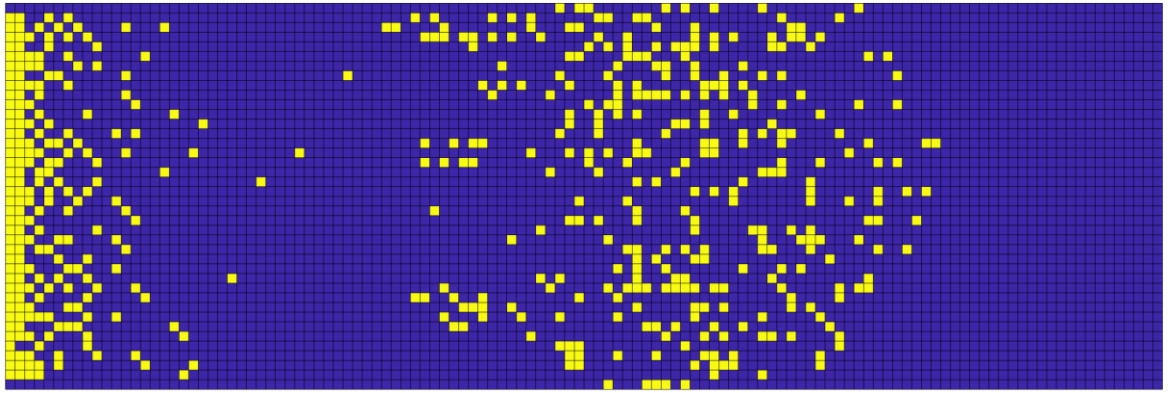


Figure 10: Evolution of the domain permeability with time

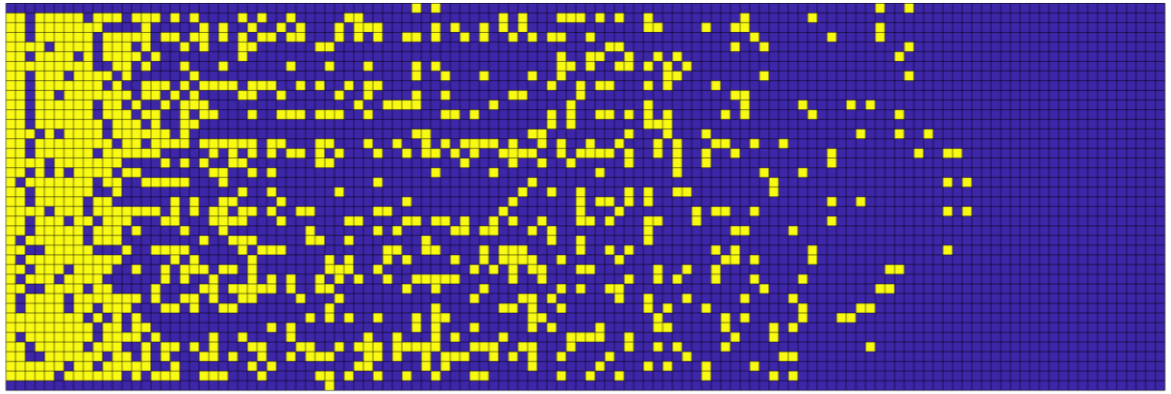
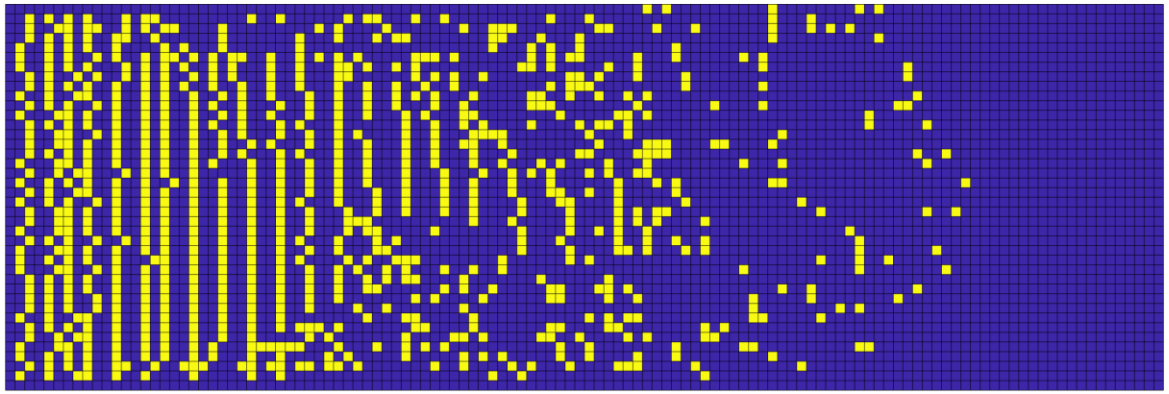
3. Results



3.5. Influence of Particle Injection Conditions – Inlet Pressure

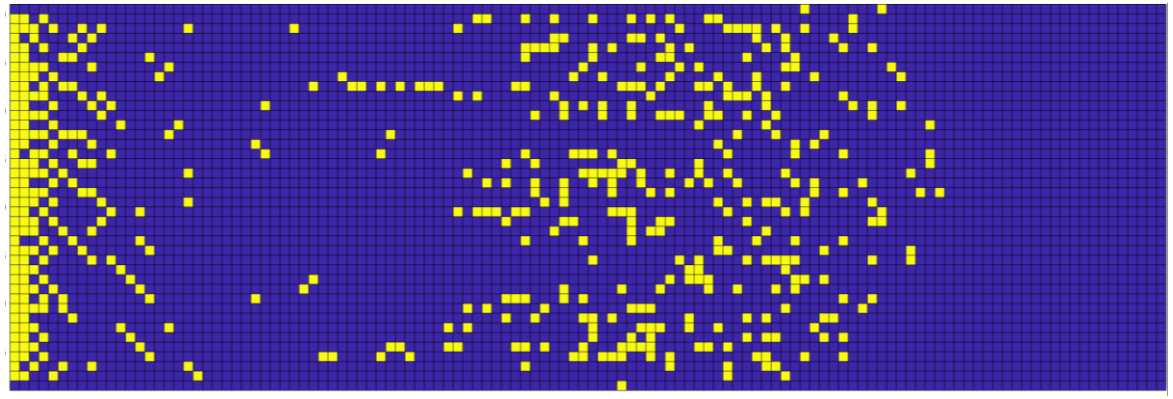
- The effect of inlet pressure on the final distribution of particles was investigated.



- The particle inlet concentration was fixed, and the results are given in Fig. 11.

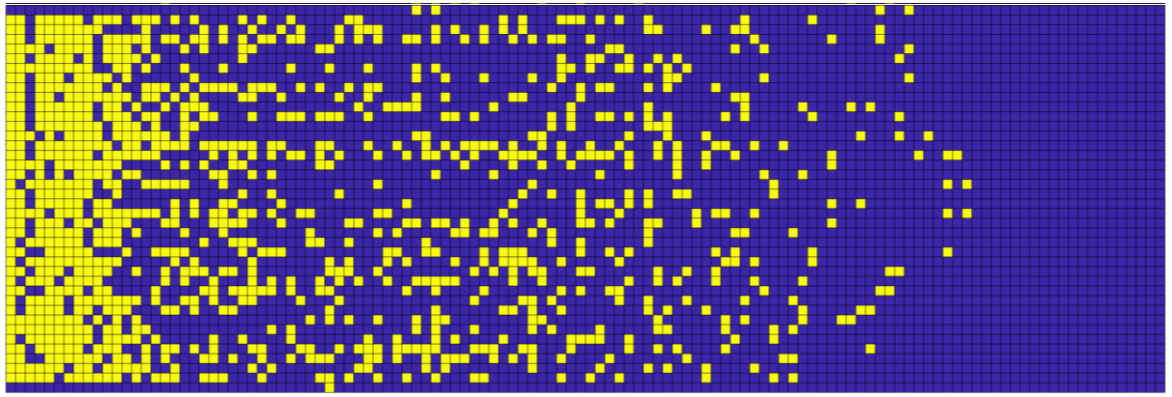
(a) 12.5 kPa inlet pressure

(b) 25 kPa inlet pressure



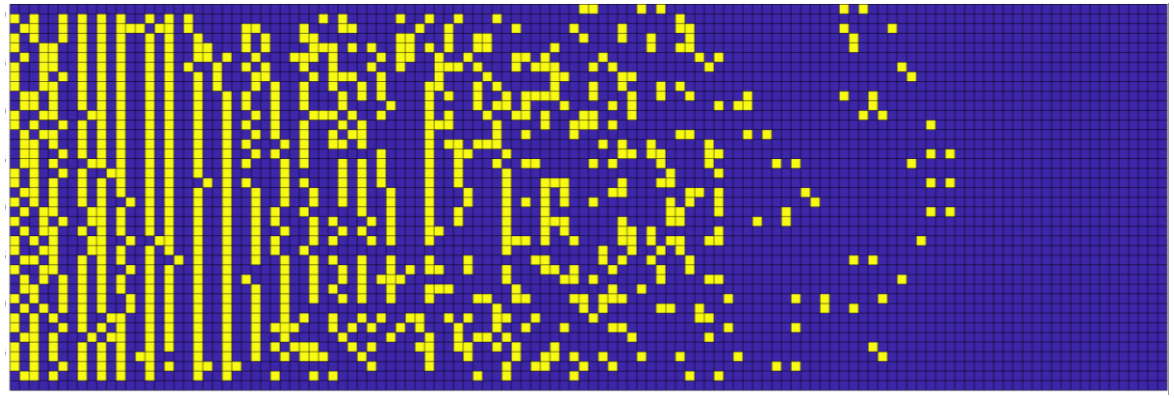
(c) 50 kPa inlet pressure

Figure 11: Variation of final particle distribution with inlet pressure



3. Results

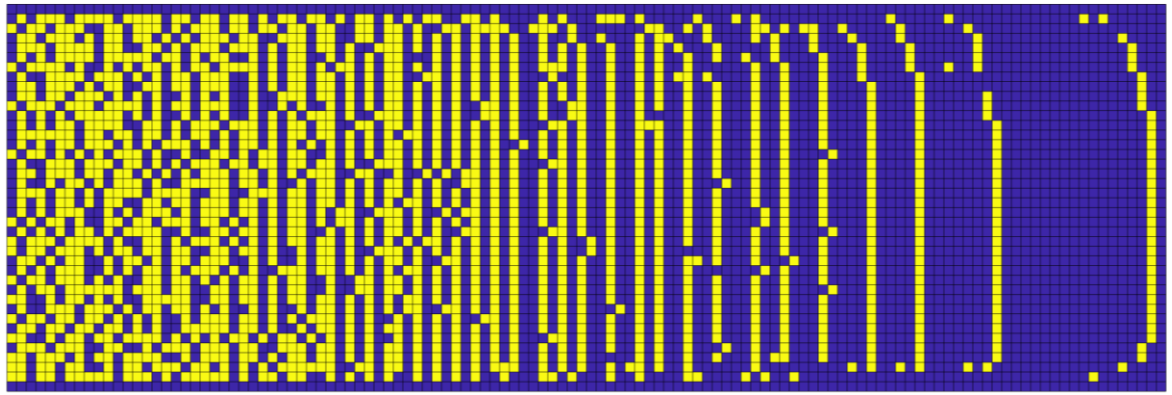
3.5. Influence of Particle Injection Conditions – Injection Rate



- The effect of injection rate on the final distribution of particles was also investigated.
- The results are analogous to those obtained for varying inlet pressure previously, as shown in Fig. 12.

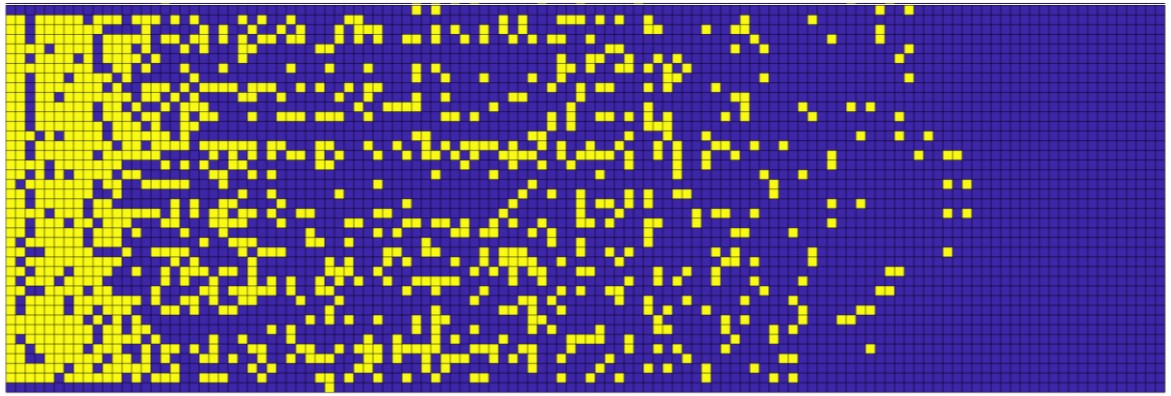
(a) 1 particle per second

(b) 1 particle per 2 seconds



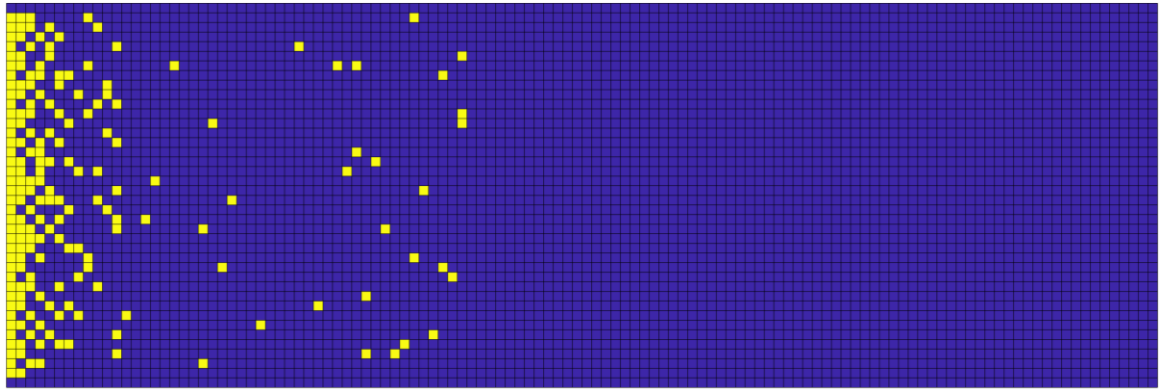
(c) 1 particle per 4 seconds

Figure 12: Variation of final particle distribution with particle injection rate



3. Results

3.6. Influence of Particle Size



- The particle size influences the rate of permeability reduction, as shown in Fig. 13.
- Larger particle sizes result in a rapid permeability reduction, leading to early particle accumulation and blockage (Fig. 13c).

(a) r = 0.4 mm

(b) r = 0.6 mm

(c) r = 0.8 mm

Figure 13: Variation of final particle distribution with particle size

3. Results

3.7. Trials with Radial Flow

- Particle transport via radial flow across a 2D mould was also investigated, where particles were introduced randomly.

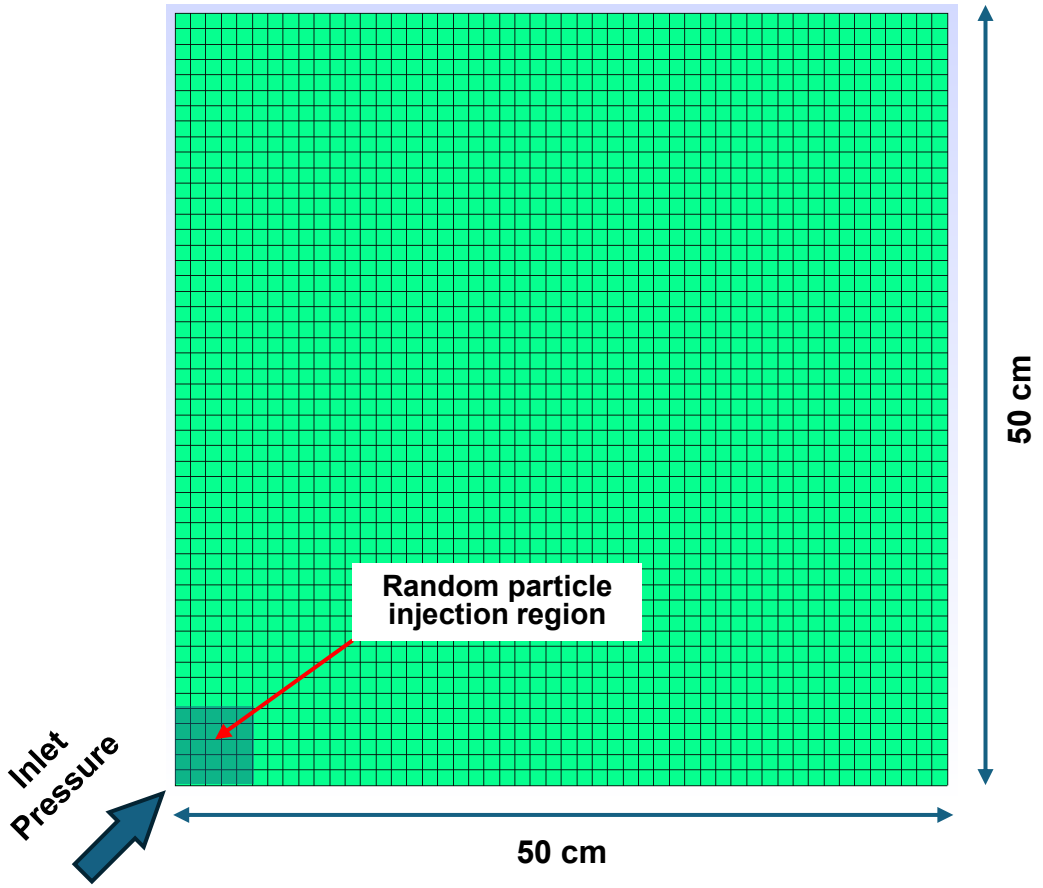


Figure 14: Radial flow geometry

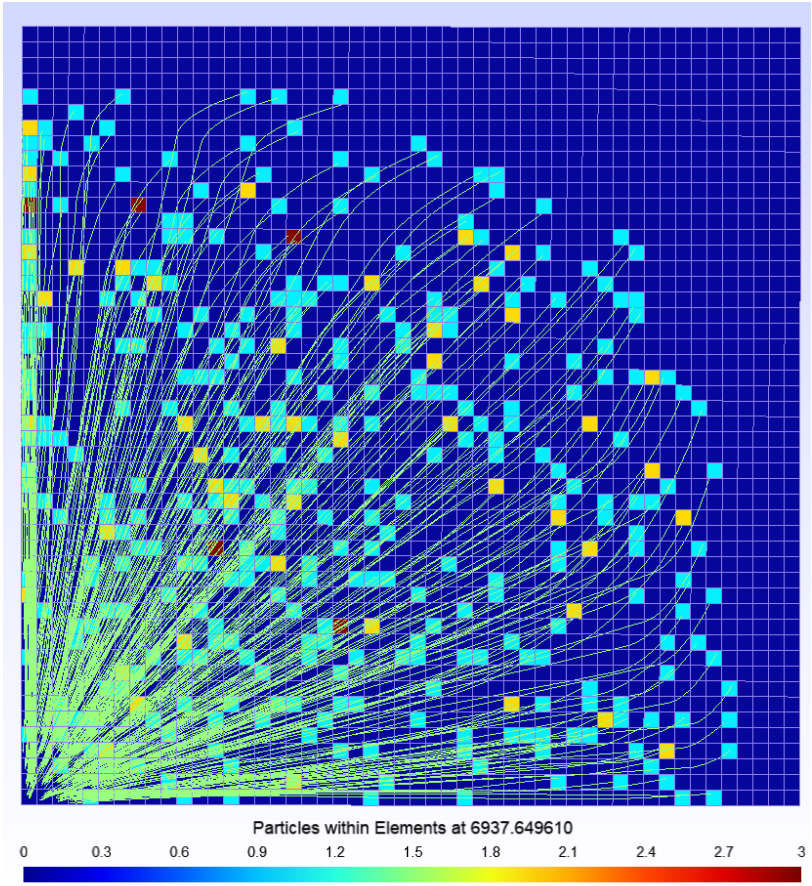

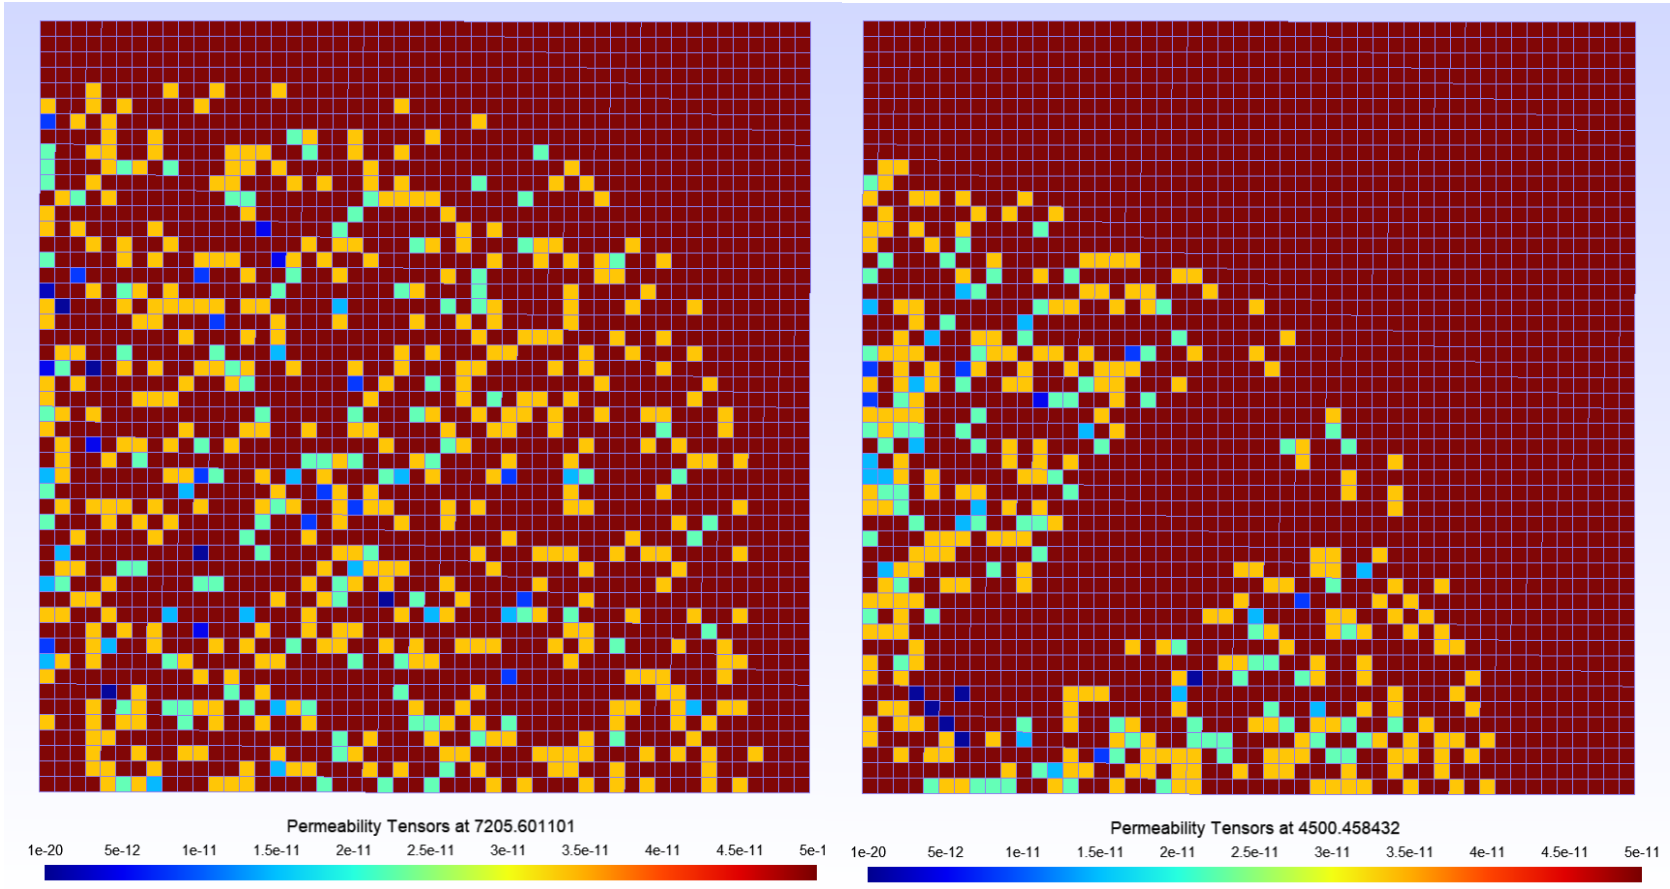

Figure 15: Particle evolution with time

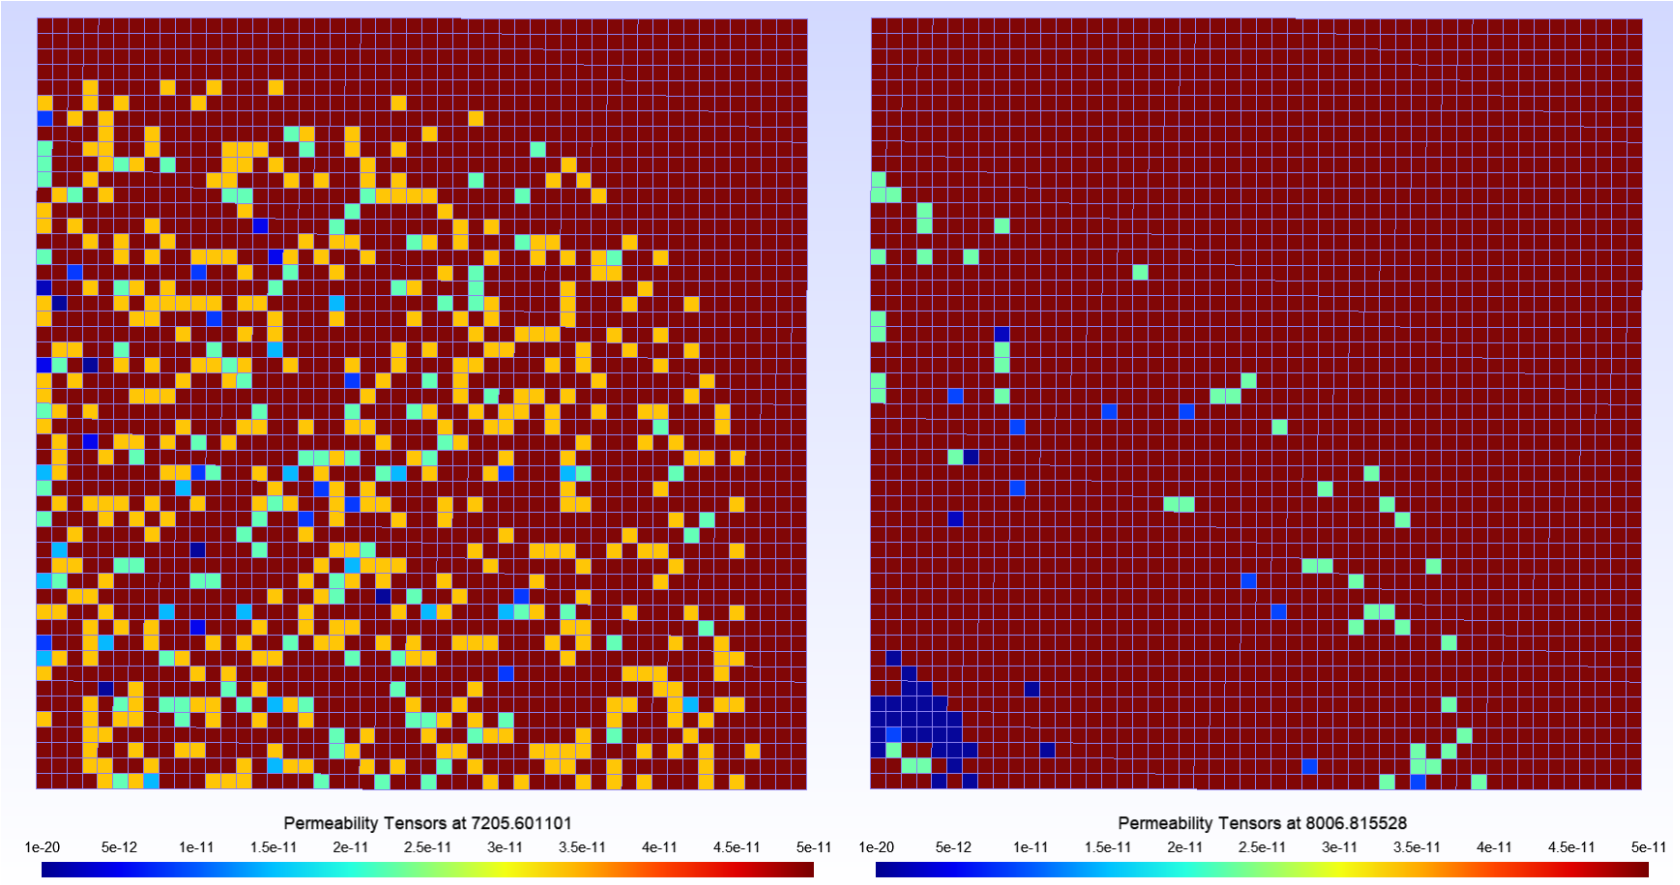
3. Results

3.7. Trials with Radial Flow

- The influence of injection rate and particle size on the final particle distribution was investigated.

- Similar to the linear flow, high injection rates resulted in particle accumulation and blockages near the inlet (Fig. 16) .

(a) 1 particle per 2 time steps



(b) 1 particle per 1 time step

Figure 16: Variation of final particle distribution with injection rate

3. Results

3.7. Trials with Radial Flow

- The influence of injection rate and particle size on the final particle distribution was investigated.
- Similar to the linear flow, high injection rates resulted in particle accumulation and blockages near the inlet (Fig. 16) .
- This was also the case for larger particle sizes (Fig. 17).

(a) r = 0.20 mm (b) r = 0.25 mm

Figure 17: Variation of final particle distribution with particle size

4. Summary and Outlook

- The transport of finite particles during resin impregnation was modelled and simulated using LIMS and MPI.
- Pressure and velocity fields are solved using LIMS, and these are used by a worker script to transport the particles.
- Updated permeabilities computed by the worker were sent back to LIMS, allowing fully coupled simulations.
- The influence of inlet pressure, injection rate, particle size and mould geometry were investigated.
- Simulating flow through further complex 3D mould geometries with varying particle sizes need to be explored.
- Particle mobility needs to be modelled and incorporated into the programme.

[2]High Performance Textiles Pvt. Ltd., Sonipat, Haryana-131101, India

ABSTRACT

The safety of workers in hazardous environments depends on advanced protective textiles capable of withstanding various real-world challenges, especially in automotive, glass, aerospace, mining, construction, and food industries where cut hazards are prevalent. Developing flexible, high-performance protective textiles is essential to meet these needs. Ultra-high-molecular-weight polyethylene (UHMWPE) is widely utilized in cut-protective textiles for its exceptional strength and durability. This study investigates the cut-performance of stainless-steel and glass fibers reinforced UHMWPE knitted fabrics under real-world industrial conditions, focusing on the impact of varying cutting angles, outdoor environments, and thermal exposure on their cut-protective efficacy in industrial and occupational settings. Reinforcement significantly affects cut-performance, with stainless-steel reinforced UHMWPE fabric (13SU) exhibited the highest tear strength (lengthwise-313.1 N, widthwise-405.8 N) and abrasion resistance (withstanding up to 800 rubbing cycles), providing superior cut-protection with cut force of 32.43 N at a 90° cutting angle. Differential scanning calorimetry (DSC) and scanning electron microscope (SEM) characterizations revealed UHMWPE's sensitivity to thermal effects, with a significant decrease in crystallinity after exposure to radiant heat flux of 20 kW/m^2 at fabric surface, leading to diminished cut-performance. Environmental durability assessments showed degradation due to galvanic corrosion, forming ketone (C=O) and hydroxyl (O-H) polar groups that altered the UHMWPE polymer structure and reduced peak intensity, as confirmed by Fourier-transform infrared (FTIR) spectroscopy. This study would be highly beneficial for industrial employees in choosing the right cut-protective fabrics based on their specific environments and working conditions.

Highlights

- Development of stainless-steel and glass fiber reinforced UHMWPE fabrics.
- TDM-100 is integrated with radiant heater to assess cut-performance under heat.
- Reinforced UHMWPE fabrics shows higher cut-performance than 100% UHMWPE fabric.
- Cut protection is highest at 90° cutting angle.
- Glass reinforced UHMWPE fabric offers better cut-protection under heat.

Keywords: UHMWPE, cut-resistance fabric, glass fibers, stainless-steel, crystallinity, composite yarns, radiant heat exposure.

1. INTRODUCTION

Occupational safety remains a critical concern worldwide, with millions of workers facing potential hazards in industries such as manufacturing, construction, and emergency services. According to the International Labour Organization (ILO), over 317 million work-related injuries occur annually, and more than 320,000 people die, leading to significant human and economic costs. Among these, injuries from sharp objects and exposure to extreme environmental conditions are particularly common, underscoring the need for effective protective measures.[1] In response to these safety challenges, various protective clothing has been designed, such as cut-resistant gloves, bulletproof vests, stab-proof suits, and protective helmets.[2-4] These advancements are intended to help the human body better withstand or even completely avoid injuries caused by sharp objects and other hazardous impacts.[5, 6] However, traditional protective solutions such as leather garments, wire mesh steel, and steel gloves have faced several limitations, including discomfort, reduced dexterity, and inadequate protection.[7] In contrast, modern protective textiles are developed using high-performance fibers such as ultra-high-molecular-weight polyethylene (UHMWPE),[8, 9] aramids,[10-12] polyphenylene benzobisoxazole (PBO) fiber,[13, 14] as well as inorganic fibers including, glass fibers,[15, 16] carbon fibers,[17] and basalt fibers[18] exhibit excellent mechanical properties, and have proven to be an effective approach for preparing cut-/puncture resistant textile materials. These advanced materials offer superior protection without compromising on dexterity or comfort. Mayo and Wetzel[19] studied the cut-resistance properties of both inorganic and organic high-performance single fibers and attributed their effectiveness to the fibers to their isotropic and anisotropic structures.[19] Additionally, a U.S. patent titled ‘Criminology’ suggests using glass fiber as a cut-resistant material, highlighting its exceptional ability to protect against sharp objects like knives and cones.[20] In a comparative study, Tuba Alpyildiz[21] developed a double-sided knitted fabric

using yarn wrapped with Kevlar 1414 fiber, which exhibited significantly higher cut-resistance than traditional weft-knitted fabrics.[21] Javid et al.[22] developed knitted gloves using a combination of core yarns like stainless-steel filament, Kevlar filament, staple spun Kevlar, and glass filament, with sheath yarns made of 100% viscose rayon, 50/50 polyester/viscose rayon blend. Their testing revealed that gloves utilizing dual-core yarns, especially those incorporating both filament and staple spun Kevlar, demonstrated superior performance in cut, tear, puncture, and abrasion resistance properties.[22] Cut-resistance clothing is primarily produced using knitting and weaving techniques, with knitting being favored for its stretchability, flexibility, and lightweight properties.[23] Research by Flambard et al.[24] found that knitted structures made from high-performance fibers offer better energy absorption during impact, making them more effective for protective clothing than woven fabrics.[24, 25]

Numerous studies have examined the mechanical properties of high-performance single fibers under various conditions, including tension at both high and low strain rates[26, 27], torsion[28, 29], and transverse compression.[30] When cutting a single fiber under tension, the fiber likely undergoes a combination of loading modes, which may include aspects of these mechanisms along with in-plane shear.[31-36] UHMWPE fiber has a molecular weight exceeding one million[37], it demonstrates significantly higher strength and cutting resistance than other fibers, making it notably difficult to cut. This exceptional durability has led to the extensive use of UHMWPE-based knitted cut-resistant protective gear, including gloves, vests, socks, and t-shirts, across various global industries to protect workers. The cut performance of these fabrics is influenced by several factors, such as outdoor environmental conditions, cutting angles, the type of reinforcement used in the core of the UHMWPE yarn, and thermal exposure. However, the impact of these factors, particularly the influence of heat, has not been previously critically analyzed. UHMWPE fibers are especially sensitive to temperature due to their relatively low melting point, below 150 °C,[38, 39] which can significantly affect their cut performance.

In this study, cut-resistant knitted fabrics were produced on 13-gauge gloves knitting machine using UHMWPE core-spun composite yarn reinforced with stainless-steel and glass fibers. The effects of various factors, including core reinforcement (stainless-steel and glass fibers), outdoor environmental exposure (up to 90 days), different cutting angles (0°, 45°, 90°), and radiant heat exposure (heat flux density of 20 kW/m^2 at mandrel), on the mechanical and cut-resistant properties were critically analyzed. To assess the impact of radiant heat on cut performance, the cut-resistant testing instrument, a tomodynamometer, was integrated with an external radiant heat exposure lamp, enabling the cut performance evaluation of the developed

samples under controlled heat conditions. This study offers critical findings that can help employees in various industries by guiding the selection of more durable and effective cut-resistant protective gear, particularly in environments with extreme conditions such as high temperatures and outdoor exposure.

2. EXPERIMENTAL DETAILS

2.1 Materials

The commercially available high-performance yarns such as 100% UHMWPE, as well as stainless-steel and glass-reinforced UHMWPE core spun composite yarns were directly sourced from HPT Pvt Ltd in Sonipat, Haryana, India. The core spun composite yarns were produced by using ring spinning process, wherein UHMWPE fibers as sheath layer and polyester fibers as intermediate layer were wrapped out with reinforced materials such as stainless-steel and glass fibres, as shown in **Figure 1 a-c**. The inclusion of intermediate layer significantly enhances the stability of the resulting yarn, preventing the core materials from coming out. The physical properties of sourced yarns are illustrated in **Table 1**.

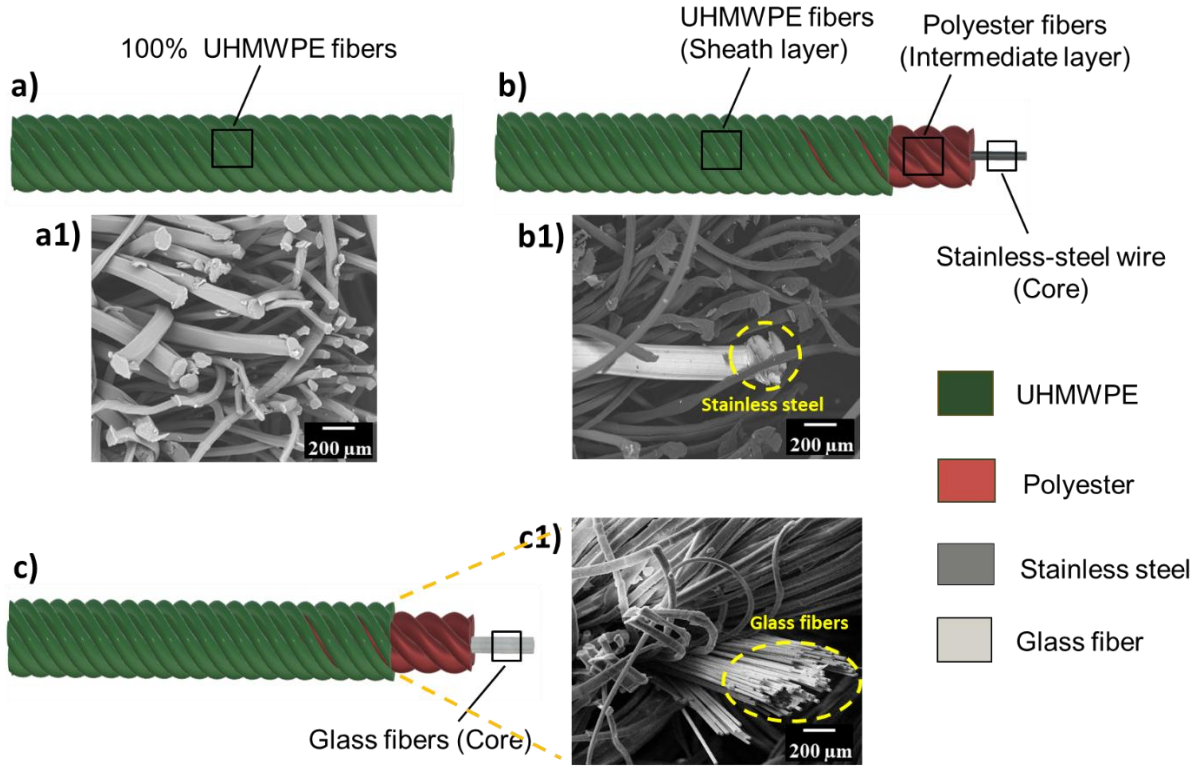

Figure 1. Schematic representation of yarn structural configuration and cross-sectional SEM images of **(a, a1)** 100% UHMWPE yarn, **(b, b1)** stainless-steel reinforced UHMWPE composite yarn, **(c, c1)** glass fiber reinforced UHMWPE composite yarn.

Table 1. Physical properties of 100% UHMWPE and core spun composite yarns

Sr. No.	Yarn type	Sheath layer		Intermediate layer		Core	
		Fiber	Fineness (Denier)	Fiber	Fineness (Denier)	Fiber	Fineness (Denier)
1	100% UHMWPE	UHMWPE	800	-	-	-	-
2	Stainless-steel/UHMWPE	UHMWPE	400	Polyester	150	Stainless-steel	200
3	Glass Fibers/UHMWPE	UHMWPE	400	Polyester	150	Glass fiber	200

Breaking load (N)	80.4	99.5	96.8
Tenacity (gf/den)	11.3	12.6	12.3
Young modulus (gf/den)	282.1	301.5	351.5
Diameter (mm)	0.82	0.85	0.85

2.2 Fabrication of cut resistance samples

The knitted cut-resistance fabrics in form of gloves were prepared on 13-gauge computerized gloves knitting machine (SHIMA SEIKI SFG-I). These glove samples are produced using the tubular knitting technology that creates a dual-layer structure, with each layer utilizing a single jersey pattern, resulting in the formation of a hollow space (pocket) between the layers (in Finger part and palm part), as shown in **Figure 2 b.** The gloves samples made from 100% UHMWPE, glass fibers-reinforced UHMWPE, and stainless-steel fibers-reinforced UHMWPE composite yarns are designated as 13U, 13GU, and 13SU, respectively. The microscopic image of the 13SU gloves is depicted in **Figure 2 d**.

Fabrication of cut resistance knitted gloves: **(a)** arrangement of loops in the needle bed on gloves knitting machine; **(b)** schematic representation of loops arrangement on needle bed during formation of finger part and palm part of the glove; **(c)** developed glove samples; **(d)** microscopic image of 13SU glove sample.

2.3 Characterization and measurement techniques

The physical characteristics of the single jersey knitted fabric, such as thickness and GSM (grams per square meter), were measured following ASTM standards D177 and D3776, respectively. The mechanical properties of the 100% UHMWPE and core-spun composite UHMWPE yarns were determined according to ASTM D2256-02. The cut resistance of all samples was evaluated using a tomodynamometer (TDM-100) cut testing instrument. Before testing, the samples were conditioned for 24 hours in a controlled environment with a temperature of 20 ± 2 °C and a relative humidity of 65 ± 4% as per standard procedures.

2.3.1 Measurement of cut-resistance properties

The cut-resistance properties of all samples were measured according to standard ISO 13997 using instrument tomodynamometer (TDM-100), as shown in **Figure 3 a.** According to this test method, sample with size of 7x7 cm fixed on mandrel by mounting tape (**Figure 3 b**), and the force required for a blade to cut the samples after a sliding displacement of 20 mm at constant speed of 2.5 mm/sec is measured. Each sample were cut 15 times under varying loads, such as the cut distances ranging from 5 mm to 15 mm, 15 mm to 30 mm, and 30 mm to 50

mm. Throughout each test, the applied loads and corresponding cut distances were collected, then corrected cut through distances (CCTD) were calculated by following **Equation 1**.

$$\text{Corrected cut through distance (CCTD)} = \frac{20}{d_o} \times d \quad (1)$$

Where d_o represents the calibration cut-through distance, calculated as the average distance from five blades on a chloroprene standard sample, and d is the cut distance measured for the test sample.

Using this data, an optimal regression line fitting curve of CCTD and load (N) was plotted (**Figure 3 c**). The load corresponding to CCTD of 20 mm was considered as characteristic cut protection force.

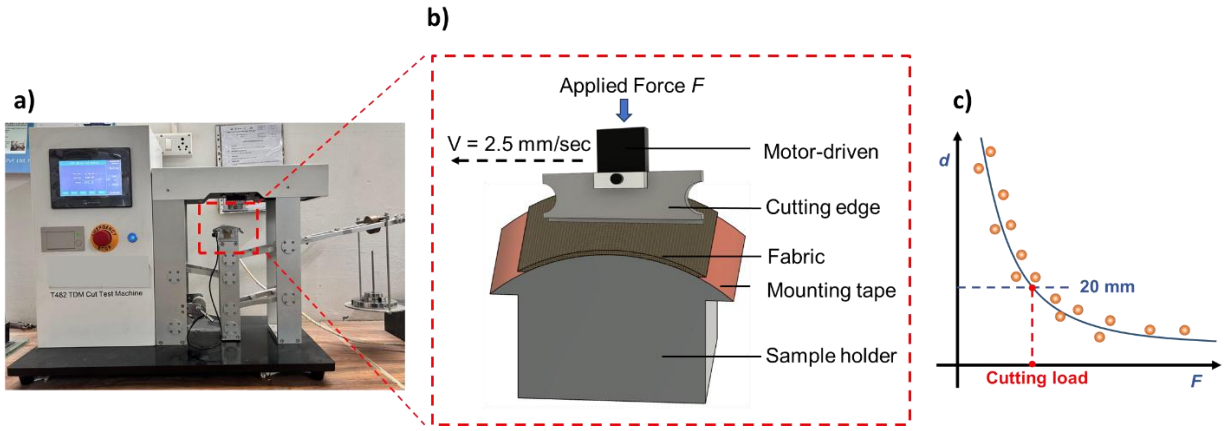

Figure 3. (a) TDM-100 cut testing instrument (b) schematic view of performing cut testing (c) plot of corrected cut through distance (CCTD) verses applied load and resulting cutting load at 20-mm CCTD.

2.3.2 Testing setup for cut performance under radiant heat exposure

The influence of radiant heat exposure on cut performance was assessed by radiant heat lamp based tomodynamometer (**Figure 4**). The heat flux was calibrated by adjusting the distance between the radiant heat lamp and the mandrel of the TDM-100. It was determined that at a distance of 28.5 cm, the heat flux density at the mandrel reached 20 kW/m². This specific heat flux was chosen based on the ISO-11612 standard, "Protective clothing – Clothing to protect against heat and flame – Minimum performance requirements," which recommends exposing protective fabrics to a radiant heat source of 20 kW/m² for a specified duration to evaluate their internal structure and shall meet at least performance Level C1. If the temperature rise within the fabric remains below a certain threshold, the material is deemed suitable for use in high-

heat environments. The heat flux from the radiant source can be adjusted depending on the intended application. After exposing the samples to radiant heat for 5 minutes, the lamp was turned off, and the cut resistance properties was measured as discussed in section **2.3.1**.

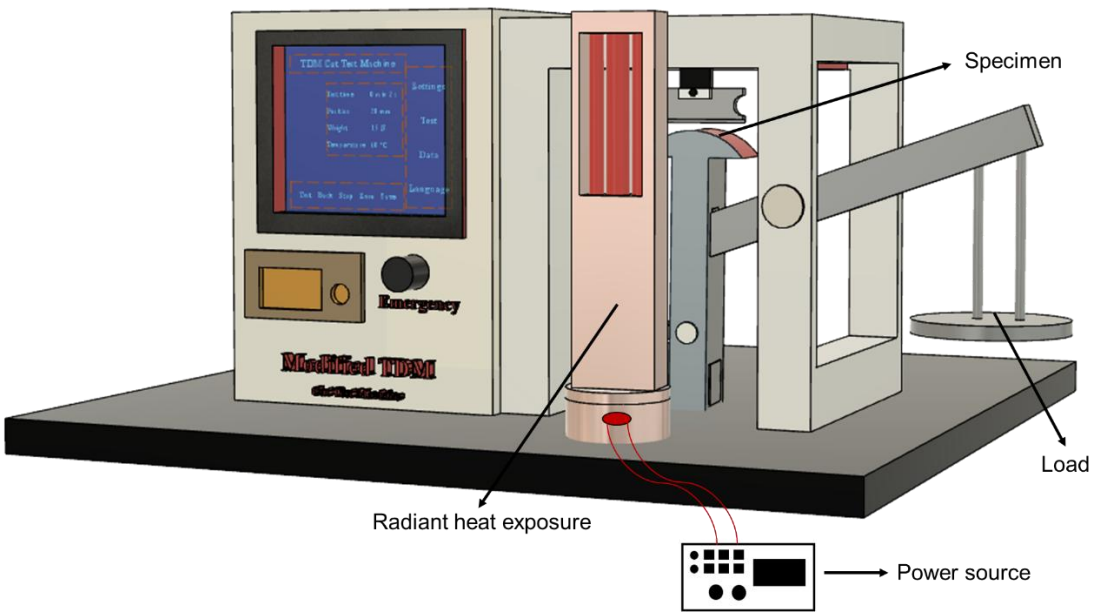

Figure 4. TDM-100 integrated with radiant heat exposure lamp.

2.3.3 Mechanical properties evaluation

The mechanical properties of all samples, including tear resistance, puncture resistance, and abrasion resistance, were evaluated according to the EN 388:2016 standard. Tear and puncture resistance tests were conducted using an electronic universal testing machine (**Supporting Figure S1**), while abrasion resistance was measured with a Martindale abrasion tester, as shown in **Supporting Figure S3**. For the tear resistance test, samples were prepared by making a 50 mm longitudinal incision on one side of 100 × 50 mm fabric strips, creating a "pants" shape (**Supporting Figure S2**). The grips of the mechanical testing frame were clamped onto the two "legs" of each sample, which were then pulled apart at a constant speed of 100 mm/min. Load-extension data were continuously recorded to determine the maximum force that the fabric could withstand before tearing. In the puncture resistance test, samples were cut into 40 mm diameter circles, and a needle was allowed to move downwards at a constant speed of 100 mm/min until it fully penetrated the fabric. The force required to achieve full penetration was recorded as the puncture load. For the abrasion resistance test, the samples with a diameter of

38 mm were cut from each fabric sample. Each sample was tested against a standard abradant fabric (180-grit, Klingspor PL31B) under a pressure of 9 kPa, and specimens were subjected to abrasion cycles until the hole formation observed.

2.3.4 Durability assessment in open environmental conditions

The durability evaluation of cut resistance fabrics under open environmental conditions is essential because these fabrics are often exposed to factors like sunlight, moisture, and temperature fluctuations in real-world use. Over time, external elements may affect mechanical and cut-resistant properties of the fabrics. This evaluation helps ensure that the fabrics maintain their protective performance over time, providing reliable safety for users. Samples of 13U, 13SU, and 13GU fabrics were exposed to outdoor conditions for 90 days, as depicted in **Figure 5**. The mechanical properties and cut performance of these fabrics were systematically assessed at 30 days intervals to analyse any changes in their durability and effectiveness throughout the exposure period.

Figure 5. Investigation of environmental effect on the performance of 13U, 13GU, and 13SU samples.

2.3.5 Thermal analysis

Differential scanning calorimetry (DSC) was done using a Q2000V24.11 Build 124 DSC analyzer, with continuous nitrogen purging throughout the process. UHMWPE/Polyester blended samples were finely granulated (3–5 mg) and sealed in aluminium pans. The samples first underwent a heating cycle from the temperature of 0 °C to 350 °C at a rate of 10°C/min.

This was followed by rapid cooling (quenching) to 0 °C, where the samples were held for 8 minutes to achieve equilibrium. The melting temperature (T_m) and crystallization temperature (T_c) were identified as the inflection point in the DSC thermograms.

2.3.6 Chemical structure analysis

Fourier Transform Infrared Spectroscopy (FTIR) was used to analyze the effects of environmental conditions on the structure of UHMWPE polymer chains and their molecular interactions. The analysis was conducted using a Nicolet iS50 spectrophotometer, equipped with an attenuated total reflectance (ATR) mode featuring a zinc selenide crystal. Spectra were recorded in the range of 4000–400 cm^{-1}, with a resolution of 4 cm^{-1}, after performing 64 scans to ensure detailed and accurate results.

2.3.7 X-ray diffraction

X-ray diffraction (XRD) analysis was performed using an XPert Pro PANalytical X-ray diffractometer to assess the crystallinity percentage and the impact of radiant heat exposure on the crystal planes within the fabric structures. The samples were scanned over a diffraction angle range of 2θ from 0° to 40°, with a scanning speed of 4°/min and a step size of 0.02°. The XRD instrument operated under conditions of 40 keV and 40 mA.

2.3.8 Surface morphology characterization

The microscopic images and surface morphology of fabric structures subjected to cut tests under radiant heat exposure and different cutting angles were examined using an optical microscope and a Zeiss EVO 18 scanning electron microscope (SEM). SEM imaging was conducted in a vacuum environment with an acceleration voltage of 20 kV.

3 RESULTS AND DISCUSSIONS

The physical characteristics of the developed samples, such as course per inch (CPI), wales per inch (WPI), stitch density, loop length, fabric thickness, and areal density were assessed and are detailed in **Table 3**. The findings indicate that after reinforcement of stainless-steel and glass fibers into the core, there was no significant increase in the areal density of any of the samples, indicating it is suitable for use in comfortable protective clothing. There are several factors that can influence the cut resistance properties, including core reinforcement, cutting angles, exposure to outdoor environmental conditions, and radiant heat exposure. These factors

have been studied in next subsection to evaluate their effects on fabric performance and durability.

Table 3. Physical characteristics of developed fabric samples

Properties	**13U**	**13GU**	**13SU**
CPI/WPI	22/15	24/16	26/15
Loop length (mm)	6.5	5.8	5.7
Stitch density (loops/inch^2)	330	384	390
Tightness factor	13.4	16.2	15.9
Areal density (g/m^2)	305 ± 5	355 ± 5	320 ± 5
Thickness (mm)	0.87	0.95	0.93

3.1 Effect of core reinforcement

3.1.1 Tear resistance properties

Tear strength of samples was determined in lengthwise and widthwise direction using ZWICK instrument with gauge length of 40 mm and at a constant speed of 100 mm/min. **Figure 6 a-c** illustrates the force-extension curves of all samples, demonstrating that as the tearing force were applied to the fabric, it increased exponentially until fabric tear. This is due to as the force increase, the yarns bunches together, which requires high force to stretch and break them. At a higher force, the curve begins to oscillate because of the fabric starts to tear one yarn at a time until at a higher force all jam up yarns ruptures at once. And it was observed from the curves that the amplitude of the oscillations in widthwise direction larger than lengthwise direction across all samples. This implies that the material in widthwise direction experiences more significant slipping or rearrangement events under stress, resulting in higher tear strength in the width-wise direction across all samples compared to lengthwise direction. (**Figure 6 d**) This phenomenon can also be attributed to the mechanics of tear propagation in weft knitted structures. When initiating a tear in the lengthwise direction of the fabric, the strain experienced in the fabric's course direction allows for greater mobility of yarn. This is attributed to higher extensibility of single jersey knitted structures in the fabric's course direction compared to the wales direction. Consequently, as the tear progresses in the lengthwise direction, the stress in

the fabric's wales direction, which is inherently less extensible, acts to restrict the mobility of the yarns. This restriction occurs because the loop in the wale or needle way has tied at the head and at the leg of the loop, resulting in minimal elongation when force is applied. As a result, a higher force is required to tear the fabric in the widthwise direction.

Figure 6 d shows that 13SU fabric highest tear strength in length wise and widthwise direction, which is 313.1 N and 405.8 N, compared to 13GU (lengthwise-224.9 N, widthwise-326.5 N) and 13U (lengthwise-212.8 N, widthwise-275.6 N) fabric, it is due to higher the tenacity (12.6 gf/den) and young modulus (301.5 gf/den) of stainless-steel reinforced yarn, as shown in **Table 2**. Basically, in a core-sheath type of yarn, the core is expected to bear the load. Moreover, slippage occurs in the composites yarn between core and sheath fibers during the breaking process and thus core material has a great contribution to the tensile load sharing. So, stronger the core material higher will be the yarn and fabric tensile strength. As a result, stainless-steel and glass fibers reinforced UHMWPE yarn shows higher tensile strength compared to 100% UHMWPE staple spun yarn.

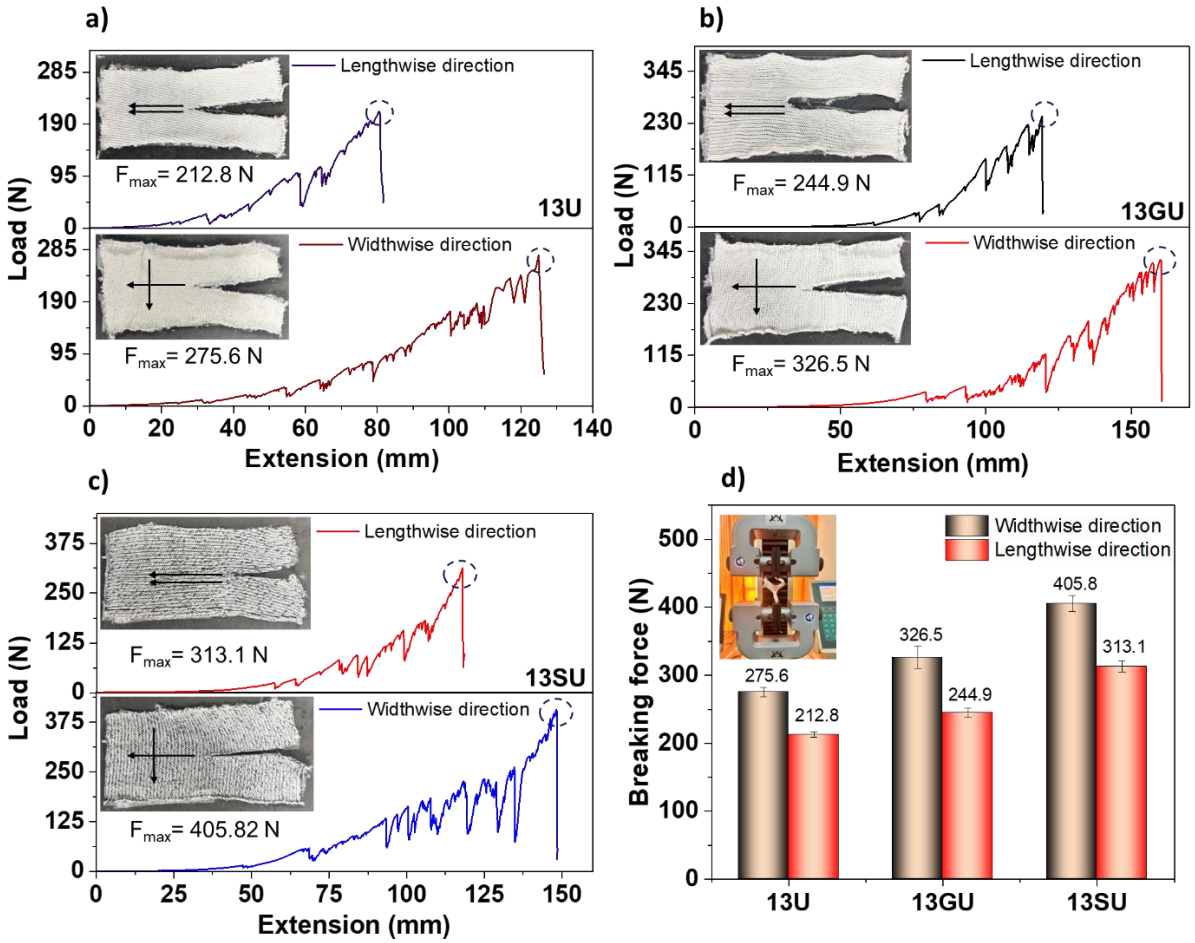

Figure 6. Load-extension curves of (a) 13U, (b) 13GU, and (c) 13SU fabrics in lengthwise and widthwise directions. (d) Comparison of breaking force required for the samples.

3.1.2 Puncture and abrasion resistance properties

All fabric samples were fixed for quasi-static puncture resistance experiments (**Figure 7 a**), and the results showed that the reinforced fabric samples (13SU and 13GU) had significant differences in their mechanical behaviour under stress compared to 13U fabric. The maximum puncture load was highest for the 13GU fabric at 111.97 N, which is 1.25 times higher than that of the 13U fabric (89.47 N), followed by 96.25 N for the 13SU fabric (**Figure 7 f**). This variation in puncture resistance is largely due to the reinforcing materials (glass fibers and stainless-steel fibers) used in the 13GU and 13SU fabrics, which significantly enhance their ability to resist puncture compared to the pure UHMWPE fabric. The presence of glass fibers in 13GU and stainless-steel in 13SU increases the energy required to penetrate the fabrics, as these reinforcements effectively distribute the stress across a larger area and absorb more energy before failure. Additionally, the 13GU fabric exhibited excellent energy dissipation

performance throughout the probe puncture phases I, II, III, and IV (**Figure 7 e**), indicating the excellent synergistic toughening properties. Friction and fiber slipping also play crucial roles in determining puncture resistance. The reinforced 13SU and 13GU fabrics create higher frictional resistance against the puncturing probe, which prevents easy fiber movement and slipping, thereby requiring more force for penetration. In contrast, the 13U fabric, lacking such reinforcements, has lower inter-fiber friction, allowing the fibers to slip more easily around the puncture point, which results in lower puncture resistance. Additionally, the strong bonding between UHMWPE fibers and the reinforcing materials in 13GU and 13SU contributes to their higher puncture resistance. Glass fibers, being stiffer and having higher hardness than stainless-steel,[40] create a rigid and well-bonded structure in 13GU, leading to the highest puncture load observed. Although stainless-steel in 13SU also enhances bonding and strength, the metal's relative flexibility compared to glass results in a slightly lower puncture load. The structural arrangement of fibers in the 13SU and 13GU fabrics, particularly the larger gaps between them, allows for more significant deformation and stretching around the puncture site before complete penetration. This is evident in the larger probe punctured openings observed in the 13GU and 13SU fabrics (**Figure 7 c-d**), whereas the 13U fabric, with smaller gaps between fibers (**Figure 7 b**), exhibits a lesser localized deformation and a pronounced "cross window" effect but with lower overall puncture resistance.

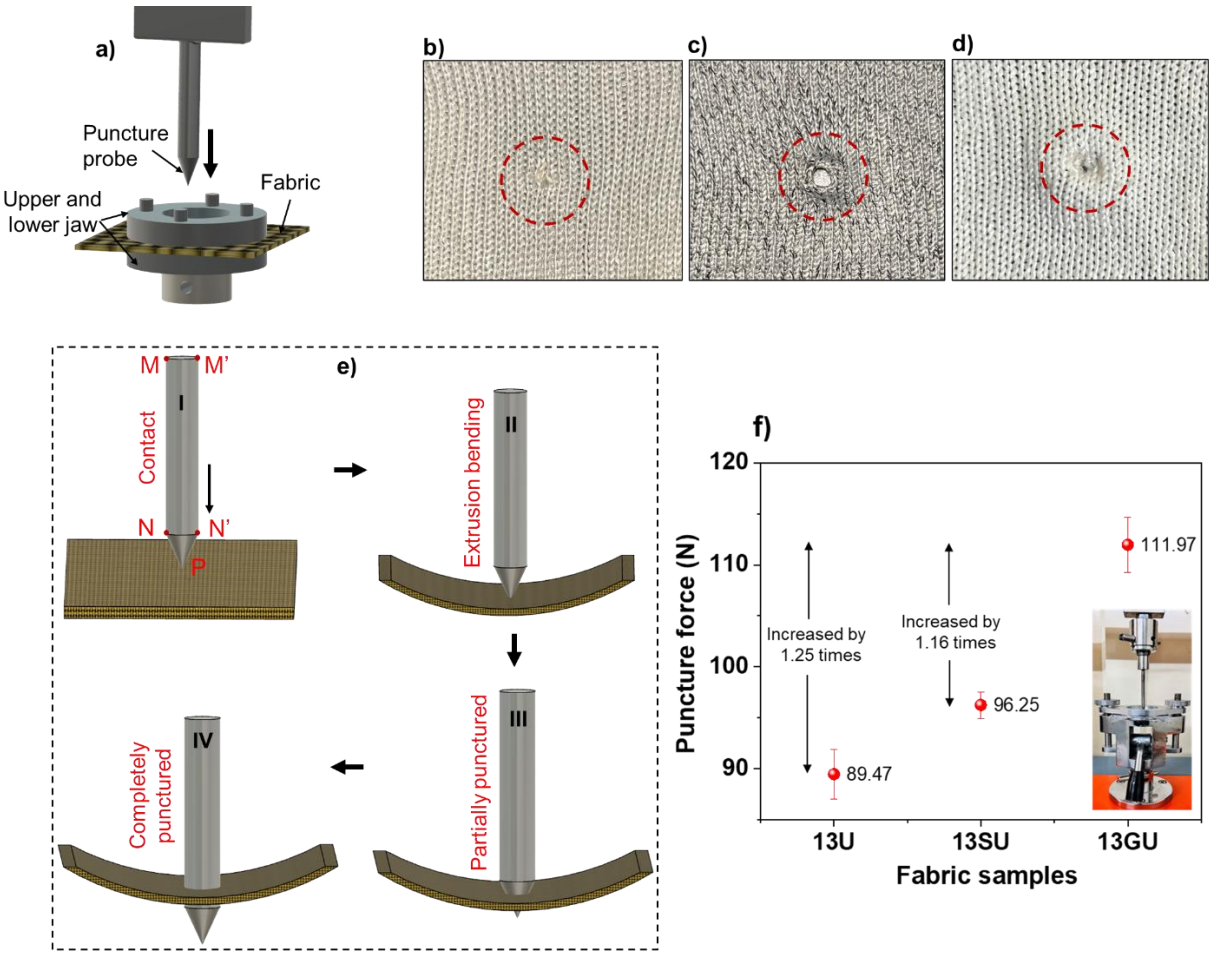

Figure 7. (a) Schematic representation of quasi-static puncture resistance test. Probe punctured deformation of (b) 13U, (c) 13SU, and (d) 13GU fabric samples. (e) Schematic diagram of the probe puncture process: **I** the puncture probe head just touched the fabric; **II** the puncture probe head started to compress the fabric; **III** the PN part of the puncture probe head pierced the fabric; **IV** the NM part of the puncture probe head entered the fabric completely. (f) Comparison of puncture force of the samples.

The abrasion resistance testing of 13U, 13SU, and 13GU fabrics was performed on Martindale abrasion tester, employing a Lissajous motion and rubbing against 180-grit Klingspor PL31B sandpaper under a pressure of 9 kPa. Abrasion resistance properties is generally influenced by factors such as, fabric thickness, GSM, tensile strength, and the type of the fibers used. The results shows that the 13SU fabric, reinforced with stainless-steel, exhibited superior abrasion resistance, with a hole forming at its surface after 800 cycles of rubbing. In contrast, the 13GU fabric, reinforced with glass fibers, showed a hole formation after 450 cycles, and the 13U fabric, composed of 100% UHMWPE, developed a hole after 350 cycles. (**Figure 8**)

The superior performance of 13SU can be attributed to the inherent properties of stainless-steel, which provide excellent resistance to abrasive forces, contributing to the fabric's high tensile strength of 804 N. The higher tensile strength enhances the fabric's ability to withstand repeated friction without significant material degradation. Additionally, 13SU recorded an extensibility of 72.3 mm/110.3 mm in lengthwise/widthwise direction before break (**Figure 10 j**), indicating a high ability to stretch under load, which plays a crucial role in its abrasion resistance. When the 13SU fabric comes into contact with the 180-grit Klingspor PL31B abrasive surface, its high extensibility allows it to deform and distribute the applied forces more evenly across the contact area. This results in a loose gripping contact with the abradant, reducing the localized stress and minimizing the damage, which in turn delays the onset of hole formation. In comparison, the 13GU fabric, while still exhibiting improved abrasion resistance over 13U, performed less favourably than 13SU due to the brittle nature of glass fibers. The tensile strength of 13GU was recorded at 569 N (lesser than 13SU), is compromised by the brittleness of glass fibers under abrasive conditions. When subjected to friction, the stiffness of the glass fibers causes a rigid response, and their brittle nature leads to breakage and dislodgement from the yarn structure, resulting in significant damage to the fabric surface and earlier hole formation. Additionally, the 13GU fabric has an extensibility of 61.6 mm/107.5 mm in the lengthwise/widthwise direction before breaking, which is lower than that of 13SU. This lower extensibility means the fabric cannot absorb and distribute abrasive forces as effectively, leading to greater damage under the same conditions. The 13U fabric, with a tensile strength of 264 N and an extensibility of 58.7 mm/99.45 mm in lengthwise/widthwise directions, exhibits the least resistance to abrasion. Its lower extensibility means that when it is subjected to frictional forces, the fabric is less able to deform and dissipate the energy generated by the abrasion. This results in a more concentrated stress on the contact area, leading to faster wear and earlier hole formation. The lack of reinforcing materials in 13U also results in a thinner fabric structure (0.835 mm) compared to 13GU (0.95 mm) and 13SU (0.93 mm), which further reduces its ability to resist abrasive forces.

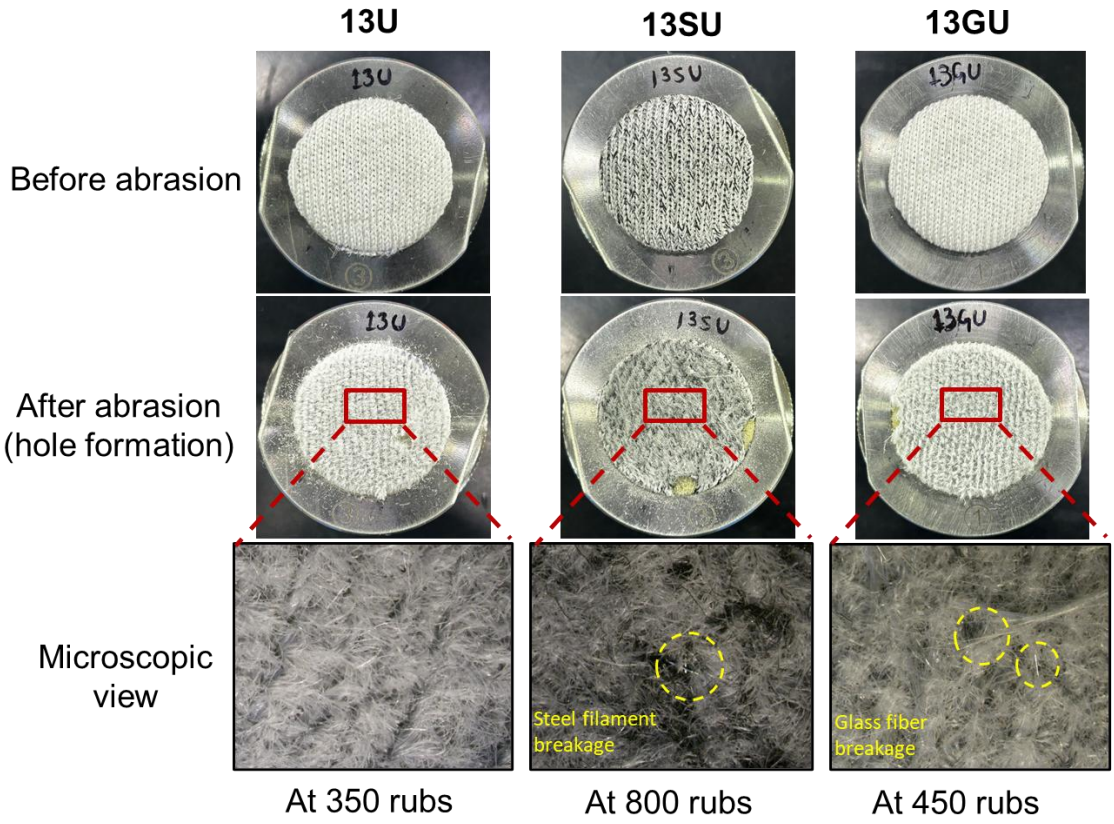

Figure 8. Optical microscopic images of the samples before and after abrasion testing until hole formation

3.1.3 Cut resistance properties

The procedure described in the **section 2.3.1** was used to evaluate the cut protection level of all fabrics. Regression curves were plotted for each sample, and the corrected cut-through distances at 20 mm were calculated from these curves to quantitatively evaluate the cut performance. As seen in **Figure 9 b-c**, the analysis revealed that cut performance of reinforced UHMWPE yarn fabrics (13SU and 13GU), was significantly superior to that of 100% UHMWPE fabrics (13U). Among the tested samples, the 13SU fabric exhibited the highest cut resistance properties, which can be thoroughly explained by XRD analysis of samples. As shown in **Figure 9 a**, the XRD peaks occurring at 21.5° and 23.9°, that are characteristic of the UHMWPE polymer. The peak intensities vary among the different fabrics, with the highest intensity observed in 13SU, followed by 13GU, and then 13U. The higher peak intensity in 13SU indicates a greater degree of crystallinity and molecular order, correlating with its superior mechanical properties and cut resistance. This increased crystallinity in 13SU, at 52.48%, can be attributed to the effective nucleating action of the stainless-steel fibers, which facilitate a more ordered alignment of polymer chains during the crystallization process. The

peak intensity in 13GU, while still higher than in 13U, reflects its relatively lower crystallinity at 51.75%, resulting in less mechanical strength compared to 13SU. The 13U fabric, with the lowest crystallinity at 48.37%, exhibits the weakest performance, as indicated by its lower peak intensity. These findings are further supported by tensile strength data, which shows that 13SU has the highest tensile strength at 804 N, followed by 13GU at 569 N, and 13U at 264 N, as discussed earlier. The enhanced tensile strength in 13SU is due to the strong interaction between the stainless-steel reinforcement and the UHMWPE fibers, enabling more effective load transfer and contributing to the material's overall mechanical strength. In comparison, glass fibers in 13GU, though beneficial, are more brittle and have a lower bonding efficiency with the UHMWPE matrix, resulting in slightly lower tensile strength.

The molecular structure of UHMWPE, primarily composed of $-CH_2-CH_2-$ units, is characterized by strong sigma (σ) bonds. However, these chains lack rigidity due to the absence of additional functional groups that could restrict chain mobility. The introduction of reinforcement materials alters this molecular structure by increasing crystallinity and improving mechanical properties. In 13SU, stainless-steel creates stronger van der Waals forces and electron cloud interactions between the polymer chains and the reinforcement material, contributing to a more stable and ordered structure that is better able to resist cutting forces. In contrast, 13GU, reinforced with glass fibers, has different interactions. Glass fibers are rigid and brittle, creating a composite with air pockets and weaker van der Waals forces compared to the metal-reinforced composite. This brittleness, along with the presence of air pockets, makes the material more susceptible to crack initiation and fracture under stress, reducing its cut resistance. During the cutting process, the behaviour of the fibers plays a crucial role. The stainless-steel in 13SU exhibits ductile cutting behaviour, deforming plastically before fracturing, which allows it to absorb more energy and resist cut-through more effectively. This ductility, combined with the strong bonding between the stainless-steel and the UHMWPE fibers, results in the highest cut resistance among the tested samples. In contrast, the lower friction coefficient of glass fibers, coupled with their brittle nature, results in a less effective resistance mechanism compared to 13SU.

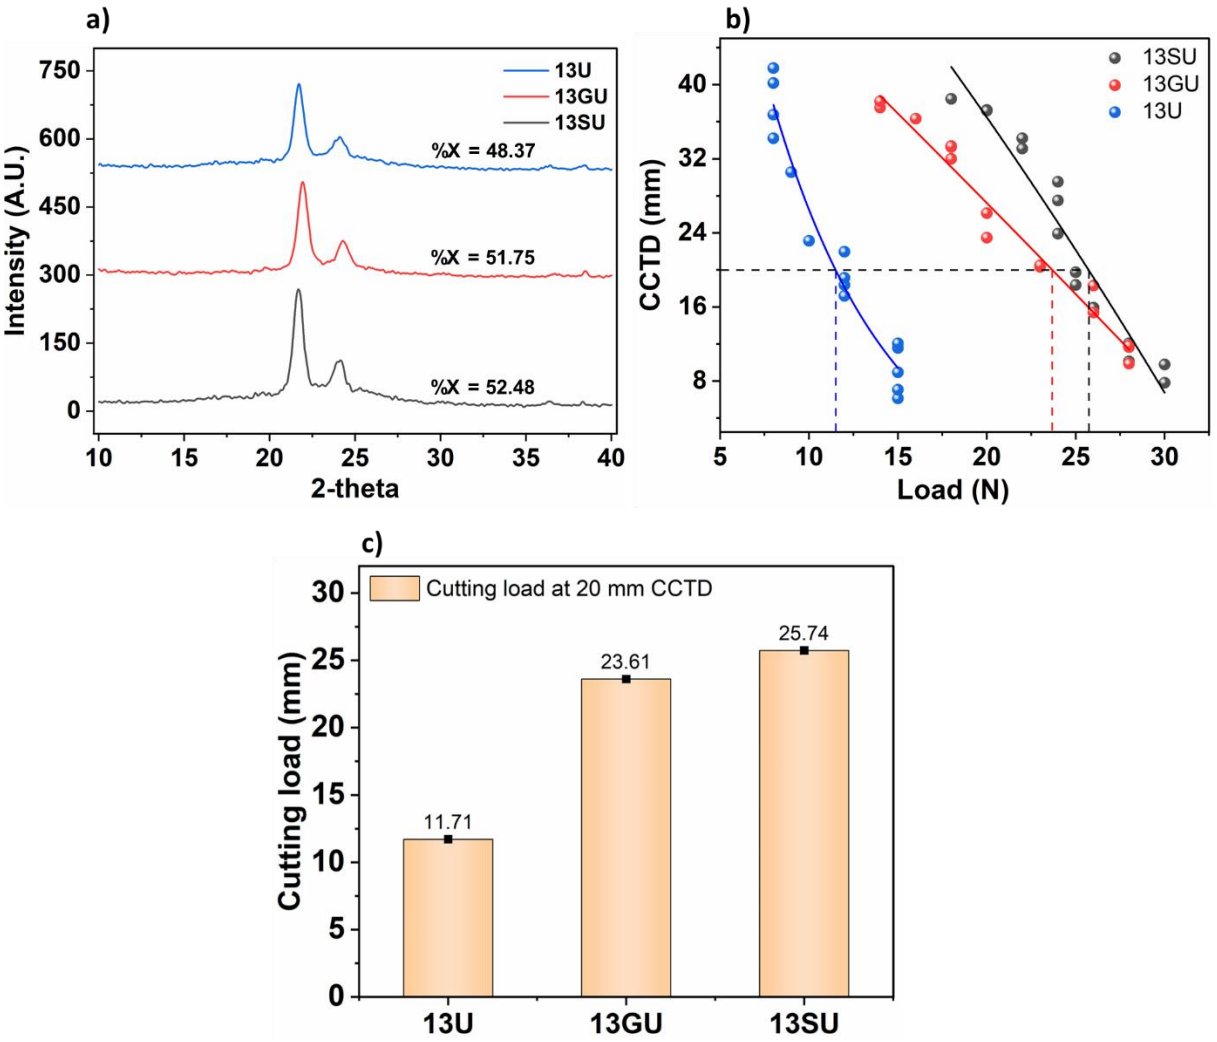

Figure 9. (a) XRD curve of fabric samples. (b) The CCTD-load data and regression line of fabric samples. (c) Comparison of cutting load at 20-mm CCTD derived from CCTD vs load curve.

3.2 Effect of cutting angles

The cut performance of all samples including 13U, 13GU, and 13SU were examined at varying angles 0°, 45°, and 90° (**Figure 10 d-f)**. At 0° (lengthwise direction), the cut forces for 13U, 13SU, and 13GU were 9.563 N, 22.609 N, and 21.784 N, respectively. At 45° (diagonal direction), the cut forces increased to 11.71 N, 25.747 N, and 23.61 N. The highest cut resistance was observed at 90° (widthwise direction), with values of 16.279 N for 13U, 32.431 N for 13SU, and 26.128 N for 13GU (**Figure 10 k**). The data indicates that the highest cut resistant values at 90° in all samples, while minimum cut resistant values occur at 0° and intermediate at 45°.

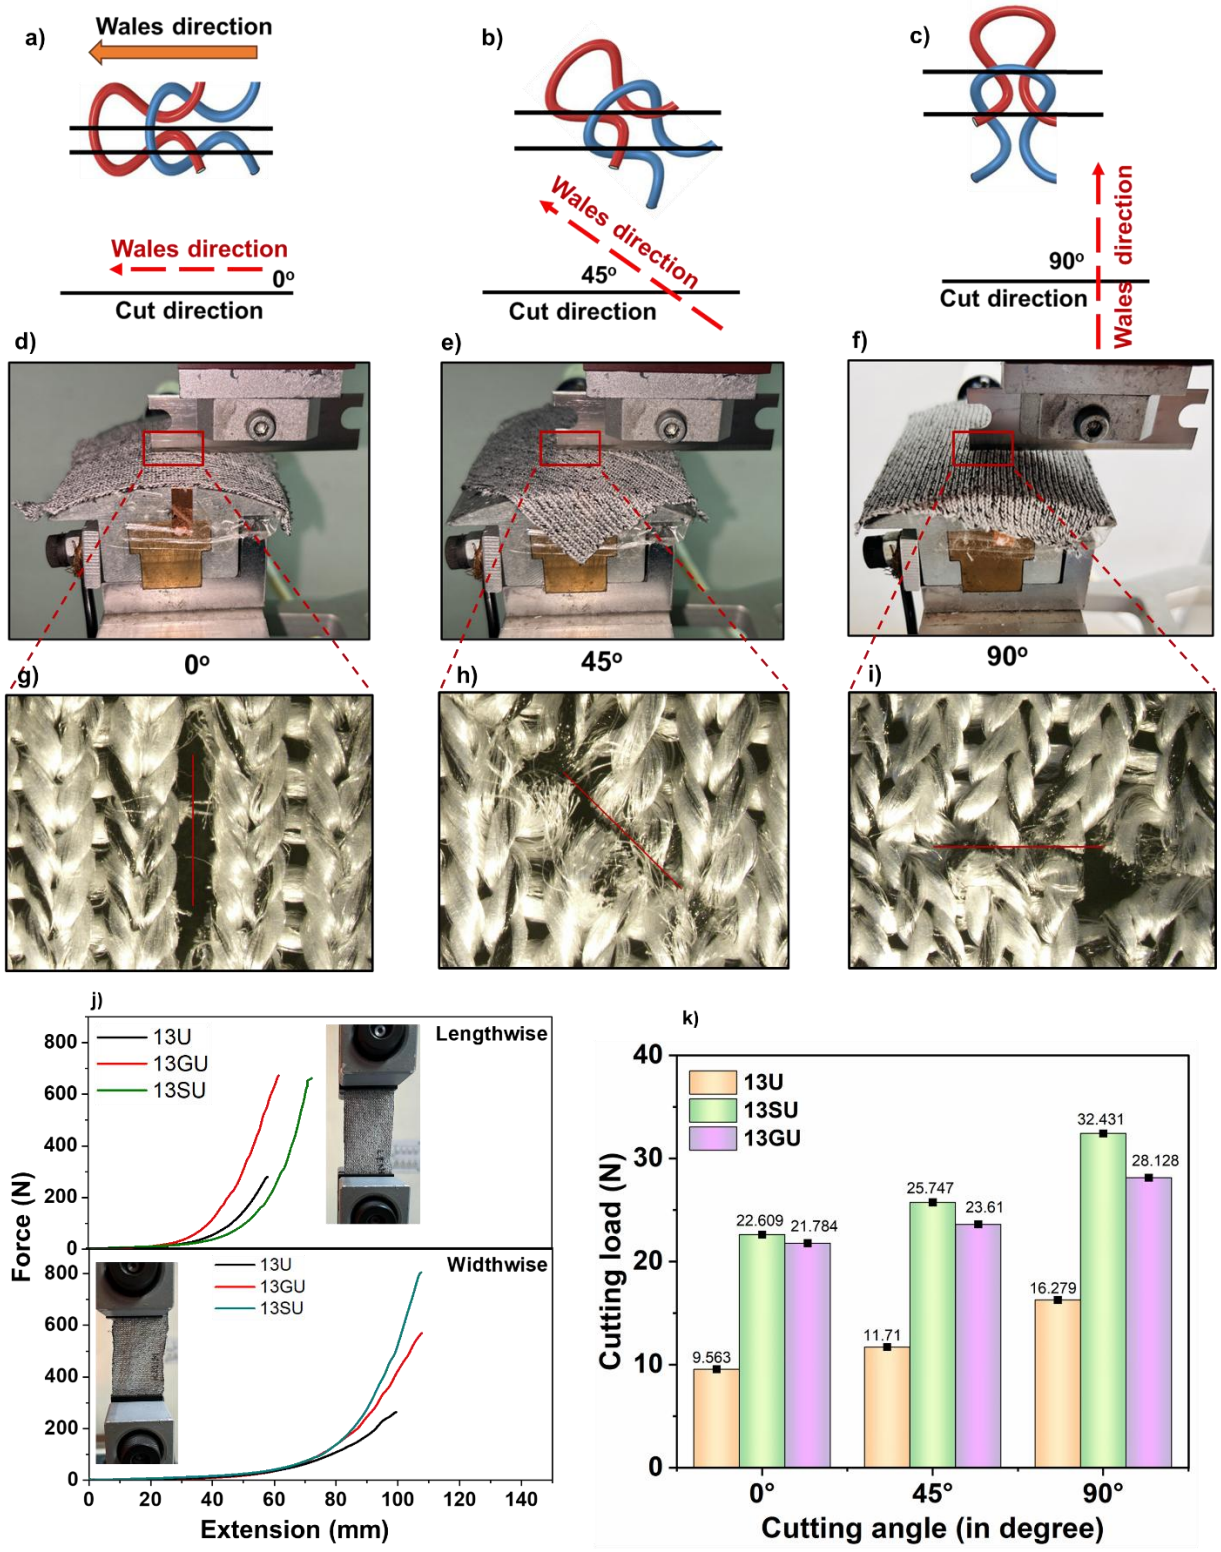

Figure 10. (a-c) Schematic representation of different cutting directions in weft plain knitted structure. (d-f) Performing cut-test on 13SU fabrics at cutting angles of 0°, 45°, and 90°. (g-i) Optical images of knit loops fractures in 13SU fabric at these cutting angles. (j) Force-extension curve of the samples in lengthwise and widthwise directions. (k) Histogram of cutting load of the samples at 0°, 45°, and 90° cutting angles.

There are several factors contribute to these observations, primarily being the extensibility of samples in both the lengthwise and widthwise directions. As shown in Force - Extension graph in **Figure 10 j**, the extensibility of 13U, 13GU, and 13SU samples in widthwise direction (99.4 mm, 107.5 mm, 110.5 mm) was higher compared to lengthwise direction (58.7 mm, 61.6 mm, 72.3 mm) because, in weft knitted fabrics the loop structure is very flexible in course direction. So, in widthwise direction, when blade moves with constant speed on fabric surface in widthwise direction (**Figure 10 f**), the fabric absorbs the mechanical energy applied by cutting force more effectively. This is due to the maximum mobility of yarns in the direction of blade movement, as shown in **Figure 10 i**. This mobility leads to an unstable contact area between the blade edge and the loops, resulting in a loose grip. Consequently, the frictional force reduced, requiring higher shear force to generate cracks in the loops. This is because of the fabric's maximal elastic potential energy in widthwise direction, which contributes to its resistant to cutting forces. In contrast, fabric's lowest extensibility in lengthwise direction, when blade moves in this direction (at 0°) (**Figure 10 d**), limits this energy absorption, and results in a better contact area with tight gripping between blade edges and loops due to lesser mobility of yarns, as shown in **Figure 10 g**. This leads to a lower shear force being sufficient to cut through the loops. The 13SU fabric, which exhibits the maximum extensibility in both the widthwise and lengthwise directions compared to 13GU and 13U, shows the highest cut performance overall, that can absorb more energy before yielding to the cutting force, contributing to its superior cut resistance. On the other hand, the extensibility of 13GU is not as high as 13SU, primarily due to the brittle nature of the glass fibers, which makes the fabric more rigid and less capable of stretching to absorb energy. This rigidity results in lower cut resistance compared to 13SU.

3.3 Effect of environmental conditions

The cut-performance of 13SU, 13GU and 13U samples was investigated by exposing them in open environment for 90 days. After a time, span of 30 days, the mechanical properties of all fabric samples are measured and reported in **Figure 11 c-f**, **Supporting Figure S4,** and **Supporting Figure S5**. The results show a progressive decrease in these properties across all samples with extended exposure to the open environment over 30, 60, and 90 days. The most significant degradation in mechanical properties was observed in the 13SU fabric, followed by 13GU and then 13U, which is due to the galvanic corrosion in 13SU, where the stainless-steel

corrodes and generates oxidative byproducts that catalyse the oxidative degradation of the UHMWPE fibers, resulting in a more rapid breakdown of UHMWPE polymer chains and a subsequent decline in mechanical properties. Additionally, due to the high thermal conductivity of stainless-steel, it efficiently absorbs and distributes heat from sunlight throughout the structure. This increased heat exposure exacerbates the thermal degradation of UHMWPE fibers, leading to further damage. The FTIR spectra of 13SU (**Figure 11 b**) reveal significant changes in the chemical structure of UHMWPE fibers over time, particularly with the emergence of new peaks at 1708 cm^{-1} and 3432 cm^{-1}, corresponding to ketone (C=O) and hydroxyl (O-H) polar groups, respectively. The intensities of these peaks increase with prolonged exposure, indicating ongoing oxidative processes that introduce these functional groups into the UHMWPE chemical structures. Environmental factors such as oxygen and UV radiation initiate free radical formation, leading to polymer chain degradation and the formation of these functional groups. Concurrently, the fundamental bands of UHMWPE, such as the C-H stretching modes at 2851 cm^{-1} and 2919 cm^{-1}, the methylene bending vibration at 1462 cm^{-1}, and the CH_2 rocking mode at 719 cm^{-1}. Over a time, by exposing the samples in open environment, the intensities of these peaks decrease, suggesting a reduction in intact methylene groups and overall degradation of the polymer backbone, further supported by the consistent decrease in the intensity of these characteristic bands, reflecting the impact of environmental exposure on the material's chemical structures. The mechanical properties of 13SU fabric, exhibit a clear decline with increased environmental exposure, consistent with the FTIR findings. Tear strength in the widthwise direction decreases from 405.8 N (non-exposed) to 391 N (30 days), 365 N (60 days), and 310 N (90 days), while in the lengthwise direction, it drops from 313.1 N (non-exposed) to 305.6 N (30 days), 287.5 N (60 days), and 245.9 N (90 days) (**Figure 11 c**). Puncture resistance performance also decreases, with the puncture load dropping from 96.25 N (non-exposed) to 92.42 N (30 days), 85.68 N (60 days), and 74.57 N (90 days). Similarly, the number of cycles to hole formation in abrasion resistance tests declines from 800 cycles (non-exposed) to 780 cycles (30 days), 750 cycles (60 days), and 700 cycles (90 days) (**Figure 11 d**). The cutting load for a 20 mm corrected cut-through distance (CCTD) shows a reduction from 25.74 N (non-exposed) to 23.37 N (30 days), 20.81 N (60 days), and 17.09 N (90 days) (**Figure 11 f**). The correlation between the FTIR spectra and mechanical properties is evident. As the FTIR spectra show increased formation of ketone and hydroxyl groups (peaks at 1708 cm^{-1} and 3432 cm^{-1}), indicating oxidation, the mechanical properties degrade. These polar group into the UHMWPE polymer disrupt the non-polar nature of UHMWPE, reducing

its hydrophobicity and weaken intermolecular forces within the UHMWPE polymer, leading to chain scission and a decrease in molecular weight, reduces its mechanical strength.

data and regression line curve (f) histogram of cutting load at 20-mm CCTD, derived from CCTD vs load curve.

3.4 Effect of radiant heat exposure

XRD curves of all exposed samples at heat flux density of 20 kW/m² on the mandrel of TDM-100, as shown in **Figures 12 a-b and Supporting Figure S6**, reveals that consistent decrease in peak intensities at 21.5° and 23.9° for all samples, indicating decreased crystallinity. This decline is attributed to thermal agitation, where increased kinetic energy disrupts the ordered arrangement of polymer chains, shifting the structure from crystalline to more amorphous. DSC analysis supports this observation, showing that UHMWPE, with a melting point (T_m) of approximately 141 °C, which is significantly lower than the T_m of 230 °C for polyester, indicating UHMWPE is very sensitive to thermal effects at lower temperatures (**Figure 12 c**). Among the fabrics, 13SU shows the most significant crystallinity loss, with an 11.72% reduction. This is likely due to the high thermal conductivity of stainless-steel fibers (approximately 13 to 15 W/m·K),[41] which facilitate rapid heat transfer throughout the UHMWPE fibers, leading to elevated temperatures within the polymer structures. As the UHMWPE polymer chains are exposed to this heat, the increased molecular motion results in entropy-driven disorder, causing a breakdown of the crystalline regions. The disruption of these regions not only reduces crystallinity but also affects the overall crystal size and morphology. SEM images of 13SU (**Figure 12 e**) reveal extensive deformation and bead formation of UHMWPE fibers throughout the fabric, correlating with a substantial drop in cut resistance from 25.74 N to 18.76 N after exposure (**Figure 12 d**). While, 13GU shows better thermal stability, with only a 6.36 % reduction in crystallinity. The lower thermal conductivity of glass fibers as compared to stainless-steel fibers, helps insulate the UHMWPE fibers and minimizes the increase in entropy within the polymer, which helps in reducing the extent of degradation. SEM analysis shows only localized deformation of UHMWPE fibers and minimal structural damage in 13GU (**Figure 12 f**), consistent with a smaller decline in cut resistance from 23.6 N to 20.17 N, indicating its superior ability to maintain performance under thermal stress. The 13U fabric, composed solely of UHMWPE, shows an intermediate response, with a crystallinity reduction of about 9%. While it lacks the reinforcing fibers present in 13SU and 13GU, it still undergoes significant thermal agitation, leading to moderate degradation. SEM images of 13U (**Supporting Figure S7**) show some fiber dislocation, with a corresponding decrease in cut resistance, though less pronounced than in 13SU.

exposed and non-exposed 13SU, and 13GU samples at 20-mm CCTD. (e-f) The SEM images of radiant heat exposed 13SU, and 13GU samples.

4. CONCLUSIONS

In this study, three types of knitted fabrics (in form of gloves) were prepared, including 100% UHMWPE (13U), stainless-steel reinforced UHMWPE (13SU), and glass-reinforced UHMWPE (13GU), using a 13-gauge gloves knitting machine. The study analysed the effect of reinforcing materials, radiant heat exposure, outdoor environmental conditions, and cutting angles on the durability and cut-resistance properties of developed samples. The findings revealed that reinforcement with stainless-steel and glass fibers significantly enhanced the mechanical (tear resistance, puncture resistance, and abrasion resistance) and cut-resistance properties. The 13SU fabric, reinforced with stainless steel, exhibited the highest overall performance under normal conditions, with an increased peak intensity and crystallinity percentage of 52.48% in its crystalline structure, compared to 13GU (51.75%) and 13U (48.37%), as confirmed by XRD graphs. This enhancement is attributed to the nucleating effect of stainless-steel, which promotes a more ordered alignment of UHMWPE polymer chains, leading to improved cut-resistance properties. However, this same reinforcement also contributed to the fabric more vulnerable to environmental degradation, particularly through galvanic corrosion and oxidative degradation, which resulted in formation of ketone (C=O) and hydroxyl (O-H) polar groups, that reduced the peak intensity and altered the molecular structure of UHMWPE polymer over time (up to 90 days), as confirmed by FTIR analyses.

