ABSTRACT

The demand for thermoset composites is growing rapidly, driven by urbanization, expanding infrastructure, the push for lightweight and fuel-efficient vehicles, and the increasing use of wind energy systems. This growth is largely due to the excellent mechanical strength, chemical resistance, and low maintenance requirements of thermoset composites.
However, these materials are difficult to recycle. Their tightly crosslinked, three-dimensional covalent structures make them thermally stable but non-meltable, which severely limits conventional recycling options. Current methods, such as pyrolysis and solvolysis, break down the polymer matrix to recover the reinforcing fibers, but they typically destroy the resin in the process. Fully recycling both the resin and fibers remains a major challenge. As a result, there is a growing push to develop more sustainable, circular approaches to composite recycling,an urgent need for the future of advanced materials.
One promising solution is vitrimer chemistry. Vitrimers belong to a class of materials known as Covalent Adaptable Networks (CANs), which rely on thermally activated exchange reactions. In vitrimers, a dynamic covalent bond is broken only when a new one is formed, keeping the network intact. These bonds become increasingly dynamic at higher temperatures, allowing the material to soften without losing structural integrity.This unique behavior enables vitrimers to be reshaped, self-heal, and even recycled in a closed-loop process, all while maintaining high performance.
In this work, we explore the practical application of vitrimer technology and highlight its potential to address one of the biggest challenges in the field: designing high-performance composites that support a circular economy.

VITRIMER CHEMISTRY IN THERMOSET COMPOSITES

Thermosetting composites are a class of high-performance materials formed by reinforcing a thermosetting polymer matrix with fibers, fillers, or other strengthening agents [1]. Unlike thermoplastics, thermosetting polymers undergo an irreversible curing process, typically initiated by heat, radiation, or chemical additives, resulting in a rigid, crosslinked molecular structure. This crosslinking imparts excellent mechanical strength, chemical resistance, dimensional stability, and thermal performance, making thermosetting composites ideal for demanding structural and functional applications. Common thermosetting resins include epoxy, polyester, vinyl ester, and phenolic systems, which are frequently combined with reinforcing materials such as glass, carbon, or aramid fibers. These composites are widely used in industries ranging from aerospace and automotive to wind turbines, and marine engineering, where lightweight yet durable materials are essential.

Despite their advantages, thermoset composites pose a major challenge: they cannot be reprocessed after curing due to their permanent covalent crosslinking of the matrices. This limits recycling options to mechanical, thermal, or chemical recovery methods (Figure 1), all of which are energy-intensive and often degrade the material quality [2,3].

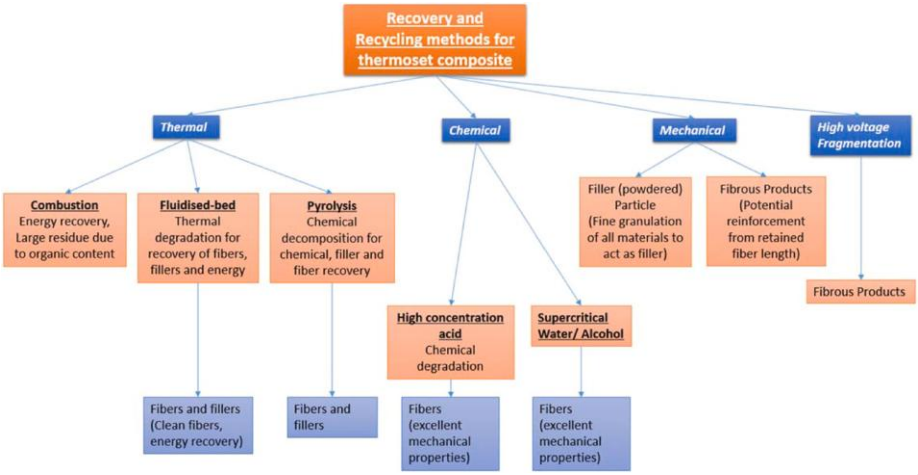

Figure 1: Traditional methods used to recycle polymer composites. Adapted from ref. [3]

To address this issue, emerging research focuses on Covalent Adaptable Networks (CANs). CANs offer the mechanical strength of thermosets along with the reprocessability and reshaping capabilities of thermoplastics. This is achieved through the incorporation into the networks of covalent bonds, which undergo reversible chemical reactions in response to external stimuli such as heat or UV light. These chemical exchanges allow the polymer network to rearrange, maintaining its overall structure and function while altering the connectivity between chains. As a result, CANs behave like traditional thermosets at low temperatures, but above a certain threshold, the dynamic bond exchange enables chain mobility and flow. Additionally, these reversible bonds allow the material to self-heal by temporarily increasing chain mobility without compromising structural integrity or mechanical properties [4-6].

Typically, bond exchange within CANs occurs through one of two mechanisms [7]: a dissociative mechanism, where crosslinks break apart into reactive fragments before reforming, or an associative mechanism, where a reactive group within the network directly replaces an existing bond through substitution (Figure 2). The associative pathway is central to the function of vitrimers, a newer class of CANs that exhibit dynamic behavior while maintaining network integrity, offering significant advantages for high-performance applications. Introduced by Prof. Leibler in 2011 [8], vitrimers have brought new challenges and misconceptions regarding their design and functionality.

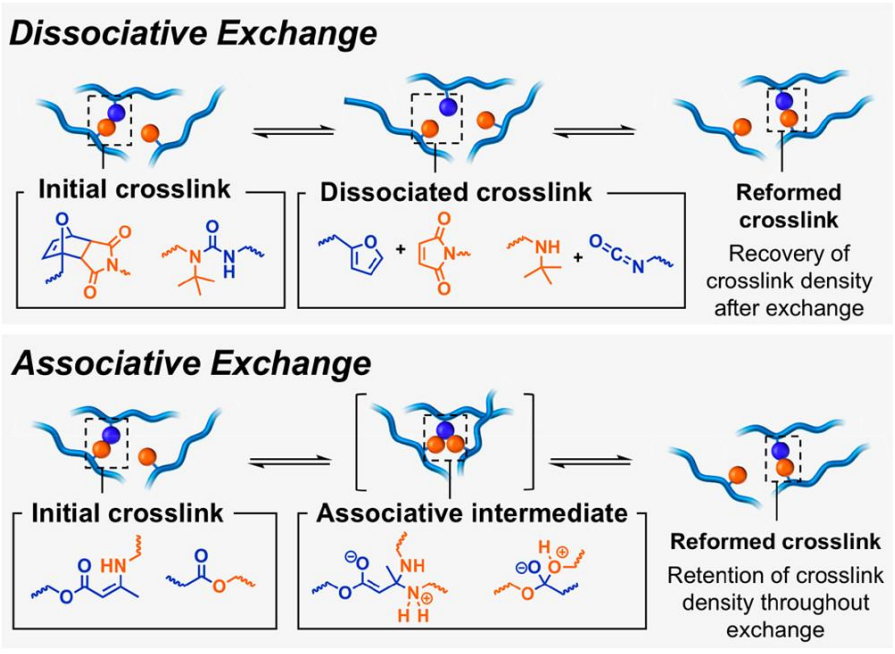

Figure 2: Schematic representation of dissociative and associative bond exchange mechanisms

governing CANs. Adapted from ref. [7]

The term vitrimers originates from their characteristic viscosity–temperature relationship, which parallels that of vitreous silica. These materials exhibit a continuous decrease in viscosity with increasing temperature, following an Arrhenius-type dependence at elevated temperatures. This behavior facilitates dynamic processes such as thermoforming, autonomous self-healing, and closed-loop recyclability through bond exchange reactions, motivating the growing interest in these systems especially in terms of sustainability in different industrial fields, including composites [9,10]. Because of this, there's growing interest in designing and developing thermoset composites using vitrimer technology. Research is now focusing on several key challenges, one of the most important being how fillers affect the movement of polymer chains, known as molecular mobility. Molecular mobility plays a major role in how the material behaves under stress (its viscoelastic properties) and how well it can be reshaped or repaired. While fillers can improve the material's strength and durability, they might also make the polymer chains less flexible. If that happens, the material's ability to rearrange its bonds—which is crucial for self-healing and reprocessing—can be reduced.

Understanding how different fillers interact with the polymer network is therefore essential for developing high-performance, recyclable vitrimer-based composites. Moreover, practical considerations related to manufacturing and scalability must be taken into account. These include the workability of the reactive mixture, its compatibility with existing processing technologies (e.g., molding, extrusion, or hot pressing), and the ability to achieve consistent and reliable performance in the final product. Parameters such as curing conditions, pot life, viscosity, and integration with reinforcement materials must be optimized for large-scale production.

Due to these stringent requirements, the range of thermosetting chemistries suitable for vitrimer formulations is currently limited. Only a few polymer platforms, those that offer a favorable balance between dynamic network behavior, filler compatibility, and processability, are considered viable for real-world applications. This limitation is illustrated in Figure 3, which outlines the most used matrix systems for vitrimer composite development.

.

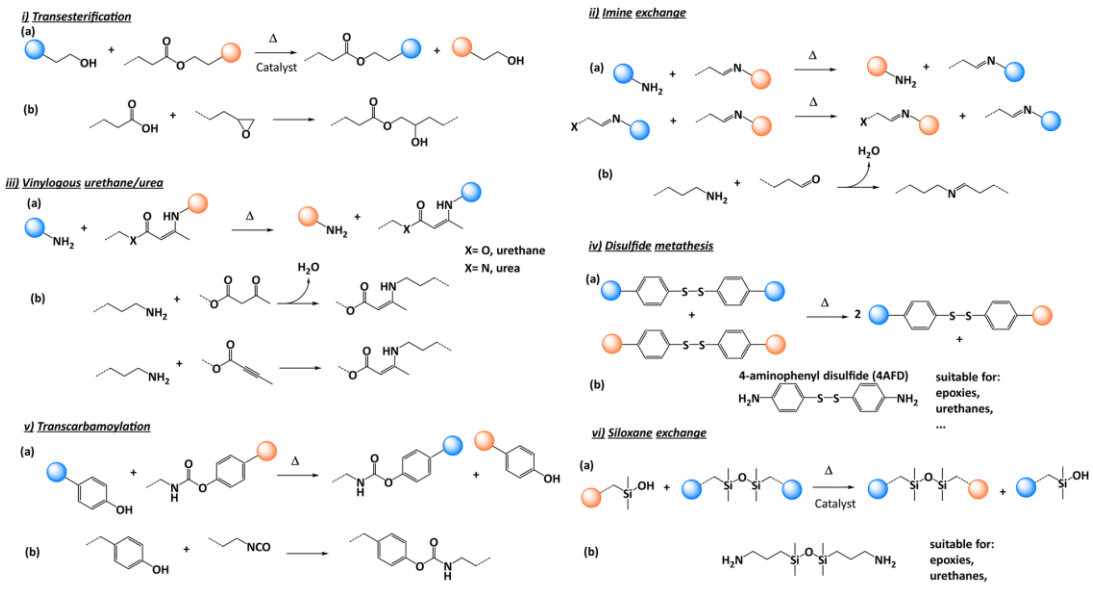

Figure 3: Vitrimer chemistry for thermoset composites. Adapted from ref. ref. [11]

In transesterification-based vitrimers (Figure 3a), epoxy reacts to form exchangeable ester linkages bearing a β-hydroxy group. This chemistry allows for tunable exchange kinetics by adjusting the type and amount of catalyst, offering control over activation energy and processing conditions. However, under off-stoichiometric conditions, careful regulation of network formation is required to prevent the

formation of non-dynamic ether linkages, which can create rigid clusters and compromise vitrimer adaptability. Imine-based vitrimers (Figure 3b) offer robust and dynamic bond exchange via free-amine or imine metathesis, with high bond stability and minimal side reactions. Their advantages include simple synthesis, tunable properties, and excellent mechanical performance, though careful water management is required during formation to prevent internal defects that may be detrimental. Vinylogous urethane-based vitrimers (Figure 3c) enable catalyst-free dynamic exchange via Michael addition or iminium intermediates, offering fast relaxation times and good stability comparable to epoxy/acid systems. Advantages include hydrolysis resistance, water-compatible synthesis, and tunable exchange through external catalysts. However, challenges include managing water release during formation and ensuring long-term stability of free amines to prevent oxidative degradation. Disulfide-based vitrimers (Figure 3d) offer catalyst-free exchange via a [2+1] radical-mediated mechanism at moderate temperatures, making them easy to implement with accessible precursors and widely used in formulations like epoxy and rubber. However, their dynamic properties can degrade over time due to thiol oxidation in air and the thermal sensitivity of the S–S bond. Transcarbamoylation (Figure 3e) enables dynamic exchange in both aliphatic and aromatic polyurethanes, with aromatic structures allowing catalyst-free reactions between phenols and urethanes. Siloxane bonds, known for their high chemical and thermal stability, are common in materials like silicone rubber and glass (Figure 3f), making them attractive for dynamic materials. While traditional silyl ethers exchange slowly, recent advances using a base catalyst have enabled much faster siloxane bond exchanges, offering promising applications in composites with readily available commercial precursors. Carbon nanotubes, graphene, glass fibers or inorganic powders, such as silica (SiO_2) or alumina (Al_2O_3) are used as reinforcement fillers for vitrimeric composites [11,12].

A growing body of literature highlights the versatility of vitrimeric composites, demonstrating their applicability across diverse technological domains. In particular, they have emerged as promising candidates in the field of smart electronics, where their dynamic properties can be leveraged for advanced functionality. In their work, N.J. Van Zee et al. [13] developed conductive thermoset composites by dispersing less than 10 wt.% multiwalled carbon nanotubes (MWCNTs) into a polyimine-based vitrimer, obtained by thermally curing terephthalaldehyde, diethylenetriamine, and tris(2-aminoethyl)amine. These composites combined dynamic covalent bond exchange with the electrical conductivity and mechanical reinforcement of MWCNTs. Remarkably, they maintained stable conductivity after multiple deformation and healing cycles, making them potential candidates for recyclable flexible electronics.

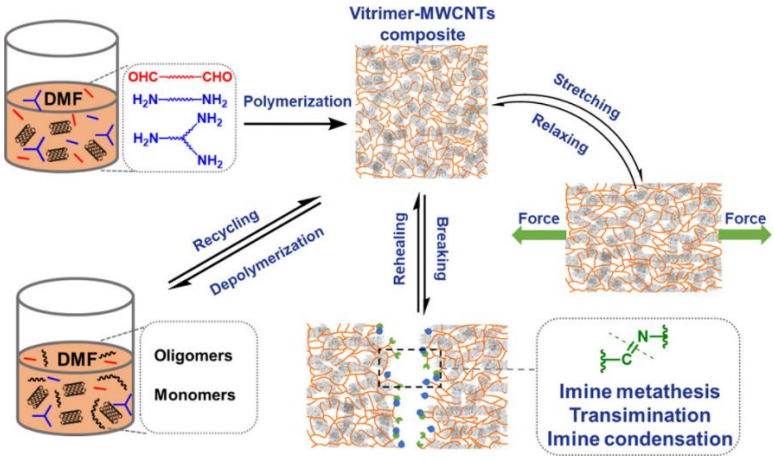

Figure 4: Polyimine-MWCNTs vitrimer composites for flexible electronics. Adapted from ref. [13]

Glass fibre-reinforced vitrimer composites have been developed using both epoxy and vinylogous urethane matrices. Prepreg sheets prepared and consolidated via hot pressing or resin transfer molding (RTM) resulted in dense multilayer composites with improved mechanical properties. Despite high fibre

volume fractions (>50 vol%), these composites retained weldability through dynamic covalent chemistries such as transesterification and amine exchange, enabling adhesive-free joining. The mechanical performance matched that of conventional glass fibre/epoxy systems, highlighting the potential of vitrimer-based prepregs for structural applications, particularly in aerospace where large or complex geometries are required.

An alternative approach is based on the conversion of permanently cured systems into exchangeable thermoset composites. This is achieved by mechanically grinding the cured resin, then treating it with a dynamic exchange catalyst and reinforcing filler under elevated temperature and pressure. The resulting material is a fully crosslinked composite that retains structural integrity while offering improved thermomechanical performance and the ability to undergo thermal reprocessing.

In their work, A. R. de Luzuriaga and his colleagues optimized a fabrication method for fibre-reinforced vitrimer composites involving hot-pressing woven carbon fibres with vitrimer powders derived from mechanically ground, cured DGEBA-based matrices [14]. The formation of the composite material occurred through exchange transesterification reactions within the hot-pressed powder, using a one-minute dry process, faster than conventional liquid-state thermoset processing. The resulting composites retained thermoformability and reprocessability, expanding their manufacturing potential and highlighting the importance of vitrimer particle size in promoting effective healing and full recovery of mechanical properties.

A notable study explored the vitrimerization of thermoset polymers using hydroxyl-rich cellulose nanocrystals (CNCs) as fillers for the fabrication of vitrimeric epoxy-based nanocomposites [15]. The process relied on the use of planetary ball milling to grind the crosslinked resin and mix it with CNCs (Figure 5).

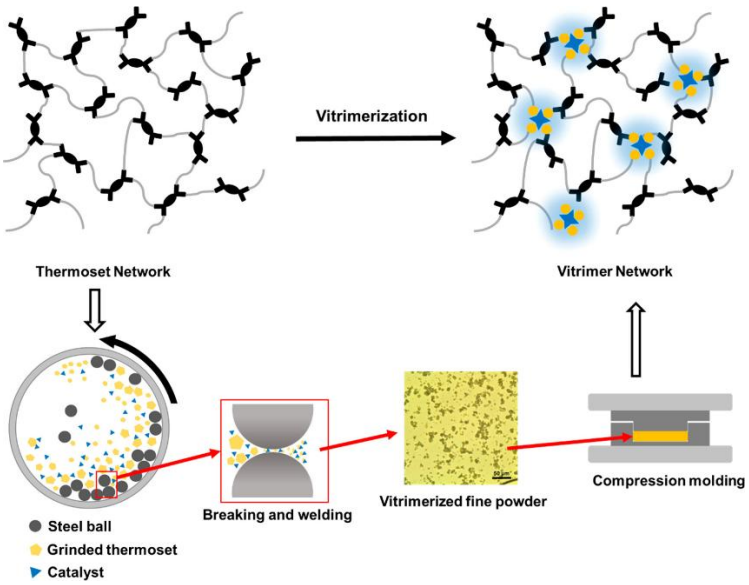

Figure 5: Catalyst-free vitrimerization based on transesterification of a thermoset resin into a vitrimeric composite through the use o planetary ball milling technique. Adapted from ref. [15]

Interestingly, the abundant hydroxyl groups on CNCs facilitate dynamic transesterification at the polymer interface, initiating mechanochemical activation and network reconfiguration thus effectively converting the rigid, irreversible network into a vitrimer composite structure. The authors demonstrated that incorporating CNCs as a source of external hydroxyl groups significantly enhanced the rate of exchange reactions and improved the thermomechanical performance of the resulting epoxy vitrimer. Beyond improving recyclability, the bio-based CNCs also contributed to mechanical self-healing and enhanced material recovery. This method offers a sustainable route for upcycling both thermoset and lignocellulosic wastes into functional vitrimer materials, making it a promising strategy for scalable, industrial applications.

In this work, a case study on the development of vitrimeric composites by modifying epoxy resins with cellulosic fibers is also discussed. The study aims at generating reliable and reproducible data on

the reprocessability of epoxy-based thermosetting resins and at elucidating the influence of key experimental parameters on both material performance and process optimization. The study begins with the preparation of a well-defined epoxy/anhydride system, which is thermally cured to form a crosslinked network representative of conventional thermoset matrices. To simulate an end-of-life treatment scenario, the cured resin is subsequently subjected to ball milling, a mechanochemical technique that reduces the material to fine powder without the use of solvents, in line with sustainable processing approaches.

The milled resin powder is then combined with a predetermined amount of hydroxyl-rich natural fibers, selected for their ability to promote dynamic transesterification reactions due to the presence of –OH functional groups. The reprocessability of the resulting formulations is systematically investigated by varying processing parameters, namely temperature, pressure, and time, during hot pressing. These parameters are chosen based on their relevance to vitrimeric bond exchange kinetics and their practical applicability in scalable manufacturing settings.

An initial qualitative assessment is conducted by evaluating the morphological homogeneity and structural integrity of the reprocessed specimens. Subsequently, a quantitative evaluation is performed by determining a global mechanical quality index, which serves as a comprehensive indicator of the physical performance and cohesion of the vitrimeric composites post-reprocessing.

This methodology aims to establish a robust experimental framework for the assessment of post-consumer thermoset waste treatment and its conversion into reprocessable composite systems. The findings are expected to contribute to the broader effort of integrating circular economy principles into the lifecycle of high-performance polymeric materials by enabling the recovery and reuse of crosslinked thermosets and reinforcing fibers.

The overarching goal of this work is to explore and validate the feasibility of producing recyclable thermoset materials with high added value. By combining renewable feedstocks with dynamic covalent chemistry and environmentally friendly processing, the activity contributes to advancing sustainable practices in the field of polymer science and composite materials. Ultimately, it aims to broaden the scope of circular strategies for thermosets, integrating waste valorization and recyclability into the design of advanced functional materials.

Keywords: Sustainable composites, Polyamide, Biocarbon, Reduced flammability, EV parts

ABSTRACT

This study investigated novel, lightweight, and sustainable flame-retardant biocomposites of polyamide 6 (PA6) and waste-derived biocarbon for electric vehicle (EV) parts to address EV challenges and promote sustainable waste management. Agricultural wheat straw and mixed paper-plastic wastes underwent pyrolysis at 600 °C, and the resulting biocarbons were employed as reinforcements at 20 and 30 wt% loading in the PA 6 matrix through melt extrusion. The mechanical and flammability characteristics of these biocarbon-loaded PA 6 composites were compared with those of 20 wt% polyurethane-treated recycled carbon fiber (PurCF) reinforced polyamide 6,6 (PA6,6) composites developed by Olonisakin et al. [1]. The morphological analysis revealed that biocarbon particles showed significant adherence and integration within the polyamide matrix, although oriented randomly, indicating a robust interfacial bond between the biocarbon particles and the polyamide matrix. The incorporation of biocarbon effectively improved the mechanical performance of the corresponding biocomposites. The heat distortion temperature (HDT) of neat PA increased from 120.8 °C to 182.4 °C and 186.3 °C with the addition of 30 wt% WSB and PPB, respectively. The inclusion of biocarbon into neat PA 6 increased the overall flame duration of composites during the vertical burning test, except for 20PPB, achieving a UL-94 V-2 rating. During the horizontal burning test, all samples demonstrated a linear burning rate of 0 mm/min, which can be attributed to the intumescent behaviour of biocarbon composites. The PA 6,6 composites exhibited higher mechanical properties compared to PA 6 composites, but inferior flame retardancy compared to PA 6 composites. The developed lightweight, sustainable PA 6 biocomposites with reduced flammability and boosted mechanical, rheological and thermal performance could potentially be applied to develop EV parts.

1 INTRODUCTION

The rapid rise in the automotive sector, particularly in electric vehicles (EVs), has intensified the need for lightweight, robust, non-flammable, and environmentally friendly materials to enhance fuel efficiency and mitigate greenhouse gas emissions. Polymer composites have garnered considerable attention among innovative materials due to their beneficial characteristics [2]. Polyamide 6 (PA6) is a prevalent engineering thermoplastic in the automobile industry, recognised for its remarkable tensile

properties, chemical resistance, and heat stability [3]. To improve its characteristics or alleviate its drawbacks, many fillers have been included in polyamide, either alone or in combination. Glass and carbon-based mineral fillers are commonly employed for their exceptional thermal stability and ability to endure the high processing temperatures of PA 6, which may exceed 290 °C [3]. However, these fillers often pose difficulties, as they may be costly, unwieldy, or environmentally detrimental. Advanced fillers such as carbon fibre, carbon nanotubes, and graphene possess great density and are significantly expensive due to their complex and costly production methods. Meanwhile, materials like talc, nanoclay, and glass fibre offer a cost-effective alternative, but they are characterised by their notably high densities. The aforementioned fillers are also unsustainable due to their derivation from petroleum-based materials or the exhaustion of natural resources. The performance of PA6 can be further improved by integrating appropriate fillers or reinforcements. The primary utilisation of petroleum-derived fillers prompts environmental and economic issues, requiring a transition to renewable and bio-based substitutes [4–6].

Biomass-derived biocarbon or biochar, a carbon-rich material generated via pyrolysis of renewable biomass sources like agricultural residues, forestry by-products, or organic waste, has been recognised as a potential reinforcement in polyamide composites. Biocarbon reduces reliance on fossil resources and offers a sustainable approach to waste management [7]. The unique properties of low density render it an appealing filler material for the development of eco-friendly composites [8]. Moreover, it is generally more cost-effective than nearly all carbon-based fillers and exhibits a lower density, which ranges from 1.34 to 1.96 g/cm^3 [8]. Biocarbon is a highly complex material. The characteristics, especially the surface chemistry, may vary considerably depending on the initial chemical composition and the processing conditions. The proportions and types of functionalities can vary significantly and are largely dependent on the pyrolysis temperature [9]. As a result of its polar characteristics, biocarbon exhibits a significant affinity for polymers of similar polarity, such as PA 6. Researchers examined various biomass-derived biocarbon sources, such as wood, miscanthus, corn cob and lignin, as sustainable reinforcing fillers for PA6 [3,5,9].

The conversion of biomass and waste materials into valuable products reduces environmental impacts and increases economic value [10]. Canada's annual production of wheat straw is estimated at 21 million tonnes [11]. Kalak indicated that approximately 360 million tonnes of biomass, specifically straw, are utilised worldwide. The applications include the pulp and paper industry, furniture and building materials, agriculture for animal feed and bedding, and the energy sector. The accessibility, affordability, and renewable nature of wheat straw make it a valuable resource for biocarbon production [12]. Research indicates that biochar derived from wheat straw can serve as a fertiliser for sustainable agricultural practices and in thermal energy storage applications. Compared to wheat straw, plastics are among the most widely used materials in various applications on a daily basis. The volume of plastic waste has significantly increased in recent years [13]. The pyrolysis of mixed plastic-paper waste into biocarbon for polymers has the potential to mitigate various environmental challenges and play a substantial role in advancing the circular economy. Biocarbon derived from waste demonstrates greater stability compared to raw biomass or waste, thereby presenting considerable potential as a reinforcing filler for sustainable polymer composites. There is a notable deficiency in research regarding the utilisation of both wheat straw and plastic-paper waste pyrolysed biocarbon in sustainable polymer composite applications, indicating a necessity for further investigation.

The primary aim of this research work is to develop waste-derived biocarbon reinforced PA6 sustainable composites with reduced flammability for automotive applications, especially for EV parts. The wheat straw and mixed paper-plastic waste were subjected to pyrolysis at a constant temperature of 600 °C, followed by ball milling for 2 hours before integration into the polymer matrix. For the first time, PA6 sustainable composites containing 20 and 30 wt% of this biocarbon were assessed in terms of physico-mechanical, thermal, rheological, and flame-retardant properties. Finally, the mechanical and flammability properties of PA6 biocomposites were compared with those of 20 wt% polyurethane-treated recycled carbon fiber (PurCF) reinforced polyamide 6,6 (PA6,6) composites developed by Olonisakin et al. [1].

2 EXPERIMENTAL, RESULTS AND DISCUSSION

2.1 Materials

Polyamide 6 (PA6): Ultramid B27E was provided by BASF. This particular grade of PA 6 has been identified by a density of 1.12–1.15 g/cm^3, melting point of 220 °C and melt flow index: MFI $_{(250\ °C,\ 2.16\ kg)}$ of 38 g/10 min. The plastic and paper waste, having approximately 20w/80w composition, was collected from the University of Guelph, Canada campus. The wheat straw was purchased from Salem Creek Farms, 2408 Concession 4, Teeswater, Canada.

2.2 Pyrolysis of wheat straw and paper-plastic waste

The pyrolysis process of wheat straw and paper-plastic waste was performed by employing a laboratory-scale pyrolysis reactor at 600 °C to produce biocarbon. All the raw waste and biomass materials were dried for at least 24 hours prior to the pyrolysis process to get a moisture content of less than 5%. To conduct the pyrolysis process, a Carbolite GLO 10/11-1G front-loading retort furnace (UK) configured in a horizontal orientation was used. About 1000 g of each raw material was put into the furnace using a steel vessel, subsequently, the atmosphere was rendered inert by flushing with nitrogen gas. A heating rate of 7.5 °C/min was utilized to attain the target performing temperature of 600 °C, upheld for a residence duration of 1 hour prior to cooling the furnace to ambient temperature for biocarbon removal for all three cases. The biocarbons were subsequently subjected to ball milling at a rotational speed of 200 rpm for 2 hours for each biocarbon sample. The overall yield of the wheat straw and paper-plastic biocarbon was 34 and 24.4%, respectively. The above-mentioned two biocarbons are designated as WSB and PPB, respectively.

2.3 Processing of PA 6 sustainable biocomposites

In order to prevent void formation and hydrolysis during the melt-extrusion process, the biocarbon and PA 6 were dried before to the processing step. Melt-extrusion was performed to make neat PA 6 and its sustainable biocomposites in a DSM Micro Xplore 15cc, Netherlands twin-screw micro-compounder for a duration of two minutes at a temperature of 250 degrees Celsius and a rotor speed of one hundred revolutions per minute. For the purpose of producing tensile dumbbell-shaped, flexural bars, and impact bars specimens in accordance with the parameters of ASTM standards, the molten polymer was first collected in a transfer device and then injected into an injection moulding machine, Micro 12cc, Netherlands. The temperature of the machine was set to 30 degrees Celsius. Prior to the testing, each sample was conditioned for a period of forty-eight hours at a humidity level of fifty percent at room temperature. Sustainable composites with both 20 and 30 wt% of each biocarbon were fabricated and designated as shown in Table 1.

Sample designation	PA 6 (wt%)	Paint char (wt%)	Wheat straw biocarbon (wt%)	Paper-plastic biocarbon (wt%)
PA6	100	0	0	0
20WSB	80	0	20	0
20PPB	80	0	0	20
30WSB	70	0	30	0
30PPB	70	0	0	30

Table 1: Compositions for PA 6 composites containing 20 and 30 wt% biocarbon

2.4 Characterizations

Using the FEI Quanta FEG 250 machine and an accelerating voltage of 20 kV, scanning electron microscopy (SEM) was used to examine the biocarbon dispersion in the PA6 matrix. The Denton Desk

V TSC sputter coater was used to gold sputter the broken surface of impact samples, with a 90-second coating period. Using the Melt Flow Indexer Qualitest 2000A in accordance with ASTM D1238, the MFI of the clean PA 6 and all sustainable composites was calculated at 250 oC with a constant load of 2.16 kg [14]. The MD-300S Densitometer (Alfa Mirage, Japan) was used to quantify the density of each specimen. In accordance with ASTM D638-14 for the tensile test at a speed of 50 mm/min for neat PA 6 and 5 mm/min for sustainable composites, and ASTM D790-10 for the flexural testing at a rate of 14 mm/min, the mechanical analysis was carried out using an Instron Universal Testing Machine (3382, MA, USA) [15,16]. Using a 2.75 J impact pendulum and the Zwick/Roell Hit25P (Ulm, Germany), the Izod notched impact test was conducted in accordance with ASTM D256 standard (test method A) [17]. Using the Q800 dynamic mechanical analyzer (DMA), the heat deflection temperature (HDT) was measured in accordance with the technical note from TA Instruments (DE, USA). Samples loaded in the three-point clamp of the instrument were heated to 250 °C with a heating rate of 2 °C/min under a force of 0.455 MPa until a deflection of 250 µm was achieved. For the composite of 20 wt% PurCF loaded PA 6,6 (PurCF20) used here to compare the results with PA 6 composites, a force of 1.8 MPa was used to measure the HDT value [1]. The flame-retardant properties of neat polyamide and its sustainable biocomposites were tested in accordance with ASTM D635-22 [34]. The vertical flammability test was performed in accordance with ASTM D3801-20a for five specimens of comparable lengths [18]. The classification of the samples was established based on the observed after-flame and after-glow durations, as well as dripping and cotton ignition during the testing process [19].

2.5 Results and discussion

2.5.1 Density and melt flow index (MFI)

Because they have such a large impact on the vehicle's total weight and fuel efficiency, low-density polymers and composites are ideal for use in automobiles [1]. The measured density of neat PA 6 and its sustainable biocomposites with two different types of biocarbon are provided in Table 2. Virgin PA 6 exhibited a density of 1.105 g/cm^3. The addition of 20 and 30 wt% of biocarbon increased the density of the resultant PA 6 composites. The density of 20 wt% PurCF-filled PA 6,6 composites was found to be higher compared to PA 6 composites with 20 wt% biocarbon but lower than those with 30 wt% biocarbon [1]. The preferred MFI of composite materials for the injection molding process should be greater than 10 g/min to achieve better processability and thereby cost and output efficiencies. **Table 2** also provides the MFI of neat PA 6 and all sustainable composites loaded with 20 and 30 wt% biocarbon, as well as PA 6,6 composite (PurCF20). It can be seen that neat PA 6 exhibited an MFI of 39.6 g/10 min, which decreased with the incorporation of carbonaceous filler such as biocarbon particles in the neat PA matrix. The incorporation of biocarbon raised the viscosity of the melt due to PA 6 chain tangling and the high aspect ratio of biocarbon promotes strong adhesion between the carbonaceous fillers and the PA matrix phase. The PPB composites exhibited a higher MFI value compared to that of the WSB composites. The reduction of the MFI of polyamide with biocarbon inclusion was extensively studied and reported in the literature [5,9]. The PA 6,6 composites exhibited higher MFI compared to PA 6 composites owing to the high MFI value of neat PA 6,6 [1].

Sample designation	Density (g/cm^3)	MFI (g/10 min)
PA 6	1.105±0.003	39.6±1.2
20WSB	1.154±0.001	21.0±0.53
20PPB	1.150±0.002	27.46±0.50
30WSB	1.197±0.005	13.7±0.41
30PPB	1.191±0.001	17.8±0.72
20rCF	1.18 ± 0.003	106.38±1.24

Table 2: Density and MFI of neat PA 6, PA 6 biocomposites and PA 6,6 composites

2.5.2 Morphological analysis

The biocarbon dispersion in the neat polyamide matrix was investigated by SEM analysis of the impact-fractured composite samples. Figure 1(a) and (b) represent the SEM images of impact fracture surfaces of PA 6 sustainable biocomposites loaded with 20 wt% of wheat straw and paper-plastic biocarbon, respectively, whereas the surface morphology of 30 wt% biocarbon-filled composites is represented in Figure 1(c) and (d). Several biocarbon particles identified on the fracture surface of all composites were noted, showing no signs of dislodgement or significant pullouts. The biocarbon particles demonstrated significant adherence and integration within the polyamide matrix, indicating effective interfacial adhesion. The platelet-shaped WSB and PPB particles are uniformly distributed within the polyamide matrix, although they exhibit a random orientation at both 20 and 30 wt% filler loading. The surface properties of biocarbon particles improved interfacial interactions with polar PA 6 chains.

2.5.3 Mechanical properties

The effect of carbonaceous filler types and concentration in PA 6 on the mechanical properties, HDT and flame retardancy was investigated and the obtained results are depicted in Figure 2. The mechanical, HDT and flammability properties of 20 wt% PurCF loaded PA 6,6 composites were also provided in Figure 2 for comparison [1]. The variation of tensile strength and modulus for polyamide composites loaded with 20 and 30 wt% biocarbon as well as PA 6,6 composites, is shown in Figure 2(a). Virgin PA 6 possessed a tensile strength and tensile modulus of 73 MPa and 2693 MPa, respectively. The incorporation of 20 wt% biocarbon enhanced tensile strength, particularly tensile modulus, relative to unmodified polyamide, and these attributes were further augmented by 30 wt% char and biocarbon-reinforced composites. This phenomenon is ascribed to the stiffening effect of high modulus filler particles, which are typically more rigid than the polymer matrix. A 34.3% and 36.8% increase in tensile modulus was achieved for the PA 6 composites using 30 wt% wheat straw and paper-plastic biocarbon, respectively, in comparison to the pure polymer. The flexural strength and flexural modulus of PA 6 were markedly enhanced with biocarbon loading, as illustrated in Figure 2(b). Both the flexural strength and modulus consistently exhibited greater values for 30 wt% biocarbon composites in comparison to those with 20 wt% filler loading. The rapid and effective transmission of stress from the polyamide to the char and biocarbon in tension mode, coupled with the confinement of the PA molecular chains by the biocarbon in compression mode, resulted in a significant improvement in flexural characteristics [5]. From both Figure 2(a) and (b), it was noted that 20 wt% PurCF-reinforced PA 6,6 composites demonstrated remarkably high tensile and flexural strength, as well as moduli, in comparison to PA 6 composites. This can be attributed to the fundamental characteristics of carbon fibre, including its stiffness, high strength, and modulus [1]. The variation in the notched impact strength of neat PA 6 and its sustainable biocarbon, as well as PA 6,6 composites, is provided in Figure 2(c). An impact strength of 57.9 J/m was achieved for neat PA 6, which decreased continually with filler loading. With 20 wt% of carbonaceous filler loading, the impact strength of neat polyamide was reduced to 35.6 and 33.7 J/m for WSB and PPB, respectively. The incorporation of reinforcing fillers significantly reduces the ductility of the composite material blend. The impact strength was further decreased with 30 wt% filler concentration in the polyamide matrix. The presence of invasive biocarbon particles may create vulnerabilities within the matrix, thus promoting crack propagation [20]. The PurCF20 composite exhibited an impact strength of 38 J/m, that is slightly higher than that for 20 wt% biocarbon-loaded PA 6 composites [1].

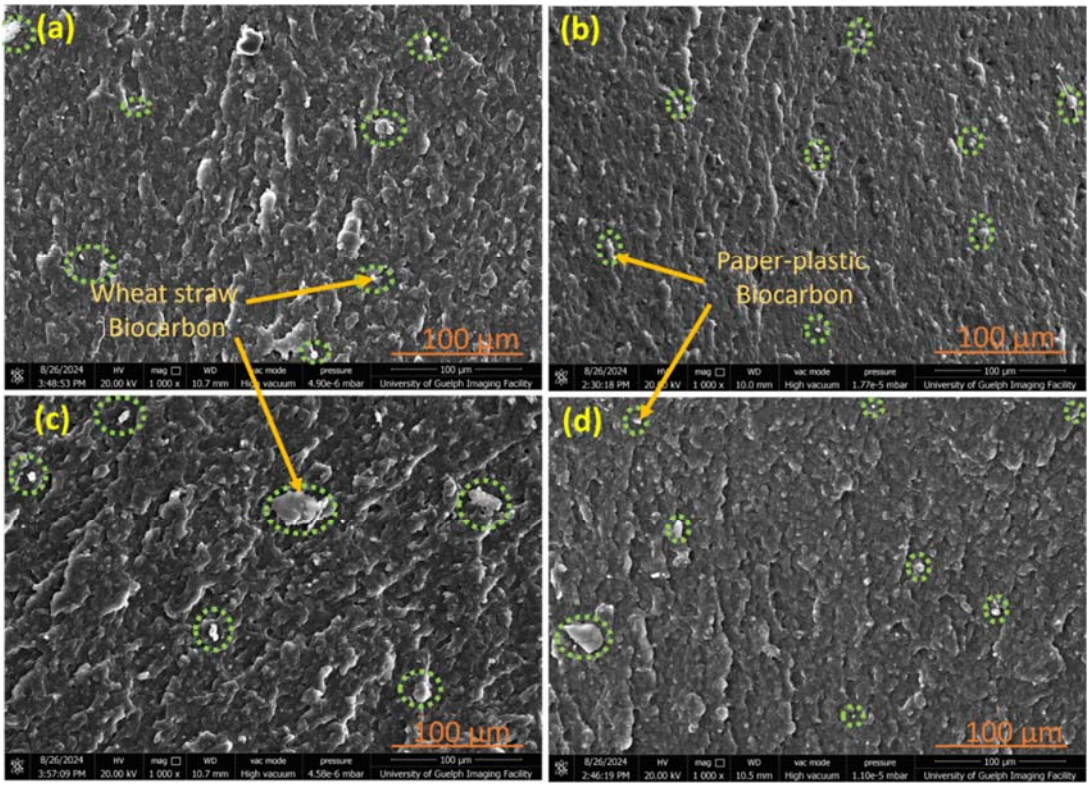

Figure 1: SEM micrographs of PA 6 biocomposites filled with (a) 20 wt% wheat straw biocarbon, (b) 20 wt% paper-plastic biocarbon, (c) 30 wt% wheat straw biocarbon and (d) 30 wt% paper-plastic biocarbon.

2.5.4 Heat deflection temperature (HDT)

HDT is a critical attribute of engineering thermoplastics, particularly in the automotive sector, as it establishes temperature thresholds for material processing [3]. HDT reflects a material's resistance to heat under a specified load. The HDT of virgin polyamide 6 composites and PA 6,6 composite (PurCF20) are plotted in Figure 2(c). The HDT value of neat PA 6 was 121 ºC, which was markedly enhanced by the incorporation of 20 wt% char and biocarbon in the matrix phase. When the biocarbon concentration in the PA matrix was increased from 20 to 30 wt%, the HDT of the corresponding composites increased further. The HDT of neat PA increased to 182.4 °C and 186.3 °C with 30 wt% WSB and PPB loading. The thermally stable biocarbon particles restricted the movement of polyamide chains, limiting the composite deformation by raising the temperature required to deform the composite materials [5]. Hence, HDT improved significantly for biocarbon composites. The higher carbonaceous content of WSB and PPB compared to PCB contributed to the greater HDT value of the corresponding composites, attributed to the boosted stiffness and rigidity of the filler particles of denser structure. The PA 6,6 composite with 20 wt% PurCF exhibited a higher HDT value of 242.9 °C measured at a force of 1.8 MPa [1].

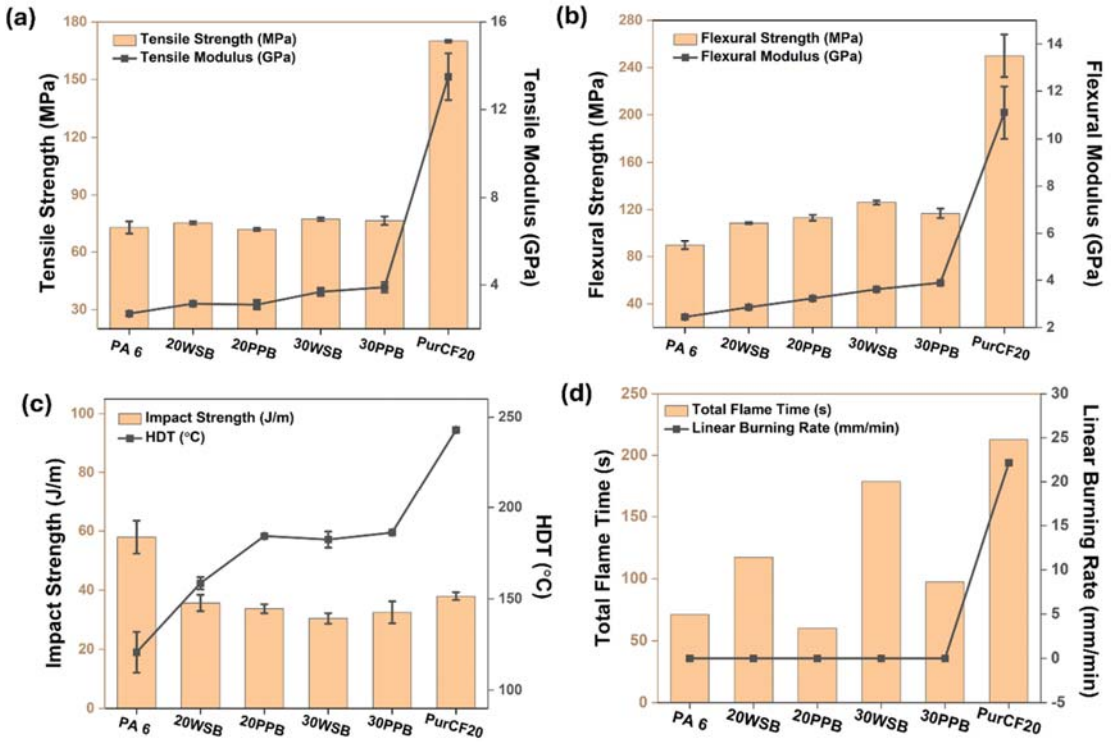

Figure 2: (a) Tensile strength and modulus, (b) flexural strength and modulus, (c) impact strength and HDT, and (d) flammability behavior in the UL-94 vertical (total flame time) and horizontal burning (linear burning rate) tests of PA 6 composites and PA 6,6 composite [1].

2.5.5 Flammability characteristics

A critical characteristic of materials utilised in the automotive sector, particularly in electric vehicle components, is their flame resistance. For these applications, the materials must demonstrate minimum flammability to the highest degree feasible [21]. The UL-94 vertical and horizontal flammability tests are among the most used methods employed to assess the flame retardancy of polymer composites. The reaction of pure PA 6 and biocarbon-infused composites to flame exposure was documented as total flame duration for five samples in the vertical test and linear burning rate in the horizontal experiment. The outcomes for PA 6 composites and PurCF PA 6,6 sustainable composites are illustrated in Figure 2(d). The incorporation of 20 wt% WSB biocarbon particles into the PA 6 matrix extended the total flame duration to 117.4 seconds. The 20PPB composite demonstrated a flame time of 59.9 seconds, which is less than that of neat polyamide. The PA 6,6 composites demonstrated a total flame duration of 212.8 seconds, surpassing that of PA 6 composites. All composites demonstrated a UL-94 V-2 classification in the vertical test. The improved fire retardancy of paper-plastic biocarbon-loaded composites is due to the emergence of a more efficient protective carbon layer resulting from the more ordered and crystalline carbon structure of PPB particles. In the horizontal burning test, both the pure polymer and composites exhibited a burning rate of 0 mm/min and were categorised as HB, as illustrated in Figure 2(d). None of the samples exceeded the 25 mm reference point, and the flame extinguished. The thermally stable carbon structure of the filler and the little nitrogen content in the filler particles resulted in intumescent behaviour when positioned horizontally. Muir et al. investigated and reported the diminished flame retardancy of recycled PA 6 infused with lignin biocarbon pyrolysed at various temperatures [22]. The PurCF20 composites showed a linear burning rate of 22.16 mm/min in the horizontal flammability test [1]. Therefore, biocarbon-loaded PA 6 composites exhibited higher flame retardancy compared to PurCF-loaded PA 6,6 composites owing to the formation of more effective char layers by biocarbon particles than carbon fibers.

3 CONCLUSIONS

This research investigated the effect of wheat straw and mixed paper-plastics derived biocarbon on the characteristics and performance of PA 6 sustainable composites intended for automotive applications, especially in EVs. The impact of 20 and 30 wt% biocarbon (pyrolyzed at 600 °C) concentration on the thermomechanical, rheological, and flammability qualities of PA biocomposites was assessed and compared with 20 wt% polyurethane-treated CF-loaded PA 6,6 composites published by Olonisakin et al. [1]. The addition of biocarbon significantly improved tensile/flexural strength and moduli in comparison to neat PA 6. The HDT increased to 186 ºC for 30PPB composites and consistently remained higher for all biocarbon composites than the neat polyamide. The integration of biocarbon extended the overall flaming duration of biocomposites to neat polyamide in the vertical burning test. Although the 20PPB composite demonstrated a shorter flame duration compared to neat PA 6, all composites, along with neat polyamide, were categorized as V-2, demonstrating dripping and ignition of cotton. In the horizontal burning test, all samples exhibited a linear burning rate of 0 mm/min, attributed to the intumescent behavior of char and biocarbon composites. The PA 6,6 exhibited higher mechanical properties compared to PA 6 composites, but inferior flame retardancy compared to PA 6 composites.

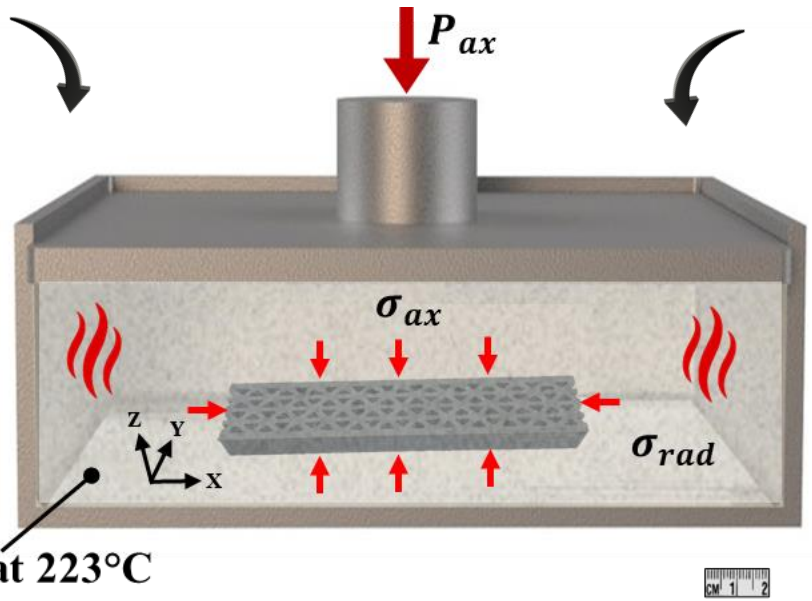
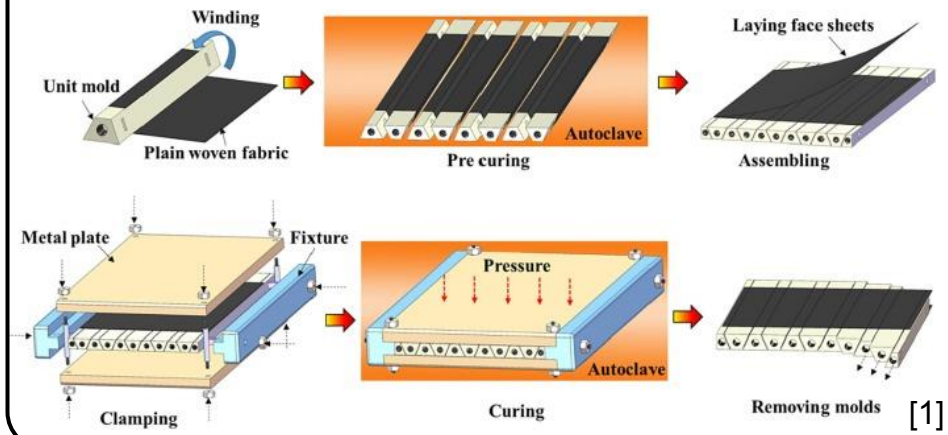
Overview

- Introduction
- HPBC process overview
- Material, LSS design and characterization tests
- Progressive damage modeling
- Results and analysis
- Conclusion



Additive manufacturing and flexible consolidation process

Material extrusion (MEX) process



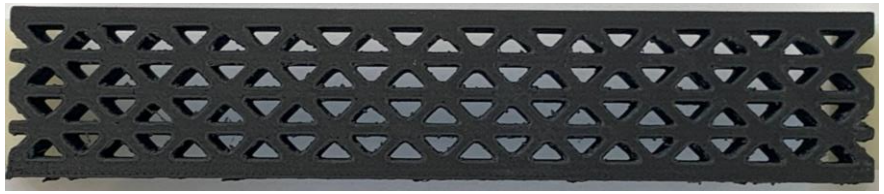
- Co-printed skin and truss core
- Trussed aligned fiber
- Doesn't required mold
- Poor consolidation

Hot powder bed compaction LSS consolidation under hydrostatic compaction

Compression molding or Autoclave curved

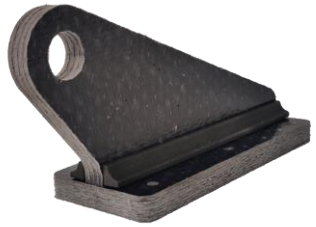
[1]

- Good consolidation
- Multi-step process
- Required multi-assembly mold



- **HPBC provides the synergy between traditional compression molding (good for consolidation but required for specific mold) and MEX process (doesn't required mold but poor consolidation)**

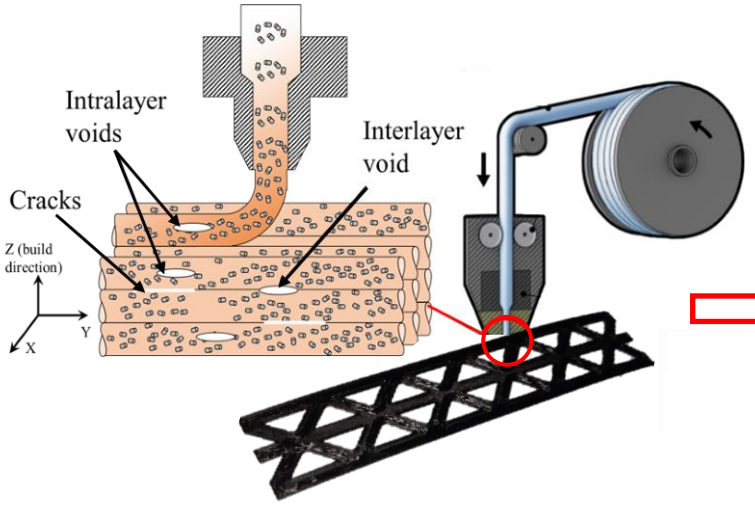
ICCM24



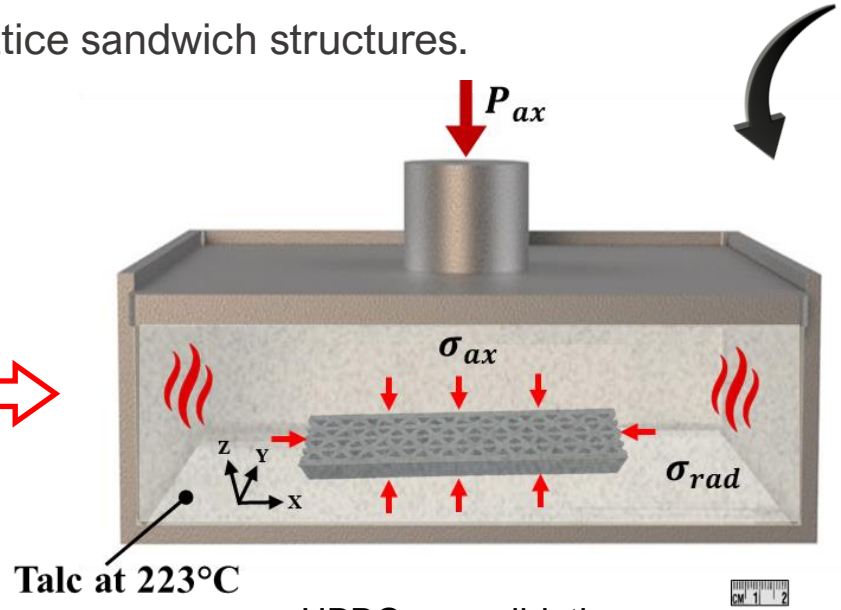
[1] Li, Xinyu, et al. "Failure Mechanisms of Fluted-Core Sandwich Composite Panels under Uniaxial Compression." Composite Structures, vol. 303, Jan. 2023

Hot powder bed compaction process

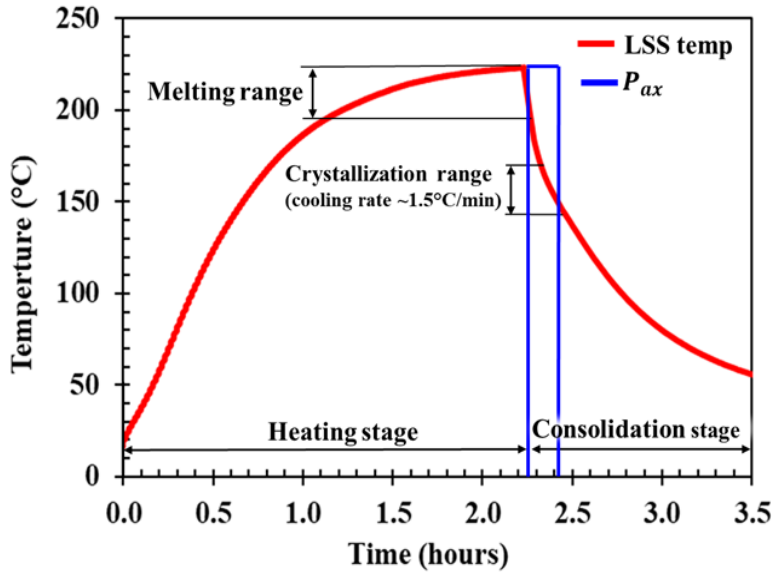
- **Powder Densification Stage:** Fine talc powder serves as a flexible medium, compacted under 1-2 tons (~500 kPa axial pressure) of load for 10 minutes.
- **Heating Stage:** Mold was heated in a convection oven to 223°C (endset of PA6 melt enthalpy) 140 minutes.
- **Consolidation of MEX part during cool-down:** During cooling, continuous compressive force was maintained, allowing molten matrix flow and void closure, improving part consolidation.
- This process supports complex geometries from subtractive manufacturing, MEX topology-optimized parts, and lattice sandwich structures.



MEX lattice structure



Subtractive manufacturing



MEX topologically optimized rocker

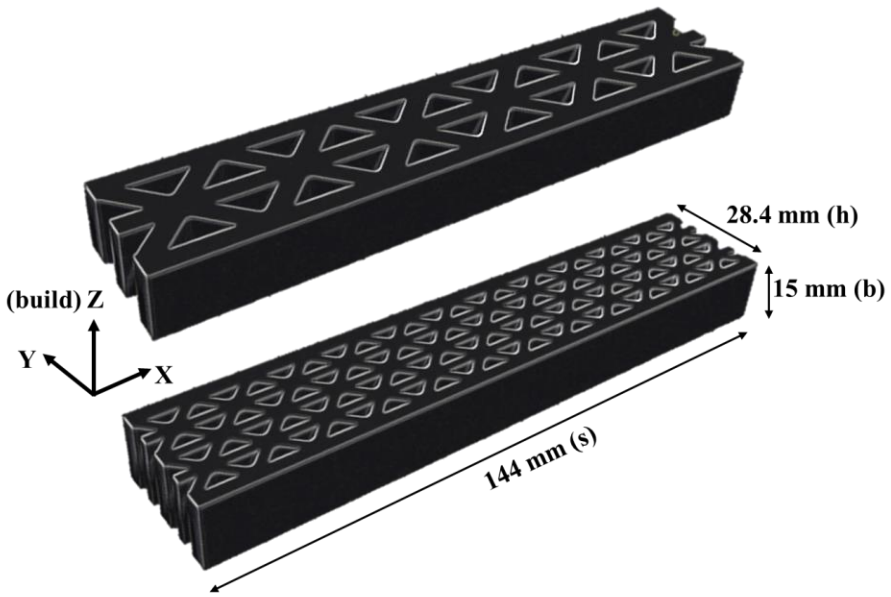
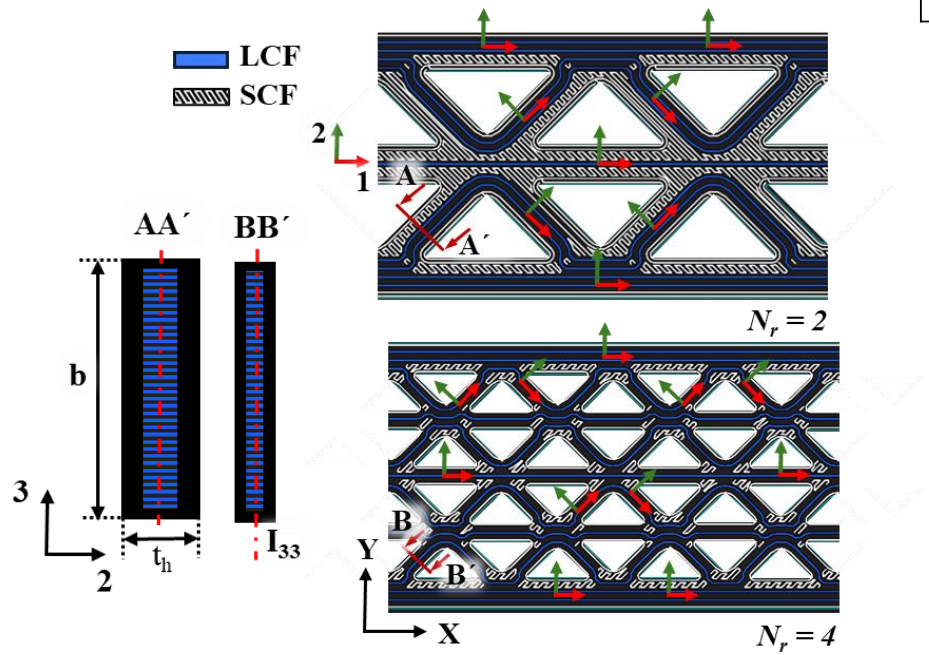
- DSC Analysis
  - Crystallinity fraction
  - Enthalpy of melting



2D-LSS design



- Two truss core configuration with same beam height, core density and LCF volume fraction
  - Nr = 4 → 4-row core with 2.2 mm trusses with 1 LCF tow per truss
  - Nr = 2 → 2-row core with 4.4 mm trusses with 2 LCF tow per truss
- Both configurations had 2 LCF tows in top and bottom skins
- Same A/l_t ratio ensured constant axial rigidity of trusses across designs.
- The design ensured that structure performance differences between pre- and post-HPBC LSS resulted solely from material and microstructural changes, not geometry variations.

Parametric geometry of LSS

Effective homogenized post-HPBC SCF and LCF properties

- A microstructure-based finite element approach using Digimat-FE was used to anisotropic homogenize the SCF layer properties.
- Microscopy analysis was used to determine a void fraction of 3.1% and a fiber length distribution of 0.098 ± 0.014 mm.
- During the MEX process, short fibers tend to align in the direction of material deposition due to shear-induced flow, resulting in a non-random fiber orientation distribution (FOD).
- Homogenized anisotropic LCF layer properties were predicted using a hybrid micromechanical model considering contributions from both continuous and highly aligned long discontinuous fibers with weight average of 0.5:0.5.

$$FOD = \begin{pmatrix} 0.04 & 0.01 & 0.03 \\ 0.01 & 0.94 & 0.01 \\ 0.03 & 0.01 & 0.02 \end{pmatrix}$$

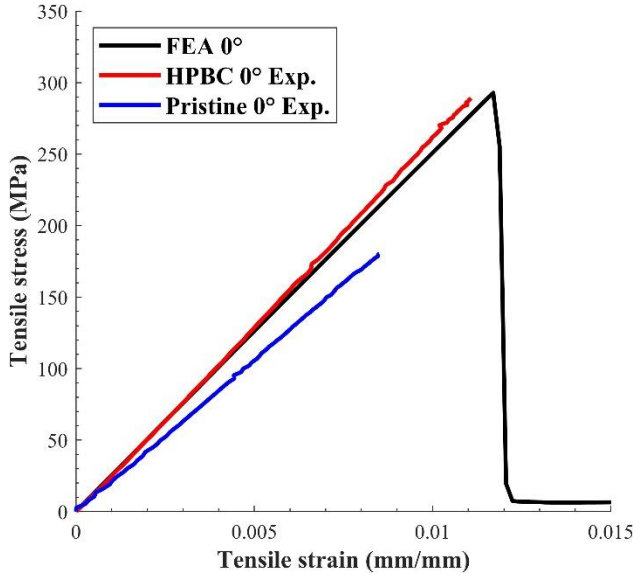
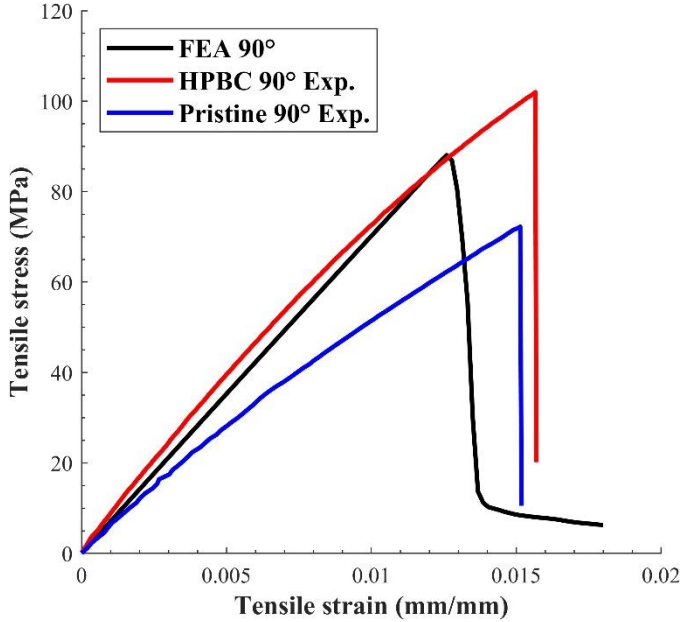
FEA modeling of tensile coupons and LSS components

- A homogenized LCF layer was sandwiched between two [+45°/–45°] oriented homogenized SCF layers.
- The LCF layer were aligned in the truss direction to capture actual fiber orientation during MEX deposition.
- Anisotropic linear elastic material was assigned at roller contact regions to avoid damage due to stress concentrations.
- The sandwich structure was meshed with finer elements (0.3 mm × 0.3 mm) in the central 48 mm region and coarser mesh (0.3 mm × 0.6 mm) elsewhere, with 0.125 mm thickness through all layers.



Continuum damage mechanics model

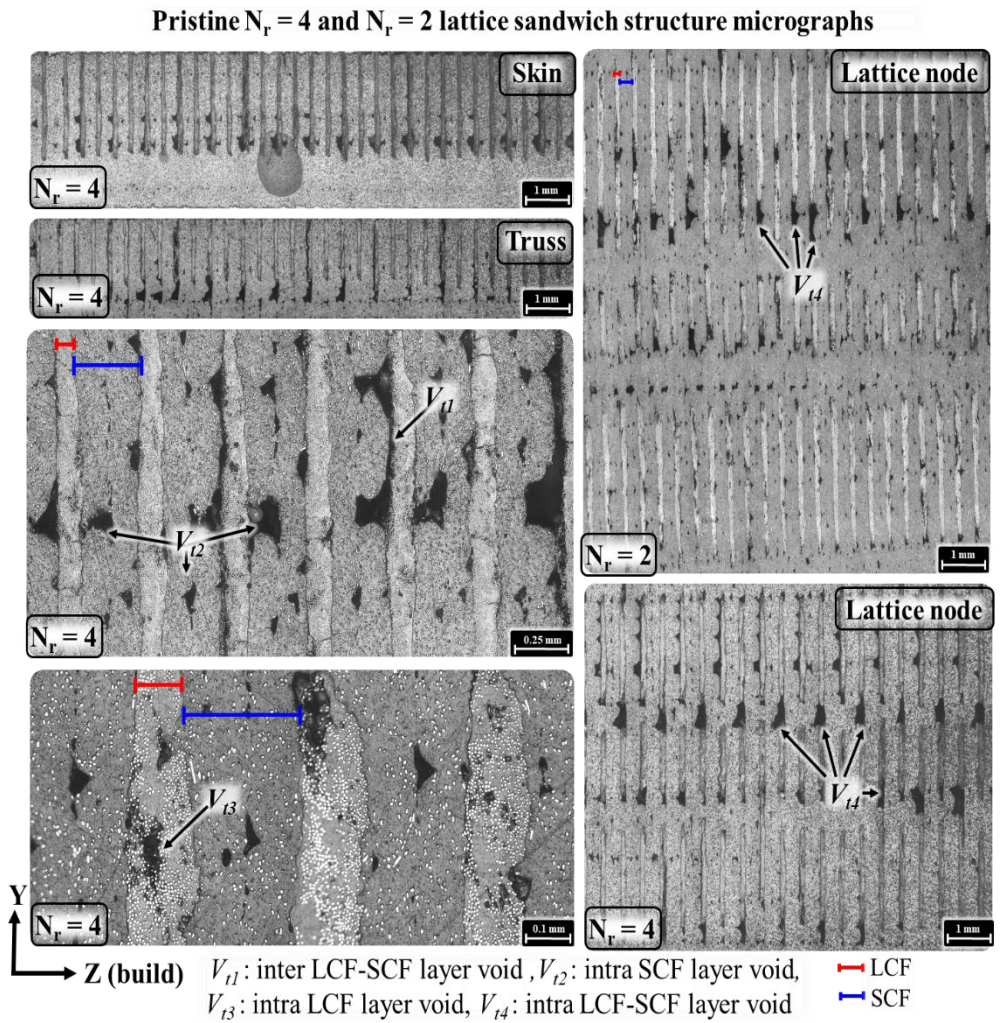
- A strain-based CDM model was implemented in ABAQUS using UMAT subroutine.
- The framework captured nonlinear fiber and matrix damage progression, enabling accurate prediction of stiffness degradation and damage progression
- HPBC-treated dogbone specimens exhibited the following properties:
  - Elastic modulus: 25.5 ± 0.61 GPa (longitudinal), 6.93 ± 0.22 GPa (transverse)
  - Tensile strength: 285.66 ± 4.83 MPa (longitudinal), 101.69 ± 1.43 MPa (transverse)



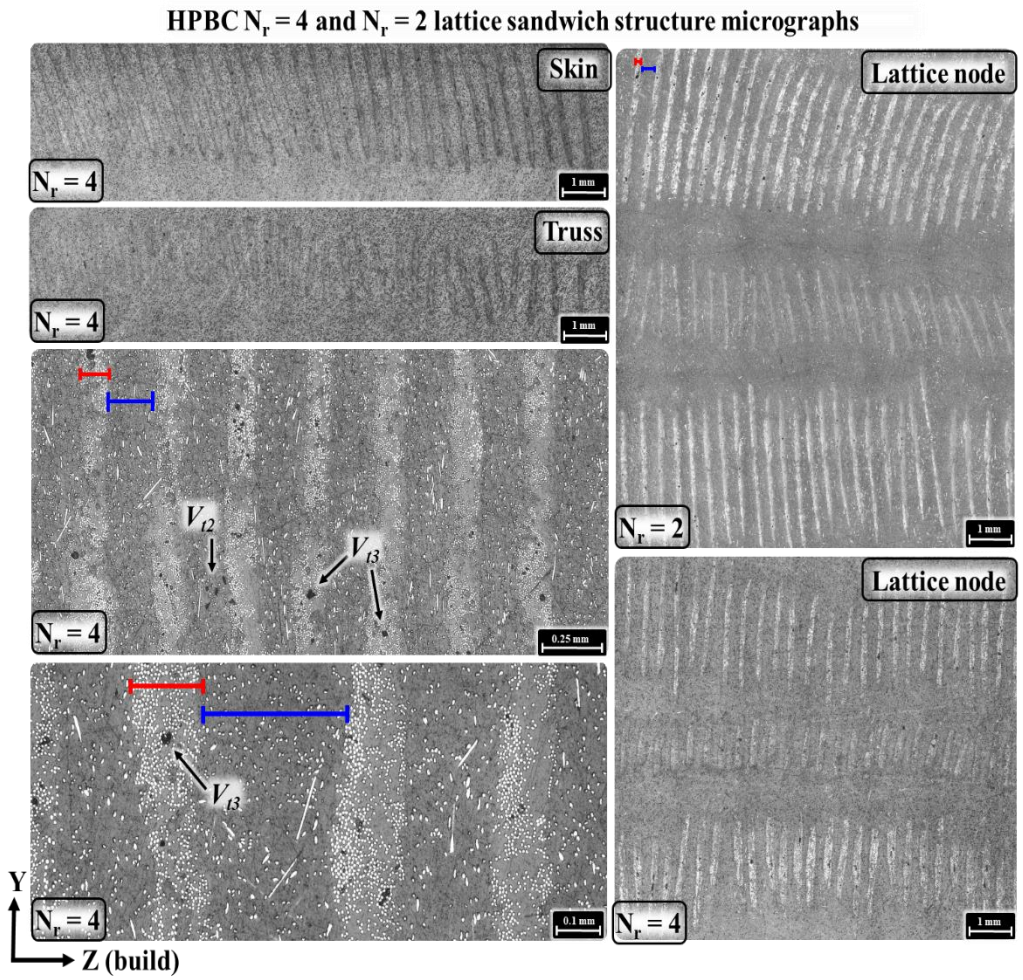
$$f_1^2 = \frac{(\epsilon_{11})^2}{\epsilon_{11}^{ft}\epsilon_{11}^{fc}} + \left(\frac{\epsilon_{11}}{\epsilon_{11}^{ft}} - \frac{\epsilon_{11}}{\epsilon_{11}^{fc}}\right)$$

$$f_2^2 = \frac{(\epsilon_{22})^2}{\epsilon_{22}^{ft}\epsilon_{22}^{fc}} + \left(\frac{\epsilon_{22}}{\epsilon_{22}^{ft}} - \frac{\epsilon_{22}}{\epsilon_{22}^{fc}}\right) + \left(\frac{\epsilon_{12}}{\epsilon_{12}^{f}}\right)^2 \qquad f_3^2 = \left(\frac{\sigma_{33}}{F_{3z}}\right)^2 + \left(\frac{\sigma_{13}}{F_{sz}}\right)^2 + \left(\frac{\sigma_{23}}{F_{sz}}\right)^2$$

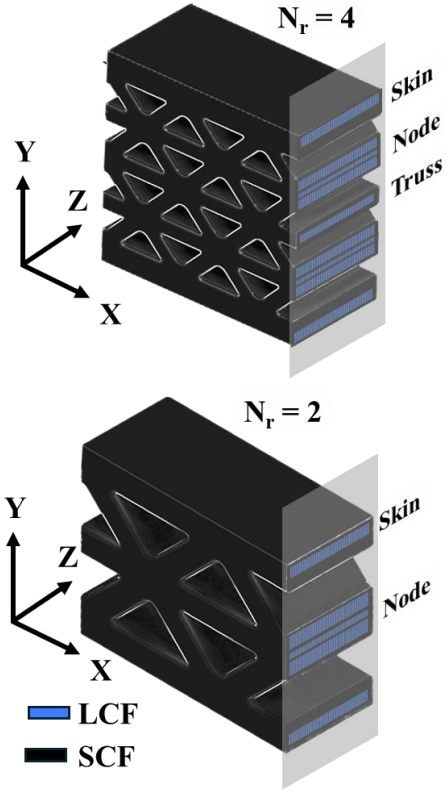
$$d_i = 1 - \frac{\epsilon_{ii}^{ft}}{f_i} e^{\left(\frac{C_{ii}\epsilon_{ii}^{ft}\left(\epsilon_{ii}^{ft} - f_i\right) \times l_c}{G_i}\right)};\ i = 1, 2$$



$$d_3 = \begin{cases} 0, & f_3 < 1 \\ 0.95, & f_3 \geq 1 \end{cases}$$

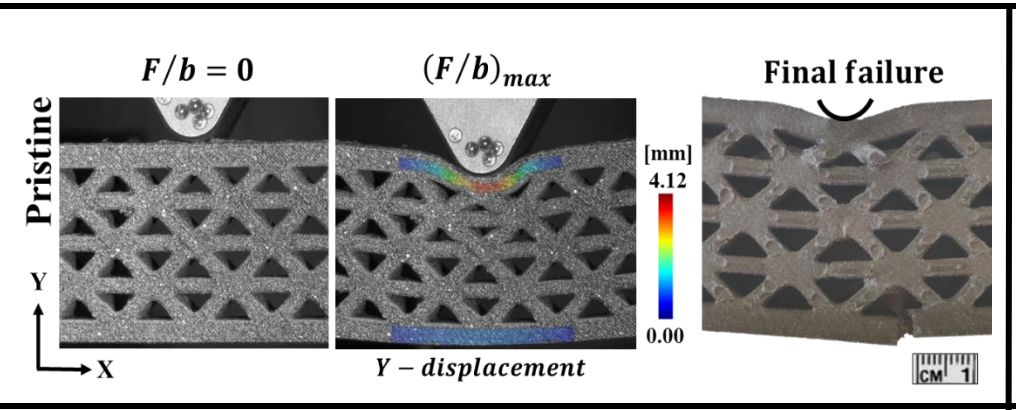


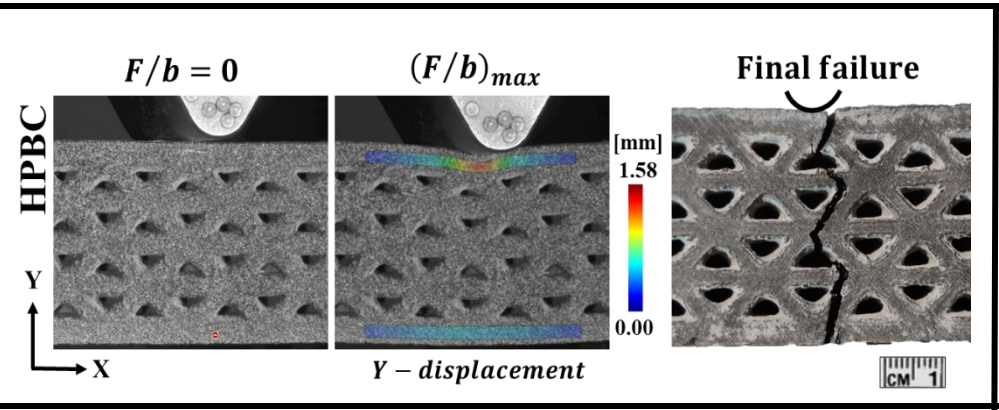
$$\sigma_{ij} = \begin{bmatrix} (1-d_1)\,C_{11}^0 & (1-d_1)(1-d_2)C_{12}^0 & (1-d_1)C_{13}^0 & 0 & 0 & 0 \\ & (1-d_2)C_{22}^0 & (1-d_2)(1-d_3)C_{23}^0 & 0 & 0 & 0 \\ & & (1-d_3)C_{33}^0 & 0 & 0 & 0 \\ & & & (1-d_1)(1-d_2)C_{44}^0 & 0 & 0 \\ & & sym. & & (1-d_3)C_{55}^0 & 0 \\ & & & & & (1-d_3)C_{66}^0 \end{bmatrix} \times \varepsilon_{ij}$$

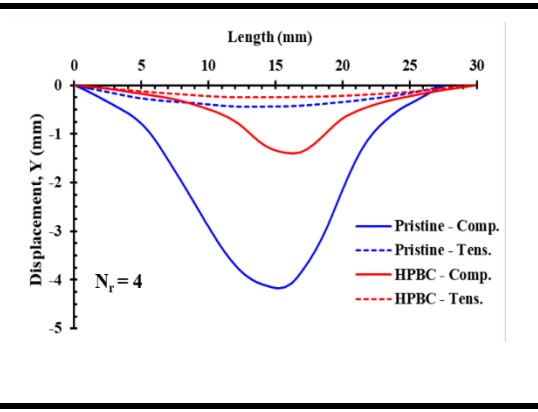


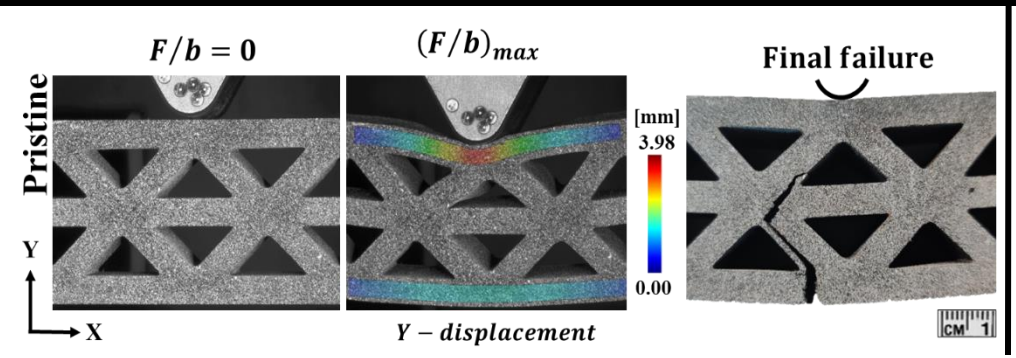
Microscopic analysis of post-HPBC sandwich beam

- The improved microstructure exhibited void content less than 2.3% and improved consolidation, with consistent shrinkage for both HPBC-treated LSS. A 17.8% reduction in width (Z-direction) and 26.4% increase in truss thickness were observed.

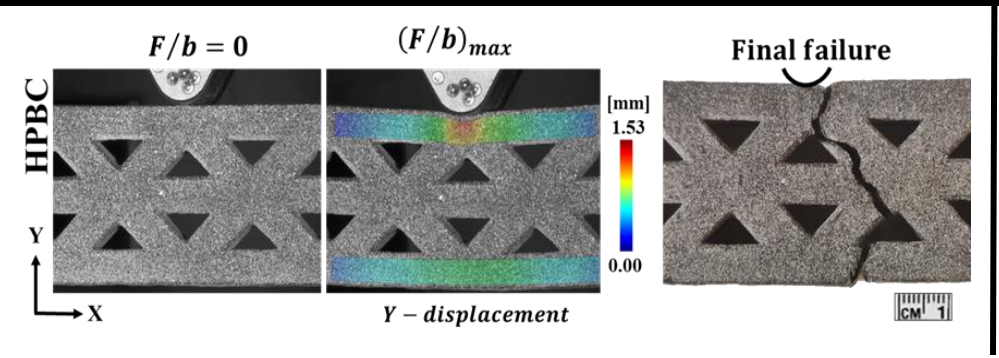




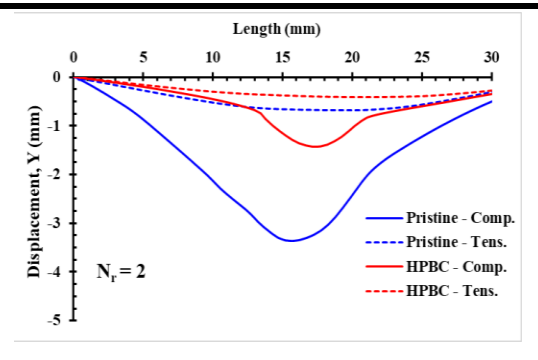


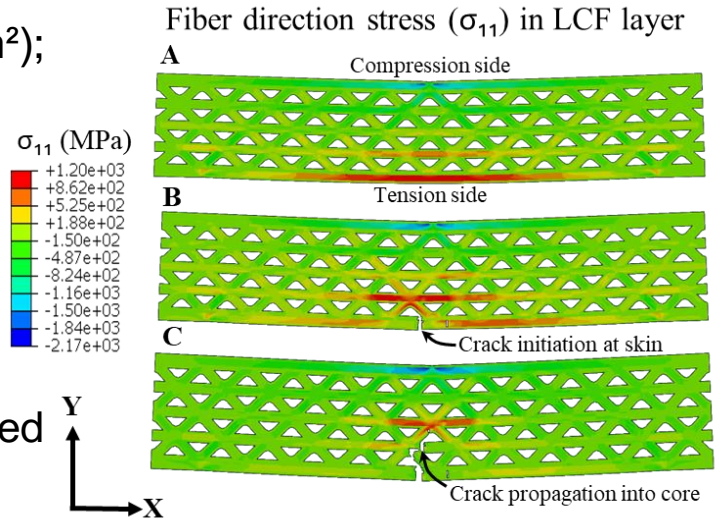


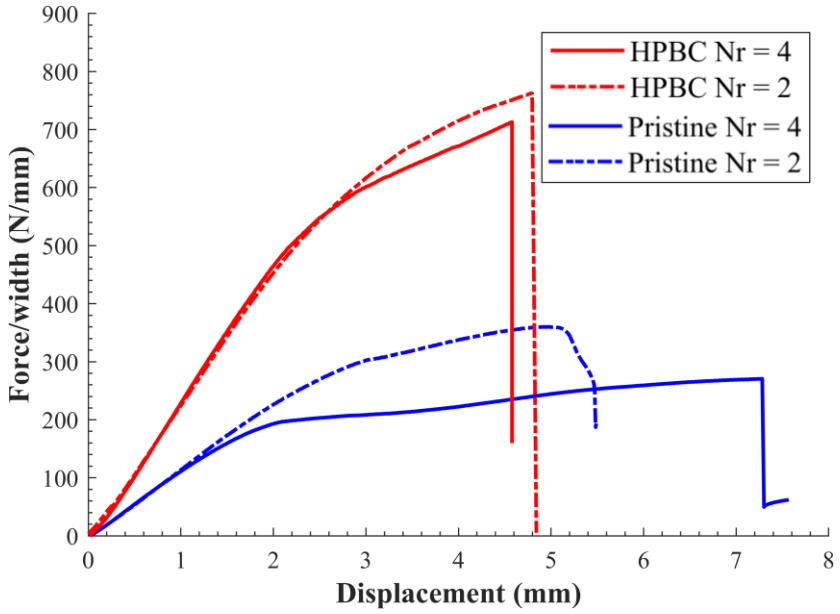
Failure analysis of LSS with DIC Y- displacement



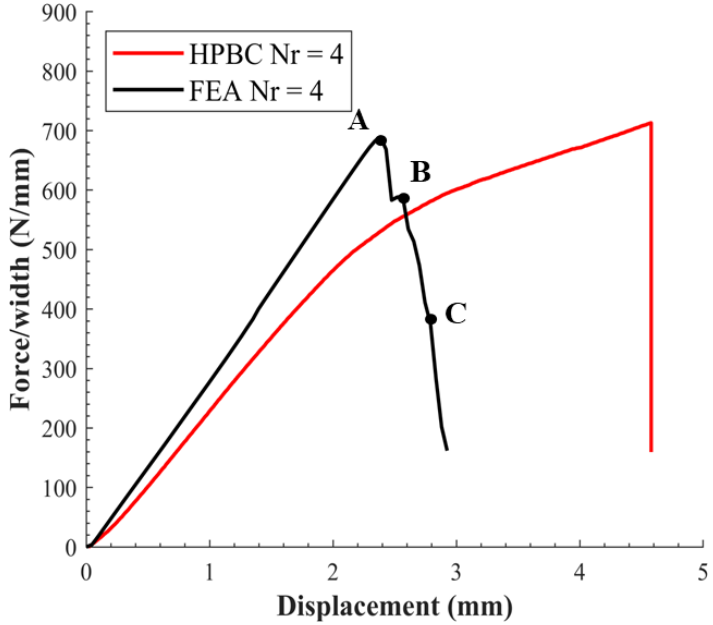
- DIC full-field displacement analysis revealed failure modes including localized skin yielding and truss buckling in LSS.
- Higher I_{33}/I_{t^2} ratio in the Nr = 2 configuration provided higher critical truss buckling load, increasing skin yielding load
- Pristine failure initiated at the tensile-side skin, propagating through the core along weak LCF–SCF interface voids.
- HPBC-treated samples showed only localized skin yielding and no truss deformation in Nr = 4 and Nr = 2.
- Performance improvements were mainly due to microstructural changes like better interlayer fusion and void reduction, not phase transformation or crystallinity fraction (HPBC :27.67 ± 1.33% ; Pristine: 33.49 ± 0.18 %), as confirmed by the DSC results.



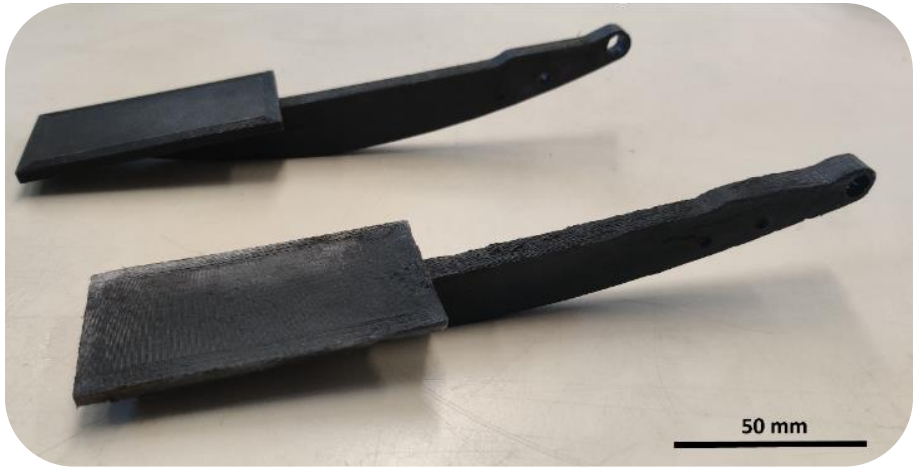




Test results and progressive damage analysis of LSS



- Both pristine LSS configurations showed similar unit width stiffness (~111.6 ± 4.4 N/mm²); however, N_r = 2 exhibited 425.1 N/mm, 30% higher strength compared to N_r = 2
- Post-HPBC, stiffness improved by 122% for both configurations;
  - Strength of N_r = 2 increased by 86%, while N_r = 4 showed a 154% stiffness gain
- The FEA predicted a stiffness of 265.3 N/mm² and strength of 689.8 N/mm.
- Crack initiation at the tension-side skin and progression into the core, was demonstrated through fiber direction stress (σ_{11}) evolution during damage propagation.



Extensive crack propagation in simulation and experiment

Conclusion

- HPBC process **improved LSS strength** by 154% and **stiffness** by 119%, without the need for rigid tooling.
- Tailored LCF–SCF reinforcement enabled **effective consolidation** in two complex cores geometry, reducing voids below 2.3%.
- DIC analysis showed failure shifted from **truss-induced skin yielding (pristine)** to **skin failure (HPBC)** post HPBC process.
- **Meso-scale CDM-based FEA approach** closely predicted stiffness, strength, and crack progression.
- A consistent **17.8% Z-direction shrinkage** was observed, enabling predictable geometry control during design.
- Combining HPBC with MEX offers a scalable, cost-efficient route for **fabricating complex, high-performance composites**.

Thank You

Extrusion-based large-format additive manufacturing (LFAM)

- Advantages of extrusion-based LFAM
  - **High deposition rate:** up to 86 kg per hour using the thermoplastic extrusion process.
  - **Processability**: facilitates the manufacturing of large-scale structures efficiently.
  - **Cost reduction**: significantly lowers tooling costs.
  - **Enhanced properties**: offers superior thermal and mechanical properties with diverse options of engineering plastics and reinforcements.

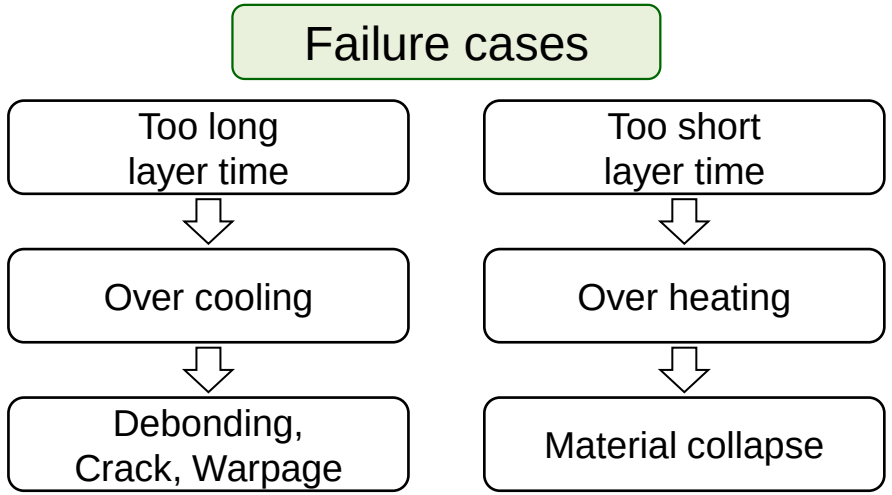
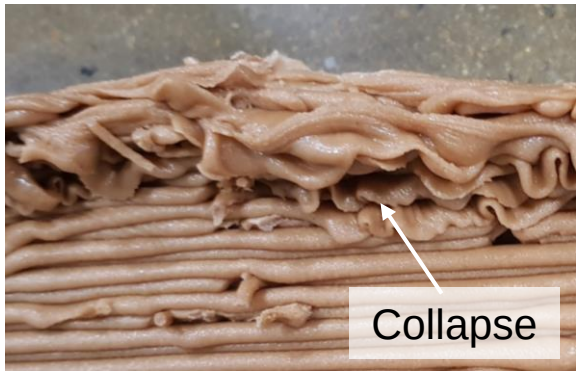
Challenges and key factors in extrusion-based LFAM



- Challenges
  - **Structural stability**: risk of failure or warpage.
  - **Skilled labor dependence**: heavily rely on the experience of skilled operators.
  - **Manufacturing variances**: variability in material, geometry, process parameters, toolpath.
  - **Anisotropic material behavior**: material properties highly dependent on the toolpath.



Warpage in a printed structure

- Key factors
  - **Temperature history:** the structural stability and defect are determined by temperature.
  - **Layer deposition time (layer time)**: the total time required for a layer to be deposited.

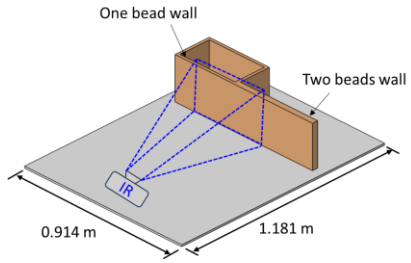
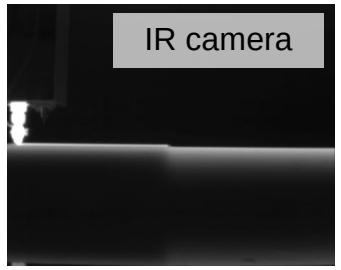
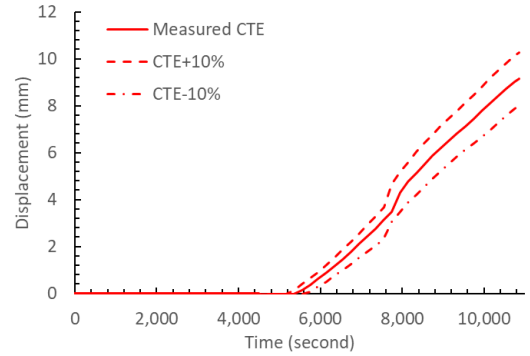
Objectives and material



- Objectives:
  - Objective 1: Evaluating the effect of bead overlap distance on thermal conductivity.
  - Objective 2: Evaluating the effect of bead geometry on temperature history during the manufacturing.
  - Objective 3: Sensitivity analysis of thermal conductivity, heat capacity and thermal expansion coefficient on temperate and deformation history.
- Material:
  - Wood flour reinforced amorphous polylactic acid (compound of NatureWorks aPLA 3D700 and American Wood Flours 100 mesh Norther Yellow Pine)

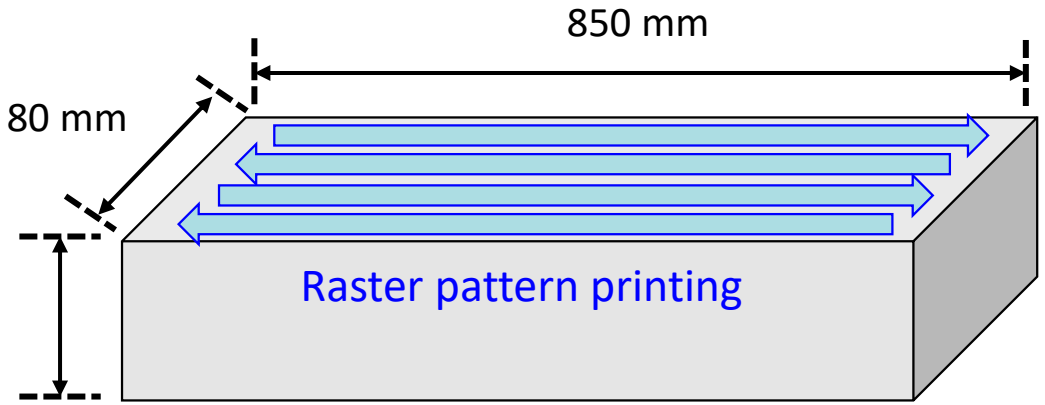


Objective1
Effect of bead overlap distance on thermal conductivity



Objective 2
Effect of bead geometry on thermal history

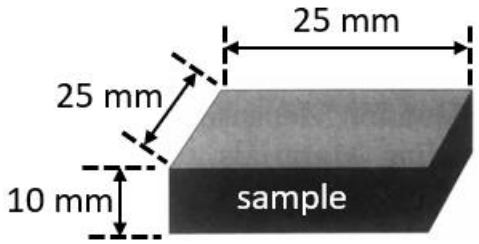
Objective 3
Sensitivity analysis of properties on temperature & deformation history



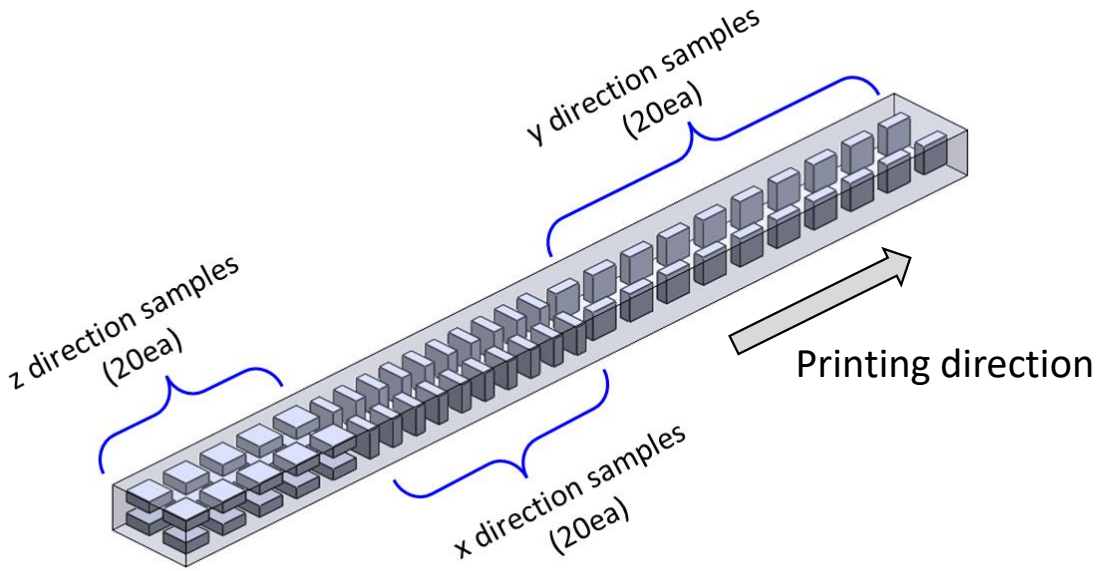
Objective 1:
Evaluating the effect of bead overlap distance on thermal conductivity.

Specimen fabrication

- Base line specimen is manufactured using compression molding at 180 °C and 50 bar.

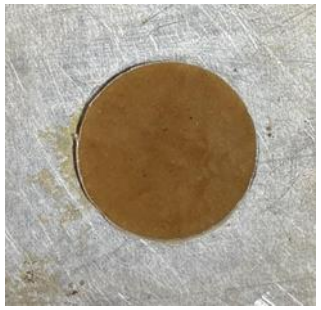


- Box print with simple raster pattern using different bead overlap distance.
  - 6 steps of overlap: 5%, 8%, 10%, 11% and 14%

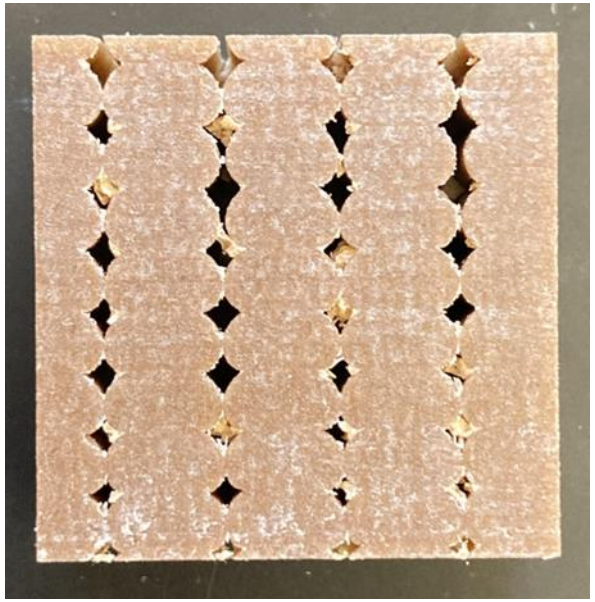


Box print geometry print

- Thermal conductivity measurement in anisotropic direction (x, y, z – direction)
  - Printing direction is defined as x-direction



Sample geometry:



Prepared specimen for thermal conductivity measurement

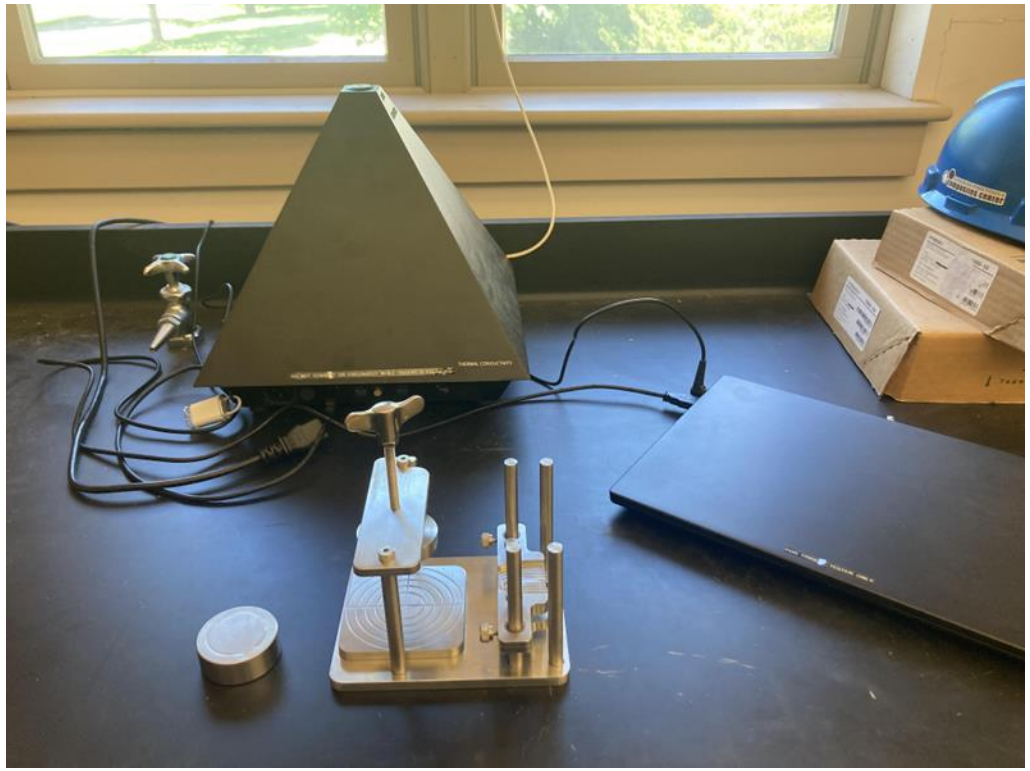
- Baseline specimen

- Specimens with different overlap distance in x, y, z direction.

5% overlap – x direction

5% overlap – z direction

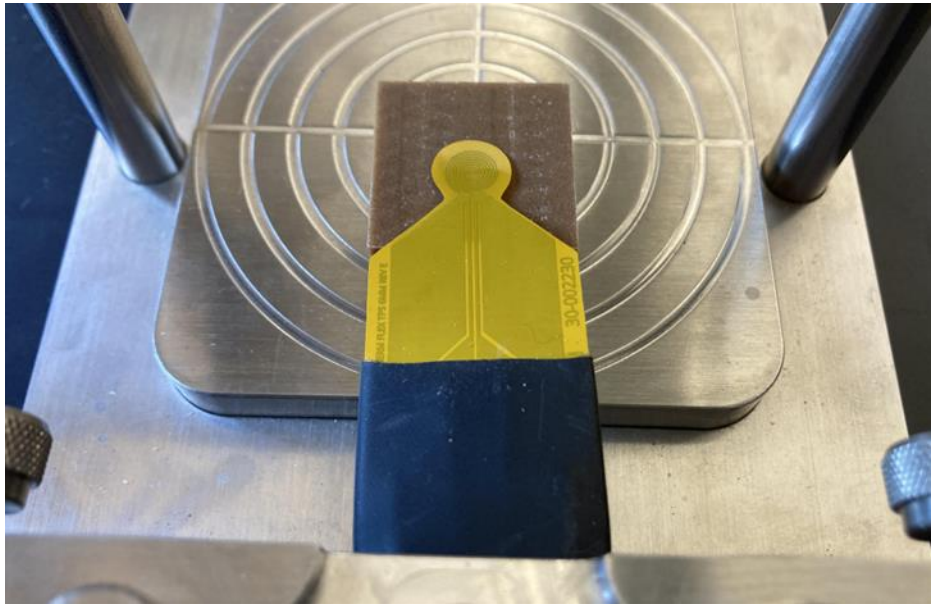
14% overlap – x direction



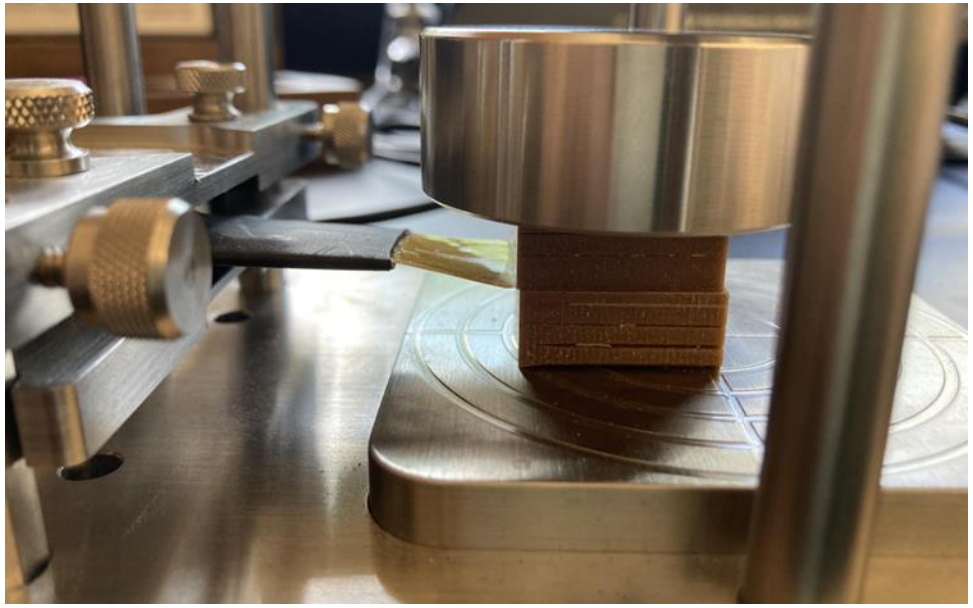
14% overlap – z direction

Heat capacity and thermal conductivity measurement

- Differential scanning calorimetry (DSC)
  - Specific heat, glass transition temperature
- Transient plane source (TPS)
  - Thermal conductivity



DSC



TPS

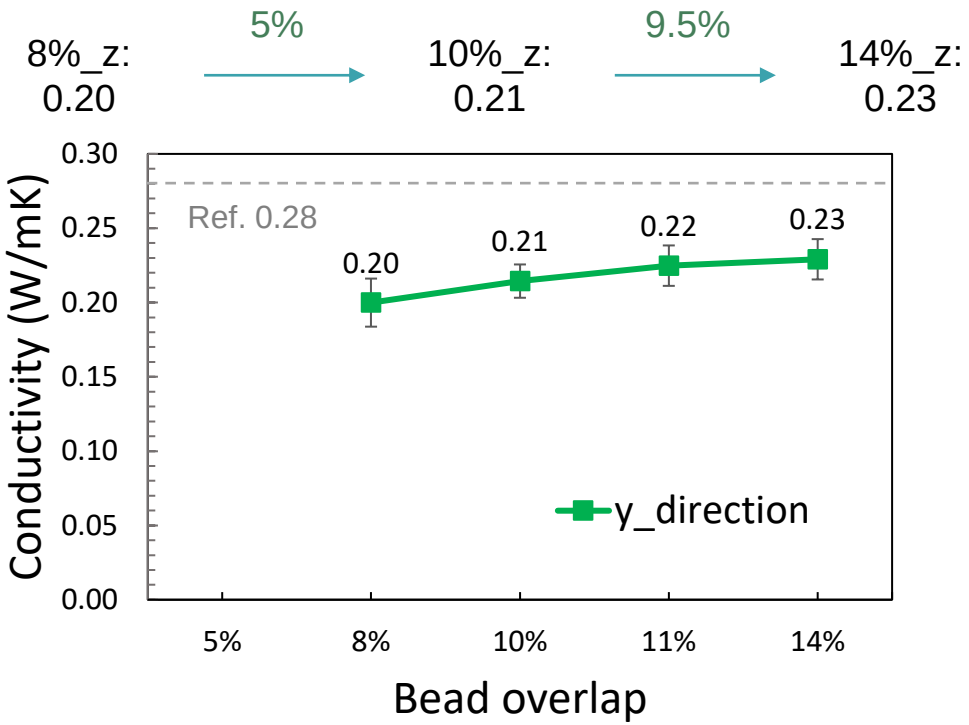
TPS test set up

- TPS test conditions
  - 6 mm sensor
  - Test time: 40 seconds
  - Power: 0.02 W

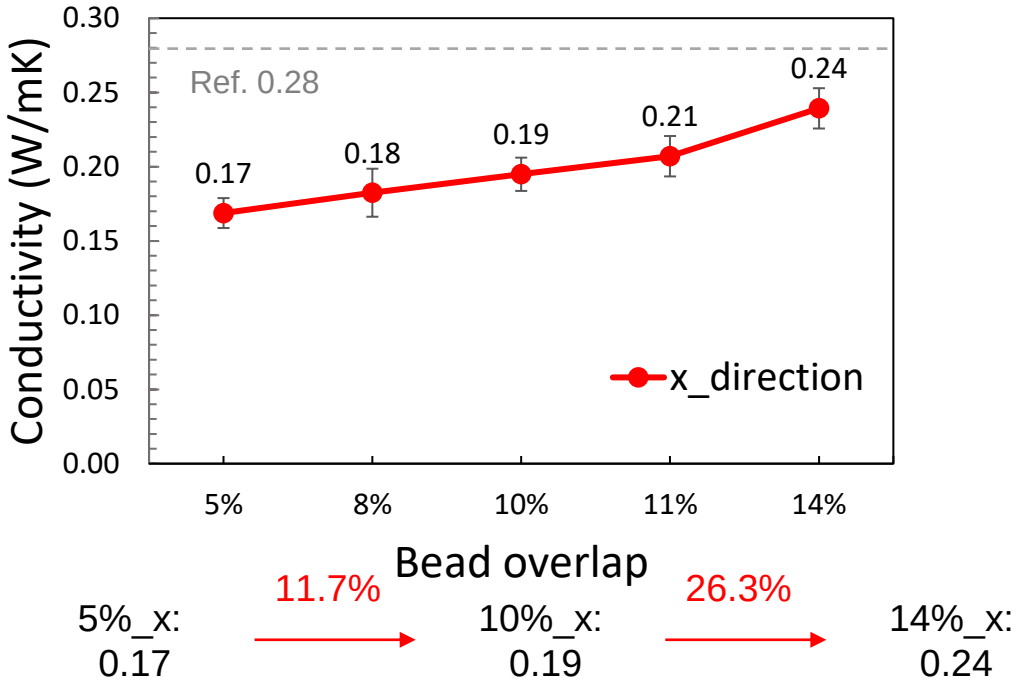
6 mm sensor

Sensor installation

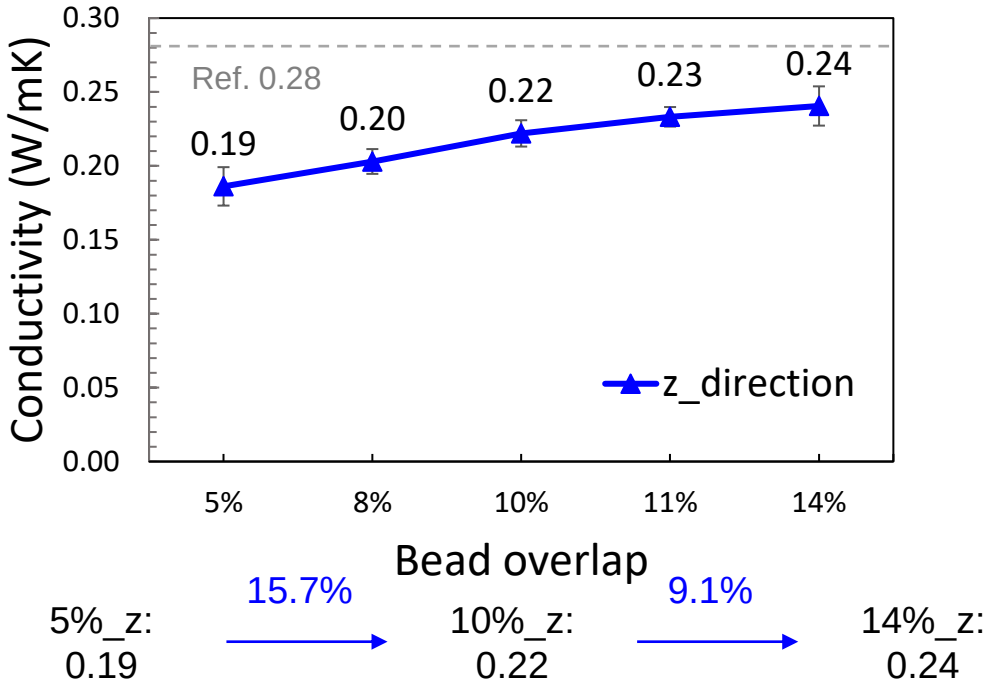
TPS test results



- Thermal conductivity $(\kappa, W/mK)$



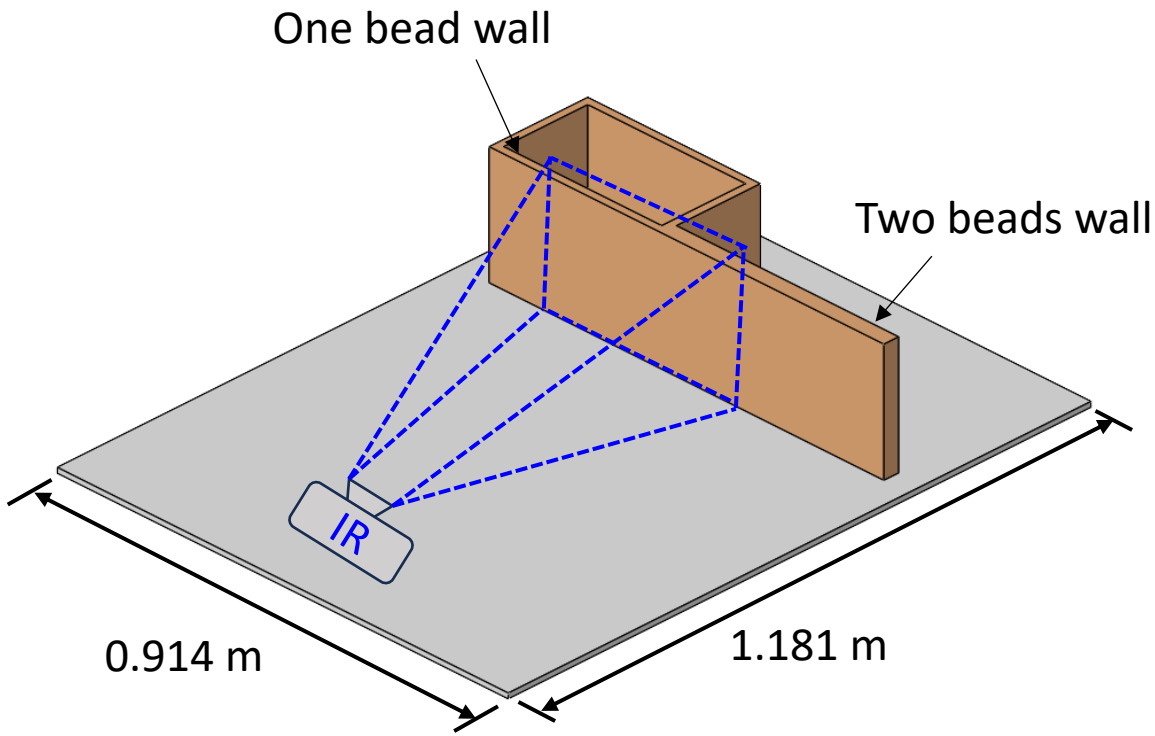
$$\kappa = \alpha \cdot \rho \cdot C_p$$



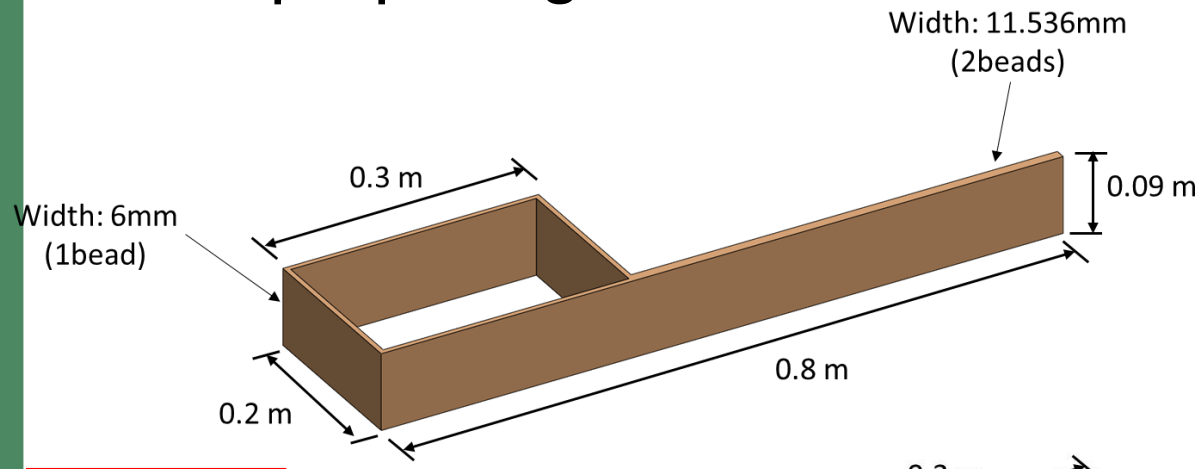
α: diffusivity (m^2/s), ρ: density (kg/m^3)

C_p: specific heat (J/kgK)

- Specific heat: 1,350 J/kgK (@ 25 ℃)

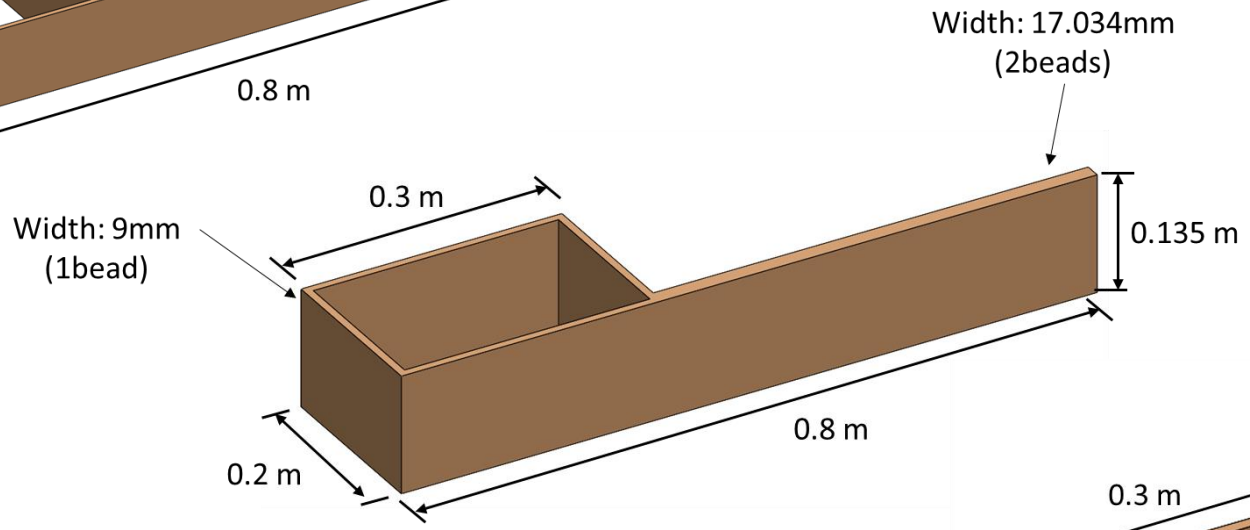


Objective 2:
Evaluating the effect of bead geometry on temperature history during the manufacturing.

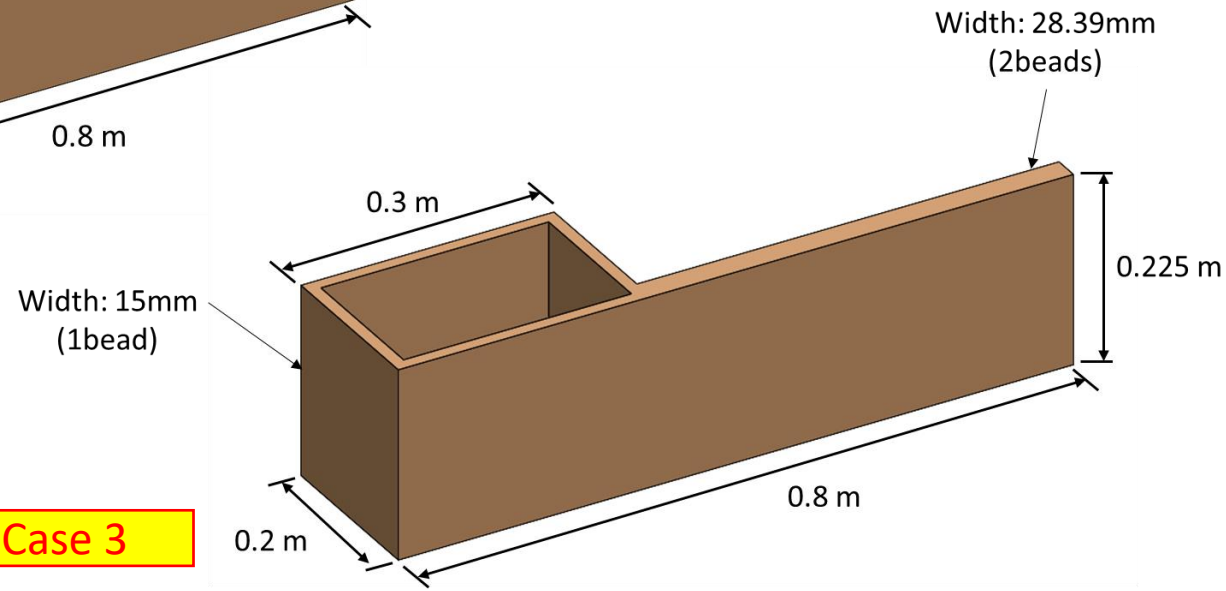


Temperature measurement during P-shape print

- Geometry: Multi-beads wall geometry with 60 layers
  - Half (one bead) : Half (two beads)
- Temperature measurement using an Infrared (IR) camera
  - IR camera: FLIR Boson, FOV: 0.4m x 0.32m
- Bead geometries:



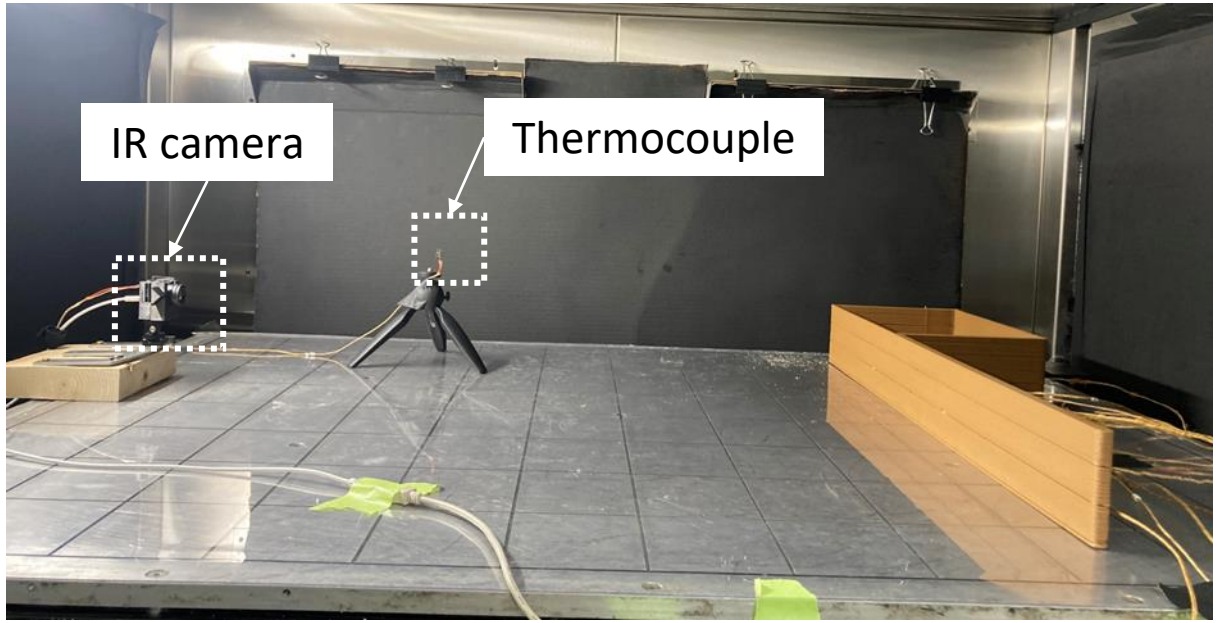
Bead geometry	Nozzle Diameter (mm)	Width (mm)	Height (mm)
# 1	4	6	1.5
# 2	6	9	2.25
# 3	10	15	3.75



P-shape print geometries

Case 1

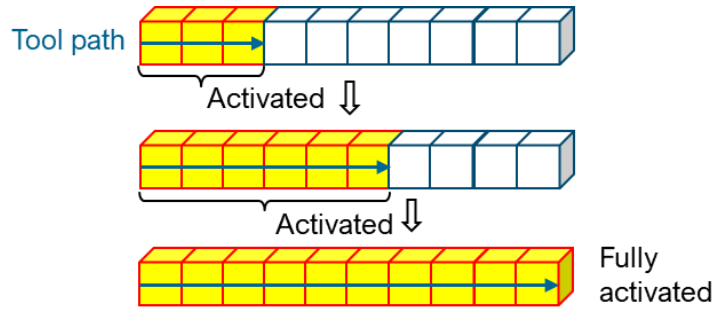
Case 2



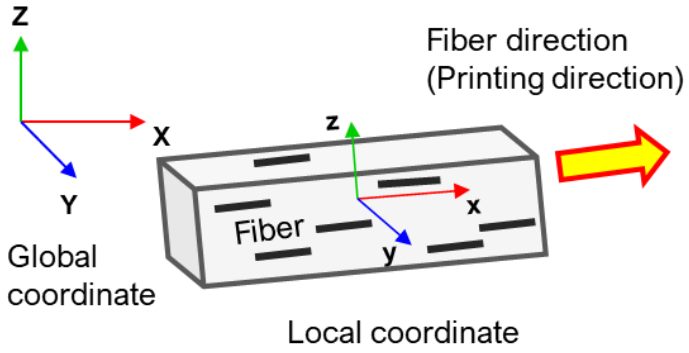
Case 3

AM printing with Juggerbot 3D (Tradesman Series P3-44)

- Used material: Wood fiber reinforced PLA (20 wt. %)
- Print speed: 1350, 848, and 425 mm/min
- Extrusion temperature: 165 ˚C
- Layer time: 90, 140, and 240 seconds

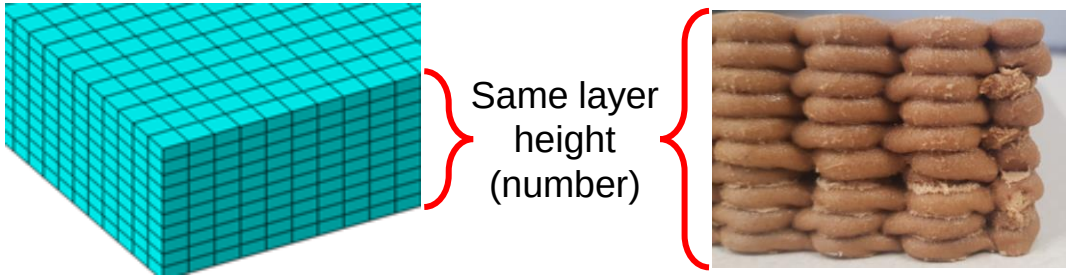


Juggerbot3D – Tradesman Series P33-44



Experimental setup

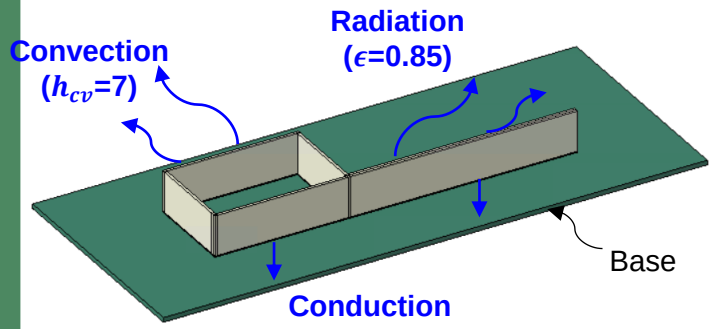
Transient heat transfer model using finite element analysis (FEA)

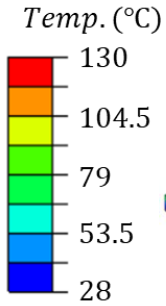


- Element activation
  - Activate elements when a tool path passes through the elements (tool path from Gcode).
  - Update boundary conditions (activate elements in extrusion temperature).

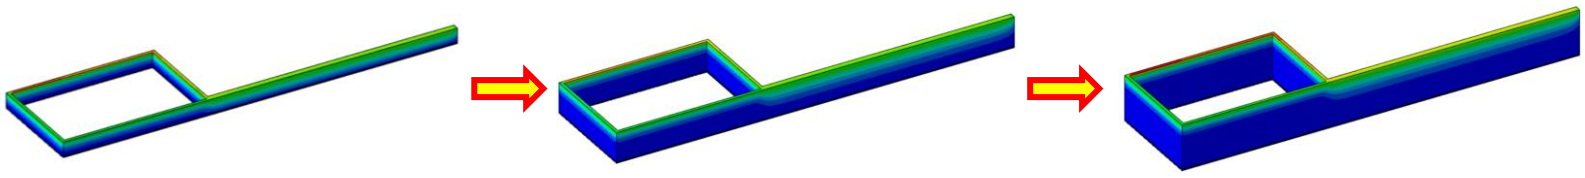
- Anisotropic thermal properties with printing direction
  - The fiber in the extruded substance is aligned with the tool path.
  - The principal direction (x-direction) is chosen as the print direction (z-direction = stacking direction).

- Layer height (number)
  - The element has the same height (number) as the real print to simulate the layer-by-layer stacking procedure.



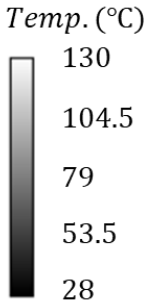


FEA heat transfer model

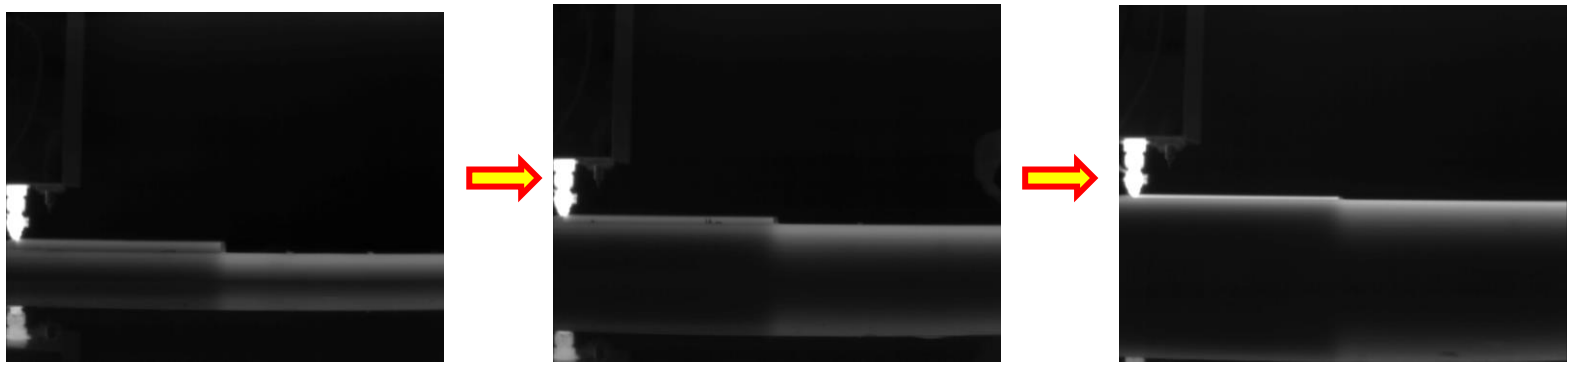


- Temperature prediction for the P-shaped print
  - Temperature history is predicted over the entire process.
  - Temperature field is displayed as color maps, with hot areas in red and cold areas in blue.
- Material properties: Wood flour reinforced polylactic acid (WFPLA, 20wt.%)
  - **Density**: 1,240 kg/m^3, **Specific heat**: 1,476 $J/kg{\cdot}K$, **Conductivity** (x, y, z): 0.198, 0.186, 0.159 $W/m{\cdot}K$

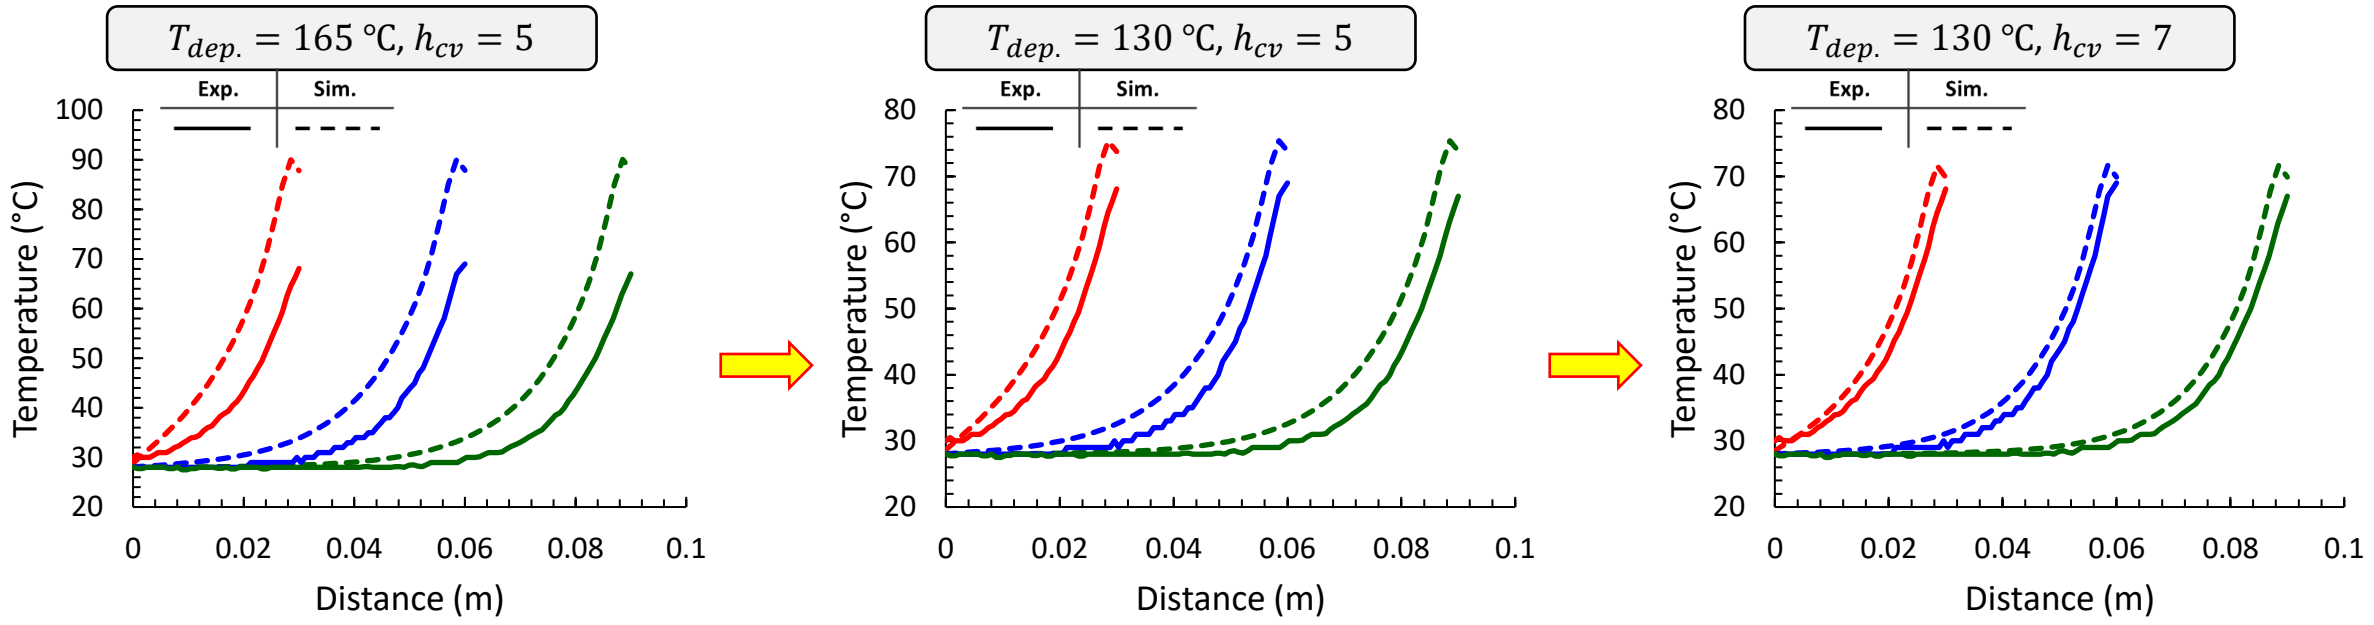
Boundary conditions



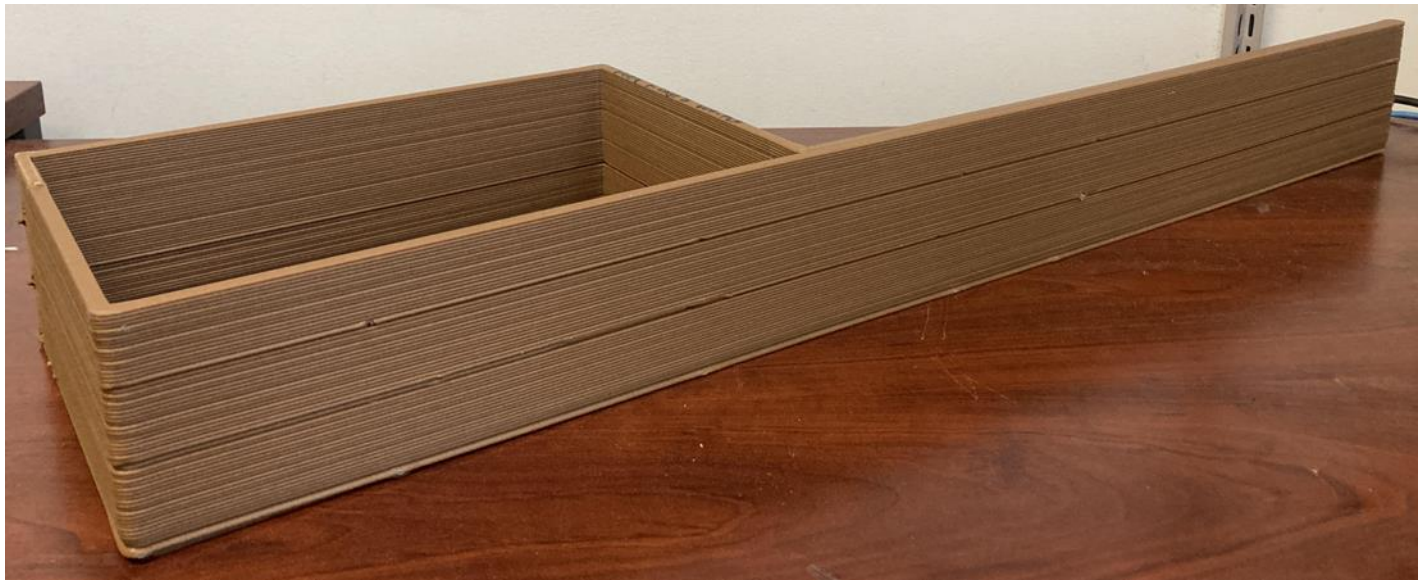
- Extrusion temp. = 130°C
- Base temp. = 28°C
- Ambient air temp. = 28°C



t = 1,800s (Layer 20) t = 3,780s (Layer 40) t = 5,780s (Layer 60)

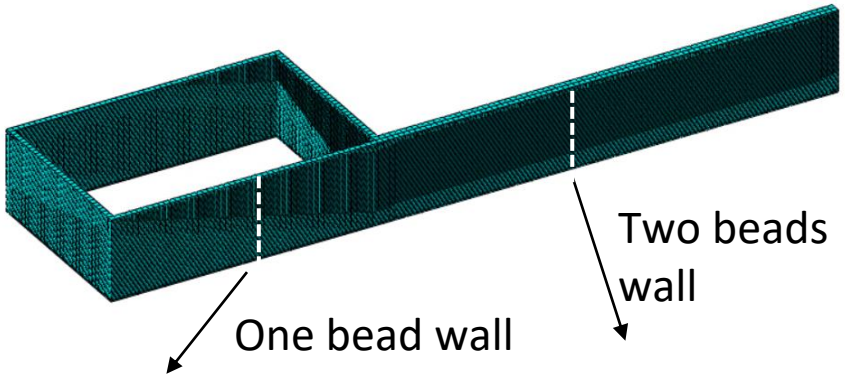


Simulation parameter calibration

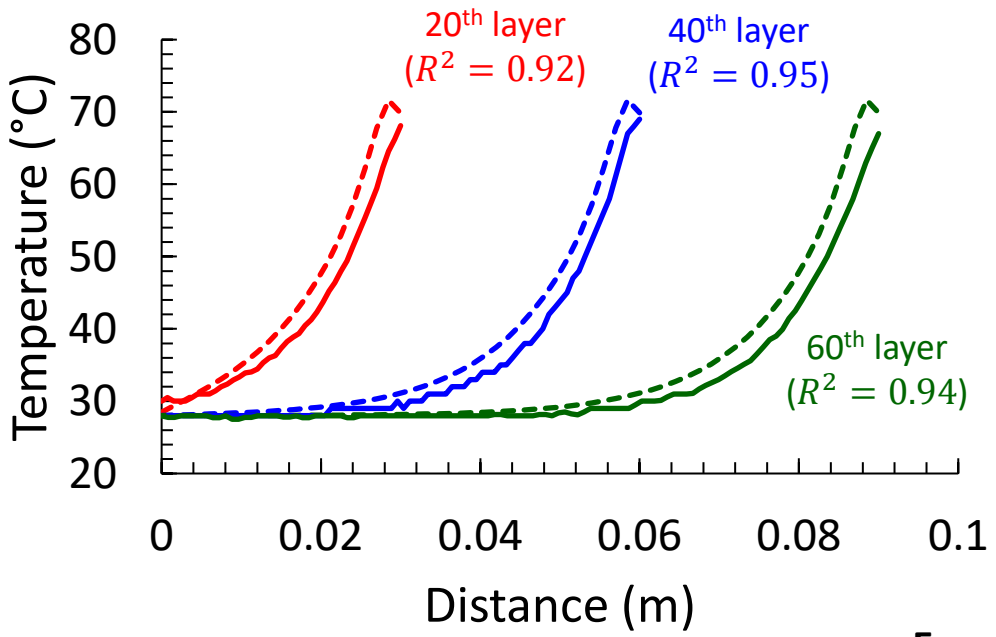


1. Deposition temperature calibration
   - Extruded material experiences rapid cooling and the simulation model lacks the ability to simulate this accurately.
   - By comparing the temperature at the center of wall position when the layer deposition process is finished, the deposition temperature is calibrated.

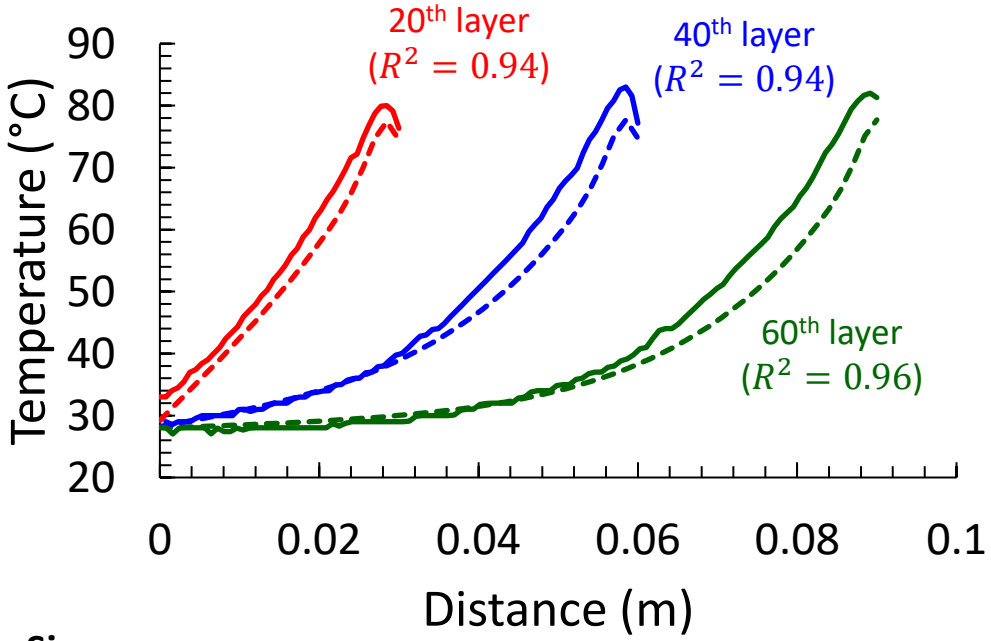
2. Convection coefficient calibration
   - By comparing the temperature profiles, the convection coefficient is calibrated.

