ICCM24

24TH INTERNATIONAL CONFERENCE ON COMPOSITE MATERIALS

AUGUST 4-8, 2025

BALTIMORE CONVENTION CENTER

BALTIMORE, MARYLAND, USA

CONFERENCE
PROGRAM

Bristol UK: A world-leading hub for composites research and innovation

Partner

The Bristol Composites Institute (BCI) and NCC work in tandem to deliver cutting-edge research and innovation with demonstrable industrial impact.

Collaborate

Academic research at the Bristol Composites Institute benefits from industry partnerships, and generates new science and technology around novel material concepts, structural design and manufacturing of composites.

Innovate

NCC bridges the gap between academia and industry, helping companies of all sizes to capitalise on cutting-edge innovations to deliver more - at every stage of their journey and across the entire product lifecycle.

Welcome to ICCM24

The University of Delaware Center for Composite Materials (CCM) is pleased to host ICCM 24 as part of our 50th anniversary celebrations. This exciting conference is being held at the Baltimore Convention Center next to the Inner Harbor with its stunning waterfront views and is rimmed with spectacular museums. The conference features a dedicated industry track, international networking opportunities and cutting-edge research and insights.

CCM, based in nearby Newark, Delaware, has been a global leader in composites research for five decades. From our inception, we've pushed the boundaries and set the standard for advanced capabilities that have shaped the composites landscape.

We welcome you to Baltimore — a city renowned for its rich cultural and historical heritage and a strong manufacturing base. In the latter half of the 20th century, the defense industry began to expand its presence in and around Baltimore. New opportunities for advanced manufacturing and information technology have emerged here in the 21st century.

Today, Baltimore is known to be a diverse community with a lively arts and culture scene, historical landmarks, museums and attractions. Known for its skilled workforce, Baltimore leverages its strengths in advanced manufacturing and biotechnology to build a better future.

In addition to the conference, welcome reception, and banquet, we hope that you'll have time to celebrate our 50th anniversary at a social event on Wednesday, August 6 at the Power Plant Live! Baltimore Inner Harbor.

Along with my co-chair, Professor Erik Thostenson, I look forward to greeting you in Baltimore to participate in ICCM 24.

General Information

REGISTRATION

Please ensure you collect your Conference Badge from the Registration Desk located in the Charles Street Lobby, Level 100 of the Baltimore Convention Center.

You are required to wear your Conference Badge at all times. The registration desk will be open during the following times:

Sunday, August 3:	2:00 PM - 6:00 PM
Monday, August 4:	7:30 AM - 6:00 PM
Tuesday, August 5:	7:00 AM - 5:30 PM
Wednesday, August 6:	7:00 AM - 6:00 PM
Thursday, August 7:	7:00 AM - 5:30 PM
Friday, August 8:	7:00 AM - 12:30 PM

EXHIBIT HALL HOURS

The ICCM24 Exhibit Hall is located on Level 100 in Hall A/B. Food functions and Poster Sessions will be held inside the Exhibit Hall.

The Exhibit Hall will be open during the following times:

Monday, August 4:	7:30 AM - 4:30 PM
Tuesday, August 5:	7:00 AM - 5:30 PM
Wednesday, August 6:	7:00 AM - 4:30 PM
Thursday, August 7:	7:00 AM - 5:30 PM
Friday, August 8:	7:00 AM - 11:00 AM

SPEAKER PREVIEW ROOM

For the program to run efficiently presentations will be preloaded on each session's laptop daily. Due to time constraints and to respect your fellow speakers, the use of individual laptops is prohibited.

The speaker preview room will provide you with a means of uploading the most up-to-date version of your presentation. You must stop by the Speaker Preview room at least one (1) day prior of your speaking session to make any necessary changes. The Speaker Preview Room will be located on Level 300 in room 302, staffed by AV technicians, and open during the following times:

Sunday, August 3:	2:00 PM – 6:00 PM
Monday, August 4:	7:30 AM – 4:30 PM
Tuesday, August 5:	7:30 AM – 4:30 PM
Wednesday, August 6:	7:30 AM – 4:30 PM
Thursday, August 7:	7:30 AM – 4:30 PM

WIFI

WIFI access is complimentary through the Baltimore Convention Center with no password required.

EMERGENCY / FIRST AID

In an emergency, dial 911 for fire, police, and ambulance. The nearest local Hospitals with After Hour care are:

University of Maryland Medical Center
Address: 22 S Greene St, Baltimore, MD 21201
Phone: (410) 328-8667

Mercy Medical Center Emergency Department
Address: 301 Saint Paul St, Baltimore, MD 21202
Phone: (410) 332-9477

University of Maryland Medical Center Midtown Campus
Address: 827 Linden Ave, Baltimore, MD 21201
Phone: (410) 225-8000

The Johns Hopkins Hospital Emergency Room
Address: 1800 Orleans St, Baltimore, MD 21287
Phone: (410) 955-5000

LANGUAGE

The official language of the 24th International Conference on Composite Materials is English.

PROCEEDINGS

All accepted presentations will be included in the official ICCM proceedings. The proceedings will be available to registered ICCM24 attendees via the official website.

INSURANCE

The 24th International Conference on Composite Materials is unable to accept responsibility for accidents or damage to the private property of participants. Please ensure that you do not leave portable and valuable pieces of equipment unattended anywhere, and that you make your own arrangements for health, travel, general and other insurance.

UNIVERSITY OF DELAWARE

CENTER FOR COMPOSITE MATERIALS

Celebrating 50 Years

Honoring the Legacy of the University of Delaware Center for Composite Materials

Since its establishment in 1974, the University of Delaware's Center for Composite Materials (UD-CCM) has consistently positioned itself at the forefront of research, education, and technology transfer in the field of composite materials. As we commemorate our 50th anniversary, we take this opportunity to reflect upon a legacy characterized by pioneering innovation, interdisciplinary collaboration, and significant global impact.

UD-CCM is internationally recognized as a Center of Excellence and has been instrumental in advancing the science and engineering of composite materials. Through over five decades of groundbreaking research encompassing materials synthesis, multifunctional systems, processing science, mechanics and design, sensing and control, and software development, we have fundamentally shaped the future of composites across diverse industries.

Our mission is defined by three core objectives:

1. To conduct transformative research that bridges fundamental discovery and real-world application.
2. To educate and inspire the next generation of scientists and engineers through immersive, hands-on learning experiences.
3. To facilitate the transition of technology to industry, empowering over 350 companies with innovative solutions and skilled talent.

With more than 53,600 square feet of advanced facilities and an investment of over $30 million in equipment, UD-CCM continues to lead in AI-enabled composites, smart materials, and sustainable composite solutions. Our efforts are supported by a robust network of federal agencies, including the U.S. Army Research Laboratory, U.S. Air Force, Office of Naval Research, DARPA, NASA, the National Science Foundation, the United States Department of Agriculture, and the Department of Energy, as well as a diverse array of industrial partners.

As we celebrate this significant milestone during ICCM24, we extend our gratitude to the visionary faculty, students, researchers, staff, and partners who have contributed to this journey. From our foundational breakthroughs to contemporary technological advancements, UD-CCM remains steadfastly committed to "Pioneering Innovation Excellence," a guiding principle that will propel us into the next fifty years.

Enjoy an evening of celebration, networking, and reflection on five decades of innovation in composites. We look forward to celebrating with you!

Join us in Celebration

We invite all ICCM24 attendees to commemorate this historic occasion at the CCM 50th Anniversary Celebration Dinner.

4:10 PM - 4:30 PM	**Experimental and Numerical Compression Analysis of 3D X-ray CT Scanned Uni-Directional Pultruded Carbon Fiber Composites** Ms Pinelopi Mageira - Technical University of Denmark	**Modeling the Impact of Void Distribution on Mechanical Properties of Short Fiber Recycled CFRTP Integration of Experimental Analysis and Finite Element Analysis** Mr Takumi Morishima - The University of Tokyo	**Electron-Beam and Gamma-Ray Radiation Treatments to Achieve High Strength in Carbon Nanotube Laminates** Mr Cecil Evers - Florida State University HPMI	**Orthotropic Impact Response of Unidirectional Glass/Epoxy Composites: A Yarn-Level Finite Element Analysis** Dr Shubham Shubham - Indian Institute of Technology Bombay	**Multifunctional Graphene-based Nanocomposites with Synergistic Effects of Chemical and Physical Interactions** Dr Seira Morimune-Moriya - Chubu University	**Additive Manufacturing Process for Fabricating Complex and Dynamic Poss-based 4D Structures** Ms Nicole Gorohovsky - Tel Aviv University	**The Discrete Model for Composites DM4C Mesoscale Modeling of Composites Via Physics-Based Discrete Mathematical Models of Fibers and Matrix** Dr Marco Salviato - University of Washington
4:30 PM - 4:50 PM	**Partially Carbonised Carbon Fibres as an Improved Multifunctional Structural Battery Electrode** Mr Ruben Tavano - Chalmers University of Technology	**High Resolution Induction Sensing for Feature Detection in Thin-Ply Carbon Fiber Reinforced Polymer** Mr Ehshan ul-Haq - Delft University of Technology	**Plasma-Treated PET Nanofibers Veils a Novel Interface Enhancement for Cryogenic Composite Applications** Mr Jeho Jin - Korea Advanced Institute of Science & Technology	**Testing and Progressive Failure Modelling of a Wind Turbine Blade Spar Capweb Joint Substructure** Dr Tobias Laux - University of Bristol	**Soft Composites for Charge Transport and Storage to Synergistically Enhance Energy Harvesting Performance of Triboelectric Generators** Miss Ziyan Gao - University of New South Wales	**Predicting and Optimizing FDM Print Performances: An AI Approach to Mechanical Property Optimization** Mr Marcello Laurenti - Sapienza	**Fatigue Simulation of Laminated Composites Under Mixed Mode Cyclic Loading Using a Damage-Mechanics-Based Fatigue Accumulation Model** Mr Rong-Can Hong - The University of Tokyo
4:50 PM - 5:10 PM	**Moisture Effects on Impact Strength and Recovery in Carbon Fiber Reinforced Vitrimers** Mr Jun Young Choi - Seoul National University	**Viscoelastic Biscale Modeling of Process-Induced Deformation in Noncrimp Fabric Composite** Ms Sera Koo - Tohoku University	**Multifunctional Carbon Nanotube-Based Composite Carbon Fibers for Enhanced Mechanical Properties** Dr Bon-Cheol Ku - Korea Institute of Science & Technology KIST	**Improving the Computational Efficiency of Impact Simulations on Woven FRP Composite Plates** Mr Jakov Ratkovic - University of Zagreb FAMENA	**Designing Novel Composite Structural Supercapacitors with Discrete Carbon Nanotube Electrodes and Polymer Electrolyte Separator Membranes** Dr Alex Harman - Defence Science & Technology Group	**Model Order Reduction Methods for Real-Time Prediction of Thermomechanical Properties of Additively Manufactured Composite Structures** Mr Pablo Castello Pedrero - Universitat Politicnica de Valencia	**Progressive Damage Behavior of Plain-Woven CFRP under Tensile-tensile Cyclic Loading** Mr Chihaya Hoshikawa - Nagoya University
5:10 PM - 5:30 PM	**A Structure-Integrated Nanocomposite Sensor System Capable of Simultaneous Measurement of Omnidirectional Strain and Temperature** Mr Sumin Lee - Korea Advanced Institute of Science & Technology	**Damage Tolerant Graphene-Metal Nanocomposite Thin Films by Chemical Vapor Deposition Synthesis** Dr Kaihao Zhang - The Hong Kong University of Science & Technology	**Unravelling the Effect of the Addition of a New Carbon Allotrope in Polymeric Composites: Investigation of Electrical Properties** Miss Silvia Zecchi - Politecnico di Torino	**Towards an Accelerated Nonlinear Solution Method Inspired by Multiscale and Multigrid Methods** Dr Ryan Whitehead - Bluehalo	**Polymer Nanocomposite Triboelectric Nanogenerators for Antimicrobial and Electrical Stimulation Platforms** Prof Yong Tae Park - Myongji University	**One Go Approach on Developing Topologically Interlocked Materials TIMs Via Fused Filament Fabrication Process** Dr Sabarinatham Palaniyappan - King Fahd University of Petroleum Minerals	**Strength Evaluation of Twill Woven CFRP Laminated Structure, Considering Knee Point** Dr Masataka Kawaguchi - Doshisha University
5:30 PM - 5:50 PM	**Prepreg Development for Rapid On-Orbit Composites Manufacturing via Frontal Curing** Mr Tyler Price - University of Illinois Urbana Champaign	**Insights from a Manufacturer Dedicated to Expanding the Role of Structural Composites in Commercial and Residential Construction** Dr Richard Rydin - Building Composites LLC	**Optimizing Hierarchical Carbon Nanotube-Grafted Carbon Fiber Production** Dr David Anthony - Imperial College London	**Strip Buckling Analysis to Predict Skin-Stiffener Debonding in Postbuckled Panels** Prof Richard Butler - University of Bath	**Wearable Body Temperature Sensing with Autonomous Self-Regulated Joule Heating and Passive Cooling for Healthcare Applications** Mr Hongxu Guo - Loughborough University	**Feasibility Study of a 3D-printed Honeycomb Core Structure as Thermal Vacuum Insulation for Liquid Hydrogen Composite Pressure Vessels** Mr Andreas Scherer - University of the Bundeswehr Munich	**High Temperature Fatigue Performance Evaluation of Fibre-Reinforced Polymer (FRP) Composites Utilizing Monotonic and Dynamic Mechanical Analysis** Dr Shoab Ahmed Chowdhury - TA Instruments
5:50 PM - 6:10 PM	**Surrogate Model-driven Automation for RVE Design and Validation of Long Discontinuous Carbon Fiber Composite Structures** Mr Akshay Zaveri - University of Connecticut	**Optimization of Processing Conditions for UHMWPE Composites in Body Armor Applications** Mr Alex Vanarelli - University of Delaware		**Influence of the Fiber Curvature on the Mechanical Properties of Long Fiber Reinforced Composites** Ms Celine Lauff - Karlsruhe Institute of Technology		**Effects of 3D Printing Orientation and Infill Patterns on the Impact Strength and Fracture Behavior of PLA-CFRP Hybrid Structures for Robotics** Mr Cheonghwa Lee - University of Connecticut	**Mechanical Characterization of MWCNT Based BFRP Composite by using the Mode I and Mode II** Dr Kalyan Singh - Indian Institute of Technology ISM Dhanbad
7:00 PM - 9:00 PM	**Welcome Reception** - *National Aquarium*						

Room 316	Room 317	Room 318	Room 319	Room 320	Room 321	Time
Aerospace Structures	AI Empowered Paradigm	Frontal Polymerization	Computed Tomography	Permeability Measurement of Textiles	Self Healing	
Analysis of the Mechanical Behaviour of CFRP Bosses in Composite Pressure Vessels Considering Different Stiffness Distributions Mr Gerrit Rehs - University of the Bundeswehr Munich	**Semantic Interoperable Data Model and Stochastic Multiscale Analysis of Short Fibre Composites** Dr Joerg Hohe - Fraunhofer-Institut fuer Werkstoffmechanik	**Multiphysics Modeling of Frontal Polymerization-Based Manufacturing of Woven Composites** Mr Michael Zakoworotny - University of Illinois Urbana-Champaign	**Deep Learning-Driven Segmentation of Resin-rich Areas in 3D CT Imaging of CFRTP-SMC** Mr Cheng Jin - The University of Tokyo	**Material Characterization for Particle-filled RTM in 3D Fibrous Preforms** Ms Leonie Marchand - GeM Lab	**Sustained Self-Sensing and Autonomous Self-healing via Electrothermal Coupling in Fiber-composites** Mr Jack Turicek - NCSU	4:10 PM - 4:30 PM
Improving Aeroelastic Performance of Hale Geometrically Nonlinear Flexible Wings Ms Najwa Zaqirah Binti Taufik - King Fahd University of Petroleum & Minerals	**A Data-Driven AI-Enabled Approach to Predict Crystal Morphology Evolution in Heterogeneous Semicrystalline Thermoplastic Composites** Mr Amit Makarand Deshpande - University of Delaware	**Energy-Efficient UV Curing of Non-Transparent Fibers in the VARI and RTM Process** Mr Jens Take - Universitut Stuttgart	**Prior Shape Analysis for Yarn Segmentation in XCT Images** Ms Hafsa El Herichi - Safran Group	**Can We Reliably Predict In-Plane and Out-of-Plane Permeability of a Reference Permeable Medium** Mr Andreas Endruweit - University of Nottingham	**Influence of the Addition of Thermoplastic Healing Agent to Epoxy Resin** Mrs Ana Paula Cysne Barbosa - Federal University of Rio Grande do Norte	4:30 PM - 4:50 PM
Ultrasonic Reconsolidation at 20 KHz: A Potential Repair Approach for Aerospace Composites Mr Balaji Ragupathi - University of Freiburg	**Graph Neural Networks for Effective Prediction of Mechanical Response in Composite Structures with Models using Unstructured Meshes** Mr Luca Patrignani - Imperial College London	**Buoyancy-Driven Convection in Adiabatic Horizontal Frontal Polymerization** Ms Laurence Rongy - Universite libre de Bruxelles ULB	**Robust Image Registration for Periodic Materials Application to 3D Woven Textiles** Mr Arturo Mendoza Quispe - Safran		**Self Healing Composites Influence of Self Healing Agent Fraction** Prof Maria Cioffi - UNESP	4:50 PM - 5:10 PM
Manufacturing Process for Large Space Structures and Supporting Long-Duration Human Space Mission Prof Susanna Laurenzi - Sapienza Universita di Roma	**AI-Based Generation of Simulation Models for Material Development from CT Data** Dr Oliver Rimmel - Math2Market GmbH	**Scaling Up the Efficient Manufacturing of Carbon Fiber Epoxy Composites Using Frontal Polymerization** Dr Yeqing Wang - Syracuse University	**Local and Global Strain and Defect Analysis of Discontinuous Glass Fiber Reinforced Polymers** Ms Julia Maurer - FHOOE Forschungs und Entwicklungs GmbH			5:10 PM - 5:30 PM
In-Situ Resource Utilization for Sustainable Space Exploration: 3D Printing PEKK-Space Regolith Composites Prof Mehdi Hojjati - Concordia University	**Hybrid 1D Convolutional Neural Network and Fuzzy Clustering for Damage Detection in Composite Plates Using Laser Ultrasonic Guided Waves** Mr Shain Azadi - Politecnico di Milano		**Mechanical Characterisation of Carbon Fibre-Reinforced Sheet Moulding Compounds and Introduction to X-ray In-situ Biaxial Testing of Composite Materials** Mr Salaheddine Madi - KU Leuven			5:30 PM - 5:50 PM
	A Bayesian Inference Approach for Estimating Heat Transfer Coefficients for Thermal Management in Composites Manufacturing Processes Prof Reza Vaziri - The University of British Columbia		**Fibre-Simulator: An Open-source Python Tool for Generating Fiber Phantoms** Ms Mary Chris Go - Universiteit Leiden			5:50 PM - 6:10 PM
Welcome Reception - *National Aquarium*						7:00 PM - 9:00 PM

Scientific Program

Time	Ex Hall C - Plenary	Room 307	Room 308	Room 309	Room 310	Room 314	Room 315
7:00 AM	**Registration Desk Open** *(closes at 5:30 PM - located in Charles Street Lobby, Level 100)*						
7:00 AM	**Continental Breakfast** *(until 8:00 AM - located in Exhibit Hall A/B, Level 100)*						
7:00 AM	**Exhibit Hall Open** *(closes at 5:30 PM - located in Exhibit Hall A/B, Level 100)*						
8:00 AM	**Welcome Remarks**						
8:05 AM	**Plenary Speaker: Composites Science and Technology Empowered by Physics Informed and Augmented Learning** Prof Francisco Chinesta, *Arts et Métiers Institute of Technology*						
Move to Level 300 for Parallel Keynotes and Technical Sessions							
9:00 AM - 9:30 AM		**Keynote Speakers** **Understanding Pore Formation in Reactive Acrylic Thermoplastic Resin Upon Polymerization** Dr Olivier De Almeida - Institute Clement Ader IMT Mines Albi	**Multiscale and Multiphysics Modelling and Characterisation of Structural Batteries** Prof Leif Asp - Chalmers University of Technology	**Thermoplastic Composites for Demanding Energy Environments: Solutions in Design and Challenges in Monitoring** Prof Gilles Lubineau - KAUST	**Shift the Paradigm of Composites Modeling Using Artificial Intelligence** Prof Wenbin Yu - Purdue University		
	Certification for Analysis Workshop	**Manufacturing: AFP/ATP 1**	**Materials and Precursors**	**Physical and Structural Behavior**	**Multifunctional Composites**	**AI Empowered Paradigm**	**Fatigue and Damage Mechanics of Composites**
9:35 AM - 9:55 AM	**9:35 AM - Welcome Remarks and Introductions** Prof Ole Thomsen - University of Bristol **9:45 AM - Integration of Multi-Scale Modeling, High-fidelity Experimentation and Bayesian Learning - Towards Certification by Analysis** Prof Richard Butler Dr Andrew Rhead - University of Bath **10:10 AM - Imaging Based Sub-Structure Testing and Data Fusion Methodologies for Integration of Virtual and Physical Data** Prof Janice Barton Prof Ole Thomsen - University of Bristol	**Investigation of the Mechanisms of Fuzzball Formation and Growth in Automated Fiber Placement AFP of Thermoset Composites** Mr Genki Matsubara - University of Washington	**Optimizing Oxidation Resistance of CC Composites with Multilayer SiC-Based Coatings for High Temperature Application** Mr Mosiur Rahaman - The University of Tulsa	**Simulation and Validation of Delamination Propagation and Migration in Composite Panels Subjected to Out-of-plane Bending** Miss Alice Pagnanini - KU Leuven	**Shape Memory Behaviour of Re-entrant Unit Cell Structure Based on 3D Printed Polyurethane Nanocomposites** Dr Yu Dong - Curtin University	**A Fast Uncertainty Quantification Method for Failure Prediction of Large Composite Structural Elements** Mr Mario Miranda - Imperial College London	**Effect of Cooling Rate on Mode II Fatigue Crack Growth Behavior in Carbon Fiber Reinforced Polyphenylene Sulfide** Dr Yu Zusho - The University of Tokyo
9:55 AM - 10:15 AM		**Enhancing Quality and Productivity in Automated Fiber Placement: Strategies for AFP Programming, In-process Inspection, and Process Optimization** Dr Jihua Chen - National Research Council Canada	**Biobased Composite Fibers and Films with Keratin from Chicken Feathers as Matrix and Calcium Carbonate as Nanoreinforcement Materials** Dr Yiqi Yang - University of Nebraska-Lincoln	**Effect of Clamping Force and Environmental Conditioning on the Mechanical Performance of Bolted Composite Laminates** Dr Neha Chandarana - University of Bristol	**Direct Ink Writing EM Radiator for Conformal Load Bearing Antenna Structure** Mr Jeaan Jeon - Inha University	**AI-Driven Method for Predicting Fibre Orientation in Composites** Mr Cesar Garcia-Gascon - Universitat Politecnica de Valencia	**Modified Curing Cycles and Accompanying Polymer and Adhesion Changes in Fiber Metal Laminates** Mr Andreas Baumann - Leibniz Institut für Verbundwerkstoffe GmbH
10:15 AM - 10:35 AM		**Smart Roller: An Essential Tool for Automated Fiber Placement** Mr Charles Picciotto - University of British Columbia	**Protein Based Bio-Composites from Cottonseed Meals Reinforced with Chitin-Nanoparticles** Miss Yuanyi Shao - University of Nebraska-Lincoln	**Numerical Simulation for Frequency Dependence of Fatigue Failure for Polymer and Polymer Composite** Dr Jun Koyanagi - Tokyo University of Science	**4D-printed Composite Structures for Space Applications Towards Multi-Axis Structural Shape-changing** Mr Julien Deschamps - Research Institute Dupuy De Lume	**Digital Twin Using Nested Machine Learning for Sintering Deformation of Ceramic Matrix Composites** Prof Jingzhe Pan - School Of Engineering University Of Leicester	**Conductive Superhydrophobic Coating on Gas Diffusion Layer for Enhanced Proton Exchange Membrane Fuel Cell Performance** Mr Myungjin Hong - Inha University
10:35 AM - 11:00 AM	**Refreshment Break** *(located in Exhibit Hall A/B, Level 100)*						

Room 316	Room 317	Room 318	Room 319	Room 320	Room 321	Time
Registration Desk Open *(closes at 5:30pm - located in Charles Street Lobby, Level 100)*						7:00 AM
Continental Breakfast *(until 8:00am - located in Exhibit Hall A/B, Level 100)*						7:00 AM
Exhibit Hall Open *(closes at 5:30pm - located in Exhibit Hall A/B, Level 100)*						7:00 AM
						8:00 AM
						8:05 AM
Move to Level 300 for Parallel Keynotes and Technical Sessions						
						9:00 AM - 9:30 AM
Thermoplastic Composites	**Frontal Polymerization**		**Computed Tomography**	**Design, Repair and Life Cycle**		
Modeling and Control of Exothermic Polymerization of an Acrylic Thermoplastic Resin in the Pultrusion Process Mr Farouk ZREIKA - IMT Mines Albi	**Optimization of Cationic Frontal Polymerization Experiments: An Analysis of Compositions Reproducibility and Materials** Mr Brecklyn Groce - Vrije Universiteit Brussel		**Alternative Reconstruction and Acquisition Techniques for Imaging Large CFRP Samples** Mr Ford Collins - University of Warwick	**Manufacturing Fiber Reinforced Recycled Pet Tapes: A Capillarity-Based Approach** Ms Elise Mathouillot - IMT Mines Ales		9:35 AM - 9:55 AM
Polymerization Induced Defects in Type IV Hydrogen Storage Tank Produced from Recyclable Liquid Thermoplastic Polymer and Carbon Fiber Dr Biltu Mahato - Luxembourg Institute of Science & Technology	**Photothermal Initiation of Frontal Polymerization for Additive Manufacturing of Discontinuous Fiber-Reinforced Thermoset Composites** Prof Mostafa Yourdkhani - Arizona State University		**Modeling the Folding and Stowing Behavior of Origami-Inspired Structures Based on the Real Composite Microstructure** Mr Israr Uddin - Khalifa University	**Reprocessing Thermoplastic Composite Trim Waste with High Temperature Compression Moulding** Dr Andi Haris - Singapore Institute of Mfg Technology		9:55 AM - 10:15 AM
Modelling Residual Stresses in Thick Section Thermoplastic Composites for Wind and Tidal Blades Ms Anastasia Tsavea - University of Sheffield			**Helical µCT Insights into Compaction Effects on Resin Distribution and Porosity in Thermo-Compressed Non-Crimp Polypropylene-glass Fiber Composites** Dr Abderrahmane AYADI - IMT Nord Europe	**Transforming Thermoplastic Waste through Manufacturing into Engineering Products** Mrs Shristi Ghosh - Georgia Institute of Technology		10:15 AM - 10:35 AM
Refreshment Break *(located in Exhibit Hall A/B, Level 100)*						10:35 AM - 11:00 AM

Time	Ex Hall C - Plenary	Room 307	Room 308	Room 309	Room 310	Room 314	Room 315
	Certification for Analysis Workshop	**Manufacturing: Process Physics**	**Materials and Precursors**	**Physical and Structural Behavior**	**Multifunctional Composites**	**AI Empowered Paradigm**	**Fatigue and Damage Mechanics of Composites**
11:00 AM - 11:20 AM	**11:00 AM - Aero Industry Building Block Certification Logic** Dr Carl Rousseau - Lockheed Martin Co	**The First European Benchmark Exercise on Squeeze Flow Testing of High-Performance Carbon Fibre Sheet Moulding Compounds** Prof Thomas Neumeyer - Leibniz Insitut für Verbundwerkstoffe GmbH	**Synthesis of Bio-Based Foams Derived from Birch Bark Extract** Ms Heather LaFrance - Rowan University	**Adhesion Mechanism Between Epoxy Resin and Thermoplastic Interlayers Modifying VARTM Processing Conditions to Improve Fracture Toughness** Dr Sagar Doshi - University of Delaware	**PEEK-Based Polymer Electrolyte with Tailored Morphology for Structural Battery Composites** Ms Mia Carrola - USAF AFRL	**A Simulation-Based Machine Learning Approach for Optimizing Preform Charges in Sheet Molding Compound Manufacturing** Dr Mikhael Tannous - Arts et Metiers Institute of Technology	**Development of a Height-tapered Double Cantilever Beam for Mode I Interlaminar Fatigue Testing** Mr Shagata Das - University of Delaware
11:20 AM - 11:40 AM	**11:25 AM - Smarter Testing Application to Composite Structures** Mr Adam Sawicki - The Boeing Co	**Rapid Curing of Composites by Filament Winding Technique** Mr Soroush Dashtizad - Arizona State University	**Rheology as a Rapid Method for Simple and Precise Determination of the Percolation Threshold in Shortfiber Polymeric Bio-composites Insights into Sus** Prof Giovanni Filippone - University di Napoli Federico II	**Influence of Laminate Surface Resin Depth on the Interface Strength of Overmoulded Composites** Dr Ruaraidh MacLennan - Queen's University Belfast	**Examination of a Novel Structural Supercapacitor Subjected to Compressive Loading** Dr Alex Harman - Defence Science & Technology Group	**Advanced Machine Learning Techniques for RTM Injection Surrogate Modeling** Ms Sofia Fernandez Leon - IMDEA Materials	**Influence of Fabric Architecture and Sizing on ILFT and LVI Property for Improving Durability and Damage Tolerance of GFRP Composites** Mr Munetaka Kubota - University of Delaware
11:40 AM - 12:00 PM	**11:50 AM - The Role of Analysis and Testing in the Engineering of Wind Turbine Rotor Blades** Mr Kyle Wetzel - Wetzel Wind	**Fabrication of SiC Fiber-Reinforced 3D Woven Composites Using Tow Sizing and Optimized Preform Structures** Mr Yoon-Min OH - Seoul National University	**Bone-inspired Self-adaptive Composites with Reprogrammable Self-folding Behaviors** Prof Sung Kang - Korea Advanced Institute of Science & Technology	**Experimental and Numerical Investigation on Lap Shear Fracture of Additively Manufactured Thermoplastic CFRP64 Titanium** Dr Keiichi Shirasu - Tohoku University	**Ultralow-Voltage High-Performance Soft Actuators using Polysulfonated Covalent-Organic Frameworks as Common Electrolyte-Electrode Hosts** Dr Manmatha Mahato - Korea Advanced Institute of Science & Technology	**A Neural Network Based Bayesian Method for Estimating and Predicting Resin Flow in Resin Transfer Moulding** Mr Nicholas Wright - University of Auckland	**Accelerated Fatigue Characterization of Advanced Composites Using Infrared Thermography** Dr Suhasini Gururaja - Auburn University
12:00 PM - 12:20 PM			**Sustainable Polymer Materials Effect of Agricultural Waste Reinforcement on the Performance of PBS and PBAT Composites** Dr Irene Bavasso - Sapienza University of Rome	**Uncertainty Quantification of a Ductile Damage Evolution Model in an Adhesively Bonded Single Lap Shear Joint** Dr Marcus Stanfield - SwRI	**Tailoring the Chemistry and Morphology of Vertically Aligned Carbon Nanotube Sponges Implications for Smart Electrodes** Mr Lev Rovinsky - Tel Aviv University	**Modeling Crack Propagation in Composites using Constitutively Informed Particle Dynamics** Dr Venkatesh Ananchaperumal - Clemson University	**Mechanical Properties and Damage Analysis of Braided CFRP Composite Rods** Dr Mazhar Peerzada - The University of Southern Queensland
12:20 PM - 1:15 PM	**Group Lunch** *(located in Exhibit Hall A/B, Level 100)*						
1:15 PM	**Plenary Speaker: Industrial-Scale Nano-Integration Strategies for Aerospace-Grade Fiber-Reinforced Polymer Composites: from Functional Coatings and Interface to Prepreg Manufacturing and Composite Repair** Prof Mehmet Yildiz, *Sabanci University*						
Move to Level 300 for Parallel Keynotes and Technical Sessions							
2:10 PM - 2:40 PM		**Keynote Speakers** **Kelly Prize: Challenges and Opportunities in Synchrotron Computed Tomography Imaging of Composites** Prof Yentl Swolfs - KU Leuven	**Crystallization Hybrid Modeling and Simulation of Robotic 3D Printing of Continuous Carbon Fiber Reinforced Thermoplastic Composites** Prof Chady Ghnatios - University of North Florida	**Process Monitoring for Defect Control – from RTM to Sandwich Panel Co-cure** Prof Steven Nutt - University of Southern California	**Manufacturing of Cellulose Composites Where the Reinforcing Fibers are Aligned in Multiple Scales** Mrs Kristiina Oksman - Lulea University of Technology	**Toward Autonomous Qualification of Aerospace Composites: From AI-Driven Calibration to Digital Estimation of Allowables** Dr Navid Zobeiry - University of Washington	

Room 316	Room 317	Room 318	Room 319	Room 320	Room 321	Time
Thermoplastic Composites		**Computational Modeling**	**Invariants and Double-Double Laminate**	**Design, Repair and Life Cycle**		
Effects of Activator and Catalyst Concentration on Reaction Kinetics and Polymer Properties in Reactive Thermoplastic Pultrusion of Nylon 6 Ms Hannah Decker - Fraunhofer Institute for Chemical Technology		**Numerical Simulation for Prediction of Residual Strength for CFRP After Cyclic Loading Considering Entropy Damage Criterion** Mr Takumi Sekino - Graduate School of Tokyo University of Science	**A Double Angle-Ply Laminate Approach to Designing for Controlled Near Zero Coefficient of Thermal Expansion** Dr Christopher York - Singapore Institute of Technology	**Artificial Neural Network-Based Sequential Approximate Optimization for Free Fiber Path Design in Variable-axial Composites** Mr Xin Wang - Hokkaido University Japan		11:00 AM - 11:20 AM
Leveraging In-situ Anionic Polymerization of Polyamide 6 for High Performance Basalt- and Flax-Fiber Thermoplastic Laminates Dr Giulia Fredi - University of Trento		**Experimental and Numerical Study on the Bending Behavior of Glass Fabric Rubber Composites** Mr Oguz Genc - Airbus Operations SAS Ecole des Mines d'Albi	**Double-Double (DD) Laminates: Homogenisation Mechanical Performance and Compression After Impact** Mr Aidan Hawkins - Queen's University Belfast	**Optimal Design of Seamless CSiC Composite with Multicooling Channels using a Data-Driven Model** Mr Kyeongmo Kang - Seoul National University		11:20 AM - 11:40 AM
High-Speed Reactive Processing of Thermoplastic Carbon Fiber-Reinforced Polyamide-6 Composites Mr Sang-Woo Kim - Korea Institute of Material Science		**Modeling High Temperature Cross-Linking Between Graphitic Surfaces and Glassy Carbon** Prof Jacob Gissinger - Stevens Institute of Technology	**Study of the Impact and Compression After Impact Behaviour of Double-Double Laminate** Mr Geoffrey Gisclon - Institut Clement Ader	**Deep Learning Guided Particle Filter for Remaining Useful Life Estimation of Composite Materials** Ms So Young Oh - UNIST		11:40 AM - 12:00 PM
Thermoplastic Infusion In-situ Polymerisation TPIIP and Double Diaphragm Forming DDF for Complex Parts at Scale Dr Gabrielis Cerniauskas - University Of Edinburgh		**Mesostructure-Informed Numerical Modelling of Post-Consolidation Architecture in Advanced Placed Ply Laminates** Mr Saral Mittal - University of New South Wales	**Probabilistic Approach to Evaluate Design Allowables for a Tailored Aircraft Composite Wing using Quad and Double-Double DD Laminates** Prof Carlos Cimini - UFMG Federal University of Minas Gerais	**Generative Model-Driven Design of Long Discontinuous Carbon Fiber Composites for Targeted Mechanical Properties** Dr Hyunsu Lee - University of Connecticut		12:00 PM - 12:20 PM
Group Lunch *(located in Exhibit Hall A/B, Level 100)*						12:20 PM - 1:15 PM
						1:15 PM
Move to Level 300 for Parallel Keynotes and Technical Sessions						
						2:10 PM - 2:40 PM

Time	Ex Hall C - Plenary	Room 307	Room 308	Room 309	Room 310	Room 314	Room 315
	Certification by Analysis Workshop	**Manufacturing: Machine Learning**	**Materials and Precursors**	**Physical and Structural Behavior**	**Multifunctional Composites**	**AI Empowered Paradigm**	
2:45 PM - 3:05 PM	**2:45 PM - Composite Structural Testing and Analysis, an FAA Perspective** Ms Cindy Ashforth - FAA	**High-Fidelity Digital Twin Autoclave Tool for Quality Informed Composite Fabrication** Dr Yuanjie Lua - Global Engineering & Materials Inc	**Enhancing Mechanical Properties and Moisture Durability of Flax Fibre Composites by Plasma Treatments** Mr Jianqun Hao - KU Leuven	**Precise Mode II Fracture Toughness Control in High-Performance Composites by Perforated Release Film Interleaves** Dr Gergely Czel - Budapest University of Technology & Economics	**Quasi-Distributed Pressure Sensors Embedded Into Surface Materials on Composite Laminates** Dr Per Hallander - Saab AB	**Inverse Design of Manufacturing Process using Physics-Informed Neural Operator Learning** Dr Zhen Li - Clemson University	
3:05 PM - 3:25 PM	**3:10 PM - Towards Certification by Analysis - Some Pragmatic Considerations** Mr Mike Hinton - High Value Manufacturing Catapult	**Smart Composite Production Line Planning using AI Based Digital Twin to Optimize the Production Planning under Uncertainty** Ms Shiva Abdoli - University of New South Wales	**Machine Learning-Based Pyrolysis Characterization in Ceramic-Matrix Composites** Ms Paulina Portales Picazo - University of Washington	**Assessment of Numerical Approaches for Quasistatic Fatigue and Dynamic Delamination Propagation in Curved Laminates** Mr Maikel Khella - Politecnico di Milano	**Comparative Study of Graphene Coated Glass Fibres and Vertically Aligned Carbon Nanotube Forests as Embedded Structural Health Monitoring Systems** Mr Tobias Karlsson - KTH Royal Institute of Technology	**Multiscale Modeling of Additively Manufactured Short Fiber Reinforced Thermoplastic Polymer Composites** Dr Taejoon Park - The Ohio State University	
3:25 PM - 3:45 PM		**Enhancing Cure Kinetics Estimation for Thermosetting Carbon Fiber-Epoxy Prepregs Through Chemistry-Informed Machine Learning** Mr Geun Young Kim - Georgia Institute of Technology	**The Effect of Functionalized Cellulose Nanocrystals on Glass Fibers Glass Fiber-Epoxy Composite Performance** Ms Kim Anh Pham - Georgia Institute of Technology		**Real Time Monitoring of Composite Laminated Structures with Embeddable Sensing Layers** Mr Joao Correia - Universidade do Minho	**Multifidelity Neural Network Approach for Warpage Prediction and Optimization in Injection Molding** Ms Elham Kianiharchegani - Brown University	
3:45 PM - 4:10 PM	**Refreshment Break** *(located in Exhibit Hall A/B, Level 100)*						
4:10 PM - 4:40 PM	**4:10 PM - Panel Discussion with Q&A** Dr Sayata Ghose - The Boeing Co Ms Isabelle Paris - Bombardier Aviation **4:55 PM - Wrap Up/Closing Comments** Prof Ole Thomsen - University of Bristol	**Mini-Orals** *See page 48 for detailed presentation schedule*					
4:10 PM - 5:30 PM	**Poster Session** *(located in Exhibit Hall A/B, Level 100)*						
7:00 PM	**Student Only Event** - *Luckie's Tavern at Power Plant Live!*						

Room 316	Room 317	Room 318	Room 319	Room 320	Room 321	Time
Thermoplastic Composites		**Computational Modeling**	**Bio Mass**	**Design, Repair and Life Cycle**		
Importance of Shearing Deformation in Dynamical Mechanical Tests for Viscoelastic Properties of Continuous Fiber Thermoplastic Composites Dr R Byron Pipes - Purdue University		**Simulating Additively-Manufactured Composite Structural Joints using FastDM4C** Dr Antonio Alessandro Deleo - ES3	**White-Rot Fungi Oxidative Cocktail as a Tool for Modifying Kraft Lignin into Sustainable Carbon Fiber Precursors** Prof Veronica Calado - Federal University of Rio de Janeiro	**Deployable Fiber-Reinforced Polymer for Robotics Application** Mr Seung Mo Son - Pusan National University		2:45 PM - 3:05 PM
A Mesoscale Model of Woven Fabric Thermoplastic Composites for Large Deformation Prof Vincent Tan - National University of Singapore		**Characterization of Additive Manufacturing Caused Defects and Their Impacts on Mechanical Properties of Polymeric Lattice Structures Fabricated by SLS** Mr Amirali Amirian - The University of Auckland	**Lignin as a Candidate for Flame-Retardant Composite Applications** Prof Veronica Calado - Federal University of Rio de Janeiro	**Framework for Optimization of AFP Composite Structures** Dr August Noevere - Collier Aerospace		3:05 PM - 3:25 PM
Tracking Ply Deformation during Thermoplastic Stamp Forming using Embedded Shape Sensor Mr Shu Minakuchi - The University of Tokyo		**Attack Angle Influence on Growth Efficiency of Vertically Aligned Carbon Nanotubes** Mr Lev Rovinsky - Tel Aviv University	**Development of High-Performance Biomass Composites using a PA11-Glycol Lignin Matrix** Dr Jonathon Tanks - National Institute for Materials Science	**Next Generation Wind Turbine Blade Repair Residual Stress and Void Analysis in UV-Cured Scarf Patches** Prof Puneet Mahajan - Indian Institute of Technology		3:25 PM - 3:45 PM
Refreshment Break *(located in Exhibit Hall A/B, Level 100)*						3:45 PM - 4:10 PM
						4:10 PM - 4:40 PM
Poster Session *(located in Exhibit Hall A/B, Level 100)*						4:10 PM - 5:30 PM
Student Only Event - *Luckie's Tavern at Power Plant Live!*						7:00 PM

Scientific Program

Time	Ex Hall C - Plenary	Room 307	Room 308	Room 309	Room 310	Room 314	Room 315
7:00 AM	**Registration Desk Open** *(closes at 6:00 PM - located in Charles Street Lobby, Level 100)*						
7:00 AM	**Continental Breakfast** *(until 8:00 AM - located in Exhibit Hall A/B, Level 100)*						
7:00 AM	**Exhibit Hall Open** *(closes at 4:30 PM - located in Exhibit Hall A/B, Level 100)*						
8:00 AM	**Welcome Remarks**						
8:05 AM	**Plenary Speaker: A Ride with Automotive Composites** Prof Srikanth Pilla, *University of Delaware*						
Move to Level 300 for Parallel Keynotes and Technical Sessions							
9:00 AM - 9:30 AM		**Keynote Speakers** **New Research Avenues, Metrologies, and Ideas for Optimizing Glass & Carbon Fiber Epoxy/Amine Composites** Dr Gale Holmes - National Institute of Standards & Technology	**Study of the Longitudinal Compressive Strength of Laminated Composites Using Various Classical and Innovative Tests at Different Temperatures** Mr Frederic Laurin - ONERA Paris-Saclay University	**Monitoring The Structural Condition of Composite Industrial Parts Through Embedded Optical Sensorization** Ms Helena Rocha - PIEP Centre for Innovation in Polymer Engineering	**Progress in Highly Aligned Discontinuous Fiber Composites** Dr Shridhar Yarlagadda - University of Delaware		
		Manufacturing: Resin Transfer Molding 2	**Materials and Precursors**	**Physical and Structural Behavior**	**Multifunctional Composites**	**AI Empowered Paradigm**	**Thermoplastic Composites**
9:35 AM - 9:55 AM		**Analysis of the Image-Based Evaluation of the Permeability of Carbon/Carbon Composites** Ms Tania Lavaggi - University of Delaware	**Studies on Cut-Protective Performance of Composites Yarn Based Knitted UHMWPE Textiles in Real-World Industrial Applications** Mr Shubham Singh - Indian Institute of Technology Delhi IIT Delhi	**Consideration of the Influencing Variables of Peel Plies on the Reaction Process of CFRP Samples Under Liquid Oxygen Environment at Impact Load** Mr Philipp Marin - University of the Bundeswehr Munich	**Nature Materials: Enhanced Functional Composites** Prof Jonghwan Suhr - Sung-Kyun-Kwan University	**Development of a Noniterative Artificial Neural Network Model for Enhanced Finite Element Analysis of Short Fiber-Reinforced Plastics** Mr Minjun Kwak - Seoul National University	**Inline Plasma Modified Carbon Fibre for Enhanced Thermoplastic Tape Manufacturing - Repurposing PA6PP Waste in New Zealand** Mr Maximilian Pitto - The University of Auckland
9:55 AM - 10:15 AM		**Monitoring RTM Infiltration Behavior of TFP Preforms Using Near-Net-Shaped Transparent Cavities** Mr Cameron Welker - Liebniz-Institut für Polymerforschung Dresden e.V.	**Single Carbon and Glass Fibre Tensile Properties and the Correlation with Their Geometry** Ms Elise Van Vlierberghe - KU Leuven	**Multidirectional Laminates with Ultrathin Plies for Cryogenic Environments Mechanical Testing and Permeability** Mr Serafn Sanchez-Carmona - University of Seville	**Self-sensing Technology for Dynamic Behavior Analysis and Damage Classification in Rotating Rotor Blades** Ms Juhyeong Jang - Ulsan National Institute of Science Technology	**Deep Learning-Based Geometrical Analysis and Tension Strain Mapping of Bamboo Fibre Microstructure** Mr Carlos Ivan Cardona Garcia - Luxembourg Institute of Science & Technology	**Mechanical Behavior of 3D Printed Carbon Fiber Reinforced Nylon Composite** Dr Siavash Sattar - Randolph College
10:15 AM - 10:35 AM		**Modelling the Polymer Resin Flow Through Fibres During Resin Transfer Moulding** Mr Rajinth Shanthar - The University of Manchester	**Tailoring Surface Chemistry and Interfacial Interactions of Carbon Fibrepolymer Composites** Prof Luke Henderson - Deakin University		**Enhanced Flow Monitoring in Resin Transfer Molding using Electrical Impedance Tomography with Embedded Carbon Nanotube Sensors** Ms Seyda Naz Alasahin - University of Delaware	**Bayesian Calibration of Finite Element C-spar Models using Digital Image Correlation** Dr Carl Scarth - University of Bath	**Influence of Specimen Geometry and UD Ply Layup on Thermoplastic Welded Double Notched Tension Test Specimen by use of Mechanical and Virtual Testing** Mr Sebastian Hamedinger - University of Applied Sciences Upper Austria
10:35 AM - 11:00 AM	**Refreshment Break** *(located in Exhibit Hall A/B, Level 100)*						

Room 316	Room 317	Room 318	Room 319	Room 320	Room 321	Time
Registration Desk Open *(closes at 6:00pm - located in Charles Street Lobby, Level 100)*						7:00 AM
Continental Breakfast *(until 8:00am - located in Exhibit Hall A/B, Level 100)*						7:00 AM
Exhibit Hall Open *(closes at 4:30pm - located in Exhibit Hall A/B, Level 100)*						7:00 AM
						8:00 AM
						8:05 AM
Move to Level 300 for Parallel Keynotes and Technical Sessions						
						9:00 AM - 9:30 AM
Aligned Discontinuous Fiber Composites	**Compressive Failure**	**Computational Modeling**	**Experimental Techniques**	**Design, Repair and Life Cycle**	**Industrial Applications**	
Characterization and Modeling of Toolply and Plyply Friction of Aligned Discontinuous Fiber Prepreg During Forming Ms Lauren Thomas - University of Delaware	**Is There a Hybrid Effect in Tensile and Compressive Failure of Carbon Fibre Composites** Prof Michael Wisnom - University of Bristol	**Lunar: A Tool for Setting Up Process Modeling Based on Molecular Dynamics Simulations** Dr Joshua Kemppainen - Michigan Technological University	**Uncertainty Quantification of X-ray CT Segmentation of Multiclass Microdamage in Advanced Composites via Deep Learning** Dr Reed Kopp - ATA Engineering Inc	**Virtual Testing of Recycled Glass Fiber Reinforced Polymer Sandwich Cores** Mr Michael Paulitsch - University of Applied Sciences Upper Austria	**Development and Manufacturing of a Conformable CFRP Tank Demonstrator with Tension-Strut-Reinforcement** Ms Elisabeth Gleis - Technical University of Munich	9:35 AM - 9:55 AM
Characterization and Modeling of Deformation Mechanisms of Aligned Discontinuous Fiber Prepreg During Thermoforming Mr Aidan Ford - University of Delaware	**FE Simulations of Large UDFRP Microstructures Under Longitudinal Compression** Dr Dimitrios Bikos - Imperial College London	**Incorporation of High-Fidelity Experimental Data into Finite Element Models for Enhanced Comparison and Analysis** Dr Meng Yi Song - University of Bristol	**A New Approach for Quantifying the Transverse Coefficient of Thermal Expansion in PAN-based Carbon Fibres at Low Temperatures via X-ray Diffraction** Mr Jiraphant Srisuriyachot - University of Bath	**Fatigue Life Prediction of Dissimilar Material Joints Using Neural Networks** Mr Young Bin Kim - Yonsei University	**Advanced Graphene-Enhanced Polyethylene Liners for Type IV Hydrogen Storage Tanks Enhancing Mechanical Properties and Gas Containment** Dr Jefferson Andrew Jeyakumar - Khalifa University	9:55 AM - 10:15 AM
Modeling Transvers Shearing Viscosity and Material Tool Friction Interaction with Rectangular Squeeze Flow Mr Rafe Garcia-Hidalgo - University of Delaware		**Simulating Particle-Based Interface Toughening Mechanisms of Laminated Composites** Dr Shiyao Lin - The University Of Texas At Arlington		**Predicting Material Properties of Shredded Recycled Carbon Composite using a Detailed Simulation Approach** Mr John Finder - TU Braunschweig Institut für Flugzeugbau und Lei	**Composite Materials Handbook CMH17: An Introduction and Overview** Mrs Teresa Vohsen - Wichita State University NIAR	10:15 AM - 10:35 AM
Refreshment Break *(located in Exhibit Hall A/B, Level 100)*						10:35 AM - 11:00 AM

Time	Ex Hall C - Plenary	Room 307	Room 308	Room 309	Room 310	Room 314	Room 315
		Manufacturing: AFP/ATP 2	Materials and Precursors	Physical and Structural Behavior	Multifunctional Composites	Industrial Applications	Thermoplastic Composites
11:00 AM - 11:20 AM		**Development and Control of Residual Stresses and Warpage During the ATP Process** Dr John Tierney - University of Delaware	**Dynamic Crush of Hollow Glass Microsphere Reinforced Polyurethane Foams** Dr Colleen Murray - University of Maryland	**Effect of Simulated Hygrothermal Ageing on the Interfacial Shear Strength of Carbon/Epoxy Composites** Mr Abdullah Iftikhar - University of Southern Queensland	**Sensing of Resin Flow and Cure in Continuous Fiber Additive Manufacturing** Mr Mohammad Tofayel Ahmed - University of Delaware	**A Novel Sleeve Assembly Method for SPM Motors using CFRP with Atypical Layup** Dr Kazunori Takagaki - Mitsubishi Electric Corp	**Effects of Fiber Type and Cooling Rate on the Crystallization Behavior of Low-Melt PAEK Thermoplastic Composites** Prof Anoush Poursartip - The University of British Columnia
11:20 AM - 11:40 AM		**Material Behavior of Prepregs in Automated Robotic Sheet Layup: A Comparative Study** Mr Moritz Lennartz - Institut for Textiltechnik of RWTH Aachen Uni	**Wearable Electronic Textiles for the Detection of Loneliness in Older Individuals** Dr Jingqi Liu - University of Leeds	**Degradation in Bio-epoxy Composites Under Hygrothermal Ageing** Ms Zaneta Senselova - University of Southern Queensland	**Featherweight Wearable Electronics Based on a PAN Electrospun Substrate** Professor Yu Shi - University of Leeds	**Feasibility of Developing Fiber-reinforced Thermoplastic Composite Couplers for Hydrogen Transmission Pipelines** Dr Chen Wang Dr Andi Haris - Singapore Institute of Mfg Technology	**Improved Thermal Conductivity and Structural Integrity in Thermoplastic Composites Using h-BN/PEEK Films and Resized Carbon Fibers** Ms Burcu Saner Okan - Sabanci University
11:40 AM - 12:00 PM		**An Investigation of Thermoplastic Tape-to-Tape Bonding Using Xenon Flash Lamp Heating** Prof David Williams - University of Bath	**Evaluation on Recession Behaviors of B4C Containing Porous Carbon Material as an Advanced Thermal Protection System** Mr Tatsuki Koshikawa - Japan	**Systematically Adapting Processing, Flame Retardancy, and Flexural Properties of Epoxy Glass Fiber Reinforced Composites for Railway Applications** Ms Sruthi Sunder - University of Bayreuth	**Electrical Impedance Tomography for Self-Sensing 3D Printed Cellular Composites** Mr Akash Deep - University of Glasgow	**In-Space Manufacturing of High-Performance Fiber Reinforced Composites Tubes** Dr Jeff Baur - University of Illinois	**Influence of Transient Radiative Heat Flux on Degree of Crystallinity in Thermoplastic Composites** Dr Paul Davidson - The University Of Texas At Arlington
12:00 PM - 12:20 PM		**A Comprehensive Approach to a Digital Twin Based on Asset Administration Shells for a Process Chain of Automated Tape Laying and Thermoforming** Prof Thomas Neumeyer - Leibniz Insitut für Verbundwerkstoffe GmbH	**Interlaminar Fracture Toughness Enhancement in Carbon Fiber Composites Via Asymmetric Flax Fiber Hybridization** Prof Jungil Song - Changwon National University	**Effect of Hygroscopic Aging on the Transverse Damage Behavior of Fiber-Reinforced Composites: A Computational Micromechanics Study** Dr Vaishakh Kottila Veedu - Brown University	**Embedding of Fiber Optic Sensors Under Industrial Conditions and Distributed Strain Sensing in Type 4 Composite Pressure Vessels** Mr Bartosz Popiela - Bundesanstalt für Materialforschung und -prüfung		
12:20 PM - 1:15 PM	**Group Lunch** *(located in Exhibit Hall A, Level 100)*						
1:15 PM	**Plenary Speaker: Assuring Safety of Composite Structures in Aviation** Ms Cindy Ashforth, *Federal Aviation Administration*						
	Move to Level 300 for Parallel Keynotes and Technical Sessions						
2:10 PM - 2:40 PM		**Keynote Speakers** **Overcoming Processing Hurdles in Multifunctional Polymers and Polymer (Nano) Composites** Prof Emiliano Bilotti - Imperial College London	**Liquid Composite Moulding Research as a Nucleus for Interdisciplinary Innovation in Composites** Prof Nuno Curado Correia - INEGI	**Generative Design of Additively Manufactured Composites with AI/ML Models** Prof Kishore Pochiraju - Stevens Institute of Technology	**Sustainable Composites Start with LCA: Seeing the Whole Picture** Prof Martina Salzano de Luna - University of Naples Federico II		

Room 316	Room 317	Room 318	Room 319	Room 320	Room 321	Time
Aligned Discontinuous Fiber Composites	Compressive Failure	Computational Modeling	Experimental Techniques	Design, Repair and Life Cycle		
Stamp Forming of Highly Aligned Discontinuous Fiber Composite Blanks via Epoxy Matrix Staging Mr Matthew Abraham - University of Delaware	**Unusual Effect of the Degree of Cure of Some Epoxy Resins on the Compressive Strength of Continuous Fibre Composites** Mr Vincent Keryvin - University Bretagne Sud	**Prediction of Microcrack Networks in Cryogenic Carbon Fibre Composite Hydrogen Tanks** Dr Wenkai Chang - University of New South Wales	**Detection of Progressing Material Defects with FMCW Radar Signals** Mr Florian Puch - Technische Universitat Ilmenau	**Composite 3D Printed Plate-Based Mechanical Metamaterials** Ms Aya Hosoi - Imperial College London		11:00 AM - 11:20 AM
Efficient Microstructural Models to Homogenize Anisotropic Viscoelastic Parameters of Highly Aligned Discontinuous Fiber Composites Mr Miguel de Carvalho Dr Nuno Curado Correia - INEGI	**Improving Fibre Reinforced Polymer Compressive Performance Through Intermittent Matrix Property Modification** Ms Hwei Linn Khoo - Imperial College London	**Compaction and Mechanical Performance of AFP Composites with Fiber Tow Gaps Experimental Investigation and Multiphysics Modeling** Mr Ahmadreza Ravangard - Old Dominion University	**Optimisation of 3D Woven Composite Structures for Bearing Performance in Single and Double Lap Joints Using Acoustic Emission Monitoring** Mr Callum Montgomery - Ulster University	**From Waste to Value Creating Composite Blends Out of Waste Low-density Polyethylene and Polystyrene for Fused Deposition Modeling Printing** Mr Ahmed Afzal - Texas A&M		11:20 AM - 11:40 AM
Tensile Behavior and Stress Relaxation of Uncured Prepreg of Aligned Discontinuous Fiber Materials Constitutive Model Development for Stretch Forming Dr Navid Niknafs Kermani - University of Delaware	**Polymer Composites Reinforced by Continuous Irregular Networks from Bioinspired Design to Fracture** Prof Tommaso Magrini - Eindhoven University of Technology	**Accelerating Progressive Damage and Failure Analysis of Composites using a Hybrid Implicit-Explicit Approach** Dr Shiyao Lin - The University Of Texas At Arlington	**Combined In-Situ Microscopy and Acoustic Emission Monitoring of Transverse Cracking in CFRP Cross-ply Laminates** Mr Spyridon Spyridonidis - University of Bristol	**Mechanical Recycling of Glass Fiber Reinforced Wind Turbine Blade Components into Reinforced Filaments for use in Additive Manufacturing** Mr Dimitrij Seibert - Leipzig University of Applied Sciences		11:40 AM - 12:00 PM
Impact of Fiber Aspect Ratio on Mechanical Performance of Short Fiber Composites Mr Uday Kiran Balaga - University of Delaware	**Bicontinuous Silica-Epoxy Interfaces** Dr Charles Shaw - Imperial College London	**Molecular Dynamics Simulation on the Failure Behavior of Carbon-Polycarbonate-carbon Structure-sensitivity Analyses of Interfacial Potential Parameter** Ms Bowen Cao - Clemson University	**Assessing the Effects of Edge-Reflections on Propagating Acoustic Waves in CFRP Panels** Ms Andrea Martinez - Delta Engineering Corp	**Enabling All-Composite Pressure Vessels Through Integrated Electrospun Nanofiber Architectures** Mr Jaejun Bae - Korea Advanced Institute of Science & Technology		12:00 PM - 12:20 PM
Group Lunch *(located in Exhibit Hall A, Level 100)*						12:20 PM - 1:15 PM
						1:15 PM
Move to Level 300 for Parallel Keynotes and Technical Sessions						
						2:10 PM - 2:40 PM

Time	Ex Hall C - Plenary	Room 307	Room 308	Room 309	Room 310	Room 314	Room 315
		Manufacturing: Process Monitoring	Materials and Precursors	Physical and Structural Behavior	Multifunctional Composites	Industrial Applications	Thermoplastic Composites
2:45 PM - 3:05 PM		**On Line Optimisation and Active Control of the Cure Process of Thick Composite Laminates** Dr Konstantinos Tifkitsis - Kalero Ltd	**Bio-Inspired Micropatterned Fibre Surfaces Alternating Adhesion Zones for Tougher Composites** Dr Carlos Fuentes - Luxembourg Institute of Science & Technology	**Study on Construction of Short Carbon Fiber Secondary Dispersion System and Its Strengthening Cement-Based Composites** Mr Dazhi Jiang - Sun Yat-Sen University	**GNP-Based Pyro-Resistive Eskin Integrated With Temperature Sensing and Self-Controlled Joule Heating Function** Mr Yansong Li - Queen Mary University of London	**PLA Reinforced with Tungsten Disulfide Nanotubes for 3D-Printed Bone Scaffold: In Vitro Assessment of Biocompatibility and Degradation** Mr Ofek Golan - Tel Aviv University	**Cooling-Rate Independent PEEK Composites via Oatmeal for High-Rate Processing** Mr Joseph Kirchhoff - University of Texas at Austin
3:05 PM - 3:25 PM		**Localised Convection Heat Transfer Coefficients in Curing Environments: A Heat Flux Approach** Mr Andrew Che - Swinburne University of Technology	**Evaluation of the Effect of Z-threaded Carbon Nanofibers on the Improvement of Flexural Properties of Carbon Fiber-Reinforced Polymer Laminates** Prof KuangTing Hsiao - University of South Alabama	**Characterization of Fiber Reinforced Thermoplastic Composites Fabricated by Composites-Based Additive Manufacturing CBAM Technology** Mr Gavin Stoker - Utah State University	**Characterisation of Embedded Channel Networks in CFRPs for Active Cooling** Mr Toby Wilcox - University of Bristol	**Friction and Wear Characteristics of 3D-Printed Carbon Fiber-Reinforced Polyamide Under Dry and Seawater Lubrication Conditions** Dr Amir Hamza Nazir Ahmed Siddiqui - Technical University of Denmark DTU	**Benchmarking of AM-CM System Capabilities: To Make Parts with Amorphous and Semi-Crystalline Composites** Dr Ahmed Hassen - Oak Ridge National Lab
3:25 PM - 3:45 PM		**Flow Analysis of the Capillary-Driven Underfill Process for the Use of Thermally Conductive Epoxy Composites in Semiconductor Packaging** Ms Jeeeun Lee - Korea Advanced Institute of Science & Technology	**Prevention of Dispersion in Flexural Strengths of Unidirectional Carbon Fiber Reinforced Composites by Applying Prepregs Containing Cellulose Nanofibe** Mr Shoutaro Shimora - Doshisha University	**Effect of Fiber Volume Fraction and Material Homogeneity on the Mechanical Performance of Recycled Woven Thermoplastic Composites** Mr Fausto Visser - TPRC	**Manufacturing Patterned Carbon Fiber Cathodes by Supercritical CO2 Spray Simultaneous Enhancement of Electrochemical and Mechanical Properties of Str** Prof Amir Asadi - Texas AM University	**Demonstration of a Novel High Pressure Vessel Structure Consisting of CFRP Overwrapped Cylinder and Belt Shaped Load Members for Fuel Cell Vehicles** Mr Ikumi Matsumoto - Tokyo University of Agriculture Technology	
3:45 PM - 4:30 PM	**Refreshment Break** *(located in Exhibit Hall A, Level 100)*						
4:30 PM - 6:30 PM	**ICCM General Assembly**						
7:00 PM - 9:00 PM	**CCM 50th Anniversary Celebration** - *Angels Rock Bar at Power Plant Live!*						

Room 316	Room 317	Room 318	Room 319	Room 320	Room 321	Time
Aligned Discontinuous Composites	Compressive Failure	Computational Modeling	Experimental Techniques	Design, Repair and Life Cycle		
Volumetric Quantification of Bridging and Wrinkling Defects in Composite Laminates Mr Cooper Williams - Montana State University	**Cure-induced Wrinkles and Compression Strength Knockdown in Unidirectional Composites** Dr Lars Mikkelsen - DTU Wind & Energy Systems	**Role of Modeling and Simulation in the Development and Application of Digital Twin for Liquid Composites Molding Processes** Dr Pavel Simacek - University of Delaware	**Application of Infrared Imaging to Reveal Hidden Defects in CFRP Laminates** Prof Janice Barton - University of Bristol	**Comparing the Local Predictions of the Strain Energy Release Rate by CZM and VCCT in Large and Curved Delaminations** Dr Luca Michele Martulli - Politecnico di Milano		2:45 PM - 3:05 PM
Interply Friction Characterization of Stretch Broken Carbon Fiber SBCF Composites During Forming Ms Tasnia Javin Nur - Montana State University	**Mechanics of Kinking in Fiber Reinforced Composites Under Compressive Loading** Dr Paul Davidson - The University Of Texas At Arlington	**Numerical Modeling of Fiber Bundle Architecture in the Robotic Coreless Filament Winding Process** Mr Sebastian Huegle - University of Stuttgart	**Combining Thermographic and Lamb Waves Investigation Data for the Characterisation of CFRP Delaminations** Dr Lea Lecointre Isaka - The University of Tokyo	**CFRP Recycling Method Compatible with a Wide Range of Epoxy Matrices** Mr Naoki Mori - Institute of Science Tokyo		3:05 PM - 3:25 PM
Sustainable Aligned Short Carbon Fibre Reinforced Composites with Electrospun Polymer Matrix Dr Shivdarshan Sherugar - University of Bath	**Fiber Waviness in Thermoplastic CFRP Mechanisms of Formation and Mechanical Influence** Mr Takayu Nishioka - The University of Tokyo	**Numerical Simulation for Thermal Cycle Fatigue Failure for Composite Materials Based on Entropy Damage Criterion** Mr Takumu Sugiyama - Graduate school of Tokyo University of Science	**Probability of Detection Analysis of Simulated Defects in Long Discontinuous Fiber Composites Via Transient Thermography** Mr Marco Didone - University of British Columbia			3:25 PM - 3:45 PM
Refreshment Break *(located in Exhibit Hall A, Level 100)*						3:45 PM - 4:30 PM
						4:30 PM - 6:30 PM
CCM 50th Anniversary Celebration - *Angels Rock Bar at Power Plant Live!*						7:00 PM - 9:00 PM

Scientific Program

Time	Ex Hall C - Plenary	Room 307	Room 308	Room 309	Room 310	Room 314	Room 315
7:00 AM	**Registration Desk Open** *(closes at 5:30 PM - located in Charles Street Lobby, Level 100)*						
7:00 AM	**Continental Breakfast** *(until 8:00 AM - located in Exhibit Hall A/B, Level 100)*						
7:00 AM	**Exhibit Hall Open** *(closes at 5:30 PM - located in Exhibit Hall A/B, Level 100)*						
8:00 AM	**Welcome Remarks**						
8:05 AM	**Plenary Speaker: Perspectives on the Application of Composite Failure Theories Since the World Wide Failure Exercise** Mr Adam Sawicki, *The Boeing Company*						
Move to Level 300 for Parallel Keynotes and Technical Sessions							
9:00 AM - 9:30 AM	**Societal and Industrial Impact Workshop** **9:00 AM - Keynote: IACMI-The Composites Institute - Enabling US Competitiveness in Advanced Composites Manufacturing - Convene, Connect & Catalyze** Dr Uday Vaidya - IACMI The Composites Institute	**Keynote Speakers** **Structural Fire Response of Polymer Composites** Prof Scott Case - Virginia Polytechnic Institute	**Next Generation Composites: Pushing the Boundaries of Performance and Sustainability** Prof Kyriaki Kalaitzidou - Georgia Institute of Technology	**Accelerating Airframe Development Tasks** Mr Carl Rousseau - Lockheed Martin	**Rapid Manufacturing Pathways for High-Performance Thermoplastic Composites** Prof Mehran Tehrani - University of California San Diego		
		Manufacturing: Forming 2	**Materials and Precursors**	**Physical and Structural Behavior**	**Multifunctional Composites**	**Industrial Applications**	**Additive Manufacturing**
9:35 AM - 9:55 AM	**9:30 AM - Fraunhofer- Applied Research for Lightweight Innovation** Dr Frank Henning - Fraunhofer Institute for Chemical Technology	**Forming Wrinkle-Free Curved C Channel with Unidirectional Fiber Reinforced Composites** Mr Suk Young Chey - Seoul National University	**Time-Dependency Phenomena in BOPP and SRPP Laminates** Miss Anna Kandinskaia - KU Leuven	**Effects of Cooling Rate on the Mechanical and Thermal Properties of Self-Reinforced Polyethylene Composites** Dr Yelin Ni - Pacific Northwest National Lab	**Evaluation of Multifunctional Properties of 2D-Materials Films Embedded Glass Fiber Reinforced Composites** Mr Muhammad Yasir Khalid - Khalifa University of Science Technology	**Design and Prototyping of Composite Deployable Booms for Solar Sails** Prof Susanna Laurenzi - Sapienza Universita di Roma	**Durability of Conventional vs 3D-printed Carbon Fiber in Harsh Saline Environments** Mr Omar El Arwadi - Texas AM University
9:55 AM - 10:15 AM	**9:50 AM - Carbon Nexus 10 years on – Lessons Learnt and Current Research Highlights** Prof Luke Henderson - Deakin University	**Draping Tool Generation for Image-Based Surrogate Draping Models using Free Form Deformation and Topography Modification** Ms Sophia Keller - University of Applied Sciences Upper Austria	**Understanding Towpreg Manufacturing — Combining Advanced Resin Formulation and Improved Processing Techniques for the Next Generation of Pressure Vess** Mr Marius Luik - University of Bayreuth	**Thermomechanical Property Evolution and Virtual Curing of an Aerospace Bismaleimide Resin via Experimentally Validated Molecular Dynamics Simulation** Mr Trevor Wavrunek - Michigan Technological University	**Fabrication of Aramid-Fiber Reinforced Composite for Improving the Shock-Wave Protection by Incorporating Polydimethylsiloxane** Mr Tae Kyeom Kim - Pusan National University	**Characterization and Mitigation of Droplet-Induced Impact Damage in Wind Blade Leading-edge Coatings** Mr PoWen Wang - University of Illinois Urbana-Champaign	**Additive Preform Molding of 3D High-Performance Continuous Carbon Fiber Thermoset Composites** Dr Kaiyue Deng - University of Delaware
10:15 AM - 10:35 AM	**10:10 AM - Fraunhofer Innovation Platform for Composites Research at Western University - High Performance Composites: Trends and Impact** Dr Frank Henning - Fraunhofer Institute for Chemical Technology *"on behalf of Prof Andrew Hrymak, University of Western Ontario"*	**Compaction and Fluid-structure Interaction Leading to Fiber Displacement in Resin Infusion of Composite Manufacturing** Dr Debabrata Adhikari - DTU Lyngby	**Modeling the Property Evolution of Cyanate Ester with Crosslinking, Strain-Rate, and Temperature** Dr Sagar Patil - Michigan Technological University	**Thermomechanical Properties Of Polybenzoxazine Resin in a Molecular Dynamics Model as a Function of Degree of Cure and Temperature** Mr Tristan Muzzy - Michigan Technological University	**Novel Recoverable Fiber Metal Laminates Based on NiTi/CFRP Thermoplastic Composites Subjected to Flexural Loading at Different Temperature Conditions** Mr Muzafar Hussain - Khalifa University	**Numerical and Experimental Analysis of Residual Deformations in Composite Plates Integration of Part/Mold Interaction and Compensated Mold Design** Prof Philippe Olivier - Clement Ader Institute	**Topology Optimization and Manufacturing of 3D Architected Composites using Additive Fiber Tethering** Mr Md Habib Ullah Khan - University of Delaware
10:35 AM - 11:00 AM	**Refreshment Break** *(located in Exhibit Hall A/B, Level 100)*						

THURSDAY, AUGUST 7

Room 316	Room 317	Room 318	Room 319	Room 320	Room 321	Time
Registration Desk Open *(closes at 5:30pm - located in Charles Street Lobby, Level 100)*						7:00 AM
Continental Breakfast *(until 8:00am - located in Exhibit Hall A/B, Level 100)*						7:00 AM
Exhibit Hall Open *(closes at 5:30pm - located in Exhibit Hall A/B, Level 100)*						7:00 AM
						8:00 AM
						8:05 AM
Move to Level 300 for Parallel Keynotes and Technical Sessions						
						9:00 AM - 9:30 AM
	Compressive Failure		**Experimental Techniques**	**Design, Repair and Life Cycle**		
	Arrest and Compartmentalisation of Unstable Compressive Failure in Carbon-Fibre Reinforced Polymer Laminates using a Ply-Discontinuity Feature Mr Bruno Santos - Imperial College London		**Experimental Characterization of Interface Failure Between Flexible and Rigid Additively Manufactured Materials** Prof Behrad Koohbor - Rowan University	**Vacuum-Assisted Techniques for Improved Repair Performance in Legacy Fibre-Reinforced Composites** Dr James Quinn - The University of Edinburgh		9:35 AM - 9:55 AM
	Effect of Heat Treatment on Compressive Strength of 3D Printed Onyx Mr Ertugrul Sari - Queen's University Belfast		**Comparative Evaluation of Size and Stacking Sequence Effects on the Performance of Thin Ply Laminates** Mr Joseph McDonald - Toray CMA	**SF6 Plasma Surface Engineered Spent Coffee Ground Derived Carbon Reinforced Waste HDPE Composites** Dr Sushrisangita Sahoo - Tuskegee University		9:55 AM - 10:15 AM
	Integration of Fuzzy Carbon Overbraids into Structural Members for Improved Compressive Performance Dr Laura Rhian Pickard - University of Bristol		**Quantitative Evaluation and Comparison of Terahertz and Ultrasonic Testing of Glass-fiber Reinforced Plastics** Mr Jens Schuster - University of Applied Sciences Kaiserslautern	**Enhancing the Mechanical and Thermal Properties of Recycled EVOH Films with Nano-Silica Incorporation** Ms Kowsar Rezvanian - Tuskegee University		10:15 AM - 10:35 AM
Refreshment Break *(located in Exhibit Hall A/B, Level 100)*						10:35 AM - 11:00 AM

Time	Ex Hall C - Plenary	Room 307	Room 308	Room 309	Room 310	Room 314	Room 315
	Societal and Industrial Impact Workshop	Manufacturing: Resin Transfer Molding 3	Materials and Precursors	Physical and Structural Behavior	Multifunctional Composites	Industrial Applications	Additive Manufacturing
11:00 AM - 11:20 AM	**Panel Discussion with Audience Q&A** Moderator: Prof Mike Hinton - High Value Mfg Catapult Panelist: Dr Uday Vaidya - IACMI The Composites Institute Dr Frank Henning - Fraunhofer Institute for Chemical Technology Prof Luke Henderson - Deakin University	**Assessing the Influence of Flax Fibers Humidity on the Properties and Processing of Composites with Infusion at Controlled Capillary Number** Dr Jean Baptiste Jouenne - ABTE	**Exfoliation and Dispersion of MXene in Epoxy Resin Using Dispersing Agents and Three-Roll Milling** Ms Kristina Zukiene - Kaunas University of Technology	**Tensile Cyclic Behaviour of Open-hole CFRP Laminates with Ultra-Thin Plies** Mr Carlos Sandino - Universidad de Sevilla	**Programmable Shape Transformation in Multilayer Fiber Composites Through 4D Printing** Mr Erdem Yildiz - University of Bristol	**Manufacturing and Experimental Testing of Carbon Fiber/Epoxy Composites using Advanced Induction Heating System** Mr Andrejs Pupurs - Riga Technical University	**Enhanced Structural Performance of Additively Manufactured 2D-Lattice Sandwich with Tailored Fiber Orientation using Hot Powder Bed Compaction** Mr Jimesh Bhagatji - Old Dominion University
11:20 AM - 11:40 AM		**Effect of Anisotropy in Fibre Bundle Spacing on Macrovoid Formation in Viscous-Fluid Impregnation to Woven Glass Fibre Bundles** Mr Tomoki Ito - Tokyo University of Science	**Identification of Cure Kinetic Parameters to Model Multiphysic Behavior of Thermoset Laminate Composite** Mr Quentin Marechal - LTDS Ecole Centrale Lyon	**Effect of Weave Architecture and Stuffer to Binder Ratio on Mechanical Performance of 3D-Woven Composite Core-Based Sandwich Panels** Mr Prabhjot Singh - Indian Institute of Technology Delhi	**Sustainable Phase Changing Fiber-Reinforced Composites** Mr Aidan Holihan - University of Tennessee	**Development of Multicell Bipolar Plate Composite Structures via Electrode Integration for Vanadium Redox Flow Batteries** Prof Jun Woo Lim - Jeonbuk National University	**Effect of Heat Treatment on the Tensile Performance of 3D-Printed Continuous Fiber-reinforced Composites** Mr Zizhao Peng - Swinburne University of Technology
11:40 AM - 12:00 PM		**RTMWorx Twins for Racetracking Classification** Mr Arjen Koorevaar - Polyworx BV	**Molecular Dynamics-Derived Mode I Traction Laws for Crystalline UHMWPE Fibrils** Dr Nuwan Dewapriya - University of Delaware	**Advanced Thermoplastic Honeycomb Cores: Efficiency Gains Through Coextruded Foamed Cell Walls in Sandwich Structures** Mr Gregor Jesse - Leipzig University of Applied Sciences	**Mechanical and Electrical Performance of Conformal Load-bearing Antenna Structures under Mechanical Loading** Dr Mitchell Dunn - The University of Queensland	**Sustainable Oxide/Oxide Ceramic Composites with Atomic Oxygen Protection for VLEO Satellite Applications** Mr Chaehwan Lim - Korea Aerospace University	**Effect of Process Parameters on Mechanical Performance of Additively Manufactured PCCF with Integrated Fiber Reinforcement using ATLAM** Mr Benjamin Steva - University of Maine
12:00 PM - 12:20 PM		**Real-Time Predictive Monitoring and Adaptive Control in Vacuum Infusion Development of a Physics-Based Digital Twin** Mr João Machado - INEGI	**Effect of Consolidation Pressure on the Deformation and Void Content Reduction within a Uniform Array of UHMWPE Fibrils** Dr Abdalsalam Fadeel - University of Delaware	**Impact and Damage Resistance of Sandwich Beams Made from Sustainable Materials at Low Temperatures** Mr Gabriel Sanchez Escudero - Universidad Carlos III de Madrid		**Electrical Insulation for Nb3Sn Superconducting Cables: Fibre Selection, Braiding Process, and Epoxy System Performance** Mr Roland Piccin - CERN	**Effect of Overlap Distance on Bead Geometry and Thermal Conductivity in Extrusion-Deposition Additive Manufacturing** Mr Eonyeon Jo - University of Tennessee Knoxville
12:20 PM - 1:15 PM	**Group Lunch** *(located in Exhibit Hall A/B, Level 100)*						
1:15 PM	**Plenary Speaker: Composites are for Bonding** Ms Michelle Johnson, *Lockheed Martin*						
Move to Level 300 for Parallel Keynotes and Technical Sessions							
2:10 PM - 2:40 PM	**Societal and Industrial Impact Workshop** **2:10 PM - Challenges and Opportunities of Translational Research** Mr Mark Summers - NCC **2:30 PM - From PhD Thesis to Industry Standard: The Power of Collaboration** Dr Sayata Ghose - The Boeing Co	**Keynote Speakers** **From Waste to Circularity: Vitrimerization in Thermoset Composites** Prof Veronica Ambrogi - University of Naples Federico II	**Integrating Machine Learning and Physics-Based Models for Probabilistic Design and Certification of Composite Laminates** Dr Roger Ghanem - University of Southern California	**Innovative Sustainable Composites for Lighter and Flame Retardant Electric Vehicle Parts to Boost Climate Benefits** Prof Manjusri Misra - University of Guelph	**Weaving Resilience: Engineering Damage-Tolerant Textile Composites** Prof Pavana Prabhakar - University of Wisconsin Madison		

Room 316	Room 317	Room 318	Room 319	Room 320	Room 321	Time
Sustainability	Compressive Failure	Computational Modeling	Experimental Techniques	Design, Repair and Life Cycle	Fire Performance	
Structural Integrity Assessment of Reused Wind Turbine Blade Composite Components using Acoustic Emission Testing and Ib-value Analysis Mr Philipp Johst - HTWK Leipzig	**Compression Behavior of Unidirectional Carbon Fiberfiller Reinforced Plastics** Dr Masahito Ueda - Nihon University	**Perforation and Penetration Mechanics of Composites: Theory, Experiment, and Finite Element Analysis** Dr Bazle Gama Haque - McLaurin Aerospace	**Mechanical and Shearographic Inspections of Stacking Sequences in Plydrop Composite Layups** Dr Hatice Sas - University of Sheffield	**Circular Economy Opportunities for Waste Glass Fibre Reinforced Sucker Rod Guides** Ms Chundu Tamang - University of Southern Queensland	**Development of Flame-Retardant Medium Density Wood Fibreboards Using Phosphorylated Casein and Polyamidoamine-epichlorohydrin Resin** Dr Nam Kyeun Kim - University of Auckland	11:00 AM - 11:20 AM
Validation of Possible Applications of Flake Laminates for Recycling of PA6-CF Production Scrap Ms Johanna Beckmann - University Paderborn	**Raman Spectroscopic and FIB-SEM Insights into Compressive Fragmentation of High Modulus Carbon Fibres Model Composites** Mr Cameron Woodgate - Imperial College London	**Finite Element Modeling of the Thermo-Oxidation Gradients in Organic Matrix Composites** Mr Juan Pablo Marquez Costa - PIMM ENSAM	**The Effect of Optical Fibre Cross-Sectional Shape and Microstructure on Out of Plane Strain Sensitivity in Flexible Photonic Sensors** Dr Robin Hartley - University of Bristol	**Life Cycle Assessment of PLA-based Green Composites Reinforced with Natural Fibers** Dr Martina Salzano de Luna - University of Naples Federico II	**Development and Synthesis of Novel DOPO-modified Epoxy Resin and its Glass and Sisal-Based 3D Woven Fiber-Reinforced Composite** Mr Shubham Agnihotri - Indian Institute of Technology Delhi	11:20 AM - 11:40 AM
Recycling of End-of-Life Wind Turbine Blades into Polymer Composites Effect of Reprocessing on Secondary Composites Mr Shashank Tumkur Karnick - Eindhoven University of Technology	**Methodology for Validating and Generating Micromodels to Predict Fiber-direction Compressive Failure in CFRPs** Dr Guillaume Seon - The University Of Texas At Arlington	**Numerical Analysis of Viscoelastic Creep and Transverse Cracking in Fiber-Reinforced Composites** Dr Yamato Hoshikawa - Tohoku University	**3D-Printed Core Reinforced with Unidirectional Tailored Fiber Placement and Braided Structures for use in Custom-Made Composite Knee Orthoses** Mr Marcin Barburski - Lodz University of Technology	**Comparison and Recycling of Uniquely Manufactured Flax Composites** Dr Monis Kazmi - University of Auckland	**Enhancing Fire Resistance of Carbon Fibre Composites Using Functionalised Ammonium Polyphosphate Nanoparticles** Prof Chun Wang - University of New South Wales	11:40 AM - 12:00 PM
Tin-catalyzed Epoxy Vitrimer Matrix: An Approach to Waste Reduction in Epoxy Composites Ms Emeline Waechter - Monash University	**Computational Investigation of Microstructural Instabilities using Discrete Model for Composites DM4C** Dr Mark Flores - ES3	**Characterization of Highly Filled Thermosetting Composite for the Numerical Prediction of Residual Stresses Development During the Production Process** Ms Joana Malheiro - PIEP Centre for Innovation in Polymer Engineering			**Effect of Halloysite Nanotubes and Waste Chicken Feathers as Fire Retardants in Green Composites** Dr Anil Netravali - Cornell University	12:00 PM - 12:20 PM
Group Lunch *(located in Exhibit Hall A/B, Level 100)*						12:20 PM - 1:15 PM
						1:15 PM
Move to Level 300 for Parallel Keynotes and Technical Sessions						
						2:10 PM - 2:40 PM

Time	Ex Hall C - Plenary	Room 307	Room 308	Room 309	Room 310	Room 314	Room 315
	Societal and Industrial Impact Workshop	Manufacturing: Urban Air Mobility	Smart Composite Materials	Physical and Structural Behavior	Multifunctional Composites	Industrial Applications	Additive Manufacturing
2:45 PM - 3:05 PM	**2:45 PM - Building a Global Extended Research Ecosystem** Mr Peter Wilkins - Baker Hughes UK **3:00 PM - The Innovation Pipeline: Collaborative Research Frameworks for the Future of Flight** Mr Tim Gaur - Airbus **3:15 PM - Stronger Together: Victrex's Collaborative Journey in Advanced Materials** Dr Claire Steggall-Murphy - Victrex **3:30 PM - From Fundamental Research to Implementation: How Public-private Participation Drives Thermoplastic Composite Innovation in the Netherlands** Ms Vanessa Marinosci - TPRC ThermoPlastic Composites Research Center	**Flexible and Efficient Manufacturing of Tailored Cabin Interior Panels for Urban Air Mobility Applications** Mr Johannes Baur - Institute of Aircraft Design Stuttgart	**Multifunctional Flexible and Biodegradable Phase Change Composites for Dual-mode Thermal Management of Lithium-ion Batteries** Mr Lichang Lu - Loughborough University	**Design and Optimization of Functionally Graded Honeycomb Structures for Out-of-Plane Stiffness and Energy Absorption** Dr Kaan Yildiz - Istanbul Technical University	**Evaluating the Impact of Carbon-Based Nanomaterials on the Thermomechanical Properties of High Performance Polymer Fibers** Prof Stergios Goutianos - Norwegian University of Science & Technology	**Optimum Boundaries for Maximum Load-Carrying Capacity of Misaligned Water-Lubricated Composite Journal Bearings Based on Elastohydrodynamics** Mr Wonvin Kim - KAIST	**Vertical Axis Wind Turbine Blade Made by 4D Printing of Composites** Dr Suong Hoa - Concordia University
3:05 PM - 3:25 PM		**Hollow Ball Core HBC Technology: A Novel Manufacturing Approach for Thermoplastic Sandwich Honeycomb Core with Design Flexibility** Mr Won Gyo Seo - Utah State University	**Detection of Delamination in CFRP Laminates by Integrated Fiberoptic Strain Distribution Sensors** Mr Tatsuro Kosaka - Kochi University of Technology	**Applicability of Gamma Irradiation for the Production of UHMWPE Composites for Joint Implant Inserts** Mr Istvan Nemes-Karoly - Budapest University of Technology & Economics	**Electrophoretic Deposition of Carbon Nanotube on Highly Aligned Short Carbon Fibers and Influence of Carbon Nanotube Coating on Piezoresistivity** Dr Amit Chaudhari - University of Delaware	**Lightweight Composite Materials for Radiation Shielding via Electrospinning Fabrication** Prof Maria Gabriella Santonicola - Sapienza University of Rome	**Toolpath Optimization of Polymer Composite Additive Manufacturing AM Printed Mold to Improve Performance for Compression Molding Applications** Dr Madhura Limaye - Oak Ridge National Lab
3:25 PM - 3:45 PM		**Hyperconnected Simulation Ecosystem Supporting Probabilistic Design and Predictive Manufacturing of Next Generation Aircraft Structures – CAELESTIS Pr** Dr Elena RodríguezSenín - AIMEN Tecnology Ctr	**Out-of-oven Manufacturing for Natural Fiber Composites with Integrated Sensing Capabilities and Water Barrier** Ms Yushen Wang - Queen Mary University of London	**Stochastic Modelling of the Spatially Distributed Viscoelasticity of Short Fibre-reinforced Composites by using Random Fields** Mr Eduard Klatt - Helmut Schmidt Univesity Hamburg	**Processing and Characterization of 3D Vascular CF/CM Composites** Mr Henry Holman - The University of Tulsa	**Innovating for a Sustainable Future: A New Class of Bare Overhead Aluminum Conductors Reinforced with Carbon Composite Strength Members** Mr Clement Hiel - CSSI New Composite Products Development	**3D-printed Stealth-Honeycomb Conductive-Nanoparticles-Filled PEEK Thermoplastic Resin Curve-Patch Composite for Enhanced RCS Reduction** Mr Jaewon Shim - Korea Aerospace University
3:45 PM - 4:10 PM	**Refreshment Break** *(located in Exhibit Hall A/B, Level 100)*						
4:10 PM - 4:40 PM	**4:10 PM - Sustainable Materials Driven Composites at Royce, 2D Materials to Textile Composites** Prof Prasad Potluri - University of Manchester **4:30 PM - How Translational Research Shapes the Future of Dental Composites from Innovation to Commercialisation** Prof Gangadhara Prusty - Australian Composites Manufacturing CRC **4:45 PM - Harnessing the Basic Research, Technical Innovation and Industrial Implementation: The Role of Chinese Society for Composites Materials** Mr Huaxin Peng - Zhejiang University **5:00 PM - Fraunhofer Innovation Platform for Composites Research at UNIST – Harnessing Global Partnership in Bridging Academia and Composites Industry in Korea** Prof YoungBin Park - Ulsan National Institute of Science Technology **5:15 PM - Beyond Academia, How ICC is Transforming Innovation into Commercial Impact** Mr Kiyoshi Uzawa - Knazawa Institute of Technology	**Mini-Orals** *See page 49 for detailed presentation schedule*					
4:10 PM - 5:30 PM		**Poster Session** *(located in Exhibit Hall A/B, Level 100)*					
7:00 PM - 10:00 PM	**ICCM 24 Conference Banquet** - *Ballroom 1, Level 400*						

Room 316	Room 317	Room 318	Room 319	Room 320	Room 321	Time
Sustainability	Compressive Failure	Vitrimer Matrix Composites	Experimental Techniques	Design, Repair and Life Cycle	Fire Performance	
Sustainable Alternatives to Thermoset Polymers for Aerospace Composites: A Comparison using LCA Mr Andrea Bologna - Politecnico di Milano	**A New Test for the Mechanical Characterisation of Composite Pultruded Rods Under Compression** Dr Gustavo Quino - Imperial College London	**Effect of Epoxy Amine Stoichiometry on the Structure Property and Reprocessing Relationships in Imine Based Vitrimer Polymer Networks and Their Compos** Prof Russell Varley - Deakin University	**Challenges and Recommendations for Longitudinal Tensile Testing of Unidirectional Composites Based on a Round-robin Programme** Prof Yentl Swolfs - KU Leuven	**Cost-Effectiveness of Structural Health Monitoring on the Lifecycle of Composite Aerospace Elements** Dr Pietro Ballarin - Politecnico di Milano	**Effect of Thermal Modification on the Fire Performance of Strand-based Mass Timber Composite Panels** Dr Avishek Chanda - Washington State University	2:45 PM - 3:05 PM
Mapping the Global Material and Energy Flows of Fiber Reinforced Polymer Composites Ms Zhuoer Li - University of Michigan	**The Experimental Investigation of the Compressive Performance of Pultruded Rod Composite Struts** Dr Bohao Zhang - University of Bristol	**Substitution Effects on Reprocessable Highly Aromatic Imine-Containing Epoxy Vitrimers** Ms Sharine Noelle Bendulo - Deakin University	**Advanced Characterization of Polymers and Composite Materials using Axial-Torsional Dynamic Mechanical Analysis** Mr Gunther Arnold - Anton Paar Germany GmbH	**Performance Improvement of Type-4 Hydrogen Pressure Vessel using Progressive Ply Failure Mechanism** Mr Akash Burolia - Indian Institute of Technology Kharagpur	**Burning Behaviour of Thermoplastic Glass Fibre Composites for a Bumper Beam Application** Ms Joana Malheiro - PIEP Innovation in Polymer Engineering	3:05 PM - 3:25 PM
Multistep Recycling of ElumT700 Composites via TuFF Technology Dr Joseph Deitzel - University of Delaware		**Cure Kinetics of a Transesterification-Type Vitrimer Derived from a Commercial Epoxy-Anhydride Thermoset** Mr Joshua Ilse - McGill University	**Identification of the Through-Thickness Orthotropic Stiffness Components of Thick Filament-Wounded Composite Tubes in an Industrial Context** Dr Isabella Jacobsen - MatchID US Inc	**Determination of Recycled Carbon Fiber Strength Distribution using Bundle Fiber Tensile Test** Mr Yoshiki Sugimoto - National Institute of Advanced Industrial Science	**Hydrochar-Based Flame Retardants from Brewers' Spent Grain for High-Performance NFRCs** Ms Alessia Pantaleoni - Sapienza University of Rome	3:25 PM - 3:45 PM
Refreshment Break *(located in Exhibit Hall A/B, Level 100)*						3:45 PM - 4:10 PM
						4:10 PM - 4:40 PM
Poster Session *(located in Exhibit Hall A/B, Level 100)*						4:10 PM - 5:30 PM
ICCM 24 Conference Banquet - *Ballroom 1, Level 400*						7:00 PM - 10:00 PM

Scientific Program

FRIDAY, AUGUST 8

Time	Ex Hall C - Plenary	Room 307	Room 308	Room 309	Room 310	Room 314	Room 315
7:00 AM	**Registration Desk Open** *(closes at 12:30 PM - located in Charles Street Lobby, Level 100)*						
7:00 AM	**Continental Breakfast** *(until 8:00 AM - located in Exhibit Hall A/B, Level 100)*						
7:00 AM	**Exhibit Hall Open** *(closes at 11:00 AM - located in Exhibit Hall A/B, Level 100)*						
8:00 AM	**Welcome Remarks**						
8:05 AM	**Plenary Speaker: Quality Measurement and Control in High Volume Composites Manufacturing: A Combined Academic and Industrial Perspective** Prof Simon Bickerton, *University of Auckland*						
9:00 AM	**Lagace Lecture: New Concepts and Products of Double-Double Laminate** Prof Stephen Tsai, *Stanford University*						
Move to Level 300 for Technical Sessions							
		Manufacturing: Welding	**Smart Composite Materials**	**Physical and Structural Behavior**		**Multiscale Behavior**	**Sustainability**
9:35 AM - 9:55 AM		**Sequential Resistance Welding of a Thermoplastic Composite Leading Edge Demonstrator from Laboratory Testing to Full-scale Welding** Mr Massimiliano Russello - AIMEN	**Effect of Atomic Oxygen Exposure on the Thermomechanical Properties and Shape Memory Behaviour of ±45° Glass Fibre Reinforced Cyanate Ester Based Shape Memory Polymer Composites** Prof Jayantha Epaarachchi - University of Southern Queensland	**Experimental Study on the Fatigue Performance of CFRP Beams with Structured Surface Load Introduction Under Cyclic Loading** Mr Torben Deutschmann - TUHH		**Multiscale Analysis for Woven Composite with Incomplete Periodicity** Mr Koki Tsuda - Nagoya University	**Composite Material Sustainability: Where are We Today and Where Do We Need to Go** Dr Edward Patton - Patton Engineering
9:55 AM - 10:15 AM		**Ultrasonic Welding of Metal and Fibre Reinforced Thermoplastics — Bond Formation and Joint Strength** Mr Moritz Liesegang - RPTU Kaiserslautern-Landau	**Performance Evaluation of Structural Behavior Monitoring using Smart Sensors** Dr Sung-Hwan Jang - Hanyang University ERICA	**Impact of Stacking Sequence on Tensile and Fatigue Performance of Quasi-isotropic Carbon/Epoxy Laminates** Mr Marc Gadinger - Friedrich Alexander Universitut Erlangen Nurnberg		**Multiscale Modeling for Bottom-up Prediction of Failure Parameters of Unidirectional Carbon-fiber-reinforced Composite Lamina from Atoms to Laminasc** Prof Yoshiaki Kawagoe - Tohoku University	**Untangling Decarbonization Strategies for Net Zero Carbon Fiber** Dr Kyle Pender - National Composites Centre
10:15 AM - 10:35 AM		**Development of Metal-carbon Composites from Poly(ether-ketone-ketone) for Ablative Thermal Protection Coatings** Ms Casey Barrett - Rowan University	**Rectifying Efficiency Measures for Vascular-based Thermal Regulation** Mr Sandeep Rajendra Kumar - North Carolina State University				**Production of Olefin-based Composite Materials by Recycling Discarded Carbon Fibres** Mr Corrado Sciancalepore - University of Parma
10:35 AM - 11:00 AM	**Refreshment Break** *(located in Exhibit Hall A/B, Level 100)*						

Room 316	Room 317	Room 318	Room 319	Room 320	Room 321	Time
Registration Desk Open *(closes at 12:30 PM - located in Charles Street Lobby, Level 100))*						7:00 AM
Continental Breakfast *(until 8:00am - located in Exhibit Hall A/B, Level 100)*						7:00 AM
Exhibit Hall Open *(closes at 11:00 AM - located in Exhibit Hall A/B, Level 100)*						7:00 AM
						8:00 AM
						8:05 AM
						9:00 AM
Move to Level 300 for Parallel Keynotes and Technical Sessions						
Experimental Techniques	**Compressive Failure**	**Vitrimer Matrix Composites**	**Fire Performance**			
Residual Strain Development in Carbon Fiber Reinforced Metal Hybrid Laminates: An Experimental Investigation using FBG Strain Sensors Mr Maximilian Pollak - Die FH OÖ Forschungs & Entwicklungs GmbH	**Laminate Hybridization using High Modulus Carbon Thin Plies for Enhanced Compressive Performance** Mr Yousef Rifai - University of Bristol	**Vitrimer Matrix Composites Manufactured by Filament Winding for Space Applications** Ms Josephine de Calbiac - Centre National d'Etudes Spatiales CNES	**Modeling and Prediction of Residual Strength of Polymer Composites Exposed to Heat** Mr Jianhua Huang - Luna Labs USA LLC			9:35 AM - 9:55 AM
Characterisation of Binder Powders in Glass Fibre Fabrics using Laser Microscopy and Deep Learning Segmentation Methods Mr Jesper Lisegaard - Technical University of Denmark	**Localized Hybridization using Boron Fibers: A Route to Improve Open Hole Compressive Performance** Dr Gursahib Singh Bhatia - Imperial College London	**Flexible and Recyclable Vitrimers for Sustainable Electronic Composites** Prof Aniruddh Vashisth - University of Washington Seattle	**Fire Modelling of Multifuel Composites with Varying Material Layers using Complex Stoichiometry** Prof Debes Bhattacharyya - University of Auckland			9:55 AM - 10:15 AM
Automated Construction of Viscoelastic Master Curves and Prony Series Models for Advanced Material Characterization Using DMA Data Mr Mahdi Tayyebati - Technical University of Denmark		**Rejuvenating Out-of-Date Carbon Fiber Prepregs with Imine-Epoxy Vitrimers** Ms Sharine Noelle Bendulo - Deakin University	**Experimental Evaluation of Interlaminar Shear Strength of Carbon Nanomaterial Z-threaded Carbon Fiber-Reinforced Polymer Laminates After Exposure to E** Prof Kuang-Ting Hsiao - University of South Alabama			10:15 AM - 10:35 AM
Refreshment Break *(located in Exhibit Hall A/B, Level 100)*						10:35 AM - 11:00 AM

FRIDAY, AUGUST 8

Time	Ex Hall C - Plenary	Room 307	Room 308	Room 309	Room 310	Room 314	Room 315
		Manufacturing: AFP/ATP 3	Smart Composite Materials	Physical and Structural Behavior		Multiscale Behavior	Sustainability
11:00 AM - 11:20 AM		**Differential Eddy Current Sensing Probe and It's Implementation in Automated Composite Manufacturing Applications** Mr Ege Arabul - University of Bristol	**Energy Efficient and Tailored Out-of-Oven Composites Manufacturing Towards Sustainable and Smart Composites** Dr Han Zhang - University of Warwick	**Fastblade: A Fatigue Testing Facility for Full Scale Blades** Dr Sergio Lopez Dubon - The University of Edinburgh		**A Novel Multiscale Digital Image Correlation Approach for Monitoring Stable Skin-Stringer Delamination Growth in Post-Buckled Composite Panels** Mr Andres Pereira - Delft University of Technology	**Sustainable Biodegradable Composites for a Circular Economy** Dr Amar Mohanty - University of Guelph
11:20 AM - 11:40 AM		**Pass Frequency as a Means for Increased LATP Productivity** Ms Emma Tobin - University of Limerick	**rCF-based Pyro-Resistive E-Skin Integrated with Temperature Sensing and Self-Controlled Joule Heating Function** Mr Yansong Li - Queen Mary University of London	**Compression-Compression Fatigue of Glass-Fibre Non-Crimp Fabric Composites by Four-Point Flexure** Ms Nicola Shepherd - The University of Auckland		**Multiscale Modelling of Cryogenic Hydrogen Permeability in Polymer-Matrix Composites** Mr Mustafa Okumus - University of Warwick	**Self-Contained Cost-Effective Plastic Recycling Facilities** Dr Ranji Vaidyanathaan - Oklahoma State University
11:40 AM - 12:00 PM			**Inspired by Ice Skates: Smart Aqueous Self-lubricating Coatings for Icephobic Applications** Ms Gelareh Momen - University of Quebec at Chicoutimi	**The Role of Pore Distribution and Hierarchical Structure of Marine Mussel Plaque Cores** Dr Tao Liu - Queen Mary University of London			**Manufacturing and Characterisation of Continuous Recycled Carbon Fibre Unidirectional Composites** Dr Monali Dahale - National Composite Centre
Move to Level 100 for Closing Ceremony							
12:10 PM - 12:30 PM	**Closing Ceremony** *(Exhibit Hall C, Level 100)*						
12:30 PM	**Box Lunch Pick-up** *(located in Exhibit Hall A/B, Level 100)*						
12:45 PM	**Bus Departs for UD-CCM Tour**						
2:15 PM - 4:15 PM	**Tour of UD-CCM**						
4:15 PM	**Depart UD-CCM and return to Baltimore Convention Center**						

Room 316	Room 317	Room 318	Room 319	Room 320	Room 321	Time
						11:00 AM - 11:20 AM
						11:20 AM - 11:40 AM
						11:40 AM - 12:00 PM
Move to Level 100 for Closing Ceremony						
Closing Ceremony *(Exhibit Hall C, Level 100)*						12:10 PM - 12:30 PM
Box Lunch Pick-up *(located in Exhibit Hall A/B, Level 100)*						12:30 PM
Bus Departs for UD-CCM Tour						12:45 PM
Tour of UD-CCM						2:15 PM - 4:15 PM
Depart UD-CCM and return to Baltimore Convention Center						4:15 PM

Poster Session

Posters will be on display in Exhibit Hall A/B, Level 100

Poster Title	Poster Presenter	Poster No.
Aerostructure Composites		
Filament Wound Carbon Fiber Reinforced Polymers Support Structures for Spacecraft Applications	Dr Abrar Ul Haq Khan Baluch	1
Aligned Discontinuous Fiber Composites		
Quantification of Alignment Quality of Discontinuous Fiber Composites Using 2D Fast Fourier Transform FFT	Dr John Tierney	2
Artificial Intelligence Empowering Composite S&T		
Specialized LLMs for Supporting Composite Material Processing and Equipment Operation	Dr Seokpum Kim	3
Composites AI: An AI-Powered Expert System for Composites Engineering	Prof Wenbin Yu	4
Biomass-Based Composite Materials		
Development and Characterisation of Bamboo and Natural Fibre Composite Wrapped Tow Reinforced Trusses	Mr Matthew Lillywhite	5
Biochar as an Alternative Filler for Composites	Prof Veronica Calado	6
Design, Repair and Life Cycle		
Machine Learning Based Residual Distortion Prediction for Extrusion-based Additive Manufacturing of Biocomposite	Ms Bhagyashree Prabhune Dr Madhura Limaye	7
AI Driven Methodologies for Advancing Composite Material Analysis and Applications	Mr Cesar Garcia Gascon	8
Designing Layered Composites for Improved Buckling Strength Using Auxetic Behavior	Dr Yeqing Wang	9
Observation of Bending Fractural Behavior of CFRTP Laminates with Fiber Discontinuity using DIC	Mr Kento Onozuka	10
Manufacturing and Mechanical Properties of Recycled Carbon Fiber Composites by Spinning Process	Mr Shinichi Tatsuta	11
A Non-Local Cohesive Zone Model for Delamination in Fiber-Reinforced Polymers Incorporating Extrinsic Energy Dissipation	Mr Xiaole Li	12
Determining Feasibility Bounds of Lamination Parameters using Neural Networks	Mr Swapan Madabhushi Venkata	13
Extension and Layup Optimization of Double-Double Laminates Based on Lamination Parameters	Mr Chen Du	14
Experimental Techniques		
Using Multiaxial Fatigue to Investigate the Anisotropic Performance in Additively Manufactured Material	Dr Peter Bailey	15
Nondestructive Assessment of Stiffness Degradation Owing to Mechanical Fatigue and Temperature-Accelerated Fatigue of GFRP by using NIR-spectroscopy	Mr Daniel Esse	16
Fire Performance of Composite Materials		
Development of Bench Scale Instrument for Testing Thermal Protective Performance in Different Orientations	Mr Sudhanshu Maurya	17
Thermal and Mechanical Analysis for Li-ion Battery Fire Containment	Dr Sindhu Bushpalli	18
Industrial Applications		
Glass Reinforced Epoxy GRE as an Alternative Pipeline for Onsite Surface Installations a Structural Integrity and Economic Feasibility Study	Mr Muhammad Tahir Waqas	19
Performance of Graphene Nanoplatelet Enhanced CFRP Composites under Post Cryogenic Thermal Cycling for Hydrogen Storage Applications	Dr Jabir Ubaid Parakkal	20
Development of Lightweight Sandwich Composites with Improved Reaction to Fire and UV Resistance	Ms Helena Rocha	21
Manufacturing		
Improving Interlayer Adhesion in Large Format Additive Manufacturing for Composite Tooling	Mr Nicolas Courion, Dr Pascal Hubert	22
Printing of Molten Metal Droplets Toward High Throughput Metal Matrix Composites Manufacturing	Dr Kaihao Zhang	23
An Anisotropic Constitutive Model for Carbon Fabric-Reinforced Shape Memory Polymer Composites Based on Phase Transition Concept	Mr Chen Jiajun	24
Manufacturing *(continued)*		
Design Optimization and Fabrication of Non-Conformal Thermal Cloak Using Continuous Embedded Metal Polymer Composites	Mr Muhammad Jawad Ahmad	25
Advanced Composite Bonding using Energy Efficient Localised Curing Based on Nanomodified Epoxy	Prof Daiva Zeleniakiene	26
Performance Evaluation of Natural Fibre Reinforced Polymer Matrix Composites Manufactured via Liquid Resin Infusion	Dr Chamil Abeykoon	27
Structural and Thermal Properties of 3D Printed Polylactic Acid Composites Filled with Bamboo Powder	Dr Chamil Abeykoon	28
Friction Behaviors of Carbon Fiber Tows and their Effect on the Manufacturability and Mechanical Properties of Composite Pressure Vessels	Ms Su Hyun Lim	29
Effect of Corner Curvature on Press Forming of Metalthermoplastic CFRP Laminates	Ms Naito Miumi	30
Multifunctional Natural Fibre Composites with Integrated Process Monitoring Damage Sensing Capabilities	Mr Yansong Li	31
Development of a Robotic Enabled Composite Part High-Resolution Inspection and Reverse Digital Twin Tool	Mr George Willis	32
Development of a 700 Bar Thermoplastic Type IV Pressure Tank for Compressed Hydrogen Storage in the Field of Mobility	Mr Pedro Abreu	33
Design and Analysis of Fiber-Reinforced Composite Hydrogen Storage Vessels for Transportation Vehicles Type IV and V	Mr Hyunchul Ahn	34
Effect of Incorporating Additional Thermoplastic into Carbon Fiber Epoxy Composites Prepared by Electrodeposition Resin Molding Method	Mr Md Tansirul Islam	35
Research on Longitudinal Torsional Ultrasonic Vibration Assisted Grinding of CFRP	Ms Yan Chen	36
Multi-Scale Modeling for the Curing-Induced Deformations of the Toughened Resin-Based Composite	Ms Meiyu Liu	37
Realtime Flowfront Prediction in Resin Transfer Molding Using Electromechanical Behavior and Generative Adversarial Network	Mr Dahun Lee	38
Development of Multifunctional Coaxial Fiber Sensor for Simultaneous Strain and Temperature Monitoring for Composite Manufacturing Process	Mr Seungyoon On	39
Materials and Precursors		
Helicobacter Pylori Detection via SERS Enhancement Using Synergistic Effects of Gold Nanorods Nano Mica Platelets ZnO Quantum Dots	Mr Ming Chang Lu	40
Effects of Dry Heat and Ultraviolet on the Tensile and Fatigue Strengths of Glass Fiber Reinforced Vinyl Ester	Mr Abdul Rahman Aravind	41
Construction of 3D Networked Epoxy Composite Using RGO and BPEI Coated Epoxy Microspheres for High Thermal Conductivity Applications	Miss Dayoung Kim	42
Enhanced Charge Transfer in Thermogalvanic Cells via Nitrogen Doping of Oxidized CNT Electrodes	Dr Seung Yeol Jeon	43
Evaluation of Cryo TMADMA for Determining the Stiffness Properties of Adhesives at Cryogenic Temperatures	Mr Patrick Nowakowski	44
Experimental Investigation of Mechanical Fiber Bundle Spreading	Miss Hannah Rabe	45
Evaluating Wool Fiber's Viability as a Sustainable Reinforcement in Composite Applications	Mr Tsegaye Lemmi	46
Valorization of Postconsumer Biodegradable Polymer Blend to Create Composites with Agroindustrial Byproducts as Reinforcing Fillers	Miss Erika Palazzi	47
Gas Diffusion Nanocomposite Layer with Enhanced Mass Transport with Surface Functionalization by Laser Irradiation	Dr Taesik Eom Prof Sang-Eui Lee	48
Novel Electrospinning PVDFBi2O3CeO2 Composite Yarns A Versatile Approach Towards Functional Xray Shielding Textiles	Miss Siyuan Zhao	49
Tribological Investigation of the Interface Between Steel Pin and CFRP Tube	Mr Floyd Daniel Bischop	50
Enhancing Mechanical and Thermal Properties of Recycled EVOH Films Using NanoSilica Additives	Ms Kowsar Rezvanian	51

Poster Session

Posters will be on display in Exhibit Hall A/B, Level 100

Poster Title	Poster Presenter	Poster No.
Materials and Precursors *(continued)*		
Interface Structure and Characterization Analysis of Carbon Fiberpolypropylene with -Crystals	Mr Dazhi Jiang	52
Microwave Assisted Synthesis and Characterization of GadoliniumDoped Nickel Ferrite Nanoparticles	Mr Ignatius Eboquansah	53
Polydopamine-Coated Hexagonal Boron Nitride for Heat Dissipation Application	Ms Yeon Hwa Jeong	54
Evaluation of the Effect of Z-Threaded Carbon Nanofibers on the Improvement of Flexural Properties of Carbon Fiber Reinforced Polymer Laminates	Prof Kuang Ting Hsiao	55
Enhancing the Properties of Laminated Composites with Vertically Aligned Carbon Nanotubes Interleaves	Mr Blagoj Karakashov	56
The Low Density and High Strength Epoxy Resin Based Solid Buoyancy Material was Prepared by a New Technology	Mr Xu Chengxin Xu	57
Development and Application of Low Smoke Epoxy Resin Based Carbon Fiber Prepreg	Mr Jiahui Tan	58
Dielectric and Electrical Properties of Polyetherketone–Silica Nanocomposites for High Performance Electronic Applications	Dr Mandar Joshi	59
Development and Characterization of a Novel FeCrAlAlumina Composite for Enhanced Corrosion Resistance and Biocompatibility	Ms Olga Tsurtsumia	60
Evaluation of the Plasticizing Effect of Polythylene Glycol 400 in a Polylactic Acid Polymer Matrix for Food Packaging Applications	Mr Daniel Alvarez Gomez	61
Multifunctional and Smart Composites		
Development of Nanomaterials-Based Antiicing-Deicing Devices for Aviation Sector	Dr Muhammad Zahid	62
Development of Phenolic Resin Nanocomposites Reinforced with Nanodiamond	Ms Yasuda Momoka	63
In-situ Synthesis of Polyamide Composites with Recycle Carbon Fiber	Mr Hasegawa Dai	64
Injectable Enzyme-free Catecholic Alginatepluronic Nanocomposite Hydrogel via the Peroxidase Mimicking Bioglass for Bone Regeneration	Mr Quyen Tran	65
Frequency-Selective Surface-Based Composite Radar Absorbing Structures Using Transferred Laser-Induced Graphene on Glass Fiber Fabric	Mr Kinal Kim, Prof SangEui Lee	66
Development of Composites Manufacturing Assisted Artificial Intelligence and Machine Learning based Automated 3D Defect Detection System	Miss Yagna Jadeja	67
Energy Storage Performance of DFO Incorporated PVDF Composite Thin Film	Mr Abhinav Yadav	68
Optimizing Conductivity and Performance of Conductive Graphene-Acetylene Black Reinforced Nitrile Rubber NBR Composites	Dr Zaheer ul Haq	69
Enhancing Ablative Resistance of Carbon-Epoxy Laminates via Interlayer of Silicone Elastomer Microparticles	Mr Se Jun Wang	70
Physical and Structural Behavior		
Insights into the Mechanical Degradation of Matrix and Fibre-Matrix Interface in Carbon Fibre-Reinforced Polymers (CFRPs) Under Hydrothermal Conditions	Dr Weizhao Zhang	71
Impact Characteristics of Sheet Molding Compound with Different Tape Morphology and Effect of Continuous CFRTP Overmolding	Mr Sang Won Lim	72
Computational Prediction of Fatigue-Induced Debonding in Multilayer Wind Turbine Blade Protective Coatings under Stochastic Raindrop Impacts	Dr Puneet Mahajan	73
Integrated Mesoscopic Modeling Scheme for 2D Woven Prepregs During Compression Molding	Mr Deyong Sun	74
Structural Integrity of Composite Manipulator Applied to the Automated Ropeway Inspection Using Flexible Multibody Dynamics Analysis	Mr ChiHyun Song	75
Multifunctional Stealthy Flexible Honeycomb Core and Lightning Protection Metamaterial Surface Composites for Lightning Strike Damage	Mr SeongHaeng Heo	76
Physical and Structural Behavior *(continued)*		
Assessing the Impact of Salt-Fog Exposure on the Performance and Recyclability of Biobased Epoxy Composites Eeinforced with Natural Fibres	Mr Vincenzo Fiore	77
Development and Modeling of Interfacially Engineered Composites with Designed Failure	Mr Gergo Zsolt Marton	78
Multiscale Analysis of Hybrid Hemp-Glass Composites for Sustainable Lightweight Automotive Torsion Beams	Mr Napat Nawawithan	79
A Novel Method for Evaluating the Biodegradability of Polymers by Tracking Changes in Tensile Properties During Degradation	Ms Lovisa Rova	80
Finite Element Model of Progressive Damage of Composite Grille Cylinder and Predication of Its Compressive Load Bearing Performance	Mr Dazhi Jiang	81
3D Printing Biosourced PLA-flax Composite Sandwich with Different Core Geometries and their Bending Behaviours	Ms Zhenyi Wang	82
Shear Thickening Fluid Thermoplastic Matrix Composite Bulletproof Vests	Mr Mauricio Jose Aires Malheiro	83
Nonlinear Behavior of Polymers and Structures Produced using Additive Manufacturing	Mr Elvijs Bojars	84
Characterization of Mechanical Properties of Induction-cured Carbon-glass-epoxy Hybrid Composites	Mr Andrejs Pupurs	85
Environmental Durability of Composites: Characterization of Temperature and Strain Rate Dependent Properties of Toughened Epoxy Resins	Dr Sagar Doshi	86
Self-Healing Composites		
Self-Healing In-situ Delamination Thermoplastic	Dr Samit Roy	87
Smart Composite Materials		
Fabrication and Characterization of Manganese Doped Cobalt Ferrite Reinforced with PVDF-TrFE for Electrical Applications	Mr Faruk Soso	88
Sustainability and Circular Economy		
Wind Blade Spar Cap Manufacture and Recycling with Discontinuous Carbon Composites	Dr John Tierney	89
Sustainability and Environmental Assessment of Composites		
Effective Decomposition Rate of Epoxy Resin using a Modified Shrinkingcore Model: Synergistic Hydrolysis and Glycolysis Reactions	Mr Jinsu Kim	90
Thermoplastic Composites		
Enhancing Mechanical Performance of Recycled CFPEKK Composites: The Role of Strand Optimization and Plasma-Activated Adhesive Bonding in Sandwich Structures	Dr Hatice Sas	91
Development and Characterization of Munja Grass Fiber-Reinforced HDPE Composites for Structural Applications	Mr Nitin Arya	92
Reconsolidation of CFPEKK Composites: Repair of Drilling-induced Damage and Hydrothermal-Aging Effects	Dr Hatice Sas	93
Effect of Needle Punching on the Dynamic Properties of Recycled Non-Woven Carbon Fiber-Reinforced Thermoplastics	Mr Zhang Fan	94

TUESDAY, AUGUST 5

Mini-Oral Schedule

Each Mini-Oral presentation will be 3 minutes.

Time	Room 307	Room 308	Room 309
4:10 PM	**Effect of Incorporating Additional Thermoplastic into Carbon Fiber Epoxy Composites Prepared by Electrodeposition Resin Molding Method** Mr Md Tansirul Islam	**Development of Nanomaterials-Based Antiicing-Deicing Devices for Aviation Sector** Dr Muhammad Zahid	**Evaulation of Cryo TMADMA for Determingin the Stiffness Properties of Adhesives at Cryogenic Temperatures** Mr Patrick Nowakowski
4:15 PM	**Advanced Composite Bonding using Energy Efficient Localised Curing Based on Nanomodified Epoxy** Prof Daiva Zeleniakiene	**Novel Electrospinning PVDFBi2O3CeO2 Composite Yarns A Versatile Approach towards Functional X-ray Shielding Textiles** Miss Siyuan Zhao	**Construction of 3D Networked Epoxy Composite Using RGO and BPEI Coated Epoxy Microspheres for High Thermal Conductivity Applications** Miss Dayoung Kim
4:20 PM	**Friction Behaviors of Carbon Fiber Tows and their Effect on the Manufacturability and Mechanical Properties of Composite Pressure Vessels** Ms Su Hyun Lim	**Environmental Durability of Composites Characterization of Temperature and Strain Rate Dependent Properties of Toughened Epoxy Resins** Dr Sagar Doshi	**Helicobacter Pylori Detection via SERS Enhancement Using Synergistic Effects of Gold NanorodsNano Mica PlateletsZnO Quantum Dots** Mr MingChang Lu
4:25 PM	**Structural and Thermal Properties of 3D Printed Polylactic Acid Composites Filled with Bamboo Powder** Dr Chamil Abeykoon	**Multifunctional Stealthy Flexible Honeycomb Core and Lightning Protection Metamaterial Surface Composites for Lightning Strike Damage** Mr SeongHaeng Heo	**Effects of Dry Heat and Ultraviolet on the Tensile and Fatigue Strengths of Glass Fiber Reinforced Vinyl Ester** Mr Abdul Rahman Aravind

Frontal Polymerization: Quo Vademus?

A Review with Consideration of Future Directions

John A. Pojman

Ad Maiorem Poimanorum Gloriam

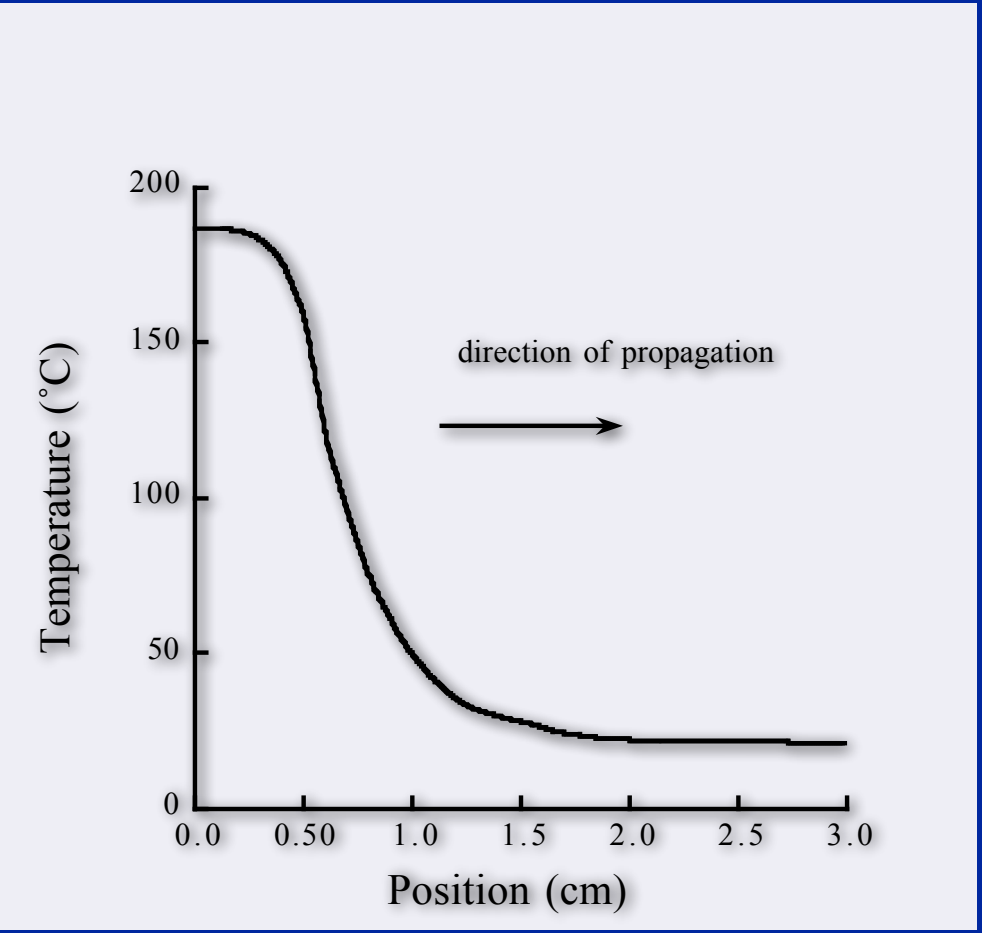
Objectives

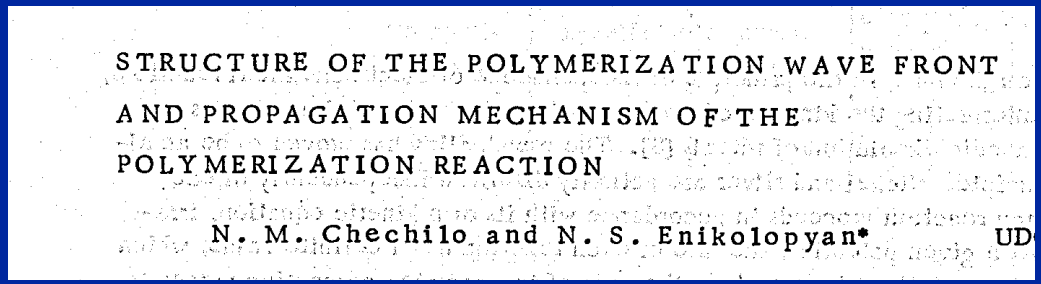
- review origins and major advances
- shamelessly promote my own work
- consider future directions for research



What is Frontal Polymerization?

Thermal frontal polymerization is the coupling of the heat release of polymerization with the Arrhenius dependence of the reaction rate in an unstirred system, i.e., “liquid flame”.

Frontal Polymerization Scheme



Large Temperature Gradient

Early History

- inspired by SHS, FP discovered in Chernogolovka, Russia

Received January 9, 1996

Frontal polymerization is a mode of converting monomer into polymer via a localized reaction zone that propagates, most often through the coupling of thermal diffusion and Arrhenius reaction kinetics. Frontal polymerization reactions were first discovered in Russia by Chechilo and Enikolopyan in 1972.[1] They studied methyl methacrylate polymerization to determine the effect of initiator type and concentration on front velocity[2] and the effect

Future Challenges

- find new chemistries
- design systems that can work at lower temperatures but still have long pot lives
- demonstrate that materials are at least as good as current ones, e.g. composites
- explore how to use the “spin modes” to create unique materials

FATIGUE DAMAGE EVOLUTION IN GLASS/EPOXY LAMINATES WITH STRESS CONCENTRATIONS: EXPERIMENTS AND MODELLING

Marino Quaresimin, Paolo Andrea Carraro and Lucio Maragoni

ABSTRACT

The work illustrates a fatigue design strategy, based on the physics of the damage evolution, developed by the Composite Group at the University of Padova over the last few years. After a brief introduction, where the motivations of the work are analyzed, examples of damage mechanisms at the macro- and micro-scale are discussed. Then the models for the quantitative description of these mechanisms are illustrated, together with experimental validation. Eventually, the application of the modelling framework to the prediction of the damage evolution in composite plate with central hole is presented.

1 INTRODUCTION

Most structural components made from composite materials are subjected to cyclic loading during their service life. This can result in the progressive evolution of damage, a corresponding loss of stiffness, and, ultimately, catastrophic failure. Designing against fatigue is therefore essential to enhance the reliability of composite structural components across a wide range of applications.

To address the growing need for fatigue-resistant composite design tools, the authors have spent several years developing a comprehensive design framework. This framework aims to predict the initiation of damage, its progression, and the final failure of composite laminates under cyclic loading conditions.

In the context of composite materials, characterized by a multitude of progressive damage mechanisms, "design against fatigue" can take on different meanings, depending on the requirements of the component. These include:

i) Design to prevent crack initiation;
ii) Design to prevent excessive stiffness degradation (damage-tolerant design);
iii) Design to prevent final failure.

As will be discussed in more detail later, damage development in composite laminates involves multiscale and hierarchical processes. These range from micro-scale damage initiation to the growth of macro-cracks and delamination, ultimately resulting in failure. The nature of these mechanisms depends on several factors, including the constituent materials, laminate lay-up, loading type, and multiaxial stress conditions [1].

To effectively tackle such a complex problem and deliver reliable design methods for each of the aforementioned objectives, it is necessary to develop models based on the physical damage mechanisms occurring at various length scales [1]. These models must then be integrated into a multiscale, multi-mechanism design strategy that must be also efficient and flexible to comply with real component design and industrial workflows.

The following sections present representative examples of the key mechanisms that drive laminate degradation and failure under cyclic loading. Subsequently, the proposed modelling strategy is introduced and an application on notched laminates is presented.

2 FATIGUE DAMAGE MECHANICS

The damage evolution in composite materials is a multiscale and hierarchical process, involving several mechanisms at different length scales. In this work, the macro-scale is related to the ply and laminate level, whereas the micro-scale is relevant to the fiber diameter and the inter-fiber spacing.

As widely proved in the literature (see Refs. [2-6] among the others), the first macro-scale damage event in a multidirectional laminate is represented by the initiation of off-axis cracks that involve the entire thickness of a ply and propagate along the fiber direction. The crack density increases during the lifetime and a saturation condition in reached after a certain number of cycles. The second observable mechanism, in chronological order, is represented by delamination. A delamination initiates from the tips of the off-axis cracks at the interface with confining layers and propagates in a direction normal to the off-axis cracks. These two mechanisms are not directly responsible for the laminate failure but cause a significant loss of stiffness that must be correctly predicted if a damage tolerant design approach is adopted. An example of the damage evolution, highlighting the initiation and propagation of multiple off-axis cracks, is shown in Figure 1.

The final failure is eventually typically controlled by the main load bearing plies, which means that it is caused by the failure of the 0°-oriented fibers.

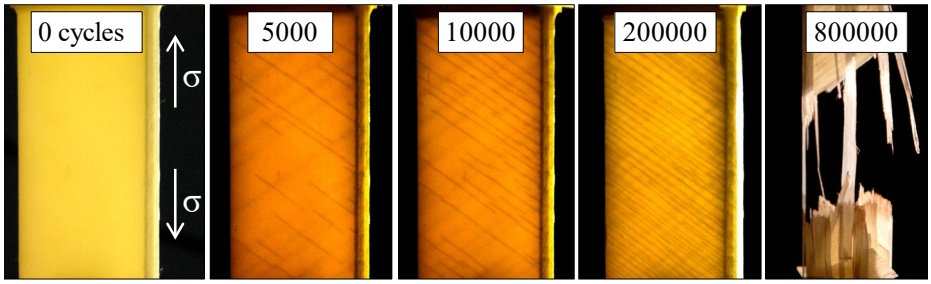

Fig. 1. Example of fatigue damage evolution and failure in a $[0/60_2/0/-60_2]_s$ laminate [6]

The mentioned macro-scale damage events have their precursors and interaction at the microscale, in the form of microcracks, fiber-matrix debonds and fiber breaks. In a damage-based approach, criteria for predicting the onset and evolution of the macroscopic damage modes should be, thus, based on the micro-scale damage mechanisms.

For instance, the micro-scale damage process leading to an off-axis crack formation consists in the initiation and growth of matrix micro-cracks, which eventually coalesce forming the off-axis crack (Figure 2). This is relevant to local stress states characterized by a sufficiently high $\lambda_{12}=\sigma_6/\sigma_2$ (shear to transverse stress ratio). For instance, Figures 2 shows such micro-cracks, in the external 45° ply of a $[45/-45/0]_s$ glass/epoxy laminate under tension/tension fatigue [7]. These micro cracks were shown to be normal to the Local Maximum Principal Stress (LMPS) in the matrix, that was then considered as the effective stress to be used for predicting crack formation in such conditions [8].

If the stress state in a ply is such that the in-plane stress component σ_6 is zero, it was proved [9] that the local stress state in the matrix, close to the fiber-matrix interface, is nearly hydrostatic. This induces a micro-scale failure mode consisting in a matrix cavitation-induced debonding, driven by the Local Hydrostatic Stress (LHS) in the matrix. This was proposed as

the effective stress to be used for predicting crack initiation under a nearly transverse stress state [8].

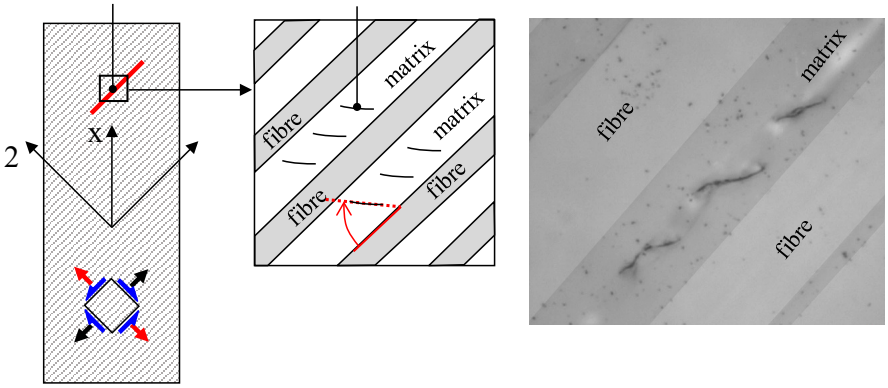

Fig. 2. Schematic and example of off-axis crack formation by initiation of inclined micro-cracks in the matrix of a 45° ply

Also the delamination and fiber failure phenomena were analyzed from the microscopic point of view, revealing their interaction with off-axis cracks. Fatigue tests were carried out on glass/epoxy cross-ply laminates. Edge micrographs of the specimens were taken, revealing the typical scenario shown in Figure 3. Delamination was triggered by the presence of the off-axis cracks. A micro-scale delamination was indeed seen to form exactly at the moment of the off-axis crack formation and then to propagate at the interface [10].

The role that transverse cracks and delamination play on the failure of the fibers is clear from Figure 3. 0° fiber breaks are concentrated in the vicinity of the transverse crack tip and above the delamination, the growth of which leads to more and more fiber breaks, until a critical condition is reached.

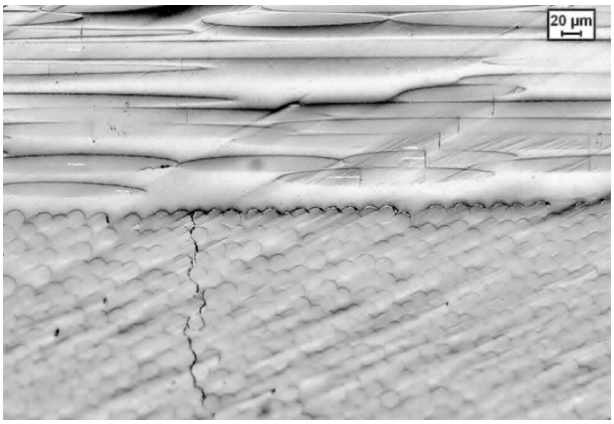

Fig. 3. Example of delamination from a transverse crack tip with broken fibers

3 PREDICTION METHODOLOGY

According to the experimental observations, the fatigue life of a composite laminate has to be divided in different phases, each characterized by a dominating damage mode. Therefore, for predicting the fatigue behavior of a composite laminate, the initiation and evolution of each mechanism has to be predicted, together with its effect on the stress re-distribution and the

stiffness degradation. In particular, within a discrete damage mechanics framework, it is necessary to:

i. Predict the cycles spent for crack initiation;
ii. Describe the crack propagation and the crack density evolution until the saturation condition;
iii. Predicting the cycles spent for the delamination initiation and propagation;
iv. Predicting the cycles spent for the failure of the fibers and the final laminate failure.

For each mechanism (mainly off-axis cracks and delamination), the associated stiffness reduction must be predicted as well.

According to this strategy, a procedure for predicting the damage evolution in composite laminates has been developed by the authors, integrating the following predictive models and criteria:

1) A criterion for predicting the off-axis fatigue crack initiation under multiaxial stress states [8];
2) A mixed mode crack propagation criterion [11];
3) A model for predicting the crack density evolution under a generic multiaxial loading, also under variable amplitude conditions [12];
4) A fracture mechanics-based model for predicting the delamination growth, in combination with multiple crack initiation and propagation [13];
5) An analytical model for describing the stress re-distributions and the stiffness degradation in the presence of off-axis cracks and delamination [14];
6) A model for predicting the load bearing fiber failure, accounting for the stress concentrations caused by off-axis cracks and delamination [15].

The entire framework was validated by means of experimental data, revealing a very good agreement both in terms of damage evolution and stiffness loss. Some examples are reported in Figures 4 -6.

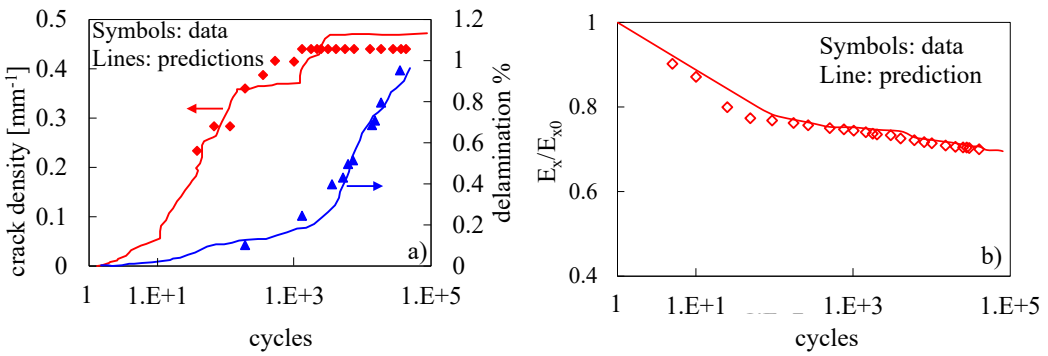

Fig. 5. Validation of the procedure in terms of a) crack density and delaminated area ratio and b) stiffness loss for a $[0/90_2]_s$ laminate

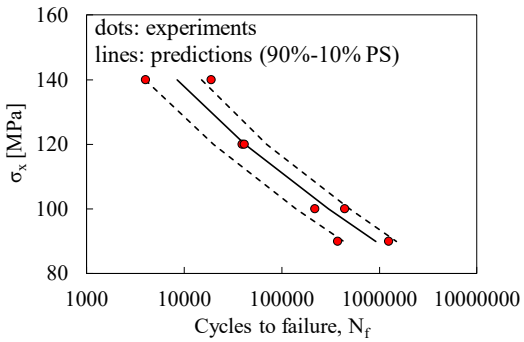

Fig. 6. Prediction of the fatigue life of $[0_2/90_4]_s$ laminates through the complete modelling framework

4 APPLICATION TO NOTCHED LAMINATES

The normal text should be written single-spaced, justified, using 11pt Times in one column. The first line of each paragraph must be indented 0.5cm..

The results shown so far were related to plain laminates, subjected to a uniform stress state. With the aim of using this strategy in the case of components with complicated geometry and loading conditions, all the developed models were implemented into a software tool (named RESCOMP – FLA) to be coupled with commercial Finite Element (FE) codes. The fatigue life can be simulated through a cycle jump approach. At each step, a linear-elastic FE analysis is carried out using layered shell elements. The results, in terms of element loads, are exported into the tool that analytically predicts the initiation and growth of damage events, as well as the element apparent elastic properties. These are then returned to the FE code as a starting point for the next cycle step. In this way it is possible to predict the damage evolution in components of any shape, that require the use of FE analyses for the assessment of the macro-scale stress distribution. At the same time the simulation is kept efficient as the discrete damage events are not physically present in the FE model, but only in a parallel database where the position of each damage mechanism is stored. As an example of applica-tion, the case of an open-hole cyclic test was is considered. Tension-tension fatigue tests were conducted on $[0/90]_s$ and $[0/45_2/0/-45_2]_s$ glass/epoxy specimens in plain and notched configurations. The notched specimens were 40 mm wide, with a 8 mm and 16 mm diameter circular central hole. For both specimen types, the progression of damage throughout the fatigue life was monitored through periodic imaging and quantified based on crack initiation and crack density evolution. As expected, cracks predominantly originated along the notch flanks, with stress concentrations playing a crucial role in the damage process. Through the tests on plain specimens, fatigue crack initiation and propagation parameters were obtained and later used to predict the damage evolution in the notched laminates, through the analytical discrete dam-age approach. As an example, the damage evolution in a cross-ply laminate with a 8 mm central hole, as predicted by the tool and obtained from tests, is shown in Figure 7, showing a good agreement.

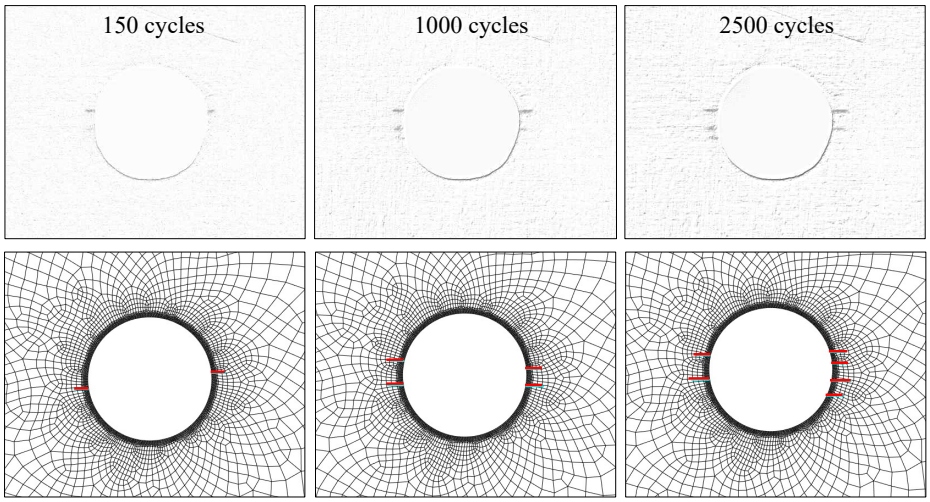

Fig. 7. Prediction of the fatigue life of $[0_2/90_4]_s$ laminates through the complete modelling framework

5 CONCLUSIONS

For an advanced and optimized design against fatigue of composite structures, tools to predict the onset and evolution of damage are required. In this work, a damage-based multiscale strategy was presented to predict the crack density evolution, the delamination growth and the associated stiffness loss in multidirectional laminates under cyclic loadings. To complete the framework and estimating the cycles to failure, a model to predict the failure of the load bearing plies has been also included.

The approach accounts for the interaction between different mechanisms. Criteria for the formation and growth of damage events were defined based on experimental observations at different length scales. The entire discrete damage approach was implemented into a software tool that the authors hope could be of help for improving the safety, the performance and the cost-efficiency of composite structures under cyclic loadings.

INVESTIGATION OF PARTICLE SIZE EFFECT ON THE FRACTURE TOUGHNESS OF POLYMER/GRAPHENE NANOCOMPOSITES AND CFRP DUE TO CRACK TIP SHIELDING

Sara Amirahmadi, Sankha Aditya, and Samit Roy

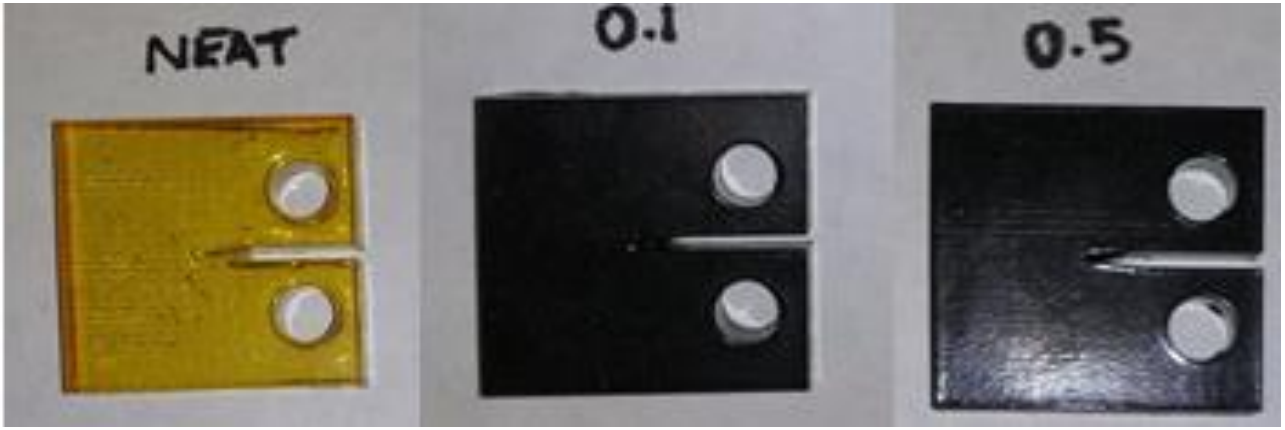
Department of Aerospace Engineering and Engineering Mechanics
University of Alabama, Tuscaloosa , USA

Keynote Talk Presented at the ICCM-24
Baltimore, Maryland
August 4, 2025

Motivation and Outline

Question: Why does the addition of stiff nanoparticles improve fracture toughness in brittle polymers with less than 1 wt% of nanofillers? Why is there a strong particle size effect ?

Research Objective: To develop an experimental/analytical approach to answer these fundamental questions to enhance optimal toughness and fatigue life of composite structures



Outline of Presentation:

- Macroscale Mode I fracture toughness test data for EPON 862 epoxy to investigate toughening effect and size effect due to graphene nanoplatelets (GNP/GOs)
- Development of a fundamental physics-based model to explain the toughening mechanism and GNP size effects at the microscale to predict macroscale toughness increase in polymers

Macro-scale Fracture Experiments to Investigate Crack Shielding Effect

Macro Scale Fracture Experiments

- Compact tension (CT) specimens were manufactured with three different graphene nanoplatelet sizes (median size 0.2, 2, and 5 microns) for 0.1,0.3, 0.5 and 0.7 wt% in epoxy, respectively
- High shear mixing and sonication were used to ensure good dispersion of GNP in EPON 862 epoxy
- At least five replicate 3 × 3 ×0.635 cm CT specimens were molded according to ASTM D5045-99 standard procedure*

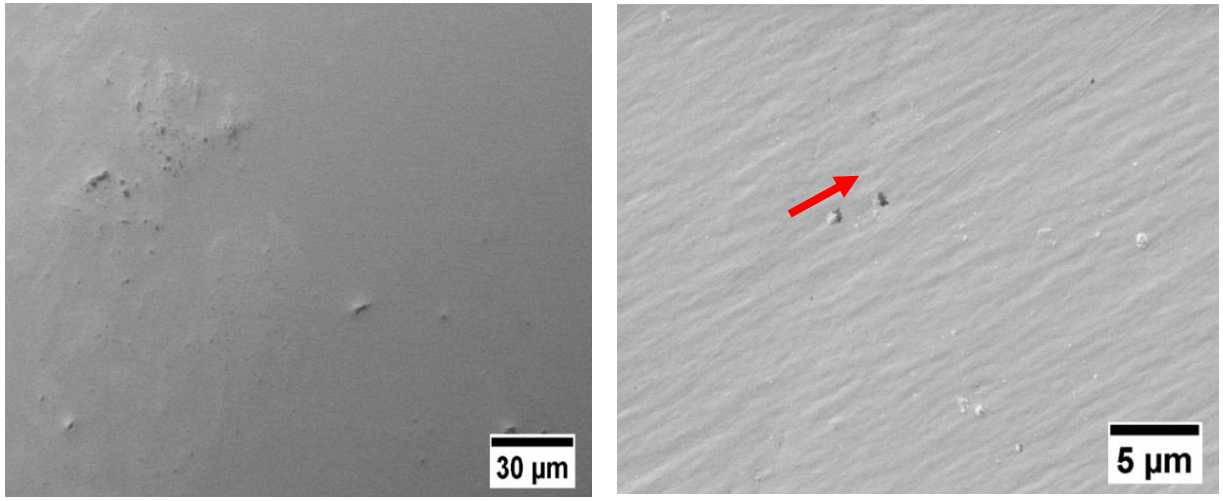
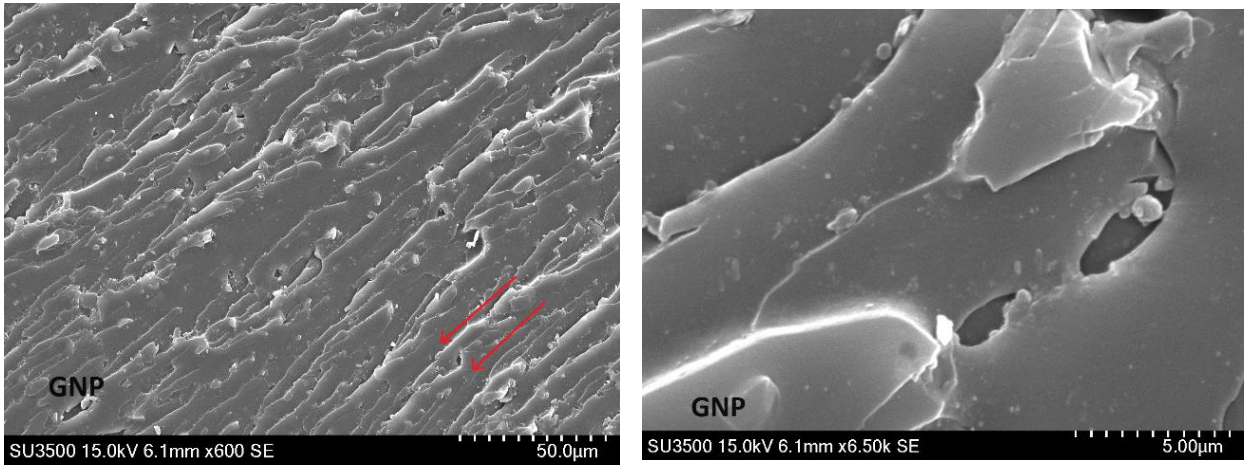
GNP Size effect in Mode I Fracture Behavior



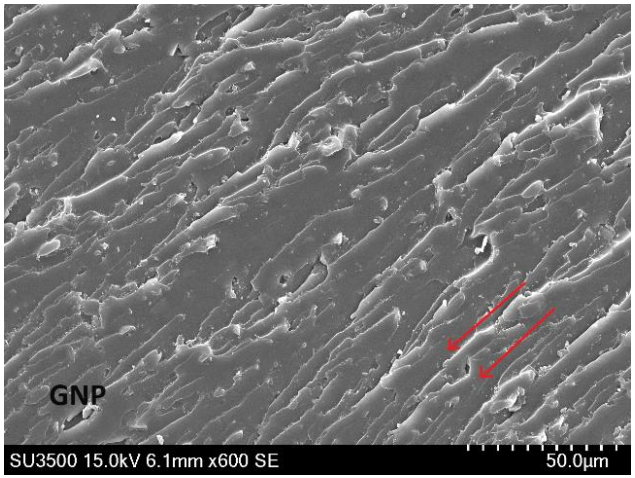
Comparison of GNP size effect on Fracture Toughness Comparison of GNP size effect on Fracture Energy

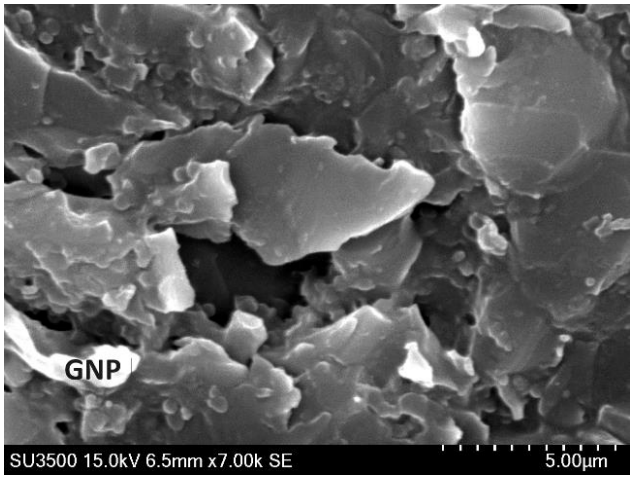


- 227 % increase in peak toughness, and 600 % increase in peak fracture energy for 0.2 micron GO @ 0.3 wt% , in comparison with baseline epoxy (0 wt%) is observed*
- Degradation in toughness enhancement due to particle agglomeration occurs earlier for 0.2 micron GO than for 2 and 5 micron GNP cases.

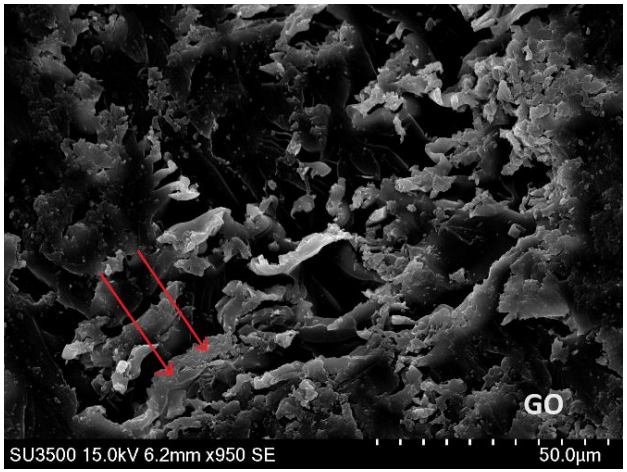
*Ref: Amirahmadi et al., *Composite Structures* 347 (2024) 118420.

SEM of Fracture Surface Morphology

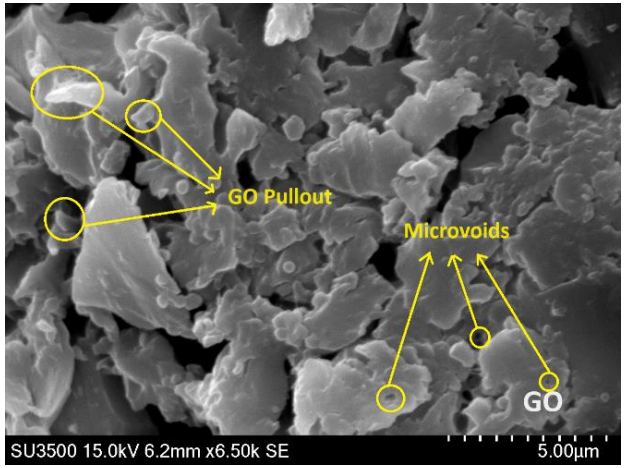




Fracture surface of baseline specimen (only epoxy resin) at (a) 500x and (b) 5000x magnification

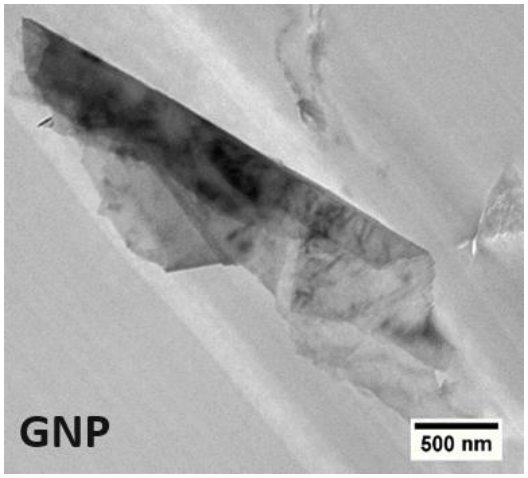


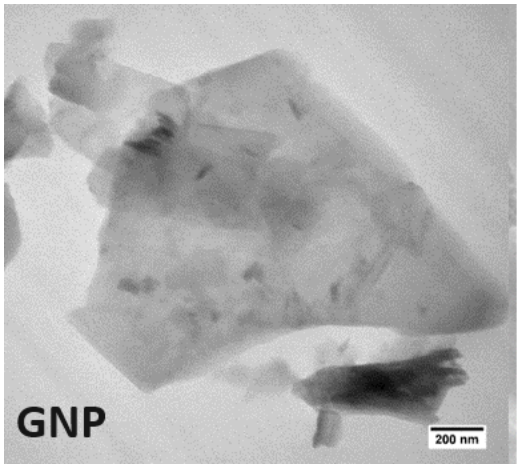
Fracture surface of 0.3 wt.% 5 µm size graphene reinforced epoxy composites

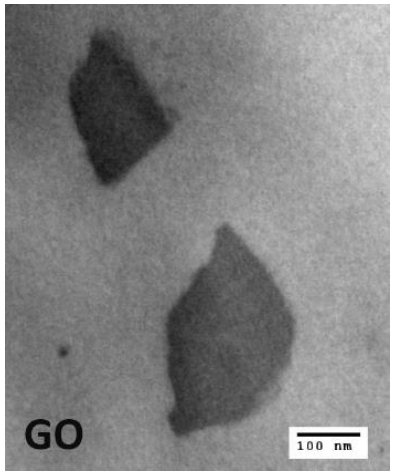


SEM of Fracture Surface Morphology

Fracture surface of 0.3 wt.% 2 µm size graphene reinforced epoxy composites



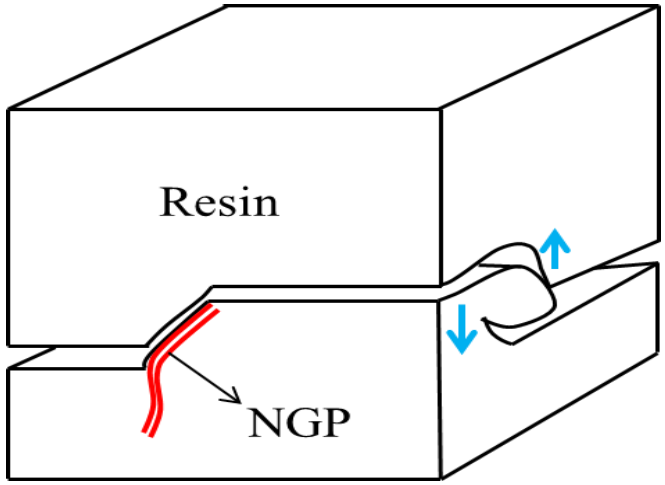




Fracture surface of 0.3 wt.% 0.2 µm size graphene reinforced epoxy composites

The 0.2 µm GO reinforced samples has a rougher morphology as compared with the baseline samples indicating **extensive damage** in FPZ at **crack initiation**, and crack deflection during **crack propagation**

TEM Imaging for GNP Dispersion



TEM images of dispersed nanographene platelets and graphene oxide in epoxy:
(a) 5 µm GNP at 0.3 wt%, (b) 2 µm GNP at 0.3 wt% , and (c) 0.2 µm GO at 0.3 wt%

Good level of exfoliation and dispersion are observed

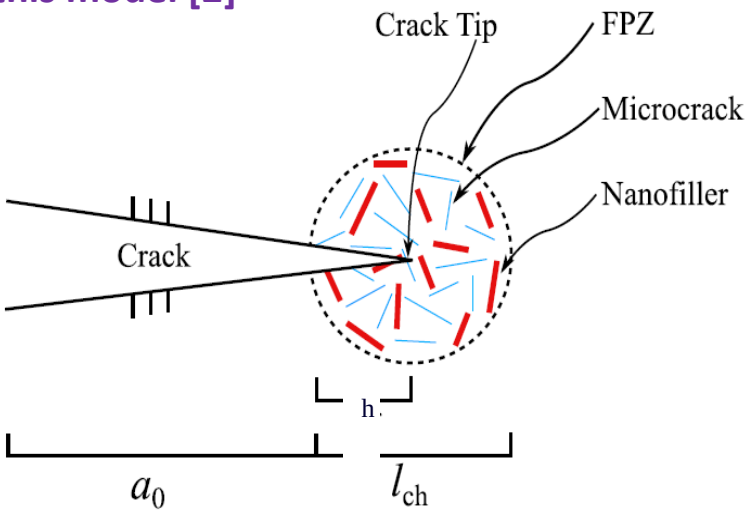
Modeling of Particle Size Effect on Crack Initiation Toughness using Mechanism Based Approach

Conventional Modeling of Toughening Mechanism Polymer Nanocomposite with Dispersed Graphene Nanoplatelets (GNP)*

1. The macroscale crack impinges on nanographene platelet and deflects
2. After deflection, the fracture process zone (FPZ) consists of cracks at two levels
3. The two cracks coalesce through a shear failure mechanism in the process zone

- This explanation may be applicable during crack growth but not during crack initiation as it assumes a running crack, because deflection/coalescence can occur only after crack growth.
- The effect of platelet size is not included in this explanation, as larger GNP size should give rise to higher toughness

*Chandrasekaran, S., Sato, N., Tölle, F., Mülhaupt, R., Fiedler, B., and Schulte, K. "Fracture toughness and failure mechanism of graphene based epoxy composites," Composites Science and Technology, Vol. 97, 2014, pp. 90-99.



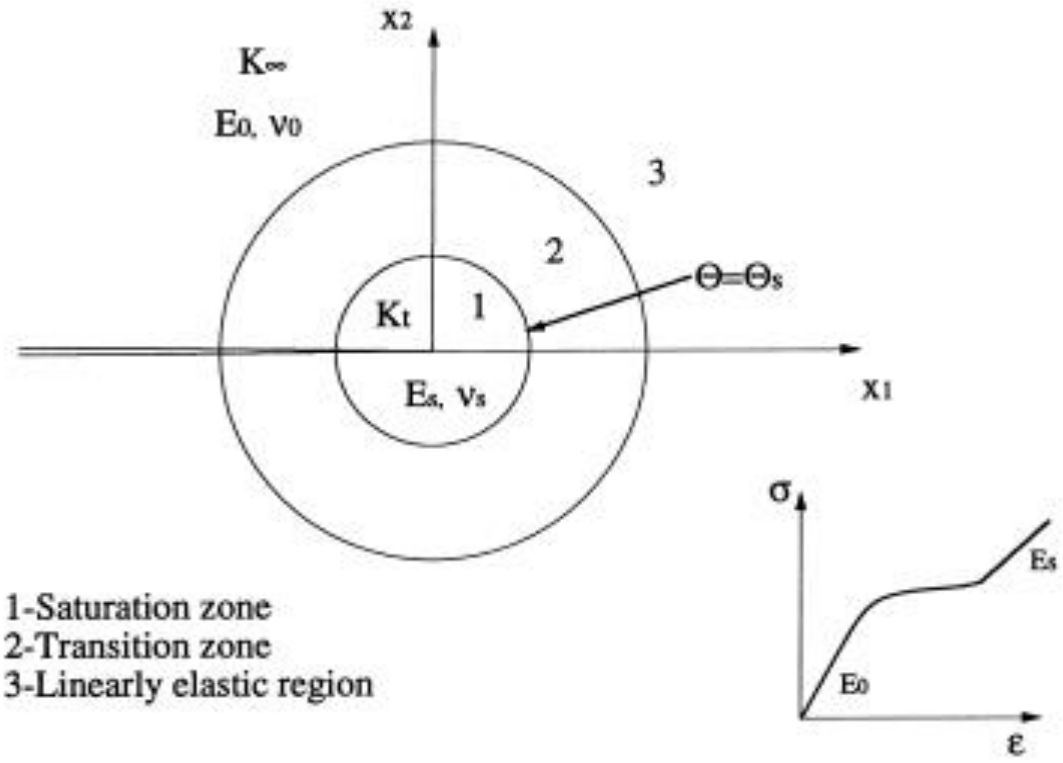
A New Approach to Initiation Toughness Modeling in Nanocomposites

- **Addition of nanoparticles transforms a brittle epoxy into a quasi-brittle material by inducing damage in the Fracture Process Zone (FPZ) near the crack-tip[1]. This results in two mechanisms:**

(a) Crack-tip shielding due to the reduction in local modulus caused by debonding (+ve effect)

(b) Micro-damage could decrease local initiation toughness near the crack tip (-ve effect)

- **These two competing effects determine overall initiation fracture toughness of the nanocomposite in this model [2]**



Fracture Process Zone (FPZ) with micro-damage for thermoset polymer with randomly dispersed graphene nanoplatelets (GNP)[1].

[2] G. Ravichandran, and C.T. Liu, Crack Tip Shielding in Elastic Particulate Composites undergoing Damage, Engineering Fracture Mechanics Vol. 59, No. 6, pp. 713-723, 1998.

Partitioning of Far-field Stress Intensity as a Product of Crack-tip Shielding and Local Toughness Change Near the Crack tip in Epoxy

From path independence of $J-$ integral [*], $J_{NCtip} = J_{N.C_{FF}}$

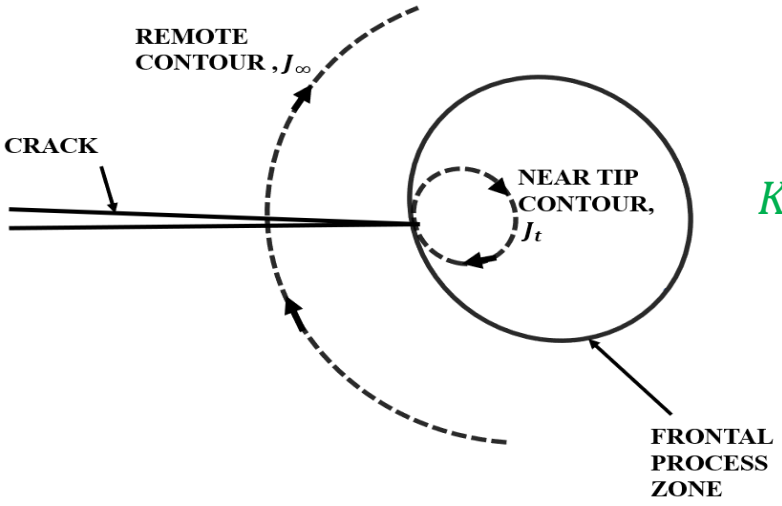
*J.R. Rice, Journal of Applied Mechanics1968

But for plane stress, $J = \frac{K^2}{E}$

$$\frac{K_{NCtip}^2}{E_{NCtip}} = \frac{K_{N.C.FF.}^2}{E_{N.C.FF}}$$

In general , $K_{N.C.FF} = K_{NCtip}\sqrt{\frac{E_{N.C.FF}}{E_{NCtip}}}$

At fracture, $K_{IC,N.C.FF} = K_{IC,NCtip}\sqrt{\frac{E_{N.C.FF}}{E_{NCtip}}}$



- The second factor on the R.H.S., $\sqrt{\frac{E_{NCFF}}{E_{NCtip}}}$, denotes the crack-tip shielding contribution
- The first factor on the R.H.S., $K_{IC,NCtip}$, is the actual local toughness at the tip of the macroscale crack in the presence of microcracks induced by nanofillers in the FPZ, and is a measure of the local toughness change due to micro-damage caused by the nanofillers
- These two competing effects determine overall far-field toughness of nanocomposite!

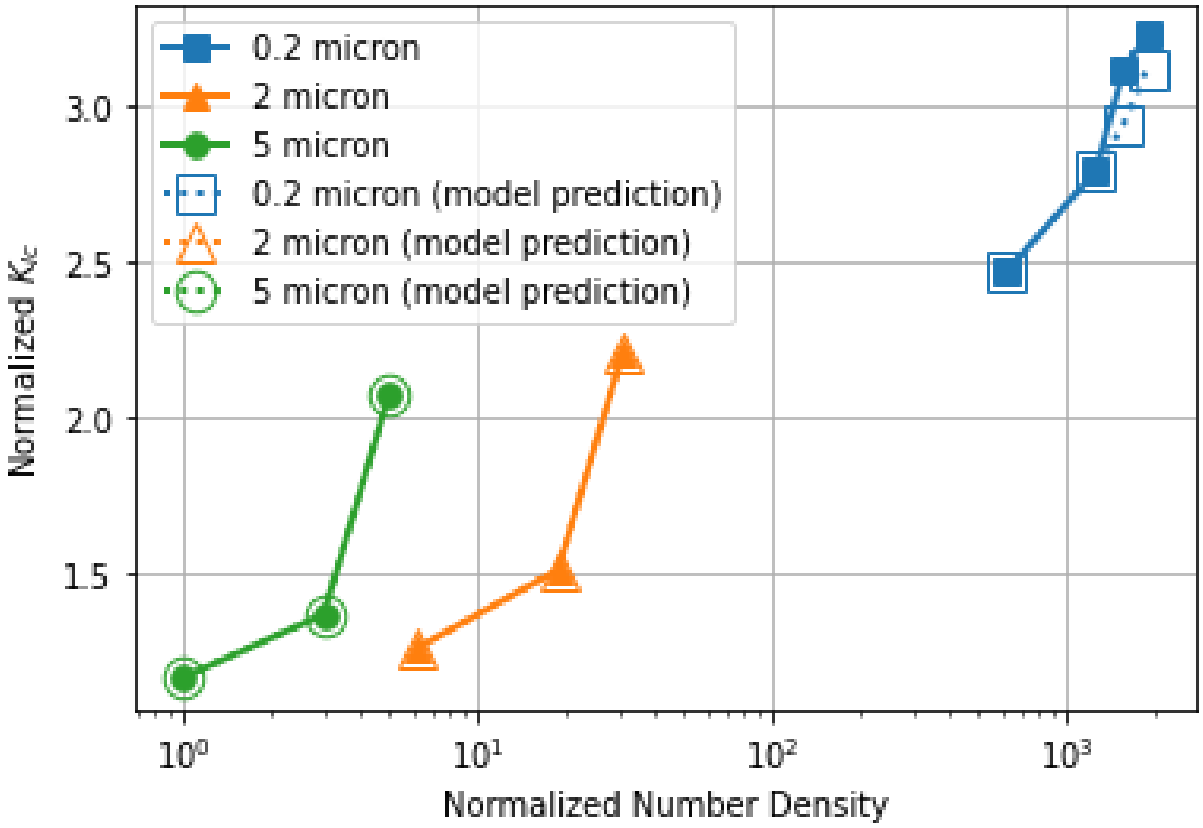
Model Development for Crack-tip Shielding and Local Toughness Change in Epoxy

$$K_{IC,N.C.FF} = K_{IC,NCtip}\sqrt{\frac{E_{N.C.FF}}{E_{NCtip}}}$$

$$E_{NCtip} = E_{epoxy}(K_{ICM}^2/K_{ICN.C.FF}^2) = E_{epoxy}(1-\beta n^q)$$

Where, K_{ICM} is the epoxy toughness, E_{epoxy} =1.68 GPa is the elastic modulus of the undamaged epoxy matrix without GNP, β (VfGNP) and *q* are power-law parameters, and *n* is the number density of GNP particles

Assuming, $K_{IC,NCtip} = K_{IC_M}(1\text{-}V_{fGNP})$



$$K_{IC_{N.C.FF}} = K_{IC_M}(1\text{-}V_{fGNP})\sqrt{\frac{E_{N.C.FF}}{E_{poxy}(1-\beta n^q)}}$$

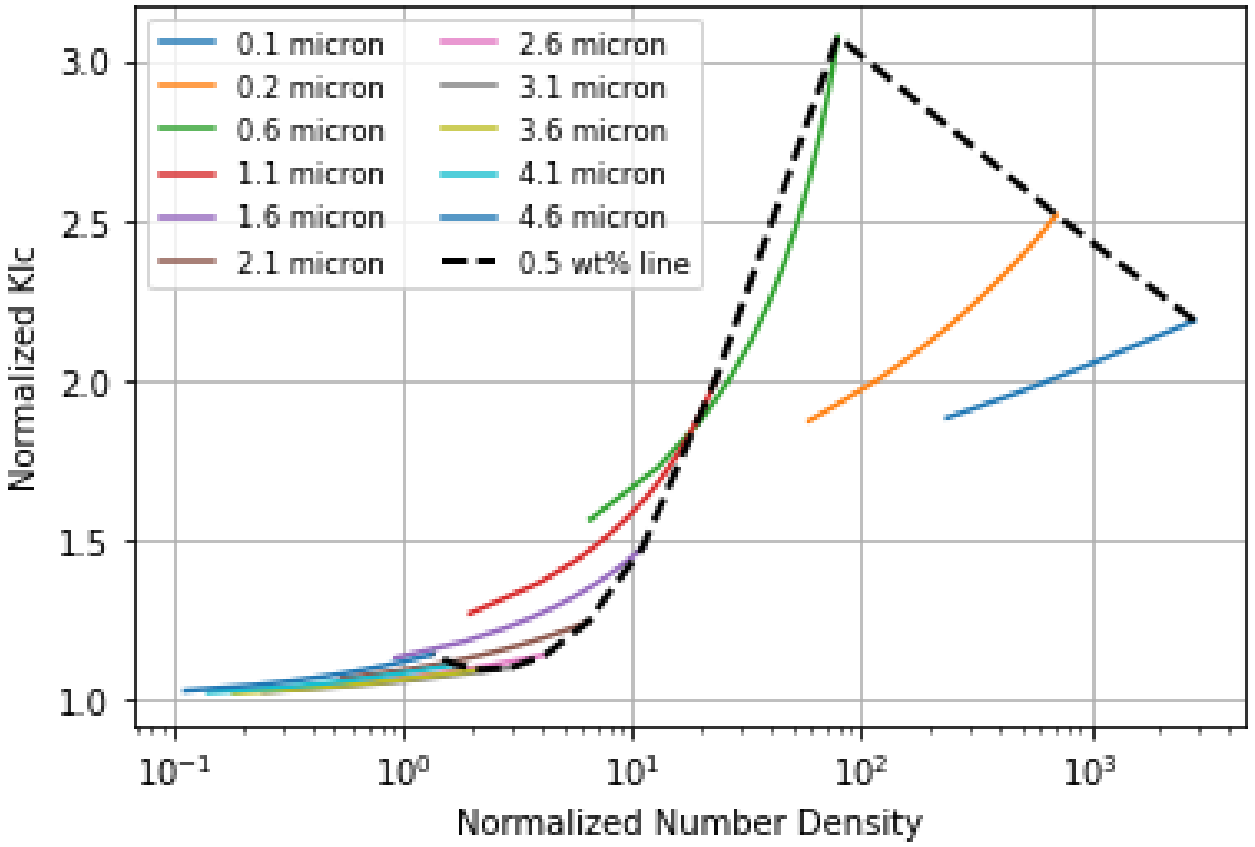
$$= K_{IC_M}(1\text{-}V_{fGNP})\frac{1}{\sqrt{\frac{E_{epoxy}}{E_{N.C.FF}}\left[1-\beta\left(\frac{V_{fGNP}}{{l_p}^2 t_p}\right)^q\right]}}$$

Where, l_p is the median particle size, and t_p is the median particle thickness.

MODEL PREDICTIONS

Comparison of Model Toughness Prediction for CT Specimens at RT

- Good agreement is observed between model prediction and actual CT test data
- The smaller the particle size greater is the toughness increase due to shielding effect
- Predicts 227 % **maximum** toughness increase with 0.2 micron GNP at 0.3 wt%
- The model is able to capture the peak increase in toughness before degradation due to agglomeration can set in. This enables unique prediction of optimum toughness!



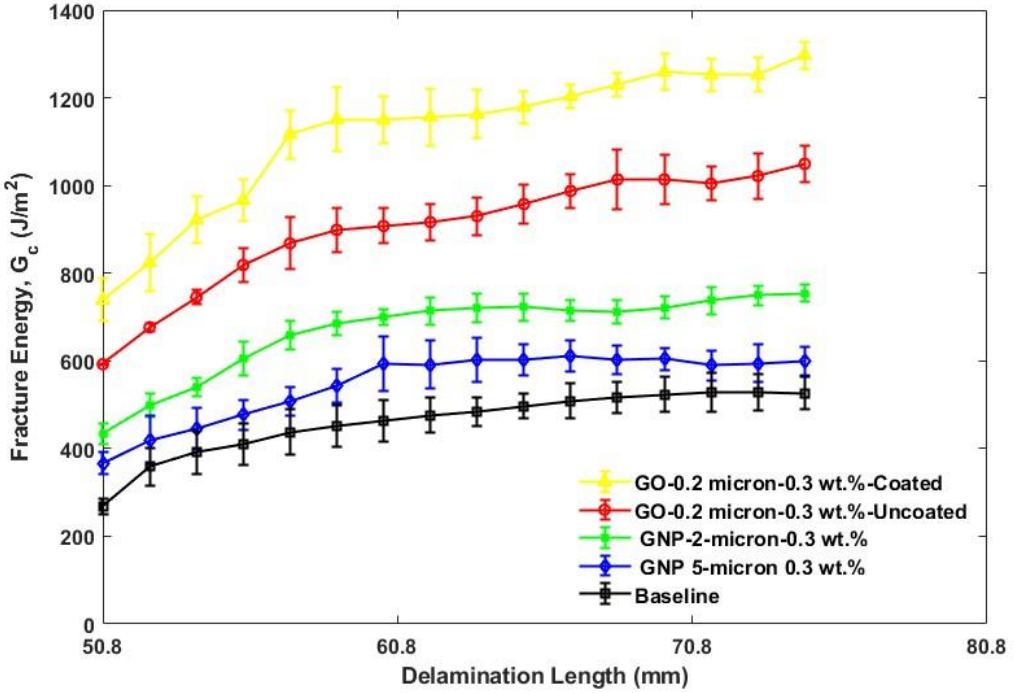
Comparison of Model Toughness Prediction for CT Specimens at RT

Comparison with Test Data from Shirodkar et al.* for GNP/Epon862 Nanocomposite

Specimen	K_{Ic} (MPa.m$^{0.5}$)	Normalized K_{IC}	Model Prediction	Percentage Difference
Baseline epoxy	0.75	1.0	1.0	0
0.1 wt % 5 µm GNP in epoxy	1.1	1.4667	1.1667	-20.5
0.5 wt % 5 µm GNP in epoxy	1.58	2.1067	2.0714	-1.7

*Ref: Shirodkar N, Cheng S, Seidel GD. Enhancement of Mode I fracture toughness properties of epoxy reinforced with graphene nanoplatelets and carbon nanotubes. Composites B Eng 2021;224. https://doi.org/10.1016/j.compositesb.2021.109177.

Optimum Model Predictions Including Cut-Off Due to Agglomeration

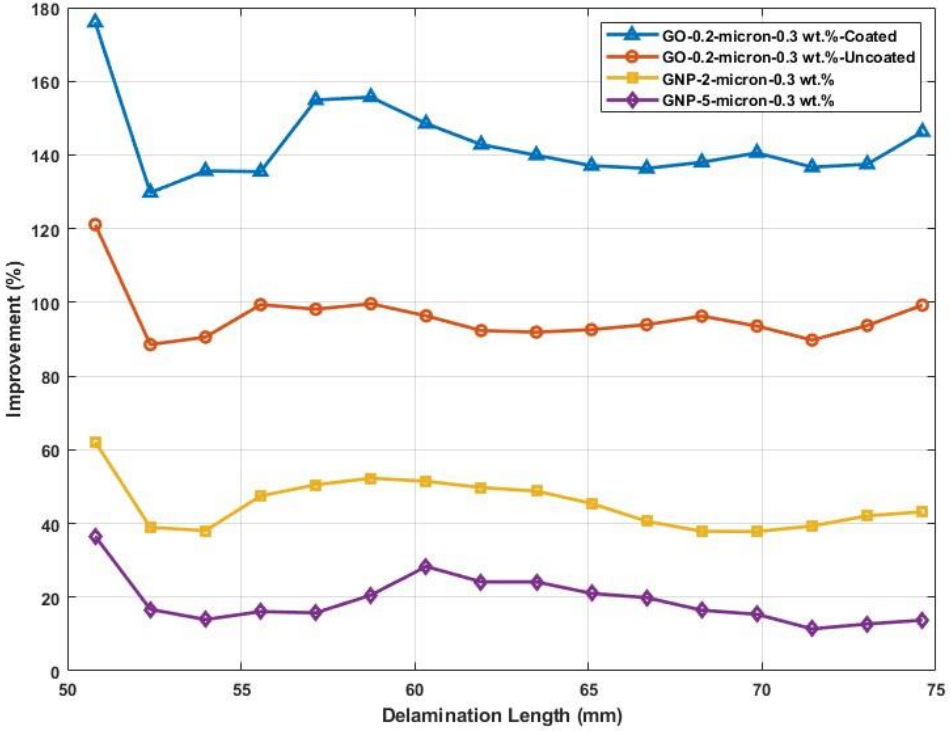


- **Using only 10 data points for model calibration, the model can predict optimum GNP size and number density required for maximum toughness enhancement**

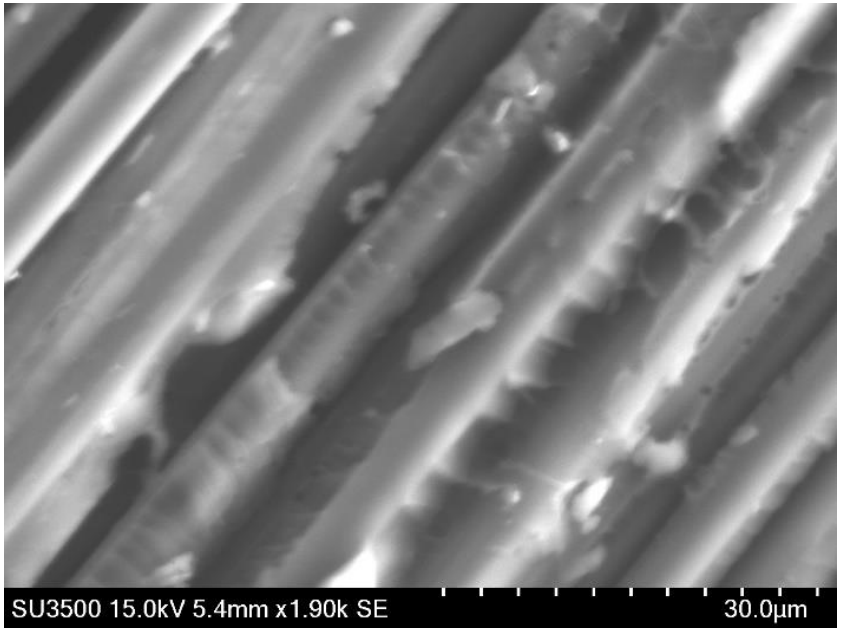
- **Predicts** 310 % **maximum** toughness increase with 0.6 micron GNP size at 0.32 wt%

GNP SIZE EFFECT IN DELAMINATION TOUGHNESS ENHANCEMENT FOR CARBON COMPOSITE

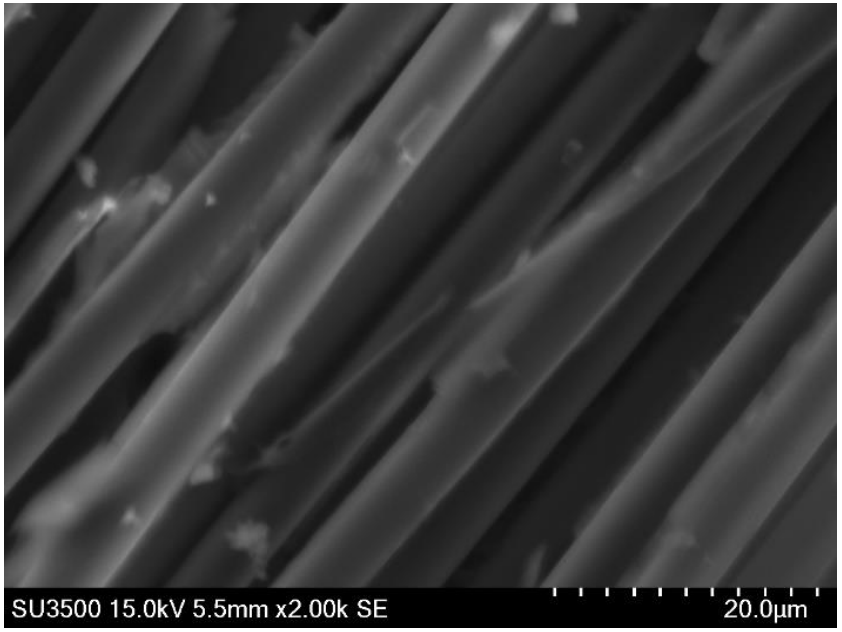
Double Cantilever Beam (DCB) Test for Measuring Mode I Delamination Toughness *



- Unidirectional IM7/EPON-862 laminates tested as per ASTM D5528 clearly indicate particle size effect as shown in the chart ; coating carbon fabric enhances toughness
- The enhancement in fracture energy is lower for the carbon composite as the toughened matrix causes the crack to partly propagate along the fiber-matrix interface



Double Cantilever Beam (DCB) Results for Mode I Delamination Toughness



- Unidirectional IM7/EPON-862 laminates tested indicate particle size effect as shown in the chart with up to 180 % improvement over baseline case at initiation
- The enhancement in fracture energy is slightly lower for the carbon composite as the toughened matrix causes the crack to propagate along the fiber-matrix interface

SEM IMAGES OF DCB FRACTURE SURFACE FOR BASELINE CASE AND 0.2 Micron GO AT 0.3 wt%

Baseline Laminate

Laminate with 0.2 micron GO at 0.3 wt%

SEM images show evidence of cohesive fracture in the polymer in the case of baseline laminate (without GNP) but crack propagates along the fiber-matrix interface for GO case

- Toughening of fiber-matrix interface in addition to matrix toughening will therefore improve overall composite delamination toughness

Summary and Conclusions

- This paper presents clear evidence of the influence of GNP size on fracture toughness and CSERR in GNP/EPON862 as well as IM7/EPON862/GNP composite

- Our test data reveals a 227% peak enhancement (that is, 3.23 times improvement from the baseline value) in mode I fracture toughness (K_{IC}) and 587% peak enhancement in Gic over the baseline epoxy for specimens with 0.2 µm GO at 0.3 wt.% , likely due to crack tip shielding.

- The enhancement in Gic for the DCB specimens show similar size effect, although the degree of toughness enhancement was lower (~180%) due to debond failure

- Fracture toughness enhancement is observed to decrease with higher wt % of GNP

- An analytical model based on crack-tip shielding due to number density of GNP particles was developed and verified with test data (A patent was filed in 2023).

- Our future work will attempt to study these mechanisms in detail using in-situ AFM and/or SEM which will be used in conjunction with 2-D digital image correlation (DIC) to obtain local in-plane strain maps to provide a clearer understanding of crack shielding mechanisms in the fracture process zone, and crack propagation

Keywords: Carbon fiber; Carbon nanotubes; Interface/interphase; Chemical Vapor Deposition (CVD); sustainable materials, lignin-derived carbon

Nanostructured materials offer the possibility to improve the performance and functionality of existing structural fibres. There are broadly two strategies (Figure 1): One involves the incorporation of the nanomaterial into existing state of the art fibres, in order to address critical weaknesses and/or introduce new functions. Examples of this first approach include the development of nanostructured interphases on existing carbon and glass fibres. Here, the nanomaterial improves load transfer between the fibre and the matrix and reduce stress concentration. Surface grafting of carbon nanotubes (CNTs) by direct CVD provides a hierarchical fibre with two differing reinforcement length scales. The advantages of this approach are well known, but typically limited by damage to the substrate fibres, and difficulties with scale-up. Informed by flow modelling and "dynamic snapshots", we have developed a continuous spool-to-spool process that produces controlled, uniform grafting throughout the tow. The products show excellent single fibre and small composite performance in thermosets[1] and thermoplastics[2], and are relevant to multifunctional applications such as structural heath monitoring[3].

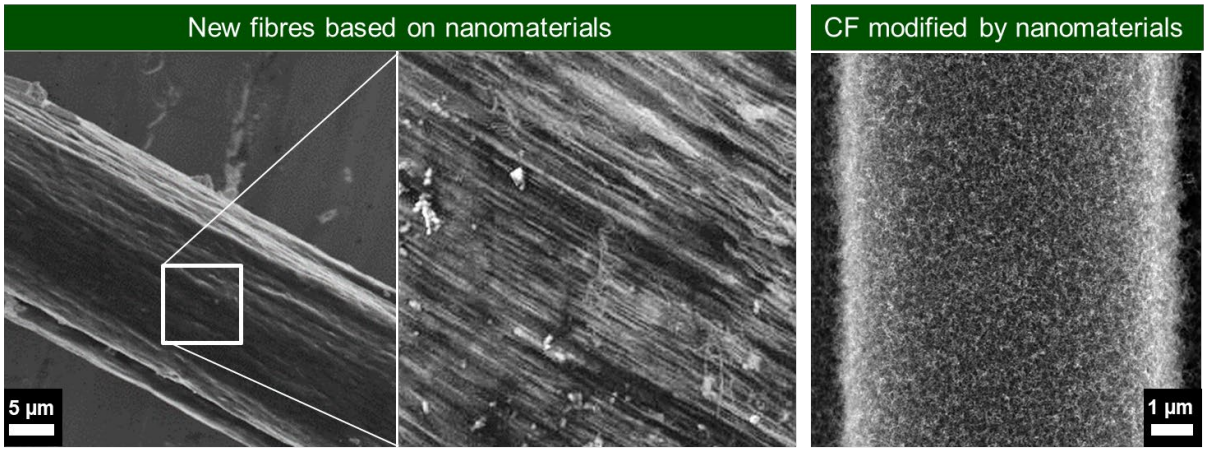

Figure 1: Schematic showing two alternative strategies for exploiting nanostructures in fibres : a) spinning new fibre systems based on 1D nanomaterial precursors (left, showing a single-wall carbon nanotube based fibre)[4] or b) modifying of an existing state of the art structural fibre with a nanomaterial enhancement (right, showing a PAN-based carbon fibre grafted with carbon nanotubes to reinforce its interphase.[2]

The second approach, which is more challenging but potentially more transformative, relies on the development of entirely new fibre systems from the nanostructured or nanocomposite constituents; however, new processes to assemble and orient the constituent nanostructures. One dimensional nanomaterials are particularly well suitable to unidirectional alignment in fibre formats. A wide range

of building blocks are possible, including nanotubes, nanorods, and nanowires, based on carbons, inorganic compounds, synthetic proteins, and biologically derived constituents; a variety of these options are explored here (Figure 2). In particular, individual perfect nanocarbon structures have exceptional properties; the challenge is often how to exploit their potential in real macroscopic systems. Whilst dry spinning approaches may be attractive, wet spinning is more obviously scalable and applicable. However, the formation of individualized solutions of functionalised single wall nanotubes (SWNTs) and graphenes is challenging. We exploit reductive charging to form pure nanotubides (nanotube anions) which can be redissolved, purified, or optionally functionalised, whist avoiding the damage typically associated with sonication and oxidation-based processing.[5] Nanotubide solutions form nematic phases which can be spun directly into coagulant baths in order to prepare functionalised SWCNT fibres in situ. Grafting of suitable polymer constituents can increase dispersibility of both nanotubes and graphenes and hence help to produce nanocomposite fibres with higher strength and strain to failure, [4] as well as multifunctional performance as supercapacitors. Non-carbon-based analogues of nanotubes offer different functions. For example, composite fibres containing inorganic (imogolite) nanotubes can generate healable structural fibres, with exceptionally high performance. [6] Imogolite nanotube dispersions also form liquid crystalline mesophases and it is possible to spin pure imogolite fibres, analogously to the carbon nanotube examples.[7] The imogolite system has the advantage of water compatibility and the opportunity for in situ process monitoring through optical birefringence and x-ray studies.[8]

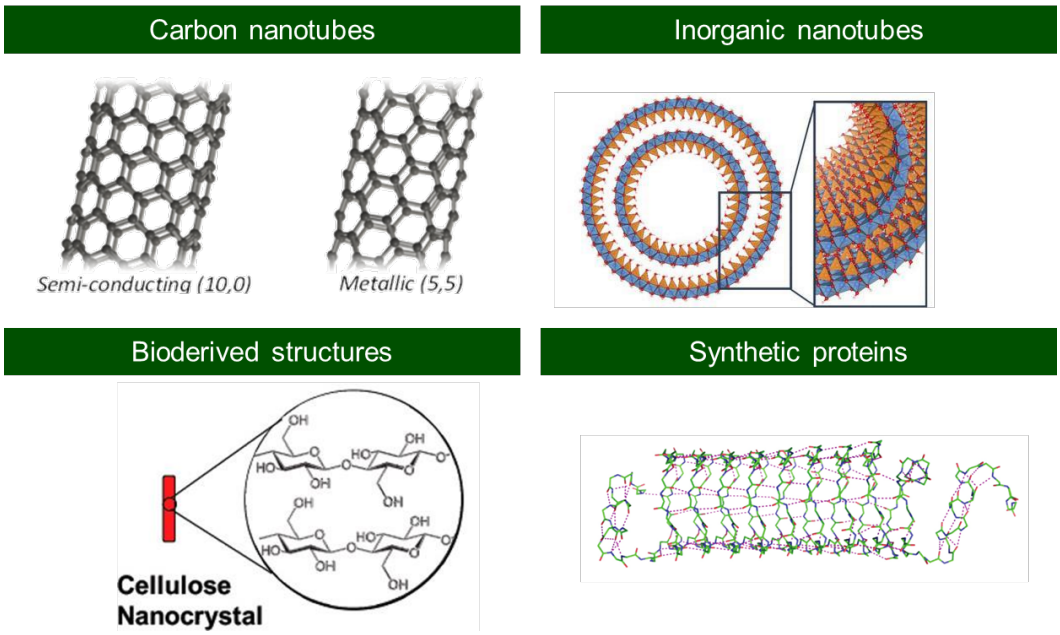

Figure 2: Schematic showing possible one dimensional nanomaterial building blocks for fibres

More sustainable fibre systems can be pursued by spinning bioderived nanomaterials, or by using nanomaterials to allow the spinning of lignin-based materials, for conversion into carbon fibre. Lignin-derived carbon fibers (CFs) are an attractive target for low-cost sustainable composite applications. Our lignin-based fibers are wet-spun using a low-cost (<$1/kg) ionic liquid, N,N – dimethylbutylammonium hydrogen sulfate ([DMBA][HSO_4]) as the dope solvent and water as the coagulation bath.[9] If the lignin is extracted from the biomass using an ionosolv approach based on the same low cost ionic liquid, it can be used directly as the feedstock for the wet-spinning process. This latter approach removes several process steps, including the need to dry the lignin powder during its isolation. An initial life cycle analysis (LCA) indicates that this new ionosolv approach offers significant scope to reduce the cost and global warming potential of lignin fibre production.[10] Very low loadings of CNTs can be used as the spinning aid for this ionosolv process, yielding fibers containing up to 96% lignin solid fraction. The presence of CNTs increases the estimated carbon fiber yield from ~40% to 54%, a critical factor for

technoeconomic outlook of lignin-based carbon fibers. In addition to enabling fiber spinning and increasing carbon yield, the CNTs may also act as graphitization templates and provide direct reinforcement of the lignin-derived carbon matrix, improving mechanical performance. Although the fibres do not yet match the strength or stiffness of state-of-the-art PAN-based carbon fibres, they may nevertheless be optimized to offer useful performance across a wide range of sectors from automotive to construction. In principle, CNTs can be bioderived, offering a fossil free route to low cost carbon fibers using only renewable carbon sources.

CONCLUSIONS

One dimensional nanomaterials are well suited to incorporation in fibre systems, both forming new types of pure fibre or in composite form. The aspect ratio and dimensionality are compatible with a high degree of alignment and efficient packing in the spun fibres, but also often generate lyotropic liquid crystal phases that play an important role in processing. Wet-coagulation spinning can exploit these phases and is readily scalable via established routes, from lab scale batches, through lab scale continuous monofilament, multifilament, and upwards towards pilot scale. Nanomaterials often offer excellent mechanical properties due to their high perfect and confined defect sizes but can also introduce a wide variety of functional benefits, including electrochemical energy storage and self-healing.

As specific examples, pure and composite carbon and imogolite nanotube fibres show promise as ductile and multifunctional reinforcements. Carbon nanotube fibres are conductive, loading-bearing, and with high electrochemical capacitance, relevant to structural supercapacitors Imogolite provides an analogous structure to CNTs that is easier to manipulate and study by POM & XRD, providing in situ insight into processing steps and other phenomenology that can be applied across the nanomaterial fibre domain.

Biomaterials provide routes to “green” carbon fibres and consumer textiles New types of lignin-derived carbon fibres, processed using water & IL only, are particularly promising for their potential low cost and reduced environmental impact. The introduction of carbon nanotubes, combined with new lignins, can improve graphitisability, yield, and performance.

While these new nanomaterials-based fibres offer great promise for the future, their commercial implementation will require time and investment. Meanwhile, nanomaterials can already be used to improve the performance existing state of the art structure fibres. For example, CNT-grafted fibres offer improved structural properties, improving interfacial strength and composite compression performance, whilst offering multifunctional opportunities for enhanced conductivity and self-sensing. A new process allows continuous uniform growth throughout a 12k fibre tow, allowing potential integration directly into existing carbon fibre production.[11]

Keywords: Carbon fiber; Carbon nanotubes; Interface/interphase; Chemical Vapor Deposition (CVD); sustainable materials, lignin-derived carbon

Nanostructured materials offer the possibility to improve the performance and functionality of existing structural fibres. There are broadly two strategies (Figure 1): One involves the incorporation of the nanomaterial into existing state of the art fibres, in order to address critical weaknesses and/or introduce new functions. Examples of this first approach include the development of nanostructured interphases on existing carbon and glass fibres. Here, the nanomaterial improves load transfer between the fibre and the matrix and reduce stress concentration. Surface grafting of carbon nanotubes (CNTs) by direct CVD provides a hierarchical fibre with two differing reinforcement length scales. The advantages of this approach are well known, but typically limited by damage to the substrate fibres, and difficulties with scale-up. Informed by flow modelling and "dynamic snapshots", we have developed a continuous spool-to-spool process that produces controlled, uniform grafting throughout the tow. The products show excellent single fibre and small composite performance in thermosets[1] and thermoplastics[2], and are relevant to multifunctional applications such as structural heath monitoring[3].

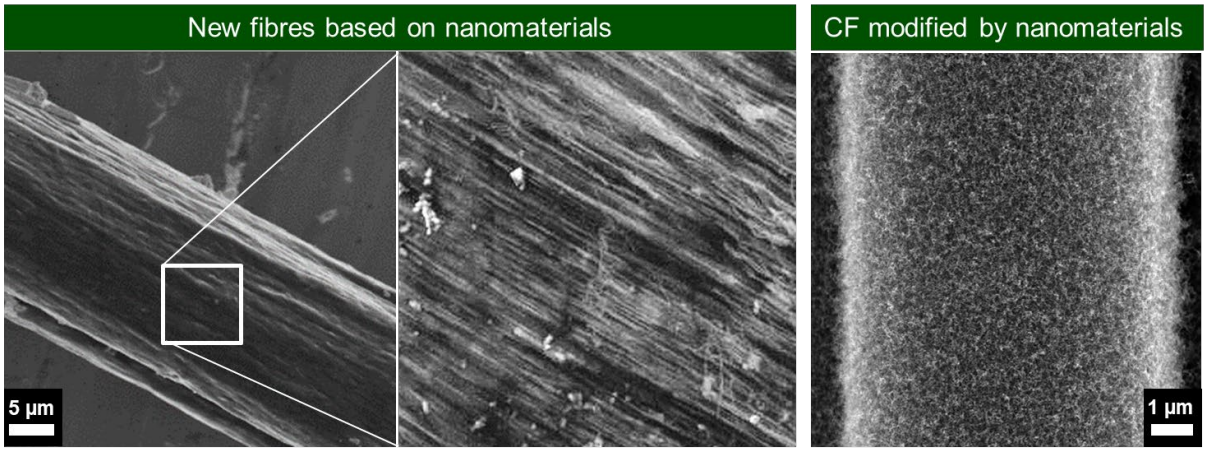

Figure 1: Schematic showing two alternative strategies for exploiting nanostructures in fibres : a) spinning new fibre systems based on 1D nanomaterial precursors (left, showing a single-wall carbon nanotube based fibre)[4] or b) modifying of an existing state of the art structural fibre with a nanomaterial enhancement (right, showing a PAN-based carbon fibre grafted with carbon nanotubes to reinforce its interphase.[2]

The second approach, which is more challenging but potentially more transformative, relies on the development of entirely new fibre systems from the nanostructured or nanocomposite constituents; however, new processes to assemble and orient the constituent nanostructures. One dimensional nanomaterials are particularly well suitable to unidirectional alignment in fibre formats. A wide range

of building blocks are possible, including nanotubes, nanorods, and nanowires, based on carbons, inorganic compounds, synthetic proteins, and biologically derived constituents; a variety of these options are explored here (Figure 2). In particular, individual perfect nanocarbon structures have exceptional properties; the challenge is often how to exploit their potential in real macroscopic systems. Whilst dry spinning approaches may be attractive, wet spinning is more obviously scalable and applicable. However, the formation of individualized solutions of functionalised single wall nanotubes (SWNTs) and graphenes is challenging. We exploit reductive charging to form pure nanotubides (nanotube anions) which can be redissolved, purified, or optionally functionalised, whist avoiding the damage typically associated with sonication and oxidation-based processing.[5] Nanotubide solutions form nematic phases which can be spun directly into coagulant baths in order to prepare functionalised SWCNT fibres in situ. Grafting of suitable polymer constituents can increase dispersibility of both nanotubes and graphenes and hence help to produce nanocomposite fibres with higher strength and strain to failure, [4] as well as multifunctional performance as supercapacitors. Non-carbon-based analogues of nanotubes offer different functions. For example, composite fibres containing inorganic (imogolite) nanotubes can generate healable structural fibres, with exceptionally high performance. [6] Imogolite nanotube dispersions also form liquid crystalline mesophases and it is possible to spin pure imogolite fibres, analogously to the carbon nanotube examples.[7] The imogolite system has the advantage of water compatibility and the opportunity for in situ process monitoring through optical birefringence and x-ray studies.[8]

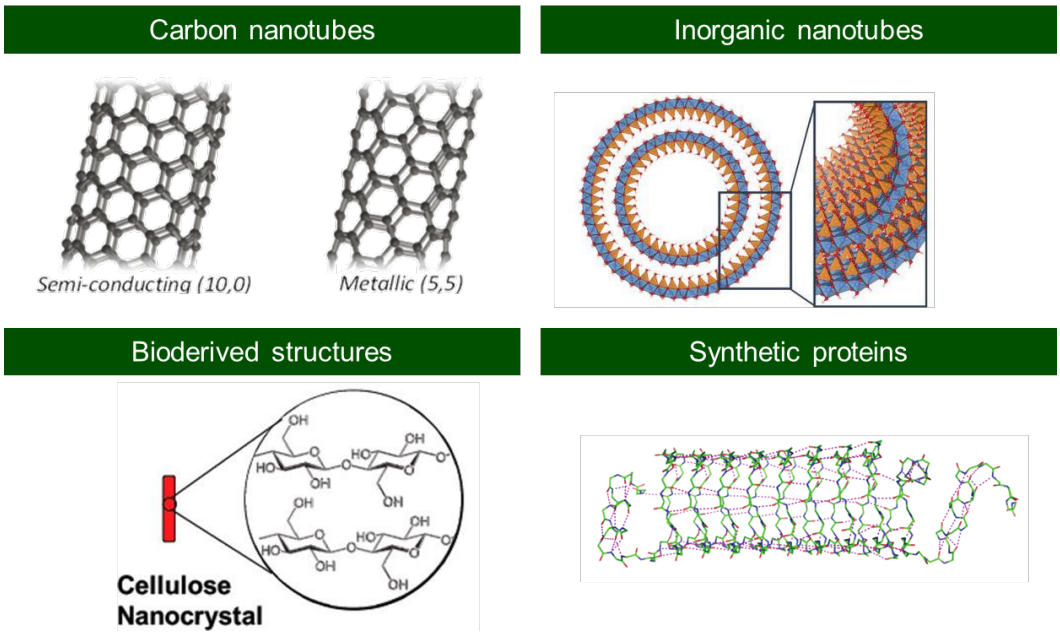

Figure 2: Schematic showing possible one dimensional nanomaterial building blocks for fibres

More sustainable fibre systems can be pursued by spinning bioderived nanomaterials, or by using nanomaterials to allow the spinning of lignin-based materials, for conversion into carbon fibre. Lignin-derived carbon fibers (CFs) are an attractive target for low-cost sustainable composite applications. Our lignin-based fibers are wet-spun using a low-cost (<$1/kg) ionic liquid, N,N – dimethylbutylammonium hydrogen sulfate ([DMBA][HSO_4]) as the dope solvent and water as the coagulation bath.[9] If the lignin is extracted from the biomass using an ionosolv approach based on the same low cost ionic liquid, it can be used directly as the feedstock for the wet-spinning process. This latter approach removes several process steps, including the need to dry the lignin powder during its isolation. An initial life cycle analysis (LCA) indicates that this new ionosolv approach offers significant scope to reduce the cost and global warming potential of lignin fibre production.[10] Very low loadings of CNTs can be used as the spinning aid for this ionosolv process, yielding fibers containing up to 96% lignin solid fraction. The presence of CNTs increases the estimated carbon fiber yield from ~40% to 54%, a critical factor for

technoeconomic outlook of lignin-based carbon fibers. In addition to enabling fiber spinning and increasing carbon yield, the CNTs may also act as graphitization templates and provide direct reinforcement of the lignin-derived carbon matrix, improving mechanical performance. Although the fibres do not yet match the strength or stiffness of state-of-the-art PAN-based carbon fibres, they may nevertheless be optimized to offer useful performance across a wide range of sectors from automotive to construction. In principle, CNTs can be bioderived, offering a fossil free route to low cost carbon fibers using only renewable carbon sources.

CONCLUSIONS

One dimensional nanomaterials are well suited to incorporation in fibre systems, both forming new types of pure fibre or in composite form. The aspect ratio and dimensionality are compatible with a high degree of alignment and efficient packing in the spun fibres, but also often generate lyotropic liquid crystal phases that play an important role in processing. Wet-coagulation spinning can exploit these phases and is readily scalable via established routes, from lab scale batches, through lab scale continuous monofilament, multifilament, and upwards towards pilot scale. Meanwhile, nanomaterials can already be used to improve the performance existing state of the art structure fibres. For example, CNT-grafted fibres offer improved structural properties, improving interfacial strength and composite compression performance, whilst offering multifunctional opportunities for enhanced conductivity and self-sensing. A new process allows continuous uniform growth throughout a 12k fibre tow, allowing potential integration directly into existing carbon fibre production.[11]

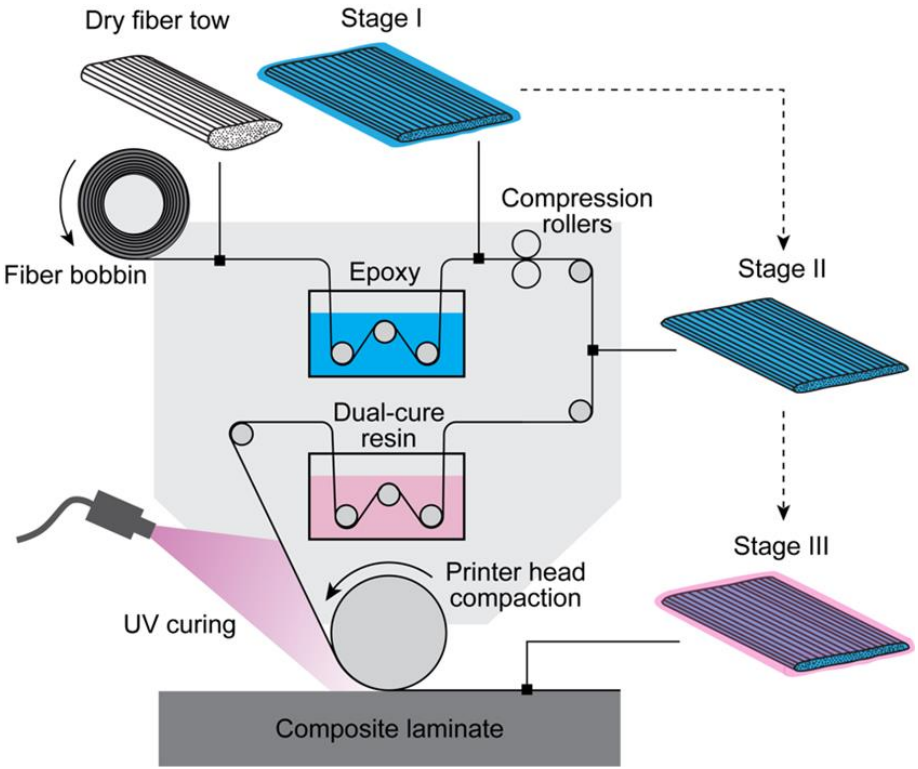
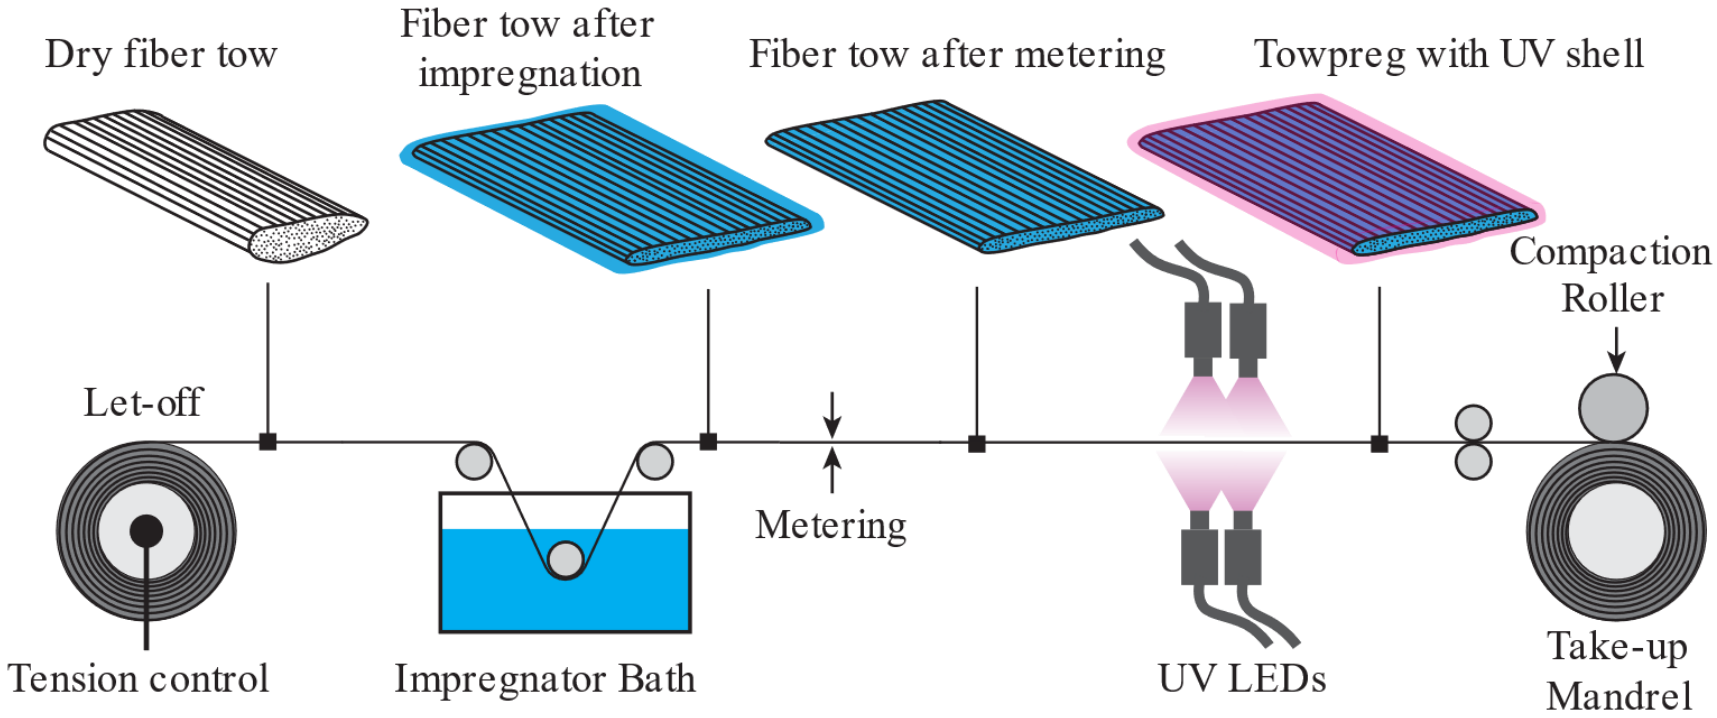
Outline

- Additive manufacturing process
- Research gaps
- Experimental setup
- Methodology
- Experimental analysis
- Conclusions

Introduction



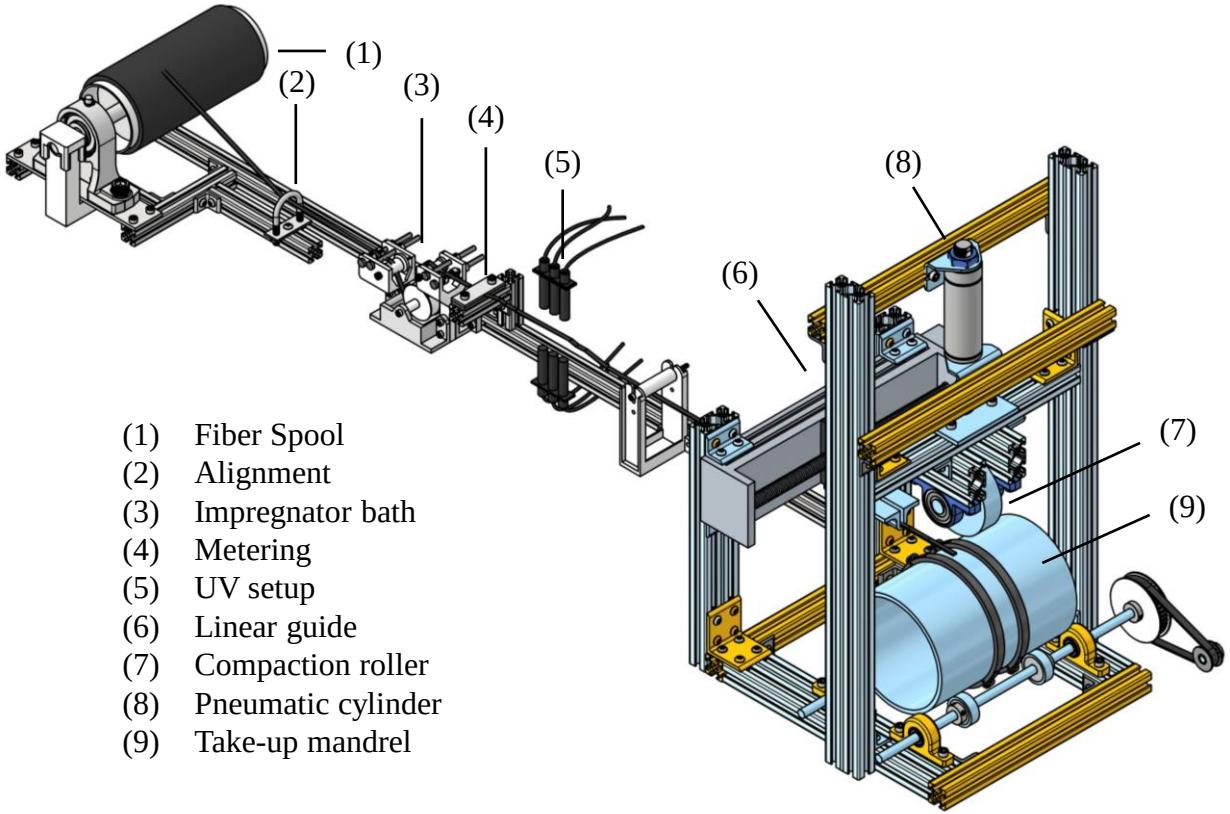
Current challenges:



- Low fiber volume fraction
- High void content
- Weak interlayer bonding

Approach

- Replicate the printing process for controlled impregnation & core shell formation.
- Quantitively apply roller assisted compaction pressure.
- Investigate the void fraction, FVF and SBS.



Introduction- Experimental Setup

ABSTRACT

Voids are well understood in traditional composite manufacturing processes. However, the evolving technology of fiber-reinforced additive manufacturing, with its unique constraints, requires adapting this knowledge to the specific materials and processes involved.

This paper evaluates the presence of different void types in continuously fiber-reinforced filaments used for composite additive manufacturing. It presents a study in which the void volume content of a filament, as well as the distribution of void sizes, is correlated with mechanical properties. Due to significant data scattering that complicates a clear evaluation, the study also investigates void mitigation strategies, focusing on the most detrimental void types in the printed parts—since the final printed component's quality is more relevant than the raw filament alone.

A distinct influence of certain void sizes is identified, indicating that these voids should be prioritized for reduction over others.

1 INTRODUCTION

Fiber-reinforced additive manufacturing, whether using short or continuous fibers, improves the properties of the base polymer depending on the type and volumetric content of the fibers. While short fibers often provide sufficient stiffness for a structure, continuous fibers are necessary to increase strength in specific sections [1].

There are different manufacturing technologies to produce such filaments. One versatile method is co-extrusion. For this technology, the German Aerospace Center (DLR), Institute of Lightweight Systems (SY), developed a patented process that uses ultrasound to improve filament quality.

Aeronautical applications require volumetric void contents below 2%. Since this applies to the final part, it is necessary to evaluate not only the void content of the filament after production but also to consider how the printing process affects voids within the filament [2].

Voids in the filaments occur at various scales. As filament diameters are about 1.1 mm (800 tex, 12K, 50% fiber volume content), the usual void classification cannot be directly applied. However, the typical classification into micro-, meso-, and macro-voids can be adapted for this purpose.

High-performance polymers such as Polyetherimide (PEI), Polypropylensulfide (PPS), and Polyetheretherketone (PEEK) are used because the material must meet high-performance requirements to justify its cost. These polymers tend to have relatively high viscosity, which challenges the co-extrusion process.

2 MATERIALS AND METHODS

Materials and production process:

The produced, printed, and evaluated filaments consist of carbon fibers from the AS7 fiber by Hexcel, which is a 12K fiber with 800 tex and no sizing. The polymer matrix is a commercially available PPS . The impregnation temperature is 330 °C, resulting in a measured dynamic viscosity of 155 Pa·s without applied shear forces.

The filament is manufactured on a co-extrusion line with a miniaturized extruder capable of processing about 2 kg of polymer per hour. The fiber insertion tool is designed to allow dry fibers to

enter while sealing the polymer-fiber contact area to up to 60 bar. An ultrasound impregnation cell is used to improve impregnation by reducing the polymer viscosity.

A hydraulically decoupled two-nozzle concept shapes the filament into a round semi-finished product according to the specimen requirements. Tempered tubes at the interface and after the last nozzle enable a gentle cooling ramp. The filament is then spooled and used on the printing end effector, where it is heated in a thermally decoupled nozzle. The nozzle diameter is only slightly larger than the filament diameter to reduce fiber buckling in the molten polymer, which can cause nozzle clogging.

Producing fiber-reinforced thermoplastic products is challenging in terms of quality assurance because the matrix material has higher viscosity and exhibits both elastic and viscous behavior [3]. Multiple production technologies exist, but most are not easily transferable between material systems. The classical fiber impregnation approach using e.g. thermoset matrix systems results in different void types—macro, meso, and micro voids—classified according to their location relative to the fiber tow [4]. Since this process uses only one tow, the classification must be adapted.

Methods:

The analysis of the filament after production and after printing single strands consists of multiple evaluation steps. First, the filaments are cut into specimens for 3-point bending tests. The specimens are marked with rotation angles to repeat measurements in six directions. Additionally, specimens are sputtered, cut, and polished to enable optical analysis of the voids present.

The bending tests are conducted according to ISO 178/141425. The bending results of each specimen are compared based on the loading direction (in 60° increments). The optical analysis results are benchmarked against overall void content measured by thermogravimetric analysis.

The optical analysis uses an automated algorithm to distinguish voids from fibers and polymer based on grey-scale thresholds. However, voids vary widely in symmetry, location, size, and shape. While the classical classification into micro-, meso-, and macro-voids could be applied to the cross-sectional Figure 1, the distinction is not always clear in literature. Therefore, voids are categorized in this paper by size into following classes: '< 0.0001 mm²', '< 0.001 mm²', '< 0.01 mm²', '< 0.05 mm²', and '> 0.05 mm²'.

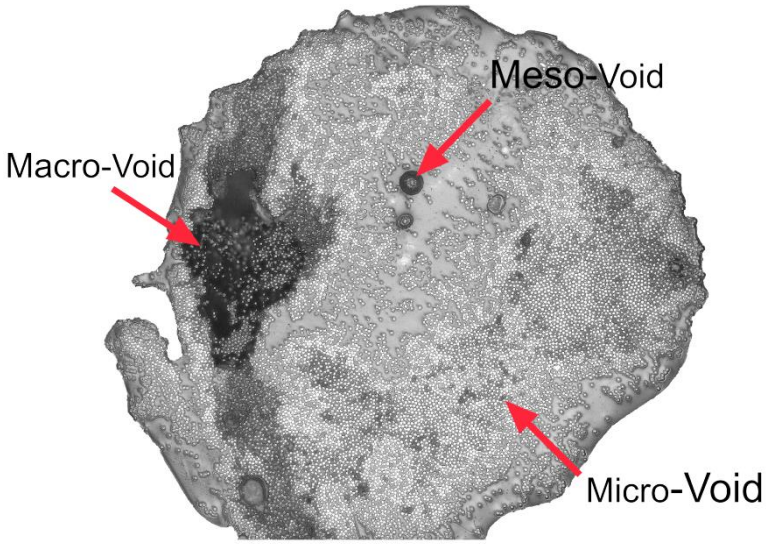

Figure 1 Modification of classical void classification

A main evaluation experiment is using three-point bending test. The experiment is designed using the norm DIN EN ISO 14125 [5]. However, since the filament is round, the pins were modified to position the filament according to the desired rotational positioning. The bending is set force driven (1N) newton to not provoke destructive testing as each specimen is needed for 6 measurements.

For the shear test, the filament is clamped into a rotational test device in which an oscillating, rotational movement is applied. Using the amplitude and the frequency, the shear modulus can be calculated [6].

3 EXPERIMENTS

To assign mechanical behavior to the voids, the described methodology was applied. Numerous filaments made from the same material combination—PPS and AS-7 fiber—were produced. However, manufacturing parameters such as production speed, impregnation pressure, and ultrasound impregnation amplitude were varied. The impregnation line speed ranged between 10 and 50 mm/s, while the impregnation pressure was set between 20 and 30 bar.

Figure 2 shows the calculated bending modulus of single filaments plotted against the global void volume content determined from cross-sectional images. For each filament, results from different angles of attack (0°, 60°, 120°, 180°, 240°, 300°) are indicated. It is important to compare opposite angles to reveal asymmetries in mechanical performance and the overall scattering of results. Average values are also presented. However, across more than 30 specimens with void volume content between 20–40%, no clear trend emerges from the data. Manufacturing pressure and speed were varied in order to produce different void volume contents.

The graph also includes information on the content of individual void size classes relative to overall void content. It appears that when a certain total void content is present, large voids dominate the void population, whereas smaller voids show less correlation with overall void content.

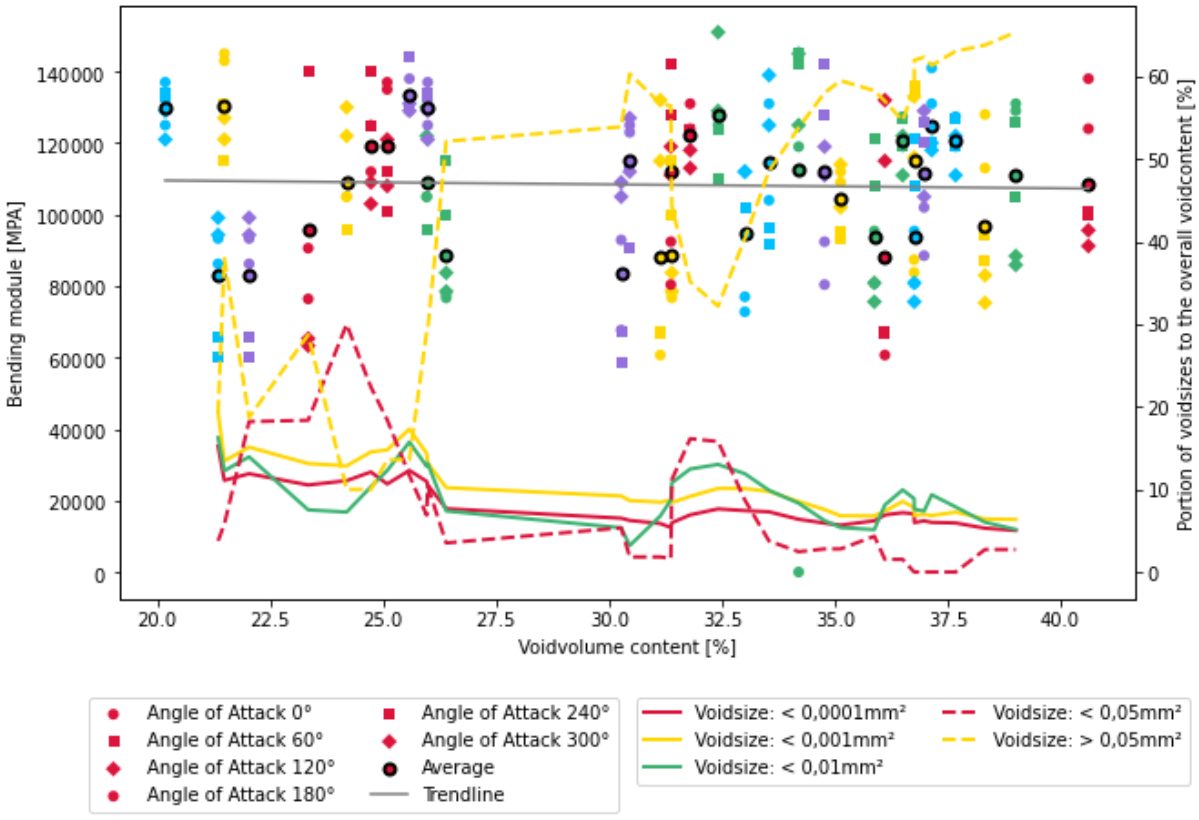

Figure 2 Bending to void volume content

Since bending tests did not reveal a significant correlation between voids and mechanical properties, the shear modulus was also tested and calculated (Figure 3). Again, results do not show a clear influence of increasing void content; interestingly, the expected loss in mechanical performance is not observed.

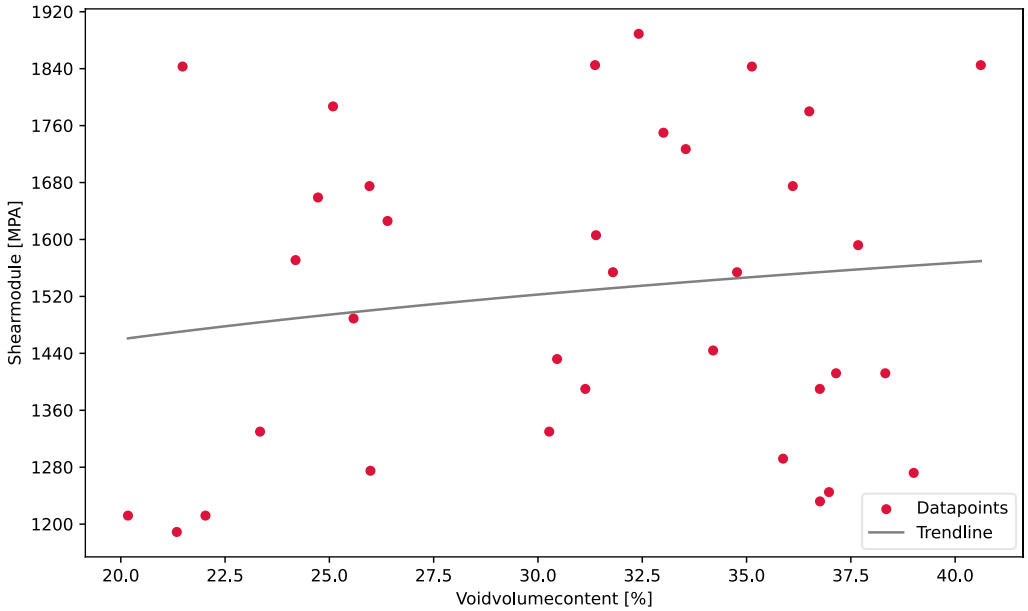

Figure 3 Shear modulus compared to the void volume content

Because void volume content does not correlate well with filament mechanical properties, a new approach is needed to analyze the influence of voids and their types. It is evident that data scattering is significant and that mechanical properties depend on additional factors which may mask the void effect. Major influencing parameters include fiber distribution and filament geometry as well as overall quality of impregnation. While the filament shape can be controlled relatively well with the machine setup, fiber distribution is less controllable and causes asymmetrical voids expected to have greater impact on bending and shear modulus than overall void content.

Since void restrictions mainly apply to the final additively manufactured part, not the filament material itself, the mitigation of voids during filament printing was evaluated.

Therefore, each filament batch was used in a classical FDM (Fused Deposition Moulding) where only a single filament was deposited, eliminating side effects like polymer oozing or acceleration/deceleration of the print head positioning system (Figure 4).

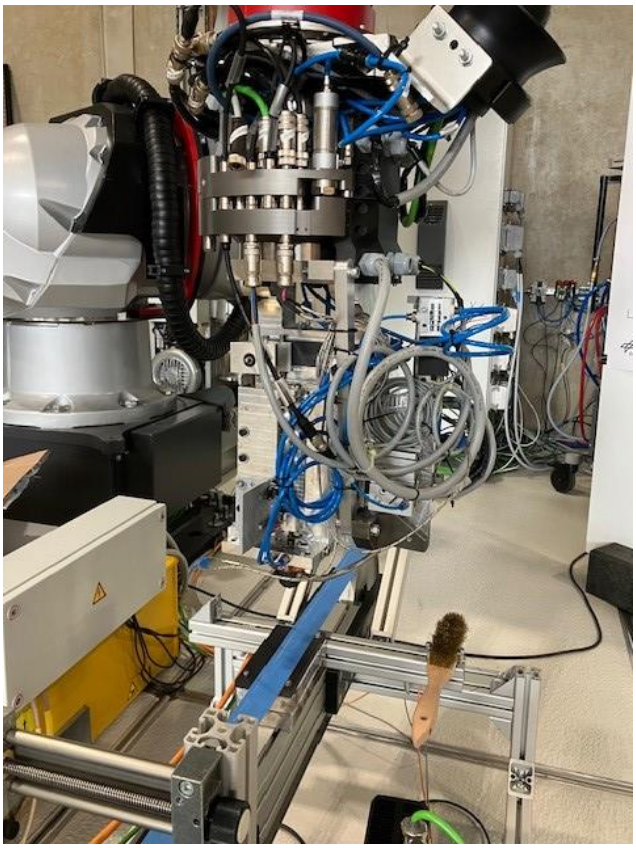

Figure 4 Filament printing

Subsequently, 3-point bending tests on printed filaments were conducted (Figure 5). Data shows a tendency of the printing influencing the bending modulus and void content, but no clear impact of printing speed is discernible.

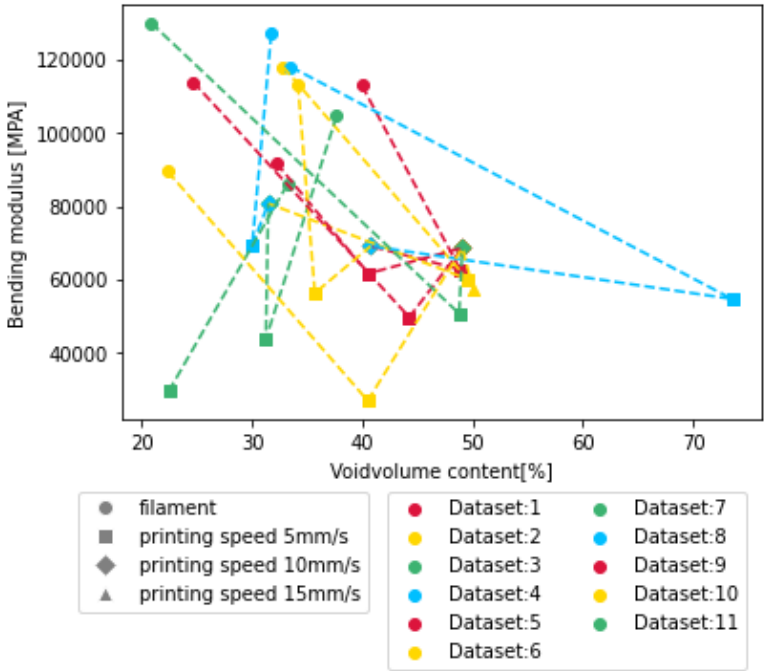

Figure 5 Bending of printed filaments

Optical evaluation of filaments before and after printing reveals a significant increase in voids due to printing.

	Filament	After printing
1		
2		

Table 1 Filament comparison to printed version

Table 1 presents four microscopic images showing large voids in filament 1 and only medium-sized voids in filament 2. Notably, printed filament 1 shows a significant increase in voids, while filament 2 only has a slight increase. Figure 6 quantifies this effect across evaluated specimens.

Voids smaller than 0.05 mm² do not tend to accumulate or grow significantly, whereas voids larger than '> 0.05 mm²' tend to increase, initiating cracks and raising overall void content during the process of printing the filament. The printing speed shows only minor influence, likely within data scattering.

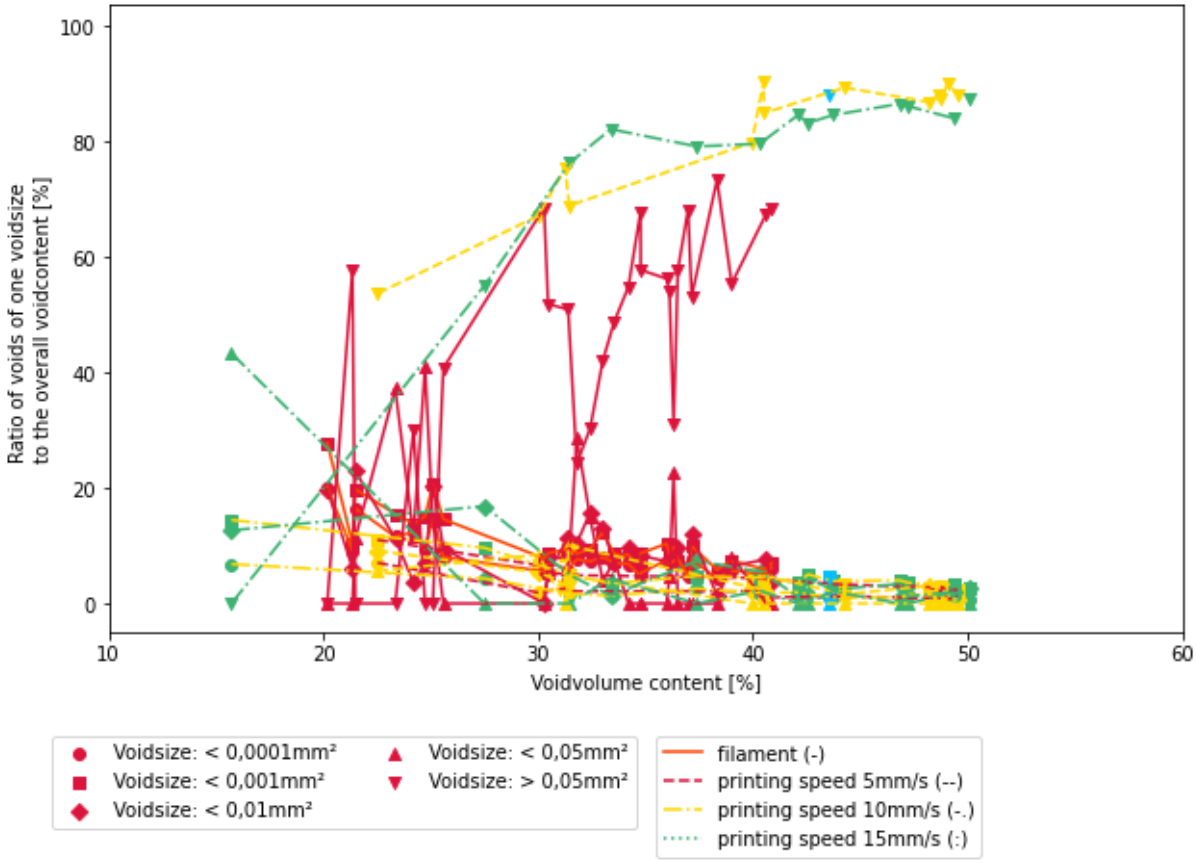

Figure 6 Void content comparison filament to printed specimen

4 CONCLUSION AND OUTLOOK

This study analyzing filaments produced by the co-extrusion process shows that the influence of voids on mechanical properties—such as bending modulus and shear modulus—is largely within the scattering caused by inhomogeneous fiber distribution as well as impregnation quality and imperfect filament geometry.

Nevertheless, certain types of voids have a notably harmful impact, especially when their mitigation is considered. While small individual voids appear largely unaffected by the printing process, larger voids significantly affect the printed parts by increasing the overall void content, which can lead to part rejection due to insufficient quality.

Given the manufacturing challenges of continuous fiber reinforced filaments, based on the utilized production process using ultrasound induced impregnation it seems to be not feasible to eliminate all voids immediately. However, this study identifies which void types should be prioritized for reduction.

Future work should investigate additional mechanical properties influenced by voids in the final parts. Moreover, improvements in fiber distribution are necessary to reduce the variability in material performance. Both theoretical considerations and engineering experience suggest that increased void content generally leads to reduced mechanical performance. By isolating other influencing factors, it may become possible to quantitatively assess the effects of void size, geometry, location, and type on mechanical behavior.

ACKNOWLEDGEMENTS

The funding body of the project Schall-FTP KA-TVP-06 within its transfer campaign (Helmholz-Gesellschaft, as well DLR Technology Transfer) is acknowledged for providing the funding of this work as part of a greater project around continuous fiber reinforced additive manufacturing.

ABSTRACT

Additive Manufacturing (AM), particularly Fused Deposition Modelling (FDM), enables the creation of intricate geometries with remarkable design freedom. Despite these advantages, the mechanical properties of FDM-fabricated parts are highly sensitive to variations in printing parameters and testing conditions. This work introduces an advanced machine learning framework aimed at accurately predicting the mechanical performance of polylactic acid (PLA) specimens, both in their pure form and when reinforced with natural fibers such as flax and wood flour. The methodology centers on Artificial Neural Networks (ANNs), specifically employing a Multi-Layer Perceptron (MLP) architecture that incorporates Gaussian and Gumbel-Gaussian activation functions. To address the challenge of high-dimensional process data, an encoder module based on a Variational Autoencoder (VAE) is integrated, enabling efficient data compression and feature extraction. The predictive capability of the model is further enhanced through a boosting neural network strategy and the application of a kernel-based truncated Taylor expansion, which together improve the model's ability to capture complex, nonlinear relationships between process parameters and mechanical outcomes. Experimental validation demonstrates the effectiveness of the proposed approach. The model achieves a low Continuous Ranked Probability Score Normalized (CRPSN) of 0.072, indicating high predictive accuracy. Additionally, the framework delivers a substantial improvement over a mean baseline, with a Skill score increase of 67%. Multi-Objective optimization carried using Non-Dominated Sorting Genetic Algorithm (NSGA-III) while inferring the trained neural network led to fast and accurate process' parameter optimization toward user defined desired mechanical properties. Experimental analysis performed by DSC confirmed the numerical relationships extracted by the two-step framework. Furthermore, results showed the proposed approach as a robust tool for guiding process optimization and material selection in additive manufacturing applications, paving the way for more reliable and tailored component performance within the constraints of AM technologies.

1 INTRODUCTION

Fused Deposition Modeling (FDM) stands as a cornerstone of Additive Manufacturing (AM) due to its accessibility, cost-effectiveness, and capacity for fabricating complex geometries. Its adoption has rapidly expanded from prototyping to end-use parts in sectors such as aerospace, automotive, and biomedical engineering, where the demand for customized, lightweight, and high-performance components is ever-increasing.

The intricate interplay between FDM process parameters affects microstructure, interlayer adhesion, and, ultimately, the mechanical behavior of printed specimens. This complexity poses significant challenges for accurate prediction and optimization of mechanical properties, necessitating advanced modeling approaches. In recent years, Machine Learning (ML) has emerged as a powerful tool for capturing the nonlinear and high-dimensional relationships inherent in AM processes. ML techniques have been successfully applied to predict both material and physical properties of FDM-fabricated parts. For example, Veeman et al. [1] developed a model to predict Rockwell hardness of ABS using process parameters and micrographs, while Castro et al. [2] utilized a Long Short-Term Memory (LSTM) neural network to forecast compressive strength from time-series sensor data, achieving high predictive accuracy. Wei et al. [3] integrated Takagi–Sugeno fuzzy inference with multilayer neural networks to optimize FDM parameters for PLA, resulting in significant strength improvements. Charalampous et al.

[4] and Shi et al. [5] further demonstrated the utility of supervised learning and feedforward neural networks for optimizing mechanical behavior and predicting properties of FDM-printed polymers. Surface quality, another critical aspect, has been modeled using artificial neural networks (ANNs) by Chinchanikar et al. [6] and Vahabli and Rahmati [7], the latter employing genetic algorithm (GA) optimization for parameter selection in medical applications.
Beyond property prediction, ML-driven approaches have been leveraged for geometric and process optimization in AM. Vaissier et al. [8] introduced a GA-based framework for optimizing lattice support structures, iteratively evolving parameters to minimize weight while maintaining mechanical integrity. The integration of ML and GA has also been explored for material discovery and multi-material design, as demonstrated by Borg et al. and Goh et al., respectively. Sondagar et al. [9] and Kosarac et al. [10] highlighted the effectiveness of ANNs in optimizing process parameters and machining conditions, even with limited datasets.

Artificial Neural Networks (ANNs), in particular, have demonstrated significant potential in modeling nonlinear dependencies within both large and small datasets. Sondagar et al. utilized ANNs to predict optimal process parameters in additive manufacturing, focusing on improving mechanical properties and dimensional accuracy. The ANN was trained on experimental datasets with inputs including temperature, speed, and layer thickness and enabled nonlinear mapping between parameters and quality metrics. Kosarac et al. optimized machining parameter using ANN trained on small datasets.
Recent studies highlighted as promising innovation direction the integration of Genetic Algorithms (GAs) for multi-objective optimization of FDM process parameters. GAs, inspired by natural selection, are adept at navigating complex, multi-dimensional search spaces to identify optimal or near-optimal solutions. In AM, GAs have been applied to optimize build orientation, packing, scheduling, and process parameters, often in conjunction with ML models to enhance both prediction and optimization capabilities. For example, hybrid ML-GA frameworks have been developed for sustainability optimization, surface roughness minimization, and mechanical property enhancement in FDM [11] , with the Non-Dominated Sorting Genetic Algorithm [12] (NSGA-II/III) frequently employed for multi-objective tasks. These approaches have demonstrated superior performance in balancing competing objectives such as strength, surface quality, and production efficiency, and have been validated through experimental studies and case analyses.

Recent studies have also explored the combination of GAs with neural networks for precision prediction and inverse design in FDM. Yang and Zhang [13] established a GA-optimized Backpropagation (BP) neural network model to improve dimensional accuracy predictions, showing that GA optimization significantly enhances model performance by avoiding local minima and improving convergence. Similarly, integrated frameworks combining LSTM networks with GAs have enabled efficient inverse design of 3D printed parts to meet target mechanical properties, further underscoring the synergy between ML and evolutionary algorithms in AM optimization.

Traditional Artificial Neural Network (ANN) architectures frequently encounter difficulties when dealing with high-dimensional process data and the intrinsic variability associated with Fused Deposition Modeling (FDM) printing [14], [15] . These challenges become particularly pronounced when numerous printing parameters are varied simultaneously, especially across wide ranges or near the mechanical limits of the 3D printer. To mitigate these issues, prior studies have typically limited their focus to a small subset of key parameters [16], [17] such as Extruder Temperature, Infill Type, and Infill Density, while holding other variables constant to improve model accuracy. However, this approach falls short of capturing the full complexity of the printing process, as it neglects intricate parameter interactions, thereby restricting the model's applicability in real-world scenarios that demand higher precision and process control.

To overcome these limitations, a novel machine learning framework has been developed, centered on a Multi-Layer Perceptron (MLP) [18] architecture augmented with a Variational Autoencoder (VAE) [19]. This design facilitates effective dimensionality reduction and feature extraction from complex input data. The framework is further enhanced by incorporating a boosting neural network strategy alongside a truncated Taylor series kernel applied to the model outputs, collectively boosting generalization performance and predictive accuracy for both physical and mechanical properties.
This study aims to comprehensively map the entire spectrum of FDM process parameters to the mechanical behavior of polylactic acid (PLA) and its natural fiber-reinforced composites (including flax

and wood flour), even under data-scarce conditions and while pushing printing and testing parameters close to the machine's operational limits. The result is a robust modeling solution capable of learning the nuanced dynamics of the process across its full domain, making it suitable for complex, real-world applications. By leveraging the statistical boosting-enhanced architecture, the framework accounts for the stochastic nature of FDM manufacturing, providing not only point predictions but also the associated statistical distributions. Treating the FDM process as stochastic rather than deterministic allows for more reliable engineering estimations, such as confidence intervals for lower and upper bounds, as well as analyses of distribution characteristics like kurtosis and skewness. Furthermore, the application of SHAP value analysis and GA parameter optimization on the virtual model environment enabled both a deeper understanding of the observed manufacturing processes and an automatic, tailormade, fast and accurate control on the specimen mechanical properties.

Extensive experimental validation on previously unseen data, including extreme conditions near the printer's mechanical constraints and across different polymer suppliers, confirmed the model's high accuracy and strong generalization capability. This positions the framework as a valuable tool for optimizing printing parameters and improving the mechanical reliability of components produced via FDM.

2 METHODS

2.1 Materials

The polymer filaments utilized in this study were commercially sourced from multiple suppliers. Neat PLA filaments were obtained from BambuLab, R3D, Sunlu, and Nanovia, while PLA filaments containing flax fibers and wood flour were acquired from Nanovia. All filament spools were kept in vacuum-sealed containers with silica gel desiccant packs and underwent additional drying at 55 °C for a minimum of 48 hours before the printing process.

2.2 Manufacturing process

During the 3D printing process, a variety of parameters play a crucial role in determining the final characteristics of the printed specimens. These parameters can notably impact heat transfer and mass flow within the extruder chamber and on the surface of the specimen, as well as influence the vibration frequency of the printer's frame.

To thoroughly assess how these printing variables affect the mechanical performance of the materials, all major process parameters were systematically varied across the full range permitted by both the equipment and the materials themselves. The specific ranges for each parameter are detailed in Table 1; except for the categorical Infill Type, these ranges represent the minimum and maximum values selected for each parameter.

Specimens were manufactured by using a BambuLab X1E, a commercial desktop 3D printer. The tensile specimen adhered to the ISO-527-2 (type 1BA, L0 = 30 mm) standard, with a nominal thickness of 2 mm and a nominal width of 5 mm. To capture the intrinsic statistical variation in the properties exhibited by the printing process, five specimens were realized for each set of parameters. In the presented analysis, the parameters intervals were maintained continuous, aside from the categorical or strictly discrete ones, and the tuples of values were chosen randomly using an uniform random distribution, within the interval boundaries, for each batch of specimens.

For each material, a total of 20 batches were realized with such criteria for a total of 100 specimens for material. Each one of them was composed by 5 specimens manufactured with the same parameters, accounting for the inner stochastic nature of the manufacturing process and thus allowing a more robust modelling. Each of those specimens were treated as single data entries to both allow a stronger modelling of the associated statistical distribution and to capture the influence of X and Y location on the build plate on the resulting mechanical properties. With those criteria, a total of 600 specimens have been manufactured and a total of 120 different parameters combinations have been explored.

Despite the relatively limited number of independent parameter combinations, typically a challenge for artificial neural network (ANN) modeling, especially in high-dimensional feature spaces, the proposed framework demonstrated strong predictive accuracy for all measured outputs. This highlights its effectiveness even under conditions of limited and unstructured data.

Table 1. Printing parameters intervals

Parameter	Intervals
Layer Height	*0.1 mm – 0.28 mm*
Line Width	*0.4 mm – 0.8 mm*
Number of Shells	*1 – 4*
Base Layers	*1 – 4*
Infill Type	*Cubic, Rectilinear, Honeycomb, Gyroid*
Infill Density	*5 % – 100 %*
Speed of Base Layers	*10 mm/s – 500 mm/s*
Speed of Infill	*10 mm/s – 500 mm/s*
Acceleration	*50 mm/s^2 – 13000 mm/s^2*
Jerk	*1 mm/s^3 – 9 mm/s^3*
Extruder Temperature	*190 °C – 240°C*
Heated Bed Temperature	*25 °C – 60 °C*
Chamber Temperature	*25°C – 60 °C*
Filament Dryer Temperature	*25 °C – 55 °C*
XY Position	*0 mm – 257 mm*

2.3 Specimen characterization

2.3.1 Mechanical properties

The uniaxial tensile tests of all manufactured specimens were carried out on a Zwick/Roell Z2.5 universal testing machine, equipped with digiClip extensometer (by Zwick/Roell) to accurately measure the strain (Fig. 1b). Tests were conducted in displacement control, varying the crosshead speed in an interval of 1 mm/min - 50 mm/min. The same strategy used in the manufacturing process was used here, so the test speed was chosen randomly in the interval boundaries for each batch of specimens. Such an approach allowed us to capture different strain-dependent mechanical behaviours, thus increasing the ANN's generalization capabilities.

2.3.2 Thermal properties

Differential scanning calorimetry (DSC) analysis of the materials was performed under a nitrogen flow of 60 mL/min (DSC 214 Polyma by Netzsch). Samples (around 10 mg) were placed in a aluminium concave crucible with a pierced lid and analysed according to the following thermal program: heating from 0 °C to 220 °C (5 min hold interval), cooling to 0 °C (5 min hold) and second heating to 220 °C, all steps performed with a rate of 10 °C/min. The thermal information gathered from this analysis have been used to enrich the input data for the modelling, leveraging the correlation between melting temperature and mechanical properties [20], thus enabling more accurate predictions.

2.4 Learning task

This study focused on examining how printing and testing parameters translate into the mechanical and physical properties observed in the specimens. This challenge can be framed as a multi-input-multi-output (MIMO) regression problem, where both the printing and testing conditions serve as inputs, and the resulting material properties are the outputs of interest. In the realm of computer science and artificial intelligence, the quality of the dataset is just as critical as the neural network's ability to generalize. To enhance the informational value of each data point, the input set was enriched by incorporating not only the thermal properties of the printed polymer but also its mechanical properties measured under standardized printing and testing conditions, including fixed strain rates.

The thermal information about the polymer and how it influences the printing process was introduced by defining four different relative temperatures defined as:

- ΔText-melt := Extruder temperature - Melting temperature
- ΔTbed-cryst := Heated bed temperature - Crystallization temperature
- ΔTbed-glass := Heated bed temperature - Glass transition temperature

- ΔTbed-ch := Heated bed temperature - Chamber temperature

Including the polymer's thermal properties in the model allowed it to distinguish between different polymers without relying on additional one-hot encoding schemes. This approach reduced the input dimensionality while establishing a meaningful correlation between the polymers' thermal and mechanical characteristics. Moreover, the temperature-dependent value shifts helped normalize the 3D printer's operating temperatures across different polymers, effectively creating a nearly uniform reference framework. This normalization eased the computational complexity of the modelling task.

Mechanical information was incorporated by producing six specimens per polymer using a fixed set of printing parameters consistent across all materials. These parameters were carefully selected to yield reliable and representative samples. For each polymer, half of the specimens were printed with a 0° raster angle and the other half with a 90° raster angle, allowing separate evaluation of the filament's intrinsic strength and the inter-layer bonding strength of parallel deposited filaments. Additionally, each polymer and raster angle combination were tested at three different strain rates, 5 mm/min, 20 mm/min, and 40 mm/min, to capture how mechanical behaviour varies with strain rate.

As a result of these enhancements, the input feature space expanded threefold, increasing from 25 to 75 features. However, the enriched data significantly offset the challenges of higher dimensionality, leading to a consistent improvement in the model's overall predictive accuracy.

2.5 Framework structure

The model architecture employed in this study is a multi-headed multilayer perceptron (MLP) featuring a Variational MLP Encoder (VE) as a shared backbone. In this design, the common backbone functions as an effective compressor that encodes and transforms the input features into a meaningful latent representation, while each individual head is dedicated to predicting a specific output feature.

Additive manufacturing (AM), particularly fused deposition modeling (FDM), operates in a partially observed environment where not all variables are known or controllable during production. To address this uncertainty, both the VE backbone and the MLP heads map their outputs onto Gaussian-shaped distributions, following approaches used in prior research dealing with uncertainty-driven scenarios. By producing statistical predictions rather than deterministic outputs, the model can more effectively navigate the loss landscape, reducing the risk of becoming trapped in local minimum.

This capability is achieved by duplicating each head and employing a Negative Gaussian Log Likelihood (NLL) loss function during training, which encourages the outputs to conform to Gaussian distributions. Consequently, the neural network can predict mechanical properties more accurately by providing both the expected mean and variance of each parameter, thereby capturing the uncertainty inherent in certain regions of the printing parameter space. For clarity, this type of neural network will be referred to as iBNN in the following sections.

To further explore the enhanced modelling capabilities offered by a more accurate statistical representation of the output, a similar NN (iBNNG) that maps the output features into a Gaussian-Gumbel [21] space has been realized.

The aforementioned statistical distribution can be defined as:

- $Y_{pdf}(x) = \frac{1}{\sqrt{2\pi\sigma^2}} e^{-\frac{(x-\mu)^2}{\sigma^2}}$ (1)
- $\mu_{pdf}(x) = \frac{1}{\beta} e^{-\left[\left(\frac{x-\mu^*}{\beta}\right)+e^{-\frac{x-\mu^*}{\beta}}\right]}$ (2)

Using this definition only three parameters – μ*, σ, β – are needed to actually represent the distribution, and they can be modelled by three different neural networks. As with the previous approach, each neural network within the triplet is a replica of the original head, which effectively reduces the hyperparameter search space during optimization. These networks were trained using a Gaussian-Gumbel Negative Log Likelihood (GGNLL) loss function combined with the Gumbel-Max reparameterization trick, enabling gradient backpropagation throughout training. The use of different statistical representations in this study allowed the model to capture both the inherent stochasticity of

the process, by mapping outputs into a Gaussian distribution, and the occurrence of catastrophic defects within specimens, by mapping into a Gaussian-Gumbel distribution, thereby providing a more precise characterization of the process dynamics.

To prevent the hyperparameter space from becoming excessively large, the MLP architecture employed here features a sequential and consistent reduction in the width of hidden layers. This layer size reduction is governed by a user-defined decay parameter, which simplifies the architectural design to just four key parameters: the number of layers, the decay rate, the initial hidden layer size, and the type of activation function. The calculation of input and output layer sizes is straightforward and summarized as follows:

- Input size of ith layer := $round\left(max\left(\frac{initial\ hidden\ size}{decay^{i-1}}, 1\right)\right)$
- Output size of ith layer := $round\left(max\left(\frac{initial\ hidden\ size}{decay^{i}}, 1\right)\right)$

In the proposed framework to further improve the predictions, the increase in accuracy offered by the boosting architectures has been leveraged; thus, similarly to the famous XGboost [22], the proposed models have been built and trained subsequentially to refine the prediction of the previous models, until no further meaningful increase of accuracy was reached.

2.6 SHAP Analysis

Following the training of the iBNN and iBNNG frameworks, a statistical analysis was conducted to assess the impact of input parameters on the models' outputs using Shapley Values. Typically, Shapley values are applied in scenarios where individual contributors have unequal but cooperative roles in achieving a collective outcome or payoff. Within the application of machine learning and AI interpretability, this mathematical tool provides quantitative estimates of each input feature's influence on the model's predictions. In the context of this study, assuming the models are accurate, these values serve as proxies to reveal the true effect of process parameters on the resulting mechanical properties.

After calculating both SHAP values and SHAP interaction values for the iBNN and iBNNG models, the insights gained were used to develop a novel kernel-based AI approach that accounts for the lack of interaction between input parameters. This kernel was designed as a truncated Taylor series expansion, where the model's output approximates the k-th order derivatives and truncation error, and can be represented as follows:

$$Y(x) = \sum_{i=1}^{N} \sum_{j=0}^{K} \frac{f_i^{(j)}}{j!}\left(x_i^j\right) \tag{3}$$

where:

- $f_i(j)$ is the j-th derivative of a generic function, relative to the i-th input variable. In this context $f_i(j)$ is approximated by the NN.
- x_i is the i-th input variable used in the i-th generic function, truncated at the K-order. Using this kernel, it was possible to force lower levels of interaction between input features, lowering the complexity of the optimization process.

The realized pseudo-physics informed NN (iPBNN) has been trained with the same methodology of iBNN and iBNNG, as shown in the next sections, truncation's degree was set as hyperparameter.

2.7 Dataset preprocess and training pipeline

The data preprocessing in this study involved a three-step procedure: one-hot encoding (OHE) , scaling, and partitioning. Following scaling, the dataset was split into training-test and validation sets with a ratio of 95:5. Because selecting optimal test points for an accurate performance metric was challenging, a 10-fold cross-validation [23] approach was employed to more reliably assess the models' predictive capabilities.

Model architecture optimization was performed using a Bayesian algorithm aimed at minimizing the test loss averaged over the cross-validation folds. The training process consisted of two main stages. First, a Variational Autoencoder (VAE) was trained on the input data. Next, a multi-headed MLP was constructed using the best-performing encoder from the VAE (the Variational Encoder, VE) as the

shared backbone. During the initial stage, a sweep evaluated 10,000 VAE models, selecting the one with the lowest average cross-validation loss. In the second stage, each MLP head underwent 10 boosting rounds, with 500 models assessed per round. After each boosting round, the top-performing model was chosen to serve as the booster for the subsequent round. This procedure was repeated for all 10 output heads, resulting in a total of 60,000 models being trained and evaluated to complete the entire training process.

2.8 Genetic Optimization

Genetic based algorithms were used on the converged AI framework to optimize process parameters on user defined mechanical and process constraints. Process parameters have been clustered into different genes using as discrimination criteria the effect exerted on the process; thus, allowing a more stable phenotypic expression and a smoother optimization. Each gene, structural, cinematic and thermic, was characterized by their own mutations, crossover and inversion coefficients to allow independent mutation dynamics and efficient hyperparameter search. Furthermore, mutation, inversion and inversion coefficients were also subjected to mutation and crossover rates to allow a smoother transition from the exploration to the exploitation stage. Finally, to allow a multi-objective optimization avoiding hierarchical objective function definition, NSGA-III [24] algorithm was used, with a population of 2048 individuals and with 100 generations per optimization.

AI fine-tuning was also performed to stabilize the NN prediction, avoiding numerical instabilities that could have occurred in interpolation or extrapolation regions. A Physic-Informed NN (PINN) criteria was then used, forcing a hierarchical relationship between the output parameters, for example Force UTS always greater than Force Yield. Since the defined soft-constrained PINN was characterized by multiple loss functions, a self-adaptive loss balanced algorithm was used to allow a faster and smoother convergence [25].

3 RESULTS AND DISCUSSION

The results are presented in the following sections. To avoid the bias associated with training and test datasets, which tend to favor overfitting, only predictions on the validation set are reported. Since conventional accuracy metrics like Mean Absolute Error (MAE) or Mean Absolute Percentage Error (MAPE) are not directly suitable for evaluating probabilistic forecasts, the Continuous Ranked Probability Score (CRPS) was employed as a generalized version of MAE for probabilistic predictions. By generating an empirical distribution (F) through N samples drawn from the probability density function, the CRPS is defined as follows:

$$CRPS(F,x) = \sum_{k=0}^{x} F(y_k)^2 + \sum_{k=x+1}^{n} (F(y_k) - 1)^2 \quad (4)$$

where n is the last element of the right tail of the PDF. To allow comparisons and a common metric through the output features, a pseudo Mean Absolute Percentage Error (MAPE) has been also introduced, based on CRPS values, called CRPS Normalized (CRPSN). Formally it has been defined as:

$$CRPSN(F,x) = \frac{CRPS(F,x)}{\frac{1}{N}\sum_{x \epsilon D}^{N} x_i} \quad (5)$$

where the denominator is the mean value of the real observed output feature.
Additionally, to facilitate a more straightforward comparison of accuracy across different models, an extra metric called Skill was introduced. This metric quantifies the improvement in accuracy relative to a naïve prediction, which is simply the mean of the observed values. Formally, the Skill metric is defined as:

$$Skill(F,x) = \frac{CRPS(x_{mean},x) - CRPS(F,x)}{CRPS\left(\frac{1}{N}\sum_{x \epsilon D}^{N} x_i, x\right)} * 100 \quad (6)$$

Lastly, to provide a more practical assessment of the models' reliability, an additional metric called the Confidence Region Score (CR score) was introduced. This metric is calculated using the 2.5th and 97.25th percentiles (Q(0.025) and Q(0.9725)), which together capture approximately 95% of the distribution's statistical significance. The CR score represents the average frequency with which the

actual observations fall within this ±2σ interval, meaning a higher score indicates a stronger alignment between the observed data and the predicted statistical distribution. Although this metric is unconventional, it enabled effective comparisons between the different statistical outputs of the model. Meanwhile, the CRPS metric provided a quantitative measure of error analogous to the Mean Absolute Error (MAE), facilitating more precise evaluations of the models' accuracy.

3.1 Framework predictions and Ablation Study

Table 2 presents CRPSN values on prediction for mechanical properties and physical properties relative to iBNN framework and its variants.

The iBNN predictions show increased variance under certain printing conditions, particularly at high Toughness values, highlighted by a high value in CRPSN for iBNN, iBNNG and iPBNN. This elevated variance is attributed to the significant statistical variability caused by unpredictable internal defects such as inclusions, under-extrusions from inconsistent filament diameter, and thermal degradation. These defects serve as nucleation points for voids and cracks, substantially reducing the specimen's maximum energy absorption and strain capacity.

Table 2. CRPSN values for every output feature, calculated on the validation partition for the proposed models, the baseline models, and the ablation study models.

Model	Rigidity	Force UTS	Strain UTS	Force Yield	Strain Yield	Strain Break	Toughness	b	h	P Tot	Mean
SVM	0.069	0.126	0.108	0.108	0.109	0.253	0.320	0.008	0.016	0.041	0.116
XGB	0.100	0.160	0.117	0.154	0.107	0.372	0.379	0.014	0.016	0.054	0.147
iBNNH	0.054	0.106	0.098	0.098	0.085	0.150	0.212	0.006	0.014	**0.031**	0.085
iBNN	0.045	0.073	0.065	**0.062**	**0.068**	0.172	**0.182**	0.005	**0.011**	0.040	**0.072**
iBNNG	0.049	0.114	0.073	0.103	0.083	0.175	0.189	0.005	0.014	0.058	0.086
iPBNN	**0.035**	**0.062**	**0.041**	**0.062**	0.084	0.176	0.292	**0.004**	0.012	0.034	0.080
BMLP	0.062	0.066	0.079	0.044	0.071	0.178	0.183	0.006	0.014	0.036	0.074
BNNH	0.067	0.091	0.067	0.078	0.102	**0.147**	0.183	0.006	0.016	0.048	0.080

Notably, the rise in confidence region values occurs consistently across all output features for the same input conditions, indicating that each model head has effectively and independently captured the process dynamics. This ability to learn variances linked to printing and testing parameters enables the model not only to predict mechanical properties in advance but also to identify and avoid parameter regions prone to unpredictable defects. Despite these high-variance regions, the models reliably capture the specimens' mechanical and physical behavior, as evidenced by consistently low CRPSN scores across all output features.

An ablation study was conducted on the proposed framework by systematically removing key components: first the Gaussian head, then the Variational Encoder, and finally the engineered input features. For clarity, models trained without engineered features are referred to as BNN and BNNG. Models without the Gaussian head are labeled BNNH and iBNNH, following the previously established naming convention. When both the head and backbone were removed, the resulting architecture became a standard Boosted MLP, referred to as BMLP. For baseline comparison, XGBoost (XGB) and Support Vector Machine (SVM) models were also included and optimized using the same Bayesian Optimization process as the main study.

Across nearly all output features, these simplified and comparative models showed higher CRPSN values than the full models. Traditional approaches like XGB and SVM also exhibited higher CRPSN values compared to both the complete and ablated neural network models. These results highlight that the proposed framework offers superior prediction accuracy in complex, highly stochastic scenarios such as FDM, outperforming conventional modeling techniques.

3.2 SHAP Analysis

AI modelling is frequently regarded as a black-box technique, effective at delivering accurate predictions but often lacking transparent and straightforward explanations of the underlying mathematical processes driving those predictions. To address this limitation, a statistical SHAP analysis was performed to uncover the physical relationships between the input variables and the model's output predictions.

The results reveal key insights into the process dynamics from a materials science perspective. For rigidity, the relative density of the specimen was the most influential factor, with lower density reducing stiffness. Additionally, a larger temperature difference between the heated bed and printer chamber negatively affected rigidity, likely due to uneven internal stresses. A similar negative correlation was observed between rigidity and the difference between extruder temperature and polymer melting point, suggesting thermal degradation of PLA, flax fibers, and wood powder. High jerk values also reduced rigidity, indicating that strong vibrations during deposition harm mechanical properties.

For toughness, the X position on the build plate had the strongest negative impact, implying that vibrations and thermal gradients near chamber walls cause defects that reduce energy absorption. Unlike rigidity, toughness was more sensitive to abrupt changes in acceleration rather than the speed of those changes. Structural parameters like shell and base layer count positively influenced toughness, highlighting the role of filament orientation. A strong negative correlation with layer height suggested the formation of meso-crystalline phases during printing, which enhance energy absorption during testing.

This hypothesis was supported by DSC analysis (Fig. 3), showing significant enthalpy release around 90–98 °C in printed specimens before and after testing, attributed to residual stress release and fusion of process-induced meso-crystals [26]. The increase in crystallinity from 6.08% to 11.35% during tensile testing confirmed these meso-crystals contribute to improved toughness.

Table 3. DSC analysis on high plastic PLA specimen in the deformed region, the undeformed region, and the reference second heating as baseline.

Specimen	$T_{cold\text{-}cryst}$ (°C)	T_{melt} (°C)	$\Delta H_{cold\text{-}crist}$ (J/g)	ΔH_{melt} (J/g)	χ (%)
As Printed	67.6	160.06	-26.25	31.91	6.08
Tested	70.01	159.06	-23.04	33.36	11.35
Reference	107.3	159.9	-27.65	35.53	8.47

3.3 Genetic Optimization

Genetic optimization was carried out on the converged and fine-tuned iBNN AI framework. To prove its effectiveness a run was performed with the objective of maximizing the Force Yield, while minimizing the theoretical density of the manufactured specimen. The results of the optimization process are shown in Figure 1, where the algorithm successfully identified the Pareto optimality frontier associated with the proposed task. Furthermore, analysing the proposed optimality frontier, it was found a significant high frequency in solutions of PLA-Flax reinforced respect to PLA-Wood reinforced, suggesting a lower fiber-matrix interface in the latter composite composition. SEM analysis on the fracture surface of PLA-Wood reinforce specimen was conducted and it was confirmed indeed the absence of an interface between PLA polymer and the wood particles reinforcement; thus, confirming the purely data-driven relationship discovered by the combined application of both NSGA-III and iBNN frameworks.

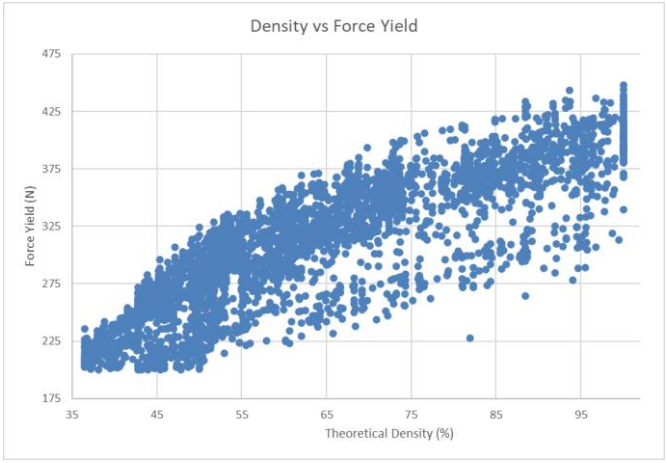

Figure 1. NSGA-III optimization using iBNN as virtual environment, maximizing Force Yield and minimizing the theoretical density of the specimen.

4 SUMMARY

This study aimed to develop an AI framework that efficiently maps printing parameters and testing conditions to the mechanical and physical properties of 3D-printed specimens, covering a wide range of process variations. The proposed model, a Boosting multi-headed Variational Encoder MLP combined with a kernel-based truncated Taylor expansion, successfully predicts outputs in both Gaussian and Gaussian-Gumbel spaces. Validated on unseen data, the models achieved low CRPS values (0.080, 0.072, and 0.086 for iPBNN, iBNN, and iBNNG respectively), outperforming traditional methods like XGB and SVM by effectively capturing variance in highly uncertain FDM processes.

SHAP analysis revealed meaningful correlations between process parameters and mechanical properties, which were experimentally confirmed, demonstrating the model's ability to learn complex relationships in additive manufacturing. Leveraging the minimal interaction between inputs identified by SHAP, a Pseudo-Informed Neural Network was created using a kernel-based truncated Taylor expansion, further enhancing performance where standard PINN approaches are not feasible.

Overall, this methodology offers a robust solution for FDM and other AM techniques, maintaining accuracy despite high-dimensional, sparse data, common in real-world scenarios with limited data availability. The coherent insights from SHAP and NSGA-III also suggest its potential as a tool not only for prediction but for understanding process dynamics.