Radiant heat exposure further impacted the crystallinity of the UHMWPE polymer, particularly in the 13SU sample, where the high thermal conductivity of stainless-steel facilitated rapid heat transfer, leading to a significant loss in crystallinity and molecular weight. In contrast, the 13GU fabric, reinforced with glass fibers, demonstrated better thermal stability due to the lower thermal conductivity of glass, which minimized the degradation of UHMWPE's molecular structure and preserved its mechanical and cut performance. The study also found that cut resistance for all samples was highest at 90° (widthwise direction) and lowest at 0° (lengthwise direction), influenced by the fabric's extensibility, which was higher in the widthwise direction compared to the lengthwise direction. This increased extensibility allowed the fabric to absorb more energy through the loops and polymer structure, thereby contributing to its superior cut resistance at 90°cutting angle.

SUPPORTING INFORMATION

1) The detailed information about the effect of outdoor environmental exposure on 13GU and 13U sample along with XRD curves, and SEM images of radiant heat exposed 13U sample.

Keywords: Fibres, Strength, Mechanical testing

ABSTRACT

Automated single fibre tensile tests were performed on carbon and glass fibres to characterise their tensile properties and cross-section accurately. An iterative compliance correction was developed to improve the strain accuracy. The results showed no correlation between tensile properties and the fibre cross-section but a clear dependency on the gauge length, lowering strength due to a higher defect probability in longer fibres. A dataset with more than 200 tests was obtained, which can be utilised to enhance simulation inputs and support predictive models for composite design.

1 INTRODUCTION

Fibre-reinforced polymer composites (FRP) gain their mechanical performance primarily from the embedded fibres. These fibres carry most of the applied loads, thereby providing stiffness and strength to the composite parts. Accurate characterisation of these fibres is essential for understanding their role within composites and for predicting the mechanical behaviour of FRP products reliably. Classic composite simulations require properties such as the fibre diameter, the Young's modulus, the strength and the failure strain. Manufacturers provide such values, but typically only an average value and no distribution of the properties. They base their mechanical properties on impregnated bundle tests, not including the effect of fibre cross-sectional variation. In literature, fibre properties are commonly determined by single fibre tensile tests (SFTT). Those tests do allow for individual fibre cross-sectional area measurements, but care needs to be taken during handling and clamping [1, 2]. Other methods are single fibre fragmentation tests, loop tests and synchrotron radiation computed tomography on unidirectional composites [2].

Common reinforcements for FRPs are carbon and glass fibres. Given that those fibres are brittle materials influenced by the presence of manufacturing defects, they exhibit strength characteristics that are best described using probability models such as the Weibull distribution [3]. The classic Weibull distribution describes the weakest-link behaviour with a scale parameter and modulus. The scale parameter is the characteristic strength at which 63.2 % of the fibres will fail. The modulus, or shape parameter, reflects the variability in strength. A strong, reliable fibre is thus characterised by a high scale and shape parameter, respectively. The drawback of this distribution is that a large data set is required for accuracy. Several authors [2, 4] have confirmed that fewer than 100 tests introduce significant errors in the Weibull parameters.

An additional concern in SFTTs is the compliance correction. Depuydt et al.[5] and Engelbrecht-Wiggans et al. [6] have noted that the compliance correction methods suggested in the testing standards for single fibres are unable to correct the measured strain values adequately. Mesquita et al. [4] added that due to the non-linear tensile behaviour of the fibres, errors are introduced in the determination of the machine compliance. They applied an iterative compliance correction by updating the strain, which shifted the stress-strain diagram, and recalculating the compliance on the new strain range. They reported that the first iteration leads to a deviation of 11 % from the real machine compliance.

In the current study, SFTTs were performed on carbon and glass fibres to quantify their properties. Correlations between the mechanical properties and the geometry of the fibres, separated into the cross-section and the gauge length, will be analysed.

2 MATERIALS AND METHODS

2.1 Fibre types

In this study, both carbon and glass fibres were tested. The carbon fibres are T700SC-12K-50C PAN-based fibres (Toray Industries, Japan) and the glass fibres are Advantex® R25HX14 E-CR fibres (3B Fiberglass, Belgium). Table 1 summarises the properties, as specified by the manufacturer.

Table 1: Fibre properties reported in their respective data sheet.

Material	Fibre type	Diameter [µm]	Tensile modulus [GPa]	Tensile strength [MPa]	Failure strain [%]
Carbon	T700SC-12K-50C	7	230	4900	2.1
Glass	Advantex® R25HX14	17-24	81-83	2700-2800	/

2.2 Automated single fibre tensile tests

The SFTTs were performed with the ALS1500-LEX820-FDAS770 device (Dia-Stron Limited, United Kingdom). The successive stages of this test are specimen preparation, dimensional measurements and mechanical testing, while the automated loading system with vacuum suction ensures transport of the specimens. More details on the functioning of the Dia-Stron device, as well as a comparison with single fibres mounted on card frames, were described by Islam et al. [7].

The fibres were meticulously extracted from the roving by hand. To limit the adhesion between fibres due to the sizing, the roving was first divided into smaller bundles, which were further separated with a fine brush. Each fibre was mounted onto two plastic end tabs fitted into the cassette slots. The cassette serves the purpose of specimen storage and facilitates specimen preparation. The slots in the cassette were spaced at a fixed length, predefining the gauge lengths of the fibres at 4, 12 and 30 mm. Alignment of the fibres was assured by V slits in the tabs and the precise rectangularity of both the tabs and slots. The fibres were glued in the tab with UV-curing adhesive (3099, Dymax Corporation, United States) at a wavelength of 365 nm for 15 s.

The dimensional measurement of the fibre was performed with the laser scanning micrometre (LSM-500S+6200, Mitutoyo, Japan) at an accuracy of 0.3 µm. The contactless measuring device was linearly calibrated between two reference fibres measured in the scanning electron microscope: 6.8-50.8 µm for carbon and 9.0-101.3 µm for glass. Calibrating each material independently ensured limited laser-material interaction on the diameter measurement. A 3D dimensional measurement was performed with approximately one longitudinal slice per 4 mm and three rotations per slice, with each approximately 220 points per rotation.

The mechanical testing of the fibre consisted of an SFTT in the extensometer with a 20 N load cell. A cross-head strain rate of 0.15 %/s was applied according to the ASTM C1557-14 standard. A gauge force of 0.5 mN was applied, and data were sampled every 100 ms.

2.3 Determination of fibre properties

The diameter measurements were filtered to remove erroneous measurements and noise [8]. Slices with an average diameter outside a range of 0.5-1.5 times the manufacturer's diameter were considered erroneous and automatically removed. The range for filtering the slice diameter was further refined to $\mu \pm 3\sigma$, with μ the mean and σ the standard deviation. Noise was removed by discarding individual data points deviating by more than 20 % of the average slice diameter. This filtering removed 6 % of

the measurements. The cross-sectional area was obtained from the surface integral in polar coordinates of the angular data points.

The acquired force-displacement curves were corrected for compliance in line with the ASTM C1557-20 standard. The SFTT at three different gauge lengths were plotted according to

$$\frac{\Delta L}{F} = \frac{l_0}{EA} + C_s \tag{1}$$

with ΔL being the recorded crosshead displacement, F the recorded force, l_0 the fibre gauge length, E the Young's modulus, A the cross-sectional area and C_s the system compliance. Fitting a straight line through the plot of $\Delta L/F$ as a function of l_0/A allows extracting C_s at the intercept (Figure 1a). The actual elongation of the fibre Δl can then be determined by

$$\Delta l = \Delta L - C_s F \tag{2}$$

This compliance correction is then applied iteratively by replacing the ΔL in equation 1 with Δl computed in equation 2, as suggested by Mesquita et al. [4]. To ensure that the iterative method converges, outliers were removed based on an interval of 100% around the mean value of the fitted slope. The system compliances obtained are 0.024 mm/N and 0.128 mm/N for glass and carbon, respectively (Figure 1b). Using the first iteration would cause a relative error up to 154 %.

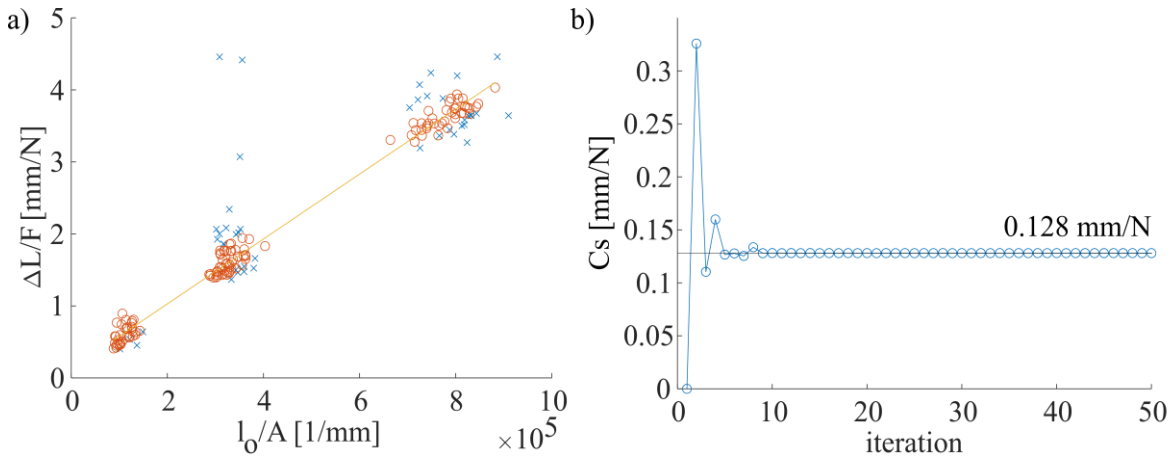

Figure 1: Carbon compliance determination: (a) final compliance curve and (b) iteration.

Stress-strain curves with a load drop were discarded from the data analysis. A load drop is defined in this study as a difference of 5 mN between successive force measurements. When such a load drop occurred before reaching 25 % of the maximum force, it was considered linked to the tab slipping in the tensile grip, and the stress-strain curve was not discarded. The modulus was determined in the range of 0.1-0.6 % strain, according to the ISO 1566-1998 standard for fibres with a nominal failure strain above 1.2 %.

3 RESULTS AND DISCUSSION

3.1 Fibre properties

From the SFTTs, the diameter, tensile modulus, ultimate tensile strength, and failure strain for both fibre types were precisely computed (Table 2). The automation ensured large datasets of approximately 200 tests, which are vital for obtaining statistically accurate parameters [4]. The average diameter of both fibre types is in line with the value provided by the manufacturer. In addition to the average diameter, the cross-sectional shape was also measured. An ellipsoidal cross-section was measured for carbon fibres, in contrast with circular glass fibres (Figure 2), consistent with observations in the literature [1]. The modulus and ultimate tensile strength were lower than the values

provided by the manufacturer. However, those properties were measured with the impregnated bundle method and are thus difficult to compare.

Table 2: Fibre properties obtained from the single fibre tensile tests with a gauge length of 12 mm (mean ± standard deviation).

Material	Number of tests	Diameter [µm]	Tensile modulus [GPa]	Ultimate tensile strength [MPa]	Failure strain [%]
Carbon	206	6.5 ± 0.3	226 ± 25	4571 ± 1092	1.75 ± 0.38
Glass	198	24.3 ± 1.4	72 ± 4	1625 ± 583	2.34 ± 0.87

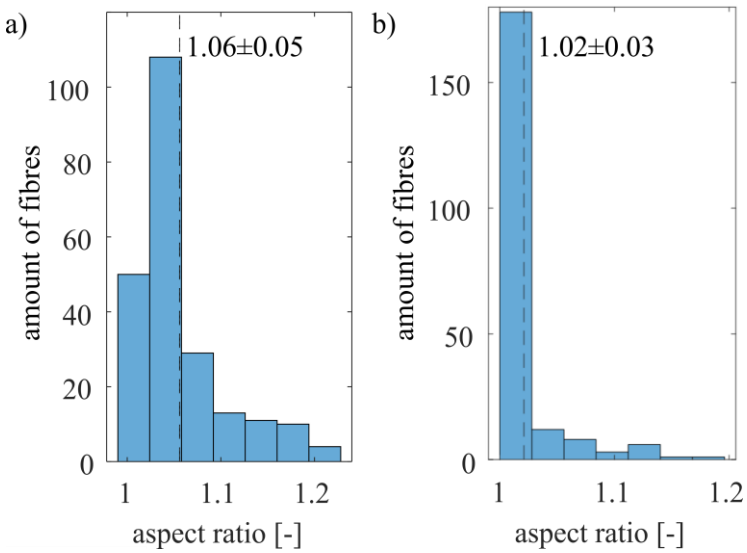

Figure 2: Aspect ratio histogram: (a) carbon and (b) glass fibres.

3.2 Correlation between tensile properties and the cross-section

The interdependence between the tensile properties and the cross-section was studied with point clouds. The relation could be observed graphically from the point cloud orientation, and the coefficient of determination R^2 provides a quantitative evaluation of the linear fit. Low R^2 indicate a limited correlation. No correlation was observed between the tensile properties and the fibre diameter or aspect ratio (Figure 3), so the results for mechanical properties are believed to be unbiased. This confirms a previous study [4], where no correlation was found between the modulus and the fibre diameter for glass and only a slight negative correlation for carbon fibres.

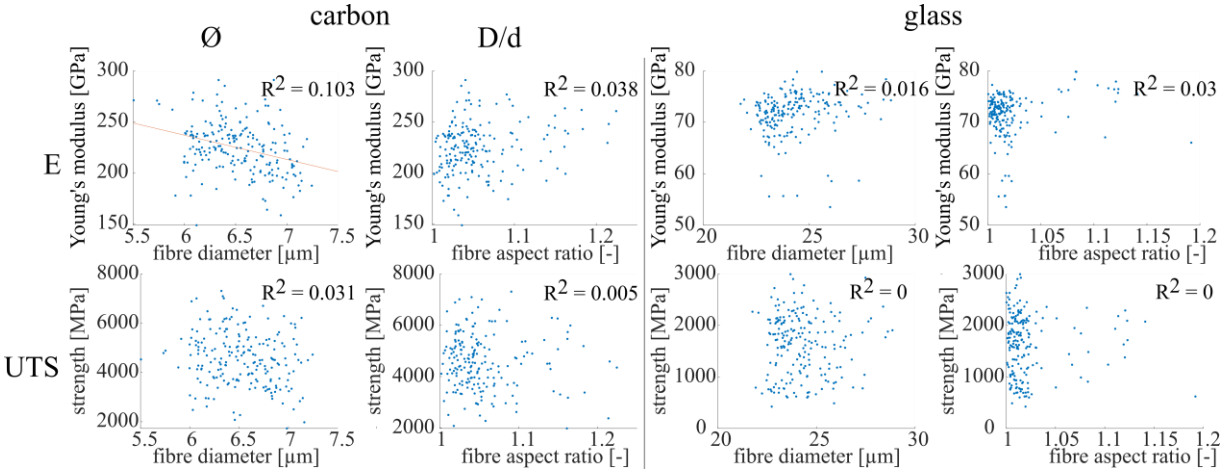

Figure 3: Point clouds indicating the correlation between tensile properties (Young's modulus and ultimate tensile strength) and the fibre cross-section (diameter and aspect ratio) for carbon and glass.

3.3 Gauge length dependency

The interdependence between the tensile properties and the fibre length was studied with the Weibull parameters (Table 3). When comparing the 30 mm fibres to the shorter ones, an obvious gauge length dependency was found, stating that there is a higher probability of finding defects in the longer fibres, resulting in a lower Weibull scale parameter (Figure 4). The Weibull modulus appeared to increase with an increasing gauge length, representing more consistent fibres with a more uniform defect distribution. By representing the strength and strain with the Weibull distribution, apparent higher values were obtained than by averaging all the tests (Table 2). Besides having a higher tensile strength, carbon fibres were observed to have a higher Weibull modulus and thus being more consistent with a more uniform flaw distribution than glass fibres. Additionally, the importance of a large data set could be confirmed as the confidence intervals reduced with an increasing number of tests.

Table 3: Weibull parameters obtained from the single fibre tensile tests (mean and 95 % confidence interval).

Material	Gauge length [mm]	Number of tests	σ_0 [MPa]	$m_{strength}$ [-]	ε_0 [%]	m_{strain} [-]
Carbon	4	55	5023 [4587, 5500]	3.1 [2.5, 3.8]	2.32 [2.14, 2.51]	3.2 [2.7, 3.9]
	12	206	4997 [4844, 5155]	4.6 [4.2, 5.1]	1.90 [1.85, 1.96]	5.1 [4.6, 5.7]
	30	60	3252 [3089, 3423]	5.2 [4.3, 6.3]	1.42 [1.34, 1.51]	4.6 [3.8, 5.4]
Glass	4	64	1591 [1454, 1740]	2.9 [2.4, 3.5]	2.60 [2.34, 2.89]	2.4 [2.0, 2.8]
	12	179	1827 [1740, 1917]	3.2 [2.8, 3.6]	2.62 [2.49, 2.75]	3.0 [2.6, 3.3]
	30	82	1208 [1107, 1319]	2.6 [2.2, 3.1]	1.48 [1.35, 1.62]	2.5 [2.2, 3.0]

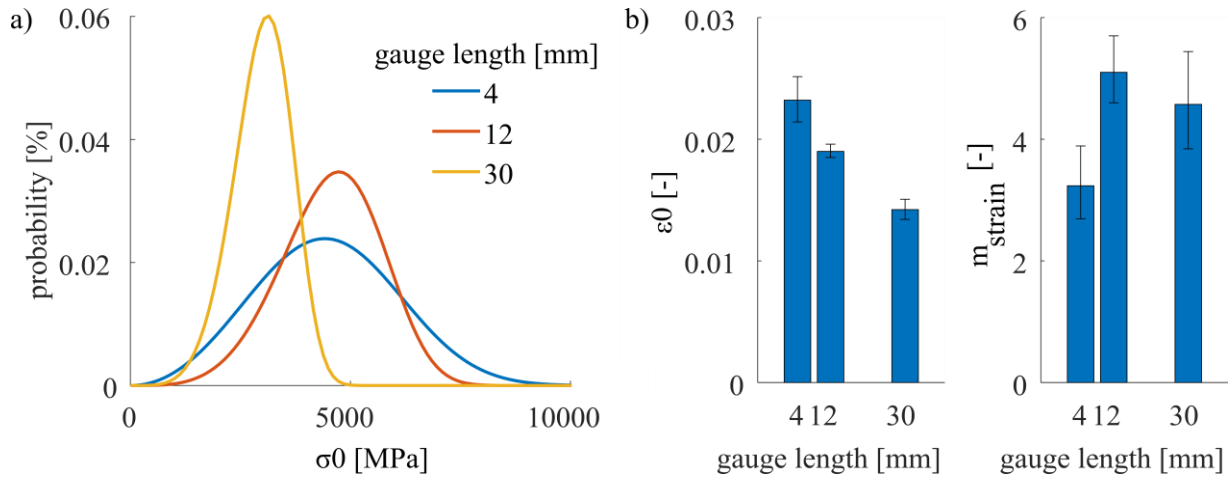

Figure 4: Weibull probability functions as a function of the gauge length for carbon fibres: (a) strength and (b) strain.

4 CONCLUSION

SFTTs were performed on carbon and glass fibres to characterise their tensile behaviour. The fibre

diameter and aspect ratio were measured longitudinally and angularly with the laser scanning micrometre. The fibre modulus, ultimate tensile strength and failure strain were extracted from the stress-strain curve. No correlation was observed between the tensile properties and fibre cross-section. A gauge length dependency was found, though, for the Weibull strength and strain, as longer fibres have a higher probability of containing critical defects.

This comprehensive study on the tensile properties of single carbon and glass fibres provides a detailed input data set for simulations and facilitates the measurement of other fibre-dependent properties. Improving predictive models based on stiffness and strength will enable the development of enhanced designs for FRP parts.

ABSTRACT

The development of sustainable, multifunctional carbon fibre (CF) composites for structural energy storage is critical for the advancement of lightweight, energy-efficient technologies. Here, we report the surface functionalization of lignin–polyacrylonitrile (PAN) hybrid carbon fibres (LCF) with poly(o-phenylenediamine) (PoPD) via electrochemical grafting using diazonium chemistry, to enhance their electrochemical properties while preserving mechanical performance. The resulting LCF-oPD fibres exhibited a significant enhancement in energy storage behaviour, achieving a specific capacitance of 9.06 F g^{-1} at 1 mV s^{-1}, an 18-fold increase compared to unmodified LCF (0.48 F g^{-1}). Cyclic voltammetry revealed distinct redox peaks for LCF-oPD indicative of the reversible redox reaction of p-quinonediamine units, while galvanostatic charge–discharge cycling over 5000 cycles showed excellent electrochemical stability, with 100% capacitance retention and ~100% coulombic efficiency. Despite the addition of the PoPD layer, mechanical testing showed no statistically significant difference in tensile strength (LCF: 1.86 ± 0.38 GPa; LCF-oPD: 2.04 ± 0.33 GPa) or Young's modulus (LCF: 186.77 ± 14.58 GPa; LCF-oPD: 192.54 ± 17.96 GPa). Weibull analysis indicated a slight reduction in failure uniformity (shape parameter decreased from 5.82 to 5.15) but a marginal increase in scale parameter (from 2.01 GPa to 2.20 GPa), suggesting improved strength distribution. These values, although lower than those of conventional PAN-derived CFs (typically ~4 GPa strength and ~275 GPa modulus), validate the non-destructive nature of the surface modification. This work demonstrates a scalable strategy for integrating electrochemical functionality into lignin-based CFs without compromising structural integrity, advancing their potential in structural supercapacitor applications and sustainable multifunctional composites.

1 INTRODUCTION

Carbon fibre composites are used increasingly across diverse industries such as aerospace, wind energy and automotive owing to their exceptional strength-to-weight ratio[1-5]. In the automotive sector, carbon fibre reinforced polymers (CFRPs) are particularly attractive because they can significantly reduce vehicle weight by up to 60%, which directly improves fuel economy[6]. However, widespread applications of CFRPs is hindered by their high production costs, largely stemming from the price of the petroleum-based precursors like polyacrylonitrile (PAN) and mesoporous pitch, which account for over half the cost of carbon fibre manufacturing[7]. To overcome this, alternative precursors such as lignin and silk are being explored[7-9]. Lignin in particular is gaining attention due to its abundance, high carbon content, renewable nature and availability as a low-cost by-product from the paper and biofuel industries[10-13]. As industries move towards more sustainable and circular practices, developing multifunctional carbon fibres, especially those capable of energy storage has become a key priority. The world Economic Forum's "Top 10 Emerging Technologies of 2025" includes structural battery composites as a transformative innovation, highlighting the growing importance of materials that can simultaneously provide mechanical strength and store energy[14]. Achieving this requires a combination

of functional materials, sustainable feedstock and scalable manufacturing approaches, which is a significant challenge.

Lignin-derived carbon materials have been extensively explored for energy storage applications[15-19], particularly in the form of carbon nanospheres[20], nanosheets[21], and nanofibers[22]. These nanostructured forms typically offer high surface areas and can be engineered with various heteroatom dopants (e.g., N, S, O)[23] to enhance electrical conductivity, wettability, and charge storage capacity. Such materials have demonstrated promising electrochemical performance, particularly in electric double-layer capacitors (EDLCs) and pseudocapacitive systems. However, these lignin-based carbons are primarily developed for non-structural applications and often lack the mechanical integrity required for multifunctional systems. In contrast, when lignin is used as a precursor for structural carbon fibres, particularly in combination with polyacrylonitrile (PAN) to form hybrid precursors, the resulting carbon fibres are optimized for mechanical strength and stiffness [24, 25]. This necessitates processing conditions that minimize porosity and surface area, which, while beneficial for structural performance, significantly limits the fibres' ability to store charge via EDLC mechanisms. Consequently, these fibres exhibit relatively poor electrochemical capacitance when directly employed as electrodes in supercapacitor applications. Although the presence of residual oxygen-containing functional groups, such as quinones, may contribute to limited pseudocapacitive behaviour [26], the effect is typically negligible and insufficient for practical energy storage.

These limitations underscore the need for the incorporation of additional electrochemically active materials to enhance the performance of lignin-based structural carbon fibers. Surface functionalization, nanoparticle deposition, or the integration of conductive polymers and metal oxides are promising strategies to synergistically improve the electrochemical activity without compromising the structural integrity of the fibre [27-32]. Such multifunctional modifications are essential for advancing the use of lignin-based carbon fibres in structural energy storage systems.

In this work, we address this challenge by using a lignin-PAN hybrid carbon fibres as a sustainable platform for structural energy storage applications. Specifically, we functionalize the surface of these carbon fibres with the conductive polymer poly(o-phenylenediamine) via reductive diazonium chemistry through a scalable modification strategy to enhance their electrochemical activity while preserving their structural characteristics. The surface modification introduces redox-active and conductive functionalities, increasing the fibre's interfacial capacitance and enabling faradaic or pseudocapacitive charge storage behaviour. This approach not only improves energy storage performance but also maintains compatibility with standard composite manufacturing processes, making it suitable for real-world structural supercapacitor integration. Our strategy demonstrates a pathway toward high-performance, multifunctional composites that align with both sustainability and performance goals, thereby advancing the practical implementation of structural energy storage systems based on renewable carbon fibre sources

2 EXPERIMENTAL

2.1 Materials

All reagents and chemicals used in this study were purchased from Sigma-Aldrich (Australia), and were used without further purification, except for 4-nitobenzenediazonium tetrafluoroborate (NBD) which was synthesized as explained below. The resulting fibres were collected after carbonization for use in this study, prior to undergoing any surface treatment.

2.2 Synthesis of 4-nitobenzenediazonium tetrafluoroborate (NBD)

The synthesis of NBD was achieved rapidly by a one-step synthesis method, where 4-nitroaniline is reacted with nitrosonium tetrafluoroborate ($NOBF_4$) in a molar ratio of 1:1.2 in dry acetonitrile in a 2-neck round bottom flask under N_2. A typical synthesis used approximately 1 g of total reactants because of the high reactivity of aryldiazonium salts. First, 4 mL of dry acetonitrile was cooled to −40 °C using a cooling bath containing acetonitrile and liquid N_2. The required amount of $NOBF_4$ was added to cold acetonitrile in 2-neck RBF with minimum exposure to air during transfer. The solution was cooled to −40 °C while stirring. The amine was added to the solution and stirred for 30 min. The RBF was then

taken out of the cooling bath and allowed to warm to room temperature while stirring for another 30 min. The desired diazonium salt product was precipitated out of ice-cold diethyl ether. The precipitated pure product was collected by filtering at the pump and stored under N_2. Purity of the synthesized diazonium salts was determined using ^{1}H NMR and ^{19}F NMR and was consisten with literature reports[27].

2.3 Electrochemical modification of carbon fiber

Electrochemical modification of CF was carried out according to literature reports[30].The set up consisted of a standard three electrode cell with a lignin carbon fibre tow **(LCF)** as the working electrode, a platinum mesh (2.5 cm^2) as the counter electrode and a leakless Ag/AgCl reference electrode (ET069-1, eDAQ) immersed in a grafting solution consisted of 20 mM o-PD and 2 mM NBD dissolved in 4:1 deionized water:ethanol solution containing 0.6 M H_2SO_4. Electrochemical grafting procedure was carried out using potentiostatic cyclic voltammetry from −1.0 V to +1.0 V (vs Ag/AgCl) for 10 potential sweep cycles at 10 mV/s with an Autolab PGSTAT204 potentiostat. Measurements were recorded using NOVA 2.0 software. Once the electro-grafting is complete, modified CF tow **(LCF-oPD)** was washed sequentially with chloroform, dichloromethane, ethanol, and acetone to remove any physisorbed materials or excess monomers, followed by drying under reduced pressure to remove any adsorbed solvent on CF surface.

2.4 Characterization of surface chemistry and morphology

A Bruker Alpha FTIR (Bremen, Germany) equipped with a germanium crystal in the attenuated total reflectance (ATR) mode was used for FTIR spectroscopic analysis. The measurements were acquired from 600 to 4000 cm^{-1} using an average of 32 scans per measurement at a resolution of 4 cm^{-1}.
Raman spectroscopy was performed using Renishaw Raman InVia Confocal Microscope. Equipped with an Ar+ laser with an excitation wavelength of 514 nm (50 mW) and a diffraction grating of 2400 mm^{-1}. After calibrating the instrument using a silica reference, spectra were obtained between 800 and 2100 cm^{-1} with an average of 5 accumulations at an exposure time of 1 s.
SEM imaging was performed on a JEOL JSM 7800F at an electron accelerating voltage (electron high tension) of 5 kV. CF samples were mounted to an aluminium pin stub using double sided carbon tape. Imaging was performed without any conductive coating to enhance the visualization.

2.5 Characterization of electrochemical properties

Electrochemical tests were carried out using a BioLogic SP-300 electrochemical station at room temperature. Cyclic voltammetry (CV), Galvanostatic charge–discharge (GCD) and Electrochemical impedance spectroscopy (EIS) of functionalized CF (tow) electrodes were tested in a three-electrode cell set up with a leak-less Ag/AgCl reference electrode (ET069-1, eDaq) and a graphite rod counter electrode in 1 M H_2SO_4 electrolyte. EIS was performed at a frequency between 10 mHz and 100 kHz with 10 points per decade and an amplitude of 10 mV. For the SSC device, measurements were conducted in a two-electrode set up. All electrochemical data was analyzed using EC-Lab v11.42 software according to previously published reports using the following equations.
The CF electrodes were tested at 100, 50, 20, 10, 5 and 1 mV s^{-1} scan rates with an electric potential window of 0.6 V. Specific capacitance values from CV were determined using Equation 1,

$$C_{CV} = \int \frac{Idv}{m\, v\, \Delta V} \tag{1}$$

where C_{CV} (F g^{-1}) is the specific capacitance, $\int Idv$ (AV) is the area of the cyclic voltammogram corresponding to discharge processes (*i.e.,* half of total area), m (g) is the CF mass of both electrodes, v (V s^{-1}) is the scan rate, and ΔV (V) is the potential window of the CV.
GCDs were measured at different discharge current densities with an electric potential window of 0.6 V. Specific capacitance values from GCD were determined using Equation 2,

$$C_{GCD} = \left(\frac{I_D}{m}\right) \frac{t_D}{\Delta V - V_{IR}} \tag{2}$$

where C_{GCD} (F g^{-1}) is the specific capacitance, I_D (A) is the discharge current, t_d (s) is the discharge time, m (g) is the CF mass of both electrodes, and ΔV (V) is the potential window of the GCD test. Since voltage drop due to internal resistance IR (**Ω**) is inevitable in GCD tests, V_{IR} has been excluded in the calculations for more accurate results due to internal resistance. GCD tests were performed at different discharge currents densities (I_D/m) (A g^{-1}).
For electrochemical impedance spectroscopy (EIS) experiments the frequency was swept from between 10 mHz to 100 kHz with 10 points per decade and a sinus amplitude of 10 mV. EIS data was analysed and circuit Zfit (Figure S8) performed using EC-Lab v11.42 software.

2.6 Characterization of surface mechanical properties

Single filament characterization for surface modified CF was carried out on a Favimat + Robot 2 (Textechno) single fibre tester. This instrument automatically measures the linear density, diameter, tensile strength and elastic modulus of individual carbon fibre and was equipped with a 210 cN load cell. A pre-tension of 0.5 cN was applied to align the fibres before testing. Linear density of each fibre was determined via vibroscopy and then a tensile load was applied to the fibres until fibre failure. A minimum of 75 individual filaments were analyzed to provide a high degree of confidence in the results.

3 RESULTS

3.1 Surface chemistry and morphology

The electrochemical surface modification of LCF was directly translated from our previous works using pristine T300 CF that was spun using a PAN precursor [27, 30]. Aryl diazonium salts have proven highly effective in our work for forming stable covalent bonds with the carbon fibre surface, and in this case, they act as anchoring sites to facilitate the subsequent oxidative polymerisation of PoPD. The proposed electrochemical grafting mechanism and the anticipated surface chemistry of LCF-oPD are illustrated in Figure 1(a). The representative cyclic voltammogram (Figure 1(b)) clearly shows the distinct reduction of the diazonium salt and the oxidation of o-phenylenediamine, leading to the formation of radical species involved in the grafting process.
SEM has been utilized to study the unique surface topographical features on LCF surfaces before and after functionalization. As shown in Figure 1(c), the SEM image of the LCF surface displays a relatively smooth texture, in contrast to the PAN-based T300 carbon fibres, which typically exhibit striations and microgrooved surface features. Following surface modification, the SEM image of LCF-oPD (Figure 1(d)) reveals a markedly altered surface morphology, characterized by a consistent coating of polymeric material. This uniform coating represents a significant improvement compared to the same polymer applied to T300 carbon fibres, where the surface coverage was noticeably less consistent [27, 30, 33]. We previously attributed this to the heterogeneous surface chemistry of T300 CF, which likely influences local conductivity across the fibre. Four-point probe measurements indicated that the electrical conductivity of the LCF (438.62 S cm^{-1}) was lower than that of T300 CFs (884.88 S cm^{-1}); however, the more uniform surface chemistry of LCF may compensate for this by enabling more homogeneous electrochemical grafting. This could facilitate even attachment of the NBD priming layer, subsequently promoting uniform oxidative polymerization of oPD.

As shown in Figure 1(e), FTIR spectrum of LCF-oPD shows distinct peaks at 1636 cm^{-1}, 1161 cm^{-1}, 1041 cm^{-1} and 865 cm^{-1} ascribed to C=N stretching in quinoid ring, C–N stretching in benzenoid units, C–N stretching and out-of-plane bending motions of C–H of 1,2,4-trisubstituted benzene nuclei, respectively[33]. Therefore, the spectral data obtained were in good agreement with the expected structure of o-phenylenediamine. The Raman spectra of LCF and LCF-oPD reveal notable differences in the D to G band intensity ratios (I_D/I_G), which provide insights into the structural ordering of the carbon fibre surface (Figure 1(f)). For LCF-oPD, the (I_D/I_G), ratio is higher (1.04) compared to that of pristine LCF (1.00), indicating an increase in structural disorder and the presence of more amorphous carbon on the surface. This change suggests that the surface modification process, involving the oxidative polymerization of o-phenylenediamine, introduces additional defect sites and disrupts the graphitic ordering of the carbon fibre surface, consistent with the formation of a polymeric coating.

3.2 Energy storage

The electrochemical properties of LCF and LCP-oPD electrodes were explored in an aqueous electrolyte (1M H_2SO_4) to understand the electrochemical performance. Cyclic voltammetry (CV) and galvanostatic charge discharge (GCD) experiments have been conducted at different scan rates and current densities, respectively. The overall capacitance of LCF-oPD is a combination of electric double layer capacitance (EDLC) and pseudocapacitance from oPD.

Representative cyclic voltammograms (CVs) recorded at a scan rate of 20 mV s^{-1} are presented in Figure 2(a). The CV trace for LCF-oPD exhibits pronounced redox peaks characteristic of the electroactive polymer, along with a broad enclosed area indicative of enhanced charge storage capacity. Each cyclic voltammogram features a pair of redox peaks corresponding to reversible redox reaction of p-quinonediamine units accompanied by the transfer of two electrons and two protons [27]

In contrast, the CV of unmodified LCF displays a featureless, nearly linear profile with a minimal enclosed area, suggesting negligible capacitive behavior. These observations are further corroborated by the galvanostatic charge–discharge (GCD) curves shown in Figure 2(b). The GCD profile of LCF shows a steep and rapid voltage response, whereas the LCF-oPD curve demonstrates an extended, more gradual charging and discharging behavior, consistent with faradaic processes. The specific capacitance values calculated across different scan rates are summarized in Table 1 and Figure 2(c), further highlighting the superior electrochemical performance of the surface-functionalized fibres. At 1 mV/s LCF-oPD demonstrated a specific capacitance of 9.06 F/g which is a ~18x improvement compared to the capacitance of LCF which was only 0.48 F/g at the same scan rate.

Electrochemical impedance spectroscopy (EIS) analysis revealed that LCF-oPD exhibits a higher equivalent series resistance (ESR) compared to unmodified LCF. This increase is likely attributed to the introduction of the poly(o-phenylenediamine) (PoPD) layer at the fibre interface, which, despite being conductive, may introduce interfacial resistance during initial formation. To assess the long-term electrochemical stability of these electrodes, galvanostatic charge–discharge (GCD) cycling was performed over 5000 cycles. The LCF electrode initially retained 100% of its discharge capacitance; however, its performance steadily declined, retaining only 69% after 5000 cycles. In contrast, the LCF-oPD electrode exhibited a gradual increase in capacitance retention, reaching and maintaining 100% by the end of the test. This trend suggests that the PoPD layer undergoes an electrochemical conditioning process, progressively improving its performance until it reaches a stable, optimized state. Additionally, the coulombic efficiency of the LCF electrode exceeded 100%, indicative of a faster or more immediate discharge process relative to charging, possibly due to surface-related parasitic effects. In contrast, LCF-oPD maintained a consistent coulombic efficiency of approximately 100% throughout cycling, highlighting its excellent electrochemical reversibility and long-term stability.

Table 1: Specific capacitance values for LCF and LCF-oPD at different scan rates and current densities

Scan rate (mV/s)	Specific capacitance (F/g)		Current density (mA/g)	Specific capacitance (F/g)	
	LCF	LCF-oPD		LCF	LCF-oPD
50	0.06	4.85	100	0.06	6.82
20	0.08	7.01	75	0.04	7.09
10	0.10	7.52	50	0.03	7.91
5	0.14	7.86	25	0.04	9.89
1	0.48	9.06	10	0.07	2.79

3.3 Mechanical properties

The graph presents a comparative analysis of the tensile strength and Young's modulus of LCF and LCF-oPD samples. Although the LCF-oPD samples exhibit marginally higher mean values for both tensile strength (2.04 GPa vs. 1.86 GPa) and Young's modulus (192.54 GPa vs. 186.77 GPa) relative to the unmodified LCF, the error (typically derived from inhomogeneous distribution of flaws along the fibre) indicate that these differences are not statistically significant. This suggests that the surface modification using oPD does not detrimentally affect the mechanical integrity of the LCF, confirming the non-destructive nature of the treatment. Nonetheless, both strength and modulus values are considerably lower than those of conventional PAN-derived carbon fibers, which typically demonstrate tensile strengths around 4 GPa and moduli near 275 GPa. This further underscores the need to balance functionality and mechanical performance in modified or recycled carbon fibers.

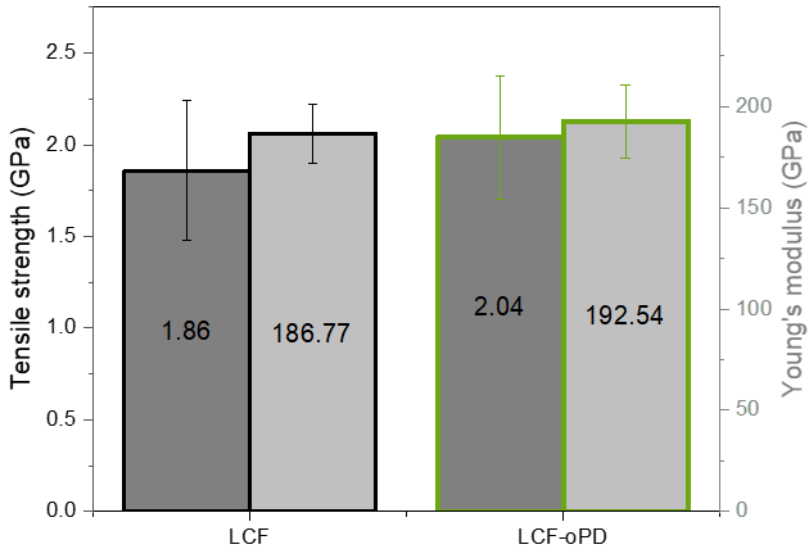

Figure 3: Comparison of tensile strength and Young's modulus of LCF and LCF-oPD

The Weibull shape parameter describes the variability of failure in a material and the scale parameter represents the strength of the fibre. A decrease in shape parameter was observed upon electrochemical functionalization of LCF with oPD (Table 2). A decrease in the shape parameter indicates more variability in terms of failure properties of the fibre, proving the fibres are slightly less consistent in terms of failure properties after surface modification. However, the Weibull scale parameter suggests an increase in the overall strength of the fibre after surface modification. Overall, the Weibull parameters suggest a less uniform failure behavior, with an increase in the overall strength after surface modification, but the average tensile strength increase is statistically insignificant.

Table 2: Mechanical properties and Weibull parameters for LCF and LCF-oPD

	Tensile strength (GPa)	Young's modulus (GPa)	Weibull shape parameter	Weibull scale parameter (GPa)
LCF	1.86 ± 0.38	186.77 ± 14.58	5.82	2.01
LCF-oPD	2.04 ± 0.33	192.54 ± 17.96	5.15	2.2

4 CONCLUSIONS

This study demonstrates the successful surface modification of lignin–PAN hybrid carbon fibers (LCF) with poly(o-phenylenediamine) (PoPD) via a scalable electrochemical diazonium grafting strategy, enabling significant enhancement of their electrochemical performance while retaining mechanical integrity. The modified LCF-oPD electrodes exhibited a substantial increase in specific

capacitance (9.06 F g^{-1} at 1 mV s^{-1}) compared to unmodified LCF (0.48 F g^{-1}) and maintained excellent cycling stability and coulombic efficiency over 5000 charge–discharge cycles. Mechanical characterization revealed no statistically significant deterioration in tensile strength or modulus following modification, confirming the non-destructive nature of the treatment.

However, the inherently lower mechanical properties of LCF (1.86 ± 0.38 GPa tensile strength, 186.77 ± 14.58 GPa modulus) compared to conventional PAN-derived CFs (~4 GPa, ~275 GPa) limit their use in high-performance structural applications. Despite this, the incorporation of multifunctionality through surface engineering makes LCF a viable candidate for structural energy storage composites, particularly where moderate mechanical demands coexist with the need for embedded energy storage. Moreover, the conductive polymer coating introduced via electrochemical grafting provides a versatile platform for further functionalization, such as the integration of MXenes or the assembly of multilayer structures with other polymers, potentially enhancing both energy storage performance and interfacial adhesion with polymer matrices. This work highlights a pathway toward sustainable, multifunctional carbon fiber composites by leveraging bio-derived precursors and advanced surface modification strategies.

KING'S College LONDON

UNIVERSITY OF LEEDS

- As Age UK noted in 2018, 1.4 million older people class themselves as often lonely, and it is estimated this will rise to 2 million people over the aged of 50 by 2025;
- A report from the UK's Department for Digital, Culture, Media and Sport suggests that the wellbeing, health and productivity cost of loneliness are approximately £2.5 billion per person-year.

Background – choice of sensors

Main symptoms that need monitoring

- Increased stress and anxiety levels
- Lack of activity, sedentary lifestyle
- Lack of communication with people
- Comfort eating/drinking
- Sleep problems
- Crying

Related Physiological signals

- Heart rate

ABSTRACT

The ablative thermal protection system (Ablator) can protect re-entry vehicles from severe aerodynamic heating during re-entry. Ablators are carbon-based materials with impregnated resin, and the decomposition of resin during re-entry prevents the temperature increase for components. Carbon monolith has been further developed as a porous carbon substrate, and it has been found that there is no significant difference in recession behaviors of carbon monoliths with or without resin. In addition, it shows superior recession behaviors to conventional porous carbons. A carbon monolith is prepared by carbonizing a porous phenolic resin (phenolic monolith) with the same structure as a carbon monolith. Since phenolic monolith is fabricated by using polymerization-induced phase separation (PIPS), it makes the addition of a second phase and the design of the structure possible. In this study, a B_4C particle dispersed carbon monolith (BCM) is prepared. The mechanical properties of them are evaluated by compression testing. The result shows mechanical properties of BCM are similar to conventional porous carbon despite the addition of a second phase. Ablation behavior is evaluated by an arc-wind tunnel test simulated for a re-entry environment. The result shows internal temperature is decreased.

1 INTRODUCTION

Ablators are well-known as one of the thermal protection systems (TPS) for re-entry vehicles and composed of carbon fibers and resin. Since the decomposition of resin (an endothermic reaction) prevents the increase of temperature for the vehicles, they protect the vehicles from aerodynamic heating during re-entry [1]. A typical example of an ablator is phenol-impregnated carbon ablator (PICA). PICA has been applied to vehicles in the Stardust mission, and the advanced version "PICA-X" has been used for the heatshield of the Space X Dragon spacecraft [2]. A notable feature of PICA is light weight because it composed of carbon felt and phenolic resin. However, it has been reported that PICA exhibits severe mechanical erosion [3].

Therefore, we have proposed to apply three-dimensional networked porous carbon (TNPC) as the substrate and prepare a porous carbon-based ablator (PCA) by impregnating TNPC with resin [4]. As a TNPC, carbon monolith has been developed and prepared by carbonizing a porous phenolic resin (phenolic monolith) with the same structure as a carbon monolith. The evaluation on carbon monolith has revealed that the carbon monolith has superior mechanical properties compared to PICA and the recession behavior has been improved by the suppression of mechanical erosion compared to PICA [5].

Since a phenolic monolith is fabricated using polymerization-induced phase separation (PIPS), the introduction of a second phase and the design of the structure are possible. A carbon monolith dispersed with ZrO_2 (ZCM) has been successfully prepared in previous studies. As the second phase, ZrO_2 was chosen owing to its low thermal conductivity (～2.5 W/m・K) and high melting point (2680 °C). It has revealed that the addition of ZrO_2 improves the recession behavior of carbon monolith and the amount of recession decreases compared to PCA. The result suggests ZCM can be applied to TPS without impregnation of resin [6]. On the other hand, the high density of ZrO_2 (~6 g/cm^3) causes the increase in weight and it makes the application to aerospace component difficult.

In response to this challenge, we have selected boron carbide (B_4C) as an alternative secondary phase. B_4C is notable for its high hardness (ranging between 38 and 44 GPa), a high melting point (2450 ℃), and a lower density (around 2.45 g/cm³) [7]. It is expected that B_4C acts as a barrier to the recession. By the oxidation of B_4C, B_2O_3 is formed and the evaporation of B_2O_3 is an endothermic process (ΔH = 322 KJ/mol, at 1250℃, 0.027 atm) and it prevents the increase of temperature for components [8]. B_4C containing carbon monolith is also expected as a candidate of advanced ablator without impregnation of resin and it will protect from severe aerodynamic heating during re-entry by the phase change of B_2O_3. Thus, we have defined this novel TPS as a "phase change shield system" (PCSS), distinguishing it from conventional ablators. The objective of this study is to develop a material process for B_4C dispersed carbon monolith (BCM) as a PCSS and evaluate the relationship between particle content, mechanical properties, thermal properties, and recession behavior under simulated re-entry conditions.

2 Experimental procedures

2.1 Fabrication of BCM

As the precursor of carbon monolith, a phenolic monolith was prepared. Then, the monomer concentration (ω, wt%) was defined as the ratio of resin and curing agent to solution by the following equation:

$$\omega = \frac{W_{resin}+W_{cure}}{W_{solution}} \tag{1}$$

$$W_{solution} = W_{resin} + W_{cure} + W_{solvent} \tag{2}$$

W_{resin}, W_{cure}, $W_{solution}$ and $W_{solvent}$ were the weight of phenolic resin, curing agent, solution, and solvent, respectively. A resol-type phenolic resin (PL2407 by Gunei Chemical, Japan), concentrated sulfuric acid, and ethylene glycol were used as resin, curing agent and solvent. These were mixed in a weight ratio of 13:1:21(hereafter as the mixed solution) in a beaker. B_4C particles (BBI10PB, particle size: 500 nm, Kojundo Chemical Laboratory Co., Ltd, Japan) were used as the particles. The mixed solution was held at 40℃ in an ambient atmosphere for 12 h to cure by using an oven (DRN320DE, ADVANTEC TOYO KAISHA, LTD. Japan). After 4 h from the beginning of curing, B_4C particles were added by 3.1, 6.1, or 9.2 vol% to mixed solution. The solution was stirred and held under a reduced pressure of about -0.08 MPa for 30 minutes using a rotary pump to remove air bubbles. After 12 h, the temperature was increased to 180℃ and held for 2 h. After that, samples were cooled to room temperature (25℃) over ~12 h. After curing, the solvent in the samples were removed in water at 80℃ for 72 h and dried in the oven at 80℃ for 72 h to obtain the B_4C dispersed phenolic monolith (hereafter denoted as BPM). BPM was carbonized at 950℃ for ~4 h in an atmospheric furnace (FT-POT-300, Fulltech) under an Ar atmosphere to obtain the B_4C particle dispersed carbon monolith (hereafter denoted as BCM). BCM with B_4C particles by 3.1, 6.1, and 9.2 vol% were defined as 3.1 BCM, 6.1 BCM and 9.2 BCM, respectively.

2.2 Basic characterization of structures for 9.2 BCM

9.2 BCM was cut into five layers as shown in Figure 1. The bottom of the beaker used during fabrication was defined as the XY plane, and the center of the XY plane in the third layer along the Z-axis was observed by scanning electron microscopy (SEM). Furthermore, the density of each layer was measured to evaluate the dispersion of particles.

2.3 Evaluation of mechanical properties for BCM

BCM was cut into rectangular blocks with size of 10×10×20 mm and 8×8×30 mm. The latter shaped continuously into a dumbbell with a cross-section of 5×8 mm in the center. The shapes of both compression test specimens are shown in Figure 2. Compression tests were conducted using a universal testing machine (model 5967, INSTRON, The U. S.), with a crosshead speed of 0.1 mm/min. The load was recorded using a 30 kN load cell, and displacement was measured using an extensometer attached to the compression jig. From these values, the Young's modulus and compression strength were evaluated.

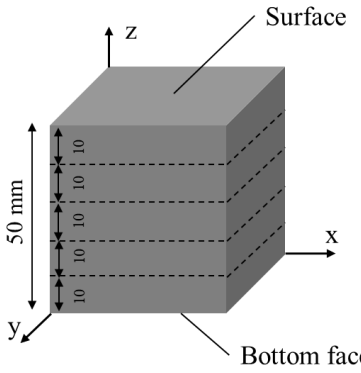

Figure 1. A schematic diagram of 9.2BCM

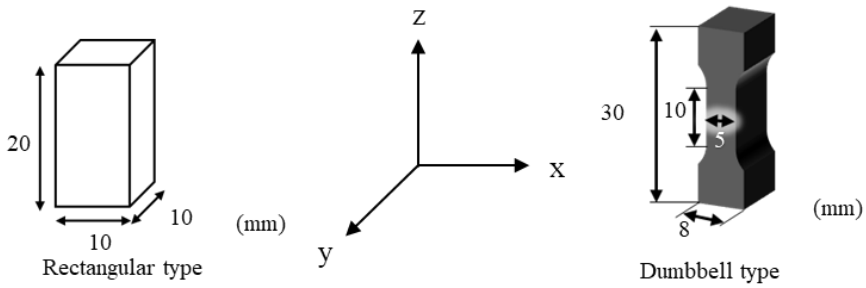

Figure 2. Shape of compression specimens

2.4 Arc-wind tunnel test

Arc-wind tunnel tests were conducted to evaluate the ablation behaviors of BCM. The tests used a 1 MW class arc heater at Japan Aerospace Exploration Agency/Institute of Space and Astronautical Science (JAXA/ISAS) in their arc-wind tunnel. In the tests, the high-enthalpy flow heated by arc heater is emitted from the nozzle into the chamber, allowing for simulated testing of atmospheric re-entry conditions. The appearance of the test specimens before and during the test in the arc heating wind tunnel were shown in Figure 3. By varying the distance between the air nozzle and the test specimen, the heat flux and dynamic pressure at stagnation point were adjusted. The size of specimens and specimen holder were exhibited in Figure 4. The specimen surface was Φ50 mm and set to bakelite holder. Nozzle distances were set at 150 mm, 100 mm, or 80 mm. The specimen surface was exposed for 30s by high enthalpy flow. The surface temperature was measured during heating by using radiation thermometer (emissivity $\varepsilon = 0.90$). The internal temperature was measured during heating and until 20 min after heating. Internal temperature was measured by inserting a type K thermocouple at 20 mm and 30 mm depth from the surface. After arc-wind tunnel test, the recession length of surface was measured by using a laser displacement sensor (LK-G155, KEYENCE CORPORATION, Japan).

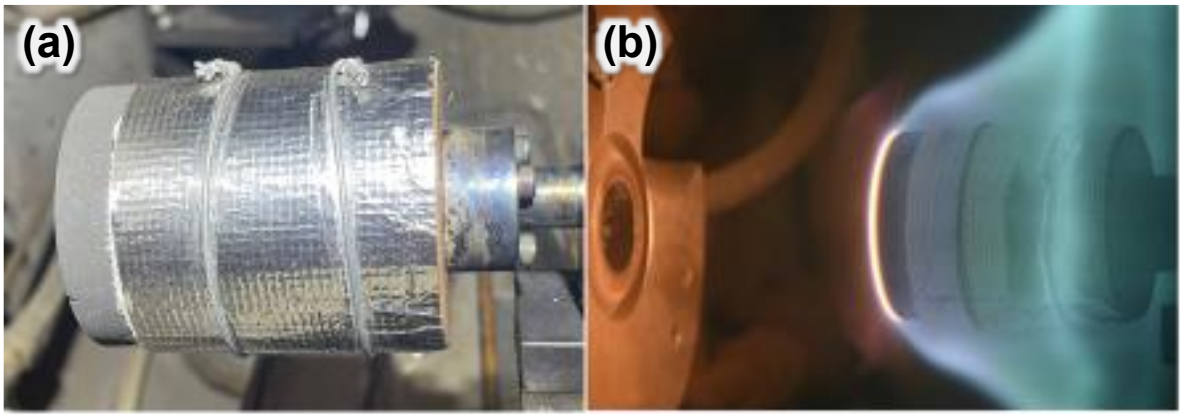

Figure 3. A typical appearance of the specimen: (a)Before test, (b)During test

Table 1. Test conditions

Test	Specimen	Nozzle distance (mm)	Exposure time (s)	Emissivity	Heat flux (MW/m^2)	Dynamic pressure (kPa)
A	3.1 BCM 6.1 BCM 9.2 BCM	150			1.92	3.09
B	3.1 BCM 6.1 BCM 9.2 BCM	100	30	0.90	3.54	10.10
C	3.1 BCM 6.1 BCM 9.2 BCM	80			6.18	20.11

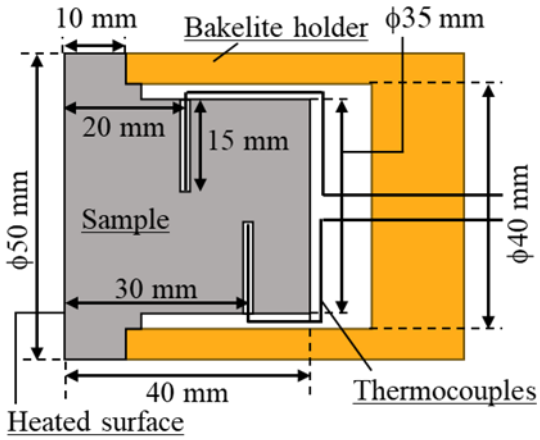

Figure 4. Cross section of arc wind tunnel specimen

3 Results and Discussion

3.1 Density of 9.2BCM

The relationship between normalized length (z) and density of 9.2 BCM and carbon monolith is shown in Figure 5. The addition of B_4C increases the density of each layer in the 9.2 BCM compared with that of the carbon monolith. Furthermore, because the relationship between normalized length (z) and density is similar for both the 9.2 BCM and the carbon monolith, the B_4C particles in the BCM are considered uniformly dispersed.

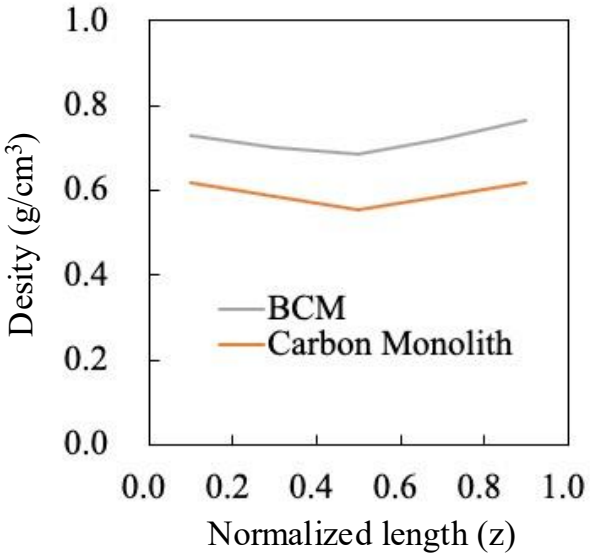

Figure 5. Relationship between normalized length (z) and density

3.2 Structural Observation

Microstructures of 9.2 BCM were presented in Figure 6. The monolith structure, which is a typical microstructure of monolith [5], is maintained even with the addition of B_4C particles. Agglomerates of B_4C approximately 2.0–3.0 μm in size were observed. However, because the monolithic structure was preserved, it was confirmed that the ZCM fabrication process can be applied to BCM.

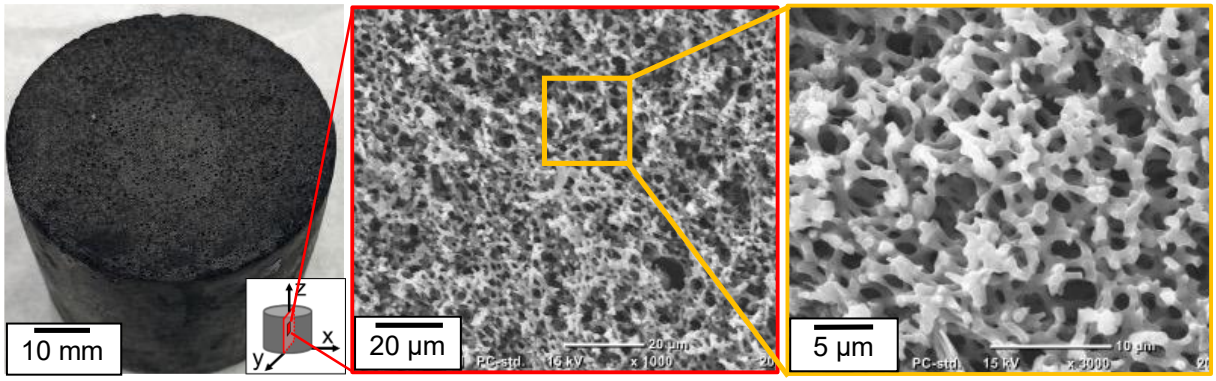

Figure 6. Typical microstructures of 9.2 BCM

3.3 Evaluation on Mechanical Properties

Young's modulus of carbon monolith, 3.1 BCM, 6.1 BCM, 9.2 BCM is 7, 3.8, 1.8 and 1.6 GPa, respectively. In addition, the compressive strength of carbon monolith, 3.1 BCM, 6.1 BCM, 9.2 BCM is ~110, ~60, ~30 and ~25MPa, respectively. These results show the compression strength and Young's modulus decrease with increase of the B_4C particles. This suggests that agglomerates influence the mechanical properties in different ways. On the other hand, the compressive strength of a conventional TNPC is ~25MPa [9] and it clearly indicates carbon monolith can maintain a certain level of compressive strength even after the addition of B_4C particles.

3.4 Arc Heating Wind Tunnel Test

The relationship between surface temperature and heat flux during tests is shown in Figure 7. In tests A and B, the carbon monolith showed a lower surface temperature than the BCM, whereas in test C this relationship was reversed. This reversal is attributed to the surface temperature in test C exceeding the melting point of B_4C, thereby causing reactions different from those occurring in tests A and B.

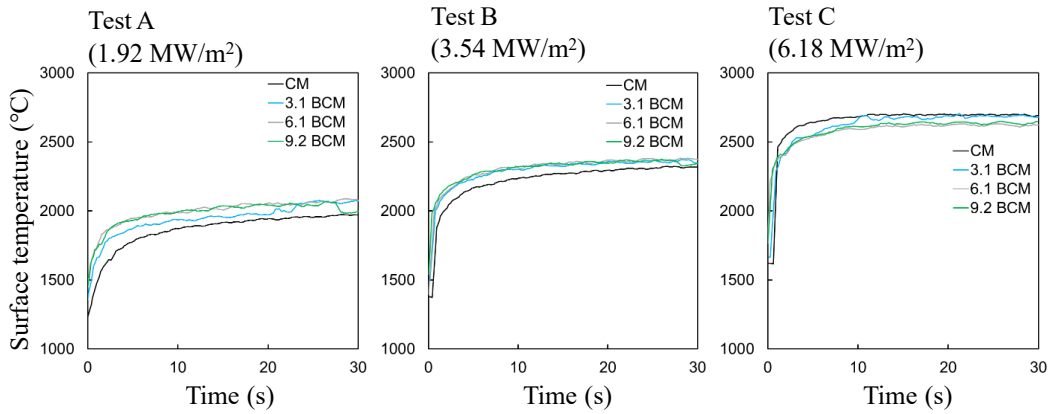

Figure 7. Temperature history of surface temperature (BCM and Carbon Monolith) [5]

The relationship between internal temperature and heat flux during tests is shown in Figure 8. At that time, the internal temperature of carbon monolith in test B could not be measured accurately because the specimen fractured. The BCM shows a lower internal temperature than the carbon monolith at every test. Moreover, the internal temperature decreases as the B_4C content increases. This can be attributed to the specific heat capacity of B_4C (1.84 J/g・K) and evaporation of B_2O_3, which is evolved by the oxidation of B_4C. The B_4C particles within the specimen absorbed heat as their temperature rose, thereby suppressing the overall temperature increase.

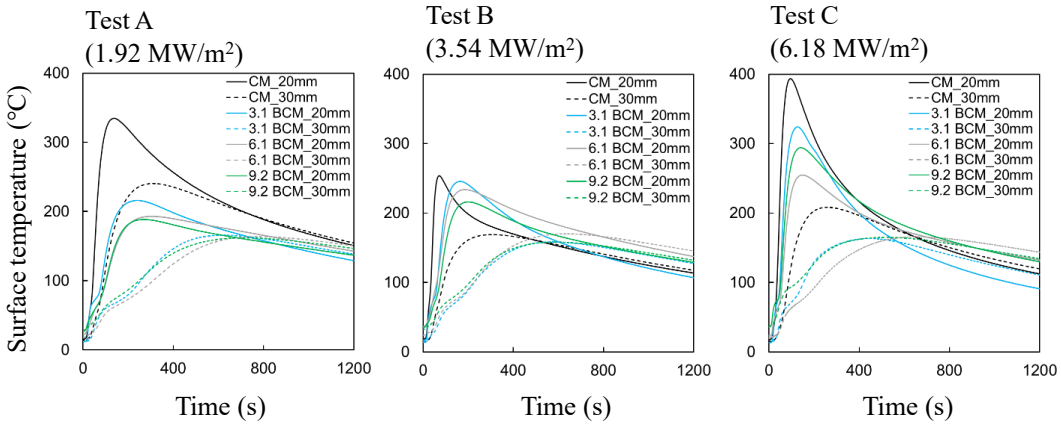

Figure 8. Temperature history of internal temperature (BCM and Carbon Monolith) [5]

4 Conclusion

BCM was fabricated by carbonizing a phenolic monolith with B_4C particles. Despite B_4C agglomerates (2–3 μm), the monolith structure was maintained. Compression tests showed that the strength decreases with the increase of B_4C content. Arc wind tunnel tests revealed lower internal temperatures for BCM than for the carbon monolith at all conditions. It was attributed to high specific heat (1.84 J / g・K) of B_4C and the evaporation B_2O_3. Thus, PCSS (in this study BCM) preserves the mechanical properties of the base monolith while providing superior thermal protection, making it a strong candidate for TPS in high-heat-flux environments.

ACKNOWLEDGEMENTS

The results of this study were derived from the arc wind tunnel tests conducted at the Institute of Space and Astronautical Science, Japan Aerospace Exploration Agency (ISAS/JAXA). The authors are grateful to Tetsuo Yoshida and Shogo Sakamoto for their assistance with these tests.

ABSTRACT

The brittle nature of the carbon fiber reinforced composites (CFRP) makes them susceptible to interlaminar fracture failures due to poor fracture toughness. This work explores the use of natural flax fiber and cellulose nanofibers to enhance the mode-I and mode-II fracture toughness of CFRP. The first part investigates the effect of asymmetric distribution of woven flax fiber in a hybrid arrangement with woven carbon fiber on the mode-I fracture toughness in comparison to CFRP. For this purpose, four different hybrid stacking sequences along with CFRP were tested using the double cantilever beam test. The critical energy release rate (G_C) evaluated exhibited a 70% increase for a one-interface carbon/flax hybrid layup. However, increasing the number of carbon/flax layers from one to four resulted in a decrease in G_C, highlighting the importance of ply placement in a hybrid arrangement for improved toughness. The experimentally evaluated G_C was used as an input in a numerical solver, which predicted the experimental response accurately. Due to the decrease in shear strength of the hybrid composite, the mode-II fracture toughness was complemented by adding cellulose nanofibers (CNFs) at the crack interface of CFRP and hybrid carbon/flax fiber reinforced composite. The CNFs were sprayed at 0.5, 0.1, and 0.2 wt% on the interface layers, resulting in an 18% and 20% increase in the mode-II fracture toughness for the CFRP and hybrid carbon/flax fiber reinforced composites, respectively. The shear strength and stiffness of the modified crack interfaces were evaluated using the cohesive zone numerical model, which showed close compliance with the experimental load-displacement plots. The fracture morphology using SEM and 3D optical microscope revealed the anchoring role of CNFs in deviating the crack path, resulting in the crack softening effect. Overall, the potential of natural fibers has been highlighted to design high-performance, lightweight, and sustainable composite structures.

1 INTRODUCTION

Carbon fiber-reinforced composites are widely used in the automotive and aerospace sectors due to their high specific strength and stiffness, enabling lightweight and fuel-efficient designs [1]. However, their brittleness and high cost limit broader application, as failures often lead to costly part replacements. To address this, hybridization with cheaper fibers like glass has been adopted, especially in interlaminar configurations where fibers are stacked layer by layer. This approach combines the strengths of different fibers while minimizing their weaknesses. Carbon/glass hybrids reduce brittleness and cost, making them popular in many applications [2]. However, growing demand for sustainable and recyclable materials calls for eco-friendly alternatives to synthetic fibers without compromising structural integrity.

Natural fibers like flax offer a promising alternative for hybridization with high-performance carbon fibers, as their specific stiffness is comparable to that of glass fibers. In hybrid composites, flax can serve as the ductile component, enhancing toughness when combined with brittle carbon fibers [3]. A common issue with CFRPs is low-velocity impact damage, which often occurs beneath the surface and remains undetectable visually. These internal damages typically develop at the fiber-matrix interface or the

interface between plies in interlaminar hybrid composites. To assess such failures, interlaminar fracture toughness tests under mode-I (opening) and mode-II (sliding) are widely employed to evaluate the toughness of composites [4].

Studies on mode-I fracture toughness for hybrid natural and synthetic fiber hybrid composites are limited in terms of taking the relevant stiffness of the beams of the double cantilever beam specimens and the utilization of asymmetric distribution of the plies to see the fracture at the natural and synthetic ply interface [5]. Moreover, the hybridization of weak natural fibers with strong carbon fibers results in a reduced shear strength, resulting in a reduction in mode-II fracture of the hybrid. For this reason, eco-friendly nano-species like cellulose nanofibers (CNFs) are adopted to offset the decrement in shear strength. But loading the CNFs at the interface so far has been in the form of interleaves that require time and extra processing steps for preparing composites with enhanced fracture toughness [6].

This work explores the effect of asymmetric hybrid placement of carbon/flax fiber composites on the mode-I fracture toughness compared to an all-carbon fiber reinforced polymer composite. Moreover, the effect of CNFs on the mode-II fracture toughness of CFRP and hybrid carbon/flax has been studied and compared with CFRP with a simple deposition method of CNFs on the interface layer. This is done to complement the decrease in shear strength due to the hybridization of flax with carbon fiber. The experimental load-displacement response has been replicated using numerical analysis, both for mode-I and mode-II fracture toughness tests. The fracture morphology of the cracked surface was observed under 3D optical microscopy and scanning electron micrographs (SEM).

2 METHODOLOGY

2.1 Materials

Plain woven CF3327-3K carbon fiber fabric was acquired from Hankuk Carbon Co., South Korea. 2-2 and Twill woven flax fiber fabric (FLAXDRYTM BL200) was supplied by EcoTechnilin, France was used as reinforcements, and Vinyl ester resin, along with cobalt naphthenate (accelerator) and methyl ethyl ketone peroxide (hardener), was supplied by CCP Composites, South Korea. was used as a matrix. The laminates were prepared by a conventional vacuum-assisted resin transfer molding (VARTM) process. A Teflon insert was used to introduce a pre-crack for the mode-I and mode-II test samples. The cellulose nanofibers were extracted from *Imperata cylindrica* grass using a hybrid chemical and mechanical treatment [7].

2.2 Experimental

The testing and specimen preparation for mode-I fracture toughness were performed as per ASTM D5528 standard using the modified beam theory. A material testing system (MTS) in a tensile mode at 3 mm/min was used to conduct the test. A double cantilever beam (DCB) test specimen was prepared, and hinges were attached using an epoxy adhesive film (Loctite EA 9695, Henkel, Korea). For the mode-II fracture toughness test, the ASTM D7905 standard was used to prepare the end-notched flexural test specimen and conduct the test. The universal testing machine (UTM) was used in a 3-point bending mode and 0.5 mm/min loading rate.

2.3 Numerical analysis

The numerical analysis was performed using ANSYS Workbench 2023 R2. For mode-I fracture toughness, a virtual crack closure technique (VCCT) was employed where the experimental G_C value was used as an input in the numerical model to simulate the experimental load-displacement behavior. For mode-II fracture toughness, a fracture energy-based cohesive zone model under pure mode-II was employed to identify the tangential contact stress (τ_{max}) and tangential contact stiffness (kt). The experimentally calculated mode-II toughness (G_{IIC}) was used directly as the critical fracture energy for tangential slip. Table 1 lists the engineering data used for the numerical analysis. A representative volume element (RVE) analysis was performed to extract the engineering data for CFRP and flax fiber reinforced polymer (FFRP).

Engineering Constants	CFRP	FFRP
ρ (g/cm^3)	1.5	1.3
$E_X = E_Y$ (GPa)	41	10
E_Z (GPa)	10	6
$\nu_{YZ} = \nu_{XZ}$	0.5	0.4
ν_{XY}	0.3	0.1
$G_{YZ} = G_{XZ}$ (GPa)	3.4	2
G_{XY} (GPa)	5	2

Table 1: Engineering Data

3 RESULTS AND DISCUSSIONS

3.1 Mode-I fracture toughness

Fig. 1 discusses the mode-I fracture toughness test. Fig. 1(a) shows the comparison of load displacement response for pure and hybrid laminates. As shown in the figure, the CFRP laminate with a peak load of 44N has the lowest load point displacement, signifying the brittle fracture. The FFRP with a peak load of 30N has a higher load point displacement, indicating its ductile nature. The hybrid laminates show a response between these two. The one interface hybrid (F/C)3/F//C/(F/C)3 exhibits the highest peak load of 50N along with the load point displacement. The peak load and the load point displacement decrease as the number of carbon/flax plies increases from one to four, showing the effect of ply asymmetry and concurrently the distribution of plies in the hybrid arrangement. The two-interface hybrid (F3C2F2//C2F2C3) exhibits a peak load at around 42N, which is like the CFRP but has higher load point displacement. For the three-interface (F2C2F3//C3F3C2), the peak load drops to 32N, which is almost like FFRP in terms of load point displacement, also. The four-interface hybrid F3C4//F4C3 exhibits similar values but lower load point displacement relevant to FFRP. Consequently, to the load displacement behaviour, Fig. 1(b) shows the critical fracture energy (G_C), which exhibits the highest value 910 J/m^2 for the one interface (F/C)3/F//C/(F/C)3 hybrid compared to 440 J/m^2 for CFRP. This is a significant improvement of 70% for the mode-I fracture toughness via hybridization. The two-interface hybrid (F3C2F2//C2F2C3) exhibits a value of 749 J/m^2, followed by the three-interface (F2C2F3//C3F3C2) hybrid at 656 J/m^2 and the four-interface hybrid F3C4//F4C3 at 430 J/m^2. The FFRP exhibits G_{IC} equivalent to 600 J/m^2 more than CFRP due to the higher load point displacement. These results indicate at the fact that a more equal asymmetric distribution of the flax plies in the beams of the DCB test specimen results in lower stiffness, causing the beams to deform more, which becomes stiff when the plies start to be grouped in other asymmetric hybrid arrangements mentioned. Fig. 1(c) shows the load displacement curves comparison of the numerical simulation model and experimental results. As exhibited, the numerical curves show close compliance in terms of predicting the peak load and the load point displacement for all the laminates, which is critical in estimating the initiation critical mode-I fracture toughness. The fracture morphology exhibited for the one interface hybrid in Fig. 1(d) shows the top view of the fractured beams, with (1) being the bottom being showing 3D optical microscopic images of the carbon ply with resin-rich region near the crack initiation point and the filament pullout indication at fiber bridging. The (2) shows the top beams' fractured surface, where the flax ply is visible underneath the resin layer on top. The texture of the opposing CFRP ply has visibly imprinted itself on the flax ply, showing mechanical interlocking effects. The SEM images taken from the side of the top flax ply show a thick resin layer on the surface of the flax ply. This shows the hydrophilicity of natural fibers, causing the resin layer to accumulate on the flax ply surface [8]. In composites, it's not an ideal

scenario as hydrophilicity leads to weak interfacial strength between the fiber and matrix, but in this case, it leads to a mechanical interlocking effect between the two different interfaces, resulting in a significant increase in the mode-I fracture toughness.

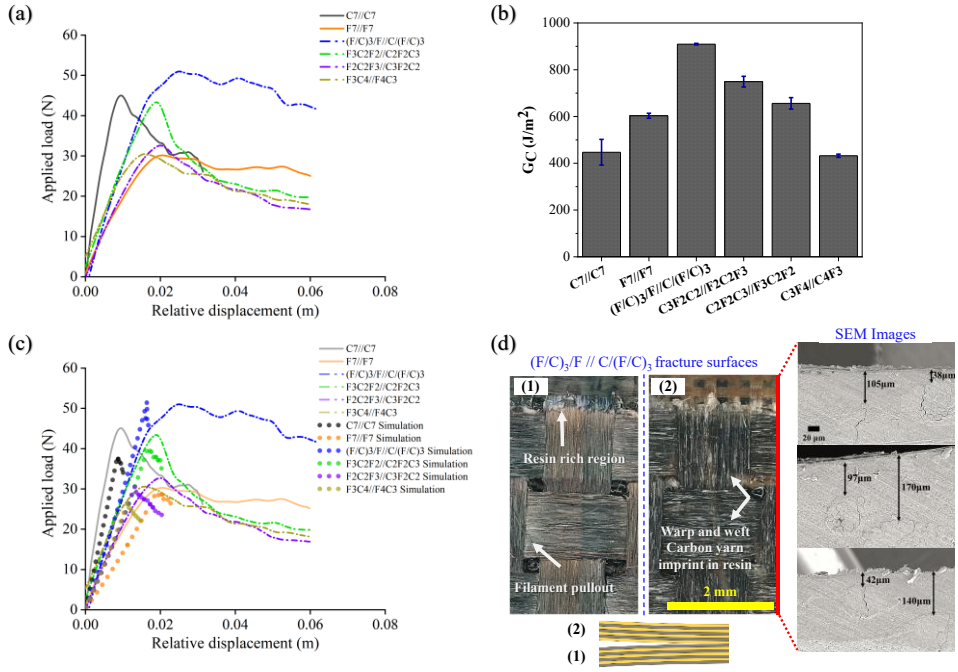

Figure 1: Mode-I fracture toughness, (a) Load displacement curves, (b) Critical fracture toughness, (c) Load displacement curves comparison, (d) fracture morphology.

3.2 Mode-II fracture toughness

Fig. 2 discusses the mode-II fracture toughness test. Fig. 1(a) shows the load displacement response of CFRP, $CFRP_{CNFs}$, hybrid, and hybrid with CNFs. From the load displacement curves, the CFRP, after reaching its peak load at around 680N, undergoes a sudden drop, which indicates the brittle fracture. The CFRP with 0.05% CNFs exhibits a peak load at around 670N, but due to the presence of CNFs, the load point displacement showed an increase compared to the CFRP. After attaining the peak load, there is no sudden drop, demonstrating the effect the CNFs have. This behaviour becomes more dominant for the CFRP with 0.1% CNFs, where the peak load reaches approximately 700N, and the crack arrest at the peak load is also more visible before the load drop. By increasing the CNFs to 0.2% the peak load reduces to around 580N, indicating the ability of the CNFs to act as an impurity at higher loading percentages, causing the crack to initiate much earlier. The reason for this behaviour is the inherent nature of the cellulose, which is derived from a natural resource, tends to be hydrophilic, resulting in reaction with matrix materials and causing the weakening of hydrogen bonding within itself. This causes a weak interfacial adhesion with the matrix, hence acting as an impurity at higher weight percentages. Similar behaviour is observed for hybrid layups [9]. In the hybrid with only flax fabric at the interface (C7/F//C7) the lowest peak load is observed at 475N, and despite no sudden load drop, the effect of placing flax fabric only at the interface was not effective. Adding 0.5 wt% of CNFs on the flax fabric at the interface (C7/F0.05% CNFs//C7) improves not only the peak load up to 500N but also enhances the crack arrest behaviour evident from the shape of the curve post peak load. A similar effect is observed for 0.1 wt% of CNFs at the hybrid interface (C7/F0.1% CNFs//C7) with a peak load at 528N, but the crack arrest post maximum load is not as dominant as the hybrid with 0.05 wt% of CNFs. Corresponding to this behaviour the G_{IIC} values are given in Fig. 2(b). The CFRP showed a G_{IIC} value of 1056 J/m^2, compared to 1045 J/m^2 for CFRP with 0.05% CNFs and 1270 J/m^2 for CFRP with 0.1% of CNFs. This shows an increase of 18% in the G_{IIC} value of CFRP with 0.1% of CNFs compared to pure CFRP. For the hybrid without CNFs, the G_{IIC} is 1006 J/m^2, which shows the decrease in shear strength of the hybrid composite. With CNFs at 0.05 wt%, the hybrid composite exhibits the highest G_{IIC}, i.e., 1295 J/m^2, while

the hybrid with 0.1 wt% of CNFs showed almost similar G_{IIC} compared to CFRP. Fig. 2(c) shows the comparison between numerical and experimental results. As shown, the cohesive zone numerical model shows close compliance to the experimental load-displacement response. In terms of the peak load, load point displacement, and the post-crack behaviour, all the attributes are correctly predicted by the numerical model for all the layups. Fig. 4(d) shows the fracture morphology under SEM for CFRP with 0.1% of CNFs and the hybrid with 0.05% CNFs. As visible from the images, the crack initiation sites showed agglomerated CNFs and fibers being pulled out from the opposing surface. This shows the anchoring role the CNFs play when loaded at their optimum amount can deviate the crack path, causing crack softening behaviour discussed from the load displacement curves. Moreover, the elongation of the crack is also due to increased fiber bridging, causing an increase in the mode-II fracture toughness.

4 CONCLUSIONS

In this study, the interlaminar fracture toughness of carbon fiber-reinforced polymer (CFRP) composites was significantly enhanced through two strategies: interlaminar hybridization with flax fibers for mode I and the incorporation of cellulose nanofibers (CNFs) for mode II. Under Mode-I loading, an asymmetric stacking sequence of flax and carbon fiber ($(F/C)_3/F//C/(F/C)_3$) demonstrated a 70% increase in critical energy release rate (G_{IC}) compared to conventional CFRP. For mode-II, CNFs were deposited both directly at the crack interface and via CNF-loaded flax fabrics. An 18% increase in G_{IIC} was observed for CFRP with 0.1 wt% CNFs, and a 20% increase for the hybrid with 0.05 wt% CNFs-loaded flax interface, indicating improved crack resistance during delamination. However, 0.2 wt% CNFs reduced performance due to excessive nanofiber content, resulting in impurities at the crack interface. Numerical simulations using the virtual crack closure technique for mode-I and the cohesive zone method for mode-II effectively replicated the fracture behavior, identifying the peak loads, load point displacements, and post-crack behavior. SEM and 3D microscopy confirmed increased fiber bridging due to mechanical interlocking in the case of mode-I fracture. In case of mode-II, crack deflection and matrix plasticity due to the presence of CNFs, contributing to a more stable delamination as opposed to pure CFRP and hybrid without CNFs. Overall, the study underscores the importance of ply architecture and nanofiber optimization for enhancing fracture toughness in CFRP composites.

ABSTRACT

Nature's materials achieve exceptional fracture resistance through architectural control, as exemplified by nacre's crack-deflection mechanisms. Inspired by this principle, we engineer composite interfaces at the microscale by patterning carbon and glass fibres with alternating adhesion zones. Using a custom atmospheric pressure plasma CVD torch, we deposit spatially controlled 3-Aminopropyltriethoxysilane (APTES) coatings with 200 µm periodicity, creating regions of high and low interfacial shear strength. This approach circumvents the limitations of bulk biomimicry by directly manipulating the critical fibre-matrix interface where fracture initiates. Computational modelling reveals the transformative potential of this architecture. Finite element analysis predicts an 80% increase in debonding lengths compared to uniformly treated fibres, while retaining 95% of interfacial shear strength—effectively decoupling the classical strength-toughness trade-off. Molecular dynamics simulations further elucidate the underlying mechanism: sequential bond rupture in high-adhesion zones transitions to progressive interfacial sliding in untreated regions, enabling 40% greater energy dissipation through controlled stress redistribution. These findings align with nacre's hierarchical energy management strategy, translated here to synthetic composites. The atmospheric plasma process demonstrates significant scalability, operating at ambient conditions with fibre translation speeds exceeding 10 m/min. Experimental validation of these computational predictions through micro-droplet pull-out tests is currently underway. By establishing a direct pathway for integrating bioinspired interfaces into industrial manufacturing, this work opens new frontiers for designing damage-tolerant composites where interfacial architecture actively governs fracture behavior.

1 INTRODUCTION

Composite materials have revolutionized aerospace, automotive, and renewable energy industries through their exceptional strength-to-weight ratios. Despite these advantages, their inherent brittleness often leads to catastrophic failure under impact or fatigue loading—a critical limitation that persists across applications from wind turbine blades to aircraft structures. This vulnerability stems from inefficient energy dissipation mechanisms at the fibre-matrix interface, where stress concentrations initiate microcracks that rapidly propagate through the material.

In stark contrast, biological materials like nacre exhibit remarkable fracture resistance despite their mineral composition. Natural selection has optimized intricate architectures where staggered aragonite platelets bonded by organic layers force cracks to follow tortuous paths, dissipating energy through protein unfolding and sacrificial bond rupture. While substantial research has focused on replicating

nacre's "brick-and-mortar" structure in bulk composites, these approaches face significant scalability challenges when applied to fibre-reinforced systems.

Our research introduces a paradigm shift by directly engineering the fibre-matrix interface—the critical region governing composite fracture behavior. Rather than mimicking nacre's macroscale architecture, we translate its underlying principle of controlled crack deflection to the microscale. By creating spatially alternating zones of high and low adhesion on individual carbon and glass fibres, we force propagating cracks to repeatedly arrest and redirect, transforming brittle failure into a stable, energy-absorbing process. This strategy preserves the inherent strength of continuous fibres while introducing new toughening mechanisms at the most vulnerable interface.

Central to this innovation is atmospheric pressure plasma CVD technology, which enables solvent-free, high-speed patterning of fibre surfaces. Unlike conventional sizing or grafting methods that produce uniform coatings, our micro plasma torch creates precisely defined interfacial heterogeneities—a capability previously unattainable in composite manufacturing. The following sections detail how this bioinspired interface design fundamentally transforms composite fracture behavior.

2 MATERIALS AND METHODS

2.1 Plasma-Assisted Patterning

Carbon fibres (Toray T800S) and E-glass fibres (Owens Corning) underwent surface patterning using an in-house micro plasma torch system. The apparatus featured a precision XYZ stage with 0.1 µm positioning accuracy, coupled with a radiofrequency (RF) atmospheric plasma source operating at 20 W. A helium-ammonia gas mixture generated a stable plasma jet, while vaporized APTES precursor was introduced downstream to ensure controlled deposition.

The patterning process involved synchronized movement of fibres beneath the plasma torch with precisely timed plasma pulses. By alternating 100 ms activation and deactivation cycles while translating fibres at 5 mm/s, we achieved periodic coatings with 200 µm spacing between high-adhesion zones. This intermittent treatment created a "digital fingerprint" of alternating bond strength along each fibre's length.

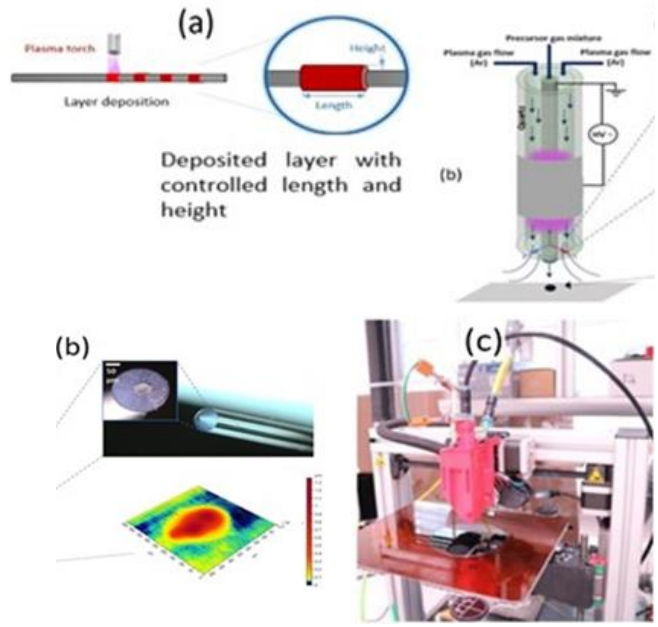

Figure 1. (a) Design of the APTES coating on carbon fibres. (b) Schematic representation of the plasma micro torch functioning. (c) Plasma torch setup

2.2 Characterization Techniques

Surface morphology of treated fibres was examined using a FEI Quanta 650 scanning electron microscope (SEM) and a Bruker Dimension Icon atomic force microscope (AFM). Chemical composition across patterned zones was mapped via energy-dispersive X-ray spectroscopy (EDX) and X-ray photoelectron spectroscopy (XPS), with particular attention to silicon and nitrogen distributions confirming APTES deposition.

Interfacial properties were quantified through micro-droplet pull-out tests according to ASTM D7337. Epoxy resin micro-droplets (Epikote 828 with Jeffamine D230 hardener) were cured on treated fibre segments and subjected to tensile displacement at 0.1 mm/min. High-speed imaging captured crack propagation dynamics during debonding events.

2.3 Multi-scale Modelling

Molecular dynamics simulations in LAMMPS modeled APTES-epoxy interfaces at the atomic scale, examining bond rupture sequences under shear loading. Complementary finite element analysis in ABAQUS simulated crack propagation through patterned interfaces, incorporating cohesive zone elements to represent alternating adhesion strengths. These models predicted stress redistribution during debonding and energy dissipation mechanisms.

3 RESULTS AND DISCUSSION

3.1 Coating Uniformity and Composition

SEM imaging confirmed the successful application of homogeneous APTES coatings along fibre surfaces, with clear transitions between treated and untreated zones (Figure 2, top left). The precision of our plasma process was validated by depositing identical patterns on silicon wafers, revealing sharply defined 200 μm features with edge resolution below 5 μm (Figure 2, bottom left).

Chemical characterization provided critical insights into bonding mechanisms. EDX mapping demonstrated distinct silicon enrichment in treated regions (Figure 2, right), while XPS analysis detected characteristic Si-O-C bonds at 102.5 eV—confirming covalent bonding between APTES silane groups and carbon fibre surfaces. AFM measurements further revealed that plasma treatment maintained surface roughness below 10 nm RMS, ensuring uniform stress transfer without introducing stress-concentrating defects.

3.2 Interfacial Mechanics and Toughening Mechanisms

Finite element modelling (FEA) reveals the transformative potential of our bioinspired interfacial architecture. Though experimental pull-out validation is ongoing, the computational evidence paints a compelling picture: alternating adhesion zones fundamentally reconfigure fracture behavior at the fibre-matrix interface. When we subjected simulated patterned interfaces to shear loading, the digital fibres exhibited remarkable behavior unseen in conventional composites.

As cracks propagate through high-adhesion regions—where APTES creates covalent bonds with both fibre and matrix—they encounter sudden energy barriers upon reaching untreated zones. Our simulations capture this critical moment: the crack tip blunts as stresses redistribute, forcing the fracture path to deflect parallel to the fibre axis. This redirection creates new fracture surfaces that absorb energy through matrix deformation and interfacial friction. The digital fibres resisted separation with 80% longer debonding lengths than uniformly bonded controls, while preserving 95% of their interfacial shear strength. This dual achievement challenges decades of composite design dogma where strength and toughness were mutually exclusive.

At the atomic scale, molecular dynamics simulations unveil the orchestrated failure sequence. In high-adhesion zones, covalent bonds fracture rapidly like snapping piano wires, immediately followed by the graceful yielding of weaker van der Waals interactions in untreated regions. This hierarchical rupture sequence—reminiscent of nacre's multi-scale energy dissipation—absorbs 40% more energy than homogeneous interfaces.

The precision of our plasma patterning process, already demonstrated through 200 µm features on silicon wafers and fibres (Figure 2), sets the stage for experimental confirmation. Current pull-out tests will measure whether physical fibres mirror their digital twins, quantifying crack propagation stability through high-speed imaging and mapping the exact correlation between pattern geometry and toughening efficiency.

3.3 Manufacturing Implications

Nature's materials achieve exceptional fracture resistance through architectural control, as exemplified by nacre's crack-deflection mechanisms. Inspired by this principle, we engineer composite interfaces at the microscale by patterning carbon and glass fibres with alternating adhesion zones. Using a custom atmospheric pressure plasma CVD torch, we deposit spatially controlled 3-Aminopropyltriethoxysilane (APTES) coatings with 200 µm periodicity, creating regions of high and low interfacial shear strength. This approach circumvents the limitations of bulk biomimicry by directly manipulating the critical fibre-matrix interface where fracture initiates.

Computational modelling reveals the transformative potential of this architecture. Finite element analysis predicts an 80% increase in debonding lengths compared to uniformly treated fibres, while retaining 95% of interfacial shear strength—effectively decoupling the classical strength-toughness trade-off. Molecular dynamics simulations further elucidate the underlying mechanism: sequential bond rupture in high-adhesion zones transitions to progressive interfacial sliding in untreated regions, enabling 40% greater energy dissipation through controlled stress redistribution. These findings align with nacre's hierarchical energy management strategy, translated here to synthetic composites.

The atmospheric plasma process demonstrates significant scalability, operating at ambient conditions with fibre translation speeds exceeding 10 m/min. Experimental validation of these computational predictions through micro-droplet pull-out tests is currently underway. By establishing a direct pathway for integrating bioinspired interfaces into industrial manufacturing, this work opens new frontiers for designing damage-tolerant composites where interfacial architecture actively governs fracture behavior.

4 CONCLUSIONS

This research demonstrates a biomimetic strategy for overcoming the strength-toughness trade-off in composites through interfacial architecture. By leveraging atmospheric pressure plasma CVD, we have successfully engineered carbon and glass fibres with spatially controlled APTES patterns, achieving alternating 200 µm adhesion zones that emulate nacre's crack-deflection principles at the microscale. Computational modelling provides fundamental insights into the mechanical behavior of this architecture: finite element analysis predicts these designed interfaces will extend debonding lengths by approximately 80% while retaining 95% of interfacial shear strength compared to uniformly treated fibres. Molecular dynamics simulations further reveal the underlying mechanism – sequential bond rupture in high-adhesion regions transitions to progressive interfacial sliding in untreated zones, enabling 40% greater energy dissipation through controlled stress redistribution.

The significance of this approach lies in its scalability and precision. The atmospheric plasma process operates without vacuum constraints at translation speeds exceeding 10 m/min, making it compatible with industrial fibre production lines. As we advance to experimental validation through micro-droplet pull-out tests, this methodology establishes a framework for designing hierarchical interfaces that fundamentally decouple strength and toughness limitations. Future work will quantify pattern-geometry effects and extend the concept to multifunctional coating systems, opening pathways for next-generation damage-tolerant composites.

ABSTRACT

As a next generation composite material, carbon fiber reinforced polymer (CFRP) has great potential to be widely used in manufacturing industries due to its outstanding mechanical properties. The high strength to weight ratio, and high stiffness inherent to CFRPs make them a desired material in various kinds of applications. CFRPs frequently experience bending loads while in use for such things as aircraft, automobiles, bridges, etc. Anisotropic behavior and limited in through thickness properties are major concerns which affect the performance of CFRPs. Moreover, in the interlaminar region, traditional CFRPs are often vulnerable to matrix sensitive damage such as compressive failure, delamination, and shear failure due to the absence of enough strength in through thickness direction. The tensile and compressive stress generated by the bending loads can weaken the interlaminar shear properties due to the absence of fibers in through thickness and ultimately can lead to catastrophic failure. This study introduces a novel approach with z-threaded CFRP (ZT-CFRP), which incorporates electrically aligned z-threaded carbon nanofibers (CNFs) as reinforcement. Flexural test using 3-point bending was performed on both control CFRP and ZT-CFRP samples reinforced with 1.0 wt.% carbon nanofiber z-threads. The results showed a 15% improvement in the flexural strength and about 36% linear elastic range increase for the ZT-CFRP laminates compared to the unmodified CFRP laminates, and validated the effectiveness of nanofiber Z-threading strategy in strengthening composite materials against flexural loading.

1 INTRODUCTION

Composite materials are quietly revolutionizing every field of engineering, offering designers new possibilities that often go unnoticed [1]. Composite materials are quietly revolutionizing every field of engineering, offering designers new possibilities that often go unnoticed [1]. Composites are highly desirable for primary and secondary structures in both military and civilian aircraft, bio engineering, sports, automobile, marine industry due to their combination of high stiffness, high strength, and low density [2-9].

Carbon fiber reinforced polymer (CFRP) stands out among fiber reinforced polymer (FRP) composites due to its exceptional properties. CFRPs are widely adopted in engineering applications where weight savings and mechanical performance are critical. It offers notably higher tensile strength, modulus of elasticity, and fatigue resistance compared to other FRPs. In addition, CFRP demonstrates excellent performance under harsh conditions, with superior resistance to fire and chemical exposure [10].

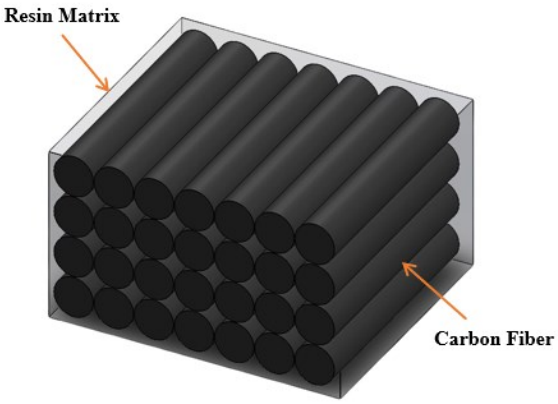

Fig 1: Typical configuration of carbon fiber reinforced polymer

CFRP exhibits desirable properties along the fiber direction; however, its material properties are significantly limited in the through-thickness direction due to the absence of reinforcing fibers as shown in Fig 1. This leads to delamination, which occurs from interlaminar stresses combined with low through-thickness strength of the material. Since the fibers within the laminate plane do not reinforce the through-thickness direction, this phenomenon arises [11]. Additionally, conventional CFRPs are prone to damage that is sensitive to the matrix, including issues like compressive failure, delamination, and shear failure in the interlaminar areas, primarily due to the lack of strength in the z-direction. The lack of reinforcement in this direction results in delamination when subjected to significant out-of-plane loads [12]. The tensile and compressive stress generated by the bending loads can weaken the interlaminar shear properties due to the absence of fibers in through-thickness and ultimately can lead to catastrophic failure

Several approaches have been explored for through-thickness reinforcement to enhance delamination resistance across the thickness. The most widely studied techniques include nanoparticle reinforcement [13-15] and stitching [16-17]. Although fiber stitching improves the interlaminar properties of CFRPs, boosting resistance to delamination and damage, it also presents challenges, such as potential fiber damage by the stitching machine and process, greater manufacturing complexity, and a reduction in overall performance for certain applications.