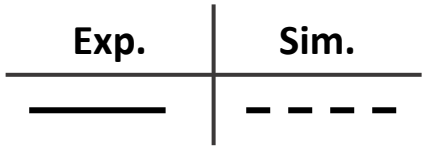


Results: P-shape print case 1



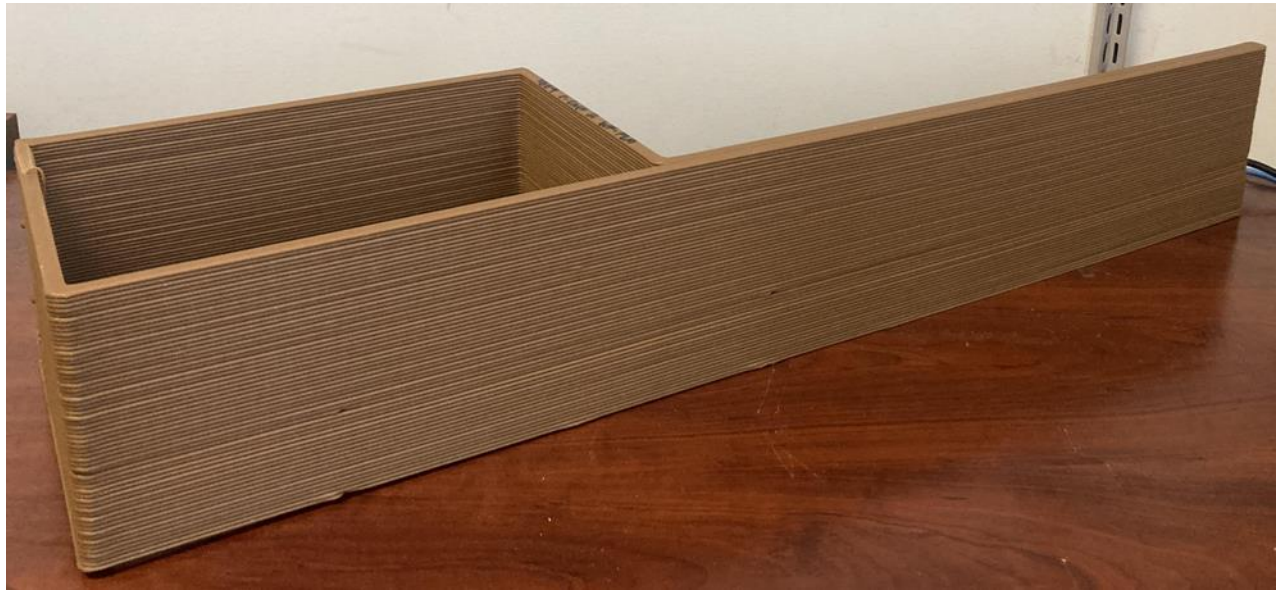
- Case 1
  - # of thermal images: 5,140
  - Layer time: 90s → theoretical printing time for 60 layers: 5,400s
  - Overall printing time with IR camera (printing + thermocouple installation): 5,763s
    - Installation time (1st and 2nd): 177s and 200s
    - Printing time: 5,386s

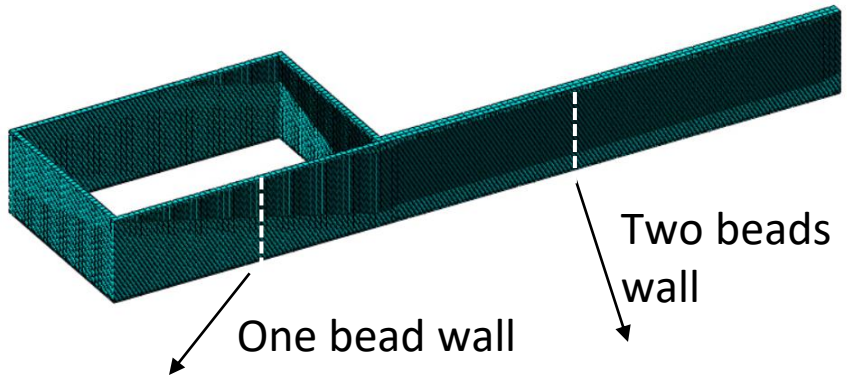




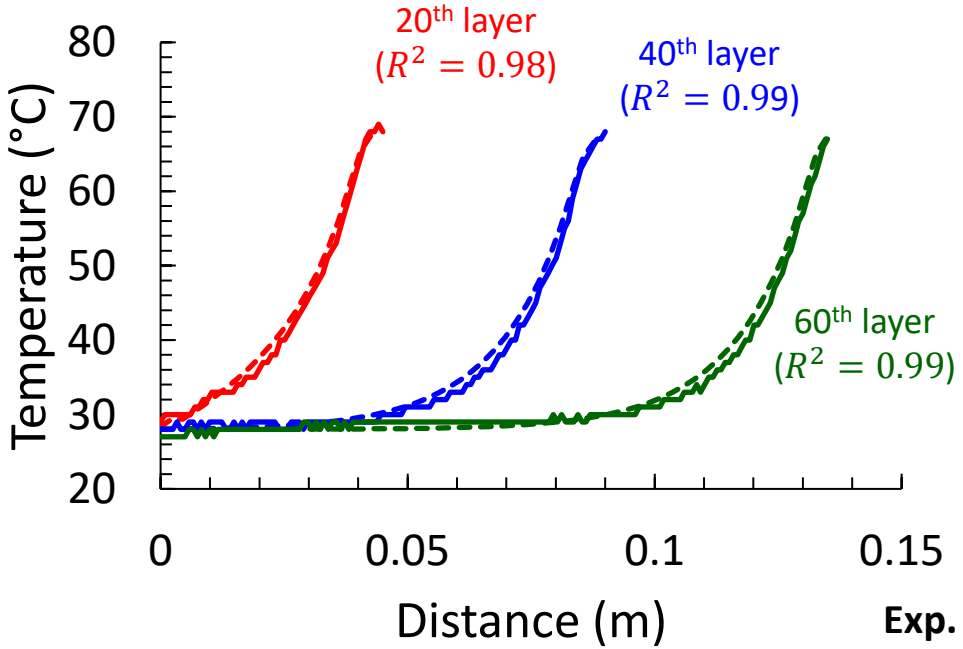
Comparison of IR thermal data with simulation _Case 1

- Boundary conditions:
  - Deposition temperature: 130 °C
  - Boundary temperature: 28 °C
  - Convection coefficient: 7
  - Emissivity: 0.85

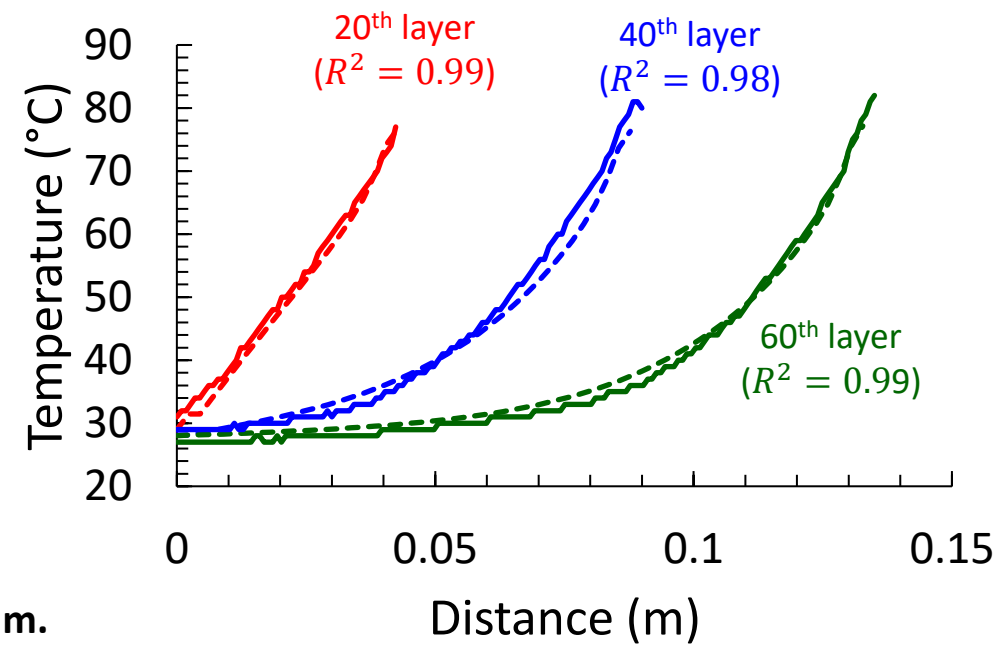


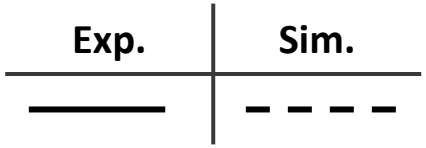


Results: P-shape print case 2



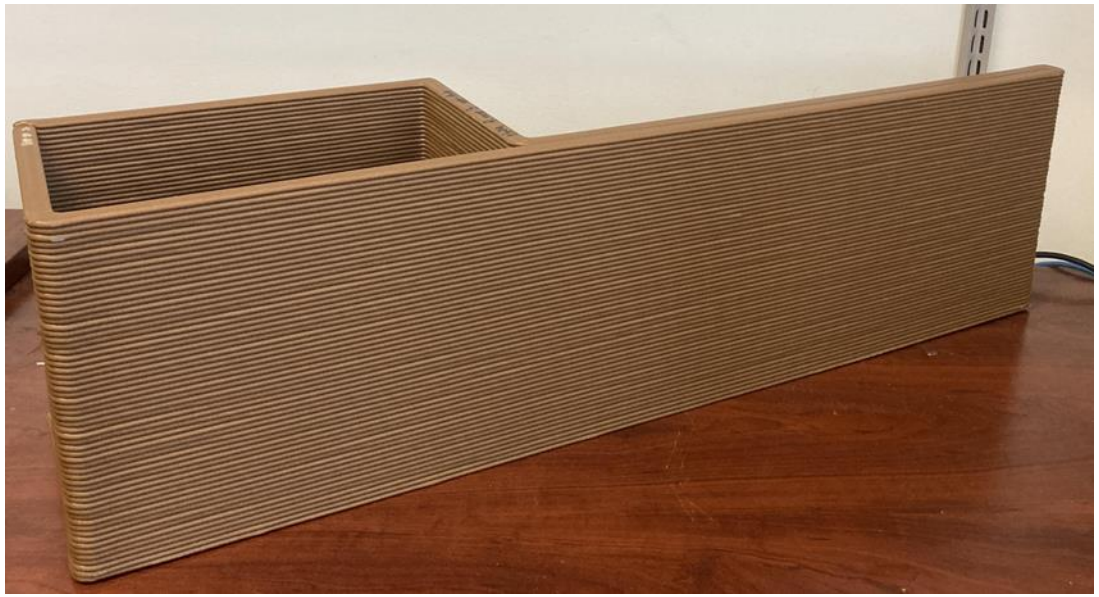
- Case 2
  - # of thermal images: 7,606
  - Layer time: 120s (1~15th) & 140s → theoretical printing time for 60 layers: 8,100s
  - Overall printing time with IR camera (printing + thermocouple installation): 8,764s
    - Installation time (1st and 2nd): 402s and 197s
    - Printing time: 8,165s

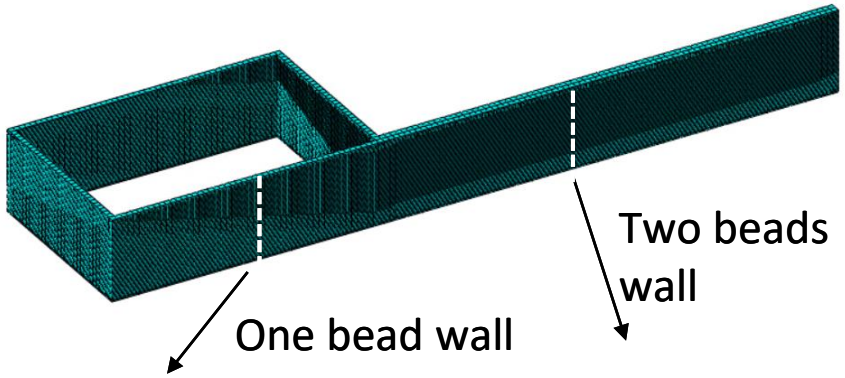




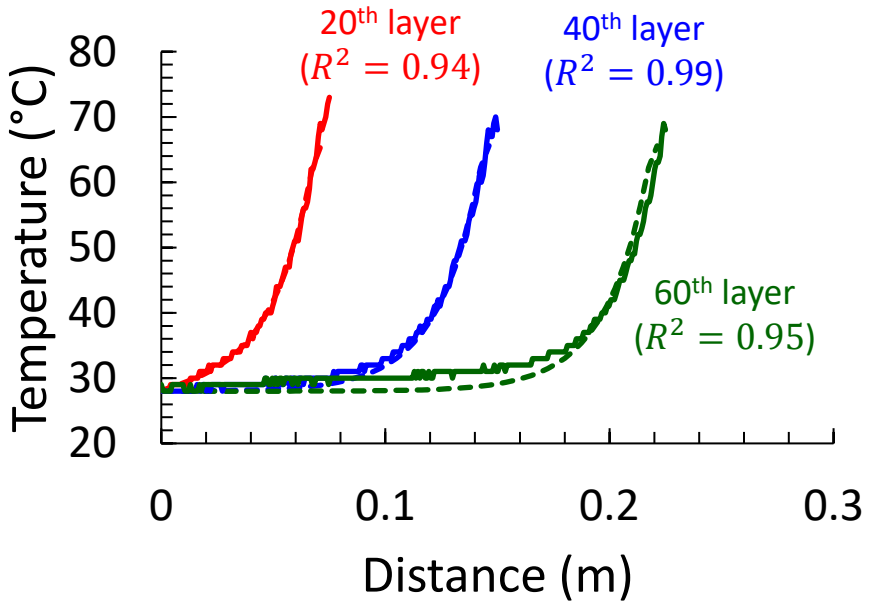
Comparison of IR thermal data with simulation _Case 2

- Boundary conditions:
  - Deposition temperature: 130 °C
  - Boundary temperature: 28 °C
  - Convection coefficient: 7
  - Emissivity: 0.85

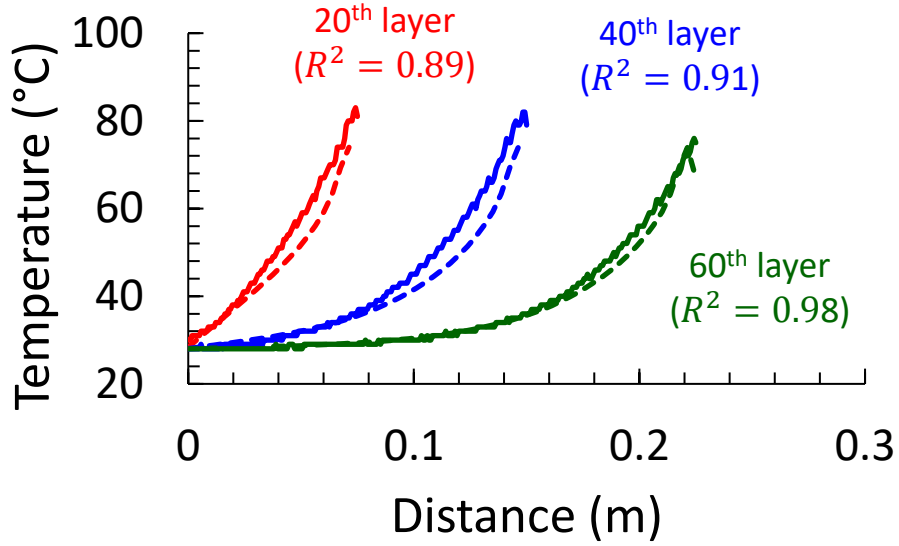




Results: P-shape print case 3



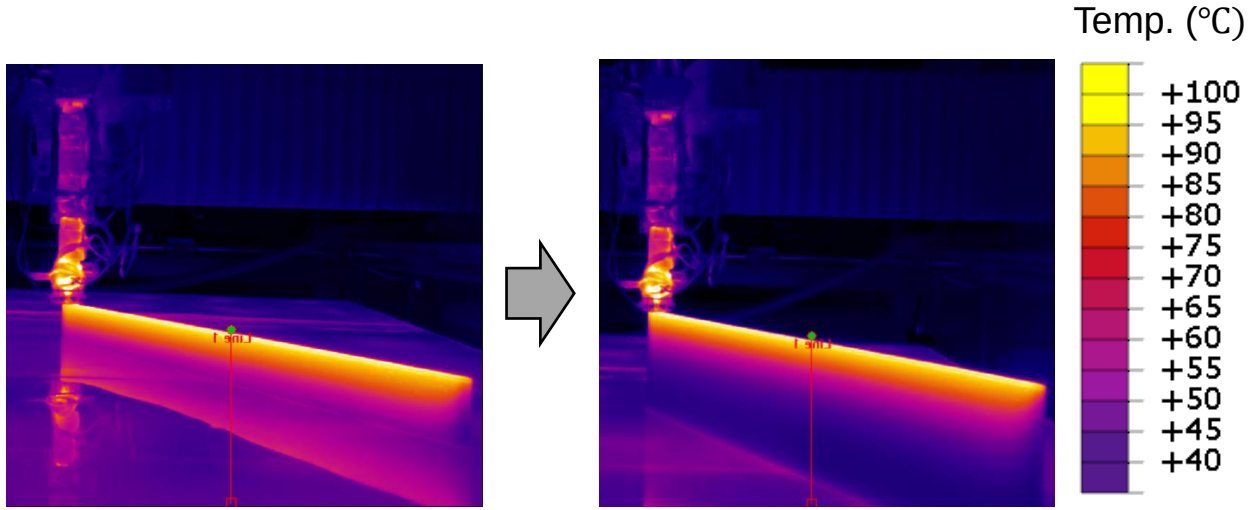
- Case 3
  - # of thermal images: 14,771
  - Layer time: 275s→ theoretical printing time for 60 layers: 16,500s
  - Overall printing time with IR camera (printing + thermocouple installation): 16,868s
    - Installation time (1st and 2nd): 225s and 170s
    - Printing time: 16,473s



Comparison of IR thermal data with simulation _Case 3

- Boundary conditions:
  - Deposition temperature: 130 °C
  - Boundary temperature: 28 °C
  - Convection coefficient: 7
  - Emissivity: 0.85

Exp.	Sim.
———	- - - -



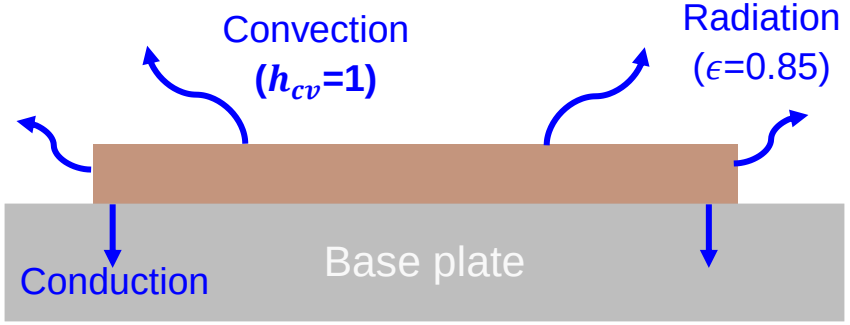
Objective 3:
Sensitivity analysis of thermal conductivity, heat capacity and thermal expansion coefficient on temperature and deformation history

Temperature and deformation measurement during wall print

- Experimental set up
  - Temperature measurement using an IR camera
  - Displace measurement using Linear Variable Differential Transformer (LVDT)
  - Wall dimensions (L x W x H, m): 1.36 x 0.0153 x 0.3
  - Bead geometry (W x H, mm): 7.65 x 2.54

Experimental set up

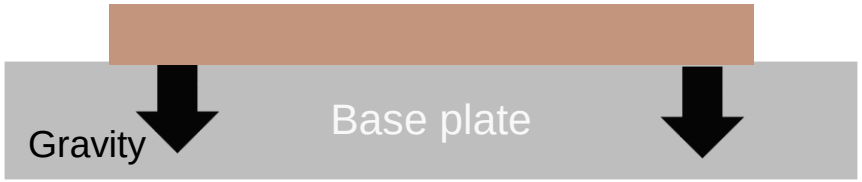
IR image of 3D printing process (Temperature measure)



Warpage measurement with LVDT

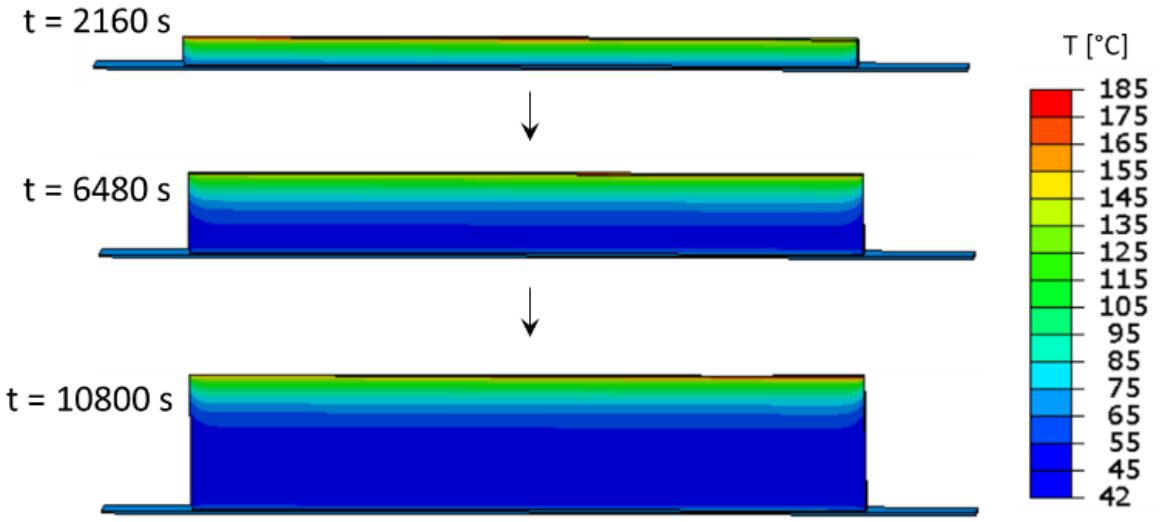
Simulation model for temperature and deformation prediction

- Sequentially coupled thermomechanical model
  - Step 1 (thermal simulation): transient heat transfer analysis is conducted to obtain the temperature field data by using the heat transfer element (e.g., DC3D8).
  - Step 2 (structural simulation): Sequentially, the mechanical analysis is conducted to obtain the stress/deformation field based on the previously predicted temperature data by using the structural element (e.g., C3D8).
- Boundary conditions



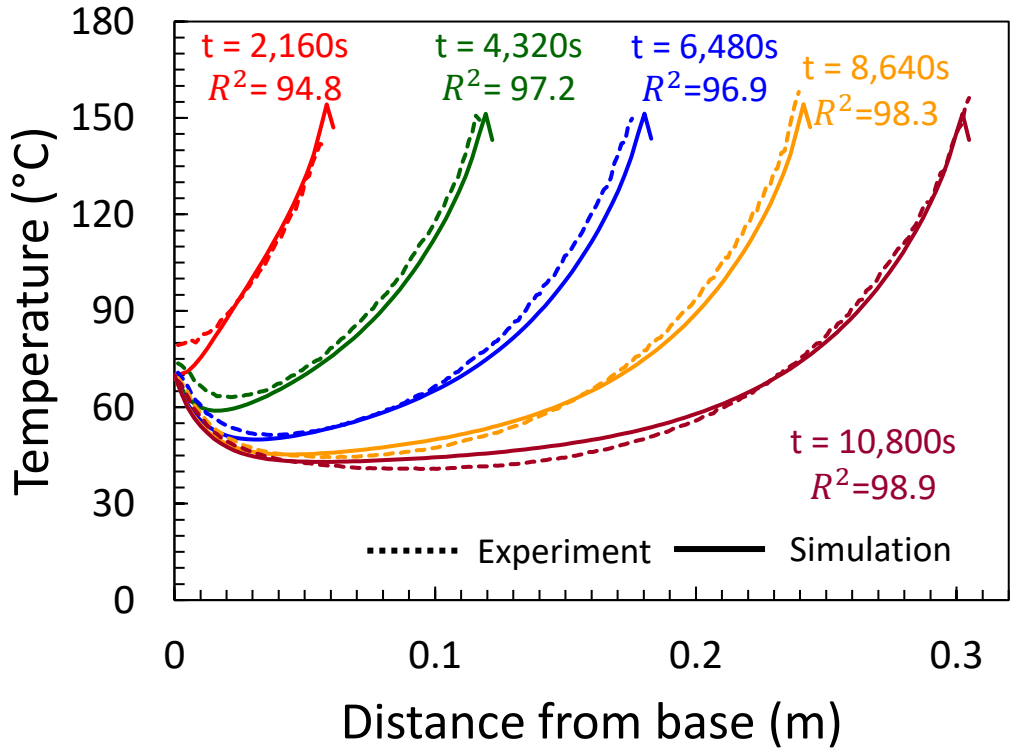
Step 1: Thermal simulation

- Deposition temperature (T_{dep}) = 210 °C
- Base temperature (T_{base}) = 50 °C
- Air temperature (T_{air}) = 30 °C



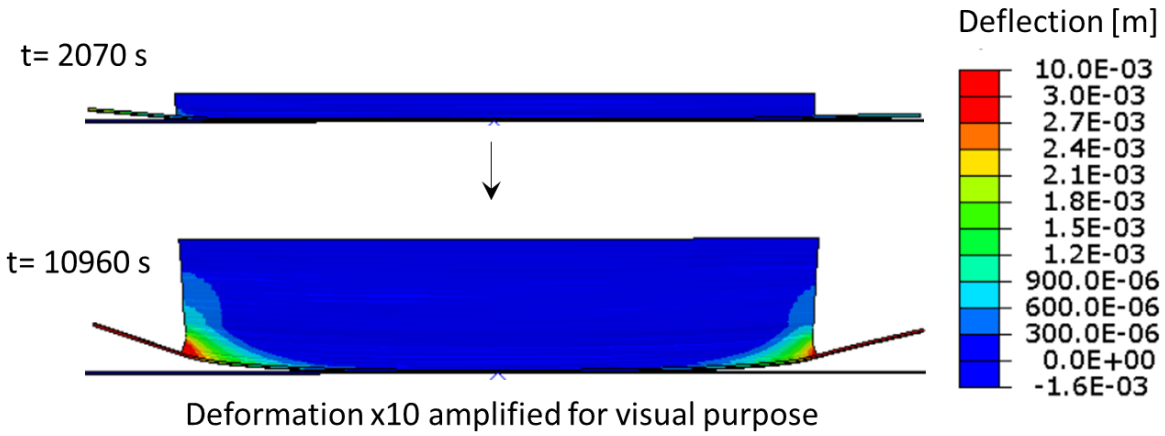
Step 2: Structural simulation

- Gravity for whole model (9.81 m/s^2)
- Base plate is fixed.

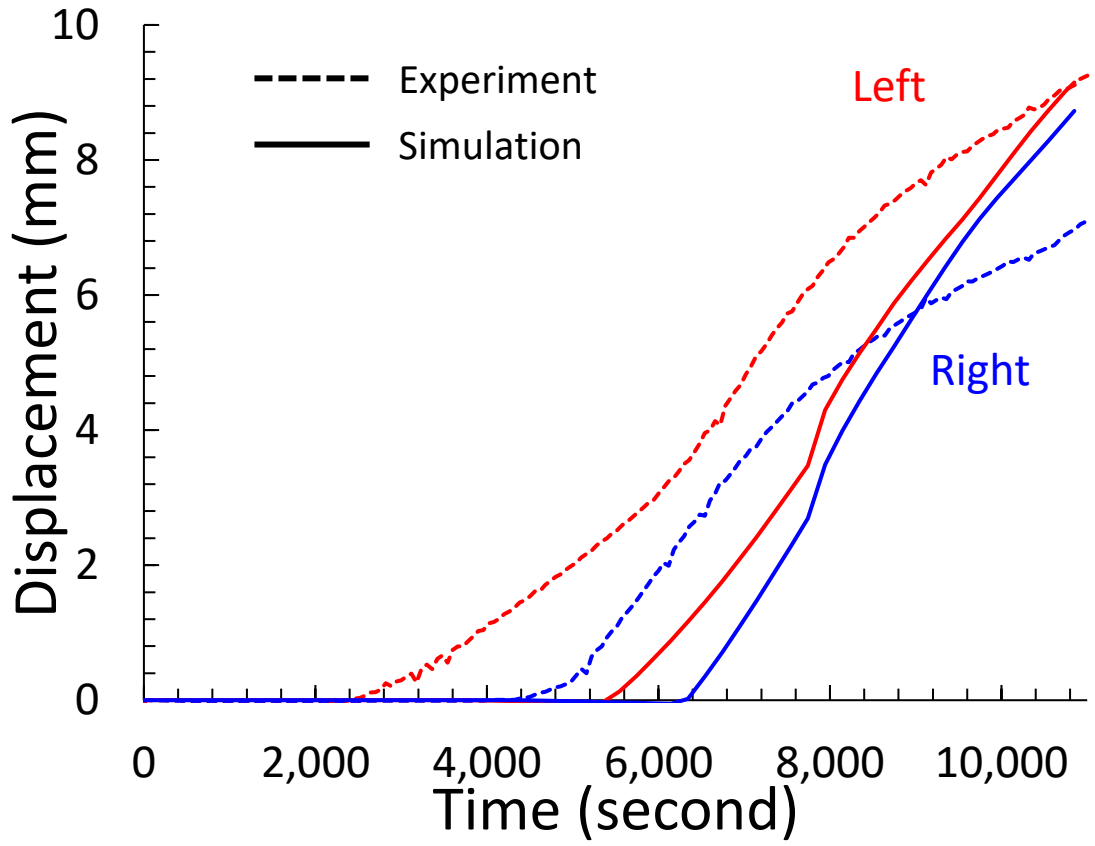


Results of temperature prediction

- Temperature at the center of the wall was recoded and compared those from experiments and simulation model.
  - Total print time (10,800 seconds) was divided in 5 intervals.
  - Each time interval the temperature from basement to surface was measured.



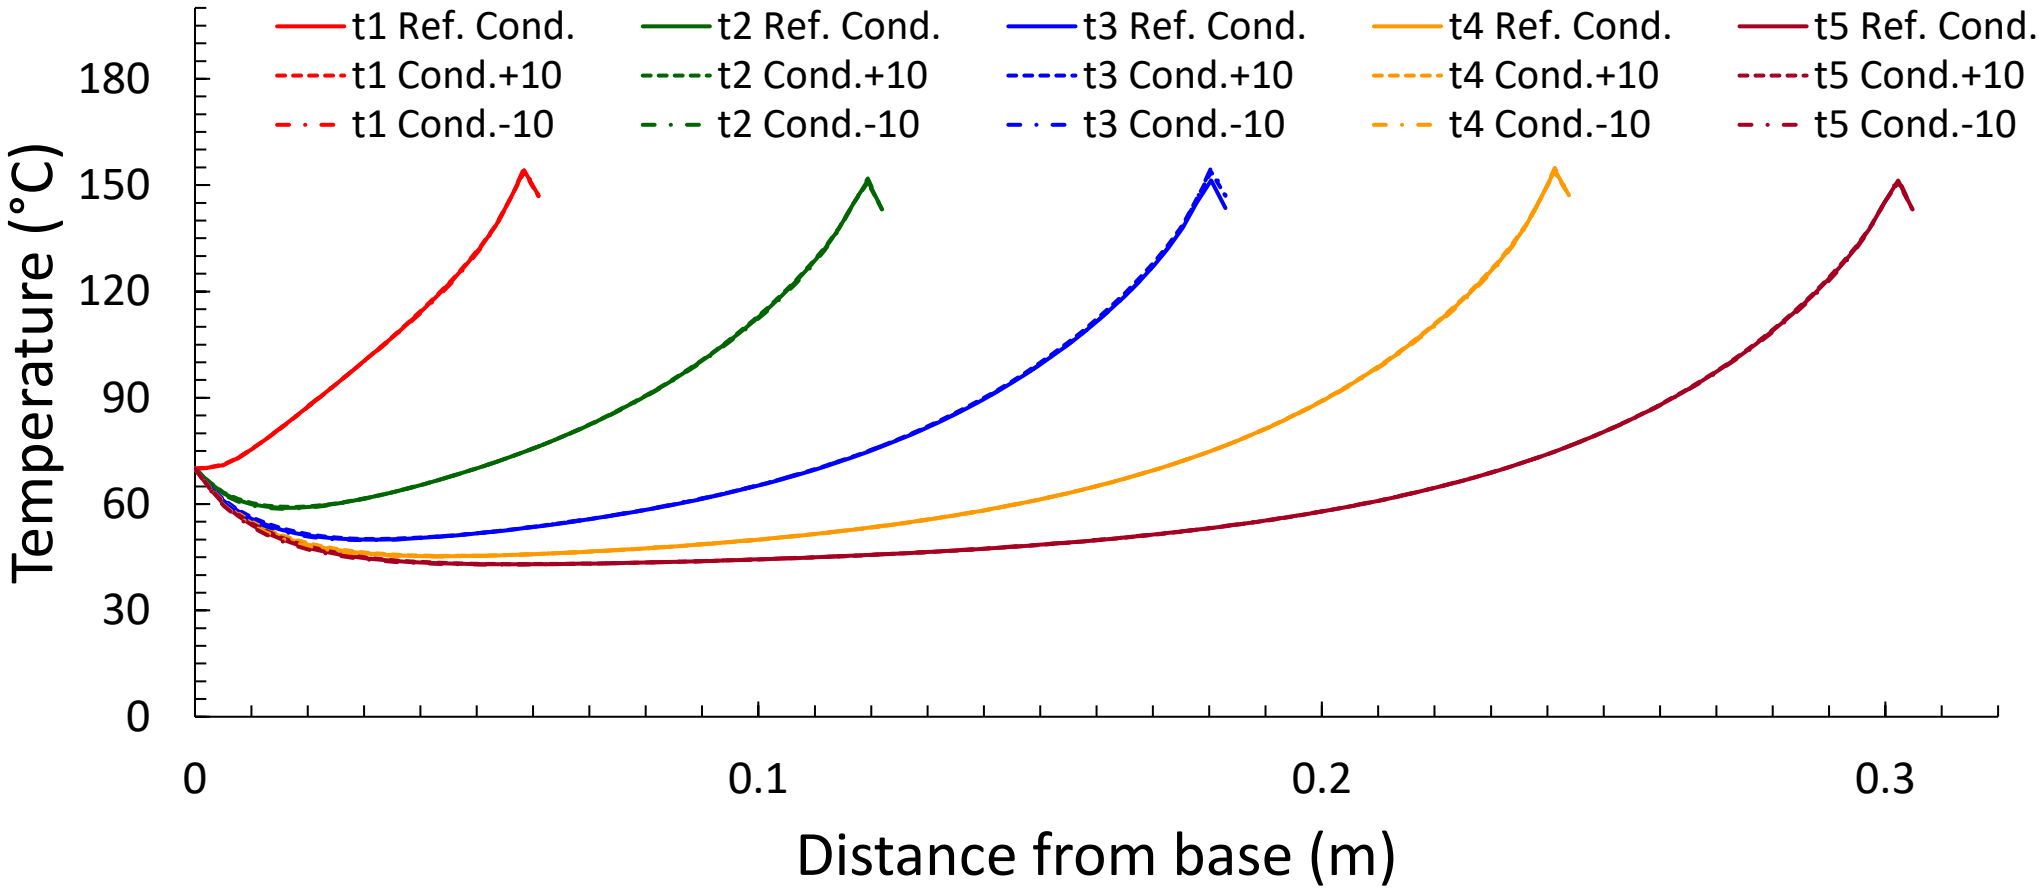
Temperature field at different time interval



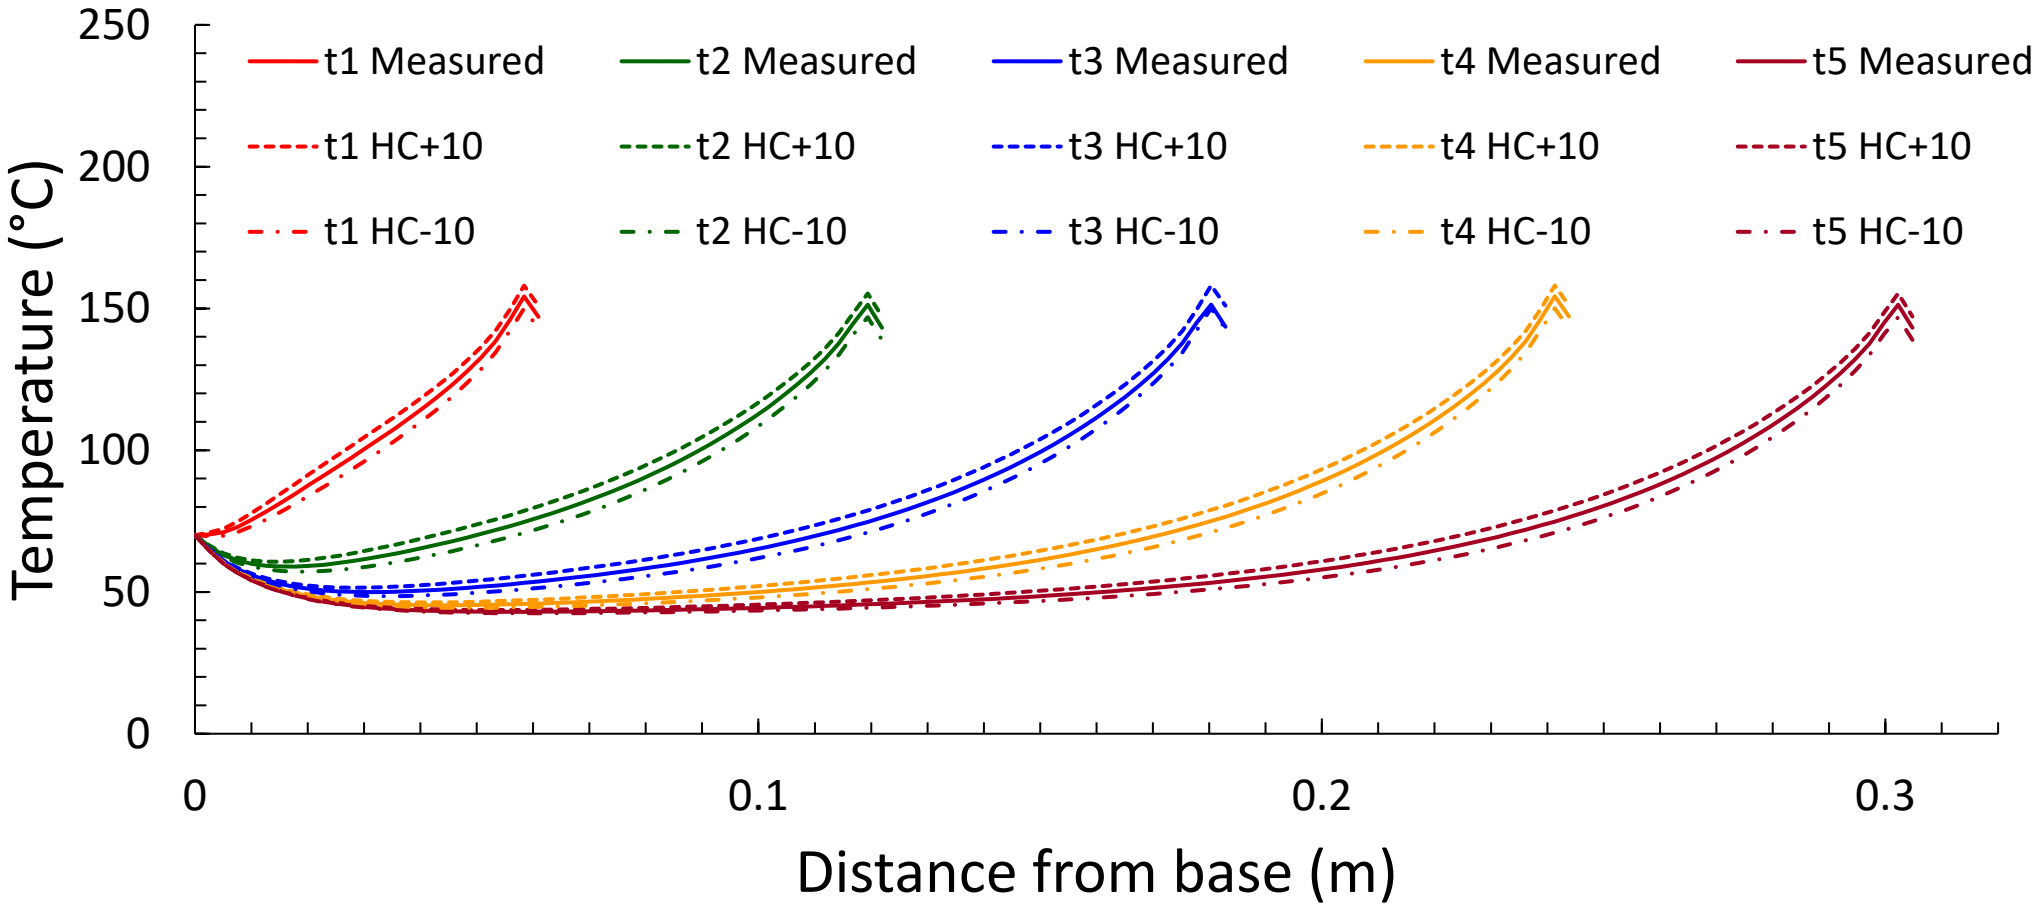
Comparison of temperature profile from experiments with those from simulation model.

Results of deformation prediction

- Deformations at the left and right corner was measured and compared those from experiments and simulation model.
  - The deformation is recorded during the whole printing process
  - In experiments, the length of left and right were different, so the deformation was unsymmetric.

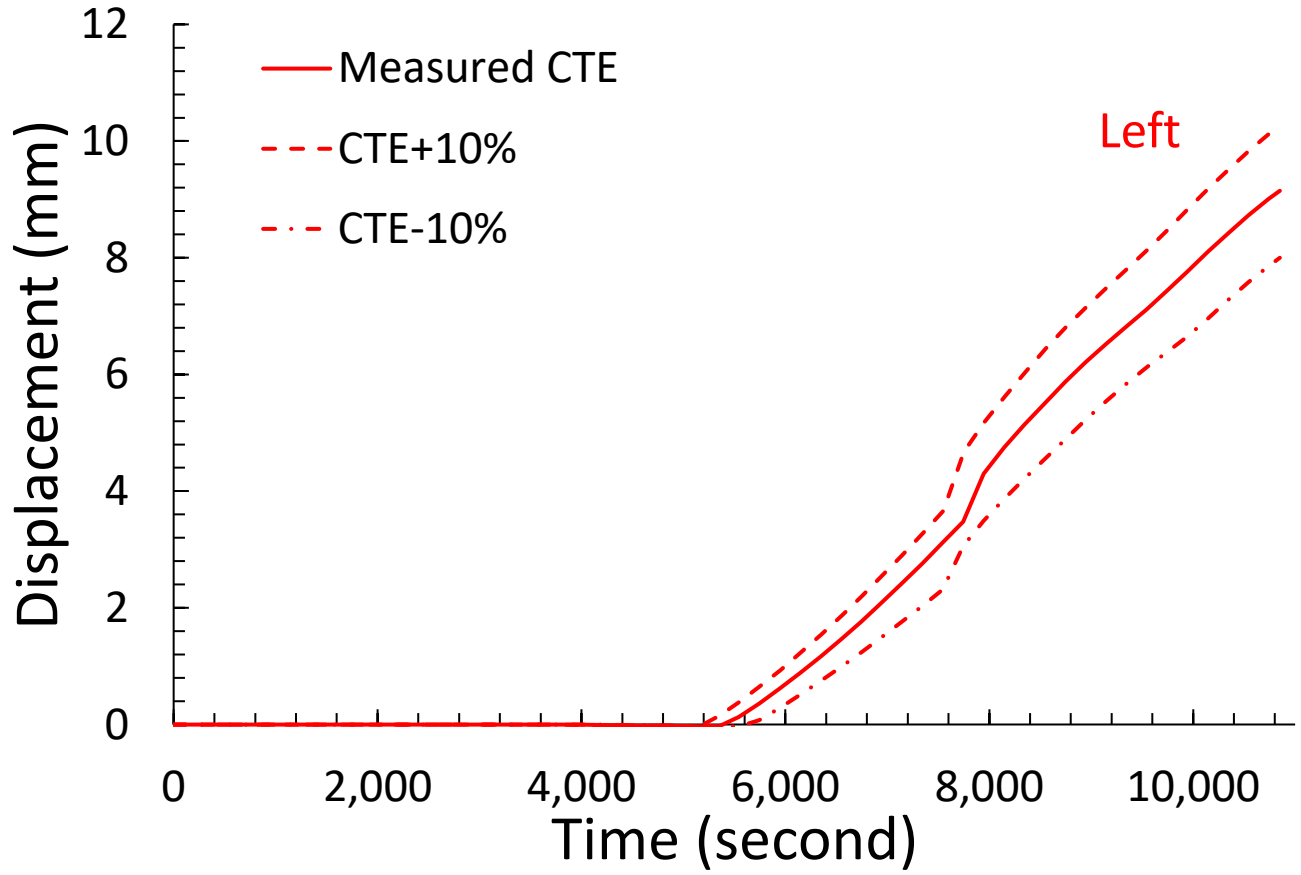


Deformation field at different time interval



Sensitivity test of thermal conductivity on temperature history

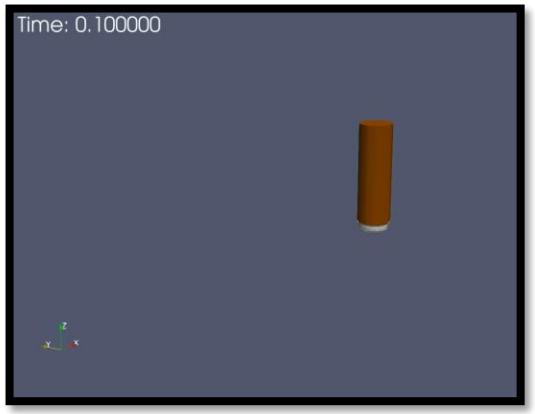
- Thermal conductivity was increased and decreased by 10%.



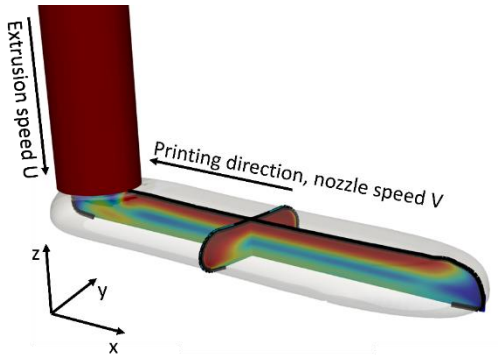
Sensitivity test of heat capacity on temperature history

- Heat capacity was increased and decreased by 10%.

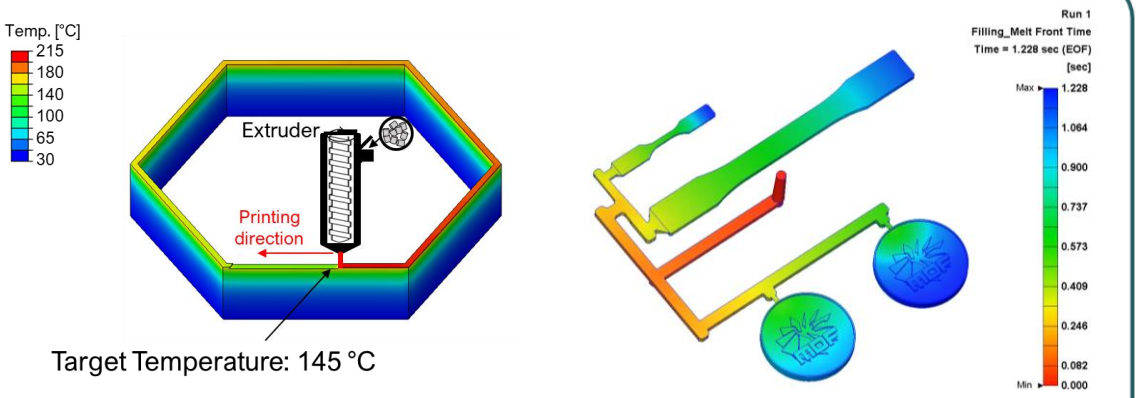
Sensitivity test of thermal expansion on deformation history



- Coefficient of thermal expansion was increased and decreased by 10%.



Summary & Conclusion



- Effect of bead overlap distance on thermal conductivity was evaluated
  - Specimens were manufactured with varying overlap distances.
  - Thermal conductivity increased as the bead overlap distance increased, indicating greater contact surface area between beads.
- Effect of bead geometry on thermal history was investigated
  - P-shaped structures were printed with different bead geometries.
  - The cooling rate decreased with the increase in bead size due to the greater thermal mass. However, the transient heat transfer model accurately predicted the temperature history regardless of the bead geometry.
- Sensitivity analysis of thermal conductivity, heat capacity, and thermal expansion on temperature and deformation history was conducted.
  - Thermal conductivity and heat capacity have minimal effect on the thermal history.
  - In contrast, thermal expansion has a comparatively greater impact on the final deformation.

Development of vertical wind turbine blades using 4D printing of composites

Emad Fakhimi and Suong Van Hoa

Abstract:

This paper presents the procedure to make vertical wind turbine blades using the technique of 4D printing of composites (4DPC). The blade is made using carbon/epoxy composite materials with fiber volume fraction of about 60%. Even though the blade has a 3D shape with curvatures, it is made using only a flat mold. The procedure can provide time and cost savings due to the fact that molds of complex curvature are not necessary. At the same time, the material is strong, stiff, and light giving further savings in weight and subsequent benefits in handling. Testing on wind turbines with original aluminum blades and with composite blades shows that the wind turbines with composite blades run at higher speeds. Also, wind turbine with composite blades gives higher efficiency than wind turbines with original aluminum blades.

Introduction:

Wind turbines are one source of generators of green energy. The majority of wind turbines are horizontal axis type, with very long blades and can generate a large amount of energy. Another type of wind turbine is the vertical axis wind turbine. These are smaller wind turbines. They are usually located on the roof of buildings. The amount of energy they generate is small but may be sufficient for energy needs in a small building. The global vertical axis wind turbine (VAWT) market size accounted for USD $12.9 billion in 2022, and is projected to achieve a market size of USD $17.7 billion by 2032 growing at a CAGR of 3.2% from 2023 to 2032. According to research conducted by the National Renewable Energy Lab ((NREL) in the U.S., VAWTs provide more yearly energy per unit area than horizontal axis wind turbines (HAWT) [1].

One example of the vertical axis wind turbine is shown in Figure 1. This wind turbine is of RX-SV2 turbine from R & X Technology company in Nantong, China. The company specifications mention it exhibits a nominal power output of 200 Watts, a wheel diameter measuring 48 cm, and a weight of 15 kg. It utilizes 2 sets of aluminum blades, with each set comprising 5 individual segments. The segments are assembled around a vertical axis, facilitated by horizontal arms. It can be observed that the blades are configured with a backward twist to reach higher performance and harvest more energy. These blades may be made by roll forming, or hydraulic pressing techniques. Either of these techniques requires a mold.

Figure 1: One example of the vertical axis wind turbine

Technique of 4D printing of composites:

4D Printing of Composites (4DPC) is a technique of composite manufacturing that does not require a mold of complex geometry. It only requires a flat mold. As such it is also called Moldless Composite Manufacturing. The technique was conceived in 2017 [2]. To manufacture a structure with curved geometry, first, a stack of soft composite prepregs (such as carbon/epoxy) is laid on top of a flat mold. The deposition can be done either by hand (for simple lay-ups) or by the use of an automated fiber placement machine (AFP) for either simple or more complex lay-ups. The AFP machine does manufacturing in an additive fashion. In principle, it is similar to a 3D printer, except that it is much larger, and it can deposit strips containing continuous fibers embedded in a polymer matrix. It can deposit strips of fiber-reinforced polymers in different directions. The lay-up sequence of the different layers in the stack is of critical importance. Rather than the usual symmetric lay-up sequences that have been used in most of the composite community, un-symmetric lay-ups are used. In the soft state of the prepregs, there is no interaction between the layers due to the difference in their fiber orientations. However, after these prepreg layers are heated to the cure temperature, the resin hardens and the layers become stiff. During the cooling process from cure temperature to room temperature, the difference in coefficients of thermal expansion between the layers along the different directions creates interaction between them. This interaction gives rise to the change in shape from flat to curved.

The 4DPC technique has been used to develop pieces with S shape [2], leaf springs [3], omega stiffeners [4], corrugated core for flexible aircraft wings [5], and conical shells (figure 2) [6]. The same concept of 4DPC is also used for the development of manufacturing of blades of the vertical axis wind turbine.

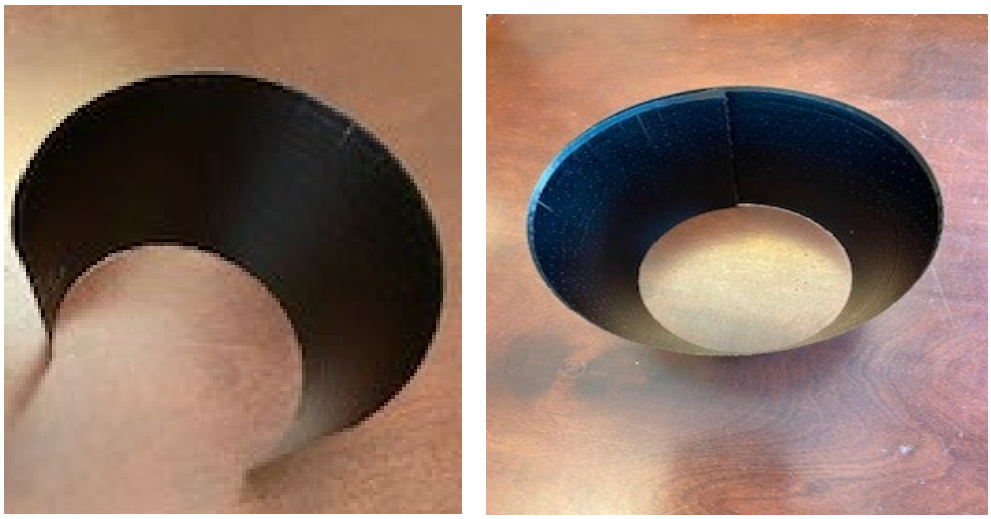

Figure 2: Conical shells made using the 4DPC technique. Left: Partial shell. Right: Complete shell [6].

Procedure to manufacture the blades of the vertical wind turbine using 4DPC:

Most of the structures presented in references [2-6] are of the forward type of problem. In the forward type of problem, some lay-up sequence is proposed, and the resulting structure is obtained. The procedure to make the blades for the vertical wind turbine follows a reverse type of problem. In the reverse type of problem, a structure with a certain shape and configuration is desired. The problem is to find the flat lay-up sequence such that when the stack of prepregs is cured and cooled to room temperature, the desired shape and configuration is obtained. This procedure consists of the following steps:

Step 1: Determination of the configuration of the existing (or desired) structure.

Step 2: Propose some lay-up sequence.

Step 3: Determination of the configuration of the structure resulting from the proposed lay-up sequence. At the initial stage, this can be a trial-and-error approach. After some experience, the trial-and-error process can be minimized.

Step 4: A final configuration that fits the most to the desired configuration is obtained.

Details of the above steps for the development of the blades of the vertical axis wind turbine using 4DPC are presented below.

Step 1: Determination of the configuration of the existing (or desired) structure

The two blades of the existing commercial wind turbine as shown in figure 1 consist of two similar blades. Each blade consists of 5 segments. Each segment is a curved piece. Figure 3 shows the 6 segments disassembled from the wind turbine. The focus of the work is to develop the procedure of manufacturing of one segment using 4DPC. Once this is accomplished, the other segments can be made the same way. They will then be assembled to make up the blade.

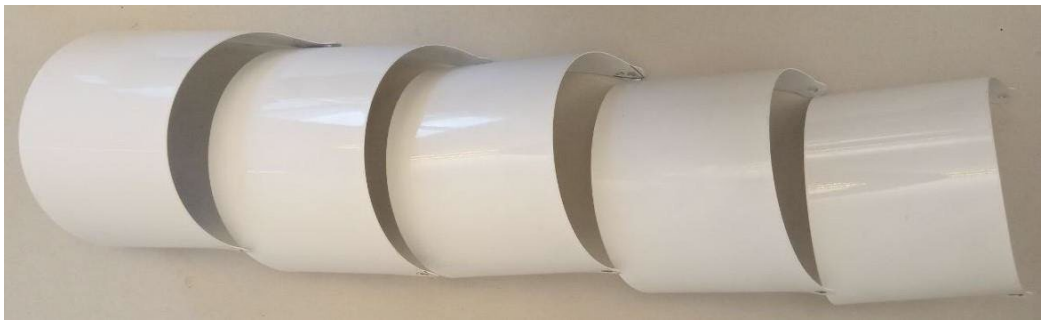

Figure 3: One segment of the blade in commercial wind turbine.

The overall dimensions of the segment is shown in figure 4.

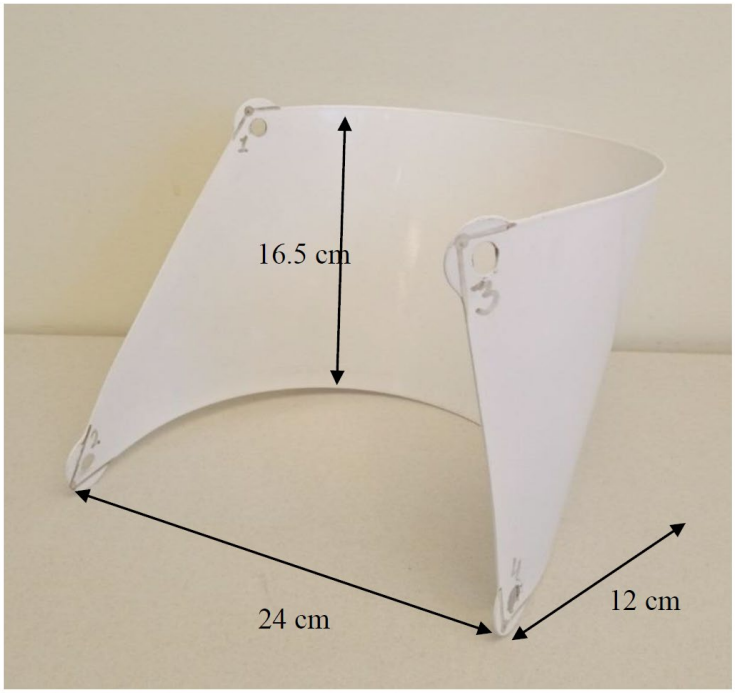

Figure 4: Overall dimensions of a segment

Detailed configuration of one segment was obtained by scanning the segment using a laser projection machine as shown in figure 5.

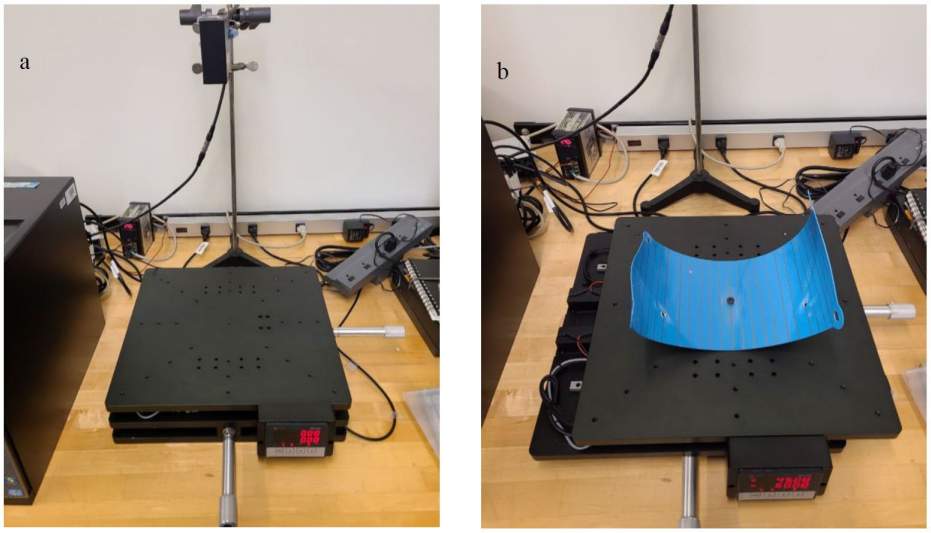

Figure 5: A segment in the laser projection machine. (a) Laser projection machine with laser mounted on top. (b) Segment on the base of the machine.

By adjusting the two probes on the right and front of the segment, the coordinates of various points on the surface can be measured, allowing for the complete generation of the surface of the segment. Two hundred points were measured. A sample of the data of 16 points is shown in Table 1.

Table 1: Sample of the data for 16 points from coordinate measurements.

No.	x (mm)	y (mm)	z (mm)	No.	x (mm)	y (mm)	z (mm)
1	0	220	0	**121**	75.4	206.6	100
10	97.1	170.5	0	**130**	152.5	114.7	100
20	109.6	51.1	0	**140**	111.3	1.9	100
30	12.5	-19.3	0	**150**	5.15	-22.5	100
61	38.6	216.6	50	**181**	116.9	186.4	160
70	130.2	139.5	50	**190**	173	80.4	160
80	109.3	21.3	50	**200**	109.3	-21.3	160
90	8.9	-21.2	50	**210**	0.4	-23	160

The data collected were processed using the surface fitting tool in MATLAB software. This generates equation (1). The linear dimensions are in meter, and the angle is in radians.

$$x = 0.12\ sin[\theta + 3.5\ z] + 0.1\ sin[3.5\ z]$$

$$y = 0.12\ cos[\theta + 3.5\ z] + 0.1\ cos[3.5\ z] \qquad (1)$$

Where z is the coordinate along the vertical direction, and θ is the polar coordinate in the horizontal plane. x and y are the coordinates in a plane parallel to the horizontal plane at elevation z. These are in meters.

The nature of the surface can be revealed by examining a few points using equation (1).

At z = 0 (the base plane), one has:

$$x = 0.12\ sin[\theta] \qquad y = 0.12\ cos[\theta] + 0.1 \qquad (2)$$

Equation (2) represents that of a circle with radius of 0.12 m (120 mm) with center located at O_b (0, 100 mm) in the base horizontal x, y plane, as shown in figure 6. The axes are x_1 (parallel with x) and y_1(coinciding with y). Note that the points at the base plane of the blade only occupy a portion of the circle with origin at O_b in the figure .

At z = 10mm (0.01 m) in equation (1) one has:

$$x = 0.12\ sin[\theta + 0.035] + 0.1\ sin[0.035] \quad y = 0.12\ cos[\theta + 0.035] + 0.1\ cos[0.035] \quad \text{or}$$

$$x = 0.12\ sin[\theta + 0.035] + 0.0035 \qquad y = 0.12\ cos[\theta + 0.035] + 0.1 \qquad (3)$$

Equation (3) represents that of a circle with radius 120 mm with the origin at O_2 (3.5 mm, 100 mm). To keep the same boundary points as for the case of z = 0 mm, the coordinate axes are x_2, y_2 (rotated 0.035 radians (2.0°)) relative to the x, y axes. .

At z = 20 mm (0.02 m), in equation (1) one has:

$$x = 0.12\ sin[\theta + 0.07] + 0.1\ sin[0.07] \qquad y = 0.12\ cos[\theta + 0.07] + 0.1\ cos[0.07] \quad \text{or}$$

$$x = 120\ sin[\theta + 0.07] + 0.007 \qquad y = 0.12\ cos[\theta + 0.07] + 0.1 \qquad (4)$$

Equation (4) represents that of a circle with radius 120 mm with the origin at O_3 (7.0 mm, 100 mm). Again, to keep the same boundary points as in the case z 0, the coordinate axes are x_3 , y_3 (rotated 0.07 radians (4.0°)) relative to the x, y axes.

At z = 165 mm (0.165 m), in equation (1) one has:

$$x = 0.12\ sin[\theta + 0.5775] + 0.1\ sin[0.5775] \quad y = 0.12\ cos[\theta + 0.5775] + 0.1\ cos[0.5775]$$

or

$$x = 0.12\ sin[\theta + 0.5775] + 0.055 \qquad y = 0.12\ cos[\theta + 0.5775] + 0.084 \qquad (5).$$

Equation (5) represents that of a circle with radius 120 mm with the origin at O_t (55mm, 84 mm). The coordinate axes are x_t, y_t (rotated 0.5775 radians (33.1°)) relative to the x, y axes. Note that z = 165 mm is at the top of the segment (subscript t). This circle is shown in figure 6.

It can be seen that even the radius of curvature of the blade remains the same as z changes, there is a shift in the center of the circle (mainly in the x direction). In order to keep the same boundary points in all cases, there is also a rotation of the axes. As such point A_b in the bottom plane moves to point A_t on the top plane (Note that figure 6 does not show the change in

elevation of the top circle). At the same time, point B_b moves to point B_t. The circular portion A_bB_b changes to A_t B_t. The rotation does not present a twist.

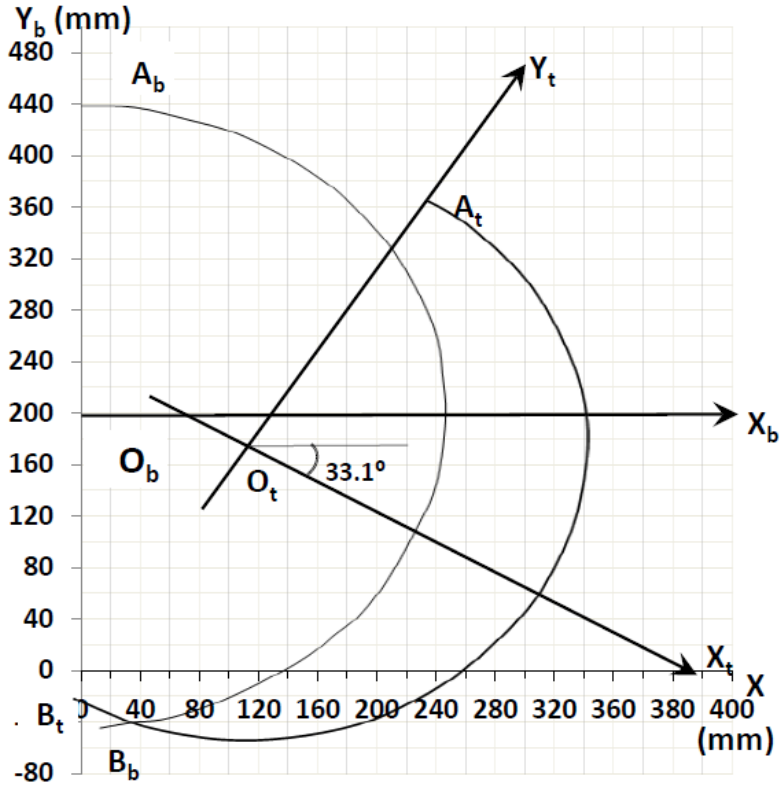

Figure 6: Curved lines connecting nodes 1 to 300 (z = 0 mm, bottom) and nodes 181 to 210 (z = 165 mm, top). Node numbers are shown in figure 7.

Using MATLAB, the whole surface of the blade as given by equation (1) is plotted and shown in figure 7.

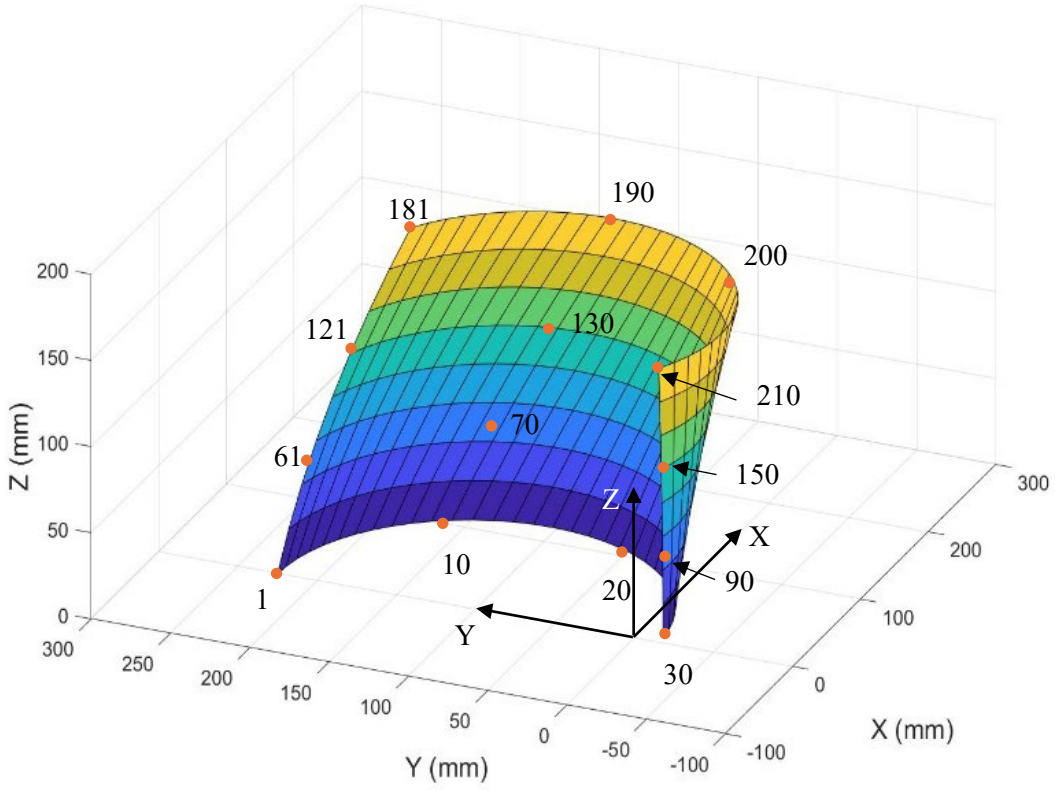

Figure 7: Plot of equation (1)

From the analysis of principal curvatures shows that the points can be classified into two groups (the edge group and the central region). The principal curvatures of these two groups are shown in Table 2.

Table 2: Principal curvatures for two regions

	K_1 (m^{-1})	K_2 (m^{-1})
Left edge (nodes 1, 61, 121, 181)	9.5	1.07
Right edge (nodes 30, 90, 150, 210)	9.3	1.10
Central region (nodes 10, 20, 70, 80, 130, 140, 190, 200)	8.2	0.52

Table 2 shows that there is a large difference between the values of K_1 and K_2. The small curvature of K_2 indicates that the structure is practically flat along this direction. As such, at any

point on the surface of the segment, cylindrical curvature exists. This means that there is no twist.

The above observations are used as guidelines for the determination of the lay-up sequence to make the segment structure using 4D printing of composites. The curvature of the central region (8.2 m^{-1}) is used as the main focus. In the following, a number of trial laminate sequences will be examined. Laminate theory will be used to determine the curvature from these laminates. The lay-up sequence yielding the closest value of curvature to 8.2 m^{-1} will be selected.

Step 2: Determination of the lay-up sequence:

The material used is carbon/epoxy prepreg (1409-D) supplied from Rockwest composites. The curing cycle is shown in figure 8.

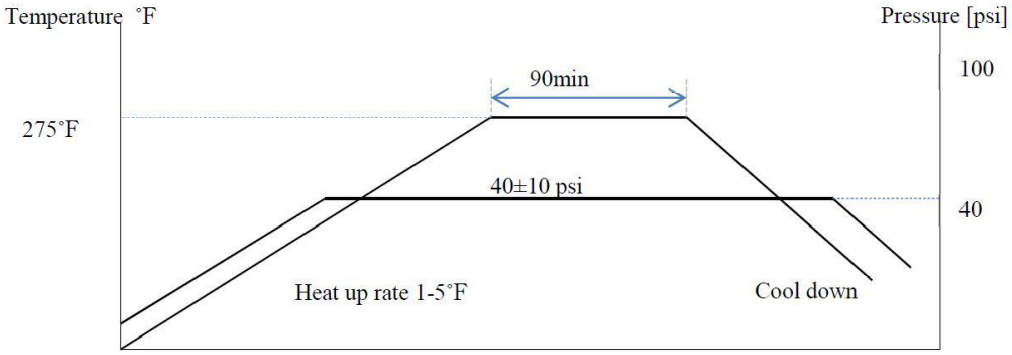

Figure 8: Curing cycle for carbon/epoxy from Rockwest Composites

The material properties are shown in Table 3. These values were measured at the Concordia Center for Composites laboratories. The other properties are taken from reference [8] as: shear modulus G_{12} = 4.4 GPa, and coefficient of thermal expansion α_1 = - 0.018 x 10^{-6}/°C.

Table 3: Material properties

E_1 (GPa)	120.2
E_2 (GPa)	7.4
ν_{12}	0.219
α_2 (10^{-6}/°C)	33.33
Thickness of one ply (h) (mm)	0.165

The curvatures are calculated using laminate theory as described in reference [2]. A Matlab program was developed for this [9]. Table 4 shows the curvatures of the different laminates.

Table 4: Curvatures of different laminates

Laminate sequence	**K_1 (m^{-1})**	**R_1(mm)**
[0/90]	11,4	74.6
[0/90_2]	9.2	92.6

[0/90$_3$]	9.1	110
[0/90$_4$]	7.8	128

Table 2 shows that the curvatures in the segment vary from 8.2 m^{-1} to 9.5 m^{-1} from the central region to the edges. From Table 4, both laminates with lay-up sequences [0/90$_2$] and [0/90$_3$] provide curvatures that fit within this window. For light weight consideration, laminates with lay-up sequence [0/90$_2$] was selected.

Step 3: Procedure to lay-up the surface of the segment:

The flat blank, which is a development of the curved segment into a flat panel, is shown in figure 9.

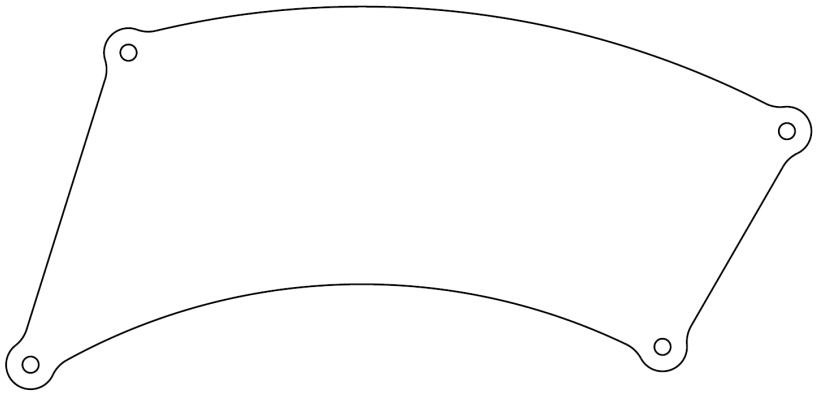

Figure 9: Flat blank as developed from the curved segment.

It was shown in the above section that as one moves along the x direction, it is necessary to rotate the x,y axes a few degrees in order to conform to the surface of the segment. In order to maintain the same radius of curvature, the same lay up sequence of [0/90$_3$] needs to be maintained. In order to address the rotation, from a 4DPC point of view, the flat is divided into four sections. The lay up sequence is rotated a few degrees as one moves from segment 1 to segment 2 etc. Figure 10 shows the lay-up sequence after the rotation. Figure 11 shows the detailed dimensions of the sections.

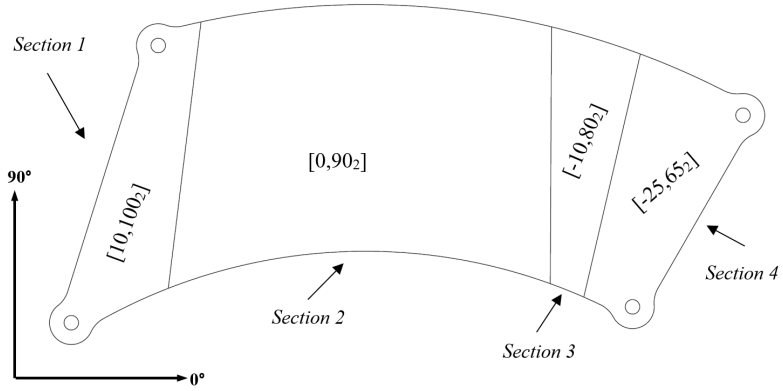

Figure 10: Lay-up sequence in the four regions of the segment

Using the above procedure, the composite segment was matched up with the aluminum segment from the commercial wind turbine. Figure 11 shows the two pieces together (blue piece is aluminum). It can be seen that the two pieces match together fairly well for the majority of the surfaces. There is a slight mismatch at the left edge.

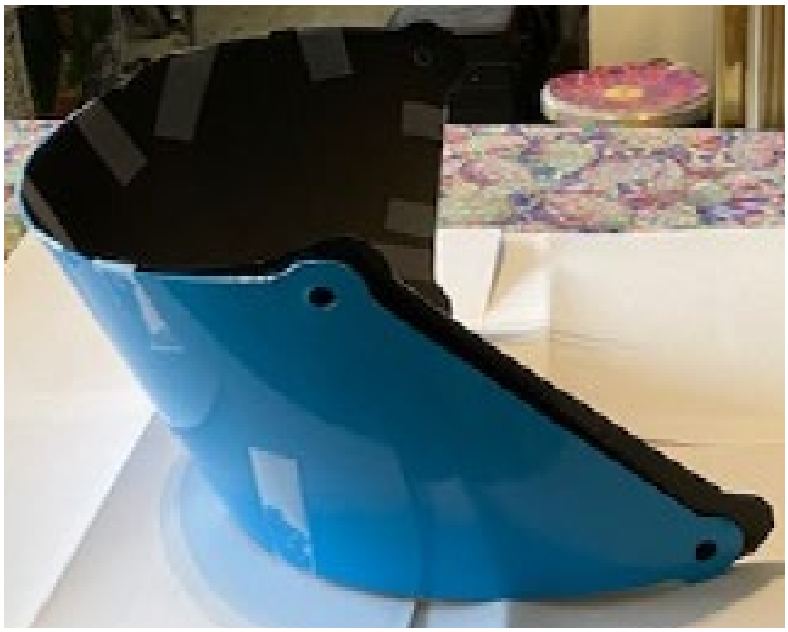

Figure 11: Comparison between the manufactured piece and the real segment.

After manufacturing all the segments, they were assembled to the central pole of the vertical axis wind turbine alongside with the aluminum blades. The final assembly of the wind turbine can be seen in figure 12.

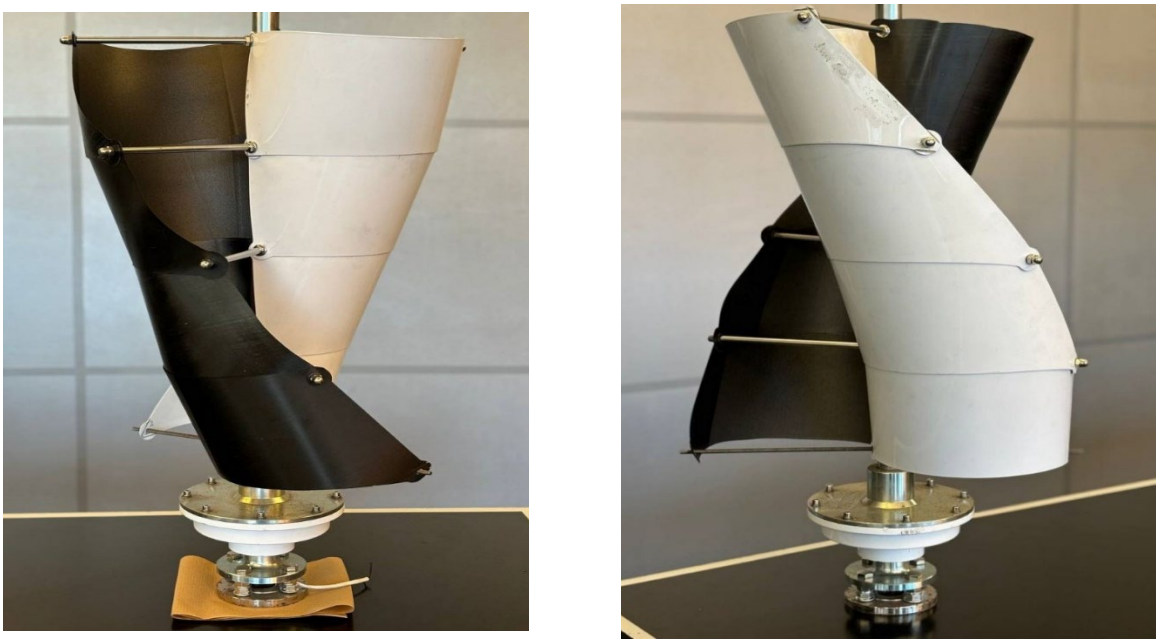

Figure 12- The final assembly of the vertical axis wind turbine blades.

Conclusion

It was shown that it is possible to make wind turbine blades for vertical axis wind turbines using the technique of 4D Printing of Composites (4DPC). The segments of the blades made have similar shape as the aluminum segment of the original design. The new method is a moldless way of manufacturing, which provides savings in cost and time. The use of composite materials offers light weight which can improve efficiency of operation.

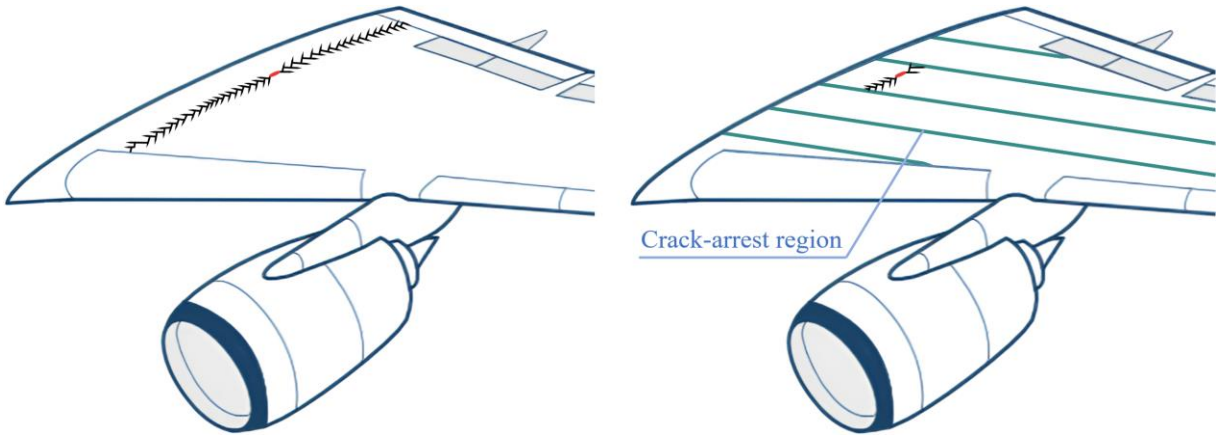
ABSTRACT

Crack-arrest strategies are central to damage-tolerant structural design, particularly in large-scale components. By halting crack propagation and compartmentalising damage, such features prevent catastrophic failure, extend service life, and enable more flexible, cost-effective, and safer design approaches. This study developed a ply-discontinuity based feature to arrest unstable cracks in multidirectional Carbon-Fibre Reinforced Polymer (CFRP) laminates under compressive loading. The method targets the arrest of unstable kink-band propagation by replacing 0° plies with off-axis ones. This reconfiguration promotes fracture energy reflection and dissipation, while altering failure mechanisms. enabling the laminate to arrest high-velocity cracks (~1 km/s) and improve ultimate failure strain. Validation was performed using IM7/8552 CFRP elements incorporating off-axis ply regions with additional local reinforcement to preserve longitudinal stiffness. Two different crack-arrest element configurations were tested. These configurations differed from one another by the off-axis ply orientations used to replace 0° plies (±30° and ±45°). Mechanical performance was monitored via strain gauges and digital image correlation. Post-failure analysis employed C-scans, radiography imaging, and scanning electron microscopy to characterise damage evolution and arrest mechanisms. Both lay-up configurations successfully arrested crack propagation and significantly increased strain capacity. Enhancements in ultimate failure strain reached up to 38% for ±30° elements and up to 100% for ±45° elements. Repeated tests confirmed result reproducibility. These findings demonstrate the potential of ply-discontinuity features for improving damage tolerance in composite structures and provide insight into their underlying failure-arrest mechanisms.



1 INTRODUCTION

Compressive performance, particularly in the presence of in-service damage, remains a key limitation in composite structural design. Compressive strength of Fibre-Reinforced Polymers (FRPs) is significantly inferior to their tensile performance, generally corresponding to 60-70% of latter [1]. Factors such as high sensitivity to manufacture defects and a complex combination of failure modes are the main responsible for this discrepancy [2-3]. Additionally, if compressive failure initiates in a component, there are no means to arrest such fracture. As a result, composite structures are typically designed under a 'no-damage-growth' philosophy. Transitioning to a 'damage-growth tolerance'

approach, where controlled crack propagation is permissible, would unlock the full structural potential of composites.

Central to this philosophy are crack-arrest strategies, which aim to contain unstable failure, compartmentalise damage and extend service life. Such features are well-established in other engineering fields. In compressed-gas transmission pipelines, ribs are used to contain long tensile cracks in metallic pipes [4,5]. Similarly, in aircraft fuselages tear straps are used to stop tear propagation in the composite skin [6]. Nevertheless, little to no research has addressed compressive crack-arrest in fibrous composite laminates.

By developing an unstable crack-arrest feature for CFRP compression, this research aspires to pave the way to fail-safe design in large composite structures. Such feature enables the design of components that remain operational following initial unstable fracture. Thus, it enhances safety and allows lighter and more permissible structural designs. These benefits are particularly critical in applications where failure has life-threatening consequences, such as in aircraft wing roots. Figure 1 exemplifies how such a feature would be able to avoid structural collapse in a damaged wing root.

(a) (b)

Figure 1: Representation of compressive-crack compartmentalisation on a damaged aeroplane wing. (a) Crack propagation from the damaged region without crack arrest mechanisms, unrestrictedly expanding across the wing's chord and causing catastrophic failure. (b) Failure compartmentalisation by periodic crack-arrest bands, allowing the wing to remain in service.

2 FEATURE CONCEPT

Unstable compressive crack propagation in CFRPs can reach speeds approaching 1 km/s [7]. This rapid growth is driven by the propagation of out-of-plane kink-bands, which then facilitate the formation of secondary fracture types [8]. Due to the high energy involved, arresting crack growth requires mechanisms that dissipate or deflect associated fracture energy. Thus, a ply-discontinuity-based feature was developed. This feature exploits the fact that kink-bands typically occurs in 0° plies and propagate perpendicular to the loading direction. Thus, by locally replacing these plies with off-axis ones, it may be possible to divert or even arrest an unstable compressive fracture. Additionally, lay-ups dominated by 0° plies ("hard lay-ups") show lower translaminar toughness than off-axis-only ("soft lay-ups") configurations. Hence, introducing ply discontinuities creates regions of higher toughness, enhancing crack containment and resistance to propagation.

Importantly, the developed feature uses only existing, certified aerospace materials. This simplifies certification and facilitates integration into current aerospace structures. Furthermore, using a single composite type also eases recycling and end-of-life material handling.

3 MATERIALS AND METHODS

To validate this concept, test elements were designed and manufactured using IM7/8552 carbon-fibre reinforced epoxy. Additional reinforcement layers were introduced in soft lay-up regions, to maintain longitudinal stiffness across the width of the panel. A U-notch (10 mm length and 5 mm diameter) was designed to induce unstable failure around -3100 με. This value was chosen for being slightly above the -2500με design limit load typically used in aerospace industry [9]. Sandwich configuration, with aluminium honeycomb core and CFRP skins, was employed to prevent global buckling during testing (Figure 2).

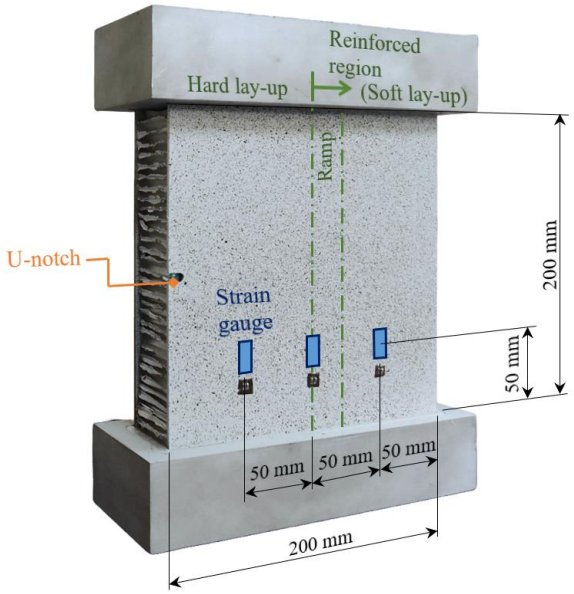


Figure 2: Compression test element geometry. Being the interest region, the frontal skin is divided in soft and hard lay-ups, and equipped with a notch to induce failure initiation. The rear skin is composed only by the hard lay-up and does not possess a notch.

The 200×200 mm element gauge area represents only a small fraction of a full-scale structure's overall dimensions. Therefore, even the loss of the entire 200mm section would not represent a significant reduction in the complete structure's load-bearing capacity. Thus, the most reliable indicator of a given element's performance is not their load capacity but their strain tolerance. This tolerance represents the structure's capability of being deformed before collapsing.

To control test variables, specific constraints were applied during the definition of the skins' lay-ups. Since the hard lay-up is multidirectional, while 0° layers were replaced by off-axis ones, the remaining plies were maintained continuous to conserve element integrity. Both lay-ups were designed as symmetrical, eliminating compression-bending coupling effects. Finally, additional plies were added to the soft lay-up to match stiffness across the element width. To minimise undesired stress concentration, the lay-up transition was implemented gradually, forming a 'ramp' profile. The front skin, identified as the primary surface of interest, was the only one containing the arrest feature.

Two different lay-up configurations were tested, differentiated by distinct off-axis ply angles (±30° and ±45°) replacing the 0° oriented plies. For each configuration two identical Crack-Arrest (CA) elements were tested, as well as a suitable baseline. This sought to ensure the reproducibility of the crack-arrest behaviour. The baselines consisted in panels without arrest feature, in which the entirety of the frontal skin was composed by the hard lay-up.

Lower longitudinal stiffness of 45° plies, when compared to 30° ones, implicated in a higher number of additional soft lay-up plies. The ±30° feature configuration had 19 and 33 plies in its hard and soft regions, respectively. Meanwhile, panels with the ±45° feature configuration had 19 and 55 plies in their hard and soft lay-ups.

The elements were tested in a 250-tonne screw-driven compression test machine under displacement control. Mechanical behaviour during tests was assessed using strain gauges and digital

image correlation, while post-failure analysis was performed through C-scans, radiography imaging, and optical and scanning electron microscopy to better understand failure initiation and arrest mechanisms.

4 RESULTS

As expected, both baseline elements suffered abrupt failures that propagated across the entire width of their notched skins. These fractures lead to the collapse of the baseline elements, with almost complete loss of load-bearing capability. The failure of the crack-arrest elements, however, was successfully stopped upon reaching the beginning of the arrest region. Following this initial failure, additional strain was endured by the elements, progressively causing smaller failure steps. Ultimate failure was achieved when the crack front reached the opposite end of the frontal skin width. Figure 3 represents the test behaviour of both baseline elements, as well as one element of each crack-arrest feature configuration. The remaining elements showed similar results to those represented, attesting to the reproducibility of these results.

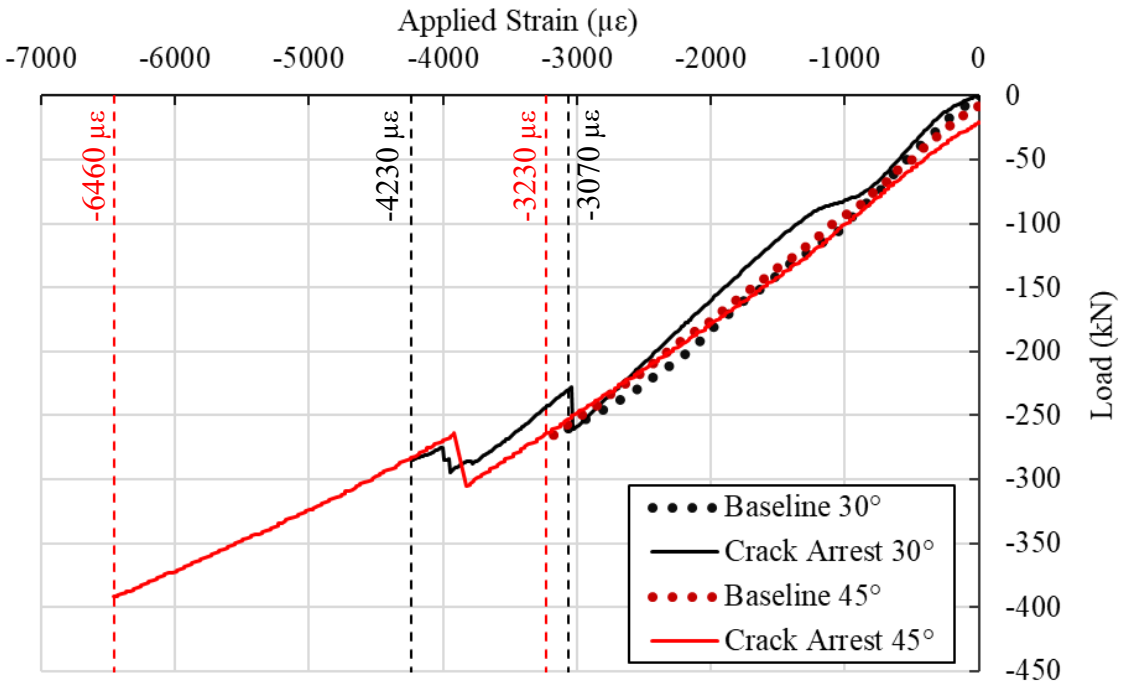

Figure 3: Evolution of applied strain for both crack-arrest configurations, as well as their respective baselines. Both configurations were successful in stopping failure propagation and increasing ultimate failure strain. Notably, the 45° configuration was able to double the strain to failure of is baseline.

It is possible to observe that both feature configurations showed elastic behaviour compatible with their respective baselines before initial failure. Additionally, the baselines failed near -3100 με strain, as per the notch design.

For the feature lay-up using ±30° off-axis plies, baseline failure happened at -3070 με, while that of the CA element started at -2980 με. The chart still portrays its subsequent growth steps, up to the ultimate failure at -4230 με. This represents a 38% increase in ultimate failure strain. Repeating the test with an identical element, similar behaviour was observed, resulting in an ultimate failure strain increase of 33%. It is notable that, although possessing the same stiffness as the baseline, the CA elements presented ultimate strains to failure one third higher than it.

Meanwhile, for the feature lay-up using ±45° off-axis plies, the baseline panel failed at -3230 με. CA failure started at -3800 με, being subsequently arrested, and final panel collapse happened at -6460 με. This constitutes a 100% increase in ultimate failure strain, with results from a repeat test showing an 85% strain increase. Hence, this configuration is capable of nearly doubling its baseline performance.

Radiographies and C-scans were employed to visualise subsurface damage in each element. The radiography images presented in Fig. 4 allow visualisation of the main failure path and secondary fractures for representative elements.

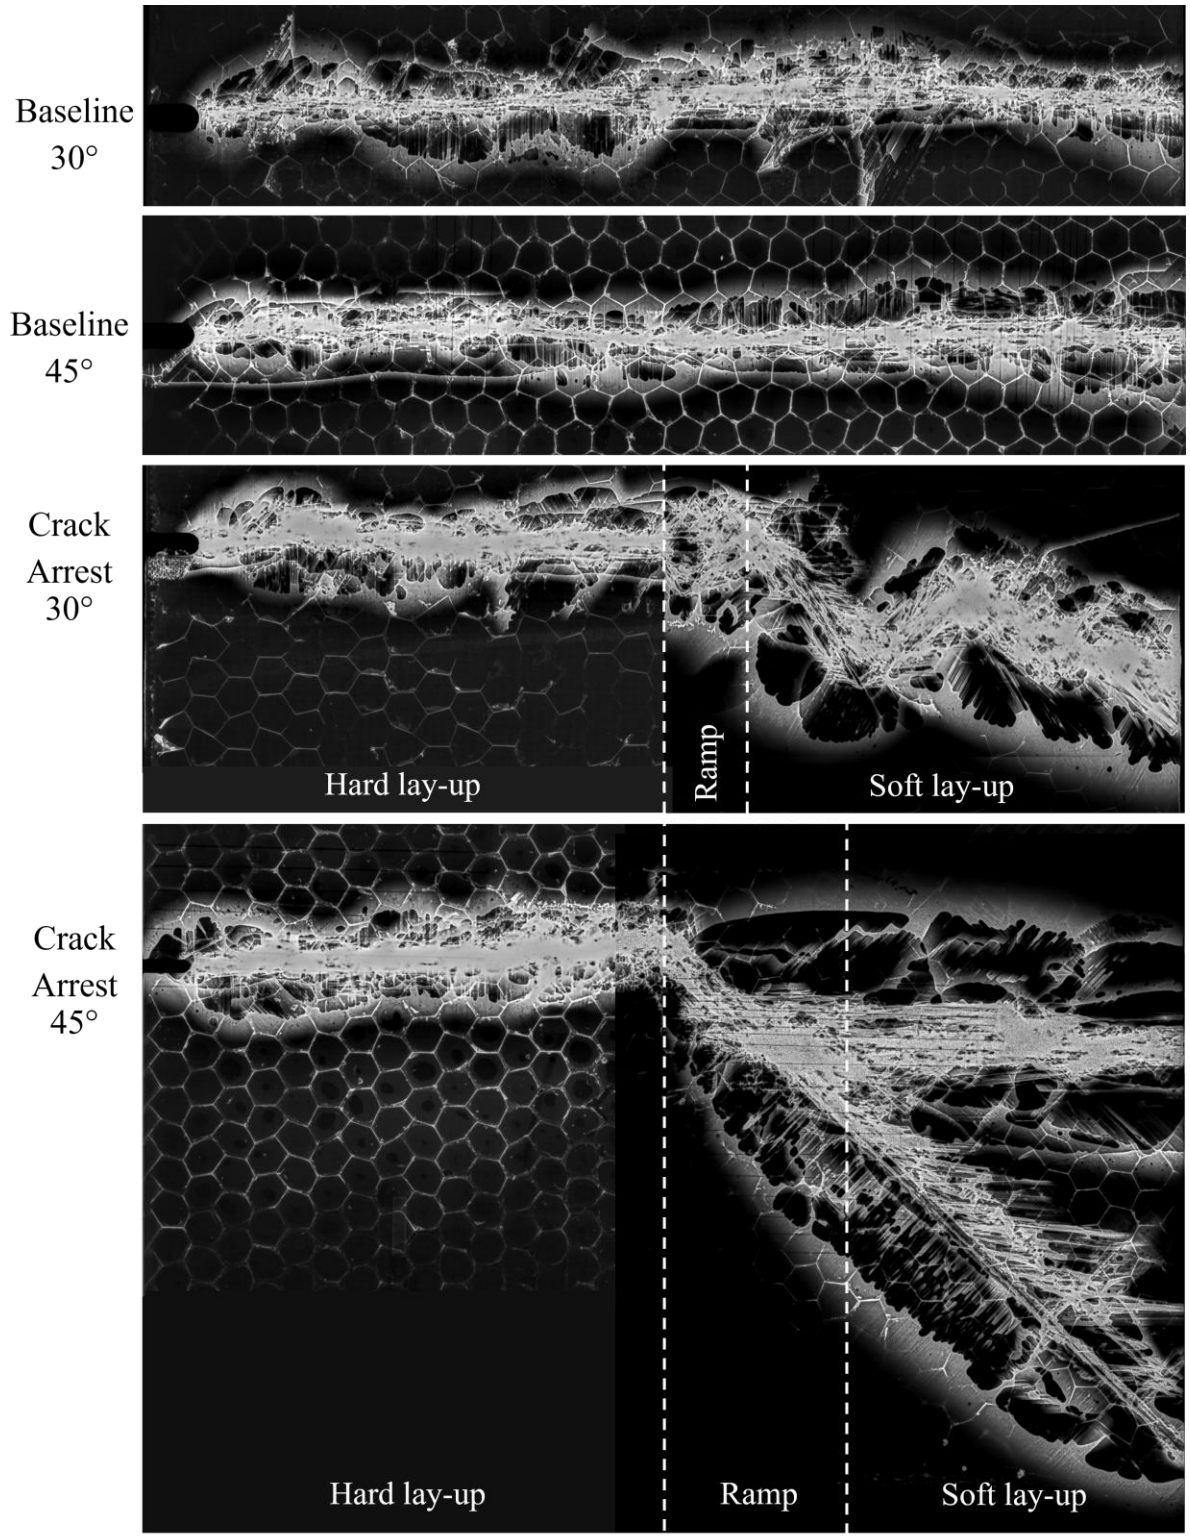

Figure 4: Radiographies of fracture regions for the different test elements, portraying the change in failure path caused by ply-discontinuity. Differences in delamination area surrounding fracture are also visible.

Both baselines behaved in a similar manner, with fracture showing a tendency of propagating perpendicular to loading direction. The same behaviour appears in the hard lay-up regions of the CA elements. However, the soft lay-up regions exhibit a modified failure path, with fracture propagating in oblique directions. Moreover, in the ±45° CA element, fracture propagation was split into two main failure paths after the initial arrest. Significantly higher amounts of delamination are also observable in the soft lay-ups, when compared to their hard counterparts.

5 DISCUSSION

Both versions of the developed feature were successful in compartmentalising unstable failure growth. However, the increase in ultimate failure strain provided by the ±45° plies was significantly higher than that of the ±30° plies. This configuration nearly doubled strain tolerance, even withstanding higher loads than its baseline despite significant panel section loss.

It is important to consider, however, the additional weight penalty inherent to this configuration. The usage of a ply direction with lower longitudinal stiffness results in a higher thickness in the soft lay-up section. Nevertheless, in real work conditions such penalty could be mitigated by adjusting the frequency and width of periodic crack-arrest bands. Moreover, this concept introduces the possibility of fail-safe design, creating thinner panels and achieving weight reduction for the overall structure.

Analysing the fracture properties in Fig. 4, a better understanding of the mechanisms responsible for the feature's success becomes possible. It is notable that, as seen in the baseline, initial fracture in the CA elements grew perpendicular to load application direction. Similar fracture morphology was also observed between these failures, consistent with the baseline's suitability as comparison. Nevertheless, following the initial arrest, the subsequent failure in the CA elements presented significant changes in both growth direction and fracture morphology. These behavioural changes hint as to the effects of the of ply replacement in obstructing the kink-band propagation.

The concepts key component is the removal of fibres that would enable kink-band to propagate in its preferential growth direction. Upon reaching a geometric discontinuity in lay-up, a fraction of the dynamic fracture energy is reflected, reducing its momentum. Beyond that, in the absence of 0° plies to allow perpendicular growth, fracture is forced to seek alternative routes. This increases the length of the failure path, resulting in higher energy dispersion and posing an obstacle to failure growth.

Together with the more tortuous failure path caused by crack deflection, the increase in secondary damage surfaces contributes to energy dissipation. These factors also hint to the reasons behind the higher performance of the ±45° feature configuration. By further redirecting the fracture's path and successfully splitting its growth into two main fronts, this lay-up potentializes energy dissipation. Similarly, this behaviour results in a significantly higher amount of secondary fracture surfaces, hampering crack growth.

6 CONCLUSIONS

A crack-arrest concept for CFRPs under compression was developed and experimentally validated. The feature successfully arrested unstable kink-band propagation, significantly delaying ultimate failure and enhancing the strain tolerance of the tested elements. Two configurations of the feature were tested, using off-axis angles of ±30° and ±45°. Their performances were compared to suitable baselines and to one another.

The feature operates by locally introducing fibre orientation discontinuities, which deflect the crack and create longer, more tortuous failure paths. This results in increased kink-band energy dissipation. Additionally, the soft lay-up experiences more secondary damage, aiding energy dissipation and enhancing crack arrest.

The ±30° feature demonstrated a one-third increase in ultimate failure strain, relative to its baseline. Meanwhile, the ±45° feature was able to nearly double its baseline's strain tolerance. When compared to one another, the ±45° feature was evaluated as the most promising, displaying larger amounts of secondary fracture and longer failure paths. Therefore, despite possessing a larger weight penalty, its significant increase in ultimate strain represents a promising route for fail-safe design.

Future work will focus on reducing the weight penalty associated to the crack-arrest feature. For that purpose, the minimum arrest band width necessary to stop failure propagation will be defined.

Additionally, a study of weight penalty reduction by reinserting stiffer plies into the soft lay-up will be performed.

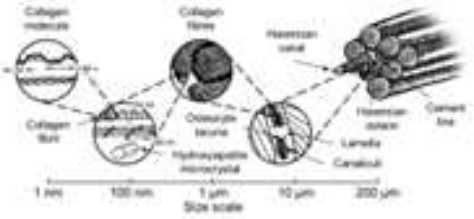
KEY RESULTS



- Struts with 0.8mm diameter rods manufactured and tested in buckling:
  - Plain rods, no overbraids
  - 8 x 1k T300 carbon fibre overbraids of lay length:
    - 2.5mm, fuzzy carbon
    - 4mm
    - 6mm
- Struts with 2.5mm lay length overbraids failed in **tension**, all others in **compression**
  - Indicates improved performance in compression with fuzzy carbon overbraid
- Hybridised carbon/aramid overbraids can improve packing while keeping ‘fuzzy carbon’ aspect
- 4x 1 T300 carbon fibre and 4x aramid initial trials carried out
  - Both tensile and compressive failure seen

Background : prediction of axial compressive strength

Fiber misalignment angle distribution

Grouping of fibers based on the misalignment angle

$$\bar{\sigma}_x = \sum_i \sigma_x^i A^i$$

The contribution of each fiber group to the load bearing was calculated and summed based on the area ratio A^i. [5)]

Compressive strength is determined by

- fiber misalignment and the distribution (mean angle ϕ_0 and the standard deviation Σ)
- shear stress-strain relation (τ_{12}-γ_{12})

5) M. Ueda et. al., Composites Part A, 175, (2023), 107821.

Objectives : Toward improved axial compressive strength

What is already clear from previous researches

- Compressive strength could be increased by

  improving shear-stress-strain relation without degrading fiber misalignment and distribution.

Objectives

- Improved axial compressive strength of UD CFRP

Contents

- Epoxy matrix was modified by three types of fillers: improving shear-stress-strain relation.
- UD CFRP was fabricated based on prepreg-autoclave molding method.
- Fiber misalignment distribution was measured by X-ray CT imaging: to ensure that the fibers are not misaligned.
- Compression tests were performed, and the compressive strength was evaluated.

Materials and Methods

- Materials

  Carbon fiber : MR50R-12M, Mitsubishi Chemical
  Epoxy resin : Bisphenol A epoxy resin (130deg cure)
  Filler : 1 (Nanoscale filler), 2.0wt%
  2 (Sub-micron scale filler), 1.5wt%
  3 (Nanoscale filler), 0.2wt%

  *Weight fraction was the ratio to the epoxy resin.
  *Weight fraction of fillers was determined based on the viscosity suitable for prepreg production.

- Prepreg : Thin-ply prepreg technique (t =0.04mm)

⇨ Four types of unidirectional prepreg sheets were fabricated with fiber volume fraction Vf = 60%.

ID	Carbon fiber	Epoxy resin	Filler	Filler content
CFRP	MR50R-12M	Bisphenol A epoxy	None	-
CFRP_1			1	2.0wt%
CFRP_2			2	1.5wt%
CFRP_3			3	0.2wt%

ABSTRACT

Compressive failure in unidirectional carbon fibre reinforced polymers remains a critical limitation in structural design. This study integrates findings from previous Raman spectroscopy analysis and a novel focused ion beam scanning electron microscopy (FIB-SEM) methodology to investigate fundamental micromechanical failure in high-modulus (HM) polyacrylonitrile carbon fibres under compressive loading. FIB-SEM offers high-resolution 3D imaging of fibre break geometries. The combination of Raman spectroscopy and FIB-SEM confirms shear-type fragmentation and interfacial debonding mechanisms previously predicted through Raman analysis, enabling a deeper understanding of compressive failure processes in Carbon Fibre Reinforced Plastics (CFRPs). To enable FIB-SEM imaging of model composite samples, careful sample preparation is required, following specific steps to allow imaging to be carried out.

1 INTRODUCTION

The compressive properties of unidirectional carbon fibre reinforced polymer composites (CFRPs) are widely recognised as inferior to their tensile performance [1], often forming a critical limitation in structural applications. Improving compression strength and reliability requires a detailed understanding of the failure mechanisms associated with each constituent material. While matrix shear yielding is commonly implicated in compression failure, the role of the fibre–matrix interface and fibre fragmentation, particularly in high-modulus (HM) fibres—is also thought to be dominant [1].

Direct mechanical testing of individual fibres in compression remains challenging due to their small scale and high aspect ratio [2]. Raman spectroscopy offers an indirect yet effective technique to probe

micromechanical and interfacial responses in carbon fibres subjected to compressive loading. The method enables spatially resolved stress mapping at sub-micron resolutions (0.5–2 μm), by detecting changes in atomic vibrational frequencies induced by deformation [3].

Previous studies have utilised Raman spectroscopy to monitor the evolution of local stress states in fragmenting HM fibres, tracking deformation across individual fibre segments [4,5]. Coupling Raman mapping with optical microscopy allows predictions regarding fibre fragmentation geometry and interfacial behaviour and how they evolve with increasing deformation [4]. To validate key predictions, an advanced imaging technique, focused ion beam scanning electron microscopy (FIB-SEM) has been employed. FIB-SEM enables nanometre-scale serial sectioning and imaging, allowing for high-resolution 3D reconstruction of fibre failure geometries. FIB-SEM is widely used in many fields for transmission electron microscope (TEM) foil preparation and preparation of specimens for micromechanical testing, including micropillar compression of carbon fibres [5,6].

In this work, FIB-SEM was applied to single fibre model composites previously characterised by Raman spectroscopy. This novel integrated approach enables the identification and high-resolution 3D reconstruction of fibre failure geometries, including shear-type fractures and interfacial debonding; offering direct validation of micromechanical predictions [4]. The combination of quantitative Raman stress mapping with high-resolution FIB-SEM imaging provides a robust framework for understanding compressive failure in HM carbon fibres.

To enable features of interest to be located and imaged with high resolution SEM, careful sample preparation methodology is required. The following discussion will focus on how samples are prepared, with some initial data to demonstrate the feasibility of the technique.

2 METHODOLOGY

Model composites were prepared by embedding a single fibre near the surface of an epoxy prism, then fragmented in uniaxial compression. Key features identified during *in situ* Raman stress mapping were located by introducing surface landmarks, allowing serial block face imaging via FIB-SEM, to explore the local microstructure in 3D at high resolution (~10 nm).

2.1 SAMPLE PREPARATION

Model composite samples used here, were prepared as described elsewhere [4,7,8]. Samples were short, 2-5 mm, single carbon fibres (Toray M46J and M55J) embedded in epoxy prisms (Huntsman LY5052 and Aradur 5052CH) forming single fibre model composites. Model composite samples were fabricated and subjected to uniaxial compression with *in situ* Raman spectroscopic measurements to measure stress. Samples discussed here were imaged in their post-fibre failure, relaxed states. Fibres in imaged samples were encapsulated ~10-30 μm below the surface of epoxy, verified with laser scanning confocal microscopy. Post-deformation, the samples were imaged using optical microscopy to identify features of interest and measure their positions along the fibres relative to local surface features. This step was essential as the fibre cannot be observed using SEM without removing the encapsulating layer surrounding the feature.

Fibre locations were marked by scratching the epoxy surface with a needle to indicate the general positions of interest. To aid fibre identification using SEM, a Parallel Bar 100 Mesh TEM grid (Agar Scientific Ltd) was adhered to the epoxy surface using polyvinyl chloride based adhesive tape, as shown in Figure 1. Optical microscopy (Euromex bScope® metallurgical microscope coupled with a VC.3040 UHD-4K camera) was used to map the features of interest relative to the TEM grid.

A conductive gold coating was sputtered onto the sample surface, with the TEM grid in place, to improve surface conductivity for SEM imaging. Multiple coatings were applied to ensure adequate conductivity. After removing the TEM grid, thin additional coatings were added to ensure the entire surface was coated but the original pattern was not hidden. The TEM grid served as a mask to create a pattern, providing clear reference lines visible in SEM.

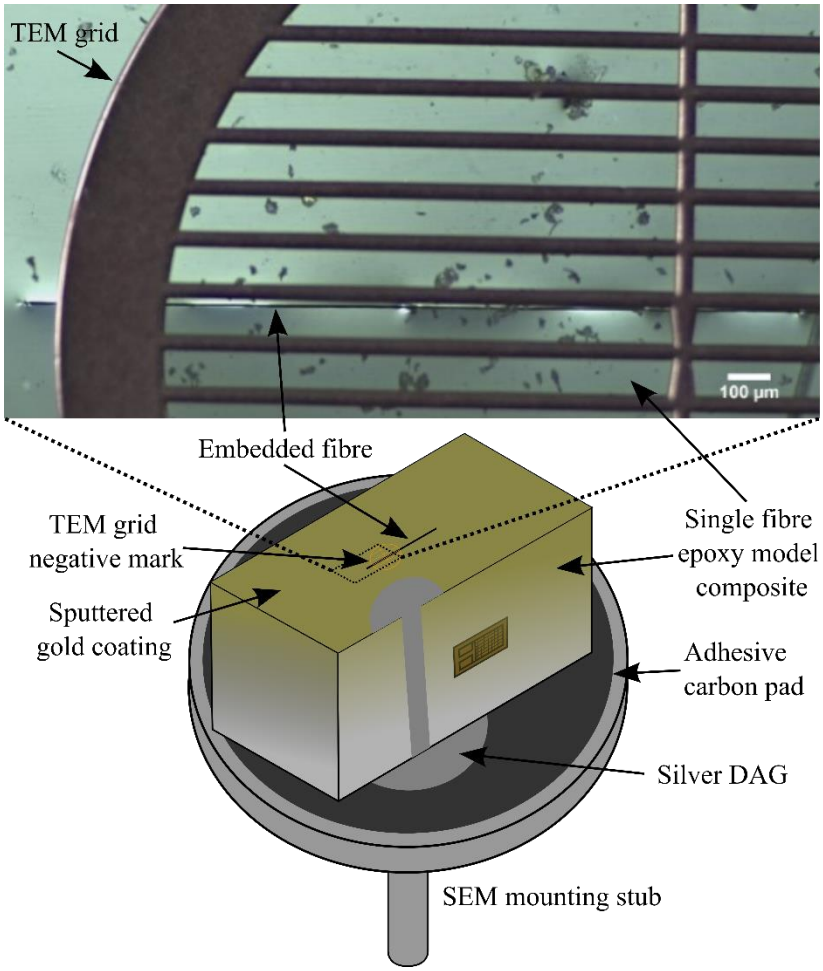

Figure 1. FIB-SEM sample preparation showing: (top) a polarised light optical microscope image of a TEM grid adhered to the surface of an epoxy prism model composite, used to locate the fibre during FIB-SEM analysis. A broken fibre is visible beneath the grid, with contrast enhanced by polarisation. A schematic illustrating the sample setup for analysing fibre features (bottom).

The samples were mounted on an SEM stub using a carbon pad, with silver electrodag paint applied from the pad to the surface of the epoxy prisms, creating a conductive bridge between the prism surface and the stub, addressing charging issues encountered when locating the sample and imaging fibre features, as epoxy is non-conductive.

2.2 FIB-SEM SECTIONING

The system used was a Thermo Fisher Scientific Helios 5 Hydra CX with multiple ion plasma FIB (PFIB) source gases available; gaseous O_2 was used here. The PFIB column had an ion beam current range of 1.5 pA to 2.5 µA with an acceleration voltage range of 500 V – 30 kV. SEM components included a FEG electron source with 350 V – 30 kV acceleration voltage, with an in-lens SE/BSE detector and Everhart-Thornley SE detectors.

Gold-coated model composite samples on SEM stubs were mounted onto the FIB-SEM stage for position of interest (POI) preparation, milling, and imaging. A process was developed to accurately locate previously identified features of interest, such as fibre breaks, utilising optical microscopy identified fibre positioning relative to surface features, e.g., the fibre ends, surface marks and the TEM grid pattern.

The first step involved determining the fibre's position, depth, and alignment. The sample was brought to the correct working distance to focus both the imaging electron beam and the milling ion

beam, with the eucentric position confirmed. During milling, the stage was tilted so the ion beam was perpendicular to the surface, while the electron beam was angled at 52° to the surface.

An oxygen (O_2) plasma was used as the ion source, effectively milling both epoxy and carbon fibres, enabling the production of high-quality polished milled sections, suitable for high-resolution imaging with minimised voxel size due to thinner slice thickness. Plasma focused ion beam (PFIB) allows higher beam currents and faster milling rates with smaller probe sizes than typical gallium FIB sources [9]. Furthermore, use of PFIB avoids implantation of ions, which commonly occurs in epoxy when using a gallium or xenon source [10].

Plasma ion beam conditions of 45 nA and 1.9 µA at 30 kV were employed to mill the epoxy gradually, preventing widespread surface damage observed at currents exceeding 1.9 µA. High power densities (>26 nA at 30 kV) were observed to cause the gold coating to flake off, damaging the sample surface.

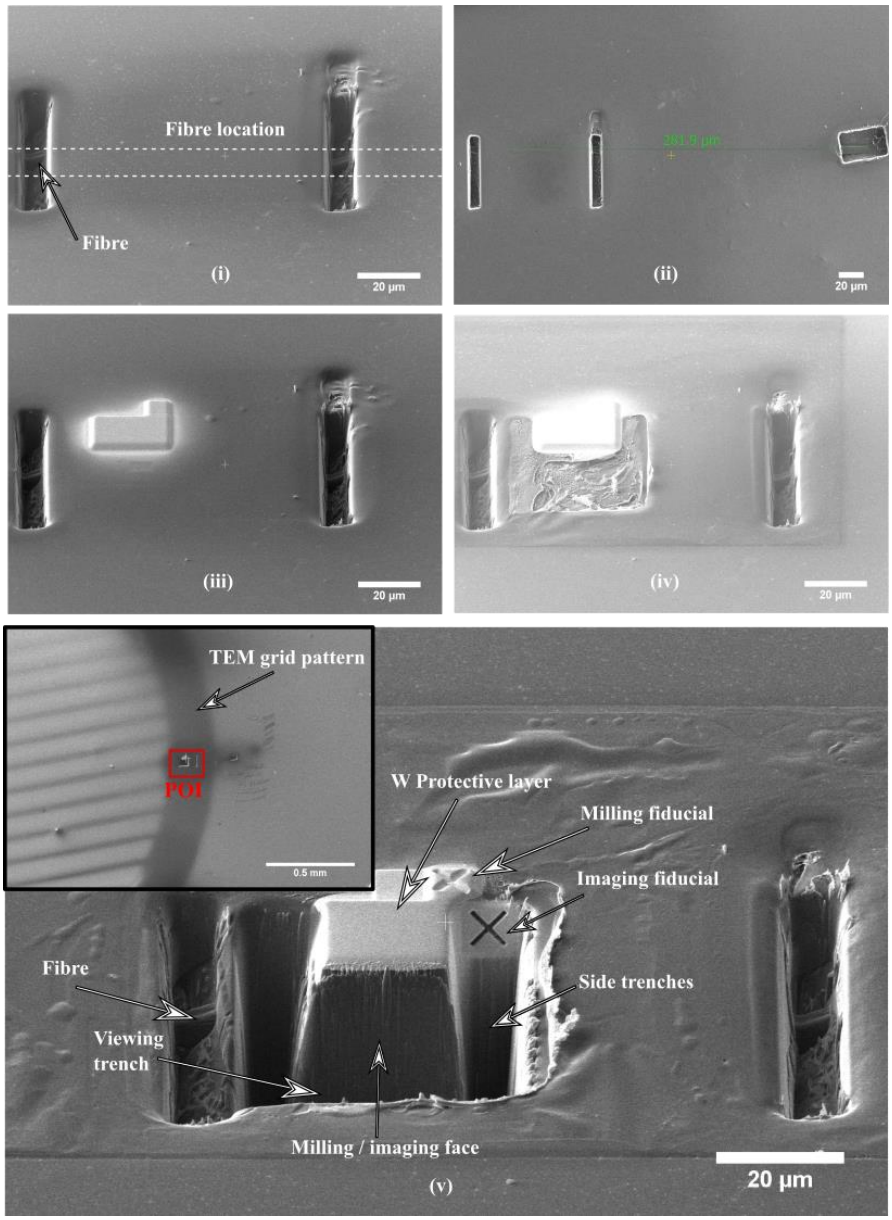

Figure 2. FIB-SEM area preparation procedure shown using representative SEM images: (i) Milled trenches exposing the fibre, (ii) measurement of the distance from the fibre end to the feature of interest, (iii) tungsten protective layer deposited over the POI, (iv) initial milling of the viewing and side trenches, and (v) the POI location on the TEM grid pattern (inset) with the final region of interest (ROI) prepared for polishing and sectioning.

Using the ion beam column's reduced-area imaging mode under these conditions, trenches were selectively etched into the epoxy approximately 50 μm away from a fibre fracture to avoid disturbing the feature of interest. Careful monitoring with both the electron and ion imaging beams ensured the trenches were milled until the fibre was exposed. The same process was repeated on the opposite side of the POI, exposing the fibre on both sides. The stage was then aligned relative to the beam using these two exposed sections, as shown in Figure 2i.

A fibre end was typically located first using the same method, providing a positional reference for identifying the feature (Figure 2ii). Once the fibre was located and the POI identified from prior measurements, a thin (<1 μm) tungsten (W) protective layer was deposited over the epoxy surface at the POI location.

The W deposition was performed by introducing an organometal precursor gas ($W(CO)_6$) via an inserted needle over the POI. The ion beam locally decomposes the gas, depositing metallic W in place [11]. A typical W protective layer is shown in Figure 2iii, which protects the POI from accidental damage, increasing local conductivity, and enhancing the surface finish of the milled face during sectioning.

The viewing and side trenches were milled to a depth well below the fibre. For instance, for a fibre at a 20 μm depth below the surface, a trench of approximately 50 μm around the POI was milled (Figure 2iv, v). Optimal fibre depths for high-quality, resolved sectioning images ranged from 10–30 μm. Beyond 30 μm, the sectioning time exceeded 12 hours with a lower imaging resolution. Fibre depths greater than 50 μm are experimentally impractical due to poor image quality and long processing times.

Imaging and milling fiducials, such as cross marks (Figure 2v), were milled into the epoxy, preferably on W-coated sections to maximise contrast. The fiducials were essential for Thermo Fisher Auto Slice-and-View sectioning, allowing automatic positional adjustments.

2.3 AUTOMATIC SLICE-AND-VIEW SECTIONING

To section the prepared POI, Thermo Fisher Scientific's Auto Slice & View 5 software was used. The programme sets milling and imaging parameters, and automatically adjusts the stage position using fiducial markers to account for the focal plane movement as material is removed. By adjusting the milling depth, slice thickness, and imaging parameters, the voxel size and processing time can be controlled. Generally, a minimum voxel size is typically desired with a reasonable processing time of under 15 hours.

The slice-and-view process removed a layer of the POI with a polishing mill pass, followed by SEM imaging, and was repeated for the set milling thickness. Autofocus was applied with each frame for optimal image quality. The output was a stack of SEM images collected imaged with the SEM's Everhart-Thornley detector (ETD), with a field emission gun electron source at 5 kV with a working distance of 4.1 mm.

2.4 IMAGE SEGEMENTATION

To analyse and process SEM image stacks obtained from FIB-SEM milling, ImageJ (Fiji, ver. 2.16.0) and Dragonfly 3D World version 2024.1 (Object Research Systems ORS Inc, Montreal, Canada, build 1601) were used for image segmentation. The segmentation process, outlined in Figure 3, began by selecting a wide field of view (FOV) of 30-50 μm to account for potential uncertainty in break feature locations within the region of interest (ROI). After image collection, image pre-treatment was required to refine the stack, cropping to remove excess background. ImageJ pre-treatment then focused on maximizing the contrast between the fibre, voids, and the matrix. A Gaussian blur filter with a standard deviation value (sigma value) of 2-3 was applied to reduce noise and improve contrast without sacrificing fine details, aiding effective ROI segmentation [12].

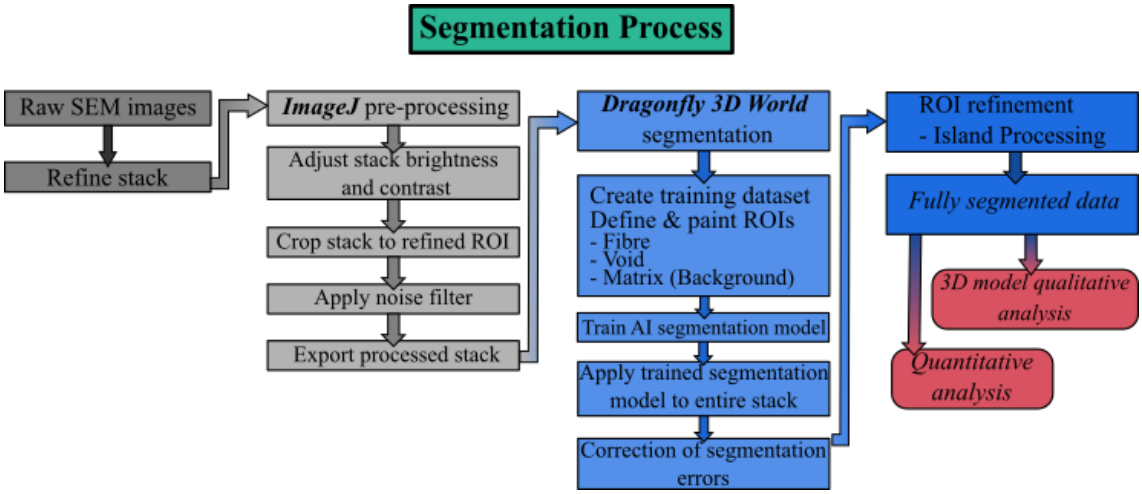

Figure 3. Flowchart for the image processing steps for FIB-SEM data segmentation.

The cropped and ImageJ-treated stacks were imported into Dragonfly, where inbuilt AI-assisted automatic segmentation models were used to process stacks of images (typically 400-700 images). A U-Net-based deep learning architecture, designed to analyse visual imagery, was trained to segment the stack. U-Net is particularly effective at handling noisy images and artifacts [13]. The model was trained by annotating 5-10 example images, defining the regions of interest (ROIs) as the fibre, void, and matrix (background). Once trained, the model can segment the entire stack, with manual review and corrections made as necessary. The accuracy of automatic segmentation improves with higher contrast between the phases, fibre, matrix and void. The fully segmented stack was then visually analysed in 3D, allowing for detailed observations of fibre breaks that may not be visible in the 2D stack. Quantitative measurements of fibre features, debond lengths, and alignment were also made using Dragonfly's analysis tools.

3 RESULTS AND DISCUSSION

The experimental methodology developed to study carbon fibre compressive fragmentation is appropriate for both finding and imaging features in high resolution. Post-processing of the produced image stacks produces 3D reconstructions of the fibre break geometries and internal structures, as illustrated in Figure 4.

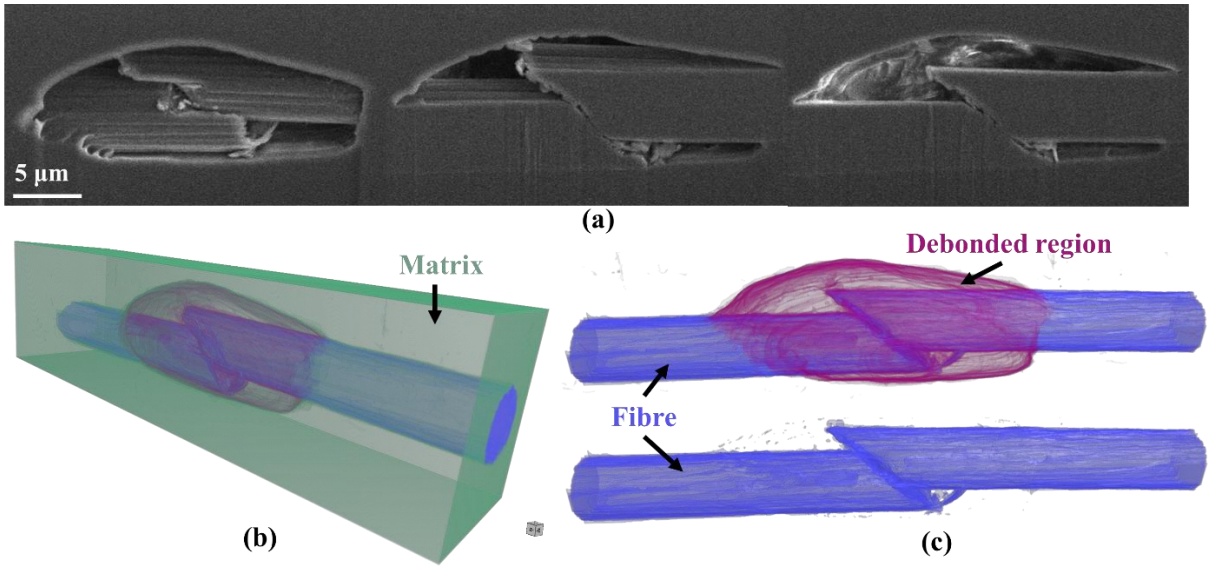

Figure 4. FIB-SEM results from a fragmented M55J sample, showing (a) SEM micrographs taken at various stages across sectioning, with (b) and (c) resulting segmented 3D models produced in Dragonfly, where (b) is an orthographic projection of the 3 segmented phases and (c) is a plan view of the fibre with (top) and without (bottom) the debonded region.

Figure 4 depicts a segmented M55J fibre which has undergone compressive failure resulting in a shear-type fibre break geometry, with the crack at approximately 47° to the fibres longitudinal axis, as previously predicted [4]. The sample experienced an initial fibre failure at a matrix strain (ε_m) of 0.5 % (peak fibre stress ~ 2.2 GPa) and was deformed until a ε_m of 1.25 %. The resulting 3D ROI models at two different viewing orientations are shown at the top of the figure, with and without the purple 'void' regions which depicts where debonding has occurred surrounding the break. This region is representative of voiding around the fibre. The fibre region is represented as a blue ROI, superimposed onto the example SEM images shown in Figure 4. The matrix is also segmented and has a ROI superimposed onto the SEM frames for clarity but is excluded in the figures.

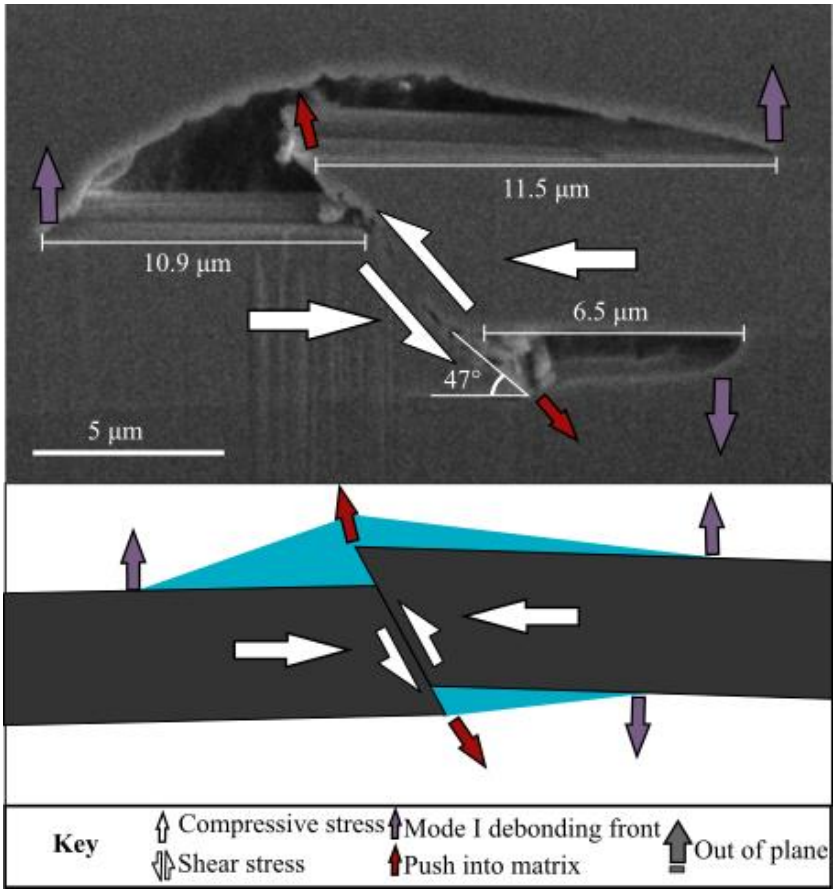

Figure 5. Observed debonding behaviour depicting fibre movements resulting in interfacial debonding observed via FIB-SEM (image (2) in Fig. 7.5), with a schematic of the mechanism predicted based on Raman stress mapping measurements (see reference [4]).

When compared to the predictions of HM fibre failure from Raman mapping data made in a previous study [4] the post-failure geometry of the fibre imaged in Figure 4 is visually similar. In Figure 5, the fibre movement prediction arrows have been overlayed to demonstrate how the fibre is predicted to have moved post-failure, pushing up into the matrix. The mode I push-off, or 'peeling', interfacial mode I debonding is evident, due to the debonded lengths on each of the fragment ends, as illustrated. The volume of the void region was 570.5 μm^3 (measured in Dragonfly) with debonded regions surrounding the break, as marked on the image in Figure 5.

4 CONCLUSIONS

The use of FIB-SEM can produce high quality 3D information regarding the geometries and internal structures of high modulus carbon fibre model composite breaks. The FIB-SEM imaging technique was developed specifically for the single-fibre model composite samples used previously with *in situ* Raman mapping under compressive loading. Key sample preparation steps have been refined, including marking positions of interest, sectioning, and image segmentation. Predictions made in previous reported work regarding interfacial debonding mechanisms, such as the "push-off" or "peeling" mode I debonding, have been validated using this approach.

Compared to other *in situ* imaging techniques, such as optical microscopy (limited resolution) or synchrotron X-ray holotomography (limited accessibility), FIB-SEM offers relative ease of access and simplicity, with higher imaging resolution, and the ability to select small specific regions of interest. Combined with Raman spectroscopy stress mapping, these complementary methodologies can contribute to a comprehensive understanding of model composite micromechanics.

ABSTRACT

Carbon fiber-reinforced polymer composites (CFRPs) enable lightweight, strong, and durable structures for a wide range of engineering applications, including aerospace, automotive, biomedical, and civil systems. To accelerate material development and reduce certification costs, there is increasing reliance on modeling within Integrated Computational Materials Engineering (ICME) frameworks. In recent years, micromodels have shown promise in predicting material allowables for structural quantification. However, the complex failure mechanisms of CFRPs—particularly fiber-direction compressive failure—continue to present challenges, especially when bridging microscale behavior with macroscale performance. Fiber-direction compressive failure, typically governed by fiber kinking due to initial fiber misalignment and shear instability, is a key limiting factor in the design of primary CFRP aircraft structures. While Representative Volume Element (RVE) models have advanced the understanding of fiber kinking, they often rely on idealized assumptions—such as uniaxial sine-wave misalignment—that do not capture the inherently random nature of CFRP microstructures and fiber architecture. Furthermore, experimental validation at the microscale remains limited.

To address these limitations, this work presents a novel computer graphics–based methodology for generating densely packed 3D micromodels with realistic, randomly distributed fibers and local 3D misalignments using the open-source software Blender. The generated models are first used in RVE simulations to investigate the effect of random misalignment on compressive strength. Comparisons with conventional RVEs using uniform and uniaxial misalignment highlight the limitations of oversimplified assumptions and underscore the importance of statistically representative geometries.

A thin four-point bend notched test specimen is also introduced as a proposed path toward experimental validation of micromodels for predicting fiber kinking. The specimen is designed to promote localized kinking and enable direct comparison with simulation results. The numerical model includes a homogenized global FE model and a locally embedded fiber-segmented micromodel to capture fiber kinking in the notch region.

1 INTRODUCTION

Carbon Fiber-Reinforced Polymer composites (CFRPs) enable lightweight, strong, and durable structures for a wide of range engineering applications, including aerospace, automotive, biomedical, and civil industries. To accelerate and reduce the cost of material design and qualification, as well as structural design, certification, and sustainment of advanced CFRPs parts, there has been a growing demand for greater reliance on modeling. In particular, recent years have seen significant progress in the development of micromodels for predicting material allowables that can be used for structural quantification. The advancement of such multiscale modeling capabilities has the potential to significantly improve the efficiency and effectiveness of composite part design within the framework of Integrated Computational Materials Engineering (ICME) [1-3]. However, the complex failure mechanisms of CFRPs continue to pose significant challenges to modeling efforts, particularly when bridging the gap between microscale behavior and macroscale performance.

A key critical challenge is the development and validation of micromodels for predicting fiber-direction compressive failure. The fiber-direction compressive strength of unidirectional CFRPs is significantly lower than the tensile strength, with experimental data typically reporting a 30-40% reduction for intermediate modulus (IM) carbon fiber material systems [4-5]. This reduction is a limiting factor in the design of primary composite aircraft structures. Fiber-direction compressive failure in CFRPs is generally governed by the formation of fiber kinking, which can involve multiple interacting microscale mechanisms such as matrix yielding, fiber-matrix debonding, and fiber fracture.

Micromechanical finite element (FE) models, often based on Representative Volume Elements (RVEs), have been instrumental in improving the understanding of fiber kinking by incorporating explicit microstructural features such as fiber distribution and misalignment [6-9]. These models have proven valuable for estimating the compressive strength based on constituent properties [8–10]. However, most existing micromodels rely on idealized representations of fiber architecture, often assuming uniform, uniaxial sine-wave fiber misalignment to initiate shear instability and formation of fiber kinking. These simplifications neglect the inherent stochastic nature of fiber misalignment that arises from manufacturing variability, limiting their predictive capability.

The synthetic generation of realistic micromodels with highly packed non-intersecting fibers with spatially varying, random 3D misalignment presents significant geometric and meshing challenges. To address this challenge, this work introduces a new methodology that leverages Blender —an open-source computer graphics software—to rapidly generate densely packed three-dimensional (3D) fiber distributions with stochastic misalignment and high fiber counts. The approach is fully automated using Python scripting and relies on Blender's rigid body simulation engine, allowing the user to specify key input parameters and apply custom constraints to control the final fiber architecture. The resulting fiber network geometry is imported into Abaqus CAE for meshing and analysis. Example of 3D models are presented to quantify the effect of misalignment randomness on the fiber compressive strength and are benchmarked against conventional micromodels with idealized uniaxial misalignment.

Beyond model generation, validation of the micromodels remains an important and unresolved issue. The strong sensitivity of the predicted fiber-direction compressive strength to geometric assumptions in the micromodels, as demonstrated in this work, reinforces the need for experimental verification. Recent validation efforts have employed in situ testing combined with ultra-high-resolution imaging techniques such as synchrotron X-ray computed tomography (CT) [10,11]. While these techniques offer valuable insight into damage mechanisms and may support model generation and validation, their reliance on very small specimens may raise concerns about the representativeness of observed failure modes. In addition, the high cost and limited availability of synchrotron facilities limit their broader accessibility.

To provide a more accessible validation pathway, this study considers a thin four-point bend notched specimen configuration. The test setup is designed to promote initiation and stable growth of localized fiber kinking while avoiding global buckling and can be implemented using a standard universal testing machine. The thickness of the specimen is reduced to one ply—approximately 180 microns—allowing the use of an embedded fiber-segmented micromodel that spans the entire width of the specimen and captures the full region where fiber kinking develops. A coarser, homogenized global finite element model is used to apply boundary conditions consistent with the experimental setup onto the embedded micromodel. This configuration enables direct comparison between experimental observations and numerical predictions, offering a promising route for verifying micromechanical simulations and advancing predictive capabilities for fiber-direction compressive strength.

2 MICROMODELS WITH IDEALIZED FIBER MISALIGNEMENT

In this section, two-dimensional and three micromodels with idealized initial fiber misalignment are used to highlight some of the key challenges and limitations of micromodels for prediction of fiber kinking and fiber-direction compressive strength in CFRPs.

2.1 Finite Element Models

An idealized fiber misalignment is introduced in the FE models using a cosine function with a half-wavelength L and an initial misalignment angle ϕ_0 as illustrated in Figure 1 and defined by Equations (1) & (2).

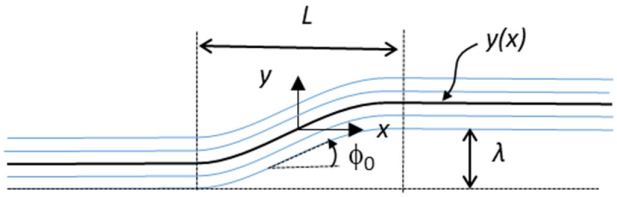

Figure 1: Idealized fiber misalignment.

$$\begin{aligned} y &= -\frac{\lambda}{2} && for\ x \le -\frac{L}{2} \\ y &= -\frac{\lambda}{2} cos\left(\frac{\pi}{L}\left(x + \frac{L}{2}\right)\right) && for\ -\frac{L}{2} < x < \frac{L}{2} \\ y &= \frac{\lambda}{2} && for\ x \ge \frac{L}{2} \end{aligned} \tag{1}$$

Here, λ is the amplitude of the misalignment curve, defined as:

$$\lambda = \frac{2L}{\pi} tan(\phi_0) \tag{2}$$

The two-dimensional FE micromodel considered in this study is shown in Figure 2. The model consists of a rectangular fiber-segmented domain with dimensions L_{tot} x H analyzed using the Abaqus finite element software. A uniform fiber misalignment is imposed perpendicular to the loading direction by shifting the Y-coordinates of all nodes according to the cosine function described above. The model is partitioned into N fiber segments and $N + 1$ matrix segments. A fiber diameter of 5 µm, representative of IM7 carbon fibers, is used to define the height of the fiber partitions while the matrix partition height is selected such that the fiber regions occupy a target area fraction of $V_f = 60\%$.

The model uses 2D plane strain quadrilateral elements (CPE4), with a unit thickness assumed in the out-of-plane direction. Abaqus built-in cohesive contact is used to model the mechanical interaction at the fiber–matrix interfaces. Boundary conditions include a fixed constraint in the axial (X) direction on one end of the model, with loading applied at the opposite end via a reference point and coupling constraints on the axial degree of freedom. A pinned condition is applied to the bottom-left corner node to prevent rigid body translation in the Y direction. Depending on the model dimensions, the total number of degrees of freedom ranged from approximately 50,000 to 150,000. The total model length selected was $L_{tot} = 200$ µm, with a nominal misalignment half wavelength of L=150 µm.

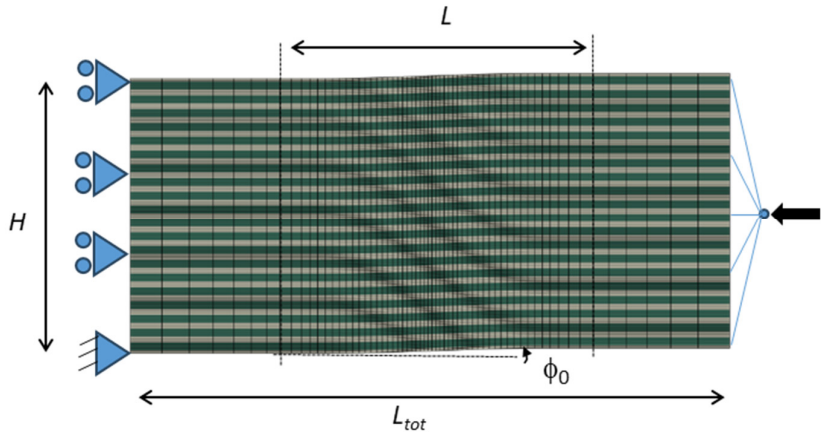

Figure 2: 2D FE micromodel

The three-dimensional FE model with idealized fiber misalignment is similar to the 2D model but incorporates a random distribution of cylindrical fibers within a $H \times W \times L_{tot}$ prismatic block of matrix, as shown in Figure 3. The model is generated by sweeping a 2D fiber-segmented cross-sectional mesh profile created using a modified Random Search Algorithm, enabling the generation of highly packed representative volume elements (RVEs). A fiber volume fraction of Vf = 60% is used in this study.

Similar to the 2D model, a uniaxial initial fiber misalignment is introduced in the 3D FE model by shifting (morphing) the mesh nodes along the transverse Z-direction. The mesh consists primarily of 8-node reduced-integration brick elements (C3D8R), with a smaller number of 6-node wedge elements (C3D6), resulting in a total degree of freedom count between 1.5 and 2.5 million. The nominal cross-sectional area of the 3D model is 50×50 μm^2, containing a total of 77 fibers. The mesh is generated using the Abaqus CAE Python scripting interface, with a minimum clearance of 0.25 μm imposed between fibers and with model boundaries to alleviate meshing difficulties and reduce excessive mesh refinements. A mesh refinement study determined that discretizing the fiber diameter with 16 elements along the circumference (element size ≈ 0.98 μm) and 120 elements along the length in the axial loading direction (element size ≈ 1.6 μm) was sufficient to achieve convergence of the peak load within 2%.

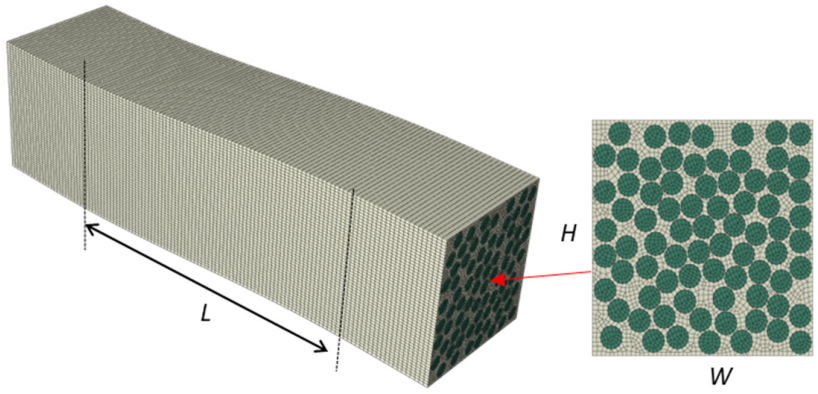

Figure 3: 3D FE micromodel.

The IM7/8552 carbon fiber/epoxy matrix material system is selected in this study due to its widespread use in aerospace applications and the broad availability of material property data. A linear elastic orthotropic material model is used for the IM7 fiber material and the local fiber orientation within the segmented fiber regions in the mesh is assigned using Abaqus tools for surface-based discrete

orientation definition, allowing the material principal directions to follow both the initial misalignment geometry and its deformation during loading. The analysis accounts for nonlinear geometry effects. For the 8552 epoxy matrix, a nonlinear plasticity-based material model is adopted, using the extended Drucker–Prager formulation available in Abaqus material models library for modeling concrete damage plasticity. The fiber–matrix interface is modeled using a cohesive contact formulation, including a bilinear traction–separation law with a quadratic damage initiation criterion and a mixed-mode, energy-based Benzeggagh–Kenane (BK) law for damage evolution. The material properties used for the IM7/8552 system are obtained from the literature [6,12].

2.2 Analysis Results

Under compressive loading, shear stresses develop in regions of fiber misalignment, leading to local fiber rotation and a further increase in matrix shear stresses as well as matrix/fiber interfacial stresses. As compressive loading continues to increase, this results in matrix yielding and/or interfacial debonding, ultimately leading to the formation of a kink band, as illustrated in Figure 4 for a 2D model.

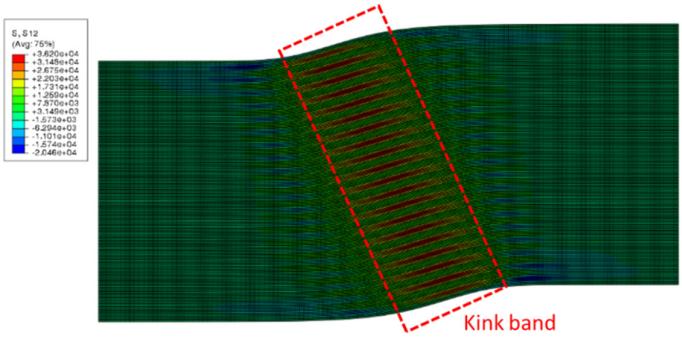

Figure 4. Kink band formation in a 2D micromodel with uniform sine curve fiber misalignment under compressive loading.

To capture the snap-back instability associated with kink band formation, the Abaqus Riks implicit solver is used for the analysis of the 2D model. Figure 5 shows an example of typical load-displacement response (normalized into a stress-strain response) with snap-back instability obtained in the 2D model with the Riks solver for an initial misalignment angle of 2 degrees.

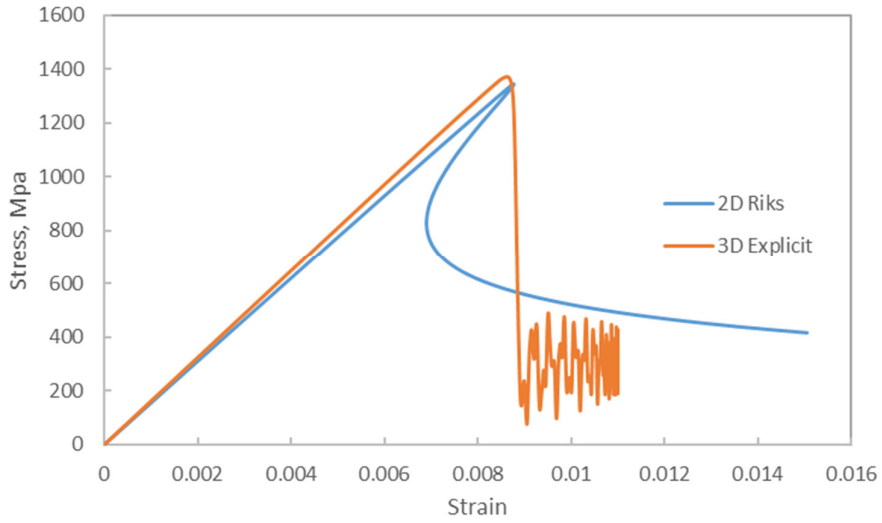

Figure 5: Typical load–displacement response for 2D (Riks) and 3D (Explicit) models showing snap-back instability.

For the 3D model, analysis is performed using the explicit dynamic solver under an applied displacement and quasi-static loading conditions. The use of mass scaling enables a computationally efficient simulation, with total simulation times ranging from 2 to 4 hours on a 60-core machine for the 3D models considered in this study, which contain between 1.5 and 3 million degrees of freedom. For comparison, an analysis of a 3D model with 1.5 million degrees of freedom required approximately 12 hours to reach the peak load using the Riks implicit solver on the same machine. It is worth noting that while the explicit solver can accurately capture the peak load prior to instability, it cannot resolve the post-peak response due to the onset of dynamic effects and loss of equilibrium. Figure 6a shows the development of plastic strain in the confined matrix regions between fibers in the area of misalignment just before instability, and Figure 6b illustrates the progression of interfacial damage. For the IM7/8552 material properties used in this study, the instability is initiated by matrix yielding, which occurs prior to full fiber–matrix debonding. Lower interfacial shear strength properties may lead to an instability mechanism dominated by interfacial debonding.

The typical load–displacement response for a 3D model analyzed with the explicit solver is compared to that of a 2D model analyzed using the implicit *Riks* solver in Figure 5.

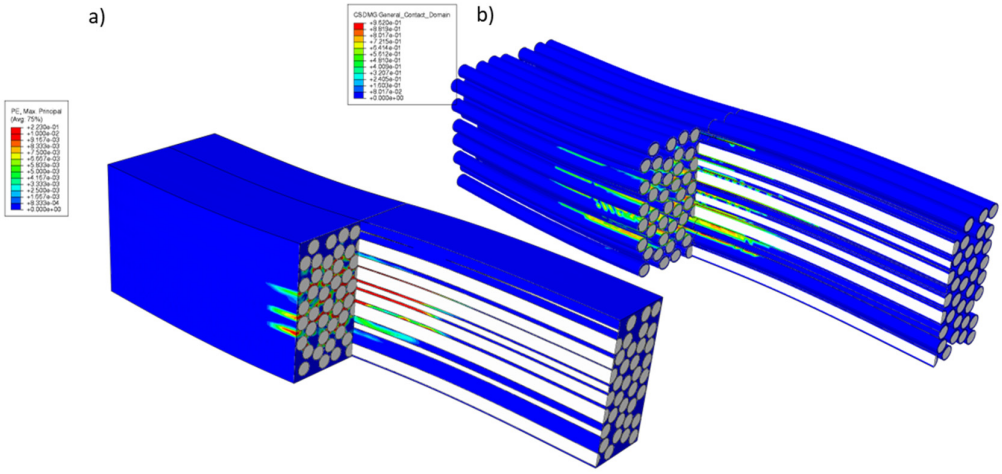

Figure 6: (a) Plastic strain localization and (b) interfacial damage near fiber misalignment prior to instability in the 3D model.

As documented in the literature, the compressive strength predicted by the typical micromodels presented above is highly sensitive to a range of parameters. These include material input properties—such as the matrix yield strength and interfacial shear strength—as well as geometric characteristics, such as the initial fiber misalignment angle and the wavelength of the sine function used to represent the misalignment. Additional challenges arise from the sensitivity of the results to model size and boundary conditions. The dependence on geometry, model size and boundary conditions particularly complicates the development of a robust model for prediction of the fiber-direction compressive strength.

For illustration purposes, the effects of some selected parameters on the load-displacement obtained with the 2D model using the Riks solver are presented in Figures 7 and 8 below.

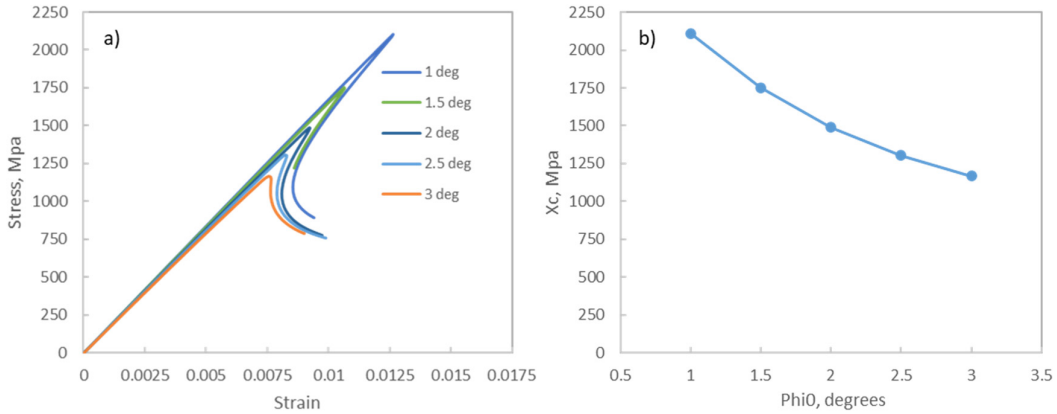

Figure 7: Effect of the misalignment angle in the 2D model: a) stress-strain response and b) compressive strength as a function of misalignment angle Φ_0.