Real-time prediction with Reduced Order Models

sPGD: Sparse Proper Generalized Decomposition

The Proper Generalized Decomposition (PGD) Method

$$f(v_1, v_2, \dots, v_n) \approx \sum_{k=1}^{m} X_1^k(v_1) X_2^k(v_2) \dots X_n^k(v_n)$$

Separated representation: $u(\vec{x}) \approx \sum_{k=1}^{m} \prod_{i=1}^{n} F_i^{(m)}(x_i)$

Solution in Space-Time: $u(x,t) \approx \sum_{k=1}^{m} X^{(m)}(x) \cdot T^{(m)}(t)$

Parametric PGD: $u(x,t,\mu) \approx \sum_{k=1}^{m} X^{(k)}(x) \cdot T^{(k)}(t) \cdot P^{(k)}(\mu)$

The Sparse (s)PGD for a 2D case

Minimization problem solved: $min \|u_m(v_1, v_2) - f(v_1, v_2)\|_2^2$

Known function: $f(v_1, v_2)$

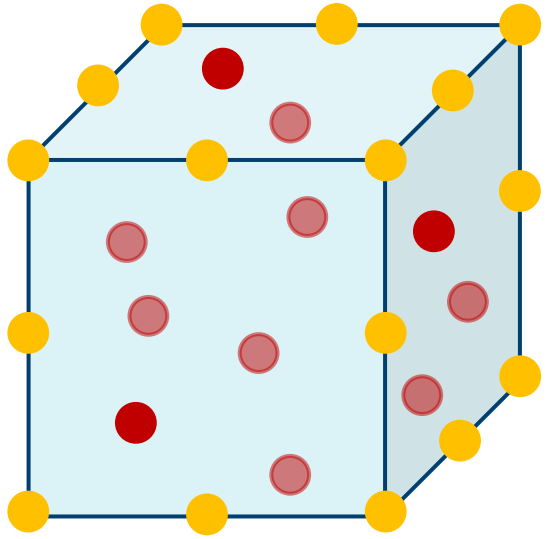
PGD approximation: $u_m(v_1, v_2) = \sum_{k=1}^{m} X_1^k(v_1) X_2^k(v_2)$

PGD function construction for n-dimensions case:

$$X_n^k(v_n) = \sum_{j=1}^{n_{cp}} N_j^k(v_n) a_{v_n,j}^k = (N_{v_n}^k)^T a_{v_n}^k$$

PGD mode: *k*

Shape functions: $N_j^k(v_n)$ $a_{v_n,j}^k$



sPGD Application: Mechanical

Double sPGD: Stress – Strain curve prediction

Matrices required:

- 3 parameters: $\{t_L \ T_N \ f_e\}$
- 50 cases:

30	230	90
30	230	100
40	240	100
50	250	100
50	250	130

- Results: 50 x (~)300 stress-strain points

→ **Double sPGD needed**

Construction approach

1. **sPGD to predict stress**
   - Strain is normalized
   - Stress points interpolated
2. **sPGD to predict max. Strain**
   - Interpolate from the max. strain
3. **Combine predicted stress and strain**

DOE: structured data cases

Sparse: randomly distributed data

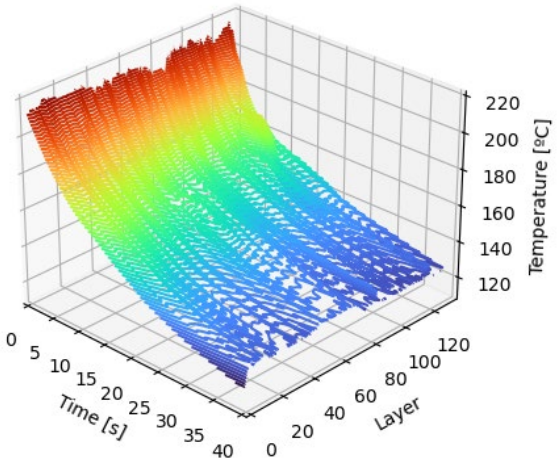
sPGD Application: Thermal

Single sPGD: Thermal evolution per layer prediction

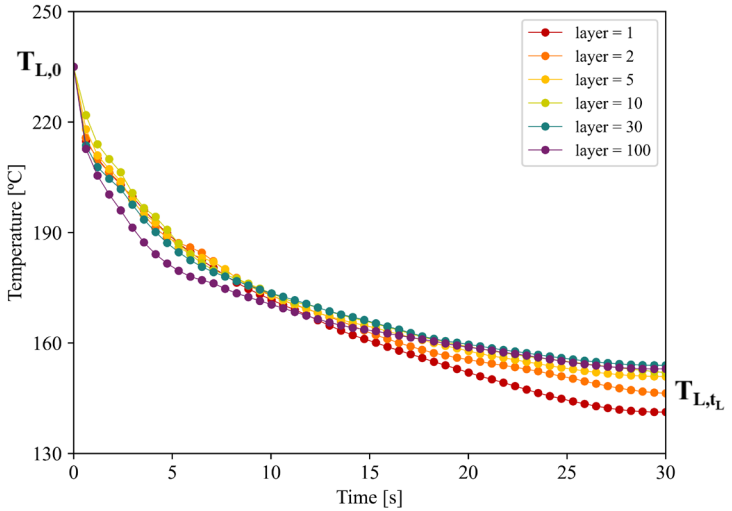
Matrices required:

- 4 parameters: **{t_L T_N f_e} + {layer}**
- 50 cases:

30	**230**	**90**
30	**230**	**100**
40	**240**	**100**
50	**250**	**100**
50	**250**	**130**



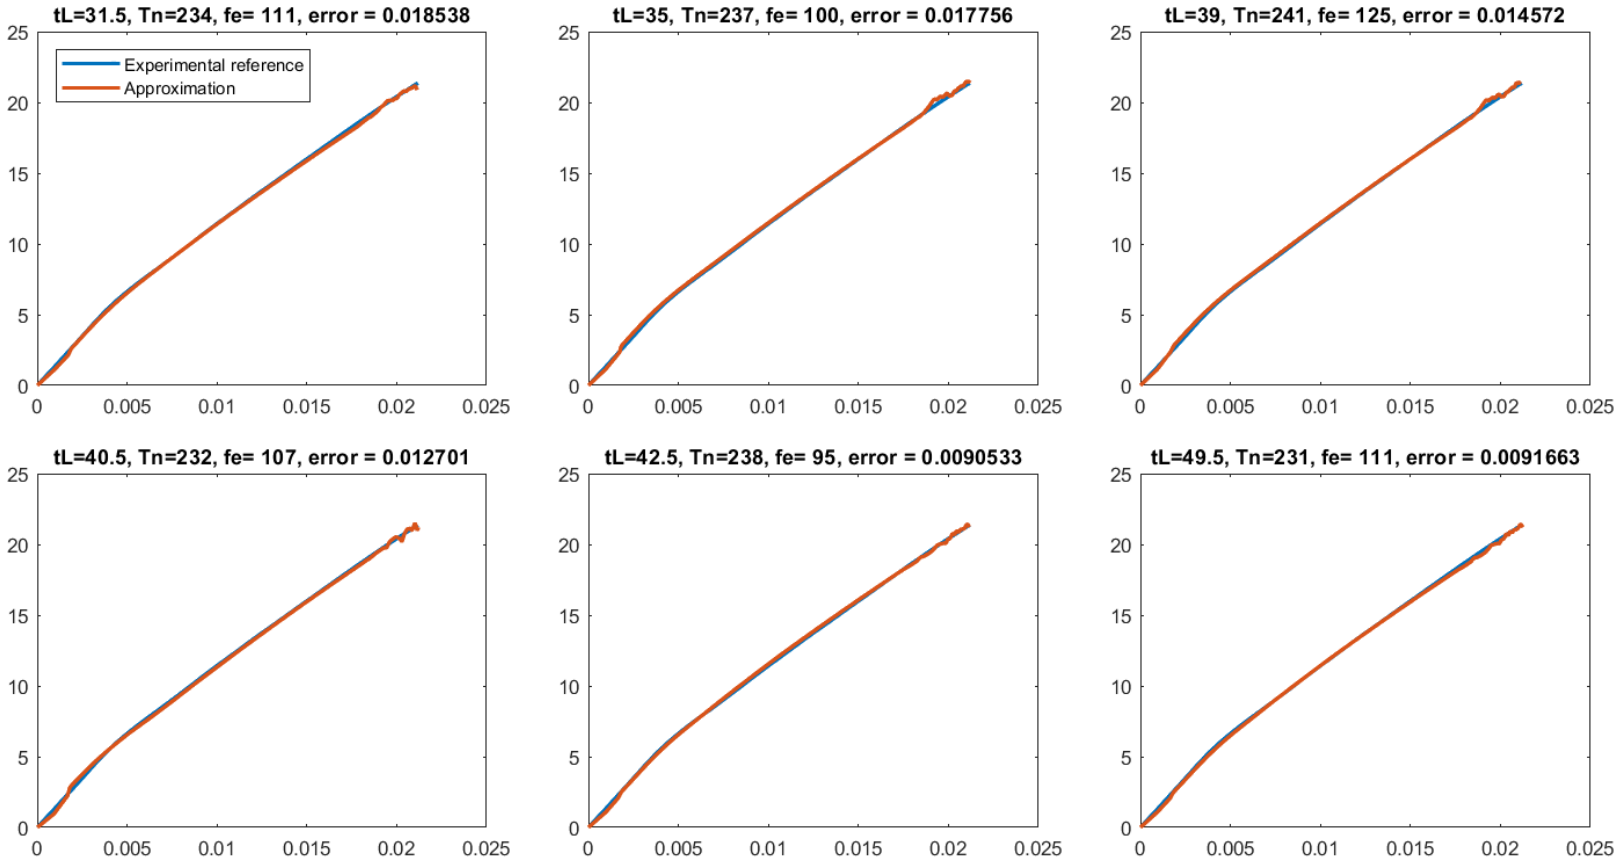
× **133 layers**



- Results: T vs t_L → **Single sPGD needed**

Construction approach

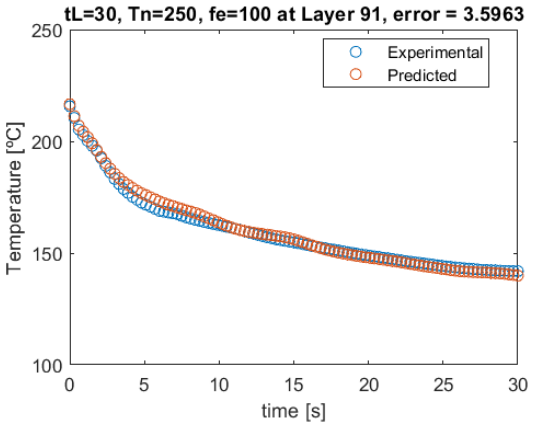
sPGD to predict the termal evolution per layer



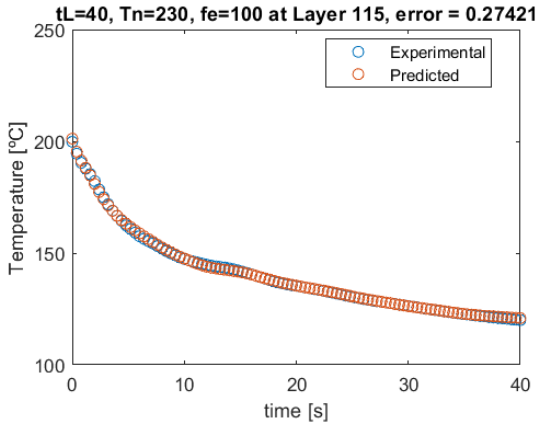
- Temperature vs time where t Є [0, tL]

sPGD Results: Mechanical

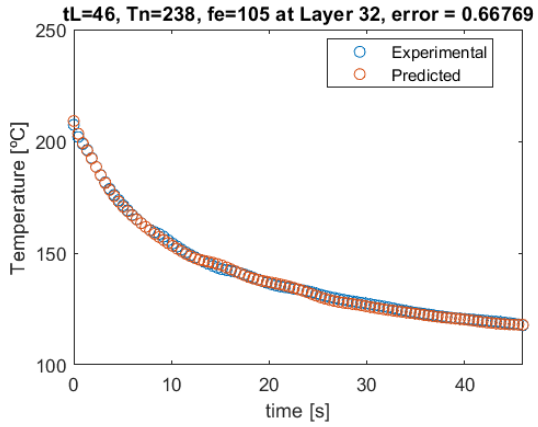
Stress – strain curves prediction



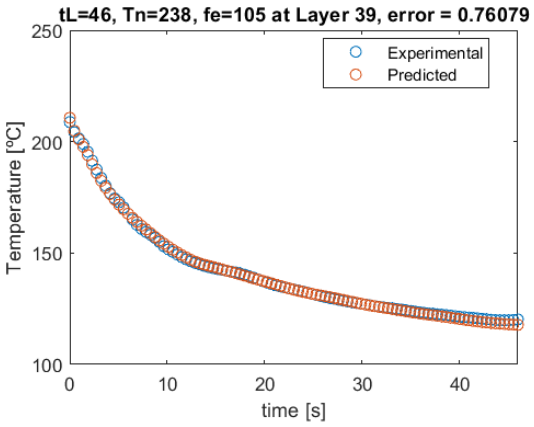
Note: Prior to sPGD application, noise removed by extrapolation of results from the lowest fracture point to the average.



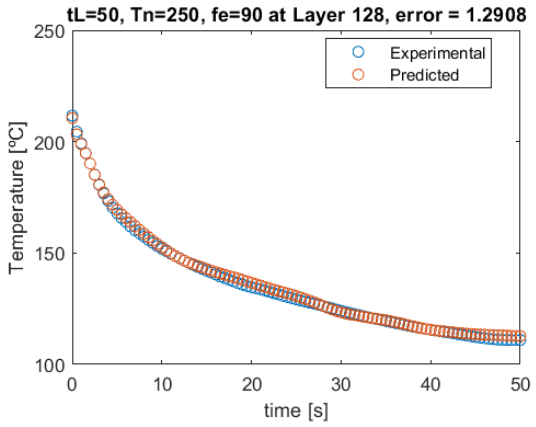
- Shape functions: **Radial basis**
- Number of control points = **6**



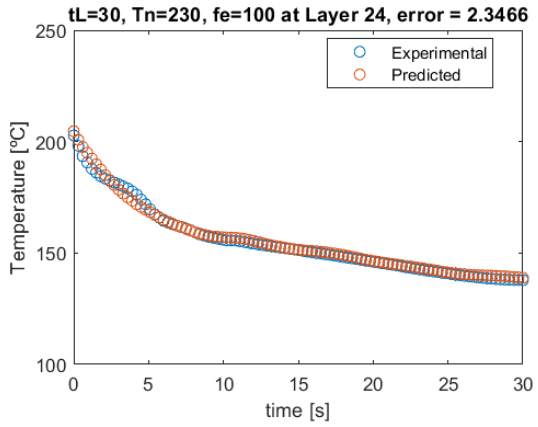
Average error = 1.36%



sPGD Results: Thermal



Thermal evolution per layer curves prediction



Note: Prior to sPGD application, termal data from the infrared data has been smoothened and cleaned to remove noise.

- Shape functions: **Radial basis**
- Number of control points = **12**

Average error = 4.96%

Conclusions

- Effective bonding between deposited layers in LFAM is achieved when the thermal gradient between adjacent layers is minimized.
- Adhesive strength is proven to be strongly correlated to termal evolution of layers.
- Interlayer adhesion quality is greatly influenced by the distance from the bed (layer number) and 3 printing parameters:
  - Time per layer
  - Nozzle temperature
  - Extrusion factor
- The reduced order model built using the Sparse PGD method predicts in real-time:
  - Stress-strain curves with an accuracy of 98.64%
  - Thermal evolution of layers with an accuracy of 95.04%
- Feeding the ROM with sparse data increases the prediction accuracy

Future work

- Feed the ROM with real-time data to optimise the interlayer adhesion at every single layer in LFAM
- Compare solution with other MOR and machine learning techniques

Keywords: CFRP Sandwich Structure, 3D Printed Honeycomb Core, Thermal Vacuum Insulation, Liquid Hydrogen Storage, Composite Pressure Vessel

ABSTRACT

Due to its approximately three times higher energy density by mass compared to conventional kerosene, hydrogen is one of the most promising technologies for reducing CO2 emissions in aviation. However, the energy density by volume is significantly lower than that of kerosene. For example, three thousand liters of gaseous hydrogen correspond only to the energy content of one liter of kerosene at ambient conditions (pressure, temperature). In the automotive sector, this problem is often solved by storing the gaseous hydrogen at a high pressure of 700 bar. Although this approach has already led to a significant improvement, it is still not sufficient for aircrafts, as weight and volume are particularly critical factors here. A further increase in energy density can only be achieved by cooling the hydrogen to 20 K (-253°C), where gaseous hydrogen turns into liquid hydrogen. At 20 K, four liters of liquid hydrogen correspond approximately to the energy density of one liter of kerosene. In order to maintain these cryogenic temperatures and minimize evaporation losses (boil-off), special requirements are placed on the cryogenic storage tanks and in particular on their insulation. Some of these cryogenic storage tanks consist of load-bearing double-wall concepts in which a vacuum ensures thermal insulation, which served as baseline for this study. The authors examined CFRP sandwich structures with 3D-printed honeycomb cores in terms of their manufacturability and their thermal insulation properties at cryogenic temperatures. 3D printing of the cores was chosen due to its advantages with respect to design freedom especially for curved structures such as tank domes but also due to its possibility of local reinforcement in areas of load introduction by means of adjustable cell density and cell wall thicknesses, anti-telegraphing design elements etc. [1]. A further advantage is the possibility to use materials with low outgassing behavior e.g. PEEK [2].

1 INTRODUCTION

The shift toward zero-emission aviation demanded innovative solutions for onboard energy storage and structural integration. Liquid hydrogen (LH_2) offered high energy density but required cryogenic

containment, which posed significant challenges for lightweight aircraft structures. This study was conducted within the framework of the CryoFuselage project, which focused on the development of insulated LH_2 tanks made from CFRP. A key objective was the integration of such tanks into load-bearing fuselage structures to enable multifunctionality and weight savings.

As a representative application case, a regional turboprop aircraft was used as an example in which a cylindrical LH_2 tank was integrated into the aft fuselage (see **Fig. 1**). Therefore, a load-bearing evacuated core concept with 3D-printed cores was chosen for the thermal insulation layer.

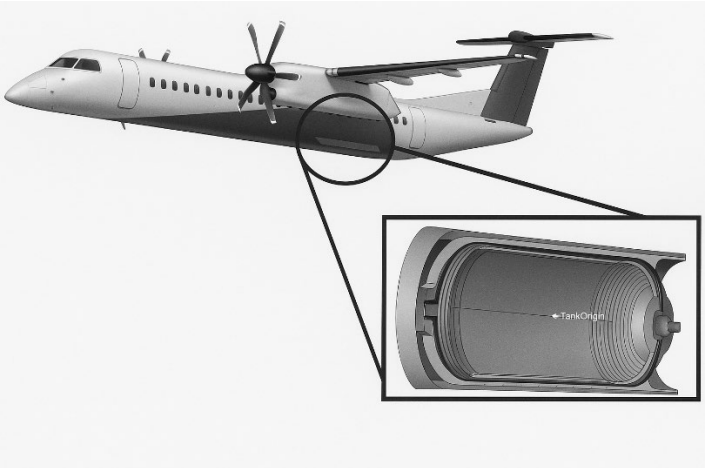

Figure 1: Schematic view of LH_2 tank in fuselage aft section

2 STATE OF THE ART: THERMAL INSULATION FOR CRYOGENIC HYDROGEN TANKS

2.1 Foam Insulation

Closed-cell foams (e.g., PU, PIR) are widely used due to ease of application and low cost. However, performance deteriorates under cryogenic conditions, and long-term dimensional stability is limited. Polyurethane (PU), polyisocyanurate (PIR), or PMI foams (e.g., ROHACELL) are established as closed-cell insulators. Their typical thermal conductivity is between 20–100 K [3-5]. They have been used, for example, in the Lockheed CL-400 [3] and in Space Shuttle tanks as spray-on foam insulation [4-5]. Oehlke [6] validates them for smaller aircraft tanks for an ATR 72, while Swanger and Fesmire [10] document mechanical and thermal aging under cryogenic cycling.

- Advantages: inexpensive, low density, simple application, load-bearing for small tank [6]
- Disadvantages: shrinkage, cracking, delamination under cycling [5-7]

2.2 Multilayer Insulation (MLI)

MLI uses alternating reflective and spacer layers and performs best under vacuum. It is highly effective against radiative heat transfer but fragile. MLI performance relies on maintaining a high vacuum and preserving separation between its reflective layers. Compression, crimping, or misalignment can collapse the insulating gaps, drastically increasing thermal conductivity. MLI cannot carry mechanical loads and must be decoupled from structural stress paths. This limits its integration in tank systems exposed to fuselage loads or direct mounting via Y-joints. Handling damage, installation variability, and lack of load-sharing capacity are key constraints. MLI systems consisting of reflective films and spacers can achieve <1 mW/m·K under high vacuum ($<10^{-3}$ Pa) [4], [6], [8]. Widely used in space applications [3], [8], they are not structurally load-bearing. Johnson [8] describes performance variability depending on the number of layers, compression, and penetrations. Swanger [4] points out outgassing and compression issues. Oehlke [6] documents a drastic increase in thermal conductivity in case of vacuum loss (×100–2000).

- Advantages: lowest thermal conductivity, very lightweight
- Disadvantages: sensitive to compression/folding, not load-bearing, high vacuum requirement [4], [6], [8]

Extensions: VDMLI and VCS
To address the limitations of classical MLI, advancements such as Variable Density MLI (VDMLI) and Vapor Cooled Shields (VCS) have been developed. Zheng et al. compare four insulation systems (MLI, MLI+VCS, VDMLI, VDMLI+VCS) and show that the combination VDMLI+VCS is thermally the most effective [9]. Wang et al. model hybrid concepts with HGM and MLI [10].

- Advantages: reduced thermal conductivity, targeted thermal optimization
- Disadvantages: not load-bearing, complex integration, vacuum still required [9], [10]

2.3 Perlite, Aerogels, HGM, Fiber-Based Insulators

Powder, granular, and fiber-based fillers (perlite, aerogel, hollow glass microspheres, glass wool) combine moderate insulation performance (10–50 mW/m·K) with more robust structure [4-5], [10-11]. Swanger [4] and Wilken [11] demonstrate stability under vacuum loss, though with higher weight. Modeling studies by Wang et al. [10] show advantages through variable density combinations.

- Advantages: robust, moderate performance, partially reusable
- Disadvantages: heavier than MLI, less geometric flexibility [4], [10-11]

2.4 Double-Wall Vacuum Insulation

Vacuum insulation uses a sealed, evacuated gap between tank walls to minimize convective and conductive heat transfer. It offers high insulation performance and can be combined with reflective coatings. A proven space architecture with an evacuated interspace. Applications include Space Shuttle ET, Delta IV, and X-33 [3], [7], [12]. Thermally efficient (<1 mW/m·K) but heavy and complex to assemble. Brewer [3] and Adler [7] describe the advantages; Johnson [12] emphasizes integration complexity.

- Advantages: high efficiency, optionally combinable with MLI [3], [7], [12]
- Disadvantages: double-wall structure, weight, complex around dome geometries [7], [12]

2.5 Evacuated Structural Sandwich Core

Sandwich structures with an evacuable cell core (e.g., perforated honeycomb) combine structural and insulation functions. The concept was introduced by Northrop Grumman in the NASA CCTD [12]; further developments in European studies (PHOEBUS, ICARUS) [13], Brewer [3] mentions early structural honeycomb approaches.

- Advantages: insulation & structure, low thermal conductivity, integrative
- Disadvantages: vacuum tightness, manufacturing complexity [3], [12-13]

3 DESIGN AND MANUFACTURING

3.1 Concept Rationale

As a thermal insulation solution, this work adopts the concept of vacuum insulation based on the Evacuated Core principle [12-13]. This approach is characterized by good thermal performance at cryogenic temperatures and the ability to structurally integrate the insulation into load-bearing components. As described in Section 2.5, this involves e.g. embedding perforated honeycomb cores into a sandwich structure and subsequently evacuating the internal cavity. Standard methods use pointwise needle-perforated or slotted Nomex honeycomb cores to ensure uniform pressure distribution and enable

outgassing. However, conventional approaches are associated with several drawbacks:

- Perforation displaces cell wall material locally, which can lead to unstable membrane regions during evacuation. These areas may deform under vacuum, a phenomenon which can be described informally as “flap effect.”
- Slotted cores exhibit reduced mechanical integrity, particularly at the interface with the face sheets, as both the continuous bonding surface and the cellular structure are interrupted.
- Traditional honeycomb structures are optimized for planar or single curved surfaces. When applied to double curved geometries (e.g., spherical domes), they suffer from the so-called saddle effect: the hexagonal cells twist or collapse due to forced adaptation, leading to geometric distortion and a significant reduction in mechanical properties [1]

3.2 Core Design

As part of the concept validation for a vacuum-insulated sandwich insulation system, an innovative approach using a 3D-printed, perforated honeycomb core was selected. This core architecture combines load-bearing capacity and thermal insulation within a single functional element. The required venting perforations are directly integrated during the additive manufacturing process, as illustrated in **Fig.2**.

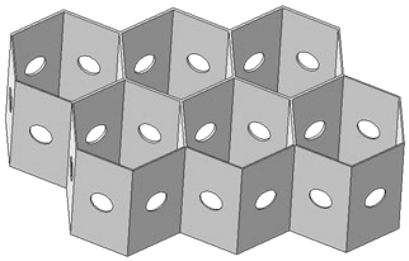

Figure 2: Perforated honeycomb

Key advantages of the 3D-printed design include design flexibility, the use of materials with low thermal conductivity and minimal outgassing (e.g., PEEK/GF), and the potential for functional integration, such as localized reinforcements or anti-telegraphing and snap-in coupling features, as shown in Fig. 3.

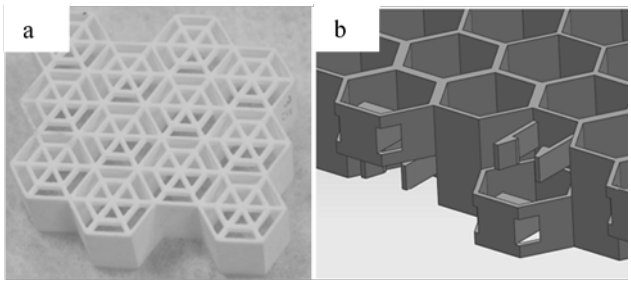

Figure 3: (a) anti-telegraphing solution; (b) honeycomb with snap-in connections [1]

However, challenges remain regarding the limited industrial maturity of the materials and processes involved, as well as the process-dependent variability in mechanical properties. One key challenge is to ensure that the materials withstand the temperature and pressure conditions of the autoclave process. The HT-PLA used in initial trials, with a heat deflection temperature (HDT) of 180 °C, proved unsuitable for autoclave curing at 130°C and an autoclave pressure of 2 bar. In contrast, the fabrication of a small sandwich panel using a 3D-printed PEEK/GF honeycomb with anti-telegraphing solution (spider-web) structure was successful. The printing was carried out on a high-performance polymer printer (INTAMSYS 410 Pro) acquired in 2024. **Fig. 4** shows both small sandwich panels, the collapsed HT-

PLA and the PEEK/GF.

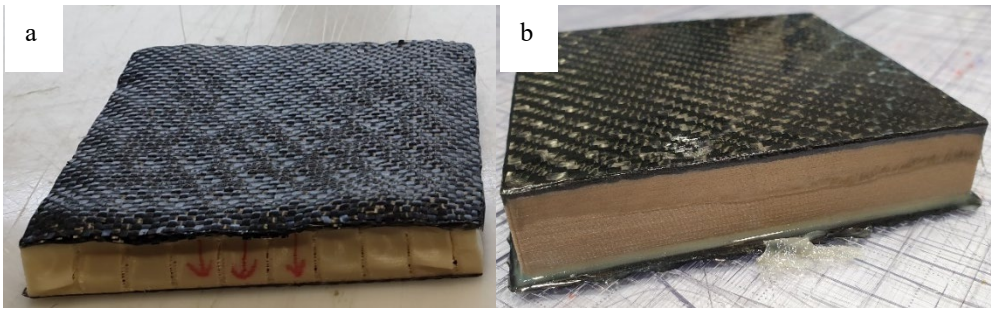

Figure 4: Autoclave process 130°C/2 bar: (a) collapsed honeycomb core with HT-PLA (HDT = 180 °C) - 2022; (b) intact honeycomb core with PEEK/GF (HDT = 300 °C) - 2024

3.3 Vacuum Panel Manufacturing

Due to printer limitations with respect to material and building space, four honeycomb core segments (each 187.6 mm × 144.3 mm × 20 mm) were printed and subsequently bonded together with a paste adhesive to form the full-size core tested in the vacuum insulation test. Future designs will consider the use of snap-in connectors, as illustrated in **Fig. 5**. Both CFRP face sheets for the sandwich panel were manufactured from four layers, each with a thickness of 0.25 mm, of a 2x2 twill weave fabric with 0/90 orientation and cured separately and bonded to the full-size core in a second step, since the originally used thermoplastic (HT-PLA) for early stages proved to be inadequate under the thermal and pressure conditions of the autoclave process, as described above. The four core segments during the bonding process, as well as the completed vacuum sandwich panel with a final format of approximately 292 mm × 378 mm, are shown in **Fig. 5**. The thickness from the top to bottom facesheet of the panel is 22 mm.

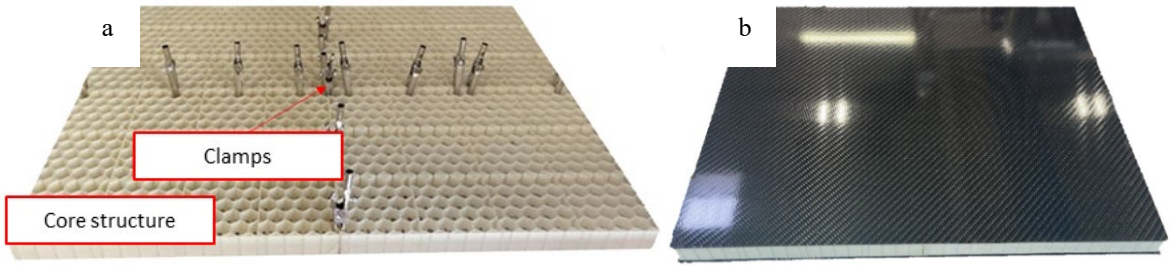

Figure 5: (a) Bonding process of four core segments; (b) final vacuum sandwich panel

4 TESTING METHODOLOGY AND EXPERIMENTAL SETUP

4.1 Test Methodology

The objective of this experiment was to qualitatively assess the thermal insulation performance of a vacuum sandwich panel incorporating a 3D-printed evacuable honeycomb core under cryogenic boundary conditions, and to investigate the impact of vacuum loss on thermal behavior. To achieve this, the test was structured into four consecutive load cases, each representing a distinct system state. The load cases are summarized in **Table 1**, along with relevant remarks regarding the temperature measurement approach:

Load Case	LC Description	Remarks on temperature measurement
LC 0	Calibration of thermocouples	with ice water / not displayed
LC 1	Evacuation of sandwich core at RT	with vacuum insulation
LC 2	Filling LN_2 / Thermal Equilibrium	with vacuum insulation
LC 3	Active venting of sandwich core / simulation of vacuum failure	without vacuum insulation

Table 1: Thermal Vacuum Insulation Test – Load Cases

4.2 Experimental Setup

Test Sample Configuration

To perform the vacuum insulation test, a dedicated test setup was constructed. For this purpose, a container was built made of four structural foam plates and afterwards bonded to the top CFRP facesheet of the composite sandwich panel with a paste adhesive to form a basin to hold LN_2 to expose the top CFRP facesheet to cryogenic temperatures. Vacuum and pressure ports were integrated in the bottom CFRP facesheet. which can be seen in **Fig. 6.**

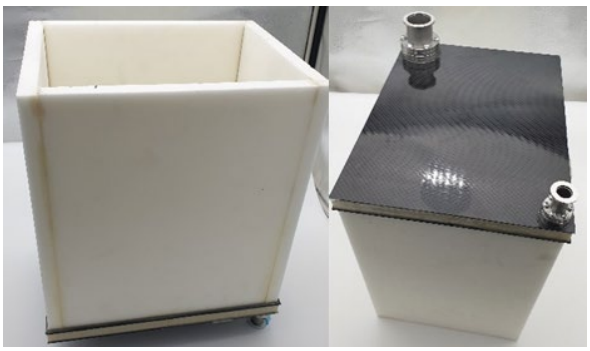

Figure 6: LN_2 foam basin and sandwich plate with ports

The principle test scheme, the temperature couples and placement of ports is given in Fig. 7.

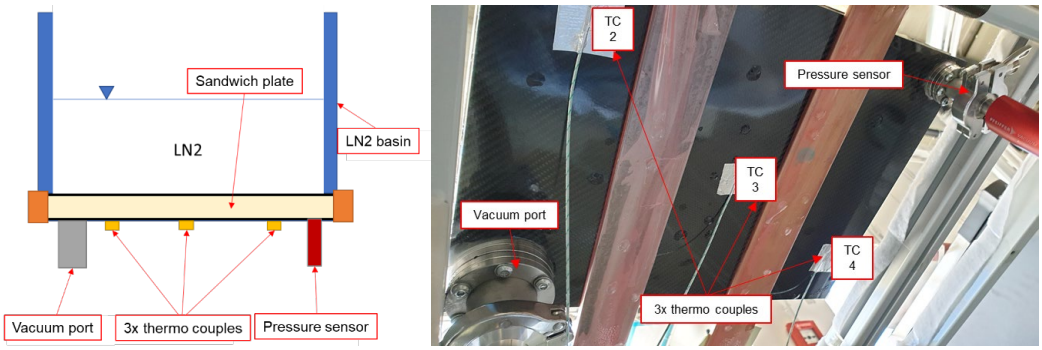

Figure 7: Thermal Vacuum Insulation Test – Test Setup

Temperature Measurement System

Temperature measurement was carried out using in total four thermocouples:

- TC1: ambient reference temperature, in 2m distance to test sample
- TC2 and TC4: located at the left and right edges of the bottom CFRP facesheet,
- TC3: located at the geometric center of the bottom CFRP facesheet.

with the following configuration:

- Sensor type: Thermocouple DT/G-TypK-2.0, Ø 2.0 mm
  - Nominal temperature range: −200 °C to +1100 °C
  - Calibration: Performed in an ice–water bath prior to testing (LC0)
  - Measurement limitation: Signal range limited to –55 °C due to DAQ configuration
- Data Acquisition System
  - Manufacturer: Gantner Instruments
  - Module type: Q.Brixx
  - Sampling & logging: via Gantner Q.station controller/Mlab software; post-processing MATLAB

Vacuum System

Evacuation of the sandwich core was performed using the following configuration:

- Pump type: Pfeiffer Duo 20M rotary vane pump
  - Nominal pumping speed: 21 m^3/h
  - Ultimate pressure (w/ gas ballast): ~1×10^{-2} mbar

In the present test setup, the pump was connected to a CF40 port located at the bottom CFRP facesheet of the sandwich panel while the pressure sensor was connected to a CF16 port.

5 RESULTS AND DISCUSSION

Before the start of the experiment, all thermocouples were calibrated using ice water, and accurate temperature readings were confirmed by comparison with the ambient hall thermometer. During the measurement, a fourth thermocouple (TC1) served as a reference for monitoring the ambient hall temperature. The temperature–time evolution recorded during the vacuum insulation experiment is shown in Figure 3. Temperature areas above 0°C are shown in light red, while temperature areas below 0°C are shown in light blue. The duration of the different load cases is separated by black vertical lines.

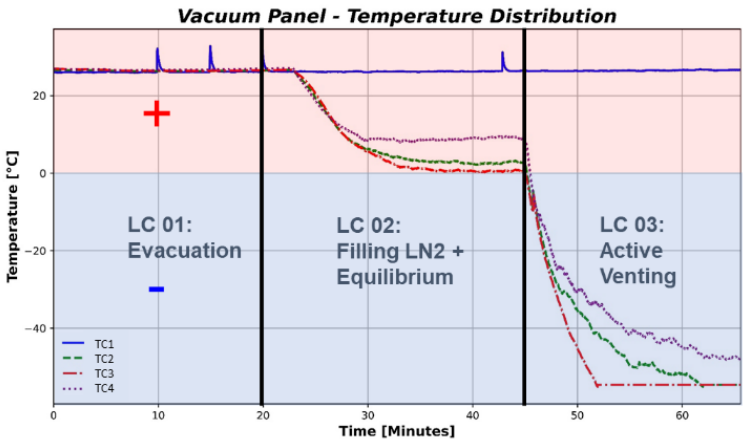

Figure 8: Thermal Vacuum Insulation Test – Temperature Measurement Results

Within the first 20 minutes of the test, during LC1, the sandwich panel was evacuated at room temperature condition and a steady pressure level of 1.7 mbar was reached in the panel. No significant

change in panel temperature was observed during this phase, confirming that no relevant thermal flux occurred prior to LN_2 filling and that all sensors operated correctly. Afterwards the vacuum pump was shut off.

During load case LC2, liquid nitrogen (LN_2) was filled in the LN_2 basin, leading to a rapid decrease in temperature at the bottom CFRP facesheet, as heat was conducted through the panel toward the fluid-sided top CFRP facesheet (−196 °C). After approximately 20 minutes, a quasi-steady thermal gradient was reached, characterized by the horizontal lines of temperature measurements of TC2-TC4. and approximately 0 °C, as recorded by TC3 at the bottom facesheet. For the single thermocouples the following temperatures were measured

- TC3 (center): 0.5 °C
- TC2 (left edge): 2.4 °C
- TC4 (right edge): 9.3 °C

This clear temperature difference between the fluid-sided top CFRP facesheet and the ambient-facing bottom CFRP facesheet indicates the panel's effective thermal insulation under vacuum condition. Slight asymmetries between TC2 and TC4 are attributed to edge effects. The pressure in the core dropped further to 0.86 mbar.

In load case LC3, active ventilation of the honeycomb core was initiated to ambient pressure condition. As a result, all three thermocouples (TC2–TV4) on the bottom face sheet exhibited an immediate and pronounced further decrease in temperature. Due to the signal range limitation in the DAQ setting (−55 °C), the lower threshold of measurement was quickly exceeded, leading to a loss of valid data below that limit.

- TC3 (center): –55.0 °C, within 9 minutes after loss of vacuum
- TC2 (left edge): –55.0 °C within 17 minutes after loss of vacuum
- TC4 (right edge): –48.2 °C by the end of LC3

In addition to the thermal measurements, visual observations revealed significant frost formation on the lower surface of the specimen, as shown in **Fig. 9** during LC3. This frost accumulation is attributed to the condensation and subsequent freezing of atmospheric moisture, driven by the steep thermal gradient across the face sheet during actively induced vacuum loss

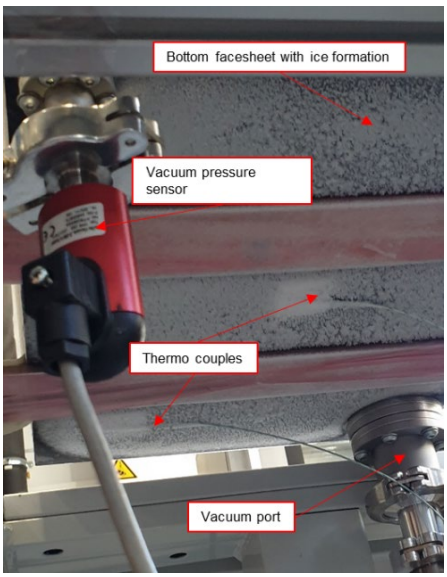

Figure 9: Thermal Vacuum Insulation Test – LC3: Frosting of bottom face sheet

The experiment confirms the proof-of-concept for a 3D-printed, evacuated honeycomb core as an integrated thermal insulation layer for cryogenic applications. Under vacuum conditions, the sandwich structure maintained a thermal gradient of nearly 200 K across a panel thickness of just 22 mm, with only minimal heat flux through the core. These results highlight the effectiveness of vacuum sandwich panels with 3D-printed evacuable cores in suppressing thermal conduction and enabling stable cryogenic temperature separation, although the sample configuration with HT-PLA as early test was not ideal. The steady-state pressure inside the core during Load Case 1 reached 1.7 mbar, which was higher than the nominal ultimate pressure of the vacuum pump. This deviation is attributed to internal outgassing from the polymer structure, in particular moisture and volatile components in the HT-PLA material, as well as anticipated minor line losses due to reduction in cross-section of the vacuum piping. The sandwich core was not pre-conditioned (e.g. by thermal bakeout), which further explains the elevated residual pressure despite continuous evacuation. In contrast, the rapid temperature decrease observed in Load Case 3, following intentional, active venting of the sandwich core, revealed the concept's sensitivity to vacuum integrity. Once the vacuum was lost, the insulation effect deteriorated within minutes, leading to a nearly uniform cryogenic transition on the ambient-facing side of the panel. This clearly illustrates the binary behavior of vacuum-based insulation systems and their dependence on stable pressure containment. Overall, the findings demonstrate that 3D-printed vacuum sandwich systems offer substantial insulation potential for use in cryogenic composite pressure vessels, as long as long-term vacuum sealing, structural robustness, and environmental durability can be ensured. While the insulation performance under vacuum was excellent, the observed failure mode highlights a key design constraint for aerospace implementation

6 CONCLUSIONS AND FUTURE WORK

The proposed vacuum-insulated CFRP sandwich panel with 3D-printed, evacuable honeycomb core was successfully tested. Results show that such structures can offer both high insulation performance and structural function, making them interesting for aerospace hydrogen tanks. Compared to foam or MLI, this concept offers superior integration potential, especially where tanks must carry load and interface with airframe structures, such as in fuselage integrated LH_2 tanks. The feasibility study successfully demonstrated the potential of a 3D-printed evacuable honeycomb vacuum core in a CFRP sandwich structure as cryogenic thermal insulation. The panel exhibited promising thermal resistance under vacuum and cryogenic temperatures. Compared to foam or MLI, the proposed system offers the unique ability to integrate insulation and mechanical function. This multifunctionality has high potential for aerospace LH_2 tanks subjected to both internal pressure and structural mounting in the airframe. Notable advantages include the design freedom for single and double-curved structures, the ability for local cell size refinement in areas with high structural demands, and the low outgassing behavior when using PEEK honeycombs. Main drawbacks are linked to loss of vacuum for such structures as intentionally induced in the LC3 load case, which is, however, a known challenge also for double-walled tanks with MLI. Additionally, the wall thickness is currently higher than that of conventional NOMEX honeycombs, negatively impacting mass efficiency. Furthermore, the component size is limited by the 3D printing hardware, necessitating segmentation for medium and large-scale structures. The material cost, especially when using PEEK, is also considerable. Nevertheless, the results provide a solid foundation for further investigations.

Therefore, the next steps will involve several focused investigations and development activities on flat samples for the 3D printed core and composite sandwich structure such as additional mechanical tests to evaluate flatwise tensile, compression and shear properties at room and cryogenic temperatures and under thermal cycling conditions. The work will also include investigations on wall thickness reduction methods and hence weight reduction and the manufacturing of single and double curved samples as well as small-scale CFRP technology demonstrator tanks. These will be used to simulate operational conditions and to verify both structural integrity and thermal behavior under realistic scenarios. In parallel, full thermal analyses will be performed.

ABSTRACT

This study investigates the effects of additive manufacturing parameters such as printing orientation and infill pattern on the impact resistance of polylactic acid (PLA) and carbon fiber reinforced plastics (CFRPs) hybrid structures. PLA was used as the filament for fused filament fabrication (FFF) to produce geometrically complex base structures, while CFRP layers were wet-layed on top of the printed PLA to reinforce the structure and enhance mechanical properties. This hybrid approach was motivated by the need to fabricate complex geometries for robotic systems using additive manufacturing, while avoiding the cost and complexity associated with large-scale composite 3D printers or tooling. Impact testing, conducted according to ASTM D4812 standards, was used to assess energy absorption. Specimens were fabricated with four distinct printing orientations (upright, on-edge, flat, and tilt) and 11 infill patterns (concentric, honeycomb, triangle, and more). Among the tested parameters, printing orientation was the dominant factor affecting impact resistance. Specimens printed in the on-edge orientation exhibited the highest impact strength, while upright specimens showed the lowest due to poor interlayer adhesion along the build direction. Infill pattern also influenced mechanical performance, with concentric and honeycomb patterns demonstrating enhanced energy dissipation and improved load distribution under impact loading. Fractographic analysis revealed brittle failure in upright specimens and interfacial delamination in on edge and flat configurations. Microscopic examination confirmed that the PLA and CFRP layers were joined primarily through mechanical interlocking. Applications of the hybrid structure to a modular mobile robotic spine component validated its effectiveness in achieving both reduced weight and impact resistant by integrating the geometric versatility of fused filament fabrication with the high strength-to-weight ratio of CFRP.

1 INTRODUCTION

In robotics, the choice of materials for robot structures is critical, as it significantly influences both the mechanical performance (e.g., strength, stiffness, density, etc.) and the efficiency of the manufacturing process (e.g., time, cost, etc.). Materials used in robot structures are broadly classified into two categories: soft materials and rigid materials [1]. Soft materials, such as polydimethylsiloxane (PDMS) and rubbers, offer advantages due to their flexibility and impact-absorbing properties, making them ideal for applications that require compliance or safe human-robot interaction [2]. However, their low stiffness and limited durability restrict their use in systems requiring high load-bearing capacity, structural rigidity, or repeated performance. In contrast, rigid materials, such as aluminum, carbon fiber reinforced plastic (CFRP), and stainless steel, are preferred for applications requiring strength, stiffness, and durability. These materials are particularly well-suited for large-scale and load-bearing systems. Aluminum is widely used in robotics compared to other metals such as stainless steel and steel, primarily

due to its cost-effectiveness, lightweight nature, and satisfactory mechanical properties. However, aluminum is still heavier than non-metallic materials (e.g., plastics, composites, etc.) and requires expensive CNC machining for manufacturing [3]. Polylactic acid (PLA) is well-known for its cost-effective and time-efficient prototyping capabilities, as well as its design flexibility. However, its applications are typically limited to small-scale systems due to its limited mechanical strength [4]. As the size of the system increases, challenges such as structural deflection, which reduces control accuracy, and a higher risk of structural failure become significant concerns. CFRP is highly effective in robot structures, particularly for applications requiring lightweight designs, suitability for large-scale systems, and high-temperature resistance. Nevertheless, their fabrication is often labor-intensive, reliant on expensive molds, and requires specialized expertise, particularly for creating structures with complex geometries [5].

Hybrid material structures with mechanical interlocking offer a promising solution by addressing the limitations of individual materials and manufacturing constraints. For mechanical material hybridization, two main categories are commonly studied: soft-rigid and rigid-rigid material hybrids. Soft-rigid material hybrids are designed to leverage the strengths of each material by utilizing rigid materials for structural support, ensuring strength and stiffness, while incorporating soft materials at connection points or contact surfaces to provide flexibility and compliance [6]. Rigid-rigid material hybrids focus on optimizing mechanical properties by combining materials with complementary characteristics. For instance, in robotic arms, CFRP is utilized to minimize weight toward the extremity (i.e., the end-effector), while metals are employed between the motor and the CFRP to ensure effective power transmission. These materials are seamlessly integrated through mechanical interlocking, enabling them to function as a unified structure and maximize the strengths of each material [7].

This study focuses on rigid-rigid material hybrid for PLA-CFRP hybrid structures, combining 3D-printed PLA with CFRP. PLA is prized for its ductility, design flexibility, and ability to form complex geometries using cost-effective 3D printing, but it lacks sufficient strength for demanding applications. In contrast, CFRP provides superior strength and an excellent strength-to-weight ratio, though its brittleness and reliance on expensive molding processes present challenges. By hybridizing these materials, the study leverages the strengths of each: PLA serves as a versatile base structure that enhances manufacturing flexibility, and its compatibility with inexpensive molds reduces overall costs for CFRP fabrication. Meanwhile, CFRP selectively reinforces areas requiring enhanced mechanical performance.

To validate the mechanical properties of PLA-CFRP hybrid materials, this research examines the impact strength and fracture behavior of PLA-CFRP composites fabricated with 11 infill patterns (aligned line; AL, adaptive cubic; AD, Archimedean chords; AR, concentric; CO, gyroid; GY, Hilbert curve; HI, honeycomb; HO, lightening; LT, Octagram spiral; OC, rectilinear; RE, triangle; TR) and four printing orientations (upright, on-edge, flat, tilt), as shown in Fig. 1(a) and 1(b) [8]. Hybrid specimens were produced by 3D-printing PLA and bonding it with CFRP layers using an epoxy-based wet layup process. Impact strength was evaluated using a Digital Izod Impact Tester (QM700A) under ASTM D4812 standards [9], and fracture behavior was analyzed [10], [11].

2 METHOD

This section outlines the key additive manufacturing parameters, including print orientation and infill pattern, as well as the method used for CFRP hybridization. Additionally, it details the fabrication procedures, specimen configurations, and testing standard employed for impact testing.

2.1 Printing Orientation

Printing orientation defines the positioning of a part relative to the Z-axis during the layer-by-layer additive manufacturing process [12]. Because bonding strength between layers along the Z-axis is generally weaker than within layers, printing orientation affects the bonding area and geometry between layers, which in turn significantly influences the mechanical performance and structural reliability of the printed components. Figure 1 presents the four printing configurations investigated in this study: upright, on edge, flat, and tilt. The Tilt orientation, ranging from 0° to 90°, was represented by a 45° angle in this work.

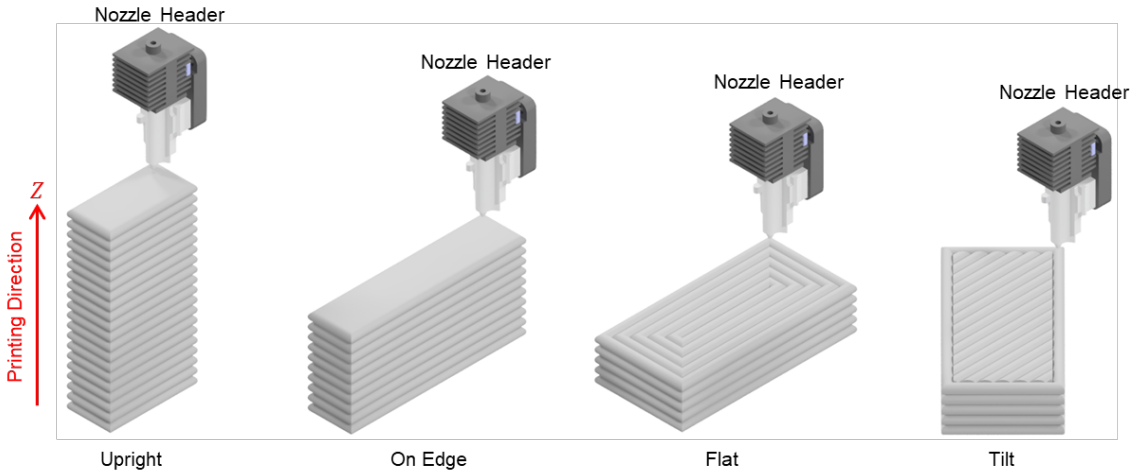

Figure 1: Schematic Illustration of Printing Orientations.

2.2 Infill Pattern

Infill pattern defines the internal geometry of a printed structure and is one of the most critical parameters in additive manufacturing [13]. It significantly influences not only mechanical performance but also weight, thermal behavior, and production time. As shown in Figure 2, this study investigates eleven infill patterns provided by the Bambu printer and Bambu Studio: Aligned Line (AL), Adaptive Cubic (AD), Archimedean Chords (AR), Concentric (CO), Gyroid (GY), Hilbert Curve (HI), Honeycomb (HO), Lightning (LI), Octagram Spiral (OC), Rectilinear (RE), and Triangle (TR). Some infill patterns, including AL, AD, GY, HI, RE, and TR, are influenced by printing orientation, resulting in slight variations in their internal geometry. In contrast, other patterns such as AR, CO, HO, LI, and OC remain largely unaffected by changes in printing orientation.

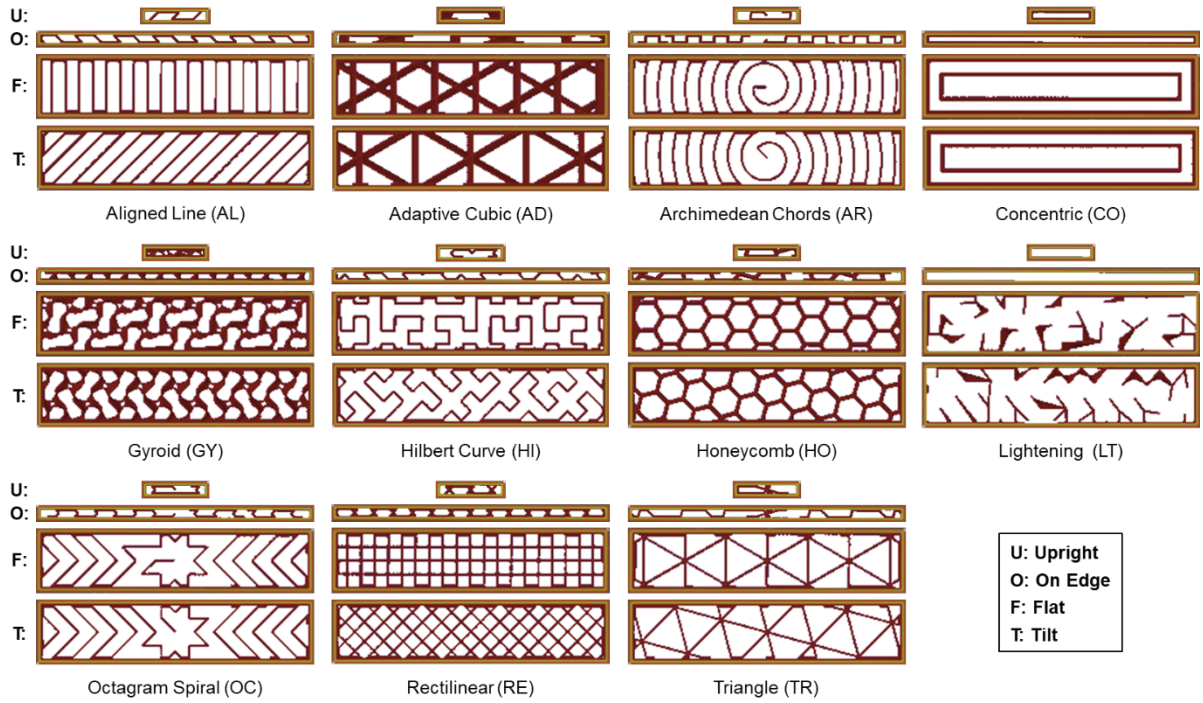

Figure 2: Infill Patterns by Printing Orientation.

2.3 PLA-CFRP Hybrid

The PLA-CFRP hybrid fabrication process involves two primary steps. In the first step, a PLA specimen is fabricated using additive manufacturing with a 3D printer [14]. In the second step, carbon

fiber reinforced polymer (CFRP) is laid up onto the PLA substrate. The CFRP fabrication requires both a fiber reinforcement and a resin matrix, with their compositions and properties detailed in Tables 1 and 2. The fiber reinforcement used in this study is a high-density 3K plain-woven carbon fabric (240 g/m², 1040 mm width, 0.30 mm thickness), making it ideal for manual lay-up processes [15]. The resin consists of RESOLTECH Epoxy System 1050 with 1056S hardener (100:35 weight ratio), exhibiting low viscosity, good deaeration, and high mechanical performance through ambient and post-curing, with a TG of up to 66.7°C and Shore D hardness above 90 [16].

Table 1: Fiber Specification.

Category	Specification
Fiber Type	Carbon Fiber
Tow Size	3K (3,000 filaments per tow)
Weave Type	Plain Weave
Areal Weight	240 g/m²
Thickness	0.30 mm

Table 2: Resin Specification.

Category	Specification
Epoxy	RESOLTECH Epoxy System 1050
Hardener	1056S
Mixing Ratio (by weight)	100 : 35 (Resin : Hardener)
Mixed Viscosity (23°C)	462 mPa·s
Gel Time (70 g at 23°C)	Approximately 37 minutes
Full Cure (Room Temperature)	14 days (TG: 49.1°C, Shore D Hardness: 89)

3 RESULTS

This section presents and validates the experimental results on impact strength, fracture behavior, and microstructural characterization of the interfacial region in the PLA-CFRP hybrid structure.

3.1 Impact Testing

Figure 3 presents the impact strength results as a function of printing orientation and infill pattern. Subfigures 3(a) to 3(d) correspond to PLA specimens fabricated in upright, on-edge, flat, and tilt orientations, respectively. The results indicate that printing orientation has a more pronounced effect on impact strength than infill pattern. Specimens printed in the upright orientation exhibited the lowest strength due to weak interlayer bonding, while the on-edge orientation showed the highest strength, as the layers were aligned perpendicular to the impact direction, thereby requiring more energy to initiate fracture. Flat and tilt orientations demonstrated intermediate performance, with the tilt orientation slightly outperforming the flat configuration. Among infill patterns, concentric and honeycomb designs provided relatively higher impact resistance, particularly in the on-edge orientation. However, their overall influence remained secondary to that of the printing orientation.

Figure 3(e) and 3(f) show the impact strength results for PLA-CFRP hybrid specimens fabricated in flat and tilt orientations. The results indicate that the overall trend related to printing parameters remains consistent with those observed in PLA-only specimens. Specifically, there is minimal difference in impact strength between flat and tilt orientations, and the effect of infill pattern is relatively insignificant in both cases. However, the application of CFRP reinforcement results in a substantial enhancement in impact resistance, with hybrid specimens exhibiting improvements of at least fivefold and up to tenfold compared to their PLA-only counterparts.

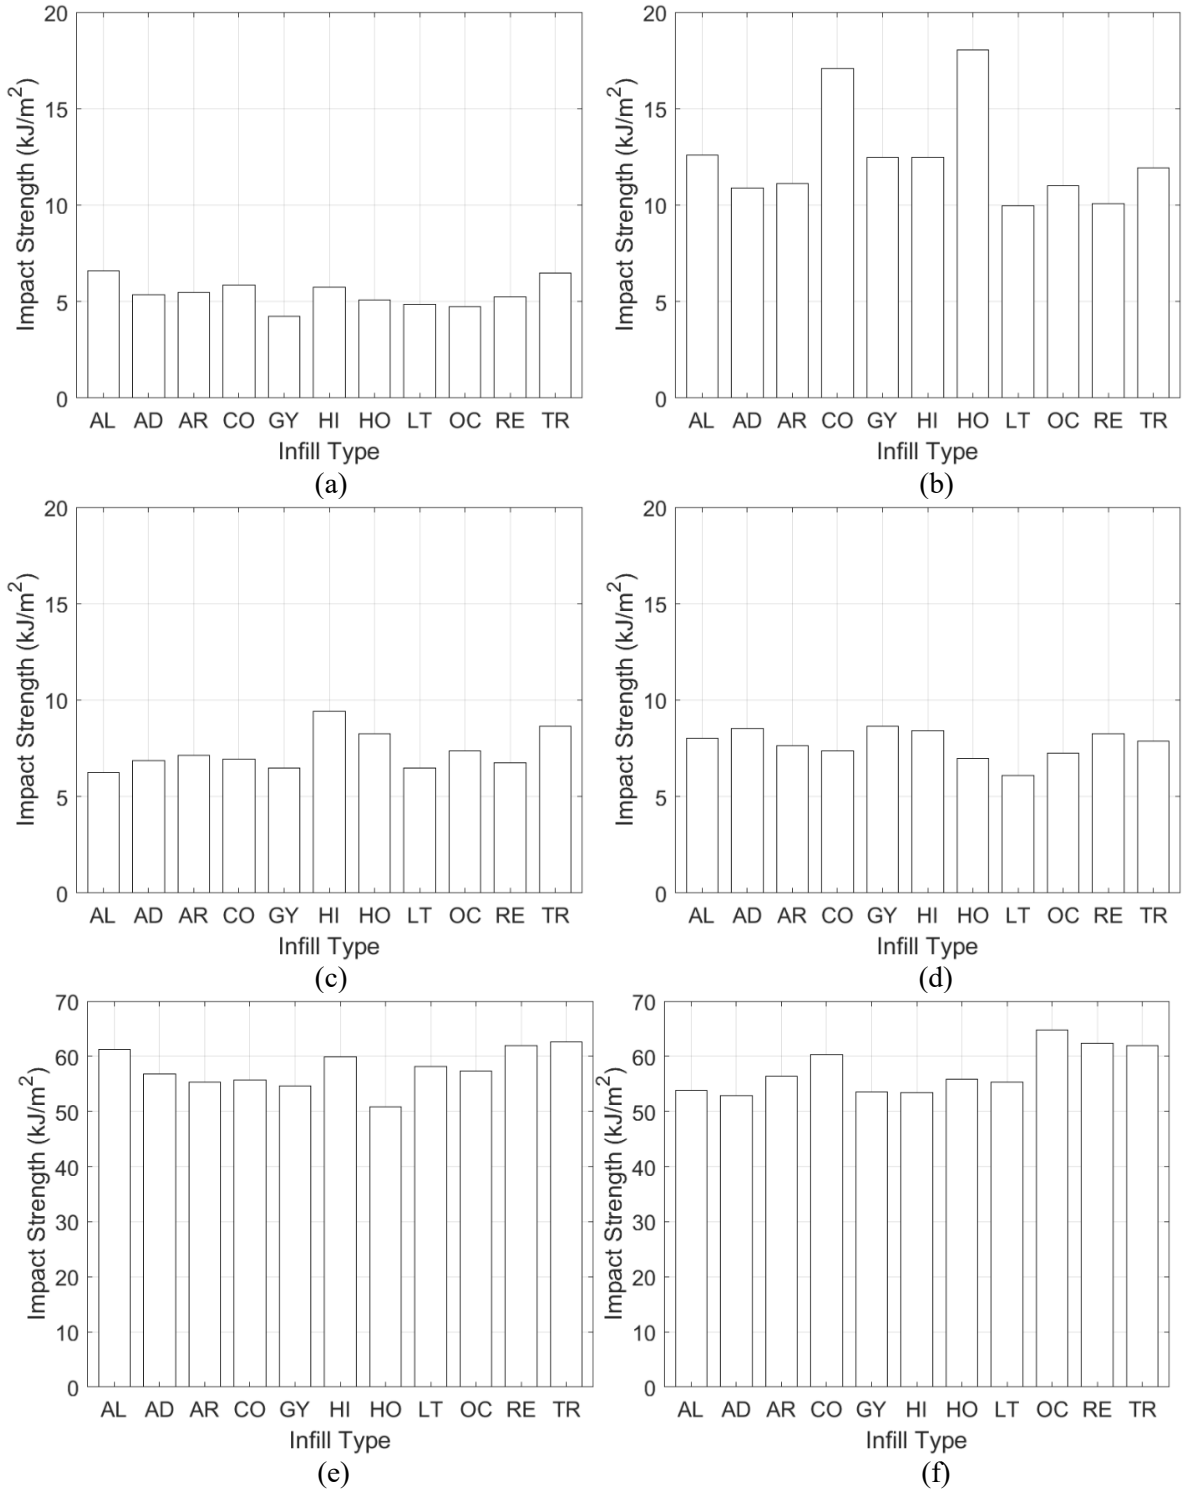

Figure 3: Impact Strength by Printing Orientation and Infill Pattern. (a) PLA upright. (b) PLA on edge. (c) PLA flat. (d) PLA tilt. (e) PLA-CFRP hybrid flat. (f) PLA-CFRP hybrid tilt.

3.2 Fracture Behavior

Figure 4 illustrates the fracture behavior of specimens with the rectilinear (RE) infill pattern across various printing orientations. In PLA-only samples, the upright, on edge, and flat orientations exhibited relatively brittle fractures with straight, vertically aligned cracks, primarily due to stress concentration along interlayer planes. In contrast, the tilt orientation showed more complex fracture surfaces with irregular crack paths following the rectilinear infill, indicating increased energy absorption and crack

deflection. Although the PLA-CFRP hybrid composites demonstrated significantly higher impact strength than the PLA-only specimens, their fracture behavior followed similar trends across printing orientations and infill configurations.

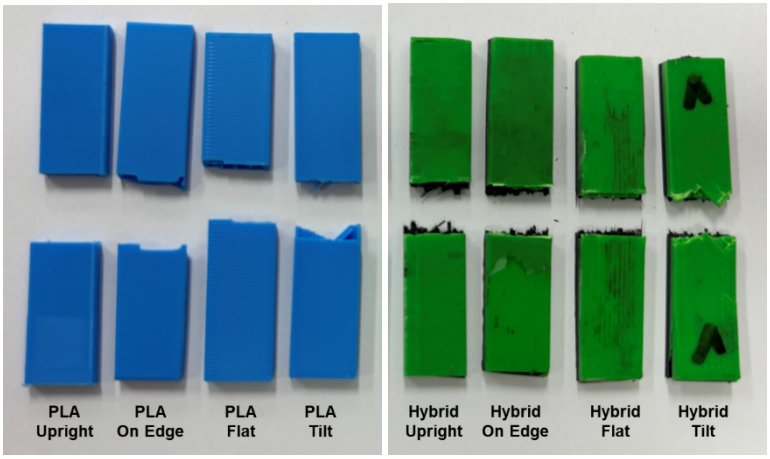

Figure 4: Fracture Behavior with Rectilinear (RE) Infill Pattern.

3.3 Microscopic Image

Figure 5 presents microscopic images of the interlocking surfaces formed at the interface between the PLA and CFRP in hybrid materials. In each image, the upper dark region corresponds to the CFRP layer, while the lower greenish region represents the 3D-printed PLA structure. All images were captured at the same magnification (scale bar = 500 μm) to facilitate direct comparison of the microstructural morphology and deposition patterns. Across all infill patterns, well-developed mechanical interlocking was observed, with minor micro voids confined to the CFRP bulk and no visible cracks. As these voids were away from the interface, bonding remained strong, contributing to improved interfacial adhesion and structural integrity.

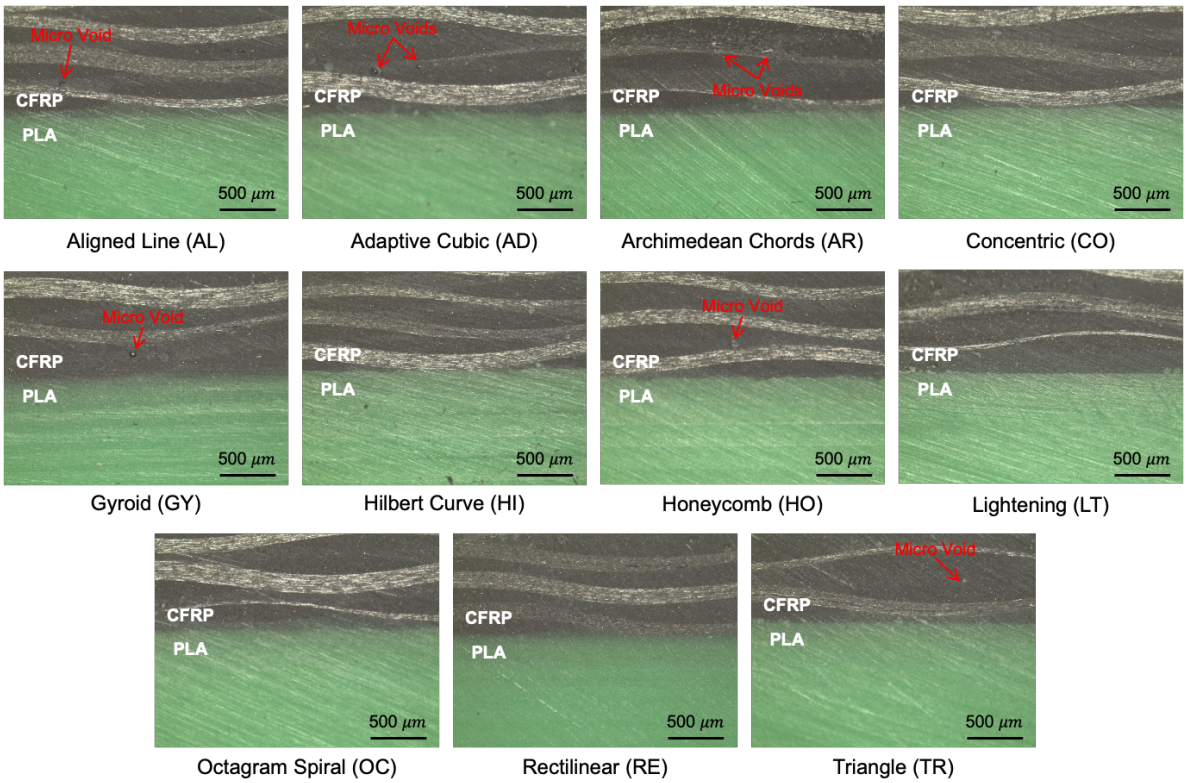

Figure 5: Microscopic Image of Interlocking Surfaces in PLA-CFRP Hybrids.

4 ROBOTICS APPLICATIONS

Figure 6 illustrates the overall fabrication process and final implementation of the proposed PLA-CFRP hybrid structure for robotic frame applications. The entire process consists of three main stages: (1) fabrication of a PLA core frame via 3D printing, (2) manual lamination of fiber and resin to form the CFRP shell frame, and (3) integration of the hybrid structure into a mobile robotic platform. This hybrid design approach, combining additive manufacturing and composite lamination, enables design flexibility, manufacturing efficiency, and improved mechanical performance, making it a promising strategy for developing next-generation robotic frames with complex functions and robust structural integrity.

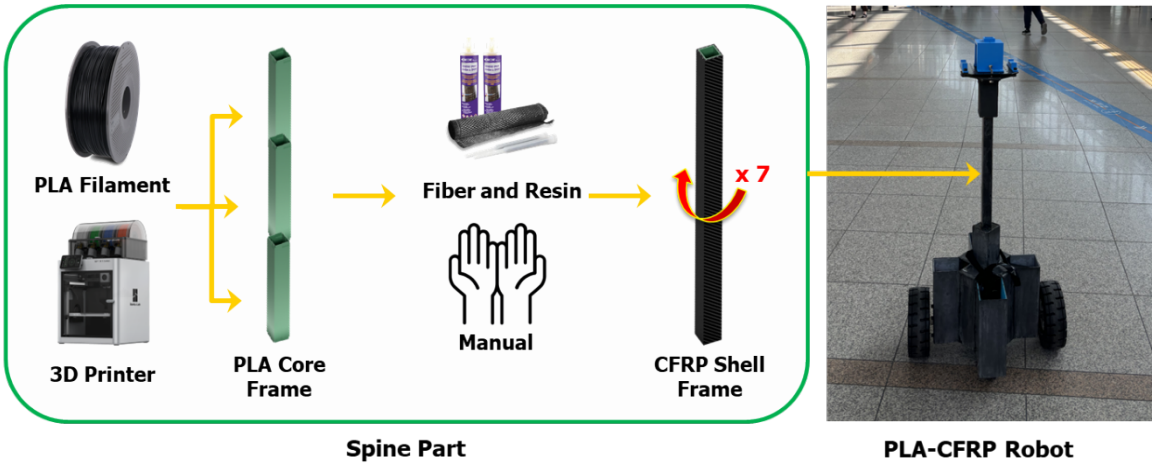

Figure 6: Fabrication Process and Robotic Integration of the PLA-CFRP Hybrid Spine Structure.

5 CONCLUSIONS

This study comprehensively evaluated the influence of 3D printing orientation and infill pattern on the mechanical behavior of PLA-CFRP hybrid structures. Impact tests identified printing orientation as the most critical factor affecting toughness and fracture characteristics, with the on-edge orientation delivering the highest impact resistance due to improved interlayer bonding, while the upright orientation exhibited the lowest performance. Among various infill patterns, concentric, honeycomb, and triangle patterns consistently showed enhanced impact strength, particularly in on-edge and flat orientations. Microscopic analysis demonstrated that mechanical interlocking at the interface, strengthened interfacial bonding and mitigated delamination. The observed fracture modes varied significantly with printing orientations, underscoring the crucial role of structural configuration in optimizing hybrid performance. The developed PLA-CFRP hybrid was successfully implemented as the central spine in a modular mobile robot, validating its applicability for lightweight, high-strength robotic components. Future work will extend to dynamic loading assessments, fatigue behavior analysis, and further optimization of multi-material interfaces to enhance the durability and functionality of hybrid structures.

Research gaps, motivation and objectives

Research gaps

- ✓ Simulation of composite damage requiring more time due to higher than anticipated complexity.
- ✓ Limited or No methodical SHM study cases for composites in Collins.
- ✓ Advancements in SHM and reliability analysis have not yet been adequately leveraged by Collins to applications.

Fan cowl

1. Products | Collins Aerospace

Motivation

- ✓ Advanced application of composite materials in aerospace products including fan cowl stiffeners, struts and brackets.
- ✓ Simplicity and efficiency of analytical models (which can facilitate structural analysis and SHM of aerospace components).
- ✓ Higher-order accuracy and enhanced physics representation of strong form solutions.

Objectives

- ✓ Formulate analytical methodology for structural analysis and prediction of damage propagation and failure in composite structures (thermosets and thermoplastics).
- ✓ Develop an efficient structural health monitoring (SHM) tool for quality check during manufacturing
- ✓ Vibration-based SHM approach based on analytical tool integrated with UBOA optimization.

Unified butterfly optimization algorithm

- Local search

$$x_i^{t+1} = \mu[x_i^t + (r^2 \times x_j^t - x_k^t) \times f_i]$$

- Global search

$$x_i^{t+1} = (1-\mu)[x_i^t + (r^2 \times g_{best} - x_i^t) \times f_i]$$

$$\mu(t) = \exp\left(\frac{t \log 2}{t_{max}}\right) - 1$$

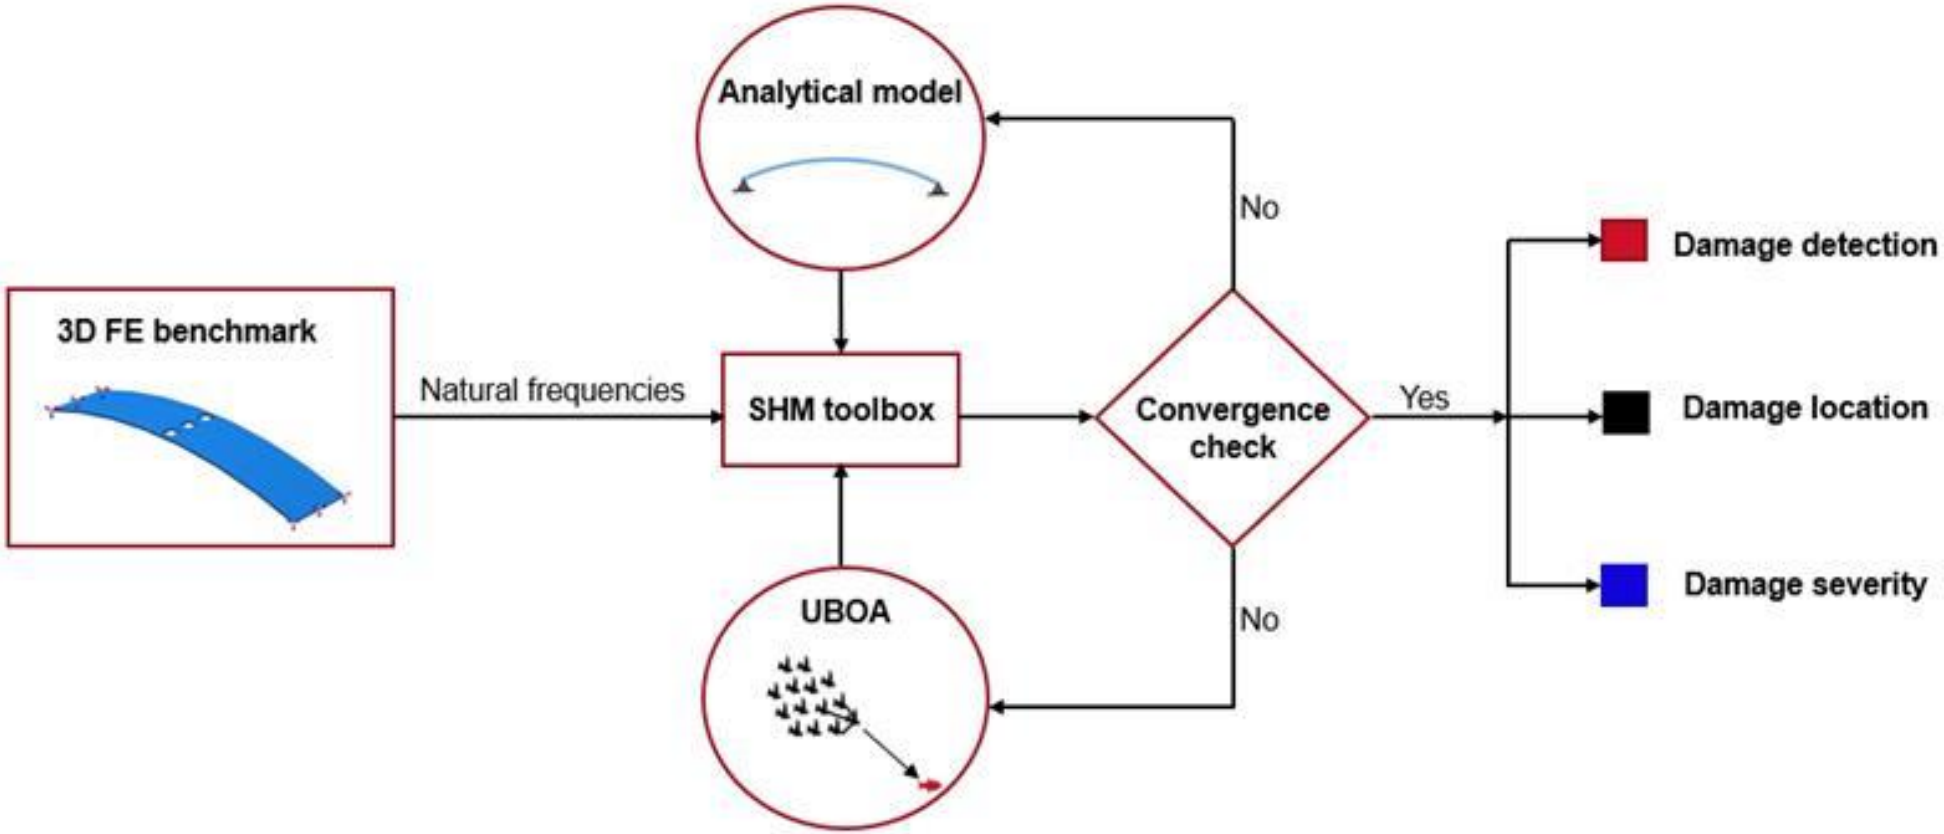
- Fitness function

$$F = \sqrt{\frac{1}{n}\sum_{i=1}^{n}(\omega_i^m - \omega_i^c)^2}$$

Position update

- Each particle/butterfly updates position using
  - Velocity-based mechanism for exploitation
  - Fragrance-based mechanism for exploration

Switching mechanism



- Algorithm alternates b/w UPSO & BOA position updates depending on fitness of the current population

Fitness evaluation

- Fitness is based on the objective function, and updates solution to move closer to g_{best}

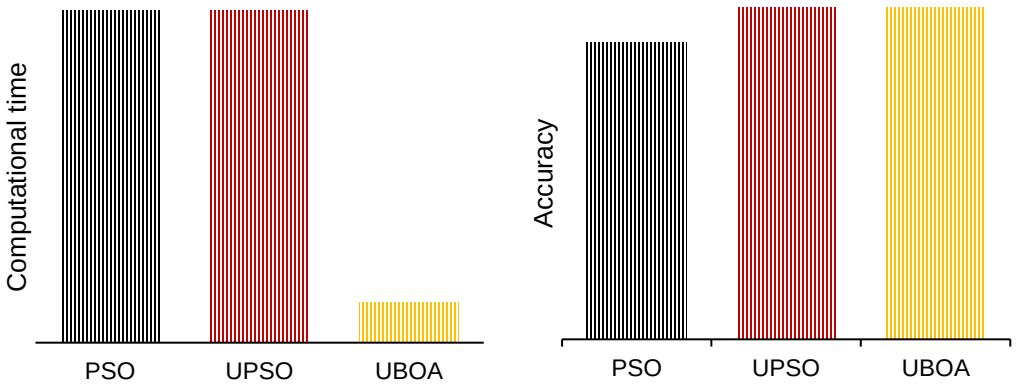
Advantages



© 2025 Collins Aerospace. | Collins Aerospace Proprietary | This slide contains technical data: UNCTD(EU)

Advantages

1D nonlinear analytical tool

- Simple computational tool for structural design as well as for SHM
- Free vibration, frequency response, buckling, post buckling, transient solutions
- Performance and efficiency of 1D model compared to 3D FEM

UBOA algorithm

- Superior convergence rates in terms of number of iterations and time
- UBOA: 75-80% increase in speed, 80-88% lower number of iterations
- Random switch b/w local and global search is supressed, minimising the randomisation of local search on global convergence, leading to better efficiency.

EFFICIENT FAILURE PREDICTION METHODOLOGY FOR HIGH ASPECT RATIO COMPOSITE WINGS WITH HIGH BEND-TWIST COUPLING

Mario Miranda[1], Alvaro Cea[1], Runze Li[1], Rafael Palacios[1] and Silvestre T. Pinho[1]

[1]Department of Aeronautics, Imperial College London, Exhibition Rd, South Kensington, London SW7 2AZ, UK

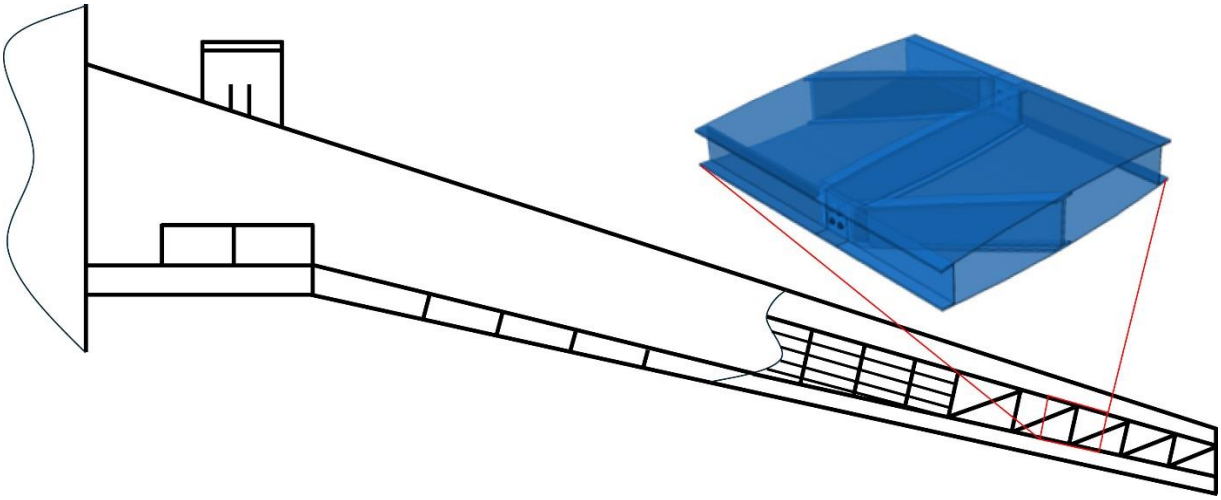
ABSTRACT

As efficiency gains in traditional aircraft designs become more incremental, high aspect ratio wings offer vastly improved aerodynamic performance but introduce complex aeroelastic and structural challenges. Innovative structural concepts for this type of wings lack corresponding sizing methods for early-stage design. This work presents a novel methodology to predict composite failure in such wings, using as a proof of concept a wing featuring a novel Z-beam wingbox structure. Our approach combines a machine learning-based surrogate model for failure prediction with a non-linear aeroelastic solver. We use superelements to represent structural configurations within a global aircraft model, enabling efficient aeroelastic response analysis. Global aircraft-level strain data is then used to compute composite ply-level failure indices of critical components using an evolved LaRC05 criterion. This enables early-stage design evaluation of innovative composite wing structures.

1 INTRODUCTION

In order to get closer to the established net-zero goals, the aeronautics industry is making changes on their aircraft for these to be more efficient. Composite materials, especially Carbon Fibre Reinforced Polymers (CFRP), have played a major role in enabling the development of lighter and more efficient aircraft, such as the Airbus A350. Other important contributors (at the aircraft level) for the increase of efficiency are better engines, and wing geometry. As the gains in efficiency in aircraft have been asymptotically stagnating with the current, well established, design philosophies, other solutions are being investigated by the industry and the scientific community. One of the most promising solutions are very high aspect ratio wings, which are known to provide higher aerodynamic efficiency. However, the increased span introduces important changes that need to be carefully addressed at the structural sizing stage. Composite failure due to non-linearities, increased aeroelastic effects and increased-bending moments, is one of the main problems that arises when considering larger spans.

Bend-twist coupling (BTC) is a feature that allows to reduce the undesirable effects of high aspect ratio wings. This effect can be either induced by using specific material properties and/or orientations, such as tow-steered composites or by wing structures which inherently present this type of behaviour. One example of the latter is Airbus's patented Z-beam wingbox [1] (Fig. 1), which can provide different levels of coupling for aeroelastic tailoring.



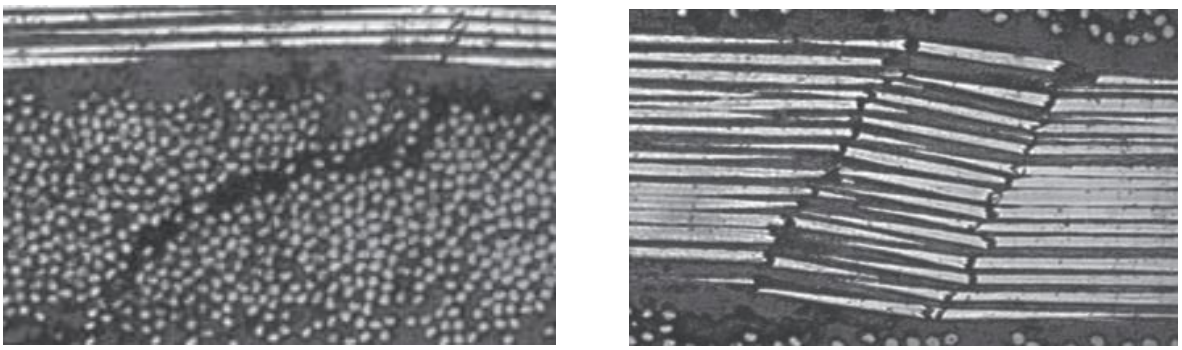


Figure 1: Z-beam concept in a high aspect ratio wing [2].

However, these novel architectures exhibit a complex composite failure response, especially due to their geometric complexity. This requires high-fidelity ply-level finite element modelling to achieve accurate structural sizing, leading to an unsurmountable computational expense at the sizing stage. This challenge is further exacerbated by the necessity of accounting for non-linear geometric effects in simulations, so that the estimated loads are not overly conservative. Consequently, there is a pressing need for efficient predictive frameworks capable of evaluating ply-level composite failure during the early design stages, where numerous structural configurations must be assessed efficiently.

In this work, we highlight a novel methodology to efficiently predict failure of composite components in high aspect ratio wings. It uses a machine learning based surrogate model [2] with an evolved [3,4] version of LaRC05 [5] for ply-level failure prediction (Fig. 2), which is coupled to a non-linear aeroelastic solver. We then developed a bespoke superelement to insert the novel wingbox concept in the outer part of the wing in a full aircraft model. Knowing the aeroelastic response, we are then able to obtain the failure indices of critical parts of the wingbox from macroscale loads.

(a) Matrix cracking (b) Fibre kinking

Figure 2: Examples of failure mechanisms that can be predicted by the failure model [5].

In conclusion, this study presents an innovative framework that solves the problem of efficient prediction of failure indices in critical regions of high-aspect-ratio composite wings during sizing. Its adaptability makes it particularly valuable for early-stage analysis of any unconventional structures, offering flexibility for researchers and industry engineers to implement custom modifications.

2 METHODOLOGY

The methodology has two separate main parts, at two very different scales. One is a surrogate model to predict ply-level damage and the other is a non-linear aeroelastic solver to simulate the full aircraft behaviour. The physics guided machine learning based surrogate model, takes as input the homogenised strains in the wingbox and its design variables, and returns the failure index of a critical detail, in this case, bolted joints [2]. Additionally, the homogenised stiffness matrix of the wingbox is obtained, which will allow its inclusion in the aircraft model. An overview schematic of the surrogate model is shown in Fig. 3.

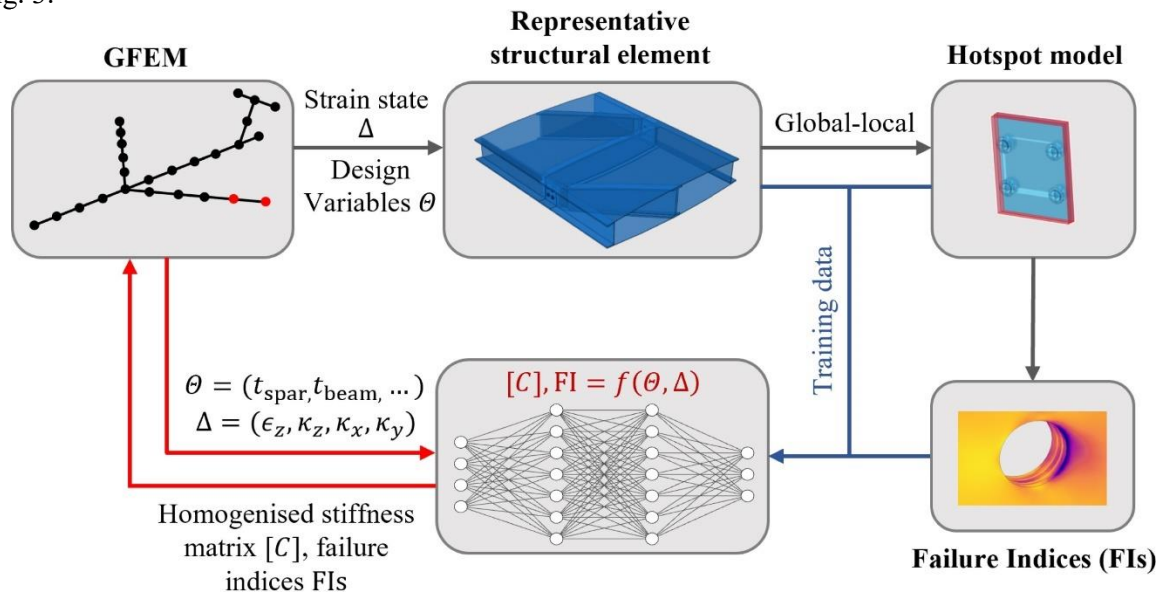

Figure 3: Multiscale analysis sequence for the prediction of ply-level failure indices [2].

The failure indices used for the surrogate model come from a detailed finite element model of the bolted connection, and are calculated using an evolved [3,4] LaRC05 [5] failure criterion. To simulate the aircraft response, a non-linear aeroelastic solver, FENIAX [6], is used. It uses the vibration modes of the condensed aircraft model to calculate the non-linear response (Fig.4).

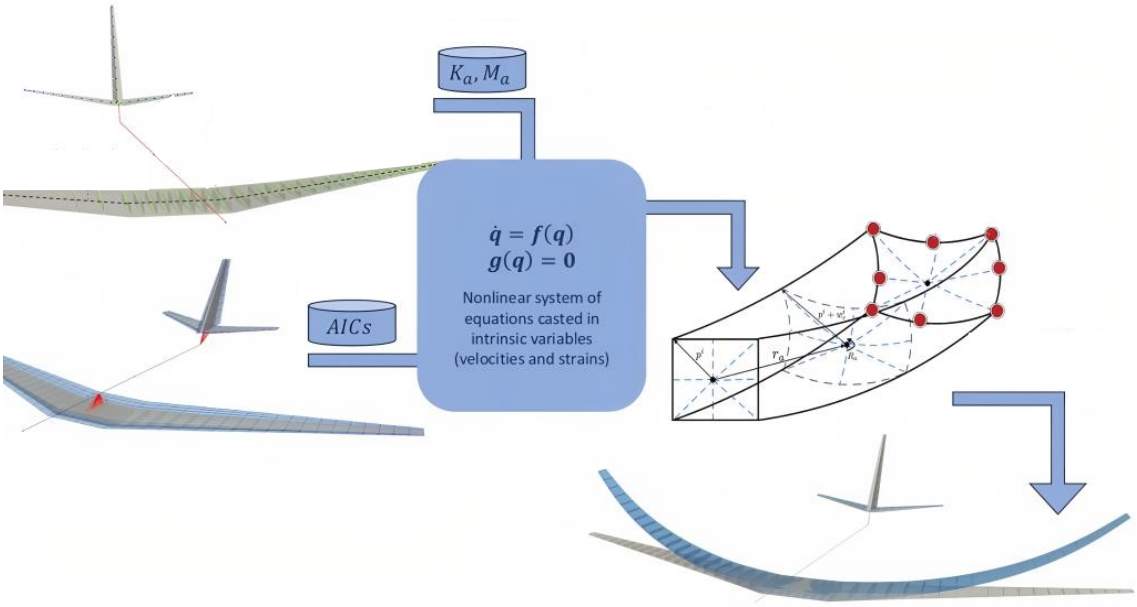

Figure 4: Workflow to obtain aeroelastic solution using FENIAX. After [6].

Superelements are then used to provide the required stiffness properties to the Global Finite Element Model (GFEM) of the aircraft. This approach is specifically useful since it allows to directly change only the outer part of the wing, not having to generate a full aircraft model for each design iteration. Additionally, since only the internal structure of the wing is being changed, i.e. there is no change in chord or airfoil shape, the aerodynamic characteristics are preserved for the entire procedure. A schematic of the overall methodology is shown in Fig. 5.

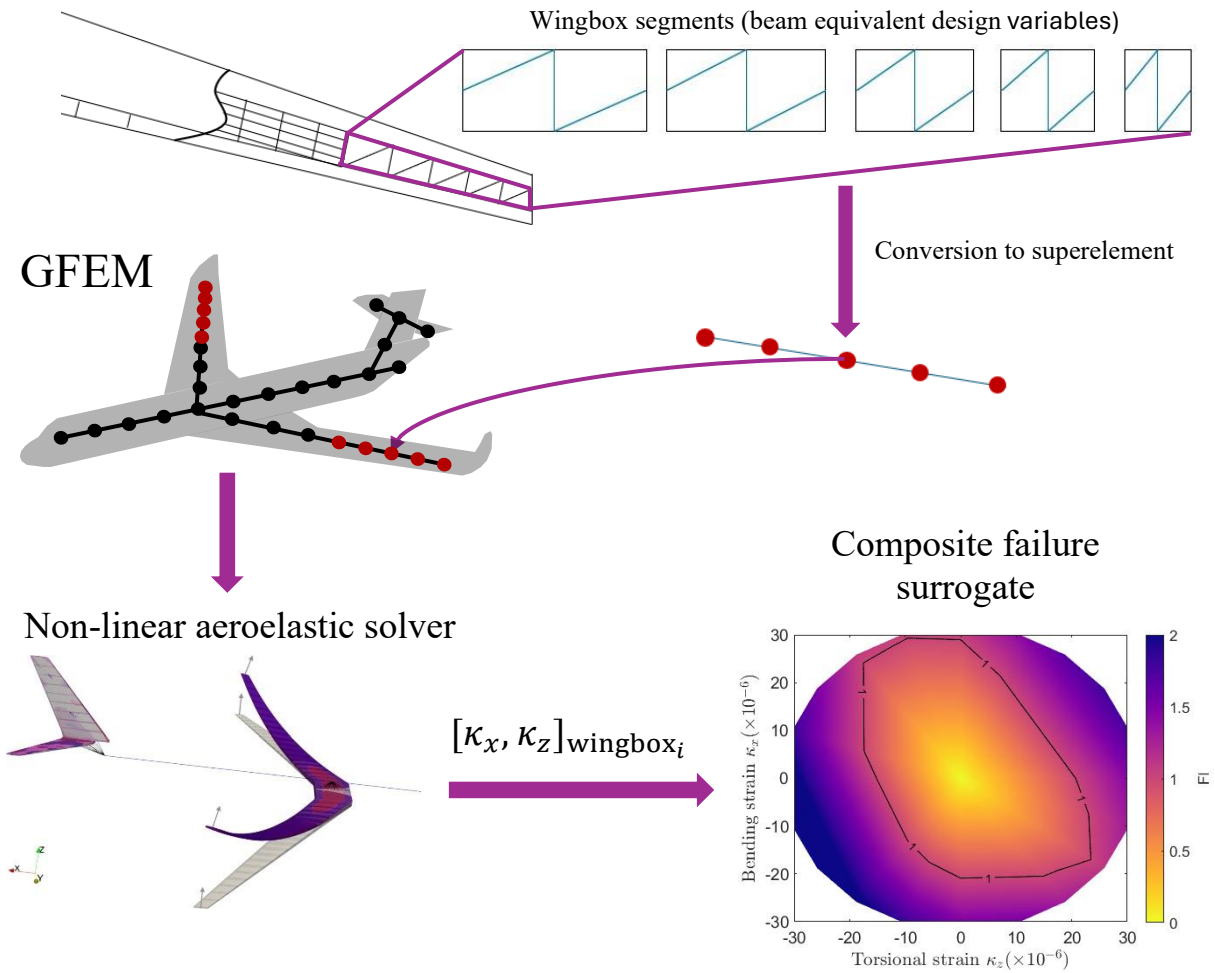

Figure 4: Overview of the methodology for composite failure prediction. After [2,6].

3 RESULTS

As a proof of concept of the multiscale structural analysis described in this work, a static follower vertical load of 21500 N is applied to both wingtips of the Bristol Ultra Green (BUG) model [7]. In this paper, a sequence of 10 Z-Beam wingboxes (as presented in Ref. [2]) is used to cover the last 11.28 m of each wing (section 3 of the wing in Ref. [7]). The homogenised strains of the first Z-beam wingbox, counted from the fuselage toward the wingtip, under the applied load (14 time steps), are presented in the failure index map shown in Fig. 6. As bending strain increases, a corresponding increase in torsional strain magnitude is observed, attributed to the bend-twist coupling characteristics inherent in the wingbox design.

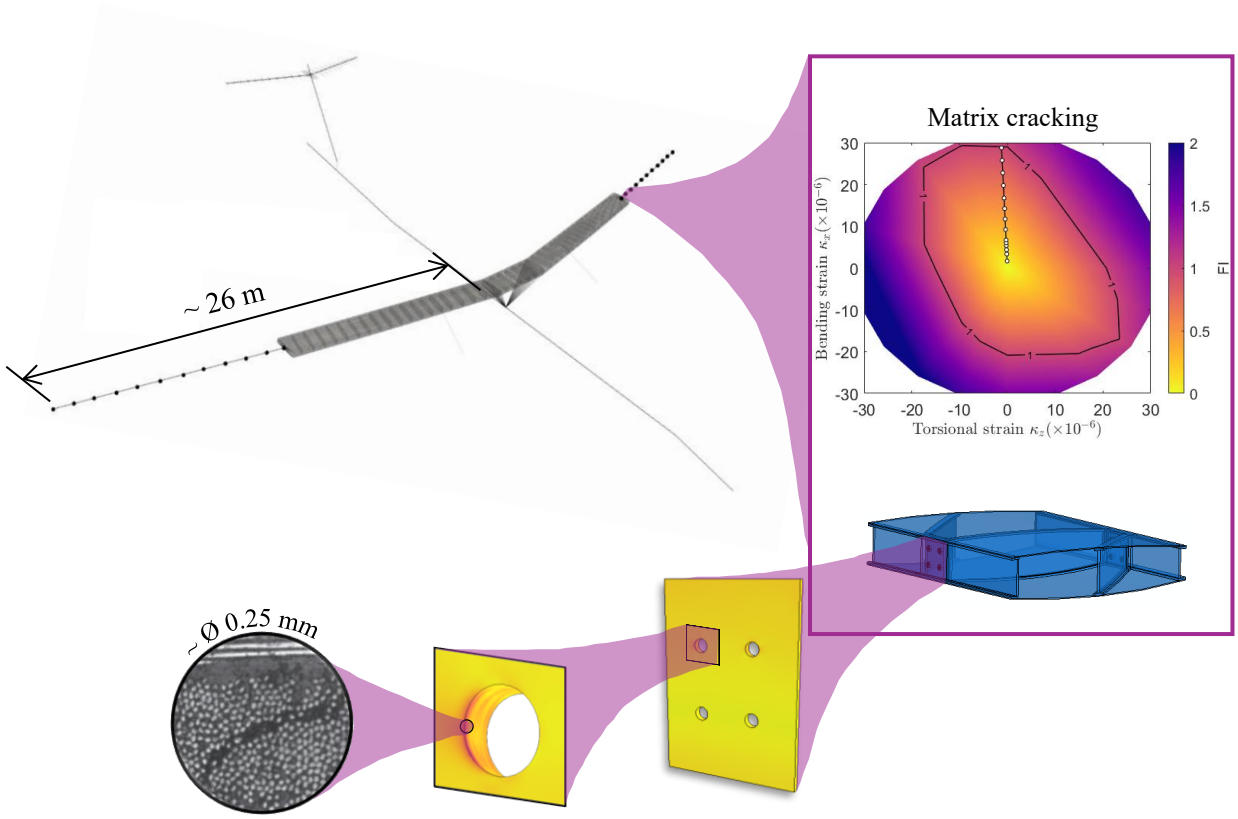

Figure 6: Prediction of matrix cracking failure mode in the outer part of a high aspect ratio aircraft [5].

The analysis reveals that matrix cracking failure occurs at the bolted joint under this loading condition. This failure mode demonstrates the effective integration of disparate length scales within the structural model, as illustrated in the figure. The coupling between local joint-level failure mechanisms and global structural response highlights the multi-scale nature of this work.

4 CONCLUSIONS

In this work, we present a multidisciplinary methodology for the efficient prediction of ply level failure in high aspect ratio composite wings. By leveraging a previously developed machine learning-based surrogate model, we accurately capture the failure behaviour of a novel composite component designed to induce bend–twist coupling. Applied to the outer wing region of a full-scale aircraft, this approach enables effective structural sizing by bridging vastly different scales, spanning at least five orders of magnitude. This methodology offers a modular and computationally efficient solution, making it adaptable to existing industrial and research workflows and thereby supporting early-stage design exploration and optimisation.

ACKNOWLEDGEMENTS

The authors would like to gratefully acknowledge the funding from Innovate UK under the Next Wing project, grant No. 10002372. The authors also thank Dr. Nicolae Lucian Iorga from Airbus UK for the support and helpful discussions.

Design Spaces for Hydrogen Storage Systems

Source: https://wave.cvc-suedwest.com/

Possible design space for hydrogen tanks on a commercial vehicle

Possible design space for hydrogen tanks in the wing (e.g. CS-23)

⇒ **Flat** or **complex shaped** design spaces for hydrogen storage available
⇒ Better **design space utilization** by combination with „thin“ pressure vessels
⇒ Target operating pressure (gaseous hydrogen) = 700 bar (**Design pressure = 1,575 bar**)

www.thefutureiscomposite.com

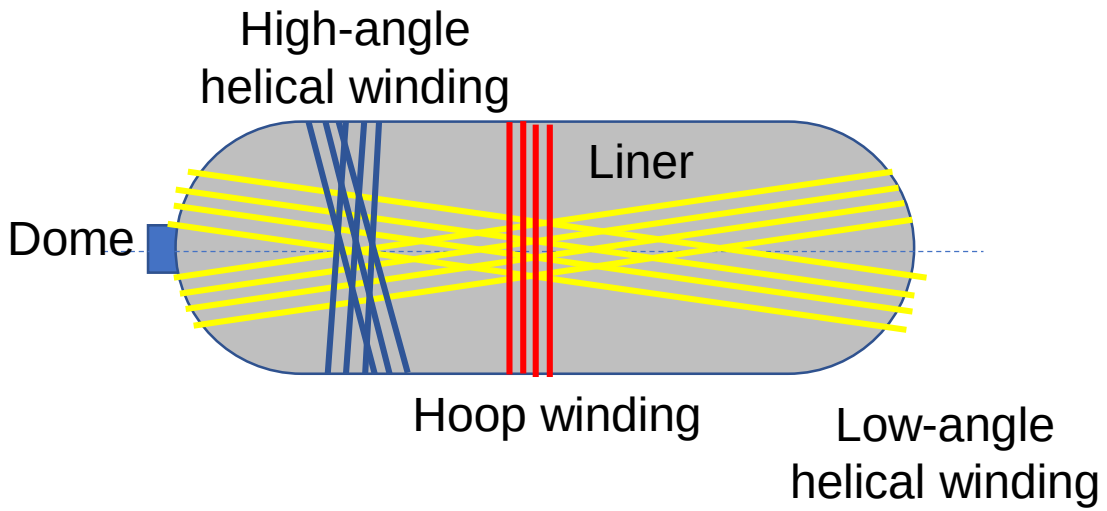
Conventional Type IV Pressure Vessels

Modern pressure vessels with CFRP (Type IV – state of the art)



Limitations due to manufacturing in a standard winding process:

No arbitrarily small diameters
⇒ Poor utilization of design space

Only small opening in the dome area
⇒ Difficult inspection and maintenance

Need for pre-manufactured liners
⇒ Costly
⇒ Difficulties in design changes (diameter, length)

No axial fibers
⇒ No additional load bearing capacities
⇒ No usage as structural part

Three pressure vessels in the wing:

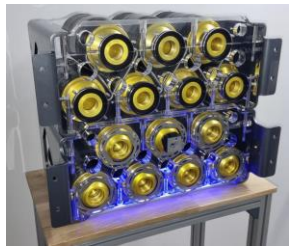
- 3500 mm length, diameter ca. 66 mm
- Mass per tank (w/o H_2): 4480 g
- H_2 per tank: **348 g**
- **Mass total (3 tanks):**
  13.440 kg (w/o H_2)
  14.486 kg (with H_2)
- **Weight efficiency: 7.2 %**

Advantages:

+ Payload space is not reduced
+ No additional drag
+ Less shift of the centre of gravity
+ Higher weight efficiency (substitution of spar)

Wingspan 3.5 - 3.8 m

Two pressure vessel in the booms:



- 2000 mm length
- Diameter ca. 66mm
- Mass per tank (w/o H_2): 2876 g
- H_2 per tank: **196 g**
- **Mass total (2 tanks):**
  5752 g (w/o H_2)
  6143.34 g (with H_2)
- **Weight efficiency: 6.8 %**

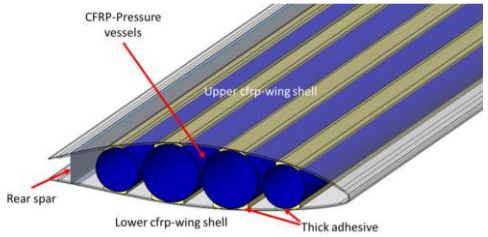
Summary

Opportunities



- **Optimized design space utilization** through small-diameter pressure vessels (usage as conformable tank)
- Patented IVW-design enables **lightweight pressure vessel** construction
- Integration of **tanks as structural components**

Challenges

- Metallic and composite parts under **high cyclic loading**
- **Relative displacement** between insert and CFRP layers
- Ensuring **sufficient coefficient of friction** between the two cones

Way forward

- **Optimizing insert geometry** to reduce weight (ongoing)
- **Validation for cyclic loading, impact, and H_2 filling** planned for 2025
- A manufacturing concept suitable for **large-scale production** *(ongoing)*
- **Proof of structural integrity** via cyclic bending tests on scaled demonstrators *(2025)*

Businesses

Our corporation, headquartered in Bethesda, Maryland, is organized around our core business areas specializing in defense tech.

Aeronautics, with approximately $28.6 billion in 2024 sales, which includes tactical aircraft, airlift, sustainment and aeronautical research and development lines of business.

Missiles and Fire Control, with approximately $12.6 billion in 2024 sales, which includes the High Mobility Artillery Rocket System (HIMARS) and PAC-3 Missiles as some of its high-profile programs.

Rotary and Mission Systems, with approximately $17.2 billion in 2024 sales, which includes Sikorsky helicopters, maritime systems, sensors, radar systems, command and control, combat simulation and training, undersea systems and full-spectrum cyber capabilities.

Space, with approximately $12.4 billion in 2024 sales, which includes development of national security, civil, commercial and weather spacecraft, strategic and missile defense solutions and hypersonics missions.

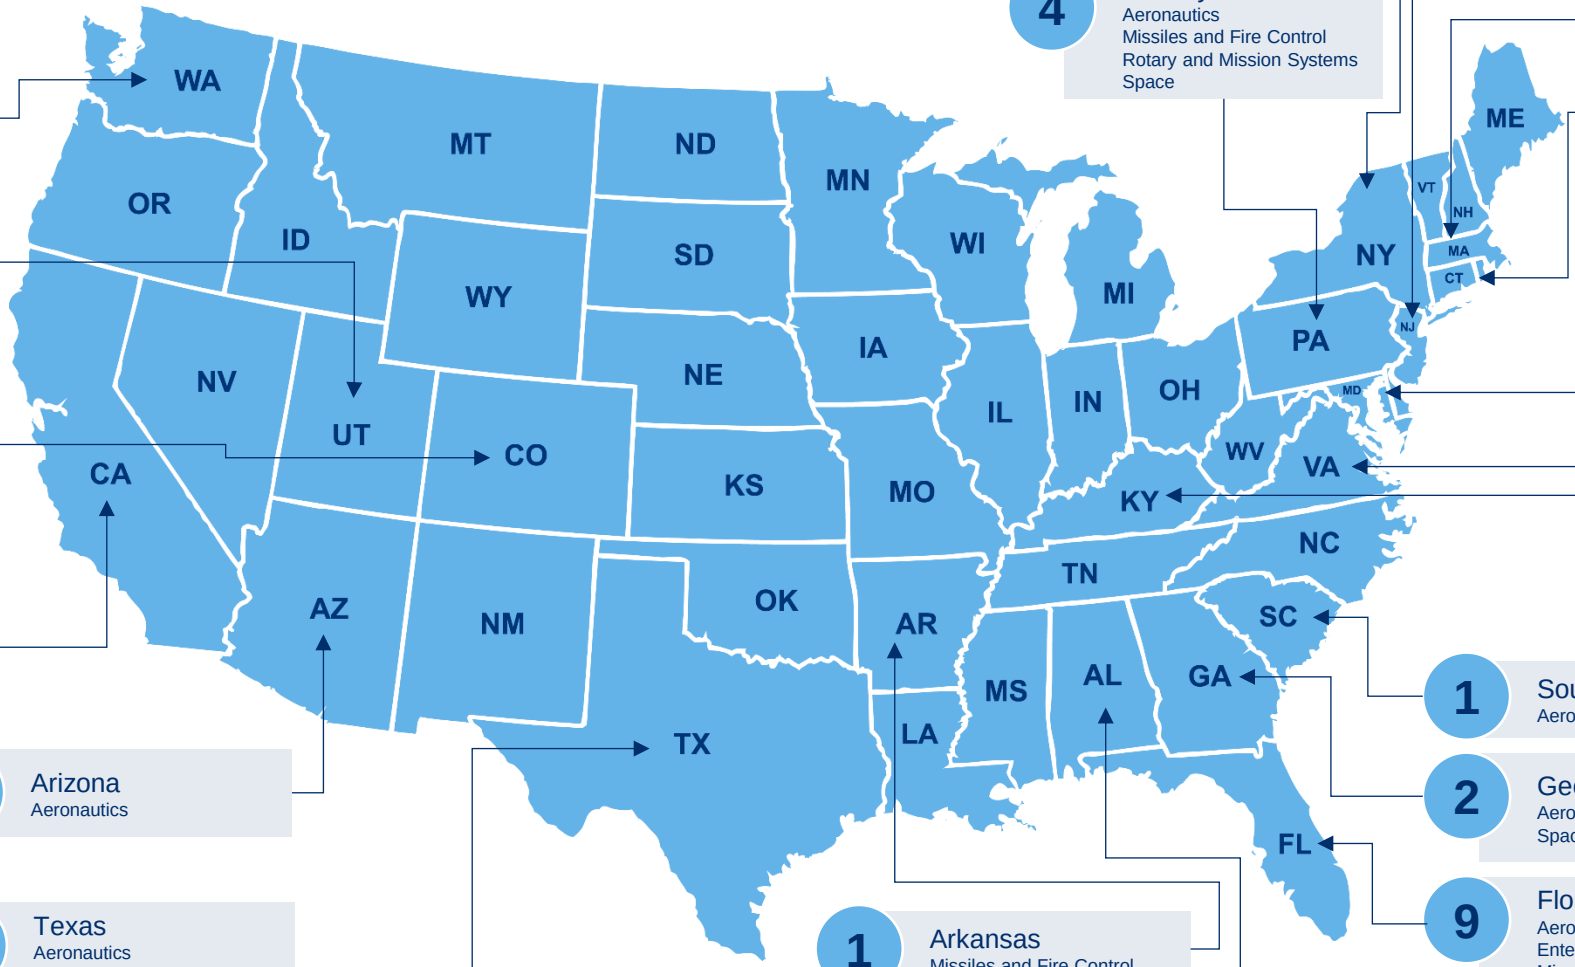
21st Century Security®

Lockheed Martin aims to build a more advanced, resilient and interoperable defense industry – working with industry and commercial partners to deliver cutting-edge capabilities faster and more affordably to customers.

The three lines of effort are:



- Aggressively adopting and inserting digital technologies into the defense enterprise with a standards-based, open architecture approach.
- Applying anti-fragility measures to ensure operations withstand shocks and disruptions on a large scale and at a faster speed.
- Fostering a more collaborative ecosystem that harnesses the advanced infrastructure of the U.S. and its allies to support America's strategic alliances.

Keywords: Finite element analysis, Composite Pressure Vessel, Layered structures

ABSTRACT

Reducing the weight of pressure vessels is a key objective in different sectors like automotive or aerospace. This can be achieved by replacing Type III and IV pressure vessels through Type V design. Nonetheless, Type V pressure vessels still use metallic bosses as an interface to surrounding structures. These metallic bosses lower the performance of the Type V design due to its mass and mechanical and thermal properties. This study investigates the feasibility of CFRP bosses using different stiffness distributions by means of finite element analysis. Different materials are investigated to demonstrate the potential of these structures. The weight benefit as well as the mechanical performance is compared to metallic bosses.

1 INTRODUCTION

The increasing demand for launch capabilities results in a high number of new players in the aerospace sector. Besides topics like reusability of launcher architectures, one aspect for being successful is to reduce the mass of the launcher architectures. [1]

In this research field, when it comes to the pressure vessel (PV) design, various studies focus on improving the performance of the PV by changing from a Type III to Type V design. By this, the metallic liner is replaced by the exclusive use of carbon fiber reinforced plastics (CFRP). This results in an estimated mass benefit of composite PVs (CPV) of up to approximately 55 % [2]. While this is an advantageous step towards lower structural mass, it also imposes design challenges, especially for the storage of cryogenic fluids. In the space sector, media such as liquid oxygen (LOx) or liquid hydrogen (LH2) are stored at cryogenic temperatures such as 77K for LOx and 20K for LH2. During the filling process of the PVs, the structure is cooled down starting from room temperature (RT) to the cryogenic service temperature. From a design perspective, this results in high thermal induced residual stresses in joining areas between different materials because of their differing coefficients of thermal expansion (CTE). State of art, type III as well as Type V designs still rely on metallic bosses as interface to surrounding structures and pipings. To reduce these thermal stresses, it is beneficial to replace the metallic bosses by CFRP material design concepts. In addition to the reduced thermal mismatch between the design materials, CFRP structures are also capable of providing higher specific strengths compared to special alloys such as Invar36. Invar36 is frequently used as a design solution to minimise the CTE difference between the metallic component and the CFRP overwrap of the PV because of its low CTE [3]. While the CTE mismatch is reduced, Invar36 has a high density of 8.1 g/cm^2 which lowers the structural performance [4]. Another disadvantage is the low strength at room temperature [5].

Concluding, the introduction of CFRP bosses leads to the following advantages:

- reduced mismatch of CTE between boss and laminate of the CPV
- increased specific strength of the CFRP boss based on the used CFRP material
- reduced density of the CFRP boss

These advantages make the development of CFRP bosses interesting for the future use in the aerospace sector. There are some studies, which highlight the potential described above of the CFRP bosses. *Whitehead et al.* integrated a CFRP boss manufactured by hand layup into a CPV to achieve weight reduction of the pressure vessel. A CFRP boss concept manufactured by resin infusion is shown by *Scherer et al.* [6]. Here, CFRP preforms are used to increase the performance of the boss structure. Another study showed that recycled material can be implemented into CFRP boss parts as core material, related to a sandwich structure design by *Korff et al.* [7]. The use of SMC bosses in an integrated Type V CPV design was demonstrated in a previous study by *Rehs et al.* [8]. Here, the performance of an SMC boss was compared to the Aluminum design in a Type V concept. Similar results for burst pressure performance as well as helium leak behaviour was demonstrated on part level. Furthermore, the manufacturing and integration of prepreg bosses on a 20L CPV was demonstrated. A weight saving of up to 57% in comparison to a steel boss is demonstrated by changing the boss material without considering the geometry. [8]

In this study, the performance increase of the CFRP bosses is assessed by the use of finite element (FE) analysis. Different materials and stiffness distributions of the CFRP boss structures are analysed based on the CFRP preform.

2 MATERIAL DEFINITION AND ANALYSIS MODEL

In this section, the material and analysis model are described. Five different materials are compared to highlight the potential of CFRP boss parts. The analysis focuses on the advantages which come with the material parameters as well as the manufacturing induced advantages.

2.1 Material Definition

Different materials can be used for the manufacturing of boss structures. Currently, state of the art boss structures are manufactured by metals such as Aluminum or Invar36. Replacing these structures by CFRP can be done using different CFRP preforms like fabrics, Sheet Moulding Compound (SMC), unidirectional (UD) prepregs or spiral ribbon.

This study focuses on the analysis of SMC and twill and UD prepregs, compared to the metal design of Aluminum 6082 and Invar36 to highlight the benefits of the CFRP structure.

Therefore, the design parameters such as strength, stiffness, density and CTE for the different materials are summarized in Table 1.

Table 1: Material data for metal and CFRP materials [4, 9-13]

Metal Materials			
Parameter		Al	Invar36
E	[MPa]	70714	143000
R_{yield}	[MPa]	298.3	270
CTE	[10^{-6}/°C]	23.5	1.3
ρ	[g/cm^3]	2.7	8.1

CFRP Materials				
Parameter		SMC	Twill Prepreg	UD Prepreg
E_f	[MPa]	25000	68000	164000
R_f	[MPa]	300	1050	2724
CTE	[10^{-6}/°C]	10	3.62	-0.5 – 12.5
ρ	[g/cm^3]	1.9	1.47	1.57

For the design of light structures different parameters are of interest, shown in Figure 1.

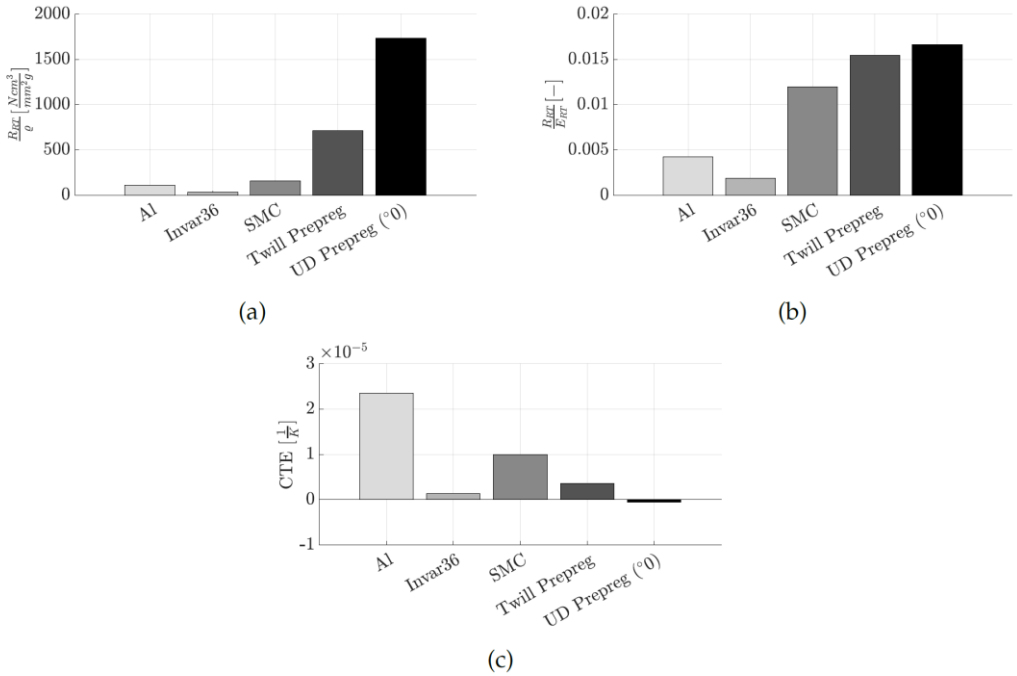

Figure 1: Material comparisons. (a) Strength to Density Ratio at RT, (b) Strength to Stiffness Ratio at RT, (c) CTE at RT

First, the strength to stiffness ratio is shown in Figure 1 (a), which is important for the lightweight potential. It can be seen, that Invar36 shows the lowest strength to density ratio and Prepreg material shows the highest strength. For the metal materials, the yield strength was chosen as strength value as typical design approaches follow a no yield design under service conditions. For the CFRP materials, the strength describes the stress at fiber failure.

Second, the design of boss structures is driven by a bending load in the boss runout. This is why a high strength to stiffness ratio is beneficial, shown in Figure 1 (b). Due to the inner pressure loading the CPV undergoes a deformation which is mainly driven by the CFRP laminate stiffness distribution. As the boss is attached to the overwrap, it undergoes this deformation as well. This deformation yields to bending in the runout. Therefore, a high strength to stiffness value of the design material is beneficial for the lightweight potential. It can be seen in Figure 1 (b) that CFRP materials offer higher values compared to the metal materials. This is also in accordance with experimental results observed in [8] on part level.

Third, for the use in cryogenic temperatures, the CTE is of interest, shown in Figure 1 (c). Here, a low CTE is proven to be beneficial. An optimal boss design would show the same CTE compared to the CFRP overwrap in the joining area. Due to the winding process and changing fiber angles in the boss region, the prediction of the CTE of the overwrap remains difficult and should be addressed in future studies. Based on the state of the art, where Invar36 proves to be a design solution it can be concluded that Invar36 and Prepreg Materials are of high interest, while SMC offers way better characteristics compared to Aluminum.

Concluding, the use of CFRP Materials for boss design proves to be a promising approach within Type V CPV design for further increasing the CPV performance index due to the following advantages:

- CFRP shows high *R/ρ* values especially compared to Invar36
- CFRP shows high *R/E* values especially compared to Invar36
- CFRP shows lower CTE values especially compared to Aluminum

2.2 Finite Element Model

A finite element (FE) model is used to predict the mechanical responses for the loading situation of the CPV including different boss designs and materials based on section 2.1.

The *Abaqus* FE-model is generated on basis of a winding simulation performed with the winding software *uChain* by *MeFeX GmbH*. The model consists of two parts, the boss part and the CFRP laminate. The CPV laminate is composed of 22 layers, containing helical and hoop layers. The design of the boss was chosen to withstand an inner pressure loading of 400 bar using Invar36 as design material. The loading is applied as inner pressure loading on the boss and the CFRP laminate inner surface as well as an axial force on a Reference Point (RP) to account for the cover loading. The load of the RP is transferred using a coupling to the boss structure. The analysis uses an axisymmetric approach using CAX3/4 element formulation with an element size of 0.75 mm. A symmetric boundary condition is used in the center of the CPV constraining the axial deformation. Second, a boundary condition is used at the RP.

Figure 2 shows boss part as well as the CFRP laminate of the CPV. The loading can be seen on the inner surface as well as the reference point.

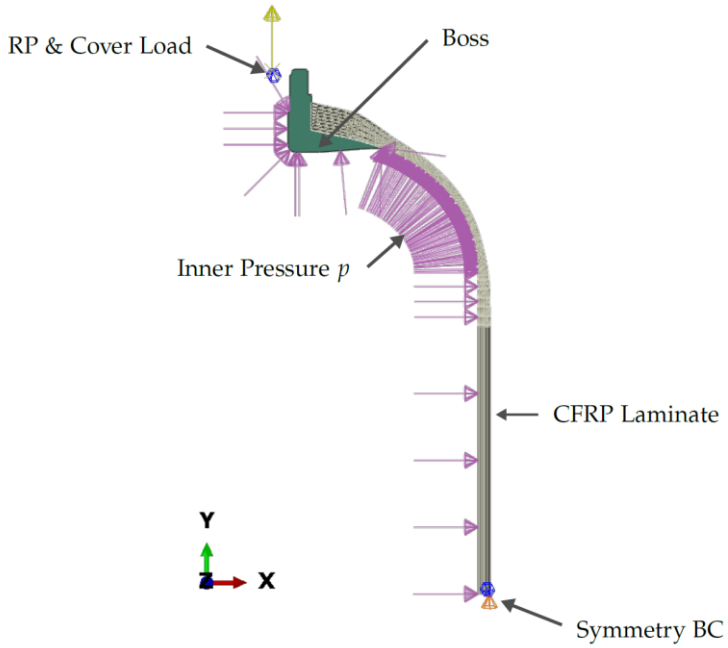

Figure 2: FE-model showing the two parts (boss and CPV laminate) as well as the loading and boundary conditions of the axisymmetric model.

Based on the shown design and FE model, different analyses are performed including geometric variations of the boss design as well as the analyses of different boss materials.

2.3 Boss manufacturing

As described before, different materials for CFRP are considered in this study: SMC and Prepreg. Based on this, the manufacturing process differs between these two materials.

In general, the CFRP boss consists of two parts. The CFRP main body and a metallic insert, which allows for connection of the CPV to pipes via standard pressure fitting [8]. The metallic insert is designed to be as small as possible to reduce weight and also have less absolute difference of thermal expansion between the parts. It is bonded to the CFRP main body in an extra step after the CFRP part is manufactured.

To use the advantages of a CFRP boss mentioned before, the manufacturing process has to be considered during the design of the boss. The two manufacturing methods are SMC compression molding and prepreg autoclave manufacturing.

In the SMC process, a preform that contains long fiber and resin is inserted in a two part heated mold. The mold is closed with a defined force to apply pressure. The viscosity of the resin decreases and can flow through the mold to fill the whole cavity and moving the fibers with it. In this process, relatively complex parts can be manufactured with short cycle times and minimal rework needed. Therefore, the process is well suited for high scale manufacturing. Another advantage of using this process for CFRP bosses is the freedom in the part geometry. The outer edge of the boss can be made thin to reduce stiffness gradients in the CPV. As the fibers in the preform have a random orientation the mechanical properties of the part will be quasi isotropic in in-plane direction.

The second manufacturing process considered for the CFRP boss is prepreg autoclave manufacturing. A positive mold which represents the underside of the boss is machined and CFRP prepreg is laid on it in multiple layers. Unidirectional and fabric material is used. The CFRP is cured inside an autoclave to apply pressure for compaction and good laminate quality. After curing the topside of the boss is milled to the exact contour as this cannot be achieved with the layup process alone. Advantages of this process are tailoring of the fiber directions to the loads in the boss and the use of endless fibers compared to isotropic materials resulting in high-strength parts. As a result, the boss can be made thinner and lighter with this manufacturing method.

Figure 3: CFRP Boss demonstrator manufactured from twill and UD prepreg. [8]

3 RESULTS AND DISCUSSION

This section presents the results of the loading and stress analysis based on Invar36 material design. Following this analysis results, different boss adaptations including geometric variations and material variations are presented.

3.1 Loading and stress analysis of the Invar36 boss design and its limitations

The detailed design procedure of the boss, which undergoes the deformation behaviour of the CFRP laminate is not focus of this study. Rather, on the basis of the shown design, different variations are analysed to highlight the mentioned potential of replacing metal bosses through CFRP design. The design is chosen for an operating CPV inner pressure of 400 bar.

For experimental validation of the shown design, the Invar36 boss with the CPV laminate was pressurized up to 500 bar using a hydrostatic pressure test bench. The design showed no failure of the boss structure.

All following results are derived at the operating pressure of 400 bar.

Figure 4 (a) shows the von Mises stress distribution of the Invar36 boss. The boss undergoes an axial displacement due to the CFRP overwrap deformation behaviour. For simplicity, the CFRP laminate is not shown in Figure 4. The volume towards the interface to the CFRP laminate is in a high tensile stress state. This is because of the bending loading situation triggered by the axial displacement of the CPV. As a result, the material towards the interface is loaded under tensile stresses, while the lower material is not highly loaded due to the presence of compressive stresses due to the bending. Reducing this area of the part is not advisable, due to the failure mode of shear out and further increasing the yielding tendency. If the part thickness becomes too low, the boss part can fail in the area which is highlighted in
Figure 4 (a). Due to the inner pressure loading, there are also stress components in the circumferential direction shown by the stress vectors of the maximum principal stresses in Figure 4 (b). Concluding, the boss stress state is complex due to the different aspects of the loading and there are different aspects to be considered in the optimization of the boss using layered structures.

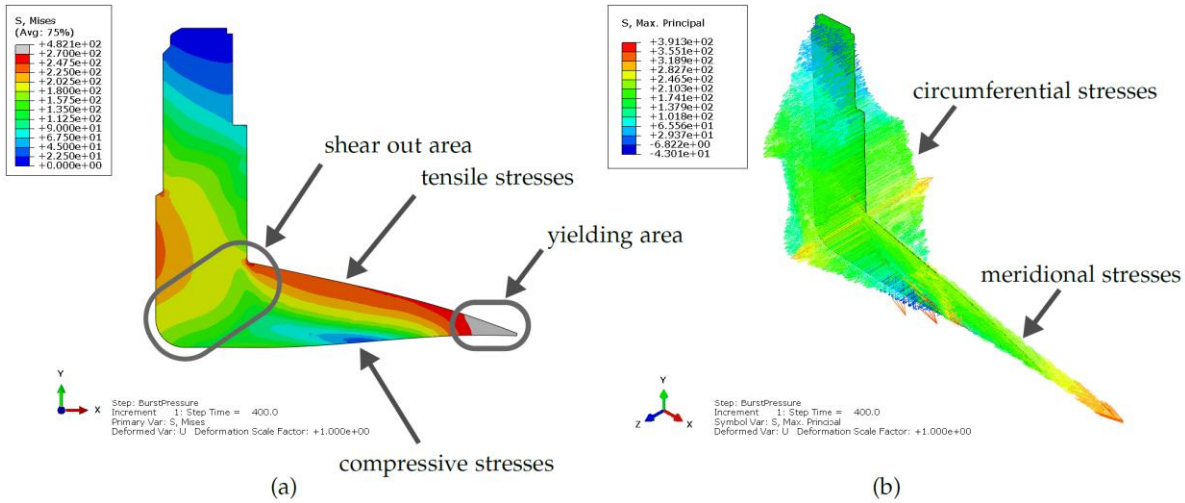

Figure 4: (a) Von Mises stress distribution of the Invar36 boss at 400 bar inner pressure loading. Stresses depicted in grey are above the $R_{p0,2}$ limit for Invar36. (b) Maximum principal stress distribution shown in vectors.

The high loading in the ending section of the boss (yielding area) can be reduced by increasing the thickness of this runout. While this accounts true for the boss, the CFRP laminate has to be also considered. This poses a design challenge. On the one side, the runout should be as thick as possible due to possible yielding failure in the boss runout. On the other side, the runout should be as thin as possible due to the presence of the stiffness jump in the interface between the boss and the CFRP laminate.

This design challenge is analysed in Figure 5. For this study, the overall boss geometry is kept similar, only the runout thickness of the boss is changed from 0.25 mm to 1.00 mm. By this, the global stiffness change of the runout variation for the CPV system is kept to a minimum. For analysis, the mean yield von Mises stress in the runout was extracted. Therefore, the von Mises stress was evaluated on the integration points in the runout volume, shown in red in Figure 5. The fiber stresses of layer 1 was derived directly in the interface boss to CFRP laminate (Layer 1 bottom) and the interface between Layer 1 and Layer 2 (Layer 1 top).

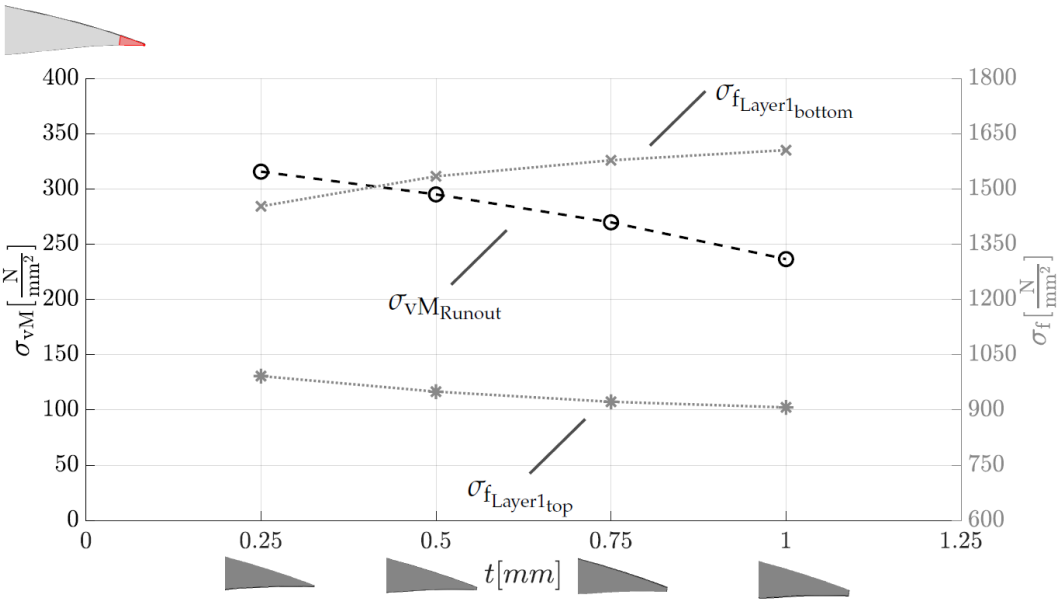

Figure 5 Fiber stress in the top and bottom of layer 1 at the location of the runout end of the boss as well as the yield stress in the runout end (shown in red) of the metal boss for an inner pressure loading of 400 bar in variation of the runout thickness end.

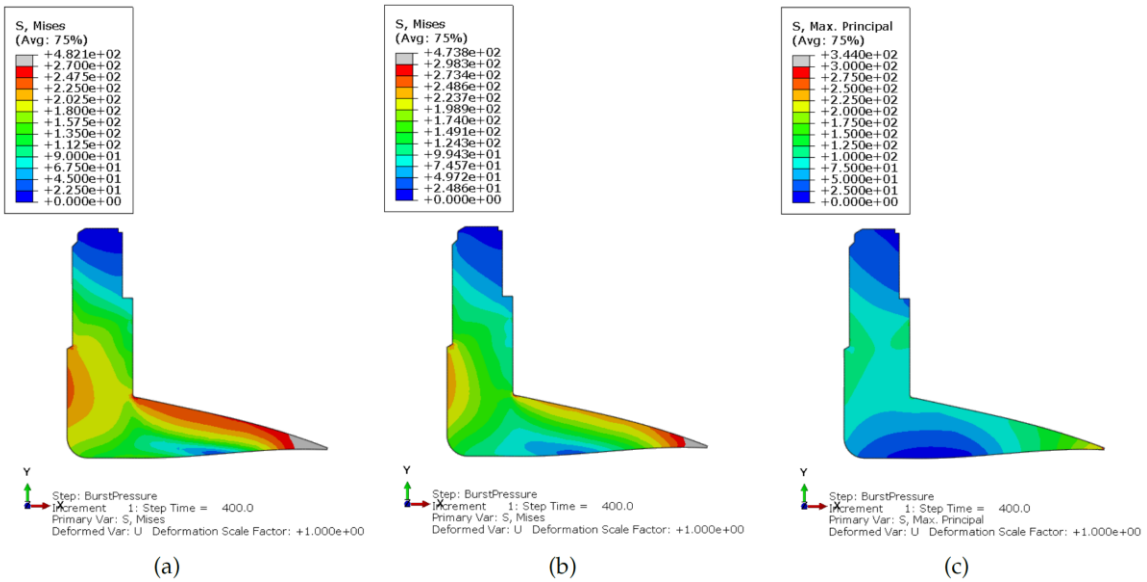
It must be noted, that the results shown in Figure 5 represent general design trends. The quantitative values may be affected by numerical singularities in the joining area of the boss and the CFPR overwrap. This is also a challenge of the boss interface and needs to be addressed in future research.

Figure 5 shows that the overall yield stress in the runout reduces with increasing runout thickness. Increasing the runout thickness therefore reduces the risk of yield induced failure as the runout area shows lower overall loading. The stresses for the fiber direction in Layer 1 of the CPV laminate show that the increase in runout thickness causes an increase in loading especially in the bottom of Layer 1. This joining area between boss and CPV laminate is a very important interface for functional requirements such as leakage, especially in Type V designs. This is why these trends shown in Figure 5 are critical.



The effect of increasing fiber stresses with increasing runout thickness is not present towards the upper layers of the laminate. The fiber stresses slightly decrease in the interface of Layer 1 and 2 which is due to the different deformation behaviour caused by the stiffness change of the boss runout.

A result of Figure 5 is that the engineer always has to choose between a low loading with regard to yielding of the boss or a lower loading of the CFRP layers in the laminate. The decrease in runout thickness is limited by the need to prevent the metallic bosses from yield failure. This is why the change of material to CFPR can be promising due to the material properties discussed in section 2.1.

Therefore, the next section discusses the change of boss material and highlights the possible benefits.

3.2 Analysis of different boss materials

Based on the results of the Invar36 boss, the use of Aluminum, SMC and prepreg materials is discussed. The design comparison between Invar36, Aluminum and SMC is shown in Figure 6.

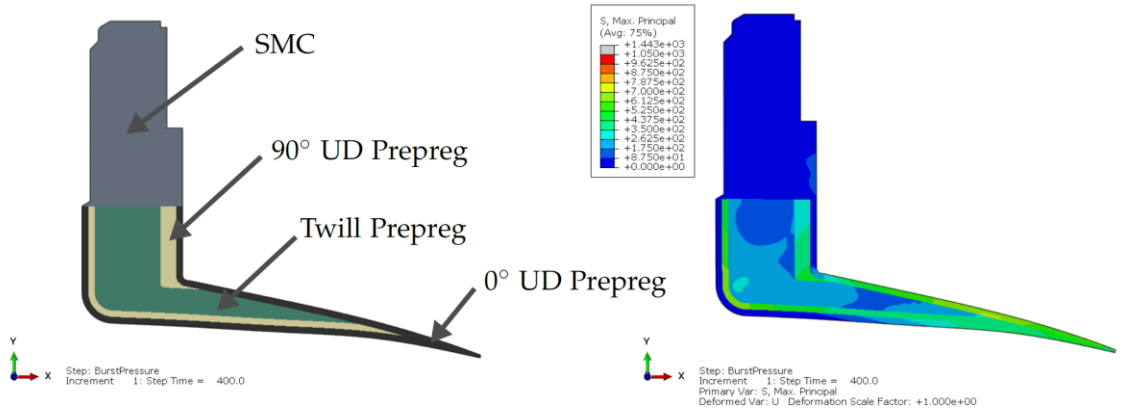
(a) (b) (c)

Figure 6: Boss Design Material Comparison: (a) Invar36 design, (b) Aluminum design, (c) SMC design. Shown is the von Mises stresses for (a) and (b) with $R_{p0,2}$ as limit, for (c) the maximum principal stresses are displayed with the failure stress of SMC as limit.

For Aluminum, the strength to density and strength to stiffness ratio is better compared to Invar36. Consequently, the yield behaviour at the same inner pressure is reduced compared to the Invar36 design, which can be seen in the von Mises stresses in Figure 6. Also, the overall stiffness is reduced, resulting in a less pronounced stiffness jump at the boss end. Both favours the Aluminum design. As a design adaptation, the thickness could be reduced resulting in lower mass not only due to the lower density but also due to the reduced need of metal material.

These benefits are limited to room temperature applications, as the CTE mismatch to the CFRP laminate is too high for the use in cryogenic conditions.

Similar results are observed for the SMC boss design. SMC offers even better strength to stiffness and strength to density values compared to Aluminum. The advantages of the Aluminum design are therefore also applicable to the SMC design. Lower density and higher strength can further decrease the weight of a SMC boss compared to Aluminum. In addition, the CTE is reduced compared to Aluminum. Further research needs to investigate until which temperatures SMC can be used in low temperature applications. Both, SMC and Aluminum also offer a significant weight decrease compared to the Invar36 design.



Based on the results discussed, a prepreg boss offers the unique chance to tailor the laminate more to the loading situation compared to isotropic materials. Above, SMC was treated as isotropic, as a simplification. Future research could also investigate the in- and out-of-plane stiffness distribution of SMC with regard to the mechanical and thermal behaviour of the CPV.

Reviewing Figure 4, the runout area should be reinforced with prepreg in fiber direction located towards the bending stresses. Like a sandwich design, fibers can be applied to the inner and outer contour and the middle section can be filled with twill prepreg, or even lower density materials as discussed in [7]. Towards the fluid adapters a high circumferential loading is observed in Figure 4. This loading can be taken up best by fibers located in circumferential direction (here called 90°).

A demonstration of this design procedure is shown in Figure 7. The layup of the prepreg boss is shown in Figure 7 (a). The SMC section in the upper part is a simplification for the analysis and not of relevance for the loading situation and offers no major influence on the deformation behavior and is therefore not further discussed.

Compared to the Invar36 design, the overall thickness is reduced, as prepreg offers higher strength compared to SMC. The results in Figure 6 (c) show that SMC already provides stresses below the strength of SMC. As a consequence, the loading of a boss with identical geometry will be even lower. That is why for this analysis, the overall thickness of the boss was lowered.

Figure 7 (b) shows the result of this analysis. Here, the maximum principal stresses are shown at 400 bar inner pressure. As a strength limit, the twill strength of 1050 MPa is chosen. As the UD strength is higher, see Table 1, this approach is conservative.

(a) (b)

Figure 7: CFRP Prepreg Boss: (a) Fiber distribution (0° following the boss contour, 90° in Z direction), (b) Maximum principal stresses with Twill Prepreg Strength as limit.

It can be concluded that the loading situation is lower compared to Invar36 design even with the lower part thickness regarding the twill strength. Also, the peak stress within the CPV laminate is reduced. Because of the use of CFRP material, the design challenge is shown in Figure 5 resolved. Low runout thicknesses are possible to the use of CFRP material with a suitable fiber orientation. This also causes the lower peak stress of the laminate at the bottom of layer 1. Additionally, the shear out failure mode can be resolved by the correct use of fiber orientation.

Comparing the volume of the two boss configurations, a volume reduction of 33% is observed for the CFRP boss. Taking the density into account, this adds up to a weight reduction of 87%. This lowers the mass from 2,29 kg per boss for the Invar36 boss to only 295 g for the CFRP bosses. Considering the neglected adapter for fluid adaption, which will lower the mass benefit, this still is a remarkable result, especially as the design can be further optimized considering the stress distribution in Figure 7 (b). Related to the overall tank mass, this would be a mass decrease of 28% for the whole CPV.

This emphasizes the structural benefit which is present in the concept of replacing Invar36 bosses through CFRP bosses. As the CTE of Twill and UD prepreg is also low, cryogenic temperatures are also in scope of the design solution. The CFRP boss offers lower mass and higher strengths compared to Invar36 and also a low CTE.

4 CONCLUSIONS

4.1 Summary

In conclusion, this study analyses and discusses the benefits of CFRP boss materials based on a tested CPV with Invar36 bosses.

First, a material comparison highlights a material selection to replace Invar36 as design material. The benefits of these materials are discussed and summarized in this study. Consequently, a FE-model is set up to investigate and evaluate the loading situation of the baseline boss material Invar36. A variation of the runout geometry is performed to show the design challenge using Invar36 as design material. Based on this, different materials for boss manufacturing are analysed. The results show that Aluminum and SMC show advantages over the Invar36 boss at room temperature. The use of prepreg materials such as UD and twill further increase these advantages. Due to the low CTE of prepreg CFRP bosses they can be also interesting in cryogenic temperatures.

Based on the results it can be concluded that the use of CFRP bosses offer a high potential for decreasing the weight of CPVs. Compared to the weight saving of changing from Type III or IV designs to Type V designs, this change of boss material should also be considered.

In addition to the weight savings of the boss itself, there is also a positive impact on the CPV laminate. The stiffness jump in the joining area of the boss to the CPV laminate can be tailored. Especially with the use of layered structures such as Twill and UD prepreg, the stiffness distribution can be adjusted to the predicted deformation behaviour of the tank system containing the boss and the CPV laminate. This has a direct impact on the design process of the CPV laminate which is expected to further decrease the system mass as helical layers, which are needed to control yielding in the boss region for metallic designs are less likely to be needed in case of a CFRP boss. Both, the lower CFRP boss weight and the lower CPV laminate weight are positive for the performance of the CPV system.

4.2 Future research

Future studies can investigate the detailed tailoring of the layered CFRP boss structure to the deformation behaviour of the CPV coupled to the CPV laminate deformation. This interaction of both parts will result in a lower overall CPV mass which can then be evaluated in an experimental campaign. A more detailed analysis of the SMC boss stiffness distribution increases the accuracy of the analysis.

Another aspect of future research is to evaluate the use of SMC in low temperature applications. It needs to be evaluated if the CTE mismatch between the CPV laminate and the SMC boss is sufficiently low enough for the use of SMC bosses at low temperatures. Detailed analysis of the deformation behaviour of the CPV laminate and the boss in a joined state are needed to evaluate this.

ABSTRACT

Recycling of end-of-use (EoU) aerospace composites and manufacturing waste has gained traction over the past decade. Conventional methods such as shredding, pyrolysis, and solvolysis are widely used, with recovery rates of 10–75% of the original mechanical performance. However, these methods often compromise value-retention factors such as fiber length, orientation, and component geometry, limiting their reuse in high-performance applications. A circular approach is therefore necessary—one that emphasizes the damage-free separation and reuse of continuous fiber-reinforced layers. Effective reuse requires either rebonding the separated layers to restore the original laminate structure or employing them as reinforcing patches in structural repairs. Recent research has demonstrated the viability of ultrasonic-assisted separation and reconsolidation to recover and reprocess carbon and glass fiber composites. In carbon fiber-reinforced PEEK systems, optimizing ultrasonic reconsolidation through Design of Experiments (DoE) has shown improvements in mechanical performance. Reconsolidation time and force—primarily governed by the temperature profile—define the process window. Hold time and holding force influence thermal characteristics and laminate integrity. Exceeding optimal holding force by 25% leads to fiber-matrix debonding and cohesive failure. When carefully controlled, ultrasonic reconsolidation provides a viable pathway for structural reuse and material circularity in thermoplastic composites.

1 INTRODUCTION

Fiber-reinforced composites are favored in aerospace and aeronautical applications due to their high strength-to-weight ratio. Carbon fiber composites, in particular, offer several advantages over traditional materials, including excellent fatigue resistance, enhanced fire and corrosion resistance, the ability to integrate functions, and flexibility in producing complex geometries [1]. These materials can be up to four times lighter than steel while maintaining comparable performance [2]. Additionally, they contribute to sustainable mobility by lowering CO_2 emissions by up to 20% during their operational life due to lightweightning [3]. However, a growing concern in the aerospace sector is the increasing volume of composite waste generated during production and at end-of-use (EoU). In line with the European Waste Directive, such waste must be managed through a hierarchy that prioritizes reduction, reuse, recycling, recovery, and finally, landfill [4]. Recycling composites remains challenging due to their complex mix of fibers, resins, and fillers, especially with thermoset matrices [5-7]. Common industrial

recycling methods like pyrolysis and solvolysis often degrade material quality [8, 9]. Therefore, recovery methods enabling reuse in high-performance applications are essential [4].

Thermoplastic composites (TPCs) offer significant advantages over thermoset composites, particularly in repairability, due to their ability to be reheated above their glass-transition (amorphous) or melting temperature (semi-crystalline). This thermal reversibility enables efficient joining and repair processes such as ultrasonic welding (USW), which has been increasingly recognized as a promising method for TPC repair. Compared to conventional fusion-based techniques like arc or resistance welding, USW offers several benefits including short cycle time, localized heating, reduced energy consumption, and high automation potential [10, 11]. USW relies on mechanical vibrations to generate heat through friction and viscoelastic dissipation at the interface, often facilitated by energy directors (EDs) in the form of thin films or meshes [12, 13]. Furthermore, successful spot welding without EDs has also been demonstrated [14, 15]. Recent advances demonstrate the growing potential of USW as a viable repair technique for TPCs. Li and Palardy reported high recovery rates (86–94.5%) in mechanical performance using USW with nanocomposite ED films across multiple repair cycles, outperforming resistance heating methods in terms of consistency and bond strength [16]. The thermoplastic matrix not only ensures strong mechanical integrity and chemical resistance but also allows repeated processing, making it ideal for sustainable repair strategies. Despite requiring more complex repair methods compared to thermosets, techniques like USW, induction, and resistance heating have shown proven effectiveness for restoring delaminated and damaged TPC structures in aerospace applications [17-19].

While ultrasonic welding (USW) is well-established for joining aerospace-grade thermoplastic composites, its application in repair remains underexplored. This study introduces our novel ultrasonic reconsolidation approach for repairing separated, multi-directional CF-PEEK laminates without energy directors. Using statistical design of experiments, optimal USW parameters were identified based on lap-shear strength. Repair quality was further assessed via 3D X-ray microscopy and temperature analysis during the post-reconsolidation phase. The influence of holding force and time on thermal behavior was analyzed in-depth. Additionally, successive repairs were evaluated through mechanical testing and microstructural analysis, highlighting ultrasonic reconsolidation as a promising alternative to conventional aerospace repair techniques.

.

2 MATERIALS AND METHODS

2.1 Thermoplastic composite laminate

Figure 1a illustrates the cross-ply thermoplastic carbon fiber (CF)-PEEK (poly-ether-ether-ketone) composite laminate examined in this study. The laminate, commercially known as CETEX-TC1200, was supplied by Toray Advanced Composites (Nijverdal, Netherlands). PEEK, a high-performance semi-crystalline thermoplastic from the polyaryletherketone (PAEK) family, exhibits exceptional mechanical strength and chemical resistance. With a glass transition temperature of 143 °C and a high melting point of 343 °C, it is well-suited for demanding aerospace and advanced medical applications. Ultrasonic C-scan inspections confirmed the laminate was free from critical manufacturing defects such as voids or delaminations. Table 1 presents the material properties of the CF-PEEK laminate as specified by the manufacturer. The laminate was fabricated with a cross-ply layup of alternating 0° and 90° fiber orientations, resulting in a final consolidated thickness of 2.48 ± 0.03 mm. Test specimens, each measuring 110 mm in length and 30 mm in width, were precision-cut from the laminate using micro water-jet cutting at Fraunhofer IWM (Freiburg, Germany), as shown in Figure 1a. The corresponding cross-sectional micrograph is presented in Figure 1c. Layer separation was achieved using a hybrid process that combined ultrasonic-assisted pre-cracking at 20 kHz [20] with mechanical delamination via a custom-built peel-off apparatus [21–23], as depicted in Figure 1b. The resulting top and bottom layer thicknesses were measured at 1.03 ± 0.05 mm and 1.74 ± 0.04 mm, respectively. The thickness of the top layer reflects the minimum achievable limit of the ultrasonic pre-cracking technique.

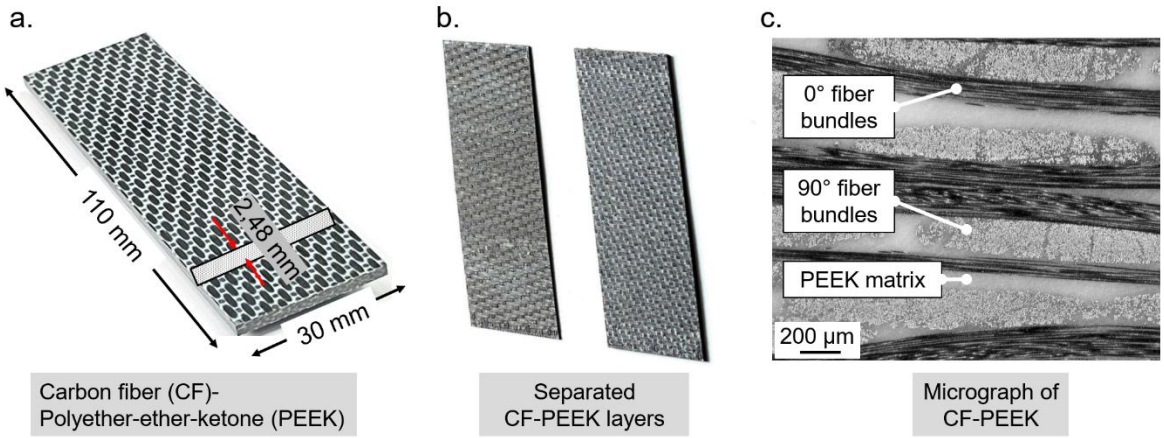

Figure 1: (a) CF-PEEK specimen with dimensions used for the investigation (b) Separated CF-PEEK layers and (c) Cross-sectional view of CF-PEEK specimen with 0° and 90° fiber orientation [24].

Material properties	Units	Values

Glass transition temperature (T_G)	[°C]	140
Melting point (T_M)	[°C]	337
Decomposition temperature (T_D)	[°C]	>550
Ultimate tensile strength 1-direction	[MPa]	776
Young's Modulus E_{11} direction	[GPa]	56.1

Table 1: Material properties of CF-PEEK laminate. The table has been already published in [24].

2.2 Ultrasonic reconsolidation of CF-PEEK at 20 kHz

Ultrasonic repair experiments were conducted using a HiQ 20-6200 ultrasonic plastic welding system from Herrmann Ultraschalltechnik GmbH (Karlsbad, Germany), equipped with a 6.2 kW generator. A schematic of the setup is shown in Figure 2a. The resonance unit included a piezoelectric converter, quick-change adapter, a 1:2 booster, and a rectangular sonotrode (75 mm × 35 mm) capable of delivering a maximum amplitude of 49 µm. The converter transformed electrical energy into mechanical vibrations at a resonance frequency of 20 ± 0.5 kHz. These vibrations were transmitted through the booster to the sonotrode and applied to the joining interface under ambient conditions. Temperature monitoring at the repair interface was performed using thermocouples. Three independent experiments were conducted to record interface temperatures during reconsolidation and post-reconsolidation. A control PC triggered data acquisition via the generator, with temperature data collected through a LabVIEW interface. The separated CF-PEEK layers were joined in a single lap-joint configuration with a 35 mm overlap length and 30 mm width, as shown in Figure 3b. The thicker layers served as the bottom adherend, while thinner layers were placed on top. Prior to welding, the bonding surfaces were cleaned with ethanol to remove contaminants, and the samples were securely clamped using toggle clamps (Figure 3c). The ultrasonic reconsolidation process window was determined using a statistical design of experiment using a non-linear statistical "Central Composite Circumscribed" (CCC) model from the software MODDE [25].

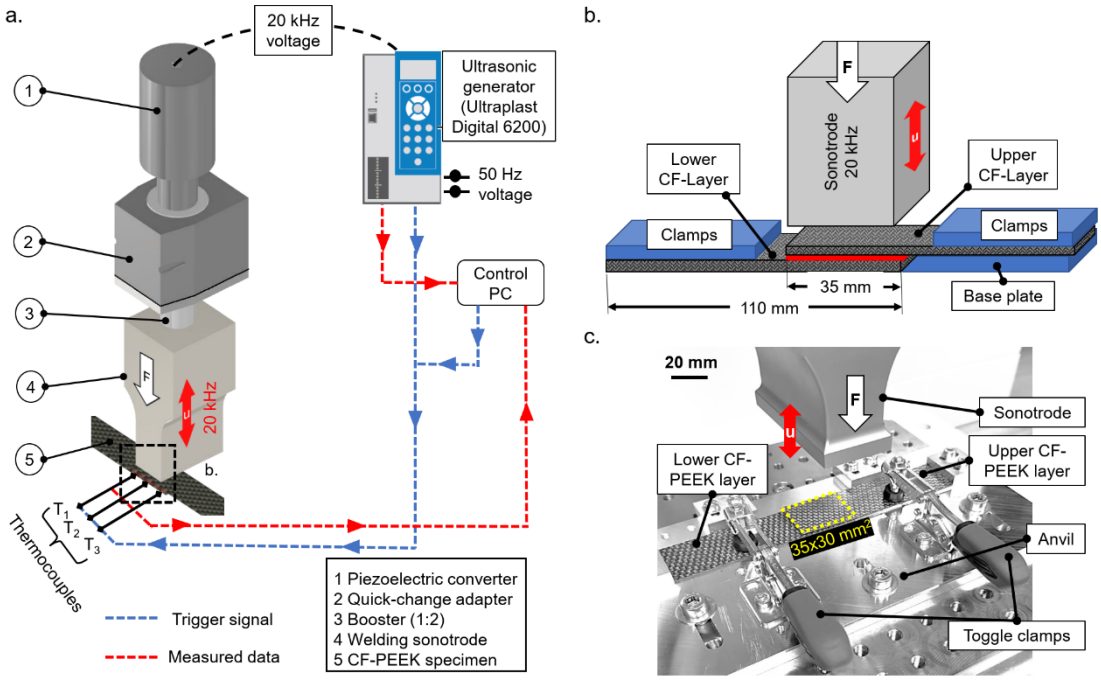

Figure 2: (a) Schematic representation of the ultrasonic repair setup with the oscillation unit. (b) Enlarged view of the clamping system at the reconsolidation zone and (c) actual setup of ultrasonic repair. Figure taken from [26].

2.3 Mechanical and microstructural characterization

The reconsolidated CF-PEEK lap-joint specimens were mechanically tested to determine their ultimate lap-shear strength using a universal testing system of type Z020 from Zwick/Roell (Ulm, Germany) with a 20 kN load cell. Tests were conducted under monotonic loading at a constant displacement rate of 2 mm/min, with the thin layer positioned on top and the thick layer at the bottom, aligned along the loading axis. Surface observations after post-failure were carried out using a Smart Zoom-5 light microscope (Zeiss, Oberkochen, Germany). Additionally, fracture surface analysis was performed using SEM (Zeiss EVO-15) to examine fiber and matrix behavior after repeated reconsolidation trials. Cross-sectional analysis on the repaired zone was not feasible as the repaired joints failed during the specimen preparation. Hence, a Zeiss Xradia Versa 520 system from Fraunhofer IAF (Freiburg, Germany) was used for the 3D X-ray microscopy (XRM) analysis on the repaired CF-PEEK samples.

2.3 Mechanical and microstructural characterization

The reconsolidated CF-PEEK lap-joint specimens were mechanically tested to determine their ultimate lap-shear strength using a universal testing system of type Z020 from Zwick/Roell (Ulm, Germany) with a 20 kN load cell. Tests were conducted under monotonic loading at a constant displacement rate of 2 mm/min, with the thin layer positioned on top and the thick layer at the bottom, aligned along the loading axis. Surface observations after post-failure were carried out using a Smart Zoom-5 light microscope (Zeiss, Oberkochen, Germany). Additionally, fracture surface analysis was performed using SEM (Zeiss EVO-15) to examine fiber and matrix behavior after repeated reconsolidation trials. Cross-sectional analysis on the repaired zone was not feasible as the repaired joints failed during the specimen preparation. Hence, a Zeiss Xradia Versa 520 system from Fraunhofer IAF (Freiburg, Germany) was used for the 3D X-ray microscopy (XRM) analysis on the repaired CF-PEEK samples.

3 RESULTS AND DISCUSSION

3.1 Identification of suitable ultrasonic reconsolidation process window

Ultrasonic repair experiments were conducted on CF-PEEK laminates to optimize process parameters and evaluate tensile lap-shear strength (F_{UTS}) performance. Surface plots were generated by varying two ultrasonic welding parameters while holding one constant: weld time t_{US} (750 ms), weld force F_{US} (601 N), and oscillation amplitude u (37.9 µm) as illustrated in Figure 3a-c. The resulting F_{UTS} values were approximately 15.65 ± 1.31 kN, 15.48 ± 1.78 kN, and 15.78 ± 1.45 kN, respectively. These results were validated through six additional trials, yielding an average lap-shear force of 15.61 ± 1.73 kN. In all cases, the tensile lap-shear force increased initially with weld time and force before decreasing, likely due to fiber bundle damage from excessive polymer squeeze-out. To prevent thermal degradation of the PEEK matrix, weld parameters were capped to ensure peak temperatures remained near 550 °C, below the decomposition threshold. The optimal process condition was identified at F_{US} = 600 N, t_{US} = 750 ms, and u = 37 µm, yielding a consistent F_{UTS} of 15.6 kN.

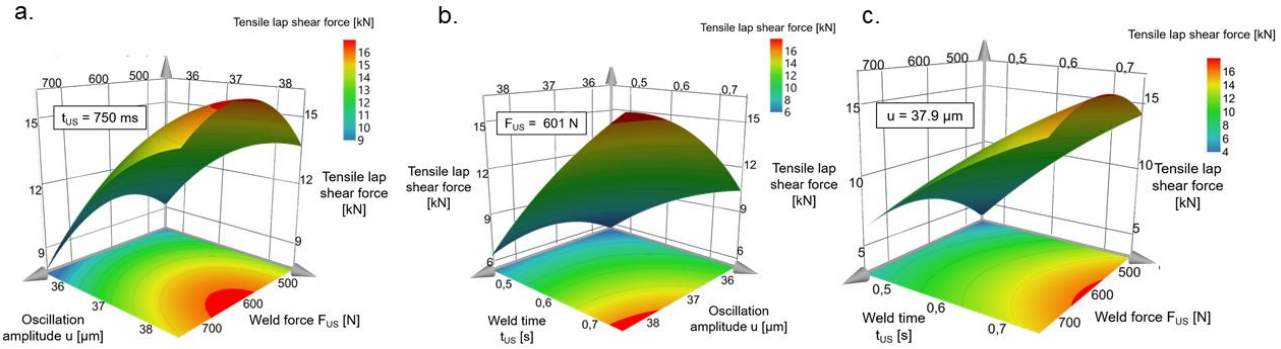

Figure 3: 3D surface plots of CCC model plotted for (a) constant reconsolidation time t_{US} = 750 ms, (b) constant reconsolidation force F_{US} = 601 N, (c) constant oscillation amplitude u = 37.9 µm. Figure adapted from [26].

Figure 4a shows the temperature measurements during ultrasonic repair revealed that oscillation amplitude significantly influences thermal behavior, whereas weld force has minimal impact. The highest temperatures recorded were 547.4 °C and 559.1 °C for the recommended parameter triple and the optimizer function, respectively. A marginal increase in amplitude by 0.9 µm resulted in a 12 °C rise in temperature, highlighting its critical role in thermal input. In contrast, variations in weld force showed negligible influence on peak temperature. When oscillation amplitude increased, temperatures exceeded the decomposition threshold, emphasizing the need for careful amplitude control. Differential scanning calorimetry revealed localized changes in crystallinity, although no significant impact on macroscopic properties was detected. Figure 4b shows the representative load-displacement curves during the tensile lap-shear test. Six repetitions have been performed for the determined suitable ultrasonic reconsolidation parameter and the average lap-shear force was found to be 15.6 ± 1.3 kN.

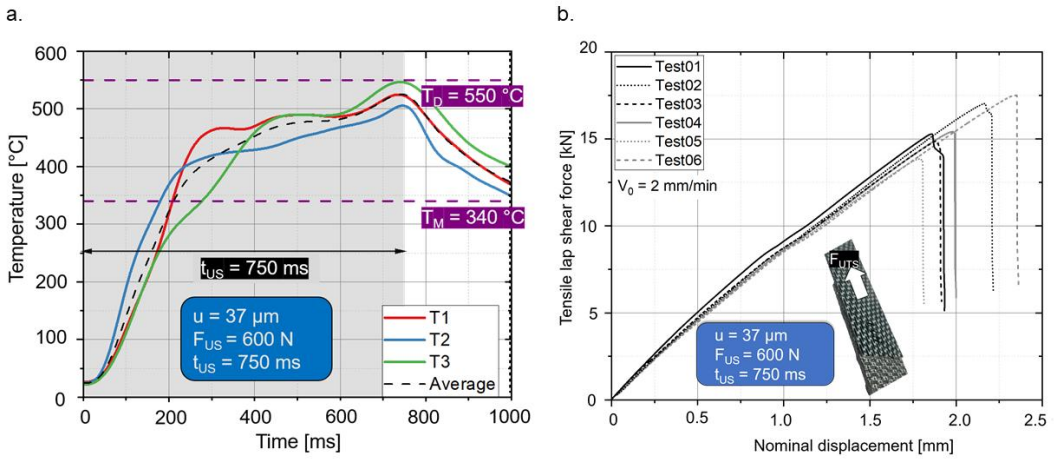

Figure 4: (a) Representative time-temperature curve for the determined suitable ultrasonic reconsolidation process parameter and (b) shows the representative load-displacement curve from the tensile lap shear test of the reconsolidated CF-PEEK laminates. Figure adapted from [26].

3.2 Temperature behavior and failure analysis during post-reconsolidation of CF-PEEK under varying holding forces and hold times

Temperature being a characteristic variable during USW influences the quality of joint performance based on ultrasonic process parameters. This section investigates the influence of holding force and hold time on the temperature distribution and microstructural behavior during the post-reconsolidation phase of ultrasonic welding in thermoplastic composites. Temperature measurements at four distinct locations (T1–T4) across the weld zone revealed spatial variation in thermal behavior, which directly influenced matrix diffusion and defect formation. The parameters used for the characterization of post-reconsolidation phase is listed in Table 2.

Oscillation Amplitude u [µm]	Reconsildation force F_{US} [N]	Reconsolidation time t_{US} [ms]	Holding force F_H [N]	Hold time t_H [s]
37	600	750	0	0
			700	2
			750	4
			800	5
			900	6

Table 2: Parameters used for ultrasonic reconsolidation experiments. The table has been already published in [24].

At a holding force of 700 N and a hold time of 2 s, temperature gradients were evident, with T1 and T2 showing 28% higher temperatures than T3 and T4. This non-uniformity suggested inconsistent residual polymer distribution, resulting in localized decomposition and pore formation (50–200 µm) due to incomplete matrix diffusion. Increasing the hold time to 4 s improved thermal uniformity and matrix diffusion, as reflected by fewer defects and better adhesion (see Figure 5a (i and ii)). At 6 s, the temperature disparity between sensors further decreased to 8%, and failure analysis showed hardened matrix improved consolidation. For a higher holding force of 800 N at 2 s, temperatures were 6% lower than those recorded at 700 N due to enhanced heat dissipation. However, despite higher pressure, insufficient hold time still led to poor matrix diffusion, though the pore size reduced to 5–50 µm. Extending the hold time to 4 s reduced temperature variation and enhanced polymer diffusion (see Figure 5b (i and ii)). At 6 s, thermal distribution became more uniform and matrix diffusion improved, with minor fiber dislocations likely caused by processing or mechanical testing. At 900 N, temperature measurements followed similar trends, though T1 data were unavailable. T2 consistently recorded higher

values than T3 and T4, but the overall temperature was 5–10% lower compared to lower forces. At 2 s, minimal porosity was observed, but significant fiber-matrix squeeze-out occurred, attributed to high compressive forces acting on the laminate before full diffusion. With increased hold time (4 s and 6 s), uniform cooling was achieved (see Figure 5a (i), but excessive pressure led to cohesive failures within the fiber bundles and even fiber breakage, indicating over-consolidation and shear-induced damage (see Figure 5a (ii) [24].

Experiments without applying holding force or hold time demonstrated a slower cooling rate. After 8 s, the temperatures at T1 and T2 remained near the glass transition temperature (T_G) of PEEK, while T3 and T4 were below T_G. Although the matrix had melted during ultrasonic reconsolidation, diffusion between fiber bundles was insufficient, leading to ductile failure of the residual matrix during mechanical testing due to inadequate solidification [24]. These results emphasize the critical role of optimized holding force and duration in achieving uniform thermal distribution, effective matrix diffusion, and defect-free welds. Short hold times, regardless of applied pressure, are insufficient for complete diffusion and defect mitigation. Conversely, excessive holding force applied for extended durations can lead to matrix squeeze-out and fiber damage. A balanced combination of force and time is therefore essential to ensure effective reconsolidation and mechanical integrity of the joint.

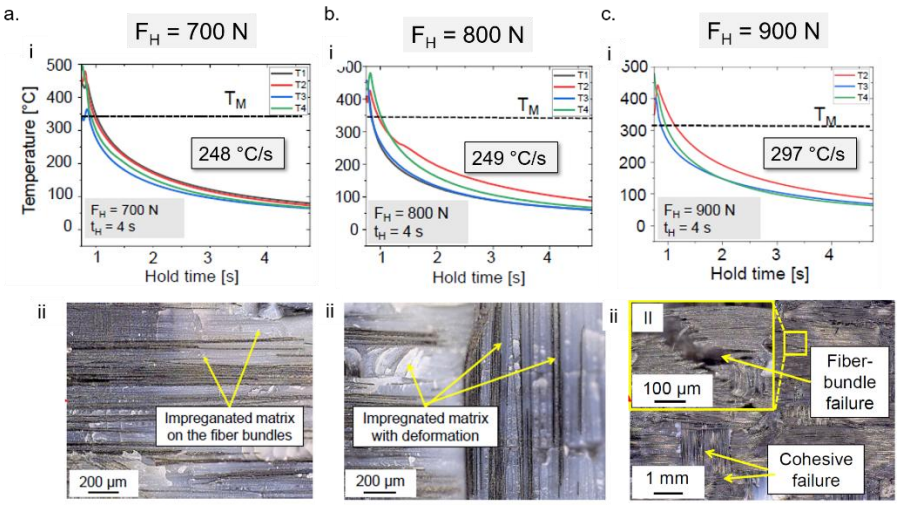

Figure 5: Temperature response during the post-reconsolidation phase, and the micrograph of the welded zone after tensile lap-shear test for (a) F_H = 700 N; t_H = 4 s, (b) F_H = 800 N; t_H = 4 s and (c) F_H = 900 N; t_H = 4 s. Figure adapted from [24].

3.3 Quality of ultrasonic reconsolidation of CF-PEEK after successive reconsolidation cycles

The mechanical performance of ultrasonically reconsolidated CF-PEEK joints was evaluated over three successive repair cycles using optimized process parameters: a holding force of 750 N and a hold time of 5 seconds. The first cycle corresponded to the initial reconsolidation following layer separation, with two additional repair cycles subsequently applied. A progressive reduction in lap-shear strength was observed with each cycle. The initial reconsolidation yielded an average lap-shear load of 15.65 ± 1.02 kN, whereas the third cycle showed a significant decline to 10.3 ± 1.5 kN, representing an approximate 35% reduction in joint strength. A representative load-displacement response revealed a drop in both load capacity and nominal displacement, with the displacement decreasing from 2.4 mm in the first cycle to 1.18 mm in later cycles [24]. The decrease in mechanical performance is attributed to surface degradation of the PEEK matrix. Repeated exposure to high temperatures during ultrasonic processing can induce thermo-oxidative degradation, forming a surface layer that inhibits effective reconsolidation, similar to observation in [27]. Although the core remains intact, the damaged surface layer likely limits matrix flow and interfacial bonding. Consequently, residual polymer accumulation with increasingly amorphous character was observed on the failure surfaces, leading to brittle failure

behavior in the later repair cycles.

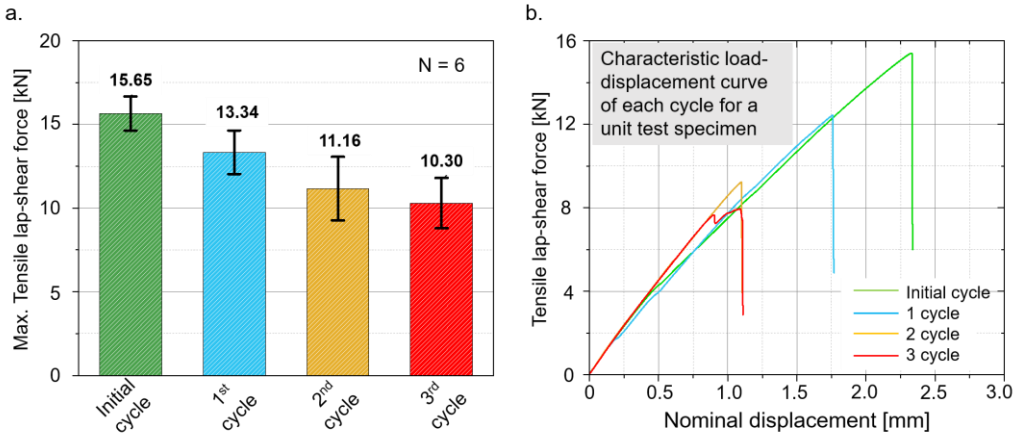

Figure 6: (a) Maximum tensile lap-shear force for 3-cycle repair of separated CF-PEEK layers by ultrasonic reconsolidation. (b) Representative load curve of a single specimen at each repair cycle tested with a displacement velocity of 2 mm/min. Figure taken from [24].

3.4 Ex-situ characterization of CF-PEEK by 3D X-Ray Microscopy (XRM)

3D-XRM scans were conducted on the repaired region within a volume of 5 mm × 5 mm, highlighted by the blue box. In a two-dimensional perspective, the scans encompass the reconsolidated interface (represented by the purple-shaded area) along with the top and bottom neighboring CF-PEEK layers (refer Figure 7a). Figure 7b shows the XRM scan in yz plane for the pre-determined ultrasonic reconsolidation process parameter which revealed void content upto 0.99% and poor interfacial contact near the weld line, attributed to uneven residual polymer distribution caused by material ejection during layer separation. This led to fiber-matrix debonding and cohesive failures above the weld interface. Additionally, fiber layer decohesion was observed near the weld zone. In contrast, specimens repaired using optimized reconsolidation and post-reconsolidation parameters exhibited significantly reduced voids (0.71%) and debonding, with no cohesive failures detected (see Figure 7c). These results confirm the effectiveness of optimized holding force and hold time time in enhancing interfacial bonding and maintaining structural integrity in the repaired CF-PEEK laminates [24].

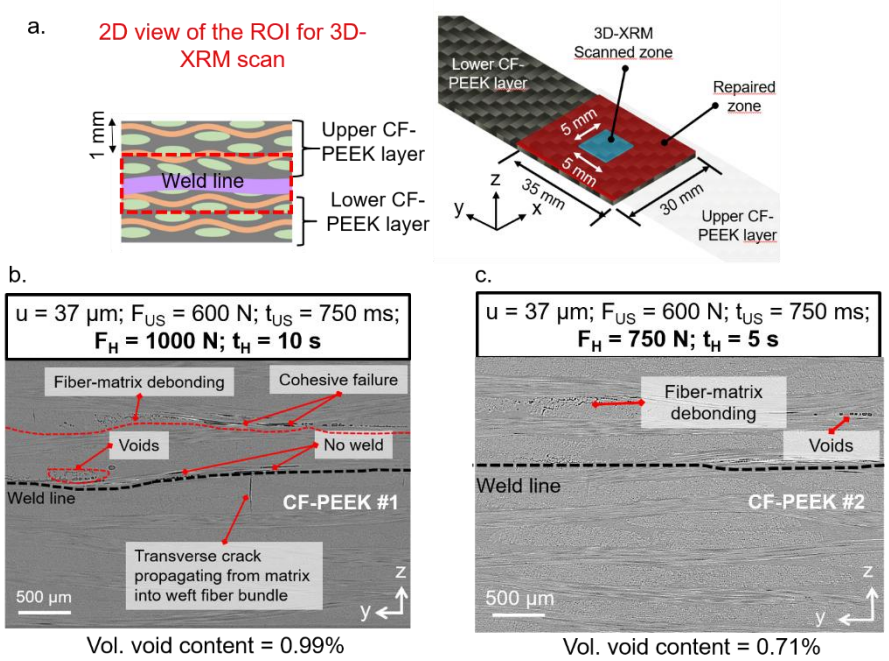

Figure 7: (a) Schematic of the CF-PEEK specimen with the identified optimal parameter scanned using 3D XRM. (b) 3D-XRM scan in yz plane for the (b) determined suitable reconsolidation parameter and for the (c) determined reconsolidation and post-reconsolidation parameter. Figure adapted from [26].

4 SUMMARY AND CONCLUSIONS

Ultrasonic repair of CF-PEEK laminates demonstrated that process parameters—particularly oscillation amplitude, weld force, and weld time significantly influence joint performance and thermal behavior. Optimal ultrasonic reconsolidation conditions (F_{US} = 600 N, t_{US} = 750 ms, u = 37 µm) consistently yielded high lap-shear strengths (approx.15.6 ± 1.3 kN) without exceeding the thermal degradation threshold of the PEEK matrix. Oscillation amplitude had the most pronounced effect on peak temperature, underscoring its critical role in thermal control during welding.

Post-reconsolidation analysis revealed that both holding force and hold time are essential for ensuring uniform thermal distribution and effective matrix diffusion. Inadequate hold time led to poor diffusion and porosity, while excessive holding force induced fiber damage and cohesive failure. A balanced condition (e.g., 750 N, 5 s) achieved optimal consolidation, minimizing voids and defects. Spatial temperature gradients across the weld zone further emphasized the need for controlled thermal management to avoid localized degradation.

Repeated ultrasonic repair cycles under optimized parameters showed a gradual decline in mechanical strength (approximately 35% after three cycles), primarily due to surface degradation and thermo-oxidative damage of the PEEK matrix. This led to reduced interfacial bonding and a shift toward brittle failure modes.

3D-XRM scans confirmed that poor reconsolidation parameters resulted in interfacial voids and fiber-matrix debonding, while optimized conditions improved bonding quality and reduced internal defects. Overall, the study demonstrates that precise control of ultrasonic and post-weld parameters is critical to ensure high-quality, repeatable repairs in CF-PEEK laminates, while repeated thermal exposure imposes limitations on long-term repairability.

5 OUTLOOK

To close the loop, alternative ways for the reconsolidation include bulk processing methods such as hot pressing are available. Therefore, a feasibility study has been carried out to assess this as an alternative to ultrasound-based reconsolidation. Hence, laminates consisting of polypropylene (PP) as a matrix and glass fibers (GF) as reinforcing fibers were cut in strips with the same process as described above and arranged in two layers in a shear edge mold. This dual layer was then reconsolidated into a single laminate in a Vogt Labopress P200S type hydraulic press at a consolidation temperature of 180°C and a pressure of 5 bar for 20 minutes. The consolidated composite laminates were then investigated by means of X-ray analysis on a Baker & Hughes Phoenix nanotom M X-ray Computed Tomography (CT) system and observation of a plastographic specimen with a Keyence 7000 optical microscope respectively.The plastographic specimen is prepared by sequentially grinding a 50 mm specimen with a cylindrical geometry (which contains a small section of the laminate embedded in an epoxy) with grit papers from coarse (320 grit for 4 minutes) to fine grain size (500, 800 and 1200 grit for 2 minutes each) on Silicon Carbide foils, followed by polishing with diamond pastes (9 micron for 3.5 minutes and 3 micron for 2.5 minutes) on a felt pad. The grinding and polishing are completed on a Streurs Tegramin-25 machine, with a continuous flow of water to clean the debris.

The laminate was segmented in a total of 720 slices in the due process of a scan that was conducted at an X-ray tube voltage of 100 kV and power of 12 W, which ran for 1500 ms. The 3D reconstruction of the laminate from CT-scan (Figure 8a) shows a consolidated PP-GF laminate, with minimal misalignments in the fiber bundle orientations and consistent bundle volumes. Furthermore, a highly regular mesostructure can be observed across major part of the Y-Z cross section (Figure 8b) of the laminate. The tows, or fiber bundles, are evenly sized and regularly spaced relative to each other. The exact cause for a section with spatially distorted fiber bundles (observed towards right hand end in Figure

8b, enclosed within the white dotted square) is likely a gap between the strips. The plastographic inspection of the X-Z plane (Figure 8c) further confirms the mesostructural observations from the CT-scan. Additionally, a homogenous distribution of fibers within the bundles can be clearly observed. Furthermore, lack of any noticeable of voids or defects confirms adequate consolidation of the laminate.

The evident regularity in the fiber distribution and a high degree of accuracy in the bundle characteristics at meso- and micro-levels, as well as a seemingly uniform quality of consolidation attest to the potential of hot pressing as an alternate reconsolidation route. Nevertheless, gaps during stacking have to be prevented as they may lead to fiber misorientation. Finally, the single strips recovered via ultrasound might not only be used for repair of existing laminates but might also serve as a basis for reuse of recycled bulk materials without significant loss of material integrity.

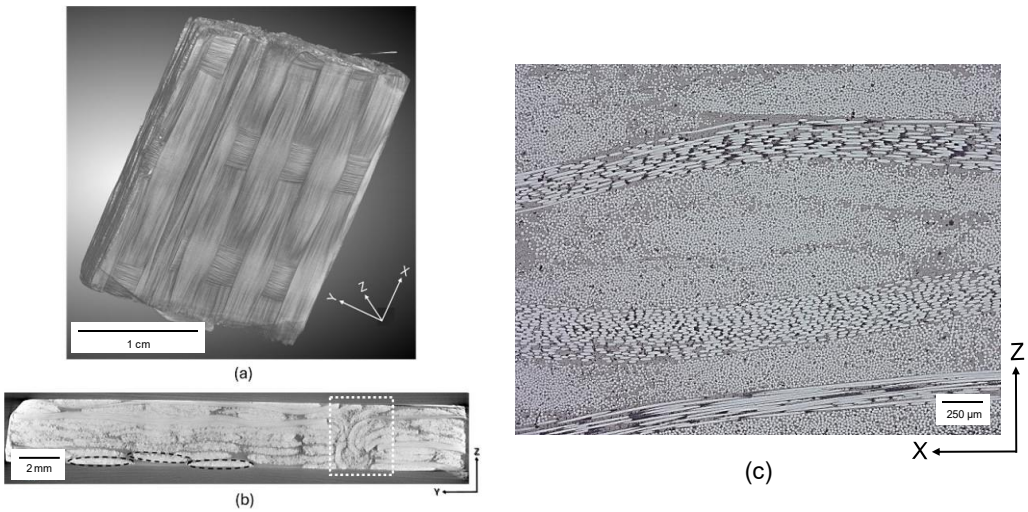

Figure 8: (a) 3D reconstruction of a PP/GF laminate consolidated with a hot press at 180°C, 5 bar for 20 minutes (b) Section of the consolidated PP/GF laminate in Y-Z plane showing mostly uniform fiber bundle (or tow) characteristics – except at gaps in between the single strips (enclosed within dotted white square). Some of the transverse fiber bundles are marked with the dotted black line (c) Plastograph of a representative section of the PP/GF laminate demonstrating regular intra-bundle fiber distribution as also nearly no defects and minimal resin-rich areas.

The evident regularity in the fiber distribution and a high degree of accuracy in the bundle orientation at a meso-level, as well as a seemingly uniform quality of consolidation attest to the potential of hot pressing as an alternate reconsolidation route. Nevertheless, gaps during stacking have to be prevented as they may lead to fiber misorientation. Finally, the single strips recovered via ultrasound might not only be used for repair of existing laminates but might also serve as a basis for reuse of recycled bulk materials without significant loss of material integrity.

ACKNOWLEDGEMENTS

The authors would like to thank the Carl-Zeiss Foundation and the Walter-and-Ingeborg-Herrmann Foundation for their financial support in the frame work of the project "Cross-scale Characterization of Robust Functional Material Systems (SCHARF)" and for all the ongoing power ultrasonic related research works at INATECH respectively. Additionally, the authors also thank Dr. Lutz Kirste and Dipl.-Ing. Mario Prescher from Fraunhofer IAF for their assistance in 3D X-Ray Microscopy measurements.

ABSTRACT

The ambition to expand human presence deeper into the solar system necessitates the development of technologies capable of fabricating, deploying, and maintaining large-scale space structures with minimal Earth-based support. Traditional logistics, reliant on frequent cargo resupply, incur exponentially increasing mass and volume penalties with distance from Earth. For long-duration lunar outposts, orbital missions, and Martian habitats, structures must be compact during launch, mechanically robust when deployed, and manufactured via scalable and adaptable in-situ processes. Composite materials are critical due to their superior strength-to-weight ratios and resistance to fatigue and corrosion. Out-of-autoclave (OoA) manufacturing techniques have emerged as key enablers, reducing production costs and increasing efficiency for large, complex components such as deployable composite booms, which facilitate compact storage and reliable deployment of membrane-supported systems (e.g., solar sails, antennas, reflectors). The integration of OoA methods with advanced materials promises transformative advances in space structure manufacturing. Concurrently, in-space manufacturing (ISM), including fused filament fabrication (FFF) 3D printing, enables on-demand production and customization of mission-critical components, decreasing dependency on Earth resupply. This study further shows the use of local material (regolith) into composite filaments suitable for FFF printing, enabling a closed-loop material lifecycle aboard space habitats. By combining ultra-thin composite booms with in-situ recycling and additive manufacturing, a sustainable, modular approach to structural maintenance and fabrication for long-duration missions on the Moon and Mars can be realized. This work presents ongoing research on OoA and ISM process development using novel materials to advance sustainable space exploration architectures.

1 INTRODUCTION

Ambitions to extend human presence deeper into the solar system are driving exceptional interest in technologies that can produce, deploy, and maintain large-scale structures in space using only minimal support from Earth. Conventional logistics chains, heavily reliant on cargo resupply, impose steep mass and volume penalties which grow exponentially with distance from Earth. For future lunar outposts, long-duration orbital missions, and Martian bases, the solution must involve structures that are compact during launch, robust when deployed, and manufactured using processes that are scalable and flexible enough to be adapted on site.

Composite materials are essential in the development of advanced space structures due to their excellent strength-to-weight ratios and resistance to fatigue and corrosion. These properties enable the

creation of lightweight yet robust components for aerospace applications, driving the need for cost-effective and scalable manufacturing methods. Out-of-autoclave (OoA) processes have emerged as a key solution, offering reduced production costs, improved efficiency, and flexibility, particularly for large, complex components [1,2]. A key application is the production of deployable composite booms, which help solve storage issues in launch vehicles and enable the deployment of large-scale structures in space. Boom structures are slender, elongated components that play a critical role in aerospace applications, particularly in the deployment and stabilization of membrane-based systems such as solar sails, antennas, and reflectors [3-5]. These structures are responsible for maintaining the desired geometry of the membrane throughout its operation, ensuring both precision and reliability.

Given the harsh conditions of the space environment, there is a pressing need for novel materials that offer enhanced durability and resilience. For instance, polymeric nanocomposites, enhanced by nanoparticles like carbon nanotubes and graphene, offer superior properties, including thermal and radiation protection, impact resistance, and enhanced mechanical performance [6-8]. These materials are adaptable to meet the specific demands of space missions, providing lightweight, multifunctional solutions. By integrating OoA manufacturing techniques with these advanced materials, the aerospace industry stands to achieve significant breakthroughs in the design and deployment of next-generation space structures.

In parallel, additive manufacturing, including 3D printing, is revolutionizing space manufacturing. This technique allows for precise customization of components and has already demonstrated its utility aboard the International Space Station (ISS) for in-situ production of tools and parts [9-11]. It allows precise customization of components and can enable the construction of habitats and infrastructure on lunar or Martian missions using local materials or recycled hardware [12-18]. Crewed missions generate streams of single-use packaging, especially in the form of food and drink containers [16-18]. These multilayer laminates, often combining LDPE, PET, and aluminium foil, present a recycling challenge on Earth, but in space, they become both a burden and an opportunity. Every gram of waste that can be repurposed into new functional feedstock eases the mass budget for resupply launches.

Both OoA and in-space manufacturing (ISM) share principles of reducing material waste and optimizing resource utilization, which are crucial for space-based operations with limited resources. OoA allows for large components without autoclave size constraints, while ISM eliminates payload limitations for constructing massive space structures. Together, advancements in composite material fabrication, OoA processes and 3D printing represent a paradigm shift in space structure manufacturing, fostering more efficient, sustainable, and scalable solutions for space exploration.

This study contributes to the expanding body of research aimed at advancing out-of-autoclave (OoA) manufacturing techniques for large-scale structures, while also exploring in-situ process technologies based on fused filament fabrication (FFF). Structural components, such as those used to deploy sensors or reflect sunlight for propulsion, can be produced in modular sections via OoA methods. When damage occurs, for example when a hinge fails or a clip snaps, discarded materials from daily operations may be shredded, reprocessed, and reprinted into functional replacements.

In this closed-loop framework, material science, structural engineering, and mission logistics intersect to create a model of sustainable space exploration. The work presented aims to highlight current research on the development of OoA and in-situ manufacturing techniques, emphasizing the use of novel materials for the construction of space structures and components intended for extended human missions on the Moon and Mars.

2 DEPLOYABLE STRUCTURES

Deployable boom structures are predominantly manufactured using carbon fiber/epoxy prepreg systems, commonly processed via autoclave curing or vacuum bag molding techniques [19–22]. While prepregs offer the advantage of precise resin control, ensuring consistent fiber wet-out and enhanced quality assurance, they inherently limit the diversity of fabric architectures that can be utilized. This limitation reduces design flexibility, particularly when optimizing mechanical properties or conformability for specific structural demands. In contrast, dry fiber reinforcements do not require refrigeration and possess a longer shelf life, thereby simplifying storage and handling logistics. Their cross-sectional geometry varies depending on specific functional requirements. Among the most

prevalent configurations, are storable tubular extendible members (STEM), collapsible tubular masts (CTM), and triangular rollable and collapsible (TRAC) booms. In the present work, the focus is directed specifically toward the fabrication of the A STEM configuration.

This study employs spread tow carbon fabrics combined with CYCOM® 823 epoxy resin. The resin was selected for its favourable viscosity at processing temperatures and its robust mechanical performance once cured.

Spread tow fabrics exemplify how incremental advancements in material architecture can unlock performance gains unattainable with conventional woven textiles. By unbundling standard fiber tows into flat tapes with highly aligned filaments, these reinforcements minimize void content and matrix-rich zones, enabling lighter and stiffer laminates at equivalent fiber volume fractions. When integrated into boom structures, spread tow tapes enhance bending stiffness and foldability, two properties often in competition in traditional woven laminates. During folding and subsequent re-extension, the laminate must endure repeated strain cycles without initiating cracks or causing fiber misalignment, a challenge that intensifies as the laminate thickness decreases to sub-millimeter scales.

The fabrication of ultrathin booms using spread tow composite technology necessitates meticulous control throughout the manufacturing process. This investigation utilizes TeXtreme® HS40 carbon fiber fabrics, featuring 12K filaments and an exceptionally low areal weight of approximately 42 g/m². Such reinforcements facilitate the production of extremely thin laminates while preserving high in-plane stiffness and excellent drapability. The lay-up procedure begins with precision cutting of fabric plies, employing custom-designed jigs to maintain strict ±45° fiber alignment. This orientation promotes optimal shear resistance during deployment and retraction cycles, which is critical for boom structures that transition from a coiled stowed configuration to a fully deployed state without suffering permanent deformation or fiber misalignment.

2.1 Fabrication of tubular extensible members

The hand lay-up technique is performed on a stainless-steel cylindrical mandrel, which acts both as a support and as a form to replicate the final tubular mast geometry. Special care is given to the manual impregnation of the carbon fabric with CYCOM® 823 epoxy resin. The resin is degassed in a Thinky ARE-250 planetary mixer prior to use, ensuring that no entrapped air pockets compromise the laminate's structural integrity. A thin film of PTFE, such as Teflease MG2, lines the mould to facilitate clean demoulding and preserve the surface finish, which is especially important in the context of structures that must withstand dynamic deployment loads. To achieve a fiber volume fraction V_f of approximately 60% in the final boom structures, an experimental investigation was carried out on various stacking sequences of auxiliary materials. Many boom samples were produced and analyzed to determine their resin content. To this end, different combinations of release films, both perforated and non-perforated, and varying numbers of peel ply layers were considered to regulate the amount of resin expelled from the composite part and thereby attain the desired V_f. The final process lay-up sequence identified as optimal for this specific laminate consists of the following: an initial layer of polytetrafluoroethylene (PTFE) tape serving as a release layer from the mold surface, followed by the composite laminate itself, then a wrap of Hi-Shrink Tape, a peel ply layer, a perforated Teflon film, a breather layer, and finally the vacuum bag. This optimized stacking arrangement is illustrated schematically in Fig. 1.

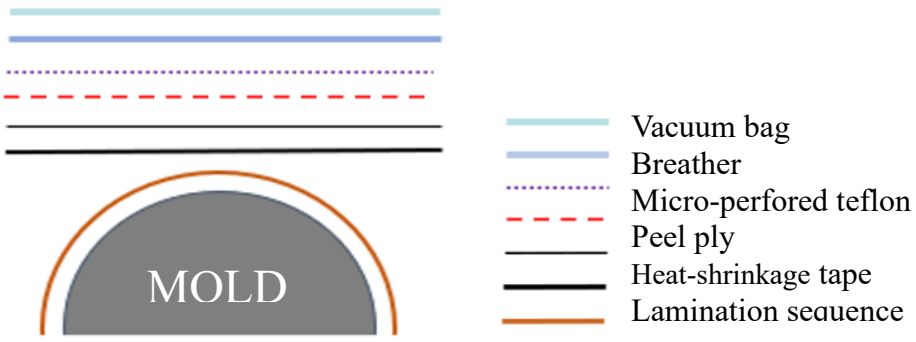

Figure 1. Consumable layer stacking sequence.

The mold used in this study (Figure 2) was specifically designed for the present application and

manufactured in stainless steel. It features a central through-hole along its longitudinal axis, allowing for the integration of thermal control actuators. One of the main challenges in the fabrication of composite booms, as opposed to flat laminate specimens, is the demolding process, i.e., the separation of the cured part from the mold surface. Typically, a release agent is applied to the mold to facilitate this operation. For the present application, the most suitable release material was identified as Teflease MG2, a polytetrafluoroethylene (PTFE) tape coated with a silicone-based adhesive. The use of this release system avoids potential chemical contamination of the resin caused by volatile compounds that may be generated during curing because of residual chemicals from conventional liquid release agents. Such volatile substances, if trapped within the laminate, could outgas once in orbit, posing a risk to both structural integrity and spacecraft subsystems. Moreover, this tape is easy to apply and does not require special safety precautions for operator health. In addition to ensuring reliable release of the cured composite from the mold, the Teflon tape also protects the mold surface from potential damage that may occur during demolding. Its use contributes to preserving the integrity of the mold and allows for an excellent surface finish of the final prototype. The lay-up of both the composite material and the consumable layers can be carried out directly on the cylindrical mold. The process begins with the placement of the first layer of dry fabric onto the mold surface. At this stage, difficulties were encountered due to the limited dimensional stability of the dry fabric, which tends to shift or deform when un-impregnated. To address this issue, a thin layer of resin was applied to the mold prior to laying down the fabric. This pre-coating promotes better adhesion between the fabric and the mold, stabilizing the positioning of the first ply.

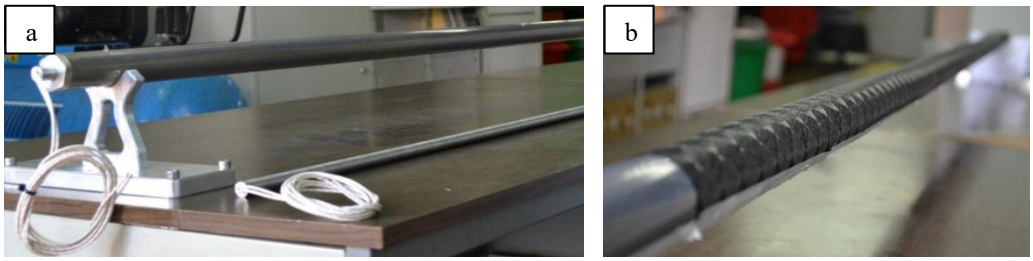

Figure 2. a) Detail of the mold surface covered with Teflease MG2 and the heating element; b) close-up of the fabric lay-up phase.

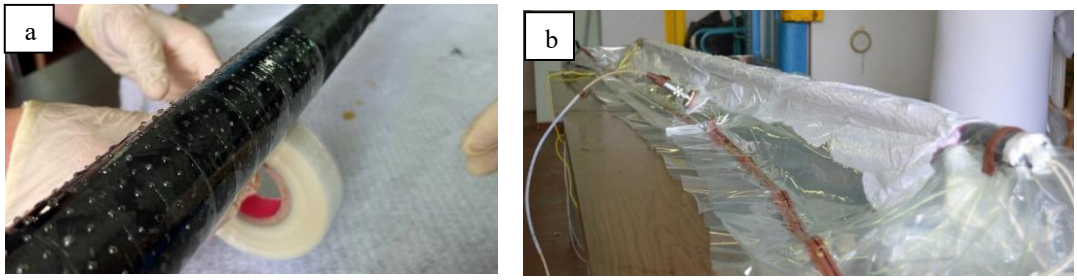

Figure 3. Application of the heat-shrink Hi-Shrink Tape; process configuration during the curing stage

Once laid up, the laminate stack is consolidated under vacuum. Breathers and perforated release films ensure that excess resin is evenly distributed and vented, minimising localised resin-rich zones which could otherwise act as failure points. After bagging, the assemblies undergo an OoA curing cycle, ramping from ambient to approximately 125–130 °C, maintaining a hold sufficient to complete the cross-linking reaction throughout the entire thickness (Figure 3). The final cured booms demonstrate minimal residual stress and excellent geometric fidelity. Despite the apparent simplicity of this process, each step embodies critical decisions that reflect the lessons learned from recent experimental campaigns on deployable structures for solar sails and high-area-to-mass-ratio devices [23-24]. To investigate the influence of key process variables, a series of prototypes was manufactured. The study focused on different laminate ply lay-up techniques, variations in consumable stacking sequences, and the selection

of cutting and sanding tools. The results of this experimental campaign, combined with detailed inspections of the fabricated components, informed the development of the processing procedure described earlier. Several representative prototypes were selected for analysis, as their post-process inspection provided critical insights that guided the refinement of the manufacturing methodology. Among the factors examined, particular emphasis was placed on the application of Hi-Shrink Tape, due to its significant impact on part quality and dimensional stability. Figure 4 illustrates two exemplar cases: on the top, a prototype produced without Hi-Shrink Tape; on the bottom, a counterpart fabricated with its use.

Figure 4. Top: 4-m prototype manufactured without heat-shrink tape. Bottom: 4-m prototype manufactured with heat-shrink tape.

Initially, a non-perforated Hi-Shrink tape was employed. While this version provided excellent compaction during curing, the resulting composite structure exhibited a degree of brittleness. Although the component retained its intended shape in the unrolled (production) configuration, it could no longer be rolled without fracturing due to an excessive accumulation of surface resin. To address this issue, a perforated Hi-Shrink tape was subsequently adopted. This alternative not only compacted the boom structure effectively but also facilitated the evacuation of excess resin during curing. The combined effect of improved compaction and controlled resin bleed led to a significant reduction in both thickness and weight of the prototype component. Specifically, the thickness decreased from 0.24 mm to 0.14 mm, as shown in Fig. 5, while the weight was reduced from approximately 20 g/m to 15 g/m.

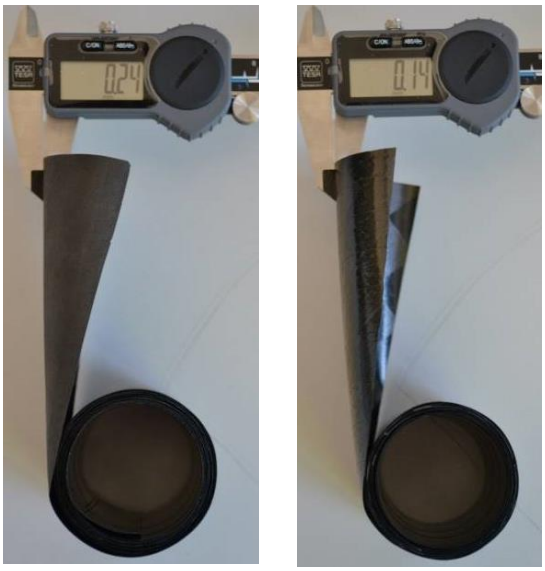

Figure 5. Thickness of the prototype manufactured without hi-shrink tape and with hi-shrink tape (right).

The reduction in laminate thickness corresponds to an increase in the fiber volume fraction Vf. This increase not only enhances the mechanical performance of the composite due to the greater contribution of the reinforcing fibers but also reduces the tendency of the structure to exhibit brittle behavior. In fact,

a resin-rich laminate would be more prone to matrix cracking during rolling and unrolling operations, eventually leading to composite failure. Furthermore, the reduced laminate thickness results in a more compact rolled configuration of the prototype (Fig. 6), thereby decreasing the overall volume and mass of the associated storage and deployment systems.

Figure 6. Prototype volume in rolled configuration: without Hi-Shrink Tape (left) and with Hi-Shrink Tape (right).

3 IN SITU MANUFACTURING

In-space manufacturing (ISM) refers to the production of components and structures directly in the space environment, rather than on Earth. It enables on-demand fabrication using local or recycled materials, reducing launch mass and mission costs. ISM supports adaptability and self-sufficiency in long-duration missions. It is a key enabler for sustainable space exploration and habitation.

In our studies, the material selected as the basis for studying in-situ manufacturing processes was low-density polyethylene (LDPE). Its hydrogen-rich composition offers inherent radiation shielding properties, particularly effective for neutron attenuation. This characteristic makes LDPE a suitable matrix for combination with high atomic number (Z) elements, enabling the fabrication of structural materials with enhanced shielding capabilities [12, 25-26]. In addition, the polyethylene is present in many elements presented on-board and it is one of the material of the astronaut food packaging [14,18]. The polymer matrix employed in this study was low-density polyethylene (LDPE) powder, supplied by Thermo Scientific Chemicals. The LDPE powder exhibited an average particle size of approximately 500 microns. The Martian regolith simulant (RE) was Biolit powder.

3.1 Fused filament fabrication for in-situ regolith/polyethylene composites

The process begins with the fabrication of composite pellets, which serve as the primary feedstock for the extrusion phase. These pellets were formulated by combining low-density polyethylene (LDPE) with varying weight percentages (5, 10, 15, 20, and 30 wt%) of Martian regolith simulant, acting as the reinforcing filler. Once prepared, the composite pellets were fed into a filament extruder (Felfil Evo), where they were melted, homogenized, and extruded into continuous filaments with controlled diameter and mechanical properties. The extrusion was carried out using a 1.75 mm nozzle at approximately 160 °C, with a screw rotational speed of 7 RPM. These parameters were carefully controlled to ensure consistent mixing and uniform filament quality—critical factors in maintaining dimensional stability and mechanical performance in the final printed parts.

To further enhance the dispersion of filler particles within the polymer matrix, the initially extruded filaments were shredded into smaller fragments and re-extruded. This additional processing step facilitated a more uniform distribution of the regolith simulant, minimized the formation of agglomerates, and consequently improved the structural and functional properties of the composite material.

Achieving the right balance between flexibility and rigidity in LDPE/regolith composite filaments is critical to ensuring both printability and mechanical reliability in fused filament fabrication (FFF) processes. While LDPE inherently offers low melting temperatures and good flexibility, favorable characteristics for extrusion, the addition of regolith simulant at high concentrations, such as 30 wt%,

tends to increase brittleness and reduce ductility. These changes can result in filament breakage, feeding instability, or inconsistent extrusion during the printing process.

Following extrusion and refinement, the filaments were spooled and prepared as feedstock for FFF-based 3D printing, enabling the in-situ fabrication of functional components in space environments. As illustrated in Figure 7a, a 20-meter-long filament containing 30 wt% filler content was successfully wound onto the spool, exhibiting adequate flexibility for handling and processing. Figure 7b highlights the tension applied to the filament during the spooling phase in the cooling stage, which is crucial for maintaining a consistent diameter and preventing deformation.

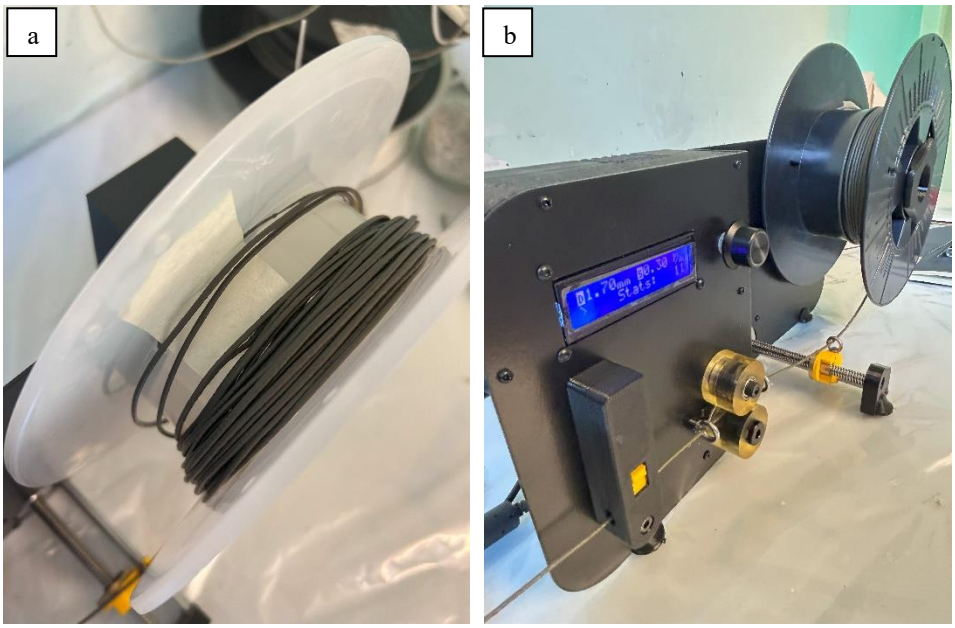

Figure 7. a) 20-meter-long LDPE/regolith composite filament with 30 wt% filler content wound onto the spool at the end of the extrusion process; b) view highlighting the filament tension during the spooling process in the cooling phase.

After the extrusion process, the LDPE/regolith composite filaments were used to fabricate test elements via fused filament fabrication (FFF), with process parameters carefully optimized to ensure print quality and dimensional accuracy. Figure 8 shows the 3D-printed specimens prepared for dynamic mechanical analysis.

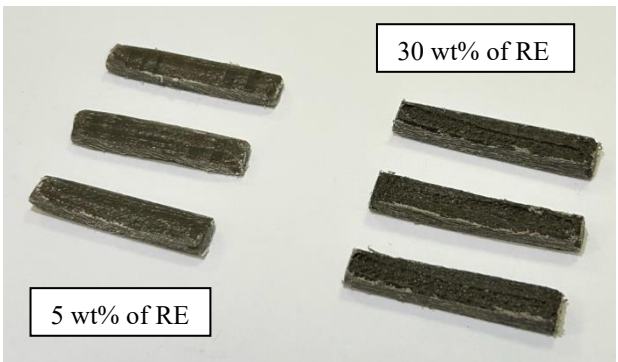

Figure 8. 3D-printed specimens of LDPE/RE composites at 5 wt% (left) and 30 wt% (right) of filler.

CONCLUSIONS

This study demonstrates the feasibility of fabricating deployable ultrathin composite boom structures and radiation-shielding materials using both traditional out-of-autoclave (OoA) and in-situ manufacturing (ISM) processes. For structural applications, the integration of spread tow carbon fiber

fabrics with a carefully optimized OoA lay-up and curing cycle enabled the production of high-performance, sub-millimeter-thick tubular booms with excellent stiffness-to-weight ratios, geometric fidelity, and foldability. The use of perforated Hi-Shrink Tape proved particularly effective in improving laminate compaction, reducing resin-rich zones, and enhancing both mechanical robustness and stowability of the final components.

Parallel efforts in the field of in-situ resource utilization focused on the development of LDPE/regolith composite filaments for additive manufacturing. The results highlight the importance of controlling filler dispersion, filament homogeneity, and mechanical flexibility to ensure reliable extrusion and printing performance in the context of fused filament fabrication (FFF). Filaments containing up to 30 wt% regolith simulant were successfully extruded, reprocessed for improved dispersion, and used to fabricate 3D-printed specimens with promising structural integrity. These findings support the viability of in-situ manufacturing strategies based on locally sourced or recycled polymers and regolith, offering a scalable pathway toward self-sustaining construction and maintenance capabilities in extraterrestrial habitats.

Together, these two experimental directions underscore the critical role of advanced material processing, both terrestrial and space-based, in enabling lightweight, deployable structures and functional components for future space exploration missions.

ACKNOWLEDGEMENTS

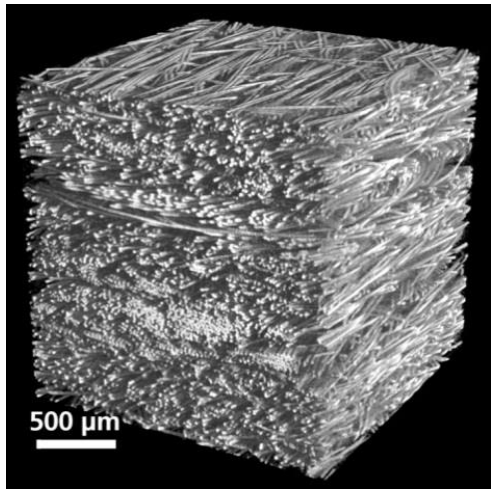
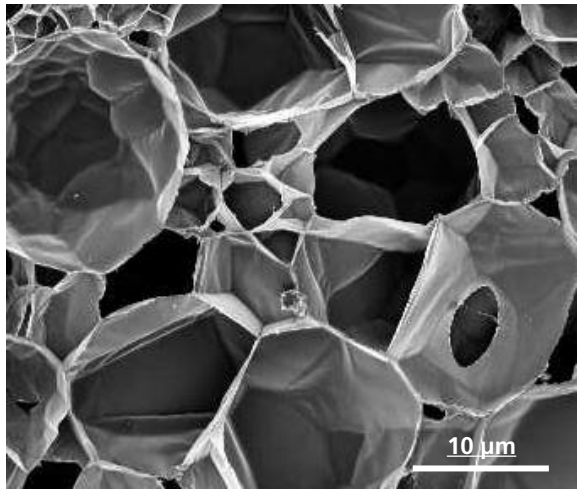
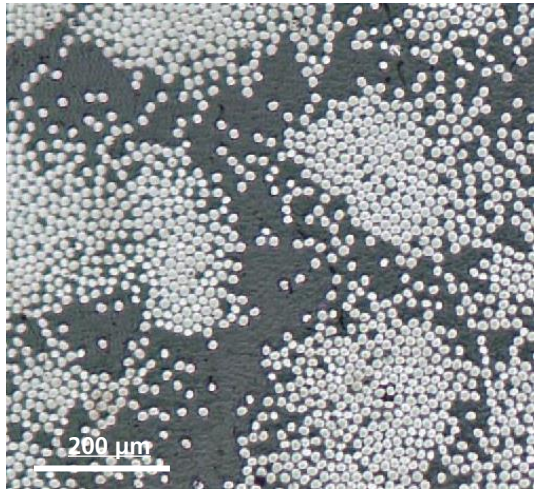
Semantic interoperable data model and stochastic multiscale analysis of short fibre composites



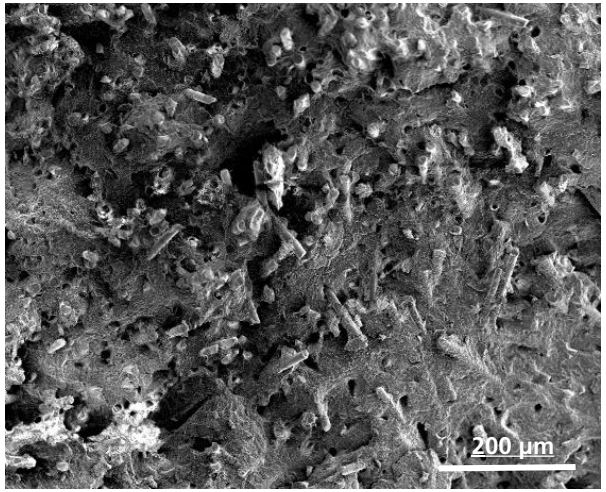
Jörg Hohe, Benedikt Rohrmüller, Patrick Schneider, Niklas Toffert, Martin Koerdel, Nicolas Christ, Carla Beckmann



- Introduction
- Experimental observation
- Numerical homogenisation and stochastic enhancement
- Semantic interoperable data model
- Example
- Conclusions



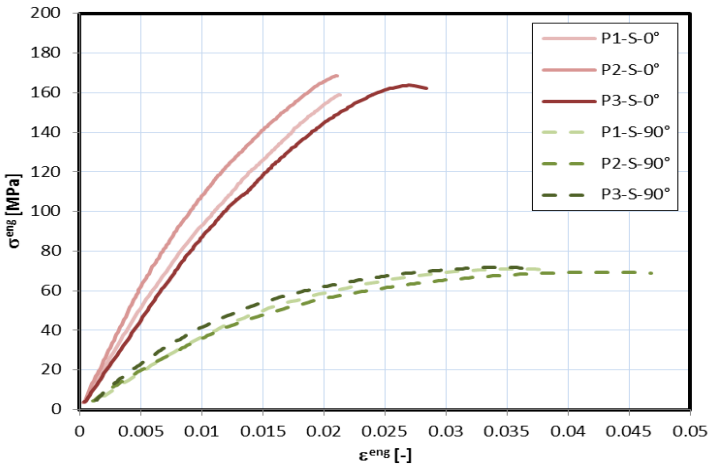
Interoperable data model and stochastic analysis of short fibre composites



Introduction

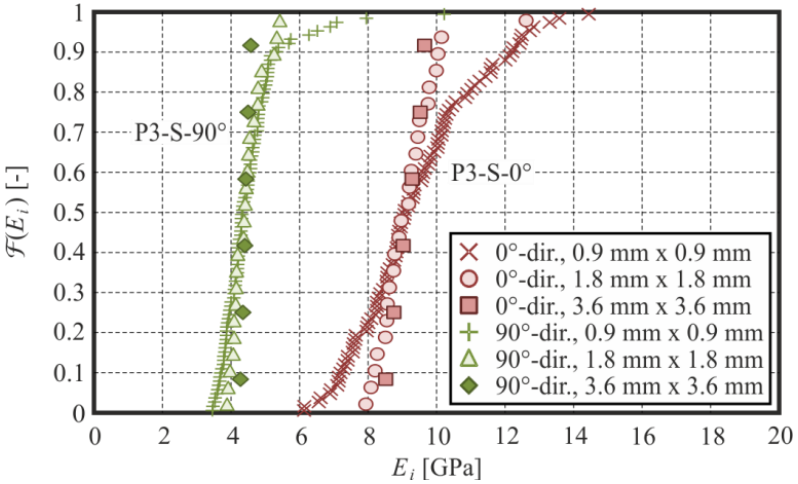
- microstructural uncertainties in composite and other microheterogeneous materials

- uncertain fibre orientation, length, density, bundle formation, ...
- uncertain particle / void size, shape, density, ...
- uncertain constituent material properties
- uncertain distribution of defects, delaminations, interface properties, crack formation, ...

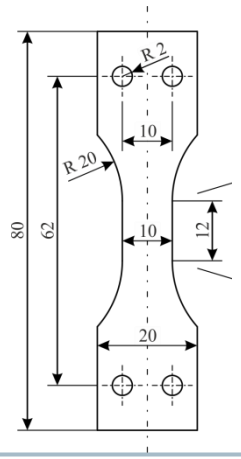


© Fraunhofer IWM unrestricted

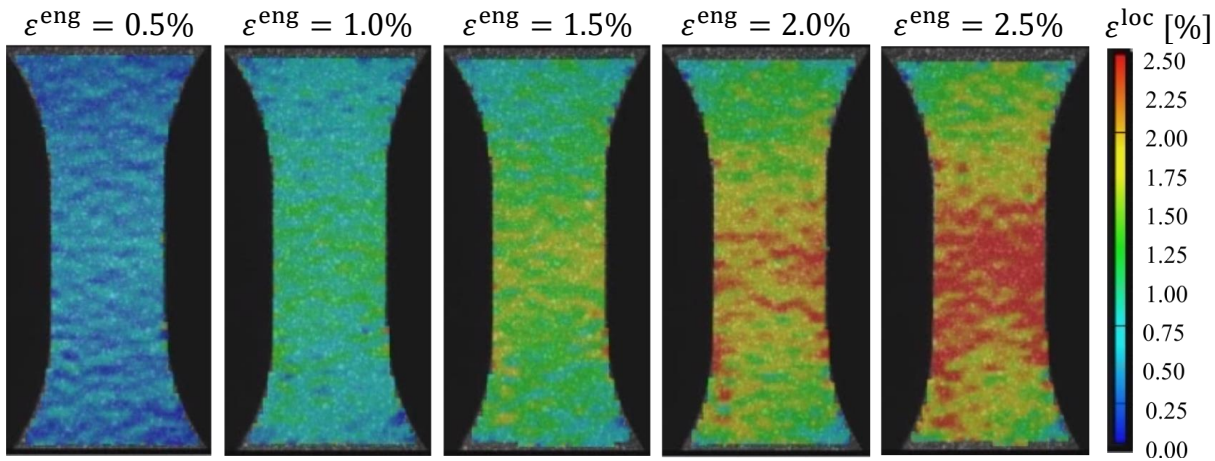
Interoperable data model and stochastic analysis of short fibre composites



Experimental observation



- example: PA66 GF40
- stress-strain response
- overall
  - tensile tests within and perpendicular to flow direction
  - section 10 mm x 3 mm
  - overall scatter
- local
  - grey scale correlation system (ARAMIS)
  - distinct scatter on length scales below 10 mm



overall stress-strain response

longitudinal and transverse Young's moduli

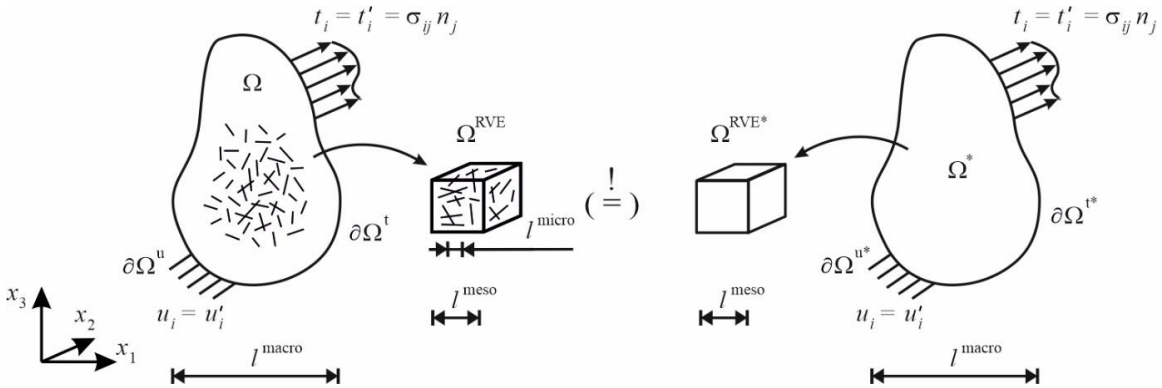
Interoperable data model and stochastic analysis of short fibre composites

Numerical homogenisation

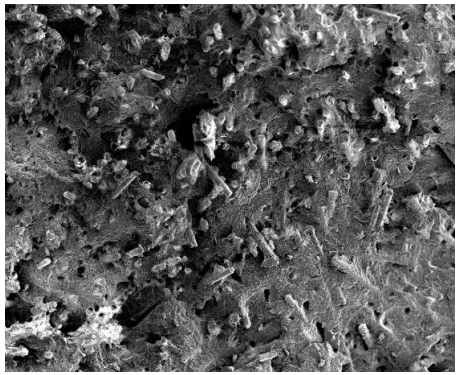
- concept of the representative volume element

- energy based equivalence conditions



$$\bar{w} = \frac{1}{V^{\mathrm{RVE}}} \int_{\Omega^{\mathrm{RVE}}} w \, \mathrm{d}V = \frac{1}{V^{\mathrm{RVE}}} \int_{\Omega^{\mathrm{RVE}*}} w^* \, \mathrm{d}V^*$$

$$\bar{F}_{ij} = \frac{1}{V^{\mathrm{RVE}}} \int_{\Omega^{\mathrm{RVE}}} F_{ij} \, \mathrm{d}V = \frac{1}{V^{\mathrm{RVE}}} \int_{\Omega^{\mathrm{RVE}*}} F_{ij}^* \, \mathrm{d}V^*$$



© Fraunhofer IWM unrestricted

Interoperable data model and stochastic analysis of short fibre composites

Numerical homogenisation

- discussion
  - requirements for the representative volume element
    - $L \gg l \gg \mathrm{d}l$
    - l sufficiently large to account for all possible microstructural effects
    - l sufficiently small for RVE representing a macroscopic material point
  - typical characteristic length scales for short fibre composites
    - $l_{\mathrm{micro}} = 100\ \mu\mathrm{m}, \ldots, 500\ \mu\mathrm{m} \quad \Rightarrow \quad l = 1\ \mathrm{mm}, \ldots, 5\ \mathrm{mm}$
    - $L \geq 2\ \mathrm{mm}, \ldots, 25\ \mathrm{mm}$
      - ➢ requirements might be contradictory
      - ➢ statistically representative volume element might not exist
      - ➢ probabilistic assessment required

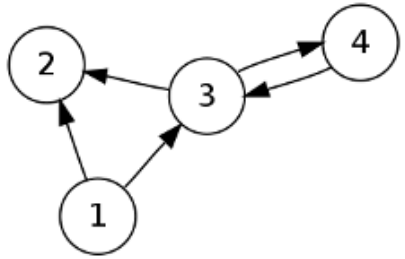
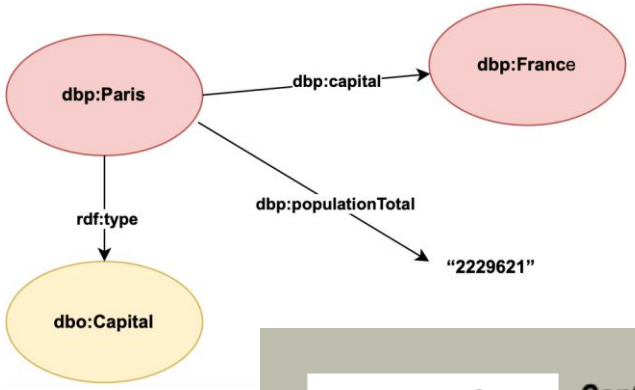
Interoperable data model and stochastic analysis of short fibre composites

Numerical homogenisation

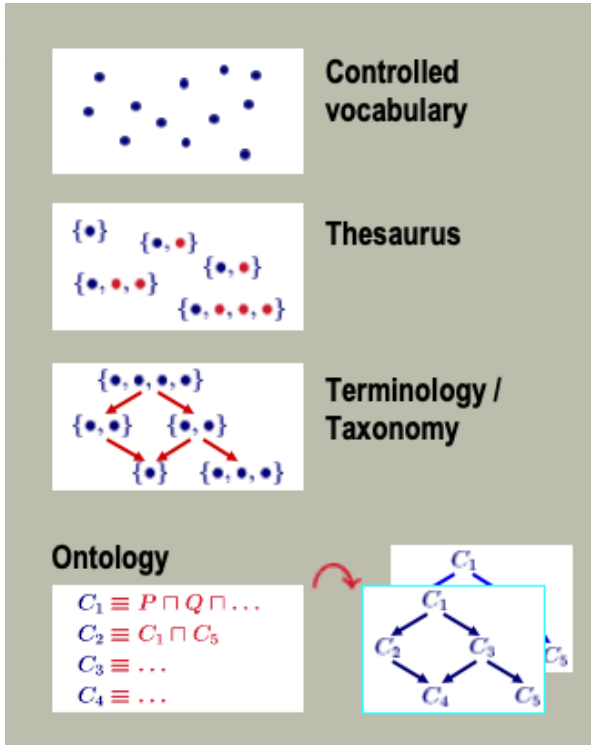
- alternative
  - approaches for assessment of the material uncertainty caused by the geometric uncertainty on the micro level
  - prediction of probability distributions for effective properties
  - probabilistic enhancement of the deterministic homogenization approach

- two different routes
  - multiple analysis of small scale testing volume elements with random microstructure
  - local homogenisation of small scale subsets in large-scale representative volume element
  - microstructure and volume related testing volume elements





© Fraunhofer IWM unrestricted



Interoperable data model and stochastic analysis of short fibre composites

Semantic interoperable data model

- stochastic multiscale analysis requires extensive data handling
  - automated procedure required
  - holistic semantic interoperable data model
- knowledge graphs and ontologies
  - data model as directed graph
    - set of nodes, e.g., 1, 2, 3, and 4
    - set of edges, e.g., (1,2), (1,3), (3,2), (3,4), 3,4)
  - what makes a directed graph “knowledgable”?
    - everything has unique IDs called URI (except data properties)
    - knowledge graph as a set of triples including the ontology
    - syntax: triple (subject-predicate-object),
      where (subject, object) induces an edge and predicate is its label
    - ontologies are the scheme of a knowledge graph (giving structure to it)

Interoperable data model and stochastic analysis of short fibre composites

Example

- dependence on orientation state (elastic moduli)
  - planar approximation of dependence on principal values of fibre orientation tensor
  - stochastic evaluation in terms of standard deviation of distance to approximation plane

© Fraunhofer IWM unrestricted

Interoperable data model and stochastic analysis of short fibre composites

Conclusions

- stochastic analysis of macroscopic material response of short fibre composites
  - interoperable data model
  - stochastic multiscale homogenization analysis
- stochastic assessment necessary due to violation of RVE size requirements
- semantic interoperable data model
  - holistic ontology for short fibre composites including entire life cycle from processing to recycling
  - modular definition enables simple integration of stochastic pre- and postprocesses
- stochastic homogenization
  - based on stochastic volume elements defined as subsets of large-scale statistically representative volume element
  - results
    - correlation of mechanical properties with fibre orientation
    - distinct local (basic) uncertainty

Introduction – Thermoplastic Composites

- Thermoplastics have been extensively used for non-structural and semi-structural purposes in electronics, automotive[1], [2], [3] and marine [4] applications.
- Additionally, there is noticeable interest in adopting continuous fiber reinforcements in thermoplastic composites in:
  - structural applications [4]
  - hydrogen storage (Type IV and Type V pressure vessels) [5],
  - medical prosthetics [6]
  - conformal electronics [7], [8]
  - sports equipment
- Globally, 7 to 9 million tons of thermoplastics were used as part of FRP composite systems [4].

Introduction – Manufacturing with Thermoplastic Composites

- Filler and fibers introduced in various forms to enhance mechanical properties.
- Trade-off in terms of added manufacturing complexity, and limitations in manufacturable geometries.
- General physics of manufacturing remains consistent across various thermoplastic composite manufacturing processes.
  - Heating:
    - pellets/filament/sheet heating above melt temperature (T_m)
  - Material Flow:
    - Suspension flow
    - Extrusion of melt
    - Draping of sheet
  - Cooling to near room temperature (T_{RT})

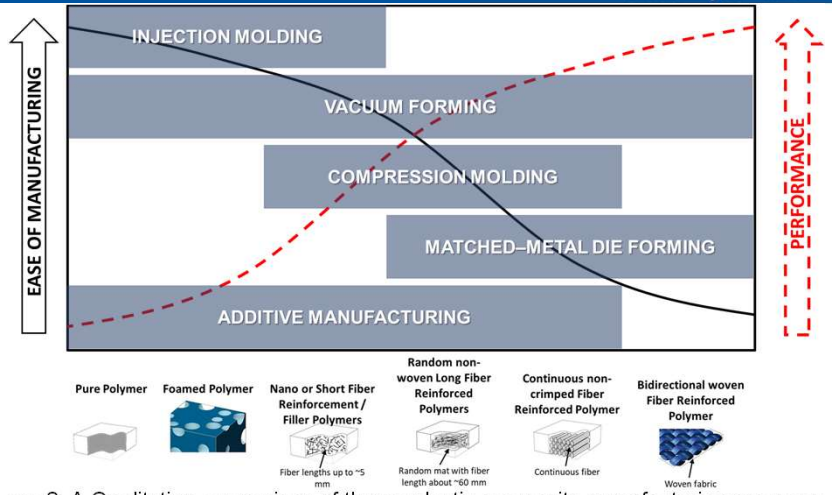

Figure 2: A Qualitative comparison of thermoplastic composite manufacturing processes

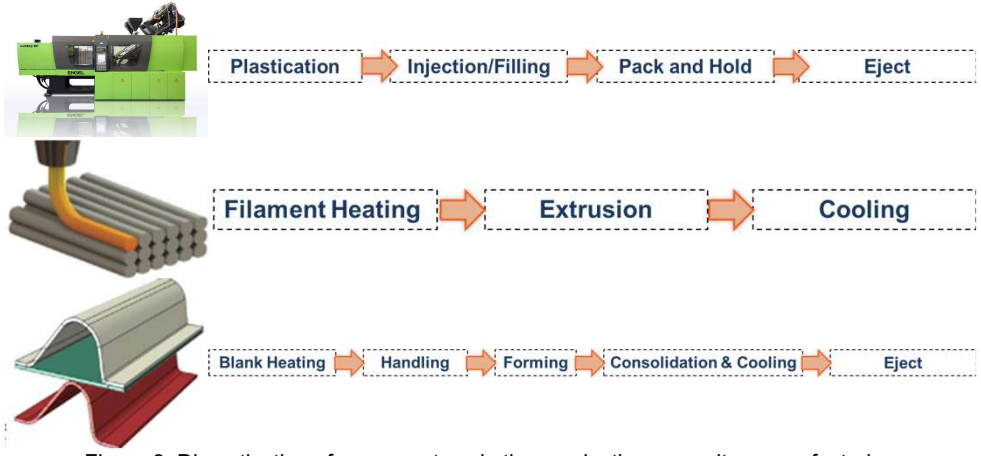

Figure 3: Discretization of process steps in thermoplastic composites manufacturing

Introduction – Semi-crystalline Thermoplastics and Crystallization

- Thermoplastics are divided into two broad categories:
  - semi-crystalline thermoplastics
  - amorphous thermoplastics
- Semi-crystalline thermoplastics form ordered structures or crystals in certain locations as polymer chains align as the thermoplastic cools.
- The cooling step, that crosses the recrystallization temperature (T_{RC}) influences the microstructure of the manufactured thermoplastic composite part.
- Microstructure influences mechanical properties.

Motivation

Why is crystal morphology and its evolution important?

- Different crystalline phase distributions within homogeneous polymer results in different mechanical properties.

Table 1: Effect of different crystalline phases of i-PP on mechanical behavior

Monoclinic α-PP	• Higher strength • Higher stiffness	Typical cooling
Trigonal β-PP [10]	• Higher toughness • lower stiffness	• Supercooling • Varying temperature gradients • Shear • **Nucleating agents**

- Smaller spherulites result in improved impact strength, tensile strength and lower water absorption rate. [11]
- Addition of fillers change the oriented crystalline phase distributions. [12]

Table 2: Effect of different processes and presence of filler on crystalline phase distributions for PA6

Compression Molding	• Pure PA6: α-PA6 + γ – PA6	• PA6 + clay: γ – PA6
Cast Extrusion Process	• Pure PA6: γ – PA6	• PA6 + clay: higher γ – PA6

- **How do we identify the right processing parameters, polymer attributes and fiber/filler to achieve desired mechanical or chemical properties?**

⇨ THROUGH EXPERIENCE … OR WE UTILIZE **PREDICTIVE MODELS**

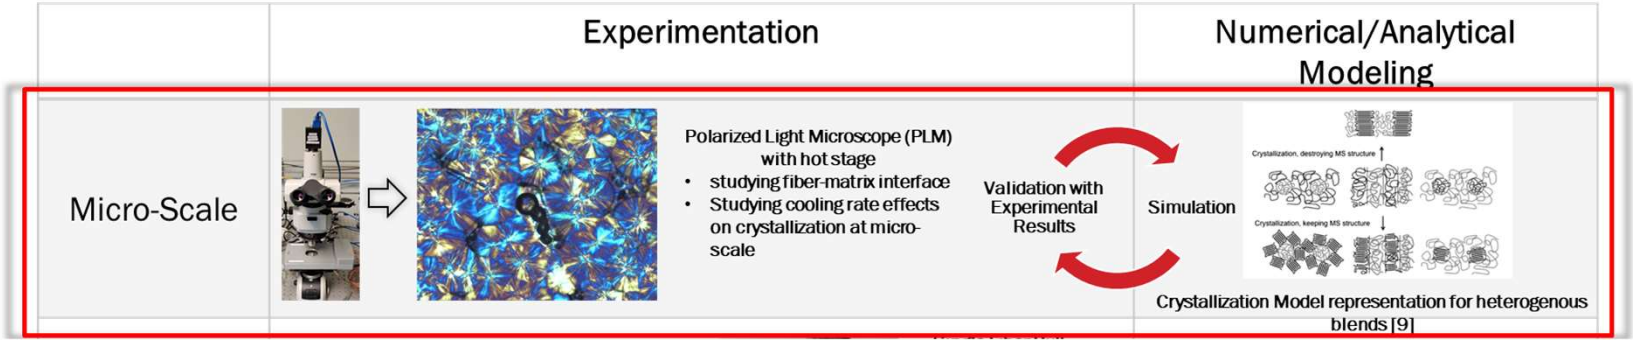
Motivation – Need for Data-driven, AI-enabled models

- Most existing models are semi-analytical i.e. they depend on:
  - Experimental data to calibrate model constants
  - Empirically derived relationships

Hoffman-Lauritzen Growth Model [13]

$$G = G_0 \exp\left(-\frac{U^*}{R(T-T_\infty)}\right) \exp\left(-\frac{K_g}{fT\Delta T}\right)$$



G = Growth speed
G0 = pre-exponential factor determined experimentally
U* = Activation Energy
Kg = kinetic parameter for nucleation
F = correction factor
T∞ = Tg – 30 K

AI Model Development Approach

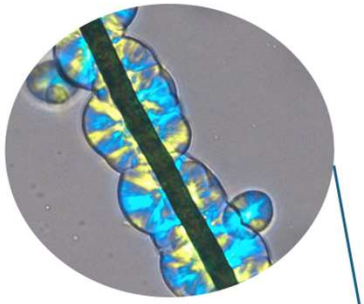
AI Model Development

Physics-Informed Network

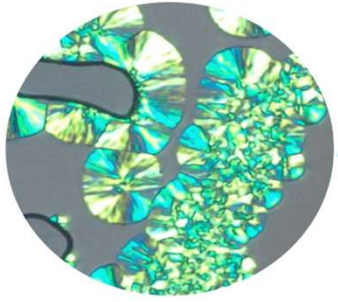
$$G = G_0 \exp\left(\frac{-U^*}{R(T - T_\infty)}\right) \exp\left(\frac{-K_g}{fT\Delta T}\right)$$

$$\phi_0 = \sum_i \frac{4}{3}\pi R_i^3$$

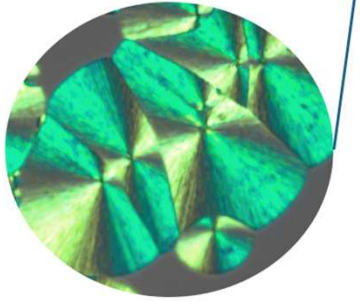
$$\frac{d\phi_0}{dt} = G\phi_1$$



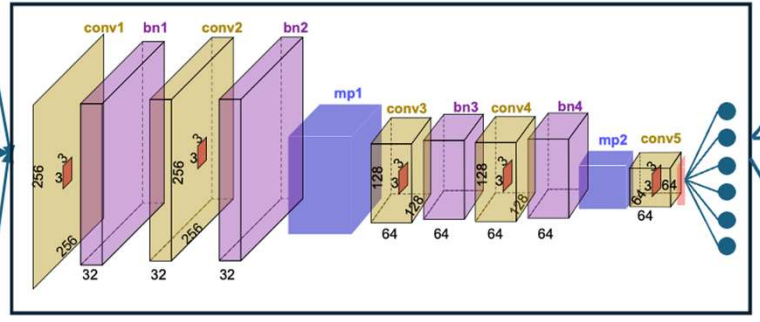
$$\frac{d\phi_1}{dt} = G\phi_2$$



$$\frac{d\phi_2}{dt} = G\phi_3$$

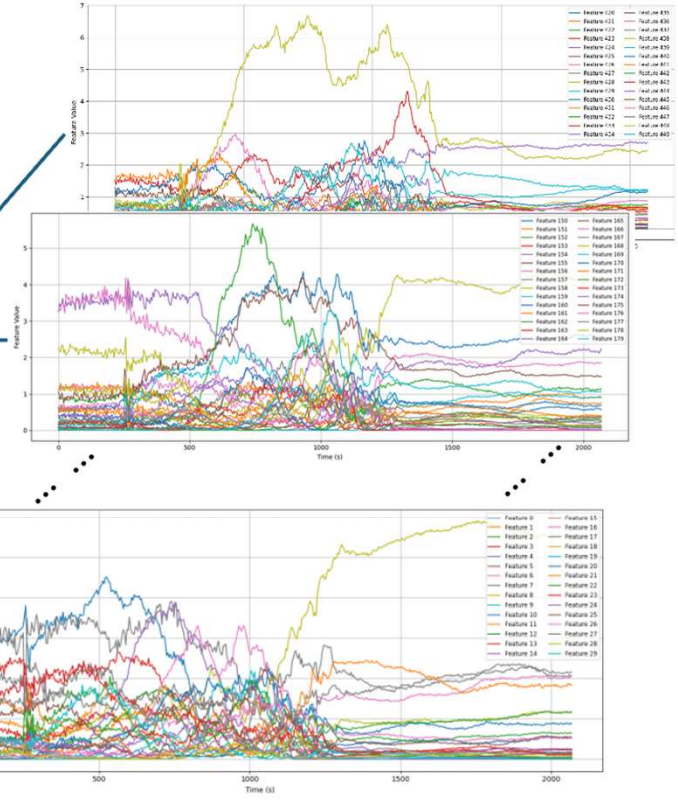


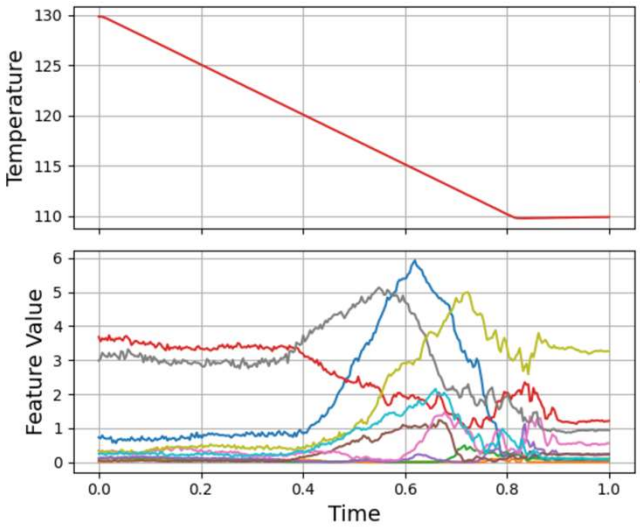
$$\frac{d\phi_3}{dt} = 8\pi\dot{N}$$

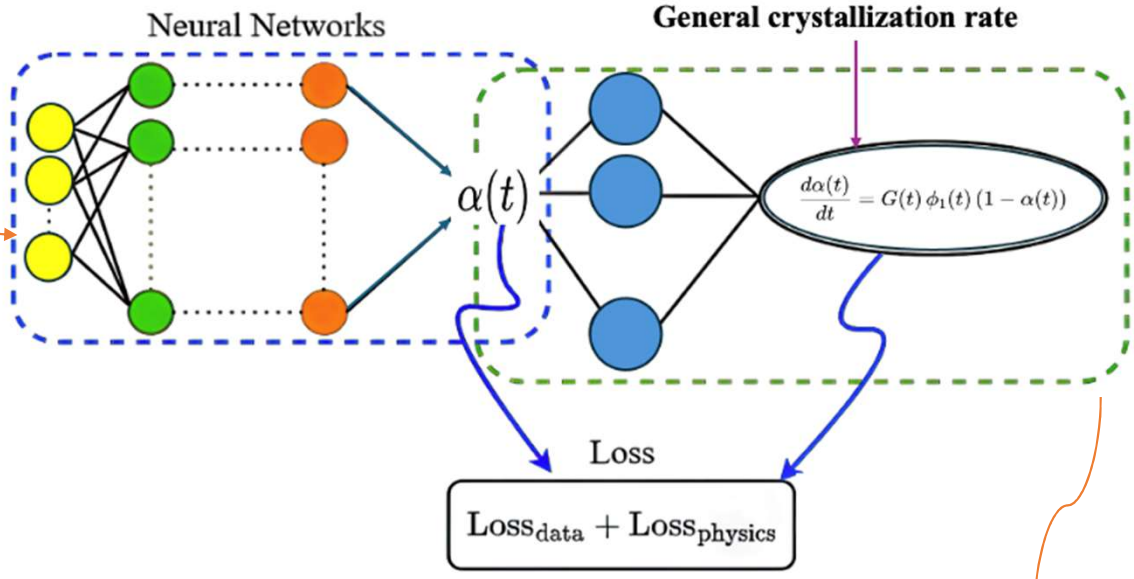


- G = Crystal growth rate (m/s)
- G_0 = Pre-exponential factor
- U^* = Activation energy for chain motion
- R = Gas constant
- K_g = Kinetic growth parameter
- $\Delta T = T_0 - T$ = Supercooling
- $f = 2T/\Delta T$ = Correction factor
- $\dot{N}$ is the nucleation rate
- ϕ_0 = Extended crystalline volume fraction
- R_i = Radius of individual crystalline structures

Feature Extraction

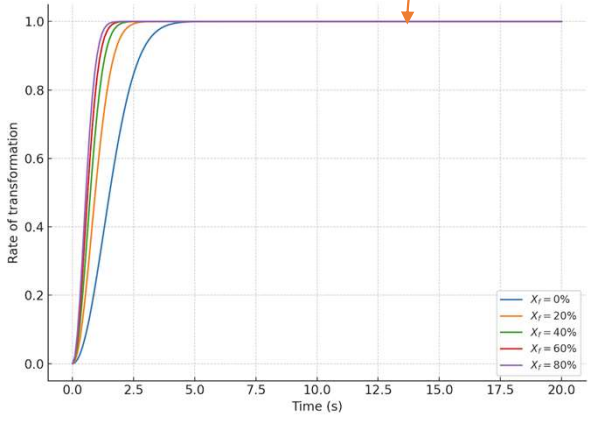






- Convolution layer
- Batch normalization
- Max-pooling
- Flatten

Features along with temperature and time were fed into the network



$$\phi_{tr}^{0}(t) = \frac{X_f}{1 - X_f} \cdot \frac{1}{R_f^2} \left[(R_f + e(t))^2 - R_f^2 \right]$$

X_f: fiber volume fraction

R_f: fiber radius

$e(t)$: transcrystalline layer thickness

Next Steps

- Experimentation
  - Incorporation of additional physical conditions such as :
    - Shear: For GF/iPP composites, transcrystalline zone appeared only when the fiber is pulled out from the melt or when shear stress is applied at given crystallization temperature [19], [20].
    - Investigation of polymer blends such as TPOs (PP + EPDM + carbon black)
  - Incorporation of XRD to provide associated crystal orientation distribution information.
- Extraction of Nucleation rate, Radial growth rate, Crystalline volume fraction change through image segmentation
  - Dragonfly © software enables image segmentation for time successive images.
- Validation of extracted feature information from CNN against data extracted through image segmentation.
- Utilize trained Physics-informed CNN to predict microstructure morphology evolution.

ABSTRACT

Graph Neural Networks (GNNs) are emerging as a transformative approach for predicting mechanical response in composite structures by naturally encoding unstructured finite element meshes as graphs. While traditional finite element analysis provides trusted solutions for structural mechanics problems, it encounters significant computational and scalability bottlenecks. We present a methodology that extends the MeshGraphNets framework with frequency-controlled hybrid local-global attention mechanisms that addresses the challenge of capturing both local behaviour around geometric discontinuities and global strain field patterns in composite laminates. Our approach integrates with industrial FEA workflows through an automated Abaqus-to-GNN pipeline that converts FEM simulations to graph representations. We validate our approach on Carbon Fiber Reinforced Polymer (CFRP) laminate plates with open holes. The results demonstrate exceptional predictive accuracy ($R^2 = 0.9775$) while achieving a 200× computational speedup over traditional finite element analysis. This represents a fundamental shift from computation-intensive iterative solving to near-instantaneous prediction for composite structure design applications.

1. Introduction

The aviation industry faces critical sustainability challenges as a major contributor to CO2 emissions [1]. This drive for sustainability is spurring novel aircraft configurations, particularly those incorporating alternative fuels, which requires a fundamental shift in design methodologies demanding high-performance predictive models of full-scale aircraft structures [2]. Finite Element Analysis offers trusted mesh-based solutions for structural mechanics problems involving partial differential equations [3]. However, FEA faces scalability and computational issues in large-scale applications, especially when various configurations need separate simulations, resulting in high computational costs [4]. Graph Neural Networks emerge as a natural solution by effectively representing and processing data on graphs [5, 6]. Pfaff et al. (2021) [7] developed a framework for learning mesh-based simulations using graph neural networks, demonstrating that GNNs can capture complex physical interactions through graph adjacencies while remaining resolution-independent [8]. While GNNs have been successfully applied to predict mechanical responses in structural components [9, 10], significant challenges remain. Current methodologies exhibit limited accuracy when addressing severe stress concentrations, particularly in complex geometries

with geometric discontinuities [11]. Additionally, they encounter difficulties with long-range information propagation during message passing, which can lead to over-smoothing issues [9]. In this work, we address these limitations by developing a novel GNN architecture that extends the MeshGraphNets model [7] with enhanced frequency-controlled hybrid local-global attention mechanisms. We validate our approach on Carbon Fiber Reinforced Polymer (CFRP) laminate plates with open holes, demonstrating excellent performance with 200× computational speedup while maintaining high accuracy for strain concentration prediction.

2. Graph Neural Networks for Mesh-Based Physics

Graph Neural Networks extend the concept of convolution to irregular topologies using message-passing mechanisms [5]. Unlike Convolutional Neural Networks which function on fixed neighborhood structures, GNNs can process unstructured mesh data directly. The process consists of three sequential operations: encoding, processing, and decoding. The **encoding** transforms raw node and edge features into latent representations through learnable transformations. The **processing** propagates information through the graph via iterative message exchange between connected nodes. The **decoding** maps the refined embeddings to target predictions. Full details will be given at the conference. For comprehensive information, please refer to the forthcoming journal paper to be submitted for publication (Patrignani, L., & Pinho, S. T., 2025).

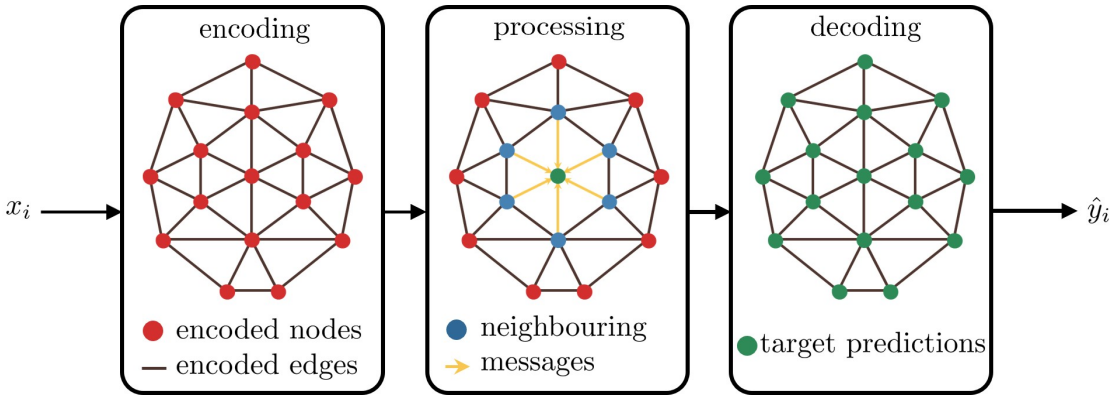

Figure 1: Graph Neural Network for Mesh-Based Physics architecture overview showing the three-stage encoder-processor-decoder framework.

3. Automated FEA-to-GNN Pipeline

We developed an automated pipeline that transforms FEA simulations into GNN training data, mapping the traditional *input-solver-output* workflow directly to supervised learning's *problem-solution* pairs. The pipeline encompasses sample generation, mesh-to-graph conversion, solver execution, and solution extraction as shown in Figure 2. This framework generates three tensor structures: node tensor encoding spatial coordinates and boundary conditions, edge tensor representing connectivity and geometric relationships, and target tensor containing solution field variables from FEA outputs. The automated framework transforms weeks of manual preprocessing into hours of computation, enabling rapid exploration across diverse structural mechanics problems.

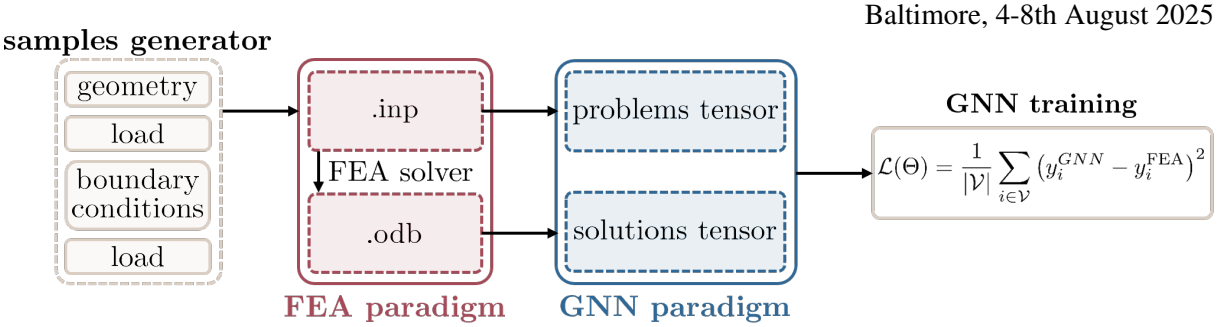

Figure 2: Automated FEA-to-GNN pipeline architecture transforming FEA workflow to GNN paradigm.

4. GNN Model for Composite Structures

This work develops a specialized GNN architecture for predicting longitudinal strain fields in CFRP open-hole tension plates. We extend the MeshGraphNets framework with frequency-controlled hybrid local-global attention mechanisms to capture both local behavior around geometric discontinuities and global strain field patterns.

4.1. Problem Setup

As shown in Figure 3, plate dimensions are randomly sampled with length and height ranging from 100 to 200 mm. Hole radius varies between 10 and 20 mm, with position factors ranging from *0.3* to *0.7* of plate dimensions. Applied displacement magnitude varies from 1 to 2 mm, generating 500 distinct samples with symmetric [0°/45°/90°/-45°]s layup configuration.

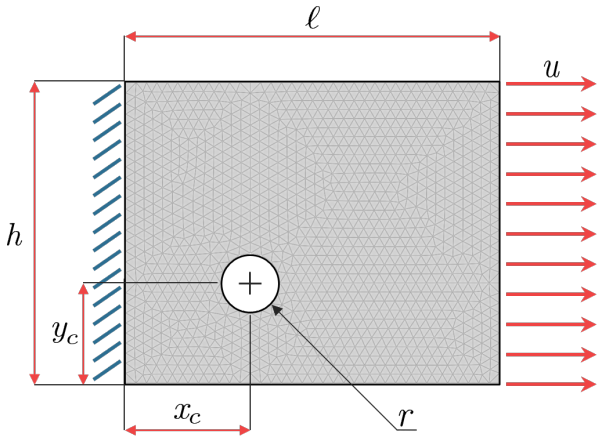

Figure 3: CFRP open-hole tension plate configuration showing variable features.

4.2. Data Representation

Node features incorporate geometric and physical information:

$$\mathbf{x}_i = [x_i, y_i, \mathbb{I}_{\text{fixed}}, \mathbb{I}_{\text{hole}}, \mathbb{I}_{\text{displaced}}, u_{\text{applied}}]^T \tag{1}$$

Edge features capture local geometric relationships:

$$\mathbf{e}_{ij} = [x_i - x_j, y_i - y_j, \|\mathbf{r}_{ij}\|_2]^T \tag{2}$$

Target variables represent longitudinal strain: $y_i = \varepsilon_{xx,i}$

4.3. Model Architecture

As illustrated in Figure 4, the model implements a three-stage encoder-processor-decoder framework with hybrid attention mechanisms.

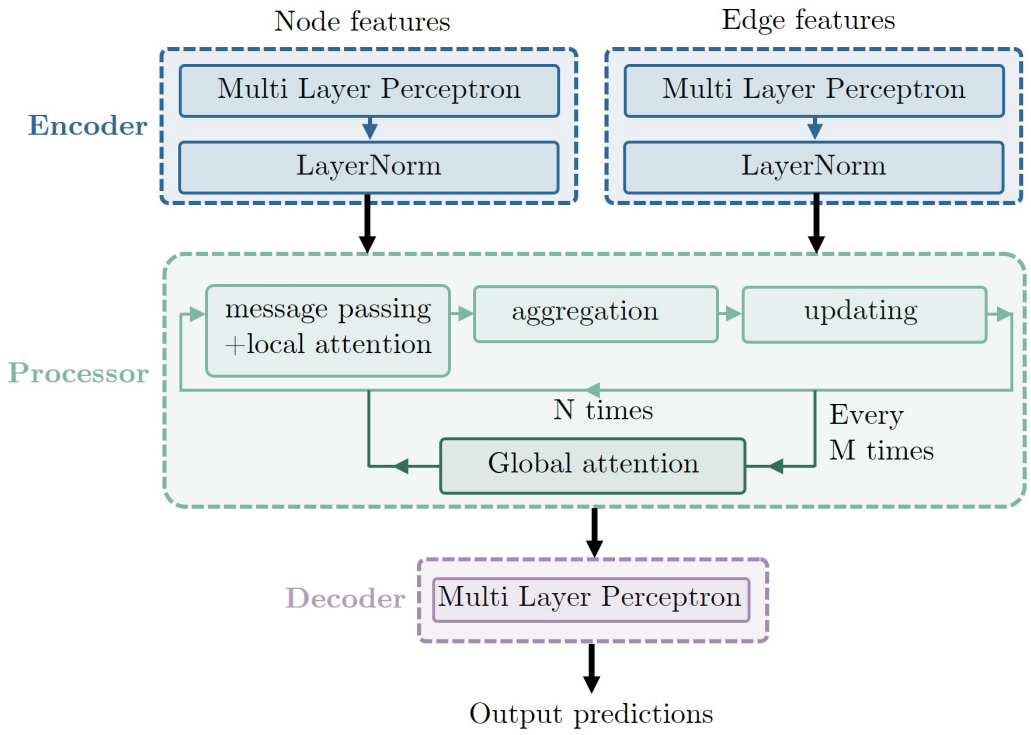

Figure 4: Complete GNN architecture with encoder-processor-decoder framework and attention mechanisms.

The processor implements message-passing with local attention at each step and global attention applied every M layers. Local attention coefficients weight neighboring information, while global attention enables direct long-range interactions following transformer architecture principles. The full details of the mathematical formulations and extended analyses of the GNN framework will be presented in the forthcoming journal paper to be submitted for publication (Patrignani, L., & Pinho, S. T., 2025).

4.4. Hyperparameter Optimization

Systematic hyperparameter tuning was performed using Optuna with Tree-structured Parzen Estimator sampling. Key findings identified learning rate and batch size as primary performance drivers. The optimal configuration achieved validation loss of 0.2621.

4.5. Results

Figure 5 demonstrates exceptional model accuracy with $R^2 = 0.9775$ and RMSE of 0.00022. The regression line closely follows the ideal diagonal, indicating minimal systematic bias across the full strain range. Training convergence analysis demonstrates substantial performance improvement with our hybrid attention architecture compared to standard message-passing, achieving approximately 64% improvement in training performance and 73% improvement in validation performance. The computa-

tional performance analysis reveals 200× speedup compared to traditional FEA, requiring only 0.5% of the original simulation time while maintaining high accuracy.

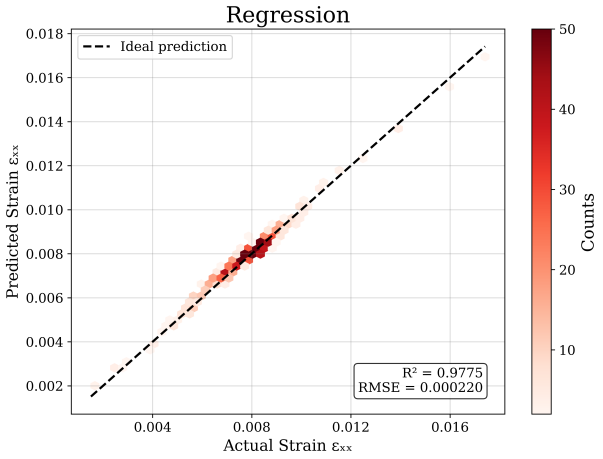

Figure 5: Predicted vs. actual strain correlation demonstrating excellent accuracy ($R^2 = 0.9775$).

5. Conclusions

This work presents a novel Graph Neural Network architecture that successfully addresses critical limitations in traditional finite element analysis for composite structural mechanics. By extending the MeshGraphNets framework with hybrid local-global attention mechanisms, we demonstrate significant computational acceleration while maintaining high predictive accuracy for strain field prediction in CFRP open-hole tension plates. Our key contributions include: (1) a hybrid attention mechanism that effectively captures local and global mechanical behaviour, achieving $R^2 = 0.9775$ accuracy while avoiding over-smoothing issues; (2) a 200× speedup compared to traditional finite element analysis; (3) an automated Abaqus-to-GNN pipeline that transforms weeks of manual preprocessing into hours of computation, facilitating seamless integration with existing commercial workflows. The demonstrated capability to predict mechanical response with minimal feature engineering requirements, combined with seamless FEA integration, positions this approach as an enabling tool for accelerating composite structure design and analysis in aerospace applications. The framework's extensibility to diverse structural mechanics problems using identical architectures represents a significant step toward practical surrogate modeling capabilities for engineering simulation.
Future research directions include extending the framework to progressive damage modeling and exploring multi-scale GNN architectures. For comprehensive details on computational complexity analysis, extended mathematical formulations, and hyperparameter optimization studies, please refer to the forthcoming journal paper to be submitted for publication (Patrignani, L., & Pinho, S. T., 2025).

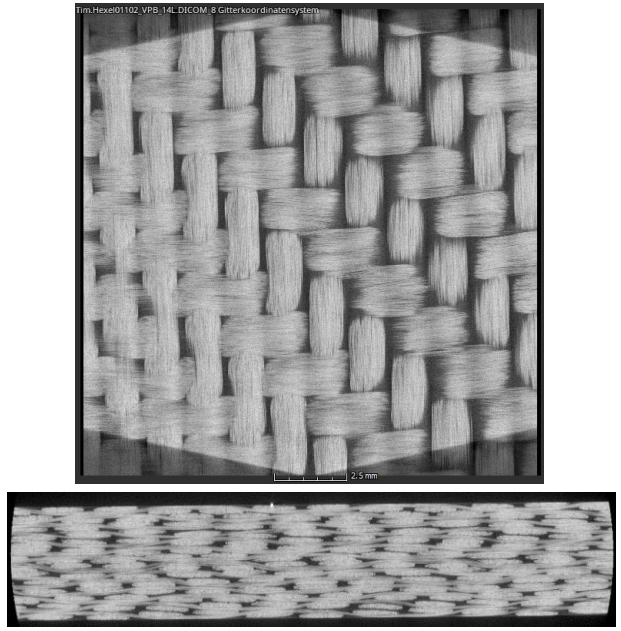
Introduction: Using µCT scans for composites development

Challenges



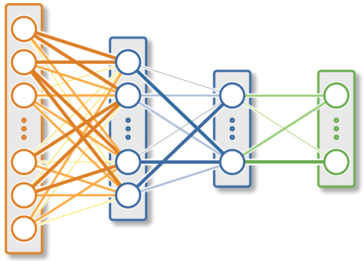
Start

Segmentation and analysis of the CT-Scans of fiber-reinforced polymer composites

Fibers cannot be fully distinguished by the software

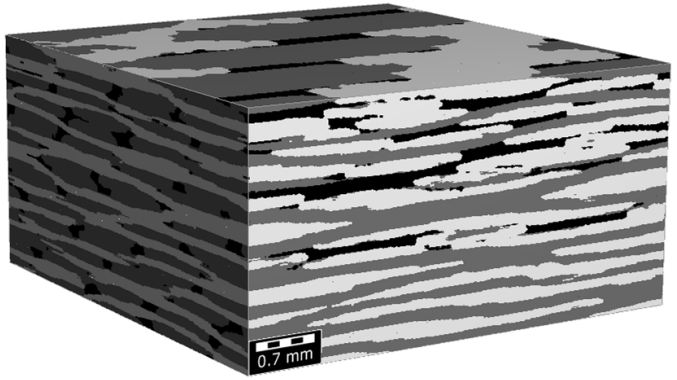
Approach

Human eye can distinguish individual fibers and tows



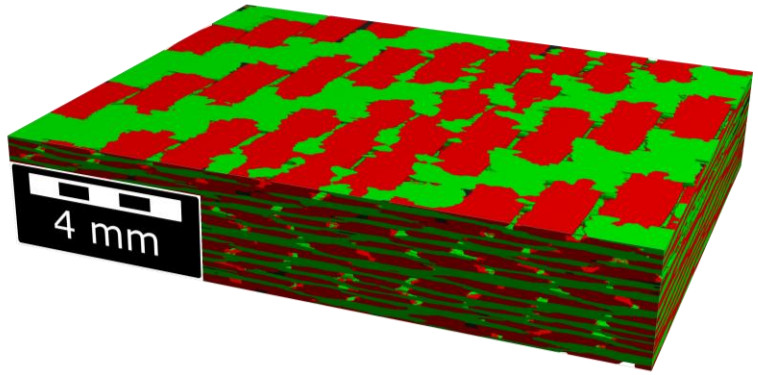
Solution

Goal

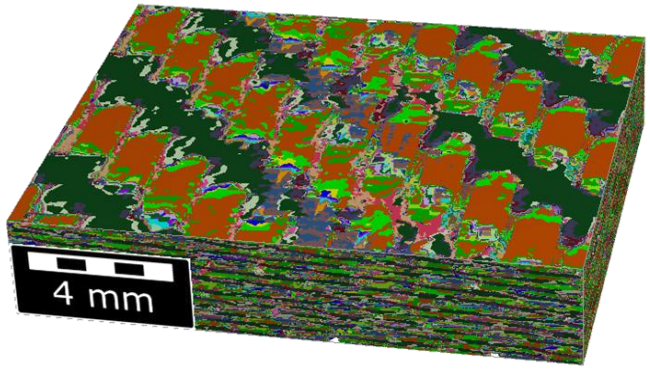


Discovering unknown material properties

Training a neural network



© Math2Market GmbH



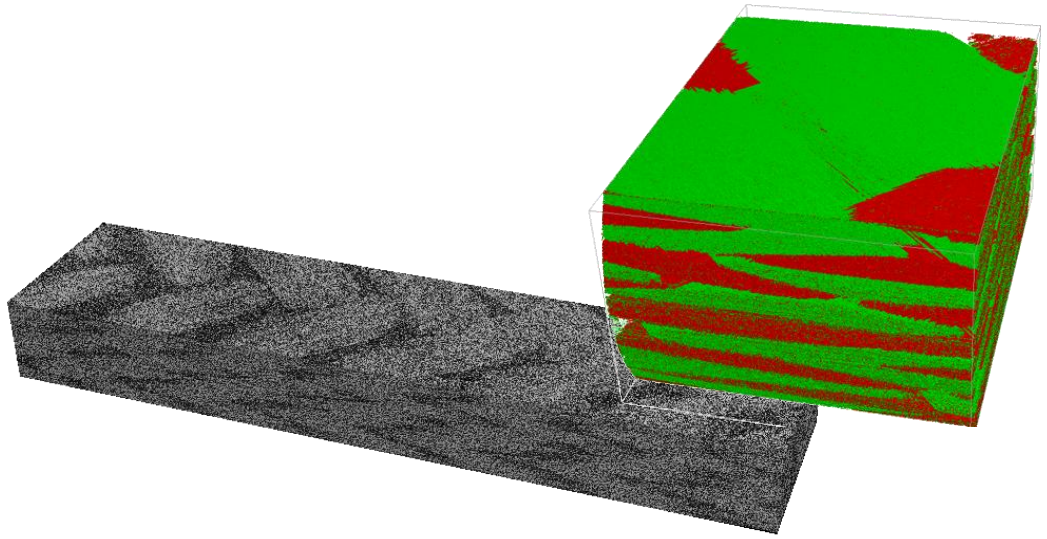
Goal in Scan Processing

Identification and separate segmentation of groups of objects (here 0° and 90° fiber bundles)

Identification of individual tows in the scan

Identification of individual tows & additional information, e.g., local fiber orientation in tows

What is the goal?



Extracting detailed and quantitative information from the scans for the simulation models

© Math2Market GmbH

GeoDict

AI-based simulation models from CT data

Development of an AI-based workflow using the example of fiber-polymer composites which closes the gap between 3D imaging techniques and synthetically generated geometry models based on statistical data from real structures to improve material development.

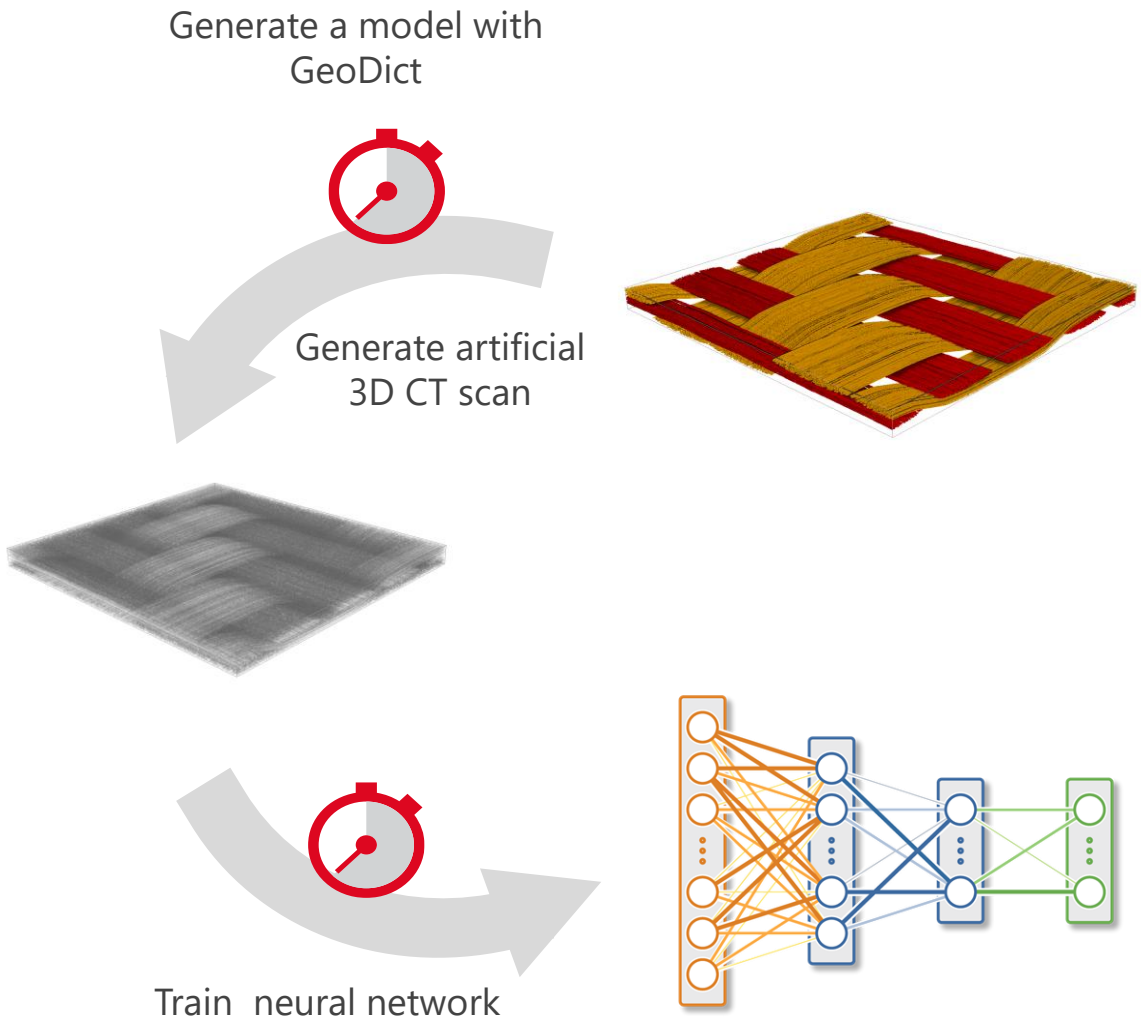
What is the use of artificial µCT images?



GeoDict

Why is it „fast“?

- No sinogram reconstruction
- No raytracing / beam simulation

This enables usage in fast parameter studies:

- Create a CT scan of a 1000^3 model in 5 minutes
- Vary image artifacts and noise
- Use artificial CTs to train neural networks

ABSTRACT

This paper introduces a hybrid learning framework for structural health monitoring (SHM) of composite laminates using laser ultrasonic guided waves (LUGWs) with limited labelled data. A lightweight one-dimensional convolutional neural network (1D-CNN) is trained on a small, spatially labelled subset to extract low-dimensional latent features from raw waveforms. These features are clustered using five classical algorithms (K-Means, GMM, BGMM, DBSCAN, and HDBSCAN) and a novel method, namely Probabilistic CNN–Fuzzy Clustering (PCFC). PCFC integrates CNN-derived class probabilities with fuzzy membership values from the Fuzzy C-Means algorithm, thereby enabling soft, uncertainty-aware clustering in the latent space. The quality of the clustering is evaluated through spatial cluster map reconstructions, with PCFC consistently producing coherent and physically meaningful clusters that are aligned with known delamination regions. In the latent feature space, Principal Component Analysis reveals a consistent separation between damaged and undamaged waveforms along the first principal component, thus offering an interpretable indicator of damage severity. The proposed approach has the potential to reduces annotation requirements by an order of magnitude and mitigate the limitations of fully supervised learning. It offers a scalable and interpretable solution for reliable damage detection in composite structures, particularly in scenarios where comprehensive labelling is impractical.

1 INTRODUCTION

Carbon-fibre-reinforced polymer (CFRP) laminates are widely employed in aerospace, aviation, automotive, constructions, and wind energy applications due to their high specific stiffness, strength, and resistance to corrosion [1]. However, their layered architecture renders them inherently susceptible to inter-ply delamination, an internal defect that reduces load-bearing capacity, degrades stiffness, and introduces stress concentrations [2]. Because delaminations are not externally visible, inspection relies on non-destructive evaluation (NDE) techniques.

Ultrasonic guided waves (UGWs) offer high sensitivity to subsurface damage and enable large-area inspection from a single excitation point, making them well-suited for volumetric structural health monitoring (SHM) [3]. When generated by pulsed lasers, UGWs can propagate into the structure without contact and maintain performance on curved or thermally challenging surfaces, enabling inspection in environments where conventional methods may fail [4]. However, the interpretation of UGW signals typically requires expert domain knowledge, a process that is both time-consuming and costly.

To reduce reliance on manual interpretation, deep learning has been increasingly applied to UGW data [5]. Convolutional neural networks (CNNs), trained on two-dimensional (2D) wavefield images or time–frequency representations, can achieve high classification accuracy. Nevertheless, these approaches often require substantial preliminary processing (e.g., windowing, padding, or wavelet

transforms) and comprise numerous f parameters, which hinders implementation on hardware platforms with limited resource [6].

One-dimensional CNNs (1D-CNNs) provide a more lightweight alternative, particularly suited to sequential data such as raw UGW signals. Convolving along the temporal axis enables 1D-CNNs to perform joint feature extraction and classification in a single, low-complexity pipeline. In comparison to their 2D counterparts, 1D-CNNs reduce the number of parameters by approximately an order of magnitude, thereby lowering computational overhead, reducing the risk of overfitting, and enabling real-time inference on consumer-grade hardware [7]. These characteristics render 1D-CNNs especially well-suited to onboard anomaly detection, a process characterised by the constraints of rapid inference and the scarcity of labelled data [8].

Despite their efficiency, even compact supervised models require fully labelled datasets that capture variation in sensor placement, laminate geometry, and damage morphology. These conditions are often impractical to reproduce comprehensively. The labelling of laser-ultrasonic datasets may involve destructive sectioning, micro-CT imaging, or artificial defect insertion. These processes are often labour-intensive and lack scalability, particularly in the context of rare or interacting damage modes. Consequently, the utilisation of supervised models that have been trained on limited labels renders them susceptible to overfitting and may impede their capacity to generalize to unseen conditions [9].