Watson et al. [18] used graphene oxide (GO) to improve the flexural properties of CFRP but incorporating GO into the composite has had minimal impact. Zhou et al. [19] found higher flexural properties by using nanoclay in CFRP composite. But high nanoclay content increases composite stiffness but reduces flexibility and energy absorption, leading to early failure under flexural stress. It also limits resin chain mobility, hindering effective stress redistribution [20]. Ulus et al. [21] also achieved higher flexural properties by using boron nitride nano particles and carbon nano tube.

This study aims to investigate flexural properties as well as observe failure mechanisms and microstructural changes that occur in the patented [22] CNF z-threaded CFRP (ZT-CFRP) after deformation in comparison to traditional CFRP. Three point bending test in accordance with ASTM D-790 will be performed to obtain the flexural properties of ZT-CFRP. As illustrated in Fig 2, in a ZT-

CFRP the zig-zag pattern of carbon nanofibers threading between carbon fiber array in the z-direction forms an interlocked multiscale fiber reinforcement network which increases the interlaminar shear properties as well as other mechanical properties such as interlaminar shear strength, in-plane shear strength, and longitudinal compressive strengths [23-26]. The z-threaded carbon fiber reinforced polymer (ZT-CFRP) laminates, due to its advanced nano-structured reinforcement network, have been shown to have strengthened mechanical [23-26], thermal [26, 27], and electrical [28] properties.

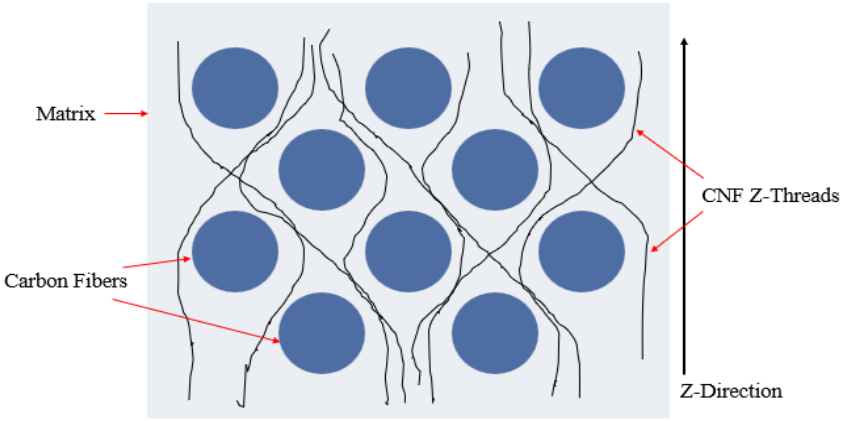

Fig 2: Principle behind the ZT- CFRP system

3 EXPERIMENTATIONS

3.1 Materials

The materials used to perform this experiment were: Hexcel AS4 unidirectional fabric (1.79 g/cm^3 fiber density, 12k tow size), Epon 862 epoxy resin and Epikure-W curing agent (Miller-Stephenson Chemical Co. Inc.), CNF PR-24-XT-PS grade (Pyrograph Products Inc.), S-191 and S-192 surfactants from BYK. Unmodified control CFRP and 1.0 wt.% ZT-CFRP were prepared in this study.

3.2 Control CFRP prepreg manufacturing

To fabricate the control CFRP, Epon-862 epoxy resin was combined with Epikure-W curing agent at a weight ratio of 100:26.5 and mixed manually. The resulting mixture underwent a 90-minute degassing process in a vacuum oven set at 120 °C. Throughout degassing, the resin was periodically monitored for B-staging every 2 to 5 minutes starting at the 45-minute mark. Once degassed, the resin blend was processed into a thin, uniform film using a proprietary film-casting technique. This film was then segmented into smaller portions and stored at −17 °C to preserve its pre-cure state for subsequent prepregging. These frozen segments were later reheated to 120 °C and subjected to hot-melt processing, during which they were impregnated into AS4 carbon fiber using a patent-pending [29] roll-to-roll ZT-CFRP prepreg manufacturing machine.

3.3 ZT-CFRP prepreg manufacturing

In the preparation of ZT-CFRP, 1.0 wt.% of CNFs were mixed with Epon-862 epoxy resin. In ZT-CFRP, achieving a uniform dispersion of carbon nanofibers (CNFs) throughout the resin blend is crucial. If not properly dispersed, the CNFs can coagulate in localized areas, compromising the material's performance. To ensure distribution, in resin mixture containing CNFs, 1 wt.% of surfactants Disperbyk-191 and Disperbyk-192 were added. This step is essential for maintaining the homogeneity of the mixture and optimizing the properties of the final CFRP product. For proper mixing, the mixture was

mixed with high shear mixture for 60 minutes in clockwise and anticlockwise directions on an equal time. After the CNFs were incorporated into the matrix, the mixture underwent mechanical mixing for one hour followed by one hour of sonication using a QSONICA Q700 sonicator until proper dispersion of CNFs was found in microscope.

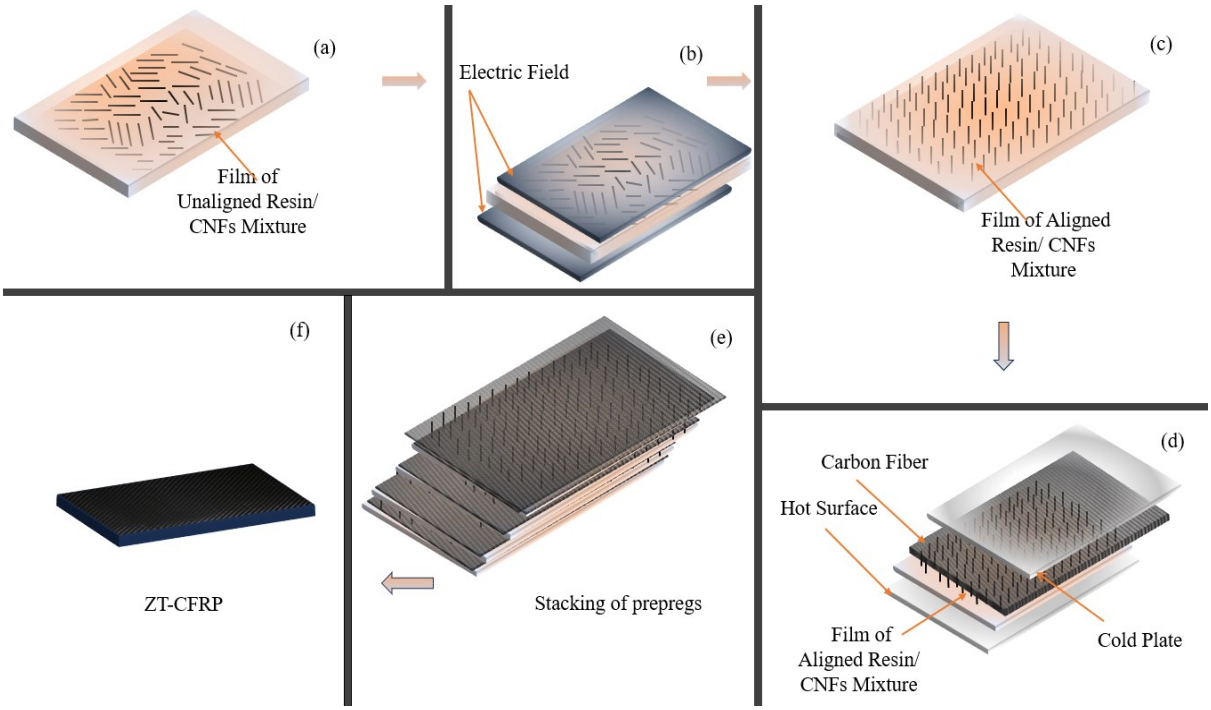

Fig 3 : Depiction of the concept of ZT-CFRP prepreg production process: (a) a thin hot-melt film consisting of B-staged resin/CNFs mixture with Epikure-w (b) Unaligned CNFs under the electric field (c) aligned resin/CNFs mixture in the cooled and solidified thin film (d) flow transfer aligned CNFs/ resin mixture with carbon fiber into dry carbon fabric using an non-isothermal hot-melt ZT-CFRP prepreg manufacturing system (e) stacking of prepregs for laminate curing (f) cured ZT-CFRP laminate

The resin mixture was initially placed in a vacuum chamber at 120 °C for 60 minutes to remove entrapped air and volatiles. Following this initial degassing, the curing agent Epikure-W was added to the epoxy resin at a stoichiometric ratio of 100:26.5 and manually mixed to ensure homogeneity. The blended solution was then subjected to a second degassing and partial curing (B-staging) process at 100 °C for 90 minutes. B-staging progress was monitored starting at the 45-minute mark, with assessments performed every 2 to 5 minutes.

For the fabrication of ZT-CFRP prepregs, the CNF/epoxy resin film was immediately passed through an applied electric field, which oriented the carbon nanofibers into a continuous, aligned structure. As the film cooled, the resin matrix solidified, preserving the nanofiber alignment within the film. The aligned CNF/epoxy film was subsequently sectioned into specified dimensions and stored at −17 °C to maintain its pre-cure state.

These CNF-aligned resin films were fed to the proprietary ZT-CFRP prepreg machine (patent-pending [29]) to impregnate an unidirectional carbon fabric containing many fiber tows and output the ZT-CFRP prepreg at the end of the machine. The final prepreg sheets, containing uniformly aligned CNFs, were again stored at −17 °C until further use in composite fabrication.

3.4 Out-of-Autoclave–Vacuum Bag Only Process for Curing Composite Laminate

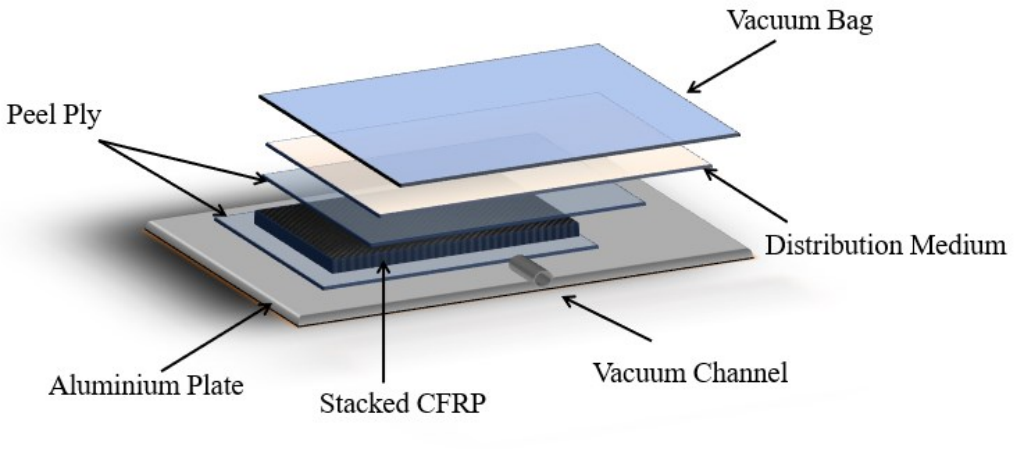

Fig 4: Schematic Diagram of OOA-VBO (Autoclave vacuum bag only) Setup.

In the Out-of-Autoclave–Vacuum Bag Only (OOA-VBO) process, an aluminum mold surface was first treated with a release agent, carefully avoiding regions designated for bonding with the sealant tape. The layup sequence included a peel ply layer, stacked CFRP plies, a second peel ply, a vacuum channel, sealant tape, and a vacuum bag, as illustrated in Fig 4. The assembly was placed in a hot press and cured at 120 °C for 120 minutes. After curing, the panel was allowed to cool under vacuum before demolding. A subsequent post-cure at 180 °C for another 120 minutes was performed to enhance the laminate's thermal and mechanical stability. This controlled process facilitates the production of high-quality CFRP laminates with aligned CNF-reinforced prepregs, ensuring optimal mechanical performance and structural consistency.

3.5 Flexural Test

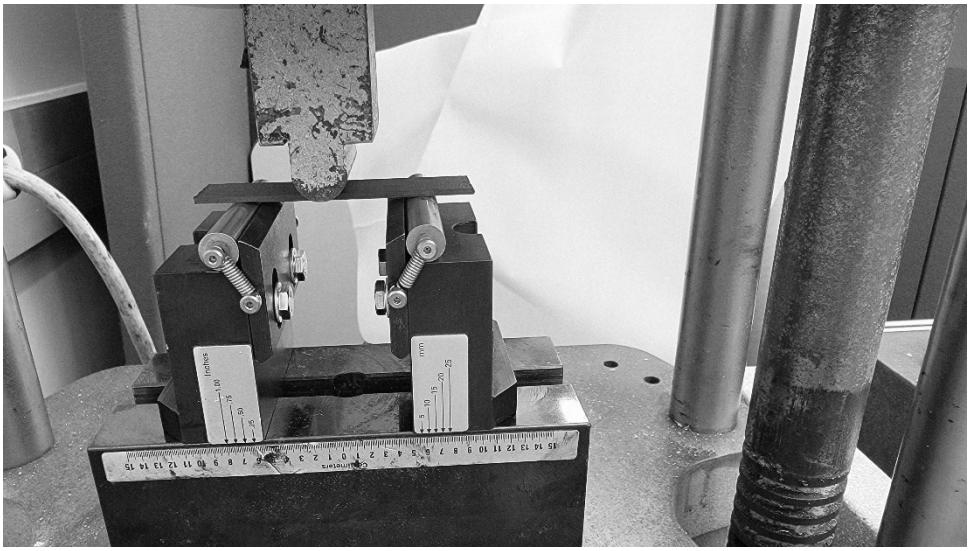

Fig 5: Experimental Setup for 3 Point Bending Test

The samples were tested using the universal testing machine (Tinius Olsen 60SL) at a constant crosshead displacement rate of 4.0 mm/sec (see Fig 5). The laminate CFRP samples were tested to evaluate their flexural bending response following ASTM D790-03 [30]. The specimens were measured 100 mm Length x 20 mm Width x 2.30 mm Thickness. The Span length was 75 mm.

4 RESULTS AND DISCUSSIONS

The flexural stress-strain curves until failure are plotted in Fig 6 for both control CFRP and ZT-CFRP and stress, strain and movement of the cross head were calculated according to ASTM D790. The average flexural stress for control CFRP was 1067 MPa while 1228 MPa for ZT-CFRP showing 15% higher strength. This enhanced in-plane shear performance indicates that the CNF z-threads reinforce the layers by forming an interlocked multiscale fiber reinforcement network in both the interlaminar zone and intralaminar zone to achieve overall reinforcing effect between carbon fibers in the laminate.

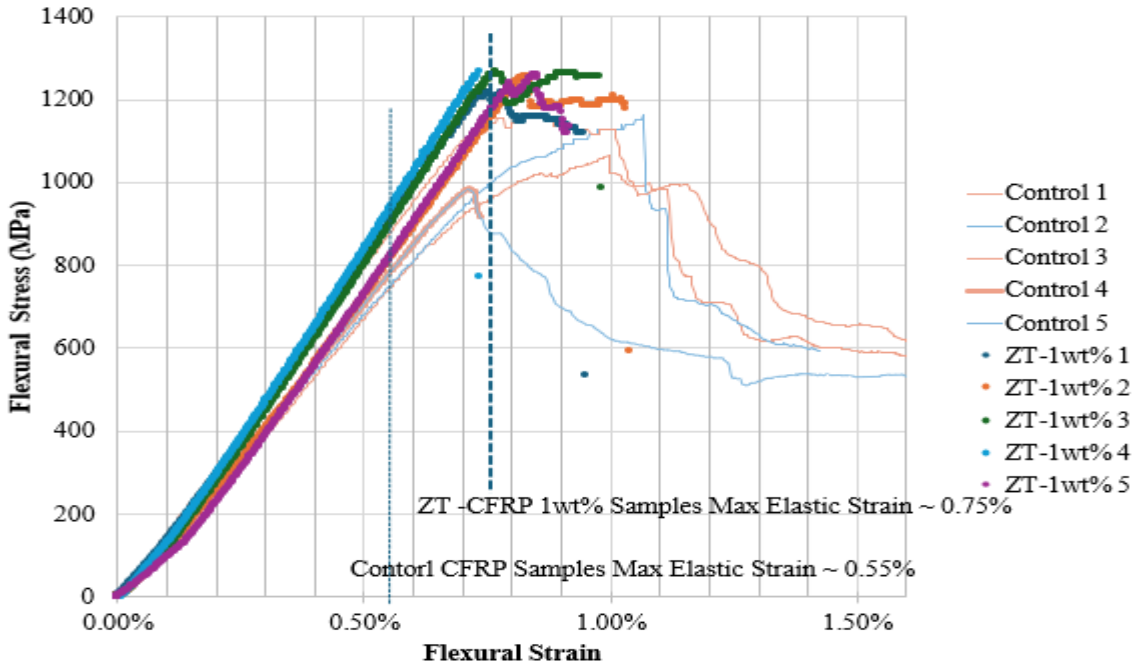

Fig 6: Stress strain curve for control CFRP and ZT-CFRP

In the three-point bending test, the control CFRP exhibited higher deflection compared to the ZT-CFRP, indicating that it is more flexible and less stiff, especially after it passed the elastic deformation range with the flexural strain ranging from 0-0.55% (i.e., the straight line range of the stress-strain curves). This greater deflection suggests that the control sample has lower resistance to bending after the elastic range, potentially due to weaker fiber–matrix interactions or lower structural reinforcement leading to the micro-level internal damages such as micro-cracks prior the total failure of the laminate. In contrast, the reduced deflection observed in the ZT-CFRP implies improved elastic performance along with extended elastic range with the flexural strain ranging from 0-0.75% (i.e., the straight line range of the stress-strain curves), likely resulting from enhanced mechanical interlocking through the CNF z-threads and carbon fibers network. The stress–strain curve of ZT-CFRP displays a significantly well-defined initial slope as a straight line compared to the control's bending down curve, indicating a more predictable and linear elastic behavior of ZT-CFRP. This is followed by a well-defined plastic deformation phase and a subsequent drop in stress after failure. Such a profile is indicative of ductile material behavior, characterized by the ability to sustain considerable deformation and absorb energy before fracturing. On the other hand, the control CFRP exhibited a gradual decline in strength accompanied by higher deflection, which is indicative of limited load-bearing capacity and reduced

structural integrity after the much earlier initial failure (as indicated by the much smaller linear elastic strain range up to only 0.55% strain) compared with ZT-CFRP (with significantly larger linear elastic strain range up to only 0.75% strain). This behavior suggests that control CFRP has a weaker reinforcement mechanism, with less energy absorption and lower resistance to crack propagation compared to ZT-CFRP. Furthermore, all five ZT-CFRP specimens showed significantly more consistent and reliable flexural performance than the five control CFRP specimens, which indicated the ZT-CFRP likely provided a more reliable reinforcement system than control CFRP, at least for bearing flexural loading. Table 1 summarizes the flexural properties of control and ZT-CFRPs.

Table 1: Flexural properties of control and ZT-CFRPs

CFRPs	Fiber Volume Fraction (%)	Avg. Force (N)	Avg. Flexural Strength (MPa)	Max. Linear Elastic Strain (%)	Max. Linear Elastic Stress (MPa)
Control CFRP	53	1076	1067	~0.55	~800
1.0 wt.% ZT-CFRP	52	1230	1228	~0.75	~1228
Improvement of ZT-CFRP	-	-	+15.1%	+36.4%	+53.5%

Fig 7: Fracture mode of control CFRP (top) and ZT-CFRP (bottom)

In control CFRP samples, interlaminar cracks tend to follow a smooth, well-defined path, indicating weak interface adhesion and a propensity for resin-dominated failure (Fig. 7). This clean separation

between layers suggests limited resistance to crack propagation across the laminate. In contrast, the ZT-CFRP exhibits a highly irregular and disrupted crack path. This behavior is attributed to the presence of carbon nanofiber (CNF) z-threads, which enhance mechanical interlocking between layers. These z-threads act as barriers to crack growth, diverting and arresting crack propagation. In some instances, the improved bonding and load transfer facilitated by the z-threads are so effective that the failure progresses through fiber breakage rather than just matrix or interface failure, highlighting a significant improvement in structural integrity and damage tolerance.

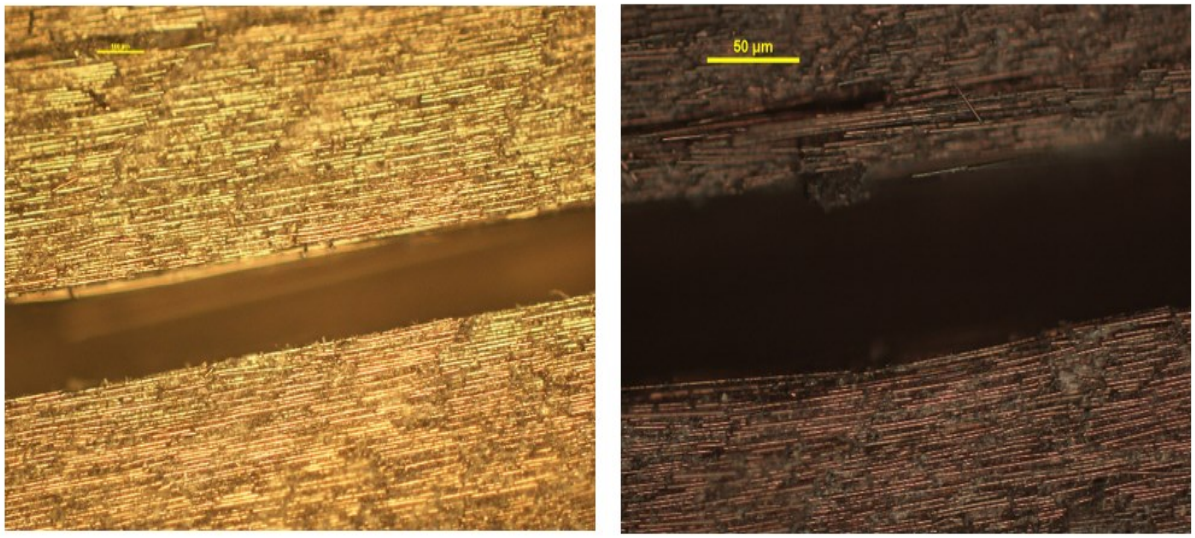

Fig 8 : Microscopic images of the control CFRP (left) and ZT-CFRP (right) at 100x magnification show distinct fracture patterns. The control CFRP exhibits a straight fracture path, while the ZT-CFRP displays a curved fracture trajectory accompanied with separation of carbon fibers.

Microscopic side-view images (see Fig 8) of ZT-CFRP reveal that the aligned carbon nanofibers (CNFs) serve as reinforcement bridges between adjacent fiber layers. These nanofibers effectively bear compressive stresses in the top layer, enhancing structural integrity. Top-view images (see Fig 9) further demonstrate that the CNFs form interlocking connections between carbon fibers, strengthening the bonding and providing support under tensile stresses in the bottom layer. This suggests that the z-threaded CNFs act as anchoring elements, resisting delamination within individual layers by holding carbon fibers together. Additionally, the reinforced bonding created by these z-threads between stacked layers is strong enough to prevent tearing or propagation of cracks into neighboring layers.

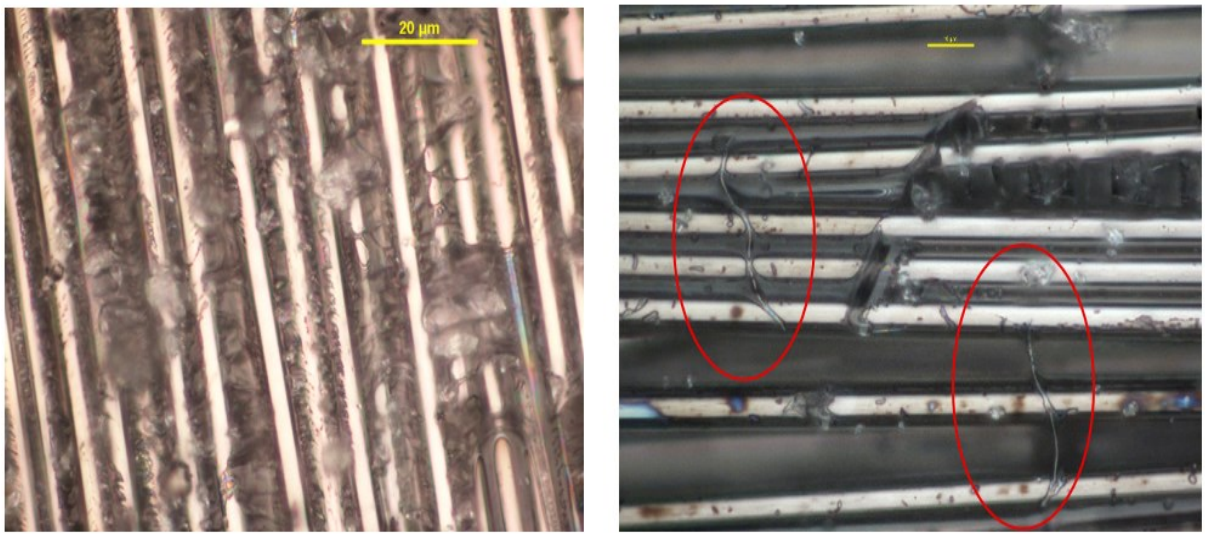

Fig 9 : Top-side microscopic images of the control CFRP (left) and ZT-CFRP (right), captured at 1000x and 1250x magnification, highlight significant microstructural differences between the two materials. The control CFRP surface appears relatively smooth and featureless at this scale, whereas the ZT-CFRP clearly exhibits an interlocked network of nanofibers.

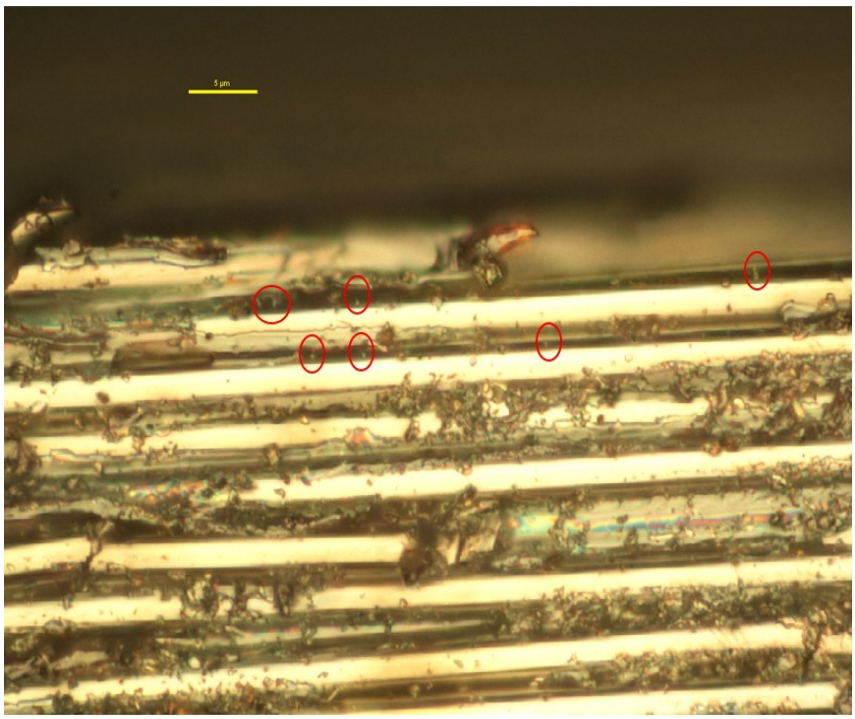

Fig 10: Presence of carbon aligned z-threaded nanofibers in through-thickness between the adjacent layers of carbon fibers.

As shown in Fig 10, the presence of carbon-aligned Z-threaded nanofibers in the through-thickness direction between adjacent carbon fiber layers significantly enhances interlaminar load transfer, improves fiber–matrix adhesion, and contributes to superior structural integrity and delamination resistance. These observations strongly support the hypothesis that enhancing interlaminar and

intralaminar load transfer through the incorporation of nanofiber z-threads not only improves fiber–matrix adhesion but also significantly contributes to the overall structural integrity of the composite under flexural bending. This improved interlaminar and intralaminar performance helps to inhibit crack propagation and increases resistance to delamination, thereby enhancing the mechanical performance of the laminate under various loading conditions including the flexural test in this study and other reported properties such as ILSS [23, 26], inplane shear strength [24], and longitudinal compressive strength [25].

5 CONCLUSIONS

Flexural properties are crucial because they directly influence how laminated CFRP panels bend, fail, and behave when subjected to bending loading. The incorporation of 1.0 wt% z-threaded CNFs into CFRP resulted in an average increase of 15% flexural strength compared to the control CFRP. The CNF interlocking networks within the ZT-CFRP prepreg significantly strengthened the intralaminar region and also contributed to a moderate enhancement in the interlaminar region. The ZT-CFRP exhibited large linear elastic range with strain ranging of 0-0.75% compared with the range with 0-0.55% of the control CFRP. The combined results showed a 15% improvement in the flexural strength and about 36% linear elastic range increase for the ZT-CFRP laminates compared to the unmodified CFRP laminates, and validated the effectiveness of nanofiber Z-threading strategy in strengthening composite materials against flexural loading. In conclusion, the ZT-CFRP specimens were found to be more linearly predictable, more reliable, and stronger than control CFRP for bearing flexural loading.

In future work, the authors intend to introduce thin carbon nanotube (CNT) interleaves between the ZT-CFRP prepreg to further strengthen the interlaminar region. This future interleaf modification on ZT-CFRP is expected to enhance the laminate's overall matrix-sensitive properties. Additionally, conducting numerical simulations of ZT-CFRP could provide valuable insights into the composite's complex behavior at the microscale, helping to better understand and optimize its mechanical performance,

ABSTRACT

The purpose of this study is to investigate the variation on flexural strengths of unidirectional carbon fiber reinforced plastic fabricated using prepreg sheets containing cellulose nanofibers (CNFs). Two types of CNFs of which the mean fiber lengths of the CNFs were approximately 6 and 22 μm, respectively, while the diameter of those were almost same, were prepared in order to compare the variation on flexural strengths of the specimens of the CFRPs under 3 point bending load. In the experiments, for comparison, specimens fabricated by conventional hand lay-up method were also prepared. The coefficient of variations (C.V.) in flexural strength were evaluatedby using universal testing machine. The test result showed that the C.V. were decreased under conditions in which relatively short CNFs contained, while the C.V. were increased under other conditions. The state of dispersion of each CNFs in resin matrix were taken by using confocal microscope. CNFs aggregates were frequently observed when relatively long CNFs were added into resin matrix. These results suggested that the dispersion of CNFs into matrix resin was insufficient when relatively longCNFs were used, resulting in increased variation in the mechanical properties of the composites.

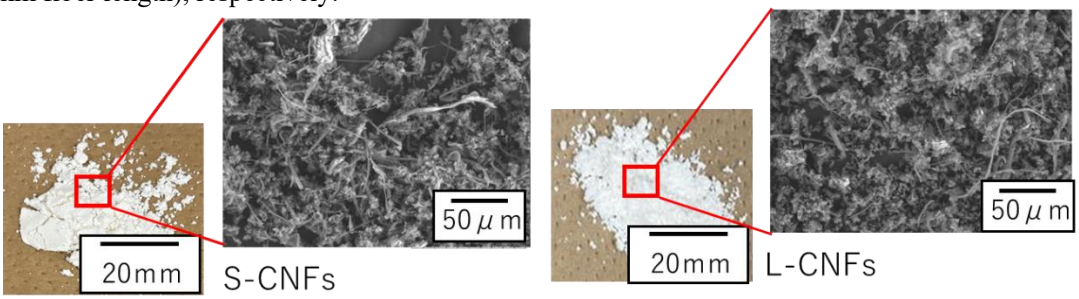
INTRODUCTION

With the rise in environmental consciousness, the demand for lightweight structural materials such as carbon fiber reinforced plastics (CFRPs) has been increasing significantly[(1)(2)] .Currently, most structural components made from CFRP are fabricated using unidirectional (UD) prepreg sheets, which are laid up to form the desired shape due to their high productivity and excellent structural integrity. Given that CFRP has a laminated structure with no interlayer reinforcement, preventing inter-laminar defects during fabrication and operation is critical to avoid degradation in mechanical performance. To enhance the interfacial characteristics of CFRP, the authors have previously proposed modifying the matrix resin with cellulose nanofibers (CNFs) and demonstrated its effectiveness using hand lay-up composites[(3)]. However, the applicability of CNFs in prepreg lay-up composites remains uncertain due to the difficulty in preparing prepregs with CNF modified matrix resin, as CNFs typically contain around 90% water by weight. . Recently, new types of CNFs that are already dehydrated and have controlled fiber lengths have been developed by Sugino Machine Co., Ltd., making it relatively easy to prepare prepregs with CNF-modified resin. Therefore, the purpose of this study is not only to investigate the mechanical characteristics and internal morphology, but also to evaluate its statistical variability of UD-CFRPs fabricated using both hand lay-up and prepreg lay-up methods, with matrix resins modified by CNFs addition, in order to clarify the applicability of CNFs. The effects of CNF mean fiber length on composites characteristics were also evaluated in terms of bulk density, porosity, and flexural performances.

2. FABRICATIONS AND MATERIALS

2-1. Materials

For hand lay-up composites, thermosetting epoxy resin (JER 828, Mitsubishi Chemical) and unidirectional carbon fiber cloth (UT70-40G, TORAY) were used as matrix and reinforcement material, respectively. For prepreg lay-up composites, unidirectional prepregs were fabricated using the same thermosetting epoxy and unidirectional carbon fiber tow (T700, TORAY). To modify the epoxy matrix, dried CNFs of two distinct lengths (BiNFi-s Sugino machine) were prepared. The mean fiber lengths of the CNFs were approximately 6 and 22 mm, respectively. Hereinafter, the CNFs are referred to as S-CNF (6mm fiber length) and L-CNF (22mm fiber length), respectively.



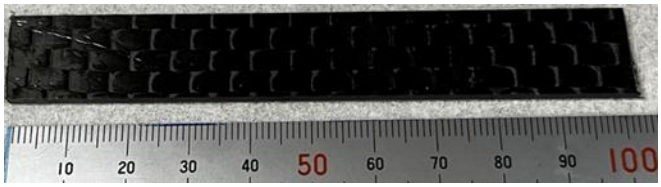


Fig.1 Example of appearance of CNFs

2-2. Fabrication method for hand layup composite

The fabrication process involved a hand lay-up method using both original and CNF-modified epoxy resins along with six layers of unidirectional carbon cloths. CNFs were added to the epoxy resin at a concentration of 0.5wt%. and dispersed via mechanical mixing for 30 min at 10000 rpm. The carbon cloths and epoxy resin were stacked and pressed under a pressure of 0.89 MPa. The stacked assembly was then cured by heating at 80 C for 1 hour, followed by 150 C for 3 hours, resulting in a 2.0 mm thick UD-CFRP laminate. The fiber volume fraction of the hand lay-up CFRP was approximately 60%. The fabricated CFRP laminates were cut parallel to the fiber direction using a diamond cutter to produce coupon-type specimens measuring 100 mm × 15 mm× 2 mm. Fig.2(a) shows the example of hand lay-up specimen.

2-3. Fabrication method for prepreg layup composite

The fabrication process involved a prepreg lay-up method using both original and CNF-modified prepreg, along with sixteen layers of unidirectional prepreg sheets. The weight fraction of added CNFs was controlled to match that used in the hand lay-up composites. The prepreg sheets were stacked and pressed under a pressure of 0.89 MPa. The stacked assembly was then cured by heating at 80 °C for 1 hour, followed by 130 °C for 3 hours, resulting in a 2.0 mm thick UD-CFRP laminate. The fiber volume fraction of the prepreg lay-up CFRP was approximately 63%. The fabricated CFRP laminates were cut parallel to the fiber direction to prepare the test specimens, as described in Section 2.2. An example of a prepreg lay-up specimen is also shown in Fig. 2(b).

(a) Hand lay-up specimen

(b) Prepreg lay-up specimen

Fig.2 Appearance of specimens.

2-4. Bulk density and porosity measurement

The bulk densities of the fabricated composites were measured in accordance with JIS Z8807 using distilled water. For each condition, at least 5 specimens were tested. The weight of each specimen was measured in air and in distilled water, and the bulk density was calculated using the following equation:

$$\rho_{sp} = \frac{Wair}{(W_{air} - W_{water})} \rho_{water} \quad (1)$$

Where W_{air} and W_{water} are the weight of the specimen measured in air and in distilled water, respectively, and ρ_{water} is the density of distilled water at room temperature. At least 5 specimens were used to calculate the bulk density of the composites.

To investigate the internal pore structure of the specimen, X-ray CT apparatus (1172, Bruker) was used. For each condition, at least 5 cross-sections were analyzed to calculate the areal fraction of internal pores relative to the cross-sectional area, hereinafter referred to as porosity.

2-5. Bending test

The bending strength of the fabricated composites was evaluated in accordance with JIS K7074. For each condition, at least 10 specimens were tested using a three-point bending setup with 80 mm support span. The specimens were loaded until failure, and the flexural strength was calculated using the following equation:

$$\sigma = \frac{3PL}{2bh^2} \quad (2)$$

where P is the maximum load, L is the span length, b is the specimen width, and h is the specimen thickness.

2-6. Short beam test

The apparent inter-laminar shear strength of the fabricated composites was evaluated in accordance with JIS K7057. For each condition, at least 5 specimens were tested using a three-point bending setup with a 10 mm support span. The specimens were loaded until failure, and the apparent inter-laminar shear strength was calculated using the following equation:

$$\tau_{ILSS} = \frac{3P}{4bh} \quad (3)$$

3. .RESULTS AND DISCUSSIONS

3-1. Effect of CNFs length on bulk density, porosity, and dispersion state

Fig.3 shows the bulk density of UD-composites with respect to mean length of added CNFs. The theoretical densities of both composites calculated based on the densities of the constituent materials and their volume fractions are also indicated by solid line. Test results indicate that the bulk density of the prepreg lay-up composites was consistently higher than that of the hand lay-up composites, regardless of the presence or mean length of the added CNFs. By comparing the theoretical and measured bulk densities of both composites, the observed differences mentioned above can not be attributed to variations in the volume fraction of carbon fibers. On the other hand, when focusing on the effect of the differences in mean length of the added CNFs, the use of L-CNFs slightly decreased the bulk density of the composites, regardless of the fabrication process.

Fig. 4 also shows the measured porosity of the UD-composites with respect to mean length of added CNFs. The measured results revealed that the porosity of the composites increased with an increase of the mean length of the added CNFs. In particular, a significant increase in porosity was observed when the hand lay-up process was employed. Previous studies have r eported that adding longer fibrous materials to the matrix resin leads to a significant rise in viscosity of resin [4][5]. In hand lay-up composites using L-CNF modified matrix resin, the formation of internal pores can be attributed to the increased viscosity caused by the addition of longer CNFs.

For detailed investigation, the added CNFs in the modified matrix resin were observed by using a fluorescence microscope and specially dyed CNFs. Fig. 5 shows the dispersion state of S-CNFs and L-CNFs in the modified matrix resin, respectively. When S-CNFs were used, the CNFs were almost uniformly dispersed throughout the matrix by mechanical mixing. In contrast, the use of L-CNFs resulted in the formation of large aggregates within the matrix. These results also suggest that increase viscosity caused by the longer CNFs may have limited the effectiveness of agitation, leading to insufficient dispersion.

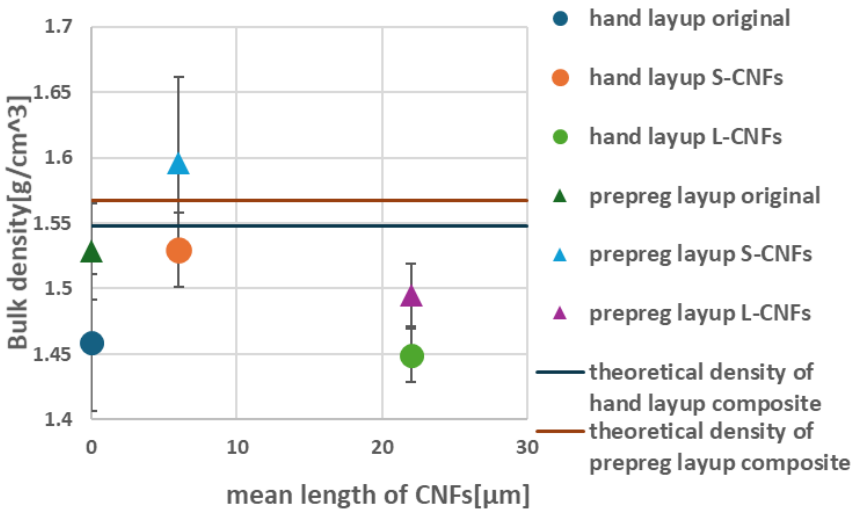

Fig.3 Relation between bulk density and mean length of CNFs

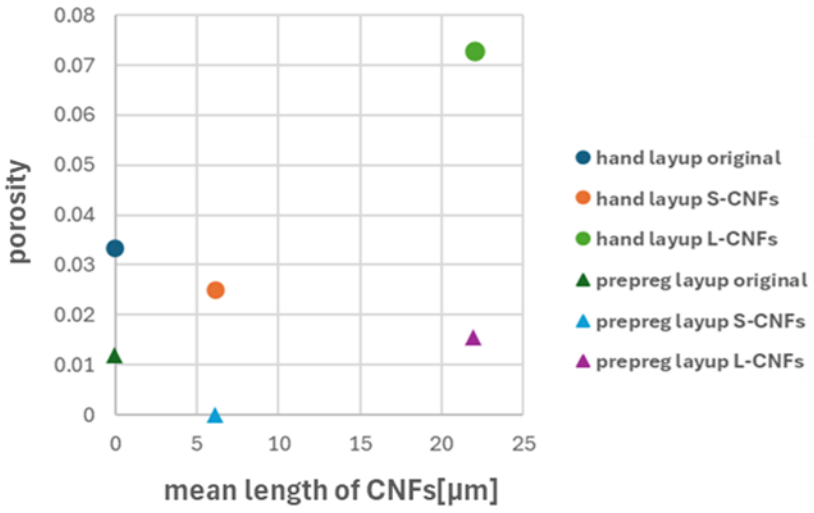

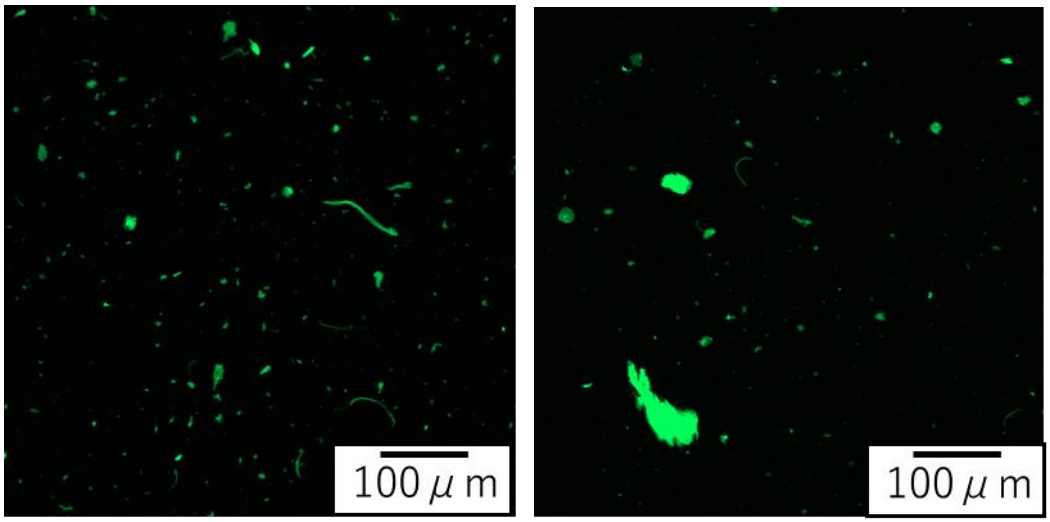

Fig.4 Relationship between porosity and length of nanofibers

(a) S-CNFs in matrix (b) L-CNFs in matrix

Fig.5 Dispersion state of CNFs in matrix resin

3-2. Effect of CNFs length on mechanical characteristics

Fig. 6 shows the mean flexural strength of UD composites as a function of the mean length of added CNFs. The test results indicated that no significant differences due to fabrication process were observed in the original and S-CNFs modified composites. On the other hand, obvious differences in mean flexural strength were observed when L-CNFs were added to the matrix. The mean flexural strength of the prepreg lay-up composites was clearly lower compared to that of the hand lay-up composites. Fig. 7 also shows the coefficient of variation in flexural strength as a function of the mean length of added CNFs. The test results indicated that the coefficient of variation for the hand lay-up composites was consistently higher than that of the prepreg lay-up composites. This can be attributed to the accumulation of errors caused by manual operations, such as fiber waviness due to uneven impregnation, variations in fiber orientation, and other inconsistencies during fabrication. Focusing on the effects of added CNFs, the addition of S-CNFs to the matrix resin reduced the coefficient of variation in the hand lay-up composites and also slightly reduced in the prepreg lay-up composites. When L-CNFs were added to the matrix resin, the coefficient of variation in the hand lay-up composites was still lower than that of the original hand lay-up composites, but slightly higher than that of the S-CNFs modified ones. In contrast, for the prepreg lay-up composites, the coefficient of variation increased obviously compared to that of the original prepreg lay-up composites. These results suggest that using CNFs of an appropriate length is effective in reducing the coefficient of variation in the flexural strength of composites, regardless of the fabrication process employed. On the other hand, it is

suggested that the use of excessively long CNFs not only increases the coefficient of variation in flexural strength but also decreases the mean flexural strength of the composites, regardless of the fabrication process employed.

Fig. 8 also shows the interlaminar shear strength (ILSS) with respect to the mean length of the added CNFs. The test results revealed that the ILSS exhibited a trend similar to that observed in the bending test. In particular, when L-CNFs were used in the prepreg composites, the ILSS was significantly degraded compared to that of the other composites. These results suggest that the presence of CNF aggregates and insufficient dispersion may have a more pronounced impact on the mechanical properties of prepreg lay-up composites compared to hand lay-up composites.

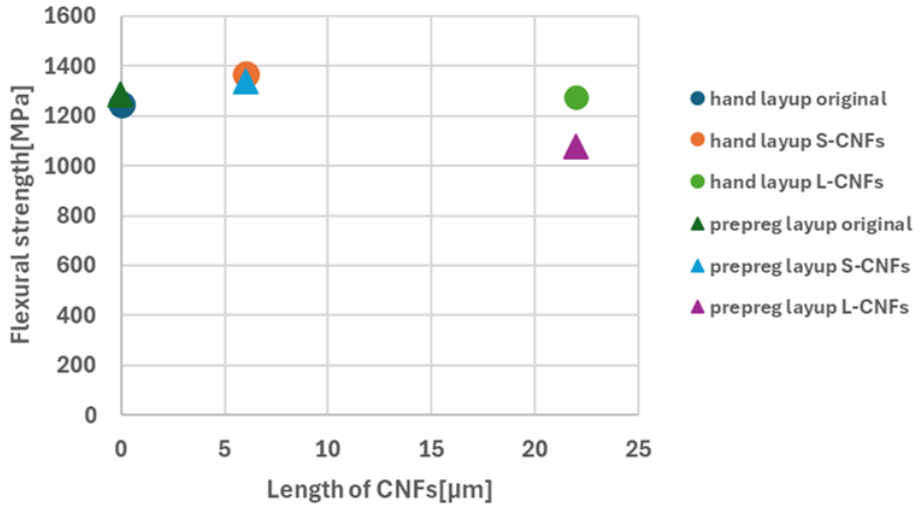

Fig.6 Relation between average flexural strength and length of CNFs

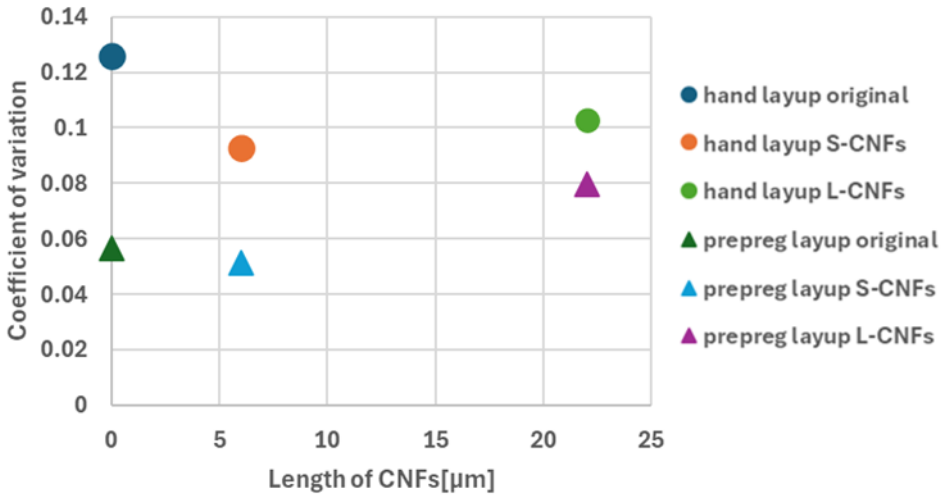

Fig.7 Relation between coefficient of variation and length of CNFs

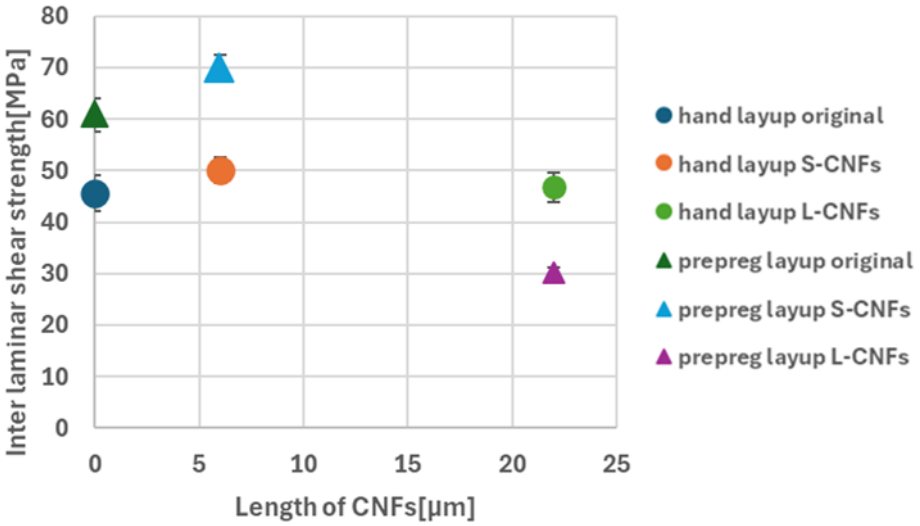

Fig.8 Relation between ILSS and length of CNFs

4.CONCLUSIONS

1. The bulk densities and porosity of the composites were influenced by the mean length of the added CNFs to the matrix resin, due to their effect on the viscosity of the matrix resin, regardless of the fabrication process employed.

2. The mechanical properties of the composites were influenced by the mean length of the added CNFs to the matrix resin, due to their effect on the formation of aggregates. This effect was more pronounced in the prepreg lay-up composites compared to the hand lay-up composites.

ACKNOWLEDGEMENTS

This study was financially supported by a research project under the“Research and Development Center for Advanced Composite Materials” of Doshisha University and Sugino Machine Limited.

Tail Rotor Blade → **A safety-critical part** [1]

O Anti-torque system

O Made of CFRPs

Damages

X High centrifugal force

X Fatigue

X Impact and wear

- Tail rotor blades play a critical role in maintaining the helicopter's balance.
- Tail rotor blades, though essential for safety, are highly vulnerable to damage.
- It is essential to monitor the structural health of helicopter rotor blades in real-time to detect potential damage early and extend their lifespan.

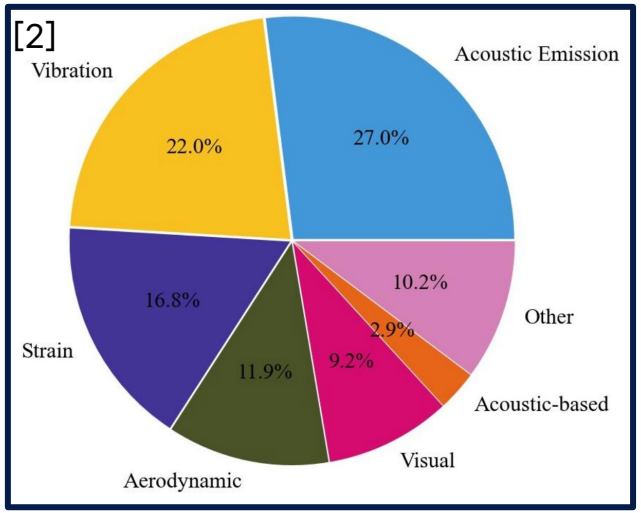
- **Limitations**

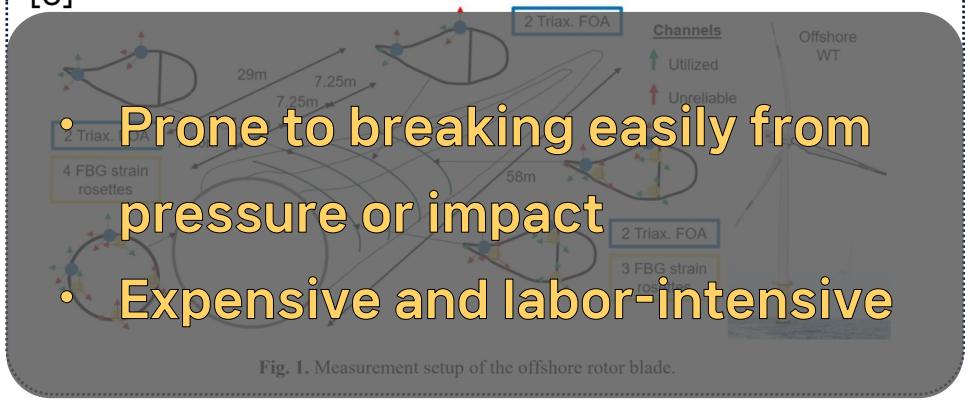
① Strain – Image

[3] [4]



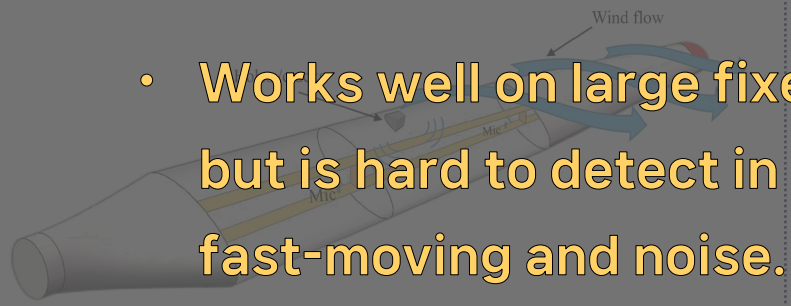
- High-speed rotation → Hard to capture stable images
- The tail rotor is small. → Difficult to capture precise images
- Operating a drone near rotating blades → Hazardous

② Visual



[5]

③ Strain - Fiber Bragg Grating



[6]

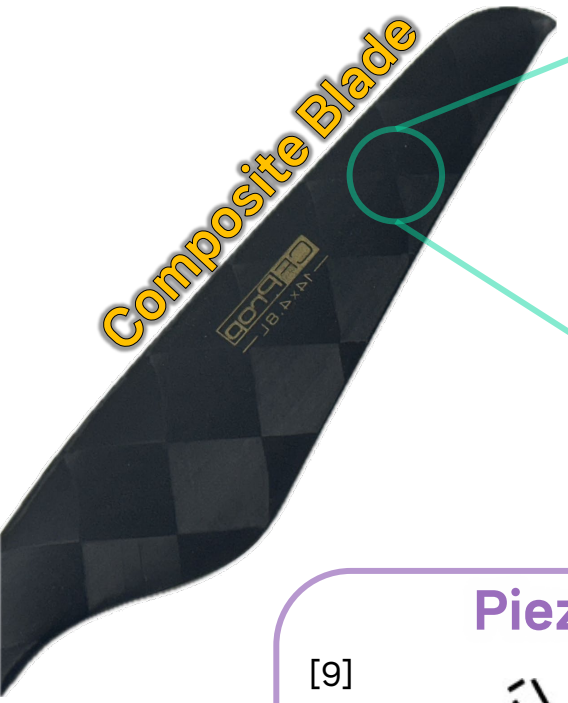
- Prone to breaking easily from pressure or impact
- Expensive and labor-intensive

④ Acoustic Emission(AE)

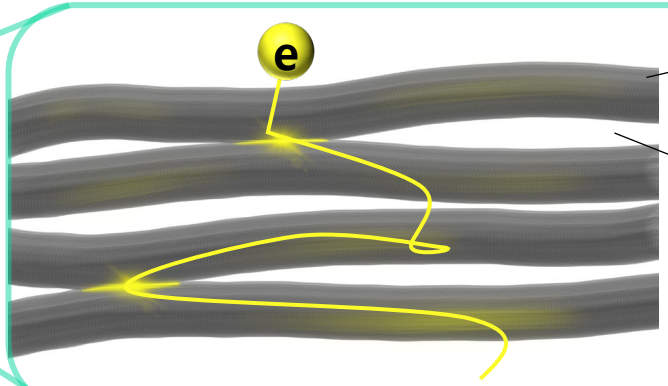
[7]

- Works well on large fixed structures, but is hard to detect in environments with fast-moving and noise.

⑤ Vibration



[8]



A **customized structural health monitoring** technology is needed for tail rotor blades.
→ Self-sensing technology is well-suited for this purpose.

- **Current Research Gap & Research Idea**

Although CFRP is widely used in rotating structures, self-sensing has not yet been applied to rotating components.

By leveraging self-sensing signals that capture strain variations induced by rotation, this approach can be extended to real-time monitoring of rotating components.

Damage Characterization

- Damage Location

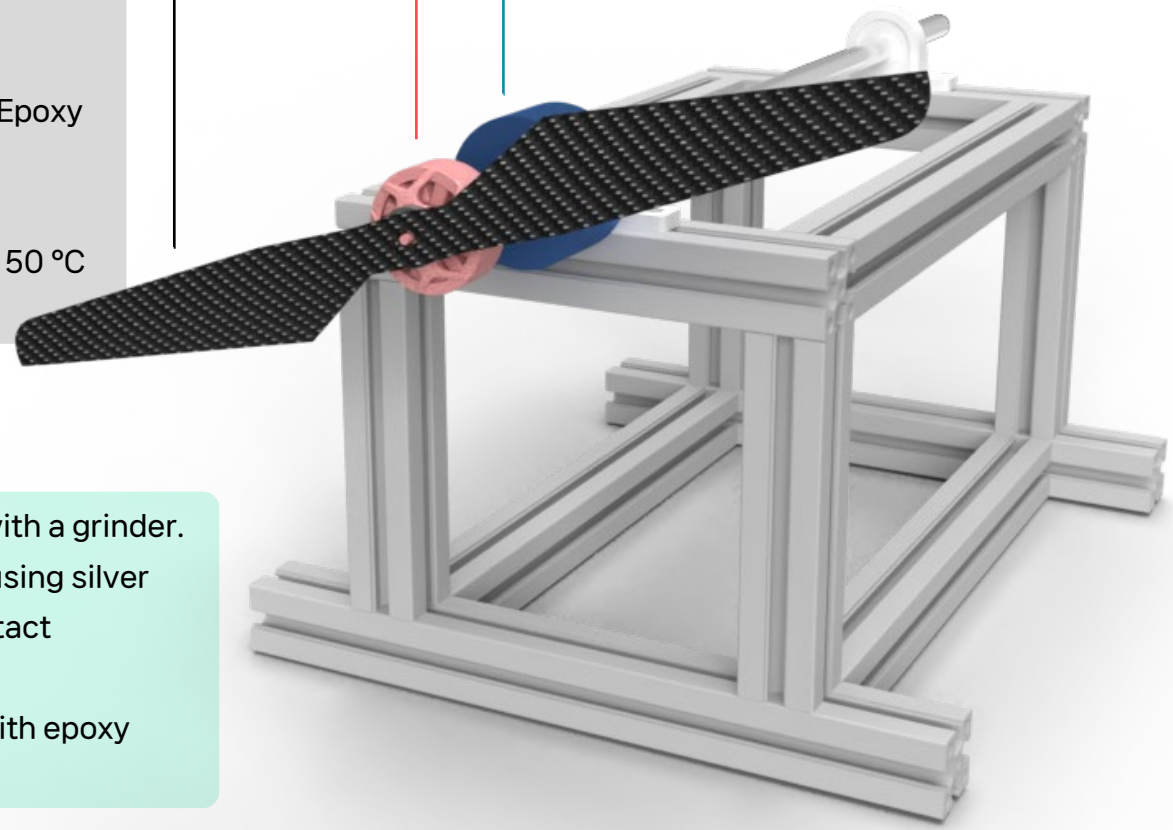
Research objective

✓ Analysis of the electromechanical behavior signals of rotating tail rotor blades

✓ Development of a structural health algorithm using the analyzed signals

→ Real-time in-situ structural health monitoring of rotating rotor blades using electromechanical behavior data

- **Testbed**



✓ T-MOTOR NS14*4.8 Prop

- Length: 35.56 cm
- Weight : 10.5g
- Materials : CF(T800) + Epoxy + PMI foam
- Max RPM : 8900 RPM
- Storage Temp: -10 °C ~ 50 °C
- Clockwise specimen

✓ Electrodes

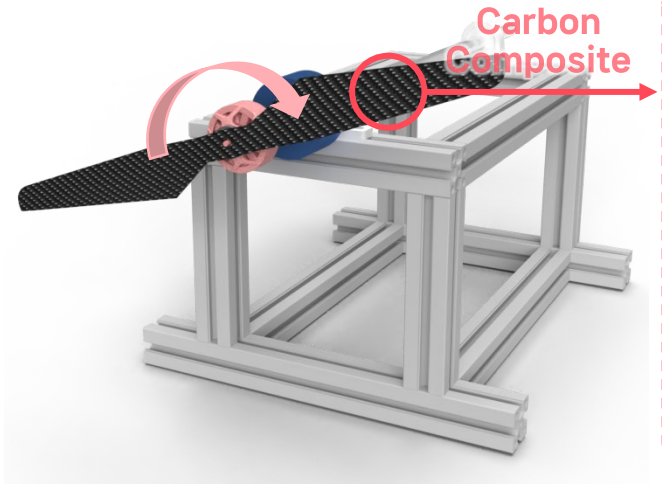
- Surface was sanded with a grinder.
- Wires were attached using silver paste to minimize contact resistance.
- Electrodes are fixed with epoxy adhesive.

✓ SunnySky V3508 High Efficiency Brushless Motor

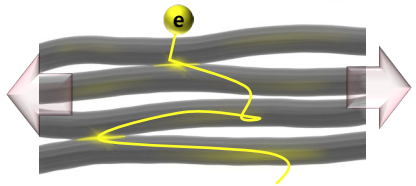
- Voltage: 22.2 V
- Max rotating speed: 8,436 RPM

✓ Covis CSH012-06-0506 Hollow Slip Rings 6ch

- No. of CH: 6CH
- Noise: < 0.01 Ω
- Rotating Speed: Max 600RPM
- Working Life: 60M cycles



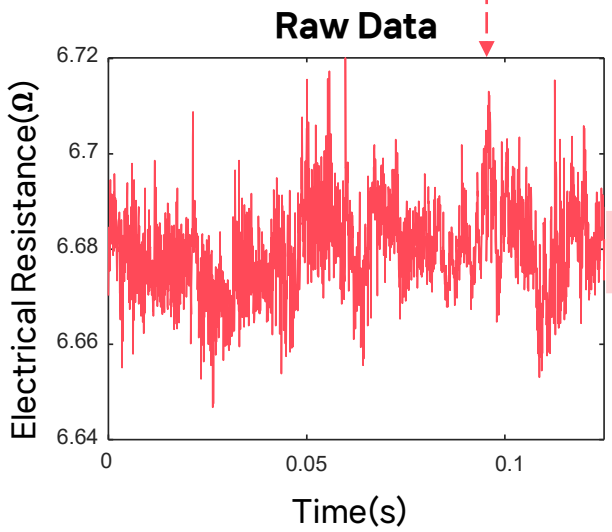
✓ Digital Multimeter Keithley 7510

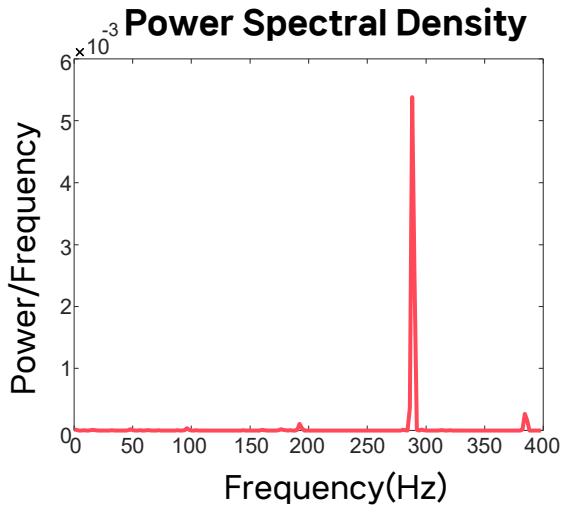


- 2 Probe measurement
- Buffer mode
- Sampling frequency: 15,220 Hz

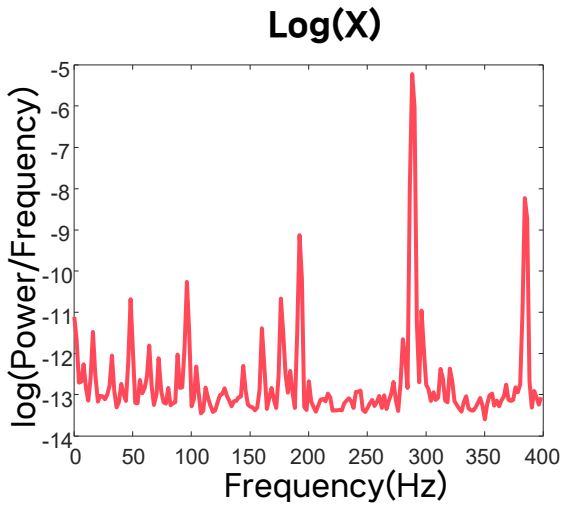
- **Classification Pipeline**

Electrical Resistance ∝ Mechanical Strain





Self-sensing



Piezoresistivity

- **Blade under Rotation**

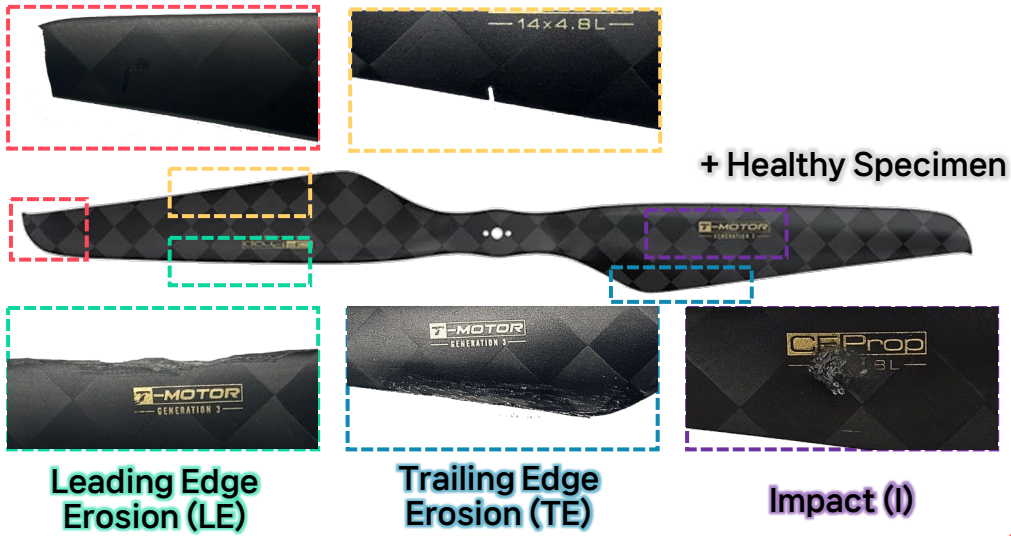
COMSOL Multiphysics
- Gravity
- Centrifugal Force
- Coriolis Effect

As the blade rotates, **gravity, centrifugal force**, and **Coriolis effect** cause strain values to differ at each position, leading to **periodic strain**.

→ **Rotational frequency-based analysis** enables evaluation of the structural state.



- **Damage Classification**

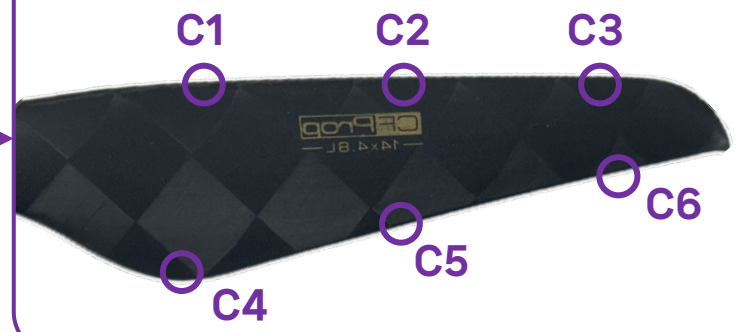
Step 1

Damage Types

Tip Fracture (T)

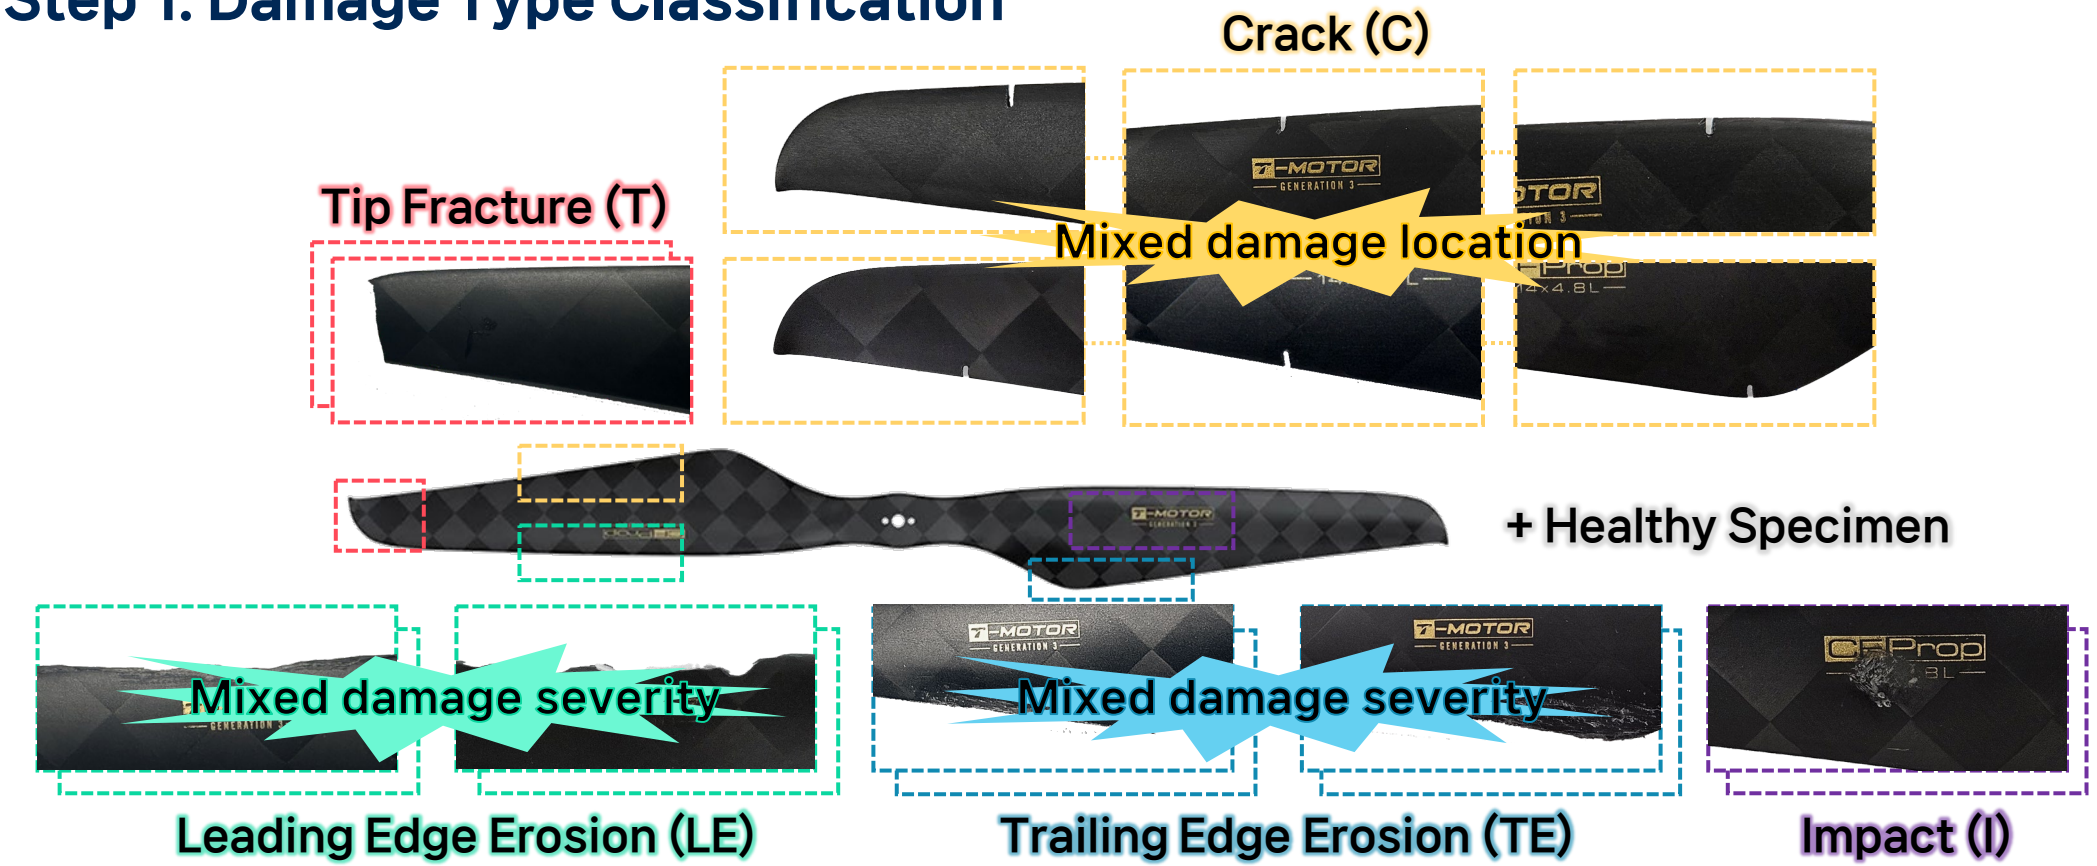
Crack (C)

Step 2



Damage Severities

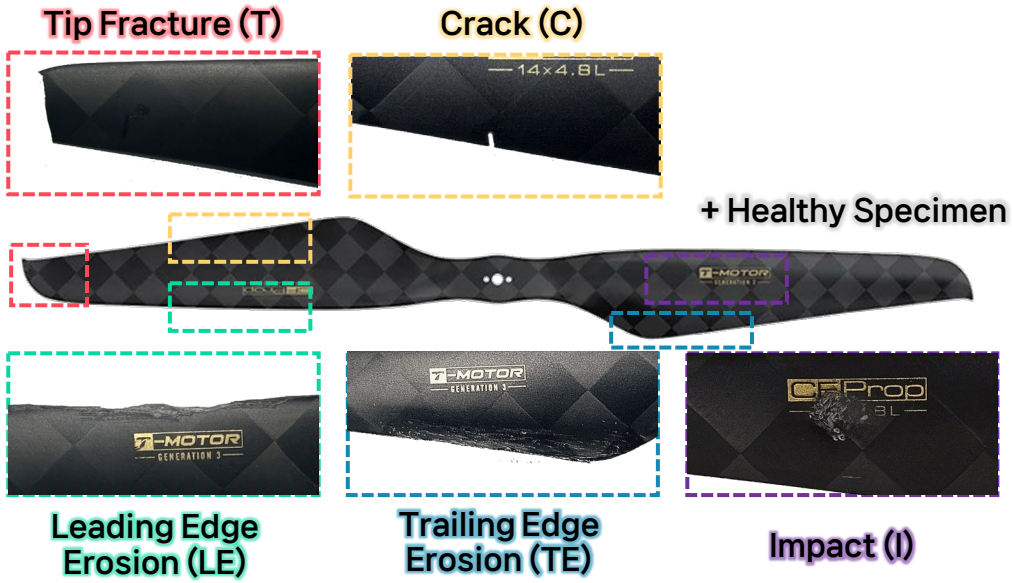
Erosion



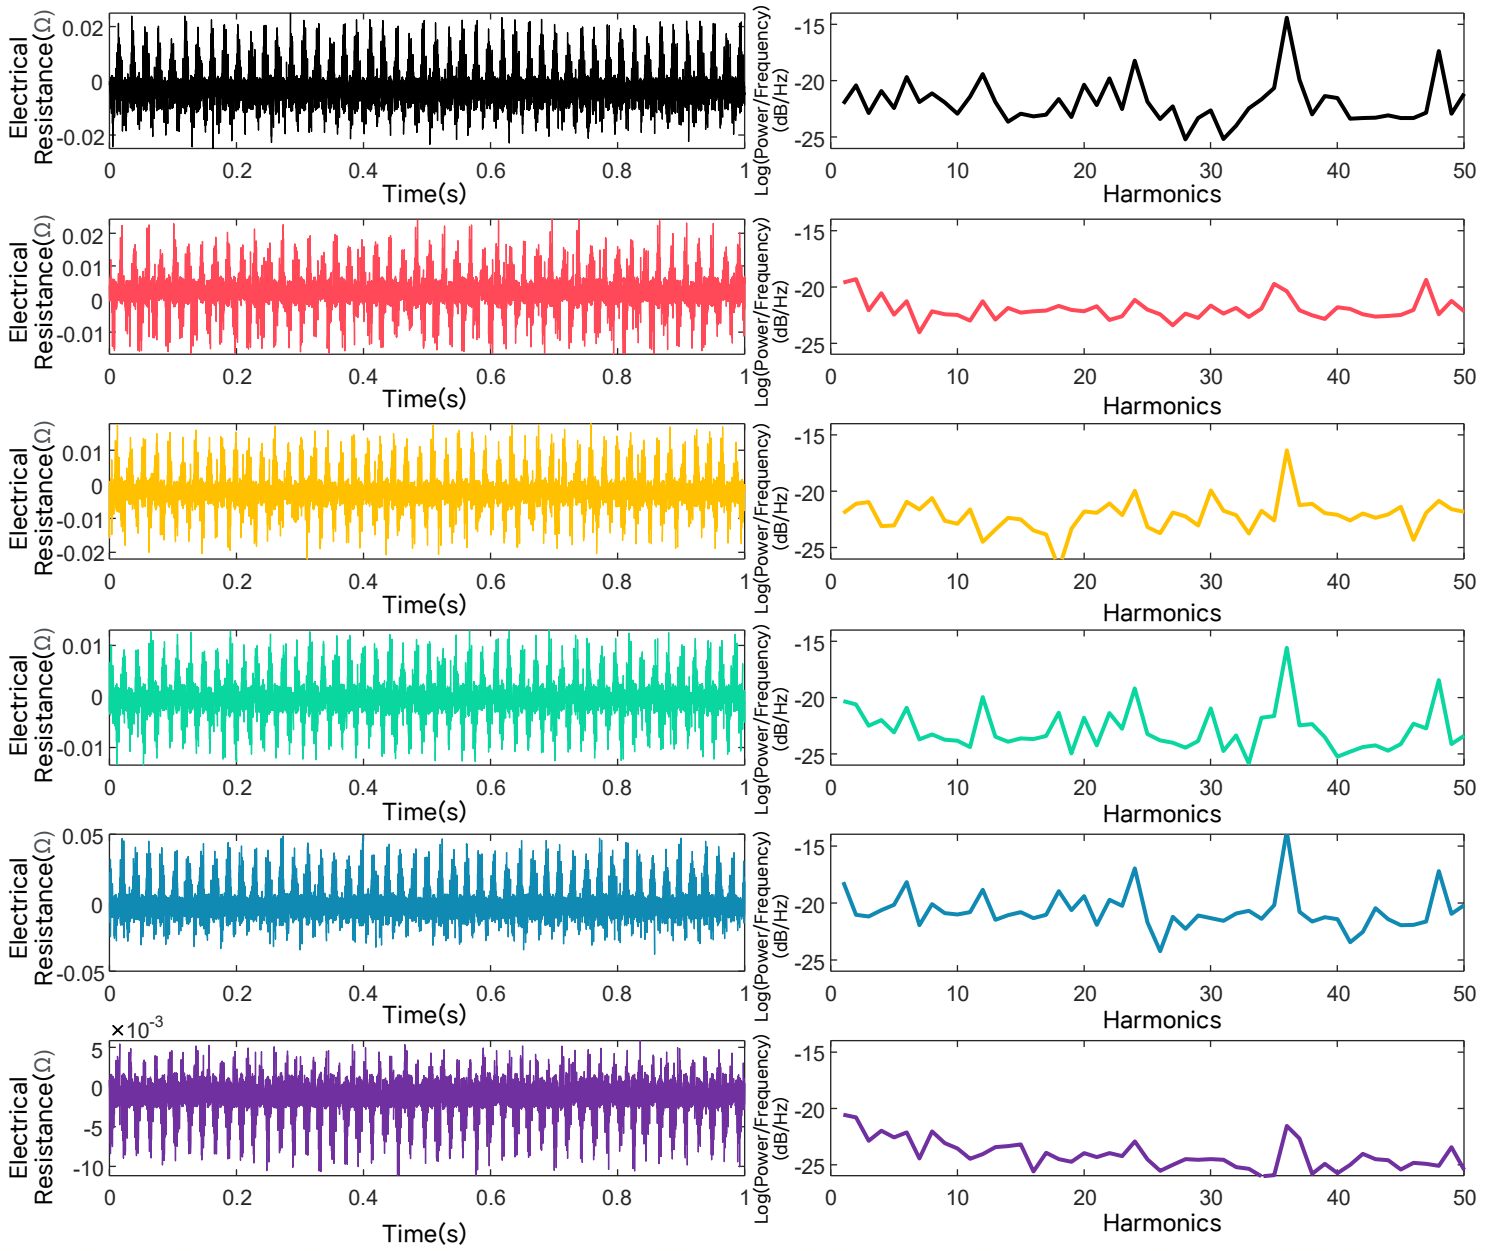
Damage Locations

Crack

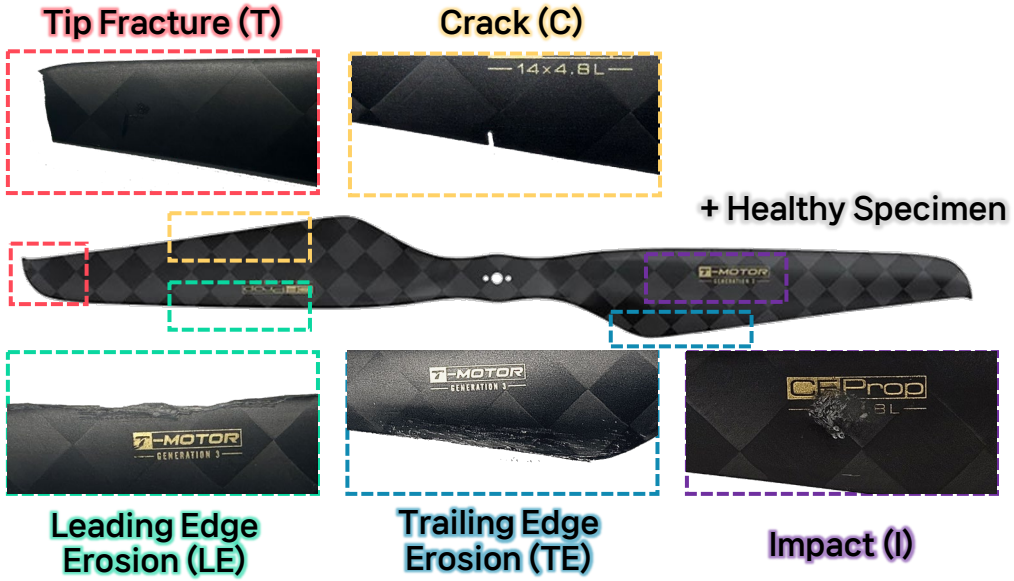
- Six damage types were first classified, followed by additional classification of severity for erosion and location for cracks.



- **Step 1. Damage Type Classification**

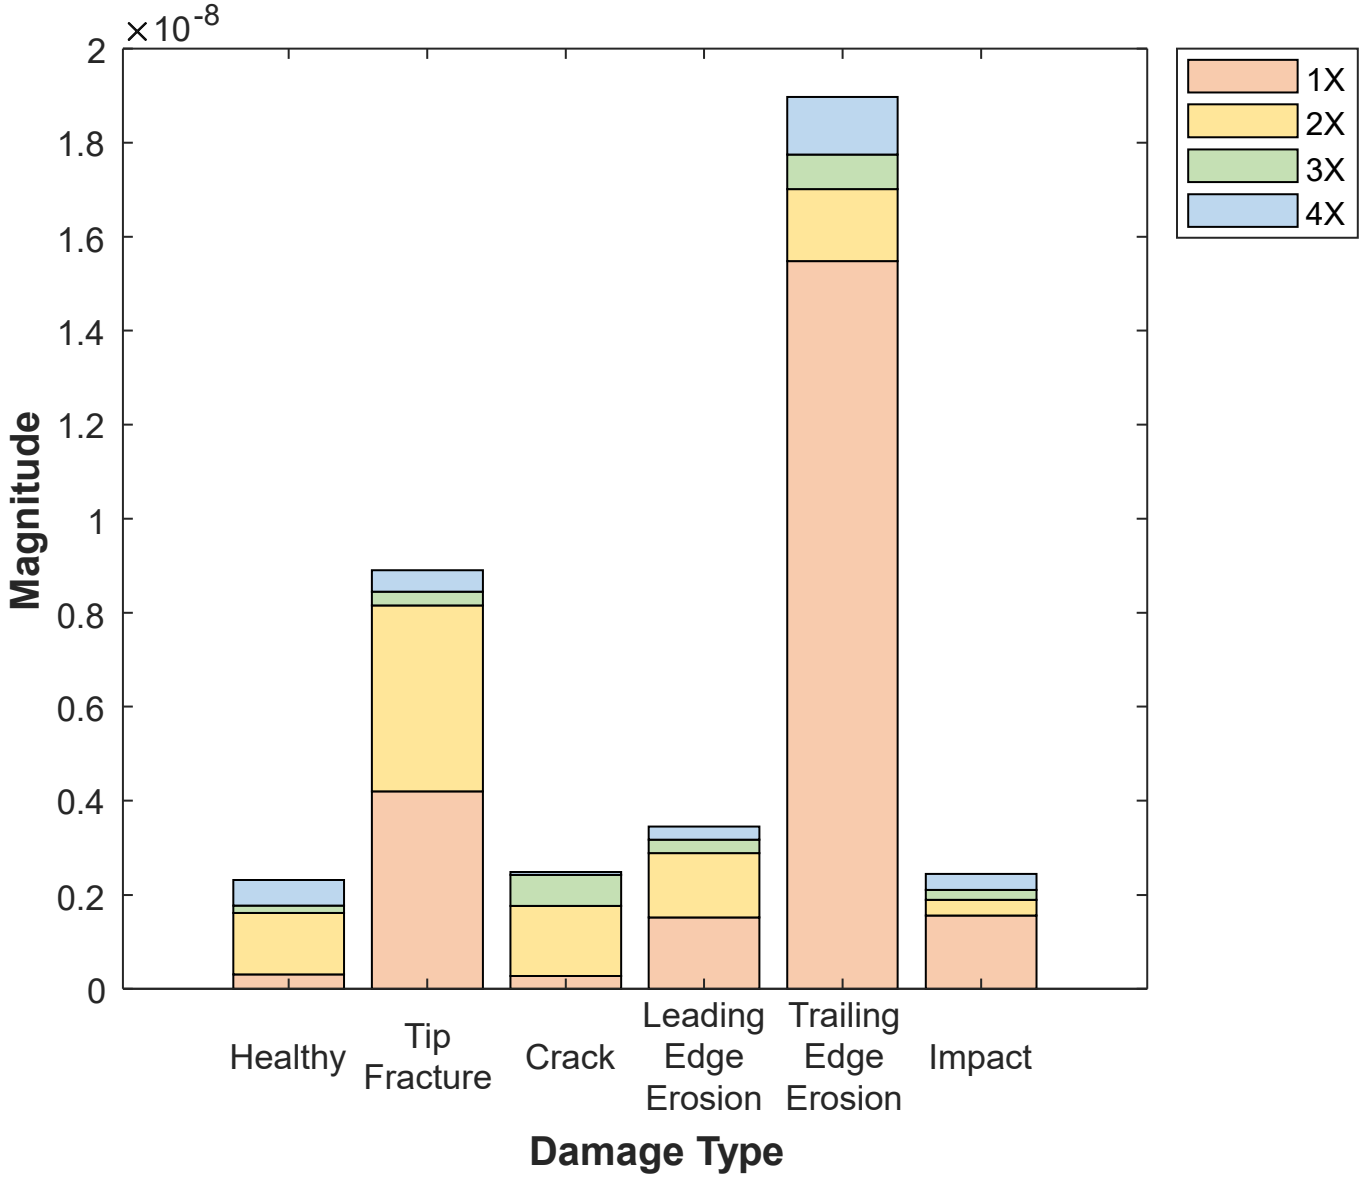


- 20 specimens with varying damage location and severity were used.

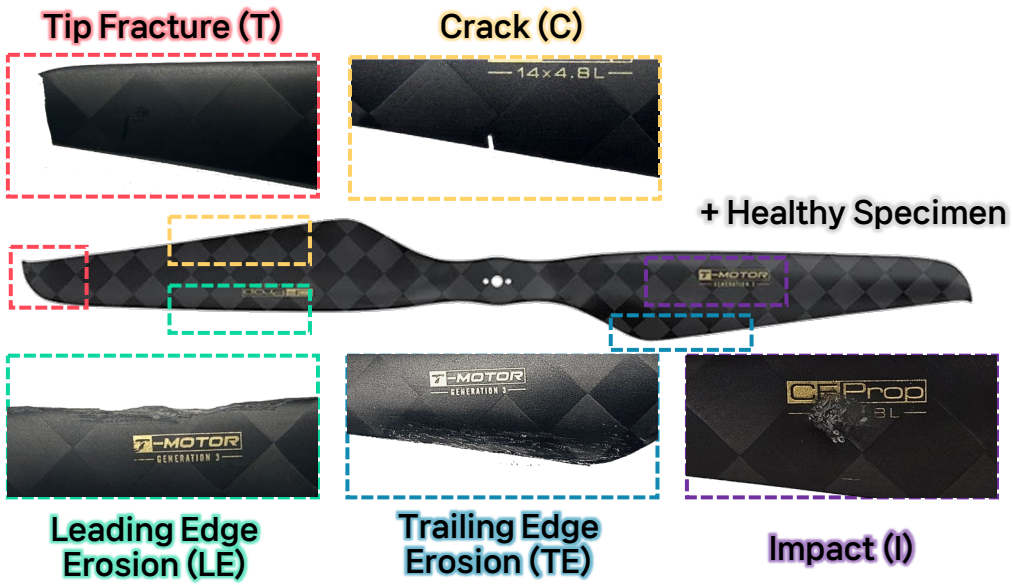


→ To extract robust damage-type information, independent of position or severity.

3. Results _ Electromechanical behavior

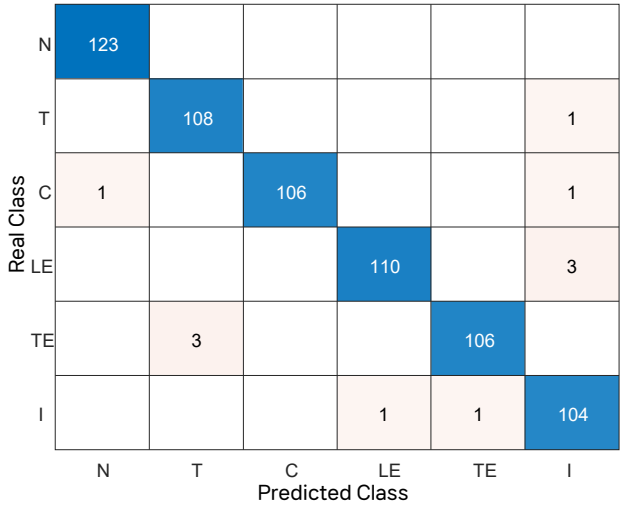


- The signal exhibits **periodicity** due to the applied periodic strain.
- If damage exists in any part, **changes in flow patterns** and **mass imbalance** cause variations in strain, which are reflected in the electrical resistance.
- **Higher-order components** arise due to structural nonlinearity, with variations depending on the type of damage.



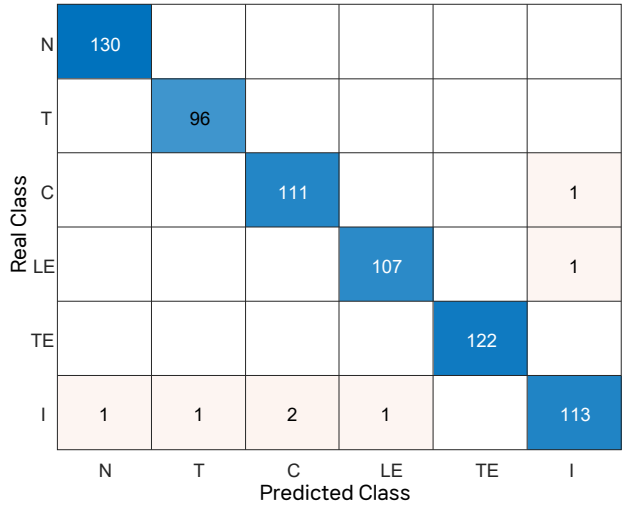
- Since the blades used in the experiment are **two-bladed**, the 2X harmonic is the most dominant in a healthy blade.
- When **damage occurs**, the proportion of the 1X harmonic increases due to imbalance.
- Each type of damage shows a distinct pattern in the magnitude and proportion of harmonics.

- **Stacked Bar Chart of Harmonics**



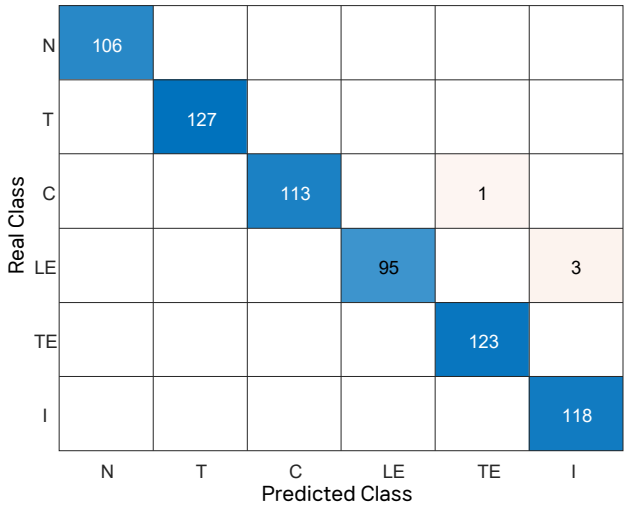
3. Results _ Classification Results

- **Step 1: Damage Type Classification**



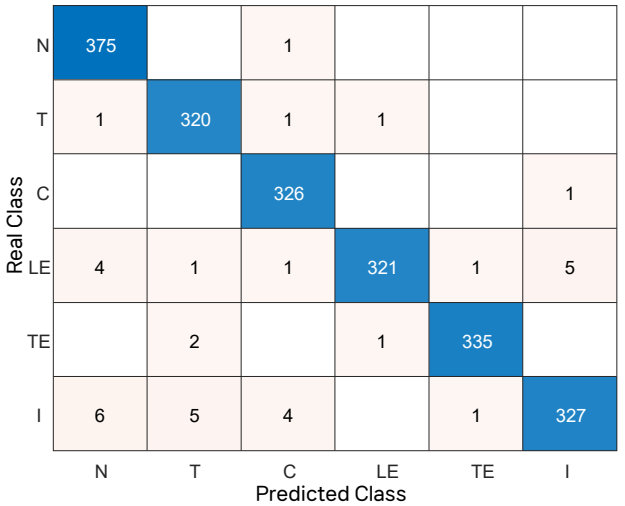
- For single RPM conditions, all damage types were classified with high accuracy.
- Even when multiple RPMs were mixed, the method maintained high accuracy, demonstrating the robustness of the signals.