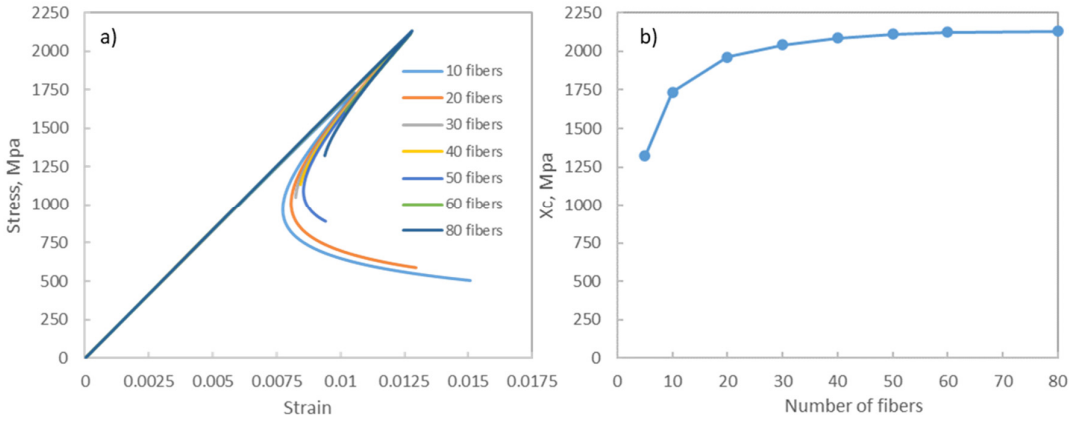

Figure 8: Effect of number of fibers in the 2D model: a) stress-strain response and b) compressive strength as a function of the number of fibers (*H* dimension in Figure 2).

Figure 7 shows the effect of the initial misalignment angle Φ_0 on the compressive strength, calculated as the peak load divided by the cross-sectional area. In these models, the number of fibers—corresponding to the height dimension *H* in Figure 2—was set to 50. As shown, the compressive strength is highly sensitive to small misalignment angles in the range of 1° to 3°, and it decreases as the misalignment increases, which is a well-known behavior. For reference, a 0° compressive strength X_c of 1540 MPa is reported for IM7/8552 in the Hexcel datasheet [13], which corresponds to a misalignment angle of approximately 1.8° in the model.

Figure 8 illustrates the effect of the number of fibers (i.e., the model height *H*) on the compressive response. As shown, the compressive strength increases with the number of fibers and appears to converge for values above 60 fibers. In these simulations, a misalignment angle of 1° was used.

Similar dependencies are observed using the 3D micromodel presented in Figure 3.

3 MICROMODELS WITH RANDOM FIBER MISALIGNEMENT

The results presented above underscore the strong sensitivity of the compressive strength predicted using micromodels to the geometric characteristics of the fiber misalignment introduced. In these models, the misalignment is idealized as uniform and uniaxial—an assumption that does not accurately reflect the inherently stochastic nature of fiber misalignment observed in real composite materials. Moreover, the common implementation approach, which involves uniformly shifting the entire volume—including both fibers and matrix—according to a prescribed misalignment function, may undermine the validity of applying periodic boundary conditions. Periodic boundary conditions are often used to reduce mesh size sensitivity and ensure representative behavior in the homogenization of RVE results.

3.1 Model Generation

One of the reasons simplified misalignment is typically adopted in micromodels is that generating highly packed representative cells with a stochastic distribution of non-intersecting fibers and spatially varying 3D misalignment poses a significant geometric and meshing challenge. To address this, a novel method based on a computer graphics modeling engine is proposed in this work. The method uses open-source computer graphics software Blender to construct complex and realistic fiber architectures.

The overall workflow for the method is outlined in Figure 9.

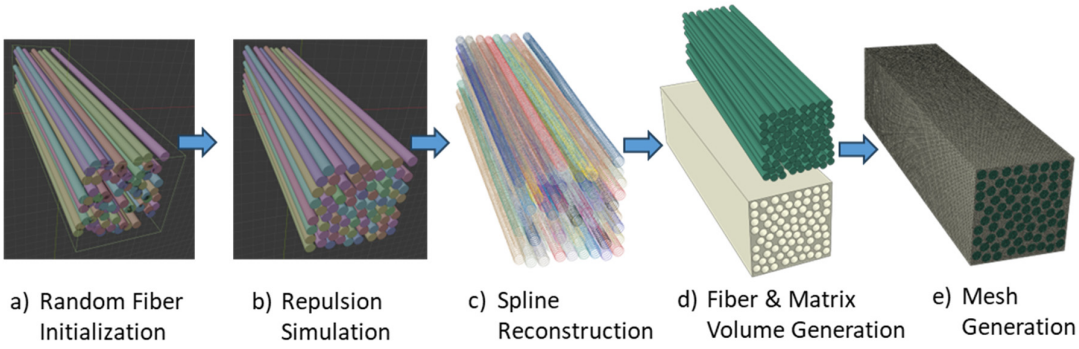

Figure 9: Workflow for generating realistic 3D fiber architectures in FE micromodels using Blender.

The process begins by creating a Blender scene that includes N randomly positioned fibers confined within a container box (Figure 9a). The container is typically modeled as a rectangular prism to facilitate the application of periodic boundary conditions in the FE model, but other shapes, such as a cylinder, can also be used. The number of fibers N is selected such that the total fiber volume matches a target volume fraction V_f relative to the container volume. Individual fibers may be randomly selected from a pre-defined collection with varying geometric characteristics, such as differences in diameter and local misalignment (undulation with wavelength smaller than the length of the container). Random rotations along all three Euler angles can also be applied to further randomize the initial positioning and include global fiber misalignment. Each fiber is modeled as a cylindrical mesh with user-defined discretization in the axial and radial directions.

The initial fiber distribution is generated using an emitter plane and Blender's hair particle system modifier. At this stage, many fibers typically intersect, as illustrated in Figure 9a. If no intersections are present, which may occur for very low fiber volume fraction, the Repulsion Simulation step b) can be skipped and the process can continue at step c). Otherwise, to remove intersections and achieve a tightly packed configuration, Blender's rigid body physics simulation engine is used.

Each fiber is assigned an active rigid body model with collision detection enabled, while the container is defined as a passive rigid body, also with collision enabled. Gravity is disabled in the simulation, and Blender's default repulsion force field is applied to all active rigid bodies (fibers). This force is proportional to the overlapping volume between intersecting objects. This setup causes overlapping fibers to repel one another at the start of the simulation, triggering collisions with neighboring fibers and the container walls. The system then evolves toward an equilibrium state in which no fibers intersect either each other or the container boundaries (Figure 9b). Surface friction and damping may be introduced to control the time needed to reach equilibrium. The final distribution and orientation of the fibers may exhibit stochastic behavior due to the combined influence of the repulsion force model, collision dynamics, and multi-body interactions. While evaluation of this stochastic behavior is beyond the scope of the present work, it is identified as a subject of future investigation.

Once equilibrium is reached, the simulation is baked, and the vertex coordinates of each fiber mesh are extracted. These coordinates are imported into Abaqus CAE, where they are used to reconstruct each fiber geometry via a series of spline profiles extruded along the fiber axis (Figure 8c). A lofted surface is generated from the spline sections and capped to create solid fiber volumes. The fiber volumes are then used to cut into a prismatic matrix block using Abaqus CAE's native Boolean operations, resulting in the final fiber and matrix volume geometry (Figure 9d).

Meshing of the fiber and matrix domains is then carried out using Abaqus CAE's meshing tools (Figure 9e). The fibers can typically be meshed using a sweep technique, enabling the generation of high-quality hexahedral or hex-dominated elements. For the matrix, sweep or bottom-up meshing strategies may be feasible when the fiber paths are relatively straight or when the fiber volume fraction is low. However, in the general case—particularly when dealing with random 3D fiber misalignment and high fiber volume fractions—free tetrahedral meshing is required to ensure successful mesh generation.

The entire process is automated by leveraging Blender and Abaqus CAE respective Python interfaces. It is worth noting that the Blender simulation is typically very fast. In this work, the 3D random positioning problem involving up to 800 fibers was resolved in under one minute.

Figures 10 and 11 present examples of fiber distributions generated with a 60% fiber volume fraction and approximately 500 fibers. Figure 10 illustrates a case in which a small degree of global fiber misalignment was introduced by allowing fiber rotation during the collision simulation. Figure 10a shows the initial fiber distribution in the Blender scene, while Figure 10b shows the final configuration after the repulsion-based collision simulation. Figure 10c provides a 3D view of the final distribution.

In the front view shown in Figure 10b, darker regions correspond to misaligned fibers. Clustering of these fibers appears in two distinct regions, suggesting a possible underlying stochastic behavior associated with the collision physics and multi-body dynamics of the packing process.

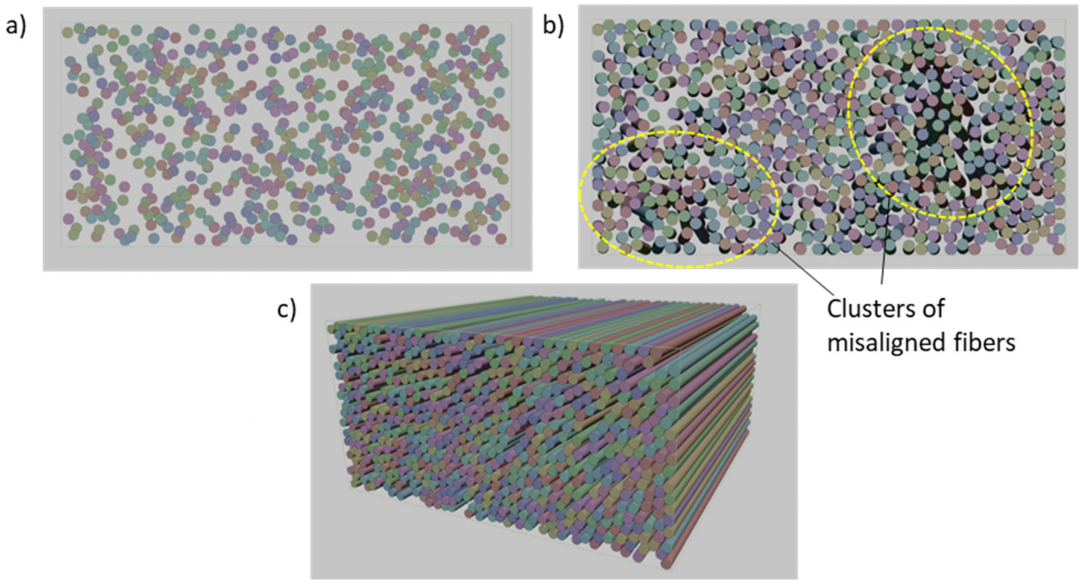

Figure 10: Example of 3D fiber distribution with global misalignment: a) initial distribution (2D view), b) final distribution in 2D view, and c) final distribution in 3D view.

Figure 11 presents an example of a fiber distribution in which a few individual fibers exhibit large global misalignment angles approaching 45°. This configuration is intended to mimic observations from CT scans of carbon/epoxy specimens where significant fiber misalignment occurred at ply interfaces due to the manufacturing process. The initial and final fiber distributions in the Blender model are shown in Figures 11a and 11b, respectively. Figure 11c shows CT data highlighting individual fibers with large misalignment angles.

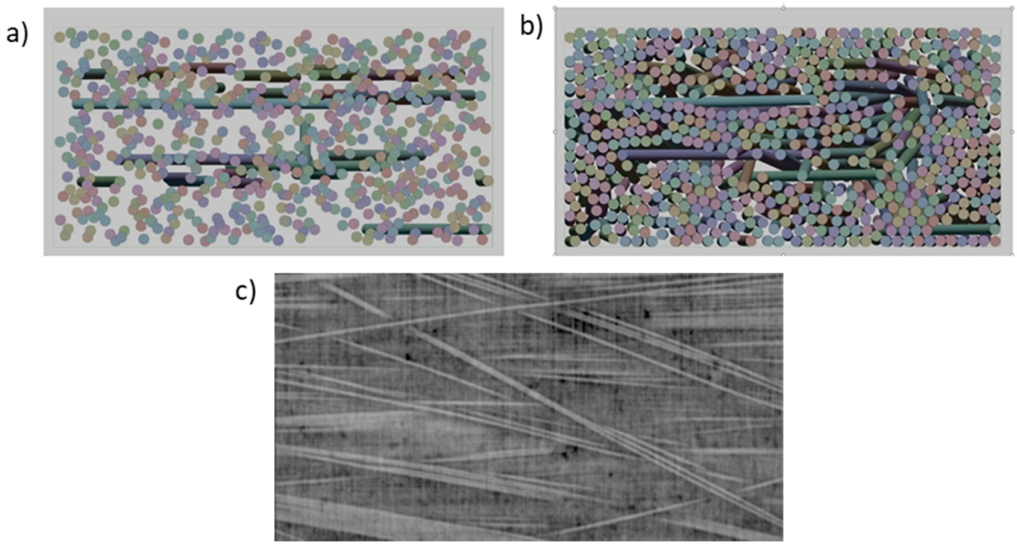

Figure 11: Example of simulated fiber distribution with large global misalignment angles: a) initial distribution, b) final distribution and c) similar fiber distribution observed in CT data.

Rigid body constraints can be applied to individual fibers to provide additional control over their final distribution. In the example shown in Figure 12, identical fibers with initial uniaxial sine-curve misalignment along the Z-axis, defined by Equation 1, are used in the repulsion-based simulation. Rigid body constraints are introduced to restrict fiber motion to translations along the Y and Z directions during the simulation, with no rotations allowed. This results in a random, non-intersecting fiber distribution with uniform uniaxial fiber misalignment, similar to the configuration shown in Figure 3. However, a key distinction is that the matrix block in Figure 12 remains a regular, undeformed rectangular prism, whereas in Figure 3, the matrix geometry is morphed to follow the fiber paths. Maintaining a prismatic matrix block in this case would enable straightforward and unambiguous application of periodic boundary conditions.

In Figure 13, the same rigid body constraints are applied, and the same fiber geometry with sine-curve misalignment is used. However, each fiber is randomly sampled from a collection of fibers that have been pre-rotated (randomly) about the X-axis. This introduces variation in the orientation of the local misalignment plane, resulting in a non-intersecting fiber distribution with randomly oriented sine-curve misalignment, as shown in Figure 13.

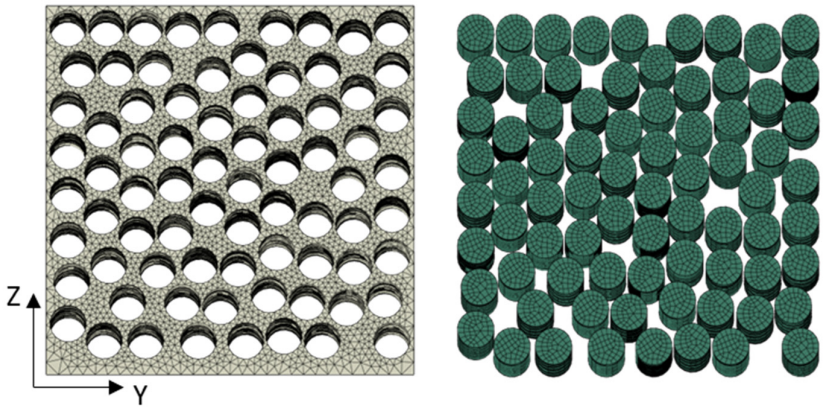

Figure 12: Random distribution of fibers with uniform uniaxial sine-curve misalignment.

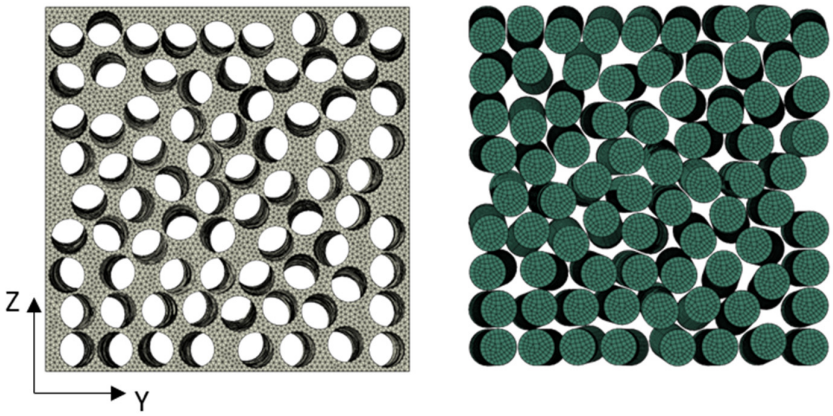

Figure 13: Random fiber distribution with sine-curve misalignment randomly rotated about the X-axis.

3.2 Analysis Results

Analysis results are presented and compared for the four 3D micromodels listed in Table 1, which outlines the key features of each configuration. All models incorporate local fiber misalignment using the sine curve function defined in Equation 1, centered at mid-length $L_{tot}/2$, with parameters $L = 150$ μm and $\Phi_0 = 1°$. Each model contains 77 fibers, corresponding to a fiber volume fraction of 60%.

The primary differences among the models lie in the orientation of the misalignment plane along the X-axis (uniaxial vs. randomly rotated) and the method used to introduce the misalignment, which affects the external geometry of the matrix volume. Model 1 uses the traditional "morphing" approach discussed in Section 2, where the mesh is deformed to follow the uniaxial sine curve. Models 2 through 4 are generated using the Blender-based approach described above, which allows for maintaining an undeformed prismatic or cylindrical matrix block. The orientation of the misalignment plane is uniaxial in Models 1 and 2 (along the XZ plane) and randomly rotated along the X axis in Models 3 and 4. Additionally, Model 4 features a cylindrical cross section, unlike the rectangular cross sections used in Models 1–3. All models use similar boundary conditions to those shown in Figure 2, and the simulations are performed using the explicit solver under quasi-static compressive displacement loading in the X direction.

	Model 1	Model 2	Model 3	Model 4
Matrix Cross Section

Features	- Uniform fiber misalignment in XZ plane - Rectangular cross section - Mesh morphed to misalignment sine curve in XZ plane	- Uniform fiber misalignment in XZ plane - Rectangular cross section - Prismatic mesh aligned along X	- Random rotation of fiber misalignment plane along X - Circular cross section - Prismatic mesh aligned along X	- Random rotation of fiber misalignment plane along X - Circular cross section - Cylindrical mesh aligned along X

Table 1: 3D micromodel configurations with varying misalignment orientation and matrix geometry.

The stress-strain response (normalized load-displacement response) for the four configurations is plotted and compared in Figure 14. The respective compressive strength values are listed in Table 2.

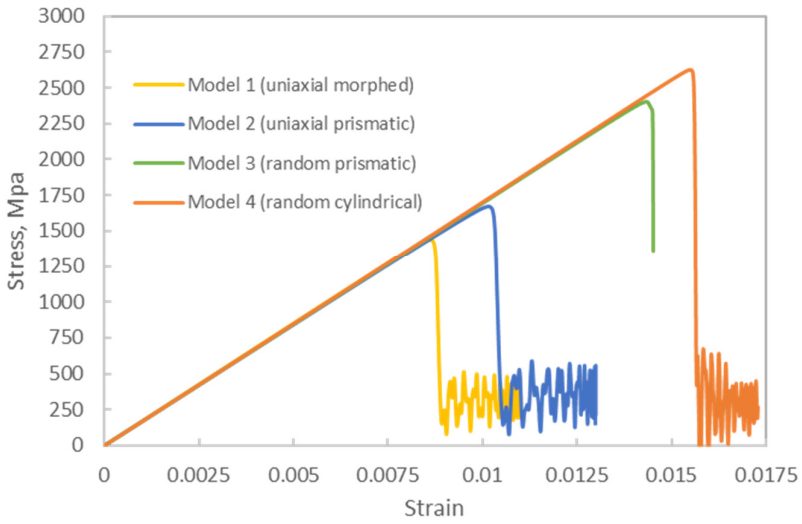

Figure 14: Effect of number of fibers on the compressive strength in the 2D model.

	Model 1	Model 2	Model 3	Model 4
X_c [MPa]	1440	1672	2404	2627

Table 2: Compressive strength values for the four 3D micromodel configurations.

A significant variation in compressive strength is observed across the different configurations, with an 80% increase between the lowest value of 1440 MPa for Model 1 and the highest value of 2627 MPa for Model 4. The substantial increase in average compressive strength observed in Models 3 and 4, compared to Models 1 and 2, can be physically justified: the random orientation of fiber misalignment delays the early development of shear stress along a preferred direction. In contrast, Models 1 and 2—with their uniaxial misalignment—promote early localization of matrix shear along the XZ plane. In Models 3 and 4, a global direction of matrix shearing eventually becomes dominant under continued compressive loading, ultimately leading to instability. Figure 15 illustrates the global shearing deformation observed in Model 3 just prior to failure, characterized by a combination of torsion about the X-axis and bending in the XZ plane.

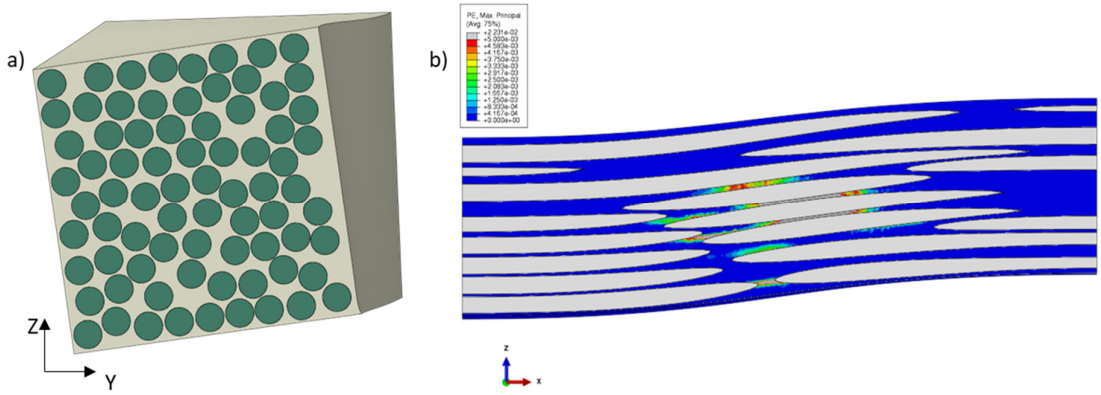

Figure 15: a) Combined torsion and bending deformation and b) development of plastic strains prior to failure in Model 3 (deformation scale is multiplied by 2).

The differences in peak load between Models 1 and 2, and between Models 3 and 4, are also notable, highlighting the influence of the cell geometry on the predicted compressive strength. This sensitivity remains a challenge for predicting the fiber-direction compressive strength of CFRPs using micromechanics modeling. Ideally, micromodel predictions using representative volume elements (RVEs) should be independent of model size and shape. Ongoing work includes the implementation of periodic boundary conditions to evaluate whether such an approach can mitigate these model dependencies.

4 THIN FOUR-POINT BEND NOTCHED SPECIMEN

The results presented in the previous sections highlight the need for direct experimental validation of micromodels for predicting fiber-direction compressive strength. To support this need, a thin four-point bend notched specimen configuration is considered. The configuration is designed to facilitate localized kinking in the notch region while avoiding global buckling. The thickness of the specimen is reduced to the minimum (one ply, or about 180 microns thick), allowing for the use of an embedded fiber-segmented micromodel directly in the notched region. This enables direct comparison between simulation and experimental results.

The test setup is illustrated in Figure 17 and includes a Plexiglas fixture that enables the observation of failure and full-field strain monitoring using the Digital Image Correlation (DIC) technique, while also preventing global buckling. Figure 17a shows an example of the DIC-measured axial strain distribution prior to failure initiation, and Figure 17b shows the out-of-plane kink band failure that developed from the notch, as visible in post-test CT data. The load-displacement responses obtained for six one-ply thick IM7/8852 specimens are shown in Figure 18. A load drop in the load-displacement response was associated with the initial kinking failure at the tip of the notch. After initiation, the kink band continued to grow in a stable manner along the transverse direction.

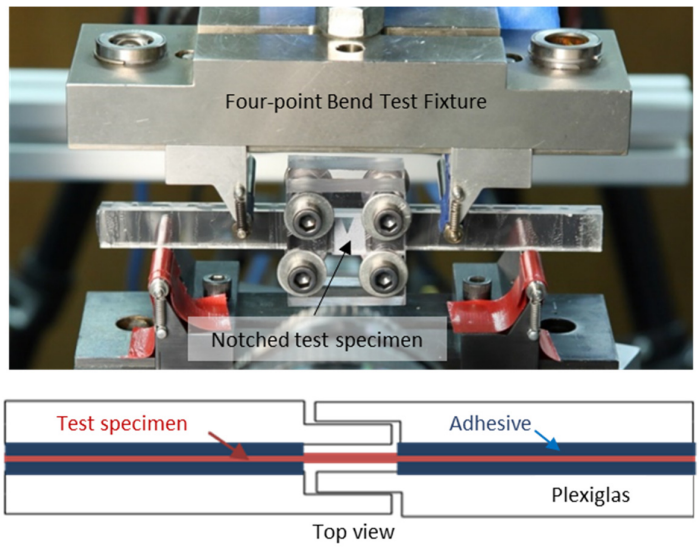

Figure 16. Four-point bend test setup.

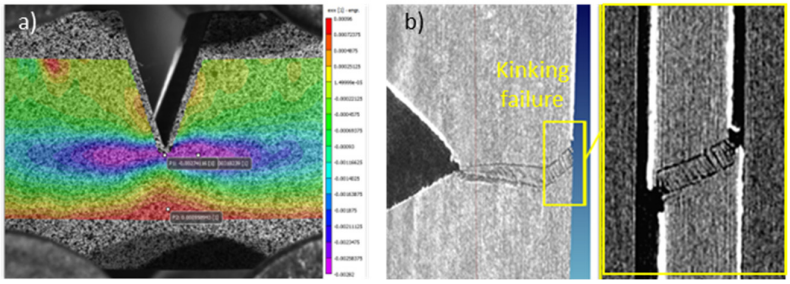

Figure 17. a) Example of DIC-measured axial strain field prior to failure initiation, and b) out-of-plane kinking failure visible in CT data.

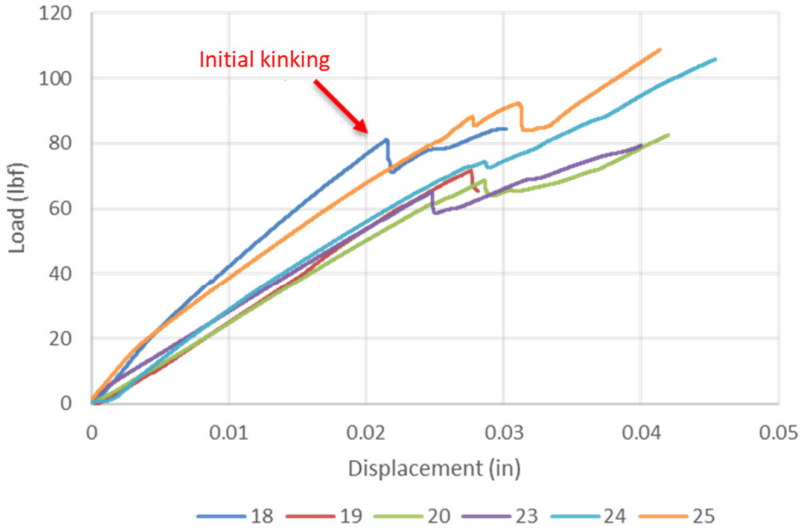

Figure 18. Load-displacement results for six IM7/8552 notched specimens.

The finite element model developed for comparison with experimental data is shown in Figure 19. A coarser homogenized global FE model is used to impose boundary conditions representative of the experiment, while the entire notch region where kinking develops is modeled using an embedded fiber-segmented local micromodel. This approach eliminates the ambiguities commonly associated with RVE size and boundary condition assumptions. Analysis and comparison with experimental data are ongoing at the time of writing.

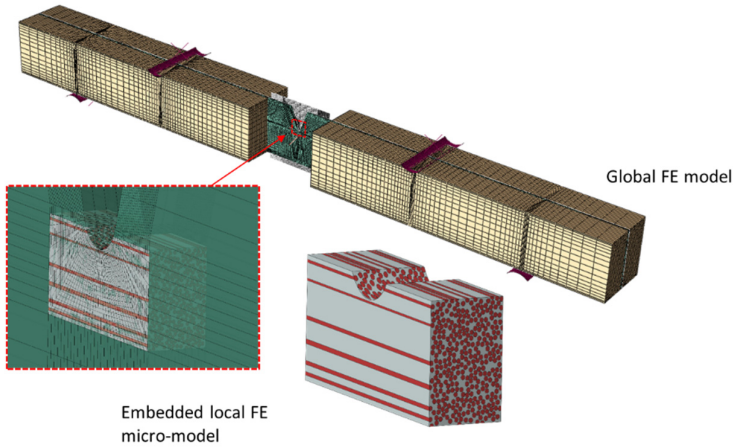

Figure 19. Embedded local and global Abaqus FE model for the Thin Four-Point Bend Specimen.

6 CONCLUSIONS

This work introduced a novel methodology for generating realistic 3D micromodels of CFRPs with random fiber misalignment for predicting fiber-direction compressive failure. A key contribution is the introduction of a computer graphics-based modeling framework using the open-source software Blender that enables the efficient creation of densely packed fiber architectures with spatially varying, stochastic misalignment. This approach addresses the limitations of conventional micromodels based on uniaxial sine-wave misalignment, which do not capture the true variability of fiber architectures in CFRPs and may lead to overly conservative strength predictions. It is also worth mentioning that the misalignment amplitude in such idealized micromodels is typically a calibrated parameter, further limiting their predictive capability.

Finite element simulations showed that both the orientation of fiber misalignment and the geometry of the representative domain can have a significant influence on the predicted compressive strength. Models incorporating randomly rotated misalignment planes led to delayed shear localization and a substantial increase in predicted strength—by as much as 80%—compared to conventional micromodels models with uniaxial misalignment. These results underscore the importance of accurately representing fiber architecture variability to enhance the reliability of micromechanical predictions.

To address the critical challenge of experimental validation, a thin four-point bend notched specimen was proposed. This configuration promotes localized kink band development while preventing global buckling. The small thickness of the specimen enables the use of a high-fidelity embedded fiber-segmented micromodel directly in the notched region for micromechanics-based simulation of fiber kinking. Preliminary test results confirmed the specimen's suitability for studying fiber-direction compressive failure through fiber kinking, laying the groundwork for direct validation.

Future work will focus on implementing periodic boundary conditions to reduce size and boundary effects and on validation using the proposed specimen configuration.

ABSTRACT

Traditional direct compression tests on pultruded rods typically generate stress concentrations around the gripping regions, preventing accurate measurement of the true compressive strength. This paper introduces the 'cradle test', a novel experimental methodology designed to better characterise the compression performance of such materials. The setup consists of a polymeric beam that 'cradles' a pultruded rod, which is adhesively bonded to the beam. The method produced consistent failure within the gauge length and clear evidence of compression-dominated failure modes. A complementary technique based on full-field digital image correlation (DIC) strain measurements was also developed to obtain the complete strain *vs*. stress response. The approach is extendable to the characterisation of other materials.

1 INTRODUCTION

Composite pultruded rods can be key in the manufacture of components and structures with enhanced compression performance, as they typically exhibit reduced fibre misalignment [1]. However, measuring their compressive behaviour is challenging. Traditional compression testing methods, such as direct compression, often fail to produce consistent failure within the gauge length [2], [3].

We propose the 'cradle test' as a new method for characterising the mechanical response of fibre composite pultruded rods under uniaxial compression [4], [5]. The test gradually generates compression on the pultruded rod by applying four-point bending on a polymeric beam to which the rod is bonded to.

In the following sections a summary of the experimental methodology and some key results will be presented. Further details on the experimental methodology, data processing and results can be found in the full journal article published by the authors [4].

2 EXPERIMENTAL

2.1 Materials and specimen design

The material system characterised in this study was a commercially available carbon fibre/epoxy pultruded rod with a diameter of 0.8 mm. The fibre volume fraction was within the range of 49-55%, measured from micrographic images of the rods' cross sections. Tensile experiments on these rods showed that their elastic modulus was 134.1±4.5 GPa. This modulus value will later serve as validation of the results.

Figure 1a shows a schematic of the cradle test specimen assembly. The design of the specimen was conducted with a combination of analytical and FEA computational tools, such that: (i) The cradle

behaves linear and does not fail before the rod; (ii) buckling is prevented; (iii) rod bending is reduced; and (iv) strains on the cradle are measurable. The cradle test beams were fabricated from 15 mm thick polycarbonate (PC) plates. Load and supports spans were selected as $L = 120$ mm and $D = 60$ mm, respectively. The final dimensions of the cradle that met the design requirements are shown in Figure 1b.

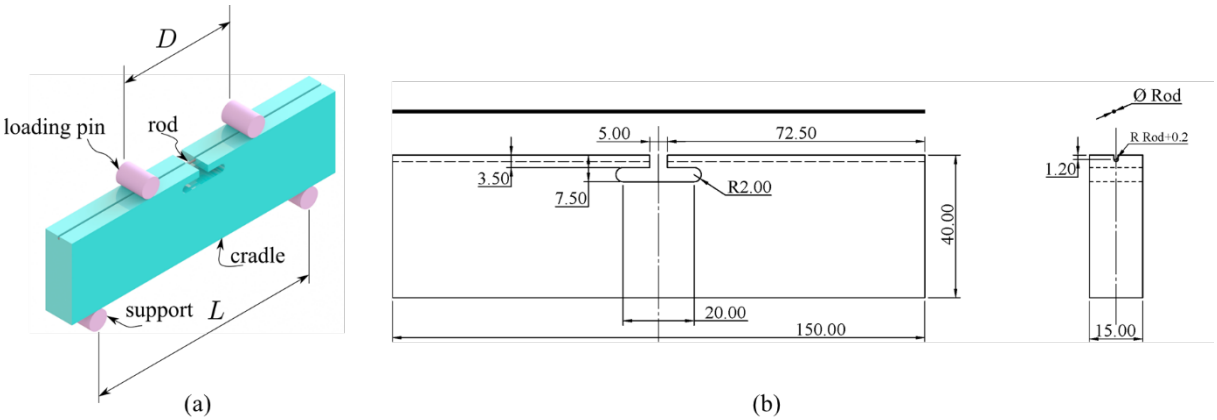

Figure 2: Cradle test design: (a) Schematic, and (b) Dimensions of the cradle test assembly.

2.2 Experimental setup

The setup, shown in Figure 2, included two cameras to image the speckled surfaces of the cradle (camera 1) and the pultruded rod (camera 2). Speckle patterns were carefully prepared to enhance the accuracy of DIC [6]. For the cradle, the 'tattoo speckle' pattern was used to provide optimal speckle sizes for the specific optical setup [7]. The experiment was conducted under displacement control at 0.18 mm/min, ensuring quasi-static loading of the specimen.

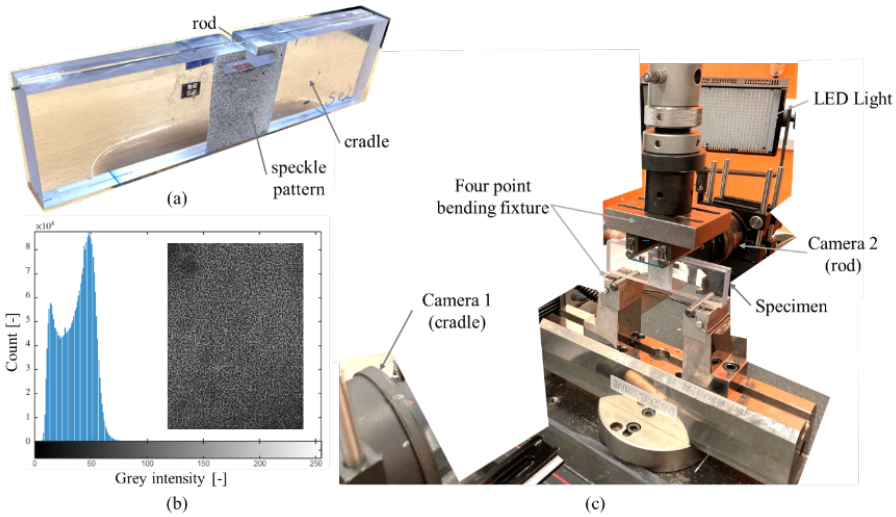

Figure 2: Prepared specimen and the loading rig and acquisition setup.

2.3 Data reduction method

By prescribing force equilibrium in the x-direction in the free body diagram shown in Figure 3, the resultant force across the cradle's midplane is equal to the absolute value of the compressive force on the pultruded rod F^r. FEA simulations demonstrated that the horizontal component of the reaction forces on the loading and supporting pins had negligible influence; therefore, they were excluded from the analysis. The compressive force acting on the rod can therefore be calculated by assuming plane stress, elasticity, and the integration of the DIC strain field of the cradle along the midplane path as shown in

equation (1).

$$F^r \approx -b \int_0^h \frac{E}{1-\nu^2} \varepsilon_{xx}^c(y) + \frac{\nu E}{1-\nu^2} \varepsilon_{yy}^c(y) dy, \quad (1)$$

where $\varepsilon_{xx}^c(y)$, and $\varepsilon_{yy}^c(y)$, are the x-, and y-strain components on the surface of the cradle along the midplane path; b is the width of the cradle (15 mm), and h is the length of the midplane path. The strain history of the rod ε^r was obtained using DIC on the images acquired by camera 2. Finally, F^r and ε^r were combined to produce the strain vs. stress curves. Figure 4 summarises the data reduction process.

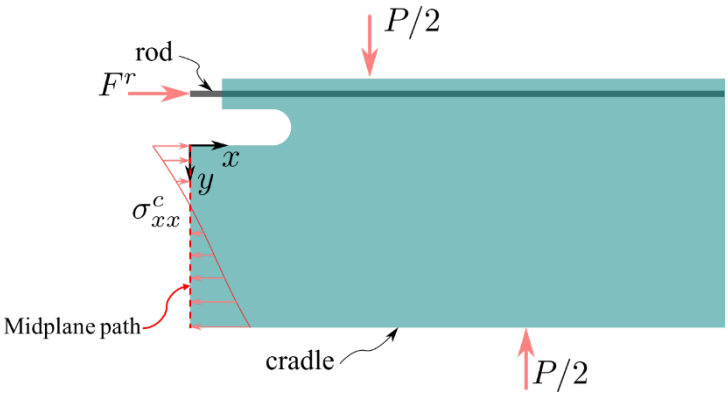

Figure 3: Free body diagram of half of the specimen.

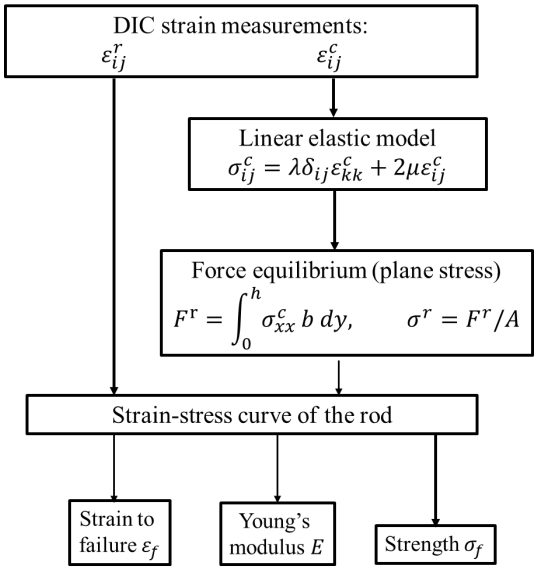

Figure 4: Flow chart of the data reduction process.

4 RESULTS

A typical displacement *vs*. load curves, and DIC strain fields measured in the experiment are shown in Figure 4a. Compression failure, away from the gripping region was consistently obtained across experiments (Figure 4b). From all tests, the DIC reconstructed strain *vs*. stress curves are shown in Figure 5. The average of the obtained elastic moduli was E=133.0 ± 11.3 GPa, close to the 134.1 ± 4.5 GPa measured from uniaxial tensile tests, validating the experiment and methodology. The average strain to failure was 1.16 ± 0.13%. The SEM images shown in Figure 6 showed fibre kink bands, a characteristic feature of compression failure.

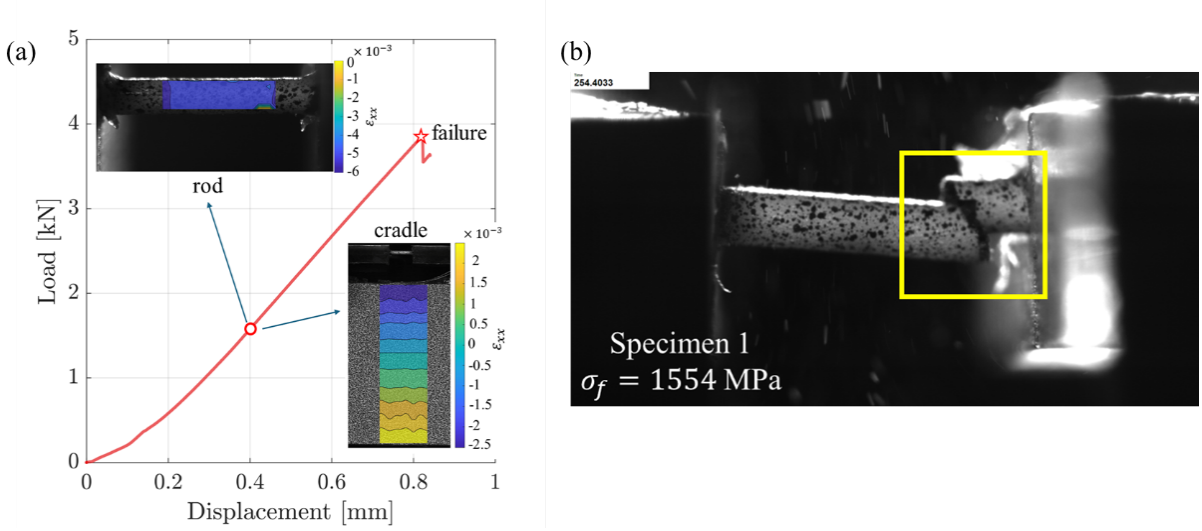

Figure 4: Data from a typical test: (a) Displacement-load curve and strain maps; and (b) pultruded rods failure mode.

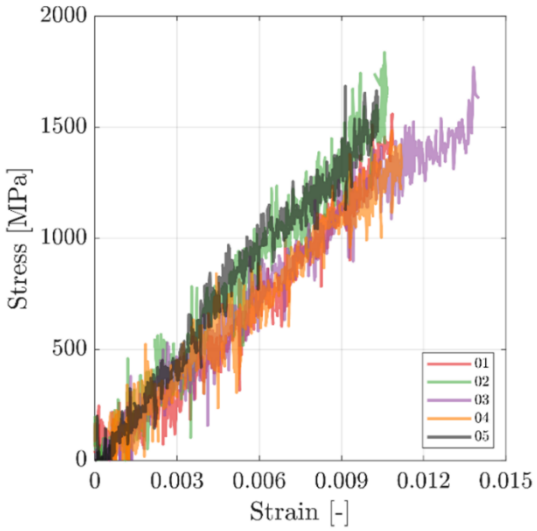

Figure 5: Strain-stress curves of all specimens

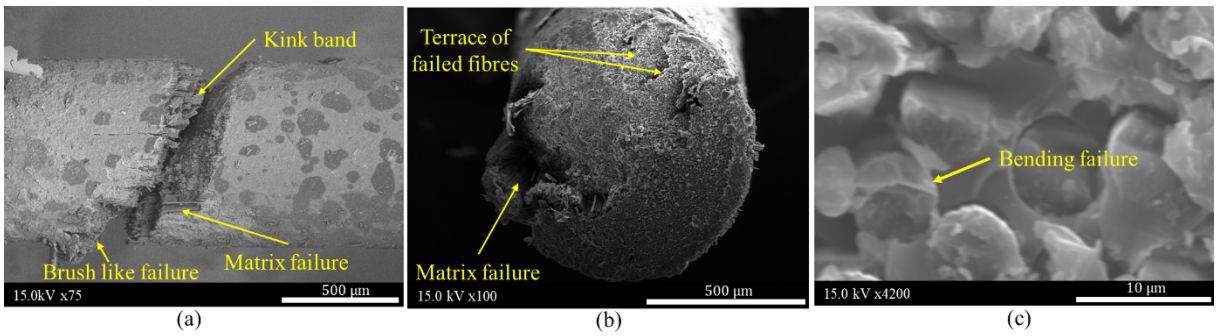

Figure 6: SEM micrography images: a) Full image of a failed specimen, b) Failure surface of another representative sample, and c) Individual failed fibres showing bending failure.

5 CONCLUSIONS

In this work, we presented and validated the ‘cradle test’, a novel methodology for characterising the compressive mechanical behaviour of pultruded rods. The main conclusions are:

- The new method simplifies specimen preparation and test setup and ensures compressive failure within the gauge length.
- The methodology can reconstruct the compressive strain vs. stress curves.
- The failure planes were located far from the bond region, suggesting mitigation of stress concentrations at gripping zones.

Further work is required to reduce the noise in the reconstructed stress, coming from the integration of the DIC strain field. The method will be used to rank various new material systems produced by pultrusion.

Keywords: Pultruded composite struts, Eccentric buckling test, Compressive performance

ABSTRACT

Pultruded carbon fibre/epoxy composites possess high fibre alignment. However, the characterisation of the compression performance of these materials in axial compression loading is sensitive to the factors such as specimen end preparation, loading misalignment and localised non-uniform loading. End fittings have been used to prevent the premature failure of these materials in axial compression test but this induced high complexity of the preparation process. In this study, we developed aneccentric buckling test methodology to investigate the compressive performance of pultruded carbon fibre/epoxy composites. The test results showed that the elastic modulus (85.5 ± 1.3 GPa) and flexural modulus (87.3 ± 3.0 GPa) were consistent with the value measured from tensile test at 88 GPa. A compressive failure strain at failure at -0.0134 ± 0.0007 was measured, which is higher compared with the reported values in literature for carbon fibre/epoxy pultruded rods. This shows that the eccentric buckling test is suitable for measuring the compressive failure strain of carbon fibre/epoxy pultruded rods.

1 INTRODUCTION

Carbon fibre/epoxy composites have been widely used in engineering applications due to their excellent mechanical performance. However, the material exhibits relatively weak compressive performance, partially due to fibre misalignment and waviness [1]. Pultruded carbon fibre/epoxy composites have been developed [2], with the applied pulling force in the pultrusion process to improve the fibre alignment of the resulting composites. Greater compressive performance is therefore expected.

Works have been conducted to characterise the compressive performance of the pultruded composites using the direct compression test method [3-6]. For example, carbon fibre/epoxy pultruded rods of 1.7 mm in diameter were bonded with metallic cylindrical holders and then loaded against upper and lower metal platens in compression until failure [3]. The results showed that stress concentration at the junction of gauge length and cylindrical holders was observed, and that the presence of voids and fibre misalignment resulted in reduced compressive strength. In another study, 6 mm diameter carbon fibre-polyester pultruded rods were snugly fitted into metallic end pieces and then tested in direct compression [4]. Test results showed that failure occurred at low compressive strain and reduced strength was measured, possibly due to stress concentration near specimen gauge section and specimen misalignment during mounting. Collars have been used to laterally support specimens upon compression. In summary, the direct compression test for pultruded rod composites requires extensive experience and skills on specimen preparation, endcap design and specimen mounting, to prevent incorrect load induction, stress concentration, buckling instability, and specimen end crushing and booming due to gripping and specimen misalignment [2].

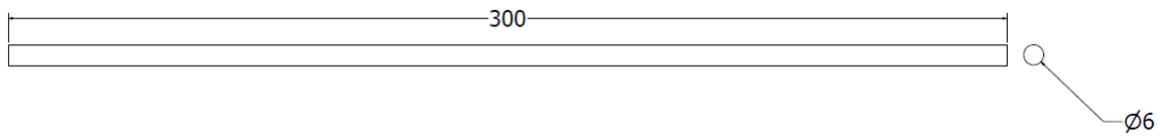
Alternatively, some of the authors of the current work have developed a ‘cradle’ test method using 4-point bending [7]. Easycomposite Carbon fibre/epoxy pultruded rods of 0.8 mm in diameter have been

tested and a compressive failure strain of -0.0116 has been reported. However, the test method may not be suitable for large diameter pultruded rods due to the complex design of the cradle.

We have developed an eccentric buckling test methodology to investigate the compressive performance of 6 mm diameter pultruded carbon fibre/epoxy composites. Compressive failure strain was measured and compared with published data measured from other test methods. This method provides an alternative way to measure the compression behaviour of circular pultruded composite rods.

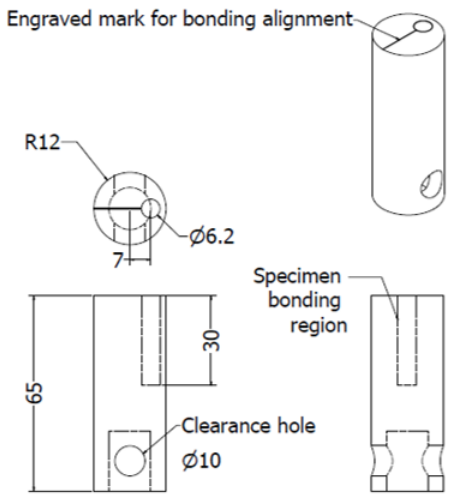
2 EXPERIMENTAL INVESTIGATION

2.1 Materials



In this study, Easycomposite pultruded carbon fibre/epoxy (ECPRs) of 6 mm in diameter, purchased from Easycomposite, UK, were used in the development of this test method. The manufacturer's datasheet indicates an elastic modulus of 28-40 GPa [8] for the rod material but a much higher value of 132 GPa has been reported for 0.8 mm diameter ECPRs [7]. Tensile tests were therefore conducted to measure the elastic modulus of the ECPR strut specimens in this study.

2.2 Specimen preparation



The as-received ECPR struts of 6 mm in diameter and 1 meter long were cut into 300 mm long (i.e. an aspect ratio of 50:1 was used). Sections of the material were cast in epoxy resin and the polished cross section was examined under microscope.

Figure 1a shows the specimen dimensions. The ECPR struts were then marked with three longitudinal lines separated by 120° on the circumferential surface at the mid-span location. Three uniaxial strain gauges were subsequently bonded longitudinally at the marked lines. A line corresponding to one of the strain gauge positions was also marked close to each end of the stut to help align the end caps.

The ECPR struts with the strain gauges were CT-scanned (Zeiss Xradia 5200, DE) to determine the actual enclosed angles between strain gauges and to measure the diameter of the struts. After this, the ECPR struts were bonded with endcaps using an epoxy resin adhesive (3M DP490, UK). The endcap, shown in Figure 1b, is designed so that the strut axis is offset by 7 mm from the loading pin centre to promote bending. During bonding, the marked lines at each end of the ECPR strut was aligned with the engraved mark on the endcaps. This ensured that one strain gauge was aligned with the nominal position of the maximum compression stress in the strut upon testing. The curing of the adhesive followed the resin manufacturer's recommendation.

(a)

(b)

Figure 1: (a) ECPR strut dimension (mm) and (b) endcap design (mm).

The centre zone of 40 mm length of each ECPR strut was painted in white using an acrylic spray paint. Once fully dried, black speckles were applied onto the paint for strain measurement with digital image correlation (DIC).

2.3 Eccentric buckling tests

Eccentric buckling tests were conducted on an Instron 1341 test machine fitted with a 5 kN axial loadcell. Figure 2 shows the test setup. The specimen was mounted onto the test machine using pins inserted through the clearance holes in the endcaps and the fixture. The mounting ensured that the strut was pin-ended and would buckle in the yz plane. Spacers were used to ensure there was no eccentricity of loading in the x-direction. The specimen was loaded in displacement-control at a constant crosshead speed of 3 mm/min until failure.

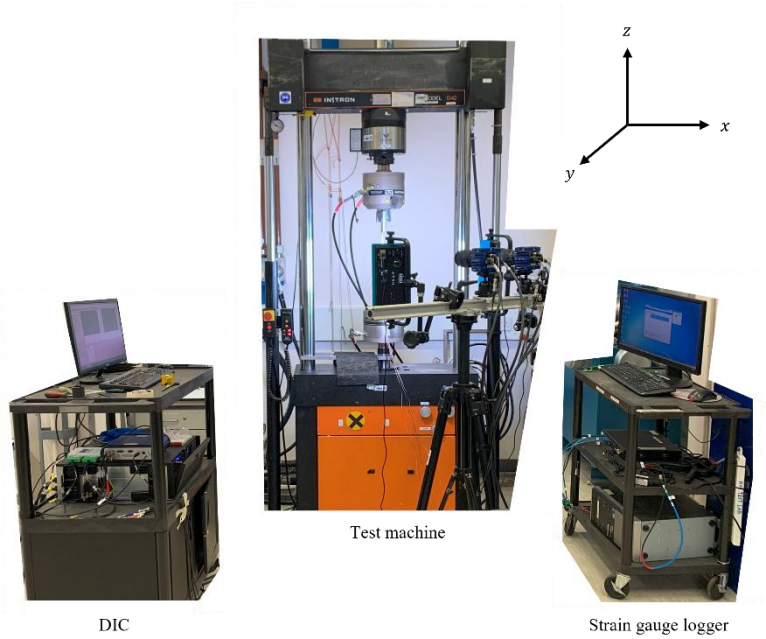


Figure 2: The eccentric buckling test setup.

Stereo DIC with two 16 mega-pixel cameras (LaVision, DE) and external LED light arrays were used to capture the full-field strain development to capture the strain development in the central zone of the strut viewed in the y-direction. The pixel size was 0.0055 mm. The captured images were processed using Davis (LaVision, DE) with a subset size of 31 pixels and a step size of 15 pixels. The bonded strain gauges were connected to the strain gauge logger for strain measurement.

Load (F) was measured from the test machine and strains were recorded by both the bonded strain gauges and the DIC, at a constant sampling rate of 1 Hz.

2.4 Data reduction

The applied stress (σ) was calculated using the equation (1)

$$\sigma = \frac{F}{A} \tag{1}$$

where A is the cross-sectional area of the strut at the mid-span position.

The critical buckling stress (σ_b) is given by

$$\sigma_b = \frac{\pi^2 EI}{L^2} \tag{2}$$

where E is elastic modulus, I is the second moment of area and L is the length between the loading pin hole centres of the endcaps.

The strain in the strut at the mid-length position can be considered as the superposition of the axial strain (longitudinal strain acting at the centroid) and the bending strain which varies linearly over the cross-section. The axial and bending strains can be determined from the three strain gauge measurements.

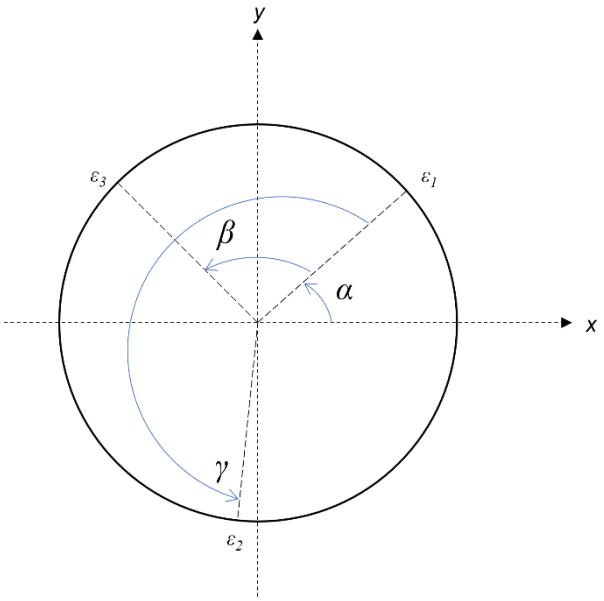

Figure 3: The schematic diagram of the calculation of axial strain and compressive strain from the three strain gauge measurements.

At the mid-span cross section of an ECPR strut specimen, three direct strains (ε_1, ε_2, and ε_3) are measured at the strain gauge locations as shown in Figure 3. Assuming linear elasticity and that buckling and bending occur about the x-axis, the neutral axis (zero bending strain) lies along the x-axis. The

maximum tensile and compressive strains, occur at the top and bottom surfaces intersecting the y-axis. The axial strain can be derived from a set of three sine wave equations related with the direct strain recorded at the three strain gauges locations. For bending about the x-axis the following equations can be established

$$\varepsilon_1 = A\sin\alpha + C$$
$$\varepsilon_2 = A\sin(\alpha + \gamma) + C \quad (3)$$
$$\varepsilon_3 = A\sin(\alpha + \beta) + C$$

where A is the magnitude of the bending strain at $y = \pm R$ (the radius of the circular cross-section), α is the unknown enclosed angle of the first strain gauge and the x-axis, β and γ are the enclosed angles between the first strain gauge and the second and third strain gauges respectively measured from CT-scan, and C is the axial strain.

From the equation set (3), and the CT-measured values of β and γ, the axial strain and the location and value of the maximum bending strain component can be determined.

The bending stress (σ_{bend}), assuming a linear elastic response, is given by the question (4)

$$\sigma_{bend} = \frac{32F(\delta + e)}{\pi D^3} \quad (4)$$

where δ is the deflection measured from DIC, e is the initial eccentricity of the load, and D is the strut diameter.

Axial modulus (E) can be determined from the applied axial stress – axial strain plot and the flexural modulus (E_f) can be derived from the bending stress – bending strain plot. These were used to compare with the elastic modulus measured from the tensile tests to validate the proposed test methodology.

3 RESULTS AND DISCUSSION

3.1 Mechanical performance of pultruded struts

Figure 4 shows the applied axial stress – axial strain responses of a typical ECPR strut specimen subjected to eccentric buckling. The dotted line is the critical buckling stress and the axial strain is calculated from the set of the three sine wave equations assuming a linear response. It can be seen that the specimen failed before reaching the critical buckling stress, as expected. The axial modulus, taken from the slope of the initial linear region at axial strains from 0 to -0.0001, is 86 GPa. This is consistent with the elastic modulus of 88 GPa measured in the tensile test but is significantly lower than the published value of 132 GPa for 0.8 mm diameter ECPR measured from the cradle test [7].

The inserted DIC images in Figure 4 shows that the specimen exhibited variation from compressive strain to tensile strain over the strut diameter. However, unexpected bands of compressive strain and tensile strain across the strut diameter have been developed. These may be due to the poor speckle quality and need further investigation. The maximum compressive strain measured from strain gauge was -0.0135. However, initial failure was observed to be by fibre breakage on the tensile side of the strut. Further investigation into the occurrence of such tensile failure via an interrupted test will be conducted.

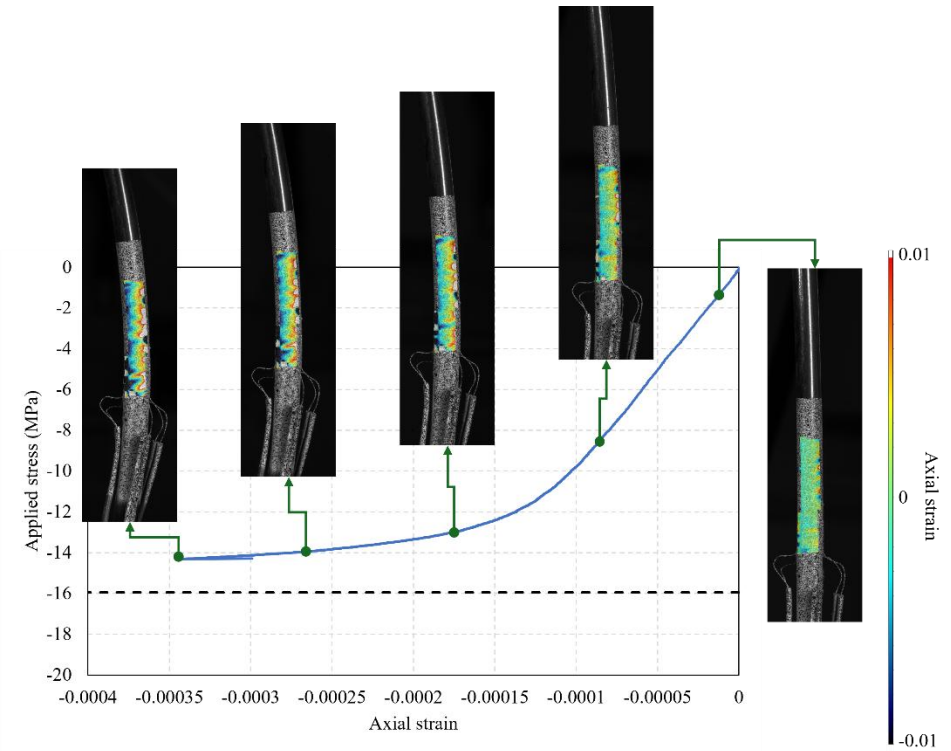

Figure 4: The applied stress – axial strain curve of a typical ECPR strut specimen subjected to eccentric buckling, with the inserted DIC images to show the compression-tension transition.

Figure 5 shows the bending stress – bending strain response of the same ECPR strut specimen at the compression side. The figure shows that a linear response of the material is observed, with the flexural modulus measured as 84 GPa. This is consistent with the axial modulus determined from the applied axial stress – axial strain plot.

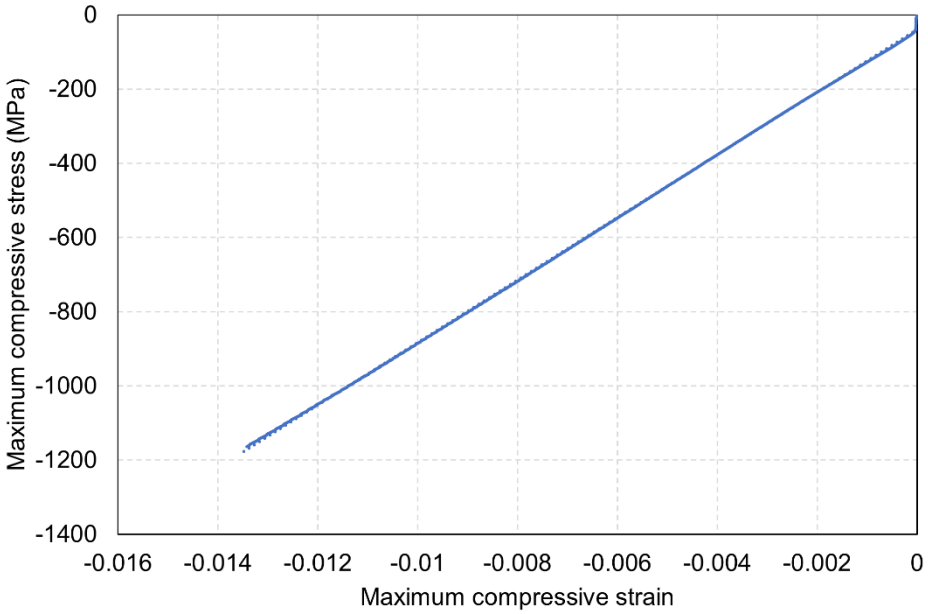

Figure 5: The bending stress-strain plot of the typical ECPR strut specimen.

Table 1 summarises, for a set of 5 repeated tests, the average axial and flexural moduli, the average measured compressive failure strain from the strain gauge close to the peak compression position and

the average compressive failure strain calculated as the maximum determined from the three strain readings and locations of all three strain gauges. (Standard deviation values are given in brackets.) It shows that the axial modulus is consistent with the value measured separately from a tensile test at 88 GPa, and that the flexural modulus shows very good agreement with the axial modulus, as expected. The compressive failure strain, is significantly higher than the failure strain values reported in literatures, although these are for other pultruded carbon fibre/epoxy materials. For example, *Soutis* reported the compressive strain at -0.0092 of 4 mm diameter T300/828 pultruded rods [9] and *Vankar et al* measured the compressive strain of 6.5 mm diameter pultruded rods at -0.0036 [10]. The high compressive failure strain may be partially due to the strain gradient in a bending test [11]. The average compressive failure strain calculated from the set of the three sine wave equations is slightly higher than the average measured compressive failure strain determined from the strain gauge located on the compressive side of the strut, but this is as expected if the strain gauge is not perfectly positioned with the maximum compressive strain location.

Average elastic modulus [GPa]	Average flexural modulus [GPa]	Average measured compressive strain [S]	Average calculated compressive strain [S]

Table 1: The average mechanical properties of ECPR strut specimens subjected to eccentric buckling test.

3.2 Microscope examination

Figure 6 shows the microscope image of the cross-section of an ECPR strut specimen. It can be seen that fibre clusters, resin-rich region and voids were formed during the pultrusion process.

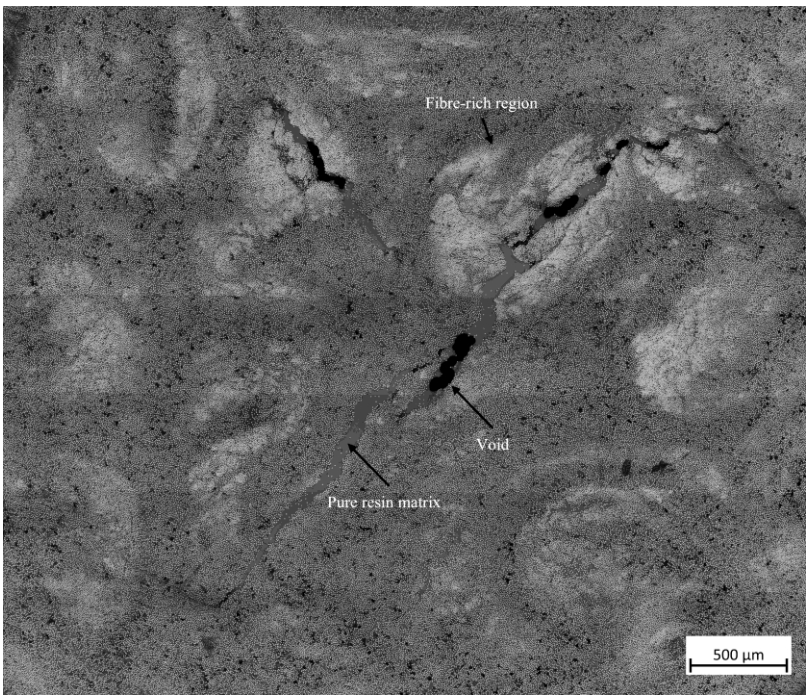

Figure 6: The microscope images of a ECPR specimen to indicate the fibre-rich region, neat resin region and voids. (20× magnification).

4 CONCLUSIONS

We have proposed an eccentric buckling test methodology to investigate the compressive

performance of large diameter pultruded carbon fibre/epoxy composites. ECPR struts of 6 mm in diameter were tested. The test results have shown that the axial modulus (85.5 ± 1.3 GPa) and flexural modulus (87.3 ± 3.0 GPa) were in good agreement with the value of 88 GPa measured in a tensile test. A compressive failure strain at failure of -0.0134 ± 0.0007 was measured, which is higher than values reported in the literature for other carbon fibre pultruded rods.

The next step of this study is to investigate the compressive performance of hierarchical pultruded rod epoxy composite struts developed within the NextCOMP research project.

ABSTRACT

Transverse impact of right circular cylinder (RCC) projectiles on finite-thickness thick and thin composite laminates are of great importance in understanding the mechanics and physics of lightweight protection materials. The fundamental objective is to optimize the deceleration of the impactor as a function of energy dissipating materials damage mechanisms in space and time following the conservation of energy and momentum.

Quasi-static punch shear test (QS-PST) experimental methodology had been developed by the author in quantifying the energy dissipating quasi-static perforation and penetration damage mechanisms of 1 to 24 layers (L) of plain weave (PW) 24 oz/yd^2 S-2 Glass/SC-15 composites. Ballistic limit experiments had been conducted on 24L and 32L thick laminates and then sectioned in understanding the ballistic damage mechanisms. It had been identified that the ballistic damage mechanisms can be simulated by the QS-PST experiments. By conducting QS-PST experiments as a function of punch diameter to support diameter ratio (SPR) and superimposing the experimental load-displacements, an envelope penetration curve had been constructed to represent 70% of the ballistic energy. A quasi-static model of ballistic penetration has been developed which also utilizes the maximum force from QS-PST experiment at SPR = 0 aka QS-Indentation (QSI) experiment and using a dynamic increase factor DIF = 1.1 yields 100% of the ballistic energy.

Finite element analysis of ballistic experiments for 11L, 24L, and 32L PW S-2 Glass/SC15 composites had been performed using rate dependent progressive composite damage model MAT162 in LS-DYNA in determining the time history of penetration resistance force and projectile dynamics. MAT162 progressive composite damage model has been proven to capture the ballistic damage mechanisms and had been validated for several composite materials.

The validated FE models are then used to simulate the ballistic limit analysis of very thick to thin e.g., 88L, 66L, 44L, 32L, 24L, 12L, 8L, 4L, & 2L PW S-2 Glass/SC15 composite laminates. From these simulations, three phases of ballistic penetration had been identified, i.e., (i) Penetration or P-phase, (ii) Transition or T-phase, and (iii) Perforation or F-phase. Calculating the through-thickness longitudinal wave velocity it has been postulated that the end of P-phase is complete when the shock wave reflects from the rear face of the target and meets the penetration font.

The classic penetration resistance test had been modified in understanding the P-phase of ballistic penetration and is termed as Depth of Penetration (DoP) test. An energy based theoretical model for the DoP experiments had been developed in calculating the characteristic time of DoP, impact contact force and projectile dynamics. A threshold velocity of penetration V_{TH} has been defined when the projectile will cease to penetrate the target. During the ballistic penetration and perforation of a finite thickness target, when the projectile velocity reduces to V_{TH}, the projectile continues to deform the remaining target and predominantly fails under tension-shear damage mechanism which is termed as the perforation or F-phase.

The relative thickness of a composite laminate has been defined based on the different phases of ballistic penetration. A thin laminate is defined as a laminate which only shows the perforation or F-phase (1L to 10L of PW S-2 Glass/SC15). An intermediate thickness laminate is defined which shows

both the transition or T-phase and perforation or F-phase of ballistic penetration (10L to 30L of PW S-2 Glass/SC15). A thick section composite laminate is defined where all three penetration phases are present, i.e., P-phase, T-phase, and F-phase (.GT. 30L of PW S-2 Glass/SC15).

Phoenix and Porwal (2003) have developed a 2D membrane theory which has been used to validate FE models for orthotropic composite materials in calculating the deformation cone/kink wave and bending wave velocities.

While the energy dissipating perforation damage mechanisms can be represented by QS-PST experiments, the penetration phase or P-phase damage mechanisms have been investigated by modifying the QSI experiments. The quasi-static indentation (QSI) strength $\mathrm{X_{QSI}}$ have been identified as a vital experiment in relative ranking of composite materials.

DoP experiments, QSI experiments, QS-PST experiments, ballistic limit experiments presented in this paper can quantify the energy dissipating penetration and perforation damage mechanisms. Theoretical models and LS-DYNA MAT162 computational analysis have provided insight in to the penetration and perforation of composites.

1 PERFORATION MECHANICS OF THIN-SECTION COMPOSITES

Transverse impact of a right circular cylinder (RCC) projectile on a 2D isotropic membrane is a good example of perforation (Phoenix & Porwal (P&P), 2003, [1]); in which, the thickness t_m of the membrane is considered much smaller than the diameter $D_P = 2r_p$ of the projectile, i.e., $t_m/D_P \ll 1$. For constant impact velocity V_P on a 2D membrane (Fig. 1), the axial/implosion membrane strain $\tilde{\varepsilon}_t(\tilde{r})$ can be expressed in terms of 1D implosion strain ε_0 and 1D cone/kink wave velocity $c_{k,0}$ in the material coordinate system as: $\tilde{\varepsilon}_t(\tilde{r}) = \varepsilon_0(r_s/\tilde{r}) \approx \alpha_0^2(r_s/\tilde{r}), r_k < \tilde{r} < r_s$, where $\alpha_0 = c_{k,0}/a_0 \approx \sqrt{\varepsilon_0} \approx \left(V_P/a_0\sqrt{2}\right)^{2/3}$. The membrane strain in the cone wave region can be expressed as: $\varepsilon_t(r) \approx \alpha^2(r_k/r), r_p < r < r_s, \alpha = c_k/a_0$, where c_k is the 2D cone/kink wave velocity in materials coordinate system. Determining $\varepsilon_t(r_p)$ and equating to the fracture strain of the material one can determine the perforation velocity of the membrane. A summary of 1D fiber theory and 2D membrane theory can be found in Ref. Haque et al., 2017 [2] and is presented in Appendix A.

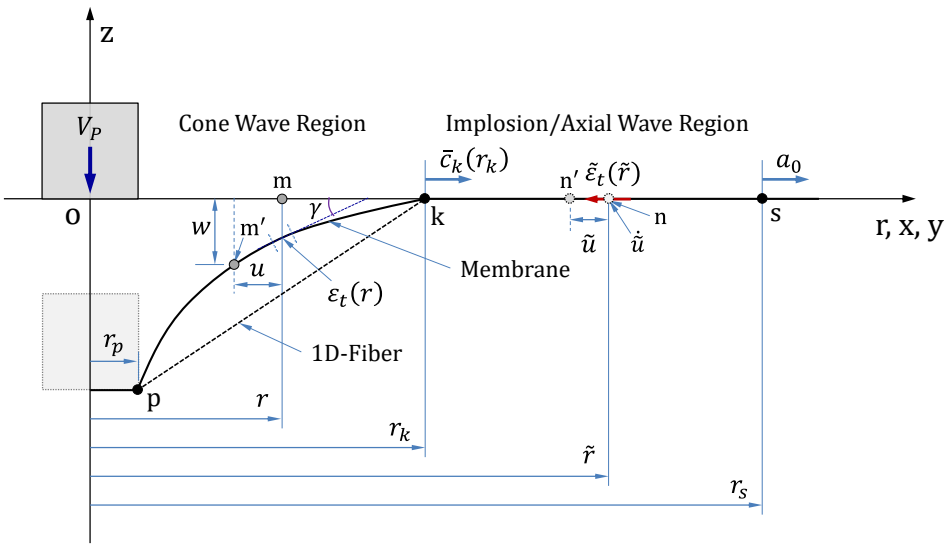

Figure 1: Nomenclature for Phoenix and Porwal (P&P, 2003) [1] 2-D Membrane Theory for Isotropic Materials. 1D axial/implosion wave velocity, $a_0 = \sqrt{E/\rho}$. Haque et al., 2017 [2].

In case of orthotropic thin-composite laminates, the use of 2D membrane theory is inadequate and thus finite element models have been developed and validated in computing the cone wave velocities (c_k) for ultra-high molecular weight polyethylene (UHMWPE) soft-ballistic sub-laminates (SBSL) [2].

Thin-composite laminates have high in-plane and shear moduli and under transverse impact exhibits cone wave propagation superimposed on out-off-plane bending waves. In this study, cone

wave velocity and bending wave velocities have been computationally determined for plain-weave (PW) S-2 Glass/SC15 (814 g/m^2, 24 oz/yd^2, 5×5 tows/in, 0.6 mm per one layer 1L) composites subjected to transverse impact velocity less the perforation velocities in the thickness range 1.20 mm (2L) $< H_C <$ 4.80 mm (8L). In Ref. Gama & Gillespie, 2017 [3]; materials and modeling parameters of a progressive composite damage model MAT162 in LS-DYNA has been validated with ballistic experiments and will be used in this paper (Appendix B). A tension-shear damage equation in MAT162 uses a new punch-shear strength (SFS=X_3^{PSS}) in simulating the perforation failure of a thin-section composite laminate.

Finite element models of 2L, 4L, 6L, & 8L laminates of dimensions 974mm x 974mm have been developed with finer mesh (0.53mm~3.7mm) in the central 178mm x 178mm region with 3 through-thickness elements for every 2 layers (3 TTE/ 2L) with free boundary condition (BC). A 50cal RCC steel projectile of is used for all impact analyses (Fig. 2).

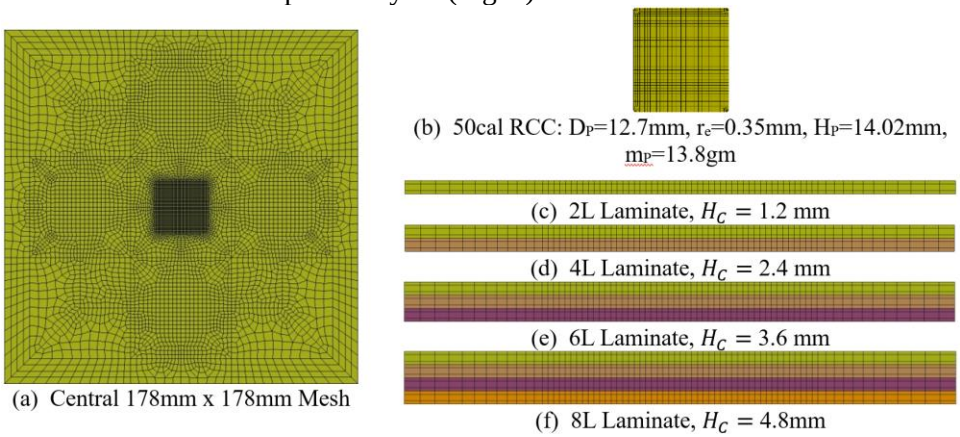

Figure 2: Finite Element Models for Perforation Mechanics Study.

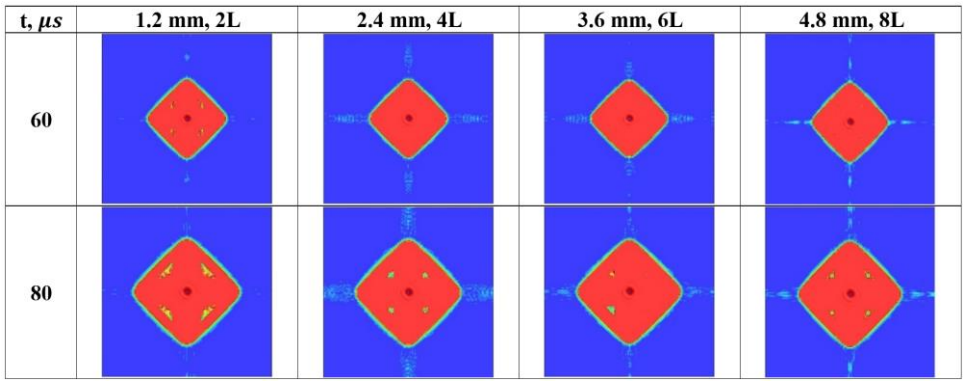

Figure 3: Cone/Kink Wave Propagation in Thin-Section Composites. Haque & Haque, 2025 [4].

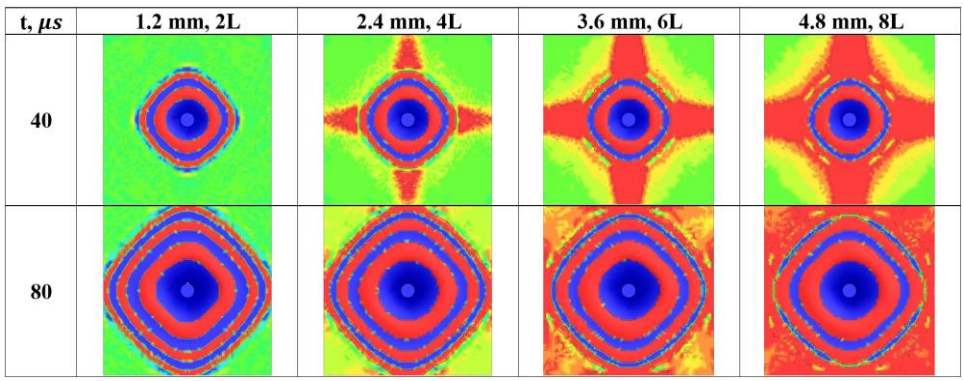

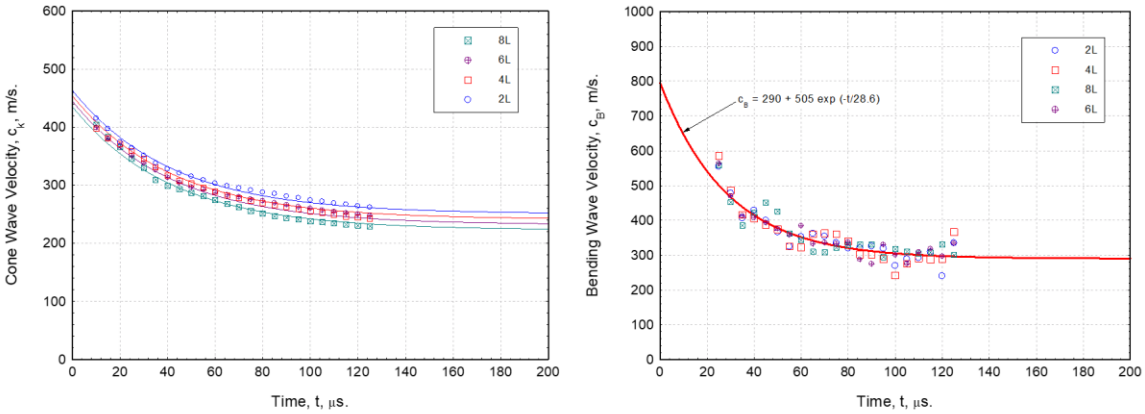

Figure 4: Bending Wave Propagation in Thin-Section Composites. Haque & Haque, 2025 [4].

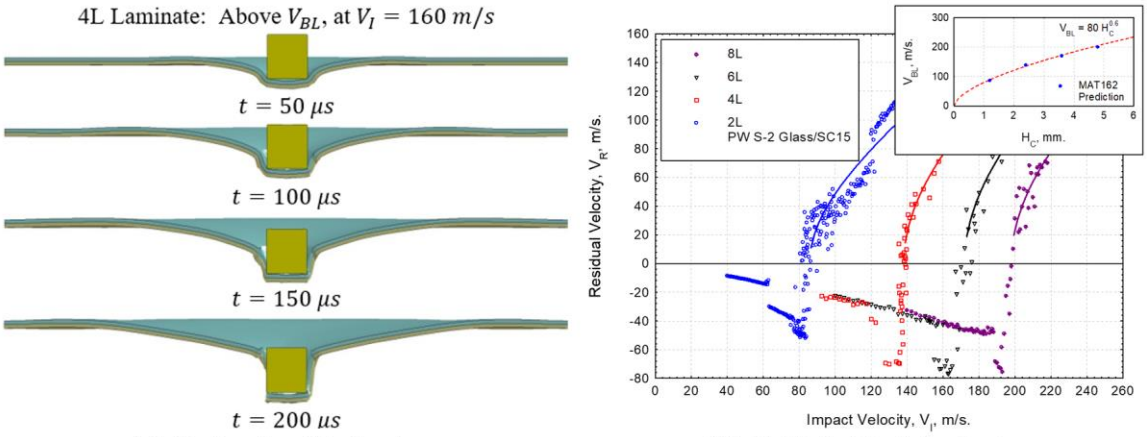
Propagation of cone/kink wave and bending wave are presented in Figs. 3 & 4 from which the time history of cone/kink waves and bending waves have been calculated and an exponential model has been used to calculate the regression parameters (Fig. 5).

$$\bar{c}_k(t) = \bar{c}_{k\infty} + [\bar{c}_{k\infty} - \bar{c}_k(0)]\exp(-t/\tau_k) \quad (1a)$$



$$c_B(t) = c_{B\infty} + [c_{B\infty} - c_B(0)]\exp(-t/\tau_B) \quad (1b)$$

Where, $\bar{c}_{k\infty} = 260 - 7.5H_C$, $\bar{c}_{k\infty}$ is in m/s, H_C is in mm, $\tau_k = 42.2\ \mu s$, $\bar{c}_{k\infty} - \bar{c}_k(0) = 212.4$ m/s, $c_{B\infty} = 290$ m/s, $c_{B\infty} - c_B(0) = 505$ m/s, and $\tau_B = 28.6\ \mu s$. Eq. (1a) can be integrated to determine the $r_k(t) = r_p + \int_0^t \bar{c}_k(t)dt$. Eq. (1) is essential in writing integral momentum and energy equations and will be presented elsewhere. Perforation mechanics and ballistics of PW S-2 Glass/SC15 thin-section composites are presented in Fig. 6.

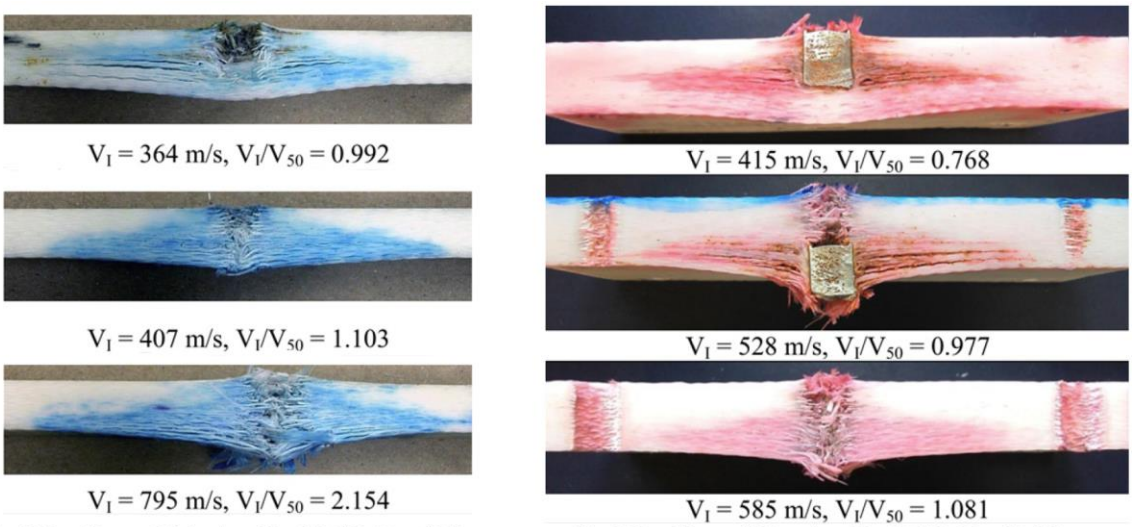
(a) Perforation Mechanics (b) Ballistic Limit Analysis

Figure 6: Perforation Mechanics and Ballistics of Thin Laminates. Haque & Haque, 2025 [4]

LS-DYNA stochastic simulations have been performed on square laminates (178mm x 178mm, all edges perfectly clamped BC) in predicting the residual velocity V_R as a function of impact velocity V_I (Fig. 6b) and Haque-Gillespie (H-G, 2015) [5] ballistic equation Eq. (2) is used to determine the ballistic limit velocity V_{BL} and model parameters, i.e., H-G jump velocity V_T, Lambert [6] parameter β^*, and H-G scaling parameter ζ (Table 1). Perforation V_{BL} as a function of H_C shows a power-law behavior $V_{BL} = 80H_C^{0.6}$ (Fig. 6b). Further discussion on perforation mechanics and ballistics will be presented elsewhere.



$$V_R = [V_T^2 + \beta^*(\zeta V_I^2 - V_{BL}^2)]^{1/2} \quad (2)$$

No. of Layers	Thickness, H_C, mm	V_T, m/s	β^*	ζ	V_{BL}, m/s
2L	1.20	4.64	0.895	0.999	85.9
4L	2.40	11.42	0.887	0.999	138.5

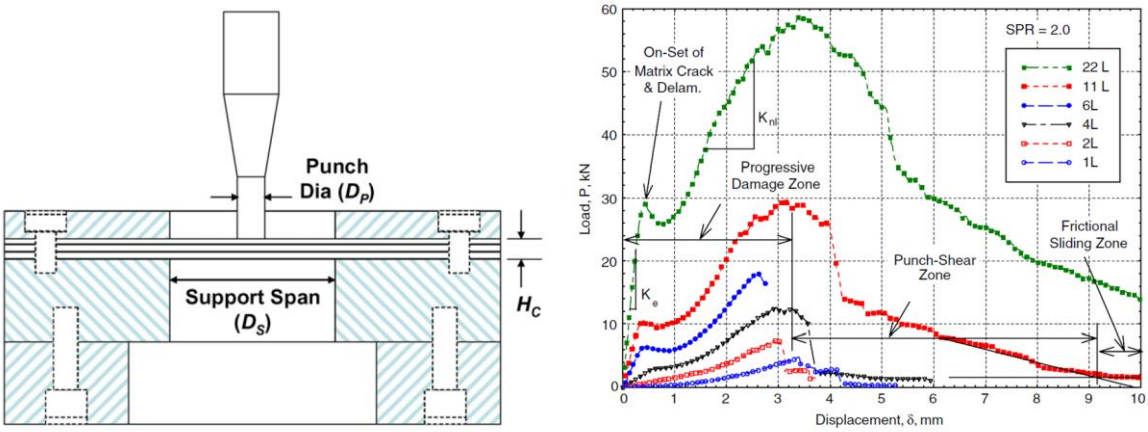
2 BALLISTIC PERFORATION AND PENETRATION DAMAGE MECHANISMS

In Ref. Gama & Gillespie, 2017 [3], ballistic experiments with a 101.6mm circular support span and perfectly clamped BC have been conducted on 22L (H_C=13.2mm) and 33L (H_C=19.8mm) with 50cal RCC and 50cal FSP projectiles, respectively (Fig. 7). The ballistic damage modes & mechanisms identified are: (i) deep penetration on the impact side, (ii) plug formation under the projectile, (iii) interlaminar delamination, (iv) tension-shear perforation damage in a thin delaminated rear-portion of the laminate. In order to understand these energy dissipating ballistic damage mechanisms, the author has developed a series of quasi-static (QS) and ballistic experimental methodologies; i.e., (a) QS punch-shear test (QS-PST), (b) QS indentation (QSI) or QS punch-crush test (QS-PCT), (c) ballistic perforation test, and (d) depth of penetration (DoP) test.

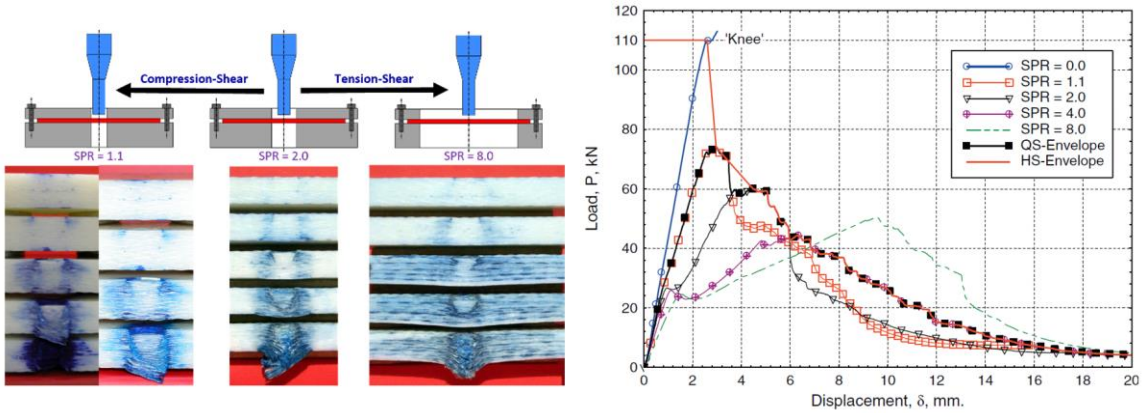
(a) 22L: V_{50} = 367 m/s. 50cal RCC: D_P=12.7mm, r_e=0.35mm, H_P=14.02mm, m_P=13.8gm



(b) 33L: V_{50} = 540 m/s. 50cal FSP: D_P=12.57mm, H_P=14.88mm, m_P=13.5gm

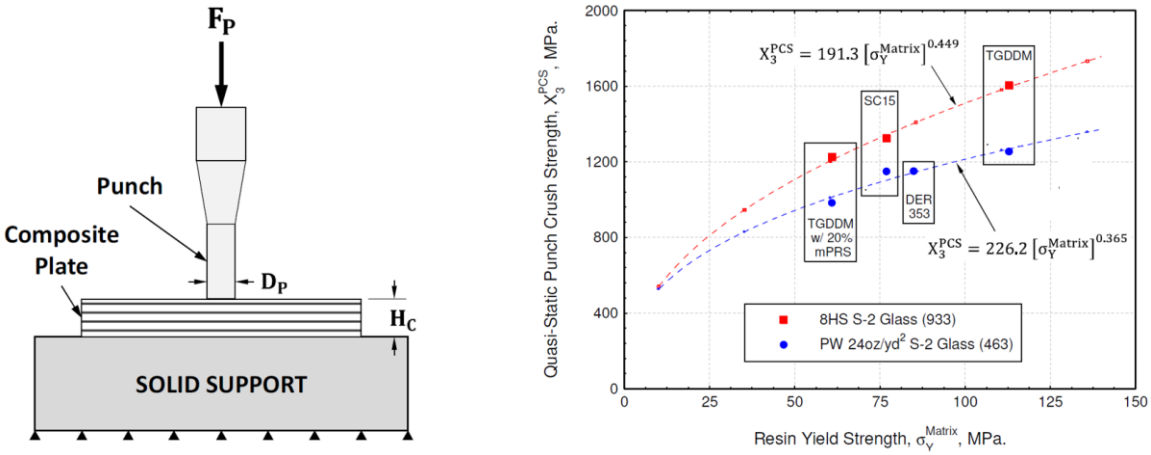
Figure 7: Ballistic Damage Mechanisms. Gama & Gillespie, 2017 [3].

3 QS-PST AND QSI EXPERIMENTAL METHODOLOGY



To quantify the energy dissipating ballistic damage mechanisms, a QS punch-shear test (QS-PST) experimental methodology (Fig. 8) has been developed by the author where a perfectly clamped laminate is subjected to transverse loading of a RCC punch (D_P) while varying the support span to punch diameter ratio (SPR=D_S/D_P) [7]. It has been shown that the ballistic damage mechanisms can be simulated and quantified by varying the SPR in the range 1.2 < SPR < 8 under load-unload-reload experimental methodology [8]. A punch-shear based penetration model of ballistic impact has been developed in Ref. [8] which can predict 97% of ballistic limit energy (Fig. 9). Punch-shear strength (X_3^{PSS}) of a composite has been defined by the author as:

$$X_3^{PSS} = \lim_{SPR \to 1} F_P^{max} / \pi D_P H_C \quad (3)$$



(a) QS-PST Experimental Setup (b) Quantification of QS-PST Energy Dissipation

Figure 8: Quasi-Static Punch Shear Test (QS-PST) Experimental Methodology. Ref. [7].

Figure 9: A QS Punch-Shear based Model of Ballistic Penetration. Gama & Gillespie, 2008 [8].

(a) QS-PCT/QSI Experimental Setup (b) X3PCS vs. Resin Yield Strength. Fig. 5b Ref. [9].

Figure 10: QS Punch-Crush Test (QS-PCT) or QS Indentation (QSI) Experiment. Refs. [7-9].

A quasi-static punch-crush test (QS-PCT, SPR=0) or quasi-static indentation (QSI) experimental methodology has been developed by the author in Refs. [7-9].

$$X_3^{PCS} = 4F_P^{\max}/\pi D_P^2 \tag{4}$$

Punch crush-strength (X_3^{PCS}) is defined by Eq. (4) which is a function of composite fiber volume fraction (FVF) and resin yield strength (Fig. 5, Ref. [9]). X_3^{PCS} is used in MAT162 as parameter SFC

to model this important damage mechanisms; and defines the threshold velocity of penetration in the depth of penetration (DoP) analysis methodology.

4 PENETRATION MECHANICS OF THICK-SECTION COMPOSITES

In addition to 2L, 4L, 6L, & 8L perforation simulations; and 11L, 22L, & 33L ballistic simulations in Ref. [3]; additional high velocity impact simulations on 44L to 88L (H_C = 26.4mm to 52.8mm) composite laminates (Fig. 11) using experimentally determined MAT162 parameters SFS = X_3^{PSS} & SFC = X_3^{PCS} are computationally determined softening [7] and rate parameters [3] (Table B1, Appendix B). Based on the observations of the 88L penetration simulations, Haque & Gillespie, 2014 [10] have identified four phases of ballistic penetration (Fig. 12), i.e., (i) Penetration or P-Phase (0 to 30 μs), (ii) Transition or T-Phase (30 to 60 μs), (iii) Perforation of F-Phase (60 to 140 μs), & (iv) Retraction or R-Phase (140 to 300 μs).

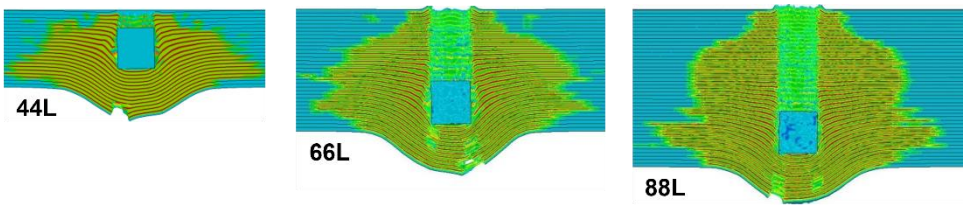

Figure 11: Penetration of 44L to 88L Thick-Section Composites.

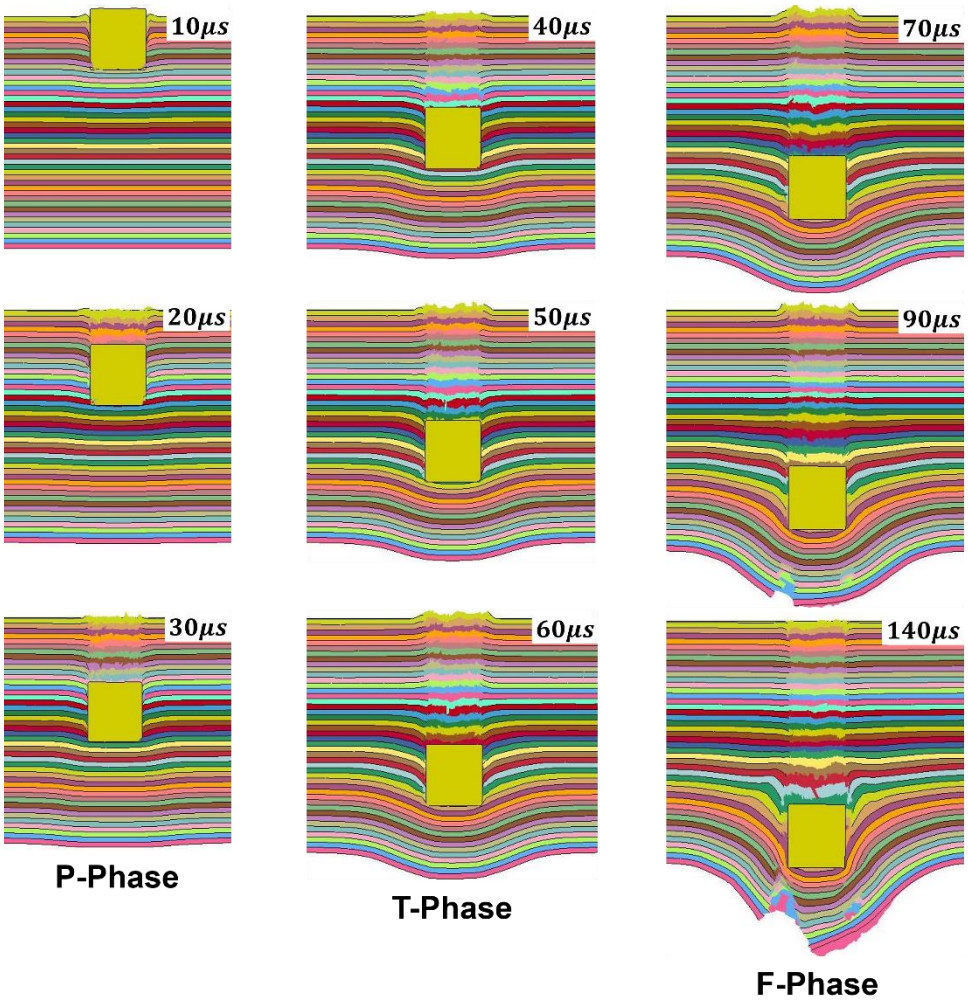

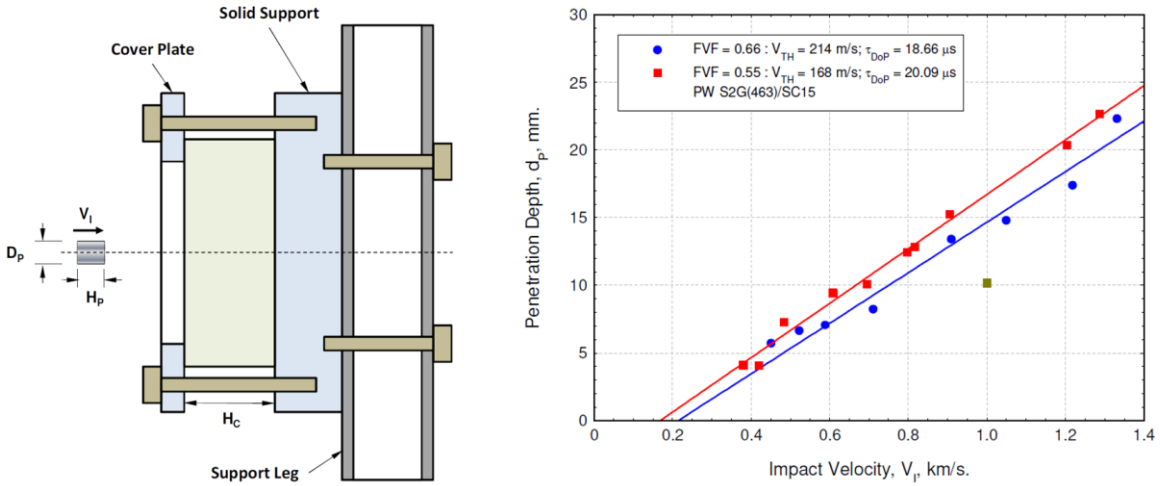

Figure 12: Ballistic Penetration or P-Phase (0 to 30 μs), Transition or T-Phase (30 to 60 μs), and Perforation or F-Phase (60 to 140 μs). Haque & Gillespie, 2014 [10].

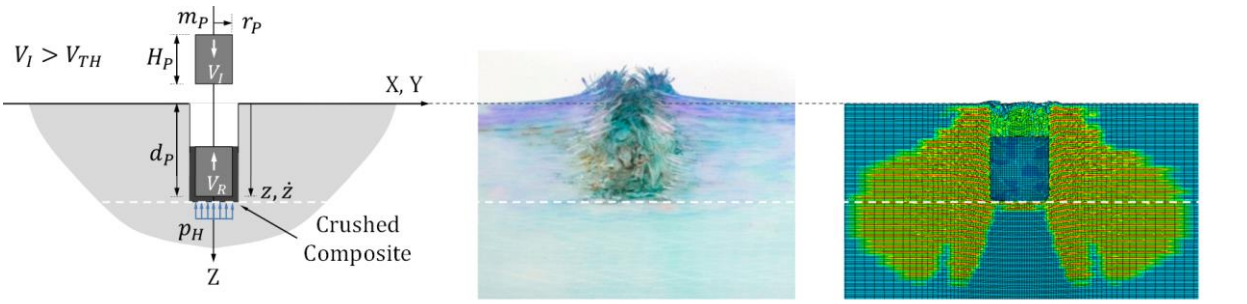
The P-Phase represents deep penetration and ejection of crushed particles under the projectile, initiation of delamination, and with near zero particle velocity of the surrounding laminate; which can be characterized by DoP experiments. During the T-Phase, significant particle velocity in the laminate is observed with delamination growth in the laminate with continued deep penetration. The end of T-Phase and beginning of F-Phase is when the penetration ceases, and the material ahead of the projectile attains the same velocity as the projectile. During F-Phase, the remaining laminate perforates under tension-shear. A thick-section laminate is defined which shows all three phase of penetration, while an intermediate-thickness laminate is defined which shows the T-phase and F-phase. A thin-section laminate is defined which only shows the F-Phase. While thick-section and intermediate-thickness laminates can be characterized by high velocity ballistic limit (HVBL) experiments, the thin-section laminates can be also be characterized by high velocity ballistic perforation (HVBP) experiments.

5 DEPTH OF PENETRATION (DOP) EXPERIMENTAL METHODOLOGY



In a DoP experiment (Fig. 13), a finite-thickness target is clamped on a rigid 'solid support' using another rigid 'cover plate.' Upon the impact of a RCC projectile on the target at an impact velocity V_I, the projectile penetrates, compresses, and crushes the composite under the projectile, the crushed particles eject through the penetration cavity around the projectile in a direction opposite to the projectile motion, and finally the projectile stops inside the target at a penetration depth of d_P; which is plotted as a function of V_I and is also known as classic penetration-resistance test. The author has developed [12] an energy based DoP model (Eq. 5) where the experimental data provides two DoP parameters: (i) V_{TH} – the threshold velocity of penetration, and (ii) τ_{DoP} – the characteristic time of DoP

$$d_P = \tau_{DoP}(V_I - V_{TH}) \tag{5}$$

(a) DoP Experimental Setup (b) PW S-2 Glass (463)/SC15 (814 g/m^2, 24 oz/yd^2) [9]

Figure 13: DoP Experimental Methodology.

(a) Nomenclature (b) DoP Damage, PW S-2 Glass/SC15 (c) LS-DYNA MAT162 Prediction

Figure 14: DoP Experimental, Theoretical, and Computational Modeling Methodology.

From the energy based DoP model (Fig. 14a), the projectile instantaneous rigid body velocity $\dot{z}(t)$ (Eq. 6a), the hydrodynamic pressure $p_H(t)$ of the crushed particles under the projectile (Eq. 6b) and the penetration resistance force $F(t)$ on the projectile (Eq. 6c) can be derived.

$$\dot{z}(t) = V_I \exp(-t/\tau_{DoP}) \quad (5a)$$

$$p_H(t) = (\rho_P H_P/\tau_{DoP})V_I \exp(-t/\tau_{DoP}) \quad (5b)$$

$$F_P(t) = (m_P/\tau_{DoP})V_I \exp(-t/\tau_{DoP}) \quad (5c)$$

Punch-crush and punch-shear are two unique damage mechanisms of the DoP experiments on thick-section composites (Fig. 14b). While punch crush of composites occurs under the projectile, the punch shear occurs along the edge of the projectile. Micromechanical punch crush damage mechanisms are (i) matrix crack, (ii) fiber fracture, (iii) fiber-matrix debonding (iv) hydrodynamic crush of both matrix and fibers; and the micromechanical punch shear damage mechanisms are (a) matrix crack, (b) matrix tension-shear, (c) fiber-matrix debonding, and (d) mode II dominated fiber fracture.

6 SUMMARY

This paper presents the fundamental understanding of the perforation and penetration mechanics of very thick to thin composite laminates developed by the author over the last two decades. In addition, new results on the cone/kink wave and bending wave propagation on thin-section composites have been presented along with stochastic ballistic limit predictions using rate dependent progressive composite damage model MAT162 in LS-DYNA. Two experimental methods for punch-shear & punch-crush developed by the author are also presented. New results of deep penetration of thick-sections composite have been presented and used to define three phases of ballistic penetration, i.e., Penetration (P-), Transition (T-), and Perforation (F-) phases. DoP experimental, theoretical, and computational models developed by the author has also been presented. The methodologies developed here will further be extended to develop an unified theory of ballistic penetration and perforation of composite laminates and left as future work.

ACKNOWLEDGEMENTS

The author gratefully acknowledges the funding for the conference attendance provided by Les Hall at McLaurin Aerospace. The research work on wave propagation in thin composite laminate conducted by Showvik Z. Haque is also gratefully acknowledged.

APPENDIX A: THEORY OF TRANSVERSE IMPACT ON FIBERS AND MEMBRANE

Theories of constant velocity transverse impact on 1D-fiber had been developed between 1945 to 1960 by Rakhmatulin and Smith. Following these classic theories, Phoenix and Porwal (P&P, 2003) has developed an axi-symmetric membrane theory for constant velocity transverse impact on an isotropic elastic membrane with a cylindrical projectile. The well-known Smith (1958, 1960) equations considers constant velocity transverse impact on a 1D isotropic fiber. Upon the impact of a projectile with impact velocity V_P, an implosion or axial strain wave of amplitude ε_0 propagates along the fiber between points 'p' and 's' with an axial wave speed of $a_0 = \sqrt{E/\rho}$ followed by a transverse cone wave with a constant cone wave front velocity, $\bar{c}_{k,0}$, at point 'k' with respect to the laboratory frame of coordinate, and forms a constant cone angle γ with the fiber axis at the projectile root at point 'p'. Smith's equations for the explosion strain ε_0, the cone wave front velocity $\bar{c}_{k,0}$ in laboratory frame of coordinates, the cone wave front velocity $c_{k,0}$ in material coordinates, and the cone root angle γ as a function of constant impact velocity V_P are given by:

$$V_P = a_0\sqrt{\varepsilon_0(1+\varepsilon_0) - \left[\sqrt{\varepsilon_0(1+\varepsilon_0)} - \varepsilon_0\right]^2} \tag{1a}$$

$$\bar{c}_{k,0} = a_0\left[\sqrt{\varepsilon_0(1+\varepsilon_0)} - \varepsilon_0\right] \tag{1b}$$

$$\frac{c_{k,0}}{a_0} = \sqrt{\frac{\varepsilon_0}{(1+\varepsilon_0)}} = \alpha_0 \tag{1c}$$

$$\sin\gamma = \frac{V_P}{a_0\sqrt{\varepsilon_0(1+\varepsilon_0)}} \tag{1d}$$

In order to express $\varepsilon_0 = \varepsilon_0(V_P, a_0)$, Eq. (1a) have been simplified to:

$$\varepsilon_0 \approx \left(\frac{V_P}{a_0\sqrt{2}}\right)^{4/3} \tag{1e}$$

Equation (1e) can noe be used to evaluate the other Eqs. (1b), (1c) & (1d). Phoenix & Porwal (2003) developed a 2D-membrane theory for isotropic materials where the cone wave velocity starts at 1D value (Eq. 1b & 1c), increases non-linearly with time and essentially forms a plateau. P&P (2003) provided analytical solutions for cone wave velocity $\bar{c}_k$ in laboratory frame of coordinates, and membrane strain $\varepsilon_t(r)$ as follows:

$$\bar{c}_k = c_k + \dot{u}_k = a_0\left\{\alpha + \frac{\alpha^2\left[\ln\alpha - \ln\left\{1 - \frac{r_p}{r_k}(1-\alpha)\right\} - 1\right]}{1 + \frac{(1-\alpha)(r_k - r_p)}{\alpha r_k}}\right\} \tag{2a}$$

$$\varepsilon_t(r) \approx \varepsilon_t(r_k)\frac{r_k}{r} \approx \alpha^2\frac{r_k}{r} \qquad r_p < r < r_s \tag{2b}$$

Where, c_k is the kink wave velocity in materials coordinate system, $\dot{u}_k = \dot{\tilde{u}}_k$ is the particle velocity at the kink point 'k', $\alpha = c_k/a_0$, r_p is the radius of the projectile, r_k is the location of the cone wave front at point 'k', and r_s is the location of the implosion wave front at point 's'. The value of α can be determined iteratively using the following formula as described in P&P (2003).

$$\alpha_{n+1} \approx \alpha_0\left(\frac{r_p}{r_k}\right)^{\frac{1}{3}}\frac{\left\{\frac{1}{\alpha_n}\left(\frac{r_k}{r_p}-1\right)\right\}^{\frac{1}{3}}}{\left\{\ln\left[1+\frac{1}{\alpha_n}\left(\frac{r_k}{r_p}-1\right)\right]\right\}^{\frac{1}{3}}} \tag{3}$$

Where $n = 0,1,2,\cdots$, and $\alpha_0 = c_{k,0}/a_0$. P&P (2003) showed that only two iterations provides quite accurate result, i.e., $\alpha \approx \alpha_2$. Once the value of α can be determined using Eqs. (3), (1c) & (1e); then Eqs. (2a) and (2b) can be evaluated. Eq. (2a) has been further reduced for 1D case in P&P (2003) to:

$$\bar{c}_{k,0} = c_{k,0} + \dot{u}_{k,0} = \alpha_0 a_0(1 - \alpha_0 + \alpha_0^2) \tag{4}$$

Eq. (4) provides a slightly smaller value of $\bar{c}_{k,0}$ as compared to Eq. (1b). P&P, 2003, showed that the cone/kink wave velocity for the 2D membrane, c_k, is equal to $c_{k,0}$ at $r_k = r_p$, increases to a maximum at around $r_k = 2r_p$, then reduces to a plateau value (higher than $c_{k,0}$) for $r_k \gg 2r_p$ for a constant value of ε_0. It is also important to mention that the 2D membrane cone/kink wave speed increases with the increase in ε_0, that is with impact speed V_P. In Ref. [8], it has been shown that for isotropic 1D fiber and 2D membrane, a finite element model can capture the theoretical physics of deformation with good correlations. We will use these 1D and 2D equations to verify the finite element models of transverse impact on thin-section composite plates.

ABSTRACT

This work outlines the development of a finite element-based numerical tool designed to simulate the thermal aging behavior of epoxy-diamine matrix composites reinforced with continuous fibers under thermal exposition to temperatures below their glass transition temperature (T_g). The approach begins with homogenization technique using a representative elementary volume (REV) that include the fibers, surrounding matrix and interfacial zones around the fibers. Periodic boundary conditions in oxygen (O_2) concentration are applied to numerically determine the effective components of the diffusion tensor for a unidirectional composite. The thermo-oxidation degradation model incorporates a strong coupling between the anisotropic diffusion of O_2 and its consumption by the chemical reaction with the epoxy matrix. The stabilizing effect of carbon fibers in mitigating this degradation is also taken into account. This framework enables the estimation of oxidation gradients across the thickness of the composite sample along its principal directions. The thickness of the oxidized layer (TOL) is calculated from O_2 consummation gradients as recently done for samples of neat epoxy resin. In order to check the robustness of the model and the proposed criterion of TOL detection, the numerical TOL values are compared to experimental measures from literature. The originality of this work lies in the assessment of anisotropic oxidation gradients in composites, particularly by accounting for the crucial role of the fiber-matrix interface and the associated interfacial diffusion in the homogenization calculation.

1 INTRODUCTION

1.1 Thermo-oxidative degradation scenario in Polymer Matrix Composites

Carbon/epoxy composites are widely used in the design of structural parts in the aeronautics sector due to their excellent specific properties. However, their exposure to high temperatures represents a crucial issue to be considered during the design and certification phases of structures. Among the identified risks, thermo-oxidative aging of the matrix plays a particularly decisive role [1]. This phenomenon leads to the formation of an oxidized layer on the surface, causing localized embrittlement and stress and strain gradients likely to cause a catastrophic cracking scenario. Fig. 1 shows the degradation scenario in a thick sample of neat resin by thermo-oxidation. In a first step (between 0 and t_l), the O_2 is consumed while it tries to diffuse in the thickness direction. In a second step (at t_F), the stress and strain fields induced on the surface allow the initiation of a crack, then its propagation in the embrittled zone. Eventually (at t_{2l}), oxidation can cross the oxidized layer/intact core interface to finally progress into the core of the composite, following a progressive damage scenario, and lead to its premature failure [2].

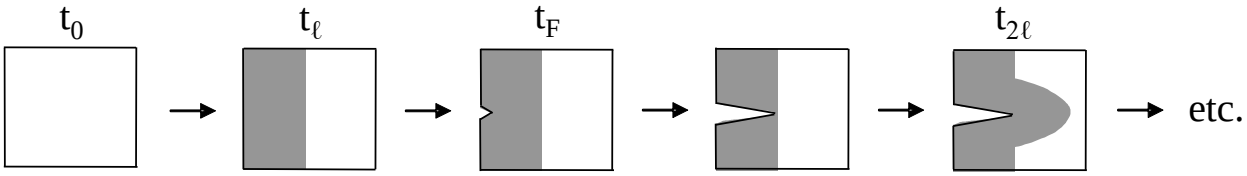

Figure 1. Scenario of crack propagation within a neat resin sample [2].

In the case of a unidirectional (UD) composite reinforced with continuous fibers, the degradation scenario depends on the anisotropy of the composite. The anisotropic oxidation gradients, due to the presence of fibers and interfaces, will lead to heterogeneity of stress and strain fields inducing crack initiation and propagation in the thickness of the oxidized layer (TOL), as shown schematically in Fig. 2:

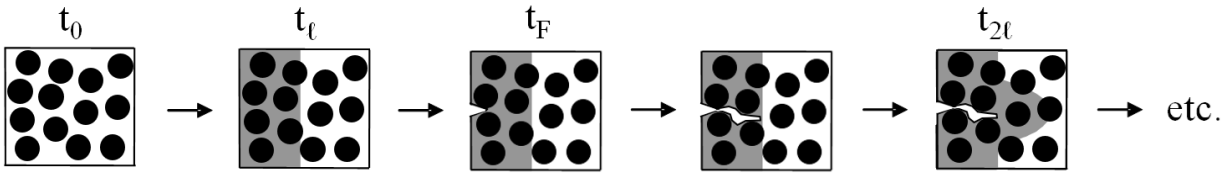

Figure 2. Scenario of crack propagation within a composite sample. View of a section perpendicular to the longitudinal direction of the fibers

In order to address this complex issue, knowledge of the link between the evolution of the TOL and the degradation of the thermomechanical properties of interest of the composites is essential, before focusing on the critical conditions of crack initiation. For this, the numerical simulation of oxidation gradients proves to be a relevant tool for predicting the value of the TOL. Recent work [3] has shown the robustness of a model developed under finite elements and based on an O_2 balance equation, coupling the diffusion of O_2 and its consumption by the chemical reaction, to predict the TOL in neat resin samples.

Concerning the prediction of oxidation kinetics, it is necessary to consider the anisotropic properties induced by the specific structure of the composites, in particular the anisotropic diffusion of O_2. In order to propose a relevant model adapted to composites reinforced by continuous fibers, the following question arises: should a specific behavior of the fiber/matrix interface be considered, in particular through interfacial diffusive and reactive terms, to faithfully describe the oxidation gradients of the composites? To answer this question, the article will aim to achieve two objectives. Firstly, it will be a question of: (i) proposing a kinetic model of thermo-oxidation of carbon fiber/epoxy-diamine matrix composites, and secondly: (ii) linking the evolution of the oxidation gradients to that of the TOL in each of the main directions of the composite (1 – fiber direction, 2 – transverse direction and 3 – out-of-plane direction). Thus, the article will be divided into two main parts. First, Section 2 will outline the numerical calculation code developed for composites. Then, Section 3 will compare the numerical simulations of this code with experimental data, in particular with TOL measurements. This last section will conclude on the key role of the fiber/matrix interface. Finally, after a conclusion, perspectives, aimed at predicting the evolution of the thermomechanical properties of interest of composites in the aeronautical field, will be drawn up.

2 MODELING OF OXIDATION GRADIENTS

2.1 Time-dependent kinetics of thermo-oxidative aging

Numerical simulation of oxidation gradients proves to be a relevant tool to predict the evolution of TOL. Recent work [3] has proposed a first numerical calculation code developed under finite elements to simulate the evolution of the oxygen (O_2) concentration in the thickness of neat resin samples. This code is based on the coupling of the two main mechanisms: (i) the diffusion of O_2 and (ii) its

consumption by the chemical reaction. In the case of unidirectional diffusion (e.g. along the thickness of the sample), this equation (Eq. 1) is written:

$$\frac{\partial C(x,t)}{\partial t} = D\frac{\partial^2 C(x,t)}{\partial^2 x} - r(C(x,t)) \quad (1)$$

C(x,t) being the local O_2 concentration, *D* the O_2 diffusion coefficient, *x* the thickness coordinate, and *t* the time. $r(C)$ represents the rate of chemical consumption of O_2, the analytical expression of which was determined by carrying out a kinetic analysis of the so-called "closed loop" oxidation reaction. This expression was generalized to the entire family of epoxy-diamine networks [4]:

$$r(C) = 2r_0\frac{\beta C}{1+\beta C}\left(1-\frac{\beta C}{2(1+\beta C)}\right)\left(\frac{1}{1+be^{-Kt}}\right)^2 \quad (2)$$

With $\beta = \frac{k_6 k_2}{k_5 k_3 [PH]}$, $r_0 = \frac{k_3^2[PH]^2}{4k_6}$, and $K = 2(r_0 k_{1b})^{1/2}\left(\frac{\beta C}{1+\beta C}\right)^{1/2}$, three parameters which are expressed as a function of the elementary rate constants of the oxidation reaction.

The integration with respect to time of $r(C)$ allows direct access to the O_2 consumption gradients:

$$Q(C) = \int r(C)dt \quad (3)$$

On the basis of this quantity representative of the oxidation kinetics, a criterion for estimating the TOL for epoxy-diamine networks exposed to temperatures on either side of their T_g has been validated [3]. This criterion compares the normalised O_2 consumption to the maximal amplitude, as shown in Figure 3 for an epoxy/DDS exposed at 200°C in air:

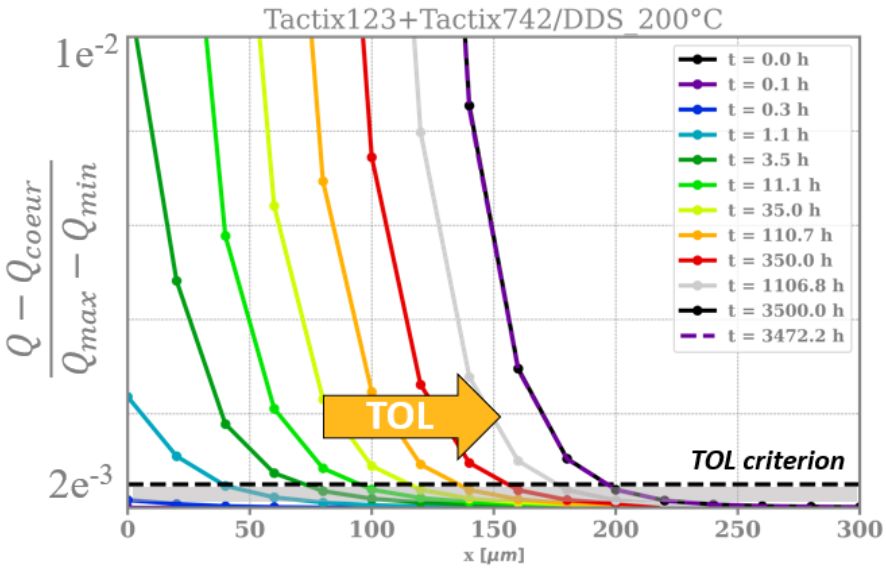

Figure 3. Normalized oxidation gradients in air at 200°C for an epoxy/DDS. Application of the oxidation criterion to estimate the TOL.

The extension of the previous model to epoxy/carbon composites involves the generalization of Eq. 1 in the 3D domain, considering the anisotropy of the composite. For this, we define the coordinate vector $\boldsymbol{x} = [x, y, z]$ corresponding to the three orthonormal directions in space. The diffusion/reaction coupling is therefore described according to the following equation (Eq. 4):

$$\frac{dC(\boldsymbol{x},t)}{dt} = \boldsymbol{\nabla} \cdot (\boldsymbol{D}(\boldsymbol{x}) \cdot \boldsymbol{\nabla C}(\boldsymbol{x},\boldsymbol{t})) + r_{UD}(C(\boldsymbol{x},t)) \quad \text{(Eq. 4)}$$

$\boldsymbol{D}$ being the effective anisotropic diffusion tensor (of order 2) and $\boldsymbol{\nabla C}(\boldsymbol{x},t)$ the O_2 concentration gradient. $r_{UD}(C(\boldsymbol{x},t))$ is the homogenized reactive term in the elementary ply of the UD composite. It is assumed that fibers can chemically play a role in oxidation kinetics, leading to a non-negligible mitigation effect. To consider it, $r_{UD}(C(\boldsymbol{x},t))$ can be written as follows to include the stabilizing effect of carbon in the vicinity of the fiber:

$$r_{UD}(C) = 2r_0 \frac{\beta^* C}{1+\beta^* C}\left(\frac{1-\varphi}{1+\varphi/2} - \frac{(1-\varphi)^2}{2}\frac{\beta^* C}{1+\beta^* C}\right)\left(\frac{1}{1+be^{-K^* t}}\right)^2 \quad \text{(Eq. 5)}$$

With $\beta^* = \frac{\beta}{1+\varphi/2}$ and $K^* = k_3[PH]\left(\frac{k_{1b}}{k_6}\right)^{\frac{1}{2}}(1-\varphi)^{\frac{1}{2}}\left(\frac{\beta^* C}{1+\beta^* C}\right)^{\frac{1}{2}}$.

$\varphi = \frac{k_C[Carb]}{k_3[PH]}$ is the efficiency of stabilization by carbon which, according to reference [5], would be of the order of 10^{-2} to 10^{-1} for certain carbon/epoxy composites. Note that, in the absence of carbon fiber ($\varphi = 0$), we find the reactive term of the neat resin (Eq. 2).

Since the reactive term $r_{UD}(C(\boldsymbol{x},t))$ is described at the UD composite scale, it is also valid at the homogenized ply scale. The following section describes the method for homogenizing the components of the effective D tensor (homogenized at the UD ply scale) using a representative elementary volume (REV) of the composite microstructure (fiber/interface/matrix) and periodic boundary conditions (PBCs) in O_2 concentration.

2.2 Effective O_2 diffusion based on a homogenization approach

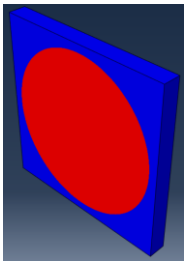
Periodic boundary conditions (PBCs) are commonly used for representative elementary volumes (REVs) to simulate an infinite and repetitive microstructure of the material. The definition of PBCs ensures that the solution obtained for the REV represents the global behavior of the reinforced composite material. In the case of thermo-oxidation, the boundary conditions must ensure the continuity of the field variable (i.e. C) and its flux (q_C) on the opposite faces of the REV [6]. For this, PBCs must accurately capture the behavior of the composite at the macroscopic scale while resolving the interactions at the REV scale, in particular for the diffusive term affecting the fibers, matrix, and interfaces.

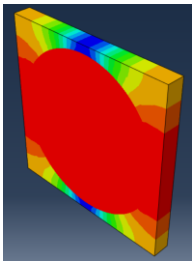
To apply PBCs in C, it is necessary to define a series of equations such that the difference of C between 2 paired nodes is imposed and equal to the macroscopic gradient of C $\boldsymbol{\nabla C}$. As an example, considering the direction d (*e.g.*, x, y, z) of the REV domain, the equation for paired nodes i and j on opposite faces A and B and distanced Δl_d is:

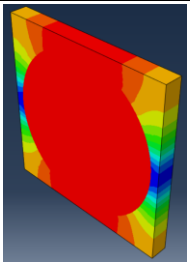
$$C_{j_{|B}} - C_{i_{|A}} = \nabla_d C \, \Delta l_d = \Delta C \quad (6)$$

With $C_{i_{|A}}$ and $C_{j_{|B}}$ the concentrations at nodes i and j, and $\nabla_d C = \Delta C / \Delta l_d$ the imposed concentration gradient, giving rise to a concentration difference ΔC across the distance between opposite faces Δl_d of the REV in the d direction. The PBCs impose a flow periodicity such that:

$$\boldsymbol{q_C}(\boldsymbol{x})_{|\boldsymbol{B}} = \boldsymbol{q_C}(\boldsymbol{x})_{|\boldsymbol{A}} = -\boldsymbol{D}\frac{\Delta C}{\Delta l_d} \quad (7)$$







The calculation of the three main components (D_{xx}, D_{yy}, D_{zz}) of the tensor $\boldsymbol{D}$ requires the performance of 3 calculations by imposing the concentration gradient between each pair of opposite surfaces according to the x, y and z directions. For each direction d, we can write:

$$D_{dd} = \frac{\langle q_{c_d} \rangle}{\Delta C / \Delta l_d} \quad (8)$$

$\langle q_{c_d} \rangle$ representing the mean flux within the whole REV volume. The three diffusion components are equivalent to D_{11}, D_{22}, D_{33} in the three principal directions of the UD composite. Table 1 gives the values of the diffusion coefficients of the constituents used for the calculation of the $\boldsymbol{D}$ tensor for two different composites exposed to a temperature of 180°C in air: (a) a simplified epoxy/carbon composite (without fiber/matrix interface) with a fiber volume ratio of $V_f = 0.65$, and (b) an idealized composite (with fiber/matrix interface) with an interphase thickness $h^{interface} = 0.15\ \mu m$. It is important to point out that this is a completely realistic interphase thickness, roughly corresponding to the average value of interphase thicknesses reported in the literature for thermosetting matrix composites. The calculations were carried out with Abaqus software. Table 2 shows a synthesis of the results obtained numerically and compared to several analytical laws proposed in the literature [7].

D_{xx}	$2.88\ 10^{-10}$	D_{yy}	$3.77\ 10^{-11}$	D_{zz}	$3.77\ 10^{-11}$

Table 2. Results of diffusion coefficients [m^2/s] from calculations in the REV with PBCs.

The results obtained clearly highlight the significant effect of the interface on the effective diffusion coefficient, particularly in the longitudinal direction. As often reported in the literature, the fiber/matrix interface of an epoxy matrix composite would be in a rubbery state at the exposure temperature of the composite. Consequently, the oxidation kinetics of the composites described by Eq. 2 must consider this influence of the interface. The following section presents a comparison of numerical simulations of oxidation gradients as well as a confrontation with the TOLs measured experimentally in literature studies.

3 NUMERICAL RESULTS AND COMPARISON WITH EXPERIMENTAL TESTS

Solving the 3D problem presented in Section 2.1 gives access to the evolution of the O_2 concentration gradient $C(\boldsymbol{x}, t)$ in the three directions of the composite frame. Simulations in air at 180°C for an epoxy/carbon composite of type 977-2/IM7 were carried out for the two composites whose effective diffusion tensor was calculated in Section 2.2: (a) a fiber/matrix composite and (b) a fiber/interface/matrix composite. For each composite, 3 configurations are simulated in order to highlight the oxidation kinetics in each direction: (i) 1 – fiber direction, (ii) 2 – direction transverse to the fibers and (iii) 3 – out-of-plane direction to the fibers.

A criterion was defined for the calculation of the TOL in each direction, as already proposed for neat resin samples [3]. In the case of UD composites, the O_2 consumption gradients ($Q(\boldsymbol{x}, t)$) are calculated by integrating over time $r_{UD}(C)$, given by Eq. 5. Thus, it is possible to estimate the evolution of the TOL for each of the studied directions (1, 2 and 3). Figure 4 shows the evolution of the TOL for the two types of composites studied: (a) with perfect fiber/matrix interface (i.e. no interface in the modeling) and (b) with idealized fiber/matrix interface (*i.e.*, modeled interphase and assumed to be in a rubbery state). These results were compared with experimental measurements [2], highlighting: (i) the anisotropy of the thermo-oxidation problem of UD composites and (ii) the importance of considering, in the proposed model, the predominant effect of the interphase on the evolution of the TOL, particularly in the longitudinal direction (1 – fiber direction).

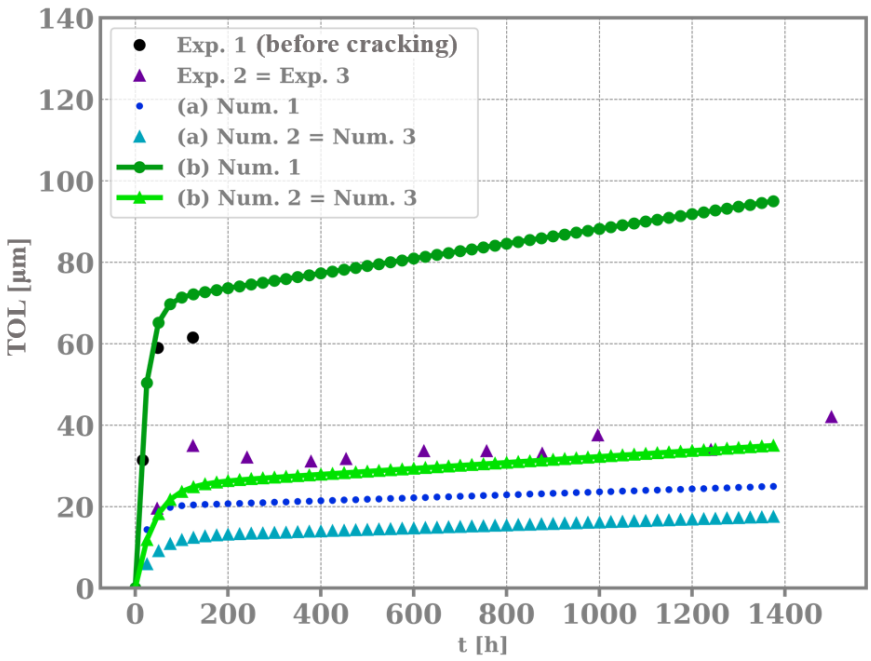

Figure 4. Comparison of experimental TOLs (black circles and purple triangles for directions 1, 2 and 3 which are denoted Exp. 1, Exp. 2 = Exp. 3, respectively) to numerical simulations for: (a) fiber/matrix composite (Num. 1 and Num. 2 = Num. 3) and (b) fiber/interface/matrix composite (Num. 1 and Num. 2 = Num. 3).

4 CONCLUSIONS AND PERSPECTIVES

A FEM-based model considering the specificities of the diffusion/reaction behavior of UD composites was proposed to describe their thermo-oxidation gradients: the stabilizing effect of carbon fiber and the anisotropic diffusion of O_2 accentuated by a fiber/matrix interphase, assumed in the rubbery state. The reactive term describing the oxidation kinetics at the UD scale has been adapted from neat resin kinetics in order to include a mitigation effect on the oxidation rate induced by the presence of fibers. Diffusion tensor homogenization calculations clearly show the significant effect of the interphase, which was numerically represented by a finite interface at the REV scale. The faster O_2 diffusion in the interphase results in an increase of the effective diffusion coefficient at the UD scale of the order of $< 10^1$ in the transverse directions 2 and 3, and of $> 10^2$ in the longitudinal direction to the fibers 1, directly impacting the TOL values. The comparison of numerical simulations with experimental data allowed to discuss and verify the hypotheses of the literature [2,6] on the non-negligible effect of the interphase, particularly in direction 1.

Future work will focus on other key aspects aimed at completing the general approach to predicting lifetime of composite under thermal aging:

(i) the experimental validation of the kinetic evolution laws of physicochemical properties (*e.g.*, r_{UD}, $\boldsymbol{D}$),

(ii) the evolution of thermomechanical properties of interest for the aeronautical field (*i.e.*, T_g and elastic properties) and,

(iii) the integration of these laws into the calculation code to access the gradients of stresses and deformations induced by oxidation, to predict the initiation, then the propagation of cracks in composites.

These steps are necessary to further investigate the coupling between damage and oxidation through a generalized approach in order to predict the lifespan of composite parts based on accurate material thermo-chemo-mechanical degradation criteria.

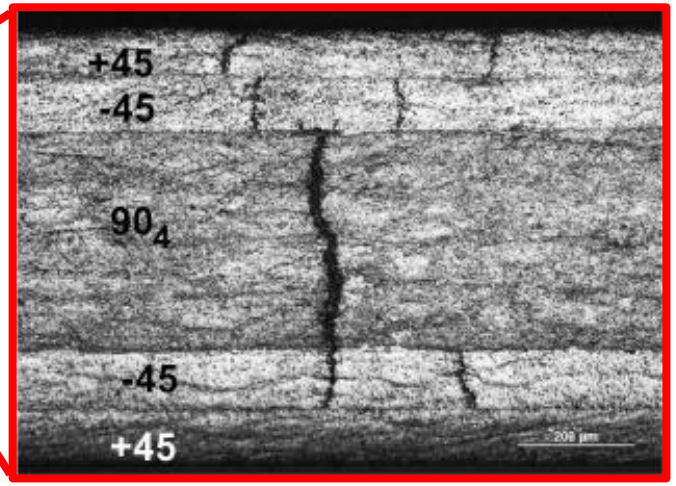
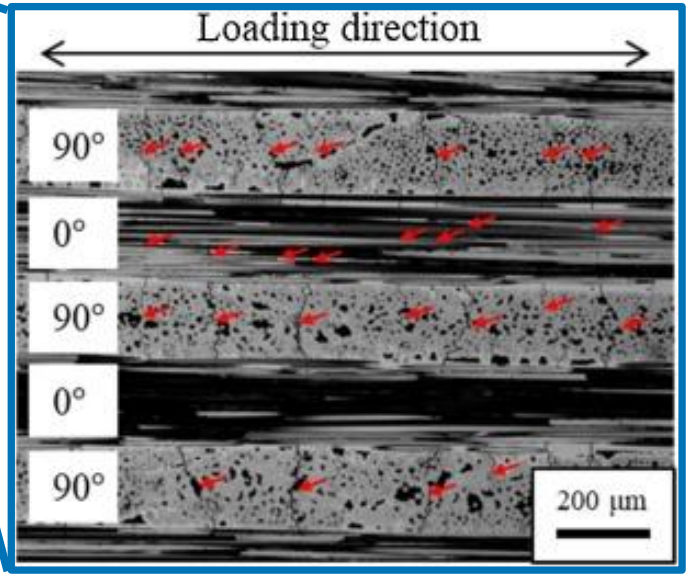
Abstract



Fiber-reinforced composites are essential in the aerospace industry, highlighting the need for an in-depth understanding of their durability. This study introduces a novel approach that integrates viscoelasticity and damage evolution based on continuum damage mechanics, employing finite element analysis. The method utilizes an anisotropic viscoelastic constitutive law to examine creep behavior under constant stress, decomposing stresses into equilibrium and non-equilibrium components. Moreover, it integrates a transverse crack damage variable associated with crack density. After solving stiffness equations, a detailed analysis of transverse crack propagation is conducted. This technique was applied to creep tests on carbon fiber-reinforced plastics and 3D woven ceramic matrix composites, resulting in strain and crack density profiles. The numerical simulations successfully reproduced experimental outcomes. The developed method offers a comprehensive tool for analyzing transverse crack propagation under viscoelastic creep conditions through finite element analysis, significantly enhancing design considerations by incorporating aspects of long-term durability.

Background



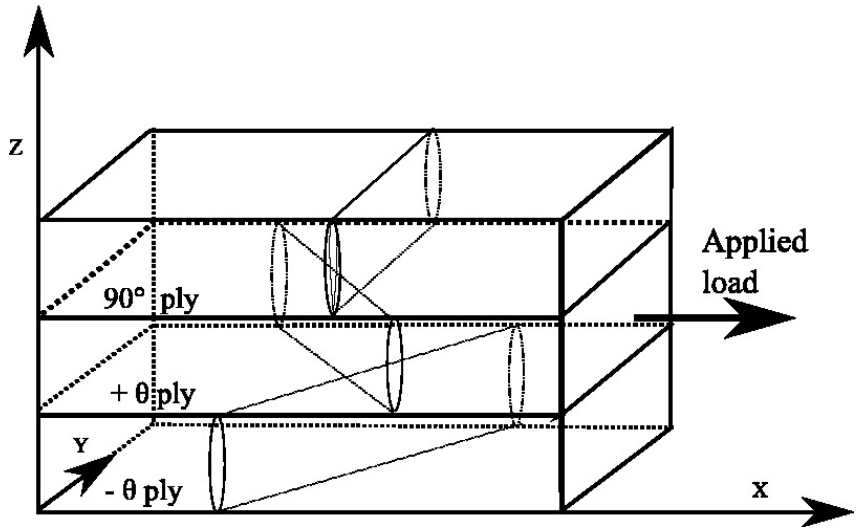
CFRP fan blades

CFRP laminate[2].

Turbine blades crafted by CMCs

Creep tests cause the transverse cracks in CMCs [3].

Applications of PMCs and CMCs in GE9X [1]



1. High bypassing (larger size)
   - ➢CFRP fan blades/case
2. Improvement in combustion efficiency
   - ➢CMC turbine blades

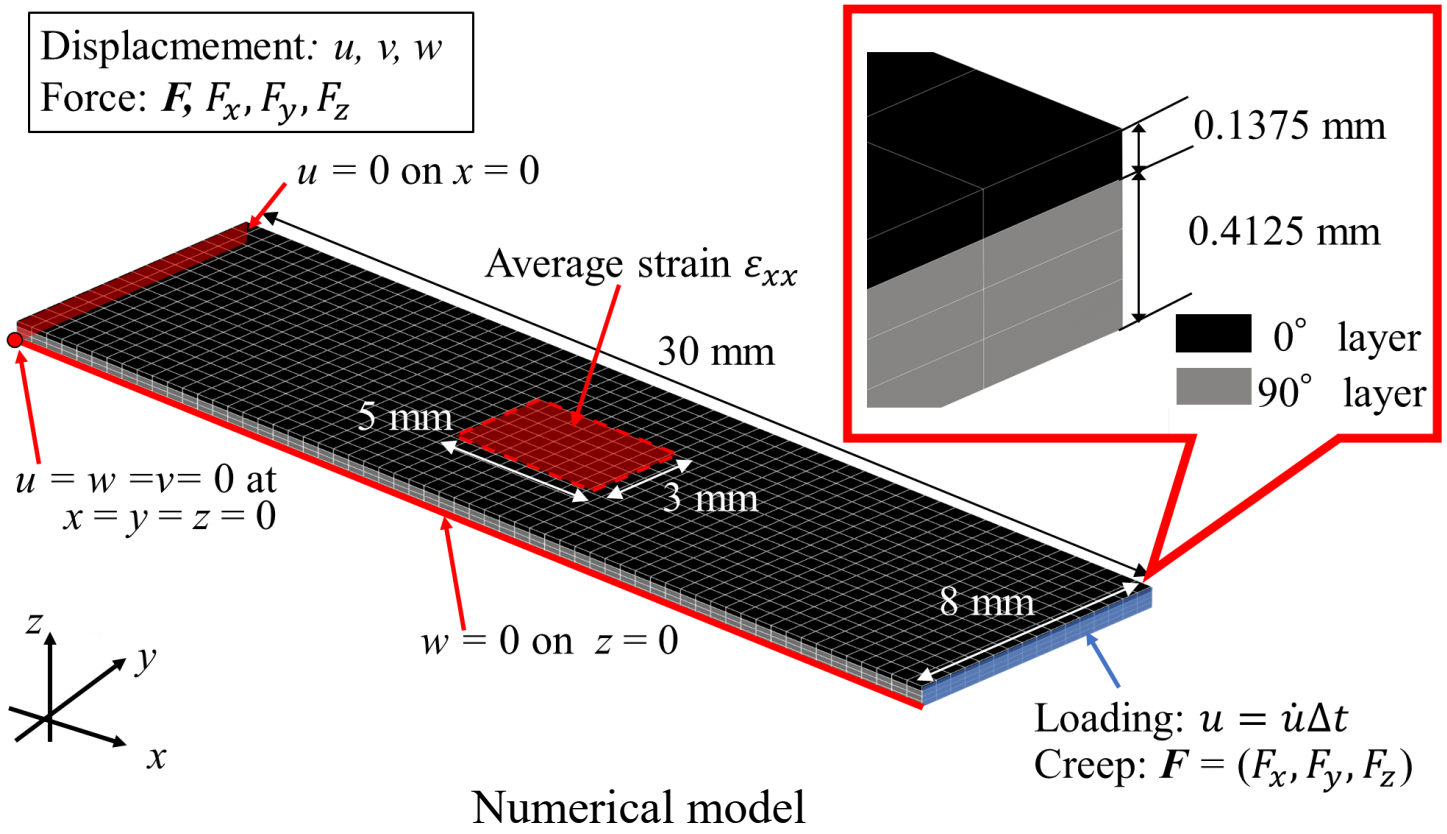
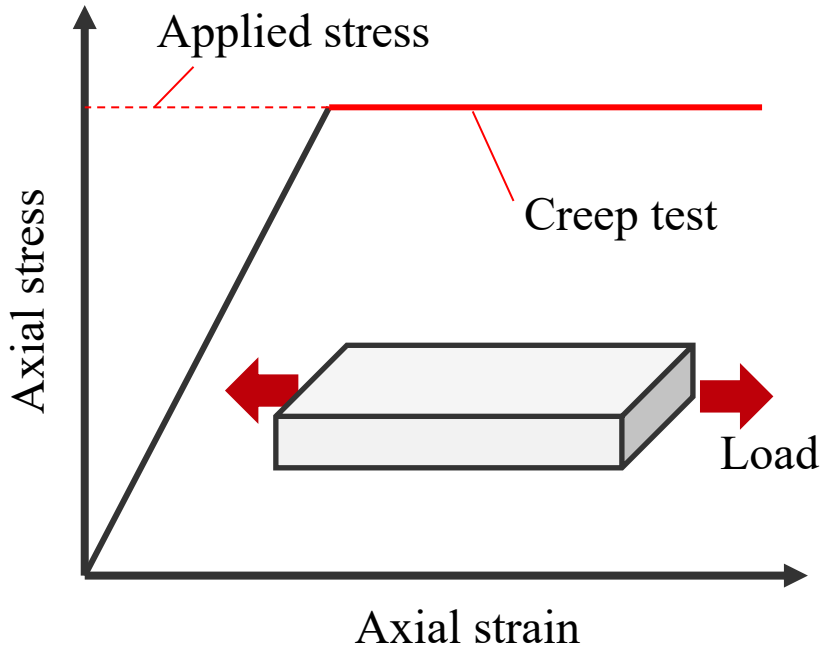
Numerical procedure :

Transverse cracking :



➢ Evaluate the crack density of each element.

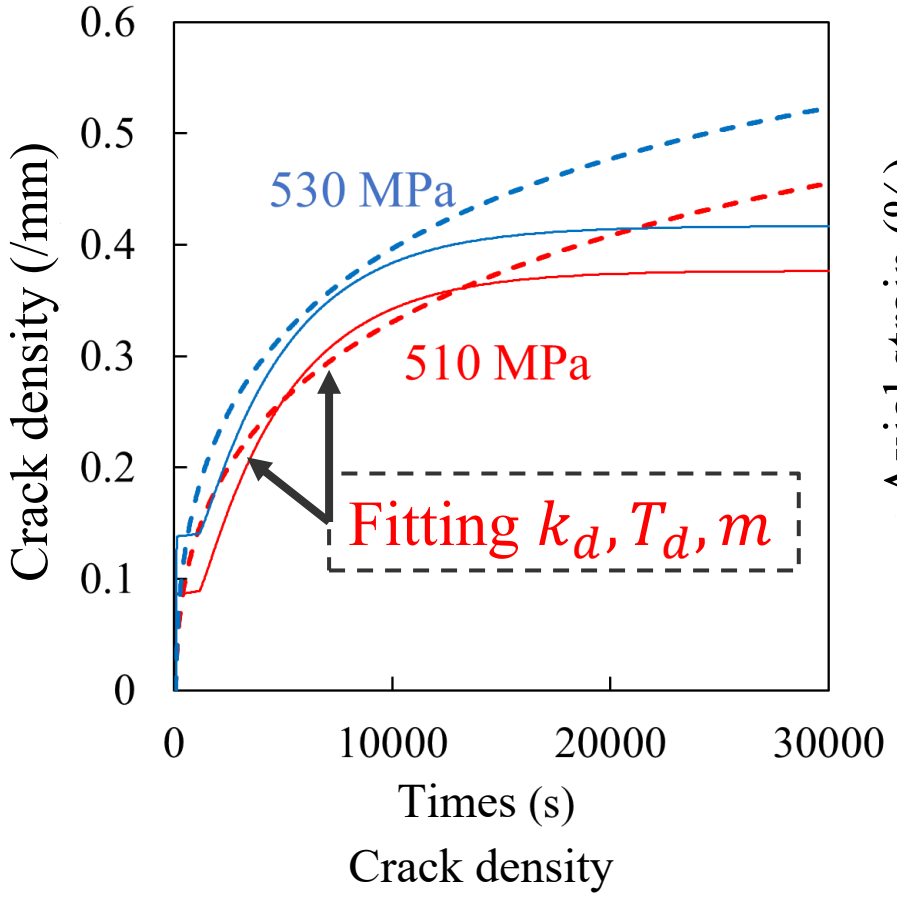


Viscoelasticity: implicit

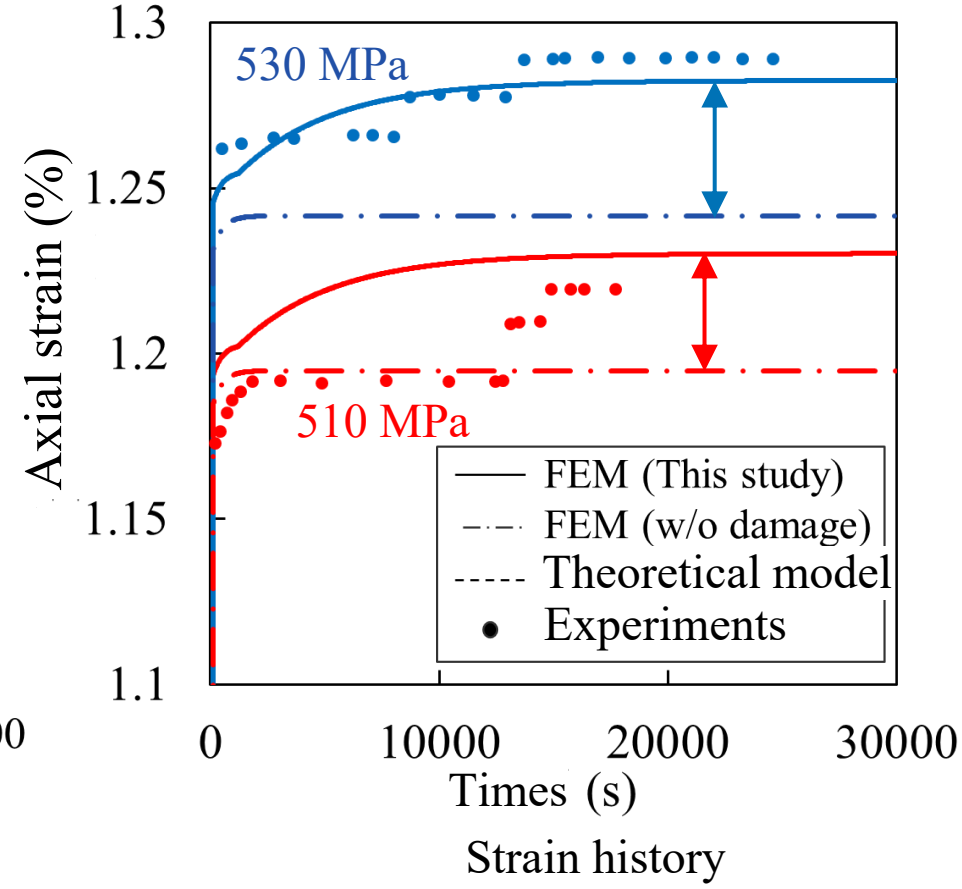
Transverse cracking: explicit.