Unsupervised learning provides a complementary strategy by means of the identification of latent structure in unlabelled UGW data. Clustering and anomaly detection techniques, including K-Means, Density-Based Spatial Clustering of Applications with Noise (DBSCAN), Hierarchical DBSCAN (HDBSCAN), Gaussian Mixture Models (GMM), and Bayesian GMM (BGMM) [10], have been employed to extract damage-related patterns without requiring prior annotation. These approaches are especially valuable when damage signatures are poorly defined, heterogeneous, or too numerous to label manually. Nevertheless, a persistent limitation remains: the resulting clusters often lack direct physical meaning and require post hoc interpretation to map to damage mechanisms. This interpretation step is subjective and prone to error, especially when defects are subtle or interact in complex ways.

To address these challenges, this paper proposes a hybrid learning framework that combines supervised and unsupervised learning. A compact 1D-CNN (~93,000 parameters) [11] is first trained on approximately 10% of the dataset using spatially defined labels. Subsequent to the training phase, the SoftMax classification head is eliminated, and the network is repurposed as an encoder that maps each input waveform to a 128-dimensional latent embedding. This embedding enhances class separability while suppressing nuisance variability.

Clustering algorithms, including K-Means, GMM, DBSCAN, HDBSCAN, and a novel Probabilistic CNN–Fuzzy Clustering (PCFC) method, are then applied in the latent space. These algorithms result in the generation of spatially coherent clusters that exhibit a high degree of alignment with delamination regions, without requiring additional supervision. The anchoring of the latent space with a small, labelled subset, is a key aspect of the framework, as it preserves physical interpretability, enables probabilistic associations with known damage states, and leverages the diversity of unlabelled data to improve generalization.

The objective of this work is to demonstrate that incorporating a limited amount of labelled data can significantly enhance the physical interpretability of clustering outcomes, and that the proposed PCFC method outperforms five state-of-the-art clustering algorithms when evaluated under a consistent neural architecture. The resulting workflow reduces annotation requirements by an order of magnitude, remains computationally efficient for embedded implementation, and addresses the supervision bottleneck that has hindered the adoption of deep learning in operational SHM systems.

The remainder of this paper is organized as follows. Section 2 details specimen fabrication, laser–ultrasonic data acquisition, and the hybrid learning pipeline. Section 3 presents clustering results, spatial reconstructions, and an encoder ablation study. Section 4 concludes with key findings and directions for future work.

2 HYBRID LEARNING METHODOLOGY

2.1. Specimen Preparation and Laser Ultrasonic Data Acquisition

Eight-ply cross-ply CFRP laminates with a $[90_2/0_2]$s stacking sequence were fabricated using Toray T700SC/2500 prepreg [12]. Each plate measured 200 × 200 mm² with a nominal thickness of 1.12 mm (0.14 mm per ply). Nine plates contained centrally embedded square Teflon inserts to simulate delaminations of 5 × 5, 10 × 10, or 20 × 20 mm², located at three interlaminar depths (0.28, 0.56, and 0.84 mm), while one plate served as an undamaged control. Laminates were cured in a vacuum hot-press at 0.08 MPa and consolidated at a pressure of 8.6 MPa and a temperature of 130 °C for 2 hours, ensuring consistent fibre wet-out and minimal void content. The central insert placement suppressed edge effects and enabled a controlled matrix of size–depth combinations for waveform-to-damage analysis.

Laser-induced UGWs (LUGWs) were generated using a non-contact Laser Ultrasonic Visualization Inspector (LUVI-CP1, Tsukuba Technology), employing a 1064 nm, 10 ns Nd:YAG laser pulse focused to a 0.25 mm radius spot. The absorbed energy (~0.1 μJ) corresponded to a fluence of 0.27 J/cm², well below the CFRP's ablation threshold, ensuring purely thermoelastic excitation [13]. A 20 × 20 mm² region centred on each delamination was raster-scanned on a 195 × 195 grid with 0.103 mm pitch, yielding 38,025 excitation points (100 points/mm²) per scan. The laser incidence angle was maintained below 2°, which is well within the ~30° tolerance for amplitude stability [14].

Out-of-plane displacements were measured using a broadband piezoelectric sensor (AE-900S-WB, frequency range 0.3–1.5 MHz, sensitivity 50 dB ± 6 dB at 500 kHz). This sensor was mounted outside the laser scan region to prevent direct optical excitation. To characterize anisotropic wave propagation, the sensor was sequentially oriented along three directions relative to the 0° surface ply: PA (0°), PB (45°), and PC (90°). Each grid point was probed using four consecutive laser pulses, and the resulting signals were averaged to improve the signal-to-noise ratio while preserving bandwidth. Waveforms were sampled at 10 MS/s over a 100 μs acquisition window, resulting in 1000 discrete amplitude measurements per waveform. This window was truncated ~20 μs before the expected A_0-mode edge reflection, estimated using a 1.5 mm/μs group velocity and 90 mm edge distance, to isolate the primary A_0 and S_0 wave packets from boundary reflections.

The dataset under consideration is comprised of 1,140,750 raw waveforms, distributed across ten plates, three sensor orientations, and 38,025 scan points per measurement. All signals were standardized using global Z-score normalization [15], defined as $x' = (x - \mu)/\sigma$, where μ and σ are the global mean and standard deviation across the dataset, respectively. This step equalized amplitude scales across signals, accelerated model convergence, and preserved waveform phase information.

2.2. CNN-Guided Hybrid Learning Framework

A hybrid learning framework has been developed that integrates a pre-trained lightweight 1D-CNN (~93,000 parameters) with unsupervised clustering to identify latent delamination patterns in UGW data.

As illustrated in , the framework leverages physics-informed features learned from a limited labelled dataset to guide the discovery of physically meaningful structures within the high-dimensional feature space. Figure 1a illustrates the spatial region-based labelling strategy used to partition the 1D waveforms into a binary classification scheme, where signals originating from within the delaminated region are labelled as "damaged," while those from outside this region are labelled as "undamaged". Figure 1b shows a 1D-CNN pre-trained using a limited labelled dataset (~10%).

The SoftMax classification layer is removed from the 1D-CNN (Figure 1c), and the high-dimensional feature representations are extracted directly from the final dense layer. These features are then visualized in latent space, as shown in Figure 1d.

As illustrated in Figure 1e, several unsupervised clustering algorithms, including the proposed PCFC, are employed within the latent feature space to discern the underlying structure in the data. Finally, the clustering results are visualized both in the latent space and remapped onto the 2D wavefield (see Figure 1f), thereby providing a spatially interpretable representation of the detected patterns.

(a) region-based labelling separating undamaged and damaged waveforms; (b) 1D-CNN pre-trained on labelled data; (c) extracted high-level features; (d) visualization in latent space; (e) clustering using various algorithms; (f) analysis of clustering results.

2.3. Data Partitioning, Labelling, and Signal Preprocessing

A spatial region-based labelling strategy was adopted to pre-train the 1D-CNN using supervised learning. One damaged plate, representing approximately 10% of the total dataset, was selected as the reference for training. This plate contained a 5 × 5 mm² artificial delamination embedded at the laminate midplane.

The corresponding wavefield, acquired using the LUVI-CP1 system, was represented as a three-dimensional matrix indexed by (x, y, t). Let $\boldsymbol{r} = (x, y)$ denote a spatial location on the plate surface and let $w(\boldsymbol{r}, t)$ be the wave amplitude at position $\boldsymbol{r}$ and time step t. At each scan point, the root mean square (RMS) amplitude, defined in Equation (1), was computed to highlight regions of elevated acoustic energy. To enhance contrast and delineate potential damage boundaries, the spatial gradient of the RMS amplitude map was then calculated, as shown in Equation (2). The resulting maps are illustrated in Figure 2a.

$$RMS(\boldsymbol{r}) = \sqrt{\frac{1}{T}\sum_{t=1}^{T} w(\boldsymbol{r}, t)^2} \tag{1}$$

$$\nabla RMS(\boldsymbol{r}) = \left(\frac{\partial RMS}{\partial r_1}, \frac{\partial RMS}{\partial r_2}\right) \tag{2}$$

Based on this processed representation, spatial masks were applied to assign coarse binary labels. Waveforms originating within the delaminated region were labelled “D” (delamination), and those outside were labelled “N” (non-delamination), as illustrated in Figure 2b. Following this region-based labelling, approximately 7,200 waveforms were identified as originating from delaminated regions, representing 6.25% of the labelled dataset. This class imbalance reflects the small physical extent of the delamination relative to the full scan area. To preserve the natural distribution of the data and prevent overfitting to plate-specific characteristics, no data augmentation was applied.

In total, this labelling procedure yielded 114,075 waveforms for supervised training. The remaining 1,026,675 waveforms, acquired from the other nine plates, formed the unlabelled pool used for unsupervised learning. All signals were standardized using global Z-score normalization and stored

alongside with categorical metadata indicating their source plate and spatial coordinates within the scan grid.

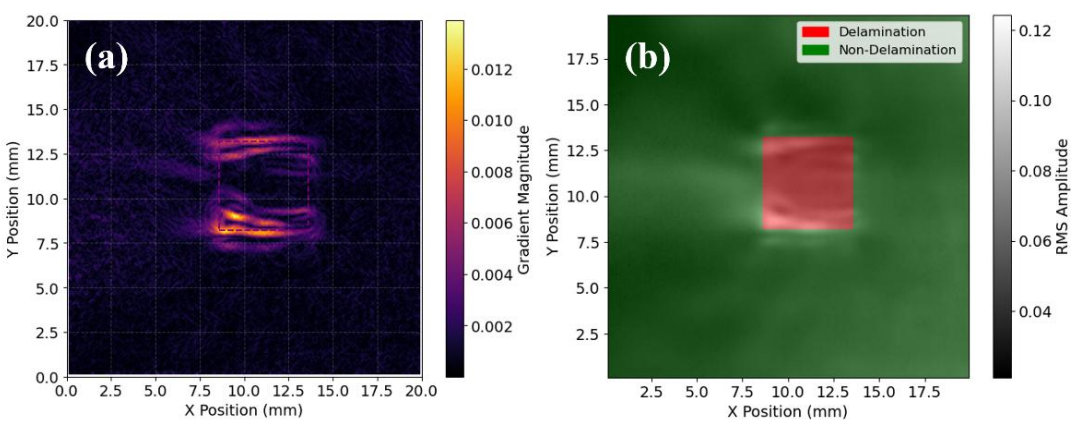

Figure 2: Two dimensional wavefield analyzed through RMS gradient (a) and with subsequent spatial-labelling mask applied (b).

2.4. Supervised Training of Lightweight 1D-CNN

A previously optimized shallow 1D-CNN architecture [11] was employed to perform supervised classification on the reduced, labelled dataset comprising 10% of the original data. The network begins with a single convolutional layer comprising 64 filters, each with a kernel size of 256. This is followed by batch normalization, a Parametric ReLU (PReLU) activation function, max pooling with a pooling size of 4, and a dropout layer with a rate of 20%. A global average pooling layer reduces the output to a 1 × 64 feature vector.

This vector is passed to a fully connected layer with 128 units. This is followed by a second dropout layer and a final dense layer with 2 output units, ending in a Softmax activation for classification. Weights were initialized using the Glorot normal scheme, and regularization techniques, including L1/L2 penalties and early stopping, were applied to improve generalization. The model was trained using the Adam optimizer with by a reduce-on-plateau scheduler handling learning rate adjustments.

The complete architecture contains approximately 93,000 trainable parameters, an order of magnitude fewer than typical 2D-CNN models, making it well suited to lightweight, real-time deployment. Training results, shown in Figure 3, demonstrate near-perfect classification accuracy with no observable signs of overfitting.

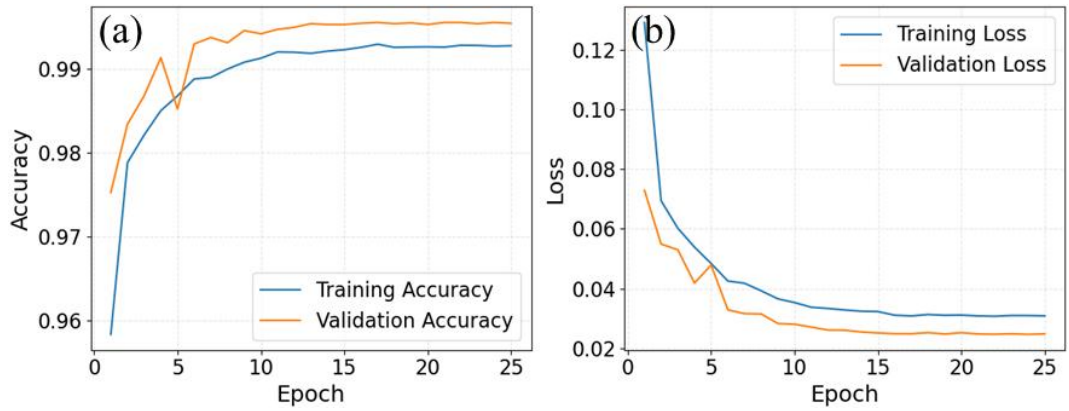

Figure 3: Supervised training results: (a) Training and Validation Accuracy, (b) Training and Validation Loss

2.5. Latent Feature Embedding and Cluster Number Estimation

To determine the optimal number of clusters k, a required parameter for many clustering algorithms, feature vectors were extracted from the penultimate dense layer of the pre-trained 1D-CNN when it was applied to the unseen dataset. This process yielded a 128-dimensional latent representation, thereby defining an encoder function $\varepsilon: \mathbb{R}^{1000} \rightarrow \mathbb{R}^{128}$. This function maps each input waveform $\boldsymbol{x}$ to a latent vector $\boldsymbol{z} = \varepsilon(\boldsymbol{x}) \in \mathbb{R}^{128}$. In this latent space, intraclass variability is attenuated, while features relevant to delamination are accentuated, thereby facilitating more effective clustering.

In the context of unsupervised learning, the evaluation of clustering quality is of critical importance in ensuring that the discovered structures represent meaningful patterns rather than artifacts arising from noise or random variation. In contrast to the supervised learning, in which the performance of the model is evaluated against a known ground truth, the unsupervised clustering relies on internal validation metrics to assess the compactness, separation, and cohesion of the clusters. These metrics enable the evaluation of clustering effectiveness in the absence of labelled data, thereby providing a framework for guiding model selection and parameter tuning.

In scenarios where no prior knowledge of the underlying class structure is available, internal validation indices assume particular importance. These indices assess cluster quality based solely on the intrinsic geometric and statistical characteristics of the data. Nevertheless, they are not without limitations. A significant number of internal metrics implicitly assume isotropic, spherical cluster shapes and are based on Euclidean distance and centroid-based formulations. Consequently, the efficacy of such methods may be diminished when applied to data characterised by elongated, overlapping, or non-convex clusters, potentially resulting in erroneous assessments of clustering performance.

To address the limitations inherent in individual internal validation indices, it is common practice to employ multiple such metrics in parallel. This enables a more robust and comprehensive evaluation of clustering quality. Each index captures a distinct facet of the cluster structure, such as compactness, separation, or cohesion, thus offering complementary perspectives on the organization of the data. The following internal validation metrics were utilized in this study: Dunn Index, Calinski–Harabasz Index, Silhouette Score, Davies–Bouldin Index, and Xie–Beni Index. The optimal number of clusters was determined by applying a majority voting scheme, with consensus across the indices indicating that $k = 2$ provided the most appropriate partitioning. A summary of the computed metric values and comparative results is presented in Table 1.

Internal Validation Metric	Optimal k	Score
Dunn Index	2	0.65
Calinski-Harabasz index	4	165000
Silhouette Score	2	0.51
Davies-Bouldin index	4	0.71
Xie-Beni Index	2	0.18

Table 1: Optimal number of clusters calculated using different internal metrics.

2.6. Unsupervised Clustering Algorithms and Proposed PCFC Method

Five classical clustering algorithms were benchmarked on the extracted latent feature space:

i. K-Means is a widely used partitioning algorithm that assigns data points to k clusters by minimizing within-cluster variance. It assumes spherical clusters of equal size and density.
ii. GMM is an extension of K-Means that models the data as a mixture of Gaussian distributions. GMMs perform soft clustering by estimating the probability that each data point belongs to each cluster.
iii. BGMM is a probabilistic generalization of GMMs that incorporates Bayesian inference. BGMMs treat the number of clusters and model parameters as random variables with prior distributions, allowing for automatic regularization and principled model selection.

iv. DBSCAN is a non-parametric algorithm that identifies clusters as dense regions in the data space, separated by lower-density areas. It is effective to identify arbitrarily shaped clusters and identifying noise points, without the necessity of inputting the number of clusters.
v. HDBSCAN is an extension of DBSCAN that builds a cluster hierarchy based on variable density thresholds. It removes the need to specify a global neighbourhood radius, making it more robust to datasets with varying local density.

In addition to these classical methods, a novel clustering approach, Probabilistic CNN-Fuzzy Clustering (PCFC), is proposed. PCFC integrates the discriminative feature extraction capabilities of a pre-trained 1D-CNN with the uncertainty modelling properties of the Fuzzy C-Means (FCM) algorithm. The 1D-CNN is employed to extract semantically meaningful representations from input signals, which are then passed through a SoftMax activation layer to generate probabilistic class assignments that reflect the underlying class structure learned during supervised training. Concurrently, FCM provides an unsupervised soft clustering mechanism, assigning each data point fractional membership across multiple clusters to capture uncertainty and gradual transitions between classes. The integration of the structured latent space generated by the CNN with the soft-partitioning behaviour of FCM facilitates effective clustering of PCFC in scenarios characterized by overlapping class boundaries and ambiguous data distributions.

Given an input sample x_i, the CNN generates class probability estimates via a SoftMax activation function, denoted as $p_{ij} = f_{CNN}^{Softmax}(x_i)$, where p_{ij} represents the predicted probability of sample i belonging to class j. To integrate these supervised predictions with fuzzy clustering, the PCFC framework introduces a hybrid membership function that combines the SoftMax output with fuzzy membership degrees computed in the CNN derived feature space. The hybrid membership degree $\hat{u}_{ij}$ of sample i in cluster j is defined as:

$$\hat{u}_{ij} = \alpha \cdot u_{ij}(z_i) + (1 - \alpha) \cdot p_{ij}, \quad with\ 0 \leq \alpha \leq 1 \tag{3}$$

In Equation (3), $u_{ij}(z_i)$ denotes the fuzzy membership degree assigned by the FCM algorithm based on the CNN-extracted feature vector z_i, and p_{ij} is the previously defined SoftMax probability. The parameter α controls the trade-off between the unsupervised fuzzy clustering and the supervised probabilistic classification, thereby facilitating the integration of data-driven uncertainty with learned discriminative structure. This formulation enables PCFC to capitalize on both the representational power of CNNs and the uncertainty-aware nature of fuzzy clustering, thus resulting in a more robust and adaptable clustering framework.

To improve the physical interpretability and visual reliability of the PCFC results when projected onto the two-dimensional wavefield domain, the continuous hybrid membership values $\hat{u}_{ij} \in [0,1]$, interpreted here as degrees of delamination, are discretized into four semantically meaningful categories:

- Non-Delamination (N): $0 \leq \hat{u}_{ij} < 0.25$. Represents signals that closely match baseline (healthy) responses.
- Quasi-Non-Delamination (Q-N): $0.25 \leq \hat{u}_{ij} < 0.50$. Indicates largely intact regions exhibiting minor variations due to benign phenomena.
- Quasi-Delamination (Q-D): $0.50 \leq \hat{u}_{ij} < 0.75$. Captures partial or ambiguous indications of damage, which are frequently linked to scattering or boundary effects.
- Delamination (D): $0.75 \leq \hat{u}_{ij} \leq 1.00$. This is indicative of significant deviations from the baseline, which is consistent with the presence of structural damage.

This categorisation of continuous fuzzy outputs translates nuanced membership values into diagnostically meaningful labels, enhancing both the interpretability and practical utility of PCFC in SHM applications.

3 RESULTS AND DISCUSSION

3.1. Spatial Analysis of Clustering Results

After clustering, the waveforms are mapped back onto the spatial grid to generate spatially resolved cluster maps, thereby enhancing visual interpretability of the results. In instances where clustering methods require a predefined number of clusters, the optimal value $k = 2$, as determined in Section 2.5., was employed.

Figure 4 presents a comparative evaluation of clustering performance on the training plate, with wave propagation along the PA direction. As illustrated in Figure 4a, K-Means provides a coarse distinction between delaminated and intact regions but lacks spatial precision. Figure 4b shows that GMM improves localization of damaged areas, however, the delineation of boundary regions remains ambiguous. BGMM offers enhanced isolation of the delaminated region and its boundaries However, it introduces excessive clusters that do not correspond to physically meaningful structures (see Figure 4c). Figure 4d reveals that DBSCAN is unable to differentiate between damaged and undamaged regions, with the majority of data points being assigned to a dominant cluster. Figure 4e demonstrates that HDBSCAN partially mitigates this limitation by identifying three principal regions, undamaged, delaminated, and transitional. However, it should be noted that the resulting clusters lack clear physical interpretability in the absence of the full 2D wavefield context.

In contrast, Figure 4f demonstrates that PCFC yields a coherent and physically meaningful clustering outcome. Hybrid membership values in the range $0.75 \leq \hat{u}_{ij} < 1.00$ reliably indicate delamination, while values in the range $0.50 \leq \hat{u}_{ij} < 0.75$ capture transitional zones influenced by wave scattering and boundary effects. The lower ranges correspond to intact regions and propagation artefacts. The integration of CNN-derived features with fuzzy logic by PCFC has been demonstrated to achieve two objectives: Firstly, it facilitates accurate damage identification. Secondly, it establishes interpretable spatial representation. This combination of features establishes the PCFC framework as a robust solution for SHM.

The results of the clustering process for an unseen, undamaged laminate are shown in Figure 5, with wave propagation along the PC direction. These examples are intended to appraise the efficacy of each algorithm in generalising and accurately identifying the absence of damage in conditions that have not been previously observed. K-Means (Figure 5a) identifies two clusters that correspond visually to the wavefront and the remaining plate area. GMM (Figure 5b) produces a similar segmentation with only minor discrepancies in point allocation. BGMM (Figure 5c) exhibits similar tendencies to earlier observations, over-segmenting the data into multiple physically implausible clusters. DBSCAN and HDBSCAN (see Figure 5d-e) both identify a dominant single cluster, accurately reflecting the uniform, undamaged condition of the plate. This outcome supports their reliability in damage-free scenarios.

As illustrated in Figure 5f, PCFC yields a result resembling K-Means. However, a salient feature of PCFC is that it assigns all waveforms membership values in the range $0 \leq \hat{u}_{ij} < 0.50$, indicating absence of delamination. The plate's status as undamaged is confirmed by the hybrid metric, which enables effective differentiation between benign wavefront structures and damage-related features.

3.2. Latent Feature Space Analysis via Principal Component Analysis

In addition to analysing clusters in remapped 2D wavefields, the latent feature space extracted by the 1D-CNN can be examined directly, independent of spatial context. The optimized network comprises a fully connected layer with 128 neurons, resulting in a high-dimensional representation that is not readily interpretable. In order to address this issue, Principal Component Analysis (PCA) [16] is employed to

project the feature space onto a two-dimensional plane whilst preserving the most significant variance in the data.

As illustrated in Figure 6, PCA projections of the latent space for the test plate measured along the propagation direction PA are presented. This visualization facilitates a comparative assessment of clustering behaviour across algorithms. It is evident that both K-Means and GMM yield analogous cluster distributions, with K-Means separating clusters near zero and GMM shifting the boundary closer to –1 along the first principal component. The results of the BGMM are sparse, unstructured clusters that lack geometric coherence. DBSCAN and HDBSCAN fail to generate meaningful partitions, often resulting in the data being collapsed into a single dominant cluster or the production of irregular groupings.

In contrast, PCFC consistently yields well-separated and physically interpretable clusters. Waveforms with low hybrid membership values $(0 \leq \hat{u}_{ij} < 0.25)$ are located on the positive side of the first principal component, whereas those with high membership values $(0.75 \leq \hat{u}_{ij} \leq 1.00)$ are concentrated around –2.5 to –3. This consistent pattern across datasets suggests a robust correspondence between the first principal component and damage severity. Specifically, waveforms from undamaged regions have a tendency to cluster in the positive domain, while those from delaminated regions map to the negative extreme, thereby providing a distinctive signature of structural integrity in composite laminates.

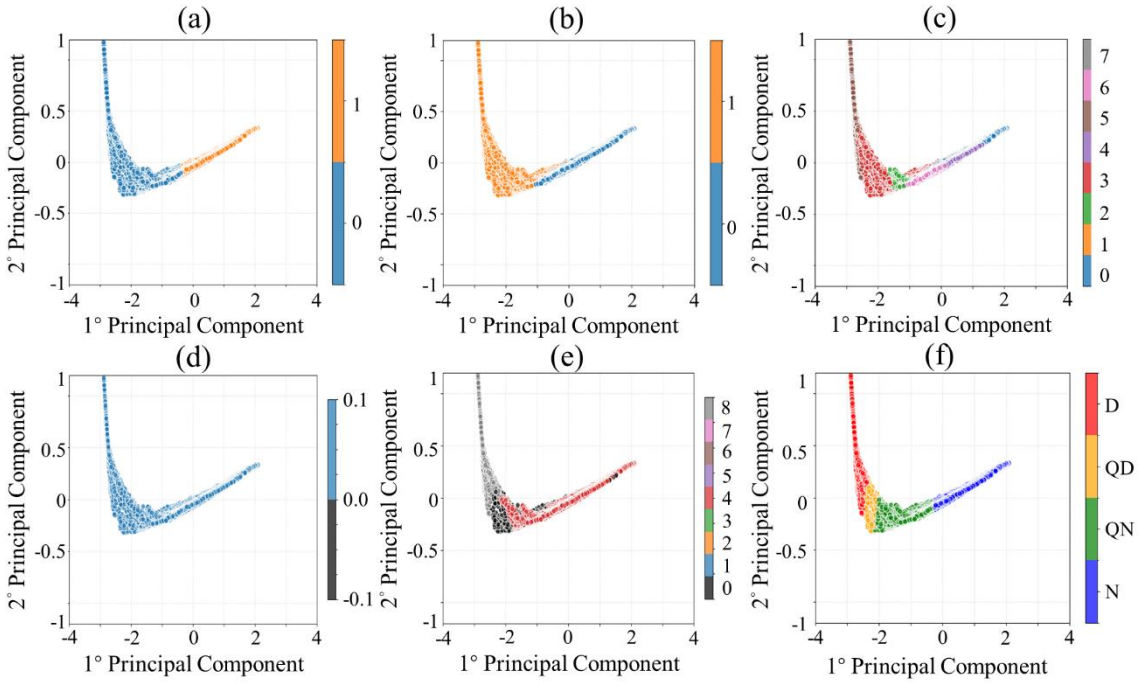

Figure 6: Feature space clustering analysis of the training plate with wave propagation PA, using: (a) K-Means, (b) GMM, (c) BGMM, (d) DBSCAN, (e) HDBSCAN, and (f) PCFC.

3.3. Effect of CNN Pre-training on Clustering Performance

To demonstrate the benefits of pre-training the 1D-CNN feature extractor, particularly in scenarios with limited labelled data, the clustering results of 2D remapped wavefields using K-Means are presented here. Figure 7 compares outputs for two laminates containing a 10 × 10 mm² delamination at different depths (0.84 mm and 0.56 mm) with wave propagation direction PA. Figure 7a–b show cluster maps from an untrained model, while Figure 7c–d illustrate the enhanced performance achieved with the pre-trained feature extractor.

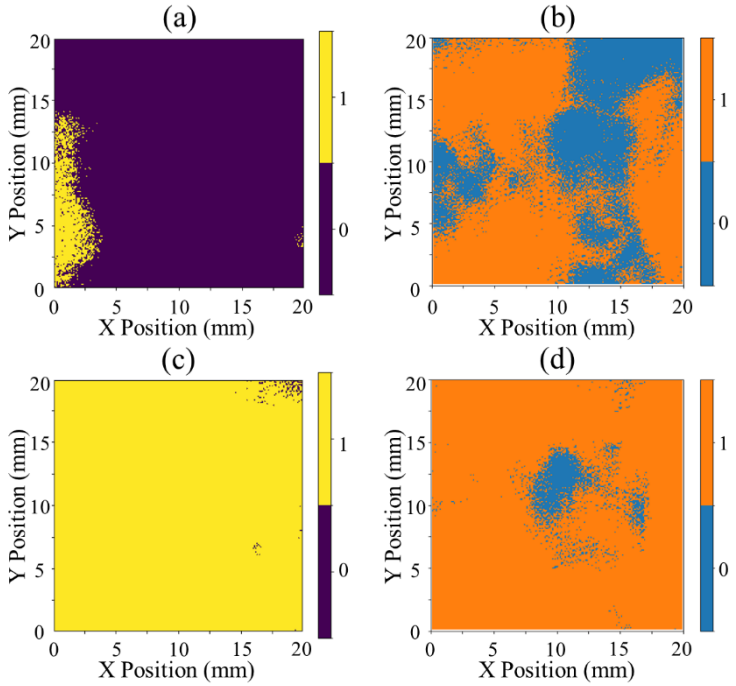

Figure 7: K-Means clustering comparison between an untrained (a, c) and pre-trained (b, d) 1D-CNN model with the same architecture, applied to plate two plates with 10 × 10 mm² delaminations located at 0.56 mm depth (a, b) and 0.84 mm depth (c, d), respectively.

4 CONCLUSIONS

This paper introduced a hybrid supervised–unsupervised learning framework designed to enable physically meaningful cluster analysis on unseen data, using only limited labelled input. Whilst the clustering itself lacks explicit physical interpretability, this limitation was addressed by incorporating a pre-trained 1D-CNN as an optimized feature extractor.

The 1D-CNN was trained on waveforms acquired from a single CFRP plate using the LUVI system. The reciprocity theorem was utilised to map these 1D measurements into 2D wavefields and to label them as “delamination” or “non-delamination” for supervised training. Following the completion of the training process, the CNN was able to extract low-dimensional feature representations from new, unlabelled datasets. This enabled clustering in a compact, discriminative space.

A comparative analysis of clustering algorithms(K-Means, GMM, BGMM, DBSCAN, HDBSCAN, and the proposed PCFC) was conducted on this embedded feature space. The proposed PCFC, which combines CNN-derived probabilities with fuzzy membership values from FCM, demonstrated consistent superiority in terms of accuracy and physical interpretability when compared to alternative methods. The visual representation of the damage was clear, and there was a strong alignment with the actual structural conditions. In contrast, DBSCAN failed to identify damaged regions, while BGMM, despite demonstrating effective segmentation performance, suffered from excessive granularity and high computational cost.

An important observation emerged from the feature space distribution: clusters associated with delamination consistently mapped to the negative axis of the first principal component (PC1), starting near −2.5, while undamaged regions aligned with the positive PC1 axis. This trend suggests a potentially generalizable indicator of delamination in unseen waveforms.

In summary, the proposed approach provides a robust, data-efficient solution for the detection of delamination, especially valuable when fully supervised datasets are not available.

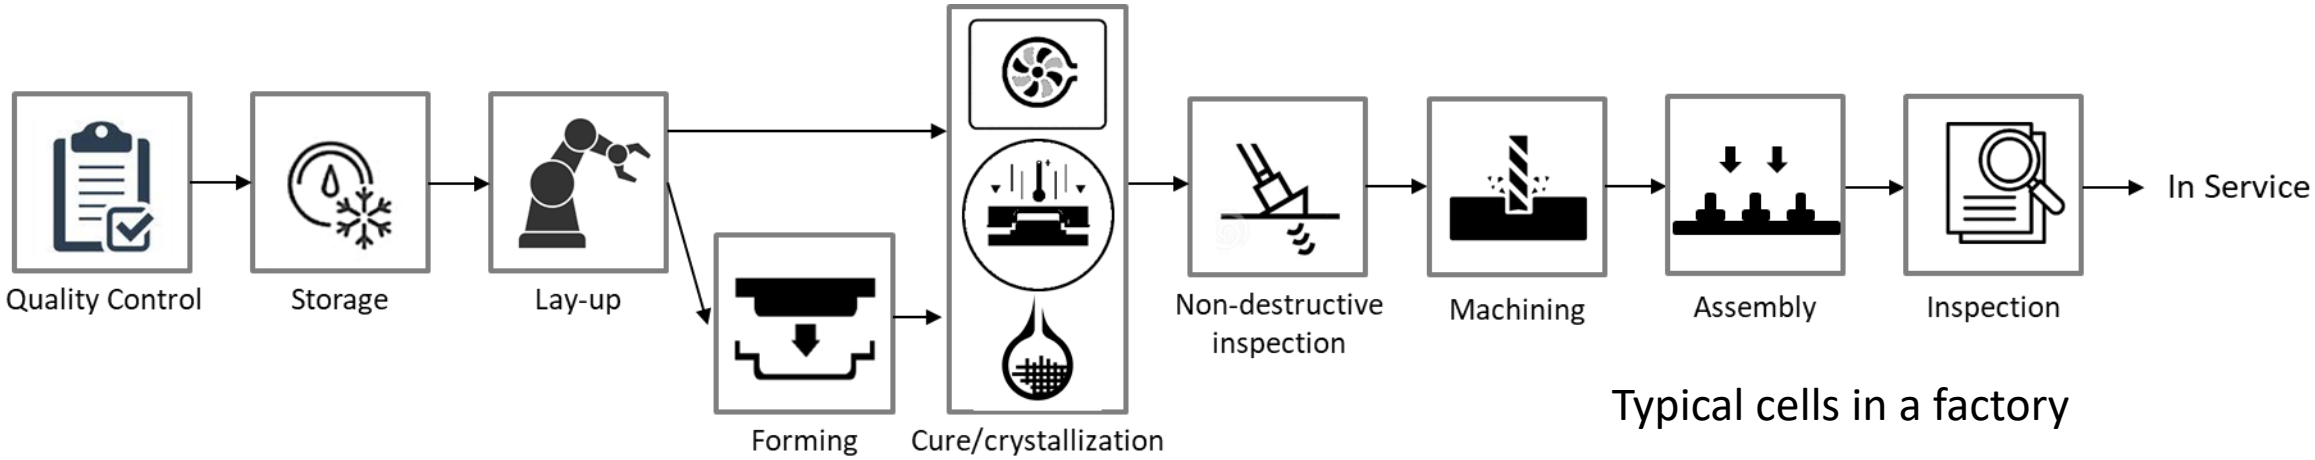
Process Simulation for Composites Manufacturing

Typical cells in a factory

For high confidence process simulation, we need (a) appropriate mathematical model(s) of the underlying physics, and (b) sufficient knowledge of initial and boundary conditions during the process

Low confidence → *High confidence*



Using process simulation as job aids to explore the process design space – *test supported by simulation*

Using process simulation for detail process design, documentation and certification – *simulation supported by test*

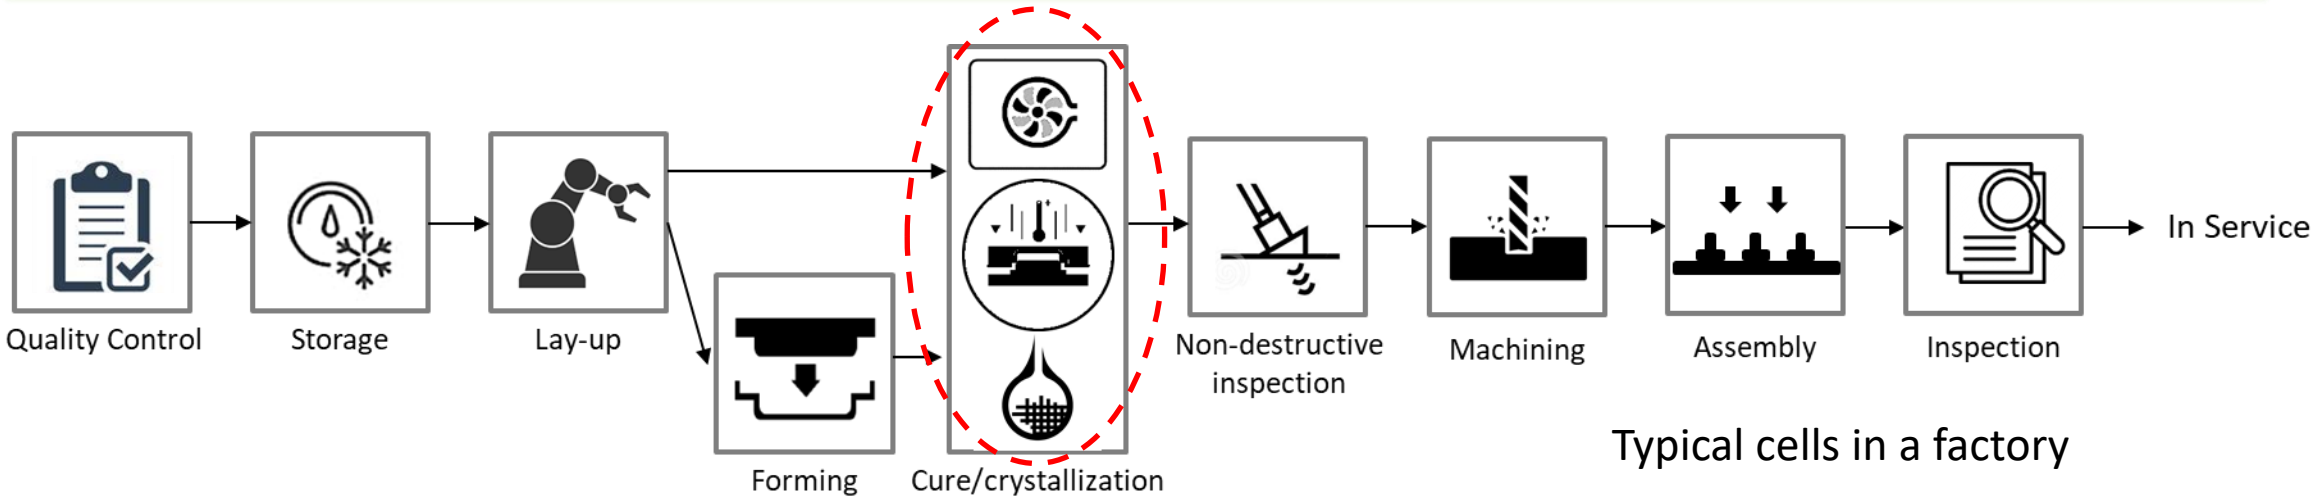
Process Simulation for Composites Manufacturing

Typical cells in a factory

The amount of test data available is limited for composites manufacturing, particularly if it is a new material, process, tooling, equipment, or product.
By definition, test data will be expensive and take time to generate



Therefore, merging simulation and test data in the most efficient manner is a critical step in maximizing the value of composites process simulation

The key questions thus becomes: how confident are we in our process simulations, can we quantify our confidence, and how can we improve it?

Process Simulation for Composites Manufacturing

Typical cells in a factory

Thermal management simulation is a relatively mature area in process simulation

1980s

- Simple single material model
- 1D governing equations
- Effects of tool-equipment interaction were not modelled
- Minimal test data

2020s

- Effects of tool-equipment interaction
- 3D governing equations
- Wide range of material constitutive models, with extensive characterized material libraries
- Commercially available and increasingly used

Next gen

- Formal addition of uncertainty
- Virtual sensors
- Optimized physical sensor installation
- Better design and manufacturing practices
- ……

Process Simulation for Composites Manufacturing

$$Governing\ equation: \quad \frac{\partial(\boldsymbol{\rho C_p T})}{\partial t} = \frac{\partial}{\partial z}\left(\boldsymbol{k}\frac{\partial \boldsymbol{T}}{\partial z}\right) + \dot{Q}$$

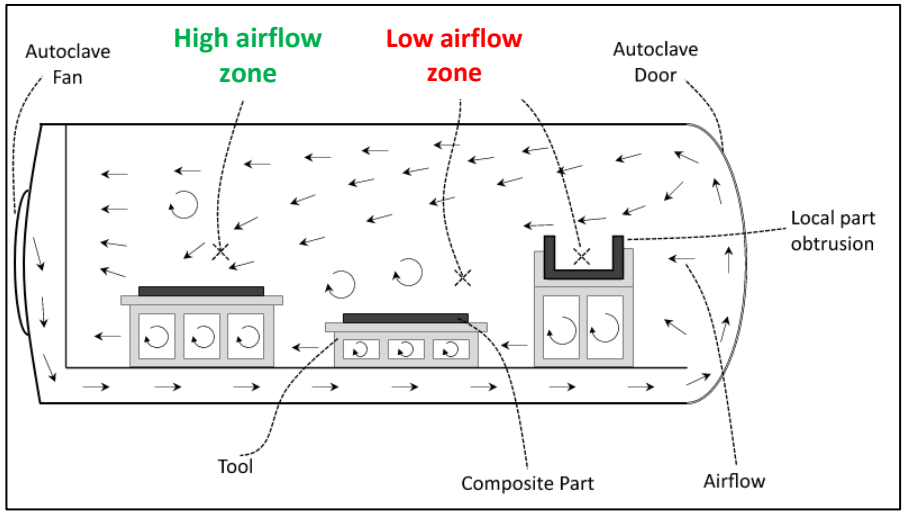
$$\dot{Q_R} = (1 - \boldsymbol{v_f})\boldsymbol{\rho_R H_R}\frac{\partial \alpha}{\partial t}$$

$$Boundary\ condition: \quad -\boldsymbol{k}\frac{\partial T}{\partial n} = -\boldsymbol{h}(\boldsymbol{T} - \boldsymbol{T_{air}})$$

$$Cure\ Kinetics\ model: \quad \frac{\partial \alpha}{\partial t} = \boldsymbol{f}(\alpha, t)$$

Heat transfer. Accessed: Nov. 25, 2024. [Online]. Available: *https://compositeskn.org/KPC/A132*

The uncertainties in a process simulation model can stem from a number of sources including but not limited to:



- **Sensor data (Temperature measurements,…)**
- **Material properties and models (Thermal conductivity, heat of reaction, density, cure-kinetics models,…)**
- **Boundary conditions (Heat transfer coefficients, …)**
- …….

In this work, we present a Bayesian inference approach in quantifying uncertainty in boundary conditions and demonstrate an example of how to propagate it in a process simulation framework

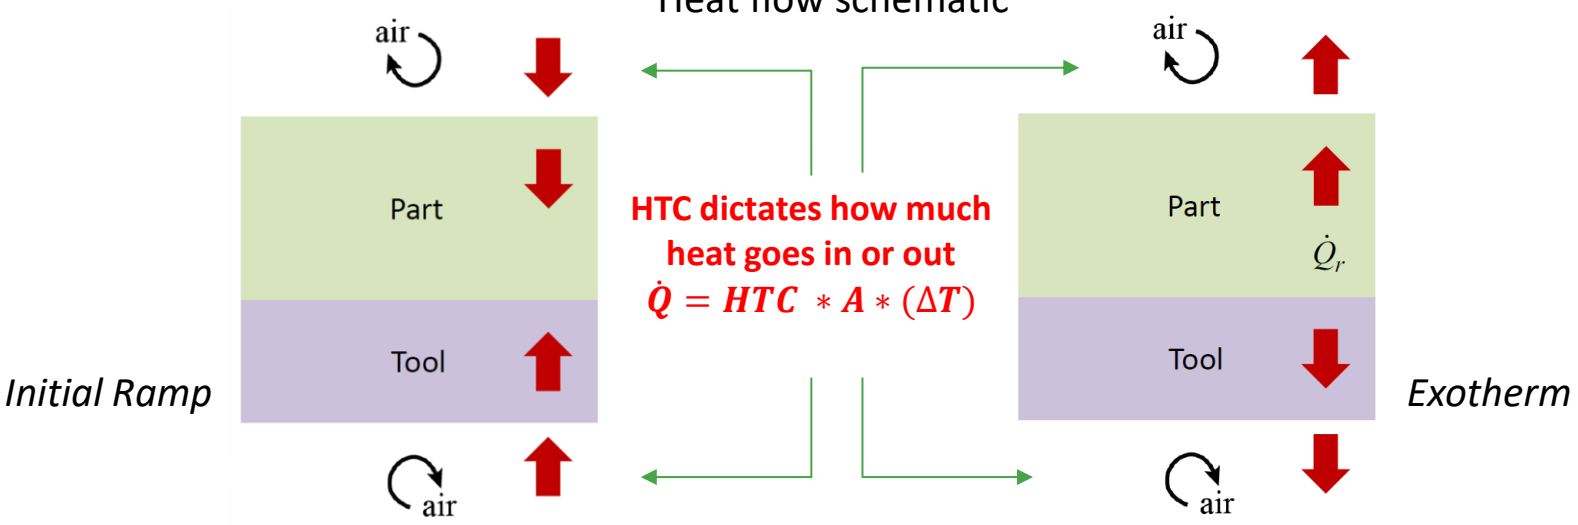
HTCs in Thermal Process Simulation – What and why?

https://compositeskn.org/KPC/A106

Airflow in a typical autoclave can be very complex

The resultant HTCs are hence critical in determining system response



In thermal simulations, the heat transfer coefficients (HTC) play a critical role in predicting the tool-part thermal response.

The HTCs can vary significantly depending on the equipment:

1. Ovens – 20-50 W/m^2/K
2. Autoclaves – 40-200 W/m^2/K (depending on pressure inside)

In current state of the art process simulation, the **uncertainty around HTCs remain the Achilles' heel**.

Uncertainty Propagation in Thermal History Predictions

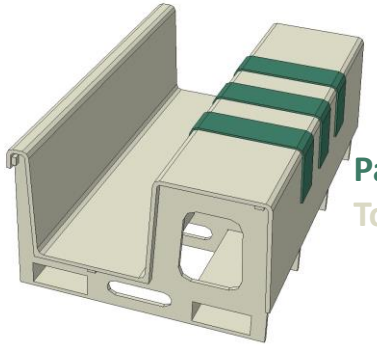
- We can correctly identify the lead and lag TCs based on the 19 working TCs.
- However, there are 9 TCs that failed during the experiments
- The actual lead and lag positions could be one of the TCs that failed.

Hence, we now also include the predictions at those TCs, to compare with the experimental data

We plot the predictions for all the TCs (working + failed)



- **Actual lead and lag locations may be different from what our experiments tell us**
- This can occur if any of the critical TCs fail during the run, or if TCs are not placed at appropriate locations!

Summary

- Quantification of uncertainty and its formal addition to process simulation models is critical in moving from a deterministic to a stochastic framework

- A stochastic process simulation framework will enable efficient yet rigorous and traceable approach to:
  - Exploration of the range of potential outcomes in a processing window
  - Evaluation of current tool-equipment configurations
  - Determination of optimum bus-stop configurations of tools in an autoclave
  - Thermal profiling of part-tool-equipment combinations
  - Identification of locations of lead and lag temperatures in a part
  - Development of virtual/proxy TC approaches for low-cost, high reliability production

ABSTRACT

Understanding the mechanical influence of microstructural variations on fibre break development is crucial for reducing uncertainties in predicting the longitudinal tensile failure of unidirectional composites. In this study, the interaction between local microstructural variations and fibre breaks is monitored using *in situ* X-ray holotomography at 150 nm resolution. Three distinctive microstructures are identified to drive the initiation and clustering of breaks. First, misplaced fibres within the 0°/0° interply region, which exhibit significant misorientation and cross multiple adjacent fibres, progressively trigger multiple single breaks and a co-planar cluster at their intersections. Second, resin-rich pockets within the 0°/0° interply region promote clustering of breaks, progressively forming a non-coplanar cluster of five breaks. This clustering is accompanied by non-uniform matrix microcracks and short interfacial debonds around the break sites. Third, larger resin-rich pockets, locally formed in regions with groups of misoriented fibres, play a critical role in driving pronounced break clustering. Their interactions exhibit severe matrix nonlinearity, as evidenced by matrix microcracks, short interfacial debonds, and damage features, including microvoids or the onset of matrix microcracks. The identified fibre break patterns, clustering behaviour, and damage associated with three microstructural cases provide new insights into how these microstructures serve as precursors to fibre break development, highlighting the importance of accounting for them in predicting longitudinal tensile failure to improve reliability.

1. Introduction

Carbon fibre-reinforced composites are now widely used in structural applications in the automotive, aerospace, and renewable energy sectors. Despite their widespread use, their relatively brittle structural response remains a key challenge in material design and failure prediction. Longitudinal tensile failure is arguably regarded as the most fundamental and crucial among all failure modes. It is widely recognised that the tensile final failure of multidirectional composites is determined by the failure of fibres oriented in the principal loading direction [1]. This failure scheme begins with the weakest fibres failing and culminates in the development of critical clusters that eventually trigger a self-sustaining cascade of fibre failures [2]. Each break diminishes load-carrying capacity, thereby redistributing the load to neighbouring fibres within a certain distance from the break. This redistribution is accompanied by shear-dominated deformation of both the matrix and the interface, involving various damage mechanisms such as matrix cracking and interfacial debonding.

To predict the size and severity of the region surrounding breaks, many studies have investigated stress redistribution around fibre breaks using finite element models [3-6]. However, uncertainties persist in these predictions, particularly because most models do not account for manufacturing-induced microstructural variations, such as severe local fibre misalignment and resin-rich pockets. In recent years, Synchrotron Radiation Computed Tomography (SRCT), pinnacle of computed tomography, has enabled 3D, *in situ*, imaging of composites at a resolution sufficient to distinguish individual fibre breaks [7, 8] and to correlate with microstructural features [9-11]. This has catalysed the opportunity for a deeper

understanding of how variations in microstructural features influence fibre breaks and, more broadly, composite strength in both experimental and numerical studies.

From an experimental perspective, Rosini *et al*. [11] examined the differences in local fibre misorientation between break and intact sites. Their statistical results demonstrated that fibres at single break sites have a higher standard deviation in their orientation distribution compared to intact fibre sites. Breite *et al*. [2] observed similar break behaviour through *in situ* SRCT, linking clustered breaks to fibre regions with significant in-plane misalignment. Findings from both studies remain limited to the initiation of single and clustered breaks, without elucidating the damage mechanisms that drive their formation and subsequent progression, or how clusters interact with local microstructural variations under increasing loads. In this context, Fritz *et al*. [12] used micro-CT to identify microstructural features in UD carbon fibre composites, but without performing *in situ* monitoring with applied loads. In particular, the study reported on the presence of *misplaced* fibres at ply interfaces, which deviate markedly from the main UD ply orientation and intersect multiple neighbouring fibres (as opposed to *misaligned* fibres, which may deviate from the nominal ply direction but are entirely constrained to their local tow).

FE models incorporating microstructural variations have also addressed their effects on stress localisation and composite strength. Malgioglio *et al*. [13] reported that increased variability in fibre misalignment reduced strength and increased the scatter in predicted strength values. Models in the study, however, are limited to the ply level. The replicated misorientation angles (-2° to 2°) remained insufficient to fully capture the range observed in commercially manufactured composites. Recently, Jafarypouria *et al*. [14] implemented microscale FE models to examine stress redistribution around a single fibre break in both misaligned and perfectly aligned fibres. This reported an increase of ~33% in the maximum stress concentration factors in neighbouring fibres for the misaligned case. However, the applicability of model is still limited by the studied range of misorientation angles (1.4° to 5°).

Although the studies discussed above have advanced the understanding of how local microstructural variations relate to tensile failure, two important questions remain open for further investigation:

- If fibres exhibit local misalignment exceeding the small angles typically studied (<5°), similar to the misplaced fibres reported by Fritz *et al*. [12], how do severely misaligned fibres interact with adjacent aligned fibres, and how does this influence break behaviour under tensile loading?
- When fibres break at sites with local microstructural variations, how do the localised stresses interact with the surrounding matrix and fibre-matrix interfaces, and how might the resulting damage cause clustering of fibre breaks?

Whilst SRCT has been shown to be a valuable tool for understanding fibre failure, imaging at resolutions better than ~500 nm is rarely conducted due to constraints in image acquisition. Given this resolution level and scale of carbon fibres, isolated matrix microcracks and interfacial debonds may not be reliably detected, because their openings may be smaller than 30% of the voxel resolution. Even if such damage features exist, they can be obscured by bright fringes originating from discontinuities (i.e. fibre breaks), which are typically observed in propagation-based SRCT. To address these imaging limitations, Chatziathanasiou *et al*. [15] conducted the first *in situ* X-ray holo-tomography of composites at a 150 nm resolution. This technique, based on phase contrast nano-imaging, enabled the detection of matrix cracks and interfacial debonds initiated from breaks in glass and carbon fibre composites.

In this work, we extend the use of 150 nm *in situ* holo-tomography to elucidate interactions between local microstructural variations and fibre breaks under longitudinal tensile loading. Our primary objective was to link microstructural variations to the initiation and progression of breaks into clusters, along with associated microscale damage, such as matrix microcracks and interfacial debonds. In particular, we focus on three distinctive microstructures influencing fibre break development: (i) misplaced fibres, *i.e.* fibres crossing several other fibres, (ii) resin-rich pockets, and (iii) larger resin-rich pockets locally formed along groups of misoriented fibres. By addressing two key research questions outlined above, this study bridges a gap in understanding the influence of microstructural variations on longitudinal tensile failure.

2. Materials and methods

2.1. Materials

$[90/0]_s$ cross-ply laminates of aerospace-grade carbon fibre/epoxy prepreg were provided by Mitsubishi Chemical Corporation, with a total thickness of ≈ 0.5 mm. MRZ65-18000 carbon fibre (Mitsubishi Chemical Corporation) was used, with a nominal fibre diameter of 5.4 μm and a tensile modulus of 287 GPa. A #350 series, amine curing epoxy (Mitsubishi Chemical Corporation) was used as the matrix and cured via a standard aerospace autoclave cycle in accordance with the manufacturer's specifications.

The epoxy matrix was doped with 2.3 vol.% of silicon dioxide particles (SiO_2, 500 nm, near-spherical) to facilitate digital volume correlation on the tomograms. The selected particle properties were intended to minimise impact on the mechanical behaviour of the polymer matrix system, as suggested in [15, 16]. While digital volume correlation analysis was performed on these material/tests, the results are not a focus of this work and will not be discussed further.

2.2. Specimen design

Double-notched specimens, with a notch section width of 0.8 mm between the notch roots, were prepared for *in situ* tensile testing. The sample geometry is described in further detail in [15]. The volume fraction of 0° fibres in the notch region, as measured from the 3D reconstructed volume, was 48.5%. The specimens were machined using waterjet cutting, a method used previously for machining similar specimens without causing significant damage. Straight aluminium tabs, 1.5 mm thick, were attached to both faces and both ends of specimens using aerospace adhesive, Scotch-Weld™ EC-9323 B/A (3M Company, Maplewood, MN, USA), to aid loading and mitigate stress concentrations at the specimen ends.

Prior to the *in situ* experiments at ID16B beamline, *ex situ* tensile tests were performed on five specimens to determine the ultimate tensile strength (UTS) specific to the notch region. Given that the 0° plies were expected to primarily determine the longitudinal tensile failure of the specimens, only their cross-sectional area prior to the onset of 0° fibre splitting was used to calculate the UTS. The average of the measured UTS values was 2545 ± 168 MPa, serving as a reference for determining the stepwise loads applied during *in situ* testing.

2.3. *In situ* synchrotron holotomography

In situ holotomography scans were undertaken at 150 nm nominal (voxel) resolution on the ID16B beamline of the European Synchrotron Radiation Facility (ESRF), Grenoble, France. Holotomography, based on phase contrast nano-imaging, delivers images with spatial resolutions down to 25 nm (voxel) and is particularly well suited to materials with low attenuation. For each scan at a given load level, four distinct holograms are acquired at different sample-to-detector distances, enabling the retrieval of detailed phase information. A single tomogram is therefore reconstructed with enhanced signal-to-noise ratio and improved image quality.

In situ tensile tests were performed using a screw-driven loading rig equipped with a 1 kN load cell, custom-designed at KU Leuven for integration with the beamline. A detailed description of the rig is provided in [15]. A tensile specimen was loaded to five incremental levels (5%, 67%, 86%, 91%, 96%) of the measured UTS, with scans taken at each level. A 2048 × 2048 $pixel^2$ detector (PCO Edge 4.2 CLHS sCMOS) was used, with geometrical magnification resulting in an effective voxel size of 150 nm. A "pink" beam with an energy of 29.6 keV was used [17]. Each scan acquired 2505 projections, with an exposure time of 10 ms per projection. Tomograms were reconstructed using in-house software at the ESRF [18].

3. Results and discussion

Fibre breaks formed in association with microstructural variations were identified in three regions (**Fig. 1**): misplaced fibres (Region 1), resin-rich pockets (Region 2), and larger resin-rich pockets locally formed along groups of misoriented fibres (Region 3). The causality of the breaks and their clustering was elucidated through hypothesised mechanisms contributing to the observed break behaviour, alongside microscale damage patterns developed near breaks.

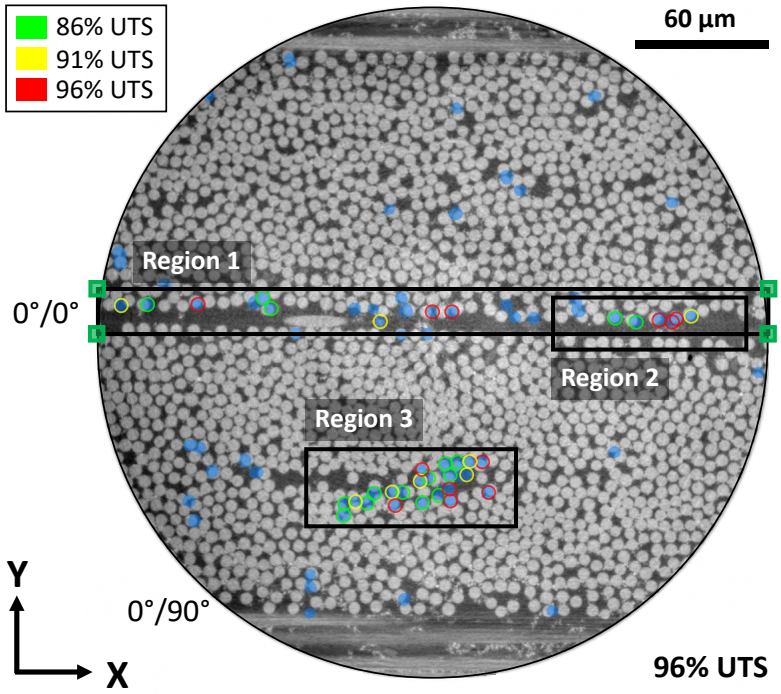

Fig. 1. A 150 nm SRCT image of the tested specimen containing two 0° plies, acquired at 96% UTS, showing all fibre breaks within the scan volume projected as blue dots. The black rectangles at the 0°/0° interply ('Region 1' and 'Region 2') and 0° intraply ('Region 3') mark the cropping regions for the stacks containing break sites identified as interacting with microstructural variations. Each region shows the projection of identified breaks, with outlines colour-coded in green, yellow, and red, to indicate their formation at 86%, 91%, and 96%, respectively.

3.1. Misplaced fibres within the 0°/0° interply region

3.1.1 Fibre breaks linked to misplaced fibres

This is the first report of fibre break behaviour occurring in regions where misplaced fibres are present, as monitored by *in situ* scans. **Fig. 2a** illustrates the XZ plane view of the stack in Region 1 at 96% UTS, revealing three misplaced fibres (labelled as fibres 1, 2, and 3) in the interply region, with misorientation angles of -26°, 79°, and -35°, respectively. These angles represent the deviation of fibre orientations within the XZ plane relative to the Z-axis loading direction, with the positive direction defined as clockwise from the Z-axis.

The three misplaced fibres appear to cross and come into close contact with adjacent fibres. To investigate how these misplaced fibres relate to break occurrence, the stack was first projected along the Y-axis using the *average intensity* Z-projection in ImageJ. **Fig. 2b** presents the resulting XZ slice, highlighting the projections of nine break sites (1 to 9) spatially aligned with the misplaced fibres. In parallel, the XY cross-sectional views of the nine breaks were visually examined. As illustrated in **Fig. 3**, crossings between misplaced and adjacent fibres appear to progressively trigger seven single breaks and one co-planar break pair ('duplet') at load levels up to 96% UTS, either within the misplaced fibres or in the adjacent aligned fibres at their intersections.

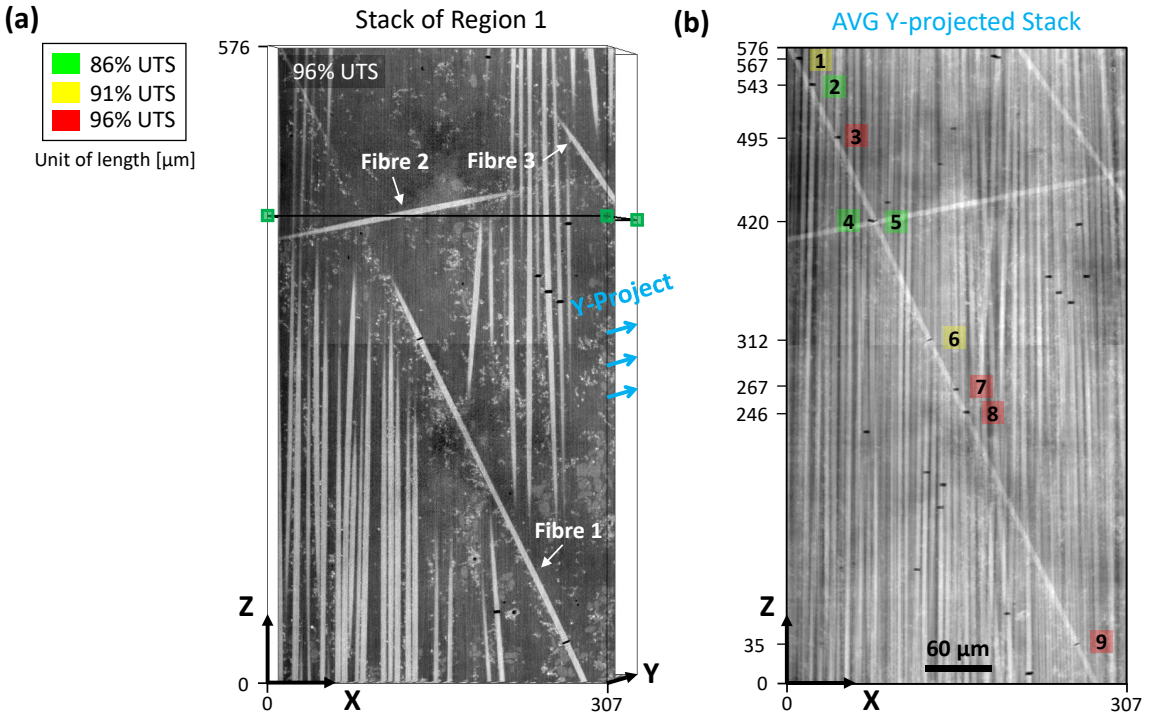

Fig. 2. (a) XZ plane view of the stack cropped from Region 1 at 96% UTS, showing three misplaced fibres (labelled 1, 2, and 3) crossing adjacent fibres. (b) XZ slice obtained by average intensity projection of the Region 1 stack along the Y-axis, revealing nine break sites at intersections between misplaced and adjacent fibres.

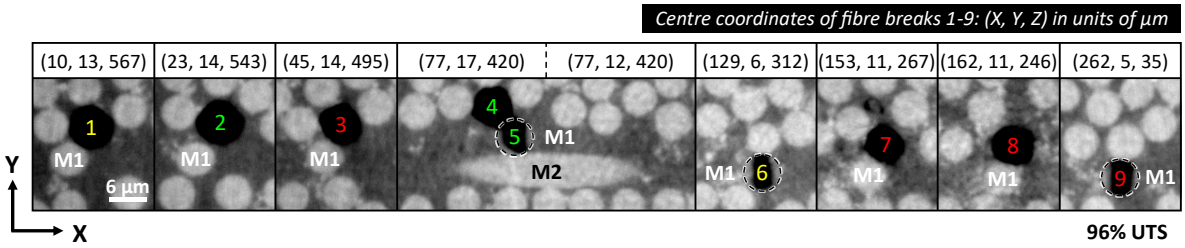

Fig. 3. XY fibre cross-sectional views of nine breaks formed within the Region 1 stack (**Fig. 2b**), with all break sites located either within misplaced or adjacent fibres at intersections. Misplaced fibres 1 and 2 are labelled as M1 and M2, respectively. Each break number is colour-coded by formation load level, with centre coordinates defined relative to the XYZ axes of the Region 1 stack.

3.1.2 Role of misplaced fibres in break initiation

We propose two hypotheses to explain the mechanisms underlying the observed behaviour. First, the formation of multiple breaks at the intersections might be related to the tow spreading and resin impregnation process during prepreg manufacturing. These two processes, when carried out using the direct contact (mechanical) method, employ spreading or impregnation rollers to flatten the fibre tows into a uniform prepreg sheet, bringing the surface fibres on each ply into contact with the rollers during processing. This contact can build up shear and frictional stresses on the fibre tows, as indicated by Moradi *et al*. [19]. It is plausible that these stresses could concentrate on misplaced and misaligned fibre tows crossing over aligned fibres on the ply surface, potentially causing damage to the filaments within the fibre tows. This, in turn, could introduce strength controlling defects at the crossing points. Consequently, we hypothesise that such defects could explain the increased prevalence of fibre breaks within the interply region. Mesquita *et al*. [20] similarly reported a higher occurrence of fibre breaks

near the ply interface in thin plies, despite the absence of strongly misaligned fibres. This was suggested to result from the fibre weakening introduced during the tow spreading, which is consistent with the hypothesis we propose.

Another possible explanation for the observed breaks (1 to 9) involves micro-mechanical influences arising from local fibre misalignments, particularly local stress concentrations at intersections between misplaced and adjacent fibres. When fibre bundles were subjected to tension, misplaced fibres themselves may have experienced bending stresses in addition to axial stresses, placing them in a multiaxial stress state. This, in turn, may induce higher shear stresses in the matrix surrounding the misplaced fibres, leading to the formation of inhomogeneous stress states in nearby fibres. Crossing over adjacent fibres, misplaced fibres are likely to have intensified local stress concentrations at their intersections. Consequently, this could impart elevated stresses to misplaced or aligned fibres, or both, increasing their susceptibility to failure. Notably, **Fig. 3** illustrates co-planar breaks (4 and 5) formed at 86% UTS, when two misplaced fibres 1 and 2 crossed and contacted adjacent fibres. This phenomenon could be attributed to intensified local stress concentrations at intersections, exemplifying the micro-mechanical influences we proposed.

3.2. Resin-rich pockets within the 0°/0° interply region

3.2.1 Fibre break clustering and microscale damage linked to resin-rich pockets

A cluster in this study was defined as fibre breaks separated by less than 10 fibre diameters longitudinally (Z-axis) and two fibre diameters radially (X and Y-axis), consistent with the definition used in [8]. **Fig. 4** illustrates the primary findings of break clustering and associated microscale damage that progressively occurred along resin-rich pockets in Region 2 up to 96% UTS.

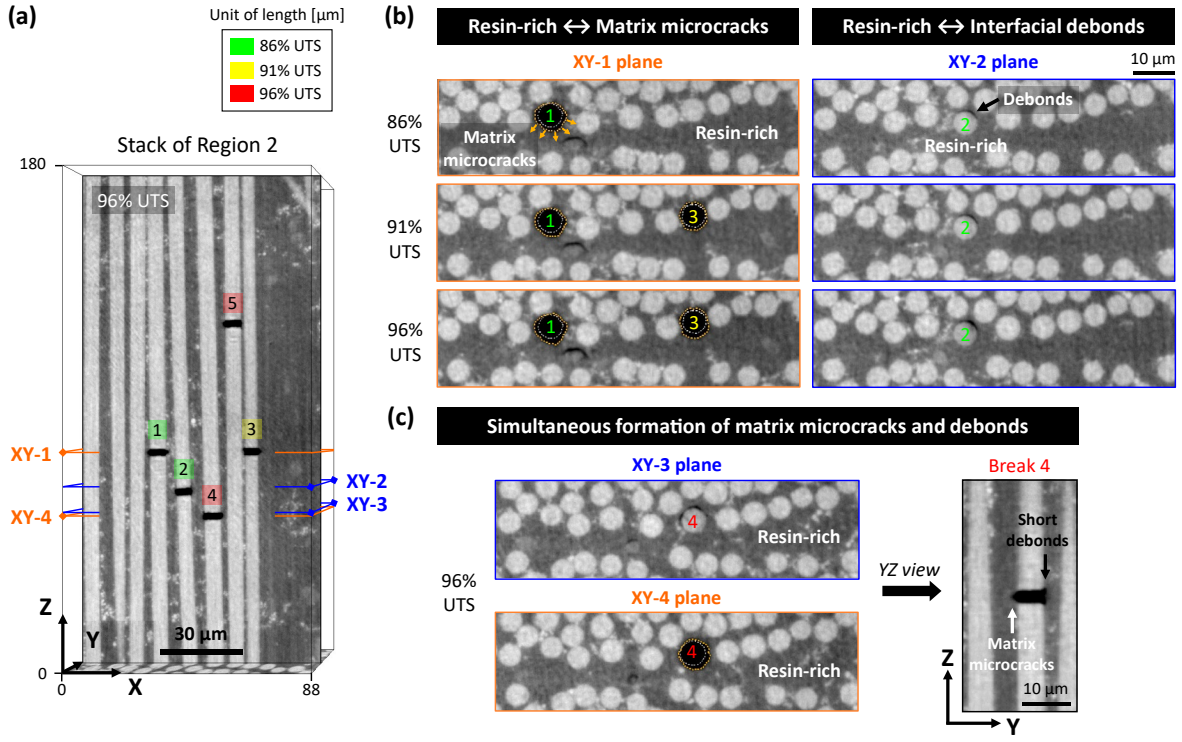

Fig. 4. (a) XZ plane view of the stack cropped from Region 2 at 96% UTS, showing non-coplanar breaks (1 to 5) near resin-rich pockets. Four marked positions (XY-1 to 4) indicate the locations used to extract XY cross-sectional planes at each break. (b) XY-1 and XY-2 planes of clustered breaks (1 to 3), revealing two distinct microscale damage patterns near resin-rich pockets, observed at 86%, 91%, and 96% UTS. The edges of matrix microcracks and fibres are delineated by orange and white dashed lines. (c) XY-3 and XY-4 planes at break 4, showing simultaneous formation of two microscale damage patterns.

No damage was observed in this region at 67% UTS. However, breaks 1 and 2 appeared as non-coplanar breaks at 86% UTS (**Fig. 4a**). The use of high-resolution phase contrast imaging facilitated a detailed examination of damage surrounding the breaks. The XY cross-sectional planes of each break reveal microscale damage in the form of matrix microcracks and short interfacial debonds (**Fig. 4b**). These two features contrast with their apparent absence around fibre breaks where no resin-rich pockets are present, as reported in [15]. Adjacent to break 1, a matrix microcrack of ~1.1 μm in extent formed at break edges facing resin-rich pockets and extended into these regions, creating a non-uniform crack pattern around the fibre circumference (see XY-1 plane). The crack tips also appear distinctly wide/blunted as they extend into resin-rich pockets, resembling those observed near break 4 at 96% UTS (see YZ plane in **Fig. 4c**). In contrast, break 2 exhibited short interfacial debonds measuring ~1.2 μm in axial length along the fibre direction (see XY-2 plane). These debonds were confined to the side opposite the resin-rich pockets, where the inter-fibre distance surrounding break 2 is small, leading to their asymmetric formation.

At 91% UTS, break 3 emerged in the vicinity of clustered breaks 1 and 2. While showing no visible debonds, the XY-1 break plane also reveals non-uniform matrix microcracks similar to those previously seen near break 1. With further loading to 96% UTS, additional breaks 4 and 5 formed in regions of fibres that were likely overloaded by neighbouring breaks 2 and 3. This consequently formed a non-coplanar cluster of five breaks (1 to 5) within approximately the same XZ plane located near resin-rich pockets. As shown in **Fig. 4c**, break 4 initiated matrix microcracking and short debonds simultaneously, consistent with the damage patterns seen near resin-rich pockets at lower loads (see XY-3 and XY-4 planes).

3.2.2 Role of resin-rich pockets in break clustering and microscale damage development

The observed patterns of matrix microcracks, characterised by non-uniform propagation towards resin-rich pockets with blunted crack tips, may be attributed to low local stiffness in resin-rich regions adjacent to broken fibre. These regions contain fewer surrounding fibres to suppress crack growth, permitting greater crack opening [5]. Despite their wide crack openings, the maximum extent of crack propagation remained relatively short (~1.6 μm). This cracking behaviour could be indicative of shear nonlinearity locally occurring in the resin-rich regions. Yang *et al.* [21] suggest that shear nonlinearity in carbon epoxy composites may originate from microscale processes such as matrix microcracking. Molecular-level plasticity in the resin is also reported as a potential source of shear nonlinearity.

In contrast, the clustered breaks exhibited asymmetric debonding that was highly localised near break edges farther from resin-rich pockets, with debond lengths reaching no more than ~1.5 μm. This debonding can be explained by the localisation of shear stresses induced by breaks, which tend to concentrate more in regions with smaller inter-fibre distances rather than near resin-rich pockets. From an energy standpoint, the short extent of the debonds suggests that the strain energy released from a fibre break was not favourably absorbed through debonding. Rather, a greater portion of the energy was likely absorbed by matrix cracking and matrix plasticity, as discussed above.

In light of these findings, the continuous formation of matrix microcracks and short debonds from 86% UTS onwards indicates that resin-rich pockets may have played a significant role in promoting break clustering. This suggests that breaks near resin-rich pockets may induce more localised stress concentrations in the matrix and interface, thereby reducing effective matrix stiffness and introducing shear nonlinearity. As a result, neighbouring intact fibres near both newly formed and pre-existing breaks may become overloaded at each load level. This could increase the likelihood of cascading effects that promote the clustering of breaks under increasing loads, which may explain the formation of non-coplanar clusters within the interply region. Furthermore, another factor contributing to the clustering could be linked to the increased prevalence of breaks at or near the ply interface (see section **3.1.2**).

3.3. Larger resin-rich pockets along misoriented fibre groups within the 0° intraply region

3.3.1 Fibre breaks linked to groups of misoriented fibres

Fig. 5 illustrates the primary findings on break initiation and clustering associated with groups of misoriented fibres and the resulting larger resin-rich pockets. The XY plane view of stack in Region 3

at 96% UTS is presented in **Fig. 5a**, showing projections of all breaks (1 to 22) formed at each load level within the stack. Groups of misoriented fibres are distributed across slices from XZ-1 to XZ-4 planes within the stack.

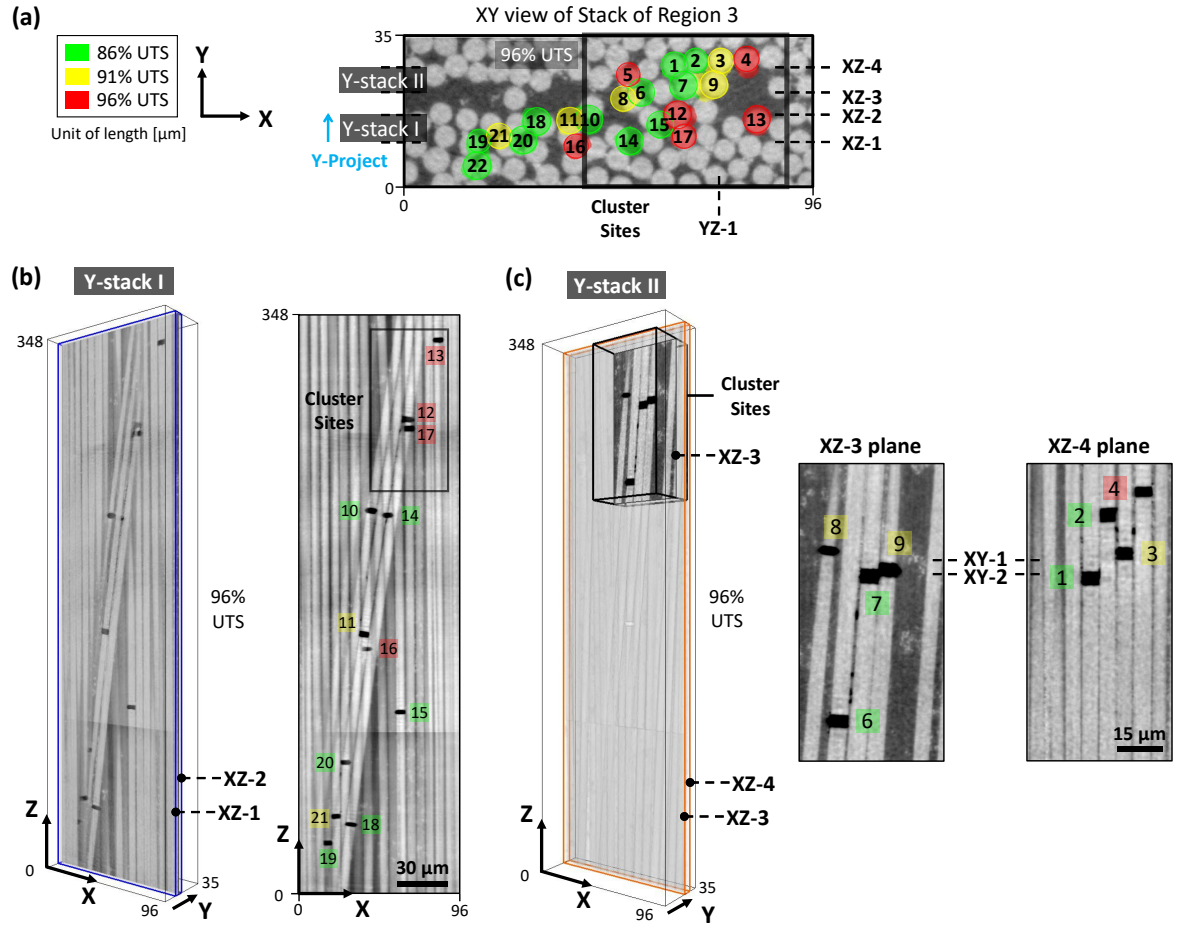

Fig. 5. (a) XY plane view of the stack cropped from Region 3, showing the projection of all detected breaks (1 to 22) within the stack, colour-coded by their formation load level. The black rectangle marks the cropping region containing the cluster sites. Five marked positions (XZ-1 to 4 and YZ-1) indicate locations used to extract XZ and YZ plane views at the cluster sites. (b) XZ plane view of 'Y-stack I' and an XZ slice obtained by average projection. (c) XZ plane view of 'Y-stack II' with magnified views of cluster sites at the XZ-3 and XZ-4 planes. Two marked positions (XY-1 to 2) indicate locations used to extract XY plane views at the cluster sites.

As shown in **Fig. 5b**, 'Y-stack I', sliced from XZ-1 to XZ-2 planes, is found to contain the most severely misoriented group of fibres, which collectively cross over adjacent aligned fibres with misorientation angles of 8°. Accordingly, larger resin-rich pockets were formed along the regions occupied by these misoriented fibres. The breaks accumulated up to 96% UTS in the Y-stack I are effectively visualised in 2D using the average projection along the Y-direction, consistent with the method used in section **3.1.1**. Breaks consistently occurred at intersections between misoriented fibre groups and adjacent fibres, closely resembling the break behaviour observed near misplaced fibres (see section **3.1.1**). As such, we propose that micro-mechanical effects, i.e. local stress concentrations arising at the intersections, could be linked to this break behaviour, consistent with the hypothesis proposed on breaks linked to misplaced fibres. In addition, Jafarypouria *et al.* [14] demonstrated that peak stress concentration factors in the neighbouring intact fibres near a break were ~33% higher in misaligned fibre bundles than in perfectly aligned ones, which further supports our hypothesis.

3.3.2 Fibre break clustering and microscale damage linked to larger resin-rich pockets

Fig. 5c presents 'Y-stack II', sliced from XZ-3 to XZ-4 planes within the Region 3 stack. A labelled region, referred to as cluster sites, contains non-coplanar breaks that developed near larger resin-rich pockets locally formed along misoriented fibre groups. Most of these breaks predominantly developed within the same XZ break planes up to 96% UTS, as revealed by 2D slices taken at XZ-3 and XZ-4 planes.

At 86% UTS, two pairs of non-coplanar breaks emerged: breaks 6 and 7 in the XZ-3 plane, and breaks 1 and 2 in the XZ-4 plane. In the XZ-3 plane, larger resin-rich pockets are clearly visible around the site of breaks 6 and 7, resulting from misoriented fibre groups. These misoriented fibres were also in contact with those identified in Y-stack I. As part of the clusters, breaks 7 and 1 lay within the same XY-2 fibre cross-sectional break plane and were located immediately adjacent to each other, forming a co-planar duplet. This co-planar duplet initiated both matrix microcracks and short interfacial debonds, showing damage patterns consistent with those observed around breaks located near resin-rich pockets (see section **3.2.1**).

At 91% UTS, three additional breaks were detected in close proximity to the non-coplanar breaks formed in the XZ-3 and XZ-4 planes: a single break 8 and non-coplanar duplet (9 and 3). The focus of observation was on breaks 9 and 3 because their break sites were immediately adjacent to the pre-existing co-planar duplet (7 and 1) and non-coplanar breaks (1 and 2). **Fig. 6a** additionally shows the breaks (9 and 3) in the YZ-1 plane view of the cluster sites. The lower left side of break 3 in the YZ-1 plane shows damage features, appearing as microvoids or the onset of matrix microcracks, within the inter-fibre matrix region between breaks 9 and 3, facing the larger resin-rich pockets. Similarly, damage features resembling microvoids were observed on the upper left side of break 3 in the XZ-4 plane (**Fig. 6a**), particularly within inter-fibre matrix region between break 2 and 3. These features were absent in the scans at lower loads, indicating that their formation is related to the surrounding break behaviour.

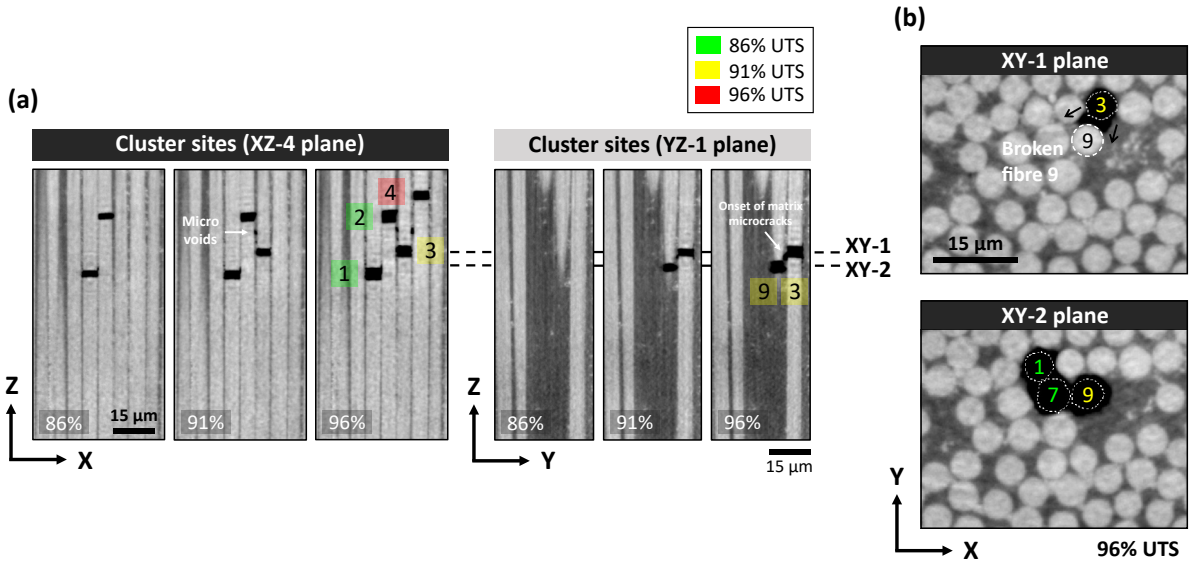

Fig. 6. (a) XZ and YZ plane views of the cluster sites (**Fig. 5c**) in 'Y-stack II' at XZ-4 and YZ-1 planes, showing non-coplanar breaks with associated microscale damage at 86%, 91%, and 96% UTS. Break numbers are colour-coded by their formation load level. (b) XY fibre cross-sectional views of non-coplanar breaks at 96% UTS, taken from cluster sites at XY-1 and XY-2 planes. Matrix microcracks near break 3 propagate extensively (black arrows), linking breaks 1, 3, 7, and 9, which formed earlier at 86% and 91% UTS.

At 96% UTS, two single breaks 4 and 13 were newly detected in fibres facing larger resin-rich pockets, with break 4 forming immediately next to the pre-existing non-coplanar cluster (1 to 3) in the XZ-4 plane. This progressive clustering also formed new microvoids within the inter-fibre matrix region between breaks 4 and 3, as observed at 91% UTS. As the pre-existing non-coplanar breaks (1 to 4) and (3 and 9) opened further with increasing load, the surrounding earlier-formed damage features (i.e. onset

of matrix microcracks) increased in size. As seen in YZ-1 plane (**Fig. 6a**), the damage features within the inter-fibre region of breaks 3 and 9 eventually coalesced, linking these two breaks that were previously unlinked at earlier loads. This damage progression, evident as significant propagation of matrix microcracks, was similarly observed along the inter-fibre regions of the pre-existing clustered breaks (7 and 9) and (7 and 1). **Fig. 6b** illustrates the XY-1 and XY-2 planes of these breaks at 96% UTS, revealing matrix microcracks at their maximum propagation in the fibre cross-sectional view. In the XY-1 plane, matrix microcracks initiated at break 3 prominently propagate across the inter-fibre matrix region toward the fibre where break 9 occurred, located near the larger resin-rich pockets. Consequently, the propagating matrix microcracks appear to connect with those surrounding clustered breaks 9, 7, and 1, forming a continuous damage zone.

Together with the micro-mechanical effects discussed earlier, we tentatively propose a hypothesis that could explain the pronounced increase in clusters near larger resin-rich pockets in Y-stack II. Following the formation of initial breaks near resin-rich pockets, stress redistribution between broken and neighbouring intact fibres may have been hindered by the combined effects of fibre misalignment, larger resin-rich pockets, and matrix nonlinearity. Moreover, the observed clustering was consistently accompanied by the formation of by matrix microcracks, short interfacial debonds, and microvoids. These damage features provide evidence of severe matrix nonlinearity in these break sites. Notably, with increasing loads, the propagation of matrix microcracks extended across the inter-fibre region, progressively linking pre-existing clustered breaks. This exemplifies the severity of matrix nonlinearity, particularly when break sites are influenced by both fibre misalignment and the resulting resin-rich pockets. Furthermore, Swolfs *et al.* [4] reported that the tips of matrix cracks may induce very high stress gradients across fibres. If so, these gradients could play an additional role in intensifying matrix nonlinearity, further supporting our hypothesis.

4. Conclusions

This study investigates the interaction between local microstructural variations and fibre breaks in 0° carbon fibre plies, elucidating how these interactions contribute to the initiation and clustering of breaks. We performed *in situ* tensile tests, combined with 150 nm-based X-ray synchrotron holo-tomography, to monitor the accumulation of breaks in regions with microstructural variations under increasing stress levels. The scans revealed three distinctive microstructural features that promote a pronounced increase in the occurrence of single and clustered breaks: misplaced fibres and resin-rich pockets within the 0°/0° interply region, and larger resin-rich pockets surrounding misoriented fibre groups within the 0° intraply region. Notably, the clustering of breaks near resin-rich pockets was consistently accompanied by non-uniform matrix microcracks, short interfacial debonds, and damage features resembling microvoids or onset of matrix microcracks. Such microscale damage strongly suggests the occurrence of severe matrix nonlinearity at these break sites, reinforcing the role of resin-rich pockets in promoting break clustering. The identified break patterns and associated microscale damage shed new light on the importance of considering their critical role in fibre break development for more reliable predictions of longitudinal tensile failure. Future work could focus on developing fibre break models that incorporate the microstructural variations identified in this study. This would help determine the extent to which these microstructural variations influence stress redistribution around breaks.

Conceptualization
Ideas; formulation or evolution of overarching research goals and aims.

Data Curation
Management activities to annotate (produce metadata), scrub data and maintain research data (including software code, where it is necessary for interpreting the data itself) for initial use and later reuse.

Formal Analysis
Application of statistical, mathematical, computational, or other formal techniques to analyze or synthesize study data.

Investigation
Conducting a research and investigation process, specifically performing the experiments, or data/evidence collection.

Methodology
Development or design of methodology; creation of models.

Software
Programming, software development; designing computer programs; implementation of the computer code and supporting algorithms; testing of existing code components.

Validation
Verification, whether as a part of the activity or separate, of the overall replication/reproducibility of results/experiments and other research outputs.

Visualization
Preparation, creation and/or presentation of the published work, specifically visualization/data presentation.

Writing – Original Draft Preparation
Creation and/or presentation of the published work, specifically writing the initial draft (including substantive translation).

Writing – Review & Editing
Preparation, creation and/or presentation of the published work by those from the original research group, specifically critical review, commentary or revision – including pre- or post-publication stages.

Keywords: Multidirectional composite, Remote mode II fracture loading, X-ray computed tomography, In situ observation

ABSTRACT

Delamination is a prevalent and life-limiting failure mode in laminated composites, with mode II delamination, driven by in-plane shear, being particularly difficult to characterise. Conventional edge-monitoring techniques are inherently limited, as they cannot capture the three-dimensional (3D) evolution of the delamination front and the associated damage mechanisms. Building on our group's recent work demonstrating the first in situ X-ray computed tomography (CT) experiment for visualising mode II delamination, this paper presents preliminary results from an ongoing study focused on capturing successive delamination migration events in multidirectional laminates. The investigated specimens feature a +45°//−45° delamination interface and ±45° angled plies. A custom-designed in situ four-point bending rig is employed for the experiments. The proposed in situ CT technique enables mesoscale visualisation of delamination migration within the bulk of the specimen—a capability beyond the reach of conventional edge-monitoring techniques. These results underscore the potential of in situ CT to advance the understanding of mode II fracture evolution in composite laminates.

1 INTRODUCTION

Fibre-reinforced composites are widely valued for their high stiffness-to-weight ratio, superior strength, and excellent design flexibility, making them ideal for lightweight structural applications. However, their susceptibility to delamination remains a major limitation, significantly hindering their broader industrial adoption. Delamination, also known as interlaminar fracture, is one of the most prevalent and critical failure modes in laminated composites. It leads to notable reductions in structural stiffness, strength, and compression-after-impact resistance. Mode II (shearing) delaminations, driven by in-plane shear loads, pose particular challenges. These often originate from off-axis cracking under tensile loads or from interlaminar shear stresses under flexural and impact loading. Unlike mode I (opening) delaminations, mode II failures are more difficult to mitigate. Therefore, accurate observation and characterisation of mode II delaminations are essential.

Conventional assessment techniques for mode II delaminations—such as visual inspection, edge microscopy, and digital image correlation—typically rely on monitoring one of the two lateral edges of the specimen to detect crack initiation and growth [1]. However, these edge-monitoring methods provide only two-dimensional insights, overlooking the full 3D morphology of the delamination front and the underlying damage mechanisms. For instance, it is well established that mode II delaminations frequently exhibit a curved front, with the crack advancing faster at the edges than in the centre. Furthermore, the fibre orientations at the delamination interface significantly affect the shape and evolution of the delamination front [2–5].

CT provides a non-destructive, volumetric imaging technique capable of capturing internal damage mechanisms in composite specimens [6]. Unlike traditional edge-monitoring approaches, CT enables full 3D visualisation of delamination propagation throughout the entire loading process. It also facilitates analysis of the interplay between delamination progression and factors such as ply

orientation at the delamination interface. The heterogeneous microstructure of fibre-reinforced composites is particularly well-suited to CT imaging, as the different material phases (i.e. fibres and matrix) can be differentiated by their X-ray attenuation properties, which depend on their chemical composition. The delamination front itself is readily identifiable as an air-filled region propagating inside the bulk. However, conventional absorption-based CT is most effective when cracks are sufficiently open and large relative to the resolution of the imaging system.

To date, most CT-based investigations of delamination in fibre-reinforced composites have been conducted ex situ. Gong et al. [2] used ex situ CT to study the effect of ply orientation on mode I delamination under both quasi-static and fatigue loading, revealing mechanisms such as delamination migration via ply splitting. Later, the same group extended their work to mode II loading using the end-loaded split test, again observing delamination migration through ex situ CT scans after each load step [7]. Similarly, Blondeau et al. [3] employed ex situ CT to analyse mode I delamination resistance in relation to ply orientation, identifying fibre bridging and delamination migration. Herráez et al. [4] extended this to mode II loading, while Pichler et al. [5] explored mixed-mode delamination. In these studies [2–5, 7], successive ex situ CT scans were used to reconstruct the sequence of damage evolution. In another example, Shor et al. [8] performed single ex situ CT scans to assess delamination in unidirectional and woven laminates loaded in mode I, mode II, and mixed-mode fracture.

In contrast, few studies have explored in situ CT monitoring of delamination in composites. Borstnar et al. [9] were among the first to capture in situ toughening mechanisms during mode I loading using a wedge-loaded double cantilever beam. Their work revealed micro-mechanisms contributing to global fracture resistance. Similarly, Chatziathanasiou et al. [10] performed in situ CT on carbon fibre-reinforced laminates under standard mode I loading, tracking delamination growth through tomogram segmentation—without contrast agents. This is advantageous, as contrast-agent immersion (common in [2–5, 7]) can alter delamination behaviour, and the time required between successive ex situ scans can lead to stress relaxation.

Recently, our group conducted the first in situ CT investigation of delamination growth and migration in fibre-reinforced composites subjected to remote mode II loading [11]. Building on that foundation, the present study aims to capture successive delamination migration phenomena in multidirectional laminates featuring a +45°//−45° delamination interface and ±45° angled plies. For this purpose, a newly developed in-house in situ loading rig is employed. Preliminary results from our ongoing work demonstrate the ability of our method to accurately track the overall delamination path and reveal mesoscale failure mechanisms. These findings contribute to addressing the fundamental question in composite fracture mechanics, regarding how local mesostructure influences the initiation and progression of delamination.

2 MATERIALS AND METHODS

2.1 Materials and specimen preparation

The composite laminate used in this study, also used in [10], was fabricated by SABCA Limburg NV using automated tape laying followed by autoclave curing. The material system consists of Cytec unidirectional prepregs, comprising Tenax HTS40 12k carbon fibres preimpregnated with the CYCOM 977-2 toughened epoxy resin.

The laminate under investigation featured a multidirectional stacking sequence consisting of only ±45° angled plies: $[(+45°/-45°)_5/+45°//-45°/(-45°/+45°)_5]$, where '//' denotes the position of the delamination plane. In this laminate, the +45°//−45° delamination interface and the two successive −45°-plies next to the delamination plane create preferable paths for delamination migration, so we can test the capability of our method to capture this damage phenomenon.

A 12.5-μm-thick Teflon sheet insert was embedded at the mid-thickness interlaminar plane of the laminate during lamination to create an artificial pre-crack [12], in alignment with ASTM D7905 [1]. The prepreg stack was cured in an autoclave under a controlled temperature and pressure cycle, ensuring consistent fibre volume fraction and minimal voids. Before the final cure, intermediate vacuum debulking steps were conducted to ensure minimal void content and optimal fibre volume fraction. These debulking cycles were carried out at room temperature, with the vacuum pressure maintained between 0.5 and 0.7 bar for at least 10 minutes per cycle. These steps serve to remove

entrapped air before high-temperature consolidation. Final autoclave curing followed the manufacturer's recommended curing cycle, applying a temperature of 180 °C and a pressure of 6 bar. Subsequent CT inspection of the cured laminate confirmed it was nearly void-free. The thickness of the cured laminate is 4.1 mm (22 plies, nominal ply thickness equal to 186 μm). More details on the manufacturing process can be found in [13].

Rectangular specimens with 10 mm width, 110 mm length, and 50 mm pre-crack length were prepared for the delamination tests. The specimens were extracted from the manufactured laminated plate using water-jet cutting, a process that introduced slight asymmetries in the height of the specimens, as shown in Fig. 1. Each specimen was marked with Tipp-Ex at the pre-crack end and at intervals along its length to retain orientation consistency during post-scan analysis. The thermal curing employed can cause partial fusion of the pre-crack interface, so we needed to perform manual separation of the crack front using a scalpel after specimen cutting and before the experiment.

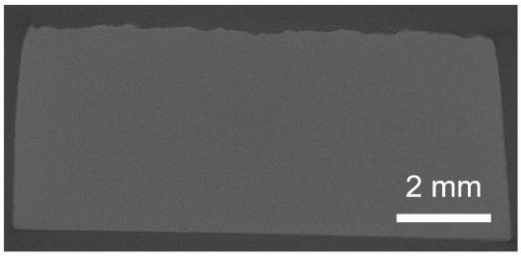

Figure 1: Specimen cross-section, depicting uneven width at the top and bottom surfaces.

2.2 Testing method

To evaluate the interlaminar fracture behaviour of the laminate under remote mode II loading, the four-point end-notched flexure (ENF) test configuration was selected. This method is well established for measuring mode II interlaminar fracture toughness in fibre-reinforced composites, offering several advantages over other testing configurations such as the three-point ENF and end-loaded split tests [14]. For example, in the four-point ENF setup, the crack front is positioned inside a region of pure bending [15] between the two inner loading noses, which reduces frictional effects and distributes the stresses more evenly [14]. Moreover, the four-point ENF test provides a more uniform and well-defined mode II loading field, while the existence of a double-span configuration improves sensitivity to crack growth and reduces excessive deflections in the test specimen. The four-point ENF configuration is also compatible with pre-inserted artificial cracks and allows for both more stable initiation and crack growth [15], making it suitable for qualitative and quantitative fracture analysis in both unidirectional and multidirectional layups.

2.3 In situ testing

Mechanical loading was applied using an in-house developed four-point bending rig, which was mounted on the rotating stage inside a lab-scale CT scanner (TESCAN UniTOM XL), as shown in Fig. 2a. The rig had some operational restrictions, including that the load cells (Sensy model 5962 500 N with Mantracourt DSCH4 MOD amplifier) capped the maximum load at 850 N, and geometric constraints imposed by the loading nose configuration, which limited specimen dimensions (see Fig. 2b). The setup featured dual rotating stages, top and bottom. The span lengths between the inner and outer loading noses were 31 mm and 62 mm, respectively.

Each specimen was loaded incrementally to initiate delamination, followed by a short relaxation period before scanning to reduce motion artefacts. Before the first scan of each testing period, a detector normalisation procedure was carried out to correct for beam profile inhomogeneities and ensure more consistent image contrast across scans. The specimens were loaded under load control, and scans were started manually at selected load steps, mostly after a load drop had been noticed. Table 1 provides the main scan parameters.

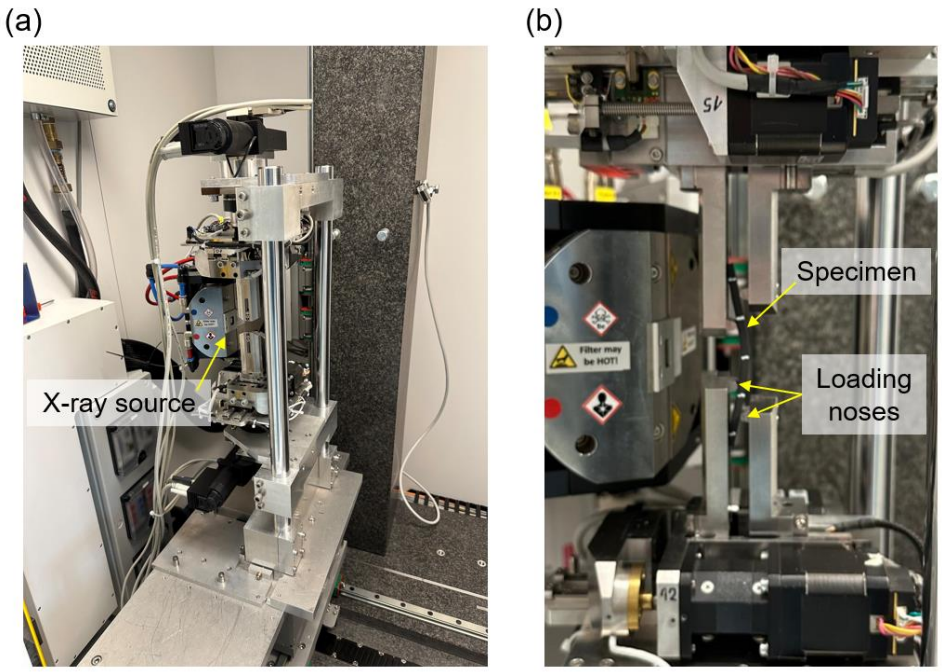

Figure 2: Experimental setup: (a) four-point bending rig mounted onto the rotating stage of the CT scanner and (b) specimen loaded in the in situ bending rig.

Parameter	Value
Tube voltage [kV]	100
Tube current [µA]	150
Power [W]	15
Voxel size [µm]	8.5
Radiographic projections [no.]	4,000
Exposure time per projection [ms]	185
Source-to-object distance [mm]	50
Source-to-detector distance [mm]	882
Scan duration [min]	~13
Pre-scan relaxation time	Until the load was stabilised

Table 1: CT scan parameters.

2.4 Image processing

Each scanned volume was reconstructed into a stack of two-dimensional slices in the TESCAN reconstruction software Panthera. A non-local means filter was applied to reduce image noise, and interactive thresholding to segment the delamination regions (i.e. air phase) from the surrounding composite material was performed in the Avizo 3D 2023.1.1 software (Thermo Fisher Scientific). Due to the similarity in grey values between the carbon fibres and epoxy resin, and too low spatial resolution, segmentation of them was not feasible. Sub-volumes were extracted to exclude rig components and noise caused by them from the field of view as much as possible, and to make the crack visible by excluding the outer layer of air.

3 PRELIMINARY RESULTS

3.1 Capture of successive delamination migrations

Fig. 3 illustrates an example of the 3D reconstructed specimen and delamination in a specific load step. Two successive delamination migration phenomena are visible. The first migration event

occurred just after delamination propagation onset at the end of the pre-cracked region. The crack initiated from the +45°//−45° pre-crack interface, jumped the two successive −45°-plies just above the pre-crack interface, and continued along the new −45°/+45° interface (see Fig. 3a). A second crack migration event was observed in the new +45°/−45° interface (see Fig. 3b), which we could not observe fully developed due to restrictions of our volume of interest.

3.2 Crack length estimations

While the crack front is not easily detectable in 3D volume renderings, the two-dimensional ortho slice views enable a more precise albeit approximate identification. The slice number corresponding to the initial crack edge at the pre-crack end can be identified, along with the slice number where the crack tip ends (both indicated in Fig. 3b). The difference between these two slice numbers is multiplied by the voxel size to obtain the total crack length in the scan volume. This method allows for reasonably accurate estimation of the crack length, despite the presence of some artefacts and the absence of clear 3D crack front segmentation.

In one of the specimens, the initial part of the crack near the pre-crack boundary fell just outside the field of view. However, based on other specimens, it was consistently observed that the crack migration began directly at the end of the pre-crack region.

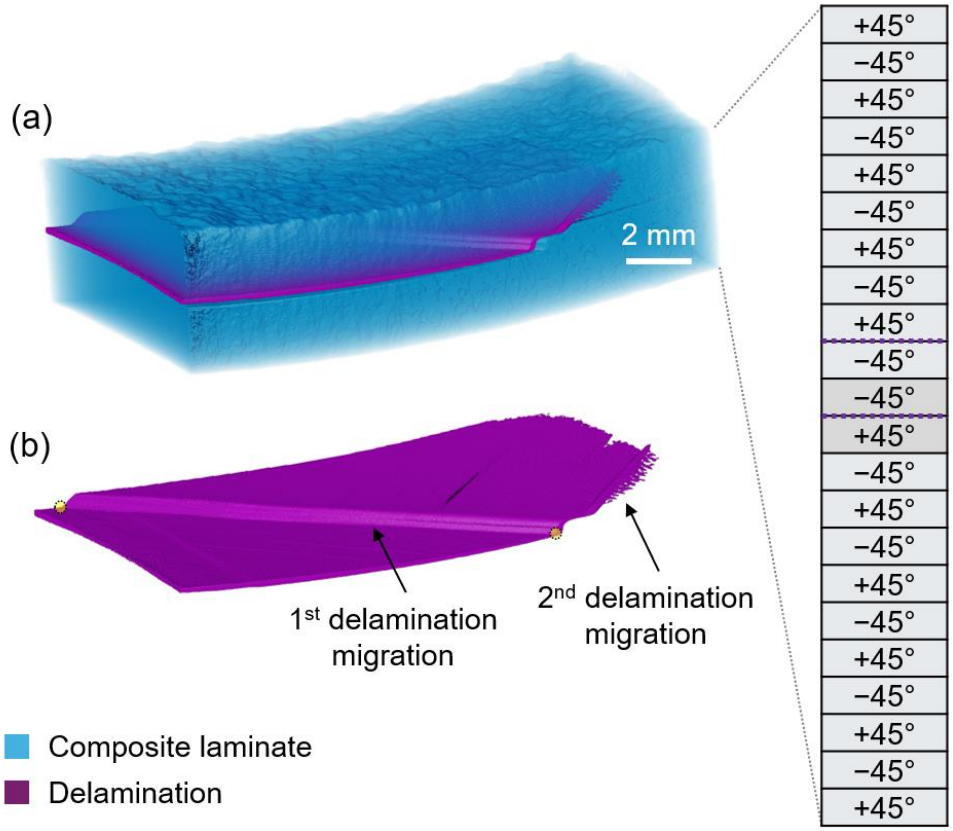

Figure 3: Capture of successive delamination migration events: (a) 3D visualisation of delamination segmentation, and (b) segmented delamination separated from the specimen.

4 CONCLUSION

This study introduced an in situ CT approach to capture successive delamination migration events in ±45° carbon fibre-reinforced laminates subjected to remote mode II loading, using a four-point ENF configuration. A newly developed in situ bending rig was employed to facilitate high-resolution imaging during loading. The results demonstrate the effectiveness of the in situ CT method and loading rig in tracking the bulk evolution of the delamination front, including the observation of two distinct migration phenomena.

Ongoing work focuses on investigating how ply orientation at the delamination interface influences migration behaviour. In addition, we aim to determine the global mode II interlaminar fracture toughness and characterise the mode mixity introduced by factors such as the inherently unsymmetric layup of multidirectional laminates and the progressive stiffness asymmetry in the four-point ENF setup as delamination advances. These efforts will contribute to a deeper understanding of how local mesostructural features govern the initiation and propagation of delamination in composite laminates and their fracture toughness.

ACKNOWLEDGEMENTS

The research leading to these results has been performed within the framework of the INFORM project and has received funding from the European Union's Horizon 2020 research and innovation programme under the Marie Skłodowska-Curie grant agreement No. 101108965. The study was also funded by the KU Leuven Research Council (project C14/21/076). The KU Leuven XCT Core Facility is acknowledged for providing the CT scanner TESCAN UniTOM XL and relevant CT acquisition tools. Technical support from the mechanical workshop and composite laboratory staff from the Department of Materials Engineering at KU Leuven is acknowledged.

ABSTRACT

This study presents in-situ synchrotron X-ray computed tomography (SRCT) of the void evolution and resin infusion behavior during a nanoporous network (NPN)-enabled out-of-autoclave (OoA) manufacturing process for aerospace-grade woven composite laminates. During the OoA process, the NPNs could facilitate gas evacuation and promote resin infusion into the interlaminar regions via the induced high capillary pressure. To better understand the underlying mechanisms of the NPN-enabled OoA process, a custom experimental setup employing a thermoelectric module was developed, which allowed active "freezing" of the resin flow during CT scanning while providing heating to promote resin flow between scans. After initial proof-of-concept tests on a lab-scale X-ray micro-CT system, the custom setup was used to scan IM7/8552 woven laminates with and without polymer aerogel NPNs at various stages of a typical composite cure cycle. These scans were conducted using SRCT at the HEX beamline of the National Synchrotron Light Source II (NSLS-II). In these in-situ scans, the baseline laminate exhibited significant void formation and coalescence at elevated temperatures due to volatile release and insufficient resin pressure. On the other hand, the laminate with polymer NPNs showed uniform resin infusion into the interlaminar regions and minimal void development. These results provided direct evidence of the critical role of NPNs in void mitigation during the NPN-enabled OoA process by maintaining open pathways for gas venting and inducing high capillary pressure that promotes resin infusion.

1 INTRODUCTION

Manufacturing of aerospace-grade thermoset composite structures heavily relies on the usage of autoclaves that supply external pressure and convective heating to cure the composite laminates and to achieve minimal void content [1–3]. However, autoclaves often impose significant energy consumption,

equipment cost, and geometric constraints on the manufacturing process for aerospace-grade composites [4]. To overcome these issues, an out-of-autoclave (OoA) manufacturing process utilizing the high capillary pressure induced by nanoporous network (NPN) materials was developed to achieve void-free aerospace-grade composites [5]. When placed at ply-ply interfaces, the NPN materials can provide a pathway for trapped gas to escape while also supplying high capillary pressure to assist resin infusion into the void-prone interlaminar regions (see schematic in Figure 1 (a)). Using this method, void-free unidirectional and woven composite laminates have been successfully fabricated using autoclave-grade prepregs with vacuum-bag-only (VBO) setups using NPNs including vertically aligned carbon nanotubes (CNTs) and polymer aerogels (see Figure 1 (c)) [6–8]. To further understand the NPN characteristics required to enable this OoA manufacturing method, detailed characterizations of the capillary pressure and permeability of various NPN materials have been performed and subsequently informed a 1-D theoretical model developed to predict resin infusion speed in different NPN materials [7,9]. However, there are still many outstanding questions about how voids evolve, and resin infuses into interlaminar regions during the NPN-enabled OoA process as resin viscosity, volatiles, and void content evolve.

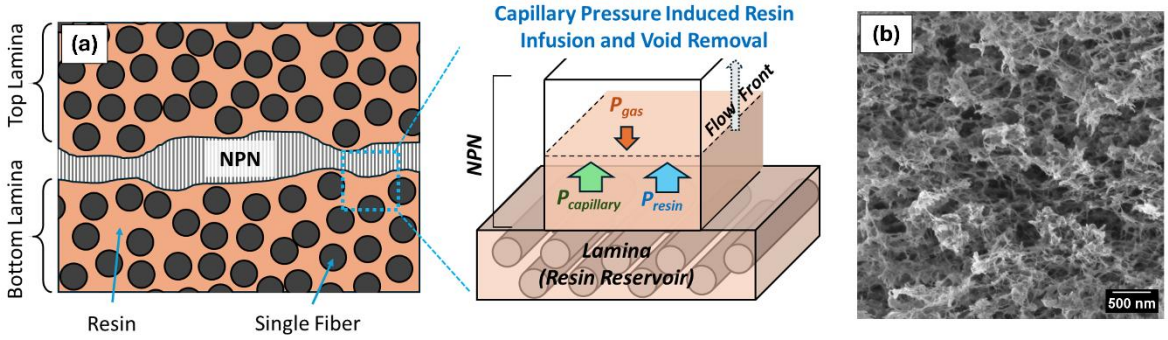

Figure 1: (a) Schematics (recreated from [5]) showing the mechanisms of capillary driven OoA curing of aerospace-grade composites enabled by the nanoporous networks (NPNs) and (b) a representative SEM image of the polymer aerogel NPN used in this study.

To obtain temporal information on the microstructure evolution of the composite laminates during the NPN-enabled OoA process, we developed an in-situ X-ray micro-computed tomography (X-ray micro-CT) experimental setup that can actively freeze the uncured laminates for stable and high-resolution CT scans at different stages of the cure cycles. Proof-of-concept experiments were first conducted on a lab-scale X-ray micro-CT to demonstrate the feasibility of this method. The same testing setup was then adapted for synchrotron radiation computed tomography (SRCT). SRCT scans were performed for IM7/8552 woven laminates with a $[0°]_5$ layup with and without polymer aerogel films as the interlayers using the High Energy Engineering X-Ray Scattering (HEX, 27-ID) beamline at the National Synchrotron Light Source II, Brookhaven National Laboratory. From the reconstructed scans taken at different time steps during a typical cure cycle, significantly different void evolution and resin infusion behavior were observed for the IM7/8552 laminates with and without polymer aerogel NPNs. For the laminate without NPN interlayers, voids can be seen emerging at elevated temperatures while the laminate with the polymer aerogel NPNs exhibited uniform resin infusion into the NPN interlayers without internal void development. The insights obtained from the in-situ SRCT scans will provide valuable learnings on the void evolution and resin infusion behavior during the NPN-enabled OoA process that can help provide a sustainable manufacturing method for high-quality void-free aerospace-grade composites.

2 MATERIAL AND METHOD

2.1 Experimental Setup

To achieve in-situ observation of void evolution and resin infusion behavior during the NPN-enabled OoA process, the resin flow inside the uncured composite laminates must be “frozen” during X-ray CT scans to enable stable and high-resolution imaging. To achieve this objective, we developed a custom

setup (see Figure 2 (a, b)) where a thermoelectric module is used to either heat the laminate to trigger resin flow or cool the laminate to "freeze" any resin motion during imaging by switching the electrodes of the thermoelectric module. To achieve efficient heating/cooling, the thermoelectric module is mounted on an off-the-shelf heat sink that provides a stable temperature near room temperature on the bottom side of the thermoelectric module (see Figure 2 (b)). A sectioned aluminum T-bar is attached on top of the thermoelectric module to conduct heat away or towards the composite laminates while also serving as a rigid and flat surface for the composite layup. Thermal paste was applied between the thermoelectric module and the aluminum support/heat sink to ensure efficient thermal conduction. The backside of the aluminum support was milled thinner to improve the transmission of the X-ray. A K-type thermocouple was mounted on the backside of the aluminum support to measure real-time temperature, which was used as input for a PID temperature controller that controls the heating/cooling of the thermoelectric module. Since the aluminum support provided a rigid and flat surface for the composite layup, a typical vacuum-bag-only setup (see Figure 2 (b)) was used which included all the necessary components, such as cork dams, caul plate, breather, vacuum port, and vacuum bag, and could accommodate laminates with a size of 0.5 inch × 0.5 inch (12.7 mm × 12.7 mm). In this study, all scans were performed on 5-ply $[0°]_5$ IM7/8552 woven laminates. Two sets of laminates were imaged, the baseline samples without any NPN interlayers and laminates with polyimide aerogel films of ~50 µm nominal thickness (supplied by Aerogel Technologies, LLC) as NPNs at every ply-ply interface. Once the layup is completed, the setup is placed on the rotating sample stage for X-ray micro-CT or SRCT imaging (see Figure 2 (c)).

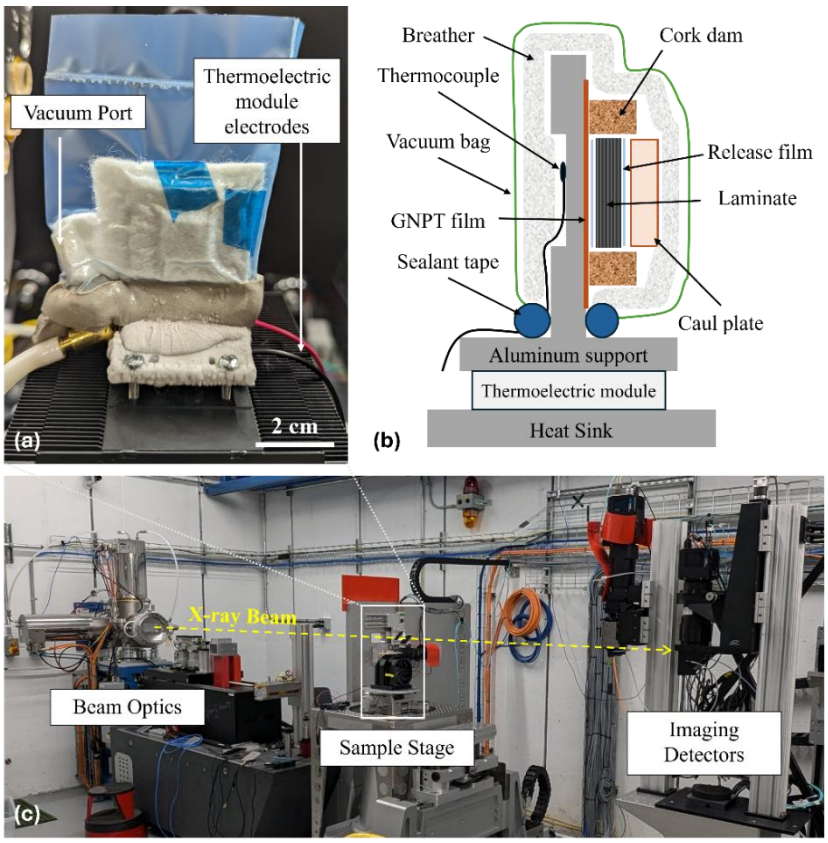

Figure 2: (a, b) Image and schematic showing the experimental setup for in-situ X-ray micro-CT inspection of void evolution within composite laminates during the curing process, and (c) test setup for SRCT at the High Energy Engineering X-ray Scattering (HEX, 27-ID) beamline, National Synchrotron Light Source II

2.2 In-situ X-ray micro-CT and SRCT procedures

Using the custom setup, in-situ X-ray CT imaging was performed using both lab-scale X-ray micro-CT (ZEISS Xradia 620 Versa) and SRCT at the Brookhaven National Laboratory using National Synchrotron Light Source II's High Energy Engineering X-ray Scattering (HEX, 27-ID) beamline. The lab-scale X-ray micro-CT experiments were conducted using the X-ray parameters of 160 keV voltage and 24 W power, with optics being a 4× objective and an HE2 filter. The optics and detector were positioned to result in a 1.6 µm voxel size. To prevent entanglement of the various wiring and vacuum hose, fan scans from -110 to 110 degrees were conducted with 3201 projections and an exposure time of 17 seconds, making the total scanning time roughly 15 hours without considering additional time for stage movement and taking reference scans. For SRCT tests, an X-ray energy of ~70 keV was used with the HEX beamline's optical module B setup, giving a voxel size of 1.3 µm and a field of view of 4.2 mm × 4.2 mm with the high-resolution sensor (3200 × 3200 pixels). Due to the high brilliance of the Synchrotron X-ray light source, a significantly reduced exposure time of 0.375 seconds was used for all the SRCT scans. Fan scans were performed from -90 to 90 degrees with 2401 projections, making each scan last for ~15 minutes.

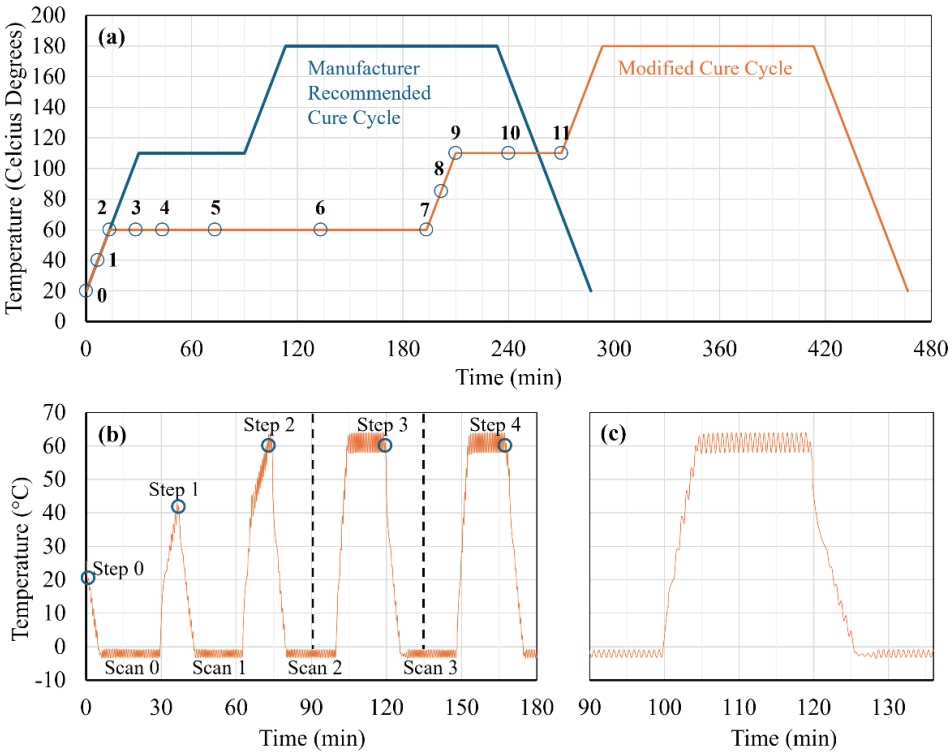

Figure 3: (a) Manufacturer Recommended Cure Cycle (MRCC) for IM7/8552 prepregs and the modified cure cycle with a 3-hour hold at 60 °C and numbered circles indicate time steps where CT inspections were performed, (b, c) representative temperature profiles recorded during the in-situ SRCT experiments.

To monitor resin infusion and void evolution within the composite laminates during the NPN-enabled OoA manufacturing process, scans were carried out at different time steps during a typical cure cycle used for the OoA process (see Figure 3 (a)). A modified cure cycle previously used to achieve void-free IM7/8552 woven composite laminates using polymer aerogel NPNs [6] was used. Compared with the manufacturer-recommended cure cycle (MRCC), the modified cure cycle has an additional 1-hour hold at 60 °C to facilitate the gradual wetting of the NPNs, which allows trapped gas to escape via the open pathway provided by the NPN interlayers. Twelve key time steps (steps 0-11) were selected for SRCT scans, while only selected scans at steps 0, 2, 4, and 5 were conducted on the lab-scale X-ray micro-CT. During the test, the thermoelectric module was controlled by the PID controller with a temperature set

point of -2.5 °C to freeze the resin flow during CT scans. After each scan, the electrodes of the thermoelectric module were reversed to enable heating. The PID setting first allowed the temperature to rise quickly at a rate of ~10 °C/min to the previous temperature step before continuing with the modified cure cycle with either a temperature ramp with a 3 °C/min heating rate or a temperature hold. Measured temperature profiles showed good agreement with the temperature set points with minor oscillations (± 3 °C) due to thermal lag between the aluminum support and the thermoelectric module.

3 RESULTS AND DISCUSSION

3.1 Proof of Concept Results using a Lab-scale X-ray micro-CT

Using the custom in-situ setup, we first obtained 3D volumetric scans of the 5-ply $[0°]_5$ IM7/8552 woven composite laminates with polymer aerogel NPNs using the lab-scale X-ray micro-CT. Scans were performed at steps 0, 2, 4, and 5. The representative slices taken from scans of step 0 (as-bagged) and step 4 (after holding 15 minutes at 60 °C) were compared side by side in Figure 4. In the step-0 scan, the polymer aerogel NPNs can be seen at the ply-ply interfaces, with only one larger void at the interlaminar region. The lack of large voids likely resulted from the open pathways provided by the NPNs for the trapped gas to evacuate to the edges of the laminates. After heating to 60 °C and the 15-minute hold, the voids observed in the step-0 scan disappeared. The thickness of the porous NPN layers was also significantly reduced due to resin infusion into the polymer aerogel NPNs. As a result of resin redistribution, a reduction in laminate thickness from ~1.3 mm to ~1.1 mm was also observed. Through proof-of-concept experiments using the lab-scale X-ray micro-CT, we successfully demonstrated that high-resolution and stable scans can be achieved using our custom in-situ setup to monitor resin infusion and void evolution.

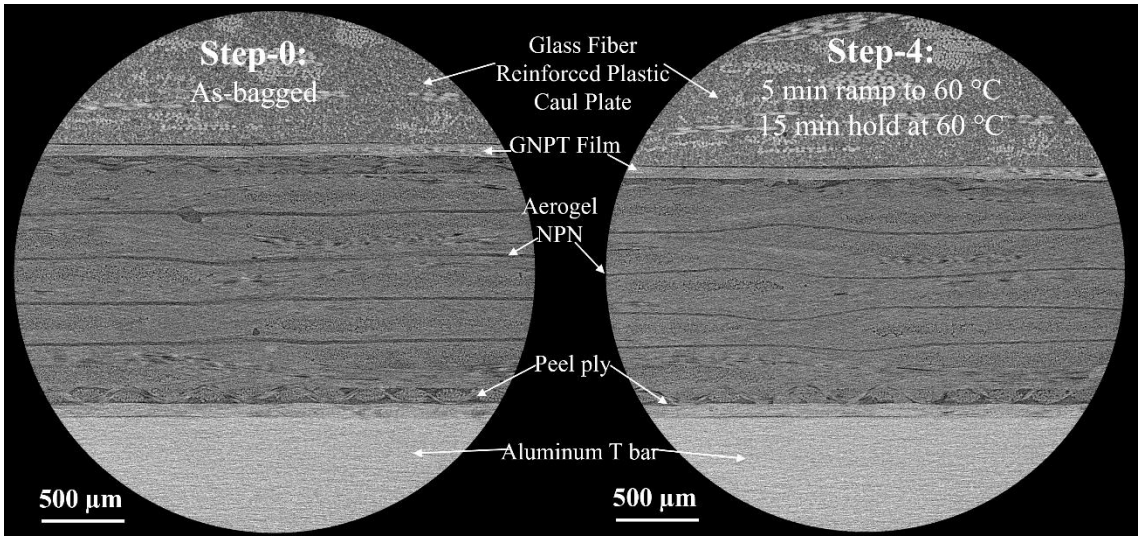

Figure 4: Representative slices taken from reconstructed volumes scanned at step-0 and step-1 for a 5-ply $[0°]_5$ IM7/8552 woven laminate with polymer aerogel NPNs at every interlayer.

3.2 Void Evolution Observation from SRCT Results

After the successful in-situ observation of resin infusion and void evolution using the lab-scale X-ray micro-CT, we performed SRCT scans using the same setup at 12 time steps (see Figure 3(a)) during the modified cure cycle for 5-ply IM7/8552 $[0°]_5$ woven laminates with and without polymer aerogel NPNs. Selected slices taken from steps 1, 5, 7, and 9 for both the baseline laminate and the laminate with polymer aerogel NPNs were shown in Figure 5. For the baseline laminate, small and medium-sized (<100 µm) voids can be observed at the early stage of the cure cycle (step-1, see Figure 5 (a)). These voids are likely air bubbles trapped during the composite layup process. After ramping to 60 °C and holding for one hour, significantly larger voids (~200-500 µm) appeared (see Figure 5 (c)). The void expansion and coalescence may be attributed to the combination of lower resin viscosity and release of

volatiles from the prepregs at elevated temperature [10]. These voids further developed after the 3-hour hold at 60 °C (see Figure 5 (e)), as part of the resin between the fiber tows migrated to fill the intralaminar voids. Once the temperature reached 110 °C (see Figure 5 (g)), large voids with boundaries partially following the contour of fiber tows were observed. These results showcased the difficulty of obtaining void-free aerospace-grade composites without the external pressure supplied by an autoclave. Compared with the baseline laminate, the one with polymer aerogel NPNs exhibited minimal voids throughout the time steps scanned. Small voids present in the early stage of the cure cycle (see Figure 5 (b)) disappeared during the 60 °C hold as the NPNs provided open pathways for the gas to escape and were not fully saturated even after 1 hour at 60 °C (see Figure 5 (d)). After the 3-hour hold (Figure 5 (f)), the NPN layers were fully saturated with resin, and a surface void developed as the resin migrated to fill the intralaminar voids within fiber tows. No significant change in void morphology was observed after the temperature ramp to 110 °C (see Figure 5 (h)).

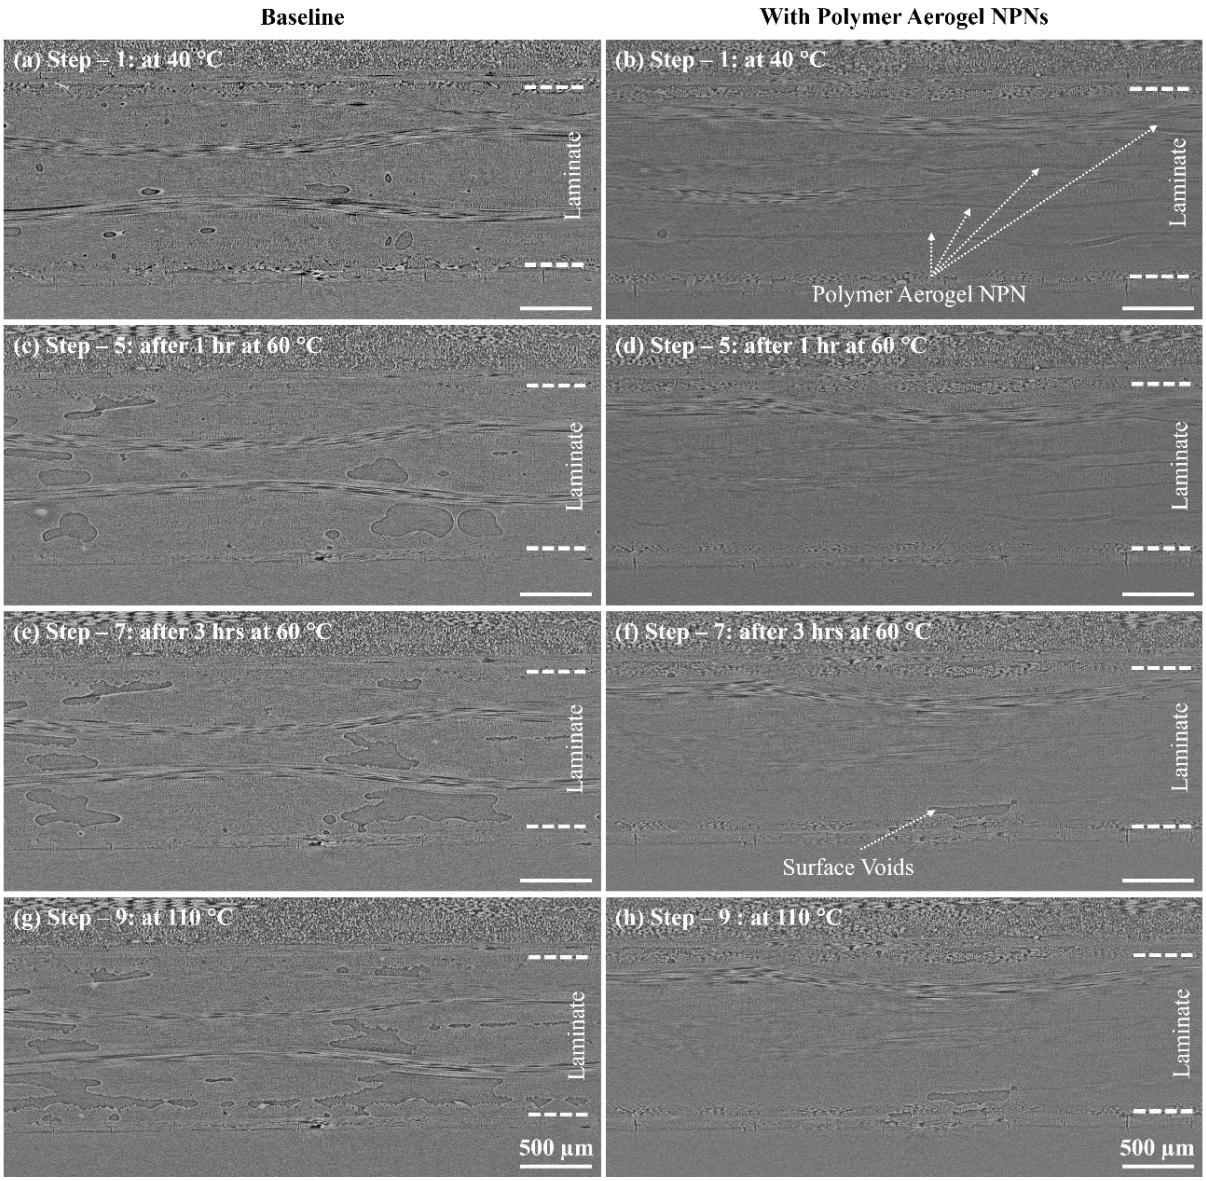

Figure 5: Selected slices from scans at various time steps showing void evolution for (a, c, e, g) the baseline 5-ply $[0°]_5$ IM7/8552 woven laminate and (b, d, f, h) the laminates with polymer aerogel at every interlayer; dashed lines marked the upper and lower surface of the laminates.

4 CONCLUSIONS

In this study, we developed a novel in-situ X-ray tomography setup to monitor resin redistribution and void evolution during the NPN-enabled OoA manufacturing of aerospace-grade composites. Using the thermoelectric module-enabled custom setup, high-resolution and stable volumetric scans of IM7/8552 woven laminates with and without polymer aerogel NPNs were successfully obtained throughout key curing stages using both a lab-scale X-ray micro-CT system and the SRCT using the HEX beamline at NSLS-II. The obtained scans provided time-resolved insights into the resin redistribution and void evolution behavior during the OoA process. Compared with baseline laminates that exhibited significant void formation and coalescence, the laminates with polymer aerogel NPNs demonstrated superior void mitigation and uniform resin infusion into the interlaminar regions. These findings, together with our prior studies on theoretical modeling and measurement of key NPN characteristics, advanced our understanding of mechanisms behind the NPN-enabled OoA manufacturing of void-free aerospace-grade composites and could inform the development and sustainable manufacturing of various aerospace-grade composite systems.

ABSTRACT

Carbon fiber-reinforced thermoplastic sheet molding compounds (CFRTP-SMCs) are gaining attention for their combination of high stiffness, formability, and lightweight characteristics. However, local heterogeneities—especially resin-rich areas formed near the edges of fiber tapes—can significantly influence mechanical and functional properties. While these regions are visually distinguishable in X-ray computed tomography (CT) images, their automated identification remains challenging due to subtle boundaries and structural complexity.

This study proposes a deep learning-based approach to automatically segment resin-rich areas in 3D X-ray CT images of CFRTP-SMCs. We first prepared composite specimens using a controlled molding process and acquired high-resolution CT scans capturing detailed internal microstructures. Since no existing methods could reliably identify resin-rich zones, we constructed a ground truth dataset via manual 3D annotation, supported by interpolation techniques. Each data sample consisted of a 3D CT image paired with a binarized label identifying resin-rich regions. We trained a 3D segmentation model using the nnU-Net framework, optimized for material imaging tasks. To enhance generalization and compensate for the limited dataset size, we applied data augmentation, intensity normalization, and cross-validation. The model architecture incorporates convolutional blocks with deep supervision to ensure stable training and accurate feature learning.

Our results demonstrate that the model accurately segmented resin-rich areas, outperforming classical texture-based methods. Crucially, it generalized well to unseen data and supported predictions on larger input volumes, confirming its robustness and scalability. This represents one of the first automated methods for 3D segmentation of resin-rich regions in CFRTP-SMCs using deep learning. The proposed framework enables more efficient and objective internal structure characterization of complex composites, opening the door to automated evaluation of local features that influence macroscopic performance.

1 INTRODUCTION

Carbon fiber reinforced thermoplastic sheet molding compounds (CFRTP-SMCs) are advanced composites composed of long, discontinuous carbon fibers arranged in randomly oriented strands (ROS). These materials exhibit mechanical properties—particularly stiffness—comparable to quasi-isotropic laminates, making them well-suited for stiffness-critical structural designs. Their excellent formability also enables the production of complex, net-shaped components, expanding their applicability in industries requiring lightweight and geometrically intricate parts. In addition, CFRTP-SMCs offer favorable characteristics such as corrosion resistance and cost-efficient processing, positioning them as strong alternatives to metal components in many applications [1,2,3,4].

A notable microstructural feature of CFRTP-SMCs is the presence of resin-rich areas, typically occurring near the edges of fiber tapes. These regions are defined by a local excess of resin and a corresponding lack of fiber reinforcement. Although relatively small in size, they can substantially influence composite properties such as strength, toughness, volume resistivity, and failure strain. Monte Carlo simulations have shown that the region within approximately 2 mm of the tape edge plays a critical role in pull-out behavior, highlighting the importance of accurately identifying these resin-rich areas.

Furthermore, these regions often delineate internal boundaries, offering valuable information about the material's microstructural architecture [5,6].

While human experts can visually identify resin-rich areas in X-ray computed tomography (CT) images, automating this process is difficult due to ambiguous boundaries and structural variability. Existing methods are typically limited to indirect estimation from 2D images, are time-consuming, and lack generalizability across different composite configurations [7,8]. The structural complexity of CFRTP-SMCs presents significant challenges for traditional analysis approaches.

To address this gap, we propose a deep learning-based framework using the nnU-Net model [9] for automatic segmentation of resin-rich areas in 3D X-ray CT images. Our approach demonstrates high segmentation accuracy and strong generalization capability, even with limited training data. This work provides a foundation for comprehensive and automated internal microstructural characterization of CFRTP-SMCs.

2 METHODS

2.1 Specimen Preparation and X-ray CT Scanning

CFRTP-SMC specimens were fabricated using an automatic press molding machine (PINETTE PEI) by stacking 12 plies of carbon fiber prepregs into panels measuring 250 × 125 × 2 mm. To facilitate high-resolution imaging, narrow rectangular specimens were cut to approximately 2 × 2 × 60 mm, optimized for microfocus X-ray CT scanning. Imaging was conducted using a TDM 1000-IS 3D X-ray CT system (Yamato Scientific Co., Ltd.), achieving a voxel resolution sufficient to capture the detailed internal morphology, including individual fiber strands and resin distributions.

2.2 Generating Ground Truth Labels and Datasets

Automating the identification of resin-rich areas in CFRTP-SMCs is complex due to the need to detect un-reinforced pixels, consider the density of adjacent fibers, and the lack of clear boundary definitions. Currently, no existing methods can automatically segment these areas; therefore, we opted for manual labeling to generate ground truth labels.

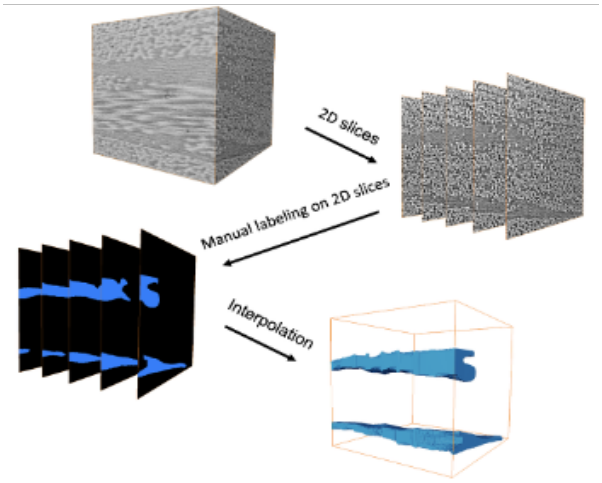

Figure 1: Workflow for manually generating ground truth labels of resin-rich areas for training data. (Scale: 256 × 256 × 256 voxels, 0.425 × 0.425 × 0.425 mm^3.)

Figure 1 illustrates the workflow for manually generating ground truth labels for training data. Raw X-ray CT images were uniformly cropped to dimensions of 256 × 256 × 256 voxels, with each voxel measuring 1.7 μm. The manual segmentation process began with the segmentation of 2D slices. Subsequently, an interpolation method was employed to automatically generate a 3D segmentation map of the resin-rich areas. The final training dataset comprised 26 pairs of 3D images of CFRTP-SMCs, with each pair consisting of a raw grayscale X-ray CT image and a corresponding binarized label image that highlighted the segmented resin-rich areas.

For dataset preprocessing, intensity normalization was applied to ensure consistency in voxel intensities across scans. Given the limited dataset size, data augmentation techniques were employed to enhance model generalization, with augmentations computed on-the-fly by CPU background workers. Additionally, a 5-fold cross-validation split was implemented to provide a robust assessment of the model's performance.

2.3 Model Training

Figure 2 illustrates the 3D U-Net architecture tailored for segmenting resin-rich areas in CFRTP-SMCs. The input patch size was set to 128 × 128 × 128 voxels, cropped from the original 256 × 256 × 256 image volumes. This relatively large patch size enables the network to capture broader contextual features critical for detecting subtle, spatially diffuse patterns such as resin-rich zones. To accommodate memory constraints, the batch size was limited to 2. To ensure stable training with small batches, instance normalization was used instead of batch normalization.

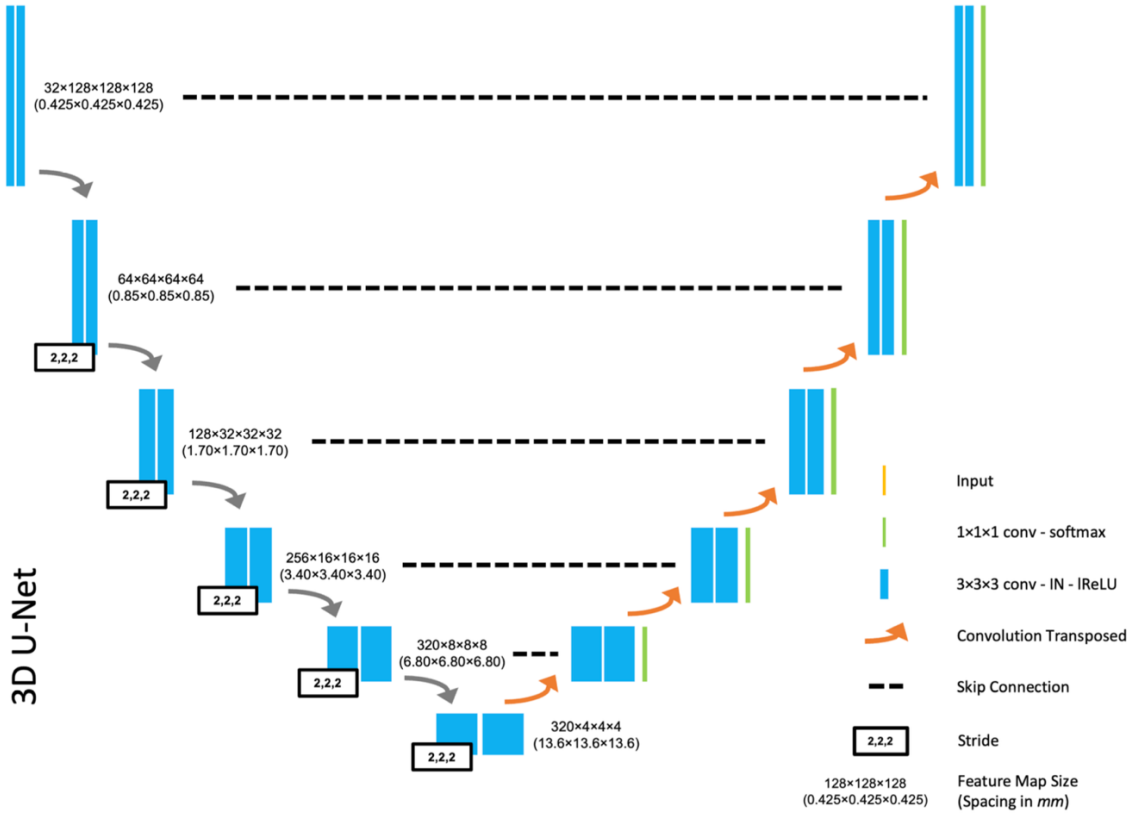

Figure 2: 3D U-Net network architecture for resin-rich areas segmentation.

The architecture consisted of a 3D U-Net with two convolutional blocks per resolution level in both encoder and decoder paths. Each block included a 3×3×3 convolution, instance normalization, and a Leaky ReLU activation with a negative slope of 0.01. Downsampling and upsampling were performed using strided and transposed convolutions, respectively. The number of feature maps started at 32 and increased with each downsampling step, capped at 320.

Training was conducted using stochastic gradient descent with Nesterov momentum ($\mu = 0.99$) and an initial learning rate of 0.01. The learning rate followed a polynomial decay policy. The loss function combined cross-entropy and Dice loss, with deep supervision applied at multiple decoder layers. We employed a 5-fold cross-validation scheme, and each fold was trained for 100 epochs with 250 mini-batches per epoch on an NVIDIA GeForce RTX 4090 GPU.

Performance was monitored using a 'global Dice' score calculated from validation patches. Most folds demonstrated stable training and convergence. One exception was Fold 4, where validation loss fluctuated due to labeling inconsistencies in the validation set.

2.4 Inference

After training, inference was performed using a sliding window strategy with the same patch size as used during training (128 × 128 × 128 voxels). To ensure smooth and accurate predictions across the entire volume, windows were overlapped by 50% in all directions. Because segmentation accuracy tends to degrade near the patch borders, a Gaussian importance weighting scheme was applied. This approach assigns higher weights to the center voxels and reduces the influence of border regions when aggregating softmax outputs.

To further enhance prediction robustness, test-time augmentation was employed by mirroring the input images along each of the three spatial axes. Predictions from each augmented version were averaged to produce the final output.

For final segmentation, we utilized an ensemble of the five models trained during the 5-fold cross-validation. Each model was used to predict on the test set, and their outputs were combined using softmax averaging. This ensemble approach helped reduce prediction variance and improved overall segmentation accuracy. The best-performing configuration, determined by the average Dice score across training folds, was used for final inference.

3 RESULTS AND DISCUSSION

3.1 Enhanced Predictions Over Manual Labeling

To evaluate the segmentation performance in more detail, Figure 3 presents three cases where the model outperforms manual labeling:

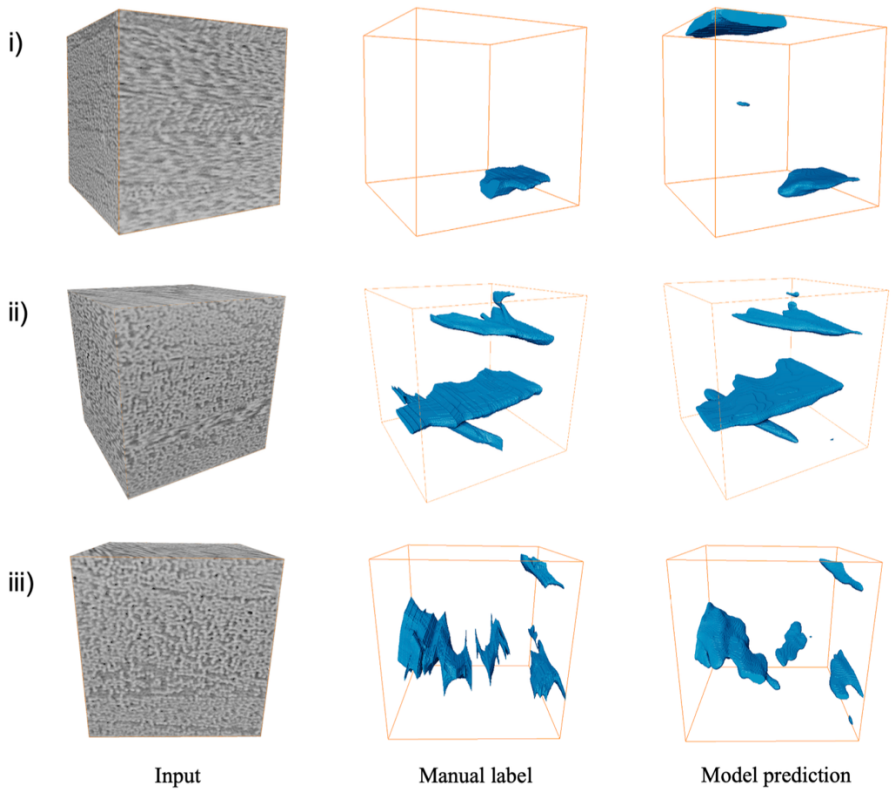

Figure 3: Three cases of the the model input (raw X-ray CT image), the corresponding manual labels of resin-rich areas, and the predicted segmentation map generated by the model. (Scale: 256 × 256 × 256 voxels, 0.425 × 0.425 × 0.425 mm^3.)

Case i: A resin-rich area was missed during manual labeling (false negative), but the model successfully detected it. This highlights the model's higher sensitivity and its ability to mitigate human oversight in identifying subtle resin-rich regions.

Case ii: Manual labeling overestimated the extent of resin-rich areas (false positives), incorrectly marking non-defective regions. The model, though slightly conservative, produced more precise segmentations with fewer false positives, particularly beneficial for identifying resin-rich zones between fiber tapes.

Case iii: For irregularly shaped resin-rich areas, manual segmentation produced coarse, discontinuous boundaries due to the limitations of 2D-based interpolation. The model, leveraging 3D analysis, achieved smooth and accurate boundary delineation.

3.2 Comparison with Texture Classification

Figure 4 compares the segmentation results of our model with those produced by a classical texture-supervised classification method implemented in Avizo. While the texture method relies on local statistical features, such as variance and histogram-based descriptors, it struggles with the complex nature of resin-rich areas. The results exhibited numerous false positives, especially near the image borders.

In contrast, the deep learning model generated cleaner and more reliable segmentation outputs. This comparison underscores the advantage of learning-based methods in capturing global patterns and spatial context, which are essential for accurately segmenting heterogeneous regions in CFRTP-SMCs.

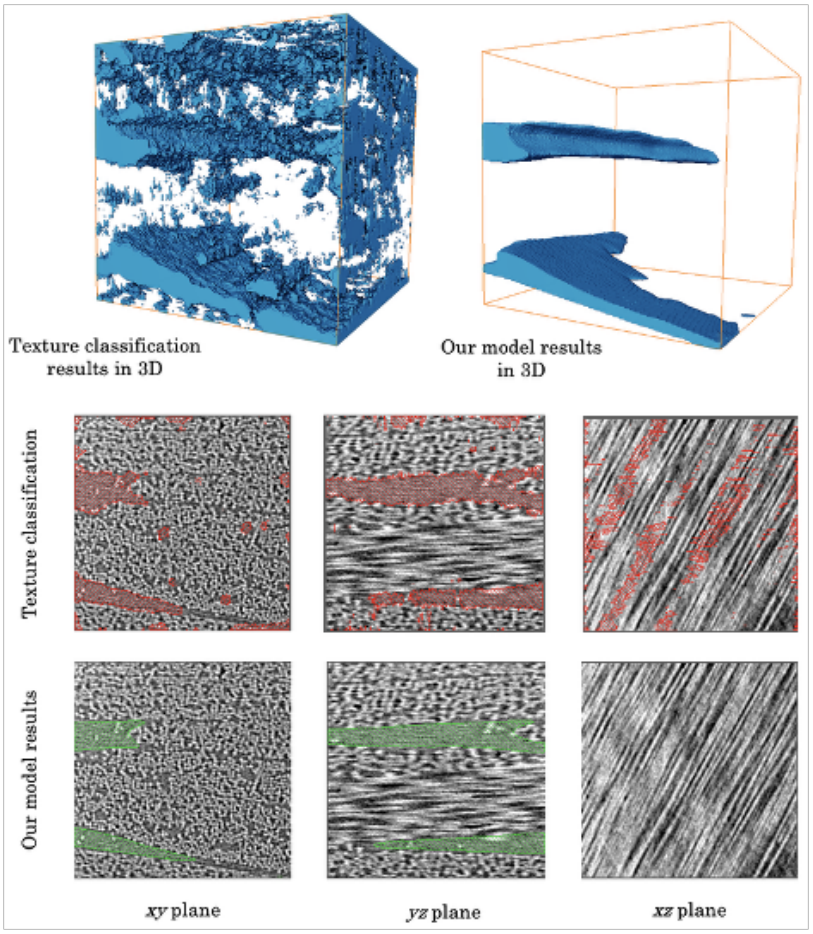

Figure 4: The comparison between the texture classification results and the segmentation of resin-rich areas generated by our model. (Scale: 256 × 256 × 256 voxels, 0.425 × 0.425 × 0.425 mm^3.)

3.3 Verification with Fiber Analysis

To validate the physical relevance of the segmented resin-rich areas, we conducted a fiber orientation analysis based on geometric correlation with parametric cylinder templates. This approach enables the identification and tracing of individual carbon fibers according to their local orientation and spatial continuity. The segmented resin-rich regions consistently coincided with zones of low fiber density, confirming their characterization as fiber-deficient, resin-rich areas. Moreover, these regions frequently appeared between fiber tapes exhibiting distinct orientation patterns, indicating that the model successfully identifies resin accumulations at inter-tape boundaries. These results demonstrate that the model's predictions are not only visually consistent with expert expectations but also structurally meaningful in the context of composite microarchitecture.

3.4 Prediction on Unseen Data

To assess generalization capability, the trained model was applied to a larger, previously unseen CT image with dimensions of 600 × 600 × 600 voxels—over 12 times the size of the training patches. As shown in Figure 5, the model successfully segmented resin-rich areas across multiple planes (xy, yz, xz) and in the full 3D volume.

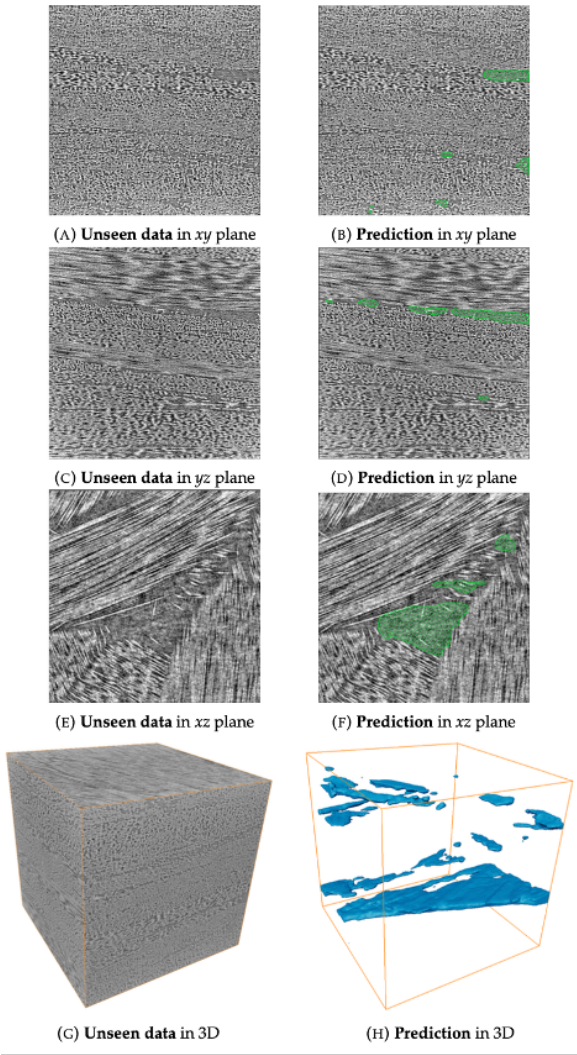

Figure 5: Prediction of resin-rich areas on unseen data. The green hatched regions indicate the model's prediction of resin- rich areas. (Scale: 600 × 600 × 600 voxels, 1 × 1 × 1 mm^3.)

The predicted regions aligned well with visually identifiable resin-rich zones, confirming that the model generalizes effectively beyond the training distribution. This robustness is particularly valuable for real-world applications involving full-scale parts, where input dimensions vary and high-resolution analysis of internal structures is critical.

4 CONCLUSIONS

This study demonstrated the effectiveness of the nnU-Net deep learning framework in automatically segmenting resin-rich areas in 3D X-ray CT images of CFRTP-SMCs. The results reveal several key advantages and implications of the proposed approach:

First, the model successfully automates the segmentation process, reducing reliance on manual labeling and improving both efficiency and consistency. It consistently produces smoother and more accurate boundary delineations than conventional 2D-based manual methods, effectively addressing interpolation artifacts and labeling noise. Moreover, its robust 3D analysis enables accurate segmentation of irregularly shaped resin-rich regions—an area where traditional techniques often fall short.

Second, compared to conventional texture-based classification methods, the nnU-Net model achieves significantly higher segmentation accuracy. While texture-based approaches are limited by local feature dependence and prone to false positives, the deep learning model captures complex structural patterns with superior generalization.

Third, the physical relevance of the predicted resin-rich areas was confirmed through fiber orientation analysis. The model's segmented regions consistently aligned with low fiber density zones and inter-tape boundaries, verifying their structural validity within the composite microarchitecture.

Finally, the model demonstrated strong scalability by accurately predicting resin-rich areas in large, previously unseen CT volumes. This highlights its robustness and practical applicability for high-resolution material characterization at various scales.

In summary, the nnU-Net model provides a reliable, accurate, and scalable solution for segmenting resin-rich areas in CFRTP-SMCs. Its integration into composite materials research holds promise for improving internal structure analysis, enabling advanced material characterization, and supporting automated quality control and performance evaluation.

ABSTRACT

This study addresses the automatic segmentation of textile reinforcements in fan blades using X-ray CT imaging at resolutions above 120 µm. The proposed approach is a scalable analysis orthogonal to the main yarn orientations (warp and weft), involving the identification of yarn centers and cross-sections on a 2D plane.

The method statistically characterizes three properties: the standard shape of yarn cross-sections using Principal Component Analysis (PCA), the continuity of each yarn path, and their arrangement relative to neighbouring yarns. These properties are exploited in a variational formulation for optimal yarn positions, displacement from previous planes, and neighbour arrangements.

Yarn center positions are determined over successive planes perpendicular to the mean yarn orientation, successfully tracking around 1,500 yarns over 900 slices with a 95\% success rate for annotated yarns. Then the process iteratively refines segmentation by erasing and re-segmenting yarns. This method shows potential for large-scale textile annotation.

1 INTRODUCTION

This work addresses the automatic segmentation of textile reinforcements in aircraft engine fan blades, imaged with X-ray CT at resolutions above 120 µm with lengths in the tens of centimeters. Previous works have used a variety of approaches ranging from image processing [1], variational methods [2, 3], and deep learning [4, 5, 6].

Yet, these studies focused on smaller samples with simpler geometries and used much higher resolutions.

Applying these approaches to the current problem is not feasible because they would require better image characteristics or expensive initialization, or the computation time would be excessive. Hence, a simple and highly scalable method is proposed based on 2D analysis orthogonal to the main yarn orientations (warp and weft).

2 APPROACH

Here, the segmentation involves identifying the yarn centers and cross sections on a 2D plane based on the known yarn positions from the previous 2D plane. For this study, because of the time-consuming nature of the task, only a subset of yarn centers for a fan blade were manually sparsely annotated.

The proposed method statistically characterizes three specific properties of the material. The first property is the "standard" shape of each yarn cross section (for each yarn type).

For this, a Principal Component Analysis is used on small images centered on the yarn centers. The obtained eigenmodes encapsulate unique, learnable features, leading to the identification of the dominant shape and some of its subtler variations. Hence, cross-correlation between the first eigenmode of each yarn type and the CT images generates a heatmap where higher values correspond to likely yarn centers.

To re-adjust the probable central positions, an alignment between the tomographic image and the principal mode is done by minimizing the squared difference between them, considering both the image and its partial derivatives. Only the positive part of the difference is used to focus on the yarn, ignoring the surrounding background in the image before squaring.

The second property of interest describes the continuous path that each yarn follows. Histograms of contiguous yarn center annotations (for each yarn) are used to model the yarn path "displacement" from one plane to the next. The third property is the specific arrangement of a yarn with respect to its (same type) neighbors. In-plane yarn center annotations are used to model this arrangement. It is observed that parallel yarns follow well-defined orderings. From the above statistics, a variational formulation that includes three energies (figure. 1) is built: the optimal position for each yarn according to the 1 eigenmodes, the most likely displacement from the previous 2D plane, and the position that considers the arrangements between neighboring yarns.

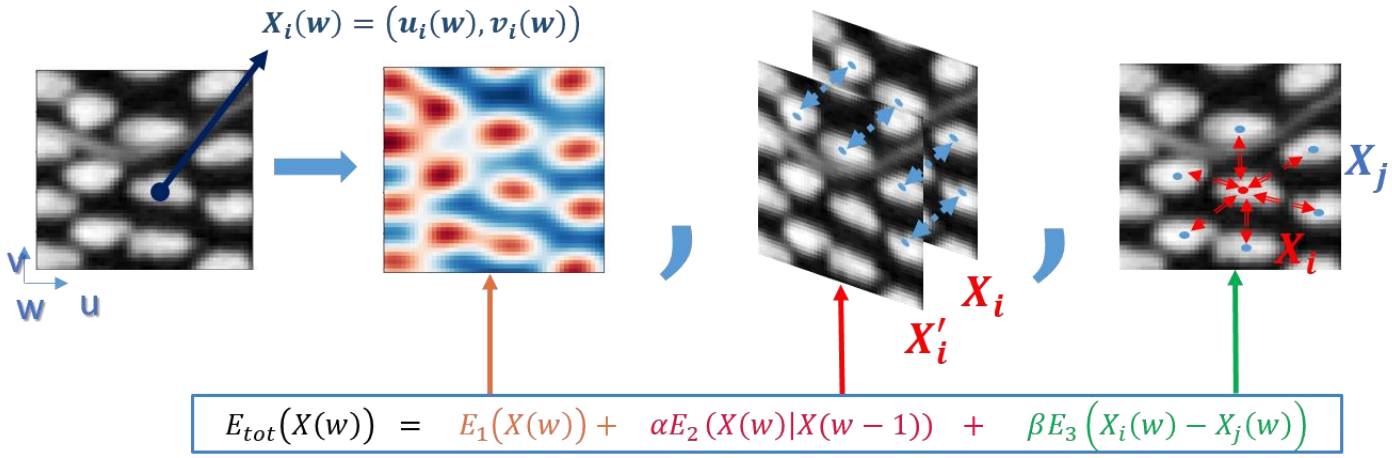

Figure 1: Variational Formulation

Then, an iterative greedy approach is used for successive planes to obtain the new yarn center positions. The initial positions are taken from the previous 2D plane, and at each iteration, the displacement to be applied to each yarn center is computed until convergence.

3 RESULTS

This approach is first applied to warp yarns. Tracking around 1,500 yarns across over 900 slices, with an average success rate of 95% for nearly 400 yarns that have available manual annotations.

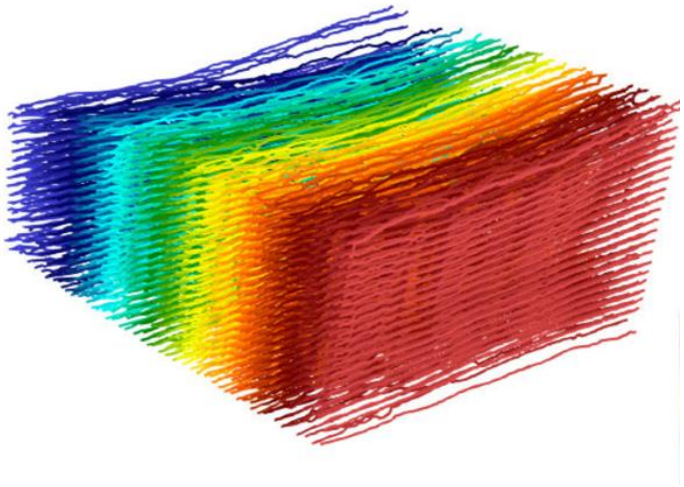

Figure 2: Computed warp yarn paths.

The estimated warp yarn paths (figure. 2) are then erased (figure. 3) from the initial CT image, isolating the weft yarns and highlighting segmentation errors, such as yarns lost during tracking. After addressing these issues, the erased image is used to segment the weft yarns using the same procedure. Then, the warp yarns are re-segmented after erasing the weft yarns, and so on. This fixed-point optimization that progressively improves the yarn segmentation is carried out until stationarity is achieved for both yarn directions.

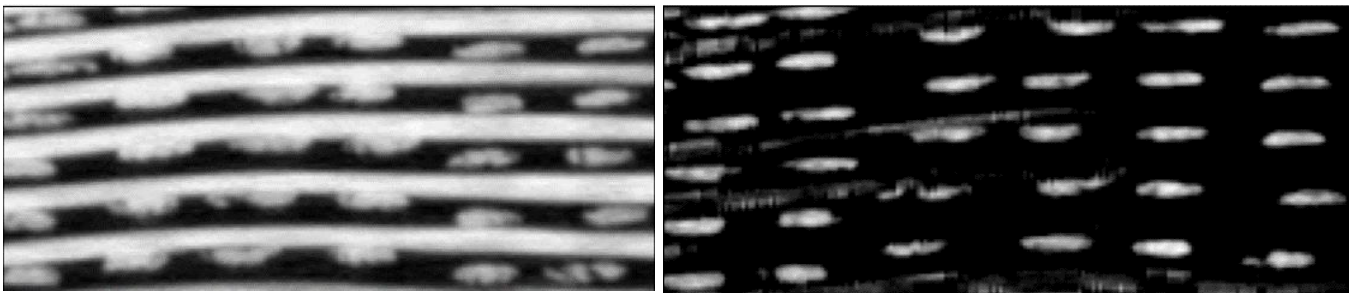

figure (a): original tomography **figure (b): erased warp yarns tomography**

Figure 3: Erasing warp yarns in tomographic image.

Finally, 1,500 warp yarns were automatically annotated and tracked over 900 slices, which amounts to 1,350,000 yarn centers. Considering that 11,460 yarn centers were used as initialization (0.85%), the method shows its potential for automatically annotating large-scale textiles. The next development phase will focus on refining the tracking process of weft yarns after the erasure of the retrieved warp paths that currently interfere with accurate tracking. This adjustment is essential to improve the tracking of yarns, ensuring that the algorithm can correctly distinguish and follow weft yarns.

ABSTRACT

This work introduces a robust finite element-based Digital Volume Correlation (FE-DVC) method tailored for the accurate registration of large-scale textile samples. By detecting and correcting shifted periodic regions, the method enables the precise alignment of sample pairs, making it possible to identify subtle textile differences such as those caused by varying weaving parameters. The proposed approach is applied to textile reinforcements used in aircraft engine fan blades, demonstrating robustness and effectiveness in addressing the challenges of complex textile registration tasks.

1 INTRODUCTION

Comparing different measurements (images) can be a challenging task when these are not expressed in the same reference frame. Image registration aims to identify the transformation that best aligns pairs of images. Various techniques exist for this purpose, but FE-based Digital Image Correlation (DIC) in 2D and its 3D counterpart Digital Volume Correlation (DVC) [1] are popular in experimental mechanics for composite materials [2]. DVC, in particular, has been used on woven composites to highlight differences between pairs of samples [3]. In this context, the found transformations inform on any textile difference between samples (e.g., different weaving parameters). These previous studies have shown some potential but have been limited to small samples.

2 METHOD

Registration on larger textiles tends to fail due to the periodicity of the material, which creates local minima that tend to localize into “regions”. Hence, the goal of the present work is to develop a general and robust FE-DVC method for registering large-scale textiles. The largest identified region is heuristically determined to be correct, while the remaining regions are considered shifted. The goal is then to find the displacement (a multiple of the textile period) that corrects the unwanted shift for each misaligned region. The proposed strategy consists in first characterizing all 3D textile periodicities (along warp, weft, and thickness directions) from the image and testing different integer multiples of these shifts which can be ranked according to the induced registration error. If any shift that reduces the registration error is found, it is used to correct the region; otherwise, the found displacement for the region is discarded and a simple extrapolation is used, starting from the largest region, to define a placeholder displacement field. After treating all shifted regions, the new complete transformation is used as initialization for another complete registration process. This process is repeated until no region boundaries remains (i.e., no more shifted regions).

3 RESULTS

The method was applied to multiple large-scale samples of textile reinforcements from aircraft engine fan blades. In all studied cases, no more than three iterations were required to identify the complete correct transformation. As an illustration, the figure below depicts a transversal view of one such textile reinforcement behind an overlay of the longitudinal strain (deformation), computed from the

displacement field obtained from registering two samples. The illustrated field shows highly localized regions in which the warp yarn columns (orthogonal to the image plane) are further apart in the moving (source) image than in the reference (target) one. These results demonstrate the robustness and generality of the proposed method. Indeed, registering different samples serves as a more challenging registration problem than the traditional task encountered in experimental mechanics of registering of the same sample subjected to an external load. Moreover, not only is the proposed method simple to implement it also is non-intrusive, thus it can be used alongside any existing registration method.

Conclusion

UNIVERSITY OF APPLIED SCIENCES UPPER AUSTRIA
OBERÖSTERREICH

- Short fibre reinforced polypropylene:
  - Defect formation and defect type depend on fibre orientation
  - Major reason for ultimate failure: matrix fracture
- Long glass fibre reinforced polypropylene:
  - No clear correlation between fibre orientation and defect type
  - Strong influence of the strength on the local microstructure (fibre bundles, curved fibres, …)
  - More quasi-isotropic behavior
- Mechanics (induced by sample geometry) overrule microstructure
- Gained results enable better understanding and (in certain cases) a prediction of the damage behaviour from a 3-dimensional perspective

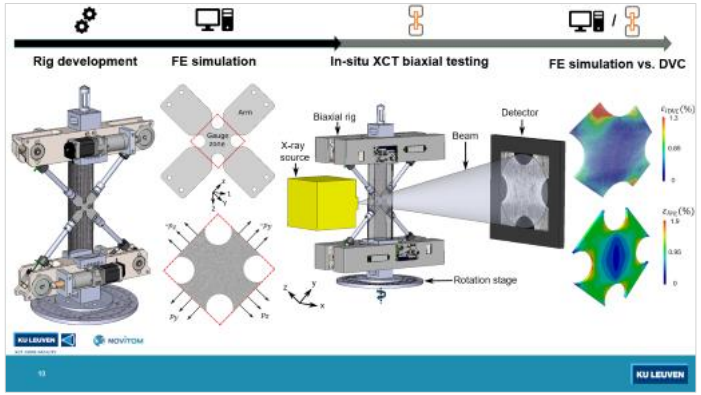
ICCM24
24TH INTERNATIONAL CONFERENCE ON COMPOSITE MATERIALS



04/08/2025

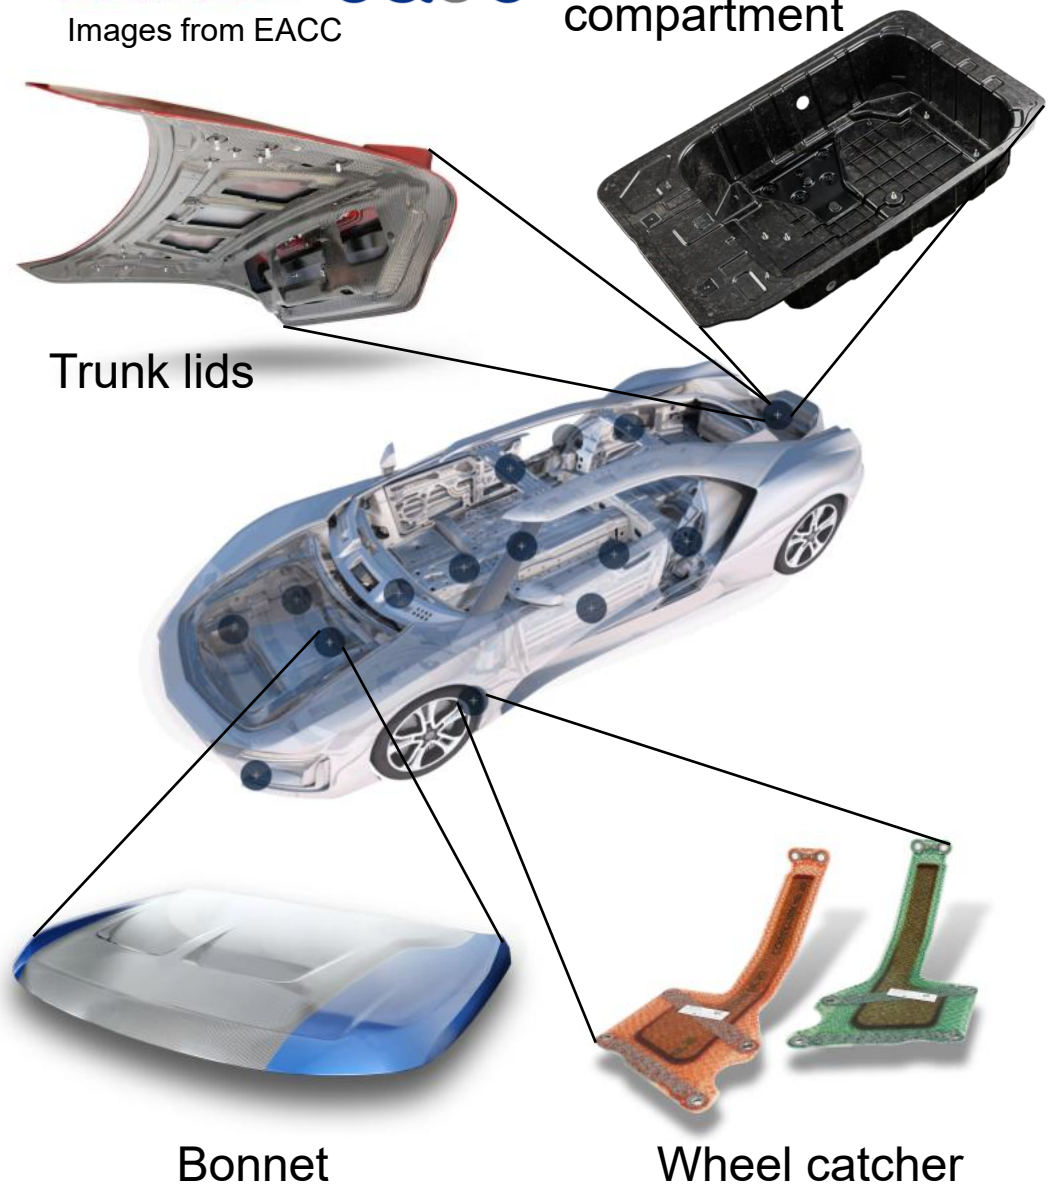
Objectives

- Understanding spatial strain distribution of SMC-CFRTP material

- Propose a new testing method to improve composites failure models

CFRTP-SMC microstructure

Fibre strands randomly oriented



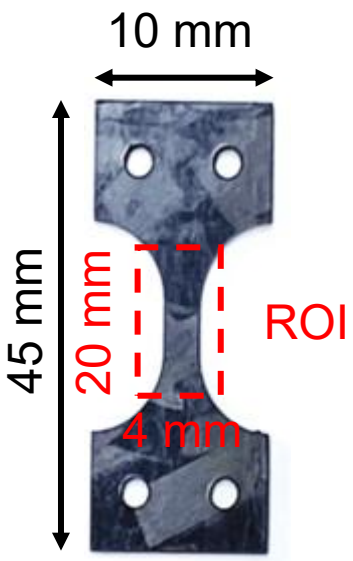
CFRTP-SMC for high volume composites

- Very formable
- Production cycle time of few minutes

Load compartment

Images from EACC

Trunk lids

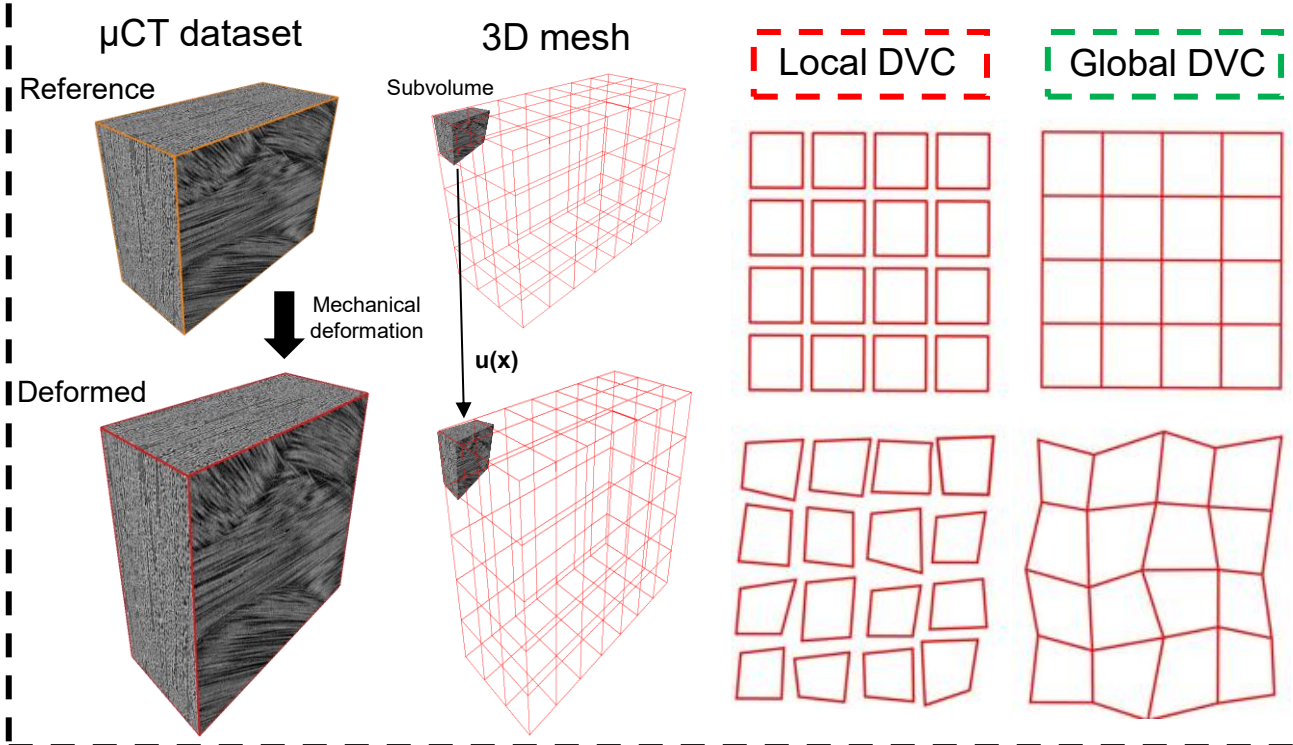


Bonnet

Wheel catcher

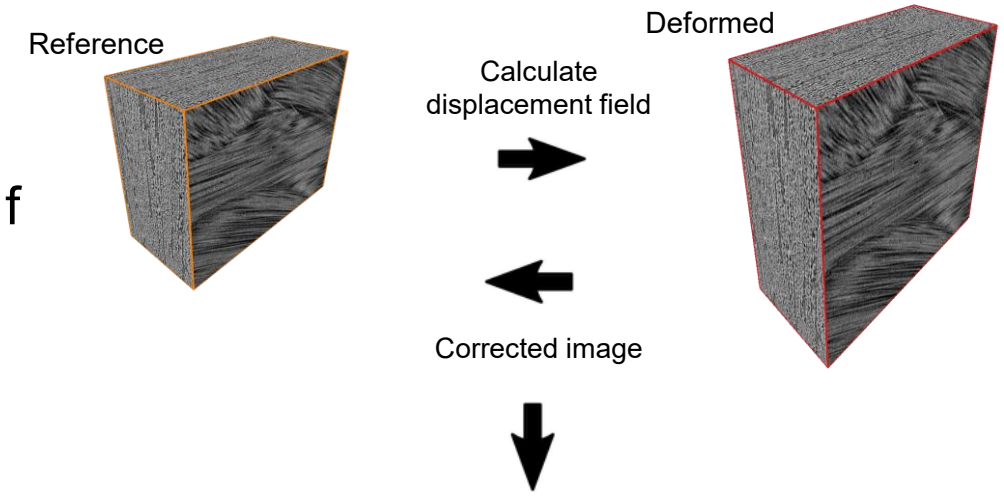
Methodology

XCT in-situ stepwise tensile test



CFRTP-SMC
tensile specimen

- Voltage: 60 kV
- Voxel size: 4 µm

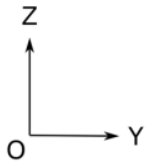


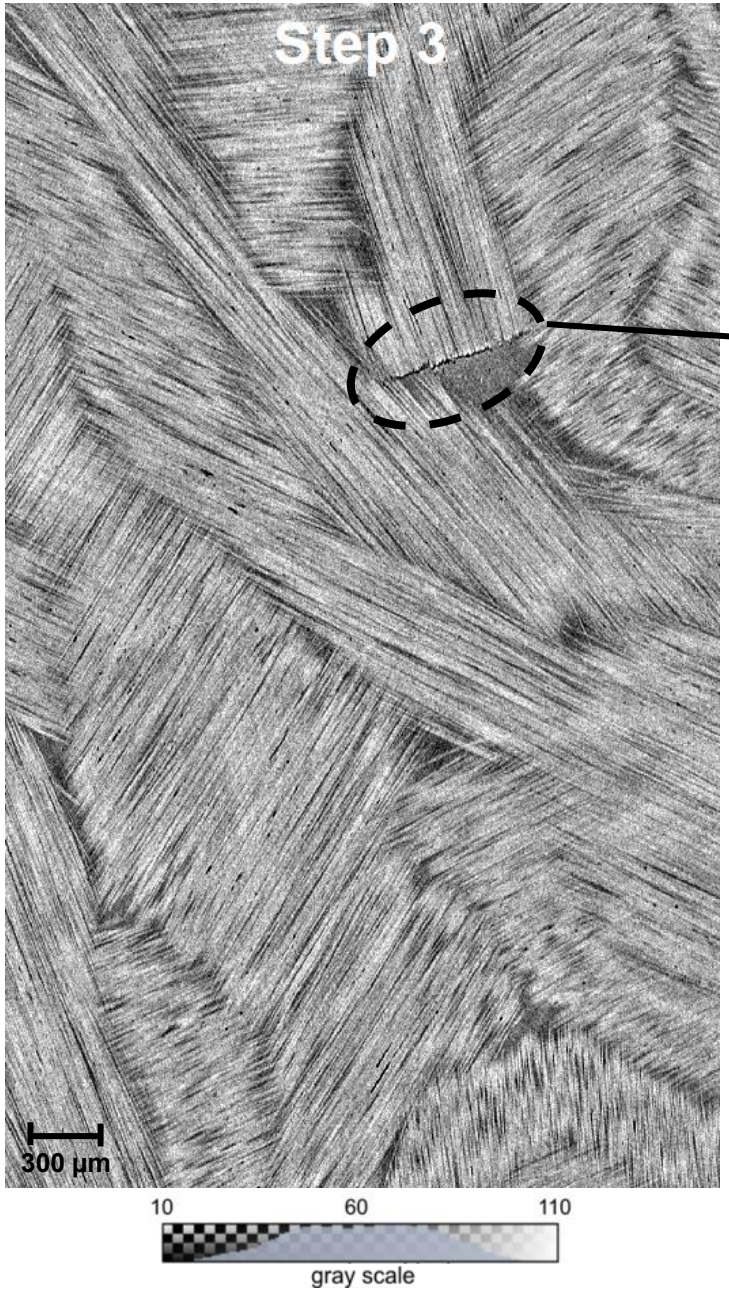
Digital Volume Correlation (DVC)

- Two-step DVC approach:
  - subset approach
  - global FE approach
- A 3D FE-based mesh is used to compute the displacements and strains

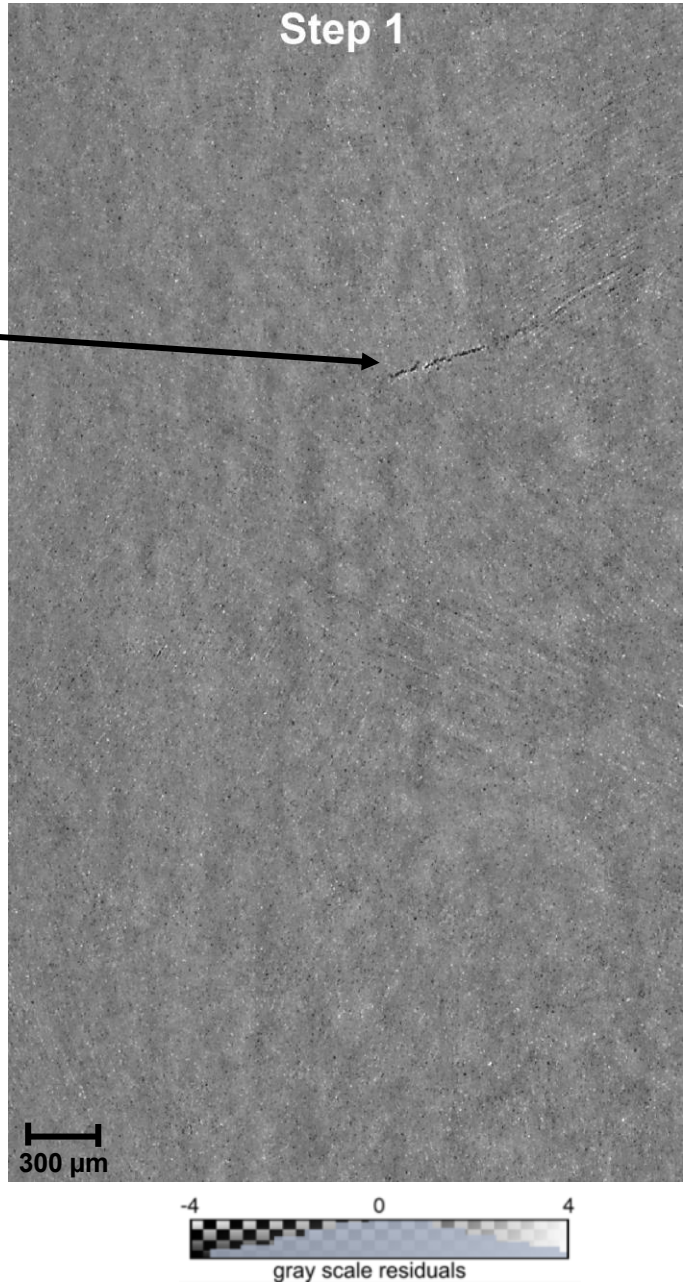
KU LEUVEN

Correlation residuals





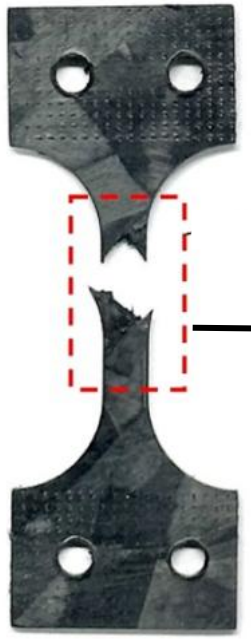
f

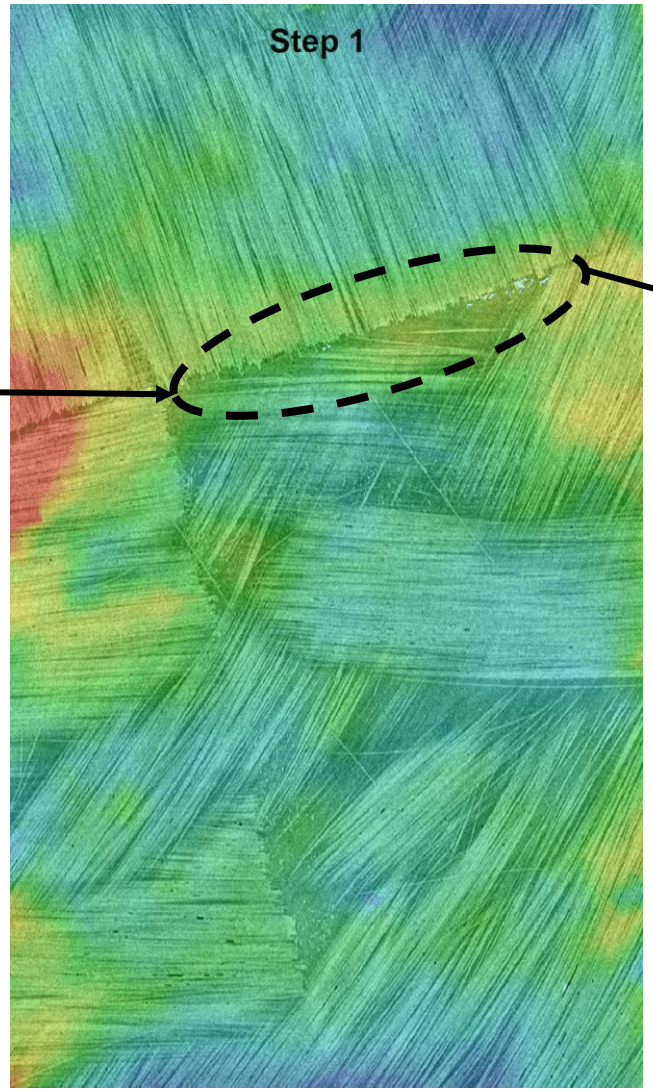


g

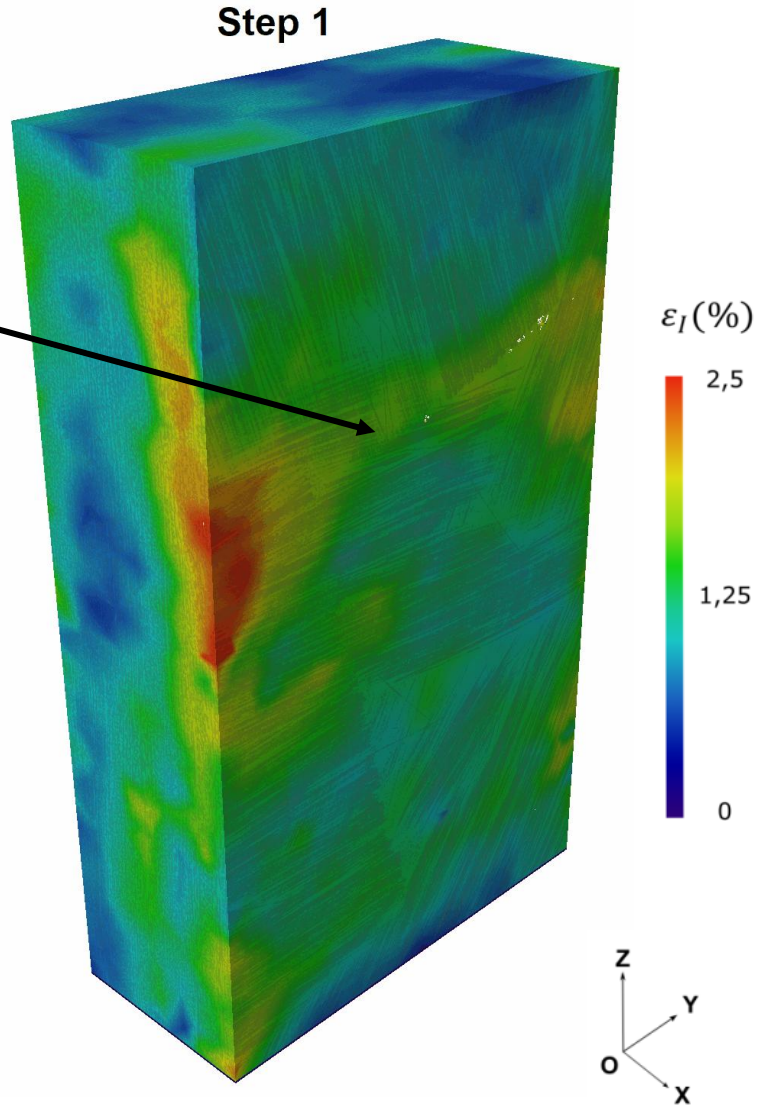
Correlations residuals = f - g

- Source of errors:
  - Reconstruction artefacts
  - Imaging noise
  - Damage





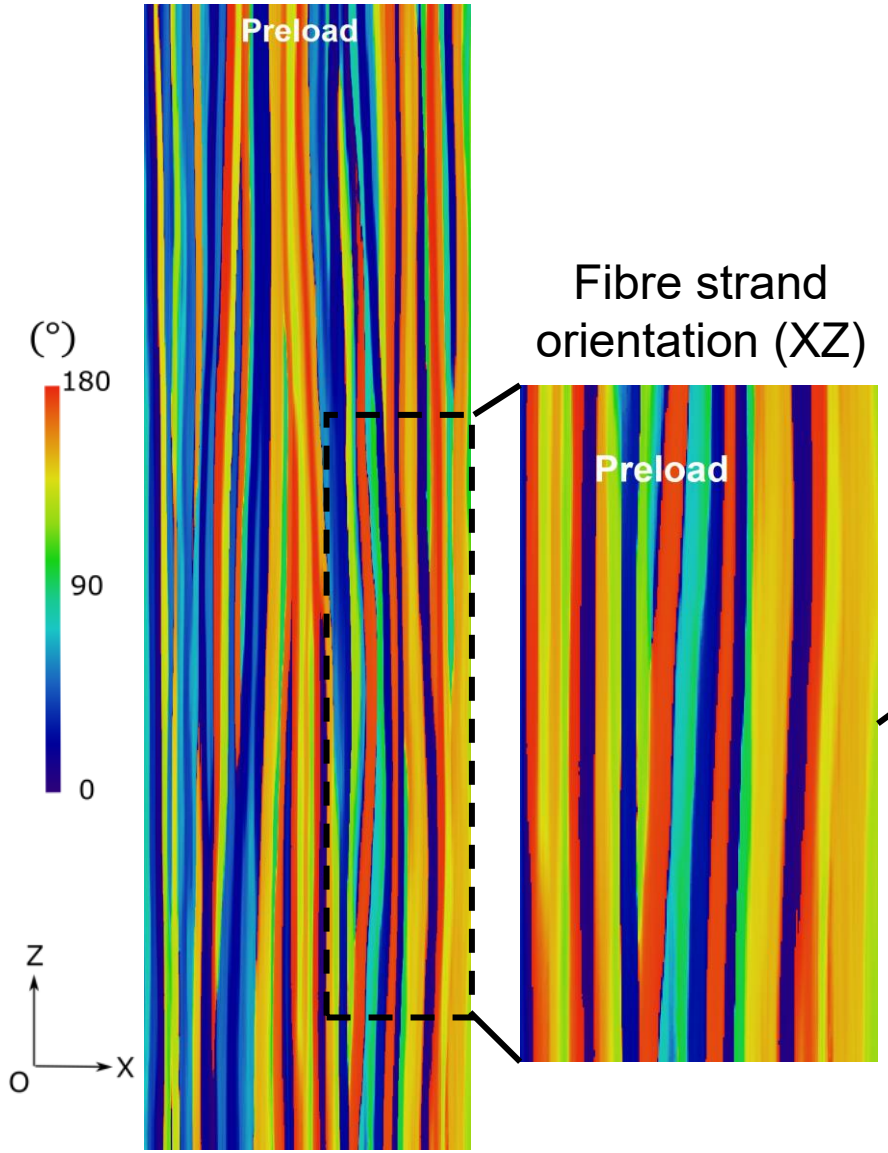
KU LEUVEN

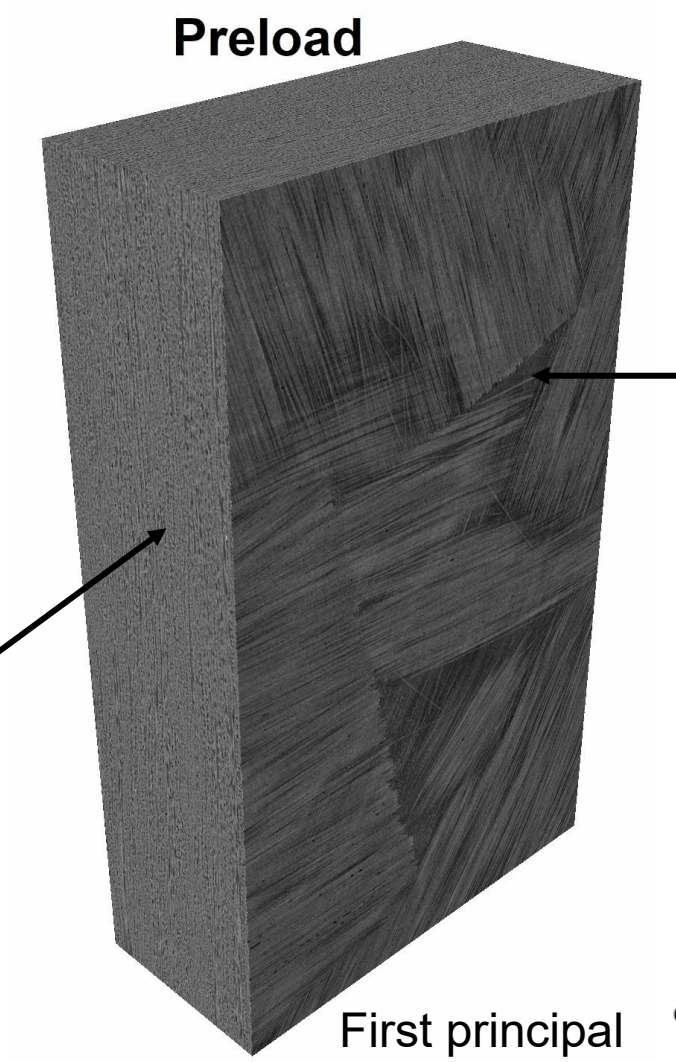


Damage analysis

First principal strain

Failed specimen

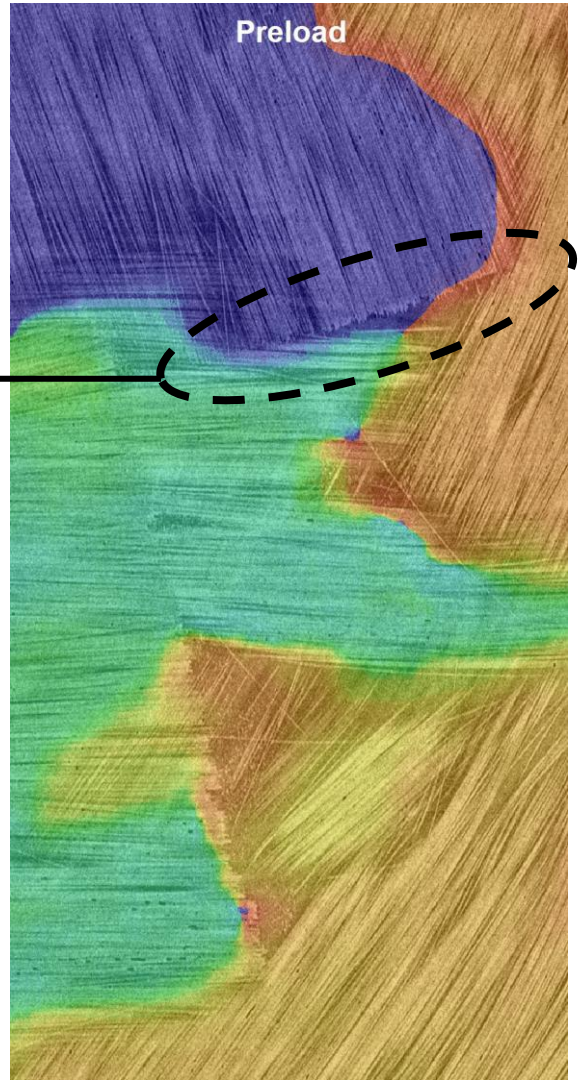




- Microcrack formation in region of high tensile strain

KU LEUVEN

DVC and fibre strand orientation



Fibre strand orientation (XZ)

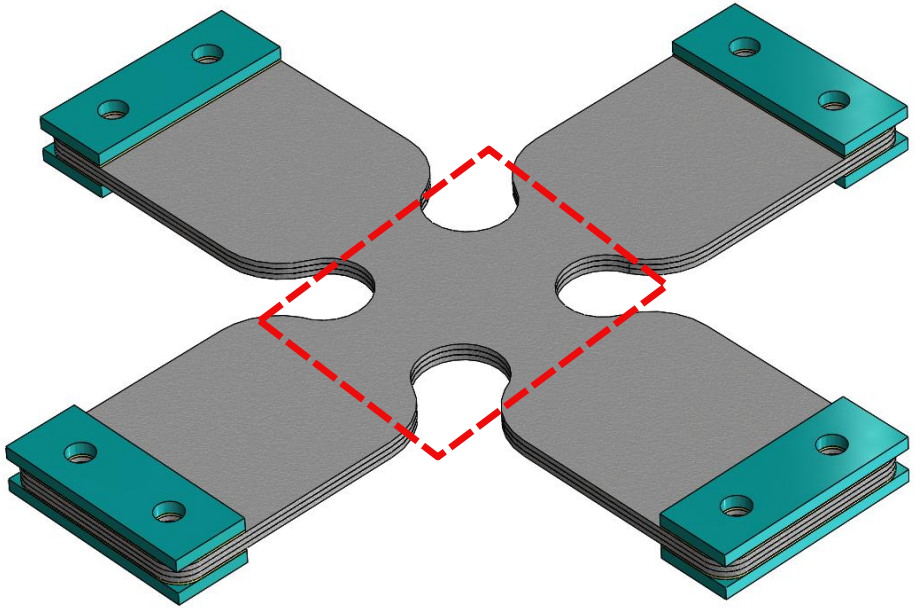
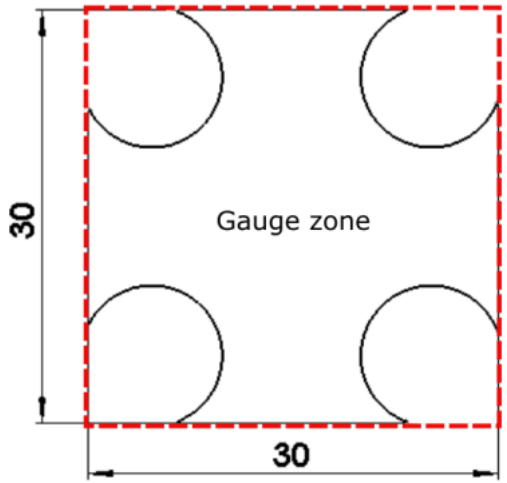
KU LEUVEN XCT CORE FACILITY

NOVITOM

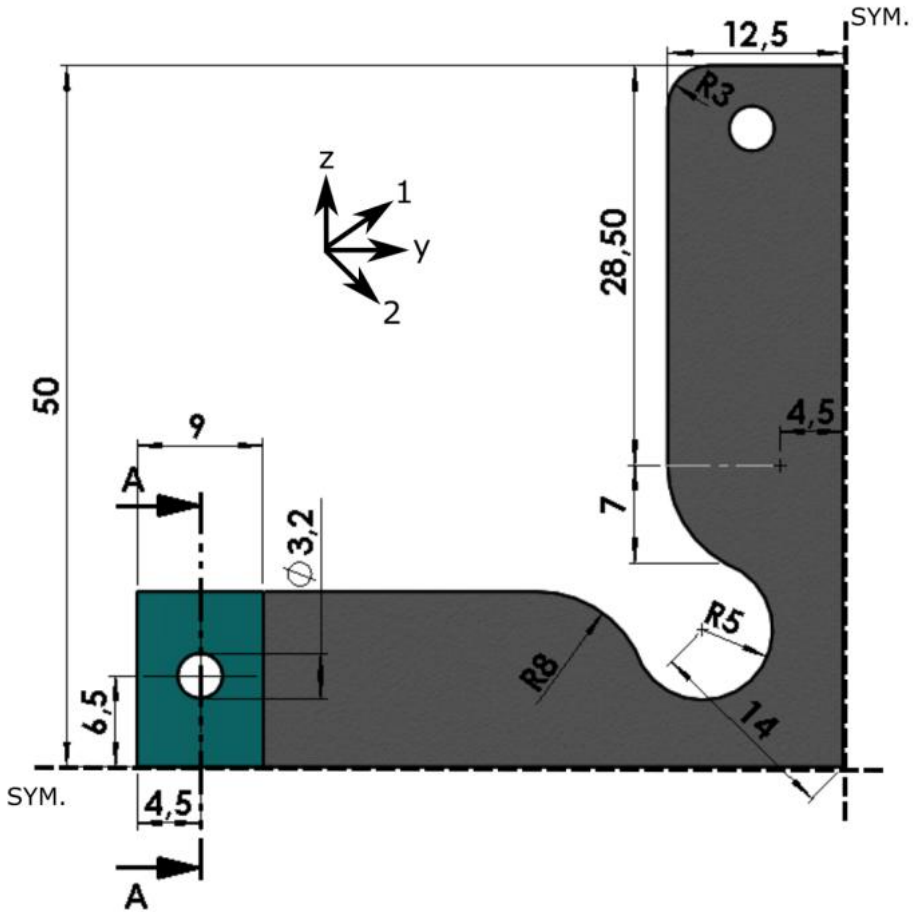
KU LEUVEN

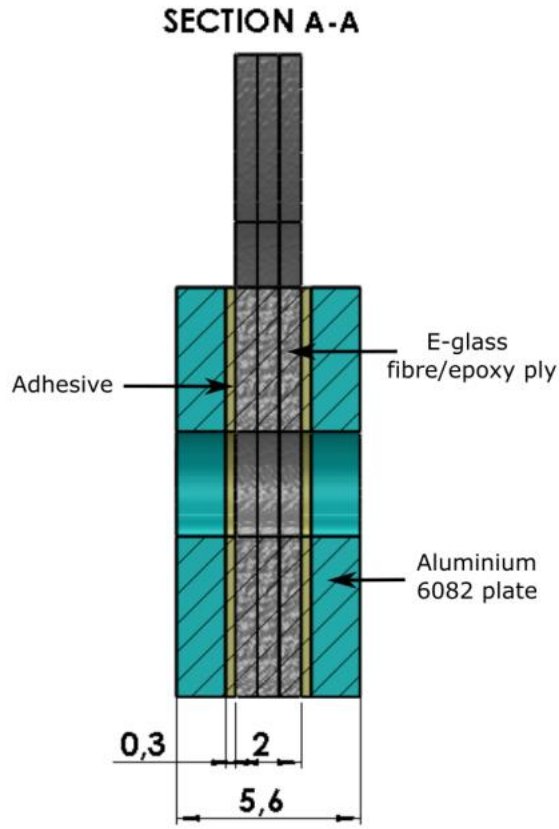


Biaxial setup



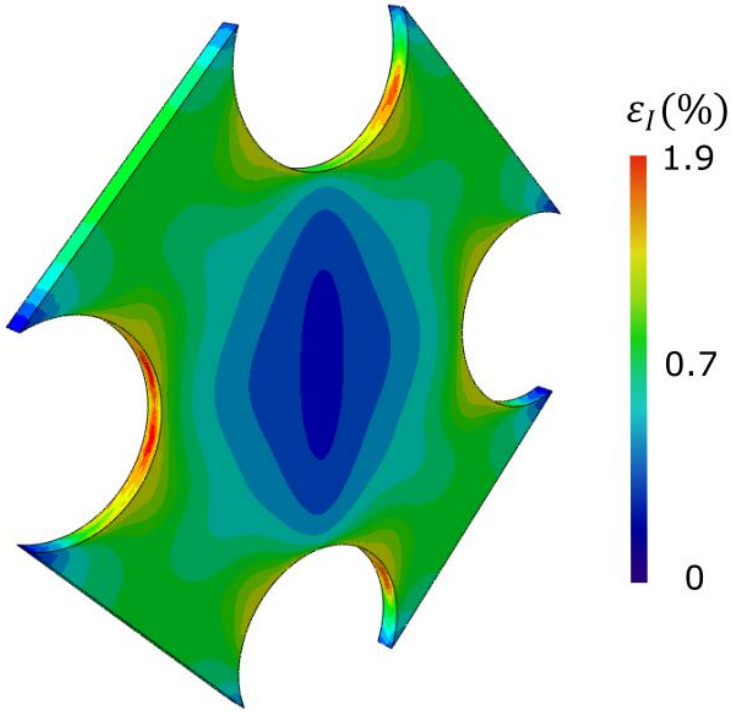
- Voxel size down to 4 µm
- Max force: 5 kN
- Max stroke: 20 mm
- Synchrotron extensible

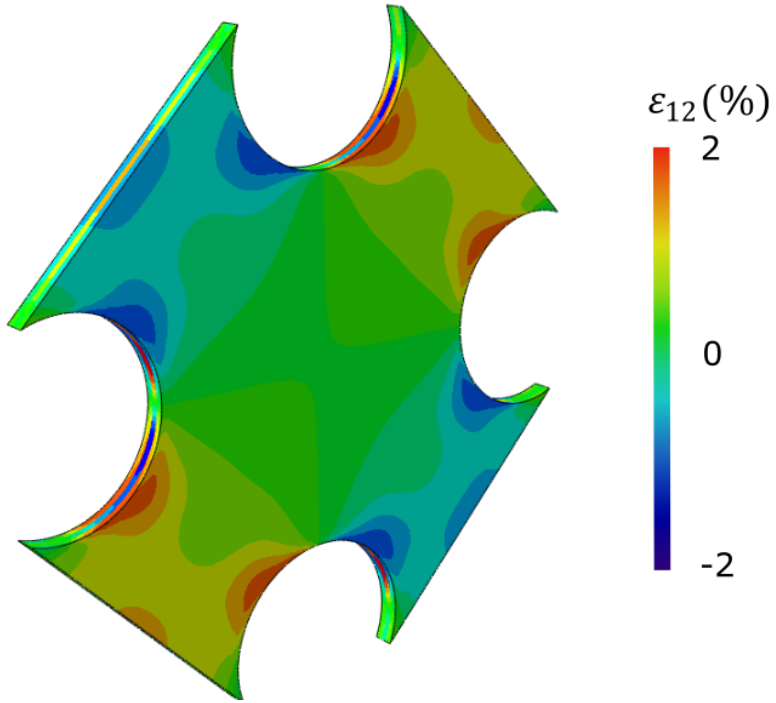


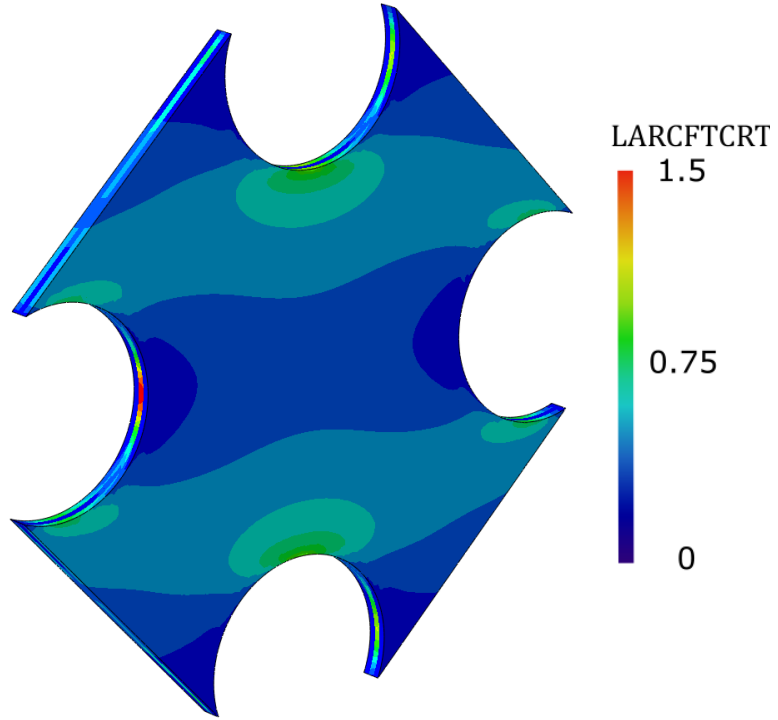


KU LEUVEN

Biaxial specimen



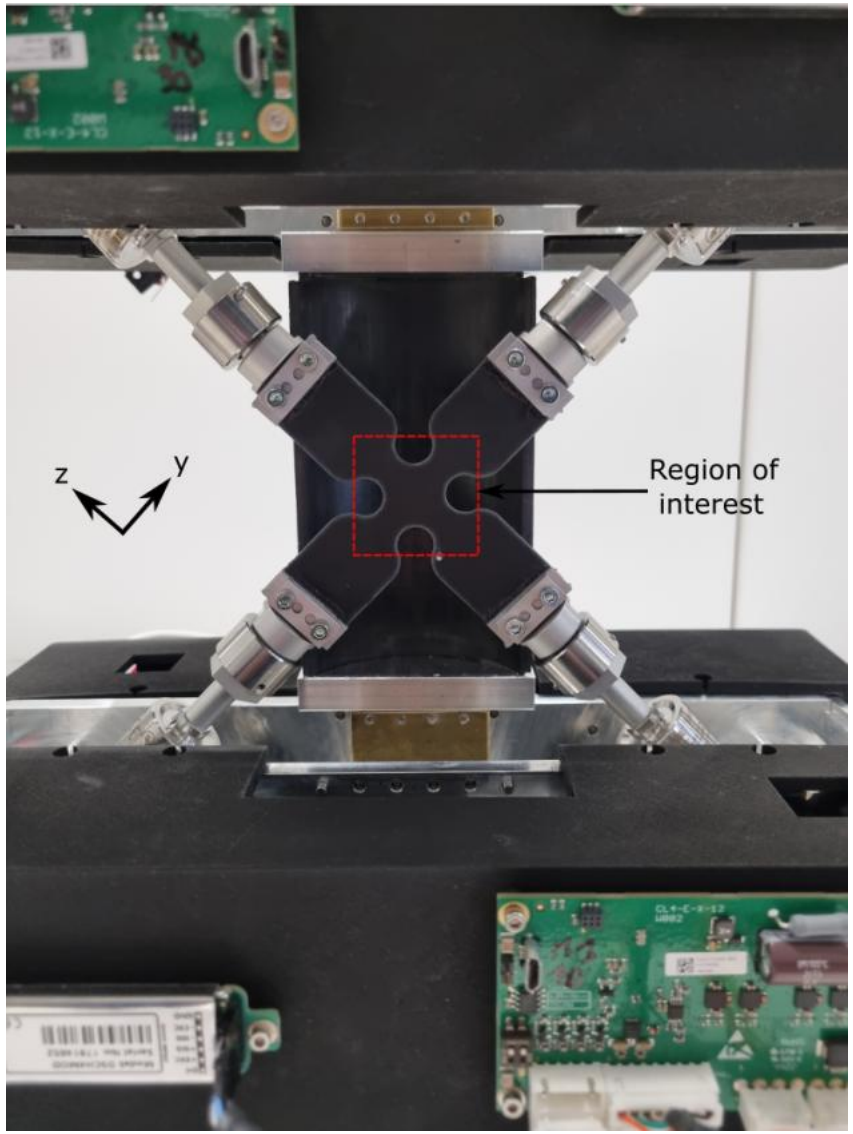




- Advantex R25HX14 E-glass/epoxy ply (fibre diameter: 24 µm)
- [+45/−45/+45] layup
- Section reduction for failure in the gauge zone
- Aluminium end tab at the grips for a better load introduction

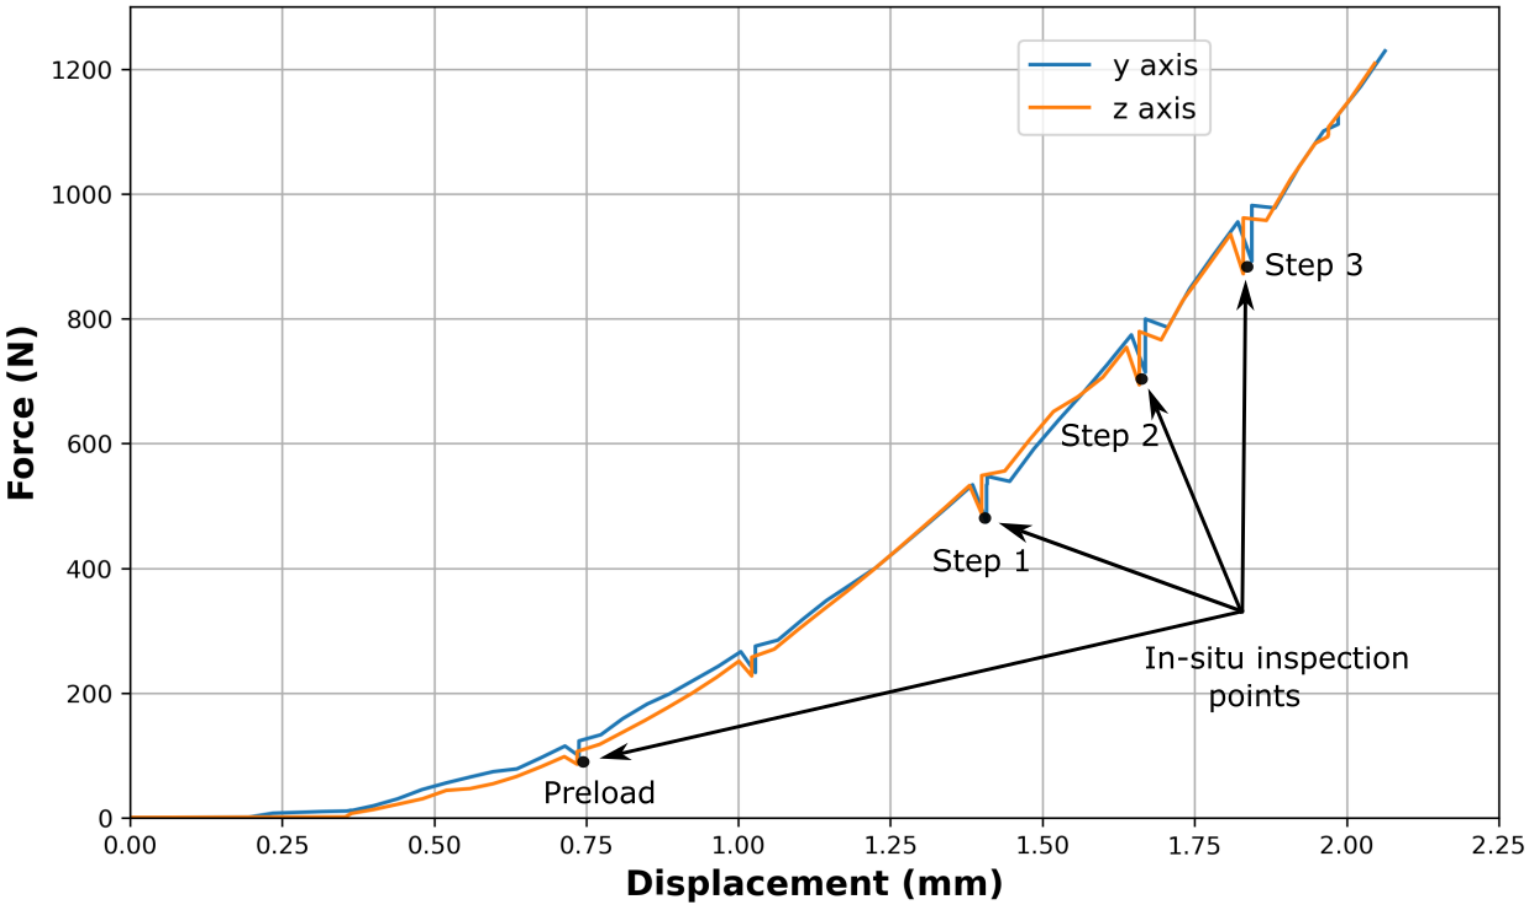
KU LEUVEN

FE strains distribution

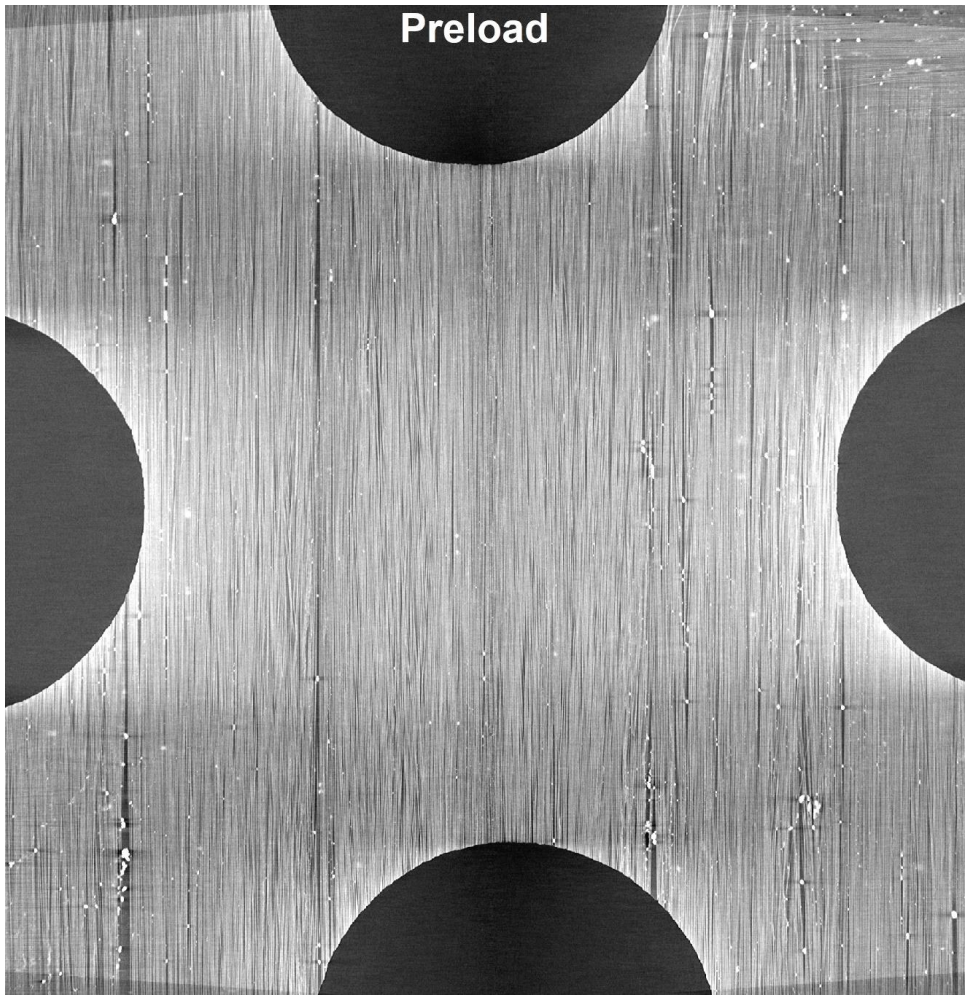


- Uniformity in shear strain
- Failure should initiate in the gauge zone

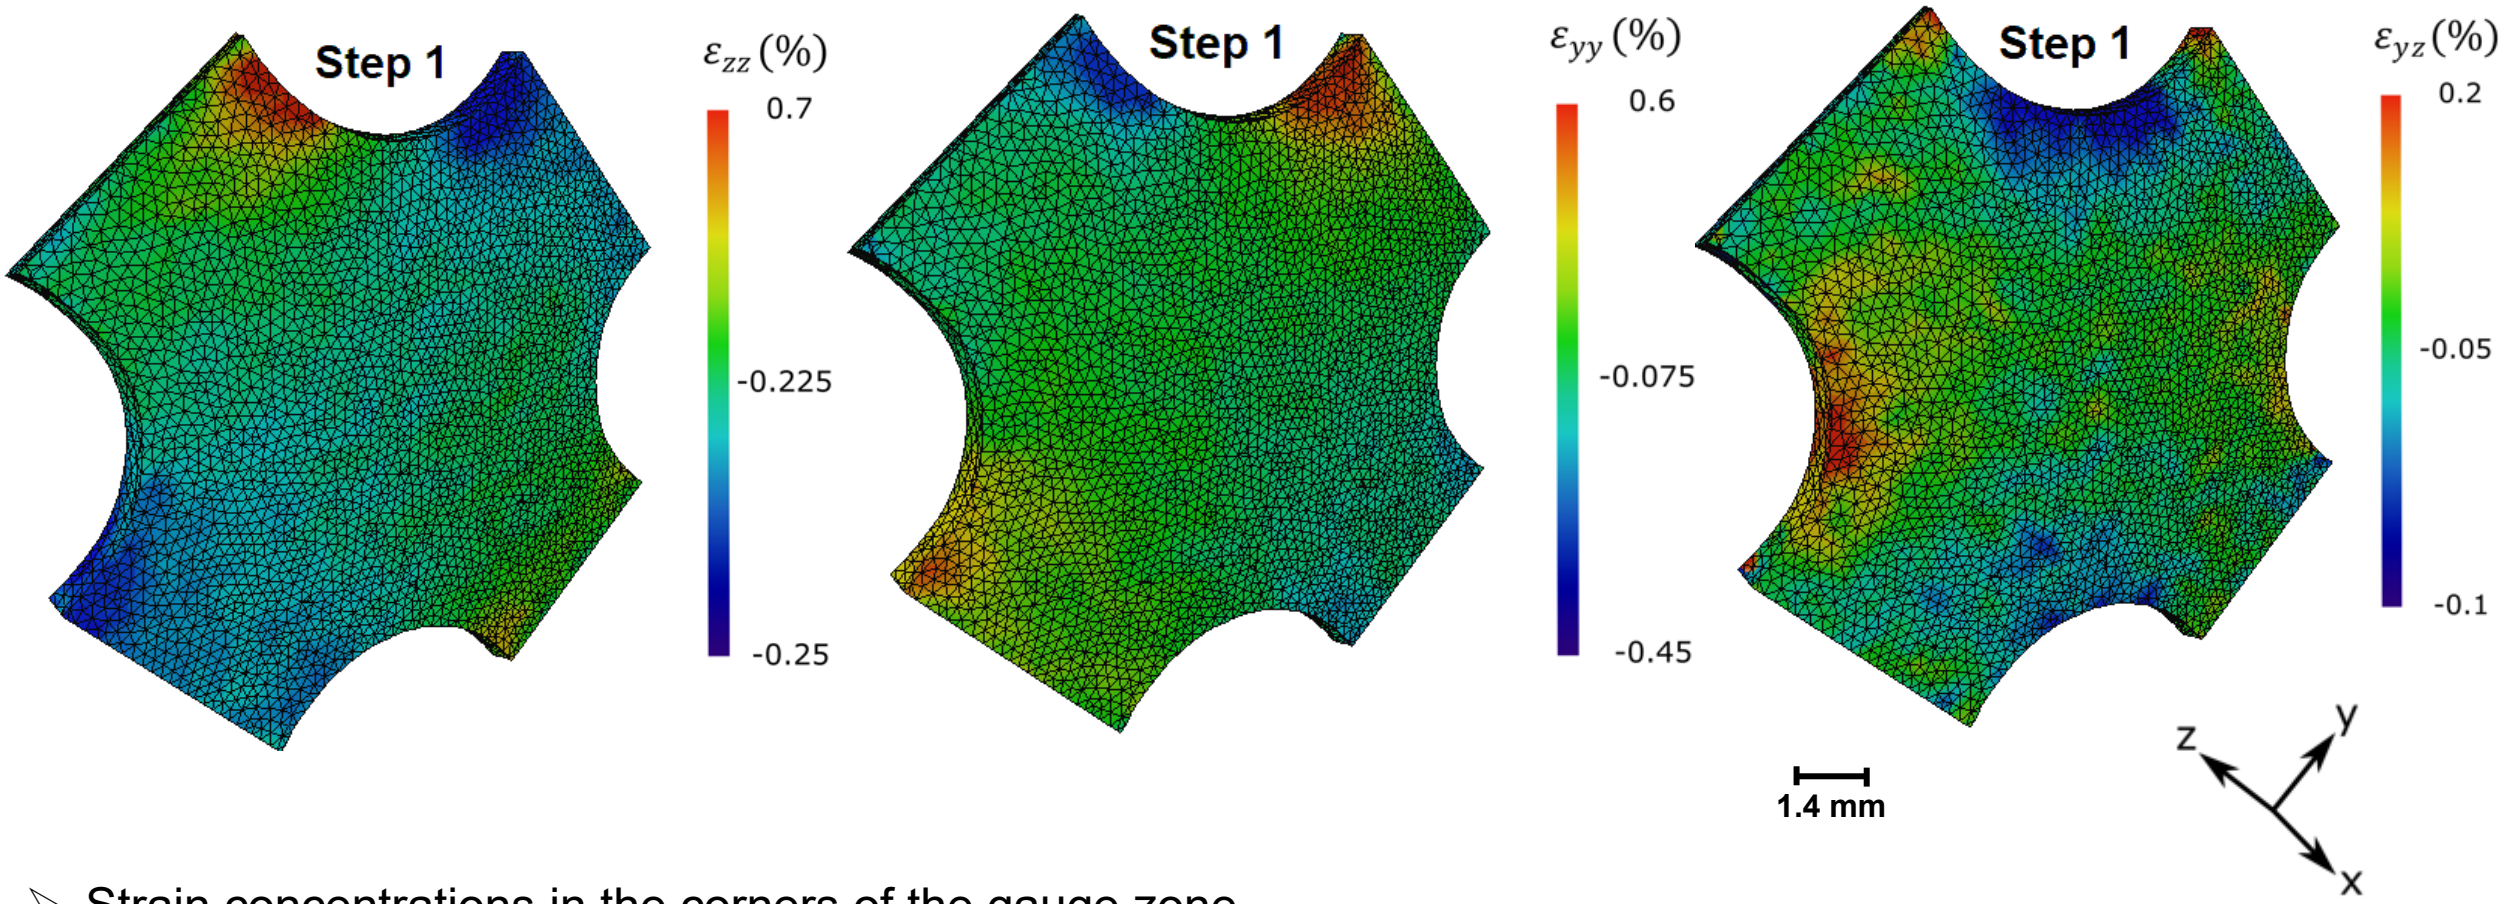
KU LEUVEN



In-situ XCT time-lapse biaxial testing

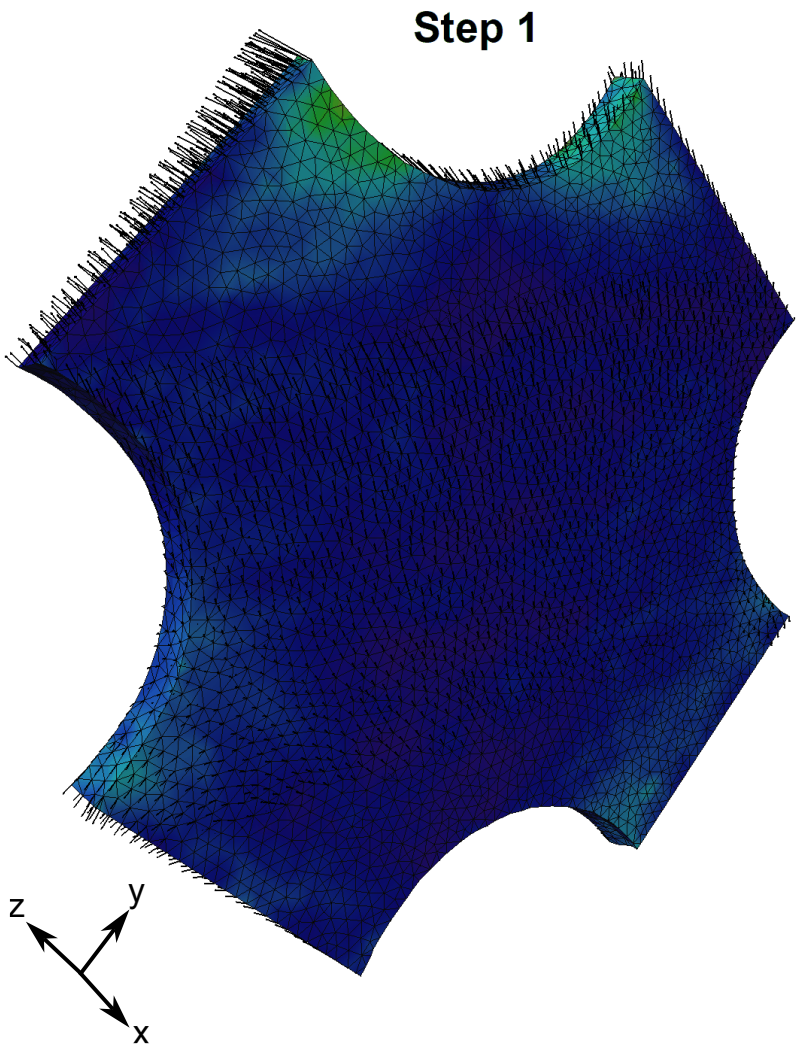


- Tube voltage: 120 kV
- Voxel size: 14 µm
- Fibre diameter: 24 µm

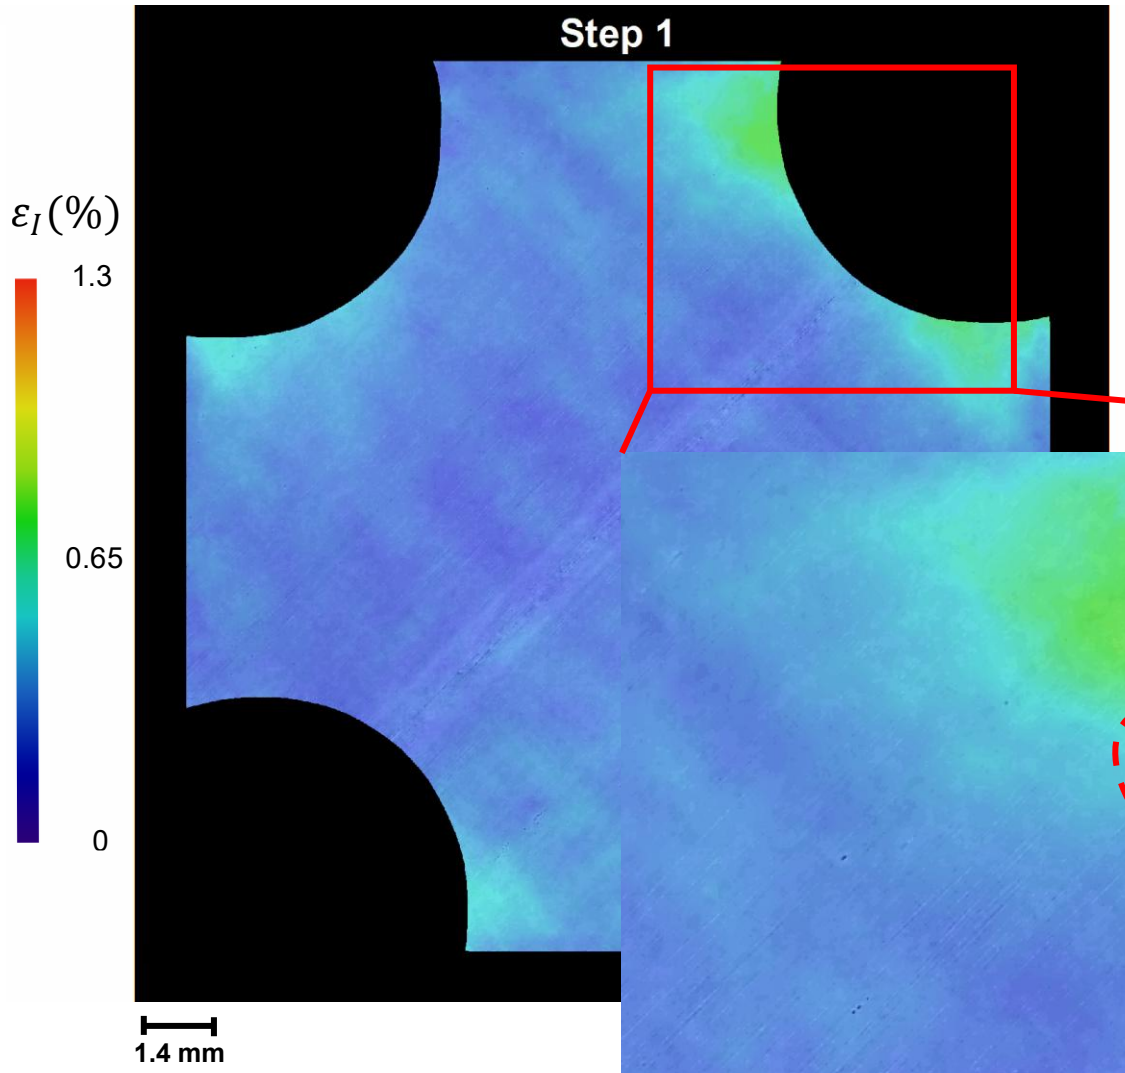


Load strategy

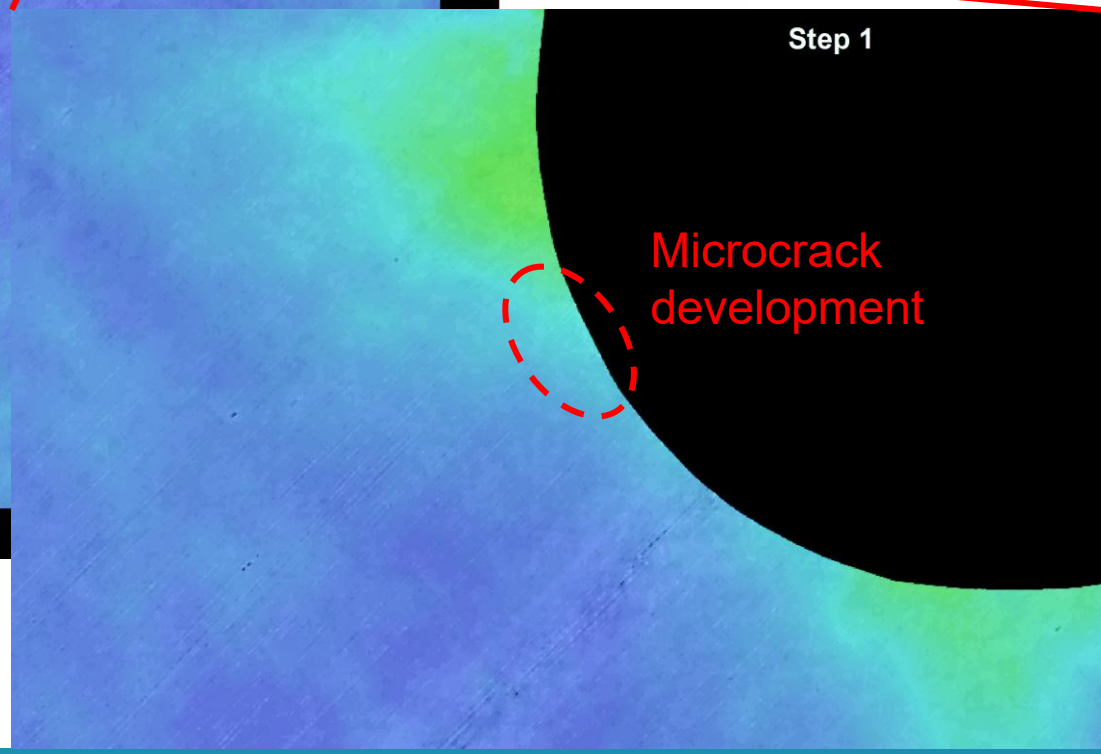
KU LEUVEN



Full strain fields



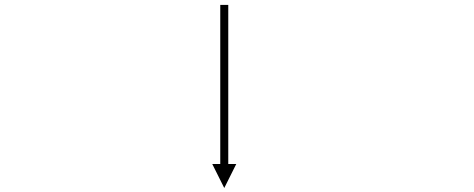
- Strain concentrations in the corners of the gauge zone



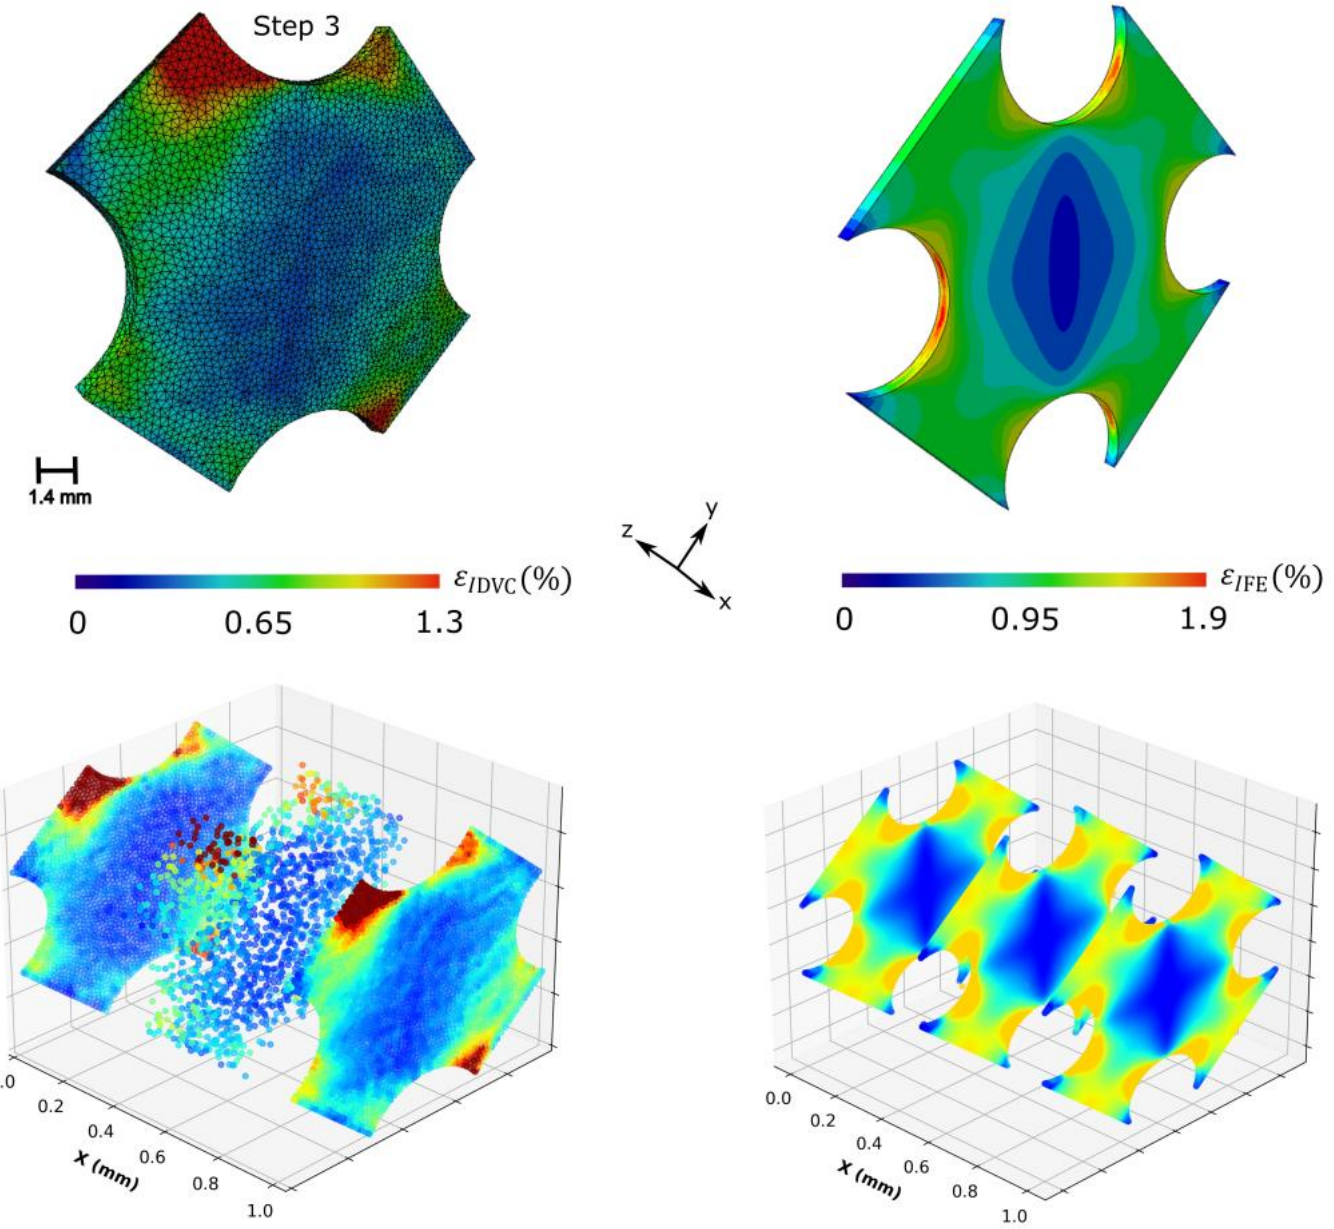
KU LEUVEN

Damage investigation

- Residuals images to detect microcrack development



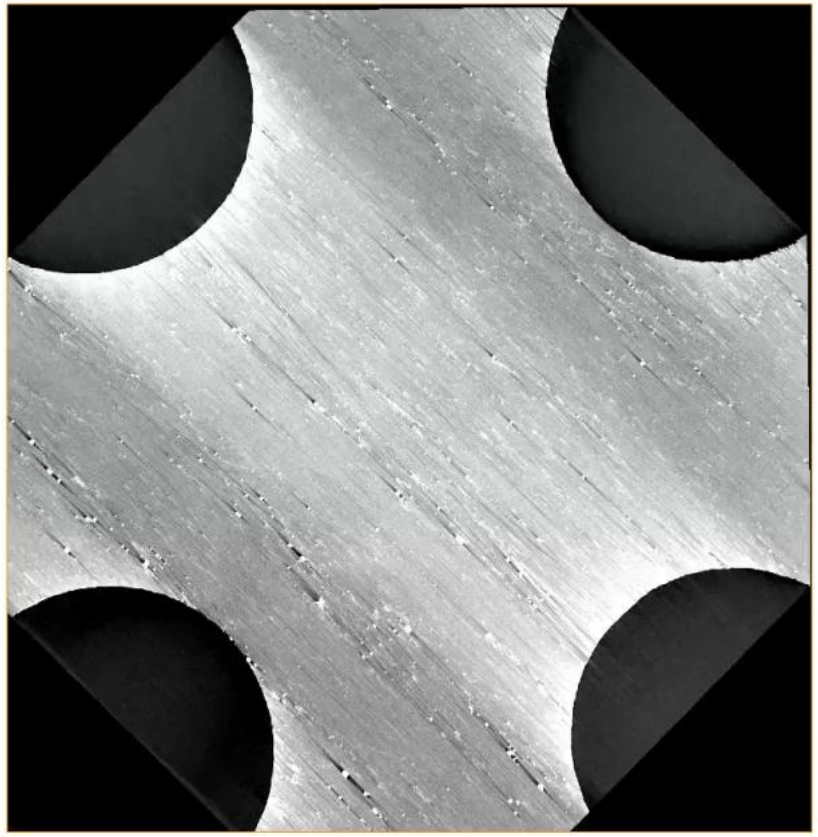
- Strain localisations in the corners



KU LEUVEN

FE vs. DVC

- Similar failure zones
- FE overestimates strain
- DVC integration improves accuracy



- More data to improve the failure models

KU LEUVEN

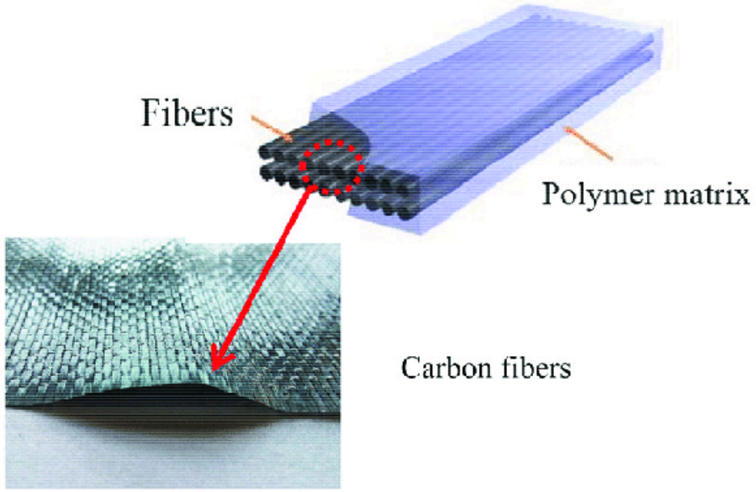
FibreSimulator: An Open-source Python tool for Generating Fiber Phantoms

Mary Chris Roperos Go | ICCM
Co-authors: Daniel Pelt, Anirudh Kohli, Philip J Withers, K Joost Batenburg



Understanding FRPs Starts Inside

- Fiber-reinforced polymers (FRPs) are critical for high-performance industries
- Strength and reliability depend on the **internal fiber structure**
- However, visualizing the internal is **challenging**
- **Tomographic imaging** is the key!

Fiber components: fiber and resin *

> But **high-quality datasets** for developing tomographic algorithms are hard to access!

* Khan, Nazrul & Halder, Sudipta. (2020). Self-healing fiber-reinforced polymer composites for their potential structural applications. 10.1016/B978-0-12-818450-9.00015-5.

Challenges in FRP imaging

- Acquiring high-quality CT datasets is **expensive** & **time-consuming.**
- Existing datasets are often **private** or **not diverse** enough for algorithm development.
- Existing simulators (e.g., PuMA, TexGen, WiseTex) are **rigid** — limited ability to model different fiber features or scanning conditions.

A Flexible Python Fiber Simulator

Top 3 advantages of what FibreSimulator can offer!

2

Generate synthetic FRP volumes with **customizable features & defects**.

1

Built in **Python** for maximum flexibility & easy extension.

FibreSimulator

3

Simulate CT scanning conditions through **ASTRA Toolbox**.

Provides realistic data for **testing** and **improving** tomographic methods.

How *FibreSimulator* builds phantom volumes

Experiments

How different parameters affect imaging

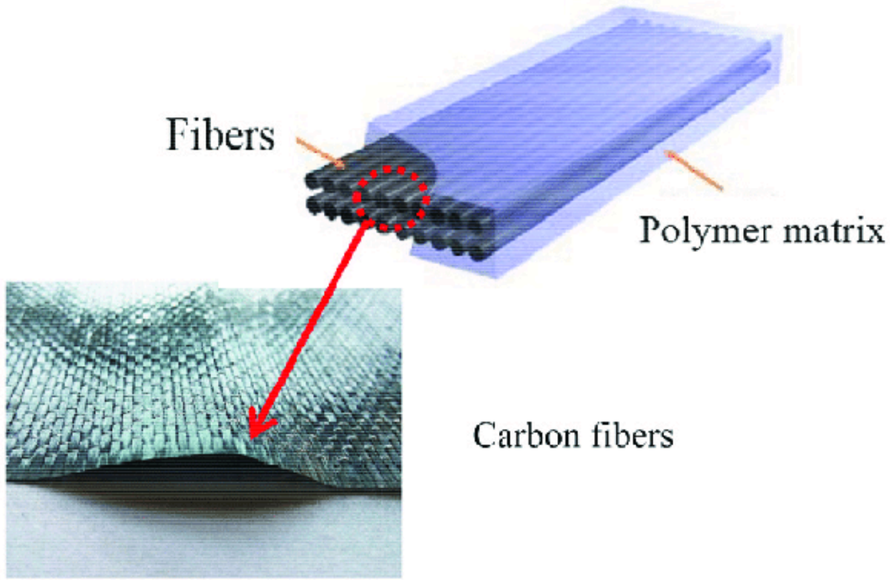
Conclusion



Key Takeaways

Methods

In real-world X-ray CT scans of FRPs:

- fiber appears as elongated cylinders
- the volume has the material classes:
  - air
  - resin
  - fiber

Fiber components: fiber and resin [1]

[1] Khan, Nazrul & Halder, Sudipta. (2020). Self-healing fiber-reinforced polymer composites for their potential structural applications. 10.1016/B978-0-12-818450-9.00015-5.

Notations & Concepts

- We define a fiber phantom as a set of fibers:

$$\mathcal{P} = \{F_1, F_2, \ldots, F_{N_f}\}$$

- Each fiber is a sequence of points:

$$\{p_n\}_{n=1}^{N_s} \subset \mathbb{R}^3$$

- Therefore, a single fiber is written as:

$$F_m = \{(p_1, r), (p_2, r), \ldots, (p_{N_s}, r)\}$$

- The total volume is:

$$V_{fibers} = \bigcup_{m=1}^{N_f} V_m = \bigcup_{m=1}^{N_f} \bigcup_{n=1}^{N_s} B(p_n, r)$$

This final equation defines the whole volume as a union of fibers where each fiber is a union of midpoints.

This continuous volume serves as the geometric model of the fiber phantom before discretization.

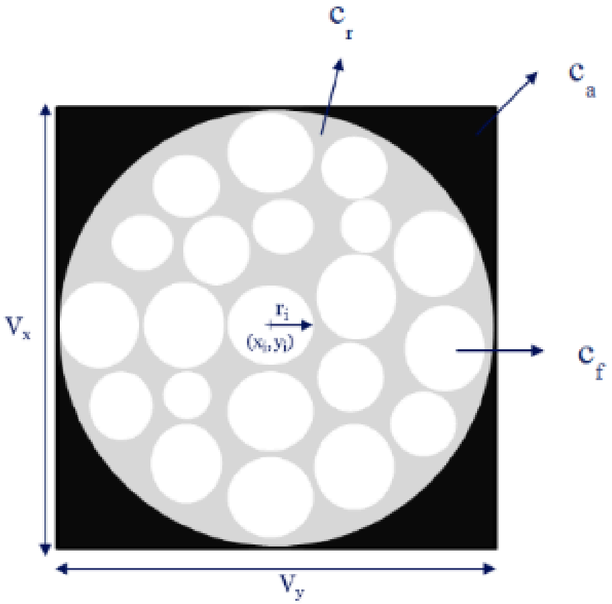
Voxel Representation

- Once all the fibers are generated in continuous space, they are converted onto voxel grid:

$$V \in \mathbb{R}^{V_x \times V_y \times V_z}$$

  where each voxel holds a scalar intensity value [0, 255].
- CT attenuation coefficients: resin, material, air

Given a volume where fibers are growing inside a pipe, a voxel is marked as fiber if its center lies inside any sphere the defines a fiber. Voxels outside the pipe are assigned the air value, while voxels in the pipe that do not contain fibers are filled with resin value.

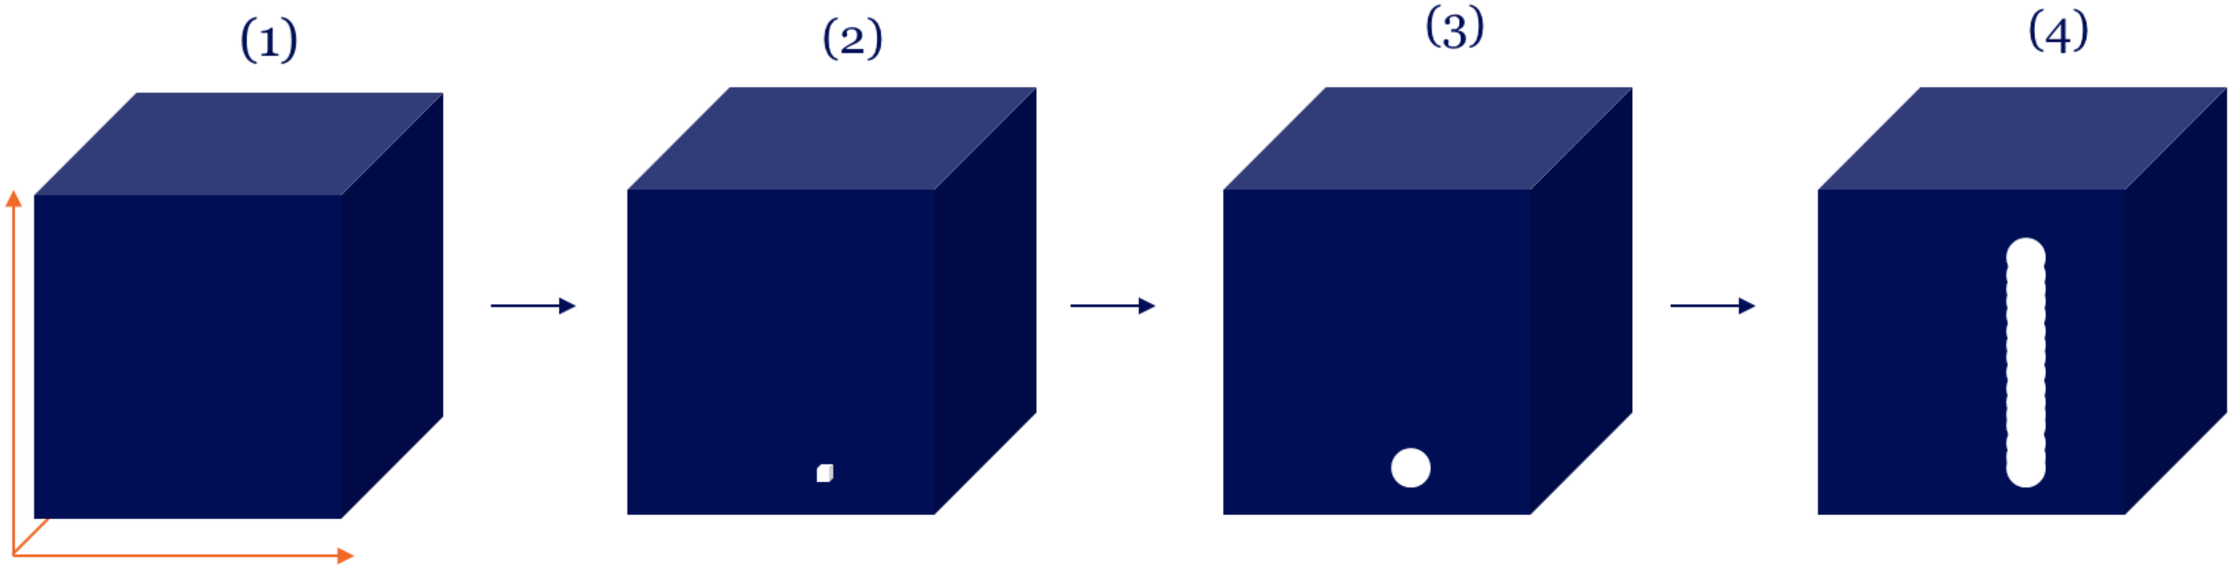


Single Fiber Generation

a) composition of single straight fiber: **overlapping 3D spheres**

b) **schematic representation** of an axial slice of a fiber phantom

(a)

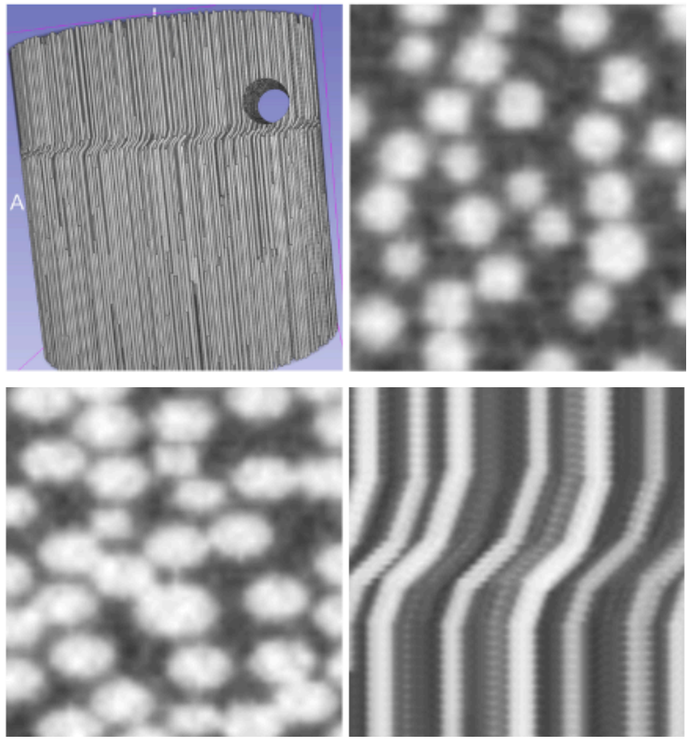


(b)

> Why use this design? It offers in **flexibility in choosing** the next point

Since the workflow of building a fiber involves growing it step by step, the user can choose the direction of growth, demonstrating flexibility.

Fiber Phantom Volume Generation



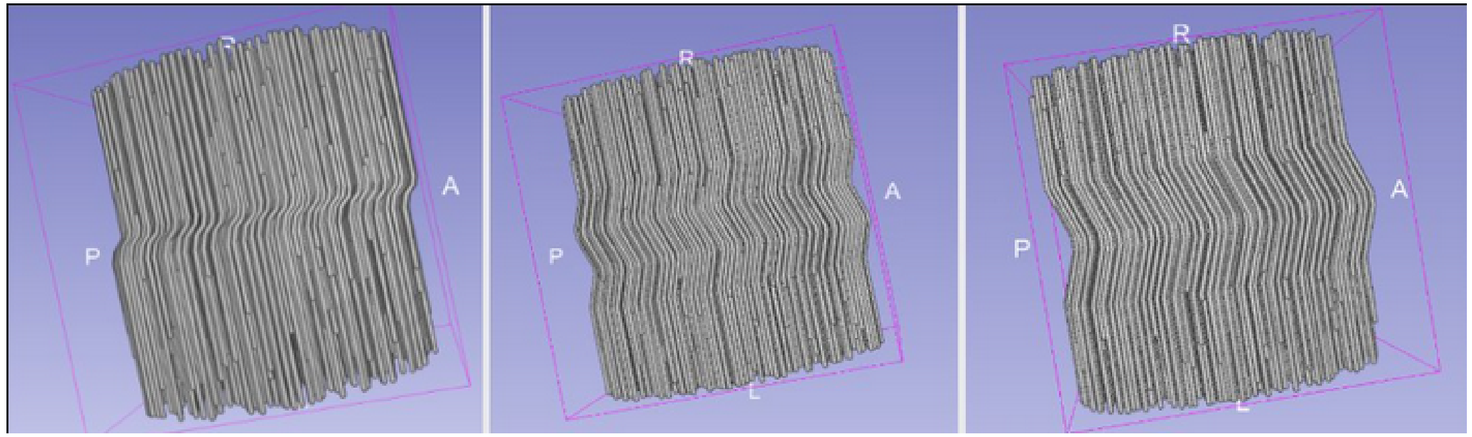
(1) Start with an empty volume.
(2) Initialize a starting point.
(3) Check if the point lies within the volume and ensure that a sphere with the given radius does not overlap with existing fibers.
(4) Grow the fiber and repeat the process until N fibers are generated.
(5) Discretize the volume and label the voxels.

repeat until N fibers are generated & fill unoccupied p_i to resin

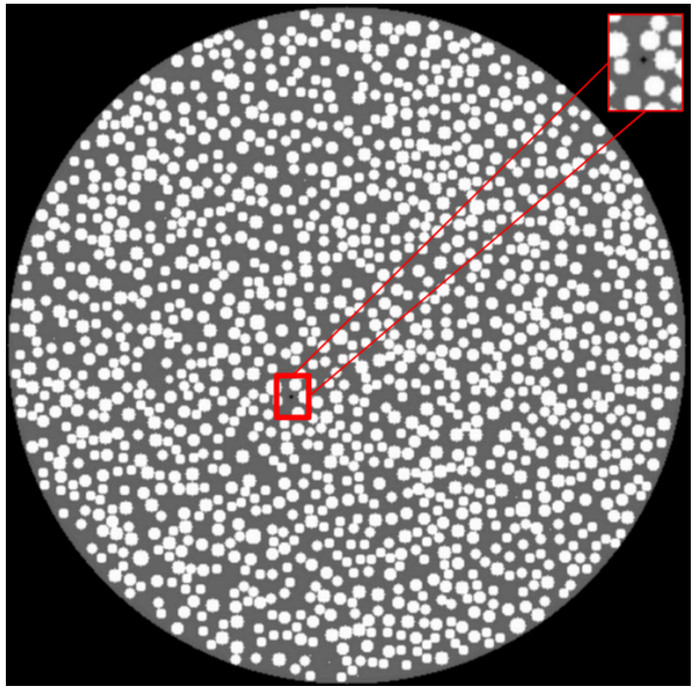
For the sake of simplicity, we grow a straight fiber in this example, meaning the next point will just be either +x or -x axis.

Fiber Phantom Volume Example

- Real composite materials:
  - wide range of structural variations
  - differences in fiber diameters
  - presence of manufacturing defects
- size of [800 x 800 x 800] showing:
  - hole
  - kinking
  - variation in fiber diameter



Visualization of a reconstructed phantom volume w/ kinking & a hole

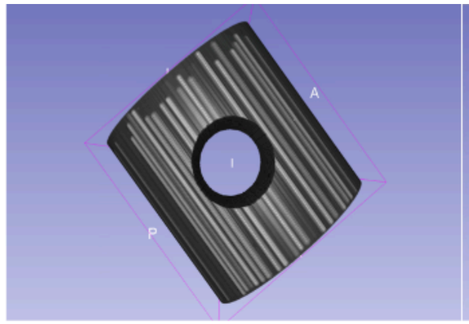


Other features

Fiber Orientation, voids

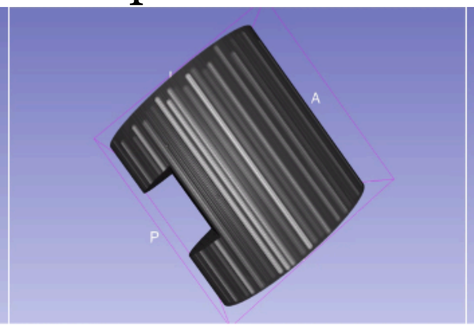
kink | full-wave | half-wave

voids



These features are commonly observed in manufactured composites and play a critical role in determining their mechanical performance. To account for this, we incorporated the simulation of these features, aiming to generate more realistic phantoms that reflect imperfections.

Other features



Geometrical Features

These types of features were prioritized for modeling due to the availability of real-world data, enabling qualitative comparison. But because of the flexibility of FibreSimulator, users can generate their own geometrical feature.

*F.B. Salling, N. Jeppesen, M.R. Sonne, J.H. Hattel, and L.P. Mikkelsen. Individual fibre inclination segmentation from x-ray computed tomography using principal component analysis. Journal of Composite Materials, 56:83–98, 2022.

Varying tomographic imaging conditions

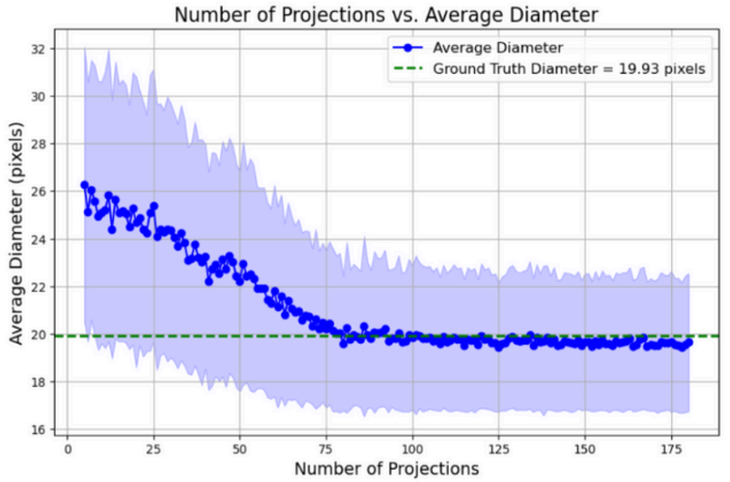
These are axial reconstruction images of a [256 x 256 x 256] volume acquired using a parallel beam and reconstructed using the SIRT algorithm.

Comparison of reconstructed middle axial slices at varying **number of projections** (top row) and **noise levels** (bottom row)

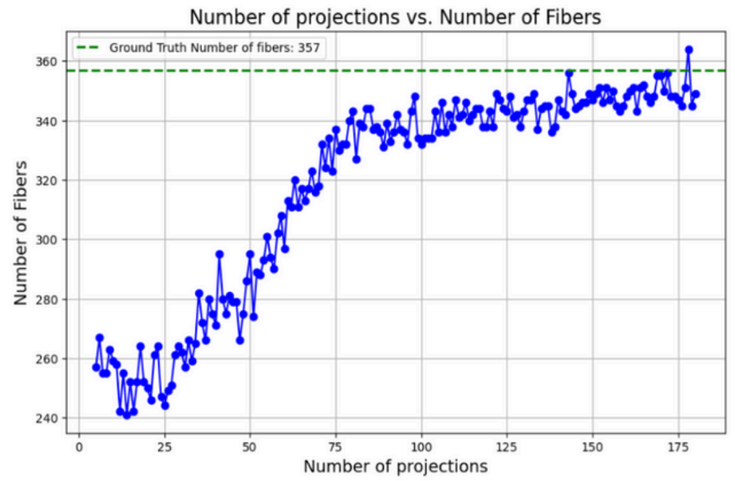
By fine-tuning the parameters in a simulated environment, users can observe their effects on image quality and make informed adjustments.

With this workflow, it ensures that actual scanning is carried out using an optimized set of conditions.

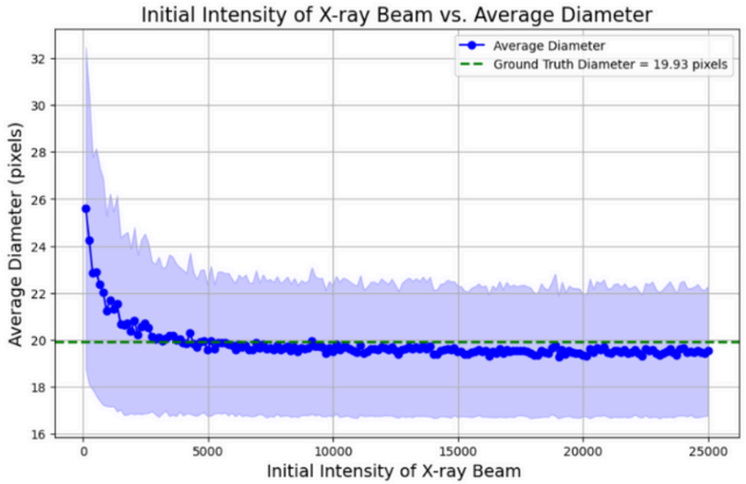
Varying tomographic imaging conditions



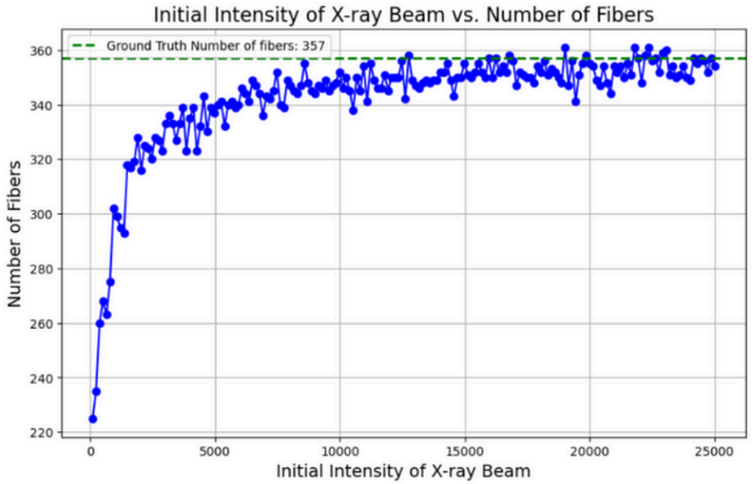
Effect on average diameter & # of fibers detected:



- Decreasing # of projections

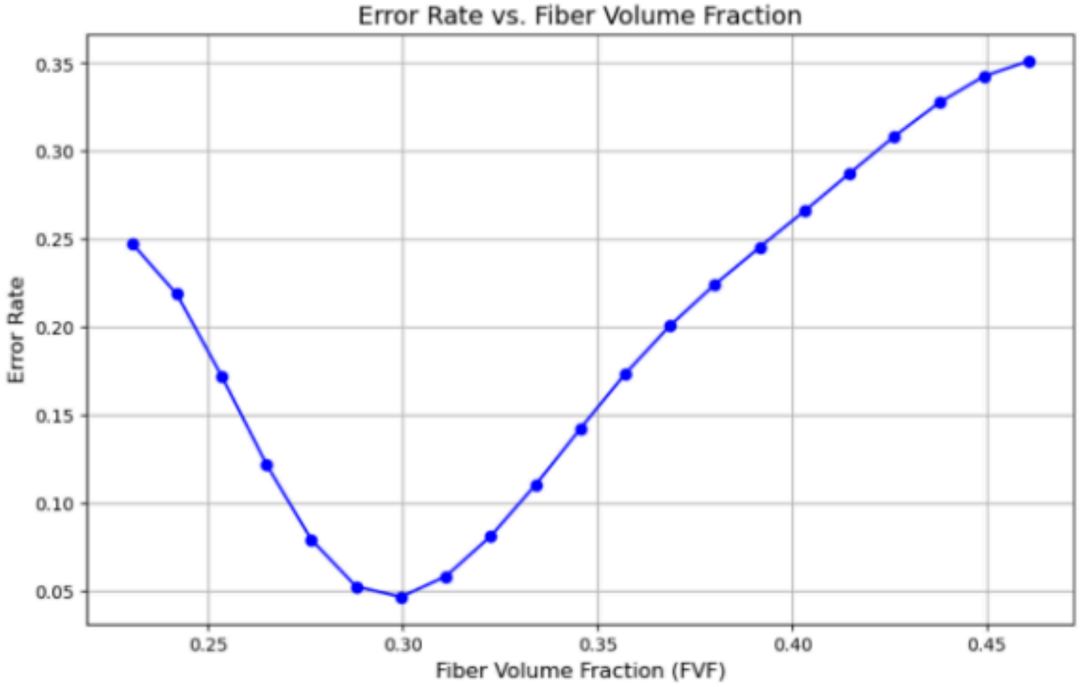


As the # of projections decreases, average fiber diameter increases. We can hardly differentiate the boundaries of the fiber, resulting in adjacent fibers appearing fused together.