< 240 RPM >



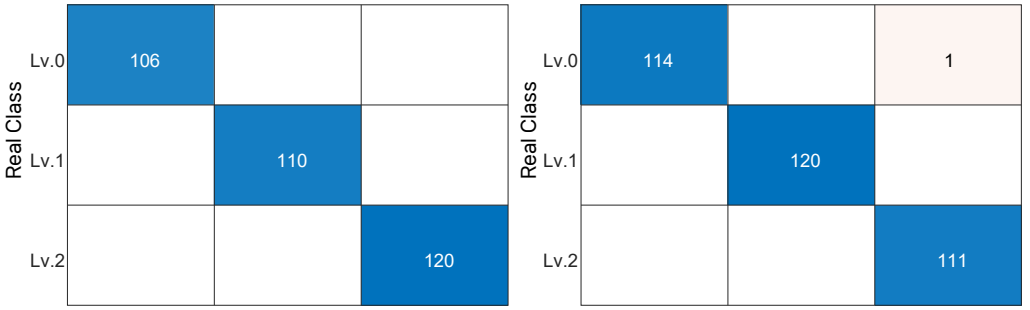
Accuracy: 98.353%

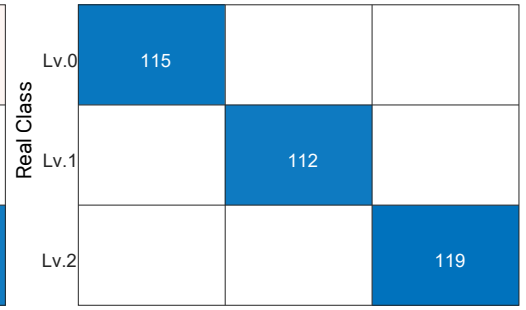
< 360 RPM >

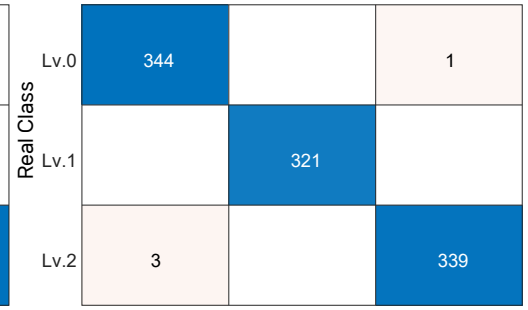


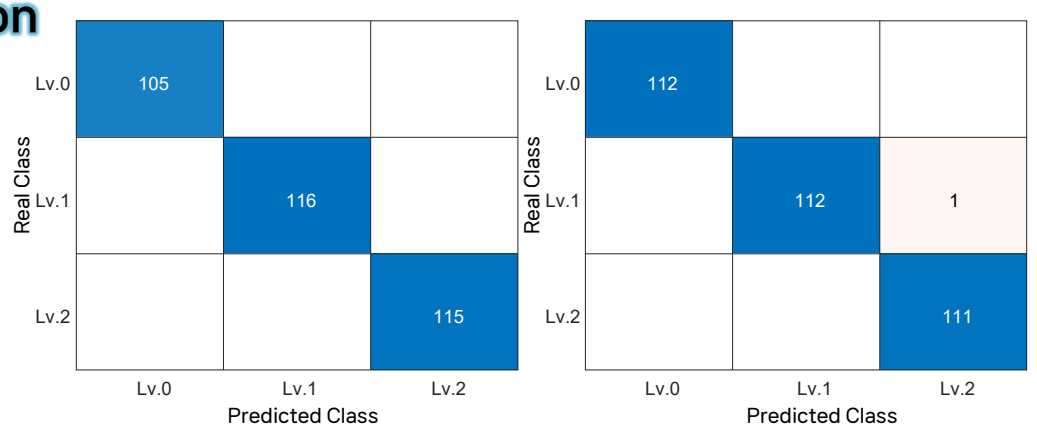
Accuracy: 98.980%

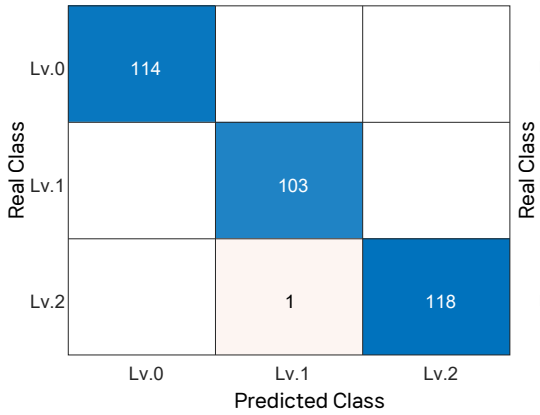
< 480 RPM >

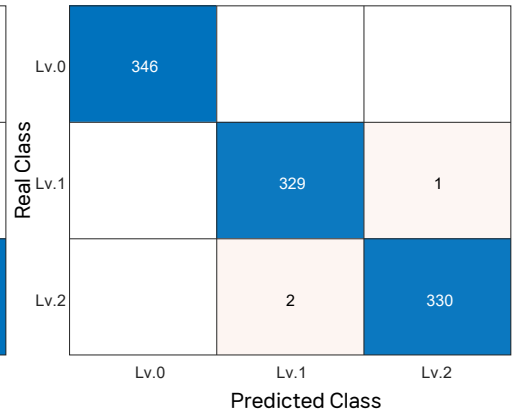












Accuracy : 99.417%

< RPM Mixed >

Accuracy : 98.235%

- **Step 2: Damage Severity Assessment**

	< 240 RPM >	< 360 RPM >	< 480 RPM >	< RPM Mixed >
Leading Edge Erosion (LE) Lv.1				
Lv.2		Accuracy: 100%	Accuracy: 99.711%	Accuracy : 100%	Accuracy : 99.603%
Trailing Edge Erosion (TE) Lv.1				
Lv.2		Accuracy: 100%	Accuracy: 99.702%	Accuracy : 99.702%	Accuracy : 99.702%

- **Step 2: Damage Localization**

Crack (C)

Leading Edge

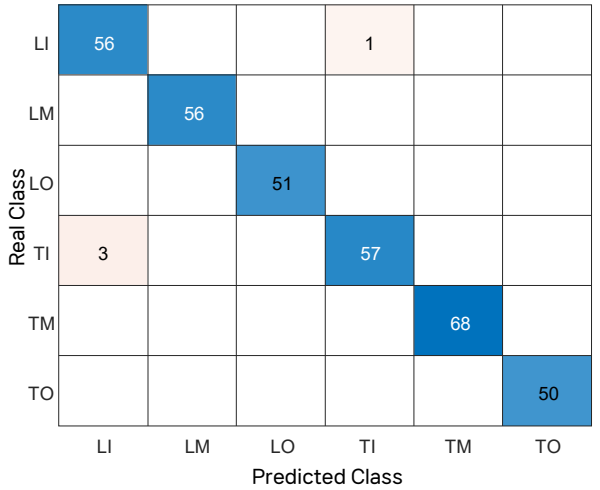
Inner(LI)

Middle(LM)

Outer(LO)

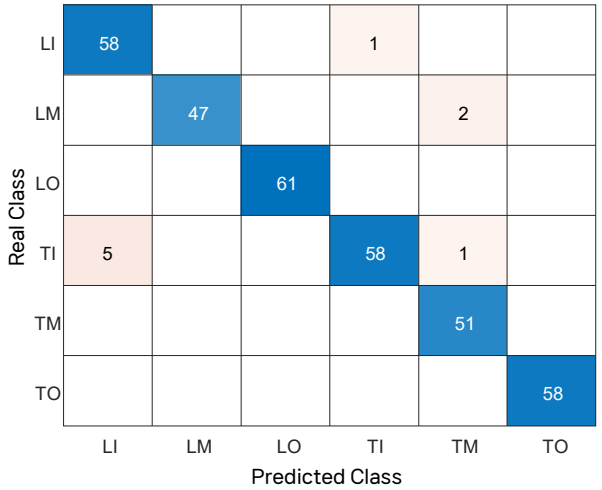
Trailing Edge

Inner(TI)



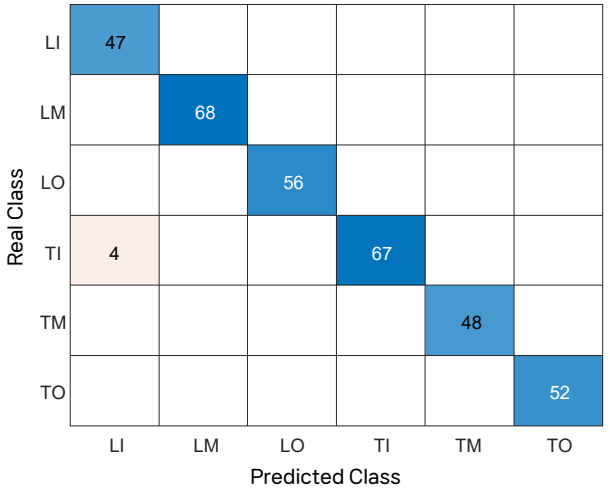
Middle(TM)

Outer(TO)



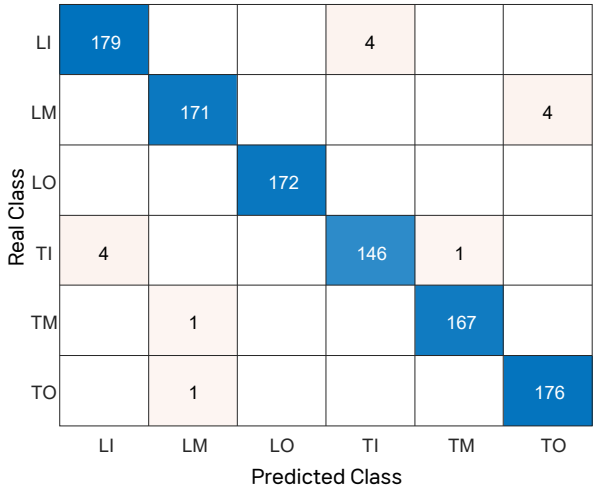
- The high accuracy in both damage severity and localization further demonstrates the robustness of self-sensing technology.

< 240 RPM >



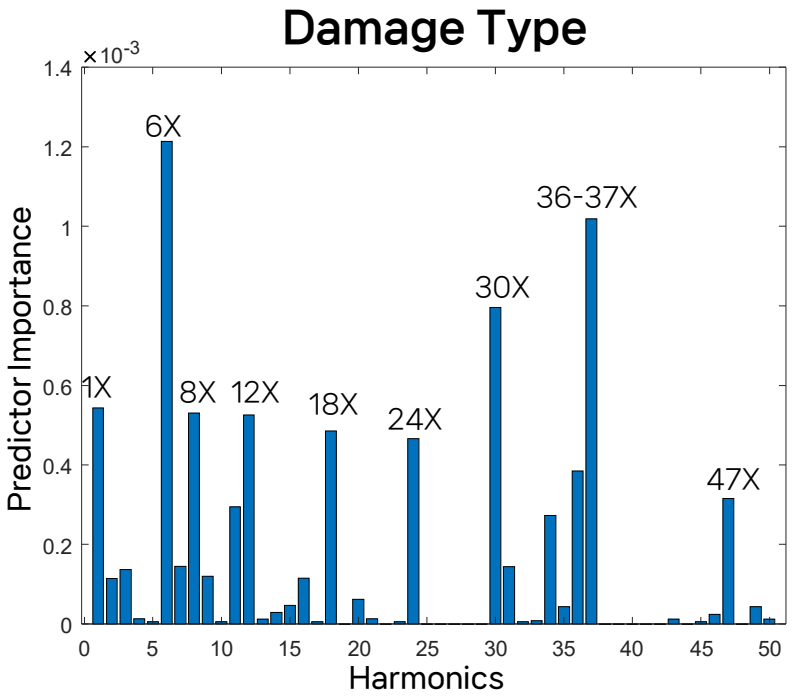
Accuracy: 98.83%

< 360 RPM >

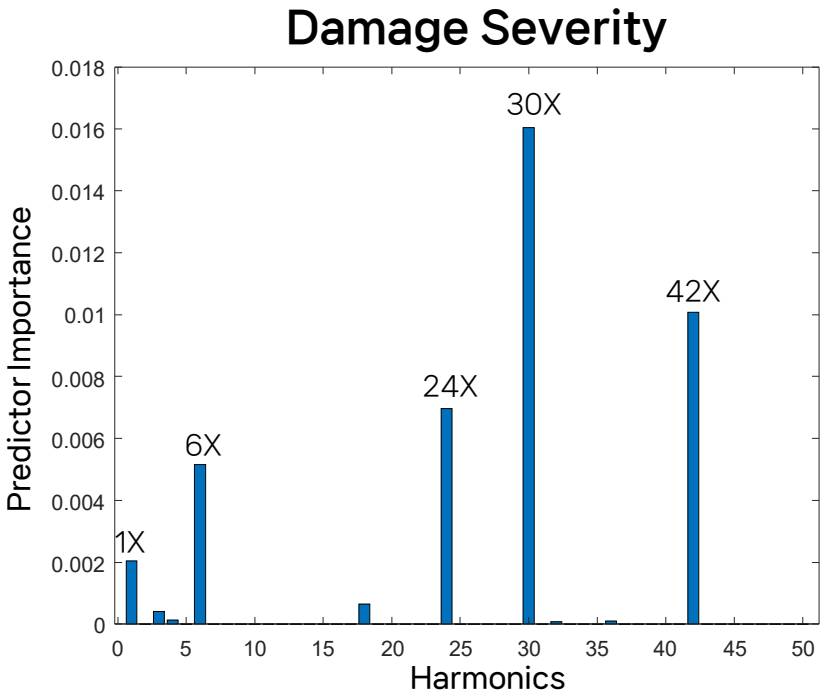


Accuracy: 97.368%

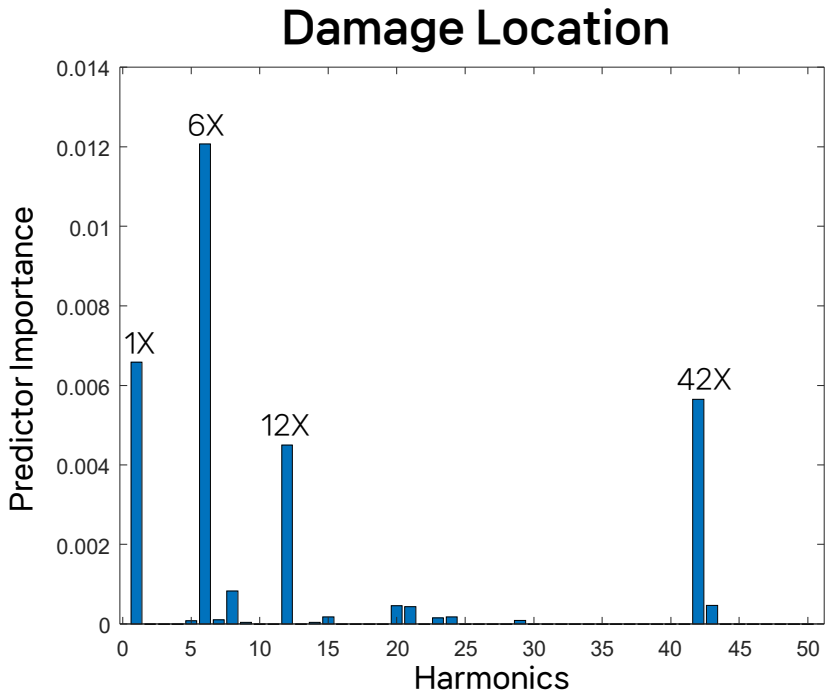
< 480 RPM >



Accuracy : 98.830%



< RPM Mixed >



Accuracy : 98.538%

- **Importance**

- Harmonics at multiples of six are generally found to be the most significant.
- The harmonics considered important vary depending on the classification target.
- This reveals how each type of damage affects different harmonic components.

• Conclusions

- ✓ Real-time Monitoring: The self-sensing technology successfully enabled real-time structural health monitoring of rotating rotor blades by leveraging the piezoresistive properties of CFRPs.
- ✓ High Accuracy: The approach demonstrated high classification accuracy in identifying damage types, severity levels, and locations under various rotational conditions.
- ✓ Improved Safety and Efficiency: This method offers a significant improvement over traditional systems, enhancing flight safety and reducing maintenance costs through continuous real-time monitoring.

• Future Work

- ✓ Investigation of the correlation between higher-order harmonics based on rotational frequencies and damage signatures
- ✓ Quantitative damage assessment

ABSTRACT

The number of in-operation composite pressure vessels is increasing, partly due to their attractiveness for on-board compressed gas storage and transport applications. A possible way to maintain the highest safety levels is through the structural health monitoring of the composite cylinders. Here, the use of fiber optic sensors appears to be a promising approach. However, the integration of the optical fibers into the composite structure of a pressure vessel has been shown to be challenging. In this study, insights on the embedding of optical fibers in the composite structure under industrial conditions are provided. A protection concept for the ingress and egress of the optical fibers is presented. Finally, the results from destructive slow burst tests are evaluated, showing no clear trend in the impact of the embedded optical fibers on the performance of composite pressure vessels.

1 INTRODUCTION

Composite materials play a major role in the transition toward a green economy. In the context of hydrogen technologies, composites are widely used for manufacturing composite pressure vessels,

which are used to transport and store hydrogen gas. Among the different types of pressure vessels, type 4 cylinders, consisting of a fully composite wrapped polymer liner, show the highest weight-saving potential. They are also characterized by the capability to withstand the highest working pressures [1, 2]. This makes them particularly attractive for on-board and transportation applications. However, the structural mechanical behavior of type 4 composite pressure vessels (CPVs) still needs to be better understood to precisely estimate their burst pressures and end-of-life performance.

A promising approach is the application of structural health monitoring (SHM) systems, both for the research purposes and for future applications in mass produced composite cylinders. Among other methods, such as acoustic emission or guided waves, in-situ strain monitoring with fiber optic sensors (FOS) delivers important information on the condition of the composite structure [3, 4]. FOS have been widely used for structural health monitoring of composite structures, with CPVs being one of the main applications [5-12]. However, the details of embedding optical fibers are either not described in the publications or do not correspond to industrial conditions. In practical applications, the integration of optical fibers in the composite structure proves to be challenging and time-consuming. To increase the competitiveness of FOS for the industrial applications, efficient processes for embedding optical fibers in composite cylinders need to be established. Furthermore, the FOS can be considered as a foreign body in the composite material, which can have an impact on its structural mechanical behavior.

In this study a setup for the integration of FOS in 6.8-liter type 4 CPVs was developed. The embedding of the optical fibers in the composite structure was integrated into an industrial filament winding process. The manufactured cylinders were tested in destructive slow burst tests. A comparison of the measured strains with finite element models is provided. Finally, the impact of the embedded optical fibers on the performance of the cylinders in slow burst tests (SBT) is discussed.

2 MATERIALS AND METHODS

2.1 Composite Pressure Vessels and Fiber Optic Sensors

Optical fibers were integrated into multiple composite layers of six 6.8-liter type 4 CPVs. The cylinders used, consisting of a PET liner as well as helical and hoop carbon fiber reinforced plastic (CFRP) layers, were designed for a nominal working pressure of 300 bar and test pressure PH of 450 bar. Figure 1 schematically shows the stacking sequence of the CPVs used. The helical and hoop layers with embedded FOS are marked. In total, the optical fibers were integrated into 6 of 15 CFRP layers. However, only 3 FOS were used to do so, each of which was embedded in two layers.

Three samples of wet filament wound CPV were used in the study to ensure the reproducibility of the outcomes. These samples differed in manufacturing parameters and loading history before the destructive slow burst test. However, the materials used, geometry, stacking sequence and processing time were the same. Each sample consisted of two cylinders with embedded FOS and three without optical fibers. The three samples are called Sample A, Sample B and Sample C for the sake of clarity:

1. Sample A: wound with a constant internal pressure in the liner, conditioned for 1000 hours under 450 bar and 65°C before slow burst tests;
2. Sample B: wound with an increasing internal pressure in the liner (see [13]), subjected to slow burst tests in a pristine state;
3. Sample C: wound with an increasing internal pressure in the liner, conditioned for 1000 hours under 450 bar and 65°C before slow burst tests.

Optical fibers SM1500(6.4/125)P by Fibercore were used as sensors. This optical fiber with 6.4 µm core diameter has additionally a 125 µm cladding and 155 µm polyimide coating diameter [14]. Because of the challenges in terms of handling the optical fibers, an additional protection, particularly in the ingress and egress from the CFRP, is needed [15]. Avoiding low radius bending caused by the boss geometry or other CFRP layers is of highest importance, since it could negatively influence the measurement quality, or even damage the optical fibers.

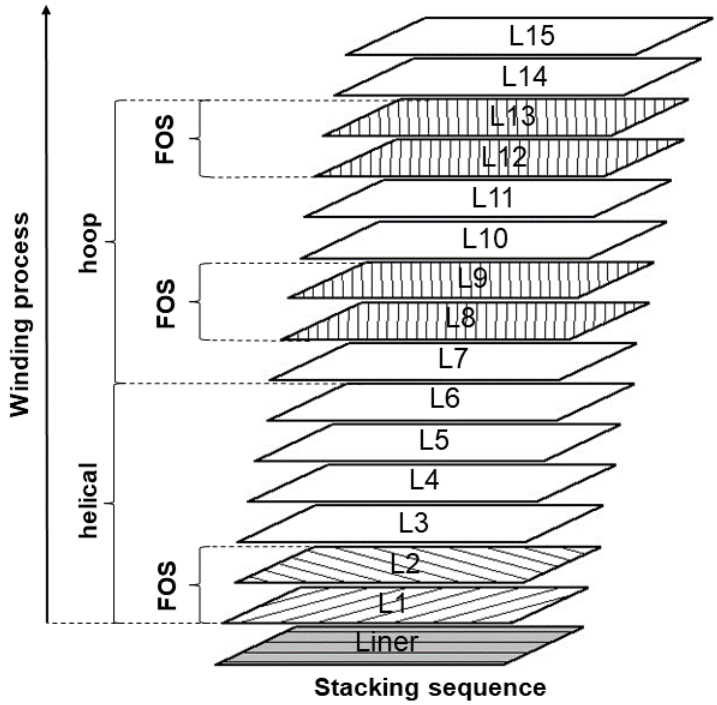

Figure 1: Stacking sequence of the used type 4 CPVs [13].

The configuration for protecting the optical fiber is shown in Figure 2. Directly behind the FC/APC plug, two protection tubes divided by a splice protection are used. The end of the 1.5 mm tube aligns with the end of the aluminum boss part or beginning of the CFRP. In the composite, only the PTFE capillary is used in the dome part, as also shown in Figure 3. It provides an additional protection in the areas in which the optical fiber leaves the fiber parallel orientation and is particularly exposed to the pressure from the winding tension of the newly wound layers.

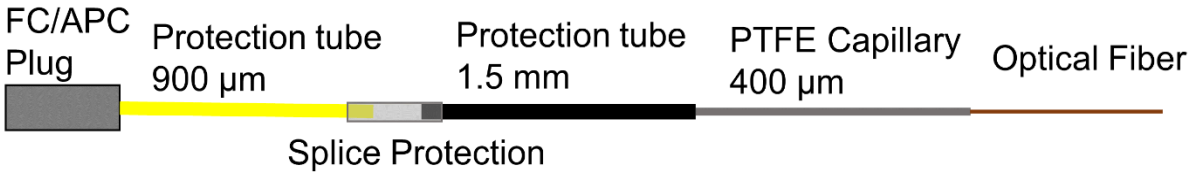

Figure 2: Concept for protection of the optical fiber at ingress and leaving carbon fiber parallel orientation.

Figure 3: Optical fibers leaving the carbon fiber parallel orientation of a hoop layer.

2.2 Finite Element Models

Finite element models were developed to discuss the strains obtained with fiber optic sensors during SBT. Since the models were extensively discussed elsewhere [13, 16], only a brief introduction based on the mentioned publications is provided at this point.

The finite element analyses were performed using ANSYS Mechanical 2023 R1. ANSYS ACP Prep/Post was used as a dedicated tool for preparing the model of the composite pressure vessel. As a basis for the geometry definition, a 3D scan of the liner was derived using Shining 3D EinScan HX. The stacking sequence of the carbon fiber reinforced layers and their nominal thickness were derived from the used type 4 6.8-liter cylinder. For the material data of the carbon fiber, resin and liner material, data sheet values and experimental data from the literature were used [17-20]. The material data for the carbon reinforced unidirectional plies was then calculated with rules of mixture according to [21] under assumption of a process typical fiber volume ratio of 60 %. A summary of the material data used can be found in Table 1 and Table 2.

Engineering constant	Abbreviation	Value	Unit
Young's Modulus in fiber direction	E_1	133500	[MPa]
Young's Modulus perpendicular to fiber direction	E_2	6380	[MPa]
Shear Modulus	G_{21}	2100	[MPa]
Poisson's ratio	ν_{21}	0.35	–
Ply thickness	t	0.45	mm

Table 1: Material data of an unidirectional CFRP ply.

Engineering constant	Abbreviation	Value	Unit
Young's Modulus	E	3600	[MPa]
Shear Modulus	G	1340	[MPa]
Poisson's ratio	ν	0.34	–
Ply thickness	t	0.40	mm

Table 2: Material data of PET liner.

The model was meshed with second order solid elements (SOLID186) with one element per composite layer. To constrain the model, displacements in x, y and z directions were suppressed at boss and the opposite dome end of the cylinder. The internal pressure loading during an SBT is applied to the whole inner surface of the cylinder. The model with the corresponding coordinate system is shown in Figure 4.

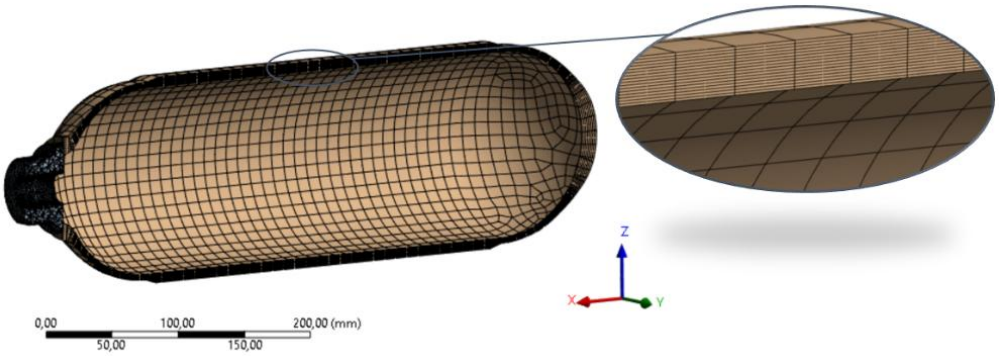

Figure 4: Finite element model used for the comparison of strains with FOS.

3 EXPERIMENTAL STUDY

3.1 Integration of Fiber Optic Sensors

For a smooth integration into the wound structure, the optical fibers for each layer were prepared on cardboard tubes in advance and placed behind the carbon fiber spools on the winding machine shafts. The length of each FOS exceeded the length of fibers used for the winding of the monitored layer by 4 m plus the distance from the cardboard tube to the wound CPV on top. The additional length was needed for ingress and egress from the CPV as well as connection to the measurement devices.

The optical fiber was led over the carbon fiber rovings and the resin bath and brought together with the carbon fiber roving directly before the pay-out eye of the winding machine. This procedure allows to avoid the contact with the epoxy resin for all parts of the sensor, which must remain flexible to later prevent damage of the optic fiber. At the same time, the optical fiber is placed onto the rotating liner together with the carbon fiber ensuring a good agreement of their winding angles. Figure 5 shows the optical fiber placed on the shaft of the winding machine and led towards the wound pressure vessel.

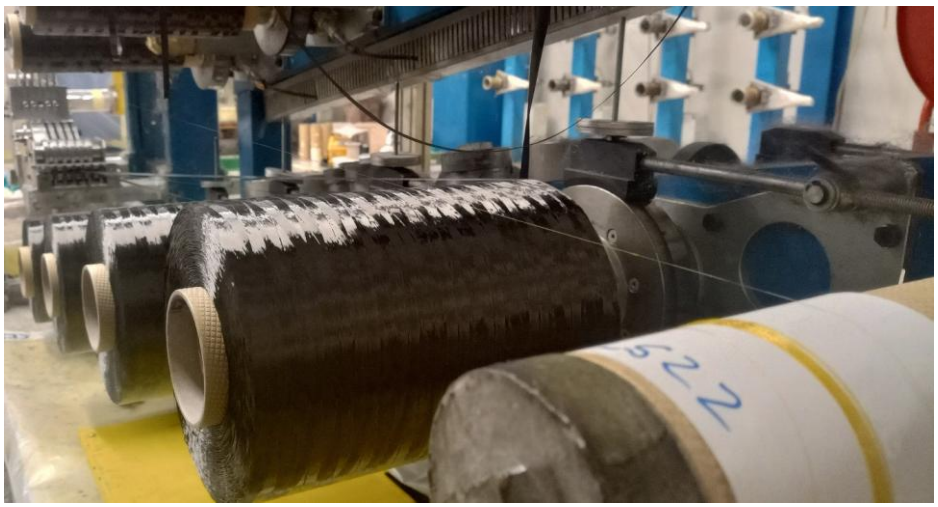

Figure 5: Optical fiber (gold in the bottom right corner) placed on the winding machine.

For ingress and egress from the CFRP, the dome part with the aluminum boss was used. Before the winding process, the boss edges were rounded to ensure a sufficient radius of all edges and to eventually avoid low radius bending of the optical fiber. The optical fiber itself was positioned in a way that ensures high bending radius, even if the optical fiber leaves the orientation of the carbon fiber roving and is particularly exposed to bending e.g., by the next carbon fiber layers (see Figure 3).

The method of integration of the FOS and the protection concept led to an excellent survival rate of the optical fibers in the project. All of the 18 embedded sensors survived the integration and could be used for strain measurements in the finished component. No adjustment of the filament winding machine was needed.

3.2 Slow Burst Tests and Strain Measurements

All 15 cylinders were destructively tested in SBT. On the one hand, the tests allowed a check of the functionality of integrated FOS by measuring the occurring strains. On the other hand, SBT are a method to assess the performance of composite pressure vessels introduced by Mair [22-25]. Therefore, an assessment of the impact of integrated optical fiber on the performance of the CPV sample is possible.

In an SBT, the pressure in a CPV is increased by 20 % of test pressure per hour, which corresponds to 1.5 bar per minute in the case of the investigated CPVs. During the tests, distributed strain measurements were performed using an ultra-high resolution optical backscatter reflectometer OBR 4600 (Luna Inc.). One measurement was performed every 5 bar, which sums up to 180 measurements up to a minimum burst pressure of 900 bar [26]. For the comparison with finite element models, an

average strain value was calculated for each measurement throughout the area of interest. For the hoop layers, two full hoop windings in the middle of the cylindrical region were considered. In case of helical windings, three sections in the cylindrical region with a length of 20 cm were defined.

4 RESULTS

4.1 Strain Distribution in Slow Burst Tests

Figure 6 shows the strains in the fiber direction in a cylinder from one specimen of Sample A subjected to an SBT. The helical winding shows significantly lower strains than the hoop windings, which was expected considering the stress distribution in a cylinder loaded with internal pressure. A good agreement between the strains measured with FOS and those calculated with finite element models can be observed. For the hoop windings a divergence of less than 10 % is present. Deviation of the material data in fiber direction can be considered as a possible cause for this behavior. The strains in the helical windings show an excellent agreement between FOS and finite element models. In general, the fiber optic sensors deliver feasible strain values and a good bonding between CFRP layers and the optical fibers can be assumed.

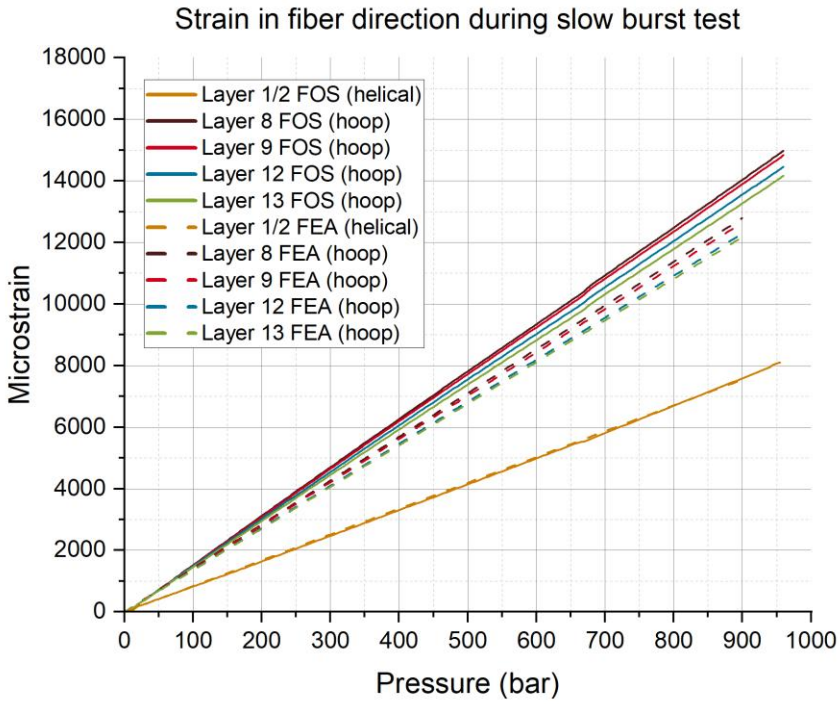

Figure 6: Strain in fiber direction during slow burst test in a CPV from sample A.

4.2 Impact of Optical Fibers on the Performance in Slow Burst Tests

No clear impact of the embedded fiber optic sensors on the behavior of the composite structure could be observed based on the post-mortem pictures of destroyed CPVs. The failure mechanisms, which were characteristic for each sample, did not vary for the CPVs with integrated fibers.

The burst pressures of all investigated cylinders are shown in Figure 7. The CPVs equipped with FOS are marked with half-filled symbols. The sample names correspond to the explanation in Section 2.1.

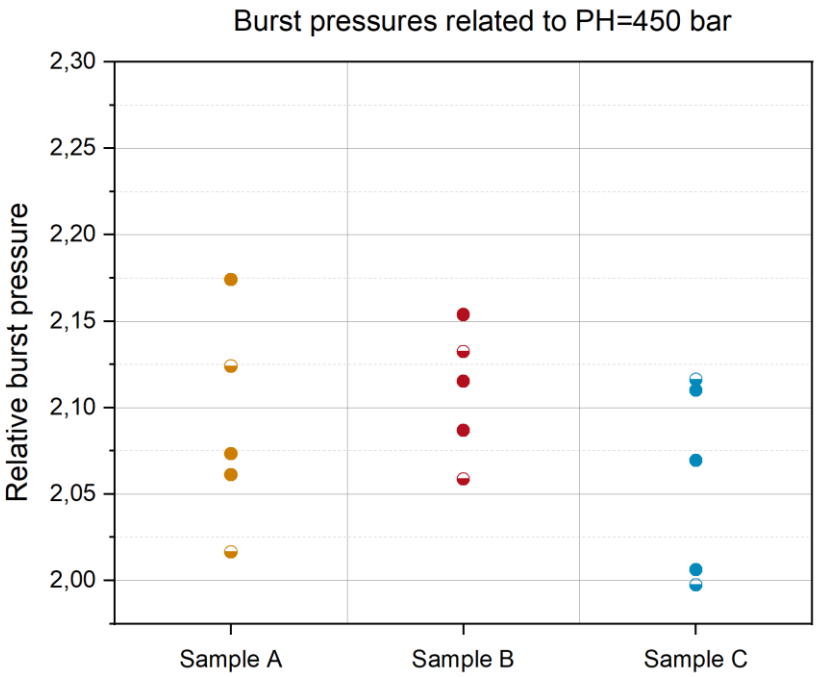

Figure 7: Relative burst pressures of all tested cylinders.

In general, the burst pressure of the CPVs with FOS are comparable with the burst pressures of the CPVs without FOS. Also, no clear trend can be observed regarding the scattering of the burst pressures. However, for each of the tested samples, the lowest burst pressure is a value obtained on a CPV with embedded optical fibers. Dixon's Q test is performed to identify if the lowest burst pressure values can be considered as outliers, which would indicate a significant impact of the integrated FOS on the mechanical behavior of the CPV. Burst pressures are arranged in increasing order and the value of Q is calculated as follows [27]:

$$Q = \frac{gap}{range} = \frac{x_1 - x_2}{x_1 - x_n} \tag{1}$$

At 95 % confidence none of the burst pressure values can be considered an outlier.

5 CONCLUSIONS

In this study optical fibers were integrated into six type 4 composite pressure vessels under industrial conditions. Three optical fibers were embedded in each composite cylinder and used for monitoring of six composite layers. No adjustments to the winding machine were needed. A protection concept for the ingress and egress of the optical fiber was developed, which resulted in an excellent survival rate of the optical fibers.

Strain measurements were performed with the integrated fiber optic sensors in slow burst tests. The obtained strain data were compared with finite element simulations showing a good agreement.

All six composite pressure vessels with embedded optical fibers and nine composite pressure vessels of the same designs were destructively tested in slow burst tests. No differences in failure mechanisms were observed within the samples. Even though a slight decrease of the mean burst pressures was observed for the cylinders with embedded fiber optic sensors, no clear trend in the influence of the embedded optical fibers on the performance of composite cylinders can be stated. An increase of the samples' size would contribute to further clarification of the influence of embedded optical fibers on the performance of the composite pressure vessels.

ACKNOWLEDGEMENTS

ABSTRACT

Carbon fibre-reinforced polymers have inherently poor thermal properties, driven by their anisotropic structure and the relatively low thermal conductivity of their constituent materials, particularly the matrix phase. This makes them unfit for use in structures surrounding heat emitting components in aircraft. This low thermal performance can potentially be mitigated via active fluid cooling through embedded networks of channels within the composite structure. In order to explore the fundamental thermal management capabilities of this approach, embedded channel networks have been fabricated and thermally tested, with the performance compared against numerical results from COMSOL Multiphysics. The channel networks were manufactured within CFRP samples by embedding metallic wires along the neutral axis during prepreg hand layup up and extracting them post-cure, with fluid fittings bonded into the inlets and outlets of each channel. The samples were thermally characterised under conductive thermal loads applied via a heating mat with increasing flow rates of coolant pumped through the channels. A range of sample and channel geometries and process parameters were tested to understand their impact on thermal performance, with particular interest in the effect of channel number and diameter, flow rate, and coolant temperature. The experiments show that up to an 80% reduction in surface temperature can be achieved through active cooling, with improvements driven by increasing the flow rate and channel volume fraction. A higher number of channels within the sample is also shown to create a more uniform temperature profile, removing hot spots on the surface. Thermal modelling results were validated against the experimental results, showing good agreement.

1 INTRODUCTION

At ambient temperatures, carbon fibre-reinforced polymers exhibit excellent mechanical properties and an especially high strength-to-weight ratio that makes them ideal for use in primary structures in aircraft. A typical aerospace-grade CFRP system can be up to seven times stronger and two times stiffer than its aluminium counterpart at only two thirds the weight, with relative performance being highest when the loads are directly aligned with the fibres [1]. However, CFRPs have comparatively poor thermal properties and low maximum service temperatures which make them unsuitable for any application where they may be exposed to significantly elevated temperatures or high thermal loads. While carbon fibres themselves exhibit moderate to high thermal conductivity (5-15 W/mK for PAN-based fibres, 500-1000 W/mK for pitch-based fibres)[2-5], the much lower conductivity of the resin matrix (0.19-0.25 W/mK) [6,7] and the anisotropy of their structure means the net conductivity for a

typical CFRP layup is somewhere in the region of 4-5 W/mK in the in-plane direction and only around 1-2 W/mK in the out-of-plane direction, much lower than a typical aerospace aluminium alloy (~230 W/mK) [8-10]. This combines with glass transition temperatures typically in the range of 150-200ºC, with even lower working temperatures quoted by manufacturers due to safety factors [11]. As a result, metallics such as aluminium or magnesium alloys are still the preferred materials for aerospace structures that must withstand high levels of thermal loading, such as electric generators and gearboxes.

Several concepts have been explored to improve the thermal properties of CFRPs including fillers, coatings and crystal structure alignment [12-14]. While these passive techniques do offer some improvement in thermal conductivity, they come at the expense of increased manufacturing and materials costs, added complexity, and still do not achieve the levels of thermal conductivity needed for many real-world applications. Instead of attempting to improve the inherent thermal properties of the CFRP system, it is attractive to consider active approaches for removing heat from the structure, for example through the use of an embedded system of channels permeated by a heat transfer fluid. This technique was first inspired by biological systems that exhibit intricate microvascular networks such as leaves or the human circulatory system and was hypothesised as a means of adding multifunctionality to a structure [15,16]. Active cooling has since been determined as one such function and has been investigated both experimentally and numerically over the last 15 years by a small number of researchers [17-23]. For instance, Pety *et al* [20] achieved up to 80% cooling efficiency (proportion of heat removed over the heat applied) in composite panels with embedded channels at flow rates up to 30 ml/min, and Coppola *et al* [17] observed a 90% retention of mechanical properties in specimen subjected to 4-point bending up to 325 ºC. While the results from these studies show effective and repeatable channel fabrication, highly efficient cooling, good retention of mechanical properties, and a large scope for optimisation, the approach has not yet made it into widespread use, in part because it has never been thoroughly characterised with regards to the numerous design and process parameters that impact the effectiveness of heat removal.

This paper attempts to carry out a thorough characterisation of channel cooling performance using a broad-spectrum design of experiments, backed up by numerical analysis, to directly measure the impact of varying the key design and operating parameters within the channel network architecture. CFRP samples containing embedded channels are first manufactured with various combinations of thicknesses, channel diameters and channel pitches. The samples are then thermally tested via conduction with respect to process parameters such as flow rate, coolant fluid, and coolant fluid temperature. The results of these experiments are then discussed to analyse the effect of these parameters on cooling performance. Finally, numerical models are set up in COMSOL Multiphysics to validate against the experimental data obtained, with the models then being ready to explore a wider and more complex design space in future work.

2 METHODOLOGY

2.1 Channel fabrication

Previous work has explored numerous approaches to fabricate embedded channels within a composite, including hollow glass fibres or steel tubes, solder removal, direct ink writing, and vapourisation of sacrificial materials (VaSC) [24-31]. However, in this work, manual wire extraction (MWE) was chosen as the preferred fabrication method due to the comparative ease of the process and because there is no requirement for post-cure treatments. MWE involves embedding high tensile strength wires within the composite structure during hand layup and removing them post-cure by pulling them out manually, leaving a hollow channel of inverse shape embedded within the composite structure [32-34]. With this method, several wires could be embedded to create a network of straight and flat channels within the CFRP, each with its own inlet and outlet.

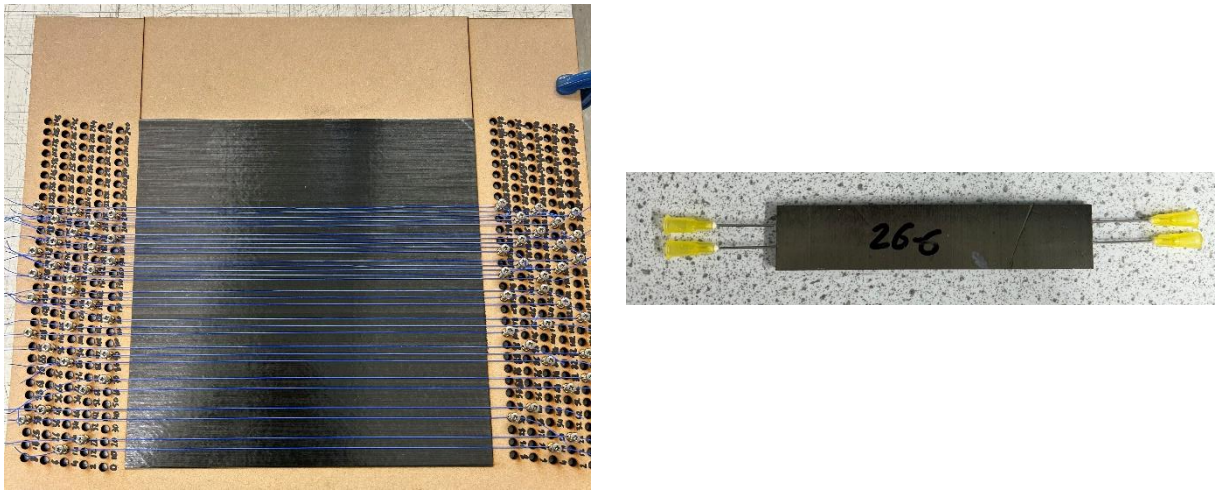

Figure 1 – a) Wire positioning jig in place over a laminate before cure b) post-cured sample with wires removed and syringe tips glued into inlet and outlet

In this work, PTFE-coated nickel-chromium (Nichrome) wires of two different diameters (0.57 mm and 0.97 mm) were used, and they were embedded at the midplane of IM7/8552 prepreg CFRP laminates during hand lay up. For both of the specimen thicknesses manufactured (2 mm and 4 mm), the ply stacking sequence was such that the wires would be entirely contained within plies orientated parallel to the channels (0º direction) to allow for the thickness of the channel to be accommodated within the layup through movement of the adjacent fibres with minimal disturbance of the off-axis plies above and below the midplane. In all cases, a large laminate (300 x 300 mm) was prepared and a series of wires (0.57 mm or 0.97 mm) at set pitches were strung across the midplane and held in place using an MDF jig with laser cut indexing holes to position screws around which the wires ends were wrapped (Figure 1a). The laminates were then cured in an autoclave under vacuum at the standard IM7/8552 cure cycle (2 ºC/min ramp up to 110 ºC, 60-minute dwell, 2 ºC/min ramp up to 180 ºC, 120-minute dwell, then cool down to ambient temperature with a vent of pressure at 60 ºC). After curing, the laminate was heated to approximately 50 ºC on a hot plate to help loosen the wires, which were manually pulled out using pliers, leaving a set of hollow channels. Finally, the large laminate was cut into smaller individual test samples (120 x 24 mm) and syringe tips (18G for 0.57 mm, 20G for 0.97 mm) were glued into the exposed channel ends using 2-part epoxy (Araldite), as shown in Figure 1b.

In order to test a large array of geometry-based parameters, laminates of thicknesses 2 mm and 4 mm were manufactured, and the wires were spaced such that the resulting collection of samples would have instances containing networks of two, three, and five evenly spaced channels. The combination of channel diameter, laminate thickness, and channel number gave rise to nine distinct sets of samples, with differing channel volume fractions, defined as the cross-sectional area of the channels in a specimen divided by its full cross-sectional area, as enumerated in Table 1.

Table 1 – Geometric parameters of samples tested

Laminate thickness [mm]	Channel diameter [mm]	Number of channels	Channel volume fraction [%]
2	0.57	2	1.08
		3	1.62
		5	2.70
4	0.57	2	0.54
		3	0.81
		5	1.35
	0.97	2	1.54
		3	2.31
		5	3.85

2.2 Thermal testing

The manufactured specimens were tested on a custom thermal conduction test rig (Figure 2). They were first placed on a silicone heater mat (from Under Control Instruments) at a set heat flux and allowed to reach steady-state temperature. The time history of the temperature distributions on the entire top surface of the specimens was tracked and captured with an IR camera (FLIR T650sc). Water at a prescribed initial temperature was then circulated through the embedded channels at a set flow rate using silicone tubing and a peristaltic pump (Watson-Marlow 503U). The water was maintained close to the desired temperature using a water bath (Grant JB Nova 12L) and was allowed to circulate around the channels until steady-state temperature was again reached. The flow rate was then increased to test the next flow condition, which was tracked with a flow meter (Omega FLR1008-D). K-type thermocouples and wet/wet pressure sensors (Omega PX26-15GV) were attached to the silicone tubing just before and after the inlet and outlet of the specimens, and the temperatures and pressures were captured using National Instruments data acquisition modules (NI 9212, NI 9219) and LabVIEW software.

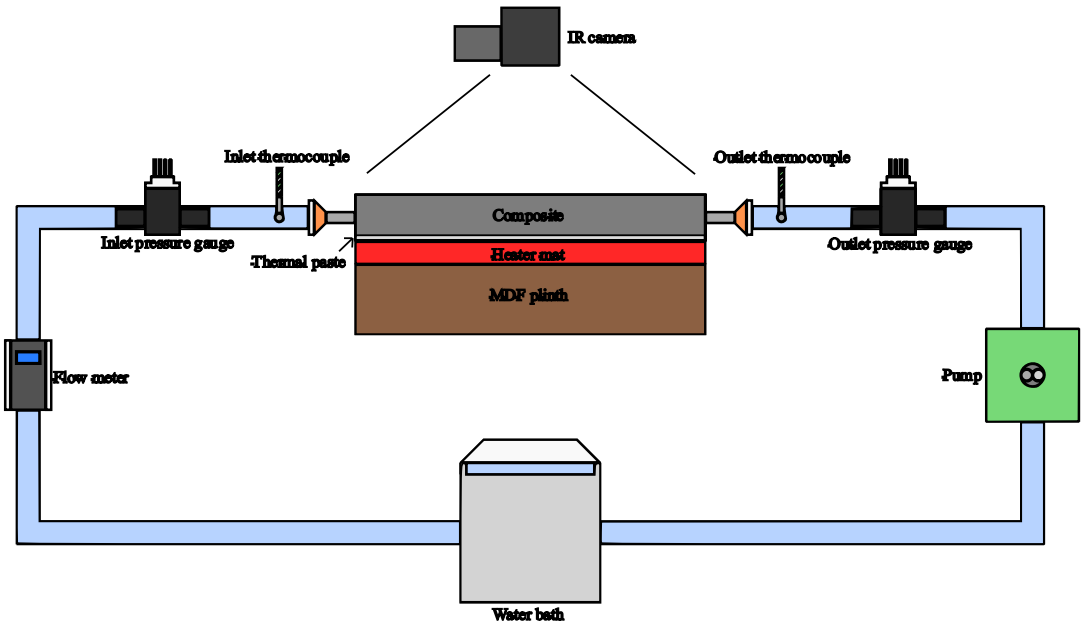

Figure 2 – Schematic of conduction test setup

Each specimen was tested at three flow rates (10, 20 and 30 ml/min) and three heat fluxes (500, 1000 and 1500 W/m^2), resulting in eighty-one separate experiments. Two sample geometries (4 mm thickness, 0.97 mm channel diameter, two and three-channels) were also chosen for further testing with higher flow rates (up to 70 ml/min), different initial water temperatures (10, 30 ^{o}C), and different coolant fluids (deionised water, mono-propylene glycol). For conciseness in this paper, the 4mm thick specimens with 0.97 mm channel diameter have been chosen as the baseline data set, with comparisons made to the other geometries.

2.3 Computational modelling

Models representing the same geometries and process parameters used in the experiments were set up in COMSOL Multiphysics using the heat transfer in solid and fluids design module. A solid body of 120 x 24 mm (4 mm and 2 mm thickness) was designed to represent the specimens with a second body of 120 x 24 x 0.5 mm was created in contact with the bottom surface of the main body to represent the heater mat. Two, three, and five-channels were then modelled with diameters 0.228 mm and 0.485 mm along the neutral axis of the main body at the desired pitches (4 mm, 6 mm, 8 mm). An example two-channel model is shown in Figure 3. The main body was assigned a custom material representing IM7/8852, with properties obtained from the material datasheet and previous experiments [35]. Built-in

material properties were used for water and silicone for the fluid channels and heater mat respectively. A full breakdown of process parameters and material properties is shown in Table 2.

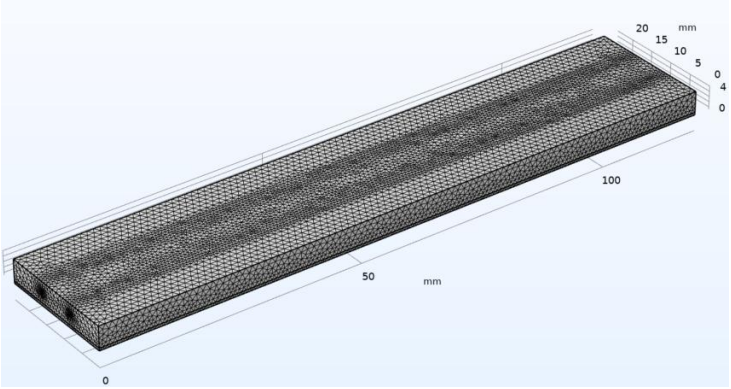

Figure 3 – Meshed COMSOL model of a two-channel specimen with 0.97 mm diameter channels

A heat source was applied to the heater mat domain to represent the desired heat flux. This was converted to raw power using Equation 1 below. External natural convection and surface-to-ambient radiation were applied to all exposed surfaces of the specimen. The channels within the specimen were grouped together and assigned a desired inlet temperature and flow rate. A global tetrahedral mesh was generated around the model, with a finer triangular mesh around the channels (548,278 total elements).

Table 2 – Parameters, model inputs and material properties for COMSOL models

Specimen Geometry	Value	Description
l	120 [mm]	Length of specimen
w	24 [mm]	Width of specimen
t	2, 4 [mm]	Thickness of specimen
r	0.285, 0.485 [mm]	Channel radius
p	4, 6, 8 [mm]	Distance between channels
Model inputs		
T_a	21-26 [°C]	Ambient temperature
T_c	14-28 [°C]	Coolant fluid inlet temperature
Q	8-33 [ml/min]	Flow rate of fluid
P	6.573-17.190 [W]	Power applied[a]
L_t	10 [mm]	Characteristic length of top surface[b]
L_s	0.984, 1.936 [mm]	Characteristic length of sides[b]
L_e	0.923, 1.714 [mm]	Characteristic length of top edges[b]
Material properties		
ρ_c	1570 [kg/m^3]	Density of IM7/8552 [35]
Cp_c	920 [kJ/kgK]	Specific heat capacity of IM7/8552 [35]
k_c	1.750 [W/mK]	Thermal conductivity of IM7/8552[c]
ϵ	0.970	Surface emissivity
ρ_w	~ 998 [kg/m^3]	Density of water[d]
Cp_w	~ 4.180 [kJ/kgK]	Specific heat capacity of water[d]
k_w	0.600 [W/mK]	Thermal conductivity of water
ρ_s	1100 [kg/m^3]	Density of heater mat (silicone rubber)
Cp_s	1.900 [kJ/kgK]	Specific heat capacity of heater mat
k_s	0.500 [W/mK]	Thermal conductivity heater mat

[a]Converted from heat flux values
[b]For external natural convection. Defined as area of surface divided by perimeter
[c]Obtained from previous, unpublished study
[d]Temperature dependent

$$P = \left(\sqrt{Q"RA}\right) * I \quad (1)$$

Where P is power, $Q"$ is heat flux, R is resistance of the heater mat, A is surface area of the specimen, and I is the current of the heater mat.

The model outputs mirrored those in the experimental test: maximum temperature of the top surface; average temperature of the top surface; and outlet temperature of the fluid. The temperature profile of the model could also be captured and directly compared to the profile from the IR images. Instead of taking generic or desired parameters (e.g. T_a=21ºC, T_c=20ºC, Q=10 ml/min) the model was set up with actual dataset specific values for ambient temperature, inlet temperature and flow rate that were captured throughout the experimental tests. This results in a model output for each individual test rather than general model results to compare against.

3 RESULTS AND DISCUSSION

During testing, the ambient temperature in the lab fluctuated depending on the outside temperature and the time of day, and this had a non-negligible effect on the temperature of the coolant fluid at the inlet to the channels, and to a lessor extent is likely to have affected the heat transferred out of the specimens. To account for the change in ambient temperature across different testing runs and datasets, the results are normalized to inlet temperature using a ratio derived from the inlet temperature and no-flow heating condition. This ratio ("effective cooling") is defined in Equation 2 below and describes the actual temperature reduction of the specimen over the maximum theoretical temperature reduction, based on the idea that the specimen temperature can approach but never be cooler than the coolant inlet temperature.

$$e_c = \left(\frac{T_{max,nf} - T_{max,Q}}{T_{max,nf} - T_{inlet}}\right) * 100 \quad (2)$$

Where e_c is the effective cooling, $T_{max,nf}$ is the maximum surface temperature of the specimen in the no-flow condition, $T_{max,Q}$ is the maximum surface temperature of the specimen for a given flow rate, and T_{inlet} is the temperature of the coolant supplied to the inlet of the channels.

The inlet and outlet temperatures could further be used to calculate a heat removal rate from the specimen, and this could then be compared to the power supplied to the specimen from the heater mat to give heat removal rate as a proportion, as shown in Equations 3 and 4.

$$q = \sum_n (Q \rho Cp \Delta T) \quad (3)$$

$$H_{\%} = \left(\frac{q}{P_m}\right) * 100 \quad (4)$$

Where q is the rate of heat removal, Q is the flow rate, ρ is coolant density, Cp is coolant specific heat capacity, ΔT is the temperature difference across the inlet and outlet of the channels, n is number of channels, $H_{\%}$ is the heat removal proportion, and P_m is the power supplied to the heater mat.

3.1 Effect of flow rate

The maximum surface temperatures and the effective cooling of two datasets are shown in Figure 4. In all samples, both the maximum and average surface temperatures decreased as flow rate increased. This began with a steep initial decrease from the no flow condition to the lowest flow rate (10 ml/min) with more marginal reductions as the flow rate was further increased. The levelling off of the effective cooling suggests that merely the presence of coolant at a minimal flow rate (10 ml/min is relatively low and easily achievable with most commercial pumps) is sufficient to cool the sample significantly. The best performing specimen geometry was observed to be the 4 mm thickness with 0.97 mm channel diameter, which exhibits up to a 116 ºC (80%) decrease in maximum surface temperature at the highest flow rate (30 ml/min), number of channels (five), and applied heat flux (1500 W/m^2). This is expected considering this configuration contains the highest channel volume fraction. However, the 4 mm, 0.57 mm specimen still exhibits a substantial surface temperature reduction (63 ºC) even at the lowest flow rate (10 ml/min), number of channels (two), and applied heat flux (500 W/m^2).

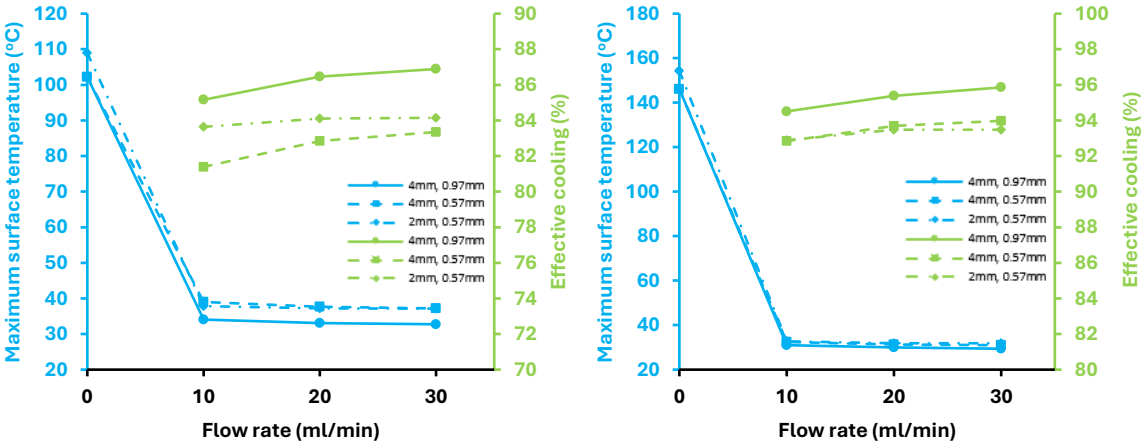

Figure 4 – Maximum surface temperature and effective cooling of specimen of all geometries and a) two-channels at 500 W/m^2 applied heat flux b) five-channels at 1500 W/m^2 applied heat flux

The temperature difference between the inlet and the outlet decreases as flow rate increases, largely due to the increased velocity in the fluid through the channel. Despite this, the heat removal proportion increases as flow rate increases, due to the fact that the increase in the flow rate outweighs the drop in temperature difference. The heat removal rates are shown in Figure 5.

Higher flow rates were tested in two and three-channel samples from the batch of specimens of 4 mm thickness and 0.97 mm channel diameter, the results of which are shown in Figure 6. Increasing the flow rate beyond 30 ml/min appears to have very little effect on further reducing the maximum surface temperature, with reductions below 0.5°C from successive flow rate increases. Increasing the flow rate above 30 ml/min does however have a significant effect on the pressure experienced across the sample (see Figure 8b in Section 3.5), leading to difficult testing conditions where the high pressure may cause leaks at the syringe/adhesive interface or in the silicone tubing. It was determined that increasing the flow rate beyond 30 ml/min is unnecessary from a cooling perspective and prohibitive from a pressure perspective, especially in the specimen containing 0.57mm diameter channels, where pressure is inherently higher to increased flow restriction.

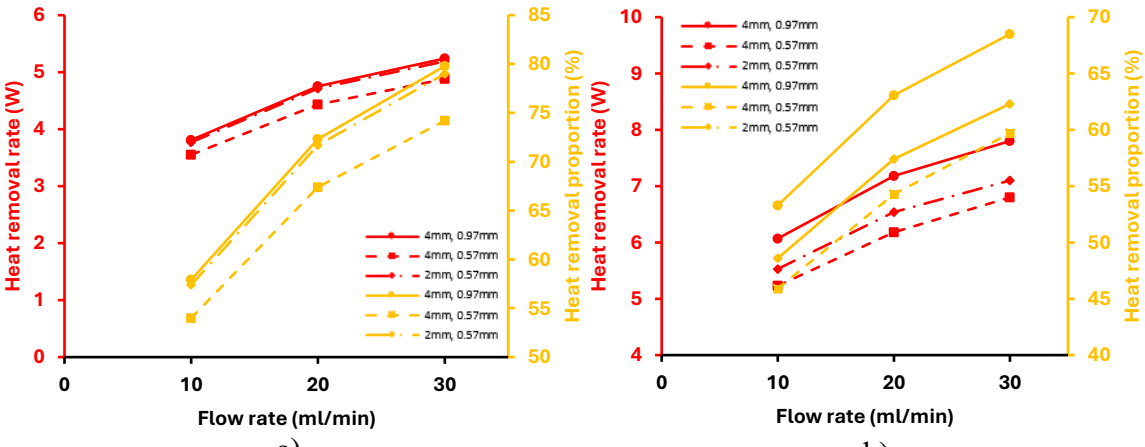

Figure 5 – Heat removal rate and heat removal proportion of specimens of all geometries and a) two-channels at 500 W/m^2 applied heat flux b) five-channels at 1500 W/m^2 applied heat flux

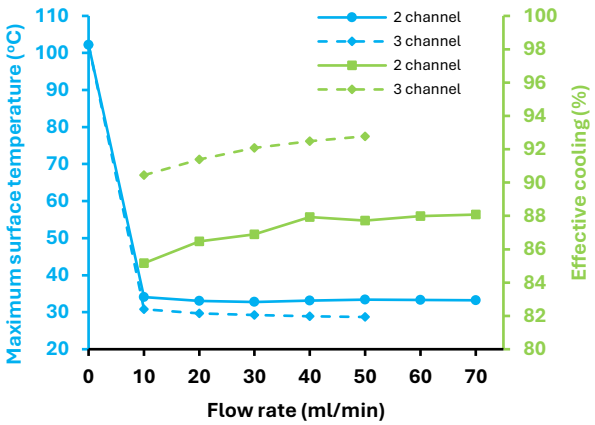

Figure 6 – Maximum surface temperature and effective cooling in a 4 mm, 0.97 mm specimen with two and three-channels at 500 W/m^2

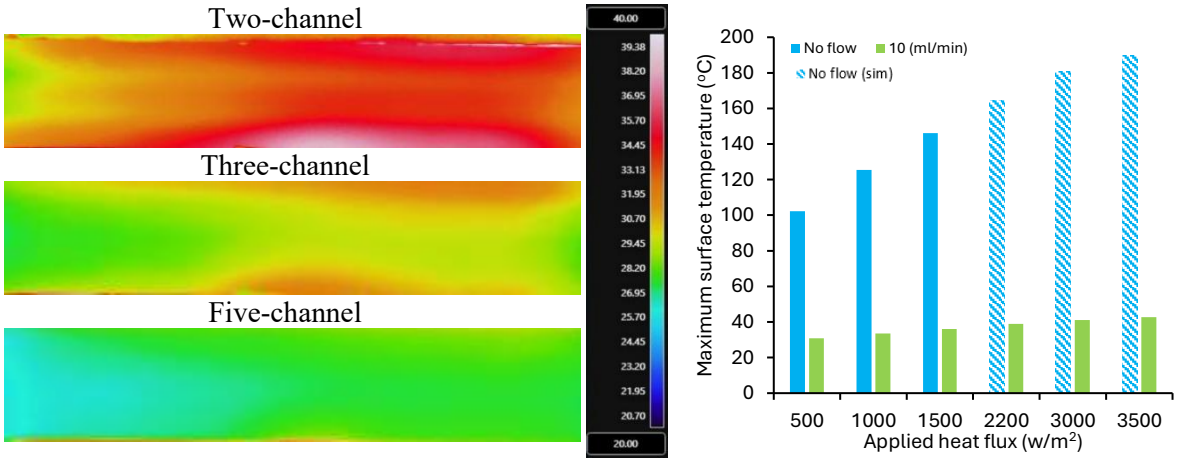

3.2 Effect of pitch

Similar to flow rate, reducing the pitch and therefore increasing the number of channels within a sample leads to a higher reduction in maximum and average surface temperatures across all samples tested. More importantly in this case, and as seen in Table 3, having more channels in a specimen leads to a smaller difference between the maximum and average surface temperatures, giving a more uniform temperature distribution across the top surface.

An increased number of channels also leads to increased heat removal from the specimen, with a 10-12% increase from a two to a three-channel specimen and a similar gain from a three to a five-channel specimen. Using the images captured by the IR camera, the temperature profiles of specimens with the same process parameters but a different number of channels can be compared directly, as seen in Figure 7a. It is observed that there is not only a lower temperature on the surface as the number of channels increases, but also less variation in colour across the top surface. For instance, the two-channel sample clearly exhibits hotter regions either side of the channels towards the edge of the specimen. These are minimised by the three-channel specimen and completely eliminated by the five-channel specimen, leading to a more uniform temperature profile. This effect is also clearly reflected in the standard deviations of temperature across the specimens (Table 3), which have a consistent decreasing trend with increasing numbers of channels for all specimen geometries.

Table 3 – Temperature difference and standard deviation for all specimen geometries at 20 ml/min and 1000 W/m^2 applied heat flux

Specimen geometry [mm]	Number of channels	Maximum temperature [°C]	Average temperature [°C]	Temperature difference [°C]	Standard deviation [°C]
4 thickness, 0.97 diameter	2	37.48	32.32	5.16	1.66
	3	32.14	29.42	2.72	1.07
	5	28.64	27.29	1.35	0.62
4 thickness, 0.57 diameter	2	41.12	36.06	5.06	2.29
	3	36.25	32.19	4.06	1.24
	5	29.86	27.25	2.61	0.71
2 thickness, 0.57 diameter	2	42.43	34.8	7.63	2.35
	3	37.44	31.28	6.16	2.24
	5	30.01	26.65	3.51	0.85

a) b)

Figure 7 – a) Surface temperature profiles of 4 mm thickness, 0.97 mm channel diameter specimens of two, three and five-channels at 20 ml/min and 1000 W/m^2 b) maximum surface temperature of a 4 mm thickness, 0.97 mm channel diameter, two-channel specimen at all heat fluxes in no-flow condition and at 10 ml/min

3.3 High heat flux

The no-flow condition can only be tested experimentally up to 1500 W/m^2 due to the temperatures on the specimen (~154 ºC on a 2 mm thickness specimen) approaching and even exceeding the maximum rated operating temperature of the heater mat (150 ºC), in addition to potential damage to the composite. As such, higher applied heat fluxes were tested in flow on conditions only, with the no-flow condition instead obtained through numerical modelling. As seen in Figure 7b, even when increasing the heat flux to 3500 W/m^2, which would result in a predicted maximum surface temperature of ~190 ºC, the presence of cooling fluid at the lowest flow rate and number of channels is still sufficient to reduce the maximum surface temperature markedly.

The higher heat fluxes were chosen based on potential applications in industry, as seen in Table 4. In all cases, the maximum surface temperature was reduced to below the maximum operating temperatures associated with these applications. This suggests that a composite structure with embedded channels could be substituted for the existing metallic casings of these components without compromising the working conditions of the component itself.

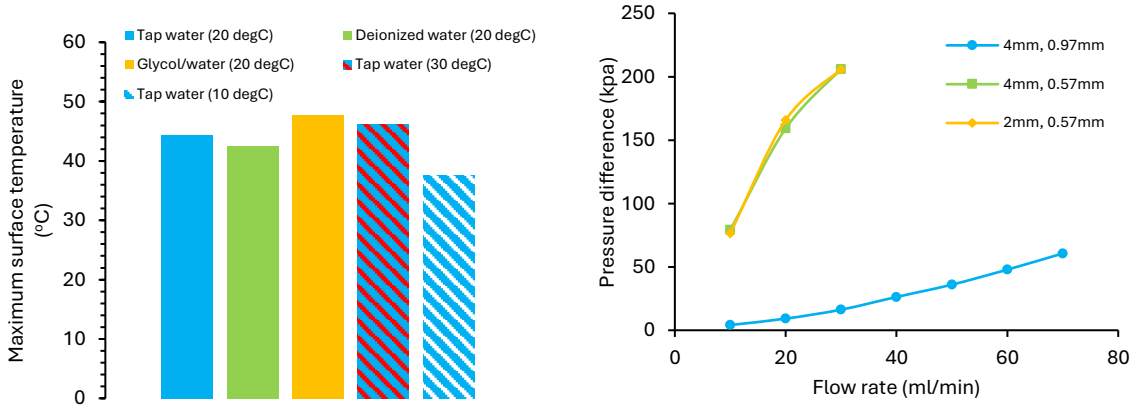

Table 4 – Application specific working temperatures and achieved cooling in a 4mm thickness, 0.97mm channel diameter, two-channel specimen

Heat flux [W/m^2]	Application	Critical temperature [ºC]	Maximum temperature no-flow [ºC]	Maximum temperature flow [ºC]	Temperature difference [ºC]
500	EV battery	55	102.81	30.79	24.21
2200	Transmission shaft	85	164.48	38.88	46.12
3000	Transmission gear	90	181.00	41.12	48.88
3500	Transmission bearing	90	189.84	42.74	47.26

3.4 Effect of coolant fluid and temperature

Deionised water and a 50:50 mixture of water and mono-propylene glycol were also tested as coolant fluids, as well as different inlet temperatures of water. As seen in the results in Figure 8a, cooling the water to below room temperature (~10 ºC) leads to an increased surface temperature reduction, with the opposite effect occurring when the water is instead heated (~30 ºC). In both these cases however, it was

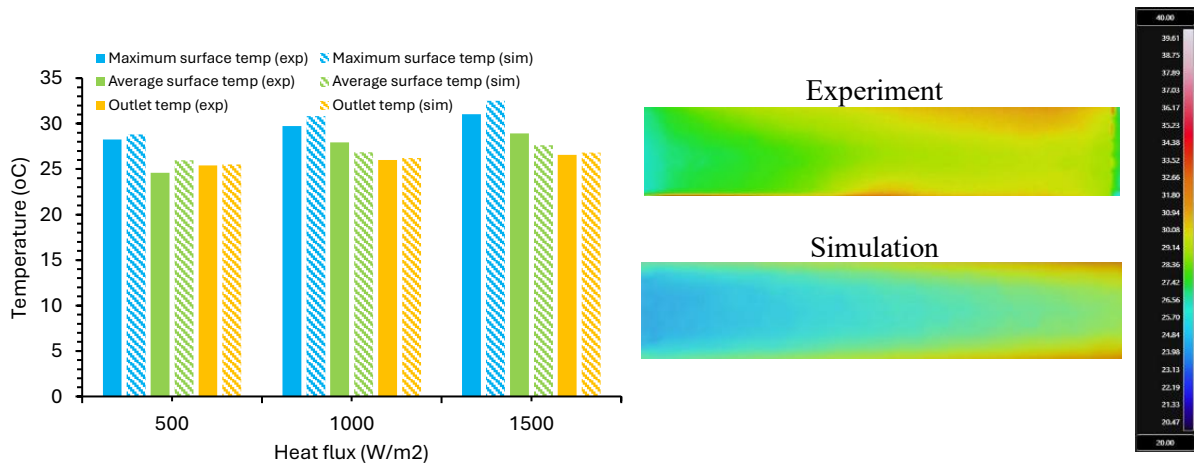
challenging to maintain the target temperature, as the water would heat or cool as it left the water bath and was pumped through the tubing towards the specimen. As a result, the actual inlet temperature was on average ~16 ºC for the 10 ºC test and ~27 ºC for the 30 ºC test. Despite this, there is still a significant improvement in temperature reduction in the sample if the coolant fluid is first cooled, and this could be a significant factor if the inlet temperature can be properly maintained.

(a) (b)

Figure 8 - a) Maximum surface temperatures of a 4 mm, 0.97 mm, two-channel specimen at 1500 W/m^2 and 10 ml/min with various coolant fluids and inlet temperatures, and b) pressure differences in all two-channel specimen geometries at 500 W/m^2 at all flow rates

Changing the coolant fluid from tap water to deionised water led to a very small (~0.5 ºC) reduction in surface temperature in a specimen heated at 500 W/m^2. This was not significant enough to justify the added complexity of introducing deionised water to the cooling system. Somewhat surprisingly, the water/glycol mixture led to a higher maximum surface temperature in comparative samples. This may be due to the mixture having higher inlet temperature (~27 ºC) than the standard water (~21 ºC) due to the initial temperature of the mono-propylene glycol. Despite this disparity in inlet temperature, the glycol/water mixture still exhibits a lower effective cooling than both tap water and deionised water. However, further tests will be performed with the glycol/water mixture at inlet temperatures more in line with the other test fluids.

3.5 Pressure



The pressure difference across the specimen is a significant factor in the testing, as a high-pressure difference can lead to difficulties with the apparatus, namely lower pumping efficiency, leaks at the syringes, or bursts in the silicone tubing. The pressure differences exhibited in the specimens of all geometries are shown in Figure 8b. In general, the inlet pressure will increase as flow rate increases across all specimens. Specimens containing 0.57 mm diameter channels will exhibit up to a twenty-fold increase in inlet pressure compared to specimen containing 0.97 mm diameter channels. Generally, there is minimal change in pressure difference across a specimen as the applied heat flux increases. However, the pressure difference decreases as the number of channels increases. A comparison of applied heat flux, flow rate and number of channels is shown in Table 5.

Table 5 – Pressure difference in a 4 mm thickness, 0.97 mm channel diameter specimen at various applied heat fluxes, flow rates, and number of channels

Applied Heat flux [W/m^2]	Number of channels	Pressure difference [kpa]		
		10 [ml/min]	20 [ml/min]	30 [ml/min]
500	2	4.14	9.17	16.27
	3	3.44	9.24	16.41
	5	2.83	8.83	13.10
1000	2	4.69	9.51	16.13
	3	3.38	9.24	16.96
	5	3.86	8.76	15.58
1500	2	4.83	10.00	16.27
	3	3.31	8.96	16.20
	5	2.96	8.82	15.58

3.6 Numerical modelling

In all instances, the experimental data was compared against the predicted results from the COMSOL models. The experimental results for maximum surface temperature, average surface temperature and outlet temperature are within 10% of the same metric in COMSOL for all datasets. In general, the outlet temperature shows the most agreement with the COMSOL results (within 0.5-3.5 %) and the average surface temperature shows the least (2.5-9.5 %). A more detailed comparison for a 4 mm thickness, 0.97 mm diameter specimen with 5-channels is shown in Figure 9a.

a) b)

Figure 9 – a) Experimental and simulated temperatures of a 4 mm, 0.97 mm, five-channel specimen at 1500 W/m^2 and 10 ml/min b) Experimental and simulated top surface temperature profiles of a 4 mm, 0.97 mm, five-channel specimen at 1500 W/m^2 and 10 ml/min

The COMSOL models can also be used to compare the simulated temperature profiles to those captured with the IR camera, as shown in Figure 9b. There is good visual agreement with several features, showing for instance that the specimen is hotter on the outlet side than the inlet side, as the fluid heats as it traverses the specimen.

4 CONCLUSIONS AND FUTURE WORK

This work undertook a combined experimental and numerical campaign to explore the ability of composite plates to be actively fluid cooled through the use of embedded channels. A large number of specimens were manufactured and tested to explore the impact of the key geometrical and operating parameters on the cooling performance achievable, which was considered in terms of both surface temperature reduction and heat flux.

The results show that embedded channels allow for highly effective cooling of the composite specimens even at low coolant flow rates and channel volume fractions. Higher flow rates and an increasing number of channels improve the effectiveness of this cooling, both in terms of maximum temperature reduction and in terms of temperature uniformity. Other parameters such as channel diameter and coolant fluid type play a lesser role. With the correct combination of parameters, composite systems can be successfully cooled to safe working temperatures based on application specific thermal loads, as evidenced in the high heat flux tests. However, pressure difference and inlet temperature of the fluid must be accurately regulated.

The COMSOL models have been validated against the experimental data and can now be used to explore a more complex design space with alternative channel architectures containing 2D shapes, branches and multi-layered sections. These will be designed in COMSOL to test their effectiveness and suitability before being manufactured and tested experimentally.

The existing specimens will be further tested to be fully characterised thermally, with particular attention taken to the effect of inlet temperature and coolant fluid. The specimens will also be mechanically characterised through tensile testing to determine the impact that the presence of the channels have on mechanical properties of the composite under various loading scenarios.

ACKNOWLEDGEMENTS

ABSTRACT

The shift toward zero-emission mobility for urban, air, and space transport requires transformative advances in structural energy storage. Carbon fiber reinforced polymer structural battery composites (CFRP-SBCs) present a compelling opportunity by integrating load bearing and energy storage capabilities. However, their practical deployment in electric aviation and e-VTOL applications is hindered by two fundamental challenges: low energy density and compromised mechanical performance. Herein, we introduce a sustainable, scalable manufacturing approach utilizing supercritical spray deposition to engineer tailorable 3D nanostructures on carbon fiber cathodes. By manipulating the amphiphilicity and droplet size of hybrid suspensions containing lithium iron phosphate (LFP) and reduced graphene oxide (rGO), distinct post-evaporation patterns, rings, domes, and disks/domes, are formed. These patterns modulate interfacial properties and electrochemical behavior, enabling the concurrent enhancement of energy density and interfacial strength, previously considered challenging. Our results show that disk/dome patterned cathodes perform better in electrochemical properties (energy density, power density, capacity) while ring patterned cathodes show higher interfacial adhesion. These results demonstrate that combining multiple patterns enables synergistic improvements in both mechanical and functional performance. This platform paves the way for the development of high-strength, high-energy-density composite systems critical to enabling future e-mobility applications.

1 INTRODUCTION

The growing demand for zero-emission vehicles for urban, air and space mobility has reignited interest in battery-powered electric mobility (e-mobility). Particularly, reshaping aviation toward a greener future by 2050 [1] will not be realized without addressing challenges in battery technology in electric flights and electric vertical take-off and landing (e-VTOL) aircrafts. Carbon fiber reinforced polymer battery composites (CFRP-SBCs), comprising polymers as electrolyte matrix and carbon fibers (CFs) as electrodes, collectors and reinforcements show a perfect synergy between structural performance and energy efficiency. However, a significant hurdle is the considerably lower energy

density (less than 40 Wh/kg in full cell configuration) [2-4] compared to the conventional batteries as well as the minimum required 400-600 Wh/kg for small-medium size planes [5], and their significantly reduced strength and stiffness (2-10 GPa modulus and ~100-200 MPa strength, 20-30% of structural CFRPs). This is arising from the inherent tradeoff between mechanical and electrochemical properties and the historical separation of batteries and structures. This is a common trait in almost all engineered materials, in which efforts to enhance multiple functions, such as energy storage and structural properties, face complexity as improvements in one compromise others. Particularly in CFRP-SBCs, two bottlenecks to achieve simultaneous high energy density and high mechanical strength are: (1) Very low ion transport in solid polymer electrolytes (10^{-6}-10^{-5} S.cm^{-1}) compared to liquid (10^{-2} S.cm^{-1}) and ceramics (10^{-5}-10^{-3} S.cm^{-1}). (2) Requirement of abundant coating of active materials on carbon fiber cathodes to reach reasonable energy density that results in weakening the interfacial adhesion with the electrolyte (and separator) that causes delamination and premature mechanical failure. Herein, we introduce scalable and green manufacturing techniques without the use of harsh solvents, wherein engineered patterns are fabricated on cathode to create tailorable microstructure for simultaneously high strength and high energy density in CFRP-SBCs.

To address the limitations of conventional lithium-ion batteries and build upon insights from prior studies demonstrating the substantial influence of nanopatterning on the mechanical robustness, thermal stability, and electrical conductivity of composites, this work explores the impact of engineered nanopatterns on LFP-rGO cathode structures. Although various fabrication techniques such as sol-gel, [6], electrophoretic deposition (EPD) [7], high-temperature reduction strategy [8], drawdown method [9], and high-energy ball milling assisted by the rheological phase method [10] have been employed to create LFP/rGO composites, these approaches do not sufficiently enable the engineering of nanoscale surface morphologies. This study, therefore, investigates optimal strategies for manipulating surface patterns to achieve desired nanoscale architectures and examines how different nanopatterns affect cathode performance. The motivation for this inquiry is rooted in evidence that tailored nanopatterns not only improve interfacial adhesion between substrates such as carbon fiber and the polymer matrix, but also significantly enhance the multifunctional performance of composites without compromising mechanical integrity [11]. By extending this concept to battery cathodes, we hypothesize that specific nanopatterning strategies can markedly improve the electrochemical performance and durability of LFP-rGO systems, offering a new pathway for advanced cathode design. This exploration specifically focuses on the influence of disk/dome and ring structures patterned on cathode surfaces within structural battery composites (SBCs), aiming to bridge the current knowledge gap in this domain. Through systematic analysis of both fabrication processes and the resulting electrochemical behavior, the study demonstrates the potential of nanoscale engineering to significantly enhance battery performance [12, 13]. These efforts are supported by the adoption of innovative fabrication techniques, notably a precision spray-deposition method, which enables controlled pattern formation and offers refined balance between power output and specific capacity, thereby embodying a rigorous approach to electrochemical tuning and optimization for LFP-rGO cathodes [11, 14-26].

Our novel, scalable and sustainable processing-manufacturing technology, in which a combination of supercritical spray technique and tailorable materials chemistry (via engineering amphiphilicity) allows creation of 3D patterns on carbon fiber-based cathodes. These patterns are combined to create desired 3D nanostructures to achieve tailorable properties. To this end, the droplet size and amphiphilicity degree of the hybrid material system contained in droplets, i.e. lithium iron phosphate (LFP) and reduced graphene oxide (RGO), are engineered based on their mass ratio and then delivered onto the carbon fibers using supercritical spray. The droplet sizes are in the range of 5 μm, as the small microscale droplets allow for faster fabrication of cathode with higher surface area that incurs higher interface with the developed electrolyte. The combination of amphiphilicity and droplet size results in three distinctive post-evaporation patterns, i.e. ring, disk, and dome. Each pattern is meticulously designed to enhance a specific functionality or property. By strategically composing these patterns with precise shape, size, and spacing, we achieve the creation of 3D nanostructured surfaces that exhibit both high energy density and exceptional mechanical strength, qualities often deemed paradoxical and unattainable with conventional manufacturing methods. The outcomes of our study are emerging key materials and a novel high-throughput manufacturing technique required for accelerated development of the next-generation multifunctional structures for battery-powered and eco-friendly mobility.

2 MATERIALS AND METHODS

Reduced graphene oxide (rGO) used in this study was sourced from ACS Material and synthesized via the N_2H_2 chemical reduction method. It appeared brownish-grey, had a thickness of approximately 1 nm, and exhibited a monolayer diameter ranging from 0.5 to 10 μm with over 90% monolayer content. Its BET surface area was measured at ~180 m^2/g, and carbon content exceeded 82 wt.%, with electrical conductivity surpassing 500 S/m. Lithium iron phosphate (LFP) from Landt International Inc. featured a particle size median (D50) of 1.302 μm, a surface area of 13.36 m^2/g, and a density of 1.14 g/cm^3. Its discharge capacity was recorded at 153 mAh/g under 0.1C at 25 °C, highlighting its electrochemical effectiveness. To fabricate composite cathodes, rGO was strategically incorporated into LFP using spray-deposition at two mass ratios: 8:1 (LFP:rGO) to produce ring-like patterns and 1:1 for dome structures. The materials were dispersed at 1.5 wt.% in dimethylformamide (DMF) and subjected to a two-step sonication process. First, LFP was sonicated at 53% amplitude for 10 minutes. Then, rGO was added and the mixture underwent an additional 20-minute sonication. The dispersion was sprayed onto acetone-cleaned aluminum substrates (19 mm diameter), which were chosen to match the dimensions required for coin cell cathodes. Each spray round was performed at 20 MPa pressure, maintaining a 15 cm distance and a 45° nozzle angle to ensure uniform coating. Pauses between rounds allowed solvent evaporation, preventing droplet agglomeration. The active material deposited was approximately 4 mg for the 8:1 sample (2.68 mg/cm^2) and 4.4 mg for the 1:1 sample (2.95 mg/cm^2). Coin cells were assembled in an argon-filled glove box using the coated cathodes, $LiPF_6$ electrolyte, lithium metal anodes, separators, spacers, and crimped stainless steel casings. Surface morphology of the deposited patterns was evaluated using a Bruker DektakXT Surface Profiler, while microstructural analysis was conducted via a Tescan FERA-3 FIB microscope. Electrochemical characterization involved cyclic voltammetry and galvanostatic charge/discharge measurements (2.0–4.25 V) using a Gamry Interface 1010E potentiostat, with CV conducted at 0.1 mV/s for 10 cycles. Specific capacities were reported based on the total mass of the LFP/rGO electrodes. We also evaluated the adhesion strength of the active material to the substrate by measuring weight loss in the tape adhesion test. The test was conducted with a 200 g for the first eight cycles, followed by 1540 g and 6540 g for the second and third eight-cycle stages, respectively.

3 RESULTS AND DISCUSSION

3.1 Cathodes Morphology

The LFP/rGO dispersion was applied to aluminum substrates/current collectors using a precision spray-deposition method. Compositions with varying LFP to rGO weight ratios were prepared and labeled as LFP/rGO-(Y:Z), where 'Y:Z' denotes the respective mass ratios. A total of 25 spray passes were performed using a 1.5 wt.% solution to deposit each formulation.

Figure 1 presents scanning electron microscopy (SEM) images of the deposited LFP/rGO ring and disk/dome patterns. These images reveal that LFP nanoparticles are predominantly encapsulated by rGO sheets and interconnected with neighboring particles following the evaporation of DMF. Figure 1a illustrates a ring-shaped pattern formed by the droplet, while Figures 1B and 1C show the material distribution at the center and periphery of the same pattern. In contrast, Figures 1E and 1F show a disk/dome pattern, where the composite material is concentrated along the outer diameter of the droplet. Compared to the dome pattern, where material is centered, the ring pattern is characterized by an empty core with materials pushed to the perimeter. These distinct morphologies arise from variations in the LFP/rGO ratio used in the spray solution.

Figure 2 provides further morphological and elemental analysis using SEM and energy-dispersive spectroscopy (EDS). Figure 2a displays a SEM image of a dried droplet from an LFP/rGO-(8:1) mixture, revealing the expected ring pattern, characterized by concentrated Fe and P signals around the droplet perimeter, with a distinct void in the center. Figures 2B and 2C, showing iron (Fe) and phosphorus (P) EDS maps, confirm this ring shape distribution. In contrast, Figures 2D, 2E, and 2F examine a droplet from an LFP/rGO-(1:1) formulation. Here, the SEM and EDS maps illustrate a diskdome morphology, marked by high material density in the center and gradual thinning toward the edges

The use of a spray-deposition approach on aluminum current collectors enables the formation of well-defined microscale patterns, ranging from rings to disks and/or domes, on the substrate surface. These patterns are dictated by the composition and amphiphilic balance of the hybrid nanoparticle suspension. Our study shows that higher rGO content, such as in the LFP/rGO-(1:1) mixture, favors disk-shaped deposits, where the droplet dries to form a dense, raised center composed of overlapping rGO-LFP clusters. In contrast, lower rGO content (e.g., LFP/rGO-(8:1)) results in ring-like patterns due to differential solvent evaporation dynamics, pushing the particles outward.

3.2 Electrochemical and Mechanical Properties

The interface between the cathode and electrolyte plays a critical role in determining the electrochemical performance of lithium-ion batteries. As such, the ability to control the deposition pattern of active materials during fabrication offers a promising strategy to tailor cathode functionality. In this study, we investigated how distinct deposition patterns, namely disk and ring structures, influence the performance of LFP/rGO cathodes. Electrochemical characterization was performed using cyclic voltammetry (CV) at a scan rate of 0.1 mV/s, comparing patterned cathodes against a classic LFP formulation (LFP:PVP:Carbon Black at 93:2:5 wt.%) (Figure 4a). Both ring and disk-patterned cathodes displayed symmetrical redox peaks, indicative of good reversibility, though notable differences emerged. The disk-patterned electrodes showed sharper peaks and higher current responses than their ring counterparts, suggesting enhanced reaction kinetics and improved charge transfer efficiency. This was further supported by a smaller voltage separation between oxidation and reduction peaks, pointing to reduced polarization. While the ring pattern exhibited broader peaks and slightly lower peak currents (~80–85% of disk), its more gradual charge transfer dynamics may be advantageous under high-rate cycling, reducing parasitic losses and extending durability.

Electrochemical impedance spectroscopy (EIS) provided further insights into charge transfer behavior (Figure 4b). The charge transfer resistance (R_{ct}) of the classic LFP cathode was significantly higher (~380 Ω) compared to both patterned variants, 220 Ω for ring and 150 Ω for disk/dome, highlighting the improved conductivity introduced by rGO. When normalized to the weight of active materials, the disk/dome-patterned cathode delivered the highest specific power and energy output, approximately 486 W/kg and 44.12 kWh/kg, while the ring-patterned version followed closely with about 10% lower values. The classic LFP cathode, by contrast, exhibited significantly lower performance in all metrics (Figure 4C).

Mechanical integrity was assessed using adhesion testing (Figure 4D), which monitored residual weight loss over multiple tape-peeling iterations. Among the three designs, the ring-patterned cathode demonstrated the slowest rate of material removal, as evidenced by the smallest slope magnitude (-2.41×10^{-4} g/iteration), indicating superior adhesion. In contrast, the classic LFP cathode exhibited the fastest material loss (-8.05×10^{-4} g/iteration), suggesting weaker cohesion. This enhanced adhesion in the ring pattern is attributed to its more compact microstructure and reduced rGO content, which minimizes lubrication effects between LFP particles. Additionally, the ring geometry, with a taller and thinner outer wall, offers a larger interfacial area and improved mechanical interlocking with the electrolyte layer, further contributing to its robust adhesion performance.

Mechanical integrity was assessed using adhesion testing (Figure 4D). Interestingly, the ring-patterned cathode exhibited approximately 25% higher tangential friction force compared to the disk/dome, indicating stronger cohesion and greater resistance to delamination. This is attributed to the lower rGO content in the ring structure, as rGO tends to act as a lubricant between LFP particles. The enhanced compactness of the ring configuration results in a more mechanically robust microstructure. Tape-adhesion tests and triboindenter results corroborated these findings. Notably, the ring pattern, characterized by a thin outer wall with an average height three times greater than that of the disk/dome structure, offers a larger interfacial area and improved mechanical interlocking with the electrolyte layer.

In summary, while disk/dome-patterned cathodes deliver superior electrochemical performance in terms of peak current, specific capacity, and output power, the ring-patterned design excels in structural robustness and interfacial stability. These complementary traits suggest that combining ring and disk/dome patterns through a controlled spray-deposition process could yield a hybrid cathode architecture optimized for both performance and durability. This hybrid approach offers greater design flexibility than traditional slurry casting, enabling tailored electrode architectures for next-generation structural battery composites.

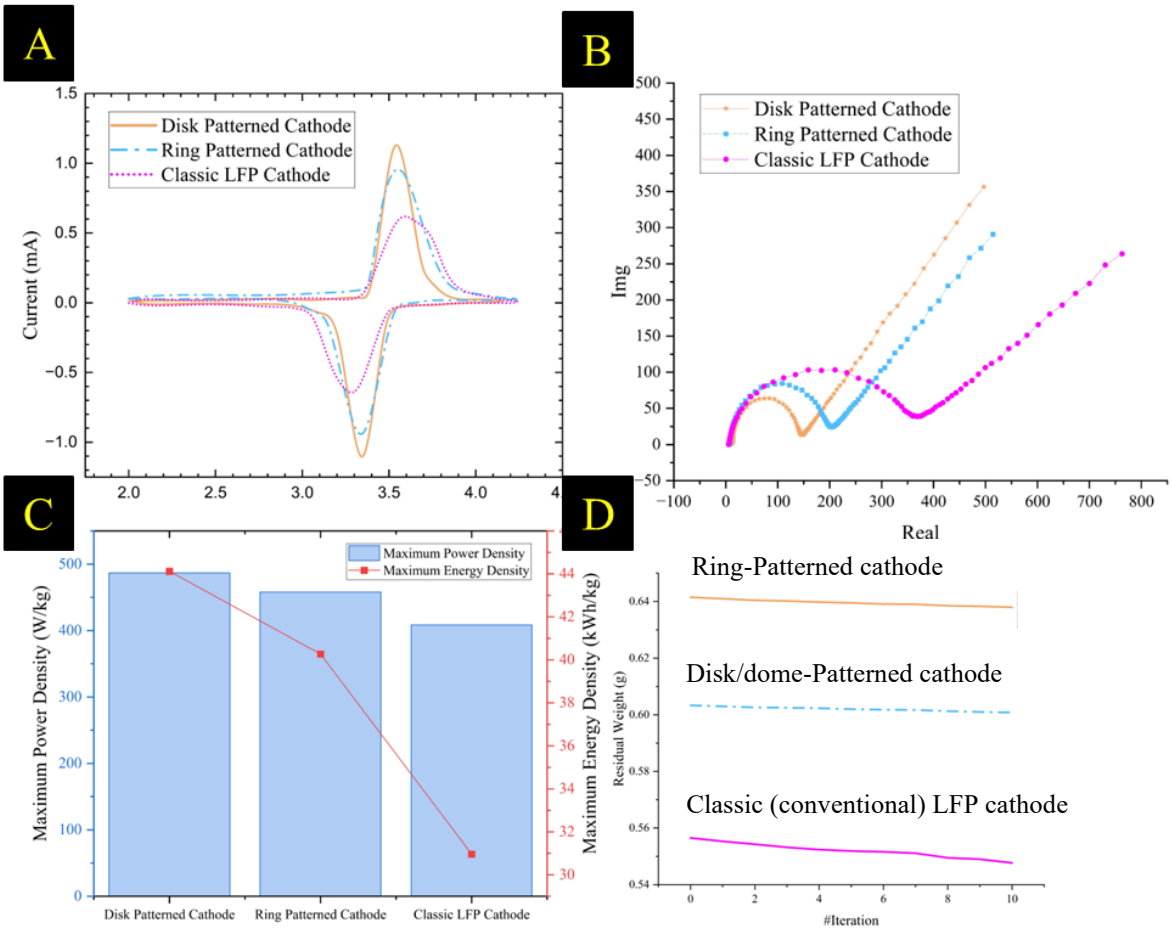

Figure 4. Electrochemical performance comparison of LFP:rGO cathodes with disk/dome and ring patterns: A) Cyclic voltammetry, B) Nyquist plot, C) Maximum power density and Energy density, and D) Adhesion mechanical test.