Validation analysis: CFRP(T800H/#3631)

Numerical model



- ✓ CFRP-Cross-ply laminate ($[0/90_3]_s$)
- ✓ Viscoelasticity : Applied in the transverse direction to the fiber
- ✓ Applied stress : 510 MPa, 530 MPa

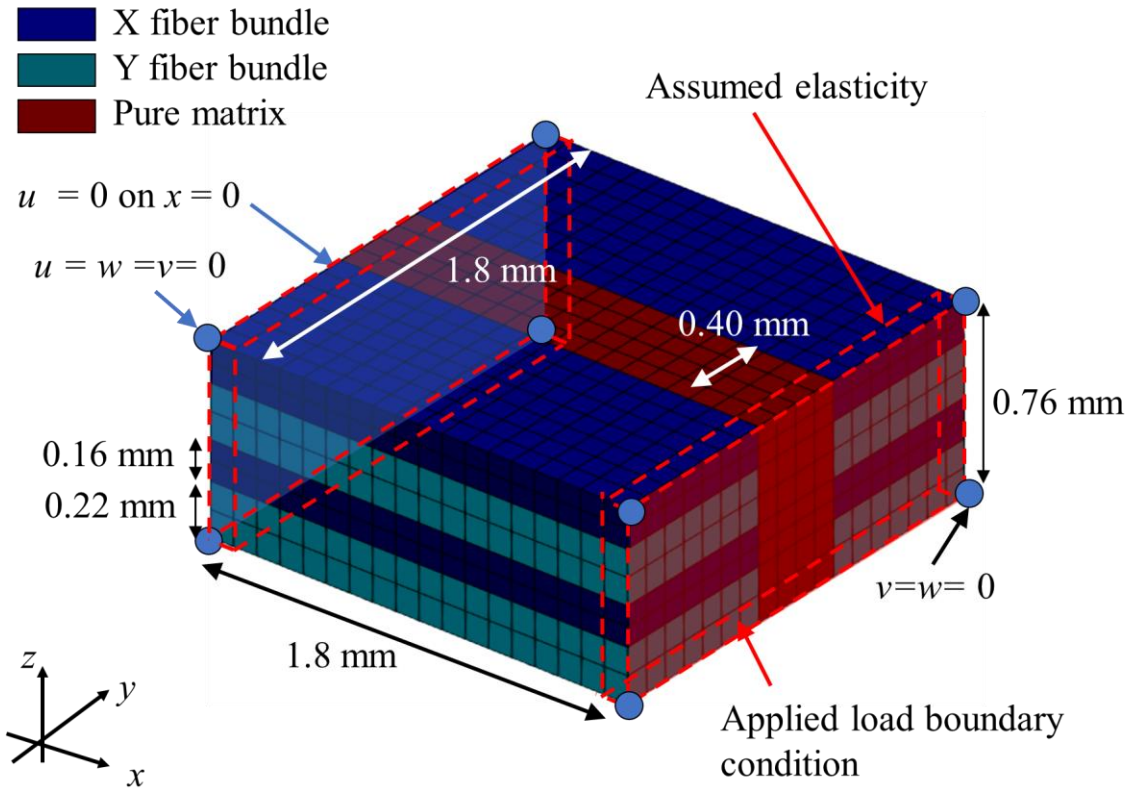


- ✓ Strain-history : Element average of model center.
- ✓ Transverse crack density : Average value of 90° layer elements

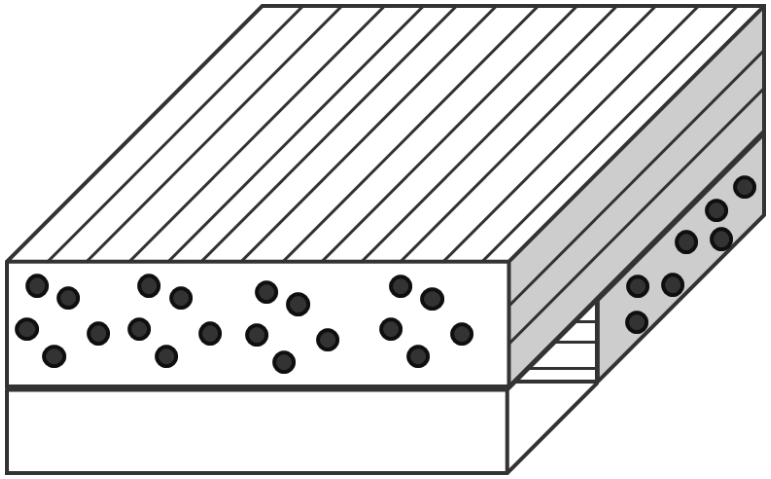
[1] Ogi and Takao, *Advanced Composite Materials,* 2001.

Validation analysis: CFRP(T800H/#3631)

Crack density



Strain history

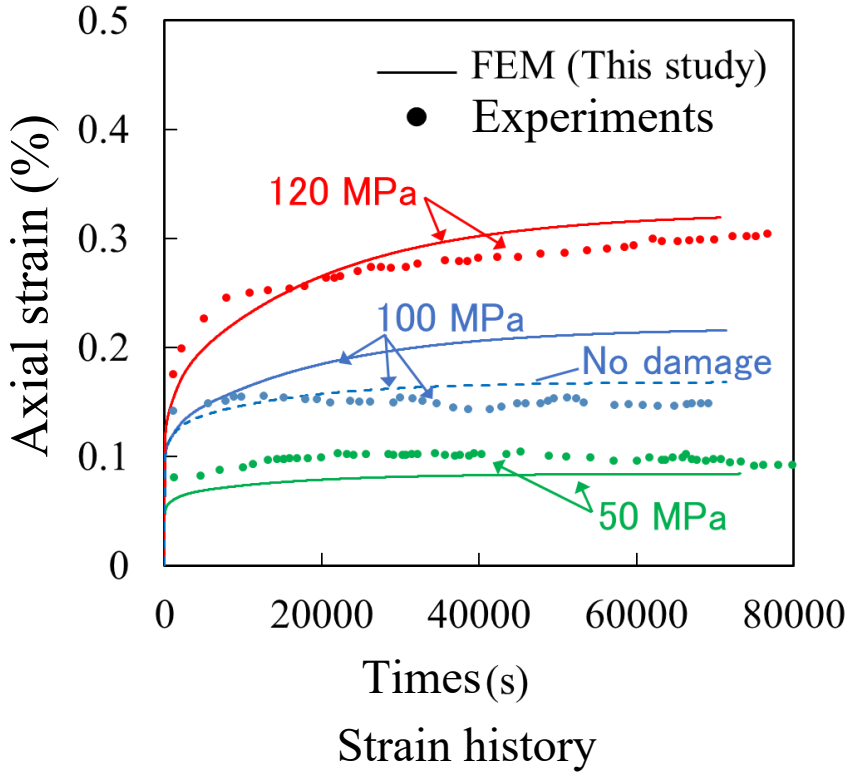


- ✓ Determine stress criterion parameters k_d, T_d, and m using crack density history [1].
  - ➢ Good reproduction of strain history of test results
- ✓ Only viscoelasticity model deviates from experimental results
  - ➢ Contribution of time-dependent damage is significant.

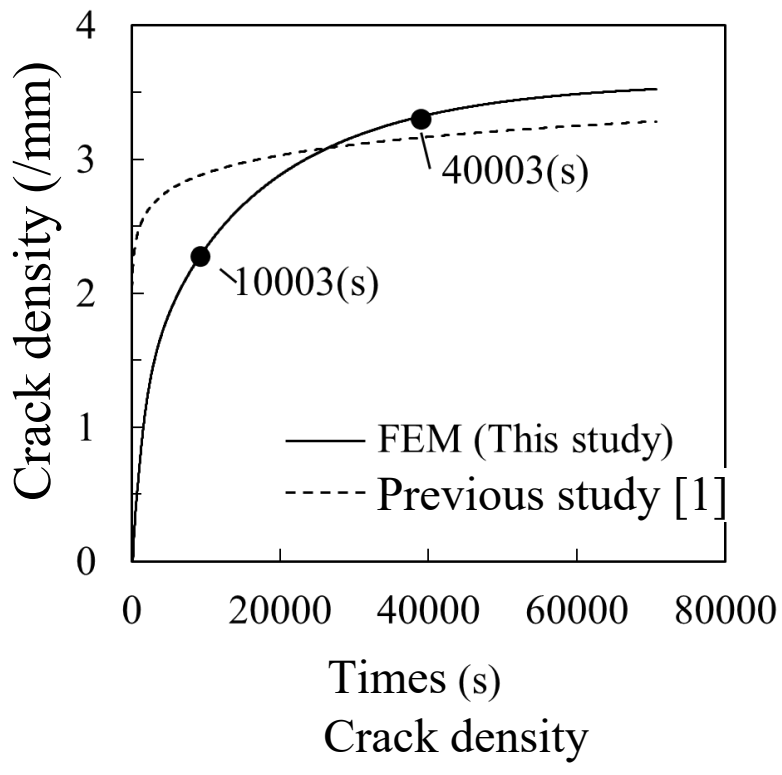
[1] Ogi and Takao, *Advanced Composite Materials,* 2001.

Validation analysis: CMC

Numerical model



CMC mosaic model [1]

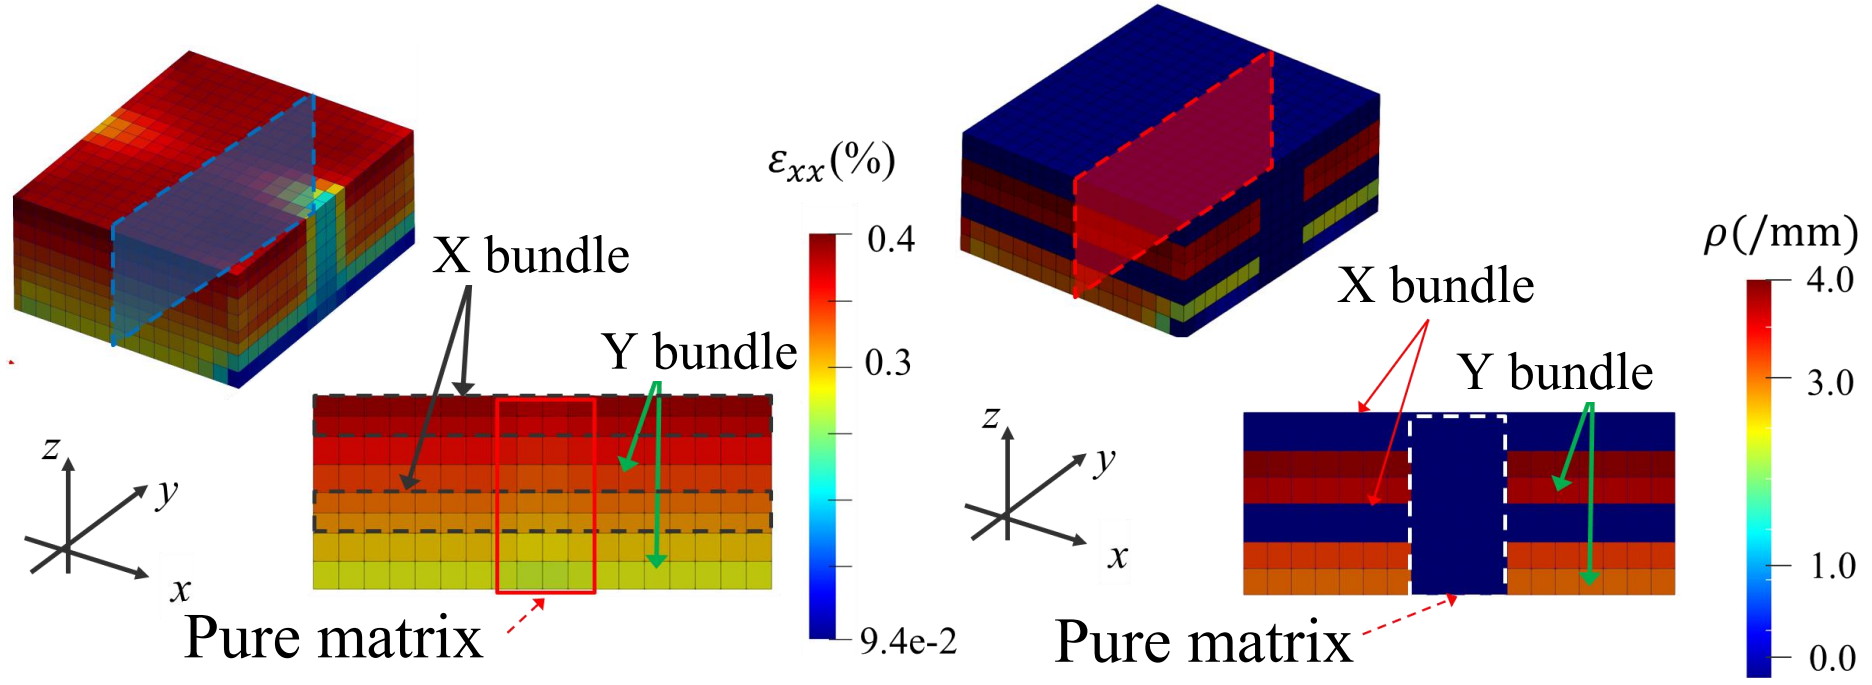


- ✓ Orthogonal woven fabric of CMC [1]
- ✓ Mosaic model consisting of X, Y fiber bundles, pure matrix [1]
- ✓ Viscoelasticity : Applied in fiber direction
- ✓ Strain history : Calculated from unit cell model load direction displacement
- ✓ Crack density : Elements average of Y fiber bundle

[1] Ikarashi Y. et al., *Journal of the European Ceramic Society*, 2020.

Validation analysis: CMC

Strain history



Crack density

- ✓ Consistent with the crack estimation curve in previous study [1] (w/o time dependency damage , k_d=1)
- ➢ Damage to fiber bundle Y is accelerated by relaxation of fiber bundle X.
- ✓ Load strain history at 100 MPa deviates from experiment
- ➢ Consistent with experimental results when assuming no damage

[1] Ikarashi Y. et al., *Journal of the European Ceramic Society*, 2020.

Validation analysis: CMC

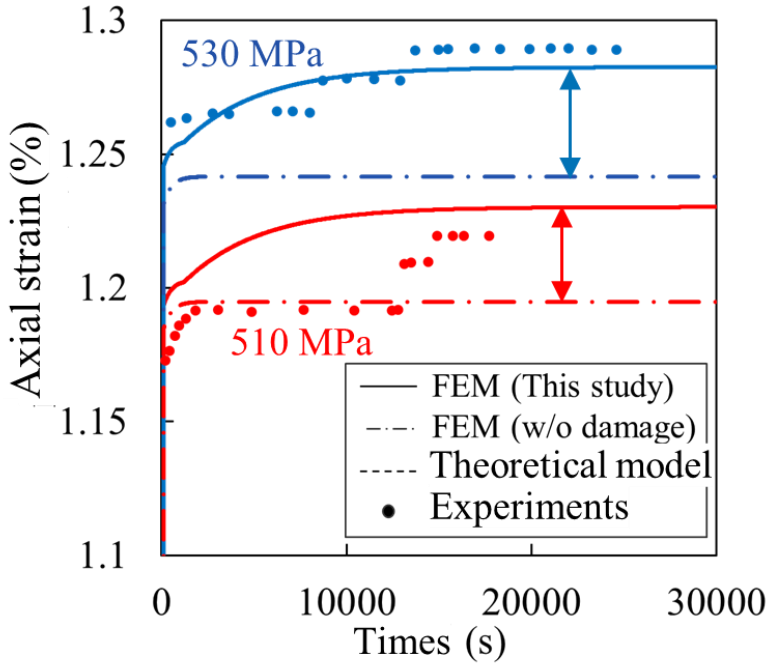
➢ Strain/damage distribution plotted at 120 MPa, creep test 40003 (s) elapsed

Longitudinal strain

Damage distribution

✓ Stronger strain and damage distribution occurs in fiber bundle Y surrounded by fiber bundle X.

➢Damage to fiber bundle Y increases due to stress relaxation caused by the viscoelasticity of fiber bundle X.



➢Creep damage mechanism of fabric CMC at the microscale is reproduced.

Summary

Development of a Quantitative Evaluation Method for Transverse Cracks in Fiber-Reinforced Composites Using FEM

- Anisotropic viscoelastic constitutive laws and a time-dependent transverse crack propagation model were implemented into the FEM.
- The method was validated through creep tests of CFRP and CMC, showing good agreement in both crack density and creep deformation.
- This study enables damage evaluation of 90° plies under creep loading using crack density.

➢Combined with fiber-direction damage and delamination models, it supports long-term durability assessment.

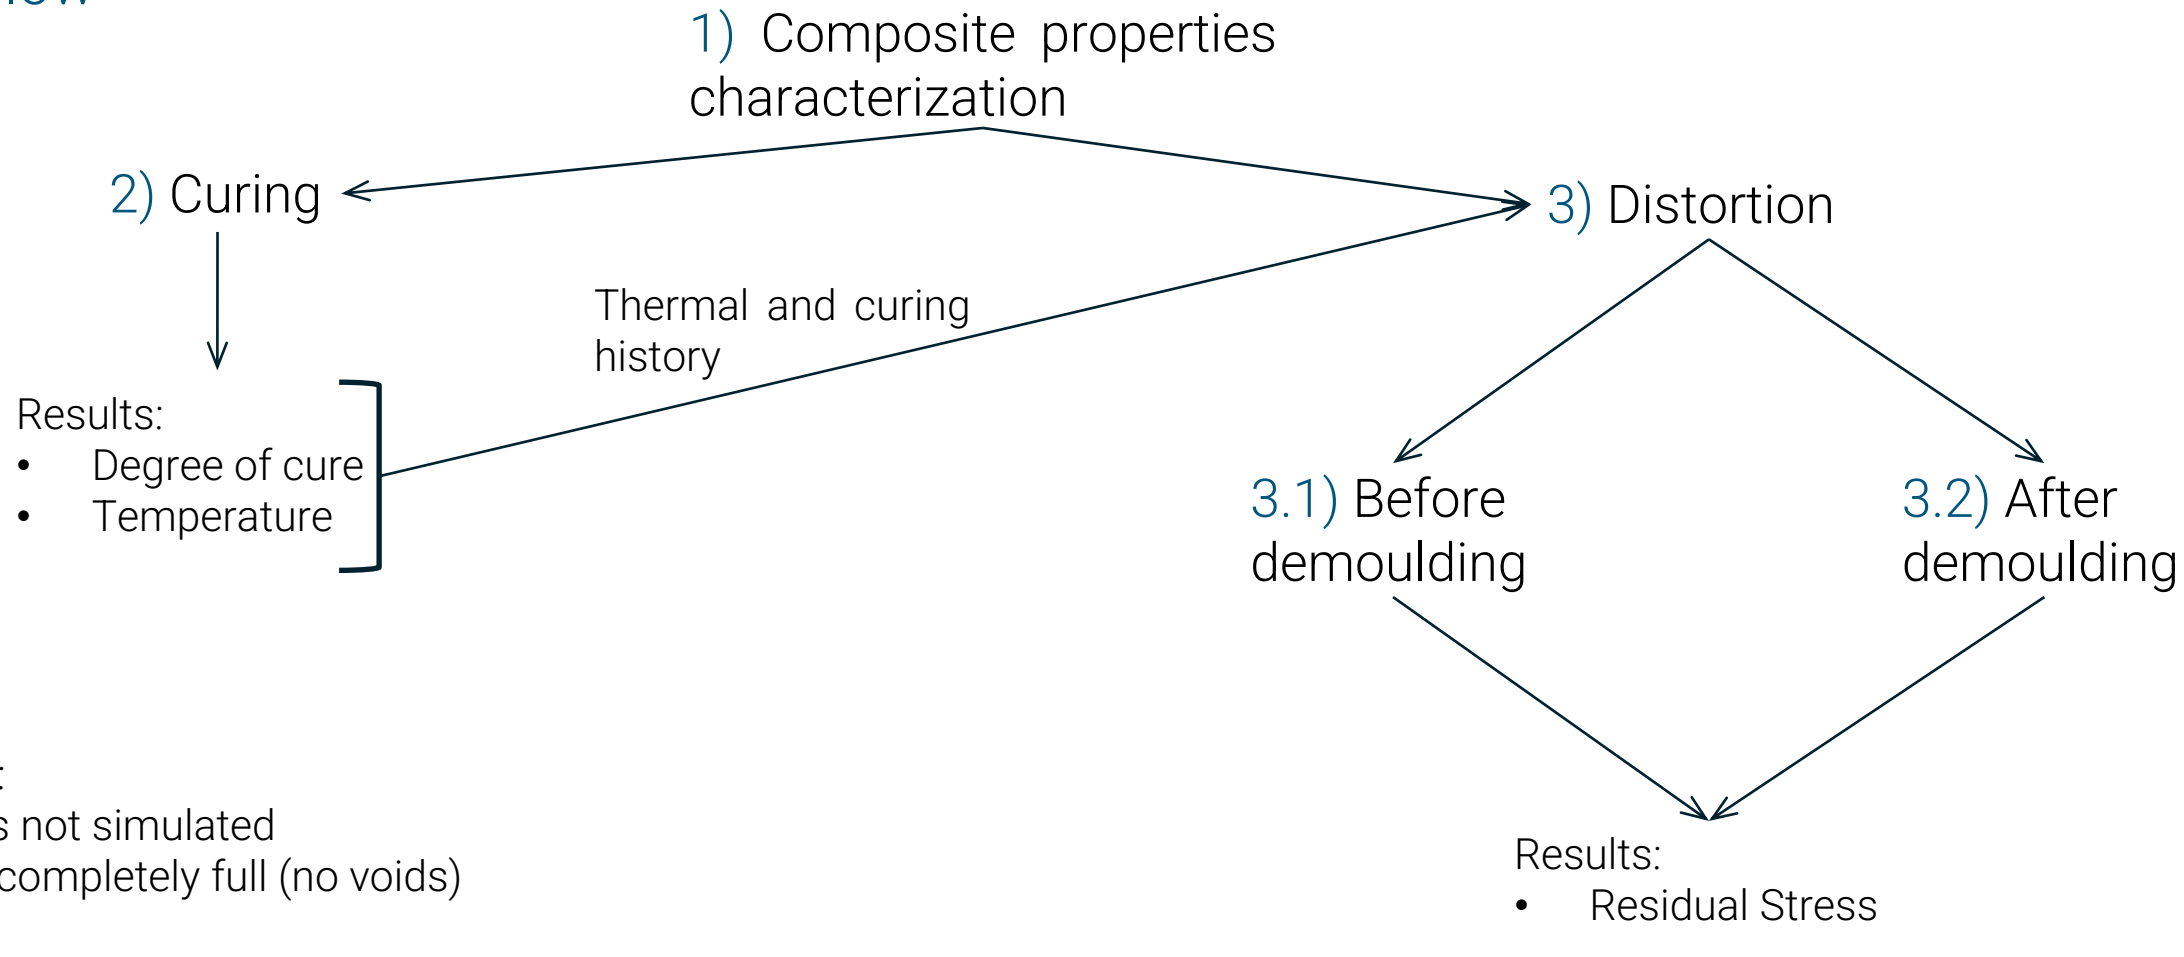
Conclusions

Introduction

- Traditionally, sanitary ware and kitchen counter tops are produced with ceramics and stone.

- Nowadays, solid surface composites are used as substitutes
  - thermoset resins filled with high percentage of mineral particles

- These thermoset resins are highly reactive, which makes the process control difficult due to the high temperature generated by the exothermic curing reaction. This intrinsic characteristic of the composite can lead to the development of residual stresses an strains, which should be minimized to assure an optimal structural behaviour of the products.



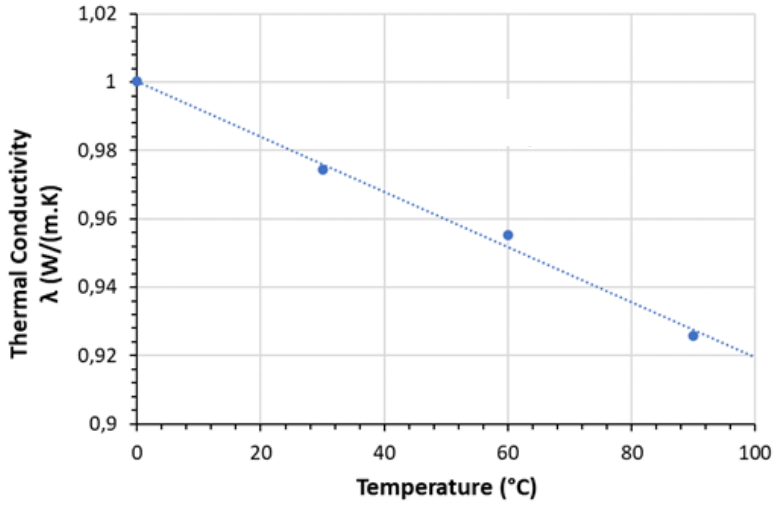
Objectives

- Predict stresses originated by the production process.
- Optimize the production process focusing on the stresses developed.

Numerical Approach

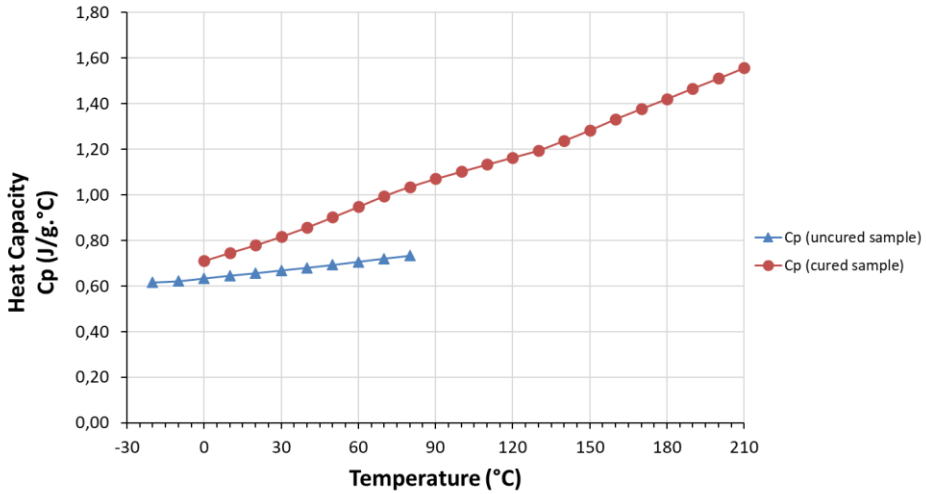
Composite:
- ≈27% of Thermoset resin (polyester based)
- ≈73% of mineral Fillers (particles)

Workflow



Assumptions:
- Casting is not simulated
- Mould is completely full (no voids)

Composite properties characterization

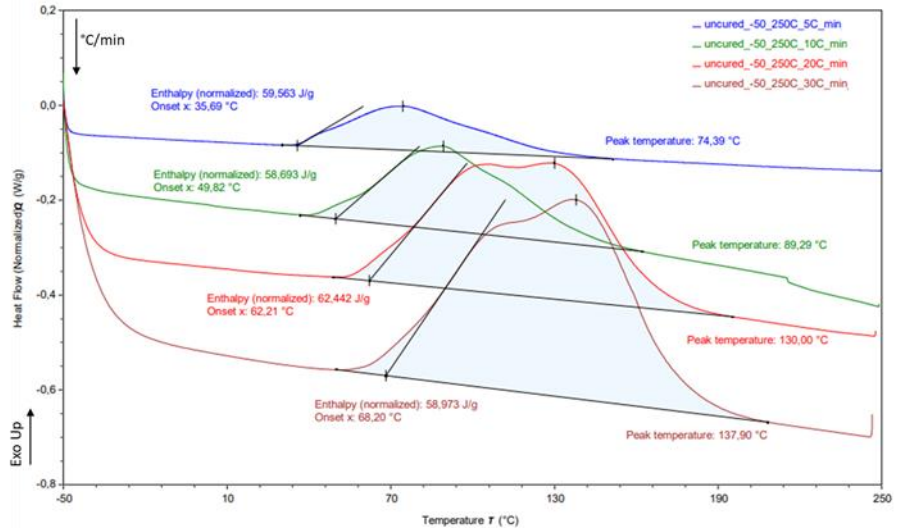


Thermal Conductivity

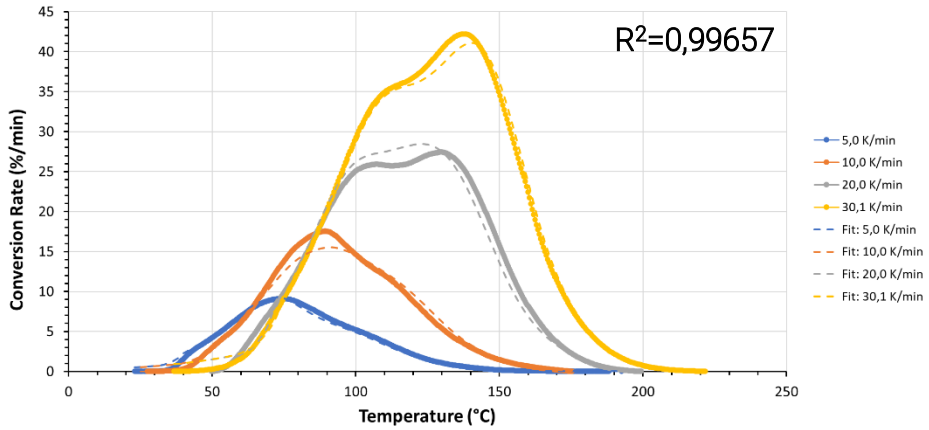
- MDSC (ASTM E1952)
- Isothermal runs (between 0°C and 90°C)
- Calibration material: polystyrene
- Specimen completely cured (with different thicknesses)
- λ = f(T)

Specific Heat

- DSC (ISO 11357-4)
- Dynamic runs (from -50°C to 220°C at 10°C/min): blank, synthetic sapphire and material
- Specimen uncured (no catalyst) and completely cured
- Cp = f (T)



Composite properties characterization

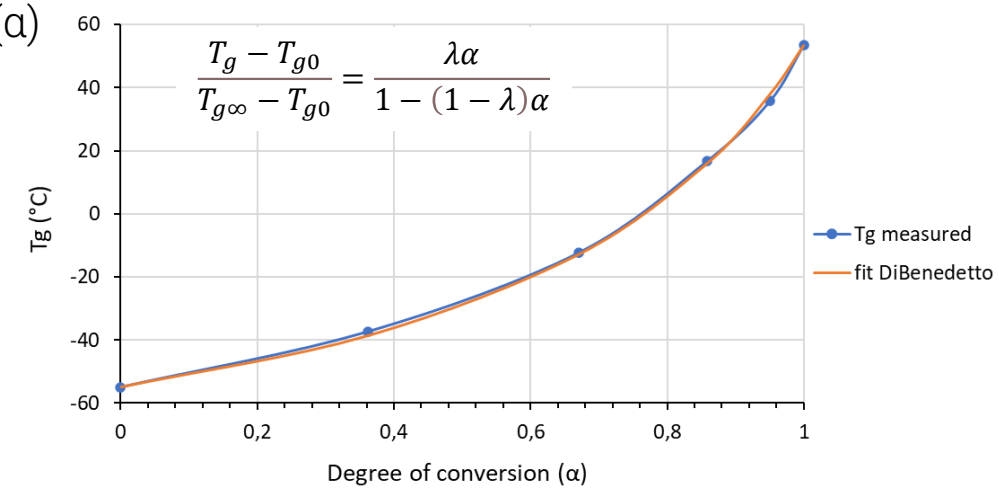


Curing Kinetics and Enthalpy

- DSC
- Dynamic runs (between -50°C and 250°C at different heating rates 5, 10, 20 and 30°C/min.)
- Specimen uncured
- Enthalpy = constant
- Friedman method (differential isoconversional method):

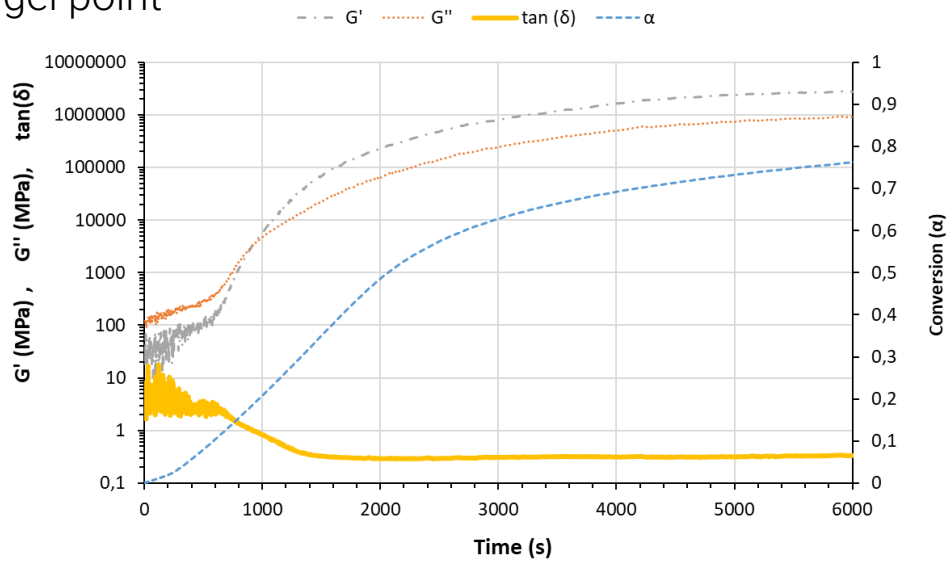
$$ln\left(\frac{d\alpha}{dt}\right)_{\alpha} = ln\left(k(T).f(\alpha)\right) = \ln\left(A_{\alpha}.f(\alpha)\right) - \frac{E_{a\,\alpha}}{RT_{\alpha}}$$

  - Model free (reaction model, f(α), unnecessary)
  - Accounts for activation energy (Ea) dependency on conversion



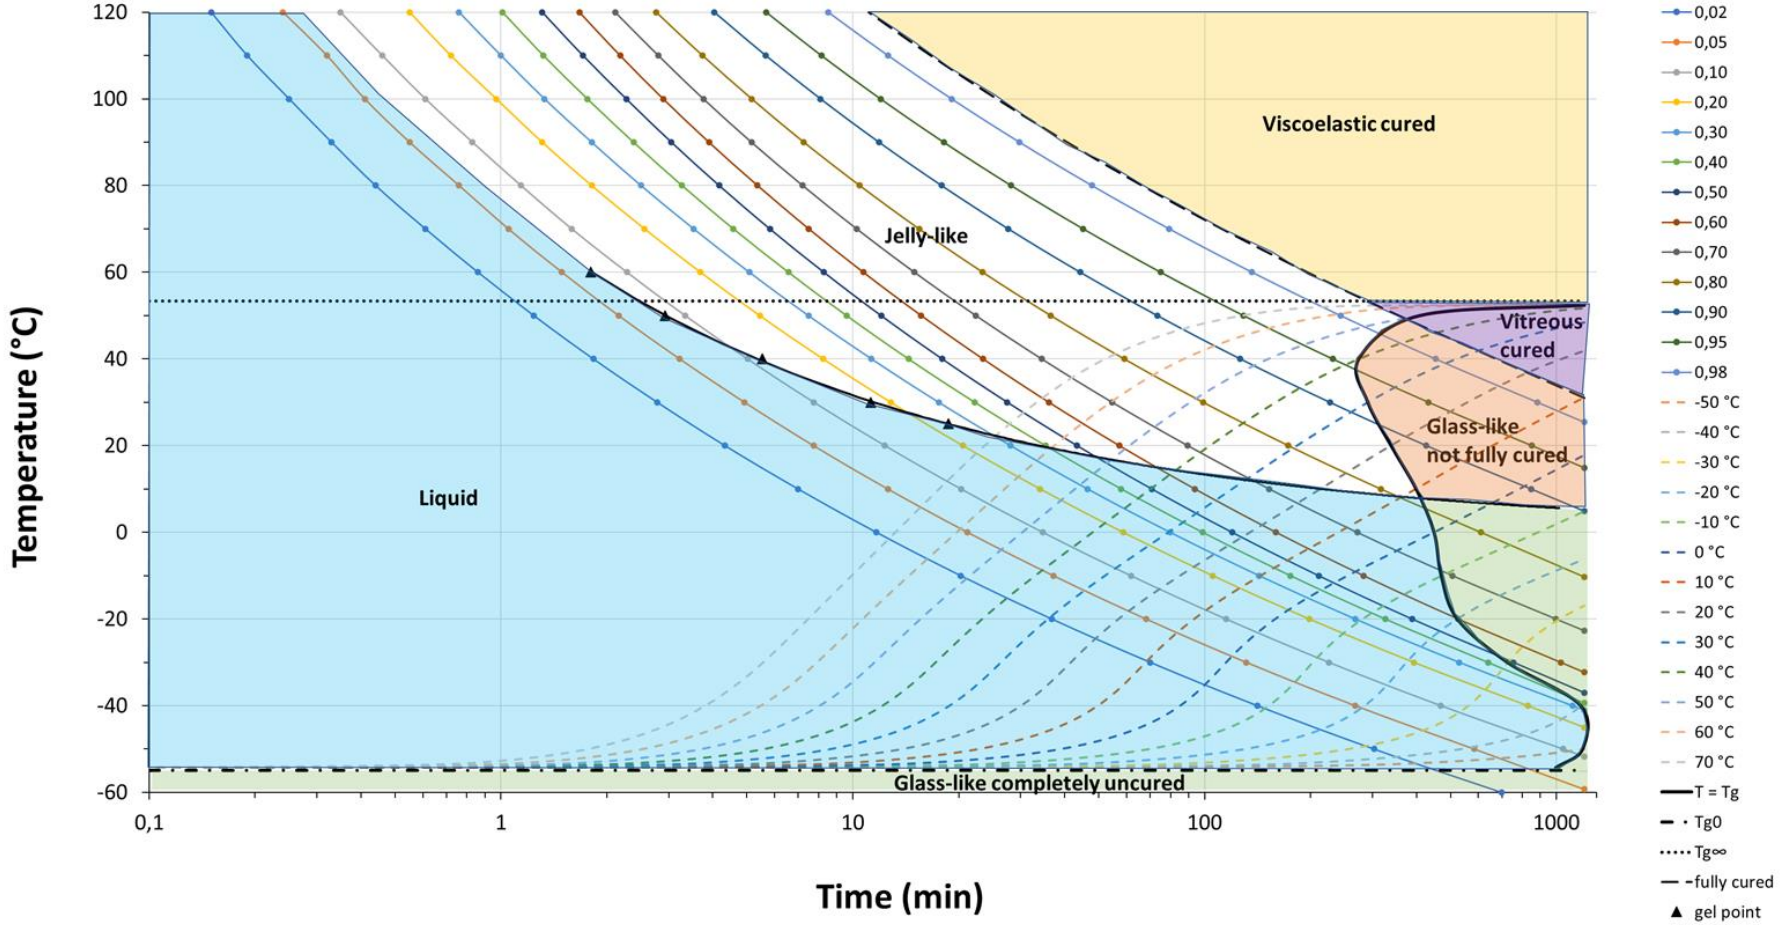
Composite properties characterization

Glass Transition temperatures



- DSC
- For Tg_0 and Tg_∞: dynamic runs (between -90°C and 250°C at different heating rates)
- For Tg_α: Isothermal run (60°C for different periods of time) followed by dynamic run (between -50°C and 250°C at 5° C/min)
- Specimen uncured (no catalyst), partially cured and cured
- Tg = f(α)

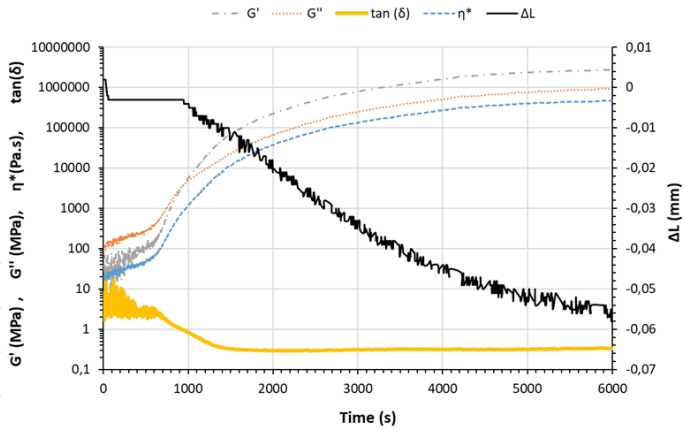
$$\frac{T_g - T_{g0}}{T_{g\infty} - T_{g0}} = \frac{\lambda\alpha}{1-(1-\lambda)\alpha}$$



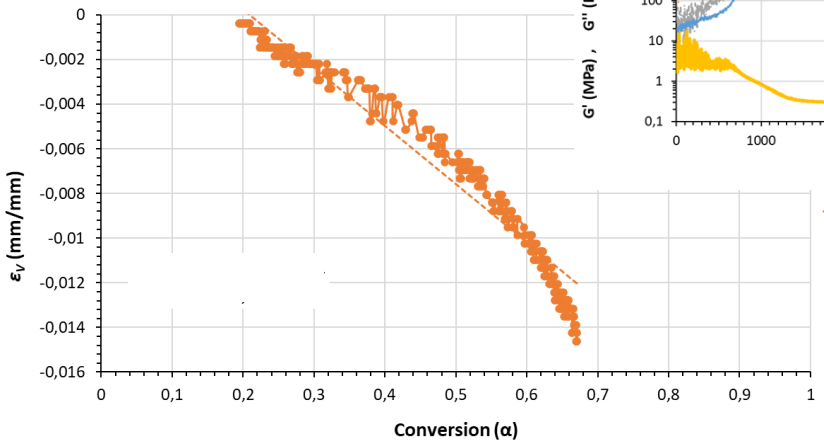
Degree of cure at gelation

- Oscillatory Rheometer (parallel plates) + DSC
- Isothermal runs (between 25°C and 60°C) + Conversion curves
- Specimen uncured
- Criteria: G' and G'' crossover point and tan(δ) = 1
- α at gel point

Composite properties characterization



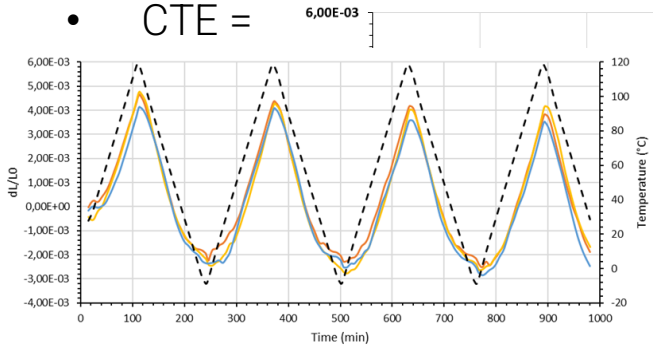
Time – Temperature – Transformation (TTT) Diagram



Composite properties characterization

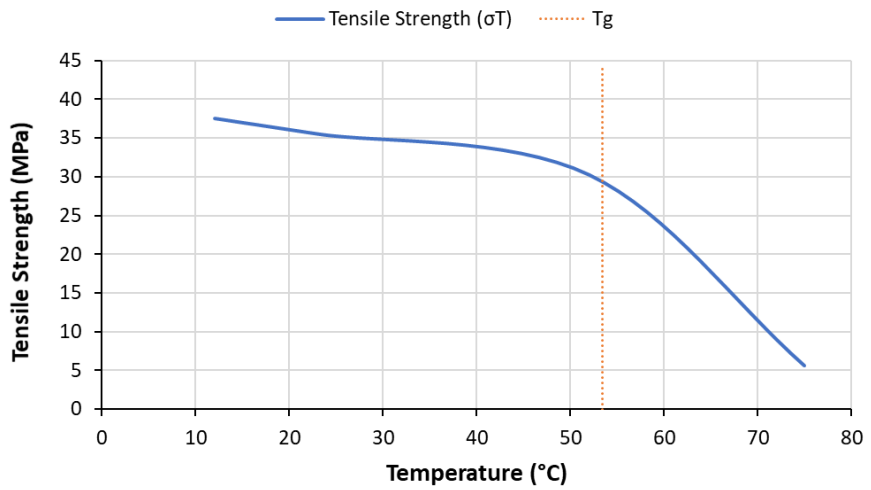
Chemical Shrinkage (CCS)

- Oscillatory Rheometer (parallel plates) + DSC
- Quasi-static isothermal runs (between 25°C and 60°C with 0.0N axial force) + Conversion curves
- Specimen uncured
- ε_V = constant



$$+\frac{1}{3}\left(\frac{h-h_0}{h_0}\right)\Big]^3 - 1$$

Thermal Expansion (CTE)



- DMA
- Quasi-static compression mode, dynamic runs (between -10°C and 120°C at 1°C/min, with 0.0N axial force)
- Specimen completely cured
- CTE =

Composite properties characterization

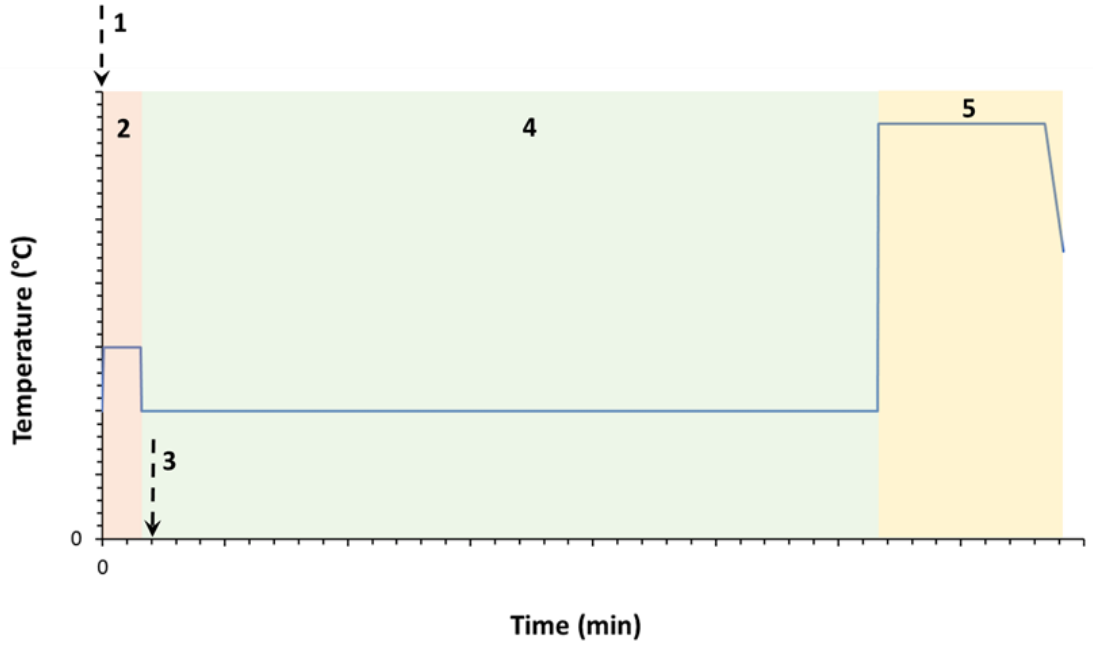
- Tensile test (ASTM D5083) + strain gauge
- Specimen completely cured
- Young Modulus, Poisson coefficient, tensile strength = f(T)

Compression properties

- Compression test (ISO 604)
- Specimen completely cured
- Compression strength = f(T)

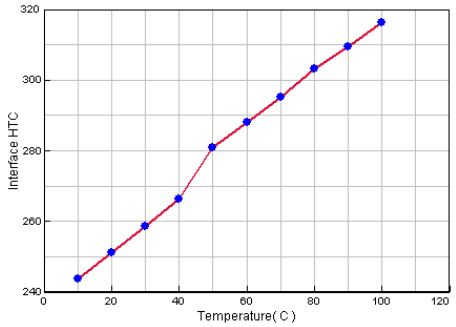


NOTE:

- Standard for sanitary appliances EN 249 requires successive thermal shock cycles of 12°C and 75°C.

Numerical Model

Production cycle



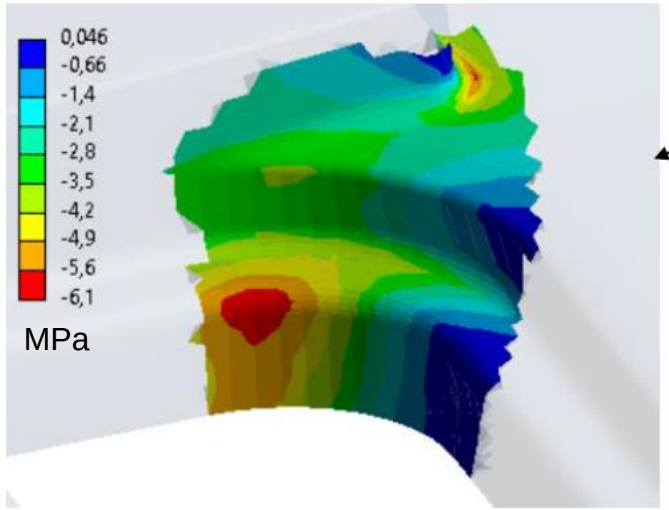
- General production cycle:
  - Casting at room temperature (1)
  - First curing stage (with controlled temperature), up to gel point (before demoulding) (2)
  - Demoulding (3)
    - after 41 min, with rotation of the part and placed on wood like racks
  - Second curing stage with or without post-curing (after demoulding) (4 and/or 5)
- First and second curing stages are varied for optimization

Numerical Model

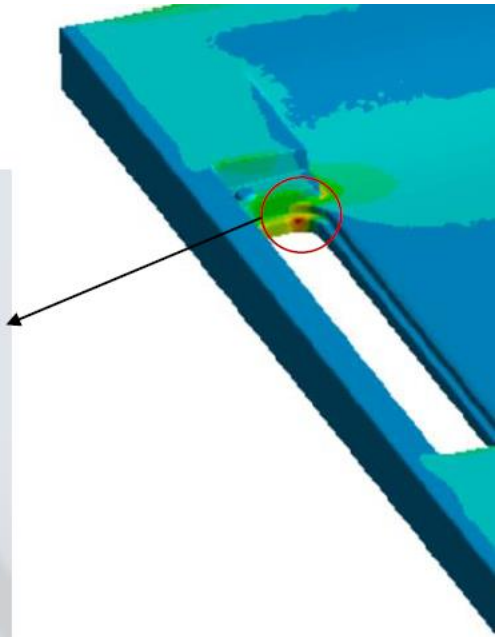
Boundary Conditions, Assumptions and Mesh

- Cavity of mould completely filled (no voids)
- Initial degree of cure: ≈ 0
- Convection coefficient: 10 W/m^{2}K (free convection of air with velocity ≈ 0 m/s, applied to all surfaces of mould and part exposed to air)
- Thermal condition at Interface: variation of HTC (W/m^{2}K) with temperature:

- Temperature cycle applied on surfaces exposed to air

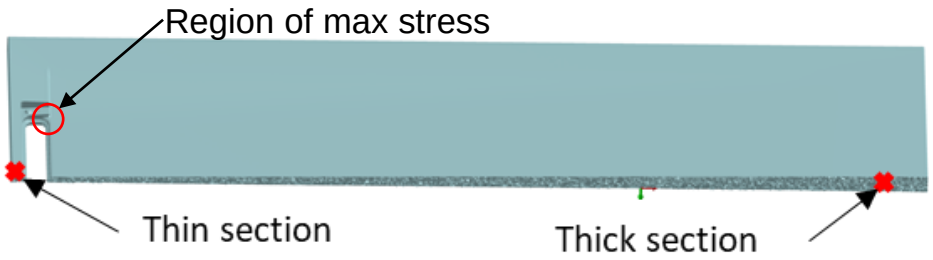


- Initial temperature: 20°C (mould) and 30°C (composite)
- Demoulding at 41 min
- Rotation of the part
- Convection through wood board: 2.5 W/m^{2}K
- Before demoulding Locking condition: contact interface between mould and composite
- After demoulding Locking condition: isostactic (rigid body motion locked)
- Effect of gravity: 9.81 m/s^2



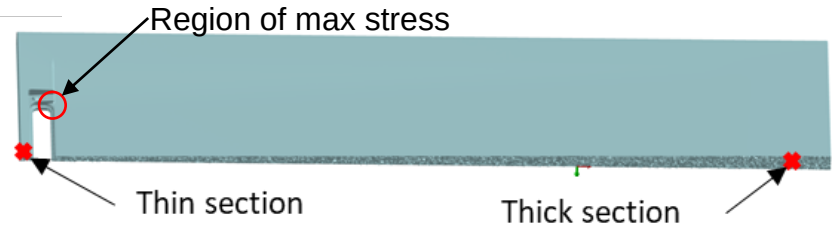
Mesh

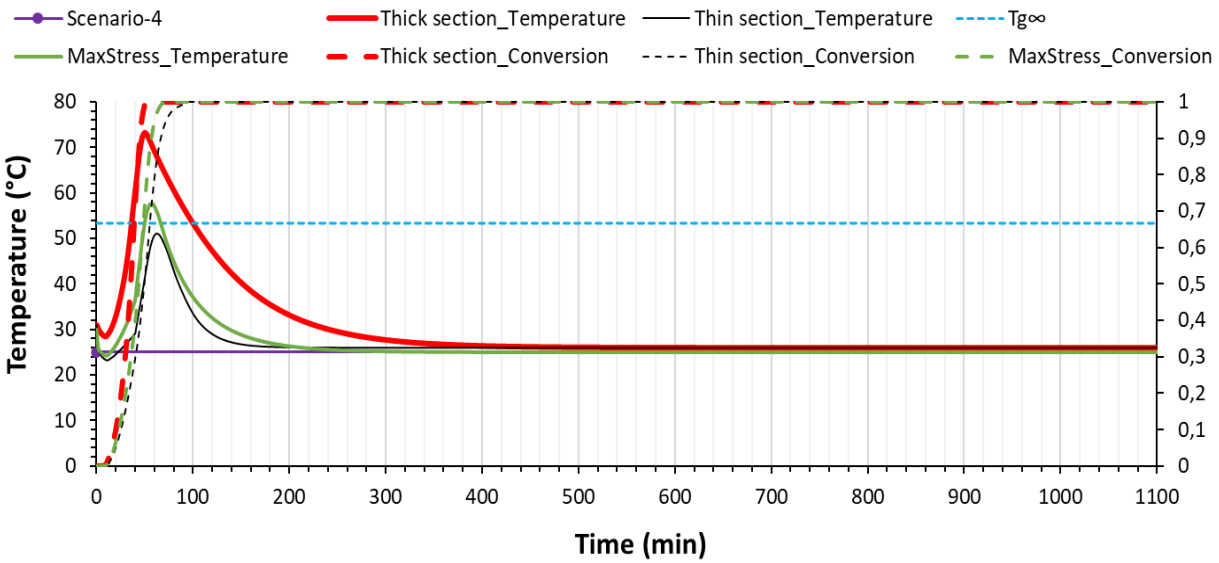
- Solid tetra elements
- Part (element size): ≈ 1.5 - 3 mm
- Mould (element size): ≈ 5 mm



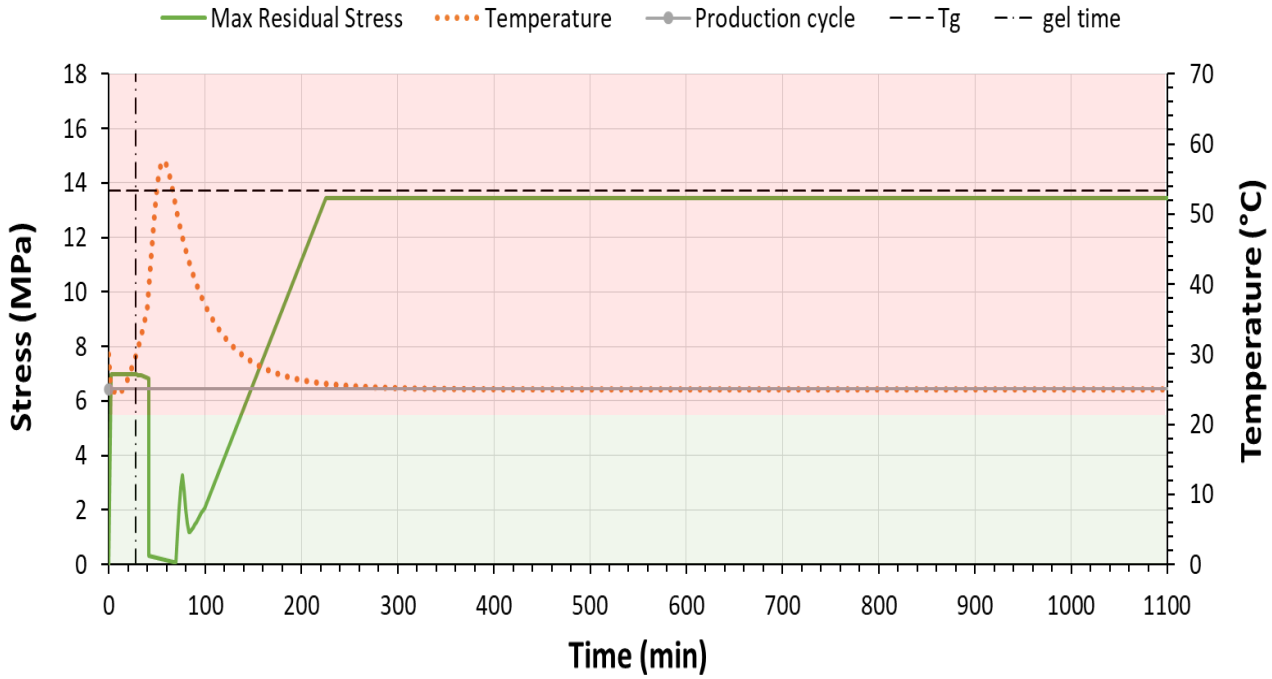
Numerical Results

- The location of the maximum residual stress is independent of the production cycle:



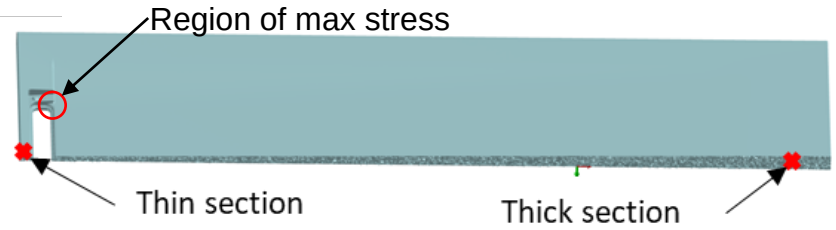


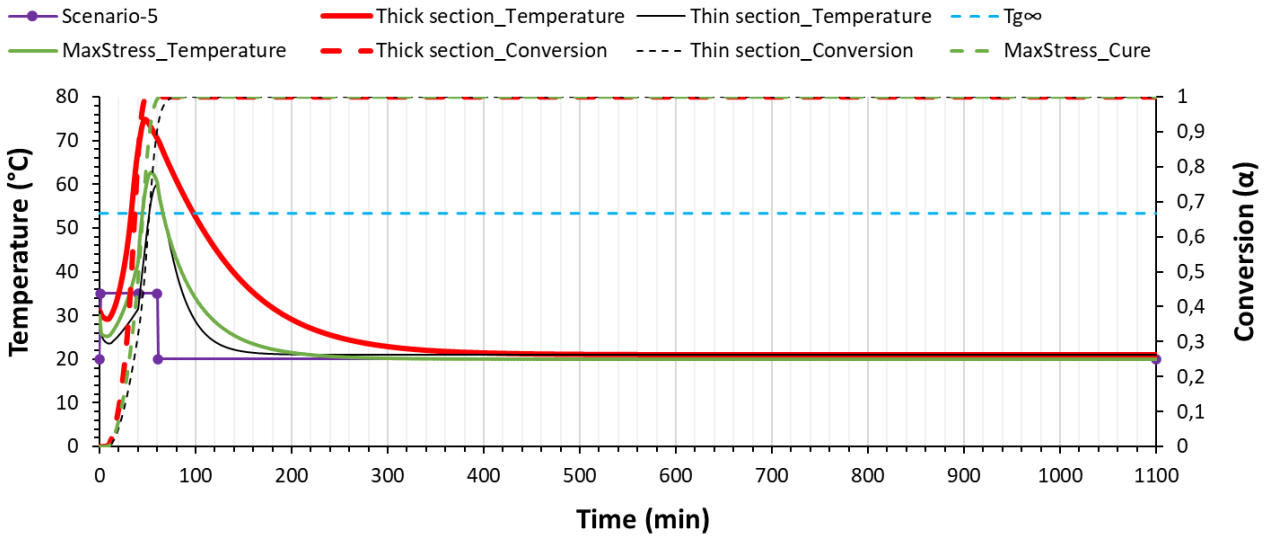
- Monitoring points:

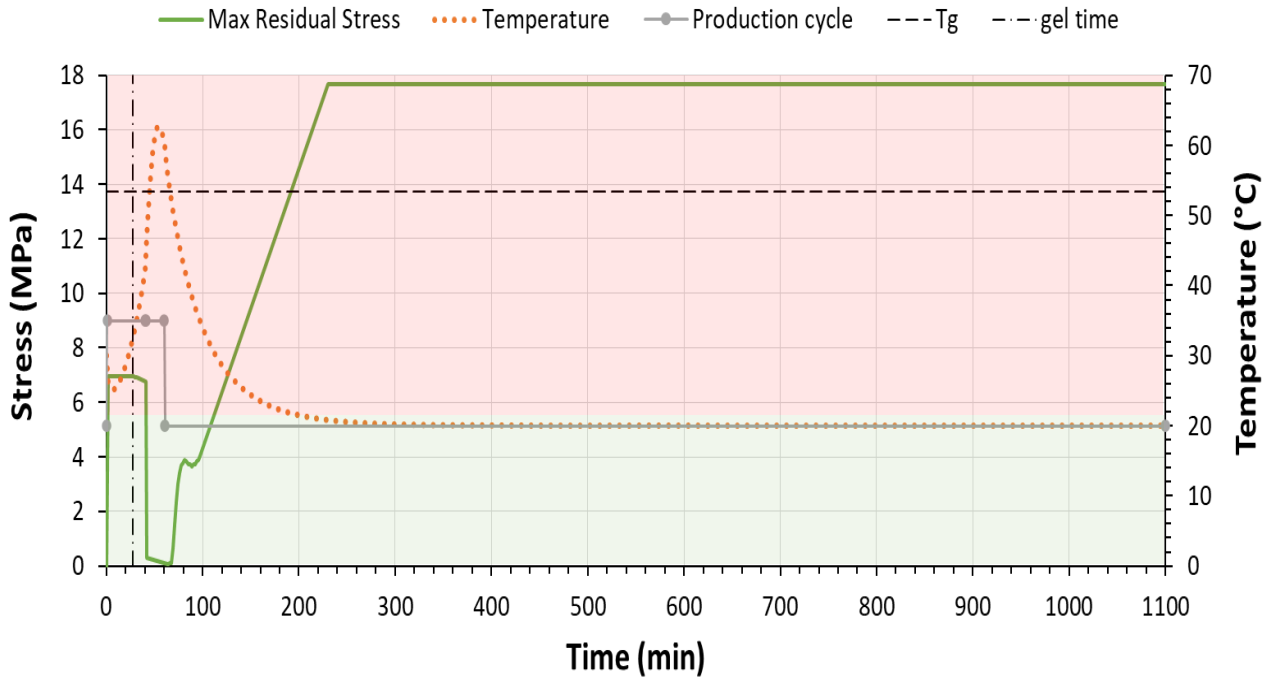


Numerical Results

Scenario: isothermal at 25°C



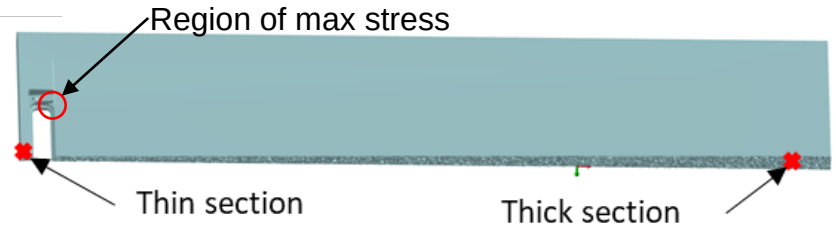


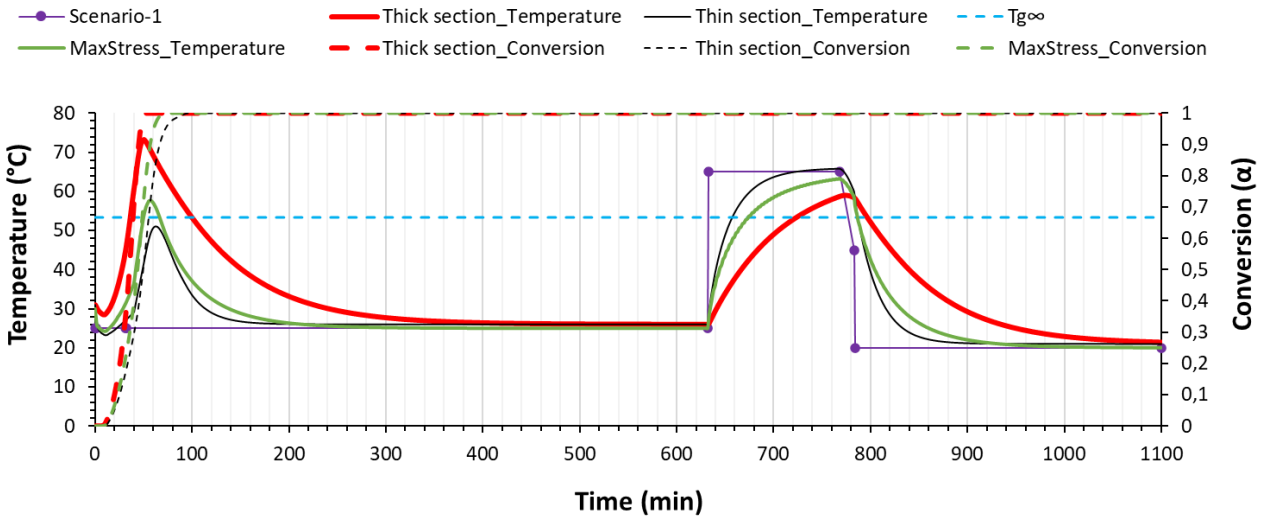


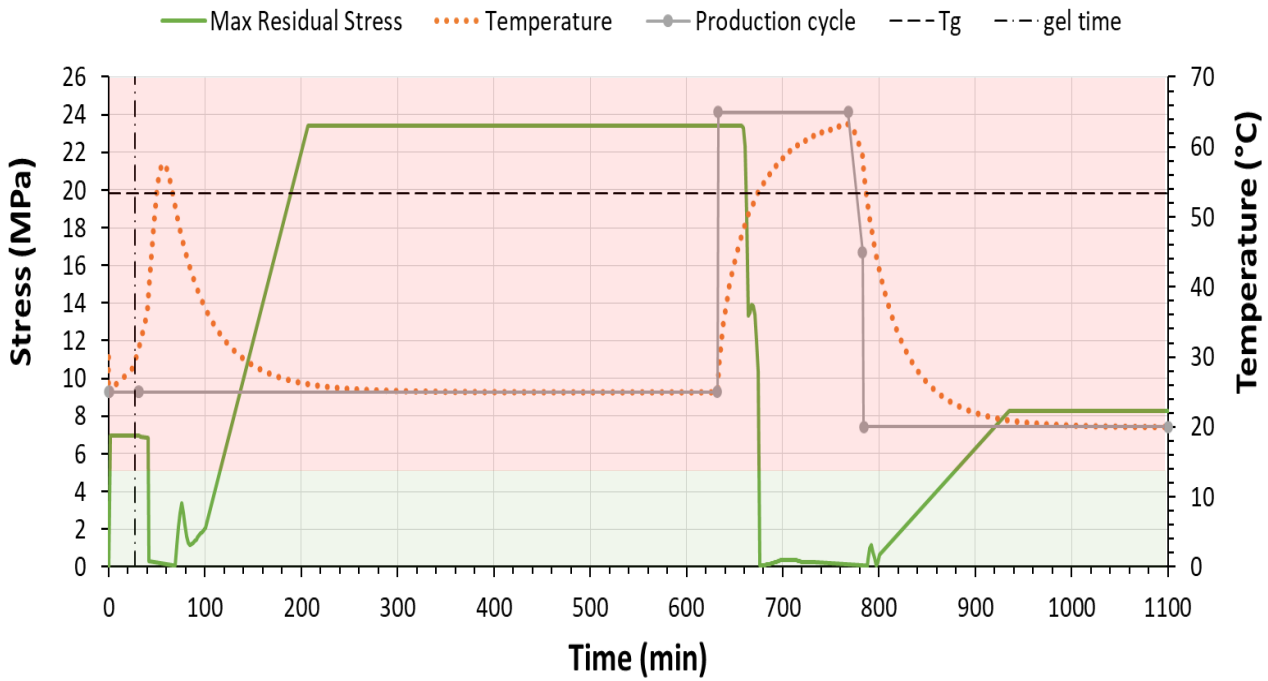
- Fully cured
- Thin section does not reach Tg_{∞}
- High residual maximum stress

Numerical Results

Scenario: isothermal at 25°C with initial heating at 35°C



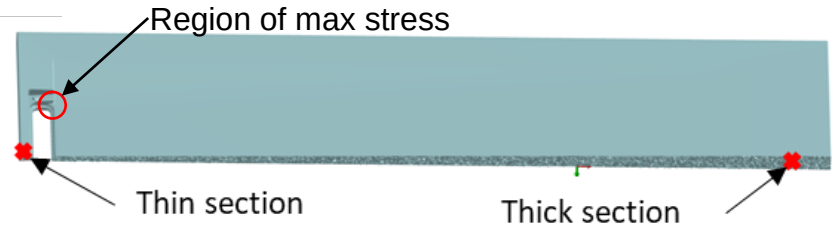


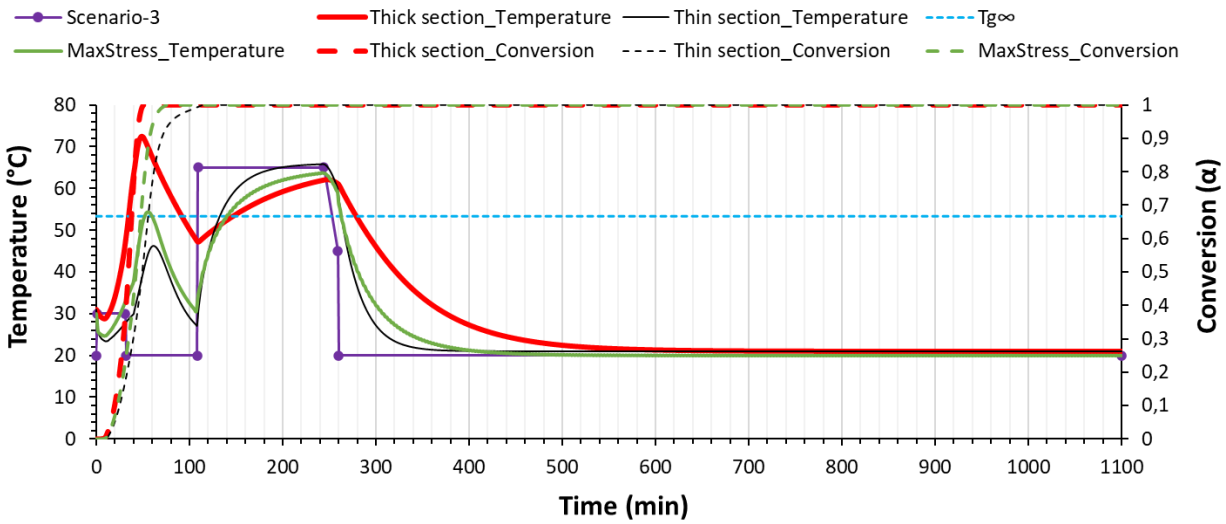


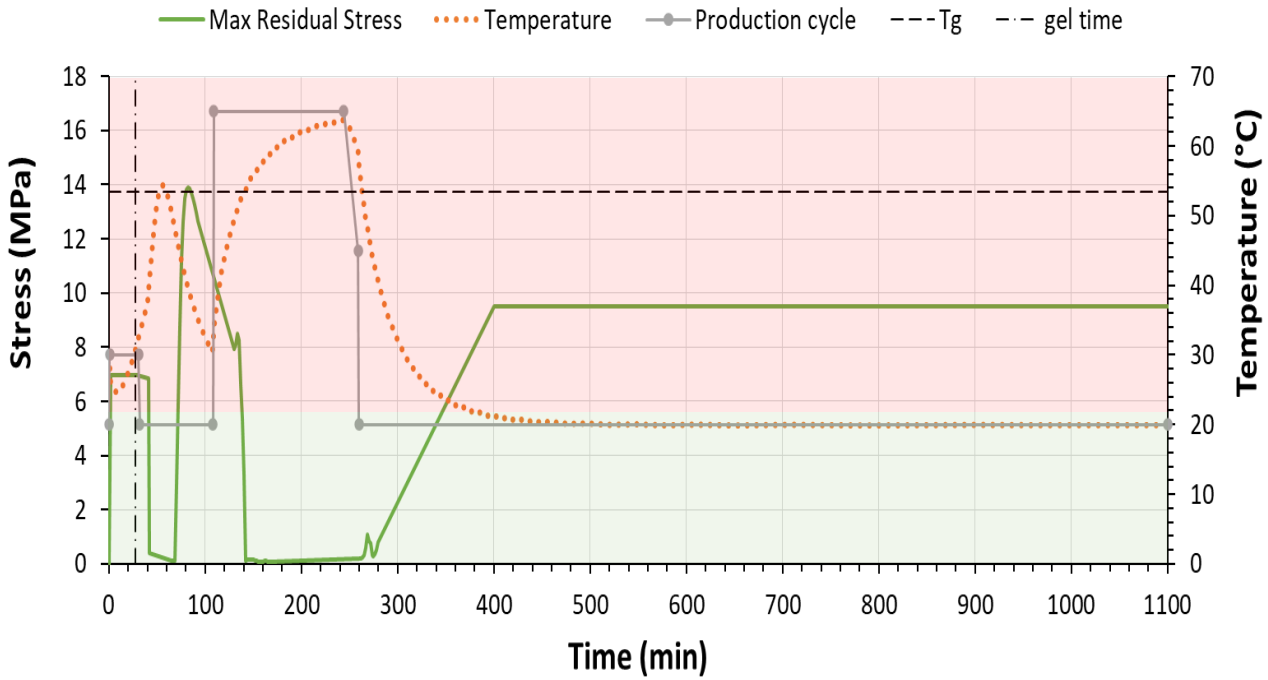
- Fully cured
- Whole part reach Tg_{∞}
- High residual maximum stress
- Initial heating does not improve residual stress

Numerical Results

Scenario: isothermal at 25°C with post-cure



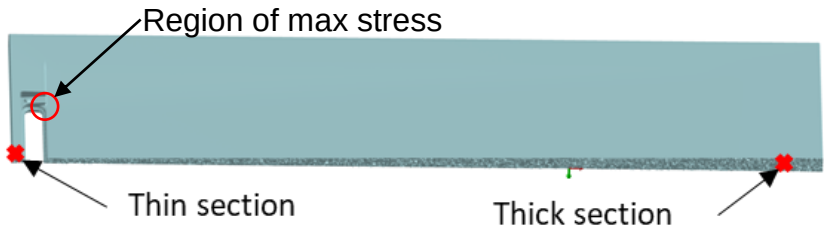


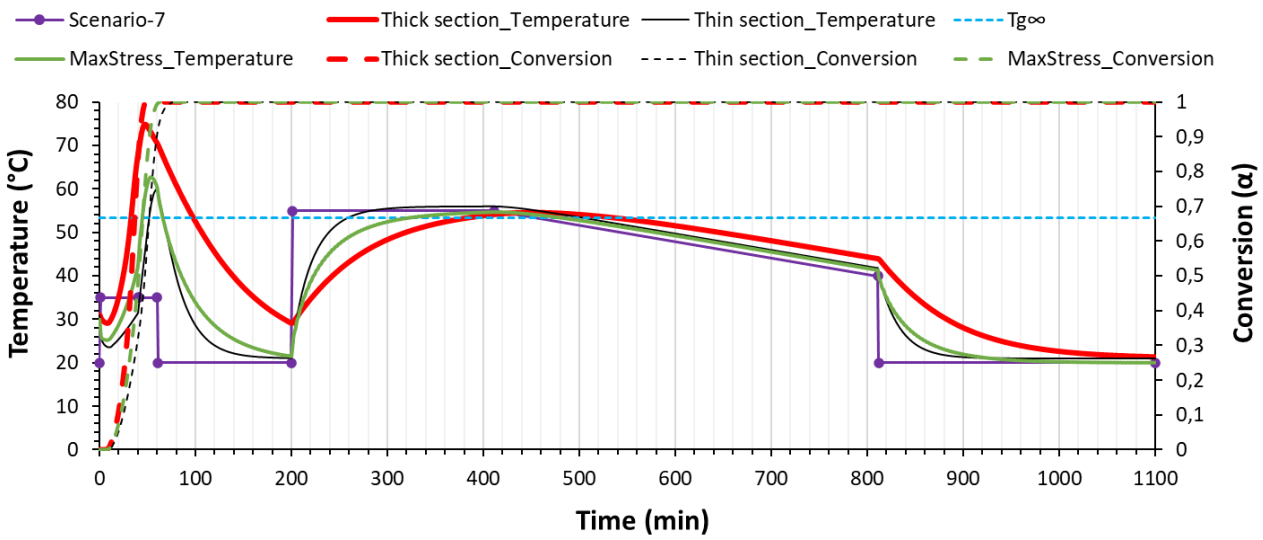


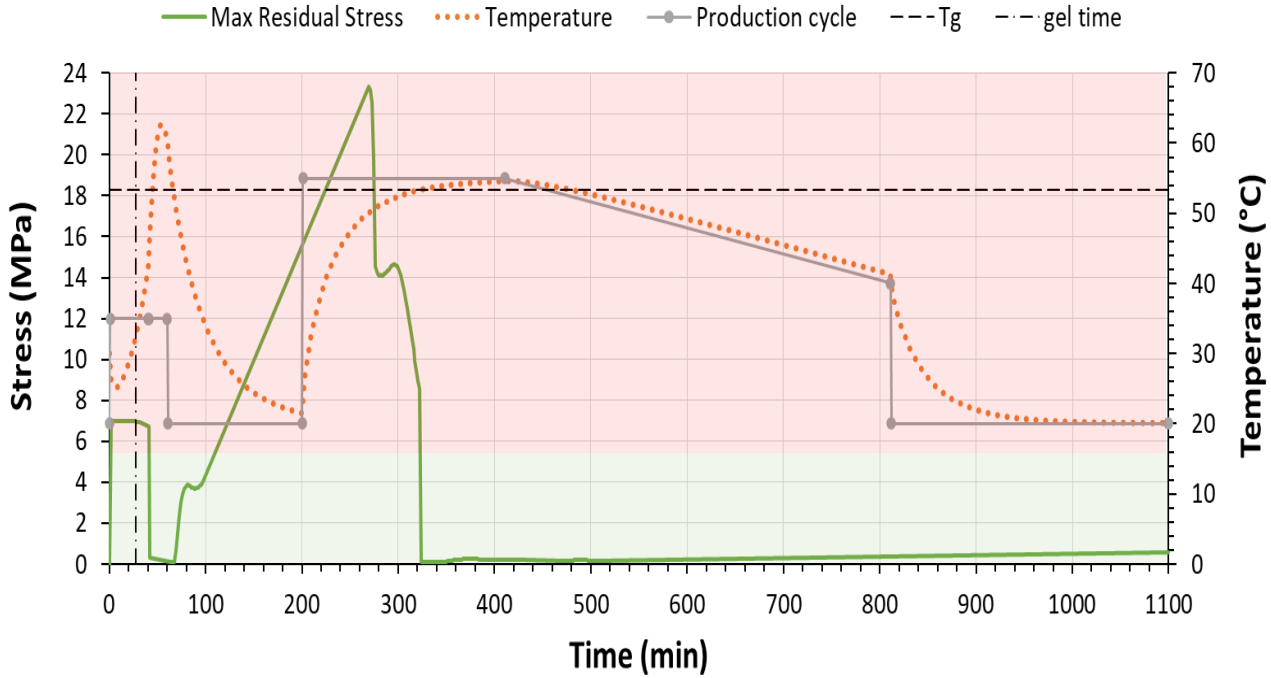
- Fully cured
- Thin section does not reach Tg_{∞} (before post-cure)
- High residual maximum stress
- Post-curing improve residual stress (but not enough)

Numerical Results

Scenario: with post-cure, without resting period

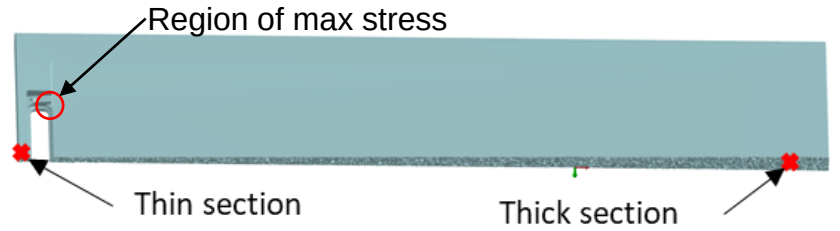




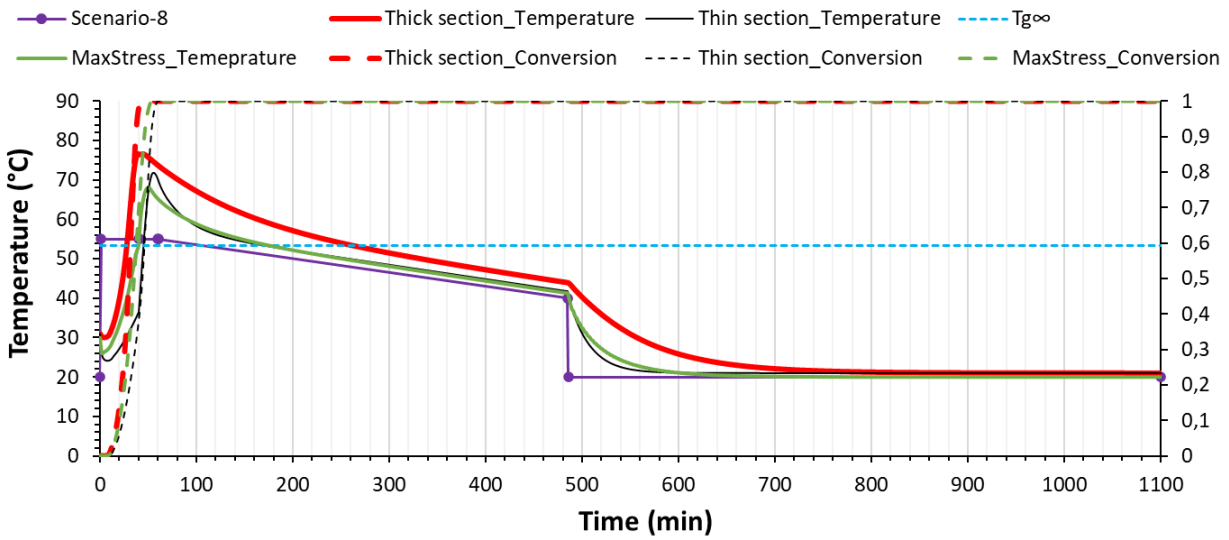


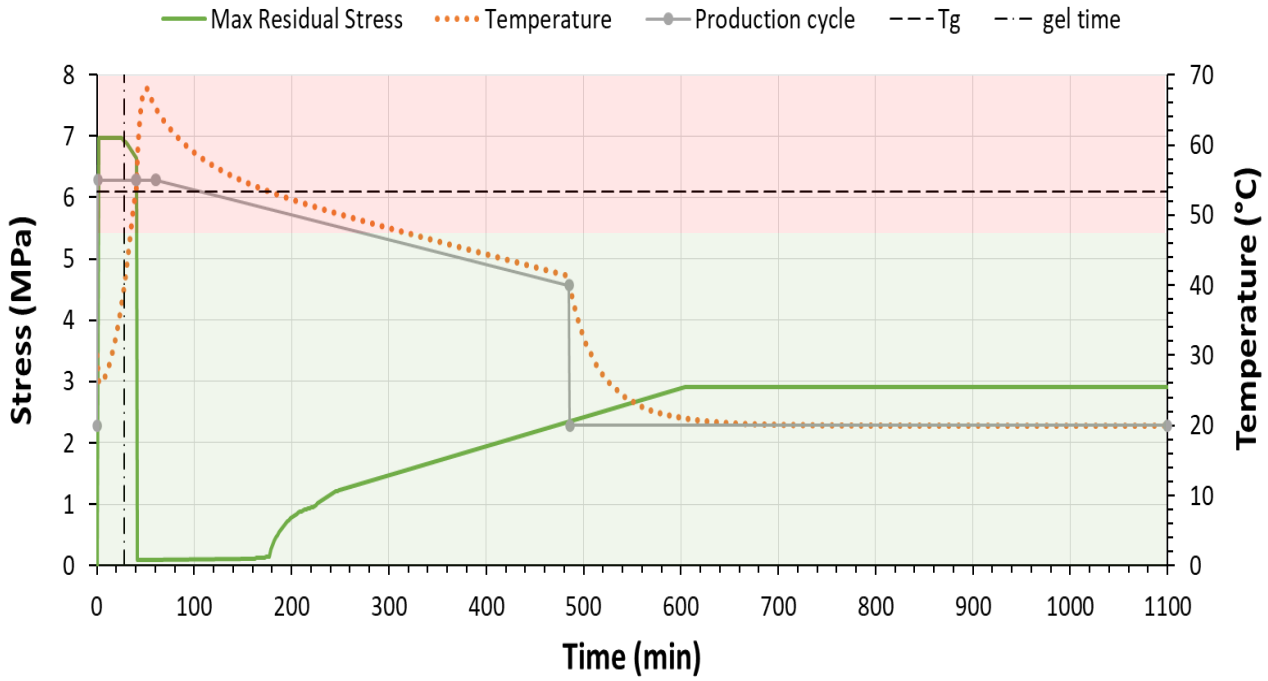
- Fully cured
- Thin section does not reach Tg_{∞} (before post-cure)
- High residual maximum stress
- Eliminating resting period does not improve residual stress

Numerical Results



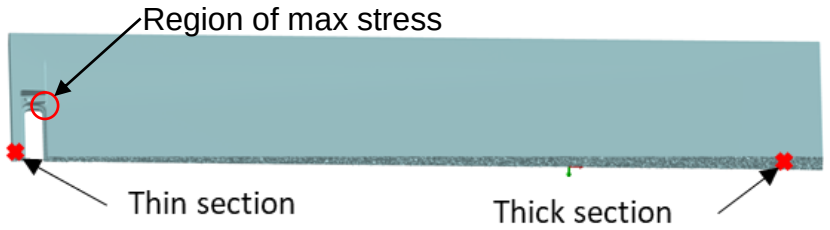
Scenario: with post-cure (extended cooling), without resting period



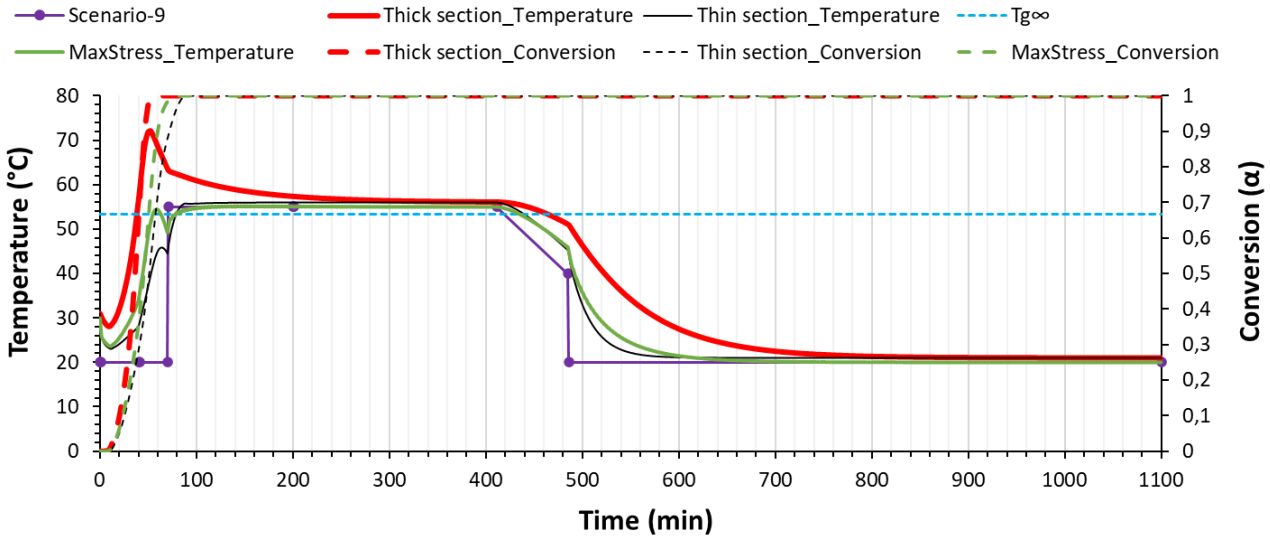


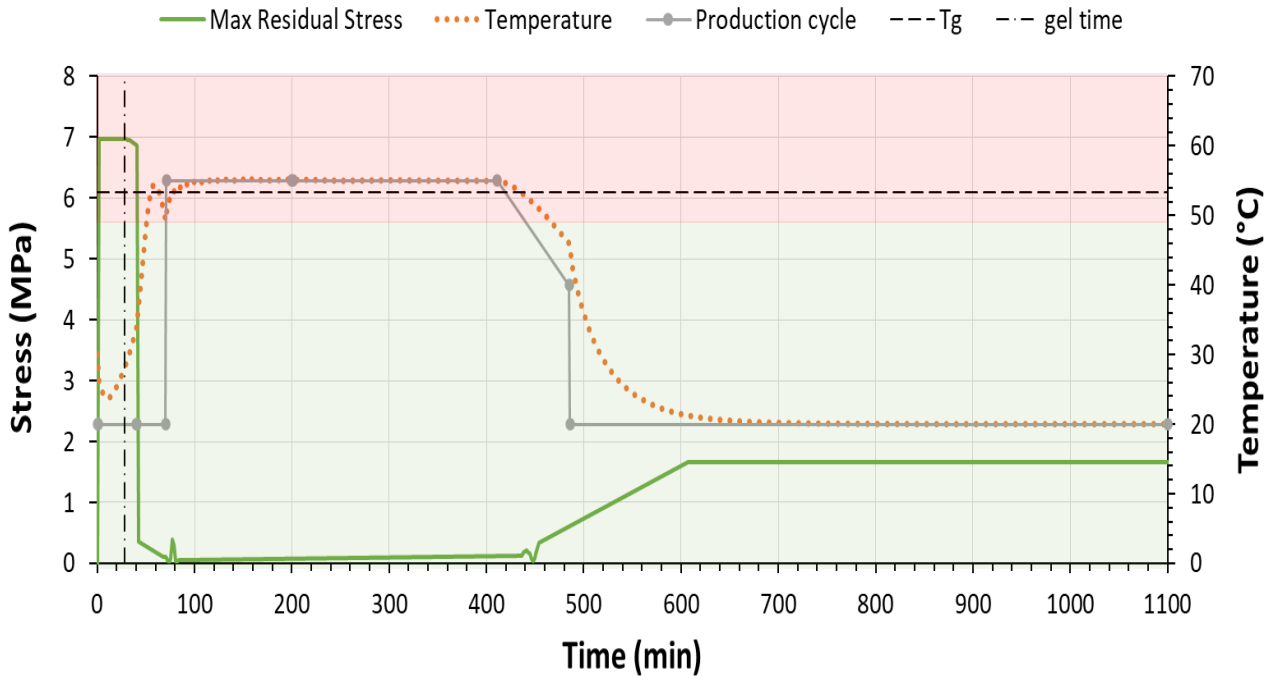
- Fully cured
- Whole part reach Tg_{∞}
- Low residual maximum stress
- Extended cooling improves residual stress

Numerical Results



Scenario: cooling control with high initial temperature (>Tg_∞)





- Fully cured
- Whole part reach Tg_∞
- Low residual maximum stress

Numerical Results

Scenario: with post-cure (cooling control), with low initial temperature (25°C)

- Fully cured
- Thin section does not reach Tg_{∞} (before post-cure)
- Low residual maximum stress

Conclusions

- Independently on the production cycle, cure is completed within 60 min, due to the heat generated by the exothermic curing reaction.
- The Tg_{∞} is only guaranteed if heating is added to the production cycle
- The magnitude of the maximum residual stress depends considerably on the thermal conditions of the production cycle.
- Post-cure, resting period and/or initial heating can be eliminated from the production cycle if:
  - Cooling is controlled
  - The Tg_{∞} is reached in the whole part

Thank you!

ABSTRACT

Some large fibre reinforced polymer (FRP) marine structures—such as the U.K.'s mine countermeasures vessels—were designed decades ago. Of these early designs, some entered production, and have been in regular service for many years. When compared to modern FRP structures, the sparsity of literature available for legacy structures means they often constitute an asset maintenance dilemma. In these contexts, certain repair variables are often fixed according to the original design and are not possible to change easily. Examples could include the materials used in the repair and laminate structure. This paper presents a study aimed at improving the effectiveness of repairs on these legacy marine FRPs by using vacuum assistance to produce higher quality repairs, without changing the materials used in, or the design of, the repairs. First, the relationship between consolidation pressure applied to a wet lay-up repair and the repair's performance, was investigated. Thereafter, a vacuum-assisted resin infusion process replaced the wet lay-up, to demonstrate further improvements in repair performance. Both of these improvements are based on the repair procedures, and are readily implementable within the asset maintenance programs of in-service legacy marine FRP structures. Extending the life of these structures by means of improved repair practices like these would mitigate their environmental impact by reducing unnecessary structure downtime and premature decommissioning, especially where end-of-life disposal processes are limited and environmentally harmful.

1 INTRODUCTION

Fibre Reinforced Polymer (FRP) composites have been widely adopted across a range of applications, with marine structures among the earliest large-scale implementations. Notably, the United Kingdom's mine countermeasures vessels (MCMVs), introduced in the latter half of the twentieth century, represent significant examples of early FRP structural use. These vessels—many of which remain in service—pose a number of challenges with respect to maintenance. For example, the original materials and lay-up configurations are typically fixed, limiting how current repair techniques may be enhanced or adapted.

The broader field of FRP repair has advanced considerably in recent decades, particularly with respect to aerospace applications, where the drive for high performance has led to increasingly sophisticated repair methodologies [1]. Within the marine domain, however, repairs are often carried out under less controlled conditions, and the dominant technique—manual wet lay-up—remains heavily dependent on operator experience. This introduces variability in the quality of repairs, particularly in relation to void content, resin distribution, and fibre alignment, all of which can significantly influence structural performance [2]. In the context of legacy marine composites, there remains a clear need for repair strategies that are both robust and compatible with existing material systems.

Scarf repair continues to be the preferred method for repairing damage on composite structures in the marine industry, primarily due to its capacity to recover in-plane load-bearing capacity when appropriately executed [3]. There are a number of different factors that affect the quality of scarf repair,

and in the following section brief accounts of parameters such as taper angle, surface preparation, and ply sequencing are provided.

The scarf or taper angle θ_{SC} is defined as the angle between the surface of the repaired laminate and the inclined plane of the bond line formed between the original material and the repair patch. Mathematically, the scarf angle is expressed in degrees, though it is commonly referenced via the taper ratio—defined as the length of the taper divided by the thickness of the laminate. Composite repair handbooks often recommend a tapered slope between 20:1 and 50:1 [4][5] although practically on ships this is not always possible and ratios of 12:1 are considered acceptable with $\theta sc < 5°$ [3]. Optimisation studies on how taper angle affects peak stresses on 8 ply thick fibre composite, have been done by Bendemra and Compston [8], with taper angles ranging from 3°to 12°. They found peak stresses increased exponentially with scarf angle, with a greater stress increase from a scarf angle of going from 8° to 12° than with an increase from 3° to 5°. A study by Ahn and Springer [5] found that increasing the scarf angle from 0.5° to 2.5° decreased the failure load although only minimally concluding scarf angle becomes increasingly relevant at larger taper angles.

To ensure a good quality bond between the old fibres and the new, surface contaminants should be reduced to a minimum. This is recommended to be achieved with the use of a solvent, often acetone [3]. Sanding is recommended to roughen up the surface abrading it and improving bond strength. Ahn and Springer [5] tested how failure load varies on a scarf repair with different grit numbers on a diamond sander. It was found that changing the grit number had a negligible effect on failure load concluding that a grit of 100 would be reasonable for scarf repair.

There are two ply sequencing techniques used in scarf repair. The first technique is to lay the smallest patch down first and increase in size towards the repair surface. The second is to start with the largest patch and decrease in size. Among marine FRP operators, The National Maritime Centre, have reported the former method produces a relatively weak resin rich layer at the surface of the repair and recommend the latter technique of placing the largest ply first [6]. Additionally, the former technique has been reported to produce weaker points of increased stress at the end of each ply, where cracks would often propagate from [3].

Adding additional layers of laminate to the repair surface, overlapping at the edge of the repair to bond to the original material has been found by Ahn and Springer [5] to increase failure load, for example, the addition of two external plies increased failure load by approximately 50%. Similar results were reported by Myhre and Beck [7]. Research into the effect of the over-ply lap length (i.e., how far the external ply extends over the repair region) was done by Bendemra and Compston [8], concluding that peak peel stress was significantly reduced by inclusion of over-plies, and identifying a critical lap length of 5 mm.

Recent work has highlighted the potential for process-level improvements—rather than material substitution—to deliver tangible gains in repair quality. In particular, vacuum-assisted techniques have shown promise in improving consolidation and reducing void formation in manually applied repairs. These approaches are especially attractive in the context of legacy FRP structures, where the scope for altering material or geometric parameters is limited.

This paper presents an investigation into the potential for improving repair performance in legacy FRP marine structures by refining the repair process itself. The study first examines the influence of consolidation pressure in traditional wet lay-up repairs and subsequently explores the application of a vacuum-assisted resin infusion method. Both approaches were designed to be compatible with the constraints typical of legacy vessel maintenance, requiring no change to material systems or laminate design. The findings contribute to ongoing efforts to support the long-term serviceability of FRP marine assets, while aligning with broader objectives around sustainability and responsible lifecycle management in composite structures.

2 METHODOLOGIES

2.1 Manufacturing original laminates

The material system and manufacturing methods were selected to represent that of typical marine composite structures. Crystic 701PAX isophthalic polyester resin and (2% by volume) Butanox M50 methyl ethyl ketone peroxide crosslinking initiator, were combined and subsequently impregnated by

hand into the reinforcing fibres. The reinforcement was Scott & Fyfe "Polyform WR" 800 g m−2 plain woven glass mat. For all original (reference and pre-repair) laminates the lay-up recipe was $[0_8]_T$. The curing cycle was 24 h at room temperature (20°C) in a closed mould process with no additional environmental control or post-curing steps.

2.2 Scarf repair design

To evaluate different repair methods, a single-sided surface-to-midplane scarf repair was designed (Fig. 1). This simulates a typical repair process that is often followed for damage that extends not further than the laminate midplane. For this type of damage, the repair is usually conducted exclusively from one side of the structure. Herein, material was removed from one surface of the laminate in a stepped pattern until the laminate midplane was reached. Thereafter, the stepped patterns were graded to create scarf angles of 5°. Dry fibre plies of the same reinforcement were cut to match the quantity and dimensions of the removed plies. These repair plies were laid up monolithically according to the direction of the parent laminate. For wet lay-up cases, the repair plies were impregnated by hand using brushes and rollers, in a ply-by-ply manner. For vacuum infusion methods, repair plies were laid up dry, and resin injected into the scarf repair zone using the parent laminate as a mould base. In all cases, one additional surface ply was applied with over-ply areas bonded to the surface of the original laminate on each side of the repair.

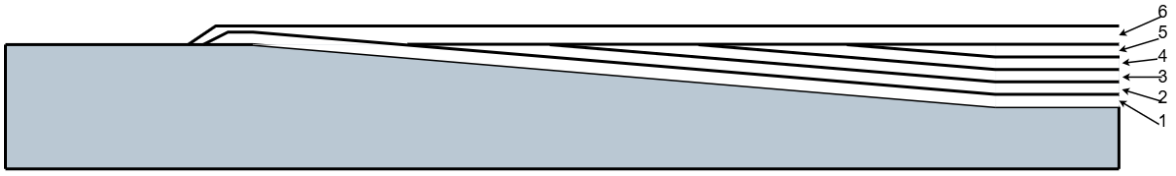

Figure. 1: Ply arrangement in laminate repair patch.

2.3 Improved repair part 1: consolidation pressure

In initial investigations, repair plies were exclusively impregnated by manual wet lay-up. Four original laminates were manufactured according to Section 2.1: one reference laminate and four test case laminates. The test case laminates were scarfed and repaired according to Section 2.2. All scarf repairs were cured for 24 h at room temperature (20°C) in a closed-mould process using a Radius 70T platen press machine with no additional environmental control or post-curing steps. To investigate the influence of pressure applied during consolidation, each scarf repair was cured at a unique value of consolidation pressure. The four values of consolidation pressure were 0 kPa, 100 kPa, 300 kPa, and 600 kPa.

2.4 Improved repair part 2: impregnation method

In a subsequent investigation, repair plies were impregnated by two methods: 1) manual wet lay-up and 2) vacuum resin infusion. Two original laminates were manufactured according to Section 2.1. Both laminates were scarfed according to Section 2.3. The first laminate was repaired in a wet lay-up process at 1 bar of applied pressure, whilst the second laminate was repaired using vacuum resin infusion to wet out the repair plies. Both scarf repairs were cured for 24 h at room temperature (20°C) with no additional environmental control or post-curing steps.

2.5 Data acquisition

2.5.2 Flexure

Five specimens per case were tested in accordance with BS EN ISO 14125 [9]. Specimens were loaded in crosshead displacement-controlled flexure at a constant rate of 4.5 mm min^{-1}, using an Instron 3369 with a 10 kN load cell and Wyoming Test Fixtures Four-Point Flexure Test Fixture (Fig. 2a). An MTS AVX04 video extensometer package was used to capture specimen central displacement data at a sampling rate of 10.02 ± 0.02 Hz. Average specimen widths and thicknesses were calculated from vernier calliper measurements taken at three locations, before a speckle pattern was applied to the central

20 mm of the specimen side (through thickness) facing the camera. Specimens were placed centrally on the (5 mm diameter) support rollers with the loading axis being normal to the long edge of the specimen. Tests were concluded at ultimate failure of the specimens, defined as an instantaneous stress drop exceeding 50% of the preceding measured value.

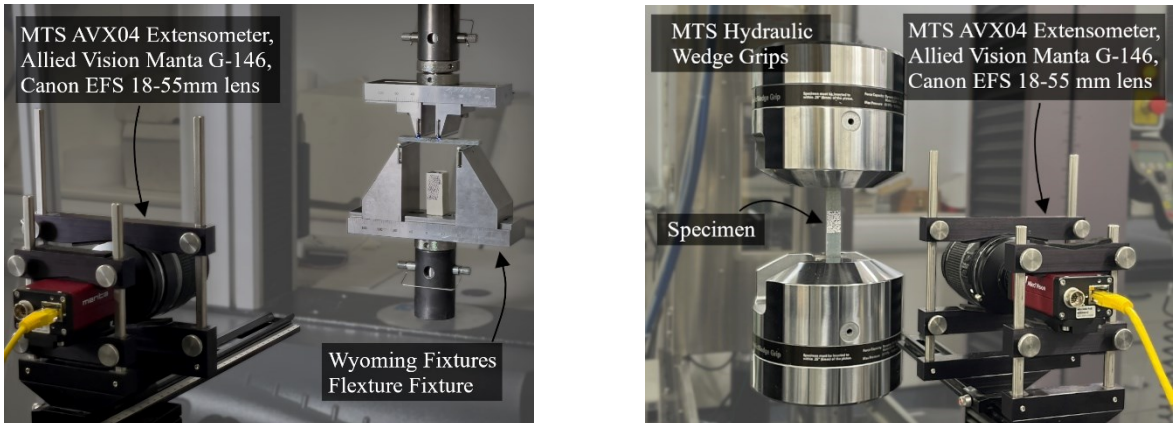
The nominal flexural stress observed in the specimen outer surface at specimen mid-span, is denoted σ_f and is defined in Equation 1 where P is the load measured, L is the specimen span (defined in the standard as (16.5×h), b is the specimen width, h is the specimen thickness. Flexural strain in the specimen outer surface at specimen mid-span, is denoted ε_f , and is defined in Equation 2 where: s is the deflection of the mid-span of the specimen under load, h is the specimen thickness, L is the specimen span (defined in the standard as 16.5h). Flexural strength, σ_{fM}, is defined as the first local maximum flexural stress observed. Flexural modulus, E_f , is defined as the initial slope of the flexural stress-strain curve, for the region $0.05\% \leq \varepsilon_f \leq 0.25\%$ (Equation 3) where ΔF is the difference in loads corresponding to deflections s'' and s', Δs is the difference in mid-span deflections (s'' and s') corresponding to flexural strains 0.25% and 0.05%, respectively.

$$\sigma_f = {PL}/{bh^2} \tag{1}$$

$$\varepsilon_f = {4.7\mathrm{sh}}/{L^2} \tag{2}$$

$$E_f = \frac{0.21L^3}{bh^3}\left(\frac{\Delta F}{\Delta s}\right) \tag{3}$$

2.5.1 In-plane shear



Five specimens per case were tested in accordance with ASTM D3518 [10]. Specimens were loaded in crosshead displacement-controlled tension at a constant rate of 2 mm min^{-1} using an MTS Criterion C45.305 (Fig. 2b) fitted with a 250 kN load cell and hydraulic wedge grips. An MTS AVX04 video extensometer package was used to capture strain data at a sampling rate of 10.02 ± 0.02 Hz. Average specimen widths and thicknesses were calculated from vernier calliper measurements taken at three locations, before a speckle pattern was applied to 50 mm of the central gauge region. Specimens were clamped in the crosshead grips with 100 kPa clamping pressure applied evenly to the entire grip region. The loading axis was parallel to the long edge of the ± 45° specimen. Tests were concluded at ultimate failure of the specimens, defined as an instantaneous stress drop exceeding 90% of the preceding measured value.

In-plane shear stress observed within the gauge region—parallel to the xy plane—is denoted τ_{xy}, and is defined in Equation 4, where P_x is the load measured and A is the original specimen cross-sectional area, as measured before the test. Shear strain observed—in the direction of the loading axis—is denoted γ_{xy}, and is defined in Equation 5, where Δl_x is the linear displacement of two targeted observation zones within the specimen gauge region, l_x is the original linear separation of the two target observation zones, as measured before the test. In plane shear strength, τ_{xyM}, is defined as the shear stress observed at γ_{xy} = 5.0%. In plane shear modulus—in the direction of the loading axis—, G_{xy}, is defined as the initial slope of the shear stress-strain curve, for the region $0.05\% \leq \gamma_{xy} \leq 0.25\%$ (Equation 6), where τ''_{xy} is the stress measured at γ_{xy} = 0.25%, τ'_{xy} is the stress measured at γ_{xy} = 0.05%, γ'_{xy} = 0.05%, γ''_{xy} = 0.25%.

$$\tau_{xy} = {P_x}/{2A} \tag{4}$$

$$\gamma_{xy} = {\Delta l_x}/{l_x} \tag{5}$$

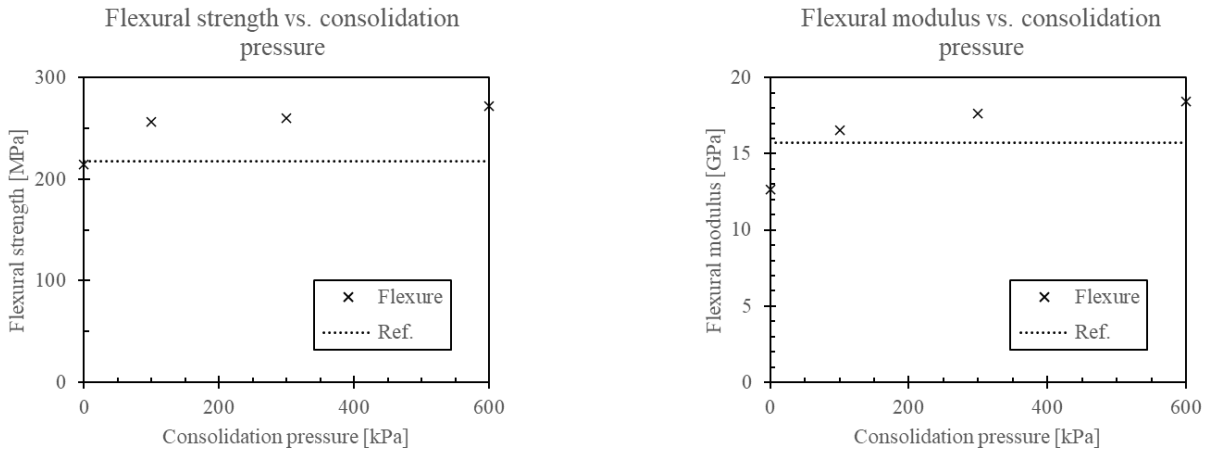
$$G_{xy} = \frac{\tau''_{xy} - \tau'_{xy}}{\gamma''_{xy} - \gamma'_{xy}} \tag{6}$$

(a) (b)

Figure. 2. Standardized experimental test setups: (a) flexure, (b) in-plane shear.

2.5.3 Density and fibre volume fraction

Density determination was completed using an Ohaus Adventurer AX324 analytical balance paired with an Ohaus density determination kit, which exploits Archimedes' principle by comparison of dry mass, A, to that observed when the specimen is submerged in a known liquid, B—shown in Equation 7, where ρ_C is the density of the specimen, ρ_O is the density of the liquid—in this case, distilled water; 0.998 g cm^{-3} at 20°C—and ρ_L is the air density (0.0012 g cm^{-3}). For each test case, five extractions of approximately 100 mm^2 were cut from random locations in the respective plates using a diamond bladed wet saw. Specimen conditioning before and after submersion was completed in a Prolan environmental chamber in accordance with ISO 185 291:2008 [11]. FVFs, V_r were measured through a pyrolysis/burn-off approach—as specified in ASTM D3171-22 Method I [12]—using a Nabertherm L15/11 muffle furnace and Haldenwanger porcelain crucibles with lids. The expression shown in Equation 8 was used to calculate the FVF where Mr is the mass of reinforcement remaining in the crucible at completion of the pyrolysis. One additional crucible containing traveller fibres verified that fibre mass-loss through the pyrolysis process was negligible. The pyrolysis cycle was determined using thermal degradation data acquired from Thermogravimetric Analysis of the same cured isophthalic polyester resin (2% hardener). The pyrolysis cycle began with a chamber ramp rate of 10°C min^{-1} from ambient temperature to a maximum temperature of 600°C. This maximum temperature was sustained for 6 hours to ensure full burn-off of all the resin in the samples. Thereafter, the furnace chamber underwent a passive cooldown to return to the ambient temperature.

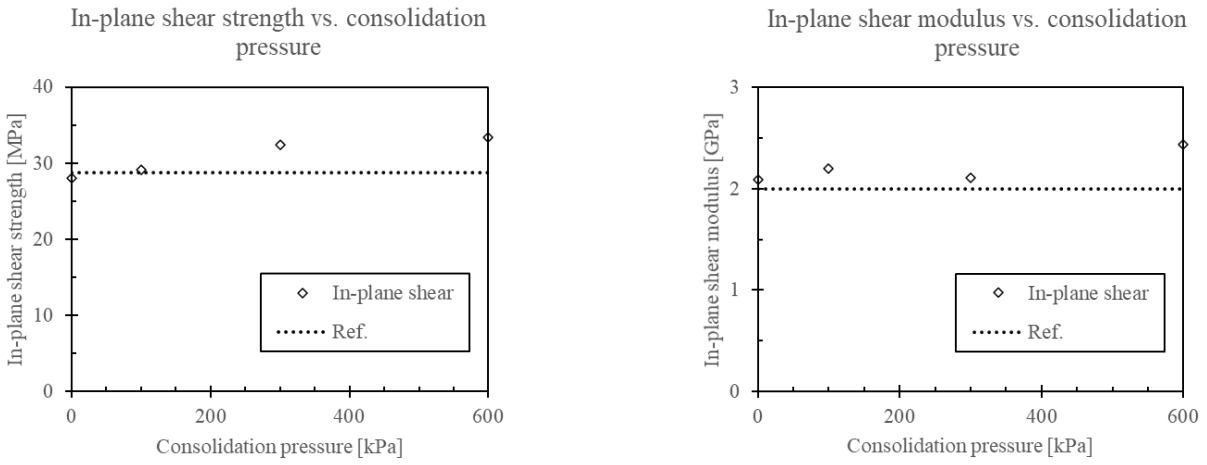


$$\rho_c = \frac{A}{A-B}(\rho_O - \rho_L) + \rho_L \tag{7}$$

$$V_r = 100\, M_r\, \frac{\rho_c}{\rho_L} \tag{8}$$

3 RESULTS AND DISCUSSION

3.1 Improved repair part 1: consolidation pressure



The flexural strengths of repaired specimens are plotted against repair consolidation pressure in Fig. 3a. Increased flexural strengths were observed for specimens with repairs cured under higher consolidation pressures. Non-linear fits were applied to the mean values from each set to infer the relationship between repair cure consolidation pressure and flexural strength within the empirical range. It is suggested that the presence of the scarf repair redistributes the internal stresses under load, and that the extra surface plies in the repair zones contributed to improved compression-under-flexure responses compared to the reference cases. Similar observations were drawn from the flexural stiffness data in Fig. 3b. Most repaired specimens exhibited higher flexural moduli compared to the reference specimens.

(a) (b)

Figure 3: Flexural properties of repaired specimens vs. consolidation pressure: (a) strengths, (b) moduli.

Similarly, the in-plane shear strengths of repaired specimens were compared to their reference specimen counterparts in Fig. 4a. Again, increased consolidation pressures were correlated with increased in-plane shear performance. Similar observations can be made about the in-plane shear moduli in Fig. 4b, which increased marginally as a function of increased consolidation pressure. However, the standard deviations of each test case are large relative to the respective means. Consequently, it is suggested that a minimum threshold repair consolidation pressure is required to ensure appropriate

(a) (b)

Figure 4: In-plane shear properties of repaired specimens vs. consolidation pressure: (a) strengths, (b) moduli.

bonding of the repair patch, however, once this threshold has been achieved, additional applied pressure may not significantly improve the in-plane shear properties of the repaired laminates. It is reasoned that since in-plane shear properties are dominated by interlaminar fracture, these damage mechanisms are not easy to treat with applied pressure alone. Furthermore, this scarf repair approach generated plies that were not in-plane with the applied load, and thereby, geometrical effects could have complicated the experimental data interpretation.

The influence of FVF on FRP mechanical properties is well documented, e.g., Refs [13-14], therefore this observation is intuitive. Higher consolidation pressures had the effect of increasing FVF through reductions in void content and increased expulsion of excess resin from the moulds. One method to control for fluctuations in FVFs, is to consider specific properties, i.e., properties divided by densities, on the basis that the specimen density implies information about the specimen volume fractions. Considering the specific flexural properties in Table 1, repairs consolidated under higher pressures performed better, implying that these improvements were not solely driven by enhanced FVFs.

Table 1: Mean specimen flexural properties as measured during part 1 of the study.

Category	$\overline{\rho}$ [g cm^{-3}]	$\overline{V_r}$ [%]	$\overline{E_{fSP}}$ [kNm kg^{-1}]	$\overline{\sigma_{fMSP}}$ [kNm kg^{-1}]
Ref.	1.72 ± 0.01	39.4 ± 0.4	9.14E+03 ± 179.1	126.3 ± 05.2
0	1.68 ± 0.01	36.4 ± 0.6	7.55E+03 ± 443.8	127.5 ± 17.1
1	1.68 ± 0.01	36.4 ± 0.5	9.86E+03 ± 397.9	152.5 ± 07.3
3	1.73 ± 0.01	40.3 ± 0.9	1.02E+04 ± 291.9	150.6 ± 06.2
6	1.74 ± 0.02	40.1 ± 1.4	1.06E+04 ± 292.3	156.3 ± 11.5

Similarly in Table 2, improvements in specific in-plane shear strengths are correlated with higher consolidation pressures. Since the repairs all fail at the repair line it follows that increased consolidation pressures would improve the quality of that repair bond through void reduction, thereby increasing the energy required to induce and propagate interlaminar cracks.

Table 2: Mean specimen in-plane shear properties as measured during part 1 of the study.

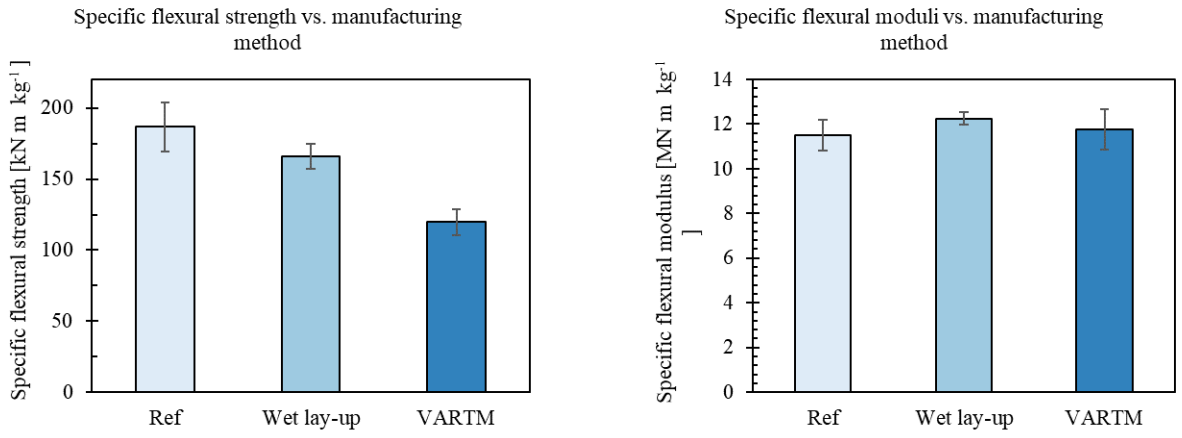
3.1 Improved repair part 2: impregnation method

Table 3 shows the mean flexural properties of the reference and repaired specimens. The reference specimens naturally showed the highest mean flexural strength, whilst wet lay-up repaired specimens were restored to 91.3% of the mean reference strength, and VARTM repaired specimens were restored to only 62.1% of the mean reference strength. Both repair methods resulted in consistent flexural moduli (20.0 - 21.3 GPa), indicating that the repair method mainly influenced strength rather than stiffness.

Table 4 shows the mean in-plane shear properties of the reference and repaired specimens. The reference specimens again showed highest mean shear strength, establishing a baseline for evaluating repair performance. The specimens repaired by wet lay-up were restored to 91.7% of reference shear strength and 69.5% of the reference shear modulus. The VARTM repaired specimens were restored to 83.9% of the reference shear strength 66.3% of the reference shear modulus. For both repair methods strength recovery was better than modulus recovery, indicating that whilst repair method changed the energy required to initiate and propagate failure, the resulting material had consistent elastic behaviour.

Table 3: Mean specimen flexural properties as measured during part 2 of the study.

Category	$\overline{\rho}$ [g cm^{-3}]	$\overline{V_r}$ [%]	$\overline{E_f}$ [GPa]	$\overline{\sigma_{fM}}$ [MPa]
Ref.	1.75 ± 0.01	39.8 ± 0.6	20.1 ± 1.2	327 ± 30.2
Wet Lay-up	1.74 ± 0.02	39.6 ± 2.0	21.3 ± 0.5	289 ± 15.3
VARTM	1.77 ± 0.03	39.3 ± 2.0	20.8 ± 1.6	212 ± 16.4



The mean specific flexural strengths (Fig. 5a) follow similar trends: the reference laminate achieved the highest specific strength, with 88% restoration of mean specific flexural strength for specimens repaired by wet lay-up and 64% restoration of mean specific flexural strength for specimens repaired by VARTM. Although a marginal increase can be seen in the mean specific flexural moduli of specimens repaired by wet lay-up compared to VARTM (Fig. 5b), there is considerable overlap of the datapoints after accounting for the standard deviations of each set. Further analysis via t-test revealed no statistical significance ($p > 0.05$) in the mean flexural moduli data.

Table 4: Mean specimen in-plane shear properties as measured during part 2 of the study.

Category	$\overline{\rho}$ [g cm^{-3}]	$\overline{V_r}$ [%]	$\overline{G_{12}}$ [GPa]	$\overline{\tau_{12M}}$ [MPa]
Ref.	1.75 ± 0.01	39.8 ± 0.6	4.0 ± 0.3	40.9 ± 3.7
Wet Lay-up	1.74 ± 0.02	39.6 ± 2.0	2.8 ± 0.2	37.5 ± 4.1
VARTM	1.77 ± 0.03	39.3 ± 2.0	2.7 ± 0.2	34.3 ± 3.4

Fig. 6a shows the mean specific in-plane shear strengths, which follow similar trends to their flexural strength counterparts. The wet lay-up repairs restored an average of 92% of the mean reference specific in-plane shear strength, whilst the VARTM repairs restored an average of 81% of the reference mean specific in-plane shear strength. For specific in-plane shear modulus (Fig. 6b), wet lay-up again out-performed VARTM in terms of performance restoration, however, neither method was able to match the specific in-plane shear modulus of the reference case. Despite the numerical differences between repair methods no statistical differences exists between repair methods for shear stress ($p = 0.078$) or modulus ($p=0.086$) indicating from a practical perspective, both methods offer statistically equivalent in-plane shear performance.

The similarities between flexural and in-plane shear performances in part 2 of this study implies that wet lay-up repairs out-perform VARTM repairs in terms of strength, whilst marginal difference can be detected in terms of stiffness.

9 CONCLUSIONS

In this paper, repair strategies for legacy fibre-reinforced polymer (FRP) marine composites, were investigated. Focus was given to process-driven improvements that do not require changes to material systems. Two approaches were considered: 1. Increasing consolidation pressure during wet lay-up repairs, and 2. Using vacuum-assisted resin infusion (VARTM) as an alternative impregnation method. Repairs cured under higher consolidation pressures resulted in increased flexural and in-plane shear strengths. These gains were partially attributed to higher fibre volume fractions, but improvements in specific strength properties indicated enhanced load transfer and bonding quality too. In the latter part of the study, VARTM repairs resulted in specimens with comparable flexural and in-plane shear strengths to the traditional wet lay-up method. Similarly, no statistically significant differences in flexural or in-plane shear stiffnesses, were detected. Overall, the findings indicate that both increased consolidation pressures and vacuum-driven impregnation methods have potential to improve the mechanical performance of repaired specimens. Beyond the structural performances, the optimization of these techniques can support broader sustainability goals (reducing unnecessary or premature disposal) by extending the useful lives of in-service assets.

ACKNOWLEDGEMENTS

The authors would like to thank John Blackford for his valuable technical assistance and insightful advice throughout this project. His suggestions for improved methods and his support in guiding the team contributed substantially to the successful completion of this work.

Keywords: Recycling, STRAP, EVOH film, Composite, SiO_2 nanoparticles.

ABSTRACT

This study investigates the reinforcement of poly(ethylene-co-vinyl alcohol) (EVOH) films—recycled through the STRAP (Solvent-Targeted Recovery and Precipitation) process with SiO_2 nanoparticles at varying concentrations (0.1, 0.25, and 0.5 wt.%). EVOH was selectively dissolved in dimethyl sulfoxide (DMSO), and SiO_2 NPs was dispersed before precipitation of the pellets. The recovered EVOH composites were extruded into blown films and characterized for mechanical, thermal, and structural properties. FTIR analysis confirmed the incorporation of SiO_2 through Si–O–Si bonding, while SEM imaging revealed dispersion quality at different loadings. Thermal (TGA, DSC) and mechanical (tensile) tests demonstrated that the 0.1 wt.% SiO_2 sample offered the most significant improvements, with an elastic modulus of 0.25 GPa and a maximum tensile stress of 11.71 MPa. Higher loadings (0.25 and 0.5 wt.%) resulted in decreased performance, likely due to nanoparticle agglomeration disrupting polymer continuity. DSC results showed that the 0.1 wt.% addition increased melting and crystallization temperatures, indicating enhanced thermal resistance, while higher loadings had the opposite effect. XRD analysis further supported these findings. A broad peak at $2\theta \approx 23°$ confirmed the amorphous nature of SiO_2 grafted to the recycled EVOH matrix. Relative crystallinity increased with 0.1 wt.% SiO_2 but declined at higher concentrations due to poor dispersion and aggregation. Therefore, low concentrations of nano-SiO_2 significantly enhanced the mechanical strength, thermal stability, and crystallinity of recycled EVOH films. These findings demonstrate the potential of nanoparticle-assisted upcycling to improve the performance of barrier polymers recovered from multilayer packaging waste.

1 INTRODUCTION

The growing accumulation of packaging waste has led to widespread interest in recycling strategies. However, materials recovered through these processes often suffer from inadequate thermal and mechanical performance, which restricts their reuse in demanding applications. One promising solution is the incorporation of nanoscale additives, which can significantly improve the functional properties of recycled polymers. Nanoparticles are particularly effective due to their high surface area, which facilitates stronger interactions at the interface between polymer chains and filler particles. These interactions can enhance properties such as strength, thermal resistance, and durability in polymer nanocomposites [1]. Silicon dioxide (SiO_2) is a frequently applied inorganic nanoparticle known for its three-dimensional framework of SiO_4 units. It exists both in naturally occurring crystalline structures—like quartz and in synthetic, non-crystalline (amorphous) forms [2]. Owing to its strong chemical resistance, heat tolerance, and mechanical strength, SiO_2 serves as a valuable additive in polymer matrices, helping to enhance durability and barrier efficiency in composite materials such as films and coatings [1,2]. In particular, amorphous SiO_2 has been recognized as a biocompatible material, making it suitable for use in food-grade and pharmaceutical applications without known adverse health effects [3]. This research focuses on the use of nano-SiO_2 as an additive in recycled ethylene vinyl alcohol (EVOH) films obtained through a selective dissolution process. The study examines the influence of different SiO_2 loadings (0.1, 0.25, and 0.5 w/w%) on the films' chemical, mechanical, and thermal properties, aiming to enhance the performance of recycled EVOH for practical reuse.

2 MATERIALS AND METHODS

EVOH pellets containing 48 mol% ethylene (grade G176B) were supplied by Kuraray Co., Ltd., Houston, TX. Amorphous silicon dioxide (SiO_2) nanoparticles and dimethyl sulfoxide (DMSO), 99.5%, were supplied by Sigma-Aldrich (St. Louis, MO), with DMSO serving as the solvent for dissolving the EVOH. Structural properties of the samples were analyzed from the X-ray Diffraction (XRD) pattern. The XRD pattern of all the samples were recorded using Rigaku Smartlab with a Cu Kα source (λ=1.5406 Å) in the 2θ range of 10–80°, scanning rate of 1°/min and step size of 0.01. A Labtech Ultra Micro Film Blowing Line (model LUMF- 150) single-screw extrusion extruder was utilized to produce films. The films' mechanical properties were examined through tensile tests conducted with a Zwick Roell Z2.5 universal testing machine. The testing followed the ASTM D882- 10 standard, using a 20 N ceramic load cell, and five samples from each batch were tested to ensure consistent results. The Fourier transform infrared (FTIR) spectra of the polymer films were obtained using a Shimadzu IRTracer- 100 spectro photometer in transmittance mode over wavelengths ranging from 500 to 4000 cm−1 at a resolution of 4 cm−1. Thermogravimetric analysis (TGA) was carried out in a TA Q 500TGA. PSPW (15 mg) samples were heated from 30°C to 600°C at a heating rate of 10°C/min under a nitrogen atmosphere.

The recycling process began by dissolving EVOH films in DMSO at a 1:10 weight-to-volume ratio. Silica nanoparticles were then added to the solution and dispersed using 10 minutes of sonication to ensure uniform distribution. Precipitation was carried out using distilled water as an antisolvent, after which the recovered EVOH pellets were thoroughly washed three times with distilled water to remove residual DMSO. The resulting material was extruded into films with a thickness of 0.03 mm and subjected to mechanical and thermal characterization. Techniques such as Fourier-transform infrared spectroscopy (FTIR), thermogravimetric analysis (TGA), differential scanning calorimetry (DSC), and scanning electron microscopy (SEM) confirmed the effective incorporation of SiO_2 NPs into the EVOH matrix.

3 RESULTS AND DISCUSSION

FTIR spectra (Fig. 1a) of neat EVOH and EVOH films incorporated with varying concentrations of SiO_2 nanoparticles (0.1, 0.25, and 0.5 w/w%), compared with pure SiO_2 nanoparticles. The characteristic Si–O–Si stretching vibration around 1100 cm^{-1} confirms the successful incorporation of silica into the polymer matrix. Progressive shifts and intensity changes in the spectra indicate increasing interaction between EVOH and SiO_2 with higher nanoparticle loading.

Thermal analysis (Fig. 1b-d) revealed that the incorporation of nano-SiO_2 significantly improved the thermal stability of recycled EVOH films, particularly at low concentrations. The addition of 0.1 w/w% nano-SiO_2 increased the melting and crystallization temperature, indicating enhanced thermal resistance and molecular ordering. In contrast, a higher concentration of 0.5 w/w% led to a decrease in both transition temperatures, likely due to nanoparticle agglomeration that disrupted the polymer's crystalline structure. These trends are consistent with prior findings on SiO_2 based nanocomposites [7]. Therefore, the addition of SiO_2 NPs, particularly at low concentrations, effectively enhanced the mechanical and thermal properties of recycled EVOH films. These results highlight the potential of SiO_2 NPs to improve the performance of recycled polymeric materials, offering a sustainable approach to high performance film production. The mechanical performance of EVOH/SiO_2 nanocomposites (Fig. 1c) varied significantly with SiO_2 content. The 0.1 w/w% SiO_2 sample exhibited the best reinforcement, showing a 177.78% increase in elastic modulus and an 88.87% improvement in Fmax, indicating excellent nanoparticle dispersion and strong interaction with the polymer matrix. At 0.25%, both modulus and Fmax dropped sharply to 33.33% and 34.83% improvement, respectively, likely due to poor dispersion and disruption of polymer continuity. With 0.5% SiO_2, a partial recovery was observed possibly due to the rigid filler effect, although dispersion remained suboptimal. Therefore, the 0.1% concentration demonstrated the most favorable mechanical enhancement. The reduction in mechanical properties at higher concentrations might be attributed to the inadequate formation of intermolecular hydrogen bonds, as reported by Voon et al. (2012), and nanoparticle aggregation, which disrupts the uniform distribution of nanoparticles within the polymer matrix [4-6].

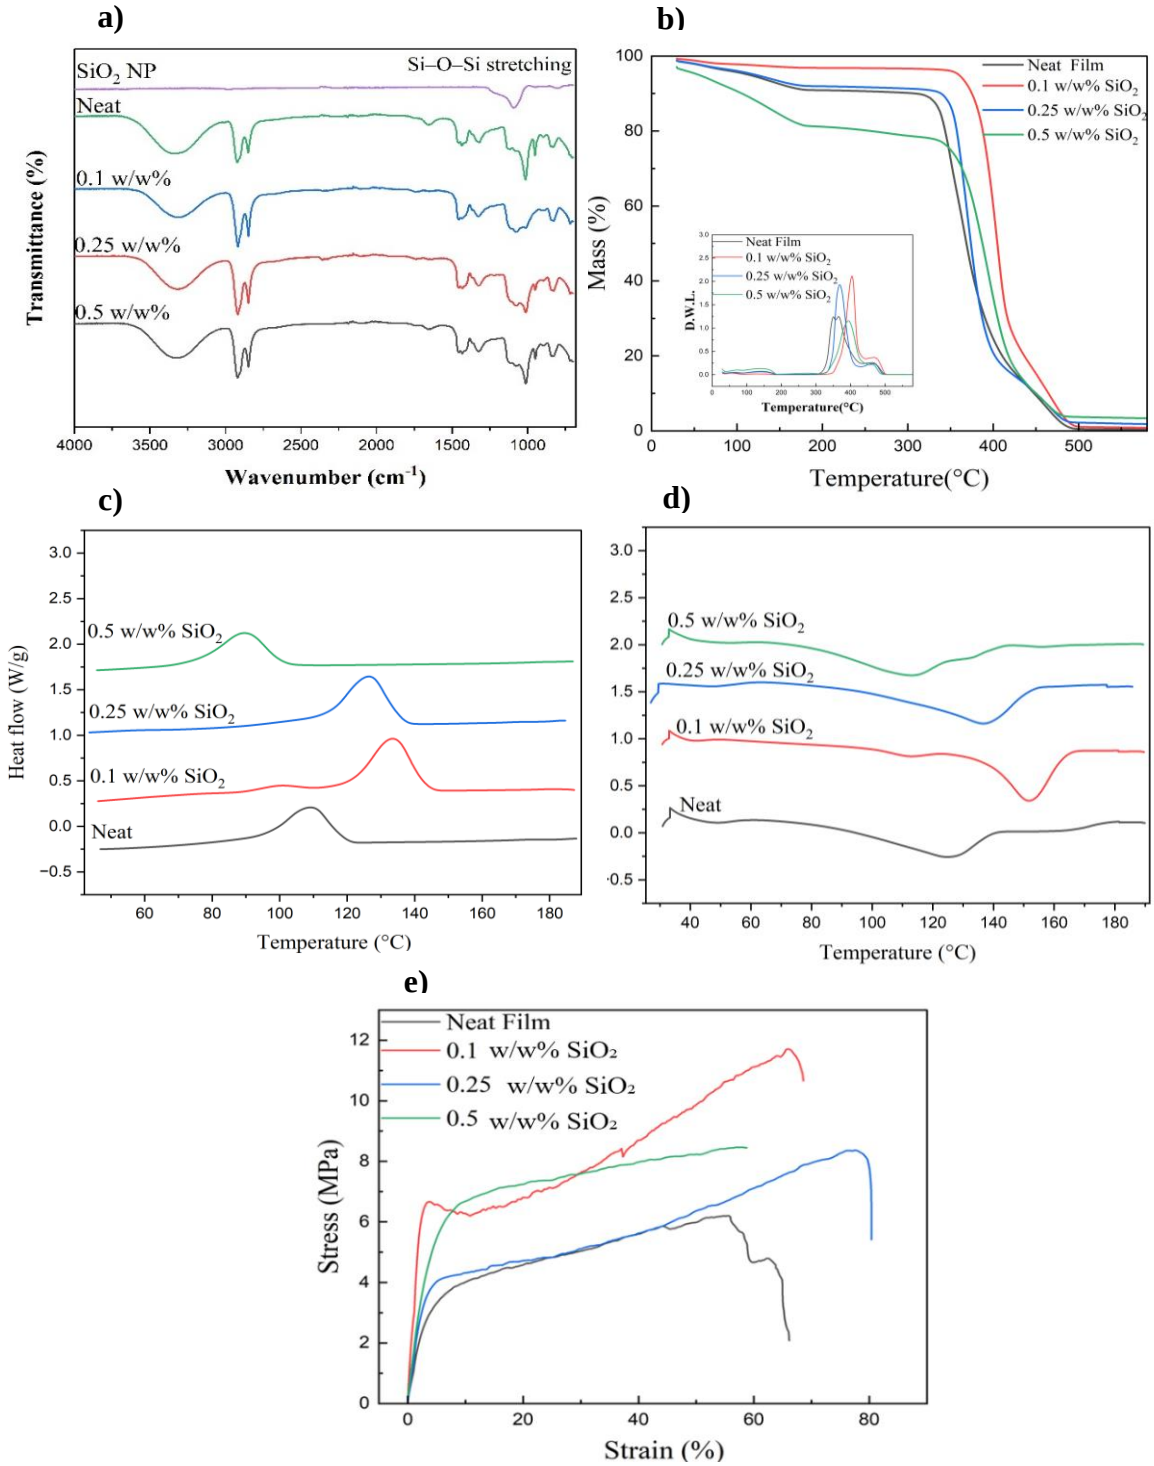

Figure 1: Impact of nano SiO2 on EVOH polymer properties: **a)** FTIR spectra **b)** TGA analysis, **c)** DSC crystallization analysis, **d)** DSC melting analysis, and **e)** Tensile test analysis.

The crystalline structure of SiO_2 nanoparticles and the changes in the crystalline structures of EVOH after incorporating SiO_2 NPs and their relative crystallinity (%) were obtained using XRD [8]. Due to the addition of the nanoparticles inside the polymer structure, some alterations of the matrix and molecular packaging crystalline structure can be found. For packaging, nanomaterials added inside this structure affect crystallinity, barrier properties, mechanical performance, and among others [9,10]. The XRD pattern of SiO_2 nanoparticles (Fig. 2a) displays a broad, prominent peak characteristic of

amorphous silica, consistent with the findings of Sun et al. (2017), who observed a similar peak around 2θ = 23°, confirming the amorphous nature of SiO_2 NPs used in alite–calcium sulfoaluminate (CSA) cement-based nanocomposites [11].

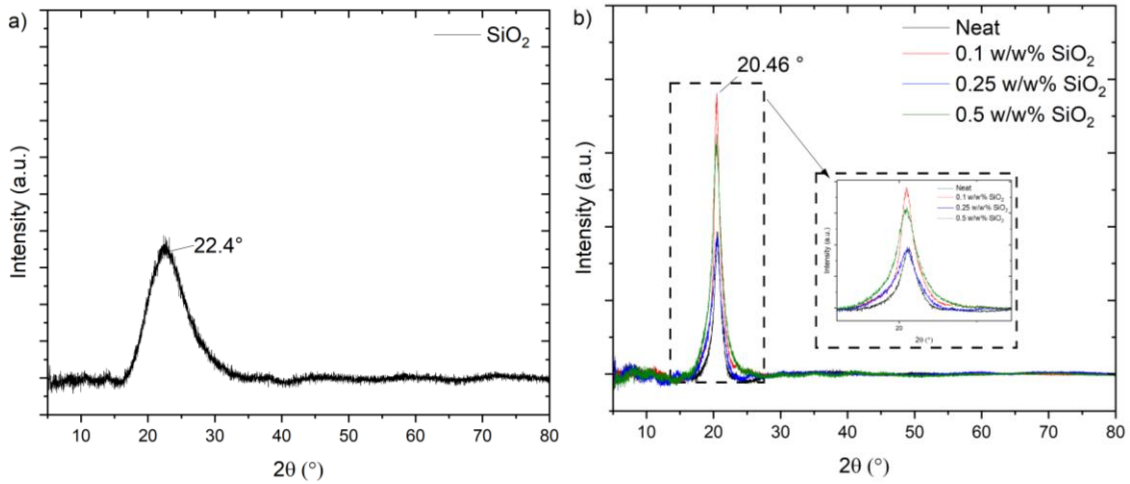

Figure 2: Diffractograms of the **a)** SiO_2 and **b)** EVOH films and their nanocomposite films, varying SiO_2 percentage (0.1, 0.25, and 0.5%).

In Fig. 2b, a distinct diffraction peak appears at approximately 2θ = 20–21° in both neat EVOH and nanocomposite films containing SiO_2 NPs, corresponding to the semi-crystalline structure of EVOH. Notably, the addition of SiO_2 nanoparticles did not introduce new peaks or cause significant peak shifts, suggesting that the crystalline structure of EVOH remains largely unchanged. The relative crystallinity, 2θ values, peak area, and full width at half maximum (FWHM) obtained through peak deconvolution are summarized in Table 1.

Table 1: Relative Crystallinity (%) obtained from XRD diffractograms for SiO_2/EVOH composite films(0.1, 0.25, and 0.5wt/wt%), area under the peak, and Full width at half maximum (FWHM) obtained by deconvolution of diffractograms.

Samples	Relative Crystallinity (%)	2θ degree	The area under the peak	Full width at half maximum (FWHM)
SiO_2	15.91	----	----	----
Neat	5.98	20.60	0.50	1.36
0.1 w/w% SiO_2	14.81	20.54	0.94	1.40
0.25 w/w% SiO_2	7.49	20.43	0.70	1.96
0.5 w/w % SiO_2	10.95	20.47	1.20	2.10

From the values presented in Table 1, relative crystallinity (%) increased when added 0.1 %. Increasing the percentage of SiO_2 nanoparticles for 0.25 and 0.5 w/w.%, a reduction of relative crystallinity was found. Wang et al. (2018) reported that there was an increase in the crystallinity of the PHBV-containing rice husk SiO_2 nanoparticles. However, exceeding 3 wt.% of nanoparticles, a reduction of the crystallinity was verified. Firstly, the increase can be associated with the anisotropic nucleation of the SiO_2 NPs. However, from its limit, this value can decrease due to the agglomeration of these nanoparticles into the polymer matrix [12]. Besides, the interaction between hydroxyl groups of the EVOH and SiO_2 nanoparticles could have created hydrogen bonds, thus forming a large amount of EVOH crystals around the SiO_2 nanostructures [13,14]. the nucleating action of the SiO_2 nanoparticles for 0.1 w/w.% inside the EVOH polymer matrix can create a tortuous pathway for the gases, increasing the barrier property of the food packaging [15].

4 CONCLUSIONS

Based on the comprehensive analysis of FTIR, tensile, thermal, and XRD data, it can be concluded that incorporating low concentrations of nano-SiO_2, particularly at 0.1 w/w%, significantly enhances the performance of recycled EVOH films. FTIR confirmed the successful interaction between SiO_2 and the EVOH matrix through Si–O–Si vibrational bands, with increasing interaction at higher loadings. However, the mechanical and thermal evaluations revealed that 0.1 w/w% SiO_2 yielded the highest improvements in modulus, Fmax, and thermal transitions, attributed to uniform dispersion and strong interfacial bonding. XRD results further supported this by showing increased relative crystallinity at 0.1 w/w%, likely due to the nucleating effect of well-dispersed nanoparticles. Higher concentrations (0.25–0.5 w/w%) led to nanoparticle agglomeration, decreased crystallinity, and diminished mechanical and thermal benefits. Overall, the 0.1 w/w% SiO_2 NPs concentration presents an optimal balance of improved mechanical strength, thermal stability, and crystallinity without compromising structural integrity, offering a sustainable solution for upcycling EVOH-based packaging waste.

ABSTRACT

Structural Health Monitoring Systems (SHMS) enable real-time monitoring of composite aeronautical structures, offering the potential to reduce maintenance efforts. However, their overall impact on the lifecycle remains uncertain. This study presents a methodology to assess the economic impact of SHMS, structured in four steps: (i) identification of SHMS applications, (ii) assessment of SHMS performance, (iii) integration of SHMS into the lifecycle, (iv) evaluation of the resulting economic impact. The methodology is applied to two distinct lifecycle stages of a composite rotorcraft blade: the Beginning of Life (BOL), which involves the development of a new sensorized component, and the Middle of Life (MOL), which focuses on its operational use and maintenance. In the BOL phase, results indicate that SHMS can offer economic advantages if they enable a reduction in the number of curing cycles below a certain threshold. In the MOL phase, while SHMS reduce manpower needs, these savings are offset by higher spare parts costs and longer repair times. The findings highlight the importance of considering both technical performance and cost implications when integrating SHMS into aerospace applications.

NOMENCLATURE

$\ldots^{as\ is}$	Superscript referring to the scenario “as is”
$\ldots^{SHMS}$	Superscript referring to the scenario “with SHMS”
$C_{acq\ sys}$	Cost of the acquisition system for the scenario “as is”
c_{blade}	Cost of the blade to the customer
$C_{cur\ cycle\ def}$	Cost to define the curing cycle
C_{energy}	Cost of energy for the autoclave
CF	Cash flow per year
C_{FBG}	Cost of 1 FBG sensor
$C_{FBG\ sys}$	Cost of the interrogation system for FBG sensors
c_{fuel}	Cost of fuel per hour consumed by the helicopter
C_g	Cost of 1 strain gauge
$C_{lab\ act}$	Cost to perform laboratory activities
C_m	Cost of the material to produce one blade

$C_{test\ lab}$	Cost to perform laboratory tests
C_{th}	Cost of 1 thermocouple
$K_{partition}$	Partition coefficient
L_{eng}	Labour rate of engineers
L_{pilots}	Labour rate of pilots
$L_{tr\ wo}$	Labour rate of trained workers
n_{auto}	Number of autoclave cycles
n_b	Number of rotor blades
n_{FBG}	Number of FBG sensors embedded in one blade
n_g	Number of strain gauges applied on one blade
n_{test}	Number of laboratory blade tests
n_{th}	Number of thermocouples embedded in one blade
R	Revenue loss
r	Discount rate
t_{auto}	Time to perform one autoclave cycle
t_{depot}	Time needed by the helicopter to reach the depot
t_{DI}	Time to perform detailed inspection
t_{eng}	Time needed by the engineers to assess the quality of the acquired data
t_{GVI}	Time to perform general visual inspection
$t_{mount\ blade}$	Time to mount one blade on the rotor hub
t_{repair}	Time to repair one blade
t_{test}	Time to perform one test on the blade
$t_{tr\ wo}$	Time needed by the trained workers to laminate, prepare the vacuum bag and demould the blade

1 INTRODUCTION

Maintenance is a critical activity for ensuring safety in the aviation sector; however, it requires substantial resources in terms of manpower, spare parts, and downtime. In commercial aviation, maintenance can represent up to 28% of total operational costs [1]. At present, maintenance activities rely on Non-Destructive Testing (NDT) techniques such as tapping, ultrasound, and radiography. While these methods are effective, they are restricted to localized inspections, must be performed while the aircraft is on the ground, and often necessitate disassembly of components for access. In comparison, Structural Health Monitoring Systems (SHMS) offer continuous, in-situ monitoring capabilities and allow for the inspection of larger areas than conventional NDT. The use of SHMS in aerospace structures has been extensively explored. For instance, [2] evaluated the performance of a fiber Bragg grating (FBG)-based SHMS on a stiffened metallic helicopter panel under different crack lengths. In [3], a strain-based SHMS was employed to detect damage in a helicopter rotor blade, while [4] used convolutional neural networks to identify damage in composite wings. Although these studies demonstrate clear benefits—particularly in improving safety and enabling condition-based maintenance—the economic impact of SHMS over the lifecycle of monitored structures remains uncertain. In [1], the deployment of Piezoelectric Wafer Active Sensors on a commercial aircraft fuselage was found to offer no economic advantage, as maintenance savings were offset by increased fuel consumption from the added SHMS weight. In [5], replacing A-check and C-check inspections with piezoelectric sensors affected aircraft performance, making SHMS economically impractical. Conversely, [6] indicated potential cost savings when SHMS replaced DVI and GVI using ultrasonic and FBG sensors on an Airbus A320. In [7], SHMS enabled greater allowable design limits and mass reduction for damage-tolerant composite structures, though no benefits were observed for structures designed against instability. To date, most existing research has focused on fixed-wing aircraft [1, 5–10], and, to the best of the authors' knowledge, no studies have assessed the economic implications

of SHMS applied to helicopter structural elements. Moreover, current literature primarily addresses the operational phase, often overlooking the possible impacts of SHMS on the production and development stages.

This study evaluates the economic impact of an optical fiber–based SHMS applied to composite rotorcraft blades. The SHMS performance was assessed using a finite element model of the blade, allowing simulation of multiple damage scenarios used to train an artificial neural network (ANN)–based damage detection algorithm. Both the Beginning of Life (BOL)—which corresponds to production—and the Middle of Life (MOL)—which concerns usage—were examined. The IDEF0 formalism was used to define key processes, inputs, outputs, resources, and constraints, thus forming the foundation for the cost model. Two scenarios were compared using the Life Cycle Cost (LCC) methodology: the current configuration without SHMS ("as-is" scenario) and an alternative configuration with blades equipped with FBG sensors ("with SHMS").

This paper is organized as follows: Section 2 presents the scenarios and associated cost models, including the methodology used to derive them across the BOL and MOL phases. Section 3 describes the cost model implementation, providing a parametric analysis for BOL and a Probabilistic Damage Tolerance Analysis for MOL. Section 4 concludes with the main findings of the study.

2 DEVELOPMENT OF THE COST MODEL

The lifecycle of any product can typically be divided into three main stages: (i) BOL, during which the component is manufactured and introduced to the market; (ii) MOL, during which the component is used and maintained by the customer to perform its intended operational functions; and (iii) End of Life (EOL), when the component is decommissioned and disposed of. This study focuses on the first two stages of the lifecycle: BOL and MOL. To evaluate the economic impact of SHMS on the rotorcraft lifecycle, the following methodology was adopted: (i) identification of the SHMS application; (ii) assessment of SHMS performance; (iii) integration of SHMS into the lifecycle; and (iv) evaluation of the economic impact. Based on this procedure, a composite rotorcraft blade instrumented with FBG sensors was selected as the reference structural element. The choice of FBG sensors is justified by their immunity to electromagnetic interference and their ability to be embedded within the composite laminate with minimal invasiveness [11].

The following subsections provide further details on each step of the proposed methodology.

2.1 Beginning Of Life

With regard to step (ii) of the procedure for assessing the economic impact of SHMS, the performance of the SHMS was not evaluated in this work, as doing so would have required an extensive experimental campaign. Instead, this section focuses on step (iii), which concerns the integration of SHMS into the rotorcraft lifecycle.

At the BOL stage, two applications of SHMS were considered in relation to the laboratory activities required for developing a new composite blade: the definition of the curing cycle and the execution of laboratory tests. The first application relates to the optimization of the curing cycle, in which the evolution of pressure and temperature over time is determined. The second involves laboratory testing to verify the structural integrity of the blade during the initial certification phase.