- Decreasing initial intensity of X-ray beam

A decrease in the initial intensity of the X-ray beam leads to a noisier image. At higher intensities, the average diameter stabilizes close to the ground truth.



Varying fiber characteristics

The rise in error can be attributed to overlapping streak artifacts, which occur when fibers are densely packed.

- Effect of increasing fiber volume fraction (FVF) to the detected # of fibers in a 120° scan
- Interestingly, the error rate follow a non-linear trend w.r.t. FVF

> Showcases the simulator as **flexible** & **adaptable tool** for studying how sample features affect fiber detectability.

Effect of varying fiber volume fraction on the detected # of fibers

Methods

How *FibreSimulator* builds phantom volumes

Experiments

How different parameters affect imaging

Conclusion

Key Takeaways

Conclusions

FibreSimulator is a tool that can asses scanning configurations, establishing its potential as a benchmark for data-driven tomographic algorithms

We **introduced** a simulator that:

- Generates **realistic** & **customizable** fiber phantoms
- Integrated with **ASTRA toolbox** for CT simulation
- Written in **Python** for flexibility

We **showed** how it can show:

- **relationships** between noise, number of projections, and reconstruction quality
- **impact of fiber density** on fiber detectability

> Future Work: simulation of additional imaging artifacts (source characteristics, beam hardening effects, and detection defect)

Thank you!

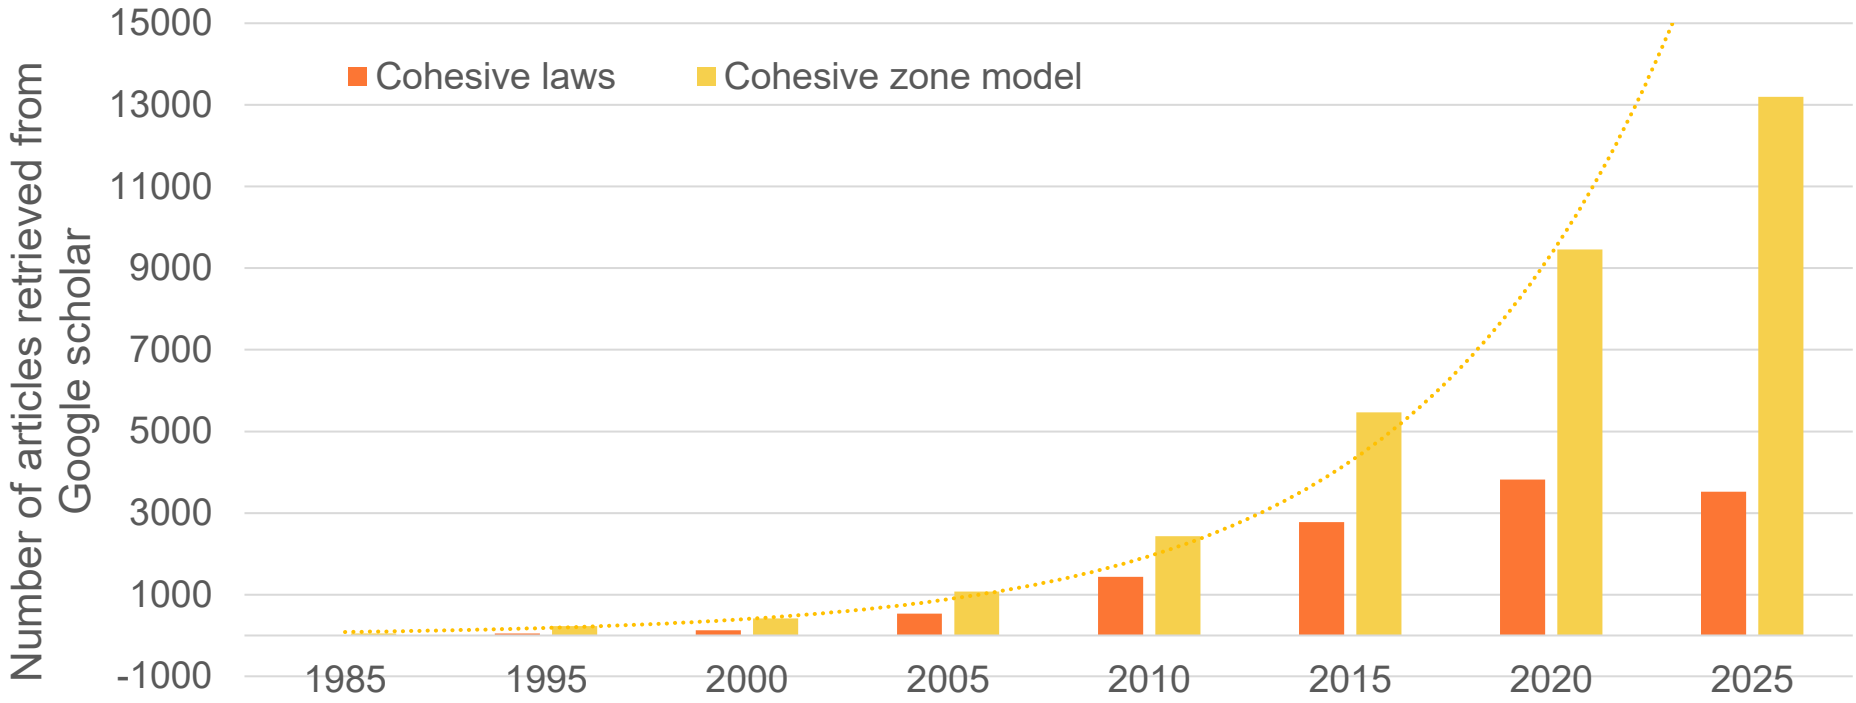
Direct approach for experimental determination of mixed-mode cohesive laws of composites with large-scale fibre bridging

Ruben Erives,
Bent F. Sørensen and
Stergios Goutianos



Overview

- Motivation
- Derivation of cohesive law
- Experimental Characterisation
- Results
- Concluding remarks
- Questions & discussion

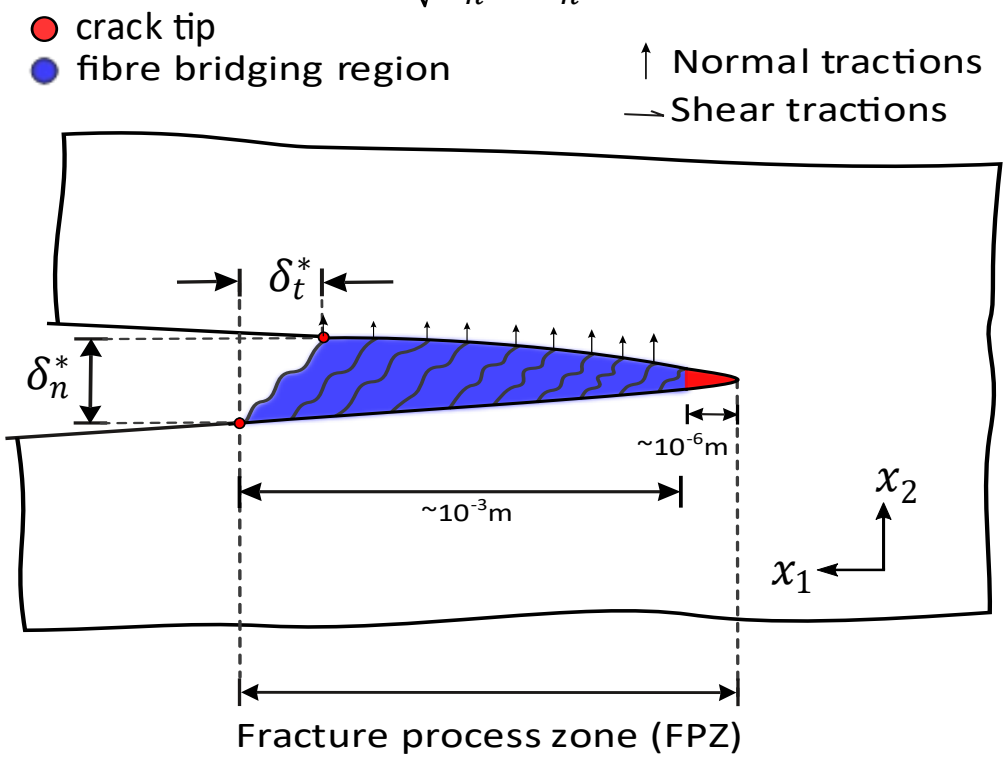
Motivation

Why is it important to measure cohesive laws?

1. While the implementation of cohesive zone models is increasing rapidly, research in determining cohesive law of composites has stalled.

Motivation

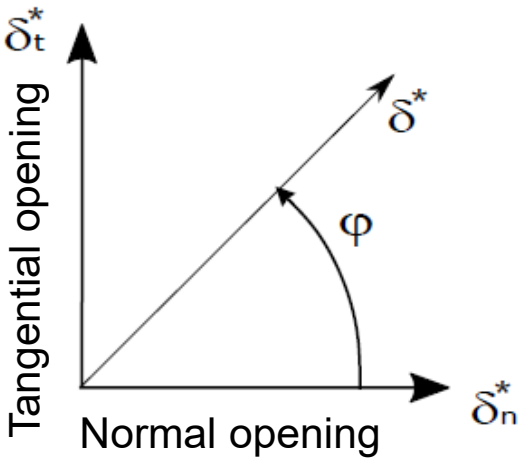
Why is it important to measure cohesive laws?



1. *Idealised cohesive* laws have several shortcomings
    1. For bi-linear cohesive laws, the traction separation law is fully determined by the combined work of the peak traction and a critical opening. Then the shape (and peak traction) are predefined
    2. Difficult or not possible to recover R-curves from pre-defined/idealised cohesive laws
2. The *shape of the cohesive traction* conveys important information of the *fracture behaviour* of a material such as failure mechanisms, the coupling between tractions, and crack growth stability among other

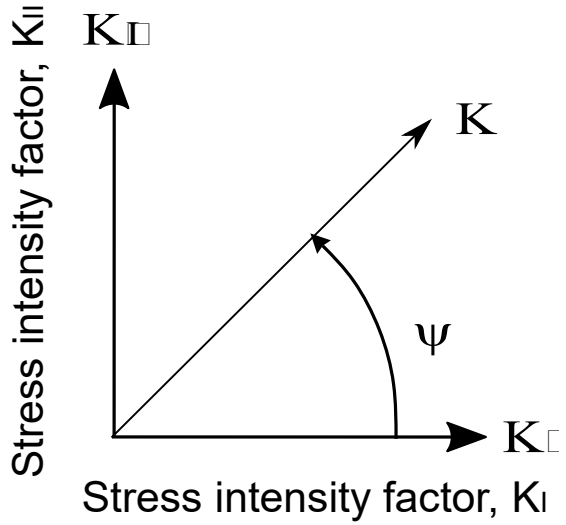
Derivation of cohesive law

Definition of end-openings and phase angle



End-opening

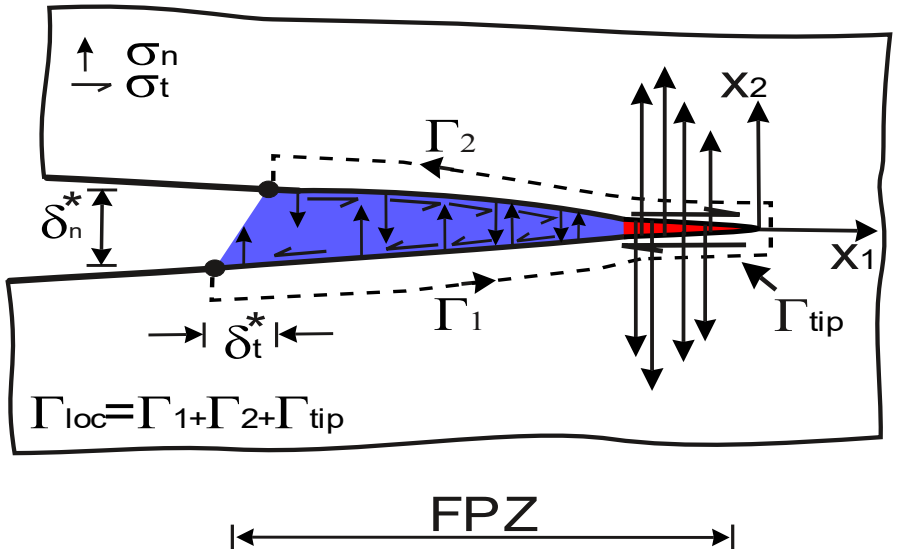
$$\delta^* = \sqrt{\delta_n^* + \delta_n^*}$$



Phase angle of end-openings

$$\varphi^* = tan^{-1}\left(\frac{\delta_t^*}{\delta_n^*}\right)$$

Phase angle of stress intensity factors



$$\Psi = tan^{-1}\left(\frac{K_{II}}{K_I}\right)$$

Derivation of a fully coupled potential based cohesive law

J-integral approach

Evaluate the J-integral around the path Γ_{loc} then:

$$J_{loc} = \int_0^{\delta_n^*} \sigma_n(\delta_n, \delta_t) d\,\delta_n + \int_0^{\delta_t^*} \sigma_t(\delta_n, \delta_t) d\,\delta_t$$

[Sørensen and Kirkegaard, 2006]

Relates Φ to R-curves → $J_R = J_{loc} = \Phi(\delta_n^*, \delta_t^*)$

Assuming that the cohesive tractions can be derived from a potential function, Φ, then

Path-independent → $\Phi = \Phi(\delta_n, \delta_t)$

$$\Phi(0,0) = 0$$

So that,

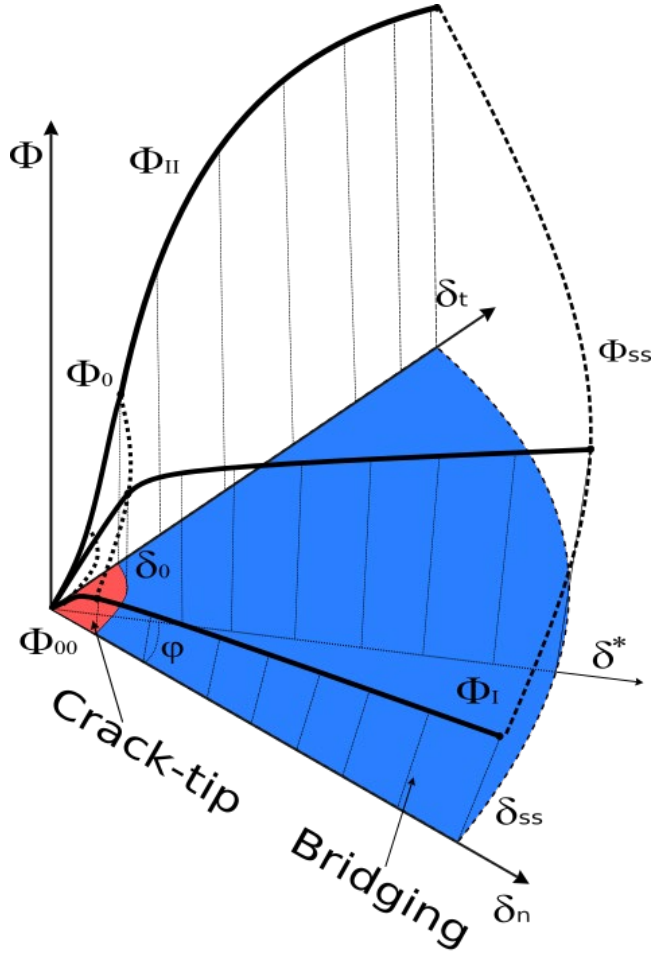
Mixed mode coupled cohesive tractions

Cartesian	Cylindrical
$\sigma_n(\delta_n, \delta_t) = \frac{\partial \Phi(\delta_n, \delta_t)}{\partial \delta_n}$	$\sigma_n(\delta, \varphi) = \cos(\varphi)\frac{\partial \Phi}{\partial \delta} - \frac{\sin(\varphi)}{\delta}\frac{\partial \Phi}{\partial \varphi}$
$\sigma_t(\delta_n, \delta_t) = \frac{\partial \Phi(\delta_n, \delta_t)}{\partial \delta_t}$	$\sigma_t(\delta, \varphi) = \sin(\varphi)\frac{\partial \Phi}{\partial \delta} + \frac{\cos(\varphi)}{\delta}\frac{\partial \Phi}{\partial \varphi}$

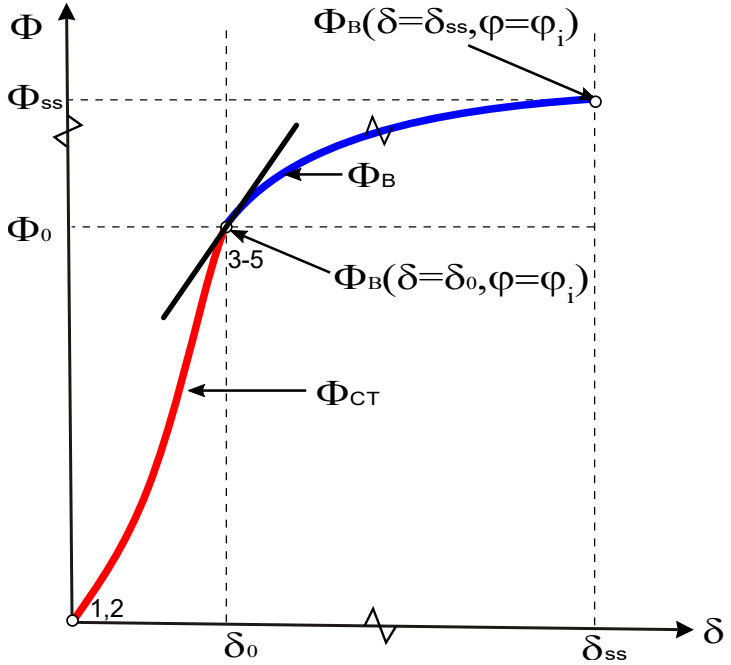
Derivation of cohesive law

Piece-wise, cylindrical potential function

- The potential function is defined in a piece-wise function:



$$\Phi(\delta,\varphi)=\begin{cases}\Phi_{CT}(\delta,\varphi), & 0<\delta^*\leq\delta_0\\ \Phi_B(\delta,\varphi), & \delta_0<\delta^*\leq\delta_{ss}\end{cases}$$



$$\Phi_{CT}(\delta^*,\varphi^*)=C_4\delta^{*4}+C_3\delta^{*3}+C_2\delta^{*2}+C_1\delta^*+C_0$$

$$\Phi_B(\delta^*,\varphi^*)=\Phi_0+(\Phi_{ss}-\Phi_0)\left(\frac{\delta^*-\delta_0}{\delta_{ss}}\right)^{\zeta}$$

- Parameters:

$$\Phi_0(\varphi),\Phi_{ss}(\varphi),\delta_0(\varphi),\delta_{ss}(\varphi),\zeta(\varphi)$$

Experimental characterisation

Specimens and test groups

Figures adapted from Erives R. et al 2023

Results

Relationship between external and local phase angle

Concluding remarks

1. A framework to extract cohesive laws of composites under large scale fiber bridging is presented
2. Extracted cohesive laws depend on physical parameters directly extracted from experimental R-curves, thus ensuing extracted cohesive laws conform to R-curve behavior
3. The measured cohesive laws resulted on *fully coupled* normal and shear tractions
4. In general, non-monotonic variation of fracture resistance and cohesive tractions can be observed for a fixed opening value

Keywords: Fatigue behaviour, High Cycle Fatigue (HCF), High-frequency testing, Thermo-mechanical coupling, Aerospace components, Master curves, Accelerated Testing.

ABSTRACT

While carbon fibre reinforced polymer composites are well-known for their high strength-to-weight ratio, their fatigue behaviour is difficult to predict. Fatigue of composites is generally considered one of the most challenging physical phenomena due to its multi-physics and stochastic behaviour. One of the most challenging aspects of exploring fatigue properties is the extensive time required for fatigue testing. To determine the fatigue life of a test specimen, the number of required load cycles ranges up to millions. The limitation of testing frequency is caused by the viscoelastic properties of the matrix material, which result in self-heating at high testing frequencies. The objectives of XCTE within the DSTANDART project are to increase the rate of mechanical testing by utilising the High Cycle Fatigue (HCF) testing technique and to understand how to measure, analyse, and decouple the thermo-mechanical forces under high rates of cyclic loading. Fatigue testing can be significantly accelerated when high-frequency testing methods are employed. This paper reports the technological advancement achieved through high-frequency testing on two aerospace components: a) a scaled turbine fan and b) a representative aero demonstrator. Both structures embed a typical design feature, ply termination, to change the thickness from the root to the aerofoil of the blade. Those terminations create resin pockets, which are known to be localised stress raisers leading to the onset of fatigue damage. The paper reports on high-frequency experiments conducted in two testing facilities. The first experiment was executed at the Rolls-Royce Mechanical Testing Operational Centre (MTOC) in Berlin (DE), the second experiment was conducted at the NLR testing facility in Marknesse (NL). High-frequency testing and analysis are now a key technology of the spin-off XCTE, which was born thanks to the D-STANDART European project.

1 INTRODUCTION

Composite structures are known to exhibit complex fatigue behaviour due to their stacking sequence and embedded features, such as fibre discontinuity, waviness, resin pockets, and voids, among others. Therefore, any composite laminate requires mechanical testing to determine the material and fatigue properties. The latter properties can be very time-consuming when the number of excitation cycles is large, and the excitation frequency is set lower than five cycles/sec to avoid any self-heating caused by the viscoelastic properties of the resin in the composites. There are numerous research studies examining the environmental and self-heating temperature effects on fatigue life [1,2,3,4,5], which suggest a substantial reduction in residual life due to the coupling between mechanical and thermal loads during fatigue cycles. Temperature-dependent material properties are of no use for engineers who develop fatigue models, assuming a constant entropy behaviour during the development of fatigue damage. The temperature effect(s) are modelled via superposition principles by using test data generated using low excitation rates under different temperature conditions. The result is that a significant amount of time is invested in generating fatigue test data to feed fatigue damage models, even when any aerospace structure can naturally be subjected to oscillatory motions exceeding five cycles per second and

environmental conditions (temperature and moisture). Within the D-STANDART project, the consortium partners investigate the effects of temperature and humidity, with one partner focusing on high-frequency testing under various environmental conditions. These tests indicate how the loss of stiffness correlates with the increase in self-heating temperature in the cross-laminate made of IM7-8552. The research will be published after the ICCM event, so it is advisable to monitor the upcoming literature.

The high-frequency tests were developed and proven in several research studies [1,2,3,4], which are briefly summarised in this paragraph. The composite sample is held by a specific fixture consisting of two rods that support the sample during the excitation of the first bending motion, allowing the structure to rotate at the clamping region. A ply-drop, or cut-ply, features the cross-ply laminate to generate a stress away from the clamping region. That stress raiser is typically placed a few tens of millimetres away from the clamp. The test is executed at a constant excitation frequency, corresponding to the pristine resonance frequency, during the fatigue test. The frequency response phase is measured by the ratio between the input stimulus (typically a base acceleration) and the output response, as measured by a laser Doppler vibrometer (LDV). The vibration amplitude is maintained constant during the fatigue test, thus achieving a displacement control test (noting that the velocity measured by the LDV is converted into displacement). The loss of stiffness as a function of the excitation cycles is measured by the frequency response phase rather than the change of the natural frequency of the test object. The phase is calculated from the inverse tangent of the ratio between the natural frequency and the drive frequency (constant). Consequently, a minimal natural frequency change is transformed into a significant phase deviation due to the tangent function. The temperature (measured by an IR camera) and vibration measurements are synchronised, with the temperature reading sampled every N elapsed cycles to avoid overloading the PC hard drive. The experiments are typically conducted inside an environmental chamber to control the ambient temperature, which scales up or down the effect of self-heating temperatures. The fatigue test data consist of frequency response phase, peak surface temperature (in the region of the ply-drop), and base acceleration versus excitation cycles. These plots will be presented in the following sections.

The experimental technique introduced in the previous paragraph to characterise the fatigue behaviour is applied to two test structures made of composite materials. The first structure is a scaled turbine fan made of a composite material, the type of which and stacking sequence were unknown to the authors [2]. The second structure is an aero demonstrator developed in the D-STANDART consortium. The demonstrator is a quasi-isotropic stacking sequence made of IM7-8552 material. The two experiments were conducted in two different industrial testing facilities. This paper will present the experiments performed and the output generated by the fatigue tests.

2 EXPERIMENTAL SETUP

This section describes the experimental setup, which is common to both experiments, despite being executed in different years. The first experiment was conducted in Rolls-Royce MTOC in 2015, while the second experiment was conducted in NLR in 2025.

The experimental setup is presented in Figure 1. The test structure is mounted on a slip table, which is connected to an electromagnetic shaker that exerts the excitation force. An accelerometer is attached to the slip table to measure the input base acceleration to the test structure. A strain gauge is mounted near the root of the test structure and is used for calibration between the input acceleration, output strain, and output displacement. The LDV and the IR camera are installed in front of the test structure. The XCTE sniper control panel is a custom-made software to control the sensors and exciter. The control panel can perform force or displacement control, depending on the test definition. Moreover, the frequency or phase lock loop at constant amplitude is yielded by a Proportional Integral Derivative (PID) control scheme.

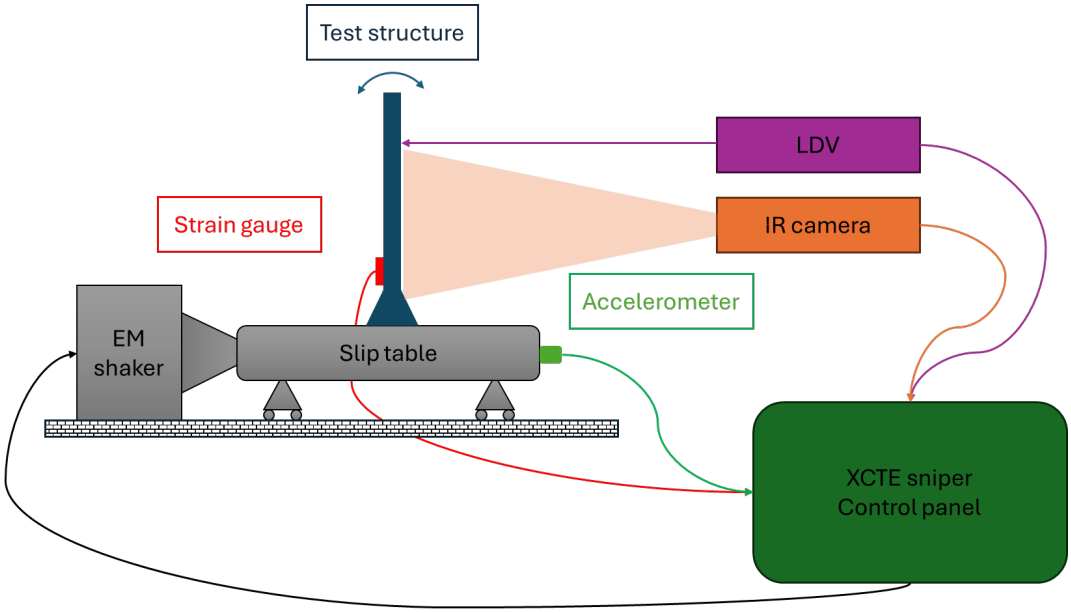

Figure 1: Test setup used for the two experiments.

The first task to accomplish is a frequency check before performing any High Cycle Fatigue with the High Frequency tests. The frequency check is a simple test where the excitation sweeps a frequency range to identify the resonances of the test structure. This step is essential to determine the first bending resonance for which a calibration step is required. In both experiments, the first mode of vibration was the target mode; however, any other fundamental mode can be tested similarly.

Once the frequency check is completed, the second task is to calibrate the base acceleration, the strain gauge, and the LDV laser output. This procedure ensures that a relationship is established between the three sensors, which typically exhibits nonlinearity due to large deformation. This calibration mustn't overload the structure; therefore, it is advisable to avoid large input forces.

At this point, the excitation frequency (resonance) and calibration are known; the final step is to set up the type of force or displacement control for the HCF test. Having decided the kind of control, the HCF can be started, and the frequency response phase is continuously tracked to monitor the loss of stiffness. At the same time, the sniper control panel measures and stores the output of the other sensors, but the strain gauge, whose wire has been cut, is not included.

Figure 2 shows a close-up of the test setup where the blade can be seen vibrating in its test fixture. Note that the test fixture was specifically designed to match the blade root. Figure 3 illustrates the complete measurement setup, as schematically depicted in Figure 1.

Figure 2: Close-up of the test setup.

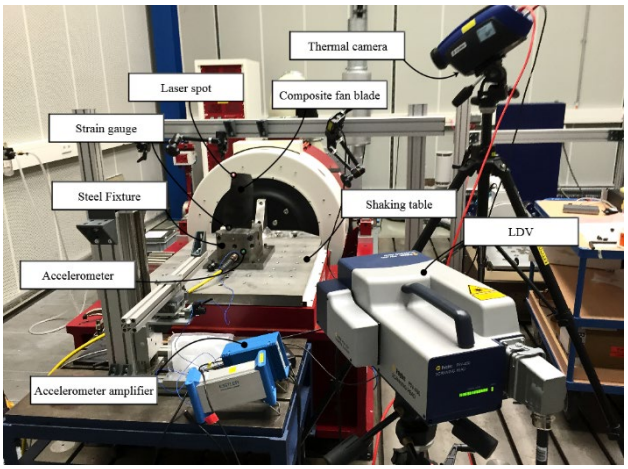

Figure 3: Blade test set up.

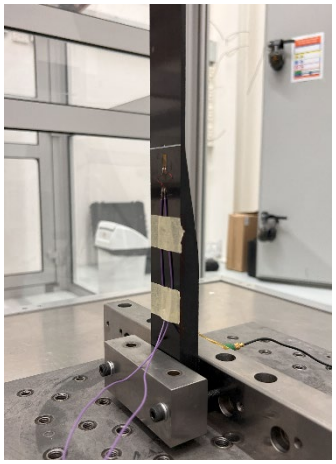

Figure 4: Close-up of the test setup with strain gauge.

Figure 5: DST aero demonstrator test set up.

Although the two experiments were conducted in different years, the modus operandi remains the same. The setup can be adapted to what the test facility can provide, as long as it can be realised as described in Figure 1. XCTE technology enables the setup, performance, and analysis of fatigue test data in hours rather than days.

The following section presents the experimental test data and how the test data from the second experiment are used to evaluate a global master curve of fatigue onset damage growth. It is worth mentioning that the first experiment could be executed using only one fan blade; hence, it was a single shot that could not be missed. The second experiment could be executed using three aero demonstrators, which allowed verifying the repeatability of the results across the three test structures. The comparison between the first and second experiments is not presented in this paper.

3 EXPERIMENTAL RESULTS

This section will present the experimental results obtained from the two experiments. It is worth explaining briefly hereafter why and what the objectives of the experiments were.

The first experiment of the composite blade had two objectives. The first objective was to prove that the fatigue behaviour observed from cross-ply laminate embedding ply drops [2,3,4] at the University of Bristol laboratory was not case-dependent. Hence, similar fatigue behaviours could be observed from scaled fan blades. The second objective was to demonstrate that such a fatigue behaviour could be reproduced and tested in an industrial testing facility.

The second experiment on the DST aero demonstrators also had two objectives. The first objective was to demonstrate that the first experiment on the fan blade was not a fortunate test case, but rather one that could be reproduced years later. The second objective was to evaluate a master curve based on the fatigue onset damage. The second goal was achieved due to the availability of three test structures and the novel testing technique used to obtain the master curve.

3.1 Calibration base acceleration, strain and displacement

Once the frequency check is executed to identify the target resonance, the calibration between the input base acceleration and the output strain and displacement responses is performed using a simple stepped sine test. The procedure consists of exciting under steady-state conditions a frequency near the resonance peak for multiple acceleration amplitude levels. The nought-to-peak of the vibration signals measured from each sensor is processed. Figure 6 shows the relationship between strain and displacement obtained from the fan blade calibration exercise. A linear relationship can be observed. However, a nonlinear behaviour might appear if the strain vs base acceleration or displacement vs base acceleration is plotted. Therefore, the calibration performed for the aero demonstrator retained the use of the three signals, rather than the two used for the fan blade.

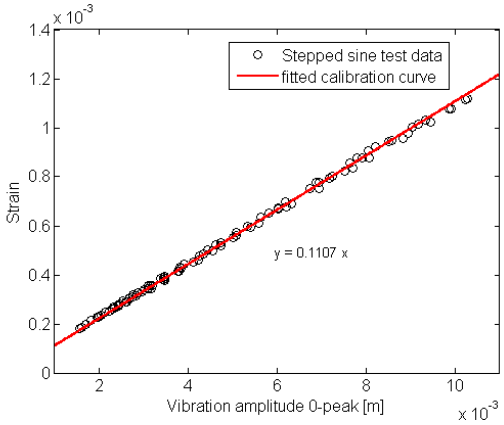

Figure 6: Fan blade strain-displacement calibration.

Figure 7 shows the relationship between the input base acceleration and the output strain for the aero demonstrator. The calibration was performed up to 5 (g) to avoid overloading the test structure. However, it is visible that nonlinear behaviour, which is extrapolated up to 15 (g), where the fatigue behaviour is expected to develop. The nonlinear behaviour is expected because of the large deformation achieved under steady-state vibrations. It is essential to perform this experimental characterisation to avoid setting up incorrect vibration amplitudes during the HCF tests.

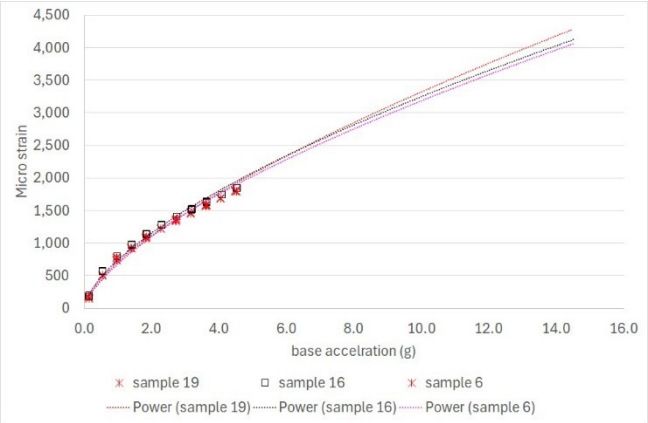

Figure 6: Aero demonstrator strain - base acceleration calibration.

3.2 Test results

This section describes the HCF test data obtained from the fan blade and the aero demonstrator. The type of HCF test is displacement control, which involves using a single excitation frequency and vibrating the target point at a constant amplitude throughout the entire duration of the HCF trial. This procedure is also applied to the aero demonstrator, using a slightly different approach, which will be described later.

The first test results presented are from the fan blade. As previously introduced, the expectation was to observe similar fatigue behaviour already observed with small coupons tested in a university laboratory. The results of the HCF test demonstrated that the experimental procedure was valid for both small coupons and scaled fan blades, thereby meeting the objectives. Figure 7 shows a plot that reproduces three curves: the frequency response phase, the base acceleration, and the surface peak temperature. It is essential to note the correlation between phase decay and the increase in acceleration. This occurs because the mechanical system loses stiffness due to fatigue, and thus, fatigue damage is initiated by the combined mechanical and thermal loads. Both the phase and the acceleration have a specular behaviour. At the same time, the surface peak temperature follows a trend similar to the

acceleration towards the end when a temperature hot spot develops. Figure 8 shows two pictures from the IR camera at two different time instants, when the surface peak temperature reveals a stress concentration (point a) in Figure 7) and when the temperature hot spot is fully developed (point b) in Figure 7).

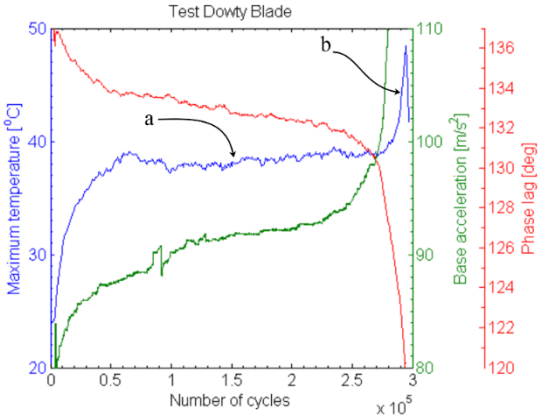

Figure 7: Frequency response phase, base acceleration and surface temperatures of the fan blade.

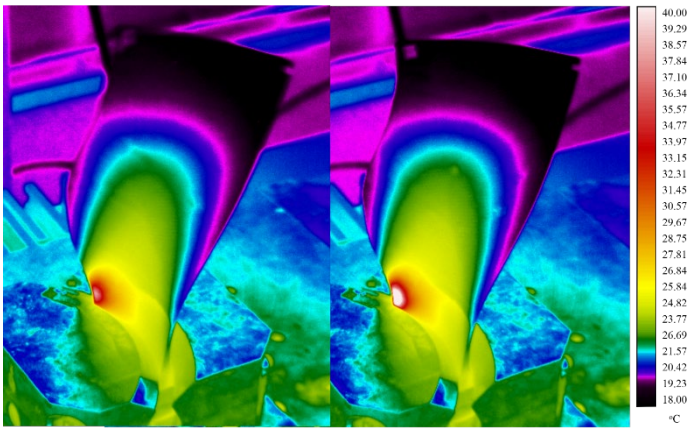

Figure 8: Surface temperature profile in point a) and b) of figure 7.

The main difference with the test carried out with the aero demonstrator was (i) to perform two HCF tests increasing the amplitudes every *N* number of cycles, instead of running a single amplitude, and (ii) to perform one HFC test at a higher amplitude than the previous two HCF tests. The latter goal was to demonstrate that one test structure was sufficient to extract a master curve capable of predicting the results of a different HCF test conducted using a new test structure.

Therefore, one aero demonstrator was tested at a very low amplitude of vibrations, which were incremented every 100,000 cycles. The test was interrupted every 100k cycles to perform nonlinear modal testing. The motivation of that modal test was to observe the change of the nonlinear dynamic response as a function of the increased fatigue behaviour. The modal test was conducted using the last HCF amplitude and was carried out quickly to minimise excessive exposure to dynamic loads. At the end of each HCF test, the frequency response phase, acceleration and surface temperature were stored for analysis. These test sequences were executed for two of the three test structures; the last one was tested to HCF using a single amplitude, which was higher than the one set up for the other two demonstrators.

The HCF test data stored from the first test structure were processed into a master curve based on the onset of fatigue damage. To achieve this, the frequency response phase curves were processed using a specific data analysis toolset to extract the loss of stiffness per unit cycle, described as $d\Phi/dN$, as a function of the input base acceleration. The same procedure was applied to the single frequency response phase curves obtained from the HCF test and plotted on the graph. Figure 9 shows the power law curve extracted from the aero demonstrator tested at several amplitudes, along with a single data point from the other test structure. The single data point (in blue) in Figure 9 lies not far off the power law curve.

Finally, Figure 10 shows the infrared image of the test structure with a fully developed temperature hot spot caused by fatigue delamination.

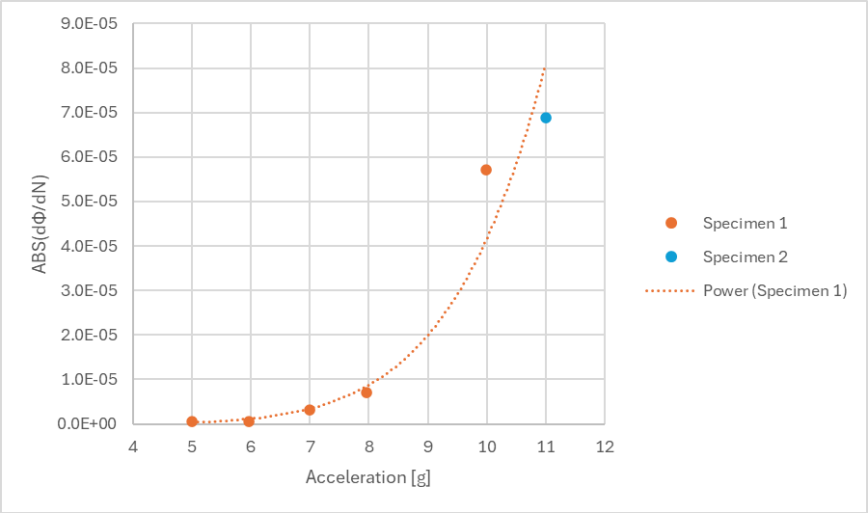

Figure 9: Master curve of the fatigue damage onset generated by specimen 1.

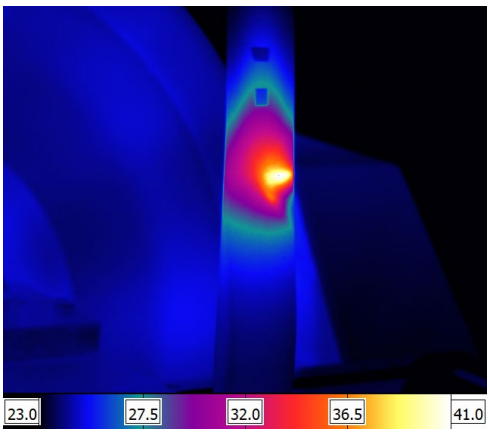

Figure 10: Infrared picture of specimen 1 with developed temperature hot spot.

There are many positive outcomes from this experimental campaign in NLR. The experimental procedure is repeatable and robust. Experiments conducted in two different environments and with two additional test structures indicate that the method for tracking the loss of stiffness is valid regardless of the geometry and material properties. Moreover, the experiments using the aero demonstrator show what was not possible with the fan blade. A single test structure can be used to evaluate a power law function that describes the loss of stiffness per unit excitation cycle as a function of the input load. In this example, the base acceleration was used instead of the strain load; however, the calibration curve allows the references to be interchangeable. Ultimately, the XCTE team had 60 hours to perform the HCF tests with three aero demonstrators in NLR. Despite the self-heating condition, which affected the residual life, the results showed that the fatigue behaviour of the aero demonstrator is a matter of hours rather than days. Finally, any analyst can commission such an experimental test to verify if the design choice delivers the expected durability or not.

4 CONCLUSIONS

This short paper presents some new developments in the area of accelerated fatigue testing developed by XCTE, as part of the D-STANDART EU Horizon project. The testing technology proved to be robust and adaptable to different laboratory environments. Two test cases were presented in the paper; one was an experiment on a composite fan blade conducted in 2015 at a facility in Berlin, and the other was a more recent experiment on an aero demonstrator. The first experiment shows the type of testing setup

and test data generated during an HCF test. The second experiment shows how the HCF test data can be converted into a power law describing the loss of stiffness as a function of the input base acceleration. The scientific value is auspicious because one test structure is sufficient to evaluate a power law describing the fatigue behaviour. The scientific impact will enable engineers to utilise XCTE testing technology to probe structures and assess the most robust design. Moreover, the effectiveness of the proposed HCF tests is demonstrated by their time-saving and potentially cost-saving benefits. The second experiment was conducted over a 60-hour time frame, which is considerably shorter than the standard mechanical tests executed at low excitation cycle rates. Hence, engineers will be able to probe their design optimisations in a very short time. The time savings will enable optimal optimisation towards the standard route of validation and verification.

Keywords: Composite Modeling, Mesoscale Simulation, Fiber Kinking, Matrix Cracking, Discrete Modeling

ABSTRACT

Fiber-reinforced composites have become integral to lightweight structural applications across aerospace, automotive, and renewable energy sectors. Accurately simulating their mechanical response remains a formidable challenge due to the intricate damage mechanisms governed by micro- and mesostructural features. This paper presents the Discrete Model for Composites (DM4C), a physics-based mesoscale simulation framework that explicitly represents fibers and matrix interactions. By modeling fibers as Timoshenko beams and employing vectorial traction-separation and frictional laws on facet surfaces derived from tetrahedral meshes, DM4C eliminates the need for artificial softening in compression or element erosion. The model is benchmarked against experimental data for IM7/977-3 and demonstrates strong predictive capability across various loading conditions, including longitudinal and transverse loading, as well as off-axis tension.

1 INTRODUCTION

Composite materials offer high specific strength and stiffness and are increasingly applied in mission-critical structures [1,2]. Despite their advantages, predicting their failure remains challenging due to their anisotropy and heterogeneous damage evolution. Traditional continuum-based homogenized models often misrepresent the underlying physical mechanisms, relying heavily on empirical calibration and complex constitutive forms. These models struggle to reproduce essential failure modes like fiber kinking or matrix-dominated microcracking.

To overcome these challenges, the Discrete Model for Composites (DM4C) has been developed as a physics-driven, mesoscale simulation tool [3-5]. In this formulation, DM4C represents fibers explicitly using Timoshenko beam elements, while matrix behavior is captured by discrete constitutive laws defined on interfacial facets of a tetrahedral mesh. This facet-based formulation facilitates a direct simulation of fracture and delamination without relying on damage heuristics or eroding elements, enabling high-fidelity prediction of complex failure phenomena.

2 MESOSCALE MODELING FRAMEWORK

In DM4C, laminate generation starts from the mesoscale. As Figure 1 shows, fibers or bundles of fibers are modeled as Timoshenko beams, offering rotational degrees of freedom and capturing bending and shear deformations. Then, a Delaunay tetrahedralization is performed to connect the nodes of each beam. The result is the three-dimensional tet mesh shown in Figure 1b. After the tets are generated, Voronoi tessellation is used to identify surfaces, called “facets”, that are orthogonal to each edge of the tets. This way, each fiber is surrounded by a set of facets that are orthogonal to the edge

connecting the beam nodes. An orthonormal coordinate system can be defined on each facet. This enables the definition of normal and shear strains and normal and shear stresses through the constitutive laws. Hence, the constitutive behavior of the matrix connecting the fibers becomes vectorial instead of tensorial. This makes it easy compared to tensorial model to simulate phenomena such as cohesive failure or friction which are very important mechanisms for polymer composites which is one of the main advantages of the microplane model developed by Bažant and collaborators for the modelling of complex damage and fracture mechanisms in quasibrittle materials [6-10].

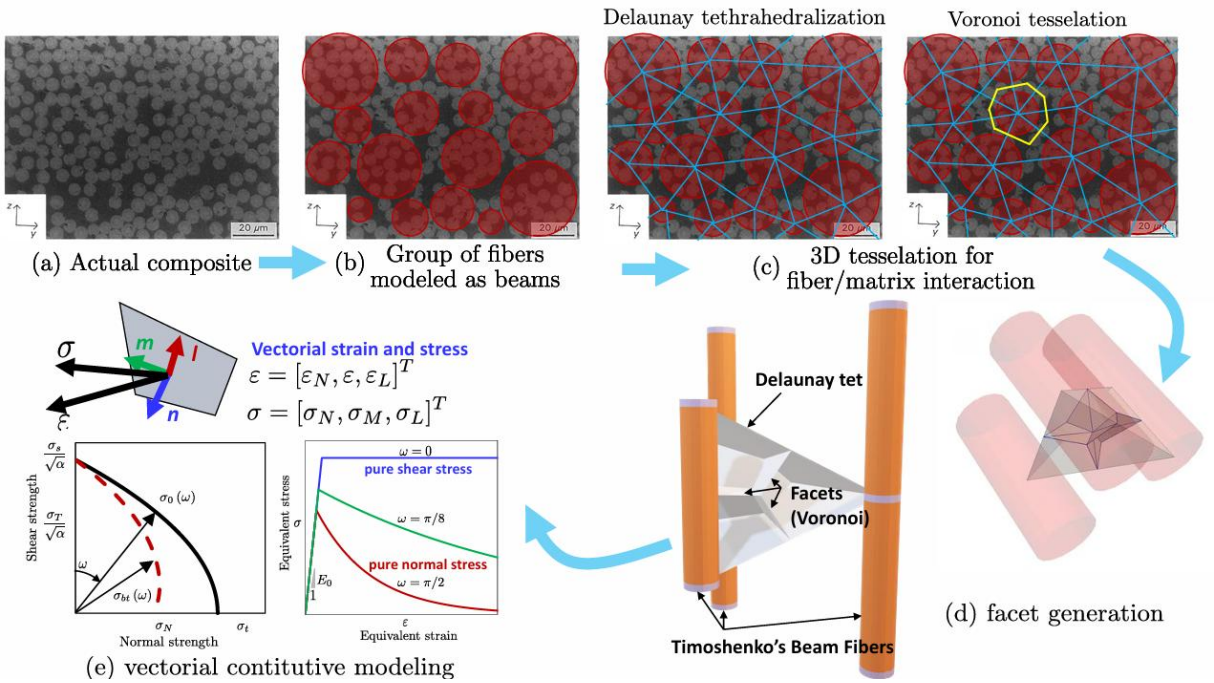

Figure 1: Schematic representation of the DM4C framework for the description of fibers and matrix in fiber composites.

In a tetrahedral element, each facet divides the domain into four subregions, with each subregion containing one of the element's nodes. At every node:
- Three edges converge.
- Each edge is shared by two associated facets.

Within each subregion, a kinematic relation is defined. These local kinematic relations allow for the computation of strain vectors corresponding to the facets of the tetrahedral element.

The displacement field $u(x)$ inside each element is defined following the kinematic relation of nodes as follows:

$$u(x) = u_i + \theta_i \times (x - x_i) = A_i(x) Q_i \tag{1}$$

where:

$$\boldsymbol{A_i(x)} = \begin{bmatrix} 1 & 0 & 0 & 0 & x_3 - x_{3i} & x_{2i} - x_3 \\ 0 & 1 & 0 & x_{3i} - x_3 & 0 & x_1 - x_{1i} \\ 0 & 0 & 1 & x_2 - x_{2i} & x_{1i} - x_1 & 0 \end{bmatrix} \tag{2}$$

The vector $\boldsymbol{x}$ is the Cartesian coordinate inside the element, and the vector $\boldsymbol{x_i}$ represents the coordinate of node *i*. The vector $Q_i^T = [\, u_i^T,\ \theta_i^T \,]$ is the ordered pair of the vector $u_i^T = [\, u_{1i},\ u_{2i},\ u_{3i} \,]$ and the vector $\theta_i^T = [\, \theta_{1i},\ \theta_{2i},\ \theta_{3i} \,]$ which are the translational and rotational degrees of freedom of node *i*.

Stress and strain vectors are defined at individual facets formulated from a Voronoi tessellation process in the tetrahedral mesh as described in the Lattice Discrete Particle Model (LDPM) [13, 14]. The strain components in each projected facet are computed leveraging the following equations:

$$\varepsilon_{Nk} = B_N^{jk}\boldsymbol{Q}_j - B_N^{ik}\boldsymbol{Q}_i \tag{3}$$

$$\varepsilon_{Mk} = \boldsymbol{B}_M^{jk}\boldsymbol{Q}_j - \boldsymbol{B}_M^{ik}\boldsymbol{Q}_i \tag{4}$$

$$\varepsilon_{Lk} = \boldsymbol{B}_L^{jk}\boldsymbol{Q}_j - \boldsymbol{B}_L^{ik}\boldsymbol{Q}_i \tag{5}$$

Once the stress vector for each facet is obtained through the constitutive relation, the nodal forces can be computed via the Principle of Virtual Work (PVW), which imposes that the total external work applied should be identical to the sum of internal work from all the facets. This leads to the following equation defining the internal energy associated with the facet *k*:

$$\boldsymbol{\delta}W_k = \ell_k A_k \sigma_k^T \delta\varepsilon_k = \ell_k A_k(\sigma_{Nk}\delta\varepsilon_{Nk} + \sigma_{Mk}\delta\varepsilon_{Mk} + \sigma_{Lk}\delta\varepsilon_{Lk}) \tag{6}$$

where A_k is the area of a projected facet *k*.

By substituting the relations between strain components and the nodal degrees of freedom to Eq. (6), the nodal force vectors, $\mathrm{F_{ik}}$ and $\mathrm{F_{ik}^T}$, for nodes *i* and *j* associated to the facet *k* can be computed as follows:

$$\boldsymbol{\delta}W_k = \boldsymbol{F}_{ik}^T\boldsymbol{\delta Q}_i + \boldsymbol{F}_{jk}^T\boldsymbol{\delta Q}_j, \text{ where} \tag{7}$$

$$\boldsymbol{F}_{ik}^T = -\ell_k A_k\left(\sigma_{Nk}\boldsymbol{B}_N^{ik} + \sigma_{Mk}\boldsymbol{B}_M^{ik} + \sigma_{Lk}\boldsymbol{B}_L^{ik}\right) \tag{8}$$

$$\boldsymbol{F}_{jk}^T = \ell_k A_k\left(\sigma_{Nk}\boldsymbol{B}_N^{jk} + \sigma_{Mk}\boldsymbol{B}_M^{jk} + \sigma_{Lk}\boldsymbol{B}_L^{jk}\right) \tag{9}$$

2.1 Fiber Constitutive Law

In DM4C, fibers, groups of fibers, and tows are explicitly represented as Timoshenko beam elements; therefore, the constitutive law is described in the integration points of a beam element.

The axial stresses are evaluated at the integration points in the cross-section of a beam element. In the elastic regime, the axial stress is linearly proportional to the axial strain as follows:

$$\sigma_f = E_f\varepsilon_f \tag{10}$$

where $\mathrm{E_f}$ is the parameter associated to the modulus of the fiber bundle and is calibrated to match the longitudinal modulus of a composite material.

When the axial stress reaches the strength limit σ_c it follows a linear softening as defined by the following equation:

$$\sigma_f(\delta) = \max\left[0, \sigma_c\left(1 - \frac{\delta-\delta_c}{\delta_f-\delta_c}\right)\right] \tag{11}$$

where δ is the elongation of a beam element, $\delta_c = \sigma_c\, L_0 / E_f$, with L_0 being the length of the beam element, is the elastic limit displacement which determines the initiation of the linear softening. Complete failure occurs when the elongation of the beam element becomes greater of $\delta_f = (2\, G_f)/\sigma_c$ where G_f is the fracture energy of fibers. In such a case, the axial stress calculated via Eq. (11) becomes zero.

2.1 Matrix Constitutive Law

The constitutive behavior of the matrix is defined at the facet level via vectorial stress-strain relationships. The equations for the elastic and inelastic behaviors are described in the following sections.

Elastic Behavior

The elastic relation for each component of strain and stress vectors resembles the Hooke's law in one-dimension:

$$\sigma_N = E_0 \varepsilon_N \tag{12}$$

$$\sigma_M = \alpha E_0 \varepsilon_M \tag{13}$$

$$\sigma_L = \alpha E_0 \varepsilon_L \tag{14}$$

where E_0 is effective mesoscale normal modulus, and α is a shear-normal coupling parameter. E_0 and α are the DM4C-matrix properties defined at the facet level that are calibrated to match the macroscopic elastic properties of a composite material in the transverse direction which is dominated by the properties of the matrix.

Tensile failure

When a facet deforms under positive normal strain, fracturing behavior determines the softening of the stress components. This behavior is characterized with the effect strain, ε, and the effective stress, σ, as defined in the following equations:

$$\varepsilon = \sqrt{\varepsilon_N^2 + \alpha(\varepsilon_M^2 + \varepsilon_L^2)} \tag{15}$$

$$\sigma = \sqrt{\sigma_N^2 + (\sigma_M^2 + \sigma_L^2)/\alpha} \tag{16}$$

The effective stress incrementally increases proportionally to the effective strain until it reaches the tensile boundary σ_{bt}. As expressed in Eq. (17), the tensile boundary σ_{bt} has an exponential relationship with the normal-shear ratio variable ω and the history-dependent maximum effective strain ε_{max} following the Macaulay's notion: $< x >= \max(x, 0)$:

$$\sigma_{bt}(\varepsilon, \omega) = \sigma_0(\omega) \exp\left(-H_0(\omega) \frac{<\varepsilon_{max} - \varepsilon_0(\omega)>}{\sigma_0(\omega)}\right) \tag{17}$$

The normal-shear ratio variable ω is computed as

$$\tan\omega = \frac{\varepsilon_N}{\sqrt{\alpha}\varepsilon_T} \tag{18}$$

where $\varepsilon_T = \sqrt{\varepsilon_M^2 + \varepsilon_L^2}$. This variable indicates the degree of interaction between shear and normal load in a facet.

In Eq. (17), $\sigma_0(\omega)$ represents the strength limit of the effective stress and expressed as:

$$\sigma_0(\omega) = \sigma_t \frac{-\sin(\omega) + \sqrt{\sin^2(\omega) + 4\alpha\cos^2(\omega)/r_{st}^2}}{2\alpha\cos^2(\omega)/r_{st}^2} \tag{19}$$

where $r_{st} = \sigma_s/\sigma_t$ is the ratio between the shear strength σ_s and the tensile strength σ_t. The elastic limit $\varepsilon_0(\omega)$ is obtained by $\sigma_0(\omega)/E_0$.

The rate of decay of the tensile boundary $H_0(\omega)$ is also dependent on ω and is defined as:

$$H_0(\omega) = H_t \left(\frac{2\omega}{\pi}\right)^{n_t} \tag{20}$$

where $H_t = 2E_0/(l_t/l - 1)$ and $l_t = 2E_0G_t/\sigma_t^2$. G_t is associated to the fracture energy of the matrix, and l is the edge length of the tetrahedron element related to the facet in the evaluation.

Frictional behavior

Facets with compressive normal stress exhibit frictional behavior which increases the shear strength. The effective shear stress:

$$\sigma_T = \sqrt{\sigma_M^2 + \sigma_L^2} \tag{21}$$

increases incrementally until it reaches the shear boundary σ_{bs} defined as follows:

$$\sigma_{bs} = \sigma_s + \alpha(\mu_0 - \mu_\infty)\sigma_{N0} - \alpha\mu_\infty\sigma_N - \alpha(\mu_0 - \mu_\infty)\sigma_{N0}\exp\left(\frac{\sigma_N}{\sigma_{N0}}\right) \tag{22}$$

where σ_s is the shear strength of a facet under pure shear loading condition, and σ_{N0} is the parameter related to the σ_N at which the initial friction coefficient μ_0 transitions to the asymptotic friction coefficient μ_∞.

Property	Value
Fiber strength limit, σ_c, (MPa)	4850
Fiber fracture energy, G_f, (N/m)	65000
Normal modulus, E_0, (MPa)	10570
Shear-normal coupling, α	0.25
Matrix tensile strength, σ_t, (MPa)	50.0
Matrix shear strength, σ_s, (MPa)	45.0
Tensile Characteristic Length, ℓ_t, (mm)	5
Softening exponent, n_t	0.3
Initial friction coefficient, μ_0	0.36
Asymptotic friction coefficient, μ_∞	0.36
Transitional stress, σ_{N0}, (MPa)	500
Compressive yielding strength, σ_{c0}, (MPa)	500
Initial hardening modulus ratio, H_{c0}/E_0	0.5
Transitional strain ratio, $\varepsilon_{c1}/\varepsilon_{c0}$	10.0
Deviatoric strain threshold ratio, κ_{c1}	1.0
Deviatoric damage parameter, κ_{c2}	5.0

Table 1: DM4C parameters calibrated for IM7/977-3

3 CALIBRATION

The DM4C formulation was calibrated against experimental results on IM7/977-3 provided by Clay and Knoth [11]. The whole gauge area of the specimen for each test was modeled using DM4C framework. To resemble the boundary conditions of the experiments, the nodes at the bottom surface were fixed in both translational and rotational degrees of freedom, and the nodes at the top surface were fixed in lateral direction so that the axial displacement is only allowed as a loading condition.

For the modeling of the gauge region, circular ``super fibers" with a diameter of 100 μm were generated and distributed in a rectangular cross-section reaching approximately 60% of fiber volume fraction. The resulting calibrated DM4C parameters are listed in Table 1.

4 RESULTS

In this section, a comparison study between the DM4C simulation results and experimental data is presented.

4.1 Longitudinal Tension

The nominal stress-strain response from the simulation is shown in fig. 2(a). As a calibration result, the longitudinal tensile strength from DM4C model is in good agreement with the experimental data.

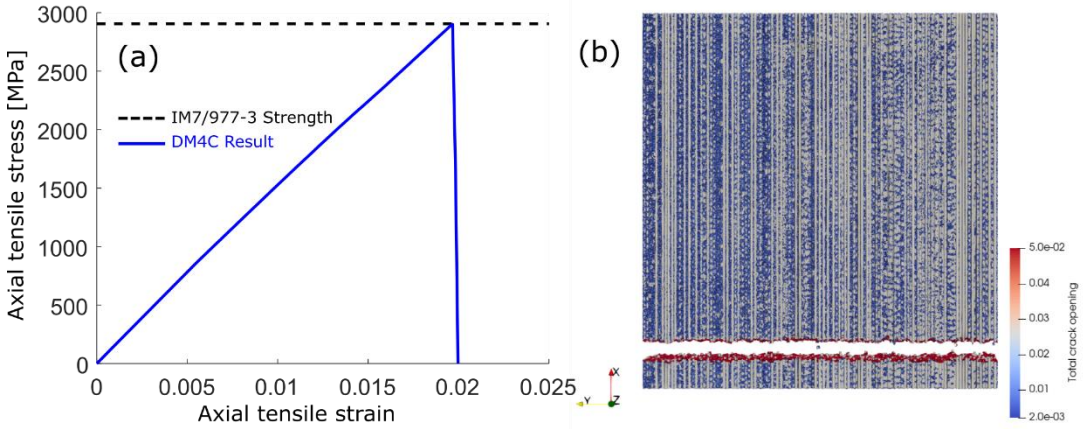

Figure 2. Longitudinal tension: (a) stress-strain curve, (b) damage morphology predicted by DM4C

In the DM4C simulation, fiber failure is the dominant mode of failure leading to the load drop under the tensile load in longitudinal direction as shown in fig. 2(b).

4.2 Longitudinal Compression

It is well-known that imperfections in fiber alignment, introduced during the composite manufacturing process, create local regions of elevated shear stress. Under compressive loading conditions, these regions of high shear stress can rapidly approach the matrix yield strength, triggering local instabilities around the fibers. Consequently, this localized reduction in shear stiffness causes fiber buckling and the subsequent formation of fiber kink bands [12].

Within the DM4C framework, artificial softening of fiber beams under compression is not employed. Instead, the primary damage mechanism causing the load drop is the localized instability resulting from a combination of fiber alignment imperfections and matrix plastic deformation. Therefore, accurately modeling these alignment imperfections is critical for calibrating the compressive strength in the longitudinal direction. The mesoscale nature of the DM4C framework allows for an explicit representation of fiber waviness induced during manufacturing.

In this study, fiber imperfection is modeled as a sinusoidal wave $y = a\cos(\pi x/\lambda)$ following Kyriakides et al. [13]. The amplitude and the half wave-length are calibtrated to match the longitudinal compressive strength of IM7/977-3. The calibrated parameters normalized by the super fiber diameter ($d = 100\sim\mu$m) of a fiber are: $a/d = 0.2$ and $\lambda/d = 27$. The slope of the sinusoidal wave characterized by the resultant parameters stays in the slope range observed in Kyriakides et al. [13].

Figure 3(a) presents the nominal stress-strain response derived from the simulations. The results demonstrate that the longitudinal compressive strength predicted by the DM4C model aligns closely with the experimental observations.

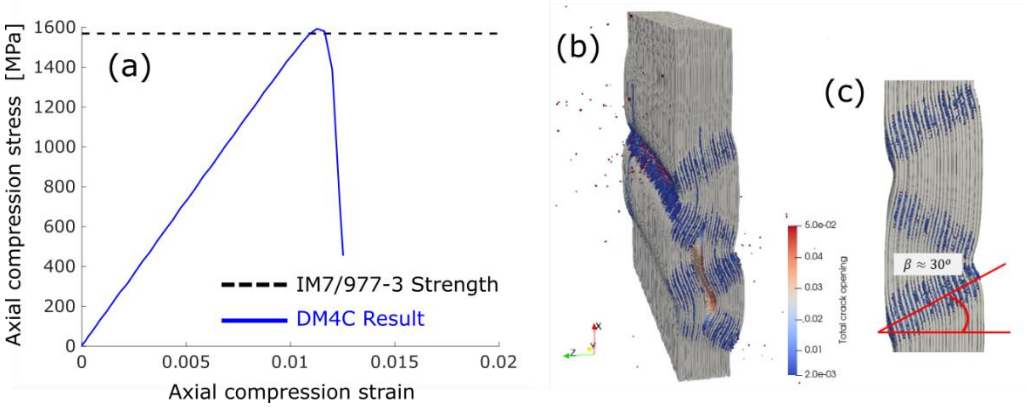

Figure 3. Longitudinal compression: (a) stress-strain curve, (b) damage morphology predicted by DM4C, (c) close up of a kink band.

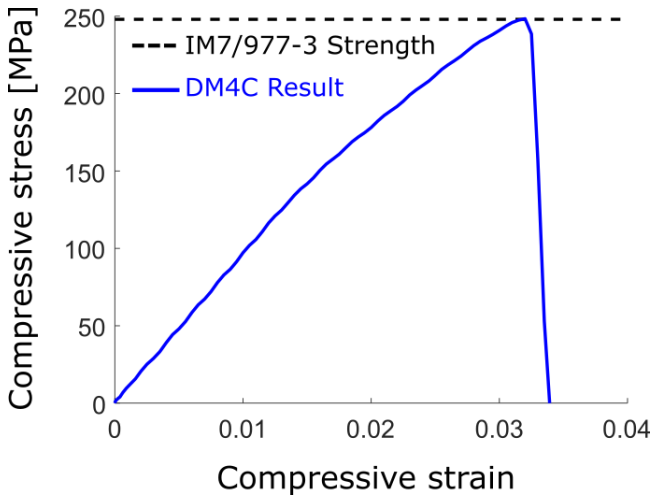

Figure 4. Transverse compression: comparison between experiments and DM4C simulations.

As illustrated in Fig. 3(b), fiber kink bands develop once the nominal stress surpasses the critical threshold. It is also important to highlight that the matrix surrounding the buckled fibers undergoes damage, further reducing local shear stiffness.

The angle of the primary kink band at the onset of load drop was measured, as depicted in Fig. 3(c). Literature indicates that kink band angles typically range between 20 and 35 degrees [14]. The kink band morphology predicted by the DM4C model closely matches this experimentally reported range.

4.3 Transverse Compression

For transverse compression loading, the nominal stress-strain response obtained from the simulation is presented in Fig. 4. The calibrated transverse compressive strength predicted by the DM4C model demonstrates good agreement with the experimental data.

Within the DM4C simulations, shear band formation emerges as the primary failure mode, leading to load drop under transverse compression. The applied boundary conditions simulate a clamped scenario, permitting only axial displacement.

Unconfined compression tests (UCT) are commonly utilized to study matrix cracking under transverse compression. Previous studies [15,16] report the crack plane angles under transverse compression to typically range between 50 and 60 degrees. Figure 5 illustrates the resultant crack plane angle as predicted by DM4C, which closely aligns with the experimentally observed range reported in the literature [15,16].

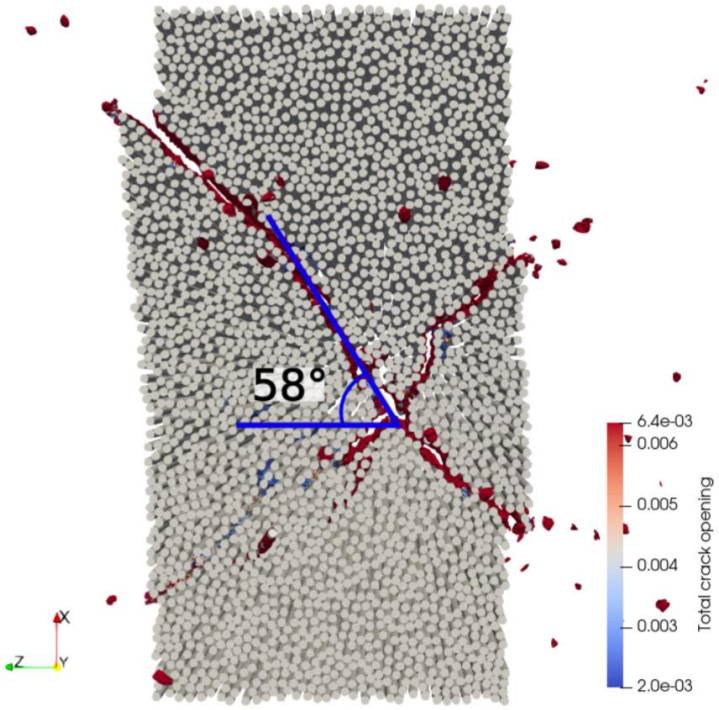

Figure 5. Transverse compression: damage morphology predicted by DM4C.

5 CONCLUSIONS

This work presented an innovative discrete modeling framework designed to accurately capture the mechanical behavior of fiber-reinforced composites. Through detailed comparisons with experimental results, our mesoscale simulations demonstrate the significant advantages of explicitly modeling fibers and matrix constituents. This explicit representation ensures that material parameters within the constitutive laws possess clear physical interpretations, simplifying calibration to match both elastic and strength characteristics of advanced composite materials like IM7/977-3. Moreover, the mesoscale approach excels at simulating complex and critical damage phenomena, including matrix micro-cracking induced by local shear stresses and fiber kink band formation resulting from fiber buckling. This modeling capability opens exciting possibilities for predicting and understanding composite material behavior under diverse loading conditions with unprecedented accuracy.

ABSTRACT

This paper introduces a damage-mechanics-based fatigue model to simulate fatigue damage accumulation in composite laminates. Unlike typical Paris-law-based models, which assume pre-existing cracks and cannot predict crack initiation, the adopted model by Yashiro and Okabe employs a single constitutive equation covering the entire fatigue process—from initiation to propagation—providing a unified understanding of damage evolution. Originally developed for single-mode loading, the model is extended here to mixed-mode conditions using a new interpolation function. Mixed-mode fatigue parameters are derived from calibrated pure-mode parameters. The study involves two main stages. First, finite element calibration is performed using standard fatigue delamination onset tests, including double cantilever beam and end-notched flexure specimens. Unlike conventional approaches focused solely on propagation data, this work establishes a link between the damage-mechanics-based model and the Paris law, validating the model across both initiation and propagation phases. Simulation results align well with experimental ranges, and the model's propagation trend corresponds with the slope of the Paris law, confirming the reliability of the calibrated pure-mode parameters. In the second stage, the extended model is applied to mixed-mode fatigue using mixed-mode bending tests. Simulations are conducted to derive G-N curves across various mode mixities. The predicted fatigue behavior shows strong agreement with experimental data, with less than 6.86% deviation in the fitted G-N curve parameters. These results validate the proposed mixed-mode formulation. Overall, this study demonstrates the capability of the extended Yashiro-Okabe model to predict fatigue crack initiation and propagation under mixed-mode loading. The proposed method offers a convenient and reliable framework for simulating delamination fatigue in composite laminates across all crack growth phases.

1 INTRODUCTION

Carbon fiber reinforced plastic (CFRP) materials, renowned for their remarkable structural integrity and lightweight properties, have seen an increasing prevalence in aerospace applications. Despite offering superior strength compared to conventional metallic materials, the assessment of their fatigue life has become a crucial concern, given their growing usage in long-term service applications. Previous

research [1] indicates that damage patterns at stresses below the static strength significantly differ from those at static failure loads. Nevertheless, due to the intricate nature of composite materials and fatigue behaviors, characterizing fatigue evolution in CFRPs remains a relatively underdeveloped field [2, 3]. Given that no fatigue accumulation model can encompass all factors, the numerical method for assessing fatigue accumulation in composite structures remains a challenging topic. The primary aim of this paper is to introduce a numerical framework for investigating the intricate mechanisms of fatigue accumulation in CFRPs.

In order to account for the discontinuous feature of material fracture, the cohesive zone model (CZM) has emerged as a popular approach for evaluating damage in structures with plastic properties. Dugdale [4] and Barenblatt [5] laid the foundational concepts of CZM, describing the yielding behavior of stresses around the crack tip. Based on the notion of yielding stress, Hillerborg et al. [6] introduced a traction-displacement relationship for fracture energy within the cohesive zone. Numerous constitutive equations for CZM have been developed [7, 8]. In this paper, Geubelle and Taylor's model [7] is adopted as the damage model for CFRP structures, as further detailed in the subsequent section.

Concerning the prediction of fatigue damage, fatigue accumulation law combined with CZM stands as the primary tool in related research. Generally, fatigue evolution models can be categorized into two primary groups: Paris-law-based and micromechanical models. The Paris law [9], originally proposed for metallic fatigue, has proven to be suitable for predicting fatigue crack growth in FRP ma-terials [10, 11]. Several studies [12–14] have developed modified versions of the Paris law to predict damage evolution under cyclic loading, incorporating cohesive elements. However, Paris-law-based methods cannot predict crack initiation and necessitate additional initiation criteria, as they assume the presence of cracks. Additionally, integrating the Paris law with CZM requires the use of a characteristic length [12–14] to calculate damage accumulation within the damaged area. However, both the characteristic length and mesh size can significantly influence the simulation results. Recognizing the limitations of the Paris law, damage-mechanics-based models have been developed to characterize all phases of fatigue growth. Nojavan et al. [15] introduced a microscopic model considering local states of cohesive stresses and displacement jumps of CZM. Okabe and Yashiro [16] also proposed a damage-mechanics-based fatigue law applicable to delamination and in-ply matrix cracking. An extended model based on Okabe and Yashiro's equation is integrated into the numerical framework presented in this paper.

However, the original model was developed for single-mode loading and does not account for the complexities of mixed-mode loading. In this case, sets of fatigue parameters of different modes needs to be conducted once the loading condition is changed, but implementing mixed mode loading tests is expensive and time-consuming. Considering the inconvenience, obtaining mixed mode parameters from the results of pure mode tests is an important work for establishing an easy-to-use fatigue simulation program. In this study, the fatigue parameters of extended Yashiro-Okabe model are calibrated by delamination onset data. After the FE calibrations, the fatigue propagation simulations are also performed to investigate the fracture behavior after crack initiation. The simulation data is compared to the experimental results in the phase of Paris law. Using simulation results in initiation and propagation, our extended fatigue model can be proved applicable in all phases of fatigue growth.

2 NUMERICAL METHOD

2.1 Numerical Program

The fatigue simulation program in this paper is established upon the work by Nagashima and Sawada [17], as illustrated in Fig. 1. Cohesive elements are employed to simulate delamination on the interfaces. In the quasi-3D program, FE models are established on a 2D-based mesh and subsequently extended into 3D elements along the thickness direction using level set functions. Detailed equations of the numerical framework can be found in [17-19].

2.2 Constitutive Equation of CZM

In this paper, we incorporate Geubelle and Taylor’s model [7] as the constitutive equation for CZM within the numerical program. To assess damage in the cohe-sive zone, a damage variable D is defined

as follows:

$$D = \max\left(D_{\max}, \min\left(1, \sqrt{\left(\frac{\delta_I}{\delta_{IC}}\right)^2 + \left(\frac{\delta_{II}}{\delta_{IIC}}\right)^2}\right)\right) \tag{1}$$

Here, δ_I and δ_{II} represent the relative displacements in mode I and mode II, respectively, and D_{max} signifies the maximum D stored at each integration point. The traction-separation law of CZM can be expressed as:

$$\tau_i = \frac{(1-D)}{D}\frac{\tau_{iC}}{\delta_{iC}}\delta_i \tag{2}$$

In Eq. (2), τ_{iC} and δ_{iC} represent the cohesive strengths and critical relative dis-placements, respectively. The use of the maximum function ensures that D mono-tonically increases and cannot decrease. Once D reaches 1, the integration point on the cohesive element fails and separates, indicating the crack growth.

2.3 Fatigue Accumulation Law

This paper introduces an extended version of the fatigue accumulation law originally proposed by Okabe and Yashiro [16]. In this fatigue model, the damage variable D is treated as a function of the number of loading cycles, N. Consequently, the fatigue accumulation law is expressed in the form of the accumulation rate, dD/dN, as follows:

$$\frac{dD}{dN} = \alpha_m \frac{F^{\beta_m}}{(1-D)^{\gamma_m}} \tag{3}$$

In this equation, α_m, β_m, and γ_m are mixed mode fatigue parameters that are determined through FE calibration using experimental data. Typically, these parameters can only be obtained from mixed mode experiments when using Okabe and Yashiro's model. However, in this study, we propose an interpolation equation for mixed mode loading based on pure mode parameters:

$$\alpha_m = \sqrt{\left(\alpha_I \frac{\delta_I}{\delta_m}\right)^2 + \left(\alpha_{II} \frac{\delta_{II}}{\delta_m}\right)^2} \tag{4}$$

Here, α_I and α_{II} represent α under pure mode I and II, respectively. Using Eq. (4), α_m can be determined using data from pure mode tests, providing a more practical approach to determine the mixed mode parameters. Similarly, β_m and γ_m are calculated in a similar manner as in Eq. (4). In Eq. (3), a dimensionless variable of stress state, F, is introduced for evaluating the states of stresses in cohesive zone:

$$F = \sqrt{\left(\frac{\tau_{Imax}}{\tau_{IC}}\right)^2 + \left(\frac{\tau_{IImax}}{\tau_{IIC}}\right)^2} \tag{5}$$

Here, τ_{Imax} and τ_{IImax} represent the maximum local cohesive stresses in mode I and II, respectively, and they are stored at each integration point. By storing the local stresses and displacements in data arrays, the damage rate of the cohesive zone can be calculated for each computed cycle.

2.4 Cycle jump strategy

To enhance the computational efficiency of fatigue simulations, a cycle jump strategy, adapted from [15, 19], has been incorporated into the numerical framework. The simulation starts at cycle number N = 1, utilizing an implicit static solver. The applied loading on the model is linearly ramped up until reaching the maximum loading. Subsequently, the increment for the next cycle, ΔN, is deter-mined using the following equation:

$$\Delta N = \frac{\Delta D_{max}}{\left(\frac{dD_i}{dN}\right)_{max}} \tag{6}$$

Here, $\left(\frac{dD_i}{dN}\right)_{max}$ represents the maximum $\frac{dD_i}{dN}$ among all integration points in the cohesive elements and XFEM segments. Once ΔN is determined, the array of the damage variable can be updated as follows:

$$D_i = D_{i-1} + \Delta N \left(\frac{dD_i}{dN}\right)_{i-1} \tag{7}$$

As the cycle number increases ($N > 1$), the external loading applied to the simulation model remains constant, forming a load envelope for the core implicit solver of the fatigue numerical program. This updating process is repeated within the fatigue simulation loop until the maximum cycle number is reached.

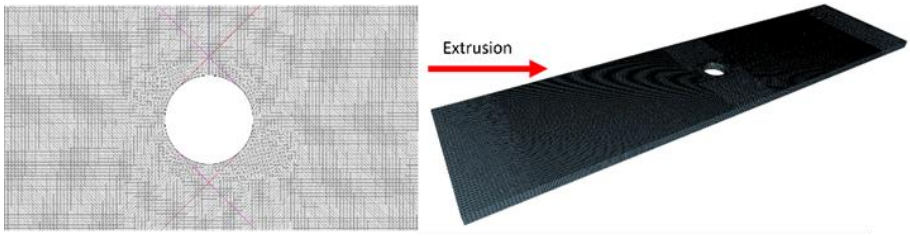

Figure 1: A scheme of modelling and extrusion process for the quasi-3D FE program.

3 NUMERICAL MODELS

To demonstrate the utility of the proposed fatigue accumulation model, we have selected the double cantilever beam (DCB), end-notched flexure (ENF) and mixed mode bending (MMB) tests as the focus of this study. For comparison with simulation results, we utilize the experimental data of fatigue progression in IM7/8552 by Murri [20], O'Brien et al. [21] and Ratcliffe et al. [22]. The numerical analysis can be broken down into the following steps:

1. Calibration of α_I, β_I, and γ_I through the DCB simulation with experimental data.
2. Calibration of α_{II}, β_{II}, and γ_{II} through the ENF simulation with experimental data.
3. Fatigue propagation simulations of DCB and ENF with the calibrated parameters
4. Development of a fatigue OHT model employing the calibrated parameters.

3.1 Calibration of Mode I Fatigue Parameters

Experimental data from the technical report by Murri [20] were introduced for the calibration of mode I parameters. The fatigue double cantilever beam (DCB) test on IM7/8552 was conducted following the ASTM D6115 standard [23]. In this study, fatigue parameters were identified using the G-N curve, which de-scribes the correlation between the maximum energy release rate under fatigue loading and the onset of crack growth cycles. For the finite element (FE) model, an initial static DCB simulation was conducted to determine the maximum dis-placement of the static DCB test. Subsequently, displacements corresponding to various residual percentages were applied for fatigue loading. This approach enabled the determination of the comprehensive G-N curve through FE analysis, and the parameters were established by fitting the simulation data to the experimental curve via a trial-and-error procedure.

The material properties of unidirectional IM7/8552 for the simulations are listed in Table 1. The geometry and boundary conditions of the FE model are depicted in Fig. 2. The fatigue DCB test model exhibited dimensions of 178 mm in length, 25.4 mm in width, 4.5 mm in thickness, and an initial crack length of 50.8 mm. Fig. 3 displays the fatigue simulation data alongside the experimental G-N curve. The solid line represents the curve fitted to the experimental data [20], while the dots represent the simulation results, accompanied by a fitted dotted curve. Through the calibration process, the mode I

parameters were determined, resulting in $\alpha_I = 0.1689$, $\beta_I = \gamma_I = 22.495$.

3.2 Calibration of Mode II Fatigue Parameters

Experimental data from the technical report authored by O'Brien et al. [21] served as the basis for mode II calibration. The fatigue end-notched flexure (ENF) test of IM7/8552 was conducted, incorporating extension from both ASTM D7905 [24] and ASTM D6115 [23], as there is no standardized mode II fatigue test. The methodology for mode II calibration followed the same process as outlined in Section 3.1.

The geometry and boundary conditions of the finite element (FE) model are visualized in Fig. 4. Utilizing the geometric specifications provided in [21], the fatigue ENF test model had dimensions of 101.6 mm in length, 25.0 mm in width, 4.445 mm in thickness, and an initial crack length of 25.4 mm. Fig. 5 presents the fatigue simulation data alongside the experimental G-N curve. The solid line represents the curve fitted to the experimental data [21], while the dots represent the simulation results, accompanied by a fitted dotted curve. Through the calibration process, the mode II parameters were determined, resulting in $\alpha_{II} = 0.11$ and $\beta_{II} = \gamma_{II} = 12.5$.

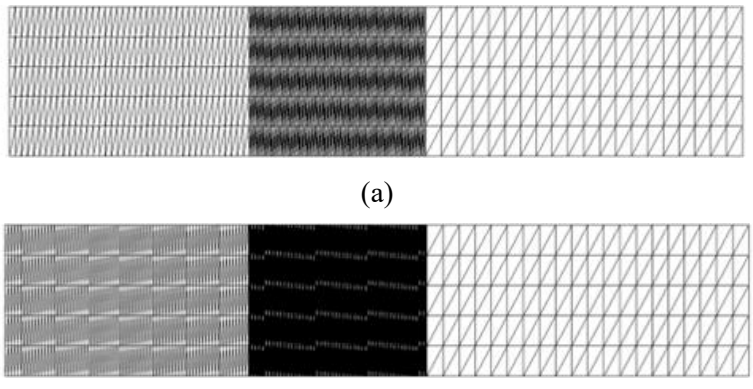
3.3 Mesh sensitivity study



In Section 3.1 and 3.2, the process of calibrating mode I and II fatigue parameters are demonstrated. However, the sensitivity of mesh size to the results of FE calibration is also important. The issue of mesh convergence could result in a huge impact on the fatigue program if the simulation data is highly dependent on the element size. In Section 3.3, simulations are performed with different FE models with different element sizes. Table 2 and 3 listed the element size and number of elements for fatigue DCB and ENF simulation, respectively. In Table 2 and 3, the line with bold text is the original element size utilized in Section 3.3. The 2D views of FE models are also illustrated in Fig. 6 and 7. The G-N curves from fatigue DCB and ENF simulations across all element sizes are depicted in Fig. 8 and 9. These figures demonstrate that the delamination onset curves align with the trend of fitted experimental curves. The variations in onset cycles across different element sizes remain within a narrow range, confirming mesh convergence in the fatigue simulations using the Yashiro-Okabe model.

Element size (mm)	Number of Elements	Number of Solid Elements	Number of cohesive Elements

4 NUMERICAL ANALYSES OF FATIGUE PROPAGATION

Using the fatigue parameters calibrated in Section 3, the simulations of fatigue propagation are performed after the fatigue onset. The curves of fatigue propagation rate relative to the input energy release rate are established. A comparative analysis of numerical results and experimental data is shown in Fig. 10, where the simulation results are represented by a blue line, experimental data by grey dots, and the fitted Paris law curve by a black line. As indicated in Fig. 10, the simulation data fits well within the range of the experimental data, and the trend of the simulation curve closely matches the slope of the fitted Paris law curve. The results depicted in Fig. 10 confirm that the pure mode fatigue parameters calibrated from the initiation tests are effectively applicable in the fatigue propagation phase.

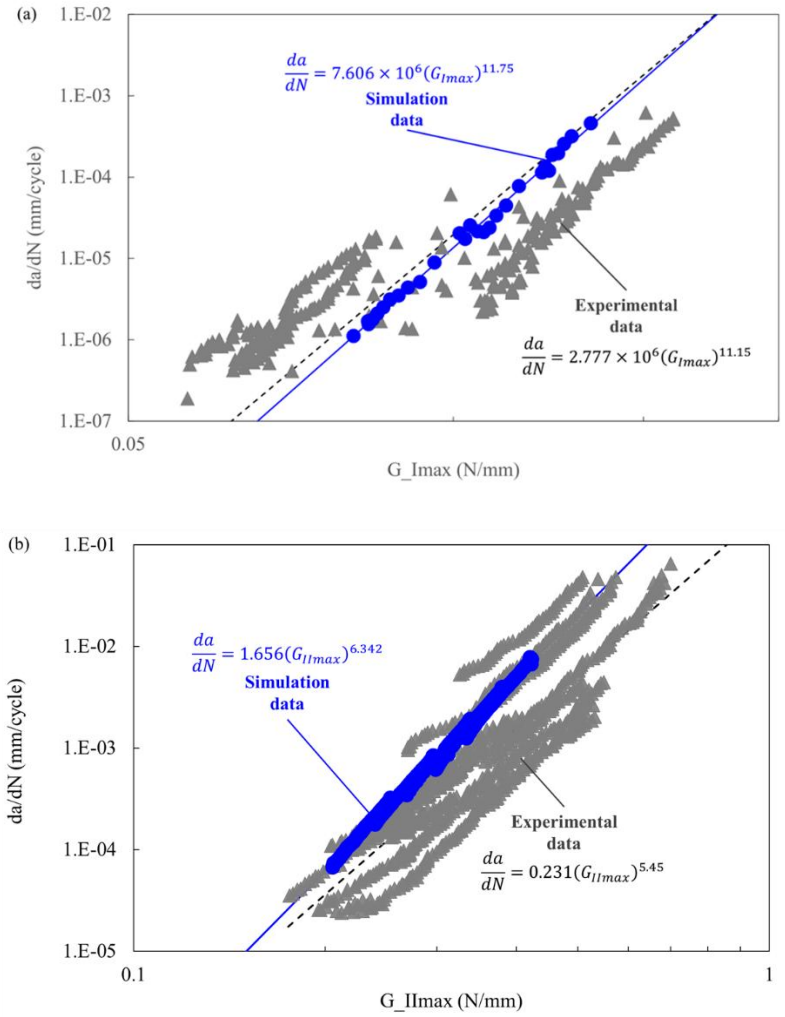

Figure 10: Curve of fatigue propagation rate to the residual energy release rate in (a) fatigue DCB and (b) fatigue ENF test and simulation.

5 VALIDATION OF FATIGUE BEHAVIOR PREDICTION FOR MODE MIXITY

The applicability of the proposed model to crack initiation and propagation under pure modes is validated in Sections 3 and 4. For mixed-mode loading, Eq. (4) is introduced as an extension of Yashiro and Okabe's model [16], and requires validation using experimental mixed-mode data. In this subsection, a finite element model of the fatigue mixed-mode bending (MMB) test is developed to predict fatigue behavior. The numerical results are compared with experimental data reported by Ratcliffe and Johnston

[22]. Simulations are performed at various levels of G_{max}, corresponding to 50%, 40%, 35%, 30%, and 25% of the static critical energy release rate G_C, defined as the sum of G_I and G_{II} at the static critical load.

Following the workflow in Sections 3.1 and 3.2, the compliance of the MMB model is monitored during the simulation to construct the G–N curves. These curves, corresponding to different mixed-mode ratios, are obtained from numerical analysis and compared with the experimental data. The FE model geometry and boundary conditions are shown in Fig. 11. Mixed-mode parameters are calculated at each cycle using the calibrated pure-mode parameters and Eq. (4). The simulation results are presented in Fig. 12, where triangular markers denote numerical results, while circular markers and dashed lines represent experimental data from [22]. As shown, the predicted fatigue life aligns closely with the experimental curves, confirming the validity of the proposed mixed-mode extension.

6 CONCLUSIONS

This paper presents a numerical scheme that combines cohesive elements with a damage-mechanics-based approach to predict fatigue evolution in laminated composites. The proposed framework effectively captures both crack initiation and propagation under cyclic loading. An extended version of the fatigue accumulation law, based on the work of Yashiro and Okabe [16], is implemented within the numerical program. The calibration methodology developed in this study enables the derivation of mixed-mode fatigue parameters from pure mode tests, with a proposed interpolation equation that simplifies the process. This extension facilitates the application of the fatigue CZM to cases involving varying mode mixities.

The numerical scheme is validated against experimental results from DCB, ENF, and MMB tests, showing good agreement with the observed fatigue behavior [20-22]. In summary, this study provides a convenient and reliable approach that leverages a damage-mechanics-based model to simulate progressive fatigue damage in composite laminates.

ABSTRACT

Carbon fiber reinforced plastic (CFRP) is characterized by high specific strength and stiffness, so applying it to structures is expected to reduce weight. Due to its high formability, woven CFRP is used in various structures. Woven CFRP is so complex to make numerical model due to its dense structure, that homogenization methods, whose modeling cost is expensive, have been used for analysis. On the other hand, modeling with orthogonal anisotropy is considered to be simple and potentially effective in strength evaluation. Currently, strength design and evaluation of structures using CFRP is not widespread enough for industrial companies, so strength evaluation is performed by testing using actual structures. Because of the high cost of tests using actual structures, it is necessary to propose a method for evaluating strength by analysis. In this study, twill woven structure is modeled as a superposition of orthogonal anisotropic materials to simplify its modeling, assuming strength evaluation could be based on the knee point, which is the maximum point that can be approximated linearly in bending behavior. On our analysis, knee point is calculated by assuming that the layer in the laminated structure that reached the breaking strength for each direction of the twill woven prepreg is broken. In this study, two types of laminates are prepared using twill woven prepregs, and the specimens are subjected to three-point bending tests and loading tests of semi-cylindrical structures. In addition, finite element analysis is applied to reproduce these tests in order to verify the validity of the strength evaluation. These results indicate that the strength evaluation of twill woven composite structures can be available considering the strength for the weakest direction of CFRP, using orthogonal anisotropy modeling.

1 INTRODUCTION

Carbon fiber reinforced plastic (CFRP) is characterized by high specific strength and stiffness, so applying it to structures is expected to reduce weight [1-2]. Due to its high formability, woven CFRP is used in various structures such as automobiles, aircraft, and wind power generation blades [3-5]. Woven CFRP is so complex to make numerical model due to its dense structure, that homogenization methods, whose modeling cost is expensive, have been used for analysis. On the other hand, modeling with orthogonal anisotropy is considered to be simple and potentially effective in strength evaluation [6-8].

Currently, strength design and evaluation of structures using CFRP is not widespread enough for industrial companies, so strength evaluation is performed by testing using actual structures [9]. Because of the high cost of tests using actual structures, it is necessary to propose a method for evaluating strength by analysis. In this study, twill woven structure is modeled as a superposition of orthogonal anisotropic materials to simplify its modeling, assuming strength evaluation could be based on the knee point, which is the maximum point that can be approximated linearly in bending behavior. On our analysis, knee point is calculated by assuming that the layer in the laminated structure that reached the breaking strength for each direction of the twill woven prepreg is broken. In this study, two types of laminates are prepared using twill woven prepregs, and the specimens are subjected to three-point bending tests and loading tests of semi-cylindrical structures. In general, knee point strength is said to be 50-60% of breaking strength, so strength evaluation on the knee point is considered effective. In addition, finite element analysis is applied to reproduce these tests in order to verify the validity of the strength evaluation. These results indicate that the strength evaluation of twill woven composite structures can be available considering the strength for the weakest direction of CFRP, using orthogonal anisotropy modeling.

2 STRENGTH OF COMPOSITE SHEET

2.1 Preface

In this study, strength evaluation is focused on knee point. Knee point is the maximum point that can be approximated linearly on the stress-strain diagram, as shown in Fig. 1. The knee point is assumed to be caused by the rupture of the weakest layer of the laminated composite. Tensile strength of the composite sheet before laminate forming is experimentally determined as breaking stress, and the strength is evaluated based on this breaking stress.

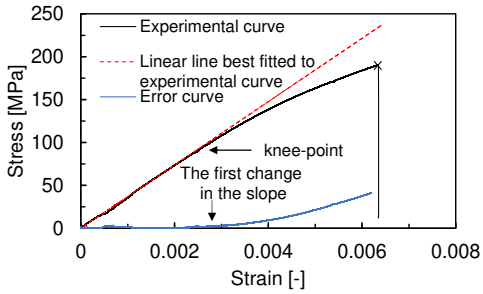

Figure 1: Composite sheet tensile test specimen.

2.2 Tensile test

Twill composite sheet of 0.25 mm thickness is used as the test material. The warp direction of twill structure is set at 0°, and the composite sheet is cut at oblique angles of 0°, 45°, and 90°.
Test specimens are prepared as shown in the Fig. 2 and aluminum tabs are adhered. Strain gauges are attached to the center, and strain measurements are performed using a measuring device. Uniaxial tensile load is applied using Autograph. Stress-strain diagrams from tensile tests of composite sheets are shown in Fig. 3. The results of breaking stress and modulus of elasticity at oblique angles of 0°, 45° and 90° are shown in Fig. 4 and Fig. 5. Both the breaking stress and modulus are lowest in the 45° oblique sheet, where the fibers are not aligned.

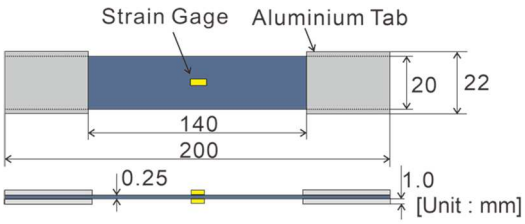

Figure 2: Composite sheet tensile test specimen.

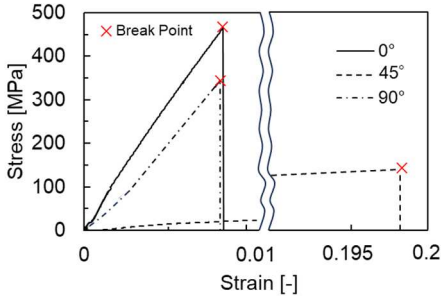

Figure 3: Stress-strain diagram for tensile testing of composite sheets.

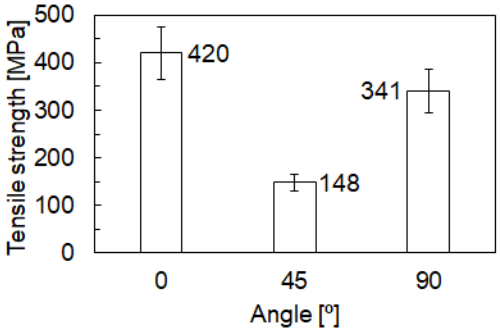

Figure 4: Tensile strength of composite sheets.

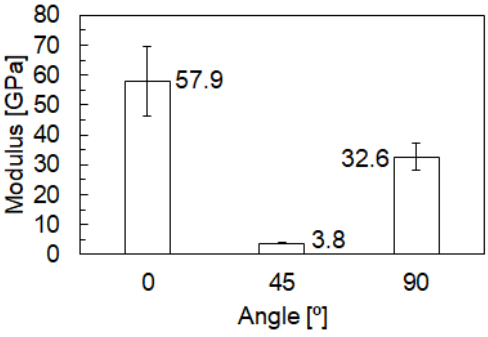

Figure 5: Modulus of composite sheets.

2.3 Tensile Analysis

The composite sheet is treated as an approximated model consisting of a unidirectional V material with only the warp component and a unidirectional H material with only the weft component, superimposed as shown in Fig. 6. The longitudinal modulus of elasticity in the L and T directions of the V material is E_{LV} and E_{TV} ($=\alpha E_{LV}$), and the transverse modulus of elasticity in the LT direction is G_{LTV}, where α is the coefficient of elasticity. Similarly, the coefficients of longitudinal elasticity in the L and T directions for the H material are E_{LH} and E_{TH} ($=\alpha E_{LH}$), and the coefficient of transverse elasticity in the LT direction is G_{LTH}. The elastic properties of the twill weave at angles of 0° and 90° are approximated by the superposition of orthogonal anisotropic materials as shown in Equation (1) below. The value of α is set to 0.032 from literature values, and the Poisson's ratio is also set to the general value of 0.3 from the same paper.

$$E_0=E_{LV}+E_{TH}=E_{LV}+\alpha E_{LH} \qquad (1)$$
$$E_{90}=E_{LH}+E_{TV}=E_{LH}+\alpha E_{LV}$$

The theoretical value of the elastic modulus of the twill woven material is also obtained by superposition of orthogonal anisotropic materials. The modulus of elasticity of the XY coordinate system tilted by an angle θ shown in Fig. 7 from the LT coordinate of the unidirectional material is obtained from equation (2) to (4), and the sum of the V and H materials is used to obtain the modulus of elasticity at that angle. ($\because l = \cos\theta$, $m = \sin\theta$)

$$\frac{1}{E_x}=\frac{1}{E_L}l^4+(\frac{1}{G_{LT}}+\frac{2\nu_{LT}}{E_L})l^2m^2+\frac{1}{E_T}m^4 \qquad (2)$$

$$\frac{1}{E_y}=\frac{1}{E_L}m^4+(\frac{1}{G_{LT}}+\frac{2\nu_{LT}}{E_L})l^2m^2+\frac{1}{E_T}l^4 \qquad (3)$$

$$\frac{1}{G_{xy}}=2(\frac{2}{E_L}+\frac{2}{E_T}+\frac{4\nu_{LT}}{E_L}-\frac{1}{G_{LT}})l^2m^2+\frac{1}{G_{LT}}(l^4+m^4) \qquad (4)$$

The composite sheet is modeled in FEMAP with NX Nastran as shown in Fig. 7. Shell elements are used and divided into 1mm × 1mm rectangular elements. The left end is fully constrained, and the other nodes are free only in the translational XY directions. The load of 1 N is applied to the right end of the model. The physical property values are obtained from Equation 1, and the elastic modulus of the V and H materials are shown in Table 1. Tensile analysis is performed using these physical properties. The distribution of the modulus of elasticity with each angle is shown in Fig. 8. The elastic modulus from the analysis is in qualitative agreement with the theoretical equation. The analytical values are slightly larger than the theoretical values, which may be due to the fact that the V and H materials suppress each other's deformation.

3 STRENGTH OF LAYERED COMPOSITE MATERIAL

3.1 Bending Test

Two types of laminated boards are made by the same composite sheet. Press molding machine (STIP05-05) is used, with molding conditions set at a pressure of 2 MPa, a molding time of 5 minutes, and a molding temperature of 275°C. The laminated board are defined as Type-A $[0°/+45°/-45°/90°]_s$ and Type-B $[+45°/0°/90°/-45°]_s$. Test specimens are cut from the laminated board and three-point bending test is conducted as shown in the Fig. 9. The load-strain diagram obtained from the bending test are shown in the Fig. 10. The knee point loads obtained from the experiments are shown in Table 2. The average load at the knee point was 100 N for Type A and 86 N for Type B.

3.2 Finite element analysis

The specimen shown in the Fig. 11 is modeled using stacked layup in FEMAP with NX Nastran. As shown in Fig. 11, the restraint conditions are as follows: the fulcrum of the 3-point bending test is constrained in the direction of translational Y and rotational X and Z direction, while the rest of the specimen is free, that is, in the translational X and Z directions and in the direction of rotation of the Y-axis.

Unit load (1 N) is applied in the negative direction of the Y-axis in the center of the specimen. In this study, the stress is analyzed by 1° with respect to the fiber direction as shown in Fig. 12 for each layer, and the load at which the composite sheet reached the breaking stress at each angle is considered as the knee-point load. The results of tensile tests are used for the rupture stress, and the rupture stress at other angles is assumed to be correlated with the longitudinal modulus of elasticity, resulting in the distribution shown in the Fig. 13. Stress contour plots of the outermost layers of both types are shown in Fig. 14. For both types, the maximum stress occurred at the loaded portion of the specimen. Therefore, the stress at the center of the loaded portion is evaluated.

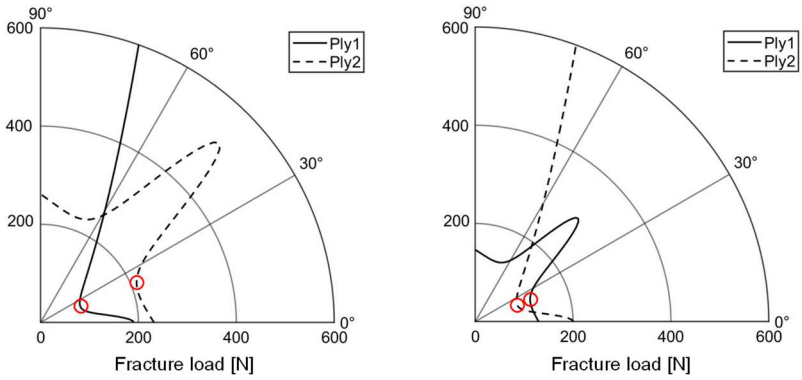
3.3 Strength evaluation



In laminated boards, 22.5° pitch direction, where the fibers are not oriented, is considered to be the weakest and most susceptible to fracture, so the stress in 22.5° direction is evaluated. Tables 3 and 4 show the stress in 22.5° direction occurring in each layer of both types. In both types, the stress occurring in Ply 1 and Ply 2 is higher than that in other Plys. In addition, the maximum stress occurred in the 0° material in both types. In this study, stresses are evaluated in 1° increments, and the fracture loads for each direction are determined. Since the stresses in Ply 1 and Ply 2 are higher than those in other plies, resulting in lower fracture loads, Fig 15 shows the distribution of fracture loads for each angle in Ply 1 and Ply 2.

Ply	Angle(°)	Evaluation angle (°)	22.5°directional stress (MPa)	Tensile strength (MPa)
1	0	22.5	1.89	165
2	45	-22.5	0.78	165
3	-45	67.5	0.28	158
4	90	-67.5	0.08	158
5	90	-67.5	-0.08	158
6	-45	67.5	-0.28	158
7	45	-22.5	-0.78	165
8	0	22.5	-1.89	165

Table 3: Analyzed stress of each ply in 22.5° direction (Type-A).

Ply	Angle(°)	Evaluation angle (°)	22.5°directional stress (MPa)	Tensile strength (MPa)
1	45	-22.5	1.36	165
2	0	22.5	1.79	165
3	90	-67.5	0.47	158
4	-45	67.5	0.10	158
5	-45	67.5	-0.10	158
6	90	-67.5	-0.47	158
7	0	22.5	-1.79	165
8	45	-22.5	-1.36	165

Table 4: Analyzed stress of each ply in 22.5° direction (Type-B).

(a) Type-A (b) Type-B

Figure 15: Distribution of fracture load at each angle in three-point bending analysis.

The knee point load is 87 N (= 165/1.89) for Type A and 92 N (= 165/1.79) for Type B, corresponding to 87% (= 87/100) and 107% (= 92/86) of the experimental values, respectively. The knee point loads in 22.5° direction are plotted in Fig. 15. They locate at about the smallest area of the distribution of the knee point load and the average load of Type-A looks larger than Type-B.

4 STRENGTH OF STRUCTURAL SAMPLE

4.1 Loading test

Laminated boards used in three-point bending tests are also used. Diaphragm molding is used to mold test sample. As shown in the Fig. 16, the laminated plate is heated to 275°C for 500 seconds using an IR oven (DIR631), and the softened laminated plate is pressed into a semicylindrical mold with a diameter of 100 mm and a length of 200 mm. A diaphragm molding machine (MEMBRA6, LEIBROCK CO.) is used to mold the sample with a molding pressure of 0.4 MPa and a vacuum time of 15 seconds to produce a semicylindrical sample. As shown in the figure, the sample is fixed to the fixtures at both ends using epoxy adhesive (Three Bond 2082C), and the test is conducted using a fixture that could apply load only to the central part of the sample shown as Fig. 18.With a test speed of 0.25 mm/min and a support distance of 175 mm, as shown in the Fig. 17. A strain gauge is attached directly below the load

application point to measure the circumferential strain. The load-strain diagram measured by the test is shown in the Fig. 19. Table 5 shows the knee point loads for both types obtained in the test. The average load at the knee point is1867 N for Type-A and 1269 N for Type-B.

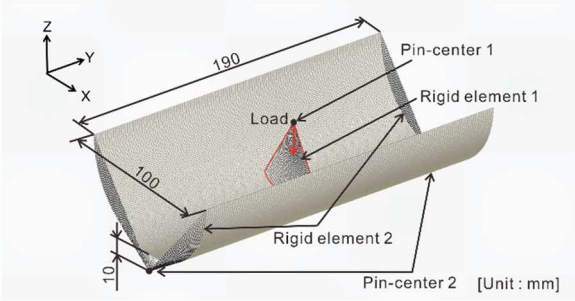
Table 5: Knee point load in Loading tests of structural sample.

4.2 Finite element analysis

The analytical model of the structural sample is created in FEMAP with NX Nastran, using shell rectangular elements with a mesh size of 1 mm. As shown in Fig. 20, a rigid element is used to apply a unit load of 1 N in the negative direction of the Z axis, with the load point as an independent node free only in the translational Z direction and all degrees of freedom dependent on the dependent node on the structural sample side. The support points at the ends are free only in the direction of rotation around the X axis as independent nodes, and the dependent nodes on the structural sample side are subordinated in all degrees of freedom. Stress contour diagrams of the outermost layers of both types are shown in Fig. 21. For both types, there is a tendency for stress concentration at the edge location of loading fixture as Fig. 18. Therefore, stress evaluation is conducted at the stress concentration area for both types. In this study, the stress is transformed by 1° with respect to the fiber direction in each layer, and the load, at which the composite sheet reached breaking stress at each angle, is taken as the knee point load.



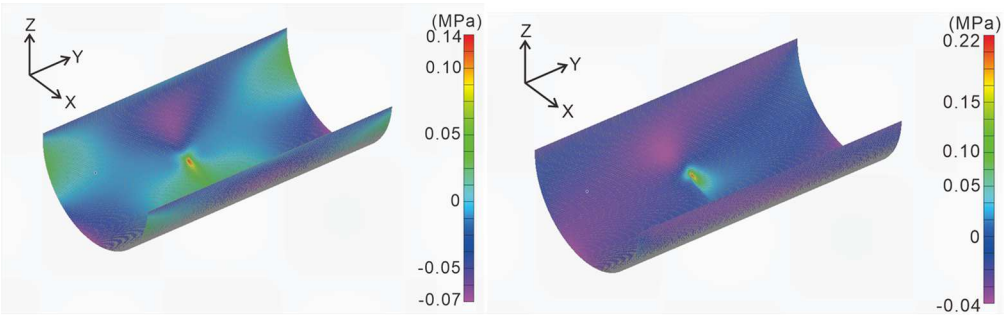


Figure 20: Analysis model of structural samples.

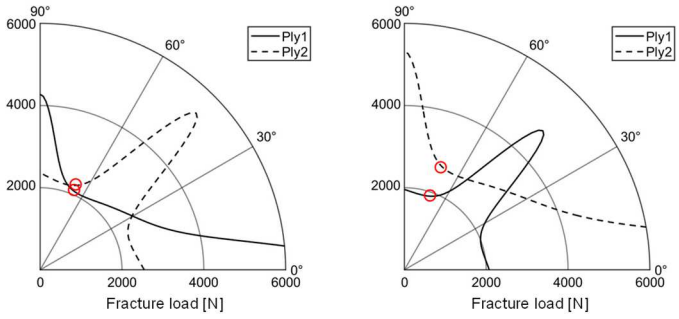
(a) Type-A (b) Type-B

Figure 21: Analysis model of structural samples.

4.3 Strength evaluation



Considering that the direction in which the fibers are not oriented is the weakest and most susceptible to breakage, the stress in 67.5° direction is evaluated. Tables 6 and 7 show the stress generated in 67.5° direction for both types. In both cases, the largest value is observed in the outermost layer. The stress obtained from the structural sample analysis is similarly converted 1° at a time from the fiber direction, and the stress generated in each direction is calculated. Similarly, the distribution of angles and fracture loads in Ply1 and Ply2 is shown in Fig. 22.

Ply	Angle(°)	Evaluation angle (°)	67.5°directional stress (MPa)	Tensile strength (MPa)
1	0	67.5	0.076	158
2	45	22.5	0.074	165
3	-45	112.5	0.035	158
4	90	-22.5	0.067	165
5	90	-22.5	0.035	165
6	-45	112.5	-0.001	158
7	45	22.5	-0.025	165
8	0	67.5	-0.021	158

Table 6: Analyzed stress of each ply in 67.5° direction (Type-A).

Ply	Angle(°)	Evaluation angle (°)	67.5°directional stress (MPa)	Tensile strength (MPa)
1	45	22.5	0.085	165
2	0	67.5	0.060	158
3	90	-22.5	0.081	165
4	-45	112.5	0.023	158
5	-45	112.5	0.013	158
6	90	-22.5	0.019	165
7	0	67.5	-0.003	158
8	45	22.5	-0.033	165

Table 7: Analyzed stress of each ply in 67.5° direction (Type-B).

(a)Type-A (b)Type-B

Figure 22: Distribution of fracture load at each angle in structural sample loading analysis.

In the structural sample analysis, the knee point is defined as the point of failure of the weakest layer, and the minimum fracture load is taken as the knee point load. The knee point loads are 2079 N (= 158/0.076) for Type-A and 1941 N (= 165/0.085) for Type-B, corresponding to 111 % (=2079/1867) and 153 % (= 1941/1269) of the experimental values, respectively. As same as bending test, the knee point loads in the weakest direction are plotted in Fig. 22. The plots of Type-A locate at about the smallest area, and also the plots of Type-B locate at the smallest area.

5 CONCLUSIONS

Tensile tests of composite sheets (CF/PA66 twill weave), flexural tests of laminated composites and loading tests of laminated structure samples, and finite element analysis are conducted to predict the initial failure load using a strength evaluation index based on the knee point of laminated composite material. The following is a summary of the findings.

- The knee point load can be predicted by obtaining the stress in each direction by 22.5° pitch in the analysis of a laminated composite bending specimen. For the laminated composite in this test, the knee point load can be predicted with the error within 13 % for the experimental value.
- The knee point load can be predicted by obtaining the stress in each direction by 22.5° pitch in the structural sample loading analysis. The laminated composite in this test can predict the knee point load with the error within 53% from the experimental value.

MECHANICAL CHARACTERIZATION OF MWCNT BASED BASALT FIBER-REINFORCED POLYMER (BFRP) COMPOSITE BY USING THE MODE I AND MODE II METHODS

Kalyan Kumar Singh[1*], Hemant Priyadarshi[1]

[1]*Indian Institute of Technology (ISM), Dhanbad, Jharkhand, India*

Abstract

Basalt fiber-reinforced polymer (BFRP) composites contain attention for their potential in high-performance structural applications due to their favourable mechanical properties and environmental benefits. This study investigates the fracture behaviour of BFRP composites under Mode I and Mode II loading with a comparative analysis of neat BFRP and doped with 1%, 2% and 3% multi-walled carbon nanotubes (MWCNT). The results shows the differences in fracture toughness, and specimens reinforced with MWCNT performed better compared to neat BFRP. The MWCNT reinforcement's configuration demonstrates synergistic effects, providing enhanced resistance to crack propagation and superior mechanical behaviour. These results demonstrate the potential utility of MWCNT doped BFRP composites in enhancing strength and stiffness for current applications.

Keywords- BFRP, Mode I, Mode II & MWCNTs.

1. Introduction

Basalt fibre-reinforced polymer (BFRP) composite is one of the high strengths to weight ratio, natural and resistance to high temperature material, which BFRP has become popular to be used as the structural and aerospace applications [1]. However, their poor fracture and delamination resistant behavior to different types of loadings are the great challenges. To solve this problem, the researchers working on the incorporation of nanomaterials in the polymer matrix, for example, multi-walled carbon nanotubes (MWCNTs), to enhance the fracture characteristics have been studied [2]. MWCNTs with excellent mechanical properties, such as tensile strength and high aspect ratio can serve as an effective reinforcement for improvement of crack bridging, energy absorption, and interfacial bonding [3]. Fracture mechanics is an essential part of the failure analysis of the advanced engineering materials of fibre reinforced polymer (FRP) composite. As strong as these materials are with excellent strength to weight properties and mechanical capabilities, they are faced with the risk of delamination or an interlaminar failure mechanism that renders structural integrity largely hampered. Composites fracture behavior is typically classified to have three possible modes: Mode-I (opening), Mode-II (sliding) and Mode III (tearing) each with a particular displacement of the fracture surface with respect to the crack front [4]. The most known among them are Mode-I and Mode-II delamination because they apply to service-related failures cases. Mode-I fracture is usually defined by the crack growing under the action of the tensile stress that acts perpendicular to the crack plane, and it is preferably observed in the Double Cantilever Beam (DCB) test. This technique delivers the Mode-I interlaminar fracture toughness G_{IC} and this measures the amount of energy to open and extend a crack [3]. Mode-II fracture, on the contrary, presents in-plane shear stresses have a parallel direction to the crack plane and is determined by the End-Notched Flexure (ENF) test, where the Mode-II fracture toughness G_{IIC} can be obtained [5]. In order to enhance interlaminar performance, recent researches have been conducted with the supplement of the nanofillers that includes multi-walled carbon nanotubes (MWCNTs)

which is capable of providing very good mechanical strengthening and interfacial bonding arrays [6] & [7]. Nevertheless, the effects of the MWCNT reinforcement largely depend on its dispersion and optimum concentration in the matrix. This article examines how loading MWCNT affects the Mode-I and Mode-II fracture toughness of basalt fibre-reinforced polymer (BFRP) laminates, to provide an answer to the best nanoparticle amount that yields the highest delamination-resistance [8].

2. Material selection and specimen fabrication

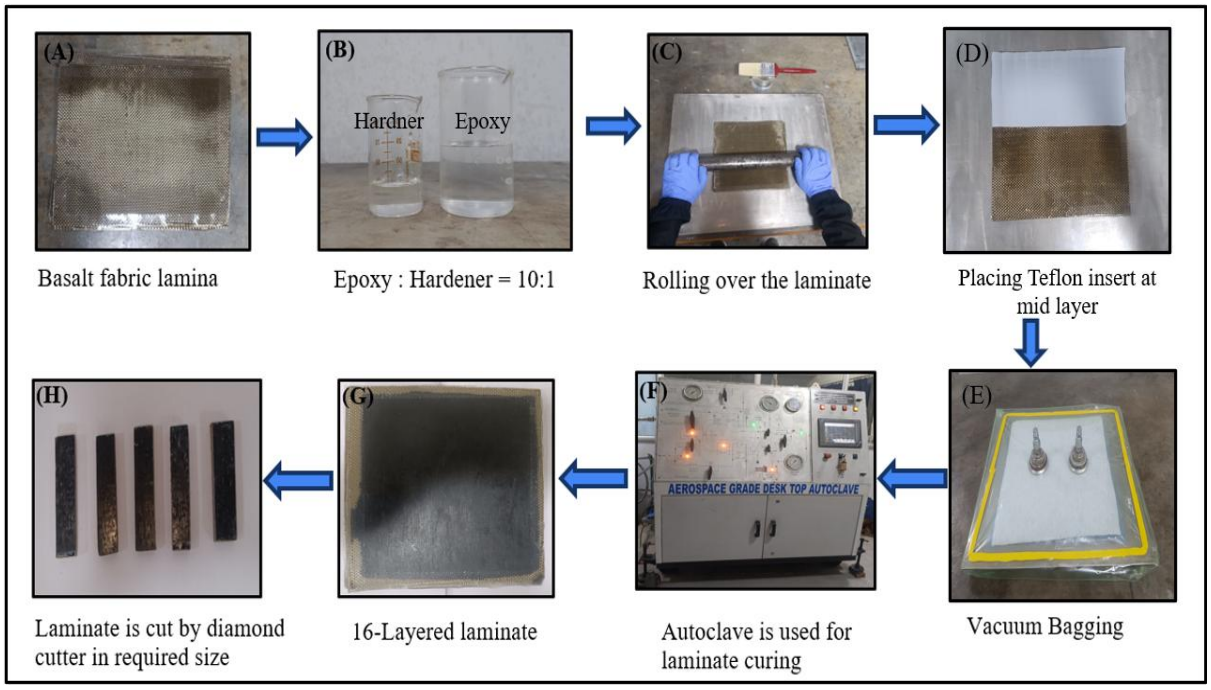

Figure 1. Fabrication process of BFRP laminate

In this study, 380 GSM woven basalt fabric was primarily used as the reinforcement material. The fabric exhibited bi-directional characteristics, with fiber diameters ranging from 12 µm to 24 µm. The basalt fabric was procured from CF Composite, Delhi, India. Woven fabrics are generally preferred for reinforcement due to their balanced in-plane properties and ease of handling during the fabrication process. As the matrix material a thermosetting epoxy resin system HY-951 epoxy and LY-556 hardener both provided by CF Composite were used. All these elements were combined at room temperature [9]. The cross-linked structure generated between the epoxy resin and the hardener improved the adhesive, mechanical properties of the matrix system. The MWCNTs was pure with 99.9 % purity were procured from the AdNano technologies at Bangalore, India. Uniform dispersion of MWCNTs in the epoxy was the objective, which was achieved with the help of a two-stage dispersion method as shown in figure 1. To begin with, the MWCNTs were added to 50 ml of acetone, mixed together with the help of the magnetic stirrer within 30 minutes in order to get a uniform mixture [10]. This was preceded by ultrasonication in a probe-type sonicator at 30 min in order to de-agglomerate the nanotubes further and improve dispersion [11]. Further, 200 ml of epoxy resin solution was added to MWCNT-acetone solution. The mixture that came about was stirred magnetically during a period of 15 minutes, and then an additional probe-style ultrasonication of 15 minutes was carried out. To remove residual acetone, the mixture was placed in an air oven at 60°C for 10 minutes. A curing agent was then added to the epoxy-MWCNT mixture in a 10:1 ratio (resin to hardener), providing a gel time of approximately 20 minutes, as recommended by the supplier, to regulate the curing process effectively [12]. Laminates were fabricated using woven

basalt fabric sheets cut to 240 × 240 mm² dimensions. The layup sequence followed a quasi-isotropic and symmetric stacking order of $[0°/\pm45°/90°]_s$. The hand lay-up technique was employed for fabrication, where the epoxy-MWCNT-hardener mixture was uniformly applied between the layers using a soft brush to ensure even distribution. Composite laminate specimens were precisely cut using Abrasive Water Jet Machining (AWJM), which utilizes a high-pressure stream of water mixed with abrasive particles. Basalt fibre laminates (200 mm × 200 mm) were firmly fixed to the machine bed to ensure stability during cutting. The process was performed at Polymer composite lab (Mechanical testing and damage analysis), Mechanical Engineering Department, IIT (ISM) Dhanbad. A CNC-controlled jet followed a programmed path to shape the specimens as per ASTM standards ASTM D5528 140 mm × 25 mm × 5 mm for Mode I and ASTM D7905 180 mm × 25 mm × 5 mm for Mode II testing [13] & [14]. The high-velocity jet removed material efficiently with minimal thermal effects, ensuring clean cuts and maintaining the structural integrity of the composites.

3. Testing and Characterization of BFRP composite laminate

All experimental investigations were carried out using a Hounsfield H50KS Universal Testing Machine (UTM) with a load capacity of 50 kN, located at the Strength of Materials (SOM) Laboratory, Mechanical Engineering Department, IIT Dhanbad. The UTM system was employed to evaluate mechanical properties of Basalt Fibre Reinforced Polymer (BFRP) laminates, including flexural strength. For each experimental test, five specimens were fabricated in accordance with the ASTM standards. A constant crosshead displacement rate of 2 mm/min was maintained throughout the tests. To monitor damage evolution in the specimens, a Celestron digital microscope with a 5 Mega pixel camera and 20–200× magnification range was utilized for real-time visual inspection during testing.

3.1 Mode-I Interlaminar Fracture Toughness (ILFT) Analysis

The figure 2 illustrates the process of Mode-I Interlaminar Fracture Toughness **(**ILFT) testing was performed following the ASTM D5528 standard, using a Double Cantilever Beam (DCB) configuration [15]. Each DCB specimen measured 140 mm × 25 × 5 mm, and an initial delamination of 63 mm was introduced during the hand lay-up process using a 50 µm thick Teflon insert placed at the mid-plane [16]. To facilitate the application of load, piano hinges were bonded to the top and bottom surfaces of the specimens using Araldite standard epoxy adhesive. To track crack propagation during the test, the specimen's side surfaces were coated with white marker and marked at 1 mm intervals. The DCB specimens were loaded under displacement control at a crosshead speed of 2 mm/min in the opening (positive) direction.

The toughness calculation was done with the following equation 1,

$$\mathbf{G_{IC}} = \frac{\mathbf{3(A1)(A2)}}{\mathbf{2}\boldsymbol{B}} \qquad \ldots\ldots (1)$$

Where, $C = \frac{u}{Pc}$;

$$ln(A1) = \left(\frac{1}{n}\right)[(-3\sum \ln a\ ) + \sum \ln C]$$

$$ln(A2) = \left(\frac{1}{n}\right)[(\sum \ln a\ ) + \sum \ln Pc]$$

u = Displacement (mm) -Vertical distance.

P_c =Critical load (N);

a =Crack length (mm);

B = Specimen thickness (mm);

C= compliance

Figure 2. The experimental setup for the Mode-I fracture toughness test.

3.2 Mode-II Interlaminar Fracture Toughness (ILFT) Analysis

Mode-II fracture behaviour was investigated following ASTM D7905, utilizing the End Notched Flexure (ENF) specimen configuration. The ENF specimens measured 180 mm × 25 mm × 5 mm, and a 50 mm pre-crack was introduced at the mid-plane using a 50 µm Teflon insert during lay-up. Tests were performed under displacement control at a crosshead speed of 2 mm/min in the negative (shear) direction as shown in figure 3. Similar to Mode-I, the side surfaces were marked at 1 mm intervals using white correction fluid to track crack growth and layer sliding. The Mode-II test configuration is shown in Figure. The critical Mode-II strain energy release rate, G_{IIC}, was calculated using the following expression based on simple beam theory for an ideally clamped ENF specimen:

The toughness calculation was done with the following equation 2,

$$G_{IIC} = \frac{9P_c^2 C\, a^2}{2B(2L^3+3a^3)} \qquad \text{..... (2)}$$

Where, P_c = maximum value of force, in the load-extension graph, a= delamination length used in fracture test, B = specimen width

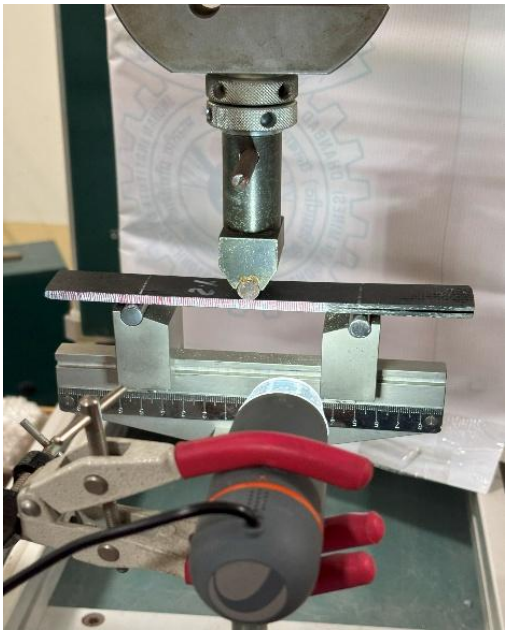

Figure 3. The experimental setup for the Mode-II fracture toughness test.

4. Results and Discussions:

4.1 Mode I Interlaminar fracture toughness

The load–displacement graph illustrates the Mode-I fracture behaviour of basalt fibre-reinforced polymer (BFRP) composites doped with varying concentrations of multi-walled carbon nanotubes (MWCNTs), revealing that the addition of MWCNTs significantly influences crack resistance [17]. Among the tested configurations, the composite with 1 wt% MWCNT exhibits the highest peak load (~39 N) and the largest displacement, indicating superior energy absorption and enhanced fracture toughness due to effective crack-bridging, pull-out, and deflection mechanisms introduced by the well-dispersed nanotubes. The 2 wt% MWCNT sample also demonstrates improved performance over pristine BFRP (~30 N peak load), although the benefit is reduced, likely due to initial signs of MWCNTs agglomeration [18]. As shown in figure 4 (a) & (b) In contrast, the 3 wt% MWCNT composite performs worse than the pristine sample, with a lower peak load (~20 N), suggesting that excessive MWCNT content leads to dispersion challenges and cracking nature of the polymers that act as failure initiation sites. The bar chart displays the Mode-I critical strain energy release rate G_{IC} of basalt fibre-reinforced polymer (BFRP) composites with different concentrations of multi-walled carbon nanotubes (MWCNTs), demonstrating the impact of nanotube incorporation on fracture toughness. The BFRP samples with 1 wt% MWCNTs composite exhibit the highest G_{IC} value (~520 J/m²), nearly doubling that of pristine BFRP (~270 J/m²), due to effective crack-bridging, nanotube pull-out, and improved interfacial strength. While the 2 wt% MWCNT sample also shows an increase in G_{IC} , a decline is observed at 3 wt%, indicating that excessive MWCNT loading may lead to agglomeration and defect formation, adversely affecting fracture resistance.

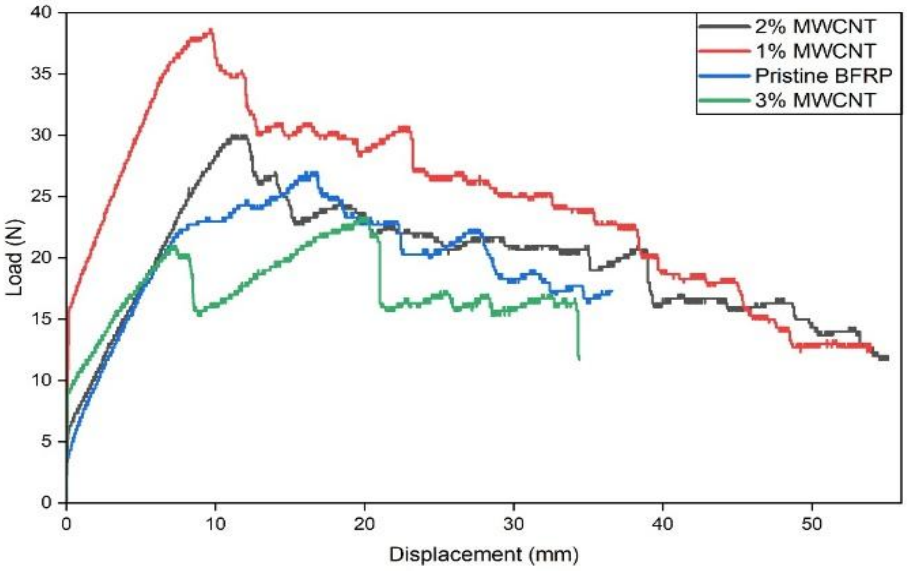

Figure 4 (a). Typical load vs displacement curves of DCB specimen.

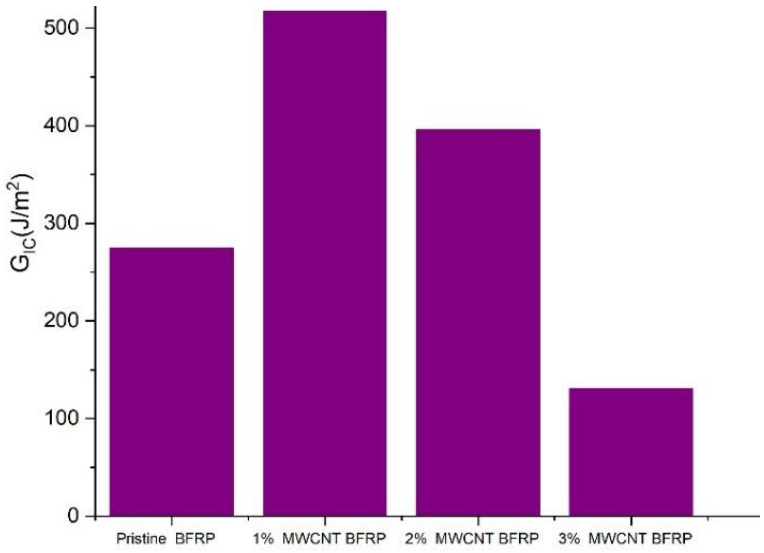

Figure 4 (b) Comparison of Mode I interlaminar fracture toughness with varying MWCNTs

Table 1. Mode1 experimental results

MWCNT wt%	**G_{IC} (J/m^2)**
Pristine BFRP	274.28
1% MWCNT BFRP	517.28
2% MWCNT BFRP	396.16
3% MWCNT BFRP	130.76

4.1 Mode II Interlaminar fracture toughness

The Figure 5 (a) & (b) illustrates Mode-II of load displacement characteristics of basalt fibre reinforced polymer (BFRP) composites, that were loaded with different amounts of multi-walled carbon nanotubes (MWCNTs) indicate a great change in the interlaminar shear strength due to the optimum number of nanotubes added. Composite with 1 wt% MWCNT has maximum load-bearing capacity, and displacement meaning that it could withstand delamination because of shear effects more due to the increase of the interface adhesion, crack-bridging mechanism, and energy dissipation mechanism because of the well-dispersed MWCNTs [19]. Comparatively, the 2% wt MWCNT sample material is also performing better than the pristine BFRP, whilst the 3 wt% MWCNT sample illustrates premature failure indicating plentiful nanotube material results in agglomerate clusters and cracking nature of the polymers that weaken the structural integrity. In the bar chart, the Mode-II critical strain energy release rate G_{IIC} is displayed as it correlates the BFRP composites of different contents of the MWCNT which demonstrates the substantial enhancement of interlaminar fracture toughness of the optimised nanotube inclusion [20]. The highest G_{IIC} value was found in the 1 wt% MWCNT BFRP composite (~1850 J/m²), and this material shows better resistance to delamination than pristine BFRP (~750 J/m²) because of the increased number of interfaces caused by MWCNT relative to the other composites, and further addition of 2 wt% MWCNTs fracture toughness was found in between 1 wt% and pristine whereas 3 wt% of MWCNT shows a decreased toughness as compare to pristine there are likely agglomerations and clumps of MWCNT.

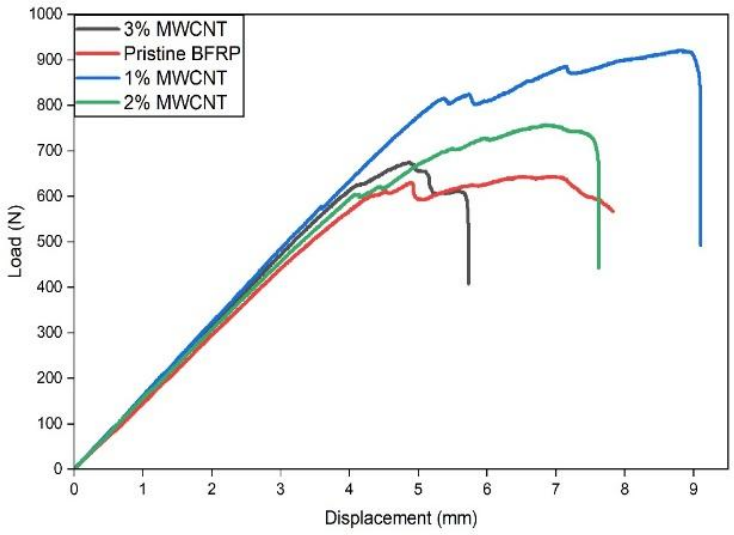

Figure5. (a). Typical load vs displacement curves of ENF specimen.

Table 2. Mode II experimental results

MWCNT wt%	G_{IIC} (J/m²)
Neat BFRP	754.00
1% BFRP	1852.20
2% BFRP	1165.05
3% BFRP	702.00

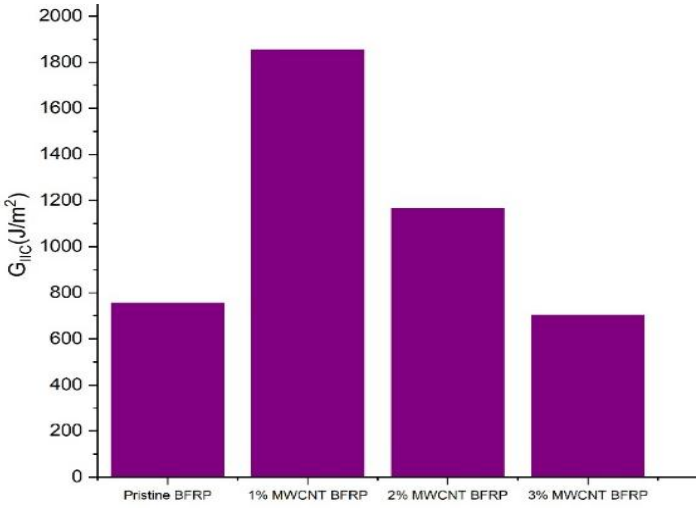

Figure 5 (b) Comparison of Mode II interlaminar fracture toughness with varying MWCNTs

5. Conclusions:

This experimental studied shows the effect of different % of MWCNTs on basalt fiber composites based on mode I and mode II Fracture toughness test and observations are given below:

- Multi-walled carbon nanotubes (MWCNTs) immersion into basalt fibre-reinforced polymer (BFRP) composites has a profound effect on Mode-I fracture toughness G_{IC}, and the performance varies hugely according to the nanotube concentration.
- BFRP with 1 wt % MWCNT exhibited the best fracture performance, with Mode-I and Mode-II fracture toughness values of approximately 520 J/m² and 1850 J/m² respectively, indicating optimal reinforcement and energy dissipation.
- BFRP with 2 wt % MWCNT showed moderate improvement over pristine BFRP, with G_{IC} around 390 J/m² and G_{IIC} about 1250 J/m².
- BFRP with 3 wt % MWCNT resulted in a decline in performance, with reduced fracture toughness $G_{IC} \approx 150$ J/m², $G_{IIC} \approx 700$ J/m²), attributed to MWCNT agglomeration and stress concentration effects.
- The pristine BFRP composite recorded the lowest toughness values $G_{IC} \approx 270$ J/m², $G_{IIC} \approx 750$ J/m²), confirming that 1 wt% MWCNT is the optimal concentration, provided the dispersion is well controlled for structural efficiency.

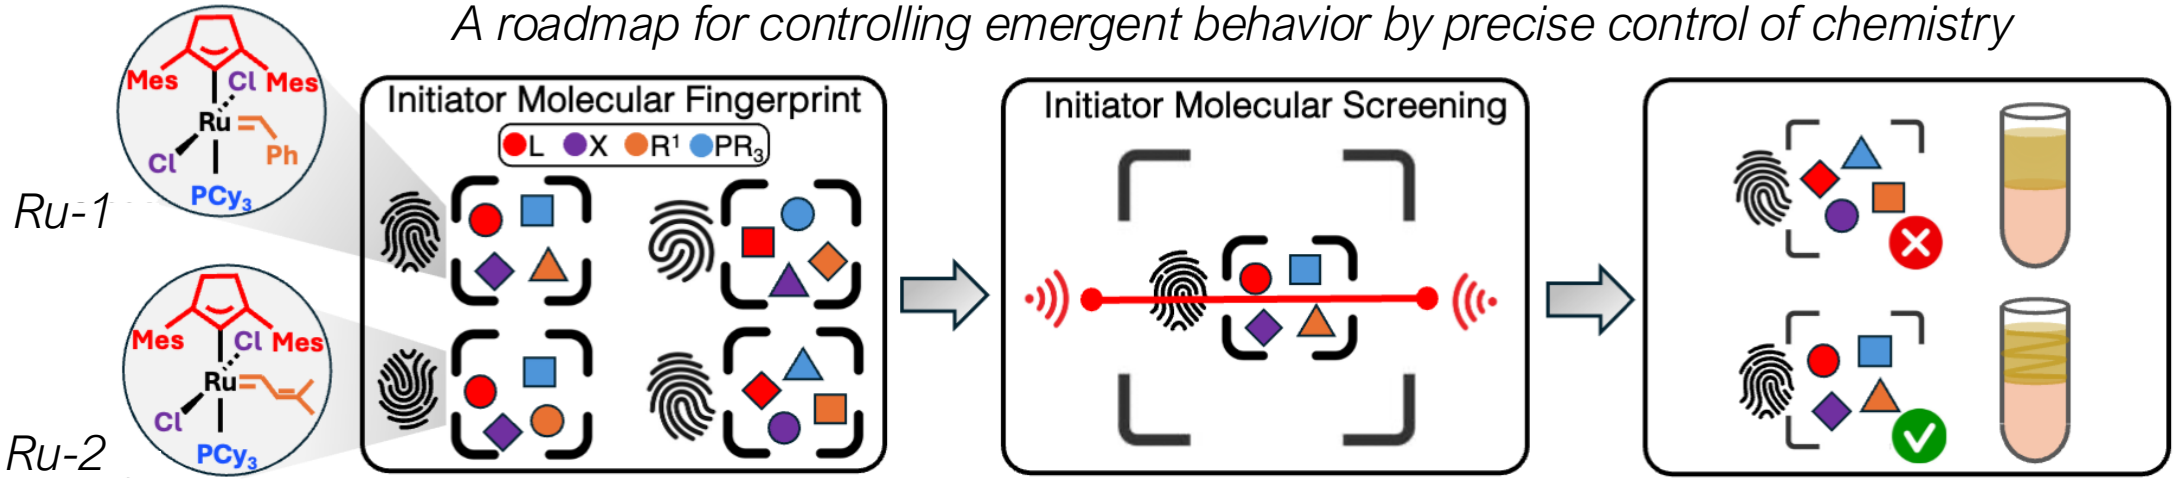

Mapping Emergent Behavior with Variation in Resin Chemistry

$$K_{eq} = \exp\left(-\frac{dH^o}{RT} + \frac{dS^o}{R} \right)$$

A roadmap for controlling emergent behavior by precise control of chemistry

Summary

1. Developed a mechanism-based reaction-diffusion framework to model the coupled three-step sequence of FROMP reaction kinetics.
2. Demonstrated the capacity of the framework to capture macroscopic FROMP observables (i.e., front velocity, maximum front temperature, front propagation mode) over a wide range of compositions + processing conditions
3. Numerically informed *a novel paradigm for emergent behavior in frontally-polymerized synthetic materials* with spatially varying mechanical properties.
4. Demonstrated the ability to map emergent behavior over a wide range of compositions + processing conditions

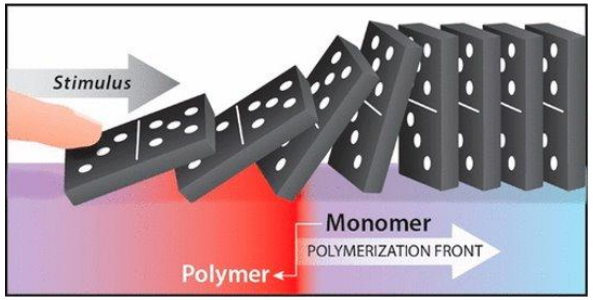
Influence of Kinetic Models on the Simulation of Frontal Polymerization

Ke Wang, Brecklyn Groce, Guy Van Assche



Sustainable Materials Engineering, Vrije Universiteit Brussel, Brussel, Belgium

ICCM24, Baltimore, Maryland, USA

August 4, 2025

Motivation

Frontal Polymerization:

✓

- Fast & energy efficient
- Longer pot-life

? → study with modelling methods

- Require precise balance of heat
  - *Premature (bulk) polymerization*
  - *Quenching of fronts*
- Instabilities

  Comes from rapid change of temperature & properties

Reaction kinetics model:

Phenomenological	Mechanistic
$\frac{d\alpha}{dt} = k(1-\alpha)^n$ *n-th order*	$A + B \xrightarrow{k} C$
α: conversion	$\frac{d[C]}{dt} = k[A][B]$

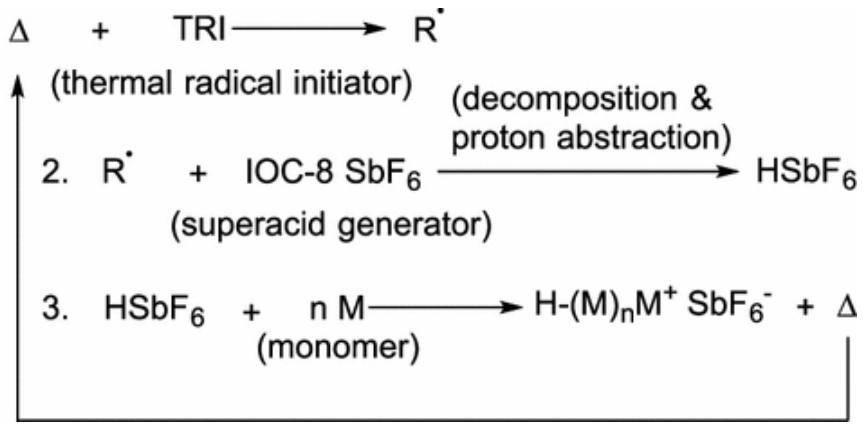
Phenomenological compared to mechanistic:

Less computation resource required

Less explanatory in mechanism, rely more on experimental data

Parameters are specific to a single formulation

Aim of this study: Propose a rational mechanistic kinetic model for **radical induced cationic polymerization (RICP)** and implement to a frontal polymerization simulation.



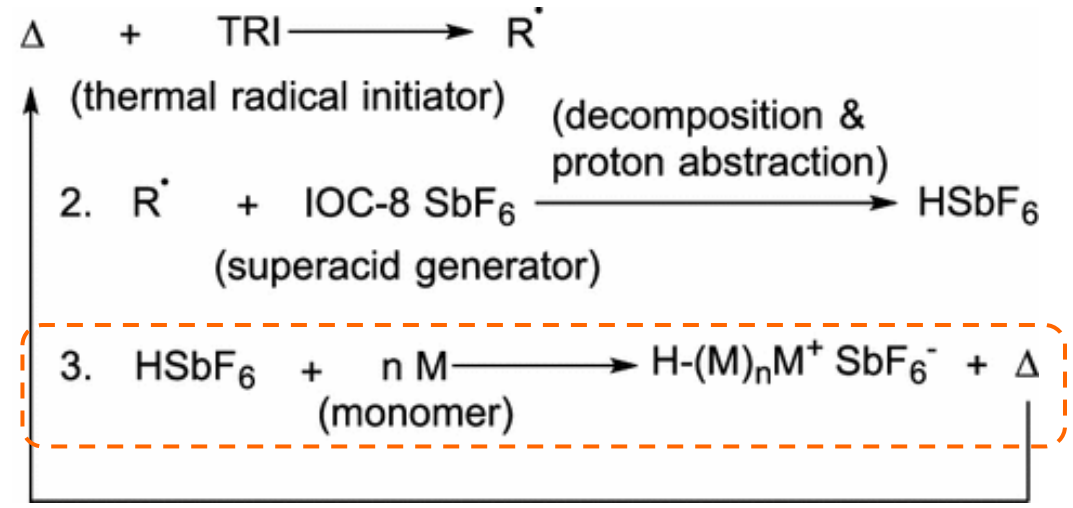
Chemistry

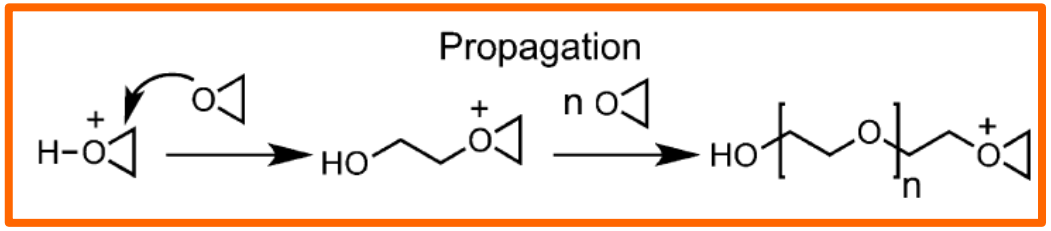
Mechanistic kinetic models with FP simulation:

Goldfeder, P. M., et al. (1997): free radical polymerization

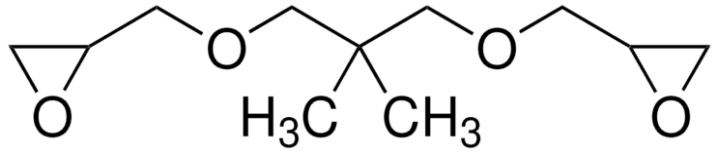
Bistri, Donald, et al. (2024): ring-opening metathesis polymerization

Radical induced cationic polymerization (RICP): Mariani, Alberto, et al. (2004)





Duo-initiator configuration: radical & cation



- Less sensitive to oxygen (as inhibitor), no termination (by combination)
- No limit on UV penetration depth (compare with cationic photopolymerization)

Groce, Brecklyn R., et al. 2023

ABSTRACT

Frontal ring-opening metathesis polymerization (FROMP) is a promising thermoset composite curing process for thermoset composites, enabling rapid and energy-efficient manufacturing through a self-energized exothermic reaction. Once initiated, the polymerization front spatially propagates through the resin matrix. Among various frontal polymerization curing strategies, through-thickness curing offers potential for scalable carbon-fiber-reinforced polymer (CFRP) composite fabrication. However, manufacturing large composite structures via through-thickness curing requires the analysis of the trade-offs among curing energy and speed, as well as new strategies for scaling up the equipment and tooling required for the heating and pressure applications. To address this issue, incremental curing methods use a fixed area tool for applying pressure and heat to initiate a through-thickness front, followed by removing the pressure and feeding the composite forward to cure the following section of the composite. This process must be optimized to maintain high cure quality while minimizing energy input to fabricate large composite structures. In this study, we develop a computational and experimental approach to optimize and validate the thermal management of incremental through-thickness FROMP for CFRP. A one-dimensional reaction-diffusion model including cure kinetics is implemented to simulate the thermal and chemical reaction with different heating profiles. Using this simple model, parametric optimization with different FROMP initiation parameters is applied to find optimal thermal management cycles to reduce energy and curing time simultaneously. In addition, the simulations consider the influence of adjacent preheated domains from previous cycles to reflect thermal conditions. Experimental validation confirms that the derived optimized curing cycles produce fully cured composite segments with consistent glass transition temperatures by the dynamic mechanical analysis, comparable to those from conventional high-energy processes. The work demonstrates the feasibility of the scalable and low-cost CFRP manufacturing via incremental through-thickness FROMP, supporting the application of future large composite structure manufacturing industries such as aerospace and automotive.

1 INTRODUCTION

Energy-efficient and fast manufacturing of thermoset polymer composites is critical for next generation high-performance materials in aerospace, transportation, marine, and energy industries [1–4]. However, conventional curing methods for thermoset polymers, such as epoxy resins, use large ovens or autoclaves for curing cycles which take many hours, requiring a significant amount of energy and time [5,6]. Here, we use frontal ring-opening metathesis polymerization (FROMP) as a promising fast, energy-efficient curing method to produce carbon-fiber-reinforced poly-dicyclopentadiene. This curing reaction is driven by the exothermic heat generated during the polymerization of the DCPD monomer in the presence of Grubbs catalyst. In the FROMP process, the exothermic reaction is spatially localized near a propagating front, which is triggered thermally at one starting location, enabling fast and low-energy manufacturing [5,7]. In composites, the front can propagate longitudinally along the fibers, or through the thickness if triggered by heat from a heated mold brought in contact with the surface of the composite. However, if insufficient energy is present at the front, for instance due to heat loss to the surrounding or fast heat conduction ahead of the front by the carbon fibers, undesired front quenching might occur [8,9]. For this reason, through-thickness curing is often preferred when large volume fraction composites are desired, as quenching is avoided with through-thickness curing [10,11]. Therefore, it is important to investigate an optimized thermal heating profile that fully cures the polymer with the desired curing time and energy simultaneously. To achieve this, understanding of the curing behavior in response to different thermal trigger profiles through theoretical and numerical modeling of FROMP is essential.

In this study, we develop a numerical optimization process for the cyclic through-thickness FROMP curing of carbon fiber-reinforced polymer (CFRP) composites to realize rapid and low-energy manufacturing of large composites. The cyclic curing enables the use of a small footprint oven to cure large area composites by cyclic feeding and through-thickness front curing in a stepped manner. Due to the exothermic heat generation, continuous external thermal energy supply throughout the process is unnecessary, allowing for various curing profiles depending on the heating method. Furthermore, in the repeated FROMP processes, changes in the initial conditions for subsequent cycles due to high-temperature regions from previous cycles require additional analysis for an optimized thermal management cycle. To address these issues, computational models considering thermo-chemical reaction-diffusion equations are utilized, providing insights into FROMP. In addition, a combination of numerical modeling and experimental validation can further enhance the reliability of FROMP manufacturing.

As shown in Figures 1(a) and 1(b), we model the frontal polymerization of CFRP and apply a gradient-based optimization process to derive an optimized low-energy-consuming heating cycle. For the modeling, we consider three different domains: heater, CFRP, and insulator. DCPD and carbon fiber are used as monomer and reinforcement in the CFRP for reaction-diffusion analysis. The simulation allows us to derive temperature changes and degree of cure variations in the domains with different heating power profiles, enabling the analysis of the impact of thermal management in cyclic curing processes. In the optimization stage, a parametric optimization algorithm is applied to the design variables (e.g., heating, cooling, feeding time, and heating power) to minimize energy consumption while achieving the desired process time and degree of cure conditions. Finally, through experiments, we analyze the curing results and demonstrate the incremental CFRP curing process of a long composite structure using a small footprint oven with lower energy consumption compared to conventional curing conditions by applying the heating cycle proposed by the model and algorithm, as shown in Figure 1(c). Based on the results obtained from this study, the optimized curing strategies can be applied to large-scale manufacturing processes by implementing energy-efficient, low-cost FROMP cycles. This result supports the advancement of sustainable manufacturing for high-performance thermoset polymers and composite materials in various applications.

2 MODELING OF COMPOSITE MANUFACTURING

2.1 Reaction-diffusion equation for incremental curing model

For the FROMP-based incremental composite model, we develop a 1D transient finite element model implemented in the FEniCS open-source finite element framework. During the manufacturing process, an insulation layer and a heater domain are required to apply pressure to the composite and initiate through-thickness FROMP, respectively. Therefore, three domains including insulation, composite, and heater layers were applied for the simulation, as illustrated in Figure 2(a). To capture the exothermic reaction and heat transfer, reaction-diffusion relations and heat conduction equations in through-thickness direction (x) were applied, as shown in Equations (1)–(4)[7,12]. Specifically, a phenomenological $g(\alpha)$ model based on the Prout-Tompkins formulation[12] was used to describe the cure kinetics as follows:

$$\overline{\rho C_p}\frac{\partial T}{\partial t} = \bar{k}\frac{\partial^2 T}{\partial x^2} + \rho_m(1-\phi)H_r\frac{\partial \alpha}{\partial t} \tag{1}$$

$$\frac{\partial \alpha}{\partial t} = A\exp\left(-\frac{E}{RT}\right)g(\alpha) \tag{2}$$

$$g(\alpha) = (1-\alpha)^n\alpha^m\left(\frac{1}{1+\exp(c_d(\alpha-\alpha_d))}\right) \tag{3}$$

$$\rho_i C_{p_i}\frac{\partial T}{\partial t} = k_i\frac{\partial^2 T}{\partial x^2}\ (i=1,2) \tag{4}$$

where $\overline{\rho C_p}$ $(J/(m^3K))$ is the homogenized volumetric heat capacity of the composite derived using the rule of mixtures, and $\bar{k}$ $(W/(m\,K))$ is effective thermal conductivity of the composite. The temperature, time, matrix density, fiber volume fraction, enthalpy of the FROMP reaction, and degree of cure are denoted by $T(K)$, $t(s)$, $\rho_m(kg/m^3)$, ϕ, $H_r(365000\,J/kg)$, and α respectively. Regarding Equation (2), time constant, activation energy, and universal gas constant are respectively denoted by $A(8.55e+15\,1/s)$, $E(110750\,J/mol)$, $R(8.314\,J/(mol\,K))$. In Equation (3), the constants used in the Prout-Tompkins model are given by $n=1.72$, $m=0.77$, $c_d=14.48$, and $\alpha_d=0.41$. Since no curing reaction occurs in the insulation ($i=1$) and heater ($i=2$) domains, only Equation (4) is applied to those regions. Other material properties used in the simulation are summarized in Table 1[7].

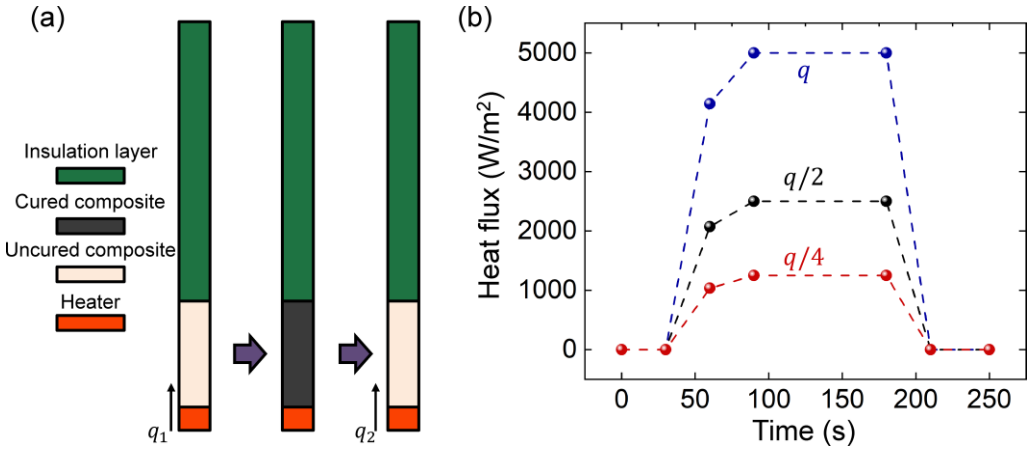

Figure 2: (a) Simulation geometry for incremental curing model, and (b) example of applied heat flux over time for initiation frontal polymerization in composite manufacturing
initial frontal polymerization for composite manufacturing

		Thermal conductivity $(W/(m\,K))$	Density (kg/m^3)	Specific heat $(J/(kgK))$
Carbon fiber	DCPD	0.15	980	1600
	AS4	10.45	1760	795
Insulation	PTFE	0.03	2200	970
	Calcium silicate	0.10	232.27	840
Heater	PI	0.12	1420	1090
	Silicone rubber	0.3	1200	1100

Table 1: Material properties of carbon fiber, insulation, and heater

For the incremental curing process, a heat flux profile $q_1(t)$ is applied in the first cycle to initiate the curing reaction in the CFRP. After the initial CFRP section is cured, a new uncured CFRP is fed into the system, and the second curing cycle begins with a heat flux profile of $q_2(t)$. This process is repeated for multiple curing cycles (see Figure 2(a)). Notably, due to residual heat from the previous cycle, the insulation and heater domains are preheated, which allows the subsequent curing cycle to achieve a fully cured result with a reduced energy input. Figure 2(b) shows examples of the applied heat flux profiles used to initiate the first curing cycle. In all simulations, the initial conditions were set as $\alpha_0 = 0.01$ and $T_0 = 20°C$.

2.2 Curing behavior under different thermal conditions

As shown in Figure 2(b), the area under the heat flux-time plots represents the energy input per unit area (J/m^2). In these examples, the applied surface energy inputs for three different cases (i.e., profiles of q, q/2, and q/4) are 724.3, 362.1, and 181.1 kJ/m^2, respectively. By using these thermal boundary conditions in the curing system, spatiotemporal distributions of temperature and degree of cure under three different curing conditions were obtained. The x-axis represents time, while the y-axis indicates spatial position through the three domains (heater, composite, and insulation), allowing observation of the temperature and cure distribution across each layer.

The thickness values of the heater, composite, and insulation layers are set to 1, 2.2, and 25.4 mm, respectively. In addition, the materials are applied as silicone, rubber, DCPD/AS4 with a fiber volume fraction of 0.65, and PTFE, respectively. We use spatiotemporal plots as a representation of the temperature evolution, represented by colored contours, along the 1-D domain during the curing as shown in Figure 3. We also construct similar contour plots for the degree-of-cure. This type of plot represents the evolution in space and time and hence a single plot replaces a 1-D movie of the curing process, obtained via numerical simulations. As shown in Figures 3(a) and 3(d), the curing is initiated

near the heater and propagates through the composite toward the insulation layer. The degree of cure eventually reaches ~0.98, indicating that full cure is achieved. Assuming 0.95 as the threshold for complete cure, this result suggests that cure time and energy input can be further optimized using a slightly lower heat flux or shorter heating duration.

On the other hand, Figures 3(b) and 3(e) show that while the FROMP is initiated with a reduced energy input, it cannot sustain propagation due to heat loss to surrounding domains, resulting in incomplete cure. Furthermore, in Figures 3(c) and 3(f), the supplied energy is insufficient even for the initiation of FROMP, and the degree of cure at the end of the composite remains at 0.23. These results highlight the importance of proper thermal management (heat flux and heating duration) to ensure complete and energy-efficient curing of composite materials.

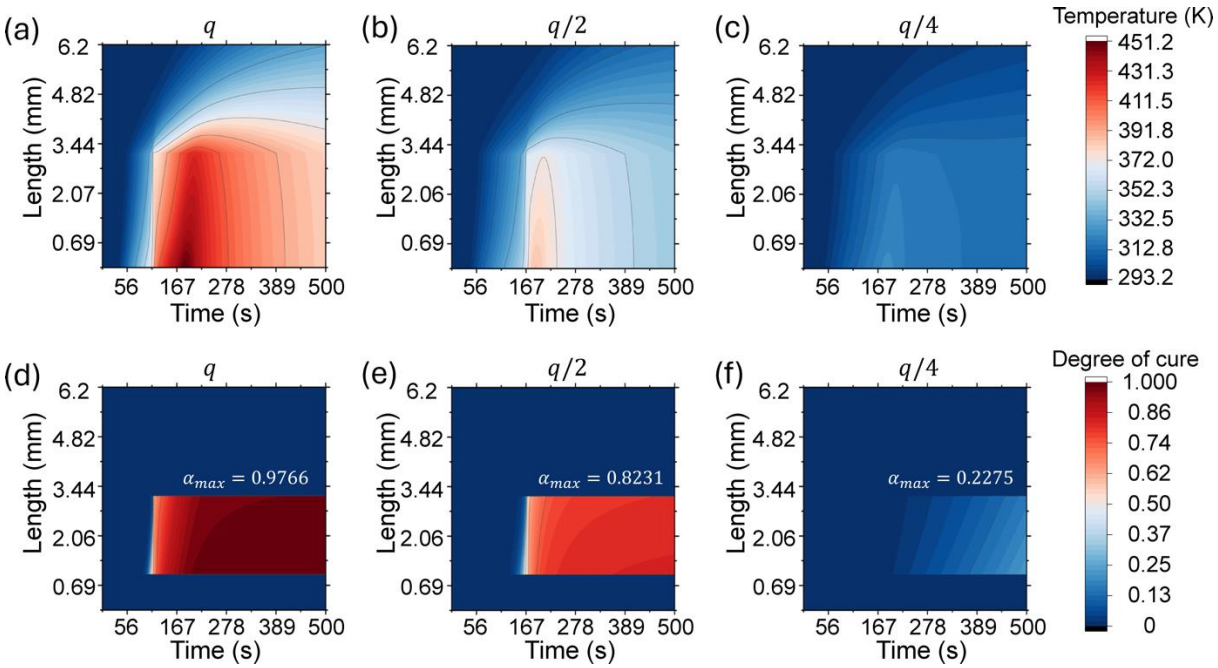

Figure 3: Saptiotemporal simulation results of temperature and degree of cure under different thermal trigger conditions: temperature distributions for (a) *q*, (b) *q/2*, and (c) *q/4*, and degree of cure distributions for (d) *q*, (e) *q/2*, and (f) *q/4*

2.3 Thermal cycle optimization

Figure 4(a) presents the results of a parametric study in which random constant heat flux values (q_h) and heating durations (t_h) are applied. For each case where the degree of cure at the end of the composite (through-thickness direction) reaches 0.95, the required time is defined as the curing time (t_c). The corresponding energy input is calculated based on a surface area of 0.012 m^2. Two cases are considered for comparison. For Case 1, heat flux is applied continuously until the composite is fully cured ($t_h = t_c$), while heat flux is terminated earlier ($t_h < t_c$), allowing the remaining cure to proceed through exothermic FROMP reaction in Case 2. These two cases are shown in different colors in Figure 4(a). As a result, a clear distinction between the two cases is identified. Overall, Case 1 uses more energy than Case 2, indicating that FROMP-based composite manufacturing can be significantly more energy-efficient. For instance, comparing the data points highlighted with green dashed lines, both cases require similar curing times, but Case 2 achieves approximately 22.12% energy savings compared to Case 1.

In addition, Case 2 demonstrates a trade-off relationship between curing time and energy input. Achieving shorter curing time requires more energy consumption, whereas longer curing time leads to lower energy input during the curing cycle. To further explore this relationship, a genetic algorithm (GA) is employed to minimize the energy consumption. The optimization result shows that compared to Case 1, energy consumption can be reduced by 33.27%, although the corresponding curing time increases from 87 to 296 s. Therefore, by evaluating a wide range of conditions, a Pareto front can be identified to balance both energy and curing time, providing guidance for the thermal profile design of the first

cycle. Moreover, since the surrounding domains are preheated by the previous cycle, subsequent cycles require less energy input. As illustrated in Figure 4(b), this concept is applied by scaling down the heat flux in the following cycles to achieve incremental curing with reduced energy input.

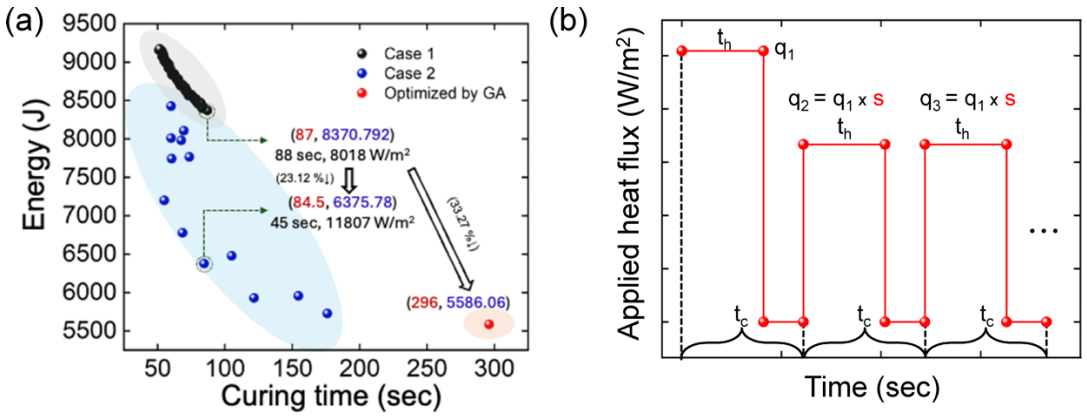

Figure 4: (a) Fully cured state and corresponding thermal conditions of curing time and supplied energy. (b) Numerical approach for determining the optimized incremental curing thermal cycle.

3 EXPERIMENTAL SECTION

3.1 Materials

For the resin system, DCPD, which is solid at room temperature, is mixed with 5 wt% ethylidene norbornene (ENB) to liquify it at room temperature and enable infusion into the carbon fibers. We refer to this mixture as DCPD in the following formulation. A molar ratio of 10000:1:1 of DCPD, second-generation Grubbs catalyst (GC2), and tributyl phosphite (TBP) was mixed using sonication to ensure uniform dispersion. For the carbon fiber layup, an AS4 carbon fiber fabric with the stacking sequence of unidirectional/biaxial/biaxial/unidirectional was used. The prepared resin was then infiltrated into the fabric preform, which was sealed in a nylon vacuum bag. To prevent premature curing at room temperature, the prepregs were stored in a freezer prior to the curing process.

3.2 Experimental setup

Figure 5(a) shows the experimental setup used to validate the optimized curing process. The temperature profiles of the heater and the composite were derived from the optimized heat flux-based thermal profile. To implement this, a K-type thermocouple and a high-sampling-rate PID controller were employed. In addition, an actuator and a calcium silicate insulation layer were used to apply a pressure of ~35 psi. Furthermore, a spring stage and microswitch were introduced to monitor and maintain consistent pressure during all curing cycles. The pressure was controlled by the displacement of the mechanical springs supporting the lower tooling plate as shown in Figure 5. An infrared camera was used to monitor the temperature of the entire system and ensure consistent initial thermal conditions.

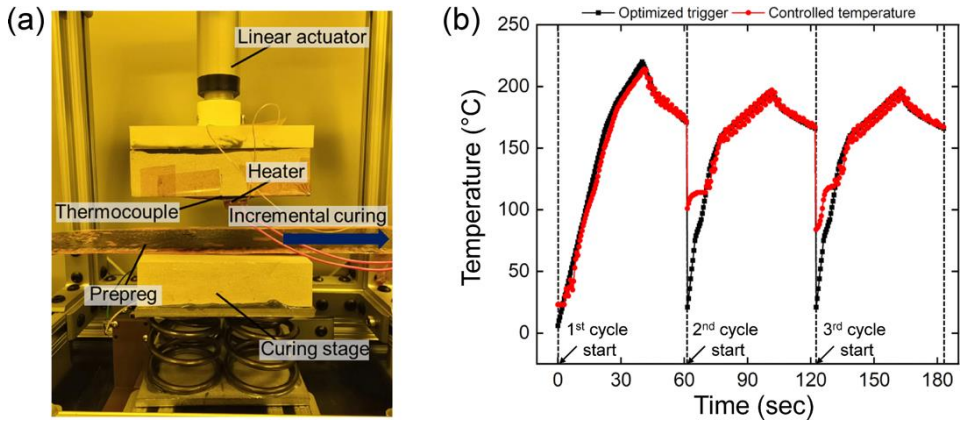

Figure 5: (a) Experimental setup for through-thickness frontal polymerization-based composite manufacturing. (b) Temperature results of three curing cycles based on the optimized curing profile

4 RESULTS AND DISCUSSION

We selected the experimental validation conditions from the Pareto front data points obtained from the simulations of the thermal profile parameters of heat flux (q_h) and heating time (t_h). Specifically, we selected 15267 W/m^2 and 41 s as the optimized thermal cycle for the first section, respectively. In addition, based on the simulation, the expected curing time (t_c) was 61 s for a single curing segment. For the following curing cycles, a scale factor of 0.56 was applied to the heating profile based on numerical fitting for the experimental validation. As shown in Figure 5(b), the intended temperature profiles were successfully applied in each curing section through precise PID control. Notably, the proposed curing cycle required only 61 s per cycle, and a composite panel of 228.6 mm × 50 mm was successfully fabricated using only 3 min and 5.05 kJ of energy.

Figure 6 presents optical images and the thermomechanical analysis of the incrementally cured composite. Before the curing process, the resin remained in a liquid state, as observed in the uncured regions, seen in Figure 6(a). The cured composite was characterized via 3-point bend dynamic mechanical analysis (DMA). As shown in Figure 6(b), the cured composite exhibited a storage modulus onset glass transition temperature (T_g) of 148 °C, which are comparable to previously reported values for fully cured systems [7,10]. These results experimentally validate the thermal profile derived from the proposed numerical approach and demonstrate its potential applicability for large-scale incremental composite curing.

5 CONCLUSION

In this work, the optimization of a FROMP-based incremental composite curing process was investigated numerically and experimentally towards enabling rapid and energy-efficient manufacturing. Through numerical simulations, various heating conditions were explored to find the Pareto front representing the trade-off between energy consumption and total curing time. Subsequently, an optimized first curing cycle condition was selected and extended to multiple curing cycles. In addition, the obtained curing cycle for the incremental curing was validated through experimental method. In conclusion, a 228.6 mm × 50 mm composite with a high glass transition temperature of 148 °C was successfully fabricated using only 5.05 kJ of energy in 3 min. The proposed approach demonstrates potential for scalable, rapid, and energy-efficient manufacturing of fiber-reinforced composites, specifically for applications in aerospace, space, and the automotive industry.

Keywords: UV-Curing, RTM, Radical Polymerisation, Energy-Efficient, VARI

ABSTRACT

This research presents an innovative approach that combines ultraviolet (UV) radiation curing with Liquid Composite Moulding (LCM) to enable a fast, energy-efficient, and digitally controllable manufacturing process for glass and carbon fiber-reinforced plastics. Conventional curing of fiber-reinforced polymers (FRPs) involves long cycle times and high temperatures, leading to elevated energy demand and tooling inefficiencies, which this work aims to overcome by targeting faster, more energy-efficient processes in line with industry needs for lightweight design, sustainability, and cost reduction [1,2]. To characterize the quality of the manufactured composites with non-transparent fibers, four-point bending tests, tensile tests, and fiber volume fraction (FVF) measurements were performed. In addition, the degree of crosslinking was analyzed, and microscopic imaging was conducted to evaluate the fiber–matrix interaction. All samples were produced using the developed UV-RTM tool, where the cavity is transparent for the UV irradiation. The bending tests showed minimum and maximum forces of 300 Pa and 320 Pa the while the tensile tests yielded ultimate loads ranging from 170 MPa to 270 MPa. The degree of cross-linking across the layer thickness was measured and had an average of 84 %. These tests were carried out for two different materials. Pure glass fiber (GF) samples served as reference samples for the samples with embroidered non-transparent carbon fiber (CF). Overall, this study demonstrates the potential of UV-based curing in LCM processes to enable a scalable, cost-effective, and sustainable manufacturing method for high-performance composite parts.

1 INTRODUCTION

Fiber-reinforced polymer composites have become a foundational material system in aerospace, automotive, and wind energy sectors due to their high specific strength, corrosion resistance, and design flexibility [3]. In the field of FRP manufacturing, conventional thermal curing processes still predominate. These methods rely on high temperatures and long processing times, making them energy-intensive and often associated with significant demands on tooling and thermal management [4]. As an alternative, UV-assisted curing is gaining increasing attention.

UV curing, an alternative method widely used in the coating and printing industries, offers rapid polymerization through radical photoinitiation [5]. While UV curing has been applied to glass fiber composites, carbon fiber's opacity poses a significant barrier to deep matrix polymerization.

Radical UV curing processes also face significant challenges that must be addressed to ensure effective polymerization. A major issue is oxygen inhibition, where the presence of oxygen interferes with the radical polymerization reaction, leading to incomplete curing at the material surface. To overcome this, curing typically needs to be performed in closed or inert environments, which complicates the process design. Alternatively, novel tooling solutions must be developed that allow sufficient UV light penetration while maintaining the necessary environmental control. Additionally, the use of non-transparent fibers poses further limitations, as their opacity prevents effective UV transmission through the composite, restricting the achievable curing depth and uniformity.

Considering these factors, this research focuses on investigating a UV-cured composite manufactured

via the LCM process, with particular attention to how variations in process parameters affect the degree of cure and mechanical properties, while aiming for a time- and energy-efficient production method that meets industry demands for lightweight construction, cost efficiency, and sustainability.

Achieving energy-efficient and cycle time-optimized curing of FRP using UV requires its integration into LCM processes and subsequent optimization. Several interdependent parameters must be considered to realize this goal. To effectively control these interactions, their influences must be systematically investigated and validated, enabling a stable and controllable process.

For good material properties, UV-intransparent CF is integrated into the process and cured. To date, it has only been possible to cure GF up to a maximum thickness using UV radiation, depending on the set process parameters and process technology. The maximum achievable thickness is influenced by the fiber volume content, the type of reinforcement fibers, the resin chemistry, and the characteristics of the UV emitter [6].

A special focus is placed on the UV-curing of CF, integrated through the Tailored Fiber Placement (TFP) process in load-path-optimized orientations, as part of the overall process development and the characterization of the resulting composite material [7]. Critical process parameters such as FVF, resin chemistry, fiber type, and emitter characteristics are investigated to develop a reliable and controllable curing system. Since UV curing does not require thermal energy input to initiate or complete polymerization, heating of thermally inert molds is no longer necessary.

This work investigates the feasibility of UV curing for carbon fiber-reinforced composites using LCM processes. Key questions include whether sufficient crosslinking can be achieved within and beneath the carbon fiber roving and whether the resulting laminates exhibit acceptable mechanical performance.

2 MATERIALS AND METHODS

2.1 Materials

All samples were produced using the resin system RAYLOK ® C1100 from Allnex GmbH (Drogenbos, Belgium) in combination with a glass fiber fabric (600 g/m²) supplied by R&G Faserverbundwerkstoffe GmbH (Waldenbuch, Germany). The composite parts were manufactured using the developed resin transfer molding (RTM) tool with an injection pressure of 2 bar. An embroidered carbon fiber roving (Tenax®-E, HTS40, X030, 12K, 800 tex, V2) was used for a higher stiffness.

The RAYLOK ® C1100 resin system is specifically designed for the production of glass fiber-reinforced composites cured by UV radiation. The curing behavior of this system is based on the free-radical polymerization of acrylate and vinyl ester groups, initiated by UV exposure. In contrast to thermally cured epoxy systems, RAYLOK ® C1100 is a single-component system offering on-demand curing. It remains stable in its liquid state until UV activation, which then triggers immediate polymer network formation.

The RAYLOK ® C1100 resin system is a styrene-free vinyl ester formulation. Its high reactivity under UV radiation enables rapid curing within seconds to minutes, offering a significant reduction in cycle time compared to conventional thermally cured systems. A notable advantage of the system is its long pot life prior to UV exposure (1-K System), which allows for extended processing windows, increased flexibility during layup or infusion, and reduced material waste.

The mechanical performance of the cured system, measured according to standard ASTM protocols, is summarized in Table 1:

Property	Value
Tensile modulus	~2.3 GPa
Tensile strength	~50 MPa
Elongation at break	~2.3 %
Flexural modulus	~2.8 GPa
Flexural strength	~80 MPa
Glass transition temperature (Tg)	~102 °C

Table 1: Material Properties RAYLOK ® C1100 [8].

2.2 Manufacturing of UV-cured composites

The RTM process was employed to manufacture specimens for mechanical characterization, enabling the production of large-scale samples (358 × 258 mm²) incorporating a multilayer glass fiber preform with an embroidered carbon fiber roving. The RTM mold consists of two rigid mold halves, sealed at the parting plane and clamped together with bolts. The cavity is enclosed on both the upper and lower sides by tempered safety glass (ESG), providing transparency for UV curing while ensuring mechanical stability and an effective seal during the infiltration process, see Figure 1. Before processing, the mold is cleaned with isopropanol and air pressure, followed by the application of a release agent (HP7, Marbocote) in three layers with degassing steps between applications. The injection and evacuation hoses are installed afterwards. The injection hose is connected to a pressure vessel, which is later filled by the resin for the infusion process, while the evacuation hose is attached to a resin trap and a vacuum pump.

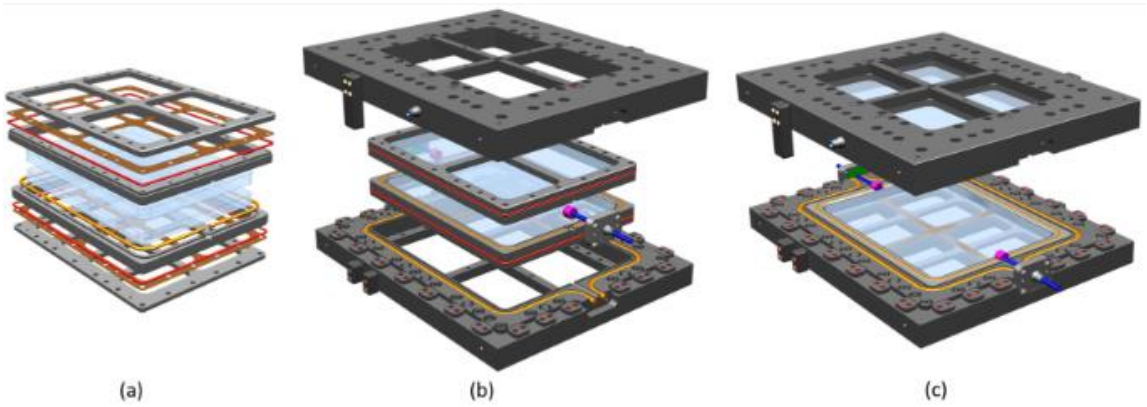

Figure 1: (a) Explosion view of glass plates and glass plate frame assembly, (b) explosion view of assembled glass plate frames and mold frames, and (c) assembled mold in open (charge) position [9].

The fiber preform is prepared by stacking three layers of glass fiber fabric, onto which a carbon fiber roving is embroidered on one Layer of glass fiber using a fine polyester thread (Serafil, 300tex, 10) on a TFP embroidery machine TCWM 102 (Tajima Industries Ltd., Nagoya, Aichi Prefecture, Japan). The embroidered fabric is cut to match the dimensions of the other layers and then positioned within the lower mold cavity (Figure 2).

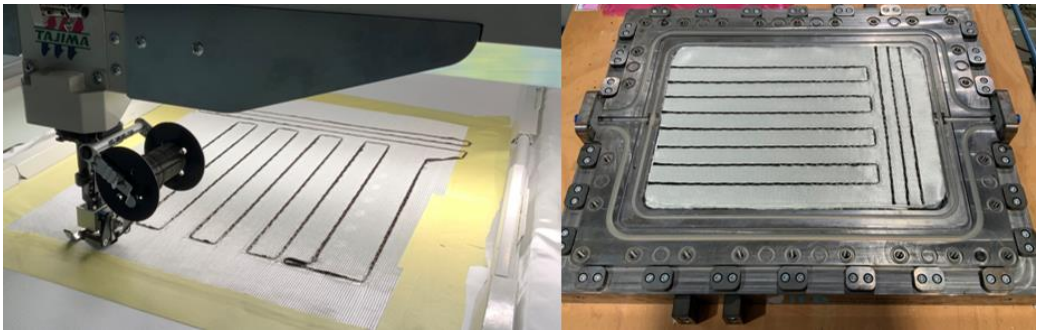

Figure 2: Embroidered machine TCWM 102 and the RTM tool with prepared Preform

Sealing plugs are installed at the resin inlet and outlet ports, and the mold halves are assembled and clamped. The resin system RAYLOK ® C1100 is injected under controlled pressure (initially 800 mbar) through the cavity, which is tilted by 45 ° to enhance air evacuation. The infiltration process was continuously adjusted to maintain a constant flow rate as the flow front progressed, resulting in a concave flow front profile due to faster resin movement near the cavity edges, see (Figure 3). The pressure is gradually decreased to 30 mbar by the end of infiltration.

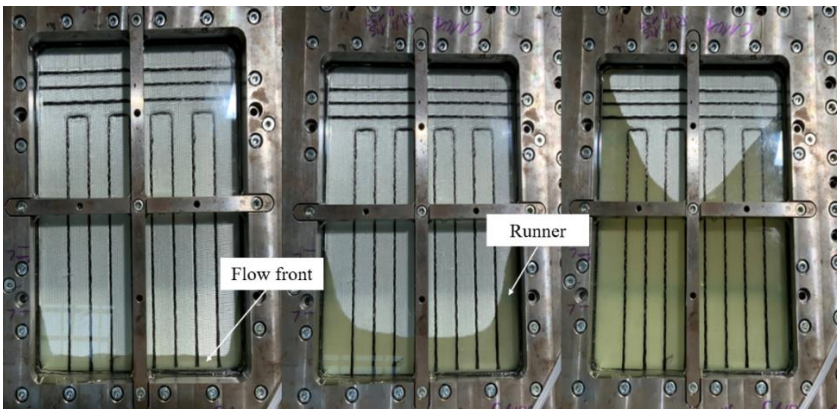

Figure 3: Flow front in the cavity of the RTM mold

Curing was conducted immediately after infiltration by irradiating the entire cavity surface through the transparent mold plate for 120 seconds using an air-cooled MZ80-395 nm UV-LED (IST INTECH Ltd, Banbury, Oxfordshire, United Kingdom), manually positioned close to the mold surface due to the window thickness.

2.3 Material characterization methods

Fourier Transform Infrared Spectroscopy (FT-IR)

The degree of cross-linking across the laminate thickness is measured using a LUMOS II FT-IR microscope (Bruker Optics GmbH & Co. KG, Ettlingen, Germany), performing measurements at 45 discrete points along the thickness direction of the samples. FT-IR analysis was conducted by comparing the C=C absorption peak intensity before and after UV curing, allowing the degree of conversion to be determined based on the reduction of reactive double bonds.

Differential Scanning Calorimetry (DSC)

The reaction enthalpy of the resin systems is analyzed using a UV-DSC 3500 Sirius (NETZSCH Group, Selb, Germany). The DSC system measures the exothermic heat flow during UV-induced

curing, enabling the analysis of reaction kinetics, curing rate, and degree of conversion in real time.

Microscopic Analysis

For microscopic analysis of the specimen cross-sections, samples were initially embedded in an epoxy resin (Struers EpoFix Resin, Struers GmbH, Willich, Germany). Subsequent grinding and polishing were performed using a Struers TegraPol-11 polishing machine (Struers GmbH, Willich, Germany). Wet grinding was conducted with diamond suspensions (Struers DiaPro, 3 µm and 9 µm), while final polishing employed alumina suspensions (Buehler MasterPrep, 0.05 µm, ITW Test & Measurement GmbH, Esslingen am Neckar, Germany) applied on appropriate adhesive discs (Struers MD-Plan and MD-Dur for diamond grinding, and Buehler Master Tex MD Rondo for alumina polishing). Microscopic investigations are conducted using a Keyence VHX-7000 digital microscope with the VH-Z20R objective (Keyence Corporation, Osaka, Japan).

Fiber Volume Content Analysis

The specimens were first dried to ensure consistent measurement conditions. For this purpose, they were placed in numbered crucibles and heated in a drying oven (BINDER, BD/ED/FD (E2)) at 70 °C for 24 hours. After drying, the samples were cooled for 15 minutes in a desiccator over silica gel. Once the specimens reached room temperature (23 °C), both the sample and the empty crucible were weighed. (DIN 29971 Sept. 1989)

Subsequently, the specimens were returned to the crucibles and heated at 600 °C for 24 hours in a muffle furnace (Heraus, KM 170, Hanau, Germany). During this process, the cured resin was thermally decomposed, leaving only the heat-resistant glass fibers. The crucibles containing the remaining glass fibers were then transferred to a desiccator to cool to room temperature. Once cooled, the crucibles with the remaining fibers were weighed again.

Mechanical Testing

The tensile properties of the UV-cured samples are evaluated according to DIN EN ISO 527-4 (Type 2) using the Hegewald & Peschke Universal Testing Machine Inspekt 250 kN (Hegewald & Peschke Meß- und Prüftechnik GmbH, Am Gründchen, Germany). The bending tests were conducted according to DIN EN ISO 14125 (Class 1) using the Hegewald & Peschke 20-1 (20 kN) testing machine (Hegewald & Peschke Meß- und Prüftechnik GmbH, Am Gründchen, Germany). The tensile test specimens have dimensions 250 mm × 25 mm x 2,6 mm. The 4th point bending test specimens measured 80 mm× 15 mm× 2.6 mm. Each specimen type is tested at least seven times. The test setup for the four-point bending and tensile tests is shown in Figure 4 (a-c).

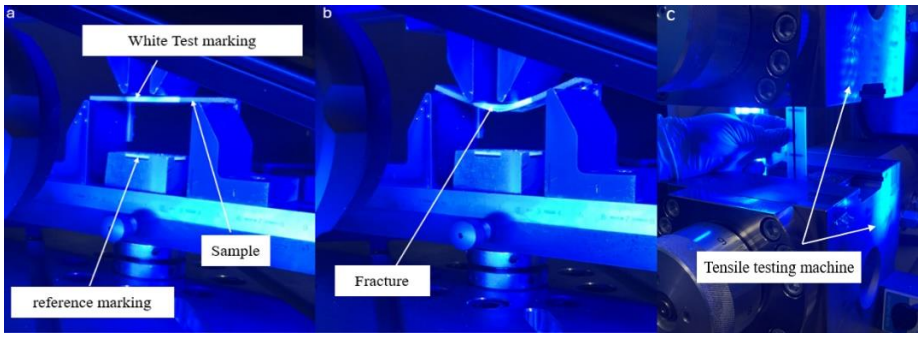

Figure 4: a) Bending test before the test, b) Bending test after fracture failure, c) Tensile testing machine with clamped sample.

3 RESULTS

For the determination of the C=C double bond conversion, cross-sectional samples were prepared in the same manner as for the microscopic analysis. The preparation process ensures consistent positioning and surface quality for accurate spectroscopic measurements. The measurement setup and a representative sample are shown in Figure 5.

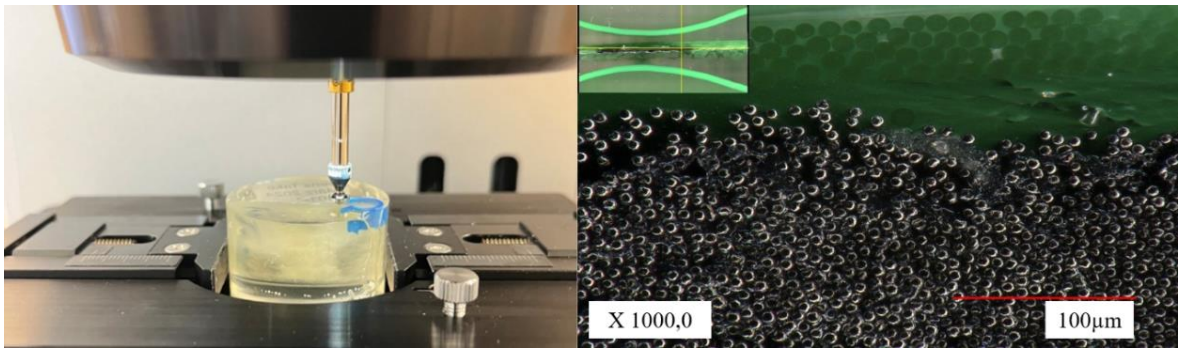

Figure 5: On the left, a measurement setup using FT-IR spectroscopy is shown. On the right, a cross-section of a sample is displayed.

Figure 6 illustrates the measurement of C=C double bond conversion in the thickness direction of the GFRP sample. An average conversion rate of 84 % is determined, excluding the top and bottom regions of the sample from the evaluation. A decrease of approximately 10 % is observed at both the top and bottom regions of the sample. This reduction is presumed to result from oxygen diffusion into the RTM mold, which may inhibit polymerization in these areas due to the oxygen inhibition effect in radical curing. To assess the spatial distribution of the conversion, three measurement series were conducted in the thickness direction of the sample. These are represented in green, yellow, and red curves on the right side of the figure, corresponding to different vertical positions within the specimen. The sample is shown in a horizontal orientation, with light exposure applied from the left side (x = 0.0 mm)**.** The right side of the figure (x = 2.4 mm) represents the bottom surface of the sample. This layout provides a clear depiction of the depth-dependent curing behavior across the composite thickness.

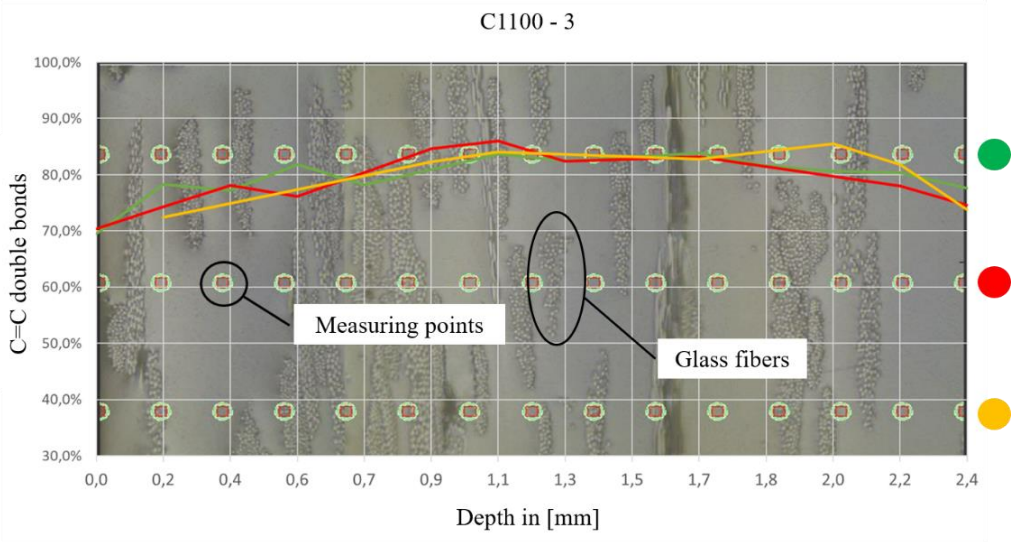

Figure 6: C=C double bond measurement of a GFRP sample, achieving an average value of 84 %.

To investigate the effect of irradiation time on the C=C double bond conversion, four samples containing the 12 K carbon fiber were prepared and subjected to different exposure durations. For the longest irradiation time of 120 seconds, a conversion rate of 84 % is achieved, corresponding to the

reference value obtained without the roving. The nine measurement points were placed above**,** within, and below the roving to evaluate the curing behavior in its immediate vicinity. (Figure 7)

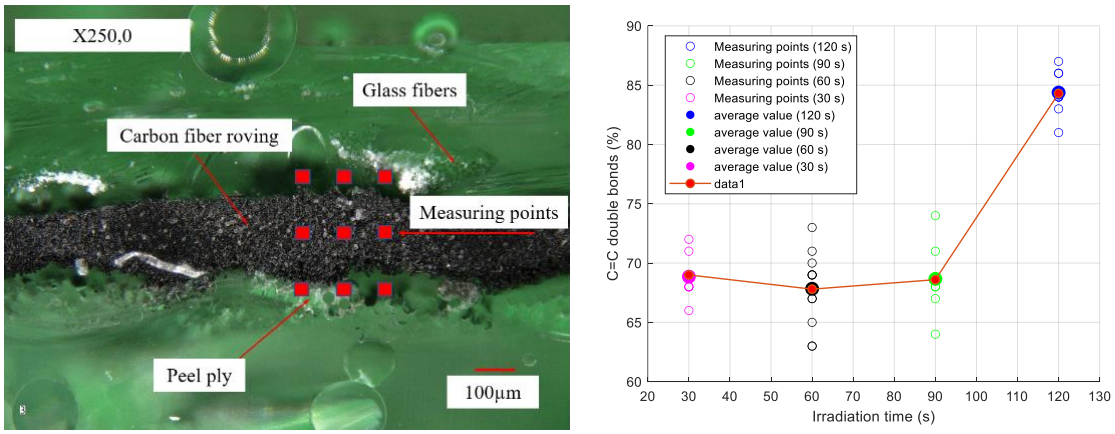

Figure 7: Sample with embedded C-Roving and marked measurement points used for determining the C=C double bond conversion and the Evaluation of the measuring points with the mean value.

The Table 2 lists the mean values of the respective samples with the corresponding irradiation times:

Sample	Irradiation Duration [s]	Mean value C=C double bonds [%]
A	30	70
B	60	68
C	90	69
D	120	84

Table 2: Measurements of the average value C=C double bonds of the samples with different irradiation times

The FVF and porosity of the seven tested samples are summarized in Table 3. The FVF ranged from 36.07 % to 37.86 %, with a mean value of 36.61 % and a standard deviation of 0.60 %. The corresponding porosity values ranged from –0.85 % to 4.76 %, with an average of 0.48 % and a standard deviation of 1.97 %. Negative porosity values are attributed to measurement uncertainty and indicate negligible or absent pore content in the respective samples.

Sample	Fiber volume content					
	Fiber			Pores		
	FVF	average	Standard deviation	Sample	average	Standard deviation
	%	%	%	%	%	%
CFK 1	36,13	36,61	0,60	0,77	0,48	1,97
CFK 2	36,50			-0,50		
CFK 3	36,67			4,76		
CFK 4	36,64			-0,85		
CFK 5	36,39			-0,55		
CFK 6	36,07			-0,51		
CFK 7	37,86			0,22		

Table 3: Measured fiber volume fractions and porosity values of the tested specimens.

The force-deflection behavior of six specimens under three-point bending is illustrated in Figure 8. All samples exhibit a comparable mechanical response, characterized by an initial linear-elastic region up to approximately 7–8 mm deflection, followed by nonlinear deformation until reaching the maximum force. The fracture loads lie between approximately 300 Pa and 320 Pa, demonstrating good

repeatability and uniformity across the specimens. After reaching the peak load, the force drops abruptly, indicating sudden failure of the specimen. Minor deviations in stiffness and ultimate load may result from local variations in fiber alignment or porosity. Overall, the results confirm consistent flexural performance of the tested composite samples.

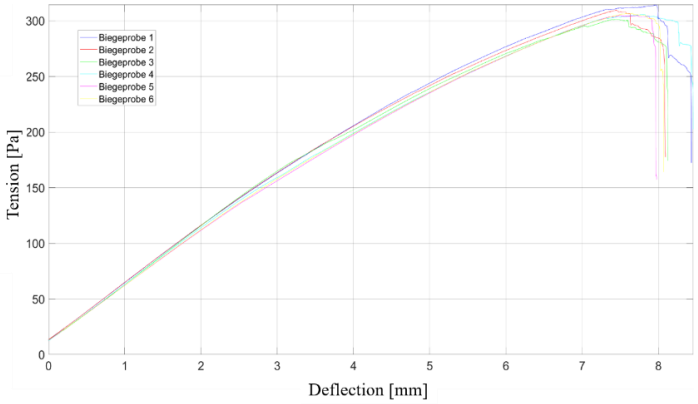

Figure 8: Force–deflection curves of six specimens from three-point bending tests, showing consistent peak loads and failure behavior.

Figure 9 presents the force-elongation curves of seven glass fiber specimens, each reinforced with an embroidered roving. The majority of specimens display a linear-elastic response up to failure, typical of fiber-reinforced composite materials. The specimens fail abruptly upon reaching their maximum load, indicating brittle fracture behavior.

Maximum forces range from approximately 170 MPa and 270 MPa, with elongations at failure between 1.0 % and 1.8 %. Specimen 6 achieved the highest load and strain before failure, suggesting improved load transfer or local reinforcement effects due to the roving structure. The similarity among most curves indicates good repeatability and consistency in material behavior and test conditions.

However, specimen 3 deviates significantly from the others, showing almost no force development and a flat response across the strain axis. This anomaly suggests a testing error, misalignment, or possible damage in the specimen before loading. Given this, it should be excluded from the statistical evaluation.

The abrupt force drops after reaching peak load confirm a brittle failure mode, as expected for glass fiber composites. The embroidered roving appears to have contributed positively to the tensile performance, though the scatter in the maximum loads indicates some variability in the stitching or local fiber alignment.

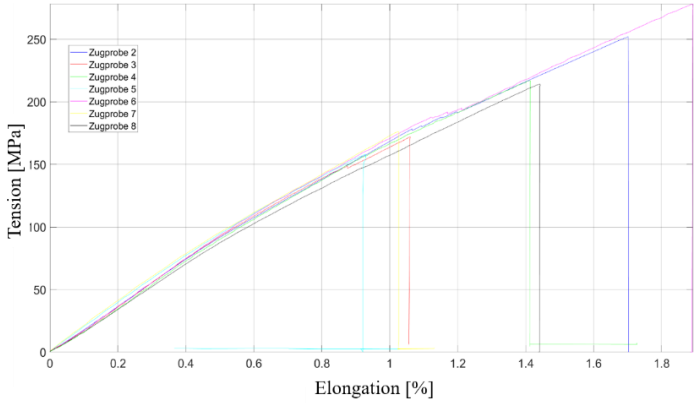

Figure 9: Tensile test results of glass fiber specimens with embroidered roving.

4 CONCLUSIONS AND DISCUSSION

This study investigated the feasibility of UV curing glass fiber-reinforced polymer (GFRP) components, locally stiffened with non-transparent stitched carbon fiber CF, manufactured via LRI processes using UV radiation. Complementary characterization was conducted to assess the degree of cure, the material characteristics, the fiber volume content, and the fiber–matrix interfacial quality.

The highest degree of cure was observed in specimens manufactured via the RTM process after 120 seconds of UV exposure, reaching approximately 84 %. Mechanical testing of RTM-manufactured specimens irradiated for 120 seconds revealed mechanical performance comparable to that of conventionally cured CFRPs. These findings confirm the viability of UV curing for CFRP components under the conditions studied.

However, the samples examined featured a relatively low carbon fiber content. Therefore, the transferability of results to structural CFRP components with higher fiber volume fractions and without glass fibers is limited. Further investigations focusing on preforms made solely from carbon fiber fabrics are recommended to evaluate the broader applicability of UV curing for structural applications.

The UV curing durations in this study were limited to four discrete intervals (30, 60, 90, and 120 s). It is plausible that intermediate exposure times could also yield cure degrees exceeding 84 %. Future research should aim to identify the optimal irradiation time with finer time resolution, particularly to better understand the inflection point in cross-linking behavior within the 90–120 s range.

Cross-sectional analysis showed consistent FVF across all samples, with an average of 36.61 % and minimal variation (standard deviation of 0.60 %). Porosity was generally low, averaging 0.48 %, although some negative values were recorded due to measurement uncertainty, indicating negligible pore content.

Mechanical testing under three-point bending showed highly consistent force–deflection behavior across six samples. Peak loads ranged between 300 Pa and 320 Pa and all specimens exhibited brittle failure after reaching maximum force. The close agreement between the curves suggests uniform fiber distribution and good reproducibility of the manufacturing process.

The tensile tests show a consistent linear-elastic behavior across all samples up to failure, with fracture forces ranging from approximately 170 MPa to 270 MPa. The elongation at break lies between 1.1% and 1.7%, indicating a brittle fracture behavior typical for fiber-reinforced thermosetting composites. The variation in fracture force may result from local differences in fiber distribution or matrix-fiber interaction quality.

The combination of high cure conversion, stable fiber volume content, low porosity, and consistent mechanical performance confirms the quality and reliability of the produced CFRP laminates.

Overall, UV curing demonstrates significant promise as a fast and energy-efficient alternative to thermal curing in composite manufacturing. The reduced curing time, combined with lower energy demand and the use of LED technology, supports the potential for more sustainable and scalable production of fiber-reinforced composites.

ACKNOWLEDGEMENTS

The authors would like to express their sincere gratitude to IST METZ GmbH & Co. KG for the excellent collaboration and for providing access to their laboratory analysis equipment, which significantly contributed to the success of this work.

We would like to thank the Baden-Württemberg Ministry of Science, Research, and the Arts for its financial support of the InnovationCampus Future Mobility.

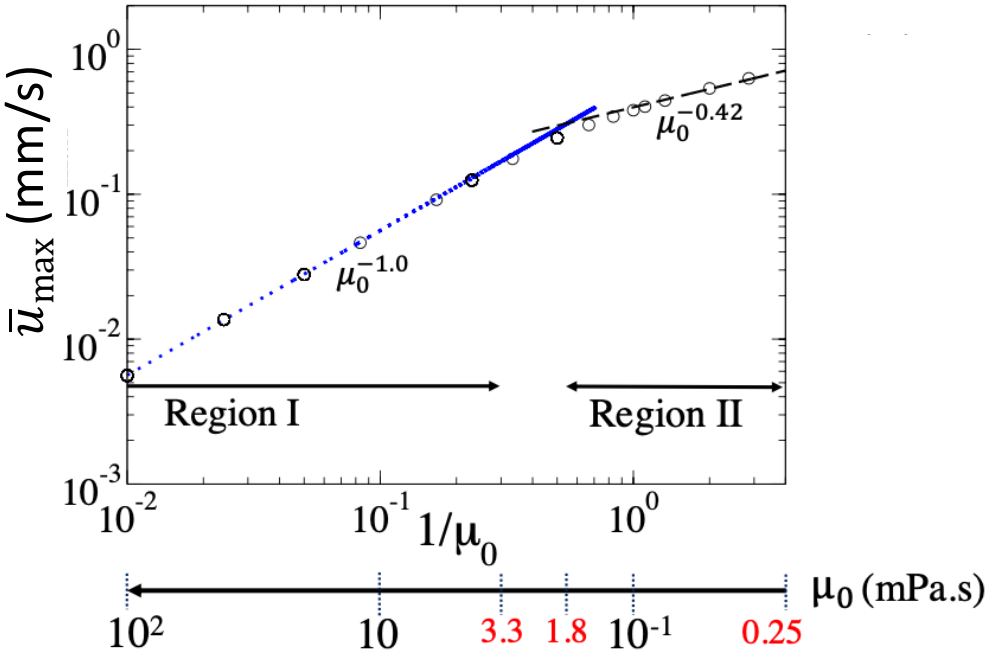
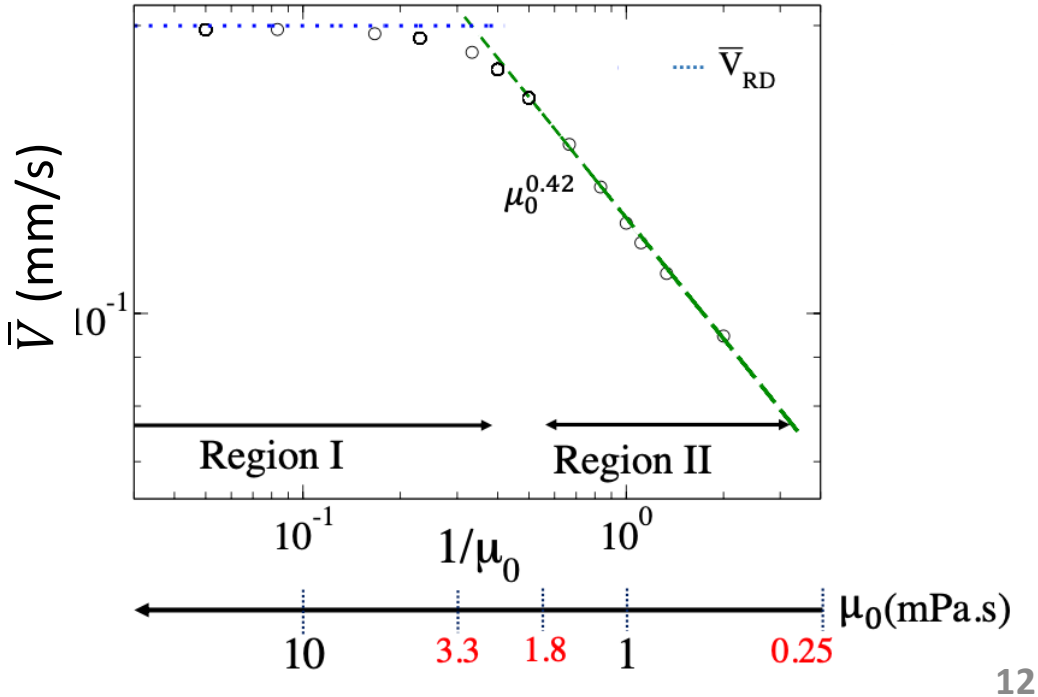
$\overline{W}$ = steady deformation



$L_z = 1.25$ mm

1. Front propagation with constant viscosity



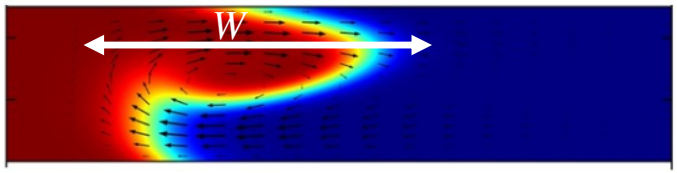
The front reaches an asymptotic dynamics, **two regimes** are observed depending on the viscosity μ_0

$L_z = 1.25$ mm

$\bar{u}_{\max}$ = maximum horizontal flow velocity

$\bar{V}$ = constant propagation speed

1. Front propagation with constant viscosity



The front reaches an asymptotic dynamics, **two regimes** are observed depending on the viscosity μ_0

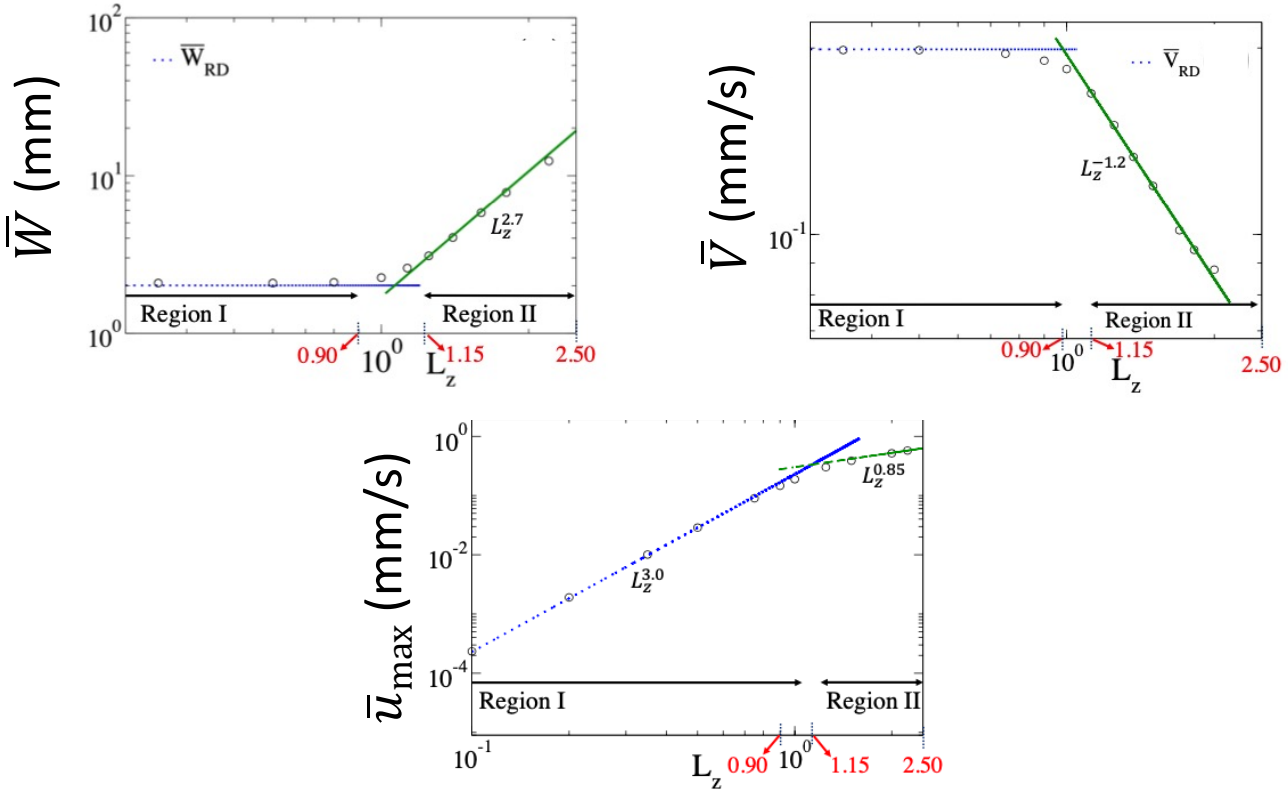
$L_z = 1.25$ mm

	Viscosity range	$\bar{u}_{max}$	$\overline{W}$	$\overline{V}$
Region I	$\mu_0 \geq 3.3$ mPa.s	μ_0^{-1}	μ_0^{0}	μ_0^{0}
Region II	0.25 mPa.s $\leq \mu_0 \leq 1.8$ mPa.s	$\mu_0^{-2/5}$	$\mu_0^{-4/5}$	$\mu_0^{2/5}$

Characteristic horizontal convective time scale:

$$t_c \sim \frac{\overline{W}}{\bar{u}_{max}} \sim \frac{\mu_0^{-4/5}}{\mu_0^{-2/5}} \sim \mu_0^{-2/5}$$

$\mu_0 \searrow$: flow and deformation $\nearrow$ but $t_c \nearrow \Longrightarrow \bar{V} \searrow$



*Different from **isothermal autocatalytic fronts** where convection increases mass transfer rates.*

Tiani, De Wit, Rongy, Adv. Colloid Interf. Sci. 225 (2018).

1. Front propagation with constant viscosity

The front reaches an asymptotic dynamics, **two regimes** are observed depending on the layer thickness L_z (mm)

$\mu_0 = 1.5$ mPa.s

1. Front propagation with constant viscosity

Summary

The front reaches an asymptotic dynamics with steady shape $\bar{W}$, constand speed $\bar{V}$, steady vortex

CONVECTION ↗ $\mu_0 \searrow$ or $L_z \nearrow$

"PASSIVE" REGIME

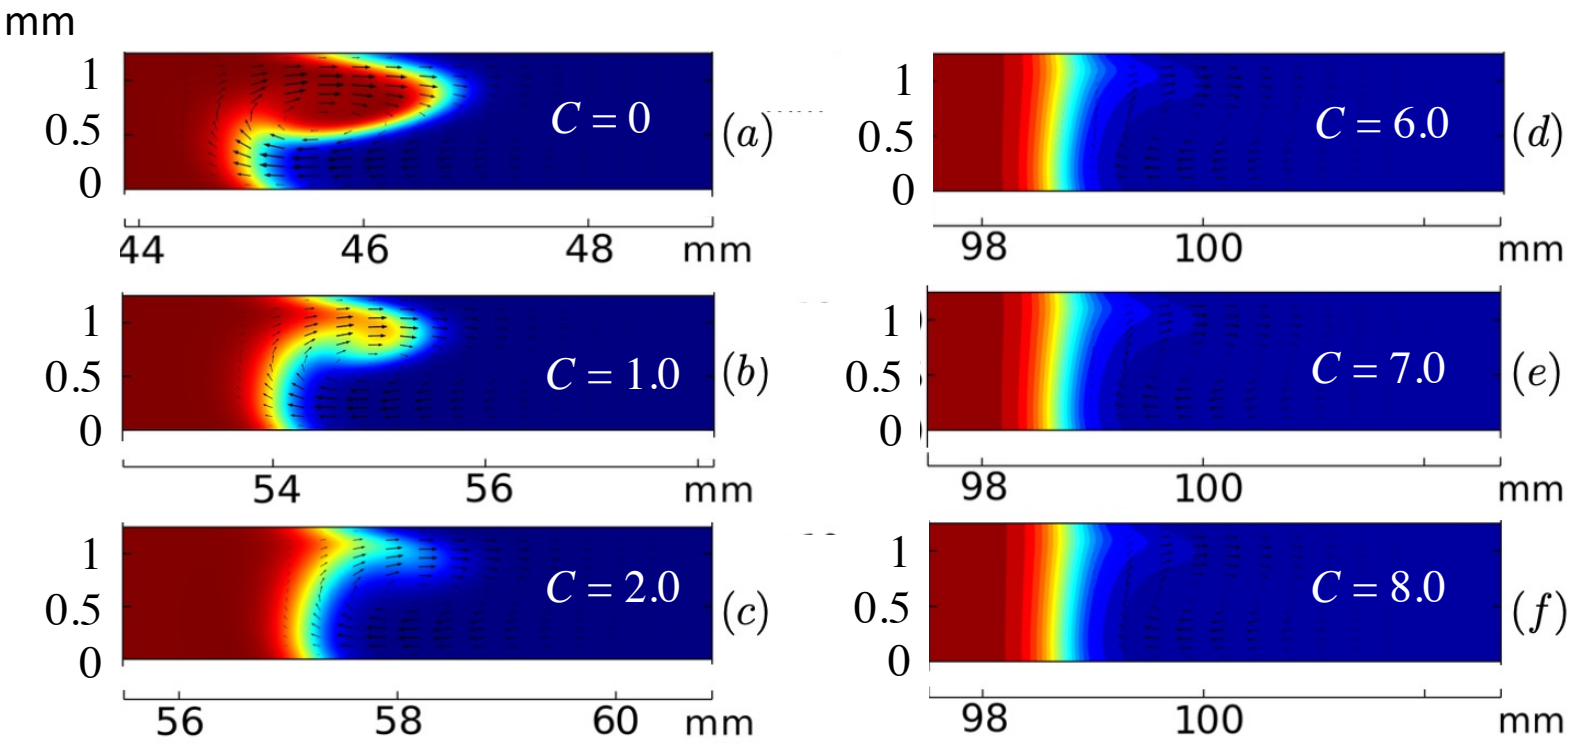
$\bar{W} \sim W_{RD}$

$\bar{V} \sim V_{RD}$ *(cf: reaction-diffusion)*

$u_{\max} \sim \frac{L_z^3}{\mu_0}$

"ACTIVE" REGIME

$\bar{W} \nearrow$

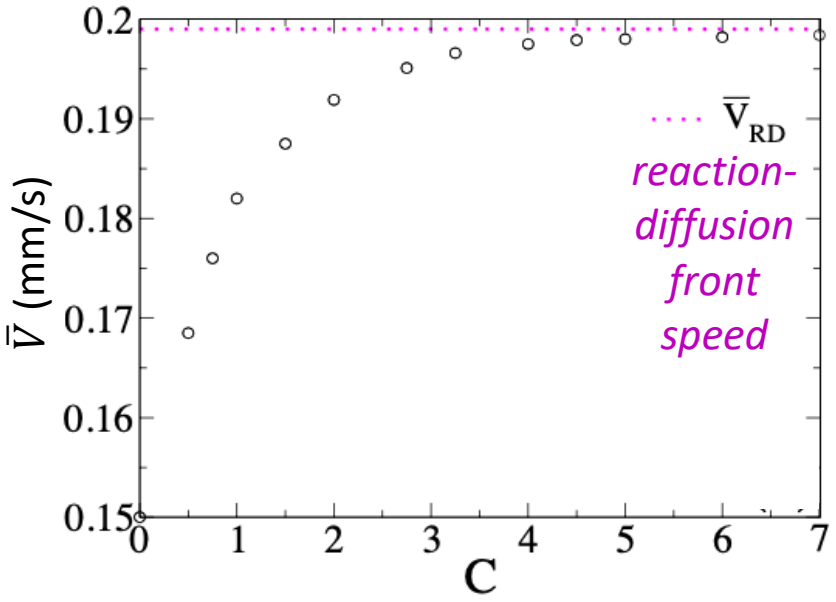


$\bar{V} \searrow$

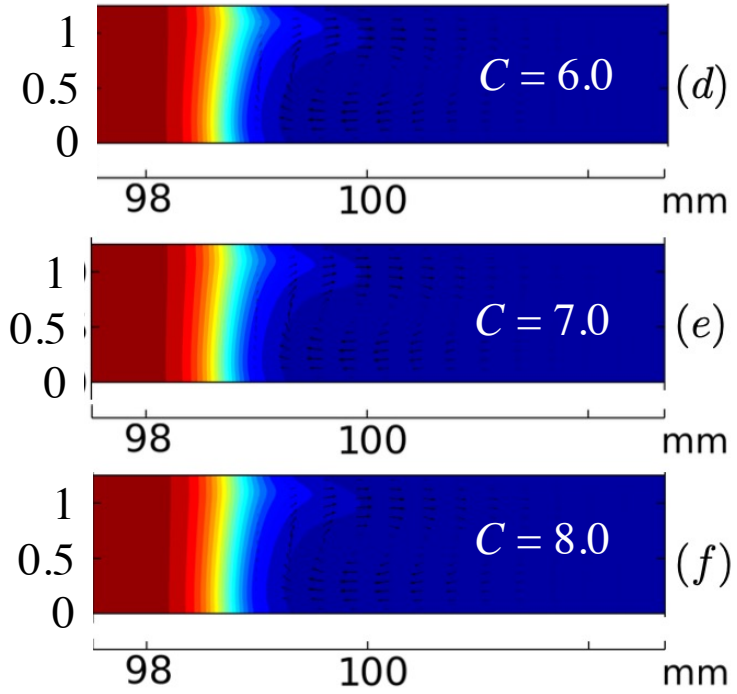
$u_{\max} \nearrow$ but more weakly (smaller scaling exponents)

2. Front propagation with varying viscosity $\mu = \mu_0 e^{C\psi}$

The viscosity increases with the degree of cure ψ.
When C increases, the deformation decreases and $\bar{V} \rightarrow V_{RD}$.



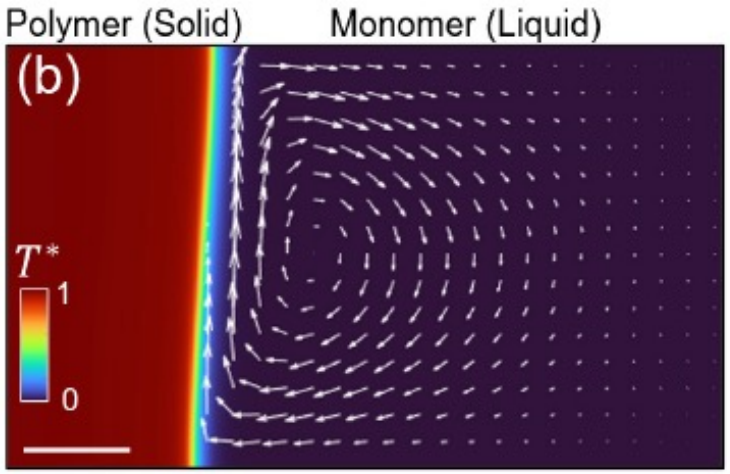
$L_z = 1.25$ mm
$\mu_0 = 1.5$ mPa.s

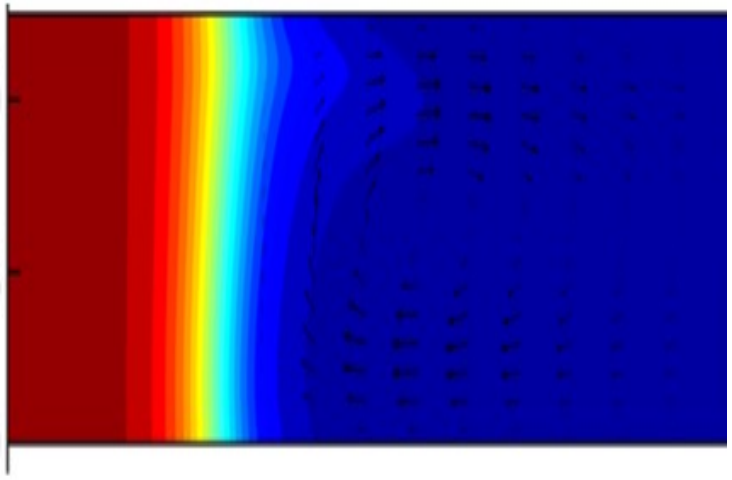


2. Front propagation with varying viscosity $\mu = \mu_0 e^{C\psi}$

The viscosity increases with the degree of cure ψ.
When C increases, the deformation decreases and $\bar{V} \rightarrow V_{RD}$.

$L_z = 1.25$ mm
$\mu_0 = 1.5$ mPa.s

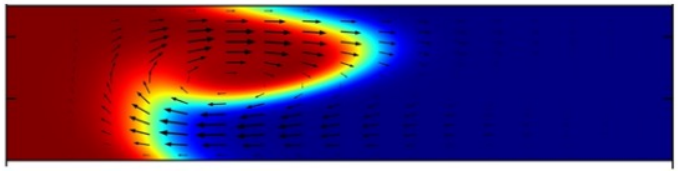




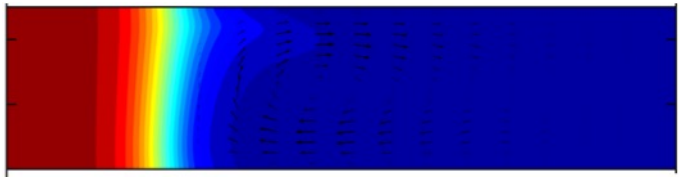
2. Front propagation with varying viscosity $\mu = \mu_0 e^{C\psi}$

The viscosity increases with the degree of cure ψ.
When C increases, the deformation decreases.

cf: Gao, Paul, Chen, Hong, Chamorro, Sottos, Geubelle, PRL 130 (2023).



$C = 8.0$



Conclusions

- **Buoyancy-driven convection** arises from **thermal gradients** across polymerization front.

- Convection strengthens when the **monomers' viscosity** is decreased or the **layer thickness** increases.
- **Asymptotic dynamics** with constant deformation ($\bar{W}$ ↗ with flow), constant speed ($\bar{V}$ ↘ with flow).
- Transition between a **"passive" regime (RD + hydro)** and an **"active" regime (chemo-hydrodynamic coupling)**.
- Viscosity increasing during reaction: flow ahead of reaction zone.

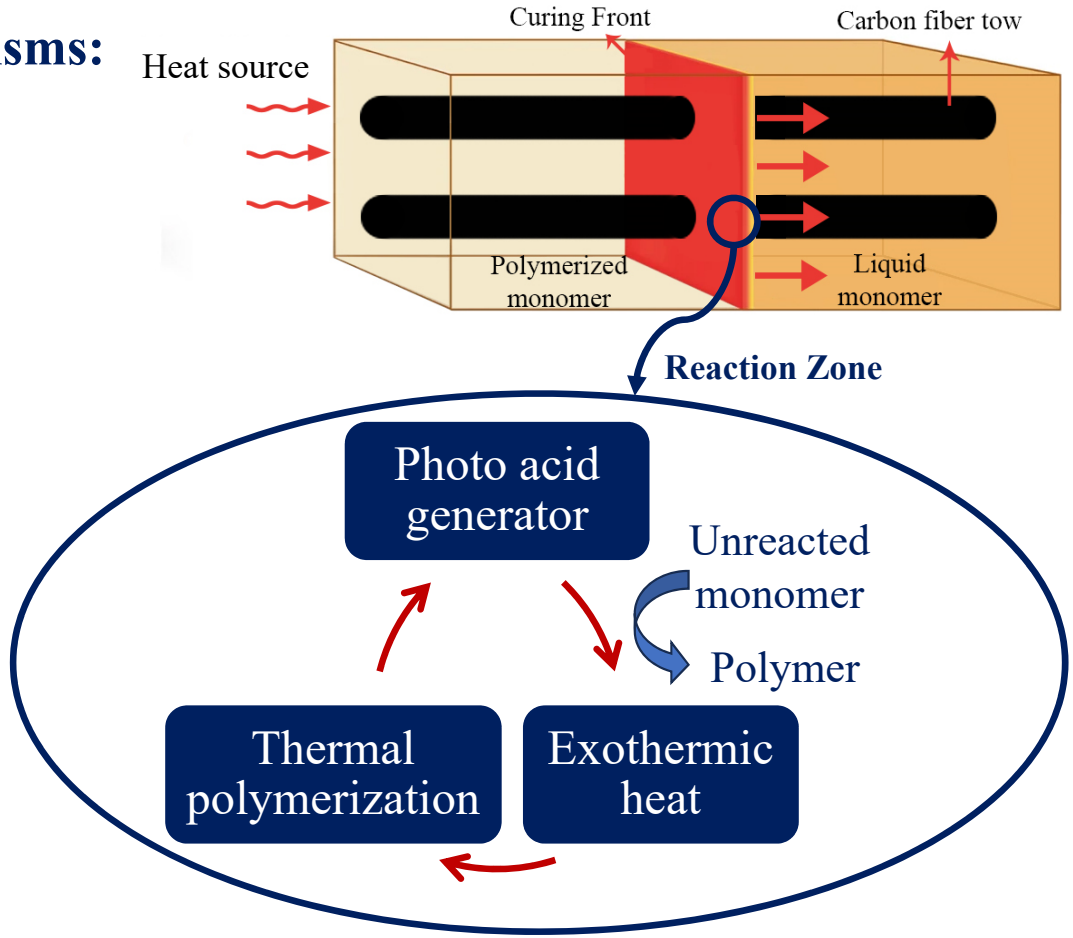
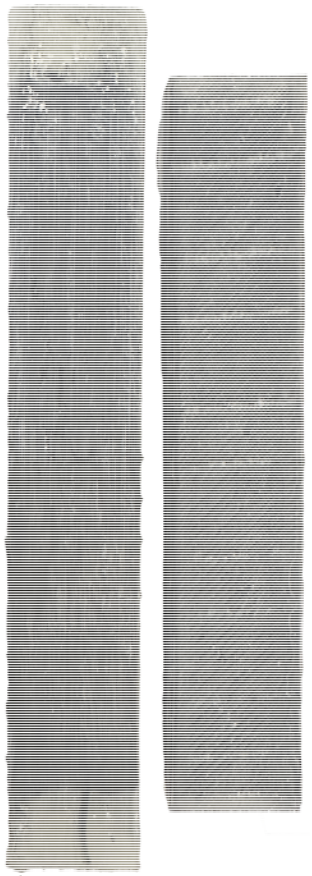
Composite Materials Laboratory



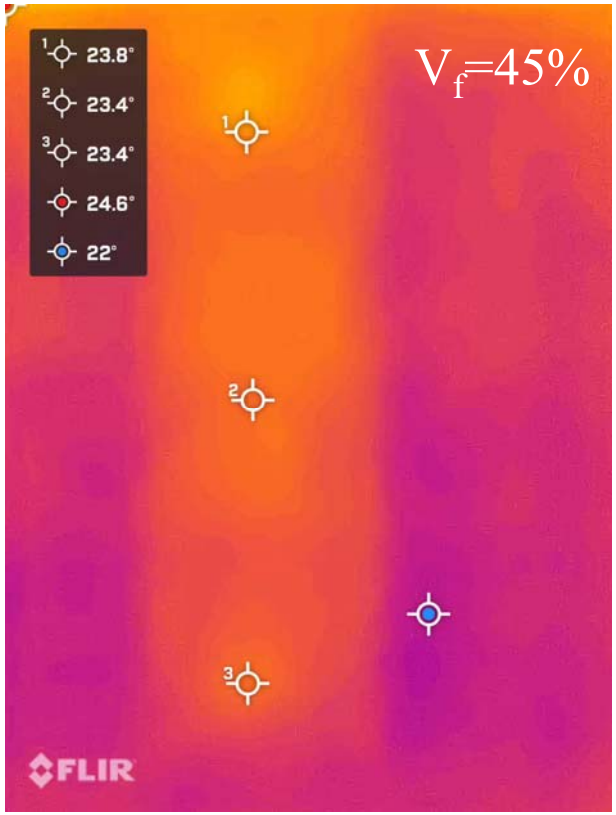
Presentation at the ICCM24 conference, Baltimore Convention Center, Baltimore, Maryland, August 4-8, 2025

Syracuse University
College of Engineering & Computer Science



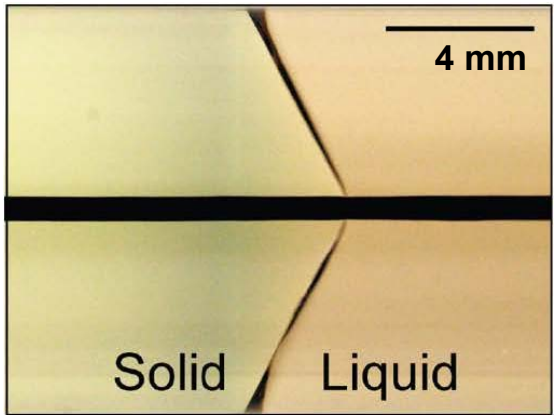
Background

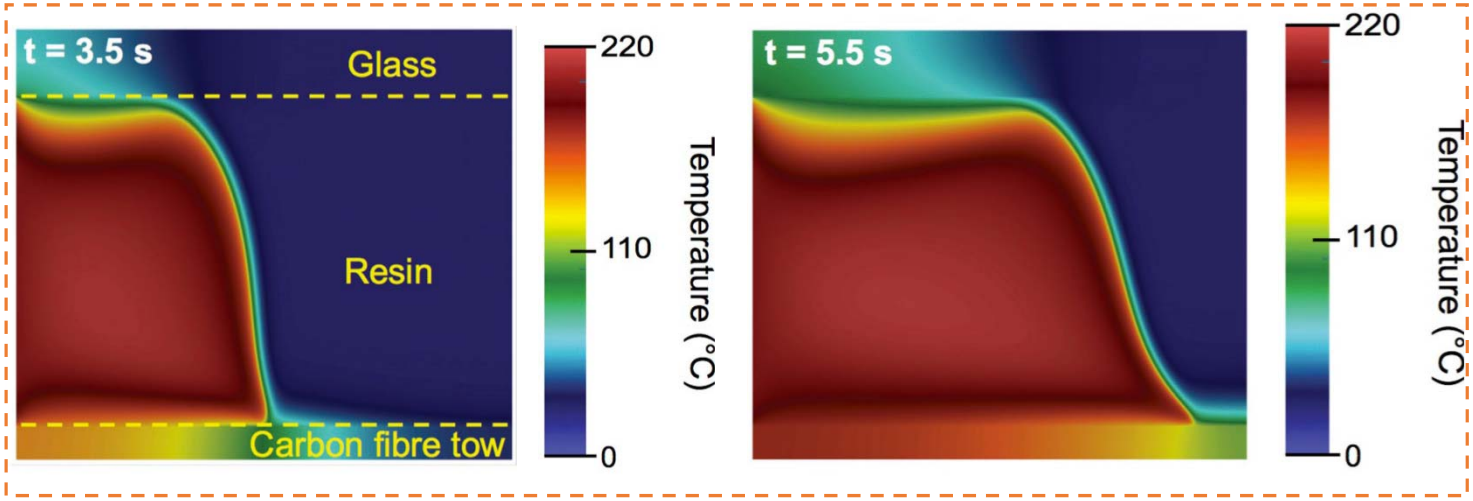
UV-induced frontal polymerization mechanisms:



- Reduce curing time from hours to few seconds or minutes
- Significant reductions in cost & energy
- Compatible with opaque FRP laminates

UV-induced frontal polymerization for CFRP composites





Curing time dropped from 15 hours to only 66-83 seconds!

Modeling of Frontal Polymerization in Carbon Fiber Composites

Experimental Data [1]
(Optical Measurements)

2D Model Simulations [1]

Existing models mainly focused on 1D and 2D configurations

Need to develop 3D models to study the effect of composite layups (e.g., unidirectional, cross-ply) and triggering directions for practical applications!

[1] . Robertson ID, et al. Rapid energy-efficient manufacturing of polymers and composites via frontal polymerization. Nature. 2018;557(7704):223-7.

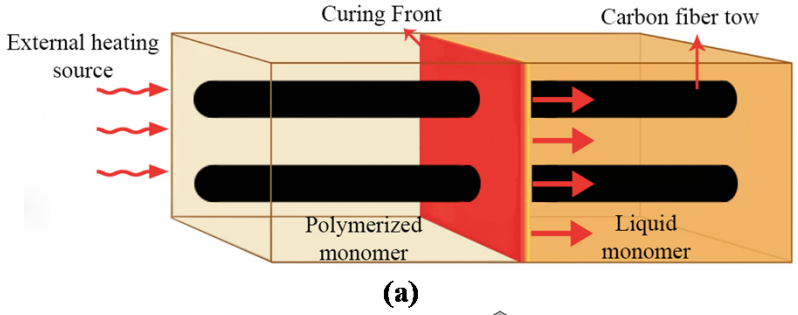
Part 1:

3D Modeling of Heat-Triggered Frontal Polymerization in CFRP

Problem Formulation

- Heat is generated by an enthalpic reaction during the frontal polymerization process:

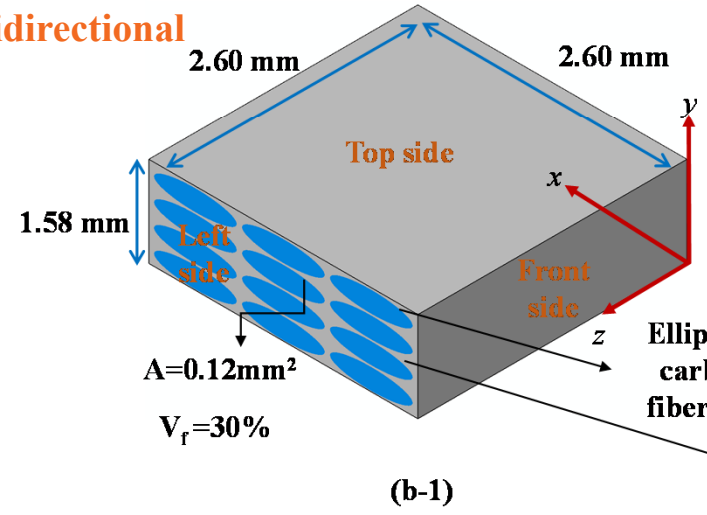
$$k\left(\frac{\partial^2 T}{\partial x^2}+\frac{\partial^2 T}{\partial y^2}+\frac{\partial^2 T}{\partial z^2}\right)+\rho H_r\frac{\partial \alpha}{\partial t}=\rho C_P\frac{\partial T}{\partial t},$$



- The curing kinetics is described by Arrhenius equation with the classical Prout-Tompkins (PT) autocatalytic model:

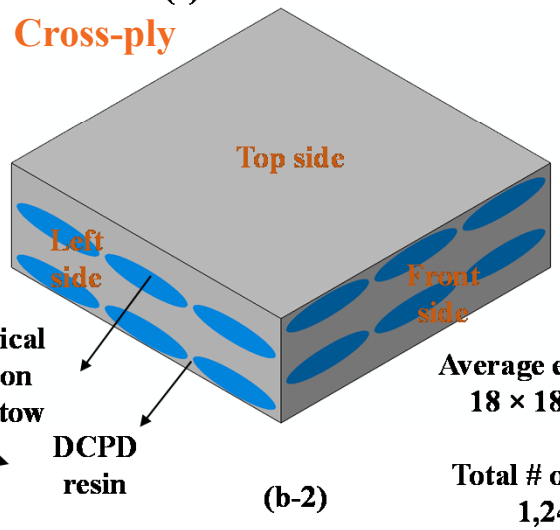
$$\frac{\partial \alpha}{\partial t}=A\,exp(-\frac{E}{RT})(1-\alpha)^n\alpha^m\frac{1}{1+\exp\left[\mathrm{C}(\alpha-\alpha_c)\right]}$$

Numerical Implementation

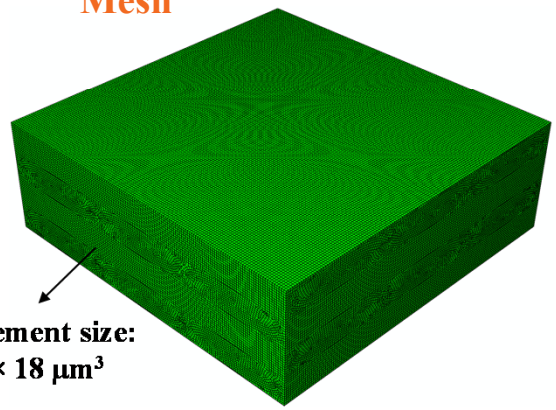


- Finite element analysis using Abaqus with: HETVAL + USDFLD user subroutines

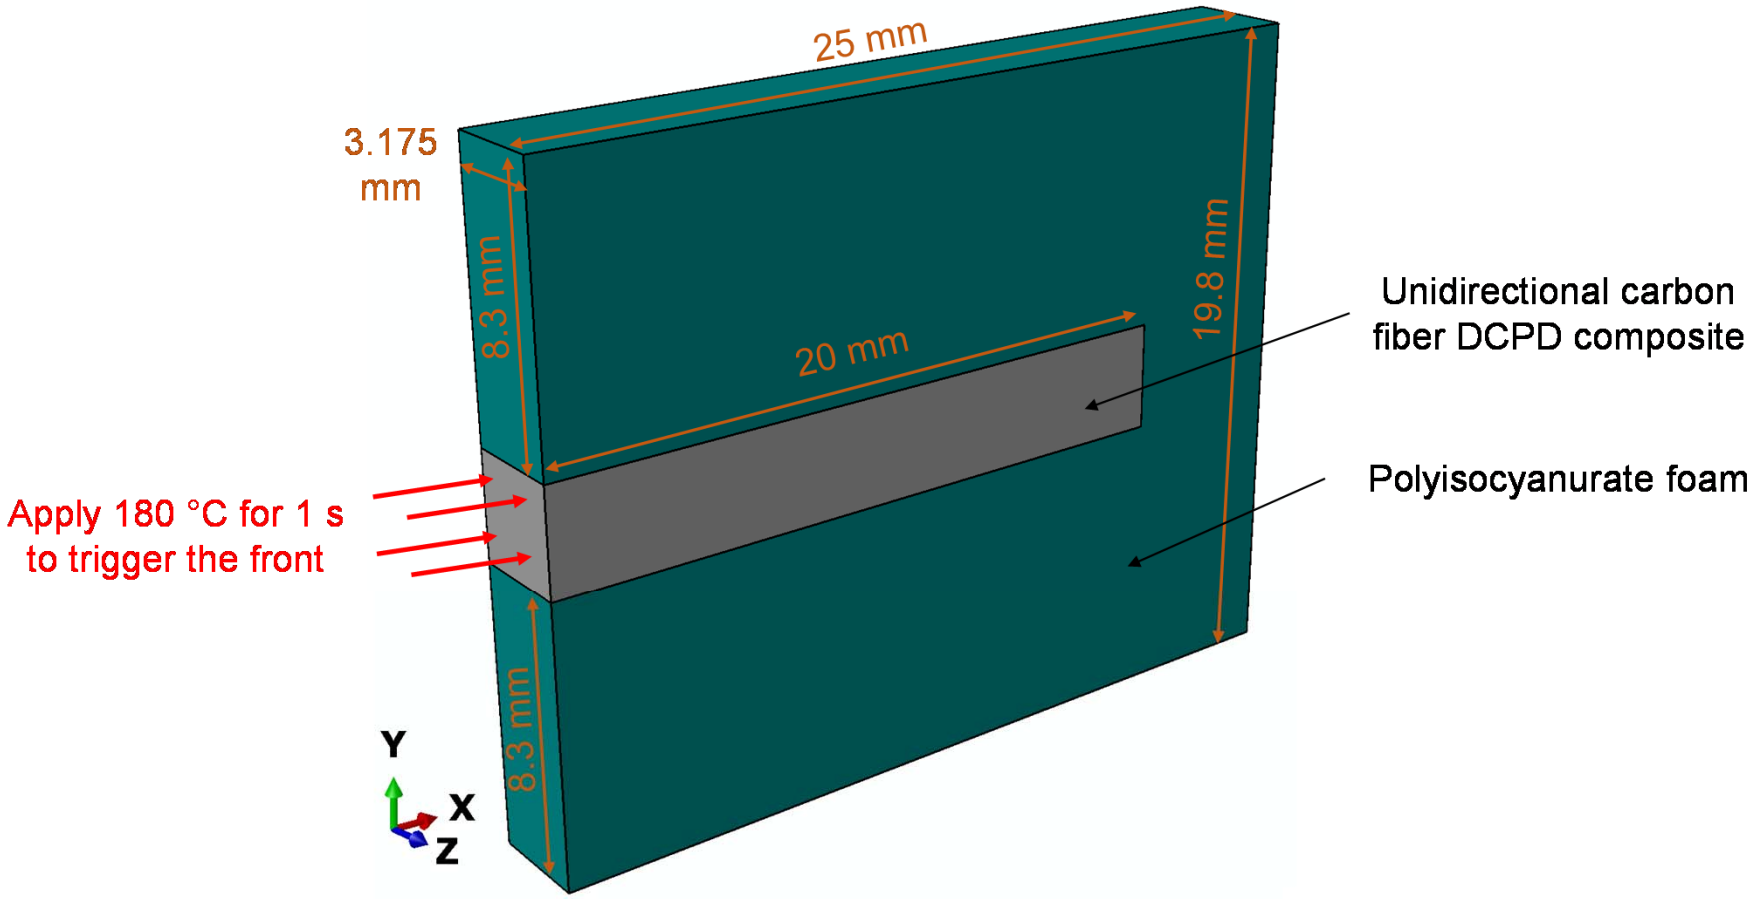
Monomer:
Dicyclopentadiene (DCPD) resin



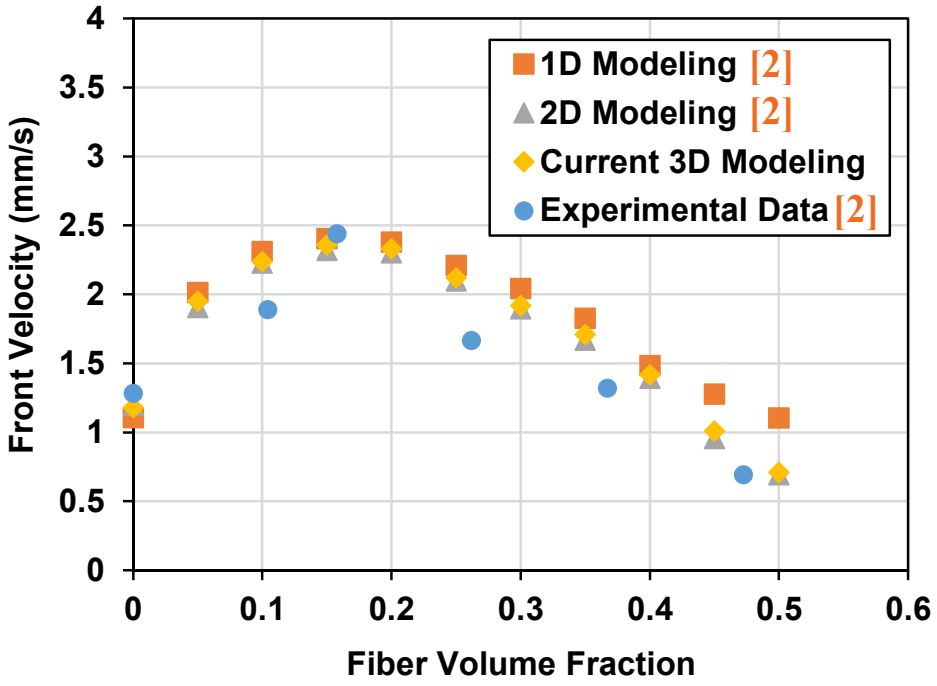
8-node linear heat transfer quadrilateral brick elements



Unidirectional



Cross-ply



Mesh

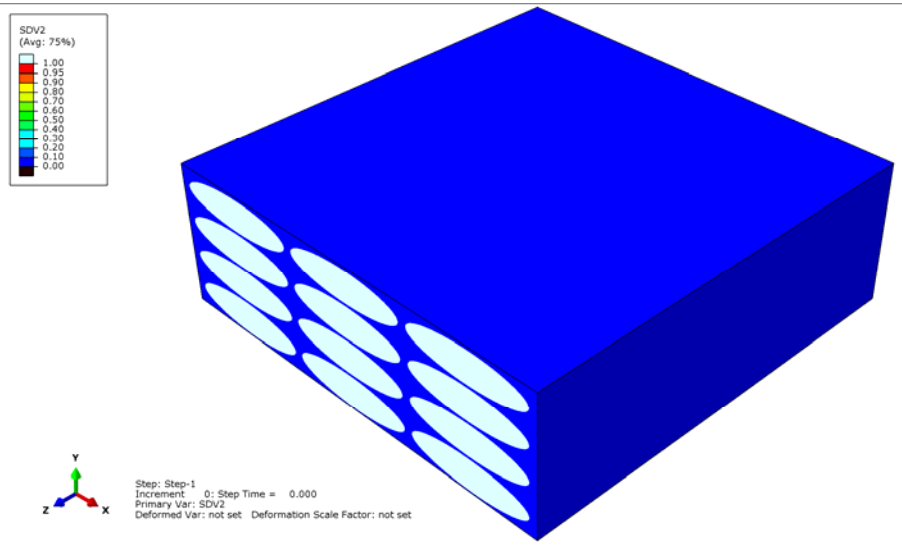
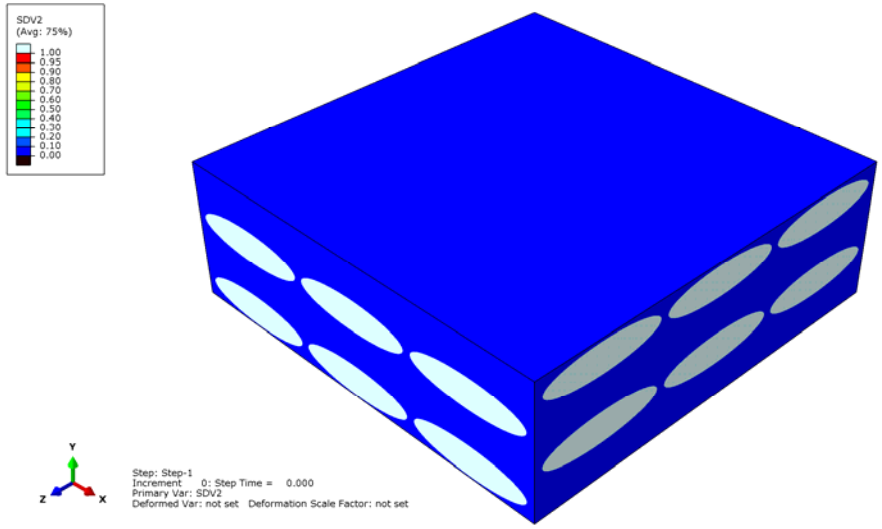
Results: Frontal Triggered from the Top Surface

Unidirectional

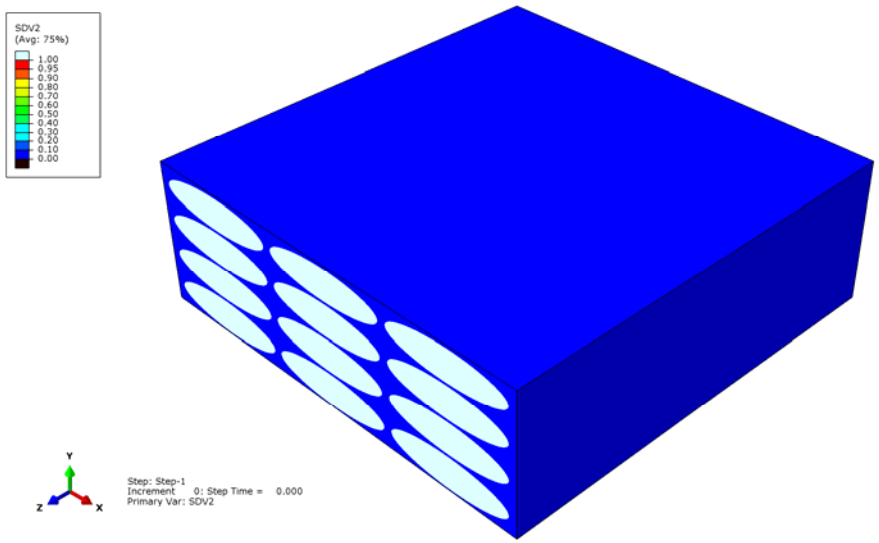


Cross-ply

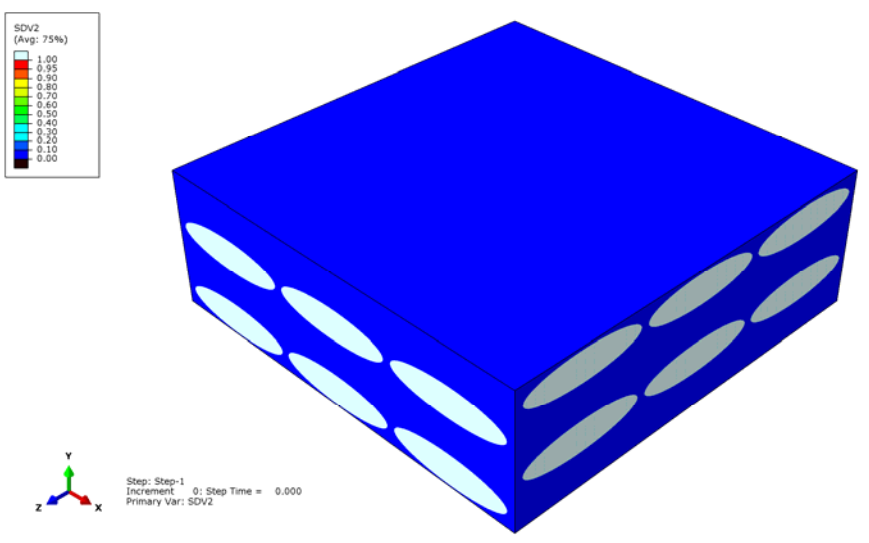


Results: Frontal Triggered from One Side

Unidirectional

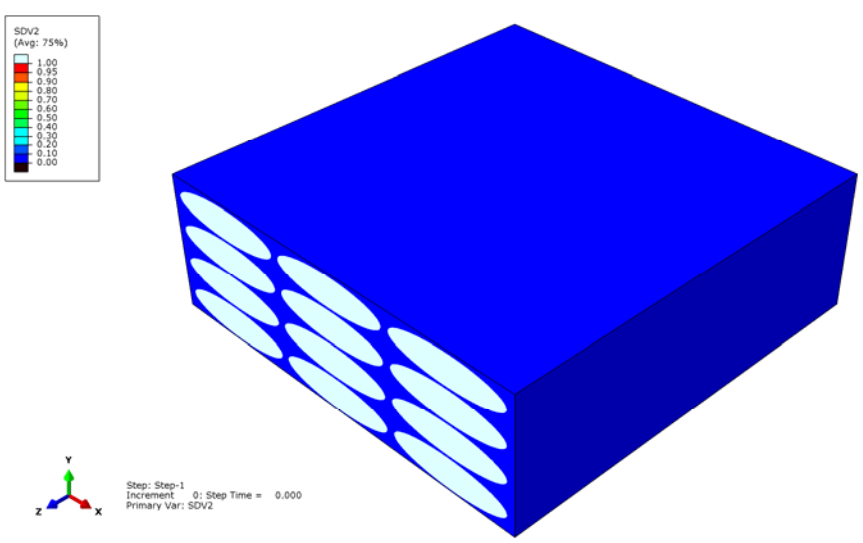


Cross-ply

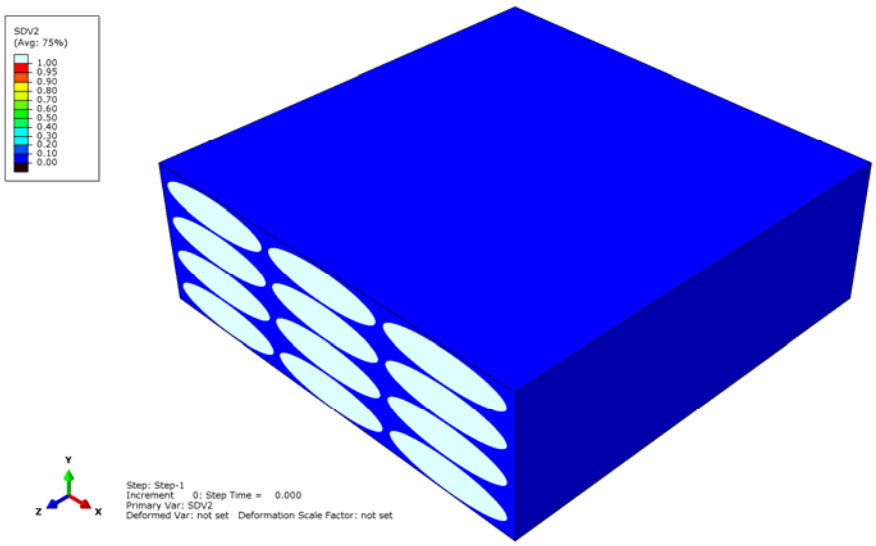


Results: Frontal Triggered from Two Sides

Unidirectional



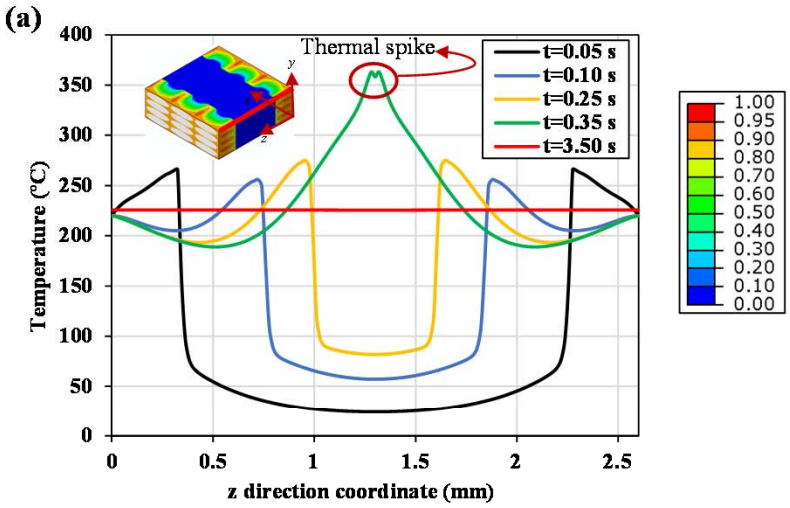
Cross-ply



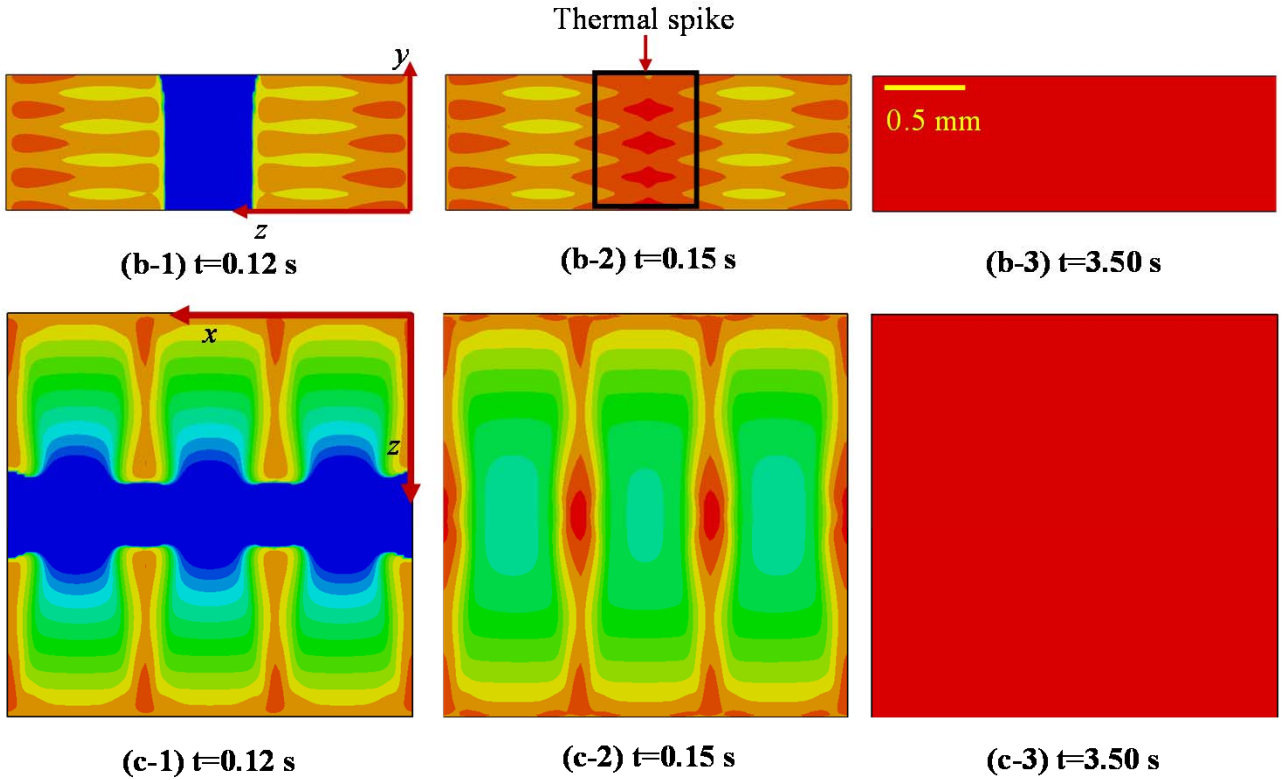
Results: Frontal Triggered from Front (Perpendicular to Fiber Direction)

Unidirectional
(triggered from front surface)

Unidirectional
(triggered from front & back surfaces)



Results – Unidirectional Layup

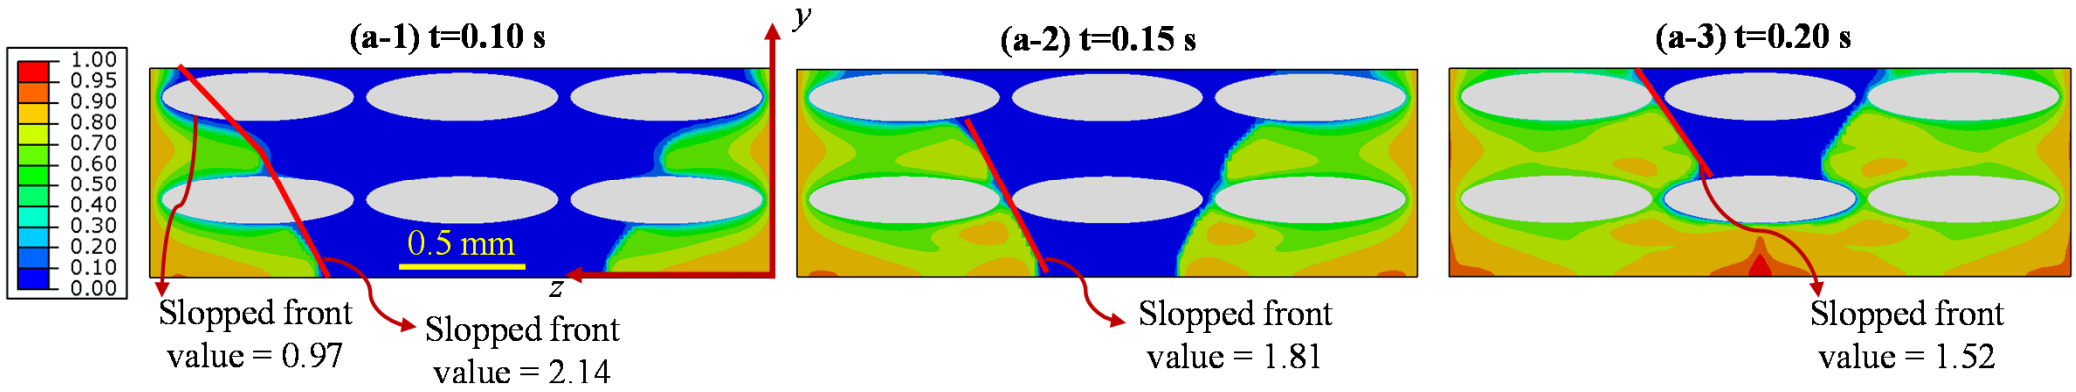


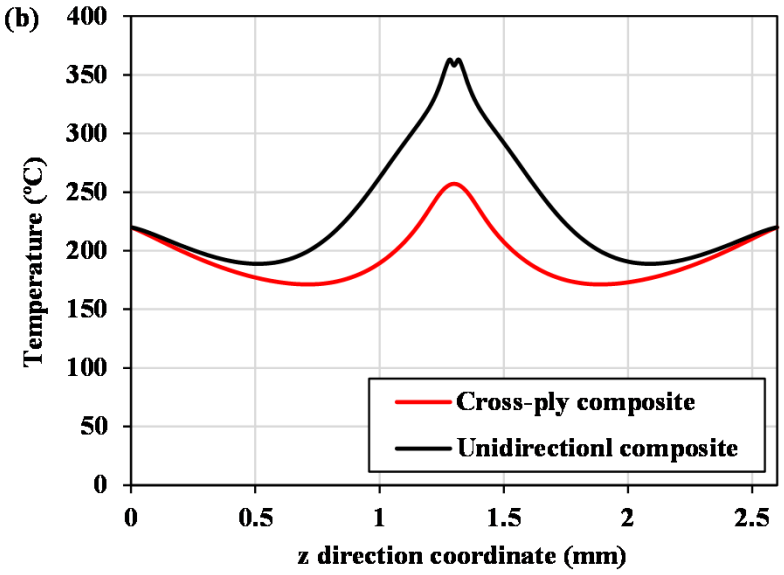
- Triggering parallel to the fiber direction leads to a faster frontal propagation and higher degree of cure
- Triggering from two sides accelerates the frontal propagation

Specimen	Initial curing duration (s)	Average front velocity (mm/s)	Average degree of cure (%)
UT	0.48	1.80	94.30
UL	0.42	6.17	95.30
ULR	0.14	9.13	99.50
UF	Not fully cured	0.27	24.80
UFB	1.11	1.16	77.30

Results – Unidirectional Layup

- Thermal spike forms when the two fronts merge if triggered from both sides
- May indicate wavy patterns or non-uniform degree of cure



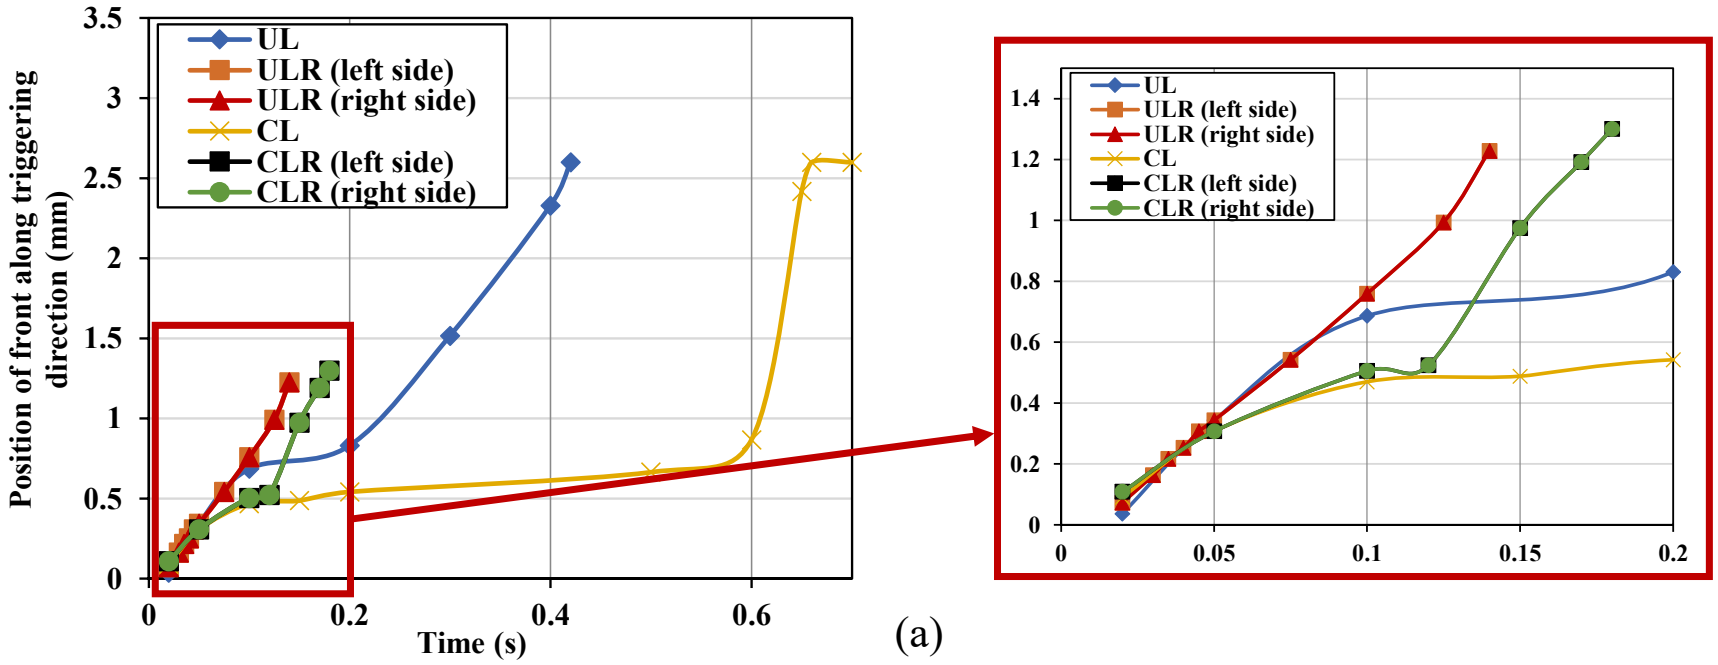


Results – Cross-Ply Layup

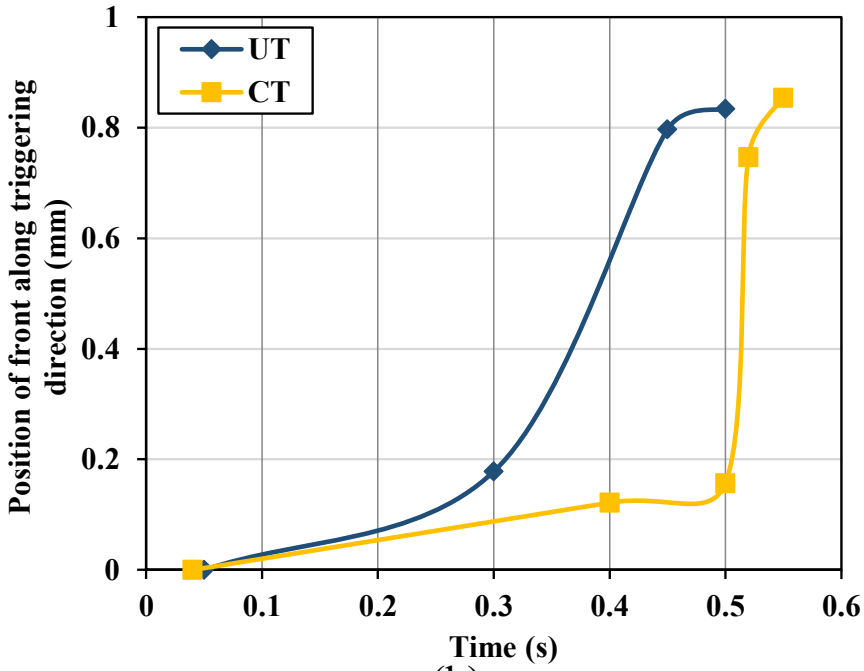
- Triggering parallel to the fiber is still preferred
- Triggering from both sides accelerates the frontal polymerization and leads to an overall higher degree of cure

Specimen	Initial curing duration (s)	Average front velocity (mm/s)	Average degree of cure (%)
CT	0.54	1.58	94.00
CL	0.56	4.59	87.80
CLR	0.17	7.27	99.40

Results – Cross-Ply Layup



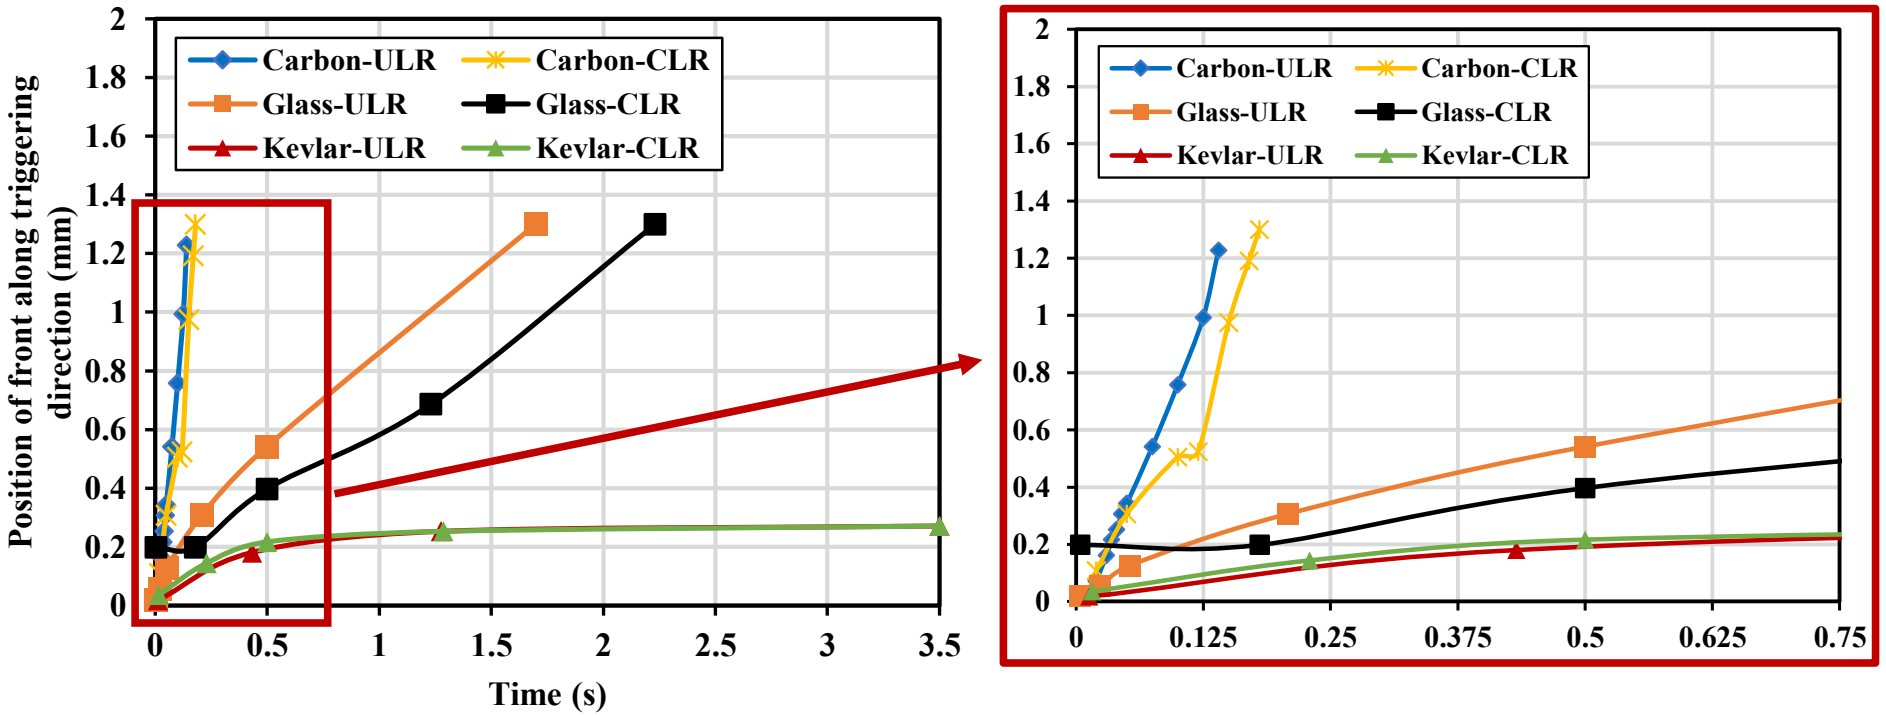
- Thermal spike still exists in cross-ply laminates if triggered from two sides
- The temperature at the thermal spike is 100 degrees lower in cross-ply when compared to unidirectional laminates



Results – Unidirectional vs. Cross-Ply

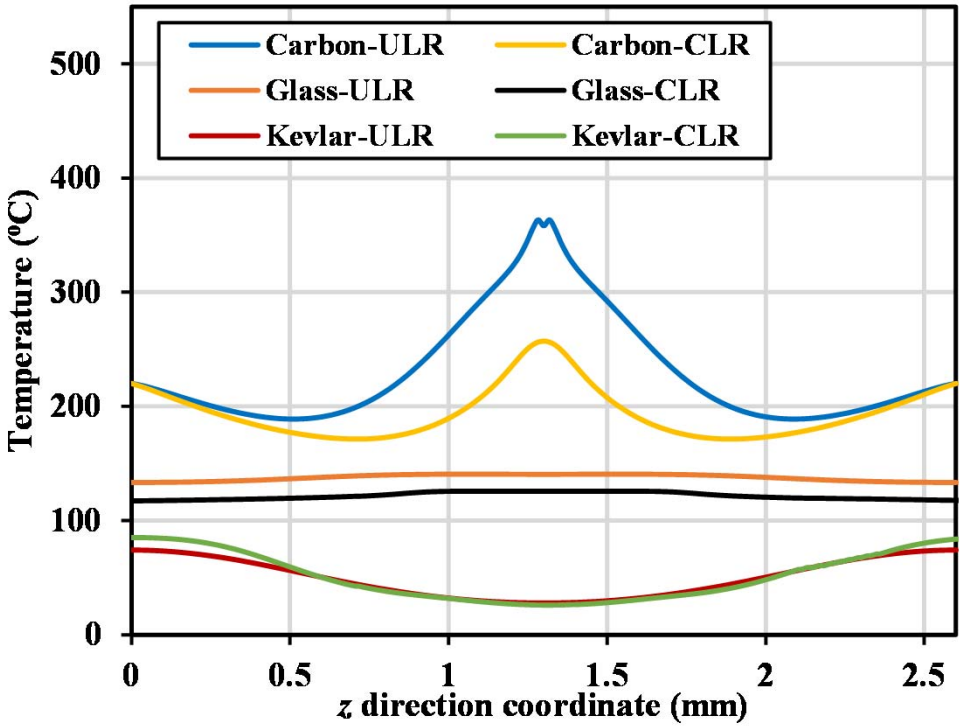
- Front propagates faster in unidirectional laminates
- Front velocity changes as the front propagates, especially in UL and CL cases

Results – Unidirectional vs. Cross-Ply



- Front velocity changes as the front propagates
- Cross-ply laminate CT case exhibits a lower front velocity in different times than the UT case

(b)

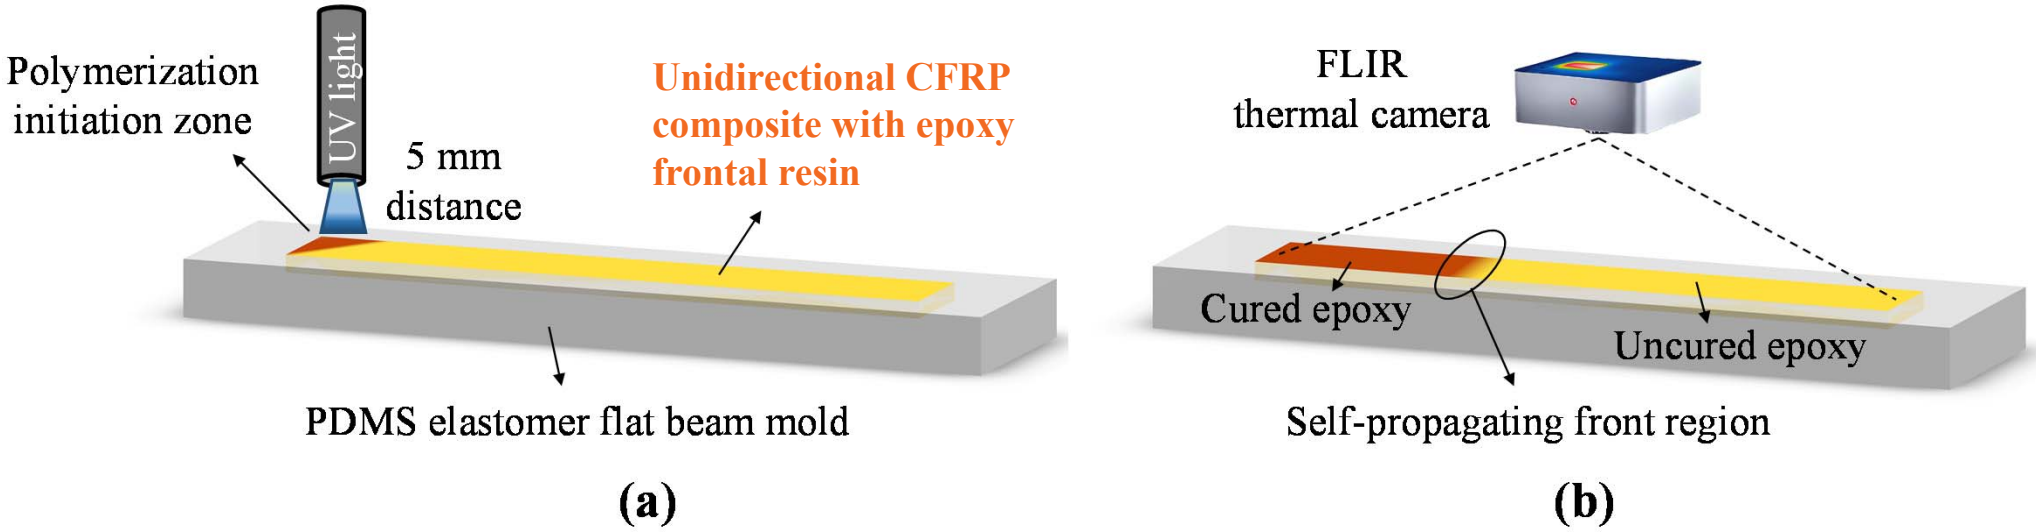


Results – Effect of Fiber Thermal Conductivity

- Three different types of fibers: 10.45 W/m·K (for carbon fiber); 1.14 W/m·K (for glass fiber); 0.04 W/m·K (for Kevlar fiber).
- Front velocity drastically decreases as the thermal conductivity decreases

Results – Effect of Fiber Thermal Conductivity

- Thermal spike temperature dropped from 255 °C and 355 °C for the carbon fiber CLR and ULR cases to only 133 °C and 117 °C for the glass fiber ULR and CLR cases
- For cases with the Kevlar fiber, the thermal spike is not formed



Part 2:

Modeling of UV-induced Frontal Polymerization in CFRP (On-going work)

Problem Setup & Objective

- 2D model for unidirectional CFRP composite with epoxy frontal resin

- **Objective:** Investigate how the UV light parameters, including UV light intensity, spot size, wavelength, and distance to the specimen surface affect the frontal polymerization process

Challenges:

- Determine the accurate curing kinetics of the epoxy-based frontal resin
  - Traditional DSC does not provide the exact same UV-induced polymerization environment
  - One possible solution is to use UV-DSC to get more accurate curing kinetics

UV-indced frontal polymerizable material system	
Frontal monomer	(3,4-epoxycyclohexane)-methyl-3,4-epoxycyclohexyl carboxylate (**ECC**)
Photo-initiator (PI)	p-(octyloxyphenyl)phenyl iodonium hexafluorostibate (**IOC-8 SbF6**)
Thermal-initiator (TI)	**benzopinacol**

Preliminary Results

Conclusion

1. 3D models of heat triggered frontal polymerization have been used to investigate the effects of laminate layup, triggering direction, and fiber types
   - We recommend to trigger the frontal polymerization along the fiber direction as much as possible
   - We should anticipate a slower frontal propagation in cross-ply laminates
   - Triggering from multiple locations will result in thermal spikes, which could indicate occurrence of high thermal residual stresses, wavy surface patterns, and/or non-uniform degree of cure

2. A simple UV-induced frontal polymerization model for CFRP composites with epoxy-based frontal resin was modeled in a 2D configuration. Currently, we face challenges in:
   - Characterization of the curing kinetics of epoxy-based frontal resin under UV conditions
   - Can be potentially solved using the UV-DSC

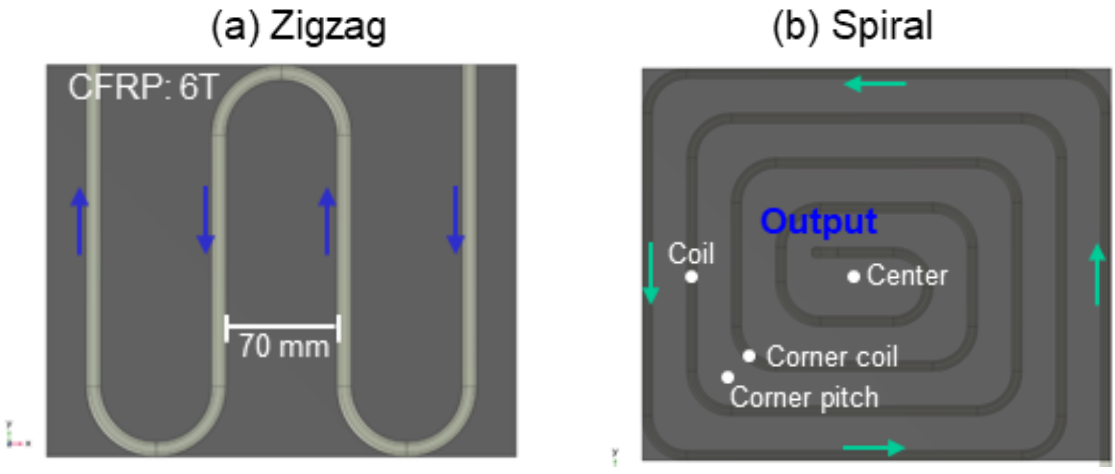
ABSTRACT

This study focuses on the development of an optimized coil pattern for uniform temperature distribution during induction heating of thermoplastic composite PP/GF using a thermoset CFRP mold. While CFRP molds offer advantages in lightweight structure and reduced heating and cooling times, they have limitations in achieving uniform heating due to anisotropy. To address this, various coil patterns were designed and analyzed for heating efficiency, resulting in a pattern capable of maintaining uniform temperature distribution even in complex geometries. The PP/GF composite produced using the optimized pattern is expected to achieve high quality without compromising mechanical properties, as compared to conventional molding methods. This research is anticipated to enhance the industrial feasibility of induction heating-based molding processes.