CONCLUSIONS

This study demonstrates that nanoscale surface patterning of active materials on cathodes, achieved through precision spray deposition, offers a powerful strategy to tailor the electrochemical and mechanical performance of lithium-ion batteries. By systematically varying the weight ratio of LFP to rGO in the spray dispersion, we produced distinct surface morphologies, disk/dome and ring patterns, that led to measurable differences in battery behavior. Electrochemical tests revealed that disk/dome-patterned cathodes deliver superior energy densities, indicating enhanced conductivity and faster charge transfer. In contrast, ring-patterned cathodes exhibit improved mechanical integrity and greater cohesion at the electrode–electrolyte interface, owing to their toroidal geometry and more compact structure.

These results highlight the trade-offs and synergies inherent in cathode design: while disk/dome patterns optimize electrochemical output, ring patterns contribute to structural durability and interfacial stability. The ability to precisely control and combine these patterns on the electrode surface introduces a novel degree of freedom in cathode engineering, offering the potential to pre-design multifunctional electrodes that achieve an optimal balance between performance and longevity. This pattern-directed strategy significantly advances the conventional two-dimensional slurry-based fabrication methods and opens new avenues for customizable, high-performance structural battery composites.

ACKNOWLEDGEMENTS

This material is based upon work supported by the National Science Foundation, Civil, Mechanical and Manufacturing Innovation (CMMI), Advanced Manufacturing, under Grants #2143286, and #2134465. The authors would like to acknowledge that the characterization part of this work was conducted at Texas A&M University Materials Characterization Core Facility, and the calculations regarding the simulation segment was performed at Supercomputer resources from Texas A&M University High Performance Computer Center (HPRC). The authors thank Dr. Liang, Humaun Kabir, and Darius Dias for their contributions to the tribology experiments.

ABSTRACT

Various characterization and certification processes are required for the use of carbon fibre reinforced plastics (CFRP) in the aerospace industry. This applies in particular if the material is in contact with reactive liquids. However, this poses a number of challenges, as the liquid oxygen used as an oxidizer, for example, can undergo a thermal reaction with the organic substances in the CFRP [**1**]. This highly exothermic reaction leads to a catastrophic failure of the entire launch vehicle. For this reason, it is essential to determine the compatibility of the tank materials used for the storage of liquid oxygen [**2**]. Several compatibility tests carried out at *University of the Bundeswehr Munich* have shown that the results obtained are sometimes subject to extreme fluctuations, which can lead to inconsistent statements about material compatibility. The influencing variables that affect the reaction process are partly unknown and are not taken into account in the standard. Based on the known problem, a newly developed test rig was set up at the *University of the Bundeswehr Munich*. The influence of the use of peel ply on the compatibility results was explicitly investigated. As a result of the stripping process, rough ridges and irregularities remain on the surface. The roughness of the component surface, caused by cavities, indentations, and surface irregularities, along with local dry spots, leads to increased reactivity of the sample in a liquid oxygen environment. As part of a series of tests to determine the influencing variables on the reaction process of carbon fibre-reinforced plastics in liquid oxygen, it was demonstrated on the test bench at the *University of the Bundeswehr Munich* that the chemical reactivity of the samples increases when using peel ply.

1 INTRODUCTION

The majority of reusable launch vehicles currently in use and those planned for the future are designed for operation with liquid propellants, using liquid oxygen (LOX) as the oxidizing agent. The state of the art to date comprises metallic tank structures that are used in current generations of launch vehicles. These structures account for over 60 % of the dry mass of a launch vehicle [**3**]. To increase the payload capacity, it is essential to reduce the dry mass. By using carbon fiber reinforced plastics (CFRP), weight savings of up to 40 % could be achieved [**3**].

However, the compatibility of CFRP materials with the LOX oxidizing agent used is a critical factor. A material is considered compatible if it does not react with LOX or potential ignition sources under the expected pressure and temperature conditions [**4**]. The avoidance of ignition events is therefore essential for the selection of suitable materials for LOX contact applications. Ignition can occur if a sufficiently high amount of energy is applied locally to the surface exposed to the LOX like shown in Figure 1 for a CFRP test Sample.

Figure 1 Exemplary reaction of a CFRP sample in liquid oxygen, in which an impact pulse of 98 J is transmitted into the sample via a Striker Pin and recorded at 240 FPS using a slow-motion camera

The compatibility of a material for use under cryogenic LOX conditions is assessed using standardized test methods. The relevant test standards include ASTM G86-17 [**5**], ASTM D2512-95 [**6**] and ISO 21010 [**7**]. Common to all methods is the transfer of kinetic energy into the material sample, which leads to an exothermic reaction with LOX in the event of incompatibility. According to ASTM G86, a material is considered compatible if no reaction occurs after 20 tests or at most one reaction after 60 tests.

A comparison of the test results according to different standards shows some considerable deviations in the assessment of LOX compatibility. The reasons for this have not yet been conclusively clarified. Although the oxidation and ignition mechanism itself is well described [4], there is a lack of reliable explanations for the random nature of the reactions and the deviations between the standards. A deeper understanding of these mechanisms is required to ensure reproducible and reliable test results for future material certifications.

The need for research therefore lies in the investigation of the reaction mechanisms of CFRP materials in contact with LOX and the identification of relevant influencing variables - particularly with regard to test stand design, sample preparation and surface properties. Experimental investigations were carried out at the *University of the Bundeswehr Munich* to analyze the influence of the sample surface on the reaction behavior. The surface topography was specifically varied by using different peel ply fabrics during laminate production. The aim is not only to determine the general influence of the surface roughness on the reaction behavior, but also to identify the causes of increased reactions.

2 STATE OF THE ART

Liquid-propellant rocket engines are widely used in modern spaceflight. With the emergence of the "New Space" movement and the development of new European launch vehicles (e.g., *Ariane 6*, *HyImpulse*, *Rocketfactory Augsburg*, *Isar Aerospace*), the demand for improved cryogenic tank systems has significantly increased. To reduce structural weight and maximize payload capacity, advanced lightweight composite materials are being integrated into launch vehicle architectures—both for primary and secondary propellant tanks. These tank structures can account for up to 60% of a launch vehicle's dry mass [3].

Future launch systems require a high propellant mass fraction to ensure performance and cost-efficiency. Due to their high strength-to-weight ratio, fiber-reinforced polymers (FRPs) are well-suited for achieving these objectives. Liquid oxygen (LOX), serving as the oxidizer in most modern vehicles such as *Ariane 6* and *Falcon 9*, is a key driver in material selection for cryogenic tanks. While CFRP-based LOX tanks offer considerable weight savings, their use introduces challenges due to potential chemical reactivity with LOX. For a material to be considered LOX-compatible, it must withstand all forms of combustible or hazardous reactions under operating conditions [10].

Material compatibility is typically assessed through a set of standardized test methods, including:

- ASTM D2512: Standard Test Method for Compatibility of Materials with Liquid Oxygen [6]
- ASTM G86-17: Determination of Mechanical Impact Sensitivity in LOX and Pressurized Oxygen Environments [5]
- ISO 21010: Compatibility of Gases and Materials in Cryogenic Containers [7]
- NASA-STD-6001: Material Flammability, Offgassing, Odor, and Compatibility Requirements [8]

At the *University of the Bundeswehr Munich*, investigations focused specifically on the influence of surface topography on reaction behavior. Prior research by *Gerzeski* [4] demonstrated that mechanical impact alone is not the sole ignition driver; surface-induced friction plays a significant role. *Gerzeski* proposed a probabilistic model combining Hertzian fracture theory and kinetic friction mechanisms to describe the transition from mechanical failure to heat generation. His findings suggest that surface irregularities, such as those introduced by peel ply usage, can result in local frictional heating, increasing the likelihood of ignition. This mechanism aligns with the so-called “hot spot” theory, widely cited in the literature as the primary cause of polymer reactivity in LOX environments. *Hongyu* et al. [9] reported that localized energy input from friction or impact can decompose polymer chains, releasing reactive hydrogen and hydroxide ions that violently react with LOX, leading to ignition or explosion. Similarly, *Li* et al. [3] describe thermal decomposition of the epoxy matrix as the key trigger for LOX reactivity, again emphasizing the role of temperature-induced hot spots.

Currie et. al [11], the addition of silicon carbide was shown to significantly increase reaction sensitivity in impact LOX tests. Its abrasive nature promotes local heating at the material surface, intensifying both reaction frequency and severity.

Similar investigations were conducted by *Duo* et al. [12], who provided a detailed analysis of the energy transfer process between the striker pin and the specimen surface. Their findings indicate that a significant portion of the mechanical impact energy is converted into heat, with localized temperature increases of several hundred degrees Celsius observed. The quality of the contact interface between the striker and the specimen, as well as the precise impact location, were identified as key factors influencing the test outcomes. According to *Duo* et al. [12], approximately 25% of the kinetic energy is dissipated through friction, while the remainder is transformed into internal energy. This frictional heating can raise local temperatures beyond the decomposition threshold of the epoxy matrix. As a result, highly reactive hydroxyl radicals are generated, which subsequently react with the surrounding liquid oxygen, potentially triggering an exothermic event.

The current study aims to investigate the formation of surface hot spots on CFRP specimens, focusing on resin-rich microstructures caused by different peel ply treatments during laminate fabrication.

3 STANDARDIZED TESTING METHODOLOGY AND EXPERIMENTAL SETUP

As part of the conducted experimental series to determine the influencing factors of auxiliary materials on the reaction behavior of CFRP specimens in liquid oxygen under impact loading, tests were carried out according to ASTM G86-17. The standardized procedure involves dropping a defined mass from a specified height onto a striker pin positioned directly on the specimen. The goal is to apply an impact energy of 98 J to the sample, derived from a 9.1 kg drop mass released from a height of 1.1 m. During the test, the specimen is placed in a test cup filled with liquid oxygen. Material incompatibility with LOX is identified based on the following observable criteria [5]:

1. Audible explosion
2. Flash (visually or electronically detected)
3. Signs of combustion, such as visible charring
4. Significant discoloration due to ignition
5. Measurable increases in temperature or pressure during testing

According to ASTM G86, a material is considered compatible if none of these reactions occur in 20 tests or if no more than one reaction is observed in 60 tests. The test specimens used are circular CFRP flat samples with a diameter of 17.5 mm and a thickness of approximately 2 mm. The ASTM G86 [5]

standard also requires the test setup to be kept as clean and contaminant-free as possible. Accordingly, the testing at the *University of the Bundeswehr Munich* is performed, exceeding standard requirements, in a cleanroom environment. The test cup, striker pin, and CFRP samples are thoroughly cleaned prior to each run. During testing, the fall time is measured to verify compliance with the expected energy input. The measured fall time must not deviate by more than ±3% from the calculated target.

In the context of this scientific investigation, the focus was not on a standard qualification test of the material but rather on identifying the influence of the peel ply treatment on the reaction behavior. For this reason, deviations from the standard procedure, specifically in terms of impact energy and number of trials, were intentionally introduced. These modifications are explained in greater detail in **Chapter 4**.

The LOX impact test facility developed at the *University of the Bundeswehr Munich* is illustrated in the following figure.

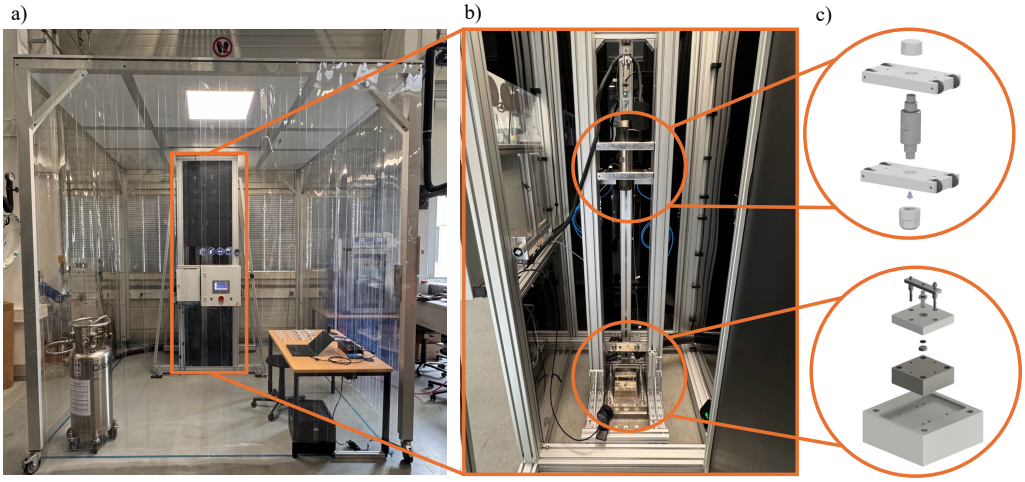

Figure 2 Test facility at the *University of the Bundeswehr Munich* for determining the LOX compatibility of CFRP specimens. a) External view of the test setup inside the cleanroom. b) Close-up of the test device where the drop weight impacts the striker. c) Technical illustration of the individual components of the test rig, consisting of the drop weight and the test chamber containing the specimen immersed in liquid oxygen

To ensure cleanliness during testing and minimize external influences on the experimental procedure, the test bench is located in a cleanroom certified according to ISO 14644 providing an air quality rating of ISO 8.The test facility at the *University of the Bundeswehr Munich* features a modular design that enables LOX compatibility testing across various energy levels. Both the drop height and the drop mass can be flexibly adjusted. Advanced sensor technology allows not only visual and acoustic monitoring of the test but also extended analytical evaluation of the reaction behavior. A fully automated pneumatic adjustment unit enables single-operator testing. Key parameters such as drop mass, fall time, and rebound height are displayed and logged via the integrated HMI system.

The test bench is enclosed in a completely darkened housing, which allows detection of even the smallest reaction events on the specimen. In addition, protective side panels shield the operator from any fragments ejected during specimen failure. To enhance safety and maintain cleanliness within the test chamber, a specialized CFPR vacuum extraction system is employed. This unit removes combustion gases and airborne debris, thereby minimizing contamination and maintaining optimal testing conditions.

4 PREPARATION OF TEST SPECIMENS AND SETUP OF LOX IMPACT TESTING

As part of the experimental campaign to investigate influencing factors on the reaction behavior of CFRP specimens under impact loading in liquid oxygen, a total of five laminate panels were manufactured. Each panel yielded 80 circular test specimens. The only variable among the panels was the type of auxiliary material (peel ply) used during fabrication. All specimens were cured

simultaneously in the same autoclave cycle.

It is well documented in the literature that surface condition can significantly influence test outcomes, as it affects frictional behavior during mechanical loading. Increased friction leads to localized temperature rises, resulting in so-called “hot spots” that promote the thermal decomposition of the epoxy matrix and may trigger a chain reaction with liquid oxygen. However, it remains unclear whether a generally rough surface is sufficient to increase reactivity, or whether the degree of surface roughness also plays a measurable role. A further question is whether surface features introduced by peel ply treatments alter the contact area between the striker and the specimen, thereby affecting the energy transmitted per unit area.

4.1 Fabrication of CFRP Test Samples

To investigate this, specimens with different frictional characteristics were prepared while all other material and process variables remained constant. The aim of the study is to evaluate the influence of surface roughness generated by different peel ply materials on the reactivity of CFRP samples. The results are compared to a reference specimen, referred to as the base plate (GP), produced without peel ply and featuring a smooth surface. **Table 1** lists the fabricated plates together with their designations, the achieved surface-roughness values, and the measured fiber volume content (FVC).

Specimen ID	Peel-Plie	FVC [%]	Ra [µm]	Rz [µm]
GP	none	66,69	0,28	1,95
AB68L-1	Peel ply 68 gsm	65,67	8,91	56,76
AB90L-2	Peel ply 90 gsm	66,97	12,80	78,57
AB100K-4	Peel ply 100 gsm	66,42	9,59	63,9
BLB- 5	Bleeder Lease	68,67	9,0	56,89

Table 1 Overview of the fabricated plates, including their designations, achieved surface roughness values, and measured fiber volume content (FVC).

For this test, all panels were made from Hexply 8552 prepreg with a symmetric 0/90 Orientation. In total 16 Layers were used to obtain a plate thickness of approximately 2 mm. During the laying process, an intermediate vacuum was drawn every 5 layers to achieve the best possible quality. To determine the surface roughness a 3D laser scanning microscope was used. The fiber volume fraction of the CFRP specimens was determined by a loss-on-ignition analysis, in which the polymer matrix was completely removed by pyrolytic burn-off in a muffle furnace.

Figure 3 shows the surface of the fabricated specimens, which differ only in the peel ply used.

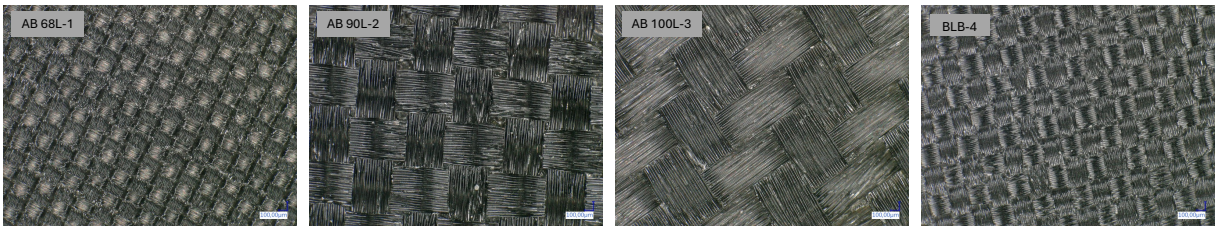

Figure 3 comparison of the surface structures of the manufactured test specimens. The texture of the respective peel ply is transferred to the specimen surface upon its removal. The pictures were taken with a digital microscope VH-ZST from Keyence with a dual zoom lens. All images were taken with the ZS 20 lens at a magnification of 100

The analysis of the surface topographies recorded after removal of the peel ply reveals pronounced differences between the specimens. Firstly, peel plies with different weave architectures were used,

resulting in variations in the spacing between warp and weft yarns. Secondly, the number of binding points per unit area differs among the samples. A detailed examination of the surfaces and their correlation with the LOX results is presented in **Chapter 5**. **Table 2** summarizes the auxiliary materials employed and their relevant properties.

Peel Ply [g/m^2]	Weave pattern	Fineness [dtex]	Material	Properties
Peel-Plie 68 g/qm	plain weave	Warp yarns 44 Weft yarns 78	PA 6.6	Finely textured, rough surface
Peel-Plie 90 g/qm	plain weave	Warp & weft 235	PA 6.6	Finely textured, rough surface
Peel-Plie 100 g/qm	2/2 twill	Warp & weft 235	PA 6.6	Finely textured, rough surface
Bleeder Lease B 62 g/qm	plain weave	-	Nylon	Coated with silicone release,

Table 2 Summary of the release fabrics used for the tests to determine the influencing factors on the reaction process under impact loading in a liquid oxygen environment

4.2 Surface Characterization:

To quantify surface roughness, selected specimens were analyzed using a confocal 3D laser scanning microscope (Keyence VK-X series). These measurements provided both qualitative surface images and quantitative roughness data. An example result is shown in **Figure 4**.

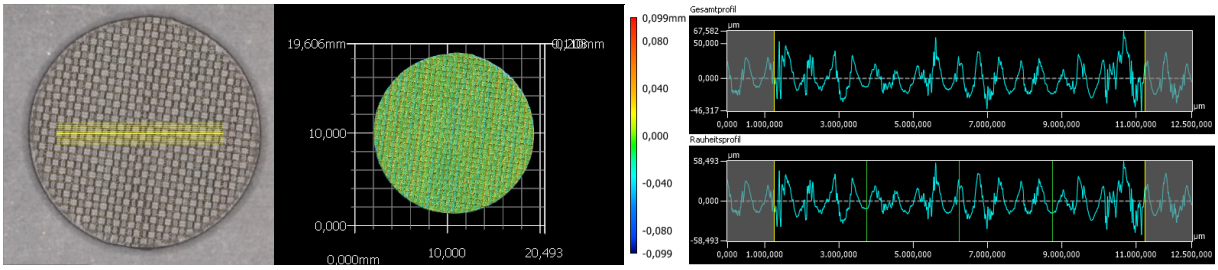

Figure 4 Representation of the analysis of a specimen labeled AB90L-2. Both the raw image of the specimen and the recorded depth profile are shown. The surface roughness was measured along the yellow marking on the specimen. The analysis of the overall profile on the right side of the figure shows the height differences on the surface of the profile.

In addition to roughness values, the contact area between the striker and the specimen must also be assessed to evaluate the relationship between peel ply surface and material reactivity: The results of these investigations are summarized in **Chapter 5**.

In addition to the characterization of surface roughness parameters, further investigations were carried out regarding the peak density (***Spd***), reduced peak height (***Spk***), and peak material volume (***vpm***). An evaluation of these parameters is presented in **Figure 5.**

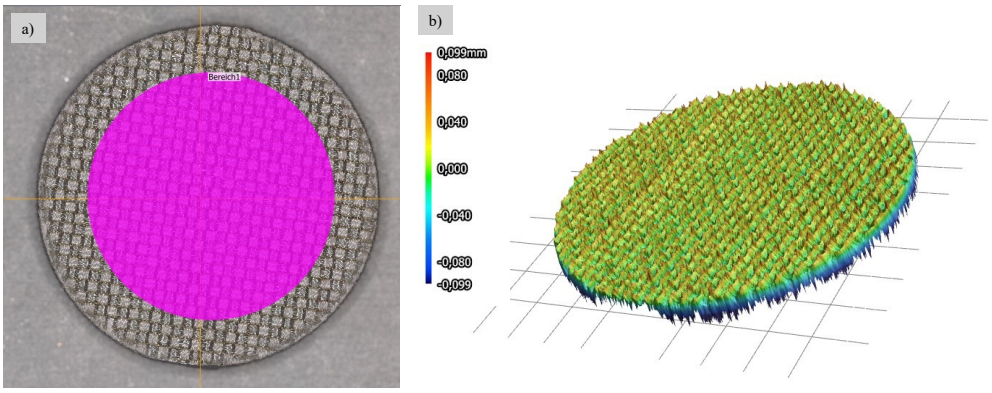

Figure 5 Analysis of the sample surface with respect to the number of peaks, peak height, and peak material volume. The peaks, consisting of matrix material, are formed by the weave structure of the peel ply and appear on the surface after the removal of the release fabric. This could affect the reactivity of the material regarding the LOX-compatiblity

The Spd (peak density) parameter describes the number of surface summits per unit area. A higher Spd value indicates a greater number of potential contact points with interacting surfaces, which can be relevant for tribological performance or adhesion behavior. The Spk (reduced peak height) parameter refers to the average height of the surface peaks above the core material surface and provides information about the prominence of surface asperities. In contrast, the Vpm (peak material volume) parameter quantifies the material volume present at a specified bearing area of p %. Beyond this, Vpm is also used to derive volumetric characteristics of the surface, including the size of the core area, the volume of reduced peaks, and the volume of reduced valleys, thereby contributing to a more detailed assessment of the functional surface profile.

To determine a significant influence between the generated rough surface and the reaction behaviour in liquid oxygen, additional parameters beyond the roughness values must be evaluated. Particular attention must be paid to the area on which the striker rests prior to impact. Reducing this contact area increases the energy input per unit area under otherwise identical conditions. Consequently, more energy is transferred into the specimen as the resin-rich peaks are indented. The causal relationship is discussed in greater detail in Chapter 5.

4.3 Test procedure

After waterjet cutting, the specimens were cleaned with isopropanol and placed in a desiccator for 48 hours. Subsequently, they were conditioned for an additional 72 hours in a controlled climate chamber to eliminate any environmental influences, particularly humidity, that could affect reactivity.

Prior to each test series, the entire test chamber and surrounding area are thoroughly cleaned. Test cups and striker pins are cleaned in an ultrasonic bath after every ten tests. Before reuse, striker pins are also cleaned with isopropanol and degassed in an oven. After cooling, they are ready for operation.

To prepare for testing, the striker pins and specimen cups are precooled in a liquid nitrogen bath. The specimens themselves are cooled in liquid oxygen immediately before testing. Once all test components have reached the required temperature, they are placed into the test chamber, which is then filled with liquid oxygen.

To determine the influencing factors on the reaction process, various energy levels must be tested, deviating from the standard procedure. The aim is to identify an energy level at which approximately 50% of the samples react. This allows for the detection of significant external changes in reactivity. In the context of this test series, the following energy levels were examined.

Energieniveu [J]	Eingestellte Fallhöhe [m]
22,3	0,250
30	0,336
40	0,448
56,3	0,631

Table 3 Overview of the investigated energy levels used in the experimental study. The energy level is derived from a 9.1 kg drop weight with varying drop heights.

For each energy level, ten samples from a single sample plate were tested. In addition to the reaction itself, the intensity of the reaction is also recorded.

5 EXPERIMENTAL RESULTS AND DISCUSSION

During the experiments, it was observed that, in addition to the number of reactions, differences in their intensity could also be identified. These variations influence, among other factors, the damage pattern of the specimen and the resulting chain reaction. The following figure illustrates the differences between various reactions and their respective intensities

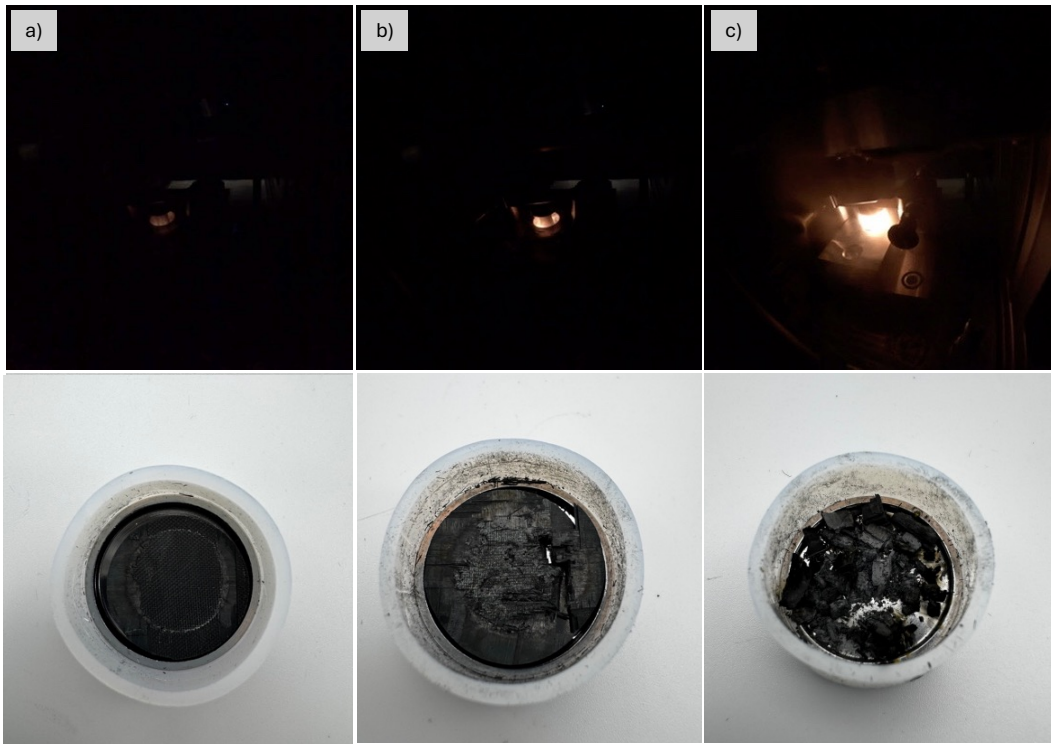

Figure 6 Comparison of reaction intensity based on the light emission and the damage pattern of the specimen. For this purpose, three different specimens were examined under identical energy conditions of 56,3 Joule: a) AB68-L reaction of very low intensity b) AB100-L low intensity reaction c) AB90-L High intensity reaction

The recorded damage pattern not only quantifies the number of reactions but also provides insight into their intensity, allowing a more differentiated assessment of the various peel-ply fabrics. Figure 6 clearly demonstrates that different peel plies, and the resultant surface characteristics, significantly influence reaction intensity. At an impact energy of 56.3 J, specimens prepared with the finest peel ply exhibited the lowest reaction intensity.

This finding must now be correlated with the number of reactions observed at the respective energy levels and with the measured surface properties of the individual specimen series. **Table 4** summarises all detected reactions across the tested energy levels together with the corresponding surface parameters of each series.

Sample	FVC [%]	Ra [µm]	Rz [µm]	Spd [1/mm²]	spk	vmp	Number of reactions for different Energy levels			
							22 [J]	30 [J]	40 [J]	56 [J]
AB68L-1	65,67	8,91	56,76	489,28	11,91	0,59	0	0	2	7
AB90L-2	66,97	12,8	78,57	448,52	22,71	1,1	1	2	9	10
AB100K-4	66,42	9,59	63,9	592,48	18,61	0,85	0	1	7	8
BLB-5	68,67	9	56,89	503,85	12,95	0,65	0	2	6	9
GP-8	66,69	0,28	1,95	-	-	-	0	0	0	0

Table 4 Representation of the identified reactions across various energy levels. In addition, the characteristic surface properties of each tested specimen plate are summarised. The table also includes the determined FVC values.

The experimental evaluation revealed that untreated base plates without peel ply produced the best results: no reaction was detected at any of the investigated energy levels. In contrast, the use of peel ply drastically altered the reaction behaviour, and all coated panels exhibited substantially more reactions. Among the peel plies tested, both the number and the intensity of reactions varied.

The 68 gsm peel ply yielded the most favourable results, with markedly lower reaction intensity. Surface roughness parameters as well as the reduced peak height and peak material volume recorded the lowest values. Although the number of surface asperities is lower than for the 100 gsm peel ply or the very fine Bleeder Lees fabric, which implies a higher induced energy per unit area, the considerably flatter asperities mean that less material must be compressed and destroyed before the striker contacts the remaining surface. Consequently, no significant difference between the BLB-5 and AB68-L specimens was observed, as their characteristic surface features differ only marginally.

The reaction behaviour of specimens with the AB100-K peel ply is particularly noteworthy. Despite a much higher asperity density compared with the other specimens, no significant difference in the number of reactions relative to BLB-5 was detected. Nevertheless, the AB100-K samples reacted far more intensely. This may be attributed to the taller asperities remaining on the surface, which permit a greater exothermic conversion of reactive material. This effect is also evident in the striker damage pattern depicted in **Figure 7**.

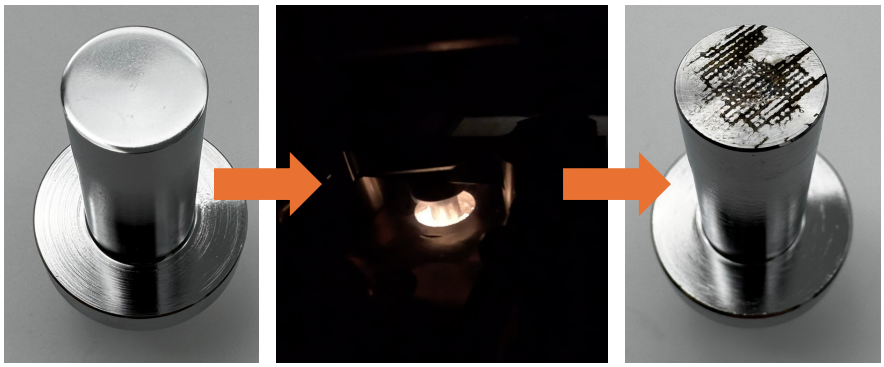

Figure 7 Surface alteration of the striker pin after an impact test at 56.3 joules for specimen material AB100-K. The specimen surface was imprinted onto the pin due to the impact. Areas of the striker that reacted with the liquid oxygen are clearly visible.

Although no substantial increase in the number of reactions was detected compared with the BLB experiments, the reaction intensity was markedly higher. As illustrated in **Figure 7**, this is reflected in the residual surface of the striker pin, onto which the specimen's surface profile is imprinted. Particular attention must be paid to the combustion pattern on the pin. While a uniformly distributed circular

reaction pattern is typically observed, the present results clearly indicate that the material reacted primarily along the protruding volumetric features of the specimen surface. Hence, the height of the residual asperities and thus the surface relief, constitutes a decisive factor, a conclusion that likewise applies to the AB90-L series.

The reaction behaviour of the AB90-L specimens is even more pronounced. Both the number and the intensity of reactions exceed those of all other series. Notably, AB90-L was the only plate to react at an impact energy of 22.3 J. This specimen exhibits the highest surface roughness and the lowest asperity density, resulting in the greatest induced energy per unit area. In addition, both asperity height and volume are maximised relative to the other specimens, so that a larger amount of reactive matrix material first comes into contact with the striker-pin during impact. This configuration accounts for the considerably stronger reactions observed. Sufficient material is present in the form of raised regions that are compressed and destroyed by the rapid impulse, thereby generating hot-spot zones that initiate and amplify exothermic reactions.

Furthermore, friction must be considered. *Gerzeski* [4] demonstrated that, despite a central impact and a fixed striker, relative movement of the pin is possible. The characteristically rough surfaces of the specimens augment such frictional effects, thereby promoting additional reaction events.

6 SUMMARY AND FUTURE WORK

The experiments conducted to determine the influence of surface characteristics generated by different peel-ply fabrics have clearly shown that increased surface roughness significantly affects compatibility performance. Compared with a smooth reference surface of the same material, a marked rise in both reaction frequency and reaction intensity was observed. The key findings are summarised in the diagram below.

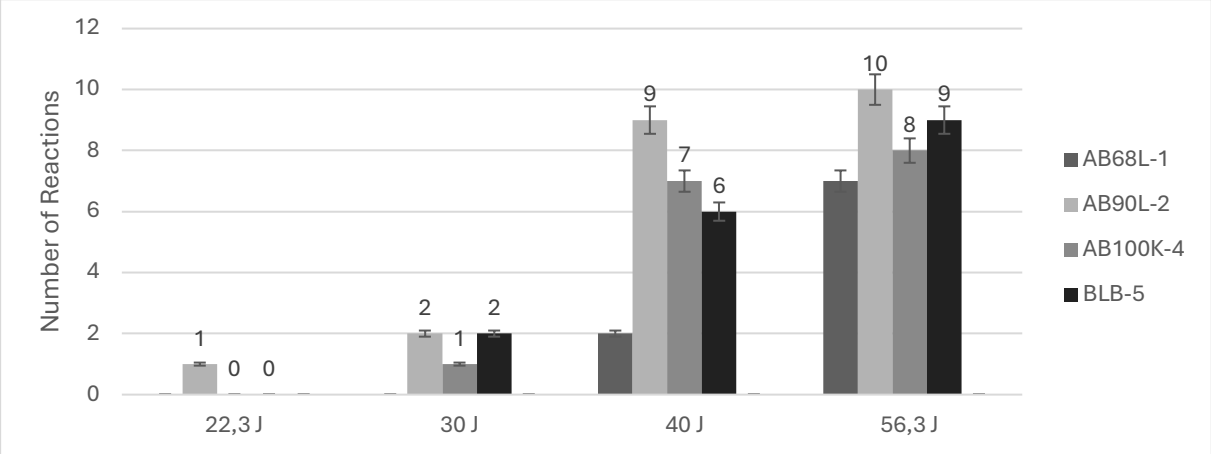

Figure 8 Comparison of compatibility results for various test specimens differing in the applied peel-ply material and, consequently, in their characteristic surface roughness properties. The results were benchmarked against the untreated base plate without peel ply, which exhibited no reaction at any of the tested energy levels. a 5% deviation of the results was assumed, which is shown in the bar chart

The results demonstrate that not only the contrast between a smooth base plate and a peel-ply surface is relevant but the specific choice of peel ply itself also exerts a decisive influence. As asperity height and the associated volume of the residual surface protrusions increase, reaction intensity rises. Variations in surface-roughness parameters and in the characteristic asperity features, such as asperity density, height, and volume, clearly deteriorated compatibility, as evidenced by the early response of specimen AB90-L at 22.3 J.

These findings underline that the surface quality of test specimens is of critical importance. The surface configuration ultimately present in the finished component can significantly affect certification with respect to liquid-oxygen (LOX) compatibility. It is therefore essential to specify precisely whether a peel-ply surface is required and, if its use cannot be avoided, to what extent subsequent surface

finishing is feasible.

Future work should focus on a detailed characterisation of the residual surface features resulting from the peel ply. Further experimental work should include specimens with post-processed surfaces to assess how surface reworking affects compatibility results compared to both the original test series and the untreated base plate. In addition, a substantial increase in the number of specimens per experimental series is recommended to enhance statistical significance.

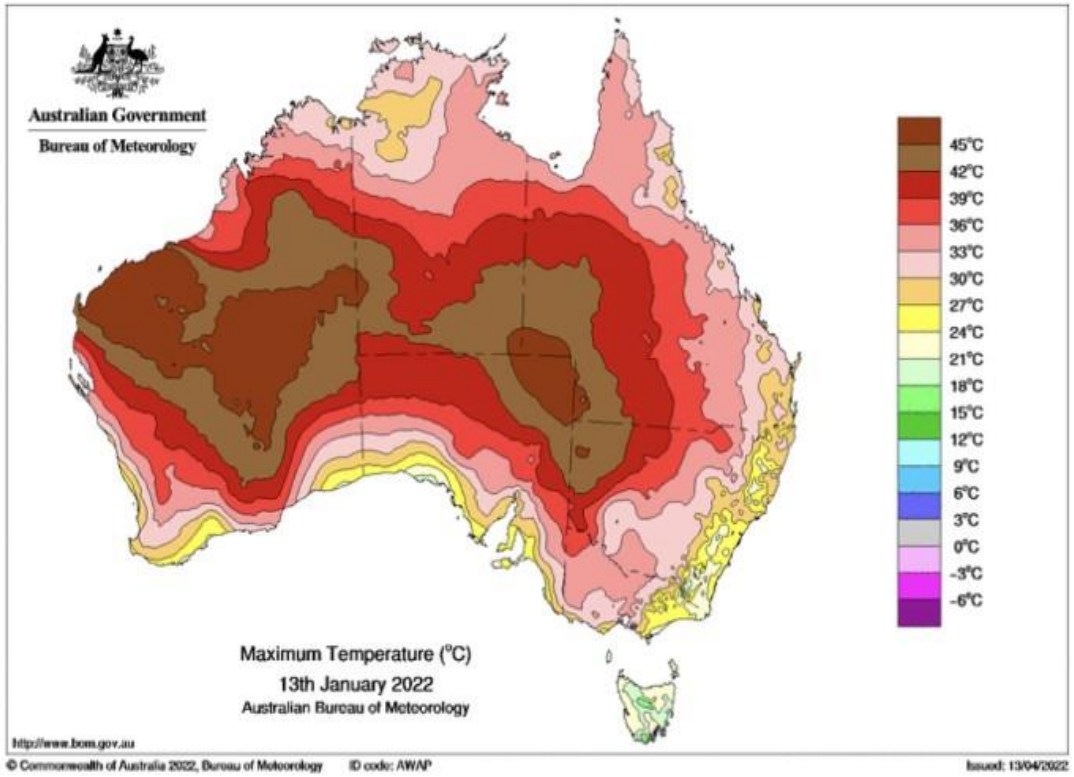
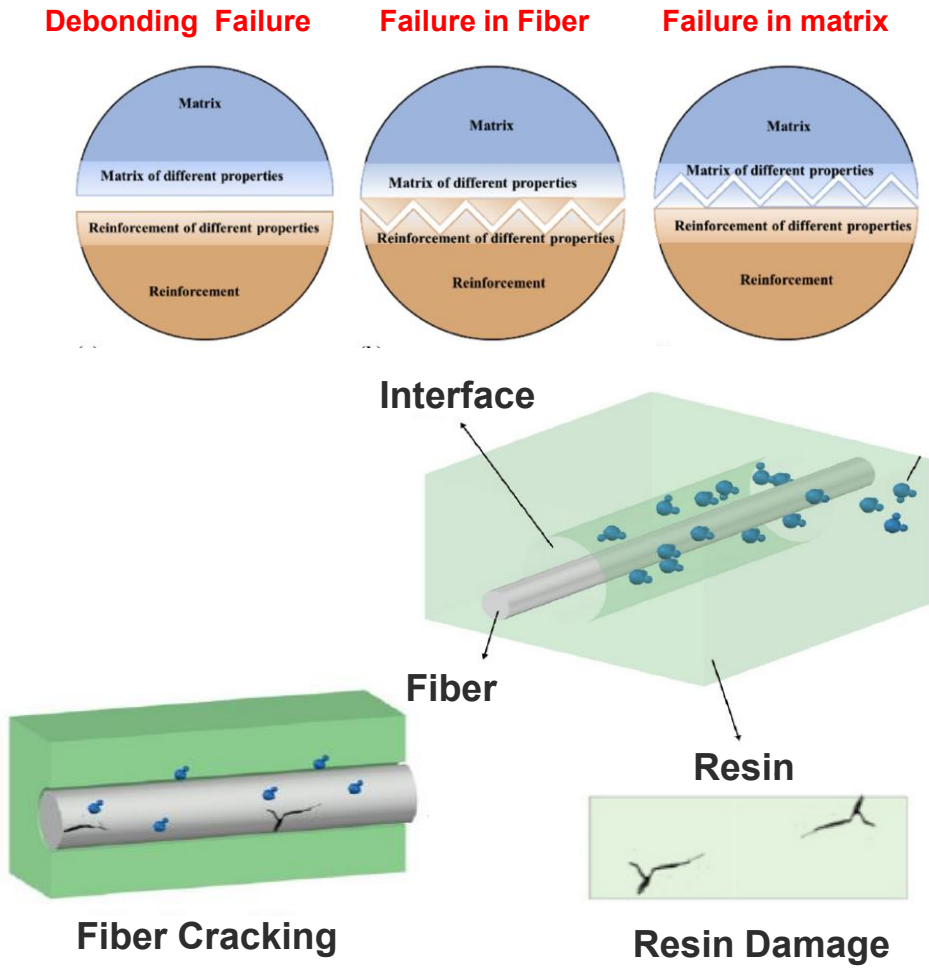
Introduction

- The global use of FRP composites in civil engineering and construction is rapidly rising because of:
  - Corrosion resistance
  - High strength-to-weight ratio
  - High stiffness-to-weight ratio



FRP Market Share by Application



https://doi.org/10.3390/fib10030027
https://doi.org/10.1016/j.compositesb.2022.110463

Introduction

- Exposure to different Environments
  - High Temperature
  - High Humidity

- Degradation in FRP composites can be due to either:
  - Resin Degradation
  - Fiber breakage
  - Interphase damage

Conclusions

- After 3000 hours of exposure, the glass transition temperature (Tg) of the epoxy resin showed an increase of up to 26%, likely as a result of enhanced cross-linking within the polymer chains.
- FTIR analysis indicated chemical degradation of the epoxy network through hydrolysis mechanisms, evidenced by the formation of additional hydroxyl groups.
- The tensile strength of both fibre yarns and resin was notably reduced following exposure, primarily due to degradation of the sizing layer on the fibres and the combined effects of plasticization and hydrolysis within the resin matrix.
- The interfacial strength was also reduced because of the damage at the fibre-matrix interface.
- A reduction in interfacial strength was also observed, attributed to degradation at the fibre–matrix interface.
- All three constituents—fibre, resin, and interface—experienced degradation; however, the resin was the most severely affected. Although unembedded fibres exhibited a greater reduction in tensile strength, this does not directly translate to composite performance, as the surrounding resin matrix in the composite structure partially shields the fibres.

Keywords: Machine learning, Flame retardancy, Glass fiber composites, Epoxy resins

ABSTRACT

Epoxy glass fiber composites offer significant weight reductions for railway applications, reducing fuel consumption by 12–14%. However, the intrinsic flammability of the epoxy matrix poses challenges in achieving HL-2 fire classification under DIN EN 45545. This study addresses this limitation by systematically identifying and optimizing phosphorus-based flame retardants (FRs) compatible with vacuum infusion. An initial pool of 14 FR additives, including both solid (e.g., ammonium polyphosphate variants) and liquid (e.g., triethyl phosphate esters (TEP)) was screened in a Bisphenol F epoxy resin preloaded with 10 wt% resorcinol bis(diphenyl phosphate) (RDP). To reduce experimental effort, a batch active learning (B-AL) approach using Gaussian process regression (GPR) was applied to select 18 formulations for thermal and rheological characterization. Simultaneous thermal analysis (STA) parameters were used as surrogates for fire behavior in cone calorimetry, while pot life and storage stability were assessed to ensure processability. Surrogate models trained on STA and processability data achieved moderate predictive performance (R^2 = 0.4–0.6). Permutation importance was used to rank the FRs, identifying silane-coated APP (APPIII), melamine-coated APP (APPIV), TEP, and DOPOI as the most influential additives. These FRs were used in a secondary design space to generate 16 randomized formulations for transfer into woven glass fiber composites. Cone calorimeter tests conducted on top- and bottom-face exposures revealed increased filtration effects with higher solid FR content. The best balance between reduction in maximum average rate of heat emission (MARHE) from 155 kW/m^2 in the reference composite to 110 kW/m^2 and standard deviation in the MARHE values were found for the resin formulation containing 9% w/w of the liquid TEP with 1% APP and 10% RDP. Further optimization is required to satisfy railway norms. This machine learning-guided framework demonstrates a scalable route to optimize FR combinations that balance fire safety and processability.

1 INTRODUCTION

Lightweight fiber-reinforced composites are vital for the railway industry, offering corresponding fuel-efficiency improvements of 12–14 % which is a compelling driver for sustainability and reduced operating costs. However, these systems, particularly epoxy (EP)–glass fiber reinforced composites (GFRCs), pose significant fire-safety challenges due to the intrinsic flammability of the EP matrix, which fails critical safety thresholds required for passenger rail applications. Materials used in railway applications must comply with DIN EN 45545-2 [1], which outlines various parameters, most notably maximum average rate of heat emission (MARHE). For Hazard Level HL-2 compliance, the MARHE limit is 90 kW/m^2, while more stringent HL-3 applications demand values $\leq$ 60 kW/m^2. Meeting EN 45545-2 using phosphorus-based flame retardants (FRs) is one approach since they act synergistically in both the gas phase—by releasing radicals that suppress flame propagation—and the condensed phase, by promoting char formation to shield the polymer. For instance, aluminium diethyl phosphinate is a well-established flame retardant for epoxies operating via this dual mechanism [2–5]. Combinatorial systems like ammonium polyphosphate (APP) or intumescent blends have demonstrated

the potential to reduce peak heat release rate (pHRR) [6–9], and thus, MARHE values [10]. The relatively low viscosity (300-2000 mPa.s) required for vacuum infusion or resin transfer molding (RTM) processing, combined with the need to avoid filtration effects [11–13], constrains FR selection to additives that maintain processability.

While full-scale cone calorimetry (EN ISO 5660-1[14]) remains the gold standard for MARHE measurements, proxy screening via simultaneous thermal analysis (STA) using parameters like thermal decomposition onset and char yield can be indicative of fire performance ahead of composite fabrication [15]. For example (Figure 1), in differential scanning calorimetry (DSC), a left-shift in the heat energy of the first peak (Q1), or a decrease in intensity of the heat energy of the second peak (Q2) correspond to a decrease of pHRR and thus, MARHE values. Similarly, the, adjusted heat enthalpy of the first thermal event (ΔH_{1adj}) in thermogravimetric analysis (TGA) also represents a decrease in the pHRR. These correlations were generated using logistic regression combined with a least absolute shrinkage and selection operator (LASSO) model for a Bisphenol F Diglycidyl Ether (DGEBF)-diethyl toluene diamine system by Binder et al. [15]. Although modified contexts may result in modified correlation strengths between STA and cone parameters, it is assumed that these correlations can be exploited to screen FR additives for transfer to composites.

Comprehensive experimental screening becomes resource-intensive given the combinatorial nature of FR systems. Krebs [16] investigated how to boost the flame-retardant performance of a high-temperature epoxy resin for both aerospace and railway applications. Screening synergistic mixtures of AlPi with zinc stannate (ZnSt), and two inorganic silicate additives, guided by Bayesian optimization (BO) via Gaussian process regression (GPR) helped simultaneously minimize a hybrid target with total smoke production (TSP) and MARHE. When transferred to GFRCs via prepregs, the BO-optimized formulation nearly satisfied a HL-2 classification. Modelling with both linear and nonlinear regressors showed that a Random Forest algorithm best captured the complex, nonlinear relationships between FR content and performance. Storage stability estimations over months for iterative machine learning (ML) experiments are time consuming; accelerated aging of resin formulations at temperatures > 25°C can be used to estimate storage stability based on differences in the initial glass transition temperature T_{g0} over shorter time periods [17].

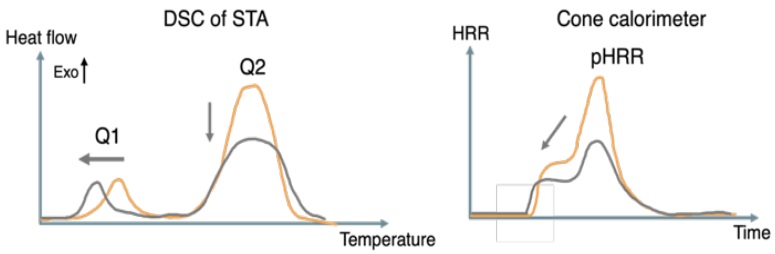

Figure 1: Correlations between heat flow in DSC measurements and pHRR measurements

The use of active learning (AL) using batch experiments (B-AL) with GPR also enables efficient exploration across the formulation space beyond BO [18–20]. This study builds upon these foundations by screening 14 phosphorus-based FR additives (gas- and condensed-phase) in a DGEBF resin containing 10 % w/w resorcinol bis(diphenyl phosphate)) (RDP). Processability via shear viscosity, and storage tests, targeting vacuum infusion compatibility. STA-informed B-AL/GPR models are used to gather data for training surrogate models for FR selection. Selected FRs based on feature importance estimations are transferred into 100 g/m² glass fiber composites via vacuum infusion across 16 randomized design trials, guided by BO. This approach integrates fire safety, processing constraints, and machine-learning-based surrogate modelling to enable accelerated material development in compliance with EN 45545 for weight-efficient and safe composite components.

2 MATERIALS AND METHODS

An overview of the methods used in this investigation is shown in Figure 2. B-AL is used as the exploratory phase to eventually reduce the number of features (FRs) for future exploitative Bayesian optimisation experiments.

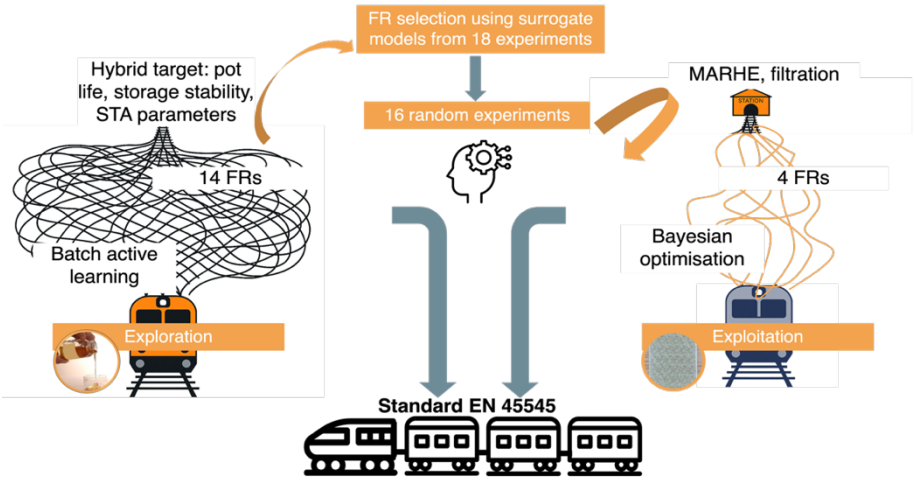

Figure 2: Overview of the methodology in the investigation

2.1 Resin preparation

A DGEBF resin system (Polyphlox 3721, Struktol GmbH) with an epoxy equivalent weight (EEW) of 235 g/Eq and a dynamic viscosity of 3000 mPa.s at room temperature containing 10% w/w of a RDP liquid FR was reacted with an IPDA-PACM hardener with an amine hydrogen equivalent weight (AHEW) of 47.6 g/Eq. DGEBF and IPDA were combined and dispersed by hand in the stochiometric ratio of 100:22 based on the following equation:

$$\text{Resin} - \text{hardener ratio} = \left[\frac{100 \times (\text{AHEW}_{\text{IPDA-PACM}})}{(\text{EEW}_{\text{DGEBF}})}\right] \quad (1)$$

2.1 Flame retardants and glass fibers

Table 1 summarizes the various FR additives used within the study for feature selection screening. RDP is already mixed at a fixed proportion within the DGEBF resin. The halogenated flame retardant PropCP is considered for a comparison with the non-halogenated FRs and not intended for transfer to the composite. DOPOI is considered as an alternative liquid FR for transfer to the composite after feature importance determination from the existing 14 initial FRs. The particle size distribution of the 50% fraction of the FRs is reported as d_{50} in µm.

Table 1: Database of FRs with varying physical forms, P content and chemical formulations for feature importance determination via B-AL trials

The variation in the fraction of the 14 FRs used for AL trials across 18 experiments is given in the heatmap in Figure 3. Aerospace textile satin woven glass fibers (GFs) (9111-FK144 from Valmiera glass) with an areal weight of ~ 105 g/m^2 coated with a silane/volan finish were used for vacuum infusion.

3 METHODS

3.1 Active learning via batch experiments for FR selection

A library of fourteen phosphorus-based flame retardants (14 features) was initially gathered (Table 1), to evaluate their relative importance with respect to STA-derived thermal metrics, pot life, and storage stability to be determined. To minimize the number of physical trials, batch active learning employing a Gaussian process regression surrogate model was implemented: the first five formulations were sampled from a constrained virtual design space of 10,000 candidates via Gaussian sampling. The total FR loading was maintained $\leq$ 10 w/w, which including RDP was $\leq$ 20 w/w. In total, 18 experimental formulations, with 5 initial experiments and subsequently 3 per round were ultimately evaluated, and

permutation-based feature-importance analysis was applied to these results to identify the most influential additives.

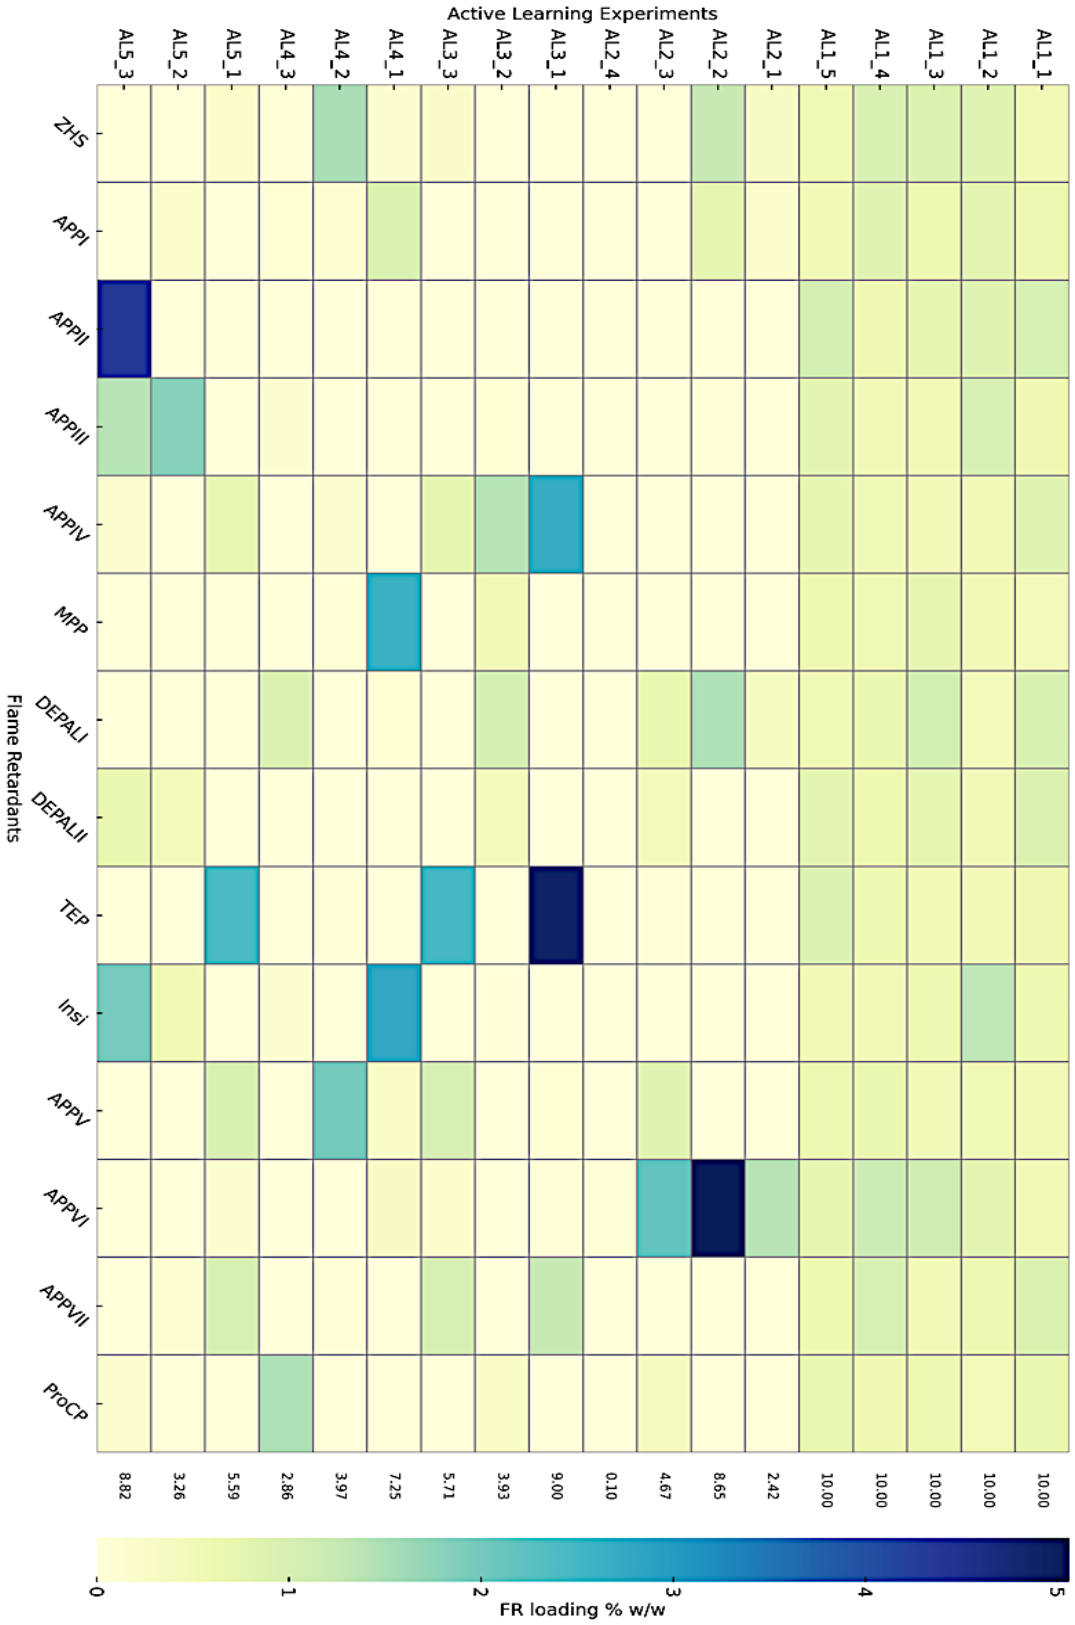

Figure 3: FR loadings in w/w for the 18 experiments based on B-AL

A hybrid target function containing 12 sub-targets was defined as:

$$\text{fFR1} = 0.25[(\text{Pot Life}) - (|T_{g0}|) + (\text{Positive parameters}) - (\text{Negative parameters})] \quad (2)$$

Here, the relevance of the positive and negative parameters is explained in Table 2. The STA parameters were each weighted based on the LASSO coefficients derived from the study by Binder et al.[15].

Influence on fire performance	Impact on pHRR	STA parameters
Positive influence on fire performance	Negative (increase in parameters implies a decrease in pHRR)	Initial sample mass, mass residue of the second peak in DSC, **heat energy of the first curing peak in DSC**, temperature at 50 % conversion of the first peak in TGA, temperature at 50 % conversion of the second peak, **adjusted heat enthalpy of the first peak in DSC**
Negative influence on fire performance	Positive (increase in parameters implies an increase in pHRR)	Total heat value in DSC**, heat energy of the second curing peak in DSC**, temperature of the second peak in DSC, heat flow of the first curing peak in DSC

Table 2: STA parameters positively and negatively influencing fire performance

3.2 Pot life

The influence of the FR additive combinations as additives for the DGEBF systems on pot life was measured using an Anton Paar Rheometer (MCR 301). The rheological properties of the resins were then evaluated at an isothermal sweep at 50 ºC for 120 mins using a parallel plate (PP25) with a gap between parallel plates of 1 mm. The pot life in mins was determined as the time at which the resin reached a complex viscosity of 2000 mPa.s. A constant strain of 0.1% was used, with a maximum torque of 140 mN/m.

3.3 Storage stability

For the storage stability measurements, the DGEBF resin was not reacted with the hardener but directly combined with the FR additives and dispersed by hand. The resins were tested in a DSC1 from Mettler Toledo (USA) directly after preparation (Day 0). A sample mass of 5-10 mg, with a temperature range of -25 ºC to 250 ºC at a ramp rate of 10 K/min was used for each measurement. A constant flow of synthetic air at 50 mL/min was maintained. The samples were subsequently stored in a Memmert ULE 400 convection oven at 50 ºC for 7 days after which a DSC measurement was performed. A benchmark of $\boldsymbol{\Delta T_{g0}} \leq 10$ ºC was used to determine the storage stability of the resins. $\boldsymbol{\Delta T_{g0}}$ was calculated using the following equation:

$$\Delta T_{g0} = T_{g0}^{Day7} - T_{g0}^{Day1} \quad (2)$$

3.4 Simultaneous thermal analysis (STA)

For STA measurements, the FRs were dispersed into the resin-hardener mixture by hand mixing and cured overnight by film casting on a glass plate at 25 °C. Subsequently, the cured resin was comminuted in a cryomill at ~ 19,000 rpm using a 200 µm sieve. Samples with a mass of ~ 10 mg were tested simultaneously for DSC and TGA parameters in a Netzsch STA 449 F3 Jupiter using a temperature range from 25 °C to 800 °C with a ramp rate of 7.5 K/min. The various parameters mentioned in section 3.1 were then extracted.

3.5 Vacuum infusion and cone calorimetry

The resin formulations were preheated to 50 °C and infused into ~ 32 layers of the GFs stacked by hand under vacuum of 0 mbar. The infused GFs, with a target fiber volume content of 50 ± 5 % were cured overnight at room temperature and subsequently cut to size (100 mm x 100 mm x 3 mm) for cone calorimeter tests. The top and bottom faces of the samples were labelled. The samples were tested in a horizontal orientation – with one sample with the top face exposed to the cone heater, and with another with the bottom face exposed, under an external heat flux of 35 kWm^{-2} and 25 mm from the cone heater following ISO 5660-1 norms. The MARHE values and the standard deviation between the top and bottom face exposures from the cone tests was calculated to determine the presence of filtration effects.

4 RESULTS AND DISCUSSION

4.1 Pot life and storage stability

Figure 4 (a) reveals that the pot life values for all 18 formulations converge within a narrow range (±10 min), suggesting a consistent impact of FR incorporation on resin rheology. No anomalous gelation behavior was observed, indicating thermal stability of the curing system under the evaluated formulations. Despite the high dimensionality of the features and targets within the AL experiments, a gradual increase in the value of the hybrid function is visible in Figure 4 (b).

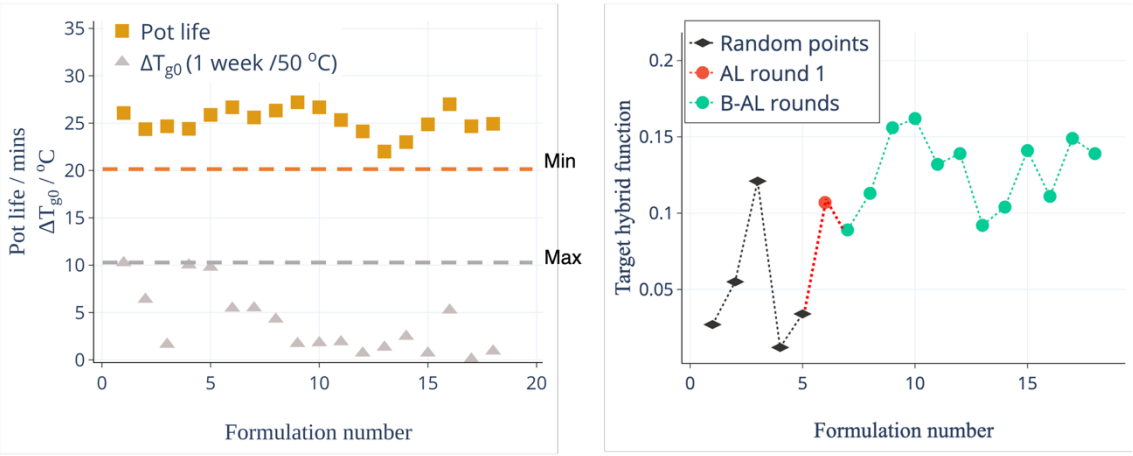

Figure 4: Variation of pot life and ΔT_{g0} for the resin formulations (a) and progress in the hybrid target across the 18 experiments (b) – Random, AL points

4.2 Training surrogate models for feature selection

The 14 input features (FR compositions) were scaled using None, MinMax, Standardisation and Robust scalers and either unpre-processed or pre-processed with techniques such as polynomial features of degree 2 (Poly2), first 5 principal components (PCA5) etc. The 12 sub-targets (see equation 2) from the 18 experiments via B-AL, the data were used as individual targets. The data from each sub-target was split into training test sets, to train 7 surrogate models – linear, random forest regression, gradient boosting regression (GBR), support vector regression (SVR), k-nearest neighbour (KNN), decision tree

(DT) and LASSO model. A five-fold cross-validation was employed for each surrogate model pipeline, ensuring that each of the 18 data points was held out once. The best pipelines of these 140 pipelines determined by those which predicted individual parameters with the highest cross validation (CV) R^2 values, lowest CV mean square error (MSE) and lowest CV mean absolute error (MAE) (Table 2) relative to the data, were selected to determine feature importance using permutation importance.

Target property (highlighted in table 2)	Pre-processing	Scaler	Surrogate model	CV R^2	CV MSE	CV MAE
Heat energy of the first curing peak	PCA	Standard	Linear	0.6320	0.0032	0.04805
Adjusted heat enthalpy of the first curing peak	PCA	None	Linear	0.5883	0.0004	0.01656
Heat energy of the second curing peak	Poly2	Robust	LASSO	0.4869	0.4298	0.5446

Table 3: Best pipelines based on 140 combinations of data preprocessing, scaling and training of 7 surrogate models

Thereby, the top ranked FRs based on feature importance were silane coated APP (APPIII), melamine coated APP (APPIV), proCP and TEP. Since proCP is halogenated, it was eliminated at this stage based on REACH regulations. While this 18-point AL dataset enabled proof-of-concept surrogate modelling, the moderate R^2 values indicate that additional rounds are required to fully capture nonlinear FR interactions. Future work will integrate high-throughput thermal screening to expand the design space. The high permutation importance of APPIII and APPIV is promising due to their known condensed-phase char-promoting behavior, while TEPs gas-phase radical-quenching action supports its intermediate ranking. DOPOI was selected as an additional liquid FR for 16 randomised trials in vacuum infusion. For this purpose, a second constrained virtual design space of 10,000 candidates via Gaussian sampling was generated with these 4 selected FRs, and 16 randomised trials were generated for vacuum infusion experiments and subsequent cone calorimeter tests.

4.3 Fire performance and filtration effects of the composites (under construction)

The pareto plot between TSP and MARHE of the randomized samples are shown in Figure 5. Sample number 14 was invalidated due to technical errors during cone calorimeter operation and showed the highest error in MARHE (±85 kW/m^2). Sample 13 containing a combination of 9% w/w of TEP with 1% w/w of APP simultaneously showed one of the lowest MARHE values and filtration effects. Although Sample 5, containing 5% w/w APPIII, 2% APPIV and 2% TEP showed the lowest MARHE values of all valid samples with significant intumescent behavior during fire testing, the difference from the top face (MARHE ~ 70 kW/m^2) and bottom face was ~ 30%. Thus, it can be hypothesized that although a potential synergistic effect is present in sample 5 with primarily condensed phase action from the APP leading to a HL-2 classification when the top face is exposed to a fire, the higher solid content present in the resin causes a gradient effect and reduces FR penetration and thus, fire performance towards the bottom of the composite. Compared to the composite without FRs, all samples containing at least 2% w/w of some combination of FRs improved the MARHE values, with the best formulation (sample 5) producing a ~ 30% reduction in MARHE.

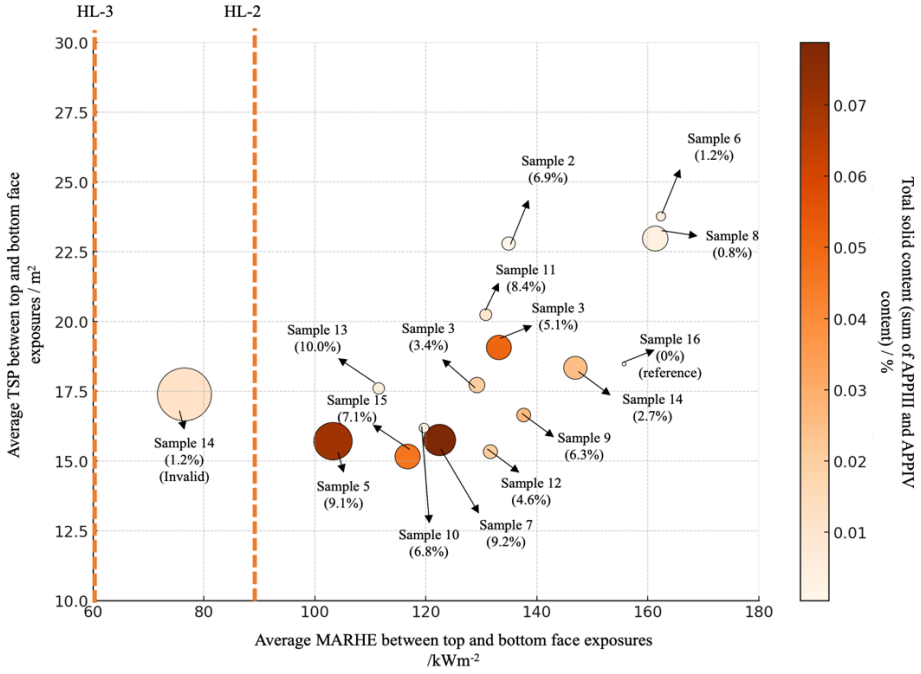

Figure 5: Pareto plot between average TSP and MARHE for the 16 samples showing solid content and filtration effects. Larger data points represent higher uncertainty in MARHE indicating higher filtration effects. All FR percentages are in addition to 10% w/w RDP content in the resin

5 CONCLUSION AND OUTLOOK

In this study, a systematic, ML-guided approach was used to identify and optimize P-based FRs as additives for EP GFRCs. From an initial pool of 14 candidate FRs, a B-AL framework using Gaussian-process surrogate models were used to efficiently screen formulations. By leveraging simultaneous thermal analysis (STA) parameters as rapid proxies for cone-calorimetry performance, we reduced the experimental burden completing 18 guided trials while still capturing feature importance. Coated APP formulations dominated the feature ranking, followed by a halogenated liquid FR and a TEP liquid FR.

16 randomized vacuum-infused composite specimens containing 4 selected FRs were fabricated and characterized via cone calorimetry under both top- and bottom-face exposures. Using only random trials, the MARHE values could be reduced by ~30%, close to the HL-2 standard for railway applications. Although successful as a proof of concept, expanding the AL dataset will help capture nonlinear synergistic effects among multiple FRs. Validation under shear rates representative of injection molding ($\approx 10\ s^{-1}$) and scale-up trials in RTM will ensure further industrial applicability. Further improvement of the FR content in the resin is also required, potentially via Bayesian optimization rounds to balance filtration effects with MARHE values until a HL-2 classification is possible.

ACKNOWLEDGEMENTS

This study was funded by AIF Project GmbH via the Zentrale Innovationsprogramm Mittelstand (ZIM) (project number: KK5120807EB4). The authors would like to acknowledge Dr. Hauke Lengsfeld for his contribution to the project.

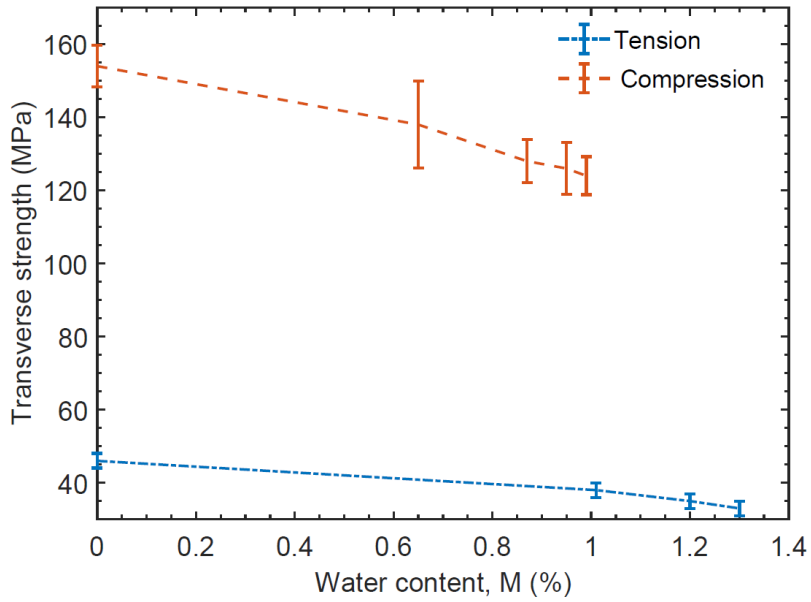
BROWN
School of Engineering

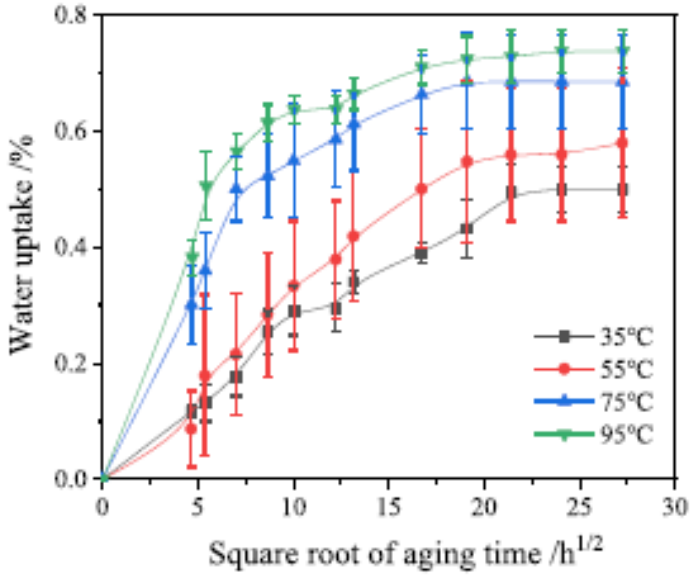


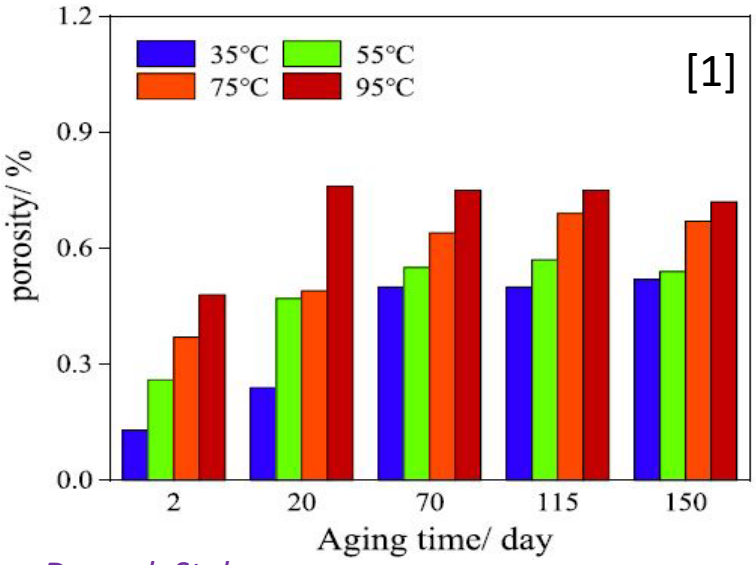
Introduction

- FRP composite: heterogeneous phase of fiber and polymeric matrix
- Application: Aerospace, Marine, and Wind turbine blades
- Exposure to extreme environments

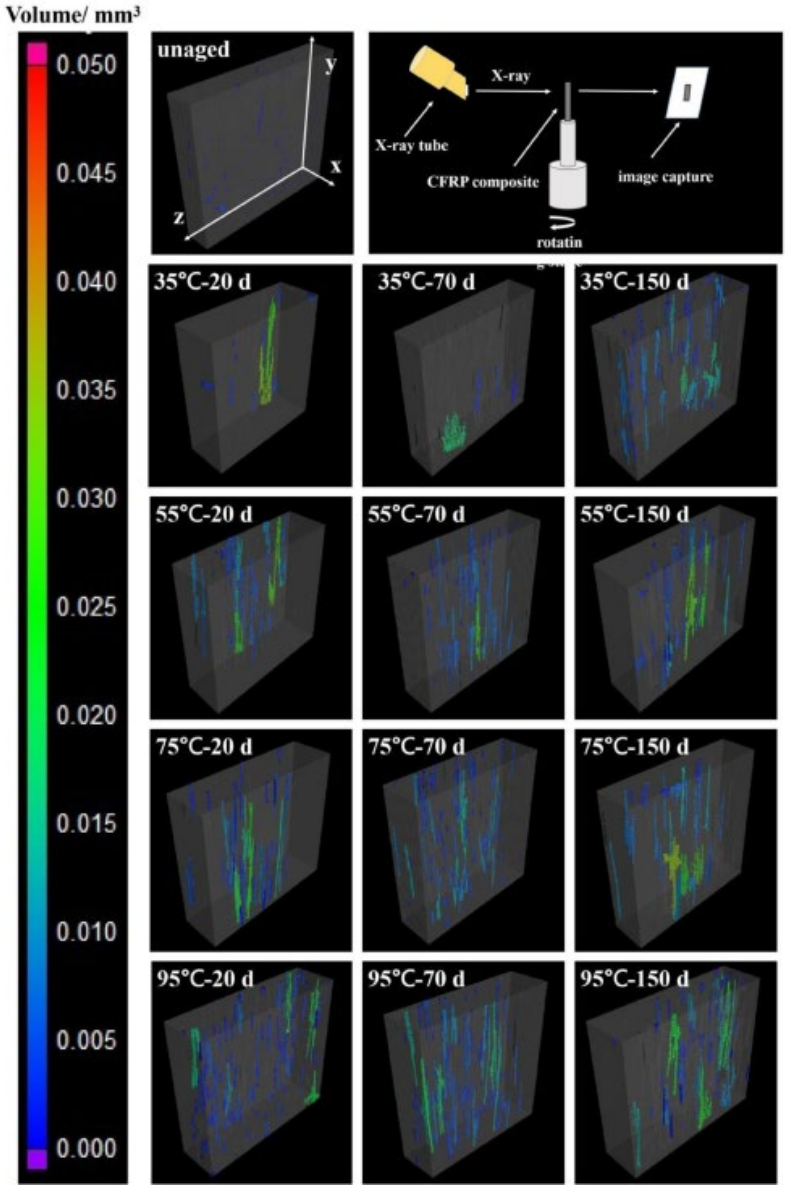
Hygrothermal exposure

- Synergetic effects of water and temperature
- No effect on fiber
- Matrix undergoes chemical and physical changes
- Mechanical properties of composite deteriorate





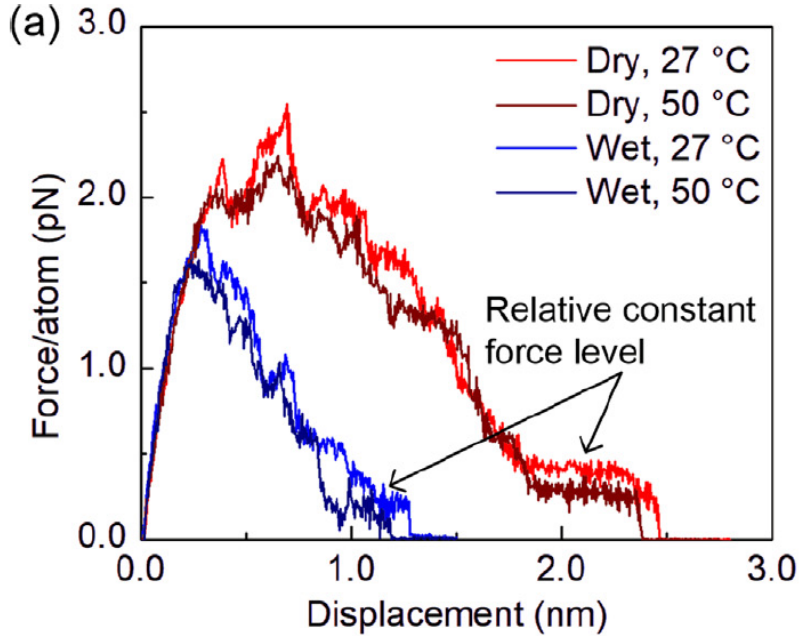
BROWN
School of Engineering



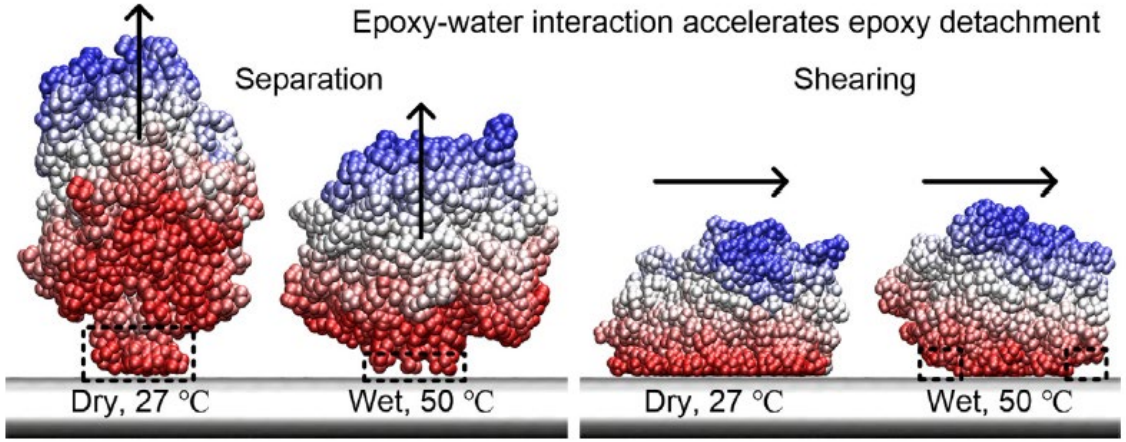
[1] Tual et al (2015) Compos. A

Background

- Material: Carbon/Epoxy unidirectional laminates
- Tests: Diffusion at various temp
- Void characterization: micro-CT scan.



- Unaged: no pores (voids)
- With water ingress porosity increases
- Void formation along the fiber at the interface

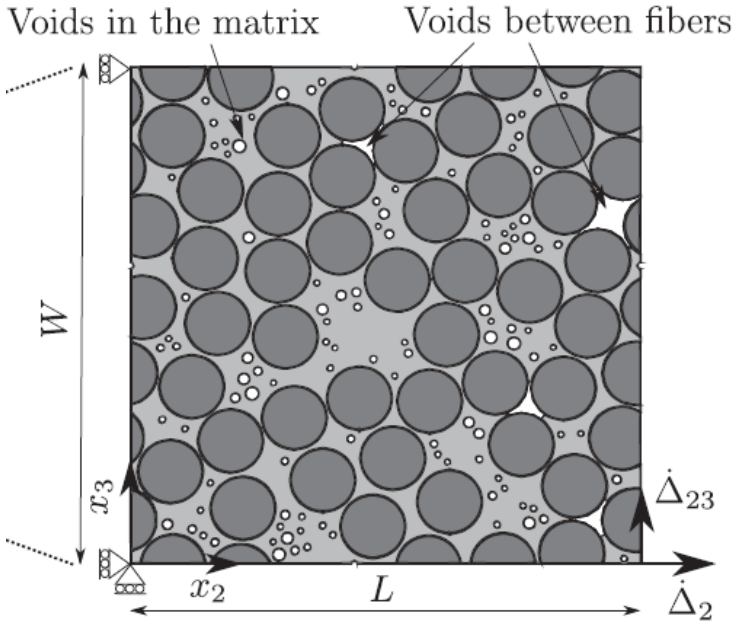


BROWN
School of Engineering

[1] Zhuang et al (2022) Polym. Degrad. Stab.

Background

- Atomistic analysis of the hygrothermal effect on carbon fiber epoxy interface.
- Water molecules drastically deteriorate the integrity of the carbon fiber/epoxy interface.
- Elevated temperature level further degrades the interfacial mechanical response.



BROWN
School of Engineering

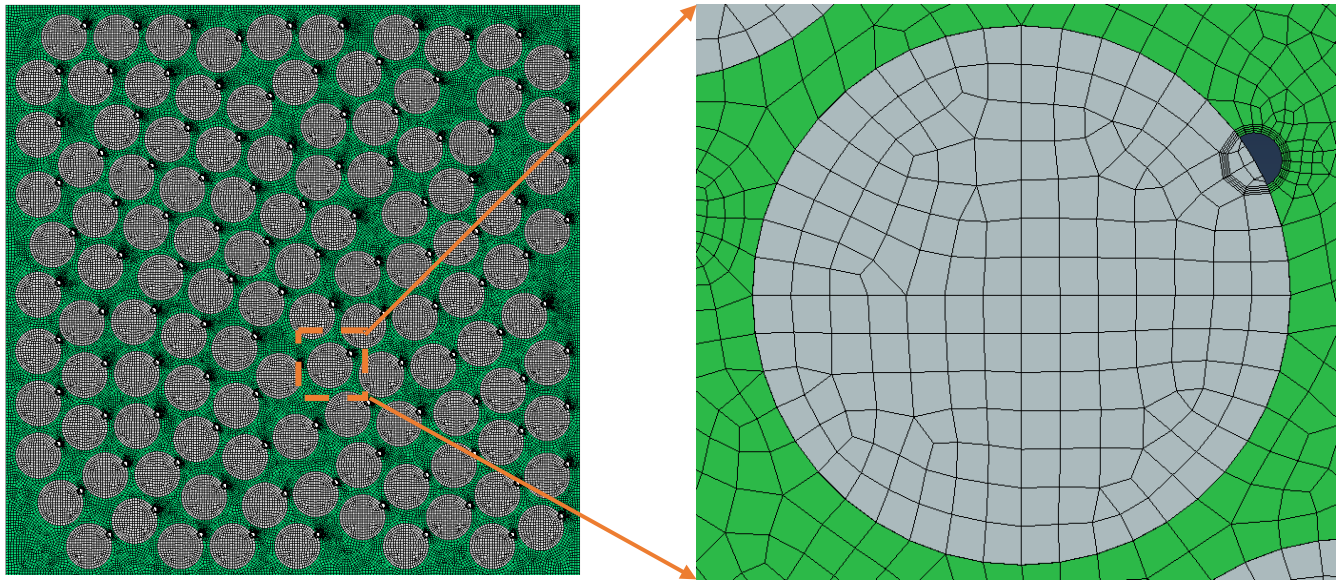
Tam et al (2019) Constr Build Mater.

Motivation and Objective

- Many studies on the influence of void on mechanical properties
- Either inter-fiber voids or matrix voids
- How process-induced voids influence the water ingress in the specimen

Void types [1]

Objective



- Systematic study of interface voids
- Develop a correlation: Moisture-induced porosity with water content in the specimen

BROWN
School of Engineering

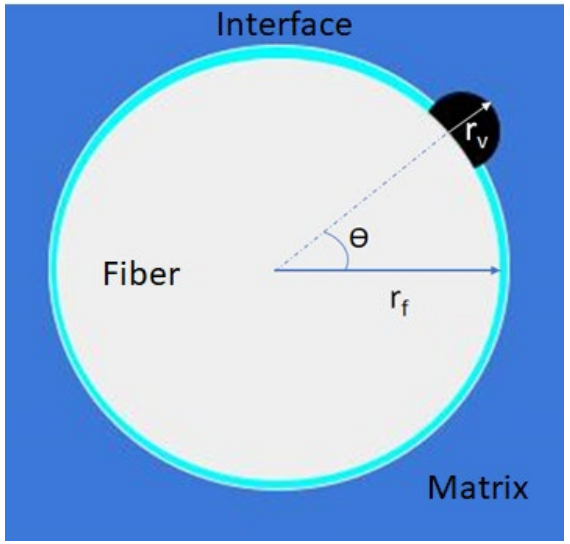
FE geometry and Modeling details

Composite: Fiber, matrix, fiber/matrix interface, void (pore)



RVE FE mesh

- Fiber vol fraction (v_f) is maintained at 0.56
- Periodic boundary condition (PBC) is applied at the boundaries
- RVE loading: a tensile strain of 1%
- Post processing: homogenized stress-strain curve

Parameters considered in the study:

1. Porosity (p in %) through r_v= [0, 0.1, 0.3, 0.6, 0.9]
2. Location of the pore (Θ) = [0^0, 15^0, 30^0, 45^0, 60^0, 90^0]
3. Relative position of pore = [interface, matrix]

$$r_v = \sqrt{\frac{2p}{v_f}}\, r_f$$

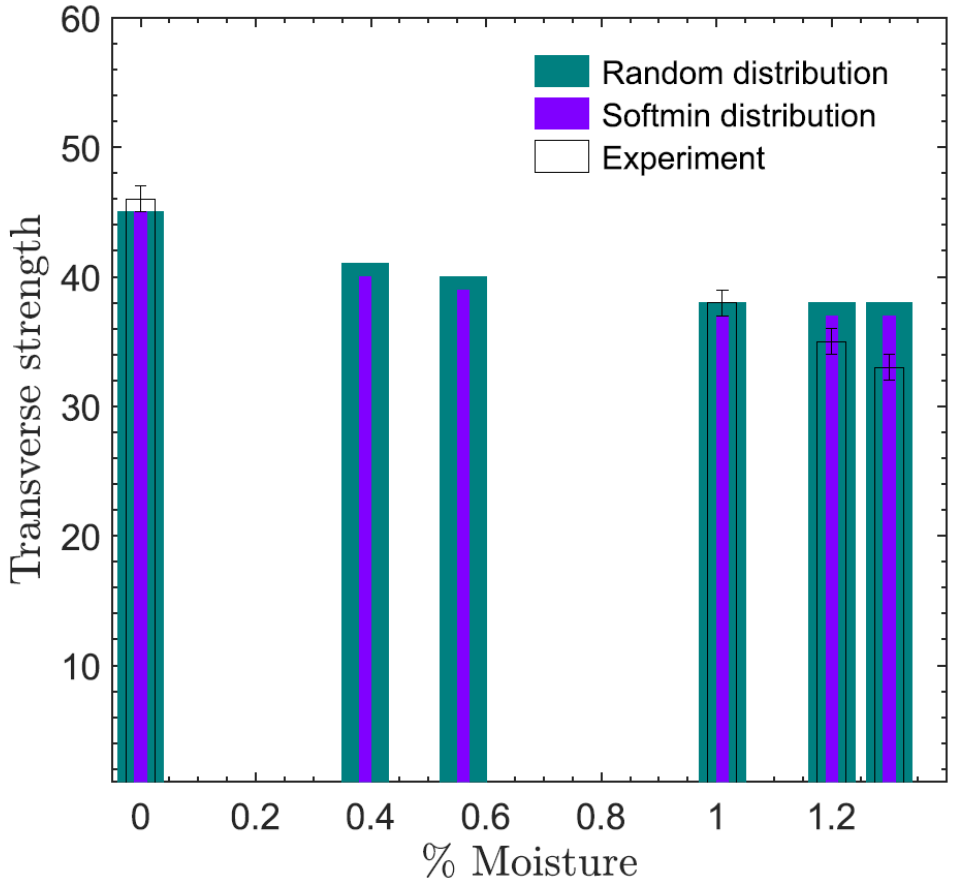
Strength prediction and comparison

- Experimental result are within the lower and upper bounds predicted by simulations

BROWN
School of Engineering



Different approach: Probabilistic interface properties

- Strength of porous RVE: lower and upper bound
- Each interface: a probabilistic strength values (σ^0_x)
- Based on percentage reduction of lower and upper bound the

$$\sigma^0_{min} \leq \sigma^0_x \leq \sigma^0_{max}$$

- Distribution: Random and Softmin

Softmin distribution $$p(x_i) = \frac{\exp(-x_i)}{\sum_j \exp(-x_j)}$$

BROWN
School of Engineering

Conclusions and future direction

- Interface void substantially influence the stress and strain distribution within the specimen
- Porosity of as small as 0.1% resulted in 15% reduction in strength
- Strength seems to depend on pore size, its orientation and location. The maximum impact is when void is at the interface and aligned along the loading direction ($\theta = 0^0$)
- A different probability-based approach to overcome the modeling complexity

Future work

- Coupled diffusion damage model for the interface and matrix material (polymer)
- Meso-scale modeling to predict the toughness of aged laminates

Geometric comparison

Geometry	Unit	2-blade		
		CAD	Actual	Offset (%)
Propeller volume	cm^3	16.76	16.67	0.5
Propeller diameter (D_P)	mm	254	254.1	0.04
Hub diameter (D_H)	mm	21.84	21.7	0.6
Hub thickness (T_H)	mm	12.2	11.8	3.3
Shaft diameter (D_S)	mm	7.37	6.9	6.4
Wing length (L_W)	mm	115.1	115.5	0.3

- Investigation to determine UAM suitability
- Printed propeller to compare with purchased
- 10 GF / PA-12 CBAM printed propellers
- Average dimensional deviations within 1mm
- ~3 hours print time compared to 35 hours FDM

06 Conclusion

- **Manufacture of CBAM to compare with FDM**
  - CBAM prints faster than FDM
  - CBAM allows for higher part density per build
  - CBAM process is more compatible with in-line assembly processes
- **Internal structure characterizations**
  - FDM contains a high amount of large inter-filament voids
  - CBAM contains a larger number of small voids
- **Testing results**
  - CBAM performs better than FDM in tensile stress due to higher fiber volume fraction and longer fibers
  - FDM performs better in compression due to the more randomly-aligned fibers
  - CBAM shows a strong dependence on printing direction, especially for compression
- **Shows promise in aerospace and automotive applications**
  - CBAM shows promise in applications requiring high performance parts
  - CBAM bridges the gap between low-volume FDM custom parts and High-volume traditional processes

Keywords: Recycling; Thermoplastic composites; mixing; homogeneity

ABSTRACT

This study investigates the effect of fiber volume fraction (FVF) and material homogeneity on the mechanical performance of recycled woven thermoplastic composites. Recycling thermoplastic composites (TPCs) offers advantages over thermoset composites by enabling complete material recycling through melting and reshaping. The research utilized shredded 8-ply Toray Cetex 1100 C/PPS 5 harness satin woven composite mixed with neat PPS polymer at various ratios to achieve target FVFs of 16%, 20%, 25%, and 50%.

Processing was conducted using an internal mixer followed by compression molding into plates. Microstructural characterization was performed using optical microscopy and image analysis to quantify fiber volume fraction distribution and fiber bundle size. Samples were mechanically tested under tensile loading conditions.

Results demonstrate that dilution and mixing significantly improve fiber dispersion compared to unmixed material. The 50% FVF unmixed sample exhibited high stiffness but poor strength and ductility due to large undispersed fiber bundles. Lower FVF samples (16-25%) showed improved dispersion and mechanical performance, though with varying degrees of scatter. The 20% FVF sample demonstrated optimal balance of properties with good dispersion and reduced bundle sizes.

Image analysis successfully correlated microstructural features with mechanical performance, revealing that bundle size distribution and local FVF variations are critical factors affecting material strength. The study provides insights for optimizing recycling processes of aerospace-grade thermoplastic composites.

1 INTRODUCTION

The composites market has seen significant growth [1], with a corresponding increase in production and end-of-life waste. While thermoset-based composites are recycled on a small scale, focusing only on fiber recovery, thermoplastic-based composites (TPCs) offer a more comprehensive recycling solution. The thermoplastic polymer matrix allows for recycling the entire material through melting and reshaping, eliminating the need to separate fibers from the matrix.