Currently, defining the appropriate curing cycle for composite elements requires several iterations, since the polymerization of thermoset composites is an exothermic process, and the internal temperature distribution often deviates from the one imposed by the autoclave. Temperature measurements are typically obtained by embedding thermocouples in the laminate, and the curing cycle is repeated and adjusted until the desired thermal conditions are achieved. In the "with SHMS" scenario, SHMS is assumed to be employed during curing by acquiring the internal temperature field via embedded FBG sensors, replacing conventional thermocouples. The superior accuracy of FBG measurements is expected to provide a more precise representation of the temperature distribution, potentially reducing the number of required curing cycles.

After defining the curing parameters, the next phase involves mechanical testing to evaluate the blade's performance. This is traditionally done by applying static and fatigue loads and measuring strain with strain gauges. In the "with SHMS" scenario, the strain gauges are replaced by FBG sensors

to provide more accurate strain measurements, potentially reducing the number of required tests. The total cost of laboratory activities for developing a new composite blade is therefore divided into two components: the cost of defining the curing cycle $C_{cur\ cycle\ def}$ and the cost of conducting mechanical tests $C_{test\ lab}$ as expressed in Eq. 1.

$$C_{lab\ act} = C_{cur\ cycle\ def} + C_{test\ lab} \tag{1}$$

The process related to the laboratory activities, modeled using the IDEF0 formalism, is illustrated in Figure 1. The IDEF0 formalism is designed to map complex processes with the aim of highlighting the following elements: (i) Activities, represented by rectangular boxes; (ii) Inputs, indicated by arrows entering from the left side of each activity; (iii) Outputs, indicated by arrows exiting from the right side; (iv) Constraints, represented by arrows entering from the top; (v) Resources, represented by arrows entering from the bottom;

The cost models were developed based on the inputs and resources required for each activity within the process. A color-coding convention was adopted to distinguish between the two scenarios: activities specific to the "as-is" scenario are shown in red, those belonging to the "with SHMS" scenario are shown in green, and activities common to both scenarios are depicted in black.

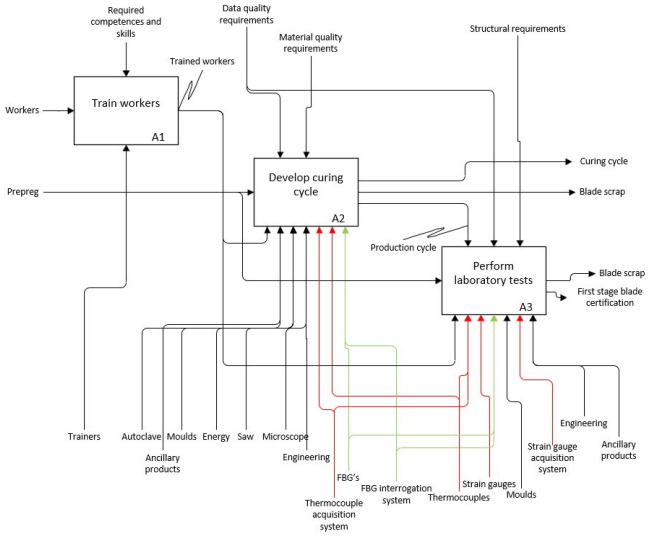

Figure 1: IDEF0 model of the process of the laboratory activities necessary to develop a new composite blade

Following the IDEF0 diagram, for the scenario "as is", the following Eq. 2 representing the cost model for the development of the curing cycle can be obtained.

$$C^{as\ is}_{cur\ cycle\ def} = \left(C_m + L_{tr\ wo} t_{tr\ wo} + n_{th} C_{th} + C_{energy} t_{auto} + L_{eng} t_{eng}\right) n^{as\ is}_{auto} + C_{acq\ sys} \frac{t_{auto} n^{as\ is}_{auto}}{t_{auto} n^{as\ is}_{auto} + t_{test} n^{as\ is}_{test}} \tag{2}$$

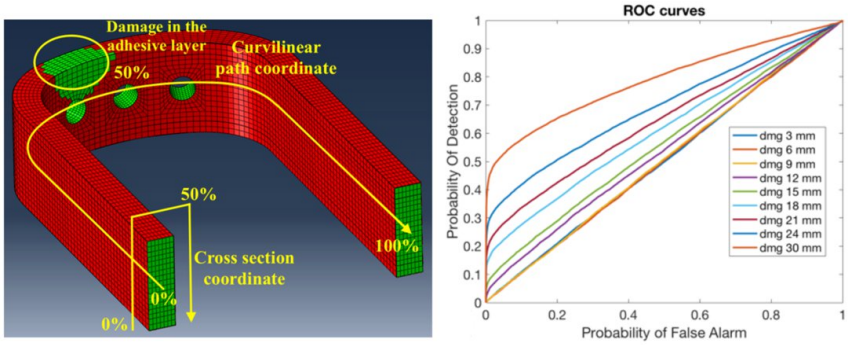
While, considering the scenario "with SHMS", the following Eq. 3 can be written.

$$C^{SHMS}_{cur\ cycle\ def} = \left(C_m + L_{tr\ wo} t_{tr\ wo} + n_{FBG} C_{FBG} + C_{energy} t_{auto} + L_{eng} t_{eng}\right) n^{SHMS}_{auto} + C_{FBG\ sys} \frac{t_{auto} n^{SHMS}_{auto}}{t_{auto} n^{SHMS}_{auto} + t_{test} n^{SHMS}_{test}} \tag{3}$$

The final terms in Eq. 2 and Eq. 3 represent the cost allocation for the acquisition system in the "as-is" scenario and the interrogation system in the "with SHMS" scenario, respectively. Both equations are linearly dependent on the number of autoclave cycles required to determine the optimal curing parameters. Additionally, it can be noted that in Eq. 2, the cost associated with thermocouples is replaced in Eq. 3 by the cost of FBG sensors.

With regard to the laboratory testing activities required to complete the initial phase of blade certification, the cost models for the "as-is" and "with SHMS" scenarios are presented in Eq. 4 and Eq. 5, respectively.

$$C_{test\ lab}^{as\ is} = \left(C_m + L_{tr\ wo}t_{tr\ wo} + n_g C_g + C_{energy}t_{auto} + L_{eng}t_{eng}\right) n_{test}^{as\ is} + C_{acq\ sys}\frac{t_{test}n_{test}^{as\ is}}{t_{auto}n_{auto}^{as\ is} + t_{test}n_{test}^{as\ is}} \quad (4)$$



$$C_{test\ lab}^{SHMS} = \left(C_m + L_{tr\ wo}t_{tr\ wo} + n_{FBG}C_{FBG} + C_{energy}t_{auto} + L_{eng}t_{eng}\right) n_{auto}^{SHMS} + C_{FBG\ sys}\frac{t_{test}n_{test}^{SHMS}}{t_{auto}n_{auto}^{SHMS} + t_{test}n_{test}^{SHMS}} \quad (5)$$

The final term in Eq. 4 and Eq. 5 represents the cost allocation for the acquisition system in the "as-is" scenario and the interrogation system in the "with SHMS" scenario, respectively. Both equations are linearly dependent on the number of blades tested. Furthermore, it can be noted that the cost of strain gauges in Eq. 4, corresponding to the "as-is" scenario, is replaced by the cost of FBG sensors in Eq. 5, corresponding to the "with SHMS" scenario.

2.2 Middle Of Life

In accordance with step (ii) of the proposed procedure for assessing the economic impact of SHMS, the performance of the SHMS was evaluated using a finite element (FE) model, experimentally validated and representing a portion of the rotorcraft blade—specifically, the blade root. Damage was assumed to occur exclusively within the adhesive layer that bonds the central core to the surrounding antitorsional layer. Various damage sizes, ranging from 3 mm to 30 mm, were analyzed and distributed across the adhesive surface. In the FE model, damage was simulated by removing the elements enclosed within a sphere, the center of which was located on the surface of the adhesive layer. An example of a 30 mm damage scenario is shown in Figure 2a. As illustrated, two coordinate systems were employed to define damage locations: a curvilinear coordinate system along the blade's length and a cross-sectional coordinate system. Damage was distributed at 10 equally spaced positions along the curvilinear coordinate, and for each position, four evenly spaced locations were selected across the cross section. This yielded a total of 40 damage locations. For each of these 40 locations, the following damage sizes were considered: 3, 6, 9, 12, 15, 18, 21, 24, and 30 mm—resulting in a total of 360 distinct damage scenarios.

The analyses served as input for training an ANN–based algorithm designed to detect the presence of damage. Strain measurements were extracted from selected elements within the FE model. Specifically, six virtual optical fiber lines were defined, each containing ten virtual FBGs, resulting in a total of 60 virtual FBGs. These were positioned inside the antitorsional layer, at a distance of 0.25 mm from the adhesive interface. To simulate realistic measurement conditions, Gaussian noise with a standard deviation of 4% was added to the sampled strain values during the training, validation, and testing phases of the ANN.

a) b)

Figure 2: a) FE model of the blade root, the central core is colored green while the adhesive layer connecting the central core to the antitorsional layer is colored red; b) Receiver Operating Characteristic curve obtained for a Gaussian noise of 4%.

A pattern recognition ANN architecture was adopted, consisting of three hidden layers with ten neurons per layer. The network's output was a scalar value between 0 and 1. A blade was classified as damaged if the ANN output exceeded a predefined threshold; otherwise, it was considered undamaged. The damage detection performance of the SHMS was quantified in terms of Probability of Detection (POD) and Probability of False Alarm (PFA), as shown in Figure 2b for a 4% Gaussian noise level. Receiver Operating Characteristic (ROC) curves were generated by varying the classification threshold from 0 to 1. POD was calculated as the ratio of correctly identified damaged blades to the total number of damaged blades, while PFA represented the ratio of undamaged blades falsely classified as damaged to the total number of undamaged blades evaluated.

Step (iii) of the proposed methodology, concerning the integration of the SHMS into the rotorcraft's lifecycle, is addressed below. In both the "as-is" and "with SHMS" scenarios, helicopter downtime was considered to result in revenue loss. It was assumed that the helicopter was owned by a leasing company renting aircraft to external operators.

For the "as-is" scenario—based on practical experience in the aerospace sector—the blade was assumed to undergo two types of inspections: General Visual Inspection (GVI), performed every 50 flight hours (FH) without removing the blade from the rotor hub, and Detailed Inspection (DI), carried out using a tap hammer every 1200 FH, requiring blade removal. The annual cash flow associated with the "as-is" scenario is expressed in Equation 6.

$$CF^{as\ is} = \sum_{i=1}^{n\ travels} 2At_{depot}K_{partition} + \sum_{i=1}^{n\ blade\ mount-sched} 2Bt_{mount\ blade} + \sum_{i=1}^{n\ blade\ mount-unsch} \frac{2}{n_b}Ct_{mount\ blade} + \sum_{i=1}^{n\ GVI} Bt_{GVI} + \sum_{i=1}^{n\ DI} Bt_{DI} + \sum_{i=1}^{n\ repairs} Ct_{repair}^{as\ is} + \sum_{i=1}^{n\ spare\ parts} c_{blade}^{as\ is} \quad (6)$$

Where the coefficients A, B, and C were defined by the Eq. 7, Eq. 8, and Eq. 9, respectively.

$$A = \left(L_{pilots} + c_{fuel} + R\right) \quad (7)$$

$$B = \left(L_{tr\ wo} + RK_{partition}\right) \quad (8)$$

$$C = \left(L_{tr\ wo} + R\right) \quad (9)$$

Several cost elements were taken into account in Eq. 6, including travel to the maintenance

depot, blade removal from the rotor hub, performance of GVI and DI inspections, blade repair, and blade replacement. A distinction was also made between scheduled and unscheduled maintenance activities. For scheduled activities, a partition coefficient $K_{partition}$ was introduced to allocate the helicopter's revenue loss R specifically to blade-related maintenance. This reflects the fact that, during scheduled downtime, multiple maintenance tasks are typically performed concurrently across different aircraft systems. Therefore, only a portion of the total revenue loss can be attributed to rotor blade maintenance. In contrast, for unscheduled activities caused specifically by the rotor blades, this partitioning is not applicable. Since these events occur outside of the planned maintenance schedule, they do not allow for simultaneous work on other components. As a result, the full revenue loss R is attributed solely to the rotor blade issue. Consequently, unscheduled activities are significantly more costly than scheduled ones. In the "with SHMS" scenario, the GVI was assumed to be carried out identically to the "as-is" scenario. However, the SHMS was intended to progressively replace the DI. During the initial years of the blade's lifecycle, the DI interval was extended to 2400 FH, supported by additional automatic inspections enabled by the SHMS. In later years, once confidence in the SHMS's performance had grown, it was assumed that the system would fully replace DI activities, achieving a fully Condition-Based Maintenance (CBM) approach.

It is important to note that SHMS data were assumed to be retrieved at regular intervals by a ground-based operator. However, if the SHMS issued an alert and no damage was identified during the GVI, the helicopter was assumed to return to the depot for a DI using the same procedures as in the "as-is" scenario.

The annual cash flow for the "with SHMS" scenario is described by Equation 10.

$$\begin{aligned} CF^{SHMS} = & \sum_{i=1}^{n\ travels-sched} 2At_{depot}K_{partition} + \sum_{i=1}^{n\ travels-unsch} 2At_{depot} \\ & + \sum_{i=1}^{n\ blade\ mount-sched} 2Bt_{mount\ blade} + \sum_{i=1}^{n\ blade\ mount-unsch} \frac{2}{n_b}Ct_{mount\ blade} + \sum_{i=1}^{n\ GVI-sched} Bt_{GVI} \\ & + \sum_{i=1}^{n\ GVI-unsch} \frac{1}{n_b}Ct_{GVI} + \sum_{i=1}^{n\ DI-sched} Bt_{DI} + \sum_{i=1}^{n\ DI-unsch} \frac{1}{n_b}Ct_{DI} + \sum_{i=1}^{n\ repairs} Ct_{repair}^{SHMS} \\ & + \sum_{i=1}^{n\ spare\ parts} c_{blade}^{SHMS} \end{aligned} \tag{10}$$

It is worth noting that different costs were assumed for both the blade and the repair time compared to the "as-is" scenario. Additionally, unlike in the "as-is" case, the travel activity in the "with SHMS" scenario was considered unscheduled, as an SHMS-triggered alarm could prompt the helicopter to return to the depot for a DI.

The Net Present Value (NPV), shown in Equation 11, was selected as the performance indicator to compare the two scenarios. This metric enables the discounting of all cash flows occurring throughout the helicopter's operational lifecycle.

$$NPV = \sum_{t} \frac{CF(t)}{(1+r)^{t}} \tag{11}$$

The two scenarios—"as-is" and "with SHMS"—were compared under the same Probability of Failure (POF) for the blade, as determined through a Probabilistic Damage Tolerance Analysis [13]. According to [14], in offshore operations, a helicopter is expected to experience one main rotor impact every 1000 FH. Assuming an average usage of 500 FH per year over a 30-year lifespan, a total of 15 impacts are anticipated throughout the helicopter's lifecycle. These impacts were randomly distributed

in the lifecycle simulation. Impact energies were modeled based on the "medium energy" distribution described in [15]. Blade degradation following an impact was assumed to follow the behavior described in [16], where helicopter blades were subjected to steel sphere impacts at varying energy levels, and data were provided for residual indentation and skin-foam disbonding area. The residual strength of the blade after an impact was estimated by calculating the ratio between the cross-sectional area affected by indentation and the original cross-sectional area. A schematic representation of the blade's strength degradation is shown in Figure 3a.

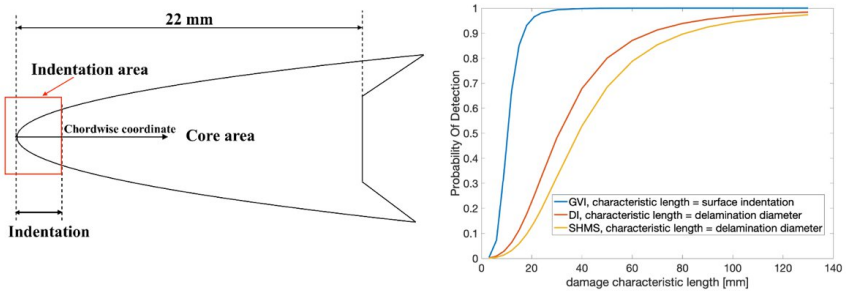


Figure 3: a) Schematic representation of the blade strength degratation function of the residual indentation; b) POD curves corresponding to the GVI, DI, obtained from [17], and SHMS, the latter calculated considering a threshold such to reach a PFA of 0.12% from the ROC curves presented in Figure 2b.

Accordingly, the following Eq. 12 was used to compute the ratio between the initial strength and the strength after an impact.

$$strength\ ratio\ = 1 - 1.5\frac{indentation\ area}{core\ area} \tag{12}$$

A coefficient of 1.5 was introduced to account for stress concentration effects. The indentation area was calculated by approximating the shape of the cross section near the leading edge with a square root function, resulting in Eq. 13. This equation expresses the indentation area as a function of the indentation depth.

$$indentation\ area\ = 2.89 \times indentation^{1.5} \tag{13}$$

Figure 3b shows the performance of GVI, DI, and SHMS in terms of the POD as a function of damage size. It is important to note that, while damage size for DI and SHMS refers to the delamination size, for GVI it corresponds to the surface indentation. The POD curves for GVI and DI were obtained from [17], while the performance of SHMS was previously derived using the FE model of the blade root. These SHMS results were assumed to be representative of the entire blade length. Assuming the total blade length is 7.5 times longer than the portion analyzed in the FE model, the number of FBG sensors was scaled proportionally. As a result, a total of 450 FBG sensors was considered for one blade.

In the Probabilistic Damage Tolerance Analysis, the load exceedance probability per FH was calculated based on [18]. The initial blade strength ratio was set to 2, representing the ratio between the failure load and the limit load. The blade's lifecycle was simulated on an hourly basis using a MATLAB script, averaging results across 30000 simulated scenarios. At each hour, the code checks whether it is time to perform an inspection. Accordingly, the inspection intervals for GVI, DI, and SHMS (the latter only for the "with SHMS" scenario) were defined as input parameters.

The cost model described by Eqs. 6–11 was implemented in the same script, which aggregates yearly cash flows across the lifecycle and ultimately calculates the NPV.

3 RESULTS

In this section, the final step (iv) of the procedure for assessing the economic impact of SHMS was completed. Table 1 presents selected values of the variables used in this study to evaluate the economic impact.

Variable	Value	Source
$C_{acq\ sys}$	13000 €	[19]
$c_{blade}^{as\ is}$	40000 €	DAER-lab
C_{energy}	10.6 €/h	[20]
C_{FBG}	90 €	DAER-lab
$C_{FBG\ sys}$	20000 €	[21]
c_{fuel}	272.64 €/h	[22, 23]
C_g	1 €	DAER-lab
C_m	1307 €	[20] and DAER-lab
C_{th}	10 €	[24]
$K_{partition}$	0.1	DAER-lab
L_{eng}	42 €/h	DAER-lab
L_{pilots}	48.2 €/h	[25]
$L_{tr\ wo}$	28 €/h	[26]
n_b	4	DAER-lab
n_{FBG}	450	DAER-lab
R	6560.6 €/h	[27]
r	8%	[28]
t_{auto}	8 h	DAER-lab
t_{depot}	0.5 h	DAER-lab
t_{DI}	15 h	DAER-lab
t_{eng}	0.0167 h	DAER-lab
t_{GVI}	0.652 h	DAER-lab
$t_{mount\ blade}$	0.5 h	DAER-lab
$t_{repair}^{as\ is}$	8 h	DAER-lab
$t_{tr\ wo}$	25 h	DAER-lab

Table 1: values and sources of the variables assumed in this study.

3.1 Beginning Of Life

The results related to the BOL analysis highlighted the presence of break-even points, beyond which one of the two scenarios becomes more economically advantageous than the other.

In terms of curing cycle development, it was found that if the number of cycles required to identify the optimal curing parameters is significantly reduced—thanks to the improved temperature field quality provided by FBG sensors—an economic benefit can be achieved. In this case, the “with SHMS” scenario becomes more favourable. For example, as shown in Figure 4a, if the number of curing cycles decreases from 26 in the “as is” scenario to fewer than 19 when using 10 FBG sensors (the “with SHMS” scenario), then the “with SHMS” scenario becomes more economically viable.

A similar trend was observed in relation to the laboratory tests required during the initial stage of blade certification. Here too, break-even points exist beyond which one scenario becomes more advantageous than the other. Specifically, if the number of tested blades can be sufficiently reduced—thanks to the improved strain field data from FBG sensors—an economic benefit is achieved under the “with SHMS” scenario. For instance, as shown in Figure 4b, if the number of tested blades decreases

from 22 in the "as is" scenario to fewer than 18 in the "with SHMS" scenario using 10 FBG sensors, the latter becomes the more cost-effective option.

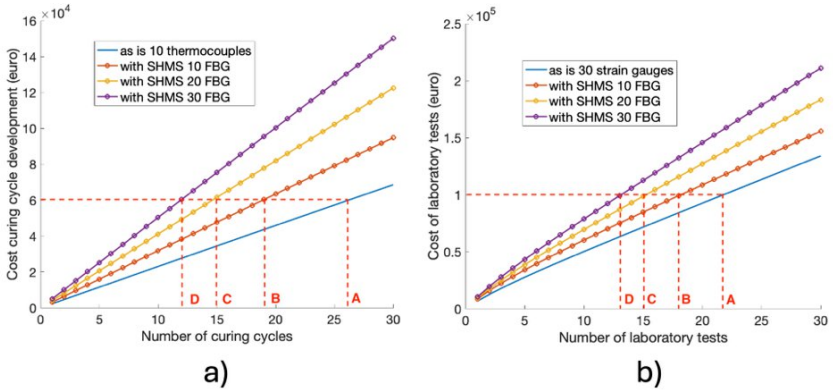

Figure 4: a) Cost of the curing cycle development versus the number of curing cycles performed, with sensitivity analysis on the number of FBG sensors embedded in the blade; b) Cost of laboratory tests versus the number of laboratory tests, with sensitivity analysis on the the number of FBG sensors embedded in the blade.

3.2 Middle Of Life

The results related to the MOL phase indicated that, in the "with SHMS" scenario, it was possible to extend the DI interval up to 2400 FH, provided that automatic inspections using SHMS were performed every 1070 FH. This extension maintained the same POF for the blade as in the original scenario. For this reason, the comparison between the two scenarios was conducted assuming an automatic inspection interval of 1070 FH for the SHMS. As shown in Figure 5, this condition is represented by the green vertical dashed line. Comparing the two scenarios at this inspection interval reveals a negative economic impact associated with the SHMS over the helicopter's lifecycle.

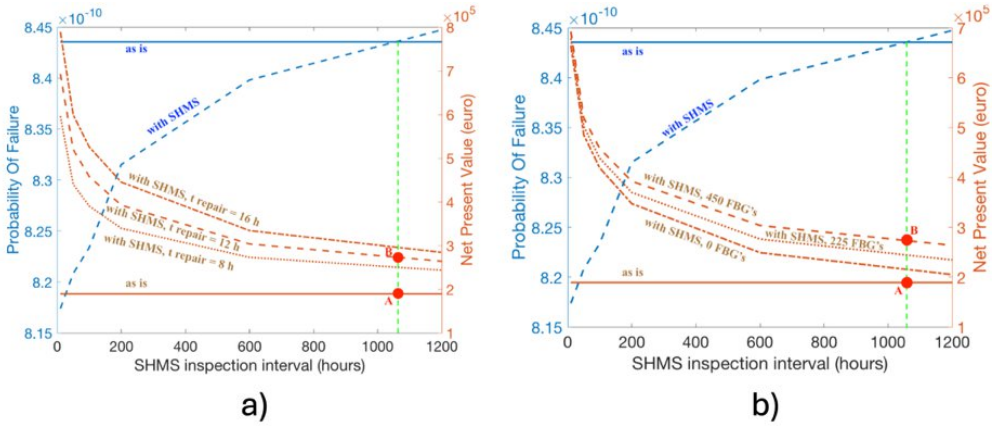

Figure 5: a) POF and NPV function of the inspection interval of the SHMS, with sensitivity analysis on the repairing time of the sensorized blade; b) POF and NPV function of the inspection interval of the SHMS, with sensitivity analysis on the number of FBG sensors charged to the customer.

Specifically, as illustrated in Figure 5, points A and B correspond to the "as is" and "with SHMS" scenarios, respectively. The NPV for the "as is" scenario is €1.89×10^5, while the NPV for the "with SHMS" scenario is €2.726×10^5. This indicates that maintenance in the "with SHMS" scenario is more expensive than in the "as is" scenario.

One of the main reasons for this outcome is the high number of unscheduled maintenance activities triggered by SHMS alarms, which makes it difficult to coordinate maintenance operations and consequently increases helicopter downtime. In fact, an analysis of the NPV breakdown shows that the use of SHMS led to a reduction in the effort required for DI, decreasing from 22% in the "as is"

scenario to 6% in the "with SHMS" scenario. However, this saving was offset by increased costs related to spare parts and repair operations.

It is also worth noting the findings from the sensitivity analyses shown in Figures 5a and 5b. These results indicate that even when assuming the same repair time of 8 hours for both standard and sensorized blades, the "as is" scenario remains the more cost-effective option. Furthermore, even under the assumption that the cost of the FBG sensors is not passed on to the customer—as illustrated in Figure 5b—the "as is" scenario continues to be the more economically favourable choice.

4 CONCLUSIONS

In this work, the economic impact of an FBG-based SHMS was investigated from two perspectives: BOL and MOL. The assessment followed the LCC methodology, which involves comparing different alternatives. In this study, two scenarios were evaluated: the current baseline scenario ("as is") and the scenario incorporating SHMS ("with SHMS").

Several key conclusions can be drawn from the analysis. First, a methodology to assess the economic impact of SHMS was developed and applied to the case of a rotorcraft composite blade. Although tailored to this specific application, the methodology can be generalized and adapted to other composite structural components. Second, at the BOL stage, SHMS implementation was shown to have a positive economic impact when a sufficient number of autoclave cycles are saved during the definition of curing parameters. Third, for the MOL stage, the use of SHMS on the composite rotorcraft blade resulted in a negative economic outcome. The savings achieved through automated scheduled inspections using SHMS were offset by the higher costs of spare parts and increased complexity of repair operations. To make SHMS economically viable, they should be applied to structural components that are difficult to access during maintenance. In such cases, the full potential of SHMS to reduce maintenance burden and downtime can be more effectively leveraged.

Future work should aim to quantify the actual reduction in the number of curing cycles and laboratory tests, made possible by the improved quality of temperature and strain field measurements obtained through FBG sensors.

Keywords: Hydrogen storage, Type-4 pressure vessel, genetic algorithm, classical laminate theory (CLT), Failure theories

ABSTRACT

This study presents an analytical and optimization-based approach to enhance the burst performance of type-4 hydrogen pressure vessels. An analytical model using Classical Laminate Theory (CLT) was developed and validated against experimental and finite element data (FEA) from Sharma et al. (2023), showing strong agreement with less than 1% error compared to FEA and 8.3% deviation from experimental burst pressure. Among various failure theories, Hashin criterion accurately predicted matrix dominated failure in the cylindrical section, consistent with experimental observations. To improve structural performance, a Progressive Ply Failure (PPF) strategy was first applied by replacing the first failed plies, resulting in a 16.28% increase in burst pressure. However, to achieve optimal stacking efficiency, a Genetic Algorithm (GA) was employed. Through iterative evolution using tournament selection, the GA achieved a 28.89% improvement in burst pressure compared to the reference model using Hashin failure. This combined approach of analytical modeling, failure prediction, and evolutionary optimization provides a reliable and scalable method for designing high-performance hydrogen storage vessels, supporting the advancement of safe and efficient clean energy systems.

1. INTRODUCTION

Compressed hydrogen is an emerging energy carrier for sustainable and clean energy systems, specifically for fuel cell vehicles (FCVs). The major challenge in hydrogen adoption is the safe and efficient hydrogen storage for onboard and stationary automobile applications. Moreover, hydrogen gas have high diffusivity (6.1×10^{-5} m^2/s at NTP), reactivity, wide flammability range (4 - 74 % v/v in air) and low volumetric storage density (0.089 kg/m^3) at atmospheric condition which resist the commercialization of FCVs [1]. Therefore, hydrogen gas needs to be compressed and stored in pressure vessels at higher pressure up to 100 MPa, to improve the volumetric storage density.

There are four types of pressure vessels categories based on their material of construction as shown in Figure 1 (A). Type-1 is a traditional metallic pressure vessel with an operating pressure of ≤ 20 MPa. These vessels are highly prone to hydrogen embrittlement and their strength-to-weight ratio is very low. Type-2 pressure vessels are upgraded with hoop winding over a metallic liner/vessel, these vessels can hold the operating pressure up to ≤ 30 MPa. Type-3 is hybrid pressure vessels with fully overwrapped with hoop and helical layers over a metallic liner, these vessels have operating pressure up to ≤ 50 MPa. Type-4 is lightest among all the pressure vessels due to their material of construction, these vessels are fully overwrapped on a high hydrogen gas barrier polymeric liner. Type-4 pressure vessels have higher operating pressure up to 100 MPa, offers higher volumetric storage density and protected from hydrogen embrittlement. However, the major challenge in type-4 composite pressure vessels is the design of the composite structure because composite is the main strength contributor whereas the liner is a non-load

sharing component which is used to hold the hydrogen gas under allowable permeation rate and providing mandrel for filament winding [2], [3]. Composite structure of the pressure is composed of many hoop (90^0 angle layer) and helical layers (other than 90^0 angle layer) arranged in a specific order to achieve the desirable burst performance of the pressure vessels as shown in Figure 1 (B). These layers can be arranged in several ways to achieve the desired burst performance. The structural integrity and burst performance of Type-IV vessels are highly dependent on the stacking sequence of the composite layers. An optimized laminate design not only improves safety and reliability but also enhances material efficiency and reduces cost.

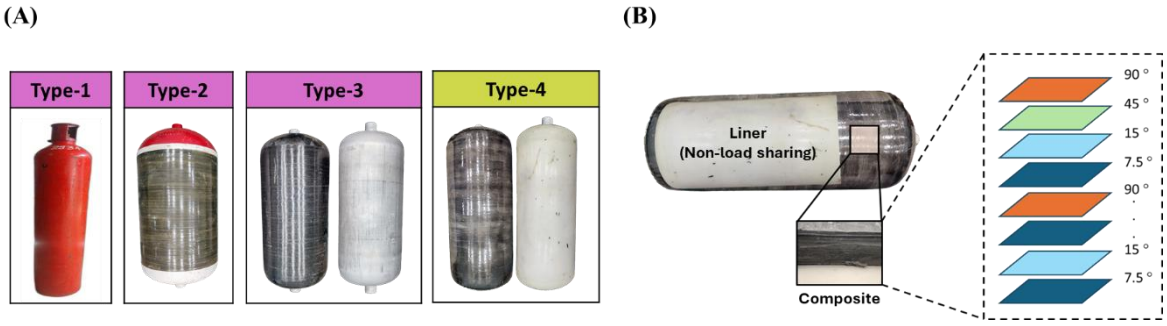

Figure 1: (A) Types of pressure vessel and (B) cross-sectional view of composite in type-4.

Several studies have been reported on the performance improvement of composites. Leh et al. developed a simulation platform to predict the burst pressure of type-4 pressure vessels using progressive failure mechanism. However, model was based conventional approach [4]. Nebe et al. investigate the burst pressure of composite pressure vessel based on first ply failure mechanism and found 67 % difference in experimental and model prediction [5]. Chang et al. worked on experimental validation of progressive ply failure using acoustic emission AMS3 (AE) system. However, his work does not involve any specific optimization technique [6]. The literature found that the progressive failure is a powerful approach for preliminary investigation of burst pressure and design. However, for fast and reliable designing of pressure vessel required a robust optimization technique to optimize the vessel design specifically layer sequence.

Alcantar et al. worked on optimization of type-4 pressure vessels using genetic algorithms and simulated annealing. the study reported 11.2 % improvement in design performance [7]. Fanding et al. integrated an artificial neural network with a finite element model to predict the first performance, and the model was accurate up to 2% of error [8].

Based on extensive literature, designing of composite pressure vessel with an optimum winding sequence for better performance is the major challenge. To address this challenge, this study integrates an analytical model based on Classical Laminate Theory (CLT) with failure criteria and optimization algorithms to improve vessel performance. The model is validated against experimental and finite element burst pressure data. A Progressive ply failure (PPF) approach is initially applied to iteratively enhance the layer sequence. However, due to its limitations, a Genetic Algorithm (GA) is introduced to perform a global optimization of the stacking sequence under mechanical and manufacturing constraints. This research aims to demonstrate the effectiveness of combining analytical modeling, failure analysis, and evolutionary optimization in designing high-performance Type-IV pressure vessels that meet stringent safety standards, such as ISO 11119-3. The findings provide a framework for systematic laminate optimization and support the advancement of safer, lighter, and more efficient hydrogen storage systems.

2. MATERIALS AND METHOD

2.1. MATERIALS

T700SC-12k carbon fiber manufactured by Toray, Japan and Araldite LY556 with hardener XY54 manufactured by Huntsman were used for the manufacturing of the type-4 pressure vessels. The composite properties were calculated by using micromechanics, measured properties are listed in Table 1 [9]. The fiber volume fraction of the composite material was 30 v/v%, measured by using muffle furnace by heating the small coupon of the composite at 600 ^{0}C temperature.

Table 1: Carbon-epoxy composite material specifications.

Properties	Symbol/unit	Carbon fiber (T700SC)	Epoxy resin Araldite LY 556 Hardener XY 54	Composite
Longitudinal modulus	E_{11} (MPa)	230000	3450	71415
Transverse modulus	E_{22} (MPa)	17000	3450	6123
In-plane shear modulus	G_{12} (MPa)	900	1280	2414
Out of plane shear modulus	G_{23} (MPa)	4600	1280	1383
Major Poisson's ratio	v_{12}	0.2	0.35	0.305
Minor Poisson's ratio	v_{23}	0.25	0.35	0.555
Longitudinal Tensile strength	X_{11}^{t} (MPa)	4900	90	1470
Transverse tensile strength	X_{22}^{t} (MPa)	-	90	88.5
In-plane shear strength	X_{12} (MPa)	600	50	118
Out of plane shear strength	X_{23} (MPa)	600	50	98
Density	ρ (kg/m^3)	1800	1150	1345

2.2. METHODS

In this study, the type-4 pressure vessel design parameters were taken from Sharma et al. [9], for modelling and validation. The type-4 vessel has 29 layers $[7.5_7/15_6/25_4/35_1/45_1/90_{10}]$ with an experimental burst pressure of 81.9 MPa. Figure 2 shows the flowchart to predict the burst pressure of type-4 pressure and the approaches to improve the burst performance. The burst performance of the pressure vessel was predicted by an analytical model of the type-4 pressure vessel using Classical Laminate Theory (CLT) in MATLAB 2024. CLT is an analytical framework to predict the mechanical behaviour of the composite laminate under in-plane loading. CLT enables the determination of in-plane stresses, strains, and deformations in a laminate composed of multiple orthotropic laminae stacked at various orientations. The analytical model was developed based on the following assumptions: 1) each lamina behaves as a linear elastic orthotropic material, 2) Kirchhoff hypothesis, and 3) Perfect bonding [10].

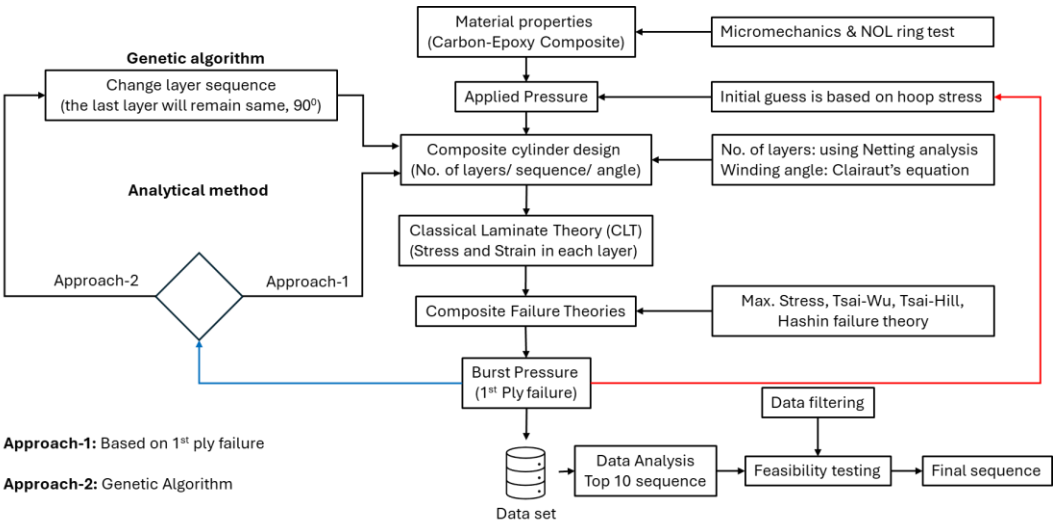

Figure 2: Flowchart for burst pressure prediction and performance improvement strategies.

The fundamental equation of CLT is given by the equation (1). This equation is used to express in-plane strain and curvature at any location of the composite [11].

$$\begin{bmatrix} N_x \\ N_y \\ N_{xy} \\ M_x \\ M_y \\ M_{xy} \end{bmatrix} = \begin{bmatrix} A_{11} & A_{12} & A_{16} & B_{11} & B_{12} & B_{16} \\ A_{12} & A_{22} & A_{26} & B_{12} & B_{22} & B_{26} \\ A_{16} & A_{26} & A_{66} & B_{16} & B_{26} & B_{66} \\ B_{11} & B_{12} & B_{16} & D_{11} & D_{12} & D_{16} \\ B_{12} & B_{22} & B_{26} & D_{12} & D_{22} & D_{26} \\ B_{16} & B_{26} & B_{66} & D_{16} & D_{26} & D_{66} \end{bmatrix} \begin{bmatrix} \varepsilon_x^0 \\ \varepsilon_y^0 \\ \gamma_{xy}^0 \\ k_x \\ k_y \\ k_{xy} \end{bmatrix} \quad (1)$$

$$A_{ij} = \sum_{k=1}^{n} \left[\left(\overline{Q}_{ij}\right)\right]_k (h_k - h_{k-1});\ B_{ij} = \frac{1}{2}\sum_{k=1}^{n} \left[\left(\overline{Q}_{ij}\right)\right]_k ({h^2}_k - {h^2}_{k-1});$$

$$D_{ij} = \frac{1}{3}\sum_{k=1}^{n} \left[\left(\overline{Q}_{ij}\right)\right]_k ({h^3}_k - {h^3}_{k-1}) \quad (2)$$

$$\begin{bmatrix} \varepsilon^0 \\ k \end{bmatrix} = \begin{bmatrix} A_1 & B_1 \\ B_1 & D_1 \end{bmatrix} \begin{bmatrix} N \\ M \end{bmatrix} \quad (3)$$

Where [A], [B] and [D] are extensional, coupling and bending stiffness matrix, respectively. These stiffness matrices are a function of the transformed reduced stiffness matrix $[\overline{Q}]$ and the total number of layers n, where h represents the thickness of each layer. Finally, the stress-strain on each layer is calculated by using equation (4). Where z is total thickness of the composite.

$$\begin{bmatrix} \sigma_x \\ \sigma_y \\ \tau_{xy} \end{bmatrix} = [\overline{Q}] \begin{bmatrix} \varepsilon_{x0} \\ \varepsilon_{y0} \\ \gamma_{xy0} \end{bmatrix} + z[\overline{Q}] \begin{bmatrix} k_x \\ k_y \\ k_{xy} \end{bmatrix} \quad (4)$$

$$\begin{bmatrix} \varepsilon_x \\ \varepsilon_y \\ \gamma_{xy} \end{bmatrix} = \begin{bmatrix} \varepsilon_{x0} \\ \varepsilon_{y0} \\ \gamma_{xy0} \end{bmatrix} + z \begin{bmatrix} k_x \\ k_y \\ k_{xy} \end{bmatrix} \quad (5)$$

Once the stress and strain in the composite are calculated, then failure theories can be implemented to find the burst pressure of the composite. However, conventional isotropic failure criteria are inadequate for the anisotropic and heterogeneous nature of fiber-reinforced composites. Therefore, Maximum stress, Tsai Wu, Tsai Hill, and Hashin failure criteria were used to predict he failure. Each criterion has a different approach in defining how and when failure occurs in a composite lamina [12], [13].

Maximum stress failure criteria: is a noninteractive, simplest and conservative failure theory that assumes failure when any individual stress component in the local lamina coordinate system exceed its corresponding ultimate strength limit as given by equation (6).

$$-(\sigma_1^c)_{ult} < \sigma_1 < \left(\sigma_1^T\right)_{ult};\ -(\sigma_2^c)_{ult} < \sigma_2 < \left(\sigma_2^T\right)_{ult};\ -(\tau_{12}^c)_{ult} < \tau_{12} < \left(\tau_2^T\right)_{ult} \quad (6)$$

Tsai Wu failure criteria: is an interactive theory which includes linear and quadratic terms to account for different strength in tension and compression. This theory assumes the failure of composite when the left side terms of equation (7) is less than 1. This criterion considers tension-compression asymmetry and stress interactions, making it more accurate but computationally intensive.

$$(F_2 + F_3)\sigma_1^2 + (F_1 + F_3)\sigma_2^2 + (F_1 + F_2)\sigma_3^2 - 2F_3\sigma_1\sigma_2 - 2F_2\sigma_1\,\sigma_3 - 2F_1\sigma_2\,\sigma_3 + 2F_4\tau_{23}^2 + 2F_5\tau_{13}^2 + 2F_6\tau_{12}^2 < 1 \quad (7)$$

$$F_1 = \frac{1}{2}\left(\frac{2}{\left[(\sigma_2^T)_{ult}\right]^2} - \frac{1}{\left[(\sigma_1^T)_{ult}\right]^2}\right);\ F_2 = \frac{1}{2}\left(\frac{2}{\left[(\sigma_2^T)_{ult}\right]^2}\right);\ F_3 = \frac{1}{2}\left(\frac{2}{\left[(\sigma_1^T)_{ult}\right]^2}\right);\ F_6 = \frac{1}{2}\left(\frac{2}{[(\tau_{12})_{ult}]^2}\right) \quad (8)$$

Tsai Hill failure criteria: is an interactive with stress component. The theory is based on von Mises distortion energy theory, which predicts the failure when left side term of equation (9) is less than 1.

$$H_1\sigma_1 + H_2\sigma_2 + H_6\tau_{12} + H_{11}\sigma_1^2 + H_{22}\sigma_2^2 + H_{66}\tau_{12}^2 + 2H_{12}\sigma_1\sigma_2 < 1 \quad (9)$$

$$H_1 = \frac{1}{(\sigma_1^T)_{ult}} - \frac{1}{(\sigma_1^C)_{ult}};\ H_2 = \frac{1}{(\sigma_2^T)_{ult}} - \frac{1}{(\sigma_2^C)_{ult}};\ H_{11} = \frac{1}{(\sigma_1^T)_{ult}(\sigma_1^C)_{ult}};\ H_{22} = \frac{1}{(\sigma_2^T)_{ult}(\sigma_2^C)_{ult}};\ H_{66} = \frac{1}{[(\tau_{12})_{ult}]^2};\ H_6 = 0 \quad (10)$$

Hashin failure criteria: distinguish between different failure modes such as fiber tension, fiber compression, matrix tension and matrix compression given by equation (11). Mostly used for progressive damage model and finite element simulation.

$$\left(\frac{\sigma_1}{(\sigma_1^T)_{ult}}\right)^2 \geq 1\ ;\ \left(\frac{\sigma_1}{(\sigma_1^C)_{ult}}\right)^2 \geq 1 \quad (11)$$

$$\left(\frac{\sigma_1}{(\sigma_1^T)_{ult}}\right)^2 + \left(\frac{\tau_{12}}{(\tau_{12}^T)_{ult}}\right) \geq 1\ ;\ \left(\frac{\sigma_2}{2(\sigma_2^C)_{ult}}\right)^2 + \left(\frac{\tau_{12}}{(\tau_{12}^T)_{ult}}\right) \geq 1 \quad (12)$$

2.2.1. APPROACH-1: PROGRESSIVE PLY FAILURE

Composite is an anisotropic material in which the failure initiates from the weakest lamina and progresses through the entire laminate in a random manner. 1st play failure in the progressive ply failure (PPF) mechanism identifies the onset of the damage in the laminate. This method provides a more realistic prediction of initial damage than global failure criteria, especially in pressure vessels where localized stress concentrations may cause early damage initiation. In this approach, FPF is calculated by using failure criteria and replacing that ply orientation with another angle to investigate the role of sequence. This method is a conventional and time-consuming method to find the best burst performance. However, this strategy is integrated with a genetic algorithm to automate the process to optimize the sequence based on targeted burst pressure. However, the FPF method helps to identify the weakest ply, its angle, and position [6], [11], [14].

2.2.2. APPROACH-2: GENETIC ALGORITHM

The stacking sequence of composite laminates plays a crucial role in determining the mechanical performance and burst pressure of Type-4 hydrogen pressure vessels. Due to the combinatorial nature of stacking possibilities, Genetic Algorithm (GA) was employed to efficiently explore the design space. In this approach, each chromosome (ply) encodes a candidate layer sequence, with fiber orientations represented as discrete values $[7.5_7/15_6/25_4/35_1/45_1/90_{10}]$. The algorithm iteratively evolves the population through selection, crossover, and mutation operations, guided by a fitness function based on performance metrics such as burst pressure and compliance with failure criteria. To assess its fitness value, an objective function is utilized. If the convergence criterion is not met, the algorithm applies genetic operators again to produce a new generation. This process repeats for multiple generations until either the convergence criterion is satisfied, or the maximum number of generations is reached. Figure 3 illustrates the flowchart of the proposed genetic algorithm (GA). This approach provides a robust and flexible framework for the design optimization of composite pressure vessels. At last, the top 10 data sets were selected for data processing, in which the pressure vessel dome geometry is designed in ANSYS to identify the uneven dome geometry at the corresponding layer sequence [15], [16], [17].

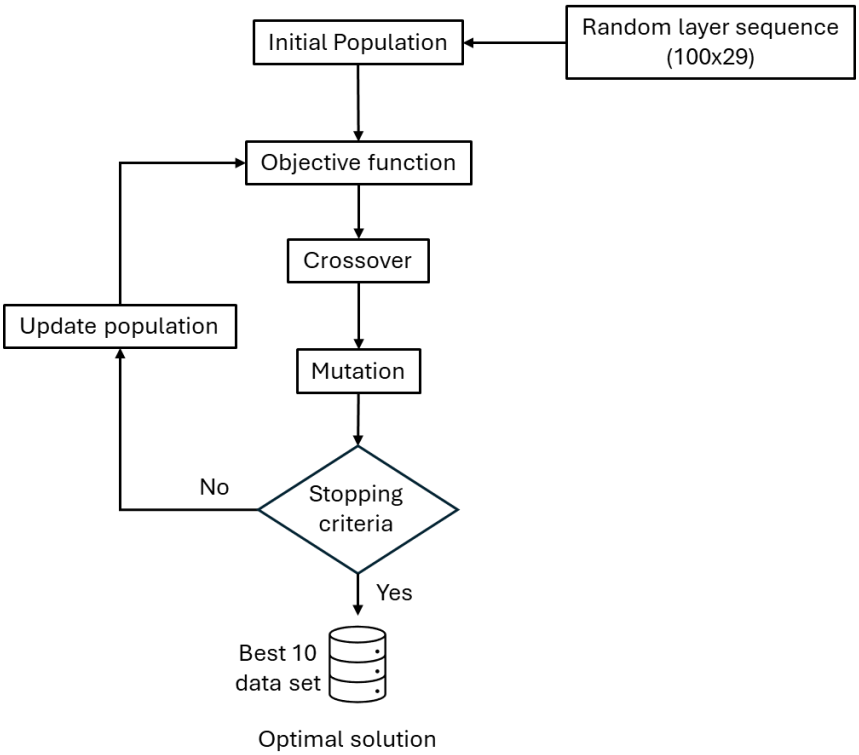

Figure 3: Flowchart for the genetic algorithm for composite sequence optimization.

3. RESULTS AND DISCUSSION

In this section, the analytical CLT model of a type-4 hydrogen pressure vessel is validated with the experimental burst pressure and finite element analysis provided by reference. The validated model is incorporated with the first ply failure strategy, followed by a genetic algorithm to improve the performance of the type-4 hydrogen pressure vessel by optimizing the layer sequence.

3.1. MODEL VALIDATION

Figure 4 (A) depicts the comparison of the analytical CLT model with the finite element and experimental burst pressure of a type-4 pressure vessel. The analysis shows that the model follows the Hashin matrix failure, which is also reported in the reference design. The burst pressure predicted by the analytical model is 75.61 MPa compared to finite element (75.3 MPa) and experimental (81.9 MPa) [9]. The model shows a good agreement with failure theory, with an error of less than 1 % with finite element and 8.3 % with experimental burst pressure. The model is also designed using finite element analysis in ANSYS to identify the safe and unsafe model of the failure. Figure 4 (B) and (C) shows that the failure of the type-4 pressure vessel lies in the cylindrical section, which corresponds to a safe failure model. Moreover, the investigation found that the Hashin failure is more realistic to predict the burst pressure due to its distinct nature in the failure model. However, the other failure theories are over-predicted, such as maximum stress due to no interaction with stress components.

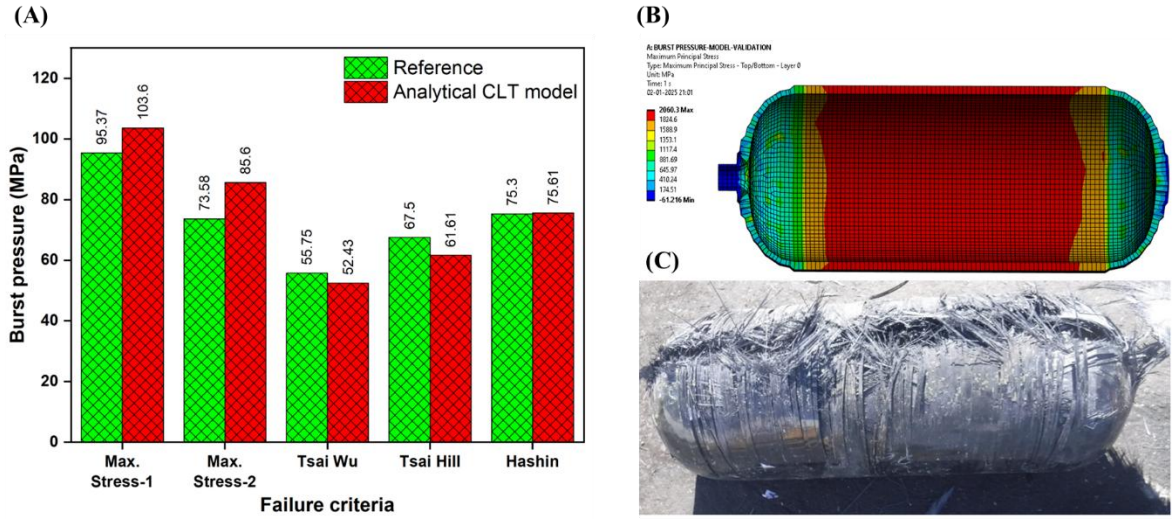

Figure 4: (A) comparison for failure criteria for analytical CLT with reference, (B) failure mode using finite element and (C) experimental burst tested type-4 pressure vessel.

3.2. APPROACH-1: PROGRESSIVE PLY FAILURE

The Figure 5 represents the theoretical burst pressure for different stacking sequences**,** changed by replacing the orientation of the first ply failure. Their corresponding values are given in Table 2. In this approach, the ply that fails first was replaced by the ply that fails last or has a different orientation, because that ply has taken the most stress till the end of the complete composite failure. The analysis shows the burst performance has been improved by 16.28 % compared to the finite element in reference for stack-2. After stack -2, it is observed that the maximum stress failure is significantly reduced which is even below the nominal burst pressure (2 time of operating pressure) as per ISO 11119-3. Therefore, the stack-3 to 5 is considered for the applicable layer sequence.

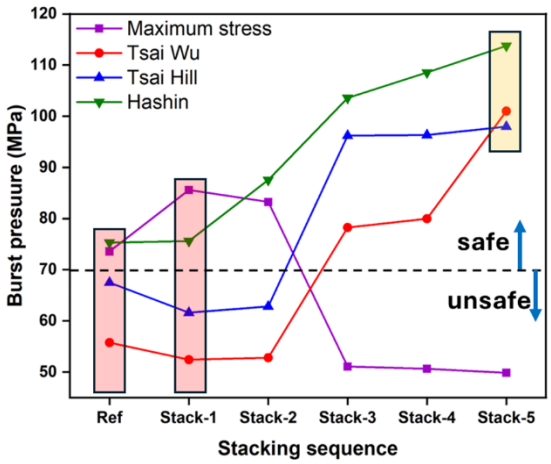

Figure 5: Bust performance improvement by PPF mechanism.

Table 2: Comparison of burst performance for different stacking sequences based on PPF.

	Stacking sequence [$90_{10}/45_1/35_1/25_4/15_6/7.5_7$]	**Max. stress**	**Tsai Wu**	**Tsai Hill**	**Hashin (matrix failure)**	**Experimental burst test**
	Reference	73.58	55.75	67.5	75.3	81.9
1	Stacking -1	85.60	52.43	61.61	75.61	
2	Stacking -2	83.27	52.81	62.82	87.56	
3	Stacking-3	51.1	78.25	96.20	103.58	
4	Stacking-4	50.64	79.97	96.34	108.57	
5	Stacking-5	49.85	101.01	97.98	113.76	

This strategy is complex, time-consuming, and fails to provide the optimum layer sequence for best performance. Therefore, the PPF is integrated with a genetic algorithm to optimize the sequence.

3.3. APPROACH-2: GENETIC ALGORITHM (GA)

In GA, the first 10 layers were fixed as they are important to generate the symmetry of the dome with the cylindrical shape, and the last layer was also fixed with 90^0 orientation because that layer helps to hold the helical layer and avoid its slippage. Since,18 layers left for implementing the GA, those layers were considered as genes of the system.

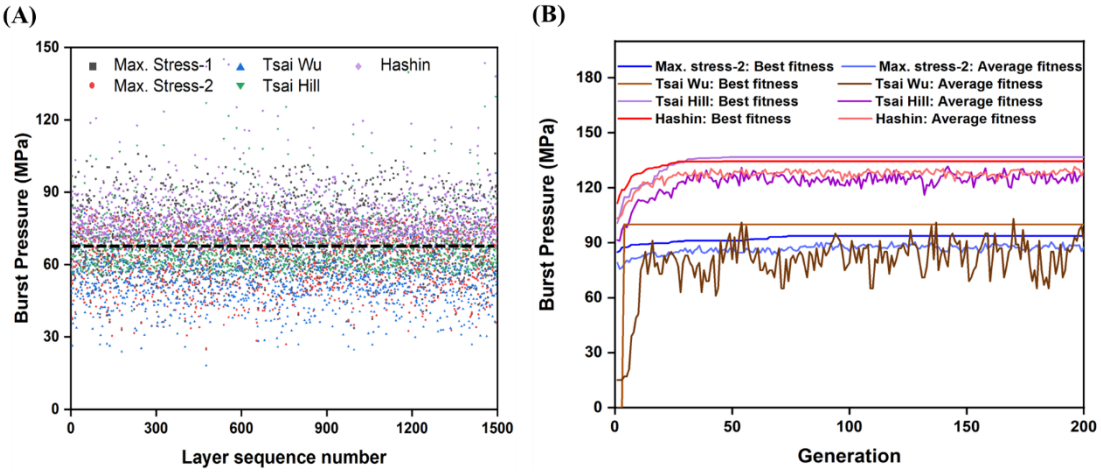

Figure 6: (A) initial population using brute force technique and (B) fitness profile for different failure criteria.

Firstly, an initial population was created using brute force technique in which random combinations are generated with all plies keeping the total number of layers the same as 29. Figure 6 (A) shows the initial population representing the theoretical burst pressure at different failure criteria. In the initial population, 100 data set points called chromosomes were filtered, which have the lowest possible burst pressure of 70 MPa under any failure criteria to meet the ISO 11119-3. These chromosomes are evaluated using a fitness function that quantifies their burst performance based on objectives function. Tournament selection technique was employed to choose the parent solution based on their fitness as shown in Figure 6 (B) **.** Now, the genes of the parents were crossover to generate a new population with different genes. To maintain diversity and avoid premature convergence, random mutations were introduced with a constraint that the new population/sequence cannot create any sequence that has more than two orientations simultaneously. This constraint helps to avoid the nonuniformity in the cylindrical shape. The best performing chromosomes were retained using elitism, and the population is iteratively evolved over successive generations. This process continues until a burst pressure approaches constant value with an convergence of 10^{-3} as shown in Figure 6 (B) . Where the average burst pressure approaches steady state after 100 generations. After the completion of the process, the optimum layer sequence is identified which have lowest possible burst pressure of 70 MPa So that the actual type-4 with optimum winding sequence should not have burst pressure less than safety factor. Table 3 listed burst pressure at the optimum layer sequence compared with progressive ply failure and reference data.

The analysis found the GA has improved the burst performance by 28.89 % compared to reference holding Hashin failure criteria.

Table 3: Comparison of burst performance.

Failure Theory	Burst pressure (MPa)					Burst performance Improvement (%)
	Experimental	Reference	Analytical CLT model	Approach-1: PPF	Approach-2: GA	
Max Stress 1	**81.9**	95.37	103.02	98.64	101.41	+ 6.33
Max Stress 2		73.58	85.6	83.27	83.25	+ 13.14
Tsai-Wu		55.75	52.43	52.81	82.89	+ 48.68
Tsai-Hill		67.5	61.61	62.82	87.24	+ 29.24
Hashin		**75.3**	**75.61**	**87.56**	**97.05**	**+ 28.89**

4. CONCLUSION

An analytical CLT model for a Type-IV hydrogen pressure vessel was validated against experimental and finite element results, showing excellent agreement within 1% of FEA and 8.3% of experimental data. The Hashin failure criterion accurately captured matrix-dominated failure in the cylindrical section, aligning with the observed failure modes. A progressive ply failure (PPF) approach provided up to 16.28% improvement in burst pressure but was limited in efficiency. To overcome this, a Genetic Algorithm (GA) was integrated, optimizing the stacking sequence while maintaining structural constraints. The GA-based method achieved a 28.89% improvement in burst pressure compared to the reference design using Hashin failure. This study demonstrates that combining analytical modeling, FPF theory, and evolutionary optimization effectively enhances the structural performance of Type-IV composite pressure vessels.

ABSTRACT

In this study, we investigated the improvement in carbon fiber (CF) bundle tensile tests. To effectively evaluate the mechanical properties of CF using the fiber bundle tensile test, measurement system compliance correction considering nonlinear behavior and Weibull analysis using curve fitting were conducted. Weibull parameters were extracted by fitting the stress-strain curves, while considering the effect of the kinetic friction force. The obtained parameters from the fiber bundle tensile test correspond to those from the single fiber tensile test. This method was also applied to the recycled CF bundles. It was found that the recycled CF bundles have orientation distributions and tends to overestimate their strength. However, it was found that this method is suitable for screening of the recycle CF bundles.

1 INTRODUCTION

Carbon fibers (CFs) have high tensile strength and high tensile modulus reinforcement fibers and are used in various field, such as in aerospace and sports gears. The demand of CFs is increasing, and the reuse and recycling of CFs are necessary to meet the increasing demand [1, 2]. The main stream of matrix polymers for CF composites are mostly thermoset resins, such as epoxy resin, and the CFs are recovered from these composites by removing the matrix resin. Several methods are used to recover CFs from their matrix polymers; however, these methods tend to degrade the mechanical properties of the recycle CFs (rCFs) and their composites [3-5]. Therefore, it is very important to evaluate the mechanical properties of the rCF.

Single fiber tensile tests are commonly carried out to evaluate the mechanical properties of rCF [6]. The strength of CFs is usually follows Weibull distribution, and a large number of tests are needed to estimate the distribution. rCFs can have a wider strength distribution compared to the virgin CFs, owing to various damages suffered during their history of usage, and recovery processes. In addition, the damage stage of the rCFs during the recovery process is not uniform, even in the same batch rCFs. Therefore, a considerably greater number, typically hundreds, of tests is necessary to accurately evaluate the strength distribution of rCFs, which is time-consuming and laborious. Addition to this, recently continuous rCFs can be obtained from hydrogen pressure tanks and efficient evaluation methods for such continuous rCF are urgent.

To overcome these issues, the fiber bundle tensile test is considered an effective method to obtain the fiber strength distribution [7-13] with smaller numbers of tests. In this method, fiber bundle stress-strain curves are obtained experimentally, and the Weibull parameters, which express the fiber strength distribution, are derived from the stress-strain curves. To effectively evaluate the fiber strength distribution, precise strain measurements should be obtained. The strain can be obtained by using the measurement system compliance correction [7, 10] and an extensometer [8, 9, 10, 13]. Recently, digital image correlation analysis has been applied as a novel non-contact strain measurement method [12].

The advantages of the fiber bundle test methods are accepted, and they are applied to measure the strength distribution of various fibers, such as CFs [7, 8, 11, 13], silicon carbide fibers [12], and glass

fibers [9]. However, these methods are only applicable to fiber bundle specimens with well-defined bundle shapes, restricted fiber numbers, and lengths. In case of rCFs, it is difficult to prepare the required bundle specimen for the bundle test as the rCFs usually have a limited length of several tens of millimeters or less. Therefore, it is important to develop an improved test method that can effectively measure the strain of shorter and thinner bundles.

In this study, we investigated the effectiveness of the measurement system compliance correction method and the calculation method of Weibull parameters for the tensile test of CF bundles using specimens of different gauge lengths. The Weibull parameters were calculated considering the effect of kinetic friction between the fibers. In addition, the validity of the fiber bundle tensile test was examined by comparing the obtained Weibull parameters with those of the single fiber tensile tests. This test method was also applied to the rCF bundles and revealed the issues.

2 EXPERIMENTAL

2.1 Materials

Virgin CF bundles with a width of 7 mm (T700S, Toray Ind.) and recycled CF bundles (Carbon Fiber recycle Industry co. ltd.) were used in this study.

The CF bundles were not impregnated with polymers to effectively evaluate the fiber strength distribution. The bundle consisted of 12,000 fibers and was coated with a sizing agent for convergence. The sizing agent was not removed to avoid disruption of the fiber orientation.

The recycled CF bundles were obtained from aerospace parts by a pyrosis method. The orientation of the recycled CF bundles was slightly disordered, so they were combed to align the fiber orientation. The thickness of the recycled CF bundles was below 0.15 mm. The cross-sectional area of the bundle was calculated by dividing the bundle liner density by the bundle density. The bundle liner density was obtained by measuring the bundle weight of the 300 mm length bundle, and a bundle density of 1.8 g/cm^3 in the catalogue data was used for this calculation.

2.2 Fiber bundle tensile test

A schematic illustration for preparation of the fiber bundle tensile test specimen is shown in Fig. 1. Specimens that have both ends of the bundle tabbed are prepared as follows. First, a cardboard with a thickness of 0.5 mm was cut into pieces as tabs (20 mm × 60 mm) and spacers (5 mm × 6 mm). Then, the spacers were fixed on the tab, and an epoxy adhesive was painted on the tab. The CF bundle was placed on the adhesive with application of tension in order to keep the bundle straight, epoxy adhesive was painted over the bundle, and covered with another tab. In this study, the distance between the tabs was defined as the gauge length. In order to conduct the system elongation, virgin CF bundle tensile test specimens with gauge lengths of 10, 50, 75, and 100 mm were fabricated. Test specimens with gauge length of 50 mm were prepared for rCF.

Tensile tests of the fiber bundles were conducted using a universal testing machine (AG-Xplus 10 kN, Shimadzu Corp.) attached to a 5 kN load cell. A pneumatic flat grip attached to the universal joint was employed. The apparent strain rate, which is obtained by dividing the cross-head speed by the gauge length, was 1 %/min. The alignment of the test system is essential for achieving uniform loading to the bundle. Therefore, the alignment of the grips was adjusted by gripping the metal plate. The alignment of the specimen was carried out by suspending a string with a load to the lower tab and adjusting the string axis and tensile axis. To ensure the alignment of the specimens, the pretention of 5 N was applied to the specimens before the test.

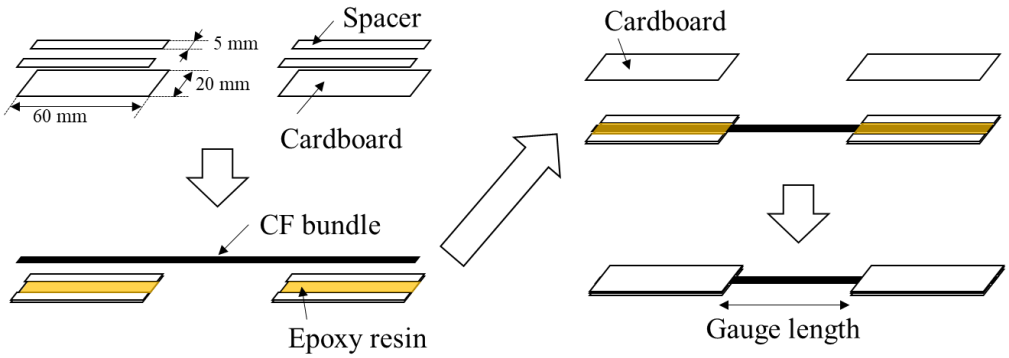

Figure 1 Schematic illustration of the preparation of the specimen.

2.3 Single fiber tensile test

Single fiber tensile test specimens with a gauge length of 10 mm were prepared by fixing a single CF to the paper templat. The specimen was placed on a tensile test machine (EZ-SX, Shimadzu Corp.) attached to a 10 N load cell. After scissoring both sides of the paper template, the tensile tests were conducted with a cross-head speed of 1 mm/min.

3 RESULTS AND DISCUSSION

3.1 Load-displacement curves of fiber bundle tensile test

Load-displacement curves of the fiber bundle tensile tests with different gauge lengths specimens are presented in Fig. 2. Progressive failures were observed in specimens with gauge lengths above 50 mm. This may be due to the difference in compliance between the fiber bundle and the measurement system. While the compliance of the bundle is proportional to the fiber length and inversely proportional to the number of fibers in the bundle, that of the measurement system is almost constant. The compliance of the bundle decreases with a decrease in the gauge length. Therefore, if the fibers in the bundle broke partially, the compliance of the bundle remained at a small value. This indicates that the applied load remained almost constant, and resulted in an unstable brittle failure of the bundle. Further, it was observed that the peak load increased with a decrease in the gauge length, except for the specimen with a gauge length of 10 mm

Fig. 3 shows the pictures of the specimens before and after the fiber bundle tensile tests. The specimens with a gauge length longer than 50 mm were dense and straight before and during tensile tests, but expanded forms after the test, reflecting the undulation of fibers after fracture. In contrast, the fibers of the specimen with a gauge length of 10 mm showed almost limited winding after the tests and were substantially ruptured. These results correspond to the different load-displacement curves in Fig. 2.

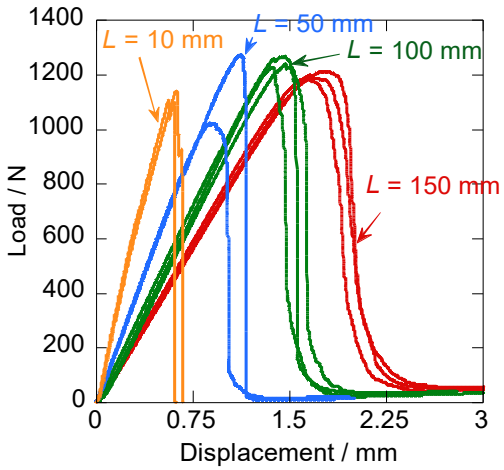

Figure 2 Load -displacement curves of fiber bundle tensile tests with different gauge lengths.

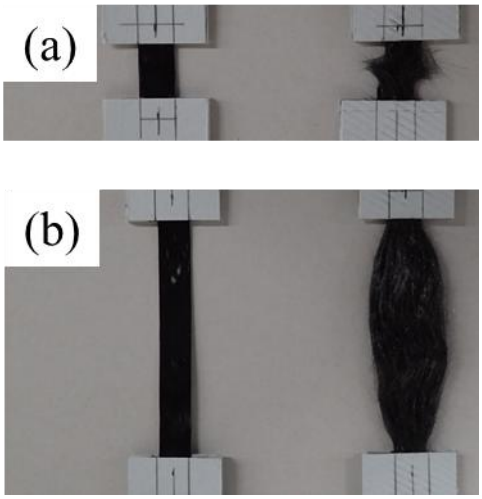

Figure 3 Pictures of the fiber bundle specimens with a gauge length of (a) 1 cm and (b) 5 cm. The specimen on the left is before the test and the specimen on the right is after the test.

3.2 Correction of measurement system elongation

Total elongation, ΔL_{total}, is the sum of the fiber bundle elongation, ΔL_{fiber}, and the measurement system elongation, ΔL_{system}, and the following equation is established[16].

$$\Delta L_{\text{total}} = \Delta L_{\text{fiber}} + \Delta L_{\text{system}} = L_{\text{fiber}} \frac{P}{SE} + \alpha \cdot \Delta L_{\text{system}} \tag{1}$$

where P is tensile load, E is fiber tensile modulus, S is cross section area of the fiber bundle, L_{fiber} is gauge length and α is shape factor which is governed by the shape of the tab and the fiber bundle as follows:

$$\alpha = \sqrt{\frac{w_0(W - w_0) \cdot \ln\left(\frac{W}{w_1}\right)}{w_1(W - w_1) \cdot \ln\left(\frac{W}{w_0}\right)}} \tag{2}$$

where W is adhesive width and w_1 is recycled CF bundle width and w_0 is virgin CF width which is used for measurement of system elongation. When $w_0 = w_1$, $\alpha = 1$.

Thus, the measurement system elongation at load P can be obtained from the slope of the plot of ΔL_{total} against the gauge length. Fig. 4(a) shows the relationship between ΔL_{total} and L_{fiber} at two loads of 250 N and 500 N. As shown in Fig. 4(a) the plots are on linear lines, and the system elongation can be obtained from the intercept of the lines.

Since the measured load was quite large in the current tests, the stress-strain relationship of the epoxy adhesive, which was used for fixing the tabs, was nonlinear. Hence, the measurement system elongation also exhibited nonlinear behavior. To evaluate the load dependence of the measurement system elongation, the measurement system elongation was calculated for various loads up to 1100 N with 50 N increments. The measurement system elongation of a fiber bundle with a width of 7 mm is represented in Fig. 4(b) with red symbols. From Fig. 4(b), it was confirmed that the measurement system elongation exhibited nonlinear behavior. By fitting the measurement system elongation with a quadratic function, $\Delta L_{\mathrm{system}} = 2.31 \times 10^{-8} P^2 + 2.63 \times 10^{-4} P + 3.06 \times 10^{-2}$ was obtained as the equation of the measurement system elongation for the 7 mm width fiber bundle.

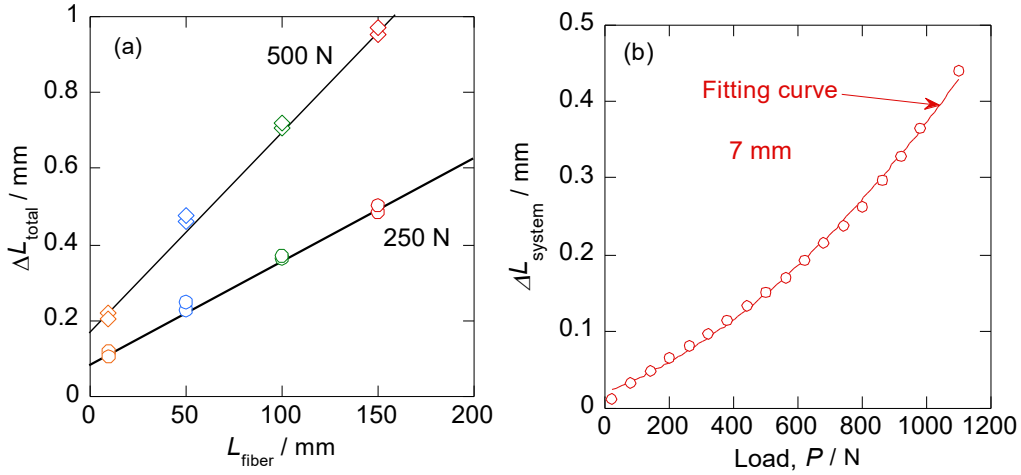

Figure 4 (a) Plots of total elongation, $\Delta L_{\mathrm{total}}$, versus gauge length, L_{fiber}, and (b) plots of measurement system elongation, $\Delta L_{\mathrm{system}}$ versus load, P.

3.3 Stress-strain curves for virgin CF fiber bundle tensile test

The stress-strain curves for the 7 mm width virgin CF bundles are shown in Fig. 5. Here, the bundle fiber strain was calculated using gauge length and bundle elongation which was obtained by subtracting the elongation of the measurement system from the total elongation. The bundle stress was calculated by dividing the load by the initial bundle cross-sectional area. In all the specimens, except for the specimens with a gauge length of 10 mm, the initial slope in the small strain region was consistent, which indicated that system elongation correction was performed properly. The deviation of the specimens with gauge length of 10 mm considered to be due to the misalignment. Even if the shift between upper and lower tabs is the same, the tilt angle of the bundle from the loading direction becomes larger for shorter gauge length. Thus, higher test accuracy of equipment and specimen placement is required to effectively experiment with the short gauge length specimens.

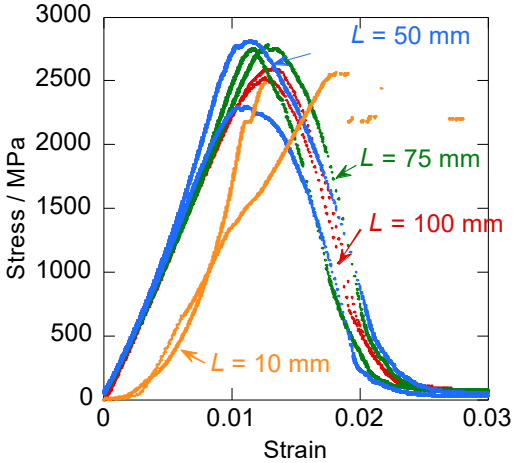

Figure 5 Stress-strain curves of virgin CF bundles with different gauge lengths.

3.4 Weibull parameters obtained from fiber bundle tensile test

Assuming that the fiber bundle is pulled simultaneously without sagging and its strength follows Weibull distribution, its stress, $\sigma_{\mathrm{measured}}$, can be expressed as follows [16].

$$\sigma_{\mathrm{measured}} = E\varepsilon \cdot \exp\left(-\frac{L_{\mathrm{fiber}}}{L_0}\left[\frac{E\varepsilon}{\sigma_0}\right]^m\right) + T\left\{1 - \exp\left(-\frac{L_{\mathrm{fiber}}}{L_0}\left[\frac{E\varepsilon}{\sigma_0}\right]^m\right)\right\} \quad (3)$$

where m is Weibull shape parameter, σ_0 is Weibull scale parameter, ε is strain of the fiber bundle, E is tensile modulus of the bundle, T is friction force between fibers in the bundle, L_{fiber} is gauge length, and L_0 is reference length (1m). E, m, σ_0, and T can be obtained by fitting stress-strain curves with equation (3).

The measured stress-strain curves for gauge lengths of 50 – 100 mm were fitted by equation (3) using generalized reduced gradient method [15] and fitting parameters were obtained. Fig. 6 shows the fitting results for the gauge length of 550 mm. It was confirmed that the whole region of the stress-strain curved was successfully fitted by the equation (3) considering the kinetic friction.

To evaluate the validity of the fiber bundle tests, the Weibull parameters obtained by the fiber bundle tests were compared to those obtained by the single fiber tensile tests. The Weibull parameters obtained by the CF bundle tensile tests corresponded moderately to those obtained by the single fiber tensile tests. Therefore, fiber bundle testing using compliance correction can be considered as a valid test method for evaluating the mechanical properties of fibers.

Figure 6 also shows the stress-strain curves from the tensile test of the rCF bundle. In this case, the rCFs originally had a tensile modulus of 230 GPa; however, the modulus of the fiber bundle was found to be low, at 51 GPa. This indicates that some fibers are not connected between the tabs. Although the rCF strength can change, the rCF tensile modulus is typically maintained. Thus, we assumed that the tensile modulus of the rCFs remained unchanged, and we obtained the rCF Weibull parameters by fitting a modified theoretical equation that included a parameter indicating the initial rCF break fraction. As a result, the Weibull parameters of the fiber were obtained: a scale parameter of 2.7 GPa and a shape parameter of 6.8. This value is in accordance with the tensile strength of virgin fiber bundles, indicating that the recycling process properly maintains fiber strength. However, this result also indicates that fibers may break during specimen fabrication (or the recycling process), so special care may be needed to obtain reliable results.

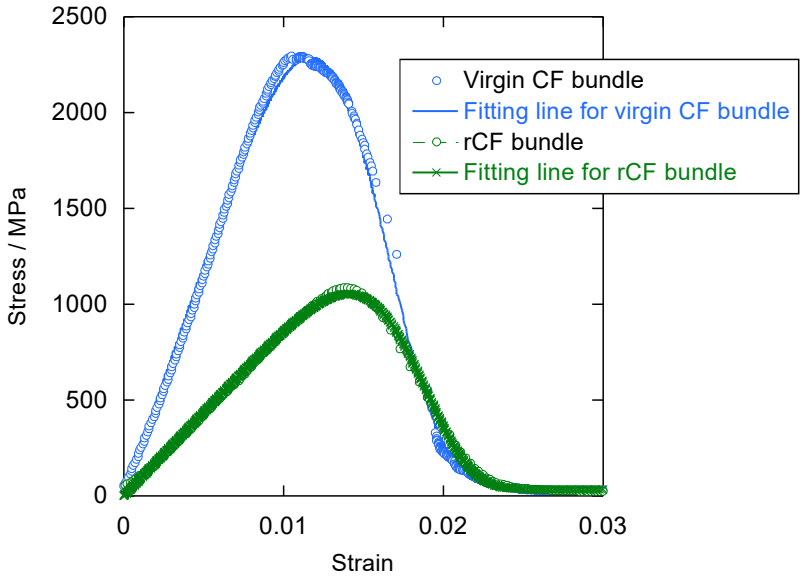

Figure 6 Stress-strain curves of virgin CF and recycled CF bundles.

4 CONCLUTIONS

In this study, fiber bundle tensile tests were conducted to evaluate the tensile strength of CF and rCF bundle. The dependence of the measurement system elongation on the fiber width was investigated. By using equation considering the effect of kinetic friction in the theoretical bundle stress-strain relationship, the Weibull parameters and kinetic friction were evaluated. The obtained Weibull parameters obtained from the fiber bundle tensile test roughly corresponded with those obtained from the single fiber tensile tests, and the validity of the fiber bundle tensile tests was confirmed. For the specimens with a short gauge length, the test was difficult due to the misalignment of the specimen from loading axis.

Even though rCF bundle seem perfectly continuous fibers, they contained discontinuous fibers. Even in such case the strength distribution could be evaluated supposing the tensile modulus. Although this method has some point such as preparation of the specimens that need to be overcome, this method can be considered as an effective method to evaluate the tensile strength of recycled CFs.

ACKNOWLEDGEMENTS

This paper is based on results obtained from a project commissioned by the New Energy and Industrial Technology Development Organization (NEDO).

Phased Test Campaign Overview

Project Goals and Motivation

- Understand how stacking sequence and thickness influence mechanical performance
- Aim at demystifying variability across reported data
- Support customer design decisions by clarifying expected performance ranges
- Recommend optimized test layups in order to broaden and secure design space

Phase 1.

- Review historical data to identify *Thickness Effect* and *Stacking Sequence Effect* from Toray's material DB
- Test 0° Tension and Quad OHT/OHC, T1100G/3960, FAW = 190 g/m^2 (CPT = 7.2 mil, 0.18 mm) — Published in ASME SSDM 2024

*Fiber Areal Weight *Cured Ply Thickness

Phase 2.

- Test UD/Quad Compression, Quad UNT/UNC, T1100G/3960, FAW = 190 g/m^2 — Published in ICCM 2025
- Test 0° Tension, Quad OHT, CLC, T1100G/3960, FAW = 70 g/m^2 (CPT = 3 mil, 0.076 mm) — To be published in ASC 2025
- Expand test matrix to varied thicknesses by ply count control — TBD

Phase 3.

- Test Quad OHT with varied stacking sequences, T1100G/3960, FAW = 190 g/m^2 — TBD
- Test Quad OHT hybridized with other materials, T1100G/3960, FAW = 190 g/m^2 — TBD
- Test Soft/Hard OHT with varied stacking sequences, T1100G/3960, FAW = 190 g/m^2 — TBD

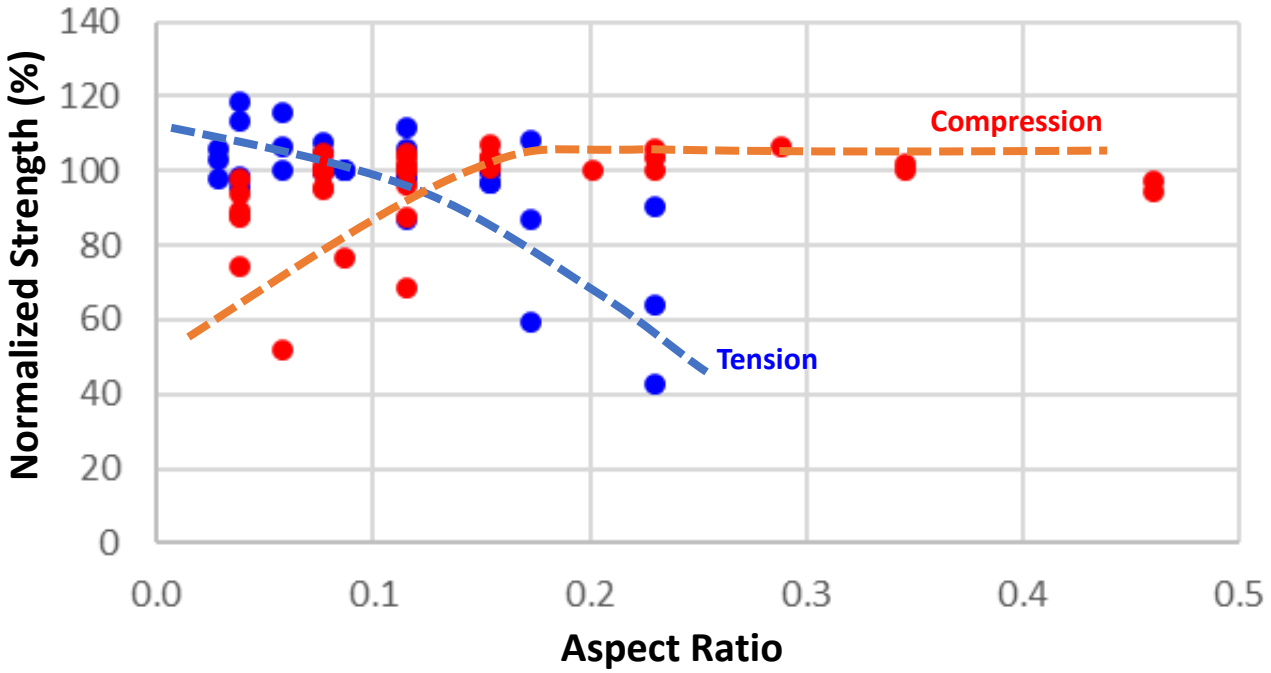
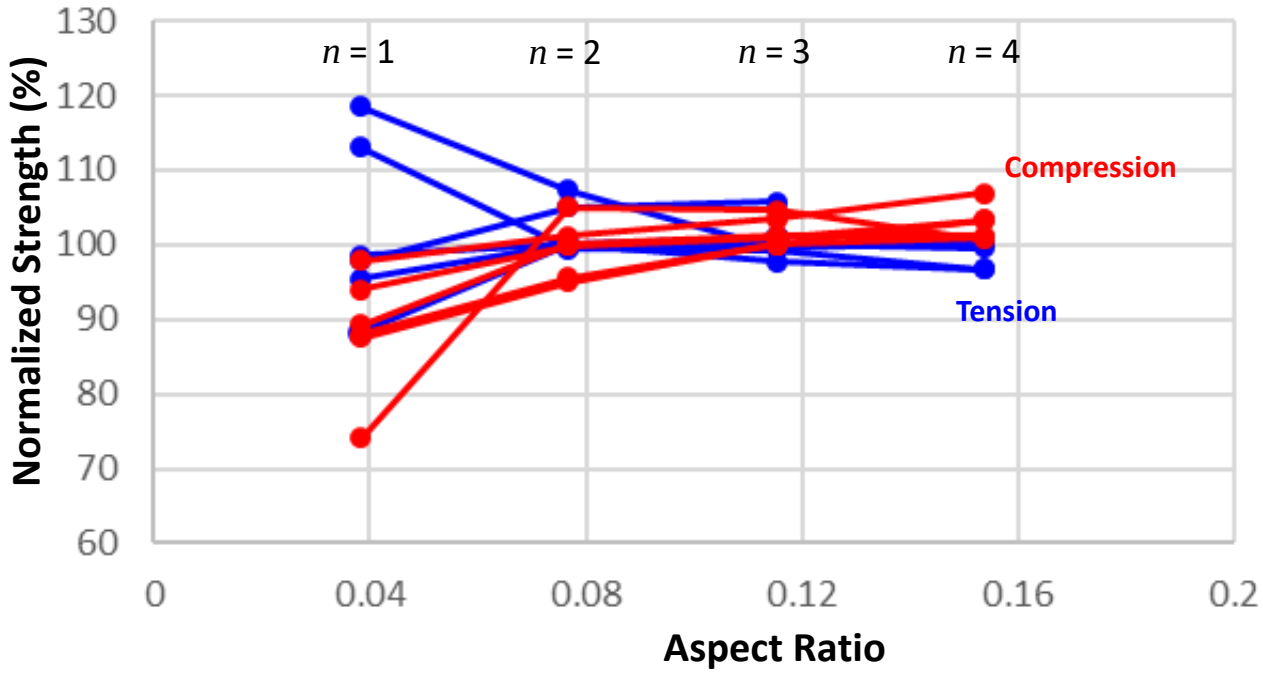
Tensile Strengths vs. Ply Count

Normalized Tensile Strengths vs. Aspect Ratio



Copyright ©2025 Toray Composite Materials America, Inc.

Summary and Design Implications-Thickness Effects



Unidirectional Thickness effects

- Tensile strength (including 0°TS, OHT, UNT) tends to decrease with increasing thickness
- Compressive strength (including 0°CS, OHC, UNC) tends to increase with increasing thickness

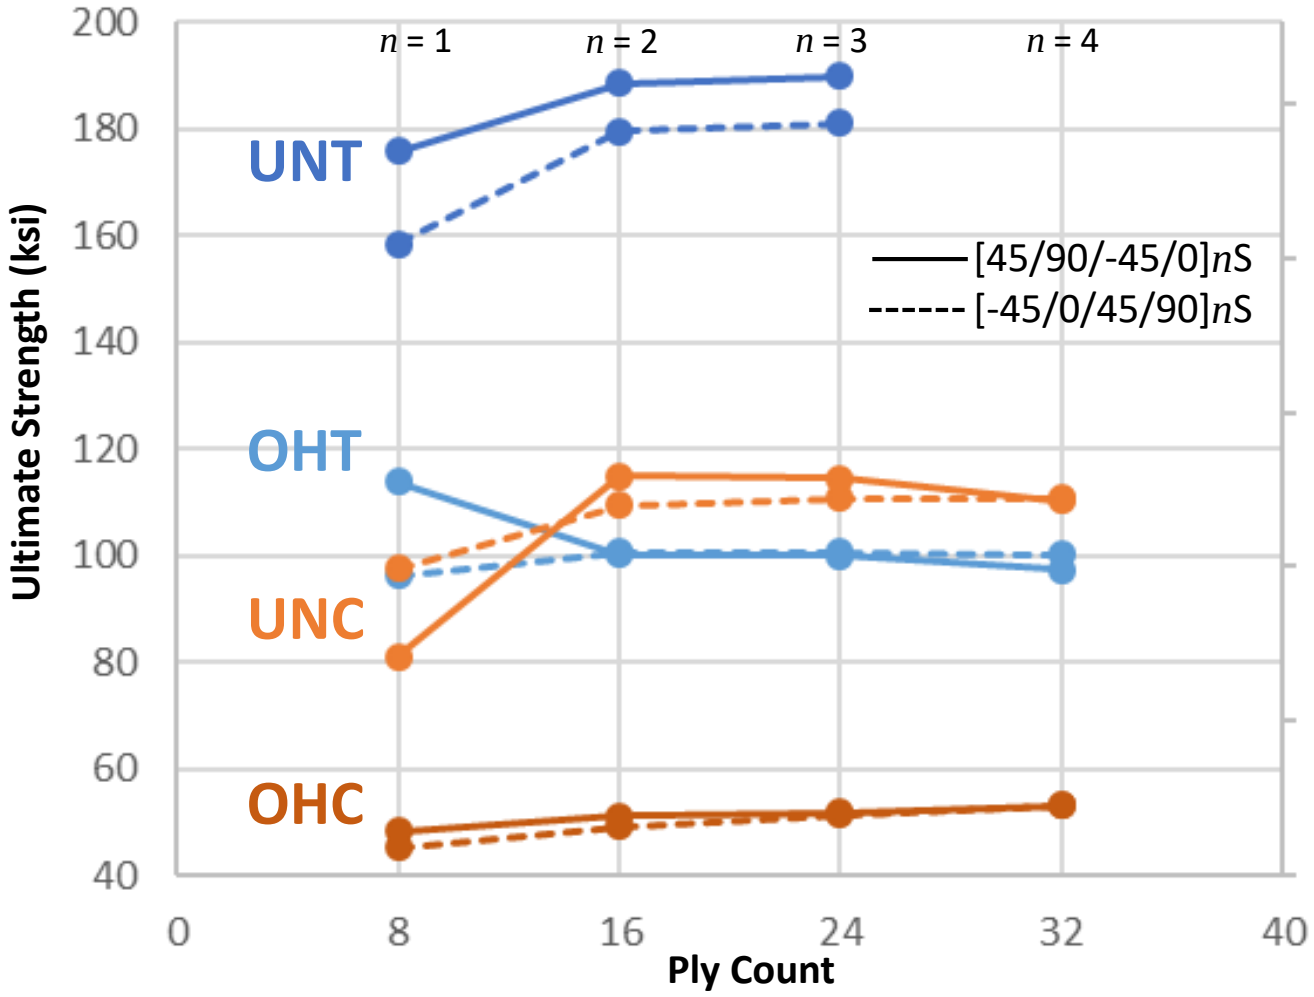
UNT/UNC, OHT/OHC Quad Layup Thickness Effects

- High scatter at ply count = 8, becomes more consistent as ply count increases
- Outliers in thin layups deserve further replication
  - Observed ~10% increase for 8-ply OHT depending on center orientation

Copyright ©2025 Toray Composite Materials America, Inc.

Summary and Design Implications-Quad Layup Choices

Stacking sequence effect in quad layup



- Quad layups with 0° in the midplane performs better, especially in tension

- Differences diminish as ply count increases
- Strength variability higher at low ply counts – stabilizes with thickness

Design implications

- Thin layups should avoid relying solely on 0° strength, thicker laminates show more reliable compression performance

- A shared *thick* panel for OHT/OHC, UNT/UNC, FHT/FHC streamlines layup, reduces lab workload, and minimizes potential confusion in lab workflows

Copyright ©2025 Toray Composite Materials America, Inc.

Conclusions (and Recommendations for Designers & Test Engineers)

- Quad layup stacking sequence significantly influences strength, particularly in thin laminates
- 0° plies in the midplane enhance tensile and compressive strength, with larger effects at low ply counts
- Thickness impacts both performance and variability – strength stabilizes with increased thickness
- High OHT outliers are repeatable and valid, warranting further targeted testing
- Future work: Expand test matrix with varied FAW and hybridized systems

Keywords: Terahertz, Ultrasonics, Nondestructive testing, Glass fiber reinforced plastics, Signal/noise ratio

ABSTRACT

Composite materials are essential in aerospace and automotive structures, yet their safety-critical use demands reliable nondestructive testing (NDT). Ultrasonic inspection is well suited for carbon-fiber-reinforced plastics (CFRP) but struggles with glass-fiber composites (GFRP) and structural foams because scattering and attenuation mask defect echoes. Terahertz testing, which uses electromagnetic waves between 0.1 and 1 THz and needs no coupling medium, overcomes these limits for non-conductive materials. Ultrasound and terahertz are therefore complementary. This paper evaluates the best choice depending on frequency, defect size and depth.

This study quantitatively compares signal-to-noise ratios (SNR) delivered by focused ultrasonic transducers (1, 2.25, 5 MHz) and continuous-wave terahertz probes (100, 150, 300 GHz). Two specimens were prepared: a 50 mm pultruded GFRP block with blind holes 2.5 - 8 mm at nine depths, and a 15 mm expanded-polypropylene foam slab with 2-12 mm holes at two depths. Water-coupled pulse-echo C-scans and matching terahertz scans were recorded with 300 µm steps. The signal-to-noise ratio was defined as the maximum defect amplitude divided by the maximum surrounding echo.

Ultrasonic testing detected most GFRP defects to 35 mm with the 2.25 MHz probe. 5 MHz resolved 2 mm holes but only to a depth of 15 mm, while 1 MHz penetrated the full block yet with blurred indications at higher depths. Terahertz produced higher SNR overall. 100 GHz was optimal for GFRP, imaging an 8 mm hole at 40 mm, whereas 300 GHz yielded the clearest foam images. The foam could not be inspected ultrasonically.

The signal-to-noise ratio increases with flaw size and drops with depth and frequency. Its optimum shifts deeper as frequency falls. Terahertz is besides the more expensive computer tomography the only effective method for closed-cell foams. For GFRP, 2.25 MHz ultrasound remains the most versatile for defects larger than 6 mm for ultrasonic testing, while terahertz offers superior signal-to-noise ratios. Combining both techniques maximizes defect detectability for non-carbon composite components.

1 INTRODUCTION AND OBJECTIVES

Composite materials are gaining increasing importance in the aerospace and automotive industries due to their advantages in weight, stiffness and strength. Because of high safety requirements in the use of these materials in primary and secondary aircraft structures, composite materials demand sophisticated nondestructive testing methods, such as ultrasonic inspection, radiography or thermography. Ultrasonic testing in particular provides excellent results for the detection of a broad variety of defects and has proven to be a reliable inspection tool in recent years and is used to inspect primary and secondary aircraft structures made of carbon fiber reinforced plastics [1, 2]. However, the range of materials has expanded considerably in recent years, meaning that glass fiber-reinforced composites and foams must also be tested non-destructively. Ultrasonic testing is very problematic with these materials due to the high scattering and attenuation.

Instead, terahertz testing can be used. It is a comparatively new NDT method that works very similarly to ultrasonic testing. Instead of mechanical sound waves, electromagnetic waves in a frequency range of 0.1 to 1 THz are used for testing. The advantage of terahertz testing is that no coupling medium needs to be used. A major

disadvantage for general use is the exclusion of testing electrically conductive materials such as metals or carbon fiber-reinforced plastics. Terahertz technology is therefore particularly suitable for testing nonconductive materials such as foams or glass fiber-reinforced plastics [2]. Both materials are difficult to test with ultrasound. However, both materials are used for demanding parts for aerospace and maritime applications (Fig. 1 & 2).

Figure 1: Sailplane made out of GFRP [3]

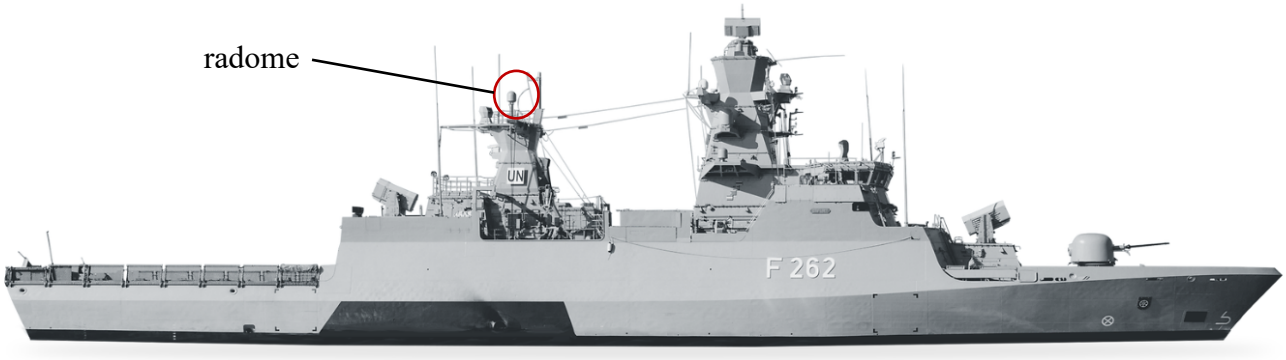

Figure 2: Foam based radome of a German corvette [4]

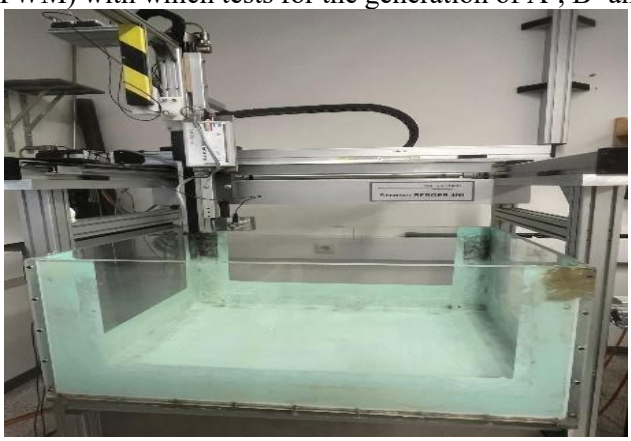
Thus, terahertz testing should not be seen as a competitive process, but rather as a powerful complement to ultrasound testing [5]. Of course, there are materials, such as GFRP, where both methods can be used. In this case, it is interesting to know which method produces the higher signal-to-noise ratio during detection depending on the test frequency, defect size and defect depth, if this is possible at all. An early comparison was done by J. Dong, et.al. in terms of a qualitative evaluation [6]. The investigation presented here focusses on a quantitative comparison of the measured signal-to-noise ratios in order to obtain the optimal test method and testing frequency.

2 EQUIPMENT AND TEST PIECES

2.1 ULTRASONIC FACILITY

The research and development described was conducted at the Institut für Kunststofftechnik Westpfalz (IKW) located on the campus of the University of Applied Sciences Kaiserslautern. The institute´s state-of-the-art ultrasonic system was manufactured by the company Hillger in Germany and operates in a frequency range from 0.1 up to 30 MHz in a fully digitized way (Fig. 3). Ultrasound can be applied water- and air-coupled. However, in this study only water coupling was used. The Hilgus-software package allows the realization of through-transmission tests and A-, B-, C-, D-, and F-scans, which e.g. allows the evaluation of frequency shift based on real-time Fast-Fourier-Transformation (FFT). In addition, full-waveform-scans can be performed allowing post-scanning gate-settings. In total, besides a trigger gate two evaluation gates can be set. Three scanning systems can be connected to the ultrasonic control unit:

- Four axes system for shell-like parts (40 x 60 x 80 cm) and short rotational parts
- Two axes system for rotational parts (length 120 cm, diameter 15 cm)
- Two axes system for through-transmission air-coupled ultrasonic testing.



in-house construction of the Fraunhofer-Institut for Techno- und Wirtschaftsmathematik (ITWM) with which tests for the generation of A-, B- and C-scans in the frequency range from 70 GHz to 500 GHz 

Figure 3: Ultrasonic scanner with immersion tank

Three focused transducers from Olympus NDT - Panametrics with center frequencies of 5 MHz, 2.25 MHz and 1 MHz were used for the ultrasonic tests (Fig. 4, Table 1).

Figure 4: 1 MHz, 2.25 MHz, and 5 MHz transducer

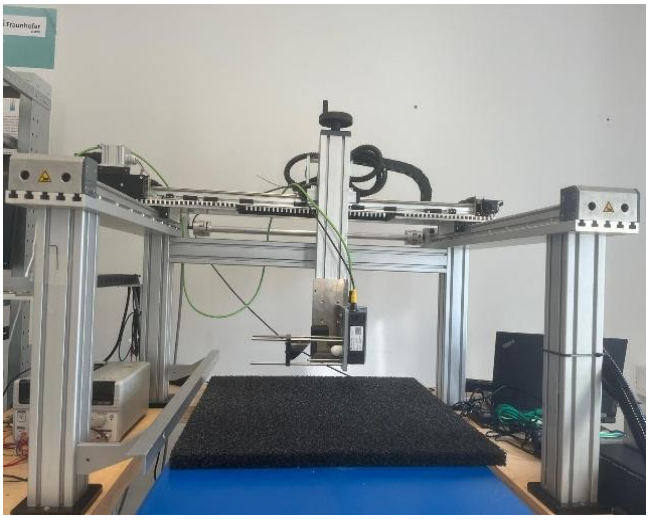
Transducer name	Frequency f [MHz]	Diameter of active element D [inch]	Focal length F [mm]	Near field length N [mm]	Bundle diameter b [mm]
V394	1	1.125	96.5	137	5.25
V304	2.25	1	76.2	244	2.07
V309	5	0.5	50.8	136	1.24

Table 1: Transducer properties

2.2 TERAHERTZ FACILITY

The terahertz test facility is an in-house construction of the Fraunhofer-Institut for Techno- und Wirtschaftsmathematik (ITWM) with which tests for the generation of A-, B- and C-scans in the frequency range

from 70 GHz to 500 GHz are possible (Fig. 5). The depth information is generated by the FMCW principle. Three probes with 100 GHz, 150 GHz and 300 GHZ were used for the measurements undertaken (Fig. 6).



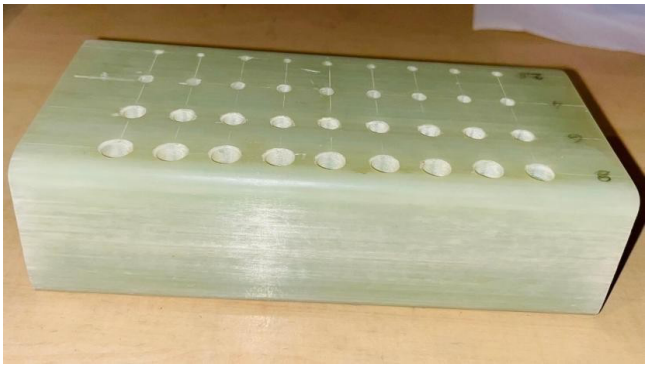


Figure 5: Terahertz facility

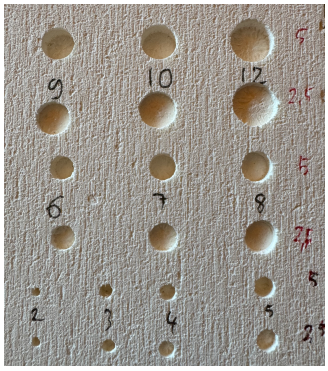
Figure 6: Terahertz probe

2.3 SAMPLES

Two test pieces were used. The first one was a pultruded glass fiber reinforced block (GFRP-block) with a thickness of 50 mm in which blind holes with diameters of 2.5 mm, 4 mm, 6 mm and 8 mm were drilled at nine different depths (5 mm, 10 mm, 15 mm, 20 mm, 25 mm, 30 mm, 35 mm, 40 mm, and 45 mm as shown in Fig. 7a. The speed of sound of this GFRP was determined to be 2.350 m/s. The second sample was an EP-foam panel (density 170 kg/m^3) with a thickness of 15 mm and blind holes (diameter 2 mm, 3 mm, 4 mm, 5 mm, 6 mm, 7 mm, 8 mm, 9 mm, 10 mm and 12mm) and depths of 2.5 and 5 mm) in two different depths (2.5 mm and 5 mm) as depicted in Fig. 7b.

a) 



b) 

Figure 7: Samples, a) GFRP-sample, b) EP-foam sample

3 EXPERIMENTAL

Ultrasonic testing of the GFRP-sample was done in pulse-echo with gates with a width of 4 µm starting at 2 µm behind the front surface echo and one gate set around the back surface echo resulting in ten C-scans for each transducer. The measurements were performed from the rear side of the sample. Because only four gates can be evaluated during one test, three measurement runs were required. The use of an auxiliary reflector did not work due to the thickness of the part and the associated attenuation of the ultrasound. The focal points were placed into

that depth were the gates were set. The C-scan were quantitatively evaluated with a custom-made program named Oculus.

The same approach was used for the foam sample but with gate lengths set around the expected defect echoes. The increment was chosen in both scanning directions to 300 µm. The foam part clamped to a stainless steel plate to avoid floating.

The terahertz tests of the GFRP-sample were performed accordingly to the ultrasonic C-scans with the focal point set in the area of interest. The foam part was inspected by means of an auxiliary reflector (steel plate) which was placed 10 mm below the rear sides of the samples. Also here, the increment was chosen in both scanning directions to 300 µm. All A-scans were stored as a full-waveform scan. Similar to the ultrasonic C-scans, the THz-C-scans of the GFRP-sample were quantitatively evaluated with features programmed into the scanning program.

4 RESULTS

It turned out that with ultrasonic testing, it was not possible to detect any defects in the foam sample. Exemplary C-scans of the GFRP-sample are shown for the blind hole defects in a depth of 15 mm (Figure 8). With the 2.25 MHz probe, most defects could be detected up to a depth of 35 mm. With the 5 MHz probe, only defects up to a depth of 15 mm could be detected. After that, the attenuation of the material was too great due to the scattering of the glass fibers. Interestingly, it was even possible to generate a backwall echo with the 1 MHz probe. However, with this probe it was only possible to image defects up to a depth of 20 mm.

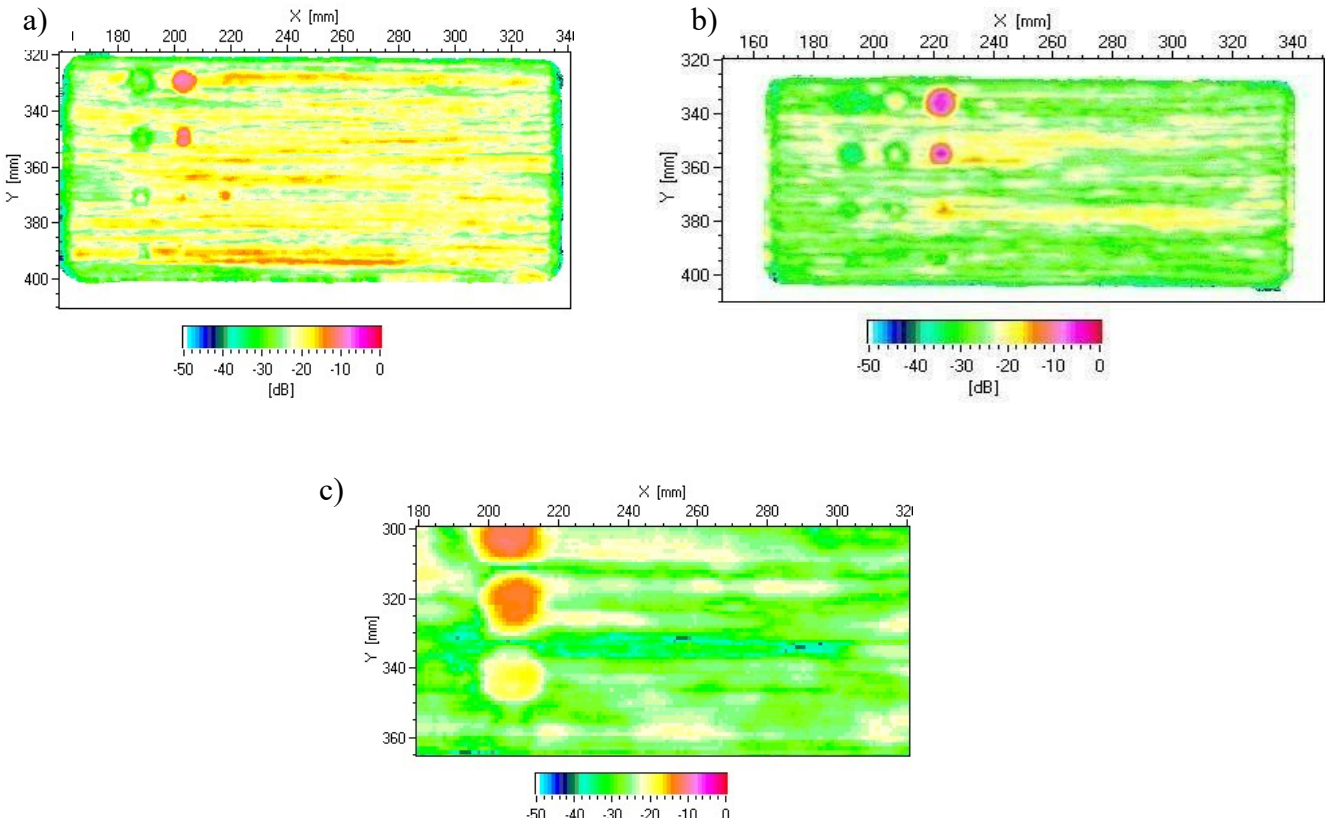


Fig. 8: C-scans of the GFRP-samples with gate set between 10 and 14 µm, a) 5 MHz, b) 2.25 MHz, c) 1 MHz

The high-lying defects (5 mm depth) could not be detected in any case because the spurs from the front surface echo covered the defect echoes. The signal-to-noise ratio decreased with increasing depth and decreasing defect size. Due to the shorter wavelength of the 5 MHz transducer in comparison to the 2.25 MHz transducer (470 µm to 0,97 µm) the 2 mm defects could be found. Furthermore, it can be noticed that the 1 MHz transducer enlarges the defects significantly.

The results of the terahertz-measurements are exemplary shown in Fig. 9 and Fig. 10. It turned out that the 300 GHz probe was not suitable to inspect the GFRP-sample. In turn, it showed the best results for the thinner foam sample.

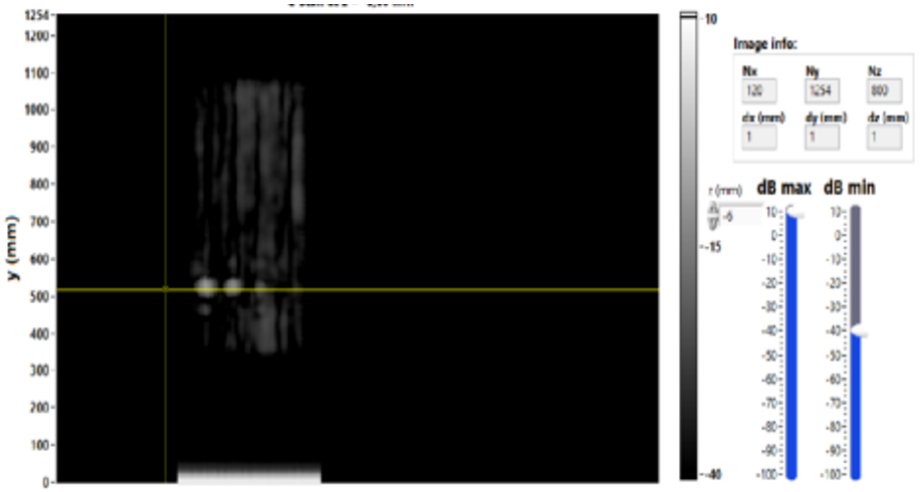

Fig. 9: THz-C-scan of the GFRP-samples with 100 GHz and a depth of 15 mm

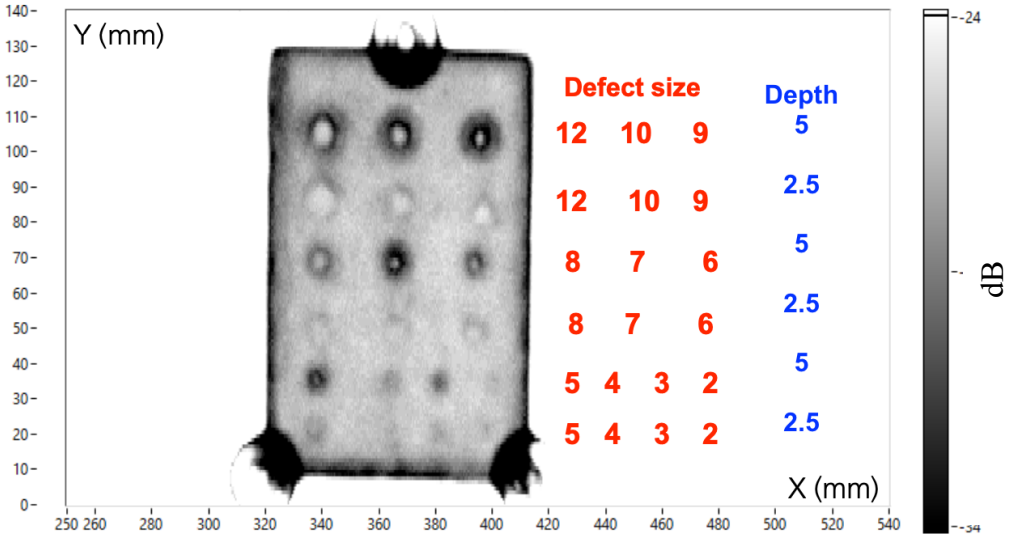

Fig. 10: THz-C-scan of the GFRP-samples with 300 GHz and a depth of 15 mm

5 EVALUATION

5.1 FUNDAMENTALS

The signal/noise ratio determines how much the echo amplitude of an indication differs from that of the flawless vicinity. In order to quantify the signal/noise ratio of an indication, four different approaches can be realized:

a. maximum indication amplitude versus maximum ambient echo
b. maximum indication amplitude versus average ambient echo
c. average indication amplitude versus maximum ambient echo
d. average indication amplitude versus average ambient echo,

where the ambient can be understood as that part of the sample not including any defects. Here, the maximum indication amplitude versus maximum ambient echo in the vicinity of the defect was used for the analysis of the

signal/noise ratio. This procedure is also consistent with the optical assessment strategy of an UT-operator to identify an indication by looking at the highest difference between indication and ambient echo amplitudes (sharpest contrast). Parameters significantly influencing the signal/noise ratio are as follows:

- depths of defect
- defect size
- transducer frequency (UT and THz)
- focal length
- bundle diameter (focal point diameter)
- active element diameter
- inspection strategy (kind of echo, position of focal point)

Focal length, focal point diameter, active element diameter and frequency are transducer properties and cannot be chosen freely [1]. The influence of the remaining four parameters was analyzed by keeping two of them constant and considering the effect of variations of the two others on the signal/noise ratio.

5.2 INFLUENCE OF DEFECT SIZE

First, the dependency of the defect size was evaluated for two different depths (10 and 25 mm). The result of this evaluation can be seen in Fig. 11 and 12.

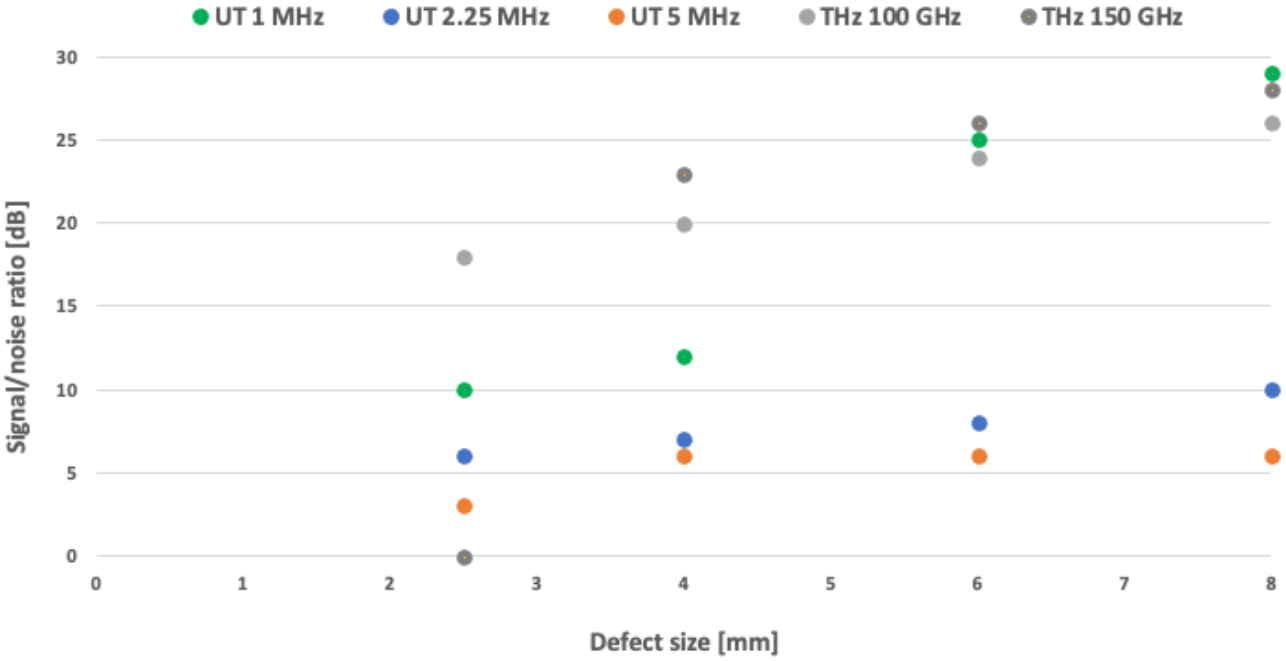

Fig. 11: Dependency of the defect size on the signal/noise-ratio (depth 10 mm)

The evaluation of the signal-to-noise ratios for the various defect sizes at a defect depth of 10 mm shows that all defects are easily detectable (Fig. 11). With ultrasound, the signal-to-noise ratios decrease with the frequency and increase with the flaw size. This is also the case with terahertz testing. Terahertz testing enables the detection of defects with a higher signal-to-noise ratio.

The result is very similar for the defects at a depth of 25 mm (half the sample thickness). The signal-to-noise ratios for ultrasonic testing are higher than for a defect depth of 10 mm, which can be explained by the surface echo that has been completely attenuated at this depth reducing the ambient noise. The signal-to-noise ratio of the 100 GHz terahertz test is again the highest. At a depth of 40 mm, only the 8 mm defect could be visualized at 2.25 MHz with ultrasound and with the 100 GHz terahertz probe with signal-to-noise ratios of just above two digits.

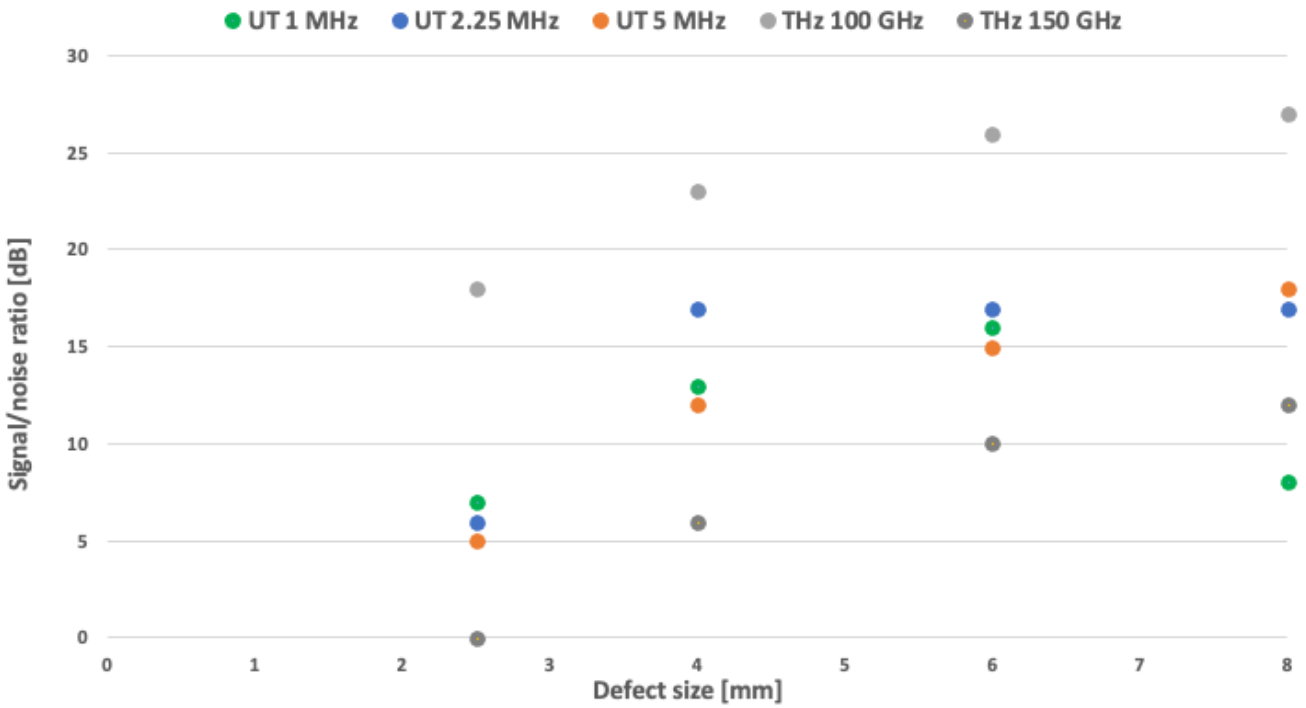

Fig. 12: Dependency of the defect size on the signal/noise-ratio (depth 25 mm)

5.3 INFLUENCE OF DEFECT DEPTH

First, the dependency of the defect depth was evaluated for a defect diameter of 8 because this defect is sufficiently large to be detected in all cases. The result of this evaluation can be seen in Fig. 13.

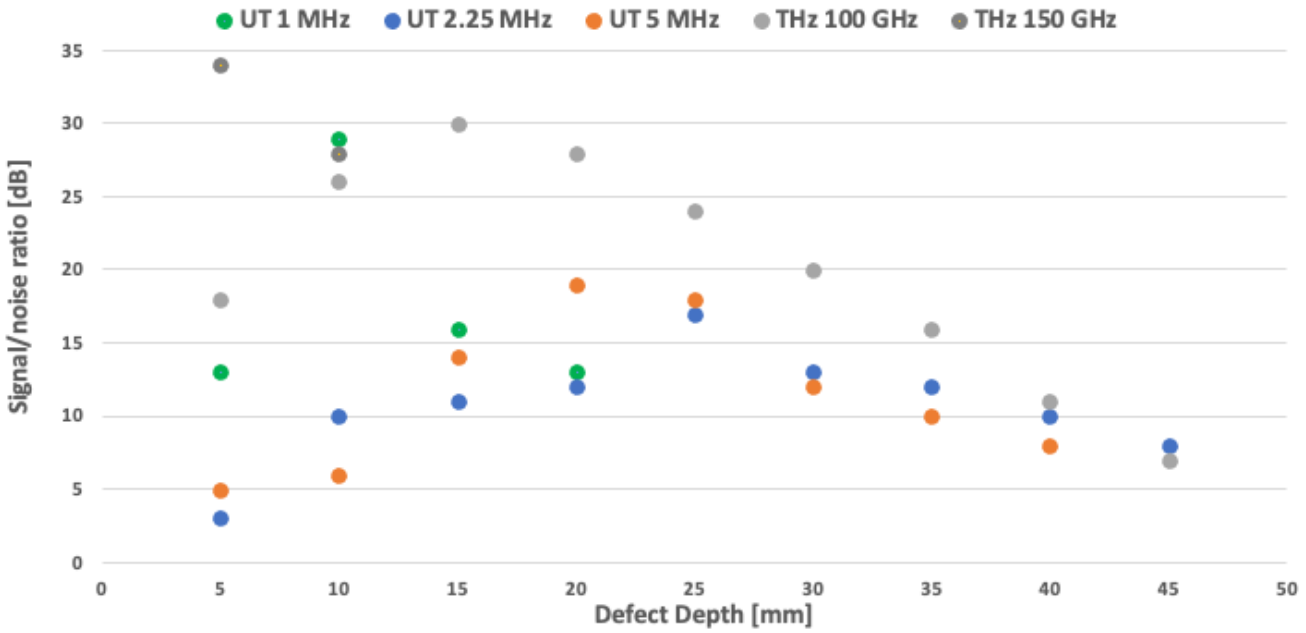

Fig. 13: Dependency of the defect depth on the signal/noise-ratio (8 mm defect)

Figure 13 clearly shows that there is an optimum for each test frequency and method. As the test frequency decreases, this optimum signal-to-noise ratio shifts towards greater defect depths. It has to be pointed out once

again that it was possible to penetrate the part under inspection with the 1 MHz probe. However, due to the focus point widening, the fault indications merged into one another, so that the indications were not evaluated.

5.4 EVALUATION OF THE FOAM SAMPLE

The evaluation of the foam sample shows a difference for the depth of the errors in this auxiliary reflector measurement. The double passing of the walls of the defect perpendicular to the beam path caused a significant attenuation of the defect in the deeper defects. This resulted in a greater signal-to-noise ratio of up to 10 dB in the defect display itself for defect sizes above 5 mm. The small defects located higher up (depth 2.5 mm) were only found with a low signal-to-noise ratio of 3 - 4 dB.

6 CONCLUSIONS

The signal/noise ratio is significantly influenced by seven parameters, which are not independent of each other. Thus, it seems to be difficult to choose the optimal transducer providing the highest detectability of defects possible whereas the defects have certain size for a given material situation. However, the minimum defect size to be detected in Airbus CFRP-aircraft components is about 6 mm in diameter according to AITM-standards. This study dealt also with smaller defects to show the limits of certain test frequencies and yielded that the 2.25 MHz ultrasonic transducer provides the highest signal/noise ratio for ultrasonic testing deeper positioned defects as depicted in Fig. 13.

The evaluation of the foam sample shows a difference for higher defects are better found with the 5 MHz probe. A very good alternative here is terahertz testing, which has a much greater selectivity of defects and defect-free areas. In addition, terahertz testing is the only NDT method besides the more expensive computer tomography with which foams can be tested in a meaningful way.

Background and motivation

FBG in standard fibre

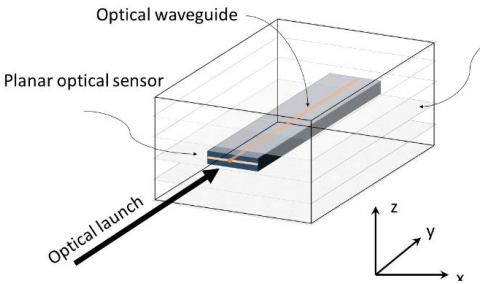
FBG in polarisation maintaining fibre

Motivation

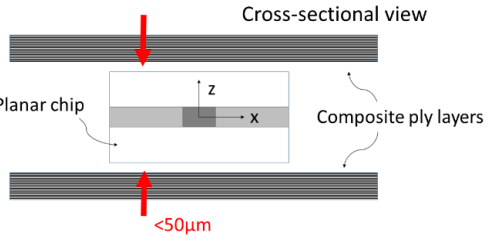
- CFRP strain monitoring often uses FBGs in standard circular fibre.
- These detect in-plane strain well, but not through-thickness strains critical in delamination, matrix cracking.
- Polarisation-maintaining fibres can detect out of plane strains through birefringent response, but…
- Circular geometry twists, making direction of strain ambiguous - $\boldsymbol{\theta = ?}$.

Objective

- Create orientation-stable, birefringent sensors that can resolve in-plane and out-of-plane strains.
- Enabling comprehensive 3D strain mapping during both manufacturing and in-service use of CFRPs.

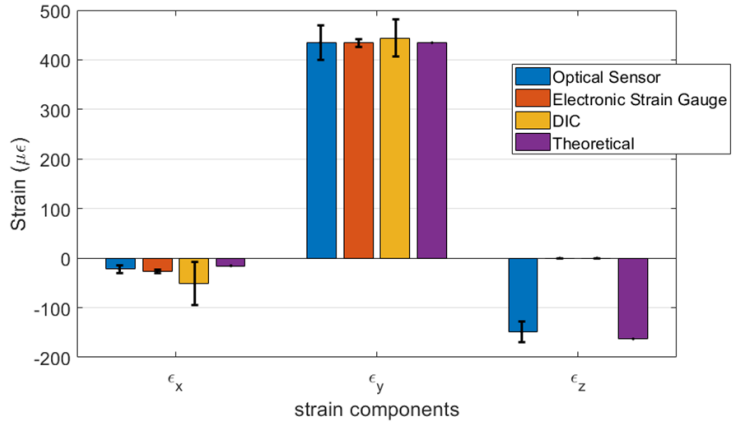


Prior Work: 3D Strain Sensing - FHD planar chips

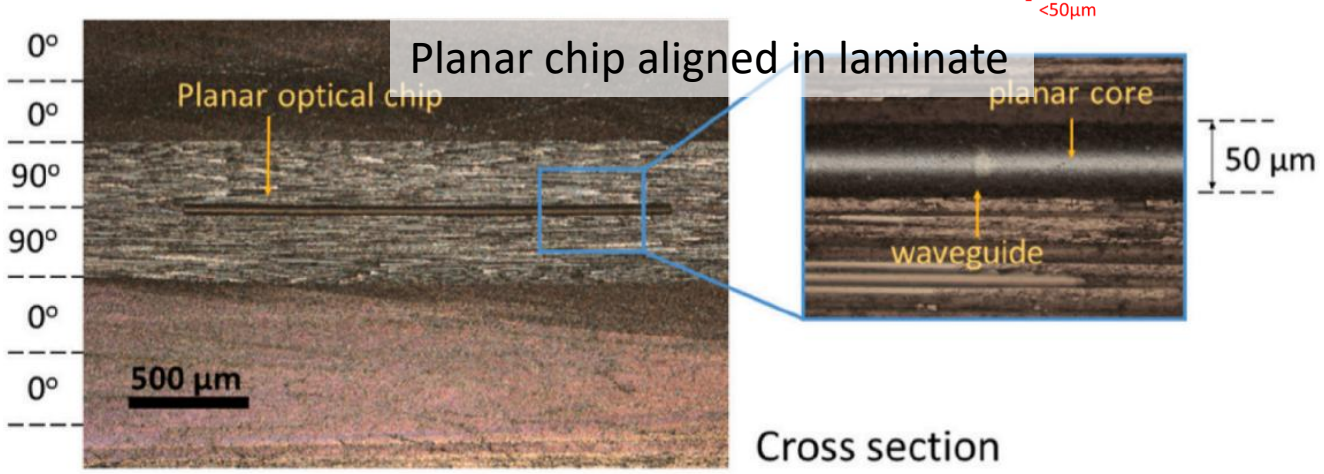


Approach: Uses a strain–optic matrix (K-matrix) derived from first principles of the photoelastic effect.
Formulation: Based on spectral shifts in TE and TM polarisations of two orthogonal waveguides:

Limitations:
- Chip-based fabrication is not scalable for long sensor lengths.
- Difficult to integrate into continuous optical fibre networks.
- Coupling to fibre and embedding chips remain complex and fragile.



$$\frac{\Delta\lambda_i}{\lambda_i} = \sum_j K_{ij}\varepsilon_j$$



Where:
- $\frac{\Delta\lambda_i}{\lambda_i}$: Normalized wavelength shift in mode i (e.g., TE or TM).
- K_{ij}: Elements of the strain–optic sensitivity matrix (based on waveguide orientation and photoelastic constants).
- ε_j : Strain components ε_x, ε_y, ε_z

CFRP tensile tests: measured strain comparison

Sensor fabrication – Flat fibres

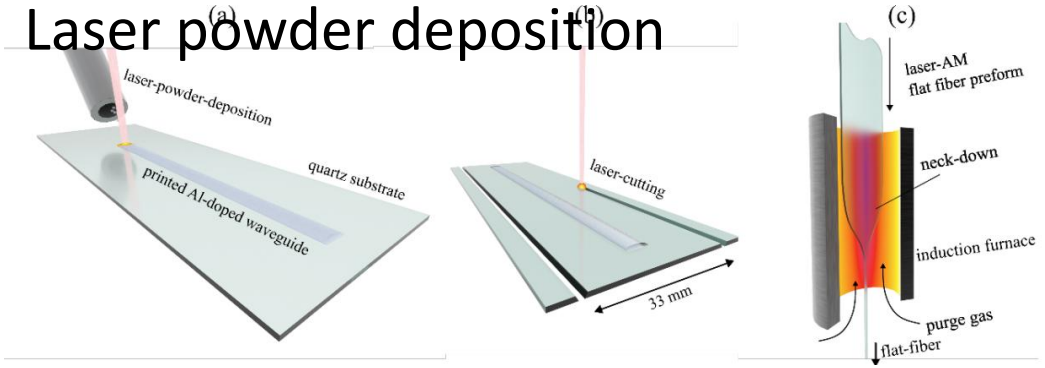
Key innovations – enable scalability and integration

Laser powder deposition of waveguides

- Precise placement of doped silica cores on flat preforms
- Avoids the need for traditional MCVD or lithographic patterning.
- Flexible core design: refractive index, geometry, and number of cores can be tuned.

Rectangular Preform Design & Stack-and-Draw

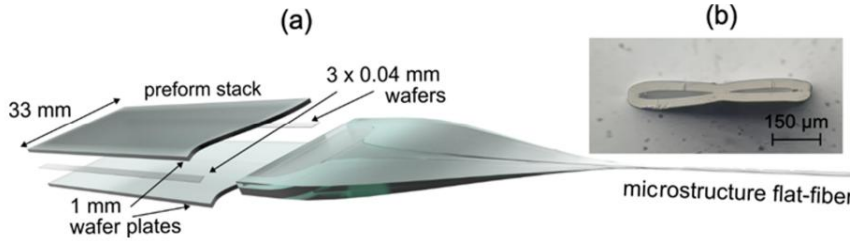
- Rectangular in cross-section → high aspect ratio final fibre.
- Compatible with standard fibre draw towers → scalable production.



Incorporation of Internal Microstructure

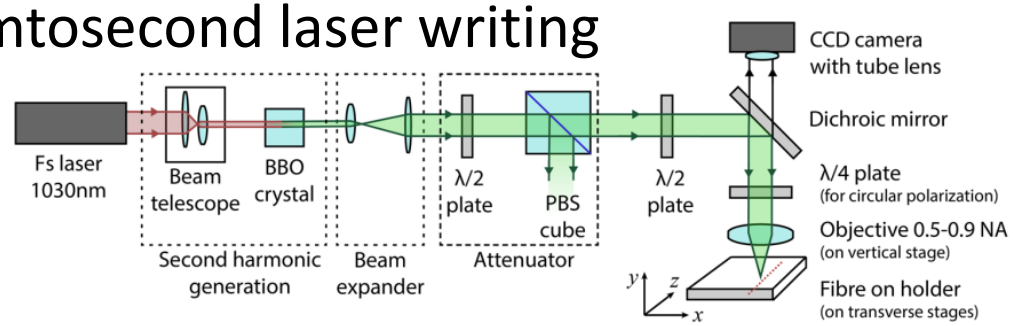
- Microstructures such as air channels can be embedded → tune birefringence

Femtosecond Laser Post-Processing



- Enables fine-tuning of waveguide paths or inscription of Bragg gratings.
- Multi-core patterning or localised index modifications.

Laser powder deposition

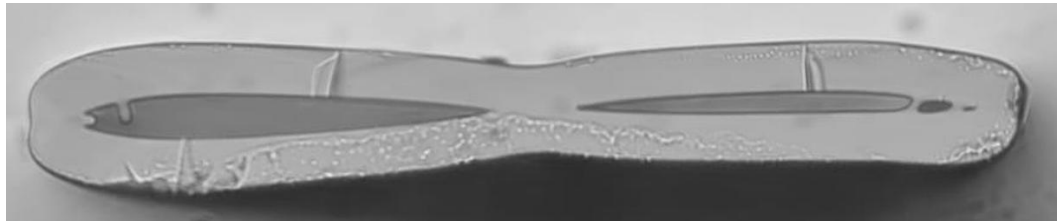


Stack and draw

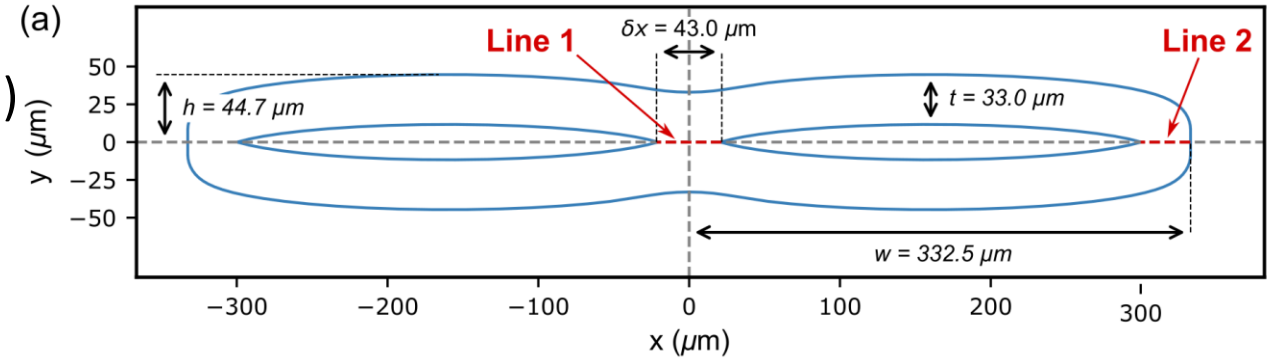
P. Maniewski, B. Moog, M. Whittaker, *Proc. of SPIE,* Vol. 13356 1335606-1

Femtosecond laser writing

T. Lee, P. Maniewski, M. Whittaker, B. Moog, M. Beresna, C. Holmes, *Proc. of SPIE,* Vol. 13639 136396V-4

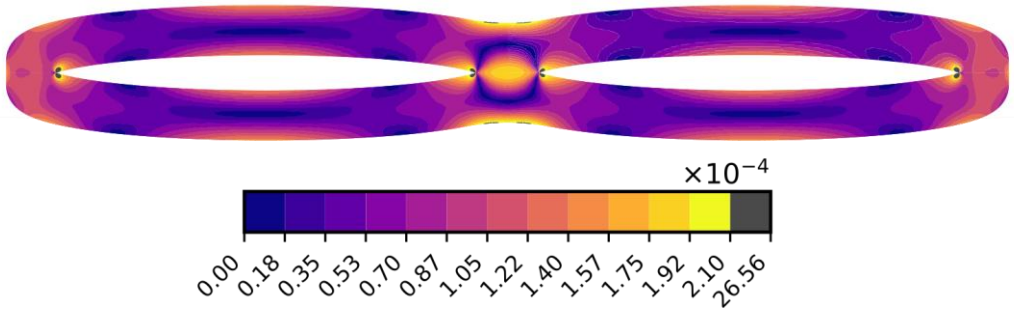


Sensor optimisation



What determines sensitivity?:

- "The degree to which the birefringence of the waveguide changes in response to through thickness strains"
- Birefringence governed by principal strains ($\epsilon_{33} - \epsilon_{22}$)



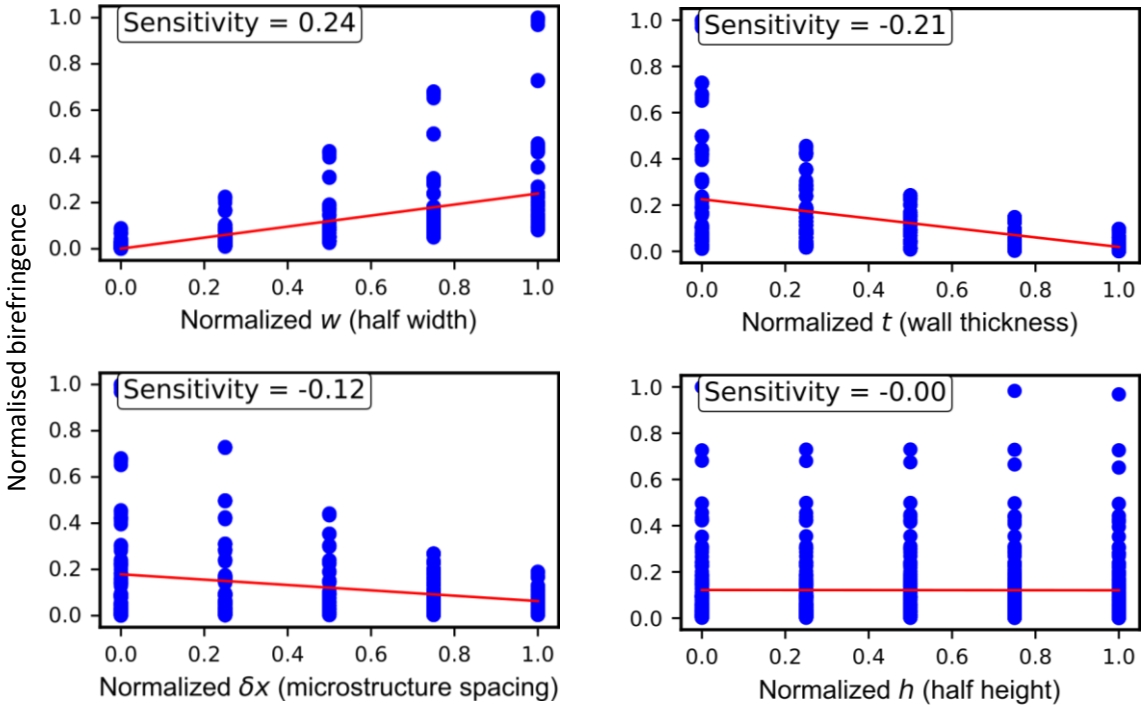
$$B = n_2 - n_3 = \frac{n_0^3}{2}(p_{11} - p_{12})(\epsilon_{33} - \epsilon_{22})$$

- Create parameterised model – vary h, t, w, and δx to vary geometry
- FEA – model fibre under 5 bar hydrostatic pressure (proxy for out of plane strain)
- Centre of fibre cross-section ($x, y = (0,0)$) ideal for waveguide placement
  - High birefringence
  - Spatially suitable

Result from 5 bar hydrostatic pressure FEA: $(\epsilon_{33} - \epsilon_{22})$

Parametric study: sensitivity to geometry

Objective:



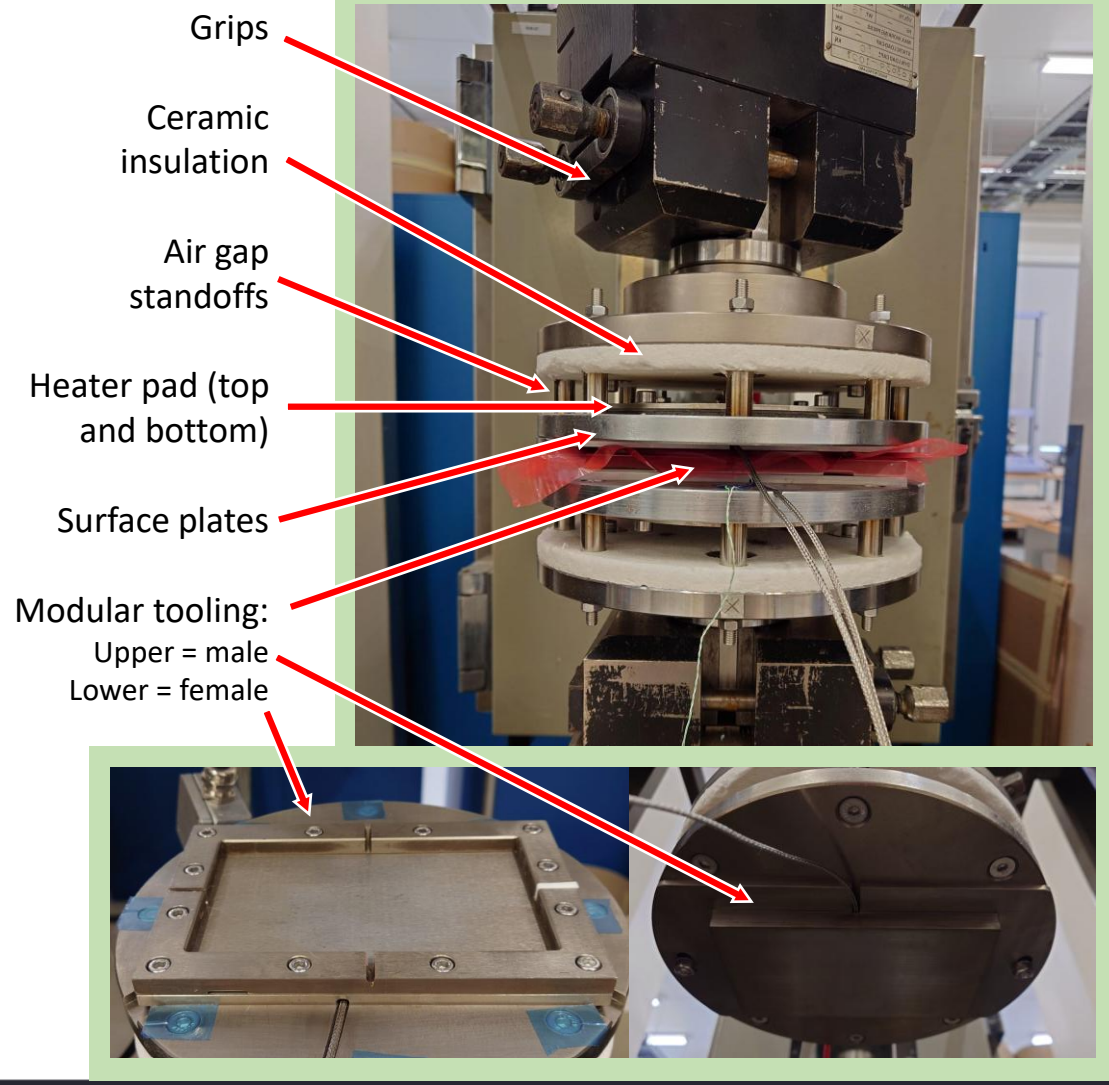
Quantify how sensitive birefringence is to variations in each geometric parameter.

Statistical method:

- All input parameters and the birefringence response are normalized [0, 1]
- A linear regression model is fitted:

$$Normalised\ Birefringence = \sum_i (Coefficient_i \times Normalised\ Parameter_i)$$

- Regression coefficients indicate **relative sensitivity**:
  - Larger absolute values = stronger influence
  - Positive vs negative = direction of effect



Key takeaway: Sensitivity is enhanced in high aspect ratio, thin-walled sensors

Integration into composite materials

Hot press: Easy fibre optic egress – rapid sensor development.

- Applications:
  - Cure monitoring and producing integrated sensor laminates
- 100 kN Test Machine
  - Displacement and load-control modes.
  - Compression grips for attaching tooling.
- Heated Tooling
  - Cavity dimensions: **84 mm × 140 mm × 10 mm** (W × L × D).
  - Embedded thermocouple slots positioned 0.5 mm below surface.
  - Small egress holes for thermocouples and optical fibres.
- Watlow EZ-Zone PID Temp Control
  - 2 tool embedded control thermocouples for PID feedback.
  - Data logging for up to 8 laminate thermocouples
- Fibre Optic Interrogation
  - SmartFibre FBG sensors (standard FBG strain sensors).
  - µHARFF FBG sensors (pressure-sensitive Fabry–Pérot type).

3D-PRINTED CORE REINFORCED WITH UNIDIRECTIONAL TAILORED FIBER PLACEMENT AND BRAIDED STRUCTURES FOR USE IN CUSTOM-MADE COMPOSITE KNEE ORTHOSES

ABSTRACT

A custom-made approach to medical devices is crucial for delivering effective therapy and enhancing quality of life. However, producing devices tailored to individual needs presents unique challenges that differ significantly from mass production. These challenges include precise measurement, specialized modeling and design, and customized tooling.

In this study, we present CAD and FEM modeling, used to create custom knee orthoses. Research indicates that 3D-printed cores can be strengthened by adding an outer layer made from various textile structures, such as braids, knits, and woven fabrics [1, 2]. Additionally, UD fibers can be effectively integrated into composites through tailored fiber placement techniques [3].

For our application, the composite structure was built using an individually designed, 3D-printed core based on a 3D scan of a human leg, embroidered unidirectional (UD) glass fibers, and a braided carbon fiber tube, all infused with epoxy resin via the infusion method [4]. Tensile tests were conducted for each textile structure orientation to model the FEM of the composite knee brace.

Our research demonstrates that the new composite can be successfully used in custom-made orthoses, with specific strength comparable to the aluminum alloy commonly used in knee braces. Additionally, the successful development of an FEM model, which allows for the analysis of various reinforcement configurations within a quasi-elastic range, was validated through tensile test of the composite.

1 INTRODUCTION

A custom-made approach to medical devices plays a crucial role in delivering effective therapy and improving patients' quality of life. This is especially important for knee orthoses, which must address not only the biomechanical requirements of the user but also their unique anatomy. In recent years, additive manufacturing and composite technologies have attracted increasing attention as they enable the production of personalized medical devices with optimized mechanical properties.

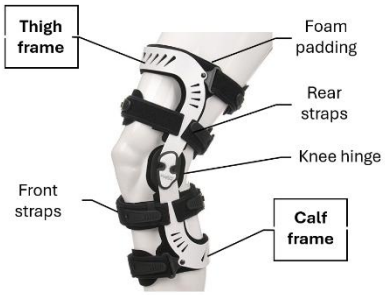

Figure 1: Main components of a knee orthosis [1].

However, the design and manufacturing of custom-made orthoses pose numerous challenges that distinguish them from mass production. These challenges include the need for precise anatomical measurements, the development of individualized CAD models, strength analysis using finite element methods (FEM), and the selection of appropriate textile structures and technologies for their integration with the composite matrix.

Previous research indicates that reinforcing 3D-printed cores with textile structures—such as braids, knits, and woven fabrics—can significantly improve their mechanical properties [2, 3]. Moreover, precise techniques like tailored fiber placement allow unidirectional (UD) fibers to be integrated into composites in a way that maximizes their potential [4].

The aim of this study was to develop and investigate the properties of a novel composite knee orthosis structure, which incorporates an individually designed, 3D-printed core, tailored fiber placement UD glass fibers, and a braided carbon fiber sleeve, all used to build the frame of the orthosis. Mechanical tests and FEM analysis were carried out to evaluate the potential of this innovative construction for orthotic applications.