1 INTRODUCTION

TInduction heating is a process that generates induced currents within a conductor through electromagnetic induction, thereby heating the conductor due to resistive losses [1, 2]. When a high-frequency alternating current flows through the coil of an induction heating device, a fluctuating magnetic field is created within the coil, forming a strong magnetic flux around it. When a conductor is placed within this magnetic field, eddy currents are generated within the conductor, flowing in a direction that opposes the change in the magnetic field, according to the law of electromagnetic induction [3]. The induced currents within the conductor produce Joule heating due to electrical resistance, resulting in rapid heating. This method of induction heating is known for its high energy efficiency, as it allows precise heating of specific regions, thereby reducing processing time [4]. Additionally, as the heating process is contactless, it does not damage the surface of the conductor. The skin effect due to high-frequency currents enables uniform temperature control in targeted areas, contributing to improved product quality [5]. Moreover, since no combustion is involved, induction heating provides a clean and safe working environment, making it a preferred heating method for mass production and automation, and an environmentally friendly solution [6].

Metal molds have traditionally been widely used in various manufacturing processes due to their high strength and thermal conductivity, but they have recently shown limitations in weight and thermal inefficiency [7]. Consequently, CFRP molds with lightweight properties and excellent thermal stability have emerged as an attractive alternative [8]. CFRP molds are lighter than metal molds and can be fabricated in thin layers, which shortens heating and cooling times and significantly reduces energy consumption [9]. Additionally, CFRP has a low coefficient of thermal expansion, which minimizes thermal deformation at high temperatures, making it suitable for precision processing, especially in



processes requiring repeated high-temperature heat treatments. Thus, CFRP molds offer a viable alternative to metal molds by addressing their limitations and proving effective in high-temperature processing applications.

Despite these advantages, CFRP molds present inherent challenges during the heating process due to their anisotropic nature [10]. The electrical and magnetic properties of CFRP vary according to the fiber orientation within the material, making it difficult to achieve uniform electromagnetic field distribution, which complicates even heating with standard coil arrangements [11]. Specifically, the induced currents generated by electromagnetic induction are often deflected or concentrated in certain directions within the CFRP, creating zones of interference where the currents cancel each other out. In these interference zones, heat transfer may be insufficient or overly concentrated, making it challenging to achieve a uniform temperature distribution across the entire mold [12]. This uneven temperature distribution can lead to inconsistencies in the quality and uniformity of processed products.

Therefore, this study aims to design a novel coil pattern that minimizes interference zones in the electromagnetic field and achieves more uniform heating by considering the anisotropic properties of CFRP molds. To accomplish this, various coil patterns were simulated, analyzing temperature distribution and magnetic field density to derive an optimal coil design. The developed pattern was successfully applied to uniformly heat CFRP molds. Subsequently, the heated CFRP mold was used to fabricate thermoplastic composites composed of commingled PP/GF, with plans to perform mechanical property tests on these composites. Through this approach, the study seeks to present an effective solution to the anisotropic challenges of CFRP molds, enhancing reliability and quality in thermoplastic composite molding processes.

2 MODELING AND NUMERICAL ANALYSIS

Induction heating of the CFRP mold was numerically simulated to optimize coil placement. The CFRP model was a plate measuring 250×300×6 mm^3, with Litz wires comprising 1,500 strands of copper wire, each 0.12 mm in diameter. The working distance (WD) between the CFRP and the coil was set to 1 mm. The coil placement was tested in three configurations: a zigzag pattern (Figure 1a), a spiral pattern (Figure 1b), and a zig-spiral hybrid coil pattern (Figure 1c) newly developed in this study. In the zig-spiral hybrid coil pattern, adjacent coils were arranged with opposite current directions, and 180° turns were also oriented to maintain opposite current directions with neighboring coils. The spacing between coils was 20 mm, with a radius (R) of 20 mm for 90° turns and 10 mm for 180° turns. If the outermost coil (last coil) reached a higher temperature than preceding coils, uniform heating could be achieved by either decreasing the spacing from the previous coil or increasing the WD of the last coil. Additionally, to prevent excessive heating between the input and output of the coil, the spacing was minimized (approximately 0.5 mm) or eliminated altogether. The operating frequency and current were set to 152 kHz and 100.8 A, respectively.

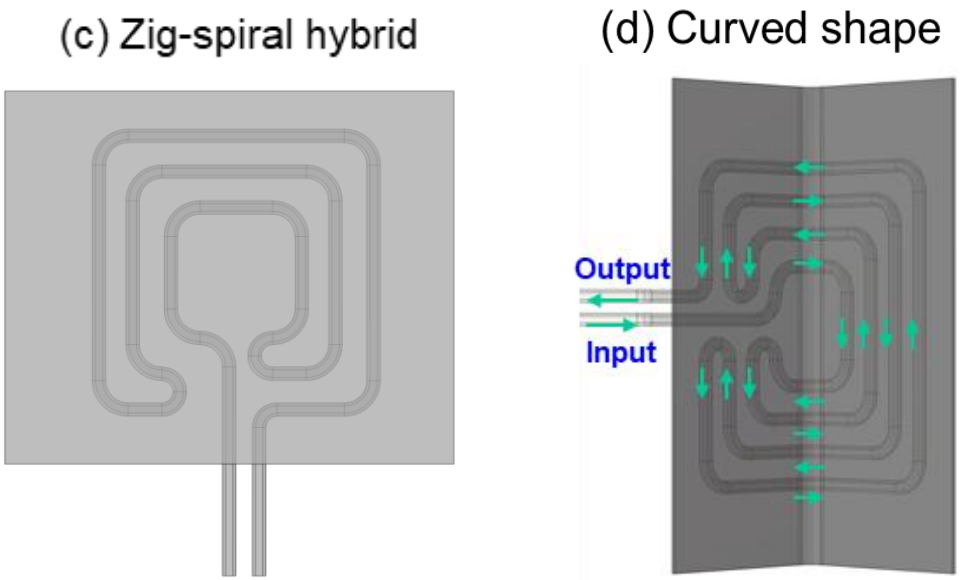


Figure 1: Coil pattern geometries: (a) Zigzag, (b) Spiral, (c) Zig-spiral hybrid, (d) Curved-shape.

COMSOL Multiphysics V6.2 software (COMSOL, USA) was used to calculate the multiphysics of the electromagnetic field, electromagnetic induction, and heat transfer. Maxwell's equation was computed in the magnetic field interface, followed by heat transfer in the solid interface, to calculate Fourier's heat transfer law. A magnetic field interface was applied to the workpiece, induction coil, and air domain. Heat transfer in a solid interface was applied to the workpiece and coil domain. A heat flux boundary condition was added for convection in air, with a heat transfer coefficient of 10 W/m2·K.

Property	Parallel	Vertical
Electrical conductivity (S/m)	3.25×10^4	0.0325
Thermal conductivity (W/m·K)	2.4	0.59
Heat capacity (J/kg·K)	820	820
Density (kg/m³)	1780	1780
Relative permeability	1	1
Relative permittivity	2156	1640

Table 1: This is the example of a table.

3 EXPERIMENTAL

3.1 Manufacturing of CFRP mold

The CFRP molds were fabricated using a high-temperature-resistant resin (LAS200M, KGF) and carbon-fiber fabric (Toray T300 plain-woven fabric, areal weight 200 g/m²) through an autoclave process. The resin was impregnated into the carbon-fiber fabric using the hand lay-up method, with 16 or 32 layers laminated on a mold of the desired shape. The resin-impregnated fabric was placed between release films and breathers, both above and below the mold, then wrapped in a nylon film and sealed under vacuum. Curing was performed at 175℃ and 7 bar pressure in an autoclave for 2 hours, following the resin's curing conditions. After demolding, the mold underwent post-curing in an oven at 200℃ for at least 2 hours. Three types of molds were fabricated: a 3 mm thick flat plate, a 6 mm thick flat plate, and a 3 mm thick plate with a 45° curvature.

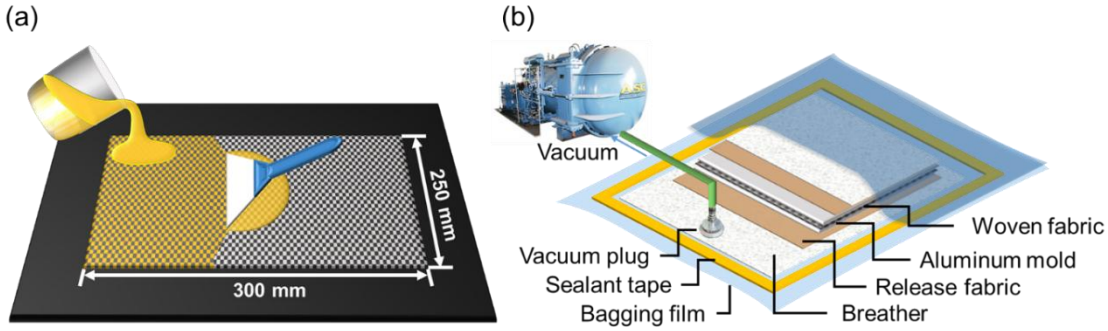

Figure 2: Hand lay-up process (a) and vacuum bagging setup (b) for CFRP mold curing.

4 RESULTS AND DISCUSSION

4.1 Optimization of coil pattern design

In the zigzag pattern (Figure 3a), the coil reached a high temperature of 404℃ at the 180° bends due to the magnetic field reinforcement effect, resulting in a non-uniform temperature distribution. For the spiral pattern (Figure 3b), the center was heated to 58.8℃, while the pitch and coil sections in the cancellation zone reached 73.3℃ and 89.6℃, respectively, and the linear coil section reached 106℃, indicating significant temperature variations across different sections. In contrast, the zig-spiral hybrid pattern (Figure 3c) exhibited a relatively uniform temperature distribution, with the center at 93.3℃, the pitch (between coils) at 108℃, the area directly above the coil at 145℃, and the last coil at 154℃, maintaining a difference of approximately 40-50℃. Temperature comparisons were illustrated in a graph after heating for 3600 seconds.

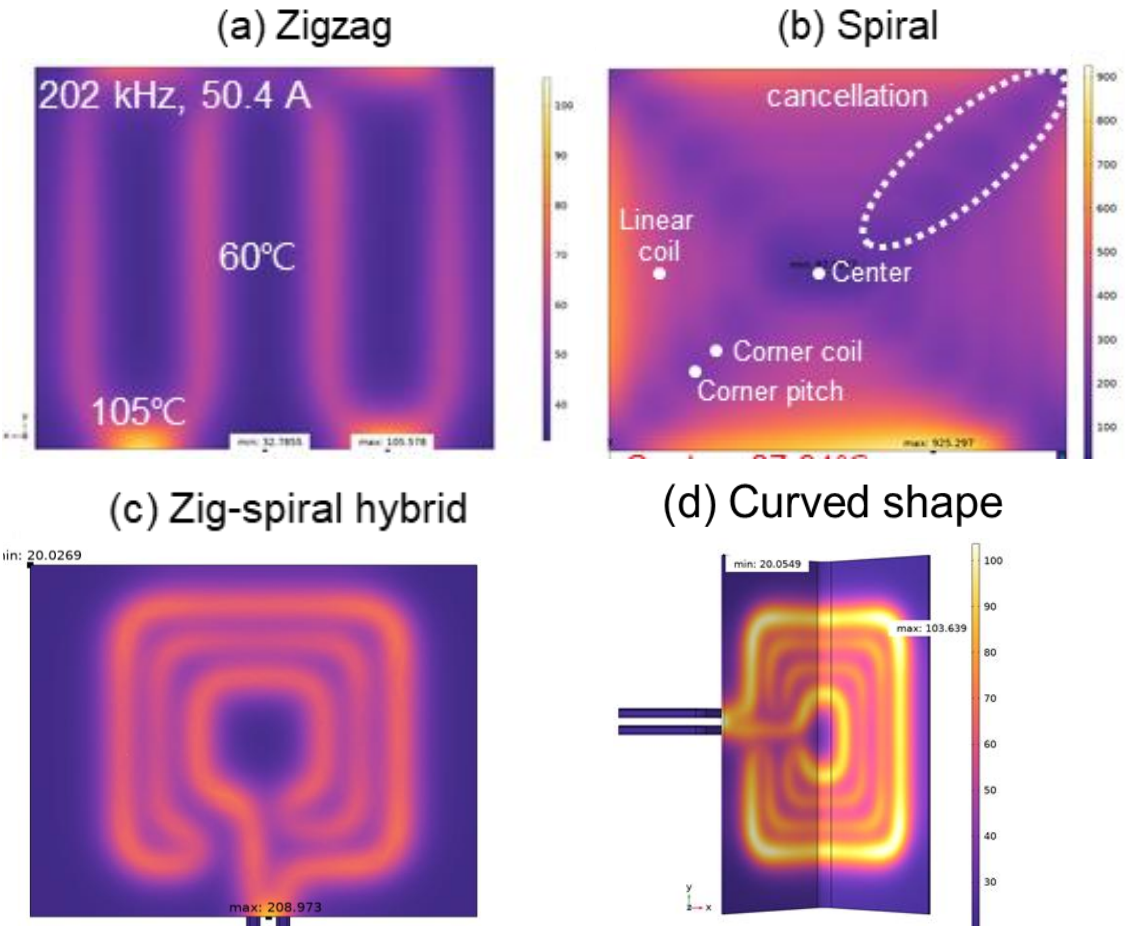

Figure 3: Temperature distribution for (a) zigzag, (b) spiral, (c) zig-spiral hybrid, (d) Curved-shape.

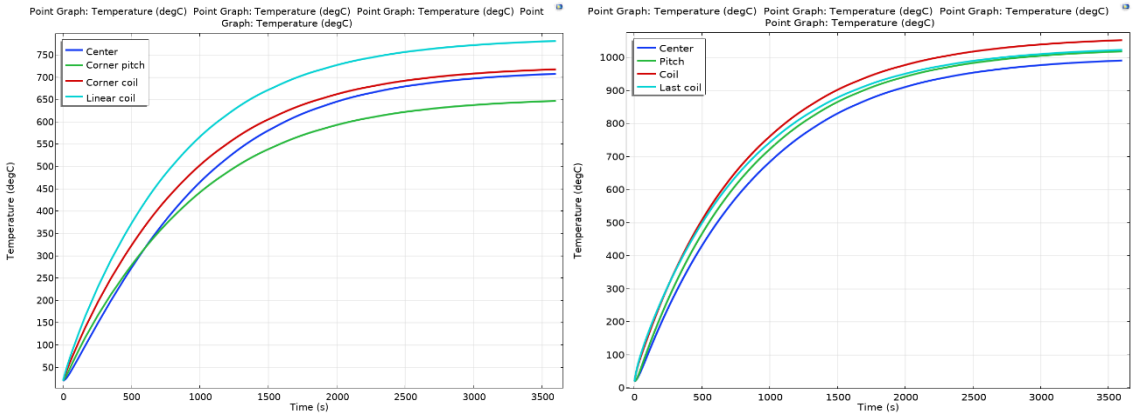

Figure 4: Temperature profiles: (a) spiral coil, (b) zig-spiral hybrid coil over 3600s heating.

5 CONCLUSIONS

An optimized zig-spiral hybrid coil pattern was proposed and validated for the induction heating of CFRP molds, addressing the challenge of uneven heating caused by the anisotropic properties of CFRP materials. Through simulation and experimental verification, the proposed design demonstrated significantly improved temperature uniformity compared to conventional zigzag and spiral configurations.

This improved uniformity is expected to reduce internal stresses, minimize defects, and enhance the quality of thermoplastic composite parts molded using CFRP tooling. The successful application of the coil pattern in heating CFRP molds and subsequent forming of commingled PP/GF composites confirms the feasibility of this approach for industrial use.

Furthermore, this study highlights the importance of coil design in electromagnetic heating applications and provides a scalable methodology that can be adapted for molds of various geometries and composite systems.

Future work will include mechanical testing of the molded composites to quantitatively evaluate property enhancement, and the development of closed-loop control systems for real-time heating uniformity monitoring. This research lays the groundwork for broader adoption of induction-based smart mold systems in high-performance thermoplastic composite manufacturing.

ABSTRACT

The Single Diaphragm Forming (SDF) process has received limited attention in the literature compared with the Double Diaphragm Forming (DDF). However, its advantages in multi-layer preforming have led to its adoption in certain manufacturing contexts. To facilitate a more comprehensive investigation of the SDF process, a compact experimental rig capable with various tool geometries was designed and constructed. Previous research has highlighted the critical influence of friction between fabric plies in forming defects during the preforming of multi-ply diaphragms. Inter-fabric sliding has been introduced as an additional quantitative metric to establish a connection between interface friction and preforming quality to enable more effective monitoring of fabric behaviour during preforming. In the SDF experiments, the opacity of both the diaphragm and fabric poses a significant challenge to direct visual tracking of the lower fabric plies using photographic or videographic methods. Consequently, an indirect measurement technique has been developed by applying pre-painted grease dots to the fabric surface and subsequently tracking their deformed configurations post-forming. This methodology has been implemented across a range of tool geometries within the SDF experiments. By comparing the experimental sliding data with results obtained from finite element (FE) simulations, the sliding metric provides valuable insights into the dynamics between fabric layers and an evaluation of the current simulation models in terms of fabric interface behaviour. Future work will focus on employing this integrated approach to further investigate the correlation between friction, inter-ply sliding and preforming defects, and on extending the sliding tracking methodology to the study of the DDF process.

1 INTRODUCTION

Diaphragm forming is an open-moulding preforming technique developed for shaping dry textile reinforcements into complex geometries before resin infusion in liquid composite moulding (LCM) processes. Compared to conventional closed-moulding or draping methods, the diaphragm forming process offers a balance between efficiency and preforming quality [1]. Owing to its compatibility with automation and scalability, the diaphragm forming process is increasingly adopted in high-rate manufacturing sectors such as aerospace and automotive, where geometric complexity and production efficiency are critical requirements. Based on the number of diaphragms involved in each manufacture,

the diaphragm forming process can be further classified into single diaphragm forming (SDF) and double diaphragm forming (DDF). By slightly compromising processing stability, the SDF reduces the complexity of the manufacturing rig and material requirements compared to the DDF. Moreover, the SDF process allows for sequentially preforming operations, thereby enabling the manufacturing of thicker fabric structures [2].

Non-Crimp Fabric (NCF) is a class of dry fibre reinforcements used extensively in the manufacture of high-performance composite materials. Unlike traditional woven fabrics, in which yarns are interlaced, NCF is composed of multiple layers of unidirectional (UD) fibres that are stitched or bound together without any crimping, which achieves better mechanical performance in the final products [3]. NCF materials can be classified in various ways, allowing for more precise descriptions based on the orientation of the UD layers, the number of plies, or the style of interlayer connection.

Numerous experimental setups have been designed and fabricated to investigate the processing mechanisms of preforming and to optimise both the procedure and product quality. Viisainen et al. [4] explained the mechanism of wrinkle generation through the draping experiments with the aid of digital image correlation (DIC) technology. Lawrence et al. [5] explored the contact situation of fabric samples under high compaction force, as well as the effect of the variability of vacuum pressure with the micro-CT devices. Yu et al. [6] discussed the effect of inter-ply sliding during multi-ply DDF under both lubricated and unlubricated conditions. Meanwhile, the finite element (FE) method has been widely applied to simulate the preforming process from both meso-level and macro-level [7-9].

This study proposes a novel design for an SDF experimental rig, upon which a new experimental methodology is developed. The method exploits the fluidity of grease on the fabric surface to monitor interply sliding between the fabric sample during the SDF process by measuring the deformation of pre-applied grease marks. A selection of experimental results derived from the proposed rig and methodology is also presented to demonstrate the applicability and effectiveness of the approach.

2 SINGLE DIAPHRAGM FORMING EXPERIMENT RIG

The SDF process, as one form of diaphragm forming, offers methodological advantages such as a simpler structure and more convenient operation compared with the DDF process. Though with higher variability, the SDF experiments can comprehensively represent the behaviour of the fabric and diaphragm under vacuum force in the DDF process. Therefore, a lab-level SDF rig has been designed and assembled to achieve rapid experiment methodology validation and simulation model validation at a lower cost.

The SDF experiment rig is designed for dry fabric preforming only, without the involvement of resin injection and heating systems. The schematic of the SDF experiment process is shown in Figure 1. By generating a vacuum between the diaphragm and rig base, the flat fabric plies are formed into 3D structures by vacuum pressure. The edge of the diaphragm is sealed against the edge of the rig base to form an enclosed chamber, after which air is evacuated from the system.

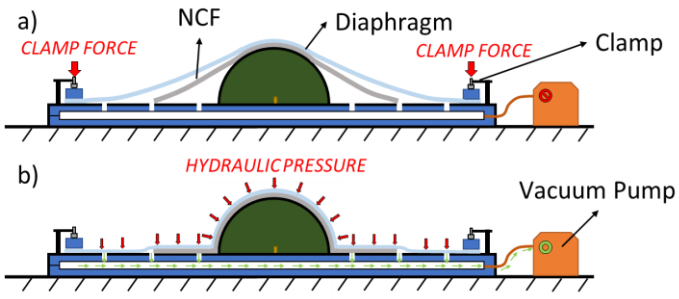

Figure 1: The scheme for the SDF process: a) Material preparation and diaphragm boundary clamping, and b) Vacuum forming

2.1 Materials

The target material in the SDF process is a biaxial ±45° NCF fabric with pillar stitch manufactured by Hexcel under the name 'HiMax™ CGL4790 - FCIM359 NCF'. The mechanical property of this material has been previously characterised through a standard picture frame test, while a shell-membrane element has been created and validated for the simulation of the NCF with the FE method [10]. The tribological properties of the NCF have been measured using the lap shear friction test developed by Lawrence et al. [5].

The StretchLon® HT-350, a high-elongation vacuum film with an elongation at break of 550% and a temperature resistance of up to 162 °C, was selected as the diaphragm material for the experiments. This vacuum film shows good ductility during stretching, which allows more deformation and maintains good vacuum integrity during the SDF process [11]. BR180 is a 140 gsm non-woven polyester felt fabric used as a breather layer during the vacuum forming of fabric laminates, which avoids the formation of bubbles and ensures the uniform application of vacuum force. Other materials and components applied in the diaphragm forming rig and experiment design are listed in Table 1.

Description	Manufacturer	Type	Reusability
Biaxial NCF	Hexcel®	HiMax™ FCIM359	No
Vacuum Diaphragm	Tygavac Ltd UK	StretchLon® HT-350	No
Lithium Grease	MG Chemicals	No. 8461 Lithium Grease	No

Vacuum Gauge	Vac Checker®	VE-VCG	Yes

Table 1: The components and materials used in the single diaphragm forming rig and experiment.

2.2 The Design of the Single Diaphragm Rig

The rig contains four main components: base, blank holder, detachable tool, and vacuum system with pressure gauge, as shown in Figure 2 a). The vacuum port is located on the side of the rig base and is connected to the pressure gauge through tubes. The digital vacuum gauge connecting the rig inlet and the gauge delivers reliable pressure measurements in the range of 1100 to 0.00 mbar and with a resolution of 0.01 mbar. The base is fixed to the experiment table with screws to avoid instability during experiments. The base is assembled with three parts: a top board with ventholes, a middle frame and a bottom board. The vacuum port is placed on the middle frame, while these components are assembled through screws near the edge and sealed with the vacuum tape and the multi-purpose sealant.

To ensure a uniform vacuum pressure, 72 ventholes with a 10 mm diameter are evenly drilled on the top baseboard except for the tool region, as shown in Figure 2 b). Breathers are laid between the tool edge and the ventholes to avoid air cavities near the junction between the tool and the rig base. The sealing strips are added between the bed and the blank holder. Under the clamp force from the blank holder, the strips deform elastically to secure good sealing during the preforming.

3 THE INTER-PLY SLIDING TRACKING METHODOLOGY

In previous research, various parameters and methodologies have been introduced to monitor and understand the behaviour of fabrics during the preforming process as detailed in the introduction. One area of research focuses on dynamically tracking the visible surfaces with videos or photos to explain the correlation between deformation and defect. Other research topic concentrates on statistically analysing the preforming results with various methods. For example, digital image correlation and micro-CT scanning are widely used for dynamic and static research, respectively. However, both processes are not sufficient to dynamically monitor the fabric behaviour in the multi-ply forming. Therefore, a novel methodology is proposed for the indirect measurement of interply sliding between fabrics by tracking the changes in marker points, which helps build a bridge between the manufacturing setup and the preform quality.

3.1 Methodology Introduction

In industrial production, grease is used to label the surface of carbon fabrics, as it provides stable and long-lasting markings with good clarity. For a period following the painting process, the grease retains a certain degree of fluidity and viscosity. Consequently, when relative motion occurs between the two contacting surfaces, the shape of the grease undergoes deformation. This inspired an experimental methodology to track the interply sliding through the deformation of painted marks between the fabrics.

The method is presented in Figure 3. Before the experiments, the grease dots are placed on the fabric sheet as marks, which are sandwiched between the interested fabric interface in the experiment. During the diaphragm forming process, the fabric plies have relative motion, while the grease dots are flattened by the compaction of fabric sheets, accompanied by the sliding-induced shape elongation. By evaluating the final shape of the grease marks, the sliding distance on the marked position is indirectly measured.

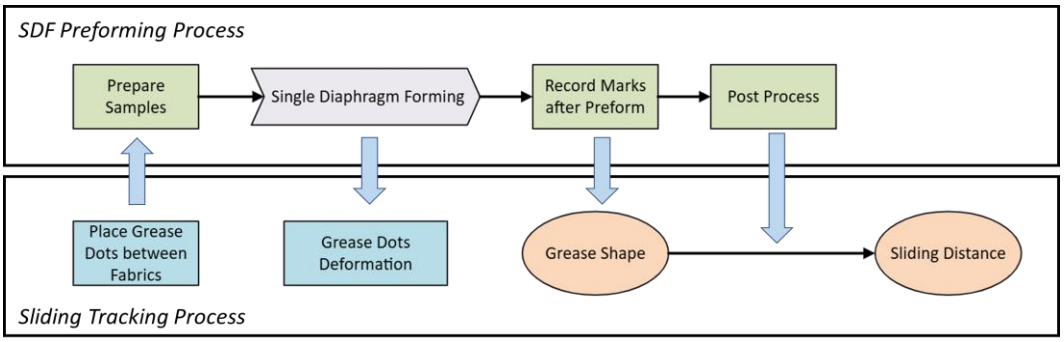

Figure 3: Flowchart of the method for measuring relative inter-ply sliding based on grease marks.

To ensure the consistency of the grease dots applied during the experiments, a PVC board with precision-drilled holes was employed as a mould for dot placement. The thickness of the mould board is 1.6 mm, while the diameter of the holes is 4 mm. The painting process is shown in Figure 4. After filling the mould hole with grease, a flat blade is used to remove the excess grease on the top of the mould. Vertically lifting the mould, the grease dot is placed on the fabric surface with the shape of a 1.6 mm high cylinder because of the viscosity and surface tension.

3.2 Method Consistency

To validate the feasibility of the proposed method, two well-designed experiments were conducted. The first assessed the stability of the grease quantity of the grease dots, while the second evaluated the morphological stability of the grease dots under pure compaction.

The weight consistency test focuses on verifying whether the quantity of grease within the dots remains uniform, assuming their external shapes are geometrically ideal. The experimental result is

shown in Figure 5. The difference in the amount of grease within each dot is mainly induced by operational errors in the experimental procedures. Therefore, the external shape of the grease dots is first evaluated and classified into two groups: dots with an ideal external shape (ideal dot) and dots with defects (defect dot). The ideal dots have an ideal cylindrical shape, while the dots with obvious grease loss or other problems (asymmetric, non-circular, etc.) are marked as defective dots.

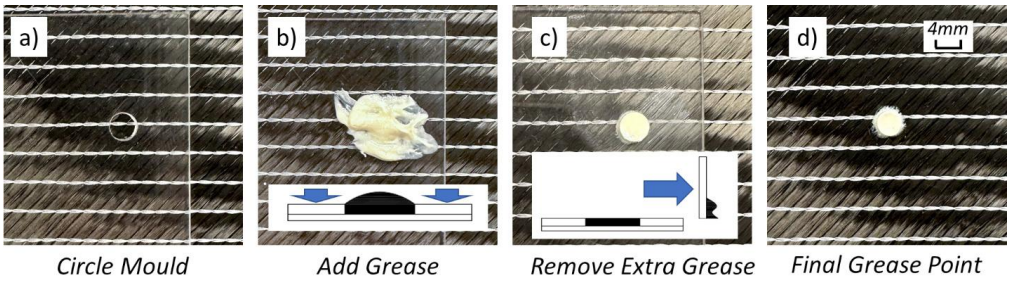

Figure 4: Fabric grease painting process with 4 mm plastic mould

The ideal dots are directly used in the experiments, while the defective dots are removed and repainted. By dot classification and replacement/discarding of defective dots, the grease weight consistency is improved. As shown in Figure 5, the coefficient of variation of the dot weight (ideal dots only) is reduced to 5.6%, which is acceptable for the following diaphragm forming experiments.

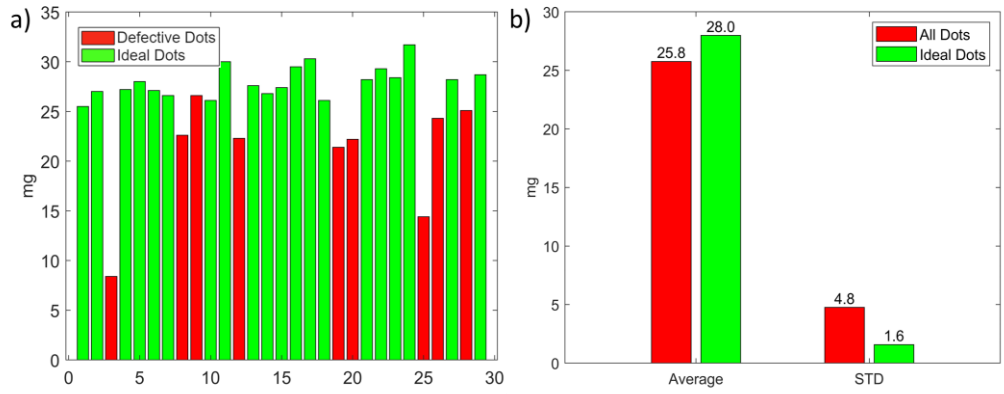

Figure 5: Grease weight consistency experiment result: a) Weight of every grease point, and b) statistical data for grease weight

The deformation of the grease shape is influenced not only by the original placement of the grease dots but also by the fabric interface properties, such as fabric direction and interface compaction force. To quantify these factors, an experiment for the grease marks with pure compaction is designed to quantify the mark shape with different fabric directions. In the experiments, the prepared fabric stacks have been sealed into a vacuum bag, while the bag is vacuumed to imitate the vacuum compaction in the diaphragm forming.

The mark shape after compaction is tracked through images, while the ideal shape of a grease dot under pure compaction was derived based on the averaged geometry of these shapes. As shown in Figure 6, the shape of the grease dots is influenced by the relative orientation of the fibre tows. In the 90° case, the grease tends to form a circular mark, while in the 45° and 90° cases, the grease shape is elongated towards the direction of the bisector of the acute angle between the tows. Among all fibre setups, the shape of the grease mark after pure compaction exhibited good stability across repeated experiments. This ensures that any subsequent changes in the grease mark morphology can be attributed solely to the sliding motion between fabric plies during the experiment, rather than to the inherent variability of the grease itself.

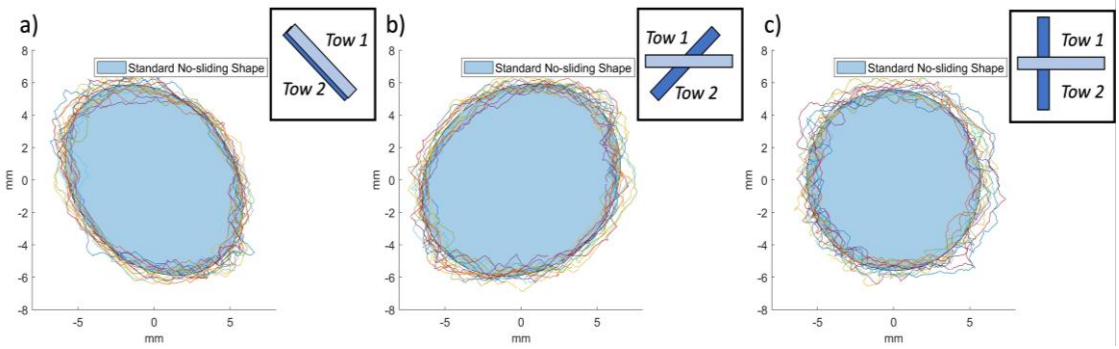

Figure 6: Standard no-sliding grease shape with Ø 4 mm mould under different tow directions

3.3 The Post-Processing of Experiment Results

In the post-processing, the shape of the grease marks is recorded through photography, as shown in Figure 7 a). The red points in the grease marks are the pre-drawn reference points to locate the original position of the mark. The reference points are painted with solvent-based markers, which dry out rapidly before the grease painting. The post-process involves mark boundary tracking and the sliding calculation. Subsequently, the boundary and initial mark centre are selected from the photos, as shown in Figure 7 b).

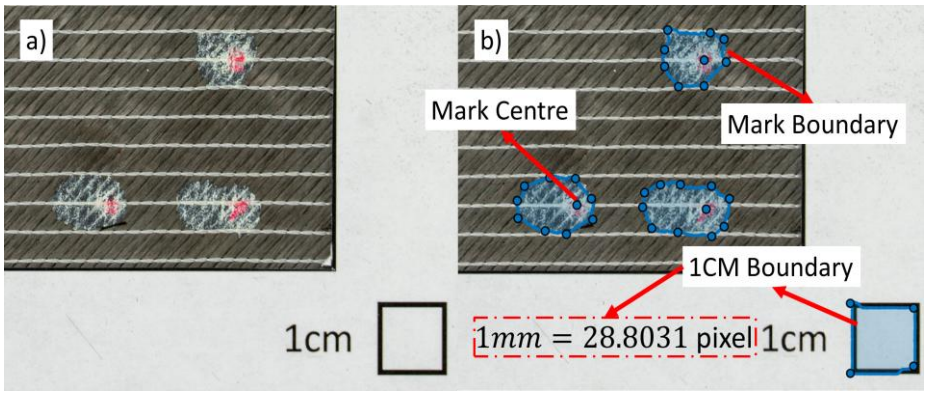

Figure 7: The image record and boundary track of the grease marks after diaphragm forming experiments.

The mark shape after sliding is similar to the trajectory of an elliptical dot translating on the plane, as shown in Figure 8 a). The selected original centre of the grease dot is marked as point B on the grease. The chord AC is the longest line segment on the figure that is intercepted by the line passing through point B. The length L1 is the sum of the grease elongation length and the radius of the no-slip mark shape in the sliding direction, while the length L2 is the radius of the no-slip mark shape in the opposite direction of sliding. As the no-slip shape is centre symmetry, the grease elongation length can be calculated as the difference between L1 and L2.

While the actual sliding distance and the measured elongation length of the grease were generally not equivalent across most experiments, a linear relationship was consistently observed between them. Based on a series of overlap tests performed at 1 bar pressure [5], the linear correlation between the two parameters is described by the following equation, as shown in Figure 8 b):

$$\textit{Grease Elongation Length} = 0.85 \times \textit{Sliding Distance} \tag{1}$$

Based on the aforementioned procedure and equation, the relative interply sliding at the grease dot position during the preforming can be derived.

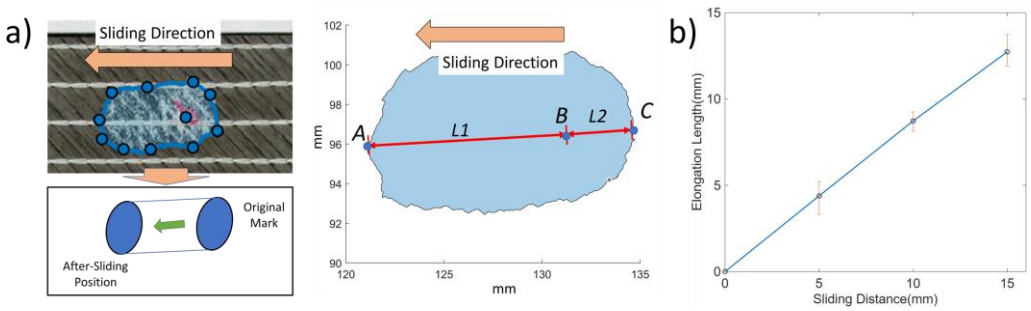

Figure 8: a) Sliding calculation for tracked grease mark shape in the post-process. b) Correlation between grease elongation length and sliding distance

4 RESULTS AND DISCUSSION

To validate the effectiveness of the aforementioned method and to enhance understanding of the SDF process, a series of experiments were conducted using the previously described SDF rig, employing the grease technique to track the sliding of specific positions. The experimental results were compared with those from finite element (FE) simulations [11], enabling an analysis of the limitations inherent in the current experimental methods and simulation models.

Four different tool geometries are included in the experiments: a hemisphere tool, a double dome tool and two spar tools with different ramp angles [4]. The hemisphere tool and the double dome tool, known as the benchmark geometries, are widely used in the preforming research on woven and NCF fabrics. In addition to wrinkling, which is the primary focus of this study, bridging is another common defect encountered during preforming. Although the impact of bridging on the manufacturing process is less severe and it can typically be eliminated in subsequent processing steps, bridging still affects the fabric behaviour during processing and therefore needs to be taken into consideration. Among the experiments conducted with the four tools, bridging is expected to occur in the benchmark tools, whereas it does not appear in the experiments using the spar tools.

4.1 The Experiment Result with Different Tools

In the experiment with spar tools, 15 grease dots were applied at designated points, maintaining a minimum spacing of 2 cm between each to prevent mutual interference. A total of 12 dots were placed at the corners of the sample, two dots were positioned along the edges, and one dot was placed in the centre as a control, in Figure 9 a). The formed fabric samples are shown in Figure 9 b) and c).

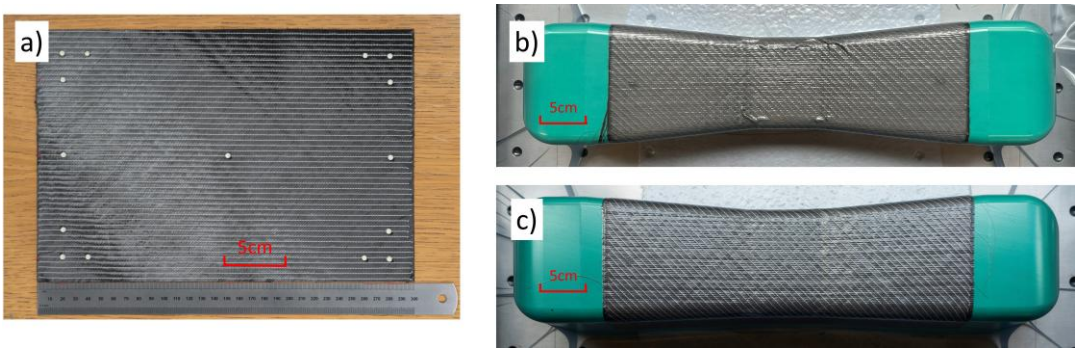

Figure 9: The SDF experiments with the spar tools: a) the prepared fabric sample with grease dots, b) the formed fabric sample with the high ramp spar tool and c) the formed fabric sample with the low ramp spar tool.

The processed sliding distances from the grease method are compared with the FE simulation result, as shown in Figure 10. The comparison shown in the figure indicates that, in both the high ramp spar and low ramp spar experiments, the sliding directions of the tracked data points closely

correspond with the predicted directions. However, the predicted sliding distances are consistently larger than the distances observed in the experiments.

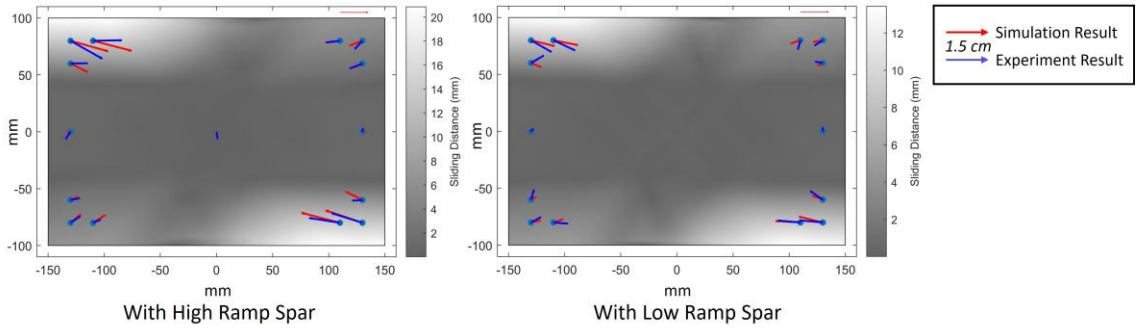

Figure 10: The sliding measurement result for the SDF experiments with the spar tools, where the sliding vectors are marked by arrows on the grease mark positions.

In the experiments with the benchmark tools, 17 grease dots were applied at designated points, maintaining a minimum spacing of 3 cm between each to prevent mutual interference. A total of 12 dots were placed at the corners of the sample, four dots were positioned along the edges, and one dot was placed in the centre as a control, as shown in Figure 11 a). The formed fabric samples are shown in Figure 11 b) and c).

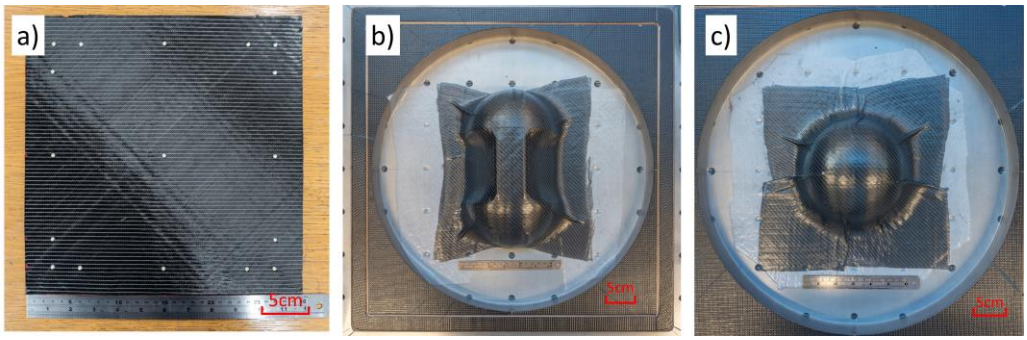

Figure 11: The SDF experiments with the benchmark tools: a) the prepared fabric sample with grease dots, b) the formed fabric sample with the double dome tool, and c) the formed fabric sample with the hemisphere tool.

The processed sliding distances are compared with the FE simulation result, as shown in Figure 12 respectively. In the figure, the sliding vectors from the grease dots in the low sliding regions show certain differences from the simulation results in both direction and magnitude.

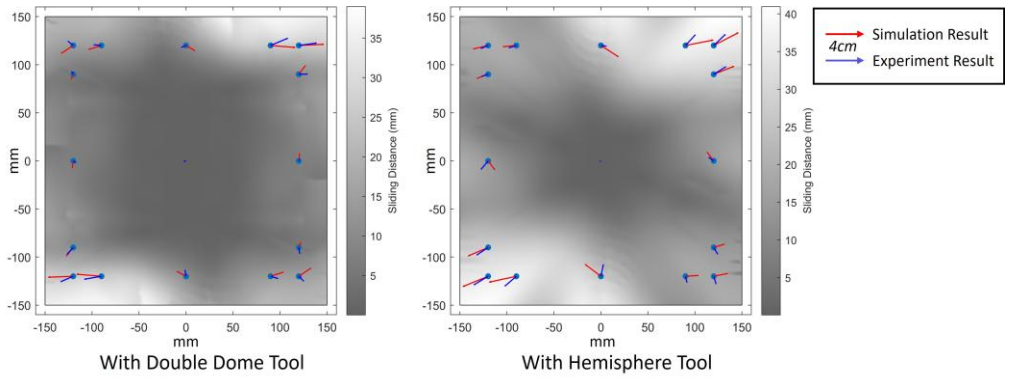

Figure 12: The sliding measurement result for the SDF experiments with the benchmark tools, where the sliding vectors are marked by arrows on the grease mark positions

In the high sliding regions (top-right and bottom-left corners), the experimental results show a good agreement with the prediction from the simulation results in the direction, while the sliding distances from the simulation are longer than those measured in the experiment, similar to the situation in the spar experiments. Overall, in the experiments conducted with the benchmark tool, the discrepancy between the experimental and simulation results was greater in both direction and magnitude.

4.2 Discussions

The application of the grease mark method in SDF experiments proved to be an effective means of tracking the sliding behaviour in specific regions. Adding additional grease dots has a negligible impact on the preforming result. A comparison between the experimental and simulation results reveals a good level of agreement in the prediction of relative sliding, particularly in regions where the sliding distance exceeds 8 mm. The current simulation model tends to overestimate the sliding distance during the SDF process, while the experimental method exhibits considerable uncertainty in capturing small-scale sliding displacements.

The error associated with the experimental methodology primarily arises from three sources. Firstly, the accuracy of sliding measurement relies on the intimate contact between the upper and lower surfaces. However, the relative opening between the fabric plies exists in the diaphragm forming process, especially for the SDF experiment, because of the lack of compaction. Secondly, the sliding trajectory is assumed to be linear, while tow twisting is ignored to reduce the complexity of the grease shape. This assumption may introduce a certain degree of error in the calculation of sliding distance, particularly in regions affected by wrinkling, where the fabric undergoes higher levels of in-plane shear. Finally, as indicated in the pure compaction experiments, even under identical experimental conditions, the grease shape exhibited in repeated trials is not entirely consistent. This is attributed to the uneven surface of the NCF material, where the irregularities caused by stitching and fabric tows affect the flow of the grease. Although this influence is not severe, it nevertheless leads to instability in the results when the sliding distances are small.

Although the above analysis highlights certain limitations of the current experimental method, it remains highly effective in tracking large interply sliding. The simulation model employed at this stage has not yet undergone specific validation or optimisation concerning sliding behaviour. As such, the discrepancies currently observed between experimental and simulation results are primarily attributed to shortcomings in the simulation model. In future work, the experimental results obtained in this study will be used to refine the simulation model to achieve more accurate predictive capability.

5 CONCLUSIONS

This paper presents the development of an experimental system, together with a methodology for tracking inter-ply sliding during forming. The experimental rig incorporates an interchangeable tooling design, enabling flexible investigation of various tool geometries and their influence on fabric deformation. Building upon the established diaphragm forming experimental procedure, a method using grease marks was developed to track interply sliding at designated locations. When the initial weight and geometry of the grease marks are controlled, identical marks exhibit comparable elongation lengths under equivalent sliding distances, with only minor variations. By calibrating the relationship between grease elongation and sliding distance through an overlap test, both the magnitude and direction of inter-ply sliding can be calculated from the deformed shape of the grease marks.

A series of SDF experiments with different tools have been conducted using the sliding tracking method, while the results were compared with finite element simulation results. Based on the comparison results, an analysis was conducted regarding the applicability, effectiveness, and associated errors of the current method. The method has been validated to be effective for tracking the long sliding distance of more than 5 mm. The sliding tracking methodology has shown its potential in simulation model validation and modification. With certain optimisation, this method can be extended

to DDF experiments and even further applied to other studies involving relative interply motion of fabric materials.

ABSTRACT

The hybrid moulding process is a combination of thermoforming and injection moulding. It enables the fully automated production of highly integrated, ready-to-install lightweight structural components based on organo-sheet semi-finished products and therefore fulfils the prerequisites for a high-volume, economical production process for lightweight components.

The paper describes the development of an emitter technology that processes modern, load-path-compatible tailored organo-sheets in which the mass utilisation in the component has been optimised. Tailored organo-sheets in particular offer the possibility of CO_2 savings through resource efficiency and substitution. By developing a high-resolution radiator field, the tailored organo-sheets can be heated homogeneously with a discontinuous wall thickness. The high-resolution radiator field is controlled via an AI-supported control system. This simplifies product changeovers and assembly work can be reduced thanks to the universal emitter field. The explanatory AI also helps to build up an understanding of the process. This increases the efficiency and flexibility of the process.

As part of a process evaluation, the influence of the developed emitter technology on the quality of the heating process, cycle times and energy efficiency will be analysed in detail. Specific key figures such as the temperature homogeneity within the organo-sheets, the heating rate and the thermal efficiency are recorded and analysed. The evaluation shows how the combination of optimised emitter technology and AI control contributes to the development of a robust, energy-efficient and high-quality thermoforming process.

1 INTRODUCTION

In the following paper, the CRISP-DM method is used as a structured framework to systematically accompany the development and evaluation of an AI-supported control system for the thermoforming process. The method is divided into six successive phases (figure 1). It begins with business understanding, in which the overarching objectives are analyzed from an application-related perspective and translated into a data-based problem definition. This is followed by Data Understanding, in which available data is collected and examined in terms of quality, structure and information content. In the Data Preparation phase, the raw data is converted into a format suitable for

modeling through selection, transformation and cleansing. This is followed by the Modeling phase, in which suitable algorithms are selected, parameterized and applied to the prepared data. This is followed by the Evaluation phase, in which the quality of the model is checked with regard to the original objectives and the procedure is critically reflected upon. Finally, the Deployment phase involves transferring the developed solution to the practical application context, for example by integrating it into existing systems or by creating usable results for the end user. [1]

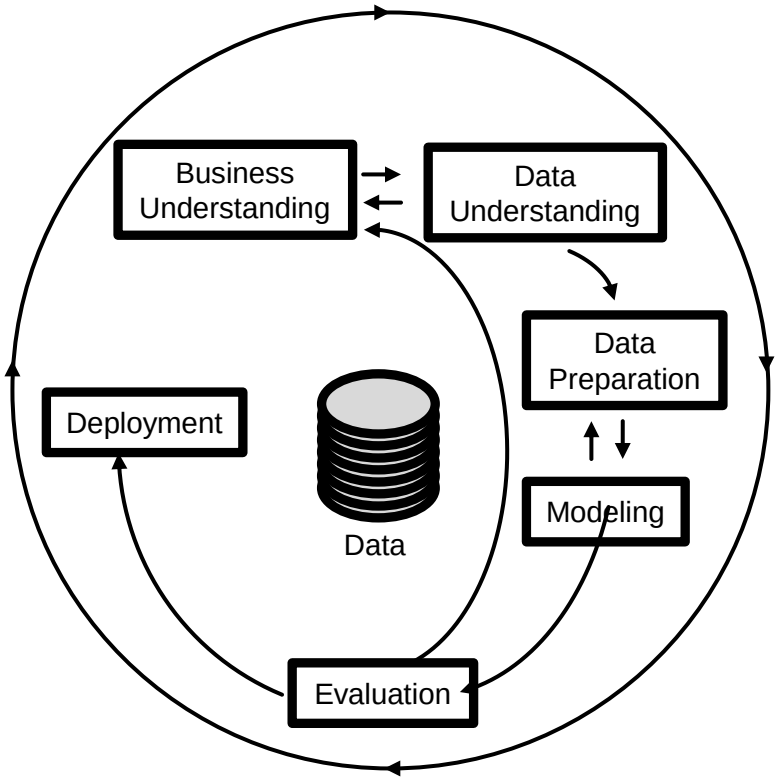

Figure 1: The six phases of the CRISP-DM method [1]

2 BUSINESS UNDERSTANDING

For ecological and economic reasons, the reduction of CO_2 emissions is a key objective in industrial production. In the context of the hybrid molding process (Figure 2), tailored organo sheets offer a promising approach to support this goal through resource-efficient lightweight construction. These are fiber-reinforced thermoplastics with specifically varied wall thicknesses or locally differentiated fiber reinforcement. This material optimization enables needs-based reinforcement along the load paths while reducing the amount of material used and thus the carbon footprint. These tailor-made semi-finished products are processed using the hybrid molding process, which combines thermoforming and injection molding and enables the highly automated production of functionally integrated lightweight components.

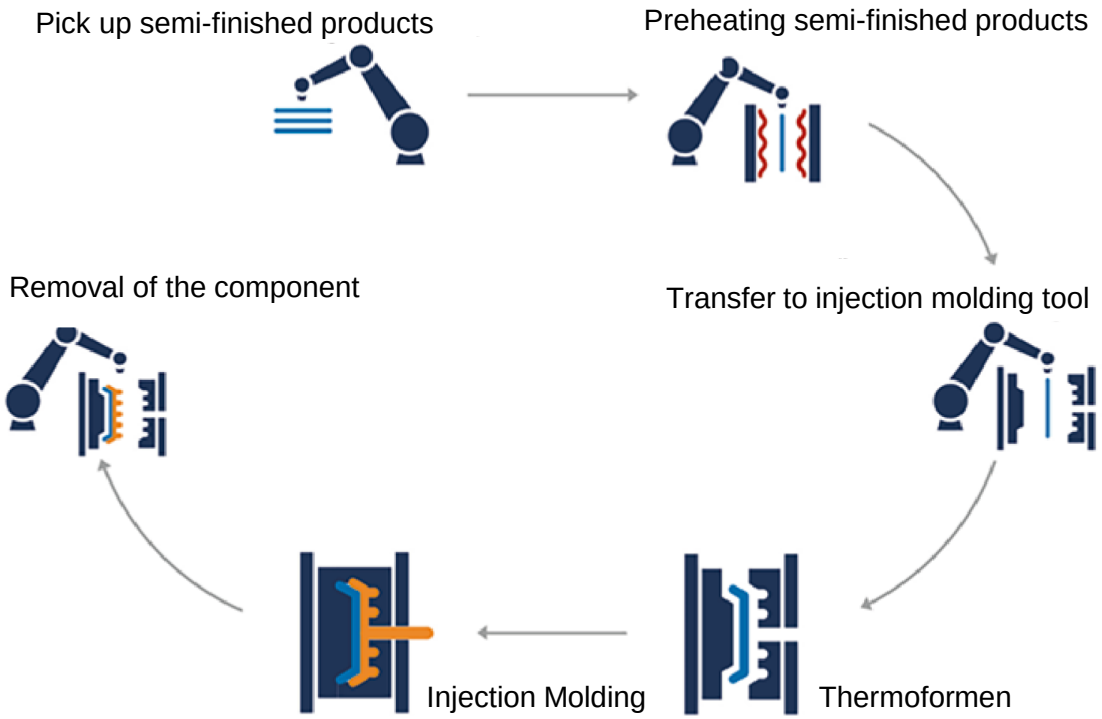

Figure 2: Process steps of the hybrid molding process [2]

However, the processing of such complex semi-finished products requires precise and locally adapted heating. The current state of the art uses large-area infrared emitters, which cannot ensure homogeneous temperature distribution in tailored organo sheets due to their low spatial resolution. This leads to local overheating or underheating and thus to quality losses in the subsequent thermoforming process. In order to make the quality of the heating process visible, a thermal imaging camera is used to analyze and evaluate the temperature distribution on the surface of the semi-finished products.

The solution presented here is based on a high-resolution infrared radiator field consisting of a large number of compact spot heaters. The resulting heating field resolution exceeds conventional systems by a factor of 25 (Figure 3). Due to the large number of individual emitters, manual parameterization is not practicable. Therefore, an automated, AI-supported power distribution is being developed with the aim of ensuring uniform temperature distribution in the semi-finished product. This uniform heating is the prerequisite for a reproducible and tool-friendly thermoforming process.

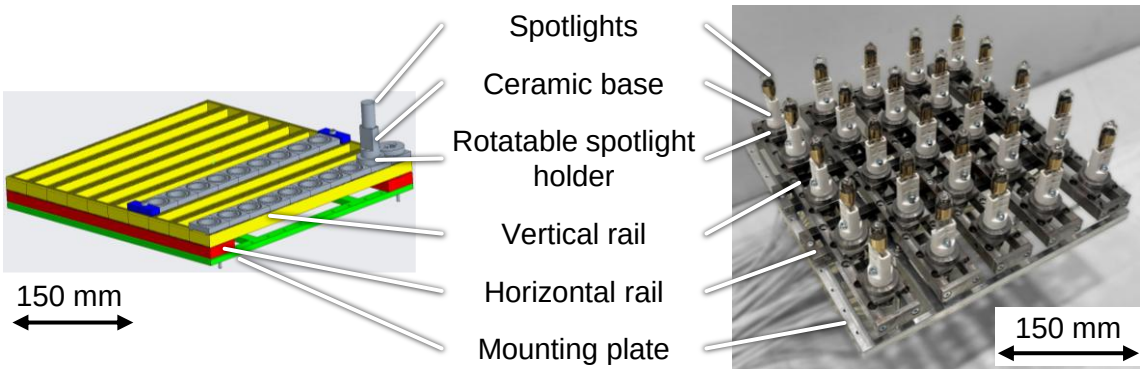

Figure 3: The high-resolution radiator field as a CAD model (left) and real image (right)

The main users of the technology are machine operators who monitor the process. As this is a further development of existing system concepts, existing interfaces must be taken into account and simple integration into established control systems must be made possible.

3 DATA UNDERSTANDING

Various data sources, including both process and sensor data, were used to develop and validate the AI-supported heating concept. The central data basis is an infrared camera that provides thermal images of the tailored organo sheet in the form of CSV files (Figure 4). These images are taken immediately after passing through the radiator field, but before insertion into the forming tool. This positioning allows potential disturbance variables that occur during transportation from the furnace to the tool (e.g. convection influences or temperature fluctuations due to radiation) to be recorded and taken into account in the analysis.

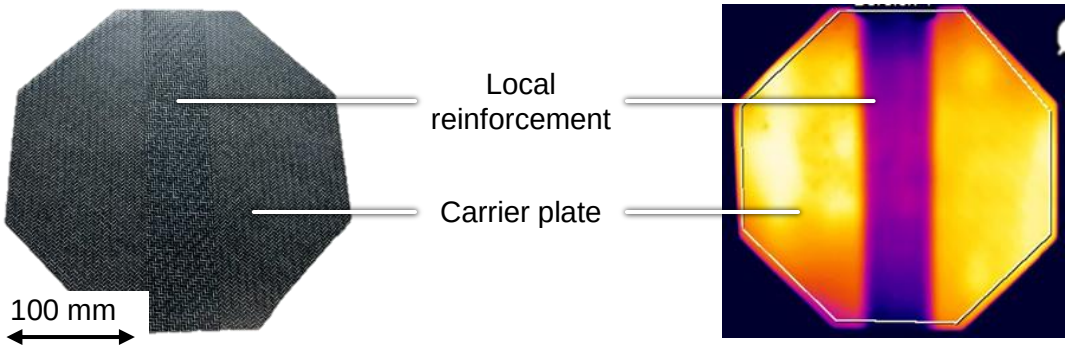

Figure 4: Tailored Organo Sheet as real image (left) and in IR image (right)

In addition to thermographic detection, non-contact temperature measurement is carried out during the heating process in the oven using a pyrometer, which is integrated into a classic control system on a PLC (Figure 5). The individual emitters are controlled via pulse width modulation, with the relative duty cycle within a network phase serving as the control variable. The control system accesses a material-specific database that contains setpoints, maximum temperatures and upper and lower specification limits for the respective organic sheet material.

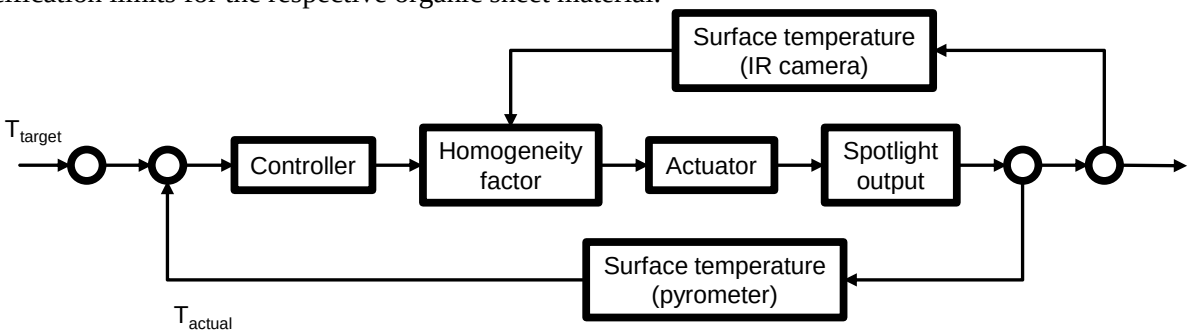

Figure 5: Controller architecture

Based on the evaluation of the thermal image data, a maximum switch-on time for the following heating cycle is specified for each spot heater via an OPC UA interface. This indirect control leads to a system-related latency between temperature detection and power adjustment, which must be taken into account when allocating data over time.

The data is collected using an adapted test setup based on a conventional IR oven, which has been expanded to include the newly developed high-resolution radiation field and thermographic measurement technology. To reduce material consumption and increase reproducibility, the heating process is carried out several times on one and the same tailored organo sheet (PA matrix with glass fiber reinforcement). The target temperature is limited to 100 °C in order to ensure thermal stress below the melting point. A defined cooling time of ten minutes is maintained between the heating cycles to ensure identical initial conditions.

Another technical aspect concerns the power supply: Due to high switch-on currents with cold infrared radiators, there is a risk of overloading the fuses. For this reason, a cascaded switch-on procedure was implemented as part of the project, which staggers the switch-on times of individual

emitters and thus enables stable operation.

The analysis of the data obtained shows a high degree of variance in the temperature distribution, particularly in areas with variable wall thickness. This heterogeneity forms the starting point for the subsequent development of a model for targeted radiator power distribution.

4 DATA PREPARATION

The central data source for modeling is the thermal image of the heated organic sheet. This is available in CSV format for each heating cycle and contains the temperature values as a pixel matrix. A threshold value method is used to separate the relevant image areas (organosheet) from the background: All pixels with temperatures above a defined threshold value are assigned to the organosheet, while pixels below this value are classified as background and excluded from further analysis. This procedure makes it possible to dispense with the product-dependent transfer of geometry information (e.g. CAD files or wall thickness curves), which simplifies system integration and increases generalizability.

To quantitatively evaluate the temperature distribution in the heated semi-finished product, the standard deviation of the temperature values within the detected component area is calculated for each image. This key figure serves as a direct measure of the homogeneity of the heating and at the same time forms the target value for the optimization model.

The data was collected as part of a systematically planned experimental setup in which the duty cycles of selected heaters were varied according to a design-of-experiment (DoE). This created a controlled variation of the heating power with the aim of investigating its influence on the resulting temperature distribution. Missing or incorrect data sets, for example due to software crashes of the IR camera, were replaced as far as possible by repeating the affected experiment. These measures made it possible to create a consistent and complete data basis for the subsequent modeling.

5 MODELING

The modeling phase comprises three consecutive steps, each of which maps specific aspects of the heating process and is linked together to enable precise prediction and optimization of the temperature distribution in the organic sheet.

In the first step, a regression-based model is set up that describes the relationship between individual radiators and their local temperature influence on the surface of the component (Figure 6). This model is furnace-specific and was determined on a reference organo sheet without local reinforcement structures. For each emitter, the extent to which its power contributes to the temperature increase in defined areas of the thermographic image is quantified. To ensure sufficient model accuracy, at least one test run is required for each emitter used. By spatially limiting the potential influence zones based on the results of this step, the test effort can be significantly reduced in the second step.

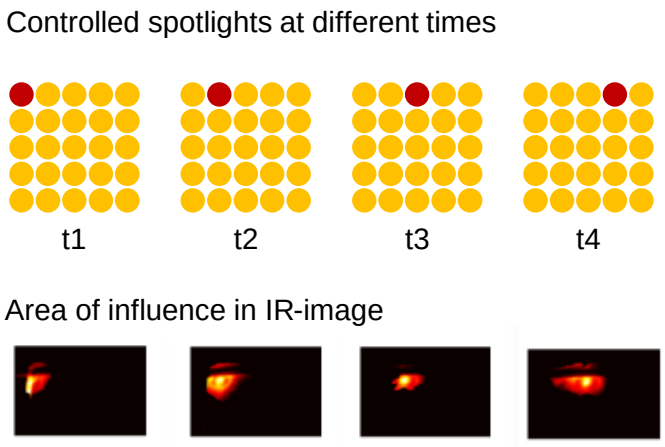

Figure 6: Correlation between emitter and IR image

The second step involves modeling the organic sheet itself. The aim is to map the thermal reaction

patterns of the semi-finished product as a function of geometry, wall thickness distribution and material behavior. Based on the radiator influence model learned in the first step, a simulation can be created that predicts a complete thermal image of the component from a given radiator switch-on scenario (Figure 7). This simulated thermography serves as the basis for subsequent optimization.

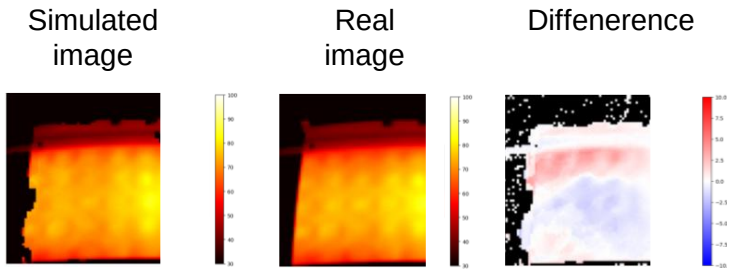

Figure 7: Comparison of simulated IR image and real recorded IR image based on the emitter parameters

In the third step, the radiator power distribution is optimized with the aim of achieving the most homogeneous temperature distribution possible across the component surface. The standard deviation of the temperature distribution within the detected organic sheet serves as the target value. A genetic algorithm is used for optimization, which strives for a global solution in the high-dimensional parameter space by iteratively varying the radiator switch-on times. The use of a simulation-based prediction model makes it possible to carry out this optimization process efficiently and in a material-friendly manner without having to carry out large-scale real test series.

This three-stage model structure allows both the physical properties of the system and data-based correlations to be taken into account. At the same time, it ensures that the final model combines high forecasting quality with realistic feasibility in process control.

6 EVALUATION

A pilot production was carried out to validate the developed model architecture. A cruiser skateboard was used as a demonstrator, which is provided with targeted local reinforcement in the area between the axles. This constructive measure enables a weight-saving design of the component and at the same time places increased demands on temperature homogeneity during the heating process. Different material systems were used to evaluate the generalizability: a laminate consisting of an organic sheet with a unidirectional tape made of hemp and polypropylene as well as another laminate based on glass fibre and polyamide. The geometry remained constant so that the influence of the material properties on the temperature behavior could be analyzed in isolation.

To validate the model, the simulated temperature image generated by the genetic algorithm was compared with real thermal images. Table 1 shows examples of the deviations between simulated and measured data based on the parameters mean value, standard deviation, minimum and maximum temperature. The differences are less than 1 K in all cases, with the mean temperature deviation being only 0.39 K. The standard deviation is particularly relevant as a target value for optimization: with a difference of only 0.83 K, there is a good match between simulation and real behavior.

Table 1: Comparison of characteristic values based on simulated and real IR images

	Average [°C]	Standard deviation [K]	Minimum [°C]	Maximum [°C]
Simulated image	70,42	4,95	50,64	78,13
Real image	70,03	5,78	50,10	79,00
Difference	0,39	0,83	0,54	0,87

An interactive dashboard was used in the pilot environment to make the model decisions comprehensible for the operating personnel and to increase practical suitability (Figure 8). This visualizes the resulting spotlight settings and enables the machine operator to understand and manually adjust the suggestions. As a result, the human operator retains the decision-making authority and a human-in-the-loop approach is implemented, which both creates trust in the AI application and increases process reliability.

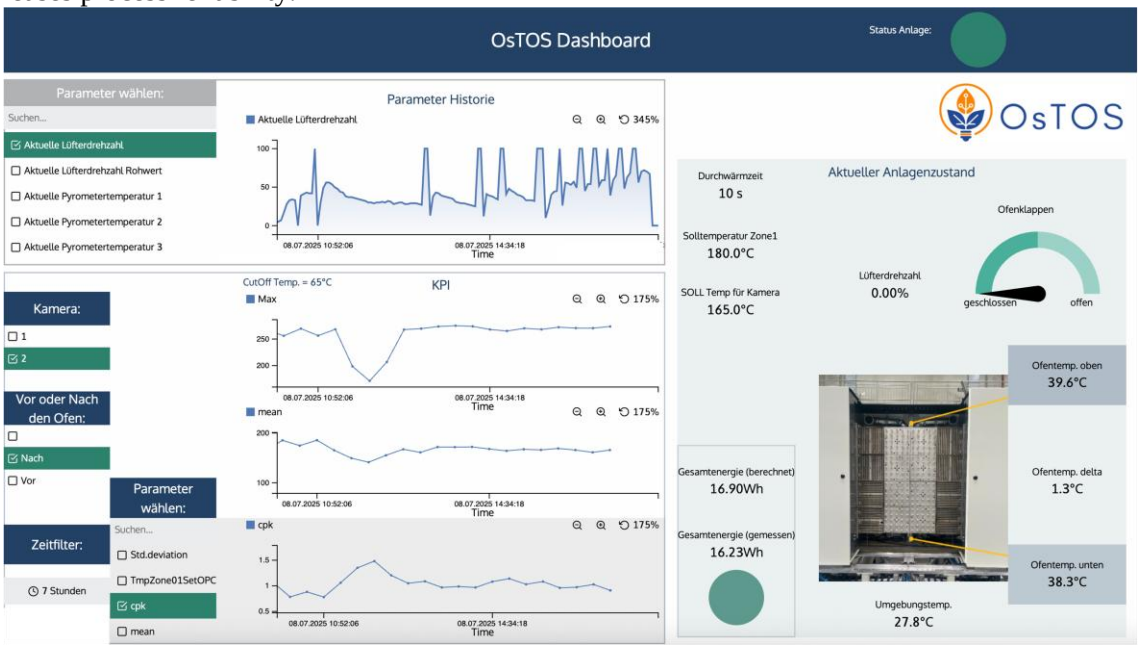

Figure 8: Dashboard for process visualization

The evaluation confirms that the model is able to predict the desired temperature distribution with high accuracy and thus fulfills the objective of developing a robust, AI-supported control concept for homogeneous heating of tailored organo sheets. In addition, the tested solution enables material-specific adaptation without the need for changes to the model structure. This ensures practical applicability in varying industrial scenarios.

7 DEPLOYMENT

The thermographic images are evaluated on an external industrial PC, which communicates with the machine control system via a standardized OPC UA interface. The AI model is executed cyclically in the production process: For each heating cycle, the relevant process data, in particular the individual duty cycles of the spot heaters, are buffered in the PLC and used for control in the following cycle. This buffered procedure allows the system to react continuously without jeopardizing the real-time capability of the control system.

The system architecture is designed in such a way that the operator can actively intervene in the process at any time. The dashboard already used in the evaluation context will continue to be used during operation. It is used to visually display the control suggestions generated by the model, to make them comprehensible and to modify them manually if necessary. In this way, humans remain an integral part of the control loop, in the sense of a human-in-the-loop approach that combines automation with operational responsibility and strengthens trust in AI-supported processes.

The deployment is currently in the final implementation phase. Initial integration tests have demonstrated the functionality of the communication and control chain as well as the practicality of the model-based control system. Specially designed demonstrator tailored organo sheets were manufactured in order to further test the generalizability and resilience of the system under realistic conditions. These consist of high-temperature resistant PAEK with carbon fiber reinforcement. (Figure

ACKNOWLEDGEMENTS

The fabrication of the tailored organo sheet demonstrators was made possible through the collaboration with Coriolis Composites, particularly Mr. Yohan Bouyssière, and the Fraunhofer IGCV, with support from Mr. Florian Jennemann. Many thanks for their valuable support.

This work is part of the research project Oven system for Tailored-Organo-Sheets (OsTOS) and funded by the Federal Ministry for Economic Affairs and Climate Action (BMWK) as part of the Technology Transfer Programme for Lightweight Construction (TTP LB) under funding code 03LB3027. The project is supervised by Project Management Jülich (PTJ). The author is responsible for the content of this publication.

NUMERICAL ANALYSIS OF MACROVOID FORMATION PROCESS IN A SINGLE-LAYERED WOVEN FIBRE BUNDLE CONFINED BETWEEN PARALLEL PLATES

M. Inagawa[1], T. Ito[1], S. Yamashita[1+] and I. Ueno[2]

ABSTRACT

We numerically analyse macrovoid formation in a single-layer woven fibre bundle confined between parallel plates, focusing on the effects of capillary number (Ca) and wettability. The volume-of-fluid (VOF) method is employed to capture the interface, and the continuum surface force method (CSF) is applied to treat the surface tension as the body force. The simulation captures the dynamic evolution of the flow front, showing that low Ca and small contact angles induce non-uniform impregnation and frequent snap-off events, resulting in forming macrovoids. Detailed analysis of velocity and shear stress distributions reveals abrupt interface deformation and local shear stress increases near snap-off regions. These localized dynamics strongly influence the progression and coalescence of flow fronts. The final macrovoid fraction decreases with increasing Ca, fibre–liquid contact angle (θ_f), and wall–liquid contact angle (θ_w). The observed dependence on a modified capillary number is consistent with previous experimental results.

1 INTRODUCTION

Void formation during the impregnation process in fibrous reform has been widely recognized as a critical issue in composite manufacturing, decreasing the mechanical properties of the final product [1-3]. The volume fraction of voids is known to depend sensitively on the capillary number $Ca = \mu \cdot U/\sigma$ [4-6], which characterizes the balance between viscous stress and surface tension. It must be emphasized that the optimal value of Ca to minimize the formation of macro- and microvoids is not universal, but rather depends on the specific geometric and wetting properties of the specific systems [7,8]. Consequently, the development of a generalized predictive model remains difficult. This system-dependent nature of void formation necessitates a more detailed investigation into the local dynamics of interface deformation and fluid displacement mechanisms, especially in terms of snap-off event which is important for the entrapment of non-wetting phase fluids in porous media [9,10].

Previous numerical simulations of impregnation process in RTM and VARTM have employed Darcy-scale models to predict the pressure and flow fields within the fibrous preform [11-13]. Whist such models are computationally efficient and provide valuable insights into macroscopic flow behavior, their formulation based on averaged quantities poses limitations in capturing local interfacial dynamics at the pore scale. In particular, detailed mechanisms such as dynamic wetting, curvature-driven pressure difference, and snap-off-induced interface redistribution are often beyond the resolution of Darcy-based approaches [14]. Consequently, predicting the precise formation processes of individual voids remains a nontrivial task within this modeling framework. Whist, investigations in soil and petroleum engineering have suggested that snap-off events—where the non-wetting phase becomes disconnected due to capillary instabilities—can influence fluid entrapment behavior, even in single-scale porous media [9,10]. These findings imply that the interaction between local pore geometry and interfacial dynamics may be more relevant than previously assumed, particularly in the context of multiphase

displacement.

In this study, we address this issue by modeling the flow field within a single-layer woven fibre bundle between parallel plates, instead of using the previous Darcy-scale approach. Using key parameters such as the capillary number (Ca), which represents the impregnation velocity of the liquid, and the wettability between the liquid and fibres, as well as between the liquid and the top and bottom walls, we analyze the behavior of the flow front and the flow field within the liquid, focusing on macrovoid formation processes.

2 METHOD

The analysis domain considered in this study is shown in Fig. 1. We simulate a single-layer woven fibre bundle enclosed by parallel plates, with the domain dimensions $(L_x\, L_y\, L_z)$ [μm] = $(9500, 700, 4600)$. The main-flow-direction length of the unit cell L_u is of 4600 μm. The distance between the warp and weft fibre bundles (or, size of inter-bundle region in the x and z directions) is set at 1.1 mm. The fibre diameter D_f is of 320 μm, and the distance between fibres d_f is of 397.5 μm = 1.242 D_f . Given the difficulty in reproducing the accurate geometry of the experimental fibres at the spatial scale of the analytical domain, the fibre volume fraction within the fibre bundle is maintained to the corresponding experimental systems, providing a relatively large fibre diameter. A no-slip boundary condition is provided to the fibre surfaces and the top and bottom walls ($(x, y = 0, z)$; $(x, y = L_y, z)$), whist mirror boundary conditions are provided to the side walls ($(x, y, z = 0)$; $(x, y, z = L_z)$). At the inlet ($x = 0, y, z$), the velocity condition $(u, v, w) = (U_\mathrm{in}, 0, 0)$ is provided, and a convective boundary condition is provided at the outlet ($x = L_x, y, z$). The properties of the liquid and gas are applied as those of 350-cSt silicone oil and air, respectively, to simulate the experiments [4]. All simulations are conducted under zero gravity acceleration $g = 0$ kg/s. The capillary number Ca is defined as $\mathrm{Ca} = \mu_\mathrm{l} \cdot U_\mathrm{in}/\sigma$, where μ_l and σ represent the viscosity of liquid and surface tension, respectively. To track the gas-liquid interface the volume of fluid (VOF) method [15] is applied, whist surface tension effects are described using the continuum surface method (CSF) [16], treating surface tension as a body force. In this study, the simulation is conducted using the `interFoam` solver of the OpenFOAM ver. 9.

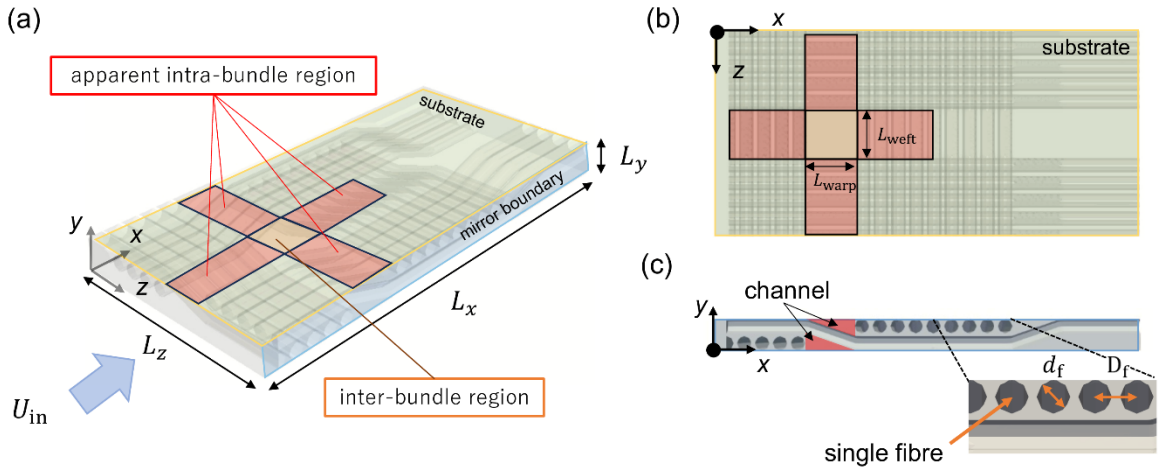

Fig. 1 Computational domain for infiltration of a viscous fluid into a single-layer woven fibre bundle confined between parallel plates: (a): bird view, (b): top view, and (c): side view.

3 RESULTS AND DISCUSSION

3.1 General impregnation process

Figures 2 (a) and (b) show the temporal variations of the permeating behaviour for $\theta_\mathrm{f} = \theta_\mathrm{w} = 20°$ via the present numerical simulation under different Ca conditions. This figure represents how the impregnating liquid (shown in deep grey) permeates a single-layer woven fibre bundle (shown in semi-

transparent light grey) under (a) Ca = 0.001, and (b) Ca = 0.01. For the sake of visibility, the flow fronts near the bottom wall (thin line) and near the top wall (thick line) are also illustrated. The normalized time, t^*, is defined as $t^* = \frac{\sigma}{\mu_l L} \cdot t$, where L is the length of the inter-bundle region in the warp direction.

In the case of (a) Ca = 0.001, the flow front advances non-uniformly near both top and bottom walls. The liquid advances preferentially in the intra-bundle region, whist significant delay occurs in the inter-bundle region. Due to this lead-lag behaviour with different spatial scales, the snap-off events occur in the apparent intra-bundle region in the downstream side of the inter-bundle region near the top wall (thick line (in blue) at $t^* = 2435$ in Fig. 2 (a)). Subsequently, another snap-off event occurs near the bottom wall (thin line (in red) at $t^* = 2675$ in Fig. 2 (a)), resulting in complete trap of the non-wetting fluid in the inter-bundle region (at $t^* = 2938$ in Fig. 2 (a)).

In the case of a higher Ca ((b) Ca = 0.01), the influence of viscous forces becomes more significant than those in the case of Fig. 2 (a), and the flow fronts near the top and bottom walls advance relatively uniformly in both of the inter-bundle and intra-bundle regions (at $t^* = 101.7$ in Fig. 2 (b)). No snap-off is observed near either wall, and the inter-bundle regions are completely filled with the permeating liquid (at $t^* = 186.4$ in Fig. 2 (b)). Under this condition, both snap-off and macrovoid formation are completely avoided. Further, the present numerical results show a qualitative agreement with the findings of previous studies using woven fibre bundles [4-7,17].

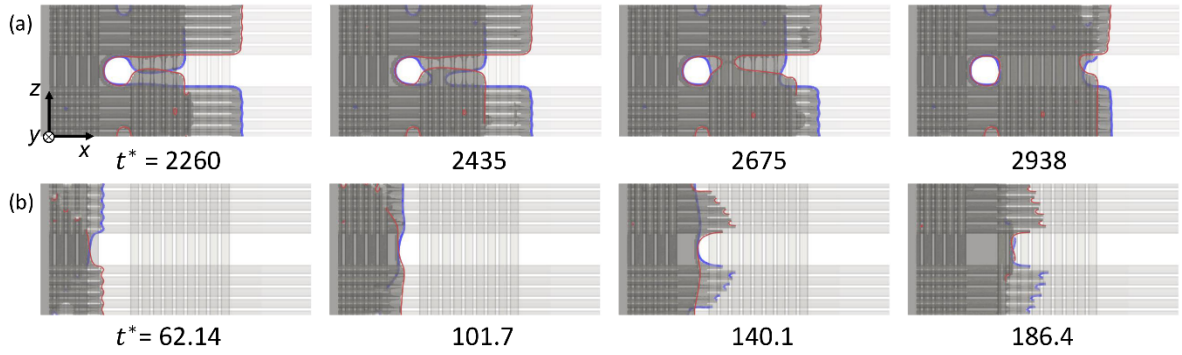

Fig. 2 Temporal variation of impregnation behavior of permeating liquid for $\theta_f = \theta_w = 20°$ under (a) $Ca = 0.001$ and (b) 0.01. Observations are made from bottom wall side. In each panel, permeating liquid is represented in dark grey, whist fibres and air are represented semi-transparently light grey. Thin- (in red) and thick- (in blue) lines denote flow fronts near bottom wall (at $y = 50$ μm and near top wall (at $y = 650$ μm), respectively.

3.2 Velocity and shear stress distributions

We discuss the effects of Ca on the impregnation process. We focus on the distributions of velocity and shear stress within the permeating liquid. Figure 3 presents successive images of distributions of the streamwise velocity (Row I), the spanwise velocity (Row II), and the shear stress in the streamwise direction (Row III) near the flow front on a plain near the bottom wall at $(x, y = 50\ \mu m, z)$. The streamwise and spanwise velocities within the permeating liquid are normalized by the inlet velocity, U_{in}, and the shear stress is normalized by the dynamic pressure $\rho_l U_{in}^2$. We first examine the effect of Ca on the velocity and shear stress distributions via Panels (a) and (b) in Fig.3.

In the case of (a) $Ca = 0.001$, when the flow front or the gas-liquid interface advances within the fibre bundle in the warp direction (at $t^* = 1525$ in Row (I)), high U_x is realized within the warp as well as in the apparent intra-bundle region, whereas low U_x is realized within the wefts. As a result, the flow front progresses non-uniformly in the spanwise direction. The liquid permeates significantly along the weft, whilst it is prevented to advance by the weft toward the streamwise direction. As time elapses, the flow front changes its advancing direction, and the encountering flow fronts merge and coalesce, causing the snap-off events (see region (A) at $t^* = 2675$). That is, in this region, there exist two gas-liquid interfaces advancing opposite directions in the streamwise direction after the snap-off: Negative

component of the streamwise velocity is distributed in the upstream side near the of upstream-side interface, whist its positive velocity component is distributed in the downstream side of the downstream-side interface. As a result, a residual bubble, or the void, is formed (at $t^* = 3164$) as demonstrated by previous experimental [7,16,18] and numerical [7-10] works. From the distribution of the spanwise velocity U_z near the snap-off region (region (A) at $t^* = 2675$ in Row (II) in Fig. 3 (a)), the liquid permeates from the spanwise direction toward this region. Then the shear stress τ_x near the snap-off region (region (A) at $t^* = 2685$ in Row (III) in Fig. 3 (a)) locally increases drastically. As the snap-off event occurs, the permeating liquid is driven further by the Young-Laplace pressure difference acting on the regions near the interfaces with different curvatures, resulting in the significant variations of velocity and shear stress.

In the case of (b) $\mathrm{Ca} = 0.01$, the gas-liquid interface advances without being held at the edge of bundles forming the inter-bundle: The absolute value of the shear stress under this condition (see Row (III)) is uniformly lower compared to Fig. 3 (a). These results indicate that Ca significantly governs the liquid mobility and the corresponding shear stress within the permeating liquid.

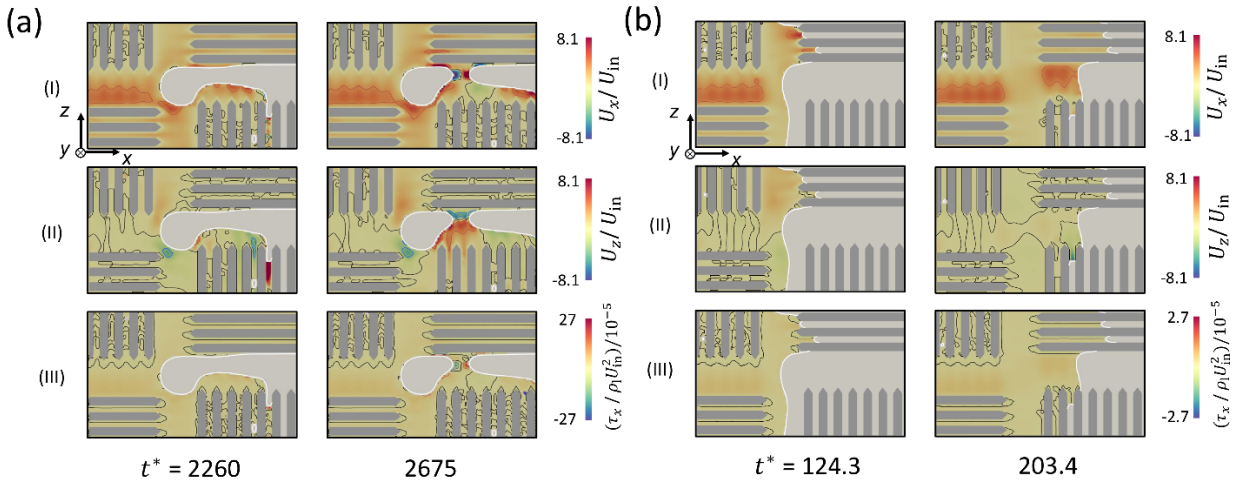

Fig. 3 Effect of Ca on velocity and shear stress distributions at $\mathrm{y} = 50$ μm. Rows (I)--(III) indicate streamwise velocity, spanwise velocity, and shear stress in streamwise direction, respectively. Conditions of Panel (a) and (b) correspond to those in Fig. 2:(a) $(\mathrm{Ca}, \theta_\mathrm{f}, \theta_\mathrm{w}) = (0.001, 20°, 20°)$ and (b) $(0.01, 20°, 20°)$.

3.3 Macrovoid fraction

We demonstrate that the snap-off event is crucial and governing factor on the entrapment of non-wetting fluid, or the void formation. In this section, we examine the correlation between the contact angles, θ_f and θ_w, and the apparent macrovoid fraction. The apparent macrovoid fraction is evaluated at each time step as the ratio of the gas volume in the mold gap to the initial gas volume in the unit cell. In other words, it represents the void fraction excluding voids formed within the fibre bundles (microvoids). Hereafter, this is referred as the macrovoid for the sake of brevity. Left panel of Fig. 4 illustrates the typical example of temporal variation of the macrovoid fraction in the unit cell from the start of impregnation under different Ca. The macrovoid fraction decreases as time elapses as indicated in the previous studies [8,11,12,17,18]. The macrovoid fraction significantly drops and converges more rapidly as the capillary number (inlet velocity) increases [8,11,12]. Under the condition $(\mathrm{Ca}, \theta_\mathrm{f}, \theta_\mathrm{w}) = (0.001, 20°, 20°)$, a macrovoid is formed, resulting in a final macrovoid fraction greater than zero. To evaluate the macrovoid fraction after a sufficient time following the completion of impregnation, the end of impregnation is defined as the point at which the variation rate of macrovoid fraction falls below $0.05\%/\mathrm{s}$ in this analysis. The macrovoid fraction at this fully developed point is referred to as the final macrovoid fraction hereafter. Figure 4 presents the final macrovoid fraction against the modified

capillary number, $\mathrm{Ca}' = \frac{\mu U}{\gamma \cos\theta_\mathrm{f}}$ [9]. The shape of symbols represents the contact angle between the liquid and the fibres, whist the hollow or filled symbols indicate the contact angles between the liquid and the walls. It is remarked that the modified capillary number, proposed by Patel et al., (1995), would not accurately measure the effect of wettability because it collapses under $\theta_\mathrm{f} = 90°$ nonetheless the flow front advances. For the sake of comparison with previous research, it is temporarily utilized. For lower modified capillary numbers ($\mathrm{Ca}' \sim 0.001$), the final macrovoid fraction decreases as either θ_f or θ_w increases. At intermediate modified capillary numbers ($\mathrm{Ca}' \sim 0.002$), an increase in θ_f suppresses the macrovoid formation altogether. At higher modified capillary numbers ($\mathrm{Ca}' \sim 0.01$), no macrovoid forms, even under small θ_f and θ_w. These findings demonstrate that the final macrovoid fraction is highly sensitive to the variation in θ_f, consistent with previous studies [7,8,19]. It is emphasized that, even under low Ca' conditions, the macrovoid fraction decreases by increasing θ_w for woven fibre bundles installed near the walls. The final macrovoid fraction decreases under larger θ_w, notwithstanding this effect is less pronounced than that of θ_f.

Through this study, we have focused on the impregnation and the void formation in a narrow space between parallel walls, and have clarified the dynamics and development process of the impregnation and void formation. We measure the influence of the dynamic wettability between the impregnating liquid and the fibre, and that between the impregnating liquid and the walls. It must be emphasized that, when forming larger-scale composite material especially in the thickness direction, the proportion of near-wall area decreases relatively, and it is essential to understand the snap-off phenomenon between and/or among fibre bundles. Furthermore, if we consider woven fibre bundles as a porous media consisting of multiple characteristic scale in space, understanding the spatio-temporal behavior of the formed voids, in addition to the impregnation and void formation processes, will definitely make an important contribution, not only to the material processing, but also to the application to separation and mixing processes of multiphase systems. Accumulation of knowledge in dynamics on the impregnation in a larger area and on the movement of the formed voids [7] is essential for comprehensive understanding and developing engineering technologies that handle multiphase fluid systems in porous media.

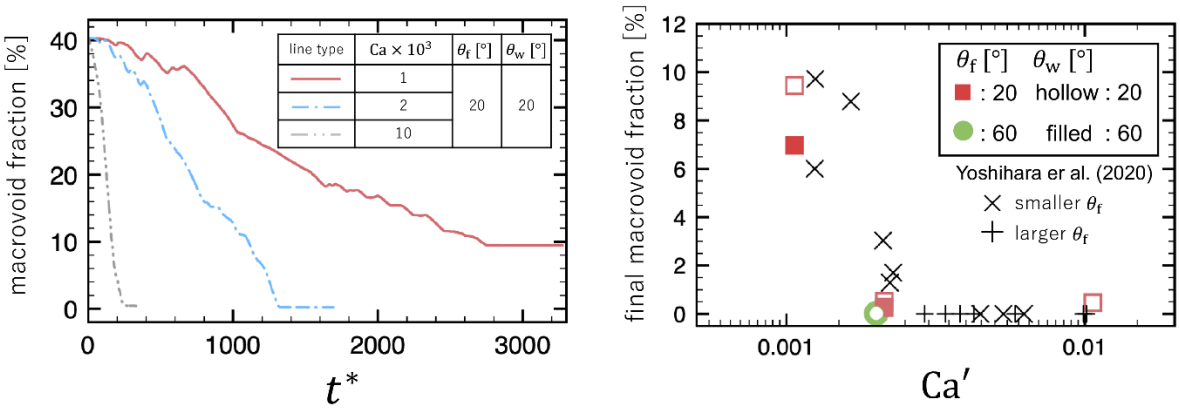

Fig. 4 Typical example of temporal evolution of macrovoid fraction for various Ca conditions under $(\theta_\mathrm{f}, \theta_\mathrm{w}) = (20°, 20°)$ (left), and correlation between macrovoid fraction in developed state and modified capillary number Ca' (right). Symbol shape in Right panel represents contact angle between liquid and fibre: square for 20° and circle for 60°. Filled style indicates contact angle between liquid and walls: Hollow (unfilled) symbols for $\theta_\mathrm{w} = 20°$ and filled symbols for 60°. Experimental data from Yoshihara et al., (2020) are also plotted in the Right panel, with crosses (×) and plus signs (+) corresponding to conditions with smaller and larger contact angle between liquid and fibre, respectively.

4 CONCLUSIONS

Displacement events of the non-wetting fluid during the impregnation process in woven-fibrous porous media are investigated, experimentally and numerically, focusing on the effects of the capillary

number (Ca) and wettability. We indicate that lower Ca not only leads to a more uneven movement of the flow front, making snap-off events more likely to occur, but also affects the mobility of the flow front. When a snap-off event occurs, the velocity of the permeating liquid increases rapidly near the snap-off occurrence region due to gas-liquid interface deformation, and the shear stress locally rises.

The influence of these factors is evident not only in the nature and behaviour of the displacement events but also in the final macrovoid fraction. A lower Ca and smaller contact angles promote snap-off events, leading to increased void trapping, whereas a higher Ca and larger contact angles favor more uniform flow and pore-filling events. The correlation between the modified capillary number and the final macrovoid fraction is particularly noteworthy, as it aligns with findings from previous studies [4,8], validating the robustness of present results.

These findings provide significant insights, not only for optimizing composite manufacturing processes to achieve more uniform impregnation and reduced void formation, but also for broader applications dealing with two-phase flow with free surface: Controlling water flow in fuel cell catalysts and managing gas/liquid separation in porous media with complex flow paths, such as in environmental control systems for orbital structures [20-23]. The ability to fine-tune flow behaviour in such systems highlights the broader impact and applicability of this research in advanced engineering and scientific fields.

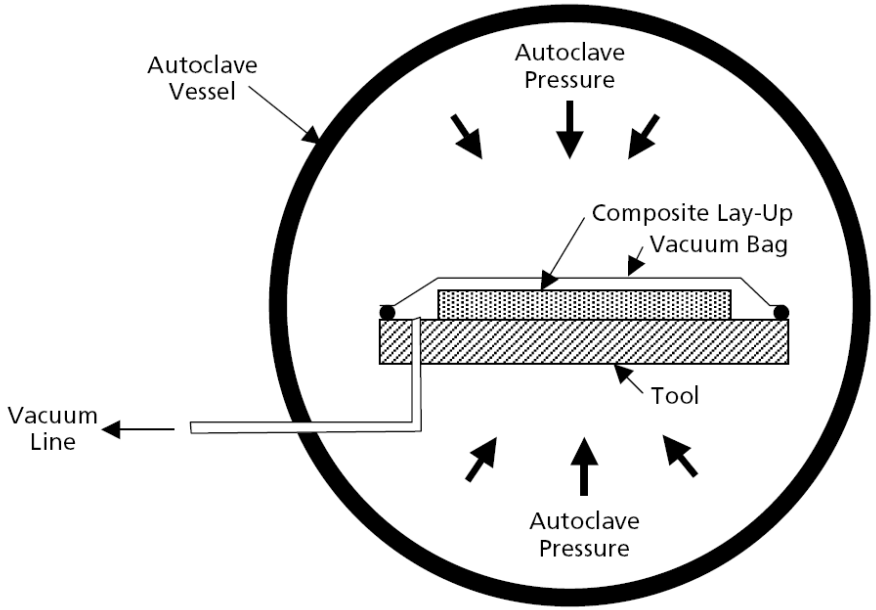
Introduction

Void formation and elimination in laminate



Schematic of interlaminar, intralaminar void formations in laminate

- When insufficient pressure is applied during curing, voids form within the laminate
- Partially impregnated dry tows disappear under vacuum-bag-only curing (i.e., **0.1 MPa** of pressure)[1]
- Complex techniques are used to eliminate interfacial entrapped airs but all have limitations[2-6]

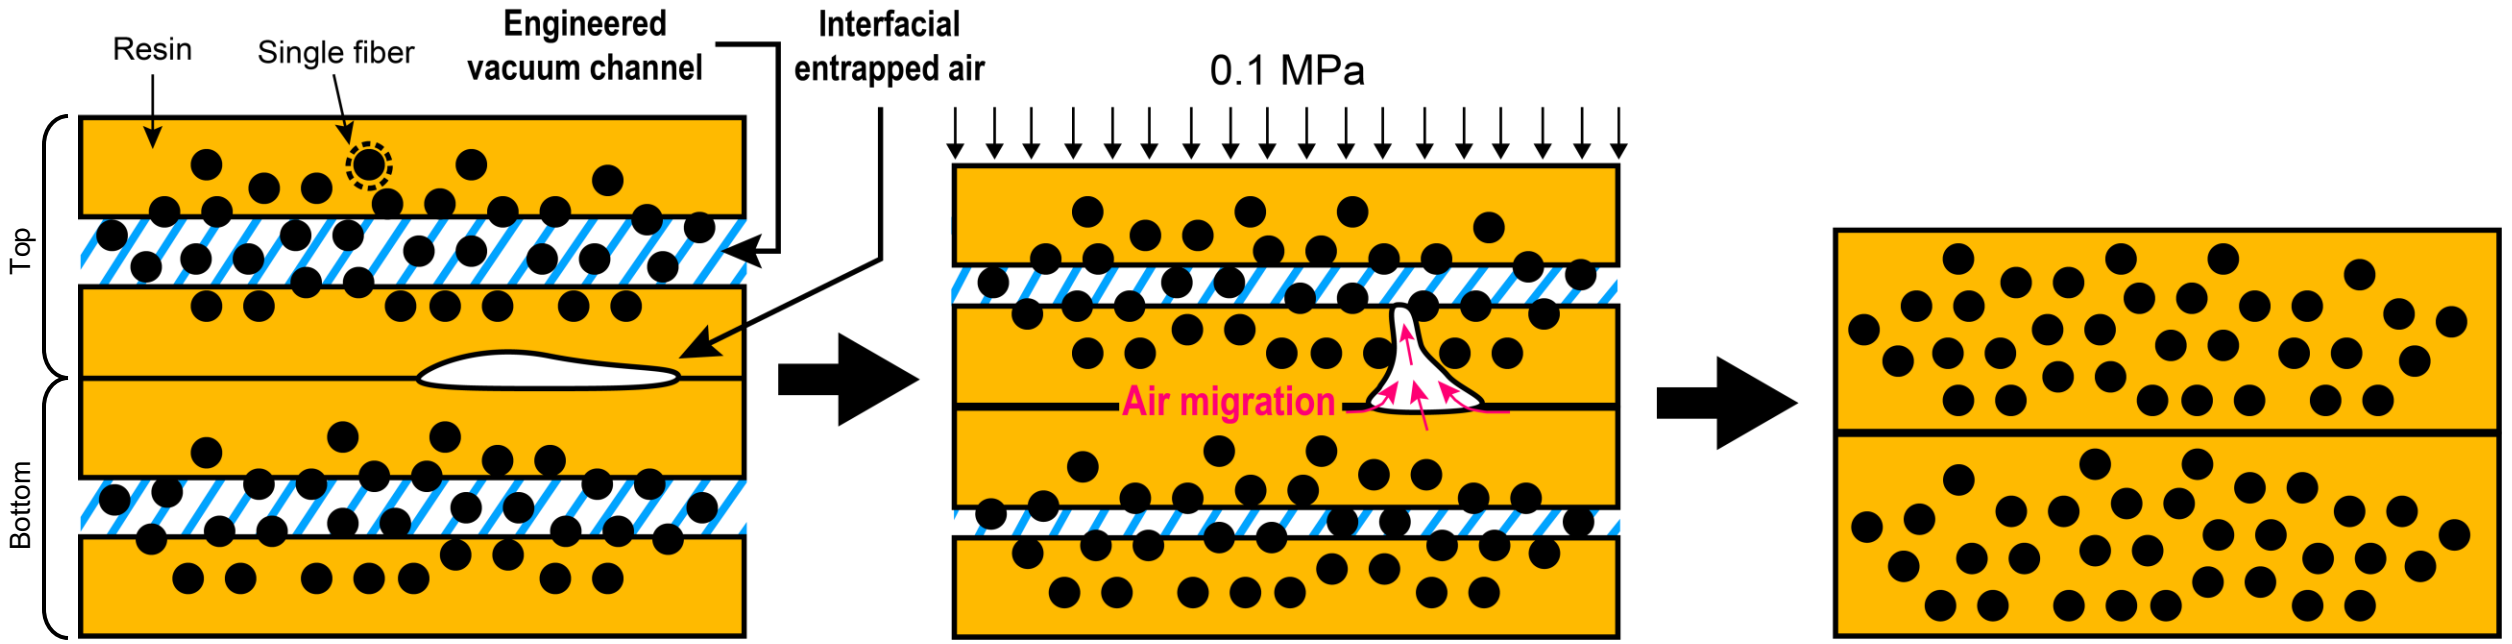
Curing with autoclave for high pressure

Schematic of autoclave curing[10]



Autoclave for Boeing 777X

- Autoclave uses **high pressure** to prevent entrapped air expansion[2]
- **Limitations** of autoclave:
  - **Capacity** of the autoclave **limits** the size and design of the parts[4,7]
  - Cost during a curing process accounts for **26%** of the total composite acquisition costs[8]

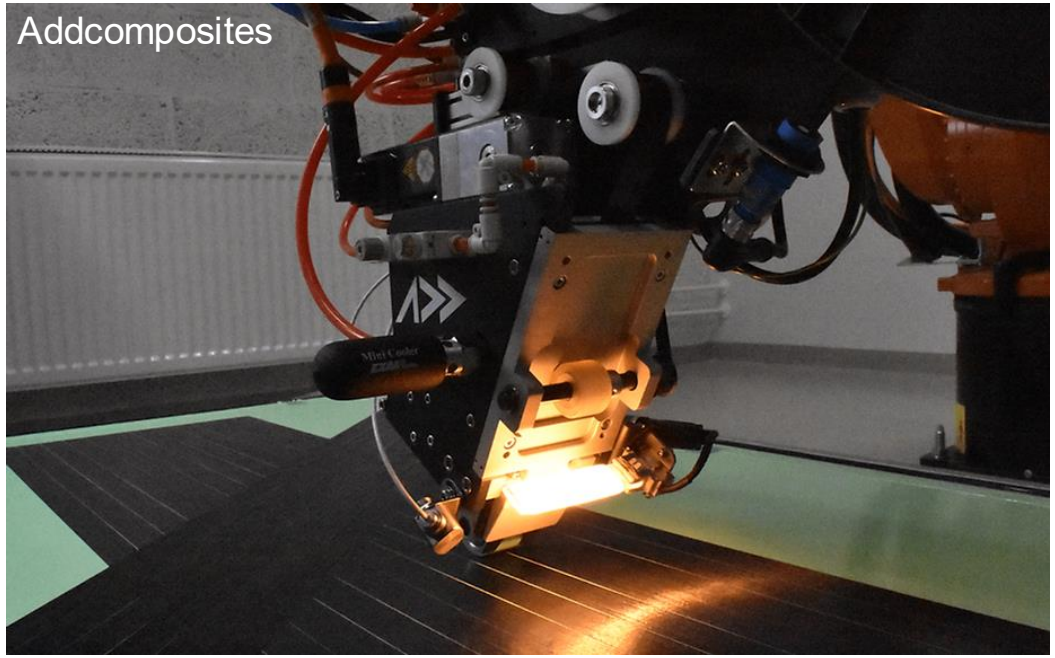
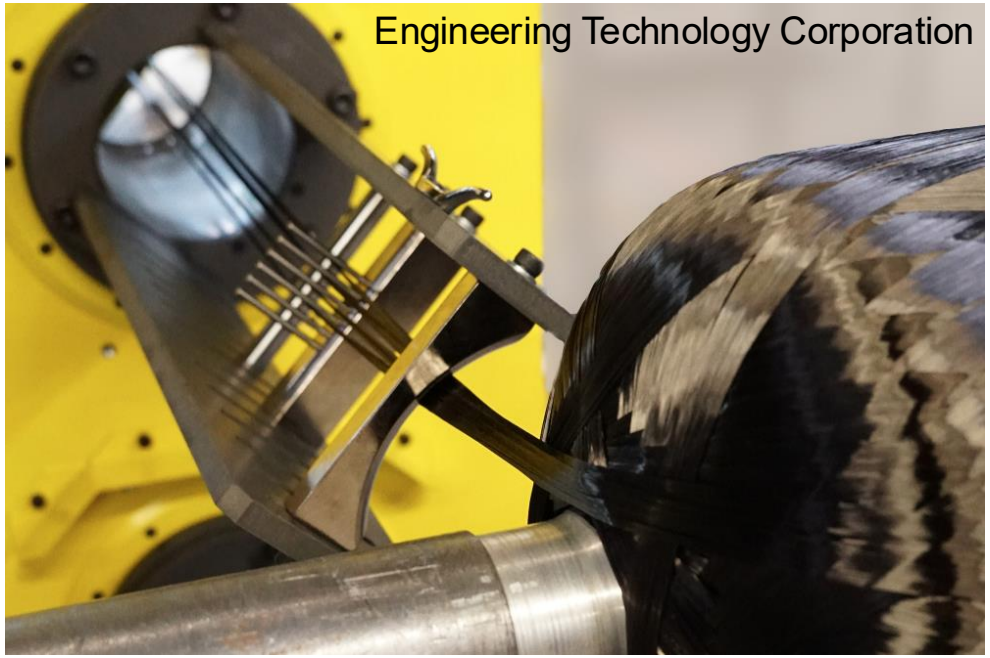
Alternative of the autoclave: Out of Autoclave (OoA) prepreg



Schematic of OoA prepreg curing process



- Debulking process is performed after every 1-3 plies for air evacuation[4]
- Engineered vacuum channels are created **intentionally** for easy air migration[4]
- **Limitations** of OoA prepreg[1,3]:
  - For high resin flow, resin composition is altered from autoclave prepregs ⇨ **low reliability**
  - Numerous factors (moisture, out-time, etc) affect void-free curing ⇨ **low stability**

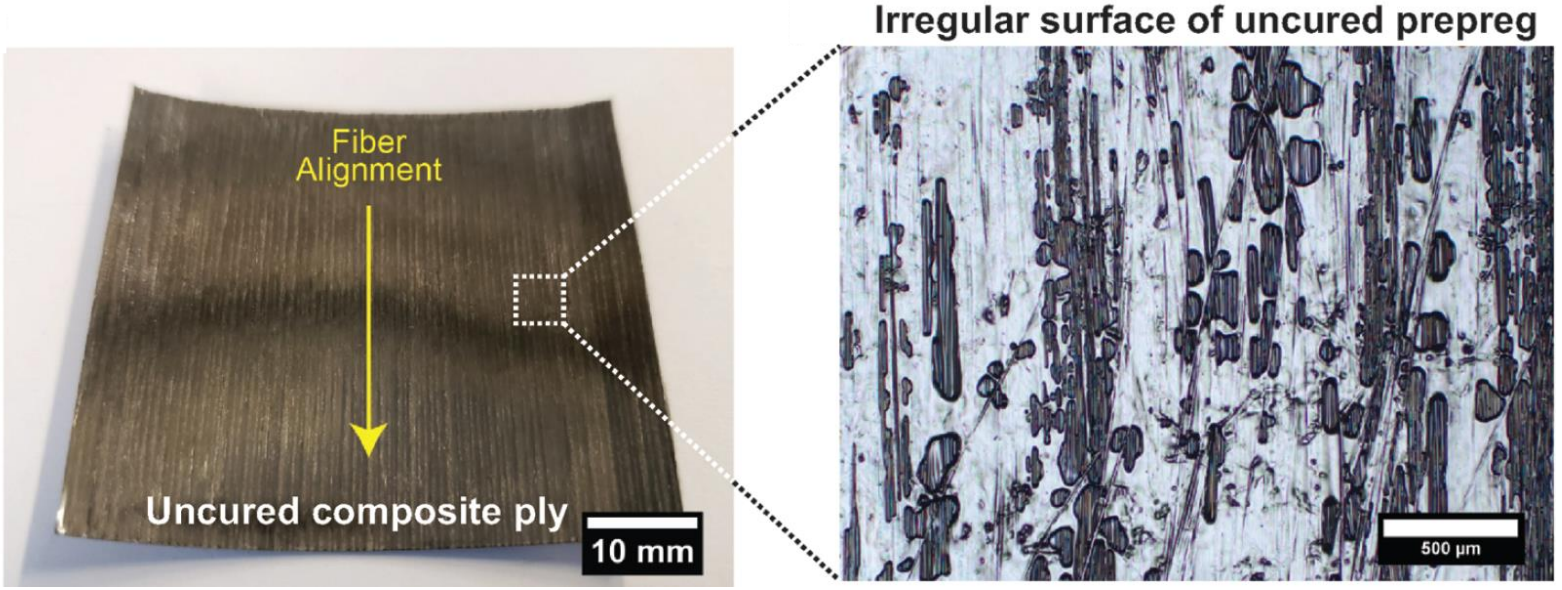
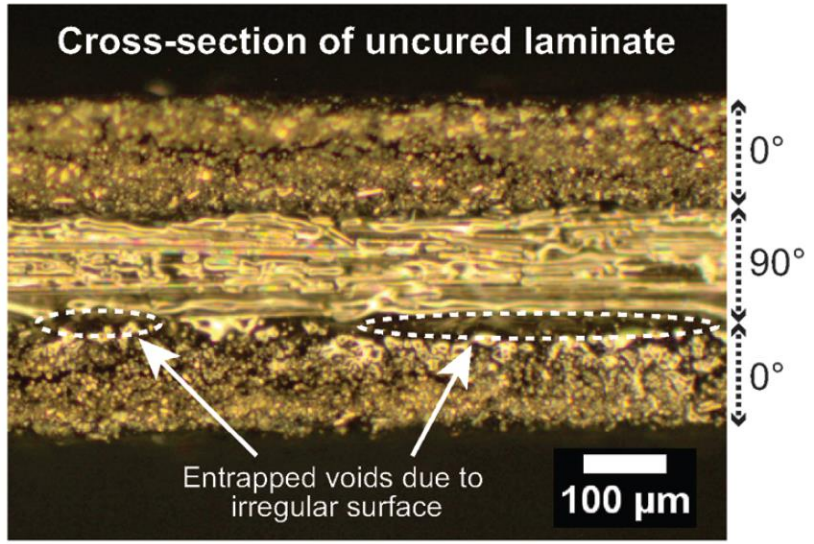
OoA manufacturing strategies for next-generation layup processes

Automated Fiber Placement (AFP)



Filament Winding (FW)



- AFP and FW are automated layup processes using robotics, offering high time and cost efficiency[9]
- Since debulking is not applicable, **high compaction pressure and fiber tension** are being studied as alternatives in these processes[10,11]
- However, excessive pressure and tension may cause resin squeeze-out or fiber misalignment[11]

Relation between prepreg surface and interlaminar void

Optical image of prepreg surface[1]

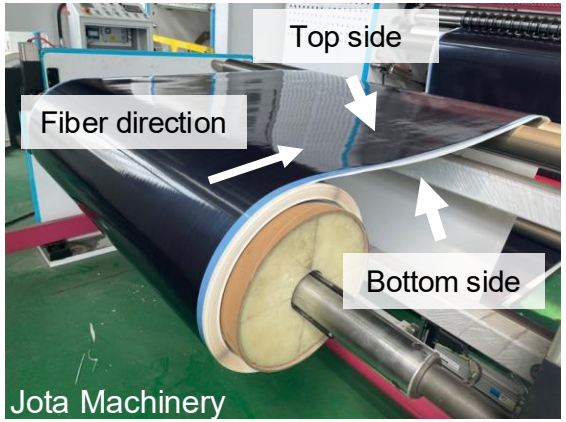
Cross-section of laminae[1]

- Rather than *compressing after layup*, eliminating the **cause of air entrapment** before layup can be more effective
- Recent study suggests that the prepreg surface may be **primary factor** in formation of the interfacial entrapped air and interlaminar void[1]

➢ Research topic: relation between **prepreg surface** and **interlaminar void** through experiments

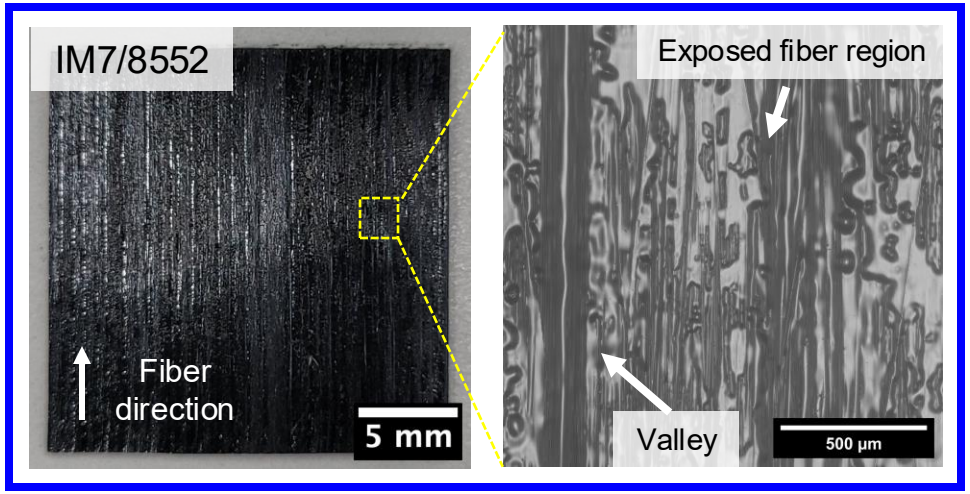
[1] J. Lee et al., Advanced Materials Interfaces, 2020.

Research objective



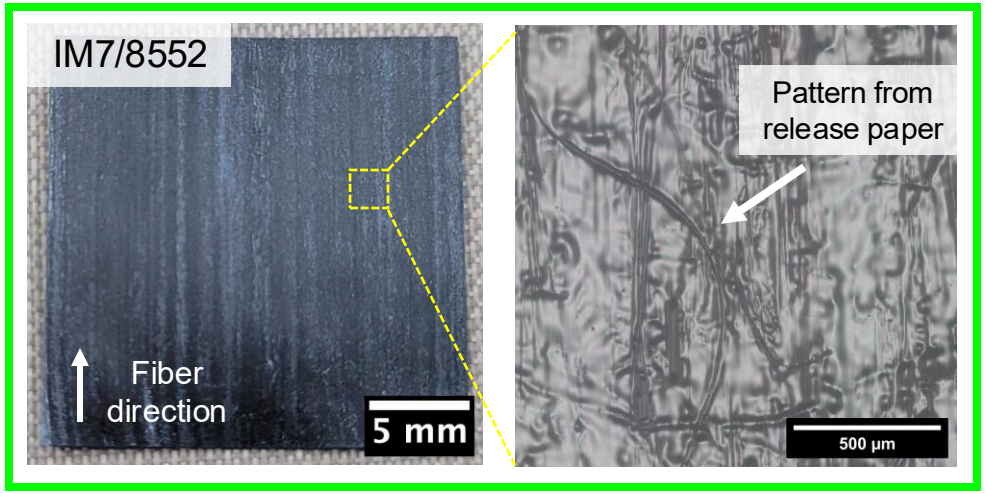
To examine relation between **prepreg surface** and **interlaminar void**, these topics need to be understood:

1. Analysis of irregular surface morphology of prepreg

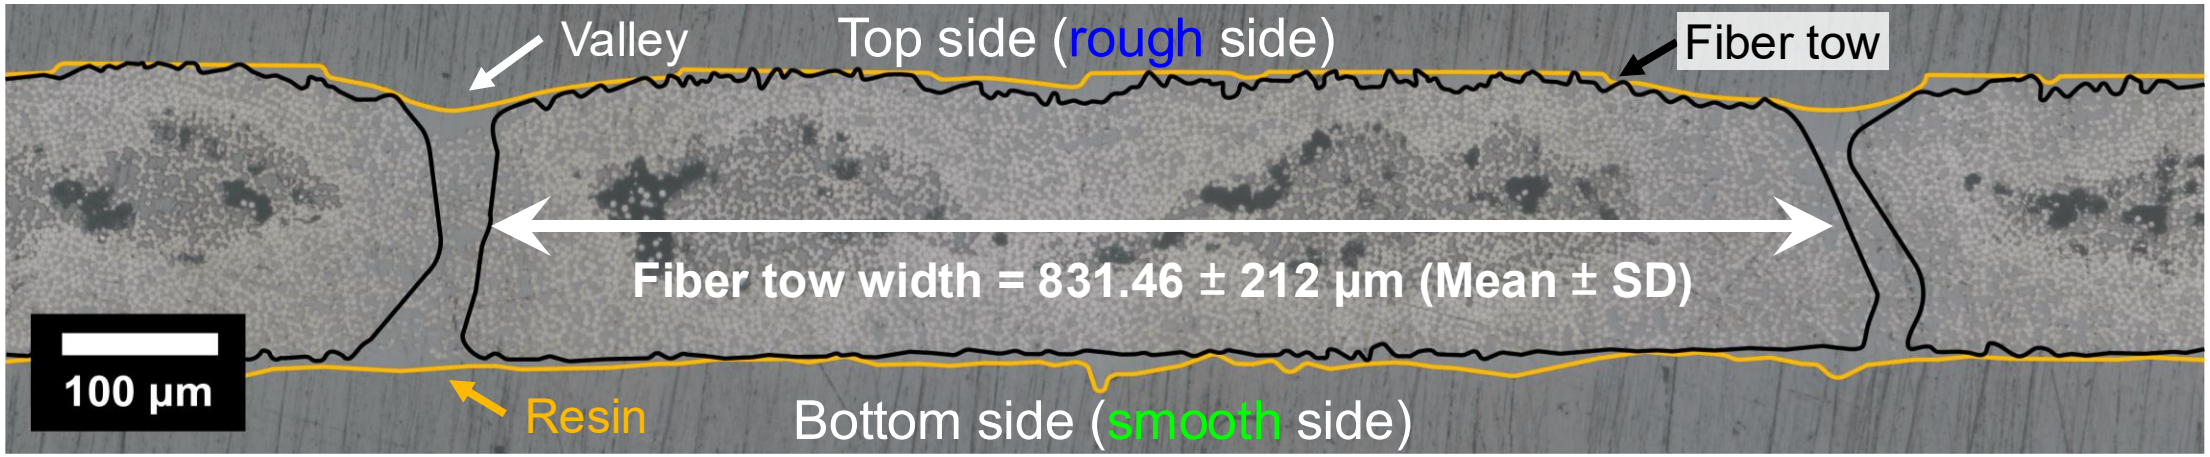


2. Study of correlation between prepreg surface and interlaminar void

Surface morphology of prepreg

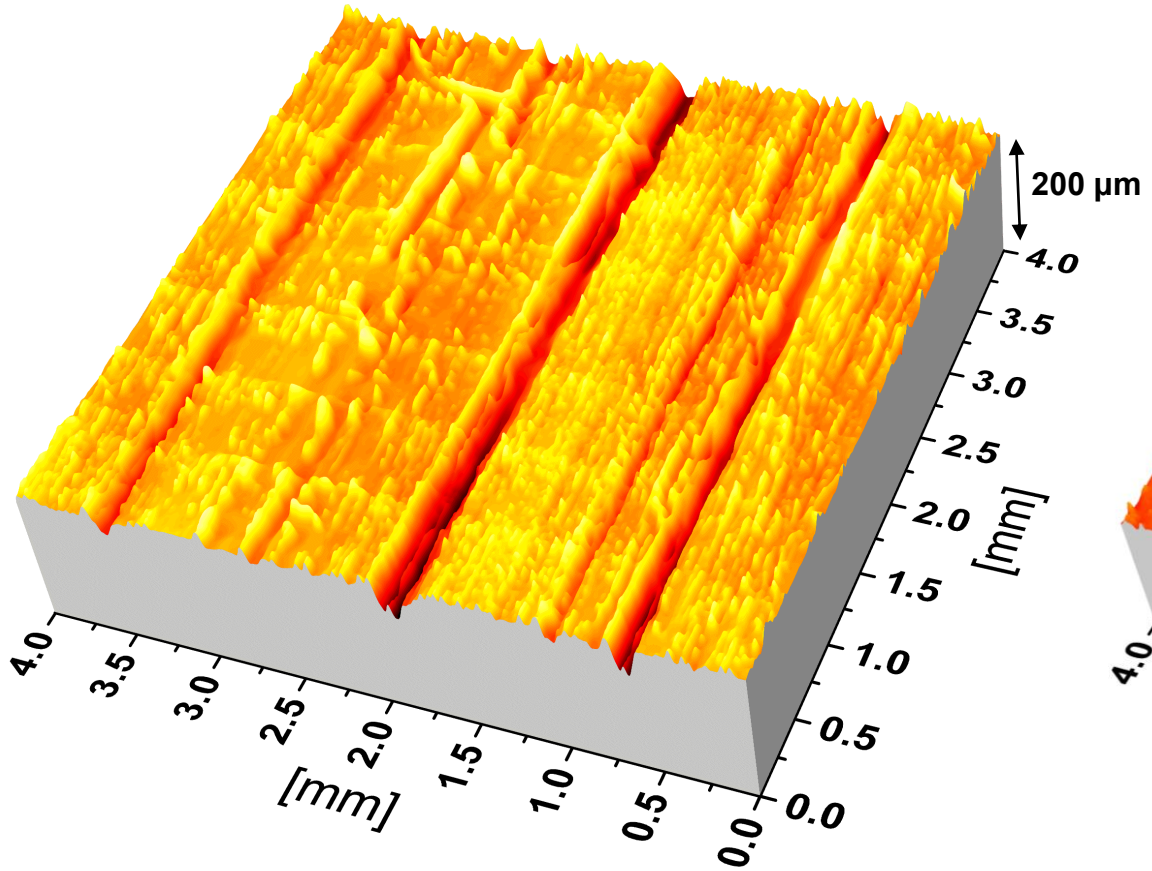


Top and bottom side surfaces of prepreg show different textures

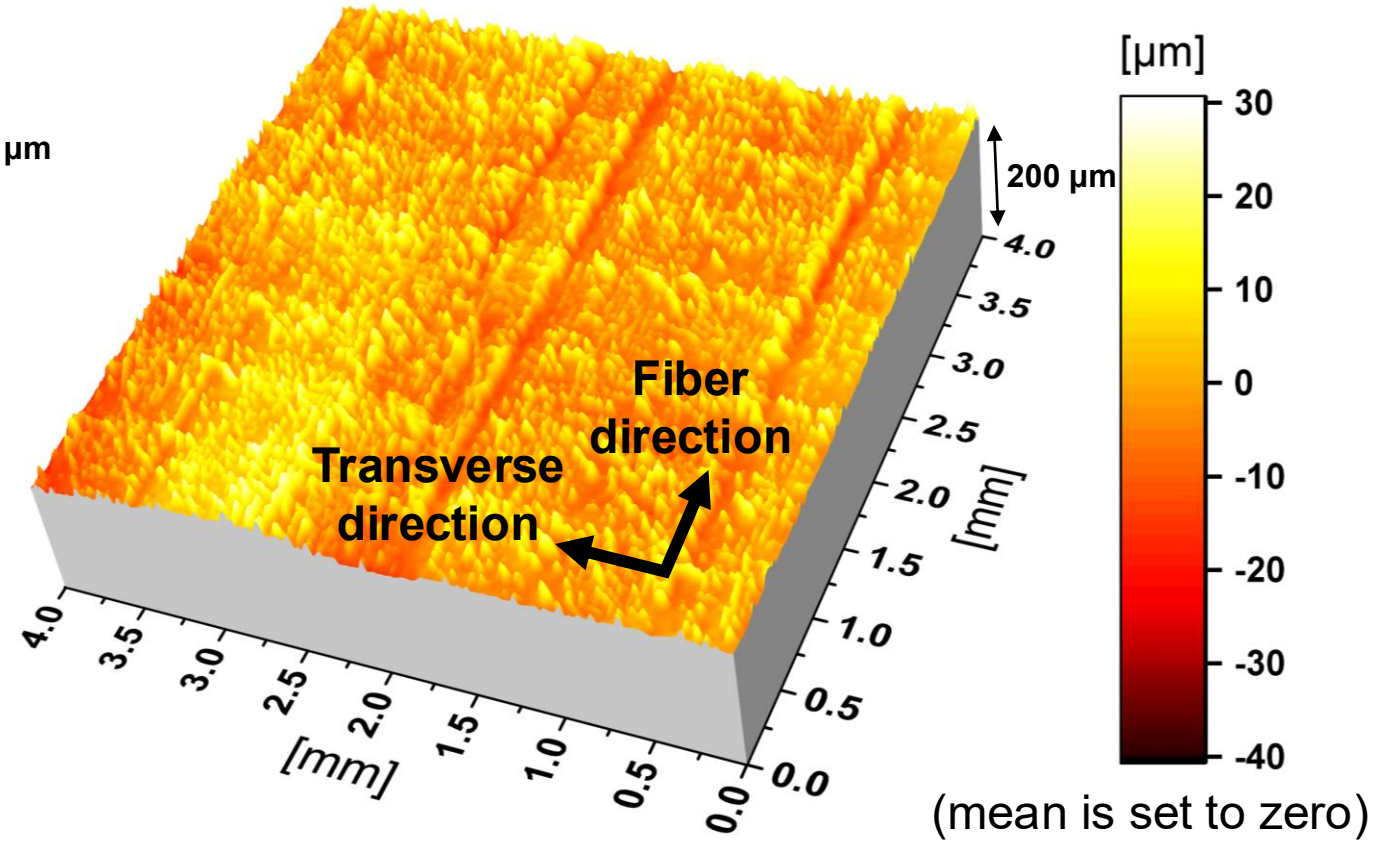


Typical unidirectional prepreg roll

Top side prepreg surface

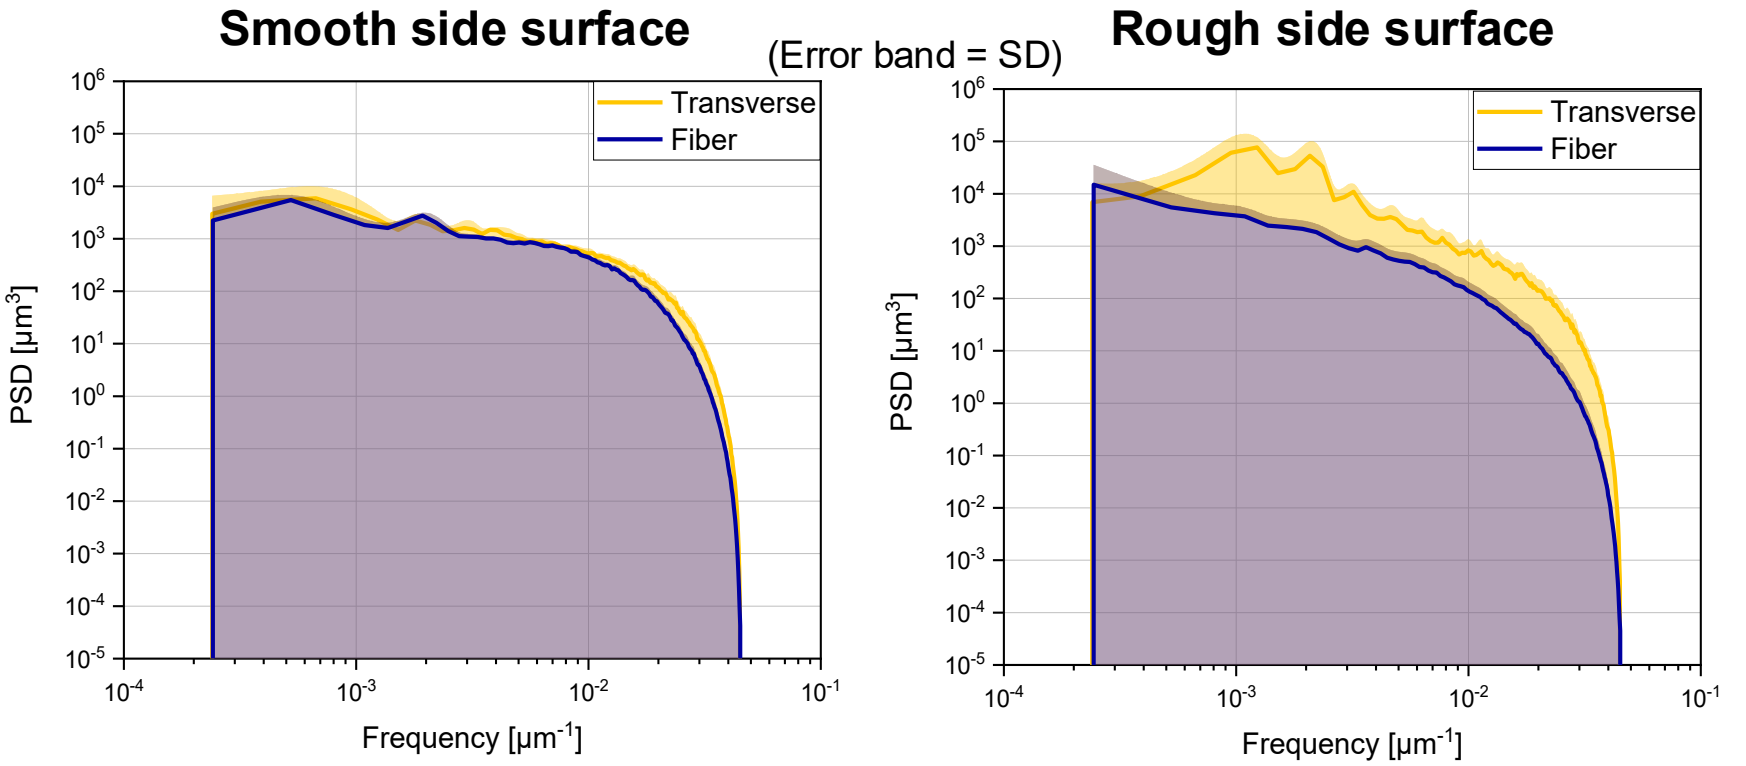


Bottom side prepreg surface

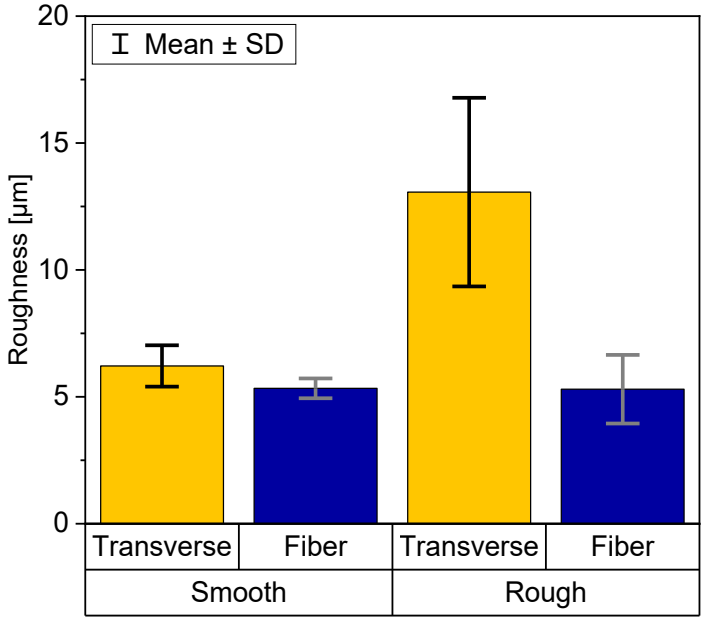


Prepreg cross-section

Height measurement of the prepreg surface



Rough side surface

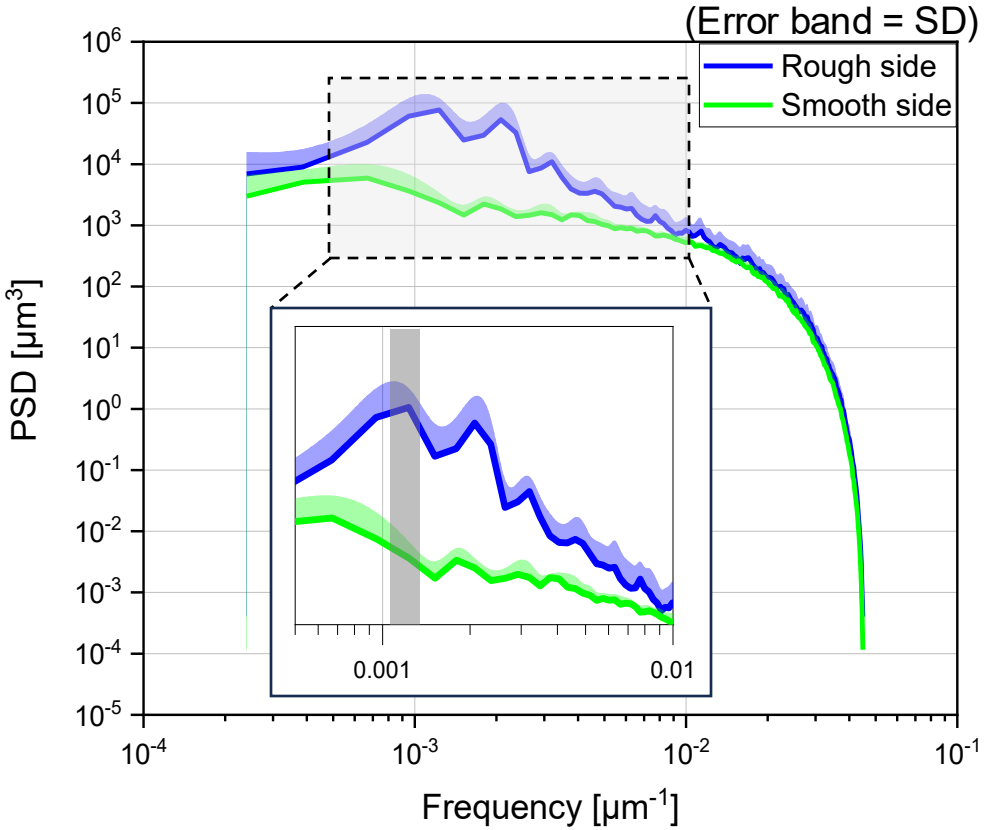


(mean is set to zero)

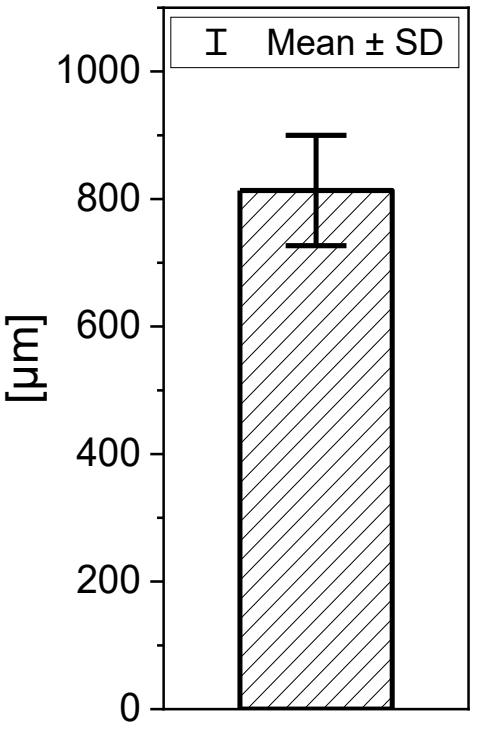
Smooth side surface

Transverse direction of rough surface has high roughness

PSD curves of rough and smooth side surface



Roughnesses of each surfaces



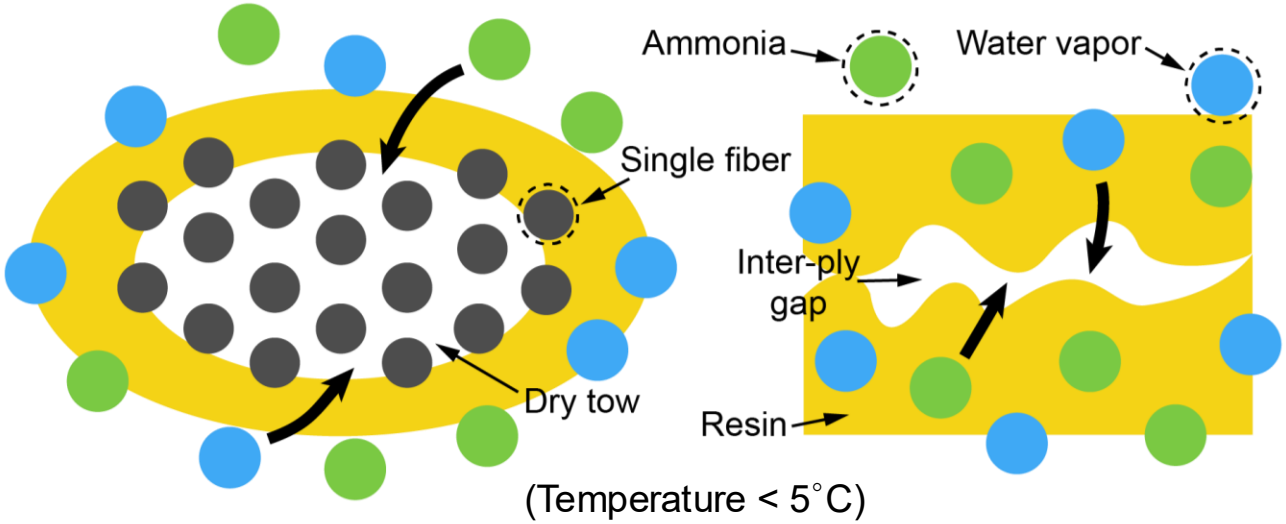
- Power Spectral Density (PSD) represents the power of **frequencies** composing a surface[12,13]
- Area under the PSD curve is related to the surface roughness
- Transverse direction of the rough side contributes to difference in roughness between two surfaces

[12] B N J Persson et al., J. Phys.: Condens. Matter 17 R1, 2004
[13] N. Youngworth et al., Optical Manufacturing and Testing VI, 2005.

Roughness difference is caused by periodicity of surface valley

PSD curves in transverse direction

Fiber tow width

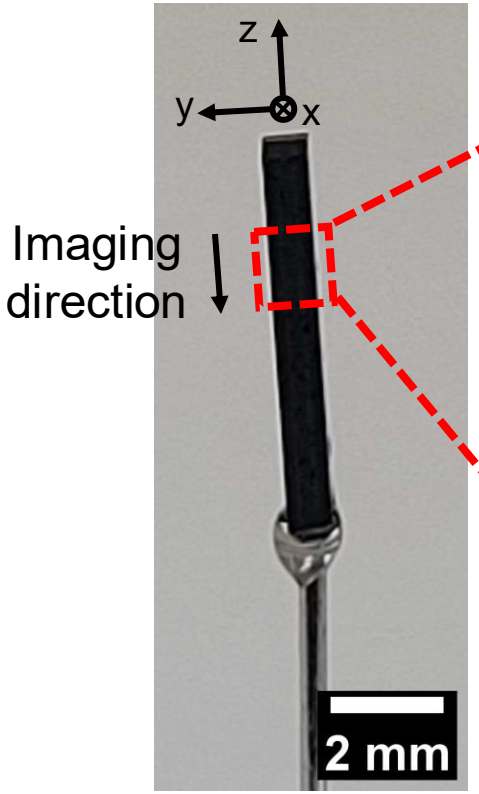


- Peak in the PSD curve indicates prominence of specific frequency component in the surface
- Rough side surface shows peak, reflecting the **periodic surface valleys**
- Roughness difference between the two surfaces arises from surface valleys at tow-tow junction

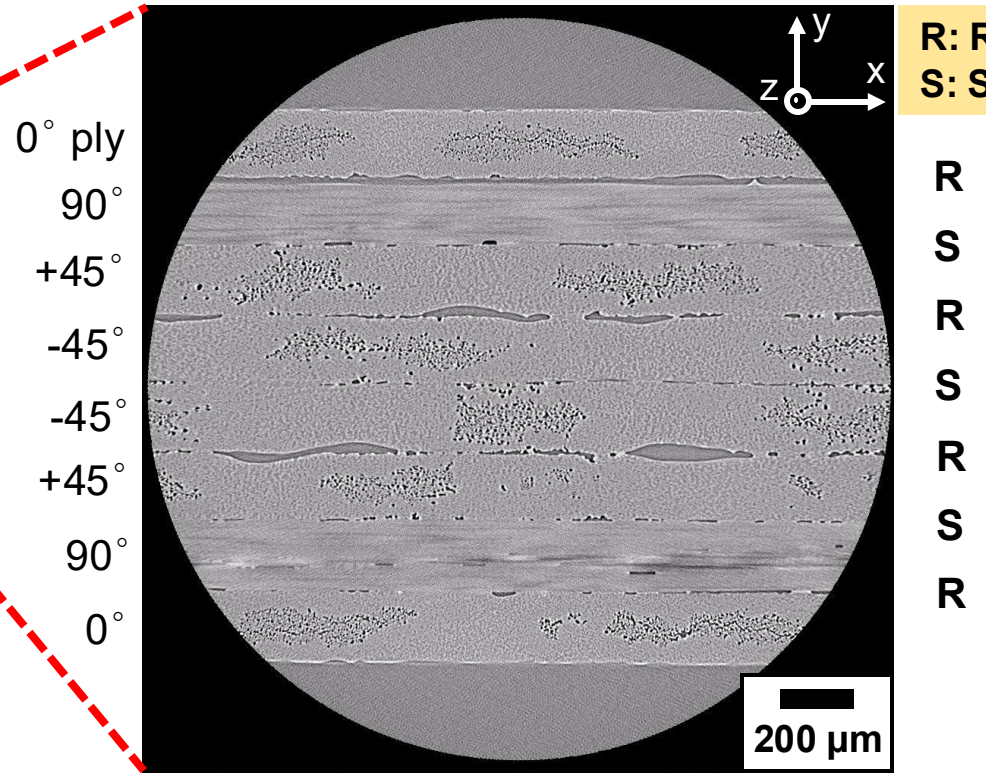
Correlation between prepreg surface and interlaminar void

Method for preserving laminae's shape: Cold-ammonia resin solidifying

Bent laminae due to gravity at room temperature



Schematic of cold-ammonia solidifying



- Since resin **deforms** at room temperature, it must be **fixed in shape** for precise imaging
- When **ammonia** and **water vapor** meet amine-curing epoxy, crosslinking is **promoted**[14]
- Maintaining temperature **below 5 ˚C** can **minimize** movement of resin[15]
- Keeping sample for 1 week at 5 ˚C, then 1 week at room temperature, can **fix** the resin

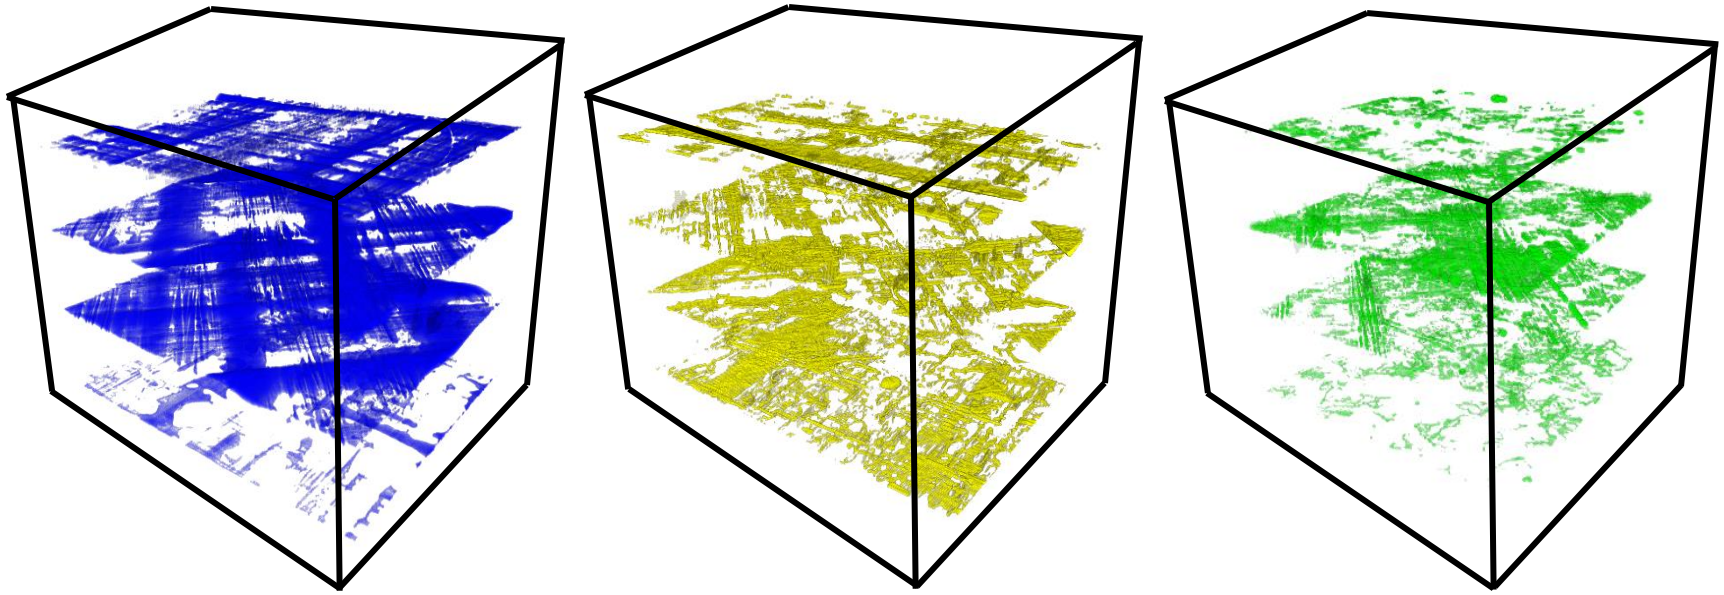
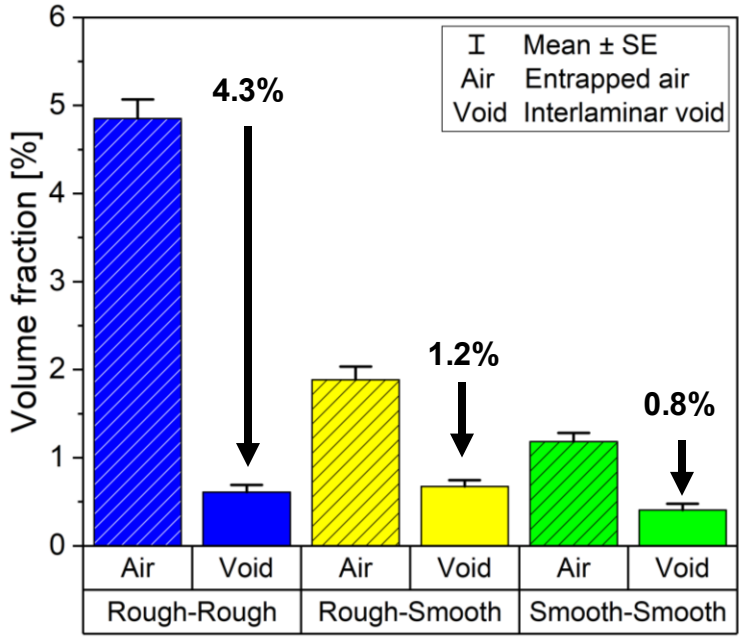
Lamina surfaces with different roughness forms different interfacial entrapped airs

Micro-CT sample



Micro-CT image sequence of laminae

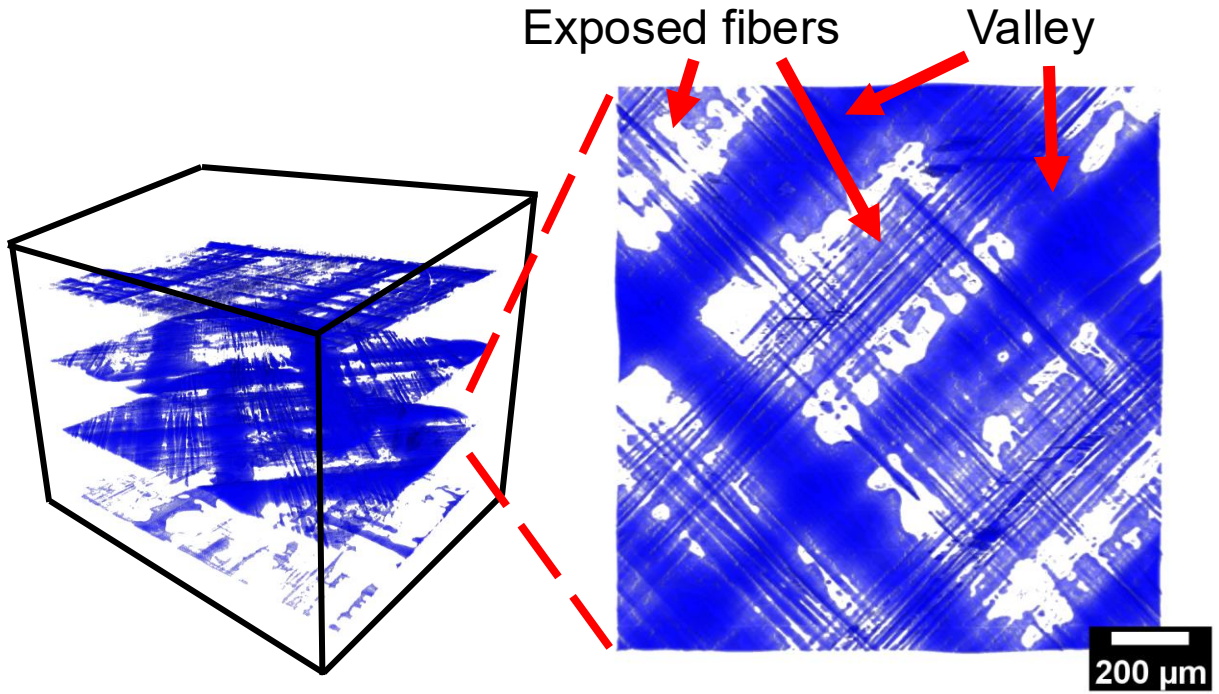
R: Rough-Rough interface
S: Smooth-Smooth interface



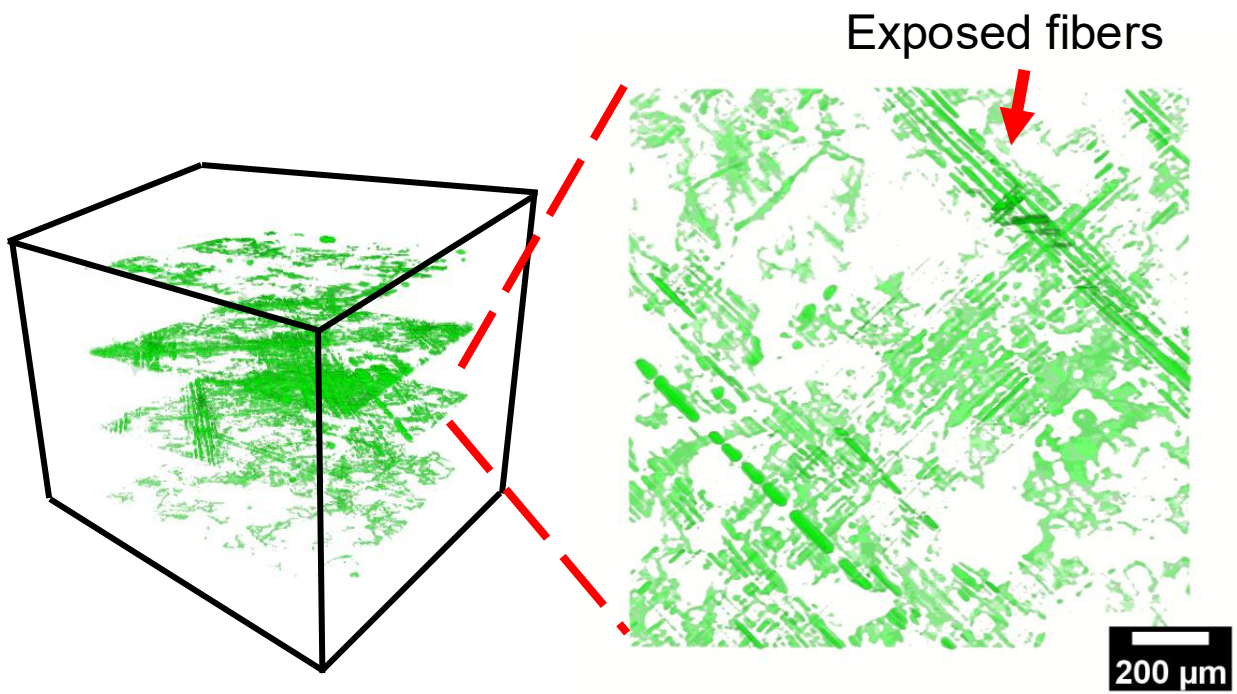
R
S
R
S
R
S
R

- Uncured laminae and cured laminate are stacked with three interface cases:
  - **Rough-Rough**, **Rough-Smooth**, **Smooth-Smooth**
- Dark regions in the micro-CT image sequence represent entrapped airs

Entrapped air and interlaminar void show weak correlation



Rough-Rough, **Rough-Smooth**, **Smooth-Smooth**
interfacial entrapped airs

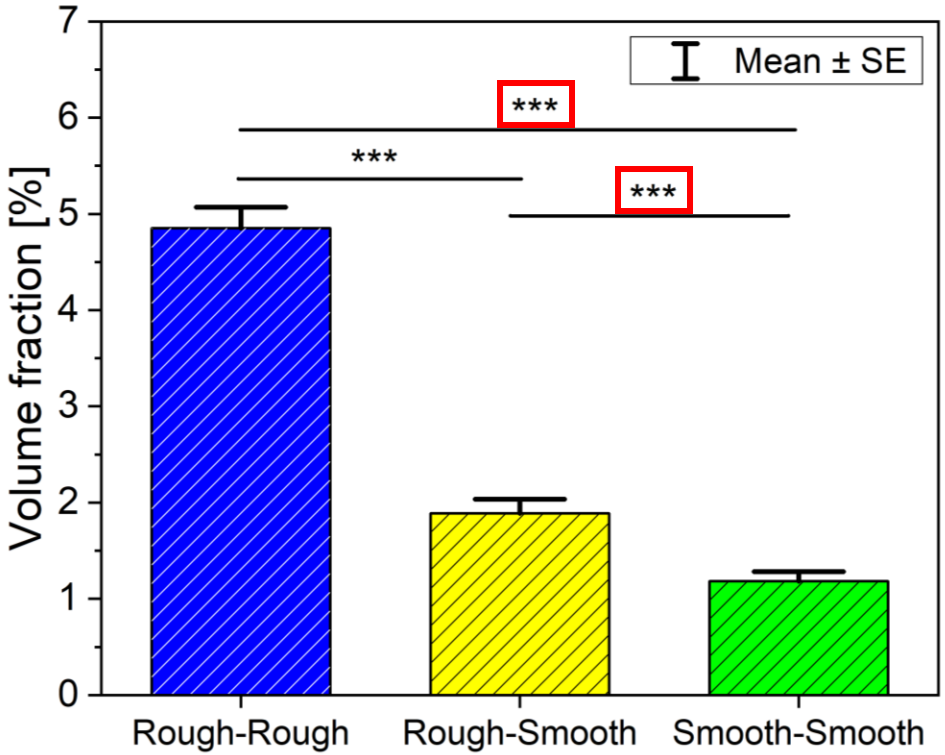


Void removal in each interface cases

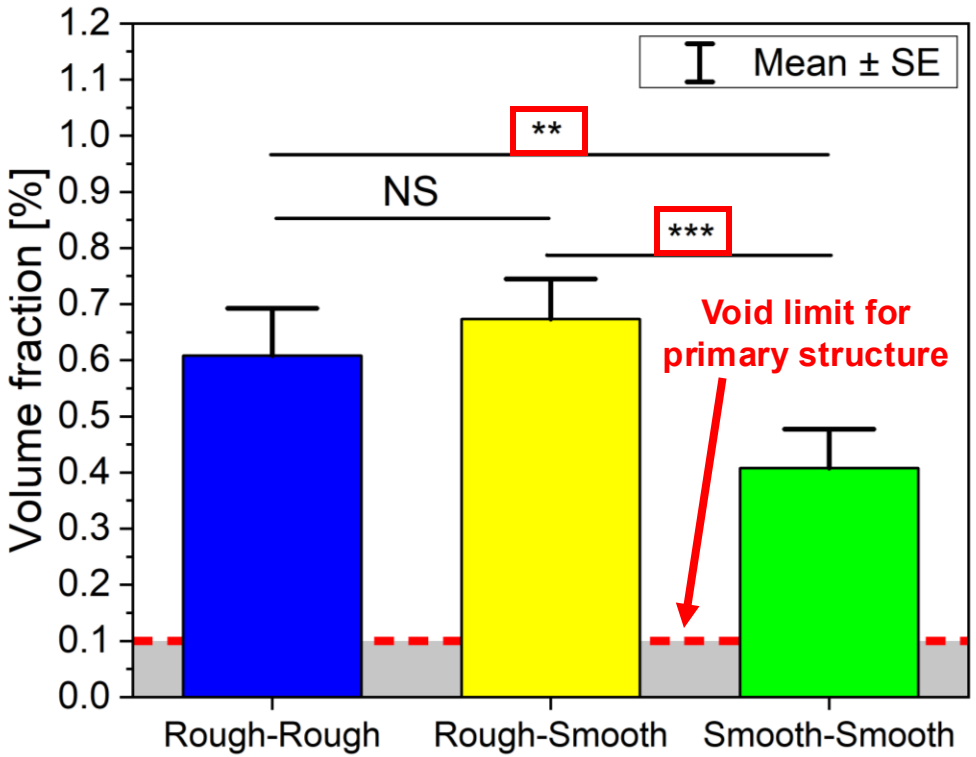
- Entrapped air is removed during curing across all types of interfaces
- The greatest amount of removal occurs at the **Rough-Rough** interface

Surface valley affects connectivity of entrapped airs

Single layer of
Rough-Rough entrapped air



Single layer of
Smooth-Smooth entrapped air



- In Rough-Rough entrapped air layer, valley induced entrapped airs are **connected** in the layer
- In Smooth-Smooth entrapped air layer, entrapped airs are **not fully connected** each other

➢ **Air permeability difference** would **affect** void morphology change during curing

Absence of surface valley can reduce interlaminar voids

Entrapped airs in each interface cases

Interlaminar voids in each interface cases

- The Kruskal-Wallis ANOVA is performed to analyze the differences among the three interface types
- **Smooth-Smooth** interface shows clear difference compared to the other two interfaces

➢ Removing surface valleys can lead to fewer interlaminar voids

Conclusion

Conclusion

- **Valleys** formed at tow-tow junctions are the major difference between both side surfaces of the prepreg
- Interfacial entrapped airs are mainly formed at **valleys** on the prepreg surface
- Minimizing prepreg surface **valleys** can reduce the amount of interlaminar void

Thank you for your attention

ABSTRACT

Carbon fiber-reinforced polymer (CFRP) composites, performance remains constrained by fiber–matrix adhesion due to the chemically inert and smooth surfaces of the untreated fibers (CFs). Chemical compatibility is usually improved by electro-oxidation followed by sizing to improve the mechanical properties, particularly in epoxy-matrix composites. Grafting carbon nanotubes (CNTs) onto CFs by chemical vapour deposition (CVD) improves mechanical interlocking but generates a chemically inert surface. This study shows that combining CNT grafting with a simple chemical treatment (sizing or epoxidation) activates the surface and maximises interfacial strength between epoxy matrix and modified fibers. Surface analysis confirmed increased oxygen content and polarity from these treatments. Single-fiber pull-out tests demonstrated that sized CNT-g-CF in an epoxy matrix achieved up to 60% higher interfacial shear strength than both unsized CFs and as-produced (unsized) CNT-g-CF. Flexural testing of unidirectional fiber reinforced epoxy composite rods (40% V_f) showed a 30% increase in flexural strength compared to unsized CFs and an 8% gain over as-produced (unsized) CNT-

g-CFs. These results highlight that chemical modification is essential to fully exploit the potential of CNT-enhanced interfaces in epoxy-based matrices.

1 INTRODUCTION

In carbon fiber-reinforced polymer (CFRP) composites, the fiber–matrix interface governs load transfer and stress distribution, directly influencing strength and toughness. However, untreated carbon fibers (CFs) have chemically inert surfaces, low surface energy, and minimal roughness, which limit bonding with polymer matrices such as epoxy-based matrices and lead to poor load transfer and reduced mechanical performance [1,2]. Conventional methods such as chemical modification (oxidation or sizing) or nanoscale roughening (grafting carbon nanotubes (CNTs), nanorods, or whiskers) can improve fiber–matrix adhesion but each has drawbacks. Strong oxidative treatments, for example, enhance surface reactivity but can degrade CF tensile strength, creating a trade-off between reactivity and structural integrity [3]. Grafting CNTs improves interfacial properties through mechanical interlocking and a larger interphase interaction volume [4], yet the high temperatures used in chemical vapour deposition (CVD) can damage the CF structure. Recent developments have enabled the continuous production of uniformly CNT-grafted CF tows, avoiding any fiber damage. However, to maximise the benefits of CNT-grafted-CFs (CNT-g-CF), chemical compatibility with the epoxy matrix must also be considered, since the as grown CNTs are chemically inert and the CVD growth conditions strip the oxide groups form the CF surface. After grafting, epoxy-based CNT-g-CF composites have a complex hierarchical structure, consisting of three coupled interfaces, as illustrated in Figure 1: CNT/CF, CNT/matrix, and CF/matrix, compared to the traditional single planar CF/matrix interface.

To identify which interface limits efficient stress transfer, each must be considered. Reported interfacial shear strength (IFSS) values in the literature vary widely (30–270 MPa) for CNT-epoxy interfaces [5], depending on factors such as CNT diameter, length, and surface defects, which enhance mechanical interlocking, together with experimental measurement difficulties. The CNT/CF junctions, formed during CVD growth, can achieve bond strengths approaching 200 MPa which far exceeds the van der Waals limit [6]. In contrast, the CF/epoxy interface is often the weakest region in unsized carbon fiber reinforced systems, with IFSS typically ranging from 30–60 MPa due to the chemically inert CF surface [2]. Note if the whole system is considered, CNT-g-CF/epoxy interfaces values also vary widely and can be affected by matrix choice (between different epoxies) and the method used to determine IFSS (~30–166 MPa) [7]. For this reason, it is often good practice to evaluate these modified fibers with an appropriate baseline and consider relative improvements.

As significant portion of the CNT-g-CF surface includes this CF/epoxy interface, any improvements to the CF/epoxy interphase region is likely to produce overall improvements in IFSS for CNT-g-CF/epoxy systems. The effect of post-treatment on any as-produced CNT-g-CFs has not been reported in relation to the IFSS in an epoxy matrix. Therefore, combining CNT grafting (mechanical) with chemical post-treatments could further improve these interfacial characteristics. An optimal fiber–matrix interface combines chemical bonding and mechanical interlocking to fully exploit the primary reinforcing fiber (CF in this instance) strength. This study demonstrates that integrating CNT-g-CFs with sizing or epoxidation achieves dual-surface engineering, demonstrating a synergistic improvement in CFRP interfacial properties.

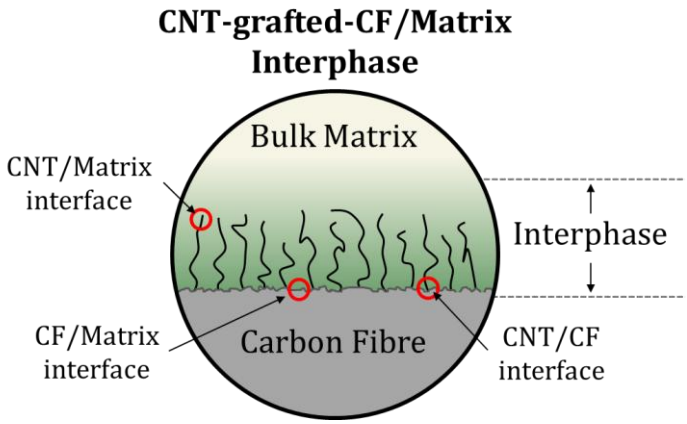

Figure 1: Schematic of CNT-reinforced interphase and its constituent interfaces.

2 MATERIALS AND METHODS

Unsized as-received carbon fibers (AS4-12K-7D, HS-CP-5000 grade, Hexcel) and as-produced CNT-g-CFs (prepared using a continuous CVD process described elsewhere [8]) were used. For the sizing treatment, a solvent-based epoxy sizing was prepared by dissolving 1.25 wt.% PRIME 27 epoxy resin (Gurit) in acetone (≥99.5%, Sigma-Aldrich); fibers were held under tension and dipped for ~2 min and then dried overnight at room temperature. Epoxidation involved immersing fibers in a 1 wt.% meta-chloroperoxybenzoic acid (≥77%, Sigma-Aldrich) solution in dichloromethane (≥99.5%) at room temperature for 3 h, rinsing in pure dichloromethane for 1 h, and drying at 80 °C for 30 min. Composite rods were fabricated by continuous fiber pultrusion. The fibers were tensioned on a spool, pulled through a bath of bisphenol A-based PRIME 27 epoxy resin with extra slow PRIME 27 hardener (Gurit), and guided through a 1.2 mm nozzle to control fiber volume fraction. Tension was applied during curing to maintain rod shape. Composites were cured at room temperature for 24 h, cut to length, and post-cured at 50 °C for 16 h.

Fiber morphology was examined using a Zeiss Sigma 300 field emission scanning electron microscope (SEM) operated at 5 kV with an in-lens detector; samples were mounted on aluminium stubs with conductive silver paint. Fiber surface chemistry was analysed by X-ray photoelectron spectroscopy using a Thermo Fisher K-Alpha+ system with a monochromated Al Kα source, keeping the chamber pressure below 5×10^{-7} mbar; fibers were cut to 10 mm, mounted on Cu-based holders with carbon double-sided tape and metallic clips. Interfacial shear strength (IFSS) was determined by single-fiber pull-out test. Single filament were embedded in epoxy droplet, with embedded lengths controlled below 80 µm to avoid fiber breakage, then pre-cured at 150 °C for 10 min, followed by room temperature curing for 24 h and post-curing at 50 °C for 16 h (following manufacturers recommendations). Single-fiber pull-out tests were performed using a KISTLER 9207 piezoelectric force sensor and a PICA P-216.9S actuator (180 µm travel, 50 N capacity); fibers were aligned and glued to the actuator needle with Born2Bond cyanoacrylate, UV-cured for 20 s, and pulled at 250 $nm.s^{-1}$. Flexural strength of composite rods was measured by three-point bending test using a Linkam MFS modular force stage with a 200 N load cell; samples (60 mm long) were tested on a 30 mm support span at 1 $mm.min^{-1}$ rate until failure.

3 RESULTS

3.1 Surface morphology and chemistry

Surface morphology is crucial for the fiber-matrix interphase, contributing through mechanical interlocking. SEM analysis (Figure 2) shows that sizing introduced noticeable surface changes. Both CFs and CNT-g-CFs were uniformly coated with resin, indicating effective wetting. In sized CNT-g-CFs, the CNT network was embedded in the resin. To quantify these effects, average roughness (Ra) was measured from SEM images as semi-quantitative method using Equation 1 through ImageJ software

(version 1.54m). The examined profiles were taken from regions less than 1 μm in length and 15% in diameter to minimize curvature effects, keeping sampling consistent to ensure comparability. Histogram stretching was also applied to enhance contrast. The CNT-g-CFs showed higher roughness (Ra = 21.4) due to the grafted nanotube network (Table 1). Sizing reduced surface roughness in both fibers. For CFs, the change was minimal, likely from resin filling surface features. In contrast, CNT-g-CFs showed a more noticeable decrease in Ra, aligning with the collapse and embedding of the CNT network in the sizing layer. This smoothing could impact resin infiltration, fiber packing, and interfacial mechanics in composite fabrication.

$$Ra = \frac{1}{N}\sum_{i=1}^{N}|y_i - \bar{y}| \tag{1}$$

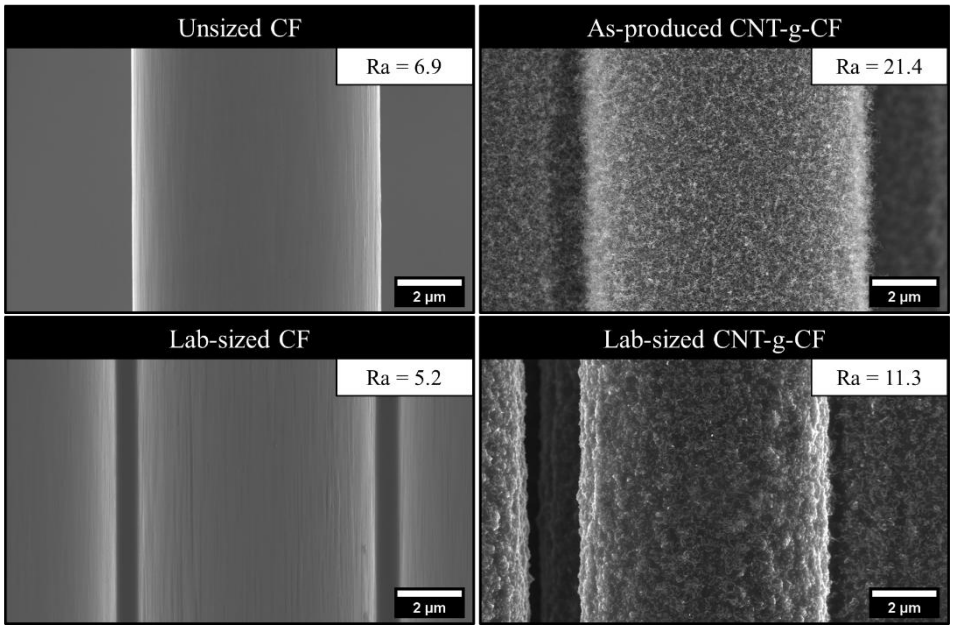

Figure 2: SEM micrographs of baseline carbon fibers and after sizing surface treatment in comparison to CNT-g-CF.

Table 1: X-ray photoelectron spectroscopy for surface composition of carbon fiber-based samples.

Element (at. %)	As-received unsized CF	Epoxidized CF	Lab-sized CF	As-produced CNT-g-CF	Epoxidized CNT-g-CF	Lab-sized CNT-g-CF
Oxygen	5.9	23.4	37.8	3.6	17.2	35.4
Carbon	94.1	76.6	62.2	96.4	82.8	64.6

3.2 Interfacial performance

The apparent IFSS (Figure 3) was calculated based on Equation 2 where one-way analysis of variance (ANOVA) test showed no significant IFSS differences between as-produced CNT-g-CFs and unsized CFs, indicating CNT grafting process did not necessarily enhance interfacial performance in the Prime 27 epoxy. Likely, the loss of reactivity of the previously oxidised CF, led to a weak CF/matrix interface and premature debonding, counteracting any benefit of the mechanical interlocking effect. Lab-sized CFs increased IFSS by 35%, demonstrating the sizing benefits for compatibility with thermosetting matrices. While epoxidation did not show great benefit with unsized CF, the epoxidized CNT-grafted-

CFs improved IFSS by 28% over as-produced (unsized) CNT-g-CF, with oxidative treatment facilitating matrix interaction. This exploitation of surface modification using CNT-g-CFs was even stronger with sizing, achieving over 60% IFSS increase (lab-sized CNT-g-CF). In low-reactivity epoxies like Prime 27, the resin bonds weakly to CF, so CNT functionalisation adds active sites that improve interfacial adhesion and load transfer. Without functionalization, CNTs mainly act as topographical elements, underlining the synergy between mechanical interlocking by CNTs and chemical compatibility from sizing.

$$IFSS = \frac{F_d}{\pi d l_{emb}} \tag{2}$$

3.3 Flexural properties

To evaluate composite flexural performance, three-point bending tests were performed on pultruded rods (40% V_f, void content below 3%), which subjects specimens to combined tensile, compressive, and shear stresses. This configuration captures how interfacial enhancements translate to macroscopic bending behavior, which involves different failure mechanisms than local fiber pull-out. The flexural strength is calculated using Equation 3 and results were normalized to the nominal composite diameter (Figure 3). Lab-sized CNT-g-CF reinforced composites exhibited a 30% increase in flexural strength compared to unsized CF reinforced composites, demonstrating that combining CNT grafting with sizing improves fiber–matrix bonding and multiscale stress transfer. Sizing also enhanced flexural strength in CF reinforced composites, although the effect was more pronounced with CNT grafting due to the additional mechanical interlocking and stiffening of matrix. In contrast, epoxidation improved interfacial shear strength but did not significantly increase flexural strength under these conditions, highlighting that strong fiber–matrix adhesion alone is insufficient without optimized matrix wettability and improved interfacial properties.

$$\sigma_f = \frac{FL}{\pi R^3} \tag{3}$$

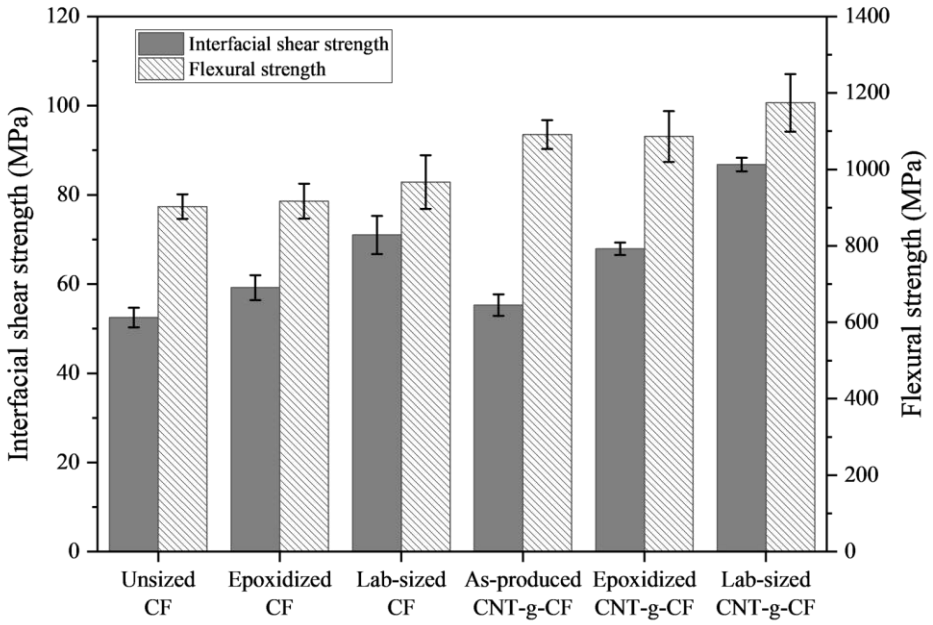

Figure 3: For corresponding modified carbon fibers interfacial shear strength was determined through single-fiber pullout test in an epoxy matrix, and flexural strength via 3-point bending test (40% V_f unidirectional epoxy composite rods).

4 CONCLUSIONS

This work demonstrates that carbon nanotube grafting alone does not fully overcome the limitations of untreated carbon fibers due to their inert surfaces in composites. Combining carbon nanotube-grafted-carbon fibers with targeted chemical treatments, such as sizing, creates a dual-surface engineered interface that improves the overall fiber–matrix adhesion and enables more efficient stress transfer. This synergy provided up to 60% higher interfacial shear strength and ~30% greater flexural strength compared to unsized carbon fibers. These results highlight the importance of integrating chemical compatibility and mechanical interlocking to maximize the performance of hierarchical interfaces in carbon fiber reinforced polymer composites.

ABSTRACT

Interleaving is a common technique used to provide localised toughening in laminated composites, improving impact and fatigue damage resistance. However, little research has explored their effectiveness in cryogenic conditions, especially under cyclic loadings. This study presents an integrated experimental and numerical approach to evaluate the capability of ultra-thin electrospun veils in delaying the onset of localised delamination areas formed at crack junctions in cryogenically cycled laminates. Cross-ply laminates were interleaved with five-micron-thick veils at each asymmetric interface and cryogenically cycled. An indirect assessment of the degree of damage was carried out by measuring the helium permeability coefficients, and the crack networks were examined using micro-computed tomography scanning and scanning electron microscopy techniques. Compared to the baseline laminates, the sudden increase in permeability after cryocycling was damped in toughened laminates, yielding a lower coefficient by one order of magnitude after the first cryo-cycle and 40% after the second cycle. A finite element modelling approach with an integrated 3-D cohesive network was used to simulate the progressive discrete crack damage in cross-ply laminates subjected to cyclic thermomechanical loading. When the thermomechanical loading is high, the interleaves will show more resistance to damage growth due to their substantial R-curve effect. When the cyclic loads are low, the damped interfaces will tend to fatigue faster because of the increased stress from resisting the opening of transverse cracks. This work can be forecasted to assess the veil's performance in quasi-isotropic laminates with asymmetric interface angles and to explore the possibility of encapsulating nanofillers into the electrospun nanofibers to promote synergic toughening effects.

1 INTRODUCTION

The heterogeneous nature of composite laminates makes them susceptible to premature cracking due to the inherent mismatch in the coefficient of thermal expansion (CTE) between the composite constituents [1]. Fibre reinforcements have extremely small CTE, while matrix CTE is relatively larger. At cryogenic conditions, the fibres tend to expand slightly and the matrix attempts to contract, promoting thermal strains at the microscopic level. At the macroscopic scale, varying ply orientations lead to differential expansion in different directions, driven by the stiff fibres within each lamina. This differential expansion generates multiaxial thermal strains, causing the matrix to go into tension and, ultimately, the initiation of microcracks.

The developed microcracks do not have sufficient energy to break the fibres, so they propagate along them longitudinally and through the thickness of the lamina [2]. The microcracks get arrested as

they approach an interface with a dissimilar ply orientation. The tip of the arrested microcrack acts as a stress raiser and induces localised delamination at the interlaminar region. These zones are the junctions that interconnect the crack network, which has direct implications for the gas leakage rates through damaged laminates. This delamination area grows as the number of service cycles increases, and subsequently, the crack opening displacement (COD) increases, leading to higher gas leakage rates [3, 4]. Delaying the onset and growth of these localised delaminations will improve the gas barrier performance of linerless composite tanks [5].

Interleaving techniques are known to provide localised interlaminar toughening effects without necessarily compromising the laminate's global response [6, 7]. These processes involve placing additional layers of materials, usually made of soft thermoplastics, between the individual plies of the composite laminate. For instance, HexPly M21 and Toray 3900-2B prepregs were toughened with polyamide particles and used to build primary structures in Airbus A350 and Boeing 777 aircraft [8-10].

Overall, the effectiveness of the interleaves in enhancing damage resistance has been extensively demonstrated in impact and mechanical fatigue problems [11]. However, there is a lack of understanding and knowledge regarding their toughening effects at cryogenic temperatures, particularly compared to the toughness enhancements achieved with thermoplastic-thermoset blends. Further investigation is needed to understand their potential use for improving the delamination resistance in composite laminates for cryogenic applications.

2 EXPERIMENTAL PROGRAM

2.1 Methodology

An epoxy resin system was used in this study, consisting of three components: bisphenol A diglycidyl ether (DGEBA, Huntsman Araldite® LY1564), methyl tetrahydrophtalic anhydride curing agent (MTHPA, Huntsman Aradur® 917-1), and tertiary amine co-hardener (accelerator 960-1). For the manufacture of composite laminates, Torayca T300 CK-12 unidirectional carbon fibre reinforcement with an areal weight of 200 gsm was utilised. Polyethersulfone (PES, Ultrason® E1010 NAT, 1.37 g/cc, BASF-Germany) was selected as the thermoplastic toughening agent. An organic solvent, N,N-Dimethylformamide (DMF, purity>99%), was used to synthesise the polymer solution for electrospinning, as demonstrated by [12]. During the electrospinning process, PES nanofibres were directly deposited onto a dry carbon fabric that was mounted onto the drum-collector. After the electrospinning process was completed, the fabric with the deposited PES nanofibres was dried in a vacuum chamber at 100 °C overnight to ensure the evaporation of any residual DMF solvent from the electrospun PES nanofibres.

Cross-ply composite laminates, having a layup sequence of $[0_3/90_3]_s$, were manufactured for a cryogenic cycling test. Two laminates were made, with and without electrospun PES veils. The toughened laminate was interleaved only at the 0/90 interfaces with a single five-micron-thick veil. The vacuum bag resin infusion technique was used to minimise the void content in the laminates. The laminate underwent curing in an ASC autoclave under an absolute vacuum pressure of negative 800 mbar inside the bag and atmospheric external pressure throughout the process. The curing schedule comprised three segments. Firstly, the laminate was dwelled at 60 °C for one hour to facilitate diffusion between the PES-veil and epoxy resin. During the second segment, the cross-linking reaction commenced as the temperature increased to 120 °C and was maintained for four hours. Finally, after consolidation, the temperature was gradually reduced to 50 °C at a rate of 5 °C per minute. The cured laminates were 250×250 mm^2 and 2.5 ± 0.04 mm thick. Each laminate was sectioned into four 100 mm squared samples with a diamond cut-off wheel on the Axitom-5TM from Struers.

The baseline and interleaved cross-ply samples were cryogenically cycled from room temperature to the liquid nitrogen (LN_2) temperature for five cycles to determine their resistance to microcracking. Direct submersion in LN_2 was avoided to minimise thermal shocks, and instead, the specimens were subject to a gradual three-stage precooling process. Initially, the specimens were placed in a freezer at -28 °C for at least an hour and then chilled at approximately -100 °C in a chamber containing LN_2 beneath the samples. After another hour, the samples were removed from the chamber and immediately immersed in LN_2 for 10 minutes. The reverse order of this process was followed for warming up the samples to room temperature. Finally, they were allowed to dry at 60 °C for two hours to remove condensed moisture before further cycling or permeability testing.

Permeability measurements are frequently used as a quantitative assessment of the progressive damage state in laminates [13, 14]. Permeability tests were performed to measure the helium leakage rates through the cross-ply laminates as a function of the number of cryogenic cycles. These tests were conducted at room temperature in compliance with the ISO 15105 standard for determining gas transmission rate (***GTR***) by the differential pressure method. The ***GTR*** can be expressed as a physical property, called the gas permeability coefficient (***P***), by taking its product with the average laminate thickness. It should be noted that ***P*** is commonly reported in the literature in metric units as standard cubic centimetres times metre per square metre times day times atmosphere ($scc \cdot m/m^2 \cdot day \cdot atm$). The standard conditions for measuring the gas volume are set to room temperature and atmospheric pressure [14]. The ASTM D1434 provides multiple factor tables for converting the permeance or gas permeability from one unit system to another.

The ***GTR*** measurements were taken using the Manometric Permeability Meter Mk VI acquired from Versaperm. The equipment setup is illustrated in Figure 1. The cross-ply sample was mounted in a gas transmission cell between a pressurised chamber and a vacuumed downstream chamber. The gas transmission area was 1/200 m^2, and the testing temperature was set to 298 K. Helium gas permeated through the laminate from the high-pressure chamber to the downstream chamber. The rate of pressure increase in the downstream chamber was recorded every second. A moving average of 50 points was applied to reduce the noise in the test data. Each sample was tested under three different gas supply gauge pressures of 1, 2, and 3 bars in order to check the consistency of permeance measurement because of potential gas leakages from the barrier seals. Measurement time varied according to the leakage rate through the damaged laminates. All the runs were continued until the time limit of one thousand minutes was reached or the pressure build-up in the downstream chamber exceeded 900 mbar to avoid damaging the low-pressure transducer. The uncycled samples reached the time limit, whereas the cycled ones had higher leakage rates and met the second test stop criterion.

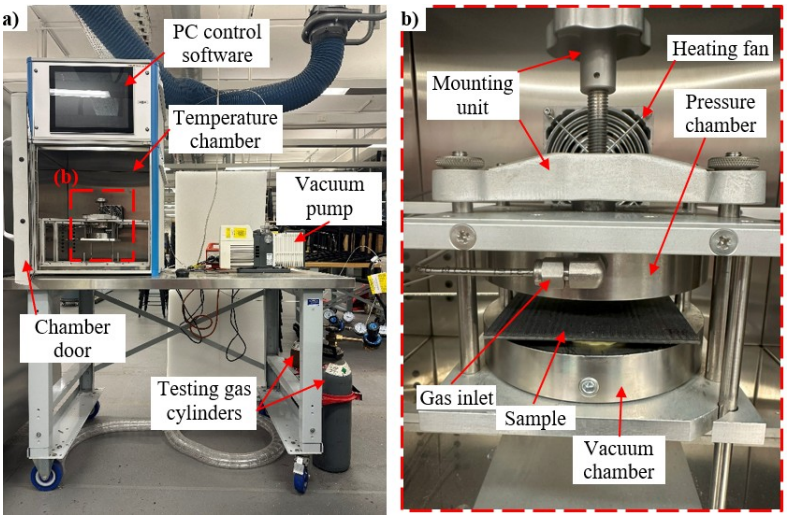

Figure 1: (a) Gas permeability tester and (b) the sample clamping fixtures located inside the temperature chamber.

Non-destructive X-ray micro-computed tomography (micro-CT) scanning is a 3-D visualisation technique that is used for the detection of internal damage in structures. Micro-CT imaging was conducted on the HeliScanTM microCT from ThermoFisher, which had a 160kV/16W Hamamatsu X-ray tube with diamond windows. The flatbed detector size was 3072×3072 pixels, and the readout rate was 3.75 fps. To achieve high voxel resolutions, down to one micron in size, the samples were carefully sectioned into small 3×3 mm pieces. This allows the sample to sit closer to the X-ray source for higher magnification. One sample was sectioned and inspected after one cryogenic cycle, and another sample after five cycles. Avizo software was used for image data processing, segmentation, and visualisation analysis.

Although the CT-scan voxel resolution was refined to detect the transverse microcracks, capturing the localised delaminations was challenging. The crack opening displacement of these delaminations was at sub-micron levels after the sample reached room temperature after cryogenic cycling. Therefore, scanning electron microscopy (SEM) was primarily used to inspect the localised delaminations at the tips of the transverse cracks identified under the microscope. For SEM analysis, the sample's edge was coated with a 40 nm thick platinum layer, and then it was examined using the FEI Nova nanoSEM-230 equipment.

2.2 Helium permeability measurements

A comparison between the determined ***GTR*** of the baseline and interleaved laminates as a function of the number of cryogenic cycles is given in Figure 2(a). The presented ***GTR*** values were averaged between the samples of each set for each gas supply pressure. The ***GTR*** results are consistent between the different pressure levels, indicating no significant gas leakage from the transmission cell during the measurements. The highest standard deviation was 7.7×10^{-14} scc/m^2·day·atm, which occurred for the uncycled specimens because the mean ***GTR*** was very low, making the measurements more sensitive to variation in specimen thicknesses. The ***GTR*** increased by two orders of magnitude after the first cryogenic cycle and systematically increased afterwards with subsequent cycles. The helium permeability coefficients of the baseline and interleaved samples are presented in Figure 2(b) versus the number of cryogenic cycles.

The permeability of uncycled samples from both sets measured a value of 8.1×10^{-16} scc·m/m^2·day·atm, which is within the same range as the results reported in [15]. After the first cryogenic cycle, the permeability of the baseline samples increased by three orders of magnitude to 1.6×10^{-13} scc·m/m^2·day·atm. In contrast, the interleaved laminates were one order of magnitude lower than the baseline, measuring 3.5×10^{-14} scc·m/m^2·day·atm. Even after two cycles, the permeability of interleaved samples was 40.6% lower than the baseline value, measuring 1.7×10^{-13} versus 2.8×10^{-13} scc·m/m^2·day·atm of the baseline.

The permeability of the baseline samples plateaus from the second cycle to roughly 3.4×10^{-13} scc·m/m^2·day·atm. A 71% increase in permeability occurred in the fifth cycle, suggesting the potential initiation of a new crack. The permeability of interleaved samples plateaus as well from the third cycle and onwards to 2.2×10^{-13} scc·m/m^2·day·atm. The error bars during this plateau overlap with those of the baseline samples. These results suggest that the interleaving technique damped damage evolution after onset during the initial stages of cryogenic cycling. With subsequent cyclic loadings, the damage reaches a saturation point in laminates with or without interleaves until a new crack forms, causing a sudden increase in the permeability coefficient. These observations are in agreement with those reported by Choi and Sankar [16], where the permeability of blocked $[0/90]_s$ laminate increased by two orders of magnitude in the first cycle and remained constant afterwards till 20 cycles.

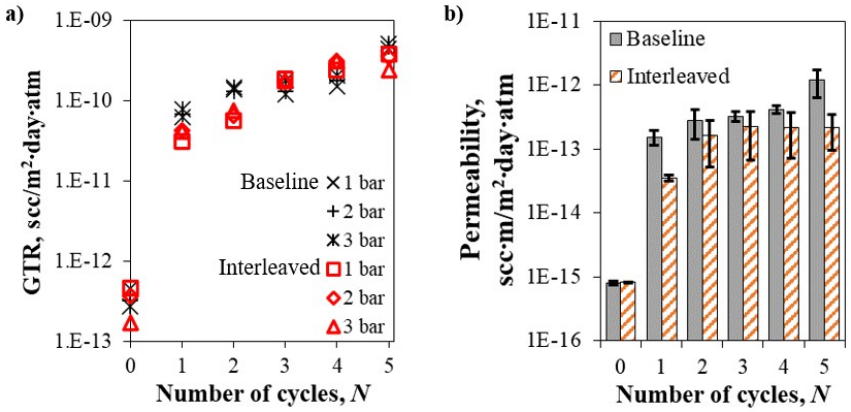

Figure 2: (a) The determined gas transmission rates (GTR) at three gas supply pressures (1-3 bars) as a function of cryogenic cycles, and (b) the corresponding average gas permeability coefficients of the baseline and interleaved cross-ply laminates.

2.3 Examination of the crack networks

Image processing was carried out to create a 3-D reconstruction of the laminate sample pieces and segment different phases within the structure, as shown in Figure 3. The network of polyester stitches was captured and illustrated in the figure. However, the attempt to reconstruct a similar network for the cracks was not successful because the crack opening displacements (CODs) were too small to trace fully. An example of a detected internal crack in a baseline laminate after one cryogenic cycle is illustrated in Figure 4. The voxel resolution of the scan was one micron. The maximum COD was determined to be 5.7 μm under the SEM, and it was reduced to submicron at the initiation and arrestment stages of the crack, making it difficult to detect. In addition, the polyester stitches had significantly higher contrast than the fibres and the matrix, resulting in blurry voxels near the stitches due to beam hardening artifacts. Micro-CT scanning of carbon fibre-based laminates is generally known to be more challenging compared to other types of fibre reinforcements [17]. Therefore, the collected scan data was primarily used to detect the locations of the cracks and their propagation path.

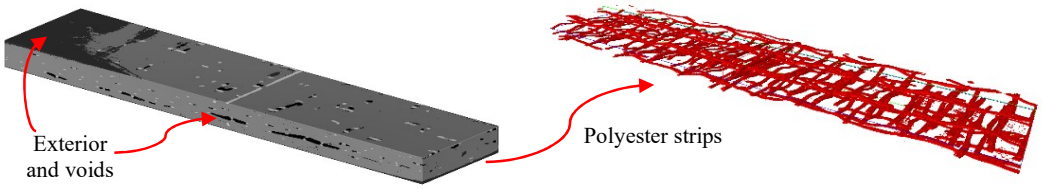

Figure 3: 3-D reconstruction and segmentation of micro-CT scan images of a section of a baseline cross-ply sample.

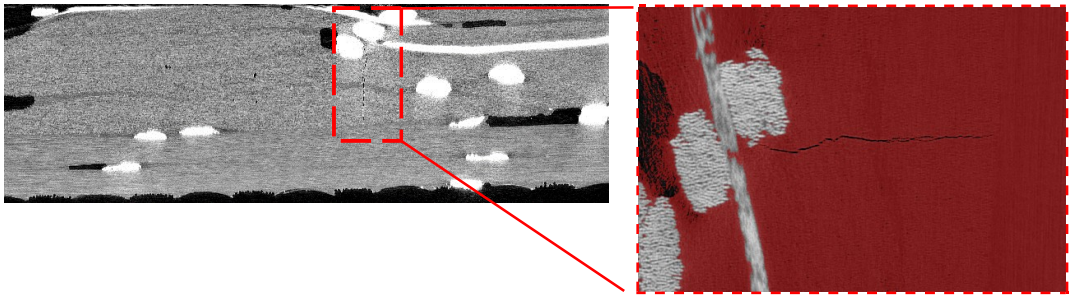

Figure 4: A 2-D X-ray image of a sectioned piece of a baseline cross-ply laminate showing a single inner transverse crack.

The micro-CT scans of cryogenically cycled laminates reveal that cracks tend to initiate from voids and polyester stitches, as in the case in Figure 4. The extension of the cracks across the sample width followed the voids and was deflected around the stitches. The minimum spacing between two fully developed sequential cracks was considered for measuring the crack density. The spacing between the inner cracks was about two times higher than the outer cracks, measuring 1.36 and 3.38 mm, respectively. In contrast, a single inner crack was detected in a 7 mm long sample and no outer cracks. This is a significant increase in the crack density versus the number of cycles, and it explains the increase in the gas permeability in the baseline laminates at the fifth cycle. However, the permeability increase ratio between the uncycled laminates and those with one cycle is significantly higher. This suggests that the increase in the permeability is not solely proportional to the crack density, but potentially the existence of delaminations as well, which were not detected in the micro-CT scans.

Upon examination under the microscope and SEM analysis, short-length delaminations in samples after one and five cycles were observed. The onset of localised delaminations occurs when the tip of the transverse crack terminates at the interface. However, this is not always the case when the singular stress field in its vicinity is not intense enough to overcome the corrected critical fracture toughness, depending on the relative thicknesses between 90°/0° [18]. The SEM micrograph in Figure 5 shows a transverse crack in an interleaved sample after one cycle. The crack initiated from the outer surface and propagated through a void located at a polyester stitch and arrested at the 90°/0° interface. Similar crack arrestment behaviour was observed on baseline samples as well after one cryogenic cycle. Fibre breakage near the arrested crack tip in the neighbouring 0° ply was not observed as reported in similar studies in [18].

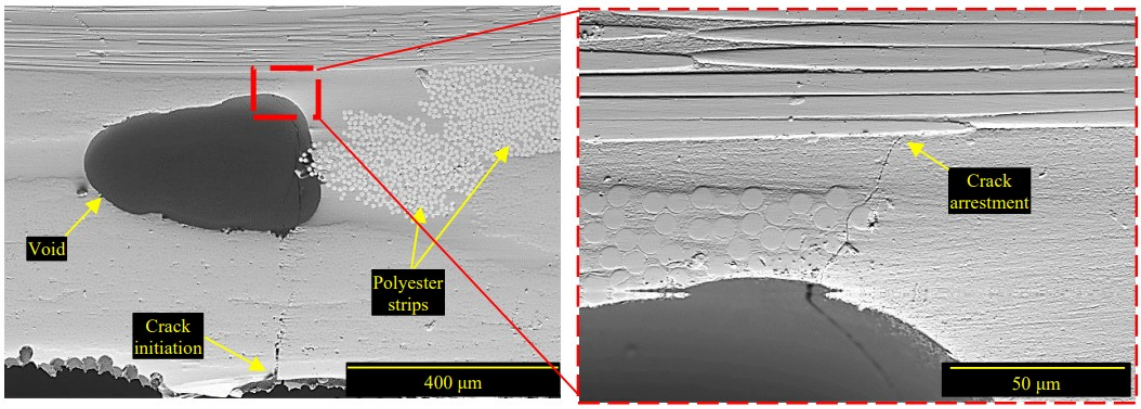

Figure 5: SEM micrograph of an interleaved sample after one cryogenic cycle, showing the initiation of a transverse crack from the outer laminate surface, its propagation through a void, and its arrestment at the interface of the adjacent ply.

Overall, no localised delaminations were observed to be induced from the tips of outer cracks, even after five cycles. For inner cracks, however, a few localised delaminations with random lengths were detected. The representative SEM micrographs in Figure 6 are of a baseline sample after five cycles, showing the branching of a transverse crack and propagating through the 90°/0° interface. The delamination propagation path seems to follow the interface of fibre/matrix. Another behaviour was noticed and illustrated in Figure 6(b) where the crack branches out before approaching the 90°/0° interface. The branched crack propagation eventually got arrested at the interface.

The process of developing these localised delaminations at the crack tips is thought to contribute to the slight increments in the gas permeability coefficient with repeated cycling after the initial cycle. However, the reason for the variation between the gas permeability trends of the baseline and interleave laminates was not clear after examining the cracks. The generation of transverse cracks was triggered by the voids, which caused a scatter in the crack densities observed between the samples. In

addition, delamination lengths were difficult to detect and quantify due to the inconsistency in their occurrence along the interfaces. This is a common challenge, and researchers tend to rely solely on counting the transverse cracks and measuring their opening displacement to explain differences in laminate permeability [13, 19]. Therefore, numerical modelling is generally used to analyse the evolution of interconnected crack networks and their potential effect on gas permeability [5, 20].

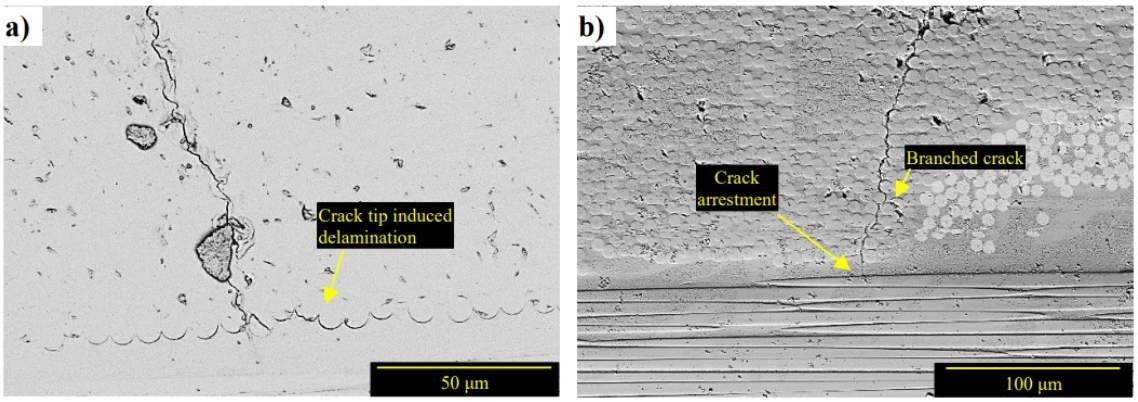

Figure 6: SEM micrographs of a baseline sample after five cryogenic cycles, showing (a) the transformation of a transverse crack into a localised delamination and (b) full arrestment of the transverse crack propagation at the interface. The crack in (b) branched out before approaching the interface.

3 NUMERICAL INVESTIGATION

3.1 Modelling approach

The ability to predict intraply discrete cracks, interlaminar delaminations, and their interactions is useful for analysing the possible ways to delay or suppress the damage in composite laminates. The cohesive network technique was employed to simulate progressive damage and map crack junctions for potential gas leakage routes. The model utilises the brick-and-mortar concept, originally proposed by Begley et al. [21], to simulate the initiation and diffusion of discrete cracks without the need to have a pre-crack. The bricks represent the continuum elements, and the cohesive elements (CEs) are regarded as the mortar.

The discrete crack locations must be predetermined to insert CEs along potential paths within continuum elements. These coordinates can be predetermined since matrix-dominant intralaminar cracks propagate along the fibre direction under thermomechanical cyclic loading. Fibre breakage appears as the final stage of failure only if the mechanical stresses are substantially high enough, causing the ultimate fracture of the structure [22]. In this study, fibre breakage was not considered a potential failure consequence of the presented thermomechanical loading case. The CEs were inserted parallel to the fibre orientation and at the interfaces to represent two premature failure modes, namely, transverse matrix cracking and interface delaminations. Contact connections were defined between adjacent strips and interlaminar regions to represent potential intralaminar cracks and delaminations, respectively. More details on the implementation of this approach and the cyclic bilinear cohesive zone model are presented in [23]. User-defined Python scripts were used within the Ansys pre-processor to automate the process of constructing a laminate model and integrating the network of CEs. A total of five Python scripts were coded to automate the process of embedding CEs within composite laminates in Ansys Mechanical software

The temperature-dependent mechanical properties and interface properties are given in Table 1 and Table 2, respectively. These properties were obtained by calibrating simple coupon models against testing data presented in [12]. The interface properties of the interlaminar and intralaminar regions differ owing to the increased surface area of the intralaminar cracks as they deflect around the

randomly distributed fibres. For simplicity, they are commonly presumed to be identical [18]. Applying this assumption herein should not influence the conclusions of this study because the delaminations are under investigation, and the transverse interface properties are identical between baseline and interleaved models. It should also be noted that the effect of asymmetric interface angles on interlaminar fracture toughness was not considered because the collected test data is limited to unidirectional samples. This limitation is not expected to produce biased results towards one of the models, but it will affect the prediction accuracy. In reality, the interleaving technique shows better toughness improvements under mode I and mode II in woven composites than in unidirectional [24].

Description	Symbol	Value at 293 K	Value at 77 K	Units

3.2 A single transverse crack under uniaxial static loading

The cohesive properties, namely the interface strengths and the critical strain energy release rates, are expected to impact the initiation of matrix cracks and the onset of delaminations. This impact is sensitive to the thickness ratio of the 90° ply relative to the 0° plies, as suggested in [18]. To investigate these effects, a 3D FE model of a cross-ply laminate under uniaxial tension was developed. The model includes two pre-existing transverse cracks at each end and one prospective crack in the middle of the span length. Three symmetry planes were prescribed to reflect the following symmetries: through-thickness mid-plane (x-z) at the bottom surface of the 90° ply, longitudinal cross-sectional plane (x-y) on all the side faces, and transverse cross-sectional plane (z-y) on the face of the 0° ply. A

3% longitudinal tensile strain along the x-axis was prescribed onto the face of the 0° ply opposite the x-y symmetry plane. The ply size was 5×10 mm and 0.2 mm in thickness. Three layup sequences were modelled, having a different number of transverse plies, namely $[90_2/0_2]_s$, $[90_4/0_2]_s$, and $[90_8/0_2]_s$. The corresponding 90° block thicknesses (t_{90}) are 0.4, 0.8, and 1.6 mm. The intralaminar contact region was prescribed the neat interface properties, whereas three sets of interlaminar cohesive properties were defined: a) the neat properties, b) interleaved properties, and c) neat properties with a 50% increase in the interface strengths (σ_n, τ_s).

The normal stresses in the 0° ply were three orders of magnitude higher than those generated in the 90° ply. Typical curves of the maximum normal stress and maximum in-plane shear stress in the laminate versus the applied longitudinal strain are given in Figure 7. The figure compares the laminate responses with the three different interlaminar contact properties. The laminate's initial linear behaviour corresponds to the elastic material properties. All curves show a small step at about 0.9% strain, and then the curve trends continue to increase linearly. This step corresponds to the initiation of the transverse crack. A shear-lag effect is observed owing to the presence of pre-cracks at the ends of the 90° ply. The thickness of the ply has a direct effect on the shear-lag distribution, where the thinner it is, the quicker the stress is transferred from the outer 0° ply to the 90° ply. The laminate configuration with the thickest transverse ply block requires higher applied strains to initiate transverse cracks. Therefore, under mechanical fatigue loadings, the characteristic crack density is expected to increase as the 90° decreases [22]. However, the normal stress severity increases in thinner transverse plies, meaning thicker blocks of transverse plies are more susceptible to microcracking at early loading stages, but the overall crack density is lowered with repeated loadings. For gas barrier applications, the use of alternating thin plies was recommended to delay the initiation of matrix cracking [16].

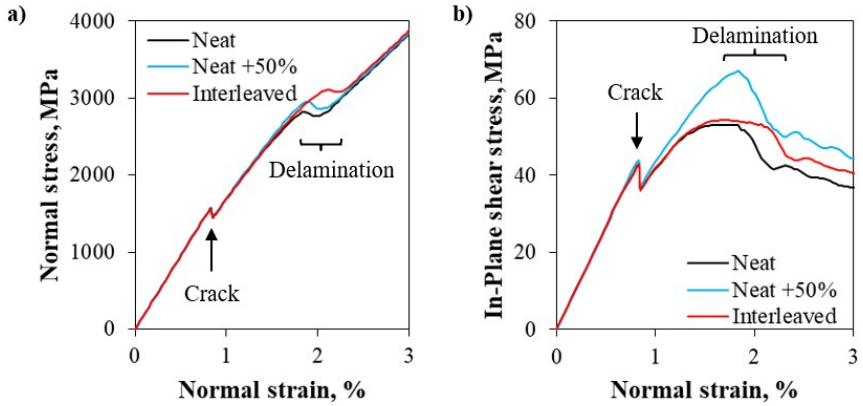

Figure 7: Typical curves of (a) the maximum normal stress and (b) the maximum in-plane shear stress in $[90_8/0_2]_s$ laminate with different interface properties at the interlaminar region.

The subsequent failure after transverse cracking is the onset of delamination, which corresponds to the second step in Figure 7. The strain to onset delaminations is delayed, as shown on the laminate normal stress response in Figure 7(a). The normal stress kept rising linearly since the 0° ply still carried the loads elastically. The delamination lengths of the models with the three different sets of interlaminar properties are illustrated in Figure 8. The figure also compares the delaminations in $[90_2/0_2]_s$ and $[90_8/0_2]_s$ laminates for each interface property set. In all the models, the delamination onset began simultaneously from all three transverse cracks owing to the uniformity of the loading and geometry. The cohesive process zone of the interleaved model was the largest due to the higher critical toughness compared to the others, which, in turn, enlarges the cohesive zone envelope. The corresponding delamination length was 21% shorter than the reference neat model. The 50% increase in the neat interface strengths reduced the convergence efficiency of the model due to the narrower cohesive process zone. It also increased the delamination length by 14% compared to the neat model. The delamination propagation length and cohesive process length were insensitive to variations in the transverse ply thickness.

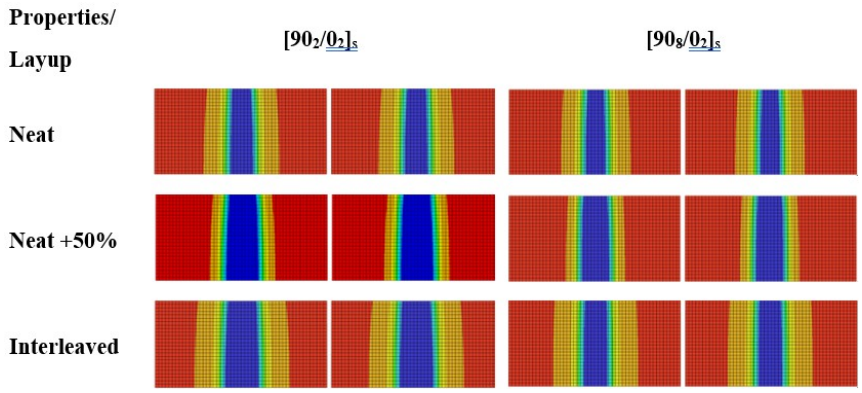

Figure 8: Top view of the models showing the sensitivity of the delamination area and process zone to the interlaminar cohesive properties relative to the min-max thicknesses of the transverse ply.

3.3 A cross-ply laminate under biaxial fatigue loading

Two $[0_3/90_3]_s$ laminate models were constructed, one with the baseline interlaminar interface properties and the second with interleaved properties. Since the mesh and contact patterns were uniform, the Gaussian (normal) distribution was used to randomise the interface strengths and the critical strain release energies, allowing the damage to onset at random locations, which was necessary to avoid convergence difficulties. Randomisation techniques are commonly employed to simulate multiple delaminations [5, 19]. To avoid creating biased results, the contact properties at each intralaminar contact region were identical between the baseline and interleaved models. The laminates were loaded for 15 cycles with a differential body temperature from 293 to 77 K. To accelerate the damage evolution, an equal biaxial tension strain of 0.1% was applied with a load ratio of 0.1. A dynamic viscous regulation coefficient of 1×10^{-3} to resolve convergence difficulties when encountered.

The predicted damage evolution in the baseline and interleaved laminates after 15 cycles is illustrated in Figure 9. After two cycles, the first fully developed matrix crack occurred in the 90° ply. The crack propagated through the thickness before extending rapidly across the width of the laminate. The initiation of this crack caused a relaxation in the 90° ply, and subsequently, the other intralaminar interfaces were undamaged. In contrast, four adjacent 0° interfaces were experiencing cohesive fatigue damage. The outer intralaminar interfaces tend to soften near the fully developed crack. The tip of a transverse crack acts as a stress raiser that triggers the formation of a stitch crack in the adjacent ply. The softening regions propagated transversely through the thickness before advancing longitudinally along fibres. That is, the energy release rate is twice as high in the transverse direction than in the longitudinal [25]. Such cracks are thin in nature, and they grow unstably in the transverse direction, quickly occupying the lamina's thickness [26]. After that, the partially developed 0° crack had no choice but to propagate longitudinally when the strain energy rate exceeded the critical fracture toughness.

Cohesive softening at the interlaminar region along the fully developed crack is observed in the enlarged image in Figure 9. The adjacent 0° ply resisted the crack openings of the damaged 90° lamina and produced high levels of interlaminar normal and shear stresses. These stresses were severe enough to overcome the interface strength of the interlaminar region. However, the energy release rate was not sufficient to onset delaminations. This explains the rare occurrence of localised delaminations at the crack tips of the laminates when examined under the SEM. The transverse matrix cracking pattern between the baseline and interleaved laminate was identical. A sudden increase in the damage occurred when the first transverse cracks initiated after two cycles. The toughened interface damped this jump in damage by 20.4% compared to the baseline. Both interfaces were linearly softening afterwards with subsequent cycling. The final damage value of the interleaved model was 16.1% lower than the reference. This indicates that the damage growth was higher in interleaved interfaces, which is

driven by the localised stress state. This stress severity was higher due to the damage effect while resisting the transverse crack opening displacements.

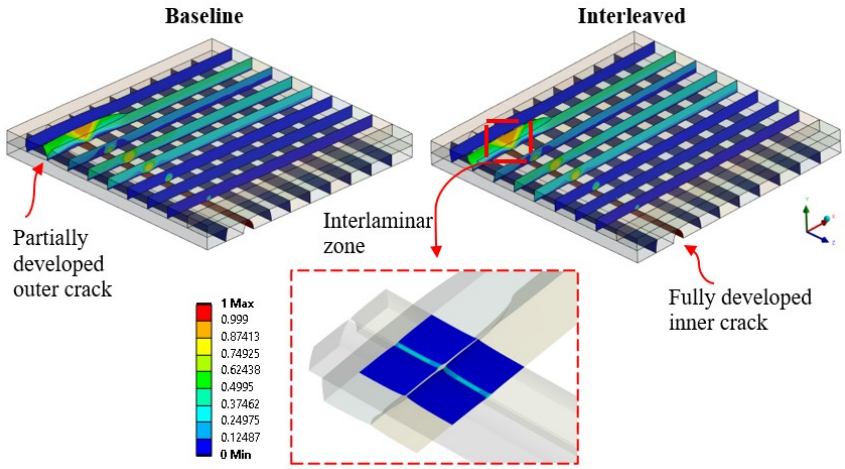

Figure 9: Predicted damage evolution in the baseline and interleaved cross-ply laminates. The enlarged region shows the softening of the interlaminar zone at the junction between two transverse cracks. The legend represents the damage parameter, where one means a fully damaged element.

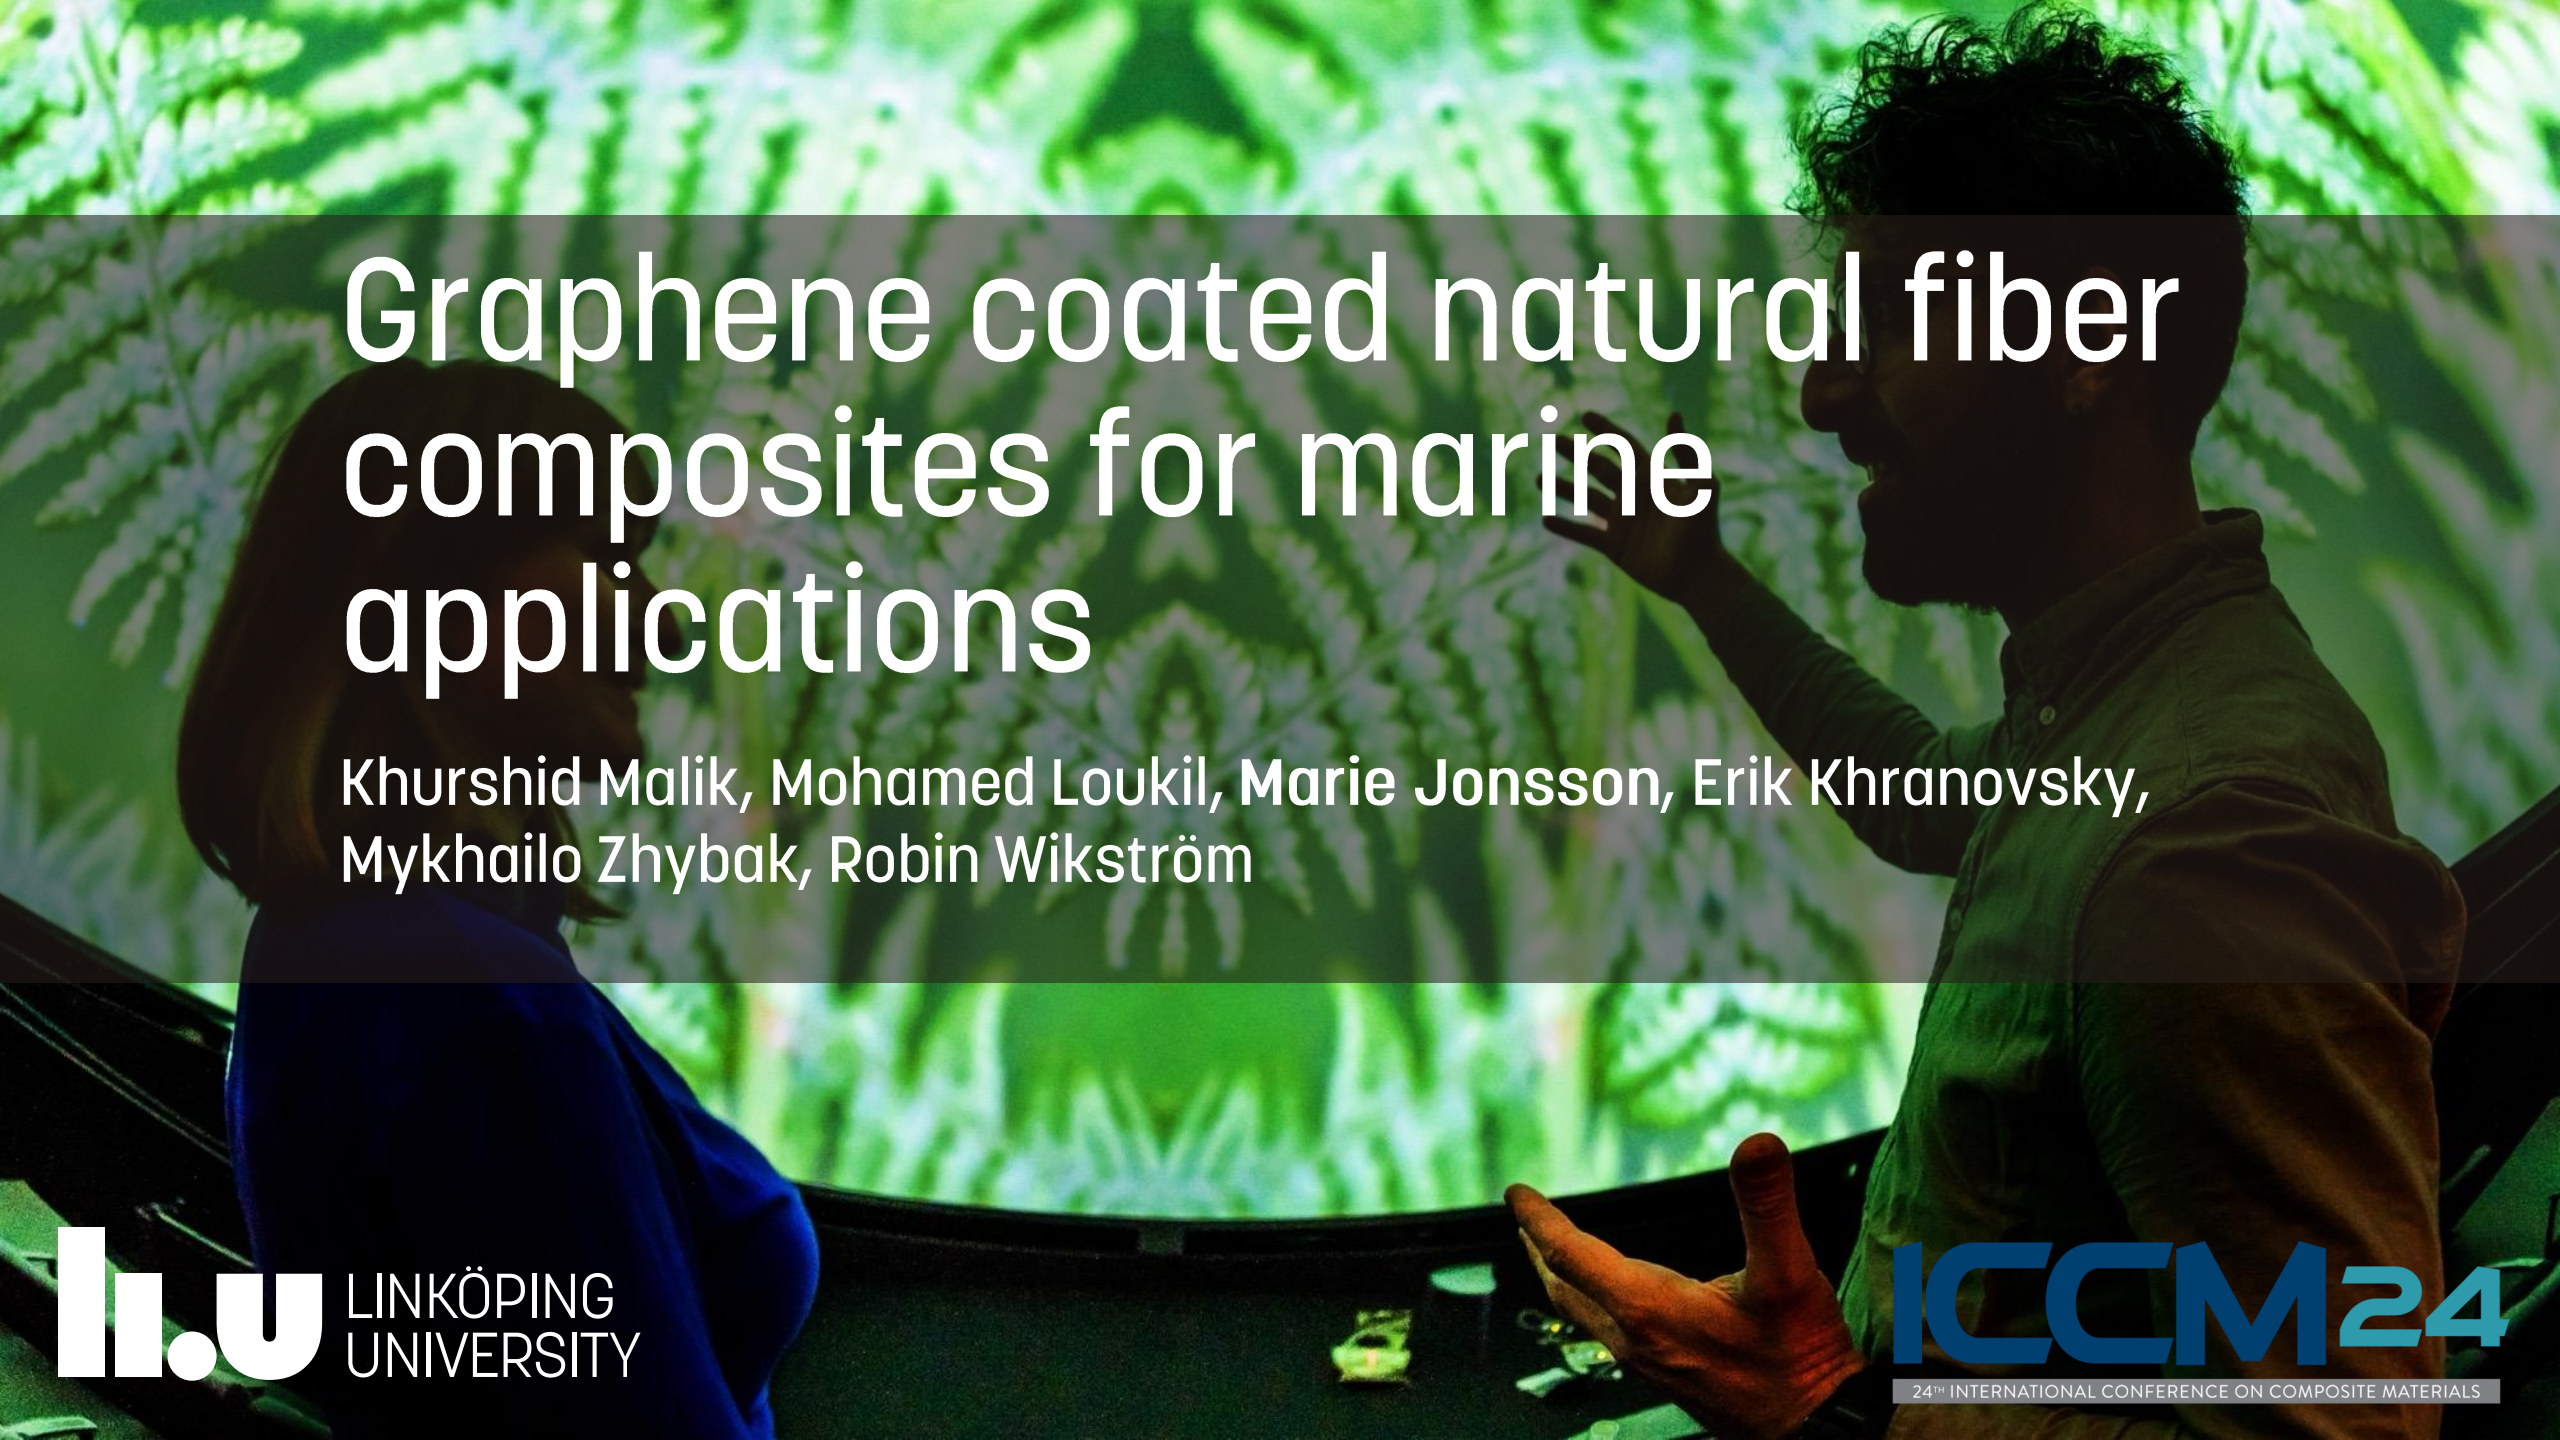
4 CONCLUSIONS

The effectiveness of the interleaving technique in minimising the interconnections in a crack network, and thus permeability coefficients, was explored in this study. Electrospun PES veils were used to toughen cross-ply laminates. Helium gas permeability rates through these laminates were measured as a function of the number of cryo-cycles. Compared to the baseline samples, the interleaving technique significantly reduced the permeability coefficient by one order of magnitude after the first cryo-cycle and by 40% after the second cycle. This suggests that the toughening effects seen in the coupon testing data have effectively reduced the crack network size. With subsequent loadings, the growth in the crack network reached a saturation point.

Examination of the cracks with micro-CT scanning and SEM techniques revealed that the inner plies had a higher crack density than the outer plies. Transverse cracks tend to extend from trapped voids in the matrix near the stitches, causing variability in crack density measurements. The majority of these cracks were arrested at the interface of the adjacent ply without branching into localised delaminations. The observed delaminations were short and random in their occurrence.

The finite element model was employed to provide a supporting analysis of these observations and to highlight the impact of the interleaving technique. The model demonstrated how PES veils delay the onset of delaminations and slow their growth rate. These effects were apparent in cross-ply laminates with multiple inner ply thicknesses. The improvement levels were consistent relative to the untoughened model as the ply thickness reduced. The onset of delamination was suppressed in all the models till a later stage of uniaxial leading when the 90° ply thickness reduces. The results from the gas permeability measurements and modelling predictions favour using the interleaving technique to improve the damage resistance in cryo-cycled laminates.



To summarise, the use of interleaves is beneficial in damping the initial evolution of damage networks. If the thermomechanical loading is high, the interleaves will show more resistance to damage growth due to their substantial R-curve effect, which was assessed experimentally in the previous chapters. When the cyclic loads are low, the damped interfaces will tend to fatigue faster because of the increase in the stress state from resisting the opening of transverse cracks.

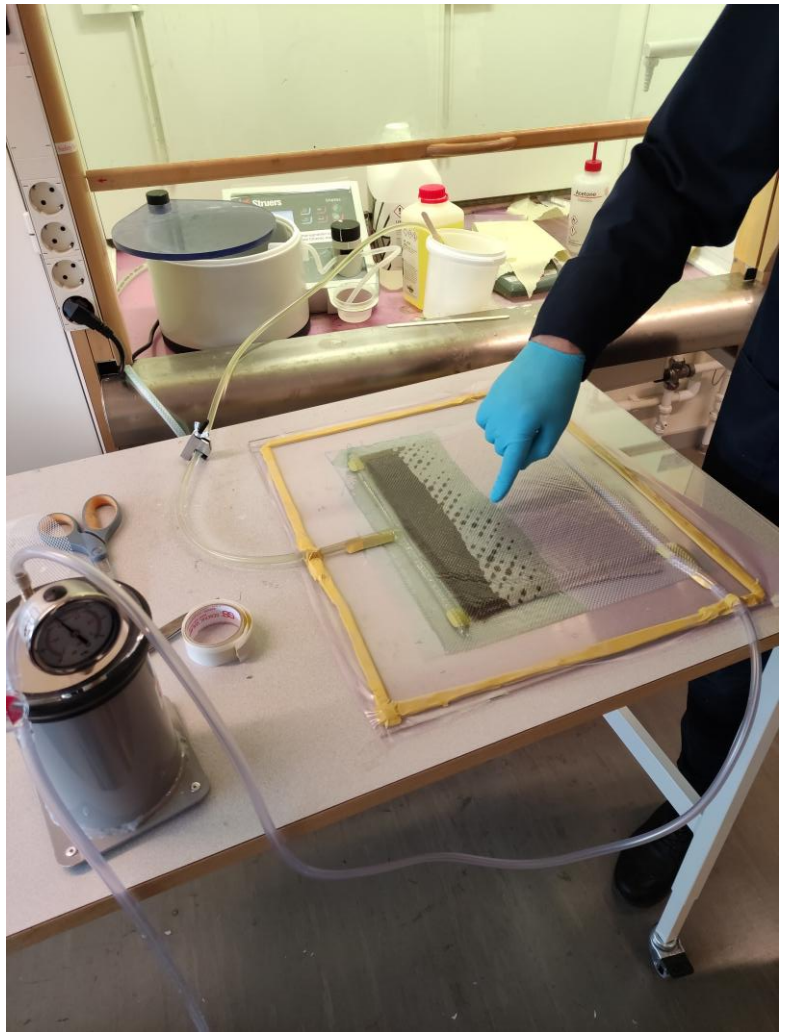
Graphene coating process

(propriatery Grafren AB)

1.
Aqueous dispersions of few-layer graphene flakes (graphene powder in deionized water without any surfactants or chemical binders). Ultrasonic homogenization for 30–60 minutes.



2.
Flax fabric immersion at room temperature. Graphene flakes adhere to the fiber surfaces through van der Waals interactions, forming a non-continuous but conformal coating.

3.
Fibers are removed and air-dried under ambient conditions or oven-dried at 60 °C to remove residual moisture.

Conclusions and future prospects

- Graphene coating successfully applied to flax fiber, enhancing composite performance.
- 1.5 wt.% graphene coating resulted in approximately 38% increase in flexural strength and a 48% rise in flexural modulus.
- The testing at the demonstrator level (Hatch) confirmed around 40% improvement in water resistance.
- To fully harness the potential of graphene in bio-composites, the following key factors are currently under investigation:
  - Graphene size, thickness, concentration and surface area
  - Desired coating thickness and Post-coating drying process
- Larger demonstrator will be manufactured
  - The fabrication process will utilize prepreg to ensure consistency and quality.

ABSTRACT

Gamma ray and electron beam irradiation are used to improve the tensile properties of scalable ultra-high volume fraction laminates made from continuous carbon nanotube (CNT) yarns. Radiation treatments simultaneously induce crosslinking and surface activation, enhancing load transfer. Yarns are treated with doses ranging from 50 kGy to 1200 kGy (gamma ray) and 40 Mrad to 300 Mrad (electron beam). Gamma ray treatment yields up to a 5% increase in specific modulus and 4.7% in specific strength, while electron beam treatment achieves increases of up to 10% and 8.9%, respectively. Surface modification is assessed via DCAT which showed a lower contact angle after irradiation, indicating the addition of functional groups. Raman spectroscopy is also used to evaluate surface changes by comparing I_D and I_G peaks. Laminate-scale specimens assess the combined impact on tensile and surface properties. Unidirectional laminates with ~80 wt.% CNTs are fabricated. The 700 kGy gamma ray laminate achieved a specific modulus of 258 GPa g^{-1} cm^3, and the 40 Mrad electron beam laminate achieved a specific strength of 2.29 GPa g^{-1} cm^3. Results demonstrate that radiation treatments enhance load transfer in CNT yarn laminates, with crosslinking playing a critical role in achieving performance beyond state-of-the-art CFRPs.

1 INTRODUCTION

Carbon nanotubes (CNTs) have mechanical and transport properties beyond current state-of-the-art materials, however achieving nanoscale properties at the macro scale remains a challenge. A key limitation of CNT-based laminates is the weak interface between CNT bundles and polymer resin systems [1], [2], [3], [4].

Crosslinking and functionalization by irradiation may mitigate this issue [5], [6], [7], [8], [9]. Other functionalization approaches have limited effectiveness on commercially available CNT yarns due to their dense and aligned networks and large diameters relative to carbon fiber [10]. Additionally. The graphitic nature of CNT yarns has resulted in very low interface strengths, with fracture usually occurring within the CNT yarns themselves [3]. Radiation techniques like gamma ray or electron beam may penetrate the dense CNT networks and provide not only surface functionalization but also

crosslinking in the interior structure [11]. There is a theoretical limit where damage to the CNT structures will become greater than effects from crosslinking and functionalization; thus a range of treatments are necessary [12].

This work compares the effects of electron beam and gamma ray treatments on highly aligned MRIALON® high strength 2-ply CSY CNT yarns, manufactured by Nanocomp Technologies, Inc. (now part of Huntsman Advanced Materials). Tensile testing of single CNT yarns is used to evaluate the effectiveness of treatment methods on improving tensile properties of the CNT materials. Dynamic contact angle testing (DCAT) is used to evaluate the effectiveness of treatment methods on improving the interface of CNT yarns. Changes to both tensile and interface properties are evaluated by comparing laminate-scale specimens made with treated yarns and CYCOM® 5250-4 bismaleimide resin, supplied by Syensqo.

2 METHODS

2.1 Electron Beam Treatment

CNT yarn was wrapped around aluminum mandrel and exposed to a high-energy electron beam with 1.5 MeV. Electron beam dose depends on the exposure time; operation was paused between each 20 Mrad dose to avoid excessive temperature increase in the sample area. CNT yarns were treated with doses of 40, 200, and 300 Mrad. Additional batches of yarns were treated at 40 and 300 Mrad for manufacturing into CNT yarn laminates.

2.2 Gamma Ray Treatment

Gamma ray irradiation was conducted at the Radiation Center, Oregon State University, using the Co60 isotope with 1.13 and 1.33 MeV photon energies. The CNT yarns were wrapped around a plastic tube and placed at the center of the irradiation chamber. The dose was controlled by the irradiation time. Six different doses were applied: 50 kGy, 100 kGy, 200 kGy, 400 kGy, 700 kGy, and 1200 kGy. Composite laminates were made from 200, 700 and 1200 kGy samples.

2.3 Ozone Treatment

Yarns were wound on a truss and placed in a container for even ozone flow. An LG-7 CD Laboratory Ozone Generator was used at 9 V output at 5 L min^{-1}. The treatment was controlled by exposing yarns for 1 hour and 3 hours.

2.4 Yarn Tensile Testing

CNT yarns were tested at large gauge lengths of 120 mm according to a previously published paper [13]. A Shimadzu Autograph AGS-X mechanical test system using Grip-Engineering Thümler GmbH TH76-1+Ko capstan grips with 2.5 cm diameter and a 500 N load cell were used. The loading rate was 3 N min^{-1}, and strain was calculated by crosshead displacement between 0.5 – 1.0%. Crosshead extension was used for the modulus calculations presented in this work due to the small size of the yarns. This makes direct comparison of modulus values with the laminate-scale specimens unsuitable; however, we assume that the trends remained consistent regardless of if an extensometer was used.

2.5 Dynamic Contact Angle Testing

Dynamic contact angle was measured using a Dataphysics DCAT15. The sample was advanced into and receded from deionized water at 1 mm min^{-1} speed with an immersion depth of 3 mm, which was repeated for 5 cycles. A wetted length was used for DCA calculations based on the measured perimeter of the yarns using a digital microscope.

2.6 Laminate Manufacturing

Unidirectional CNT yarn composite laminates were fabricated using a filament winder and confined mold as shown in Figure 1a-d. Yarns were wrapped in the recessed area of the mold, shown in Figure

1a, then densified (1b), then a thin film of CYCOM® 5450-4 BMI is applied to the densified yarn stack (1c) and cured for 6 hours at 204 °C in a hot press [10]. The resultant laminate is shown in Figure 1d.

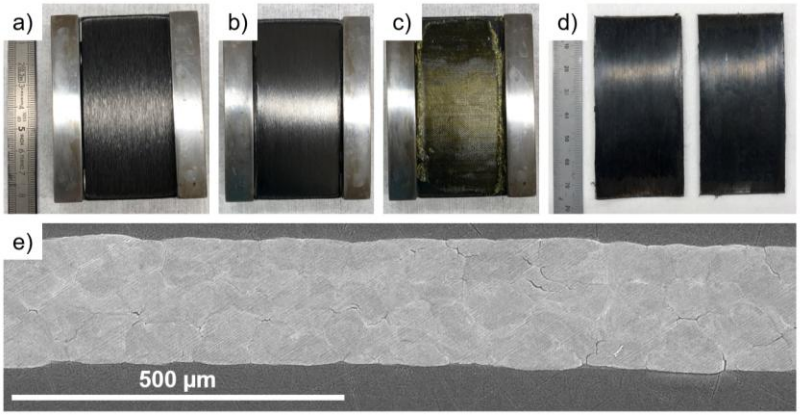

Figure 1: (a) CNT yarns wound on recessed mold, (b) yarns after densification, (c) resin applied to yarns, and (d) The laminates after curing. (e) shows a cross section image of the laminate.

The laminates manufactured with this technique have extremely high reinforcement concentrations, of over 80 wt.% CNTs. Figure 1e shows an SEM micrograph of the cross section of a laminate embedded in mounting resin. Typical composite cross sections have clear distinctions between the reinforcement and the matrix, but the densification step plastically deforms the CNT yarns together and limits resin content to an extremely low amount between adjacent yarns. This allows for favorable reinforcement-dominated properties when compared with state-of-the-art carbon fiber composites. Moreover, the high degree of densification and mechanical interlock mitigates the low interface strength of CNTs with polymer resins [10].

2.7 Laminate Tensile Testing

The CNT yarn composite laminates were cut to 2-3 mm wide by 80 mm long tensile test coupons and an aluminum jig was used to obtain a consistent gauge length of 25 mm. An Instron 5969 load frame equipped with a 50 kN load cell and MTS 646 hydraulic collet grips were used and tested at 0.3 mm min^{-1}. Strain was calculated with an Epsilon One optical extensometer. The modulus was taken via loading, unloading, and reloading cycles over the range from 400 MPa to 1200 MPa [14].

3 RESULTS AND DISCUSSION

Specimens from a single roll of yarns were sent for electron beam and gamma ray treatment to minimize any effects of roll-to-roll variation. The effects of treatment on mechanical properties were measured by tensile testing individual CNT yarns, while functionalization was measured with DCAT and Raman spectroscopy. Both effects were evaluated by fabricating laminate scale specimens with polymer resin to form a comprehensive assessment of the viability of irradiation treatment techniques. Due to the large quantity of yarn required for laminate fabrication, each laminate was made with a different roll of yarn from the same lot.

3.1 Electron Beam Treatment

Measuring the cross-section area of CNT yarns is impractical at scale, so the SI units of linear density were used: tex (g km^{-1}). Linear specific tensile strength, reported in units of (N/tex) is dimensionally equivalent to volumetric specific strength units of (GPa g^{-1} cm^3).

Results from tensile testing of CNT yarns are shown in Figure 2. Tex, shown in Figure 2a, tended to increase with temperature, except for the lowest treated specimen of 40 Mrad which was below the control. Figure 2b compares how the ultimate force varied with treatment, with no clear linear trend ($r = 0.45$). Therefore, the specific properties are dominated by the changes in linear density, resulting in the 40 Mrad yarn demonstrating an increase in both specific strength and specific stiffness while the 200

Mrad dose was most like the control and the higher mass of the 300 Mrad specimens caused it to have the lowest specific properties.

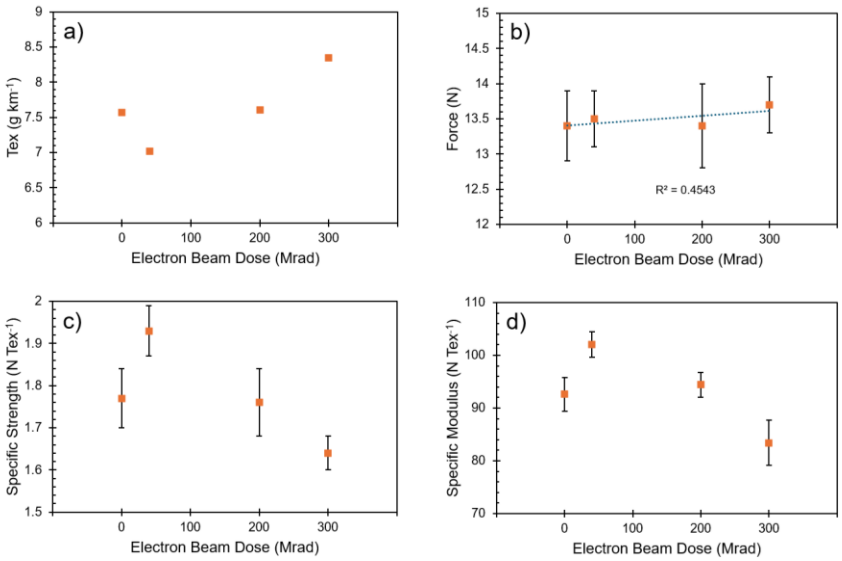

Figure 2. Electron beam treated CNT yarn tensile results. (a) compares linear density in units of tex (g km^{-1}), (b) compares ultimate force, (c) specific strength, and (d) specific modulus.

Raman spectroscopy was used to evaluate the ratio of the I_D band to I_G band. Increases in disorder related I_D band indicate potential functional sites after electron beam treatment. Figure 3a shows a significant increase in the I_D band in a randomly oriented CNT network, while Figure 3b shows the trend holds for the CNT yarns. The I_D band at 300 Mrad treatment is most similar to a gamma ray treatment of 50 kGy, shown in Figure 3b.

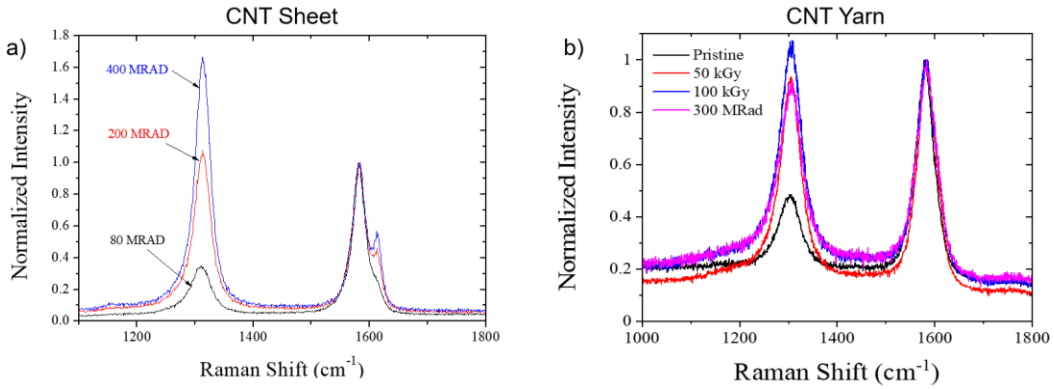

Figure 3. Raman spectroscopy comparing I_D and I_G of (a) randomly oriented CNT sheet treated with electron beam, and (b) CNT yarns treated with electron beam or gamma ray.

Figure 2 shows decreasing specific tensile properties with treatment, while Figure 3 suggests increasing interface properties. Therefore, a laminate scale specimen which relies on both is needed to gain a comprehensive assessment of the effectiveness of electron beam treatment. Interestingly, the higher properties at lower dose shown in Figure 2c and 2d are also present in the laminate scale specimens in Figure 4a and 4b. The most significant improvement was in the specific strength at a treatment of 40 Mrad, which reflects the yarn tensile results. However, the improved interface may be responsible for the slight increase in both specific strength and modulus at 300 Mrad, since those properties decreased in the yarn tensile test.

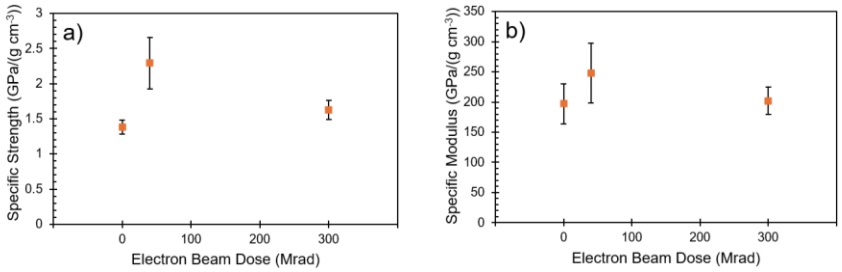

Figure 4. Electron beam treated CNT yarn laminates (a) specific strength and (b) specific modulus.

3.2 Gamma Ray Treatment

Gamma rays cause damage to CNT walls, opening sites for cross linking between adjacent CNT bundles and functional groups on the outer surface. The dose was controlled by altering the time the specimen was exposed to the source, allowing for a large quantity of yarn to be treated.

Figure 5 compares how the tensile properties of the yarns evolved with treatment. As the dosage increased so did the mass of the yarns and therefore also the linear density, shown in Figure 5a. This effect was more pronounced at higher dosage. Figure 5b shows a concurrent increase in ultimate force which increased linearly with treatment ($r = 0.955$), unlike the electron beam. However, the increase in force was less than the increase in tex, so the specific strength, expressed in units of N tex^{-1}, decreased at the higher levels of treatment, shown in Figure 5c. The 200 kGy specimen had the highest specific strength, and while this may be due to the low tex measurement, it also had the highest specific modulus, shown in Figure 5d.

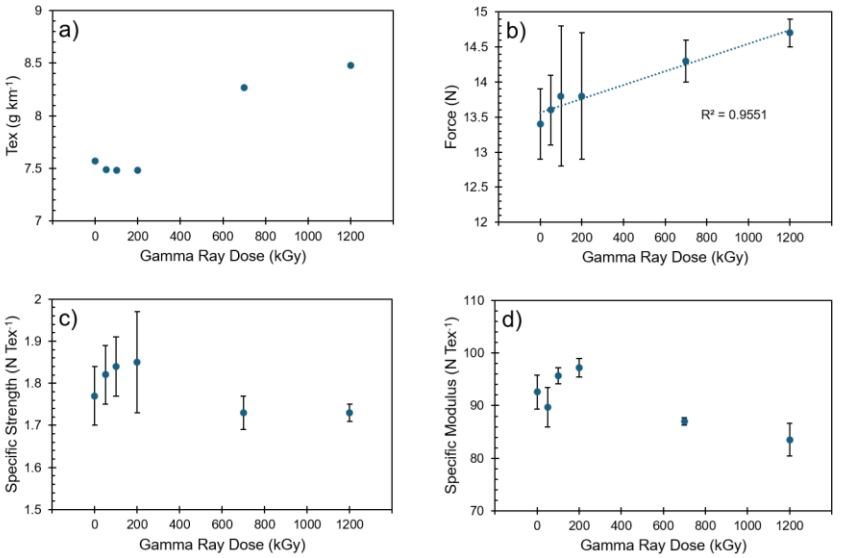

Figure 5. Gamma ray treated CNT yarn (a) linear density, and tensile results. (b) shows ultimate force, (c) specific strength, and (d) specific modulus.

Dynamic contact angle measures both the initial interaction with the liquid, in this case deionized water, and the effect of advancing and receding through the medium. The average contact angle of the yarns which were later used for laminate scale specimens is reported in Figure 6. There is a clear inverse relationship between treatment and contact angle, indicating the presence of functional groups which will likely increase the interface between treated CNT yarns and various polymer resin systems.

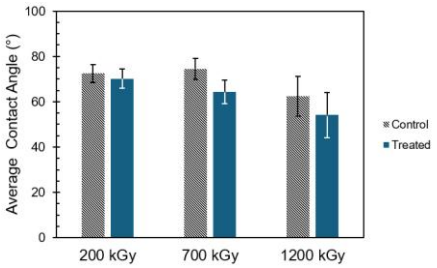

Figure 6. Average dynamic contact angle of the CNT yarns used for the gamma ray treated laminates.

There exists an optimal dose which combines the ideal amount of cross linking and surface functionalization, therefore treated CNT yarns were fabricated into laminate scale specimens. These specimens combine the effects on mechanical properties of the yarns in Figure 5 with the interface properties in Figure 6. Each treated laminate had greater specific strength and modulus than the control, shown in Figure 7a and 7b, respectively. The optimal combination for proved to be the 700 kGy treatment, due to combining the effects of increased specific mechanical properties and increased interface properties.

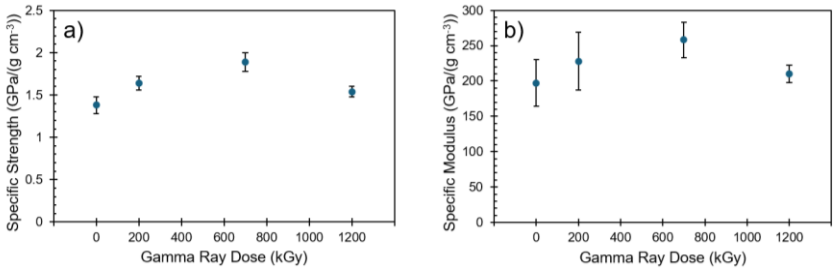

Figure 7. Gamma ray treated laminate tensile (a) specific strength and (b) specific modulus.

3.3 Ozone Treatment

The primary goal of ozone treatment is to functionalize the surface of the CNTs to improve bonding with resin. Like other treatments, the linear density slightly increased with exposure to ozone, shown in Figure 8a. Unlike other treatments, the ultimate force steadily decreased ($r = 0.997$) with treatment because ozone does not crosslink the dense CNT network but damage the CNT structures. Accordingly, Figure 8c shows the treatment resulted in decreased specific strength, while the specific modulus (Figure 8d) was relatively unaffected.

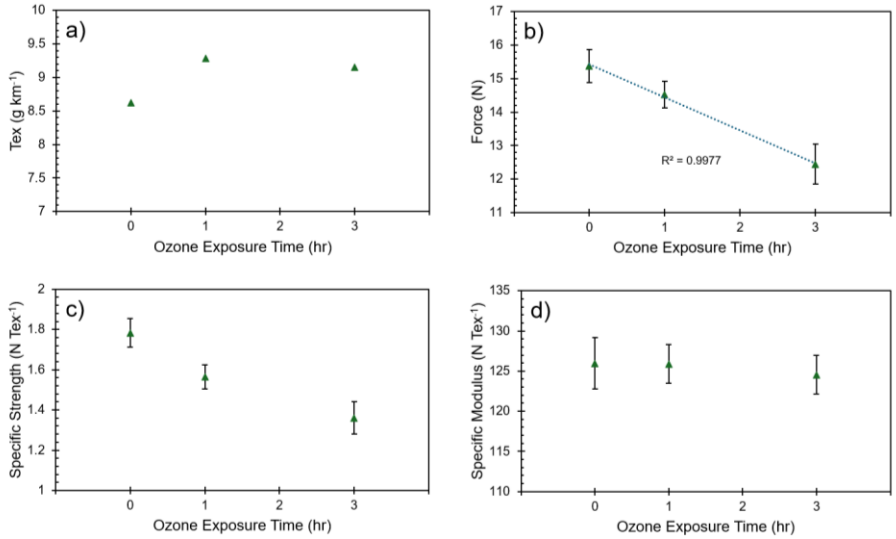

Figure 8. Ozone treated CNT yarn tensile results including (a) linear density, (b) ultimate force, (c) specific strength, and (d) specific modulus.

Figure 9 shows the advancing, receding, and average contact angle of ozone treated yarns and deionized water. While both treatments decreased the contact angle, the difference between one hour and three hour treatment was minimal.

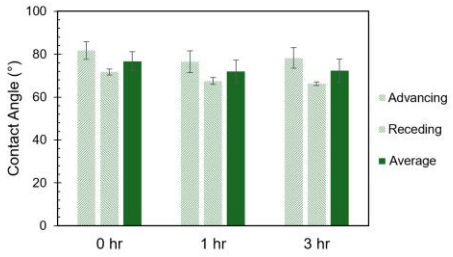

Figure 9. DCAT of yarns exposed to ozone for varying times.

4 CONCLUSIONS

Figure 10 shows how radiation treated CNT composites compare with state-of-the-art unidirectional carbon fiber composites. Laminate properties seem to depend on both crosslinking and surface activation. Gamma ray and electron beam treatments improved both specific strength and modulus over the control laminate; there was an optimal dose of 40 Mrad for the electron beam treatment and 700 kGy for the gamma ray. While ozone treatment may be easier to implement, it was likely not as effective in adding functional groups to improve the interface as the radiation techniques. Additionally, the lack of crosslinking means that ozone treatment by itself will likely have limited success in improving CNT yarn laminate mechanical properties.

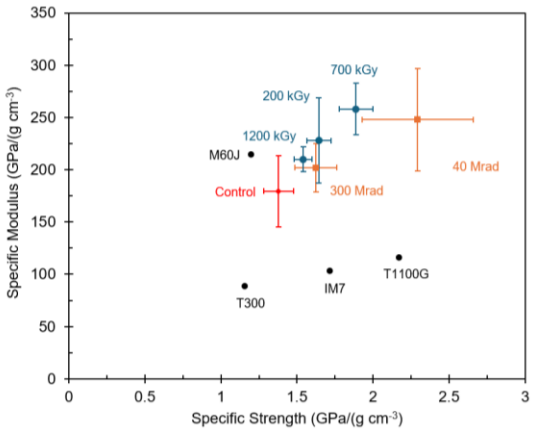

Figure 10. Chart comparing specific strength and specific modulus of radiation treated CNT yarn laminates and state-of-the-art unidirectional composites.

The laminate results show that both interface properties and tensile properties must be considered when using single yarn-scale specimens to predict the performance of composite specimens. The optimal dose in both cases was a treatment that improved both mechanical and interface properties, with lower doses not having as much improvements, or higher doses reducing mechanical properties.

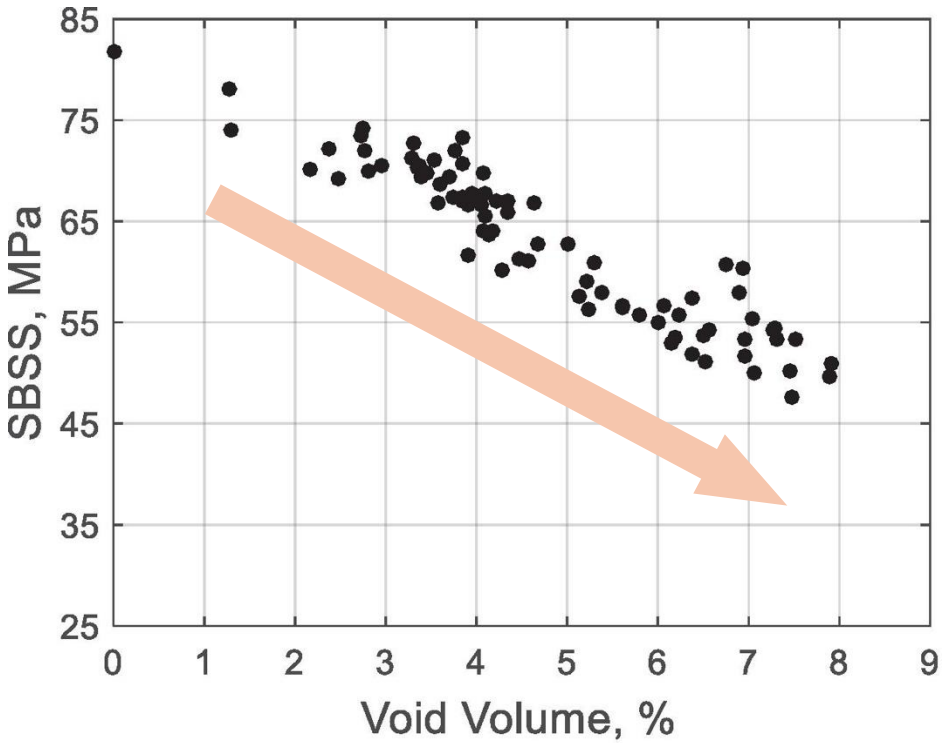
Research Background

Conventional Autoclave Manufacturing for High Pressure

- Composites are typically manufactured using autoclaves, which apply **heat** and **pressure** to cure the material and produce a **void-free structure**.
- However, autoclaves have several **limitations**, including **high energy consumption**, **large space requirements**, and their tendency to become a **bottleneck** in the production process [1].

<Void Content Difference Between VBO and Autoclave>



<Autoclave for Boeing 777X Composite Wings [2]>

[2] https://www.seattletimes.com/business/boeing-aerospace/boeing-shows-off-new-777x-wing-center/

Effect of Voids on Mechanical Properties

- **Minimizing voids** is critical, as voids significantly degrade the mechanical properties of the final product.
- Therefore, there is a **need for Out-of-Autoclave (OoA)** manufacturing processes that can ensure **void-free composites**.

Use of Nano-Porous Networks – Alternative to Autoclaves

- One solution is to **interleave nanoporous networks** within the composite prior to curing, allowing them to conform to and fill the rough interfaces between adjacent prepreg layers [5].
- Additionally, these nanoporous networks generate **capillary pressure** during curing, which can partially **substitute** external pressure provided by an autoclave [6].
- Furthermore, the nanoporous networks can **enhance toughness** by acting as a **buffer** for coefficient of thermal expansion (CTE) mismatches, which arise from the differing orientations of prepreg plies [7].

Candidates for Nano-Porous Network - Polymers

- Engineering polymers are promising candidates for nanoporous networks due to their **high strain capacity** and **toughness**, making them effective CTE buffers.
- **Polyamide** (PA) -based composite reinforcements—such as XLB from Nanolayr—are already **commercially available**.
- However, some high-toughness engineering polymers, including PEEK, HDPE, and UHMWPE, **cannot be easily fabricated into nanostructured forms** [9,10].

Importance of Cryogenic Properties in Aerospace Composites

- **Mechanical performance at cryogenic temperatures** is critical, particularly with the growing use of cryogenic fuels and composite overwrapped pressure vessels (COPVs).
- However, **PA exhibit poor mechanical properties under cryogenic conditions**, limiting their applicability in such environments.