A recycling approach for TPCs that has shown potential is schematically shown in Figure 1 [2]. The first step consists of mechanical recycling, by shredding the composite into flakes having a processable size (10 mm to 20 mm). Afterwards, the material can be diluted with additional polymer to facilitate compounding and then molding.

In the resulting discontinuous fiber reinforced recycled compound, significant attention is given to the fiber length, as it is an important factor influencing mechanical performance [3]. However, additional factors need to be considered, as they also contribute to the mechanical performance, such as fiber orientation and homogeneity of the fiber distribution.

A homogeneous distribution of the fibers in the polymer matrix is a critical factor in ensuring a high and consistent performance of both virgin and recycled composites. For short-fiber composites, homogeneity can be achieved relatively easily as standard mixing methods mix well but cause fiber breakage. For long fiber composites, heterogeneity is more pronounced, particularly when dealing with aerospace grade TPCs as the input material to be recycled has an initial high fiber volume fraction. Additionally, during the mixing process, the composite flake or tape structure needs to be disentangled to create a homogeneous material. A solution is to reduce the fiber fraction by incorporating additional polymer matrix during the mixing step [2]. This step is essential for distributing fibers evenly, significantly improving the uniformity of the final composite material.

In the recycling process the optimal final fiber volume fraction is not well defined at this point in time. In general, for virgin composites, it is well known that with low fiber volume fractions there is little reinforcement to ensure high mechanical performance. On the other hand, with high fiber volume fractions a drop in the material strength was observed when dealing with discontinuous fibers [4], [5]. This result suggests that other factors are limiting the performance at high fiber volume fraction. This indicates that more aspects need to be considered when recycling aerospace-grade composites, as they are characterized by a high fiber volume fraction, up to 60%.

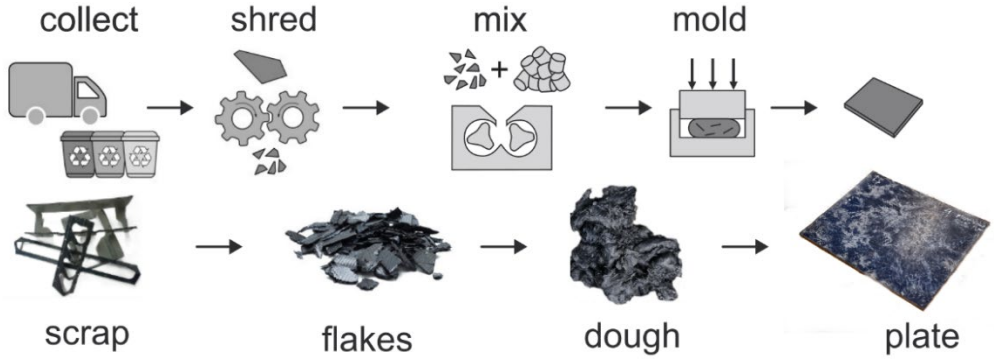

Figure 1: Thermoplastic scrap processing cycle

2 METHODOLODY

2.1 MATERIALS & PROCESSING

The current study aims to investigate the recyclability of unidirectional and woven TPCs, understanding the effect of morphology of the recycled compound on the mechanical performance. The two components used in processing are shredded 8 ply thick consolidated laminates of Toray Cetex 1100 C/PPS 5 harness satin woven composite and for the matrix material Celanese Fortron 214 PPS is added.

Using an internal mixer, a Brabender Plastograph EC Plus W50 EHT measuring mixer, C/PPS scrap was compounded with different fractions of neat PPS as described in Table 1. All samples were processed for 5 minutes at 320°C and 5 RPM rotational speed, and a fill fraction of 0.7, occupying 35 ml of the available 50ml chamber. To create 50 grams of compounded composite material. Except for the undiluted scrap material of 50% FVF, which is intractable in the mixer and thus is compression molded as is.

Subsequently, these were compression molded at 50 bars of pressure into plates of dimensions 125 × 125 x 2 mm. Figure 2 shows the specimen layout. Each plate contains nine tensile specimens conforming to ISO 527-2-12A dimensions and was used for 16 micrographs. The tensile specimens were milled out of the plates.

Target FVF [%]	Fiber wt%	Mix time [min]	Additional polymer [wt%]
16	20	5	65%
20	25	5	56%
25	31	5	46%
50	57	0	0%

Table 1: Mixing parameters operated in the internal mixer.

For the microstructural characterization, the material in between the tensile bars was embedded in epoxy for polishing. For each imaging plane two areas (A and B as indicated in Figure 2) were imaged on a Keyence vhx-7000 optical microscope. Each image spans 5.4 x 2.1 mm at a resolution of 0.3 µm, resulting in 16 micrographs and an imaged area of 181.44 mm^2 per plate.

Tensile testing was performed in an Instron universal testing machine. Mechanical tests were performed at 23°C degrees and a constant crosshead displacement resulting in an engineering strain rate of $\dot{\varepsilon} = 10^{-3}$. The strain was measured using an Instron AVE2 video extensometer with a gauge length of 20 mm.

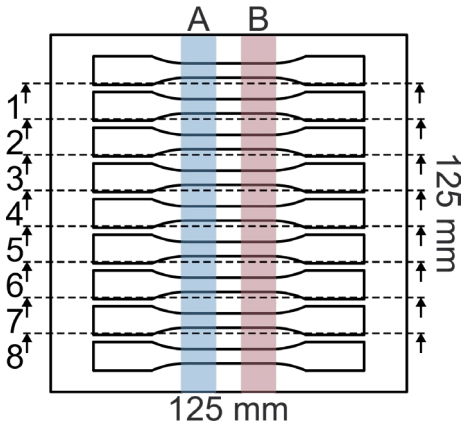

Figure 2: Specimen dimensions and microscopy section planes

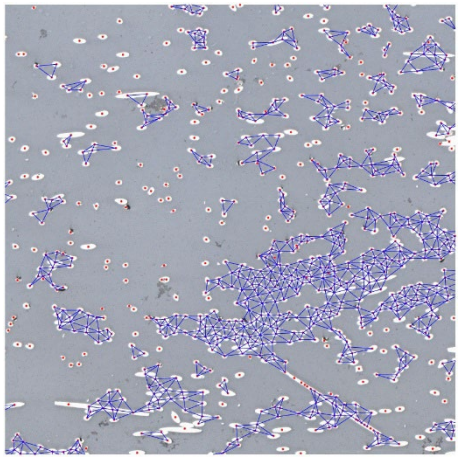

Figure 3: Example of the bundle triangulation of the 20% sample in location A-2

2.1 IMAGE PROCESSING & ANALYSIS

Image analysis of the fiber dispersion starts with identifying the locations of the fibers, subsequently the distribution is analyzed. As a first step, the image is binarized using the distinct peaks that are present in the image histogram. Each peak represents one of three components of the image, the mounting epoxy, the matrix material, and the fibers. A binary mask is constructed by taking the luminosity value in the middle of these peaks as the boundary. This binary map is used as the first check of the FVF by comparing the number of pixels assigned to the matrix and the fibers.

Second, the binary mask of the fiber locations is used to analyze the local fiber volume fraction. This method is based on analyzing the local fiber volume fraction compared to the mean fiber volume fraction. These steps are used to calculate the Intensity of segregation (IoS), as is used in analyzing mixtures in chemistry [6], [7]. However, on a pixel level the volume fraction is binary, therefore an averaging step is used at different cell sizes to get the local fiber volume fraction. The variance of the fiber volume fraction of the sample is divided by the variance of the fiber volume fraction before mixing. As 16 micrographs are analyzed per sample the IoS is calculated per micrograph and then averaged to get one IoS value for the sample. The spread of the IoS values within the sample can be used to show the bandwidth of the IoS.

Third, the fiber centers are analyzed using the MATLAB regionprops function, with the fiber centers a triangulation of the fiber centers is constructed. Then any links in the triangulation longer than three times the average fiber diameter are removed and any resulting links that are lines and do not form a

triangle are removed. The resulting triangulation corresponds to the bundles present in the composite. An example part of the triangulation is shown in figure 3. This process is analogous to the image analysis by Vincent et al [8].

3 RESULTS

The results are treated in the following order: first, the microstructure is discussed, then the image analysis results are treated, concluding with the mechanical results.

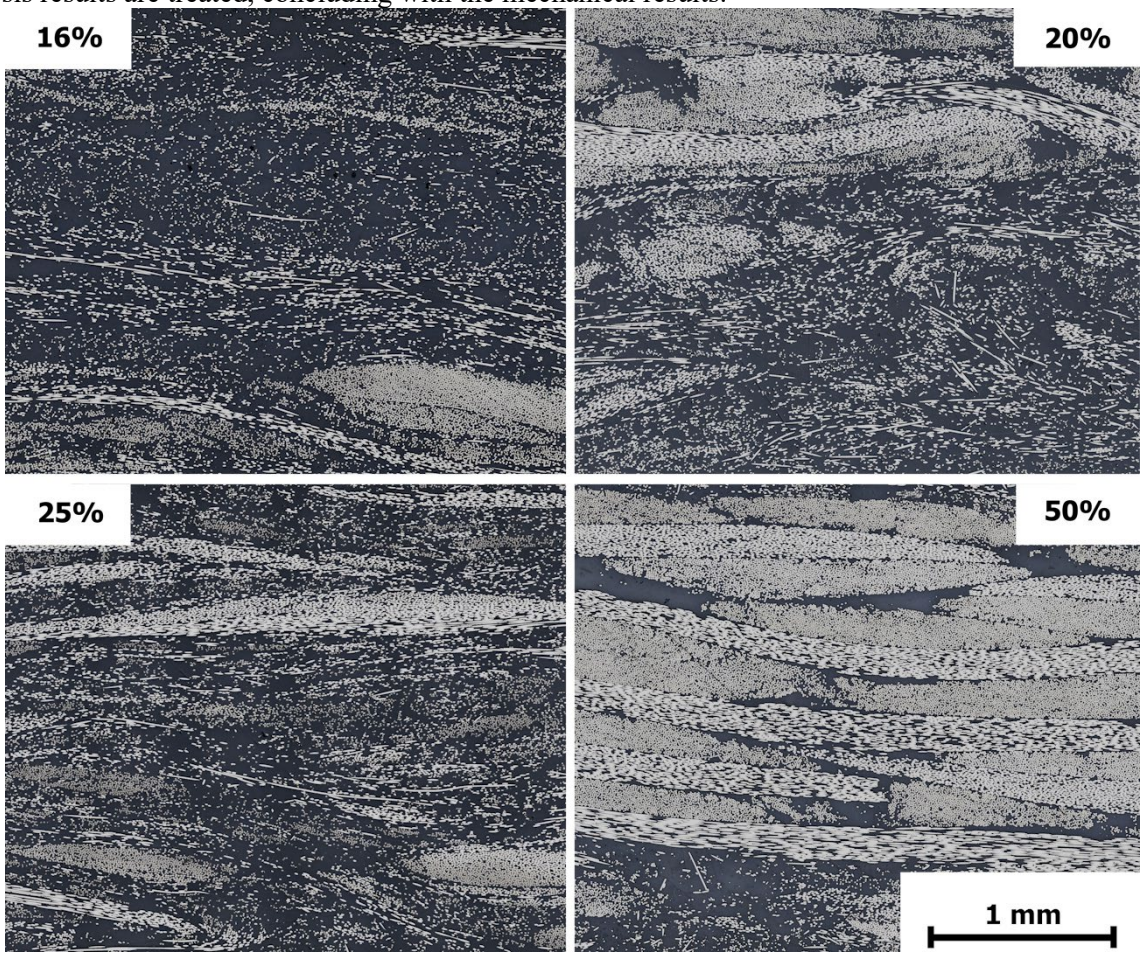

Figure 4: Cropped cross sections from the A-2 plane of all the samples having a global fiber volume fraction of (a) 16%, (b) 20%, (c) 25%, (d) 50%.

3.2 Microstructure

Figure 4 shows example cross sections of the plate specimens from plane 2 and location A as indicated in Figure 2. A first observation from the micrographs is that no voids could be found, indicating good consolidation. Second, the microstructure differs significantly. In Figure 4a of the 16% FVF specimen, both well dispersed fibers that have almost equal spacing to their neighbors exist, as well as the presence of a large undispersed fiber bundle originating from the 3K bundles present in the woven scrap material. A similar structure can be seen in the example of the 20% FVF sample, as well as undispersed bundles and dispersed individual fibers, a matrix-rich area is present in between two fiber bundles. By contrast the example of the 25% FVF sample shows only dispersed fibers and smaller fiber bundles. Lastly the unmixed 50% FVF specimen in Figure 4d shows stacks of fiber bundles with small resin rich areas and surprisingly small areas of dispersed fibers. Concluding, the microstructures of these materials show different characteristics depending on the fiber volume fraction. However, only qualitative information can be gathered directly from micrographs.

3.2 Image analysis

To validate the approach for thresholding the average volume fraction of each of the 16 micrographs per specimen is compared to the average volume fraction as is targeted through the compounding mixture.

Figure 5a shows the correlation between the input target FVF of the compounding process and the measured fiber volume fraction in the image analysis. First it is evident that the two measures of the fiber volume fraction agree quite well. Second, the lowest and highest FVF mixtures have a significantly higher spread in the fiber volume fraction.

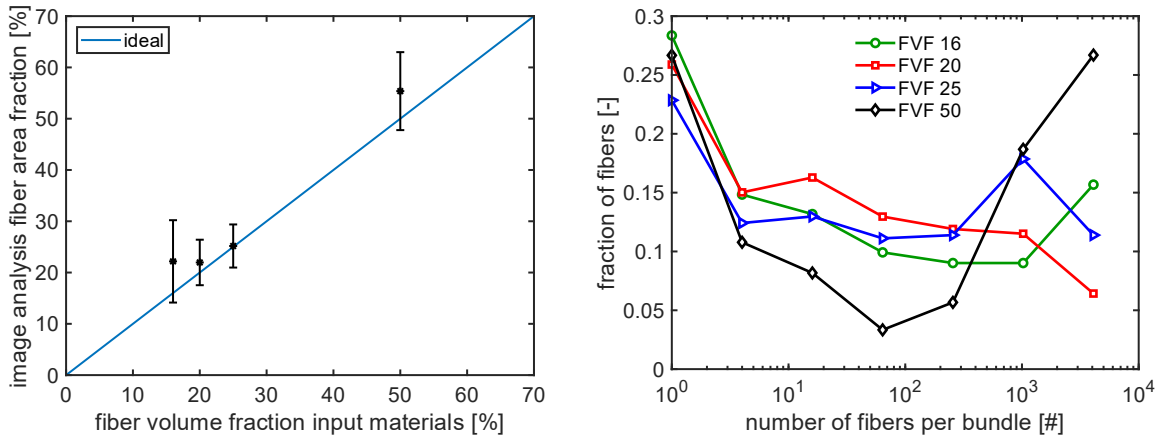

Figure 5: (left) Relation of the fiber volume fraction from the input materials to the fiber volume fraction from the micrographs. (right) Distribution of the fibers present in the volume over the bundle size that contains them.

Figure 5b shows the distribution of the bundle sizes that the present fibers are contained within. It is evident that the dilution and mixing step result in a large change in the microstructure. This is well reflected in the change in the bundle size distribution from the 50% FVF sample compared to the mixed and diluted samples. Between the three diluted samples, the 16% FVF sample shows the largest remaining portion of large bundles. While the reduced bundle size of the 20% FVF samples indicates a good dispersion of the initial bundles.

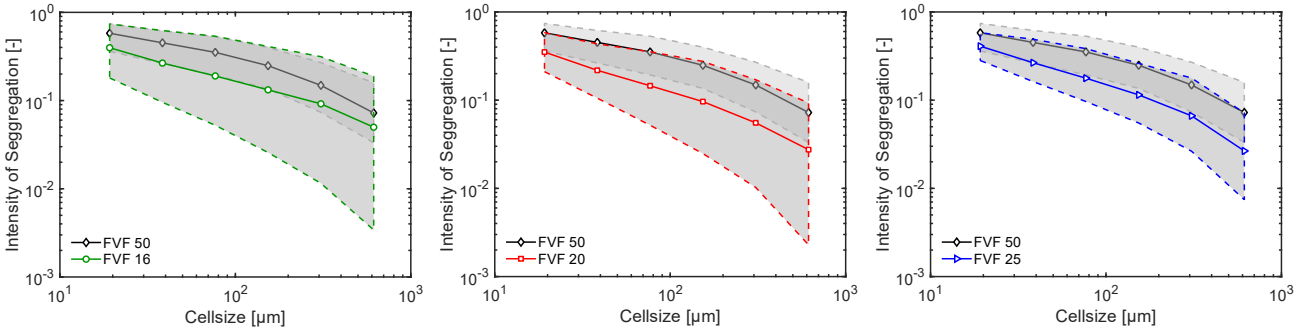

Figure 6: IoS of the three mixed samples compared to the IoS of the unmixed 50% FVF samples (black) as a function of the averaging cell size. The areas contained by dashed lines indicate the bandwidth of the IoS.

The IoS of the three mixed samples are shown in Figure 6 and compared to the IoS of the unmixed sample. The value of the intensity of segregation relates to the variance of the fiber volume fraction. The 16% FVF sample shows an average IoS that is lower than the 50% FVF sample indicating some dispersion. But the bandwidth includes the whole range indicating that there are micrographs that have a similar variance in volume fraction as the unmixed 50% sample. All the way up to a low value of FVF. The 20% FVF sample has a lower average IoS and the maximum IoS is close to the mean of the unmixed 50% sample. Similarly, the 25% sample has a low average IoS and similar maximum values of IoS. However, the bandwidth is much lower.

Next to the fiber volume fraction, the fiber orientation in a specimen relates directly to the strength and stiffness of the material. After mixing the material is large in volume and during compression molding the height is reduced from 30mm to 2mm, meaning it is reasonable to assume a 2D random fiber orientation. However, it is good to check this assumption. By using the identified ellipses traced by the fibers in the cross sections the orientation in 3D can be determined. From these orientations an average orientation tensor can be constructed. The resulting tensors aligned with expectations for a 2D random case, showing diagonal components of 0.5 in the long directions of the plates. Only the 25% FVF sample showed a slight preferential orientation of 0.57 in the tensile direction and 0.34 perpendicular to it and 0.08 for the out of plane component.

3.3 Mechanical results

Aside from the fiber volume fraction and the fiber orientation, the fiber length is also of influence. It should be noted that only 50% FVF was not processed in the mixer and thus did not undergo a step where significant fiber attrition can occur. For these kind of fiber loadings and this type of mixer it has been reported that the weight average length is typically reduced to or below 500µm [9]. Therefore, the 50% FVF specimen has a significant advantage in fiber length compared to the other three samples.

Figure 7 shows the tensile curves for the different samples created. The scatter in results is evident from all the tensile curves. The bundle size distribution results are reflected in the large difference in performance between the mixed and diluted samples and the unmixed 50% FVF sample. The unmixed 50% FVF material has high stiffness but very poor strength and ductility. The 16% FVF sample that showed a spread in local FVF values from the image analysis and large remaining bundles also has a large spread in mechanical performance. So, the extremes of the samples show a correlation with the fiber bundle distribution and the local volume fraction.

The middle ground occupied by the FVF 20% and 25% samples show more subtle differences. The FVF 20% sample shows a large scatter in stiffness but a smaller scatter in strength, and most interesting two groups of failure strains. The FVF 25% by contrast, has a narrow distribution in stiffness but a large scatter in strength, but also shows the highest strength values of all specimens.

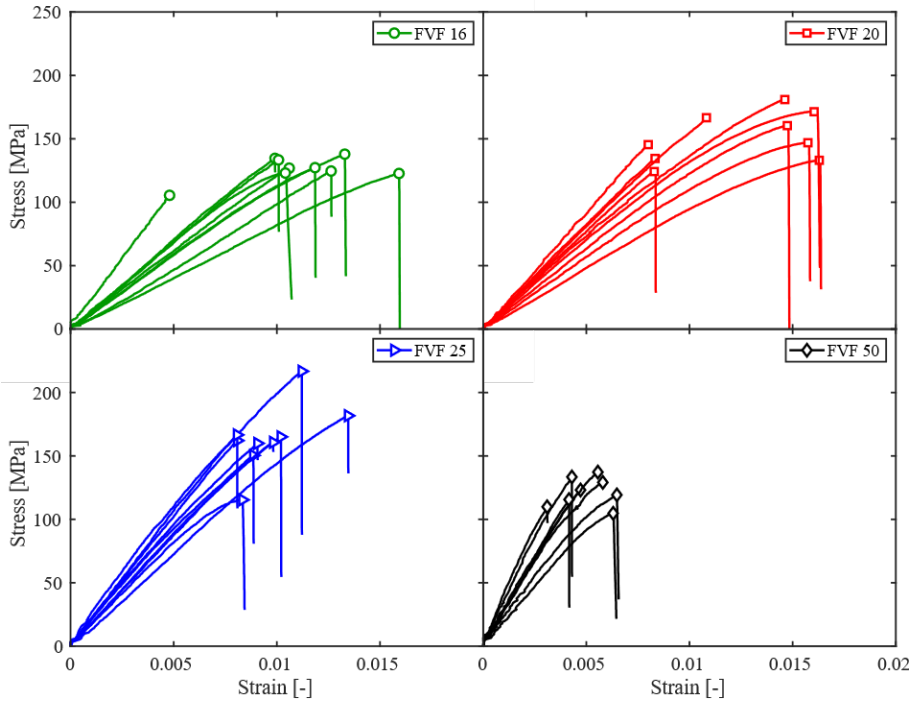

Figure 7: Tensile results of the reprocessed scrap materials

In conclusion, the performance of the material shows no trivial relationship between the fiber volume fraction and the resulting strength. However, at the high fiber volume fraction the performance is the worst even though that sample also has the highest fiber length, but the low homogeneity is likely inhibiting performance.

9 CONCLUSIONS

Using the current image analysis techniques, it is shown that the fiber volume fraction can be calculated quite accurately. Second, the bundle size distribution of the microstructure can provide a first indication towards the expected strength of the material. Interestingly, the sample with a high-volume fraction and the longest fiber length does not show the best performance. The benefits of dispersing and diluting woven composite scrap became evident in mechanical testing. Significant improvements in performance can be achieved by decreasing the fiber volume fraction and higher homogeneity could play a part in this relation.

ACKNOWLEDGEMENTS

ABSTRACT

To meet increasing legislative demand for a circular plastics economy, novel technology is needed to produce high-performing composites from waste polymers. Introduced processes must be low-cost and environmentally friendly to be future proof. In this paper, a novel slot-channel melt impregnation tool was used to produce continuous carbon fibre (CF)-reinforced thermoplastic tapes with fewer processing steps than state-of-the-art powder and commingling processes. Process applicability was tested for polyamide 6 (PA6), PA6 blended with polypropylene (PP), and waste film linear low-density polyethylene (LLDPE) containing PA6. For the first time, an atmospheric pressure plasma jet with air carrier gas was applied in-line to enhance the melt impregnated tapes. The slot-channel melt impregnation process operated more consistently with the active in-line plasma surface treatment as a result of improved fibre alignment and cohesion by pneumatic spreading. The slot-channel melt impregnator produced tapes with high degrees of impregnation for all matrix systems, irrespective of the reinforcement treatment. Compression moulded PA6 and PA6/PP (50:50 wt.%) matrix composite short beam strength significantly benefited from CF plasma surface treatment, increasing by 45.2% and 89.8%, respectively. The 36% increase of O/C elemental composition on the CF surface did not enhance PA6/LLDPE (20:80 wt.%) composite performance because the dominant dispersive matrix is incompatible with the polar fibre surface. The present work introduces a viable thermoplastic tape manufacturing process that can effectively impregnate dry fibres with as-received and shredded waste polymers. This process is especially promising because it significantly enhances tapes made with a PA6/PP matrix, a common hard-to-recycle blend that is currently not repurposed in New Zealand.

1 INTRODUCTION

Polymeric waste is poorly utilised in New Zealand. Out of the estimated 45,000 tonnes of plastic collected for recycling annually, up to 90% are exported [1]. While large quantities of engineering thermoplastic such as nylon are available for reuse in municipal and post-industrial waste, they are usually considered as hard to recycle by council recycling schemes [2]. Consequently, clean recovery of polyamides is currently under prioritised, leading to potential contamination and phase separation of

waste thermoplastic with non-compatible polymers [3]. Such incompatibilities reduce the matrix strength [4] and compatibilisation between the fibre surface and multiple matrix constituents [5]. Despite the aforementioned concerns, technology to produce fibre-reinforced thermoplastic composites with matrices containing waste polymer must be developed to meet the demand for a circular plastics economy. An appropriate issue to address is that 39% of plastics in Europe were converted to packaging in 2020 [6], necessitating processes that re-use polymeric film blends. This work investigates the feasibility of producing carbon fibre (CF)-reinforced thermoplastics constituting a blended polyamide 6 (PA6) matrix. Mixtures of PA6 with polypropylene (PP) or polyethylene (PE) are commonly found in hard-to-recycle packaging films.

Enhanced bonding between the incompatible CF-reinforcement and the blended matrix, without the use of wet chemical treatments, is of primary interest to align with the environmental motivations of this project. This paper instead presents a continuous air plasma functionalisation process to rapidly modify the CF surface for interface enhancement, similar to other works in the literature [7, 8, 9, 10]. Two novel contributions are presented in this work. Firstly, the integration of in-line plasma treatment with a novel slot-channel melt impregnation process is studied. Secondly, the process is used to elucidate the influence of plasma surface treatment on tape matrices constituting (i) PA6, (ii) PA6/PP made from virgin constituents to emulate the waste mixture, and (iii) waste PA6/PE film. Overall, issues encountered when processing continuous fibre-reinforced composites from hard-to-recycle waste polymers are demonstrated, and the performance enhancement by rapid in-line plasma modification is shown using the short beam strength test.

2 METHODOLOGY

2.1 Materials

Commercial high-strength, standard modulus polyacrylonitrile-based CFs were supplied unsized by Hyosung (Tansome H2550, Republic of Korea) as continuous 12K tows (tex = 800 $g.km^{-1}$, filament diameter = 7 μm, tensile modulus = 250 GPa, tensile strength = 5516 MPa, elongation = 2.2%, untwisted). Unsized CFs were utilised in this work to remove the complexity of size burn-off and degradation during surface treatment [11]. The virgin PA6 matrix used in this work was Ultramid B3S (BASF GmbH, Germany). Before compounding or melt impregnation, the hygroscopic PA6 was dried at 92ºC for 24 h. The virgin polymer blend matrix, emulating a hard-to-recycle waste blend, admixed MOPLEN HP400N PP (LyondellBasell, USA) to the PA6. Waste polymer films were sourced from an Auckland, New Zealand-based recycling facility.

2.2 Continuous plasma surface treatment

The pulsed DC plasma source utilised in this continuous treatment was a Tantec-X PLX (Denmark) atmospheric pressure plasma jet (APPJ) with an excitation frequency, power, and flow rate range of ~40.4 kHz, 416 W and 1400-2500$L.h^{-1}$, respectively. Figure 1 depicts the experimental setup for in-line plasma treatment. The fibre tow was let-off (2) from a bobbin and aligned with the plasma treatment zone (6). Vertically offset nitride-hardened 5 mm steel pins spread and tension the tow (5). The line-speed of 0.83 $m.min^{-1}$, yielding a good degree of impregnation, was controlled by a belt pulling unit prior to take-up on a winder. The working gas flow rate and fibre-nozzle distance used for tape manufacturing were 2200 $L.h^{-1}$, and 10 mm, respectively. The selection of these parameters is elucidated in Section 3.1 by optical emission spectroscopy (OES) and high-speed imaging.

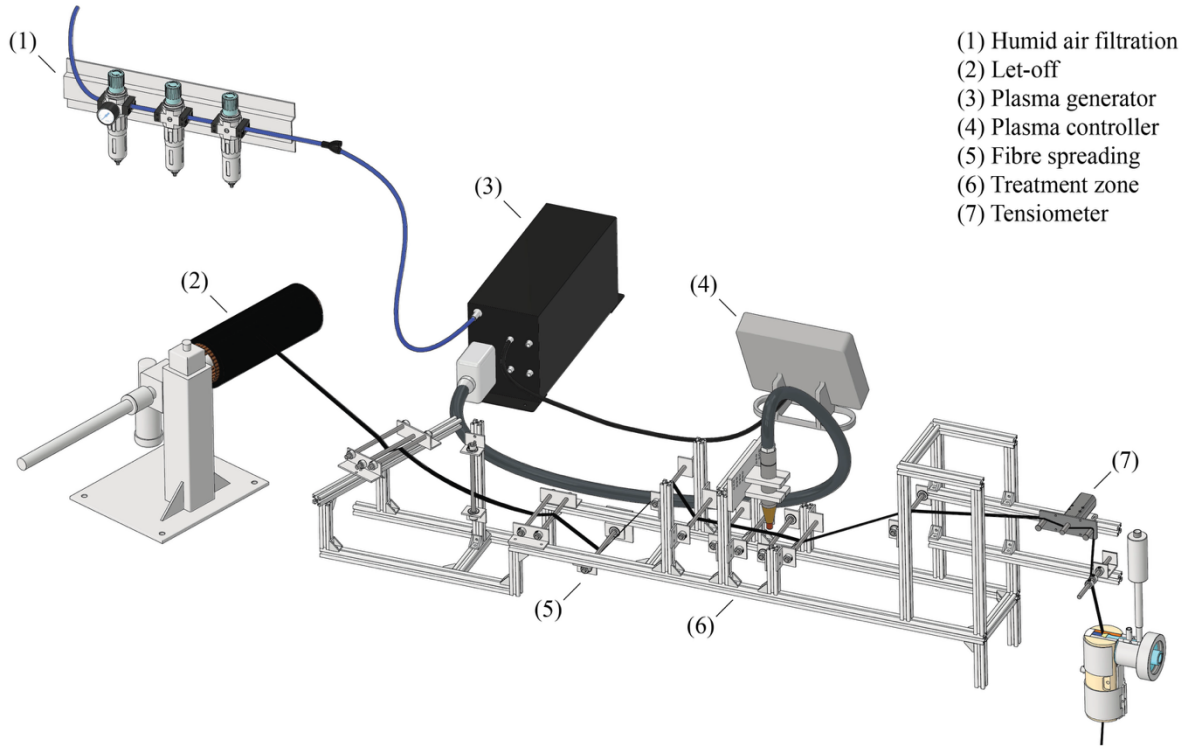

Figure 1: Continuous APPJ treatment setup schematic to modify the CF surface in-line prior to melt impregnation.

2.3 Optical emission spectroscopy

OES was applied to inspect spatial and working gas flow rate trends of reactive species in the air plasma discharge. The optical emission spectrographs were acquired on an EPP2000 portable spectrometer (Stellarnet, USA) by targeting a fibre optic cable mounted to a three-axis micro-positioning table. Spatial emission variation was measured along the APPJ system line of axial symmetry with coordinates centred at the nozzle exit. Measurements were acquired for distances from 2 to 12.5 mm and working gas flow rates between 1400 and 2200 $L.h^{-1}$.

2.4 High-speed imaging

A VEO 410L (Phantom, USA) global shutter and mono sensor, high-speed camera equipped with a 105 mm Micro-NIKKOR (Nikon, Japan) lens was used to capture the plasma discharge at the nozzle exit. An exposure time, frame rate, aperture and exposure index of 490 µs, 2000 fps, f/4 and 6400, respectively, were used to capture diffuse and filamentary discharge frames for nozzle-fibre distances between 6 and 12 mm.

2.5 X-Ray Photoelectron Spectroscopy

Functionality of the CF tow top surface was assessed by X-ray photoelectron spectroscopy (XPS). Samples were stuck on vacuum safe sticky tape immediately after plasma treatment to be placed in the XPS vacuum chamber, pumped down within 4 hours of the plasma treatment, and measured within 72 hours. The XPS measurements were acquired on an Axis Ultra (Kratos analytical, USA) using monochromatic Al Kα X-rays with a power of 124 W. The survey and high-resolution scan pass energy was 160 and 20 eV, respectively. Elemental composition was calculated from the survey spectrum.

2.6 Polymer processing

The virgin polymer blend was melt-blended in a corotating twin screw extruder (Brabender, GER) with a diameter and length-to-diameter ratio of 20 mm and 40, respectively. Blends were extruded at a screw speed of 60 rpm and a downstream temperature profile of 190 – 200 – 210 – 220 – 230 – 240ºC. Waste polymer film was shredded into flakes. The flakes were dried and directly used in the melt impregnation process. Filamentary extrusion to pelletise the waste polymer was avoided to minimise degradation and processing costs.

2.7 Differential scanning calorimetry

Polymer constituent mixtures were characterised by differential scanning calorimetry (Netzsch, DSC300 Caliris classic, Germany). All samples were annealed at 275 ºC, and subsequent melting endotherms were measured between -25 and 275ºC at a heating rate of 10ºC.min^{-1} in a nitrogen atmosphere.

2.8 Melt impregnation process

The impregnation die utilised in this work had a wavey geometry with a slot channel through which the fibre and polymer passed, as depicted in Figure 2a with a three-dimensional view in Figure 2b. The process is analogous to pin-driven impregnation in a melt chamber. Its difference lies in the small channel cross-section that develops elevated melt pressure. The impregnator was baselined on a non-vented 19/20 single-screw extruder (Brabender, Germany) that was flood-fed with dry PA6, PA6/PP, and shredded waste film. Samples made from as-received or plasma surface-treated reinforcement are identified as CF and pCF, respectively. After melt impregnation, the out-of-tool tape passed over two hot pins at 270ºC (Figure 3) in order to post-consolidate and smoothen the tape surfaces.

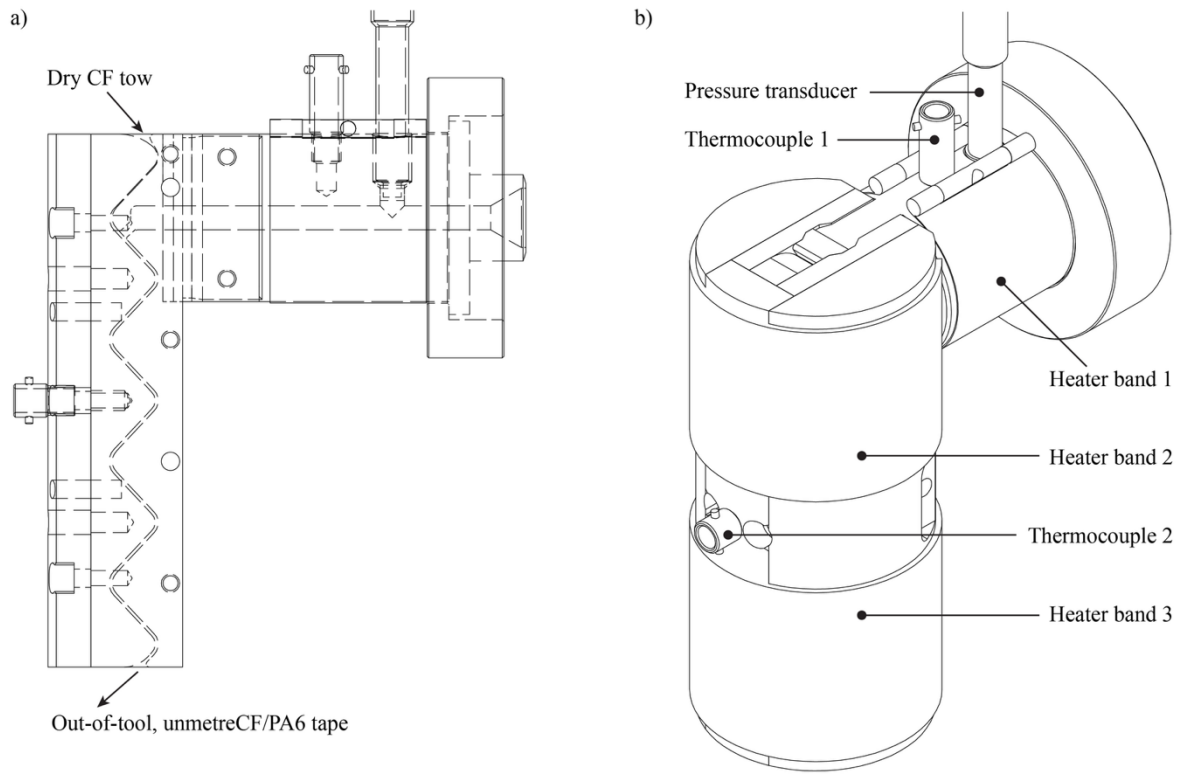

Figure 2: (a) Schematic of the wavy slot channel cross-head thermoplastic melt impregnator. The skeleton drawing omits the thermal conductor jackets and the heater bands over the slot for clarity. Image (b) illustrates the assembled tool including heater bands and instrumentation.

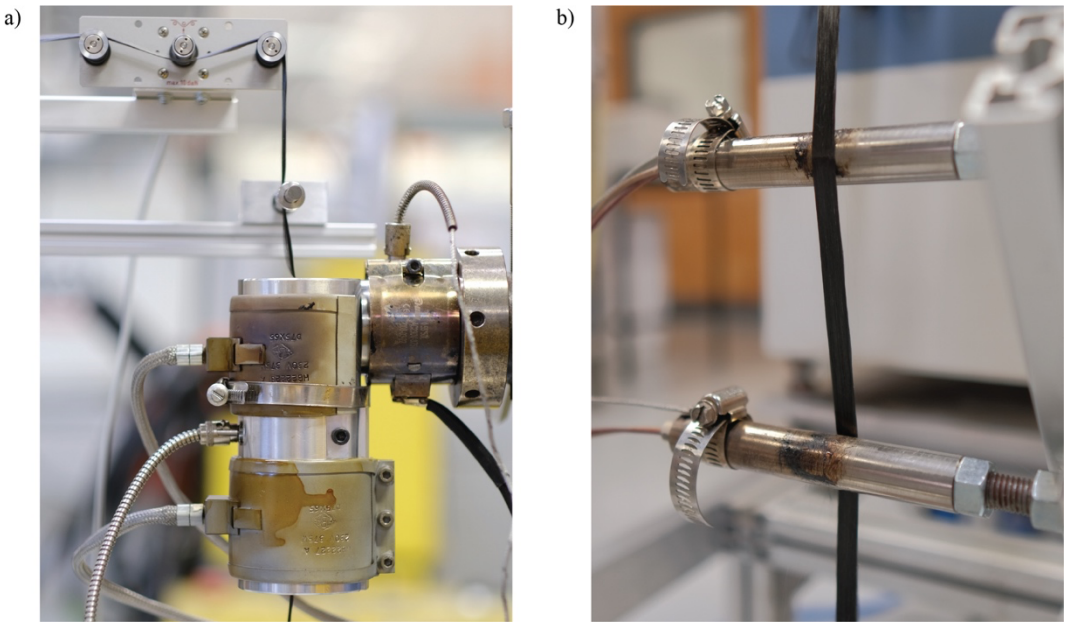

Figure 3: Images of (a) the instrumented cross-head melt impregnator and (b) the out-of-tool tape passing over two hot pins below the melt impregnator.

2.9 Cross-sectional microscopy

Tape quality was qualitatively inspected by microscopy. Out-of-tool and hot-pin post-consolidated tapes were mounted in SpeciFix-40 (Struers, Denmark), polished to a finish of 0.05 µm and ultrasonically cleaned to remove contamination from pores. Cross-sectional micrographs were acquired on a DSX1000 (Olympus, Japan) digital microscope.

2.10 Mechanical characterization

After drying for 24 hours, the tapes were stacked in a 3 mm thick compression mould to produce samples for short beam strength testing according to ASTM D2344. The compression moulding temperature and compaction pressure were 280ºC and 16 bar, respectively. The pre-heating and compression cycle times were 8 and 2 min, respectively. A 10-minute water cooling cycle reduced the mould temperature to 40 ºC. The diamond-cut unidirectional laminates (18 mm x 6 mm x 3 mm) were environmentally conditioned prior to testing at room temperature and 50% relative humidity. At least five specimens were tested for each sample.

3 RESULTS AND DISCUSSIONS

3.1 Plasma characteristics and carbon fibre surface modification

APPJs have a higher spatial heterogeneity compared to plasma devices with tubular or parallel plate electric field configurations. The spatial heterogeneity is presented in Figure 4 using OES data, where the maximum emission intensity of atomic oxygen exponentially decays with increasing distance from the nozzle exit. Critically, the emission intensity is more sensitive to position than the working gas flow rate.

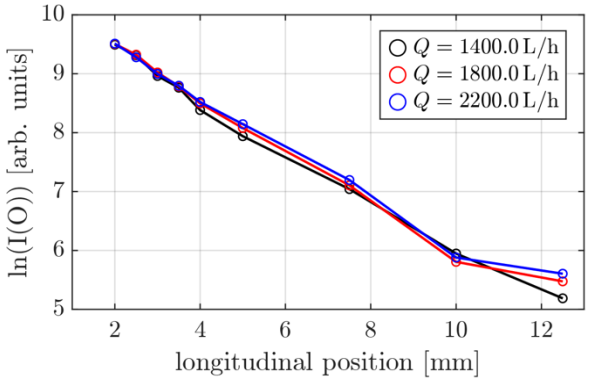

Figure 4: Optical emission spectroscopy logarithmic maximum emission intensity of the 777 nm atomic oxygen band for varying working gas flow rate. The longitudinal measurement point along the APPJ centre line was measured with respect to the nozzle exit.

Since emission intensity is proportional to species density, the logarithmic decay from Figure 4 suggests that the CF tow should pass through the APPJ treatment zone with a minimum nozzle-fibre distance for maximum exposure. However, the electrical conductivity of CFs disallows small nozzle-fibre distances. This is due to a transition from diffuse to filamentary plasma discharge when moving the fibre tow surface closer to the nozzle exit. Figure 5 illustrates the discharge mode transition behaviour for a fixed working gas flow rate of 1800 $L.h^{-1}$ at nozzle-fibre distances between 6 and 12 mm. It shows that distances beyond 10 mm yield diffuse plasma for the fixed flow rate. However, we have previously shown that the working gas flow rate also governs the discharge mode [12].

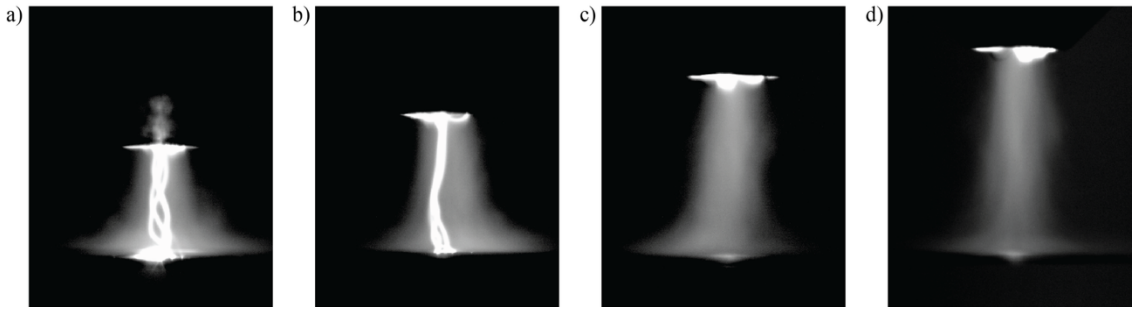

Figure 5: High speed camera frames of the APPJ interacting with the CF tow. The nozzle fibre distances for images (a) – (d) are 6, 8, 10, and 12 mm, respectively.

Fibre surface functionality after plasma treatment at a fixed distance and a fixed working gas flow rate is also a function of residence time [12]. Since the in-line plasma treatment residence time in this work is governed by the overall melt impregnation line speed, for the sake of brevity, surface functionality for varying line-speed is not presented. Instead, we show the as-received and plasma-treated CF surface functionality measured by XPS in Figure 6, where the line-speed, working gas flow rate and nozzle-fibre distance were 0.83 $m.min^{-1}$, 2200 $L.h^{-1}$, and 10 mm, respectively. Visually inspecting the C 1s band in Figure 6a gives the impression that the C-OH, C-O-C and C=O concentrations have increased after surface treatment. The O 1s peak in Figure 6b gives further evidence for an increase in R-O-R and -OH functionality. However, a similar increase in =O functionality is not observed, indicating that the C=O peak fitting of the C 1s peak may be subject to fitting error. Overall, the survey spectra reveal an O/C increase of 36%.

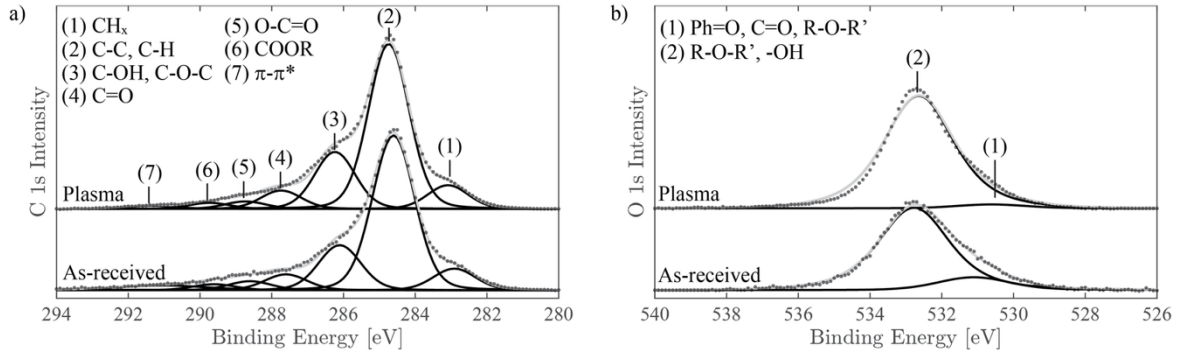

Figure 6: High-resolution XPS spectra of the (a) C 1s and the (b) O 1s band before and after plasma surface treatment. The line speed, working gas flow rate and nozzle-fibre distance were 0.83 m.min^{-1}, 2200 L.h^{-1}, and 10 mm, respectively.

3.2 Polymer mixture characterisation

DSC was used to detect the waste film composition. Table 1 summarises the peak melting temperatures of the various phases in each sample. The neat PA6 melting curve has a single peak at 220ºC with a heat of fusion of 61.54 J.g^{-1}. Blending PA6 with PP adds a peak at 163ºC with a heat of fusion of 50.73 J.g^{-1}. This confirms the 50:50 ratio in the blend, as the PA6 heat of fusion has been reduced by 52%. The waste film exhibits a similar PA6 melting peak at 220ºC with a heat of fusion of 12.06 J.g^{-1}. Assuming that it has an equivalent heat of fusion as the neat PA6 Ultramid B3s, the PA6 mass fraction in the hard-to-recycle film is approximately 20%. Most of the hard-to-recycle film is linear low-density polyethylene (LLDPE), as ascertained from the low-temperature melt peak at 128.9ºC [13].

Table 1: PA6, PA6/PP and waste film DSC data

Sample	Peak temperature 1 [ºC]	Peak temperature 2 [ºC]	Peak area 1 [J.g^{-1}]	Peak area 2 [J.g^{-1}]	PA6 mass fraction
PA6	-	220	-	61.54	1
PA6/PP	163	220	50.73	29.44	0.48
Waste film	128.9	218	98.58	12.06	0.2

3.3 In-situ plasma treatment for enhanced melt impregnation

Subtle separation of fibres from the unsized CF tow (Figure 7a) can lead to pronounced fibre misalignment and eventual failure of the tape manufacturing process. Fibres entering the viscous melt in the impregnator tend to wash out, necessitating careful control of the fibre alignment in the dry tow. It was found that the tow was firmly bundled when the in-line plasma treatment was active (Figure 7b). This led to diminished fibre washout and eliminated spontaneous process failure. Improved tow cohesion and uniform alignment by plasma treatment are explained by the pneumatic spreading effect of the dry air flowing through the nozzle.

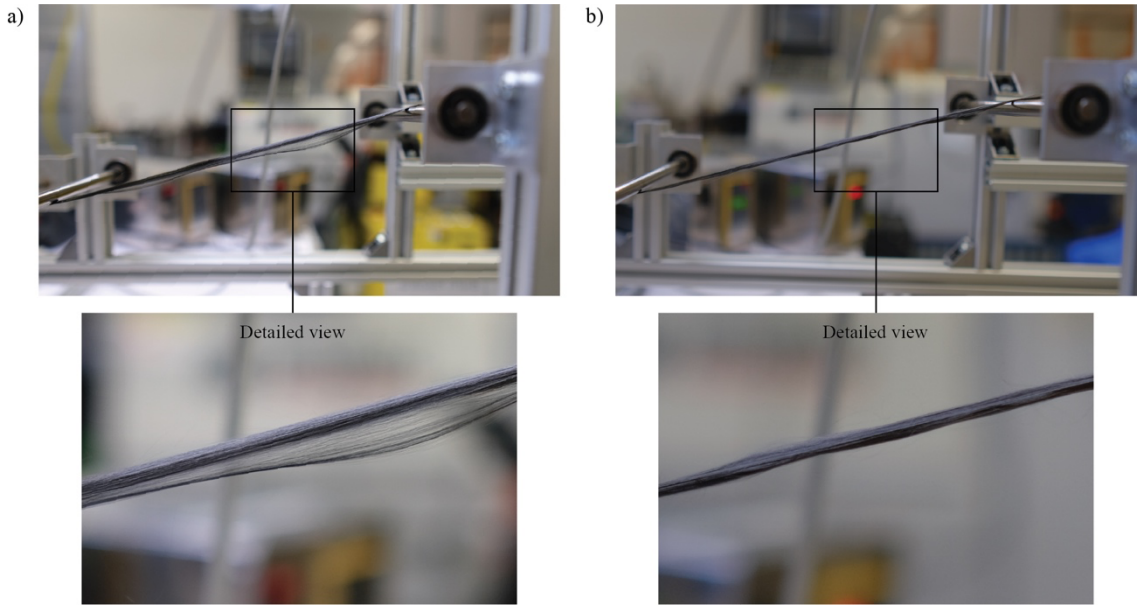

Figure 7: Images of the dry (a) as-received and (b) in-situ plasma surface treated CF tow passing between guiding pins leading to the melt impregnator.

3.4 Melt impregnated carbon fibre tape properties

After melt impregnation and hot-pin post-consolidation, at a fixed speed, the tape quality for the three matrix systems was assessed by cross-sectional microscopy, depicted in Figure 8. The tape dimensions changed for the various matrices. PA6 tapes (Figures 8a and 8b) were around 4.8 mm wide. PA6/PP (Figures 8c and 8d) and PA6/LLDPE (Figures 8e and 8f) tapes were wider, with widths of approximately 6.3 and 6.2 mm, respectively. Plasma surface treating the CF appears to have had an effect on the PA6/PP tape, where the width increased to approximately 7.3 mm. Overall, these results suggest that the plasma surface treatment has little effect on the tape dimensions.

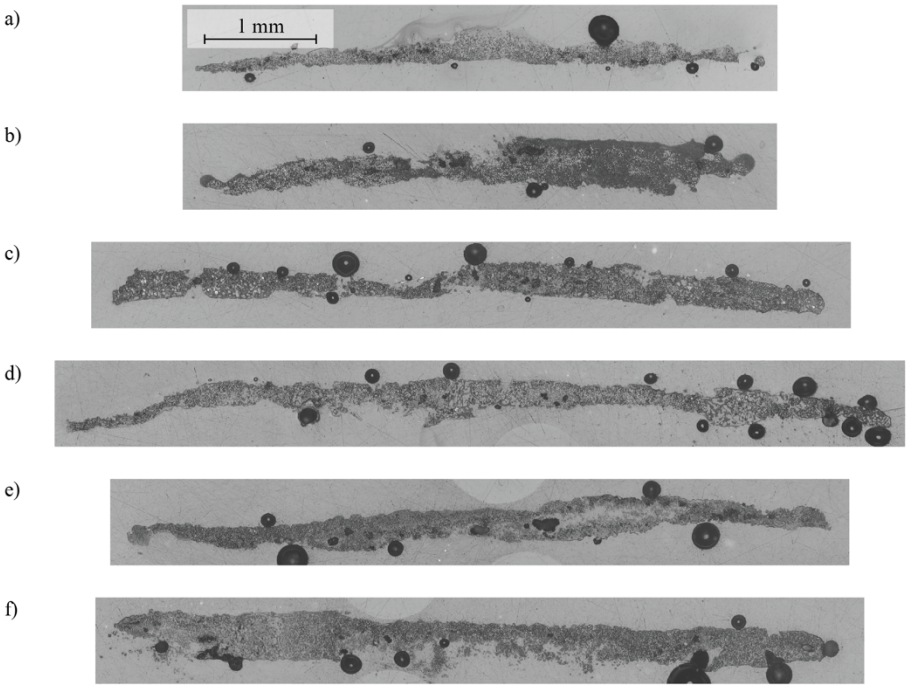

Figure 8: Cross-sectional micrographs of composite tapes constituting (a) CF/PA6, (b) pCF/PA6, (c) CF/PA6/PP, (d) pCF/PA6/PP, (e) CF/rPA6/rLLDPE, and (f) pCF/rPA6/rLLDPE.

Blended polymeric matrices can shape intricate morphologies that strongly govern the composite performance [14]. Micro-scale cross-sectional images of fibre-reinforced PA6/PP and PA6/LLDPE tapes are illustrated in Figures 9a and 9b, respectively. Evidently, the PA6/PP composite, with a 50:50 wt.%, exhibits a co-continuous morphology. The heterogeneous dispersion is especially visible in resin-rich areas. Composites made from the waste film had a mixture ratio disparity (Section 3.1). Hence, it is expected that the LLDPE would form a continuous matrix phase with dispersed PA6 particles. However, the presence of PA6 particles is not easily observed in Figure 9b. It may be that the shredded PA6/LLDPE film did not melt-blend effectively in the single screw extruder, leading to distinct phases at a larger scale. The PA6-LLDPE mixture quality during extrusion and its effect on composite performance must be assessed in future work.

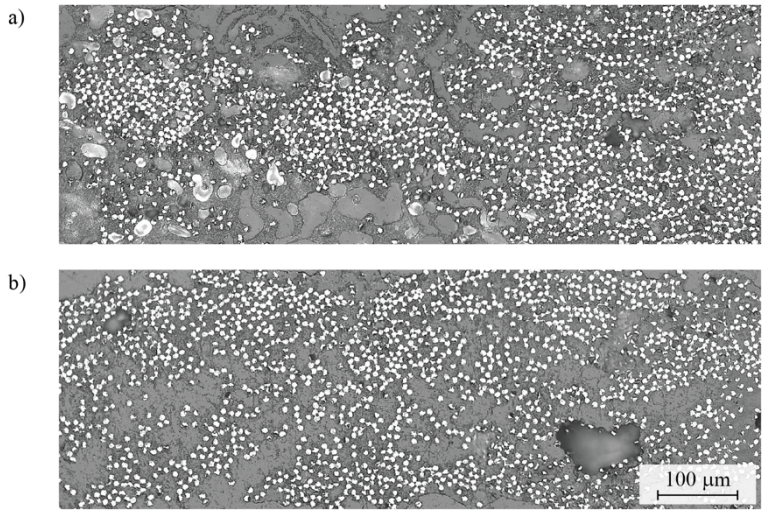

Figure 9: Cross-sectional micrographs of composite tapes constituting (a) CF/PA6/PP and (b) CF/PA6/LLDPE.

The cross-sectional images show that the melt impregnation die can produce high-quality tapes with PA6, PA6/PP, and PA6/LLDPE matrices. Compared to state-of-the-art powder and commingling impregnation processes, the introduced melt impregnator minimises intermediate processing steps, such as powderisation, powder dispersion, or filament drawing. The introduced process is also solvent-free. Everything considered, the plasma-enhanced melt impregnation process minimises environmental harm and processing complexity while facilitating the use of hard-to-recycle polymeric blends, as demonstrated with PA6/PP and PA6/LLDPE. It is a viable process to directly impregnate dry fibres with shredded waste polymer and easily integrates in-line fibre treatment.

3.5 Composite properties

Short beam strength of unidirectional fibre-reinforced samples is plotted in Figure 10. Plasma surface treating the CF statistically significantly increased the short beam strength for composites with PA6 and the PA6/PP matrices. For the first time, we show that in-line plasma surface treating CF increased the mean PA6 and PA6/PP matrix composite short beam strength by 45.2% and 89.8%, respectively. Importantly, the PA6/PP matrix composite made from as-received fibre failed by inelastic deformation (Figure 11). Plasma surface treating CF changed the composite failure to be caused by inelastic deformation and interlaminar shear. Plasma treatment had no effect on composites made from the hard-to-recycle film. These composites also had a significantly lower short beam strength compared to the PA6 and the PA6/PP matrix composites.

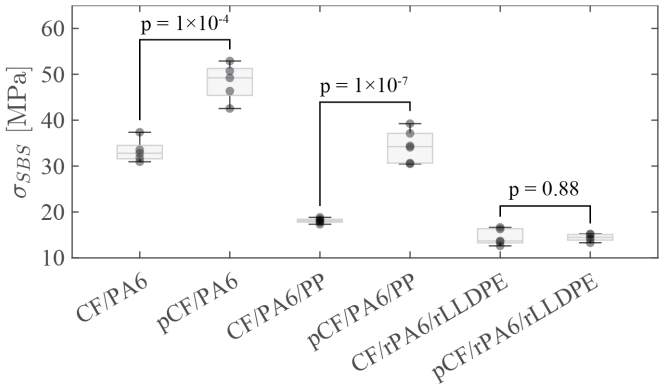

Figure 10: Short beam strength boxplots of unidirectional CF-reinforced (a) PA6, (b) PA6/PP, and (c) recycled PA6/LLDPE. The two-sample t-test statistical significance is indicated between as-received and plasma surface treated CF samples for the three matrix systems.

The short beam strength curves in Figure 11 show that plasma surface treating the CF significantly stiffened the PA6/PP matrix composite and altered the failure mode to inelastic and interlaminar shear. This can be explained by enhanced bonding between the functionalised pCF surface and PA6, constituting 50% of the matrix. Co-continuous PP in the matrix continues to bond poorly to the incompatible PA6 and the functionalised pCF. Composites made from the hard-to-recycle polymer failed inelastically. Plasma treatment had no statistically significant beneficial effect on these composites, suggesting that a higher PA6 content is needed for enhanced bonding with the polar pCF surface. This highlights that the surface functionality must be tailored to suit the polymeric matrix. In the case of PA6/LLDPE waste, the polar PA6 blended with dispersive LLDPE must be compatibilised, for instance, using maleic anhydride [15] or by plasma modifying the bulk polymer blend in a reactive extrusion process [4]. When both matrix constituents are polar, the interface can benefit from a 36% increase in O/C ratio on the CF surface (Section 3.1). Moreover, even if pCF-PA6 bonding is enhanced in the PA6/LLDPE (20:80 wt.%) composite, the small dispersed PA6 content in the LLDPE phase with a seven times lower Young's modulus leads to poor load transfer to the pCF and PA6. The combination of weak interfacial bonding and poor load transfer led to comparatively weak PA6/LLDPE matrix composite performance.

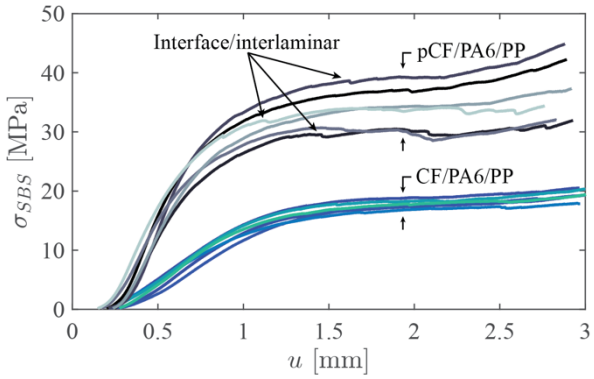

Figure 11: Short beam strength curves for as-received and plasma surface treated unidirectional CF-reinforced PA6/PP composite.

4 CONCLUSIONS

This paper presents two important contributions. Firstly, a novel slot-channel melt impregnation tool was used to produce CF-reinforced tapes from hard-to-recycle polymer blends found in the New Zealand waste stream. Namely, PA6/PP (50:50 wt.%), which was produced from virgin polymer, and

PA6/LLDPE (20:80 wt.%) waste film. Secondly, for the first time, an APPJ treatment was integrated to surface treat CF immediately prior to melt impregnation. During tape production, the in-line plasma treatment enhanced fibre alignment and cohesion in the tow by pneumatic spreading below the jet. As a result, process failures by fibre washout in the melt impregnator channel, which occasionally occurred with as-received fibre, were eliminated. This work demonstrated that increasing the CF surface O/C ratio by 36% leads to significantly enhanced fibre-matrix bonding in compression moulded composites made from melt-impregnated tapes containing primarily PA6. The CF surface treatment increased the mean PA6 and PA6/PP matrix composite short beam strength by 45.2% and 89.8%, respectively. The small PA6 content in the PA6/LLDPE matrix hindered significant composite performance enhancement by polar fibre functionalisation. Consequently, the dry air plasma surface treatment is not compatible with all matrix systems. Specifically, the dry air plasma-modified CF surface is highly compatible with the polar PA6 but remains incompatible with dispersive LLDPE. Hence, a compatibilisation process of the blend is needed for improved composite performance when the dispersive matrix constituent is dominant. Overall, the introduced slot-channel melt impregnation process effectively produces fibre-reinforced hard-to-recycle polymer tapes while minimising additional processing steps that are needed in powder or commingling impregnation. Plasma surface modifying the reinforcement effectively strengthened interfacial adhesion with polar matrix constituents.

ABSTRACT

Fused Filament Fabrication (FFF) using fiber-reinforced thermoplastics is a promising technology for producing fiber-reinforced composite parts with complex geometries, offering structural-grade mechanical behavior along with lightweight properties and recyclability. This study investigates the tensile and failure behavior of composites printed using a dual-nozzle FFF system. Short carbon fiber (SCF)-reinforced nylon was combined with continuous carbon fiber (CCF) nylon layers to produce a hybrid configuration. Various CCF stacking sequences of FFF composite laminates were examined to investigate their impact on the overall mechanical behavior. A finite-element progressive failure (PFA) model was developed using a continuum damage approach. This allowed the prediction of the failure mode in SCF/CCF-reinforced FFF composite and capture various failure modes in the hybrid material system, enabling an understanding of the material's failure behavior. The simulation results were validated using experimental tensile testing for various stacking sequences. The proposed computational approach can be used as a predictive design tool for the mechanical behavior of hybrid fiber-reinforced composites fabricated via FFF.

Keywords: Fiber reinforced composites; Additive manufacturing; Continuum damage mechanics; Progressive failure modeling

1 INTRODUCTION

Advanced carbon fiber–reinforced composites are increasingly adopted in aerospace and other structural applications for their high specific strength and stiffness [1], [2]. Recent additive manufacturing techniques, such as fused filament fabrication (FFF), now enable the fabrication of hybrid composite laminates that combine continuous carbon fiber (CCF) with a short carbon fiber (SCF) reinforced nylon matrix within a single printed part [3]. In this approach, a thermoplastic matrix filament (commercially known as Onyx, containing dispersed short carbon fibers) is interleaved with layers of continuous carbon fiber, resulting in a multi-material laminate structure [3], [4]. Dual-nozzle 3D printers (e.g., Markforged Mark Two) deposit the SCF/ nylon material and embed CCF in specified layers, allowing tailored fiber orientations and placement throughout the part [3]. This hybrid architecture aims to leverage the ease of printing and the toughness of short-fiber nylon material, while harnessing the high load-carrying capability of continuous fiber reinforcement. The resulting printed laminates can achieve structural-grade performance in lightweight designs, with the continuous fibers bearing primary loads and the short-fiber thermoplastic providing matrix support and geometric complexity.

Although the FFF process offers structural and manufacturing advantages, the mechanical response of such hybrid laminates is governed by the complex interaction of multiple constituents and orientations [5]. The presence of two distinct reinforcing forms (continuous fiber layers vs. short-fiber matrix layers) creates multiple potential damage mechanisms that can interact. In matrix-dominated

regions (the SCF/nylon layers and off-axis plies), the material may experience matrix cracking and fiber–matrix interfacial debonding, whereas in fiber-dominated CCF layers, tensile loading can cause abrupt fiber bundle fracture when their strength is exceeded [1]. At the same time, the weak interfaces between dissimilar layers are susceptible to delamination. Experiments on 3D-printed CCF/SCF laminates under flexural and tensile loading indeed reveal a combination of these failure modes. For instance, Barber et al. observed extensive interlayer cracking (delamination) between printed layers at failure, occurring at both homogeneous SCF–SCF interfaces and at the heterogeneous SCF–CCF boundaries, with the SCF–CCF interfaces showing the most severe splitting [3]. Capturing the location and mechanism by which each of these damage modes initiates is crucial for understanding the progressive failure of the hybrid composite.

The mechanical behavior of 3D-printed hybrid composites is primarily governed by their anisotropic, heterogeneous architecture, which combines continuous fiber-dominated layers with more compliant short fiber-filled thermoplastic regions [6]. A clear understanding of how layer orientation, material morphology, and interface design influence the structure–property relationships in these hybrid laminates is essential for advancing their use in structural applications. Under service loads, these hybrid laminates inevitably accumulate damage in multiple modes – e.g., matrix cracking, fiber fracture, fiber/matrix debonding, and inter-layer delamination – all of which progressively degrade the structure's stiffness and strength [1]. Furthermore, phenomenological failure theories (e.g., Tsai–Wu, Hashin) have been developed for composites, achieving reasonable predictions of initial failure to some extent. However, these criteria provide only a static snapshot of failure onset and do not describe how damage propagates. As a result, traditional single-mode or empirical failure models often fail to predict the ultimate strength of hybrid composites when multiple damage mechanisms interact. This limitation motivates the use of a progressive failure analysis (PFA) approach that can track damage initiation and propagation across all relevant modes. While recent studies have explored the mechanical performance of such systems experimentally [1], modeling efforts that quantitatively capture progressive damage and failure evolution in these multi-material, printed architectures remain limited. Existing modeling efforts often rely on simplified elastic assumptions or empirical failure criteria [7], [8], [9], which limits their ability to capture the progressive damage processes that emerge in layered hybrid architectures. More advanced approaches incorporating cohesive zone modeling and continuum damage mechanics (CDMs) have been proposed for conventionally manufactured composites [1], [10], [11], but their extension to printed hybrid composites remains scarce. This study addresses that gap by presenting a progressive failure framework that applies CDMs to simulate multi-mode failure evolution in 3D-printed CF–SCF laminates with varying stacking sequences.

In this study, a finite element-based PFA framework was developed to predict the failure behavior of a hybrid 3D-printed composite laminate reinforced with both short and continuous carbon fibers. The framework incorporates a CDM model for individual plies, featuring cohesive zone elements between layers to simulate interfacial interactions. The hybrid architecture, comprising layers of unidirectional continuous fibers and ±45° short fiber-reinforced plies, introduces complex failure interactions due to differences in fiber length, orientation, and reinforcement scale. The CDM-based approach enables a unified simulation of interacting failure modes. The model emphasizes the role of anisotropic material behavior introduced by the layered deposition process and varying fiber orientations. By tracking damage initiation and evolution at the ply level, the framework captures the onset and progression of failure, providing insights into the underlying failure mechanisms. This CDM-based PFA framework demonstrates its effectiveness in predicting the stress–strain response and failure mode of hybrid printed composites, supporting its applicability for performance-driven virtual testing of additively manufactured composite structures.

2 MATERIAL AND PROCESSING

The composite system investigated in this study consists of a dual-material configuration: a SCF reinforced nylon filament, known commercially as Onyx, and nylon reinforced with CCF. Onyx contained ~30% by weight and serves as the semi-structural material matrix. Though it contains discontinuous carbon fibers for enhanced stiffness and strength, the primary reinforcement is derived from CCF layers.

Fabrication was carried out using a Markforged Mark Two 3D printer, which utilizes FFF. The printer has two independent nozzles integrated into a shared print head, one dedicated to extruding the Onyx matrix and the other to laying CCF along predefined paths. During printing, the Onyx filament is heated and deposited layer by layer to form the structural base. CCF tows are then embedded within specific layers at programmed orientations to reinforce the part. The higher temperature of the extruded Onyx results in localized reheating of the underlying layers, promoting interlayer adhesion.

Dog-bone specimens were designed in Autodesk Inventor, sliced in Eiger.io, and fabricated using a hybrid 3D printing process with Onyx as the matrix material and CCF as reinforcement. Each specimen consists of six embedded CCF layers arranged in one of the following configurations: $[0]_6$, $[90]_6$, $[0/90/0]_6$, and $[60/120/0]_6$. The CCF layers are separated by two-layer SCF interleaf regions with a [+45/−45] raster orientation, which serve to enhance interlaminar bonding and enable more effective load transfer between plies. Additionally, the top and bottom surfaces of the specimen consist of four SCF layers, $[+45/-45]_2$, providing structural symmetry and improved surface quality. This architecture yields a multilayered composite with a hierarchical structure that promotes damage dispersion and load redistribution, as further analyzed. The stacking configurations and print orientations of the tested specimens are summarized in Table 1. Fig. 1 illustrates the composite architecture and internal structure. A schematic of the laminate illustrates the stacked configuration of CCF and SCF layers, while microscopic imaging of a representative sample reveals the layered morphology and typical porosity features throughout the laminate. The magnified image of the SCF interleaf reveals void clustering along raster boundaries—features that may impact interfacial strength.

Drying was performed in a closed oven at 70 °C (below the glass transition temperature of nylon), with samples covered in release film to prevent sticking. Moisture removal from the nylon matrix improves stress distribution and increases mechanical strength by mitigating plasticization effects.

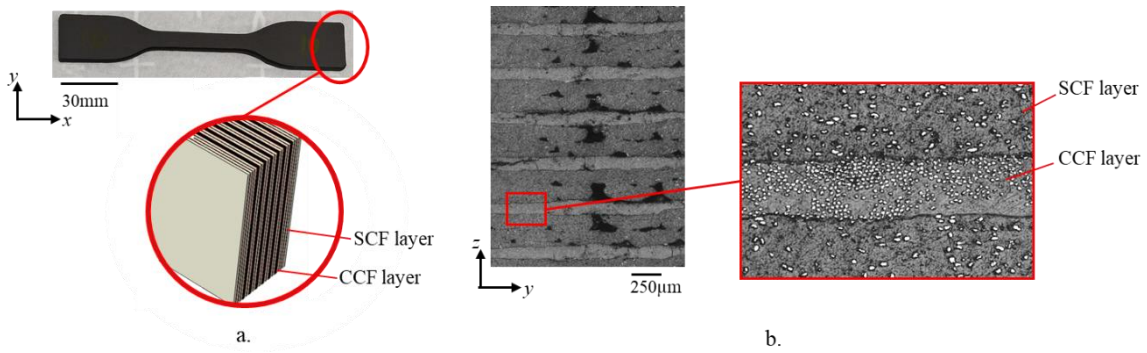

Fig. 1 (a) Geometry and layered architecture of the 3D-printed composite specimen. (b) Cross-sectional microstructure

Table 1. Layered Architecture of Hybrid CCF and SCF Laminates

Sample ID	CCF Orientation	SCF Orientation	SCF Layering Structure
S1	$[0]_6$	[+45/–45]	2 SCF layers between CCFs; outer SCF layers: $[+45/–45]_2$
S2	$[90]_6$	[+45/–45]	Same as above
S3	$[0/90/0]_s$	[+45/–45]	Same as above
S4	$[60/120/0]_s$	[+45/–45]	Same as above

3 EXPERIMENTAL CHARACTERIZATION METHODS

3.1 Mechanical Testing

Tensile testing of dog-bone samples was conducted using an MTS Systems. The samples were tested

with a crosshead rate at 1 mm/min until failure occurred. The MTS machine used for tensile testing is equipped with TestWorks4 software. Tensile tests were conducted on each sample with different layer print orientations. After the failure, the stress-strain curves are obtained from each test run.

3.2 SEM Analysis

Microscopic analysis, using scanning electron microscopy (SEM), was employed to investigate the fracture surface morphology of the post-mortem tensile samples. Representative sections of each sample type were used for microstructural analysis. Before imaging, the samples were sputter-coated with a thin layer of Au to enhance surface conductivity and image quality under the SEM. High-resolution SEM images were acquired to examine fracture surfaces and identify failure mechanisms.

4 MODELING PROCEDURE

A finite element analysis (FEA) was used to simulate the tensile behavior of 3D-printed samples. FEA simulation was performed using the Abaqus Implicit commercial software. The model accounted for the material with the printed stacking of SCF and CCF reinforcement. Finite element domains were assigned coordinate systems for every printed layer with a specified material orientation to represent the orientation during printing. CDM was used to model the homogenized material behavior of SCF and CCF layers, assuming transverse isotropy. Cohesive interfaces were implemented to model interactions between the layers by defining the bonding behavior.

4.1 Virtual Sample Modeling Generation

A custom Python-based script was developed and integrated with Abaqus to automate the generation of FEA models for 3D-printed composites. A virtual specimen of 3D printed material is modeled as a continuum in (x, y, z) space (Fig. 2). The stacking structure is generated with specified stacking sequences, ply orientations, thicknesses, material properties, mesh configurations, and cohesive interfaces. The geometry of the laminated composite was defined based on user inputs for the number of stackings, ply orientations, and thicknesses. Each layer was meshed with assigned element orientations using a discrete field. The meshing resolution was controlled using input parameters for element size, allowing accurate modeling of the laminated structure. Sub-domains were assigned local coordinate systems $(1,2)$ to represent individual stacking orientation (Fig 2b). Cohesive interfaces were implemented between each layer to simulate interlaminar bonding. Traction-separation laws were assigned to model the interaction and failure behavior at the interfaces. Cohesive tie constraints were defined to link the cohesive layers with adjacent plies, enabling the simulation of delamination and interfacial failure under tensile loading. Boundary conditions were applied to replicate tensile testing, including displacement and fixed constraints. CDM was implemented to capture progressive damage and failure behavior in the plies.

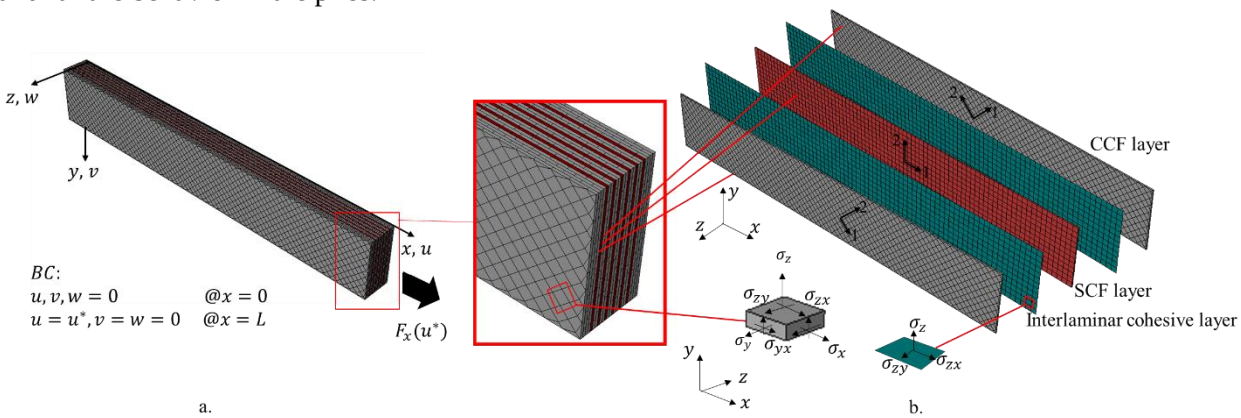

Figure 2 a. Generated morphology of virtual 3D printed sample b. The orientation of the stacking

4.2 Constitutive Properties and Damage Modeling for Bundles

A continuum damage model was employed to describe the failure modes in the longitudinal and transverse planes of the 3D-printed materials. A user material (UMAT) FORTRAN subroutine for Abaqus standard implicit was used to simulate the damage initiation and propagation in the printing direction and transverse plane. The longitudinal damage, d_1, considers stiffness degradation in the direction of the freeze-casting, while the transverse damage index, d_2, reflects the degradation of the material stiffness in the transverse direction to the printing direction. The material constitutive relationship followed the transversely isotropic behavior, as shown in Eq. 1.

$$\begin{bmatrix}\sigma_{11}\\ \sigma_{22}\\ \sigma_{33}\\ \sigma_{12}\\ \sigma_{13}\\ \sigma_{23}\end{bmatrix}=\begin{bmatrix}C_{11} & C_{12} & C_{13} & 0 & 0 & 0\\ C_{12} & C_{22} & C_{23} & 0 & 0 & 0\\ C_{13} & C_{23} & C_{33} & 0 & 0 & 0\\ 0 & 0 & 0 & C_{44} & 0 & 0\\ 0 & 0 & 0 & 0 & C_{55} & 0\\ 0 & 0 & 0 & 0 & 0 & C_{66}\end{bmatrix}\times\begin{bmatrix}\varepsilon_{11}\\ \varepsilon_{22}\\ \varepsilon_{33}\\ \gamma_{12}\\ \gamma_{13}\\ \gamma_{23}\end{bmatrix} \quad (1)$$

where C_{ij} is the damaged stiffness matrix depending on the undamaged stiffness components (C_{ij}^0) and damage variables in principal directions (d_{i}). The damage stiffness components were defined by Eq. 2.

$$\begin{aligned} &C_{11}=(1-d_1)C_{11}^0;\ C_{12}=(1-d_1)(1-d_2)C_{12}^0\ ; \quad (2)\\ &C_{13}=(1-d_1)(1-d_2)C_{13}^0\ ;\ C_{22}=(1-d_2)C_{22}^0;\\ &C_{23}=(1-d_2)C_{23}^0\ ;\ C_{33}=(1-d_2)C_{33}^0\ ;\ C_{44}=(1-d_1)(1-d_2)C_{44}^0\ ;\\ &C_{55}=(1-d_1)(1-d_2)C_{55}^0\ ;\ C_{66}=(1-d_2)C_{66}^0 \end{aligned}$$

Eq. 3 shows the damage initiation criteria, f_1, in the printing direction when the corresponding criterion reaches one. Hill's anisotropic failure criterion, f_2, was used to define the damage initiation in the transverse plane (Eq. 4).

$$f_1=\sqrt{\frac{\sigma_{11}^2}{\sigma_{11}^{f,t}\sigma_{11}^{f,c}}+\sigma_{11}\times\left(\frac{1}{\sigma_{11}^{f,t}}-\frac{1}{\sigma_{11}^{f,c}}\right)} \quad (3)$$

$$f_2=\sqrt{\left(\frac{1}{\sigma_{22}^{f,c^2}}-\frac{1}{2\sigma_{11}^{f,c^2}}\right)(\sigma_{22}-\sigma_{33})^2+\frac{1}{\sigma_{23}^{f\ 2}}\sigma_{23}^2} \quad (4)$$

where $\sigma_{\mathrm{ii}}^{f,t}$ and $\sigma_{\mathrm{ii}}^{f,c}$ are the failure stresses in the principal directions in tension and compression, respectively. The damage variables (d_1 and d_2), evolves from 0 to 1, where 0 represents the undamaged material, and one corresponds to the fully damaged state (E. 5).

$$d_i=1-\frac{\sigma_{\mathrm{ii}}^f}{C_{\mathrm{ii}}f_{\mathrm{i}}}\exp\left(\frac{\sigma_{\mathrm{ii}}^f\left(\sigma_{\mathrm{ii}}^f/C_{\mathrm{ii}}-f_{\mathrm{i}}\right)l^*}{G_c}\right),i=1,2 \quad (5)$$

where, l^* is the characteristic element length associated with the material and G_c is the fracture energy in the lamellar direction. Material constitutive properties for CCF and SCF stacking are represented in Tables 2-3 and are derived using micromechanical models as described in Appendix A.1 and A.2. The assigned transverse tensile strength for the CCF layers reflects the influence of the ductile SCF matrix in which the continuous carbon fibers are embedded. While this value is higher than typical for thermoset-based unidirectional laminates, it is consistent with prior observations in layered

discontinuous fiber composite (LDFC) systems, where matrix ductility and constrained damage propagation contribute to enhanced transverse performance [12], [13].

Table 2. Stiffness and strength properties for 3D printed CCF layers

Material property	Value
Longitudinal modulus, $\boldsymbol{E_{11}(MPa)}$	60,000
Transverse modulus, $\boldsymbol{E_{22}}$, $\boldsymbol{E_{33}(MPa)}$	5,000
Shear modulus, $\boldsymbol{G_{12}}$, $\boldsymbol{G_{13}(MPa)}$	3,000
Shear modulus, $\boldsymbol{G_{23}(MPa)}$	1,000
Poisson's ratios,$\boldsymbol{\nu_{12}}$, $\boldsymbol{\nu_{13}}$	0.29
Longitudinal tensile strength,$\boldsymbol{F_{1t}(MPa)}$	100
Transverse tensile strength,$\boldsymbol{F_{2t}(MPa)}$	200
Fracture energy $\boldsymbol{G_c[kJ/m^2]}$	8

Table 3. Stiffness and strength properties for 3D printed SCF layers

Material property	Value
Longitudinal modulus, $\boldsymbol{E_{11}(MPa)}$	5,000
Transverse modulus, $\boldsymbol{E_{22}}$, $\boldsymbol{E_{33}(MPa)}$	1,800
Shear modulus, $\boldsymbol{G_{12}}$, $\boldsymbol{G_{13}(MPa)}$	2,000
Shear modulus, $\boldsymbol{G_{23}(MPa)}$	690
Poisson's ratios,$\boldsymbol{\nu_{12}}$, $\boldsymbol{\nu_{13}}$	0.38
Longitudinal tensile strength,$\boldsymbol{F_{1t}(MPa)}$	100
Transverse tensile strength,$\boldsymbol{F_{2t}(MPa)}$	50
Fracture energy $\boldsymbol{G_c[kJ/m^2]}$	4

The CDM with transversely isotropic damage for 3D printed stacking combined with a cohesive zone modeling (CZM) at the interfaces between printed stacking to capture debonding using a traction separation law. Eq. 6 shows the constitutive equation of traction separation, where interlaminar σ_{ij} stress, δ_j is the relative separation between the elements, d is the damage variable, and $k_i^0 = 730 \times 10^6\, {MPa}/{mm}$ is the initial stiffness.

$$\begin{bmatrix}\sigma_{13}\\ \sigma_{23}\\ \sigma_{33}\end{bmatrix}=\begin{bmatrix}(1-d)k_1^0 & 0 & 0\\ 0 & (1-d)k_2^0 & 0\\ 0 & 0 & (1-d)k_3^0\end{bmatrix}\begin{bmatrix}\delta_1\\ \delta_2\\ \delta_3\end{bmatrix} \quad (6)$$

The failure initiation criterion of the delamination between the printed layers is given by Eq. 7 where $N_{max} = 40\ MPa$ and $S_{max} = T_{max} = 60\ MPa$ represent the normal and shear cohesive strengths, respectively.

$$(\frac{\sigma_{33}}{N_{max}})^2 + (\frac{\sigma_{13}}{S_{max}})^2 + (\frac{\sigma_{23}}{T_{max}})^2 = 1 \quad (7)$$

The propagation of the delamination is defined by a linear fracture mechanism of power law through Eq. 8 [14].

$$\frac{G_I}{G_{IC}} + \frac{G_{II}}{G_{IIC}} + \frac{G_{III}}{G_{IIIC}} = 1 \quad (8)$$

where G_I, G_{II}, G_{III} are the work done by the tractions and their corresponding displacements in the normal and shear directions, and $G_{IC}, G_{IIC}, G_{IIIC}$ are the critical strain energy release rates corresponding to the fracture modes, where $G_{IC} = 1\ ^{kJ}/_{m^2}, G_{IIC} = G_{IIIC} = 2\ ^{kJ}/_{m^2}$.

5 NUMERICAL AND EXPERIMENTAL RESULTS

5.1 Comparison of Experimental and Numerical Modeling Predictions

Figure 3 shows the stress–strain behavior of 3D-printed composite laminates consisting of CCF/LCF layers. Four different CCF stacking sequences, [0], [0/90/0], [60/120/0], and [90], are examined under uniaxial tensile loading, with both experimental results and simulation data presented for comparison. Figure 4 compares the average UTS of hybrid 3D-printed laminates. Experimental results are shown with error bars representing standard deviation, while red markers indicate predictions from simulations. The [0] CCF laminate exhibits the highest stiffness and strength, as the fiber alignment is parallel to the loading direction, and the ±45° SCF layers provide additional shear resistance without significantly compromising axial load transfer. The [90] CCF laminate, with fibers oriented transverse to the loading direction, exhibits the lowest tensile strength and stiffness, as the load is primarily borne by the ±45° SCF layers, which have lower axial modulus compared to the CCF interlayers. The $[0/90/0]_s$ and $[60/120/0]_s$ laminates demonstrate intermediate strengths, governed by the presence of off-axis CCF layers that reduce axial stiffness, while the alternating ±45° SCF layers enhance damage tolerance and redistribute local stress. The simulation results, based on continuum damage mechanics, align well with the experimental data, capturing the variation in stiffness, peak strength, and strain at failure across stacking sequences. These findings confirm the role of CCF layup design and the synergy between reinforcement and matrix orientations in determining the strength of additively manufactured composite laminates.

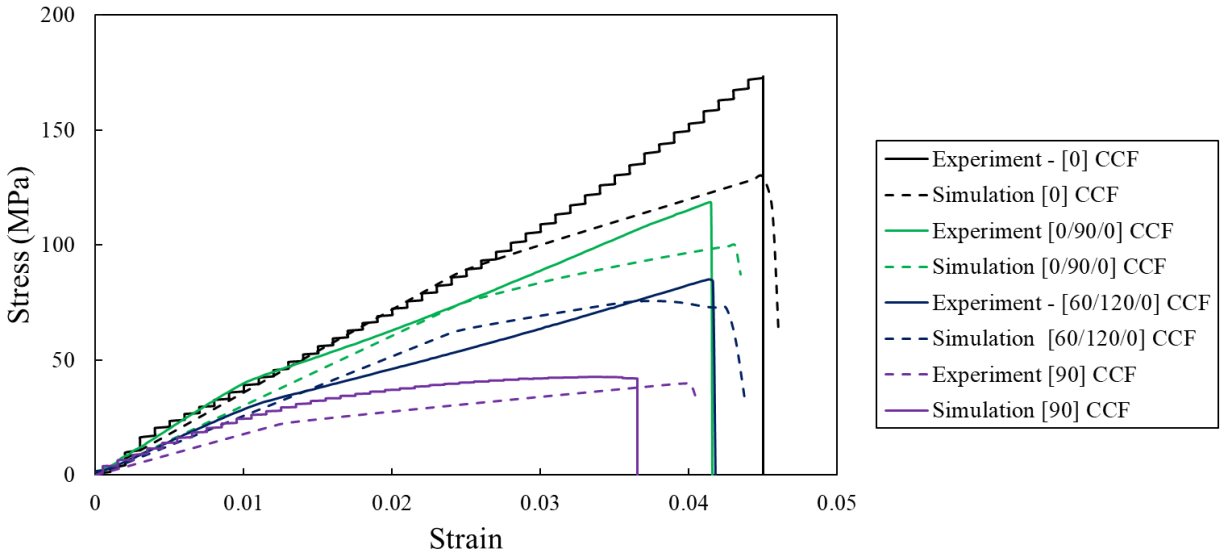

Figure 3. Stress–strain curves from experimental tests and finite element simulations for hybrid 3D-printed polymer composite laminates with different CCF stacking

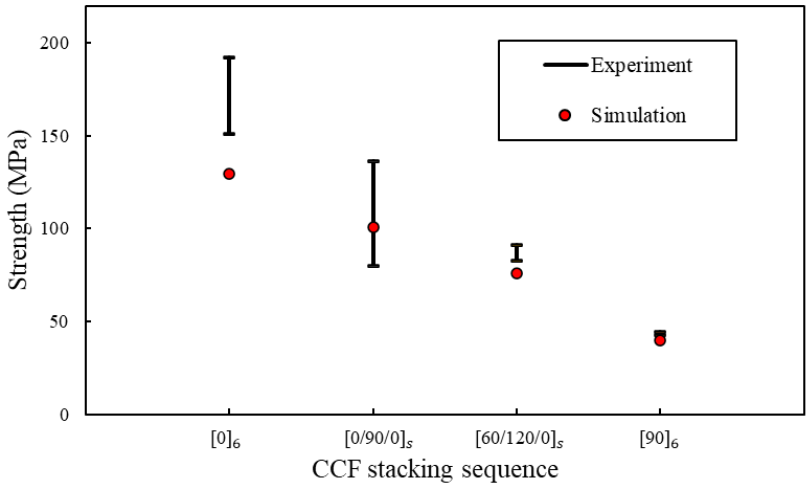

Figure 4. Comparison of experimental and simulation results for the ultimate tensile strength of hybrid 3D-printed polymer composite laminates with different CCF stacking.

5.2 Damage Propagation

Failure in the hybrid 3D-printed polymer composite laminate arises from the complex interplay of multiple damage mechanisms, including fiber/matrix debonding, matrix cracking, interstacking delamination, and fiber pull-out. The damage is spatially distributed throughout the composite volume, reflecting the heterogeneous nature of the printed architecture and interfaces. Initiation and propagation occur concurrently at multiple sites, driven by the tailored stacking sequence and directional deposition of both continuous and short fibers. This architecture introduces intrinsic structural redundancy, allowing for local load redistribution after damage initiates. As a result, the laminate exhibits multi-site failure behavior.

The fracture surfaces observed in the SEM images (Fig 5) reveal mix-mode failure mechanisms within the 3D-printed composite laminate composed of CCF and SCF matrix stacking. Figures a. and b. shows the fracture surface of $[0]_6$ CCF stacking sample (200×) and highlights failure in the continuous fiber region, where long, aligned fibers exhibit pull-out and interfacial debonding. This suggests that failure was dominated by fiber–matrix interface separation. Fig. 5b (350×) shows the fracture surface of the SCF stacking region, characterized by a rough short fiber pull-out and matrix cracking.

Figures c. and d. shows the fracture surface of $[90]_6$ CCF stacking sample. Long-aligned fibers protrude from the matrix, indicating a dominant fiber pull-out mechanism. The gaps between the matrix and fibers suggest interfacial debonding between the CF and the surrounding polymer. Figure d shows the visible gaps between the stacking point and interlaminar delamination and interstacking shearing. Figures e. and f. show the fracture surface of $[60/120/0]_s$ CCF stacking sample. Figure F's upper stacking displays SCF stacking with rough, polymer-rich morphology, randomly oriented broken fibers, and matrix cracking. The central region includes a distinct, aligned bundle of CF, indicating fiber pullout and matrix fiber debonding.

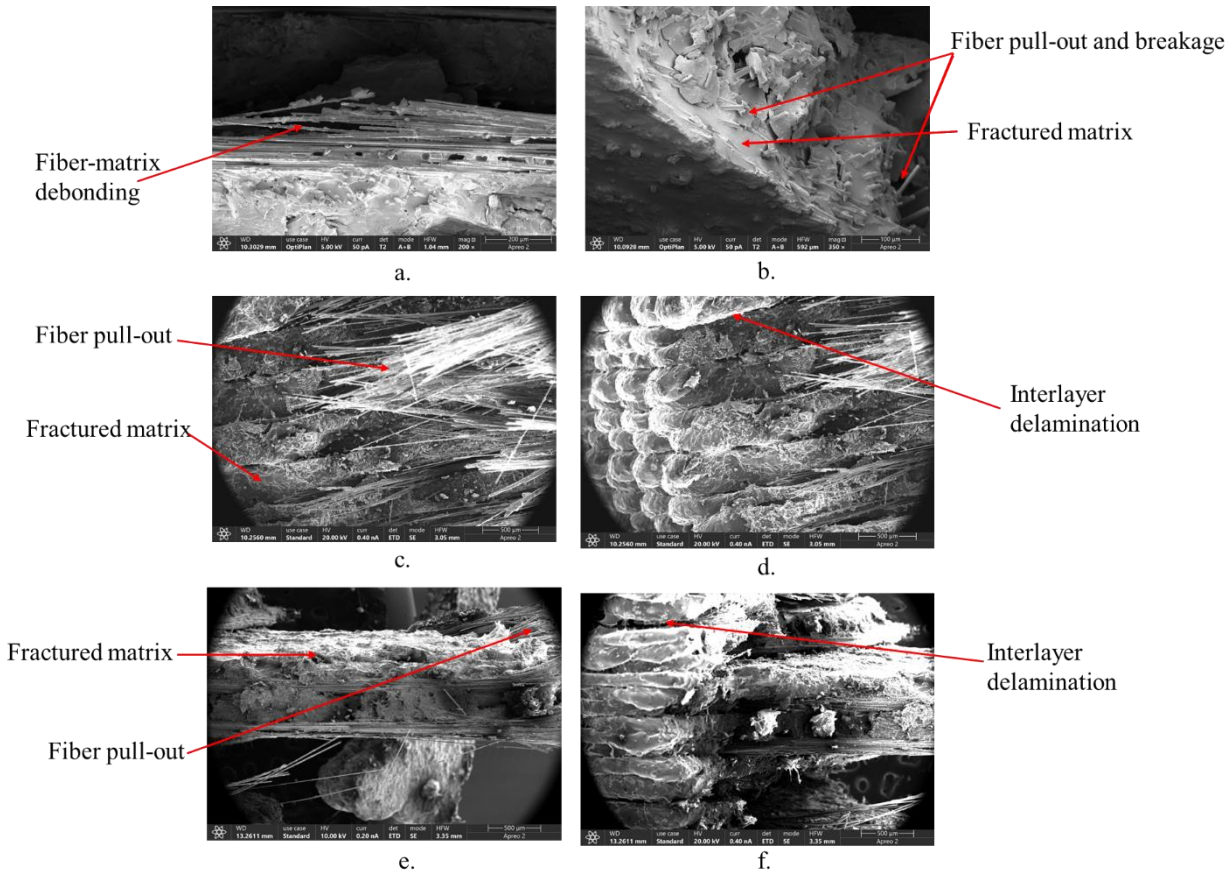

Figure 5. SEM images of fracture surfaces in hybrid 3D-printed polymer composite laminates with continuous carbon fiber (CCF) interstacking: (a) and (b) correspond to the $[0]_6$ stacking, (c) and (d) to the $[90]_6$ stacking, and (e) and (f) to the $[60/120/0]_s$ stacking configuration.

Figure 6 illustrates the cumulative relative frequency distributions of the damage variables in the simulations. The figure highlights distinct damage indices in the fiber direction (d_1) and the transverse direction (d_2), revealing the directionality and progression of failure at peak stress. The 0° CCF stacking exhibits concentrated and localized damage in the fiber direction (d_1), which can be attributed to the fiber breakage under axial tensile loading. This confirms that the stacking is the primary load-bearing component, effectively resisting tensile stress until failure initiation. Transverse damage (d_2) in these stackings remains limited and confined, suggesting strong out-of-plane stability and minimal matrix cracking attributed to the alignment and stiffness of the continuous fibers. In contrast, this configuration's SCF stacking displays more widespread and diffused damage patterns. The d_1 field in the SCF stacking shows scattered failure. The d_2 damage in these regions is more prominent and spatially extended, indicating matrix-dominated transverse cracking and reduced out-of-plane resistance.

In the $[90]_6$ CCF sample, the layers are oriented perpendicular to the loading direction, resulting in negligible or delayed fiber-aligned damage. Consequently, they do not significantly contribute to axial load bearing. Instead, transverse damage becomes dominant, manifesting as matrix cracking. The simulation results also show the dominant d_2 damage for CCF and SCF stacking.

The $[0/90/0]_s$ interstacking CCF laminate**,** the 90° CCF, and the SCF stacking dominate the transverse damage (d_2) field. This pattern reflects the matrix-dominated failure behavior of the 90° plies, which contribute minimally to axial strength. The SCF stacking further exhibits extensive transverse matrix cracking due to shear-induced stresses. In the $[60/120/0]_s$ CCF laminate, the d_2 field shows localized transverse damage in the 60° and 120° CCF stacking. The SCF stacking exhibits widespread

transverse damage, as seen in extended matrix cracking and interfacial failure under combined transverse and shear loading.