2 MATERIALS

2.1 Unidirectional glass fiber (UGF)

The unidirectional (UD) reinforcement was fabricated using tailored fiber placement (TFP) technology on a ZSK JCZA 0109-550 embroidery machine (Figure 1). Three layers of E-glass roving (density $\rho = 2.54$ g/cm³, linear density 600 tex, silane-sized, supplied by Krosglass S.A.) were stitched onto a 280 × 280 mm polyester substrate with an areal density of 50 g/m². Non-load-bearing threads were used for stitching: polyester 2 × 10 tex and polyamide 11 tex on the top side. The glass fibers were arranged at a density of 42 rovings per centimeter, with a stitch length of 4 mm. The total areal weight of the UD reinforcement was determined to be 2 755 g/m², comprising 2 520 g/m² from the glass fibers, 120 g/m² from the polyester threads at the bottom, and 65 g/m² from the polyamide threads at the top.

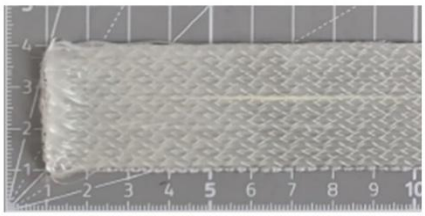

Figure 1: Unidirectional E-glass textile reinforcements produced by tailored fiber placement (UGF).

2.2 Braided carbon fiber (BCF)

A 2×2 biaxial braided sleeve, shown in Figure 2, was manufactured from carbon fiber using 12K GRAFIL 34-700 rovings (density $\rho = 1.8$ g/cm³, linear density 800 tex) by Eurocarbon B.V. (reference D144/11). The fabric exhibited an areal weight of 665 ±10 g/m² and was braided at an angle of ±30°, with a pick density of 20 picks per decimeter. For preparation, the braided tube was slit lengthwise and its edges were reinforced with tape to prevent fraying.

Figure 2: ±30° 2×2 biaxial braided carbon fiber sleeve (BCF).

2.3 Multi-layered composite (MLC)

Two types of textile reinforcements, UGF and BCF, were positioned on a 3D-printed (3DP) core and infused with resin under vacuum conditions. For the UGF layer, a strip measuring 30 × 250 mm was applied, while the BCF reinforcement used a smaller-diameter braided sleeve (Eurocarbon B.V., D-048-14, with an areal weight of 665 g/m² at a ±30° braid angle). Figure 3 presents a cross-sectional view illustrating the dimensions and stacking sequence of the composite structure.

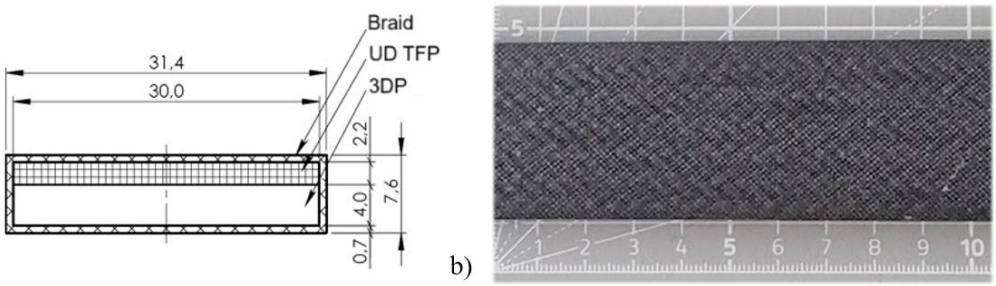

Figure 3: Structure and dimensions of the Multi-Layered Composite (MLC).

The core was manufactured by powder bed fusion using an HP Jet Fusion 3D 4200 printer, employing Multi Jet Fusion (MJF) technology. PA12 powder served as the build material, processed with an 80/20 ratio of recycled to fresh powder. The layer thickness was set to 0.08 mm, and the balanced printing mode achieved a speed of 4 115 cm³/h with solid infill. Components were spaced with a 5 mm gap, resulting in a packing density of 8.98%. The printed cores were oriented along the X-axis, and the final material density was measured at 1.01 g/cm³. Following the printing process, the cores underwent cleaning via sandblasting.

2.4 Composite preparations

The textile layers were arranged on a flat glass plate layered with peel-ply, infusion mesh, and a vacuum bag. Resin feed and evacuation points were set on opposite edges of the fabric assembly. For the MLC configuration, the resin inlet was located at the start of the core and the outlet at its far end. The infusion process employed a mixture of HAVEL Composite LH145 epoxy resin combined with HAVEL Composite H135 hardener at a 100:35 weight ratio. Following resin impregnation, the composites were cured at 25 °C for at least 24 hours before being shaped and oriented for testing, with final cutting performed by water jetting.

3 METHODS

3.1 Tensile test

Tensile testing was performed following ISO 527-4 [6], with data analysis based on ISO 527-1 [7]. The tests utilized an INSTRON universal testing machine (Model 8982), operating at a crosshead speed of 1 mm/min. Five specimens from each configuration were tested until failure. Strain measurements were obtained using a 50 mm gauge-length extensometer. For UGF and MLC samples, the specimens measured 2.2 × 25 × 250 mm, and the initial distance between grips was set at 150 mm. To reduce stress concentrations during testing, end tabs made of epoxy-impregnated carbon fiber twill were bonded to these samples. In the case of BCF specimens, due to the geometric constraints of the flattened braided sleeve, the dimensions were adjusted to 25 × 150 mm, and end tabs were omitted.

3.2 Finite Element Analysis (FEA) of MLC

The FEA of the MLC was performed using ANSYS APDL. A model was developed to accurately represent the mechanical behavior of the composite under tensile loading conditions. Key parameters were used to determine the stiffness matrix and to analyze the influence of different materials on the modulus of the MLC.

In the FEA model, one end of the specimen was fully fixed in all degrees of freedom to represent the stationary grip of the tensile testing machine. The opposite end was subjected to a displacement along the loading axis (Z-axis) corresponding to the maximum experimental strain. A quasi-static analysis was performed up to the elastic range identified in the experimental results.

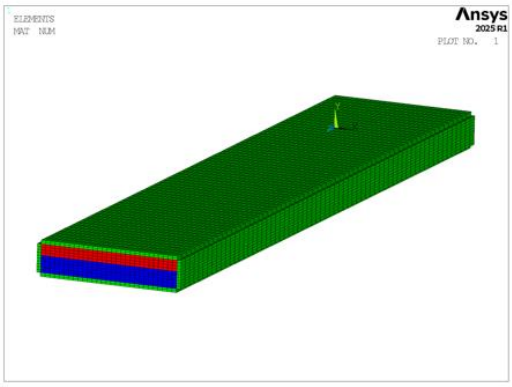

Figure 4: Finite element analysis (FEA) model of Multi-Layered Composite (MLC).

The geometry of the MLC, presented in Figure 4 was defined by specifying the number of layers, their orientations, and thicknesses. A finite element mesh was generated using SOLID185 elements for the 3DP core and SHELL181 elements for the UGF and BCF reinforcements. Material properties were assigned to each layer, taking into account orthotropic elastic behavior.

4 RESULTS AND DISSCUSION

4.1 Tensile tests of composite layers

Tensile tests were performed on the UGF and BCF structures. The resulting tensile stress–strain curves are shown in Figure 5, while Table 1 provides a summary of their corresponding mechanical properties.

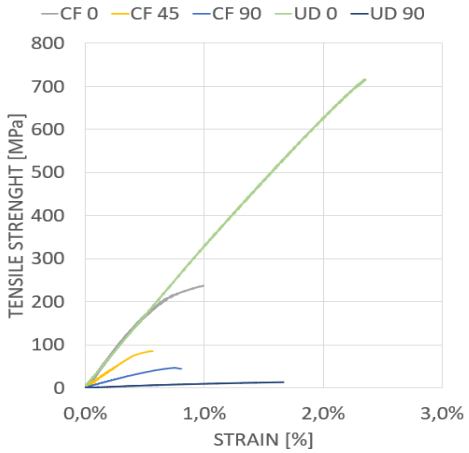

Figure 5: Tensile stress-strain curves of composite layers.

Parameter	UGF 00	UGF 90	BCF 00	BCF 45	BCF 90
Tensile strength σ_m [MPa]	730 ±44	12 ±1,5	219 ±16	64 ±5	39 ±2
Tensile strain ε_m [%]	2.3 ±0,2	1.3 ±0,2	0.8 ±0,1	0.4 ±0,1	0.8 ±0.1
Tensile modulus E_t [MPa]	32 860 ±485	5 870 ±450	35 880 ±1 570	18 950 ±1 430	7 060 ±240

Table 1: Tensile parameters of composite layers.

Significant differences in tensile strength were observed between the two structures. The UGF fabrics demonstrated approximately three times higher tensile strength in the 0° orientation compared to the

BCF braided structures, although the braided samples showed a tensile modulus about 8% higher. In the tested samples, only a single reinforcement layer was used, which had a substantial impact on the measured tensile properties.

It is important to note that in typical braided structures, fibers form a continuous pattern, whereas in rectangular tensile samples, fibers are cut, disrupting their continuity. During tensile loading, fibers can stretch and reorient along the applied force direction, particularly if they were initially set at an angle. This behavior affects the measured tensile strength and strain, meaning these parameters may not accurately represent the tensile strength of the braided structures. Moreover, research indicates that the initial modulus values for samples oriented at 0° and 90° are similar, suggesting comparable moduli in both directions despite differences in tensile strength [8].

4.2 Tensile tests of MLC

The MLC was fabricated using a 3D-printed core combined with two types of textile reinforcements, which were impregnated with epoxy resin. Tensile tests were then carried out on the prepared samples. Table 2 summarizes the key parameters of the MLC. Additionally, the accompanying graph highlights the Initial Linear Line (ILL), representing the elastic region of the MLC; here, ILL+ indicates the upper bound and ILL- the lower bound of the modulus.

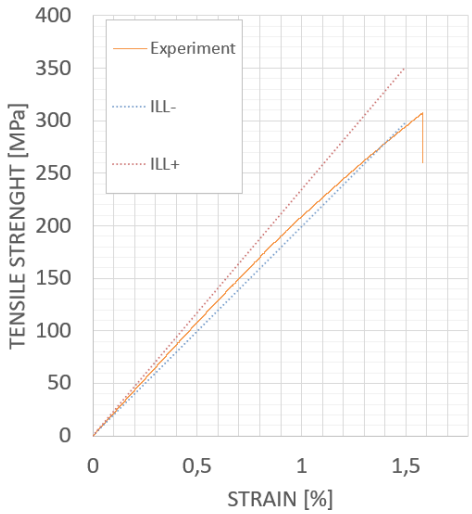

Figure 6: Tensile stress-strain curves of the MLC.

Parameter	MLC
Tensile strength σ_m [MPa]	302 ±13
Tensile strain ε_m [%]	1.5 ±0.1
Tensile modulus E_t [MPa]	21 700 ±1 800

Table 2: Tensile parameters of the MLC.

The stress–strain response of the MLC displayed quasi-elastic behavior, with a slight reduction in slope detected between approximately 0.4% and 0.6% strain, as marked by the ILL. This reduction indicated a decrease in structural stiffness, although the composite still maintained its ability to bear loads. The carbon fiber layer was the first to fail, accompanied by the characteristic sound of carbon fiber fracture, which was evident in the graph as a further slope reduction around 1% strain. This abrupt failure of the carbon layer also led to the destruction of the 3D-printed core at a strain of about 1.5%. Following the failure of the BCF layer, the UGF reinforcement continued to support the load until it ultimately fractured, corresponding to the final drop in the stress–strain curve. The samples obtained after tensile and flexural testing are shown in Figure 7.

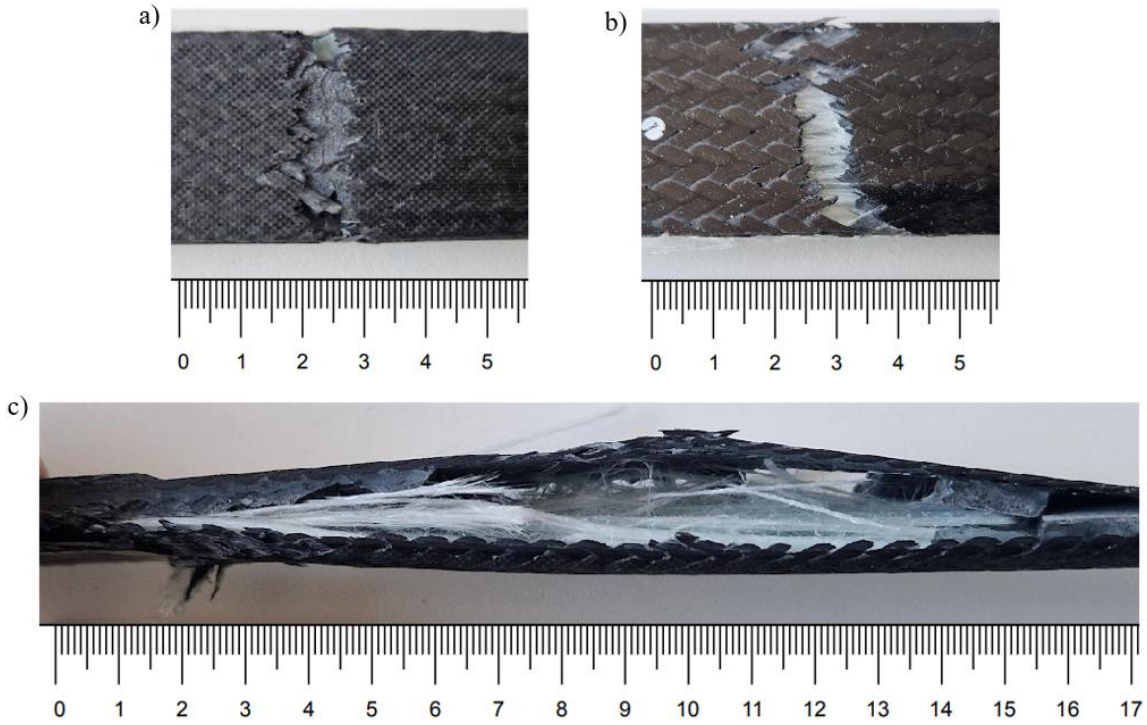

Figure 7: Samples after tensile test. a) bottom view b) top view c) side view.

Figure 8 shows the specific strength and specific modulus of different materials, calculated as the ratio of the respective material property to its density. The MLC was assessed relative to the EN AW 6061 T6 aluminum alloy, commonly used in knee brace manufacturing, as well as the PA12 material produced using powder bed fusion technology [1, 8].

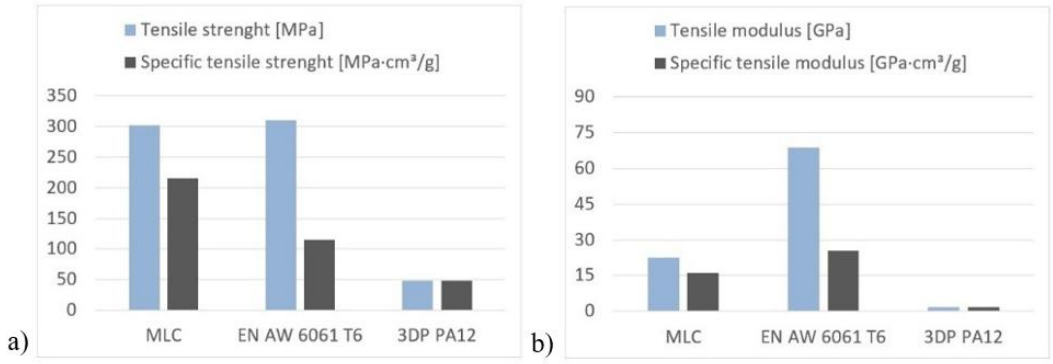

Figure 8: Comparison of the (a) specific strength and (b) specific modulus of various materials.

It is important to highlight that these parameters describe the materials as homogeneous structures and are intended solely for comparative purposes and assessing the potential of the new composite. While both aluminum and the MLC demonstrated the highest tensile strength, the MLC achieved a superior specific tensile strength, enhancing its effectiveness in applications where a high strength-to-weight ratio is essential. In terms of tensile modulus, the aluminum alloy showed a value approximately three times greater than that of the MLC. However, the stiffness of the composite could be increased by enlarging its cross-sectional area through the addition of extra FRC layers. When comparing specific modulus, the gap between aluminum and the MLC narrowed considerably to around 60%. The 3DP material displayed the lowest values across all parameters. Given that aluminum production requires expensive, single-use tooling, and that 3DP alone offers limited strength and stiffness, the MLC presents a promising solution for manufacturing custom-made components.

4.3 Finite Element Analysis (FEA) of MLC

The MLC was manufactured using a 3DP core with two types of textile reinforcements and infused with an epoxy resin. The samples underwent tensile testing, and the results were compared with the finite element model predictions, as presented in Figure 8 and summarized in Table 3.

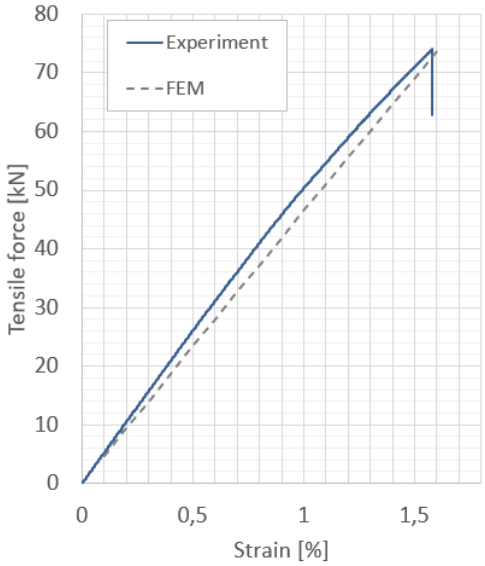

Figure 9: Comparison of experimental and FEM tensile force–strain curves for the MLC.

Parameter	Experiment	FEM +30°/-30° Model	Error
Elastic modulus [MPa]	21 670 ±1 780	19 500	10%

Table 3: Comparison of tensile test results with FEM model.

The FEM simulations demonstrated a good correlation with the experimental results, showing only a 10% deviation in the elastic modulus, which confirms the reliability of the numerical model for predicting the behavior of various material configurations.

UD Configurations	Elastic modulus [MPa]	Difference vs. MLC
3DP/BCF/UD Carbon fiber	39 800	+104 %
3DP/BCF/UD Aramid	26 200	+34,4 %
3DP/BCF/UD Flax	15 900	-18,5 %

Table 4: Comparison of elastic moduli of different TFP UD reinforcements.

The analysis indicates that incorporating unidirectional carbon fibers could potentially double the modulus of the composite, significantly enhancing stiffness, while substituting flax fibers leads to a modest 18.5% reduction in modulus. This highlights the possibility of tailoring mechanical properties to specific applications and suggests that natural fibers like flax offer a promising, eco-friendly alternative for other applications.

5 CONCLUSIONS

This study demonstrated that the hybrid MLC composite, combining a 3D-printed core with tailored textile reinforcements, offers promising potential for use in personalized knee orthoses. The composite exhibited tensile strength comparable to aluminum while achieving approximately twice the specific tensile strength, indicating an excellent strength-to-weight ratio essential for lightweight medical

devices. Although the MLC's elastic modulus was three times lower than that of aluminum, the difference in specific modulus was significantly reduced, highlighting its suitability for applications requiring high stiffness-to-density performance.

Finite element simulations showed good agreement with experimental data, deviating by only 10% in elastic modulus, thereby validating the numerical model for predicting various material configurations. Furthermore, the analysis confirmed that incorporating carbon fibers as unidirectional layers could substantially increase the modulus, whereas using flax fibers resulted in only a moderate reduction of 18.5%, offering an environmentally friendly alternative. Overall, the presented approach enables the development of customized, high-performance orthopedic devices that can be tailored to individual anatomical and mechanical requirements.

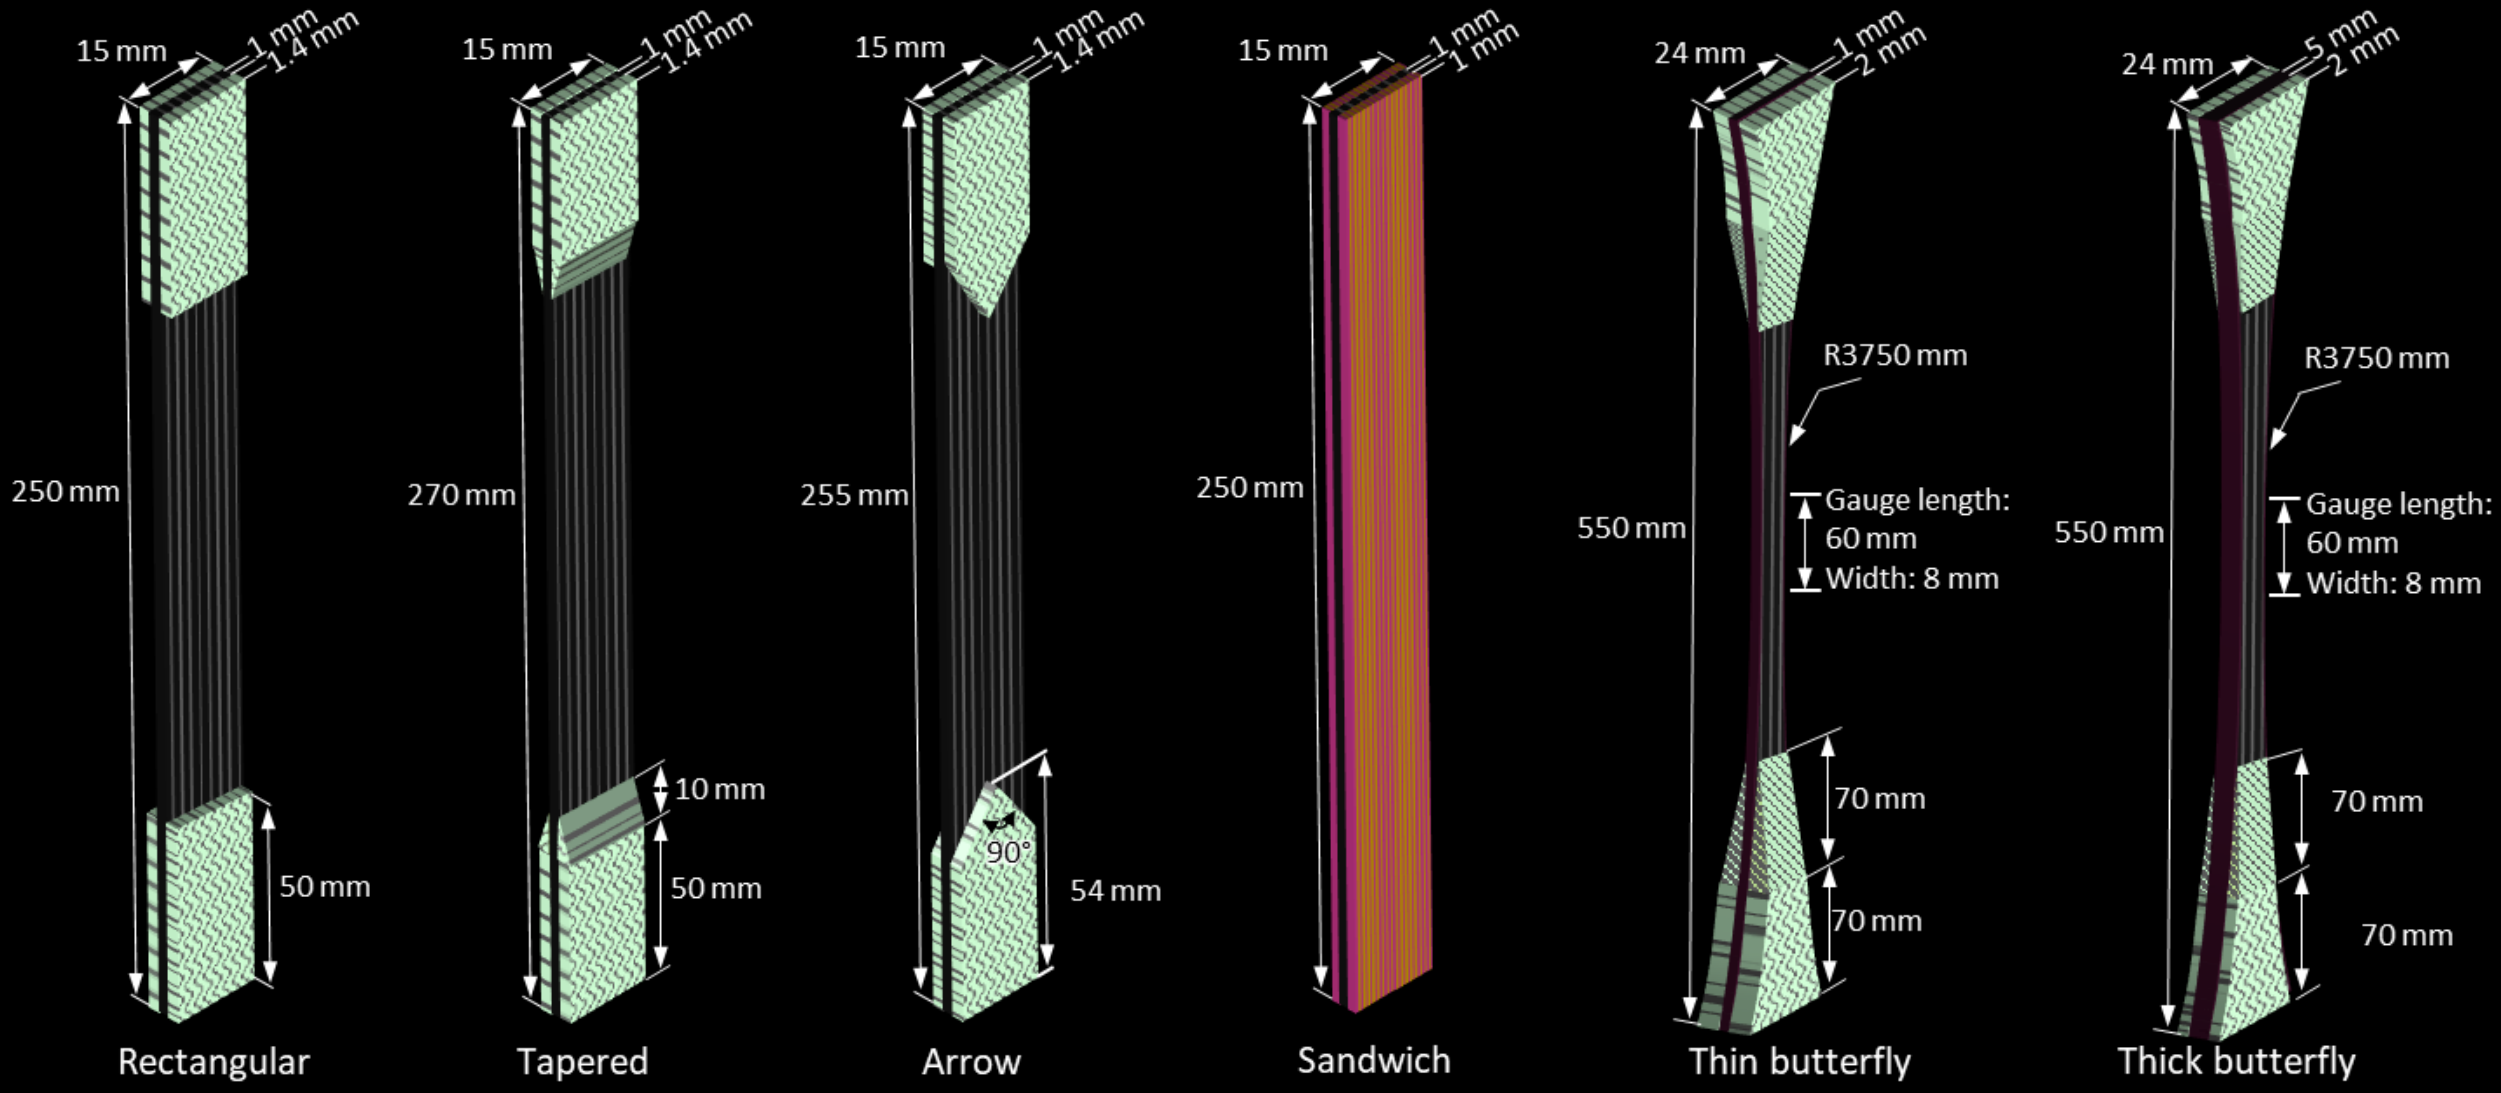
The challenges of tensile testing composites

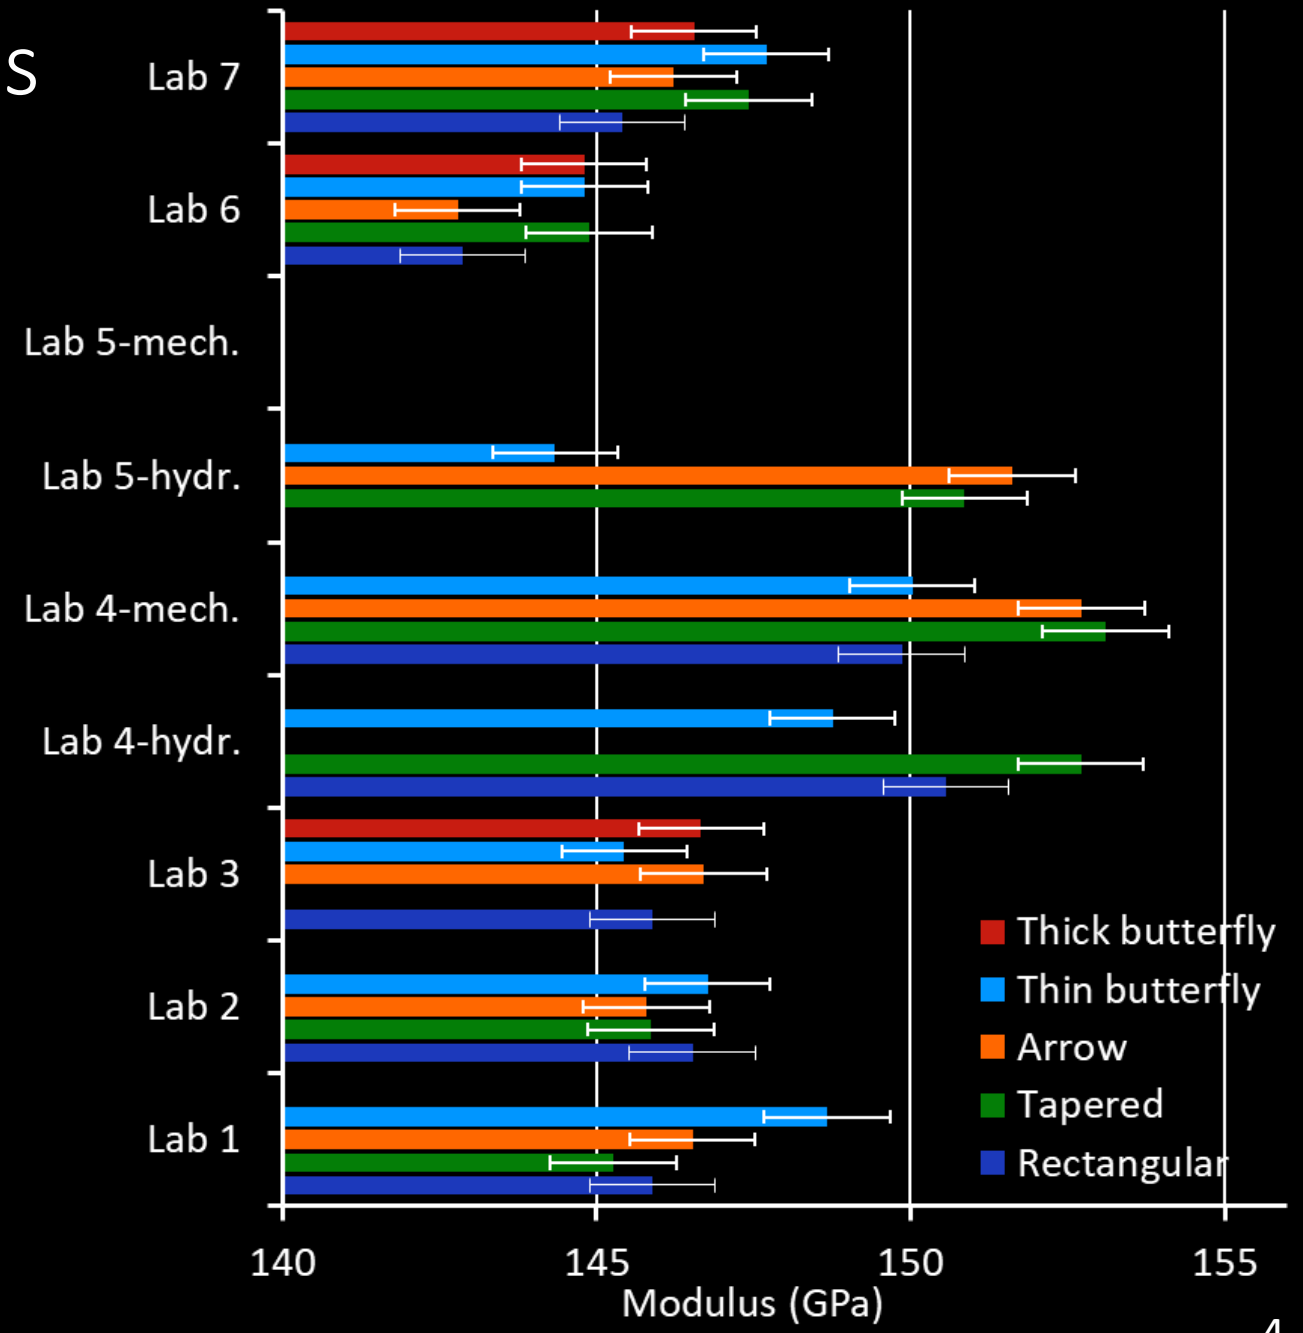
Stress concentrations

Korkiakoski et al. (2016)



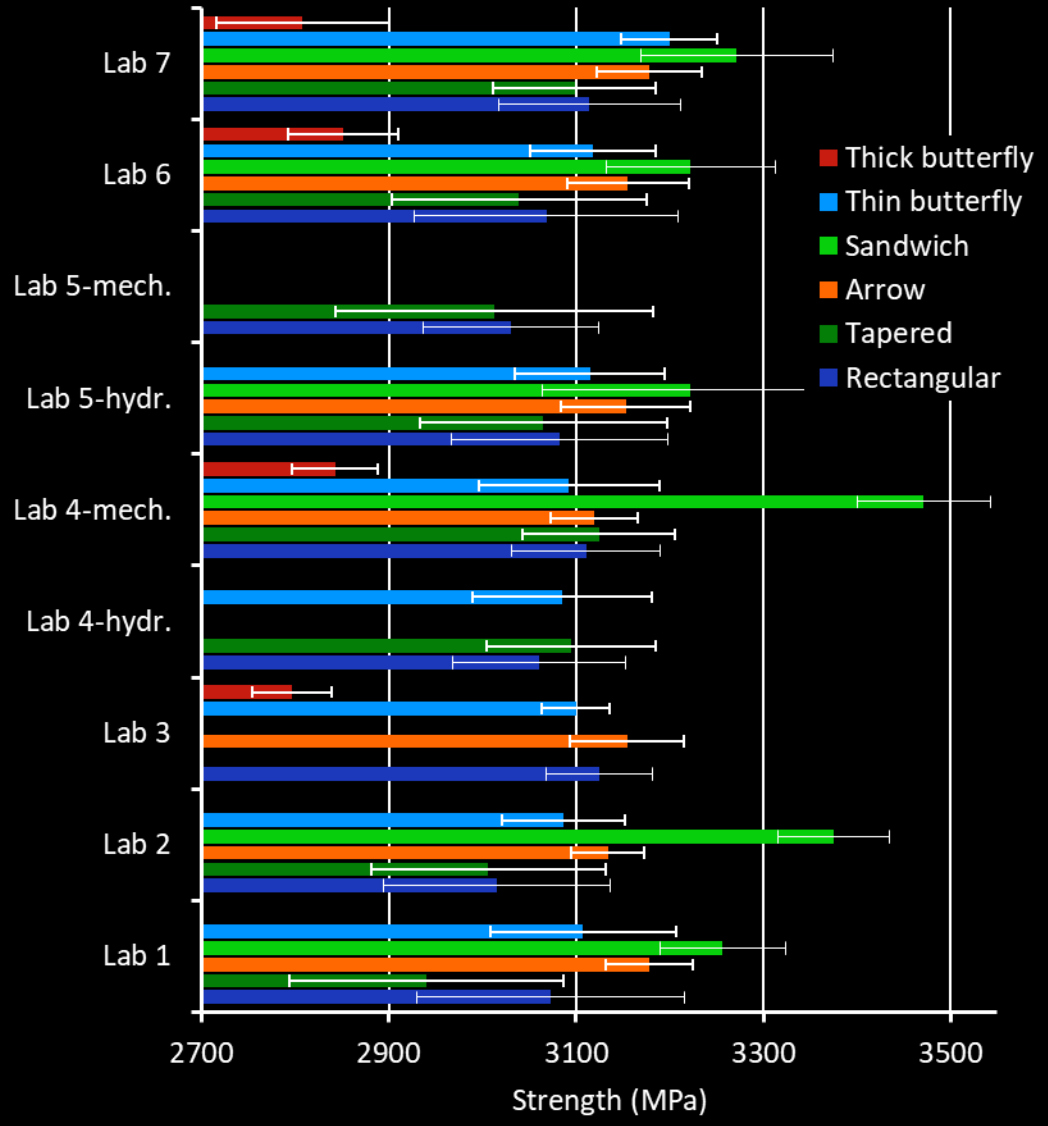
Failure near the grips/tabs

De Paiva et al. (2006)

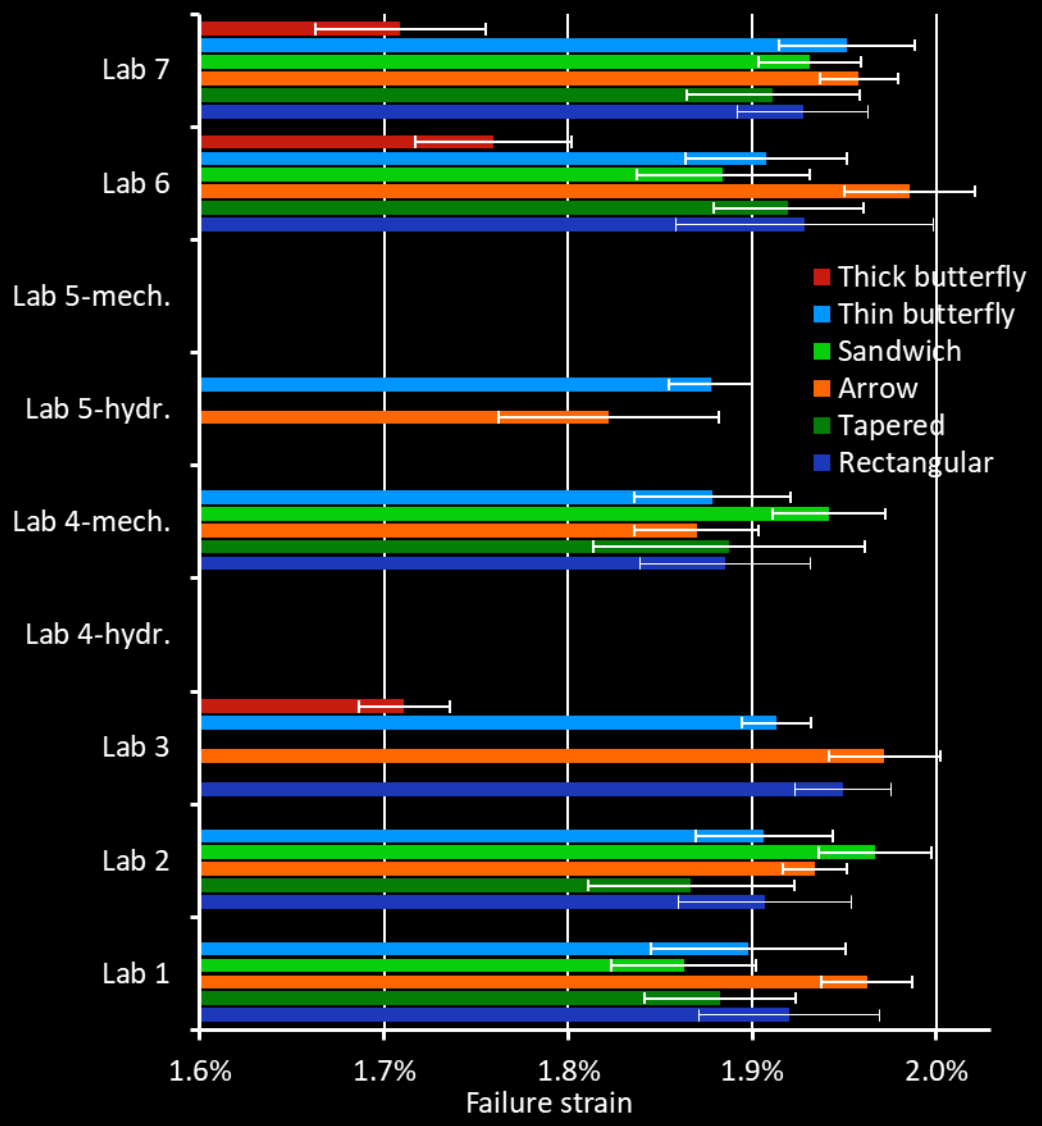


Difficult to detect failure location

Portnov et al. (2006)

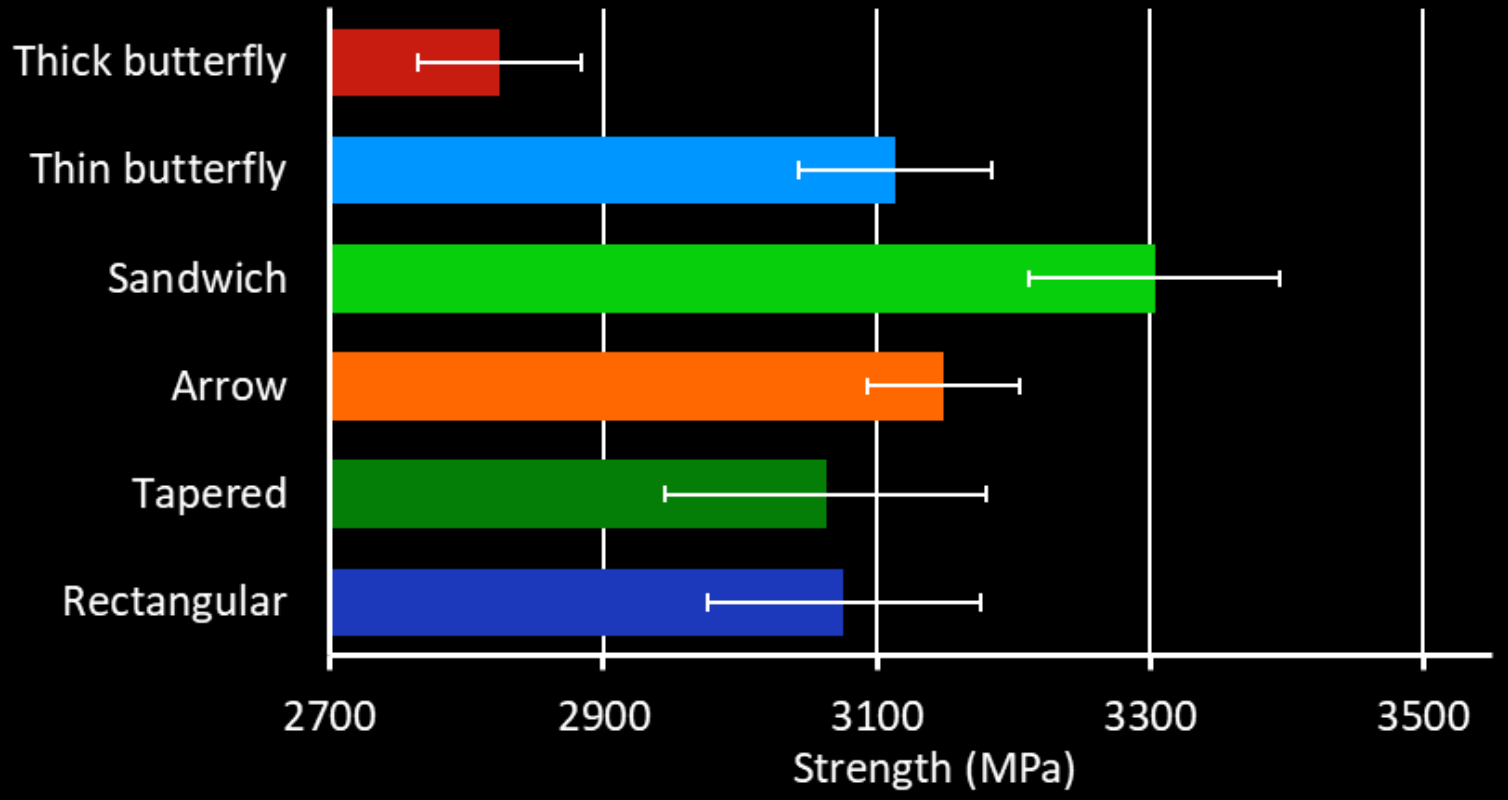


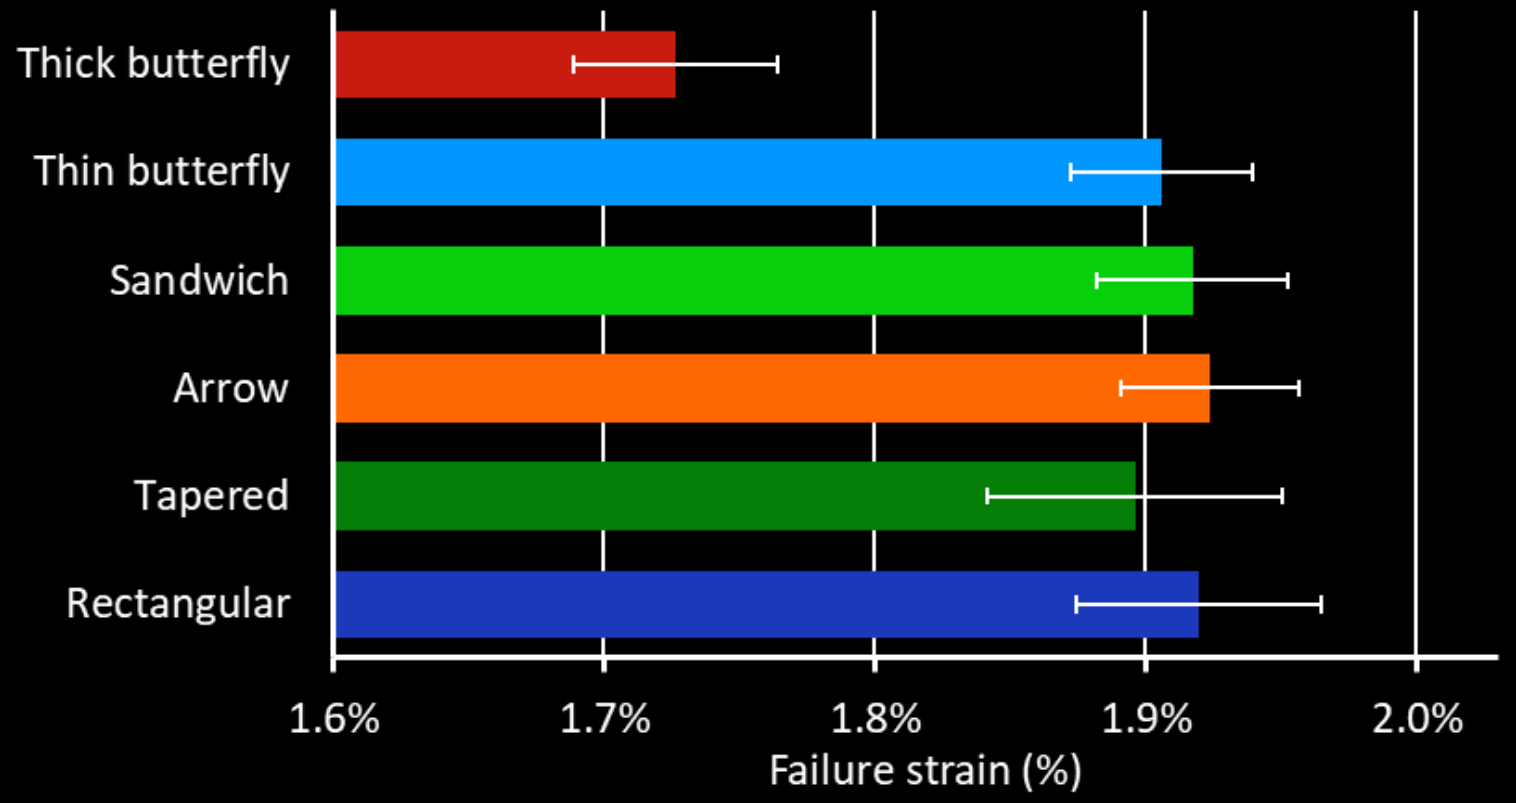
6 specimen designs and 7 labs



Minor differences in modulus between labs

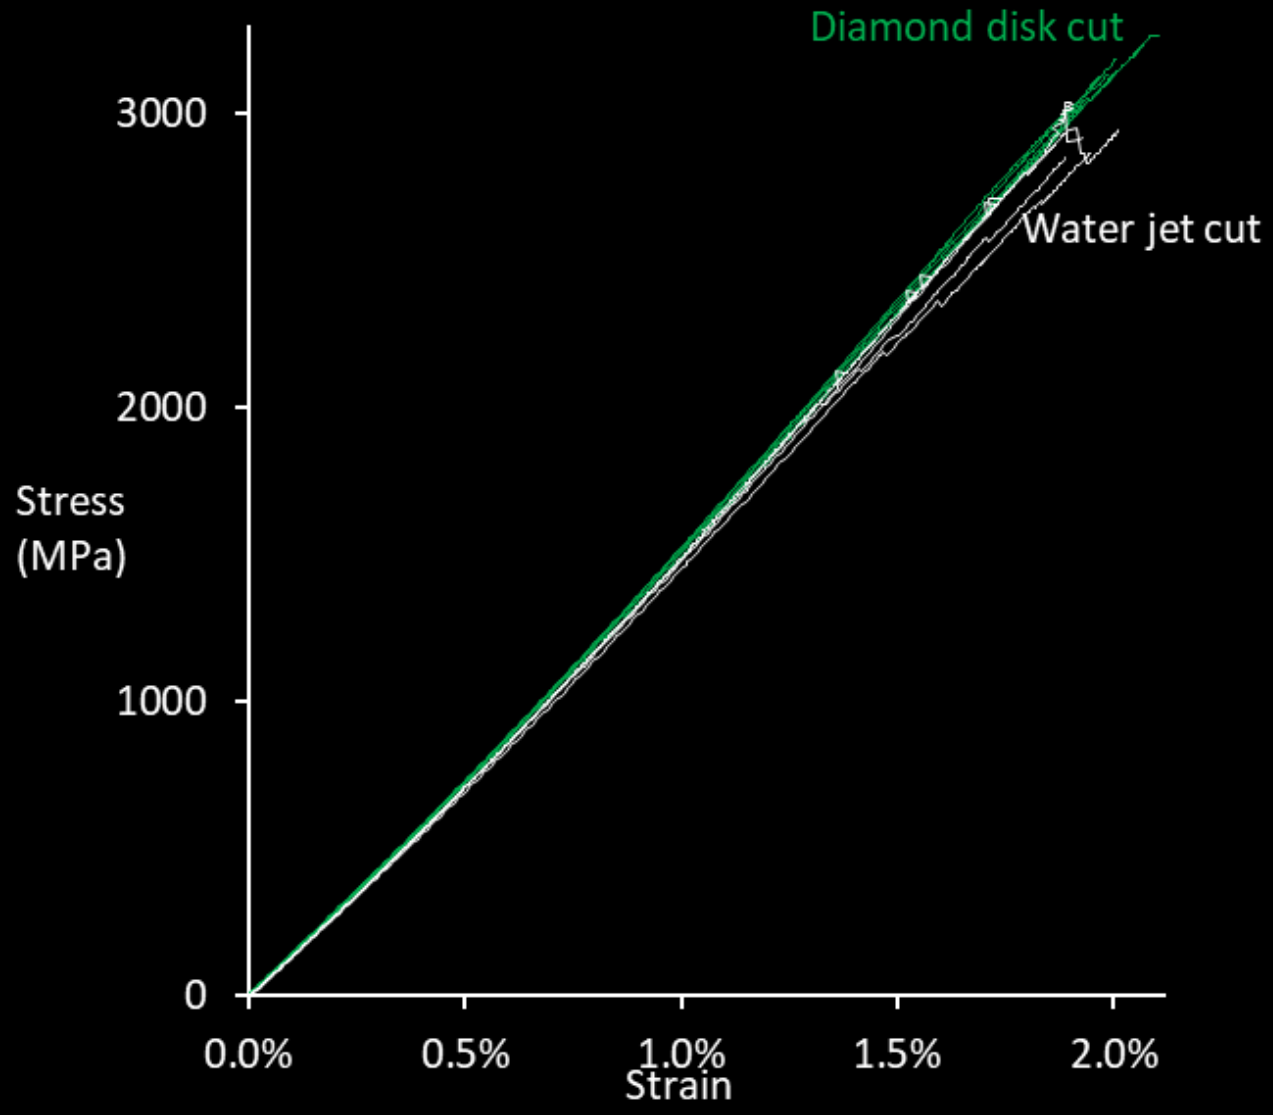
Minor differences in strength and failure strain



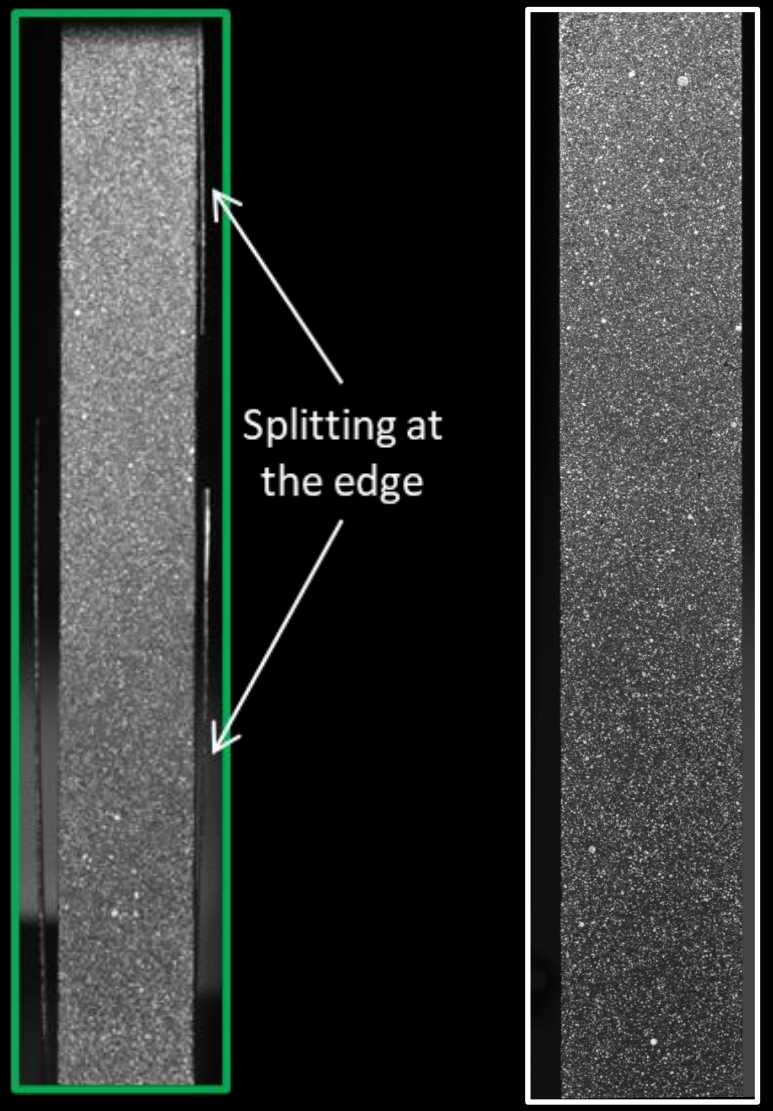


Some differences in measured strength

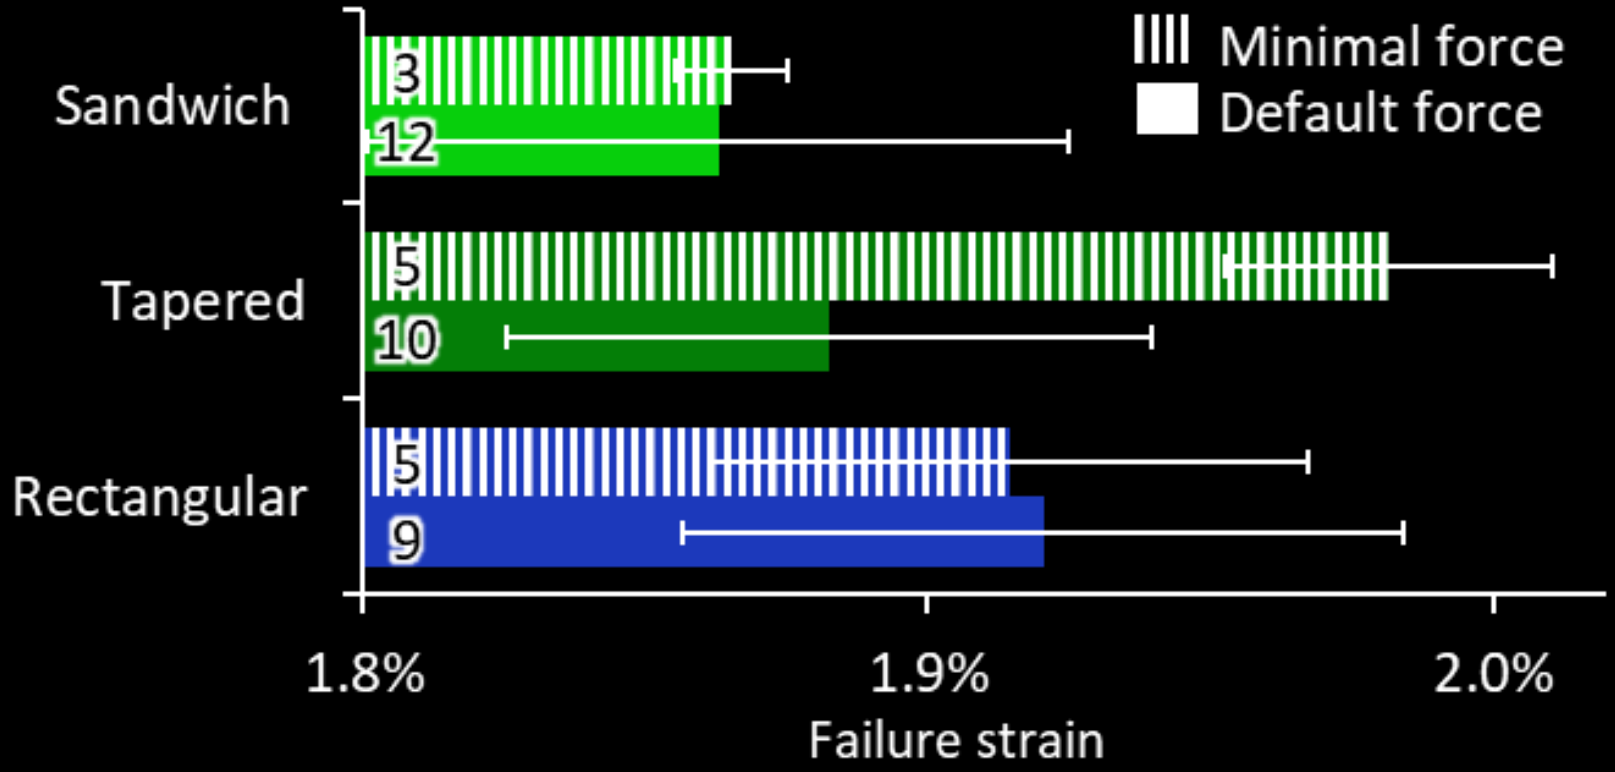
Continuous tabs: mainly due to inaccuracy in stress back-calculation



Thick butterfly: premature splitting + size effect (3-5.5%)



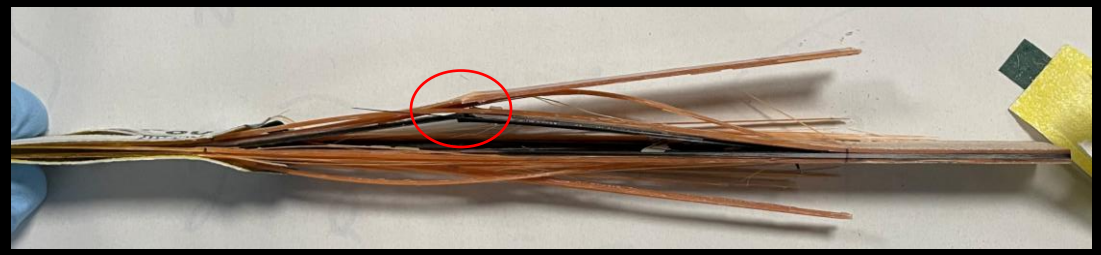
Very consistent failure strain values



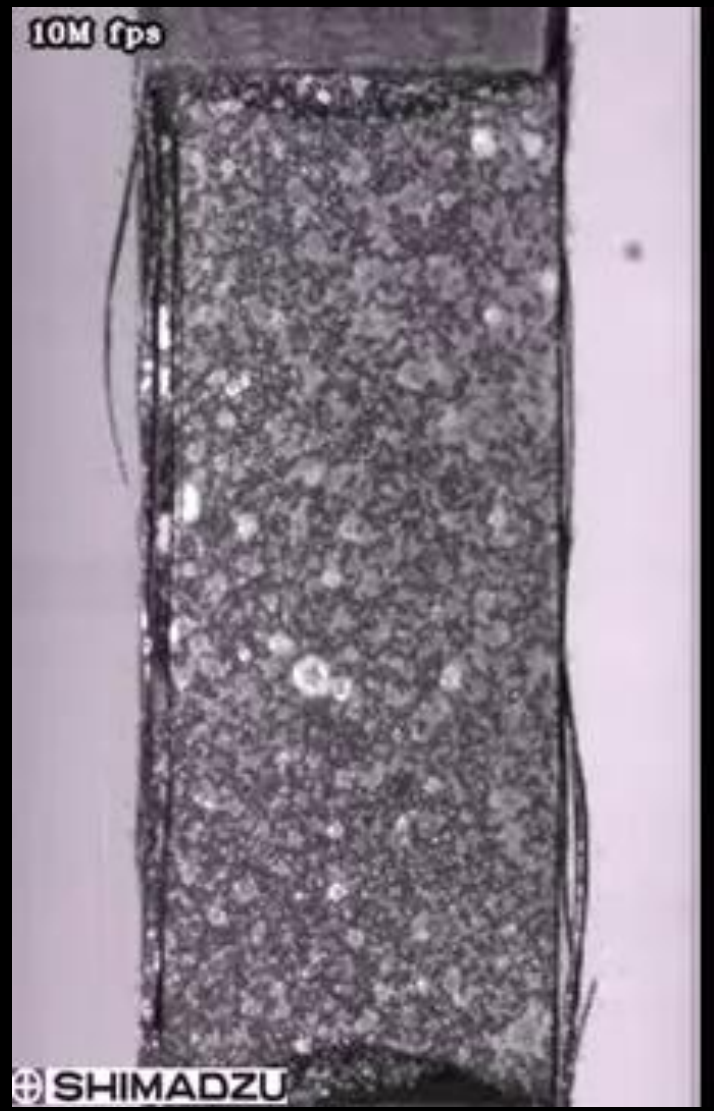
Diamond disk or water jet cutting?

Don’t apply too much gripping force

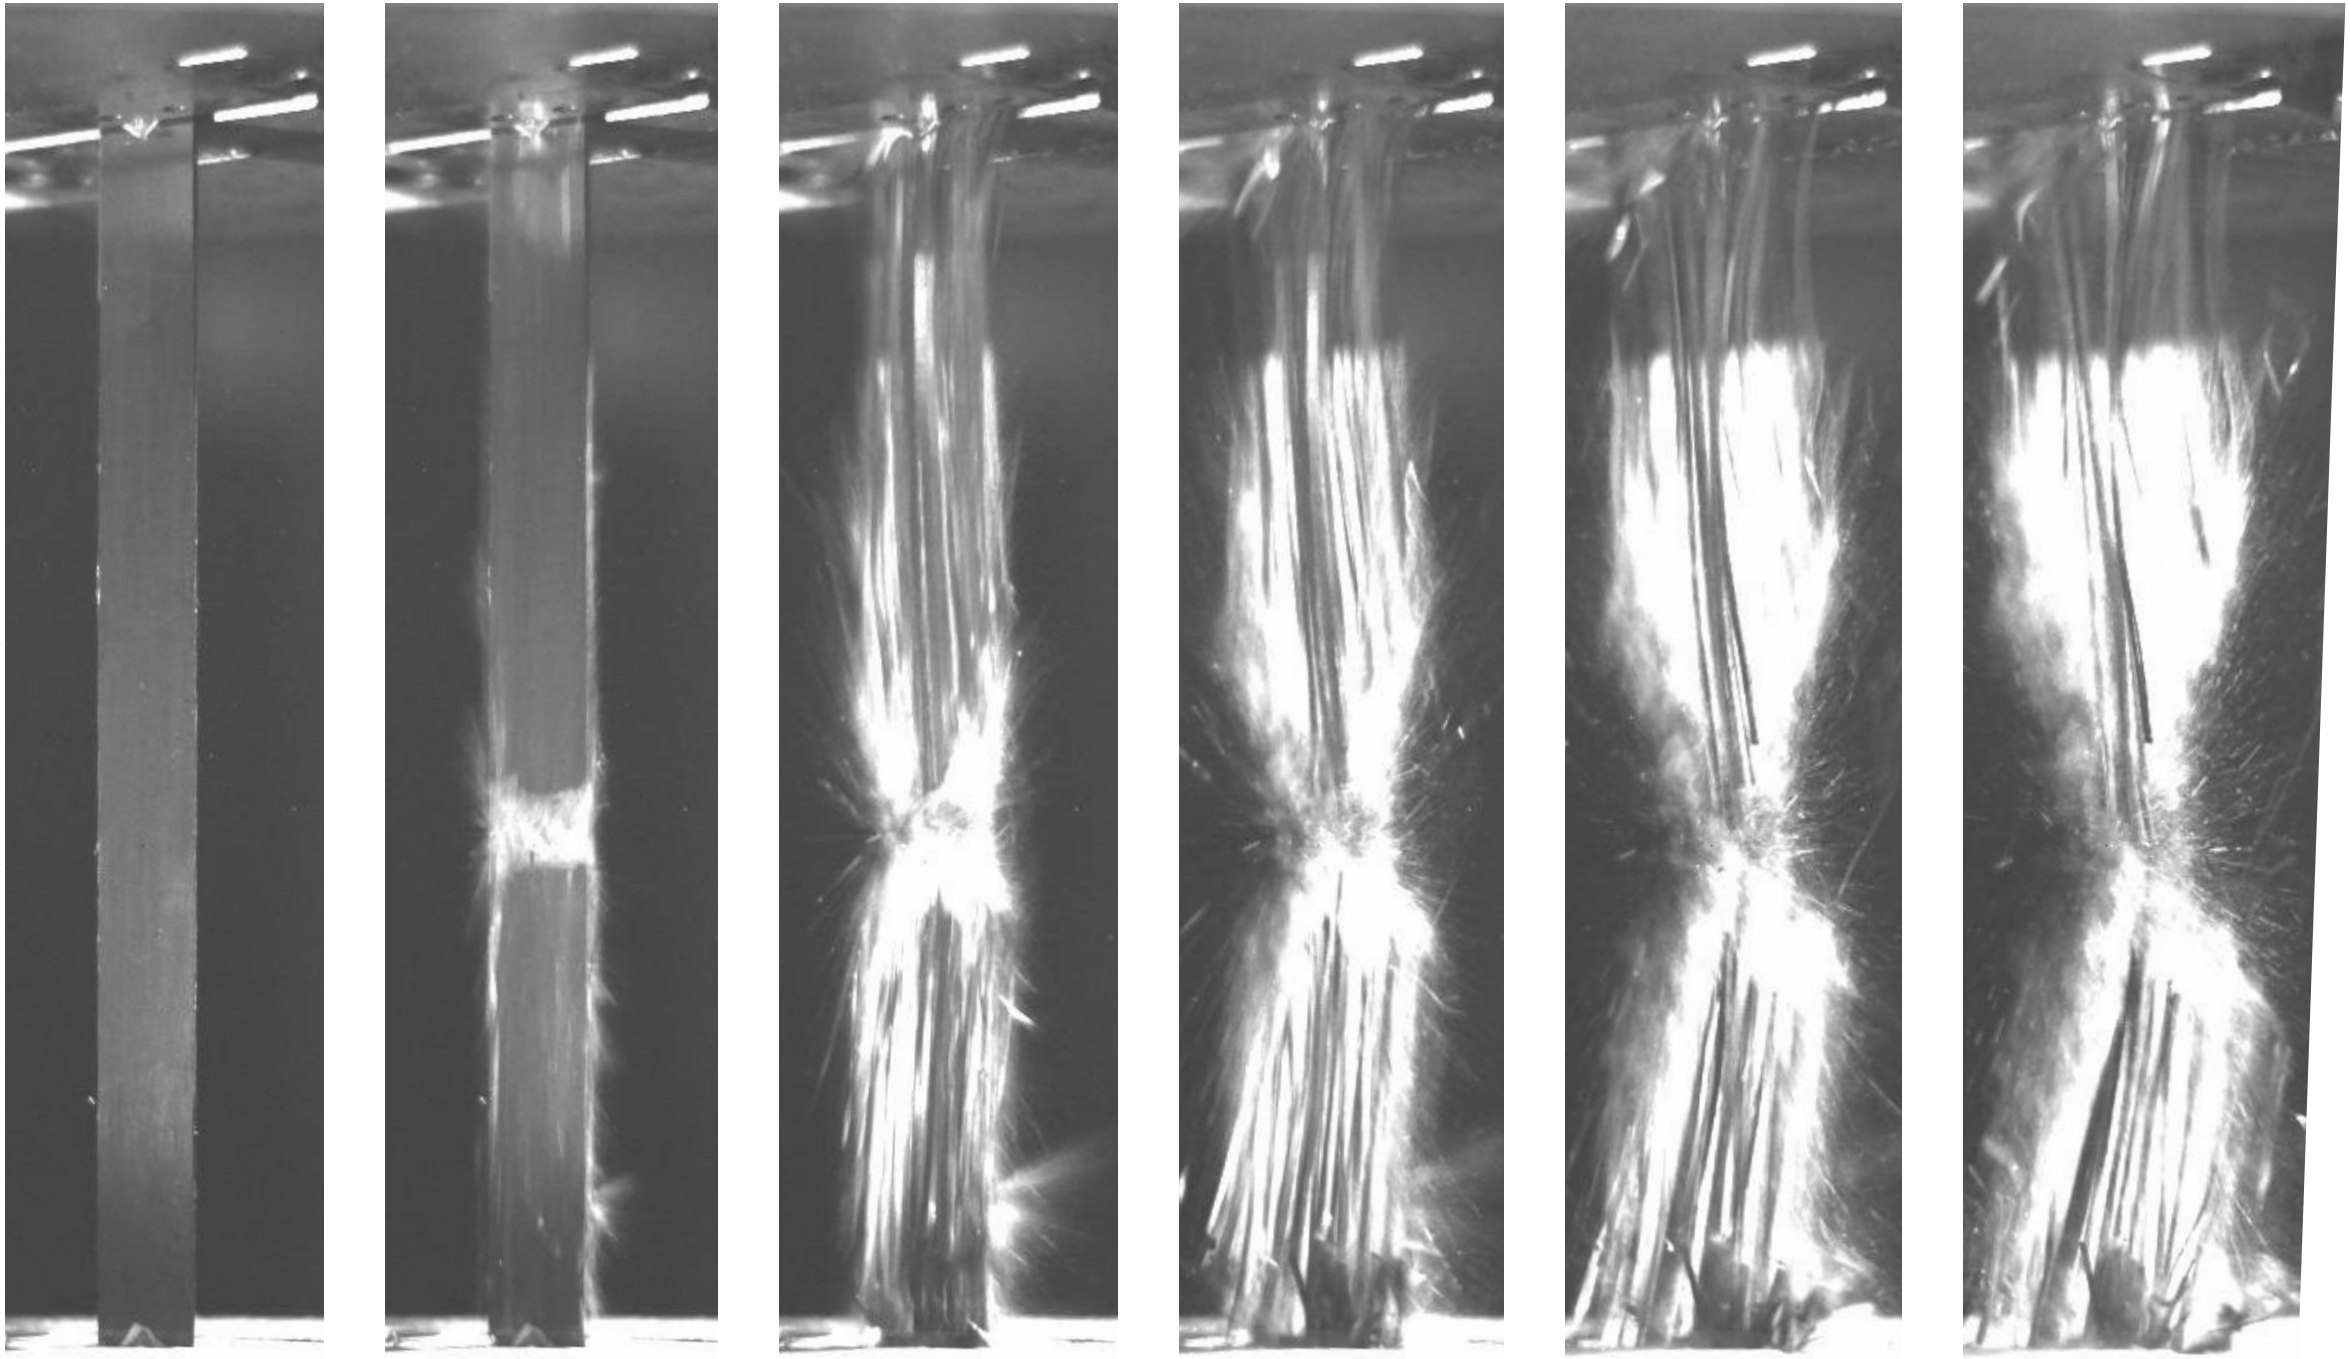
Enough to avoid slippage, but no more!



Detecting the failure location



Observing postmortem = impossible



Two solutions:

- Continuous tabs
- High-speed imaging at 10 Mfps

Reference +0.1 ms +0.2 ms +0.3 ms +0.4 ms +0.5 ms

Recommendations

Lab-to-lab variations larger than design-to-design variations

➔ Reliably measurements possible, if:

- Very well aligned fibres, plies, and cutting
- High-quality edge

Non-standardised designs: high failure strain and strength

Standardised designs: almost as good

Sandwich coupons: great for failure strain

Thick butterfly specimens underperformed, but different purpose

Recommendations

Determine failure location: 1000 fps camera or faster

Non-contact strain measurements methods preferred

Discard specimens with significant load drops (>3% of tensile strength)

Desired outcome:
Minor modifications to test standards

ζ → **dynamic fingerprint** unique for each material?

→ Distinguish anisotropic structures and its dependency on temperature and frequency

SUMMARY

- Use of measurements with rotational and axial drive enable determination of $|G^*|$ and $|E^*|$ on the same specimen under the same conditions and in one single experiment
- For homogeneous and isotropic samples → Complex Poisson's ratio, $|\upsilon^*|$
- For anisotropic materials, information of the material in longitudinal and torsional direction can be determined ($E', E'', tan\delta_E, G', G'', tan\delta_T$) →$|E^*|/|G^*|$= function(T,f)
- Results with µXRCT indicated differences in average fiber size and fiber alignment and hence a different level of anisotropy - as predicted by ζ = $tan\delta_G/tan\delta_E$
- ζ = $tan\delta_G/tan\delta_E$ could be a new dynamic fingerprint unique for each material
  - Distinguish anisotropic structures and its dependency on temperature and frequency → Significant time saving compared to other conventional methods

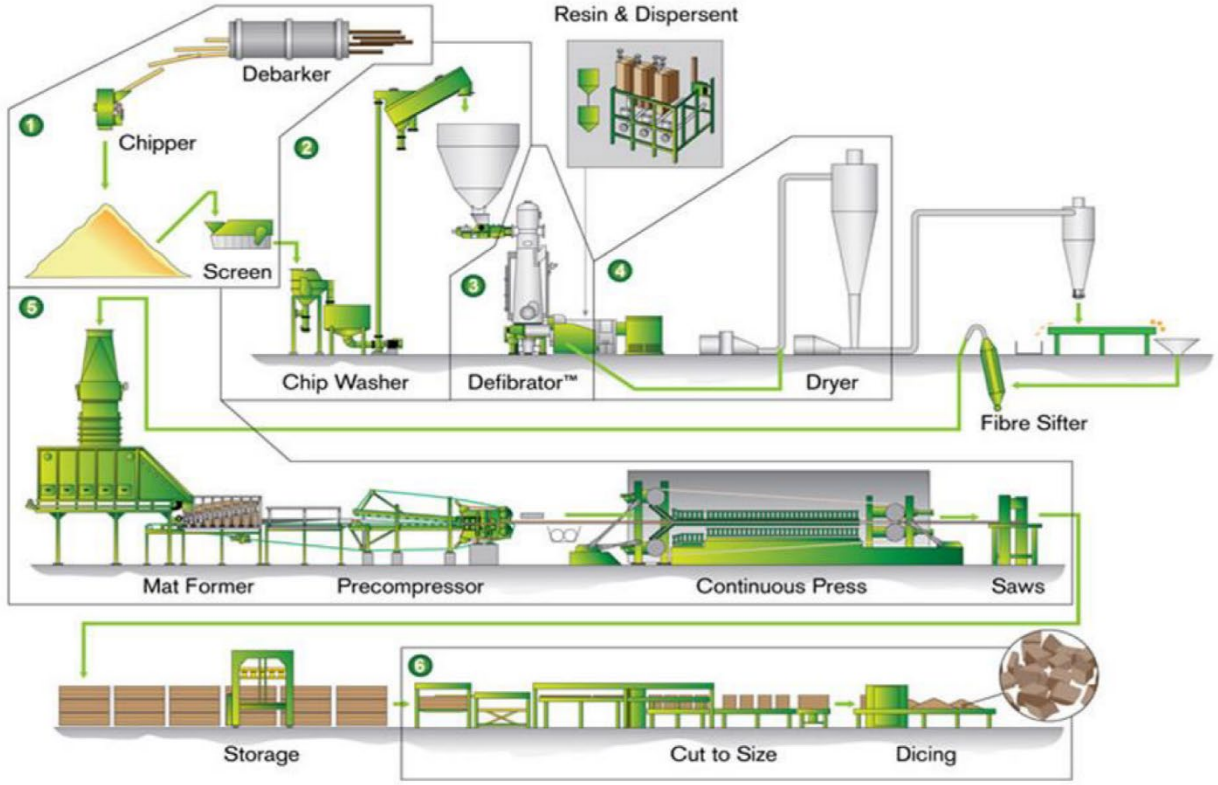
CENTRE FOR ADVANCED MATERIALS MANUFACTURING & DESIGN

UNIVERSITY OF AUCKLAND
Waipapa Taumata Rau
NEW ZEALAND

Background



Medium Density Fibreboard

- A type of engineering wood product
- Consisting of wood fibre and binder
- Good quality of surface

Application

- ❑ Furniture
- ❑ kitchen cabinets
- ❑ Mouldings
- ❑ door parts
- ❑ laminate flooring

1. Getting wood chips from pulp, waste, residual wood and logging
2. Removing impurities from chips after screening
3. Refining wood chips using pressurised refiners (pressurised disk refining)
4. Blending wood fibres with binders and sometimes wax
5. Forming a mat and hot pressing
6. Cooling and cutting to size

Background

Fire Resistant Study

- (In 1963) Inorganic chemicals in solid pine wood, analysed by residual char weight measurement; Browne & Tang
- (In 1983) Polyurethan-based FR coating on plywood surfaces in the ASTM E119-20; White et al
- (In 2012) Nanoclay in UF-based MDF, analysed by TGA; Reza et al
- (In 2019) Combination of different types of chemicals in MUF-based MDF, analysed by cone calorimeter; George et al

Binder Toxicology Study

- (In 1992) Suspected formaldehyde emission from pressed-wood products; Oston & Fellin
- (In 1998) Regulated formaldehyde emission from building materials; Kavvouras et al
- (In 2004) Categorised formaldehyde as carcinogenic for humans; Gatlin et al
- (In 2013) MUF culminating the desirable bonding strength of MDF, but still higher emission of the formaldehyde; Zhang et al
- (In 2018) Combination of UF and MF complying with formaldehyde emission regulations (EC-32-17); Zhang et al

Challenges

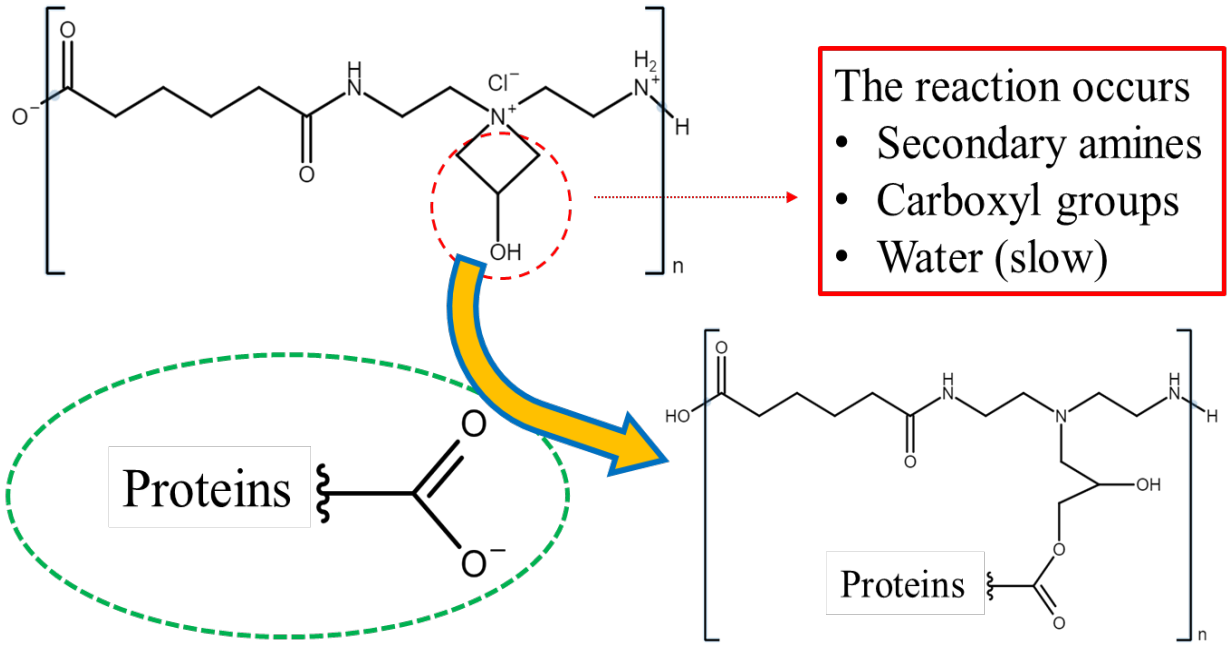
Fire hazard

- (In 2007) The addition of 6 % inorganic salts, such as borax and diammonium phosphate, decreased the internal bond strength by ~33 % in the PF-based MDF samples; Ayrilmis et al
- (In 2009) The incorporation of 30 % mineral-based chemicals, such as sodium aluminate and aluminium trihydrate, dropped the internal bond strength of the UF-based MDF samples by ~26 %; Hashim et al

➢ Corrosive side effect
➢ Toxic fumes (during combustion)
➢ Mechanical properties drops

Toxic binder

- (In 2000) Adverse health effects (nausea, eye, and throat irritation) in humans at more than 0.1 mg/L airborne formaldehyde concentration ; Athanassiadou
- MDF products made in NZ based on a MUF binder have 0.3 mg/L formaldehyde emission that complies with JIA A 5905 standard (Max. 0.5 mg/L of formaldehyde emission)



➢ Residual formaldehyde in the binder
➢ Process of the binder manufacture
➢ Hydrolytic degradation of the cured binder, particularly under high temperature and humidity

Motivation and Concept

- **Combination binder system**

Polyamidoamine-epichlorohydrin (PAE)

- ✓ Relatively low toxicity
- ✓ Good bonding with natural materials

Casein

- ✓ Char forming ability due to a rich of acid sources and blowing agents (carboxyl/sialic groups & amine groups)
- ✓ The excellent flame-retardant performance of casein has been identified in different material systems (textile substrates and polymer composites); Alongi et al and Zhang et al

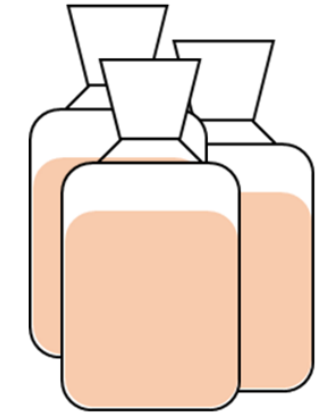
Material and Manufacturing Parameters

- Material composition of MDF panels

Sample	PAE (%)	Casein (%)	Moisture content (%)
4.4PAE8	4.4	-	8
4.4PAE8 30CP	4.4	30	8

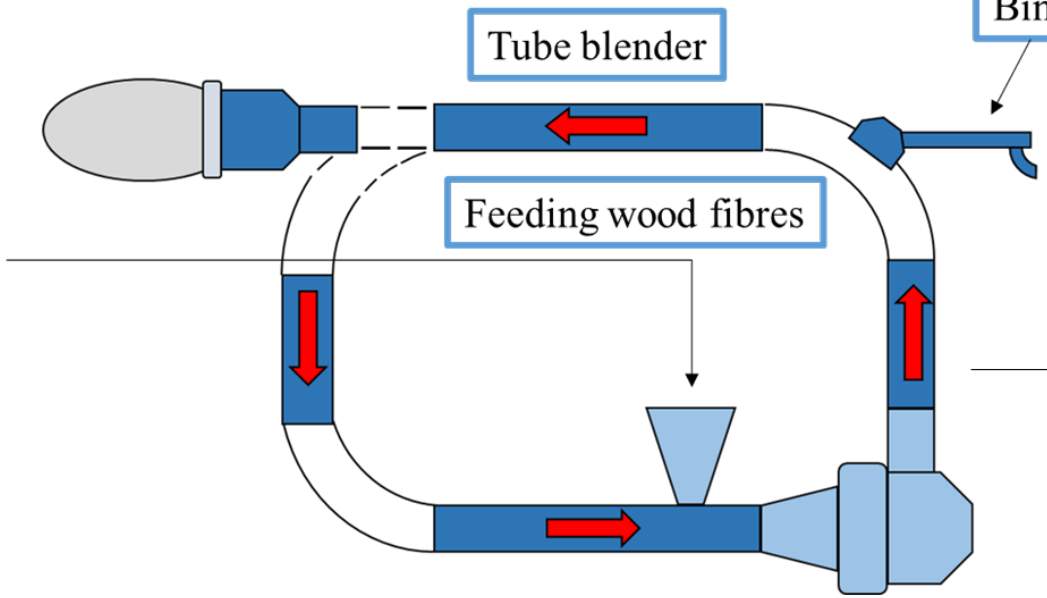
- Manufacturing parameters

Resin content (%)	Moisture content (%)	Hot-pressing time (s)	Hot-pressing temperature (°C)	Target density (kg/m^3)
4.4	8	150	180	**750**

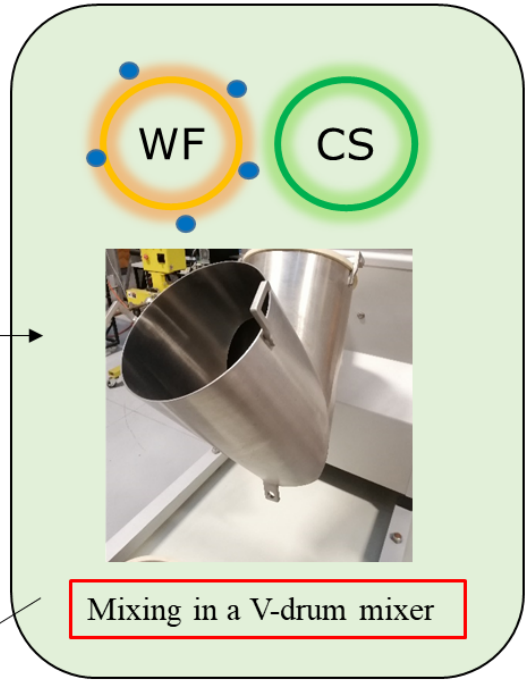


✓ Moisture content (MC) and the resin ratio were suggested from the supplier.

✓ Parameters are from the previous research regarding formaldehyde-free resin-based MDF manufacture.

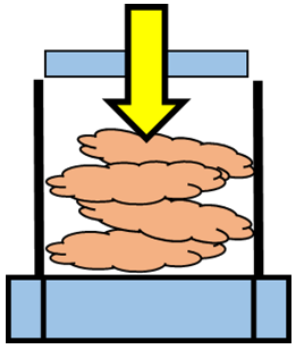


✓ The resin system is a combination of modified soy flour and PAE resin.

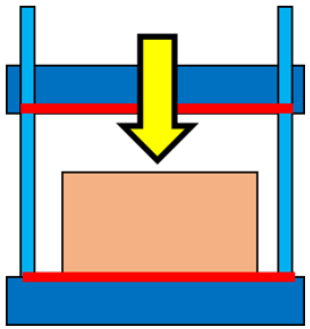


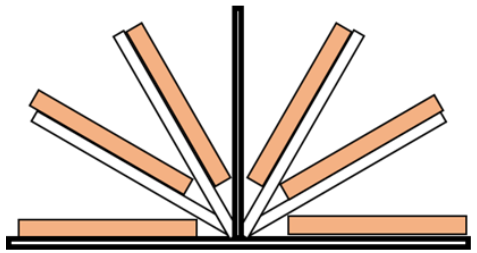
✓ A density range of MDF is 650 – 800 kg/m^3

Manufacture of Casein-based MDF



Wood fibres

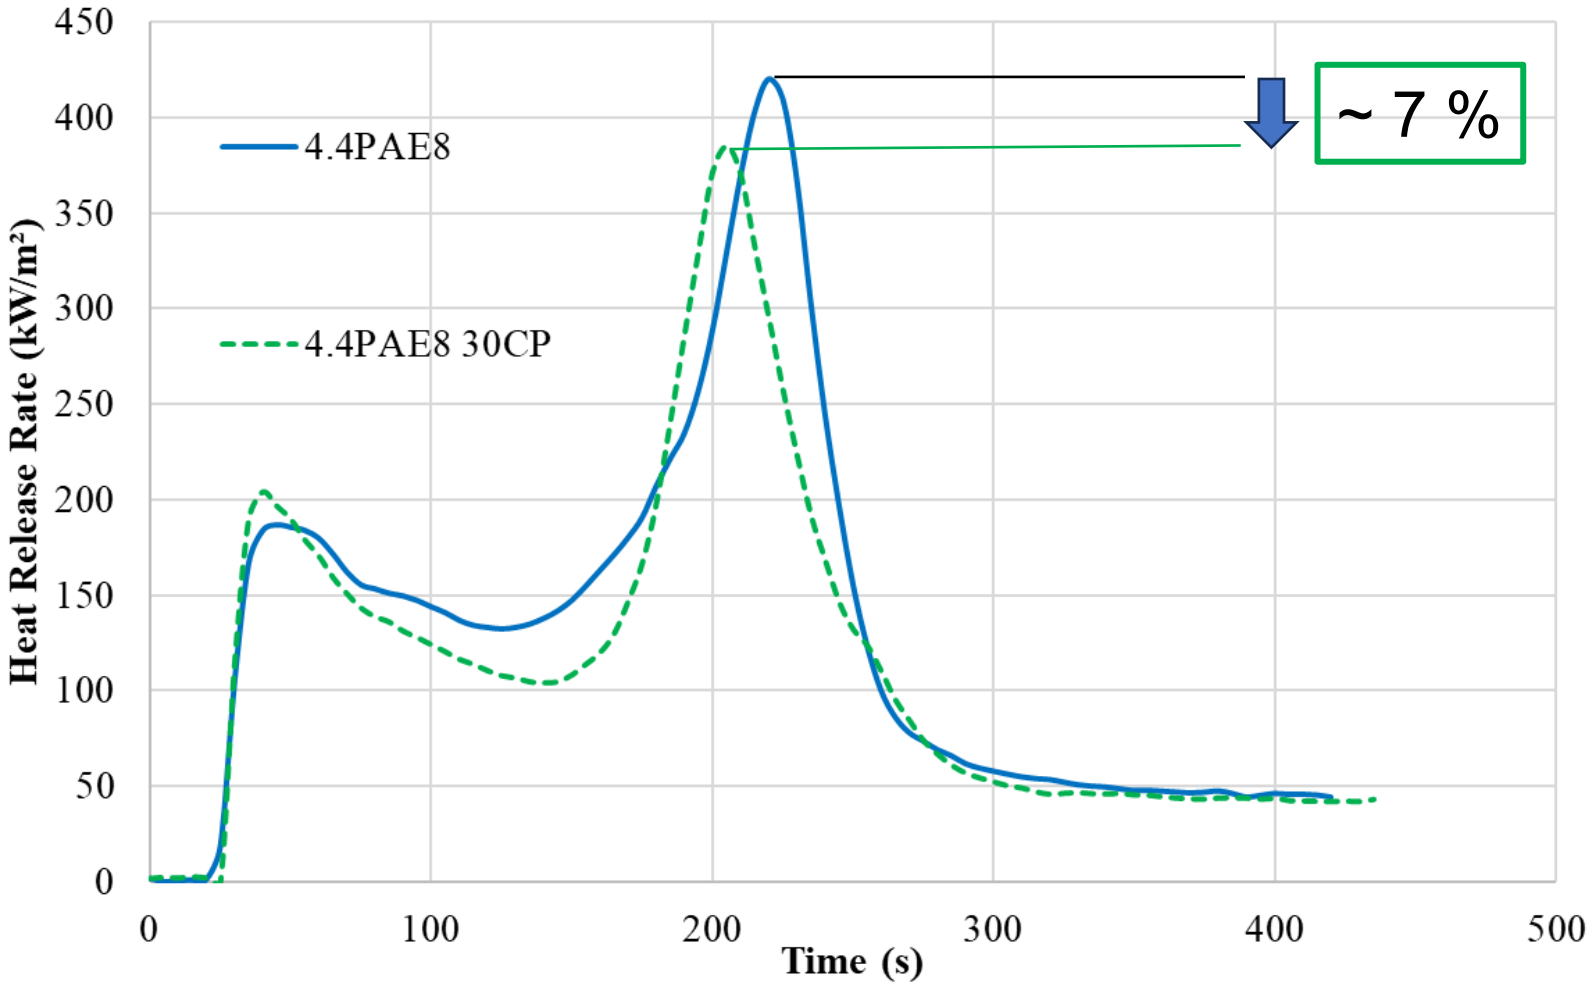




Mixing in a V-drum mixer

Pre-pressing and mat forming

Hot pressing



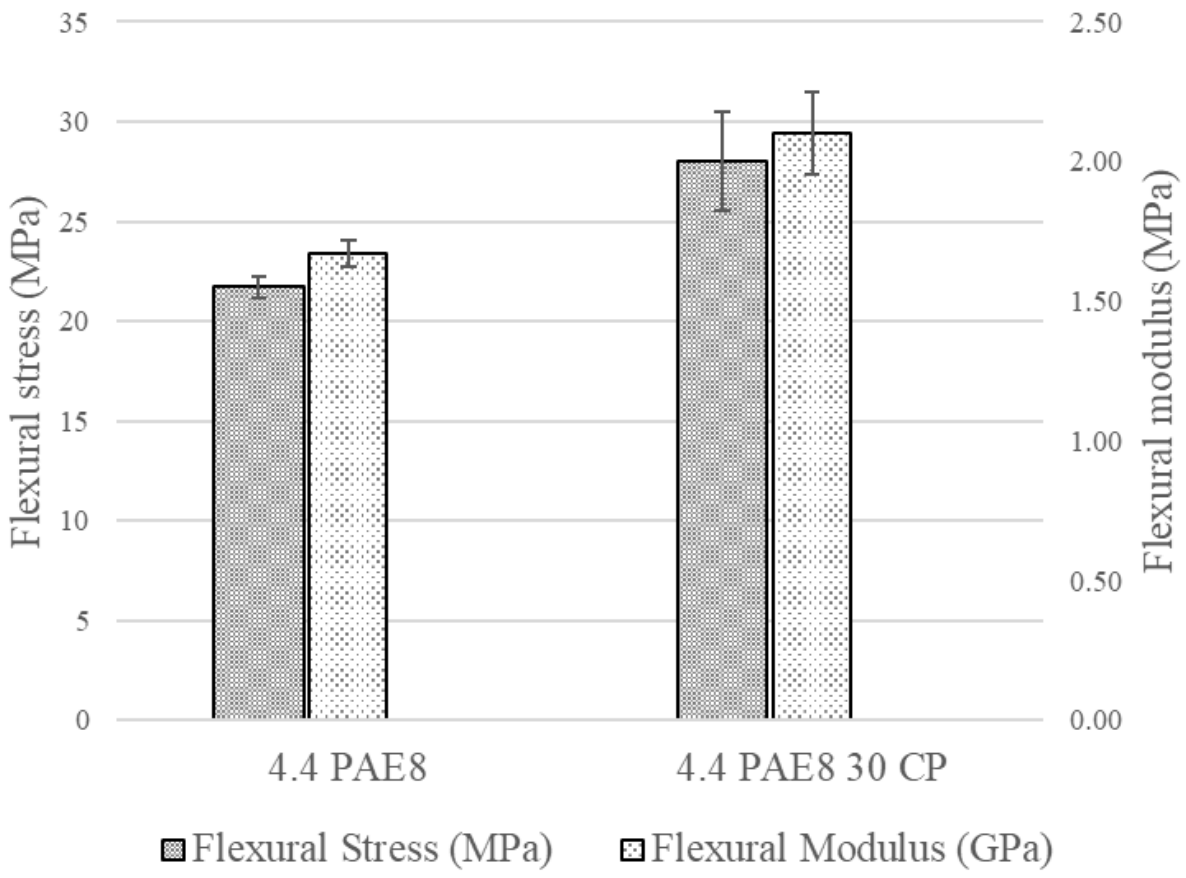
Cooling

- Wood fibres (WF) that have been sprayed with binders are mixed with casein particles in a mechanical mixer.

Heat Release Rate

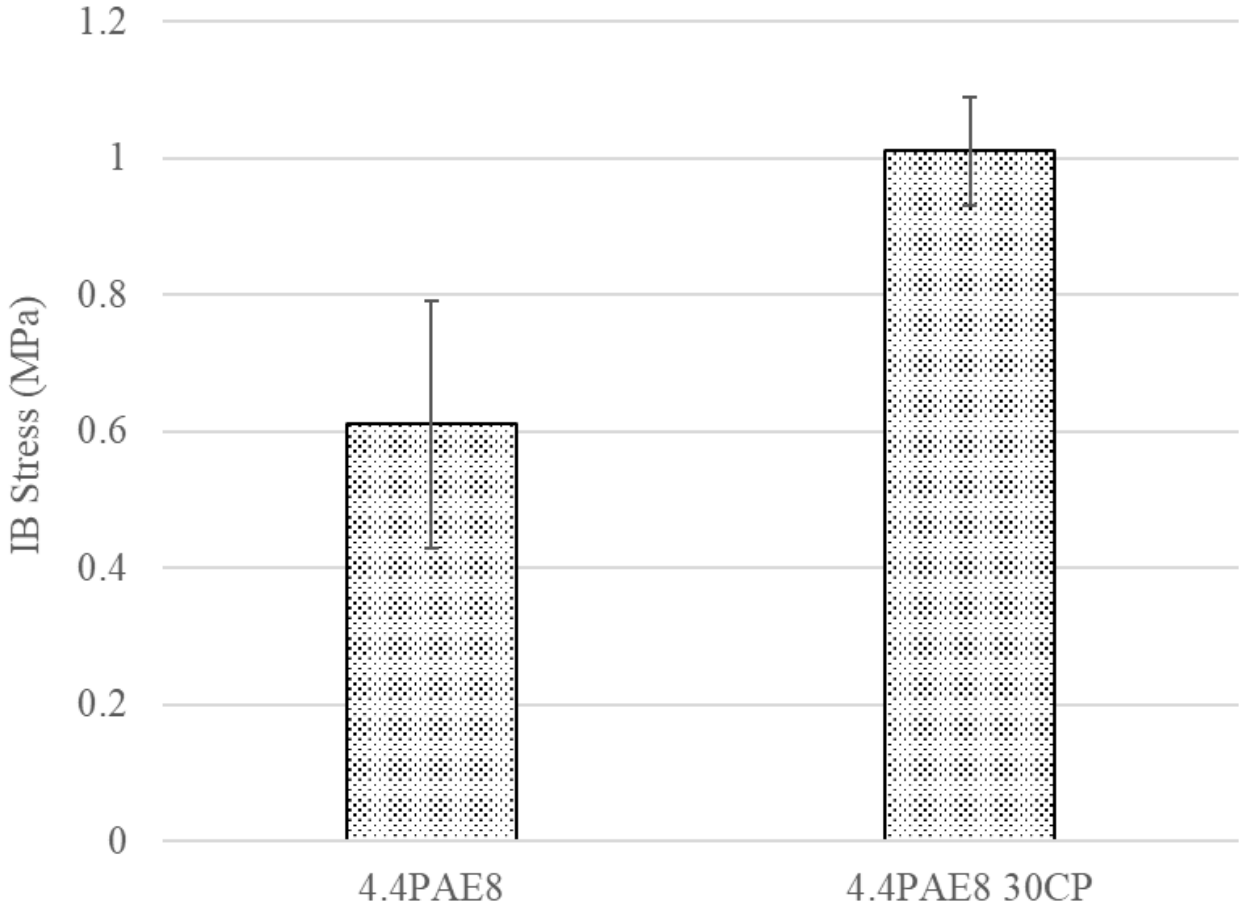
- **Effect of casein on heat release rate of MDF**

Heat release rate (HRR)



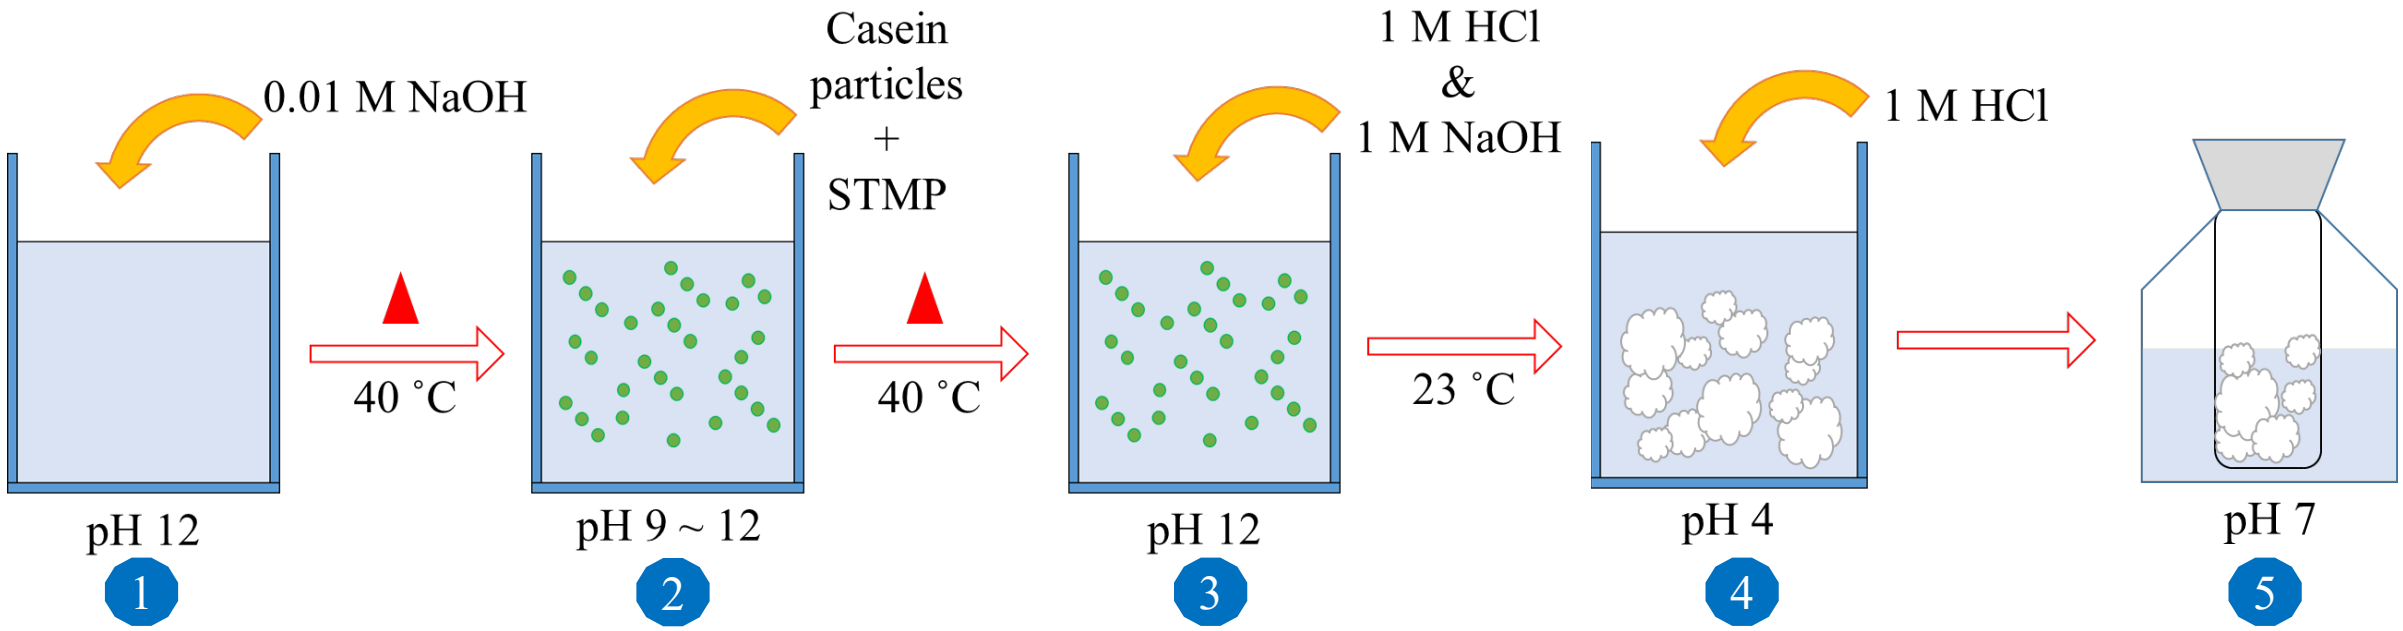
- ✓ The rate of fire growth
- ✓ The size of the fire
- ✓ An effective heat of combustion

The addition of 30 % casein particles reduces the peak heat release rate of the MDF sample by ~ 7 %.



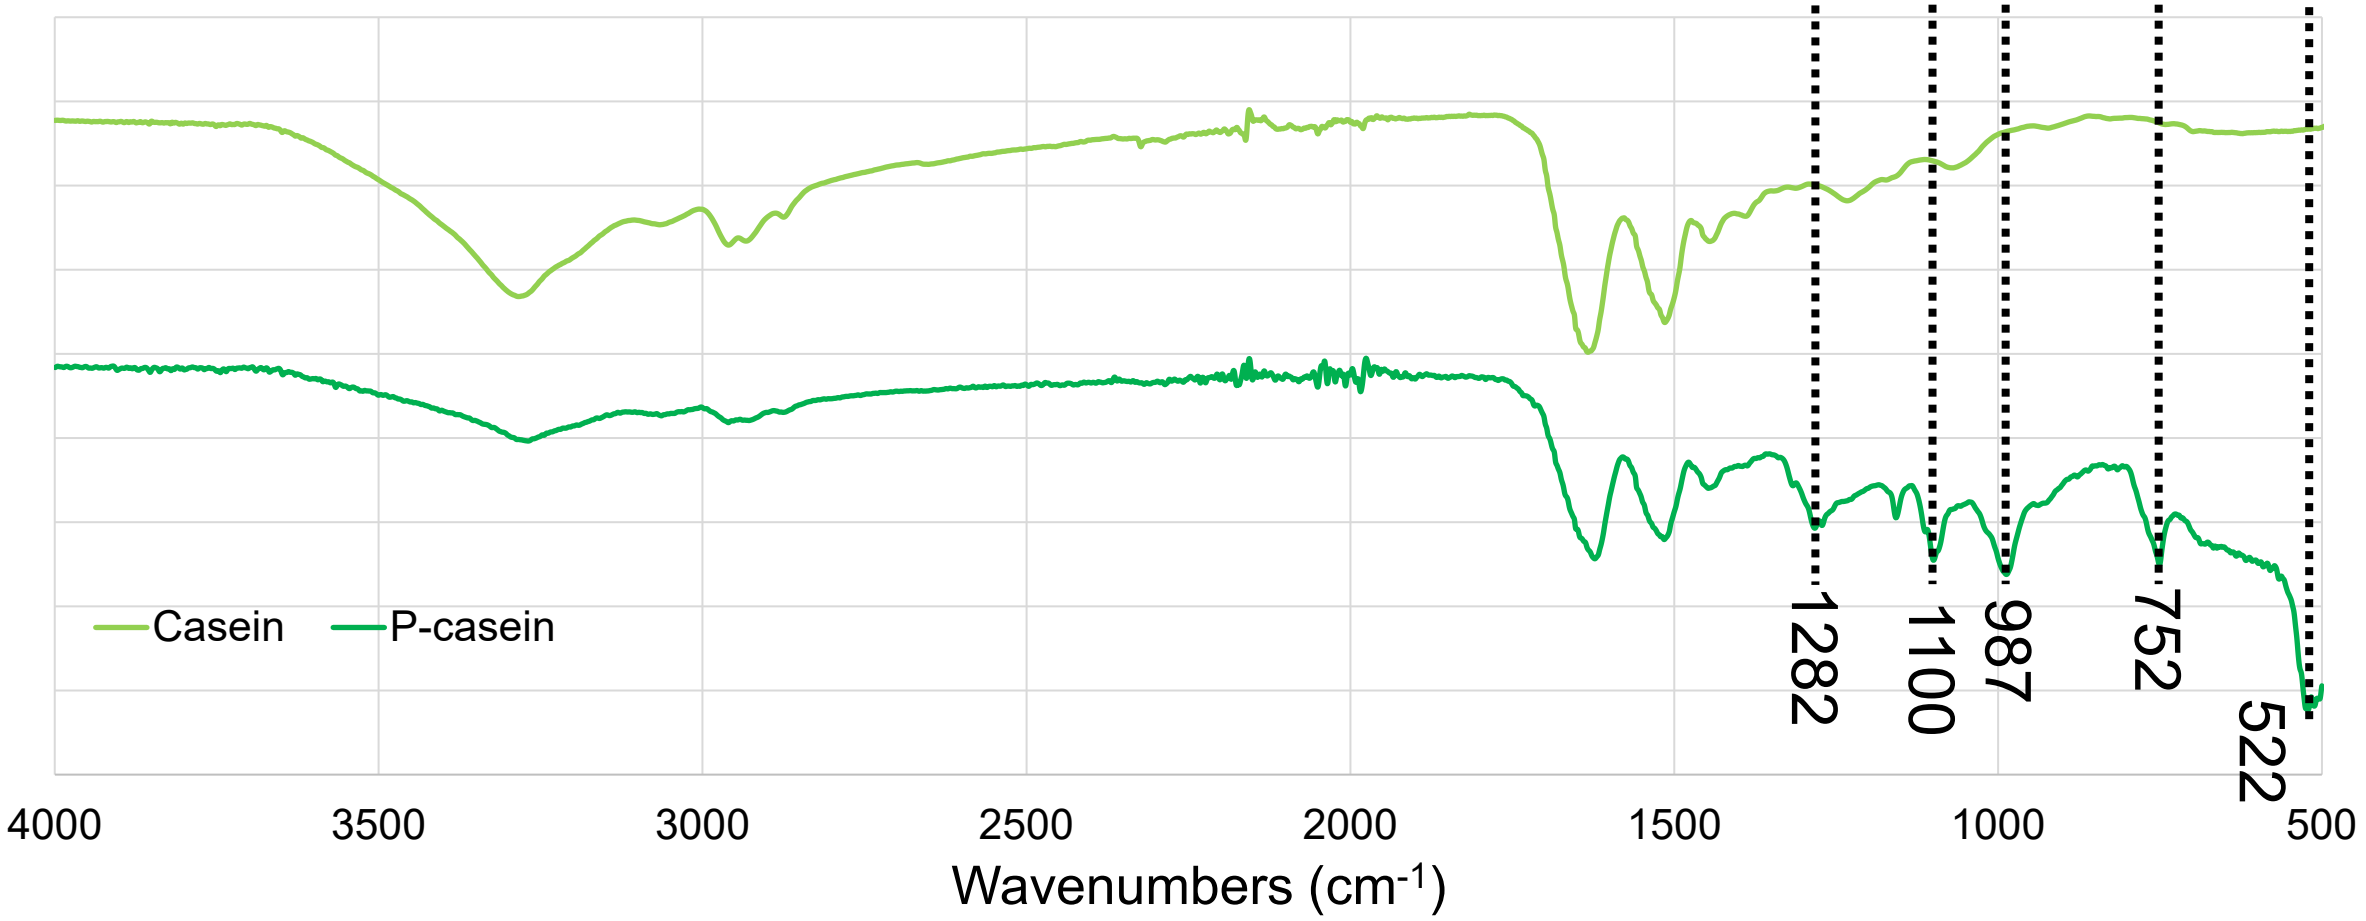
Mechanical Properties

- **Mechanical properties of PAE-based MDF samples using casein particles**



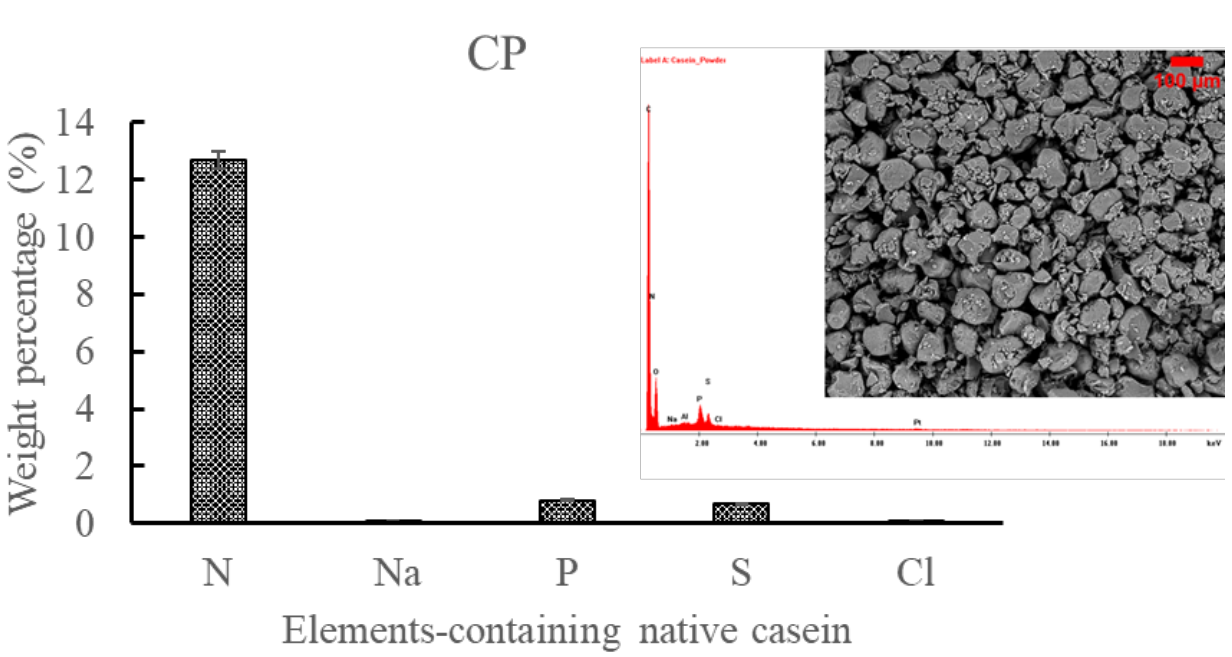
➢ **Flexural strength**

➢ **Internal bond (IB) strength**

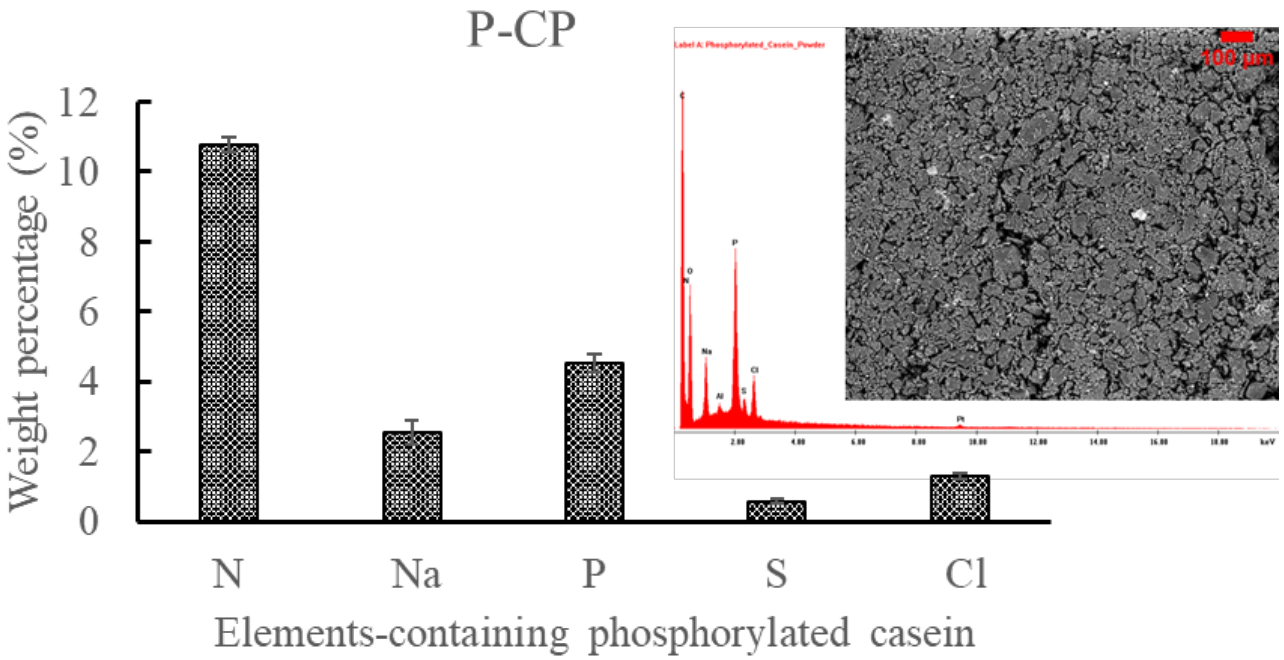


Phosphorylation of Casein

1. Preparing 0.01 M sodium hydroxide (NaOH) solution to make a pH 12 environment. Heating the NaOH solution at 40 ˚C.
2. Casein particles are added when the solution temperature reaches 40 ˚C. Sodium trimetaphosphate (STMP) is slowly added. (when STMP is added, the pH value decreases due to the reaction)
3. Dropping 1 M hydrogen chloride (HCl) or NaOH in the casein-STMP solution to remain the pH value at 12. Total reaction time is 1 hour.
4. Quenching the reaction by the removal of the heat. Decreasing the pH value at 4 by dropwise addition of 1 M HCl.
5. Collecting the treated casein curd by a coffee sieve and washing them with distilled water.

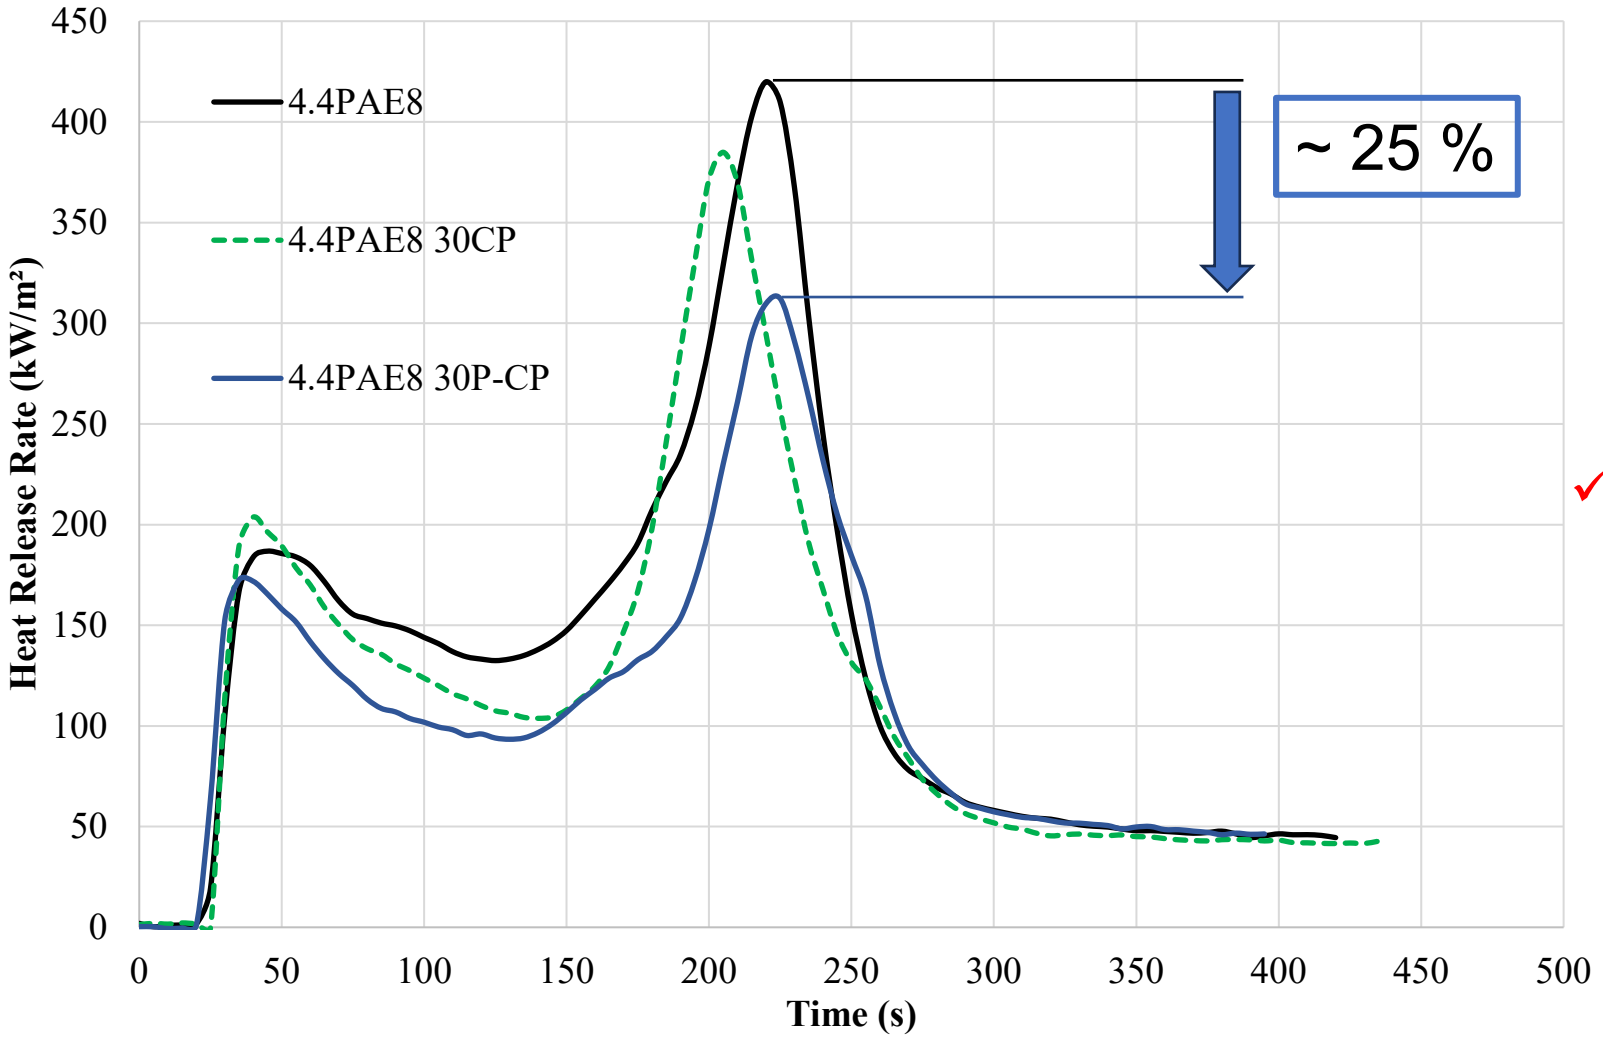


Fourier Transform Infrared Spectroscopy



- 752 cm^{-1} is the most important peak to identify the bonding formation of hydroxide groups (casein) and phosphate groups (STMP) through phosphorylation.
- Other vibration bands; 522, 987, 1100, and 1282 cm^{-1} are attributed to O-P-O, P-OH, P-OH, and P=O stretching, respectively.

Energy dispersive X-ray (EDX)

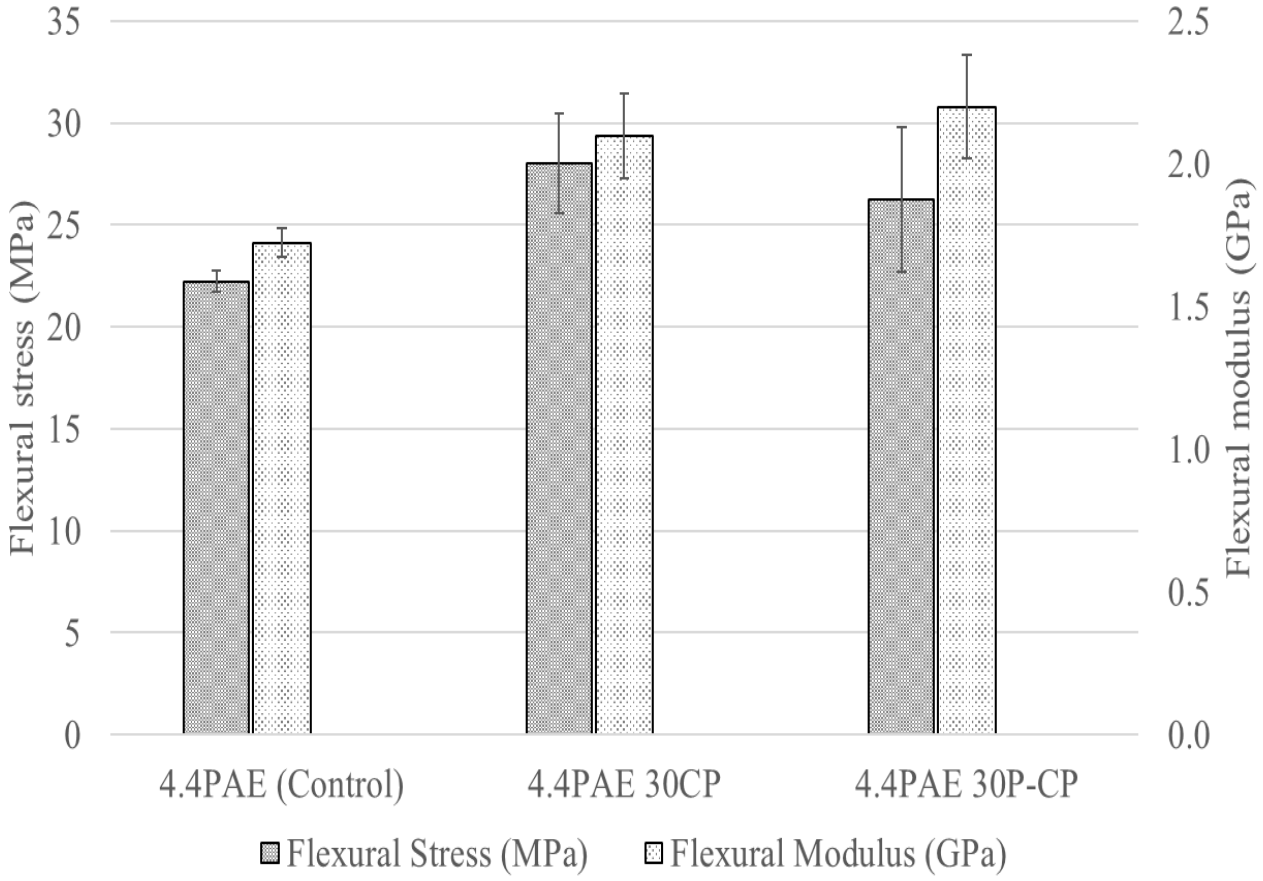


- **Elemental composition of casein and phosphorylated casein**

✓ Sodium (Na) and choline (Cl) contents in the structure of the phosphorylated casein increase by 2.3 % and 1.6 %, respectively.

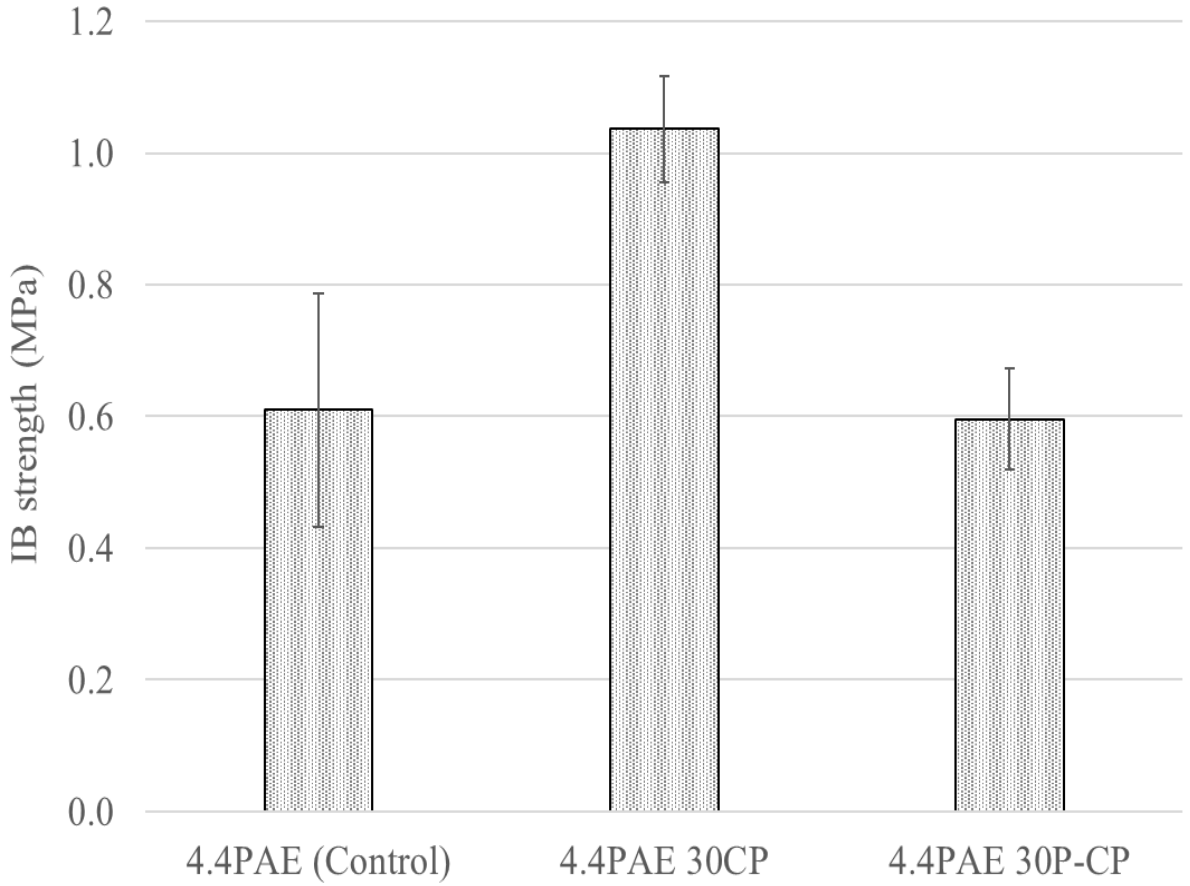
Heat Release Rate

Heat release rate (HRR)



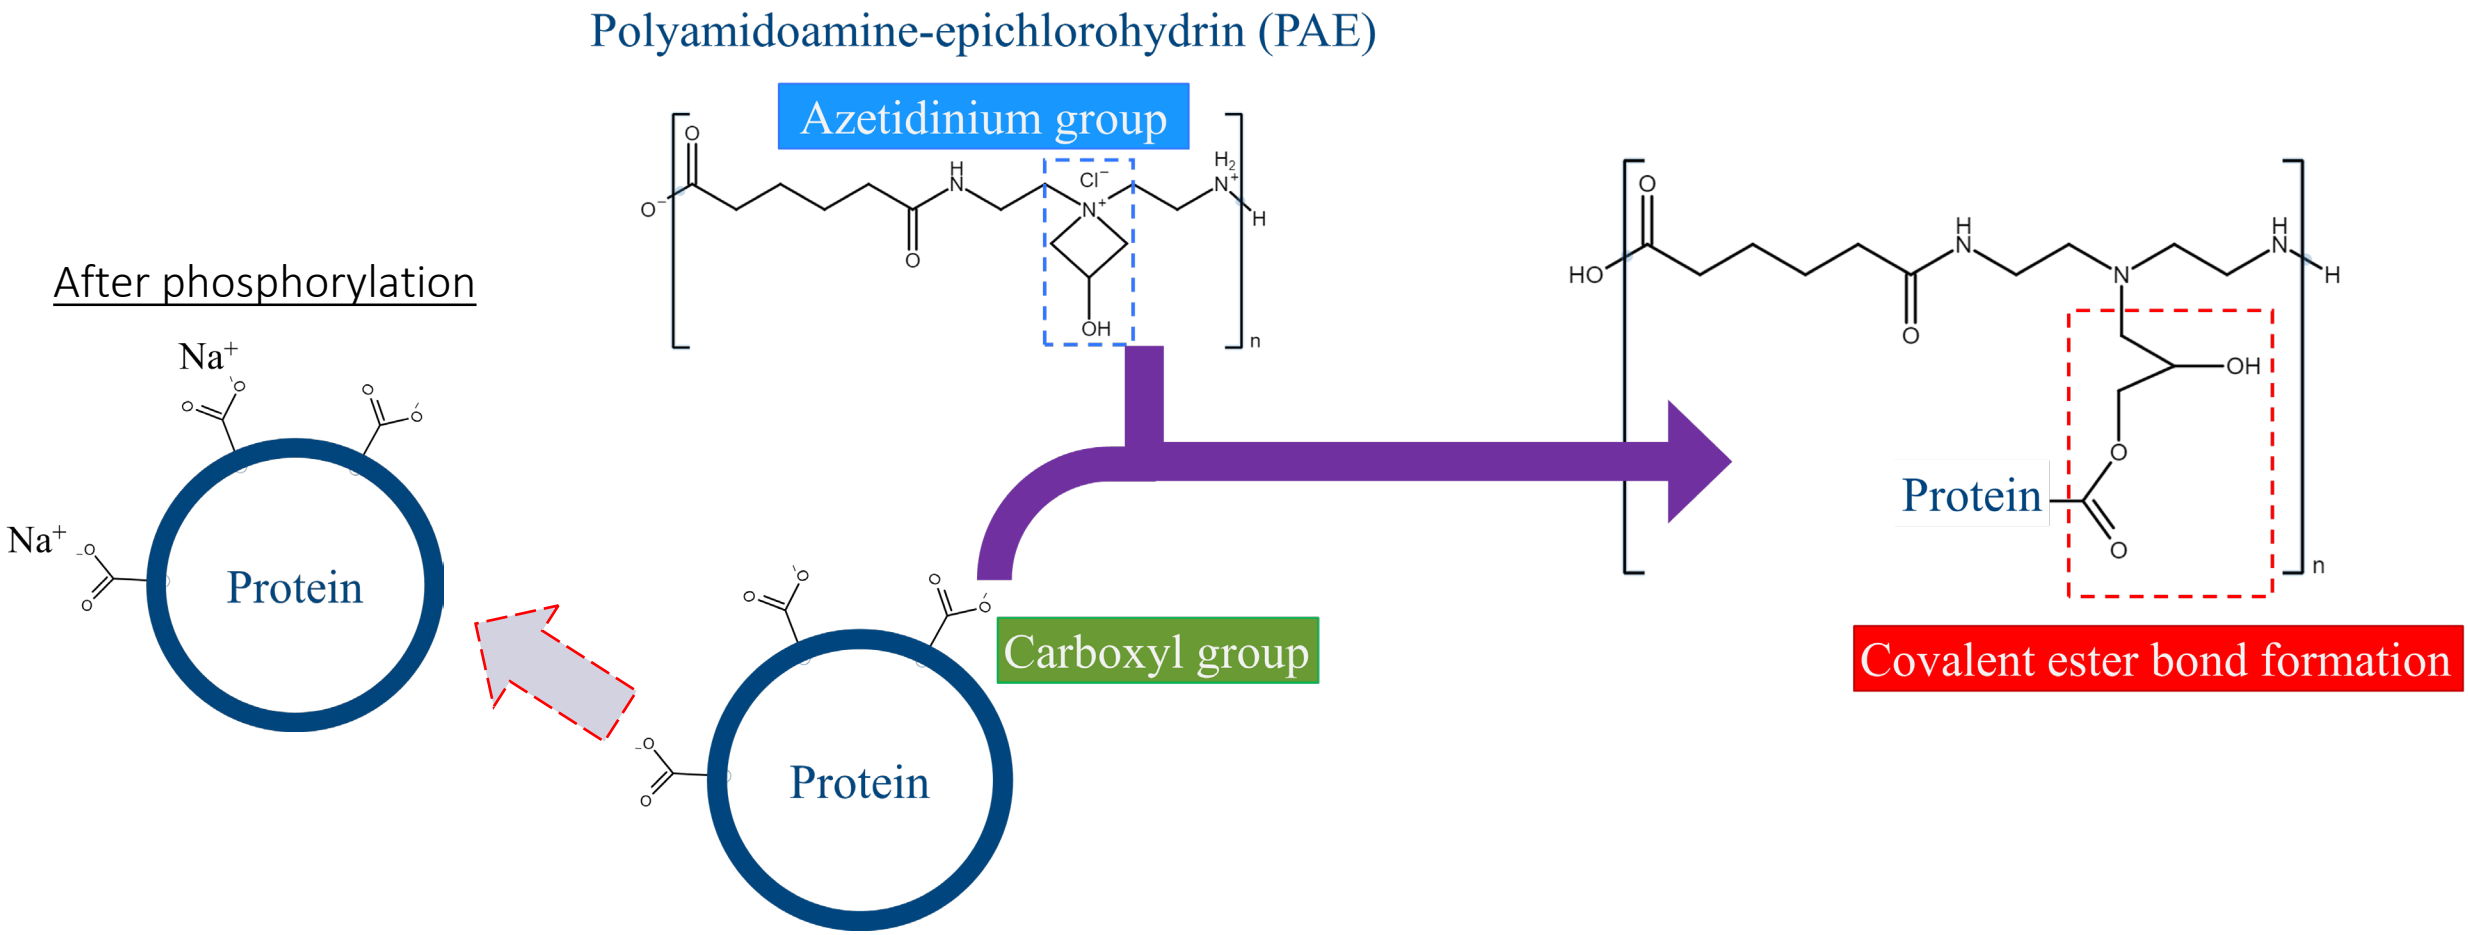
- ✓ The rate of fire growth
- ✓ The size of the fire
- ✓ An effective heat of combustion

✓ **The addition of 30 % phosphorylated casein particles most effectively reduces the peak heat release rate of the MDF sample by ~ 25 %.**



Mechanical Properties

- **Effects of 30 % P-CP addition on mechanical properties of 4.4PAE8 MDF**



➢ **Flexural strength**

➢ **Internal bond (IB) strength**

Hypothetical Reaction Disturbance

- ✓ It is assumed that sodium carboxylate (-COONa) like a sodium salt may not function as a carboxyl group capable of reacting with the azetidinium group of the PAE.

Conclusions

- Casein was successfully phosphorylated to improve its char forming capability.
- MDF panels with density of ~730 kg/m^3 were manufactured using casein powder and PAE resin as a formaldehyde-free binder.
- Phosphorylated casein reduced peak heat release rate (~ 25%) of MDF with more effective char formation in comparison with one of the panel with non-treated casein.
- The addition of phosphorylated casein to the MDF improved both flexural modulus (23 %) and stress (16 %), compared to the panel with non-treated casein.
- Phosphorylation of casein retained internal bond strength of MDF.

DEVELOPMENT AND SYNTHESIS OF NOVEL DOPO-MODIFIED EPOXY RESIN AND ITS GLASS AND SISAL-BASED 3D WOVEN FIBER-REINFORCED COMPOSITE

Keywords: flame retardant resin, 3D woven fiber reinforced composite, Glass fiber, Sisal fiber

ABSTRACT

The growing demand for advanced materials in the construction industry has led to an increased focus on developing flame-retardant and mechanically robust composites. Epoxy resins, known for their excellent adhesive and mechanical properties, have become popular for matrix materials in fiber-reinforced composites. However, conventional epoxy resins are inherently flammable, which limits their applicability in high-temperature or fire-prone environments. This study addresses this limitation by developing and synthesizing a novel flame-retardant epoxy resin with modified 9,10-dihydro-9-oxa-10-phosphaphenanthrene-10-oxide (DOPO). Modified DOPO epoxy resin was synthesized and utilized as a matrix for 3D woven glass and sisal fiber-reinforced composites to enhance their flame-retardant properties. The 3D woven structure of the composite was chosen to improve load-bearing capacity and impact resistance, addressing the limitations of conventional 2D woven or random fiber composites in structural applications. The development of 3D woven glass and sisal fiber reinforced composite was done by VARTM method. The developed resin was characterized by FTIR, ^{1}H NMR, and ^{31}P NMR. The composites were comprehensively characterized to assess their thermal stability and mechanical properties. Flame retardant properties of the composites were determined by limiting oxygen index (LOI), vertical burning tests, and cone calorimetry. Tensile and flexural strength tests are employed to evaluate the changes after modification. The highest LOI value achieved was 29.4. Cone calorimetry analysis demonstrated significant improvement in flame retardancy. The mechanical properties exhibited a decline in both tensile and flexural strength.

1. INTRODUCTION

Fiber-reinforced composites (FRCs) are widely utilized in the construction, automotive, and aerospace sectors owing to their superior mechanical strength, high strength-to-weight ratio, and design flexibility. Epoxy resins, frequently used as matrix components in these composites, provide exceptional mechanical and chemical resistance qualities [1–5]. Nonetheless, their intrinsic flammability considerably restricts their applicability in contexts where fire safety is paramount.

Inorganic (e.g., magnesium hydroxide, boric acid) and organic (e.g., phosphorus- and silicon-based compounds) flame-retardant additives have been integrated into epoxy resins to address this issue [6,7].

Glass fiber-reinforced composites (GFRC) are extensively utilized for their superior strength and rigidity, whilst natural fibers such as sisal provide ecological advantages, economic viability, and moderate mechanical properties [8,9]. Nonetheless, both glass and sisal fiber composites exhibit inadequate flame resistance, especially when integrated with combustible epoxy matrix. Recent advancements in flame-retardant resins and additives have enhanced fire performance; nonetheless, issues persist in attaining uniform dispersion and preserving mechanical integrity [10–14].

The majority of fiber-reinforced composites (FRCs) are constructed from two-dimensional woven, stitched, or braided fabrics, frequently demonstrating constrained interlaminar strength and damage tolerance. Conversely, 3D woven fabric structures provide superior mechanical qualities, particularly in the thickness dimension, through the integration of binder yarns [15,16]. Although the benefits of 3D woven composites are recognized, few research have investigated their incorporation with flame-retardant epoxy matrices.

This study fills the research gap by synthesizing novel DOPO-modified epoxy resin and employing it as a matrix for 3D woven glass and sisal fiber-reinforced composites. The main aim is to assess the flame-retardant and mechanical characteristics of the developed composites. Characterization encompasses Limiting Oxygen Index (LOI), vertical burning assessments (UL-94), cone calorimetry, and tensile and flexural strength evaluations to determine the efficacy of the DOPO alteration and the composite structure for high-performance, fire-resistant applications.

2. EXPERIMENTAL

2.1 Materials

9,10-Dihydro-9-oxa-10-phosphaphenanthrene-10-oxide (DOPO), terephthaldicarboxaldehyde (TDCA) was purchased by TCI India Pvt Ltd. E-Glass roving of 900 Tex was procured from Owens Corning (India) Private Limited. Sisal yarn of 1000 Tex was purchased from Dinesh Industries, Jaipur, India. Diglycidyl ether of bisphenol A(DGEBA) was obtained from Atul Industries Ltd., India.

2.2 Synthesis of resin

0.1 mole (13.41 gram) of terephthaldicarboxaldehyde (benzene-1,4-dicarbaldehyde) and 0.2 mole of DOPO (43.24 gram) were added in dry toluene of 250 mL in a three-necked flask under a nitrogen environment. The reaction mixture was refluxed for 5 h at 100°C. The reaction mixture was cooled to room temperature. It was filtered and washed with toluene. The obtained solid was dried at 70°C in an oven. The synthesized compound (modified DOPO) was confirmed by FTIR and NMR spectra.

FTIR (cm^{-1}): OH stretching (3240 cm^{-1}), C=H stretching (2860 cm^{-1}), C-H stretching (2820 cm^{-1}), C=C stretching (1590 cm^{-1}), C-H scissoring (1430 cm^{-1}), P=O stretching (1120 cm^{-1}), C-H rocking vibration (713 cm^{-1}).

^{1}H NMR (500 MHz, DMSO-d6, ppm): 5.10–5.45 (m, 2H), 7.62 (m, 1H), 7.78–7.90 (m,2H), 8.04 (m, 1H), 8.10–8.33 (m, 4H).

^{13}C NMR (500 MHz, DMSO-d6, ppm): 120.02, 124.00, 124.76, 124.94, 125.89, 127.02, 127.46, 131.17, 134.17, 136.68, 154.40

^{31}P NMR (500 MHz, DMSO-d6, ppm): 31.19.

DGEBA and modified DOPO were mixed in a molar ratio of 1:1 and heated up to 135°C. The reaction was carried out until a homogeneous solution was obtained for 45-55 min. Fig 1 depicts the synthesis scheme of the product. The reaction between DGEBA and modified DOPO is illustrated in Fig 1. The trap air was removed from the mixture under vacuum for 5 min. The resin was directly used for making composites.

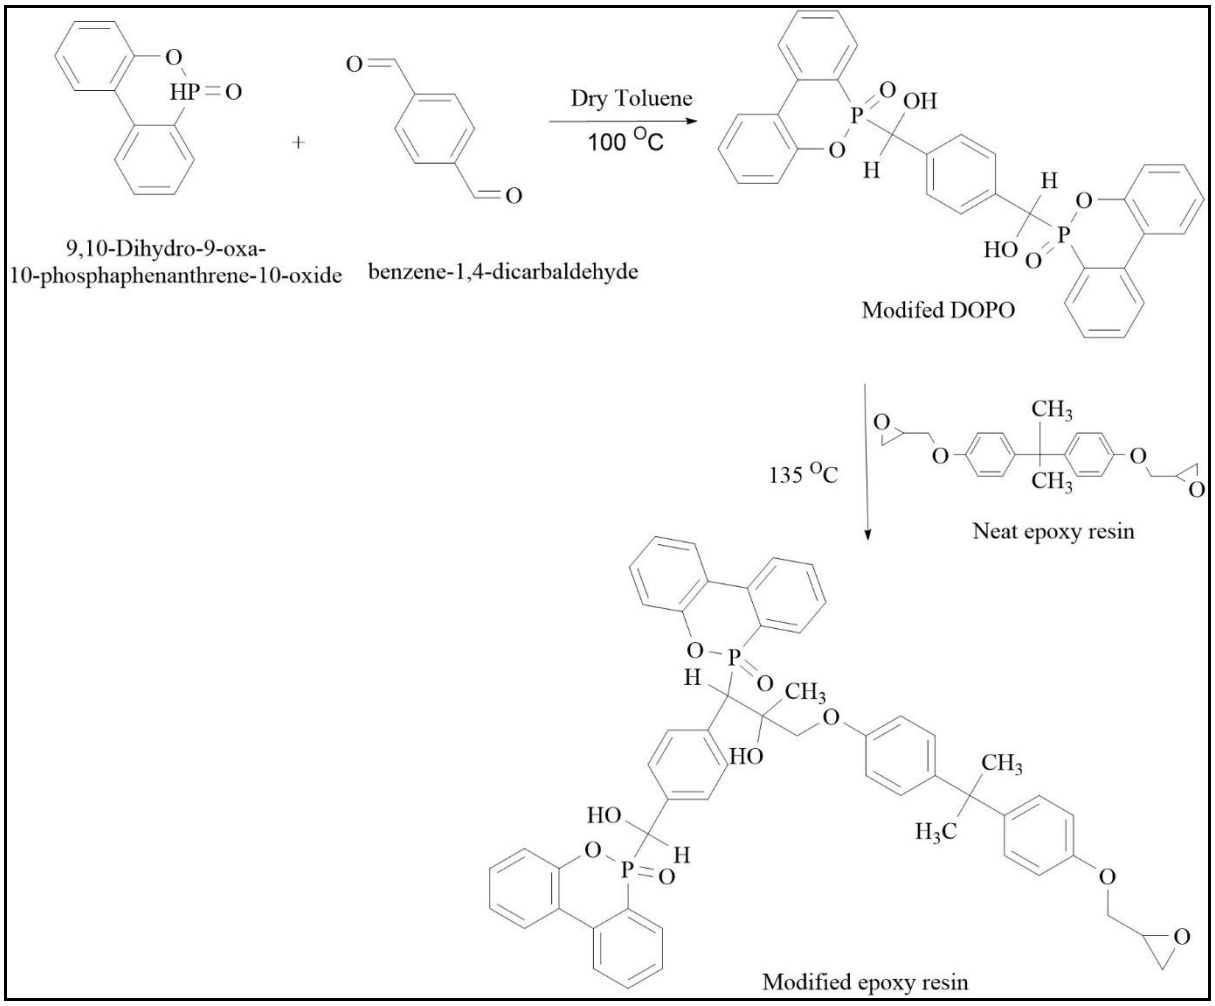

Figure 1: Synthesis of modified resin

2.3 Characterizations

FTIR spectra were obtained at wavenumber ranges of 400–4000 cm^{-1} using Nicolet iS50 FTIR spectrophotometer. All NMR spectra were performed on a Bruker 500 NMR spectrometer (500 MHz) using DMSO-d6 as solvent.

2.4 Development of fiber-reinforced modified epoxy resin-based composites

A four-layer 3D orthogonal fabric of glass and sisal fiber was developed in the customized rapier loom. Vacuum-assisted resin infusion (VARI) method was used to prepare composite materials [17]. The curing process was performed at ambient temperature for 8 h.