Limitation of PET – Poor Adhesion with Composites

- PET exhibits **poor adhesion to epoxy**, which limits its effectiveness as a reinforcing material in composites [16].
- Composites interleaved with PET veils demonstrated **no significant improvement in toughness** [17].

- This study focuses on **plasma treatment** to enhance PET's adhesion to epoxy, enabling its use as a **nanofiber reinforcement** and potentially improving **cryogenic toughness.**

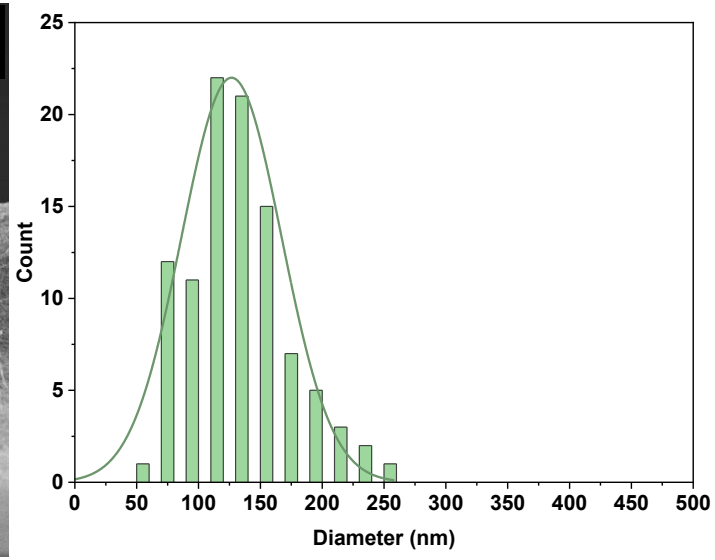
Material & Methods

Synthesizing Nanofibers - Electrospinning



- Electrospinning is a technique that uses a high-voltage electric field to draw a polymer solution into fine fibers, which solidify as they reach a grounded collector [18].
- This enables the fabrication of **nanoscale fibers**, offering enhanced mechanical properties across a range of polymers [18].
- Fiber diameter is controlled by **adjusting key process parameters** such as voltage, flow rate, and solution concentration [19].

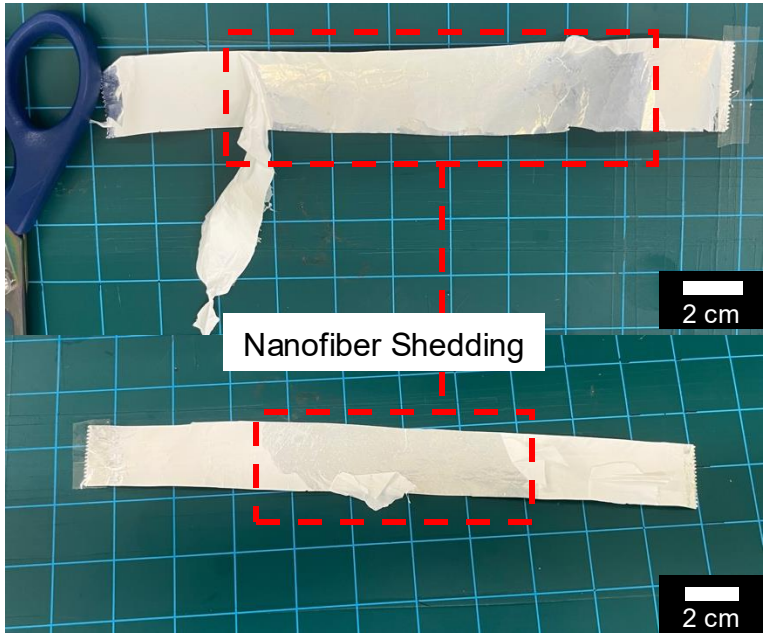
Plasma Treatment for Improving PET Adhesion

- Plasma treatment has been widely employed in previous studies as an effective method to enhance the surface adhesion of PET to epoxy [20,21].
- However, the application of atmospheric plasma treatment to **improve adhesion of nanofibers** is being explored for the **first time** in this research.



<Atmospheric Plasma Generator & Schematic of Plasma Treatment>

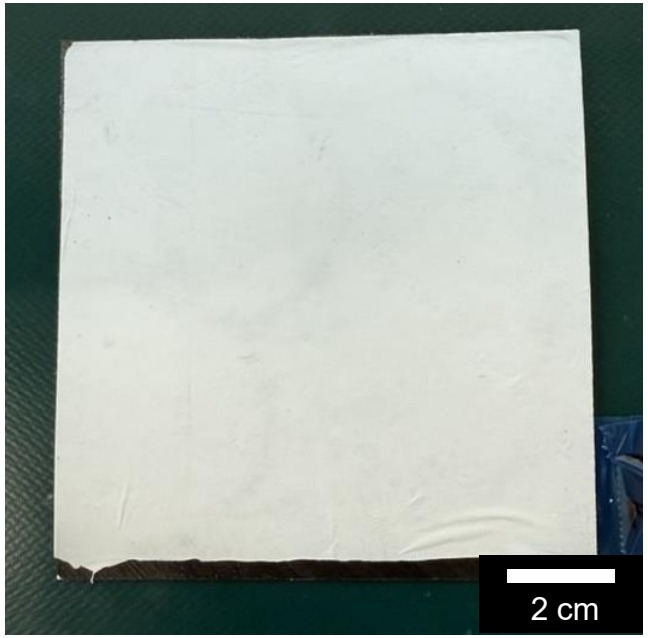
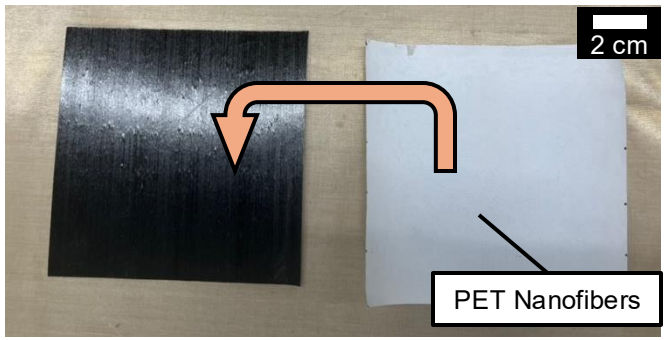
Use of Metal Mesh to Prevent Shedding of Nanofibers

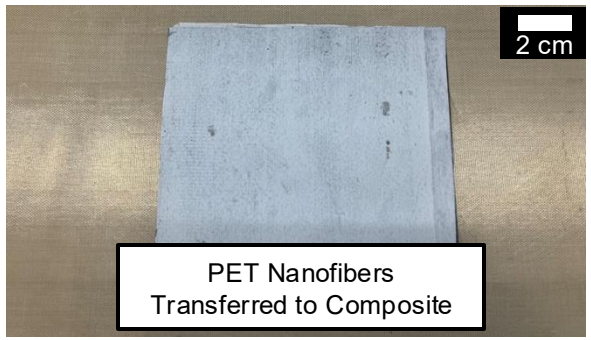


- High air pressure (6 bar) generated by atmospheric plasma can **dislodge nanofibers**, reducing their effectiveness.
- A **metal mesh** support (60 & 2500) enables **closer** and **longer plasma exposure** while preventing nanofiber shedding.
- With a 1 cm nozzle-to-sample distance, both mesh prevented nanofiber shedding, while achieving comparable plasma treatment efficiency.

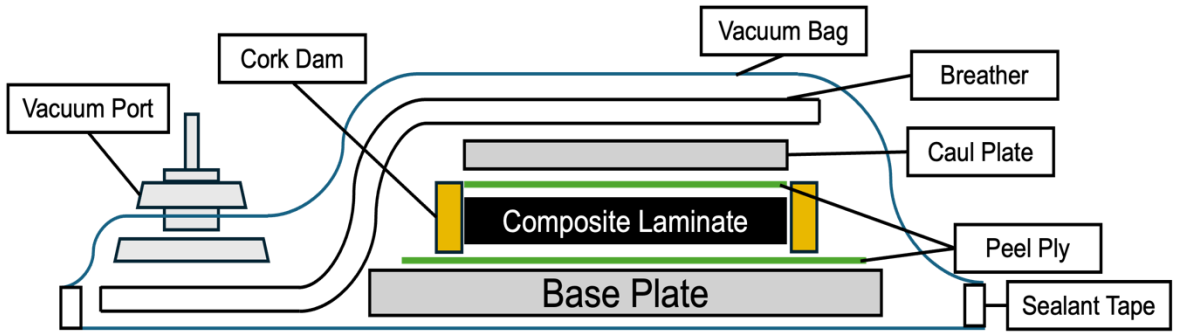
<Shedding of Nanofibers due to Plasma Treatment>



<Use of 60 Mesh & 2500 Mesh to Prevent Shedding>

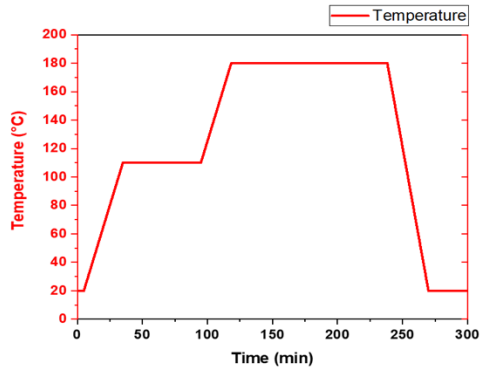


<PET Nanofibers Transferred to Composites after Plasma Treatment>



Composite Curing Process with Interleaved Nanofibers

- After plasma treatment, PET nanofibers are **interleaved between each lamina** during the prepreg layup process.
- The laminates are then cured using a **Vacuum-Bag-Only (VBO)** method, following the standard cure cycle for IM7/8552.
- Three sample types were prepared: baseline (no interleaved nanofibers), As-spun PET, and Plasma-treated PET.



<Composite Laminate Interleaved with PET Nanofibers>

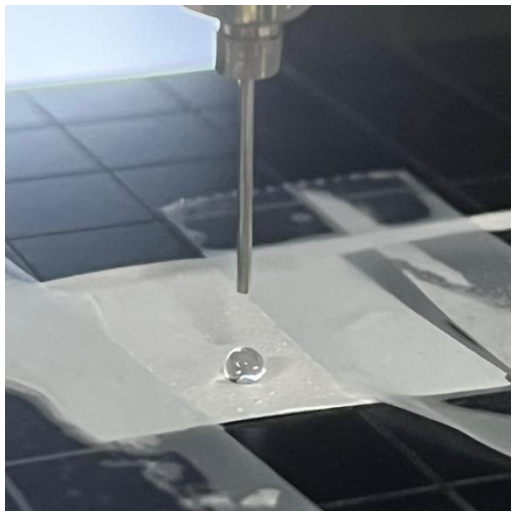
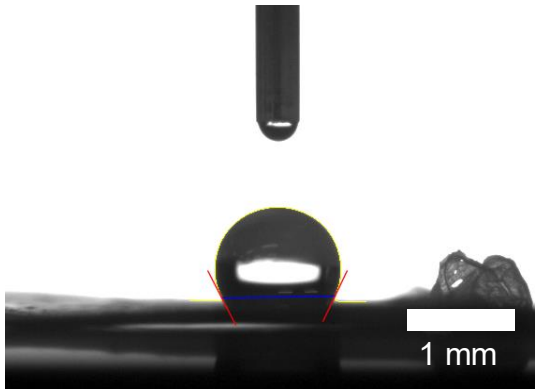
Results & Discussion

Morphological & Chemical Composition Change after Plasma Treatment

PET Nanofiber Morphology Change after Plasma Treatment

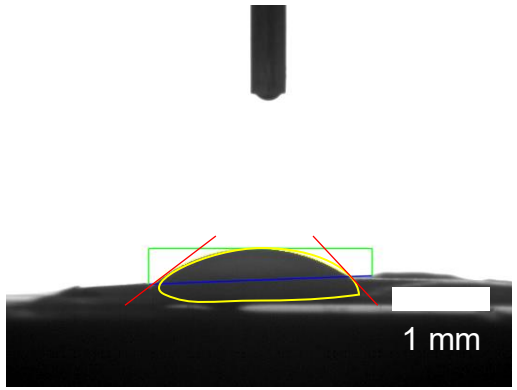


- Despite **6 bar of air pressure** and **120 °C gas temperature** involved in plasma treatment, SEM analysis confirms that **nanofiber structure** remains **intact**.
- The use of a metal mesh enables effective plasma exposure while preserving the **integrity of the nanofibers**.
- These findings indicate that even after plasma treatment, PET nanofibers can act as **nanoporous networks** that help **eliminate voids** in composite materials.

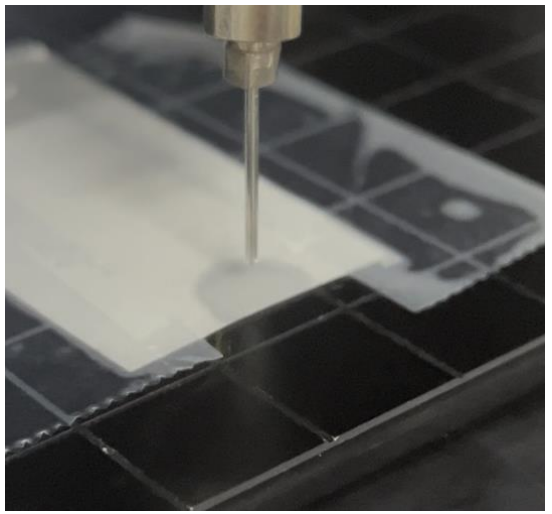


<SEM Images of Electrospun PET Nanofibers Before & After Atmospheric Plasma Treatment>

Surface Energy Increase via Plasma (Contact Angle Analysis)

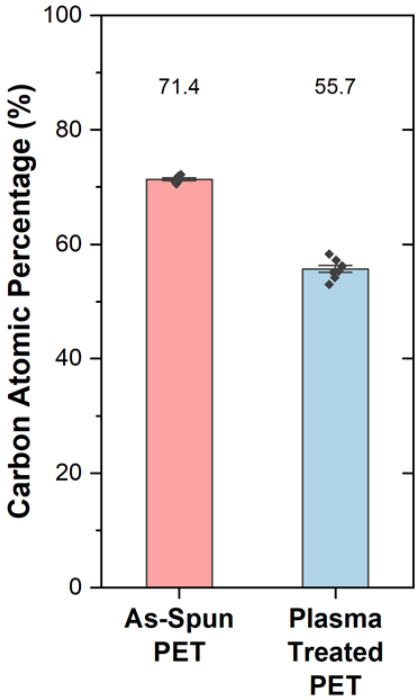


- Contact angle analyzer was used to assess change in the wettability of PET nanofibers.
- Reduced contact angle with deionized water indicates **increased hydrophilicity**, confirming a **rise in surface energy**.
- Consistent with previous studies on PET films, plasma treatment enhances the hydrophilicity of PET nanofibers, demonstrating its **effectiveness even in nanostructures**.
- For more detailed and quantitative analysis on increased hydrophilicity, X-ray Photoelectron Spectroscopy (XPS) was conducted.

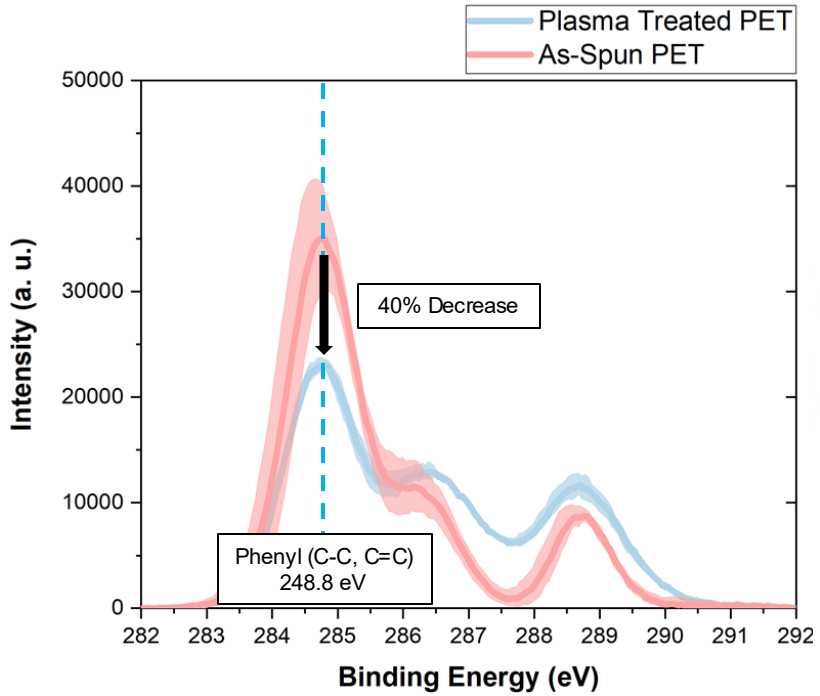


Before Treatment:
120° with DI water

Plasma
Treatment

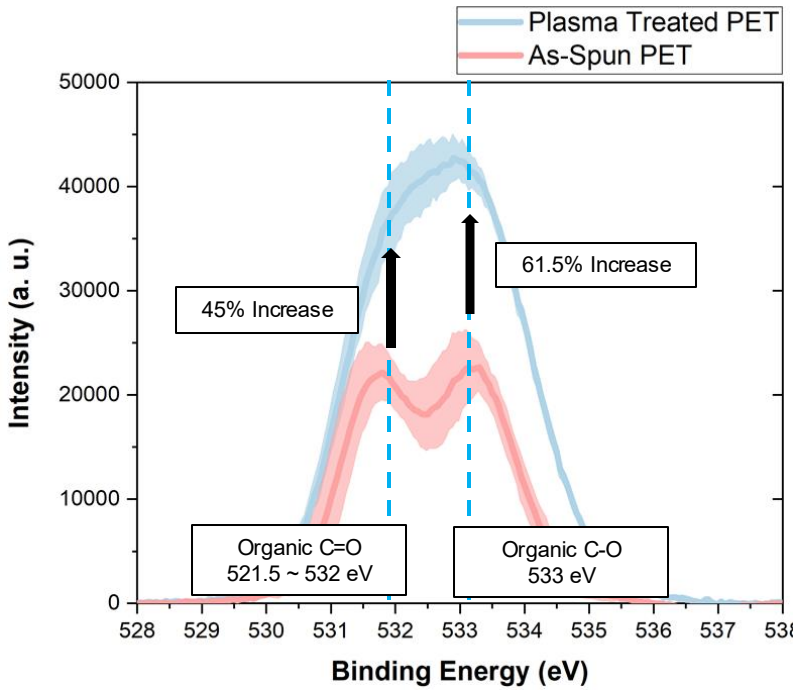


After Treatment:
30° with DI water



<Contact Angle Difference Before & After Plasma Treatment>

Surface Energy Increase via Plasma (XPS Analysis)



- Atomic composition showed a 15% decrease in carbon content and a 12% increase in oxygen content.
- High-resolution C-scan revealed **40% reduction in phenyl** (C–C, C=C) bonds, while O-scan showed a **45%** increase in organic C=O and a **61.5%** increase in C–O bonds, explaining the **enhanced hydrophilicity** and **increased surface energy**.
- These indicate a **potential enhancement in adhesion to epoxy**, which will be assessed through Short Beam Shear (SBS).

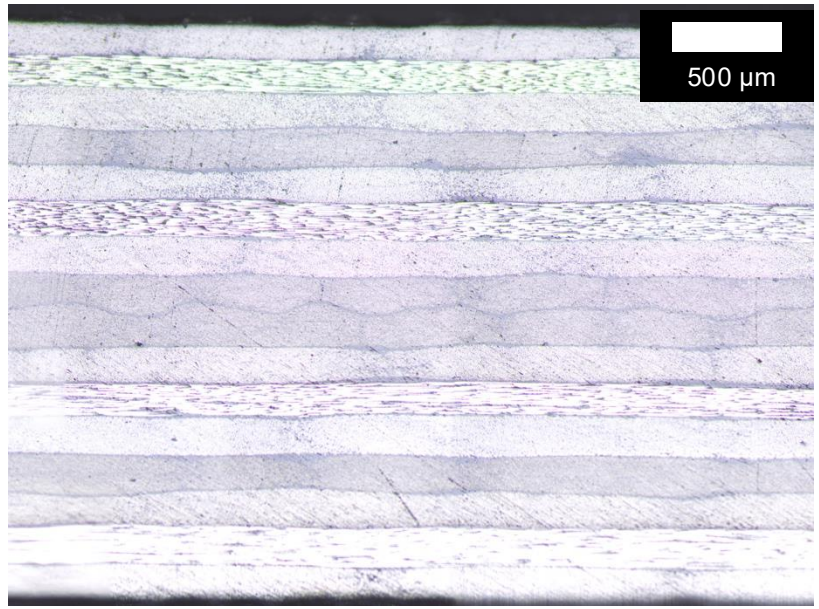
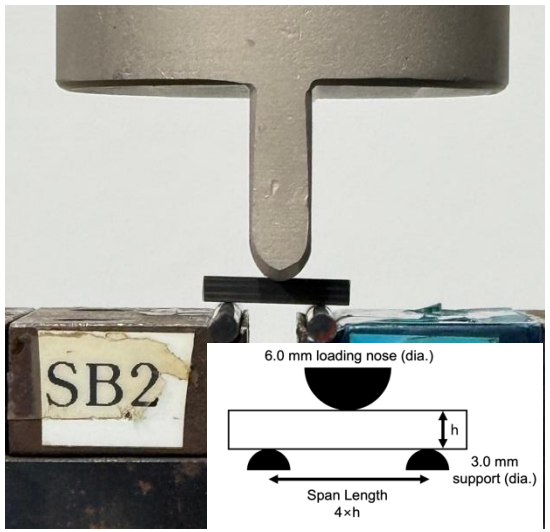
Void Elimination using Nanofiber Interleaved Composites



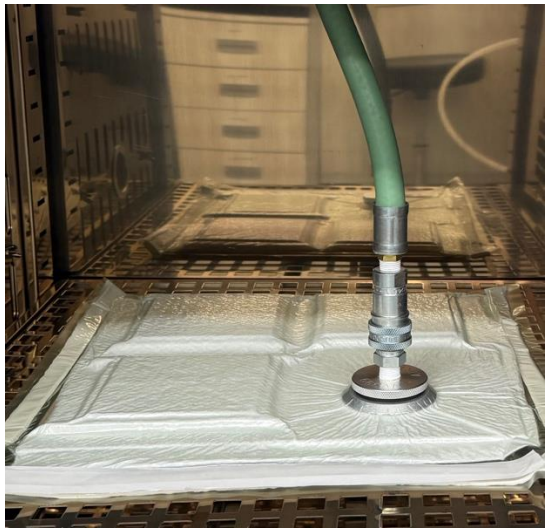
- Void content were analyzed using **IM7/8552 prepregs** (Hexcel) with $[45/0/-45/90]_{2s}$ layup cured with **VBO method**.
- Void content of 1.6% present in the baseline samples were **eliminated** in both PET-interleaved composites.
- Plasma-treated PET nanofibers are capable of generating sufficient capillary pressure during curing also confirming the conservation of nanofibers.

<Baseline Composite>

<As-Spun PET Composite>



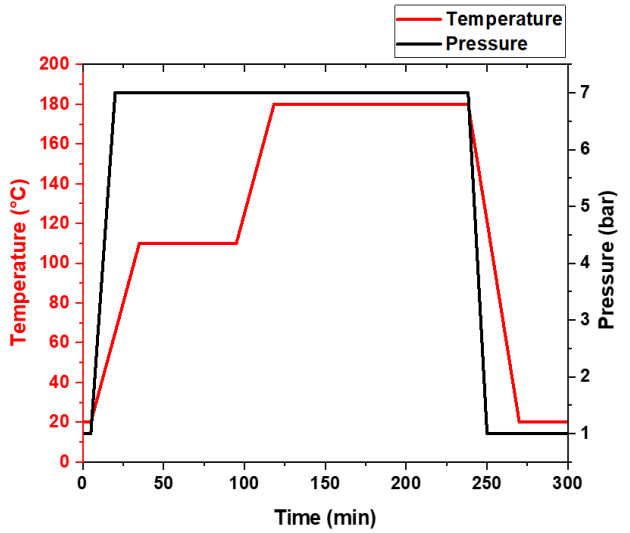
<Plasma PET Composite>



Short Beam Shear (SBS) Tests for Analyzing the Toughening Effect of PET Nanofibers

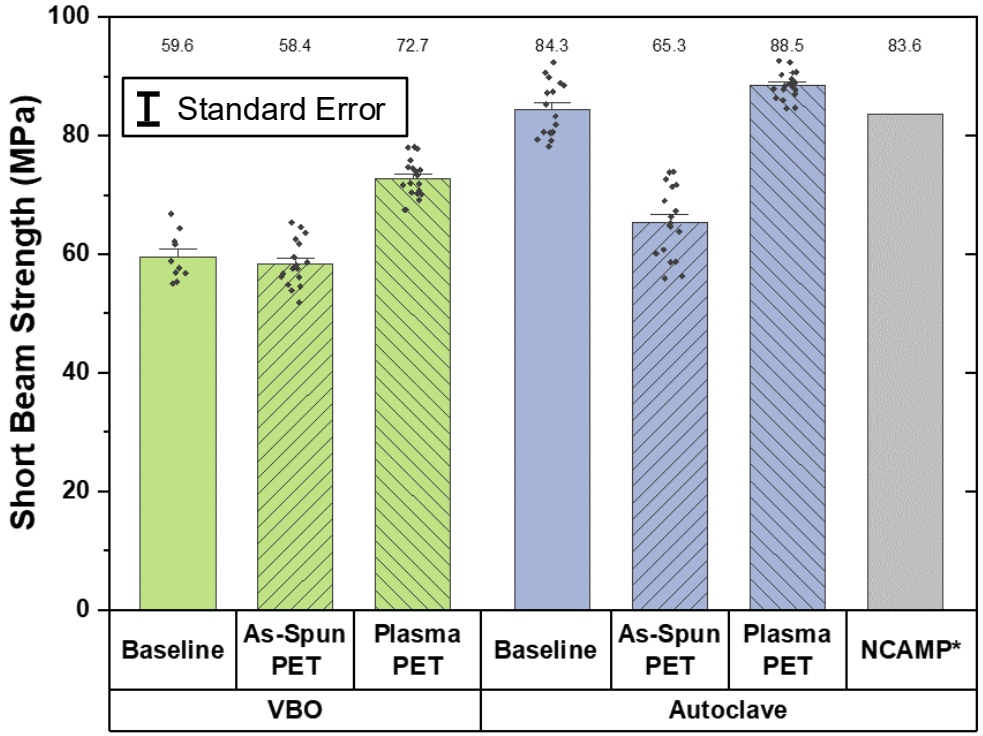
Short Beam Shear (SBS) Test Setup – ASTM D2344

- To evaluate the reinforcing effect of plasma-treated PET, SBS tests were conducted on three types of composites: **Baseline, As-spun PET, and Plasma-treated PET**.
- SBS tests were performed in accordance with **ASTM D2344**, using **IM7/8552** prepregs (Hexcel).
- **$[45/0/-45/90]_{2S}$** layup configuration was employed, and samples were fabricated using **both VBO and autoclave processes**.
- This layup structure **enables comparison with reference data** from the National Center for Advanced Materials Performance **(NCAMP)**.

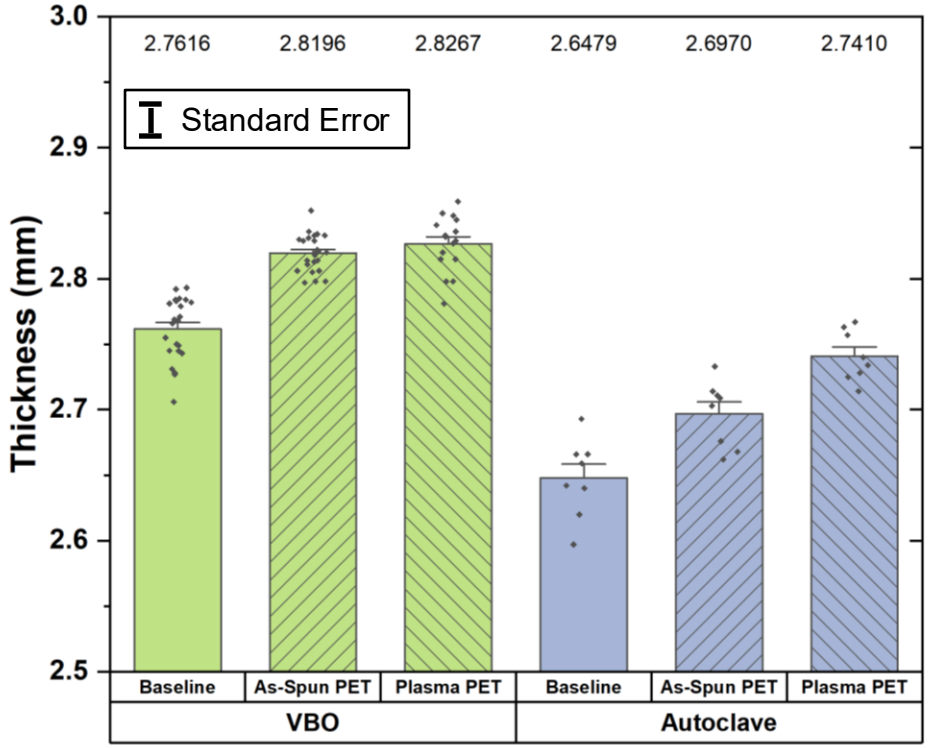


<Schematic & Setup for SBS>

<VBO Curing>



<Autoclave Curing>



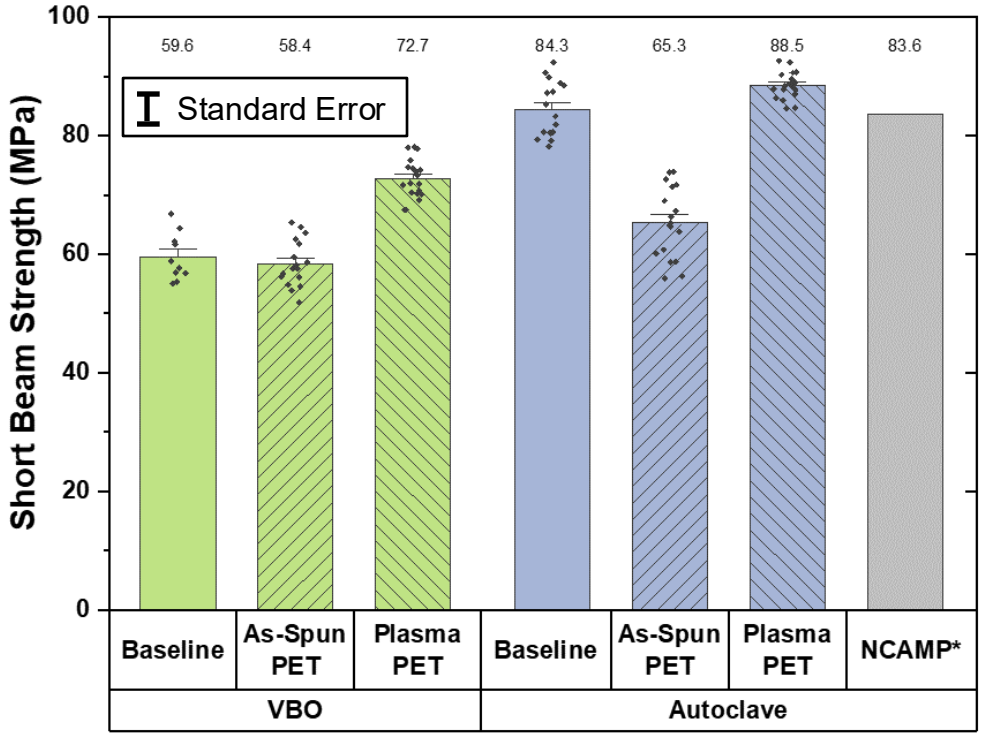
<Manufacturer Recommended Cure Cycle for IM7/8552>

Short Beam Shear (SBS) Result Comparison

- Plasma-treated PET composites exhibited **improved Short Beam Strength** compared to their respective baselines.
- Although the SBS value of Plasma PET (VBO) was lower than that of the Baseline (Autoclave) sample, this difference is likely attributed to **variations in specimen thickness**.

<Short Beam Strength Comparison>

<Thickness Comparison>



KAIST Laboratory for Advanced Materials and Processes

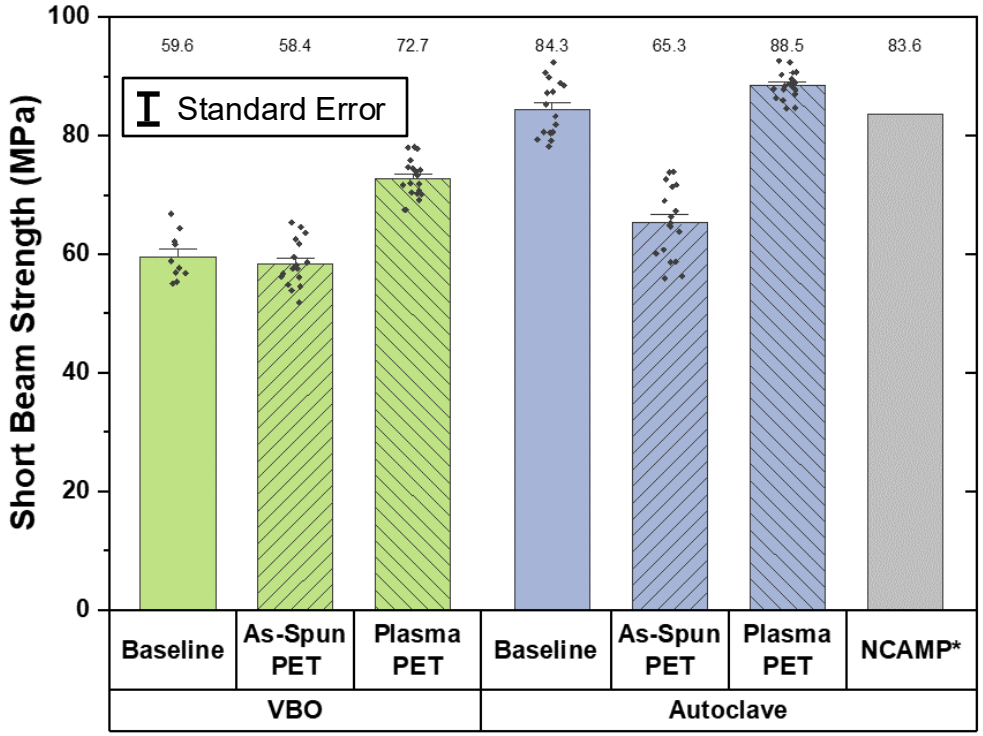
ICCM24 24TH INTERNATIONAL CONFERENCE ON COMPOSITE MATERIALS

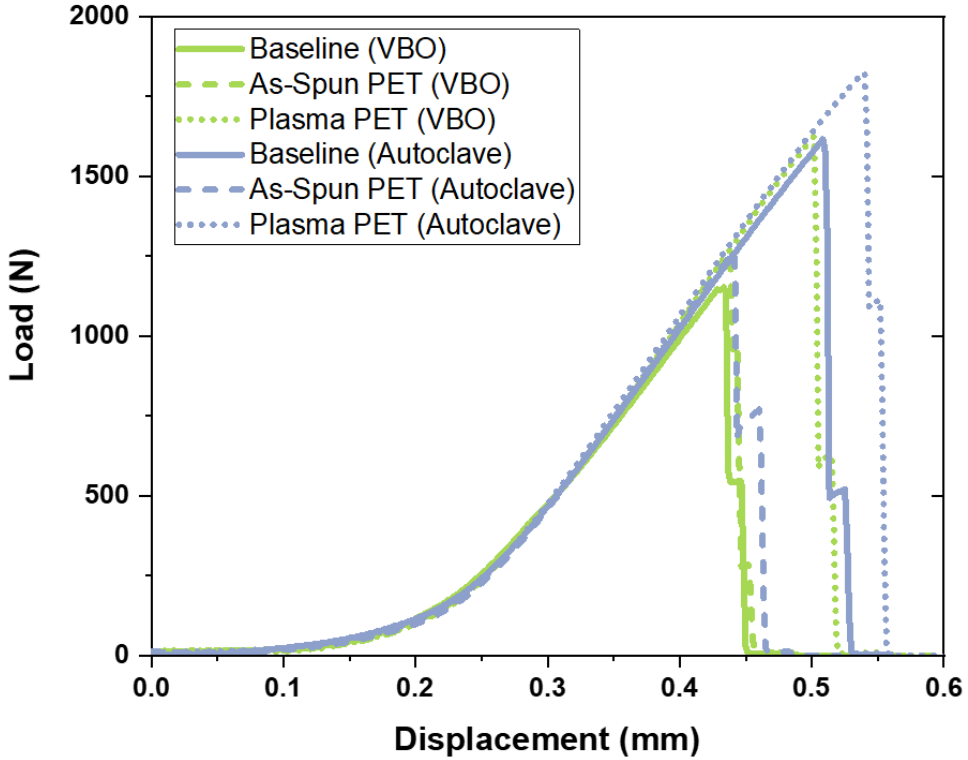
Short Beam Shear (SBS) – Load v. Displacement

- Furthermore, load v. displacement curve shows **no significant difference in maximum load** between the Baseline (Autoclave) and Plasma PET (VBO) specimens.
- While both show similar maximum load, Short Beam Strength of the VBO specimen appear lower due to its greater thickness.

<Short Beam Strength Comparison>



<Load v. Displacement Curve >



NCAMP* : National Center for Advanced Materials Performance IM7/8552 Datasheet

Short Beam Shear (SBS) – Load v. Displacement

- In contrast, **both As-spun PET** specimen showed Short Beam Strength values **comparable to Baseline (VBO)**.
- **Low adhesion of PET** did not contribute to composite reinforcement and may have **behaved similarly to voids**.
- Additionally, comparison with NCAMP* reference values confirmed that the Short Beam Strength value of the Baseline (Autoclave) specimen closely matched the standard, **validating the reliability of the experimental results**.

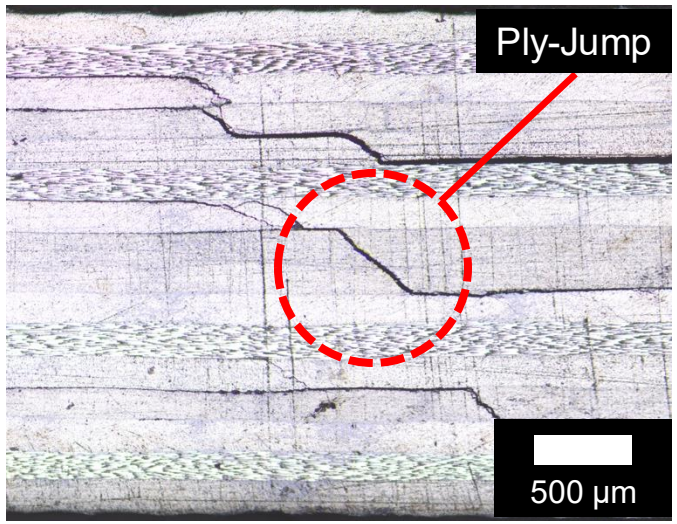
ICCM24 24th INTERNATIONAL CONFERENCE ON COMPOSITE MATERIALS

SBS Result Comparison – Crack Analysis (VBO)

- Optical microscopy revealed that Plasma-treated PET composites exhibited more frequent occurrences of **“ply-jumps”** compared to untreated PET composites.
- The increased number of ply-jumps suggests that plasma treatment enhances PET adhesion [22], thereby contributing to more **effective composite reinforcement**.
- Also, the higher surface area created from the crack indicates a higher energy flux [23], indicating toughening of plasma treated PET nanofibers compared to As-spun PET nanofibers.

<As-Spun PET interleaved Composites after SBS>



<Plasma Treated PET interleaved Composites after SBS>

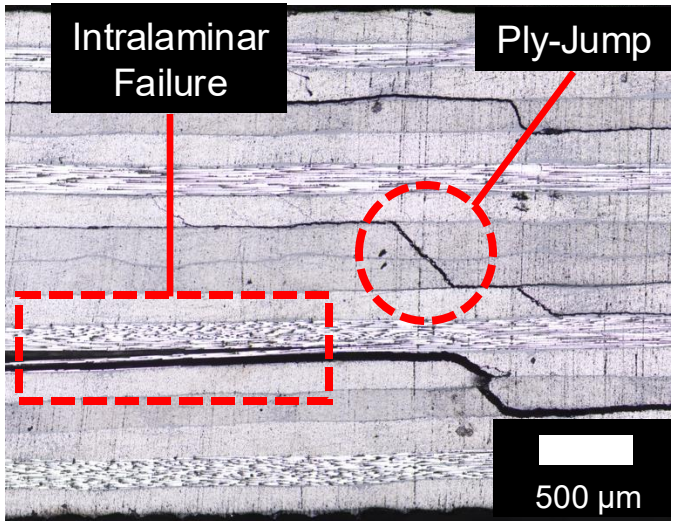
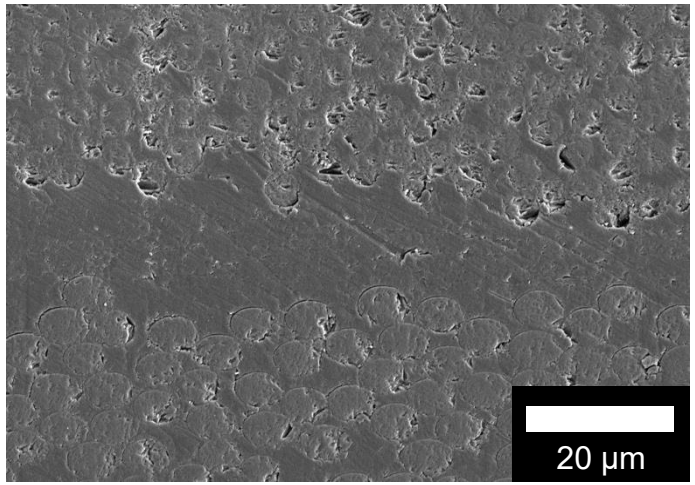
[23] Sharon, Eran, Steven P. Gross, and Jay Fineberg. "Energy dissipation in dynamic fracture."Physical review letters 76.12 (1996): 2117.

SBS Result Comparison – Crack Analysis (Autoclave)

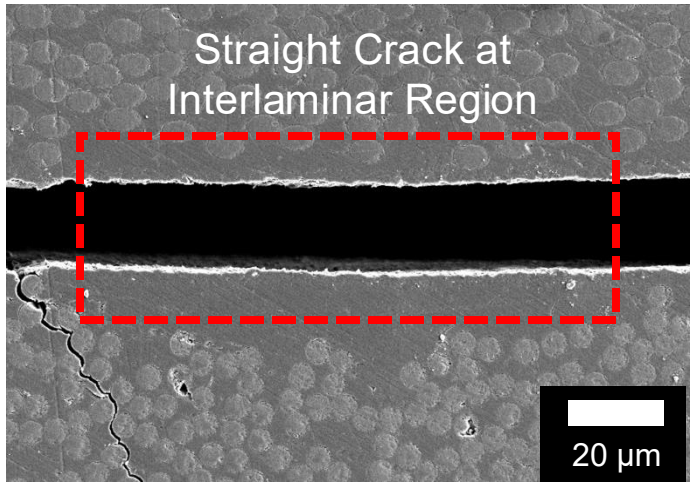


- **Similar increases in ply-jump frequency** were observed in Baseline (Autoclave) and Plasma-treated PET (Autoclave), whereas As-spun PET—even when processed via autoclave—showed no ply-jump formation.
- These results, along with SBS values, confirm the **reinforcing effect** of plasma-treated PET in composites.
- Furthermore, the observed intralaminar failure suggests that plasma-treated PET nanofibers enhance composite toughness not only by eliminating voids but also by **directly strengthening the interlaminar region**.

<Baseline Composites after SBS>

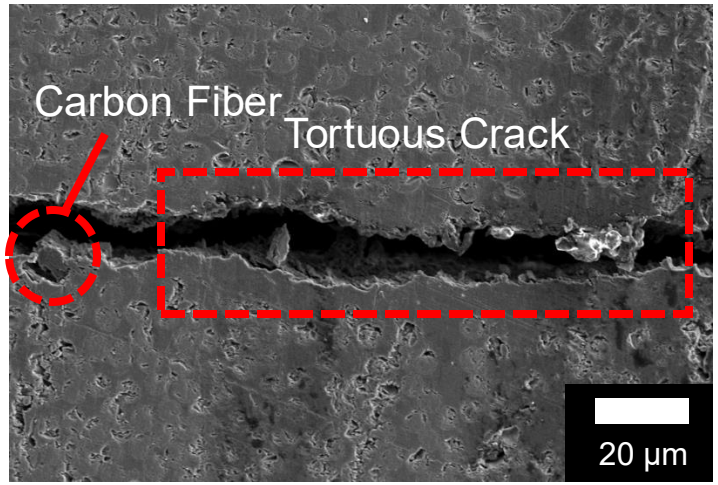


<As-Spun PET Interleaved Composites after SBS>



<Plasma Treated PET interleaved Composites after SBS>

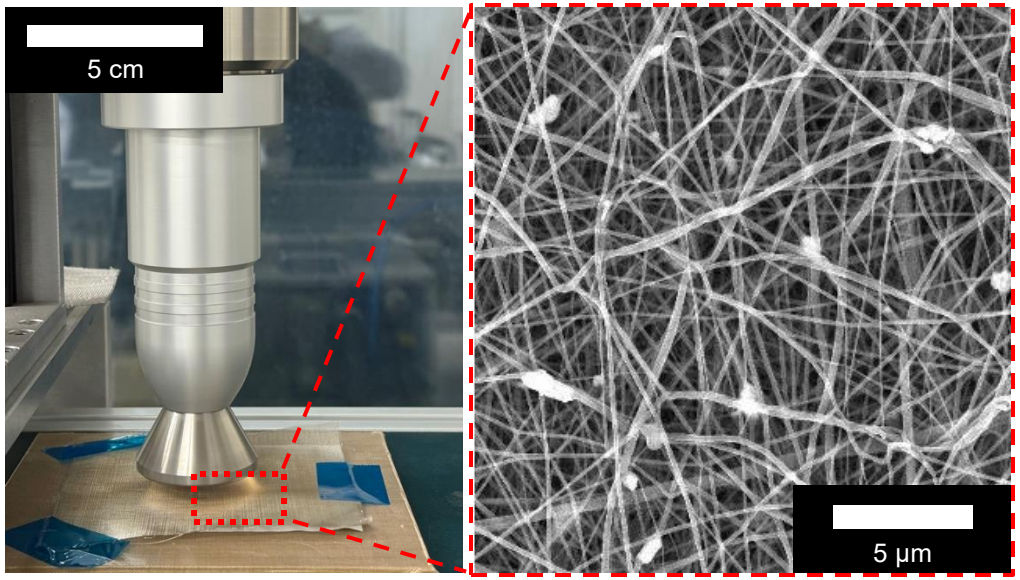
SBS Result Comparison – Crack Analysis (VBO, SEM)



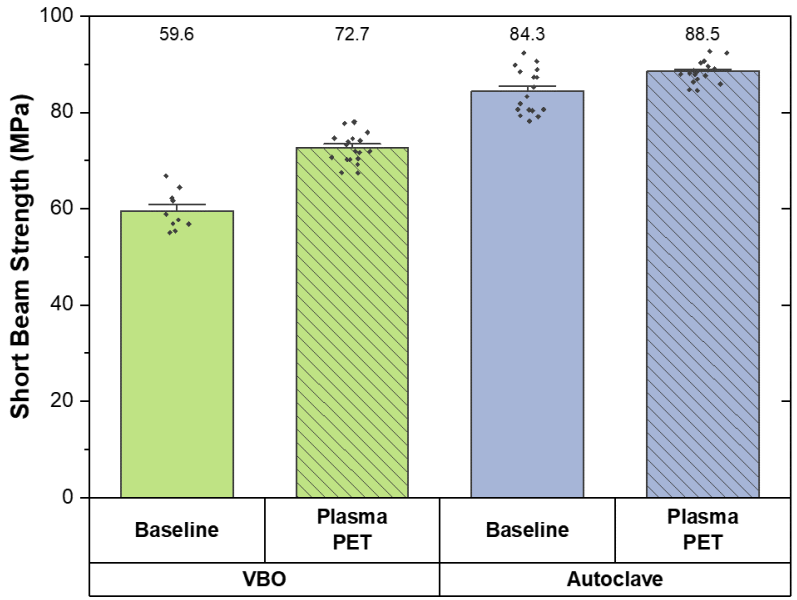
- To perform a more detailed analysis of the fracture surfaces, the interlaminar regions of VBO composites containing As-spun PET and Plasma Treated PET were examined using SEM, both before and after SBS testing.
- In composites with As-spun PET, the fracture path propagated linearly through the interlaminar region.
- In contrast, composites with plasma-treated PET exhibited a more complex fracture path, propagating through both interlaminar and intralaminar regions, **indicating increased adhesion** from non-linear, more tortuous fracture behavior.

<PET Nanofiber Region Before SBS>

<As-Spun PET Composites after SBS>



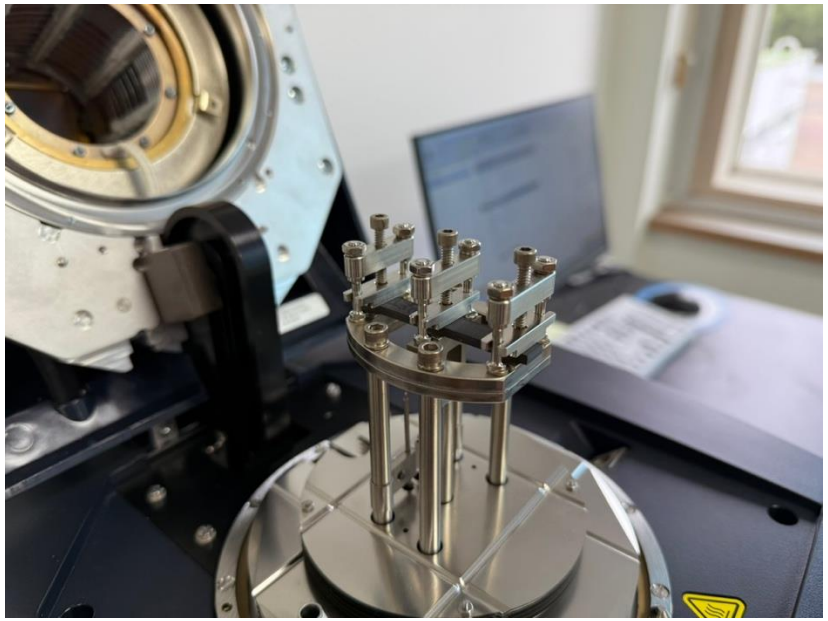
<Plasma Treated PET interleaved Composites after SBS>



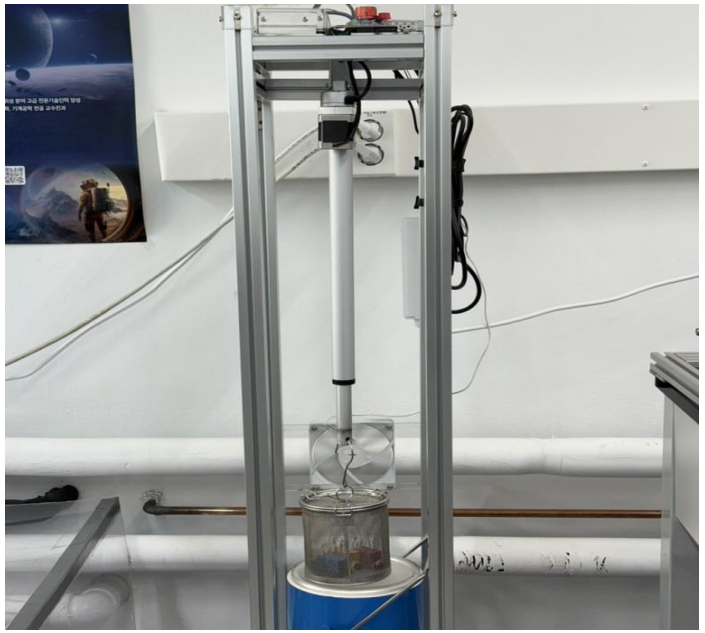
Conclusion & Future Work

Conclusion

- This research has:
  1. Developed an atmospheric plasma treatment method that **functionalizes nanofibers without damaging their morphology**, **enabling previously unused materials as nanoporous networks** for void elimination.
  2. Shown that plasma-treated PET nanofibers markedly increase short beam shear strength, **overcoming their adhesion with epoxy,** and **reinforcing composites**.



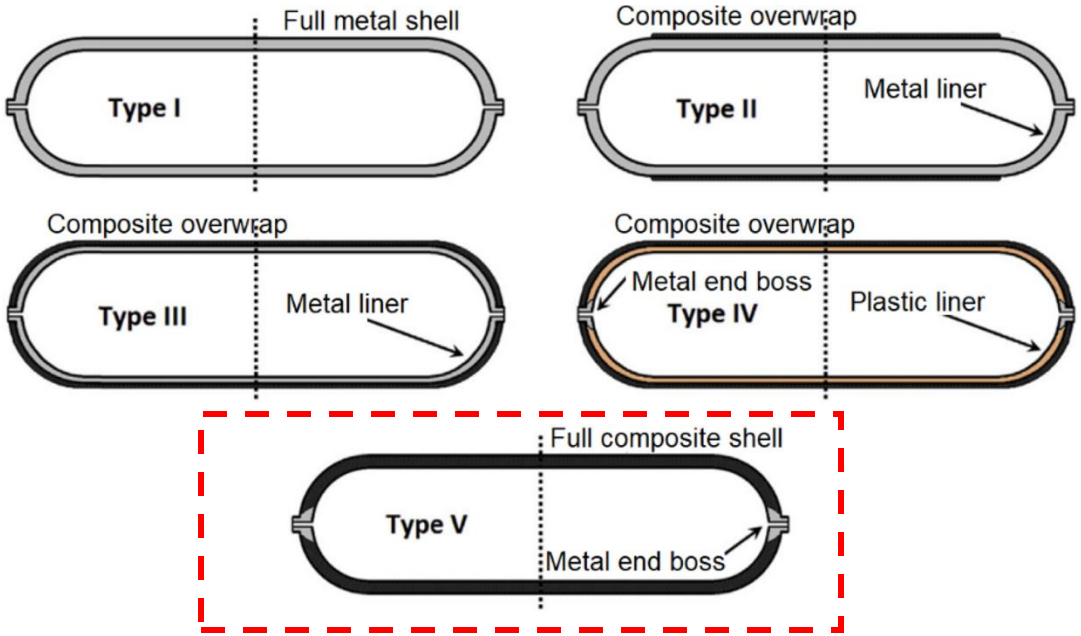
<Retention of Nanofibers after Plasma Treatment>



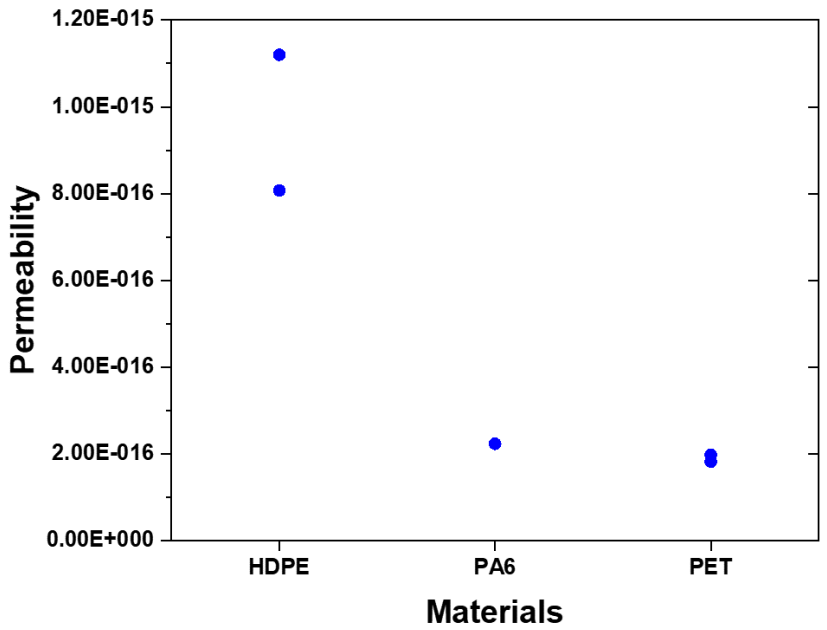
<Increased Short Beam Shear Strength with Plasma PET>

Future Work – Dynamic Mechanical Analysis (DMA)

- Dynamic Mechanical Analysis (DMA) in **dual-cantilever mode** will be conducted to evaluate composite modulus.
- Temperature sweep from –100 °C to 300 °C compared the **low-temperature modulus and glass-transition temperature (T_g)** of baseline, PET-interleaved laminates, and **PA-interleaved laminate** (Xantulayr, XLB) will be added for comparison.
- DMA measurements will be repeated after 500 liquid-nitrogen cryogenic cycles to assess modulus retention.
- **$[0/90]_{4S}$** layup with IM7/8552 prepreg is chosen to maximize coefficient-of-thermal-expansion mismatch during cycling.



<DMA 850 (TA) – Dual Cantilever>



<Cryogenic Cycle>

Future Work – Permeability Measurements

- Higher **post-cycling storage modulus** of PET-interleaved laminates compared to baseline laminates demonstrates their **suitability for reusable space-launch structures**.
- Future work will focus on **permeability tests of PET interleaved composites** for use in **Type V composite overwrapped pressure vessel** (COPV), focusing on **low hydrogen permeability of PET** while being **capable of multiple use**.

ABSTRACT

In this work, we demonstrate an alternative strategy for enhancing the mechanical performance of carbon fibers by incorporating polyphenylene sulfide (PPS) into carbon nanotube (CNT)-based systems via a CSA-assisted wet-spinning approach. PPS, typically insoluble and highly crystalline, was successfully processed to form composite fibers, which exhibited significant improvements in tensile properties following thermal treatment. The results indicate the effectiveness of PPS incorporation without traditional stabilization steps. This method may provide a scalable and cost-effective route for multifunctional carbon fiber production.

1 INTRODUCTION

Carbon nanotube (CNT) fibers have gained recognition as a potential next-generation carbon fiber due to their outstanding mechanical and electrical properties [1-6]. Efforts to enhance CNT fiber performance have primarily focused on increasing CNT length or crystallinity, but these strategies face thermodynamic and practical limitations [7-8]. As an alternative, researchers have begun incorporating other carbon materials or polymers into CNT fibers to leverage synergistic effects and reduce reliance on costly CNTs [9-11].

Wet-spinning of CNT fibers using chlorosulfonic acid (CSA) offers a versatile platform, as CSA can not only dissolve CNTs but also sulfonate otherwise insoluble polymers [10-16]. This enables the co-processing of CNTs with sulfonated polymers into composite fibers. These sulfonated polymers are advantageous in that they can generate radicals during pyrolysis, which in turn form covalent bonds with CNTs—either between CNTs themselves or between CNTs and polymer chains [17-20]. This radical-mediated crosslinking enhances the structural cohesion and mechanical integrity of the resulting carbon fibers [21-24].

Carbon nanotube (CNT) fibers have attracted considerable attention as a new class of carbon fiber materials due to their exceptional electrical, thermal, and mechanical properties. However, their broad commercialization remains constrained by high production costs and technical limitations related to CNT alignment and interfacial bonding. Recent approaches have explored hybridization with polymers to enhance spinnability, reduce cost, and improve mechanical integrity.

Among these, poly(p-phenylene sulfide) (PPS) presents a promising option due to its aromatic backbone and high carbon yield upon pyrolysis. Despite its poor solubility in most solvents, PPS can be sulfonated and processed in chlorosulfonic acid (CSA), forming anisotropic liquid crystalline dopes in combination with CNTs [25-30]. This co-processing enables the fabrication of CNT–PPS composite fibers via wet-spinning. Upon carbonization, the composite fibers benefit from radical-mediated crosslinking between PPS and CNTs, potentially improving the mechanical integrity of the final carbon fiber.

In this study, we examine the structural and mechanical evolution of CNT–PPS fibers as a function of PPS content and heat-treatment temperature. Our goal is to establish processing–structure–property relationships that support the design of high-performance CNT-based carbon fibers using PPS as a functional additive and carbon source.

2 RESULTS AND DISCUSSION

The wet-spinning process allowed for uniform mixing of CNTs and sulfonated PPS (sPPS), forming composite fibers with smooth morphology and good spinnability even at high PPS loadings. Following drying and heat treatment, structural transformations such as de-sulfonation and crosslinking led to noticeable changes in fiber morphology and density.

Thermal analysis revealed that sPPS enhanced the thermal stability and char yield of the composite fibers. This was attributed to the generation of radicals during thermal decomposition, which promoted covalent bonding within the fiber structure. These interactions supported better structural coherence and higher carbon retention.

Mechanical testing showed that the incorporation of PPS improved tensile strength and modulus after carbonization. An optimal PPS content of around 30 wt% yielded the best performance, balancing reinforcement from PPS-derived carbon with effective load transfer through CNT-PPS bonding. Excessive PPS content, however, led to turbostratic structures and reduced mechanical integrity due to misalignment and void formation.

Small-angle and wide-angle X-ray scattering analyses confirmed that increasing PPS disrupted CNT alignment, which impacted the modulus. Transmission electron microscopy further visualized turbostratic carbon domains originating from sPPS, which were distinguishable from CNT regions.

Overall, the combination of PPS and CNTs, processed through CSA-assisted wet-spinning and tailored heat treatment, enabled the production of carbon fibers with improved mechanical properties and structural integrity. The findings highlight the importance of optimizing composite composition and processing conditions to maximize performance.

4 CONCLUSIONS

This study demonstrated a practical route for manufacturing CNT-based composite carbon fibers by incorporating sulfonated PPS through a liquid crystalline wet-spinning process. The fibers exhibited improved mechanical properties after controlled thermal treatment, attributed to enhanced carbon yield and covalent interaction between CNTs and PPS. The optimized composites balanced CNT alignment with polymer-derived carbon reinforcement, resulting in high-performance structural materials. This approach holds promise for scalable and cost-effective production of next-generation carbon fibers

ABSTRACT

The discovery of new carbon allotropes has led to major advancements in materials science, as each new form of carbon has unique properties that can lead to new applications. The variety of structures and characteristics existing in carbon allotropes provides unprecedented mechanical, electrical, and thermal properties. However, even though these new forms are revolutionary, their synthesis process is difficult. The production processes are complex and often need extreme conditions or highly specialized production techniques, which make their production and application challenging.

A recent milestone in this field has been the identification of the hexagonal carbon allotrope RH6-II developed through a novel morphing mechanism in graphene nanostructures, which represents a significant shift from traditional sp^2-bonded carbon structures, introducing a hybrid bonding configuration of sp^2 and sp^3 carbons. This new structure showed unique atomic arrangements that differentiate it from conventional graphene or diamond structures. In this work, we build upon these findings by investigating the effect of the incorporation of RH6-II allotrope within polymeric composites. Given the increasing electrical conductivity with RH6-II content, these nanostructures hold potential for applications in structural composites, where both mechanical reinforcement and enhanced electrical properties are desirable. Future improvements in RH6-II production yield could further facilitate its use in various composite applications.

1 INTRODUCTION

The research for innovative carbon-based reinforcements for structural and functional purposes is one of the most advanced frontiers of materials science. During the past half century, the discovery of fullerenes [1], carbon nanotubes (CNTs) [2] and graphene related materials [3] has dramatically changed the world of research. Nevertheless, the carbon family has recently grown by adding a new carbon allotrope named morphed graphene [4-6]. Morphed graphene, shown in Figure 1, is composed of

distorted covalently cross-linked graphene layers bonded with a sp^2 hybridization but a sp^3-like arrangement. Among its phases, morphed graphene RH6-II phase is a rippled structure emerging when graphene sheets undergo mechanical deformation induced by compressive strain promoted by ball milling [4]. RH6-II phase is formed as a result of energy minimization under strain when the pristine graphene buckles rather than stretches further or tear. This structural change decreases the overall elastic energy of the system leading to a stable, non-planar configuration. Though the atomic connectivity of graphene remains intact, the out-of-plane deformation significantly alters its physical properties. Electronically, the RH6-II morphology can induce changes in the band structure of graphene. Local curvature generates strain fields that open small bandgaps or produce pseudomagnetic effects, which are absent in pristine graphene.

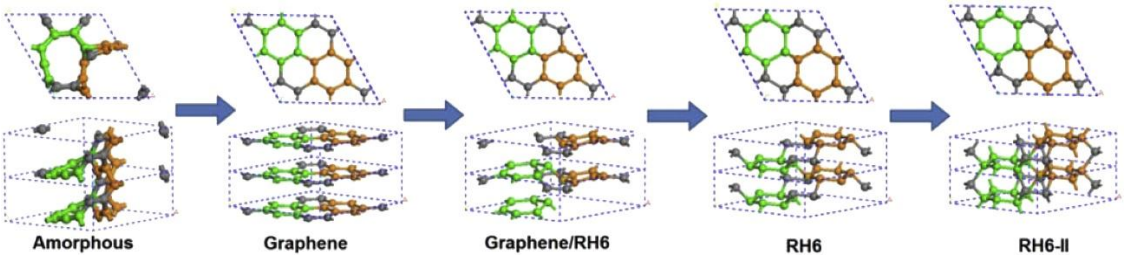

Figure 1: Mechanical synthesis of morphed graphene. Reprinted with permission.

Morphed graphene is characterized by astonishing properties as mechanical reinforcement agent in a wide range of matrices in concentrations ranging from 1 wt% up to 5 wt.% [7-10] showing mechanical properties improvements of up to 2 orders of magnitude with an increase of 73%, 25% and 250% in elastic energy ratio, hardness and toughness [7-11]. On the other hand, morphed graphene electrical properties are not well described and actually neglected in the composite science. Accordingly, this work will investigate the electrical properties of morphed graphene containing polymeric composites in both DC and AC regimes also considering how the surface properties are changing in a wide range of filler concentration.

2 MATERIALS AND METHODS

2.1. MATERIALS

The morphed graphene was manufactured using PetCoke a very abundant oil-and-gas soot byproduct. The PetCoke was ground in a Nutribullet® for periods of 1 minute at a time until fine powder (-150 mesh) was produced. The fines are collected and milled for periods of 1 h to 10 h in a Spex mill. The final product is morphed graphene (MG). The Spex procedure was previously reported in [4, 5, 12].

Poly(vinylbutyral)(PVB) was purchased by Sigma Aldrich and used without any further purification.

Composites were prepared by mechanically mixing morphed graphene with PVB in acetone and cast into molds until the solvent was evaporated.

2.2 CHARACTERIZATIONS

Raman spectroscopy was performed using a Renishaw inVia spectrometer (H43662 model, Gloucestershire, UK) equipped with 514 nm laser line with a 100× objective. Raman spectrum was recorded in the range from 250 cm^{-1} to 4000 cm^{-1}. Raman spectrum was fitted by using the methodology proposed by Tagliaferro et al. [13].

Morphed graphene morphology was studied by using a field emission scanning electron microscope (FESEM, Zeis SupraTM40, Oberkochen, Germany) equipped with an energy dispersive X-ray detector (EDX, Oxford Inca Energy 450, Oberkochen, Germany).

XRD analysis were run on a powder sample using aPanalytical X'PERT PRO PW3040/60 diffractometer, with Cu K αradiation at 40 kV and 40 mA, Panalytical BV, Almelo in the 2θ range from 10 to 80 °with a step size of 0.013 °.

The wetting properties were investigated by optical contact angle (OCA) measurements with the sessile drop technique, using an OCAH 200 (DataPhysic Instruments). Two different liquid probes were used: water (H_2O) and diiodomethane (CH_2I_2). Each liquid drop (1 µL in volume) was dispensed, and the image of the drop on the sample was acquired with the integrated high-resolution camera. The drop profiles were extracted and fitted with dedicated software (SCA20) using the Young-Laplace method, and contact angles at the liquid-solid interface between fitted function and baseline were calculated. For each sample and each liquid probe, the contact angle measurement was repeated three times on different areas. The polar and dispersive components if the surface energy were evaluated by applying the Owens-Wendt method [14].

The DC electrical conductivity of the composites was measured at room temperature (295 K) by electrically contacting the composite samples in the four-point van der Pauw configuration by using thin gold wires and conducting silver paste (RS Components, Sesto San Giovanni, Italy). The resistance of each van der Pauw configuration was measured using the four-probe resistance option of a 34410 multimeter (Keysight Technologies, Santa Rosa, CA, USA). The conductivity was then calculated as $\sigma = R_s^{-1}t^{-1}$, where R_s is the sheet resistance obtained by solving the van der Pauw equation, and t is the thickness of the material.

The complex permittivity of the samples was measured in the GHz range by means of a cylindrical coaxial cell (EpsiMu toolkit [15]), containing the sample as a spacer between inner and outer conductors, whose diameters are 0.6 cm and 1.3 cm, respectively. Two conical parts link the cell to standard connectors, allowing it to keep the characteristic impedance to 50 W, thus avoiding mismatch and energy loss. The cell is connected to a ZVK Vector Network Analyzer (Rohde & Schwarz GmbH, Munich, Germany), suitably calibrated, and measurements are analyzed with a two-port transmission line technique. The electromagnetic properties of the sample are determined by de-embedding and the Nicolson-Ross-Weir transmission/reflection algorithm [16, 17].

3 RESULTS

3.1 Physico-chemical properties of MG and related composites

Morphed Graphene was analyzed using Raman spectroscopy in the range from 250 cm^{-1} to 4000 cm^{-1} as reported in Figure 2.

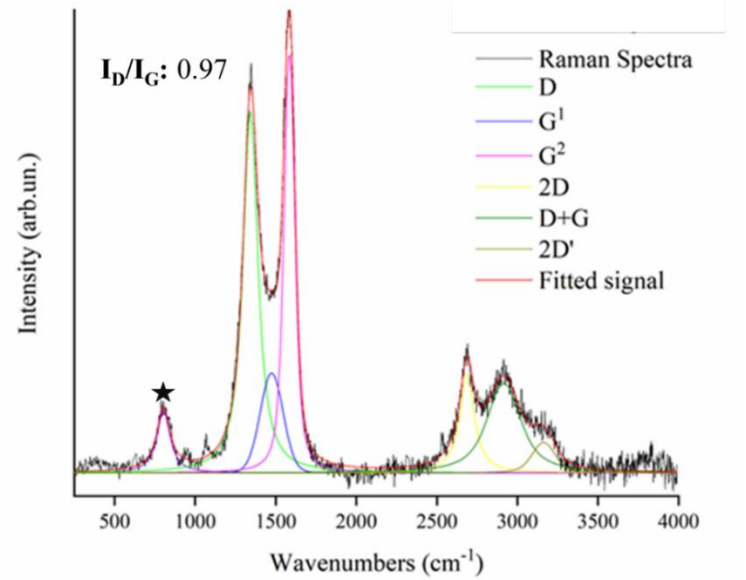

Figure 2: Raman spectra of morphed graphene in the range from 250 cm^{-1} to 4000 cm^{-1} fitted accordingly with the procedure reported by Tagliaferro et al.[13]

As shown in Figure 2, the D and G peaks are represented by a component (named D) centered at 1343 cm^{-1} and two components named G^1 and G^2 centered at 1480 cm^{-1} and 1580 cm^{-1} respectively [18]

while the 2D region is composed by three components known as 2D, D+G, 2D centered at 2687, 2915 and 3163 cm^{-1} respectively. According to Shimoidara et al. [19], the G^2 peak is originated from graphitic domains characterized by a high order of bond angle while G^1 arises from amorphous domains with greater disorder. The ration between G^1 and G^2 can be used for the evaluation of bond angle disorder and morphed graphene is characterized by a value of 0.41 inferior that is considerably lower than non-activated carbon black that is close to 0.6 [19]. This suggest that the milling process promotes a greater angular order, as also evidenced by the ID/IG ratio of 0.97. Such a value suggests the presence of a long-range structural order, comparable to that observed in non-graphitizable carbon treated at high temperatures [20-29]. Moreover, the calculated volumetric crystallite size L_a is 17.2 nm [30]. It is also noticed the presence of a peak centered at 863 cm^{-1} (marked with a star) due to iron oxide trace or organic-rich residue from the original pet coke [31].

Morphed Graphene was analyzed using XRD spectroscopy in the range from 10° to 80° as reported in Figure 3.

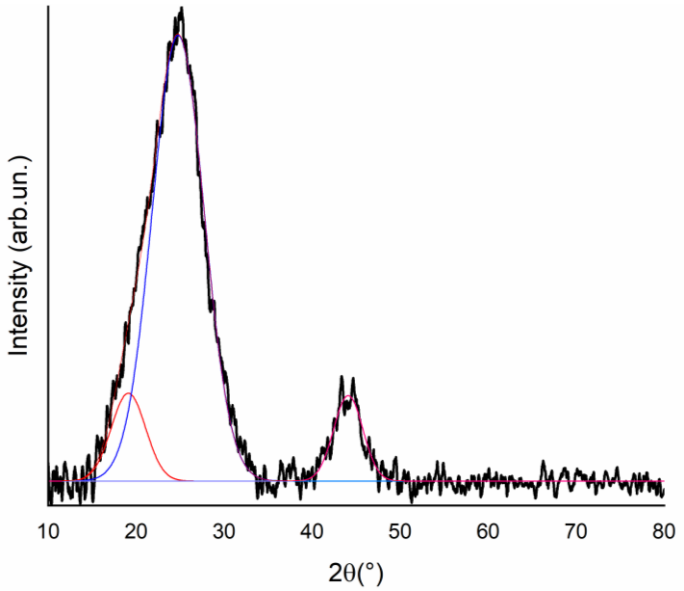

Figure 3: XRD spectra of morphed graphene between 10 to 80°.

XRD spectra show three large components centered at 19.1, 24.7 and 44.1° respectively as reported by Calderon et al. [4] due to different lattice modes. Using the component at 24.7° (basal lattice mode), RH6-IIa phase with a crystallite size of 1.52±0.29 nm calculated using Scherrer equation [32] in agreement with TEM data reporter by Calderon et al. [4].

The morphological analysis reported in Figure 4 showed the presence of round shaped particles with an average size of 41±6 nm and a carbon content of up to 90.2 wt.% and an oxygen amount of 9.8.

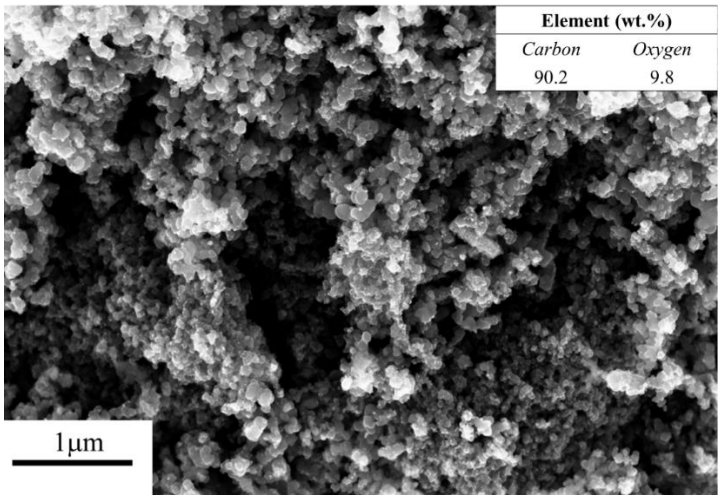

Figure 4: Morphological and elemental analysis of RH6-II.

For both atmosphere (air and argon, see Figure 5) the TGA of morphed graphene have a weight loss between 25 and 100 °C due to the moisture of the sample. In air atmosphere there is a significant weight loss starting around 350 °C, with a rapid decomposition occurring up to approximately 550 °C, after which the weight stabilizes, indicating complete degradation of the combustible components. This sharp weight loss suggests oxidative degradation. In contrast, under an argon atmosphere, the weight loss is more gradual and continues over the entire temperature range. This indicates that in the absence of oxygen, the material decomposes more slowly, likely through pyrolysis rather than combustion. Overall, the data highlights the strong influence of the atmospheric environment on the thermal degradation behavior of the material.

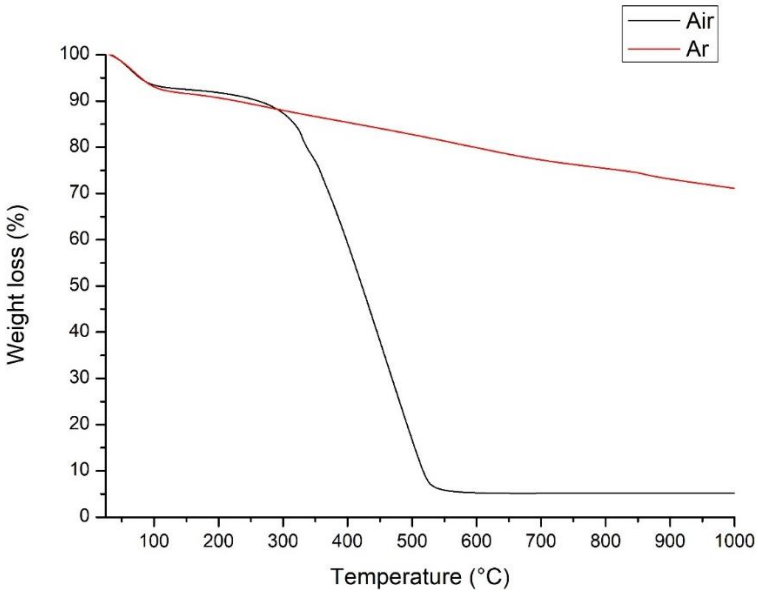

Figure 5: Thermogravimetric analysis (TGA) of morphed graphene in argon and air condition.

As shown in Figure 6, the superficial energy of the composite system, determined from contact angle measurements showed a two-regime behavior as a function of RH6-II content. In the low concentration range up to 40 wt.%, the superficial energy remains almost constant at 40 mN/m, indicating that the addition of RH6-II does not significantly alter the wettability of the composite surface. This suggests that RH6-II particles were either well embedded within the PVB matrix or did not form a continuous

surface layer that modifies the overall surface chemistry. Above a threshold concentration of 50 wt.%), a sharp increment in superficial energy was observed together with a strong linear dependence on RH6-II content ($R^2 \approx 0.98$). This drastic change supported a percolation-like behavior where RH6-II particles begin to dominate the surface properties. The structure of RH6-II, characterized by a hierarchical arrangement of conductive domains and amorphous regions, plays a crucial role in this transition. At low concentrations, the polymer matrix drives the surface properties whereas at high concentrations, RH6-II's intrinsic surface chemistry, including its potential oxygen-containing functional groups and rough morphology, enhance the surface energy.

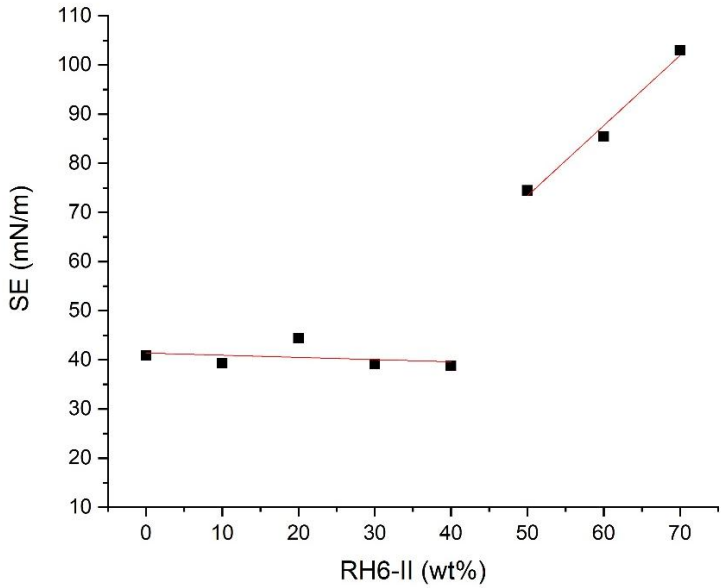

Figure 6: Contact angle measurement of RH6-II loaded PVB composites.

As shown in Figure 7, the DC electrical conductivity measurements revealed clear percolative behavior in the PVB-based composites containing RH6-II as a conductive filler. For RH6-II loadings lower than 10 wt.%, no measurable conductivity values were obtained, and therefore these points are not reported in the figure. This suggests that at such low filler content, the RH6-II particles remain too isolated to establish conductive paths, and the composite maintains an insulating behavior similar to that of neat PVB (1×10^{-13} S m^{-1} {Roy, 2014 #500}) due to the too dispersed filler particles being unable to form percolating conductive pathways. A dramatic increase in DC conductivity by nearly 10 orders of magnitude ($6.6\pm2.7\times10^{-4}$ S m^{-1}) was observed at a RH6-II loading of 10%, which indicates the successful establishment of a percolative conductive network across the sample. Increasing the filler content up to a RH6-II loading of 50% results in a further increment of the DC conductivity by another order of magnitude (up to a value of $8.9\pm0.4\times10^{-4}$ S m^{-1}) with no sign of saturation. Indeed, the inset to Figure 6 shows that the experimental conductivity values as a function of the filler concentration are in fair agreement with the expected behavior for a percolative network

$$\sigma \propto (x - x_c)^{\beta}$$

where σ is the DC conductivity, x is the concentration of conductive particles, x_c is the critical concentration for percolation, and β is the percolation exponent. The fit to our experimental data gives $\beta \approx 1.5$, as expected for a standard three-dimensional network {Kirkpatrick, 1973 #501} and indicates that the improvement in conductivity can be largely ascribed to an increment in the percolation probability in the entire RH-II loading range. As the filler content exceeds 50 wt.%, conductivity may approach saturation, resembling the behavior of a conductive network with an insulating phase dispersed within it. Compared to other conductive fillers, RH6-II provides distinct advantages: whereas graphene offers high conductivity, its dispersion in polymer matrices is challenging, and sedimentation can disrupt electrical continuity. Carbon black, on the other hand, consists of nanometric spherical particles with lower intrinsic conductivity than RH6-II, requiring higher loadings to achieve percolation. The observed

percolative behavior in RH6-II-based composites confirms its potential as an effective conductive filler, with possible applications in electromagnetic shielding, EMI attenuation, and flexible electronics.

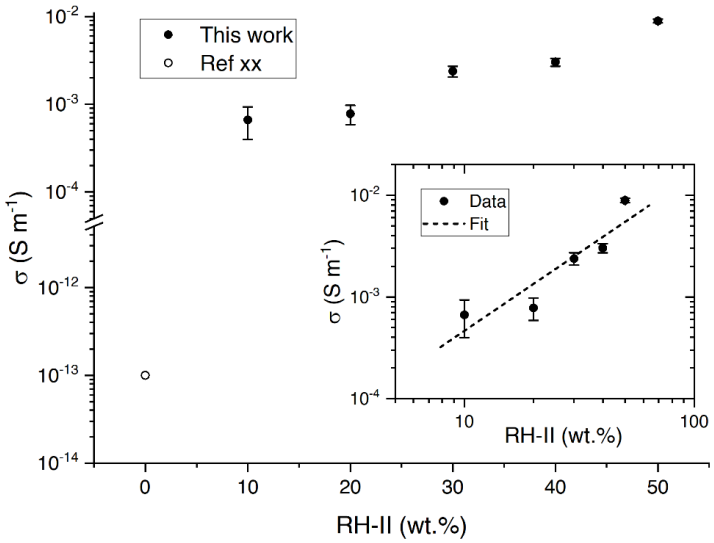

Figure 7: DC electrical conductivity of RH6-II loaded PVB composites in ambient conditions (filled circles) and literature value for neat PVB (hollow circle) {Roy, 2014 #500}. Inset shows the same data in bilogarithmic scale (filled circles) with the fit to standard percolation theory (dashed line).

3.2 Modelling of shielding properties of MG containing composites

The electromagnetic shielding properties in the GHz frequency range can be modelled starting from the microwave characterization, in terms of the complex permittivity $\varepsilon = \varepsilon' - j\varepsilon''$. The real part of the permittivity for the reference PVB is shown as a function of frequency in the lower panel of Figure 8, while its increments $\Delta\varepsilon'$ in composites with different RH6-II contents – with respect to the neat material – are shown in the upper panel.

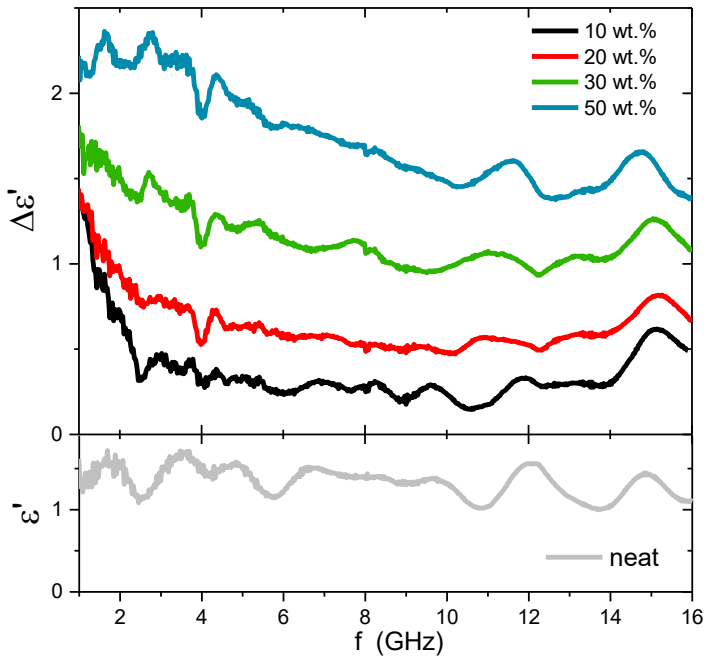

Figure **8**: Real part of the complex permittivity for the reference PVB sample (lower panel) and its increments in composites with different RH**6**-II contents (upper panel).

The AC conductivity σ is related to the imaginary part of the permittivity by $\varepsilon'' = \sigma/\omega\varepsilon_0$. In Figure **9**, the AC conductivity as a function of the RH**6**-II content, obtained at different frequencies, is compared to the DC conductivity already reported in Figure 7.

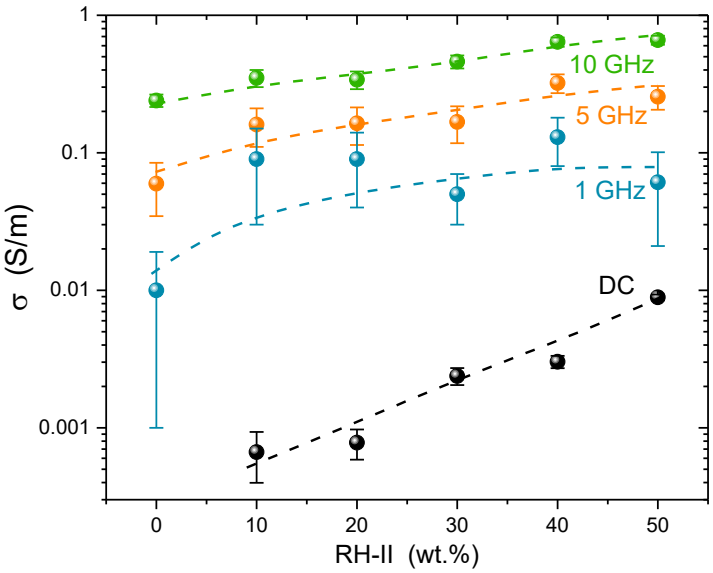

Figure **9**: DC and AC conductivity for composites with different RH-II contents. Lines are guides to the eye.

Finally, the ratio of the imaginary to the real part of the complex permittivity gives the loss tangent, that can be used together with the conductivity in the formulae reported in Ref. 28 to calculate the overall electromagnetic shielding efficiency

$$\boldsymbol{SE = 10\, log_{10}\left(\frac{P_i}{P_t}\right)}$$

as a sum of absorption, reflection, and multiple-reflection contributions (here, $\boldsymbol{P_i}$ and $\boldsymbol{P_t}$ are the incident power and the power transmitted through the shield, respectively). It turns out that the dominant term is the absorption one, and that a significant shielding efficiency can be obtained at frequencies above about 3 GHz (Figure 10).

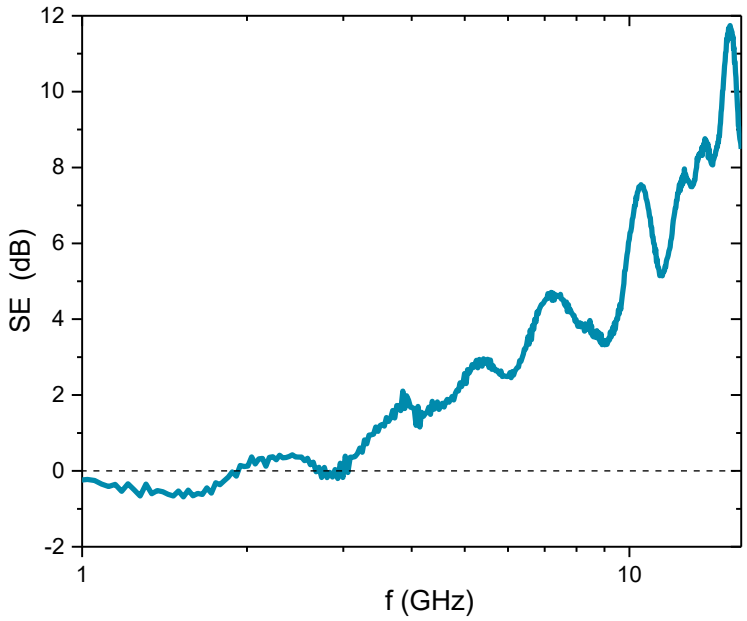

Figure 10: shielding efficiency for a 10-mm-thick composite with RH6-II content of 50 wt.%, as a function of frequency.

4. CONCLUSIONS

In this study, we investigated the electrical properties of RH6-II in both AC and DC regimes by incorporating morphed graphene into a filmable polymeric matrix. The analysis of physicochemical properties allowed us to draw a complete picture of the exotic RH6-II supporting our further considerations based on solid structural insights. Electrical analysis highlighted a stable charge transport mechanism over the examined frequency domain with SE dominated by absorption mechanism. The evaluation on a 10 mm RH6-II based composite showed that SE increased significantly above 3 GHz supporting the utilization of these species for high-frequency electromagnetic interference in which multiple layers of the composites are added. Accordingly, these materials can be used in aerospace layered composites as engineered connection layers between structural ones or in advanced communication devices such as those operating using 5G technology and electronic components that demand robust EMI protection without requirements of thickness. Furthermore, the combination of mechanical flexibility and processability of these composites together with their SE properties can find application in smart devices for biomedical applications including in vivo sensors due also to the high surface energy that can prevent the proliferation of bacterial biofilm.

ABSTRACT

The promise of state-of-the-art-fiber reinforced composites containing carbon nanotube-grafted-carbon fibers has been in development since the early 90s. The main hurdle to manufacturing a hierarchical reinforced composite coupon/component, is the volume of modified fibers required. This requirement, is in turn dependent on repeatable, well-controlled and robust growth regime to ensure that the carbon nanotube coverage is uniform and consistent along the fibers, and subsequently throughout the composite. Failure to ensure that the modification is constant can result in stress concentrations in the regions of the fibers with variable length/coverage. Whilst there has been some limited development in woven fabrics being modified by growing carbon nanotubes in closed chemical vapor deposition (CVD) tubular reactors; to achieve a route towards industrial scale-up modification of the fiber tow is required, as well an open CVD reactor to facilitate the fibers being passed through the reactor unimpeded making the process continuous. The production of spool-to-spool open CVD on whole carbon fiber tows has been reported previously, but with limited evidence of prolonged and robust conditions, or a constant carbon nanotube-grafted-carbon fiber product over tens or more meters. Presented here are results of optimizing the carbon nanotube growth process on carbon fiber 12K tow in a bespoke open CVD reactor.

1 INTRODUCTION

The incorporation of high-performance nanomaterials like carbon nanotubes (CNTs) at the critical fiber-matrix interface in composites have been proposed to address an inherent weakness. One method to introduce these nanomaterials at this particular interfacial region is to produce hierarchical fibers (exhibiting two length scales of reinforcement), for example carbon nanotubes grafted/grown on the surface of carbon fibers (CNT-g-CFs). Particularly promising is the improved apparent interfacial shear strength of the fiber-matrix interphase of CNT-g-CFs with thermoplastic matrices shown at the single fiber level (+53%, polypropylene) when compared to an unsized carbon fiber baseline [1].

Yet, the increased production of hierarchical fibers is a challenge due to growth conditions for CNTs necessitating high temperatures and an inert environment, further complicated because carbon fibers are susceptible to damage in the process [2]. Parameters were identified to synthesize CNT-g-CF without loss of performance of the underlying fiber at the 12K tow level and in a continuous process (spool-to-spool) [3], and attention turned to increasing the scale of production. CNT chemical vapor deposition (CVD) growth conditions are notoriously sensitive to activation/reduction gases, availability of carbon feedstock as well as the catalysts composition/loading on the substrate, additionally influenced by the temperature on reaction rates and catalyst wettability kinetics; and in a continuous in-line process the fiber pull-through rate which is linked to dwell duration in reduction/growth regions. Achieving robust production of CNT-g-CFs for a prolonged duration and to modify a significant length of tow has therefore been difficult.

We present our latest work using a reaction snap-shot methodology developed from [4], which was employed to glean information at various positions inside the reactor. With these insights, reactor conditions were altered and extended CNT-g-CF production achieved with controlled lengths of 300 to 1000 nm growth of multiwalled CNTs with diameters ~10 nm (+30 m 12K tow, 16 h in a single session). To fully evaluate the CNT-g-CF we developed a protocol which was reliable and provided an unbiased evaluation (using sections of up to 10 m long 12K tow). The protocol included a machine learning evaluation script inspecting electron micrographs and determining if CNTs were present on the fiber surface and the whole tow was examined to determine intra-tow regions (and full coverage of nanotubes). Average CNT coverage (uniformity) along the length of tow was evaluated through global methods for example, additional weight gain from CNT growth which was correlated to gas sorption analytical analysis (specific surface area). Mechanical properties of composites made wholly from CNT-g-CFs will also be presented at the conference.

2 MATERIALS AND METHODS

- Polyacrylonitrile (PAN)-based unsized carbon fiber (AS4-12K-7D, HS-CP-5000 grade) with diameter of 7.1 μm was supplied by Hexcel Composites (Duxford, GB), and used as a continuous tow of 12K fibers.

- The precursor bi-catalyst solution for carbon nanotube synthesis consisted of nickel (II) acetylacetonate (≥98%, VWR, GB) and iron (III) nitrate nonahydrate (≥98% ACS reagent, Merck, DE) in ethanol (96%, Brenntag, AT) in a 1:0.64 mol, respectively.

- The carbon source, reduction, and carrier gases for the reactions was acetylene in nitrogen (1.3 vol.% in 98.7 vol.%, respectively), hydrogen in nitrogen (2.4 vol.% in 97.6 vol.%, respectively), and nitrogen (99.998 vol.%), respectively. All gases were purchased from BOC gases, GB.

The equipment for CNT deposition and synthesis on carbon fibers is detailed elsewhere [3] and open CVD reactor shown in Figure 1. In short, unsized CFs were used as received, and then pre-deposited at a rate of 20 m/h with an in-line plasma oxidation pre-treatment, a bi-catalyst with a residence duration of 1 min and dried at 40 °C and 70 °C, producing approx. 200 m of treated tow. The collected and spooled precursor bi-catalyst deposited CFs were then passed, in inert conditions, through an open chemical vapor deposition reactor at 550 °C at varied at pull-through speeds of 1.92 m/h and 3.36 m/h

and subjected to reaction gases. After an initial inert gas sleeve, sequential regions of reaction gases for reduction (to activate the bi-catalyst), and a carbon rich gas (to grow the carbon nanotubes), and finally a second inert gas sleeve where the modified fibers were collected on a motorized spool. Fiber morphology was characterized by scanning electron microscopy (SEM), using a Zeiss Sigma 300 (DE) at an operating voltage 5 keV where whole 12K section of carbon fiber samples were sampled. ImageJ software (version 1.52p, NIH) [6] was used for image analysis. The specific surface area of samples was characterized following ISO 9277 Standard with gas sorption isotherms using nitrogen using a Quantachrome NOVAtouch gas sorption analyser (Anton Paar gmbH, AT) with Quantachrome TouchWin software (version 1.22, Anton Paar gmbH, AT) and BET (Brunauer, Emmett and Teller) method used to analyze collected data.

3 RESULTS

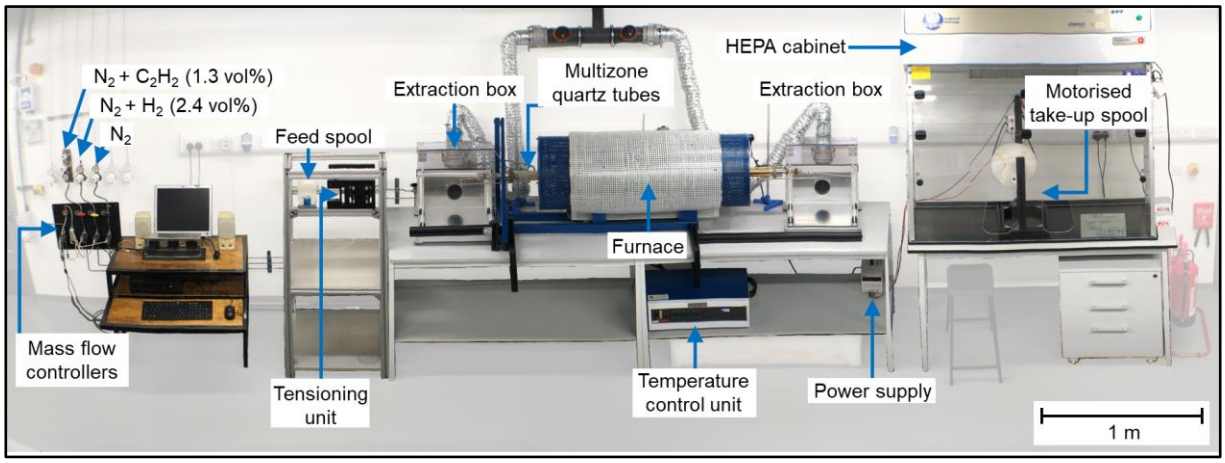

Figure 1: Overview of open CVD reactor showing continuous spool-to-spool configuration.

Figure 2: An example spool of CNT-g-CF used to determine the weight percentage of carbon nanotubes on the fiber after synthesis on open CVD line (12 m).

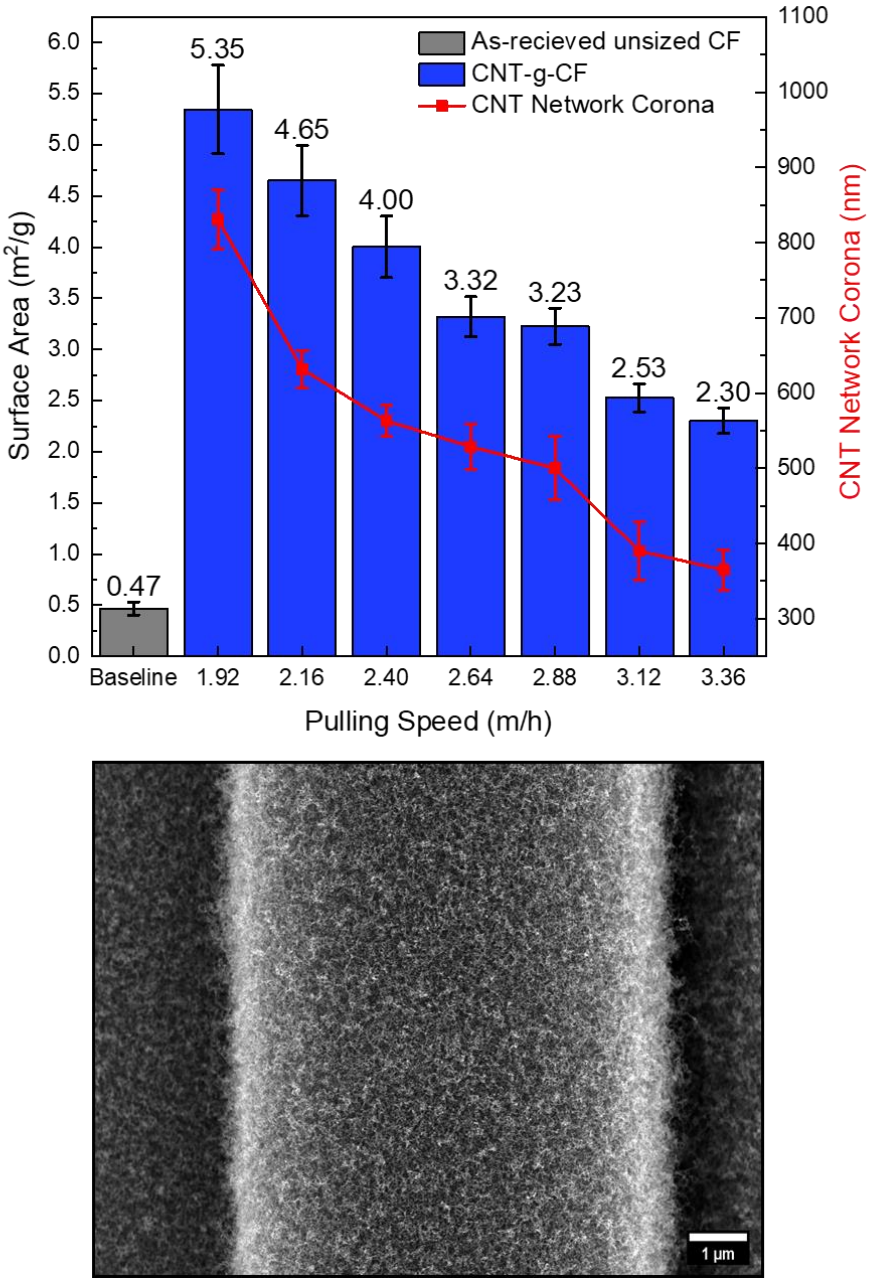

Figure 3: Top, Specific surface area measurements and CNT network corona length as a function of varying pull-through speeds, and Bottom, SEM micrograph of CNT-g-CF at a pulling speed of 1.92 m/h. Adapted from [5].

Sample	Specific surface area (m^2/g)	CNT weight percentage (wt. %)	CNT perpendicular thickness to fibre/corona (nm)
As-received unsized carbon fibre	0.47 ± 0.05	NA	NA
CNT-g-CF (1.92 m/h)	5.35 ± 0.38	2.9 †	856 ± 91
CNT-g-CF [ref. 3, y2020]	0.53 ± 0.05	0.1 *	126 ± 69

Table 1: Comparison between as-received fiber and previous CNT-g-CFs with optimized CNT-g-CF growth. Specific surface area determined BET analysis, relative increase in CNTs grown on the fiber surface as a weight percentage with † weight percentage determined though weighting spool using a balance and +10 m of modified 12K tow, * from ref. 3 weight percentage using specific surface area and geometric considerations and a specific surface area estimate of CNTs of 260 m^2/g to determine relative CNT loading (sample length ~0.15 m), and CNT length determined through scanning electron microscopy analysis.

4 DISCUSSIONS

The open CVD reactor conditions including reactive gas flow rates/relative concentrations, temperature, and pull-through speed were changed to determine a stable growth regime of CNTs on the carbon fiber [7]. Further details on the protocols including a machine learning evaluation script inspecting electron micrographs and determining if CNTs are present will also be included in this publication. Stable CNT growth was achieved for a standard modulus commercially available unsized 12K carbon fiber tow over a length +30 m with the specific surface area and weight uptake (Figure 2), and an extensive microscopy analysis was completed. A uniform growth at the currently optimized synthesis parameters produced a CNT-g-CF with perpendicular CNT forest growth ca. 850 nm, which for a ~7 µm fiber diameter will not impact the potential fiber volume fraction in a composite considering ideal hexagonal packing [3, detailed in supplementary information]. Once a baseline set of conditions was established, a second test to determine the effect of varying pull-through rate was performed with CNTs length and specific surface area of the resultant CNT-g-CFs characterized (Figure 3, Table 1). Note that due to the arrangement of the reactor, altering the pull-through rate changed the relative catalyst reduction duration as well as the CNT synthesis duration (inherently linked), which in turn also altered the overall dwell duration in the reactor (in a fixed configuration). When the pull-through speed is altered it is clear that this impacts both the corona length (perpendicular forest height from the fiber surface), and the surface area. These two properties are fundamentally linked as the growth of CNTs provides the main contribution of the specific surface area. Considering that the reduction and the growth duration are currently altered, modification to the CVD parameters for CNT growth could be altered further to increase CNT growth (corona length) or conversely increase pull-through speed for a desired CNT corona length.

A comparison to the previously published results [3], which detailed the initial concept and reactor design, clearly indicates that an improved CNT growth has been achieved, with an increase in CNT weight percentage on the order 250% and an increase in corona length of about 5 times.

5 CONCLUSIONS

The results presented are another step towards the scaled production of carbon nanotube-grafted-carbon fibers. The continued development to increase production of these hierarchical fibers over the past 5 years is clear, and a more robust growth regime with better understanding of the critical carbon nanotube open chemical vapor deposition synthesis parameters have been confirmed. The next stage of development for manufacturing carbon nanotube-grafted-carbon fibers should be directed toward implementation into larger furnaces and full tension creel-controlled systems. Further investigations into hierarchical fiber reinforcement should be made in parallel with larger coupons, and their performance in a range of matrices including thermoplastic and thermoset.

ABSTRACT

Structural batteries [1] combine structural load bearing capabilities with electrochemical functionalities. In order to achieve this dual purpose, the battery must be able to function electrically while sustaining mechanical loads. This work presents a simultaneous electromechanical (SEM) testing of a structural battery pouch cell under three-point flexural load while electrochemical testing. An important component is the current collectors, which are expected to function as conveyors of the electric current generated by the battery's electrochemical reactions, as well as possessing mechanical stiffness. This presentation also describes the selection of carbon fiber-based collectors considering the tensile properties and electrical resistivity of the fabricated current collectors. Current collectors fabricated using 5% PVDF (Polyvinylidene Fluoride) as the polymer matrix is used to fabricate PEO solid electrolyte based structural battery pouch cells employing Lithium Iron Phosphate (LFP) cathode and Lithium Titanium Oxide (LTO) anode, with a cellulose separator. In addition to conventional electrochemical testing of pouch cells, SEM tests are carried out to demonstrate the working of the cell under mechanical load and demonstrate the effect of mechanical loads on electrochemical performance. It is hoped that this and similar SEM tests will contribute to the development of eventual standards for the evaluation of structural batteries.

1 INTRODUCTION

Structural batteries are multi-functional material systems designed to store electro-chemical energy while serving as structural load bearing members of a system such as an electric vehicle. Structural batteries are a potential solution to improve drive range of electric vehicles, drones, etc. According to a study [2], the drive range of an electric car may be increased by 70% with the introduction of structural batteries while maintaining the weight of a vehicle.

Most structural battery prototypes published today employ liquid [3,4] or bicontinuous electrolytes [5–7]. Bicontinuous electrolytes suffer from the ionic conducting liquid phase squeezed out under certain loading conditions such as compression, as reported by Tavano *et al* [8]. In this work, a Polyethylene Oxide (PEO) based solid electrolyte [9] is used for developing the structural batteries. Carbon fibre is widely employed as an electrode in many prototypes and when carbon fibre is employed as an electrode, issues such as the high first cycle capacity loss make it difficult to balance charge capacity of the electrodes which is essential to fabricate full cells. In this work, carbon fibre is employed only as a current collector and Lithium Titanium Oxide (LTO) is used as the anode with Lithium Iron Phosphate (LFP) as the cathode.

Most structural battery research do not report the effect of mechanical loads on electrochemical cycling. This work aims to illustrate the importance of demonstrating the working and quantifying the effect of mechanical loads of structural battery prototypes. First, a suitable current collector is developed and selected for fabricating structural battery pouch cells with PEO based solid electrolyte and LFP and LTO electrodes. The developed prototype is tested in bending to demonstrate the effect of flexural loads on the electrochemical performance of the pouch cell.

2 METHODOLOGY

The development of current collectors by optimizing for the amounts of PVDF and electrically conductive carbon nanotubes (CNT) are discussed in section 2.1. The pouch cell fabrication and electrochemical testing is discussed in section 2.2. The simultaneous flexural and electrochemical testing of the pouch cells is reported in section 2.3

2.1 Current collector fabrication and testing

The carbon fibre based current collectors are fabricated from T300 unidirectional (UD) carbon fibres. The current collector needs to efficiently conduct current and bear loads. In this work since loose carbon fibres are not efficient in bearing various loads, a polymer matrix Polyvinylidene Fluoride (PVDF) is used to develop current collectors in this work termed as CF-PVDF current collectors. PVDF is used since it is a commonly used binder in battery electrode slurries, and known to not have any adverse side-reactions with other chemicals used in battery fabrication. However, PVDF is an insulator, so the quantity of the PVDF deposited must be optimized. Similarly, carbon nanotube suspensions (TUBALL^{TM}) used for improving battery electrode slurries are also applied on bare T300 carbon fibres to fabricate CF-CNT current collectors. The different current collectors fabricated are listed in Table 1.

Table 1: Fabricated composite current collectors

Materials	Sample label
pure Carbon fiber	CF
CF-PVDF made with 1%PVDF-DMF (Dimethylformamide) solution	1%CF-PVDF
CF-PVDF made with 5%PVDF-NMP (N-Methyl-2-Pyrrolidone) solution	5%CF-PVDF
CF-CNT coated twice	CF-CNT-2c
CF-CNT coated once	CF-CNT-1c
CF-CNT coated once and deposited PVDF	CF-CNT-PVDF

The various carbon fibre current collectors were fabricated and tested for their resistance and tensile behaviour as shown in the flowchart in Figure 1 below. The fabrication, testing methods and the development of current collectors are reported in more detail in [10]. The results of the resistance and tensile measurements are summarised in section 3.1 to guide the selection of the current collector.

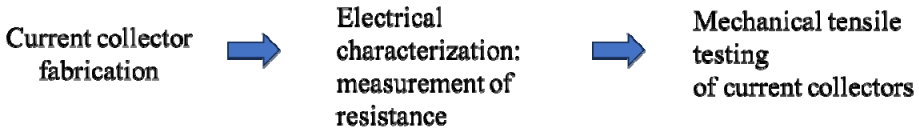

Figure 1: Current Collector development workflow

2.2 Pouch cell fabrication and testing

The LFP and LTO slurries and the PEO slurries are prepared as per the recipes in appendices A1 and A2 respectively. Once the slurries and the electrolyte are prepared, a battery can be fabricated with any of the current collectors described above. In this work, the 5% CF-PVDF current collector was used to fabricate pouch cells and carry out the simultaneous testing of electrochemical and mechanical loads since it exhibited relatively good electrical conductivity, tensile properties and is suitable for pouch cell fabrication, as explained later in section 3.1. Two current collectors (cut to 30-40 mm in length and 10-15mm width) are then coated with LFP and LTO slurries as shown in the leftmost images in Figure 2 and dried in an oven. A cellulose separator is coated with the PEO electrolyte on both sides and dried in an oven. The anode, the cellulose separator infused with the PEO electrolyte and cathode are assembled and placed in a pouch cell film which is partially sealed and vacuum dried at 80°C overnight to remove moisture. The dried pouch cell is then vacuum sealed. The whole fabrication procedure is shown in Figure 2.

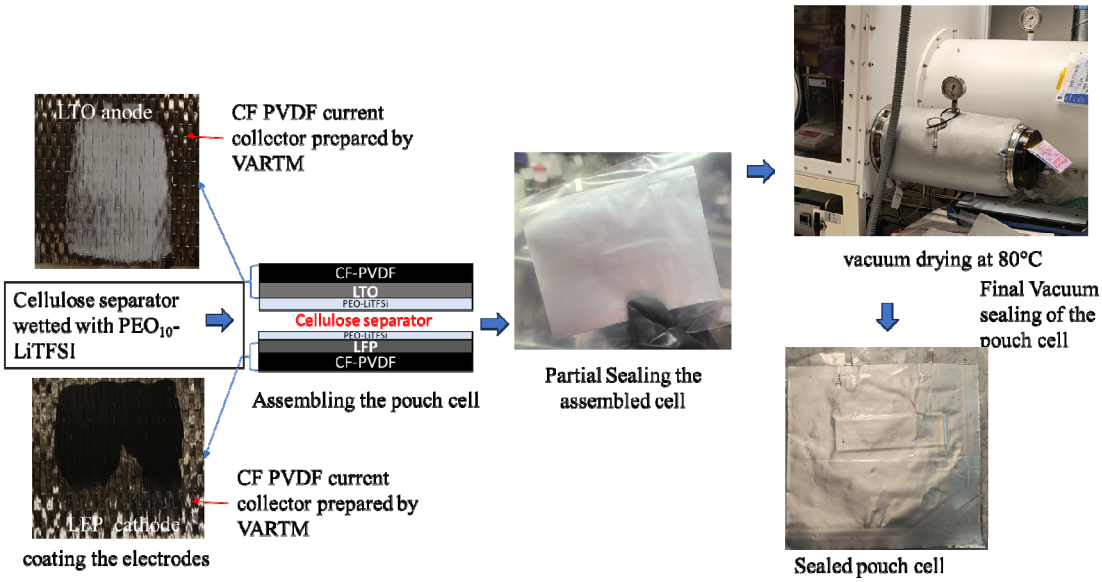

Figure 2: Pouch cell fabrication

The fabricated pouch cell was electrochemically tested at constant current magnitudes corresponding to rates of 0.1C and 0.2C at 60°C. The pouch cells were charged and discharged between 1 and 2.5V. The high temperature electrochemical performance is also compared to the cell's electrochemical performance at room temperature.

2.3 Simultaneous Electro-Mechanical (SEM) testing

Most research work [3–7,11] follows a sequential workflow of designing structural batteries, demonstrating the electrochemical performance of the battery and evaluate the mechanical behaviour (with tensile testing) of the structural battery as shown in Figure 3(c). The demonstration of electrochemical and mechanical performance in isolation (isolated multifunctionality) does not quantify and determine the electrochemical performance of the structural battery under mechanical loads (simultaneous multi-functionality). If structural batteries are to be practically realized, simultaneous electro-mechanical tests as shown in the flowchart in Figure 3(d) are essential to demonstrate that the structural battery can operate under mechanical loads. However simultaneous tests are challenging since the time scales involved in the electrochemical tests (at low charging currents) are long compared to time scales of typical mechanical tests and the lack of test standards.

This work aims to demonstrate the effect of mechanical three-point bend loads on electrochemical performance [12] and that the fabricated structural battery prototype continued operating after the test. The simultaneous electro-mechanical (SEM) testing of the cell was carried out with a set-up shown in Figure 3(a). The set-up comprises a universal testing machine Instron 5848 and NEWARE battery tester. The cell was loaded to an extent such that the pouch cell does not mechanically fail (indicated by a load drop) or electrically short to demonstrate the operation of the cell under load. The loading pin was held at the constant cross head displacement during the SEM test and then subsequently unloaded. The pouch cell with the encapsulation intact loaded in 3 point bending is shown in Figure 3(b).

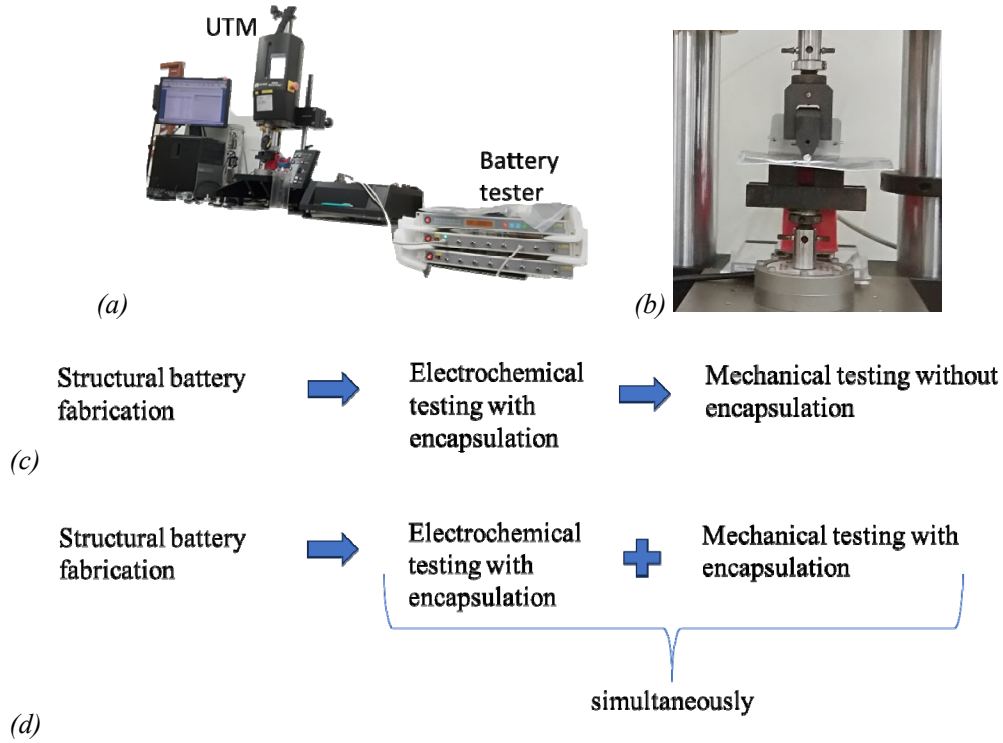

Figure 3: (a) Simultaneous electrochemical-flexural testing experimental set-up;(b) A pouch cell undergoing a 3-point bend test; (c) research work flow of structural battery found in literature; (d) Simultaneous electro-mechanical testing

3 RESULTS AND DISCUSSION

3.1 Current collector selection

In this section, the current collector selection is justified based on the resistivity measurements and the tensile behaviour of the current collectors[10]. The tensile behaviour and resistivity measurements of various current collectors are summarized below.

Current collector tensile behaviour

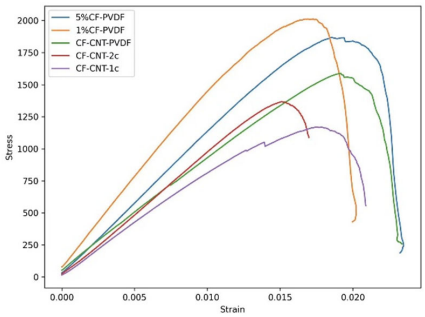

Figure 4: Tensile stress-strain behaviour of different current collectors

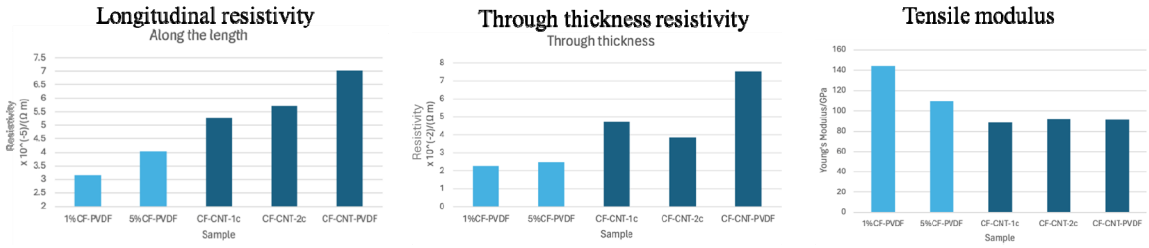
The tensile stress-strain behaviour of various current collectors is shown in Figure 4 and the tensile strength and modulus are tabulated in Table 2. The CF-PVDF current collectors exhibit a higher tensile strength and tensile modulus compared to the CF-CNT current collectors.

Table 2 Tensile properties of various current collectors

Sample	Strength(MPa)	Young's Modulus(GPa)
1%CF-PVDF	1970.9	140.1
5%CF-PVDF	1649.1	104.5
CF-CNT-1c	1246.8	88.5
CF-CNT-2c	1172.9	89.9
CF-CNT-PVDF	1601.2	91.5



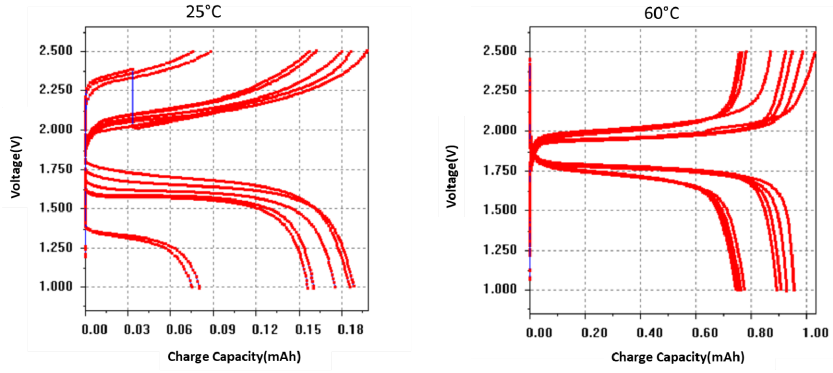
Current collector resistivity

The resistivities of various current collectors are tabulated in Table 3. Despite PVDF being an electrical insulator, the CF-PVDF current collectors exhibit a lower longitudinal (along the fibre direction) and through thickness resistivity compared to the CF-CNT samples. This might be because the CF-CNT current collectors do not have a uniform distribution of the electrically conductive CNTs through the thickness.

Table 3 Electrical resistivity of current collectors along the fibre (longitudinal direction) and the thickness direction

Sample label	Longitudinal resistivity (Ωmm)	Through thickness resistivity(Ωmm)
CF	0.021	48.092
1%CF-PVDF	0.032	22.593
5%CF-PVDF	0.041	24.505
CF-CNT-2c	0.057	38.254
CF-CNT-1c	0.053	46.939
CF-CNT-PVDF	0.070	75.211

Comparison of current collectors



(a) (b) (c)

Figure 5 Comparison of (a) Longitudinal resistivity;(b) through thickness resistivity and (c) Young's modulus across fabricated composite current collector samples

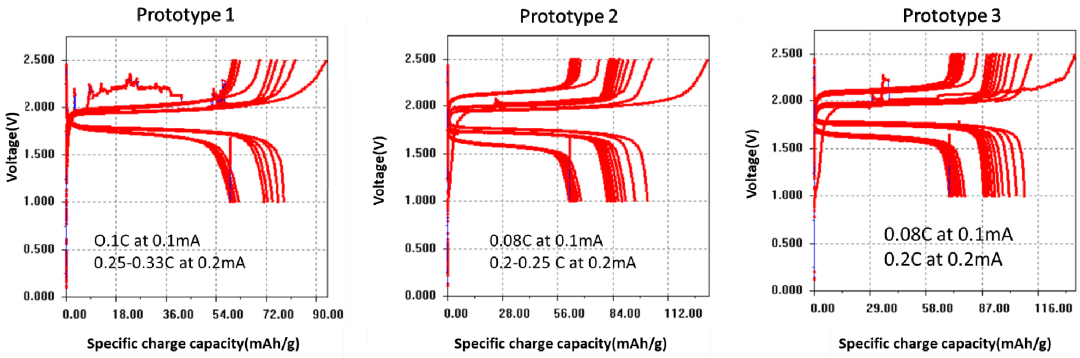
The various current collectors are compared in terms of longitudinal resistivity, through thickness resistivity and tensile modulus in Figure 5. The 1% CF-PVDF current collector exhibit the least resistivity and highest tensile modulus. However, since the various tows of the 1%CF-PVDF current collector samples were not well bonded to one another (Figure 10 in the appendix), it was difficult to fabricate pouch cells with the 1%CF-PVDF current collectors. Instead, 5% CF-PVDF current collectors were used to fabricate the structural battery pouch cells whose electrochemical performance is discussed in the next section.

3.2 Pouch cell electrochemical performance

The pouch cells fabricated were electrochemically tested as described in section 2.2 by charging and discharging between 1 and 2.5V at 0.1C and 0.2C charging rates. The voltage capacity graph of a single pouch cell at room temperature and at 60°C are shown in Figures 6(a) and (b), respectively. The capacity at room temperature is lower than the capacity at 60°C since the ionic conductivity of the PEO based solid electrolyte is sub-optimal at room temperature. The pouch cells' performance at 60°C shows reasonable repeatability as observed from the voltage-specific capacity graphs of three pouch cells in Figure 7, indicating a repeatable battery fabrication process. The capacity fading observed in the prototypes' performance at 60°C is similar to the PEO cells cycled at high temperature reported in literature [13].

(a) (b)

Figure 6: Voltage-capacity behaviour of structural battery pouch cell of the configuration shown in Figure 2 at (a) 25 °C; (b) 60°C



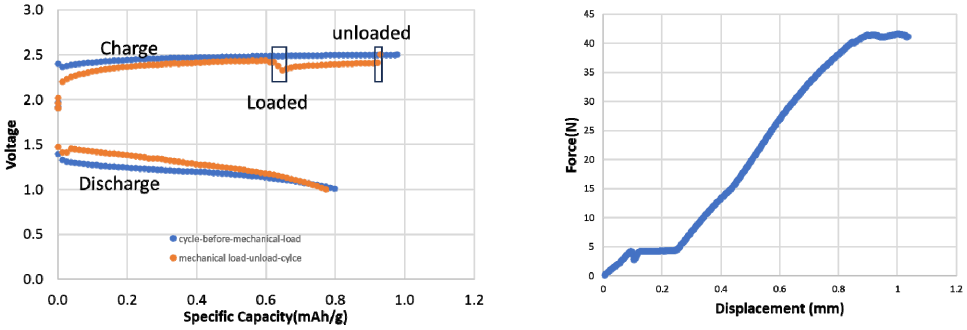


Figure 7: The voltage capacity graphs for three pouch cell prototypes cycled at 60°C

3.3 Simultaneous electro-mechanical testing

Simultaneous Electro-Mechanical (SEM) testing of a pouch cell was carried out as described in section 2.3. The voltage specific capacity of the cell before loading is shown in Figure 8(a) by the blue curve. The cell was loaded to about 40N in three-point bending (as seen in Figure 3(b)) corresponding to 1mm cross head displacement as shown in Figure 8(b). The loading pin was held at the same position after loading the cell. The load decreased after the initial loading but was not recorded and therefore not reported here. Although the load is not constant, but the loading pin position is held stationary during the SEM test.

Since the test is carried out at room temperature, the capacity is lower and a higher charging rate is used to decrease the total testing time. The voltage decreases upon loading during charging as can be seen in the loaded box in Figure 8(a) This most likely is due to the decreased resistance upon loading due to better contact during the loading of the pouch cell. The cycle shown in orange in Figure 8(a) was charged during the application of the three-point bending (i.e. the orange curve between the loaded and unloaded boxes) The lower voltage observed in the charging phase of the cycle in orange is due to application of the mechanical load. Subsequently, the voltage is seen to increase upon unloading during the charging phase.

(a) (b)

Figure 8: (a) Voltage vs specific capacity of cell before and after applying a bending load. The voltage decreases upon application of load most likely due to decreased resistance because of improved contact. The SEM test is conducted during the charging phase represented by the orange curve between the “loaded” and “unloaded” boxes. (b) Force-displacement graph during the application of load (i.e. “Loaded” box) in Figure 8(a).

Figure 9 shows the subsequent three cycles after the initial cycles plotted in Figure 8(a). The performance of the cell improved in the immediate cycle (grey plot in Figure 9) after the SEM test depicted in Figure 8(a) as evident from the increased capacity. This suggests that the pouch cell is in an improved state of contact (leading to decreased cell resistance) during the

1st (grey plot in Figure 9) and 2nd cycles (yellow plot in Figure 9) after SEM. However, by the third cycle (red plot in Figure 9) after the SEM test, the capacity of the cell returned to the pre-SEM level (blue plot). In conventional battery testing, these type of contact effects are avoided, and the best possible electrochemical performance is obtained by using a fixture shown in Figure 11 in the appendix. This demonstrates the need for simultaneous electro-mechanical testing of structural battery pouch cells since the effect of load on electro-chemical performance is quantified and simultaneous multi-functionality is demonstrated. Structural battery research needs to progress from an isolated multi-functionality evaluation (Figure 3(c)) to simultaneous multi-functionality evaluation (Figure 3(d)) as discussed in this work for practical realization of structural batteries.

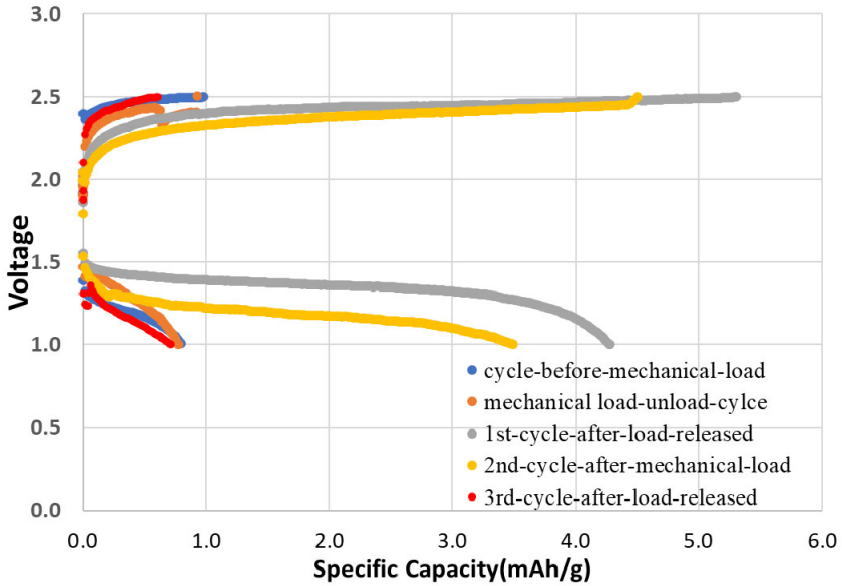

Figure 9 The comparison of the voltage vs specific capacity after the mechanical 3-point bending test. The orange and blue curves are the same cycles from ***Error! Reference source not found.***. The subsequent cycle displays an increase in charge and discharge capacity that decreases in the subsequent cycles suggesting that the improved contact that was established during loading relaxes with time returning back to the previous state (See 3rd cycle after load released (red curve) and cycle before mechanical load (blue curve)).

4 CONCLUSION

Carbon fibre based current collectors are used to develop PEO solid electrolyte based structural battery prototypes. The current collector with 5% PVDF solution was used to make the prototypes even though 1% PVDF samples exhibited the least resistivity and higher tensile properties since 1% CF PVDF current collectors are not suitable for making large pouch cell prototypes (as explained in section 3.1). The optimum amount of PVDF is indicated to lie between 1% and 5% CF-PVDF as observed from the measurements.

Pouch cells made with LFP and LTO electrodes with PEO solid electrolyte were successfully demonstrated to cycle electrochemically at room temperature and 60°C. These prototypes have been demonstrated to be fabricated with reasonable amount of repeatability as indicated in the performance of 3 pouch cells. Finally, a proposed Simultaneous Electro-Mechanical (SEM) flexural test has been performed. The battery could operate during and

after the test. The batteries exhibited higher capacities in the subsequent cycles mostly due to improved contact but eventually relaxed and returned to pre-SEM capacity.

Research and development of standards for these and similar simultaneous electromechanical tests and exploring alternate time-efficient methods to demonstrate simultaneous multi-functionality is necessary for the evaluation of structural batteries.

The support of A*Star under Structural power for portable and electrified transportation; grant no. A20H3b0140 is gratefully acknowledged.

APPENDIX

A.1 Anode and cathode slurry preparation:

LFP + C : 88:5 mass ratio of LFP powder and Carbon (C65) Black Powder are mixed using a pestle and mortar for cathode.

(a) 1 g of LFP + C mixed above

(b) 1.2 g of DMF (N, N Dimethylformamide) solvent

(c) 4.5 g of PEO10-LiTFSI-DMF solution

(d) 4 g of 5% PVDF-DMF solution (a 5:95 mass ratio of PVDF-DMF solution)

(e) 2 g of 0.4%Single Walled Carbon Nanotube (SWCNT) 2% PVDF in NMP (N-Methyl pyrrolidone)

The above ingredients are added in glass bottle as per the weights one by one and centrifuged at 2000rpm for two minutes after the addition of each component from (b) to ensure uniformity of the slurry.

For the anode, LTO + C: 90:5 mass ratio of LTO powder and Carbon (C65) Black Powder is mixed with a pestle and mortar and replaces the LFP+C in the above recipe

A.2 PEO_{10}-LiTFSI solid electrolyte preparation:

Add 1 g of LiTFSI (Lithium bis(trifluoromethanesulfonyl)imide) and 1.533 g of PEO(poly(ethylene) oxide) in glass bottle inside a glovebox to avoid moisture absorption. Add DMF(Dimethylformamide) solvent such that the total solid content (PEO + LiTFSI) is 10% of the total mass after adding DMF. Place a stirrer bar and place in oil bath at 80°C and stir at 500 rpm for 12 hours to prepare the electrolyte.

Figure 10: 1% CF-PVDF fabricated sample with disconnected individual tows- makes it difficult to assemble cells

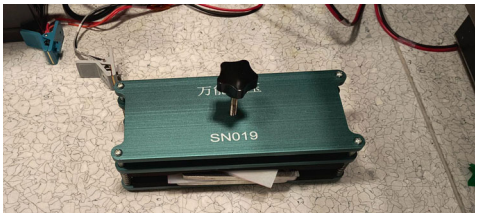

Figure 11: Fixture used in conventional pouch cell testing to ensure proper contact within the cell and ensure the best battery performance

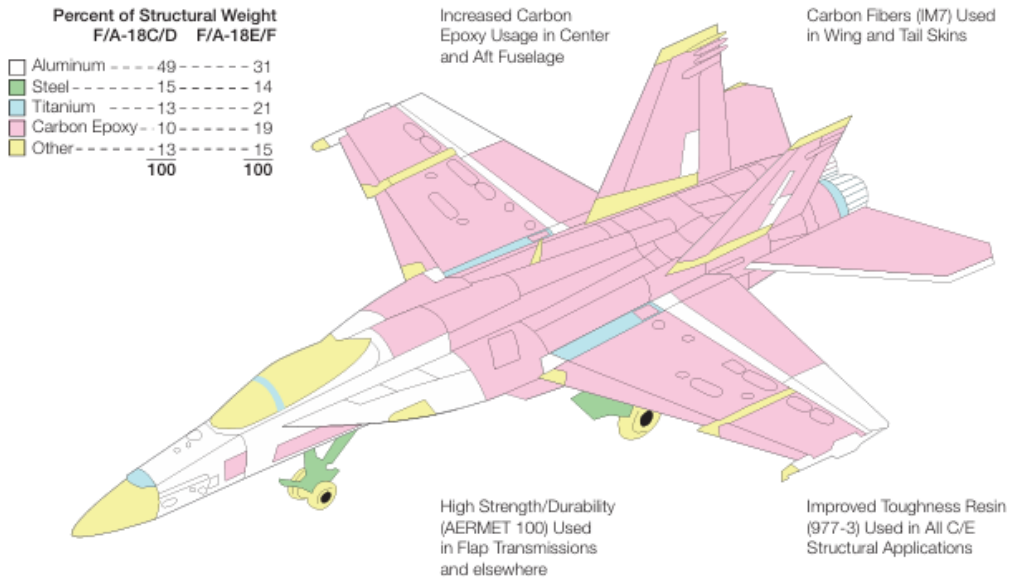
Self-healing of Structural Damage in Thermoplastic Composite Laminates via Incorporated Nano-engineered Heating Architecture

Hyungmin Kim, Sumin Lee, Jeonyoon Lee

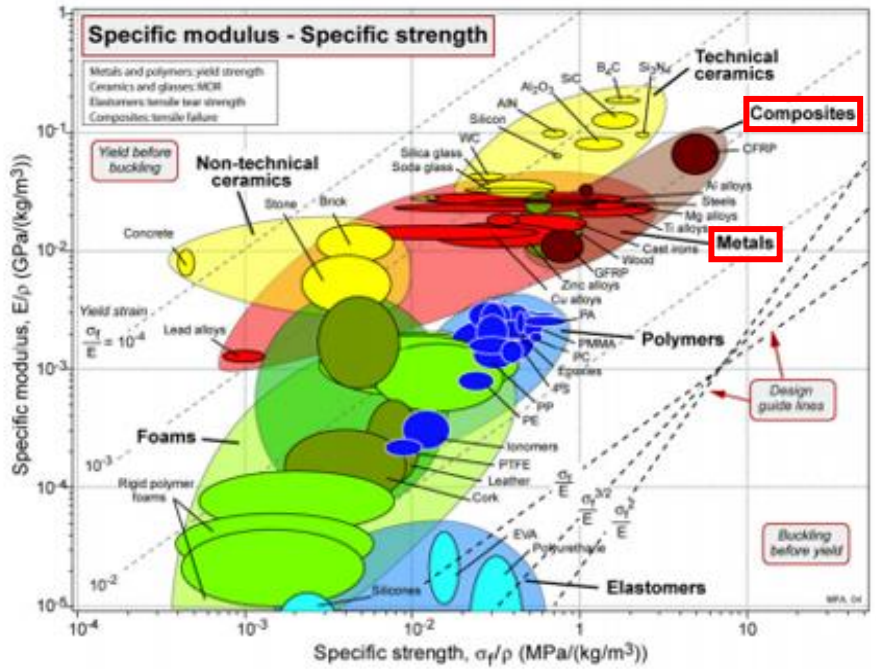
August 4th, 2025

Korea Advanced Institute of Science and Technology
Department of Aerospace Engineering



Contents

1. Research background
2. Design of the Nano-engineered heating architecture
3. Mechanical test methods for quantifying the self-healing effect
4. Analyzing the morphological results and the mechanical properties
5. Conclusion and future work

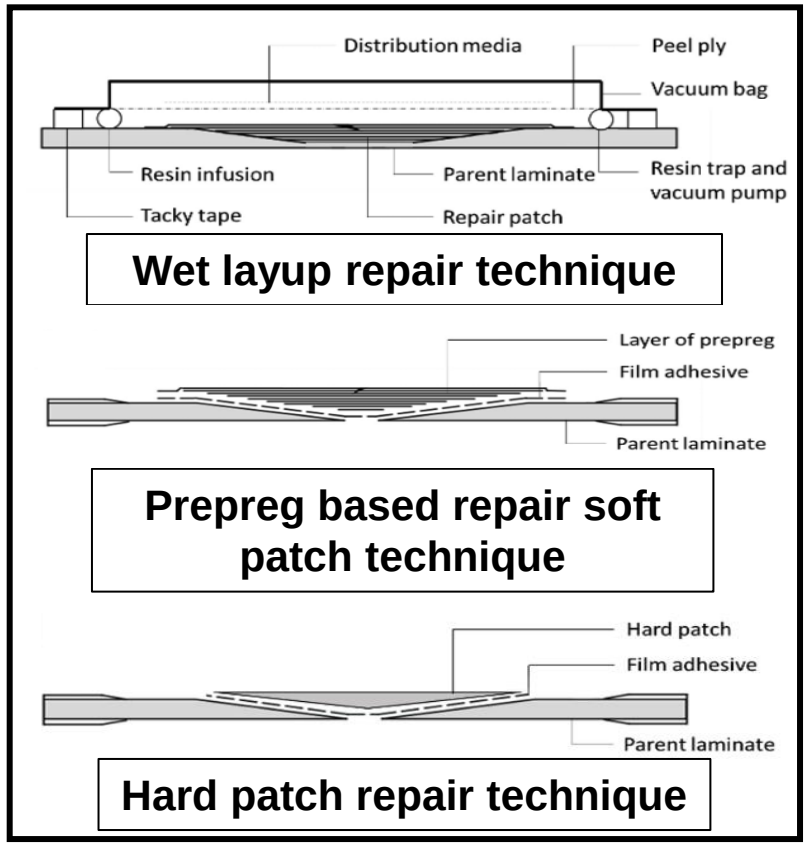


Research Background

The Growing Importance of Composites in the Aerospace Industry

- Composites are a good choice for maximizing payloads and aircraft performance due to high strength-to-weight ratio
  - Reduced aircraft weight leads to lower operational costs
  - Usage of composites are rising both in commercial and military applications

<Wide use of composite materials in Boeing fighter jets F/A-18C/D and F/A-18E/F [1]>



<Composites vs. Metals: Specific stiffness and Specific strength[2]>

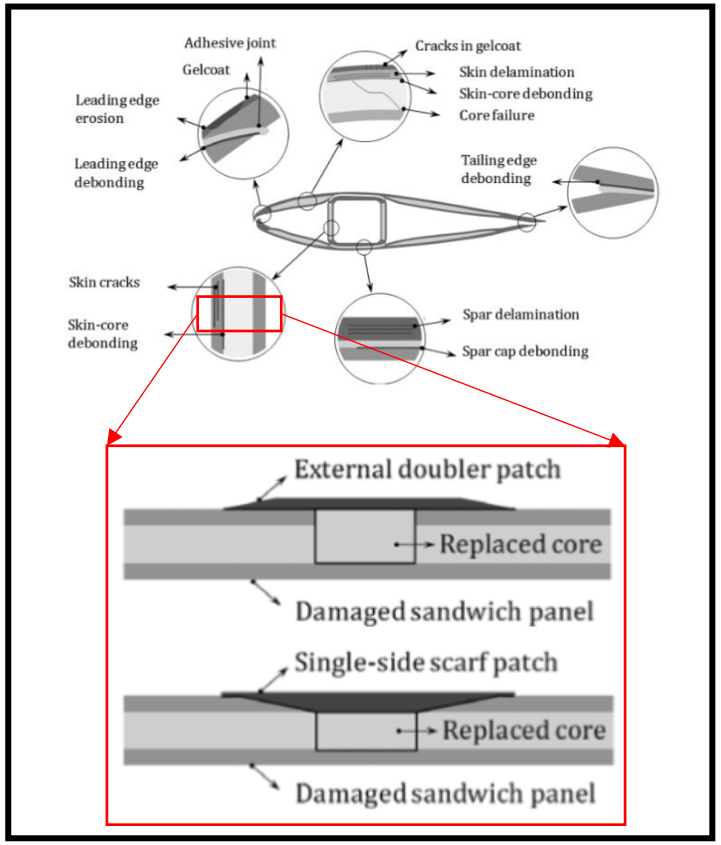
Existing Repairing Mechanisms of Composites



- In-situ inspection and direct addition of composite material into the damaged region is currently utilized
- Repair techniques and researches of thermoset matrix composites are more common

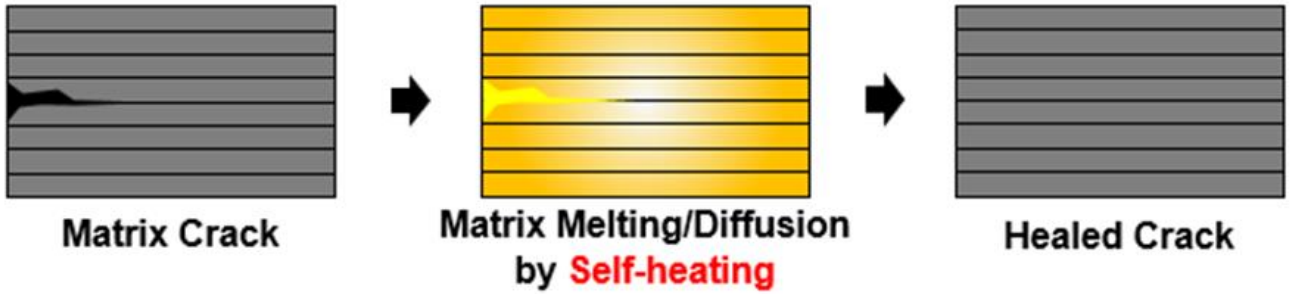
Rising Solution: Self-healing via Joule Heating

<IR Recording of the CNT Heater>



<Measured Voltage(3.73V) and Current(4.06A)>

<Temperature-Time Plot>

- CNT bucky paper based heater possesses Joule heating capabilities to ~100℃ in 50s with $3.73V \times 4.06A = 15.1438W$ and the aspect ratio of 25mm(width)/40mm(length) = 0.625
- Thermoplastic resin can be reconsolidated into the damage cracks with the heat from the CNT bucky paper

Further Research Required for the Self-healing Architecture

<Schematic of the Self-healing process>

① **Sustainable self-healing structure and method throughout the entire temperature cycle**

- Self-healing cycle based on manufacturer's instructions
- The nanoarchitecture must be free of electrical shorts via sufficient electrical insulation

② **Consistent mechanical test methods for self-healed composites testing**

- Finding the appropriate mechanical test for thermoplastic matrix based composites
- Sufficient amount of test data for such materials is required for further self-healing research

Thesis Objectives

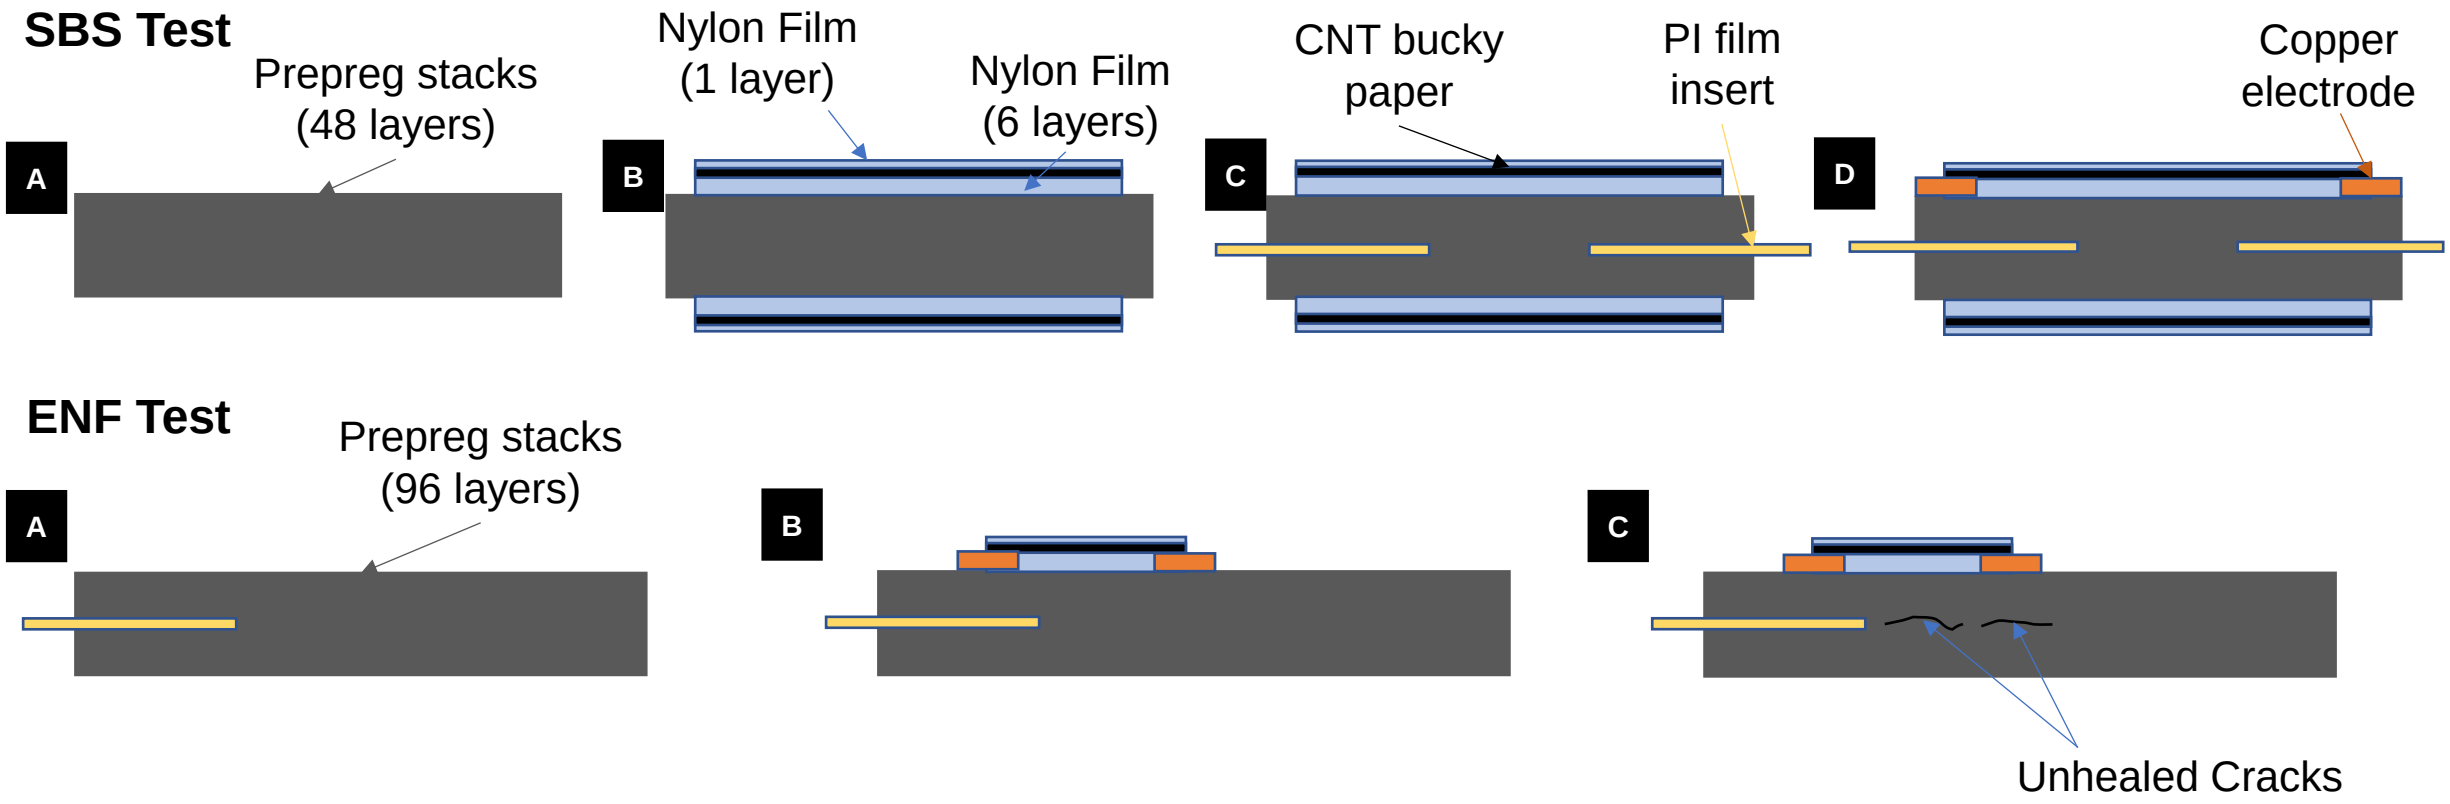
1) Design of **CNT heater-based nano-engineered heating architecture**

   - Targeting on structurally incorporated nanocomposite integration

2) **Short Beam Shear(SBS)** and **End-Notched Flexural(ENF) Testing** of nanocomposite-integrated structure for self-healing efficiency

   - Stiffness analysis via the SBS test

   - Mode II Toughness analysis via the ENF test

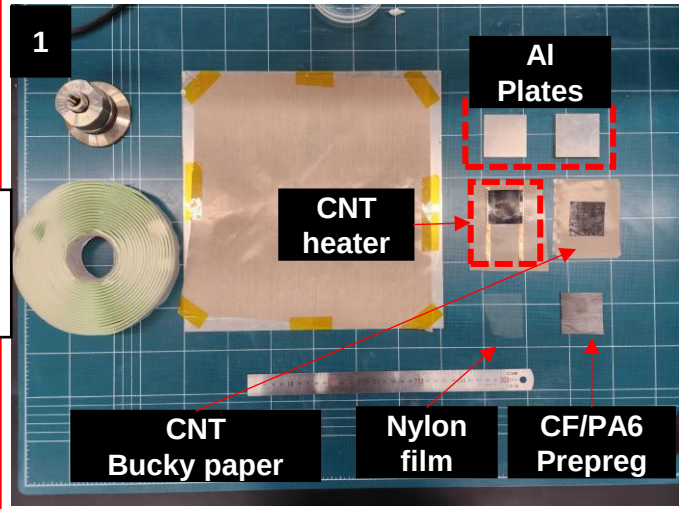


3) **Morphological analogy** of the self-healing effects on the nanocomposites

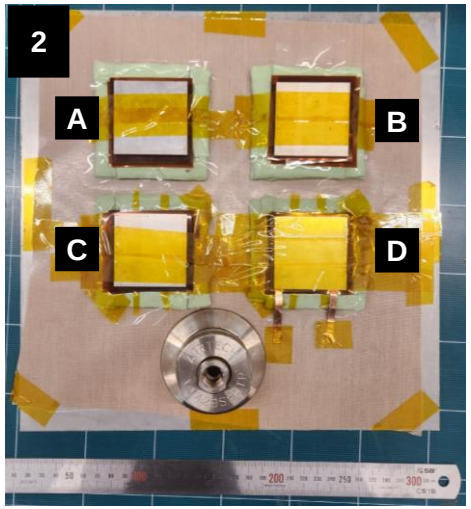
   - Visual effects of the CNT-heater self-healing via the optical microscope

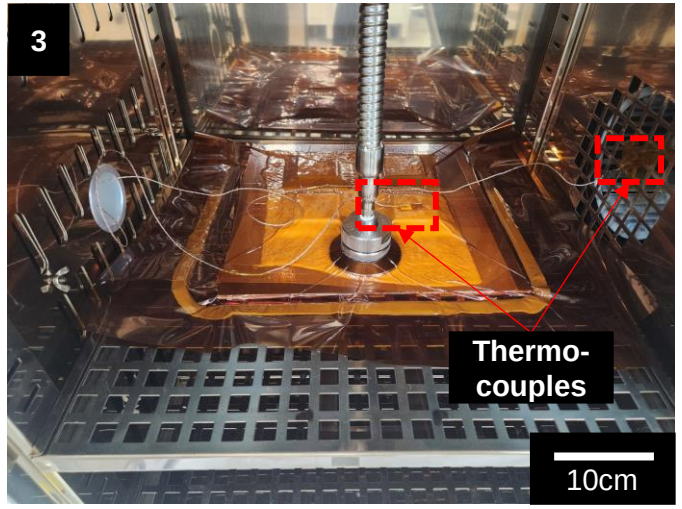
   - CT, Crystallinity(Thermophysical) N/A

Design of the Nano-engineered Heating Architecture



Design of Composite Surface Incorporated Heater Architecture





- CNT bucky paper is added on both top and bottom of the SBS sample groups B, C, D to control the structural conditions that might affect the mechanical properties
- The PI film insert is removed after initial curing(manufacturing) for mechanical testing
- ENF Sample C is equal to Sample B after mechanical testing(cracks propagated)

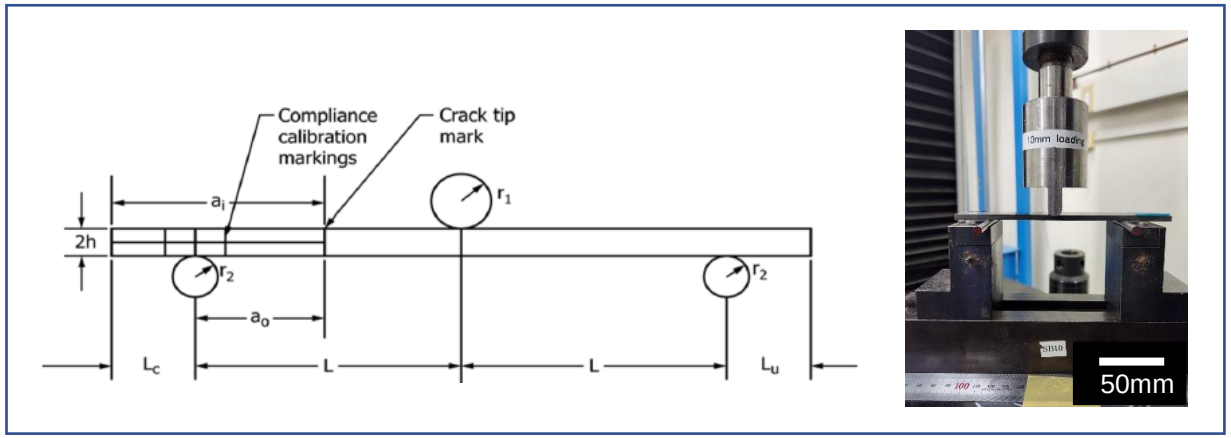
Short Beam Shear Testing(SBS) for Self-Healing Effects on the Stiffness

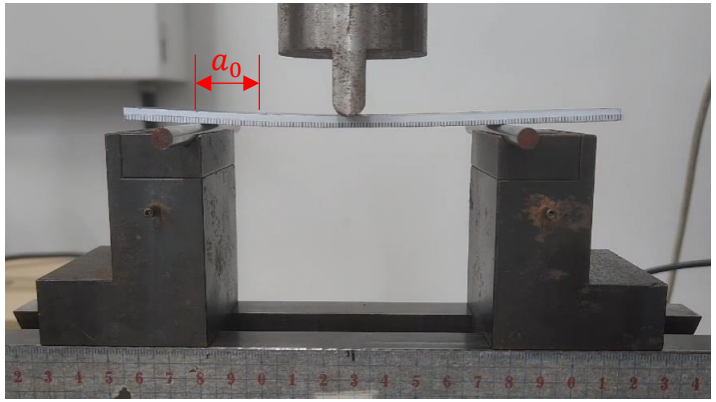


<SBS Test Setup Design(Left) & Actual Photo(Right)>

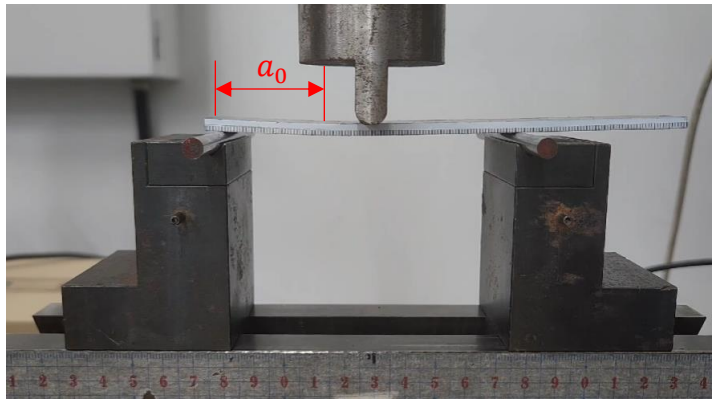
Specification

- Thickness(h) : ~2mm
- Width(b): ~4mm(b = 2t)
- Length(l): ~12mm
- Loading nose radius (r_1): 3mm
- Supports radius (r_2): 1.5mm
- Span Length(s): 8mm
- Loading speed: 1mm/min

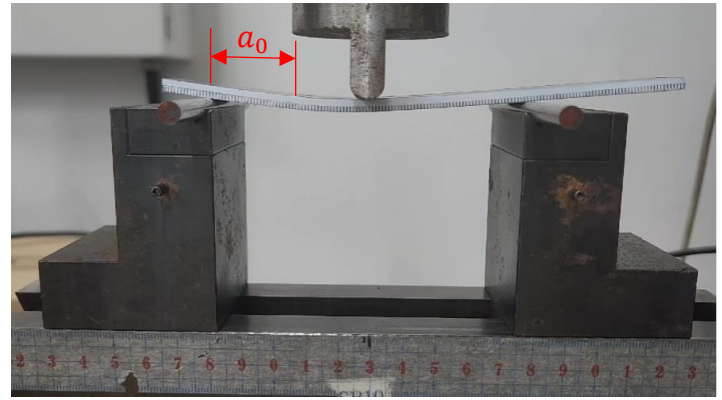
- Termination condition
  - 30% Load drop off
  - The loading nose travel distance exceeds the sample nominal thickness
  - 2-piece failure
- Short beam strength calculation(Peak load = P_{max})
  - $F_{sbs} = 0.75 \times \frac{P_{max}}{bh} (b = specimen\ width, h = specimen\ thickness)$



End-Notched Flexural Testing(ENF) for Self-Healing Effects on the Mode II Toughness

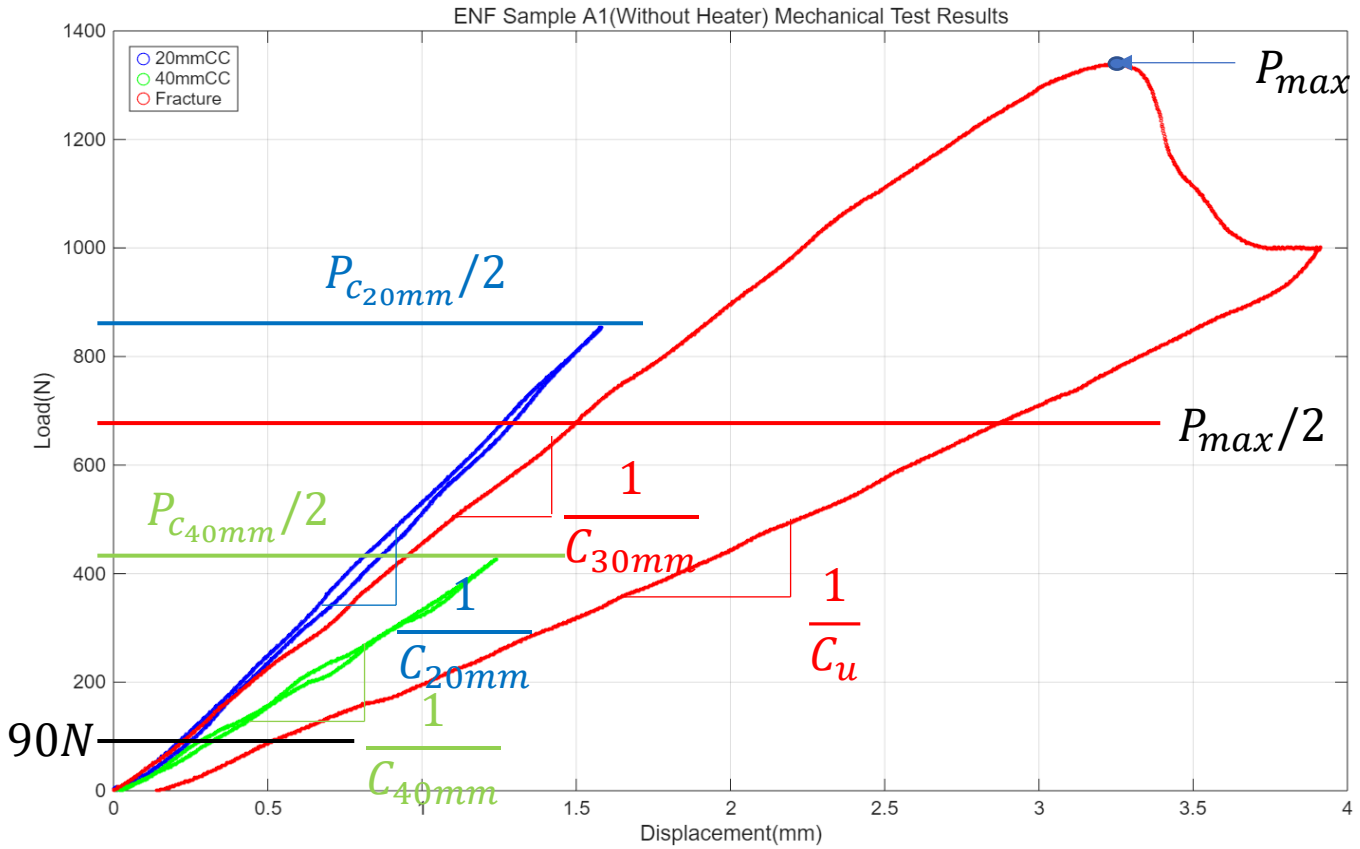


<ENF Test Setup Design(Left) & Actual Photo(Right)>

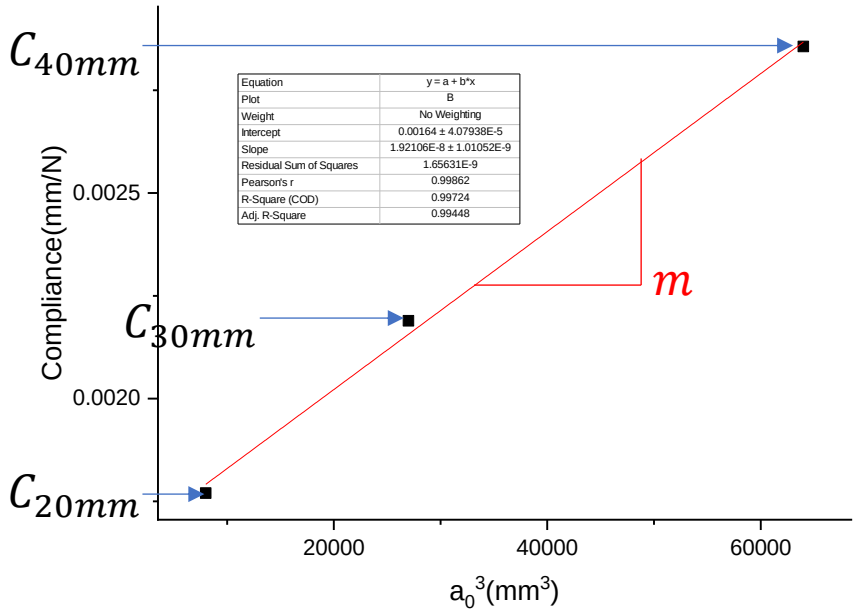


Specification

- Thickness(2h) : 3.4-4.7mm
- Pre-crack length (a_i): ~45mm
- Left supports – crack tip length(a_0): 20mm, 40mm(Compliance Calibration), 30mm(Fracture Test)
- Loading nose radius(r_1), Supports radius (r_2): 5mm, 3mm
- Total Sample Length, Width: ≥160mm, 19-26mm
- Span Length(2L): 100mm
- Loading speed, Unloading speed: 0.5mm/min, 0.5mm/min



<Compliance Calibration Tests(Left: $a_0 = 20mm$, Right: $a_0 = 40mm$)>



<Fracture Tests($a_0 = 30mm$)>

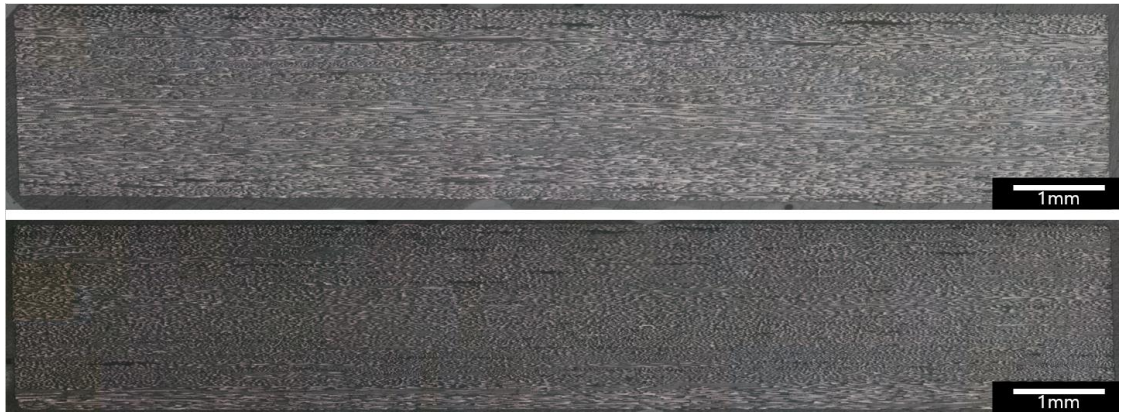
End-Notched Flexural Testing(ENF) for Self-Healing Effects on the Mode II Toughness

<Calculating the Compliances from the Load-Displacement Curve>

$$P_{c_{a_0}}(\mathrm{a_0 = 20mm, 40mm}) = \frac{4B}{3a_0}\sqrt{G_{IIc}E_{11}h^3}\ a_0^3$$

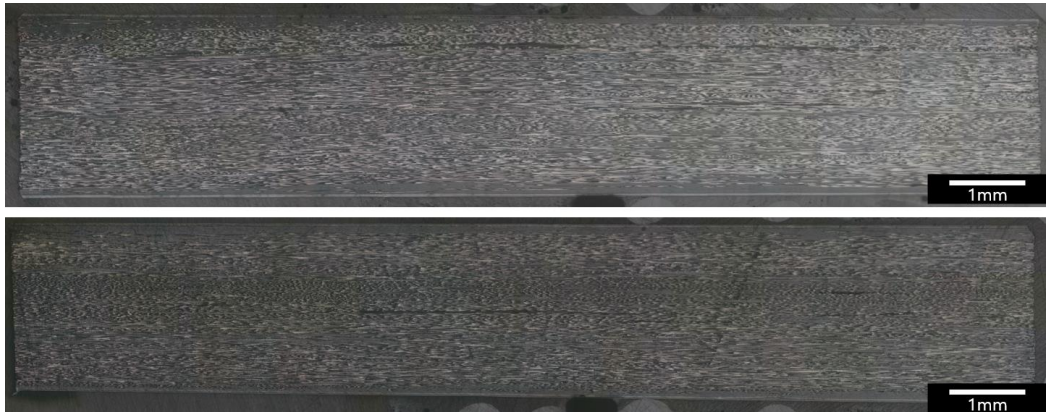
<Calculating the slope of the Compliance-Crack length(a_0) linear fit>

$$G_Q = \frac{3mP_{max}^2a_0^2}{2B}\ (a_0 = 30mm, Fracture\ Test)$$



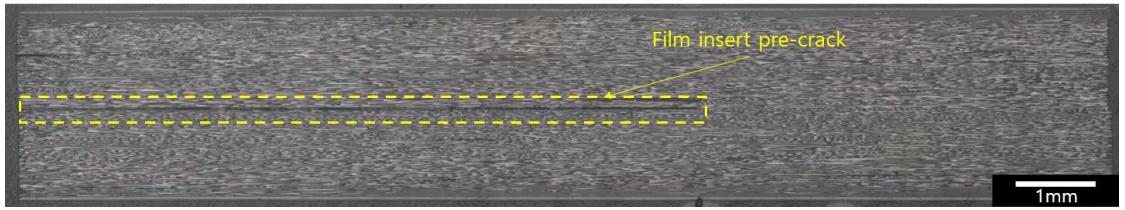
$$\text{If } 0.15 \le \left(\frac{P_{c_{a_i}}a_i}{P_{max}a_0}\right)^2 \le 0.35\ (\mathrm{a_i = 20mm, 40mm}),$$

$$\mathbf{G_Q = G_{IIc}}$$

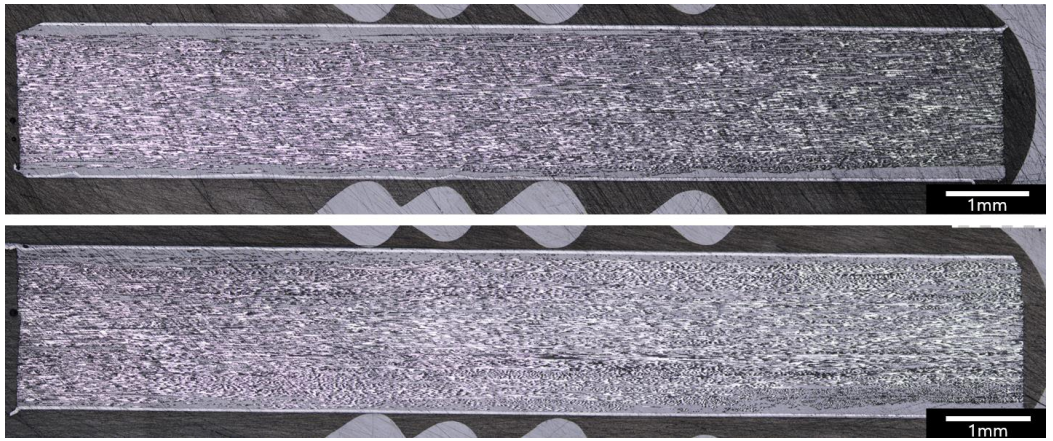


Specimen Morphology and the Mechanical Test Results

Morphological Analysis of SBS Specimen

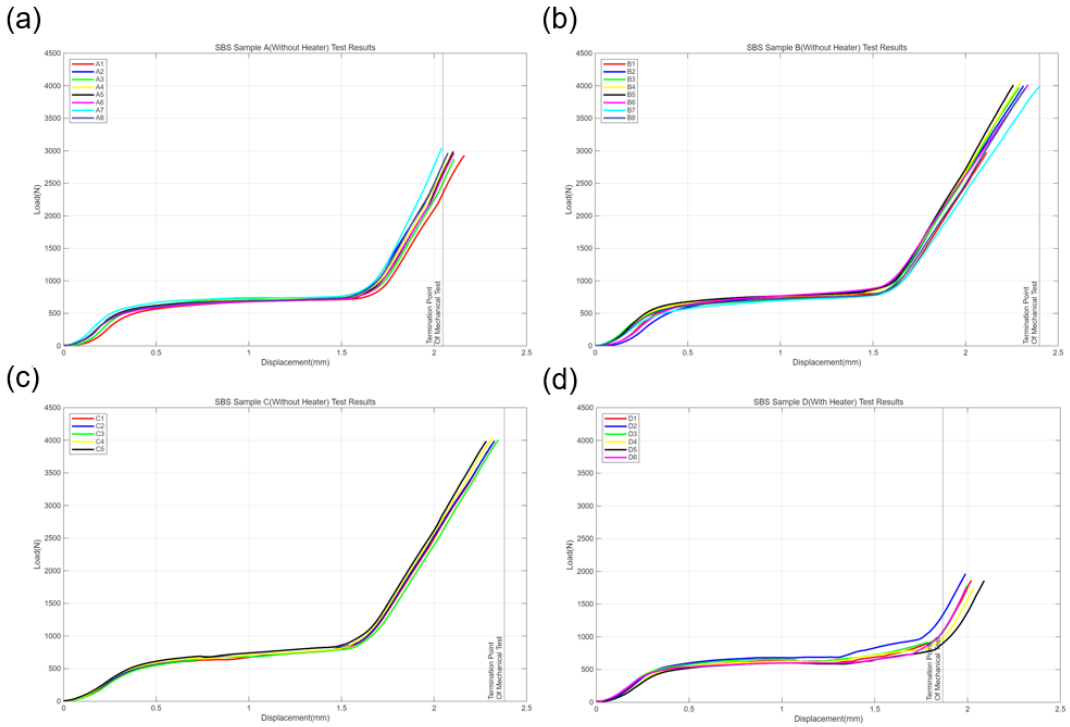


- Visible crack by the film insert is completely reconsolidated in the self-healed Sample D specimen
- Morphologically the self-healing effect is confirmed

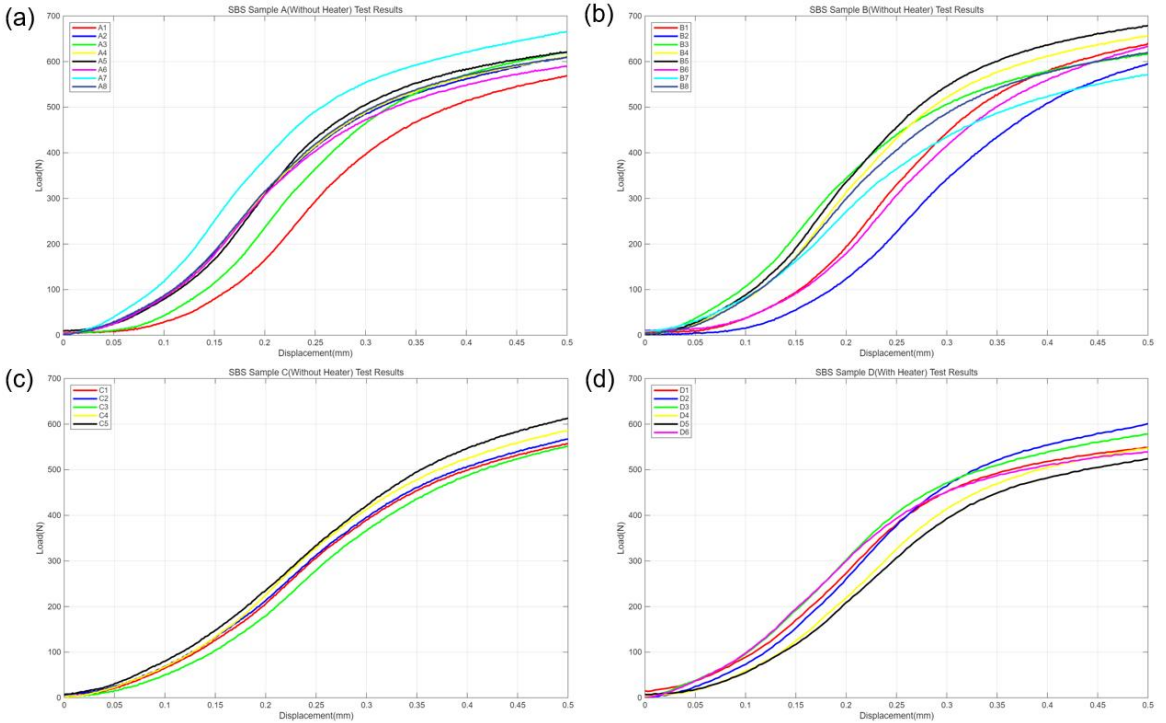


<Sample A(Length X Thickness)>

<Sample B(Length X Thickness)>

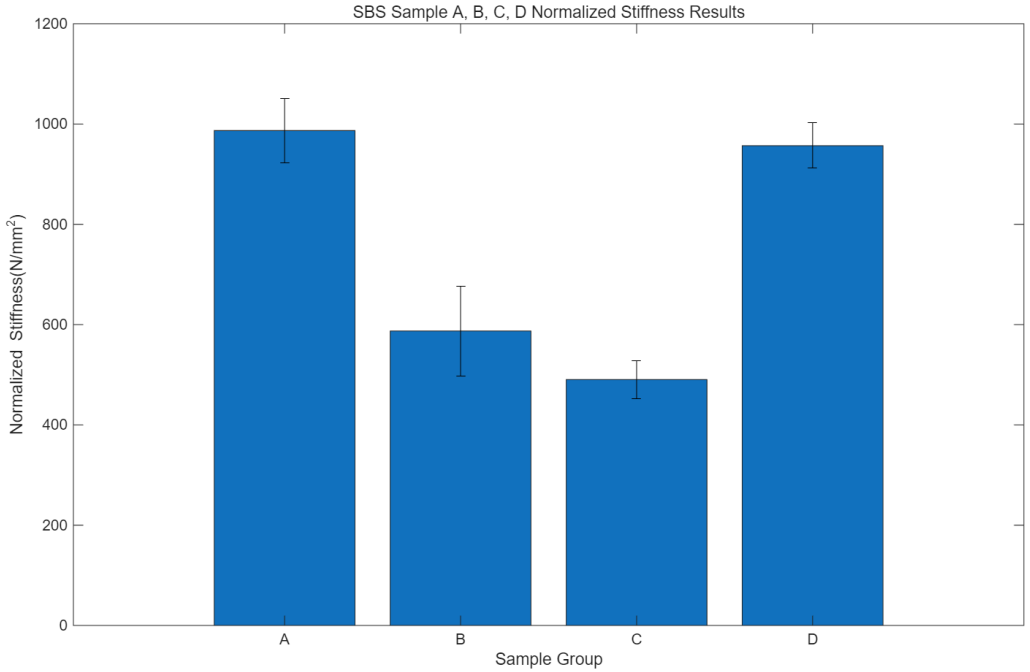


<Sample C(Length X Thickness)>

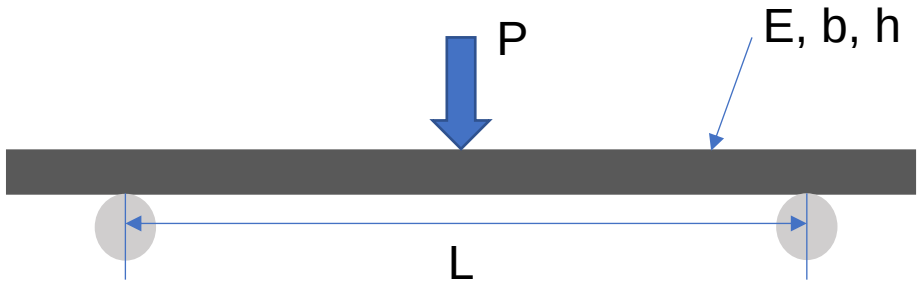


<Sample D(Length X Thickness)>

Stiffness Comparison Results of SBS Specimen



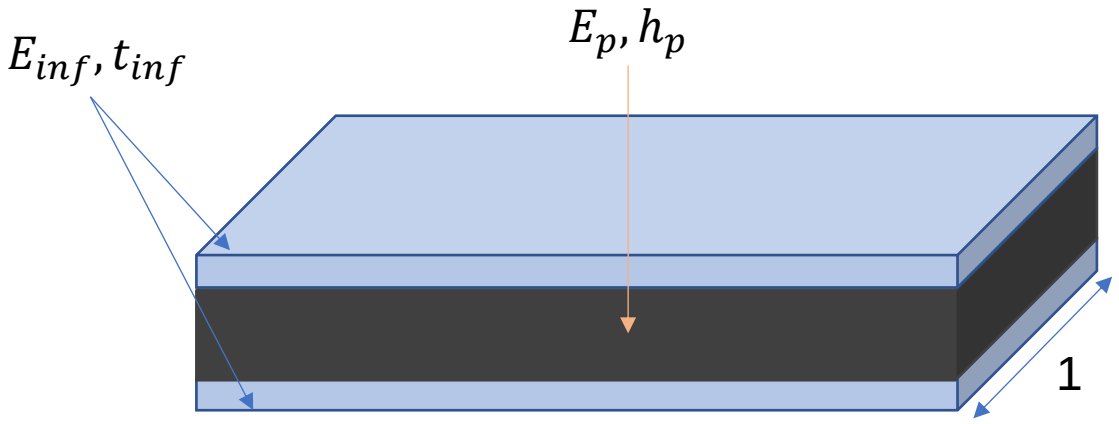
<Load-Displacement Curves of all specimens>



<The Initial load increasing region of the load-displacement curves>

- Maximum derivative value of the initial load-increasing region is selected to represent the bending stiffness
- The calculated bending stiffness is normalized by the second moment of area

Stiffness Comparison Results of SBS Specimen



$$K(bending\ stiffness) = \frac{48EI}{L^3}, I = \frac{bh^3}{12}$$

Sample Group	A	B	C	D
Normalized Stiffness(N/mm^2)	986.9234 ± 64.3291	587.3051 ± 89.5869	490.4462 ± 37.9087	956.8082 ± 45.1380

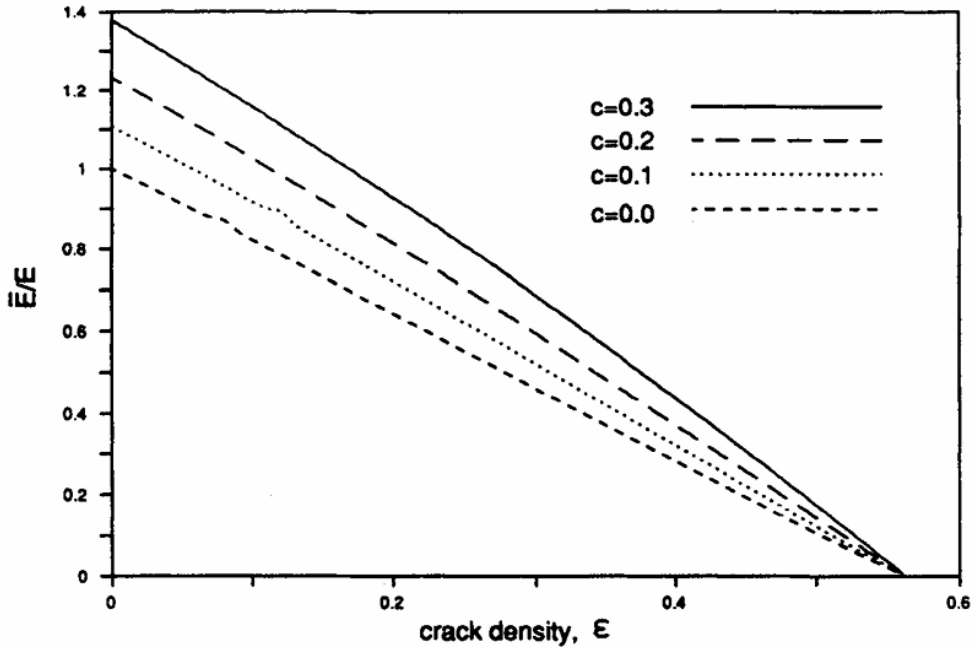
- The bending stiffness is normalized according to the 3-point bending beam theory
- The order of magnitude for bending stiffness is A > D > B > C, with A and D showing similar values

$$K_{normalized} = \frac{1}{12}E = \frac{L^3}{48bh^3}$$

Explanation of Each Stiffness Comparison (A > B)

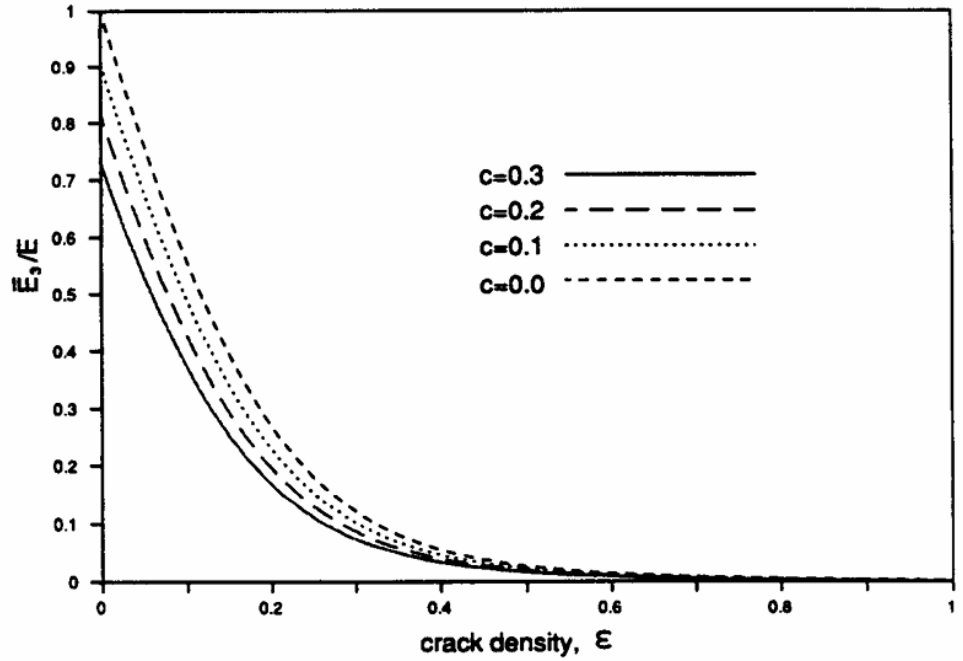
<A sandwich-structured composite material>

*per unit width



$$(EI)_{total} = E_{inf}\frac{1}{12}\left[(h_p + 2t_{inf})^3 - h_p^3\right] + E_p\frac{1}{12}h_p^3$$

$$= \frac{E_{inf}t_{inf}h_p^2}{2}\left(1 + 2\frac{t_{inf}}{h_p} + \frac{4}{3}\left(\frac{t_{inf}}{h_p}\right)^2 + \frac{1}{6}\frac{E_p h_p}{E_{inf}t_{inf}}\right)$$

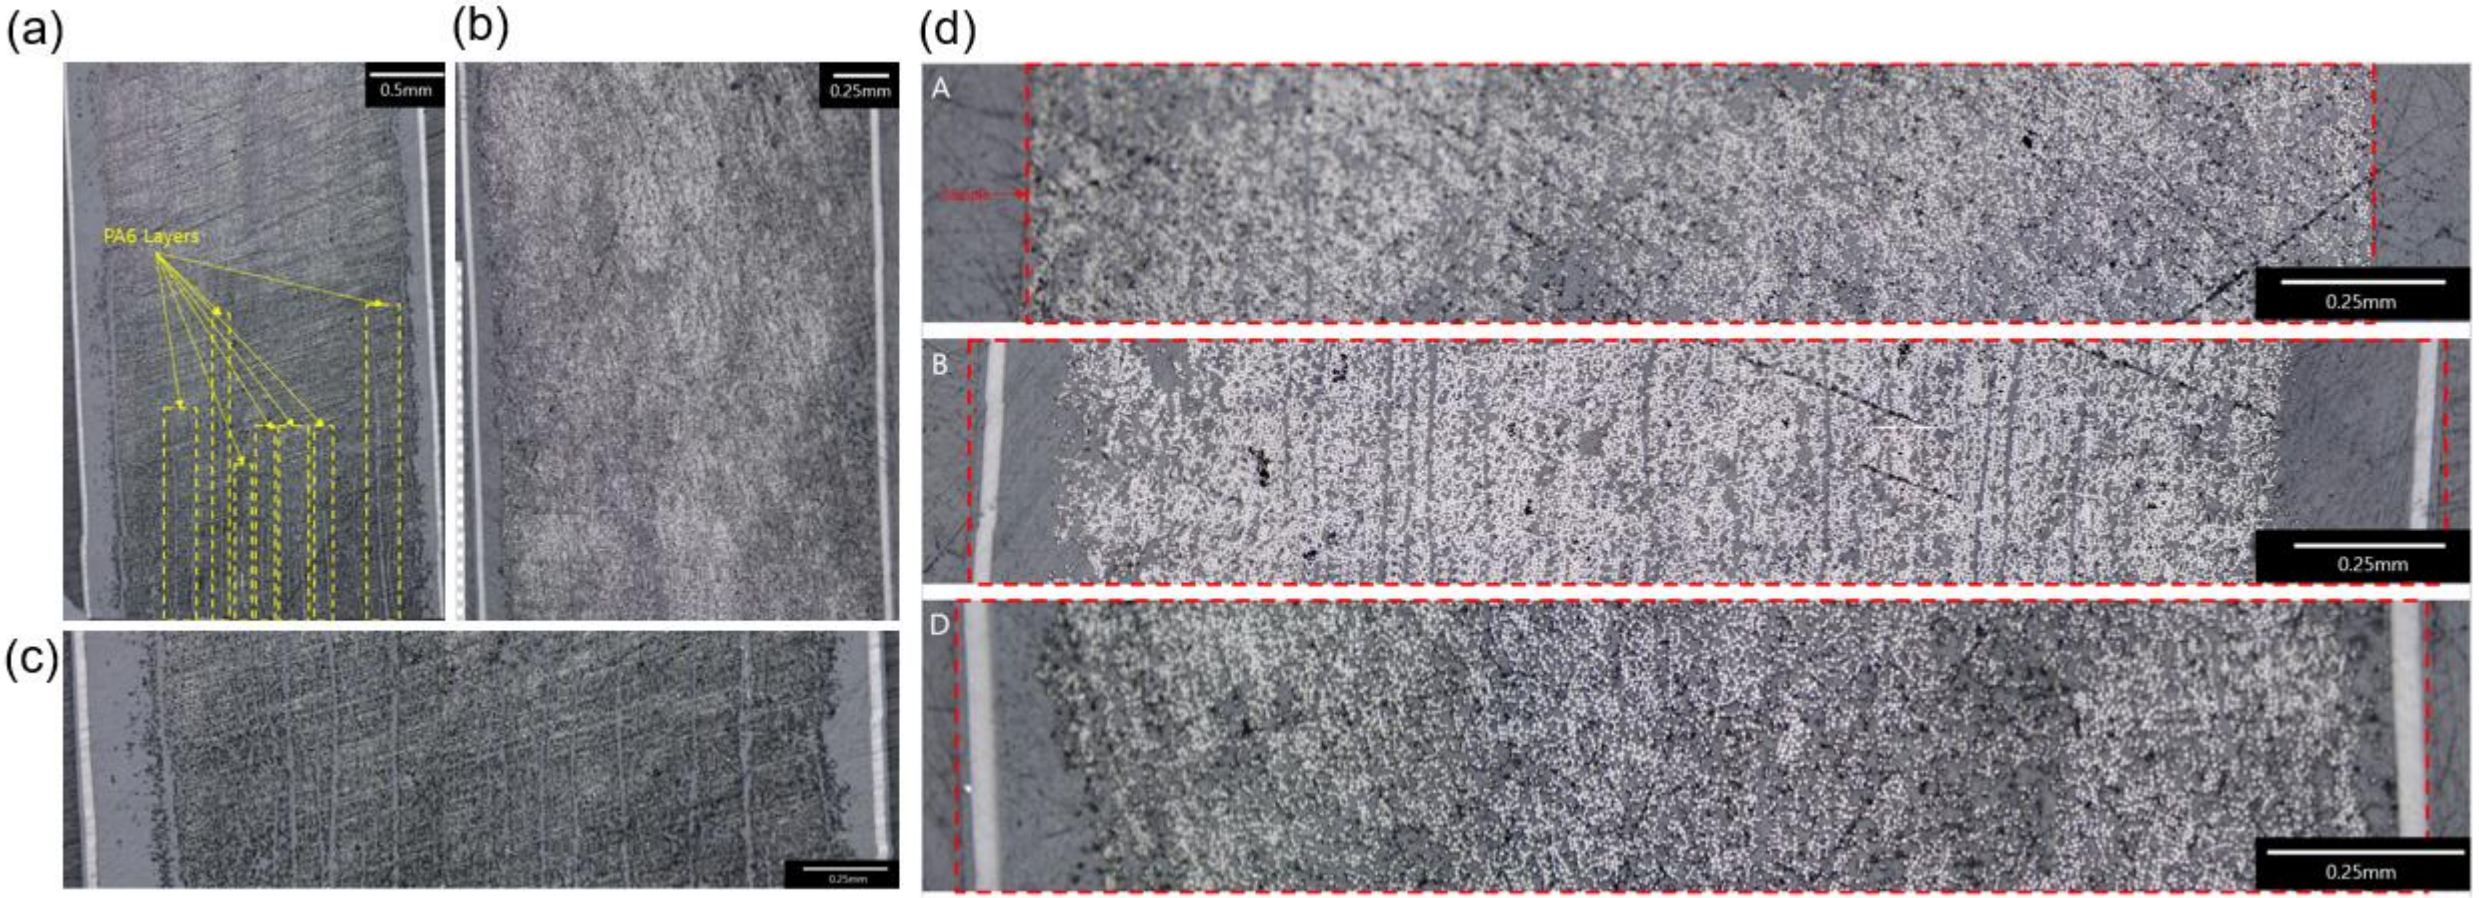


$$I_{total} = \frac{(h_p + 2t_{inf})^3}{12}$$

- Sample group B resembles a sandwich-structured composite panel material, with the bucky paper-nylon infusion layer as the outer skin
- The Young's modulus of the sample group B specimens are calculated theoretically, and compared with the values of the sample group A specimens
- The ratio of the sample group B to sample group A experimentally turned out to be 0.595, while the theoretical ratio based on parameters obtained through morphology turned out to be 0.61638

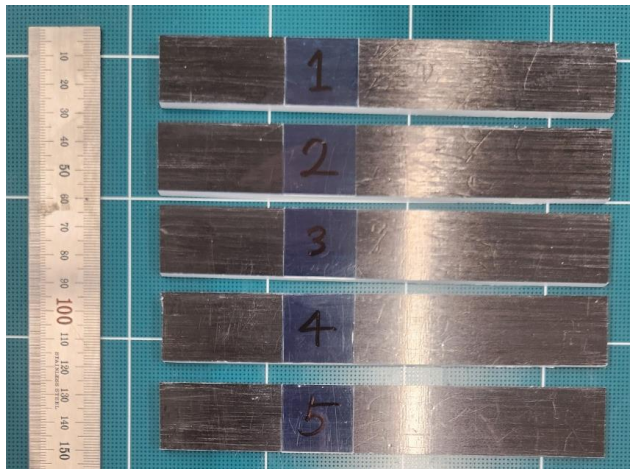
Explanation of Each Stiffness Comparison (B > C)

<Ratio of effective Young's modulus with randomly distributed microcracks to the plain Young's modulus[1]>



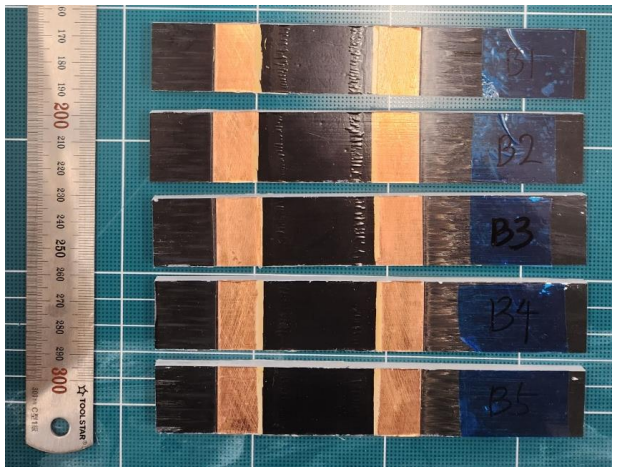
< Ratio of effective Young's modulus with parallel layered microcracks to the plain Young's modulus[1]>

- Intuitively the presence of the pre-crack should decrease the mechanical properties(Young's modulus, or normalized bending stiffness)
- Y Huang et al. showed that the presence of micro-cracks, such as in this research, possess a decreasing effect in the total effective modulus value

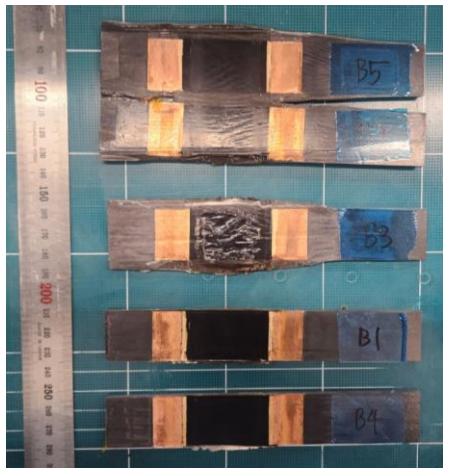


[1] Huang, Y., K. X. Hu, and A. Chandra. "The effective elastic moduli of microcracked composite materials." *International journal of solids and structures* 30.14 (1993): 1907-1918.

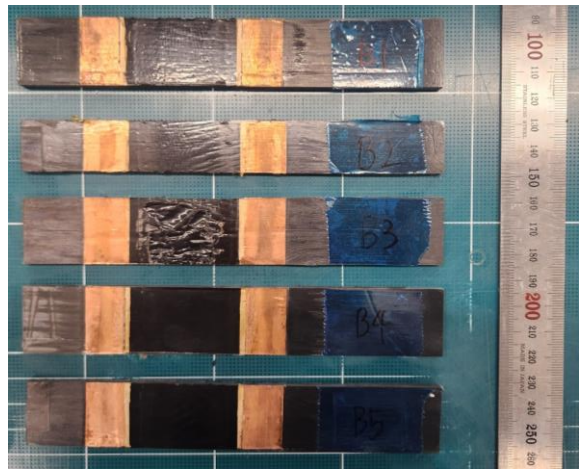
Explanation of Each Stiffness Comparison (A > D > B)



Morphological Analysis of ENF Specimen

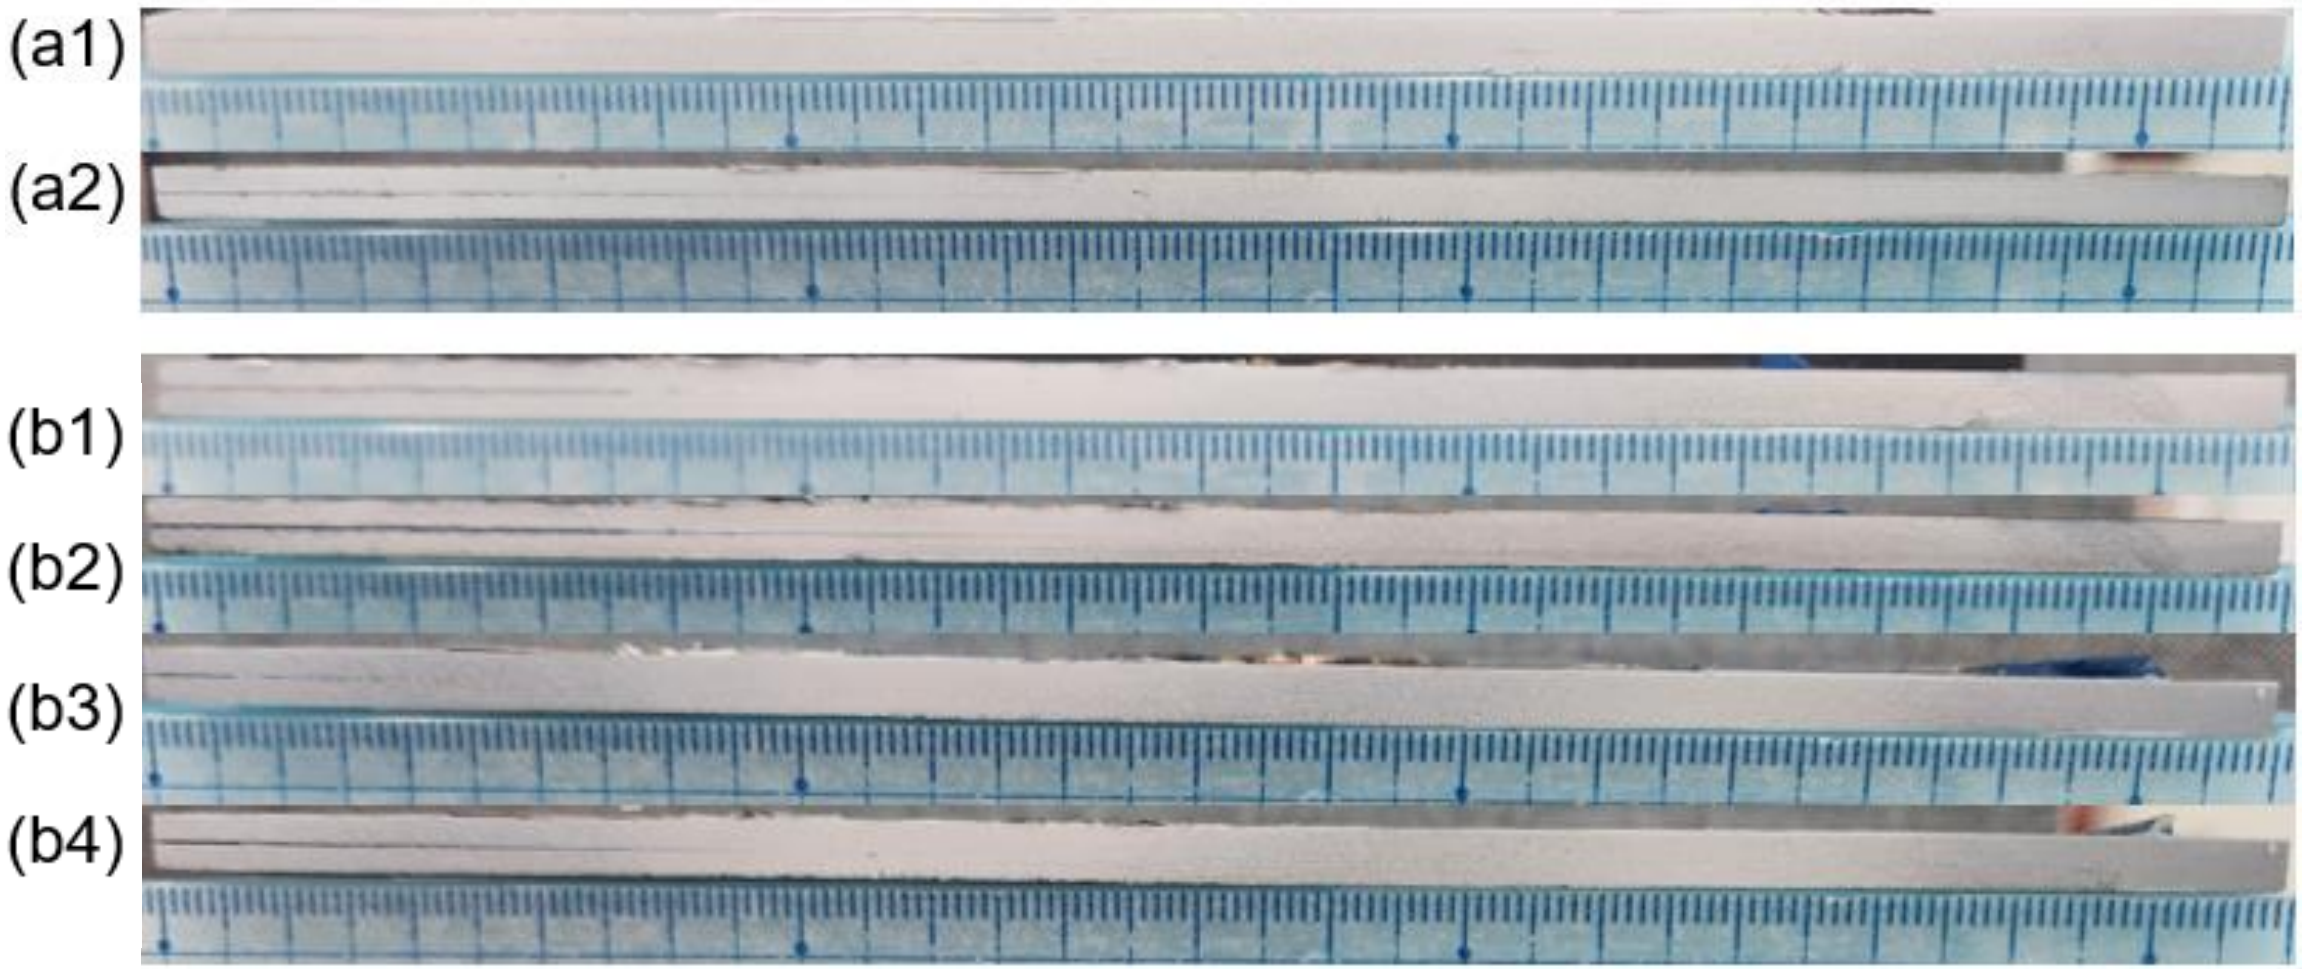


(a)

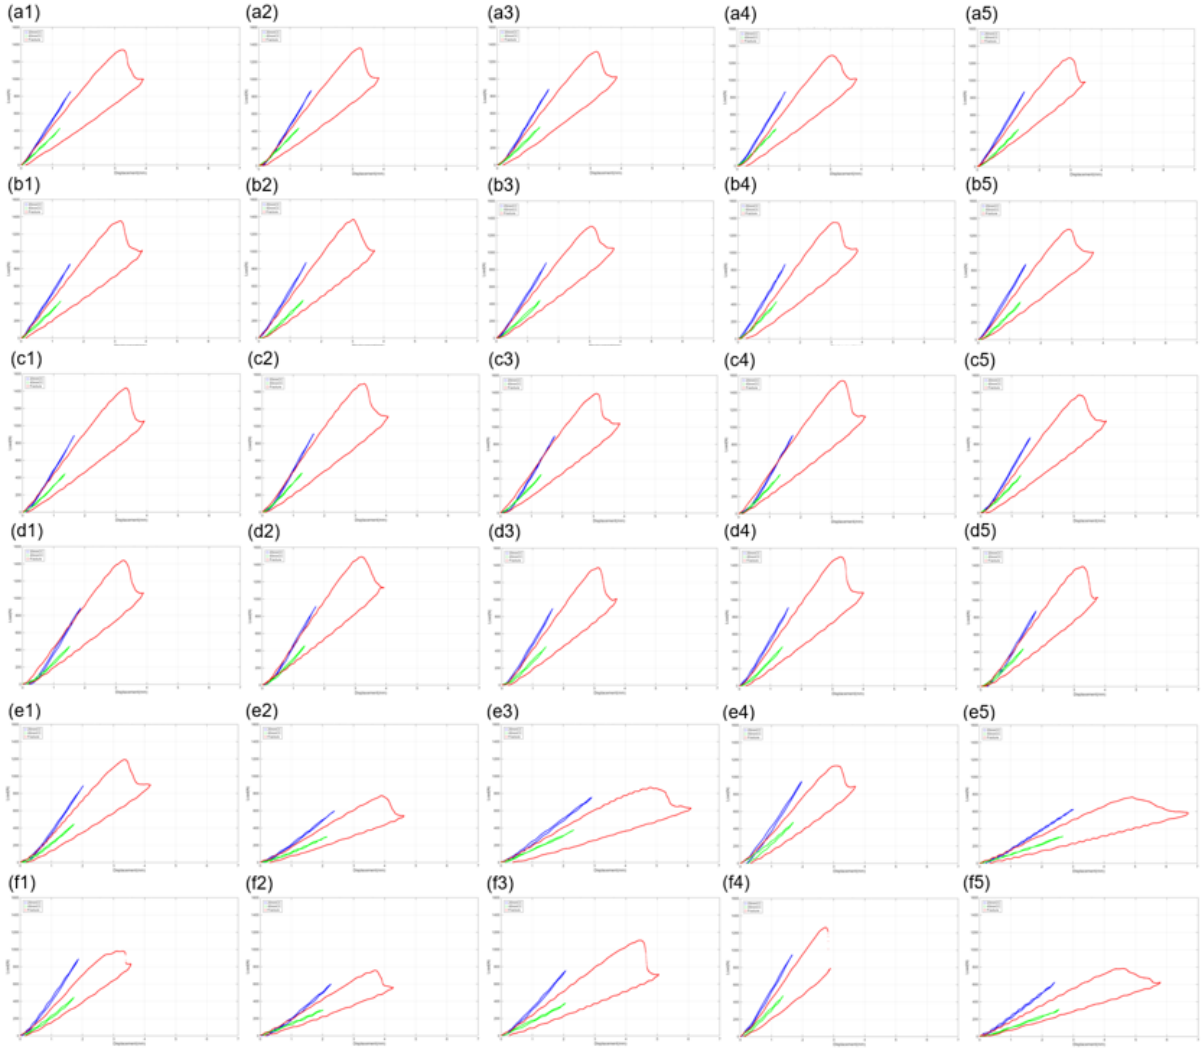


(b)

(c1)

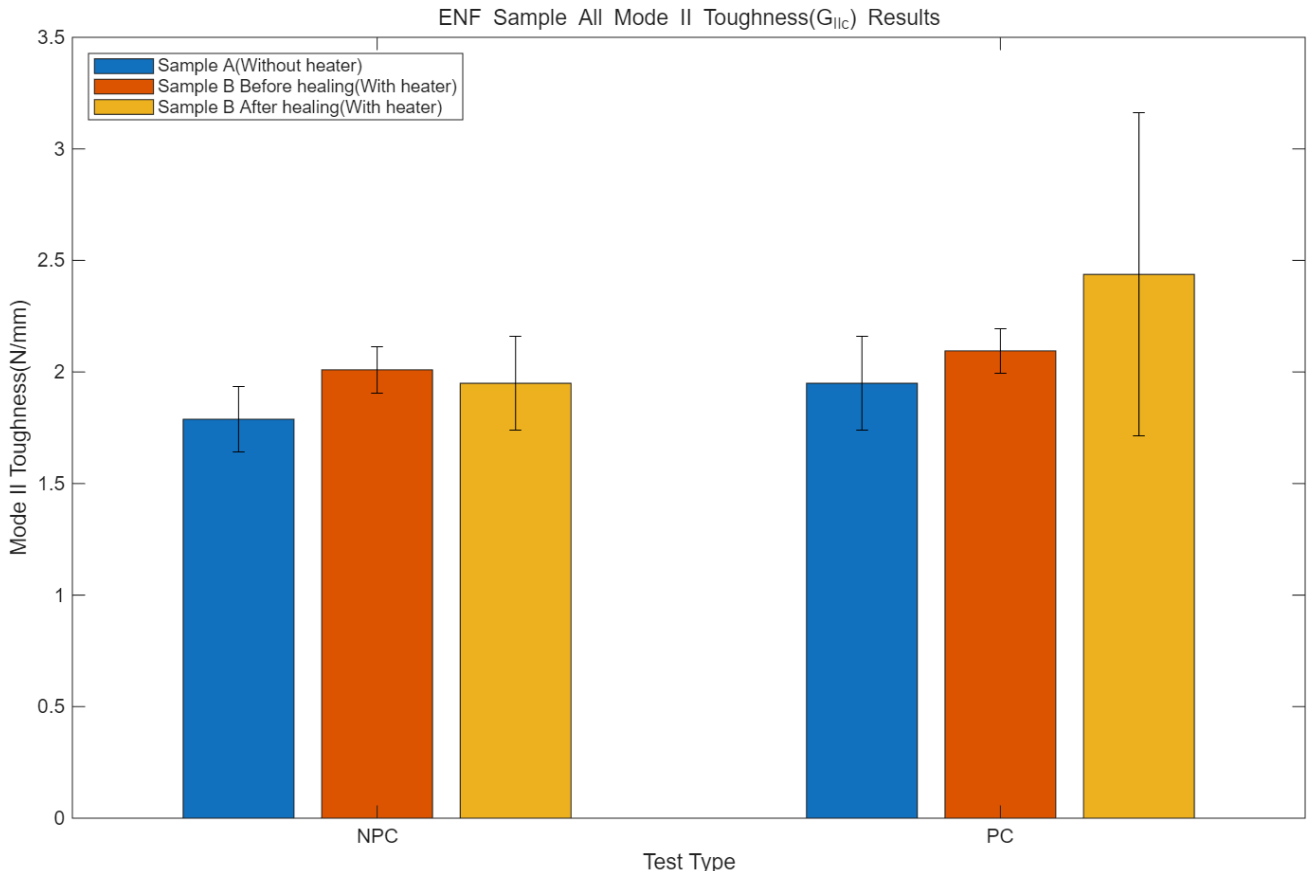


(c2)



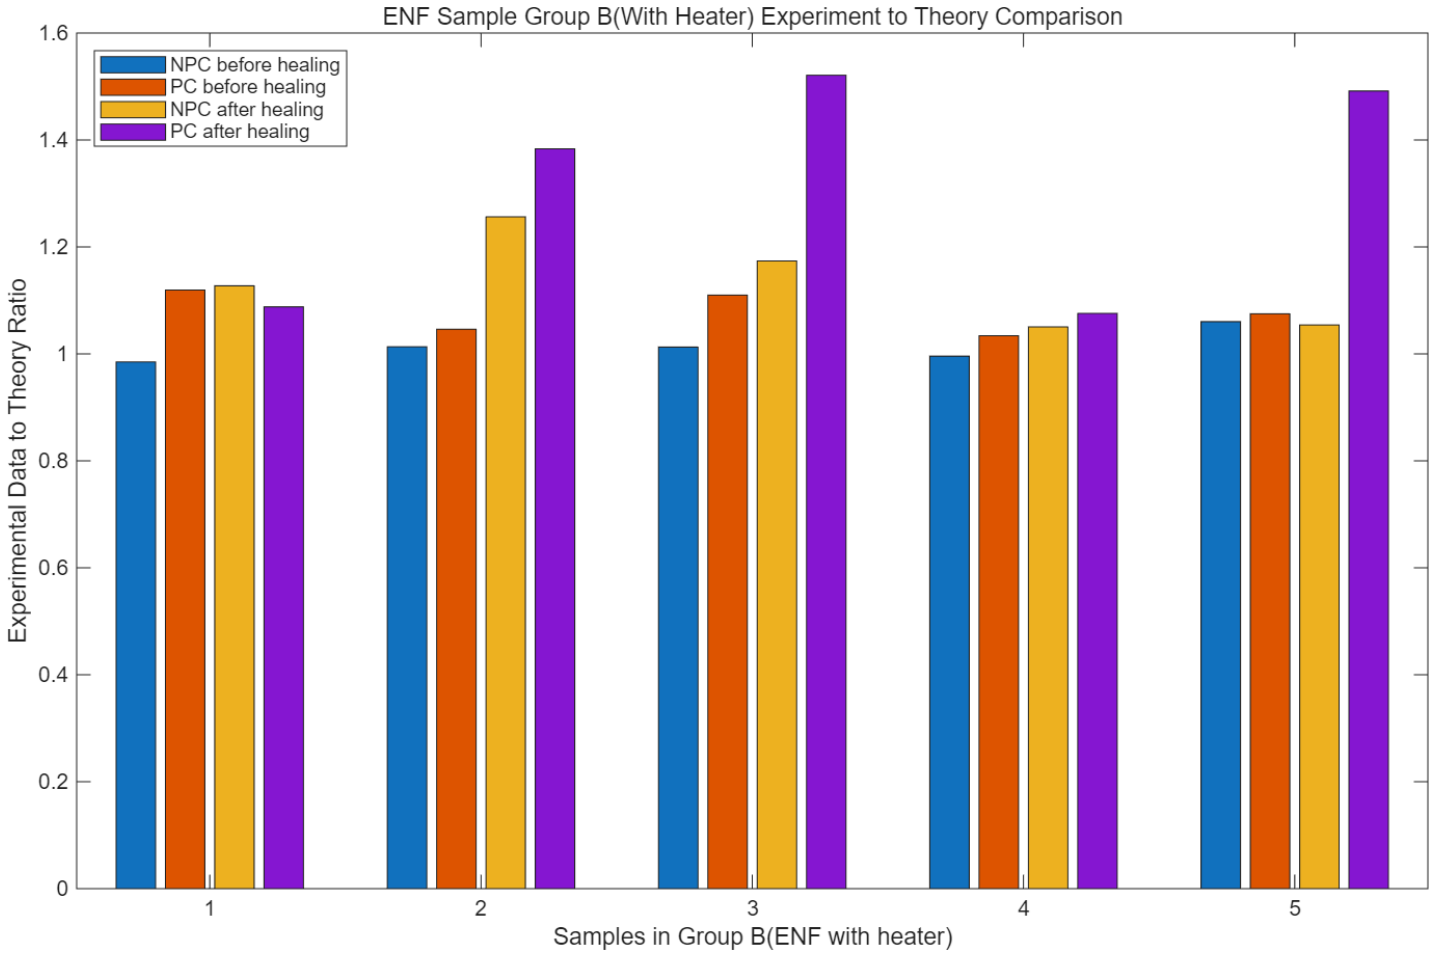
- Specimens in sample group A showed uniform geometry as a baseline control group (a)
- Specimens B2, B3, B5 in sample group B (b) showed deformations after self-healing (c1)
- All specimens in sample group C(after self-healing) were trimmed into a parallel rectangular shape for the ENF testing (c2)

Morphological Analysis of ENF Specimen

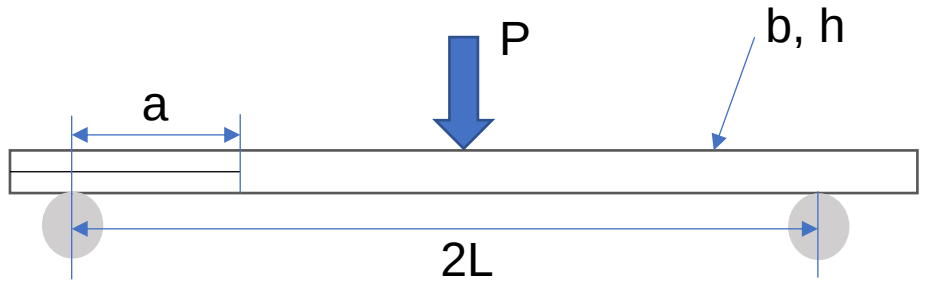


Load-Displacement Curves of all ENF Specimens

- Specimens in sample group A and B showed consistent and resembling load-displacement curves
- Variations occurred for sample group C specimens, due to the geometry deformations of each specimens via the self-healing process
- The mode II toughness was calculated based on the compliance data obtained via linear fit of each curves



$$G_{IIC} = \frac{3mP^2a^2}{2b} (ASTM\ D7905)$$



Mode II Toughness Comparison Results of ENF Specimen

Sample Group	A	B	C
G_{IIC}(NPC)	1.7882 ± 0.1463	2.0095 ± 0.1036	1.9494 ± 0.2094
G_{IIC}(PC)	1.9494 ± 0.2094	2.0946 ± 0.1006	2.4373 ± 0.7253

Mode II Toughness Comparison Results of ENF Specimen: Experiment vs. Theory

$$G_{II} = \frac{9CP^2a^2}{2b(2L^3 + 3a^3)} (Theory, [1])$$

$$G_{IIC} = \frac{3mP^2a^2}{2b} (ASTM\ D7905)$$

$$\frac{Experiment}{Theory} = \frac{m}{\frac{3C}{2L^3 + 3a^3}}$$

Conclusion and Future Work

Conclusion

1) Morphology presents the self-healing is successful for both SBS and ENF specimen

   - Pre-crack(SBS) and propagated crack(ENF) shown reconsolidation

2) Short Beam Shear(SBS) specimens showed around 90% bending stiffness recovery compared to the baseline specimen

   - Self-healing results in the composite parts resembling that of the plain specimen without the nano-engineered architecture

3) End-Notched Flexural(ENF) specimens showed around 90% mode II toughness recovery after self-healing compared to before self-healing

   - Average recovery rates of form-preserved specimens showed around 80% recovery rate
   - More form-preserved specimen data required

Future Work

1) Increasing the Mode II toughness data of the ENF test specimens
   - Utilizing the form-preserving technique via the metal mold

2) Finding the temperature cycle for 100% self-healing efficiency
   - Increasing the holding time or the cooling phase
   - Adjusting the other temperature cycle parameters

3) Developing the self-healing technique without the vacuuming procedure
   - Different polymer matrices without discoloration with oxygen exposure as for PA6
   - Raising the self-healing convenience and efficiency

ABSTRACT

Here in, polyamide 66 nanocomposites with graphene-based nanofillers were prepared and the structure and the properties were investigated. In order to achieve the high dispersibility of the nanofillers, the nanocomposites were prepared by in-situ polymerization. As graphene-based nanofillers, graphene oxide and the chemically modified GO were used. It was revealed that the mechanical properties and the thermal properties significantly increased by the incorporation of graphene-based nanofillers. The nanocomposites with chemically modified GO showed higher Young's modulus, tensile strength and thermal properties. These results indicates that the synergistic effects of chemical and physical interfacial interactions in the nanocomposites achieved the excellent reinforcement effects.

1 INTRODUCTION

Since the first development of polymer nanocomposites by Toyota Central R&D Labs., Inc., research on polymer nanocomposites has intensively been conducted for various applications. So far, many types of nanomaterials have been investigated as nanofillers for polymer nanocomposites, such as nanocarbons, nitride compounds, nanofibers and so on. Among them, nanofillers with high aspect ratio have been revealed to show excellent reinforcement effect to achieve the significant improvement in the properties of polymer materials. Graphene is a single layer of graphite with one-atom-thickness and has high aspect ratio. Graphene have attracted great attention because of itsexcellent mechanical properties, thermal properties, electrical properties and so on since Geim et al. won the Nobel Prize in physics for discovering and identifying its unique properties.

In this study, graphene-based polyamide 66 (PA66) nanocomposites were prepared by in-situ polymerization. In the process of in-situ polymerization, polymerization proceeded under the presence of fillers. Therefore, the dispersibility of a filler in a solvent can be maintained even in the nanocomposites. In addition, fillers can chemically react with polymer matrices during the polymerization, resulting in the strong interfacial interactions through covalent bonds. We used two types of graphene, graphene oxide (GO) and the chemically modified GO (GO-DDA) and investigated the effect of the surface functional groups of graphene oxide (GO) and the chemically modified GO (GO-DDA) on the structure and the properties of the nanocomposites.

2 SAMPLE PREPARATION

GO aqueous suspension or GO-DDA was dispersed in pure water. The amount of filler was controlled to be 0.1 wt% in the suspension. The suspension was ultrasonicated for 90 min in water bath to obtain the high exfoliation of GO or GO-DDA. The GO or GO-DDA suspension was added to the mixture of hexamethylenediamine and sodium hydroxide solution and then stirred for 1 h (mixture 1). The organic chloride mixture which contained adipoyl chloride and carbon tetrachloride (mixture 2) was prepared in the other beaker. The mixture 1 was slowly added to the top of the mixture 2 using a glass rod. The condensation polymerization of PA66 was proceeded at the interface between mixture 1 and mixture 2

under the presence of GO or GO-DDA. The reaction product was wound on the glass rod, followed by washing with water and ethanol for several times. For the purification, re-precipitation with phenol and methanol was carried out to remove the unreacted solvents and low-molecular-weight products. After vacuum filtration, the product was washed with water, dried at 40 °C for 48 h and then in vacuum at 40 °C for 72 h. The dried product was put between aluminum plates with a spacer and then melt pressed at 270 °C to obtain the PA66/GO nanocomposite or PA66/GO-DDA nanocomposite with a thickness of 0.2 mm.

3 RESULTS AND DISCUSSION

Figure 1 Optical images of PA66, PA66/GO nanocomposites and PA66/GO-DDA nanocomposites.

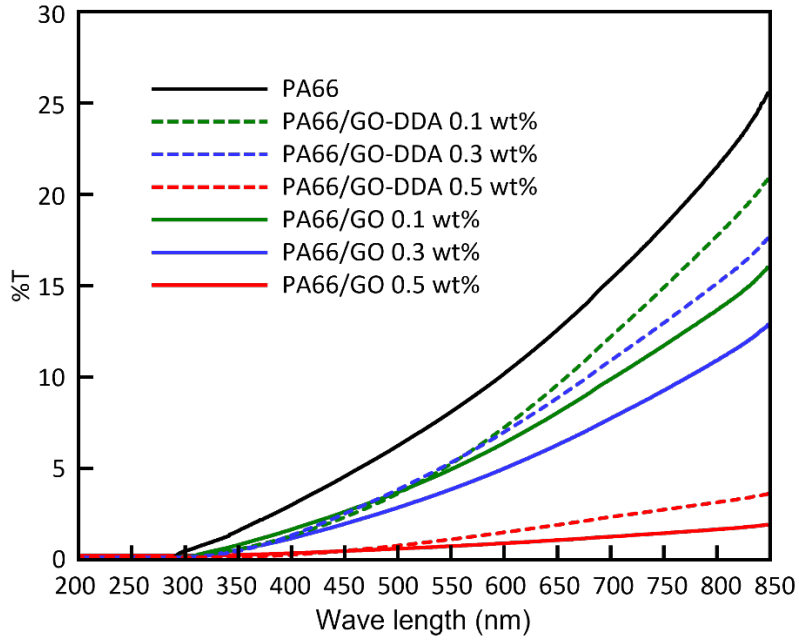

Figure 2 UV-vis spectra of PA66, PA66/GO nanocomposites and PA66/GO-DDA nanocomposites.

Figure 1 and Figure 2 shows the optical images and UV-vis spectra of PA66, PA66/GO nanocomposites and PA66/GO-DDA nanocomposites, respectively. The nanocomposites exhibited the favorable transparency, indicating the homogeneous dispersion of the fillers. Compared to the nanocomposites with GO, the nanocomposites with GO-DDA shows higher transparency. It was suggested that the dispersibility in PA66 was improved by the chemical modification of GO.

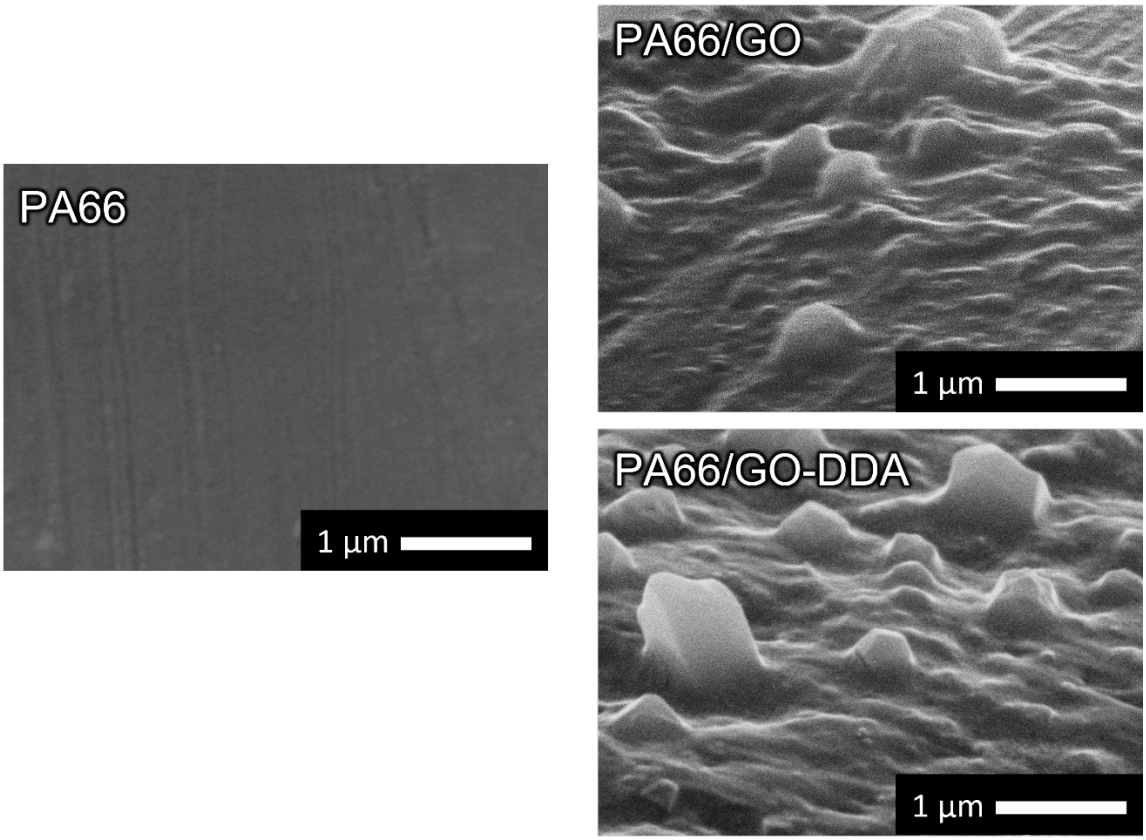

Figure 3 SEM images of PA66, PA66/GO nanocomposites (0.5 wt%) and PA66/GO-DDA nanocomposites (0.5 wt%).

Figure 3 shows SEM images of the cross section of PA66, PA66/GO nanocomposites and PA66/GO-DDA nanocomposites. The filler content was 0.5 wt%. It was revealed that the fillers were homogeneously dispersed and highly aligned in the in-plane direction of the nanocomposites.

Figure 4 shows XRD profiles of PA 66, PA66/GO nanocomposites and PA66/GO-DDA nanocomposites. All the profiles show the characteristic peaks of (100) and (010)/(110) of PA66 at 2 theta of 20.9 ˚ and 24.2 ˚, respectively. Since there is no shift in peak position, there is no change in d-spacing by the addition of GO or GO-DDA. The crystallinity estimated from the profiles are inserted in Figure 4. The crystallinity of the nanocomposites increases with the addition of GO or GO-DDA. It is well known that nanofillers can act as crystallization nuclei in polymer nanocomposites. At the same time, nanofillers can increase the viscosity of composite suspensions/solutions and cause the low molecular mobility which decrease the crystallinity. These counter effects can also occur in PA66/GO nanocomposites and PA66/GO-DDA nanocomposites. It is assumed that the former effect might be slightly dominant in the present nanocomposites.

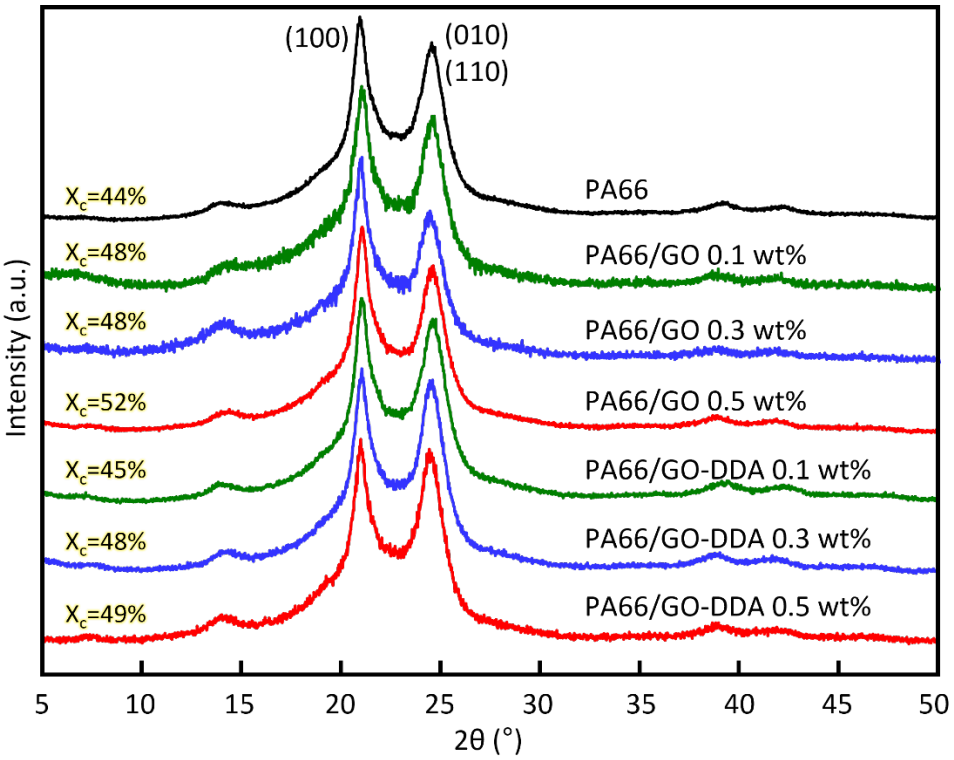

Figure 4 X-ray diffraction profiles of PA66, PA66/GO nanocomposites and PA66/GO-DDA nanocomposites.

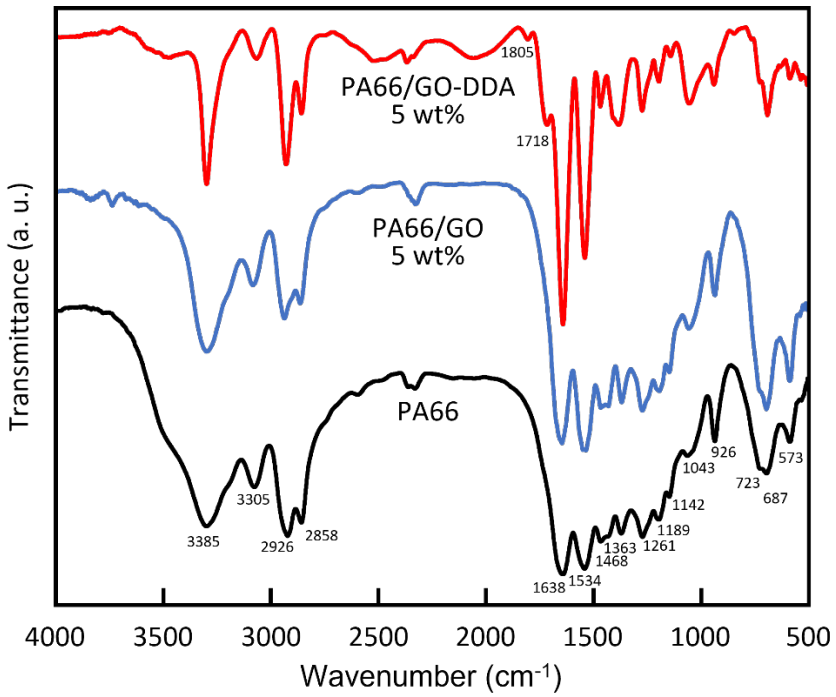

Figure 5 ATR-FTIR spectra of PA66, PA66/GO nanocomposites and PA66/GO-DDA nanocomposites.

Figure 5 shows the ATR-FTIR spectra of PA66, PA66/GO nanocomposites and PA66/GO-DDA nanocomposites. The characteristic bands derive from amide bonds in PA66 are observed for all the spectra. Both of the bands at 3385 cm^{-1} and 3305 cm^{-1} are attributed to N-H stretching vibration, while the lower wavenumber indicates the effects of intermolecular or intramolecular hydrogen bonds of PA66. The intensity of the bands at 3305 cm^{-1} of the PA66/GO-DDA nanocomposites is weaker than that of the PA66/GO nanocomposites, indicating the decrease of hydrogen bonds due to the substitution of carboxy groups to DDA on GO surface. Furthermore, the PA66/GO nanocomposite had the highest amide bond content, followed in the order of PA66/GO-DDA nanocomposites > PA66. It is revealed that the formation of amide bonds is facilitated in the process of the *in-situ* polymerization of the nanocomposites.

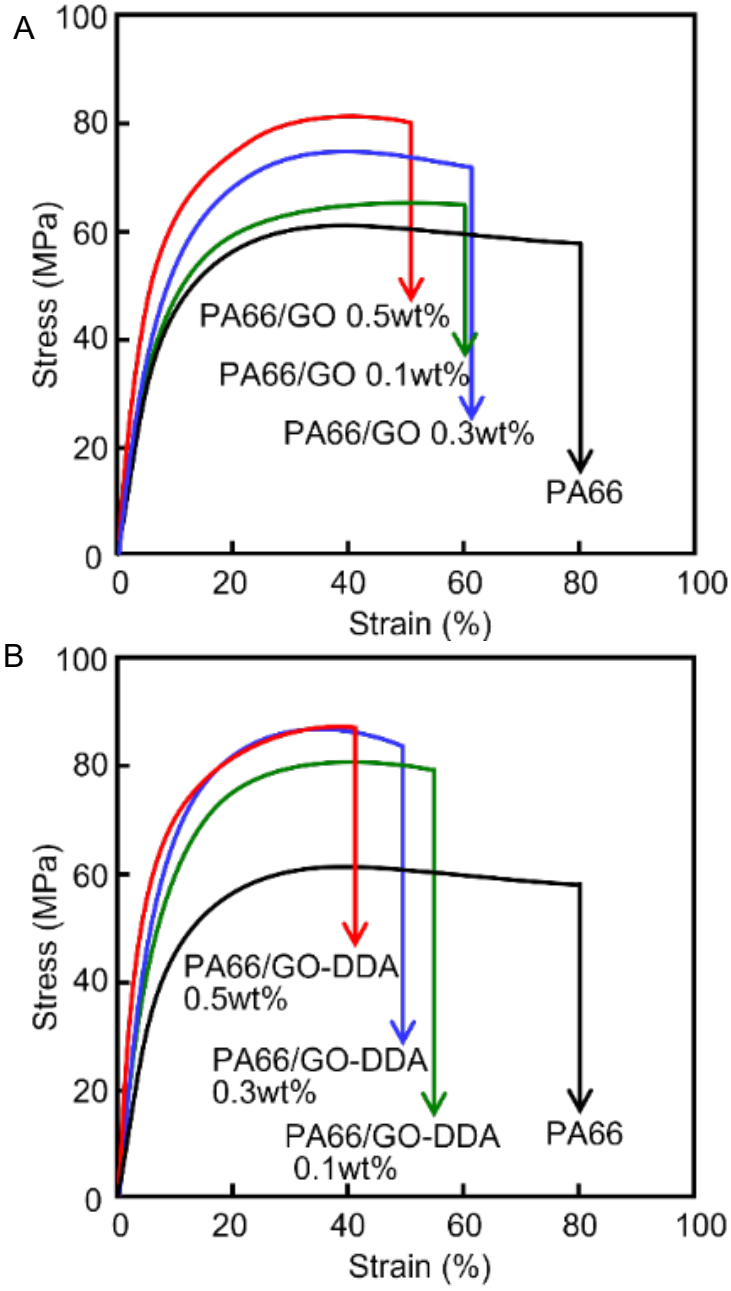

Figure 6 Stress-strain curves of (A) PA66/GO nanocomposites and (B) PA66/GO-DDA nanocomposites

Figure 6 shows stress-strain curves of (A) PA66/GO nanocomposites and (B) PA66/GO-DDA nanocomposites. It was revealed that the Young's modulus increased by 75% and 100% by the addition of 0.5 wt% of GO and GO-DDA, respectively. The strong reinforcement effects of the fillers were successfully imparted to the nanocomposites by the strong interfacial interactions and the high dispersibility with in-plane alignment. From the theoretical analysis using Halpin-Tsai model, the Young's modulus of the PA66/GO-DDA nanocomposites was revealed to be higher than that of the theoretical value at all the filler content. It was assumed that the physical interactions between PA66 and DDA molecular chains on GO-DDA played the important role in the reinforcement of the nanocomposites.

As for the thermal properties, the nanocomposites showed excellent thermal resistance. For example, the thermal decomposition temperature increased by 26 ˚C and 31 ˚C by the addition of 0.5 wt% of GO and GO-DDA, respectively. The molecular motion of PA66 was restricted by the highly dispersed/ aligned fillers with strong interfacial interactions. In addition, generation of volatile decomposition products were effectively barriered by the 2D fillers aligned to the in-plane direction.

In conclusion, the synergistic effects of chemical and physical interfacial interactions of the graphene-based nanocomposites lead the superior reinforcement effect in the mechanical and thermal properties at low content.

4 CONCLUSIONS

In this study, PA66/GO nanocomposites and PA66/GO-DDA nanocomposites were prepared by in-situ polymerization. As a result, the high dispersibility with in-plane alignment of the fillers was achieved in the nanocomposites. The crystallinity increase by the incorporation of GO or GO-DDA, indicating the nucleation effects by these nanofillers. ATR-FTIR spectra indicate that amide bonds are formed at the interfaces between PA66 and the fillers for both PA66/GO nanocomposites and PA66/GO-DDA nanocomposites. The excellent reinforcement effects on the mechanical and thermal properties are revealed. Compared to PA66, the Young's modulus increases by 92% for the nanocomposites at only 0.3 wt% loading of GO-DDA, while it increases by 42% for the nanocomposites with GO at the same content. In addition, the thermal decomposition temperature of the PA66/GO-DDA nanocomposite at 0.3 wt% is 31 ˚C higher than that of PA66. It is assumed that the synergetic effect of chemical and physical interfacial interactions lead the superior reinforcement effects of the PA66/GO-DDA nanocomposites at low content.

SOFT COMPOSITES FOR CHARGE TRANSPORT AND STORAGE TO SYNERGISTICALLY ENHANCE ENERGY HARVESTING PERFORMANCE OF TRIBOELECTRIC GENERATORS

Keywords: Triboelectric Nanogenerator; Multilayer Structure; Surface Potential; Volume Charge Distribution

ABSTRACT

The incorporation of interlayers between the charge-generating layers and current collectors of triboelectric nanogenerators (TENGs) has been found as an effective strategy to significantly increase power output, indicating their critical role in charge retention. However, there is a lack of direct experimental evidence of charge distribution in the interlayers. We introduce herein a novel approach of self-bonding and de-stacking to quantitatively characterize volume charge distributions within the interlayers as well as the charge-generating layers. The total charge within each layer is determined by measuring their surface potential. Applying this method on multilayer TENGs composed of different materials shows that the charge-generating layer holds roughly the same amount of charge independent of the interlayer characteristics, while the interlayer can store electrical charges depending on its conductivity and dielectric constant. At an optimal balance between these properties, a 220% increase in electrical output has been found compared to conventional TENGs without interlayers and a 50% increase over those with only one interlayer.

1 INTRODUCTION

Triboelectric nanogenerators (TENGs) have emerged as a promising technology, which are operated through the coupling effects of triboelectrification and electrostatic induction. It offers several advantages, including large range of material selection, lightweight, low-cost, high-power output, making them highly adaptable for diverse applications. Several studies have shown good potential of integrating TENGs into medical and therapeutic application [1-3]. However, the development of triboelectric materials with high power output performance are crucial to power medical devices. Various methods have been previously explored to enhance the performance of TENG by improving permittivity of composite materials, performing surface engineering [4, 5] and so on. The above methods have contributed significantly to improving the output performance of the TENGs.

However, the performance of TENGs is largely influenced by the surface charge density of the triboelectric material.[6] Unfortunately, surface charges tend to decay quickly due to factors such as air breakdown, ambient humidity and charge diffusion which can significantly reduce the output.[7] Delaying the surface charge decay time is particularly important to improve the output performance of TENGs. Triboelectric charge drift or diffusion is one of major factor causing triboelectric charges decay.

During continuous operation of TENG, the negative triboelectric layer captures negative triboelectric charges from the positive triboelectric layer, accumulating them on its surface. At the same time, the bottom electrode beneath the negative triboelectric layer generates induced positive charges via electrostatic induction establishing an upward electric field.[8] Consequently, triboelectric charge decay occurs through charge drift and diffusion. The drift is driven by the electric field, and the diffusion driven by the electron's concentration gradient.

To mitigate triboelectric charge dissipation in TENG, an effective strategy involves employing composite films that incorporate high-permittivity fillers within the triboelectric layer. For instance, Tantraviwat et al enhanced the dielectric constant by incorporating PDMS with $BaTiO_3$ which significantly boosted the output performance.[9] Furthermore, conductive fillers have also been incorporated into composites because of its great charge storage capacity to enable charge transport deeper within the film and boost performance.[10] For example, Sun et al. used a conductive MWCNT network in TPU film, significantly enhancing output current by dispersing surface charges into the TPU layer's interior.[11]

Another effective strategy to reduce charge diffusion and drift involves embedding an intermediate layer between the triboelectric layer and electrode, which can transport, storage and block charges. High-permittivity materials such as TiO2[12, 13] and BTO[14] have been developed as charge-blocking layers to enhance TENG output. For example, Park et al. showed that incorporating a TiOx electron-blocking layer with high permittivity enhanced TENG output power by 25 times, owing to its combined electron-blocking and polarization effects [13]. Similarly, Wu et al. introduced a SiO_2 layer to trap charges on hydrophobic fluoropolymer surfaces, leading to the development of a novel charge-trapping nanogenerator[15]. Furthermore, Jiang et al. demonstrated that placing a charge-trapping-blocking intermediate layer composed of rGO and Ag nanoparticles between the triboelectric layer and the electrode can significantly boost the output performance.[16]

Although interlayers have been shown to be effectively enhanced the power outputs of TENGs, direct experimental evidence regarding how the charges are distributed beneath the surface of the charge generating layer remains limited. This leaves a significant gap in understanding the volume charge distributions within the interior of various interlayer types, such as transporting layer,[11] storage layer,[16] and blocking layer.

In this study, we present a novel approach for quantifying the electrical charge distribution beneath the charge-generating surface using a stacking and de-stacking technique. To investigate the influence of dielectric constant and conductivity on charge distribution, we developed a composite tri-layer TENG comprising a PDMS-based charge generating layer, a charge-transporting layer (PDMS nanocomposite with multi-wall carbon nanotube MWCNT) and a charge-storage layer (PDMS nanocomposite with $BaTiO_3$). By adjusting the concentrations of nanofillers, we tuned the electrical conductivity and dielectric constant of the interlayers to determine the optimal combination for maximizing output performance. Enabled by a commercially scalable fabrication process, the composite tri-layer TENG holds strong potential for advancing high performance, self-powered wearable and implantable medical devices.

2 RESULTS AND DISCUSSION

Figure 1 provides a schematic overview of the multilayer composite TENG device structure including intermediate layers. In this configuration, a thin PDMS film acts as the negative triboelectric

layer, while the bottom aluminum film serves as the electrode. The top aluminum film functions both as the positive triboelectric layer and as an additional electrode. To enhance performance of the TENG, intermediate layers were introduced between the PDMS and aluminum electrode. An $MWCNT/PDMS$ hybrid layer was incorporated as a charge transport layer, while a $BaTiO_3/PDMS$ hybrid layer served as a charge-storage layer. As illustrated in **Figure 1a-c**, three designs were developed: Design A, consisting of a pristine PDMS thin layer; Design B, featuring a PDMS layer with a $BaTiO_3/PDMS$ hybrid layer inserted between the PDMS and the aluminum electrode; and Design C, which included both an MWCNT/PDMS hybrid layer and a $BaTiO_3/PDMS$ hybrid layer inserted between the PDMS and the aluminum electrode.

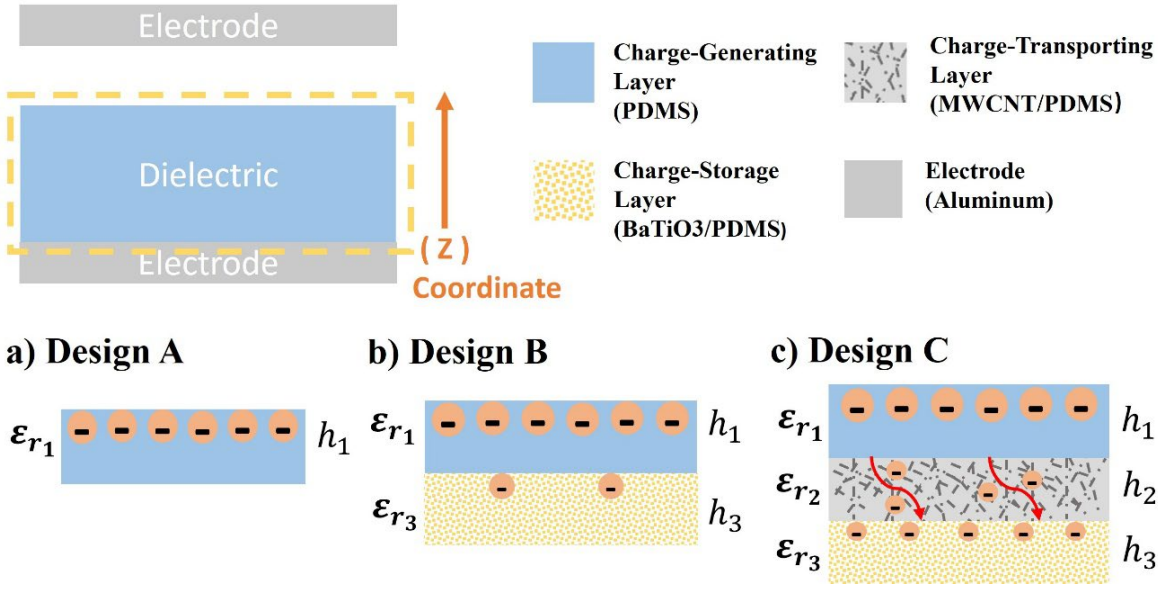

Figure 1: Multilayer TENG Configurations. a) Design A features a single PDMS layer. b) Design B includes one intermediate $BaTiO_3/PDMS$ layer as charge-storage layer. c) Design C incorporates two intermediate layers: MWCNT/PDMS as charge-transporting layer and $BaTiO_3/PDMS$ as charge-storage layer.

2.1 ELECTRICAL CHARACTERIZATION OF DIFFERENT MULTILAYER COMPOSITE TENGS

Based on the prepared composite films, the electrical output performance of samples was tested in the vertical contact-separation mode during the experiment. **Figure 2a** demonstrated the working principle of the multilayer composite TENG. The electricity generation cycle is governed by the combined effects of contact electrification and electrostatic induction. When the aluminium film contacts the PDMS surface, electrons transfer between the two-contacting surface due to their different electron affinities (**Figure 2a(i)**). As the aluminium film moves away from the PDMS, a potential difference is established, driving electrons through the external circuit from the top electrode to the bottom one (**Figure 2a(ii)**). This current continues until an equilibrium is reached at the point of maximum separation (**Figure 2a(iii)**). When the aluminium film returns toward the PDMS surface, the process reverses: electrons flow from the bottom to the top electrode (**Figure 2a(iv)**). Through repeated contact and separation, the multilayer composite TENG generates alternating current (AC) electricity,

which can be rectified and stored in a battery or capacitor to power electronic devices. During this cycle, electric charges also flow through the PDMS and the charge-transporting layer (**Figure 2a(ii)**), driven by the internal electric field. This charge flow continues from the generation surface to the storage layer until a new equilibrium is reached.

Figure 2b-d plots the output performance of different multilayer composite TENGs working at the frequency of 2 Hz. The pristine TENG without the additional layer shows a peak open-circuit voltage (V_{oc}) of 243 V, peak short-circuit current (I_{sc}) of 1.2 μA and transferred charge (Q_{sc}) of 33 nC. Later, Design B with a $BaTiO_3$/PDMS hybrid layer exhibits enhanced output, with the V_{oc}, I_{sc} and Q_{sc} of 575 V, 3 μA and 54 nC respectively. Design C with the MWCNT/PDMS and $BaTiO_3$/PDMS hybrid layers demonstrate further enhancement in output performance with V_{oc} of ~1103 V, I_{sc} of 6.18 μA and Q_{sc} of 73 nC respectively. Accordingly, the enhancement of the output I_{sc} with the MWCNT/PDMS and $BaTiO_3$/PDMS hybrid layers is almost 5 times that of the pristine TENG.

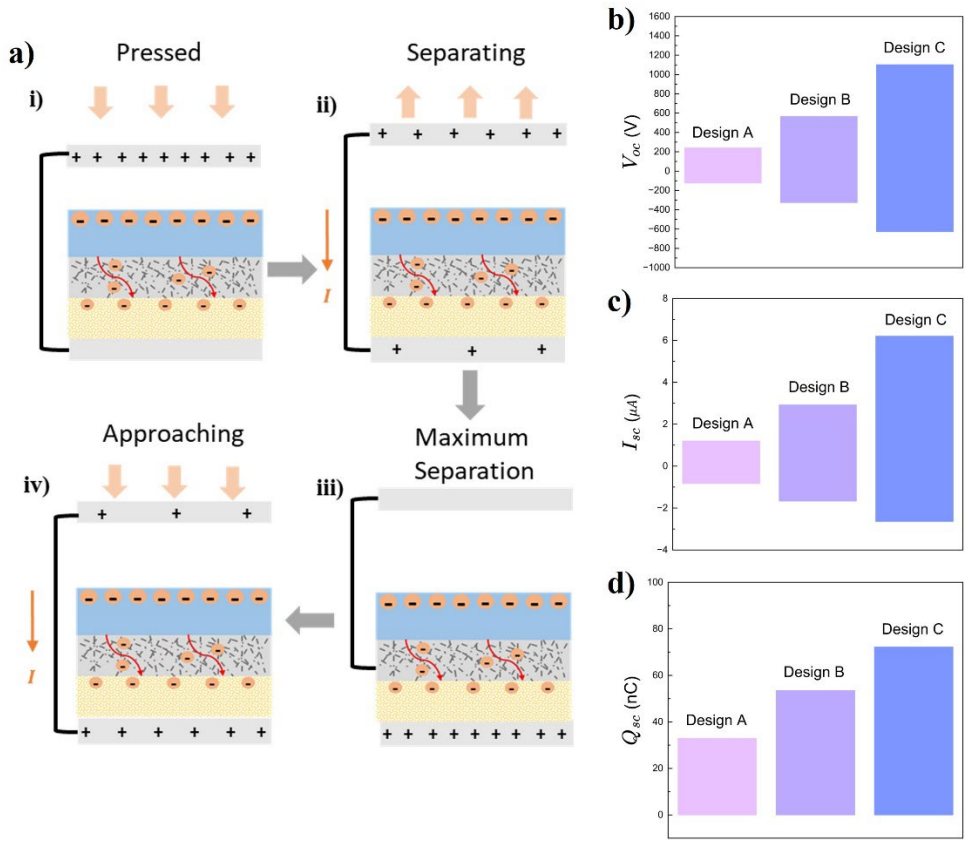

Figure 2: Electrical Characterization of different multilayer composite TENGs. a) Working mechanism of the tri-layer TENG. b) V_{oc} of TENGs. c) I_{sc} of TENGs. d) Q_{sc} of TENGs.

As electrons accumulate on the contact surface, they induce positive charges on the bottom electrode, forming a vertically upward built-in electric field between the surface and the electrode. This field initiates two modes of electron transport: drift which is driven by the electric field, and diffusion which is caused by the concentration gradient of electrons. Both mechanisms can lead to the recombination of triboelectric electrons with the induced positive charges on the electrode, resulting in charge loss. Moreover, triboelectric electrons may also recombine with adsorbed positively charged ions or air particles, further contributing to the performance degradation observed in conventional TENGs.[17]

To overcome these limitations, we incorporate a charge transport layer and a charge storage layer between the triboelectric layer and the bottom electrode. The charge transport layer provides a conductive pathway, enabling efficient migration of triboelectric charges away from the surface. This mitigates repulsive interactions with incoming charges, thereby improving charge accumulation efficiency.[11] The charge storage layer, characterized by strong electron-trapping capability, suppresses recombination between electrons and induced positive charges.[13] Additionally, embedding high-permittivity fillers into these layers enhances the overall dielectric constant, further boosting the output performance of the composite tri-layer TENG.[9]

To evaluate the charge accumulation performance of three multilayer composite TENGs, a series of contact-separation tests were conducted using a linear motor with a 1 mm displacement, 100 N contact force, and 2 Hz frequency. The electrical performance of three test samples was compared. The corresponding open-circuit voltage and maximum charge transfer density for each design are presented in **Figure 3a-b**. Design A showed a moderate voltage increase from 97 V to 243 V. Design B demonstrated greater improvement, with V_{oc} rising from 230 V to 575 V, attributed to the enhanced permittivity and electron-trapping capability of the $BaTiO_3$/PDMS layer.[18] In Design C, the incorporation of a conductive intermediate layer with the MWCNT/PDMS transport layer enable an V_{oc} of 238 V and then eventually saturating at 1103 V. The sharp rise in voltage suggests effective charge storage within the composite tri-layer TENG. Design C reached a maximum charge transfer density of 3.3 nC/cm^2, which is 3 times compared with that of Design A, which did not include intermediate layers. This improvement is primarily attributed to the charge transport layer, which facilitates the movement of triboelectric charges away from the surface. By alleviating charge repulsion during subsequent cycles, it significantly boosts the device's overall performance.

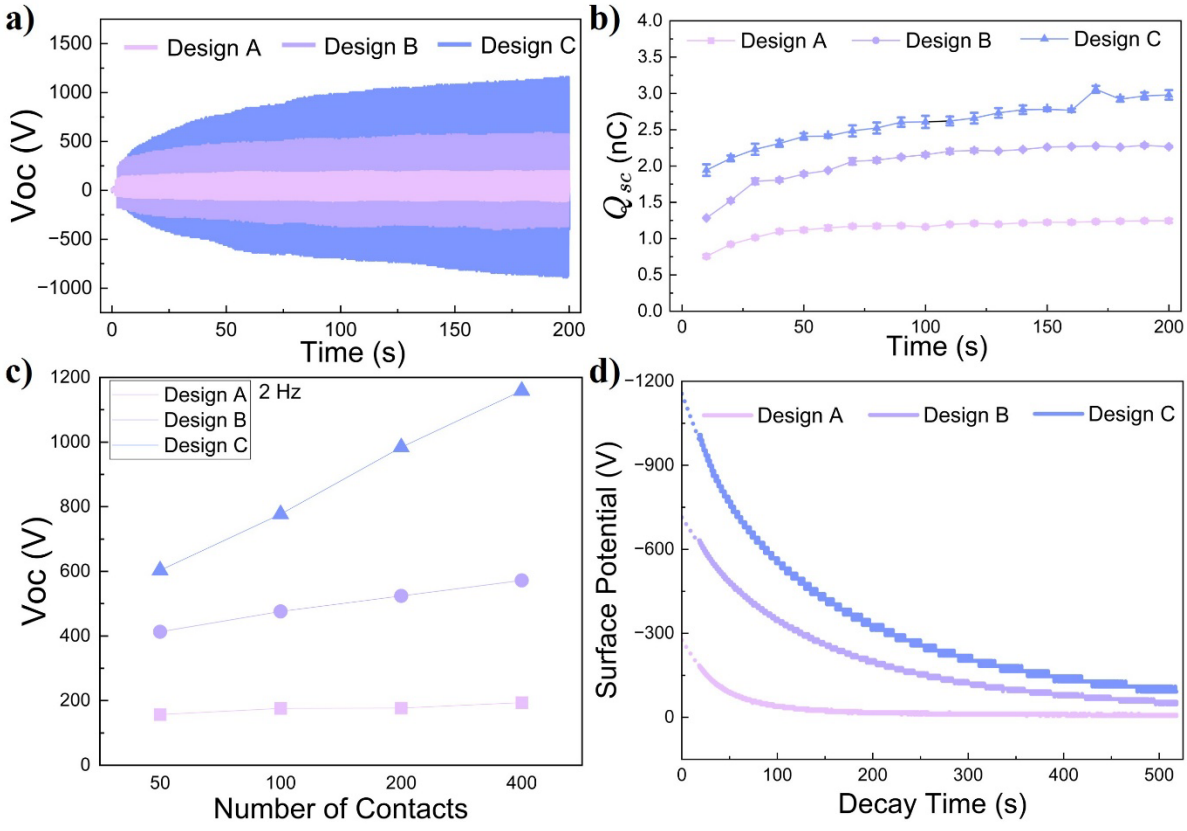

Figure 3: Charge accumulation of multilayer composite TENGs. a) V_{oc} (open circuit current). b) Q_{sc} (transferred charge density). c) after-contact surface potential of different designs. d) Surface potential decay of different designs.

2.2 SURFACE POTENTIAL CHARACTERIZATION FOR DIFFERENT MULTILAYER COMPOSITE TENGS

The origin of surface charge is a fundamental aspect of TENG, essential for visualizing and quantifying the creation and dissipation processes of triboelectric charges during contact and separation movements[19]. To better understand this, we systematically investigated the performance of Designs A, B, and C using surface potential measurements, with the aim of confirming the advantages of the MWCNT/PDMS charge-transporting layer and the $BaTiO_3$/PDMS charge-storage layer. Any residual charges on the surface of each test layer were neutralized before measurement to ensure a zero-surface potential which is verified by the electrostatic voltmeter. The surface potential was then measured at 3 mm to accurately assess the charge characteristics on the nanocomposite surface. These measurements were performed after driving the TENG samples using a linear motor operating at a frequency of 2 Hz and a force of 100 N.

As shown in **Figure 3c**, the surface potential trends are similar with those of the V_{oc} across all designs, with potential values increasing as the tapping time rose. This correlation indicates that the surface potential is directly tied to the contact-separation numbers. For Design A, the surface potential stabilized around -300 V after 50 s tapping time, indicating a limitation in net charge accumulation due to contact electrification. In comparison, the surface potential of Design B continued to rise after 25 s of tapping, eventually stabilizing at approximately -700 V after 100 s. This enhancement is contributed by the $BaTiO_3$/PDMS layer, whose high dielectric constant and strong electron-trapping ability effectively reduce electron recombination, thereby improving both charge retention and surface potential.[9, 20]. As a result, the elevated surface charge enhanced electrostatic induction at both electrodes, leading to increases in V_{oc}, I_{sc}, and Q_{sc}. With the addition of an intermediate MWCNT/PDMS transporting layer, Design C exhibited a continuous rise in surface potential from approximately -870 V to -1160 V which is nearly four times compared with that of Design A. The charge transporting layer enables deeper migration of charges away from the surface, reducing electrostatic repulsion on incoming charges and promoting more efficient charge accumulation at the top interface. This improvement not only enhances the charge storage capacity but also increases the depth of charge retention within the triboelectric material.

To evaluate the charge-storage capabilities of the TENGs, surface potential decay was measured following 200 seconds of tapping. Due to an 18s delay between the linear motor halting and the positioning of the electrostatic voltmeter probe, surface potentials were estimated by extrapolating the measured data to time zero using a double-exponential fitting function: $V = Ae^{-\frac{x}{\tau}} + Be^{-\frac{x}{\tau}}$, as shown in **Figure 3d**. The extrapolated surface potentials after 200 s of tapping were approximately -300 V, -700 V, and -1160 V for Designs A, B, and C, respectively. Designs B and C exhibited prolonged surface potential retention compared to Design A, with Design C maintaining a measurable potential for over 8 minutes after continuous contact cycles. Design A experienced a more rapid decay, whereas Designs B and C displayed nearly identical and slower decay rates. These findings confirm that the integration of MWCNT/PDMS and $BaTiO_3$/PDMS interlayers play a crucial role in stabilizing and enhancing the

output performance of the TENG.

To further investigate the charge distribution the mechanisms contributing to the enhanced output performance and particularly the effects of the conductive filler (MWCNT) and the high-permittivity filler ($BaTiO_3$), we conducted additional experiments to examine the surface potential of each individual layer in Designs A, B, and C.

As illustrated in **Figures 4**, each design was fabricated layer-by-layer. Design A served as the baseline and did not contain any fillers. Design B incorporated a layer-by-layer assembly with a pure PDMS triboelectric layer and an additional layer containing the dielectric filler $BaTiO_3$. Design C included a triboelectric layer, a charge-transporting layer, and a charge-storage layer. To ensure consistent testing, a linear motor was employed to ensure 200s tapping time at 2 Hz frequency and 100 N force for all three designs. Furthermore, we measured the surface potential layer by layer using a peeling method which allowed for a precise assessment of each layer's contribution to the overall charge distribution. Surface potentials for the layers were measured using an electrostatic voltmeter setup as presented in **Figure 4b**, where the measurement probe was set at 3 mm above a separated PDMS layer that was placed on the ground plane. The probe of an electrostatic voltmeter detects the electric field and measures voltage relative to the ground plane on which the dielectric layer is placed.

Surface potential measurements were conducted layer by layer using a peeling method, as illustrated in **Figure 4a**, enabling precise evaluation of each layer's contribution to the overall charge distribution. As shown in **Figure 4c**, Design C exhibited the highest total surface potential among the three configurations. The surface potentials of the PDMS charge-generating layers in Design B (~334 V) and Design C (~350 V) were slightly higher than that in Design A (~300 V), suggesting that the interlayers contributed to the increased potential in Design C. The charge-transporting layer in Design C showed a relatively low surface potential (~200 V), indicating its limited charge retention capacity due to high conductivity which an attribute that facilitates efficient charge transfer to deeper layers. Notably, the surface potential of the charge-storage layer in Design C was significantly higher than in Design B, confirming that the addition of a charge-transporting layer between the PDMS and $BaTiO_3$/PDMS layers enhanced charge transfer and accumulation, thereby improving the surface potential of the charge-storage layer.

Based on the measured surface potentials, the volume charge density can be determined using Gauss's law. For a single dielectric layer with cross-sectional area S and thickness d, placed on a grounded plane at $z = 0$, the total enclosed charge between z and $z = d$ can be expressed in terms of the volume charge density ρ

$$Q_{enclosed} = S\int_z^d \rho dz = S\rho(d-z) \quad [1]$$

The electric displacement field *D* at a distance z above the ground plane can be expressed as:

$$D = \frac{Q_{enclosed}}{S} = \rho(d-z) \quad [2]$$

The resulting electric field within the dielectric material is:

$$E(z) = \frac{D(z)}{\varepsilon_0\varepsilon_r} = \frac{\rho(d-z)}{\varepsilon_0\varepsilon_r} \quad [3]$$

where ε_0 represents the permittivity of air, ε_r is the relative permittivity of the dielectric material.

The surface potential at the top surface ($z = d$) is determined by integrating the electric field from a position z up to *d*:

$$V(d) = -\int_z^d Edz = -\frac{d^2-\frac{1}{2}d^2}{\varepsilon_0\varepsilon_r} = -\frac{\rho d^2}{2\varepsilon_0\varepsilon_r} \quad [4]$$

Using Equation [4], the volume charge densities of the three individual layers in the tri-layer PDMS stack were calculated to be 920.634 nC/cm^3, 501.816 nC/cm^3, and 648.587 nC/cm^3, as depicted in **Figure 4d**. These values highlight the variation in charge distribution across the different material layers.

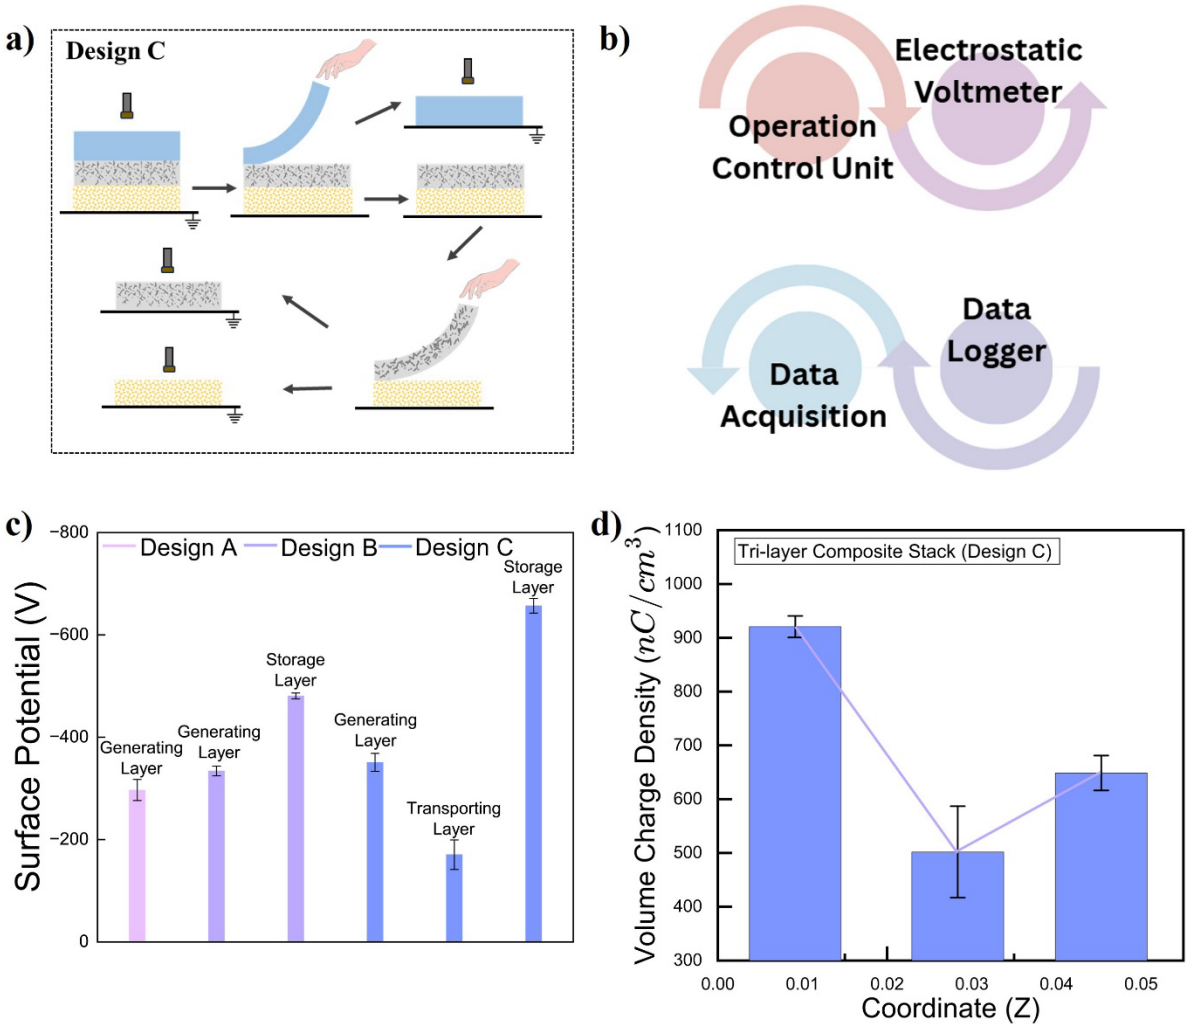

Figure 4: Surface potential measurement and volume charge density analysis in multilayer TENG with composite materials. a) Schematic representation of the surface potential measurement procedure for different TENG design layers. b) Illustration depicting the steps involved in surface potential measurement. c) Experimental results showing the measured surface potential across layers in various TENG configurations. d) Trend of volume charge density within the multilayer composite stack.