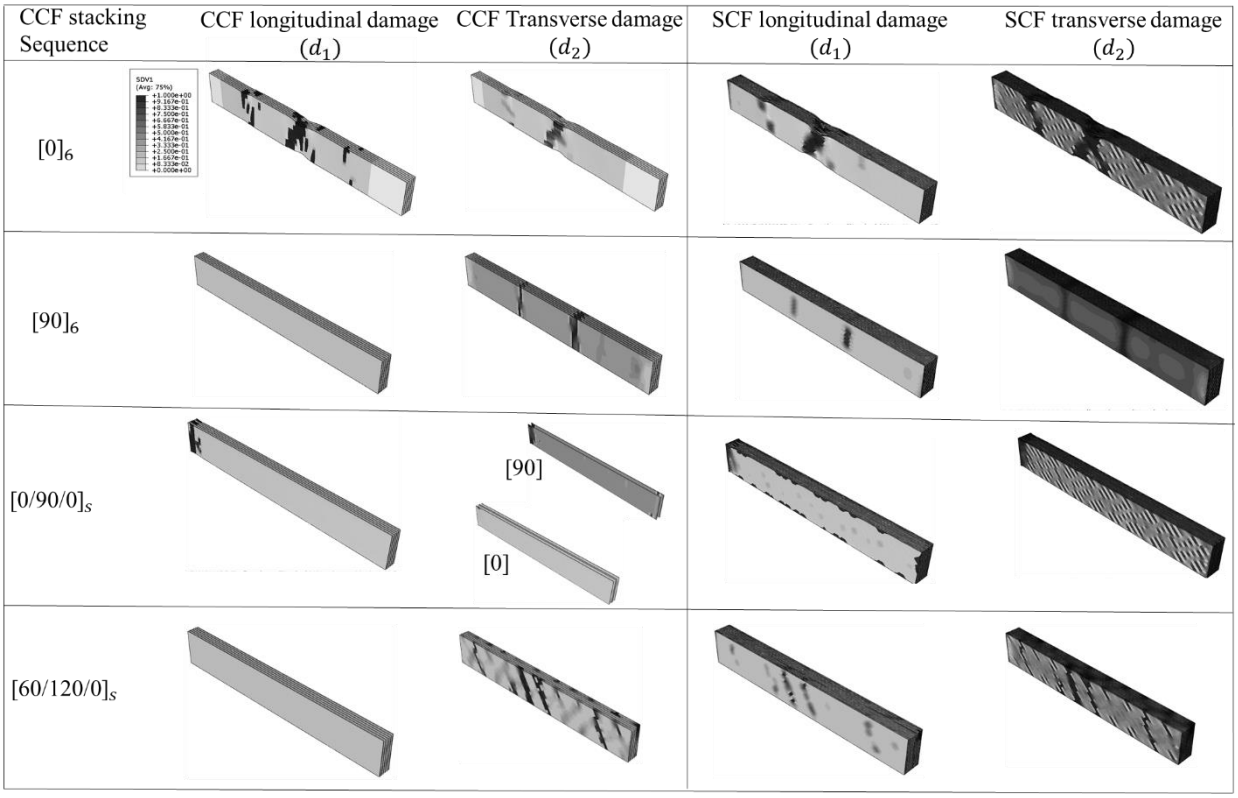

Figure 6. This is an example of a figure.FE simulation results showing fiber-direction (d_1) and transverse (d_2) damage distributions in 3D-printed laminates with various CCF stacking configurations

6 CONCLUSIONS

This study developed and validated a progressive failure modeling framework for 3D-printed hybrid composite laminates composed of CCF and SCF-nylon to predict mechanical behavior and failure evolution. Various stacking sequences were fabricated to investigate the influence of fiber orientation and hybrid architecture on mechanical performance. The finite element model, based on CDM, captured intralaminar damage mechanisms, such as fiber fracture and matrix cracking, as well as interlaminar delamination through cohesive interface modeling. The model showed close agreement with experimental tensile results, not only in terms of ultimate tensile strength and stiffness but also in spatial damage distribution, except for the [0]° CCF configuration, where the prediction underestimates the strength due to limitations in calibrating the longitudinal tensile strength and fiber-dominated failure parameters. Results revealed that stacking configurations with off-axis CCF layers and SCF interleaves led to higher accumulation of transverse and shear-driven damage, while unidirectional fiber alignments promoted fiber-dominated failure. While further calibration of principal material properties is warranted, this modeling framework enables the predictive analysis of printed composites with variable fiber orientations and material interactions, supporting virtual design optimization in advanced engineering applications.

APPENDIX A

A.1 Constitutive Properties of CCF

The printed CCF stackings are modeled as a unidirectional composite of continuous carbon fibers embedded in the SCF matrix. The fibers are assumed to be perfectly aligned in the 1-direction (longitudinal), and the composite is treated as anisotropic.

The fiber volume fraction is V_f= 0.4. The constituent properties used in the calculations are:
- Carbon fiber: $E_f =$ 190 GPa, $G_f = 20$ GPa, $\nu_f = 0.2$
- SCF matrix: $E_m =$ 1.8 GPa, $G_m = 0.7$ GPa, $\nu_m = 0.42$
Longitudinal modulus (: E_{11}) is calculated using the Rule of Mixtures:

$$E_{11} = V_f \times E_f + (1 - V_f) \times E_m \quad \text{(A-1)}$$

To account for imperfections and practical limitations, a conservative value of E_{11} = 60,000 MPa is assigned.

Transverse modulus (E_{22} = E_{33}) is estimated using the Inverse Rule of Mixtures:

$$1/E_{22} = V_f/E_f + (1 - V_f)/E_m \quad \text{(A-2)}$$

Shear moduli (G_{12} = G_{13}):

$$1/G_{12} = V_f/G_f + (1 - V_f)/G_m \quad \text{(A-3)}$$

Transverse shear modulus (G_{23}) is matrix-dominated: $G_{23} \approx G_m$= 1,000 MPa
Poisson's Ratios:

$$\nu_{12} = V_f \times \nu_f + (1 - V_f) \times \nu_m \quad \text{(A-4)}$$

$\nu_{13} = \nu_{12}$ (assumed symmetry)
Longitudinal tensile strength (F_{1t}):

$$F_{1t} = V_f \times \sigma_f + (1 - V_f) \times \sigma_m \quad \text{(A-5)}$$

($\sigma_f = 2000MPa, \sigma_m = 80MPa$)

A.1 Constitutive Properties of SCF Layers

Fibers in these layers are assumed to be partially aligned due to the extrusion process, and the resulting material is treated as anisotropic.

The effective elastic modulus is calculated using the Halpin–Tsai equation:

$$E_c = E_m \times [(1 + \xi \times \eta \times V_f)/(1 - \eta \times V_f)] \quad \text{(A-6)}$$

where

$$\eta = (\frac{E_f}{E_m} - 1)/(\frac{E_f}{E_m} + \xi) \quad \text{(A-7)}$$

(ξ = 2)

Tensile strength is estimated using a modified Rule of Mixtures:

$$\sigma_c = \eta_0 \times \beta \times V_f \times \sigma_f + (1 - V_f) \times \sigma_m \quad \text{(A-8)}$$

η_0 = 0.4 (orientation efficiency), β = 0.6 (length efficiency)

ABSTRACT

Thermoplastic composites can play a key role in developing future forms of transportation due to their high mechanical performance as well as their wide range of automatable joining and manufacturing methods. Thermoplastic welding techniques like induction and resistance welding provide flexible joining methods for many applications such as skin-stringer joints in an aircraft fuselage. With various welding processes existing, finding a suitable testing method to compare these processes would be beneficial. This paper shows the sensitivity of an ASTM D3165 based testing method (designated as double-notched tension test in this paper) especially to notch depth, as well as the three different laminate layups. It highlights the challenges to sample preparation and result interpretation, as well as the suitability of the testing method for the comparison of different welding techniques. Virtual testing is performed with a continuum damage finite element model, which is capable of mapping inter and intra-laminar failure, as well as failure of the welding zone itself to gain insight into the mechanical behavior of the tested sample.

1 INTRODUCTION

Upcoming urban and advanced air mobility (UAM & AAM), as well as new generation single aisle aircraft raise the need to evolve established materials and processes to enable manufacturers to satisfy the rising demand for all types of aircraft. Global commercial aircraft OEM forecast that traffic will more than double in the next two decades, requiring more than 40,000 aircraft deliveries, depending on high-rate capable production technologies. The Multi-Functional Fuselage Demonstrator (MFFD) developed and manufactured as part of the Clean Sky 2 Program with 14 project participants shows the application of over 40 airframe production technologies, highlighting dustless joining with thermoplastic welding methods. [1]

Manufacturing targets of electric vertical take-off and landing vehicle (eVTOL) OEM have been constantly adapted over the last years [2] and are highly depending on regulatory requirements, which are widely still work in progress like in the “Innovate28” plan of the Federal Aviation Administration (FAA). Nevertheless, when successfully regulated, that type of aircraft is capable of further improving urban transportation [3], since it offers a safer, quieter, more economic aircraft, compared to common vertical take-off and landing vehicles such as helicopters. [4]

Essential for the application of this material class is the understanding and consideration of various factors, like material behavior and testing, process-specific characteristics or numerical simulation methods. This paper addresses the applicability of a specific testing method (ASTM D3165) for thermoplastic welded joints as well as its numerical analysis with finite element (FE) simulation to find out if it's suitable for the quantitative comparison of different adherend architectures and welding procedures.

2 TEST DESCRIPTION

The test selected to compare different welding techniques is based on the ASTM D3165 - "Standard Test Method for Strength Properties of Adhesives in Shear by Tension Loading of Single-Lap-Joint Laminated Assemblies" [5] and further designated as double-notched tension test (DNT) within this paper. The schematical test setup can be seen in Figure 1. There are several sound reasons for choosing that specific testing method. Firstly, the geometrically induced secondary bending is reduced, compared to the commonly used single lap shear test, since the specimen is providing a higher bending stiffness outside the shear zone due to increased specimen thickness. Also edge effects showing up in joining and manufacturing processes, for instance during induction welding, can be reduced. Examples would include no excess matrix material which would normally squeeze out at the overlap edges of a single lap shear test (Kupski et. al [6] considered the induced skew for adhesively bonded single lap joints) or increased current densities near the edge [7,8] when joining with induction welding. Further, the steps of the test procedure show low complexity, which enables an efficient execution of test campaigns on common universal testing machines.

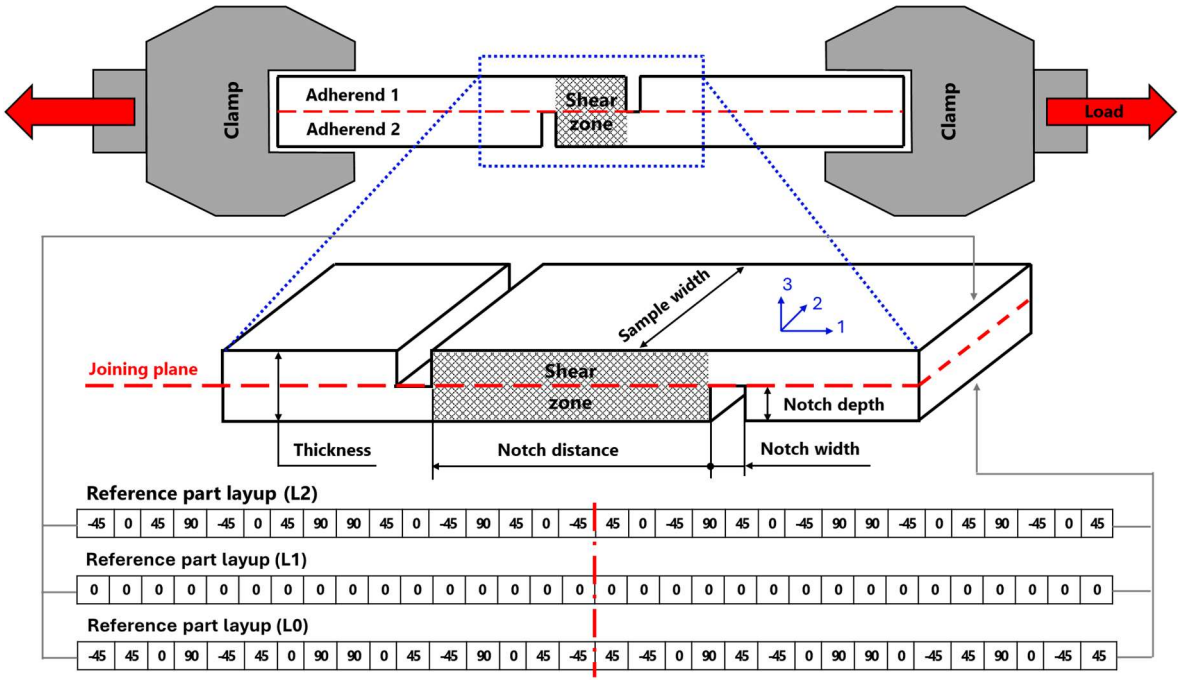

Figure 1: Schematical test setup and layup description.

The load is applied with a displacement rate of 1.27 mm/min via clamps to the specimen, where the load is transferred to the shear zone through a combination of shear and peel forces, resulting in a multiaxial stress state of the specimen. This scenario reflects critical, as well as relevant loading conditions when thinking of welded, thin-walled composite shell components.

3 SPECIMEN DESCRIPTION

The material used in this research is Toray® Cetex® TC1225, a unidirectional carbon fiber reinforced semi-crystalline low melt polyaryletherketone (PAEK) Tape from Toray Advanced Composites (TAC), the Netherlands. Considering future component manufacturing, the UD tape material is processed to laminate plates in a hot press, previous the actual joining procedure. This way, the material is experiencing the pressure and temperature it would receive in an actual manufacturing process like thermoforming. That's reasonable since the high process temperatures around 400°C can lead to degradation of the thermoplastic matrix material, which stayed well below 5% within this research.

After the hot press consolidation, the manufactured composite laminate plates are co-consolidated in an autoclave according to the processing guidelines for TC1225 LMPAEK composites from TAC, providing sample plates, from which the actual specimen are manufactured by milling. The specimens tested have a total length of 175 mm, a sample width of 25 mm and a notch distance of 12.7 mm. The notch depth as well as the thickness of the laminate varied over the specimen.

4 NUMERICAL SIMULATION

This study employs the finite element analysis software *Abaqus/Explicit* to perform dynamic structural simulations of the Double-Notched Tension (DNT) test. The numerical model is designed to replicate the experimental setup with high fidelity, enabling detailed investigation of damage initiation and progression within the composite structure. The following sections describe the modeling approach, material definitions, boundary conditions, and contact formulations used in the simulation framework.

4.1 Material Parameter

Due to the limited availability of material-specific parameters, the simulation model was based on data from the literature corresponding to a similar material system—an unidirectional carbon fiber-reinforced high-performance thermoplastic polymer. The material parameters used in the simulations are summarized in Table 1.

Material parameter		Value
E_1	[MPa]	138300
$E_{2,\,3}$	[MPa]	10400
$\nu_{12,\,13}$	–	0.316
ν_{23}	–	0.487
$G_{12,\,13}$	[MPa]	5190
G_{23}	[MPa]	3500*
X_T	[MPa]	2350
X_C	[MPa]	1621
Y_T	[MPa]	87
Y_C	[MPa]	273
$S_{12,5\%}$	[MPa]	90
S_{13}	[MPa]	90
S_{23}	[MPa]	90
G_{Ic}	[kJ/m^2]	0.7
G_{IIc}	[kJ/m^2]	1.45
η_{BK}	–	2.9
ζ_{1+}	[kJ/m^2]	125
ζ_{1-}	[kJ/m^2]	61
ζ_{2+}	[kJ/m^2]	1.12
ζ_{2-}	[kJ/m^2]	18.3

* $G_{23} = E_3 / (2 * (1 + \nu_{23}))$

Table 1: Material parameter for numerical simulation. [9, 10, 11]

4.2 Modelling Technique

An explicit finite element model was developed employing continuum shell elements to represent the composite plies. Interply and welding zone behavior were incorporated using a general cohesive contact formulation. Each individual ply was discretized with a single element through its thickness, and the built-in Hashin continuum damage model in Abaqus was utilized to simulate energy-based matrix and fiber damage, as well as ply failure.

The interply and welding zones were modeled using general contact with defined contact pairs, each assigned cohesive properties to capture energy-based cohesive damage and failure mechanisms. Load application was implemented by coupling the specimen's end surfaces to a reference point via tie constraints, where boundary conditions were imposed. A steadily increasing velocity was applied at the reference point to introduce the quasistatic displacement speed of the testing machine. Figure 2 shows a schematical representation of the FE Model.

A mesh convergence study was performed to validate the accuracy of the explicit dynamic structural simulations conducted in Abaqus/Explicit. The model was discretized using the SC8R elements. Several mesh densities were evaluated, focusing on key response parameters such as stress distribution and nodal displacements. Convergence was observed with a mesh consisting of approximately 438,000 elements and 897,000 nodes, beyond which further refinement produced negligible changes in the results. This mesh configuration was therefore adopted for all subsequent analyses to ensure computational efficiency without compromising accuracy.

To find out how valid the resulting simulation outcomes of this modelling technique are, the test shown in [11] was simulated with the modelling technique and simulation data described and shown above. The resulting failure load of the simulation is well withing the test range shown in [11].

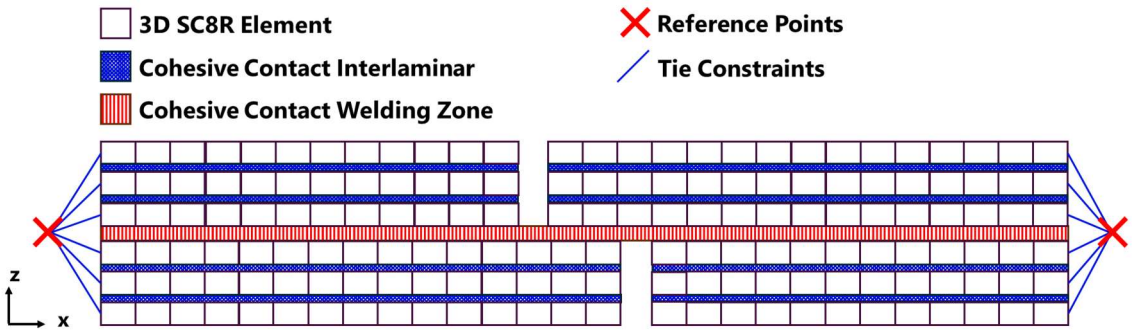

Figure 2: Schematical representation of FE model.

4.3 Virtual Testing of Notch Depth Variation

To investigate the impact of different parameters, a virtual testing is performed. Specifically, a variation of the notch depth for three different Layups is presented within this paper.

During the research it was found that the notches, which are milled in the double-notched tension specimens, are one of the most challenging topics in the manufacturing process of the test samples. For that reason, the effect of possible deviations in the depth of the notches was investigated by virtual testing. In more detail, the notch depth varied from ± 2 plies around the welding plane, which would result in a total amount of possible configurations of $2^5 = 32$ for two notches. That number was reduced to 15 when accounting for symmetries. The simulated configurations can be seen in Figure 2, where the notch-overlap u is introduced in Equation 1 as the difference between the total of the notch depths d_1 and d_2 and the laminate thickness T, where all values are discrete with increments of the ply thickness t. A positive notch-overlap indicates the number of milled-through plies, whereas a negative notch-overlap shows the number of continuous plies, which do not get machined at all.

$$u = (d_1 + d_2) - T$$
$$d_1,\ d_2,\ T \in \{n \cdot t \mid n \in \mathbb{N}^0\} \tag{1}$$

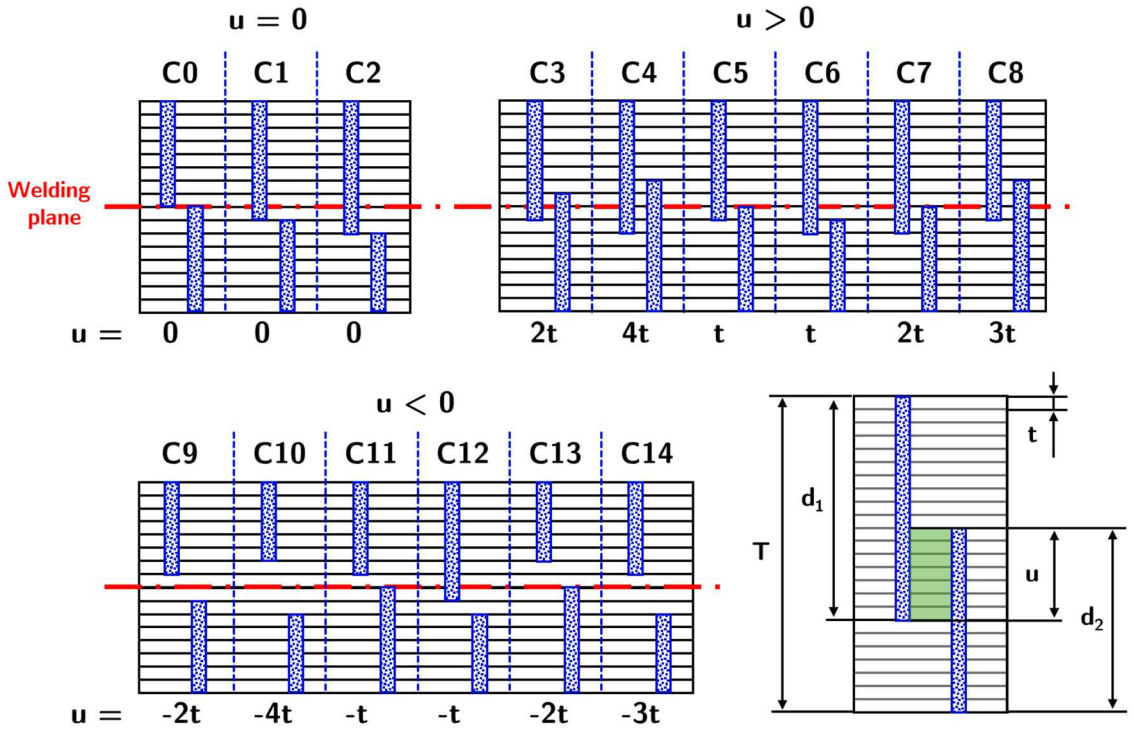

Figure 2: Virtual tested notch depth configurations.

5 RESULTS

The results of the virtual testing of the notch depth variation can be seen in Figure 3. For comparison, the resulting failure loads of the respective simulations have been normalized about configuration 0 of layup 0. The graph shows that some laminate configurations are more sensitive to the introduced notch overlap than others. For laminate 1 the notch overlap has a high impact on the resulting failure load, where laminate 0 shows to be less sensitive.

L2 has, similar like L0, a quad based symmetric layup. They differ by the quad sequence -(-45/45/0/90) for L0 and (-45/0/45/90) for L2. Compared to L0 the simulation results show higher values for L2, when the 0° ply near the welding zone is still intact. Once that ply gets separated, the laminate performs worse than L0. This behavior is most likely due to the fact that of all plies in the quasi-isotropic laminate, the 0° plies are delivering the highest proportion to the laminate's bending stiffness. Once they are damaged, the bending stiffness drops dramatically and the flexural deformation is increased, which reduces the load transmission through shear and increases bending and peel stresses.

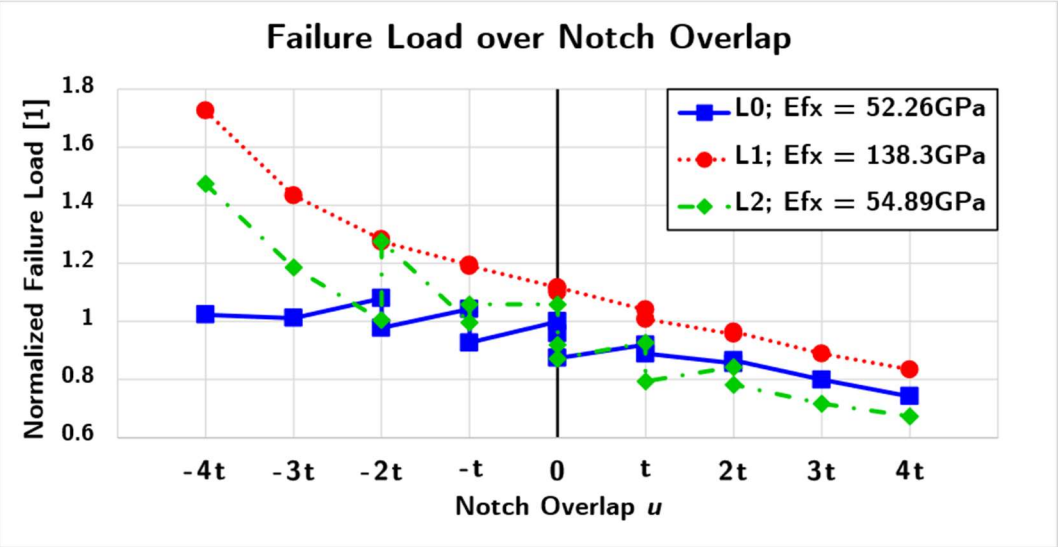

Figure 3: Virtual testing failure load results over notch overlap *u*.

The normalized results for the mechanical testing can be seen in Figure 4. The test value highlighted with a circle in Figure 4 serves as the reference for the normalization of the test data. It is related to the simulation value and multiplied by the baseline used for the normalization of the simulation data.

The results of the mechanical testing are indicating a dependence of the resulting failure load to the introduced notch depth machined in the samples. Further L1 is showing significant higher failure load values than L0 and L2.

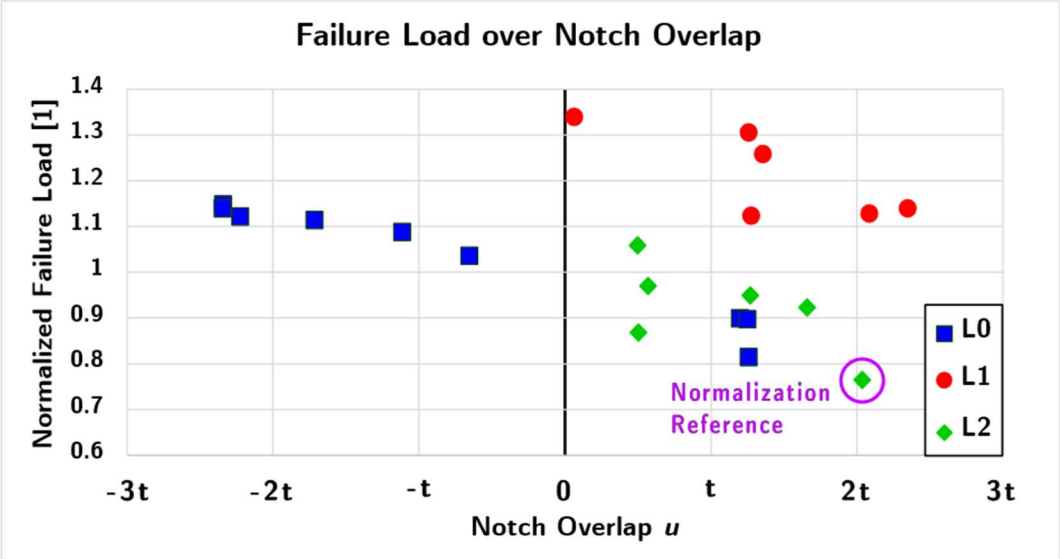

Figure 4: Mechanical testing failure load results over notch overlap *u*.

Figure 5 shows the results of the mechanical (MT) and virtual testing (VT). Simulation as well as mechanical testing results show both a tendency of decreasing failure load with increasing notch overlap.The simulation and the tested samples show good agreement for L0 and L2. For L1 the simulation shows an underestimation compared to the failure laod of the mechanical tests.

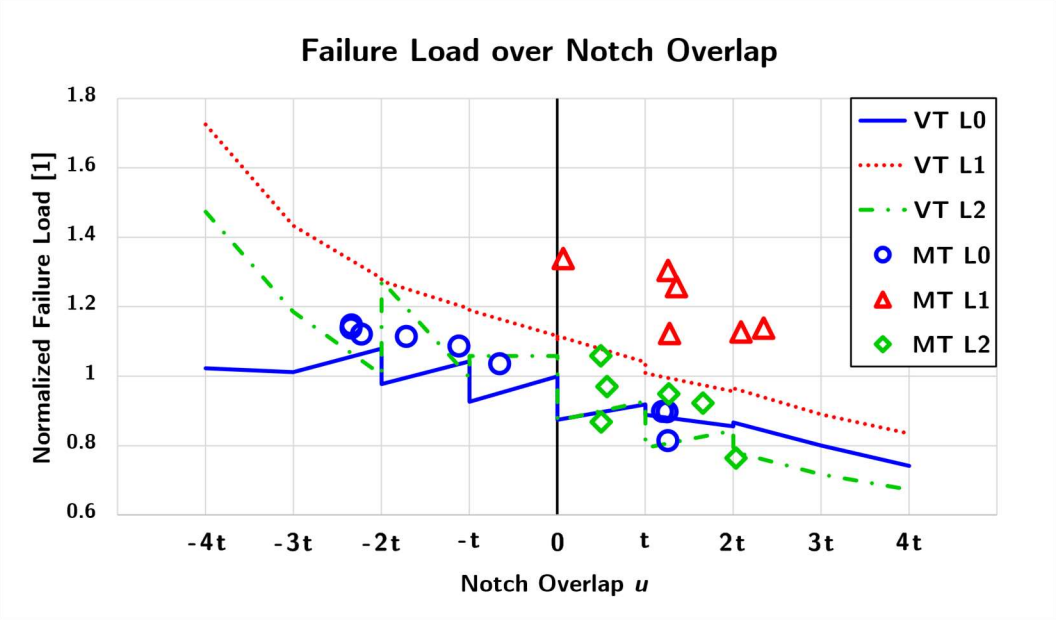

Figure 5: Comparison of virtual and mechanical testing: failure load result over notch overlap u.

6 CONCLUSIONS

The results of the mechanical and virtual testing strongly indicate a dependency of the failure load on the notch depths of the double-notched tension test specimens, which also prove to be layup dependent. This dependency is further influenced by the laminate layup, with a major effect observed when 0°-plies are cut.

For accurate and reliable results, it is crucial to precisely determine the notch depths prior to mechanical testing to ensure all plies are correctly machined.

In scenarios, where intact, continuous plies are still present (configurations with a negative notch overlap parameter u), the test primarily measures the tensile strength of the intact plies rather than the weld performance, leading to questionable conclusions regarding the weld's integrity. Therefore, test configurations with intact continuous plies are not recommended.

While the present study focuses on the influence of the notch overlap parameter u, it is important to acknowledge that the actual position of the overlap can also play a significant role in the resulting failure load, particularly depending on the laminate layup and the position of the 0°-plies. In certain configurations, the notch overlap may be less critical, still delivering usable results for comparison. Further investigations are necessary to comprehensively understand the influence of the notch overlap's position. The notch centroid is proposed as a useful parameter for identifying the actual overlap position, offering the possibility for a more detailed insight, than the current overlap parameter alone.

The double-notched tension test demonstrates potential as a comparative method for evaluating welded laminates, provided that high precision and low tolerance are guaranteed during notch manufacturing. The acceptable tolerance is, however, dependent on the laminate layup and the position of the 0°-plies within. It must be noted that this test method exhibits high sensitivity to relatively small deviations in notch depth, indicating a lack of robustness. Consequently, the applicability of the double-notched tension test requires detailed evaluation for each specific case to ensure its suitability and the reliability of the obtained results.

Physics-Based Process Simulation

- Physics-based modelling is founded on our understanding of causality of events
- The phenomena of interest are modelled using mathematical representations
- In Process Simulation, a physics-based model needs to include representations of:
  - **Material**
  - **Shape**
  - **Tooling**
  - **Equipment**
  - **Process**
- The more complex the system, the more useful process simulation becomes!
- Process simulation should be used at all stages of the lifecycle of a product, even before building the equipment and tooling

Importance of Crystallization/Melt Kinetics

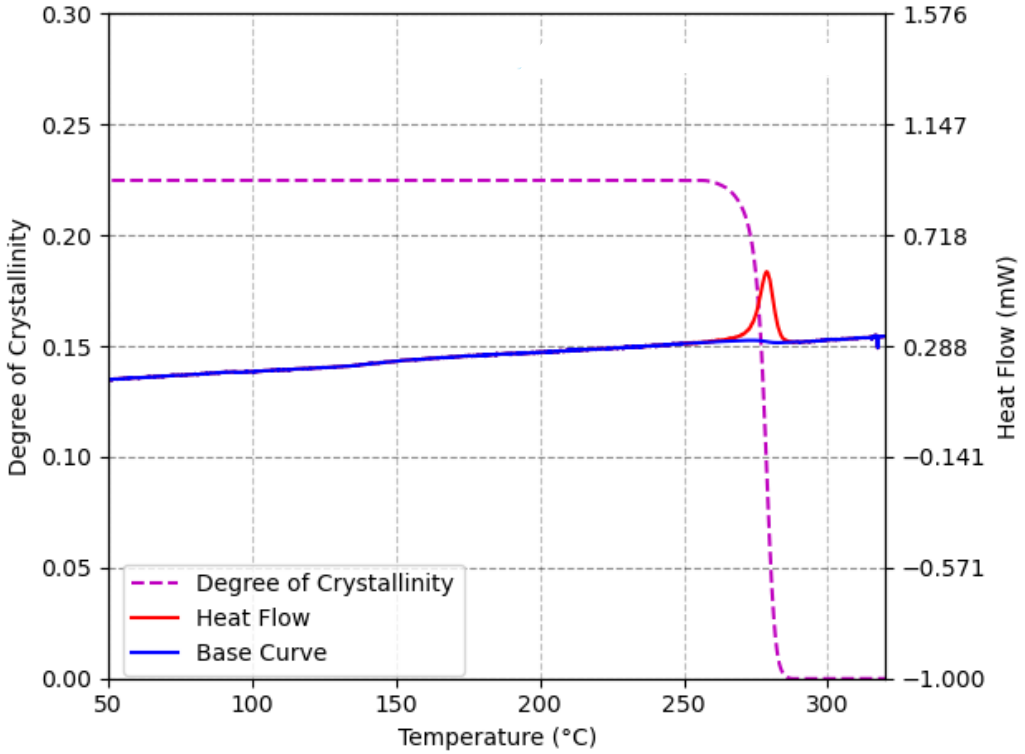
- Degree of crystallinity: Key state variable for all downstream material models in thermoplastic composites process simulation.
- Thermoplastic composites continuously undergo crystallization and melting during manufacturing processes.
- Cooling rate significantly impacts the degree of crystallinity in the final composite part.
- Unlike thermoset cure kinetics, thermoplastic crystallization kinetics can be influenced by the fiber type.

Importance of Crystallization/Melt Kinetics

- Toray Cetex® TC1225 LM-PAEK composites:
  - Lower processing temperatures due to reduced melt temperature.
  - High service temperatures comparable to PEEK and PEKK due to similar glass transition temperatures.

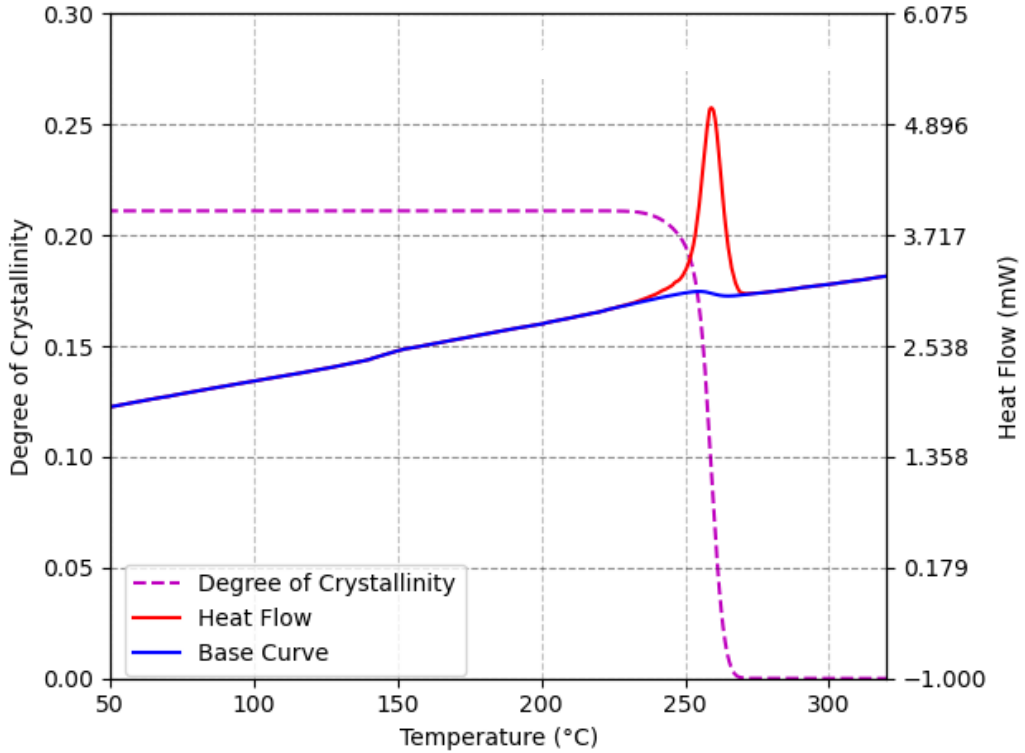
- TC1225 UD tapes available with various fibers, notably T700G and T1100G.

- Study objectives:
  - Investigate cooling rate and fiber type (T700G, T1100G) effects on crystallization behaviour.
  - Develop crystallization/melt kinetics models for accurate process simulations.



Materials and Methodology

- Case Study Materials:
  - Toray Cetex® TC1225 LM-PAEK UD tape, two fibre types:
    - T1100G
    - T700G
  - $T_g = 147\ ℃\ (297\ °F)$
  - $T_m^0 = 305\ ℃\ (581\ °F)$
  - Processing temperature: $340 - 385\ ℃\ (644 - 725\ °F)$
  - Resin mass fraction: 34%



- Differential Scanning Calorimetry (DSC) tests (Using a PerkinElmer DSC 8500 machine):
  - Dynamic melt crystallization tests (1 CPM – 250 CPM)
  - Isothermal melt crystallization tests
  - Dynamic melting tests (1 CPM – 250 CPM)

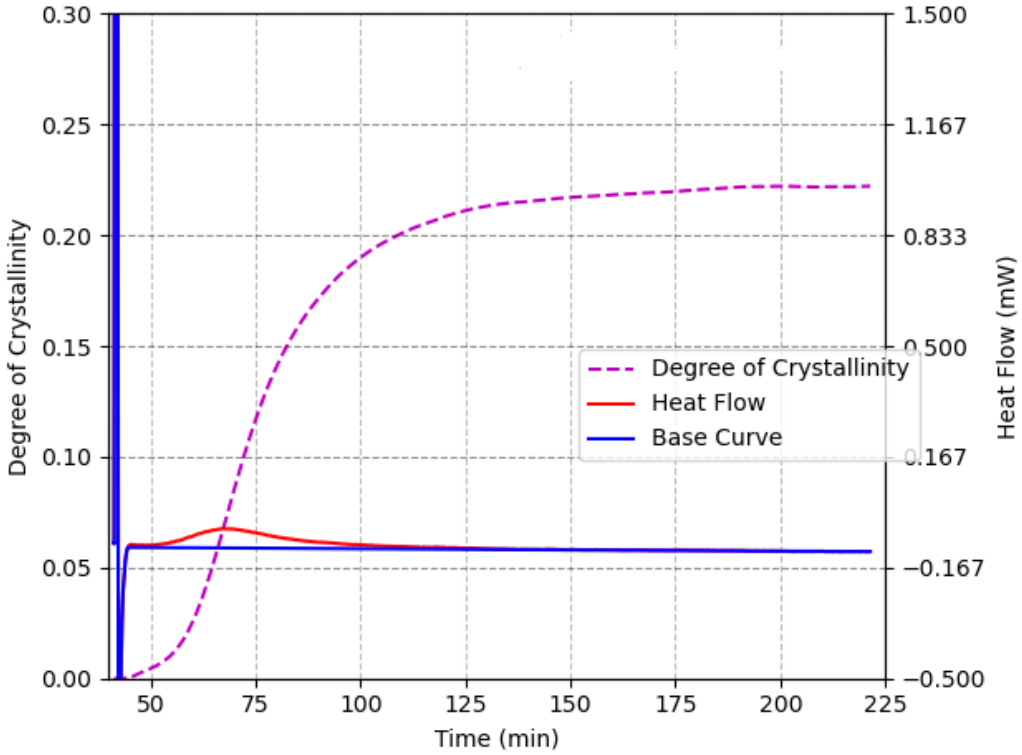
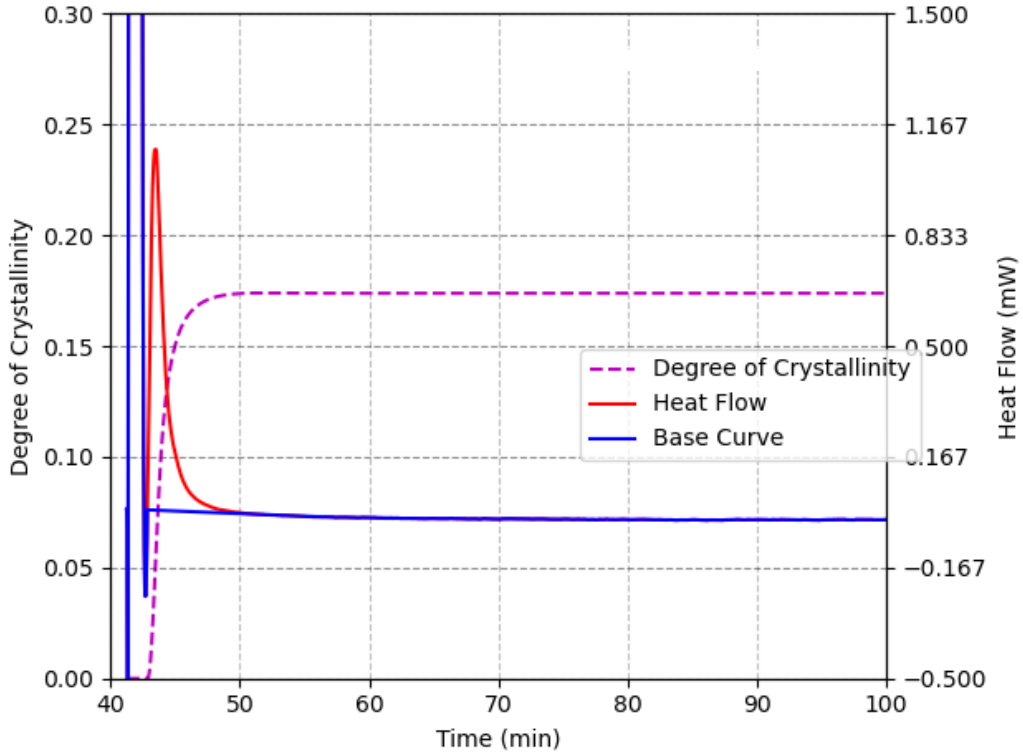
Cooling at 90 ℃/min



Effect of Cooling Rate on Crystallization

- Experimental Observations:
  - Increasing the cooling rate shifts crystallization initiation to lower temperatures.
  - Completion of crystallization also occurs at lower temperatures as cooling rate increases.



- Impact on Degree of Crystallinity:
  - Higher cooling rates lead to a decrease in the final degree of crystallinity.
  - Reduced crystallinity can influence mechanical and thermal performance of the composite.

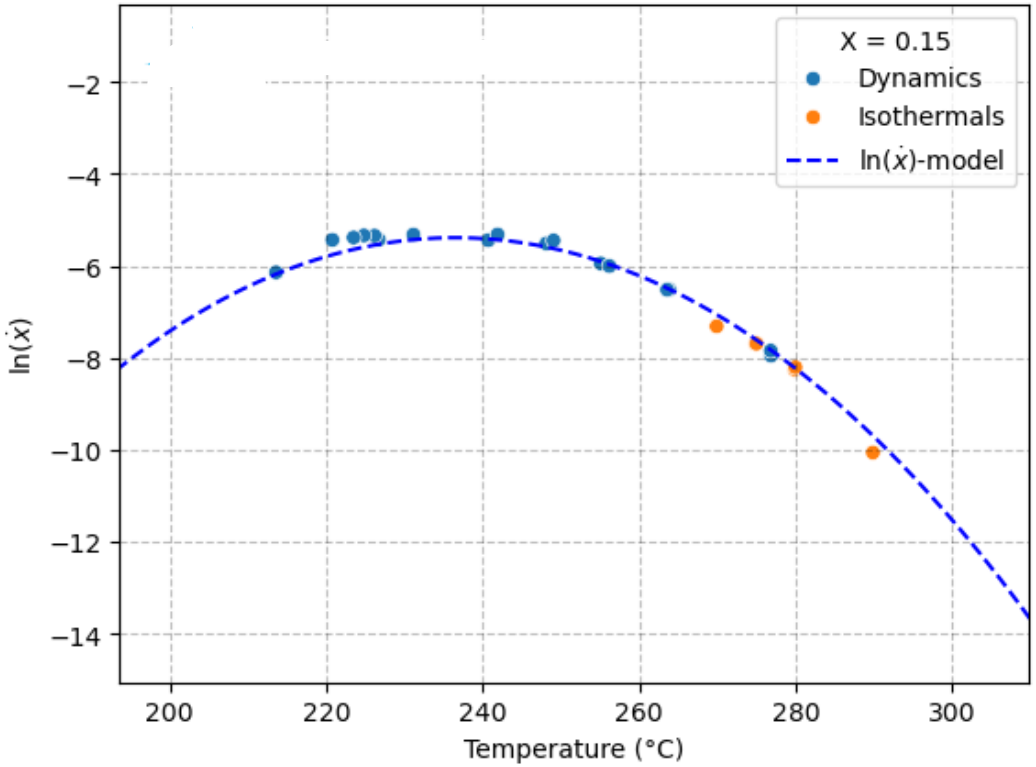
Crystallization-Melt Kinetics

- Most of the works in the literature consider isothermal or non-isothermal crystallization, separately, while in reality, cycles are combined
- Most crystallization kinetics models in the literature do not account for the induction time
- There are very few works which consider melt kinetics models



- We believe that state-of-the-art crystallization/melt kinetics models for thermoplastics must include:
  - Rate type (differential form): suitable for an arbitrary temperature cycle
  - Induction time
  - Accurate representation of melt kinetics

Crystallization Kinetics

Iso-conversional Crystallization Data – T1100G Fibre

$X = 0.02$

$X = 0.15$

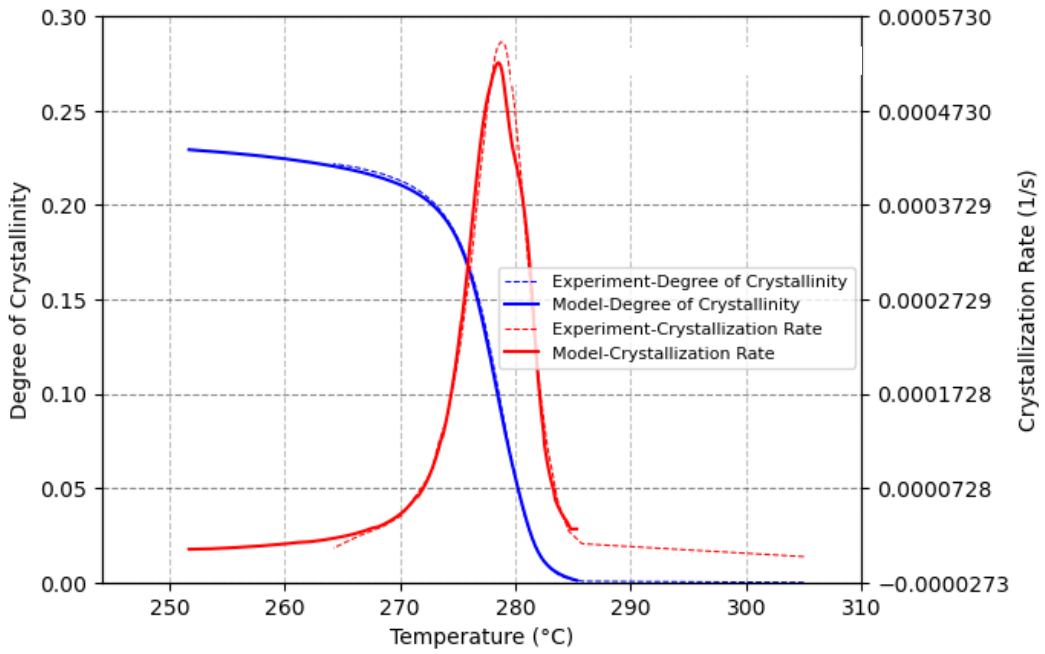
Crystallization Kinetics Model

- No significant difference in crystallization mechanisms in isothermal and non-isothermal crystallization.

$$\frac{dX}{dt} = K(T)f(X)$$

- Two competing mechanisms in crystallization:

$$(T_m^0 - T) \nearrow \Rightarrow \frac{dX}{dt} \nearrow \qquad (T - T_g) \searrow \Rightarrow \frac{dX}{dt} \searrow$$



$$K(T) = K_0 e^{\frac{-E_g}{R(T-T_g)}} e^{\frac{-E_m}{R(T_m^0-T)}}$$

- There is an “induction time” model to capture the induction time or incubation period.

Model: Effect of Fibre Type

Can one material model predict the crystallization kinetics of CF/LM-PAEK for another fiber type?

Understanding and Modeling the Effect of Fiber Type on the Crystallization Kinetics of a Thermoplastic Matrix Composite
Tristan Wiedmann, MASc Thesis, Institute of Aircraft Design, University of Stuttgart, August 2024

Summary and Conclusions

- Toray Cetex® TC1225 LM-PAEK/T1100G UD tape and Toray Cetex® TC1225 LM-PAEK/T700G UD tape were characterized for crystallization and melt kinetics
- Increasing the cooling rate shifts crystallization initiation to lower temperatures.
- Higher cooling rates lead to a decrease in the final degree of crystallinity.
- Fiber type affects both the induction time and the crystallization behavior. A complete crystallization kinetics characterization is required for each fiber type.

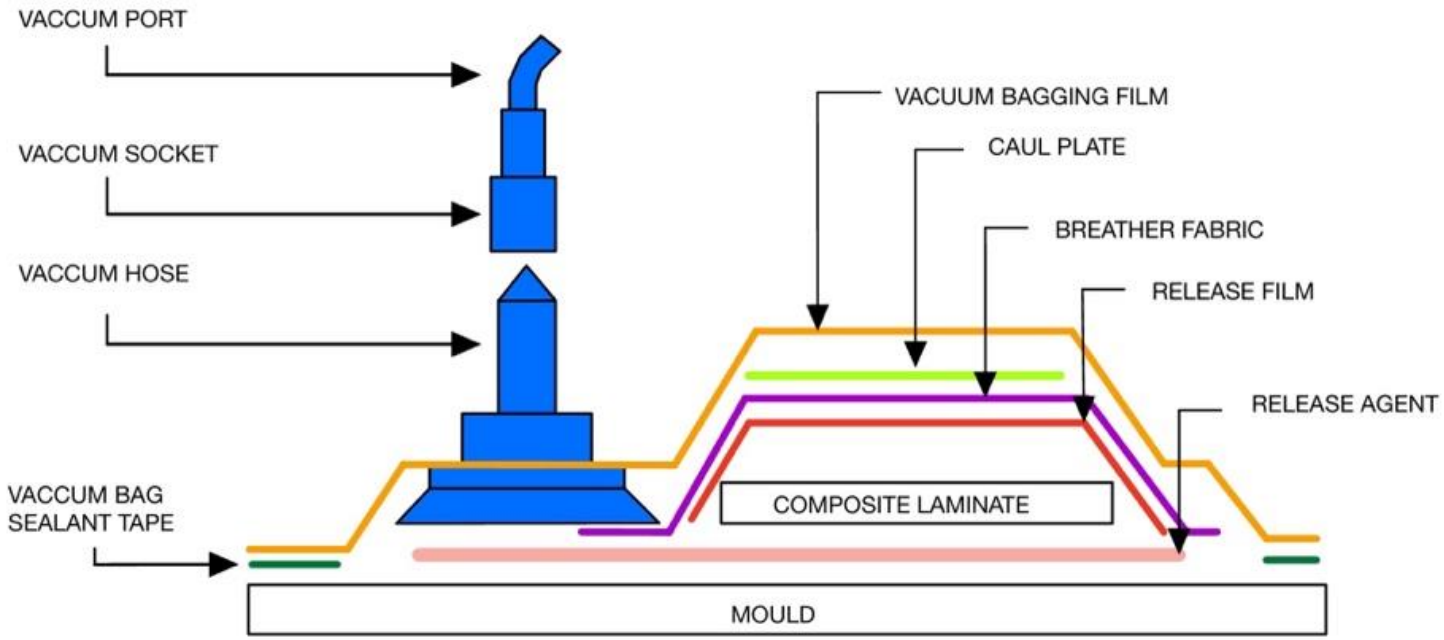
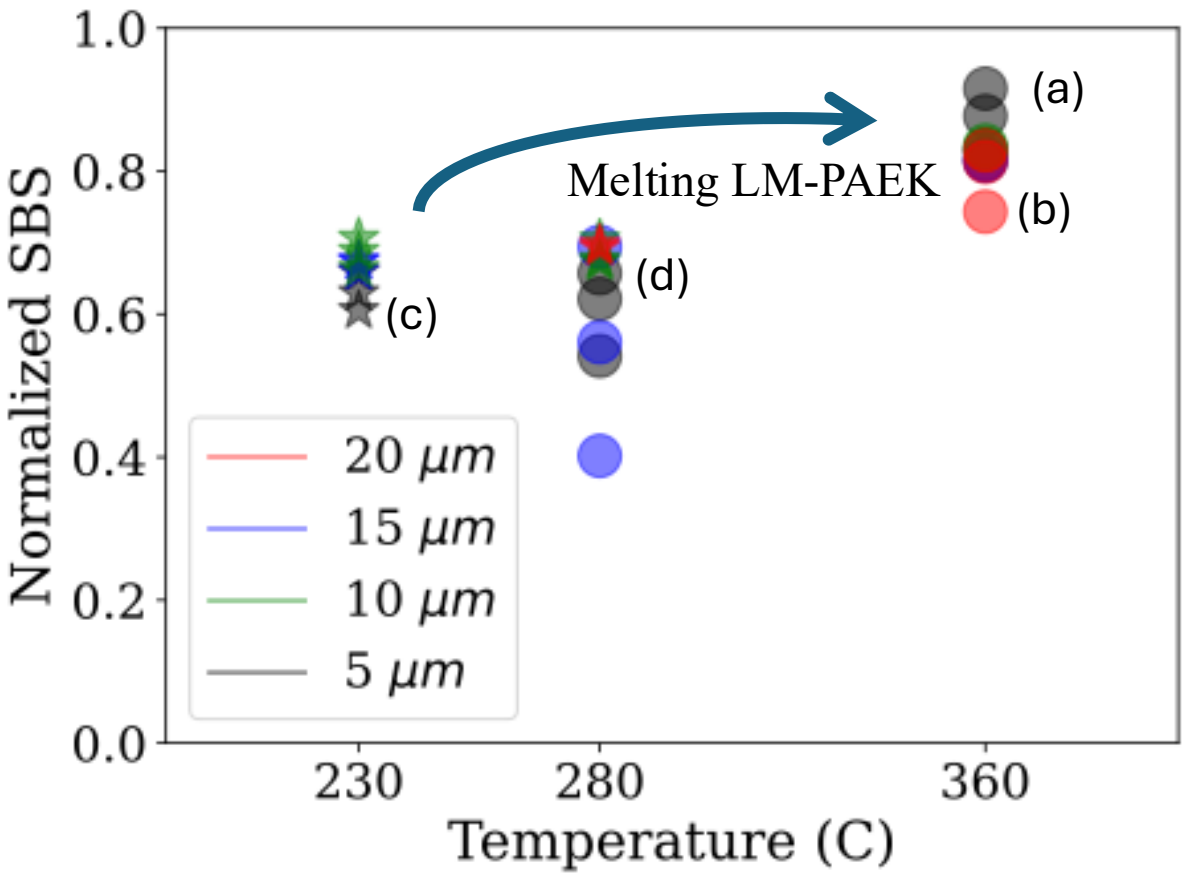
Two-Step Experimental Plan

Materials

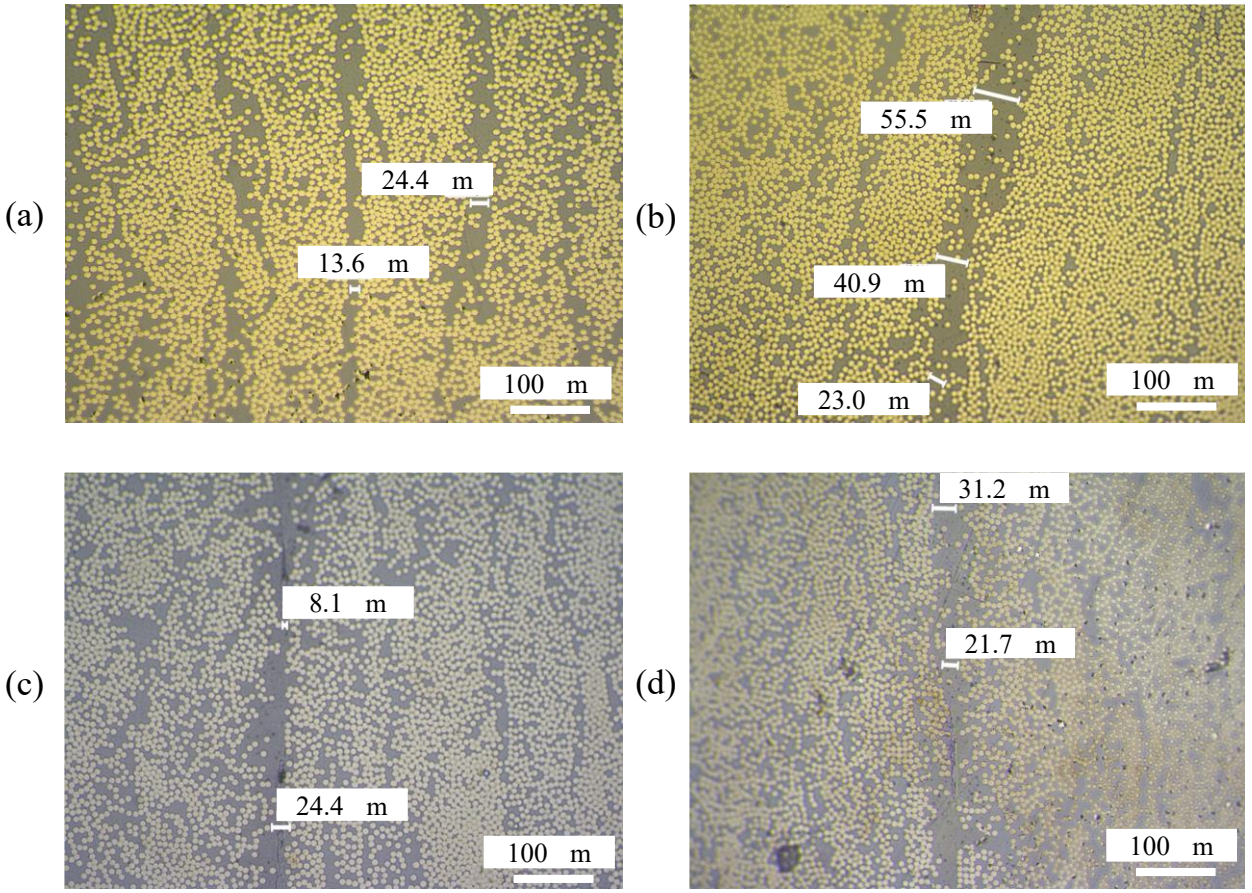


- Low Melt PAEK™ (LM-PAEK), with 55% fiber volume fraction, supplied by Toray (TC1125)
- Polyetherimide (PEI, Ultem 1000), supplied from piezopvdf as a neat polymer 5-micron film

Both Steps Were Done in a Vacuum Bag Only Setting



PEI Thickness (μm)	Step Two Temperature (℃) – 30 mins
5	230
10	280
15	360
20	



*Melt Temperature of LM-PAEK (305 ℃)

All bagging materials supplied by Airtech

Amorphous Bonding: Unlocking Processing Below Melt Point

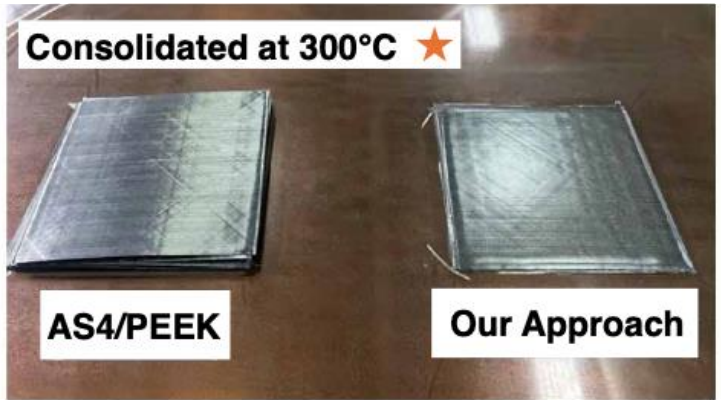
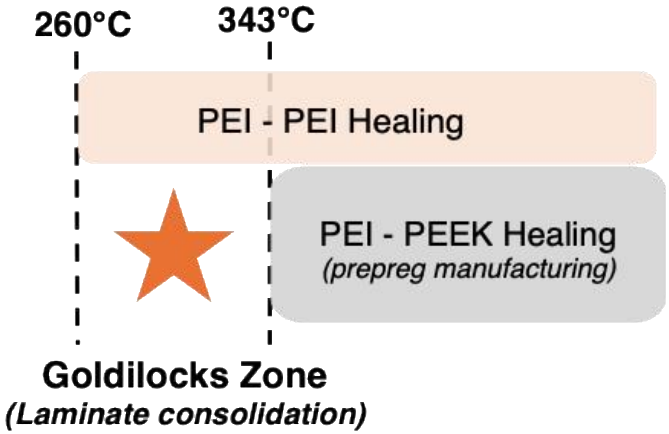
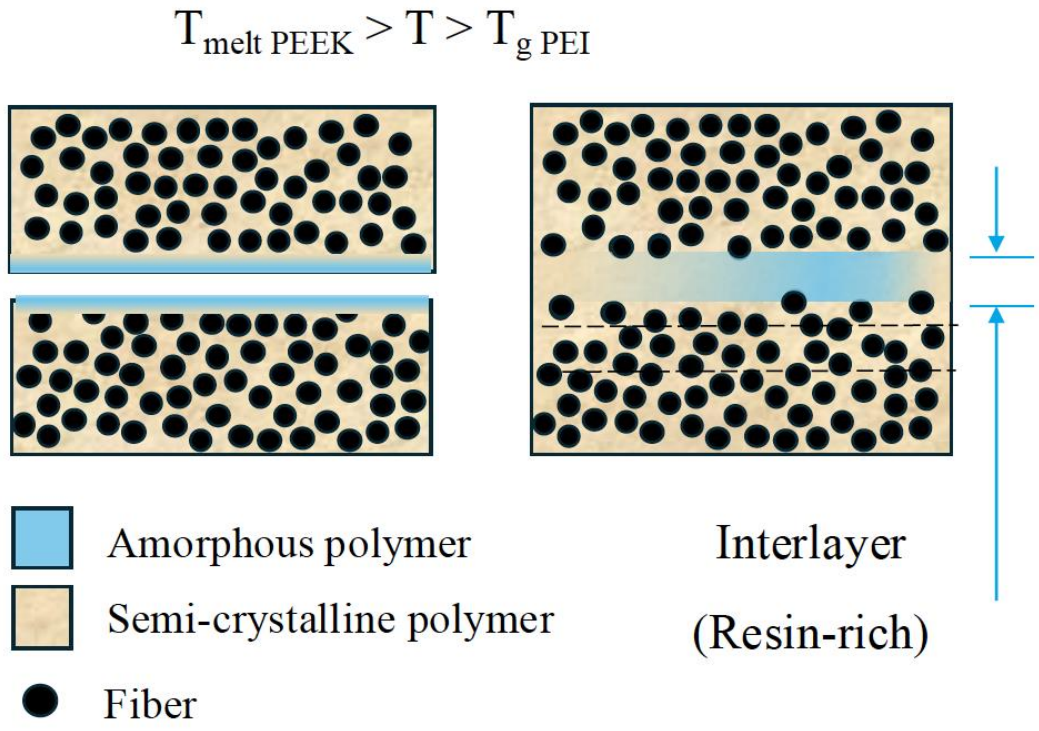
UC San Diego
JACOBS SCHOOL OF ENGINEERING



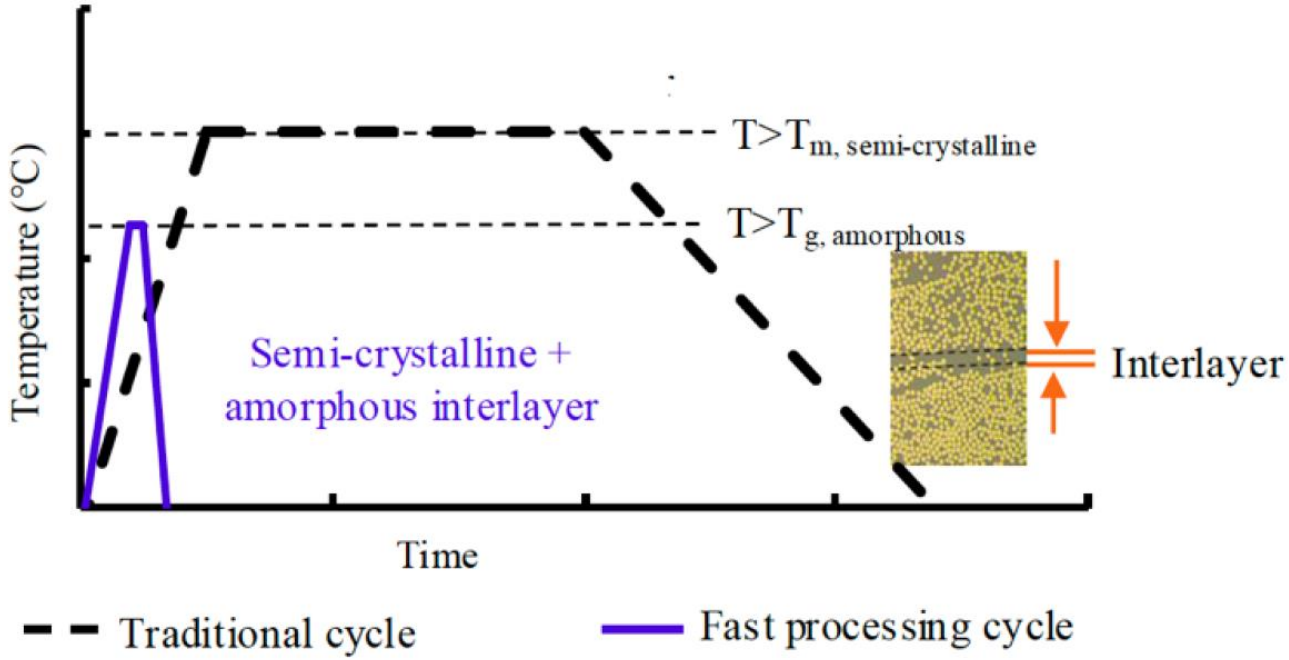
NASA

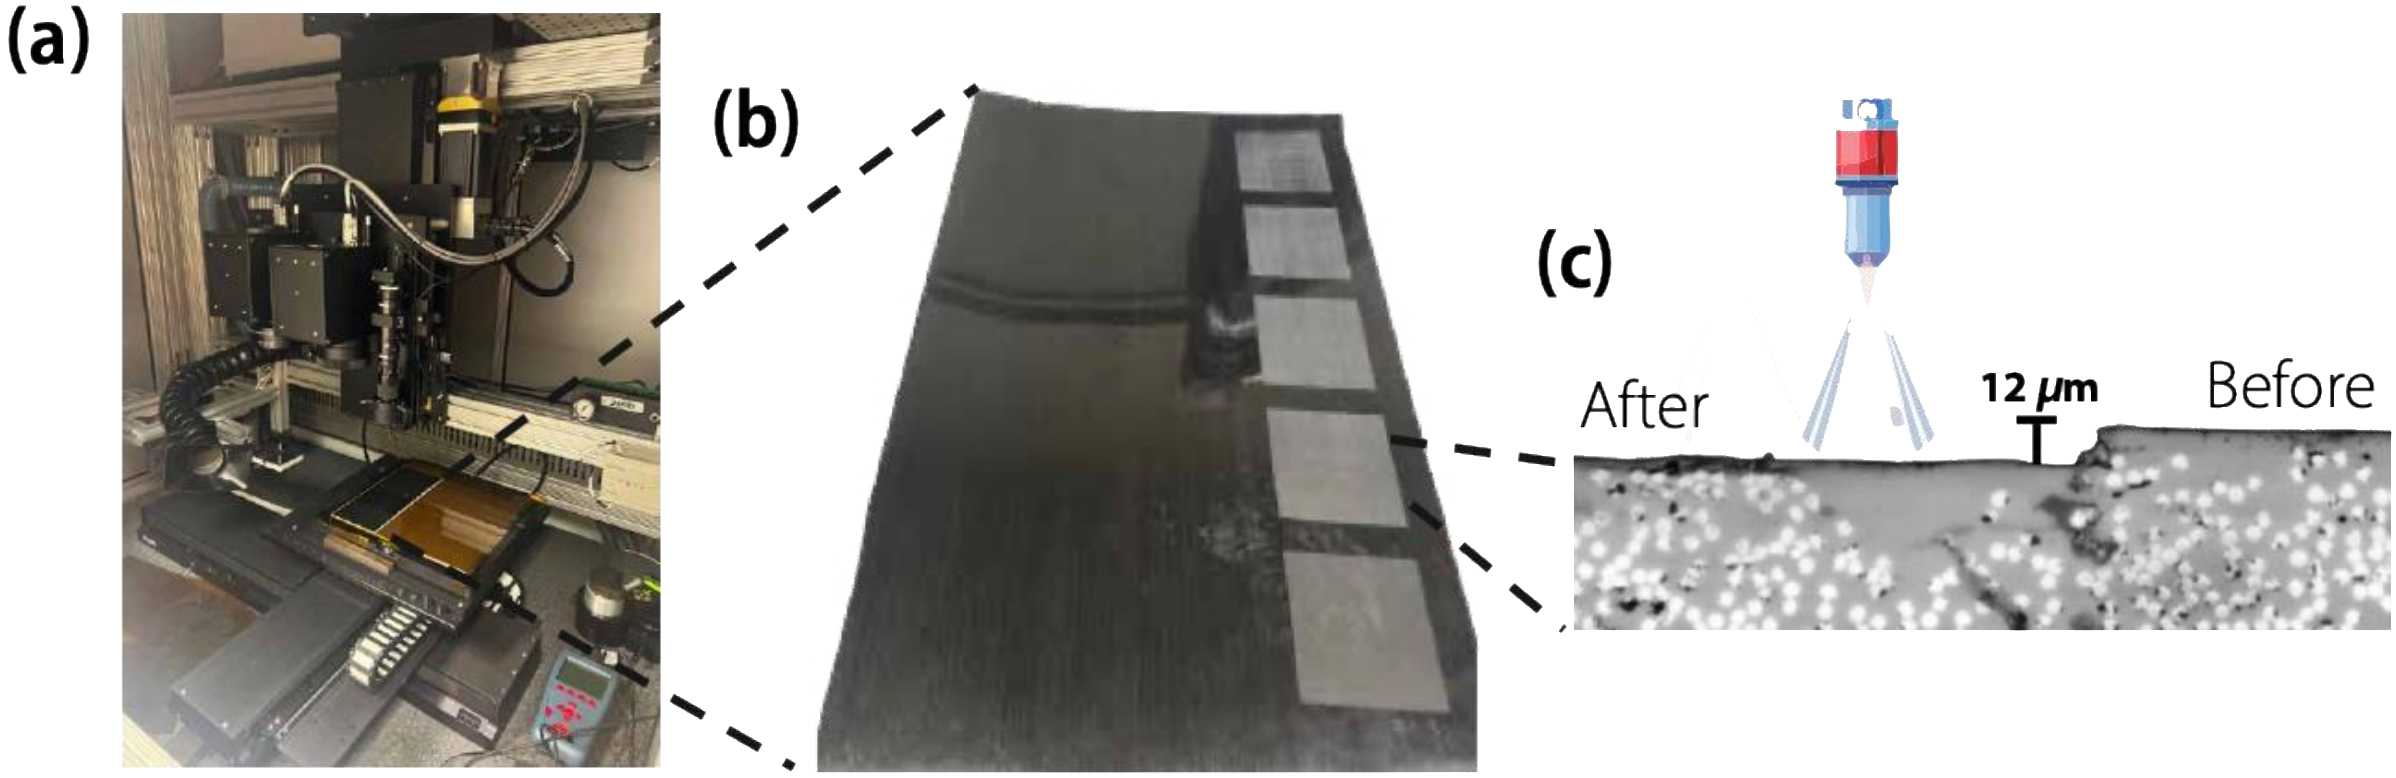


OATMEAL is Engineered to be Cooling-rate Agnostic



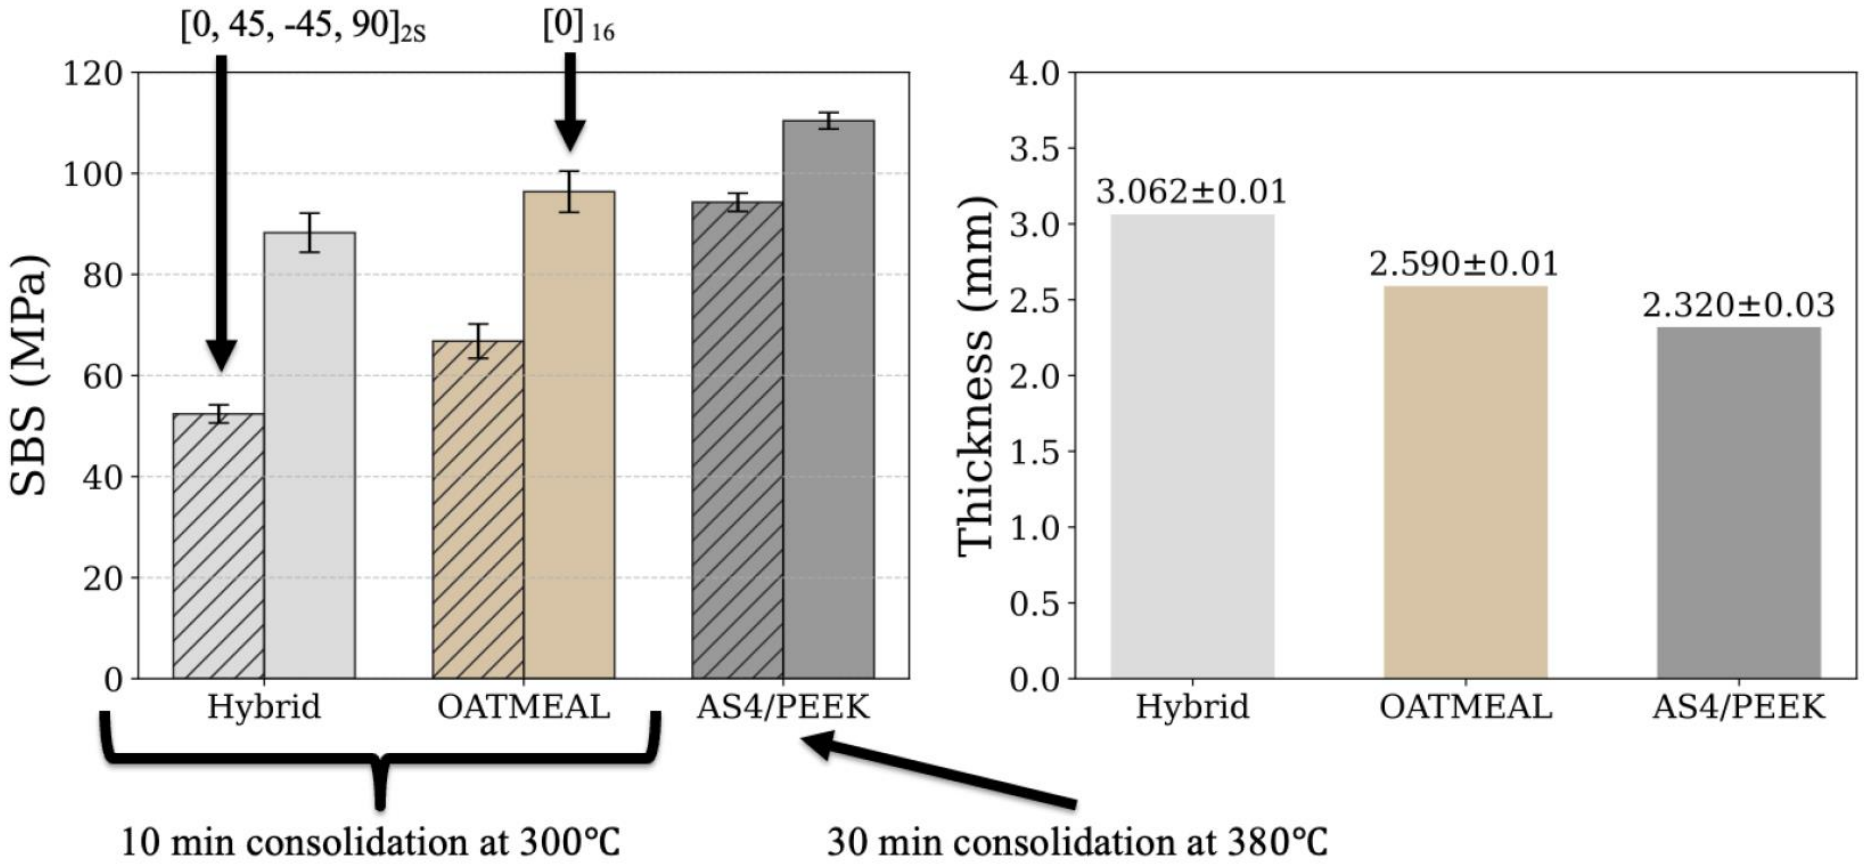
Consolidation possible without melting crystals





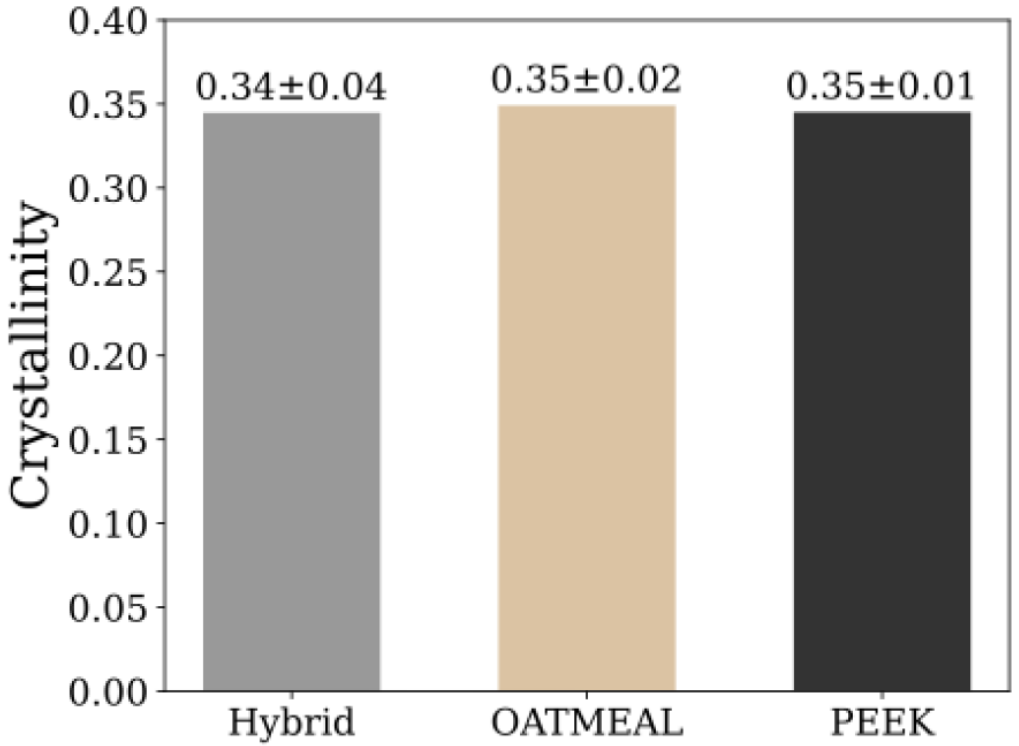
The added amorphous polymer enables sub-melt consolidation (without losing crystalline history)

Why OATMEAL?

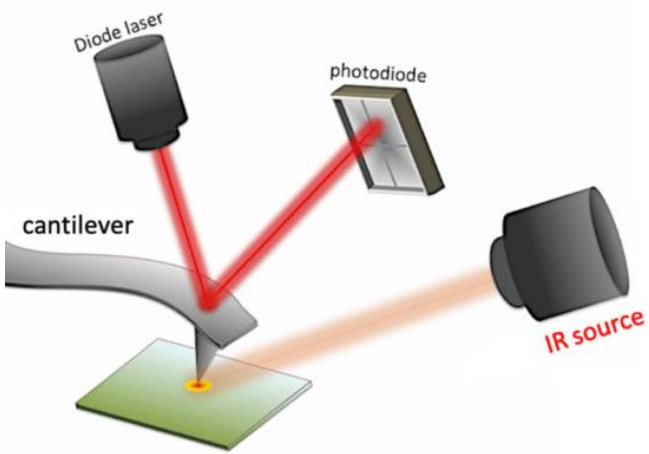


$T_{melt\ PEEK} > T > T_{g\ PEI}$
Amorphous polymer
Semi-crystalline polymer
Fiber
Interlayer
(Resin-rich)

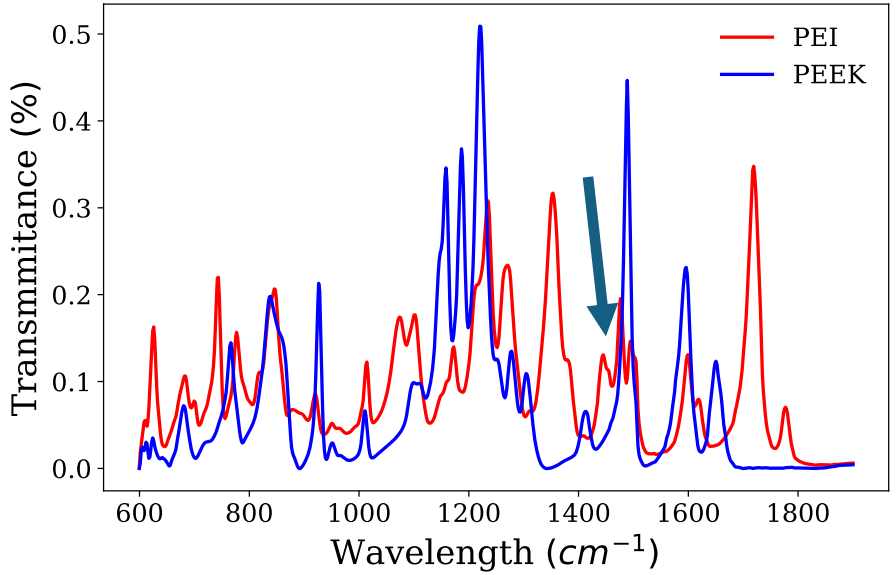
Temperature (°C)
$T>T_{m,\ semi\text{-}crystalline}$
$T>T_{g,\ amorphous}$
Semi-crystalline + amorphous interlayer
Interlayer
Time
Traditional cycle
Fast processing cycle

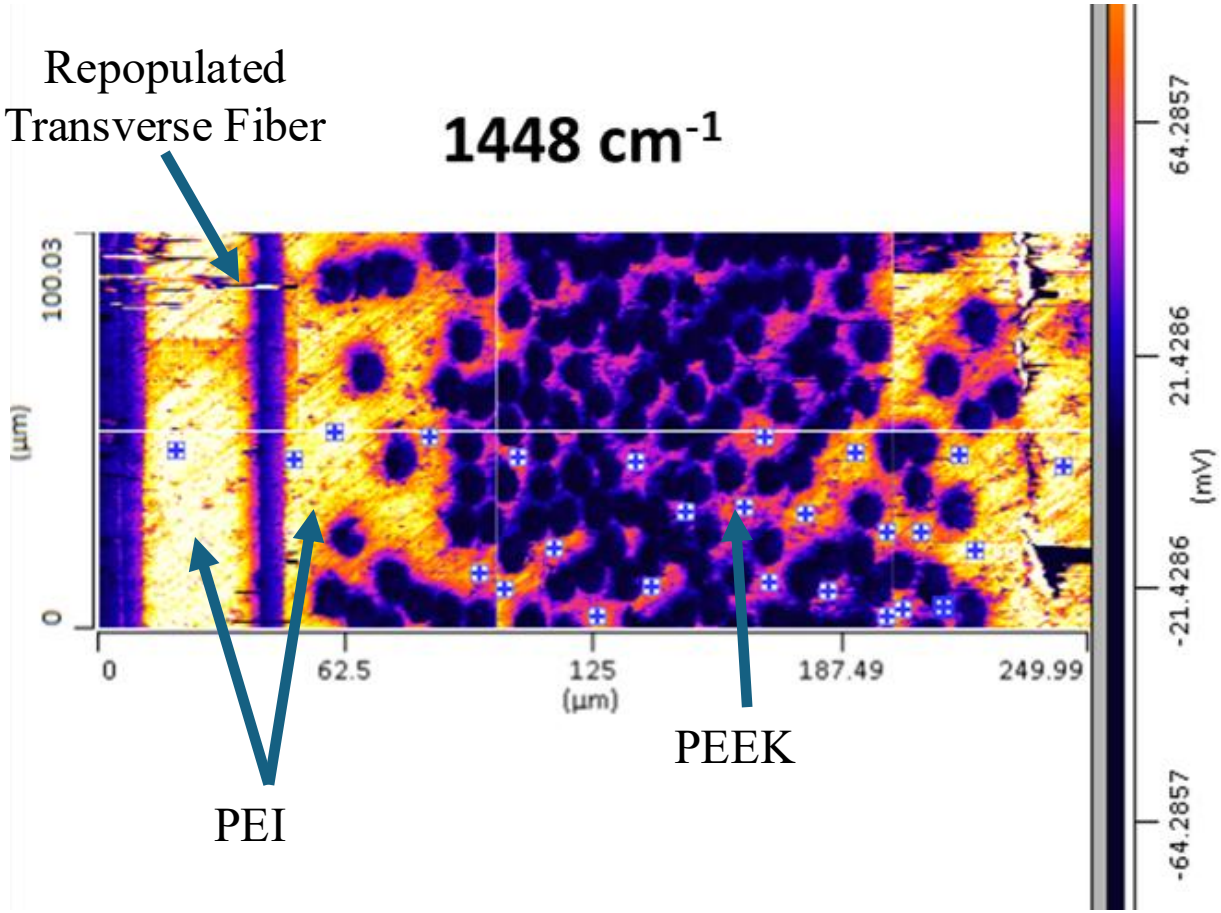


Laser Ablate Excess PEI to Improve Performance



Performance improves after laser ablation





Crystallinity Measurements

AFM-IR Shows Us that PEI Interdiffuses ~25-30 Microns

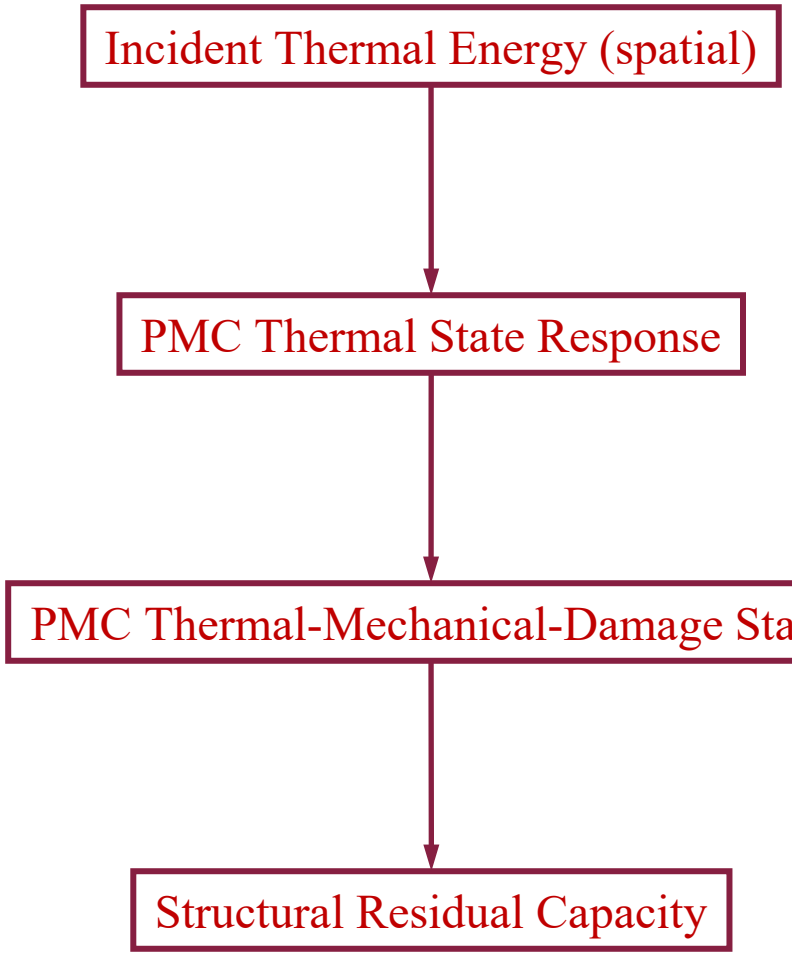
Motivation: How did I get into this business?