2.5 Measurement of flame-retardant properties of composites

The flammability of all the samples was determined using the limited oxygen index (LOI), according to ASTM D2863. Vertical flammability test was conducted according to the UL-94 standard. The cone calorimetry test was done according to the ASTM E1354.

2.6 Evaluation of mechanical properties of composites

According to ASTM D3039 and ASTM D7264, tensile strength and flexural rigidity were obtained.

3. RESULTS AND DISCUSSION

3.1 Characterization of intermediate and resins

Fig 2 indicates the FTIR spectra of modified DOPO. The FTIR spectra showed the bands of OH stretching (3240 cm^{-1}), C=H stretching (2860 cm^{-1}), C-H stretching (2820 cm^{-1}), C=C stretching (1590 cm^{-1}), C-H scissoring (1430 cm^{-1}), P=O stretching (1120 cm^{-1}), C-H rocking vibration (713 cm^{-1}).

This suggested the formation of modified DOPO.

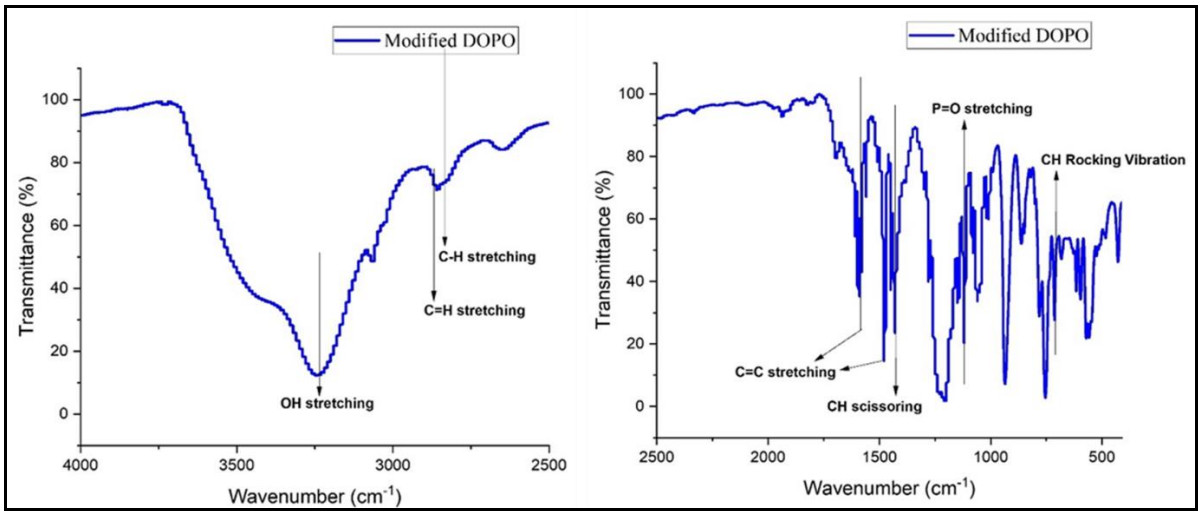

Figure 2: FTIR spectra of modified DOPO

^{1}H NMR spectra of modified DOPO are recorded in Fig 3. Types of A and B hydrogen showed multiplet in the 5.10-5.45 ppm region. Aromatic hydrogen showed various peaks: 7.62 (multiplet for one hydrogen), 7.78–7.90 (multiplet for two hydrogen), 8.04 (multiplet for one hydrogen), and 8.10–8.33 (multiplet for four hydrogen). Thus, it confirms the chemical structure.

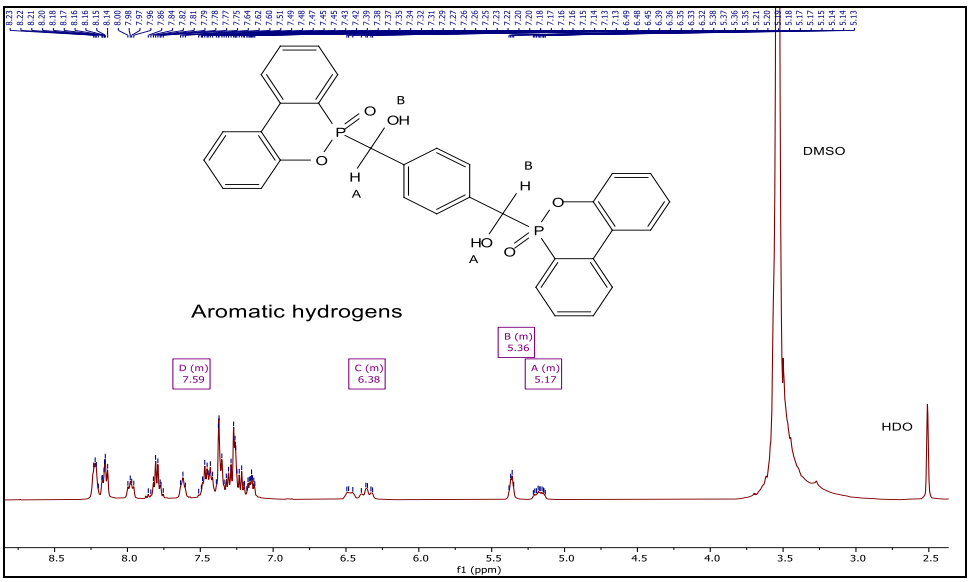

Figure 3: ^{1}H NMR spectra of modified DOPO

^{13}C NMR spectra of modified DOPO are recorded in Fig 4. Various carbon atom peaks were obtained at 120.02, 124.00, 124.76, 124.94, 125.89, 127.02, 127.46, 131.17, 134.17, 136.68, 154.40. As confirmed by ^{13}C NMR, the presence of various carbons suggested the chemical structure of modified DOPO.

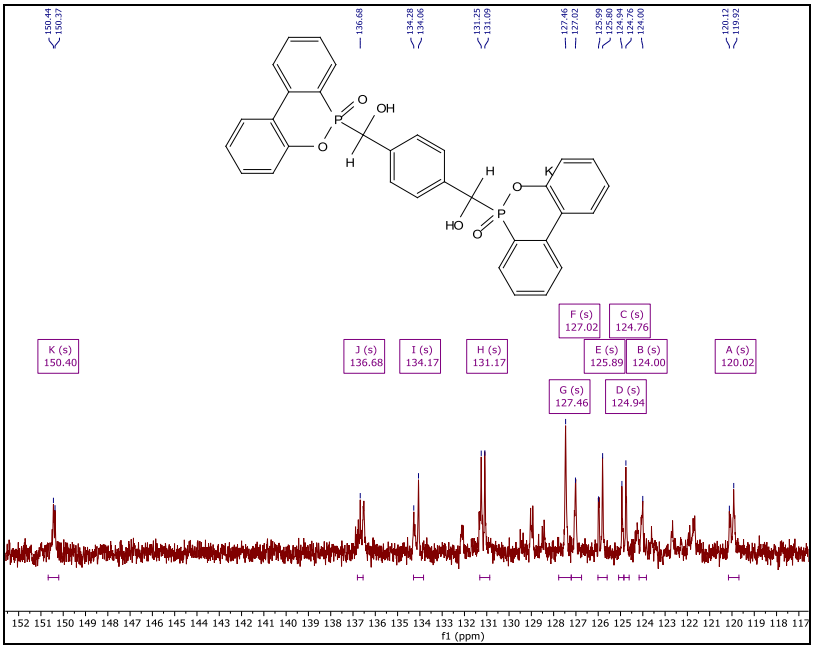

Figure 4: ^{13}C NMR spectra of modified DOPO

^{31}P NMR spectra of modified DOPO are depicted in Fig 5. One peak at 31.19 ppm was obtained due to one type of phosphorous atom attached to direct oxygen. Thus, FTIR and NMR spectra confirm the successful synthesis of modified DOPO.

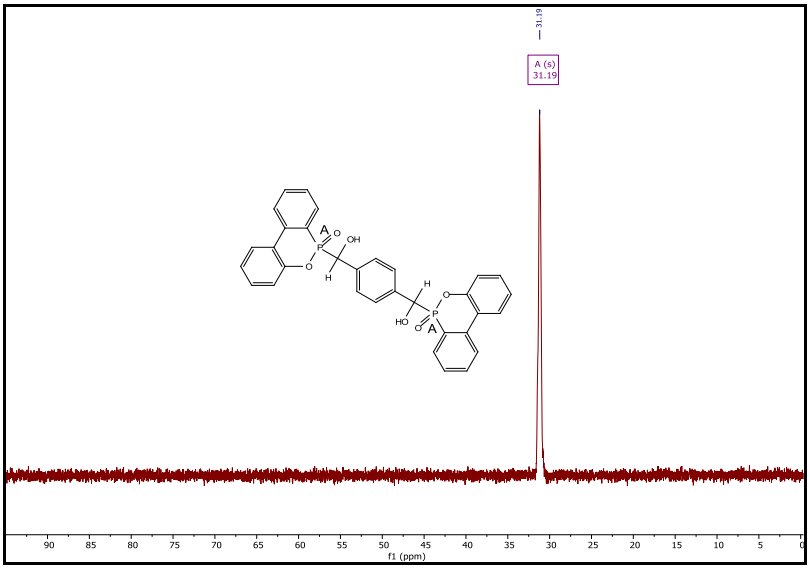

Figure 5: ^{13}C NMR spectra of modified DOPO

3.2 Flame retardant properties of composites

LOI (%) values of epoxy resin and modified epoxy resin-based glass and sisal fiber-reinforced composites are shown in Fig **6**. EP stands for neat epoxy resin; MEP indicates modified epoxy resin. The LOI (%) value was observed in the neat epoxy resin-based glass (EP-GC) and sisal fiber (EP-SC) composite, which was 22.5 and 22.8, respectively. After the modification in epoxy resin, the LOI (%) value of glass and sisal fiber composite became 29.4 and 28.6. The results show a significant improvement in the limiting oxygen index. This proves the efficiency of modified resin to protect composites from flames.

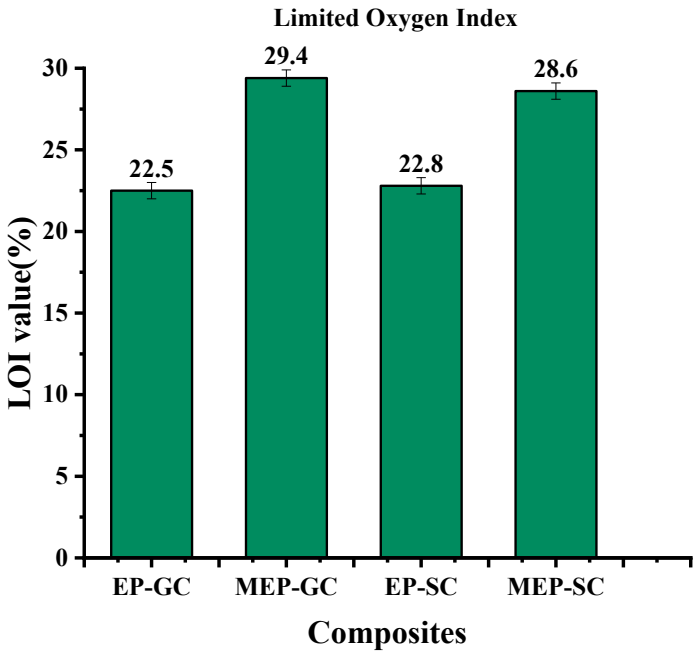

Figure 6: LOI value of neat and modified epoxy resin composite

The vertical burning test of composites is shown in Table 1. Results indicate that after the modification, the rating of composites has improved. The results demonstrate a significant improvement in the rating of vertical flammability, confirming the modified resin's effectiveness in enhancing the composites' flame resistance.

Table 1: UL 94 rating of composites

COMPOSITE SAMPLES	UL-94 TEST RATING	SIGNIFICANCE
EP-GC	NR	No rating
MEP-GC	V2	Burning stop in 30 seconds
EP-SC	NR	No rating
MEP-SC	V2	Burning stop in 30 seconds

3.3 Cone Calorimetry Test

Neat epoxy glass exhibits the highest peak heat release rate (pHRR) of 390.2 kW/m^2. After the modification, the pHRR value of the epoxy glass composite was 275.69 kW/m^2. The same patterns are

shown in the case of epoxy sisal and modified epoxy sisal composites (Fig 8), which exhibit 897.43 and 767.57 kW/m^{2,} respectively. Using the modified epoxy resin, a 29.3% reduction in the peak heat release rate was achieved with glass fiber, while a 14.47% reduction was observed with sisal fiber. These variations are attributed to the interaction between the resin and fibers and the distribution of the resin within the fiber matrix. Moreover, the modified resin exhibits an early release phenomenon (at a shorter time), which is attributed to the decomposition of flame-retardant moieties such as P=O, thereby protecting the composite from further burning.

Glass fiber is inherently flame-retardant; however, incorporating a neat flammable resin renders the composite flammable. The synthesized resin significantly enhances the flame-retardant properties of glass fiber-based composites, effectively making them inherently flame-retardant.

On the other hand, sisal is highly flammable. In this case, the developed resin protects the fiber and the entire composite, reducing its flammability. In conclusion, modifying the resin with phosphorus-containing groups imparts flame-retardant protection to the composites.

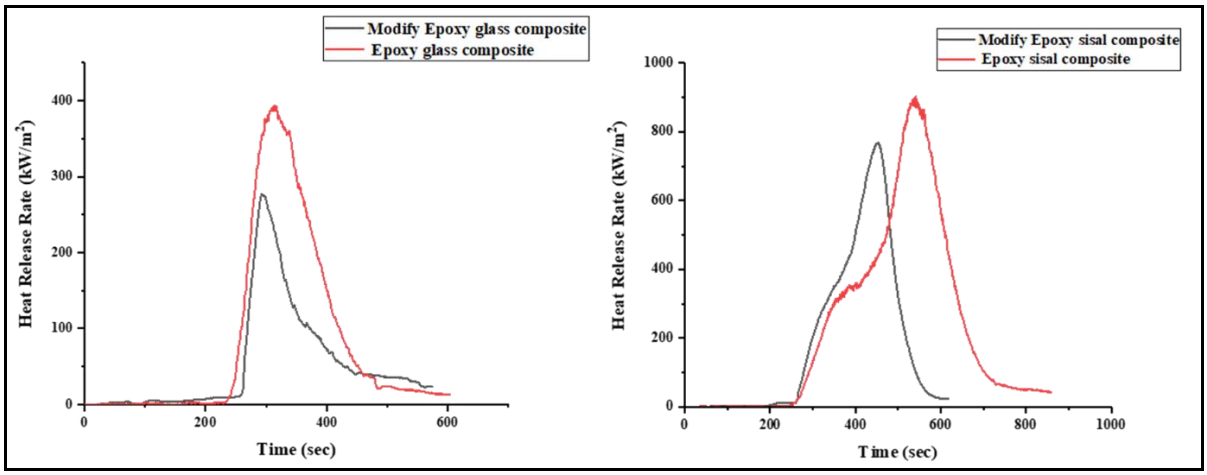

Figure 7: HRR value of neat and modified epoxy resin composite

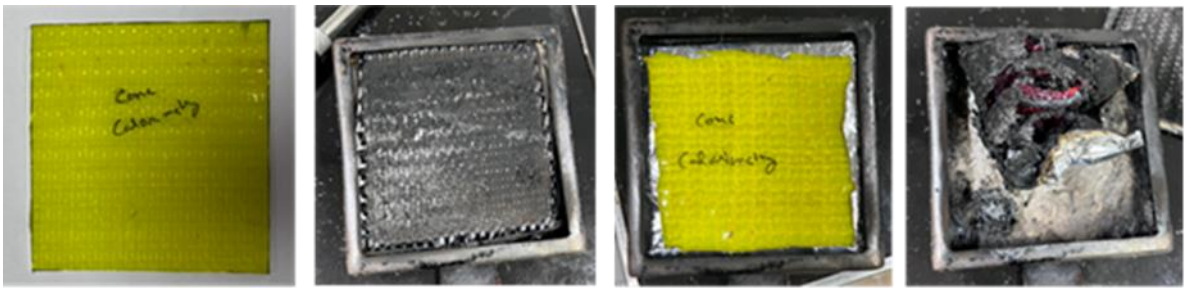

Figure 8: (Left) modified epoxy glass composite and (Right) modified epoxy sisal glass composite

3.6 Mechanical Properties of Composites

The tensile properties and flexural rigidity of neat and modified epoxy glass and sisal fiber-reinforced composites are presented in Figs 10 and 11. The curves in these figures show that the tensile and flexural properties of the modified composites are inferior to those of neat epoxy after incorporating modified DOPO into the epoxy resins. This decline in mechanical performance aligns with reported studies, which suggested that a high concentration of phosphorus-containing flame retardants often has a detrimental impact on the mechanical characteristics of the polymer matrix [18,19].

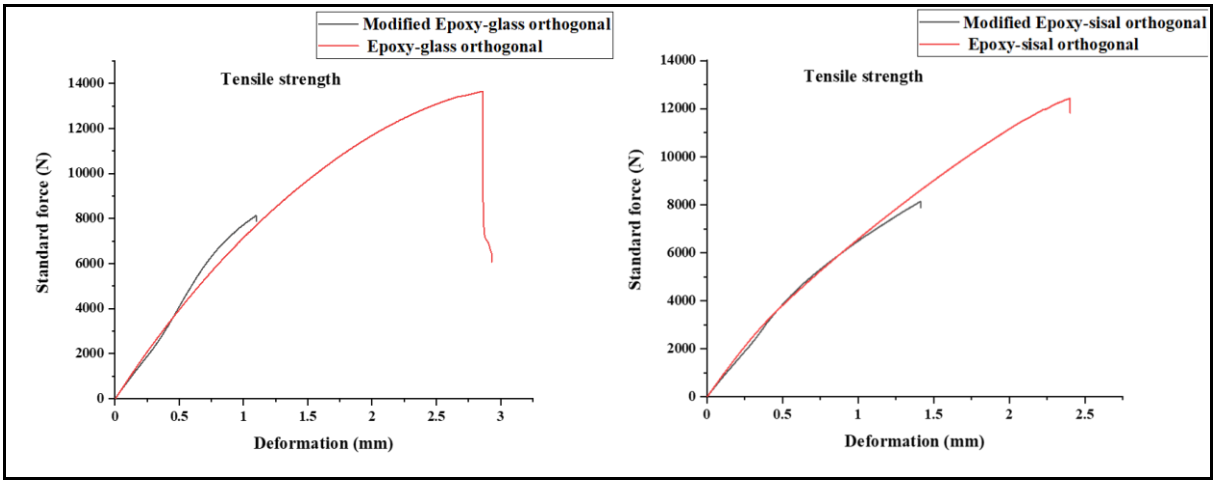

Figure 9: Tensile strength of composites

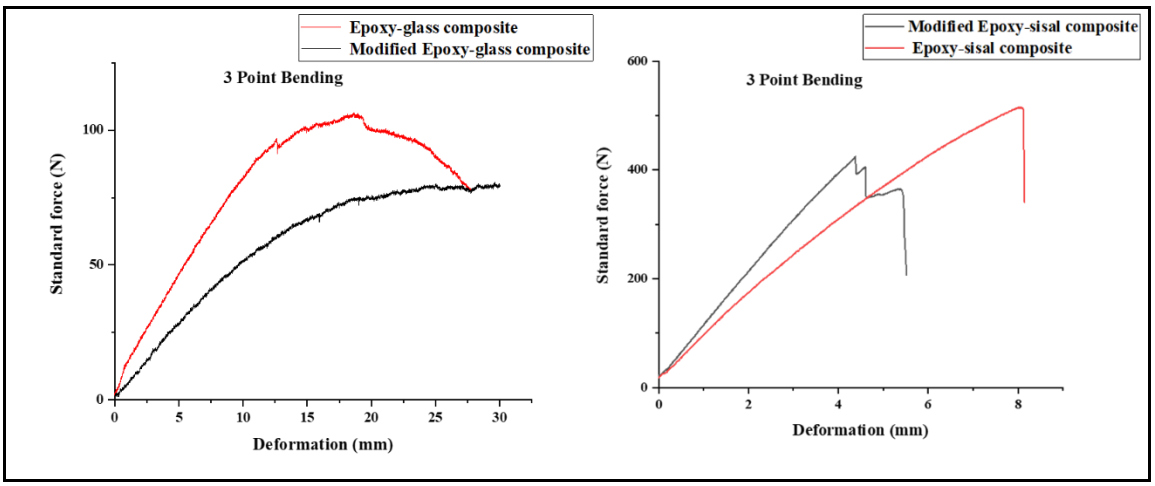

Figure 10: Flexural rigidity of composites

4. CONCLUSION

A novel DOPO-modified epoxy resin was successfully synthesized, and 1H NMR, 13C NMR, and 31P NMR confirmed its chemical structure. The high phosphorus content of the modified resin imparted excellent flame retardancy to epoxy resins. The LOI value of composites was increased from 21 to 29 and UL-94 test rating was improved from no rating to V-2 rating. The significant decrement of 30% s in case of glass and almost 15% in sisal shown in peak heat release rate. Using a 3D woven fiber architecture further contributed to improved structural performance, particularly in load-bearing and impact resistance. However, the integration of the flame-retardant additive resulted in a reduction in mechanical properties, including tensile and flexural strength. Overall, the study demonstrates a promising approach to enhancing fire safety in fiber-reinforced composites for construction and structural applications, highlighting the need to balance flame retardancy with mechanical performance. This work provides a novel route for developing efficient flame-retardant composites for high-performance materials for construction, automotive, and aerospace applications.

ABSTRACT

Epoxy-based carbon fibre reinforced composites (CFRPs) are widely used in aerospace, transportation, and construction due to their high strength-to-weight ratio. However, epoxy resins are flammable and can ignite and burn when exposed to fire, producing highly toxic smoke gases. The CFRPs' poor fire resistance is primarily due to the epoxy resin's inherent flammability. One common method to address this issue is to incorporate flame-retardant fillers into the matrix. However, existing flame-retardant particles typically range from tens to hundreds of microns, significantly decreasing the strength and fracture toughness of the composites.

To address this challenge, in this study, a novel strategy is proposed to functionalize ammonium polyphosphate (APP) with NH_3^+ groups from an amine-based hardener, yielding hardener-functionalized APP nanoparticles (HF-APP). These nanoparticles were further downsized from 14μm to 0.2μm by sonication and uniformly dispersed into the epoxy matrix of CFRPs. At a 30wt% loading, the modified composites exhibited a 50% reduction in peak heat release rate and an increase in the limiting oxygen index to 49. Additionally, substantial improvements were observed in flexural strength, short beam shear strength, and interlaminar fracture energy. Finite element analysis further revealed that HF-APP nanoparticles undergo filament-like separation at high stress levels, effectively mitigating interfacial stress concentration and preserving structural integrity. This multifunctional approach offers the significant potential for developing flame-retardant CFRPs capable of withstanding extreme environments while maintaining high mechanical and fracture properties, a feat previously unattainable with conventional methods.

1 INTRODUCTION

Epoxy resins and their composites are limited in their use in demanding fire protection environments due to the flammability of epoxy resins [1], their limiting oxygen index (LOI) is approximately 20%, rendering these materials extremely flammable even after the ignition source is removed [2]. This poses a serious threat to fire safety, especially in enclosed or high-risk environments such as rail tunnels and aircraft cabins. When exposed to fire, epoxy-based composites can undergo rapid thermal degradation, produce toxic smoke, and lose structural integrity, increasing the risk of structural failure, impeding evacuation and suppression measures. To mitigate these hazards, international flame-retardant standards have been established for materials used in railway vehicles and other public safety-critical areas, with emphasis on indicators such as ignition resistance, flame propagation, smoke release, and toxic gas emissions. However, meeting these standards while maintaining the high mechanical strength essential for structural performance remains a major engineering challenge.

To enhance the fire resistance of CFRPs, flame-retardant additives such as aluminium hydroxide, magnesium hydroxide, and APP are commonly incorporated into the matrix [3]. Organic additives,

including halogenated compounds and phosphorus-based molecules, are also widely used. While these approaches are effective in reducing flammability, high loadings (over 30wt%) are typically required hydroxide [4-6] which damage mechanical properties such as tensile and flexural strength. Moreover, the ununiform dispersion and weak interfacial bonding of large-sized additives (10 to 100 of microns) with the epoxy matrix can lead to stress concentrations and reduce fracture toughness [7]. Reactive strategies involving phosphorus, silicon, or halogen containing curing agents have been proposed to chemically integrate flame-retardant elements into the polymer network without significantly altering the resin's thermomechanical properties [6]. However, many of these approaches change the curing kinetics or final network structure of the epoxy, resulting in reduced stability or unpredictable performance.

In this study, we propose an innovative method to enhance the flame retardancy of epoxy and CFRP composites while maintaining or even improving their mechanical properties. APP particles were chemically functionalized via cationic ion exchange with NH_3^+ groups from an amine-based curing agent, yielding HF-APP particles [8]. This functionalization enabled the particles to participate in the curing reaction with eppxy, improving compatibility and interfacial adhesion with the epoxy matrix. The particles were further downsized via probe ultrasonication and filtration, resulting in submicron nanoparticles denoted as SHF-APP with improved dispersibility. Composites fabricated using these modified particles exhibited significantly enhanced flame-retardant performance, including a 50% reduction in peak heat release rate and a LOI value up to 49, while maintaining over 90% of the tensile strength of neat epoxy at 20wt% HF-APP loading. Mechanical tests further demonstrated improved flexural strength, short beam shear strength, and interlaminar fracture energy. Finite element analysis revealed that HF-APP particles can deform or split under stress, reducing their stress concentration effects and minimizing mechanical compromise. These results highlight the dual functionality of HF-APP in simultaneously curing and reinforcing the epoxy matrix, offering a potential solution for high-performance, fire-safe CFRP structures in transportation and construction industries.

2 GENERAL SPECIFICATIONS

2.1 Material and methods

The materials used in this study include bisphenol A-type epoxy resin (DGEBA), APP, and an amine-based hardener. APP was surface functionalized via mixing with the curing agent, enhancing its compatibility with the epoxy matrix. The functionalized APP was further downsized to nanoparticles and then incorporated into the epoxy resin at various loadings (10–30wt%) to prepare the modified systems. CFRP laminates were further fabricated using a hand lay-up process followed by vacuum-assisted resin transfer molding (VARTM). The flame-retardant performance of the composites was characterized by LOI, UL-94 vertical burning tests, and cone calorimetry, while mechanical properties were evaluated through tensile, flexural, and interlaminar shear strength tests. Scanning electron microscopy (SEM) was employed to analyze the morphology and dispersion of the modified particles within the matrix.

2.2 Results and discussion

2.2.1 Flame retardant tests results

The flame-retardant performance of epoxy matrix was significantly enhanced by incorporating HF-APP. In cone calorimetry, neat epoxy exhibited a peak heat release rate (PHRR) of 1841 kW/m² and a total heat release (THR) of 62.4 MJ/m². With 30wt% HF-APP, the PHRR drastically dropped to 37 kW/m², and the composite self-extinguished during testing, with THR approaching zero. In contrast, unmodified APP only reduced the PHRR to 856 kW/m² at the same loading. The total smoke release (TSR) was also significantly reduced by HF-APP, achieving a 95% decrease at 30wt% loading, compared to a 50% reduction by APP. The LOI increased from 20 (neat epoxy) to 44 for HF-APP/epoxy composites at 30wt%, highlighting their resistance to ignition.

For CFRP systems, the PHRR was reduced from 408 kW/m² (unmodified epoxy matrix) to 103 kW/m² with 30wt% HF-APP. LOI values rose from 36 to 49. Notably, only 10wt% HF-APP was sufficient to achieve the highest V-0 rating in UL-94 vertical burning tests, whereas 30wt% APP or 20wt% SHF-APP was required for the same level. The flame-retardant performance of SHF-APP composites was found to be intermediate between that of APP and HF-APP. While the further reduction in particle size led to a slight increase in PHRR, it also resulted in a decrease in THR, indicating a balance effect in performance matrix. Overall, SHF-APP exhibited flame-retardant behavior comparable to HF-APP, suggesting that the nanoscale particle size maintains thermal protection while offering potential advantages in mechanical reinforcement. These results highlight SHF-APP as an effective alternative that balances flame retardancy with enhanced structural performance.

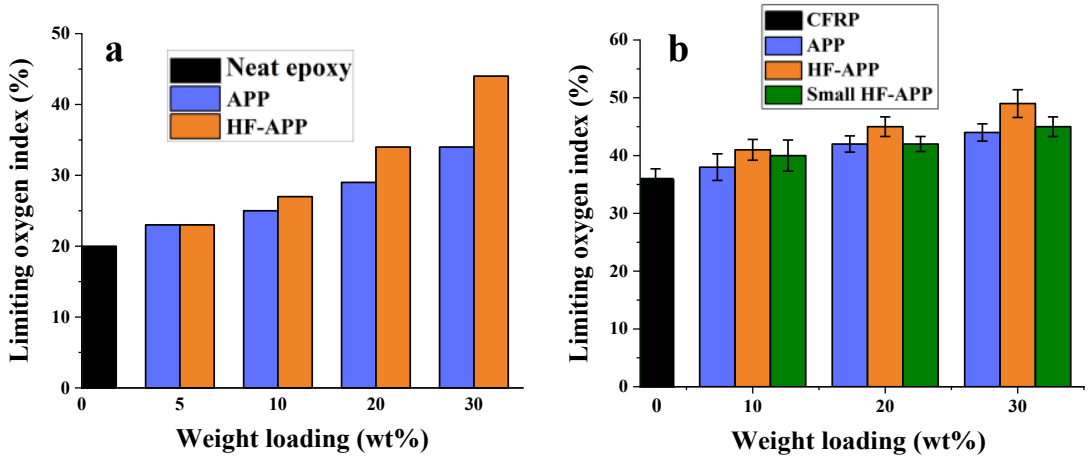

Fig. 1 LOI values of CFRPs with different weight loadings of APP, HF-APP, and SHF-APP in the epoxy matrix.

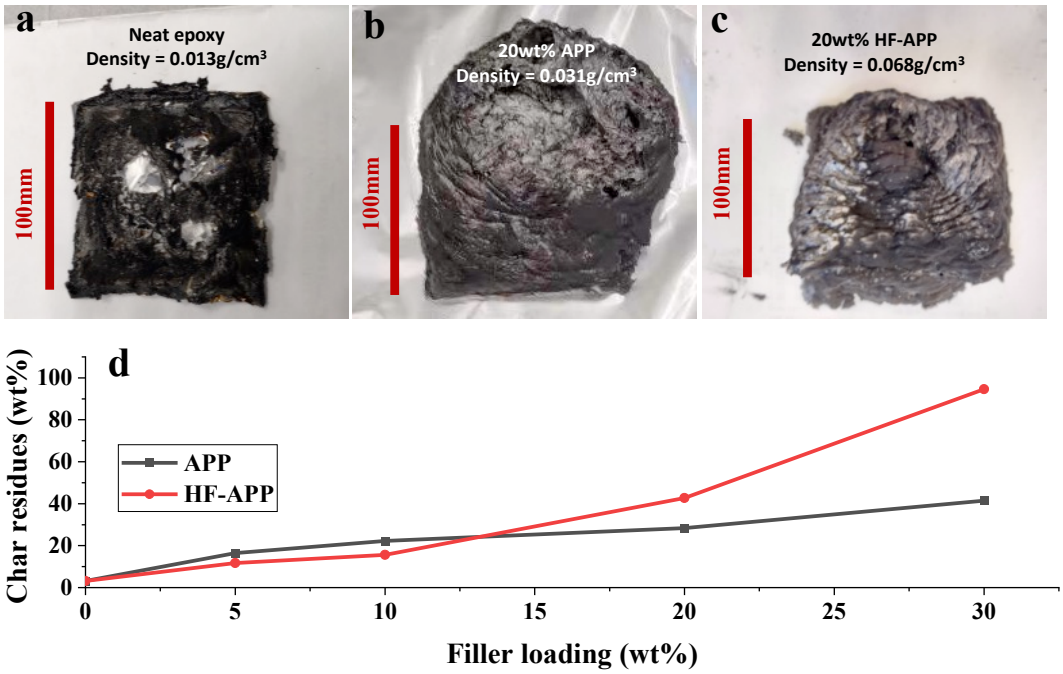

Fig. 2 Char residues: neat epoxy (a), 20 wt% APP/epoxy (b), 20 wt% HF-APP/epoxy (c) and weight percentage of residues (d) from cone calorimeter tests.

2.2.2 Mechanical tests results

The mechanical performance of CFRPs incorporating APP, HF-APP, and SHF-APP were systematically evaluated through tensile, short beam shear, and interlaminar fracture tests. The short beam shear strength was largely preserved even at high additive concentrations. Both APP and HF-APP modified composites maintained over 90% of the strength of the unmodified laminate at 30wt%. Notably, SHF-APP led to a 30% increase in short beam shear strength, attributed to more uniform matrix distribution, reduced interlaminar cracking, and improved fibre alignment. Interlaminar fracture energy (G_{IC}) was also investigated, showing that while APP and HF-APP caused moderate reductions at higher loadings, SHF-APP at 30wt% retained nearly the full fracture toughness of the baseline CFRP. These results indicate that HF-APP improves strength retention in epoxy matrices, and SHF-APP enhances interlaminar properties in CFRPs, offering a potential method to flame-retardant composites with minimal reduction in mechanical performance.

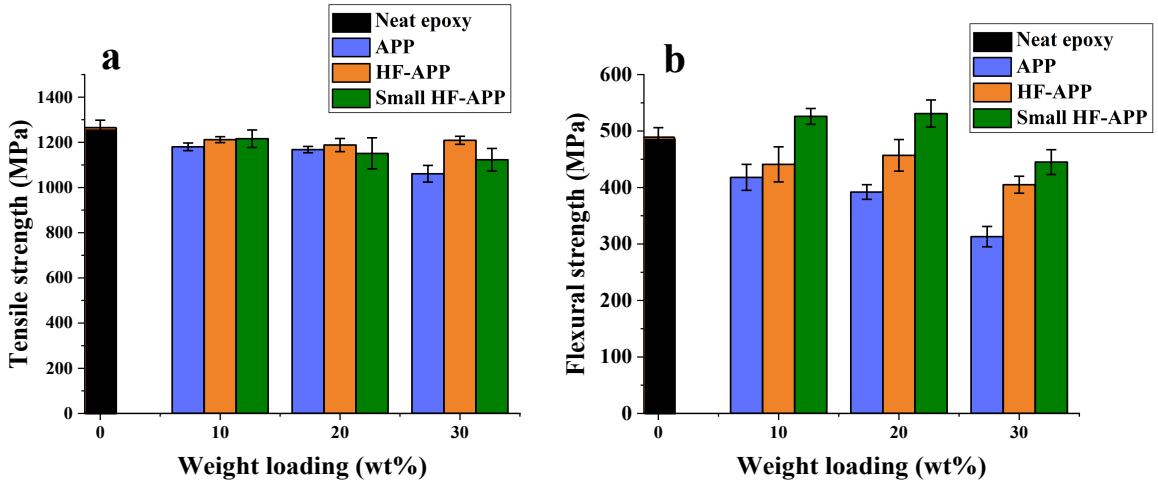

Fig. 3 Strengths of CFRPs with different weight loadings of APP, HF-APP, and SHF-APP particles: tensile strength (a) and flexural strength (b).

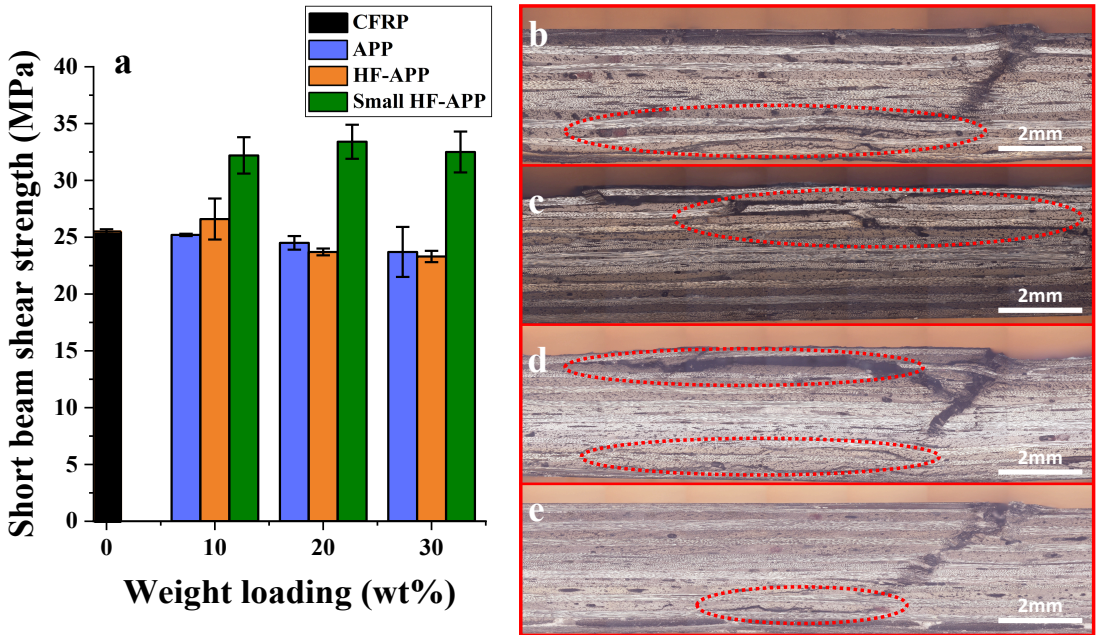

Fig. 4 Short beam shear strength (a) of CFRP with different weight concentrations of APP, HF-APP, and SHF-APP. Microscopic optical images of samples' cross sections of CFRP (b) and CFRP with 30wt% APP (c), HF-APP (d), and SHF-APP (d) after short beam shear test.

2.2.3 Comparison of the key results

A comparative analysis of mechanical strength retention and flame-retardant performance was conducted for epoxy matrix and CFRP systems incorporating unmodified APP, HF-APP, and SHF-APP, alongside other modification strategies such as ATNi [9], and DDM [10] functionalized APP. In the epoxy matrix system, tensile tests revealed that at 10wt% loading, HF-APP achieved the highest retention of mechanical strength, closely matching the performance of APP@ATNi, while also delivering the most obvious reduction in PHRR. HF-APP exhibited comparable enhancements in LOI, char residue, and total heat release (THR), demonstrating its balanced improvement in both structural and flame-retardant properties.

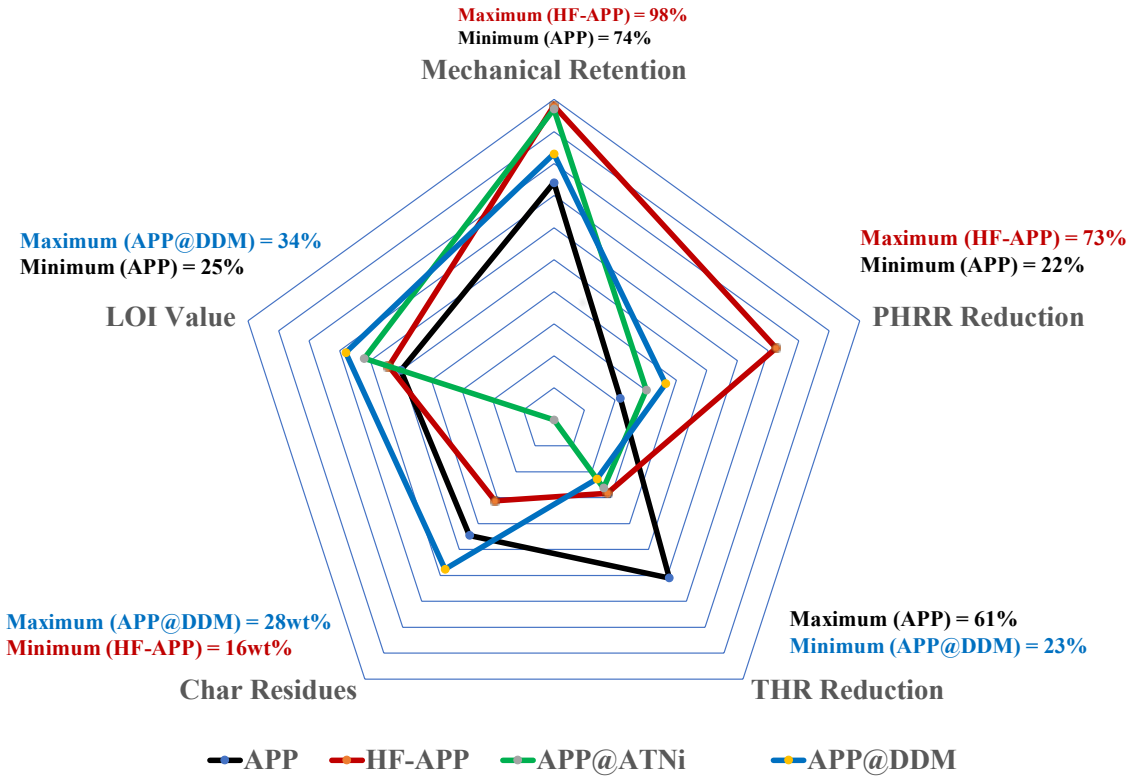

Fig. 5 Comparisons of the unmodified APP and HF-APP with APP@ ATNi and APP@DDM at 10wt% loading.

In contrast, SHF-APP demonstrated the best mechanical advantages. Specifically, the short beam shear strength and interlaminar fracture toughness were significantly improved by SHF-APP compared to both APP and HF-APP, while maintaining flame-retardant effectiveness equivalent to HF-APP. Furthermore, the cumulative percentage changes across seven key performance indicators highlighted SHF-APP as the most balanced and effective additive for CFRP applications. These results suggest that while HF-APP is optimal for preserving tensile performance in epoxy matrices, SHF-APP particles are more suitable for CFRP composites where interlaminar properties and fire safety must be simultaneously optimized.

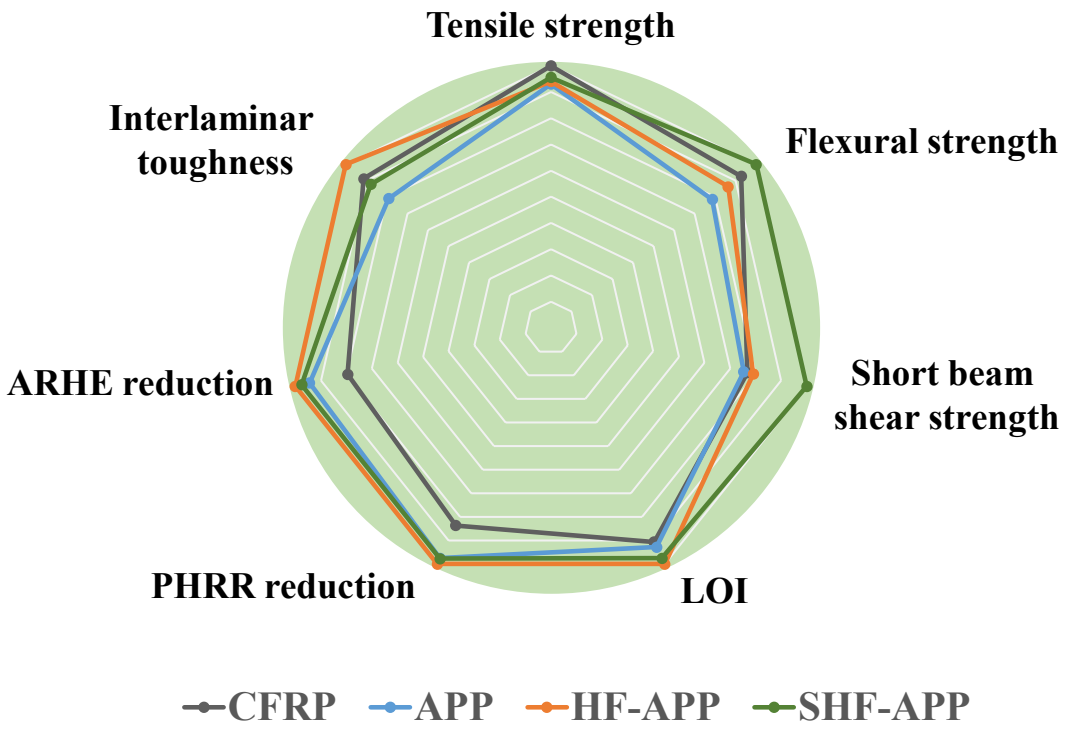

Fig. 6 Comparison of the mechanical and fire-retardant performance indicators of the four types of CFRPs.

3 CONCLUSION

In this study, a novel strategy was developed to enhance the flame-retardant performance and retain the mechanical integrity of epoxy resins and their CFRPs through the functionalization of APP using an amine-based curing agent. In the epoxy system, the resulting HF-APP exhibited strong interfacial compatibility with the matrix and a filamentous morphology that effectively mitigated stress concentrations. At 20wt% loading, HF-APP reduced the peak heat release rate and total heat release by 87% and 83%, respectively, while maintaining 92% of the tensile strength of the neat epoxy. By reducing the average particle size of HF-APP from 14μm to 0.12μm via probe ultrasonication, SHF-APP particles were obtained. These particles preserved the flame-retardant performance of HF-APP while further improving short beam shear strength and interlaminar fracture toughness due to enhanced matrix uniformity and fibre alignment. These improvements were attributed to improved dispersion, stress transfer, and the formation of dense char layers during combustion. The modified system met the highest fire safety classification (HL3) under EN 45545-2:2013, demonstrating its suitability for railway applications. The findings of this study provide new insights into the structure–property relationships of flame-retardant fillers in polymer composites, offering potential methods for developing multifunctional CFRPs that meet both fire safety standards and mechanical performance requirements for applications in transportation, infrastructure, and high-performance engineering.

Keywords: Thermal modification; Cross laminated timber; Sustainable building construction materials; Wood strand composite; Fire reaction properties; Fire resistance properties

ABSTRACT

The demand for mass timber panels has risen sharply, driven by the growing need for sustainable construction materials. However, concerns regarding the durability and fire performance of wood-based composite materials have led to the development of various treatment processes. Among them, thermal modification is a widely adopted process in the industry to enhance the dimensional stability and durability of wood-based materials. At the same time, the emphasis on high-quality lumber for cross-laminated timber (CLT) panels has diminished the utilization of small-diameter timber (SDT) for CLT panels. Effective use of SDT is essential for maintaining forest health and mitigating forest fires. This study explores the use of SDT strands, both untreated and thermally modified, in the production of mass timber panels. Thermal treatment was conducted in an industrial autoclave to ensure uniform processing. The resulting composite panels exhibited excellent mechanical performance, notably enhanced shear strength due to the reduction of rolling shear effects. Fire testing revealed that thermal modification had no significant impact on either fire reaction or fire resistance properties of the mass timber panels produced using control and thermally modified wood strand composite material. While the flexural stiffness remained largely unchanged, the panels demonstrated slight reductions in flexural strength and significant improvements in shear and internal bond strength.

1 INTRODUCTION

Sustainable materials have seen an increase in interest for different applications in the built environment [1]. The use of cross-laminated timber (CLT), which can transfer forces in two directions, has been one such application in demand as a sustainable building construction material [2].

Traditionally, these CLT panels are made from high-quality lumber, the processing of which is economically viable to the sawmills [2]. The manufacturing cost of CLTs is higher than that of other wood-based panels due to the stringent quality control protocols for the lumber that is used in the panels. However, low-quality small-diameter logs are readily available in the US forests as a result of hazardous fuel-removal thinning operations to mitigate forest fires and ensure healthy forests [3-5]. There is commercial interest in producing value-added products using these small-diameter logs, and manufacturing mass timber panels using strand-based technology fits the bill as it does not require high-quality lumber for the production of wood strand composite materials [3, 6-8].

One of the primary challenges in using cross-laminated timber (CLT) for exterior applications is its high susceptibility to moisture uptake [9], which significantly limits its use in outdoor environments. To address this limitation, various strategies have been explore, most notably, chemical modification of the wood to enhance its dimensional stability and overall durability. However, chemical modifications, such as chromated copper arsenical and micronized copper azole, are known to be hazardous to the environment. Enhancing the usability of SDT necessitates procedures that improve its longevity, dimensional stability, and overall product performance while imparting minimal damage to the environment. This study proposes the method of thermal modification of strands to achieve more dimensionally stable and more durable mass timber panels [1]. Thermal modification has been studied extensively for lumber to enhance its dimensional stability and durability. Thermal modification (TM) provides a sustainable substitute for chemical alteration, using heat as the principal agent in either dry or wet conditions. In wet processes, water or steam is used, with the possibility of recycling waste for energy recovery or biofuel generation. Dry techniques use air or inert atmospheres for comparable advantages [10]. TM reduces wood's hydrophilicity by partially extracting hemicellulosic sugars [11], thus improving dimensional stability and decay resistance. Pressurized settings further expedite the breakdown of the complex hemicellulose structure, thus imparting decay resistance and decreasing moisture absorption while preserving or marginally increasing stiffness as the degree of crystallinity is increased [12]. Therefore, the current research employed a pressurized TM technique for the strands to augment hemicellulose breakdown, strengthen resistance to fungal decay, and alleviate moisture-related problems while preserving mechanical integrity.

Fire performance is a critical consideration for mass timber panels, especially in light of increasingly stringent global fire safety regulations for building materials. While wood offers several advantages as a structural material, its inherent combustibility poses challenges in applications requiring enhanced fire resistance [13]. One potential mitigation strategy involves the use of organic wood preservatives—traditionally applied to protect against biological degradation, which may also influence the material's combustion behavior [14]. Investigations examining the combustion characteristics of prevalent species such as Norway spruce (*Picea abies*) and Scots pine (*Pinus sylvestris*) have shown distinct species-specific variations in burn patterns, mass loss, and charring zone thickness [15]. Similar variations are found in heat-treated woods. The findings are affected by wood density, resin content, and preservative treatments [15]. Comprehensive studies on the influence of TM on the fire performance of full-scale structures are limited. Additionally, there is also a divided belief on the advantages or disadvantages of TM on the fire performance of mass timber panels [8, 9]. Thus, it is also critical to have a comprehensive understanding of the influence of TM on strand-based mass timber panels, in both fire reaction and fire resistance properties. Therefore, the objectives of this study are to evaluate the effects of thermal modification on the structural performance of the proposed strand-based wood composite mass timber panels and to investigate the influence of thermal modification on the fire reaction and fire resistance properties of the panels.

2 MATERIALS AND METHODS

2.1 Panel production

Wood strands were produced from lower-grade lumber sourced from small-diameter Engelmann spruce (*Picea engelmannii*) and lodgepole pine (*Pinus contorta*), referred to as ESLP. The materials were procured from Idaho Forest Group. The sourced timber (thickness between 25.4 to 50.8 mm) was cut into 150 mm long slats, soaked in water to increase the moisture content above the fiber saturation point to around 40-50%, and stranded using a CAE disc strander (Kadant, Inc.) at WSU's Composite

Materials and Engineering Center (CMEC). The generated wood strands were approximately 148 mm in length, 19 mm to 38 mm in width, and 0.381 mm to 0.508 mm in thickness. The produced stands were then conditioned at 21.1°C and 65% relative humidity (RH) to attain a moisture content of 12% before thermal modification. The TM was carried out in an industrial autoclave at Therma Wood Technologies (TWT), Ronan, Montana, USA. The modification was carried out in an inert condition, using nitrogen, at 165°C and 0.8 MPa pressure in a 12 m^3 autoclave for 7.5 h.

After thermal treatment, the strands were again conditioned at 21.1°C and 65% RH for about three weeks before making flat 6.35 mm thick, 1220 mm wide, and 2440 mm long veneers with a target density of 640 kg/m^3. Polymeric methyl diphenyl diisocyanate (pMDI) adhesive, supplied by Henkel, was applied at 5 wt.% and atomized onto the strands using a drum blender. The veneers were made with strands oriented primarily along the long direction in a hot press (Ironworks Press Machine). The veneers were then assembled into laminated strand veneer lumber (LSVL) with final dimensions of 38.1 mm in thickness, 610 mm in width, and 2440 mm in length. The sanded veneers were initially coated using a 10 wt% aqueous solution of primer (Loctite HB 3105) before applying the polyurethane (PUR) adhesive (HBX 602 PURBOND). PUR was applied at a coverage rate of 20 g/m^2, using the automated glue spreading technique of the USNR CLT Press 1.83 m by 3.66 m (USNR, Woodland, Washington, USA), available at WSU's CMEC. The same press from Ironworks was then used to make the LSVL panels, details of which are provided in [1]. The LSVL panels were then cross-laminated to develop the cross-laminated strand veneer lumber (CLSVL), using the same PUR adhesive with a 20 g/m^2 spread rate. Cold pressing was used for making both LSVL and CLSVL panels. The final CLSVL panels were made at a thickness of 114.3 mm, a length of 3000 mm, and a width of 1830 mm. The USNR CLT Press was utilized to make the CLSVL panels.

2.2 Mechanical performance

Flatwise third-point bending tests were performed according to ASTM D198-22a [18], where a span-to-depth ratio of 18 was maintained for the CLSVL (2286 mm by 305 mm by 114 mm) panels. A 222 kN load cell, attached to a hydraulic actuator, with string pots having stroke lengths of 250 mm, available at WSU's CMEC, was used for performing the flexural tests. The test setup is provided in Figure 1 (a). Flatwise center-point bending tests were again conducted to ascertain the shear characteristics of the mass timber panels, again as per ASTM D198-22a standard [18]. Here, the span-to-depth ratios for both the panel types were reduced to four, as per the standard, resulting in 203 mm long, 89 mm wide, and 38 mm thick LSVL panels and 584 mm long, 305 mm wide, and 114 mm thick CLSVL panels. The same 222 kN load cell and strain pots were used. The testing setup is illustrated in Figure 1 (b).

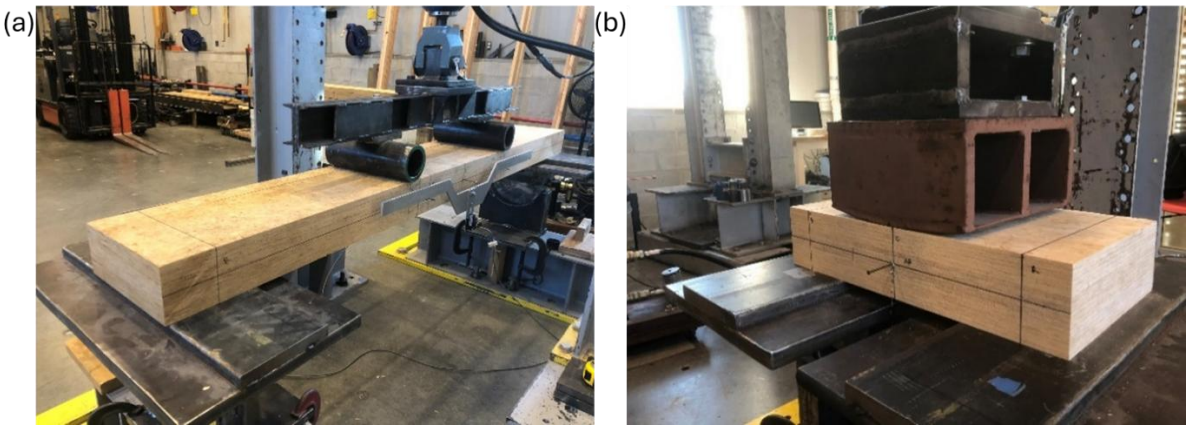

Figure 1: Illustration of the testing setups for (a) flexural test and (b) shear test as per ASTM D198-22a standard [18].

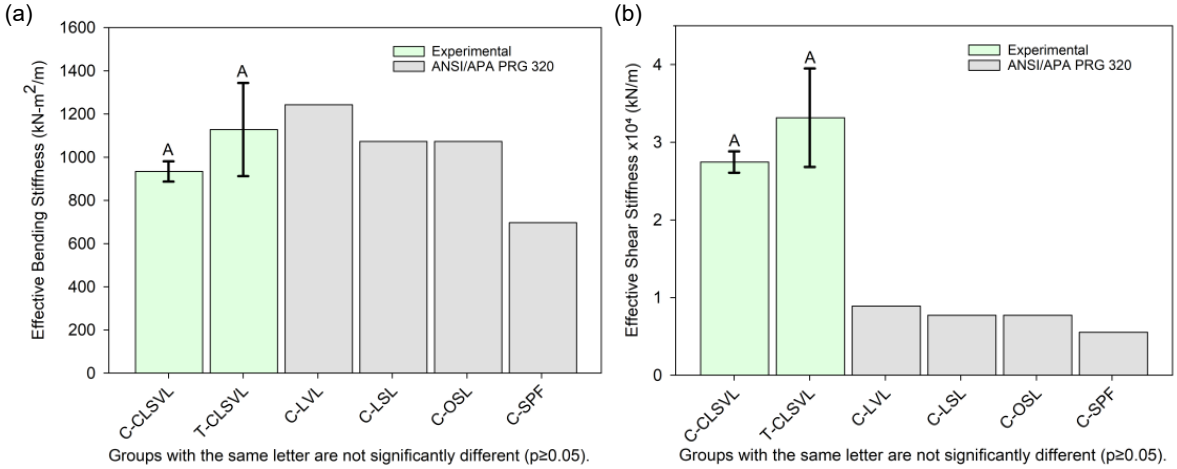

2.3 Fire performance

Bench-scale cone calorimeter tests were also conducted as per the ASTM E1354-23 [19]. The tests were carried out in the horizontal orientation at the University of Auckland (UoA), New Zealand, on the CLSVL panels prepared from both thermally treated strands and untreated (control) strands. The

limitation in sample holder thickness at UoA (50 mm) required the CLSVL samples to be cut in half to ensure the thickness of each specimen was less than 50 mm. The sample dimensions were maintained at 100 mm by 100 mm. The ASTM E119-24 [20] standard was followed to perform the fire resistance testing at two different scales on the CLSVL panels at Western Fire Center. A small-scale furnace test was eventually carried out with 1.19 m by 1.5 m by 0.11 m samples, which were not loaded and the fire rating was calculated based on either the time the wall resisted the heat transmission in a way that the unexposed side did not reach a temperature of 139°C or the time when the panel failed structurally due to buckling at the junctions under gravity load. Sixteen thermocouples were installed on each panel to monitor temperatures at every 38.1 mm increment through the panel thickness, extending up to 114.3 mm from the exposed surface to also monitor the temperature on the unexposed side. The full-scale furnace tests on horizontal walls were then carried out with 3.01 m by 3.5 m by 0.11 m samples, as per the ASTM E119-24 standard. The standard requires a minimum 9.3 m^2 surface area of exposure, which was met in the current study. The samples were loaded in compression with a uniformly distributed load of 355.86 kN, which resulted in 9.43 kN/m of loading as per the anticipated loading of 2-layered structures. The fire rating was again calculated based on either the time the wall with the compression loads resisted the heat transmission until the temperature on the unexposed side reached 139°C or the time when the wall panels failed under the gravity and applied loads. Twenty thermocouples were used in each panel, six equally distributed at 38.1 mm depths until the unexposed side was reached, with two at the junctions on the unexposed side created during the assembly of the LSVL panels.

3 RESULTS AND DISCUSSIONS

Mechanical testing revealed significant advantages of the strand-based mass timber panels, termed cross-laminated strand veneer lumber (CLSVL), over conventional CLT panels; particularly the elimination of rolling shear, a common failure mode that limits the load-carrying capacity of CLT in high-rise constructions. Additionally, CLSVL demonstrated comparable or superior mechanical performance in several aspects when compared to other mass timber panels made from the same species [21]. Figures 2 (a) and (b) illustrate the comparative effective bending and shear stiffnesses, respectively, of the mass timber panels. The elimination of rolling shear failure [6] resulted in a significant increase in the shear stiffness of the strand-based panels, resulting due to the distribution in grain orientation in the plane of the panel. Internal bond strengths of the composites, as per ASTM D1037-13 [22], also showed enhanced performance with values of 1.08 MPa (COV = 16 %) compared to only 0.3 MPa (COV = 46 %) for the panels made from control or not thermally modified strands.

Note: C-LVL = CLT from Laminated Veneer Lumber, C-LSL = CL from Laminated Strand Lumber, C-OSL = CLT from Oriented Strand Lumber, C-SPF = CLT from SPF lumber

Figure 2: Comparative test results for (a) effective bending stiffness and (b) effective shear stiffness.

Fire reaction property analysis using a bench-scale cone calorimeter, as per ASTM E1354-23, showed similar trends in heat release rate (HRR) and mass loss for both CLSVL panels made from control (C-CLSVL) and thermally modified (T-CLSVL) strands, as illustrated in Figure 2. The peak

heat release rate (PHRR) shifted, with higher values for the T-CLSVL (351.7 ± 41.1 kW/m^2), compared to 310.1 ± 10.1 kW/m^2 for the control samples, Figure 3 (a). Although the time to PHRR was longer for the T-CLSVL panels (45 ± 5.4 sec) compared to 35 ± 6.2 sec for the control. The total heat evolved was also almost similar for both the panel types tested. The time to ignition was longer for the T-CLSVL panels by about 33% compared to the C-CLSVL panels, which can be attributed to the reduced amount of weak hemicellulose and volatiles from the surface. The time to flameout was almost similar with only 6% average variation. This indicates that although the time to ignition was later, the amount of fuel in the material reduced during the TM process, resulting in a similar time of flameout. Both samples showed good barriers against flame propagation, with an initial peak in HRR and then a steady, low HRR throughout the burning phase, as can be observed from Figure 3 (a). These are synchronous to fire-resistant specimens, showing a significant amount of char formation on the upper layers that can protect the subsequent layers, giving a good amount of time for evacuating the premises during fire. The mass loss rate was similar for both samples, as can be observed from Figure 3 (b). The char formed in the T-CLSVL samples was 3.3% of the initial mass, 40% higher than that of the control specimen. The T-CLSVL samples also took 33% longer to ignite and 22% longer to reach the PHRR, indicating better fire reaction properties compared to the control. However, the time to flameout was lower by 6%, which again can be attributed to the lower availability of fuel due to the loss in TM. The total heat evolved was almost similar, with the T-CLSVL having a slightly higher PHRR by about 11.8%. Overall, both the C-CLSVL and the T-CLSVL showed promising fire reaction properties.

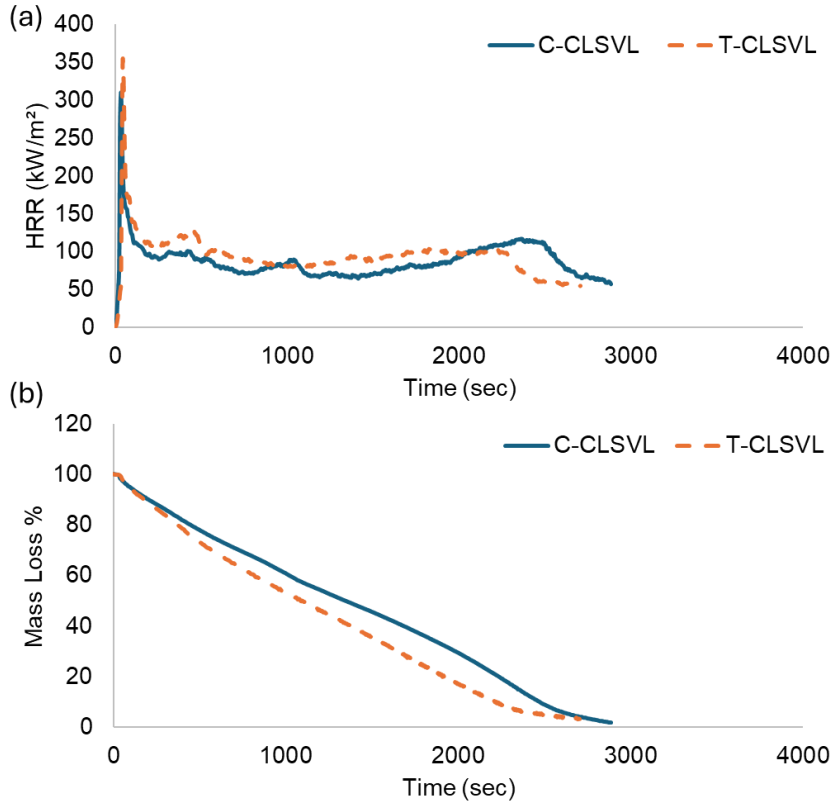

Figure 3: Representation of the (a) HRR and (b) mass loss percentage of the control and TM CLSVL panels when tested in the cone-calorimeter as per the ASTM E1354-23 standard

Small-scale fire resistance tests on C-CLSVL and T-CLSVL panels, based on ASTM E119-22 standard, were performed. Control and TM strands were used to fabricate 24 veneers that were 1.22 m by 1.83 m (4 ft by 6 ft) for the layup of the panels. The control veneers had an average density of 642.34 ± 40 kg/m^3 (40.1 ± 2.5 lb/ft^3), and the TM veneers had 644.58 ± 16.02 kg/m^3 (40.24 ± 1 lb/ft^3). The final wall assembly, after installation, was 1.19 m by 1.5 m by 0.11 m. These specimens were not loaded, therefore, the main criterion for judgment, as per ASTM E119-20, was that the transmission of heat through the wall will not have raised the temperature on its unexposed side more than 139°C (average) above its initial temperature, or if a temperature higher than 30% (181°C) of the specified limit occurs

at any one point (single-point) on the unexposed side of the assembly. Both specimens were able to meet the 1-hr wall rating requirement, with the control being able to maintain the testing criteria for 102 min (rounded off to the nearest integral minute). The treated had a successful test for 64 min (corrected time), after which, although the sample did not fail, the testing apparatus failed to maintain pressure. A comparison of the temperatures on the three levels of the panels (1.5 in or 38.1 mm layer, 3 in or 76.2 mm layer, and unexposed side) at 60 mins showed that the C-CLSVL samples had better fire resistance compared to the TM counterparts.

Finally, full-scale vertical fire resistance testing, as per ASTM E119-20, was carried out on the panels with a continuous compressive load on the top surface, as illustrated in Figure 4. The load-bearing calculations were carried out as per the expected loading on 2-layered structures, which came out to be 9.43 kN/m or 6957 lb/ft, giving a total load of 355.86 kN or 80,000 lbs. The utilization ratio of 0.163, as per interaction equations, was used to understand the loading requirements. The results further strengthened the previous conclusion from the small-scale test, that both wall structures successfully met the 1-hr load requirements. However, similar to small-scale testing, the C-CLSVL panel was able to withstand the load for 71 mins, compared to 64 mins by the T-CLSVL wall specimen. The control performed slightly better under fire resistance, which might be attributed to the reduction in strength due to the TM of the strands. It must also be noted that the panels failed due to buckling under compression loads at the joints in the outer layer, as illustrated in Figure 3. Thus, if the veneers were laminated directly without processing them into lumber, the buckling issue could be eliminated. This has the potential to enhance the fire rating of the panels and possibly impart better fire resistance properties of the T-CLSVL panels due to the enhanced stiffnesses.

Figure 3: Loaded full-scale wall test for (a) C-CLSVL and (b) T-CLSVL before and after fire test as per ASTM E119-20 vertical wall testing procedure.

4 CONCLUSIONS

Thermal modification had an overall positive impact on the mechanical properties of the panels, evidenced by a 260% increase in internal bond strength and a 21% improvement in both effective bending and shear stiffnesses, without a statistically significant change in flexural strength. In contrast, its effect on fire performance was largely neutral, with no significant differences in most fire reaction and resistance metrics; however, a slight decline in the overall fire rating was observed. To address this limitation and meet fire safety standards, the application of an external fire-resistant layer—such as gypsum board, which is commonly used in buildings worldwide—is proposed. Given the environmental concerns and non-renewable nature of gypsum, alternative solutions are being explored. Preliminary research is investigating the use of fire-resistant fabrics, which may enhance fire performance while reducing reliance on gypsum-based materials in residential construction. Additionally, the lab-scale requirement of sectioning the LSVL panels for sanding and priming, if eliminated, can potentially reduce the buckling issues at the joints and possibly increase the fire rating of the overall panels, where the enhanced stiffness due to thermal modification can potentially also help increase the fire resistance properties of the panels.

ACKNOWLEDGEMENTS

Keywords: Biocomposites, Hydrochar, Flame resistance, Mechanical properties, Phytic acid

ABSTRACT

In this study, a sustainable flame-retardant biocomposite was developed by incorporating hydrochar (HC) derived from Brewers' Spent Grain (BSG) into a polylactic acid (PLA) matrix. HC was produced via hydrothermal carbonization (HTC), yielding a porous, carbon-rich material characterized by a high content of oxygen-containing functional groups. The filler was further functionalized with phytic acid (PA) to introduce phosphorus-based flame-retardant functionalities (HC-P). The effectiveness of the modification was confirmed through FT-IR, while SEM-EDS, BET and elemental analysis were used to assess the structural and surface properties of HC. PLA composites containing 20 wt.% of HC and HC-P were prepared via melt blending and compression molding, and characterized by TGA, DSC, DMA, and flexural testing. HC incorporation led to earlier thermal degradation and reduced mechanical performance, attributed to poor interfacial adhesion and filler aggregation. However, PA functionalization improved thermal stability and partially restored mechanical properties by enhancing filler–matrix compatibility and dispersion. Cone calorimeter tests revealed that the HC-P composite exhibited improved flame-retardant performance, with reductions of 15% in peak heat release rate (pHRR), 13% in total smoke release (TSR), 12.5% in specific extinction area (SEA), and 12.9% in MARHE compared to the unmodified composite. These results highlight the dual role of phytic acid in promoting char formation and limiting flammable volatile release, demonstrating the potential of functionalized hydrochar as an effective bio-based flame retardant for PLA composites.

1 INTRODUCTION

The rapid expansion of manufacturing industries has increased the demand for materials with improved strength, lower density, reduced cost, and enhanced sustainability. Composite materials have

emerged as one of the materials that can meet this growing demand. Growing environmental awareness has highlighted the impact of plastic pollution and fossil fuel use, driving industries to adopt renewable raw materials and develop biobased polymers to reduce environmental impact [1]. Among biopolymers, polylactic acid (PLA) stands out as a promising material produced from renewable sources like corn starch and sugarcane [2]. Its biodegradability, biocompatibility, and suitable mechanical performance have made it a widely used alternative to traditional petroleum-based plastics in various fields, including packaging, textiles, biomedical applications, and composite materials. However, biopolymers like PLA are generally more expensive than petroleum-based plastics, limiting their broader adoption [3]. A common strategy to reduce costs while preserving environmental benefits involves creating biocomposites by partially replacing the polymer with low-cost, natural waste-derived fillers [4]. Moreover, PLA exhibits certain drawbacks that limit its use in more demanding applications, as low thermal stability, brittleness, and high flammability [5]. To address these limitations, recent research has focused on incorporating functional reinforcement to enhance performance and lower production costs.

Various additives and fillers—such as antioxidants, plasticizers, stiffeners, and flame retardants—are widely used to enhance specific polymer properties. However, some stiffening fillers fail to balance stiffness and toughness, and many conventional fillers raise environmental and health concerns due to their toxicity (e.g., phthalates, PBDEs [6]). As a result, there is increasing interest in greener alternatives that combine performance with safety. Carbon-based materials like carbon nanotubes, carbon black, biochar, and graphene [7,8] are particularly promising due to their high surface area, carbon content, and hydrophobicity. However, materials such as grapheneand nanotubes remain costly and complex to produce. Biochar (BC) is a sustainable carbon-based filler with high thermal stability, hardness, surface area, chemical stability, and electrical conductivity [9]. These properties make it a promising alternative to conventional fillers for improving the mechanical, electrical, and flame-resistant performance of PLA-, HDPE-, and PP-based composites. Among carbon-based materials, hydrochar (HC) is emerging as a sustainable and promising filler for polymer composites, although it remains less studied than biochar, carbon black, or carbon nanotubes. HC is produced via hydrothermal carbonization (HTC), a low-temperature (180–300 °C), water-based thermochemical process that converts wet biomass under autogenous pressure [10]. Unlike pyrolysis, HTC allows direct processing of high-moisture feedstocks, such as agricultural residues or food waste, eliminating energy-intensive drying and offering higher solid yields. These features support its economic viability and align with circular economy principles by converting organic waste into valuable carbon-based materials. When combined with biodegradable polymers like PLA, HC contributes to the development of sustainable, carbon-neutral or even carbon-negative composites. In this work, we propose hydrochar (HC) derived from Brewers' Spent Grain (BSG) via hydrothermal carbonization (HTC) as a sustainable carbon-based filler for PLA composites. BSG is the primary by-product of the brewing industry, accounting for around 85% of its total waste, with an estimated annual output of 25–40 million tonnes globally and 3.4 million tonnes within the EU [11]. This lignocellulosic residue is rich in organic matter but contains a high moisture content (70–90 wt.%), making it prone to microbial decomposition and the development of unpleasant odors. In warm climates, its shelf life may be limited to 7–10 days, posing challenges for storage and transportation [12]. As a result, BSG is often disposed of through unsustainable practices such as landfilling. HTC offers an effective valorization route by processing wet biomass without prior drying, making it particularly suitable for BSG and contributing to circular waste management strategies. To the best of the authors' knowledge, no study has investigated the use of hydrochar (HC) derived from Brewers' Spent Grain (BSG) as a filler in polymer composite materials. Only a few studies have explored HC obtained from other biomass sources for composite applications. Ye et al. conducted a comparative study on HC and biochar from wood chips as fillers in PBAT-based biodegradable composites. HC acted as a nucleating agent and influenced the hydrophobicity of the composites. Unlike biochar, which increased stiffness at the expense of toughness, HC provided an improved balance between stiffness and toughness, with optimal performance achieved at 10 wt.% HC treated at 300 °C [13]. Nizamuddin et al. developed PLA-based composites incorporating 5–20 wt.% HC from rice husk via melt processing. The addition of HC significantly increased the tensile modulus (from 2.63 to 4.24 GPa at 20 wt.%) due to mechanical interlocking and polymer infiltration into HC pores. However, tensile strength and elongation at break decreased, attributed to weak interfacial adhesion and particle agglomeration. HC also acted as a nucleating agent and enhanced the thermal stability of the composites [14]. Bejenari et al. investigated

HC from spruce bark waste in an aromatic bio-epoxy resin system, where HC acted as both a filler and a co-reactant in the crosslinking process. This dual role led to increased reaction enthalpy, a reduced curing temperature range, and significantly improved thermal stability and hardness, demonstrating HC's potential to produce stiffer and more sustainable materials [15]. Therefore, using HC as a filler in biopolymers offers a promising strategy for developing biocomposite materials by lowering costs, potentially enhancing the polymer's mechanical properties, and adding value to waste in accordance with circular economy principles. However, one of the main problems with biocomposite materials persists: their poor fire resistance. Biopolymers like PLA are inherently highly flammable [16]. Flame retardants (FRs) are essential for improving the fire safety of composite materials by preventing ignition and slowing combustion. While halogen-based FRs were widely adopted in the 1970s for their high efficiency at low loadings, their use has raised serious environmental and health concerns due to the release of toxic gases and persistent pollutants. As a result, increasing regulations and environmental awareness have driven the development of halogen-free, bio-based flame retardants as safer and more sustainable alternatives [17]. Among halogen-free alternatives, phosphorus-based flame retardants are gaining significant interest due to their structural versatility, variable phosphorus content, and oxidation states (0 to +5), which enable tailored flame-retardant mechanisms suited to different polymer matrices [18,19]. Incorporating flame retardants (FRs) directly into the polymer matrix is the most common method to enhance fire resistance of bio-based composites. However, this approach often results in compatibility issues between the FRs and PLA, negatively impacting the mechanical properties of the composites due to increased melt viscosity and potential phase separation [20,21]. An alternative strategy involves grafting or adsorbing the FR onto the filler, thus improving fire resistance without compromising composite integrity, especially in systems using hydrophilic FRs and hydrophobic polymer matrices, such as PLA [22]. In this paper, we aim to address key challenges associated with polymeric biocomposites, such as high cost and poor fire resistance, by developing a PLA-based biocomposite reinforced with hydrochar (HC) derived from beer production waste. To enhance fire resistance, we also propose the surface modification of the filler using phytic acid. Phytic acid (PA), with its high phosphorus content (~28%) and non-toxic, eco-friendly profile, is gaining attention as a sustainable flame retardant and alternative to halogenated compounds [23]. It acts in both the condensed and gas phases, promoting char formation and releasing phosphorus radicals that quench flame-propagating species, while generating inert gases that dilute combustible elements [24]. In composite materials, PA has been used to modify reinforcing phases to enhance flame resistance. Liu et al. treated ramie fibers with PA, increasing LOI and char yield but reducing mechanical strength, which was mitigated through hybridization with glass fibers [25]. Costes et al. improved PLA flame retardancy by melt blending lignin with PA, achieving a 44% reduction in peak heat release rate, UL-94 V-2 classification, improved thermal stability, and enhanced elongation at break [26]. In the literature, one study reports the use of carbon-based materials as fillers in combination with phytic acid: Zhong et al. prepared flame-retardant bamboo biochar (mBC) via hydrogen peroxide oxidation followed by modification with phytic acid and urea to add phosphorus and nitrogen groups. Incorporating 10 wt.% mBC into PLA improved flame retardancy, achieving UL-94 V-0 and raising the LOI from 20.7% to 28.3%. Cone calorimeter tests showed a decrease in ignition time (63 to 38 s at 20 wt.% mBC) and reduced heat release due to stable char formation. Despite some loss in mechanical strength from filler–matrix incompatibility, performance remained acceptable [27]. In this study, hydrochar was produced from Brewers' Spent Grain (BSG). Compared to biochar, hydrochar naturally possesses a surface rich in oxygen-containing functional groups and exhibits a highly porous structure. These features eliminate the need for oxidative pretreatment, thereby avoiding the associated safety risks. The use of hydrochar not only reduces energy consumption during filler production but also makes the modification process more sustainable. The produced hydrochar was characterized for its structure by Scanning Electron Microscopy (SEM) coupled with Energy Dispersive Spectroscopy (EDS), its chemical composition through elemental analysis, and its porosity by Brunauer–Emmett–Teller (BET) measurements. Following characterization, the hydrochar was modified by reaction with phytic acid. This modification was carried out in aqueous solution at room temperature, with pH adjustment facilitating the formation of ionic and hydrogen bonds. The modified filler (HC-P) was analyzed by Fourier Transform Infrared Spectroscopy (FT-IR) to confirm the effectiveness of the surface modification and subsequently

incorporated into polylactic acid (PLA) matrices at a loading of 20 wt.%. The resulting composites were evaluated for their mechanical, thermal, and flame retardant properties using cone calorimetry.

2 MATERIALS AND METHODS

2.1 MATERIALS

A PLA Luminy® LX175 (96% L-isomer), provided by TotalEnergies Corbion, was utilized as the polymer matrix. Brewers' Spent Grain (BSG) was provided by research center CERB (Italian Brewing Research Centre, Perugia, Italy). Phytic acid solution 50 % (w/w) in H_2O and sodium hydroxide (NaOH) were obtained from Merck KGaA (Darmstadt, Germany).

2.2 HYDROCHAR SYNTHESIS AND COMPOSITE MANUFACTURING

Brewers' Spent Grain (BSG), with a moisture content of 83.5%, was first homogenized by grinding and then mixed with distilled water to obtain a dry-to-water ratio of 1:2. The resulting mixture was placed in an autoclave hydrothermal reactor, where hydrochar (HC) was produced through hydrothermal carbonization (HTC). The reaction was conducted at 230 °C for 4 hours.

5g of hydrochar were reacted with 13.1 mL (14.4 mmol) of phytic acid. The pH was adjusted to 4.5 using sodium hydroxide (NaOH), and the mixture was stirred at room temperature for 24 hours. The modified hydrochar (HC-P) was then collected by filtration.

Fabrication of the PLA reinforced with untreated hydrochar (PLA-HC) and PLA reinforced with modified hydrochar (PLA_HC-P) composites was performed using Brabender-like equipment (Rheocord EC, Haake Inc.) and a lab hydraulic press (Collin model P400E) to process them into plates (100mm × 100mm × 4mm). Before compounding, the HC and HC-P as well as the PLA pellets were dried in a vacuum oven at 70 °C for 4 h. The micro compounder was used to mix HC and HC-P with PLA setting the rotation speed of 60 rpm at 180 °C for 5 min. The PLA composites were then compression molded at 180 °C using a pressure profile as follows: 2 min at 0 bar – 1 min at 5 bar – 1 min at 10 bar and 1 min at 20 bar. Finally, the cooling step down to room temperature was carried out while maintaining the material at the maximum pressure set (20 bar). The reinforcement content was kept at 20 wt.%.

2.3 CHARACTERIZATION TECHNIQUES

The effectiveness of hydrochar (HC) modification with phytic acid was evaluated using Fourier Transform Infrared Spectroscopy (FT-IR). Spectra were recorded with a Bruker VERTEX 70 spectrometer equipped with a diamond attenuated total reflectance (ATR) accessory. Measurements were performed in the mid-infrared range (400–4000 cm^{-1}) at a resolution of 4 cm^{-1}, averaging 128 scans per sample.

The surface morphology of the hydrochar (HC) was examined using Field Emission Scanning Electron Microscopy (FE-SEM) combined with Energy Dispersive X-ray Spectroscopy (EDS). Imaging was performed on a Tescan Mira3 system at an accelerating voltage of 10 kV. Prior to analysis, the samples were sputter-coated with a thin layer of gold to enhance conductivity.

Thermogravimetric analysis (TGA) was performed in accordance with ISO 11358, using a TG209 F1 Libra instrument (Netzsch). Samples were heated from room temperature to 800 °C at a constant rate of 10 °C/min under a nitrogen atmosphere.

Differential scanning calorimetry (DSC) was carried out in accordance with ISO 11357 using a DSC 300 Caliris (Netzsch), under a nitrogen flow of 40 mL/min. The thermal program consisted of a heating–cooling–heating cycle from 25 °C to 200 °C at a rate of 10 °C/min. Melting and crystallization temperatures, along with the degree of crystallinity (Xc, see Equation 1), were determined as the average values from three independent measurements:

$$\chi_c = \frac{(\Delta H_m - \Delta H_{cc})}{\Delta H_m^0 \, x \, \varphi} \, x \, 100 \qquad (1)$$

where ΔH_{cc} and ΔH_m represent the cold crystallization and melting enthalpies of the PLA composites, respectively; φ is the weight fraction of PLA in the composite; and ΔH_m^0 (93 J/g) is the enthalpy of fusion for 100% crystalline PLA [28].

Elemental composition was analyzed using a UNICUBE® elemental analyzer.

Surface area and porosity were measured by N_2 adsorption–desorption isotherms at −196 °C using a Micromeritics Triflex analyzer. Samples were outgassed at 300 °C for 4 hours before analysis. Isotherms (p/p_0 = 0.01–0.99) were analyzed with 3Flex software (v4.05), and the BET equation was applied to calculate the specific surface area.

The thermal conductivity of the composites was measured using a TCi C-Therm thermal conductivity analyzer (C-Therm Technologies Ltd., Fredericton, Canada).

Dynamic mechanical analysis (DMA) was used to evaluate the thermo-mechanical behavior of the materials in the solid state under oscillatory loading. The storage modulus (E′), loss modulus (E″), and damping factor ($\tan\delta = E''/E'$) were recorded as a function of temperature. Tests were performed in three-point bending mode using a DMA 242 E Artemis instrument (Netzsch), in accordance with ISO 6721. Specimens (60 × 10 × 4 mm³) were heated from 25 °C to 75 °C at a rate of 2 °C/min, with a constant oscillation frequency of 1 Hz.

Flexural tests were performed on 80 × 10 × 4 mm^3 specimens using a Zwick/Roell Z2.5 machine, following ISO 178 (span-to-thickness ratio 16:1, crosshead speed 5 mm/min).

Fire behavior was evaluated using an oxygen consumption-based cone calorimeter (CCT), specifically the FFT Cone Calorimeter model from Fire Testing Technology Limited. In accordance with ISO 5660 standards, tests were conducted with an incident heat flux of 35 kW/m². The specimens, placed horizontally under a cone-shaped heater, measured 100 × 100 mm² with a thickness of 4 mm. Each formulation was tested using three replicate samples.

3 RESULTS AND DISCUSSION

The raw material, Brewers' Spent Grains (BSG), and the resulting hydrochar (HC) produced via hydrothermal carbonization (HTC) were morphologically characterized by SEM analysis as shown in Figure 1. The BSG (Figure 1a) exhibits a compact and relatively smooth surface morphology, with aggregated structures and limited visible porosity. After HTC treatment, a substantial morphological transformation is observed (Figure 1b): the HC displays a more fragmented and porous structure, characterized by rougher surfaces and irregular agglomerates. This change is consistent with the partial carbonization and structural reorganization of the lignocellulosic matrix induced by the HTC process.

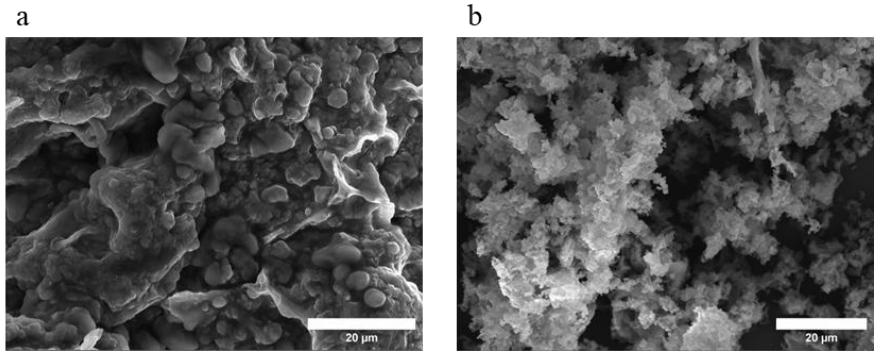

Figure 1: SEM analysis of (a) as-received Brewers' Spent Grains (BSG) and (b) hydrochar (HC)

Elemental analysis was performed on both dried BSG and the resulting hydrochar. The raw BSG exhibited a composition of 46.3% carbon, 4.71% hydrogen, 3.79% nitrogen, and 0.063% sulfur. After HTC treatment, the hydrochar showed a composition of 60.5% carbon, 6.9% hydrogen, 2.8% nitrogen, and 0.3% sulfur. The observed increase in carbon and hydrogen content, together with the relative decrease in nitrogen, reflects the fundamental chemical transformations induced by the HTC process. Specifically, HTC promotes the removal of nitrogen-containing compounds via volatilization or dissolution in the aqueous phase, resulting in a more carbon-enriched solid. This behavior is consistent with findings reported by Kruse et al., who attributed the decrease in nitrogen content to the degradation

of proteins into amino acids and subsequently into volatile species such as ammonia and amines. The preferential loss of nitrogen and retention of carbon-rich structures leads to a more aromatic and condensed hydrochar, particularly when protein-rich feedstocks like BSG are used [29]. The BET specific surface area of HC was measured at 6.63 m^2/g, while the pore volume derived from BJH analysis remains low, suggesting the presence of a predominantly mesoporous to macroporous network. These textural features are consistent with those typically observed in non-activated hydrochars produced under mild hydrothermal conditions [30,31]. The hydrochar was then functionalized with phytic acid units via a reaction carried out at room temperature using water as the solvent. This functionalization aimed to introduce phosphate groups onto the hydrochar surface, potentially enhancing its effectiveness as a flame retardant for biocomposites. The FT-IR spectra of HC show a broad band between 3100 and 3700 cm^{-1} attributed to O–H stretching vibrations in hydroxyl and carboxyl groups. Peaks at 2921 and 2855 cm^{-1} correspond to aliphatic C–H stretching and deformation vibrations [32]. The band at around 1060 cm^{-1} is associated with β-glycosidic bonds in cellulose and hemicellulose [33]. An absorption peak near 1515 cm^{-1} indicates aromatic ring stretching vibrations, suggesting the presence of aromatic structures [34]. The peak at approximately 1700 cm^{-1} corresponds to C=O groups, while bands in the range 1030–1160 cm^{-1} relate to cellulose components [33]. The FT-IR spectrum of HC-P showed new signals at 1059 cm^{-1} and 921 cm^{-1}. Phytic acid typically exhibits signals associated with the asymmetric and symmetric stretching vibrations of P–O–C groups at 1071 cm^{-1} and 996 cm^{-1}, respectively[35]. The shift in the newly observed signals may suggest interactions between phytic acid and functional groups on the hydrochar surface [36]. PLA-based composites were prepared by incorporating 20 wt.% of either HC or HC-P as reinforcing agents. The thermal degradation behavior of neat PLA and its composites with HC and HC-P was investigated by TGA, as reported in Table 1. The incorporation of HC into the PLA matrix leads to an earlier degradation, as evidenced by the decrease in T_5%, T_{10}%, and T_{max} values. This behavior can be attributed to two main mechanisms. The first is related to the presence of HC, a carbonaceous material with a porous structure and high surface area, which facilitates the formation of thermally conductive networks within the PLA matrix. Indeed, the thermal conductivity of PLA reinforced with HC increased by approximately 80% compared to neat PLA, enhancing heat transfer efficiency throughout the material. As a result, the composite heats up more uniformly and rapidly under thermal stress, leading to an earlier onset of thermal degradation [37]. The second possible mechanism involves chemical interactions between the biochar surface and the PLA matrix. Similar observations have been reported for PLA composites containing grapevine-derived biochar (GVC), where the filler was found to catalyze the scission of PLA macromolecular chains. This resulted in a reduced average molecular weight and a narrower molecular weight distribution. Such molecular-level degradation can also contribute to the earlier thermal decomposition observed in PLA/HC composites [38]. Interestingly, the composite containing phytic acid-modified hydrochar (PLA_HC-P) shows slightly delayed degradation compared to PLA_HC, with T_5% and T_{10}% values of 301.1 °C and 332.6 °C, respectively. Its T_{max} (368.1 °C) is also close to that of neat PLA (369.6 °C). While thermal conductivity remains similar to PLA_HC, this delayed degradation suggests a stabilizing effect of phytic acid. Such behavior may be attributed to phosphorus-containing groups from phytic acid, which are known to promote char formation and interfere with radical degradation pathways [39]. Moreover, the final residue increases significantly with the addition of HC (8.93%) and even more so in PLA_HC-P (10.3%), compared to neat PLA (1.5%). This trend reflects the presence of the carbon-rich filler and the additional contribution of phytic acid, which is known to promote carbonization reactions and enhance char yield during thermal decomposition [40].

	$T_{5\%}$ °C	$T_{10\%}$ °C	T_{max} °C	Residue wt.%
PLA	340.2	347.3	369.6	1.5
PLA_HC	297.3	319.2	359.0	8.9
PLA_HC-P	301.1	332.6	368.1	10.3

Table 1: TGA results of PLA, PLA_HC and PLA_HC-P

Composites materials were then characterized by DSC analysis (Table 2). The incorporation of 20 wt.% hydrochar (HC) into PLA resulted in a decrease in the glass transition temperature (T_g). This reduction may be attributed to a combination of factors. On one hand, the presence of polar functional groups on the HC surface can increase the free volume between PLA chains, enhancing chain mobility and thereby lowering T_g [41,42]. On the other hand, the possible presence of residual moisture and hydroxyl groups on HC may have contributed to partial degradation of PLA chains during melt mixing, leading to a lower molecular weight and, consequently, a reduced T_g [43]. However, an increase in the crystallinity was observed. This is likely due to the ability of HC particles to act as nucleating agents, promoting crystal growth and enhancing overall crystallinity [13]. This effect thus seems to coexist with an increase in the amorphous fraction, as indicated by the shift in T_g. This could be the result of heterogeneity in HC dispersion or partial PLA degradation, leading to localized changes in chain mobility and crystal structure. PLA reinforced with phytic acid-functionalized hydrochar (PLA_HC-P) showed a slight increase in T_g compared to PLA_HC. This may be attributed to improved interfacial interactions between HC and the PLA matrix, promoted by phytic acid, which can reduce the interfacial free volume and limit chain mobility [26]. Nonetheless, the T_g remained lower than that of neat PLA, and a reduction in crystallinity was observed in comparison to PLA_HC.
This behavior could be explained by multiple concurrent phenomena, including a potential and mild plasticizing effect of phytic acid on the PLA matrix, which can increase chain flexibility and thus reducing crystallinity [44,45].

Sample	T_g (°C)	T_{cc} (°C)	T_m (°C)	ΔH_{cc} (J g^{-1})	ΔH_m (J g^{-1})	χ_c (%)
PLA	59.6	117.6	147.9	11.4	15.9	4.9
PLA-HC	53.6	118.9	147.2	19.1	23.8	6.3
PLA_HC_P	54.8	115.9	146.7	22.5	24.8	3.1

Table 2: DSC results of PLA, PLA_HC and PLA_HC-P

Dynamic mechanical analysis (Table 3) provided further insights into the thermomechanical behavior of the composites. The storage modulus (E′) of PLA_HC was significantly lower than that of neat PLA, suggesting a plasticizing effect induced by the presence of hydrochar. This reduction in stiffness may be attributed to the limited interfacial adhesion between HC and the PLA matrix, and the tendency of HC particles to form aggregates, which can act as stress concentrators and disrupt efficient load transfer[46]. Consistent with DSC findings, the glass transition temperature (T_g) of PLA_HC was shifted to lower values, indicating increased chain mobility likely related to the presence of polar groups on HC and possible partial degradation of PLA during processing. Interestingly, the PLA_HC-P sample exhibited a moderate increase in storage modulus compared to PLA_HC and a less pronounced shift in T_g. This suggests that the phytic acid functionalization may improve compatibility and interfacial interaction between HC and the PLA matrix [26].

Sample	E' (MPa)			T_g (°C)
	at 40 °C	at 50 °C	at 60 °C	
PLA	3229	3130	398	63.8
PLA_HC	2487	527	22	58.2
PLA_HC-P	2687	2023	20	59.5

Table 3: DMA results of PLA, PLA_HC and PLA_HC-P

The flexural tests showed (Table 4) a decrease in flexural strength and elastic modulus for both PLA_HC and PLA_HC-P composites compared to neat PLA, with strain at maximum load remaining relatively unchanged. Although DSC analysis revealed an increase in crystallinity for PLA_HC, the mechanical weakening observed can be attributed to poor interfacial adhesion and the formation of HC aggregates, which act as stress concentrators and impair effective load transfer [13]. Conversely, PLA_HC-P exhibited reduced crystallinity relative to PLA_HC, which might lower stiffness. Nevertheless, interfacial interactions due to phytic acid functionalization help recover mechanical performance by minimizing aggregation and promoting better stress transfer. This balance results in PLA_HC-P having somewhat better flexural properties than PLA_HC, despite the decreased crystallinity.

	Strain %	**Flexural Strength MPa**	**Flexural modulus GPa**
PLA	3.9 ± 0.1	98.6 ± 1.7	3.5 ± 0.2
PLA_HC	3.2 ± 0.3	53.5 ± 3.0	2.5 ± 0.2
PAL-HC-P	3.9 ± 0.1	57.0 ± 4.3	2.5 ± 0.7

Table 4: Flexural results of PLA, PLA_HC and PLA_HC-P

The PLA composite reinforced with phytic-acid-modified hydrochar (PLA_HC-P) showed notable improvements in fire behavior compared to the unmodified system (PLA_HC). Specifically, cone calorimetry revealed a 15% reduction in peak heat release rate (pHRR), a 13% decrease in total smoke release (TSR), a 12.5% reduction in specific extinction area (SEA), and a 12.9% decrease in maximum average rate of heat emission (MARHE). These results indicate that the incorporation of phytic acid enhances the flame-retardant performance of the composite. The phosphorus-rich structure of phytic acid likely promotes the formation of a stable and protective char layer during combustion, which limits heat and mass transfer. Moreover, the modification alters the thermal degradation pathway, reducing the release of flammable volatiles and smoke. This suggests a synergistic flame-retardant effect, combining condensed-phase char promotion and gas-phase flame inhibition, resulting in improved fire safety of the PLA-based composite.

4 CONCLUSIONS

This work demonstrates the potential of hydrochar (HC) derived from Brewers' Spent Grain (BSG) as a sustainable filler for PLA-based biocomposites. The hydrothermal carbonization (HTC) process enabled the direct valorization of wet agro-industrial waste into a porous, carbon-rich material without the need for drying or activation. Structural, morphological, and chemical characterization of the HC—through SEM-EDS, FT-IR, BET, elemental analysis, and Boehm titration—confirmed the development of a heterogeneous, oxygen-functionalized surface suitable for further chemical modification. Surface functionalization with phytic acid (PA) introduced phosphorus-containing groups onto the HC, as confirmed by FT-IR analysis, with the aim of enhancing flame retardancy and improving compatibility with the PLA matrix. Thermal analysis indicated that HC alone tended to promote earlier degradation of PLA, while phytic acid modification delayed degradation and enhanced char formation, suggesting increased thermal stability. Calorimetric data showed changes in crystallinity behavior, with HC promoting nucleation and PA-modified HC slightly suppressing it, likely due to altered filler–matrix interactions.

Dynamic mechanical and flexural tests highlighted a reduction in stiffness and strength with HC, partially recovered when the filler was functionalized, confirming the positive effect of PA on dispersion and interfacial adhesion. Cone calorimeter tests showed that the addition of phytic-acid-modified hydrochar (PLA_HC-P) resulted in improvements in fire behavior, with reductions of 15% in pHRR, 13% in TSR, 12.5% in SEA, and 12.9% in MARHE compared to the unmodified composite. Overall, the combined use of hydrochar and phytic acid offers a promising strategy to produce bio-based composites with improved thermal stability, enhanced flame retardancy, and acceptable mechanical properties, while promoting circular economy principles through the upcycling of food industry residues.

ABSTRACT

The solar sail is a promising propulsion concept that utilizes solar radiation pressure to navigate in space without propellant, enabling missions otherwise unattainable with traditional propulsion methods (e.g., electric or chemical propulsion). This paper presents the design of the structural subsystem of a 35x35 monolithic solar sail, with a specific focus on composite the deployable booms responsible for deploying and tensioning the sail membrane. Structural numerical analyses are conducted both on a full-scale model of a single boom and on the solar sail system. The former is intended to estimate the critical buckling load of the composite booms, the latter is used to determine the axial load acting on the boom tips due to membrane tension and to evaluate maximum sail displacements caused by solar radiation pressure. The axial load acting on the boom tip must remain below the critical buckling value, and the maximum displacement of the sail must not exceed 1% of the sail's side length. In this work, we designed composite deployable booms to meet these requirements and prototyped them at lab-scale.

1 INTRODUCTION

Solar sail propulsion systems have long been of great interest for space missions. Unlike chemical or electric propulsion, which require onboard propellants, solar sailing uses an external source of propulsion, harnessing the Sun's power through the momentum transfer of photons that impact and reflect off the membrane [1].

Spencer and co-authors provide a survey of the state-of-the-art of the solar sailing technology [2]. According to their work, the first advanced conceptual study dates to the late 1970s when the Jet Propulsion Laboratory designed a spacecraft that would make a rendezvous of Halley's Comet. Later, the DLR-ESA-INVENT carried out the first ground test of a fully deployable solar sail structure in 1999. During the test, four carbon fiber reinforced polymer (CFRP) booms were deployed with the four triangular segments of the sail [3]. In 2010, the interplanetary kite-craft accelerated by radiation of the Sun (IKAROS), sponsored by the JAXA, was launched and successfully deployed a 196 m2 solar sail on route to Venus [4]. Meanwhile, NASA developed the Nano Sail-D mission to demonstrate both the deployment of a sail from a three-unit CubeSat and the sail capability of accelerating spacecraft de-orbiting thanks to the increased atmospheric drag. The first Nano Sail-D unfortunately underwent a launch failure, whereas its flight spare satellite, NanoSail-D2, successfully deployed a 10m2-sail from a three-unit CubeSat. However, the results were not those expected since NanoSail-D2 remained in orbit for 240 days before re-entry even if it was supposed to deorbit from the initial 650 km altitude in 70-120 days [5]. Likewise, the LighSail programme, by the Planetary Society, involved solar sail technology using three-unit CubeSat. During this programme, LightSail-1 successfully deployed a 32 m2-solar sail [6] and, for the first time, LightSail-2 exploited the solar radiation pressure to perform an

apogee raising from a low Earth orbit (LEO) [8]. On April 23, 2024, the NAS's mission Advanced Composite Solar Sail System (ACS3) featuring a square-shaped solar sail with an approximate 0 m side was launched and successfully deployment of the composite boom solar sail in LEO in August 2024 [7].

For solar sail missions, the general trend is to use four deployable booms to unfurl and tension the sail. Deployable booms can be categorized according to the cross-section geometry, the most popular being: Storable Tubular Extendible Member (STEM), Collapsible Tubular Mast (CTM), and Triangular Rollable and Collapsible (TRAC). A STEM is generally made of a thin-walled composite shell with circular cross-section [8], a CTM is made of two thin flexible shells with a bi-convex shape bonded at their edges cite [9,10] a TRAC is composed by two curved C-shaped section joined along one[11,12], and a SHEARLESS boom is formed by coupling the edges of two cylindrical shells front-to-front by a tightly-fitted outer sheath [13,14]. In this work, we consider CTMs.

The design of deployable booms serving as fundamental structural component in the solar sail system is particularly delicate. These booms must apply enough tension to the membrane to avoid significant out-of-plane deflections, while also withstanding compression without buckling. While numerical analysis can come at hand, structural simulations of solar sail systems often struggle with convergence due to the nonlinearities introduced by the large, thin membranes and the slender, flexible booms [15]. In 2002, Murphy and co-authors proposed a pre-tensioning method to solve convergence issues [16]. The pre-tensioning step allows the membrane to get out-of-plane stiffness to run the subsequent dynamic analysis and get the system's first ten natural modes. Talegani et al. maintained the same strategy and, in addition to predict the vibration modes, performed a geometrically nonlinear static analysis to evaluate the full-scale deformations of the pre-tensioned solar sail systems [17]. Sleight and Muheim performed a parametric study on a 150 m sail with a variable pre-stress at the center of its triangular segments (from 0.1 to 5 psi) [18]. After pre-tensioning, the sail deflection shows an inflection point as the pre-stress level increases from 1 to 3 psi, while the boom deflections increase continuously, as well as its compression level. Sleight and Muheim used a fictitious thermal load to contract the cables connecting the booms and the sail corners. Different thermal field results in a variable pre-tensioning scenario. Other methods were proposed to simulate pre-tensioning such as the quasi-random application of small out-of-plane forces to get a feasible static sail [19]. In this work, we use the pre-tensioning method with a fictitious thermal field.

In previously presented works, system-level models of solar sail structures often lack detail in the representation of individual booms. These components are frequently simplified as one-dimensional beams, with the material typically assumed to be isotropic, whereas in reality, booms are thin-walled shells that may exhibit local instabilities and are often made of composite materials with inherently anisotropic properties. In this work, we aim to investigate the behavior of the boom more thoroughly, treating it as an integral part of the solar sail structure. To this end, we perform a structural analysis of both a single boom and the full solar sail system, modeling the boom in both cases as a two-dimensional shell with anisotropic properties. Two full-scale finite element method (FEM) models are developed. The first is a model of the boom, aimed at evaluating its critical buckling load. The second is a system-level FEM model of the solar sail, consisting of the sail membrane and the boom acting as a support structure. This model is intended to assess the maximum out-of-plane displacement of the sail under solar radiation pressure. The buckling analysis results from the first analysis are then compared with the compression forces acting on the boom to verify whether the boom is truly capable of providing the required tensioning.

2 FINITE ELEMENT MODELS

This section describes the numerical model of the boom used to evaluate its buckling load and the numerical model of the solar sail system developed to identify the compression induced on the booms due to sail's tensioning and the deflection of the tensioned membrane due to solar pressure. The ABAQUS software has been used, which has been compared and validated against other finite element software [17].

2.1 BOOM FINITE ELEMENT MODEL

To ensure efficient impulse transfer and manoeuvrability, the membrane must be placed under tension. As a result, the booms are primarily subjected to axial compression, necessitating a buckling analysis. This analysis provides estimates of the critical load that would cause structural collapse, enabling the application of appropriate pre-tensioning.

The boom is modelled by sketching its cross-section geometry, shown in Fig. 1, where r_1 = 39 mm is the radius of the central arc segment, r_2 = 18 mm is the radius of the edge arc segment, w = 6 mm is the width of the flange, called web, and the subtended angle $\alpha_1 = \alpha_2 = 90°$. The cross-section has then been extruded to a length of 24.75 m. This length was selected to be half of the diagonal of a 35 m square, as the CTMs are intended to support the 35-by-35 meter monolithic solar sail. The boom is modelled as two separate shells, bonded along the web region through tie constraints.

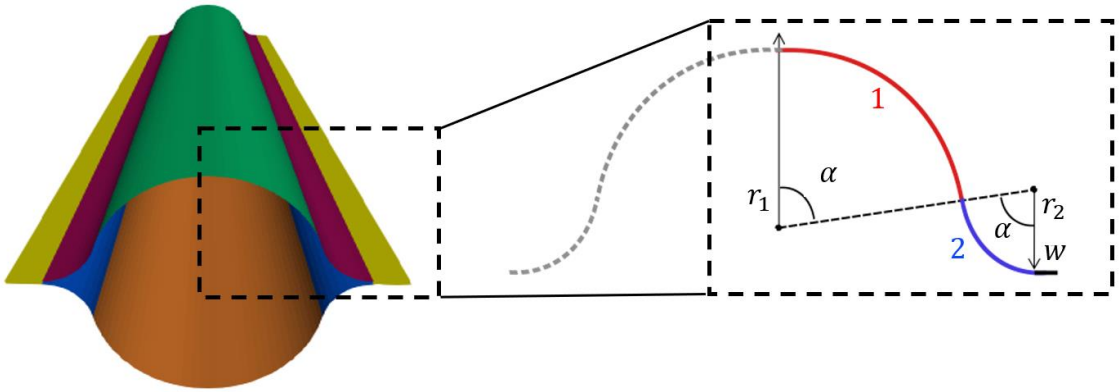

Figure 1. Geometric description on the composite boom.

The mesh consists of 60,500 shell-S4R elements for each shell. In this model, the edge points at the root cross-section are fully constrained in translation and rotation to simulate the interlocking with the bus. In contrast, the edge points at the tip cross-section are constrained in z-rotation only. Additionally, a unit load is applied at the CTM's tip.

The boom is made of a 2-ply composite laminate featuring an anti-symmetric lay-up with fiber orientations of ±45°, a total thickness of 0.16 mm, and a density of 1371 kg/m³. The reinforcement is composed of 6k Toray T300 carbon fiber spread tows, woven into a plain weave fabric. The matrix is the CYTECH CYCOM® 823 epoxy. The mechanical behavior of such material is represented using the ABD stiffness matrix, initially computed via classical laminate theory (CLT). The ABD entries were subsequently refined based on an experimental characterization campaign conducted on specimens made from the same material system. The ABD matrix is as follows, where sub-matrix A is in N/m, while sub-matrix D is in Nm:

$$ABD = \begin{bmatrix} 4.357e+06 & 3.903e+06 & 0 & 0 & 0 & 0 \\ 3.903e+06 & 4.357e+06 & 0 & 0 & 0 & 0 \\ 0 & 0 & 4.074e+06 & 0 & 0 & 0 \\ 0 & 0 & 0 & 9.296e-03 & 8.327e-03 & 6.362e-03 \\ 0 & 0 & 0 & 8.327e-03 & 9.296e-03 & 6.362e-03 \\ 0 & 0 & 0 & 6.362e-03 & 6.362e-03 & 8.692e-03 \end{bmatrix} \quad (1)$$

In this model, the edge points at the root cross-section are fully constrained in translation and rotation to simulate the interlocking with the bus. In contrast, the edge points at the tip cross-section are constrained in z-rotation only. Additionally, a load is applied at the CTM's tip.

The simulation consists of a preliminary linear buckling analysis, followed by a non-linear Riks analysis [14, 20]. In the linear analysis, a unit tip load is applied to the boom to determine its critical buckling load. This critical load is then used in the subsequent non-linear analysis, which is conducted on an imperfect geometry. Geometric imperfections are introduced by superimposing the first three buckling modes, obtained from the linear analysis, onto the undeformed boom geometry. The amplitudes of the mode shapes are scaled to 1%, 0.5%, and 0.25% of the laminate thickness for the first, second, and third modes, respectively. The non-linear analysis is performed using the arc-length method [21–23], with the load applied incrementally through adaptive step sizes.

2.2 SOLAR SAIL SYSTEM FINITE ELEMENT MODEL

The solar sail system is composed by four supporting booms, placed along the diagonals of a 35 m square solar sail. The sail is supported by four 20 cm cables, which simulate the connection between the booms and the sail. The inner ends of the cables are attached to the corners of the sail, while the outer ends are connected to the tips of the booms via MPCs. Interactions between the assembly parts are modelled through the *General contact giving a "Hard" Contact normal behavior which avoids penetration between their surfaces.

The sail is modeled as a membrane, whose section has a thickness of 2.5 μm [24]. The sail is discretized by M3D4R elements, which are 4 node quadrilateral membrane elements, with reduced integration and hourglass control.

Each cable is modelled as a wire with a circular cross-section of radius 1.58 mm. Cables are discretized by T3D2 elements which are 2-node linear 3-D truss.

The booms are modeled as shells. Its geometric description is given in subsection 2.1. The booms are discretized by S4R elements

The sail and the cables are made of Kapton and Kevlar respectively. Their density and mechanical properties are taken from literature, and they are given in Table 1 [17].

Properties		Kapton	Kevlar
E	[GPa]	2.48	62
ν	–	0.34	0.36
ρ	[Kg/m^3]	1425.2	1440.0

Table 1: Properties of Kapton and Kevlar [17]

The simulation consists of two steps. The first step is the sail tensioning, which involves providing the connection cables with a thermal field. This field is fictitious and acts on cables only, therefore the coefficient of thermal expansion (CTE) is given only for Kevlar, with CTE = $4.6\ 10^{-6} \circ C^{-1}$ [8]. A decrease in temperature causes the cables to contract, which results in tensioning the membrane. In this step, geometric non-linearity is considered. The second step involves applying solar pressure, where a pressure of 2.0334×10^{-5} Pa is applied to surface of the tensioned membrane facing the Sun.

The Interactions, loads and boundary conditions acting in the FEM model of the solar sail system are shown in Fig. 2.

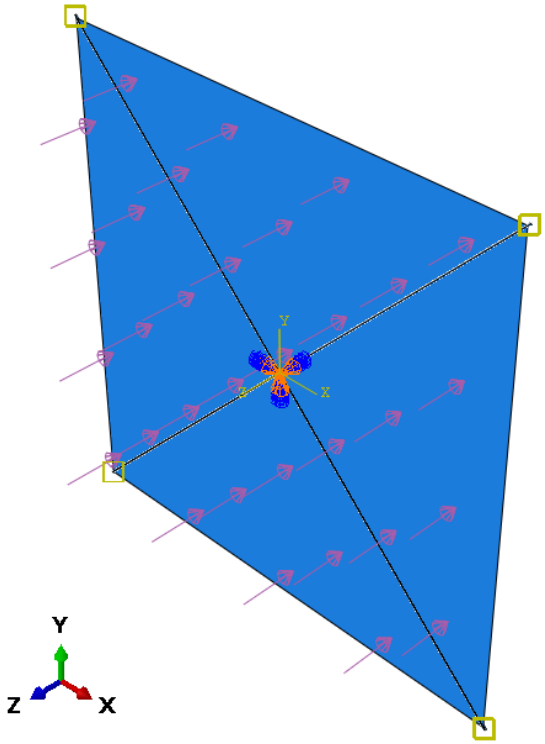

Figure 2. Interactions, loads and boundary conditions acting in the FEM model of the solar sail system.

A dynamic explicit procedure is used, with default values of automatic stabilization. The "improvedDTmethod" algorithm is used to improve the speed of the analysis, allowing to identify the critical time step and avoiding numerical singularities. To further control the analysis, a viscous pressure is introduced as damping effect, limiting the rise of the system kinetic energy and simulating a quasi-static analysis. The viscous pressure used is $3.6\ 10^{-6}$, considering a c_v of $2\ 10^{-2}$ accordingly to Mallikarachchi and Pellegrino's work [25].

3 RESULTS

This section presents both the results of the simulation at the individual component level and at the system-level. The results at the system-level are reported separately for the two consecutive analysis steps: the pre-tensioning and the solar pressure loading results are provided in Sec.3.2.1 and Sec.3.2.2, respectively.

3.1 BOOM FINITE ELEMENT MODEL RESULTS

Firstly, results of the mesh sensitivity analysis are reported in Fig. 3. The starting mesh was composed of about 30000 elements, with an approximate global size of 2 cm. It's shown that the critical buckling load converges at a value of about 1.71 N for a number of elements greater than 60500 for each boom, which is an optimal trade-off between computational time and results accuracy. Such a mesh determined a critical load of 1.7018 N, deviating from the convergence value by approximately 0.65%. The first three buckling modes are presented in Fig. 3.

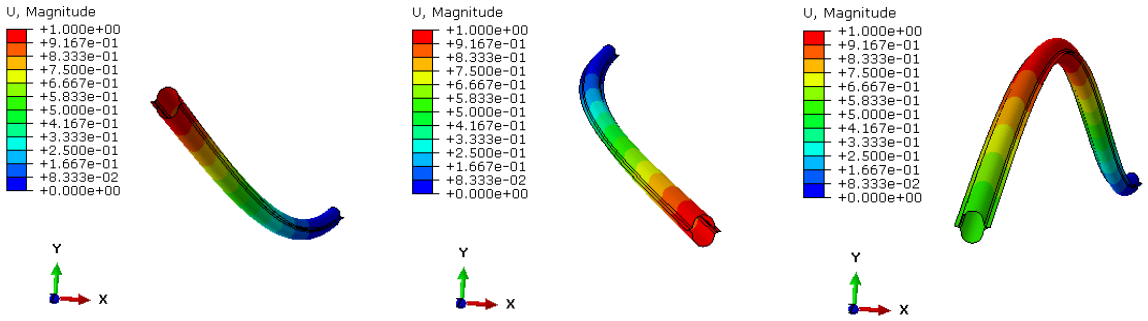

Figure 3. First three linear buckling modes; from the left: 1.7018 N, 1.7607 N, 15.318 N.

The Riks analysis yields the force at the tip vs. tip displacement curve, shown in Fig. 4. The maximum of the curve determines the buckling load of the first mode. The non-linear simulation shows that instabilities occurred at about 1.696 N, reaching 99.7% of the axial load computed in the linear analysis.

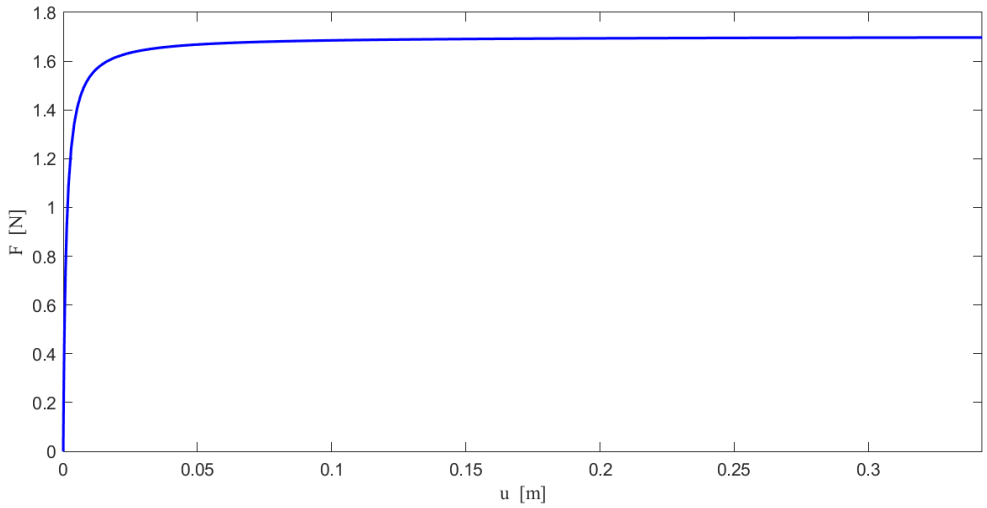

Figure 4. Axial load vs tip displacement curve by the nonlinear buckling analysis.

3.2 SOLAR SAIL SYSTEM FINITE ELEMENT MODEL RESULTS

In Sec.3.2.1 the minimum stress of the membrane due to the pre-tensioning is provided after a sensitivity analysis. Tensioning the sail will cause its stretching. So, the displacement fields are presented as well to evaluate how much and in which directions the membrane is stretched. Subsequently, in Sec.3.2.2 we present the displacements obtained from the solar radiation pressure application to the tensioned system. In plane and out-of-plane fields are evaluated for the membrane, showing very small deformation and therefore the capability of the proposed design to operate properly in the working.

3.2.1 Pre-tensioning results

In Fig. 5 shows the stress distribution over the sail after the pre-tensioning step is shown, where it was determined that a thermal load of -500°C is consistent with the loads observed on the sail surface. Indeed, a stress intensification is registered at the four corners of the sail, with a maximum value of about 2.2 MPa, while the remainder of the membrane is stretched with a stress of the order of Kpa, that

are compatible with the sail material properties, as established in [24]. At this point, the stress over the cables is 49 KPa, that induce a tensioning force on the boom tip of 0.38 N, preserving the integrity of the structure as the nonlinear critical load is about 1.696 N.

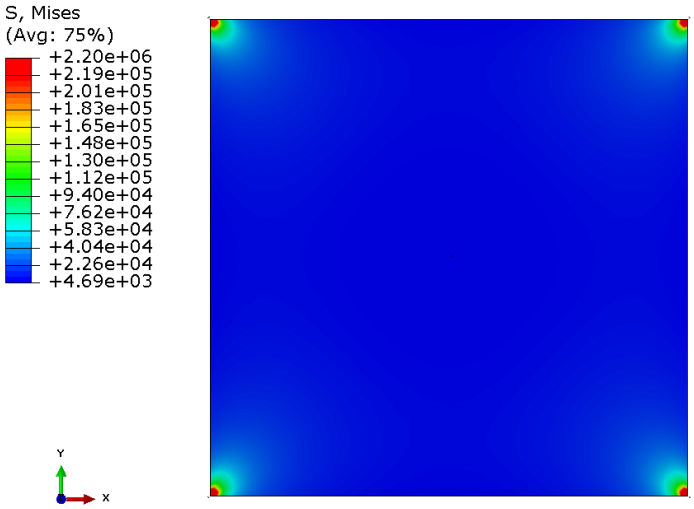

Figure 5. Mises stress distribution over the sail after pre-tensioning phase.

The in-plane displacement observed are less than 1 mm, denoting that the membrane is practically flat and stretched over all the surface, as shown in Fig. 6. Since the sail was defined with membrane-type elements, the out-of-plane displacements cannot be computed without an orthogonal load.

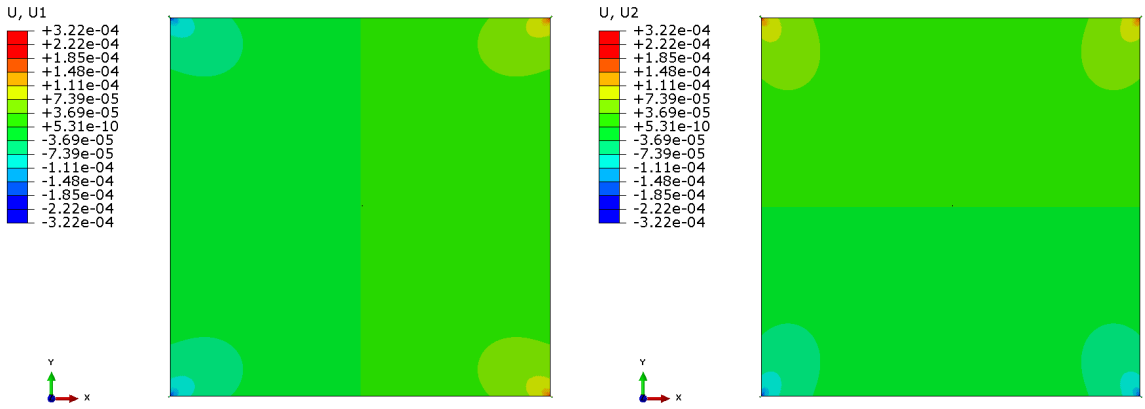

Figure 6. In-plane displacements of the sail after pre-tensioning phase: horizontal displacement on the left, vertical displacement on the right.

3.2.2 Solar pressure loading results

After the application of the solar radiation pressure, perpendicularly to the sail surface, the stress level changed slightly, preserving the same distribution of the previous step as reported in Fig. 7. The stress

value on the cables is slightly reduced compared to the simple tensioning phase; consequently, the boom structures will be able to sustain the overall load computed in the nonlinear analysis avoiding buckling occurrence.

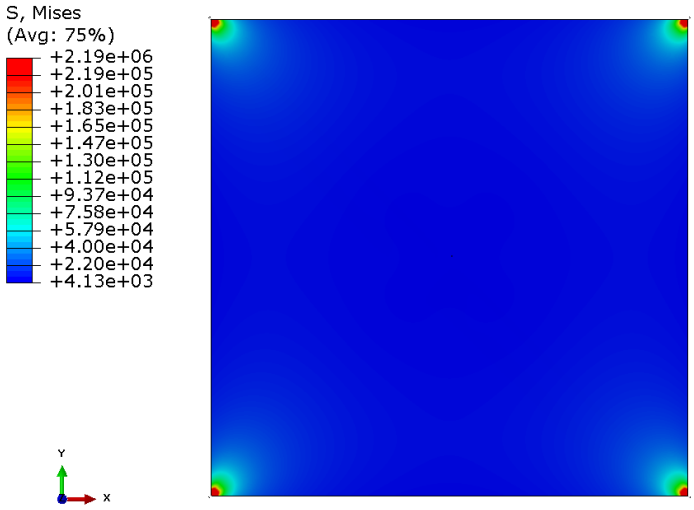

Figure 7. Mises stress distribution over the sail after solar pressure loading.

Similarly, the in-plane displacements are substantially unchanged, Fig. 8, while a negative out-of-plane displacement is observed, aligned to the solar radiation pressure. Due to the presence of the boom structure behind the solar sail, the contact region is identified and highlighted in the contour plot in Fig. 9.

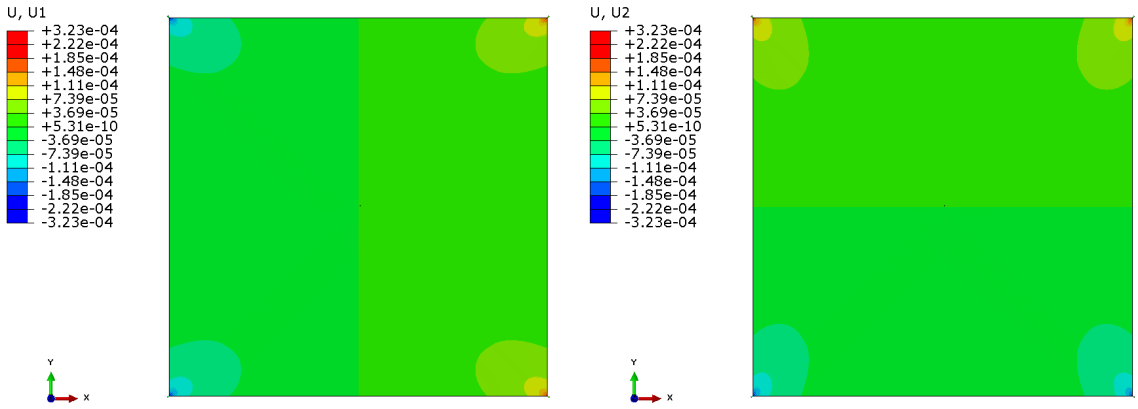

Figure 8. In-plane displacements of the sail after solar pressure loading: horizontal displacement on the left, vertical displacement on the right.

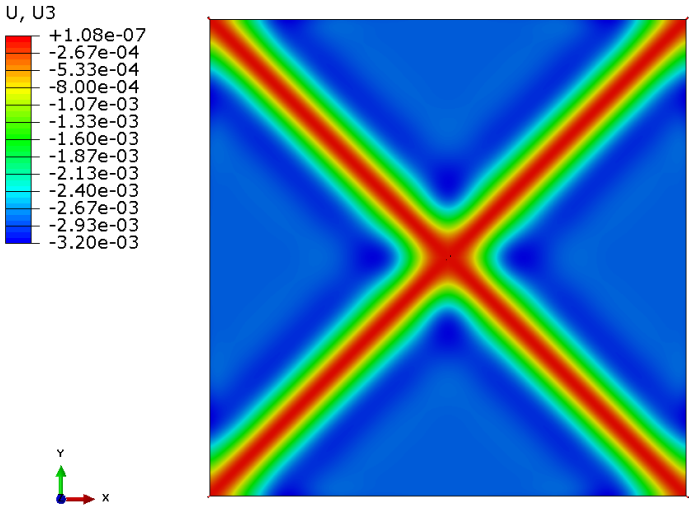

Figure 9. Out-of-plane displacement over the sail after the solar pressure loading.

4. LAB-SCALE BOOM PROTOTYPING

Lab-scale CTMs, each 70 cm in length and with a cross-section featuring all characteristic dimensions scaled at a 2:3 ratio compared to the reference design, were fabricated using a two-step, out-of-autoclave curing process. The two composite shells were cured separately and subsequently bonded together during a second curing cycle.
For each shell, the laminate lay-up and consumable layers were manually draped over a custom-designed mold, Fig. 10.

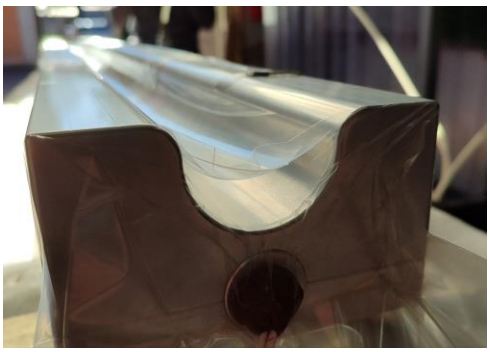

Figure 10. Customized mold for out-of-autoclave boom manufacturing.

The lay-up was then vacuum-bagged together with the mold, and the curing was performed using a feedback-controlled thermal system. This system consists of electric heating cartridges for heat input, a thermocouple for temperature monitoring, and a proportional-derivative temperature controller that regulates current flow to the cartridges. The heating cartridges are inserted into a through-hole running along the axis of the mold, while the thermocouple is placed directly on the mold surface to accurately track its temperature. The temperature controller is positioned for easy access and operation throughout the curing process. The components are shown in Fig. 11.

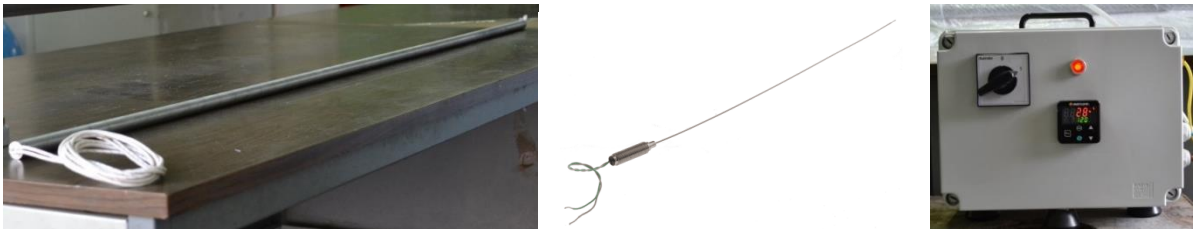

Figure 11. Feedback thermal control system.

The temperature cycle set at the temperature controller is the curing cycle as established per data sheet of CYCOM®823 RTM. (Cure temperature: 125°C, Cure time: 60 mins, Heat up rate: 2°C/min, Pressure: 0bar). At the end of the first cure, the shells were allowed to cool to room temperature and the demolding was performed. Then, a single ply of structural adhesive AF163 − 2K was used to bond together the two shells along their edges, with a cure cycle of 60 mins at 135°C.
In Fig. 12 the manufacturing steps are presented alongside and the prototype, which is characterised by a mean thickness of 0.16 mm.

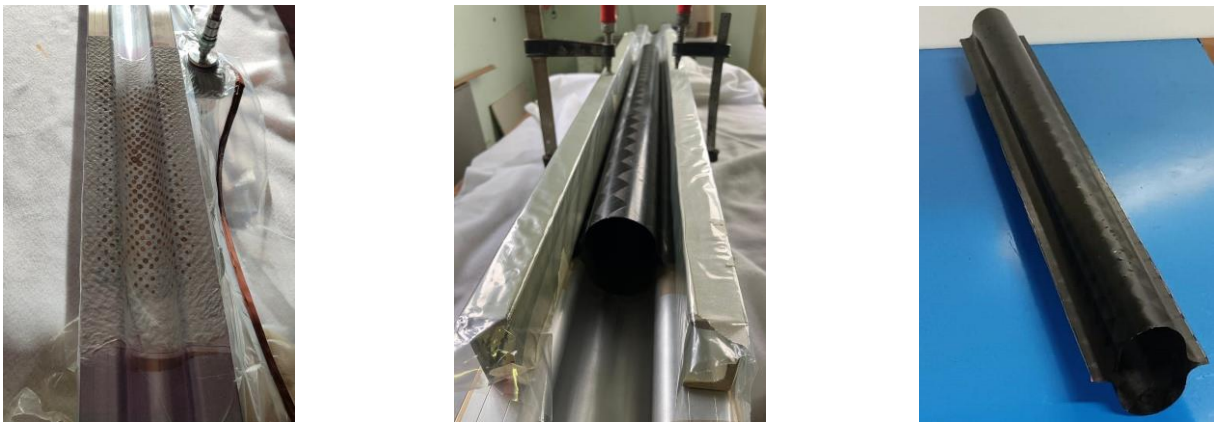

Figure 12. Subsequent steps of boom manufacturing: shell curing cycle with vacuum bag lay-up, adhesive curing cycle, finished boom prototype.

9 CONCLUSIONS

In this work, the design for the boom supporting a 35 by 35 monolithic solar is presented, investigating its structural performances. First of all, the boom critical load at buckling is evaluated. Then the structural behaviour of the solar sail at a system level is investigated. A pre-tensioning value is selected such that the sail achieves stiffness without compromising the boom stability, i.e., compression load acting on the boom tip smaller than its critical buckling value. Within the limits of the maximum stress the sail can sustain, a load on the cables of 0.38 N is reached and the integrity of the boom structures is preserved. Finally, the out-of-plane displacements of the tensioned sail after the application of the solar radiation pressure are evaluated showing negligible deflections. Indeed, the out-of-plane maximum displacements of the membrane is about 3 mm, and the membrane-sail can be considered satisfactorily flat, thus providing a proper solar thrust. Based on these promising results a lab-scale boom prototype has been developed using an out-of-autoclave manufacturing process. Particularly, a two-step technique is proposed, realizing the two half shells of the boom and bonding them with a structural adhesive. The final prototype presents a mean thickness of 0.16 mm and well-aligns with the nominal curvature provided by the mold.

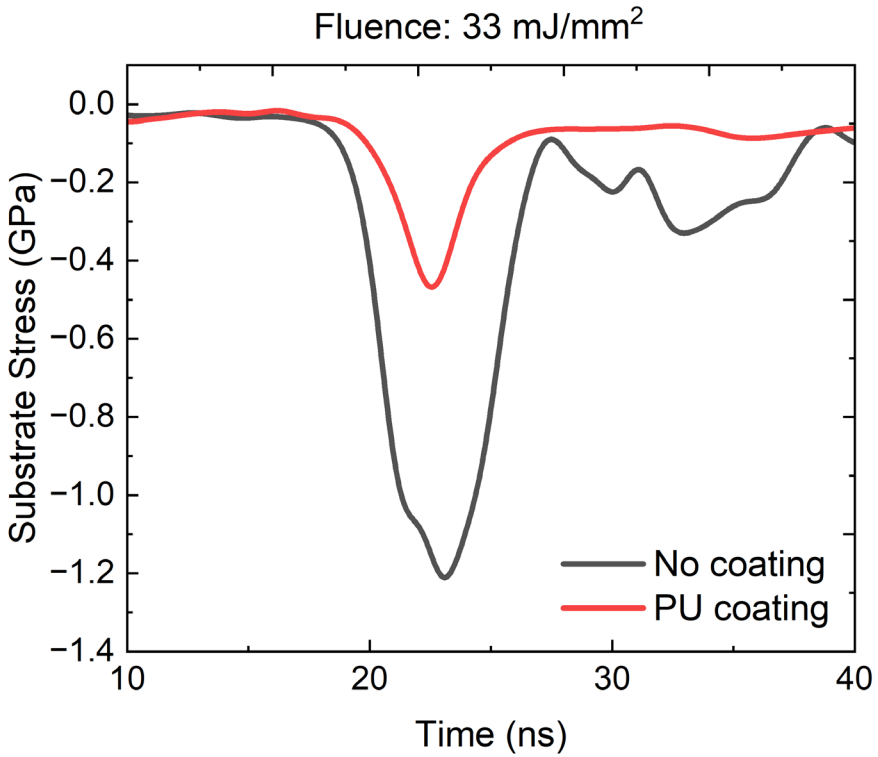
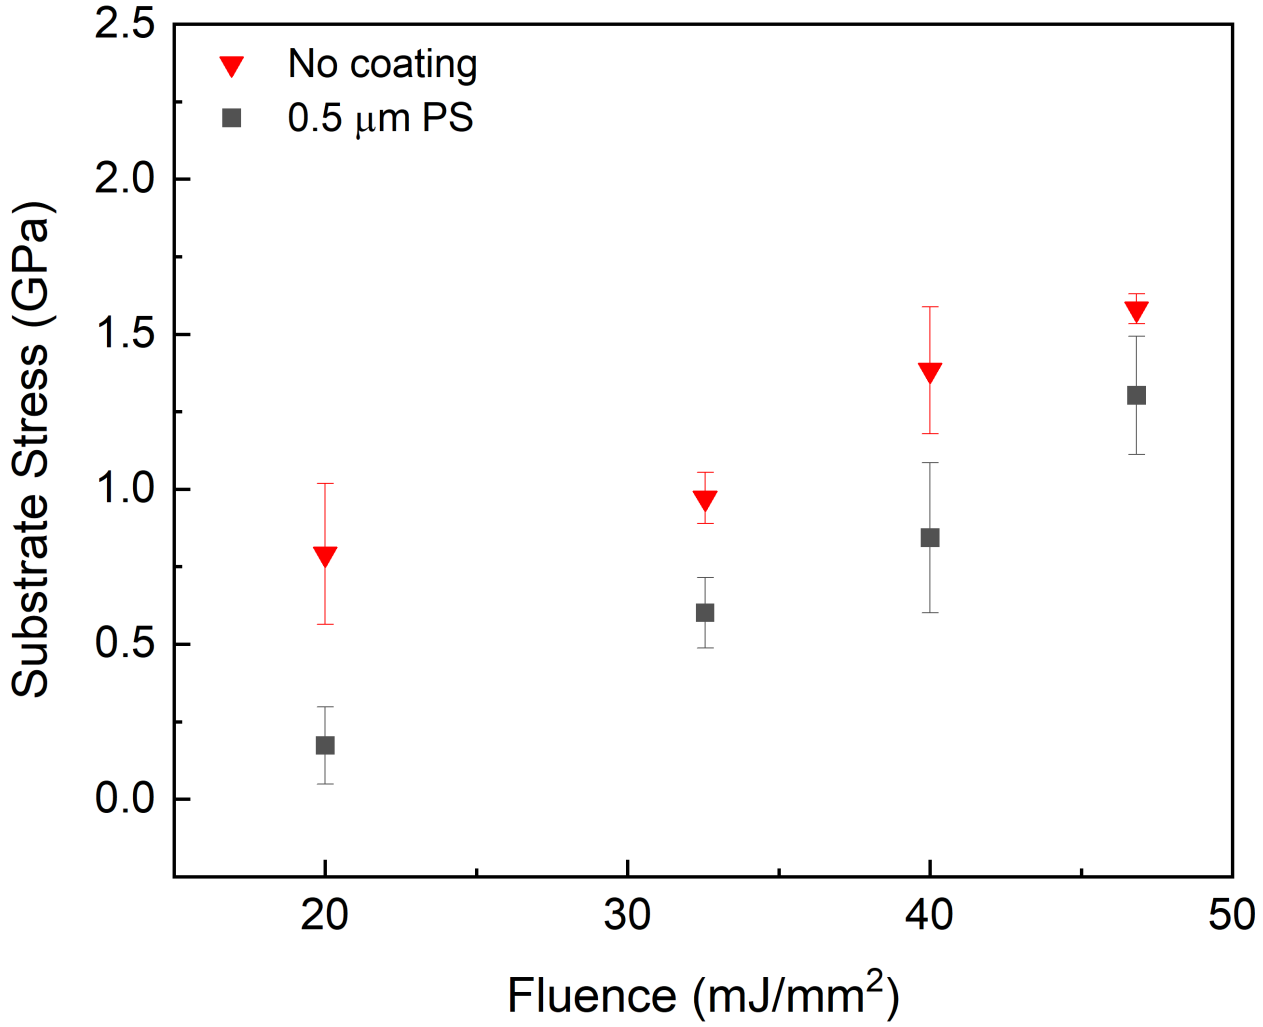
Polystyrene Coating Preparation



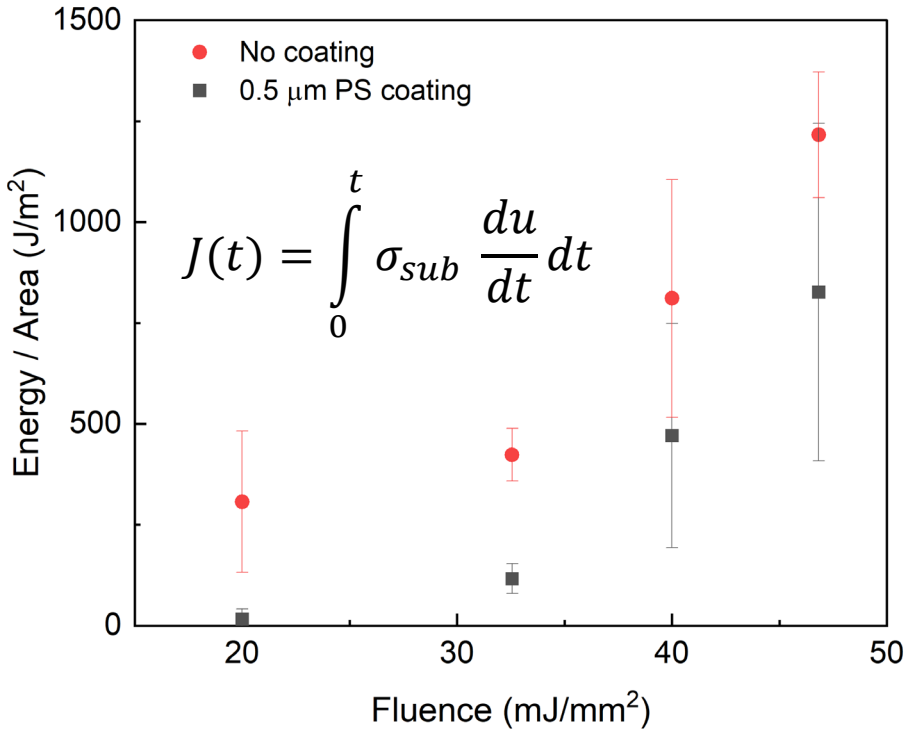
PS Coating Preparation :

Etch the glass substrate using 30% nitric acid → Prepare a 5 wt% solution of polystyrene in toluene → Sonicate the solution for 1 hour → Spin coat the solution at 5000 rpm (ramp: 15 s, dwell: 30 s) → Dry the coated sample in a toluene-saturated environment

Spin coating steps	Ramp	Dwell	RPM
Time (s)	15	30	5000



Polyurethane Coating Stress Wave Dissipation



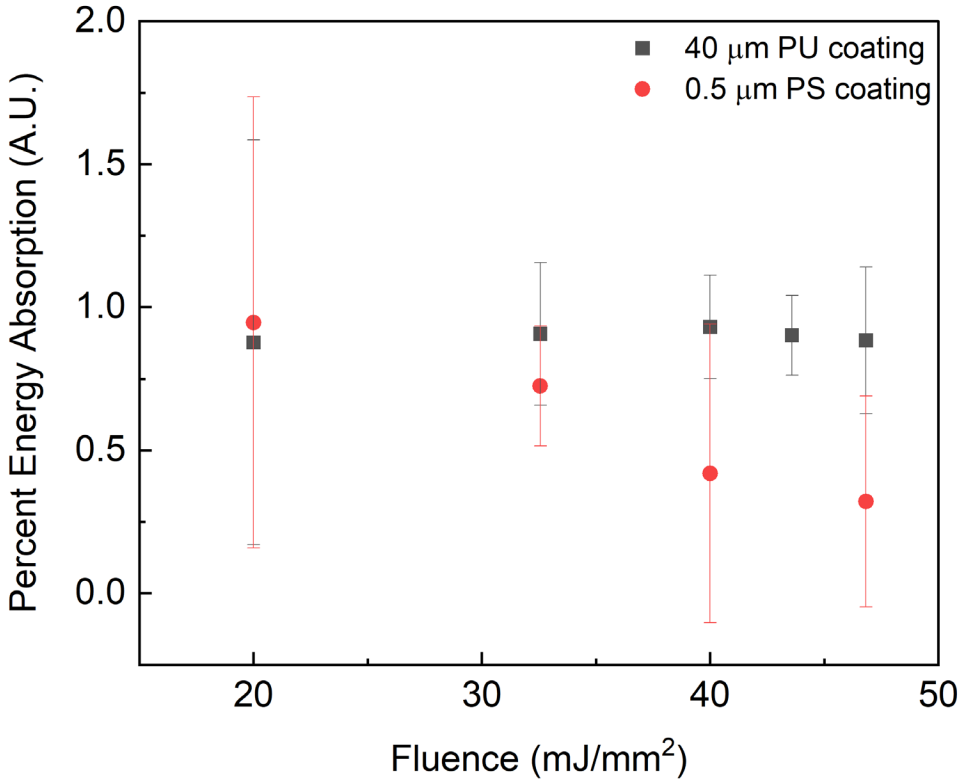
PU sample stacking	Sandwich
Water glass	8 µm
PU coating	40 µm
Reflection	200 nm

Polystyrene Coating Stress Wave Dissipation

PS sample stacking	Sandwich
Water glass	4 μm
PS coating	0.5 μm
Reflection	200 nm

Preliminary Comparison of Stress Wave Energy Absorption by PU and PS Coatings

We evaluated the stress wave energy absorption by polyurethane (PU) and polystyrene (PS) coatings compared to an uncoated control



Total transmitted energy J(t) (J/m^2)

$$J(t) = \int_0^t \sigma_{sub} \frac{du}{dt} dt$$

Percent energy absorption (%)

$$= \frac{J_0 - J(t)}{J_0}$$

J_0: Transmitted energy of the substrate stress
J(t): Transmitted energy of the sample without coating

The effects of thickness on dissipation will be studied in future work.

Summary

- Developed a high-throughput, material-efficient laser-induced stress wave platform for evaluating erosion-mitigating coatings on coupon-scale samples.
- Demonstrated tunable stress wave generation by adjusting laser fluence and confinement layer thickness.
- Preliminary results show both polyurethane (PU) and polystyrene (PS) coatings reduce transmitted stress wave energy compared to uncoated samples.
- Future work will incorporate self-healing functionality and dynamic networks into coatings to achieve active mitigation of erosion damage.

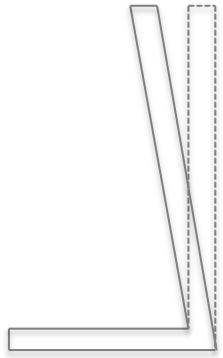
Introduction

- Composite materials play a key role in the aerospace industry
- Significant mass reduction
- Manufacturing processes are costly, partly due to process-induced deformations
- Prediction methods lack accuracy, especially for thin composite parts



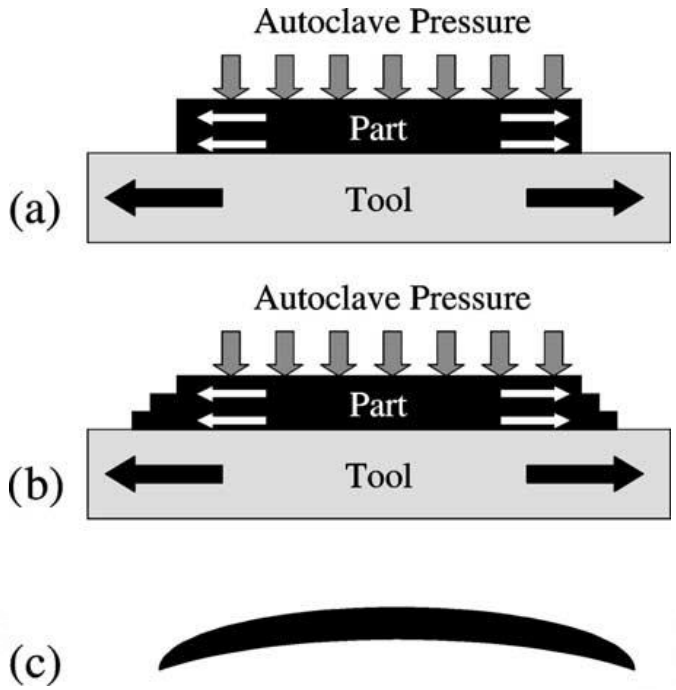
Thin plate warpage [Twigg 2004]

Need for a more accurate model for thin composite parts

Residual deformations of composite parts manufactured in autoclave

- "Composite parts never have the same dimensions as the tool on which they are processed " [Kappel 2018],
- Two types of deformation: spring-in and warpage [Moretti 2020],
- Need to design a compensated mold [Wucher 2014],
- Costly process: based on experimental iterations.

Spring-in



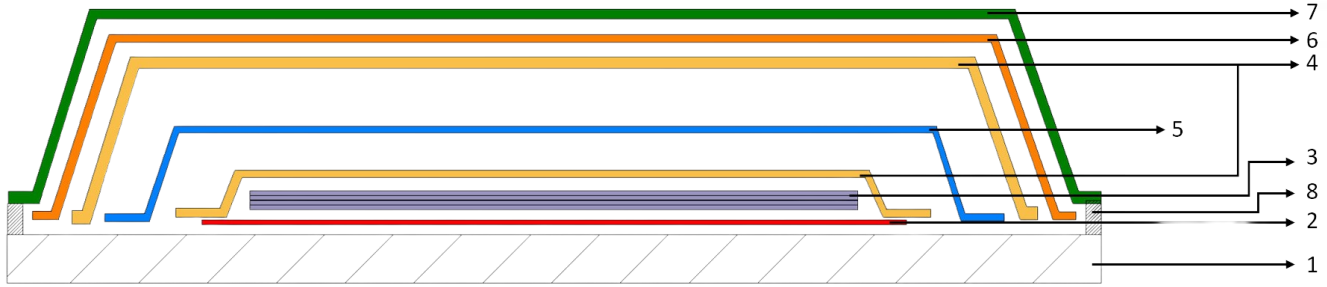
Warpage

Industrial and scientific challenges : prediction of residual deformations, and limiting experimental iterations

The main mechanisms generating residual deformations

- Thermal expansion mismatch [Wisnom 2006],
- Chemical shrinkage [Li 2004],
- Part/mold interaction [Twigg 2004] ,
- Thermal gradients [Bogetti 1992] ,
- Fiber volume fraction [Hubert 2001] .

Part/Mold Interaction [Twigg 2004]



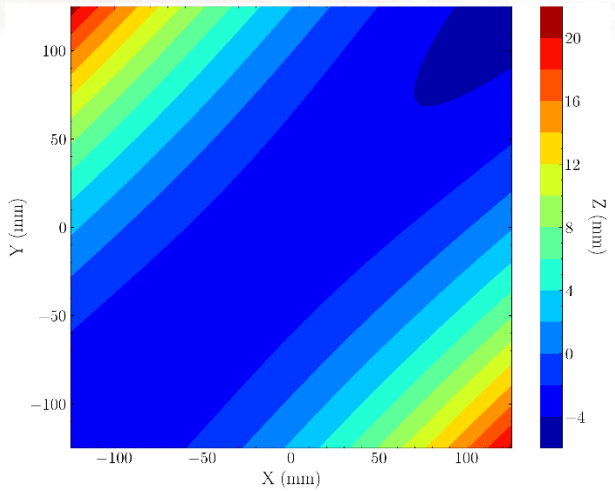
Numerous mechanisms with variable influence: multiphysical modeling is necessary

Table of contents

- Experimental analysis of thin plates process-induced deformations
- Numerical analysis of thin plates process-induced deformations
- Conclusions and perspectives

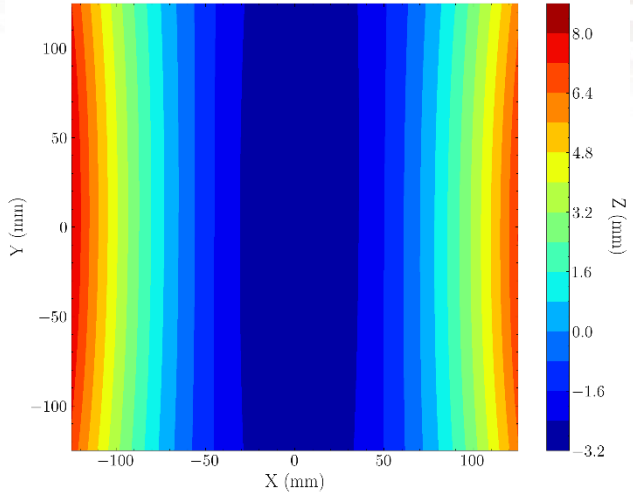
Laminated Plate Manufacturing

- Size 250 x 250 mm,
- Material AS4/8552,
- Layups : [0,90,90,0], [0,90,0,90], [-45,45,45,-45], [-45,45,-45,45],
- Aluminum mold,
- Application of the cycle indicated in the documentation.