The relationship between TENG output and external resistance under a 2 Hz excitation frequency and 100 N contact force is shown in **Figure 5**. As expected by Ohm's law, the output voltage increased with external resistance, while the current correspondingly decreased. The peak power density of the composite tri-layer TENG was observed across varying load resistances, reaching a maximum of 1.22 W/m^2 at 300 MΩ. This level of output is sufficient to power many wireless wearable and implantable medical devices, highlighting the strong potential of the composite tri-layer TENG. Nevertheless, extending the operational lifespan of wearable and implantable medical devices will

require not only efficient power generation but also optimized power management systems and reduced device power consumption.

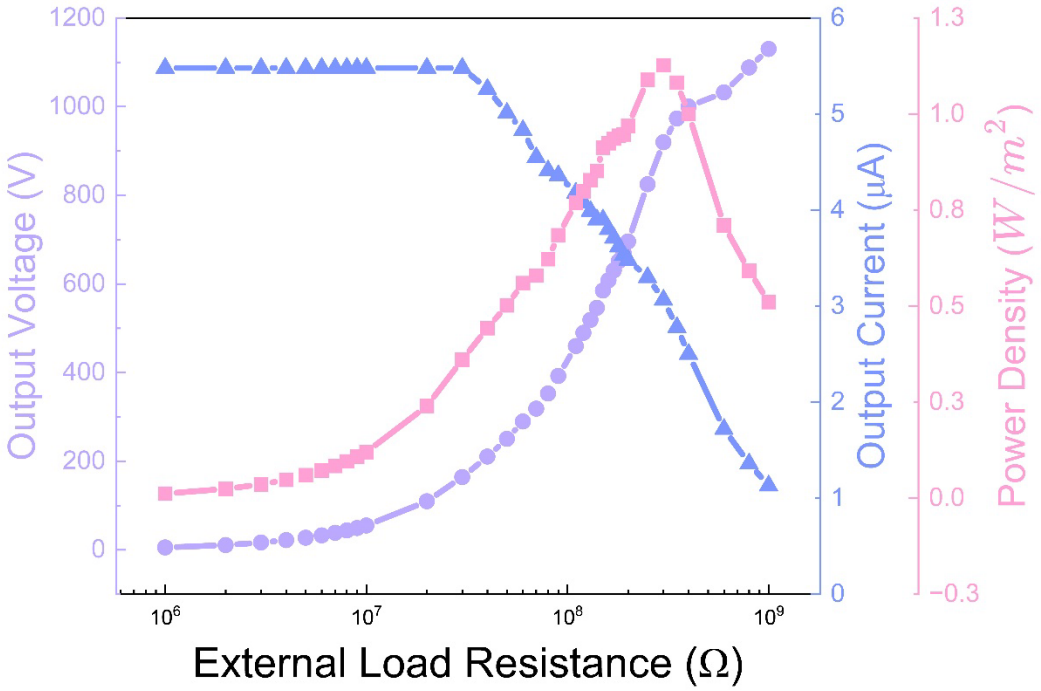

Figure 5: Effect of external load resistance on the output characteristics of the TENG, showing the variations in voltage, current, and power density.

3 CONCLUSIONS

This study introduces a novel approach for measuring and understanding charge distribution beneath the friction surface, utilizing a tri-layered composite TENG stack design. By examining the individual layers of this stack, we quantified the charge distributions within the individual layers of the TENG. These results were achieved through in-depth investigation of the enhancement mechanisms, including physical characterizations and detailed electrical measurements. For the first time, we visualized the surface potential of layers beneath the triboelectric layer, shedding light on charge distribution below the surface and confirming the effectiveness of the MWCNT/PDMS charge-transporting layer and the $BaTiO_3$/PDMS charge-storage layer using surface potential measurements.

Based on these findings, a high-performance tri-layered composite TENG was developed featuring a structural design that incorporates intermediate layers. These layers are composed of MWCNT/PDMS and $BaTiO_3$/PDMS hybrid films, serving as the charge-transporting layer and charge-storage layer respectively. This combination enabled electrical charges to be stored in the dielectric component without affecting the charges in the generating layer, significantly increasing the TENG's transferred charge density to 3.3 nC/cm^2 and a maximum power density of 1.2 W/m^2. The new tri-layered composite TENG demonstrates significant potential for integration into self-powered medical devices. Future research will focus on optimizing the materials and device architecture to enhance durability, efficiency, and pave the way for broader adoption in medical and consumer electronics.

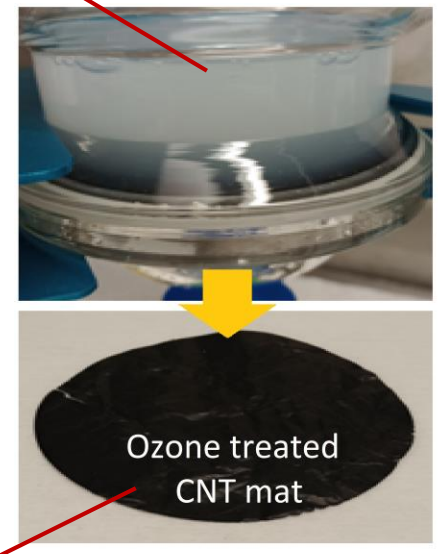
PUBLIC RELEASE

Composite Structural Supercapacitors (SSCs)

- Improvement in Size, Weight, and Power (SWaP) energy storage to mobile devices or transportation vehicles
- Electrode and electrolyte materials have been well developed for SSCs
- However, little work has focused on developing materials for the SSC separator layer
  - Common materials: cellulose filter paper, glass fibre fabric, aramid fibre fabrics, porous polymer membranes
- Non-conductive porous materials such as boron nitride nanotubes (BNNTs) can be incorporated to one surface of the electrode material, removing the need for the separator layer altogether

PUBLIC RELEASE

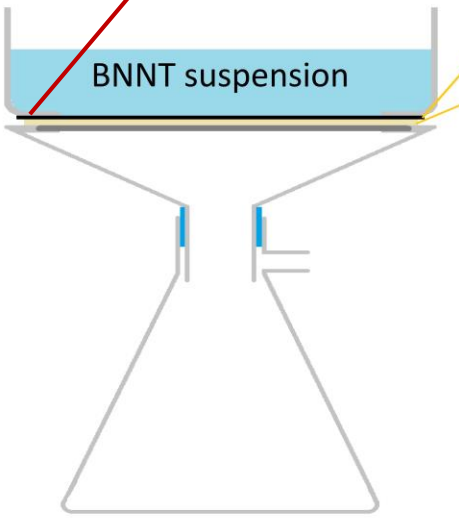
Boron Nitride Nanotubes (BNNTs)



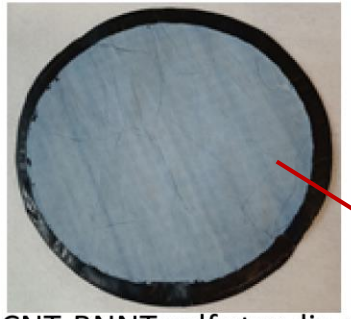
- Strong, light weight and chemically resilient
- Thin film materials that possess high structural integrity and porosity
- Dimensionally stable and capable of withstanding high temperature
- High potential for high-power composite structural supercapacitors applications

This work combines commercially available carbon nanotube (CNT) mat with BNNTs coating to produce a high-performance fibre-reinforced polymer composite using industrial autoclave curing techniques.

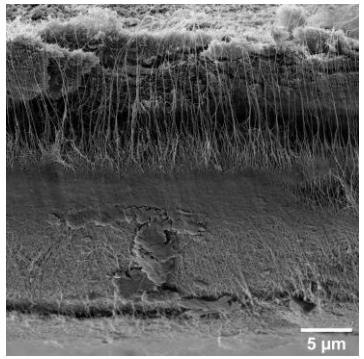
PUBLIC RELEASE



BNNTs Coating Method

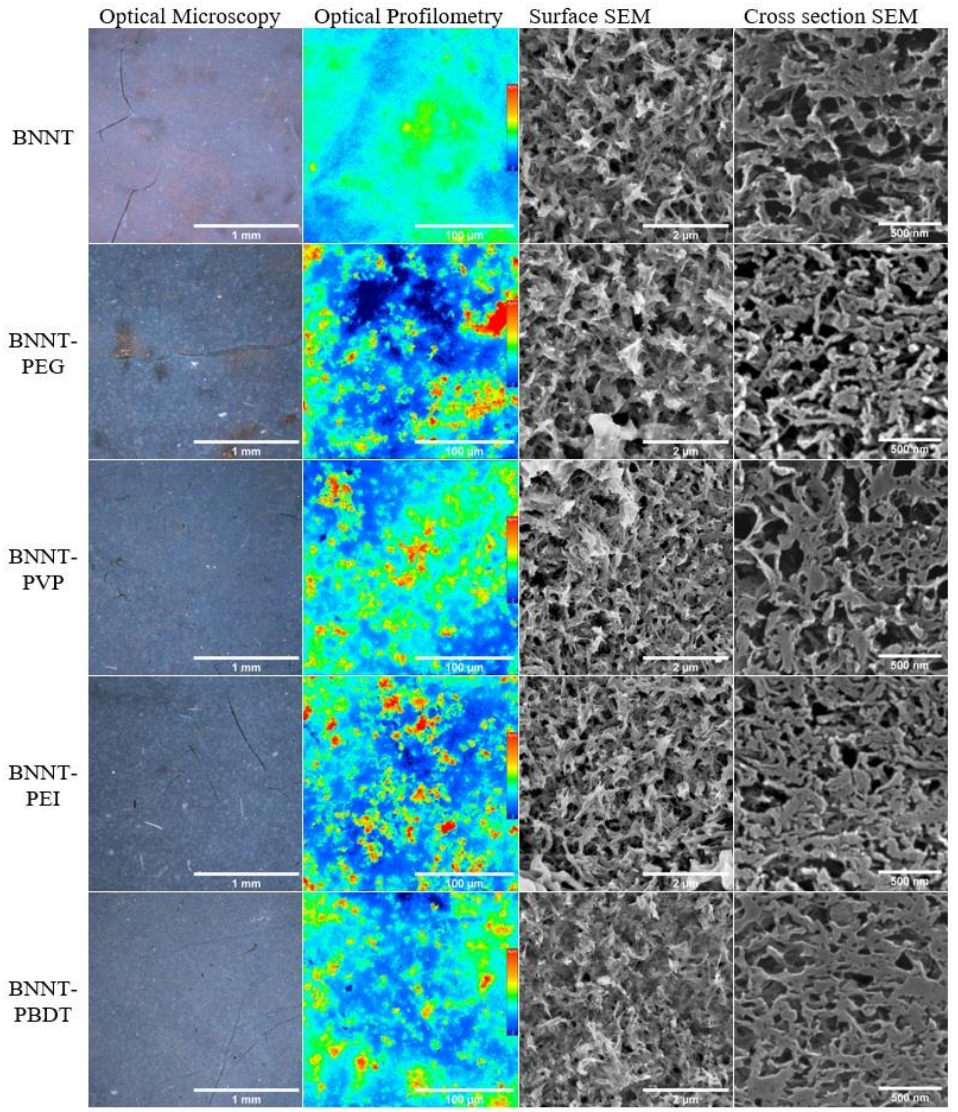


Stable dispersed mixture of BNNTs, achieved using sonicated ozonolysis. Sonication reduces the size of large BNNT agglomerates and cleaves BNNTs to decrease their average length.



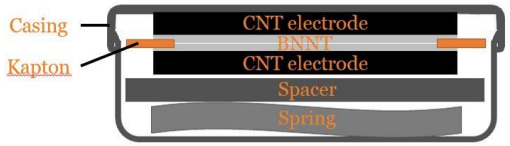
Oxygen-functionalised CNT Mats, treated for 6h prior to BNNT coating. This process enhances the water permeability for better vacuum filtration.

Porous support underneath CNT Mat can be tailored using a glass fibre filter paper to control coating homogeneity.

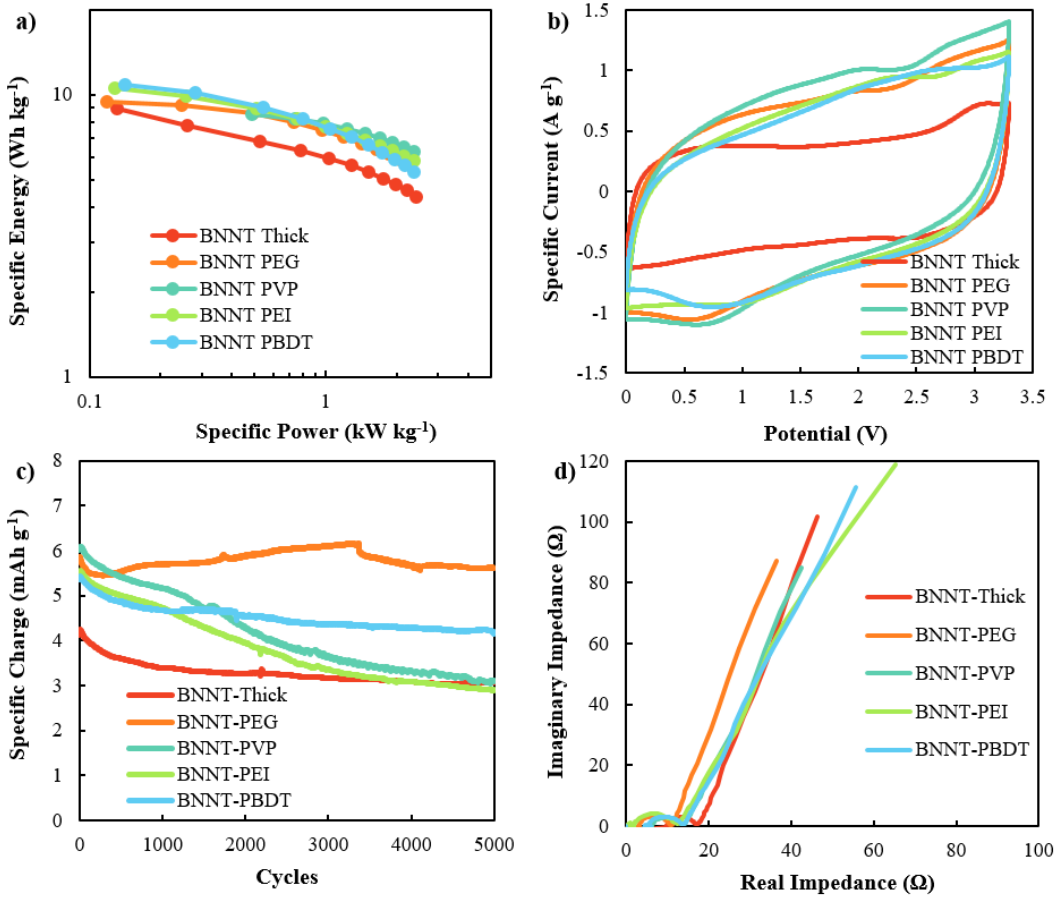


CNT-BNNT self standing electrode and separator

Dried CNT-BNNT film. Polymeric binder can also be combined in the BNNT suspension before vacuum filtration for more uniform coating.

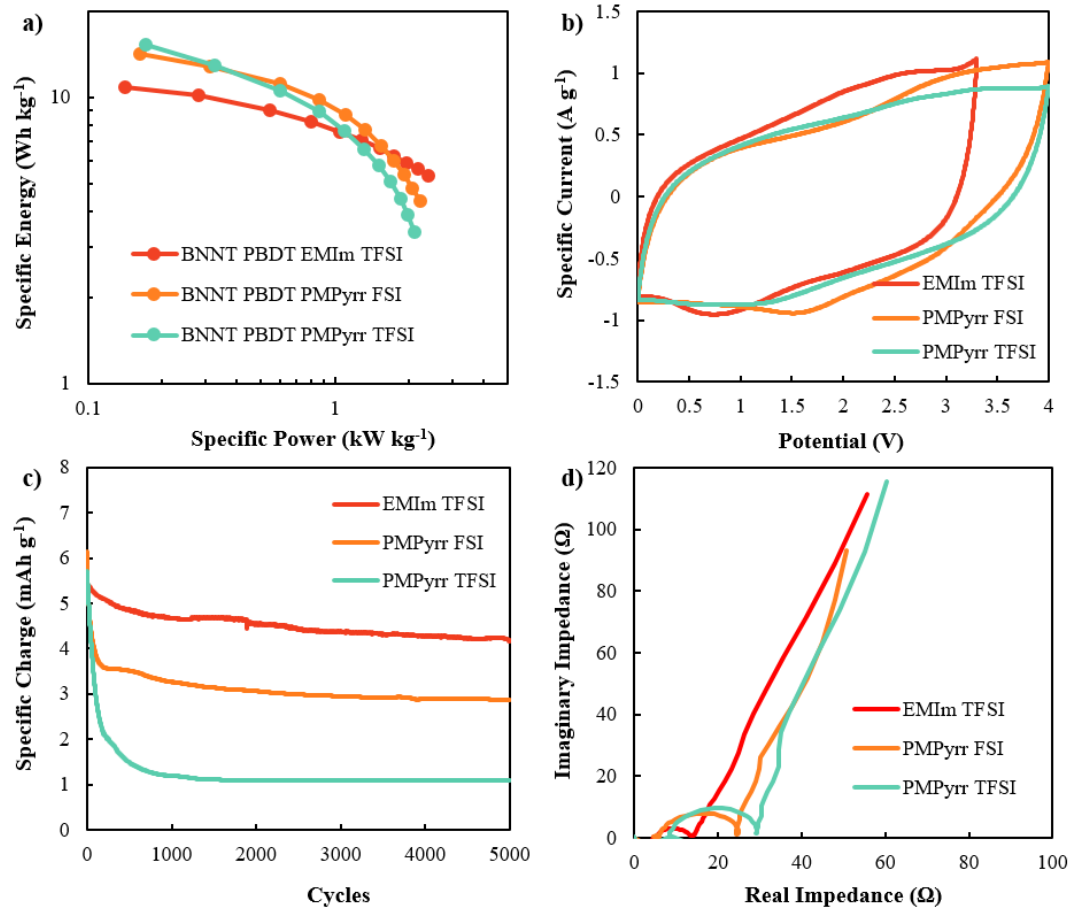


Coating Characterisation

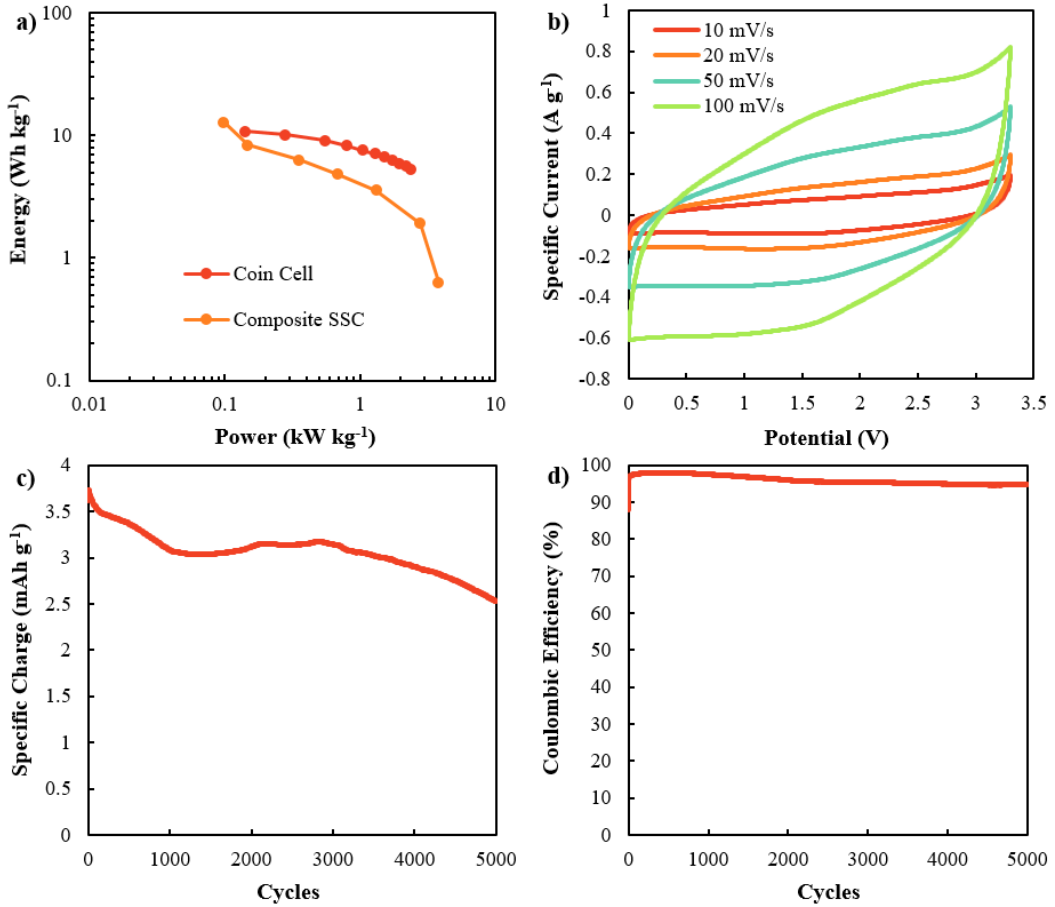


- Four different binders were used: PEG, PVP, PEI, PBDT
- Addition of PEG, PVP and PBDT has significantly improved coverage of CNT mat creases
- Some agglomerates (white spots) can form during deposition due to dispersion instability
- Addition of polymeric binders leads to micro-scale network
- BNNT-PBDT coating demonstrated the best overall characteristics, with homogeneous coverage and limited agglomerate formation

Coating Electrochemical Performance

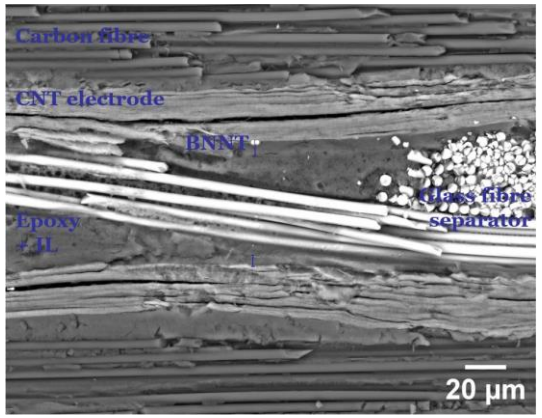


- 2016 Coin cell with CNT-BNNT as electrodes
- EMIM TFSI ionic liquid as the electrolyte
- BNNT-PBDT
  - Best performance at low cycling rates
  - Excellent capacity retention
  - Coulombic efficiency above 98%
- BNNT-PVP and BNNT-PEI: deterioration and loss in capacitance after 2,000 cycles

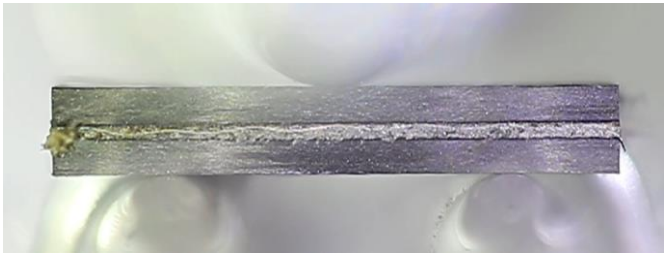


BNNT-PBDT Electrochemical Performance

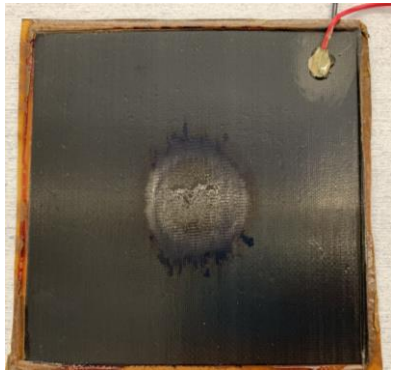
- Best microstructure and all round electrochemical performance with EMIM TFSI electrolyte
- Stable operation up to 4V
- Pyrrolidinium electrolytes have higher specific energies at low charge-discharge rate, but worse performance at higher cycling rate, which decreases further with extended cycling.
- Alternative polymer systems required to improve the performance of the pyrrolidinium electrolytes



Composite SSC using CNT-BNNT



- Manufactured using industry standard vacuum-bag and autoclave-cure techniques
- Composite device demonstrated better performance than the coin cell, with 12.8 $Wh.kg^{-1}$ at 0.0984 $kW.kg^{-1}$
- Good capacitance observed from CV curve
- High coulombic efficiency maintained after extended cycling (above 94%)
- Highly suitable for integration into composite structures



Conclusions

- CNT-BNNT coatings were produced using four different polymeric binders: PEG, PVP, PEI, PBDT
- Coin-cell testings demonstrated good performance with selected binders
  - PBDT showed the best overall electrochemical results
  - High specific energy up to 15.2 $Wh.kg^{-1}$
- Composite structural supercapacitor performance exceeded the coin cell performance
- Strong viability of CNT-BNNT coatings for integration into large-scale composite structures

ABSTRACT

Two epoxy paste adhesives, one polyurethane paste-adhesive and one epoxy film adhesive, were tested for their ability to operate in bonded carbon composites joints which are exposed to a cryogenic environment as it is existent in a liquid hydrogen storage tank. Due to different coefficient of thermal expansion (CTE), a thermal mismatch occurs between the composite and adhesive layers which can lead to thermally induced cracks. Therefore, for the design of the bonding area the thermal and mechanical properties, including the CTE, of the adhesives are considered as key elements. The CTE of the adhesives was measured in a cryogenic TMA according to the ISO 11359-2 at temperatures from 4 K up to 350 K. The tensile properties of the adhesives were determined according to the DIN EN ISO 527-2 at 296 K and in liquid nitrogen (LN_2) at 77 K. In addition, the viscoelastic properties of the adhesives were determined in a temperature range from 173 K up to 473 K by dynamic mechanical analysis (DMA). All in all, the results show a quite similar thermo-mechanical behavior of the tested adhesives, with an increasing stiffness and a significantly decreasing thermal expansion coefficient with decreasing temperature.

1 INTRODUCTION

The demand for emission-free aviation is increasing and liquid hydrogen (LH_2) has a high potential as propellant for emission-free aircrafts. Therefore, intensive research into liquid hydrogen storage systems has begun, as weight-optimized storage is a key element in the implementation of emission-free aviation. Due to its lower specific density and the possibility for load-adapted fiber orientation, the structural weight of a liquid hydrogen tank can be significantly reduced by using carbon fiber reinforced plastics (CFRP). [1] However, the assembly of such CFRP based components to an LH_2 storage tank is challenging in several ways such as by structure, tightness and other constraints, which become effective especially at the typical LH_2 storage temperature of 20 K. [2]

The thermo-mechanical behaviour of adhesives in cryogenic conditions has not been sufficiently investigated yet. There is a minor of studies, which deal with the determination of mechanical and fracture behaviour of adhesives for LH_2 steel and CFRP-Tank structures. [3, 4, 5] Furthermore, test methods for determination of mechanical properties of epoxy based composite materials in cryogenic conditions are not standardized yet and will be developed within the framework of this study [6, 7].

The main objective of this project is to develop resource-efficient processing, joining and assembly methods for CFRP LH_2 tanks based on simulation- and test-based verification of cryogenic bonded joints. Two epoxy paste adhesives, one polyurethane paste-adhesive and one epoxy film adhesive, were tested for their ability to bond CFRP composites, in the context of cryogenic hydrogen storage. The design of the bonding area requires consideration of the adhesives thermal and mechanical properties, including the coefficient of thermal expansion (CTE).

2 METHODOLOGY

2.1 Test specimen preparation

The manufacturing and preparation of test specimens was conducted at Airbus Materials laboratory. While the processing of the film adhesive and prepreg adherent substrates was conducted using established standard procedures, the fabrication of test coupons made from adhesive pastes had to be optimized to reduce air entrapment and void formation within the adhesive bulk material. Figure 1 shows the preparation of the specimen for CTE, tensile strength test and DMA measurement.

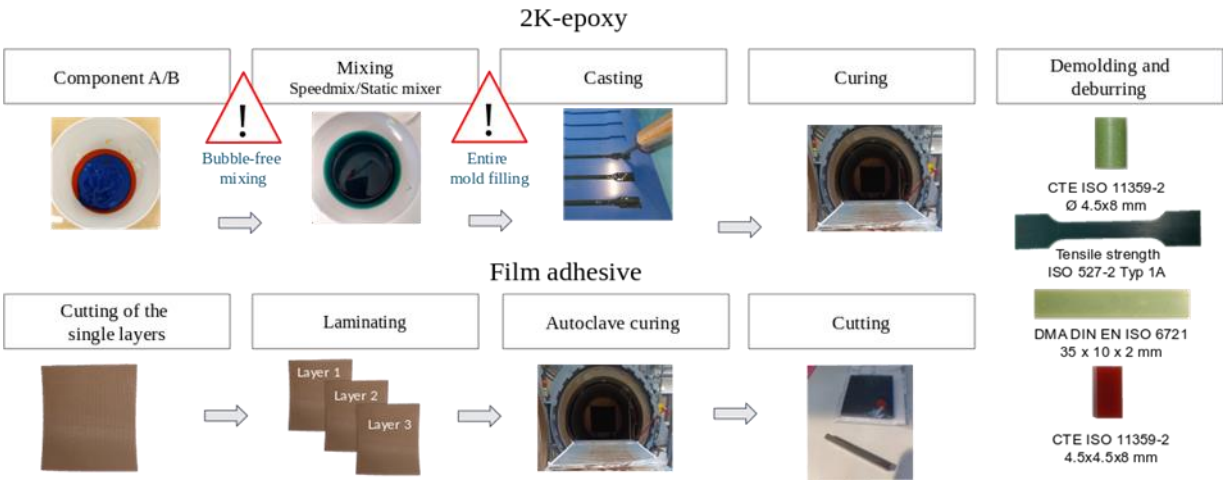

Figure 1: Specimens manufacturing and preparation

Four variants of adhesives are tested having the following characteristics:

ID	Chemistry	Curing characteristics	Typical field of application
1	2-part epoxy paste	Hot curing	Structural bonding of composites
2	2-part epoxy paste	Cold & hot curing	Shimming & Bonding
3	2-part polyurethane paste	Cold curing & tempering	Multi-purpose e.g. insulation of cryo tanks
4	1-part epoxy film	Hot curing	Structural bonding of composites

Table 1: Variants of adhesives

2.2 Tensile Testing

Tensile tests were performed according to DIN EN ISO 527-2 for the evaluation of strength, stiffness and poisons ratio of the adhesive bulk material at the ILK of the TUD. For the testing at room temperature the majority of test specimens were mounted on a ZwickRoell Z2.5 testing machine equipped with a 2.5 kN load cell, a video extensometer and pneumatic clamps. However, a few specimens exposed such a high yield strength that the testing of those adhesive candidates required a switch to a Z250 testing machine with a 10 kN load cell and wedge sample holders.
Test speeds for 296 K are 1 mm/min (modulus up to 0.25 % elongation), then switch to 5 mm/min (strength, adhesive 1, 2 and 4) or 50 mm/min (strength adhesive 3, due to high elongation at break).
The tensile test at 77 K was performed on a Zwick 1475 universal testing machine using a 10 kN load cell with a specially developed test setup (Figure 2, left).

Cryogenically suitable strain gauges (HBM 1.5/350 XC11) on both sides of the specimen were used for strain measurement. The specimen is clamped using a knurled specimen holder, and the clamping force is achieved by two screws tightened to a nominal torque appropriate to the material – typically 8 Nm. This test setup thermally decouples the specimen environment from the testing machine and ensures testing with the specimen completely immersed in liquid nitrogen. After filling the fixture with nitrogen, the test has only been started when minimal nitrogen evaporation is observed, i.e., when all parts of the clamping system and the specimen have reached the test temperature of 77 K (see Figure 3). Due to the very low strains to fracture observed under cryogenic conditions, the test speed at 77 K was set to 1 mm/min for the entire test, contrary to the standard.

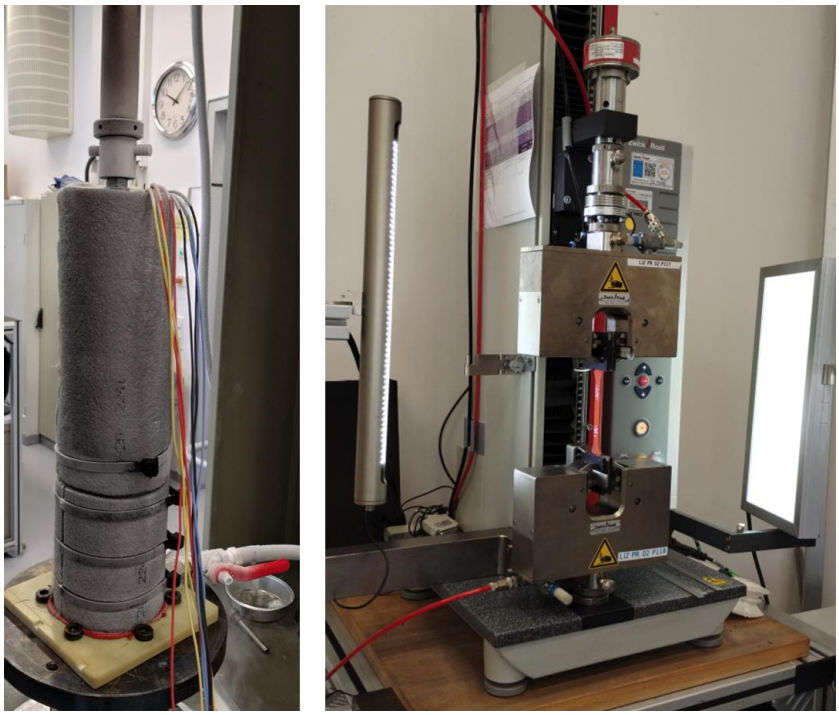

Figure 2: Testing device for tests at 77 K (left) and testing machine for tests at 296 K (right)

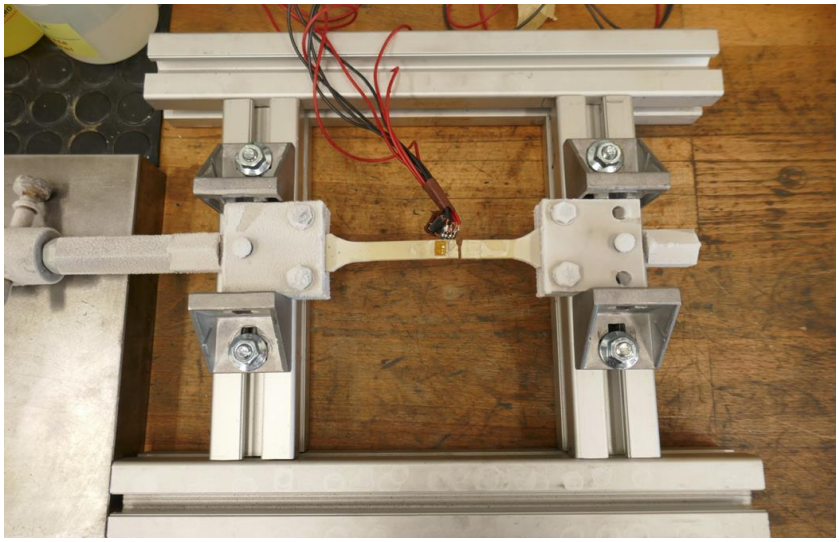

Figure 3: Clamps in assembly device after test

2.3 Thermo-mechanical analysis (TMA)

At FIBRE, the CTE was determined using expansion-probe TMA in a standard and cryogenic conditions following the ISO 11359-2 at temperatures from 4 K up to 350 K (see Figure 4). To ensure the cold temperatures during testing, the measurement chamber is placed in a helium closed loop cryostat. This requires a three times longer dilatometer than in a standard TMA. To compensate for this, an up to ten times higher load than described in the ISO standard has to be applied to the specimen. This again requires extreme care concerning the mechanical contact of the quartz glass dilatometer to the specimen. A controlled cooling rate of 0.5 K/min and a heating rate at 1 K/min were applied in order to get insights on the temperature-dependence.

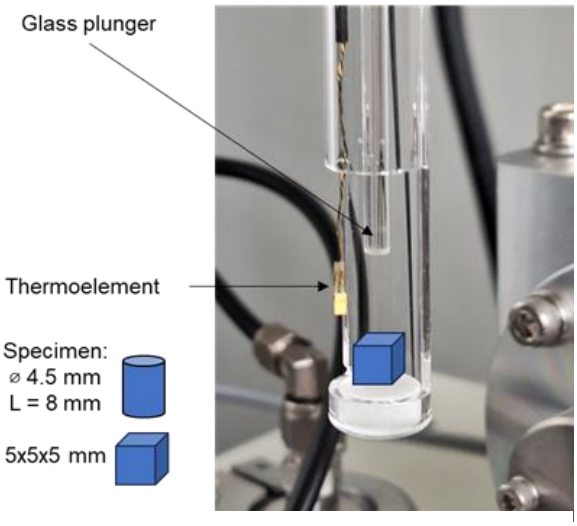

Figure 4: Cryo-TMA test stand and specimen

All specimens were preconditioned in a standard TMA Q800 from TA Instruments. The preconditioning was conducted as follows:

1. Apply a load of 25 mN
2. Cool and equilibrate at 223 K
3. Heating run at 5 K/min to 343 K
4. Hold isotherm for 5 min
5. Cooling run at 5 K/min to 223 K
6. End of measurement

The samples were weighed before and after each conditioning step and each measurement to determine the changes in moisture content. The results show, that the moisture content has an influence above around 263 K, but not below. Nevertheless, the preconditioning was used to ensure equal conditions of the specimen before the cryogenic CTE measurement.

2.4 Dynamic mechanical analysis (DMA)

The temperature-modulus behavior tests (see Figure 5) were conducted using an Anton Paar MCR-502s rheometer in torsion mode according to ISO 6721-7 [8].
To perform the tests following settings have been used:

- Testing instrument: MCR-502s rheometer (Anton Paar Germany GmbH)
- Specimen shape: Rectangular bar with a gauge length of approximately 22 mm, a width of approximately 10 mm, and a thickness of approximately 2.2 mm
- Heating rate: 4 K/min
- Test atmosphere: Air
- Amplitude of the dynamic angular displacement θ_A: 0.1 %
- Test frequency: 1 Hz
- 5 Tests per material

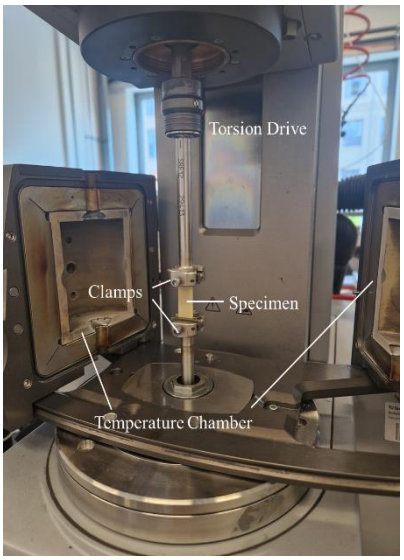

Figure 5: DMA test setup

3 RESULTS

3.1 Tensile Testing

The results show a significant difference in the Young's modulus, which increases significantly with decreasing temperature. The strengths also tend to increase, but less significantly and not for all adhesives tested. The graphs in Figure 6 show the average values of the results from seven samples.

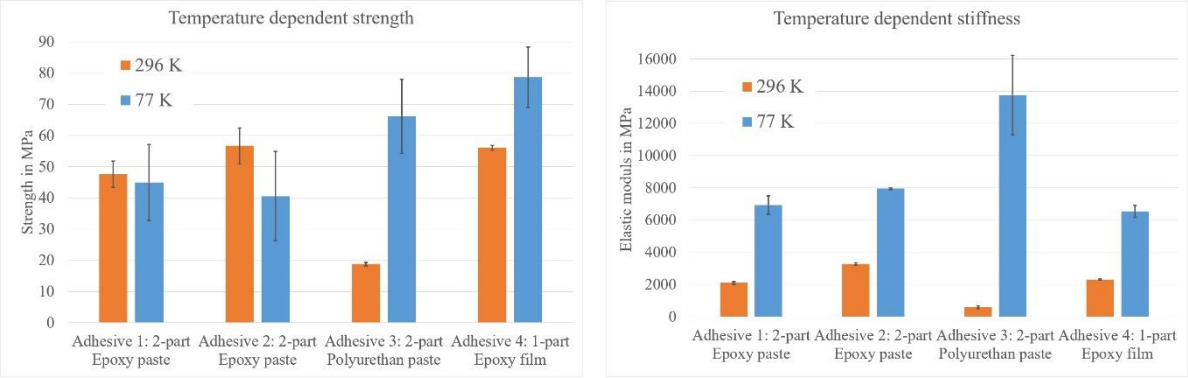

Figure 6: Temperature dependent strength and stiffness of adhesives at 296 K and 77 K

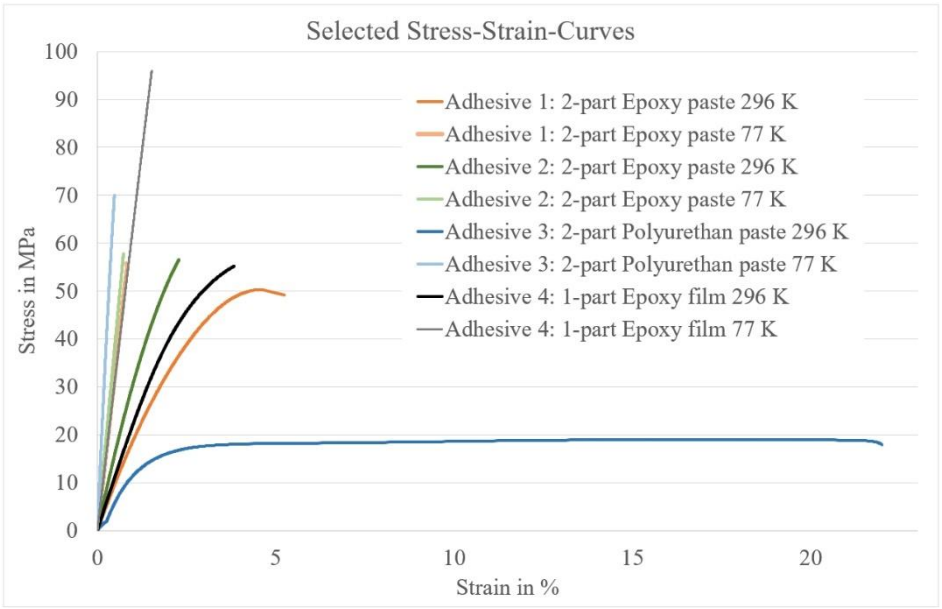

Figure 7: Representative stress-strain-curves at 296 K and 77 K

3.2 Thermo-mechanical analysis

The CTE results show a comparable decrease of the CTE with decreasing temperature, while the difference of the value is decreasing with lower temperature. In addition, at temperatures below 73 K a smaller decrease is visible, and the CTE of the various adhesives is similar. At temperatures below 93 K the CTE is remains almost constant for all adhesives.
Due to the higher load of 500 mN a delayed measurement signal in the area around the glass transition temperature (Tg) is generated, which leads to an incorrect output (see Figure 8, adhesive 3). Therefore, the determination of the CTE and glass transition must be decoupled. This means, in the cryogenic TMA the CTE is measured from 4 K up to T_g of each adhesive. Above T_g the CTE is determined in a standard TMA according to the ISO 11359-2. The glass transition temperature is shown in the results of the DMA in the following chapter.

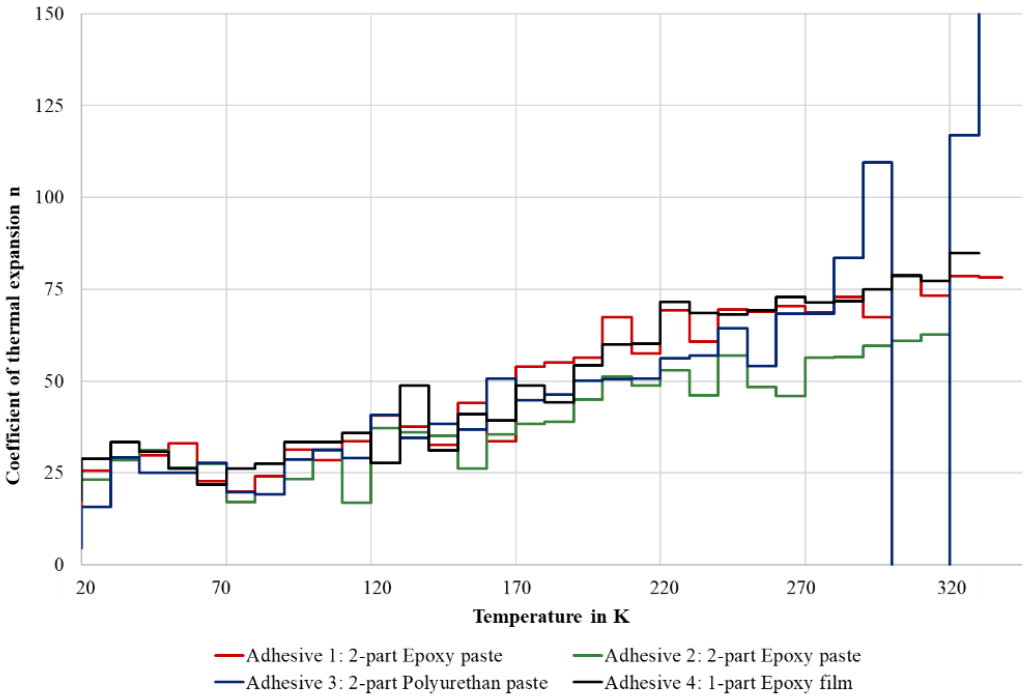

Figure 8: Coefficient of thermal expansion of 4 adhesives

3.3 Dynamic mechanical analysis

Representative curves selected from the five result curves for the respective adhesive are shown in Figure 9. The typical glass transition temperatures are clearly visible. The glass transition temperature of the polyurethane adhesive is only slightly above room temperature, whereas the epoxy resins exhibit significantly higher glass transition temperatures. It is also clearly evident that the elastic moduli of all polymers increase with decreasing temperature; it should be noted that the scale is non-linear. This clearly supports the results of the tensile tests conducted at two selected temperatures.

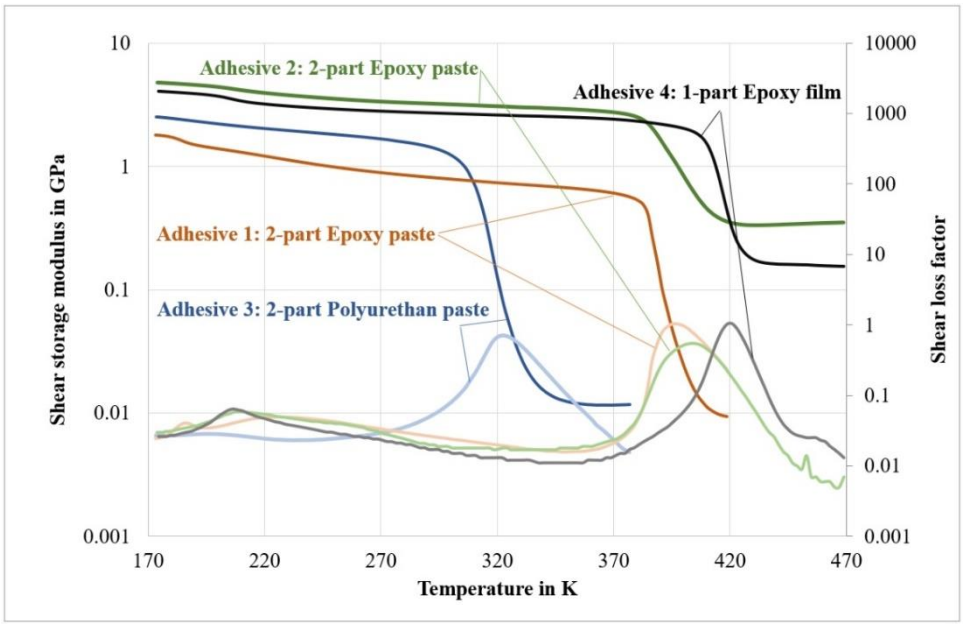

Figure 9: Results of DMA test for 4 adhesives, representative curve of 5 samples selected

4 CONCLUSIONS

The stiffness properties of various epoxy adhesives were successfully determined using novel cryogenic testing procedures. In general, the results show a quite similar thermo-mechanical behavior of the tested epoxy adhesives at cryogenic temperatures. As the temperature decreases, all tested adhesives exhibit an increase in stiffness, with the polyurethane-based adhesive showing a particularly pronounced stiffening effect. While the epoxy adhesives respond in a very much comparable manner under cryogenic conditions, significant differences in individual properties remain. Most notably, the elongation at break decreases considerably for all materials, indicating increased brittleness at low temperatures. In contrast, the strength results are inconsistent, and display no clear trend across the different adhesives. These findings highlight the importance of carefully considering the response of individual materials when selecting adhesives for cryogenic applications.

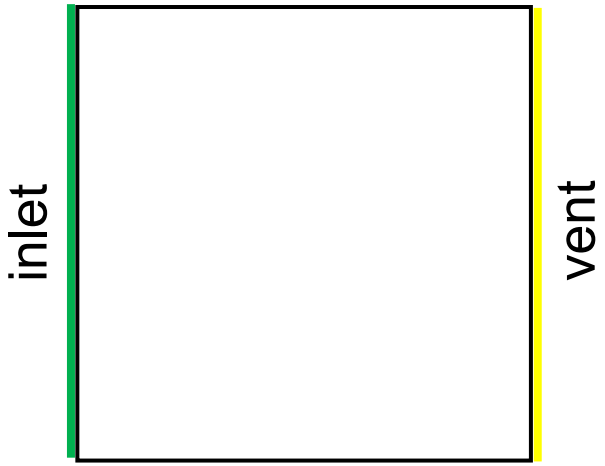
Motivation

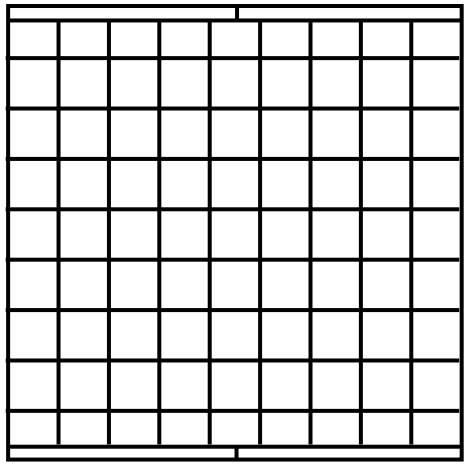
"Conventional" permeability testing (as in ISO 4410)



- Flow experiments
- Simple geometries
- Uses analytical solution for relation between flow velocity and pressure gradient
- Results in one permeability value or a set of principal permeability values at a nominal fibre volume fraction
- Does not really work if there are local variations in permeability or edge effects (racetracking)

Idea

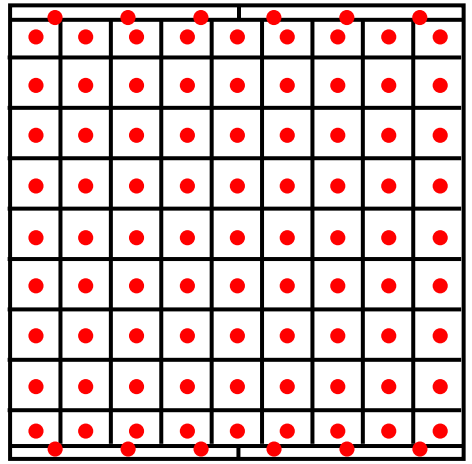
Recover local distributions of fibre volume fraction and permeability in specimens with non-uniform properties in real time; potentially in the presence of racetracking.



Method

Domain for flow analysis

- $300\ \text{mm} \times 300\ \text{mm}$
- linear inlet and vent
- constant pressure difference
- constant viscosity

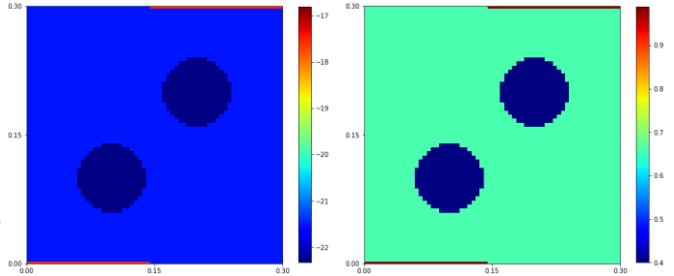


Partitioning of domain

$9 \times 9 + 2 \times 2$ (racetracking)

➡ 85 unknown values of permeability and porosity

Virtual pressure sensors

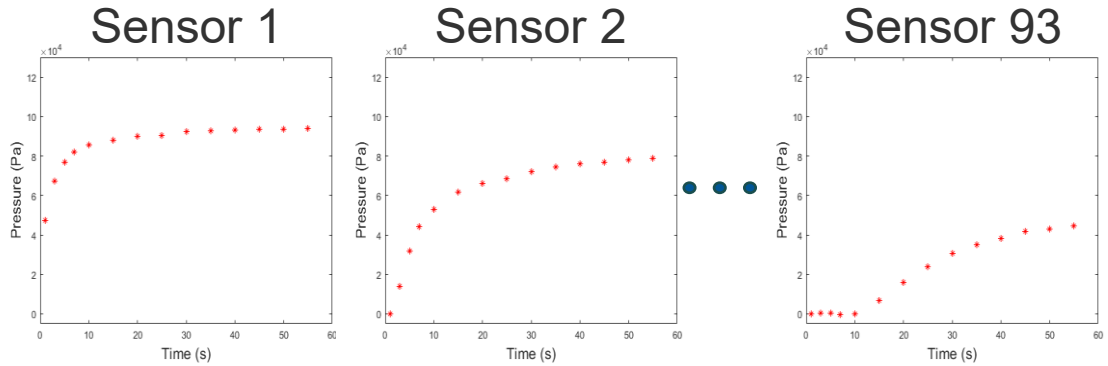


record pressure as a function of time

- for all sensors
- or for subsets

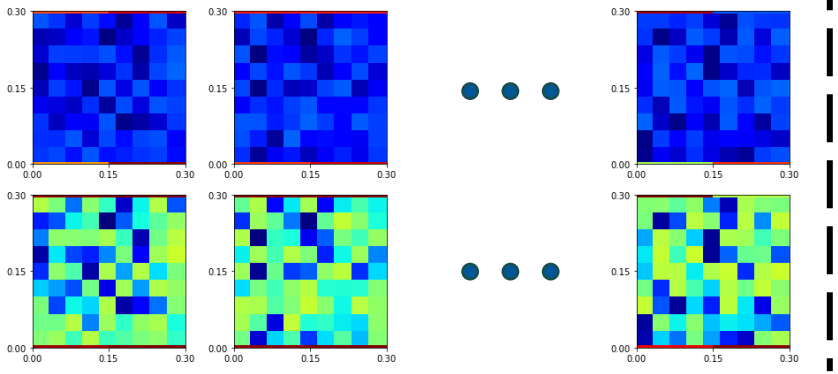
Method: Inversion

(Unknown) true distribution of permeability and porosity



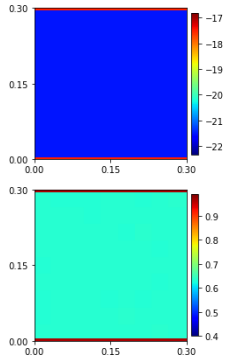
$\log K^{\dagger}$

$\Phi^{\dagger}$



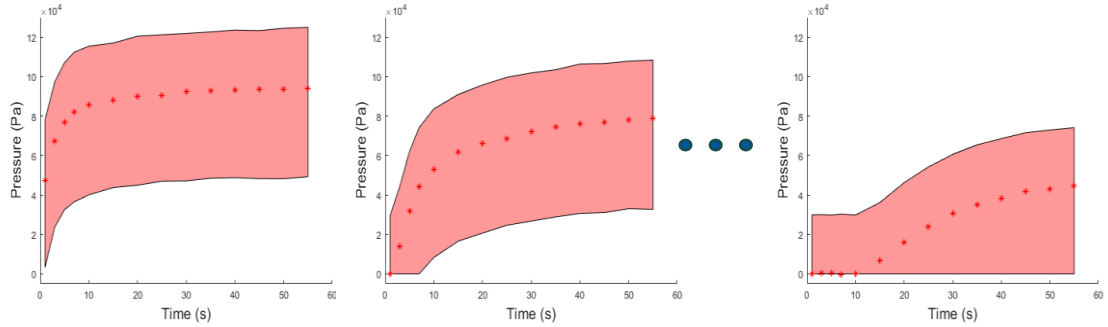
experiment

Recorded pressure-time curves



Recover local properties

Ensemble of J samples

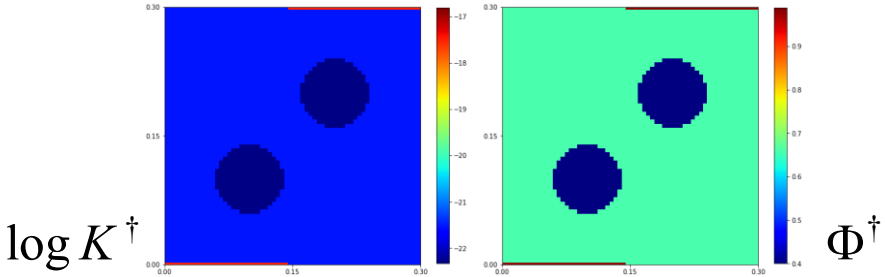


Mean

First guess (“prior”)

CVFEM simulations

Results from all J samples



Not a good match with recorded data

Update ensemble

University of Nottingham

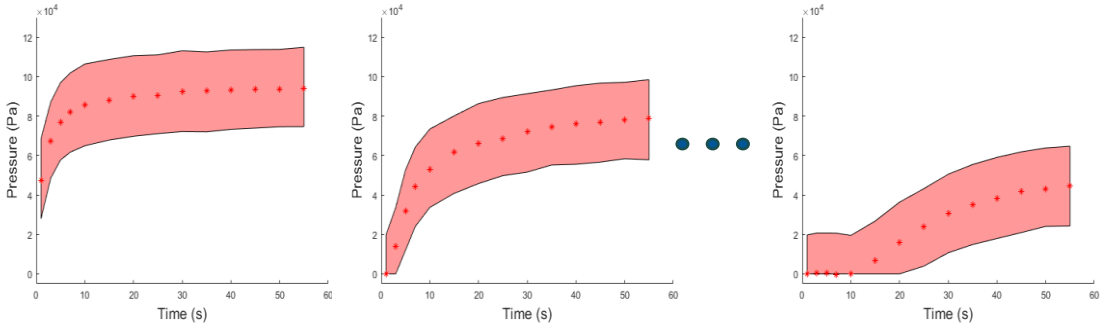
Ensemble of J samples

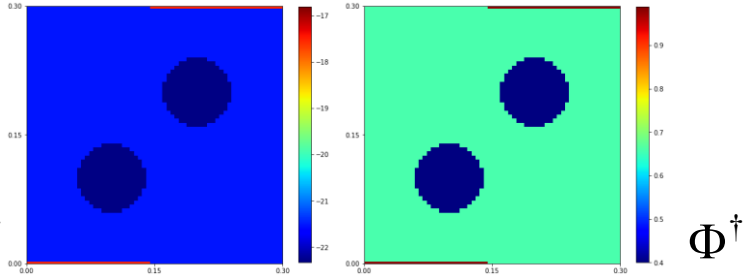


Mean

updated

CVFEM simulations

Results from all J samples

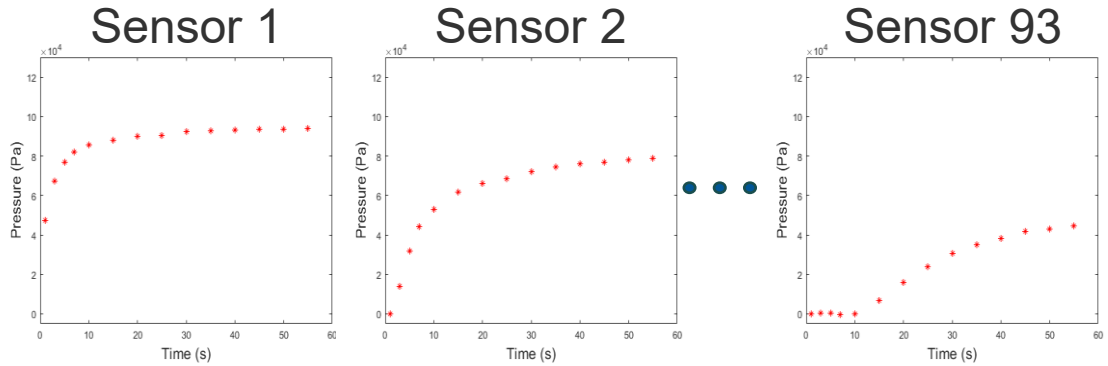


Improved, but still not a good match

Update ensemble

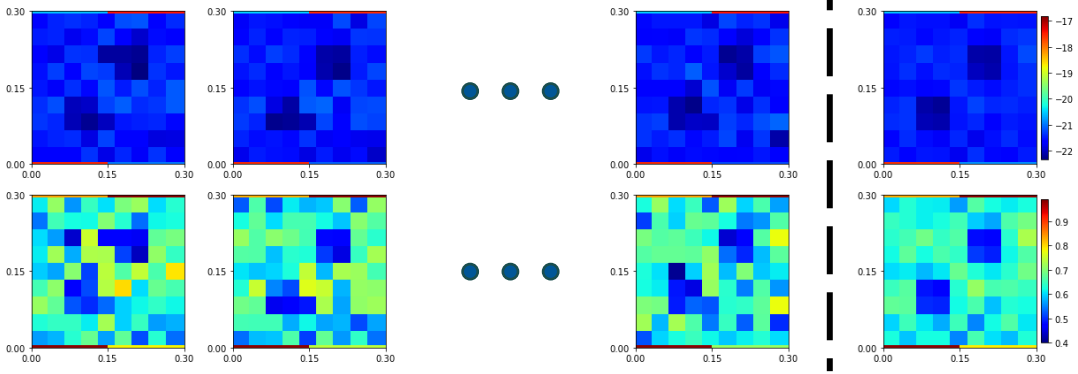
Method: Inversion

(Unknown) true distribution of permeability and porosity



$\log K^{\dagger}$

$\Phi^{\dagger}$

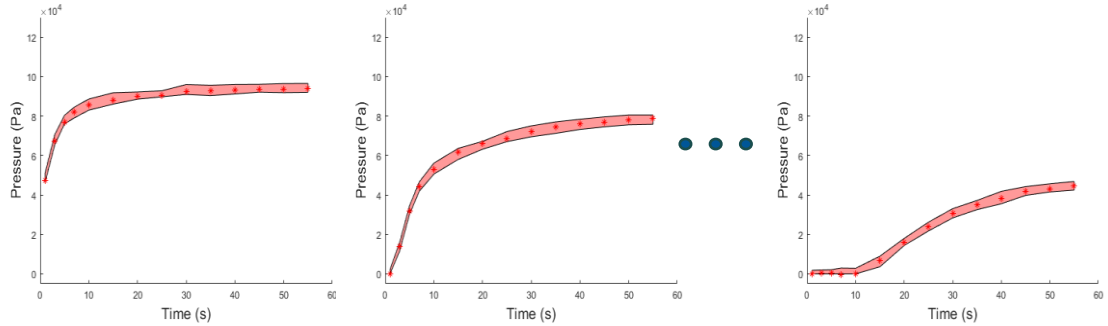


experiment

Recorded pressure-time curves

Recover local properties

Ensemble of J samples



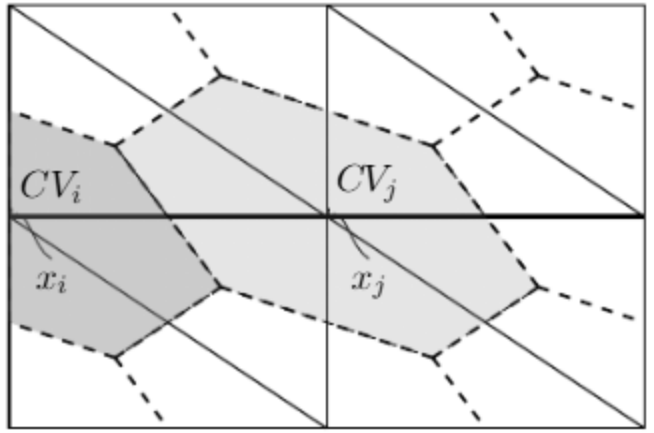
updated

Mean

CVFEM simulations

Results from all J samples

Acceptable match



➡ Ensemble is “posterior” approximation

Method: Surrogate

Run time for each CVFEM simulation ~100 s

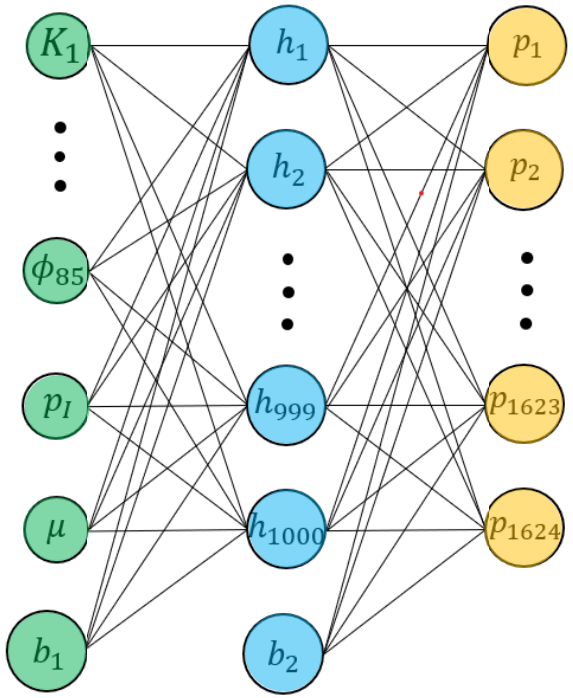
Simulations for thousands of samples required.

➡ Even with parallel computing, finding posterior approximation takes hours.

Wells, H., Park, M., Matveev, M., & Tretyakov, M. (2024). RTM-Flow: Control volume FEM solver for 2D moving boundary problems (v2.0). Zenodo. https://doi.org/10.5281/zenodo.12583662

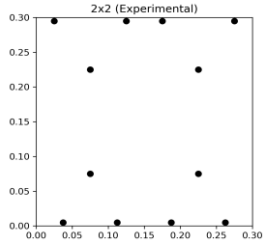
To speed up inversion:

Generate a data set based on CVFEM simulation for 50,000 samples, all with different properties.

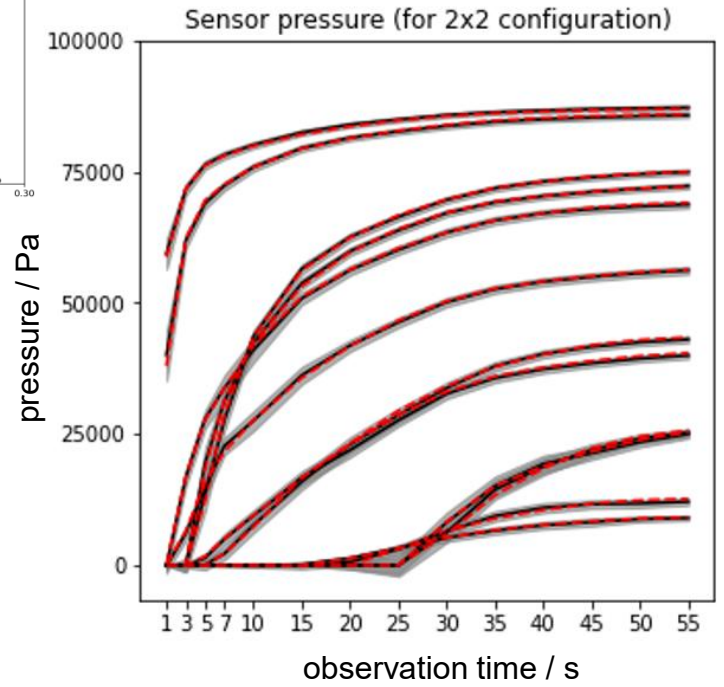


Use Artificial Neural Network as surrogate to interpolate outputs for unseen parameter sets, near-instantaneously.

Method: Surrogate



85 values of
- permeability
- porosity



Injection pressure
Viscosity

One hidden layer,
1000 nodes

Pressure values
- all sensors
- 14 observation times

Red: CVFEM simulation
Black: Neural network prediction
Grey: surrogate uncertainty

	Relative error (average)	Execution time (average)
CVFEM	-	109 s
Surrogate	1.15 %	3.52×10^{-4} s

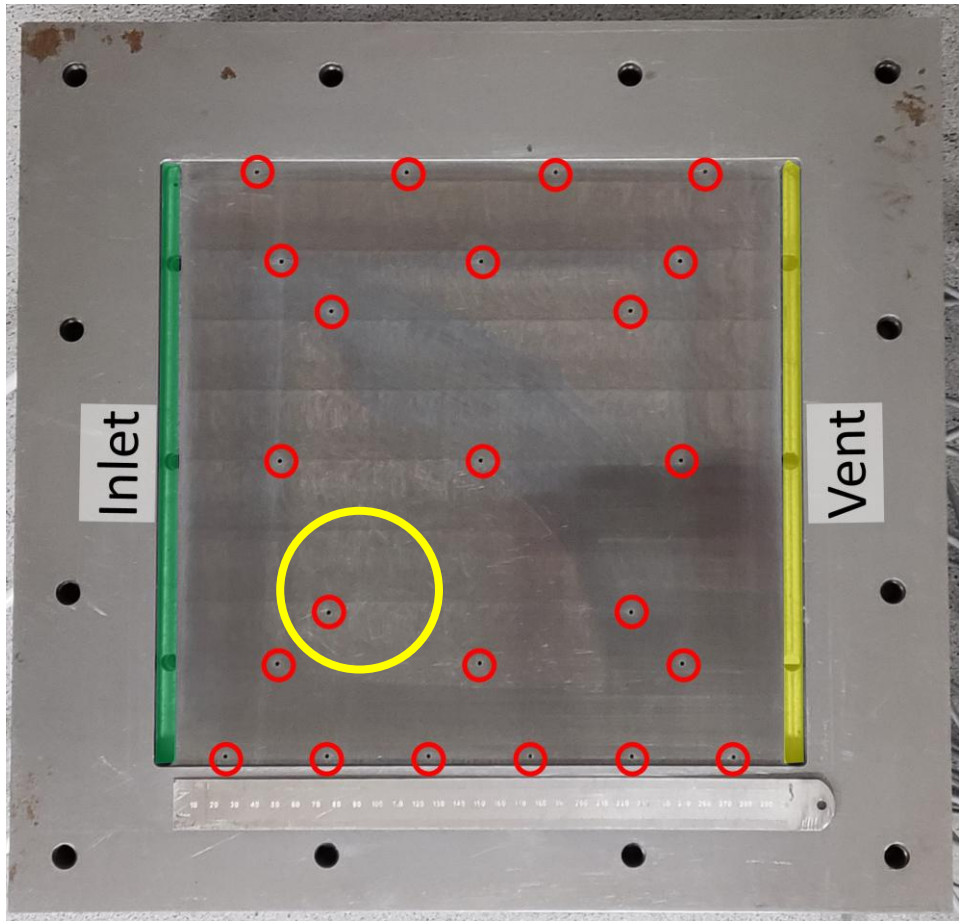
- averaged on sub-domains identified as “background”, “inclusions” and “racetracking channels”.

	background		inclusions		racetracking channels	
	K / m^2	Φ	K / m^2	Φ	K / m^2	Φ
“truth”	4.50×10^{-10}	0.66	2.05×10^{-10}	0.40	2.50×10^{-8}	0.98
recovered	4.65×10^{-10}	0.64	2.18×10^{-10}	0.45	2.39×10^{-8}	0.98
Δ	+ 3 %	- 3 %	+ 6 %	+ 12 %	- 4 %	± 0 %

Quantitatively, porosity and permeability can be recovered with acceptable accuracy.



Virtual experiments: Results

Number of sensors considered in inversion

Uncertainty in recovered permeability decreases with increasing number of sensors.

Lab experiments: Set-up

- 300 mm × 300 mm, 2.1 mm height
- 23 pressure sensors
- transparent lid for flow front tracking

Reinforcement:
Random glass fibre mat;
$S_0 = (210 \pm 15)\ \mathrm{g/m^2}$

Example lay-up:
- 7 layers (background)
- 10 layers, 80 mm diameter (inclusion)

Test fluid:
Synthetic engine oil; $\eta \approx 0.1$ Pa.s

Pressure difference:
$\Delta p \approx 10^5$ Pa

Recovery of porosity and permeability as flow front propagates

Visual flow front tracking

Log-permeability

Porosity

Note: 19 sensors considered here (2×2 omitted)

Lab experiments: Results

Permeability and porosity

Comparison with results from “conventional” permeability testing (uniform, at comparable number of layers, n, and cavity height, h)

	background		inclusion	
	K / m^2	Φ	K / m^2	Φ
conv.	6.29×10^{-10}	0.73	3.77×10^{-10}	0.61
recovered	5.86×10^{-10}	0.72	3.34×10^{-10}	0.57
Δ	- 7 %	- 1 %	- 11 %	- 8 %

$$\Phi = 1 - \frac{n S_0}{\rho h}$$

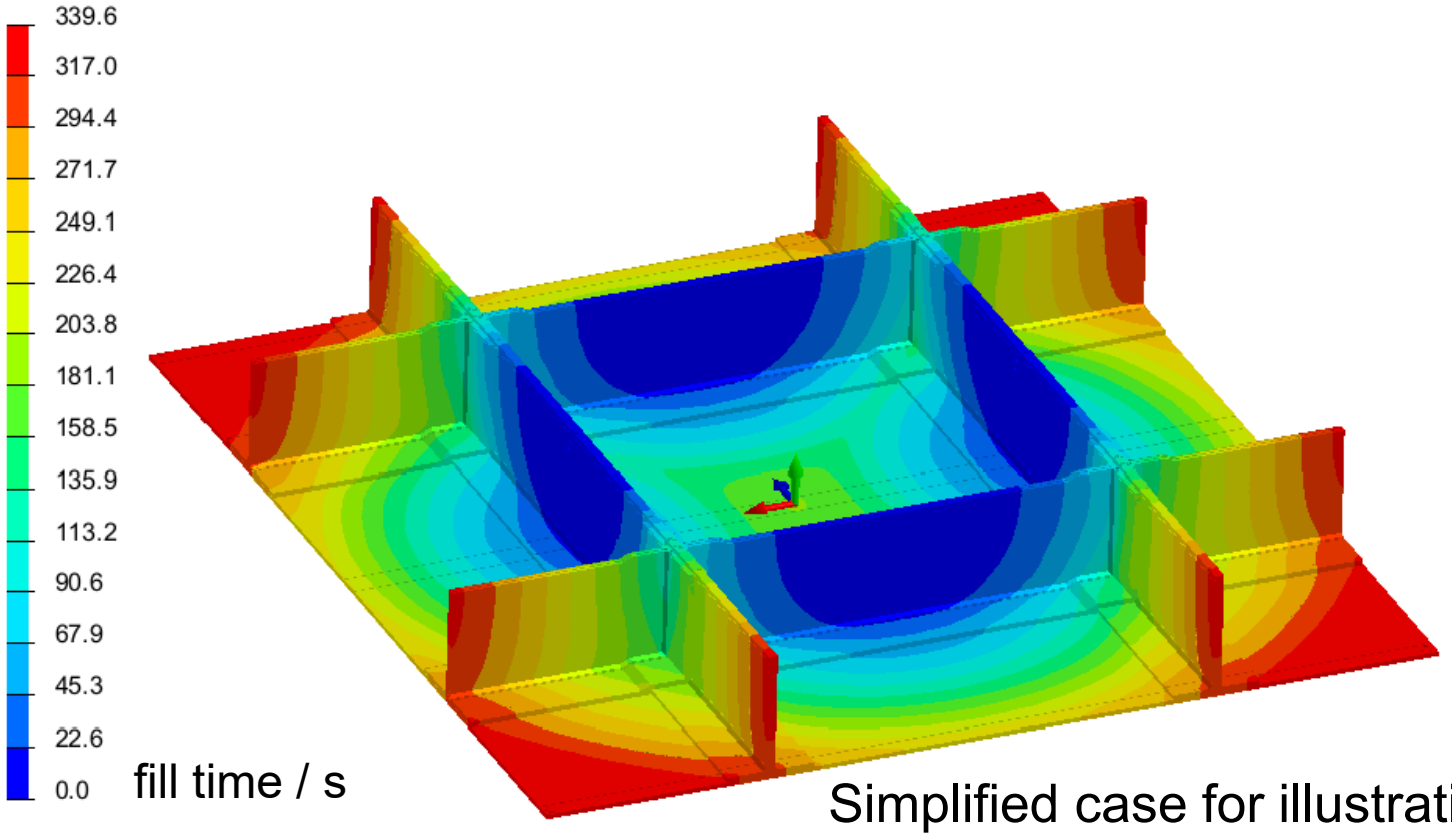
K interpolated at Φ based on “conventional” test series

Quantitatively, recovered porosity and permeability are reasonably consistent with results from “conventional” testing.

Note: Results from “conventional” testing are affected by uncertainty as well.

Conclusions

An Artificial Neural Network surrogate was combined with a stochastic inversion algorithm to estimate local reinforcement permeability and porosity in real time based on in-process data.



Virtual and lab experiments indicate that

- positions and shape of inclusions and racetracking channels can be identified correctly;
- recovered values of permeability and porosity are generally in good agreement with the corresponding “true” values.

As the reinforcement properties can be recovered in real time, integration of this algorithm within active process control systems is feasible.

Outlook

Recover local permeabilities for more complex geometries

Simplified case for illustration

Example: “stiffened panel”

complex overlap configuration
+ noodle regions
+ racetracking

4 inlets, 5 vents

20 pressure sensors,
visual monitoring on flat side

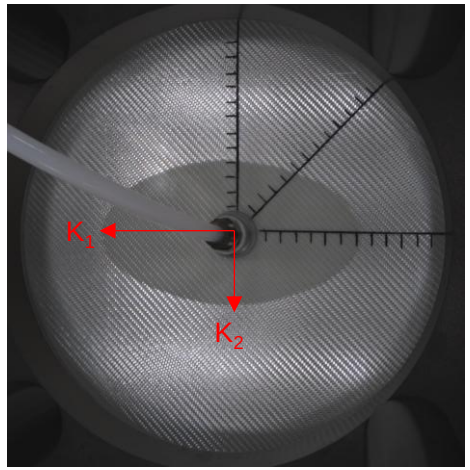
A Practical Approach to Uncertainty and Validation of Process Simulation for LCM Manufacture



Dr Ana Yong

National Physical Laboratory

Background

- In the manufacture of composites by liquid composite moulding (LCM), a liquid resin is infused through a textile reinforcement within a mould that provides the shape and thickness of the component being made. To ensure the efficient and complete saturation of the reinforcement, simulation can be used as part of the design of the manufacturing process.
- One of the key data inputs used in the simulation of the manufacturing process is the permeability of the reinforcement, K. Here, Darcy's Law is applied to measure how well a fluid will flow through the reinforcement. Following several decades of study and interlaboratory trials, a standardised method for the experimental measurement of the in-plane permeability is available (ISO 4410:2023).
- While extensive research has been carried out into both the determination of permeability and simulation of manufacture, industry uptake of these tools remains low due to lack of familiarity and confidence in the application and resulting data.

The in-plane permeability can be measured by injecting a model fluid into a dry textile specimen and monitoring the flow front progression with respect to time. The major and minor permeability values (K_1 and K_2) are then calculated using Darcy's Law:

$$v = -\frac{K}{\eta} \cdot \frac{\Delta P}{\Delta L}$$

K = permeability (m^2); ΔP = pressure drop; ΔL = flow length; v = flow velocity; η = fluid viscosity

Objectives

- The work presented here was carried out with the aims of bringing together the knowledge of how to simulate the manufacture of a composite part via LCM, and the experimental measurement of permeability as one of the major data inputs for simulation.

- The final goal is to increase industry use of these tools, in support of the development of manufacturing processes that are time and cost efficient and result in high quality parts.

- The work will test the robustness of these tools and provide an assessment of the expected level of accuracy of the process from characterisation through to simulation, in order to build more trust in the data outputs and enhance their useability.

- The work will provide an understanding of the main contributors to uncertainty, and how these can be mitigated or managed.

- The final outcomes will provide a source of open access information that can be used by anyone to understand the tools, where a lot of previous knowledge has been commercially protected.

Preliminary case study: flat panel

- An initial case study was carried out as an initial proof of concept of how the accuracy of the permeability can influence the result of the simulation and the basis of the next phase of work.
- An FE model of the NPL RTM tool was created using Abaqus CAE. The filling of the tool was simulated using LIMS. Permeability values used in the simulation were taken from values experimentally measured following the standard test procedure described in ISO 4410:2023 and supporting research. [1][2]
- An interlaboratory comparison exercise, carried out as the precursor to ISO 4410:2023, showed that data between sites can vary as much as 40%. To assess the impact of this level of uncertainty, the simulation was rerun using permeability data 40% higher and lower than the experimentally obtained values. The results are summarised in Table 1.
- The comparison of the simulated to the experimental values is given in Table 2.

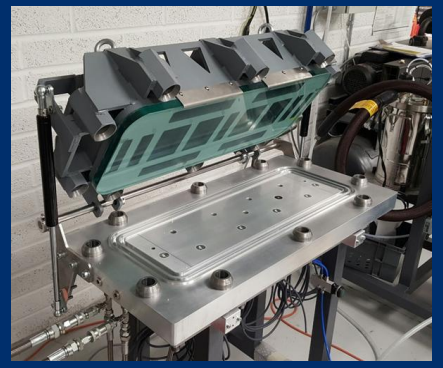


Table 1. Effect of permeability variation on simulated fill time

	Kxx (m^2)	Kyy (m^2)	Fill time (min:s)
Original	2.3e-11	4.24e-12	19:47
Higher	2.76e-11	5.088e-12	16:29
Lower	1.84e-11	3.392e-12	24:43

Table 2. Comparison of simulated to experimental fill times

Simulated	Test 1	Test 2	Test 3
19:47	12:35	12:50	11:00

Second case study: complex shape

- Following the preliminary work, a second case study was carried out following the same steps of (1) measure the permeability; (2) simulate the mould filling and (3) compare the simulation to experimental values.
- In this second case study, a more complex shape was used. Here, the experimental work and simulations were carried out on a double-dome shape (Fig. 5). This shape is commonly used in the study of composites manufacture as it allows for the examination of the effects of a number of different geometrical features.
- Here, as the fabric is now draped over a 3D shape, the draping results in different areas of shear. The shearing of the fabric is known to change the permeability in localised areas, where opening up of the tows provides for easier flow and a higher permeability.
- The effect of simulating the mould filling using locally different permeability values was studied by first measuring the permeability of specimens that had undergone controlled degrees of shear, with the aim of applying these to the model for increased accuracy.

Fig. 5. Double dome mould

Sheared permeability measurement

- The permeability of sheared specimens was measured using a specially designed frame as shown in Fig. 6. Here, the specimens were clamped along two parallel edges of the frame. The frame was able to move in a scissor movement, allowing for a pure shear condition.
- Specimens were made from 3 layers of fabric and tested at a cavity height of 0.7 mm to provide a fibre volume fraction of 0.5. The number of layers used here reflected the setup used in the double-dome mould experiments. This is fewer layers than would typically be used in an in-plane permeability measurement, however keeping the number of layers low provided the additional benefit of minimising any differences in shear angle between each layer.
- The frame was used with the top part of NPL's radial permeameter.
- Flow front data was processed using NPL's flow front detection algorithm, which tracks the elliptical flow front and automatically calculates the in-plane permeability.

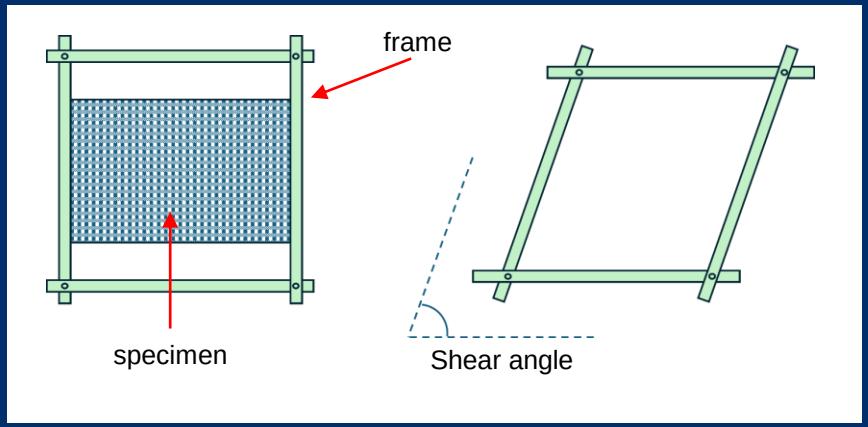

Fig. 6. Schematic diagram of shear frame

Sheared permeability test results

- As seen in the example in Fig. 7, the shearing of the fabric resulted in a flow front that was not perfectly elliptical. It should be noted that the algorithm used to calculate the permeability continuously fits the moving flow front to a perfect ellipse, which resulted in a reduced applicability here. At present, radial permeability measurement is always based on an assumed elliptical flow, so this remains the most current solution available.
- The permeability values were plotted against the known angle of shear of the specimens and plotted against the fit established in previous works. As seen in Fig. 8 and Fig. 9, the data showed a reasonable fit to the expected trend.

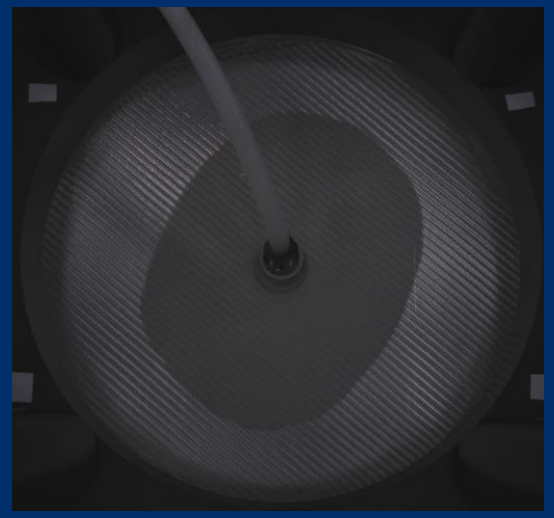

Fig. 7. Example flow through sheared specimen

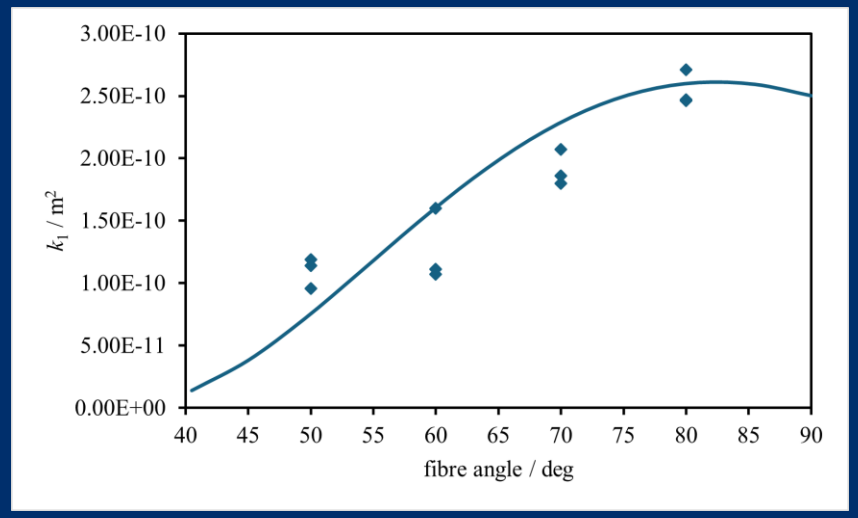

Fig. 8. k_1 values against shear angle

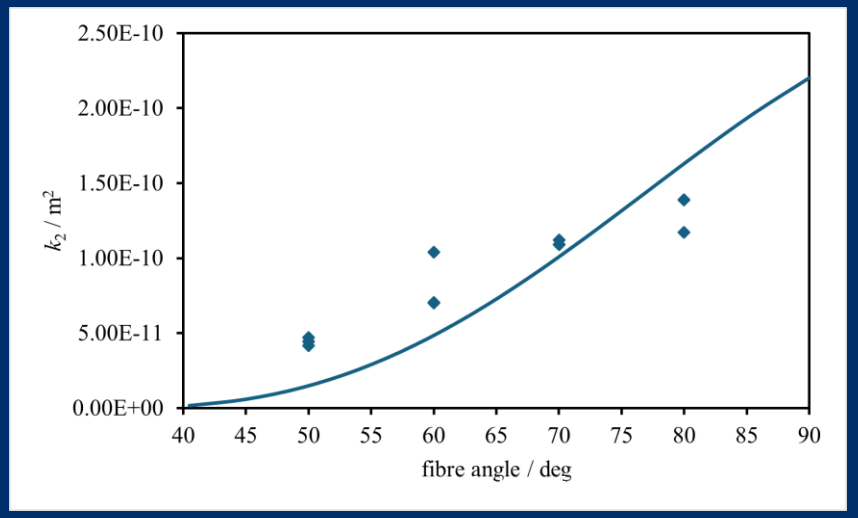

Fig. 9. k_2 values against shear angle

Simulation of the mould filling

- Flow through the mould was simulated using uniform permeability values taken from measurements carried out following the standard method, i.e. a flat and unsheared specimen (Fig. 11)
- The drape of the fabric over the mould was then modelled (Fig. 10) to obtain the localised shear angle of the fabric at different parts of the model component. This was used to apply localised permeability values taken from the sheared specimen tests. The flow was then modelled as shown in Fig. 12. Here we can see the change in predicted flow front.

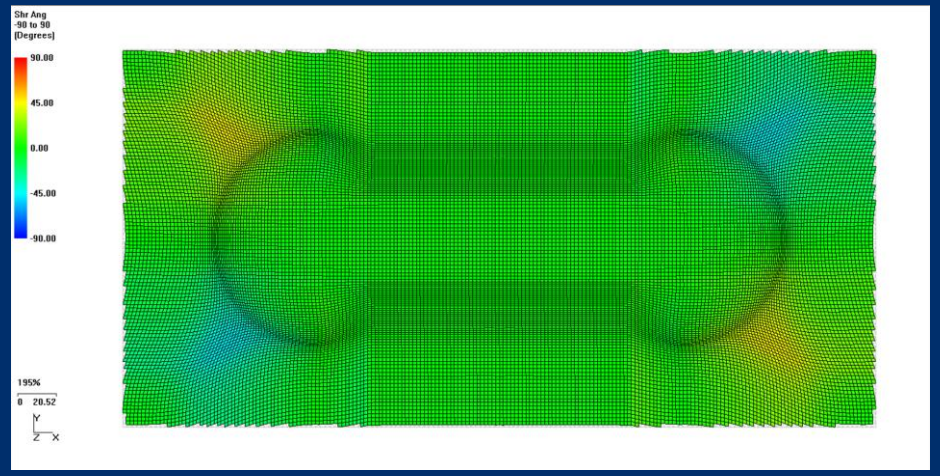

Fig. 10. Model of fabric drape in mould

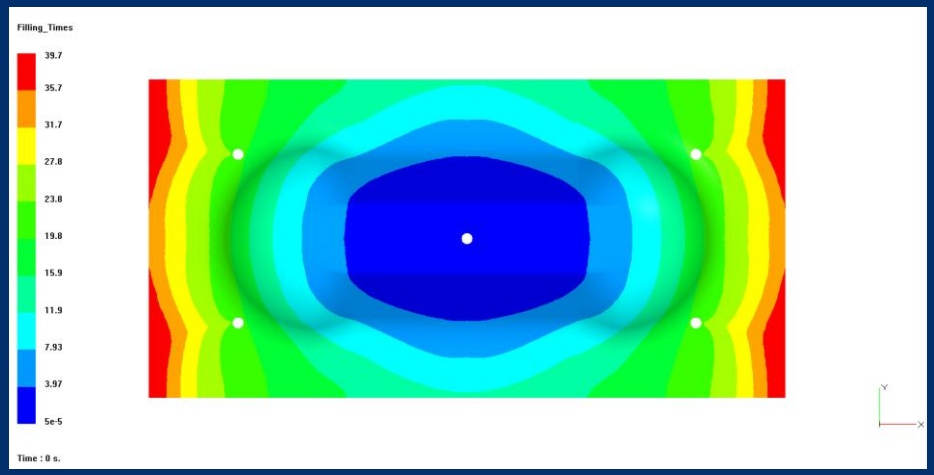

Fig. 11. Simulated mould filling using uniform permeability values

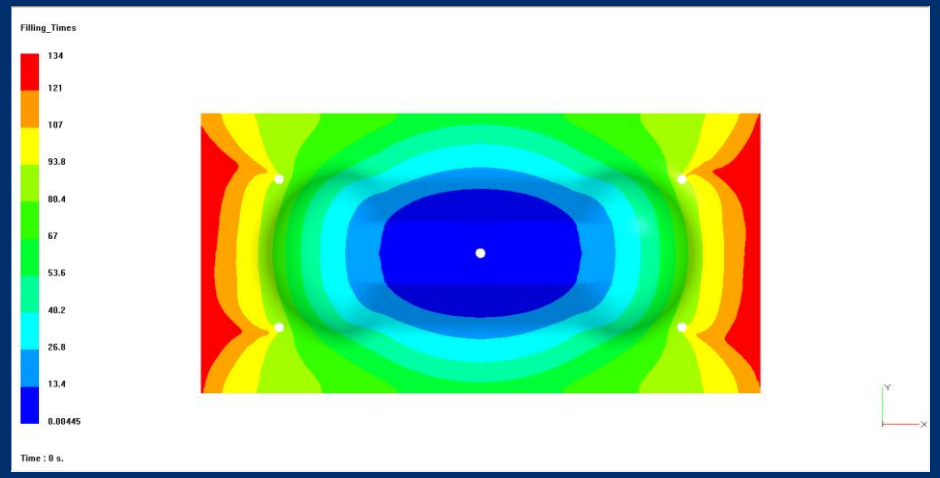

Fig. 12. Simulated mould filling using non-uniform permeability values

Infusion into the double-dome mould

- Laboratory-scale infusions were carried out using the double-dome mould at the University of Nottingham. The fabric was the same Hexcel 2/2 twill woven fabric as characterised in the permeability measurements and engine oil was used as a model fluid. Injections were carried out at 0.1 MPa
- Using video footage of the experiments, the movement of the flow front was tracked using NPL's automated system. These data were used to generate colour maps of the flow front progression
- The scale of the colour map was programmed to produce clear and readable isolines. An example output is shown in Fig. 13.

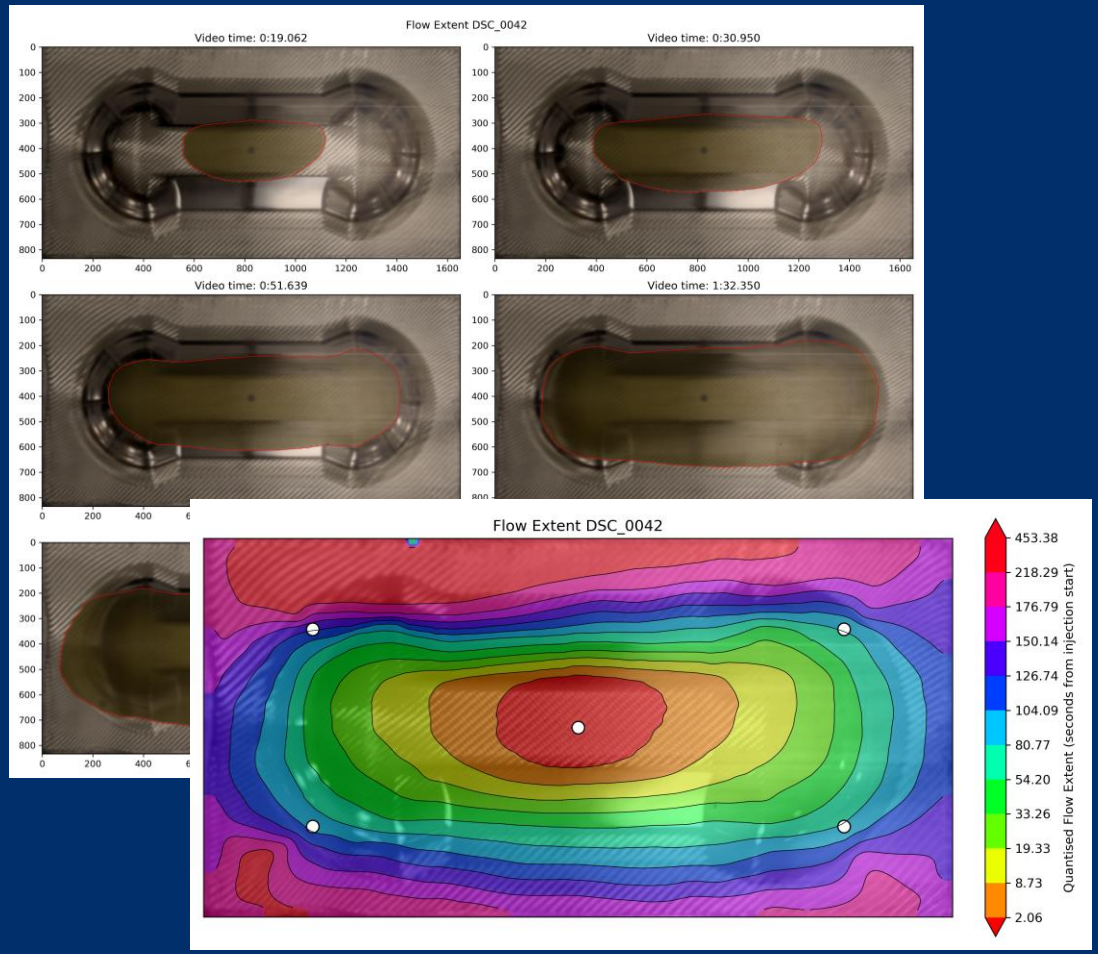

Fig. 13. Generation of colour maps of flow front progression

Time-stamping the flow front progression

- In order to be able to compare the experimental values to simulated data it was necessary to time stamp the images using a means that would be comparable to the simulation. Homography transformation (projective transformation) was used to align the video images to the simulated images, using the inlet and vent holes as the reference.
- Markers were placed on the cardinal axes at the time bounds of the simulated images to enable comparison with the flow arrival time from the experimental measurements (Fig 14). A representative graph is given in Fig. 15 of the progression of the flow from the experimental data. For increased accuracy, in further work these points will be taken from the mesh of the simulation in order to assign a scale to the distance markers. The next step will be to fine tune the simulation for comparison to these experimental data.

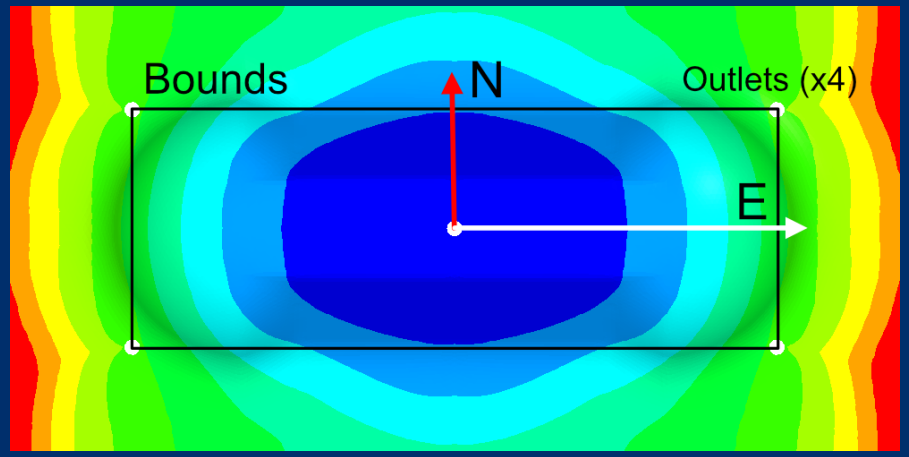

Fig. 14. Cardinal axes

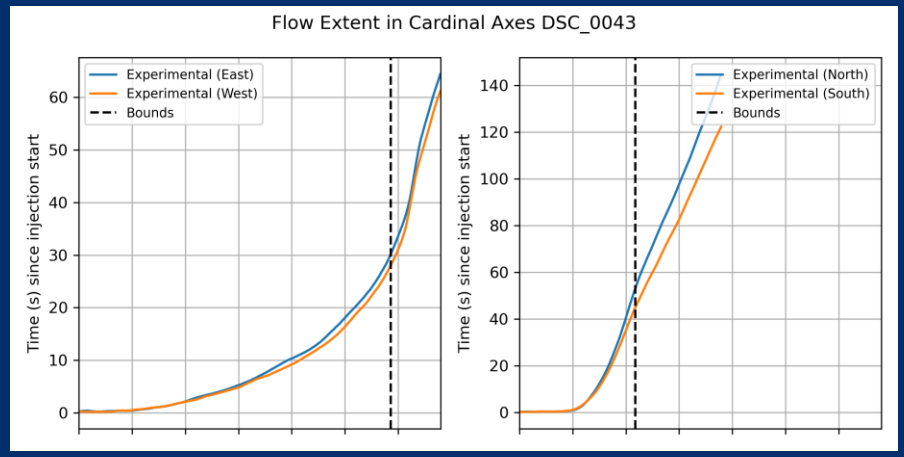

Fig. 15. Flow front progression

Accuracy of permeability

- In order to ensure the most accurate simulation, the permeability input data need to be precise. As shown in the preliminary case study, changes in the permeability input data can have a significant impact on the simulation of even a simple shape. Throughout this work, a number of areas of improvement have been identified for further development, including:
  - The low number of layers used in the measurement of the permeability of sheared specimens was beneficial in ensuring that any difference in the degree of shear between the layers was minimised, however this may affect accuracy of permeability measurement in other ways such as increased impact of surface effects of the tool on the volume fraction, e.g. parallelism of the top and bottom plates and any features of the tool such as sensor placement.
  - The compliance correction required for cavity height settings was proportionally quite high – 0.2 mm correction for a 0.7 mm thickness setting. Ensuring the correction is carried out is essential to accurate reporting of the volume fraction.
  - It was noted that care was required during loading and unloading of specimens with respect to any fluid remaining in the system. If fluid remained, it would leak prematurely onto the specimen, prior to the start of the controlled injection and potentially contain bubbles. Therefore, the best course of action was to begin each test with an emptied inlet tube.
  - The tool used to measure the sheared specimen permeability had been significantly modified from the method used to measure the permeability following the standard method, effectively resulting in what could be considered a “different” tool. Interlaboratory trials have shown variability between different tools which can significantly impact mould filling simulations.
  - Benchmarking trials using nominally the same fabric have shown that there is batch to batch variability in the architecture at scales relevant to permeability measurement. Different values were measured on different batches of the “same” fabric. [3][4]

Uncertainty of measurement

- In order to further understand the accuracy of the permeability measurements, measurement uncertainty evaluation was performed by identifying and quantifying the sources:
  - Injection pressure
  - Fluid viscosity
  - Radius of injection port
  - Volume fraction
  - Flow front position
  - Time

- Using Monte Carlo simulation, it was possible to quantify the uncertainty for each measurement at 95% CI at 11% for K_1 and 12% for K_2 (Fig. 16).

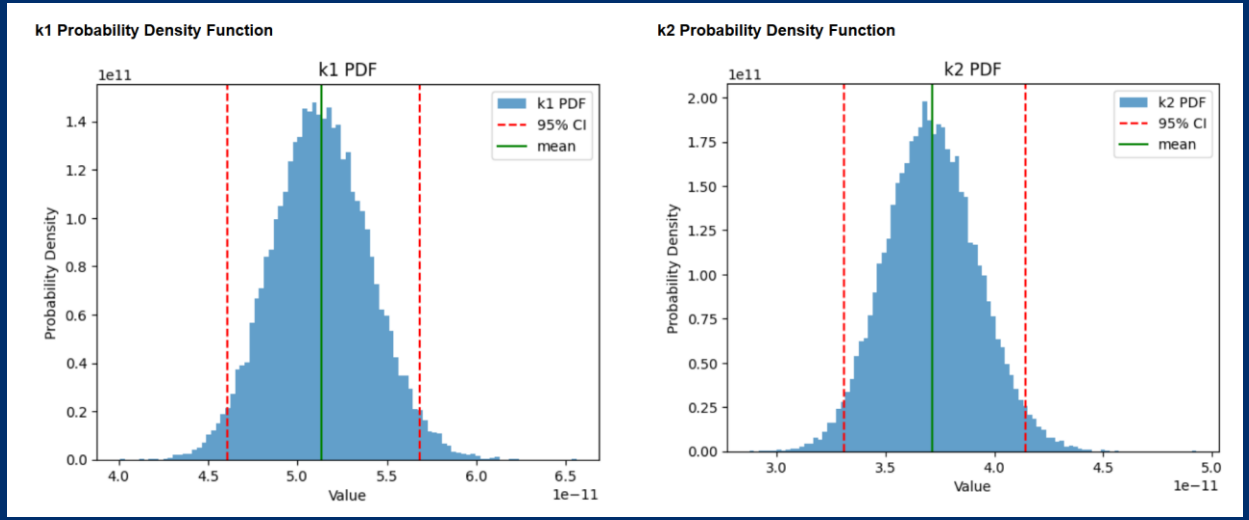

Fig. 16. Histogram showing measurement uncertainty

Proposed next steps and concluding remarks

- The two case studies presented here show a preliminary effort to assess the accuracy of mould filling simulations and the impact of permeability values as an input parameter.
- The permeability of sheared specimens was successfully measured, and the influence of mapping a non-uniform permeability onto simulations of the mould filling vs using a uniform value was shown.
- In the next steps, following refinements to the simulations, these results will be put together to form a complete picture and provide an accessible understanding of the process of characterising textile reinforcements and simulating the manufacture of a composite part.
- Here, some of the complexity of this process has been shown, highlighting the importance of putting these methods through their paces at all stages from fabric characterisation through to simulation and manufacture.
- Ongoing work is being carried out into the virtual characterisation of permeability, which may pave the way for a suitable alternative to experimental measurements [ref].

Acknowledgements

Keywords: 3D reinforcement, Physical properties, Microstructure, Filtration, Retention

ABSTRACT

In the case of severe thermo-mechanical loads, the composite materials of this study are manufactured through Resin Transfer Molding process in which a particle-filled thermosetting resin is injected into a 3D fibrous preform.

The challenge is to control the process by building a model that couples flow in porous media, particle filtration, and material properties' evolution induced by the filtration phenomenon. Such a model requires material properties related to particle-filled resin rheology and fibrous preform permeability as inputs.

Experimental methods were used in order to characterize the materials of the study taking into account the fibrous preform architecture. An initial phase consisted in characterizing the particle-filled fluid with experimental tests and determining the preform microstructure with micro-tomography. In a second phase, a new non-destructive method was developed to measure the three-dimensional permeability of a 3D anisotropic fibrous reinforcement using an air-flow bench.

The material data generated from the characterization will further be implemented in the coupled flow-filtration model.

1 INTRODUCTION

3D fiber-reinforced composite materials are often used for thermal protection systems (TPS) that are exposed to severe thermo-mechanical loads. The 3D composites investigated in this study are manufactured through RTM (Resin Transfer Molding) process in which a thermosetting resin is injected into a 3D fibrous preform (Fig. 1). The 3D composites are further functionalized by two means: (i)

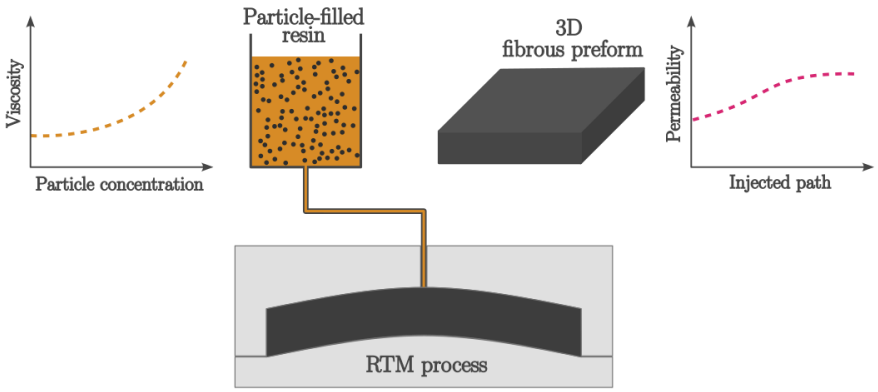

Figure 1: Study process overview.

adding fillers to the resin and (ii) generating a fillers' content gradient in the fibrous preform. Therefore, the challenge consists in controlling this process, which involves the flow of particle-filled resin through a three-dimensional fibrous preform.

In order to control the particle content during the injection, one must build a model that couples flow in porous media, particle filtration, and material properties' (e.g., viscosity and permeability) evolution induced by the filtration phenomenon [1], [2], [3], [4]. Such a model requires material properties related to particle-filled resin rheology and fibrous preform permeability as inputs. Literature showed that the resin viscosity increases with the particle concentration. Because of the addition of particles, the particle-filled fluid may exhibit different behaviours than the neat fluid [1], [4]. Previous studies developed different experimental methods for fibrous reinforcement permeability measurement. These methods are usually destructive and apply to 2D reinforcements [5].

This work aims to extend the understanding of the flow behaviour and architecture of the three-dimensional fibrous network geometries during Resin Transfer Moulding. Experimental methods were used in order to characterize the materials of the study taking into account the fibrous preform architecture.

An initial phase of the work consisted in characterizing the particle-filled fluid and determining the preform microstructure. The rheology of the particle-filled fluid was analysed in order to determine the influence of filler content on the viscosity. Then, micro-computed tomography was used to analyse the three-dimensional fibrous preform architecture. In a second phase, a new non-destructive method was developed to measure the three-dimensional permeability of the fibrous reinforcement using an air-flow bench. Using an inverse method, the preform permeability 3D tensor is determined from experimental and numerical simulation results

2 MATERIALS

A first phase of the work consisted in characterizing the materials of the study. The particle-filled fluid rheology was determined and the 3D fibrous preform microstructure was analyzed.

2.1 Suspension characterization

A model suspension was chosen in order to develop experimental methods by fluid flow. Glycerin SOLVAGREEN® from Carl Roth was mixed with ethanol at a percentage of 65/35% by mass. The glycerin-ethanol is then mixed with carbon blacks using the T25 digital Ultra-Turrax disperser to homogenize the suspension. The model suspension of the study is studied with variable particle contents to measure the viscosity as a function of particle concentration as shown in figure 2.

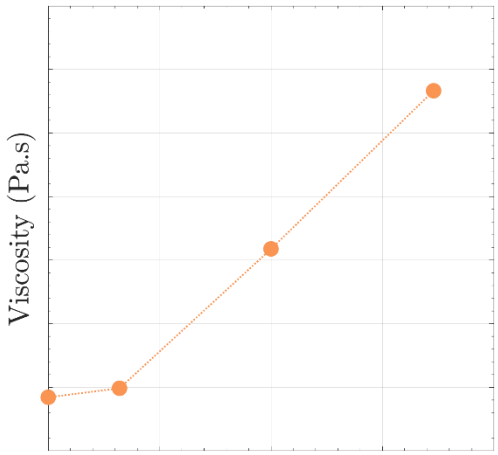

Figure 2: Evolution of the suspension viscosity as a function of the particle content.

2.1 Fibrous preform morphology

The 3D fibrous preform architecture is obtained by non-woven horizontal ply stacking made of carbon fibers whose orientations vary periodically in a balanced way. The three-dimensional structure is built by transferring fibers in the vertical direction, i.e. through the thickness. Samples of the dry fibrous preform were analyzed by micro-tomography to better examine its microstructure. The micro-tomography tests were conducted with a XRadia XCT-400 to obtain images of the fibrous preform slices through its thickness. According to the sample size, the image resolution varies from ~40µm to ~6µm.The 3D volume were reconstructed from the micro-tomography images (Fig. 3 left) and the fiber orientations was analyzed by image treatment. As shown in figure 3 (right), in-plane images were segmented by fiber orientation using the ImageJ plugin OrientationJ.

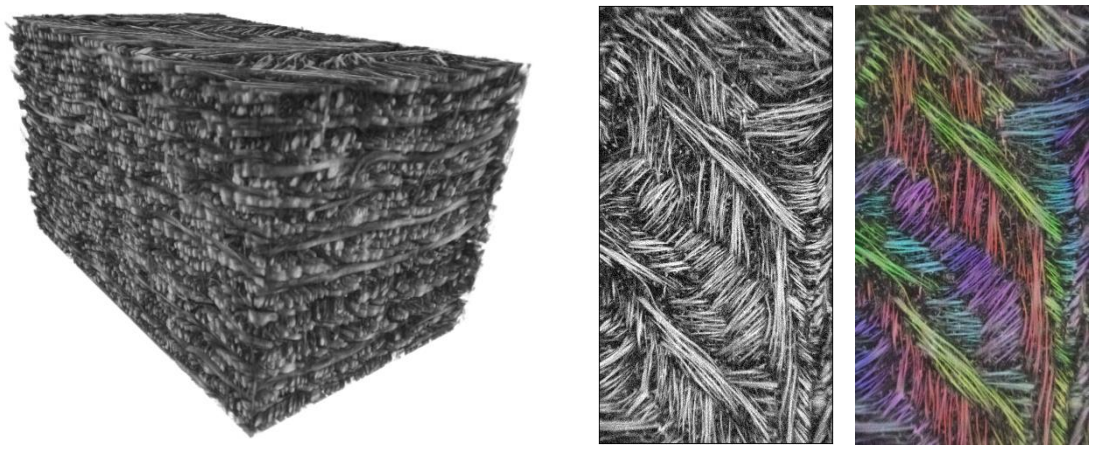

Figure 3:3D reconstruction of the fibrous preform (left) and image segmentation by fiber orientation (right) of micro-tomography images. The color map indicates the orientations of the fibers.

3 A NEW NON-DESTRUCTIVE 3D PERMEABILITY METHOD FOR ANISOTROPIC 3D FIBROUS PREFORM

Accurate measurement of the three-dimensional permeability tensor of fibrous preforms is essential for the prediction and optimization of resin flow in Liquid Composite Molding processes. In 3D fibrous reinforcements, resin can flow not only in the in-plane directions but also through the thickness, due to the presence of fibers transferred in the transverse direction. Moreover, because the fibrous preform presents an anisotropic three-dimensional architecture, the determination of the 3D permeability tensor becomes more complex.

To this day, different experimental methods of fibrous reinforcement permeability measurement exist [5]. While experimental methods to measure 1D, 2D or 3D permeability of fibrous reinforcements are commonly used, they are often limited to destructive methods since liquid is used to saturate the fiber bed. Non-destructive methods such as gas-based permeability measurement offer a cleaner, relatively faster alternative. By imposing gases like air to flow through dry preforms, pressure or flow rate difference is measured to determine permeability values [6], [7]. However, these experimental methods are typically constrained to 1D and 2D flows.

We thus propose a new experimental method to determine the 3D permeability tensor of a thick anisotropic fibrous preform using a transient air flow using an inverse method. This method has the advantage to be non-destructive, to limit the number of sample to the to-be-processed preform and of not requiring the sealing of the material.

3.1 Description of the experimental setup

The test rig (Fig. 4) consists in a cavity, where the fibrous preform is placed, formed by a bottom plate, a frame and a top plate. The cavity is sealed with the two plates above and below the preform (in

contact), leaving the side faces free. Depending on the preform thickness, the frame can be adapted. The bottom plate presents several locations in order to place pressure sensors according to the measurement configuration and the preform geometry. Moreover, the top plate presents one pressure sensor location. On the bottom plate, an air inlet is connected to a vacuum pump allowing imposing pressure in the cavity for the measurement. During a measurement, a transient air flow is thus imposed inside the cavity where the fibrous preform is, from an initial pressure P_0 to P_{end}. An automated data acquisition line saves the pressure sensor measurement. It is possible to conduct the experiments by raising pressure method (RPM) or dropping pressure method (DPM). These tests were conducted using the RPM method where the pressure of the cavity during the measurement goes from $P_0 = P_{vacuum}$ to $P_{end} = P_{atm}$ by opening the inlet to ambient air.

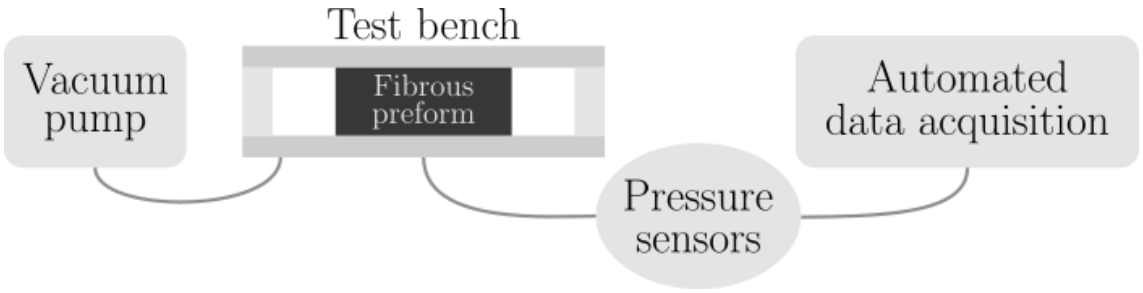

Figure 4: Schematic diagram of the experimental setup.

The aim of the experiment is to measure the pressure difference at several locations of the fibrous preform during the imposed transient air flow. This pressure difference between sensors allows determining each component of the 3D permeability tensor. This experimental method is decoupled in two steps (Fig. 5): (step 1) in-plane flow and (step 2) transverse flow.

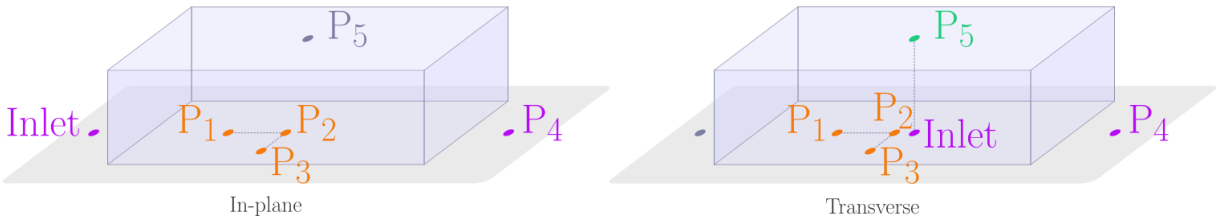

Figure 5: Schematic diagrams of the in-plane (step 1, sensor P5 is not active) and transverse (step 2) measurement configurations.

During step 1, air flows in through the inlet point and the pressure in the cavity (out of the preform) is measured by the sensor P4. This measurement represents the pressure imposed on the lateral sides of the fibrous preform because the pressure in the cavity is considered to be homogenised quasi instantaneously. Then, air flows through the fibrous preform and the pressure is measured at points P1, P2 and P3.

During step 2, a transverse airflow is imposed by letting the air in at the centre of the preform, on the bottom plate side. The pressure measurement by sensor P5 is added, which is located on the upper plate, on the top face of the preform and above the inlet. In this way, air flows within the entire preform and the pressure sensors P1, P2 and P3 measure the in-plane pressure as in step 1. In addition, the sensor P4, placed in the cavity, measures the pressure outside the preform to be implemented as a boundary condition applied at the lateral sides of the preform.

Figure 6 shows the experimental pressure measured by the sensors in both configurations (step 1 and step 2). The transient phase of the pressure curves is observed and can be distinguished between sensors. This transient part of the curves highlights the delay between sensors, which will is used for numerical resolution and the permeability identification.

During these measurements, only one material sample is tested and the fibrous preform remains intact after each test. Thus, the tests can be repeated as many times as necessary.

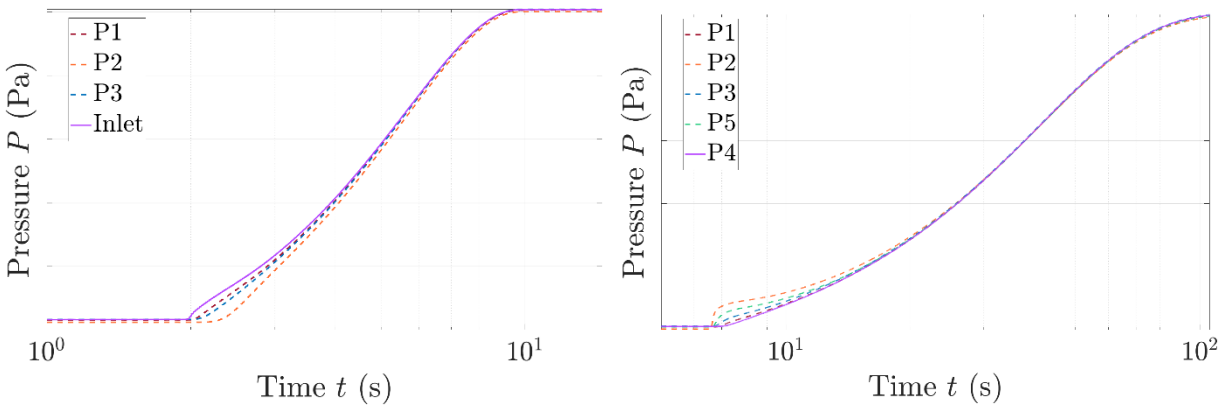

Figure 6: Experimental results of pressure sensors in both configurations: step 1 in-plane (left) and step 2 transverse (right)

3.2 Numerical model

Because of non-linearity and the three-dimensional flow, numerical model is needed to extract the permeability tensor components. The simulation tool COMSOL Multiphysics® is used to implement air flow through the 3D fibrous preform. Two distinct numerical models are established replicating both experimental measurement steps.

Three governing equations are necessary to solve for the pressure inside the fibrous preform as the three unknowns of this problem are the fluid pressure, velocity and density. In the case of viscous flow [6], the equations are: (1) the fluid mass conservation (assuming the preform does not deform while the fluid moves inside), (2) the momentum equation (Darcy's law) and (3) equation of state of an ideal gas. They result in equation (4) that is implemented in the numerical model solved for the pressure.

$$\frac{\partial \rho}{\partial t} + \nabla \cdot (\rho v) = 0 \tag{1}$$

$$v = \frac{\overline{\overline{K}}}{\phi \mu} \cdot \nabla P \tag{2}$$

Where ρ and μ are the fluid density and viscosity, respectively, ϕ is the preform porosity and v is the pore-scale fluid velocity.

In the case of anisotropic porous media, the permeability $\overline{\overline{K}}$ is a symmetric third second order tensor:

$$\overline{\overline{K}} = \begin{bmatrix} K_{xx} & K_{xy} & K_{xz} \\ K_{yx} & K_{yy} & K_{yz} \\ K_{zx} & K_{zy} & K_{zz} \end{bmatrix}$$

$$pV = nRT \tag{3}$$

$$\frac{\partial P}{\partial t} = \nabla \cdot \left(\frac{\overline{\overline{K}}}{\phi \mu} \cdot P \nabla P \right) \tag{4}$$

In this study, the permeability tensor principal axes (*1,2,3*) are considered aligned with the experimental bench axes (*x,y,z)* so that the permeability tensor is simplified as a diagonal tensor such as:

$$\bar{\bar{K}} = \begin{bmatrix} K_1 & 0 & 0 \\ 0 & K_2 & 0 \\ 0 & 0 & K_3 \end{bmatrix}$$

To identify the permeability tensor by inverse method, two models (Fig. 7) are build according to the experimental configurations:

- **Step 1** (in-plane flow): a 2D model where the initial pressure condition reads the initial pressure P0 applied to the 2D preform domain. As a Dirichlet boundary condition, the transient inlet pressure that is measured by the cavity sensor (P4) is applied around the 2D preform domain. The pressure P is then solved for $K_1$and K_2 intervals to get pressure located in points P1, P2 and P3 used in identification of the in-plane permeability components $K_1$and K_2 by the inverse method.

- **Step 2** (transverse flow): a 3D model where the initial pressure condition reads the initial pressure P0 applied to the 3D preform domain. There is a no flow condition applied to the top and bottom faces of the domain. As Dirichlet boundary conditions, the centre point on the bottom face is set as the inlet and the cavity transient pressure (measured by P4) is applied to the four lateral faces. The in-plane permeability components $K_1$and K_2 previously identified are set as model parameters and the pressure is solved for a K_3 interval. Pressure located in points P1, P2, P3 and P5 are saved to be used in identification of the transverse permeability component K_3 by the inverse method.

Both models are initialize with the preform dimensions, the material parameters such as the fluid (air) viscosity μ and the fibrous preform porosity ϕ.

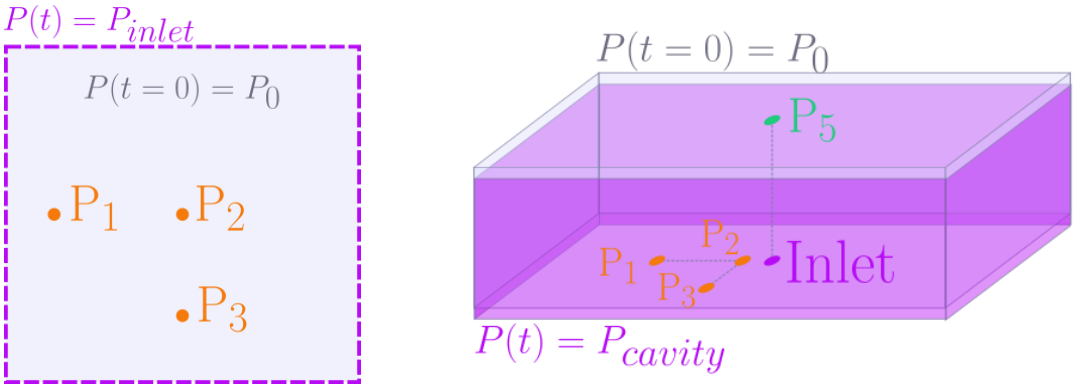

Figure 7: Boundary conditions applied to the step 1 (left) and step 2 (left) numerical models

3.3 $\bar{\bar{K}}$ determination by inverse method

The full 3D permeability tensor of the fibrous preform $\bar{\bar{K}}$ is determined with an inverse method illustrated in the figure 8. First, the in-plane components $K_1$and K_2 are identified by minimizing a cumulated error ϵ (equation (5)) by time step on each pressure sensor measurement and for each $K_1$and K_2 couple, between experimental measurement P_{exp} (step 1) and the corresponding numerical solution P_{sim} (2D model of step 1).

$$\epsilon(K_1, K_2) = \sqrt{\frac{1}{N_t}\sum_t \left(\frac{P_{1_{exp}} - P_{1_{sim}}}{P_{1_{exp}}}\right)^2 + \left(\frac{P_{2_{exp}} - P_{2_{sim}}}{P_{2_{exp}}}\right)^2 + \left(\frac{P_{3_{exp}} - P_{3_{sim}}}{P_{3_{exp}}}\right)^2} \quad (5)$$

The couple (K_1, K_2) is solution of the minimum cumulated error ϵ, such as shown in figure 9.

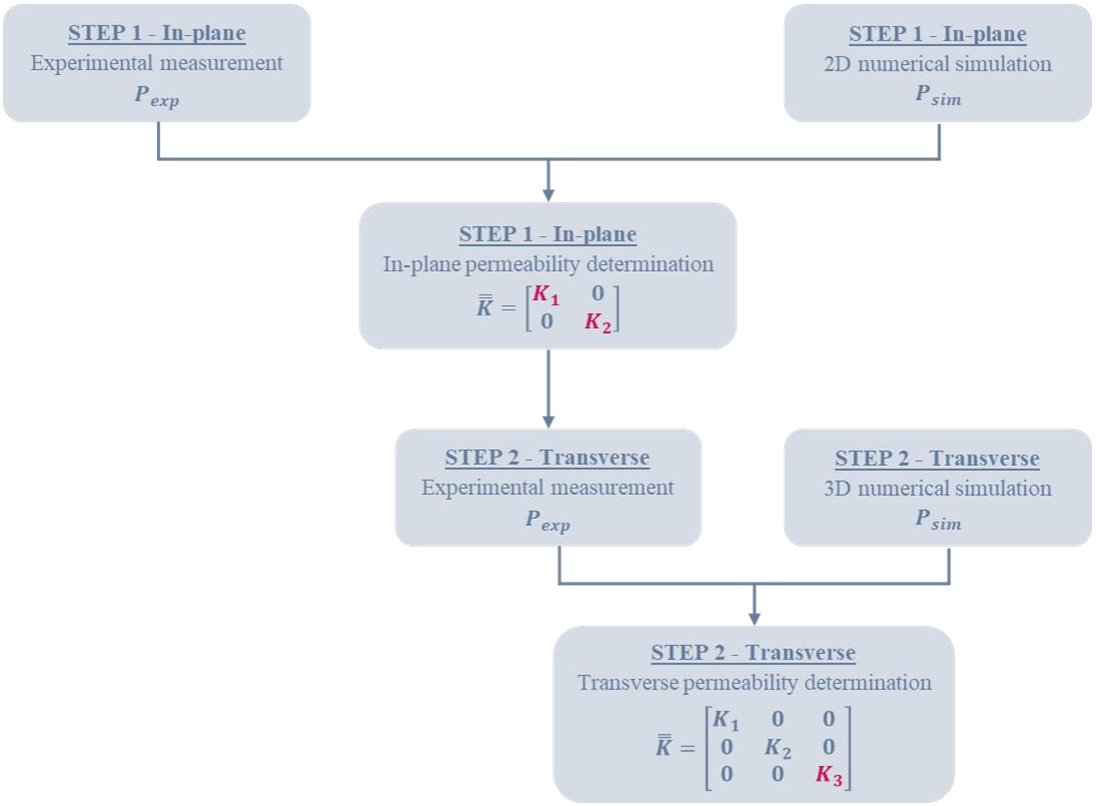

Figure 8: Schematic of the inverse method used to determine the 3D permeability tensor of an anisotropic 3D fibrous preform.

Secondly, the 3D numerical model for step 2 is solved with the identified in-plane permeability $K_1$and K_2 as parameters for a set of K_3values. Then, the transverse component K_3 is identified by minimizing the cumulated error (K_3) (Fig. 9), as in equation (6), between experimental measurement P_{exp} (step 2) and the corresponding numerical solution P_{sim} (3D model of step 2).

$$\epsilon(K_3) = \sqrt{\frac{1}{N_t}\sum_t \left(\frac{P_{1_{exp}} - P_{1_{sim}}}{P_{1_{exp}}}\right)^2 + \left(\frac{P_{2_{exp}} - P_{2_{sim}}}{P_{2_{exp}}}\right)^2 + \left(\frac{P_{3_{exp}} - P_{3_{sim}}}{P_{3_{exp}}}\right)^2 + \left(\frac{P_{5_{exp}} - P_{5_{sim}}}{P_{5_{exp}}}\right)^2} \quad (6)$$

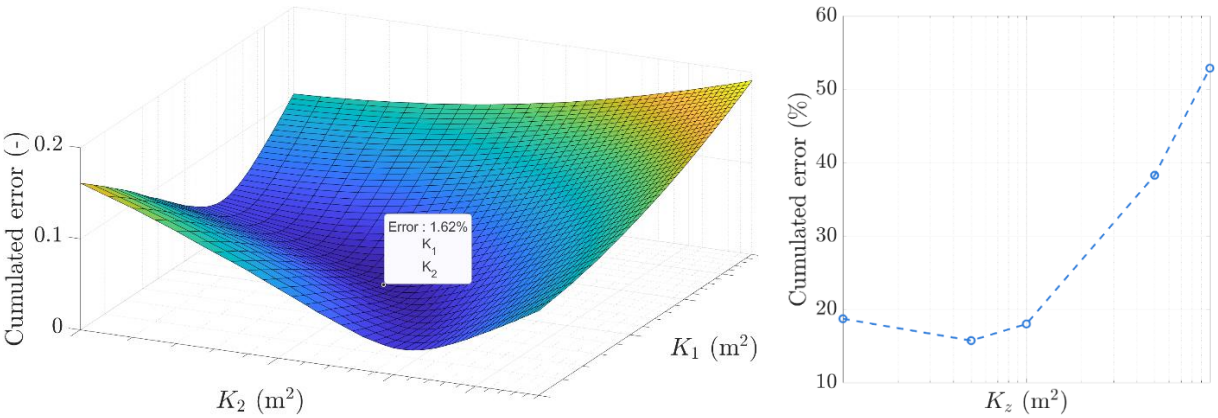

Figure 9: Plots of the cumulated errors $\epsilon(K_1, K_2)$ for in-plane (left) and $\epsilon(K_3)$ for transverse (right) permeability tensor components identification.

5 CONCLUSIONS

To control particle-filled RTM in 3D fibrous preforms, a model should be built so as to couple flow in porous media, particle filtration, and material properties' evolution induced by the filtration phenomenon. Such a model requires material properties related to particle-filled resin rheology and fibrous preform permeability as inputs. To do so, a material characterization work was conducted, which consisted first in the study of particle-filled fluid rheology, also in the understanding of the 3D fibrous preform using micro-tomography and then in the preform permeability determination.

A new experimental methodology to measure a 3D anisotropic fibrous preform permeability tensor using a transient air flow has been described. This fast and non-destructive method is based on the gas pressure measurement at different locations of the preform during the transient air flow. By decoupling the measurements into two distinct steps, in-plane and transverse, the 3D permeability tensor components can be identified by an inverse method. To do so, a cumulated error by time steps and between the experimental pressure sensor measurements and numerical pressure solution is minimized. First, the in-plane permeability tensor components $K_1$and K_2 are identified by solving a 2D numerical model. Then, a 3D numerical model, replicating the second step of the experiment, is solved with the identified $K_1$and K_2 as inputs to determine the remaining transverse component K_3.

The material data generated from the characterization will further be implemented in the coupled flow-filtration model. Perspectives are to assess and validate the model with experimental protocol.

REFERENCE MEDIUM

Unit cell

Periodic assembly

OVERVIEW & OBJECTIVES

Overview

- Numerical benchmark study focused on **simulating in-plane (K11(Kxx), K33 (Kzz))** and **through-thickness (K22 (Kyy))** permeability of an **engineered textile-like reference medium**
- The computer-aided design (CAD) file represents a **3D-printable porous structure** intended for **calibration of permeability test rigs**
- Data collected from multiple simulation teams using **identical geometry**

Objectives

- Assess **variability** of permeability prediction by the participants from multiple institutions using the same digital geometry
- Establish **reference values (K11, K22, K33)** based on consensus reported by simulation results
- Support **future calibration** of experimental setups through a **well-characterized, repeatable digital reference medium**

OVERVIEW OF KXX, KYY, KZZ STATISTICS

Component	Typical range	Notes
Kxx	~5.76E-11 to ~1.8E-08	Most values are clustered between 2.4×10^{-9} and 3.0×10^{-9} m^2, with a few outliers on the higher end (notably 1.80×10^{-8} and 9.49×10^{-9} m^2).
Kyy	~4.63E-12 to ~2.424E-9	The most variable component of all three directions. This could reflect asymmetric flow pathways, differences in mesostructural alignment, or artifacts from simulation resolution.
Kzz	~1.49E-11 to ~8.79E-09	Relatively consistent compared to Kyy, with many values close to 6–7 $\times 10^{-10}$ m^2 Outliers (e.g., 8.79×10^{-9} and 4.22×10^{-9}) suggest localized channels or voxel resolution effects.

PERMEABILITY COMPARISON: UNIT CELL VS PERIODIC ASSEMBLY

CORRELATION

- Kxx and Kzz may have moderate correlation.
- Off-diagonal terms are negligible; cross-correlation with diagonal terms is insignificant

SYMMETRY CONSISTENCY

Looking at whether **K12 = K21**, **K13 = K31**, etc.

Cross-term symmetry	Pattern
Y/Y/Y (Symmetric)	Reported by OpenFOAM (B) and FEMS (C) runs
N/N/N (Asymmetric)	Reported by GeoDict and many others: may reflect minor numerical asymmetries or anisotropy.

OBSERVATIONS

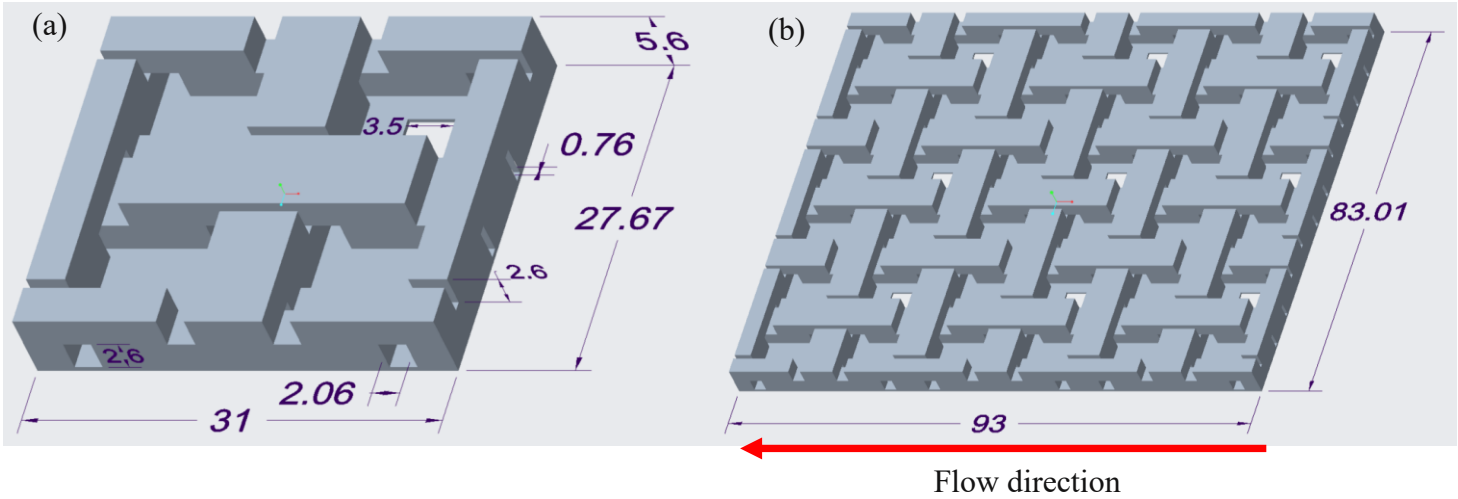
- Anisotropy is evident, with Kxx consistently larger than Kyy and Kzz in most samples.
- Outliers in Kyy and Kzz suggest localized flow instabilities or non-uniform compaction..
- Measurement robustness is acceptable for Kxx and Kzz; however, Kyy data would benefit from increased replicates or better control of preform architecture.
- Off-diagonal terms (K12, K13, K23) are generally very small or zero, indicating near-symmetry and negligible coupling effects.
- Symmetry indicators (K12=K21 etc.) mostly “Y” but some “N” or “N (diff X%)” showing small asymmetries.
- Porosity mostly consistent around 34%.

FUTURE WORK / NEXT STEPS

Investigate the effect of geometric scale on permeability predictions

- Perform CFD simulations on scaled versions of the current RVE geometry:
  RVE × 0.1 and **RVE × 0.01**
- Analyze whether the **permeability tensor K** remains clustered (directionally consistent and within the same order of magnitude) across scales
- Document any shifts in anisotropy or permeability magnitude due to scale changes

Motivation:



- Understanding scale dependence is crucial for **validating CFD results** when extrapolating from microscale geometries to macroscale behaviors
- Although physical 3D printing and experimental validation of very small-scale RVEs may not be feasible, simulation outcomes can still inform:
  - Limitations of current CAD-based permeability predictions
  - Guidelines for scale selection in future digital calibration designs

Broader impact:

- Enhances the **robustness of digital twin strategies** for permeability benchmarking
- Supports development of **scalable reference materials** for various rig sizes and flow regimes

PHASE II: ENLARGED RVE ANALYSIS

- New geometry scaled ×2.8 used for experimental validation
- Participants to simulate and report **Kxx, Kyy, Kzz**

(a) Unit cell CAD design with all channels, (b) CAD model of the full-scale interconnecting channel (All dimensions are in mm).

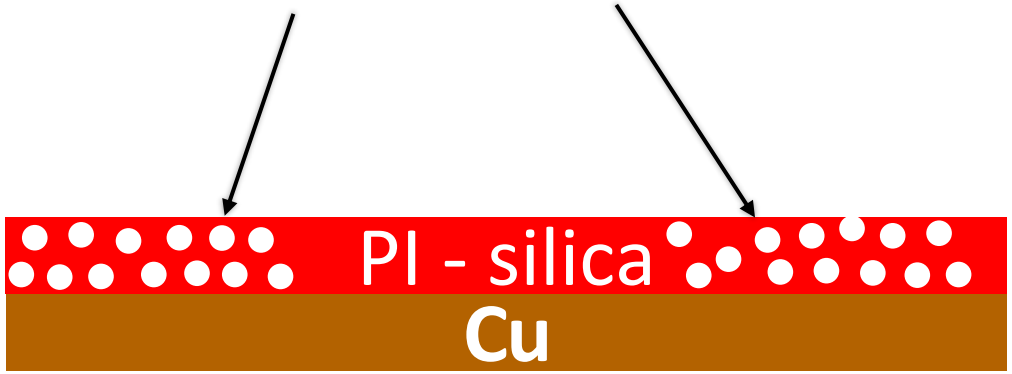
Determination of Mechanical Properties of Polyimide - Silica Nanocomposite Using Micromechanical Modeling

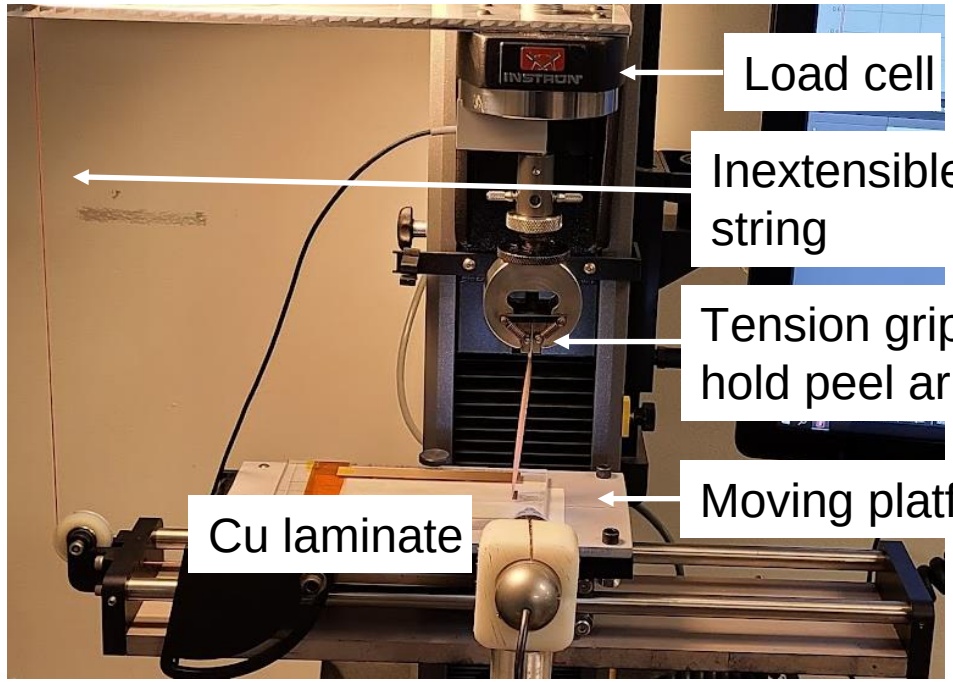
August 4th, 2025



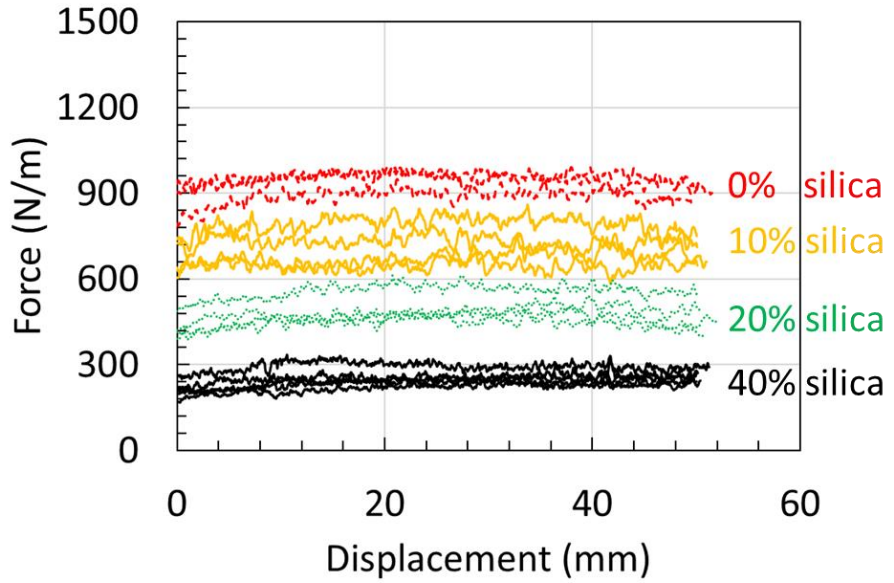
Nithin Kaliyath Parambil, Sagar Doshi, John Gillespie Jr.

UNIVERSITY OF DELAWARE
CENTER FOR COMPOSITE MATERIALS
Celebrating 50 Years

Motivation



- The demand for high-speed electronics is rapidly increasing, leading to more demanding printed wiring board (PWB) requirements.
  - 5G Communication Devices
  - Solid-State Drives (SSDs)
  - Microprocessors etc.
- A typical PWB is made by bonding dielectric films like polyimide to electrically conductive copper foil, such as rolled annealed (RA) copper.
- PWBs are expected to become thinner, more flexible, durable, and compatible with high-frequency 5G performance.
- Polyimide films naturally have a higher coefficient of thermal expansion (CTE) than copper foils, which results in a mismatch and causes residual thermal stresses.



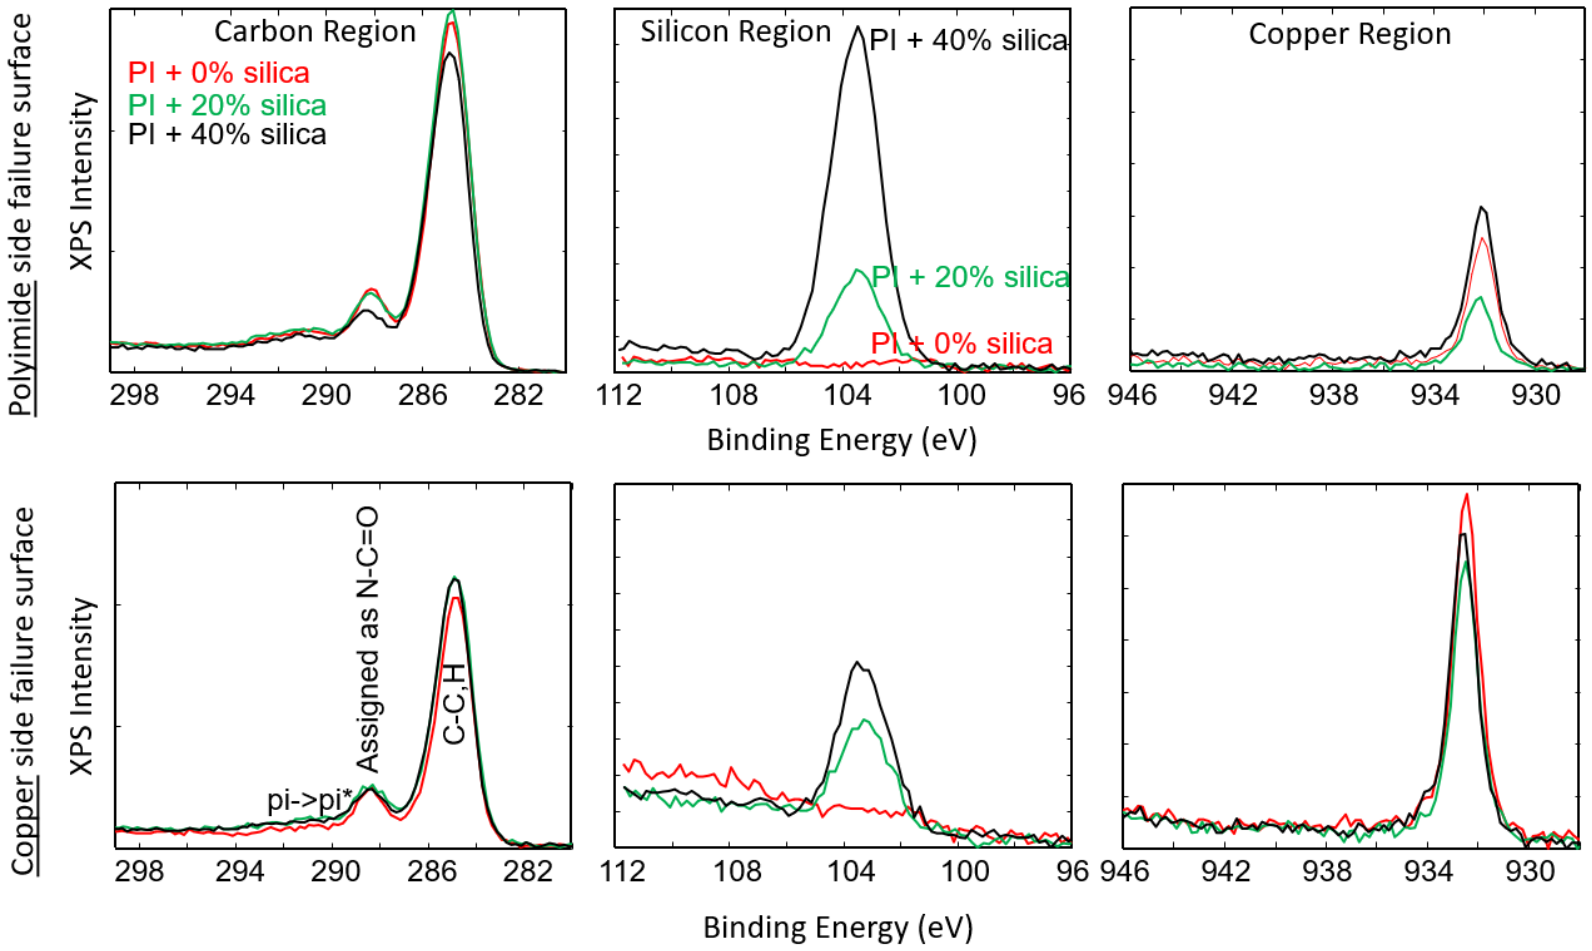
To reduce the CTE mismatch, silica nanoparticles can be added to the polyimide films to lower their CTE.

The focus of this work is to understand crack propagation in the PI-Silica substrate

90° Peel Test – Current Configuration

Force – displacement curve

Plastic deformation of copper after the peel test



- The force-displacement curve obtained from the peel test does not accurately represent the adhesion properties of Cu-PI.
- To capture the adhesion properties of Cu-PI, it is necessary to separate all other deformation energies from the materials, such as the plastic deformation of copper.

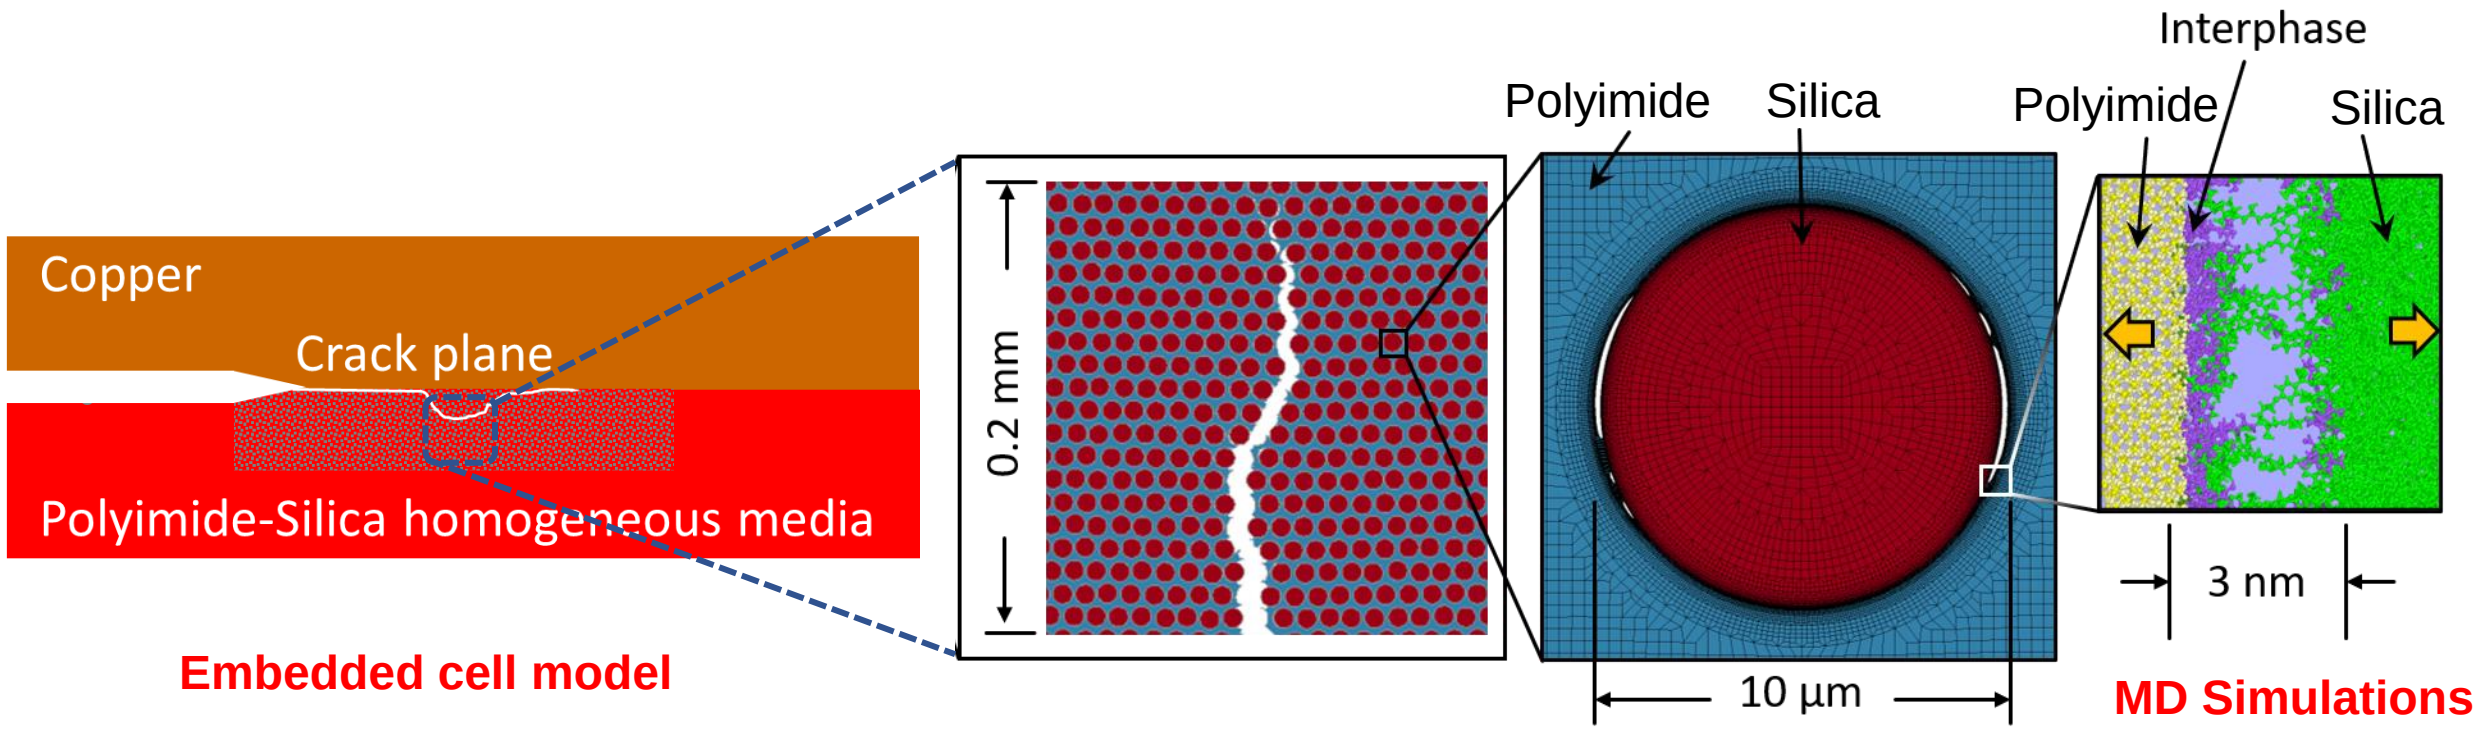
Crack Propagate Through PI Film (XPS Experiment)

UNIVERSITY OF DELAWARE
CENTER FOR COMPOSITE MATERIALS
Celebrating 50 Years

Surface of Cu side and PI side after peel test

- XPS (X-ray Photoelectron Spectroscopy) was used to analyze each side of the failure interface.
- The surface analysis reveals that crack interpenetration is occurring within the PI film.
  - PI material is present on both sides of the crack surface.
  - This indicates that the crack does not propagate along the PI–Cu interface, but rather through the bulk of the PI film.
  - Further investigation is needed to understand the role of embedded particles within the PI.

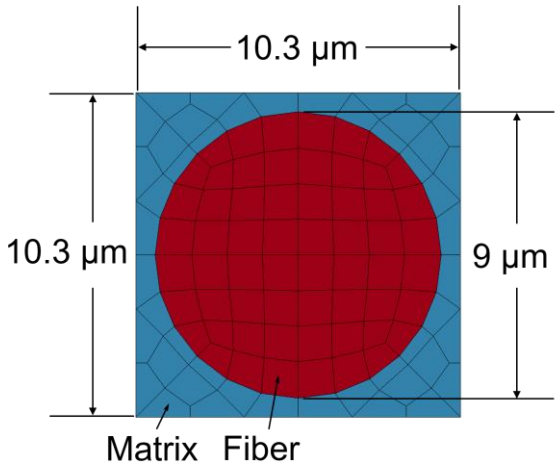


*2024 ACS Materials and Interfaces, Doshi, Parambil, Gillespie et al.

Finite Element Analysis (Bridging length scales)

- Establishing RVE
  - Residual stress (polyimide/silica)
  - Inelastic properties of polyimide
  - Traction law (polyimide/silica) (from MD modeling)
  - Predict the effective properties
    - Relate to particle debonding/cracking

- Copper bulk properties
- Traction law (copper/surface of polymer (MD modeling))



Failure mode could be at the interface or cracking through the polyimide depending on level of adhesion

Materials Properties and FE Model

Polyimide (PI)

Silica Nanoparticle (SNP)

Single particle composite (cut section for better view)

$$V_s = \frac{4}{3}\pi R^3$$

$$V_r = L^3$$

$$V_p = \frac{V_s}{V_r}$$

Maximum V_p when $L = 2R; V_p = \frac{\pi}{6} = 0.52$

Mechanical properties

	Modulus (GPa)	Yield stress (MPa)	Poisson's Ratio	CTE (ppm/°C)
Polyimide (PI)	3.81 ± 0.05	76 ± 1	0.34	20
Silica	73		0.17	0.52

- Volume fraction V_p= 5.7, 12 and 26.5%

Theories for Elastic modulus

- Einstein's equation
  - Based on the rigid particle assumption

$$\frac{E_c}{E_m} = 1 + 2.5V_p$$

- Guth's equation
  - Added a particle interaction term in the Einstein equation

$$\frac{E_c}{E_m} = 1 + 2.5V_p + 14.1V_p^2$$

- Halpin and Tsai's equation
  - Semi-empirical relationship

$$\frac{E_c}{E_m} = \frac{1 + A_1 B_1 V_p}{1 - B_1 V_P} \qquad B_1 = \frac{\frac{E_p}{E_m} - 1}{\frac{E_p}{E_m} + A_1}$$

  - A_1=1

- Assumption of theoretical model
  - Perfect bonding between interface
  - No residual stress
  - Both fiber and matrix are elastic

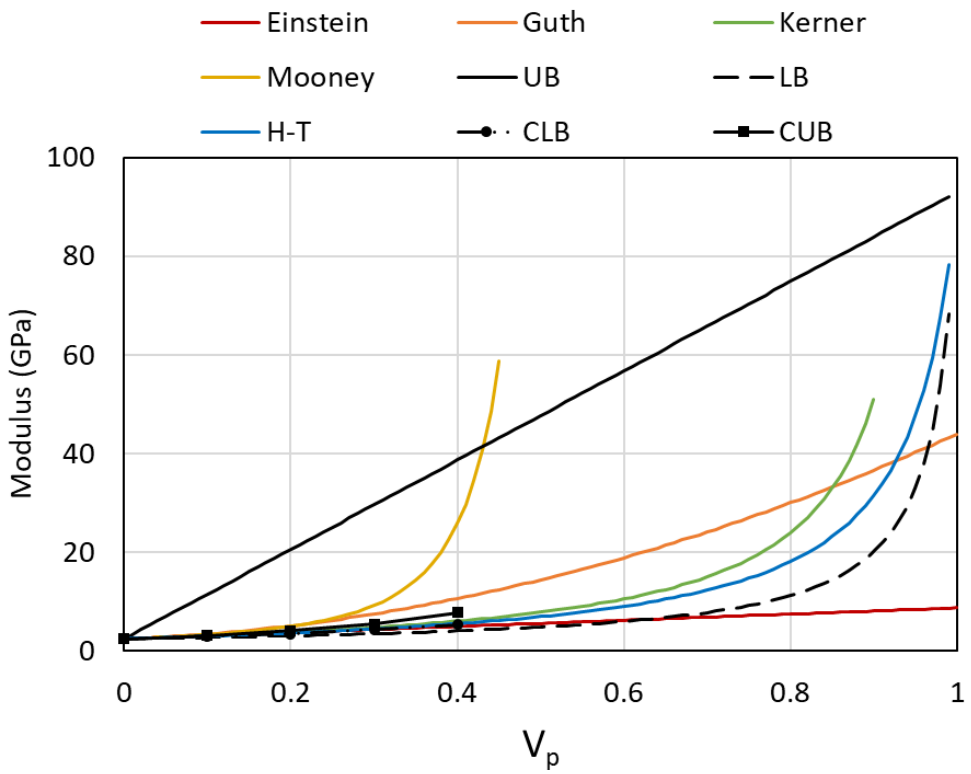
- Kerner's equation
  - $E_p >> E_m$

$$\frac{E_c}{E_m} = 1 + \frac{V_p}{(1-V_P)} \frac{15(1-\nu_m)}{(8-10\nu_m)}$$

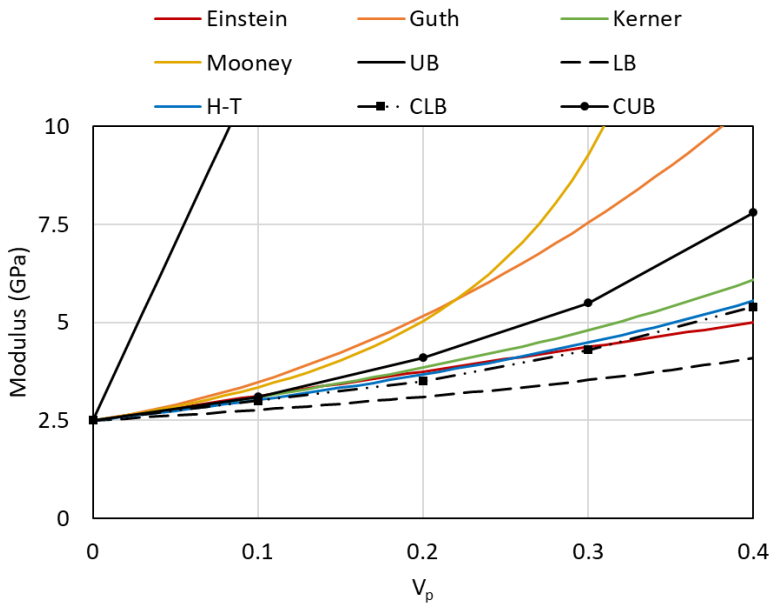
- Mooney's equation

$$\frac{E_c}{E_m} = exp\left(\frac{2.5V_p}{1 - sV_P}\right)$$

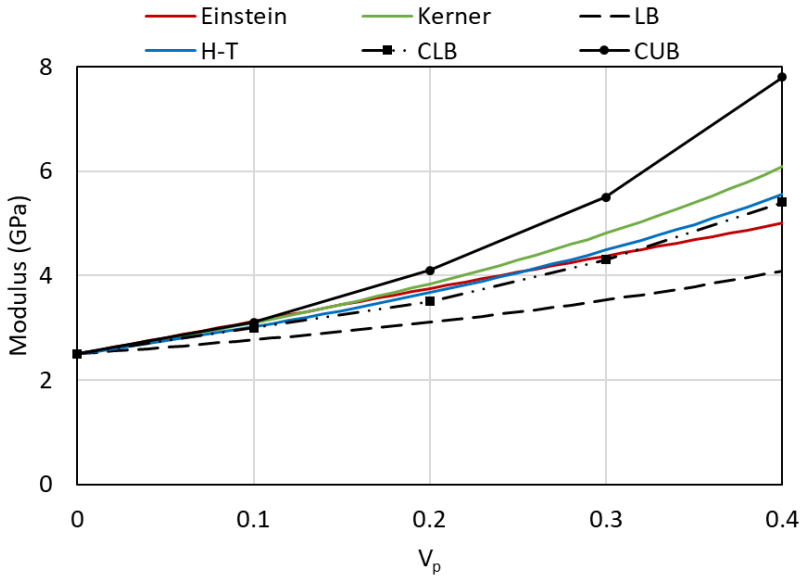
  - s = 1.43



- Lower bound



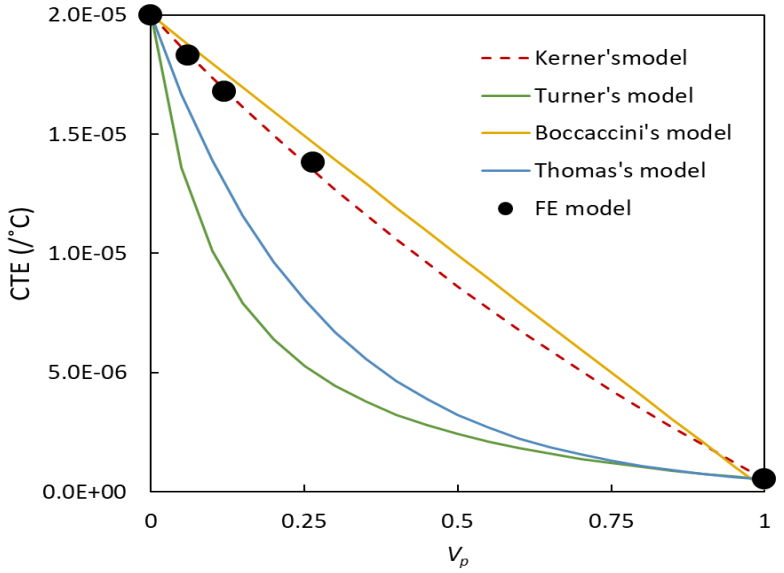
$$E_c^{lower} = E_p E_m / \left[E_p(1 - V_P) + E_m V_p\right]$$

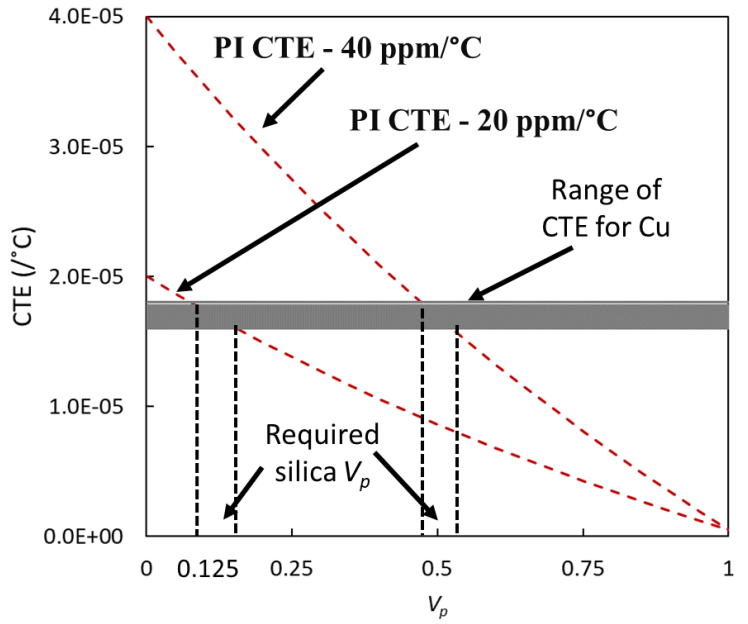


- Upper bound

$$E_c^{upper} = \left[E_p V_P + E_m(1 - V_p)\right]$$

Effective Modulus at Different V_p



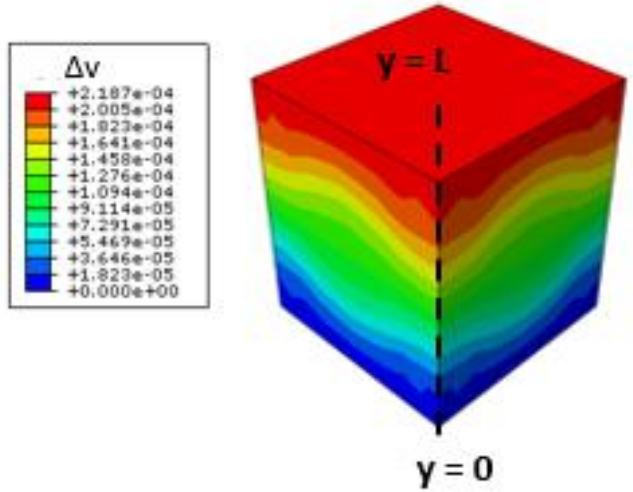


- Experimental comparison is needed to determine the best fit for the model.

Comparison of CTE with Theoretical Model

- Results from various analytical models are compared with the proposed FE model.
- Kerner's model shows strong correlation with the FE model.
- The bounds for the CTE of copper is 16 - 18 ppm/°C
- PI (polyimide) CTE values considered: 20 ppm/°C (room temperature) and 40 ppm/°C (higher temperature).
- The required silica Vp is determined to be approximately 0.125 at room temperature and 0.5 at the higher service temperature range.

Boundary Conditions for FE Model



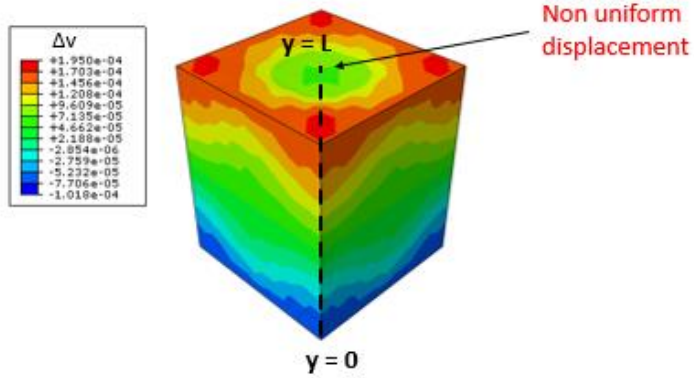
UNIVERSITY OF DELAWARE
CENTER FOR COMPOSITE MATERIALS
Celebrating 50 Years

Constant Displacement (CD) BC

$$\varepsilon_y = \frac{\Delta v}{L} \qquad \varepsilon_z = \frac{\Delta w}{W}$$

$$\nu = -\frac{\varepsilon_z}{\varepsilon_y} \qquad E = \frac{\sigma_y}{\varepsilon_y}$$

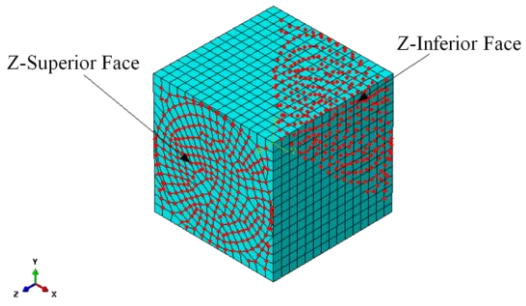
$$\sigma_y = \frac{average\ force}{area}$$



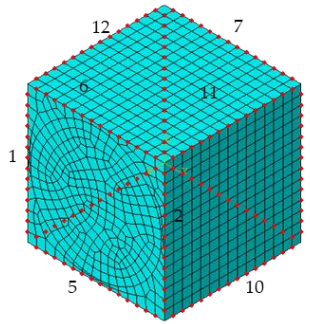
Tensile loading in y direction

Constant Pressure (CP) BC

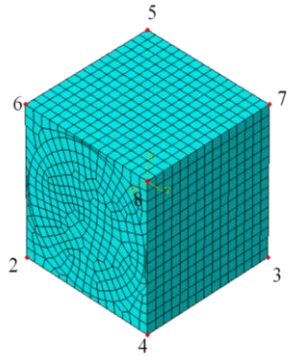
$$\varepsilon_y = \frac{\Delta v}{L} \qquad \varepsilon_z = \frac{\Delta w}{W}$$



$$\nu = -\frac{\varepsilon_z}{\varepsilon_y} \qquad E = \frac{\sigma_y}{\varepsilon_y}$$



$\Delta v = Average\ displcament$



Tensile loading in y direction

- The 3D generalized plane strain boundary condition is not straight forward in Abaqus
- Plane surface should be plane
  - Edges are shared with two planes
  - Vertices are shared between three planes
- "Equation" option in Abaqus is suitable for applying multiple DOF constraints
- Both the resin and particles are modeled using three-dimensional eight-node elements (C3D8).
- For the elastic analysis, a converged mesh size of 2 nm was obtained.

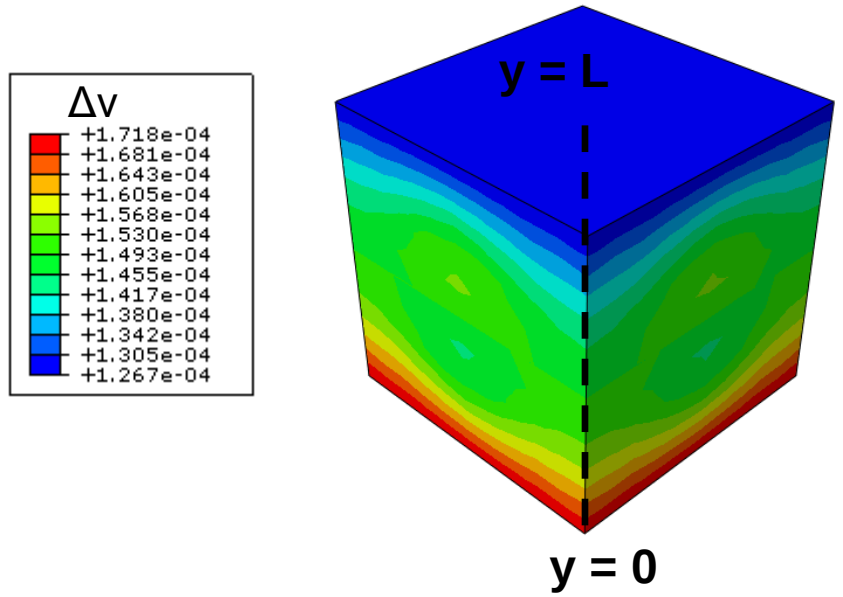
Effective CTE and Modulus Calculation

In put

	Modulus (GPa)	Yield stress (MPa)	Poisson's Ratio	CTE (ppm/°C)
Polyimide (PI)	3.81 ± 0.05	76 ± 1	0.34	20
Silica	73		0.17	0.52

Effective CTE - Simulation result

V_p(%)	5.7	12	26.5
CTE (ppm/°C)	18.3	16.8	13.8



Elastic modulus – simulation result and validation

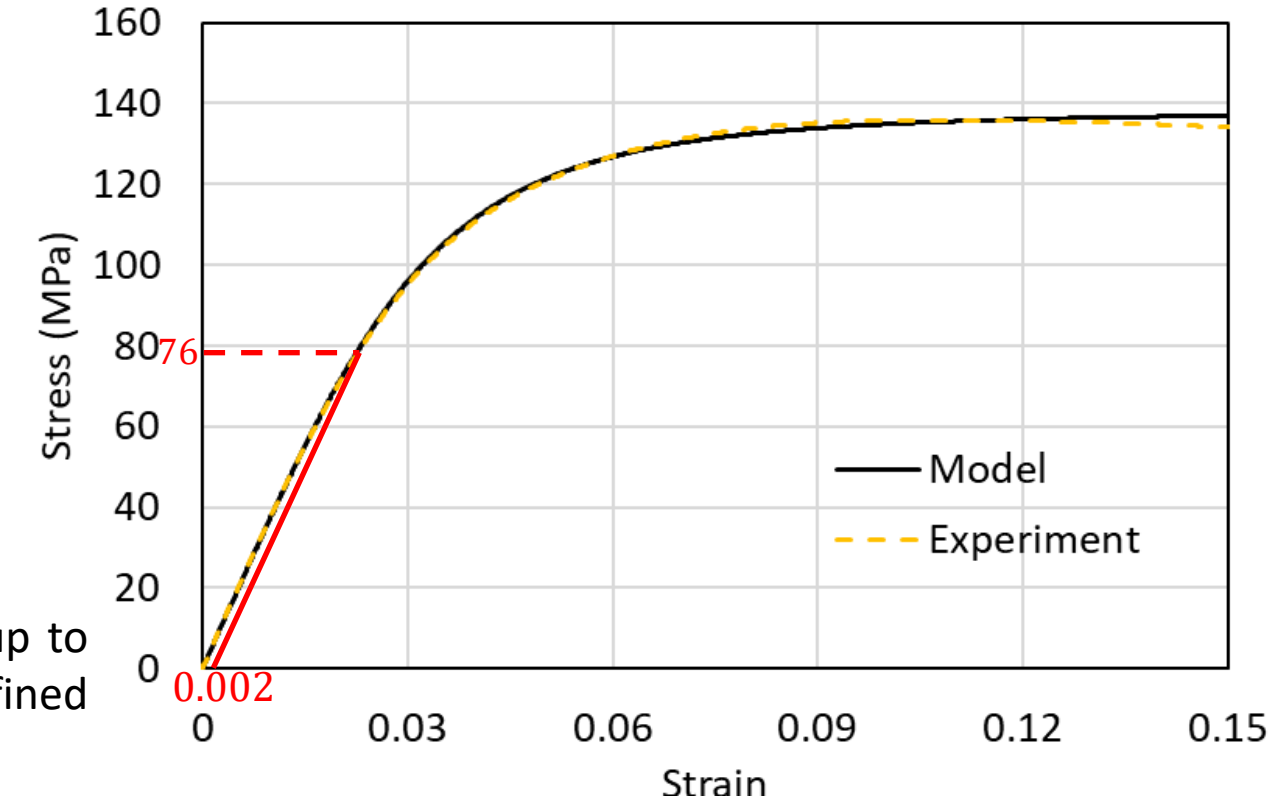
V_p (W_p) (%)	5.7 (10)	12 (20)	26.5 (40)
Experiment (MPa)	4407 ± 96	4948 ± 159	6417 ± 102
FE model - CD (MPa)	4280	4898	7748
FE model - CP (MPa)	4197	4618	5908

- Strains in all three directions are equal

$$CTE = \frac{\varepsilon_x}{\Delta T} = \frac{\varepsilon_y}{\Delta T} = \frac{\varepsilon_z}{\Delta T}$$

$$\varepsilon_y = \frac{\Delta v}{L}$$

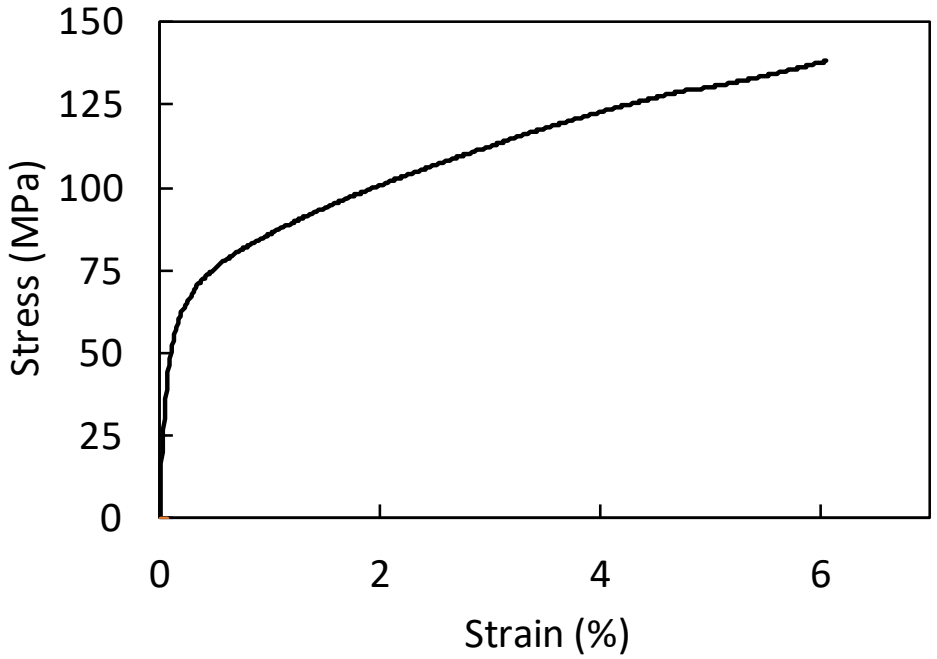
Stress-Strain Curve of Neat PI



› Stress-strain curve of PI is fitted to a Ramberg-Osgood equation in terms of strain:

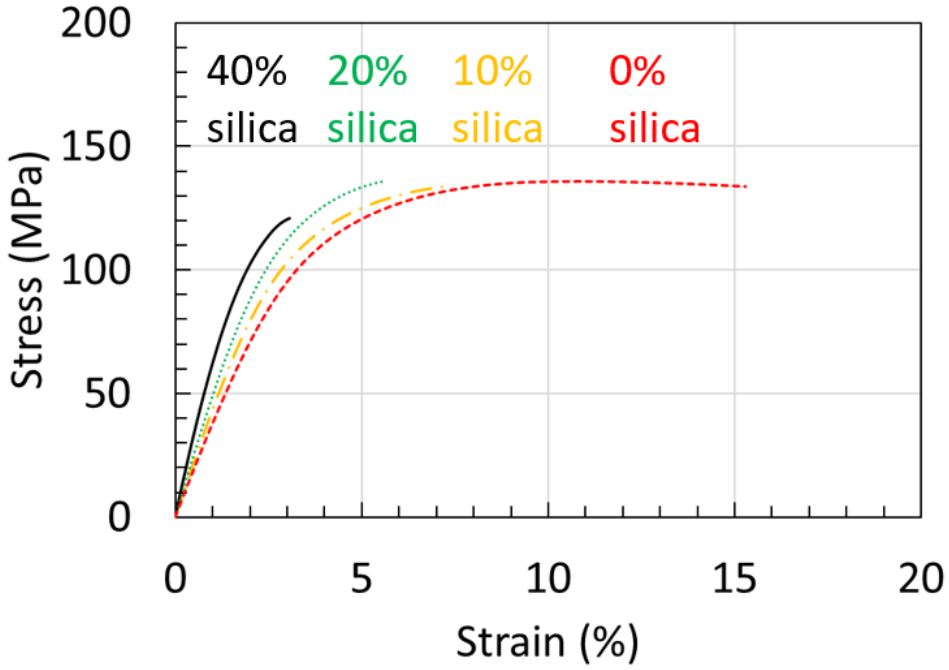
$$\sigma = \frac{E\varepsilon}{\left(1 + \left(\frac{E\varepsilon}{\sigma_0}\right)^a\right)^{\frac{1}{a}}}$$

$$a = 2.7$$



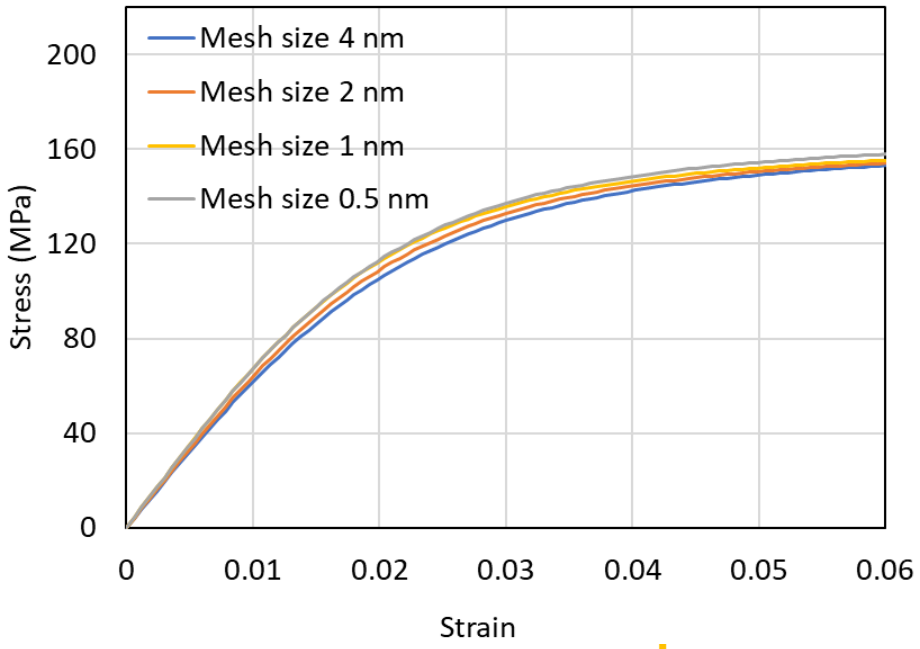
$$\sigma_0 = 138\ MPa$$

$$E = 1.4\ GPa$$

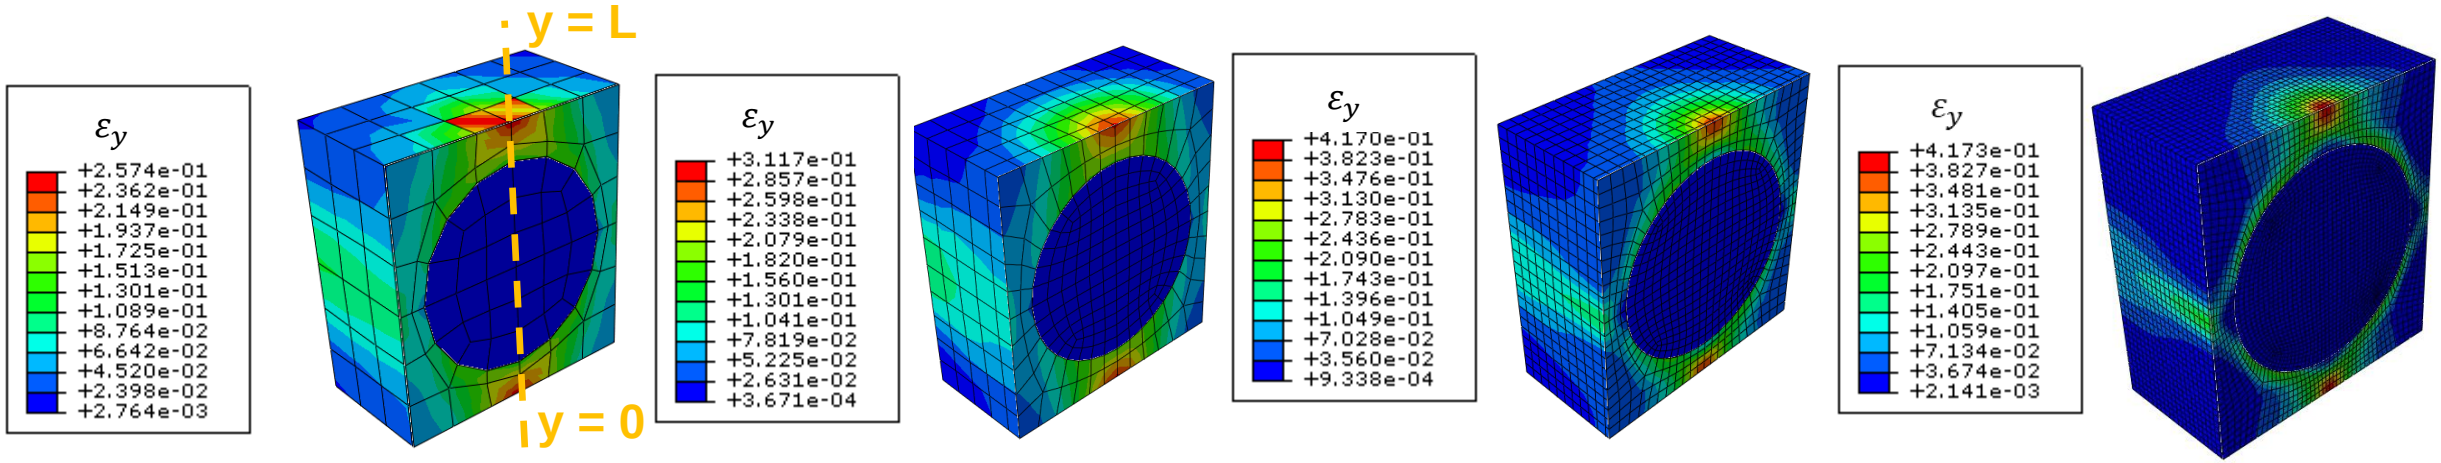


- In Abaqus, the resin is modeled as linear elastic up to the yield stress, and the nonlinear behavior is defined using the tabular input method.
- Resin failure is modeled as ductile damage using a strain-based failure criterion.

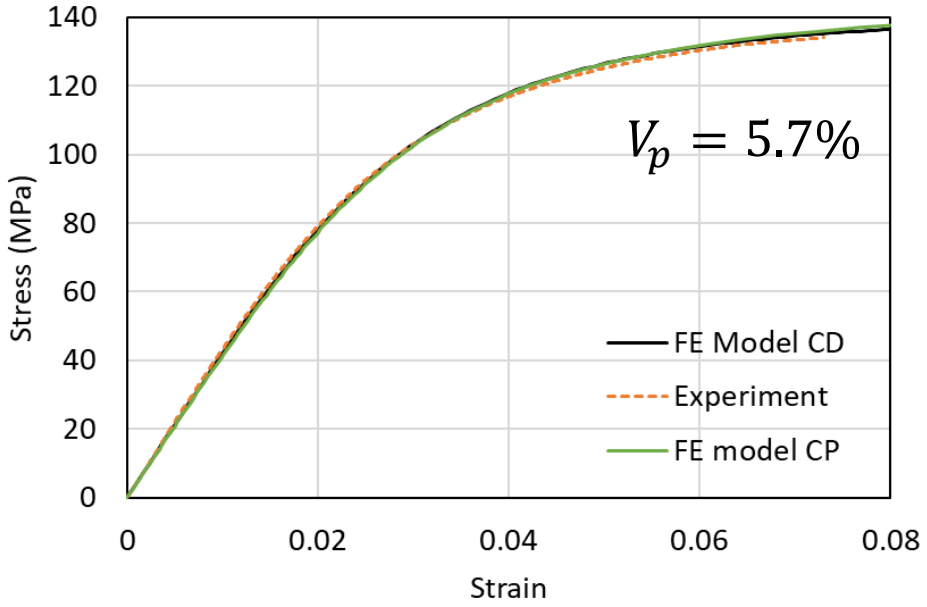
Mechanical Properties of Cu and PI (with silica)



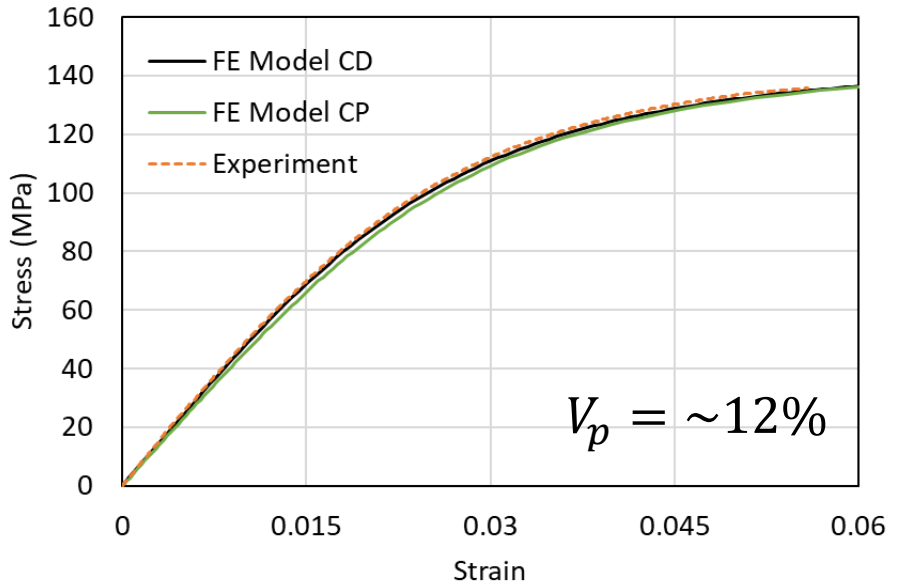
Property of copper considering the processing conditions



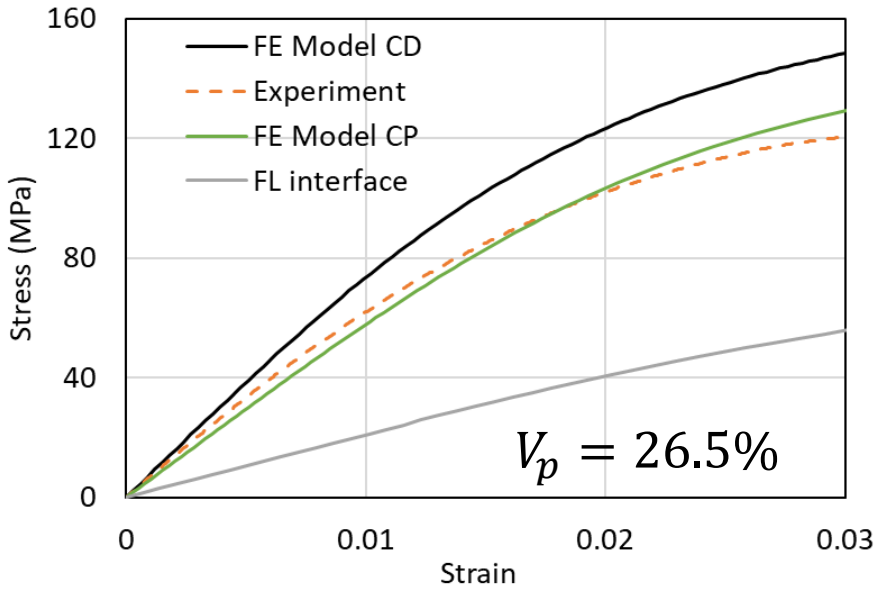
Property of PI – Silica films at different silica weight fraction



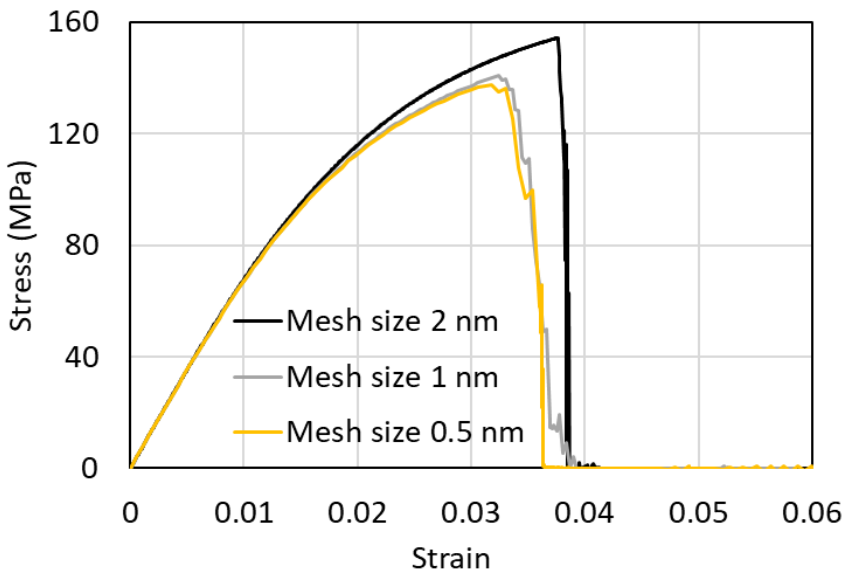
Mesh Convergence Study – Constant Displacement (V_p = 26.5%)



- Mesh convergence studies were conducted with different sizes ranging from 4 nm to 0.5 nm.
- Both global and local properties were studied.
- It was observed from the plot that, after a mesh size of 2 nm, both elastic and plastic solutions converged within a 5% error.

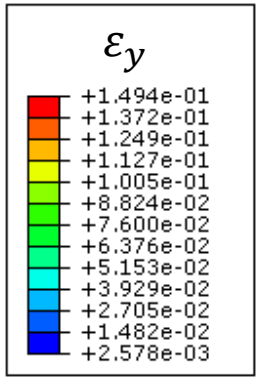


Stress – Strain Curves at Different V_p

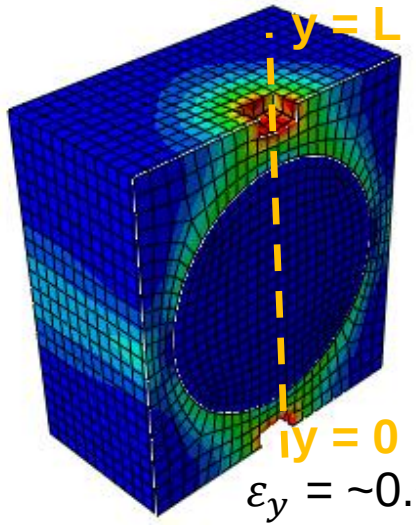


- Inputting the stress – strain curve of PI and changing the V_p
- Comparing FE results with experiment
- With out considering thermal loading

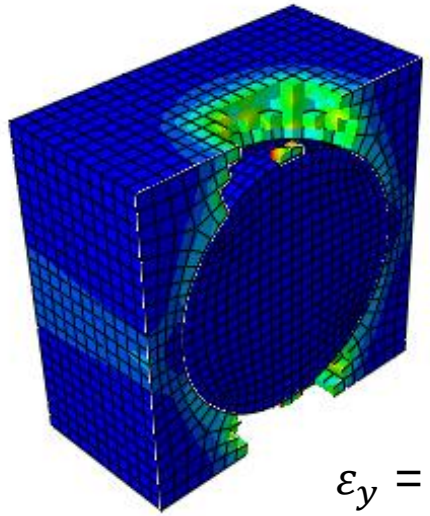
Constant Displacement (CD)
Constant Pressure (CP)
Frictionless (FL)



- At lower V_p, FE results has good correlation with experiments
- At V_p = 26.5% experimental stress – strain curve is close to the FE model with constant pressure BC
- Perfect bonding is the upper bond and FL is the lower bond.
  - Need to include residual stress, frictional sliding and include traction law to predict debonding between interface

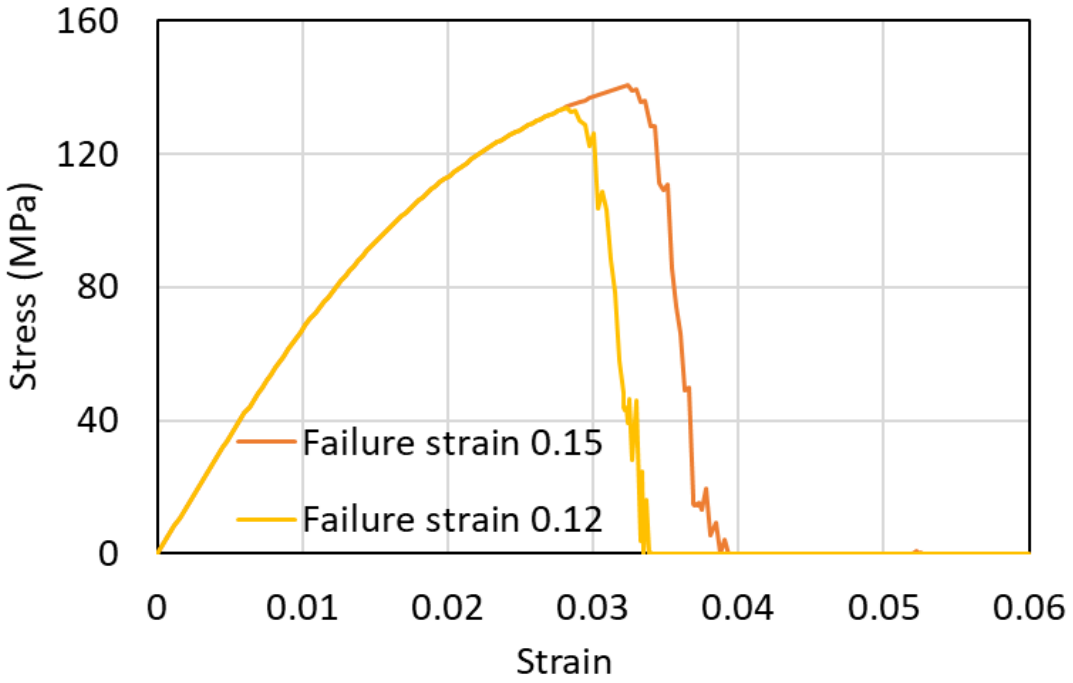


Mesh Convergence Studies with Damage (CD)



- Inputting the stress – strain curve of PI and strain to failure from experiment (~15%)
- V_p = 26.5%
- Perfect bonding between PI and Silica interface
- With out considering thermal loading
- Both failure stress and energy (area under the stress – strain curve) are very sensitive to mesh
- It is observed from the plot, after mesh size of 1 nm both failure stress and energy are converged with in the 5% error

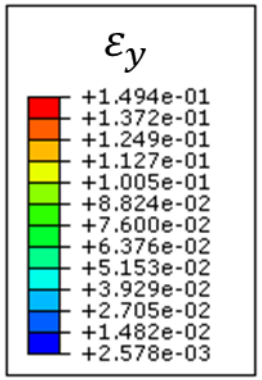
mesh size = 1 nm



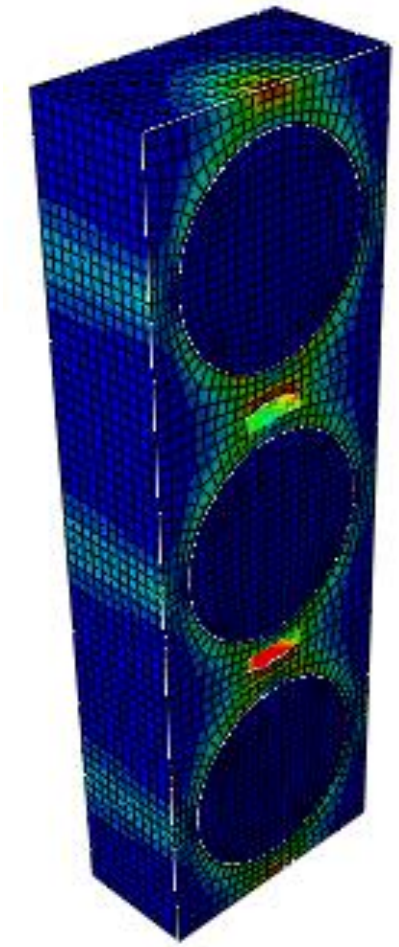
ε_y = ~0.035

ε_y = ~0.037

Effect of Failure Strain (CD)

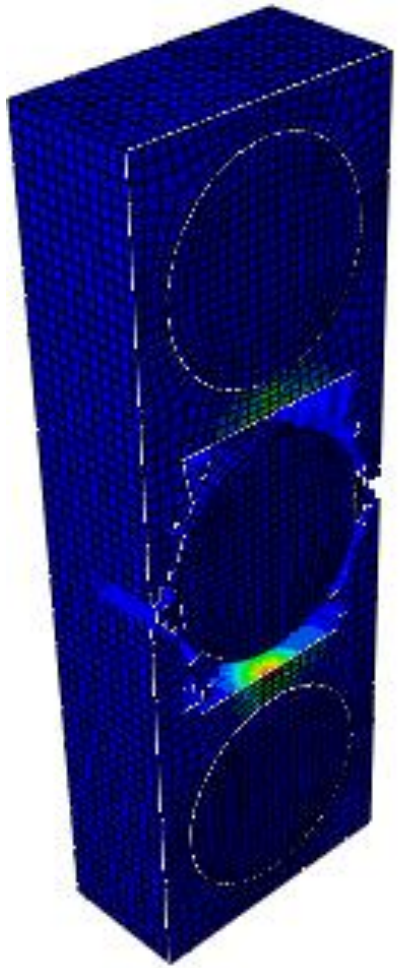


Plastic strain to failure from experiment = ~0.13 and ~0.10



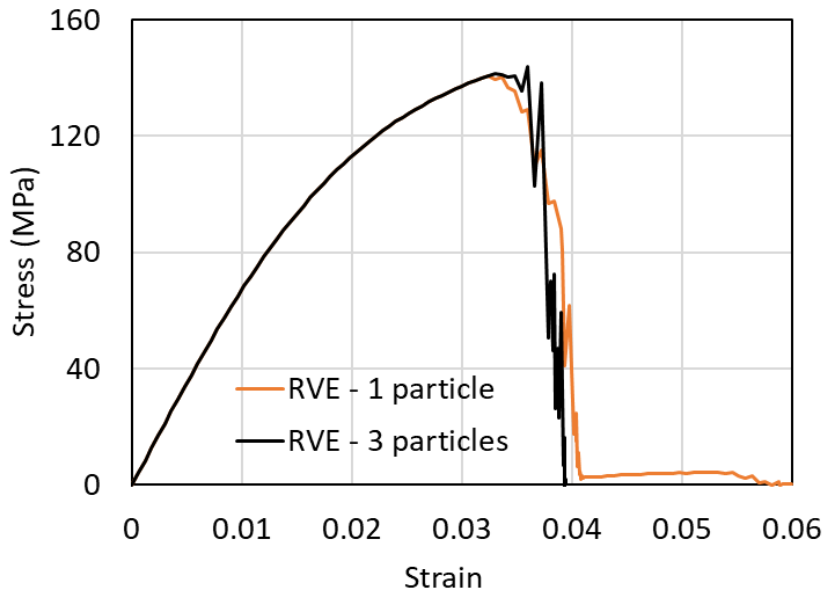
- Inputting the stress – strain curve of PI and varying strain to failure (15% to 12%)
- V_p = 26.5%
- Perfect bonding between PI and Silica interface
- With out considering thermal loading

- Damage initiation/propagation may change if we consider other damage mechanisms in the model

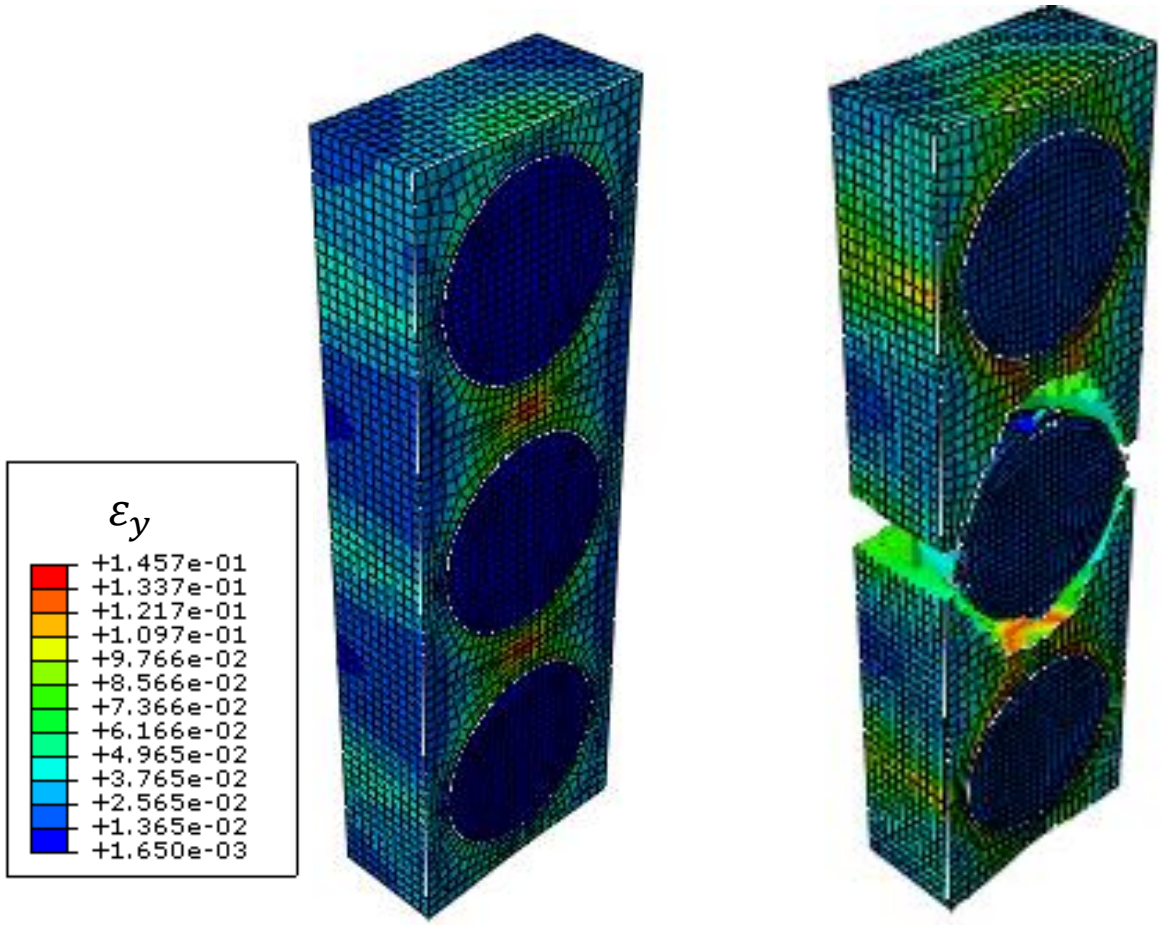


Considering Three Particles RVE (CD)

mesh size = 1 nm

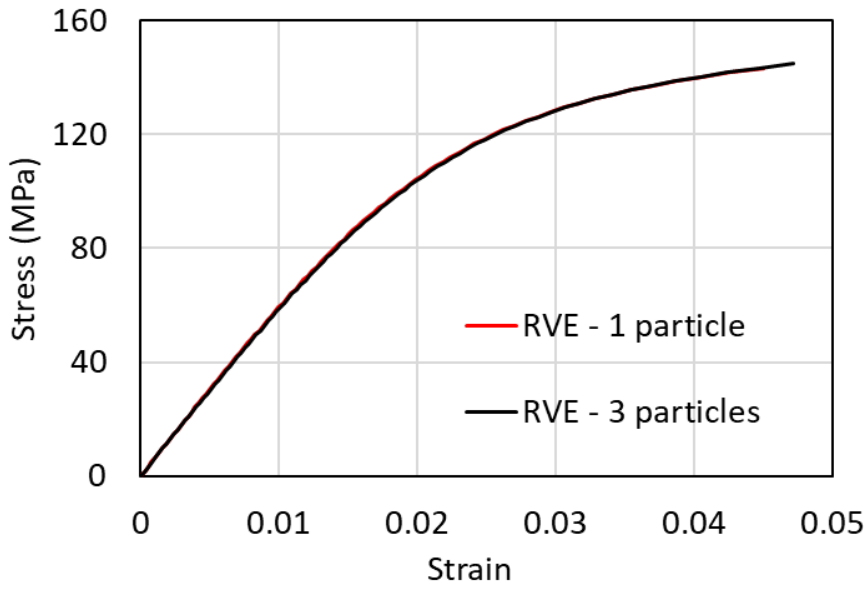


ε_y = ~0.035



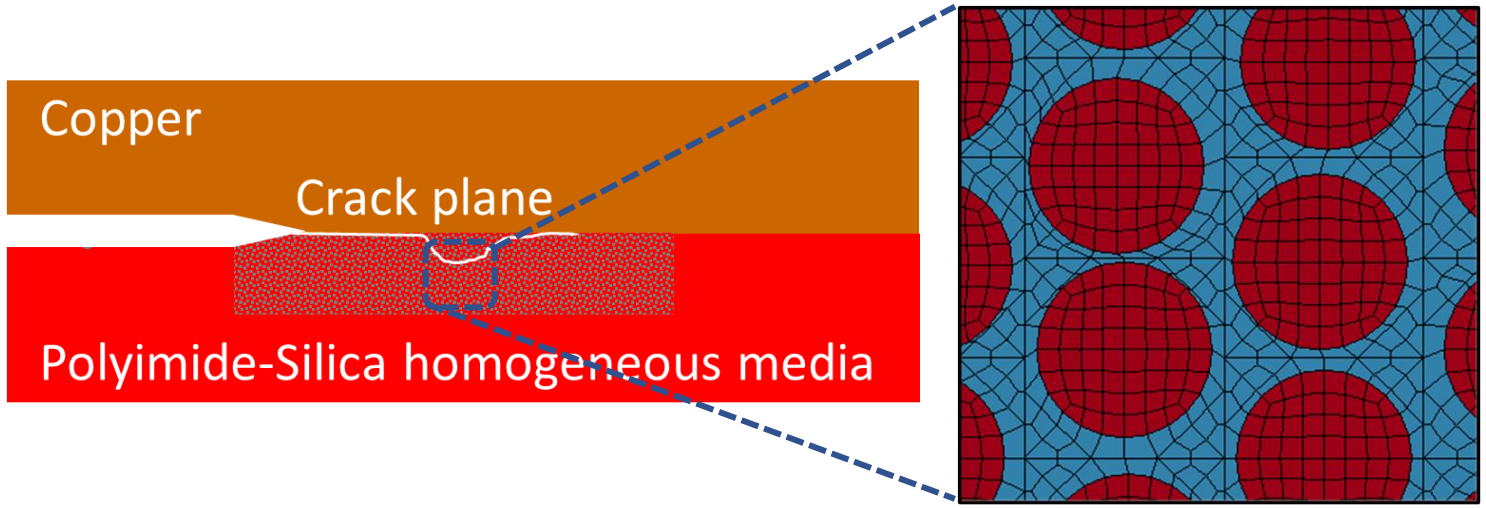
ε_y = ~0.038

- Considering three particles in the RVE as the first step of building cell model
- Inputting the stress – strain curve of PI and strain to failure from experiment (~15%)
- V_p = 26.5%
- Perfect bonding between PI and Silica interface
- With out considering thermal loading
- Only middle region has failure criteria



Considering Three Particles RVE (CP)

mesh size = 1 nm



$Applied\ pressure = \sim 135\ MPa$

$Applied\ pressure = \sim 140\ MPa$

- Considering three particles in the RVE as the first step of building cell model
- Inputting the stress – strain curve of PI and strain to failure from experiment (~15%)
- V_p = 26.5%
- Perfect bonding between PI and Silica interface
- With out considering thermal loading
- Only middle region has failure criteria

Conclusion and Discussion

- Single RVE study has completed and compared with experiment.
- Including CTE and different damage mechanisms study the RVE at different loading conditions and volume fractions.
- Develop the cell model by inputting the properties of the constituents and stacking the RVE with a random distribution.
  - Residual stress
  - Resin Plasticity
  - Frictional sliding and interface debonding
- Next, measure the peel strength of copper/polyimide laminates to understand the underlying mechanism.

Acknowledgments

- The project was funded by DuPont Specialty Materials, USA.
- Special thanks Dr. Nicholas Shevchenko for his assistance in manufacturing the 90° peel test setup and Dr. Steve Sauerbrunn for helping with thermal characterization.
- Discussions with Dr. Joseph Deitzel on SEM micrographs and thermal analysis results were valuable in understanding the key mechanisms.
- Comments and suggestions from DuPont team members during biweekly meetings are greatly appreciated.

MICRO-SCALE SIMULATION FOR NONLINEAR STRESS–STRAIN BEHAVIOR OF UNIDIRECTIONAL CARBON FIBER/ PHENYL–ETHYNYL TERMINATED POLYIMIDE TRIA-X COMPOSITES

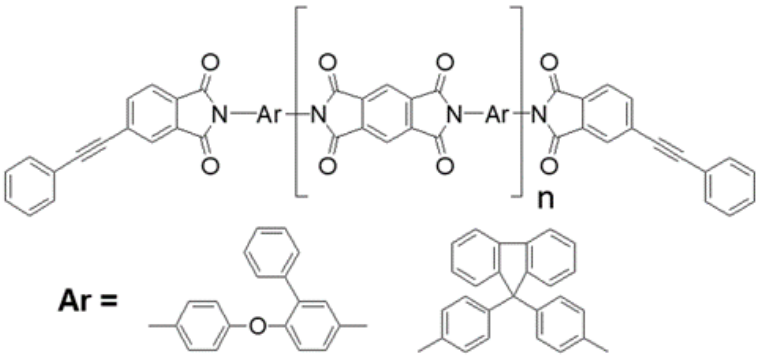
ABSTRACT



TriA-X, a phenylethynyl-terminated polyimide resin with a Kapton-type structure, has a glass transition temperature of 350°C or higher and is a promising matrix resin for heat-resistant CFRP (Carbon Fiber Reinforced Plastics). This study attempted to predict the mechanical behavior of carbon fiber/TriA-X composites (CF/TriA-X) using micro-scale analysis. Based on the experimentally obtained mechanical properties of the cured resin, the constitutive model for linear viscoelasticity and viscoplasticity were applied individually, and the time and temperature dependent mechanical behaviors were taken into consideration. The viscoelastic parameters were determined from the results of creep tests without residual strain, while the viscoplastic parameters were obtained by subtracting the viscoelastic strain from the total strain of the creep tests that produced residual strain. Using microscale models consisting of fiber and matrix, the nonlinear mechanical behavior of unidirectional CF/TriA-X (UD-CFRP) under off axis tension was calculated using finite element analysis code Digimat FE (Hexagon) considering the viscoelastic and viscoplastic behavior. As a result, the stress-strain curves of off-axis UD-CF/TriA-X composites at room temperature were good agreement with the experimental results.

1 INTRODUCTION

In recent years, carbon fiber reinforced plastic composites (CFRP), which have high specific strength and stiffness, were widely applied to airframe structures to reduce aircraft weight and maintenance costs. Most of the CFRP for aircrafts consists of an epoxy resin matrix, with operating heat resistance temperatures limited to 120°C. By contrast, CFRP consisting of heat-resistant resins such as bismaleimide and polyimide have higher operating temperature of 200 to 300°C, which is superior to that of epoxy resins. Among heat-resistant resins, polyimide resin has a high glass transition temperature (Tg), excellent mechanical properties, chemical stability, and low thermal expansion coefficient. Therefore, it is expected to be used as a matrix resin for heat-resistant CFRP to be applied to parts requiring high heat resistance, such as turbofan engine parts and the airframe of supersonic aircrafts, which have been difficult to apply with conventional epoxy-based CFRP [1-3].

Generally, addition-type (thermosetting type) polyimide resins have high heat resistance, corrosion resistance, mechanical strength, and good moldability, however, they tend to have poor toughness [4]. Furthermore, heat-resistant resins, including polyimide, are generally not easy to mold because it is difficult to obtain low viscosity enough to enable melt molding even in high-temperature environments. To solve this problem, a phenyl-ethynyl terminated addition polyimides (PETI) had been studied, mainly

by NASA. However, the glass transition temperature of typical polyimide resin PETI-5 is only 260-270°C, and it has been difficult for a long time to achieve both heat resistance and mechanical properties [5-9]. Yokota et al. successfully developed for synthesizing an addition-type polyimide (Triple A (TriA) polyimide) with both heat resistance, toughness, and moldability using an asymmetric chemical structure for the polymer main chain. Based on this concept, Miyauchi [6] et al. developed an additive polyimide TriA-X (TripleA-X), having the chemical structure shown in Scheme 1. Cured TriA-X polyimide has high heat resistance and good mechanical properties. TriA-X has higher toughness and heat resistance than conventional polyimide resins, having a softening temperature of 350-370°C and an average strain at break of about 11% for cured resin [10]. TriA-X is expected to be used as a matrix resin for heat-resistant CFRPs, however the mechanical properties of the resin or of composites have not sufficiently understood.

Scheme 1: Chemical structure of TriA-X imide oligomer [6].

Meanwhile, unidirectional CFRP (UD-CFRP) is known to exhibit nonlinear stress-strain behavior because of viscoelastic deformation of matrix resin in the off-axis tensile test. Furthermore, the nonlinear stress-strain behavior of CFRP has time- and temperature-dependence. In polyimide-based CFRP, studies have also been conducted to predict nonlinear behavior by theoretical equations based on experimental results [11]. In structural design using heat-resistant CFRPs, it is necessary to evaluate the mechanical properties at various temperatures, however obtaining material strength data by experimental methods is costly and time-consuming. For this reason, it is expected to establish a technique to predict various mechanical properties of CFRP at a wide range of temperatures based on the properties of resin obtained from experiments.

The aim of this study is to predict the mechanical behavior of UD-CFRP with thermosetting polyimide TriA-X as a matrix at elevated temperatures from the experimentally obtained material properties of matrix resin. In this paper, the mechanical properties of cured neat TriA-X resin are evaluated to model its stress-strain behavior, and the nonlinear mechanical behavior of UD-CFRP is predicted from stress analysis of a unit cell model consisting of fiber and matrix.

2 MECHANICAL PROPERTIES OF POLYIMIDE RESIN TRIA-X

2.1 Material and specimen

Cured resin plates were obtained from imide oligomer TriA-X powder (n=4). The curing temperature was 370°C. After curing, strip-shaped specimens (120 × 10 × t 2.8 [mm^3] and 140 × 10 × t 2 [mm^3]) were cut from each resin plate using a cutting machine and provided to tensile testing. The glass transition temperature of the cured resin was about 350°C, obtained from the change in storage modulus by dynamic viscoelasticity (DMA) measurement.

2.2 Experimental procedure

Tensile tests including creep/recovery tests were conducted for cured resin specimens. A servo-hydraulic testing machine (Model 8804, Instron, USA) equipped with a convection type environment chamber (oven) was used for tensile testing. A 5 kN load cell was used to measure the load.

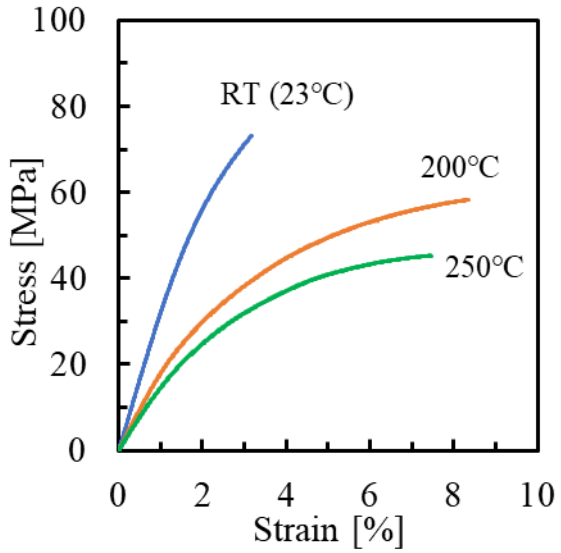
Monotonic tensile tests were conducted under a constant displacement of 1 mm/min until final failure. A contact-type extensometer (Model 633.11C-14, MTS Systems Co.) with a gauge length of 25 mm was used to measure the longitudinal strain. Test temperatures were set to be 23°C, 200°C and 250°C.

Creep/recovery tests were conducted under constant displacement and load-controlled conditions. The holding loads were 20, 30, 40, 60, and 80 MPa, and the time holding was 1 hour, followed by 3 hours of no load (0 MPa). The loading rate up to the holding load was 35 N/min.

Loading/unloading tensile tests were conducted under a constant displacement rate of 0.1 mm/min or 10 mm/min. When the crosshead displacement reached 1, 2, and 3 mm, the load was unloaded to 0 N and then reloaded, respectively. The test temperatures for the creep recovery and loading/unloading tests are 23°C and 200°C, respectively.

2.3 Experimental Result

Stress-strain curves obtained from monotonic tensile testing at 23, 200, and 250°C are shown in Fig. 1, and the initial elastic modulus of and strength at break calculated in the strain range 0.05-0.25% are summarized in Table 1. A significant decrease in stiffness with increasing temperature was observed.



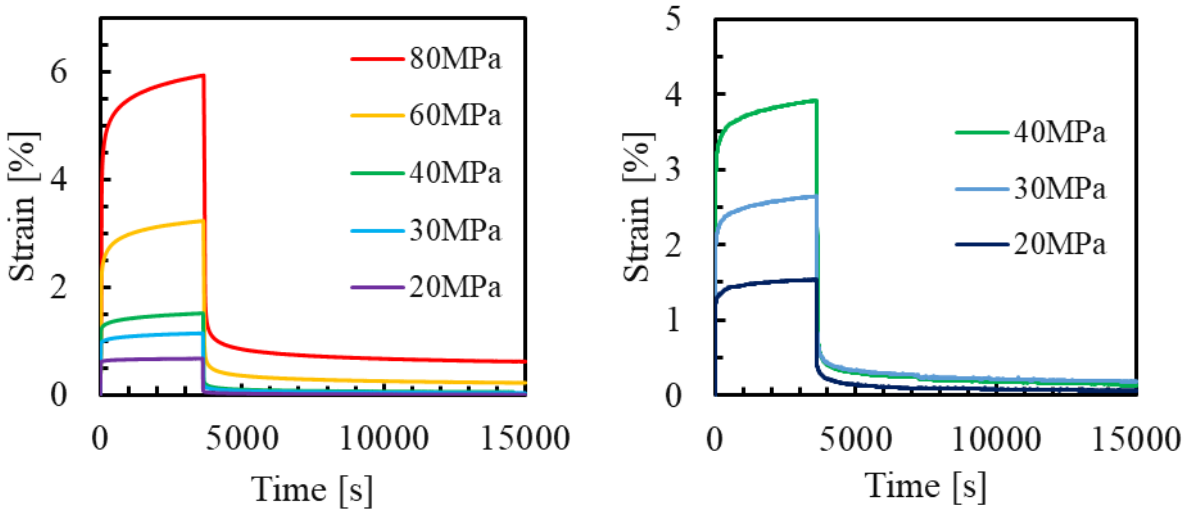


Fig. 1: Stress-strain curves of cured TriA-X polyimide specimens.

Table 1: Initial elastic modulus and rupture strength of cured TriA-X.

Temperature	Young modulus [GPa]	Rupture strength [MPa]
RT (23°C)	3.28	78.0
200°C	1.91	58.2
250°C	1.59	45.2

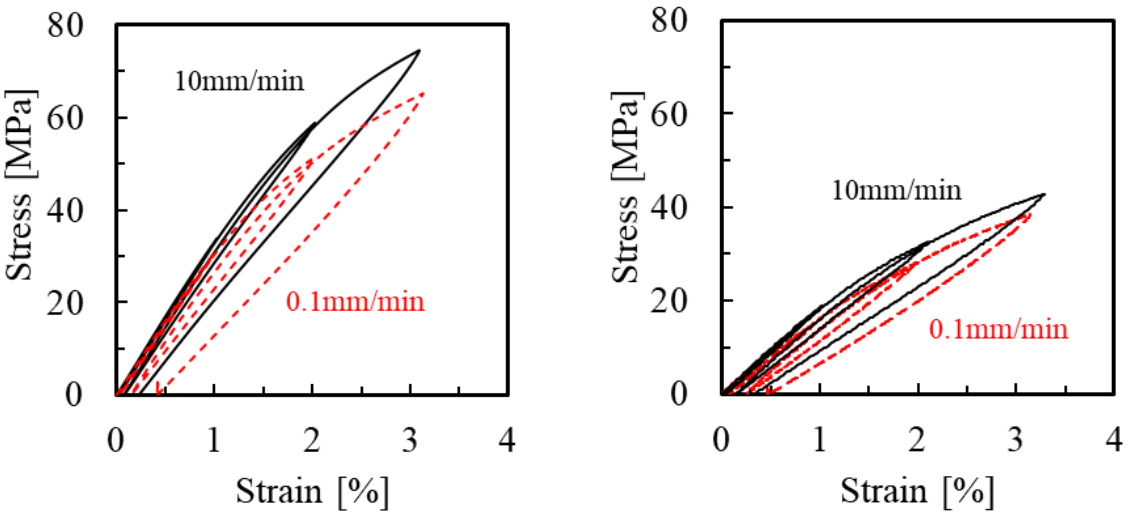

Fig. 2 (a) and (b) present the strain-time curves obtained by the creep/recovery tests. The results show viscoelastic behavior (creep and recovery behavior) at all stress levels [12]. In room temperature, residual strain was not observed at room temperature at holding stresses of 20 and 30 MPa, while residual strain due to viscoplasticity or plasticity was seen at stresses above 40 MPa. It was also confirmed that the creep strain increased with increasing temperature, even at the same holding stress.

(a) 23°C. (b) 200°C.

Fig. 2: Strain-time curves of cured TriA-X polyimide specimens at 23°C and 200°C.

Fig. 3 (a) and (b) show the stress-strain curves obtained by the loading/unloading tests. Hysteresis behavior in the nonlinear region is observed for all test conditions. Also, the relation between the residual strain after every load-unloading test cycle and the maximum stress during each cycle is depicted in Fig. 4. As shown in Fig. 4, significant residual strain is observed from the third cycle at 23°C and from the second cycle at 200°C. Additionally, residual strain increased rapidly with maximum stress, and the degree of increase was more pronounced at higher temperatures and slower loading rates. The hysteresis behavior and the decrease in stiffness with decreasing loading rate indicate that the resin exhibits remarkable viscoelastic behavior.

(a) 23°C. (b) 200°C.

Fig. 3: Stress-strain curves of cured TriA-X polyimide specimens at 23°C and 200°C under load/unload tests.

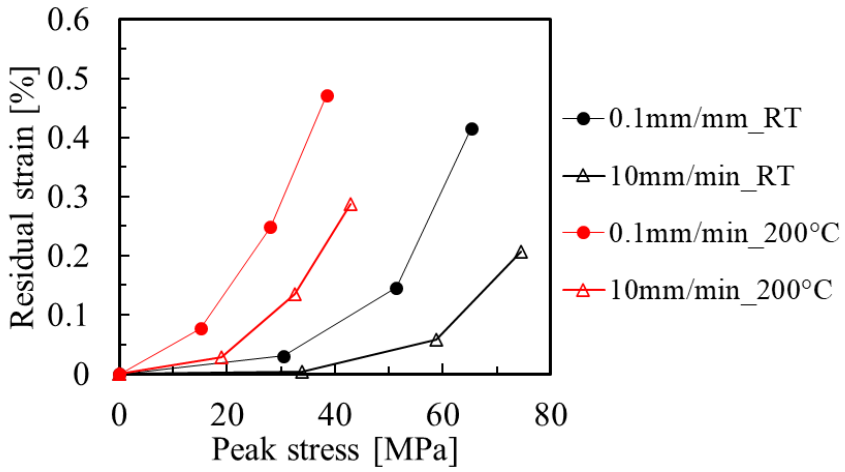

Fig. 4: Residual strain-peak stress curves of cured TriA-X polyimide specimens at RT (23°C) and 200°C under loading/unloading testing.

3 MECHANICAL MODELING OF CURED TRIA-X POLYIMIDE RESIN

3.1 Viscoelastic model

The experimental results of cured TriA-X resin suggest that the nonlinear behavior at room and elevated temperatures cannot be expressed using a simple viscoelastic model. Therefore, strictly speaking, it is considered appropriate to use nonlinear viscoelastic and plastic (or viscoplastic) modeling. In this study, we focus only on the time dependence of monotonic loading, and attempt to model the nonlinear stress-strain behavior in the loading using linear viscoelastic and viscoplastic models approximately.

In the viscoelastic-viscoplastic model, the total strain ε is expressed as the sum of the viscoelastic strain ε^{VE} and the viscoplastic strain ε^{VP}.

$$\begin{aligned} \varepsilon &= \varepsilon^{VE} && (\sigma_{eq} < \sigma_Y) \\ \varepsilon &= \varepsilon^{VE} + \varepsilon^{VP} && (\sigma_{eq} > \sigma_Y) \end{aligned} \tag{1}$$

The viscoelastic strain ε^{VE} is 0 when the Mises equivalent stress σ_{eq} is lower than the yield stress σ_Y, which means only viscoelastic deformation. The viscoelastic constitutive model is defined as follows.

$$\sigma(t) = G(t):\varepsilon(0) + \int G(t-\tau):\dot{\epsilon^{ve}}(\tau)d\tau \tag{2}$$

$$\text{with } \varepsilon(0) = \lim_{\substack{t\to 0 \\ t>0}} \varepsilon(t) \text{ and } G(t) = 2G_R(t)I^{dev} + K_R(t)1 \otimes 1 \tag{3}$$

The shear modulus $G_R(t)$ and bulk modulus $K_R(t)$ are described using the generalized Maxwell model.

$$G_R(t) = G_0\left[1 - \sum_{i=1}^{n} e_i\left(1 - e^{-\frac{t}{\Lambda_k}}\right)\right] \tag{4}$$

$$K_R(t) = K_0\left[1 - \sum_{i=1}^{n} e_i\left(1 - e^{-\frac{t}{\Lambda_k}}\right)\right] \tag{5}$$

where G_0 is the initial shear modulus, and K_0 is the initial bulk modulus. To conduct a finite element analysis, the relaxation modulus (Prony series e_k, Λ_k) in equations (4) and (5) must be obtained from the results of creep tests for the cured TriA-X resin. In this research, the relaxation modulus was determined as follows. First, the creep test results at 20 MPa, where almost no residual strain occurs

after unloading, were fitted with a generalized Voigt model (n=3) as shown in Fig. 5. Next, the Prony series (n=3) was obtained by the Laplace transform for the Voigt model [13]. The determined Prony series are shown in Table 2.

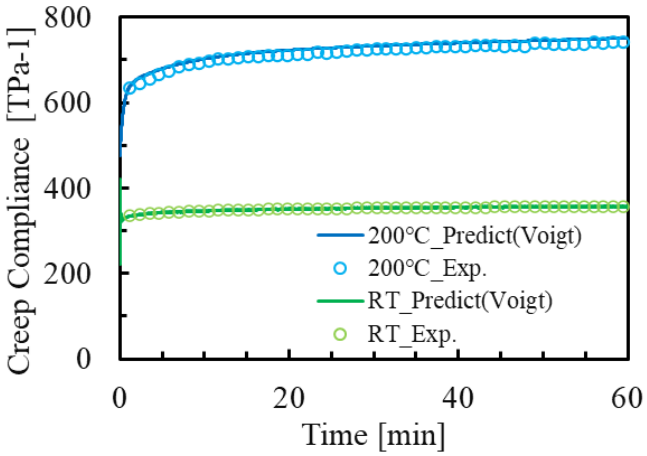

Fig. 5: Relationship between creep compliance and time of TriA-X polyimide specimens at 23°C and 200°C.

Table 2: Prony series.

		23°C	200°C
Λ_1	[min]	1.91×10^{-1}	4.02×10^{-1}
Λ_2	[min]	6.07	5.44
Λ_3	[min]	1.14×10^{2}	1.08×10^{2}
e_1	[-]	8.30×10^{-2}	1.76×10^{-1}
e_2	[-]	4.10×10^{-2}	9.02×10^{-2}
e_3	[-]	5.66×10^{-2}	9.20×10^{-2}

The initial shear modulus G_0 and initial bulk modulus K_0 were calculated from Young's modulus E obtained in the monotonic tensile test using the following relationships.

$$K = \frac{E}{3(1-2\nu)} \tag{6}$$

$$G = \frac{E}{2(1+\nu)} \tag{7}$$

where ν is Poisson's ratio, which is 0.37. The initial shear modulus and initial bulk modulus at each temperature are shown in Table 3.

Table 3: Initial shear modulus, G_0 and initial bulk modulus, K_0.

	23°C	200°C
G_0 [MPa]	1.20×10^{3}	6.98×10^{2}
K_0 [MPa]	4.20×10^{3}	2.45×10^{3}

3.2 Viscoplastic model

When the Mises stress σ_{eq} exceeds the yield stress σ_Y, plastic deformation occurs. The viscoplastic strain ε^{VP} was represented using the J_2 plasticity model as a time-dependent viscoplastic constitutive equation as follows;

$$\sigma_{eq} = \sigma_Y + R(p) \tag{8}$$

where $R(p)$ and p are hardening stress, and accumulated plastic strain, respectively. In this study, uniaxial tensile analysis is treated, therefore the Mises stress, σ_{eq} is equal to the axial stress, σ_{11} . $R(p)$ is approximated by the following power law.

$$R(p) = kp^{m_1} \tag{9}$$

where k is the hardening modulus and m_1 is the hardening exponent. The viscoplastic stress f is defined as follows.

$$f = \sigma_{eq} - \sigma_Y - R(p) \tag{10}$$

The accumulated plastic strain rate $\dot{p}$ is expressed by the equation (11).

$$\dot{p} = \frac{\sigma_Y}{\eta}\left(\frac{f}{\sigma_Y}\right)^{m_2} \tag{11}$$

where η is the viscoplasticity coefficient, m_2 is the viscoplasticity index, σ_{eq} is the equivalent stress, and σ_Y is the yield stress. Substituting equations (9) and (10) into equation (11) and arranging,

$$\dot{p} = \frac{\sigma_Y}{\eta}\left(\frac{\sigma_{eq} - \sigma_Y - kp^{m_1}}{\sigma_Y}\right)^{m_2} \tag{12}$$

The constants k, m_1, η and m_2 in Eq. (12) were determined by simultaneously fitting the experimental results of monotonic tensile tests, loading/unloading tests, and creep tests for cured TriA-X resins. As described in Chapter 2, TriA-X resin exhibits nonlinear viscoelastic behavior over a certain stress level, however, since only the monotonic loading is considered in this paper, linear viscoelasticity and viscoplasticity are applied in the model. Viscoplastic strain was calculated by subtracting the viscoelastic strain obtained from the 20 MPa test results from the creep strain measured at 60 MPa and 40 MPa at 23°C (RT) and 200°C, respectively. Table 4 shows the constants k, m_1, η, m_2 and yield stress σ_Y obtained at room temperature and 200°C.

Table 4: Viscoplastic parameter.

	23°C	200°C
Hardening modulus, k [MPa]	211	230

4 NUMERICAL SIMULATIONS FOR NONLINEAR STRESS–STRAIN BEHAVIOR OF UNIDIRECTIONAL CFRP LAMINATES

4.1 Numerical Analysis Method

Tensile analysis of unidirectional reinforced CFRP in off-axis direction is conducted at 23°C and 200°C using a microscale representative volume element (RVE) model composed of matrix resin and fibers to predict the nonlinear stress-strain behavior of UD-CF/TriA-X. Digimat-FE (MSC Software, Hexagon) was used to make finite element model and set boundary conditions. Also, MS/Marc (MSC Software, Hexagon), standard solver of Digimat, was used for the finite element analysis (FEA). In order to simulate the tensile strength of unidirectional CFRP in the 30°, 45° and 90° directions, the REV models shown in Fig. 8 were made. The sizes of each model are presented in Table 5. All models are voxel meshes with hexahedral brick elements applied.

Table 5: RVE size and number of elements/nodes.

	30°	45°	90°
X (mm)	0.0154	0.0108	0.0764
Y (mm)	0.00889	0.0108	0.0764
Z (mm)	0.0133	0.0132	0.0132

Number of nodes	132651	132651	132651

(a) Fiber angle 30°. (b) Fiber angle 45°. (c) Fiber angle 90°.

Fig. 8: Unit cell (RVE) model for microscale analysis.

Table 6: Material properties of carbon fiber, MR50 (Mitsubishi Chemical).

		Value
Fiber diameter	[mm]	0.006
Axial young's modulus E_{11}	[GPa]	2.95×10^2
In-plane young's modulus E_{22}	[GPa]	14
In-plane Poisson's ratio ν_{12}	[-]	0.2
Transverse Poisson's ratio ν_{23}	[-]	0.25
Transverse shear modulus G_{12}	[GPa]	27.6
Thermal expansion coefficient α_{carbon}	[K^{-1}]	-4×10^{-7}

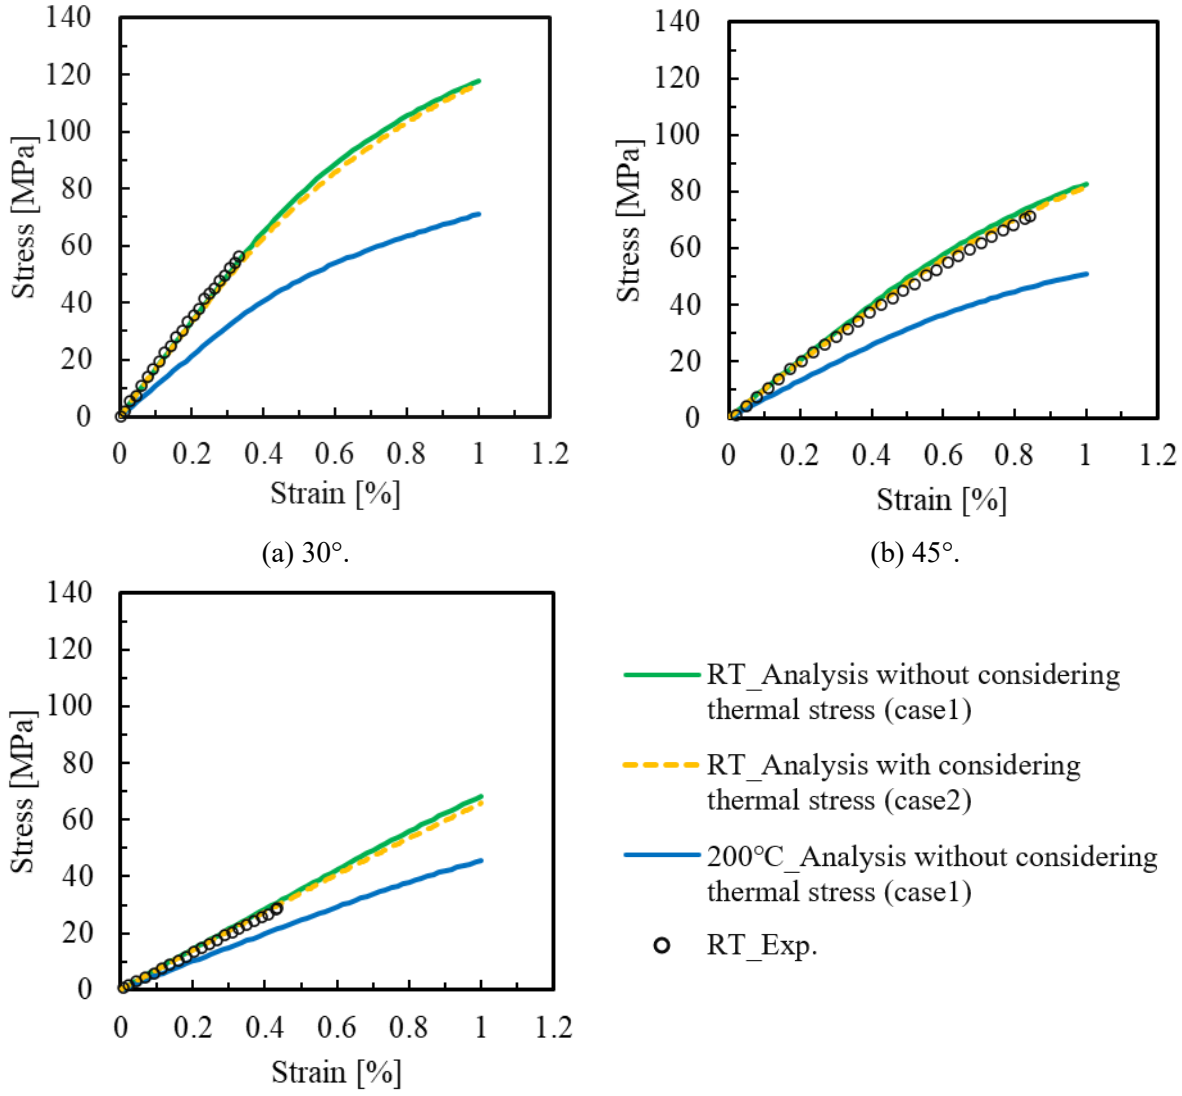
Table 6 shows the mechanical properties of the PAN-based carbon fiber (MR50, Mitsubishi Chemical Corporation) used in the calculations. The fibers were treated as isotopic elastic material. The fiber volume fraction is 0.56, in agreement with the experimental results. For the matrix resin, the viscoelastic/viscoplastic model defined in the previous section is applied, and it is assumed to be an isotropic material. The periodic boundary conditions are applied to each surface. The test condition in the analysis was strain control. To have the same strain rate as the experimental data, the loading rate was set to 0.0002083 [1/s]. Calculations were performed under the following two conditions (Case 1 and Case 2) for load and temperature to investigate the effect of thermal residual stress.

1. Mechanical load (Enforced displacement (strain) 1%) is applied at constant temperature (23℃, 200℃).
2. After giving the same temperature change of 370°C to 23°C as during processing, the temperature is maintained at the test temperature (23°C) and mechanical load (Enforced displacement (strain) 1%) is applied.

For the analysis of Case 2, the time-temperature superposition principle (TTSP) was applied to the viscoelastic model as follows;

$$\sigma(t) = \int_{-\infty}^{t} E(\tau - \acute{t}, T) : \frac{\partial \varepsilon^{ve}}{\partial \acute{t}} d\acute{t} \tag{13}$$

$$\text{With } E(t,T) = 3K_R(t,T)J + 2G_R(t,T)K \tag{14}$$

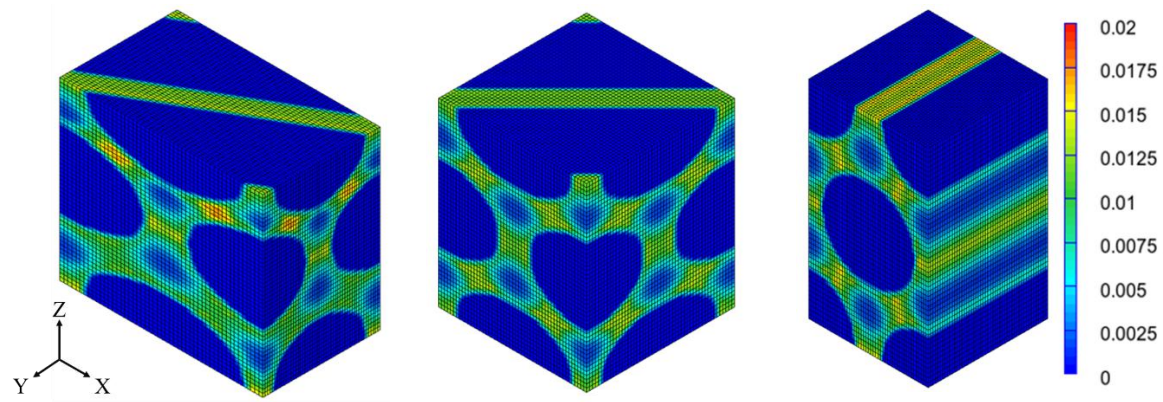


$$\Delta(t) = \int_0^t \frac{d\acute{t}}{A_T\big(T(\acute{t})\big)} \Rightarrow \frac{d\Delta}{dt} = \frac{1}{A_T\big(T(t)\big)} \tag{15}$$

where A_T is the shift function in the time-temperature conversion law, using the Arrhenius law. Applying Eq. (15) to Δ_k in Eqs. (4) and (5), the temperature dependence of the relaxation modulus can be taken into account. The activation energy used in the Arrhenius equation was estimated from the master curve of the storage modulus at 30°C using the results of dynamic viscoelasticity (DMA) tests of resins from 30°C to 390°C. The estimated activation energy was 160 kJ/mol. In addition, the coefficient of thermal expansion (CTE) of the cured TriA-X is 6×10^{-5} K^{-1}[14].

4.1 Numerical Analysis Result

Stress-strain curves obtained from stress analysis for the 30°, 45°, and 90° directions and experimental results at room temperature obtained in the previous study are depicted in Fig. 9 (a), (b) and (c). The analytical results at room temperature were generally in good agreement with the experimental results, confirming that the analytical model was approximately valid.



A contour plot of plastic strain is presented in Fig. 10, immediately after cooling in Case 2. For all fiber orientation angles analyzed in this study, plastic strain was observed in the resin at close fiber spacing. In Fig. 9, when comparing the stress-strain curves at 23°C without (Case 1) and with (Case 2) thermal residual stress, significant differences were not observed. The possible reason for this is that in the model considering the thermal residual stress, although plastic deformation occurs once in the resin due to the difference in thermal shrinkage between the resin and the fiber, the time of increase in plastic strain is the same as in the model not considering the thermal residual stress. From these results, it is expected that there is little need to consider thermal residual stress at room temperature as well as 200°C, which is closer to the process temperature than room temperature.

5 CONCLUSIONS

The mechanical properties of cured neat TriA-X resin are evaluated to model its stress-strain behavior, and the nonlinear mechanical behavior of UD- CF/TriA-X is predicted from stress analysis of a unit cell model consisting of fiber and matrix. The results obtained are as follows.

(1) The viscoelastic-viscoplastic constitutive equation was applied to the cured TriA-X resin, and the necessary material parameters were determined from the tensile test results. The resin model created accurately reproduced the experimental results at both 23°C and 200°C.

(2) The micro-scale analysis was conducted for the representative volume element model consisting of fiber and TriA-X matrix with applying the viscoelastic-viscoplastic model. The numerical results showed good agreement with the experimental results at room temperature. It was also confirmed that the effect of thermal residual stress during processing was relatively small for the tensile test results.

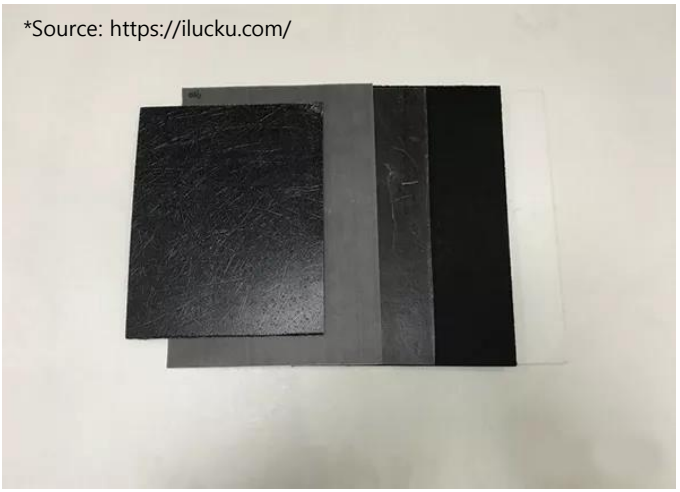
Motivation & Background

☑ What is GMT (Glass Mat Thermoplastics)?



- lightweight composite material that uses thermoplastic resin as a matrix and glass fiber mat as a reinforced skeleton

☑ Key Advantages

- High specific strength, Excellent impact resistance
- Good formability for complex shapes
- Recyclability suitable for sustainable applications.