Buckling of laminate



Articles from tests conducted at Southwest Research Institute - Summer 2002

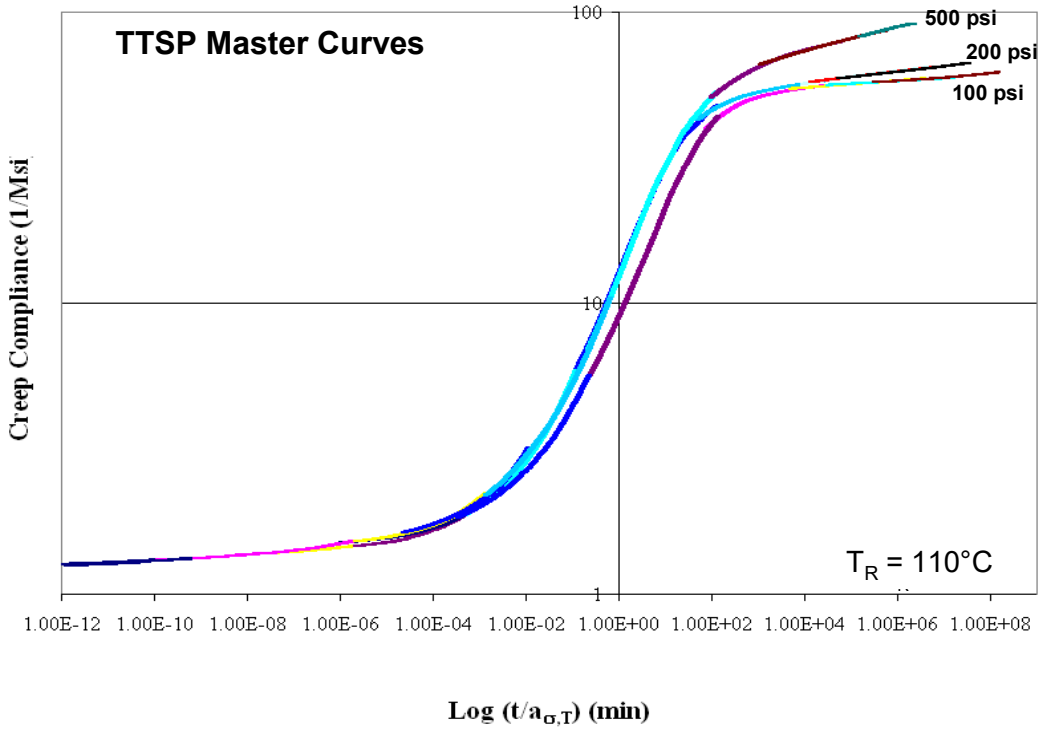
Presentation Overview

- Framework for analysis of failure of composites subjected to combined fire and mechanical loading
- Micromechanics of failure
  - Compression controlled failures
  - Tension controlled failures
- Laminate-level response
- New measurement techniques
- Integration with numerical tools
- Ongoing applications
- Conclusions
- Acknowledgements

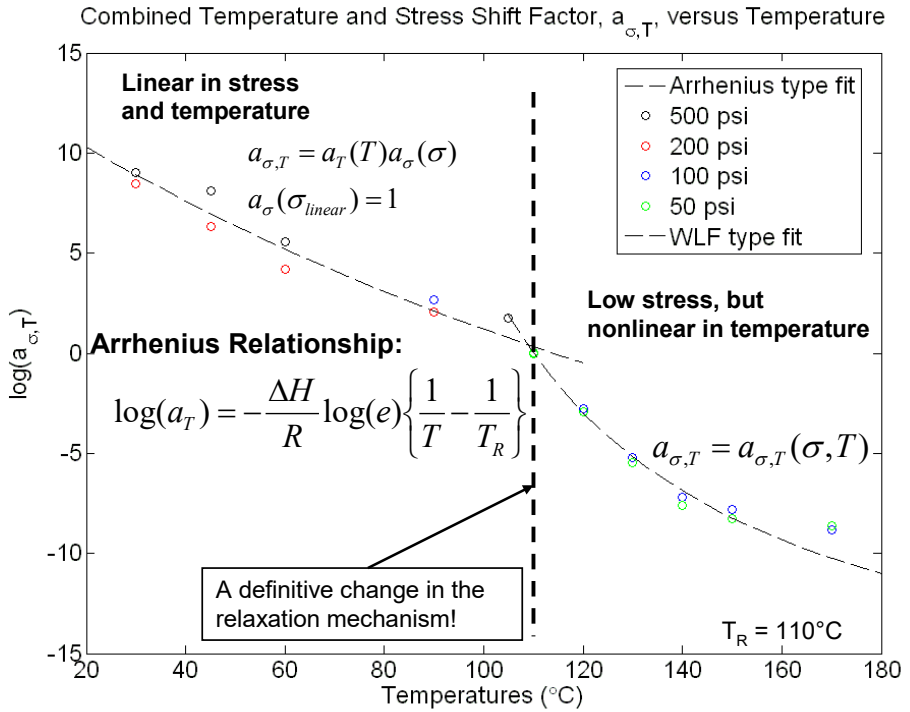
Framework for Analysis

$q''(x,y,z,t)$

- Property evolution (decomposition)
- Intumesence
- Delamination
- Volatile evolution



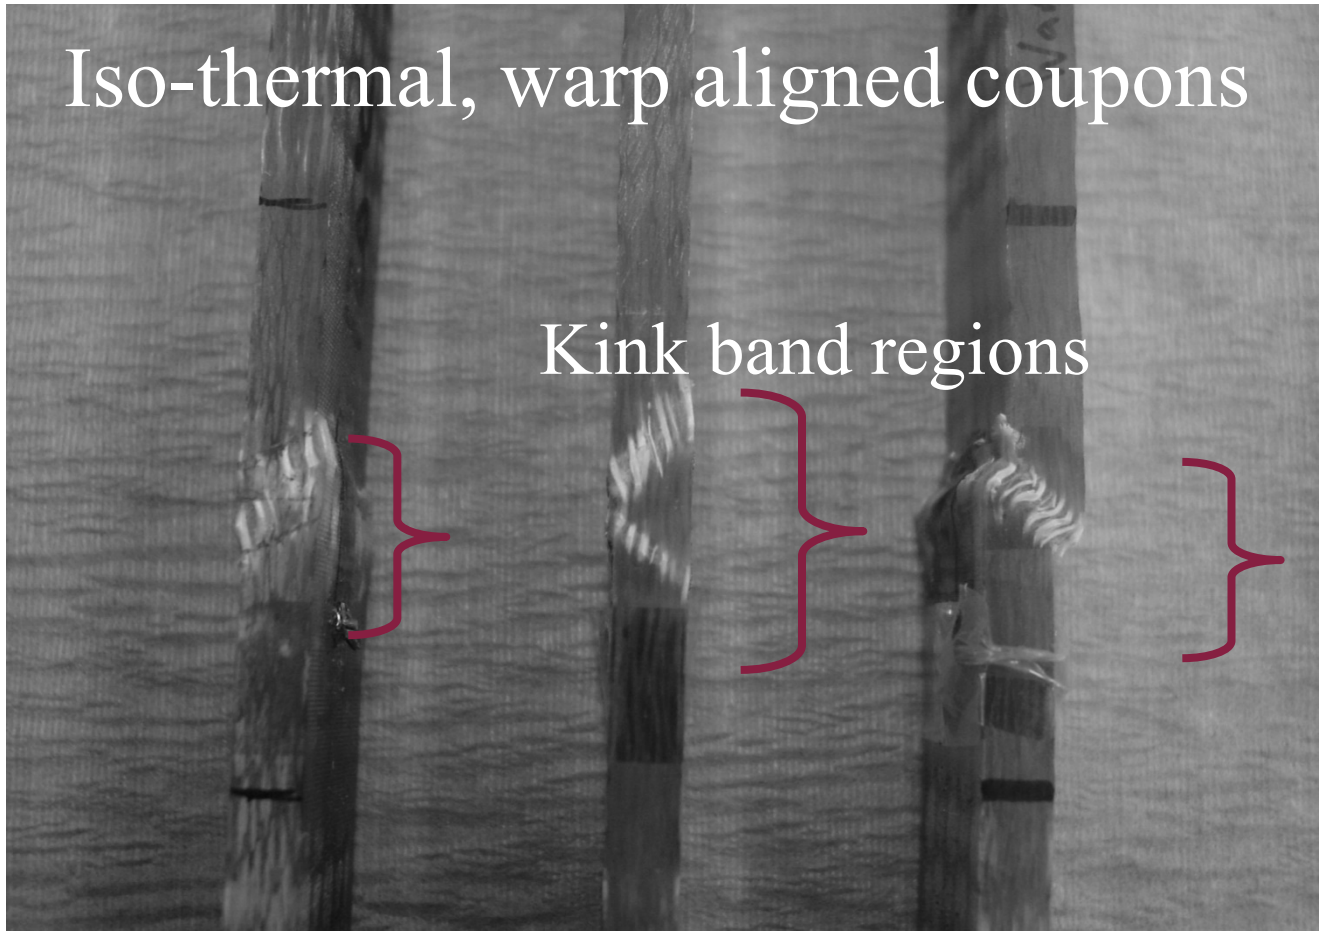
- $E_{ij}(T,t)$ - *creep*
- $X_{ij}(T,t)$ - *creep rupture*



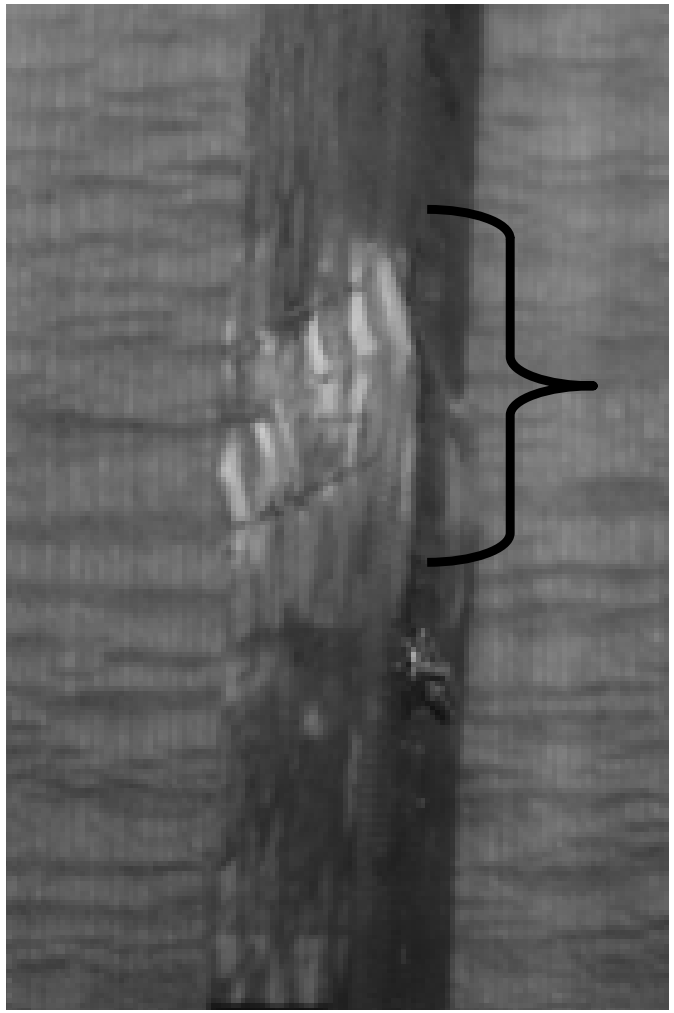
Limit state

- Local failures
- Global buckling
- Local buckling (delamination)
- Deflection

Viscoelastic Characterization: E-glass/Vinyl Ester



$[\pm 45]_{2s}$ Laminate
Vetrotex 324/Derakane 510A-40

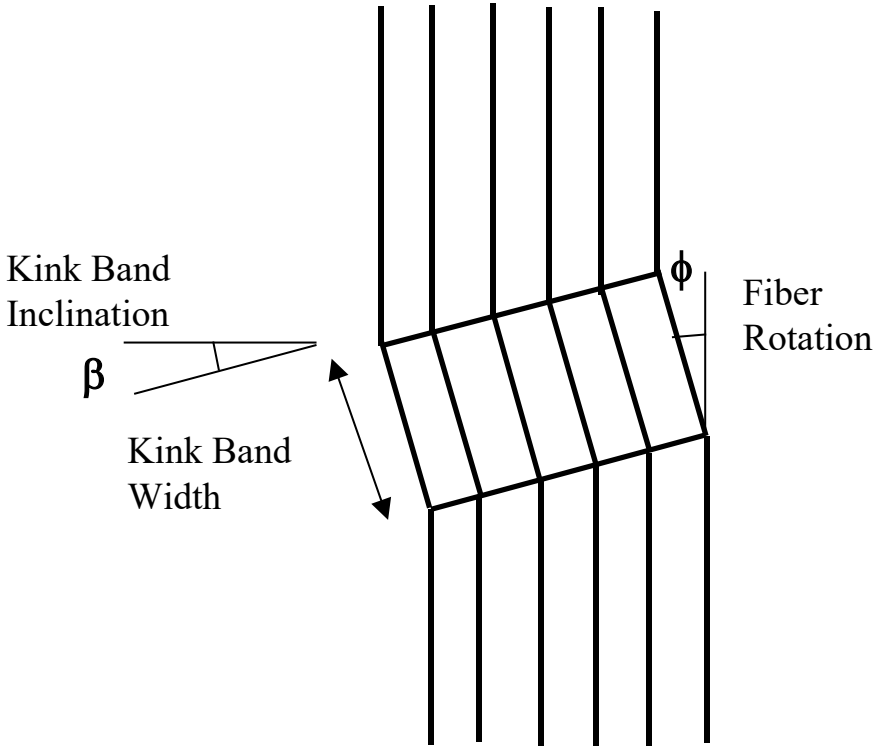


Creep and recovery data (30° to 170°C & 0.05 to 4 ksi) modeled using Zapas/Crissman visco-plastic model describing creep response to a wide range of temperature & loads

Observations of High Temperature Compression Failures

Vetrotex 324/Derakane 510A-40

Compression Mechanics



Use Budiansky & Fleck compression strength model, assuming a Ramberg-Osgood shear stress-strain relation

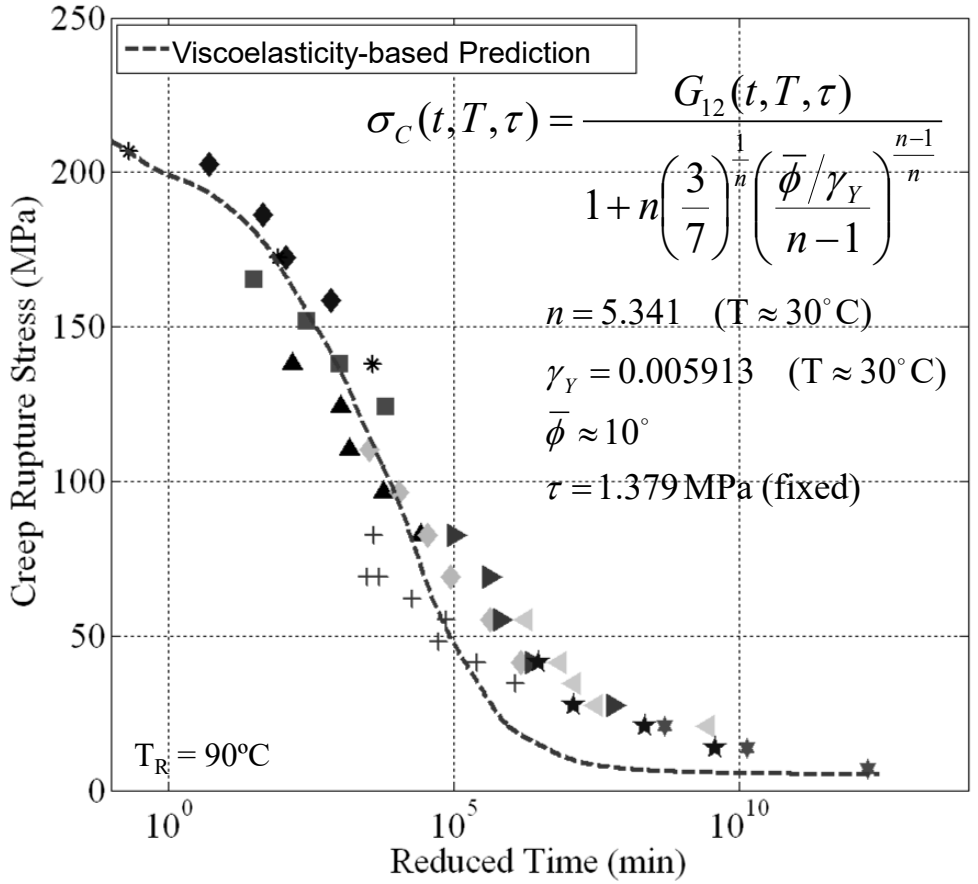
$$\frac{\gamma}{\gamma_y} = \frac{\tau}{\tau_y} + \left(\frac{3}{7}\right)\left(\frac{\tau}{\tau_y}\right)^n$$

Compression strength modified as a function of temperature and time

$$X_c(T,t) = G(T,t)\left[1 + n(T)\left(\frac{3}{7}\right)^{\frac{1}{n(T)}}\left(\frac{\bar{\varphi}}{\gamma_y(T)\left(n(T)-1\right)}\right)^{\frac{n(T)-1}{n(T)}}\right]^{-1}$$

Compression Mechanics

Use Budiansky & Fleck compression strength model, assuming a Ramberg-Osgood shear stress-strain relation



$$\frac{\gamma}{\gamma_y} = \frac{\tau}{\tau_y} + \left(\frac{3}{7}\right)\left(\frac{\tau}{\tau_y}\right)^n$$

Compression strength modified as a function of temperature and time

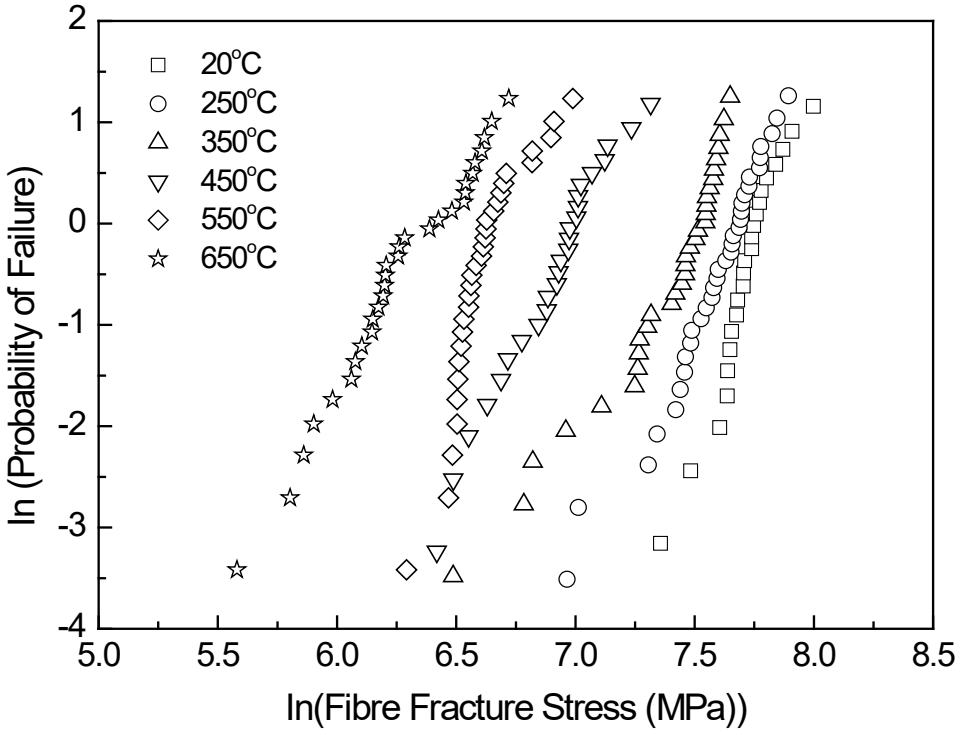
$$X_c(T,t) = G(T,t)\left[1 + n(T)\left(\frac{3}{7}\right)^{\frac{1}{n(T)}}\left(\frac{\bar{\varphi}}{\gamma_y(T)\left(n(T)-1\right)}\right)^{\frac{n(T)-1}{n(T)}}\right]^{-1}$$

Isothermal Compression Creep Rupture

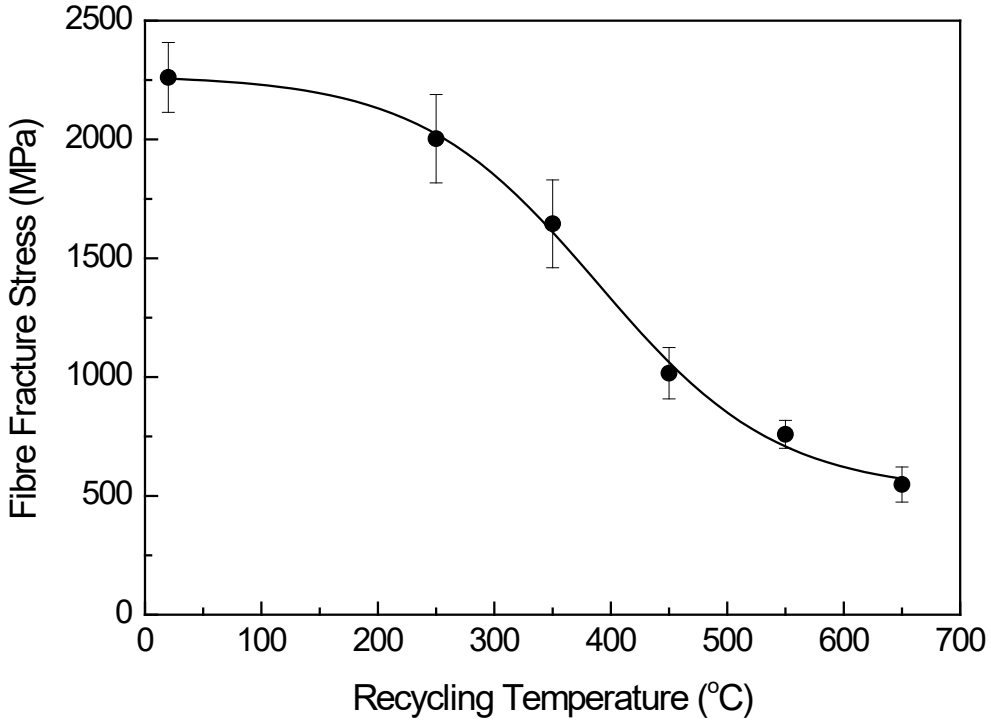
Shift factors from shear creep compliance used to collapse compression creep rupture data

$$X_C(\xi) = \frac{G_{12}(\xi)}{1+n\left(\frac{3}{7}\right)^{\frac{1}{n}}\left(\frac{\bar{\phi}/\gamma_Y}{n-1}\right)^{\frac{n-1}{n}}}$$

$$n = 5.3 \quad (T \approx 30^\circ C)$$



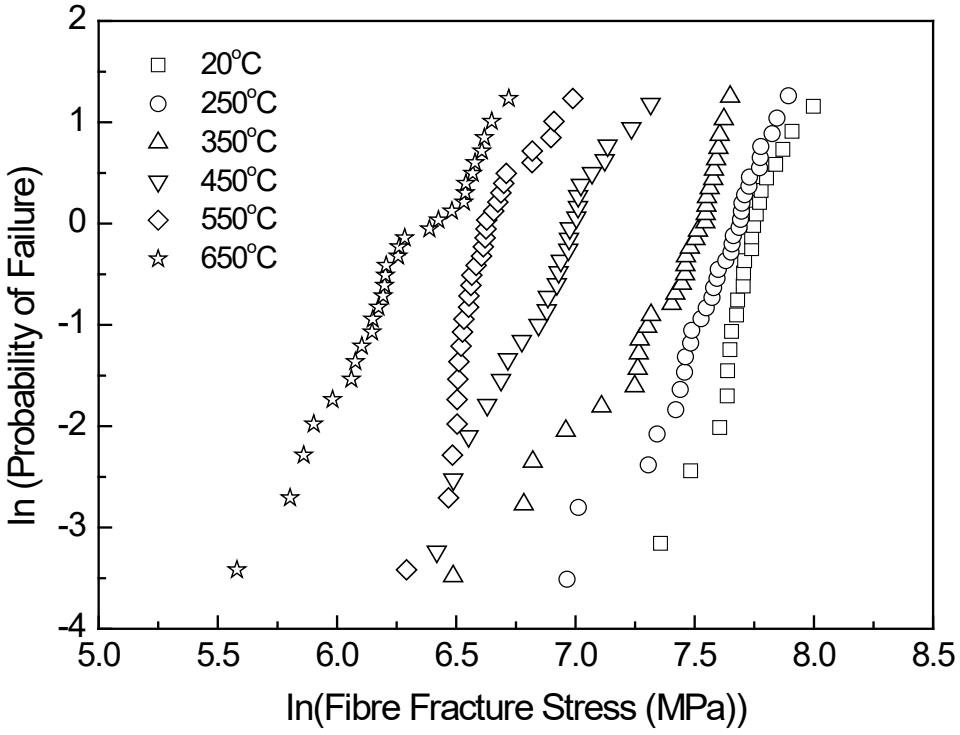
$$\gamma_Y = 0.59\% \quad (T \approx 30^\circ C)$$



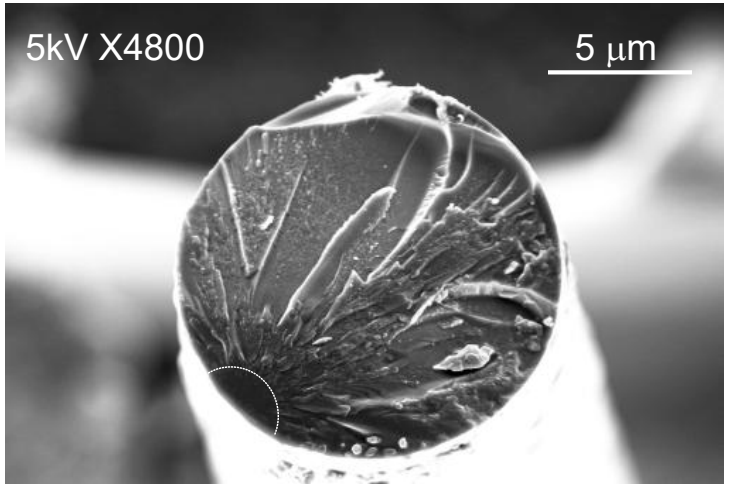
$$\bar{\phi} \approx 10^\circ$$

Warp $[0°]_{10}$ and Weft $[90°]_{10}$ coupons of Vetrotex 324/Derakane 510A - 40

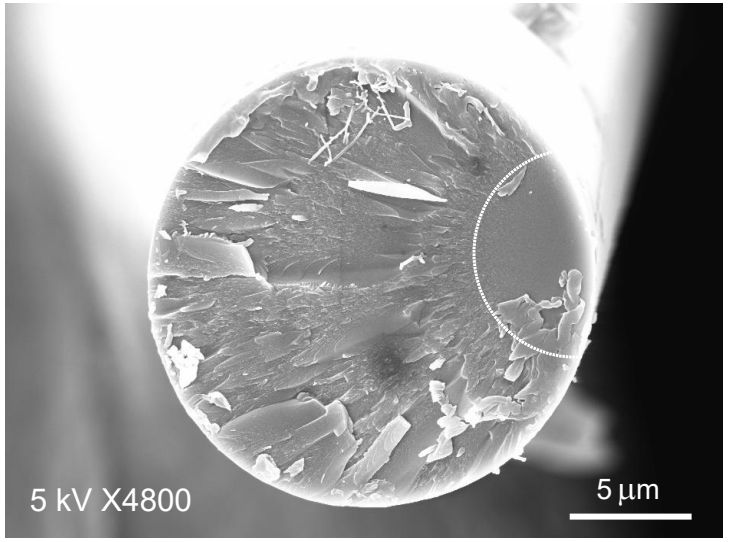
Key Conclusion: Temperature-dependent compression strength and time-dependent compression creep rupture are both manifestations of the same viscoelastic behavior of composite



Temperature Effects on E-Glass Tensile Strength

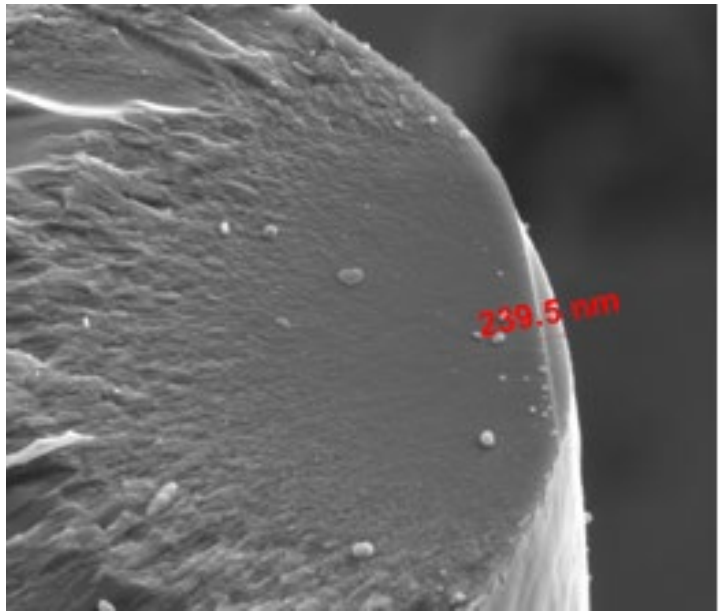


Not only applies to fire, but also thermal recyling

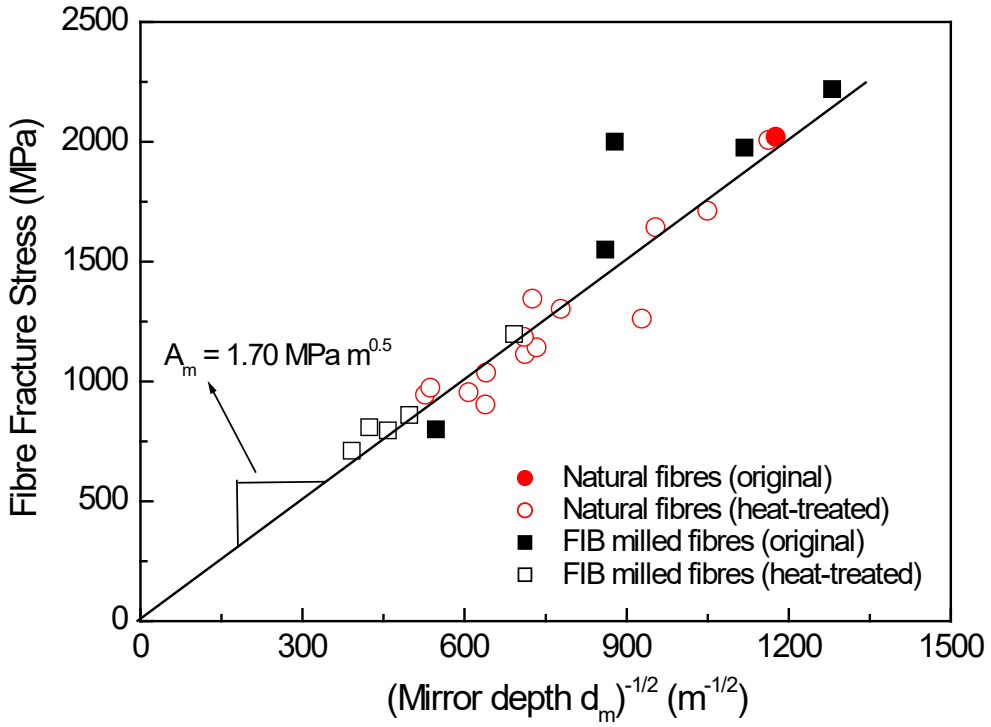


Temperature Effects on E-Glass Tensile Strength

No exposure

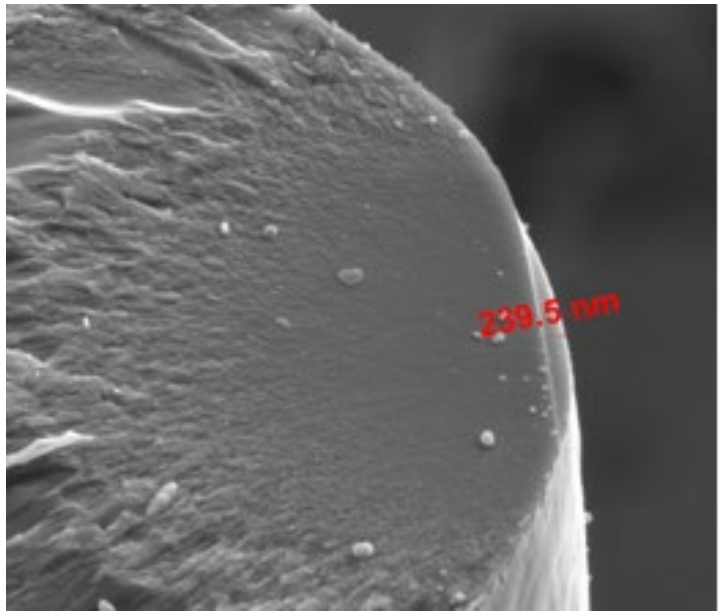


450°C exposure

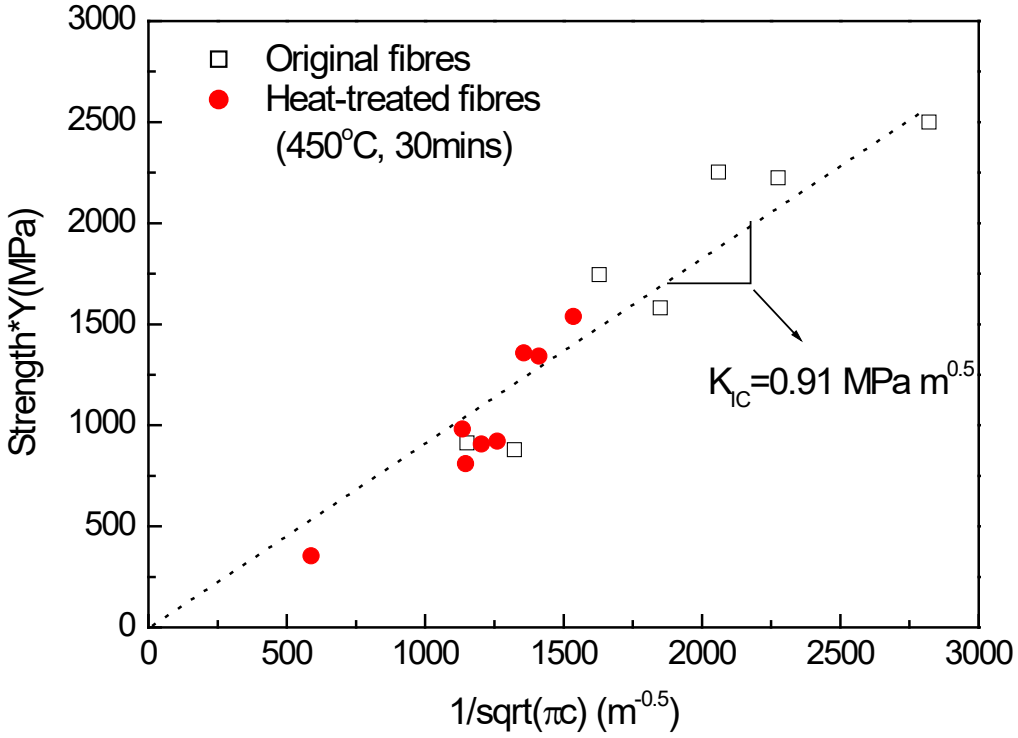


Temperature Effects on E-Glass Tensile Strength

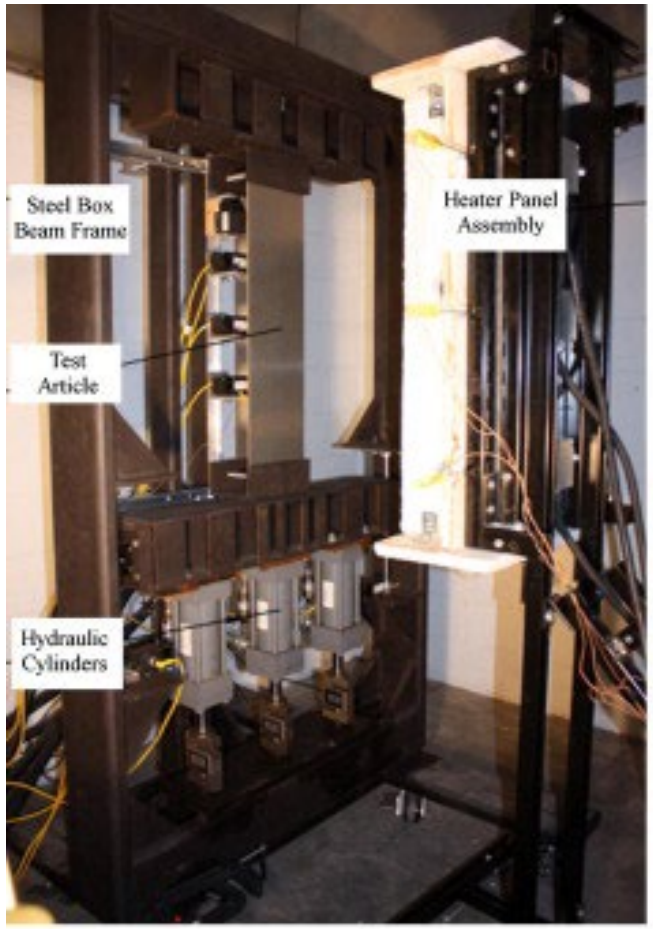
Are Flaws Growing or is Bulk Toughness Decreasing?



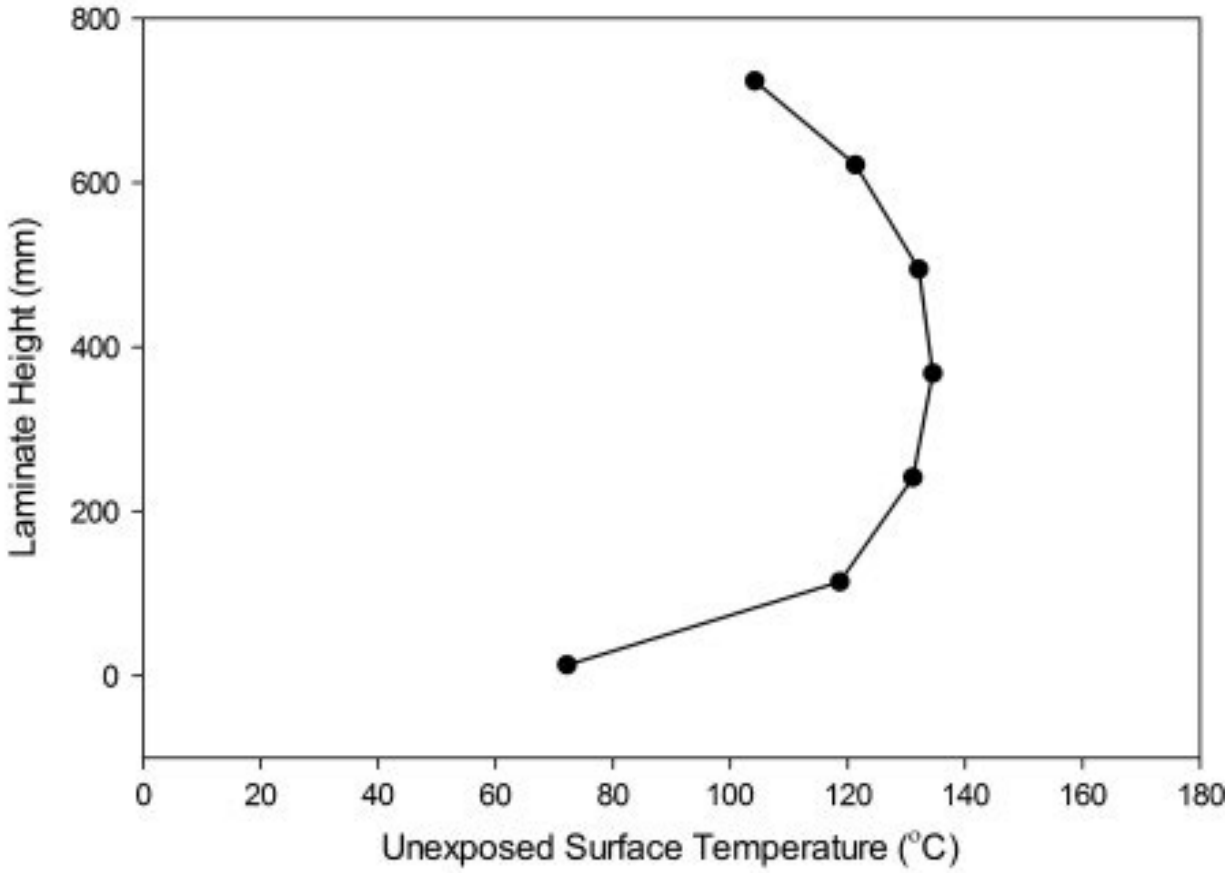
Fracture surface of glass fiber containing straight FIB milled notch (239.5 nm deep)



Temperature Effects on E-Glass Tensile Strength

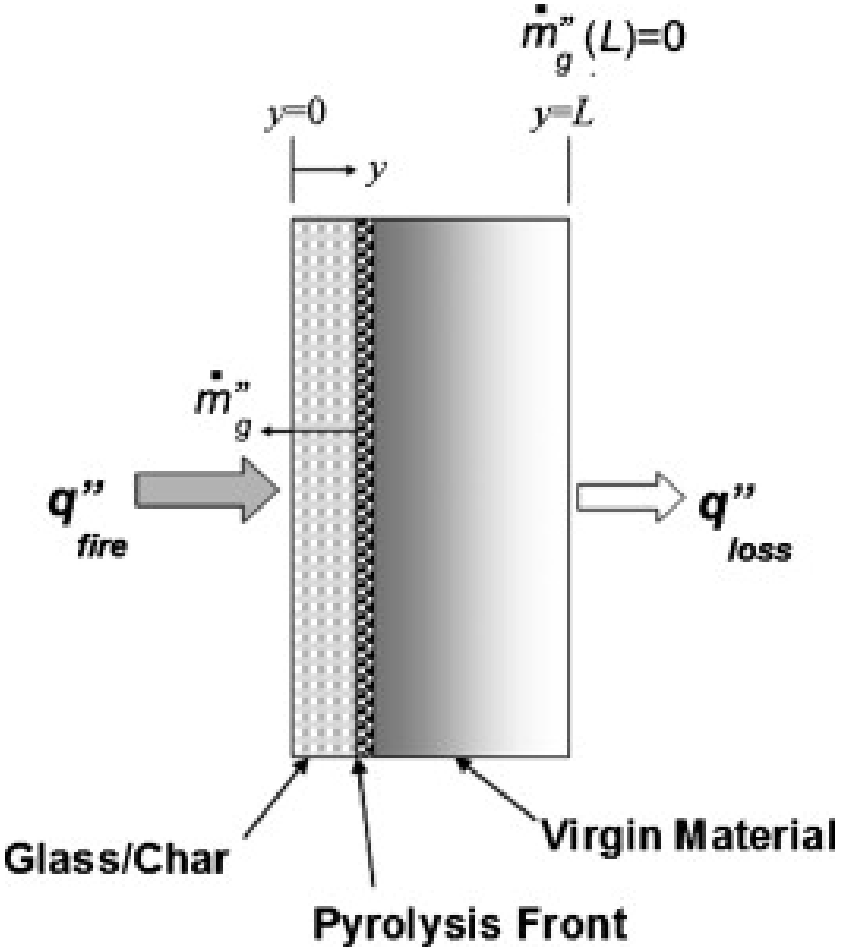


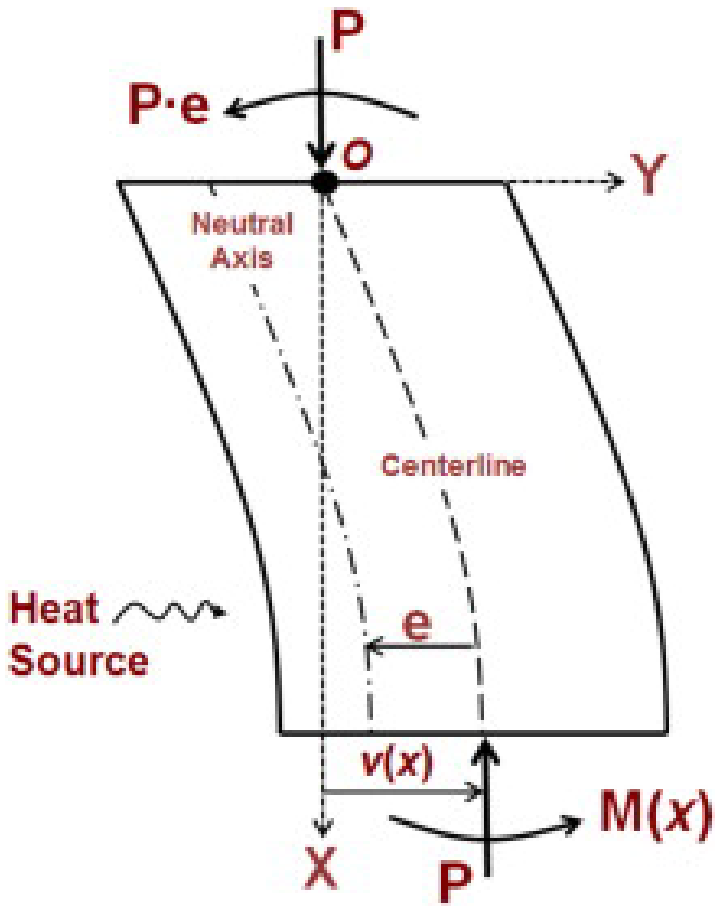
Are Flaws Growing or is Bulk Toughness Decreasing?



Fracture surface of glass fiber containing straight FIB milled notch (239.5 nm deep)

Sustained Compression Load & One-sided Heat Flux Exposure

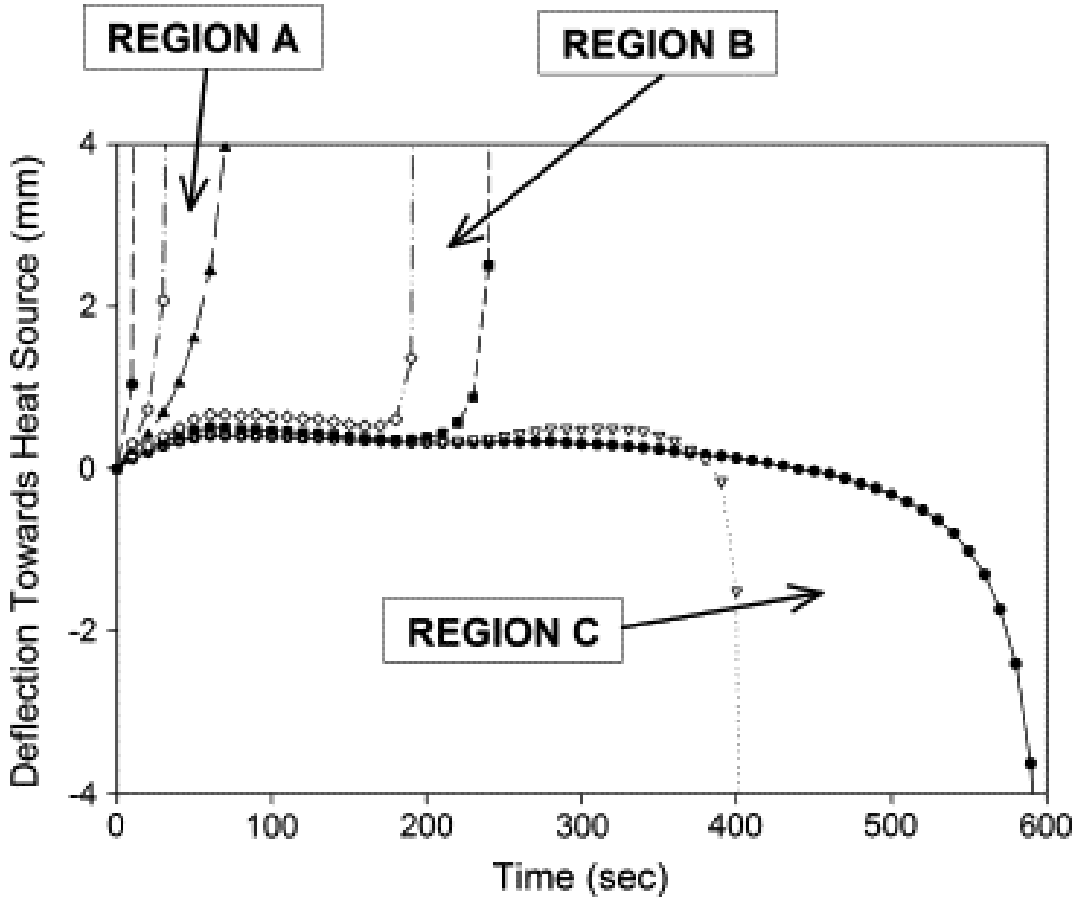


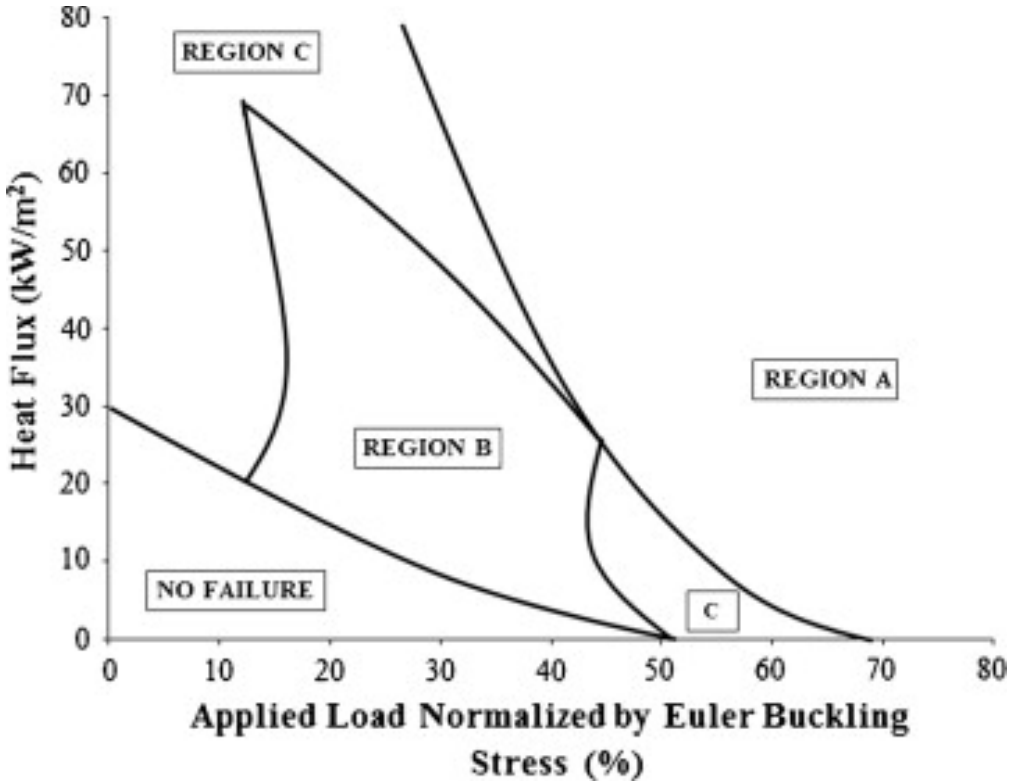


(a)

(b)

Sustained Compression Load & One-sided Heat Flux Exposure

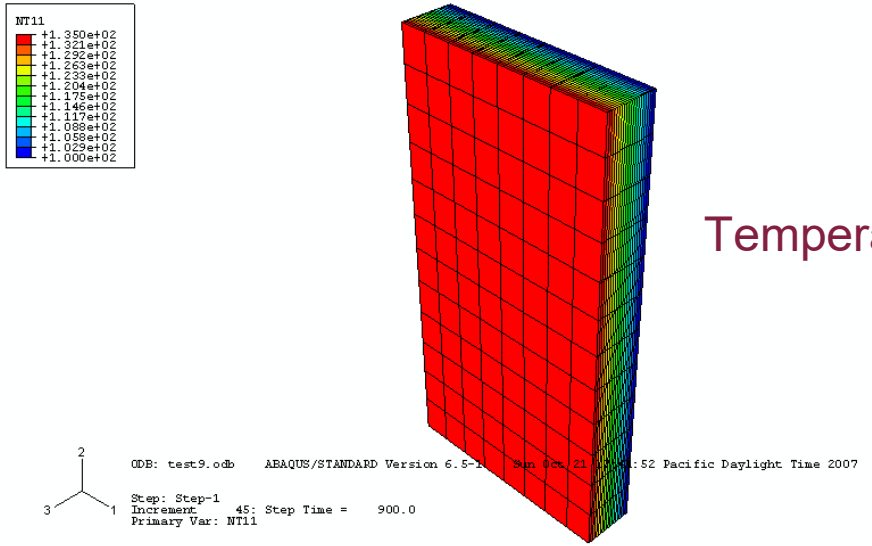




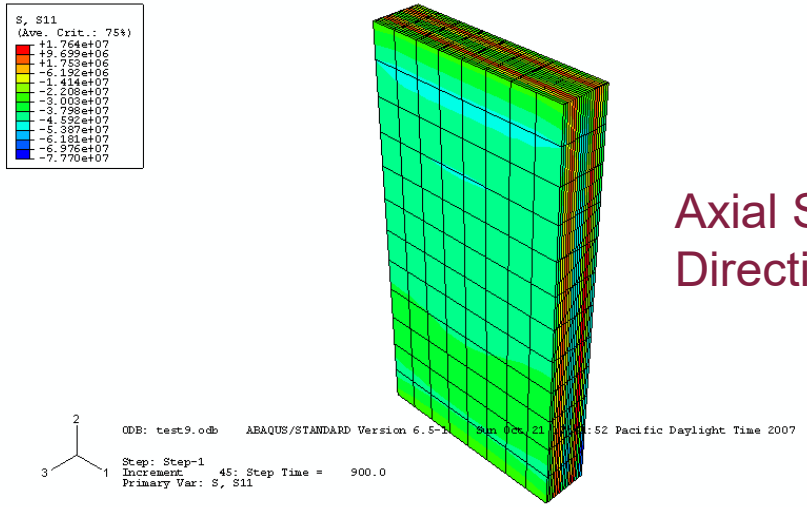
$$(EI)_{eq}\frac{d^2\theta(x)}{dx^2}+P\theta(x)=\left(M^{T}_{x,\theta}+Pe_0\right)\left(\frac{8-8K}{L^2}x-\frac{4-4K}{L}\right)$$

Simple Mechanics Model to Predict the Response

Sustained Compression Load & One-sided Heat Flux Exposure

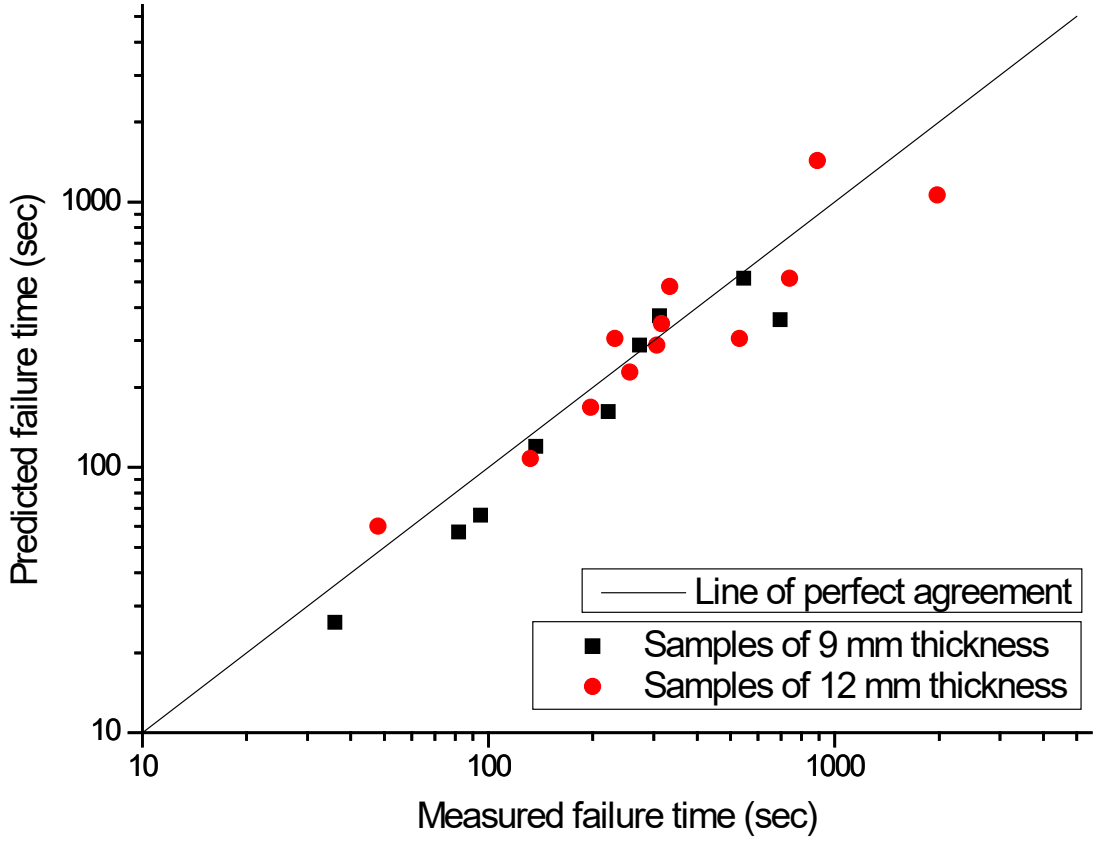


Simple Mechanics Model to Predict the Response



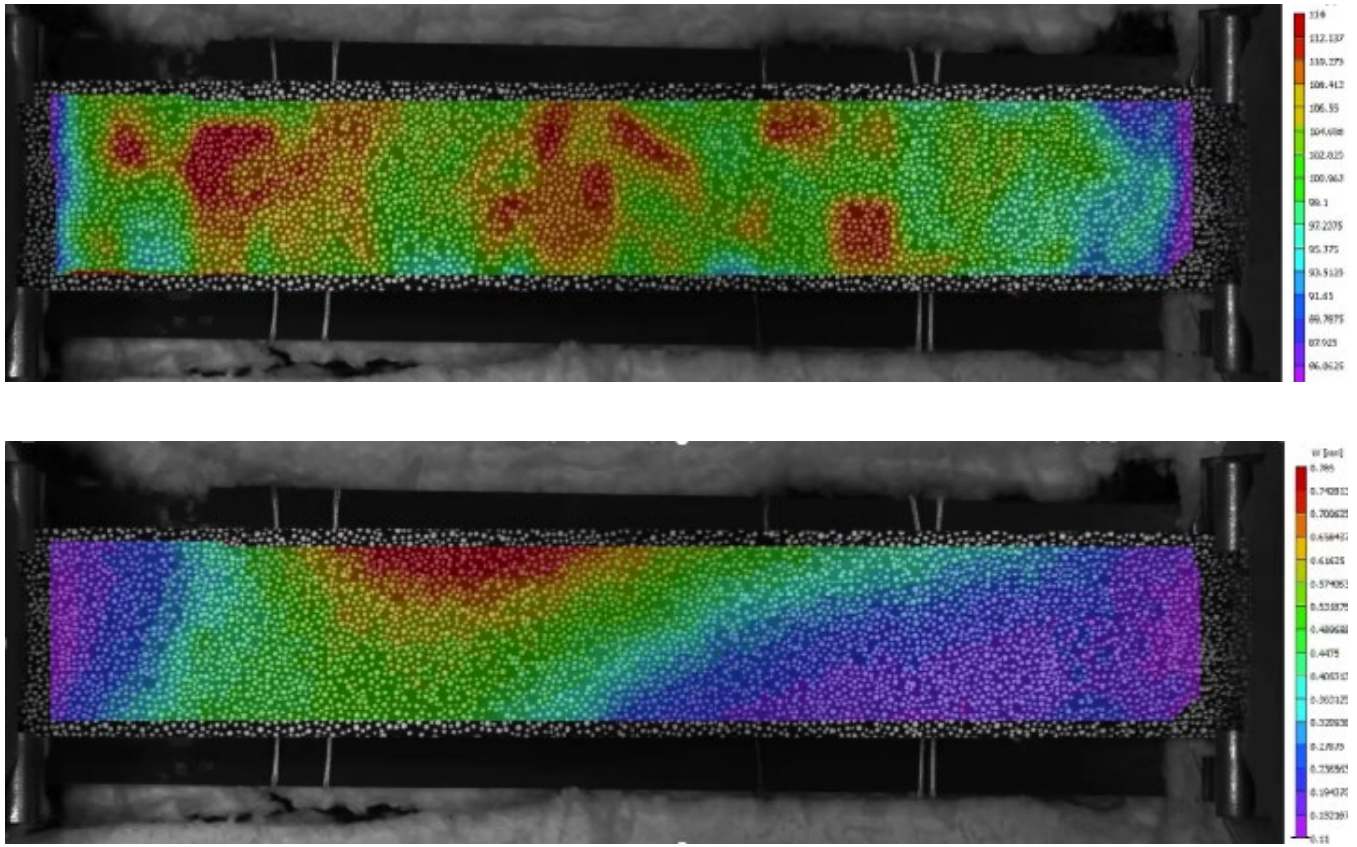
Coupled Viscoelastic, Thermomechanical Model

- Combine partial differential equations representing
  - Viscoelastic mechanical constitutive equation, using rule of mixtures for char and virgin material
  - Decomposition reaction equation (solid mass)
  - Heat transfer equation (temperature)
  - Gas diffusion equation (gas pressure)
- Solve using finite element method in Abaqus
  - Constitutive behavior in UMAT
  - Heat transfer and decomposition in UMATHT1
  - Gas diffusion in UMATHT2 (with pressure, rather than temperature as the variable)
  - Overlay elements used: UMAT and UMATHT1 applied to first layer; UMATHT2 applied to second layer
  - State variables and common blocks



Validation: Experimental Data from RMIT

Temperature



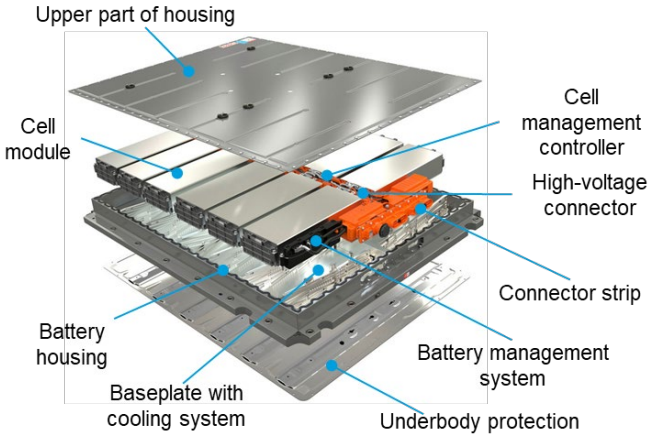
Axial Stress in Fiber Direction

Comparison of the predicted and experimental failure times (compression controlled failure)

Measurement Improvement: TDIC

- Heat flux of 10kW/m^2 (minimal decomposition of front skin)
- No insulation of specimens on back surface to allow for field measurements.
- DIC average on back face recorded for each test.
- Non-uniform heat flux observed due to different densities of balsa
- Delamination of front skin ‘cools’ back face.

Thermoplastic Battery Enclosures for Electric Vehicles



Lithium-Ion Batteries in Electric Vehicles (EVs)

EVs have attracted substantial interest due to greater efficiency and potential reduced emissions of CO_2.

Challenge: Limited lithium-ion battery capacity

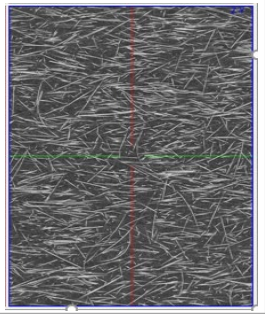
- Larger number of lithium-ion batteries
  - Increase in weight
  - Risk of fire and explosion

Metal-intensive Battery Pack

Volkswagen. (2019). Key components for a new era – the battery system.

Solution?

Replace metallic battery packs with **intumescent thermoplastic polymer-based** composite systems



- Reduced weight
- Improved fire protection
- Lower thermal conductivity

RESEARCH PLAN

Selected Materials

Flame-retardant polypropylene (FR-PP) composites with 30% glass fiber-reinforcement **with controlled characteristics**

- Fiber length
- Flame retardancy

Injection-molded with random fiber length & orientation distribution

Material Characterization

- Thermogravimetric Analysis; TGA
- Thickness expansion
- Thermal Conductivity
- Specific Heat
- Dynamic Mechanical Analysis; DMA

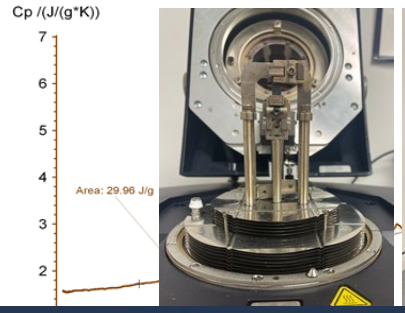


Plate Responses to Fire & Mechanical Loads

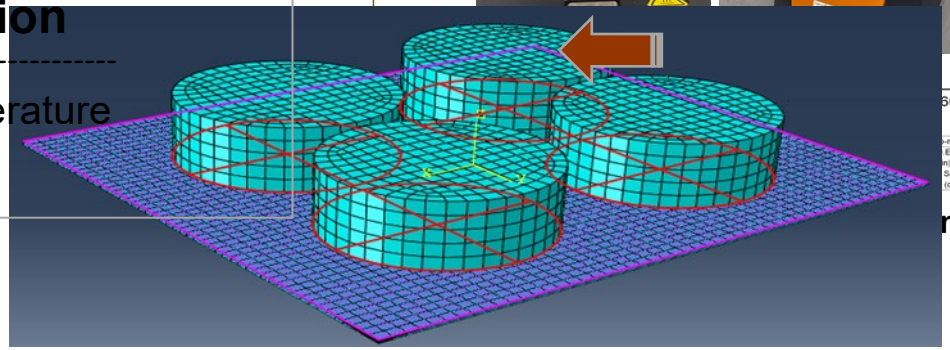
- Custom Set-up
- Inverse Heat Transfer; IHT
- IR Temperature Measurements
- DIC Deformations
- Thermocouple Measurements

Simulations



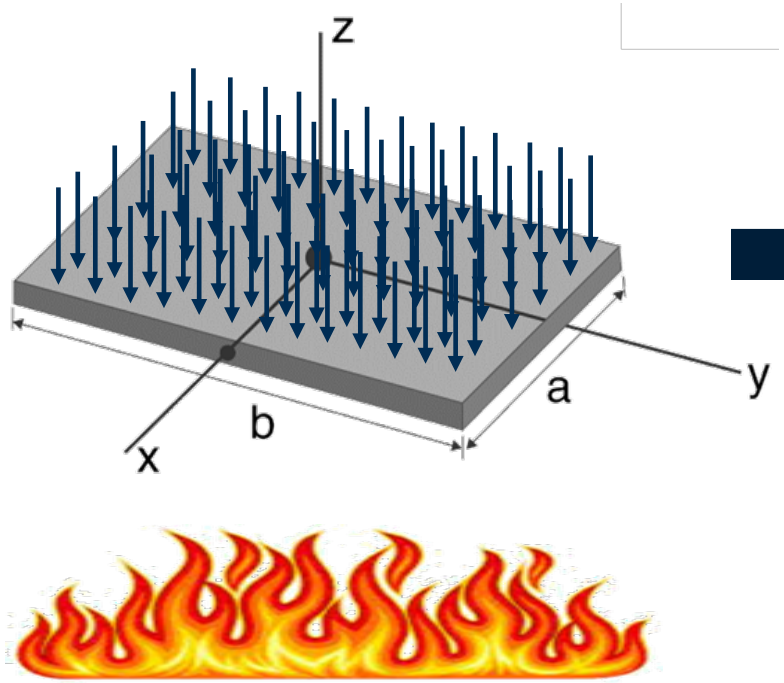
IHT or Fire Dynamics Simulator (FDS) for Thermal Loading

Abaqus for Coupled Thermomechanical Modeling

- Thickness expansion via Effective Thermal Conductivity
- Viscoelasticity via Prony Series & User TRS Subroutine
- Thermomechanical Contact Simulation

Validation

- Unexposed Temperature
- Deflection



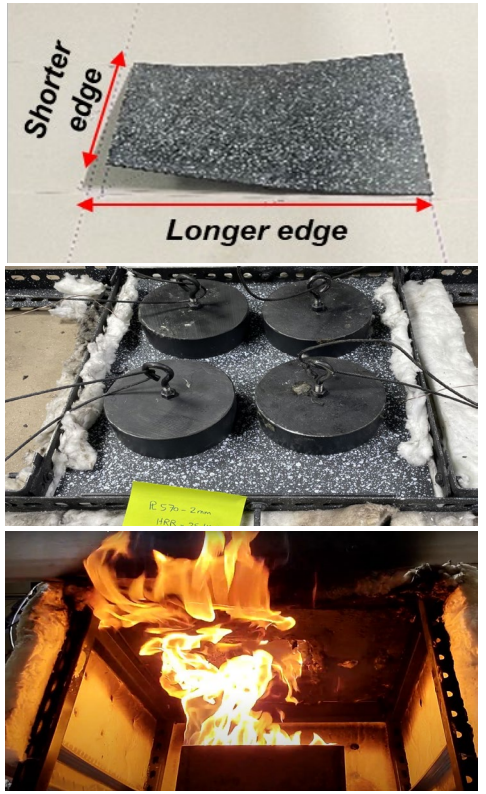
EXPERIMENTAL SETUP

OVERALL GOAL: To predict the coupled thermomechanical behavior of thermoplastic composites for newly manufactured battery pack systems.

Joel, M. EV Battery Types - A Simple Guide. How Does an Electric Vehicle Battery Work? 2024

Lithium-ion battery on top of each plastic module exerts an approximately total gravity weight of 1.1 kN/m^2

External fire or thermal runaway convective and radiative heat source



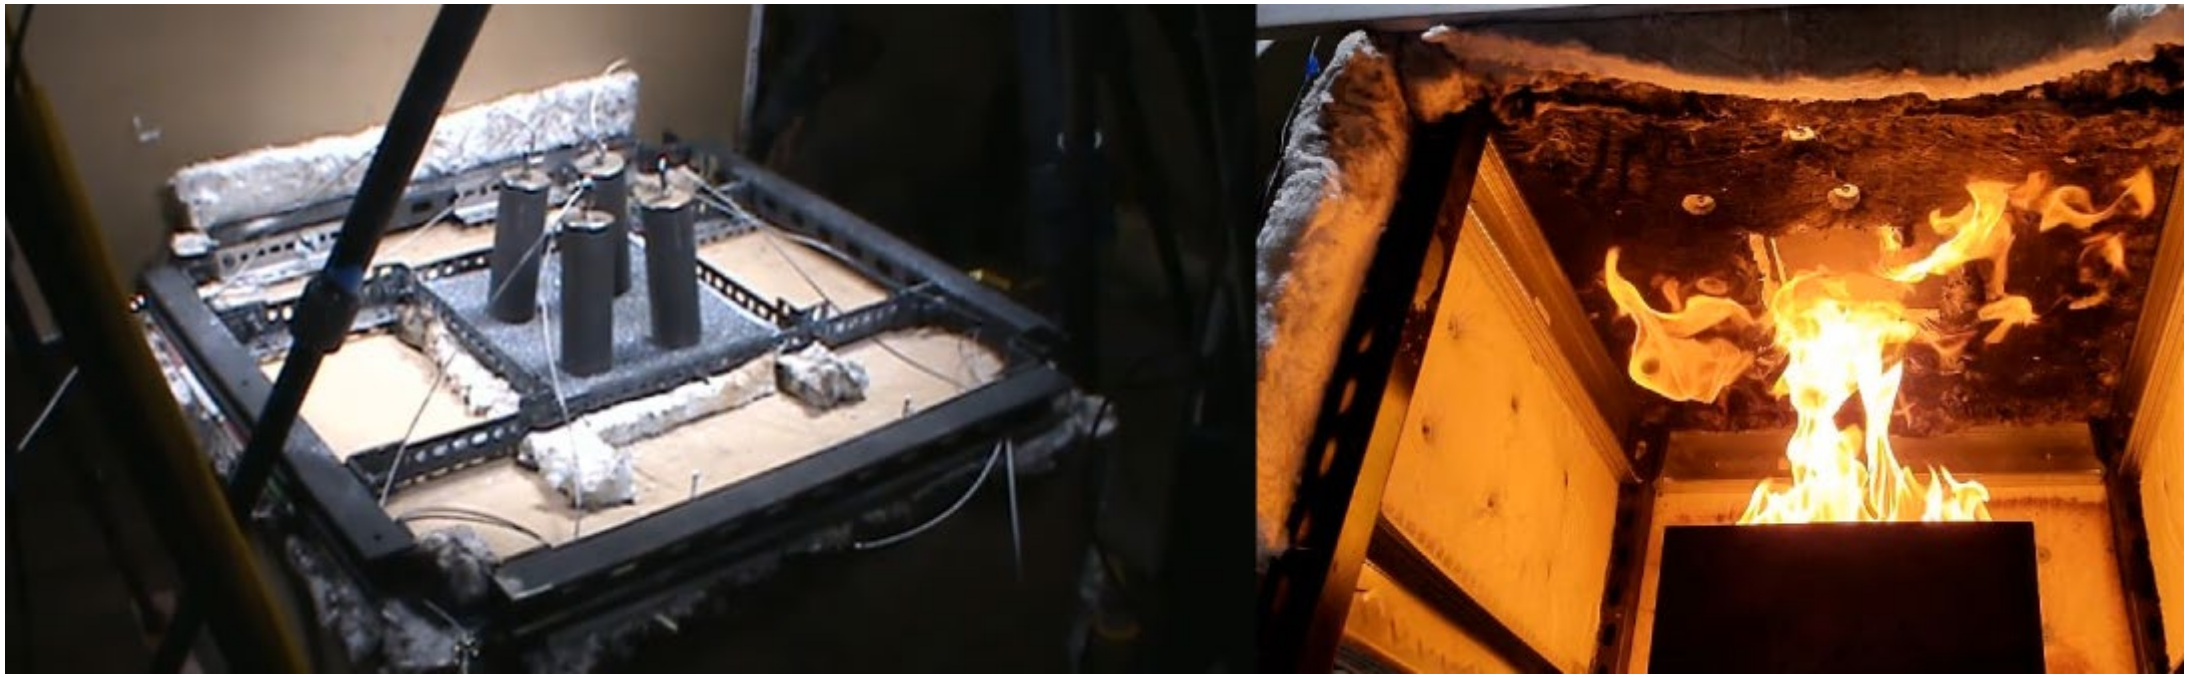


Plate-scale testing

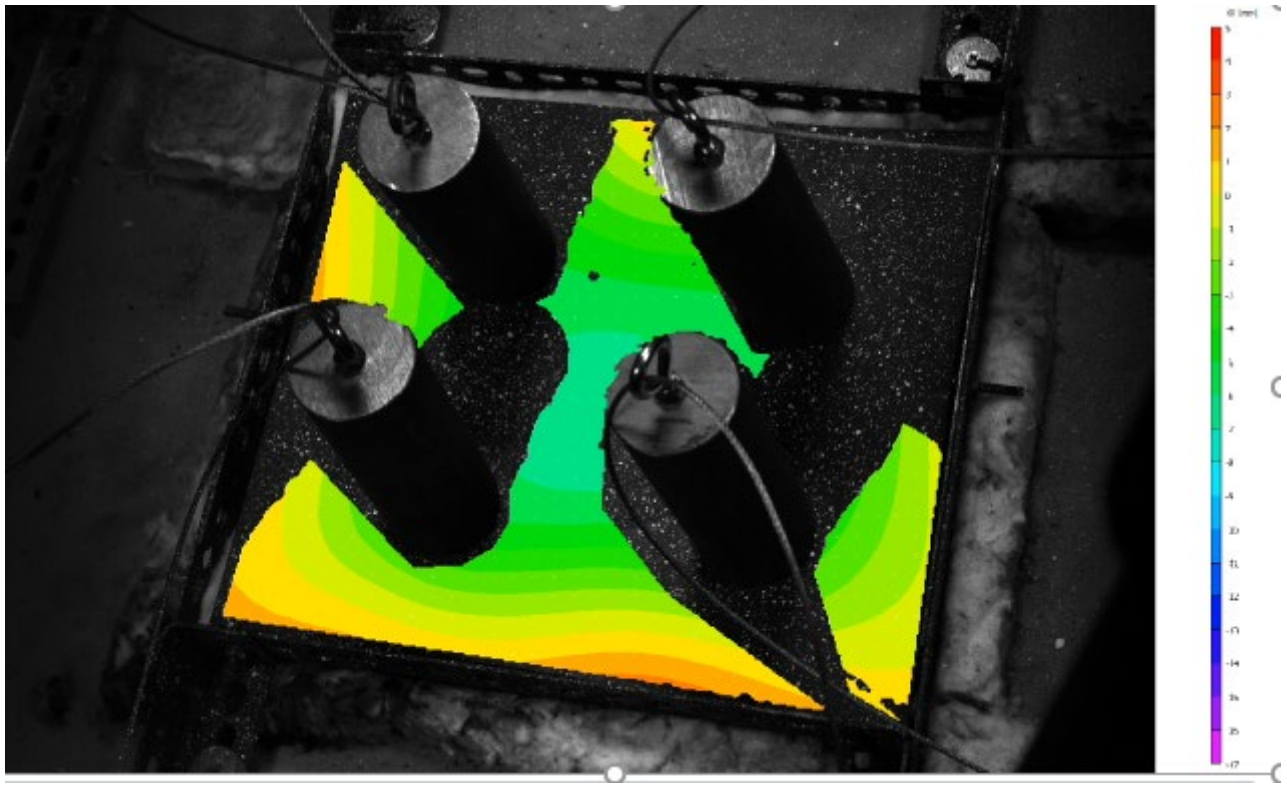
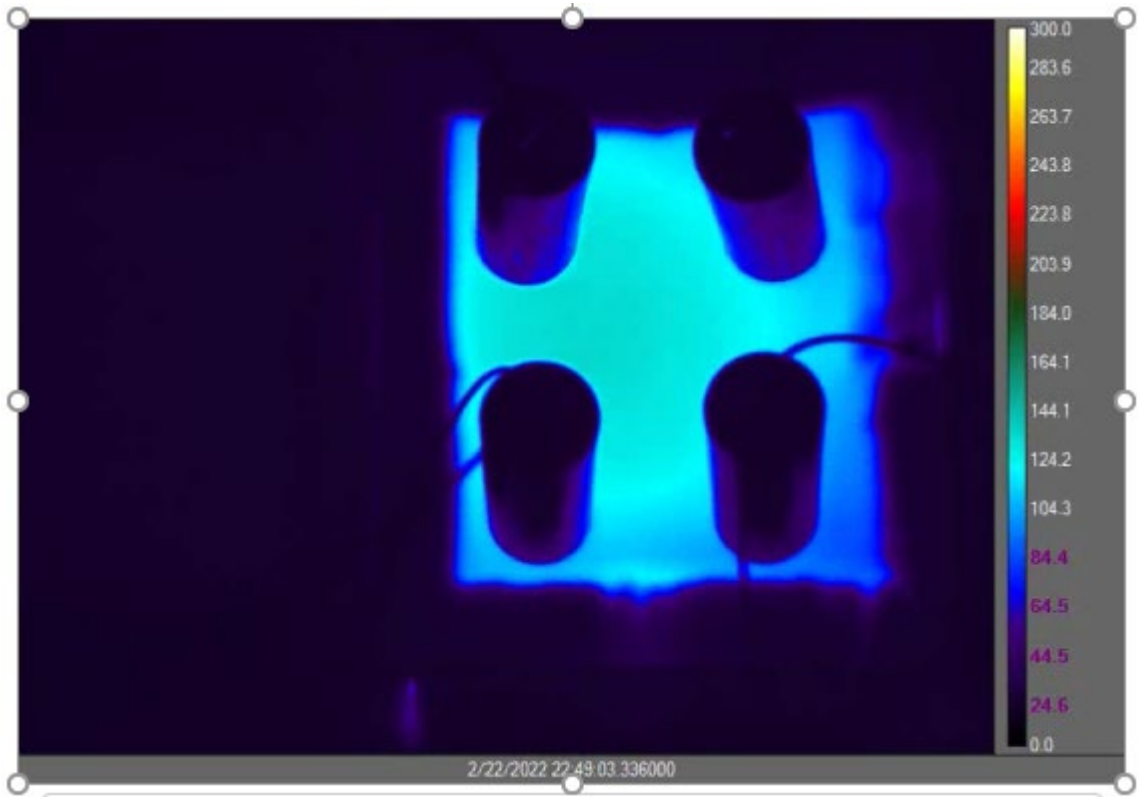
SAND-BURNER EXPOSURE

Mechanical Loading & Fire



Weight of battery enclosure ≈ 90 N uniformly distributed over the area of the plate.

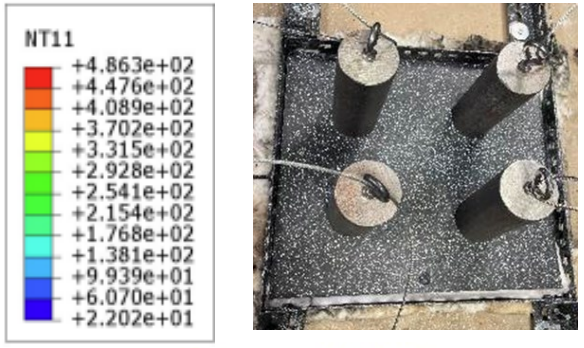
Initial tests: Four equal 22.5 N and 50 mm diameter steel cylinders weights.



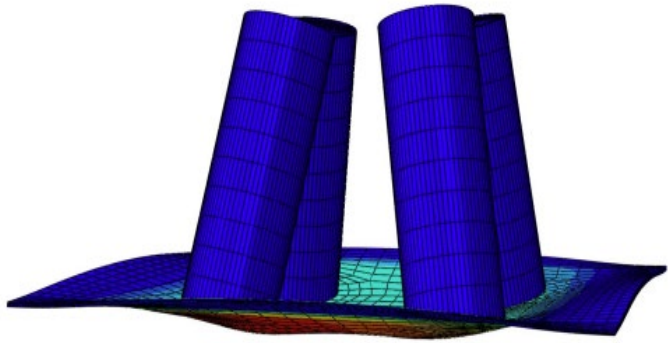
TDIC Measurements of Temperature and Displacement

TDIC Measurements

Out-of-Plane Displacement

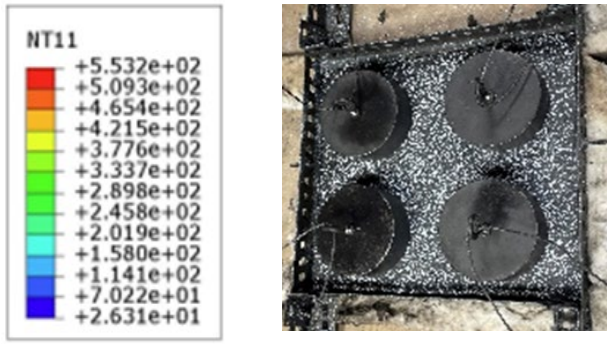


Temperature

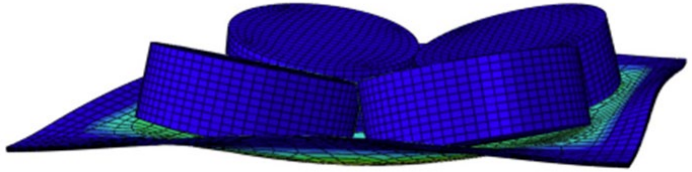


THERMOMECHANICAL MODELING

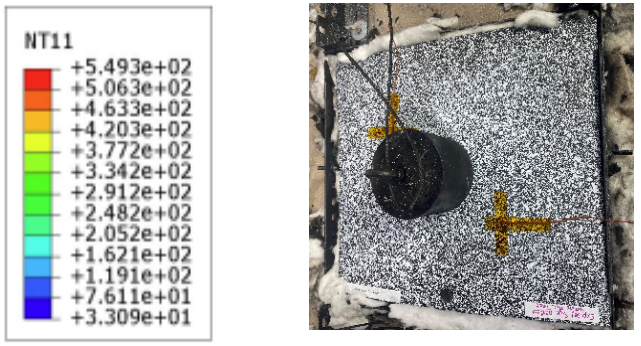
Loaded Plates

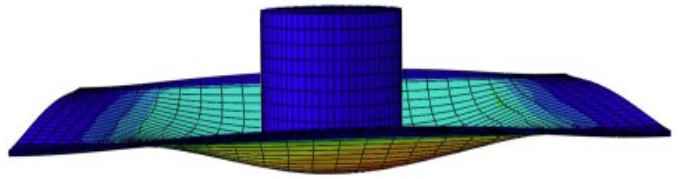


Subjected to one-sided external fire and various mechanical loading scenarios



4 × 50 mm diameter weights





4 × 100 mm diameter weights

1 × 75 mm diameter weights

Conclusions

- Developed a framework for analysis of failure of composites subjected to combined fire and mechanical loading
- Examined micromechanics of failure using combination of experiments and analysis
  - Shift factors indicate that viscoelasticity controls compression failure (same shift factors for shear creep compliance and compression creep rupture data)
  - Good success in using Budiansky-Fleck type compression model to predict failures
  - Fiber tensile strength changes with temperature in E-glass fibers linked to surface flaw growth
- Relatively simple laminate-level mechanics models can explain key features of laminate out-of-plane deformation during simulated fires
- Integration of material models with numerical tools allows use to predict the failure of E-glass/vinyl ester laminates in a wide range of configurations and size scales
- New measurement techniques such as TDIC have promise in leading to greater understanding of the underlying behavior and validation of modeling tools
- Currently applying to long and short fiber thermoplastic composites for electric vehicle applications

Abstract

- ***Lockheed Martin has a clear mandate from gov't customers to accelerate the air vehicle development timeline relative to what industry has traditionally done.***
- ***The airframe, though higher TRL/MRL than most systems on new platforms, is the most time-consuming component to develop.***
- ***Digital transformation into model-based engineering is intended to be a major contributor to compressing development timelines.***
- ***Airframe development involves a myriad of individual processes that are hard to standardize/digitize, hindering significant schedule advancement.***

Objectives

- ***Examine various engineering processes for inefficiencies, bottlenecks, and potential for improvement.***
- ***Suggest ways to overcome inertia in process standardization, digitization, and airframe development timeline compression.***

LOCKHEED MARTIN

Airframe Development Timelines

- *1st flight generally X- or Y-variant.*
- *B1A cancelled, B1B IOC shown.*
- *B2, F22, and F35 redesigned before IOC.*
- *F22 avionics further delayed IOC.*
- *Recent IOC timelines affected by extensive mission/vehicle system flight test requirements.*

Industry needs shorter timelines for both 1st flight as well as production aircraft IOC. Cannot fully redesign Y-variant for production.

Airframe Development Timelines

Sources of timeline expansion over last 80 years:

- ***Additional requirements (DaDT, ballistic tolerance, crash, lightning strike, stealth)***
- ***Advanced design/mfg concepts (Titanium, composites, bonded joints, hot structures, complex systems interfaces)***
- ***Advanced methods/tools (3D part models, detailed FEMs, complex loads, structural optimization)***
- ***Staff inexperience (many now only do 1 or 2 development programs in career)***
- ***Ill-defined/non-standard workflows, data mining limitations, over-engineering and re-processing***

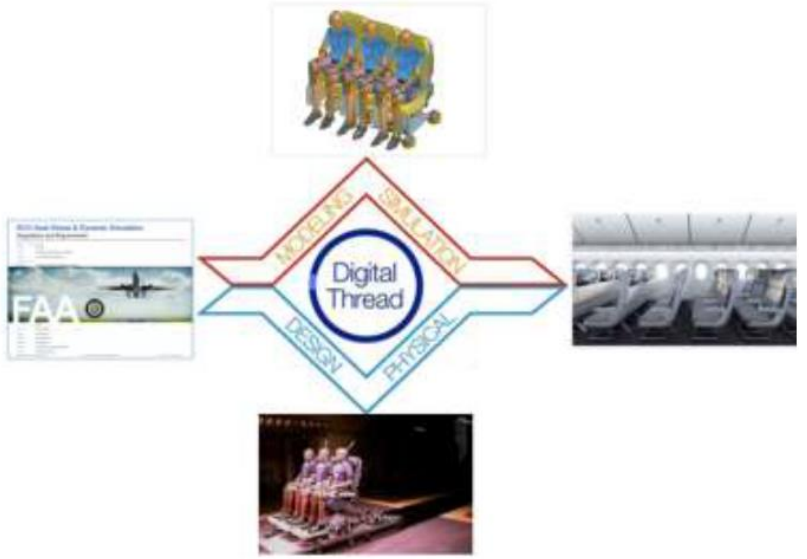
- ***Proposed Process Changes***
- ***Summary***



©2025 Lockheed Martin Corporation. All Rights Reserved

LOCKHEED MARTIN

Proposed Process Changes

- ***Aero needs to re-tool its structures conceptual design approach, both with guidelines and staffing (maybe not tool automation?)… get this right and fewer disruptive major downstream changes will be required.***
  - *Get the right SME's involved at the right times.*
  - *Lay out the major airframe structure ("big bones") efficiently, then accommodate various systems (not the other way around).*
- ***Cross-team communications need to be greatly improved.***
  - *Feedback loops need to be standardized and digitized.*
  - *Hand-offs between Aero-&-Loads, Mass-Properties-&-Loads/Dynamics, Loads-&-FEM, etc. are too slow because of the need for translation into the format the receiving team needs.*
- ***Too much detail goes into AVFEM too early. FEM team needs better pre-design guidelines.***
  - *CAD surfaces for AVFEM meshing, material data from PLM and IDAT to FEM, fastener hangpoints & metadata all need to be standardized and streamlined.*
  - *Layout phase and maybe BTP FEM's do not need sprung skins, 2.5D flanges, DFEMs, etc.*

Proposed Process Changes

- ***ICAT stress Digital Transformation tools are more mature than those for other analysis disciplines, but analysts need to be trained to minimize – rather than maximize – efforts.***
  - *Limit amount of detail and load cases in finite element models to only what is required for a given phase of development.*
  - *Ignore tertiary details and non-critical parts prior to BTP phase but properly set the big-bones arrangement at Conceptual Design Review (CoDR).*
  - *Agree on a limited number of loads updates and schedule the rest of the analysis tasks around these deadlines.*
- ***SLA input into pre-design, layout, and BTP phases needs to be streamlined/simplified and new guidelines for limited life vehicles developed.***
  - *SLA is unnecessary for certain classes of vehicles and for limited life prototypes.*
  - *SLA should be greatly simplified in all development phases through BTP. Post-BTP SLA can and should be more detailed for manned aircraft fleets with complex service life spectra.*

LOCKHEED MARTIN

Summary

- ***Airframe development is a complex, iterative process with many inter- and intra-discipline data handoffs.***
- ***Timelines for airframe development have generally increased over time due to additional requirements, advanced design and manufacturing concepts, and a combination of more advanced tools being used by less experienced engineers.***
- ***Digital transformation efforts, particularly in stress and service life analysis, have demonstrated the value of standardized workflows in reducing analysis spans but have not been widely adopted.***

Recommendations

- ***Modify structures conceptual design approach to optimize major airframe structure before accommodating various systems components.***
- ***Improve cross-team communications with standard digital data handoffs in accordance with a program milestone-based schedule.***
- ***Define appropriate amount of detail required in finite element models based on phase of program and ensure Design & Extremal Loads processes align with required FEM inputs.***
- ***Develop training to emphasize the appropriate level of detail of analysis at each phase of a program and minimize analysis effort needed to achieve program requirements.***

24TH INTERNATIONAL CONFERENCE ON COMPOSITE MATERIALS

Rapid Manufacturing Pathways for High-Performance Thermoplastic Composites

Mehran Tehrani

Associate Professor

Callaway Golf Endowed Chair

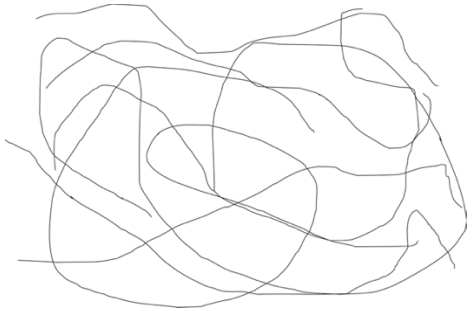
Structural and Materials Engineering

Advanced Composites & Aerospace Structures

August 07, 2025

UC San Diego

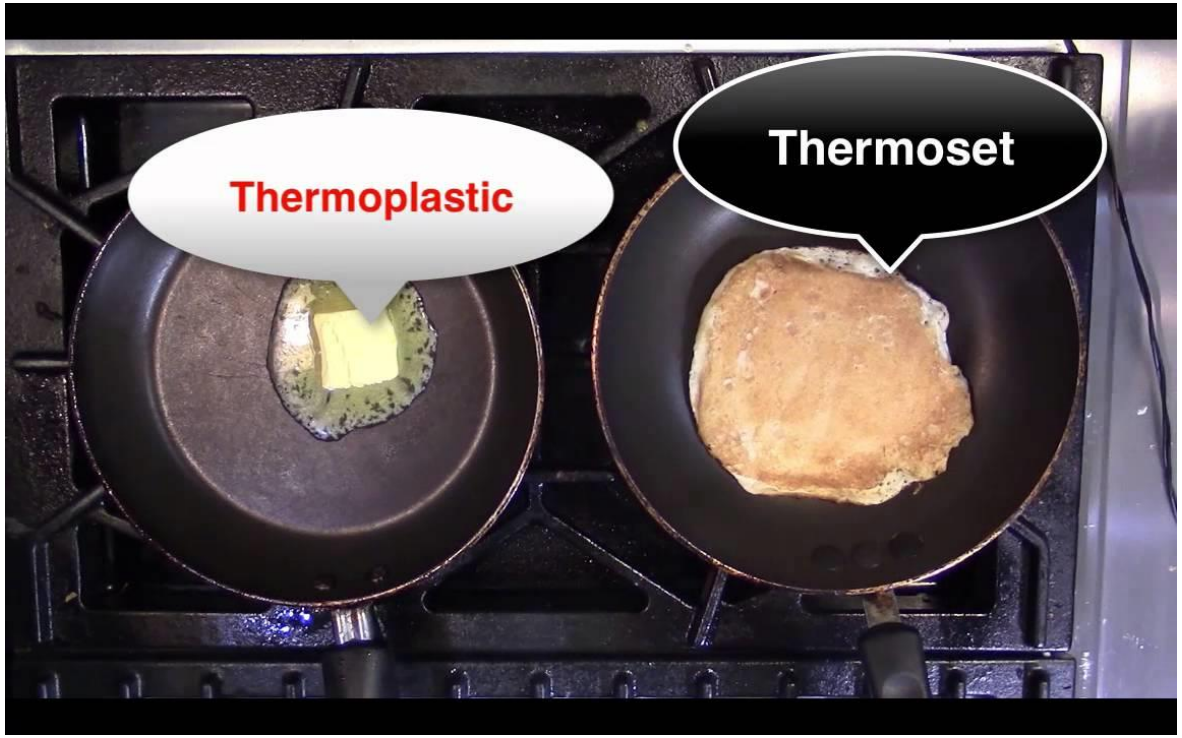
Outline



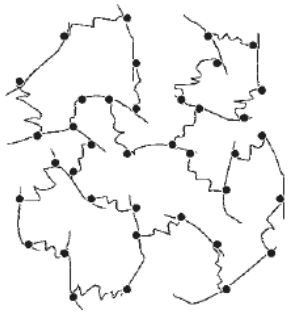
- Introduction to thermoplastic composites and their manufacturing
- In-situ consolidation of thermoplastic composites (TPC)
- Engineered pathways for post-consolidation of TPCs
- Energy-efficient Aerospace-grade Laminates = OATMEAL

Introduction

Matrix: Thermoplastics vs Thermosets

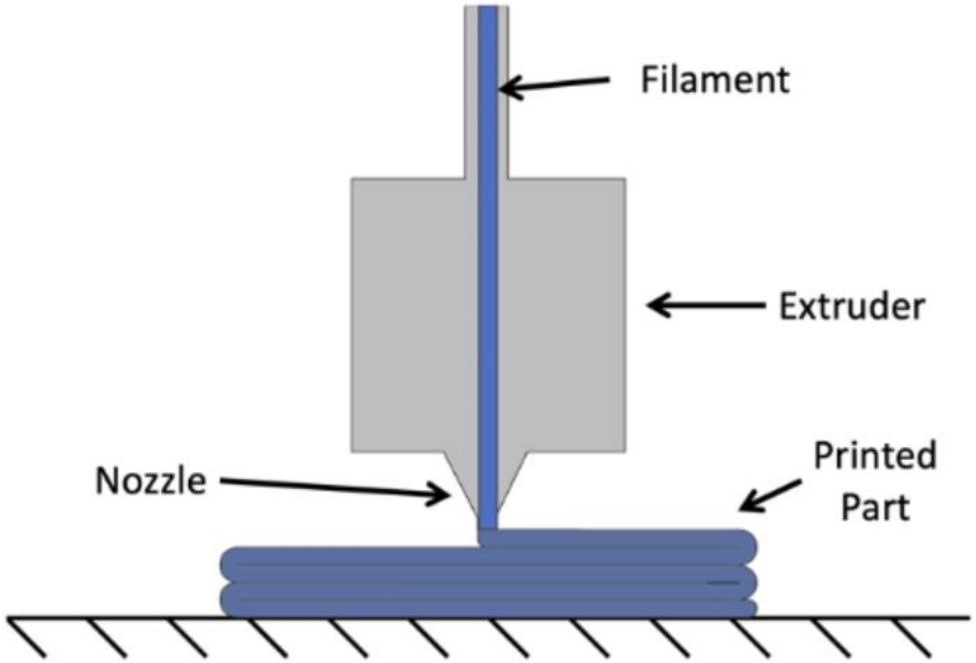


Thermoplastics
Reversible melting



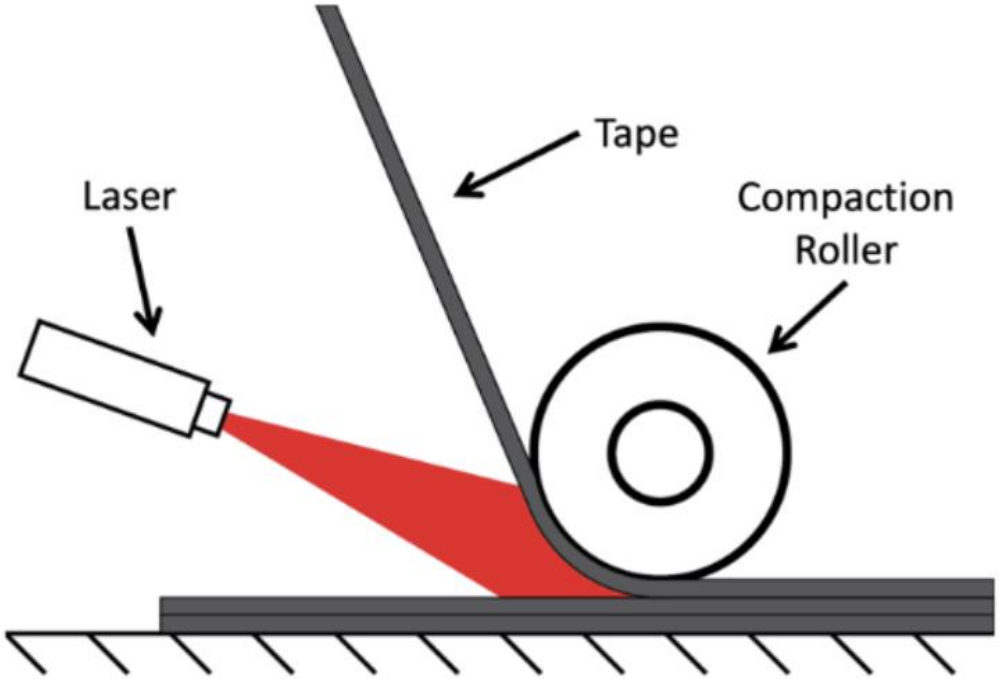
Thermosets
Irreversible curing
(heat or UV activated)

More viscous



Less viscous

These properties affect processing

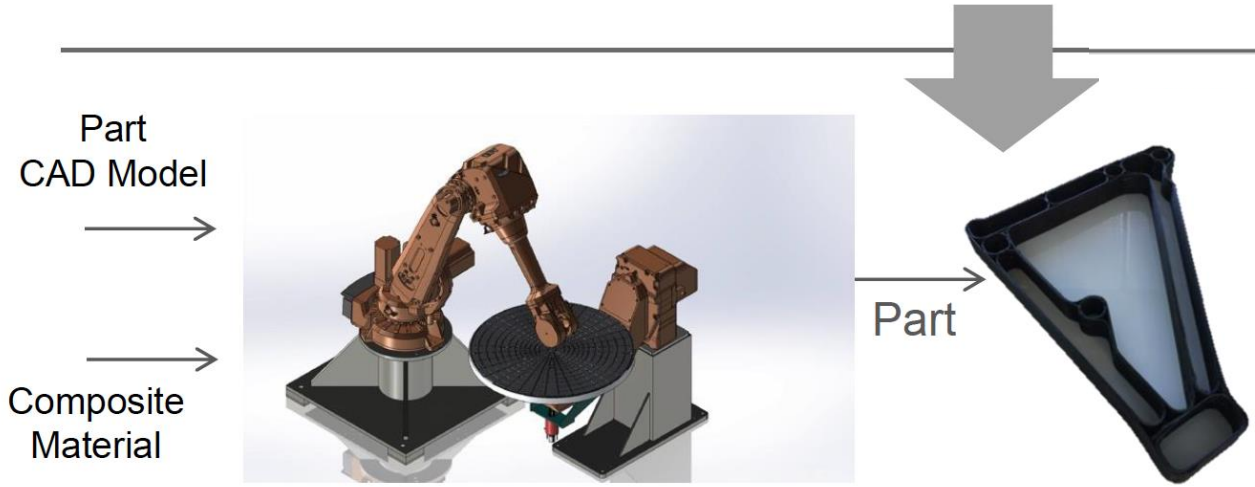


Images are from the internet.

Additive Manufacturing of TPCs

Material Extrusion (ME)

Fused Filament Fabrication (FFF)



Directed Energy Deposition (DED)

Laser-Assisted Automated Fiber Placement (AFP)

Advanced Manufacturing of Thermoplastic Composites