Glass Mat Thermoplastic(GMT) Composites for Automotive Applications

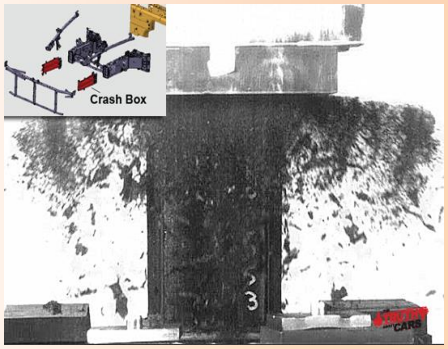
*Source: https://www.fiberglassfiber.com/

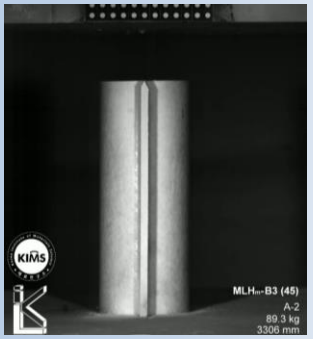
❑ Application to automotive parts

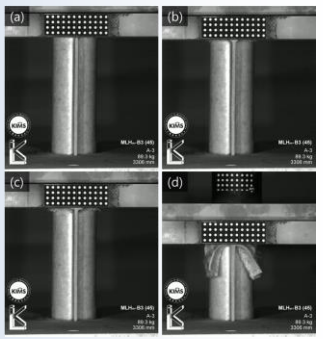
- Bumper System
- Battery enclosures
- Under body
- Crash boxes
- Seat frames
- Dashboard
- Others

Motivation & Background

☑ **Failure mode & Crashworthiness of GMT tubes**







- **Stable progressive splaying failure mode** enabled by high toughness of thermoplastic matrix.
- Enhanced **crash energy absorption** significantly

☑ **Modeling & Simulation Requirements**

- **Material modeling** for progressive failure in GMT tube with random fiber orientation
- **Efficient FE modeling** to replicate **both the splaying failure** and **energy absorption response**

☑ **Aim of this study**

- **Analysis of failure and energy absorption behavior** of Advanced GMT Tubes
- **Proposal** of **a practical crash simulation framework** for GMT tubes

	Thermoset composites tube	Thermoplastic composites tube(GMT)
Comparison of Failure modes	 	 
	• Transverse shearing & Fragmentation Mode	• Lamina bending & Splaying Failure Mode

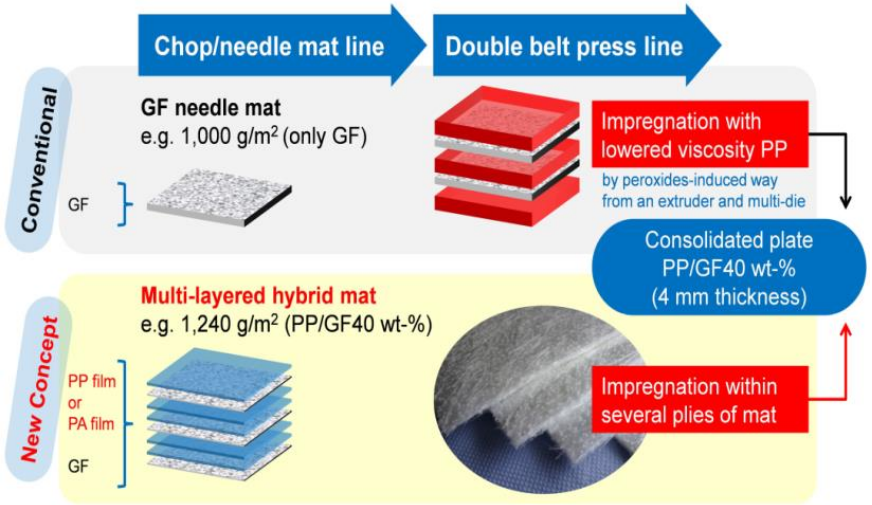
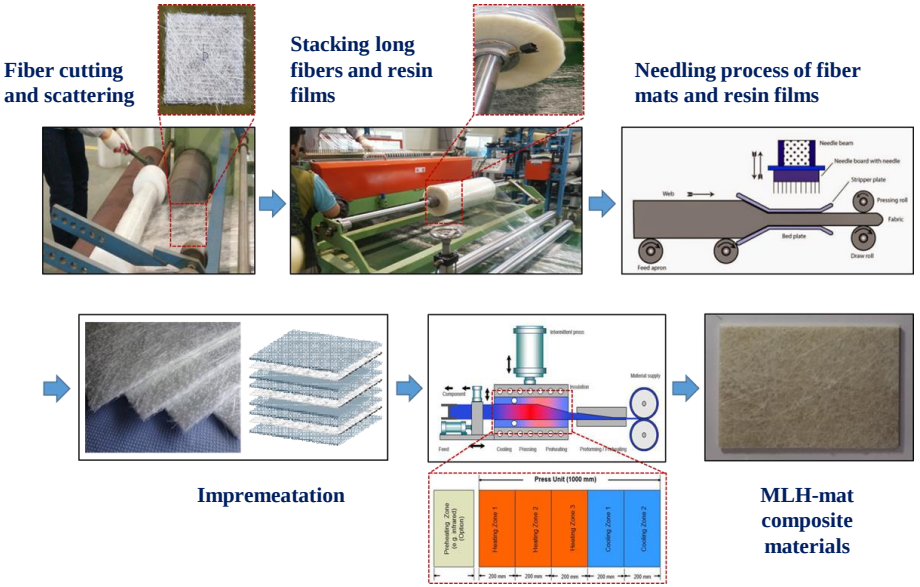
chapter 02

Material Characterization

Advanced Glass Mat Thermoplastic



☑ Multi-layered Hybrid(MLH) Mat



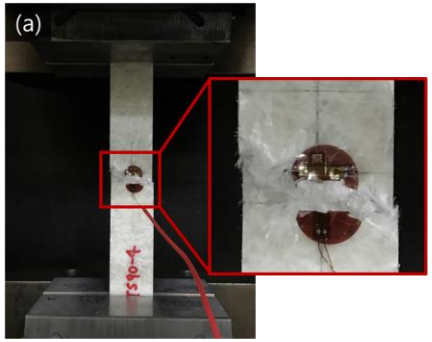
- Fabricated by **alternately stacking resin films and chopped long glass fibers**
- **Minimized the resin flow path** improving **the impregnation quality** of high-viscosity **thermoplastic resin**

☑ Fabrication of MLH-mat composites

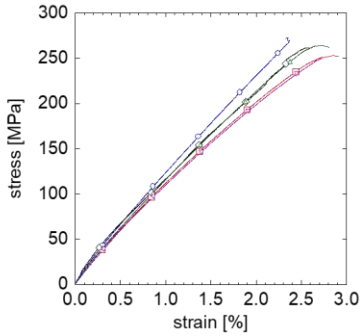
- GF/PA6 MLH-mat ▶ **Glass fiber mat – 125 g/m², PA6 resin films – 33 g/m²**
- 26 plies stacked to form MLH-mat composite plates ▶ **Total thickness : 2.4 mm , Fiber volume : 40 % vol.**

Multi-layered Hybrid(MLH) mat – Advanced Glass Mat Thermoplastic

❑ Comparison of conventional GMT and MLH-mat

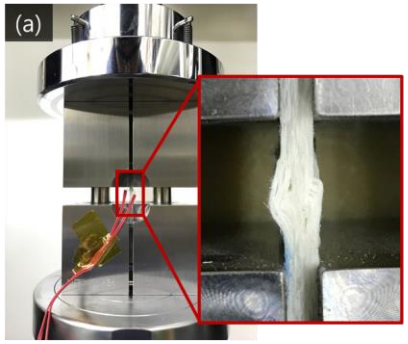


Mechanical properties and Fracture toughness evaluation

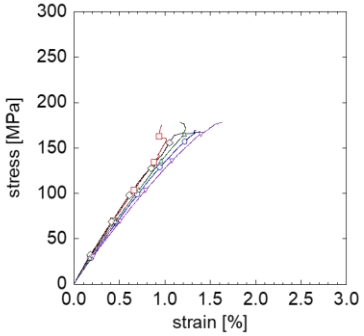


☑ Static mechanical properties

- Tensile, Compressive and In-plane shear Tests results



Static mechanical properties

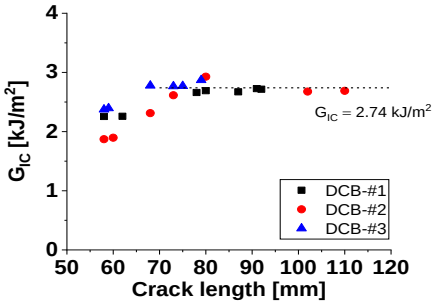


Tension – ASTM D3039

Compression – ASTM D3410

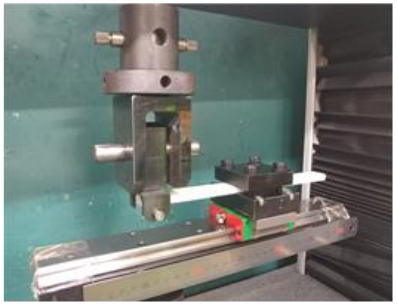
Property	Strength [MPa]	Modulus [GPa]	Poisson's Ratio
Tension in longitudinal dir.	250	13.1	0.32
Tension in transverse dir.	260	12.5	0.32
Compression in longitudinal dir.	174	15.1	-
Compression in transverse dir.	162	14.9	-
In-plane shear	132	5.0	-

Material Characterization

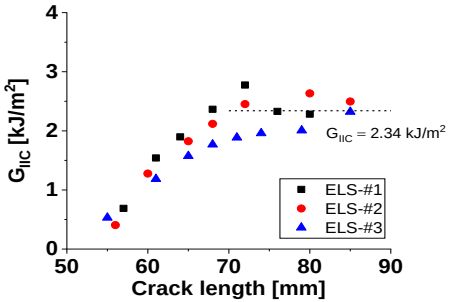


Mechanical properties and Fracture toughness evaluation

☑ Fracture toughness evaluation

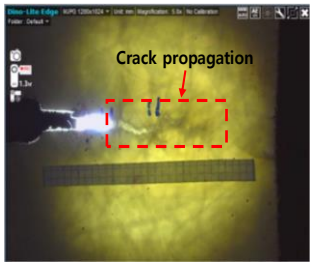


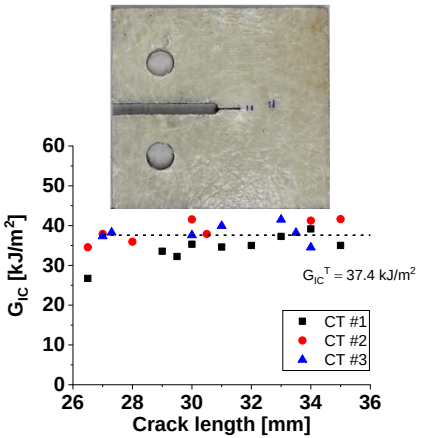
- **Inter**-laminar fracture toughness : ❶ Mode I (DCB tests) = 2.74 kJ/m^2 | ❷ Mode II (ELS tests) = 2.34 kJ/m^2
- **Intra**-laminar fracture toughness : ❶ Compact Tension = 37.4 kJ/m^2 | ❷ Compact Compression = 40.2 kJ/m^2



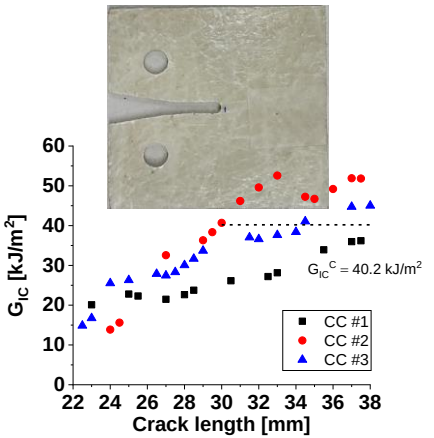
Inter-laminar fracture toughness tests

❑ Mode I(Double Cantilever Beam) tests results

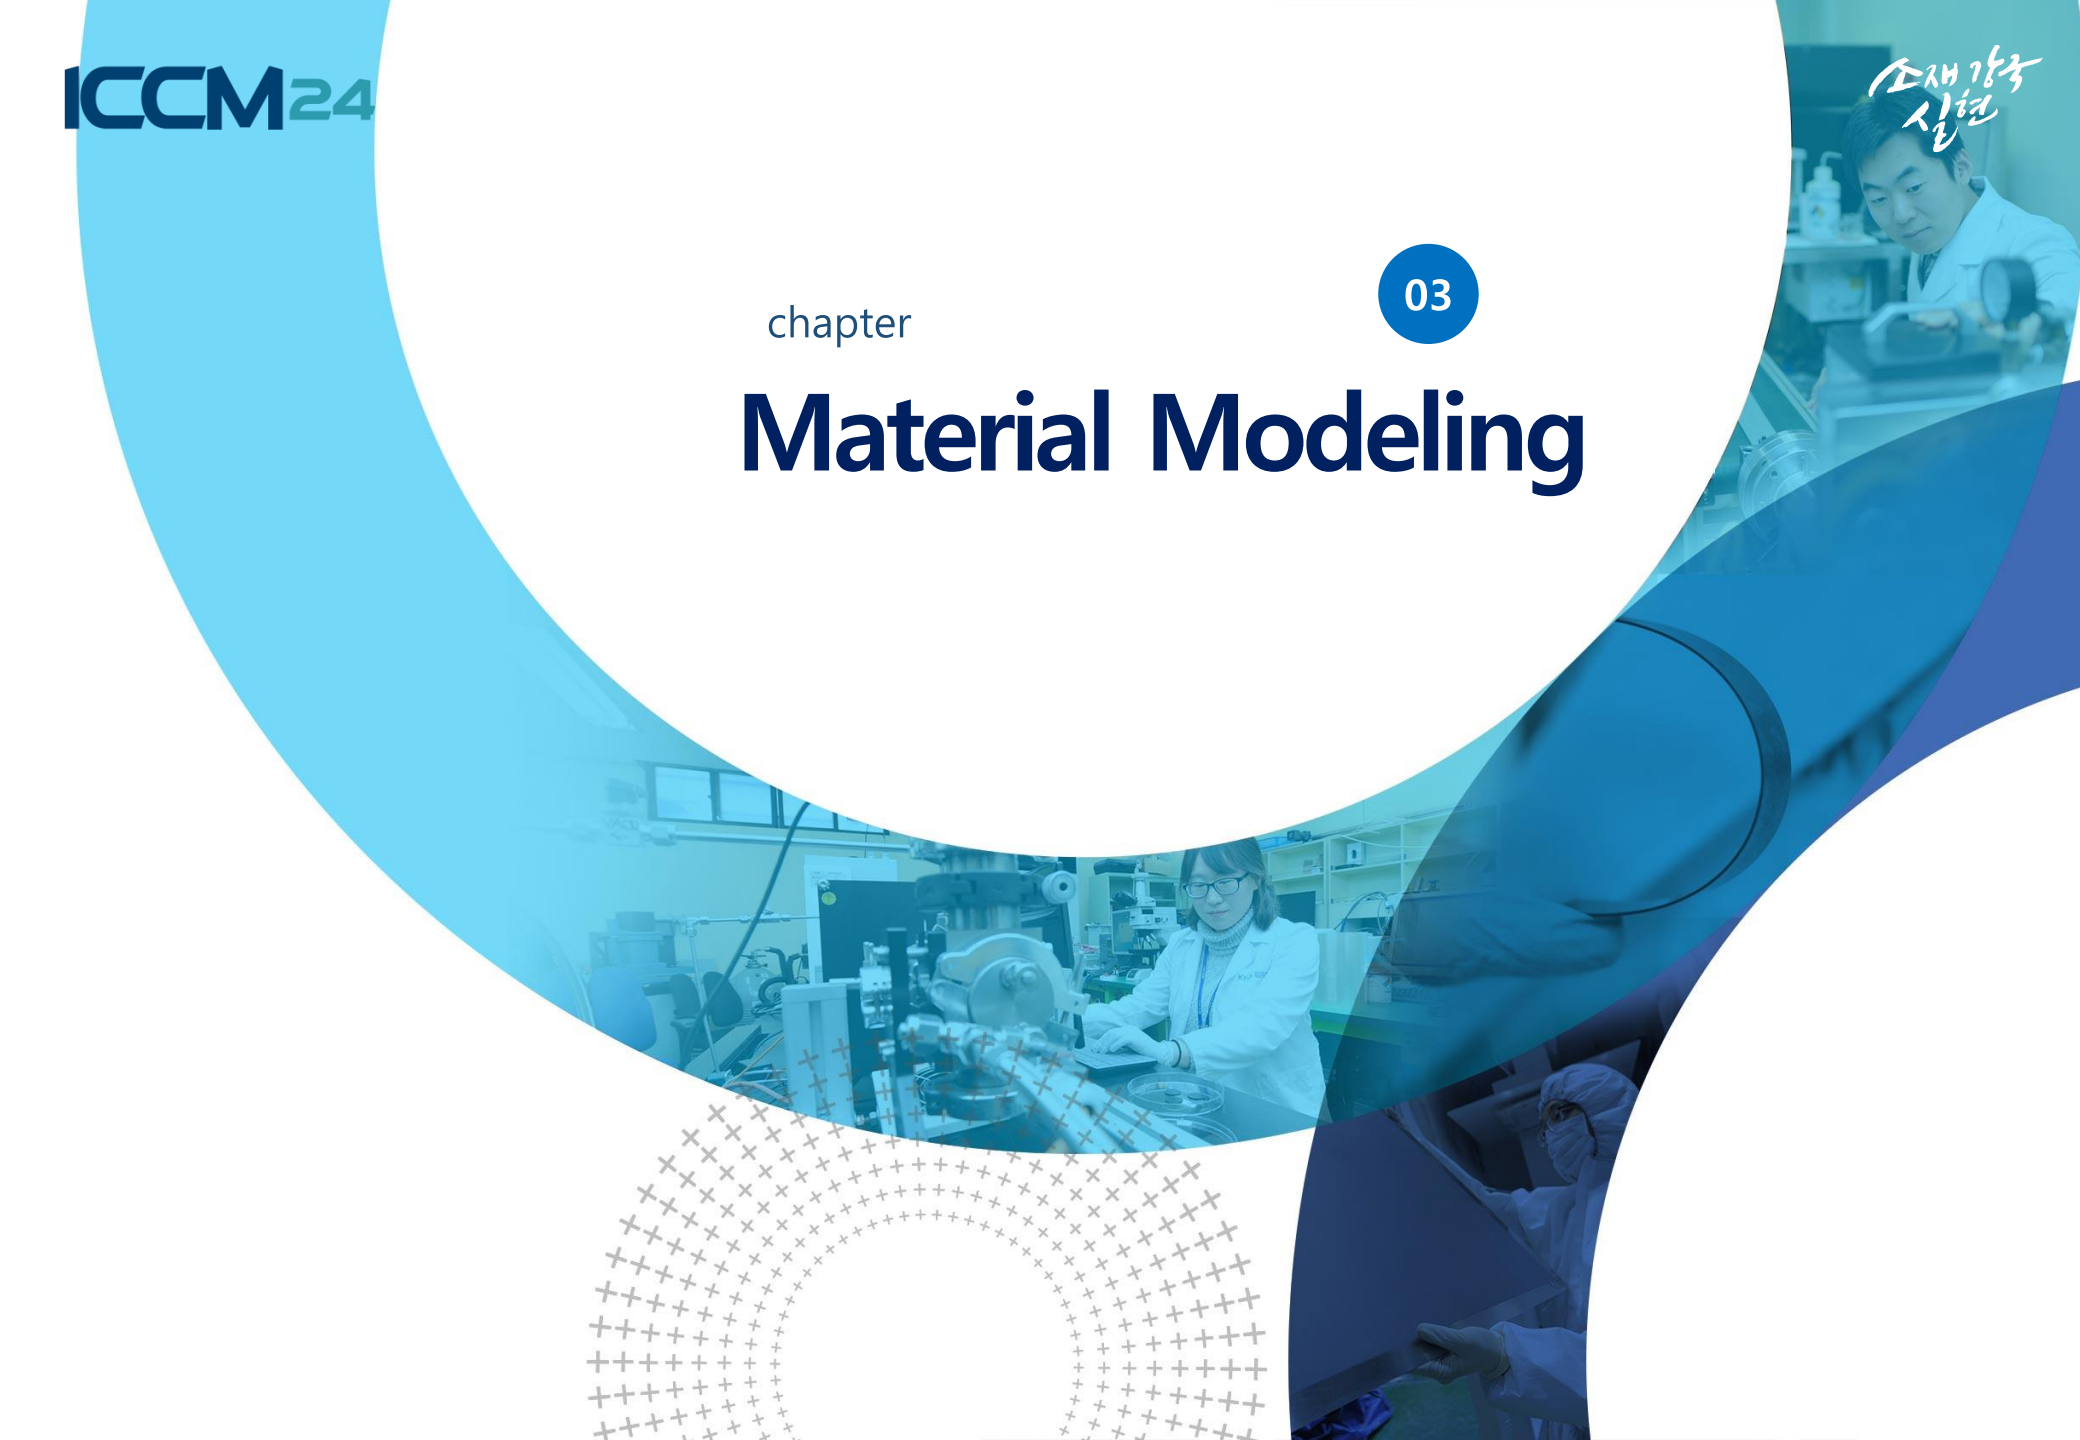




❑ Mode II(End-Loaded Split) tests results



Intra-laminar fracture toughness tests



❑ Compact tension

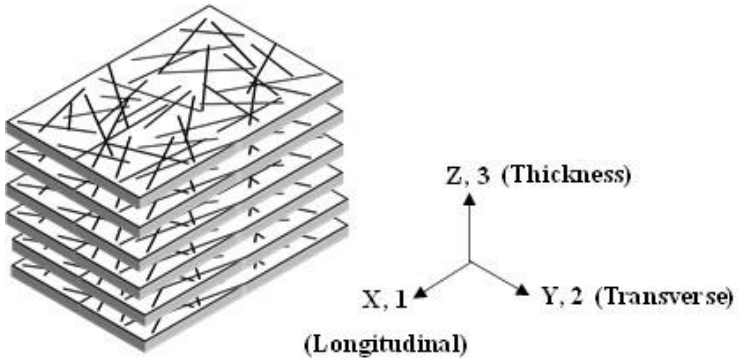
❑ Compact compression

ICCM24

chapter 03

Material Modeling

3D Progressive damage model for MLH-mat composites



☑ Motivation for material modeling of MLH-mat composites

- Requirement for a material model **suitable for randomly oriented fiber-reinforced composites**
- Need for a damage mechanics-based model incorporating experimentally measured fracture toughness

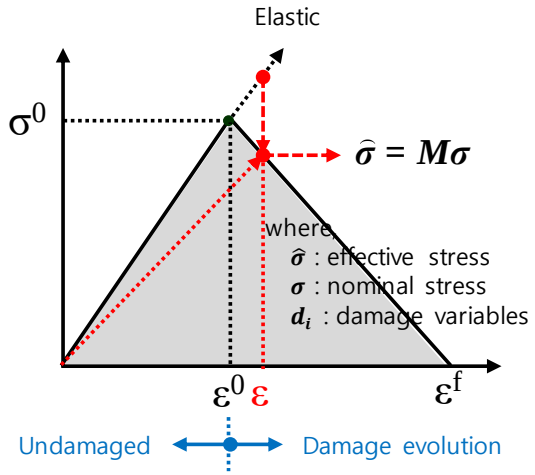
☑ Modeling Strategy – Damage initiation

- Modification of **the 3D Hashin-type failure criterion** for randomly oriented fiber-reinforced composites
- Inclusion of shear stress effects in all directions to reflect matrix-dominated failure

Material modeling for MLH-mat composites

❑ **Schematic diagram of randomly oriented fiber composites**

Failure mode	Damage initiation criteria
$\sigma_{11} \geq 0$	$f_{1T} = \left(\frac{\sigma_{11}}{X_{1T}}\right)^2 + \left(\frac{\sigma_{12}}{S_{12}}\right)^2 + \left(\frac{\sigma_{13}}{S_{13}}\right)^2$
$\sigma_{11} < 0$	$f_{1C} = \left(\frac{\sigma_{11}}{X_{1C}}\right)^2 + \left(\frac{\sigma_{12}}{S_{12}}\right)^2 + \left(\frac{\sigma_{13}}{S_{13}}\right)^2$
$\sigma_{22} \geq 0$	$f_{2T} = \left(\frac{\sigma_{11}}{X_{2T}}\right)^2 + \left(\frac{\sigma_{12}}{S_{12}}\right)^2 + \left(\frac{\sigma_{13}}{S_{13}}\right)^2$
$\sigma_{22} < 0$	$f_{2C} = \left(\frac{\sigma_{11}}{X_{2C}}\right)^2 + \left(\frac{\sigma_{12}}{S_{12}}\right)^2 + \left(\frac{\sigma_{13}}{S_{13}}\right)^2$
$\sigma_{33} \geq 0$	$f_{3T} = \left(\frac{\sigma_{11}}{X_{3T}}\right)^2 + \left(\frac{\sigma_{12}}{S_{12}}\right)^2 + \left(\frac{\sigma_{13}}{S_{13}}\right)^2$
$\sigma_{33} < 0$	$f_{3C} = \left(\frac{\sigma_{11}}{X_{3C}}\right)^2 + \left(\frac{\sigma_{12}}{S_{12}}\right)^2 + \left(\frac{\sigma_{13}}{S_{13}}\right)^2$
Shear failure in 1-2 plane	$f_{12} = \left(\frac{\sigma_{12}}{S_{12}}\right)^2$
Shear failure in 2-3 plane	$f_{23} = \left(\frac{\sigma_{23}}{S_{23}}\right)^2$
Shear failure in 1-3 plane	$f_{13} = \left(\frac{\sigma_{13}}{S_{13}}\right)^2$



❑ **Modification of the 3D Hashin-type damage initiation criterion**

3D Progressive damage model for MLH-mat composites

☑ Modeling Strategy – Damage evolution

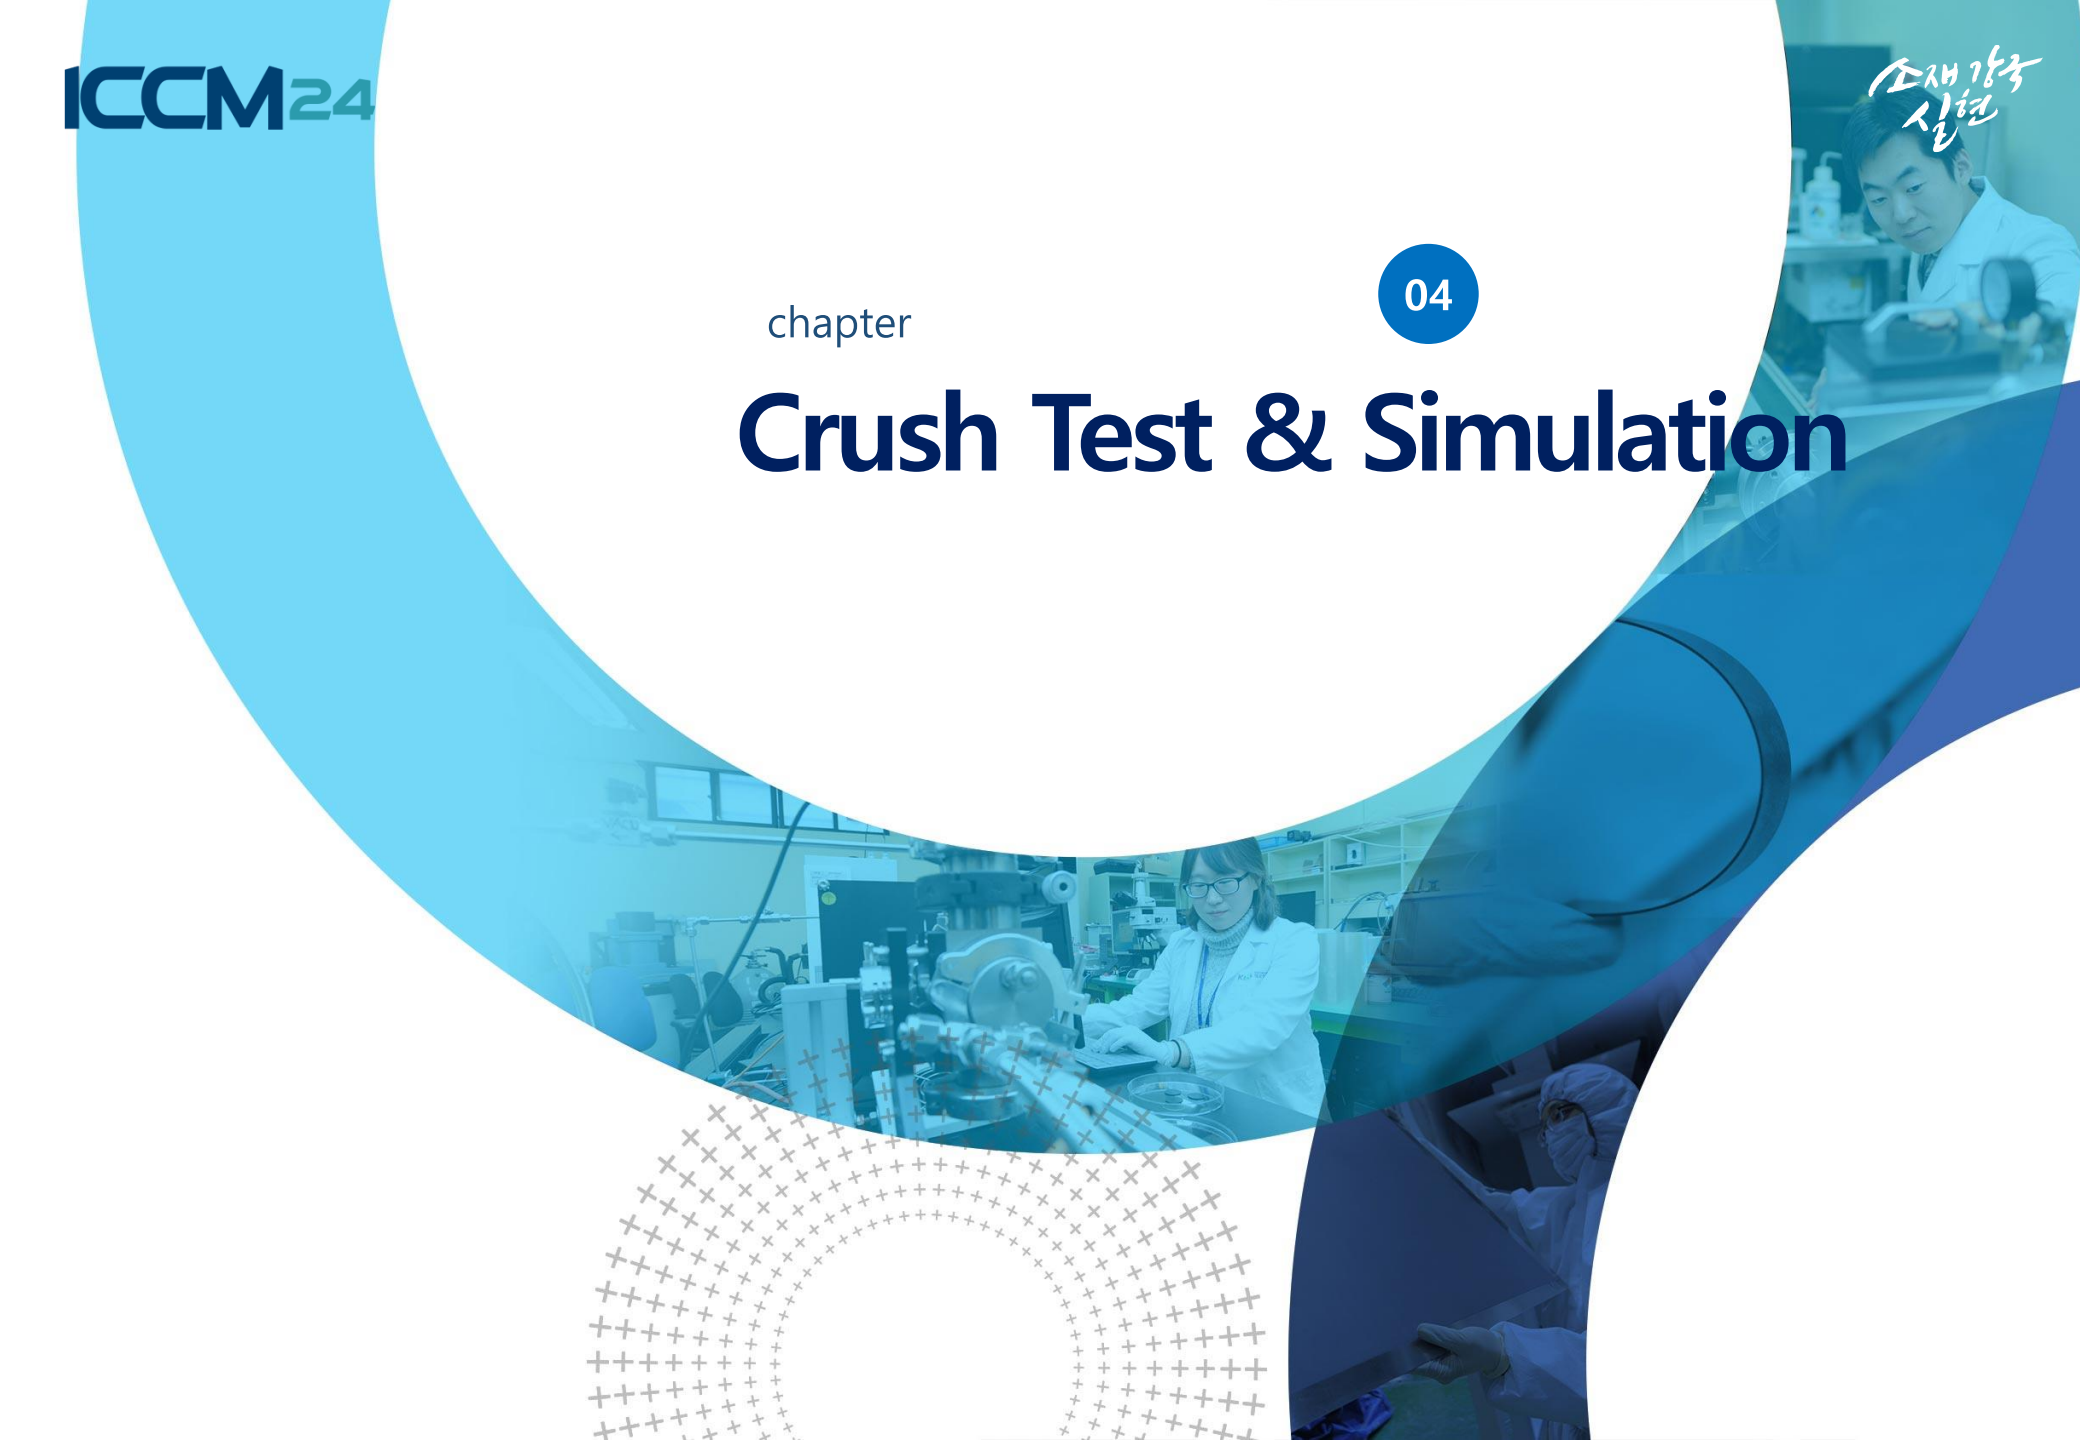
- Adoption of **a constitutive model** based on the **Continuum Damage Mechanics(CDM)**
- Simulation of **gradual stiffness degradation** during progressive damage evolution
- Incorporation of **intra-laminar fracture toughness** for realistic simulation of **complex damage mechanisms** in composite structures
- Implementation of the 3D progressive damage model into **LS-DYNA solver** using **UMAT subroutine**

Material modeling for MLH-mat composites

$$\varepsilon = S : \hat{\sigma} = S : M : \sigma = H\sigma \;\Rightarrow\; \sigma = H^{-1}\varepsilon = C_d\varepsilon$$

$$C_d = \begin{bmatrix} C_{11} & C_{12} & C_{13} & 0 & 0 & 0 \\ & C_{22} & C_{23} & 0 & 0 & 0 \\ & & C_{33} & 0 & 0 & 0 \\ & & & C_{44} & 0 & 0 \\ & \textit{Symmetric} & & & C_{55} & 0 \\ & & & & & C_{66} \end{bmatrix} \Rightarrow$$

$$\begin{aligned}
C_{11} &= (1-d_1)E_1[1-(1-d_2)(1-d_3)v_{32}v_{23}]/\Delta \\
C_{22} &= (1-d_2)E_2[1-(1-d_1)(1-d_3)v_{13}v_{31}]/\Delta \\
C_{33} &= (1-d_3)E_3[1-(1-d_1)(1-d_2)v_{12}v_{21}]/\Delta \\
C_{12} &= (1-d_1)(1-d_2)E_1[v_{21}+(1-d_3)v_{31}v_{23}]/\Delta \\
C_{13} &= (1-d_1)(1-d_3)E_1[v_{31}+(1-d_2)v_{21}v_{32}]/\Delta \\
C_{23} &= (1-d_2)(1-d_3)E_2[v_{32}+(1-d_1)v_{12}v_{31}]/\Delta \\
C_{44} &= (1-d_{12})G_{12} \\
C_{55} &= (1-d_{23})G_{23} \\
C_{66} &= (1-d_{13})G_{13}
\end{aligned}$$



$$\Delta = 1-(1-d_2)(1-d_3)v_{32}v_{23}-(1-d_1)(1-d_3)v_{31}v_{13}-(1-d_1)(1-d_2)v_{21}v_{12}-2(1-d_1)(1-d_2)(1-d_3)v_{13}v_{21}v_{32}$$

❑ **progressive constitutive model based on continuum damage mechanics**

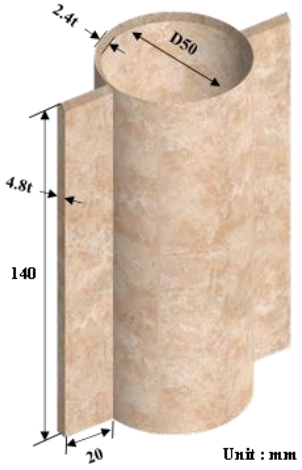
Crush Test & Simulation

Crush Test & Simulation

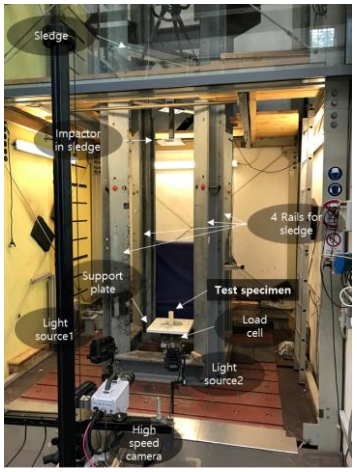
ICCM24

Crush tests of the MLH-mat Tubes



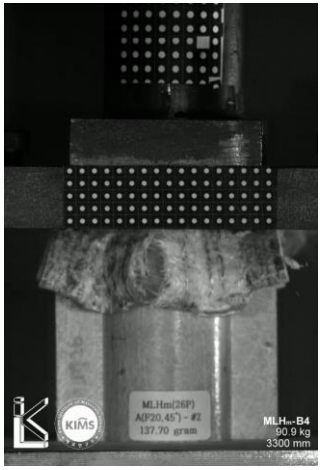
☑ Specimen preparation

- **Shape** : A circular cylindrical shell with flat vertical flanges on both sides
- **Fabrication process** : Hot forming of two half-shells with flat flanges, followed by thermal fusion bonding along the flanges

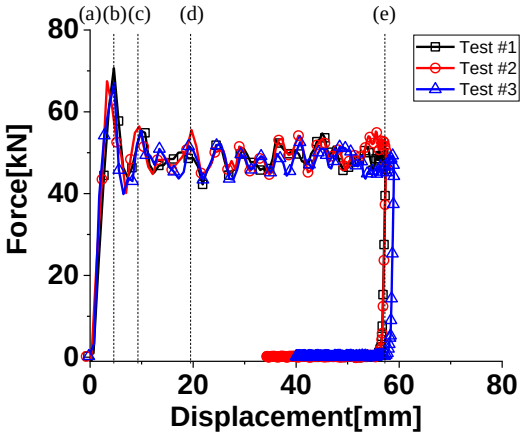


☑ Test Conditions & Results

- **Test conditions** : ❶ Impactor Mass = 90.9 kg | ❷ Impact velocity = 7.86 m/s
- **Test Results(Ave.) :** ❶ Specific Energy Absorption(SEA) = 48.9 J/g | ❷ Crush depth = 57.9 mm



Crush Tests of the MLH-mat Tubes



❑ **Specimen dimension**

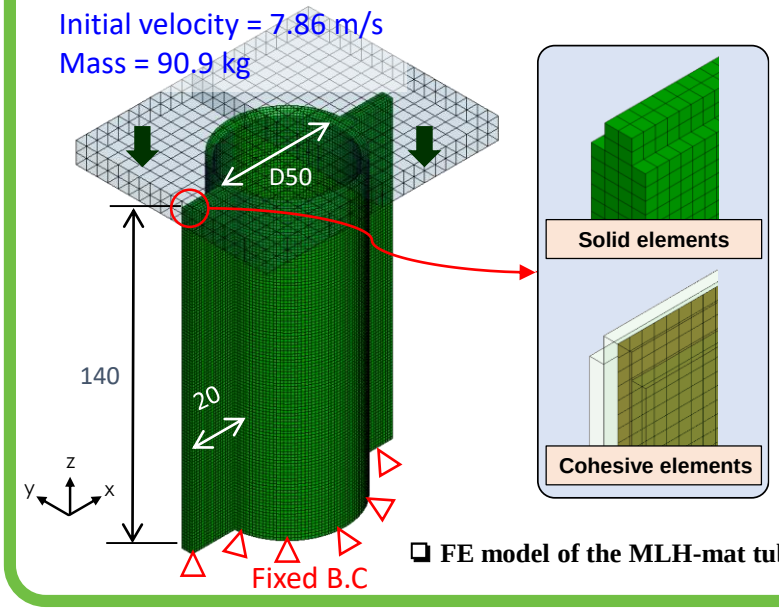
❑ **Crush test setup**

❑ **Crush test results (Final shape | Force–displacement curves)**

KIMS 한국재료연구원 Korea Institute of Materials Science

Crush Test & Simulation

Crush Simulation of MLH-mat Tubes



☑ FE model of the MLH-mat tube

- **Solid elements with four layers along the thickness direction** to enhance computational efficiency
- **Cohesive elements** embedded **at the mid-plane of the MLH-mat tube** to enable **the splaying failure mode**
- Rigid body elements used for the impactor, matching the conditions of the physical crush test

☑ Material model

- **MLH-mat material** ⇒ Proposed 3D Progressive damage model
- **Interlaminar behavior** ⇒ Cohesive material model (MAT_COHESIVE_MIXED_MODE in LS-DYNA)

Crush Tests of the MLH-mat Tubes

❑ FE model of the MLH-mat tube

Stiffness	E_1 [MPa]	E_2 [MPa]	E_3 [MPa]	G_{12} [MPa]	G_{23} [MPa]	G_{13} [MPa]	v_{12}	v_{23}	v_{13}
	13,100	12460	12460	5032	5032	5032	0.32	0.32	0.32
Strength	$X1T$ [MPa]	$X1C$ [MPa]	$X2T$ [MPa]	$X2C$ [MPa]	$X3T$ [MPa]	$X3C$ [MPa]	S12	S23	S13
	250	174	260	162	260	162	132.8	132.8	132.8
Fracture toughness	G1T[kJ/m²]	G1C [kJ/m²]	G2T [kJ/m²]	G2C [kJ/m²]	G3T [kJ/m²]	G3C [kJ/m²]			
	112.9	37.9	112.9	37.9	112.9	37.9			

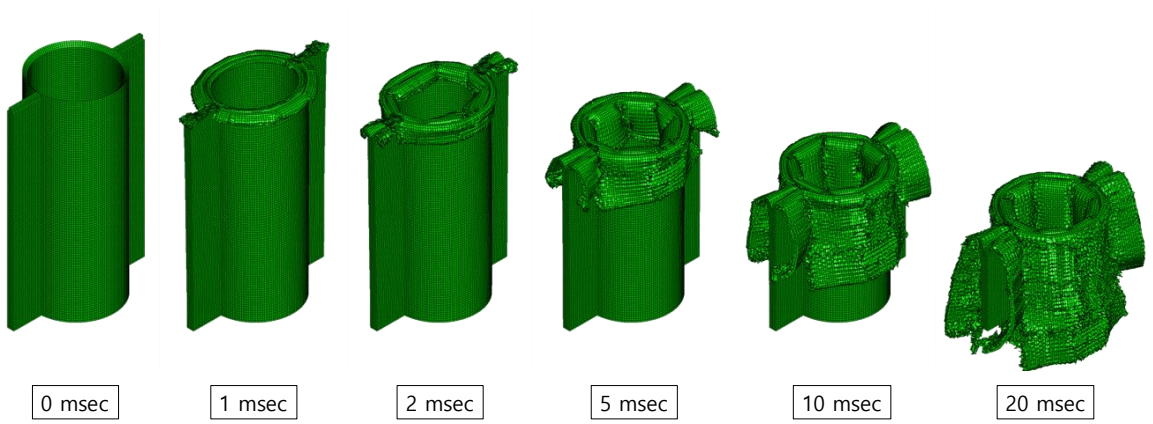
Intra-laminar fracture toughness

❑ Material parameters of the proposed 3D progressive damage model

1	MID	RO [g/m³]	ROFLG	INTFAIL	EN	ET	GIC	GIIC
	3	3.30e-5	1.0	1.0	3,000	3,000	2.88 (To be Calibrated)	2.30 (To be Calibrated)
2	XMU	T	S	UND	UTD	GAMMA		
	1.0	80.0	80.0	0	0	1.0		

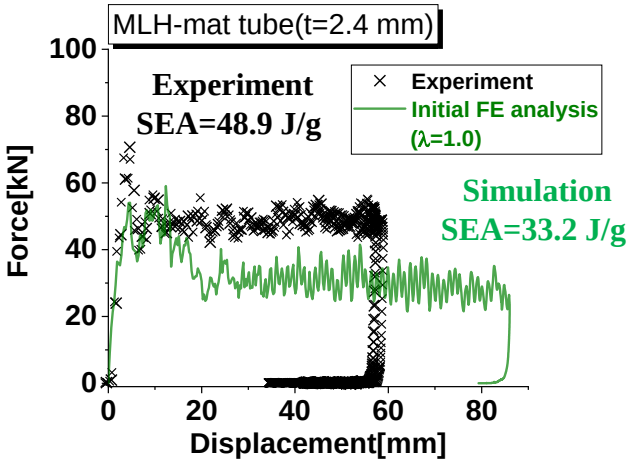
Inter-laminar fracture toughness

❑ Material parameters of the cohesive material model



Crush Test & Simulation

Crush Simulation of MLH-mat Tubes



☑ Initial simulation result

- **Observation of a stable splaying failure mode** enabled by **cohesive element deletion** under impact loading
- **Underestimation of energy absorption performance** due to **simplified modeling of interlaminar fracture**
  - **FE simulation** → Interlaminar fracture **only considered at the mid-plane of the tube** for **computational efficiency**
  - **Actual test** → Interlaminar fracture **observed at multiple ply interfaces** throughout the thickness
- **Necessary to calibrate interlaminar fracture toughness** to match the **experimental energy absorption performance**

Crush Simulation Results before calibration

❑ **Sequential images of the MLH-tube in the initial crush simulation**

❑ **Force–displacement curve of crush simulation before calibration**

Crush Test & Simulation

Crush Simulation of MLH-mat Tubes

☑ Calibration for interlaminar fracture toughness

- **Proposal of a fracture toughness correction factor (λ)** to adjust the **interlaminar fracture toughness value** for crash analysis
- **Definition of λ** as a **multiplier** applied to **Mode I and Mode II fracture toughness** from **experimental tests**
- **Establishment of an objective function** based on the **difference between force–displacement curves from test and simulation**
- **Optimization of λ** using LS-OPT with the **response surface method**, finally **converged to 6.87**

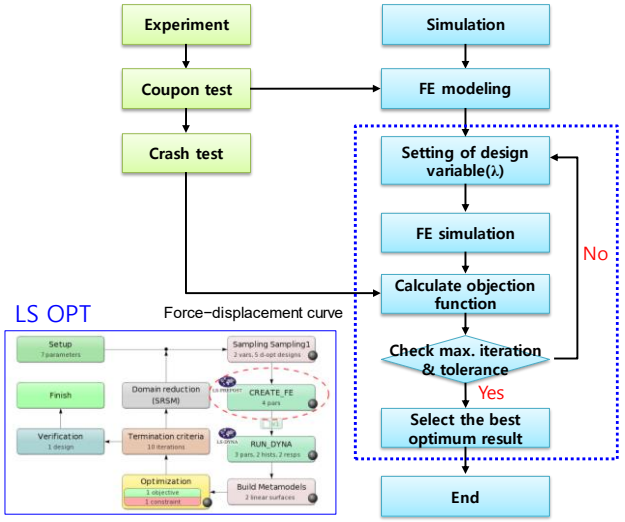
Crush Simulation Results before calibration

❑ **Fracture toughness correction factor(λ)**

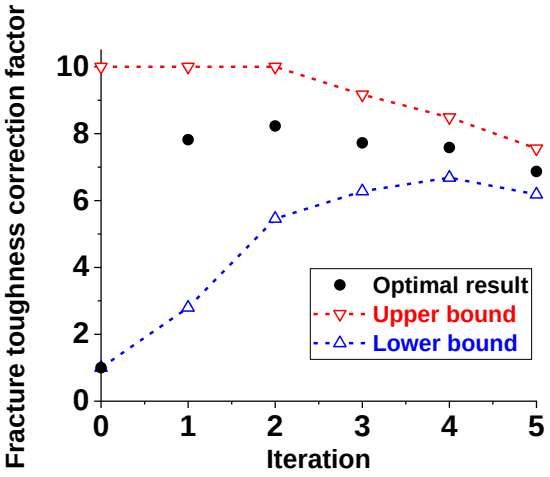
$$G_{IC}^{FEA} = \lambda \cdot G_{IC}^{Exp}$$

$$G_{IIC}^{FEA} = \lambda \cdot G_{IIC}^{Exp}$$

❑ **Definition of object function**



Find λ



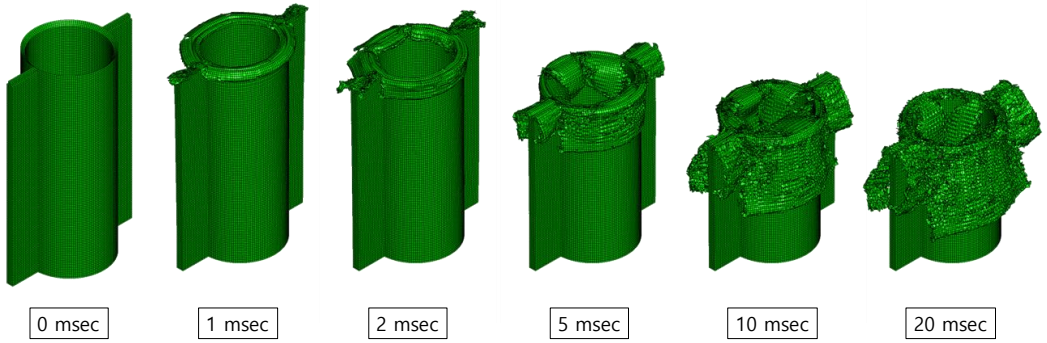
To minimize

$$f(\lambda) = \sqrt{\frac{1}{n}\int_{i=0}^{n}\left(y(x_i) - \hat{y}_\lambda(x_i)\right)^2}$$

Subjected to $\mathbf{1 \le \lambda \le 10}$

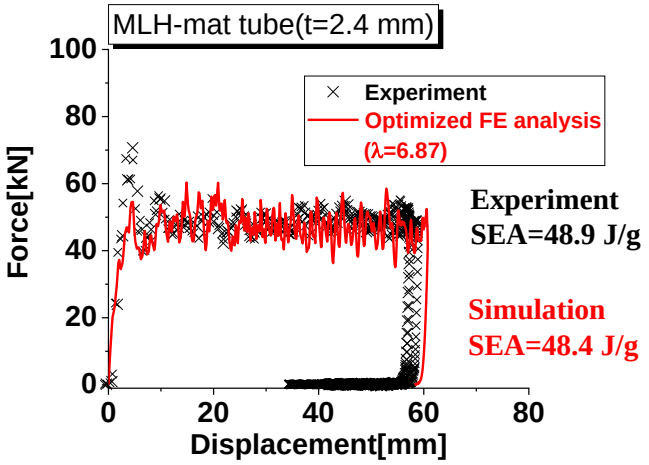
$y(x_i)$: Force from simulation
$\hat{y}_\lambda(x_i)$: Force from tests

❑ **Optimization of calibration parameter for interlaminar fracture toughness using LS-OPT**



Crush Test & Simulation

Crush Simulation of MLH-mat Tubes

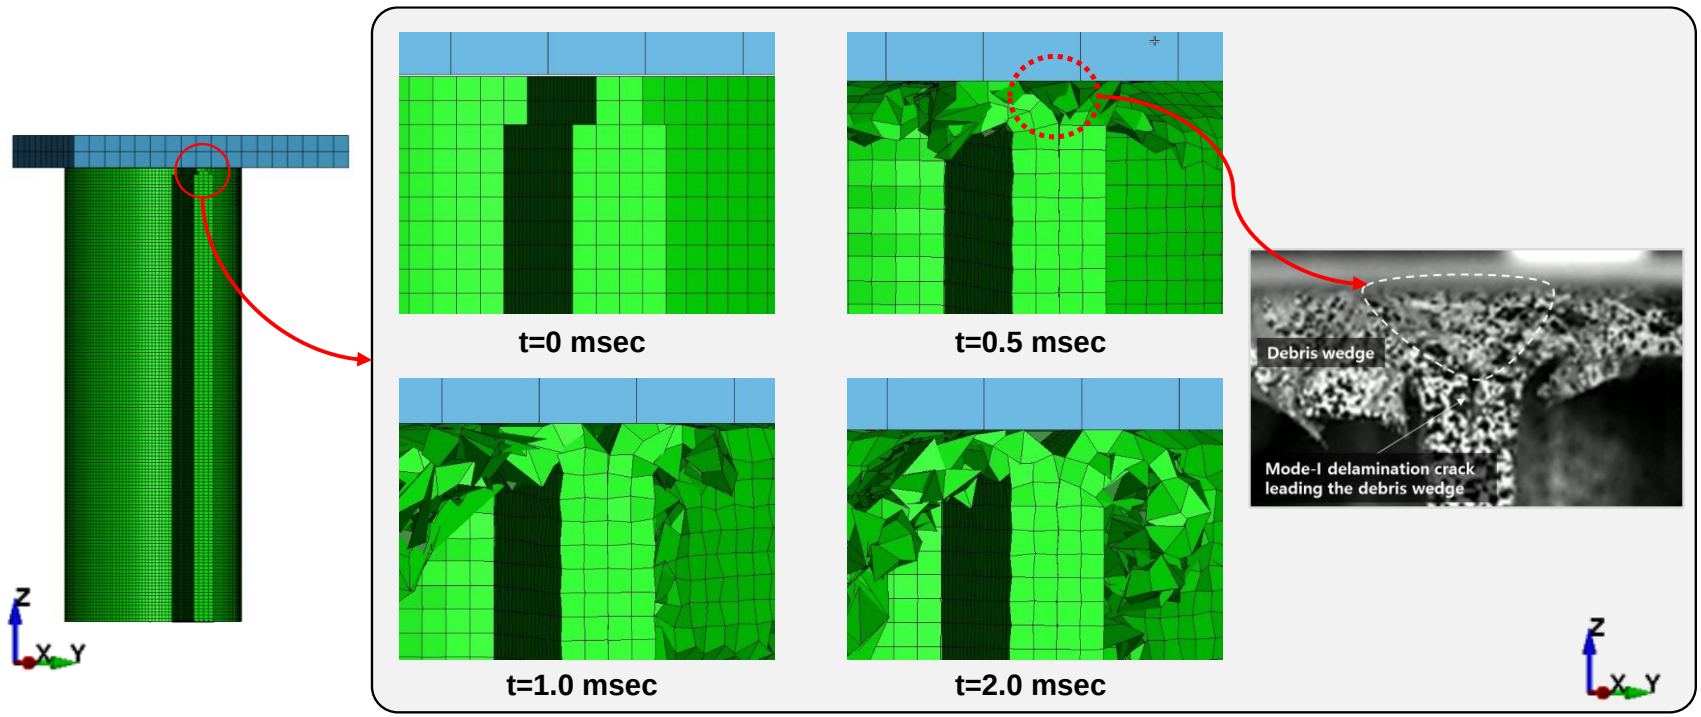


☑ Simulation results after calibration

- **Visualization of stable crushing** and **complete energy absorption** in the **optimized crush analysis**
- **Increase in mean crash force** and **energy absorption,** reaching values **comparable with experimental results**
  ⇒ **Prediction Results :** ❶ SEA = 48.4 J/g | ❷ Crush depth = 60.3 mm
- **Excellent agreement** with experimental results, with **small deviation** of **1.02% for SEA,** and **4.14% for crush depth**
- **Confirmation of λ as a critical factor** in **improving prediction accuracy** of crash energy absorption for the MLH-mat tube

Crush Simulation Results after calibration

❑ **Sequential images of the MLH-tube in crush simulation after calibration**



❑ **Force–displacement curves of crush simulation after calibration**

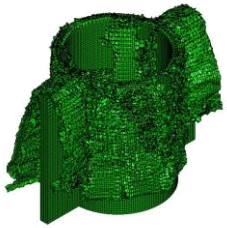
Crush Test & Simulation

Crush Simulation of MLH-mat Tubes

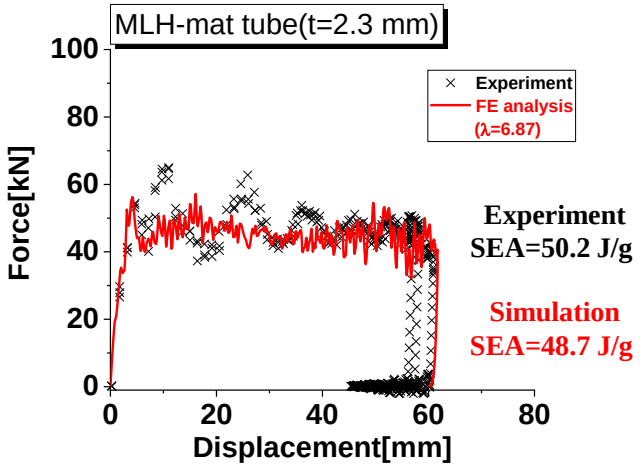
☑ Failure mechanism and energy absorption

- **Identification** of the **splaying failure mechanism** through optimized crush simulation and comparison with test results
- **Observation of Mode I delamination** as the **dominant cause of splaying**, triggered by **debris wedge formation** at the crash front
- **Quantitative analysis** showing **interlaminar failure contributes to 39.4%** and **intralaminar failure to 61.6%** of total absorbed energy
- **Emphasis on** the critical role for **accurate estimation** of **energy absorption by interlaminar failure**

Crush Test & Simulation



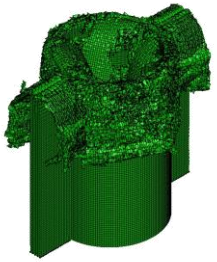
Crush Simulation of MLH-mat Tubes

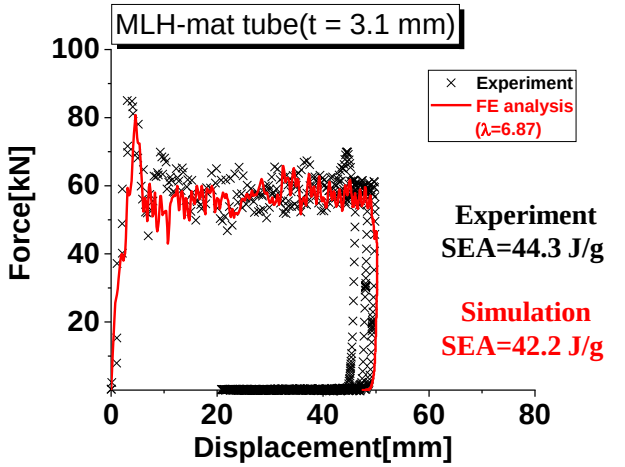


☑ Validation under geometry variation

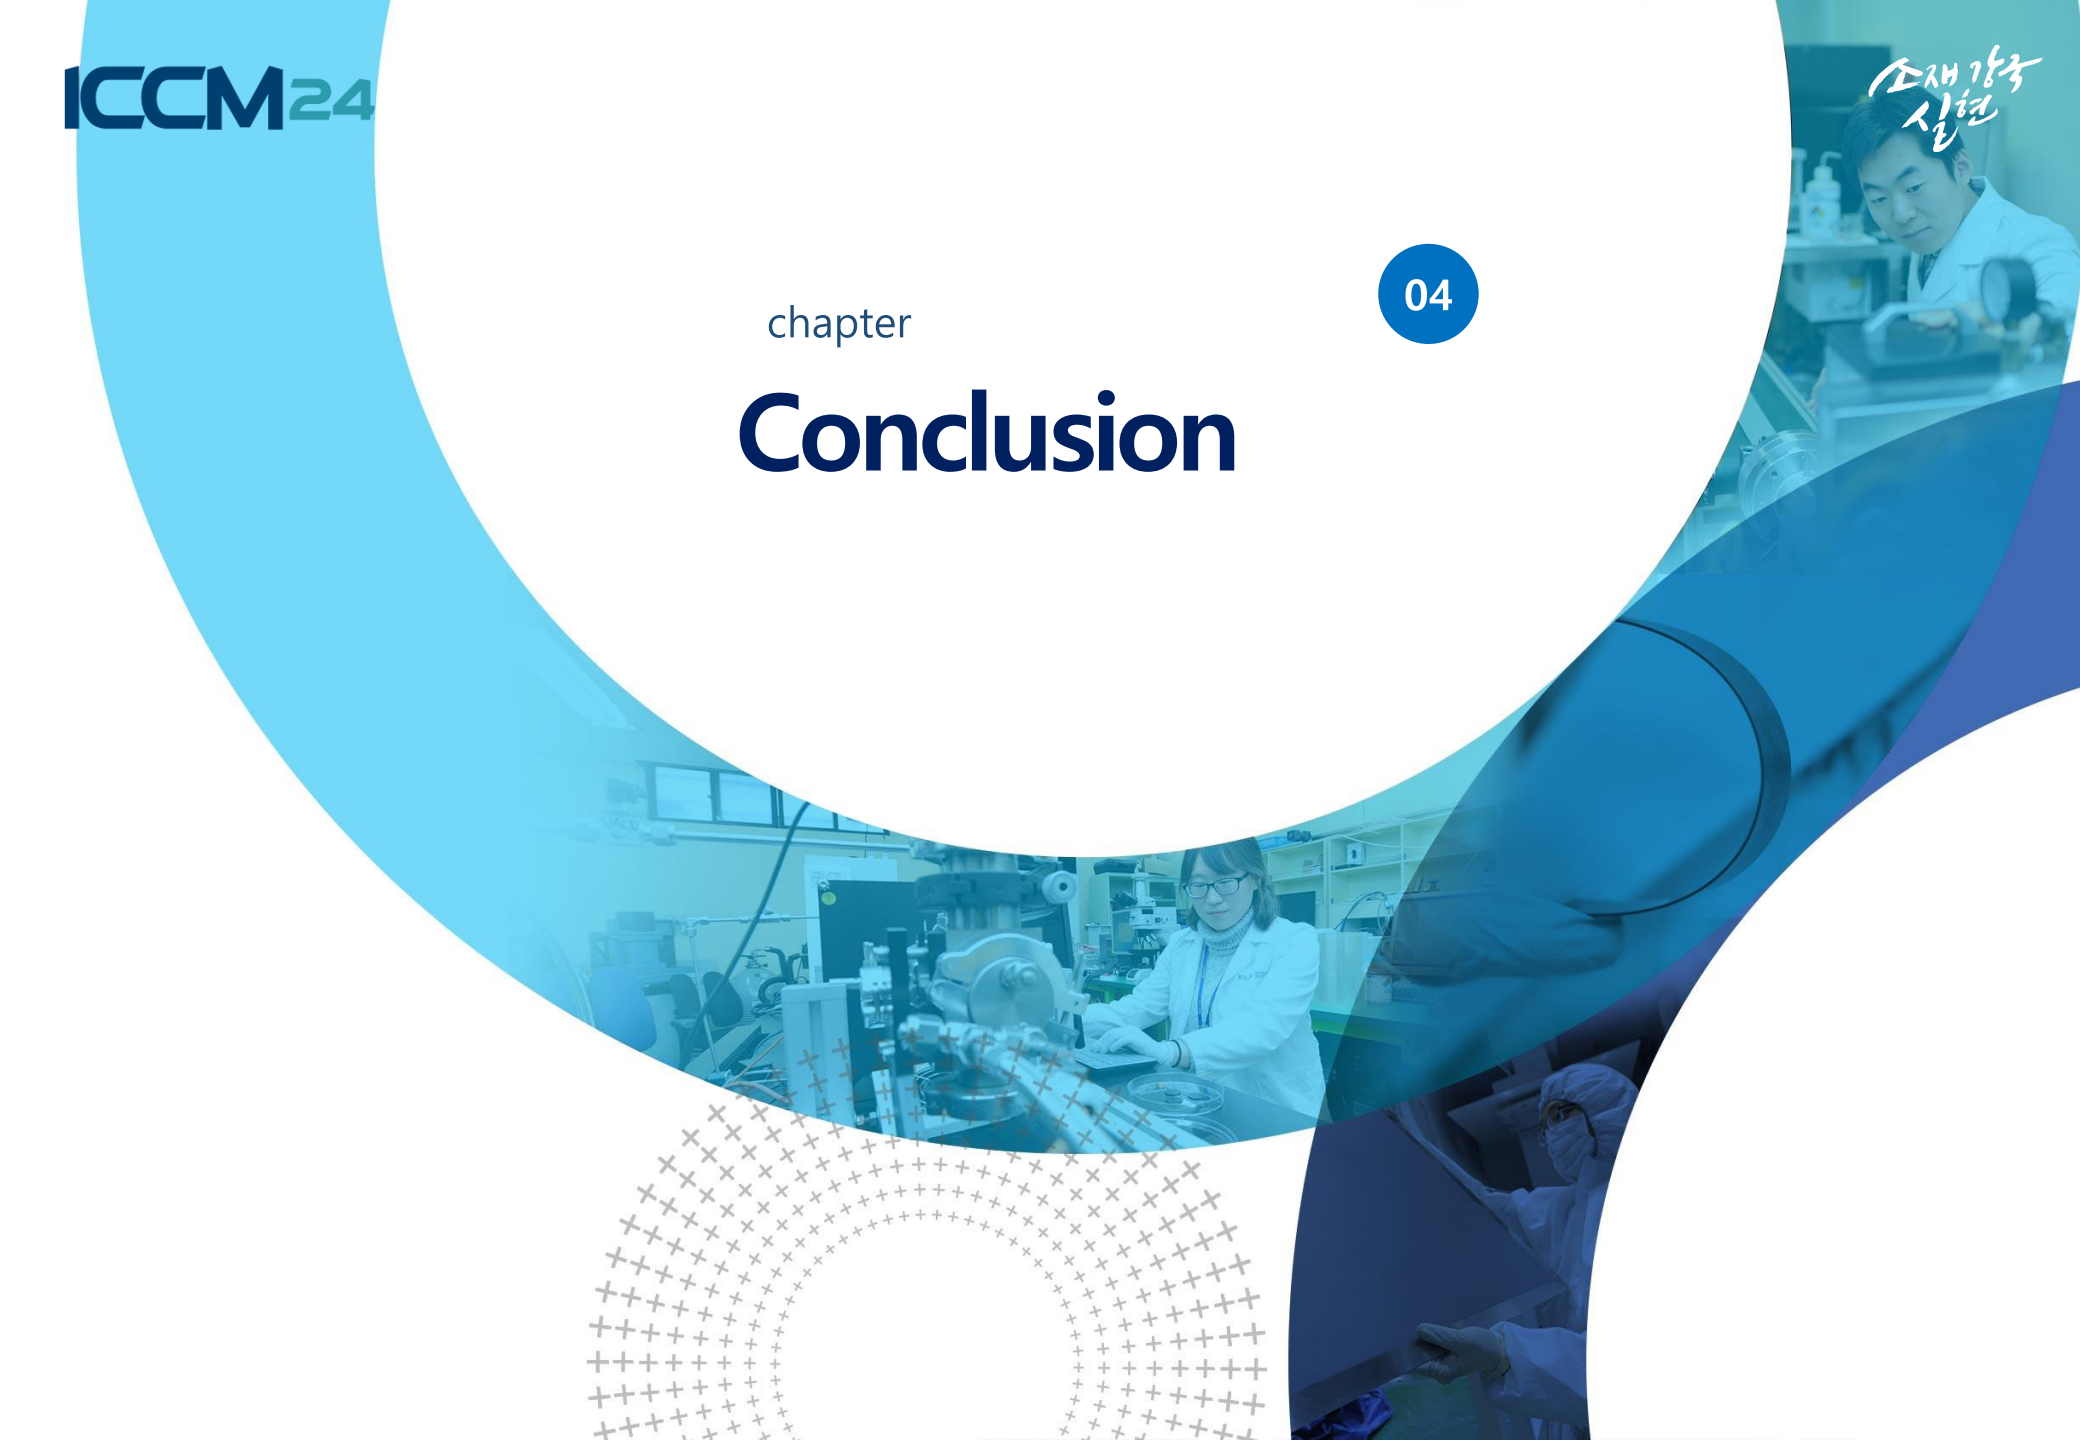
- **Necessary to validate applicability** of the proposed crush **simulation method** under **tube geometry variation**
- **Application of the same correction factor (λ = 6.87)** to **tubes** with **2.3 mm** and **3.1 mm** thickness
- **Consistent crush simulation results** with **test results** within **deviation of 5.1%** for **SEA** and **crush depth**
- **Demonstration of reliability and applicability for the proposed method** under **moderate geometric changes** without **re-calibration**

Validation of the proposed method for dimensional variation





❑ Crush test and simulation results (Thickness = 2.3 mm)



❑ Crush test and simulation results (Thickness = 3.1 mm)

ICCM24

chapter 04

Conclusion

Conclusions

☑ **Characterized** the mechanical properties and fracture toughness of **the MLH-mat material**, confirming its quasi-isotropic behavior due to **random fiber orientation**

☑ **Developed** a crash analysis method using a **3D progressive damage model** and **mid-plane cohesive elements** to **simulate splaying failure**

☑ **Introduced** a **fracture toughness correction factor (λ)** and optimized it to ensure **accurate prediction of energy absorption**

☑ **Proposed a practical crush analysis framework** for industrial application, demonstrating **reliable performance** under **moderate geometric variation.**

Influence of Consolidation Pressure on Tensile Strength of Ultra High Molecular Weight Polyethylene Composites

27 JUNE 2025

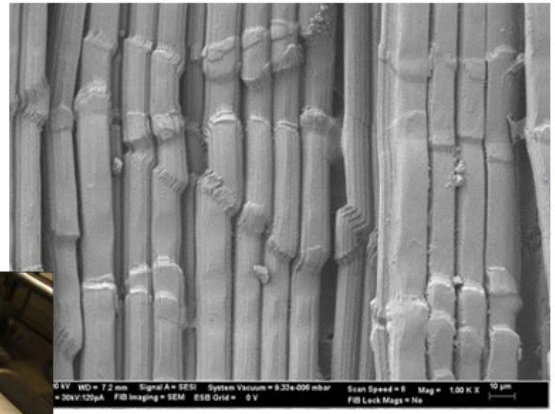
Molla Ali, Travis A. Bogetti, Michael Yeager,
Joseph M. Deitzel, Jack Gillespie

Distribution Statement A: Approved for public release: distribution is unlimited.

Background

https://www.army-technology.com/contractors/personal/dsm-dyneema/

https://www.samsonrope.com/resources/defense/air

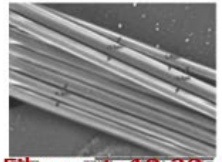


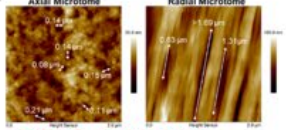
https://www.freepik.com/premium-photo/fully-equipped-special-forces-military-unit-tactical-gear-wartime-ai_42288360.htm

- Ultra High Molecular Weight Polyethylene UHMWPE is unique for its low density and high tensile strength
- It is light weight and provides higher protection
- This is used in high velocity impact resistant applications: protective shields, armored vehicles, helmets, bulletproof vests, short arrest systems for aircraft

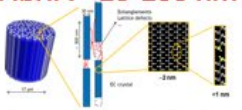
Goal of the Program

Goal: Understand how consolidation process variables Temperature(T), Pressure(P) and time (t) control composite microstructure (*Reduce voids, Increase fiber volume fraction, Minimize filament damage*) to improve composite performance (*Reduce weight, Maintain Performance, Reduce dynamic deflection, Maximize energy absorption*).





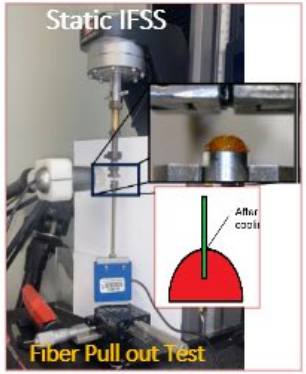
Scale



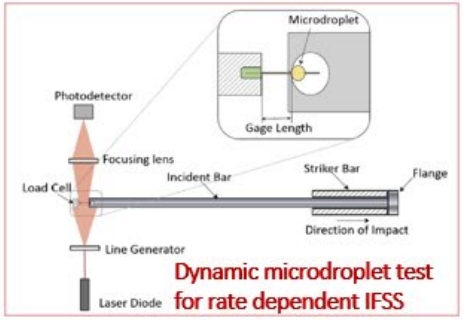
Virgin SK99 Fibers

AFM Images of Microtomed Post-Draw Fibers

Objectives and Approach

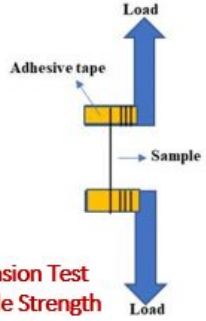


OBJECTIVES:



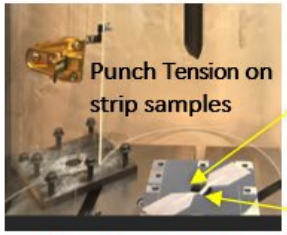
- Study the tensile strength of UHMWPE composites as a function of consolidation pressure
- Study the void fraction and thickness reduction as a function of consolidation pressure
- Study the consolidation pressure induced micro damage on the UHMWPE sheet composites
- To understand the tension failure modes and damage mechanisms
- To have a correlation of fiber strength to [0/90/0/90] sheet strength taking void and compressive strain into account
- To have insight on how to improve the Tension performance of this material

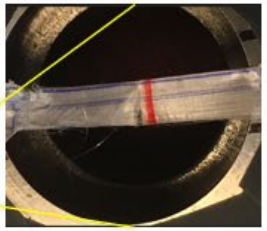
APPROACH:



- To develop an experimental methodology for tension test of UHMWPE composites
- To develop lab scale consolidation of UHMWPE following the exact thermal and pressure profile prescribed by DSM Dyneema
- To perform tension test on unconsolidated HB210 WHMWPE thin sheets and composites consolidated at various pressures [1ksi, 2ksi,3ksi, 6.5ksi,8.25ksi & 10ksi]
- Consolidation pressure induced micro damage analysis
- Results and discussions

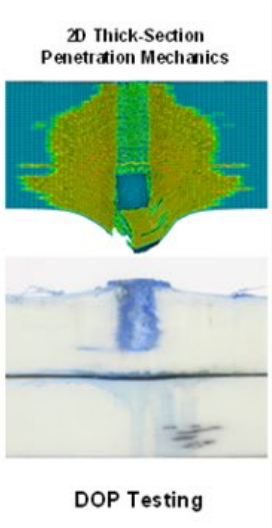
Overview of the Test Methods





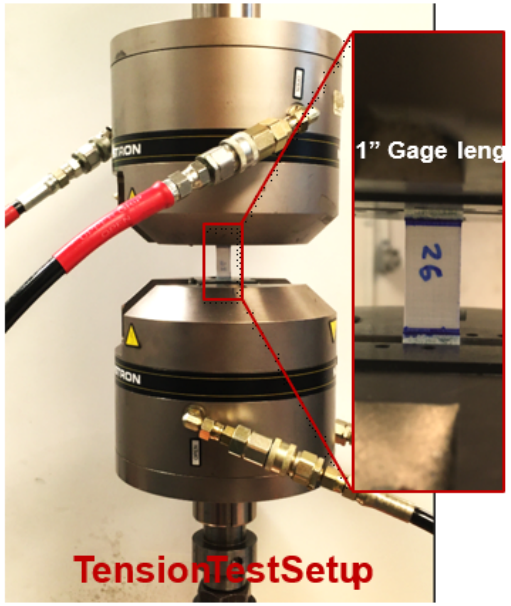
IFSS: Interfacial shear strength

Fiber Tension Test
for Tensile Strength

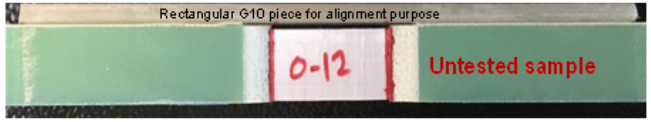


- Vertical load applied
- Specimen failed in tension
- Include tension and in plane shear

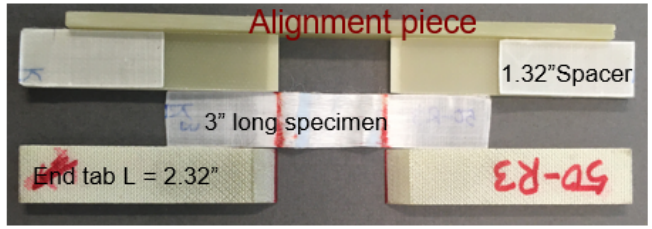
- Include tension, in plane shear, punch shear which are useful for studying mixed loading that occurs during impact



- Tension properties can be achieved directly from axial tension of sheets
- It enables effects of consolidation pressure on microstructure and tension properties to be quantified
- Challenge is the slippage in the grip



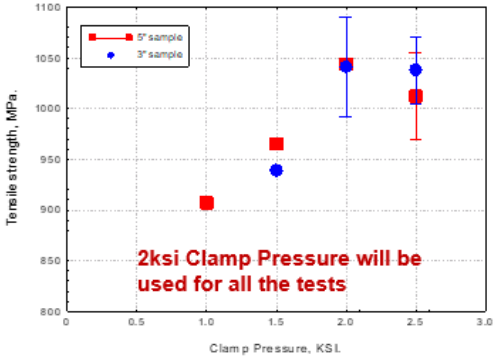
Development of Tension Experiment

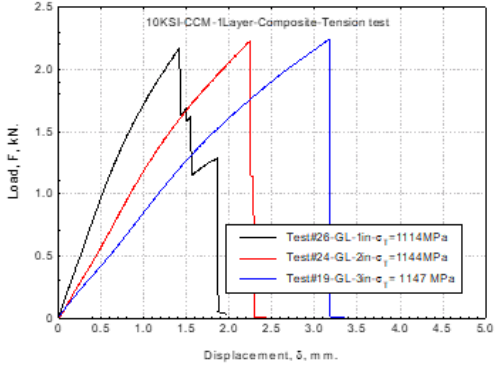


UNIVERSITY OF DELAWARE
CENTER FOR COMPOSITE MATERIALS
Celebrating 50 Years

- Instron: 1331
- Load cell: 100kN
- Grips: Hydraulic
- Clamp Pressure: 2ksi
- Displacement rate = 0.05 in/min

Specimen prep

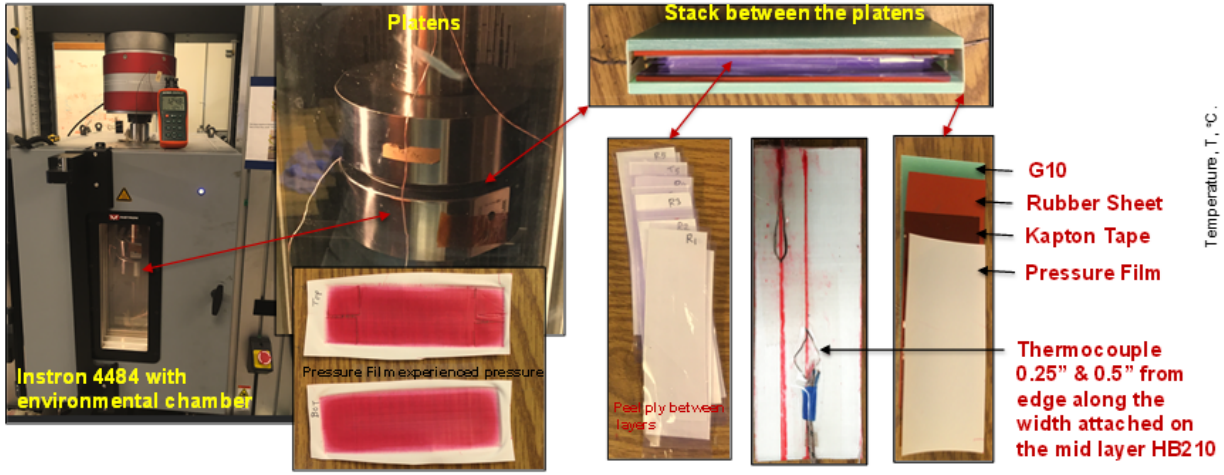




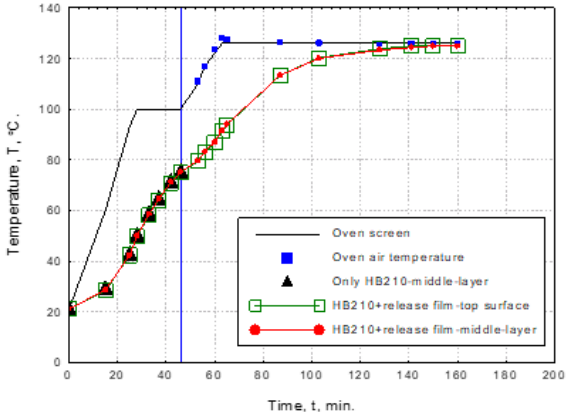
All pieces have been assembled and kept in place with the help of tape

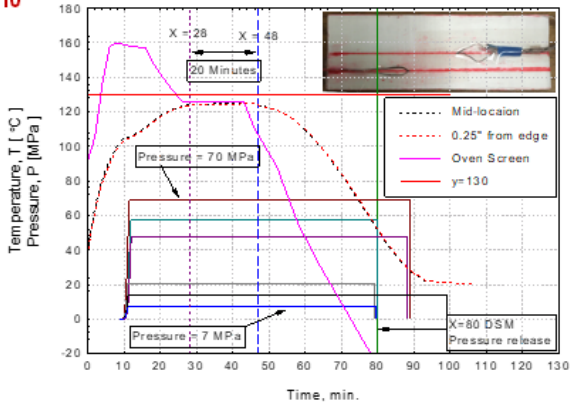
Specimen Dimensions:

- Specimen Length : L = 5.64" [1.32" Spacer + 3" Sample + 1.32" Spacer]
- Width W = 0.5"
- Thickness T = 0.157 ± 0.006 mm
- Tab: L = 2.32"
  W = 0.6"
- Gage Length = 1"
- Specimen & Spacers are Consolidated at same Pressure



Tensile Strength vs Clamp pressure

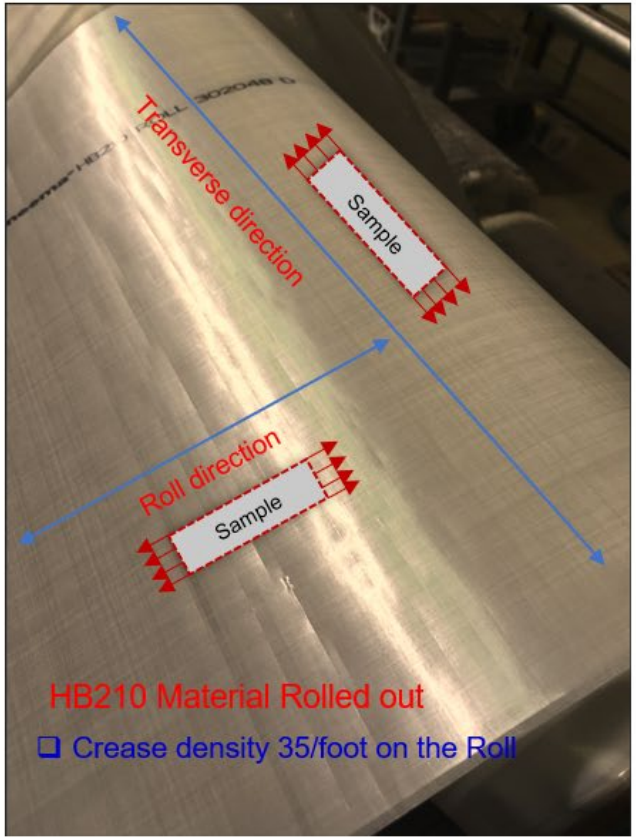


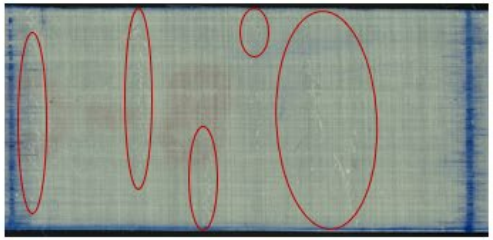


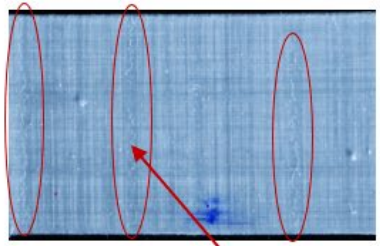
Load vs Displacement of Tension Test with Gage Length GL = 1", 2" & 3"

Consolidation Process of 1L Dyneema Sheets

UNIVERSITY OF DELAWARE
CENTER FOR COMPOSITE MATERIALS
Celebrating 50 Years

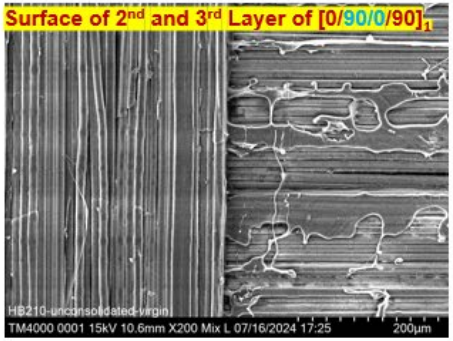




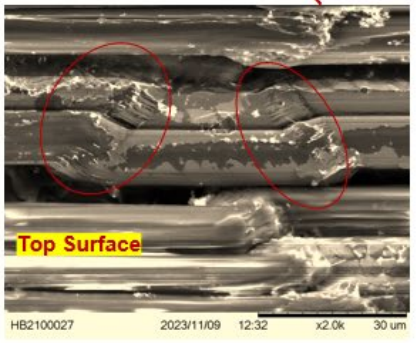


- Pressure Source: Instron 4484, Load Cell: 150kN
- Heat source: Environmental Chamber
- Two identical Metal platens have been used on top and bottom
- Both the setup and the material stack arranged in a symmetric way
- No noticeable temperature gradient through the thickness of the stack with & without separation film [release film]
- Oven air temperature is recorded to validate oven screen temperature and found to be identical
- Temperature along the width of the sample recorded 0.25" &0.5" inside from the edge location of the middle layer and found to be the same
- Pressure films have been used on the top & bottom layer which show uniform pressure distribution

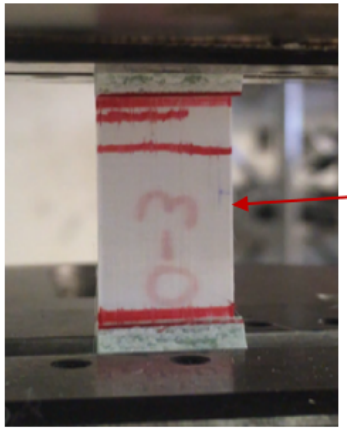
Material Under Study: Dyneema HB210

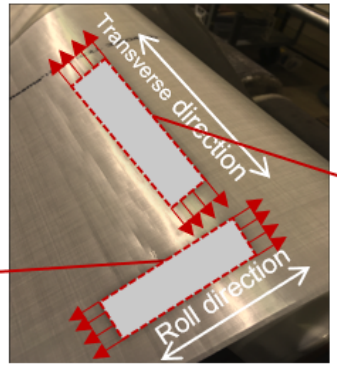


UNIVERSITY OF DELAWARE
CENTER FOR COMPOSITE MATERIALS
Celebrating 50 Years



Every crease is not similarly severe & all the creases are not continuous from one edge to the other in the gage section of the samples



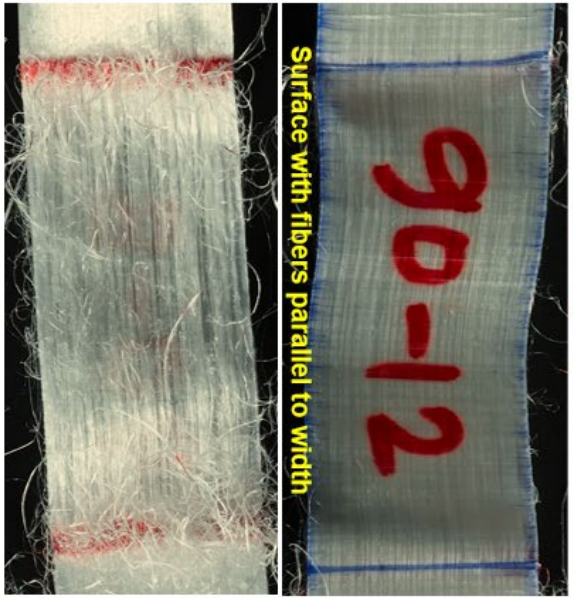


- ❑ Lots of Crease visible on the unconsolidated Dyneema HB210 surface
- ❑ Crease density 4/inch on a 3" X 1" sample
- ❑ Crease direction is parallel to transverse direction
- ❑ Roll samples have crease defects but not transverse samples
- ❑ Crease kinks introduce more voids in the material
- ❑ Resin Reach & resin Lean Areas are Observed inside the $[0/90/0/90]_1$ Sheet

Representative Failure modes in Videos

Roll direction test video

Transverse direction test video



- Transverse samples have been picked to study the effect of consolidation pressure on tensile strength to avoid the effect of original crease defects

- Fails progressively [these samples have crease effect]
- Fibers fail in a cluster at a location then another location, then another location & eventually catastrophic failure happens at the end

- Roll direction samples show 7% strength reduction due to creases
- Transverse sample is least sensitive for creases

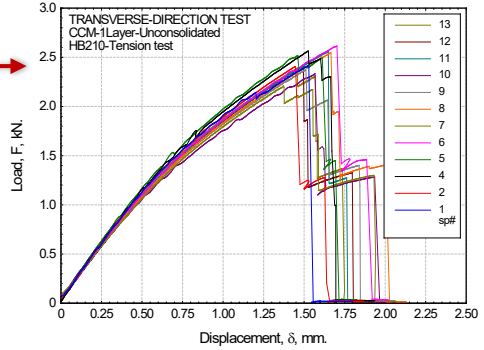
- Fails instantaneously [these samples don't have crease defect in the load carrying fibers]
- In some cases, fiber failure initiates in a cluster at a location but in a moment catastrophic failure happens all over

Representative Failure Modes in Pictures

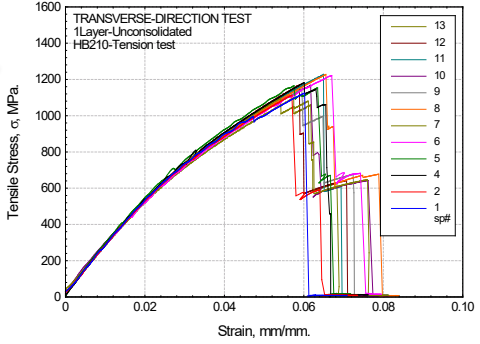
Transverse direction tested sample

Tested sample pulled in loading direction separates into two pieces as above pictures

- Sample surface with fibers parallel to the loading direction shows catastrophic failure
- but surface with fibers perpendicular to loading direction don't show failure as they don't carry load

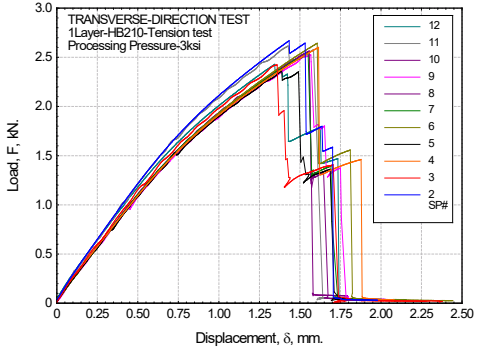


Roll direction tested sample

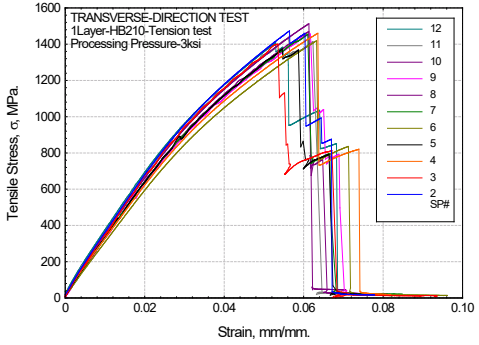


Load vs Displacement & Stress vs Strain Plots of UHMWPE

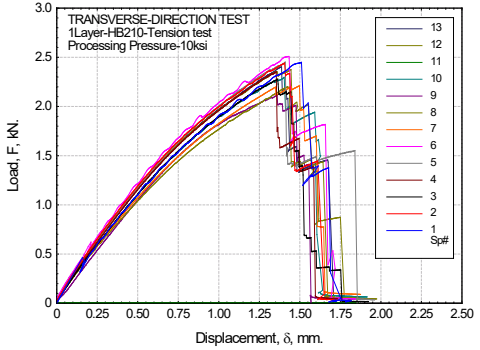
Load vs Displacement

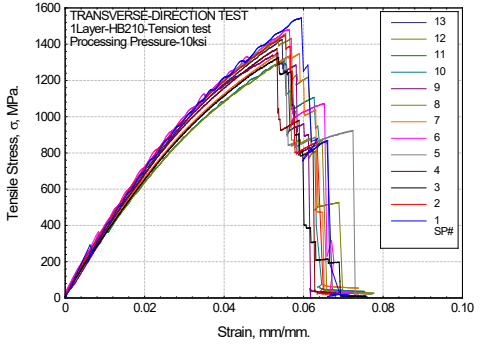


Stress Vs Strain



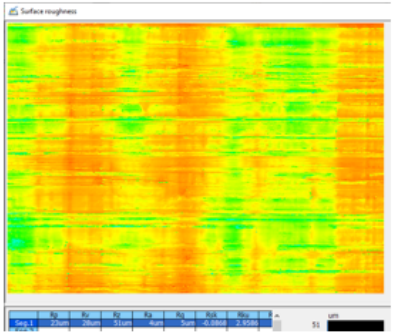
Unconsolidated





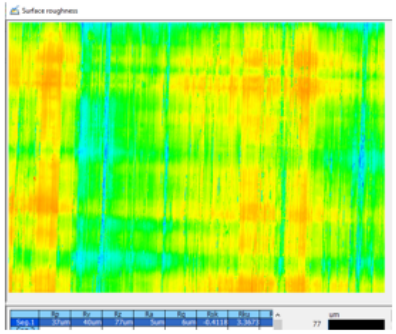
Consolidated @3ksi

Consolidated @10ksi



More Progressive Failure Happens to Materials Consolidated at Higher Pressure

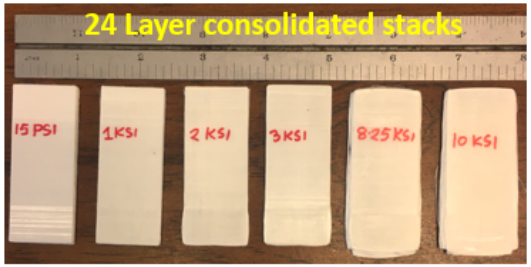
Sheet Surface Roughness Study



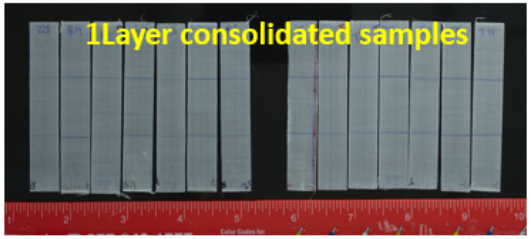
UNIVERSITY OF DELAWARE
CENTER FOR COMPOSITE MATERIALS
Celebrating 50 Years

Thickness of 1 Layer sheet – 2* surface roughness = Roughness free thickness of the sheet

3ksi-top-surface Rz = 51 um

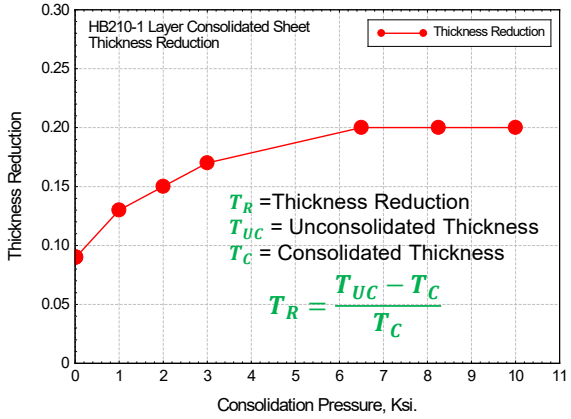


3ksi-bot-surface Rz = 56 um

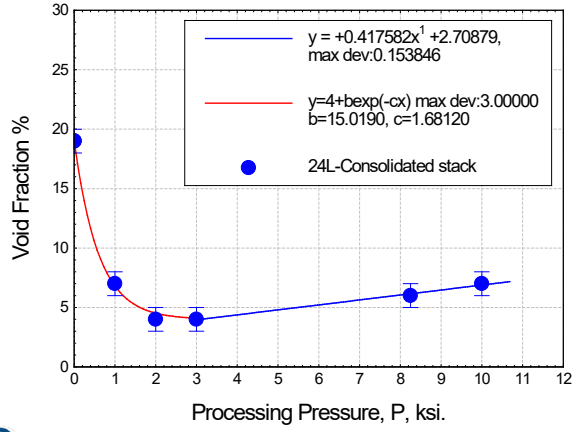


Micrometer T = 157 um

- Confocal roughness Rz of HB210 sheet shows that the surface has hills and valleys
- roughness free thickness is required to get accurate tensile strength
- Micrometer measurement of thickness includes the surface roughness

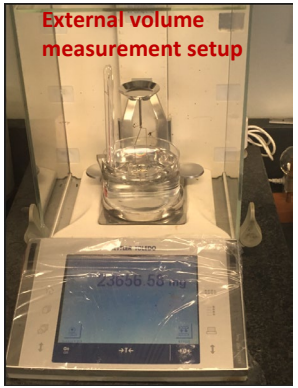


- Thickness of 24 Layer stack includes 2 rough surfaces
- Total thickness of 24 counts of 1 individual Layer sheet has 48 rough surfaces
- Average roughness of one surface can be calculated from the above two micrometer measurements



Consolidation Pressure	[Unconsolidated]	1ksi	2-ksi	3-ksi	8.25-ksi	10-ksi
Single sheet roughness, $R_{avg.}$, microns	24 ± 5	22 ± 4	23 ± 3	20 ± 5	16 ± 5	19 ± 5
Roughness free thickness, um	167 ± 7	146 ± 4	140 ± 4	135 ± 4	135 ± 5	130 ± 3

Thickness Reduction & Void fraction with Consolidation Pressure



- Gas Pycnometer provides Skeletal volume
- Archimedes method provides external volume
- Void fraction can be calculated from these two volume

Challenges with Archimedes' Principal:

- TPU is hydrophilic
- Sample sucks in water
- external volume gets compromised

consolidation Pressure	Void Fraction	uncertainity of Void Fraction
1ksi	7	1
2ksi	4	1
3ksi	4	1
8.25ksi	6	1
10ksi	7	1
Unconsolidated	19	1

Solution:

- Applying paraffin coat on the material to prevent water suction
- The volume of a piece of glass slide has been measured using Archimedes principal to validate the process

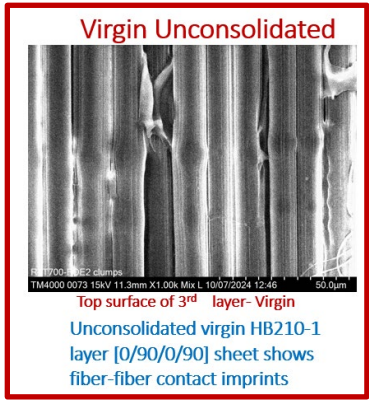
Tensile Strength & Evolution of Pressure Induced Damage

UNIVERSITY OF DELAWARE
CENTER FOR COMPOSITE MATERIALS
Celebrating 50 Years

Strength $\sigma = \frac{1}{2}V_f X_f (1-V_V)$

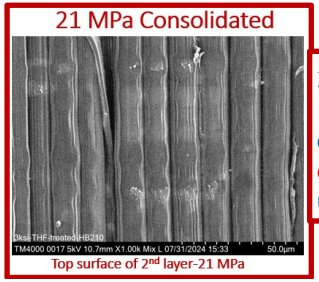
[Contribution of matrix in not included in the equation]

where



σ = Tensile strength of 4 layer sheet

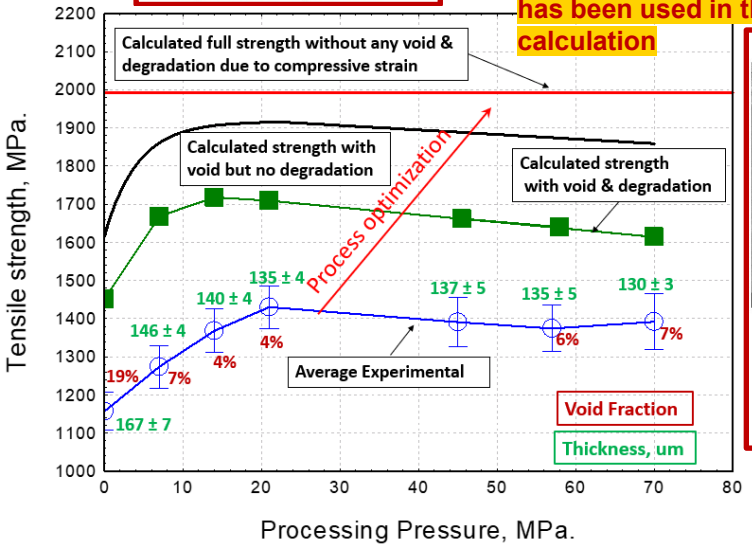
V_f = fiber volume fraction



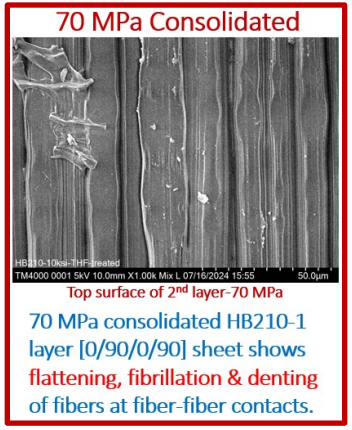
V_V = the void fraction

X_f = Fiber tensile strength

- **Processing condition that guarantees higher void and thickness reduction without any pressure induced denting, flattening, spilliting may increase tensile strength to some extent**



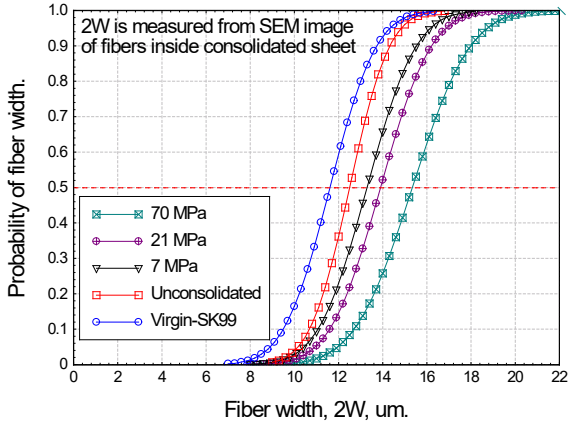
Fiber layers of [0/90/0/90] sheets have been peeled off and looked under SEM

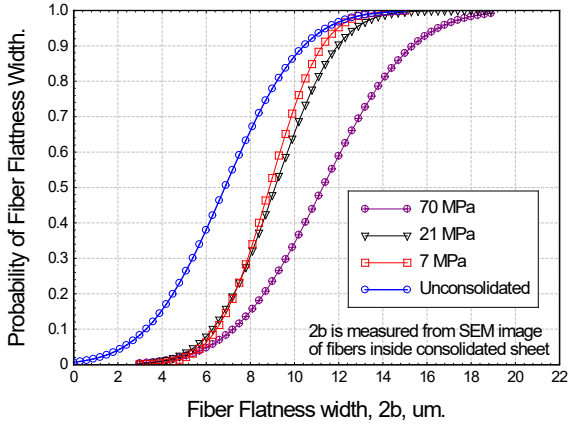


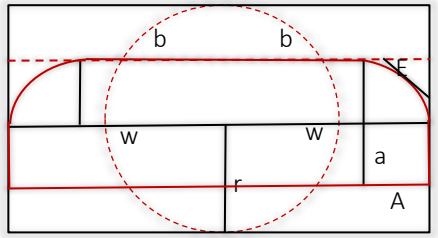
21 MPa consolidated HB210-1 layer [0/90/0/90] sheet shows fiber-fiber contact imprints which is in the form of dents are more frequent and severe than unconsolidated material

- **Void reduction benefits get defeated by pressure induced damage in fibers for consolidation pressure more than 21 Mpa**

50% Fiber failure strength has been used in the calculation





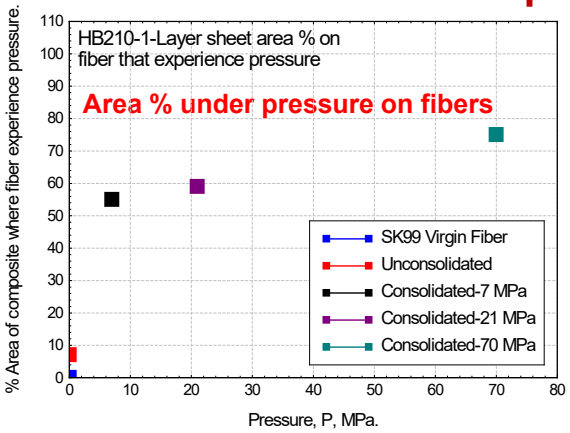


Consolidation pressure, MPa	[Unconsolidated]	7	14	21	46	58	70
Experimental Avg. strength, MPa	1157±50	1274±56	1368±57	1430±56	1391±64	1374±61	1392±73
Calculated Strength, MPa	1454	1668	1703	1705	1662	1640	1617

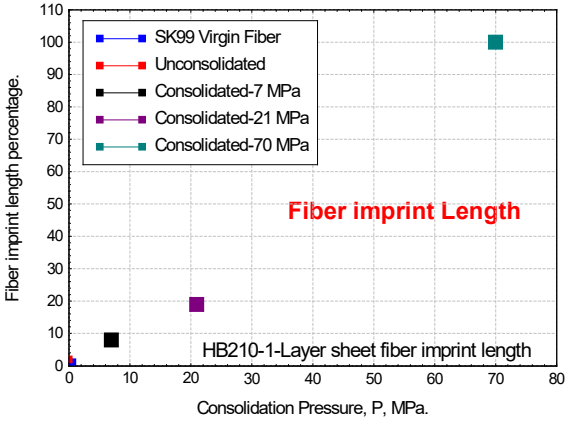
Fiber damage analysis as a function of Processing Pressure

Measurement of fiber width growth & fiber surface flattening

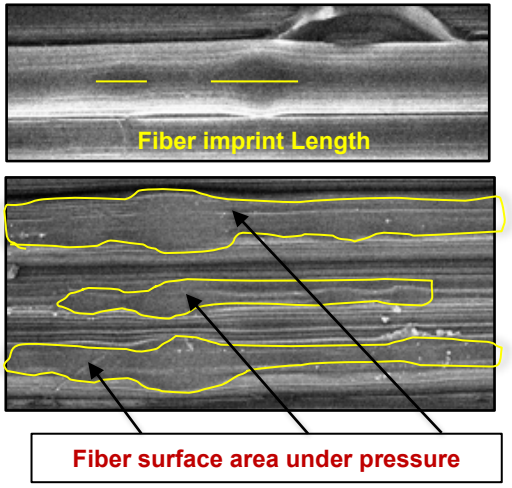
- 2W = Width of the compressed fiber in the sheet
- 2b = Flatness width on the surface of a fiber in the sheet



Material	Avg. 2b, um	Avg. 2W, um
SK-99 fibers	0	11.61 ± 1.65 [200+]
Unconsolidated	6.85 ± 2.79[17]	12.50 ± 1.42[250+]
7 MPa	8.87 ± 1.87 [180+]	13.29 ± 1.74[220]
21 MPa	9.12 ± 2.21[150+]	13.90 ± 1.80[250+]
70 MPa	11.28 ± 3.17 [150+]	15.34 ± 2.06 [340+]



NOTE: [count of measurements]



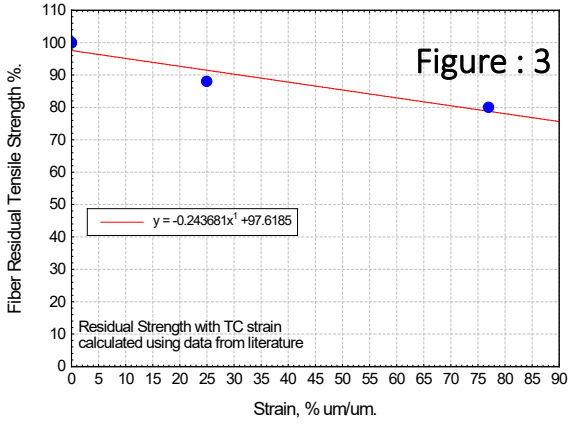
- Width 2w of a fiber & the flatness 2b on the surface of a fiber inside the [0/90/0/90] sheet grows as a function of consolidation pressure
- Growth of fiber width is restricted by adjacent fibers and matrix
- Growth in width causes splitting and separation of fibril bundles in a fiber which may result is early failure there

Fiber damage analysis as a function of Processing Pressure

Measurement of Imprints & Surface deformation

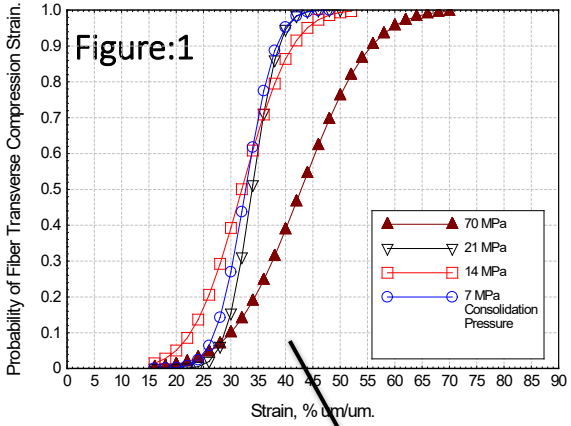
Fiber layers of [0/90/0/90] sheets have been peeled off and looked under SEM & all measurements are conducted on the SEM images

Material	Area % under pressure on fibers	Length % having imprint
SK-99 Virgin fiber	0	0
Unconsolidated	7	2 [17]
7 MPa	55	8 [250+]
21 MPa	59	19 [250+]
70 MPa	75	0



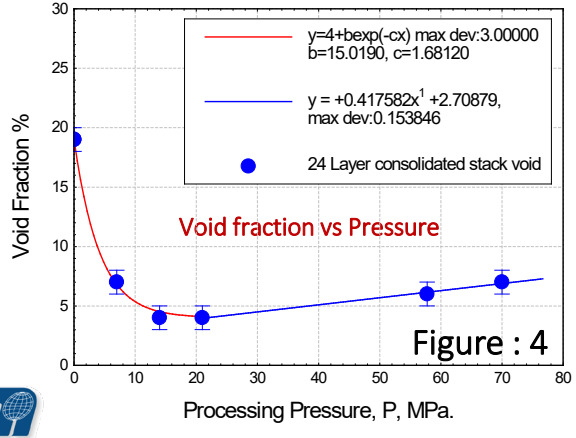
NOTE: [count of measurements]

- Percentage of the length occupied by all imprints on all the fibers in an image has been calculated and plotted as a function of consolidation pressure which shows a linear increase and it is 100% at 70 MPa
- The area percentage on the fiber surface inside a sheet that experience pressure is counted and found to increase as a function of consolidation pressure. 75 % of the total area experience pressure at 70 MPa

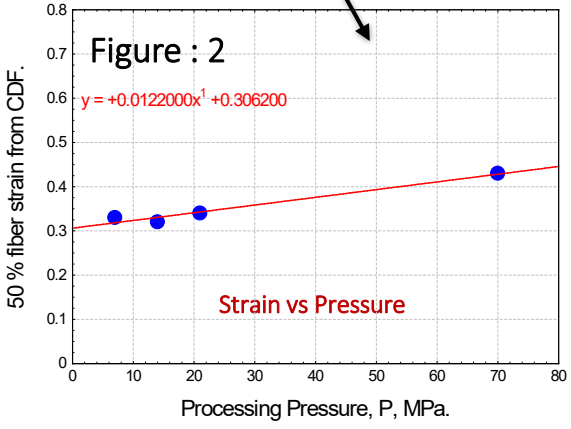


Determination of Sheet Strength Using Void fraction & Strain

UNIVERSITY OF DELAWARE
CENTER FOR COMPOSITE MATERIALS
Celebrating 50 Years



Residual Tensile Strength as a Function of Fiber Compressive Strain



Fiber Strain distribution @ different Processing Pressure

- Fiber strain has been calculated using the deformation geometry of the compressed fibers
- Figure:1 shows the strain distribution @ different processing pressure
- Figure : 2 uses 50% fiber strain from Figure : 1
- Figure : 3 uses UHMWPE fiber residual strength data from literature
- Figure : 2, Figure : 3, Figure : 4 have been used to calculate sheet tensile strength

	Fiber strength						
	at 50% failure probability			4800	Mpa

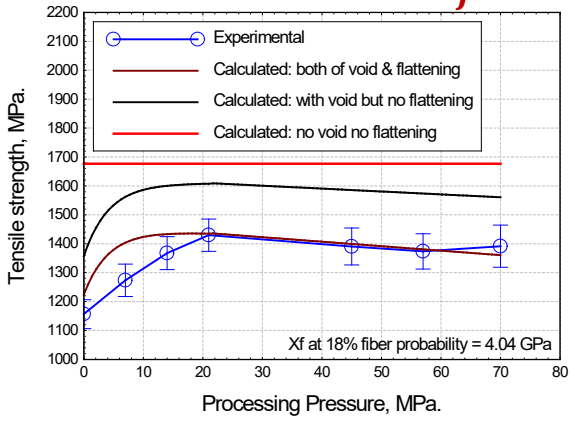
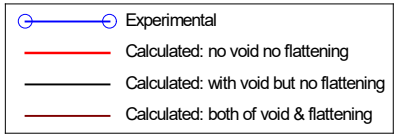
Sheet Tensile Strength @ % of Fiber Failure

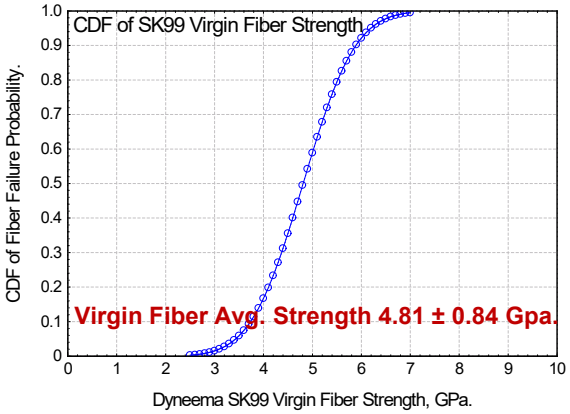
UNIVERSITY OF DELAWARE
CENTER FOR COMPOSITE MATERIALS
Celebrating 50 Years



$0.50*X_f$



$0.20*X_f$



$0.18*X_f$

- Sheet tensile strength has been calculated using different % of fiber failure probability

- Fiber failure strength at 18% failure probability estimates sheet strength matching to experimental data
- This indicates that 18% fibers failure initiates catastrophic failure in the sheet
- There could be other mechanism responsible for lower experimental strength at consolidation pressures less than 21 MPa

SUMMARY AND FUTURE WORKS

Summary & Conclusion:

- An Experimental methodology for tension test of Dyneema thin composites has been developed
- A lab-scale manufacturing technique has been developed to make Dyneema composites following the exact DSM provided thermal and pressure profile
- Void fraction as a function of consolidation has been determined
- Evolution of micro damage inside the sheet as a function of consolidation pressure has been studied
- A competing mechanism is found where tensile strength increases with increase in consolidation pressure due to void reduction and thickness reduction but it shows a reduction at higher pressure due to pressure induced damage like flattening, splitting, denting
- A correlation has been established to get UHMWPE sheet tensile strength using single fiber strength taking sheet void reduction and fiber compressive strain into account as a function of consolidation pressure
- Processing condition that guarantees higher void and thickness reduction without any pressure induced denting, flattening, splitting may increase tensile strength to some extent

ABSTRACT

This study investigates several strategies to improve the computational efficiency of numerical simulations aimed at predicting impact damage in woven fibre reinforced composites. Utilisation of homogenised ply-scale modelling, performed using a VUMAT user-defined material model, was justified for plain weave woven laminates. The commercial finite element software Abaqus/Explicit was used for progressive damage modelling in woven carbon fibre reinforced epoxy laminates. Along stress-based failure initiation criteria and energy-driven damage evolution, complete loss of load-bearing capability is captured by effective failure strain-based element removal, thus enabling the accurate assessment of full perforation energy margin. Validation of the numerical model was performed through impact simulations at two energy levels in which steel spherical impactors induce damage in composite plates made of plain weave CFRP with the layup $[45, 0, 45, 0, 45]_s$. The results have shown that in this study the homogenised approach has performed well, and that careful implementation of simplifications in the model leads to significant improvement in computational efficiency while retaining the accuracy level. Namely, a remarkable total time reduction of over 75 % was achieved from initial model. Thus, the final model is rendered much more suitable for practical, industrial purposes in which large structural components are examined.

1 INTRODUCTION

Utilization of composite materials in aeronautical, automotive, military and other major industry segments is well established. Due to many advantages, such as more balanced properties, enhanced impact resistance and improved ease of handling [1], woven carbon fibre reinforced plastic (CFRP) composites are seeing continuous increase in utilization in important structural elements. However, based on the available references, it can be concluded that woven CFRP materials are significantly less investigated compared to their unidirectional (UD) CFRP counterparts [2]. Thus, the uncertainties concerning the assumptions and simplifications introduced in modelling that are still existent even regarding the UD composites, are projected to the woven composites as well, and are perhaps even more pronounced.

Research studies focused on woven CFRP are usually performed at the microscale, e.g. [3], due to their complex microstructure. The microstructural geometry of these materials consists of interlaced and interconnected fibre bundles in warp and weft directions, potential voids, resin pockets or resin-rich zones and interfaces between fabric bundles and matrix. For the same reasons, micromechanical modelling of woven composites is significantly more challenging than that of UD composites [2]. The microscale approach enables capturing the behaviour of the micro-geometrical features of the woven material in the most accurate manner. However, this capability is accompanied with an enormous computational cost, deeming the micromechanical approach inapplicable for engineering problems. In

the microscale modelling approach, a single unit cell that would be represented by a single finite element in the homogenised approach, is discretized using many finite elements with explicit contact interactions between them. This level of detail dramatically increases the computational cost compared to the homogenised ply-scale approach.

However, despite capturing many microscopic features of woven fabrics, these detailed models still rely on certain assumptions and are subject to uncertainties—particularly concerning void content and the simplified representation of bonding between individual fibres and the matrix, as well as between fibre bundles and the matrix [2]. Additionally, the need to impose idealised boundary conditions introduces further sources of uncertainty in the analysis.

Multiscale methods enable application of micromechanical approaches in the engineering applications. However, these models contain algorithms that analyse the material at various scales and are thus even more complex. Furthermore, multiscale models for woven composites require calculations on some of the analysed regions to be performed multiple times, i.e., at different scales. Consequently, although multiscale approaches offer improved computational efficiency compared to microscale models, they are still too computationally demanding for engineering applications. This is particularly the case in transient dynamic analyses, where explicit finite element simulations require extremely small time increments.

In contrast, well-defined ply-level homogenisation approaches can simplify complex numerical simulations, offering considerably increased computational efficiency. The selection of the material segment used to construct a homogenised volume element (referred to as HVE in this work) can vary based on its size and location, allowing flexibility for different woven fabric architectures. The HVE strategy proposed in this work is based on the experimentally determined properties of woven composites. As the internal geometry of the fabric is not considered explicitly, the need for specifically defined boundary conditions is eliminated. Instead, the approach assumes that the finite element boundaries align with the interlacing regions of the woven fabric. The HVE discretisation approach is explained visually in Fig. 1. As shown, the possible HVEs in woven composites differ by the boundary conditions corresponding to neighbouring fibre bundle interlacings causing variances in stiffness and strengths. In finite element modelling, this variety can be reduced by limiting the average in-plane size of the finite elements employed to the width of a single fibre bundle or, alternatively, to a specified natural number of fibre bundles. Figure 1 presents the Plain Weave, 2x2 Twill and 4H Satin weave fabrics with various HVEs obtained by identifying different 1 x 1 (blue squares) and 2 x 2 (magenta squares) fibre bundle elements. For the clarity of the display, not all existing variants of 2 x 2 HVEs were marked on Figure 1 for the Twill and Harness Satin weaves.

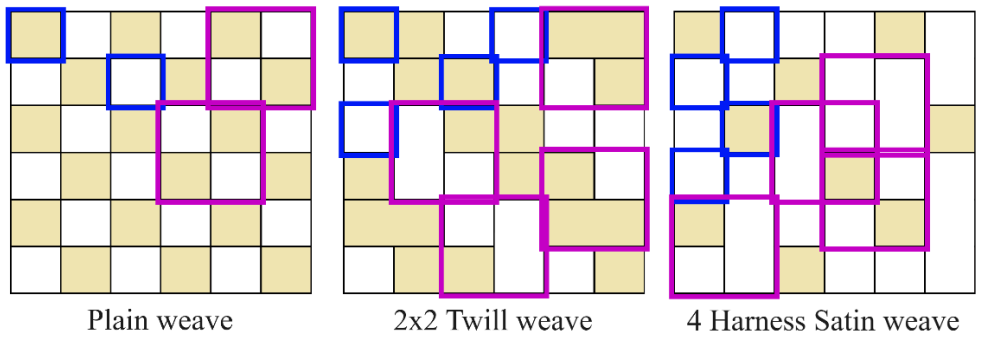

Figure 1. Various possible homogenised volume elements (HVEs) for Plain weave, 2x2 Twill weave and 4 Harness Satin weave woven fabrics: 1 x 1 (blue) and 2 x 2 (magenta) fibre bundle sized HVEs

By increasing the HVE dimensions, the numerical problems are simplified as the microstructural geometry is more homogeneous and the overall number of degrees of freedom is reduced. However, a compromise between accuracy and computational efficiency has to be made to simulate engineering problems. Even in the case of utilization of the smallest HVE (1 x 1 fibre bundle size), the computational efficiency of homogenized approaches is still superior compared to the micromechanical or multiscale approaches.

Despite having the most interlacings and thus potentially the highest quantities of resin-rich zones, resin pockets and voids – all of which reduce their strength, Plain weave fabrics have the most balanced properties when considering the HVEs of the material. Moreover, with the correct size of the homogenised finite element modelling, plain weave fabrics are the only fabric type that can be discretised by only a single variant of HVE. This is shown in Figure 1, in which for the Plain weave fabric two of all of the HVE sizes (1 x 1 and 2 x 2) are marked. However, their boundary conditions, number and position of interlacings in these sets of two HVEs are the same, hence rendering the same properties, with the assumption that warp and weft fibre bundles are equal.

Furthermore, various positions of the, e.g., 3 x 3 HVEs are obtainable. Of all of the possible HVEs in the Plain weave fabric, the only ideally balanced and homogenised, i.e. presumably orthotropic, are the ones that are perfectly cut along the fibre bundle boundaries and the ones cut exactly in the middle of warp and weft fibre bundles.

Clearly, it is impractical to try to fit the HVEs discretising the model to correspond to the exact positions of the fibre bundles in the real structure to be modelled. However, it is evident that the largest error, i.e., discrepancy, in the position between the utilized HVE and the closest one of the ideal cases is half of the width of the fibre bundle. Moreover, the larger the HVE, the less significant this error is. For example, for a 2 x 2 HVE, the maximum error in position is 25 % of the length of the homogenised element, whereas for the 5 x 5 HVE, the error is 10 % of the length of the homogenised element. Despite the large percentage of these errors defined in this manner, it is evident that it is practically negligible considering the overall length of the structure. For example, for a structure with a 100 mm length in the examined direction, considering a 1 mm fibre bundle width, for any chosen size of the HVE, this error in the shifting of the position of the HVEs is, at maximum, only 0.5 %.

In this study, the homogenised ply-scale approach is utilized, mainly for computational efficiency, as it is by far the most efficient approach and the only practical solution for applications in explicit dynamic analyses as elaborated previously. In the light of the aforementioned problems with homogenised ply-level discretization of woven fabric plies, to reduce uncertainties and retain physical meaningfulness of the model, application of this model is restricted to plain-weave woven fabric plies. Furthermore, the in-plane dimensions of the finite elements modelling the woven fabric composite structures are defined by and restricted to the width of the fibre bundles, thus rendering the approximately 1 x 1 x 0.21 mm solid finite elements.

2 METHODOLOGY

The material behaviour is assumed to be elastic orthotropic prior to any damage initiation. Additionally, for all three shear modes, a non-linear behaviour is modelled. Because of the assumed orthotropy of the material, shear behaviour is decoupled from normal behaviour, simplifying the implementation of shear non-linearity.

2.1 Shear Non-Linearity

Non-linearity is especially pronounced in the shear response of woven composites. This nonlinear behaviour is introduced according to the stress to strain relation proposed by Coles et al. [4]:

$$\tau_{ij} = S_{ij} \cdot \left[1 - \exp\left\{-\frac{G_{ij}^0 \cdot \gamma_{ij}}{S_{ij}}\right\}\right],\ i,j = 1,2,3, i \neq j. \quad (1)$$

In Eq. (1), S_{ij} is the shear strength, G_{ij}^0 is the shear modulus and γ_{ij} is the instantaneous engineering shear strain. The shear stress vs. shear strain plot obtained by the non-linear formulation provided in Eq. (1) for the values of shear strength $S_{ij} = 100$ MPa and shear modulus $G_{ij}^0 = 4$ GPa respectively, is shown in Figure 2.

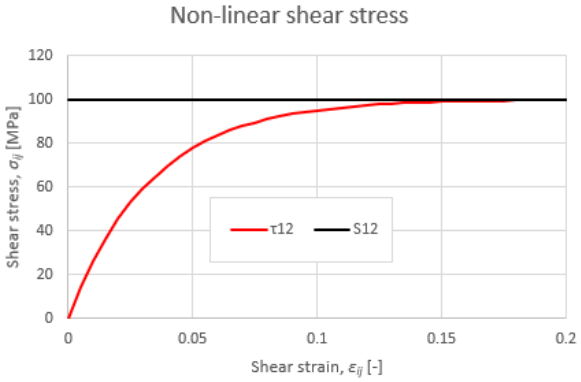

Figure 2. Non-linear shear behaviour: stress-strain plot

2.2 Failure criteria

The in-plane failure initiation corresponding to fibre rupture is modelled using the interactive stress criteria adopted from the study [4] for warp (FF1) and weft (FF2) direction in tensile (T) and compressive (C) loading conditions:

$$FF1T = \left(\frac{\sigma_{11}}{X_t}\right)^2 + \left(\frac{\tau_{12}}{S_{12}}\right)^2 + \left(\frac{\tau_{13}}{S_{13}}\right)^2 \geq 1, \tag{2}$$

$$FF1C = \left(\frac{\sigma_{11}}{X_c}\right)^2 + \left(\frac{\tau_{12}}{S_{12}}\right)^2 + \left(\frac{\tau_{13}}{S_{13}}\right)^2 \geq 1, \tag{3}$$

$$FF2T = \left(\frac{\sigma_{22}}{Y_t}\right)^2 + \left(\frac{\tau_{12}}{S_{23}}\right)^2 + \left(\frac{\tau_{23}}{S_{23}}\right)^2 \geq 1, \text{ and} \tag{4}$$

$$FF2C = \left(\frac{\sigma_{22}}{Y_c}\right)^2 + \left(\frac{\tau_{12}}{S_{23}}\right)^2 + \left(\frac{\tau_{23}}{S_{23}}\right)^2 \geq 1. \tag{5}$$

In Eqs. (2) - (5), σ_{11}, σ_{22}, τ_{12}, τ_{13} and τ_{23} are the stress components, whereas X_t, X_c, Y_t, Y_c are the warp and weft tensile and compressive strengths, respectively, while S_{12}, S_{13} and S_{23} are the shear strengths of the material.

Matrix micro-cracks forming and coalescing into larger cracks is exhibited by shear non-linear material behaviour, according to e.g. [5, 6]. Interactive quadratic stress criteria are used for evaluating intralaminar matrix tensile (MFT) and compressive (MFC) damage initiation. Matrix failure is defined using the through-thickness normal and all three shear stress components, while the failure mode is predicted based on the sign of the through-thickness stress:

$$MFT = \left(\frac{\sigma_{33}}{Z_t}\right)^2 + \left(\frac{\tau_{12}}{S_{12}}\right)^2 + \left(\frac{\tau_{13}}{S_{13}}\right)^2 + \left(\frac{\tau_{23}}{S_{23}}\right)^2 \geq 1, \tag{6}$$

$$MFC = \left(\frac{\sigma_{33}}{Z_c}\right)^2 + \left(\frac{\tau_{12}}{S_{12}}\right)^2 + \left(\frac{\tau_{13}}{S_{13}}\right)^2 + \left(\frac{\tau_{23}}{S_{23}}\right)^2 \geq 1. \tag{7}$$

2.3 Progressive Damage Evolution

Progressive damage evolution is modelled by the degradation of material stiffness through modification of the stiffness matrix. The damage variable d can be considered as an internal parameter describing the reduction of the load bearing material surface from the undamaged state to the current, instantaneous state, as proposed in the early studies by Murakami [7], Matzenmiller et al. [8] and Zako et al. [9]. The stress reduction related to material damage can be described by the following simplified general relation:

$$\sigma = (1 - d) \cdot \sigma' = (1 - d) \cdot \mathbf{C}\varepsilon = \mathbf{C}_d\varepsilon, \tag{8}$$

in which σ' is the nominal, undamaged stress vector determined by the Hooke's law from the undamaged stiffness matrix $\mathbf{C}$ and strain vector ε while assuming the orthotropic linear elasticity of the material. In

Eq. (8), the damaged stiffness matrix $\mathbf{C}_d$ has been introduced by combining the damage vector d consisting of warp direction d_{f1} and weft direction d_{f2} damage variable with the undamaged stiffness matrix $\mathbf{C}$. This can be expanded for the first three, i.e., normal, coupled components as:

$$\mathbf{C}_d^N = \frac{1}{\Delta}\begin{bmatrix} d_{f1}E_{11}(1-d_{f2}\nu_{23}\nu_{32}) & d_{f1}d_{f2}E_{11}(\nu_{21}+\nu_{23}\nu_{31}) & d_{f1}E_{11}(\nu_{31}+d_{f2}\nu_{21}\nu_{32}) \\ d_{f1}d_{f2}E_{11}(\nu_{12}+\nu_{32}\nu_{13}) & d_{f2}E_{22}(1-d_{f1}\nu_{13}\nu_{31}) & d_{f2}E_{22}(\nu_{32}+d_{f1}\nu_{12}\nu_{31}) \\ d_{f1}E_{11}(\nu_{13}+d_{f2}\nu_{12}\nu_{23}) & d_{f2}E_{22}(\nu_{23}+d_{f1}\nu_{21}\nu_{13}) & E_{33}(1-d_{f1}d_{f2}\nu_{12}\nu_{21}) \end{bmatrix}. \quad (9)$$

Damage in the shear components is modelled as:

$$\mathbf{C}_d^S = \frac{1}{\Delta}\begin{bmatrix} d_{f1}d_{f2}G_{12}^0\Delta & 0 & 0 \\ 0 & d_{f2}G_{23}^0\Delta & 0 \\ 0 & 0 & d_{f1}G_{31}^0\Delta \end{bmatrix}. \quad (10)$$

When damage is initiated, the initial, intact shear moduli G_{ij}^0 in the Eq. (1), should be replaced by the corresponding damaged stiffness matrix components introduced in Eq. (10). In the above equations, the remaining unintroduced variables are:

$$\begin{gathered} \Delta = 1 - d_{f1}d_{f2}\nu_{12}\nu_{21} - d_{f2}\nu_{23}\nu_{32} - d_{f1}\nu_{13}\nu_{31} - 2d_{f1}d_{f2}\nu_{12}\nu_{21}\nu_{21}, \\ d_{f1} = (1-d_{11}^t)(1-d_{11}^c), \text{ and} \\ d_{f2} = (1-d_{22}^t)(1-d_{22}^c). \end{gathered} \quad (11)$$

The parameters $d_{ii}^{t/c}$ in Eq. (11) are the four different damage variables. These variables, corresponding to fibre tensile and compressive (upper index t/c) damage in warp and weft directions (lower index ii) are calculated according to, e.g., [10], by the relation:

$$d_{ii}^{t/c} = \frac{\varepsilon_{ii}^f \cdot (\varepsilon_{ii} - \varepsilon_{ii}^0)}{\varepsilon_{ii} \cdot (\varepsilon_{ii}^f - \varepsilon_{ii}^0)}. \quad (12)$$

In Eq. (12), ε_{ii}^0 is the corresponding equivalent strain at failure initiation, ε_{ii} is the instantaneous equivalent strain value, while ε_{ii}^f is the strain value of total rapture. The total rapture strain is determined depending on the corresponding fracture energy Γ_{ii}, corresponding equivalent stress at the point of failure initiation according to the failure initiation criteria in Eqs. (2) – (5), σ_{eq}, and the characteristic finite element length as: $\varepsilon_{ii}^f = 2 \cdot \Gamma_{ii}/(\sigma_{\text{eq}} \cdot L_c)$. The characteristic finite element length is introduced to ensure mesh-objectivity in the strain softening constitutive behaviour.

The presented formulation is a modification and a combination of the approaches presented by Hu et al. [11] and Coles et al. in [4] that represents a reasonable and physically sound approach to the modelling of the materials stiffness degradation.

Element deletion due to damage is employed in certain specific conditions. A total loss of load bearing capability is considered to occur only if fibre laid in both in-plane directions (warp and weft) have undergone total rupture. Thus, the finite element is removed when either tensile or compressive damage variables in both warp ($d_{11}^{t/c}$) and weft ($d_{22}^{t/c}$) directions reach their maximum defined value, which is chosen to be 0.98 to avoid numerical problems associated with excessive distortion of degraded finite elements.

Furthermore, to prevent large distortions and unphysical deformations of degraded finite elements, as well as to capture the matrix failure, along with enabling the accurate simulation of perforation behaviour of the laminated structures, the effective failure strain (EFS) element removal criterion is implemented. This criterion is defined as:

$$\varepsilon_{\text{eff}} \leq \varepsilon_{\text{eff}}^{\max}, \quad (13)$$

where $\varepsilon_{\text{eff}}^{\max}$ is the semi-empirical material parameter, defining the maximum effective strain that a material point, i.e. single finite element with reduced integration could sustain, above which complete

material failure is expected. In the Eq. (13), effective strain ε_{eff} is calculated based on the deviatoric strain components e_{ij} as:

$$\varepsilon_{\text{eff}} = \sqrt{2 \cdot e_{ij}^2/3}. \tag{14}$$

The maximum effective strain $\varepsilon_{\text{eff}}^{\text{max}}$ is taken to be 0.3 in this study. This value is in similar to the values employed by other researchers, such as in [12], when using similar failure strain element removal criteria.

2.4 Interlaminar behaviour

Zero-thickness cohesive finite elements (COH3D8) were used to model the ply interfaces. To capture delamination phenomena, the Abaqus built-in decoupled traction-separation cohesive material model was used in this study. The model employs quadratic traction failure initiation criterion, and the B-K energy driven delamination propagation, with the B-K factor set to η = 2. Furthermore, the interface stiffness parameters were estimated according to the relationship suggested in [13]: $K_{nn} = E_{33}/h_0$, $K_{ss} = G_{13}/h_0$ and $K_{tt} = G_{23}/h_0$, where E_{33}, G_{13} and G_{23} are the matrix material elastic properties, and h_0 is the assumed thickness of the interface. As proposed in [13, 14] the interface thickness h_0 can be taken as 1/10 of the thickness of the ply.

Cohesive element removal was set when the damage variable reaches the value of 0.98 for stability reasons.

3 NUMERICAL MODEL

Numerical simulations of the impact experiments in [14] have been used in this study to validate the model. Thus, a 12.7 mm diameter spherical steel impactor with the total falling mass of the drop weight apparatus equal to 1.573 kg was simulated to impact the plain weave woven CFRP plates. Simulations of two impact energies (16 J and 28 J) were performed.

Several FE modelling strategies were investigated. The rectangular plate with the dimensions 100 x 150 mm has been modelled with solid (C3D8R) elements in Abaqus. The layup is $[45, 0, 45, 0, 45]_s$ layup, resulting in the 2.1 mm total thickness. A single finite element has been employed in the thickness direction for each composite ply. Thus the numerical model consists of a total of 150,000 C3D8R finite elements. At all interfaces of the composite plies a total of 135,000 zero-thickness cohesive COH3D8 finite elements were utilized for delamination modelling. Results obtained using this modelling strategy are further denoted as “Full” simulation results.

The plate is simply supported along all edges at its backside. The steel impactor was modelled as a discretely rigid body, and all of its degrees of freedom were constrained, except for the vertical movement. General contact algorithm was employed with hard normal and tangential contact with a defined penalty frictional coefficient of 0.3. The model is schematically represented in Figure 3.

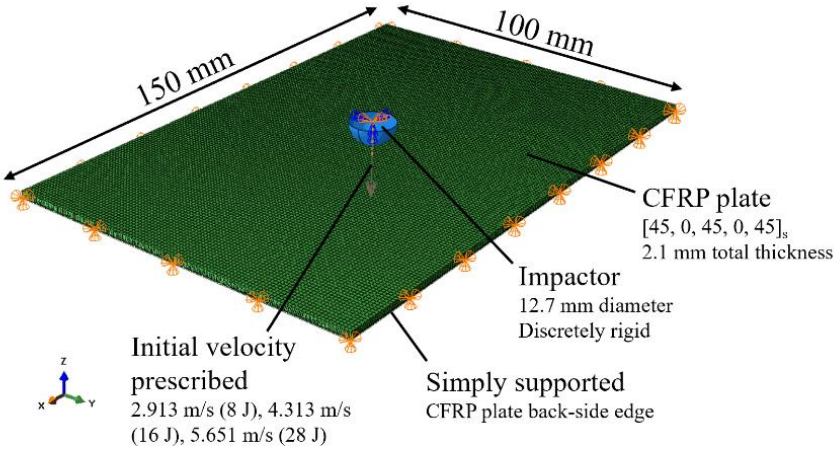

Figure 3. Numerical model with boundary conditions and loading

The mechanical intralaminar and interlaminar properties were taken from [14], and the already mentioned related study [13] of the same research group. All of the necessary intralaminar stiffness constants, strengths and fracture energies are listed in Tables 1, 2 and 3, respectively.

Table 1. Intralaminar elastic properties of the plain weave CFRP ply

property	E_1	E_2	E_3	G_{12}	$G_{13} = G_{23}$	ν_{12}	$\nu_{13} = \nu_{23}$
unit	[GPa]	[GPa]	[GPa]	[GPa]	[GPa]	[-]	[-]
reference	[14]	[14]	[14]	[14]	[13]	[14]	[4]*
value	60.8	58.25	2.97	4.55	1.08	0.07	0.35

* Value calculated based on the value in [4], according to the ratio of η_{12} values from [14] and [4]

Table 2. Intralaminar strengths of the plain weave CFRP ply, taken from [14]

property	X_t	X_c	Y_t	Y_c	S_{12}	$S_{13} = S_{23}$
unit	[MPa]	[MPa]	[MPa]	[MPa]	[MPa]	[MPa]
value	621	760	594	707	125	150

Table 3. Intralaminar fracture energies of the plain weave CFRP ply, taken from [14]

property	G_{ft}	G_{fc}	G_{mt}	G_{mc}	G_{sh}
unit	[kJ/m^2]	[kJ/m^2]	[kJ/m^2]	[kJ/m^2]	[kJ/m^2]
value	75	25	2.5	2.5	2.25

The interlaminar fictitious penalty stiffness constants are K_I = 141430 N/mm^3, K_{II} = 216670 N/mm^3 and K_{III} = 514290 N/mm^3, based on the values of shear moduli reported in [13]. The remaining interlaminar model properties are taken directly from [14] and are as follows: N = 75 MPa, S_{II} = 125 MPa, S_{III} = 150 MPa, G_I = 0.6 kJ/m^2, G_{II} = 5.5 kJ/m^2, G_{III} = 5.5 kJ/m^2.

To investigate the effect of the employed cohesive elements on the computational efficiency, a modelling strategy without cohesive elements at the ply interfaces was performed. Consequently, this model consists only of the solid finite elements of the composite plies, without the ability to simulate the delamination failure mode. The results obtained by this simulation type are remarked as the "Bulk" simulation results.

The next modelling strategy consists of a hybrid approach that was tested for increasing the computational efficiency while retaining the capability to accurately assess both intralaminar and interlaminar damage. In this model, the VUMAT user-defined material is employed only on the central 50 x 50 mm part of the composite plate, whereas on the remaining, outer portion of the plate, the Abaqus built-in orthotropic material with the same elastic properties was employed. Furthermore, the cohesive interface model with zero-thickness cohesive finite elements was included only on the central 50 x 50 mm portion of the plate as well. Hence, the outer part of the plate is incapable of assessing any failure and damage mode. This model is in the Results section denoted as "Hybrid" simulation model and results.

Figure 4 schematically presents the employed meshing strategy in the transition zone from the outer composite plate area (Abaqus built-in orthotropic material model without damage) to the inner area of specific interest (VUMAT material model + cohesive zone for delamination) for impact analyses.

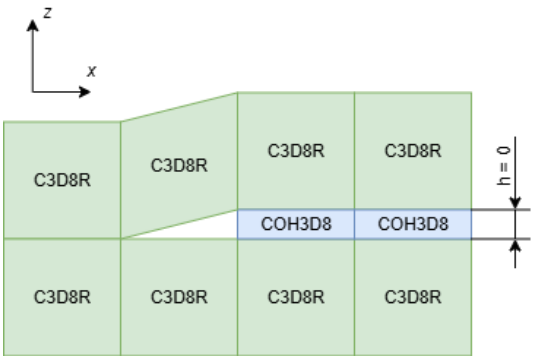

Figure 4. Meshing strategy in the transition zone from outer to inner plate area

All simulations were performed on a desktop workstation using 22 2.2 GHz processors. The details on the finite element meshes for the three simulation modelling approaches are summarized in Table 4.

Table 4. Details of the finite element meshes for different modelling approaches

	"Full"	"Bulk"	"Hybrid"
Total number of nodes, [-]	305,020	167,761	191,170
Total number of elements, [-]	285,000	150,000	172,500
VUMAT elements, [-]	150,000	150,000	25,000
Cohesive elements, [-]	135,000	0	22,500

4 RESULTS

Figure 5 shows the comparison of numerical to experimental impactor displacement history and contact force history for the impact energy of 16 J. Both graphs contain results obtained by employing the presented three modelling approaches, namely: "Full", "Bulk" and "Hybrid".

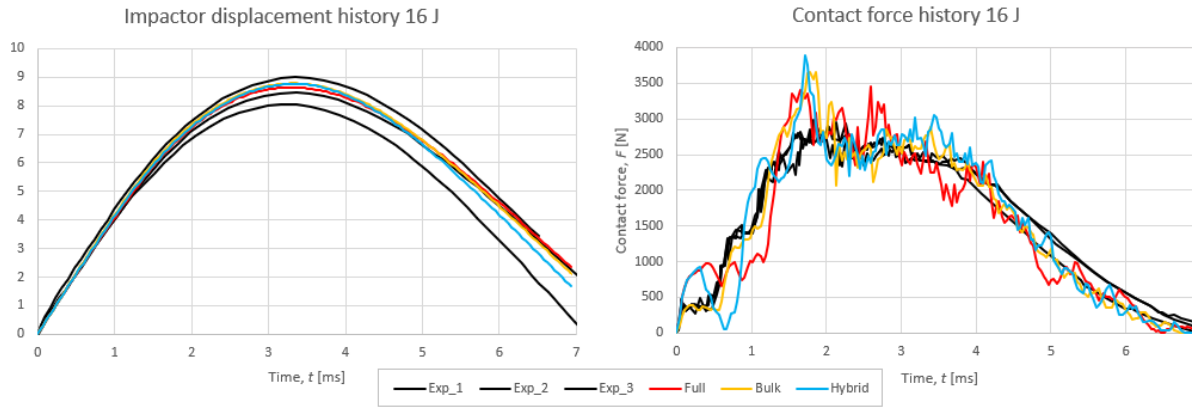

Figure 5. Comparison of numerical to experimental results [14] for the 16 J impact: contact force and impactor displacement

The results in Figure 5 indicate that, overall, the simulation results correspond well with the experimental data in both plots. A more pronounced difference is observed in the contact force history, where all three models similarly overestimate its magnitude. This tendency to overpredict the contact force may be related to an underestimation of the plate's final absorbed energy and additional investigation will have to be performed to identify the source. Additionally, the lower predicted absorbed energy could result from insufficient estimation of interlaminar damage, which will be examined in the continuation of this work. The overall slope of the numerical curves matches the experimental curve slope reasonably well. The contact force history graph shows that the "Bulk" simulation results align more closely with the experimental data. Contrarily, the simulations incorporating cohesive elements

("Full" and "Hybrid" models) show oscillatory behaviour. Additionally, the oscillation frequency is higher in the "Hybrid" simulation. This is likely related to the smaller area covered by cohesive elements in that case, which reduces the time needed for stress waves to reflect from the boundaries of the delamination modelling region. Figure 6 shows a comparison between experimental and numerical delamination areas for the two investigated impact energies. The red outlines (profiles) were derived from C-scan images presented in [14], while the orange and blue regions indicate the areas where cohesive elements were completely removed in the "Full" and "Hybrid" simulations. In the lower part of the figure, the green and purple regions correspond to solid intralaminar elements exhibiting tensile or compressive matrix damage in the "Full" and "Hybrid" models.

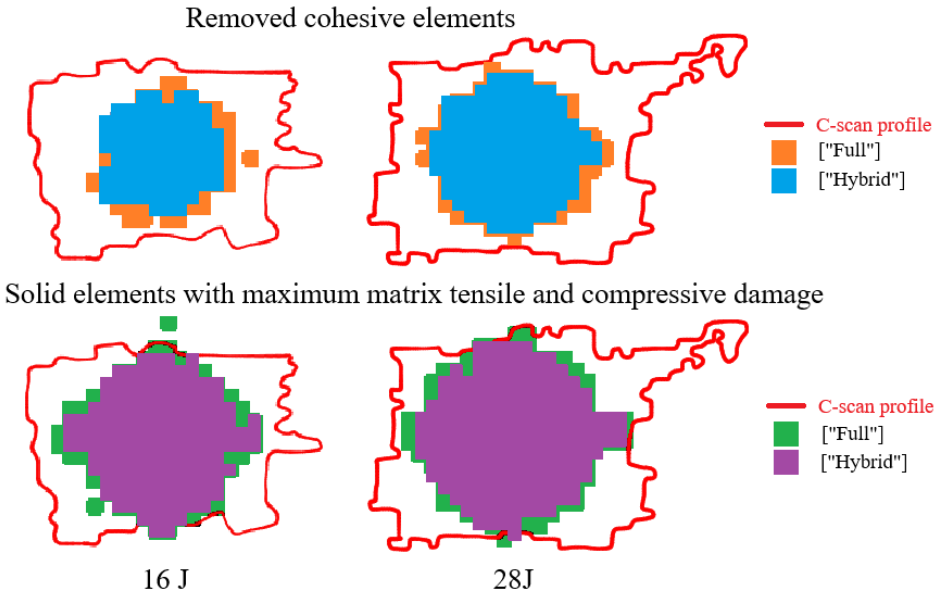

Figure 6. Comparisons of "Full" and "Hybrid" simulations' numerically and experimentally [14] obtained delamination areas for impacts of 16 J and 28 J

Figure 6 shows that the simulated delamination areas are smaller compared to the experimental results. Furthermore, the comparison indicates that including elements with matrix damage (tensile or compressive) leads to a better match with experimental results. As discussed in [15] and [16], increasing load causes matrix micro-cracks to merge into larger intralaminar cracks. When such a crack extends to the ply boundaries (interfaces between the plies) it leads to initiation and growth of delamination, explaining the motivation for the comparison presented in Figure 6. From the perspective of the experimental findings in the existing studies such as [15, 16] and their confirmation from Figure 6, it seems that the phenomenological approach of connecting the interlaminar damage initiation to the propagation of intralaminar matrix damage in the adjacent plies could lead to improved overall delamination extent predictions. This is one of the main objectives of the authors' current effort to develop a joint, combined VUMAT for both intralaminar and interlaminar composite progressive damage modelling.

For the computationally efficient "Hybrid" simulation, the discrepancy between numerical and experimental area in Figure 6 is barely larger than the one found in the comprehensive "Full" simulation model in which both intralaminar and interlaminar damage assessment is available for the whole volume of the composite plate. For the 16 J and 28 J impact cases, the "Hybrid" simulations' results predict slightly lower extent of interlaminar damage compared to the "Full" simulations.

Finally, Table 5 summarizes the computational times for both investigated impact energy levels using all three simulation models, along with the corresponding percentages in reduction.

Table 5. Summary of all computational times - all three simulation strategies employed at both impact energies

	Time analysed, [ms]	"Full", [min]	"Bulk", [min]	Reduction from "Full", [%]	"Hybrid", [min]	Reduction from "Full", [%]
16 J	7	2893	424	85.34	604	79.12
28 J	4	1882	404	78.53	410	78.21

From Table 5, it is clear that a significant increase in computational efficiency is achieved by both strategies: I) removing the interlaminar damage modelling from the model in "Bulk" simulations and II) reducing the zone of interest of the composite plate in which both intralaminar and interlaminar damage evaluation is available only to the central region of the composite plate in "Hybrid" simulations. It is visible that the reduction of computational time is constant in the case of "Hybrid" simulations.

On the other hand, different time savings were achieved by employing the "Bulk" simulations. These differences are attributed to different numbers of semi-detached cohesive finite elements which do not constructively contribute to the analysis model but deteriorate the stable time increment (STI). These highly distorted elements are a byproduct of removal of adjacent intralaminar solid elements of the plies above and below the interface. Because some of their nodes are free-floating, these semi-detached elements do not bear any load and thus could not be effectively removed from the simulation by reaching the maximum defined load driven, i.e., displacement driven damage variable value. The number of semi-detached cohesive finite elements is a function of, among other factors, the intensity of loading conditions and subsequent rate of removal of adjacent intralaminar solid finite elements.

Hence, it is expected that further improvements in the computational efficiency could be achieved by effectively removing any semi-detached cohesive elements from the simulation. This is another objective of the aforementioned key future agenda goal – development of the joint VUMAT user-defined material that is constituted of both intralaminar and interlaminar progressive damage material models.

9 CONCLUSIONS

In this study, several FE modelling strategies have been investigated in the impact damage simulations in woven CFRP structures. Validation of the numerical model and the investigated modelling strategies was performed using experimental results of impact damage. The investigation is focused on plain weave woven architectures.

The numerical results overall demonstrated good agreement with experimental data for the simulated impact energies. Application of the VUMAT material model and interlaminar damage modelling to the central interior region of the plate ("Hybrid" simulations), it was possible to maintain satisfactory accuracy of the simulations at significantly lower computational time. However, this approach requires careful application, particularly regarding the accurate definition of the zone of interest or the anticipated damage region. A preliminary, faster simulation without interface modelling, e.g. using the "Bulk" simulations used in this work, can help identifying the likely extent of intralaminar damage before performing the detailed analysis.

The presented results are part of an ongoing investigation aimed at developing accurate numerical models for impact simulations in engineering problems As stated throughout the Results section, future work will be focused on integrating the user-defined material behaviour of the plies and ply interfaces into a single VUMAT subroutine, which is considered to be a direction for further improvements in both accuracy and computational efficiency. Furthermore, as the constitutive model of the cohesive models will be user-defined, strain rate effects will be included in the subsequent models to additionally improve accuracy in the impact damage prediction.

ABSTRACT

Numerical modelling of nonlinear behavior in composites represents a significant computational challenge, which this paper seeks to address. We are developing a family of numerical methods capable of efficiently and accurately solving general nonlinear multiscale problems. The essential components of the method are described along with possible future variations. The results of a preliminary implementation of the basic method are shown for simple linear and nonlinear elasticity. These demonstrate the capability of this approach to produce fine scale results in a scalable fashion.

1 INTRODUCTION

All engineered structures exhibit structural variation across length scales. Material structures at small length scales lead to emergent responses at larger length scales, which complicates modeling the behavior of a material without experimentally testing the response at the relevant length scale. Composite materials exacerbate this challenge by extending the range of possible variation due to the multiple constituents, which simultaneously offers many potential advantages for material design. The phenomenon of progressive failure introduces additional unique challenges as failure modes at small scales eventually coalescence to form a dominant crack at a larger length scale, bridging length scales as failure evolves. These challenges have motived significant effort towards the development of multiscale modeling methods that each aim to strike a particular balance between computational efficiency, which favors modeling at coarser scales, and accuracy, which favors modeling at finer scales.

One collection of popular approaches are the various homogenization and homogenization-adjacent methods, which tend toward computational efficiency over local fine scale accuracy. While these can vary in the details, from asymptotic perturbation approaches [1] to variational techniques [2] to other simplifying assumptions [3, 4], the underlying principle is that the microstructure has sufficient regularity, typically periodic or statistically periodic, that one can consider a small number of local microscale problems, which are generally regarded as infinitesimal compared to the macroscopic domain. Regardless of the specific method, the responses from these microscale problems are then used to determine effective macroscopic properties, with each local problem contributing to the properties of a specific subset of the domain. These models are effective within the assumptions about periodicity and scale separation, such as in a unidirectional fiber composite sheet under loads well within the elastic regime. They can even accommodate moderate deviations from these assumptions, and with further model complexity, their applicability can be extended [1, 3, 5]. However, their effectiveness significantly diminishes when these fundamental assumptions are entirely violated. This limitation is particularly evident in phenomena like discrete fracture, where highly localized fine-scale details and their macroscopic effects pose a significant challenge for homogenization methods.

On the other side of the spectrum are methods which still produce a global fine scale solution but use various techniques to try to accelerate that solution over just directly solving on a global fine mesh. These techniques include domain decomposition [6, 7], multigrid methods [8, 9], and the MsFEM approach [10, 11, 12]. In the first, subdomain problems are alternated with the global problem, while in the second, coarser representations of the problem are alternated with the fine scale representation. In

Distribution Statement A. Approved for public release: distribution is unlimited. Case number: AFRL-2025-3173

both cases, the goal is to save effort on the global fine problem, making progress with other, faster alternatives and somehow incorporating that progress into the global fine solution. The third case does not alternate but instead produces a full set of multiscale basis functions on a relatively coarse grid, which are determined using local solutions on a much finer grid. This frontloads a large amount of effort on a finer grid, but the later solution process involves much fewer degrees of freedom (DoFs), despite a solution with nominally fine grid resolution. While there are technical difficulties that must be addressed in all these cases, especially around discontinuities and nonlinearity, and these methods will in general require more effort than a homogenizing approach, the fact that these methods produce a global fine solution is appealing for complex geometries where the fine detail of the stress and strain is potentially critical anywhere in the component.

A third class of methods are global-local methods, which in some sense combine features of the previous two classes. For much of the domain, a relatively coarse, typically homogenized, method is applied, while at specific regions of interest, typically geometric features like corners and holes which induce stress concentration, a much finer method, possibly just a direct solve on a fully resolved grid, is used [13]. This is feasible as it involves only a smaller portion of the domain. The fine scale solve is then incorporated into the global domain, involving additive error correction, basis enrichment [14] (similar to MsFEM but with a specific solution rather than a general fine basis), or a connection between the fine and coarse solutions through boundary conditions along the fine-coarse boundary. The key to these methods is generally that the fine scale problem is only tackled on small portions of the domain, and hence the effort is minimized while still producing fine detail at the regions of interest.

However, as geometries and microstructures grow both more complex and defy length scale separation, it becomes difficult to determine the location of critical stress concentrations *a priori*. In the most challenging cases, stress concentrations and eventually fracture initiation can form across much of the domain, rendering the traditional global-local ideas irrelevant. In this paper, we describe a method which is applicable to fracture in complex aperiodic geometries, requiring the capability to produce a solution at the finest scale. The method presented combines concepts from multigrid techniques and global-local methods to produce a method that is adapted for efficiency in nonlinear problems and flexibility for a variety of material models.

2 METHODOLOGY

Our proposed method broadly takes the structure of a multigrid method, with the displacement field solved on a hierarchy of meshes of different characteristic sizes, and with corrections passed between them. Nonlinearity is addressed primarily by formulating the coarse grid correction in terms of the Full Approximation Scheme (FAS), in which the right-hand side of the coarsened equations receives a correction term relative to just the coarsening of the original right-hand side. Briefly, given a fine displacement field at iteration n, u_n^f, with residual function r^f, the coarse problem to solve is $r^c(u^c) = r^c\left(P\, u_n^f\right) - P\, r^f(u_n^f)$, where r^c is a suitably defined coarse residual and P is the matrix that maps from a vector on the fine mesh to the corresponding vector on the coarse mesh. The FAS correction is the two terms on the right side, rather than just solving $r^c(u^c) = 0$. Approximately solving this coarser problem hopefully smooths the longer wavelength error components, and the result is used to correct the fine problem, with $u_{n+1}^f = u_n^f + Q(u^c - Pu_n^f)$ where Q is the matrix which maps a coarse vector to its corresponding fine vector. The definitions of r^c, P, Q are what characterize the specific multigrid approach and are discussed below, with particular focus on ensuring that the computational cost of r^c scales appropriately with the mesh size for a nonlinear problem.

The primary distinguishing feature in our approach is the extensive incorporation of operations on an overlapping set of patches covering the domain into the operators r^c, P, and Q. By performing patch-local operations, and blending the results across the overlap regions, globally consistent fields can be obtained without needing to handle globally sized arrays, while also easing parallelism of the method. It also should allow for some degree of adaptivity in the future, where computation is only required for patches where nonlinearity is evolving while leaving the remaining patches unmodified.

Distribution Statement A. Approved for public release: distribution is unlimited. Case number: AFRL-2025-3173

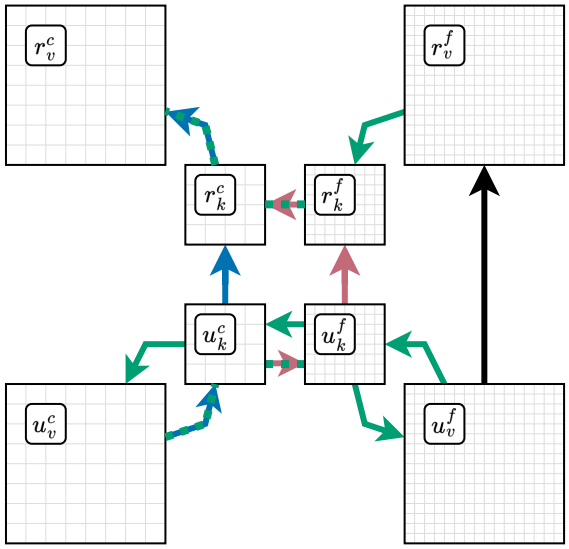

Figure 1: Schematic showing the functional links between patch and global meshes (large and small squares), coarse and fine meshes (left and right sides), and displacements and residuals (bottom and top squares). Blue and red arrows indicate chains of functions over which are autodifferentiated. Green arrows (or arrows with green dashes) are the functions which are composed into the global coarsening and refining maps.

In order to work effectively with unstructured meshes at each scale, none of which necessarily nest with each other, we define our grid transfer operations in terms of L^2 projections between the Finite Element spaces on the respective meshes. Such non-nested meshes greatly increase flexibility in mesh generation while still allowing for each mesh to conform to the features which are present at that scale, so it was important to be able to handle them. However, since a projection defined on the entire domain would quickly become computationally intractable, involving the inversion of a fine-mesh-sized mass matrix $M_{ij}^f = \int \phi^i \phi^j dV$, we instead use projections restricted to the aforementioned patches, which collectively cover the entire domain. The resulting patch projections can then be smoothly blended into a global result. The diagonal and horizontal arrows in green in Figure 1 illustrate the component operations of the overall P and Q (right to left and left to right respectively): splitting from a global array to a collection of patch arrays, projecting the patch arrays, and reassembling the patch arrays into a single global array. Note that we omitted any arrows for refining of the residual, as that is not something required in multigrid. One factor that must be kept in mind with non-nested meshes is the potential for issues along the boundary. When a coarse element barely intersects the fine domain, projection of the "ghost" nodes outside the domain will be poorly conditioned. We are continuing to explore more rigorous bounds on when this ill-conditioning will prevent or impair convergence, but provided the grids are chosen appropriately, it can be mitigated.

The remaining operator to define is the coarse residual. Since for nonlinear problems, the constant re-evaluation of a Galerkin coarse residual $r_g^c(\cdot) = P\, r^f(Q\,\cdot)$ is as expensive as re-evaluating the fine residual itself, even slightly more expensive with the projections, we required a faster approximation. Note that there is no such issue for linear problems, as the coarse matrix can be evaluated once, with subsequent matrix-vector products only involving coarse-mesh-sized arrays. The key is a residual which does not directly invoke the fine problem, and its fine-mesh-sized operations. Our solution was to locally expand this residual as a Taylor series around the current reference displacement, then store the first couple of Taylor coefficient arrays instead. These can be used for a few iterations of nonlinear smoothing, converging towards the zero of the truncated residual, before moving the solver iterations to another scale, eventually returning with an improved reference displacement about which to recompute the coefficient arrays. This still provides meaningful progress towards the exact solution, at a much lower computational cost, before moving to the next scale. Note that the general principle of a multigrid method is that at each scale a portion of the error is smoothed, and the progress is passed either up or down to smooth a different portion of the error. As the reference displacement converges towards the solution, the accuracy of the root of this truncated residual improves, and hence we can still attain similar

Distribution Statement A. Approved for public release: distribution is unlimited. Case number: AFRL-2025-3173

accuracy to the case where we had used the Galerkin residual throughout the process.

A further improvement in speed is possible by performing the Taylor expansion on individual patches and blending the resulting patch residuals into a global residual. While this introduces inaccuracy along the patch boundary nodes, by applying the blending weights to these patch residuals at the fine scale before projecting back, in the "Patch Galerkin" residual whose derivatives are being examined, the resulting errant nodes receive a weight of zero, so accuracy is comparable to the globally computed coefficients. Additionally, the global Jacobian in this approach, while never explicitly formed due to the use of matrix-free global solvers, is markedly sparser due to the coupling of nodes only within patches and more amenable to parallelization. Figure 1 illustrates this patch-wise Taylor coefficient breakdown, with coefficients computed based on the derivatives along the red path and then used for residual evaluation along the blue path. Currently, we are leveraging the automatic differentiation abilities of the JAX library both to automatically compute and cache the derivatives along the red path, as well as to obtain Jacobian-vector products along the blue path for use in a matrix-free solver.

While effort on the coarse mesh dramatically reduces the effort required on the fine mesh, the final component of our proposed method addresses the fact that a multigrid method benefits from smoothing the fine error on the fine mesh. Operating on the entire fine domain is not cheap, but working on each patch independently at the fine scale will in general require less effort, since it scales linearly with the number of patches. Importantly, when applying a smoother at the fine scale, the solution on a patch will likely be inaccurate near the patch boundary, since the solution is fixed based on the solution projected from the coarse scale to ensure well-posedness. However, since the various patch results are blended to obtain the global fine solution, where the edges of each patch receive blending weights of zero, these inaccurate values along patch boundaries contribute little to the resulting fine-scale displacement field. Moreover, by cycling between patch-level iterations at the fine scale and iterative corrections at the coarse scale, according to the principle of multigrid methods, the solution along the boundary of patches at the fine scale improve with each cycle. We will show in the next section that such a cyclic approach can achieve errors well below that of just the coarse grid, while not yet as accurate as a global fine solution. The technique is partly inspired by the GFEM^{gl} technique of Duarte et al [15, 14], although that method was applied only to specific subsets of the domain and incorporated the fine information as a basis enrichment rather than a multigrid correction.

The approach laid out above forms the foundation for a family of patch-based multigrid approaches that we foresee exploring in the future. We could more directly adapt the GFEM^{gl} approach by using the patch solutions as basis enrichment functions. The method could be made at least partly adaptive, with fine scale computational effort only done on those patches in which the coarse solution changed by some threshold. The approach also opens many questions, such as the choice of which scales to act on patch-wise and which to handle as a single global domain or decisions about tradeoffs around the number of iterations on each scale. We will explore these questions and more variations in the future as the general technique is applied to larger, more complex problems.

3 RESULTS

The current implementation of proposed method has not been optimized, so the discussion here will focus on the error convergence performance both on a per-iteration and limiting basis, but we expect that effort on the coarse scale will reduce fine scale effort such that the total time is reduced. This should especially be true as the problem begins to scale up, which given the lack of optimization is not something that has been done at this point. For a rough idea, in the nonlinear sample problem below both the fine scale smoothing across all patches and solving the global coarse problem using already-computed Taylor coefficients took on the order of 30ms, while a global fine scale solution took on the order of 2 seconds. Computing the coefficients is currently the bottleneck, taking multiple seconds as well. However, these times are based on a single CPU, whereas the eventual plan is to work on GPUs, which is straightforward in JAX and which will greatly improve the efficiency of the autodifferentiation. It should also be emphasized that coefficient computation time scales primarily with patch size, which can be fixed independent of problem size, whereas the time for a direct fine scale solve scales with domain size.

The following examples consider an elastic body with nonuniform material properties. Body force

Distribution Statement A. Approved for public release: distribution is unlimited. Case number: AFRL-2025-3173

and boundary conditions were imposed to produce a known non-constant solution, and the displacement field was initialized to a zero solution on both the fine and coarse scales. The fine mesh was composed of 1054 linear triangle elements tiling a rhomboid shape, while the coarse mesh was a structured grid of 113 regular quadrilateral elements that covers the fine domain. The meshes were divided into 9 overlapping patches in a 3 by 3 layout. Figure 2 shows the global meshes on the left, with the overlapping bands highlighted in green. On the right, both meshes are split out onto individual patches, illustrating the boundary mismatch between the two.

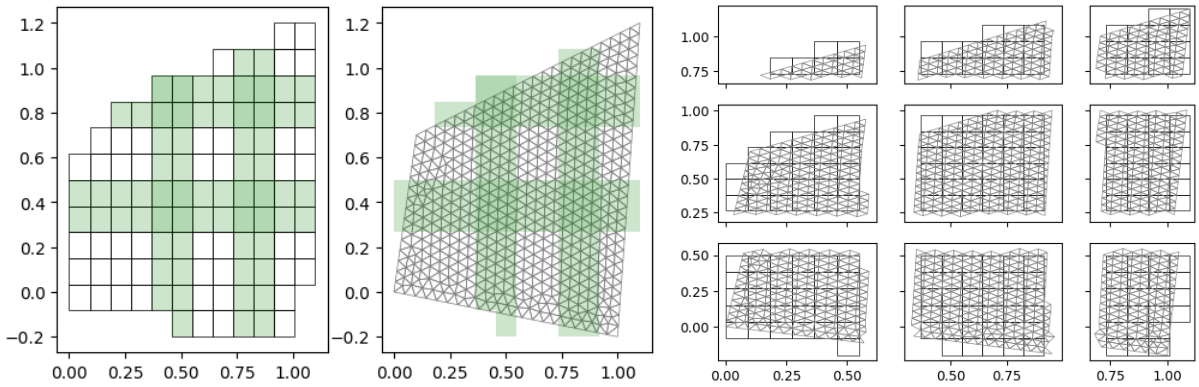

Figure 2: Trial problem mesh structure for coarse (left) and fine (middle) meshes. Green bands denote the overlap regions between neighboring patches. Individual patches are shown on the right.

Dirichlet boundary conditions were enforced directly in the residual function through the Taylor coefficients, and consequently, the coarse mesh received no explicit boundary conditions. However, boundary conditions were explicitly imposed on the fine solution after every fine update. Figure 3 shows the magnitude of the constructed exact solution used in the following problems alongside its coarse projection.

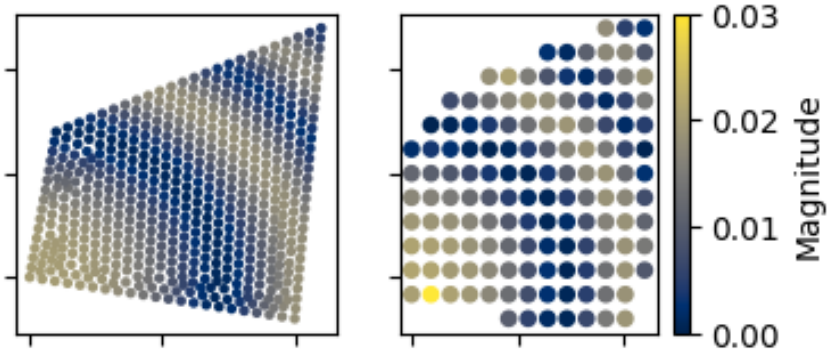

Figure 3 Manufactured fine grid solution (left) and the patch-wise projection onto the coarser grid (right) using the patches shown in Figure 2

3.1 Solving Exclusively on the Coarse Mesh

Figure 3 shows the evolution of the L^2 error of a linear elastic and geometrically nonlinear elastic problem solved only on the coarser grid, with the only fine mesh action being implicit in the re-computing of Taylor coefficients periodically. Each odd tick on the x-axis corresponds to a global solve on the coarse mesh. For the nonlinear case, that involved four Newton iterations using one set of Taylor coefficients, while for the linear case a single use of a direct solver suffices. In both cases, the required linear system solves were done to machine precision. Each even tick on the x-axis denotes an update of the Taylor coefficients, which in the linear case amounts to changing the right-hand side of the FAS equation since the higher order coefficients are constant.

Distribution Statement A. Approved for public release: distribution is unlimited. Case number: AFRL-2025-3173

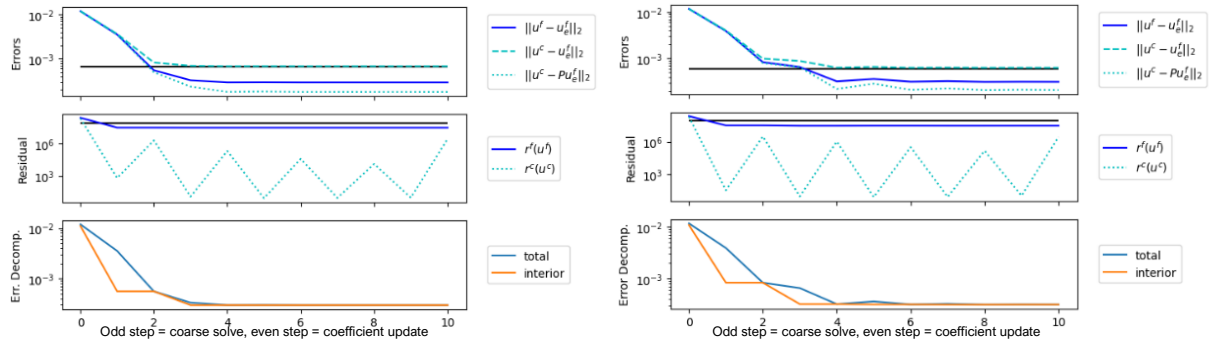

Figure 4: Error and residual convergence for linear (left) and nonlinear (right) elastic materials, alternating coarse iterations with coefficient updates.

The horizontal line in black for the error indicates the "coarsening error", that is $\left\|Pu_{ex}^{f} - u_{ex}^{f}\right\|_2$. Since in a multigrid FAS cycle, the coarse solution will converge to Pu_{ex}^{f}, this is in some sense the best case for the coarse solution, and indeed the error of the coarse solution against the fine bottoms out there. However, even though we are at no point solving the fine problem, just using these coarse updates and imposing the Dirichlet conditions is sufficient to produce a fine solution that is slightly more accurate. This is further illustrated by the first few pairs of steps in the third plot, which separates the error specifically on interior nodes. It should also be pointed out that the coarse residual is not actually oscillating between multiple orders of magnitude. Since each even step updates the coefficients, we are using a new, theoretically more accurate, residual function on the same coarse displacement, and thus seeing some of the remaining error in the coarse solution.

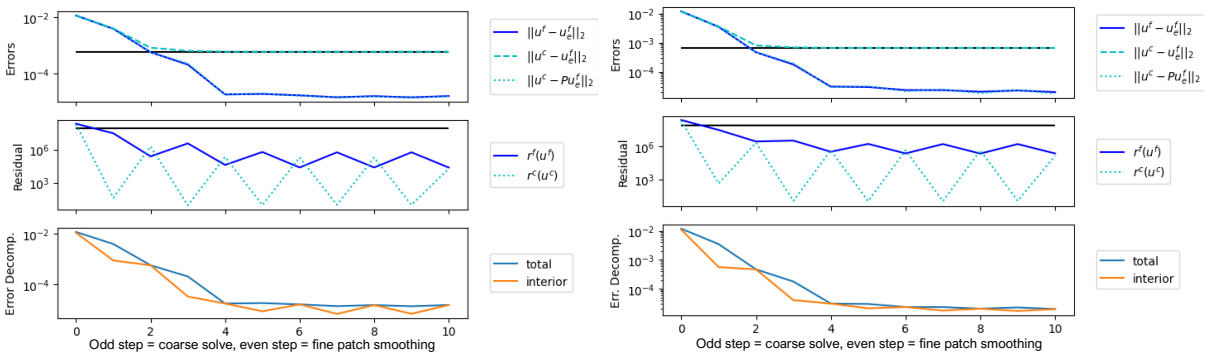

Figure 5: Error and residual convergence for linear (left) and nonlinear (right) elastic materials, alternating coarse iterations with fine patch iterations.

3.2 Incorporating a Smoother on Fine Scale Patches

In the previous section, solves are only performed on the coarse mesh using the projected Taylor coefficients from the fine mesh, but in this section, we illustrate the effect of alternating between coarse scale solutions and fine patch smoothing for the same two problems. Figure 5 shows the error and residual information as before, which shows that the fine scale smoothing dramatically improve the limiting accuracy of the solution. Interestingly, the rate of convergence is similar for the first few cycles compared to the case of exclusively using coarse solves in the previous section. However, the convergence does bottom out abruptly after the second cycle. The third row of plots in Figure 8 separately shows the error within the interior of the domain and the total error, which shows that the interior error fluctuates without affecting the total error. While numerical precision contributes to this issue, this also suggests that solves on the coarse mesh improve interior nodes while also negatively impacting the error along the boundary. It is therefore possible that better handling of the boundary could further improve the asymptotic level of convergence. Further simulations have also shown that the asymptotic convergence level is sensitive to the details of the patch layout in ways that are not yet fully

Distribution Statement A. Approved for public release: distribution is unlimited. Case number: AFRL-2025-3173

clear. However, we anticipate being able to reduce the asymptotic error significantly further.

4 CONCLUSIONS

We have implemented a novel multigrid technique which takes influence from a variety of existing multiscale methods to enable rapid solution of complex multiscale nonlinear problems. In principle, it can be applied directly to any nonlinear phenomenon for which we can model the fine scale behavior. We have demonstrated the capacity to solve nonlinear elastic problems to well below the error level of a coarse mesh using solely coarse solves and patch-local smoothing. Interestingly, the nonlinear and linear cases demonstrated similar convergence rates and asymptotic levels. As this study considered only geometrically nonlinear hyperelasticity, which is smooth in nature, it remains to be seen whether more complex nonlinearity, particularly highly localized nonlinearity such as cohesive fracture, exhibits a similar behavior.

Moving forward, we are prioritizing transitioning the implementation to GPUs. This will be simplified greatly by the fact that the current implementation is built in JAX, which can be adapted to GPUs nearly transparently. The GPU transition will allow for significant scaleup in feasible problem size, allowing for the exploration of larger meshes, deeper mesh hierarchies, and three-dimensional domains. The other main priority is expanding the breadth of physical phenomena under consideration, especially incorporating fracture. As noted above, this only requires implementing the fine scale model of these phenomena in our JAX-based framework, as the coarser levels incorporate the nonlinear physics through the Taylor coefficients, independent of the underlying mechanisms.

ACKNOWLEDGEMENTS

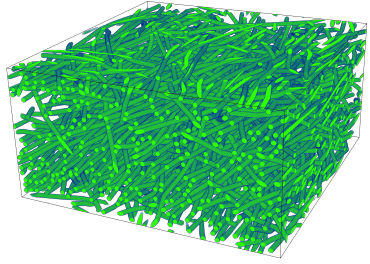
Richard Butler

Influence of the fiber curvature on the mechanical properties of long fiber reinforced composites

Celine Lauff, Matti Schneider, Thomas Böhlke | 04.08.2025, ICCM 2025

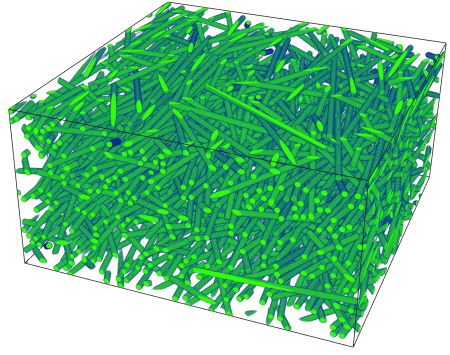


Motivation

(Andrä et al., 2014)

Information on real microstructures, e.g., from μCT-scans

Microstructure generation



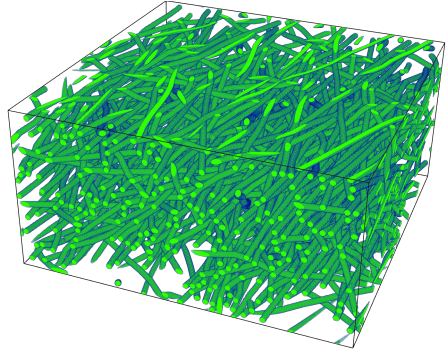
Synthetic microstructures

State of the art - selected literature

Modeling the fibers as straight cylinders:

- Sequential insertion algorithms:
  - Random sequential addition (RSA) algorithm
    (Feder, 1980; Widom, 1966)
  - Extensions of the RSA algorithm
    (Chen et al., 2019; Lauff et al., 2023; Tian et al., 2015, 2021)
- Collective rearrangement algorithms:
  - Mechanical contraction method (MCM)
    (Williams et al., 2003)
  - Sequential addition and migration (SAM) algorithm
    (Mehta et al., 2022, 2024; Schneider, 2017)

↯ limited to short fiber-reinforced microstructures



State of the art - selected literature

Modeling the fibers with curvature:

- RSA and compression in thickness direction
  (Fliegener et al., 2014)
  - \+ Enables industrial fiber packings
  - \- Computationally complex finite element analysis is necessary
- Fused sequential addition and migration algorithm
  (Lauff et al., 2025a, 2024)
  - \+ Computationally efficient
  - \+ Enables industrial fiber packings

↯ no fiber curvature control

Overview

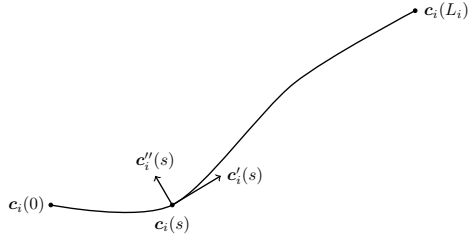
1 Description of discontinuous long fiber-reinforced microstructures

2 fSAM algorithm for long and curved fibers

3 Extension of the fSAM algorithm for curvature control

4 Computational investigations

Description of discontinuous long fiber-reinforced microstructures



Curved fiber

- Fiber described by curve:

$$\boldsymbol{c}_i : [0, L_i] \longrightarrow Q,$$
$$Q = [0, Q_1] \times [0, Q_2] \times [0, Q_3]$$

- Parametrization by arc length:

$$\|\boldsymbol{c}_i'(s)\| = 1, \quad s \in [0, L_i]$$

description of a curved fiber

(Schneider, 2022)

Description of discontinuous long fiber-reinforced microstructures

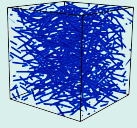
Fiber orientation tensors

(Advani et al., 1987)

$$\mathbb{A}_{\langle k \rangle} = \frac{1}{L} \sum_{i=1}^{N} \int_0^{L_i} \boldsymbol{c}_i'(s)^{\otimes k} \, \mathrm{d}s$$

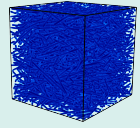
$$\boldsymbol{A} \equiv \mathbb{A}_{\langle 2 \rangle}, \quad \mathbb{A} \equiv \mathbb{A}_{\langle 4 \rangle}, \quad L = \sum_{i=1}^{N} L_i$$

Description of discontinuous long fiber-reinforced microstructures



Fiber orientation tensors

(Advani et al., 1987)



$$\mathbb{A}_{\langle k \rangle} = \frac{1}{L} \sum_{i=1}^{N} \int_0^{L_i} \boldsymbol{c}_i'(s)^{\otimes k} \, \mathrm{d}s$$

$$\boldsymbol{A} \equiv \mathbb{A}_{\langle 2 \rangle}, \quad \mathbb{A} \equiv \mathbb{A}_{\langle 4 \rangle}, \quad L = \sum_{i=1}^{N} L_i$$

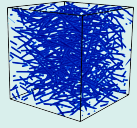
Fiber volume fraction

$\phi = 5\%$

$\phi = 20\%$

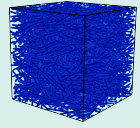
$$\phi = \frac{V_f}{V}$$

Description of discontinuous long fiber-reinforced microstructures



Fiber orientation tensors

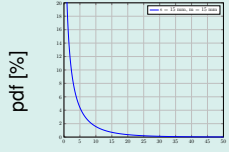
(Advani et al., 1987)



$$\mathbb{A}_{\langle k \rangle} = \frac{1}{L} \sum_{i=1}^{N} \int_0^{L_i} \boldsymbol{c}_i'(s)^{\otimes k} \, \mathrm{d}s$$

$$\boldsymbol{A} \equiv \mathbb{A}_{\langle 2 \rangle}, \quad \mathbb{A} \equiv \mathbb{A}_{\langle 4 \rangle}, \quad L = \sum_{i=1}^{N} L_i$$

Fiber volume fraction



$\phi = 5\%$

$\phi = 20\%$

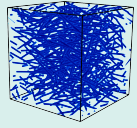
$$\phi = \frac{V_f}{V}$$

Fiber length distribution

aspect ratio:

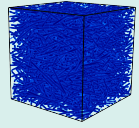
$$r_a = \frac{L_{\text{mean}}}{D}$$

Description of discontinuous long fiber-reinforced microstructures



Fiber orientation tensors

(Advani et al., 1987)



$$\mathbb{A}_{\langle k \rangle} = \frac{1}{L} \sum_{i=1}^{N} \int_0^{L_i} \boldsymbol{c}_i'(s)^{\otimes k} \, \mathrm{d}s$$

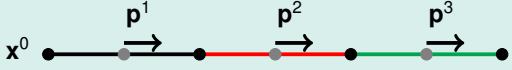
2 fSAM algorithm for long and curved fibers



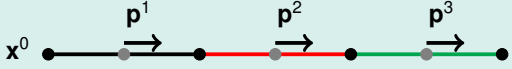
3 Extension of the fSAM algorithm for curvature control

4 Computational investigations

fSAM algorithm for long and curved fibers

Discretization for long and curved fibers

- Parametrization:



starting point $\mathbf{x}^0$
directions $\mathbf{p}^a$
lengths $\ell = \frac{L}{n}$

$\Big\}\ a = 1, \ldots, n$

fSAM algorithm for long and curved fibers

Discretization for long and curved fibers

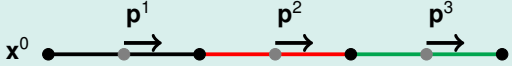
- Parametrization:

starting point $\mathbf{x}^0$
directions $\mathbf{p}^a$
lengths $\ell = \frac{L}{n}$

$\Big\}\ a = 1, \dots, n$

- Coordinate vector:

$$\mathbf{q} = \left[\left(\hat{\mathbf{x}}^0\right)^{\mathsf{T}} \quad \left(\mathbf{p}^1\right)^{\mathsf{T}} \quad \cdots \quad \left(\mathbf{p}^n\right)^{\mathsf{T}} \right]^{\mathsf{T}}$$



with normalization:

$$\hat{\mathbf{x}}^0 = \hat{\mathbf{Q}}^{-1}\,\mathbf{x}^0 \quad \text{with} \quad \hat{\mathbf{Q}} = \mathtt{diag}(Q_1, Q_2, Q_3)$$

fSAM algorithm for long and curved fibers

Discretization for long and curved fibers

- Parametrization:

starting point $\mathbf{x}^0$
directions $\mathbf{p}^a$
lengths $\ell = \frac{L}{n}$
$\Big\}\ a = 1, \dots, n$

- Coordinate vector:

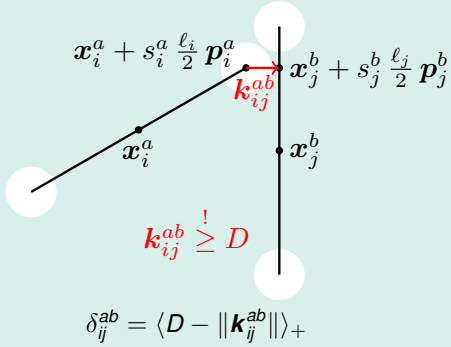
$$\mathbf{q} = \left[\left(\hat{\mathbf{x}}^0\right)^\mathsf{T} \quad \left(\mathbf{p}^1\right)^\mathsf{T} \quad \cdots \quad \left(\mathbf{p}^n\right)^\mathsf{T} \right]^\mathsf{T}$$

with normalization:

$$\hat{\mathbf{x}}^0 = \hat{\mathbf{Q}}^{-1}\,\mathbf{x}^0 \quad \text{with} \quad \hat{\mathbf{Q}} = \mathtt{diag}(Q_1, Q_2, Q_3)$$

Configuration space

$$\mathcal{R} = \left\{ \mathbf{q} \in \mathbb{R}^{3(n+1)} \mid \boldsymbol{\Phi}_1(\mathbf{q}) = \mathbf{0} \right\},$$



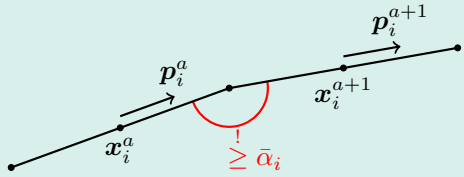
$$\boldsymbol{\Phi}_1(\mathbf{q}) \mathrel{\hat{=}} \left[\Phi_1^1(\mathbf{q}) \quad \cdots \quad \Phi_1^n(\mathbf{q}) \right]^\mathsf{T} \quad \text{with} \quad \Phi_1^a(\mathbf{q}) = \frac{1}{2}\left(\|\mathbf{p}^a\|^2 - 1 \right), \quad a = 1, \dots, n$$

fSAM algorithm for long and curved fibers

Minimization problem

$$F(\mathbf{q}_1, \ldots, \mathbf{q}_n) \longrightarrow \min_{\mathbf{q}_1,\ldots,\mathbf{q}_n} \quad \mathbf{q}_i \in \mathcal{R}_i$$

$$F(\mathbf{q}_1, \ldots, \mathbf{q}_n) \mathrel{\hat{=}} \underbrace{\frac{1}{2} \sum_{i,j=1}^{N} \sum_{a=1}^{n_i} \sum_{b=1}^{n_j} \left(\delta_{ij}^{ab}\right)^2 + \frac{w_{\mathbb{A}}}{8} \|\mathbb{A} - \mathbb{A}^{\mathrm{r}}\|^2}_{\text{non-overlap condition and fiber orientation tensor}}$$



fSAM algorithm for long and curved fibers

Minimization problem

$$F(\mathbf{q}_1, \ldots, \mathbf{q}_n) \longrightarrow \min_{\mathbf{q}_1,\ldots,\mathbf{q}_n} \quad \mathbf{q}_i \in \mathcal{R}_i$$

$$F(\mathbf{q}_1, \ldots, \mathbf{q}_n) \mathrel{\hat{=}} \underbrace{\frac{1}{2} \sum_{i,j=1}^{N} \sum_{a=1}^{n_i} \sum_{b=1}^{n_j} \left(\delta_{ij}^{ab}\right)^2 + \frac{w_{\mathbb{A}}}{8} \|\mathbb{A} - \mathbb{A}^{\mathrm{r}}\|^2}_{\text{non-overlap condition and fiber orientation tensor}}$$

$$+ \underbrace{\frac{w_\rho}{2} \sum_{i=1}^{N} \sum_{a=1}^{n_i - 1} \left(\rho_i^a\right)^2}_{\text{angle constraint}}$$

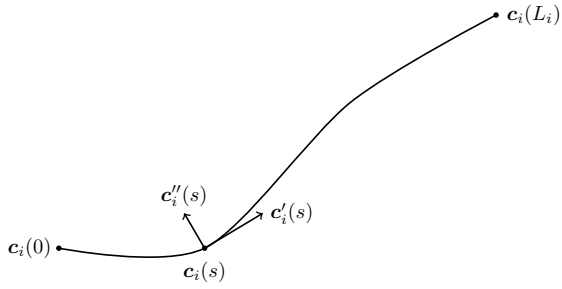
$$\rho_i^a = \left\langle \cos\alpha_i - \boldsymbol{p}_i^{a+1} \cdot \boldsymbol{p}_i^a \right\rangle_+$$

Overview

1 Description of discontinuous long fiber-reinforced microstructures

2 fSAM algorithm for long and curved fibers

3 Extension of the fSAM algorithm for curvature control



4 Computational investigations

Extension of the fSAM algorithm for curvature control

Quantifying the fiber curvature of a single fiber

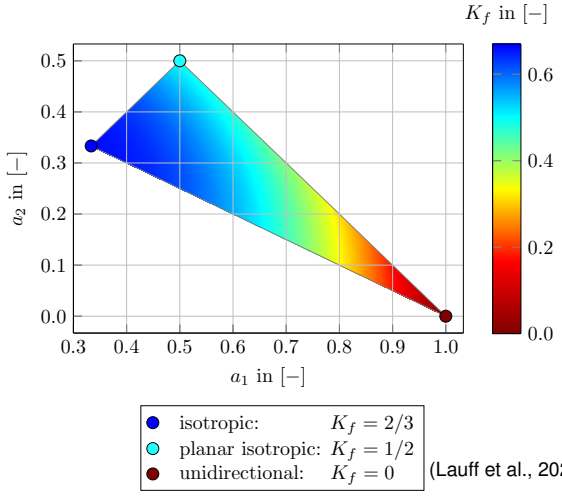
- Fiber orientation of a single fiber:

$$\boldsymbol{A}_f = \frac{1}{L} \int_0^L \boldsymbol{c}'(s) \otimes \boldsymbol{c}'(s) \, \mathrm{d}s$$

description of a curved fiber

(Schneider, 2022)

Extension of the fSAM algorithm for curvature control

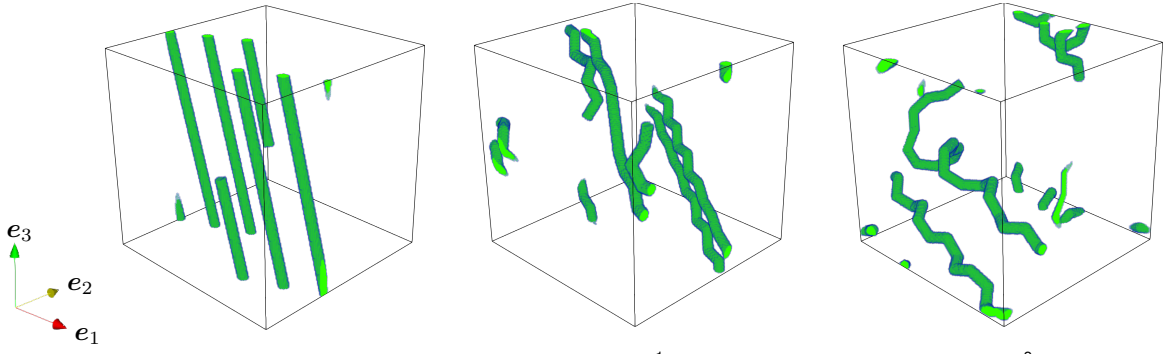


Quantifying the fiber curvature of a single fiber

- Fiber orientation of a single fiber:

$$\boldsymbol{A}_f = \frac{1}{L}\int_0^L \boldsymbol{c}'(s) \otimes \boldsymbol{c}'(s)\,\mathrm{d}s$$

- Deviation from straight curve (DSC):



$$K_f = \mathrm{tr}\left(\frac{1}{L}\int_0^L \left(\boldsymbol{A}_f - \boldsymbol{c}'(s) \otimes \boldsymbol{c}'(s)\right)^{\otimes 2}\,\mathrm{d}s\right)$$
$$= 1 - \|\boldsymbol{A}_f\|^2$$

(Lauff et al., 2025b)

Extension of the fSAM algorithm for curvature control

Quantifying the fiber curvature of a single fiber

(a) $K_f = 0$ (b) $K_f = \frac{1}{3}$ (c) $K_f = \frac{2}{3}$

(Lauff et al., 2025b)

Extension of the fSAM algorithm for curvature control

Volume-averaged DSC:

$$\bar{K} = \frac{1}{L_{\text{total}}} \sum_{i=1}^{N} L_i \, K_f^i,$$

Objective function with extended curvature control

$$F(\mathbf{q}_1, \ldots, \mathbf{q}_n) \longrightarrow \min_{\mathbf{q}_1, \ldots, \mathbf{q}_n} \quad \mathbf{q}_i \in \mathcal{R}_i$$

$$F(\mathbf{q}_1, \ldots, \mathbf{q}_n) \hat{=} \underbrace{\frac{1}{2} \sum_{i,j=1}^{N} \sum_{a=1}^{n_i} \sum_{b=1}^{n_j} \left(\delta_{ij}^{ab}\right)^2 + \frac{w_{\mathbb{A}}}{8} \|\mathbb{A} - \mathbb{A}^{\mathrm{r}}\|^2}_{\text{non-overlap condition and fiber orientation tensor}} + \underbrace{\frac{w_\rho}{2} \sum_{i=1}^{N} \sum_{a=1}^{n_i - 1} \left(\rho_i^a\right)^2}_{\text{angle constraint}} + \underbrace{\frac{w_{\bar{K}}}{8} n_s \left(\bar{K} - \bar{K}^{\mathrm{r}}\right)^2}_{\text{DSC}}$$

Overview

1 Description of discontinuous long fiber-reinforced microstructures

2 fSAM algorithm for long and curved fibers

3 Extension of the fSAM algorithm for curvature control

4 Computational investigations

Computational investigations

Algorithmic Choices

- Relative error of the fiber orientation state < 10^{-4}
- Relative error of the DSC state < 10^{-3}
- Minimum distance: $2.0 \mu m$
- Maximum segment length: $\bar{\ell} = 25 \mu m$
- Maximum bending angle: $\bar{\alpha} = 30°$
- Closure approximation: Exact closure
  (Montgomery-Smith et al., 2011a,b)

Computational investigations

Algorithmic Choices

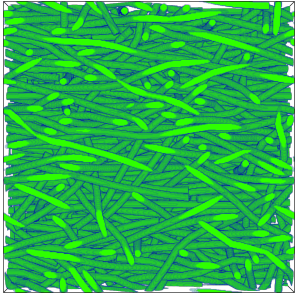
Homogenization with an FFT-Solver (Schneider, 2021; Zeman et al., 2010)

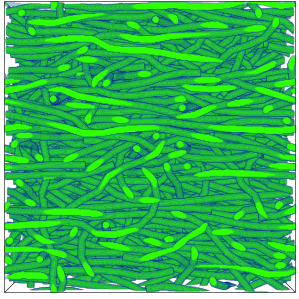
- Approximation of the **orthotropic** engineering constants
- Polypropylene matrix: $E = 1.25$ GPa, $\nu = 0.35$ (DOW® Chemical Company, 2003)
- E-glass fibers: $E = 72.0$ GPa, $\nu = 0.22$ (PPG Fiber Glass, 2013)

Computational investigations

Generated microstructures with varying fiber curvature

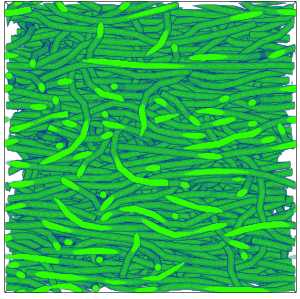


isotropic:	$K_f = 2/3$
planar isotropic:	$K_f = 1/2$
unidirectional:	$K_f = 0$

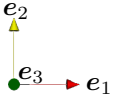


(Lauff et al., 2025b)

Computational investigations

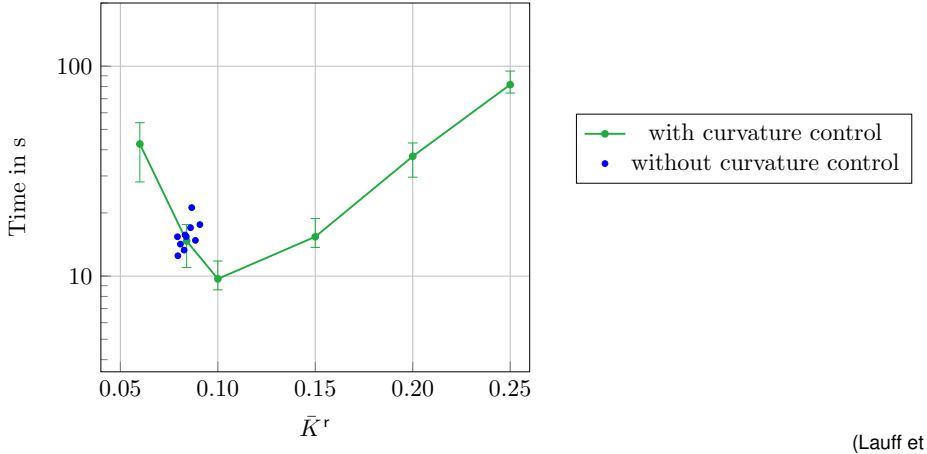


Generated microstructures with varying fiber curvature



(a) $\bar{K} = 0.06$

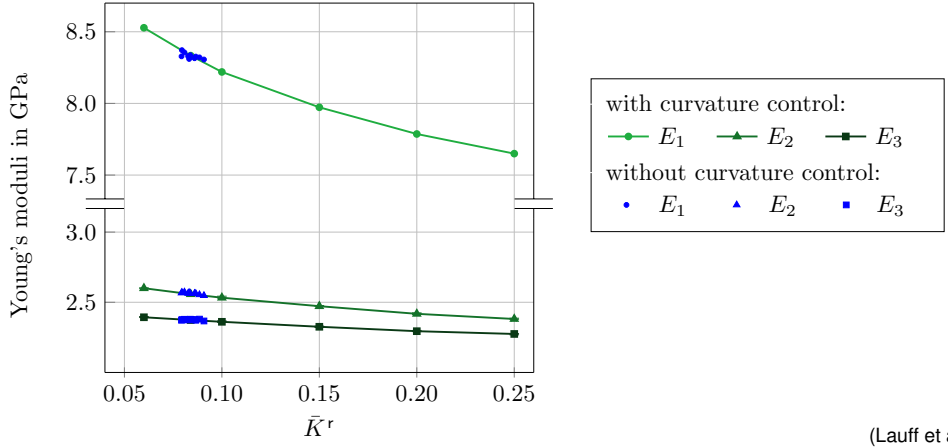
(b) $\bar{K} = 0.15$



(c) $\bar{K} = 0.25$

(Lauff et al., 2025b)

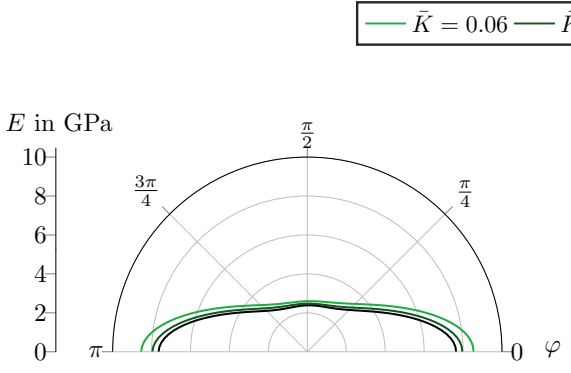
Computational investigations



Runtime for the microstructure generation

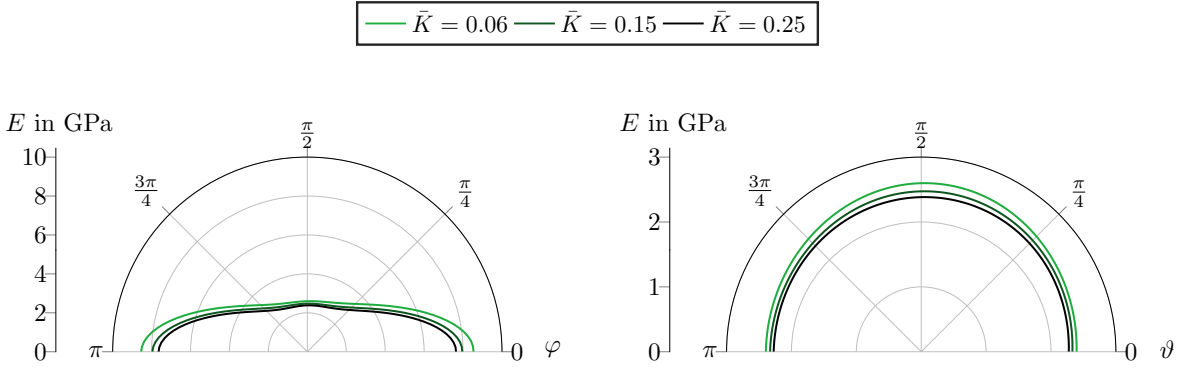
(Lauff et al., 2025b)

Computational investigations



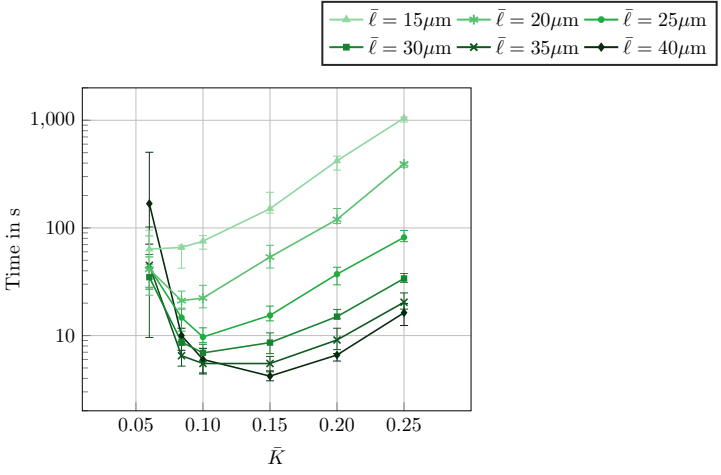
Effect of the fiber curvature on the mechanical properties

(Lauff et al., 2025b)



Computational investigations

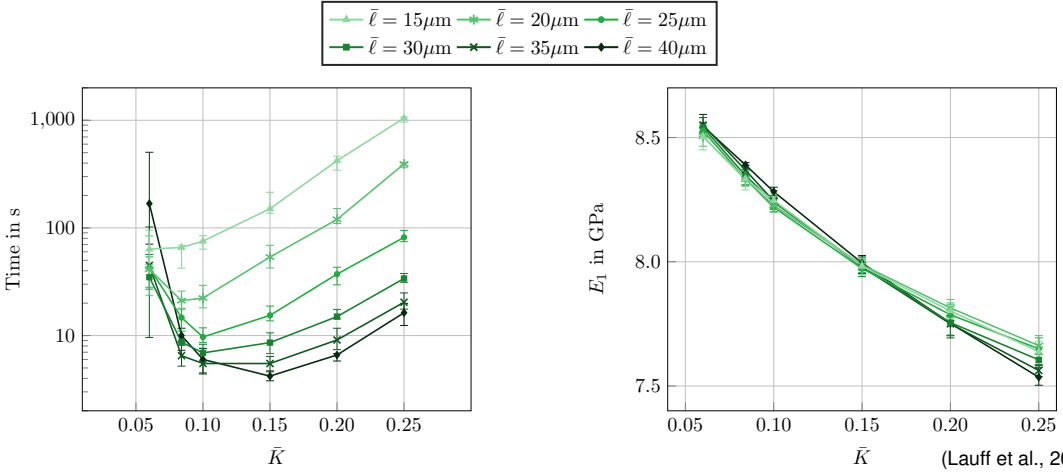
Effect of the fiber curvature on the mechanical properties



Computational investigations

Effect of the fiber curvature on the mechanical properties

Computational investigations



Study on the maximum segment length

(Lauff et al., 2025b)

Computational investigations

Study on the maximum segment length

(Lauff et al., 2025b)

Conclusion

- fSAM algorithm with **fiber curvature control**
  - Novel measure to quantify the fiber curvature: **deviation from straight curve** (DSC)
  - Extension of the objective function

Conclusion

- fSAM algorithm with **fiber curvature control**
  - Novel measure to quantify the fiber curvature: **deviation from straight curve** (DSC)
  - Extension of the objective function
- Computational investigations
  - fSAM algorithm is capable of realizing a **wide spectrum of curvatures**
  - Significant **Young's moduli reduction** for increased fiber curvature

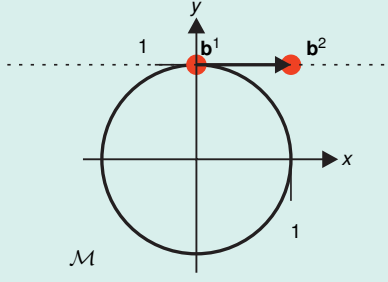
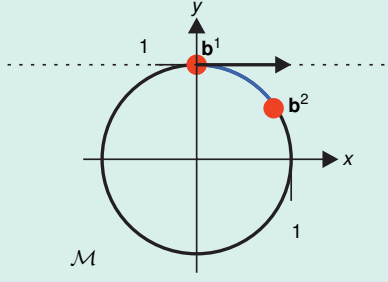
fSAM algorithm for long and curved fibers

Solving the minimization problem

$$F(\mathbf{q}) \longrightarrow \min_{\mathbf{q} \in \mathcal{R}}$$

- Gradient descent approach
  - ↯ Standard gradient descent approach: **q** may leave its configuration space



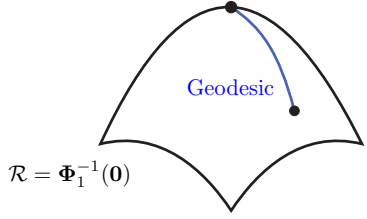


fSAM algorithm for long and curved fibers

Solving the minimization problem

$$F(\mathbf{q}) \longrightarrow \min_{\mathbf{q} \in \mathcal{R}}$$

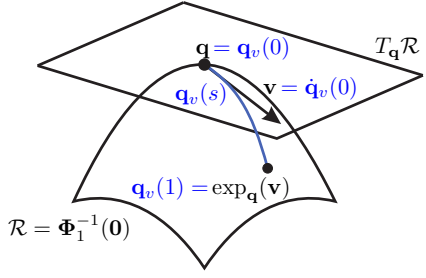
- Gradient descent approach
  - ↯ Standard gradient descent approach: **q** may leave its configuration space



fSAM algorithm for long and curved fibers

Moving along the geodesics

- Geodesic (Petersen, 2016):
  - Shortest path between two points on a manifold
  - Minimizing the energy functional



fSAM algorithm for long and curved fibers

Exponential mapping

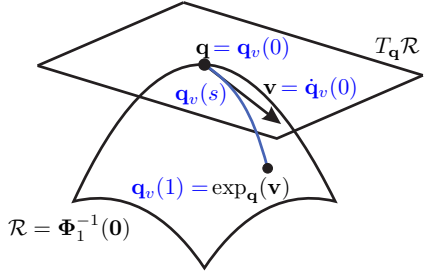
- For the geodesically complete Riemannian manifold $(\mathcal{R}, \mathbf{G})$:
  - Input:
    - Tangent vector $\mathbf{v} \in T_{\mathbf{q}}\mathcal{R}$
    - Point on the manifold $\mathbf{q} \in \mathcal{R}$
  - Output:

$$\exp_{\mathbf{q}}(\mathbf{v}) = \mathbf{q}_v(1)$$

    - $\mathbf{q}_v : [0, 1] \to \mathcal{R}$: unique geodesic with $\mathbf{q}_v(0) = \mathbf{q}$ and $\dot{\mathbf{q}}_v(0) = \mathbf{v}$

fSAM algorithm for long and curved fibers

Exponential mapping



- For the geodesically complete Riemannian manifold $(\mathcal{R}, \mathbf{G})$:
  - Input:
    - Tangent vector $\mathbf{v} \in T_{\mathbf{q}}\mathcal{R}$
    - Point on the manifold $\mathbf{q} \in \mathcal{R}$
  - Output:

$$\exp_{\mathbf{q}}(\mathbf{v}) = \mathbf{q}_v(1)$$

  - $\mathbf{q}_v : [0, 1] \to \mathcal{R}$: unique geodesic with $\mathbf{q}_v(0) = \mathbf{q}$ and $\dot{\mathbf{q}}_v(0) = \mathbf{v}$

Adapted gradient descent approach

$$\mathbf{q}^{k+1} = \exp_{\mathbf{q}^k}\left(-\tau_k \nabla_{\mathbf{q}} F\left(\mathbf{q}^k\right)\right), \quad k = 0, 1, \ldots,$$

Index

- Motivation
- Self-healing in epoxy and epoxy-matrix composites
- Influence of thermoplastic particles in epoxy
- Conclusions and outlook

Motivation

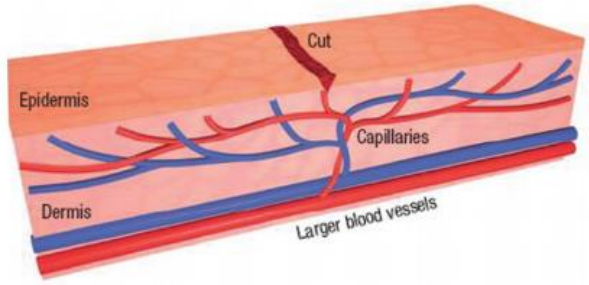
- Composite materials
  - ✓ Exposure to environmental factors and mechanical loading may lead to the formation of microcracks
    - *Microcracks difficult to detect*
    - *Costly repairs / failure*

www.reinforcedplastics.com

www.energes.com.br

Superstrata Bike

www.nauticexpo.com

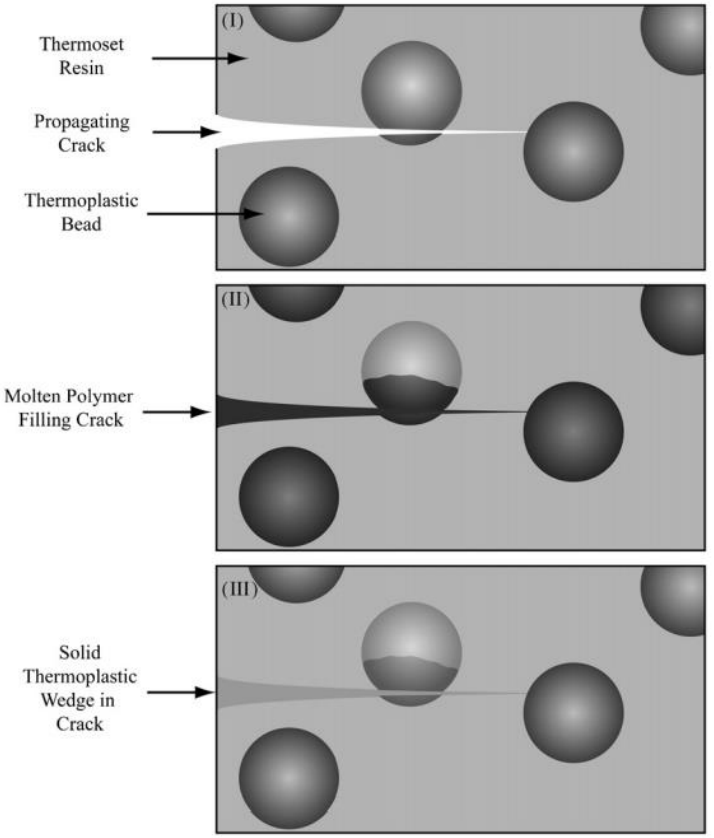


www.asdnews.com

Self-healing materials

- Alternative to conventional repair methods to heal microcracks in the structure
  - ✓ Extension of service life
  - ✓ Reduction of maintenance cycles
  - ✓ Increase reliability

Bio-inspired



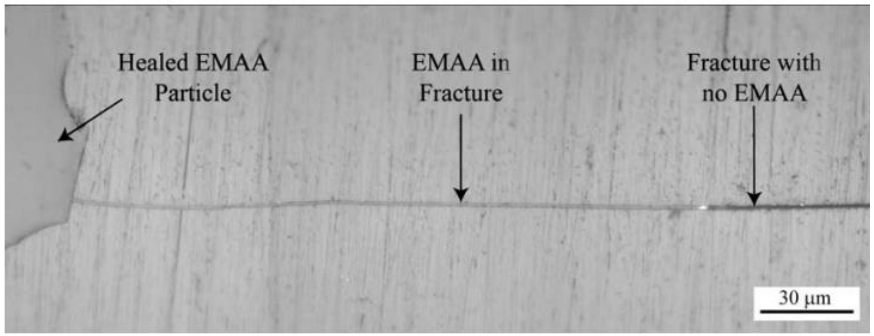
- Repair associated to restoration of properties:

$$\text{Healing efficiency} = \frac{\textit{Property value}_{\,healed}}{\textit{Property value}_{\,initial}} \times 100$$

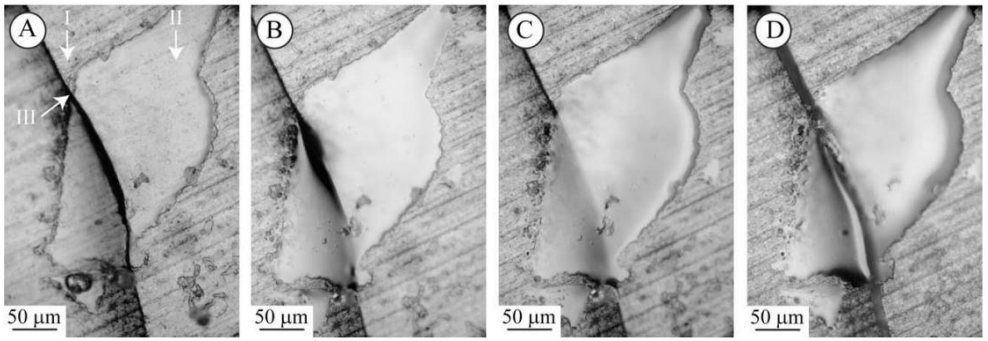
Self-healing in epoxy and epoxy composites

- Thermoplastic healing agents

  - ✓ Addition of thermoplastic particles to epoxy matrix
  - ✓ Heating during healing cycle allows increase in mobility of thermoplastic material and flow to damaged areas
  - ✓ Thermoplastic as a crack filler capable of re-bonding fracture surfaces.



D. Y. Wu et al, Prog. Polym. Sci. 33 (2008) 479–522



Self-healing in epoxy and epoxy composites

MEURE; WU; FURMAN, 2009:

- Addition of 15 wt.% of thermoplastic particles (polyethylene-co-methacrylic acid) (EMAA) to epoxy resin
  - ✓ Decrease in modulus + increase in fracture strength
  - ✓ Recovery = 85% (TDCB) and 100% (SENB)

healed SENB showing the fracture plane

(I) epoxy resin, (II) an EMAA particle and (III) crack

EMAA particle healing and formation of an adhesive EMAA layer between adjacent epoxy fracture surfaces

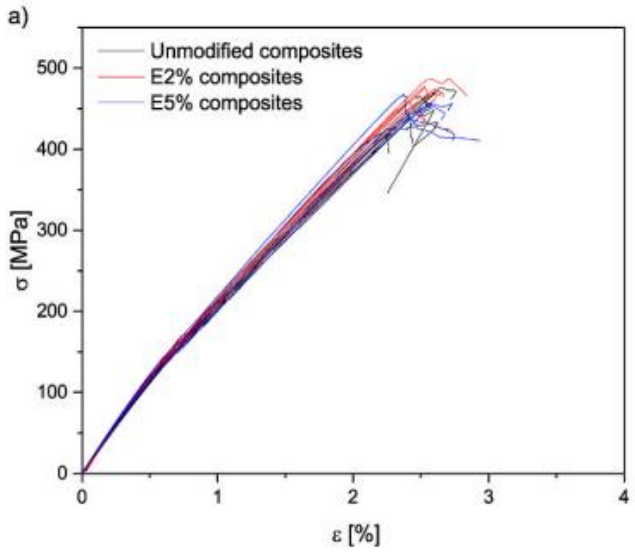
Fatigue behavior of self-healing glass fiber/epoxy composites with addition of poly (ethylene-co-methacrylic acid) (EMAA)



Allana Azevedo do Nascimento [a,*], Volker Trappe [b], José Daniel Diniz Melo [a], Ana Paula Cysne Barbosa [a]

[a] Federal University of Rio Grande do Norte (UFRN), Av. Senador Salgado Filho 3000, CEP, 59078-970, Natal, RN, Brazil
[b] Federal Institute for Materials Research and Testing (BAM), Unter den Eichen 87, 12205, Berlin, Germany

Fatigue behaviour and self-healing

- Composites with 2 wt% and 5 wt% of EMAA were manufactured by resin infusion using glass fibers impregnated with EMAA
- Healing efficiency: number of cycles to failure of specimens subjected to cyclic loading
- No significant effect on glass transition temperature, tensile strength or modulus of elasticity

Allana A. do Nascimento, Volker Trappe, José D. D. Melo, Ana P.C. Barbosa, Polymer Testing 117 (2023) 107863

Fatigue behaviour and self-healing

- 5 wt% of EMAA: reduction of the fatigue life
- 2 wt% of EMAA: slight increase in life
- greatest number of cycles to failure of composites: with 2 wt% of EMAA
- greatest healing efficiency: healing cycle after 10^3 loading cycles, as compared to 10^4 loading cycles: healing can be more efficient if activated in early stages of damage.

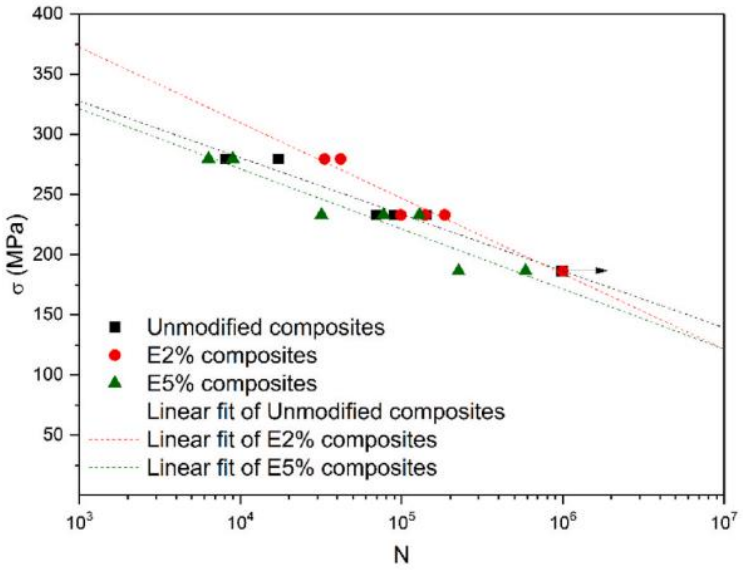


Table 3. Average healing efficiency of unmodified and modified composites.

Sample	η (%)	
	10^3	10^4
Unmodified composites	105.9	31.2
E2% composites	102.1	27.4
E5% composites	199.6	37.7

Preliminary results on crack propagation

- Crack propagation in SET samples investigated for neat epoxy and epoxy with 5 wt.% of thermoplastic (EMAA) particles, with 2 different particle sizes

- Preliminary results indicate that cracks seems to propagate faster for neat epoxy than for epoxy modified with thermoplastic material

Fracture surface of neat epoxy SET sample

Conclusions and outlook

- Self-healing with thermoplastic particles as alternative to heal material and extend service life
- Healing can be more efficient if activated in early stages of damage
- Trade-off between healing efficiency and the reduction of mechanical properties must be considered
- Ongoing studies on crack propagation of epoxy with and without thermoplastic particles

ABSTRACT

Polymer composites used in structural applications are subjected to dynamic loads that can generate fatigue-induced microcracks. As these microcracks grow and merge, they lead to material failure, thereby reducing the service life of the component. To address this challenge, a promising strategy involves the development of smart self-healing polymers that, similar to biological systems, respond to damage by activating self-repair mechanisms, effectively enhancing the durability and lifespan of the material. This study investigates the interlaminar shear behavior of 5HS carbon fiber/epoxy composites containing varying amounts of the self-healing agent EMAA, processed via RTM. It examines the influence of agent content on mechanical performance and confirms, through thermal analysis, the feasibility of laminate fabrication, though particle dispersion may limit agent volume. ANOVA results show that EMAA content has a higher effect on mechanical response than internal dispersion. Weibull analysis indicates a linear decrease in shear strength with increased EMAA due to reduced stiffness from its ductile nature. Healing was most effective in interlaminar regions, achieving up to 62% recovery in shear strength, 106% in toughness, and 57% crack area reduction. Predictive modeling supports optimizing healing agent levels to meet design needs while reducing experimental effort and cost.

1 INTRODUCTION

Carbon fiber-reinforced polymer (CFRP) composites with continuous fibers are extensively employed in aerospace applications. From 1980s, the AV-8B aircraft incorporated CFRP in 27% of its components, followed by the Boeing 787 that increased to 50% in its fuselage structure in 2000. More recently, advancements in urban air mobility (UAM) have been directed toward achieving fully fiber-reinforced structural designs, aiming for 100% composite reinforcement [1].

The use of RTM process for manufacturing high fiber volume fraction composite parts replacing autoclave manufacturing is quickly gaining momentum [2-3]. RTM manufactured components can also be co-cured with stiffener and rib structures. Although this reduces assembly time it opens up the possibility of poor mechanical properties in through the thickness direction [4] with damage usually occurring at the fiber/matrix interface in the form of microcracks or micro delamination [5], influencing adversely the fracture toughness [6].

Micro cracks can compromise the structural integrity of a vehicle and can reduce the vehicle life or result in a potentially injury of passenger safety. In recent years many repair techniques have been developed by transportation industry, and the goal of these repair methods is to fix visible damages on

composite polymer structure, however, for invisible damage inside the component during service life, traditional methods of repairing are not effective [7].

One emerging approach for mitigating or preventing damage is the use of healing agents, especially considering the high costs associated with replacing failed components. Incorporating self-healing agents offers the potential to enhance the safe operational lifespan of structural parts [8-10].

Since 2008, thermoplastic polymers have been explored as self-healing agents in high-performance composites, with the goal of addressing microcracks generated under mechanical stress [11]. These polymers act by interpenetrating into the damaged regions and forming chemical bonds at the crack surfaces, thereby helping to prevent failure. Meure et al. [12] incorporated EMAA (polyethylene-co-methacrylic acid) into an epoxy matrix, producing particles around 250 μm in size via cryogenic grinding and impact milling. Although this approach reduced the energy needed for activation, it also compromised the mechanical integrity of the healing material. The same researchers later examined the influence of pressure on healing, using EMAA films in epoxy systems. They identified gas bubble formation and chemical interactions involving oxirane, amine, and hydroxyl groups, and applied increased pressure to suppress the bubbles [13].

Further work by Varley et al. [14] revealed that ionomers in EMAA could effectively repair impact damage, triggered by ionic activation and reversible thermal behavior. Additives were shown to enhance plasticization and ion cluster mobility, which improved healing performance. Additionally, EMAA and EMA (polyethylene-co-methyl acrylate) have been utilized as co-polymeric healing agents in prepreg-based composites, where they were converted from pellets into thin films through hot pressing [15].

However, the presence of the self-healing agent in the polymeric resin introduces a new phase into the matrix, which can significantly alter the elastic behavior of the composite, which raises the following question: what is the influence of the healing agent fraction on the mechanical behavior of the material? Then, there is a requirement to know about the material's post-repair properties, analyzing the distribution of the agent within the material regions, and employing statistical tools to validate the results and predict the materials behavior, aiming to reduce both project time and cost.

2 EXPERIMENTAL PROCEDURES

The manufacturing process employed was the resin transfer molding (RTM) Radius 2100cc RTM Injector according to the Figure 1

Figure 1 – RTM system

The self-healing thermoplastic agent was cryogenically milled using a high-energy grinder, then sieved through a 100-mesh screen to obtain a fine particle as it can see in the Fig. 2, which were subsequently blended with the resin prior to molding. This mixture was injected into the fiber reinforcement within closed mold under regulated thermal and pressure conditions.

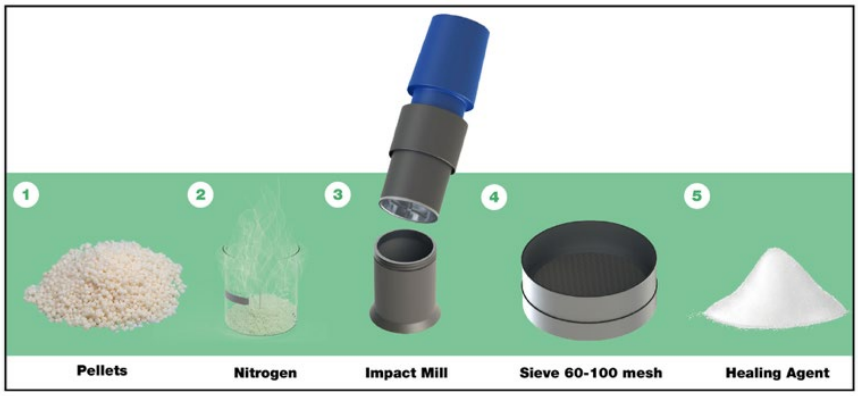

Figure 2 - Schematic steps of the thermoplastic self-healing process. (1) Pellets; (2) frozen pellets with liquid N2; (3) impact mill; (4) sieve, and (5) self-healing powder (150–250 μm) [16]

Processing parameters settled for both laminates are shown in Table 1.

Table 1 – Processing parameters

Laminate	Injection pressure MPa	Vacuum level [MPa]	Injection temperature (°C)	Curing cycle (min)
A and B	*0.2*	0.05	125	180-240

The fiber preforms consisted of eight symmetrically arranged layers, achieving a fiber volume fraction of 55%. Composite samples were sectioned using a metallographic cutter from allied high-tech products, equipped with a diamond blade, following the dimensional specifications outlined in ASTM D2344. For microscopy evaluation, specimens were embedded in Bakelite and cure at 170°C for 7.5 min, polished with diamond suspensions (9 μm to 1 μm) and finished with 0.05 μm alumina suspension. Cross-sectional image was performed using a Tescan Vega 3 scanning electron microscope., according to the ref. [17].

3 RESULTS

The average and standard deviation measurement data of self-healing fraction in the laminates composite processed by RTM is shown in Table 2. The reference composite is called A without adding a healing agent (i.e., 0%). The C-B laminate represents a composite with 2.41% of self-healing agent, while the C–C represents a laminate with 9.79% of self-healing agent average fraction. Through the image treatment, it was possible to measure the diameter size distribution of self-healing particles along the C–B and C–C composites, as shown in the histogram of Fig. 3a. Both composite families had the same processing procedures, modifying only the EMAA particle fraction. For specimen C–B, the largest diameter concentration is found in the range 20–30 μm (i.e., 41.73%), with a low fraction for particles >100 μm (3.98%).

Table 2: Agent fraction data.

Healing agent Fraction		
laminate	Average	Standard deviation
A	2.41	1.60
B	9.79	2.30

The self-healing particle diameter distribution in A and B coposites was measured and it was seen that in A, most particles fall within the 20–30 µm range (41.73%), with few exceeding 100 µm (3.98%). In contrast, increasing the thermoplastic content in B shifts the peak to 60–70 µm (31.08%) and raises the >100 µm fraction to 17.29%. This suggests higher particle agglomeration in B, increasing size variation and standard deviation. Higher healing agent content led to particle coalescence during manufacturing, enlarging particles and reducing dispersion uniformity. This inhomogeneity can affect self-healing efficiency, as a more uniform particle distribution improves the likelihood of crack interaction and closure through thermoplastic flow and reconnection [18].

Irregular shapes were no significant—0.05% in A and 0.09% in B laminates. As with diameter distribution, B showed higher morphological variation due to particle coalescence. Despite this, circular and elliptical shapes remained consistent across both laminates, indicating that coalescence increased particle size in B without altering morphology. While larger particles may improve localized healing, they reduce macro-healing effectiveness by concentrating the agent in fewer regions, limiting its interaction with diverse cracks [19].

The fig. 3 presents the ILSS curves for the reference laminates (no self-healing agent), the laminate with 2.41% healing agent before (A) and after repair (AB), and with 9.79% agent before (B) and after repair (RB).

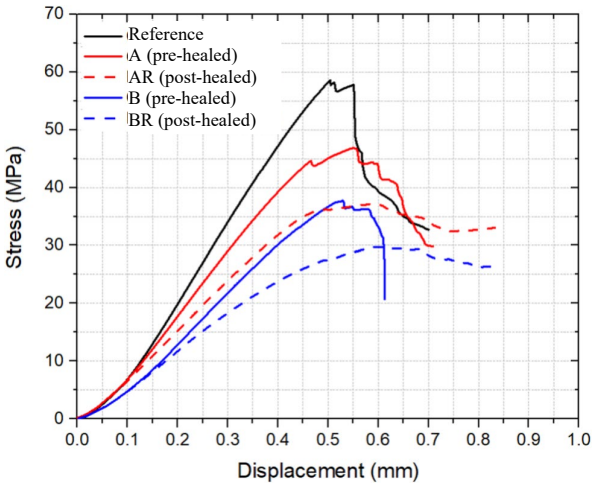

Figure 3 - ILSS curves [1].

The stress–displacement curve (Fig. 3) shows a reduced stiffness attributed to the addition and increasing EMAA content comparred the reference. After testing, self-healing samples were heated at 150 °C for 30 min. activate healing. The post-healing curves exhibit smoother behavior and lower load capacity, reflecting the ductile nature of the thermoplastic agent compared to the highly crosslinked epoxy matrix [20].

ANOVA was performed to assess the contribution of the self-healing agent fraction to the variability in mechanical properties and to test the null hypothesis (H_0) of no significant difference between fractions. The alternative hypothesis (H_1) assumes the agent fraction affects mechanical performance. Analysis was conducted in Minitab 18 with $\alpha = 0.05$ and 95% confidence, comparing between-group variance (agent fraction) to within-group variance (test repeatability).

The equations used in the ANOVA method to calculate the F-factor are shown in Table 3, where *n* is the number of data points, *C* is the group number, *xi* is the group mean, *x* is the overall mean, *xji* is each individual value, and the F-factor indicates whether the self-repair fraction's variation has higher variance than the mechanical response's standard deviation. The p-value is tabulated based on the degrees of freedom and F-value.

Table 3 - Structured form of the ANOVA model

Variation	SS-total	DF	MS	F-factor
Between-groups	$S_a = \sum_{i=1}^{c} n(\bar{x}_i - \bar{x})^2$	$V_a = C - 1$	$SM_a = \frac{S_a}{V_a}$	$F = \frac{SM_a}{V_a}$
Whithin-groups	$S_b = \sum_{i=1}^{c} \sum_{j=1}^{n} (\bar{x}_{ji} - \bar{x})^2$	$V_b = n - 1$	$SM_b = \frac{S_b}{V_b}$	

n *= number of experimental observations;* ***C*** *= group identifier (or group index);* $\bar{x}_i$ *mean of the* i*-th group;* $\bar{x}$ *= grand mean (overall mean across all groups);* $\bar{x}_{ji}$ *= individual observation* j *within group* i*;* ***F*** *= F-statistic, representing the ratio of the between-group mean square to the within-group mean square*

The variation in interlaminar shear strength was characterized using a two-parameter Weibull distribution, as presented in Equation (1) [20]. This distribution enables the estimation of failure probability across different reliability levels and is widely adopted for analyzing the variability in brittle failure of composite materials. Linearization of the Weibull distribution was performed using Equation (2), allowing for the estimation of the shape parameter (m) and the scale parameter (X_U).

$$P(\bar{x}) = \bar{e}\left[-\frac{x_c}{X_u}\right]^m \tag{1}$$

$$ln\left[\left(\frac{1}{1 - P(\bar{x})}\right)\right] = m.ln(x_c) - m.ln(x_u) \tag{2}$$

In addition to the probabilistic approach, Response Surface Methodology (RSM) was applied to model and predict the mechanical behavior as a function of key processing parameters, specifically the self-healing agent fraction (*SH, in %*) and displacement (*D, in mm*). This approach enabled the development of predictive models for both the pre-healing condition (σ_N) and the post-healing condition (σ_R), as described in Equation (3).

$$Y = \beta_0 + \sum_{i=1}^{k} \beta_i \bar{x}_i + \sum_{j=1}^{k} \beta_j \bar{x}_j + \sum_{i=1}^{k} \beta_{ii} \bar{x}_i^2 + \sum_{j=1}^{k} \beta_{jj} \bar{x}_j^2 + \sum_{j=i}^{k} \beta_{ji} \bar{x}_i \bar{x}_j \tag{3}$$

Where *Y* represents the predicted response, an the variables *xi* and *xj* correspond to the levels of the processing parameters, the beta coefficients (β) represent the constant term, the linear effects, and the interaction effects between the variables.

An analysis of variance (ANOVA) was conducted to assess the influence of the self-healing agent fraction on the mechanical properties. Prior to the healing process (Table 4), the between-group variance was found to be statistically significant (**F > Fcritical, p < 0.05**), indicating that variations in the self-healing agent fraction have a substantial effect on the mechanical response. The contribution percentage (PC) of the between-group variance reached **87.6%**, whereas the within-group variance accounted for only **12.4%**, confirming the dominant influence of the healing agent fraction on the composite's performance.

Table 4. ANOVA pre-repair action

Variance	*SS*	*DF*	*MS*	*F-ratio*	*p-values*	*Fcrítico*	*%*
within-group	65.213	5	13.04	0.72	0.620	3.32	12.40
between-group	460.67	2	230.34	12.79	0.001	4.10	87.60
Total	525.89	10					-

Sum of Squares (SS); Degrees of Freedom (DF); Mean Square (MS); Variation between sample means / Variation within samples (F – F-ratio) and Percentage Contribution ***(%)***

Following the healing process (Table 5), an inverse trend was observed. The within-group variance increased substantially (**% = 76.56%**), while the between-group contribution decreased (**% = 23.43%**). Moreover, both F-values were lower than Fcritical, with p-values exceeding 0.05, indicating that the effect of the self-healing agent fraction became statistically insignificant post-repair. This behavior is attributed to the inherent variability in crack propagation and closure, as well as the stochastic nature of damage localization after failure, which introduced higher dispersion in the post-healing mechanical results.

Table 5. ANOVA post-repair action.

Variance	*SS*	*DF*	*MS*	*F-factor*	*p-value*	*Fcrítical*	*%*
Within-group	45.56	5	9.11	0.45	0.79	5.05	76.56
Between-group	13.94	1	13.94	0.69	0.44	6.60	23.43
Total	59.50	6					

Sum of Squares (SS); Degrees of Freedom (DF); Mean Square (MS); Variation between sample means / Variation within samples (F – F-ratio) and Percentage Contribution ***(%)***

Weibull distribution modeling (Figure 4) demonstrated an excellent fit to the experimental data, both before and after the healing process, with a coefficient of determination $\mathbf{R^2 > 0.99}$.

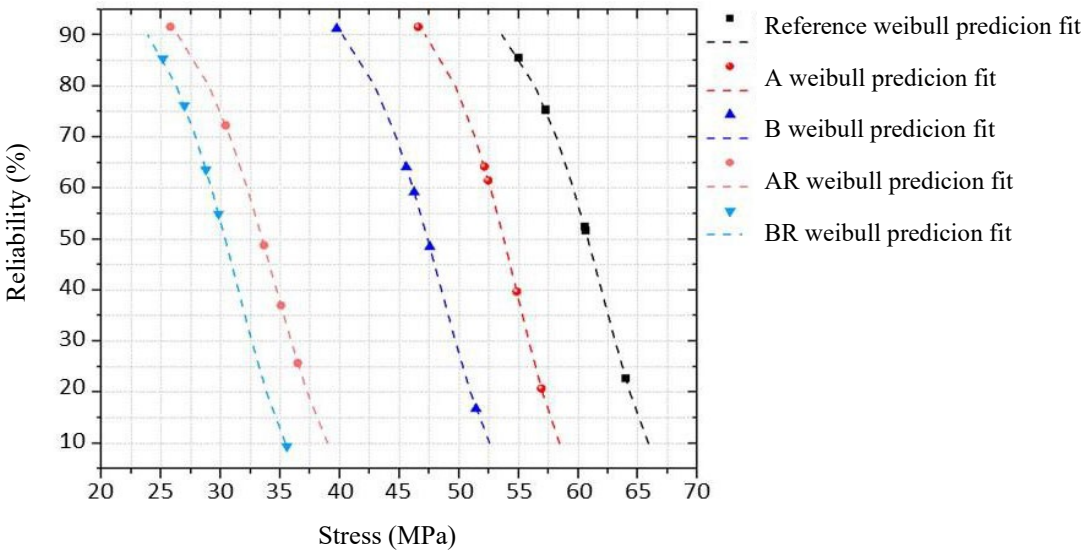

Fig. 4 - Sensitivity analysis of the predicted ultimate shear stress pre- and post-healing.

The analysis revealed that increasing the self-healing agent fraction led to a progressive reduction in maximum interlaminar shear strength at a given reliability level. This reduction is associated with particle agglomeration effects and lower fracture consolidation efficiency at higher healing agent concentrations.

A three-dimensional Response Surface Methodology (RSM) surface was also generated, effectively describing the mechanical response as a function of SH and D, enabling predictive capabilities beyond experimentally tested conditions. The models presented a maximum error of less than **3.9%**, with **R^2 > 0.93**, demonstrating robust predictive accuracy. The resulting predictive equations are as follows 3 and 4:

- **Pre-healing mechanical behavior**:

$$\sigma_N = -7.33 - 1.11SH + 195.46D + 0.067SH^2 - 179.25D^2.D \quad (3)$$

- **Post-healing mechanical behavior**:

$$\sigma_R = -3.11 - 0.28SH + 126.23D - 0.037SH^2 - 99.90D^2 - 0.63SH.D \quad (4)$$

These predictive models provide a valuable tool for design optimization of self-healing laminated composites, supporting the selection of the optimal healing agent fraction to balance mechanical performance and repair efficiency. Additionally, the generated response surfaces contribute to reducing experimental efforts, time, and costs associated with mechanical testing.

The findings highlight that although the inclusion of self-healing agents enhances damage tolerance, excessive fractions lead to a notable reduction in mechanical properties without proportional gains in repair efficiency. Therefore, optimizing the healing agent content is essential for maintaining a balance between structural integrity and autonomous repair functionality.

4 CONCLUSIONS

It was evaluated the influence of thermoplastic self-healing agent fraction on the shear behavior of CFRP through comprehensive mechanical and statistical analyses. The distribution of self-healing particles, morphology, and repair performance were characterized. Key findings include:

- Stiffness values is reduced with the addition of the self-healing agent due to reduced bond density in the thermoplastic within the thermoset matrix;
- Higher agent fractions lowered repair efficiency, attributed to intralaminar fracture and thermoplastic coalescence (larger particle size), indicating a threshold for injection processing;
- ANOVA revealed that the agent fraction had a higher influence than internal variation among similar laminates prior to repair;
- Self-healing achieved average recoveries of 62% in shear strength, 106% in toughness modulus, and a 57% reduction in crack size;
- Predictive modeling of interlaminar shear behavior identified optimal agent fractions that meet design goals while reducing time and cost.

ABSTRACT

This work presents a numerical prediction of the compressive strength of pultruded carbon composite profiles. Predictions based on input data acquired through 3D X-ray computed tomography scanning. The X-ray data are derived from real uni-directional pultruded samples and used for the determination of the fiber orientation distribution of the composite through the structure tensor analysis mathematical method. The fiber and matrix material properties are determined through experimental testing both of composite samples derived from the same pultruded profiles as the ones of the X-ray scanned specimens and of matrix samples. The compressive strength of the composite is acquired and compared to the numerically obtained values. Apart from the fiber and matrix properties, the fiber orientation distribution, the voxel size and the fiber diameter serve as input for the model. The model is two-dimensional, subjected to compressive loading, while material homogenization of the fibers and matrix is performed. The formulation ensures that the model is mesh independent. Apart from the prediction of the compressive strength, the numerical model provides information on the kink band formation in the material sample. The results show the effect of each X-ray scanned slice's fiber orientation distribution to the material's strength. It is also shown that the numerical compressive strength values could serve as a prediction for the actual ones in the case that the fiber orientation distribution is the sole material variation found in a pultruded composite. This study forms the basis for a more extensive investigation presented in ongoing work.

1 INTRODUCTION

Pultruded unidirectional carbon fiber composites are commonly used as structural elements in wind turbine blades, particularly in the load carrying spar cap, where high compressive strength is required [1-4]. Due to the nature of the manufacturing process, pultrusion is related with enhanced fiber straightness and constant cross section of the manufactured composite. However, small deviations in fiber orientation can significantly reduce the material's capacity to sustain compressive loads and trigger kink band formation [5]. This study introduces a numerical modelling approach to predict the

compressive strength of such composites, using fiber orientation distribution extracted from X-ray computed tomography (CT) scans as the primary input.

Fiber orientations will lead to shear loads in the matrix material. When the matrix shear loading capacity is reached, excessive fiber rotation occurs resulting in the formation of kink bands [5]. Researchers have used extensively 3D X-ray scanning techniques to develop three-dimensional methods to estimate the fiber orientation distribution in real composite materials [6, 7]. Volumetric data of composite sample acquired by X-ray CT scanning can be used as an input for the structure tensor analysis, an image analysis mathematical method for the determination of the fiber orientation, as described by Jeppesen et al. [8, 9]. The structure tensor analysis, used in this work as well, allows for the calculation of the local gradient of intensity in a neighbourhood around each voxel of the examined scanned volume, and is stored in a matrix. Through eigenvalue decomposition of this matrix, the dominant fiber orientation can be found and, subsequently, being mapped to the integration points of a finite element (FE) model's mesh [10].

Kyriakides et al. [11] and Vogler et al. [12] developed a two-dimensional discretized model to study the mechanisms of compression of unidirectional fiber composites, including fiber orientation variations. The kink band formation was investigated while it was found that fiber non-uniformity affects greatly the compressive limit load. A two-dimensional numerical model was developed by Christoffersen and Jensen [13, 14] to study the kink band formation on composites. The material was described by an elastic-plastic constitutive law, while homogenization was applied on the constitutive properties. Ferguson et al. [7, 15] adapted the method above and, after extracting the fiber orientation distribution from X-ray CT scanned composite data by using the structure tensor analysis and mapping it to the model, was able to predict the compressive strength and the initiation of the kink band formation. The solution acquired following this approach is mesh dependent [16].

Fleck and Shu [17] presented a theoretical homogenized numerical model. In the model, the fiber microrotation was described by introducing a scalar kinematic variable θ, the fiber diameter served as length scale and the fiber bending's effect on the stiffness was included. Poulios and Niordson [17, 18] developed a similar homogenized numerical model. It also included a kinematic variable θ, but contrary to the one mentioned above this is a vector. Two independent constitutive material laws described the composite's components, with the fibers and the matrix following hyperelastic and hyperelastoplastic behavior respectively. Similar as above, the fiber diameter was used as length scale and the fiber bending effect on the stiffness was included. This FE model was used for the study of composite materials under compressive loading following the assumption of idealized fiber orientation imperfections. The kink band formation was thoroughly investigated and, after comparing the fiber-matrix homogenized micromechanical model with the corresponding fiber-matrix discrete one, the former was found accurate and in good agreement. Mageira et al. [20] first studied a real composite case with the method described above. Carbon fiber composite data acquired through X-ray CT scanning served as input for the model.

The presented work continues the method built in [20] by adding experimental testing to compare and evaluate the numerical obtained values of the compressive strength of real composite samples with the corresponding experimentally obtained ones. To the knowledge of the authors, a comparison between experimental and numerical values based on real data using the homogenized model developed by Poulios and Niordson is introduced for the first time here. The method includes the acquisition of 3D X-ray data from samples from a carbon composite pultruded profile. By using the structure tensor analysis, the fiber orientation distribution can be determined and serve, along with the material properties obtained after experimental compression testing, as an input for the FE model. The two-dimensional numerical model from [17, 18], built in the finite element library GetFEM, has been adapted to include the extracted fiber orientation data. The results show the kink band formation in the examined sample and the prediction of the compressive strength of it; the latter is compared with the corresponding experimental values. The work presented here are part of a larger framework, which is further developed in an extended study [21]. This study contributes to the improvement of the numerical prediction of the compressive strength of unidirectional composites by integrating real fiber orientation data with a mesh-independent homogenized finite element model.

2 THEORY

The two-dimensional numerical model is an implementation of the composite material homogenized formulation developed by Poulios and Niordson [18]. Key points of the formulation include the decomposition of the homogenized composite's kinematics into the ones of the fiber and the matrix. Apart from the displacement variable $\boldsymbol{u}$, an additional kinematic filed variable, $\boldsymbol{d}$, is introduced. Both are two-dimensional vectors, while a plastic multiplier scalar variable ξ_m is also used. It describes a scaled version of the increment $\Delta\gamma_m$ of the accumulated plastic strain γ_m, between two consecutive time steps. Considering the above, there are five degrees of freedom in total per node (u_1, u_2, d_1, d_2, ξ_m). The method results in the model's mesh independence, meaning that the element size does not affect the results. A detailed description of the homogenized formulation can be found on [19], while more information on the presented implementation, including the calculation steps, is available on [21].

The fibers' behavior is described by standard isotropic hyper-elasticity defined by the Young's modulus E_f and the Poisson's ratio ν_f. The matrix's behavior is described by standard isotropic hyper-elastoplasticity, with the matrix's hyper-elasticity defined in a similar manner as above (by the Young's modulus E_m and the Poisson's ratio ν_m). The plasticity of the model's material is depicted through the Ramberg-Osgood constitutive law applied on the matrix. This material model can capture the non-linear strain hardening relationship, described by two fitting parameters, $\sigma_{0,m}$ and n_m. The Ramberg-Osgood material model is:

$$\varepsilon_{eq,m} = \frac{\sigma_{eq,m}}{E_m} + \frac{3}{7}\left(\frac{\sigma_{eq,m}}{\sigma_{0,m}}\right)^{n_m} \tag{1}$$

where $\varepsilon_{eq,m}$ is the effective von Mises strain and $\sigma_{eq,m}$ the effective von Mises stress for the matrix. Apart from the aforementioned fitting parameters and fiber and matrix properties, the model requires the fiber volume fraction V_f and the fiber diameter h_f as an input. The latter enables the model to account for the fiber's bending effect. The numerical model was built in GetFEM [22], an open-source FE library with interface for Python.

3 METHOD AND RESULTS

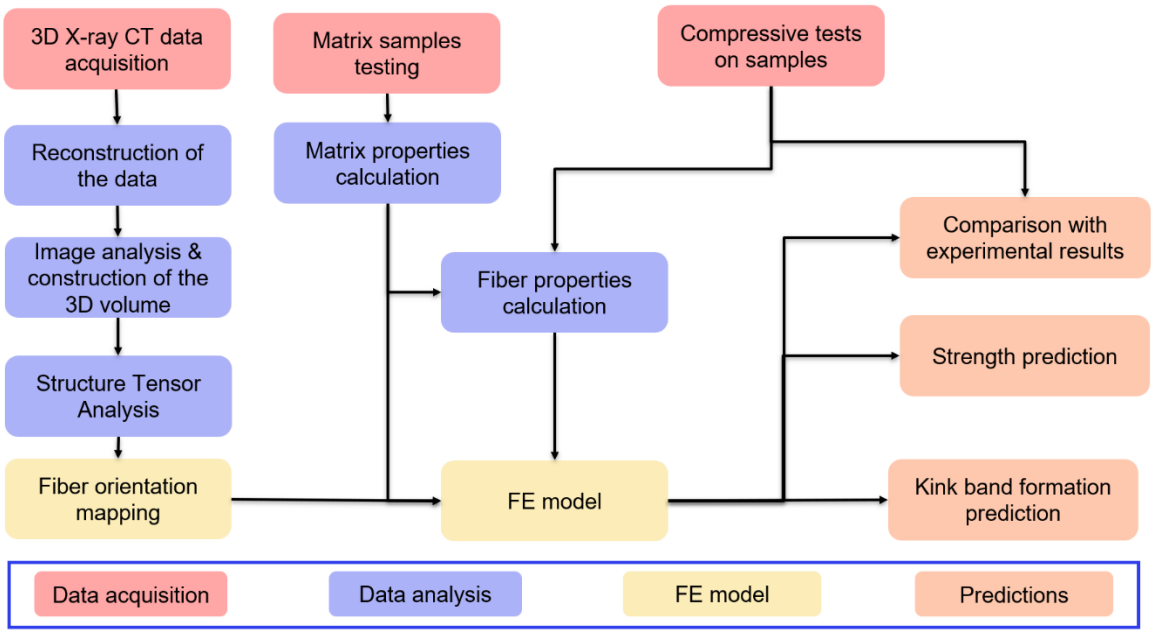

Figure 1: The developed methodology used in this work, described in a flow chart.

The methodology followed in this work, presented in Figure 1, started with the acquisition of the X-ray CT data of the unidirectional carbon composites, their analysis and, subsequently, the calculation of the fiber orientation distribution and its mapping on the FE model. Material characterization was carried out for the fibers, the matrix and the whole composite (it should be noted that in this work, the term fiber corresponds to what is considered filament, as it is widely used in similar articles). Along with the fiber orientation distribution, the extracted material properties served as the input for the numerical model. In this way, the predictions of the compressive strength and the kink band formation could be obtained. Mageira et al. [21] provides a more thorough description on the whole process and results.

3.1 X-ray CT data acquisition and results

Three samples were cut from a pultruded carbon profile. Their geometry was cylindrical as can be seen in Figure 2, with a diameter and length of 1 mm and 20 mm respectively. The samples were X-ray fully scanned at DanMAX beamline of the MAX IV synchrotron facility. The projection field was 1.2 x 1.2 x 1.2 mm^3 and the voxel size was equal to 0.55 μm. Considering that the average size of the single carbon fiber diameter is 7 μm, this voxel size ensured clear capture of the data, as it can be seen in the zoomed detail of Figure 2b. For the demonstration of the method and due to page limitations, only the results of the sample numbered six are presented in this work.

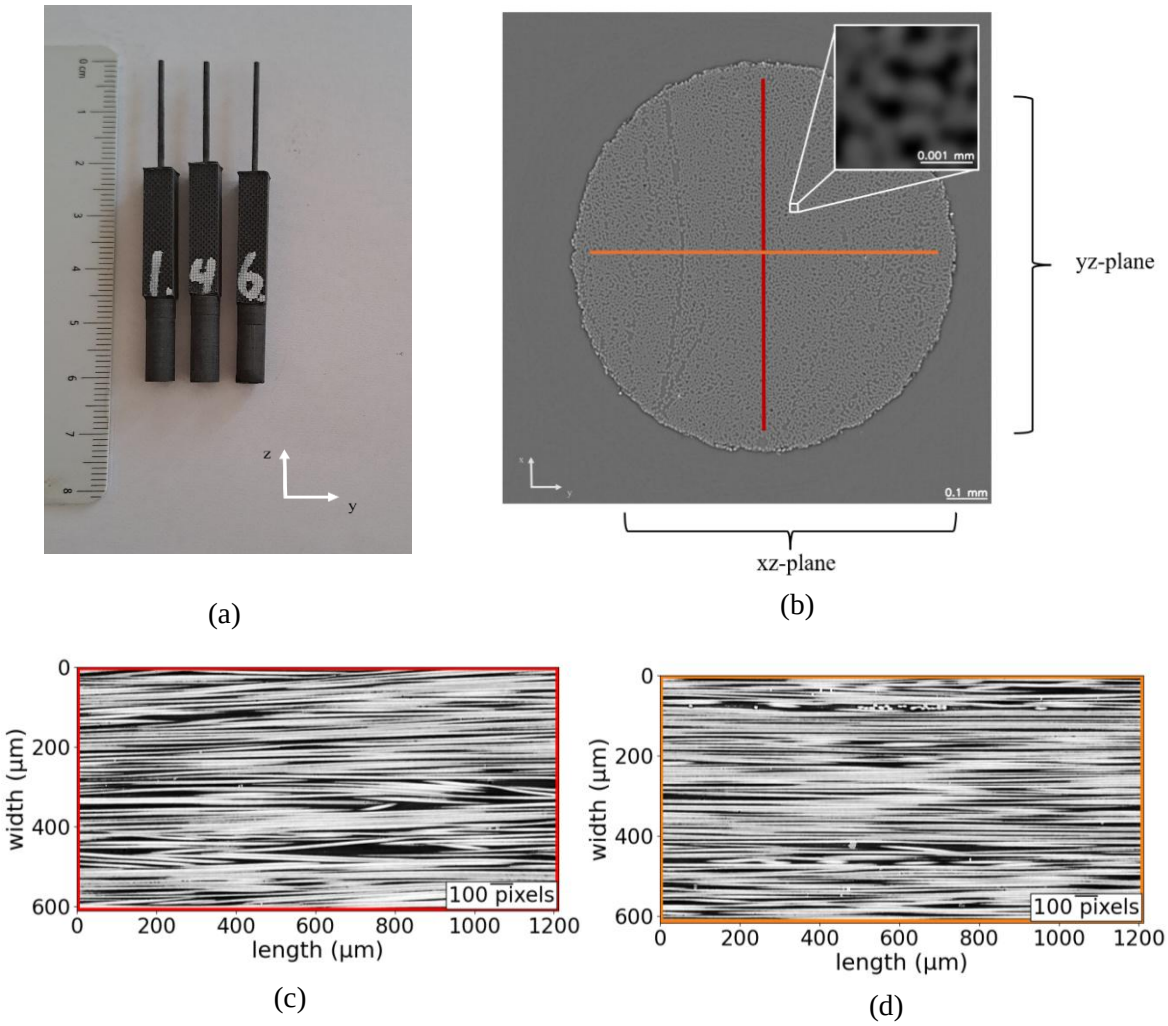

Figure 2: (a) The scanned unidirectional carbon composite samples. Each sample is fixed on a base used for mounting during 3D X-ray scanning. (b) Representative slice showing the cross section of one of the examined samples, as it is after reconstruction. The zoomed image shows the level of detail and quality of the scan. The characteristic kidney-shaped cross section of carbon fibers can be observed.

The two planes are annotated. The coloured lines represent the top view of the slices showing the longitudinal direction of the fibers, that can be seen in the bottom of the figure, for the yz-plane (c) and the xz-plane (d). These slices serve as an input for the structure tensor analysis.

Figure 2b show a slice of the scanned sample after reconstruction, showing the cross section of it. The images representing the slices were cropped and stacked accordingly to create a digital subvolume of the total scanned samples' volume. The subvolume had a thickness corresponding to 100 slices. Through its creation, the slices related to the planes that show the longitudinal direction of the fibers could be acquired. These slices and their corresponding subvolumes were essential for using the three-dimensional structure tensor analysis for the determination of the fiber orientation distribution. In Figure 2, the two planes, xz- and yz-, are annotated. Five slices were considered in this work, per orientation. An example of each plane's slice showing the longitudinal direction of the fibers can be seen at the bottom of the figure; these two slices and their corresponding results are the ones thoroughly presented in this work.

3.2 Material results

The material properties that serve as an input for the numerical model and thus need to be determined experimentally are the Young's moduli and Poisson's ratios of the fiber and the matrix, the fiber volume fraction and average diameter and the fitting parameters of the Ramberg-Osgood model for the matrix system. The first step was the determination of the mechanical properties of the composite material. To achieve this, samples were cut from the same pultruded profile from which the scanned samples were acquired. These samples were subjected to compressive testing. The Universal Testing Machine used had a load cell of 250 kN, and the applied testing speed was 1 mm/min. The strain range considered for the calculation of the composite's Young's modulus was 0.05 - 0.25 %, according to ISO-14126 [23]. As it can be seen in Figure 3, most of the samples broke outside their gauge area, due to the shear control of the failure [7]. For that reason, the acquired values of the compressive strength should be considered conservative.

(a)

(b)

Figure 3: (a) The examined dogbone-shaped samples, after the compression test. (b) The failure outside the gauge area of most of them can be noted. For the development of the kink band outside the gauge area, please refer to [7].

The matrix was vinyl ester, with its stress-strain curve shown in Figure 4, and the values of its Young's modulus and Poisson's ratio in Table 1. As mentioned in the Theory section, the Ramberg-Osgood material model was used to describe the behavior of the matrix numerically. The values of the parameters are $\sigma_{o,\,m}$ = 104.37 MPa and n_m = 2.35, and were found by fitting the Ramberg-Osgood material model on the matrix stress strain curve, as shown in Figure 4. The Young's modulus of the fibers was determined through back calculation by using the rule of mixture, since the matrix and composite material properties were already known. The detailed description and analysis of the material data are presented on [24].

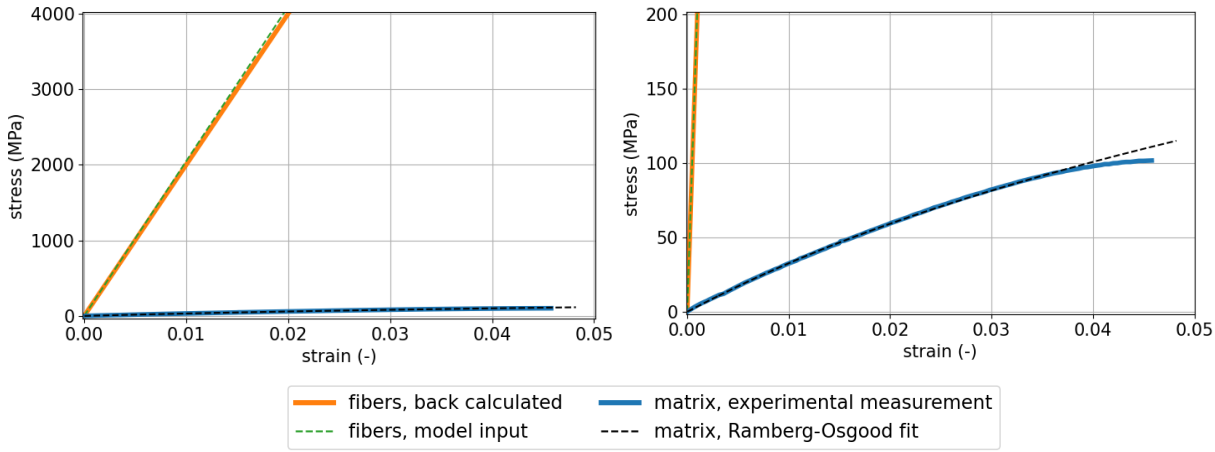

Figure 4: The stress-strain curves for the fibers and the matrix (left). A zoomed area of the graph is included (right). The fit of the Ramberg-Osgood material model for the matrix can be observed, as well the numerical model's material input for the fibers.

The average values of the calculated properties are presented on the following table:

Magnitude		Composite	Matrix	Fiber
Young's modulus E	[GPa]	137.5 ± 1.7	3.55	204.8 ± 4.1
Poisson's ratio v	[–]	–	0.4	0.26
Volume fraction	[%]	–	33.6 ± 0.9	66. 2 ± 0.8
Fiber's diameter	[μm]	–	–	7

Table 1: The mechanical properties and material parameters acquired after characterization of the composite, the fiber and the matrix.

3.3 Fiber orientation distribution results

The structure tensor analysis was used to determine the fiber orientation distribution. A short description of the method is included in the introduction, along with references regarding where to find details on it. For information on how it was applied on this dataset, please refer to [21].

After the decomposition of the eigenvalues, the corresponding eigenvectors were calculated, and the dominant fiber orientation was found. For the two-dimensional model used, the representation of the fiber orientation is a two-dimensional projection of the eigenvector $\boldsymbol{r}_1$ to the yz- or xz-plane, respectively. The subscript 1 identifies the dominant fiber orientation. To show the fiber orientation, the elevation angle φ was used, formed and calculated as shown in Figure 5. In the same figure, the elevation angle distribution on a slice is presented.

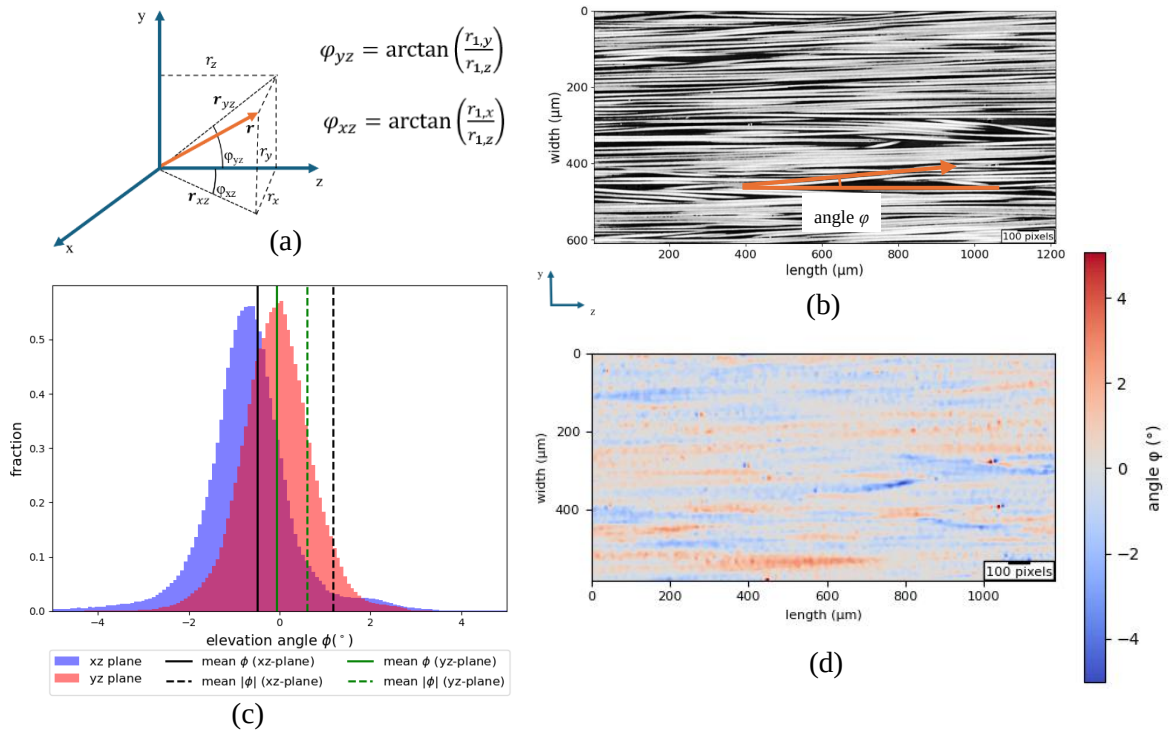

Figure 5: (a) The coordinates system used for this work, along with the dominant eigenvector $\boldsymbol{r}_1$, its projections at the yz- and xz-planes and the corresponding elevation angle for each case. Right next to it, the equations for the calculation of the elevation angle, per plane. (b) A yz-plane slice used for the 3D structure tensor analysis, with the elevation angle for a fiber shown. (d) The distribution of the elevation angle of the same slice as in figure 5b. (c) Distribution of the elevation angles for one slice per plane. The slices used are same as in Figure 2.

Figure 5 shows also the histogram of the distribution of the elevation angle's values for each examined plane. In the same figure, the values of the mean elevation angle φ, as well as of the mean absolute elevation angle, $|\varphi|$, are presented. The mean absolute elevation angle is chosen as a single value to represent both the magnitude and the scatter of the fiber orientation distribution [7, 24, 25]. For both planes, the vast majority of the values of the elevation angle ranged between -3° and 3°, something that is due to the unidirectionality of the pultruded material and the high quality of this manufacturing process. For the xz-plane, the mean elevation angle φ = -0.50° and the mean absolute elevation angle $|\varphi|$ = 1.17°. For the yz-plane, the corresponding value of the mean φ = -0.07°, and for the mean $|\varphi|$ = 0.61°.

3.4 Mapping of the fiber orientation distribution

The fiber orientation distribution serves as an input for the numerical model by its mapping to the integration points of the elements. A file containing the distribution of the elevation angle φ regarding the undeformed slice modelled is read by the FE code. The cosine and sine of each value of the elevation angle are calculated and saved as the following unit vectors, $\boldsymbol{N}$ and $\boldsymbol{T}$:

$$\boldsymbol{T} = \begin{Bmatrix} \cos(\varphi_0) \\ \sin(\varphi_0) \end{Bmatrix} \text{ and } \boldsymbol{N} = \begin{Bmatrix} -\sin(\varphi_0) \\ \cos(\varphi_0) \end{Bmatrix} \quad (2)$$

Each pair of $\boldsymbol{N}$ and $\boldsymbol{T}$ is mapped on an integration point. The unit vector $\boldsymbol{T}$ describes the direction parallel to the fibers, while the unit vector $\boldsymbol{N}$ the direction perpendicular to the fibers. The number of the mesh elements corresponds to the size of the examined slice, through the coupling of an elevation angle value with an integration point.

3.5 Numerical results

The numerical model was built in GetFEM. The coordinate system of the simulation is similar to the one related to the X-ray CT scanned samples presented on Figure 2. The model was two dimensional and was subjected to compression.

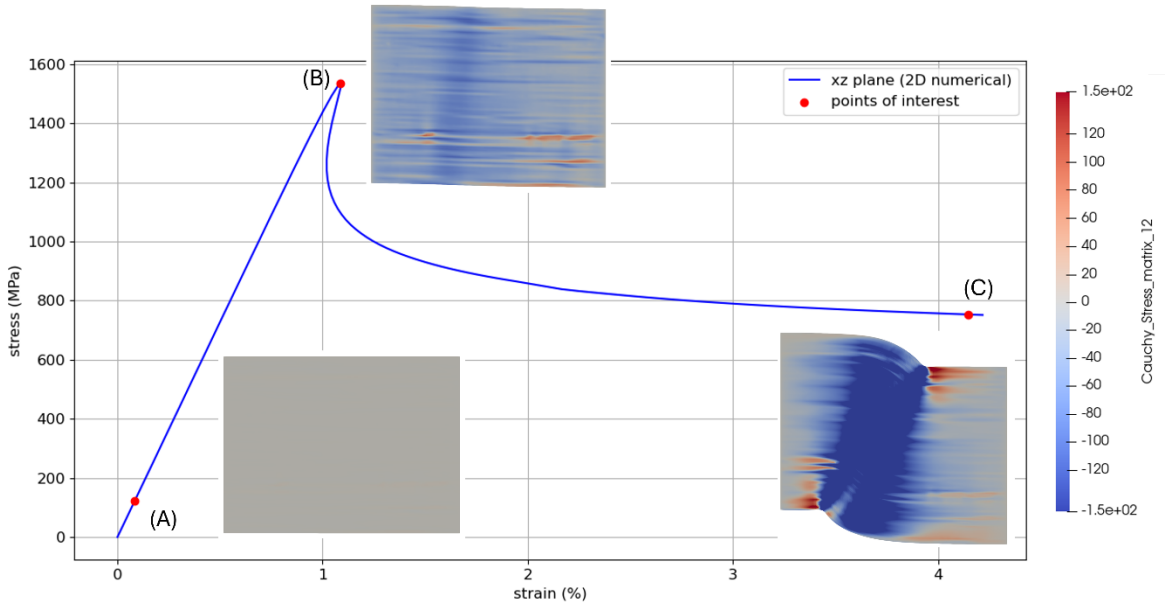

Figure 6: The stress-strain curve, for a single numerical case (xz-plane). Three points of interest are annotated as (A): just after the start of the compressive loading, (B): at maximum compressive stress and (C): at the latest stages of the simulation. For the same points, the distribution of the matrix's Cauchy shear stresses on the examined slice is shown, with the related scale bar included on the right of the graph.

Figure 6 shows the predicted stress-strain curve of one simulated slice. In addition, the distribution of the matrix's Cauchy shear stresses at the early loading stages, at the point of failure and after it can be observed, along with the gradual formation of the kink band. The stress-strain curve follows an almost linear trend, until the maximum stress value is reached and thus failure occurs. During the compressive failure of a composite, particularly when it is unidirectional, the material's limit load is reached in an area of localized strain [27], leading to the abrupt and excessive bending of the fibers, and subsequently to the kink band formation.

In the numerical model, the stress-strain curve follows a snap-back trend, which is a characteristic of the unidirectional composite's kink band formation during a FE simulation [25]. The snap back behavior is due to the localized fiber rotation leading in a load drop which results in elastic unloading in the material outside the kink-band region.

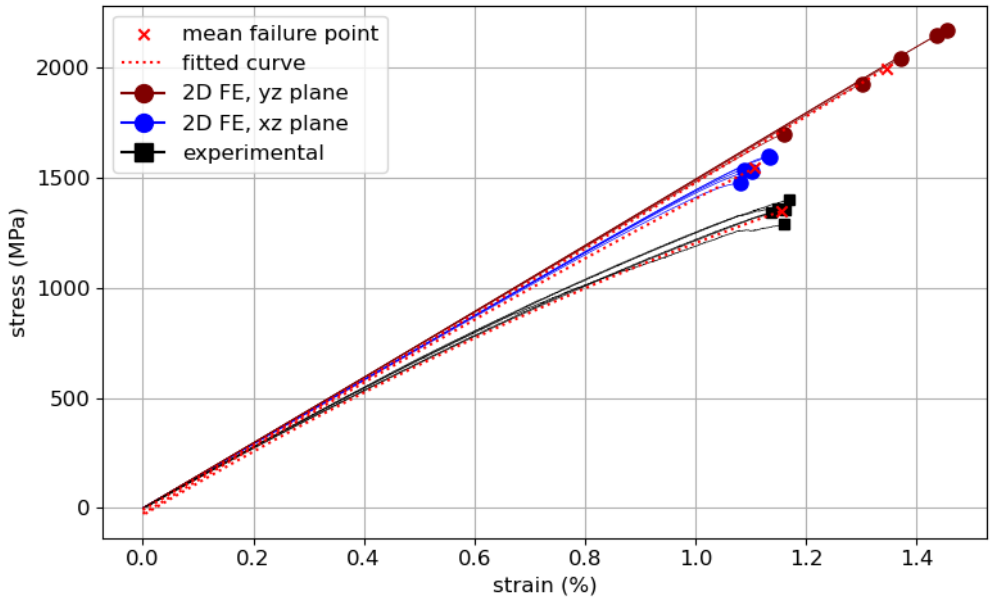

Figure 7: The stress-strain curves of the numerical data, for both planes examined, along with the results acquired through experimental testing. The maximum stress value is marked, for each case. A fitted curve for both the numerical and the experimental response, along with the mean failure point of each case, are included.

In Figure 7, the stress-strain curves for both the experimental and the numerical (for both planes) results is shown. The initial part of the experimental and numerical curves follows a similar trend. After this, however, the trend of the experimental measurements follows a curvature, govern by the non-linearity of the fiber material [28]. The numerical results show a stiffer response, which, as argued by Ferguson et al. in [7], is expected for a two-dimensional plane strain numerical model [25].

In the same figure, the value of the mean maximum stress (annotated as mean failure point) is included. For the numerical simulations, this value is 1546 MPa (xz-plane) and 1997 MPa (yz-plane). The corresponding experimental value is 1349 MPa. These results, along with the Young's moduli, average strain, mean elevation angle and mean absolute elevation angle are presented on Table 2. The compressive strength on yz-plane was on average 29% larger than the one of the xz-plane, and the compressive strength of xz-plane was 15% larger than the experimental values, on average. The Young's moduli of the numerical simulations were close to the experimental value, being 6% different for the yz-plane and 8% for the xz-plane.

Magnitude		Numerical, yz-plane	Numerical, xz-plane	Experimental
Young's modulus E	[GPa]	145.5 ± 0.2	148.0 ± 0.2	137.5 ± 1.0
Strength σ_{max}	[MPa]	1997 ± 110	1546 ± 29	1349 ± 23
Strain ε at max load	[%]	1.35 ± 0.07	1.11 ± 0.02	0.98 ± 0.02
Mean angle φ	[°]	0.19 ± 0.10	-0.63 ± 0.15	–
Mean absolute angle $\lvert\varphi\rvert$	[°]	0.63 ± 0.05	1.24 ± 0.07	–

Table 2: Average values of strength, strain, mean elevation angle and mean absolute elevation angle regarding the numerical results, along with the average values for stress and strain obtained through experimental testing.

The difference between the experimental and numerical compressive strengths can be attributed to

several factors. Geometry and loading conditions of the tested samples may have introduced local stress concentrations [7], with some samples failing outside the gauge area due to shear, which the model does not capture. In addition, the volume fraction of the fibers and the matrix were considered constant in the model, while, according to Kyriakides et al. [11] and Jensen [29], the varying volume fraction leads to a decrease in the sample's ability to resist kink band formation, and thus probably to a slightly reduced compressive strength. The fiber-matrix interface, which affects load transfer, and thus the compressive strength, is also not included. Finally, as a two-dimensional model, it cannot capture out-of-plane variations in fiber orientation distribution, possibly leading to a higher numerical value of compressive strength.

Considering the above, the compressive strength predicted by the numerical model can represent the potential strength of the composite, accounting for its fiber orientation distribution, under pure compression where shear effects are negligible.

4 CONCLUSIONS

In this work, X-ray CT images of pultruded carbon fiber reinforced composite samples were used to predict the compressive strength of the material by using a built numerical model. Key part of the two-dimensional, mesh independent, homogenized model was the inclusion of the composite's real fiber orientation distribution. The numerical results of the predicted compressive strength were compared with the corresponding experimental values, with the former being higher than the latter ones. This difference was expected, mostly due to the model being two-dimensional, the effect of shear during the experimental testing and any potential imperfections of the tested samples. Thus, the numerical results could serve as the prediction of the compressive strength of a composite considering its fiber orientation distribution. Through this work, the effect of fiber orientation distribution, dependent on pultrusion parameters, on the composite's compressive strength is shown. Based on these findings, adjustments to the pultrusion process could be made to improve the mechanical properties of wind turbine composite blades.

Student Status Confirmation Form for the ICCM Tsai Award

May 26th, 2025

I, Lars Pilgaard Mikkelsen, hereby confirm that Pinelopi Mageira, who applied for the ICCM Tsai Award, was, at the date of the abstract submission November 15th, 2024, a PhD student under my supervision at Technical University of Denmark.

Conceptualization
Ideas; formulation or evolution of overarching research goals and aims.

Data Curation
Management activities to annotate (produce metadata), scrub data and maintain research data (including software code, where it is necessary for interpreting the data itself) for initial use and later reuse.

Formal Analysis
Application of statistical, mathematical, computational, or other formal techniques to analyze or synthesize study data.

Investigation
Conducting a research and investigation process, specifically performing the experiments, or data/evidence collection.

Methodology
Development or design of methodology; creation of models.

Software
Programming, software development; designing computer programs; implementation of the computer code and supporting algorithms; testing of existing code components.

Validation

Verification, whether as a part of the activity or separate, of the overall replication/reproducibility of results/experiments and other research outputs.

Visualization
Preparation, creation and/or presentation of the published work, specifically visualization/data presentation.

Writing – Original Draft Preparation
Creation and/or presentation of the published work, specifically writing the initial draft (including substantive translation).

Writing – Review & Editing
Preparation, creation and/or presentation of the published work by those from the original research group, specifically critical review, commentary or revision – including pre- or post-publication stages.

PARTIALLY CARBONISED CARBON FIBRES AS AN IMPROVED MULTIFUNCTIONAL STRUCTURAL BATTERY ELECTRODE

Abstract

Carbon fibres are increasingly explored for use in structural battery electrodes due to their ability to combine mechanical strength and stiffness with electrochemical functionality. The properties of carbon fibres are largely governed by their microstructure, which is shaped by the processing conditions—particularly the carbonisation temperature. This study focuses on exploring how partial carbonisation during manufacture influences the multifunctional performance of carbon fibres. The manufactured fibres are subjected to mechanical and electrochemical tests to evaluate their tensile properties, and reversible capacity. The results confirm previously reported multifunctionality trade-offs: when comparing to conventional intermediate modulus carbon fibres, by reaching a maximum temperature of 900 °C (compared to the usual 1500 °C) the electrochemical capacity increases at the expense of mechanical performance. Up to a 50% reduction in tensile modulus is observed alongside a 40% improvement in electrochemical capacity. These findings highlight the potential to greatly expand the achievable multifunctionality window for carbon fibres by adjusting the maximum carbonisation temperature, enabling a versatile design of active materials for structural energy-storing applications.

Introduction

The development of multifunctional materials is paving the way for significant changes in energy storage solutions for transportation and portable devices. One of the most promising concepts are structural battery composites (SBCs), which combine structural functions with the ability to store electrical energy. By embedding energy storage directly into load-bearing components, such as those in electric vehicles, designers can reduce weight, increase efficiency and consequently extend driving range. Structural battery composites embody this dual functionality, enabling materials to perform as both batteries and composite panels. Typically, a structural battery features a configuration where a thin-ply carbon fibre tow acts as the negative electrode, layered with a separator and a counter electrode[1–6]. These layers are infused with a structural battery electrolyte (SBE), which provides load transfer capabilities and ionic transport[7–11]. Due to their multifunctionality, carbon fibres not only provide structural reinforcement but also serve as lithium hosts and electron conductors.

While the mechanical properties of commercial carbon fibres are well-characterised, owing to their established role in composite reinforcement, their electrochemical behaviour remains less understood. Works by Jacques et al. and Duan et al. helped shed light on how lithium insertion alters the physical and mechanical characteristics of these fibres[12–15]. Additional investigations by Kjell et al. evaluated the electrochemical performance of widely used PAN-based carbon fibres[16], and Hagberg et al. examined the capacity and coulombic efficiency of intermediate modulus (IM) fibres (such as T800 and IMS65) in contrast to high modulus (HM) fibres like M60J, using precise coulometry techniques[17]. IM fibres generally exhibited superior electrochemical capacity, though the exact mechanisms behind this disparity were not initially clear.

Fredi et al. employed high-resolution transmission electron microscopy and in-situ Raman spectroscopy to uncover the underlying lithiation processes in T800, IMS65, and M60J fibres[18]. Their findings revealed that IM fibres behave somehow similarly to amorphous carbon during lithium insertion, with each fibre displaying unique performance characteristics. Conversely, the HM fibre followed a graphite-like staging mechanism, which was hindered by defects in its large crystalline domains. This structural obstruction contributed to its lower lithium capacity. Further insights into the performance differences between IM fibres were offered by Johansen et al., who investigated the role of heteroatoms in the carbon fibre microstructure[19]. They discovered notable variations in nitrogen content: IMS65 contained 20.5% pyridinic and pyrrolic nitrogen compared to just 14.2% in T800. These nitrogen configurations typically appear at defect sites and facilitate lithium coordination, suggesting that the higher concentration of these species in IMS65 may account for its enhanced capacity.

Asp et al. demonstrated the potential of intermediate modulus (IM) carbon fibres for multifunctional energy applications by integrating T800 fibres into a laminated structural battery composite, where the fibres functioned as the negative electrode[20]. Their prototype achieved an energy density of 24 Wh/kg alongside a mechanical stiffness of 25 GPa, exemplifying the material's dual structural and electrochemical roles. More recently, by using carbon fibres coated with lithium iron phosphate as the active material for the positive electrode, Chaudhary et al. managed to realise the first all-fibre structural battery. They boosted the structural battery performance leading to a significant improvement in the mechanical performance, with a tensile modulus of 76 GPa and a slight decrease in the energy density to 30 Wh/kg[21,22].

Despite such advancements, significant challenges remain. Commercially available carbon fibres have traditionally been optimised solely for mechanical properties, particularly strength and stiffness, without consideration for electrochemical functionality. This presents complications for multifunctional applications, not only because critical details such as the precursor materials and processing conditions are often proprietary, but also because the fibres are typically coated with sizing agents whose chemical composition is unknown, potentially interfering with their performance in electrochemical applications.

In an effort to better understand how lithium interacts with carbon fibres and to identify which microstructural characteristics enhance electrochemical performance, Xu et al. and Tavano et al. manufactured custom-made carbon fibres. The same PAN-based precursor was used in both cases, but each study introduced distinct modifications during fibre processing. Xu et al. varied the tensile force applied during the stabilisation stage, while Tavano et al. adjusted the carbonisation temperature profiles. These deliberate alterations allowed them to systematically investigate the effects of processing conditions on the resulting fibre properties. Their findings revealed a fundamental trade-off between mechanical properties and electrochemical performance. As the electrochemical capacity of the fibres improved, a corresponding decline in mechanical performance was observed, highlighting the inherent antagonistic character between these two functional objectives in carbon fibres. Furthermore, it was shown that fibres with a less ordered microstructure, specifically those with reduced crystalline carbon content, smaller crystallite sizes, and increased interlayer spacing within the crystalline regions, exhibited superior lithium storage capabilities. These results suggest that while high structural order favours mechanical strength, a more disordered carbon structure can be advantageous for lithium intercalation, pointing to the need for careful optimisation when designing carbon fibres for multifunctional applications.

In the current study, we investigate a custom-made carbon fibre manufactured only by a partial carbonisation step. The resulting carbonaceous microstructure attributes peculiar properties to the fibres, enabling us to further expand the design window for structural battery composites. Previous studies have focused on HM and IM carbon fibres. HM fibres have high mechanical performance but almost non-existent lithium storing capabilities. IM fibres show a good multifunctionality compromise. With partially carbonised carbon fibres, the mechanical properties are significantly decreased but unmatched reversible

electrochemical capacity is reached. These types of fibres can prove useful for applications that need energy storage at low mechanical requirements, and can guide the development of a new category of multifunctional fibres.

Experimental

Materials: Carbon fibres were produced at Carbon Nexus, Institute for Frontier Materials at Deakin University, Australia, using a research-grade production line. The production process followed similar criteria as in the previous studies by Xu et al. and Tavano et al.[23,24]. The precursor material was a 24 K tow of polyacrylonitrile (PAN) fibres sourced from Bluestar Ltd (China). Following stabilisation, the fibres were subjected to a carbonisation process only in the low temperature carbonisation furnace (LT furnace), reaching a maximum temperature of 900 °C. During production, the fibre line operated at a speed of 30 m/h, resulting in residence times of approximately 2 h in the stabilisation step and 2.5 minutes in the low-temperature carbonisation furnace. Throughout the oxidation phase, the fibres were subjected to an average tension of 2300 cN. This tension was adjusted in the carbonisation stage, with values maintained at 1200 cN during the low-temperature carbonisation. After exiting the LT furnace, the carbon fibres were directed to a winder for collection.

For the electrochemical characterisation, half-cells were assembled. Glass fibre separator (Whatman GF/A, ~260 µm thick), lithium metal foil (99.9%, 0.75 mm thick), lithium bis(trifluoromethanesulfonyl)imide (LiTFSI, anhydrous, 99.99%), propylene carbonate (PC, ≥99%, acid <10 ppm, H_2O <10 ppm), and ethylene carbonate (EC, 99% anhydrous) were all purchased from Sigma Aldrich (USA). The copper foil, nickel foil and silver glue used for the cell assembly were purchased from Ted Pella, Inc. (USA).

Physical properties: Fibre density was assessed using a Ultrapyc 1200e pycnometer (Quantachrome, Austria), with three replicate measurements. The fibre diameter was obtained combining the fibre density with the vibrational analysis conducted via a Favimat+ single fibre tensile test machine (Textechno, Germany) prior to mechanical testing. Conductivity was evaluated via the four-point probe method, with ten measurements carried out to ensure reproducibility and consistency. Surface area measurements were obtained using Brunauer–Emmett–Teller (BET) analysis, conducted on an inverse gas chromatography surface energy analyser (Surface Measurement Systems, UK) with octane gas adsorption at 30 °C. Complementary imaging of the carbon fibre surfaces was performed using a field emission scanning electron microscope LEO-1550 (Zeiss, Germany) to reveal surface texture and morphology.

Raman spectroscopy: Raman spectra were recorded using a WITec alpha300 R spectrometer (WITec GmbH, Germany), equipped with a confocal microscope Zeiss LSM (Zeiss, Germany) and a 50× magnification objective lens Zeiss EC Epiplan (NA = 0.75) (Zeiss, Germany). All measurements were carried out at room temperature (23 °C) using a 532 nm laser excitation source. The laser, focused to approximately 300 nm spot size, enabled detailed analysis of individual carbon fibres. Data acquisition was performed in backscattering geometry, using a 100 µm slit, a 600 lines/mm diffraction grating, and no optical filters. The spectra were collected using a charge-coupled device (CCD) detector. To enhance the signal-to-noise ratio (S/N), each spectrum was composed of 60 accumulations, each with an exposure time of 1 second. Post-processing of the spectra was performed using the software Project FIVE (WITec GmbH, Germany). A linear baseline was subtracted to correct for background fluorescence, and Savitzky-Golay smoothing was applied to further reduce noise. Spectral peaks were analysed in terms of Raman shift, intensity, area, and full width at half maximum (FWHM), using Lorentz function fitting. For visual comparison, all spectra were normalised to the most intense peak.

Mechanical Properties: Mechanical properties, including tensile strength, elastic modulus, and strain to failure, were characterised using single filament tensile testing with a Favimat+ machine (Textechno, Germany), equipped with a 210 cN load cell and a 20 mm gauge length. Tests were performed according

to ASTM D3822-07 at a constant strain rate of 1 mm/min. Seventy-five individual fibres were tested for each fibre type.