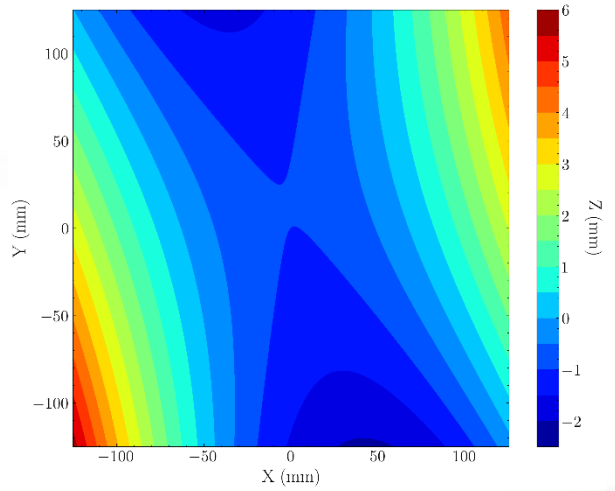
Reference	Designation
1	Aluminium mold
2	Peel ply
3	Composite part
4	Perforated release film
5	Bleeder ply
6	Breather ply
7	Vacuum bag
8	Sealant tap

Indirect measurement of the tool/part interaction effect

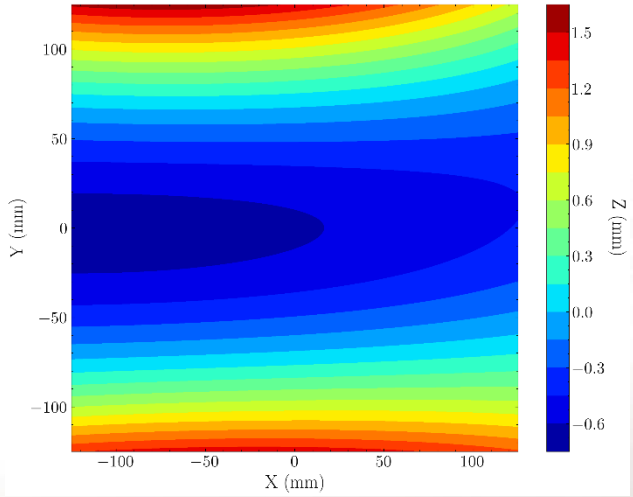


Displacement field measurement

- Dimensional control by stereo **DIC**: non-contact measurement,
- Low dispersion across repeated tests
- Large out-of-plane deflections observed, despite symmetric layup



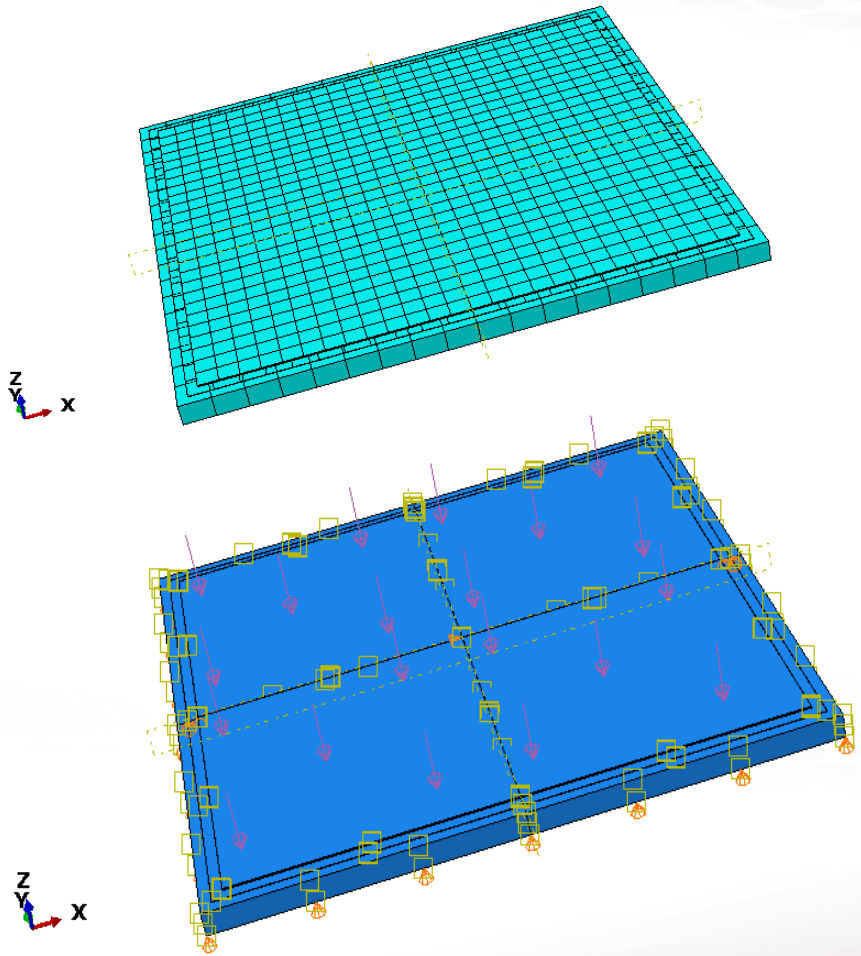
Layup	Measured Flatness
[-45,45,-45,45]	25,6 mm
[0,90,0,90]	11,2 mm
[-45,45,45,-45]	7,8 mm
[0,90,90,0]	2,2 mm



[-45,45,-45,45]

[0,90,0,90]

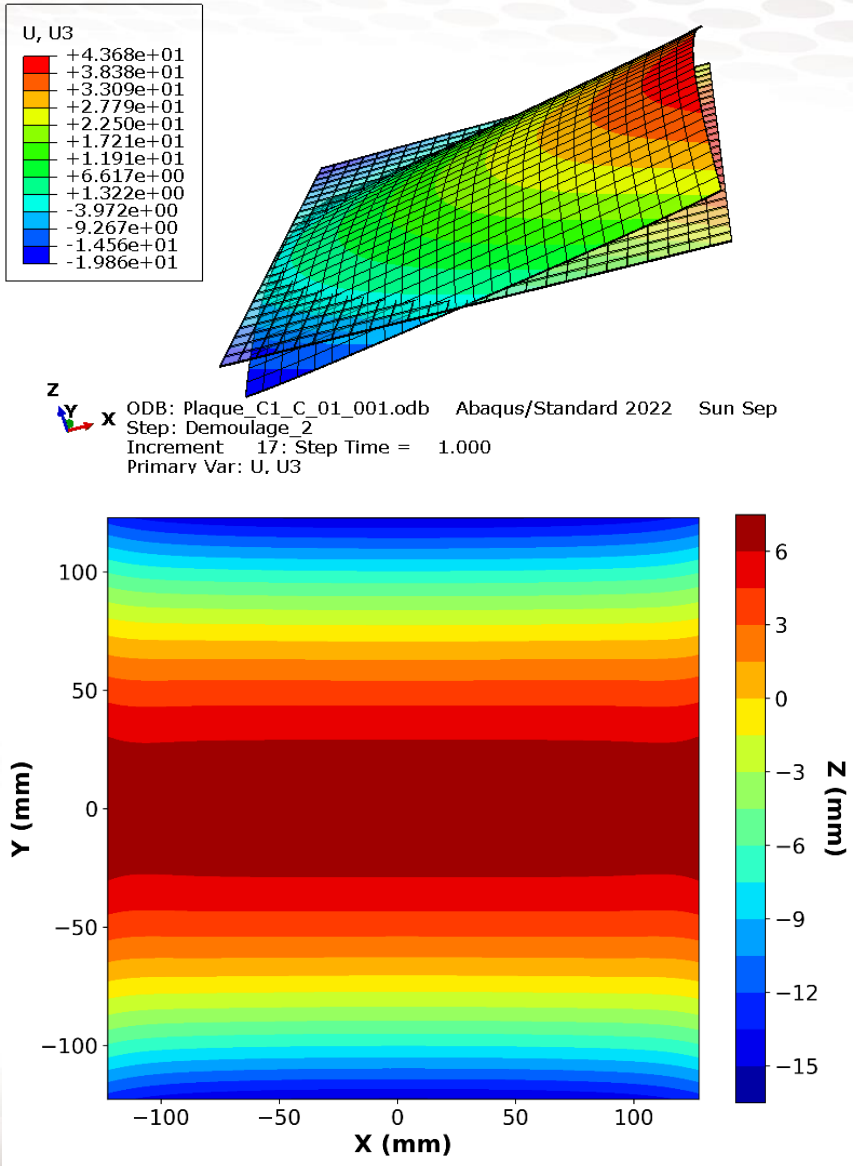
[-45,45,45,-45]



[0,90,90,0]

Significant influence of the tool–part interaction mechanism

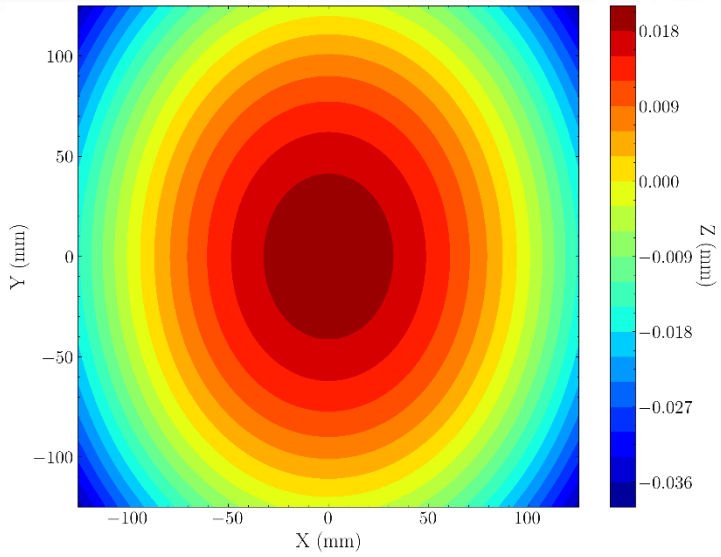
Cure modelling



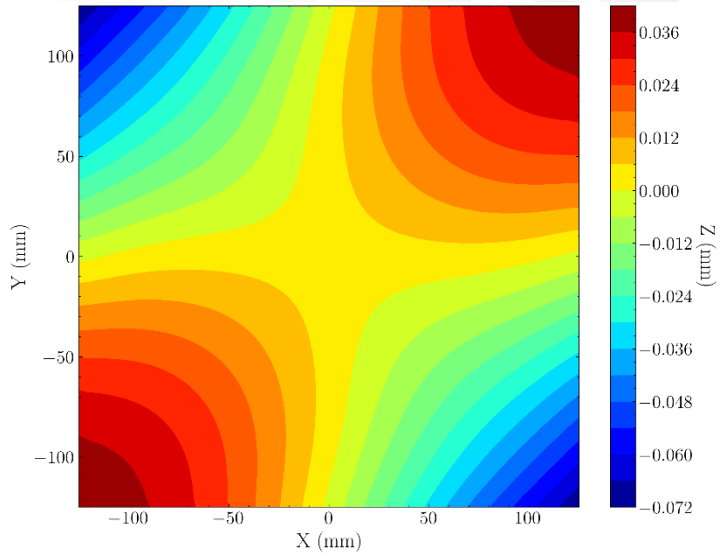
- Development of a UMAT user subroutine in Abaqus : use of the CHILE model
- Frictional contact between mold and part
- Application of pressure and thermal cycles
- After demolding : isostatic positioning

Boundary conditions for demolding affect the displacement field ➔ comparison with experimental results is impossible

Correction of the displacement field



- Need to correct the displacement fields,
- Minimizing the gap between the initial and final shapes,
- Find the translation and rotation matrices of the vector base,
- Then, apply the translation and rotation to the final shape

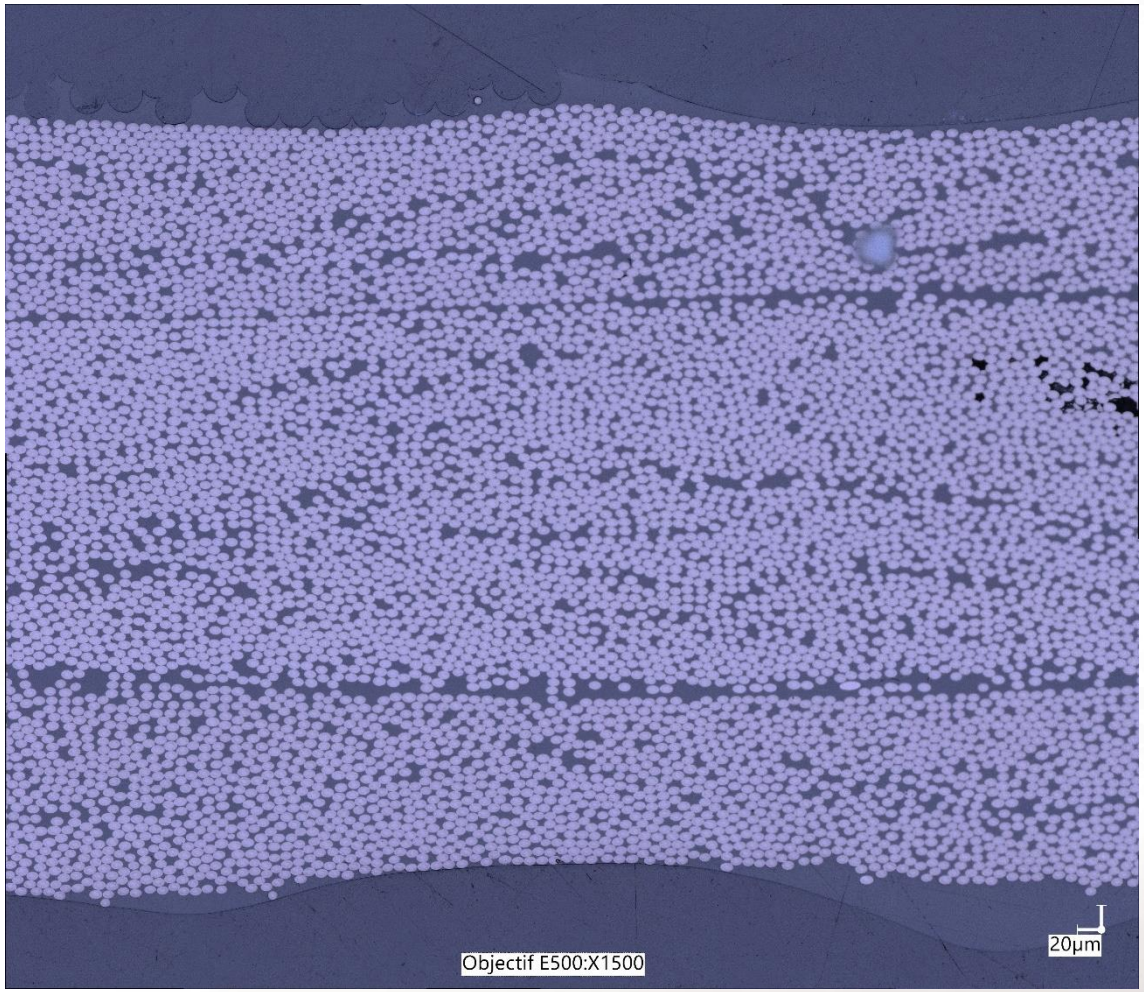


Full cure modelling

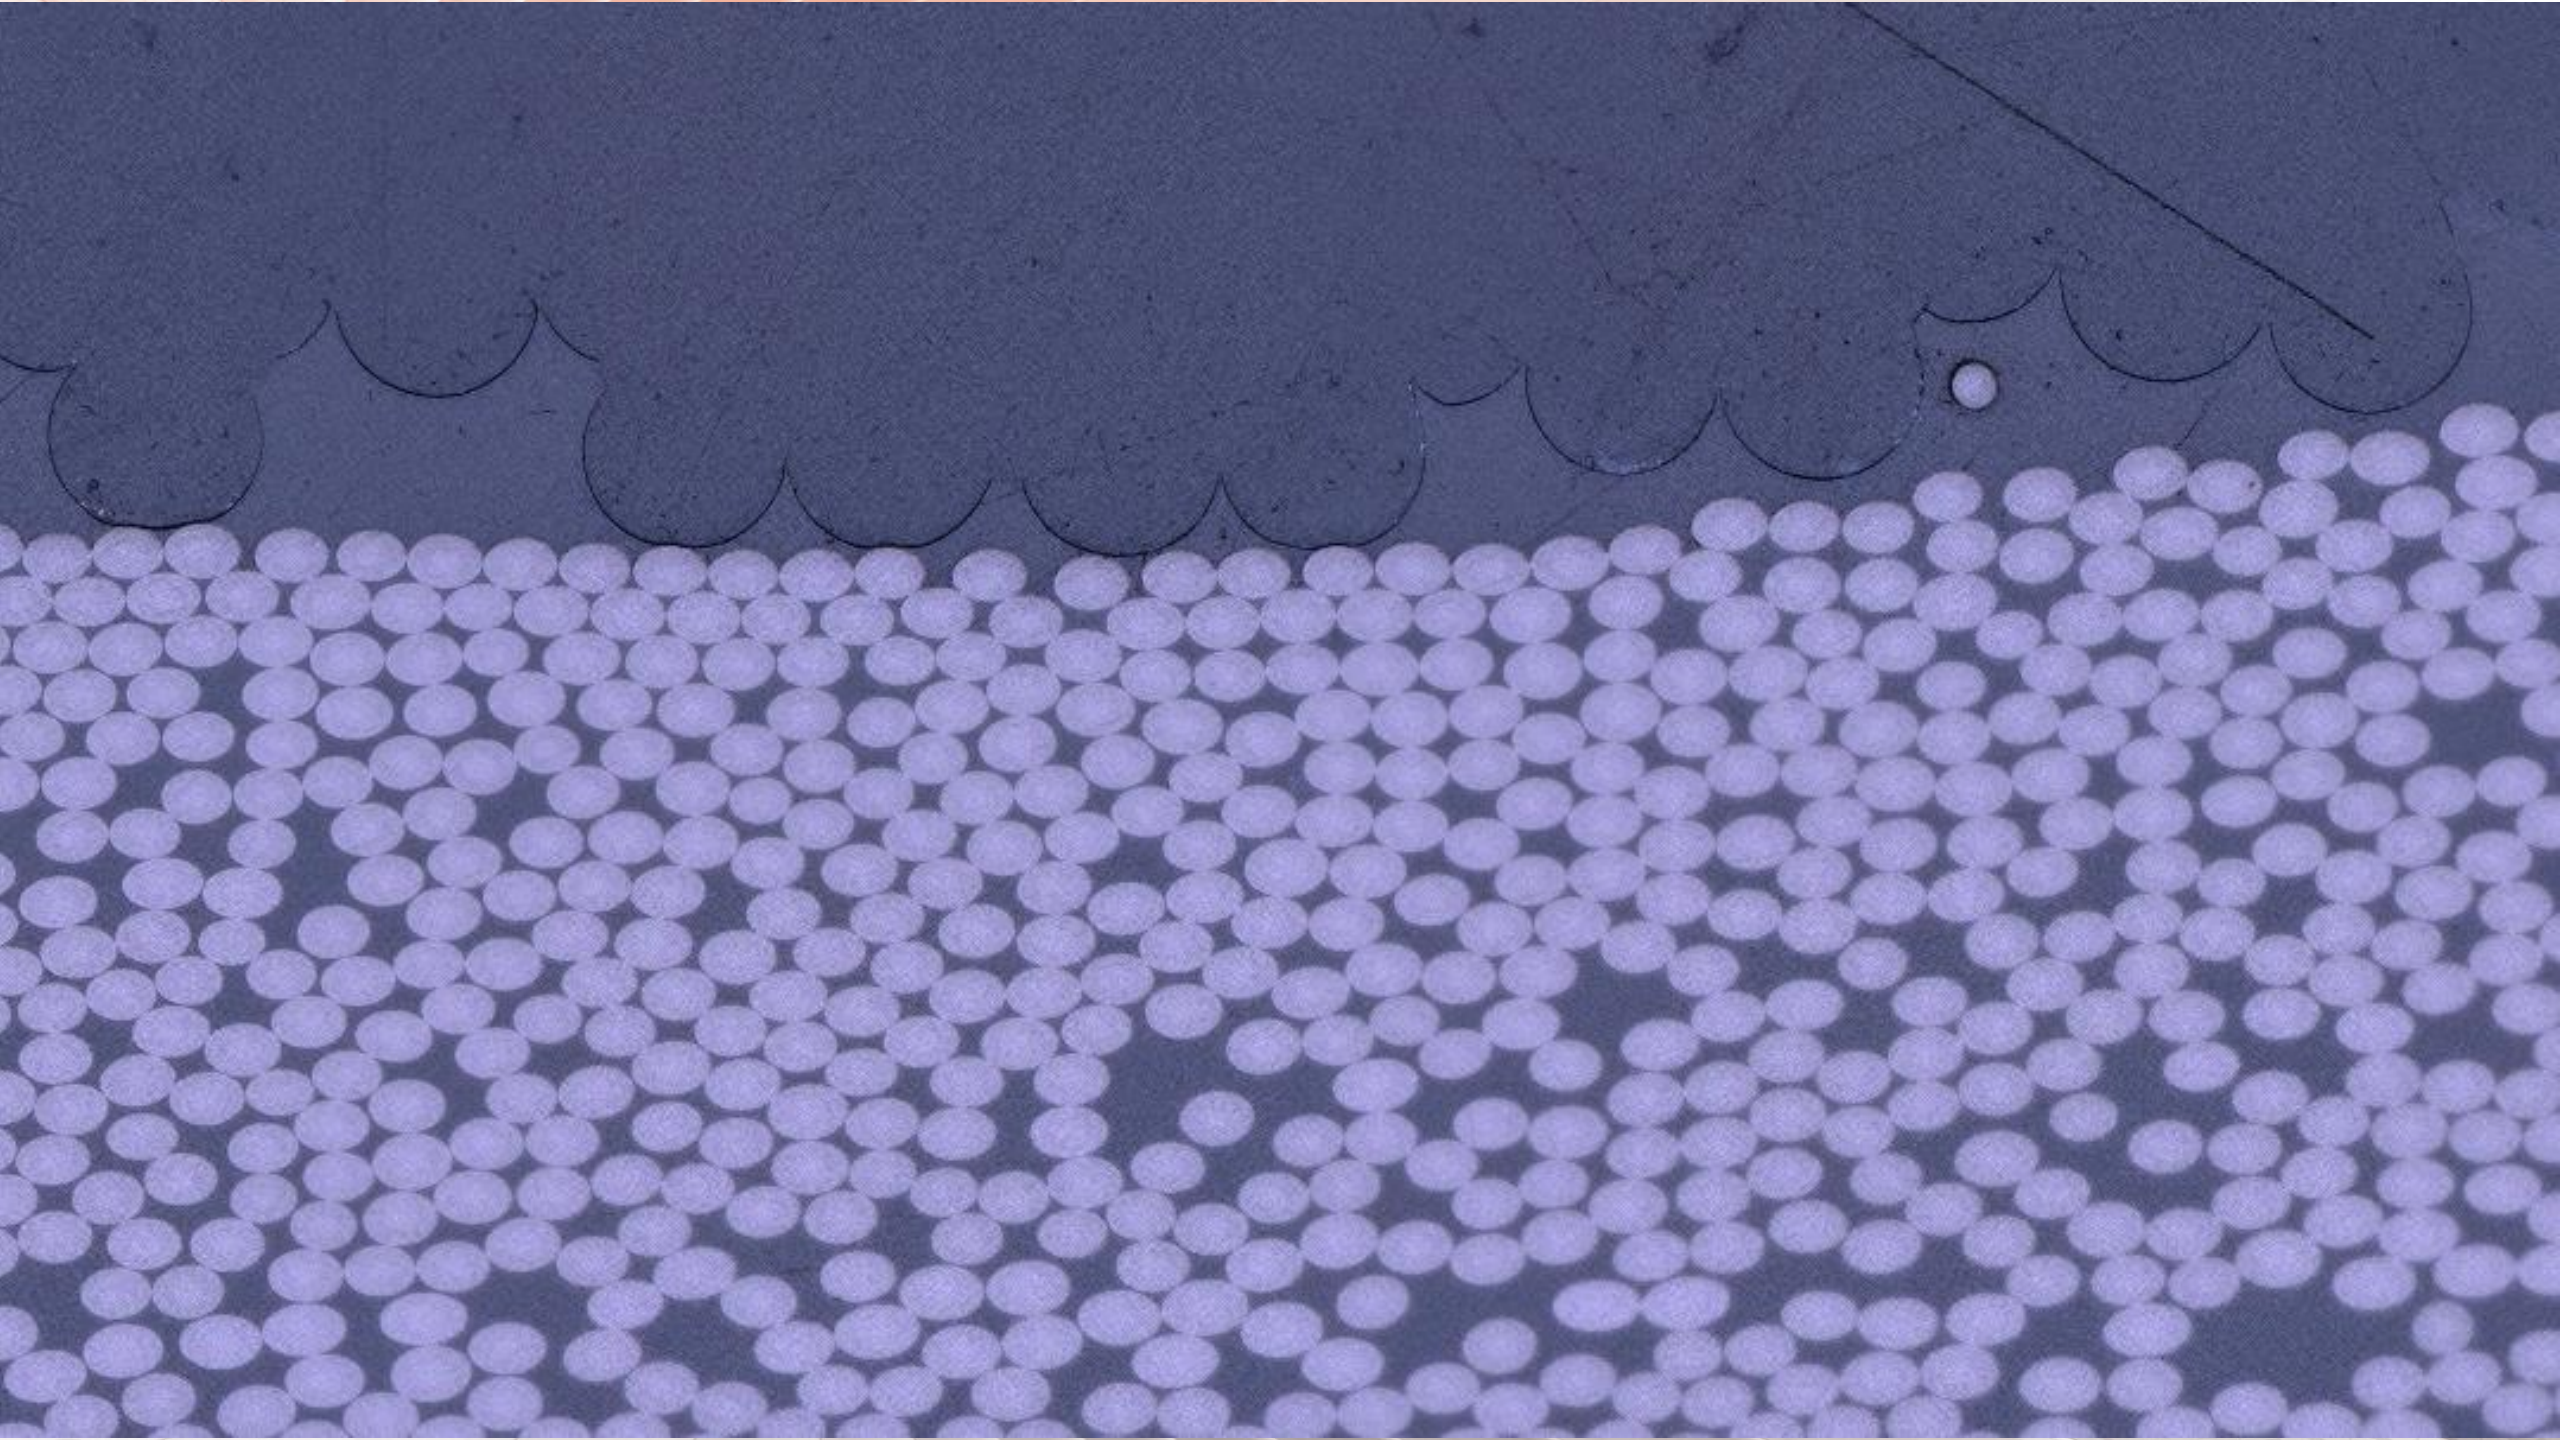
- Main assumption : part free of stress before gelation
- Friction interaction occurs during a small temperature variation before glassy state,
- Practically no stress storage due to the tool/part interaction

The assumption of a stress-free part before gelation is incorrect ?

[0,90,90,0]



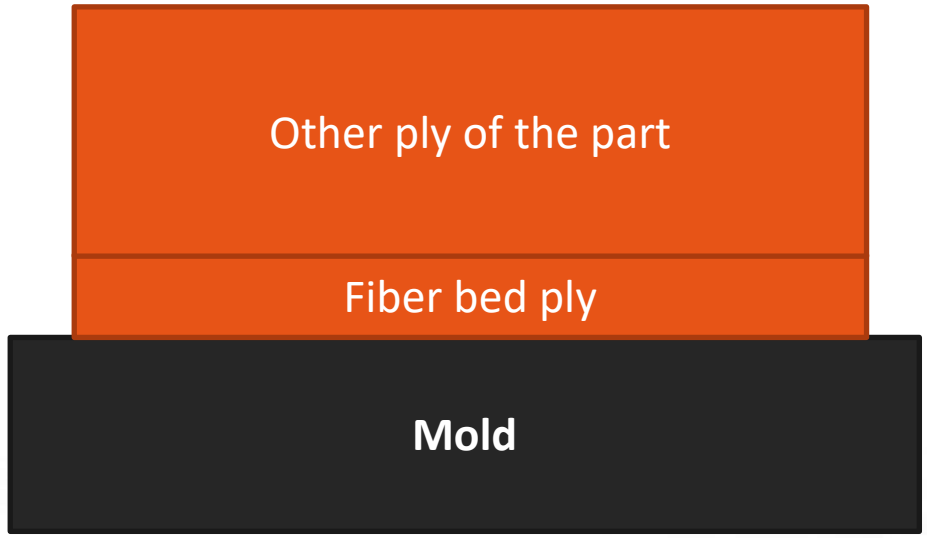
[-45,45,45,-45]



Layup	Measured Flatness	Predicted Flatness
[-45,45,-45,45]	25,6 mm	27,48 mm
[0,90,0,90],	11,2 mm	11,63 mm
[-45,45,45,-45]	7,8 mm	0,11 mm
[0,90,90,0]	2,2 mm	0,06 mm

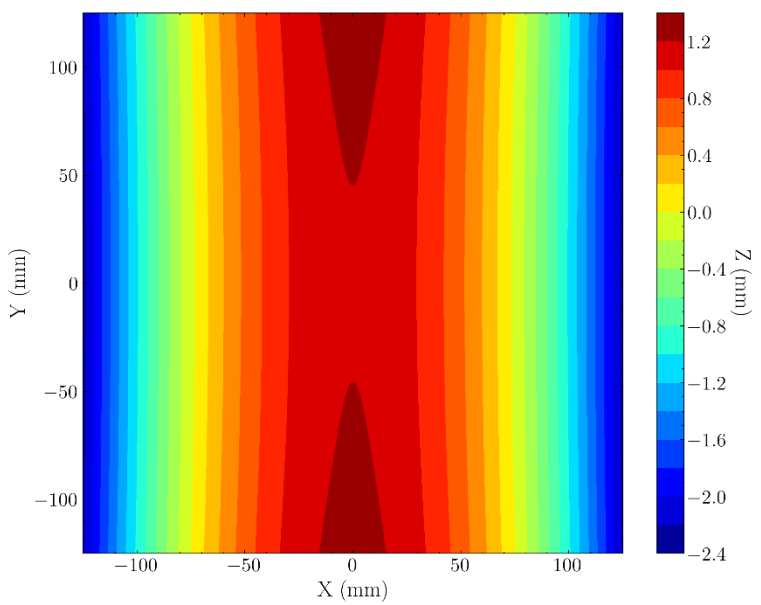
Investigation of Tool–Part Mechanical Interaction Effects

- Some fibers remain in contact with the mold surface
- The assumption of a stress-free state before gelation is not valid
- A sliding friction condition occurs between the mold and the fiber bed
- Tensile stresses are locked-in in the fibers constrained by the mold

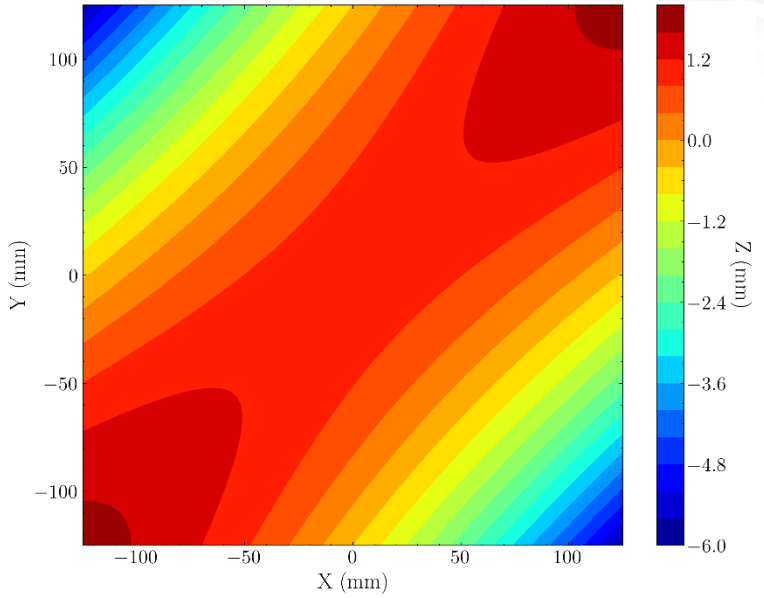


The assumption of a stress-free part before gelation is incorrect

Full cure modelling with tool part interaction : viscous stage



- Simulation without considering the microscale,
- Two materials during the viscous phase
- Frictional contact between mold and part (with f=0.1)
- Displacement continuity assumption between composites plies

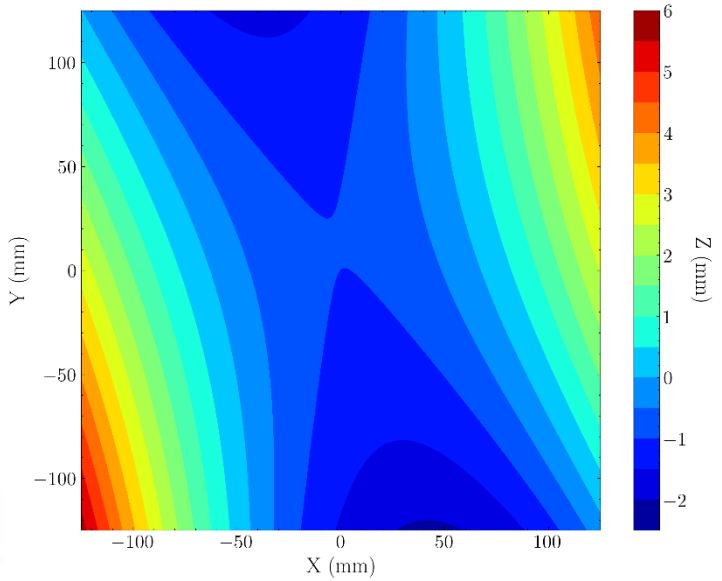


Modelization of the fiber bed stress by considering a ply of fiber in contact with the mold

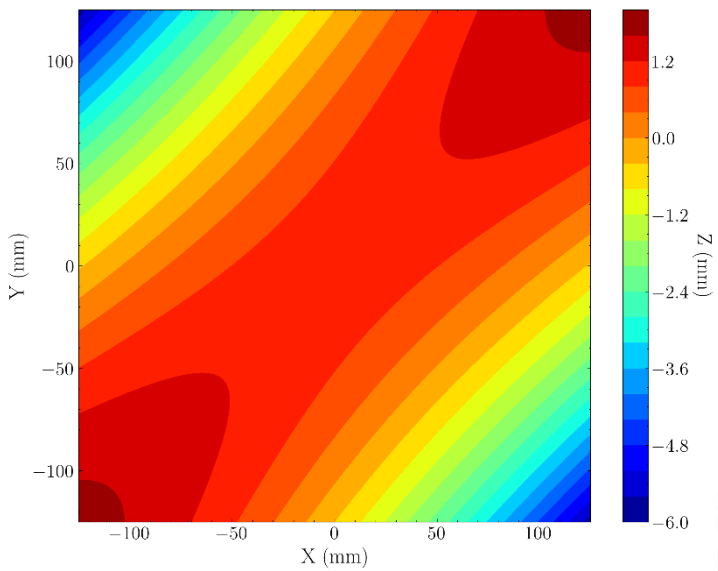
Full cure modelling with tool part interaction : results

- Development of a UMAT user subroutine in Abaqus : use of the CHILE model
- Frictional contact between mold and part (with f=0.1),
- Considerable improvement of the prediction,

[0,90,90,0]



[-45,45,45,-45]



Layup	Measured Flatness	Predicted Flatness
AS45	25,6 mm	27,48 mm
AS90	11,2 mm	11,63 mm
S45	7,8 mm	6,60 mm
S90	2,2 mm	3,46 mm

Full cure modelling with tool part interaction : results

- Asymmetrical layup : out-of-plane residual displacements developed during the glassy stage,
- A friction interaction only during the rubbery stage can not describe the tool part interaction effect,
- Tool part interaction phenomenon takes place during the viscous stage,

Measured shaped (part is returned)

Predicted shaped

Further investigations are needed to improve model accuracy

Conclusions and Perspectives

Conclusions

- An experimental analysis of residual deformations was conducted
- The tool–part interaction was investigated
- A complete simulation method was developed
- A significant improvement in warpage prediction was achieved by accounting for tool–part interaction

Perspectives

- Improve the tool–part interaction modeling through micromechanical analysis
- Focus upon the role of peel-ply
- Apply the in-house digital compensating mold design method
- Validate the compensating mold design using the current part configurations

Keywords: Vanadium redox flow battery, Integrated structure, Low interfacial contact resistance, High conductivity, Multi-cell structure.

ABSTRACT

The bipolar plate is a crucial element of the vanadium redox flow battery (VRFB) as it serves as both the electrical path for the electrolyte and the structural support for the cell within the VRFB stack. The graphite material has been used as the bipolar plate, mostly due to its excellent electrical conductivity. A significant limitation of the VRFB is the presence of several core components. Hence, the internal contact resistance (ICR) arises between the electrode and bipolar plate within the cell stack, and it is significantly greater than the bulk resistance of the corresponding specimens. This study focuses on creating an integrated assembly of the electrode and bipolar plate to address the limitations of the ICR. The integrated assembly was constructed using a single carbon felt specimen. The study resulted in the development of an electrode-integrated BP that exhibited a 28% decrease in overall resistance and a 175% improvement in mechanical properties. Gas permeability and acid aging tests confirmed that the electrode-integrated BP exhibited zero gas permeability and was therefore durable. In conclusion, a two-cell charge/discharge test confirmed that the energy efficiency of the integrated structure had increased by 6.3%. The proposed integrated structure is thus a potentially advantageous substitute for conventional BP and CF electrode assemblies.

1 INTRODUCTION

There is a growing interest in using renewable resources for power production due to environmental concerns about the usage of non-renewable resources like fossil fuels [1,2]. Solar and wind energy are highly accessible, cost-effective, and environmentally friendly sources of energy [3,4]. Nevertheless, the generation of power from these renewable energy sources is irregular, requiring the development of large electrical energy storage systems [5]. This issue has led to significant progress in the research and development of electrical energy storage devices, particularly in the past few decades. Vanadium redox flow batteries (VRFB) show great potential as energy storage systems due to their optimum combination of safety, durability, stability, and efficiency. A standard Vanadium Redox Flow Battery (VRFB) consists of several cells, two pumps, and two electrolyte tanks. The structure of each cell consists of two bipolar plates (BPs), two electrodes, and a membrane.

The membrane acts as a barrier between the two half-cells in the VRFB. The electrode facilitates the formation of reactive sites and electrical pathways for the electrolyte. It is often made of carbon and graphite felt. The VRFB stores energy in the two electrolytes containing different redox couples, V^{2+}/V^{3+} and VO^{2+}/VO_2^{+}, which generate a potential difference through an electrochemical redox reaction. This

results in a charge-discharge reaction. The BPs provide pathways for electrical current to flow between adjacent cells while also isolating each individual cell. Consequently, a BP must possess certain characteristics, including a high electrical conductivity, a low permeability of vanadium sulfuric acid electrolytes, and chemical stability. Although VRFB (Vanadium Redox Flow Battery) is being more commercialized, there is still a persistent requirement to investigate further methods of improving efficiency and lowering expenses. The power capacity of the VRFB is governed by the size of the stack area and the number of stacks, while the energy capacity is dictated by the quantity of electrolyte. In the case of a multiple-stack VRFB, improving cell resistance might lead to enhanced performance.

In VRFB, there is a contact between the Bipolar Plate (BP) and electrode in the VRFB. This interface gives rise to problems associated with interfacial resistance (ICR) as shown on Fig. 1. In order to address these ICR (Internal Cell Resistance) difficulties, it is necessary to apply a high compaction pressure to the VRFB (Vanadium Redox Flow Battery) stack. However, the VRFB experiences a low applied pressure due to structural constraints, resulting in a decrease in viscous dissipation. Therefore, the internal contact resistance (ICR) has a substantial impact on the cell efficiency of the vanadium redox flow battery (VRFB) and causes a reduction in efficiency. Lim et al. proposed an integrated structure of a carbon felt electrode (CFE) and BP for VRFB, which was created by local thermoplastic welding [6]. The structure of the CFE-BP assembly demonstrated a decrease in electrical resistance and an increased level of energy efficiency due to the reduction in contact resistance. However, the mechanical characteristics of the CFE can be compromised because to the reduction in porosity caused by the compaction pressure applied during the production process.

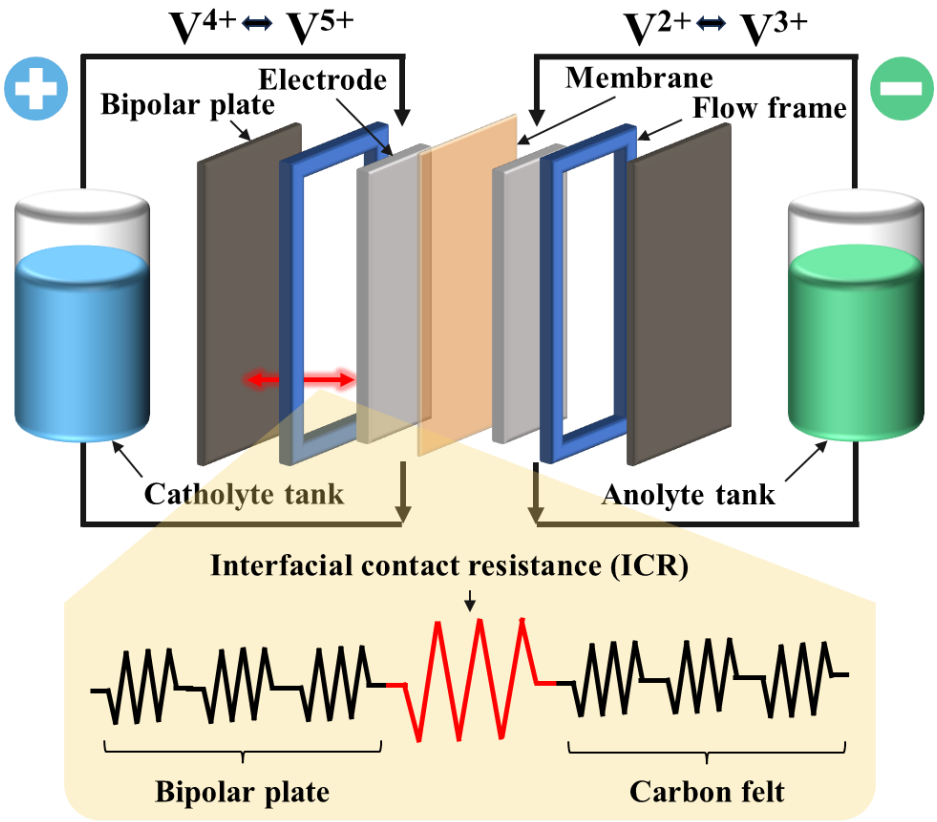

Figure 1: Schematic of vanadium redox flow battery (VRFB) and interfacial contact resistance.

We proposed a carbon felt electrode (CFE)-BP-Carbon felt electrode (CFE) (CFE-BP-CFE) composite structure that generates repetitive units of multi-cell arrays from a single CF in order to overcome these issues. By utilizing this approach, the degradation of mechanical properties caused by the compressive pressure of the CF electrode is prevented. The CFE-BP-CFE composite structure was

fabricated using one single CF in order to reduce contact resistance between the CFE and BP, as well as adjacent cells; this structure established an electrode-BP-electrode interconnection with the CF fibers. By partially impregnating the electrode section with a soluble resin, the CFE section, which measured 4 mm in thickness from both surfaces of a 10 mm single CF, was rendered impermeable. This impregnated CFE section was protected from the compaction pressure utilized during BP fabrication. Significant hydrophilicity was achieved by thermal treatment, enabling the electrode section to be filled with regular glucose and porosity to be eliminated under CF pressure. Following this fabrication, a two-cell test was conducted to evaluate the total resistance, gas permeability, and charge/discharge cycle of the battery.

2 EXPERIMENTAL SECTIONS

2.1 Fabrication of the integrated structure

The CFE-BP-CFE integrated structure was fabricated from the single CF. The properties of the CF are shown in Table 1. The assembly is prepared in the compression mold. The carbon felt electrode portion is filled with the regular glucose to secure it from the pressure of the compression mold. The bipolar plate portion is fabricated by the epoxy resin by partial impregnation in the vacuum oven and subsequently in compression mold. The detailed procedure of fabrication is shown in Fig. 2.

Thickness	Density	Tensile strength	Porosity
10 mm	0.08 g/cm^3	0.15 MPa	92-94%

Table 1. Properties of carbon felt.

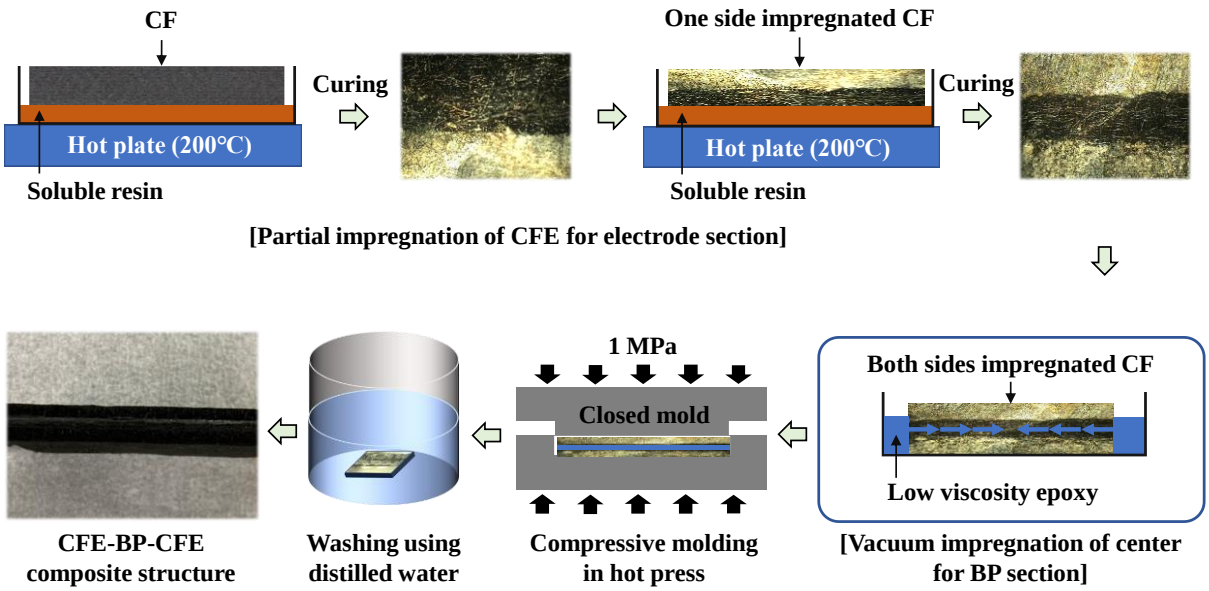

Figure 2: Experimental procedure of the carbon felt electrode-bipolar plate-carbon felt electrode (CFE-BP-CFE) composite structure.

2.2 Characterizations

The areal specific resistance has been calculated using the four-point probe method. The permeability of the CFE-BP-CFE composite structure was measured using gas sensors. Acid-aging test has been conducted to check the stability of the bipolar plate. Charge-discharge test was carried out to check the performance of the integrated assembly of the electrode and bipolar plater for VRFB. The setup pf charge discharge test using integrated structure is shown in Fig. 3.

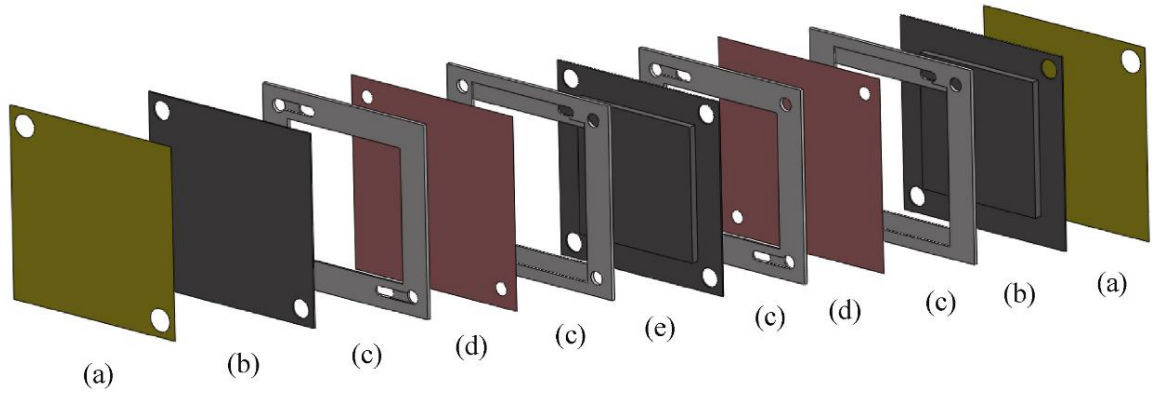

Figure 3: Schematic of core components of two-cell assembly: (a) Current collector; (b) Bipolar plate-carbon felt electrode (BP-CFE) composite structure; (c) Flow frame; (d) Membrane; (e) Carbon felt electrode-bipolar plate-carbon felt electrode (CFE-BP-CFE) composite structure.

3 RESULTS AND DISCSUSSION

An optical microscope image of the 4-mm-thick impregnated layer is presented in Fig. 4(a). The same procedure was applied to the opposite side of the CF. Fig. 4(b) displays the CF with glucose partially impregnated from both sides. Fig. 4(c) presents optical microscope images of the cross-section of the fabricated CFE–BP–CFE composite structure. The central region, corresponding to the bipolar plate (BP), shows uniform epoxy impregnation. Notably, Fig. 4(c) reveals the presence of interconnected carbon fibers bridging the BP and CFE layers. These fiber connections establish a continuous electrical pathway between adjacent cells, thereby improving the overall electrical conductivity of the integrated BP–CFE structure.

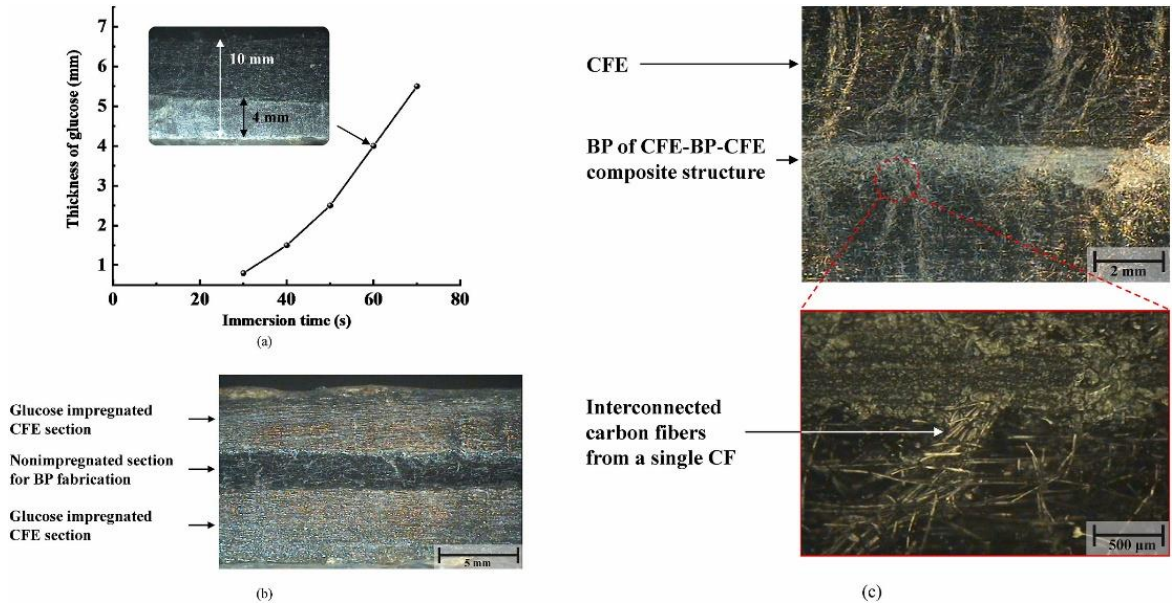

Figure 4: Optical microscope images: (a) Thickness of glucose in partially impregnated carbon felt (CF) as a function of immersion time; (b) Cross-section of carbon felt electrode (CFE) showing glucose impregnation from both sides; (c) Cross-section of the CFE–BP–CFE composite structure.

Figure 5 demonstrates the overall resistance of three structures: the conventional structure with commercial graphite composite BP, the CFE, and the designed CFE-BP-CFE composite structure. As expected, the total electrical resistance decreased in proportion to the increase in compaction pressure. The total resistance of the CFE-BP-CFE composite structure was measured to be about equivalent to

that of the CFE. However, the resistance of the CFE was found to be 28% lower than that of the conventional construction. The reason for this is that the CFE-BP-CFE composite structure consists of a single CFE, and both surfaces of the CFEs are consistently linked with carbon fibers through the central BP section.

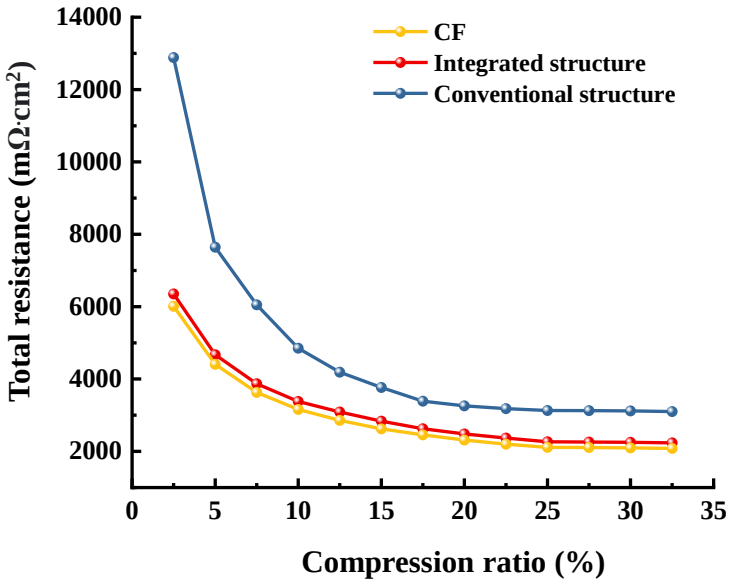

Figure 5: Total resistance of CF, Integrated structure and Conventional structure.

Figure 6 demonstrates the results of the charge/discharge test for both the integrated and conventional assemblies using a two-cell VRFB configuration. The galvanostatic charge/discharge test of the integrated structure demonstrated a reduced discharge voltage and a higher charge voltage. The energy and voltage efficiency of the CFE-BP-CFE composite structure two-cell assembly were enhanced by a significant 6.3%. The decrease in the Ohmic loss in the cell was attributed to the integration of BP and CFEs, resulting in a reduction in the total resistance of the cell. The performance of the CFE-BP-CFE composite structure was improved by the interconnected fibers of BP and CFEs, which created continuous electrical paths. However, the coulombic efficiency remained constant for both setups.

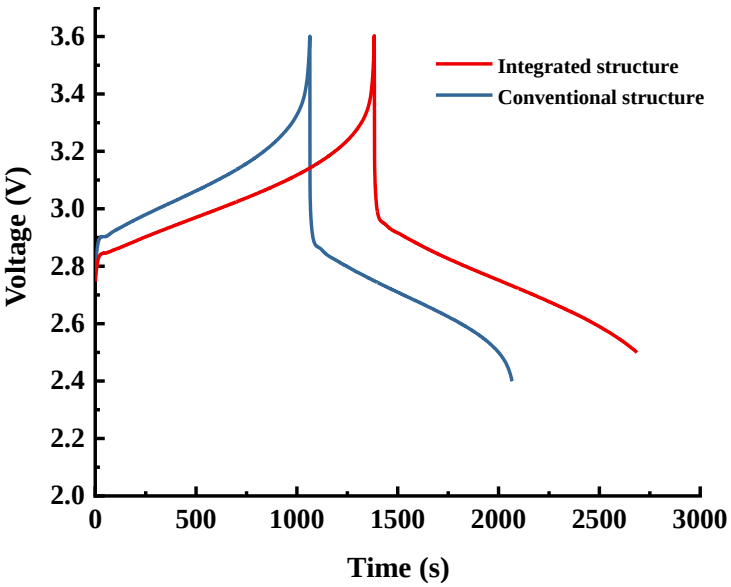

Figure 6: Charge discharge curve of Integrated structure and Conventional structure.

4 CONCLUSIONS

This paper presents the development of a composite structure consisting of a CFE-BP-CFE configuration, achieved through the utilization of a novel fabrication technique that effectively addresses the issue of ICR. The electrode and BP parts were linked together using carbon fibers, since the integrated structure was created from a single sheet of carbon fiber (CF). The proposed structure demonstrated a 28% reduction in resistance compared to the standard structure, which was roughly equivalent to the resistance of a single CFE. Additionally, the charge/discharge test conducted on the suggested construction with two cells showed a longer duration for both charging and discharging, as well as a 6.3% improvement in energy efficiency compared to the conventional structure. This improvement can be attributed to a decrease in Ohmic potential and a reduction in total resistance. The CFE-BP-CFE composite structure minimizes the quantity of core components in the VRFB stack while preserving the stack's efficiency through the use of lower compaction pressure. Hence, the created CFE-BP-CFE composite structure has the potential to serve as a substitute for traditional VRFB components, offering enhanced performance. Furthermore, the VRFB system can be successfully commercialized based on its economic and engineering viability.

V. Conclusions

Conclusions

Korea Aerospace University

MCML
MULTIFUNCTIONAL COMPOSITES & MANUFACTURING LABORATORY

- In this study, we conducted space environment assessments and thermal shock evaluations to develop a new concept discharge wall for a plasma thruster operating in VLEO.
- The evaluation of the VLEO environment showed no significant changes in chemical structure or tensile strength after prolonged exposure to atomic oxygen.
- Plasma erosion tests showed that the material had a higher erosion rate than Boron Nitride Grade HP, and no phase transformation was observed.
- **In future works,** the investigation will be expanded to evaluate structural integrity under plasma-exposed conditions.

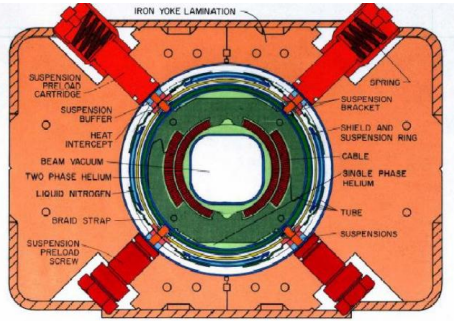
Electrical Insulation for Nb_3Sn Superconducting Cables

Roland Piccin, Vincent Schenk, Javier Osuna, Christian Scheuerlein, Francois-Olivier Pincot (CERN/TE/MSC/SMT)

07/08/2025, ICCM Conference Baltimore

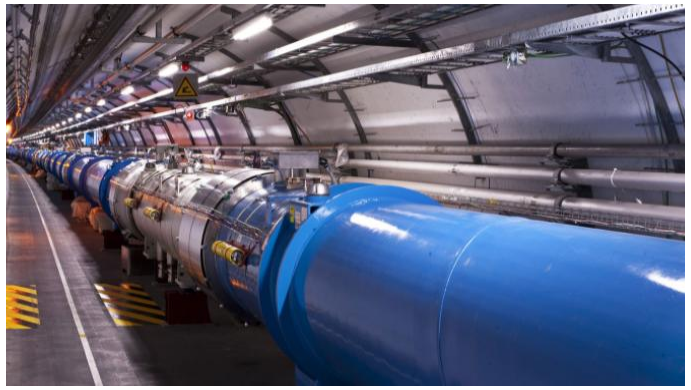
Table of contents

1. Introduction to Superconductivity and Particle Accelerators
2. The Challenge of Electrical Insulation in Nb_3Sn Magnet
3. Insulation Materials and Processing
4. Electrical Performance
5. Conclusions and Perspectives

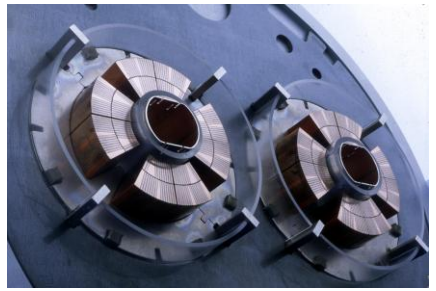


From Discovery of Superconductivity to Large-Scale Particle Accelerators

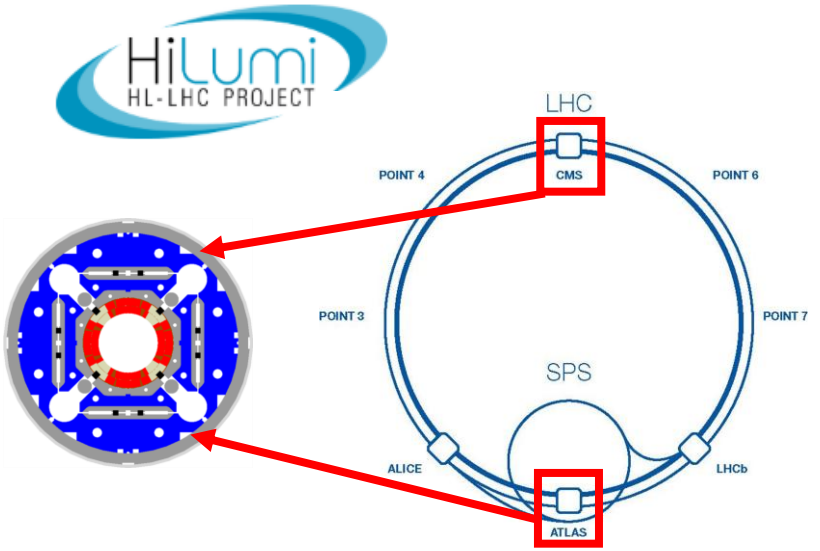
- **Superconductivity** is a property of certain materials that exhibit **zero electrical resistance** below a critical temperature (Tc). Enables current flow without power loss due to **absence of the Joule effect**.



- **Discovered in 1911** at Leiden University (Netherlands) by **Heike Kamerlingh Onnes**. He was awarded the 1913 Nobel Prize in Physics.

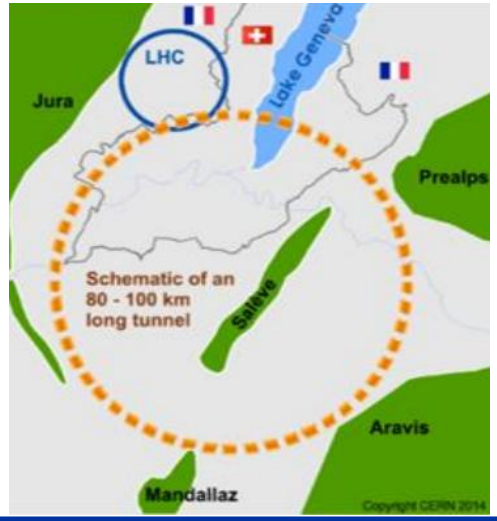


- In **the 80's** the **first large-scale applications** of superconductivity begun to appear: **Tevatron** particle accelerator built at Fermilab (USA). 774 x 4.3T dipoles 6-m long used to bend the particles in the ring.



- **In 2006** the **Large Hadron Collider (LHC)** was commissioned at CERN (Switzerland). The largest existing particle accelerator with a 27-km circumference.

HL-LHC and Beyond... Future Circular Collider (FCC) at CERN

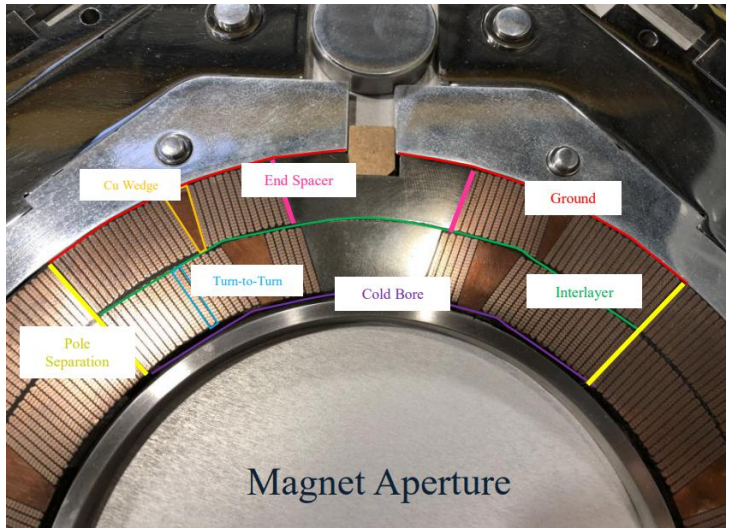


- The next step for CERN is the **High-Luminosity upgrade (HL-LHC)** aiming at increasing the collisions thus the view of rare phenomena, precision of the measurements and opening the way to new discoveries.
- **For the first time, Nb_3Sn magnet will be installed in an accelerator**. 30 powerful quadrupoles installed around ATLAS and CMS detectors
- **HL-LHC will start operation in 2030.**

- Scienitfic community is discussing about a 90.7-km-Circumference **Future Circular Collider (FCC)** at CERN developed with a 2-stage approach: FCC-ee from the **mid-2040s** and FCC-hh from **the 2070s**.

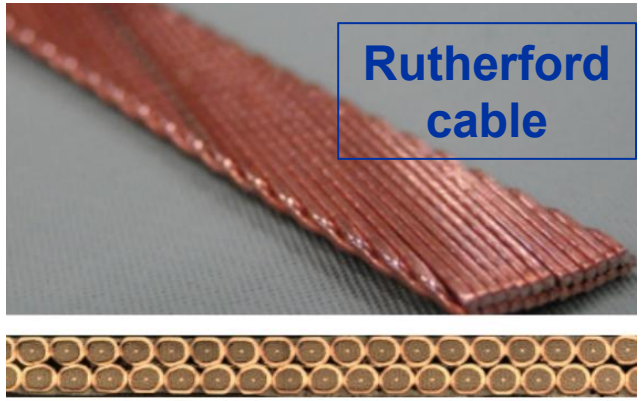
- It calls for development of **Nb_3Sn accelerator dipole magnets with 14 T operational field** with focus on **sustainability**, **cost** and **large-scale production**. This is the scope of **High Field Magnet (HFM) program**

HFM
High Field Magnets

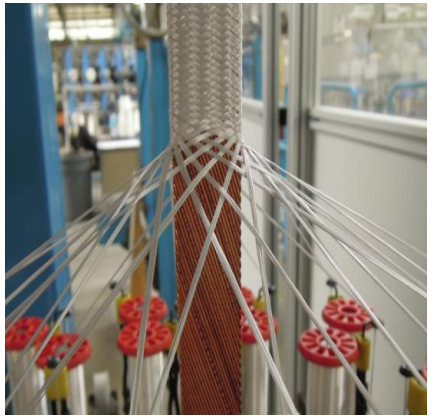


Nb_3Sn Coil Insulation Systems

- During construction and operation, superconducting magnets as well as their insulation systems are exposed to cryogenic temperature (1.9 K), high radiation levels (1 – 30 MGy) and mechanical loads, especially during assembly (~100 MPa).
- A robust electrical insulation is key to assure reliability and performance of the magnets.
- Within HFM program, an R&D work package is devoted to the development of **enhance electrical insulation systems** for Nb_3Sn coil.



Nb_3Sn Rutherford-type cable



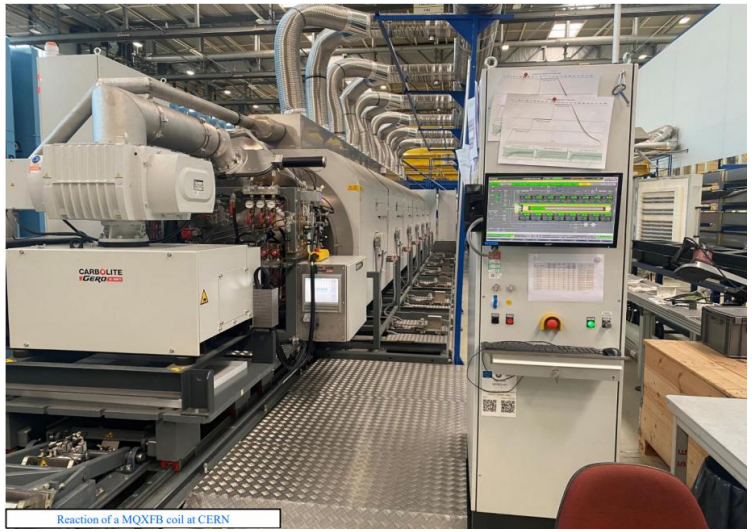
What is demanded to an insulation system for HFM?

- To have **high dielectric strength (voltage withstand ~ 2 kV)**
- To have **good mechanical properties** (at each stage of magnet manufacturing and operation, loads ~100 MPa)
- To have a **high radiation hardness (up to 30 MGy)**
- To be as thin as reasonably achievable (in consideration of all other requirements)
- To possibly have **good thermal properties** (high heat capacitance and conductivity)
- Others…

Manufacturing a Nb_3Sn coil (1/2)

Courtesy of CGP (Omerin Group)

INSULATION



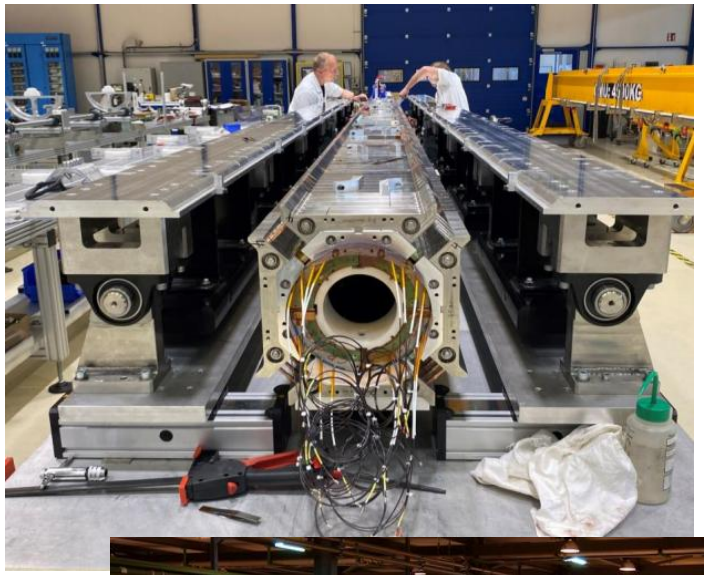
The insulation is constituted by a glass fibers braided onto the Nb_3Sn cable.

Topic #1

COIL WINDING

The cable is wound around a pole mounted on a steel mandrel. For long coils (> 8 m) the winding process is carried out by an automatic winding machine.

REACTION HEAT TREATMENT



The “reaction” process is required to create the intermetallic compound Nb_3Sn. Coil heated to about 650-700 °C in vacuum or inert gas (argon) atmosphere for roughly 50 hours.

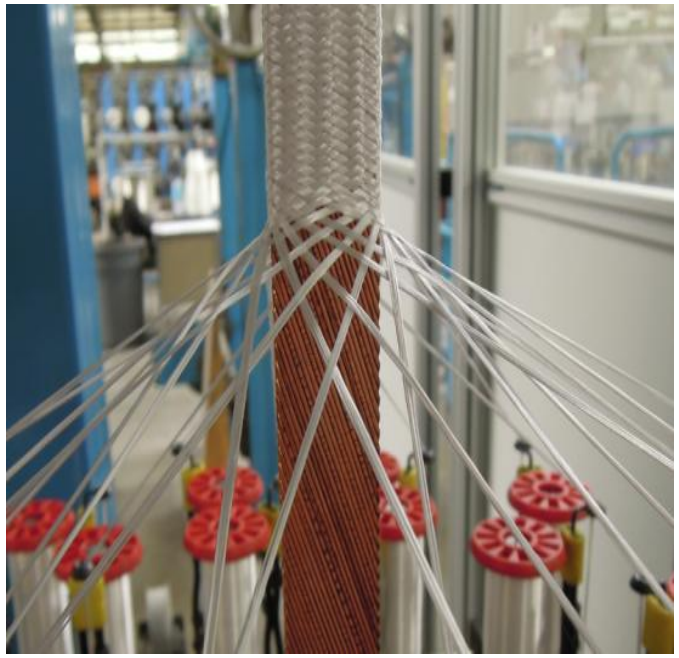
Topic #2

Manufacturing a Nb3Sn coil (2/2)

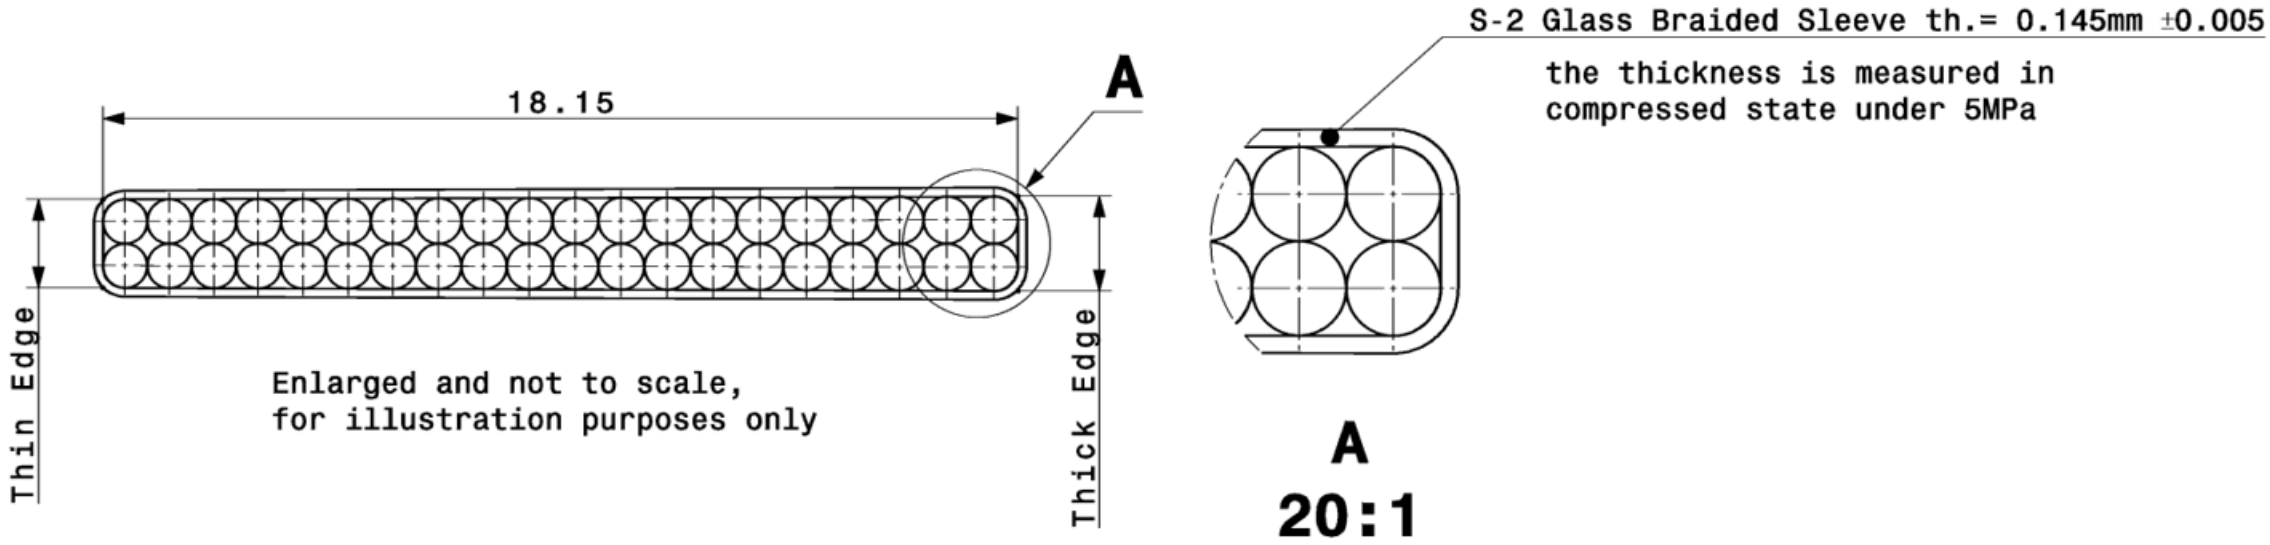
MQXFB coil inside the impregnation tank CERN

VACUUM IMPREGNATION

After reaction the Nb_3Sn becomes brittle. Carefull handling is required. The coil is vacuum impregnated with epoxy to create a monoholitc component and provide dielectric insulation.



Topic #3

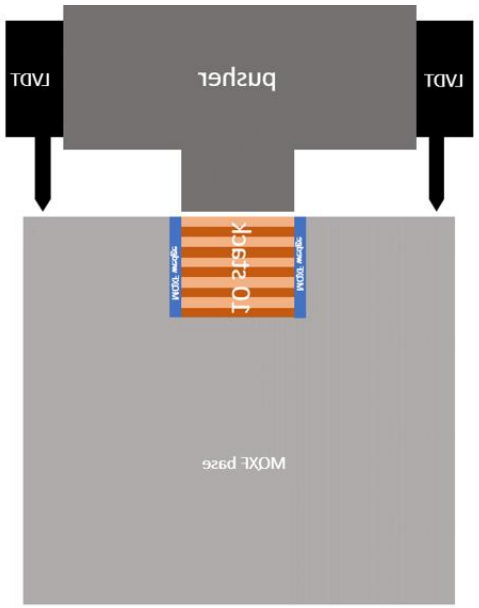


The following steps include the assembly of the coils in a coil-pack, assembly of the yoke, welding, insertion in the cryostat, testing and installation…

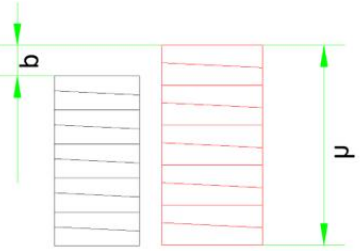
Cable Insulation

Cable Insulation

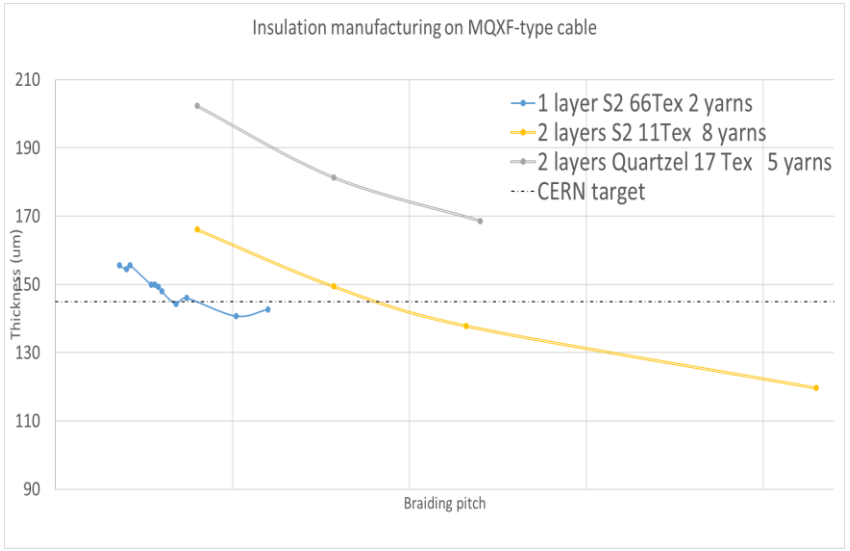
- Fiber is **braided** directly around the Rutherford-type conductor
- Typically, **S2 glass** is chosen for the higher mechanical properties and thermal stability compared other glass fibers
- Conductor **insulation thickness 0.145 ± 0.05 mm**



Control of Insulation thickness

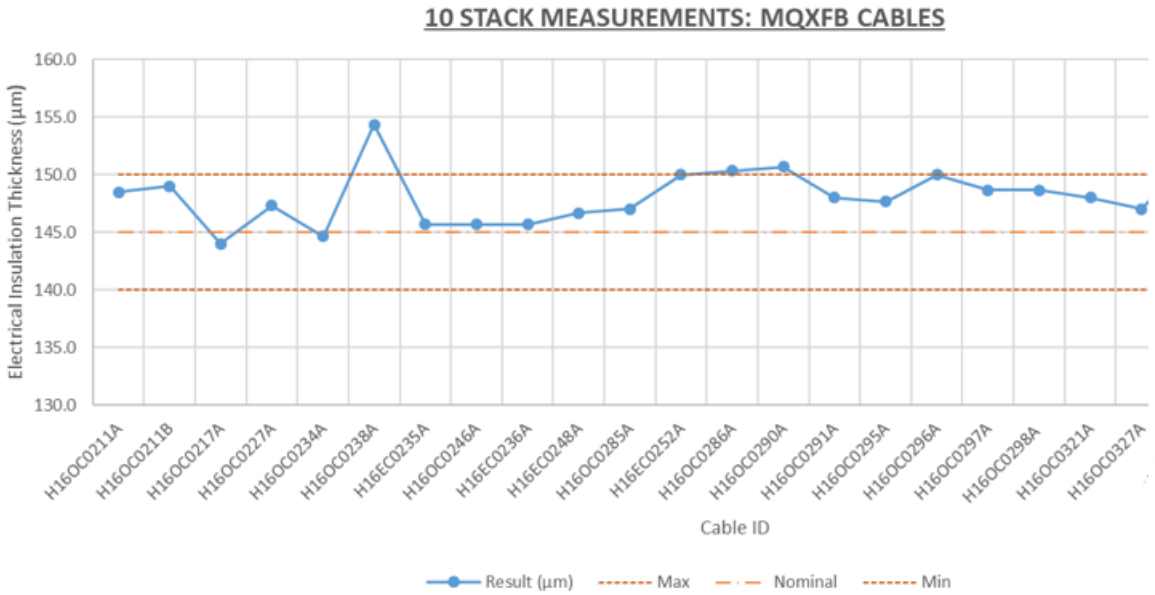


- The **target insulation thickness** is achieved tuning the braiding pitch.
- **Control of insulation thickness** is extremely important because tight tolerances required during the magnet assembly.



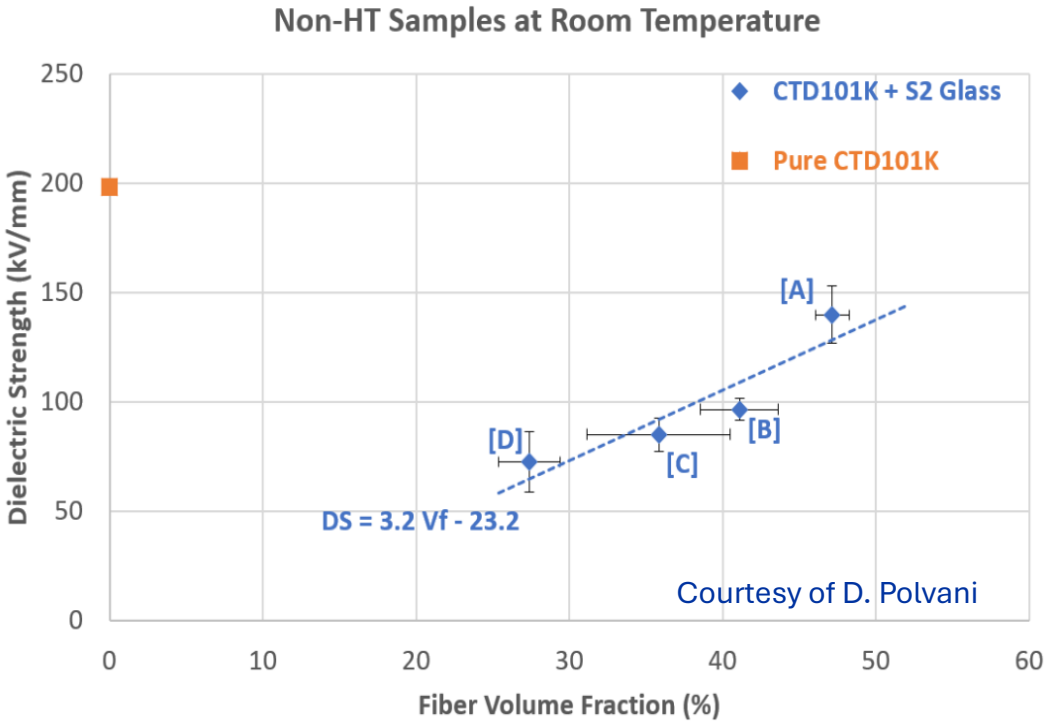
$$p = LVDT_{insulated}(\sigma_t) - LVDT_{bare}(\sigma_t) = \boldsymbol{t_{insulation}} * 20$$

- **Quality control** of each insulated Unit Length (UL) is measured with "**10-stack**". Difference of consecutive measurements of a stack of 10 conductors with braided sleeve and without:



Insulation thickness set-up: "10-stack measurement"

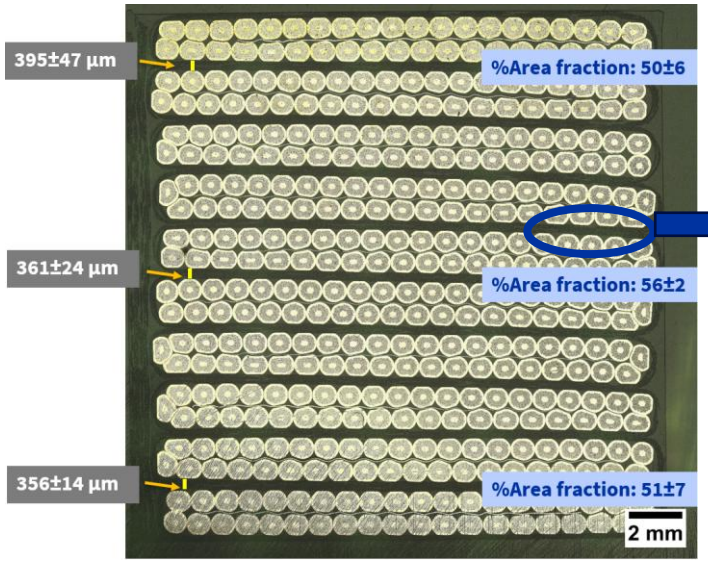
Insulation thickness for different braiding pitches



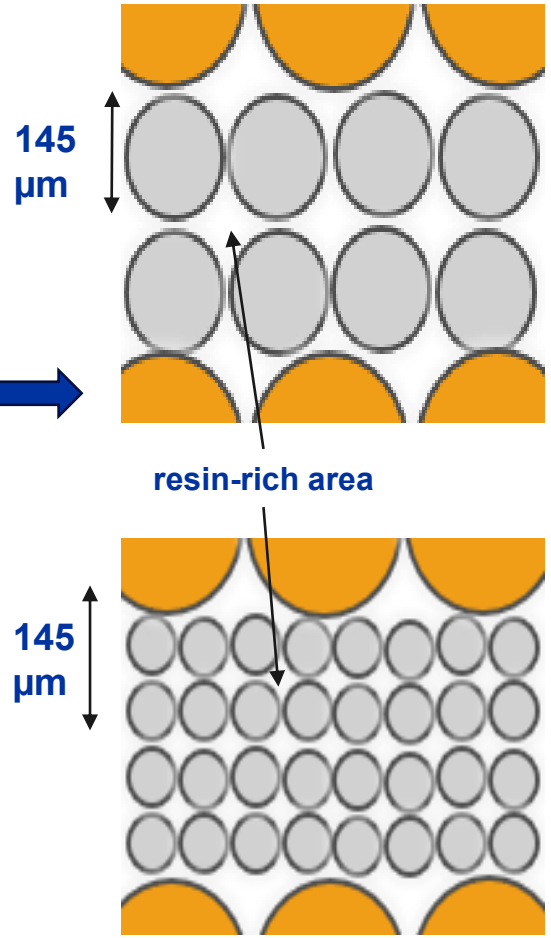
Insulation thickness for different UL (E. Fernandez Mora)

Braided Insulation Layout

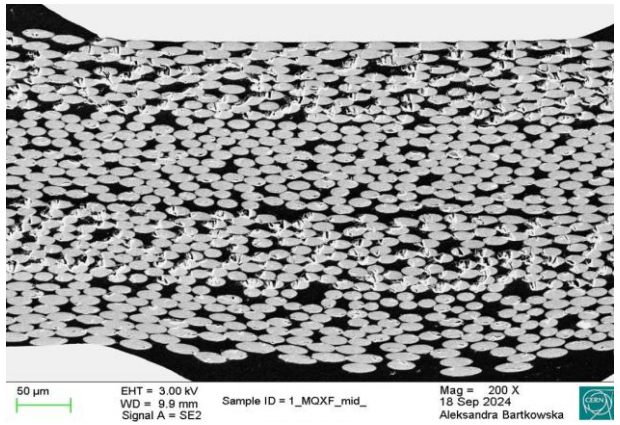
- **Fibre volume fraction Vf** determine final properties of the insulation dielectric strength, mechanical strength, thermal conductivity and Coefficient of Thermal Expansion (CTE)

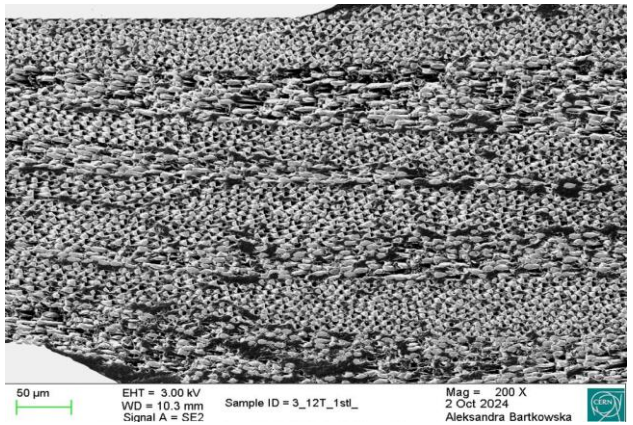


- Typical **target of fibre volume fraction is > 50%**



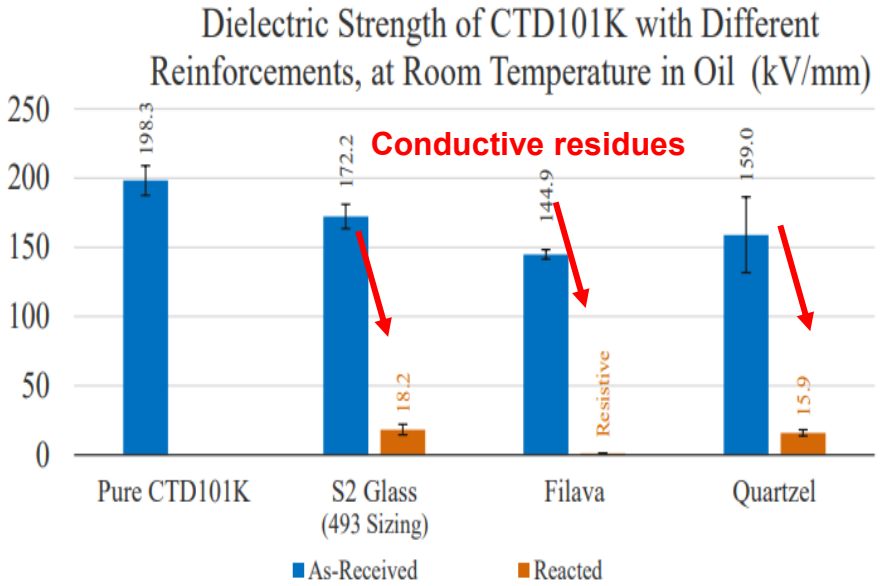
- Two types of braiding layout: **single** (filament Ø=9 µm) and **double sleeve** (filament Ø=5 µm). Both types display a **Vf ~ 60%**

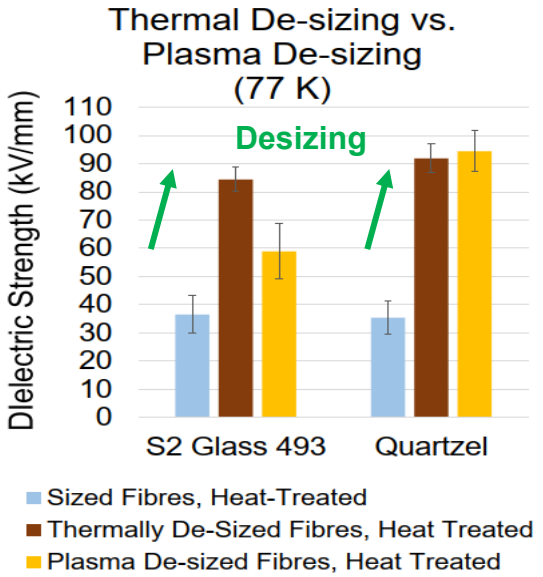


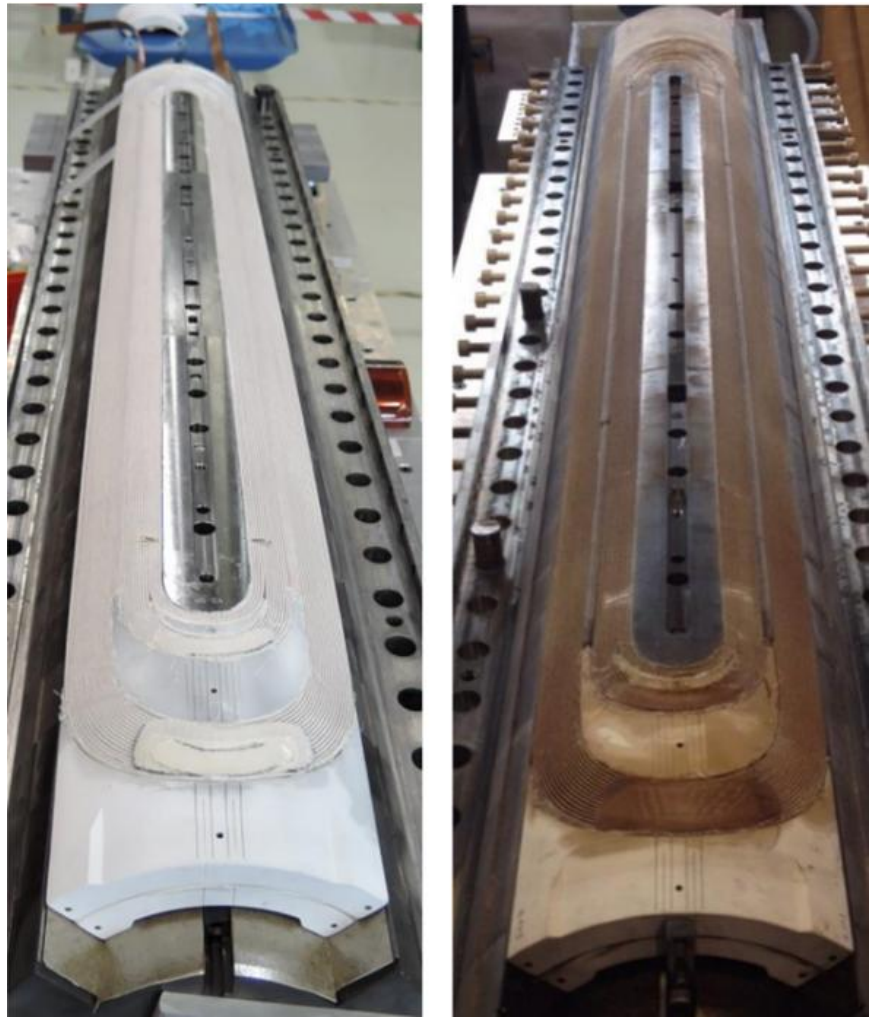


Braided Insulation Layout

Double sleeve has the advantage of having smaller epoxy volumes therefore less stored strain energy (accumulated during cooldown 300 K -> 4K). Epoxy cracks when stored strain energy is grater than work of fracture



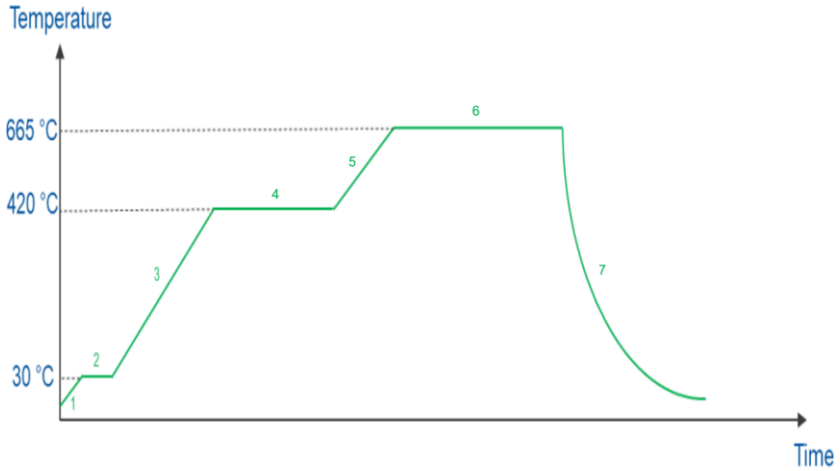




Fiber desizing

Nb_3Sn reaction treatment: Desizing effect

- The insulated coil is heated to about 650-700 ℃ in vacuum or inert gas (argon) atmosphere for roughly 50 hours. This is the reaction cycle of Nb_3Sn.
- The sizing undergoes a **pyrolysis** leaving **conductive products** on the fibers.
- Conductive products **impact the dielectric strength** of the insulation. The effect is less dramatic at cryogenic temperatures



Superconducting coil before and after heat treatment

J. Osuna et al, *"Advanced Composite Insulation Systems in Nb3Sn Superconducting Magnets for Accelerators: Electrical Characterization of Laminates at Cryogenic Temperatures"*, accepted for ICEC/ICMC 2024

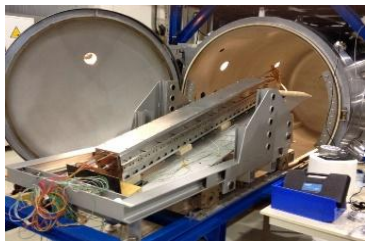
Thermal and Plasma Desizing

Desizing methods:

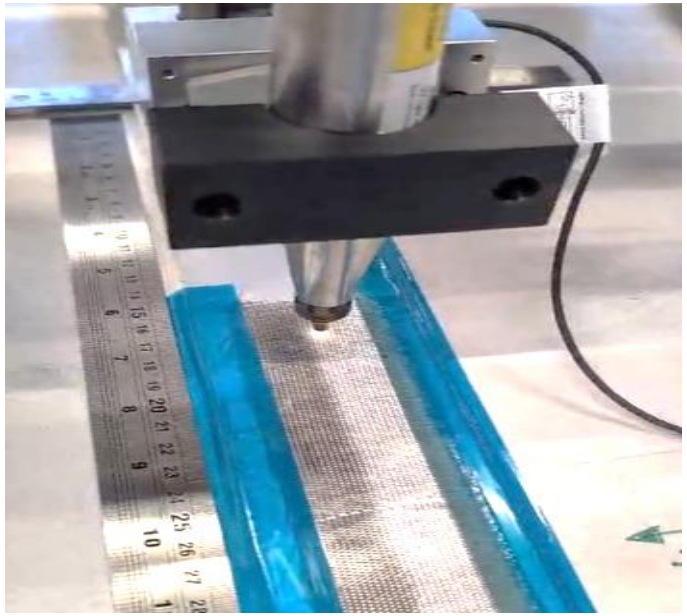
- **Thermal desizing** consists of injecting oxygen to burn off the sizing during the reaction treatment
- **Plasma desizing** consists of using a plasma torch to burn off the sizing before the cable is wound

Typical Nb3Sn reaction cycle

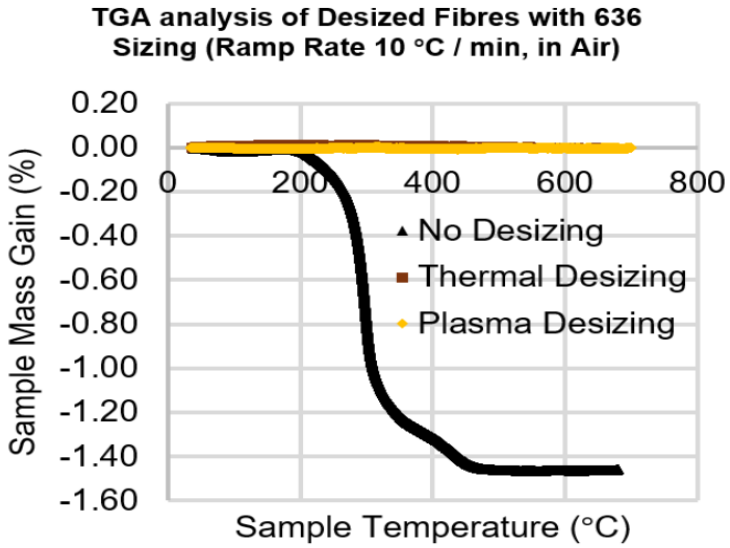
Plasma →



Thermal →



1. Braiding
2. Winding
3. Reaction
4. Impregnation

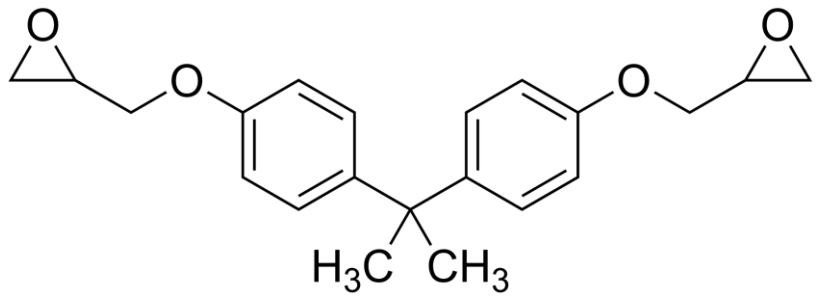


Plasma treatment on reacted glass fibres

Epoxy systems

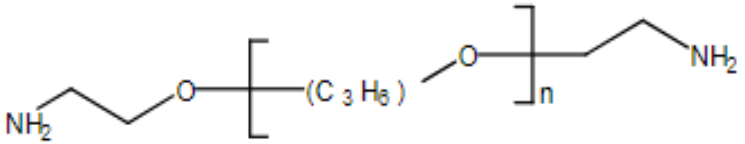
Impregnation systems

Current status on impregnation systems:



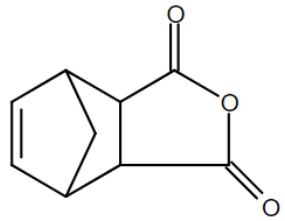
- In most cases, **epoxies** are used for impregnation
- Among them, two families of hardeners can be used: **amine and anhydride**
- Other chemicals can be added to tailor processing and end properties such as accelerator or flexibiliser

Desired properties for processing:

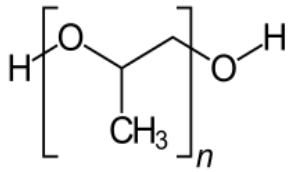


- **Low viscosity / long pot life** (coils are 8 to 15 m long)
- Low shrinkage during curing and low exothermic behaviour
- **Low curing temperature** to reduce thermal stresses

Desired end properties:



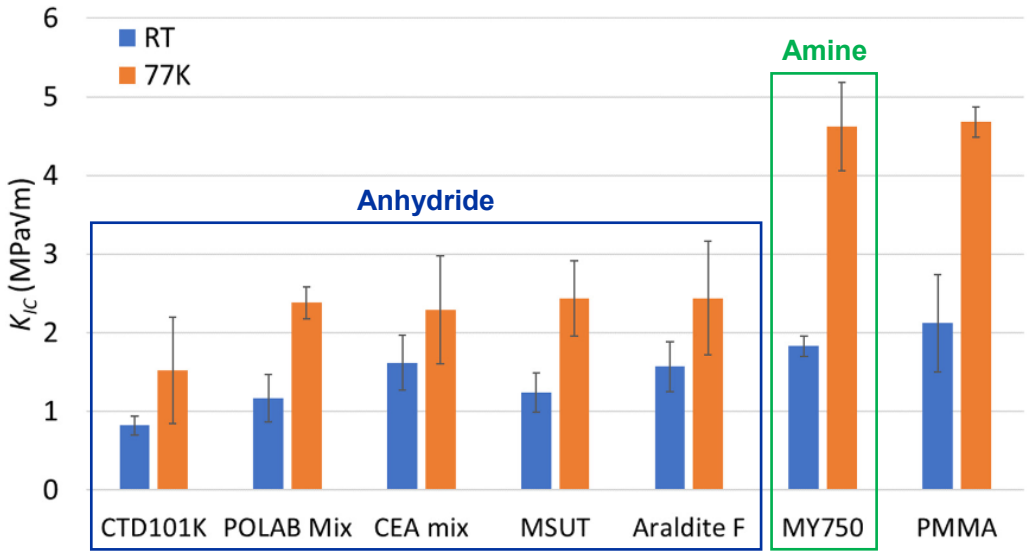
- **High dielectric strength**
- **Good mechanical properties**
- Thermal shock resistance
- **High radiation hardness (dose depends on where the magnet is installed in the accelerator – few MGy to 30 MGy)**
- Lowest possible CTE mismatch with coil constituents



DGEBA epoxy resin

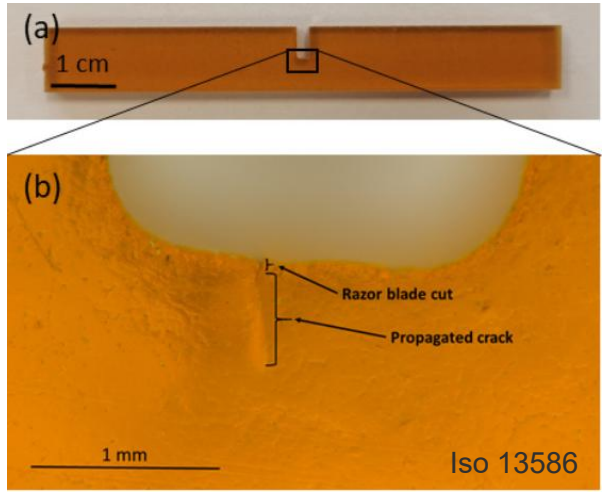
Amine hardener

Anhydride hardener



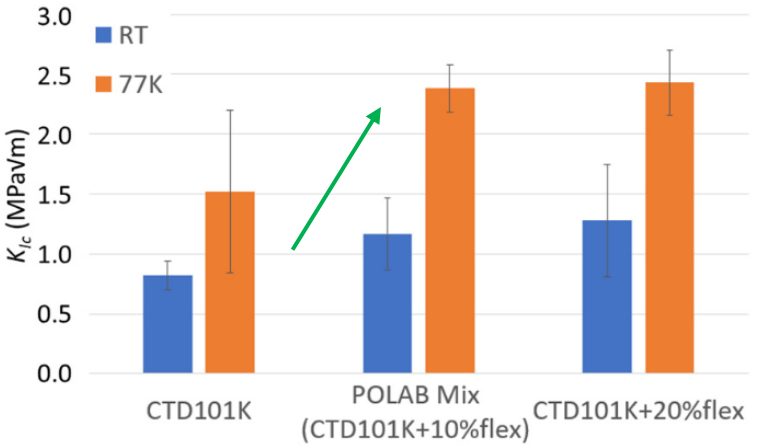
Flexibiliser

Fracture toughness of epoxies



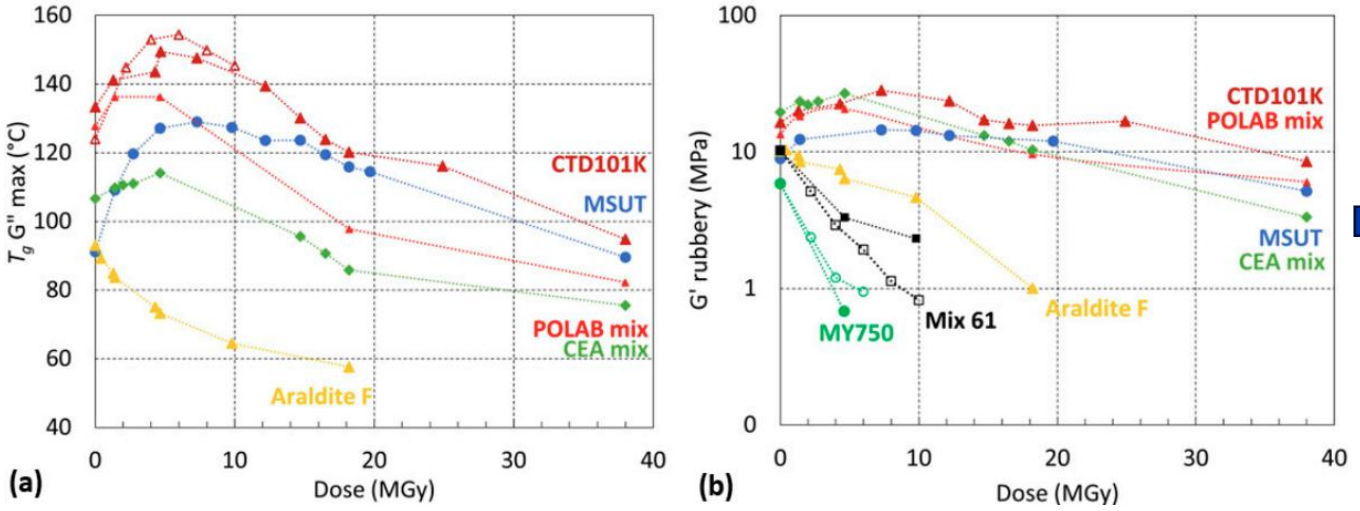
Fracture toughness of different epoxies at room temperature and 77 K:

- Overall, the **fracture toughness of anhydride epoxies is lower than amine epoxies, especially at low temperatures**
- To toughen CTD101K epoxy, a flexibiliser DY040 was added (10 and 20 w%), leading to a toughness increased by 50 % at 77 K

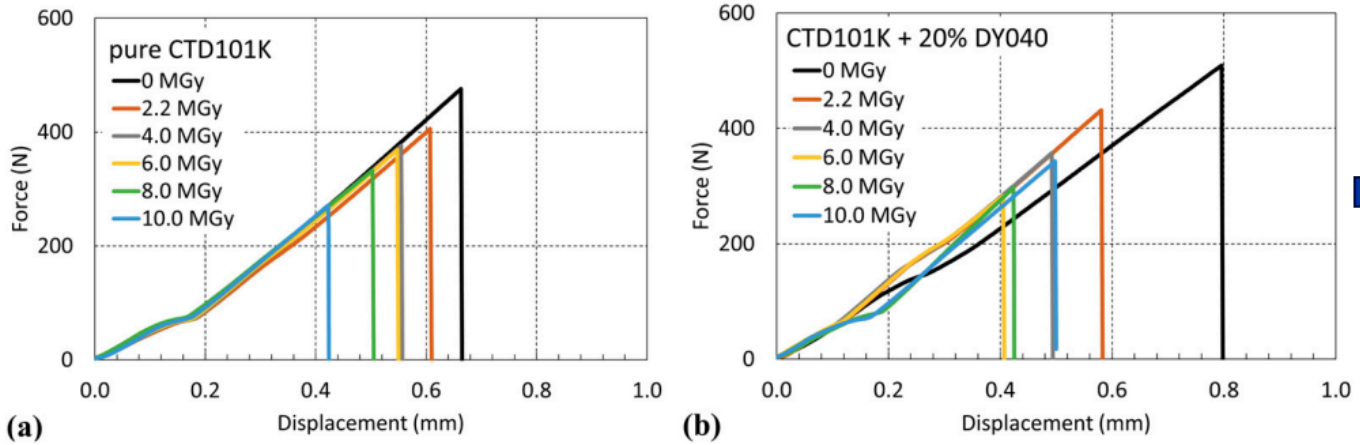


Fracture toughness of different polymers

Epoxy resin + flexibiliser



Fracture toughness test sample

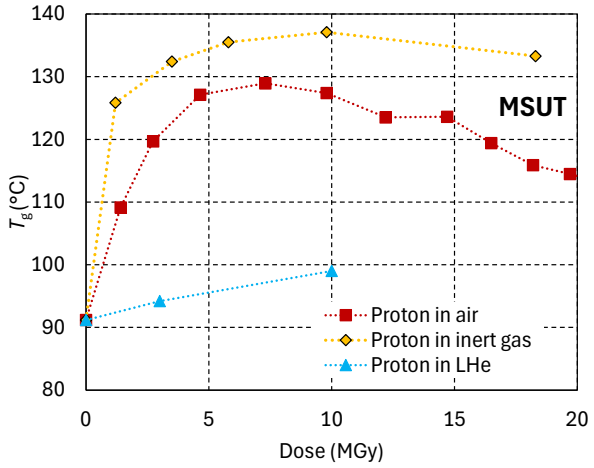


Fracture toughness of CTD101 flexibilised

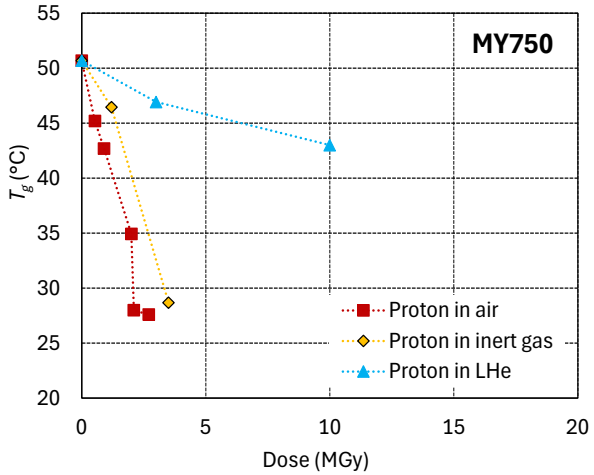
A. Gaarud, et al, "*Fracture toughness, radiation hardness and processibility of polymers for superconducting magnets*" Polymers 2024, 16(9), 1287

Influence of the chemistry on the radiation hardness

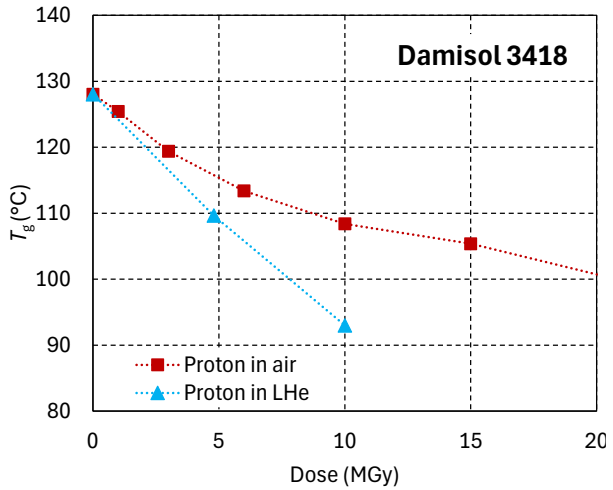
Dynamic Mechanical Analysis (DMA) study of irradiated epoxies:



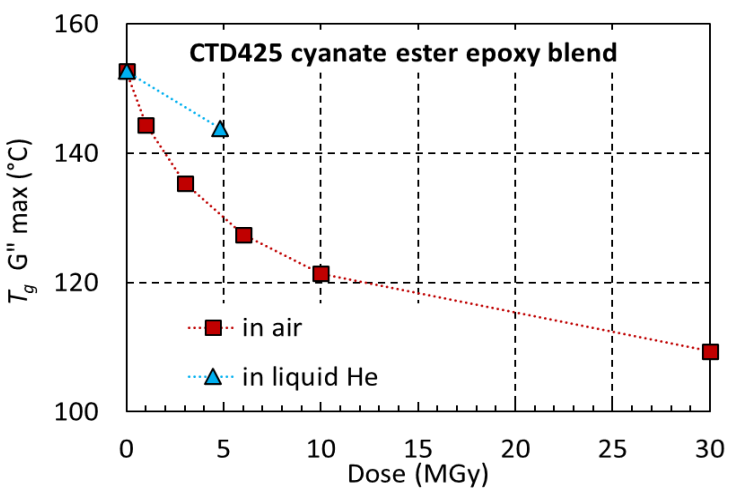
- **The epoxies with anhydride hardeners are more resistant to radiation** e.g. CTD101K, MSUT (MY740) and CEA mix (CY 192-1) compared to epoxies using amine- based hardeners (Mix 61 and MY750)



CTD101K vs CTD101K + DY040 (POLAB mix):



- DMA (up to 38 MGy) and 3-point bending (up to 20 MGy) studies did not reveal significant change of radiation hardness between the two systems
- **DY040 can be used to increase fracture toughness without impacting the radiation hardness**



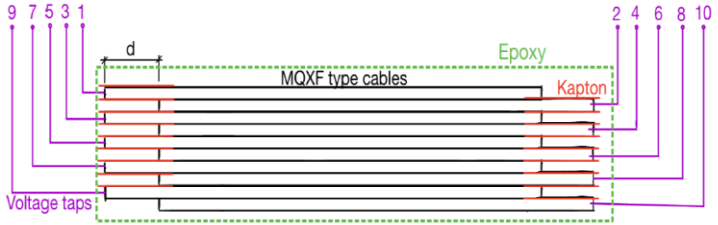
D.M. Parragh, et al, "*Irradiation induced aging of epoxy resins for impregnation of superconducting magnet coils*", IEEE Trans. Appl. Supercond., 34 (3), (2024), Art. no. 7800107
A. Gaarud, et al, "*Fracture toughness, radiation hardness and processibility of polymers for superconducting magnets*" Polymers 2024, 16(9), 1287

Influence of irradiation environment and temperature

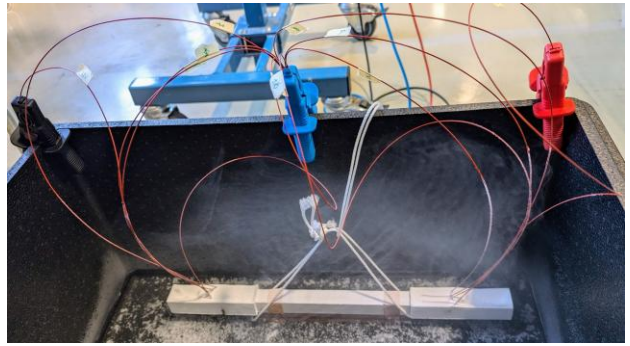
DMA study of irradiated epoxies in air, inert gas or liquid helium:

- Strong different efficiency for producing radiation damage, depending on the irradiation temperature
- More cross-linking and less chain scission in inert gas
- **Cross-linking is nearly completely suppressed in liquid helium**
- The temperature effect on chain-scission is materials dependent

To predict the dose limits of organic materials in superconducting magnets, **irradiations need to be performed at cold**



New set up for cold irradiation test campaign under construction at CERN

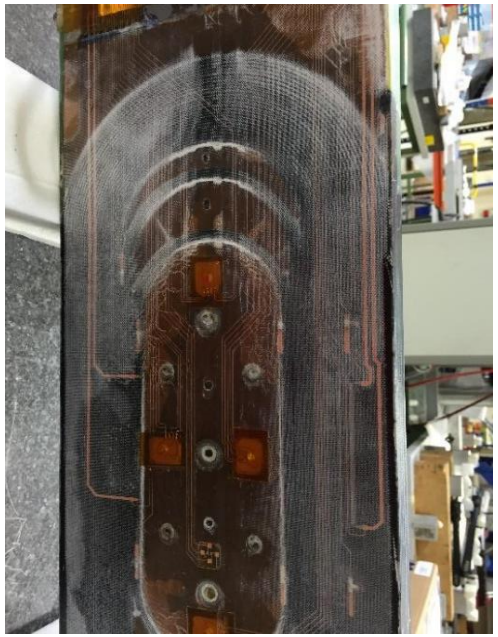


D.M. Parragh, et al, "*Irradiation induced aging of epoxy resins for impregnation of superconducting magnet coils*", IEEE Trans. Appl. Supercond., 34 (3), (2024), Art. no. 7800107
A. Gaarud, et al, "*Fracture toughness, radiation hardness and processibility of polymers for superconducting magnets*" Polymers 2024, 16(9), 1287

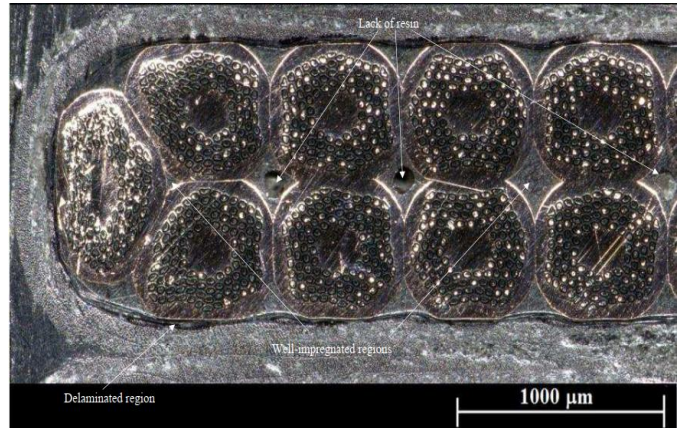
Electrical Performance

Insulation Quality and Electrical Performance

- For High Field Magnets expected **voltages to ground and between turns** range approximately around **1.5 kV** and **100 V** respectively.



Representative samples of turn-to-turn insulation (HV 10-stacks)

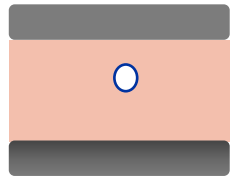


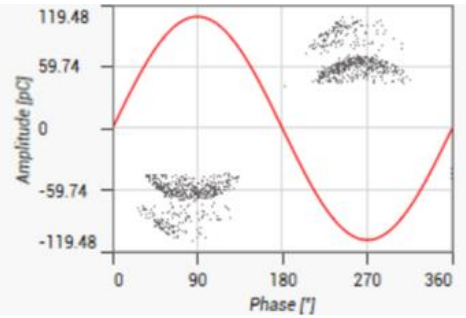
- The **quality** of the insulation is assessed **by voltage withstand test** and **partial discharge (PD).**

- Turn-to-Turn insulation withstand >2.5 kVdc before and after controlled cold thermal cycles down to 77 K (LN_2)

- **Partial Discharges (PD)** are localized breakdowns. It can appear in voids, cracks, across the insulation surfaces and in air (corona).

- **PDs can reveal the presence of defects** in the insulation that may develop in failures if subjected to repeated thermal cycles or mechanical loads

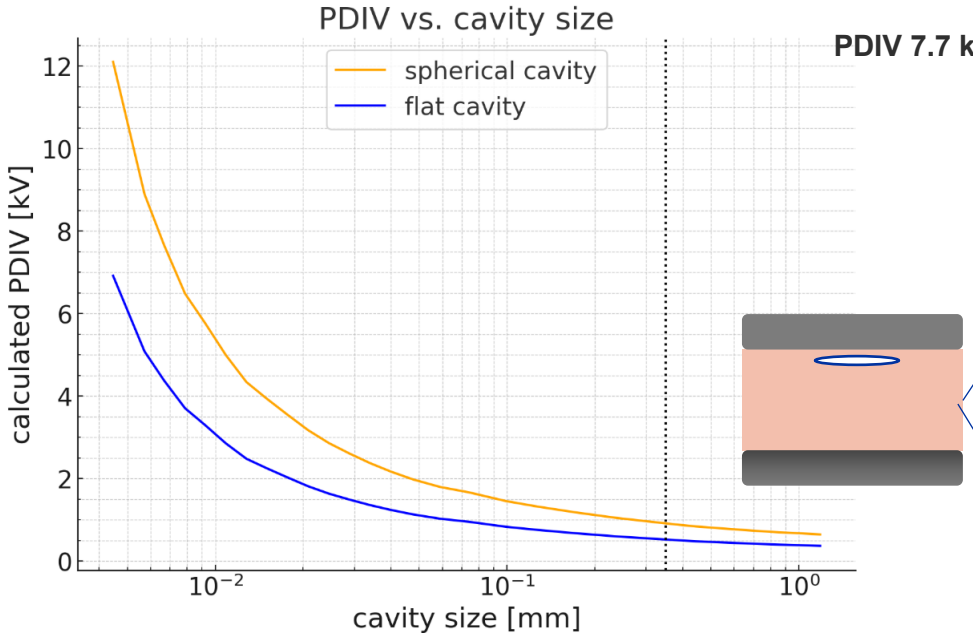




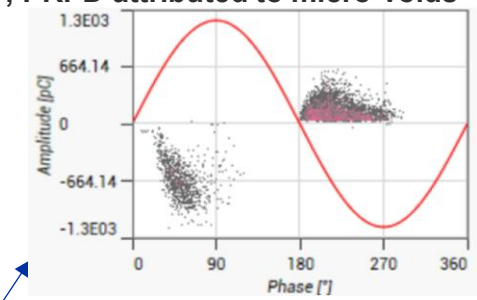
Example of carking on coil after exposure to liquid Helium (right); delamination and cavities on insulated cable. SMC coils (Courtesy of J.C. Perez)

Partial Discharges

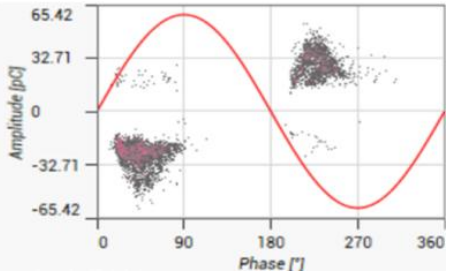
- The size and shape of a defect can be estimated by **Paschen Law of gases**, the PD inception voltage (**PDIV**)* and the interpretation of the Phase-Resolved PD (**PRPD**) pattern.



- Defect free Turn-to-Turn insulation are **PD free up to ~ 8 kV**. It is possible to assume that **cavities**, if present, **<~ 6 µm**.



- **PDIV** occurs on some samples around **4 kV**. Possible **flat cavity or delamination** of approximately **10 µm** (or spherical voids ~25 µm).



- PD inception voltage of insulation that underwent **five thermal cycles in LN2** was on the range of **2.5 kV.** Possible flat cavity or delamination of approximately **15 µm** (or spherical voids ~30 µm).

PDIV 7.7 kV; PRPD attributed to micro-voids

PDIV 4 kV; PRPD attributed to delamination

PDIV 2.5 kV; PRPD attributed to delamination

***voltages expressed in peak values**

PD data from D. Polvani - internal document (EDMS)

Conclusions and perspectives

- **Robust electrical insulation** is essential for the reliability of Nb_3Sn superconducting magnets for particle accelerators
- **Control of the braiding process** is necessary to meet tight magnet construction tolerances and insulation quality.
- **Desizing techniques** (thermal, plasma) are promising in improving dielectric performance, but scale-up and validation in coils are ongoing.
- An epoxy system tailored with flexibiliser can **enhance fracture toughness** at cryogenic temperature without compromising radiation hardness – critical for long-term performance.
- **Partial Discharge (PD)** testing is a valuable diagnostic tool to assess insulation quality and detect early signs of degradation due to thermal-mechanical induced stresses.

04. CONCLUSION

Conclusion

1. This study is the first to propose the **optimal boundary for achieving maximum load-carrying capacity, incorporating the effects of turbulence, bearing deformation, and misalignment**.

2. The inclusion of these factors **narrowed the recommended operating range**, highlighting the importance of considering them to ensure the high reliability of the system.

3. Furthermore, this research introduces **novel frameworks** to explain **the shift in optimal boundaries for maximum load-carrying capacity** caused by **turbulence, bearing deformation, and misalignment**.

Keywords: Composite fibers, Electrospinning, Radiation shielding, Thermal properties, Electron microscopy

ABSTRACT

This work focuses on the design and fabrication of innovative polymer-based radiation shields by using the electrospinning technique. A strategic architecture of the fibers is developed to enhance the radiation shielding properties of the composite material, and to preserve flexibility and adaptability to different surfaces. The polymer-based fibers are synthesized using a non-toxic solvent mixture, following a sustainable and environmentally friendly approach that avoids the use of conventional toxic solvents. The polymer concentration and solution formulation were optimized to ensure electrospinnability. The influence of electrospinning parameters (voltage, flow rate, and collector distance) on fiber morphology was systematically investigated. To explore potential improvements in shielding performance, high-Z lead-free fillers (Bi_2O_3, Gd_2O_3, and WO_3) were considered in simulation studies and theoretically evaluated for their photon attenuation efficiency when embedded in the polymer matrix. Photon attenuation properties were analyzed using the XCOM database across a wide energy range (0.001–10 MeV), relevant to space environments, including solar X-rays, solar gamma rays, and cosmic gamma radiation. Several experimental techniques were used to analyze the properties of the electrospun mats. Fourier-transform infrared spectroscopy (FTIR) was used to investigate the chemical structure, while scanning electron microscopy (SEM) provided insights into the microfiber morphology. Differential scanning calorimetry (DSC) was carried out to evaluate the thermal properties of the electrospun fibers, also in consideration of the temperature fluctuations that are typically found during space exploration missions.

1 INTRODUCTION

As human space exploration advances toward longer and more complex missions, the development of advanced radiation shielding materials becomes increasingly critical to protect both astronauts and spacecraft electronics from the harmful effects of ionizing radiation [1]. This radiation arises primarily from solar particle events, solar-origin X-rays and γ-rays, and high-energy galactic cosmic rays, all of which pose cumulative biological and technological risks in low-Earth orbit and beyond [2]. Conventional shielding strategies have long relied on bulk metallic barriers, particularly lead, due to their high density and effective photon attenuation. However, such materials are inherently rigid, heavy, and environmentally hazardous, making them unsuitable for modern aerospace systems where weight constraints, flexibility, and sustainability are essential [3].

In response to these limitations, there is growing interest in the design of polymeric composite materials that combine lightweight polymer matrices with high-Z fillers capable of attenuating high-energy radiation [4]. This approach enables the fabrication of shielding materials that are not only mechanically adaptable but also engineered at the micro- or nanoscale to enhance radiation interaction cross-sections. Among advanced polymeric materials, polyimide (PI) stands out due to its exceptional

thermal and chemical stability, high mechanical strength, and inherent flexibility, making it a preferred material for aerospace applications [5-7].

Meanwhile, the pursuit of sustainable technologies has accelerated the replacement of toxic heavy metals with lead-free high-Z oxides, such as bismuth oxide (Bi_2O_3), gadolinium oxide (Gd_2O_3), and tungsten oxide (WO_3) [8, 9]. These materials offer high photon attenuation performance across broad energy ranges and have been increasingly explored for use in next-generation shielding composites [10]. To fabricate these advanced fibrous composite structures, electrospinning has emerged as a powerful and versatile fabrication method. This technique enables the production of uniform fiber mats with a high surface-area-to-volume ratio and allows for precise control over fiber morphology and architecture [11, 12]. Electrospinning is scalable from laboratory to industrial production, making it a promising route for large-scale production of lightweight shielding composites.

In the present work, polyimide fibers were successfully fabricated via electrospinning using non-toxic solvents and characterized using scanning electron microscopy (SEM), Fourier-transform infrared spectroscopy (FTIR), and differential scanning calorimetry (DSC). To explore their applicability in radiation shielding, a simulation-based study was conducted to evaluate the theoretical performance of these fibrous structures when integrated with lead-free high-Z oxide fillers. Photon attenuation properties were calculated using the XCOM photon cross-section database over a wide energy range (0.001 to 10 MeV), encompassing the primary spectral domains of space radiation. The findings support the viability of these polyimide-based composites as lightweight and sustainable alternatives to conventional metallic shielding for future space missions.

2 MATERIALS AND METHODS

2.1 Materials

The following chemicals were obtained from the indicated sources and used without further purification: 2,2-bis [4-(4-aminophenoxy)phenyl] hexafluoropropane (4-BDAF, Tokyo Chemical Industry, Tokyo, Japan); 2,2-bis(3,4-dicarboxyphenyl) hexafluoropropane dianhydride (6FDA, Alfa Aesar, Kandel, Germany); dimethyl isosorbide (DMI, Sigma-Aldrich, Milan, Italy); acetone (ACS reagent, ≥99.5%); acetic anhydride (Chem-Lab, Zedelgem, Belgium) and pyridine (Honeywell Riedel-de Haën, Charlotte, NC, USA). Ultrapure water (resistivity 18.2 MΩ cm) was obtained from a Direct-Q3 UV water purification system (Millipore, Molsheim, France).

2.2 Electrospinning

The polyimide (PI) used in this study was synthesized via a two-step process, as previously described in our earlier work [5]. After synthesis and purification, the resulting polyimide was obtained as a dry powder. The PI powder was dissolved in a solvent mixture of acetone and DMI at suitable ratio before the electrospinning process.

A custom-made experimental setup for electrospinning/electrospraying was employed to fabricate the polyimide fibers, providing precise control over process conditions and reproducibility [13-15]. A green electrospinning approach was employed by use of the non-toxic DMI/acetone solvent system. Process parameters (polymer concentration, solvent ratio, applied voltage, and flow rate) were optimized to yield uniform fibers. The optimized conditions, identified through preliminary screening, were applied throughout. Following electrospinning, the resulting fiber mats were subjected to thermal treatment at 150 °C for 2 hours to ensure complete removal of residual solvents and to promote further imidization of the polymer structure.

2.3 Characterization methods

The morphology of PI microfibers was examined via SEM (VEGA II LSH, Tescan, Czech Republic) after gold sputter-coating (Cressington 108, UK). Fiber diameter distribution was quantified using ImageJ (v1.51w) with the DiameterJ plugin (v1.018). Thermal behavior was assessed by DSC (Pyris DSC 8500, PerkinElmer, USA) under nitrogen flow (40 mL/min), using ~10 mg samples in sealed aluminum pans, scanned from 25 to 300 °C at 10 °C/min. FTIR analysis was performed with a Nicolet™

Summit spectrometer (Thermo Fisher Scientific, USA) equipped with a diamond ATR, recording spectra in the 4000–600 cm^{-1} range at 4 cm^{-1} resolution (64 scans, air background subtracted).

2.4 Radiation shielding simulations

Simulations of the composites radiation shielding properties were performed using the XCOM photon cross section database developed by NIST, incorporating total attenuation coefficients inclusive of coherent scattering [16]. The study focused on photon interactions within the 0.01–10 MeV energy range, encompassing the most relevant spectral domain for radiation exposure in low Earth orbit (LEO) and interplanetary space [17]. This range includes contributions from solar X-rays, gamma radiation from solar flares, and galactic cosmic photons, making it representative of operational space conditions [18]. Simulations were performed on pure polyimide ($C_{46}H_{12}F_6O$), high-Z oxides (PbO, Bi_2O_3, Gd_2O_3, and WO_3), and their corresponding composites with polyimide as the matrix. The selected fillers include lead oxide (PbO) as a conventional reference and three lead-free alternatives, bismuth oxide (Bi_2O_3), gadolinium oxide (Gd_2O_3), and tungsten oxide (WO_3), chosen for their high atomic numbers, chemical stability [19-21]. Two filler loadings (20 and 50 wt%) were selected as the most realistic concentrations, balancing processability, dispersion quality, and shielding effectiveness, under the assumption of uniform distribution within the polymer matrix. The total linear attenuation coefficient (μ) for each sample was calculated using the rule of mixtures, accounting for the weighted contributions of each component's mass attenuation coefficient (μ/ρ) and density. To assess the relative performance of the composites with respect to the neat polymer, a dimensionless attenuation ratio R was introduced, defined as:

$$R = \frac{(\mu/\rho)_{composite}}{(\mu/\rho)_{PI}} \quad (1)$$

where $(\mu/\rho)_{composite}$ is the mass attenuation coefficient of the filled system, and $(\mu/\rho)_{PI}$ is that of the pristine PI. This ratio, evaluated at a reference energy of 0.5 MeV, enables a direct and density-independent comparison of shielding efficiency across all compositions [22].

3 RESULTS AND DISCUSSION

3.1 Fabrication of PI microfibers by electrospinning

The electrospinning process was optimized by varying polymer concentration, solvent composition, voltage, and flow rate. Uniform fibers were obtained using a polyimide solution in a non-toxic binary DMI/acetone solvent system. The resulting mats were thermally treated at 150 °C for 2 h to remove residual solvents and promote further imidization. Figure 1a shows a representative SEM image of the thermally treated fibers, revealing smooth, bead-free, randomly oriented filaments. The corresponding diameter distribution (Fig. 1b), obtained using DiameterJ, resulted in a mean diameter of 1.16 ± 0.59 μm, with 36.9% porosity and an intersection density of 0.43 intersections/μm^2. This microstructure indicates a highly porous and interconnected architecture suitable for functional filler integration.

A qualitative assessment of flexibility is shown in Figure 1c. The mat was manually folded and released, demonstrating elastic recovery without visible damage or permanent deformation.

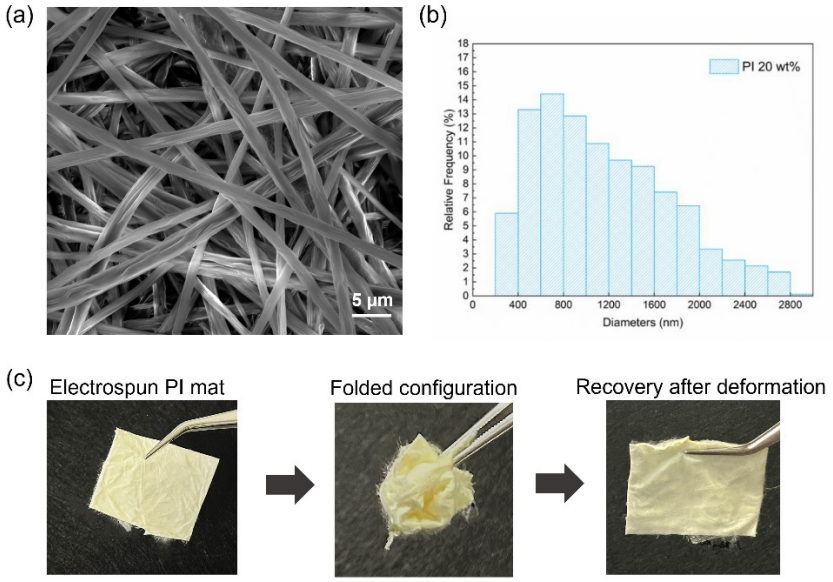

Figure 1: (a) SEM image of electrospun polyimide fibers after thermal treatment at 150 °C for 2 hours. (b) Fiber diameter distribution histogram. (c) Qualitative flexibility assessment: the mat is shown in its original state (left), after folding (middle), and following shape recovery (right).

3.2 Chemical and Thermal Properties of PI electrospun fibers

FTIR spectroscopy was employed to assess the chemical structure of electrospun polyimide fiber mats (20 wt%). Figure. 2a shows the chemical structure of aromatic PI with trifluoromethyl functional groups. The spectrum (Fig. 2b) exhibits well-defined imide-associated absorption bands, including the asymmetric and symmetric C=O stretching vibrations at 1784 and 1724 cm^{-1}, respectively. The C=C stretching of the aromatic moiety is evident at 1504 cm^{-1} and remains unaltered. The absorption at 1379 cm^{-1}, assigned to C–N stretching, and the band at 724 cm^{-1}, corresponding to C=O bending, further corroborate the presence of the imide group. The absence of characteristic bands associated with unreacted amine and carboxylic acid groups (3330, 1710, 1650, and 1550 cm^{-1}) indicates a high conversion degree of poly (amic acid) into polyimide [5]. Minor features in the 2921–2850 cm^{-1} region are attributed to C–H stretching vibrations from residual solvent species.

Differential scanning calorimetry (DSC) was employed to evaluate the thermal behavior of electrospun PI fiber mats. The thermogram of the untreated fibers showed two distinct exothermic peaks at 220 °C and 232 °C during the heating (Fig. 2c). In contrast, the thermogram of the thermally treated PI fibers (150 °C for 2 h) does not exhibit any thermal events within the investigated temperature range, confirming the absence of residual transitions or structural rearrangements. The absence of thermal events up to 300 °C confirms the thermal stability of the treated fibers, making them suitable for aerospace applications requiring resistance to prolonged thermal exposure.

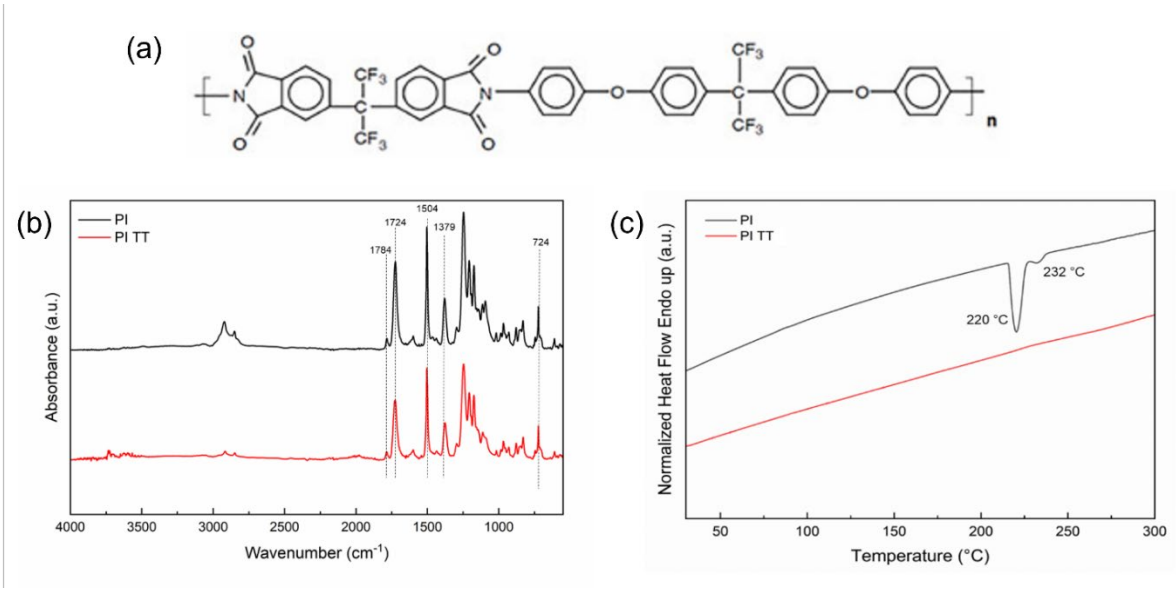

Figure 2: (a) Chemical structure of the in-house synthesized polyimide [5]. (b) FTIR spectra of electrospun PI fiber mats, untreated and thermally treated at 150 °C for 2 hours. Data are offset for clarity. (c) DSC thermograms of untreated and thermally treated PI fibers.

3.3 Simulations of radiation shielding capability

Figure 4 presents the simulated mass attenuation coefficients (μ/ρ) of the investigated fillers and polyimide-based composites across the 0.001–10 MeV photon energy range. As expected, PbO exhibited the highest attenuation due to its high atomic number. However, Bi_2O_3 demonstrated nearly equivalent performance, particularly within the 0.01–1 MeV range, which is highly relevant for shielding against solar and cosmic photon fluxes in low Earth orbit (LEO).

Upon incorporation into the PI matrix at 20 wt% and 50 wt% loading (Fig. 4c and 4e), all fillers led to an increase in attenuation relative to the pristine polymer. This effect becomes more pronounced at higher concentrations, with clear differences observed in the 0.1–1 MeV range (Figure. 4d and 4f), which corresponds to the energy window where Compton scattering dominates and shielding demands are most relevant to space radiation environments [23]. A comprehensive summary of the simulated mass attenuation coefficients (μ/ρ) at 0.5 MeV and the corresponding normalized attenuation ratios (R) relative to pristine PI is presented in Table 1. At 50 wt% filler loading, the Bi_2O_3-filled composite demonstrated superior attenuation performance compared to the PbO-based sample, with a marginally higher R value (1.416 vs 1.407).

Although composites incorporating WO_3 and Gd_2O_3 show comparatively lower R values, they still provide a significant improvement over unfilled polyimide. These results validate the role of high-Z oxide fillers in improving the photon-attenuation ability of polymer-based materials. In particular, Bi_2O_3 emerges as a very promising lead-free alternative that can offer attenuation performance equal to or marginally better than that of conventional lead-containing materials, while providing enhanced environmental sustainability and chemical stability features required for next-generation aerospace shielding materials.

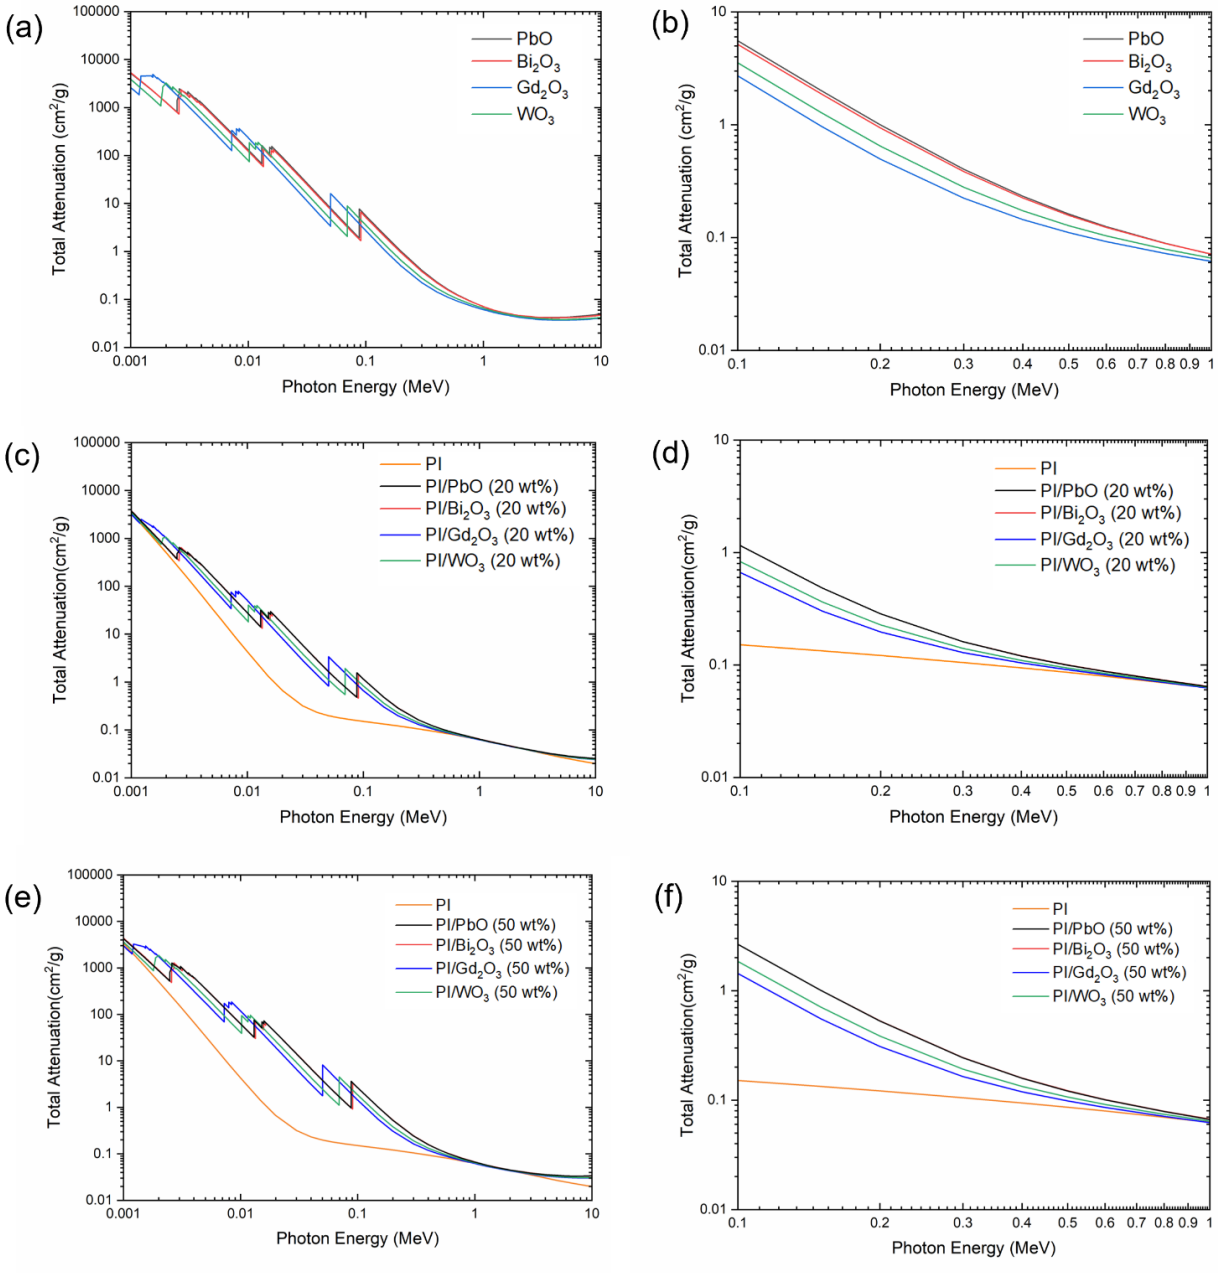

Figure 4: Simulated photon attenuation of polyimide (PI) composites using XCOM. Total attenuation coefficients (0.001–10 MeV) were computed via the NIST XCOM database, including coherent scattering. PI/WO_3 (50 wt%)	0.107	1.240

4 CONCLUSIONS

Flexible polyimide-based fibrous mats were successfully fabricated via green electrospinning using a non-toxic solvent system and subsequently stabilized by heat treatment. The resulting materials exhibited uniform morphology, flexibility, and thermal stability up to 300 °C, confirming their suitability for use in space environment. A comprehensive characterization revealed smooth, bead-free fibers with a highly porous and interconnected microstructure. Radiation shielding simulations using XCOM demonstrated that PI composites loaded with lead-free high-Z oxides significantly enhance photon attenuation. Among the candidates, Bi_2O_3 showed performance comparable to or exceeding that of Pb, particularly in the 0.1–1 MeV range relevant to space radiation. These findings highlight the potential of PI/Bi_2O_3 composite mats as lightweight, flexible, and more sustainable alternatives to conventional shielding materials for future space missions.

Keywords: Unidirectional fiber, Laminate Wrinkling, Double Diaphragm Forming, Prepreg

ABSTRACT

Wrinkling is a critical challenge when forming complex, double-curved shapes using unidirectional fiber composites. These defects degrade mechanical properties and dimensional accuracy, limiting industrial applicability. While Double Diaphragm Forming (DDF) is used to suppress wrinkles using elastic diaphragms, it is less effective for thick laminates, particularly those with quasi-isotropic fiber orientations. High interply shear resistance in such laminates restricts internal deformation, causing wrinkling. Additionally, diaphragms between the tool and laminate reduce precision and complicate removal.

This study presents a novel forming technique that sequentially laminates thin layers directly on the mold surface to achieve the required thickness. It uses a long inflatable tube to press the laminate during forming, replacing the traditional diaphragm. The tube can be removed after forming, eliminating interply shear and enabling wrinkle-free forming on the tool surface. The material used is SKYFLEX USN150A (SK Chemical), a unidirectional carbon fiber prepreg with epoxy resin (4900 MPa strength, 240 GPa modulus, 1.82 g/cm³ density, 150 g/m² areal weight, 36% resin content, no scrim). Though not aerospace-grade, it is well-suited for process development.

The method was validated by forming a C-channel with eight plies (stacking sequence: (0/90/45/–45)s) using four two-ply forming cycles. The final part measured 1140 mm in length with a 1000 mm inner flange radius. Thickness was measured at 268 points using micrometers, yielding an average of 2.149 mm and a standard deviation of 0.081 mm. Minor variations were observed at edges and flanges, influenced by fiber orientation and curvature. Differences between 0°/90° and ±45° laminates suggest the need for preform shape adjustment. After forming, the part was vacuum-bag cured at 125°C under 200 kPa for 2 hours.

This technique offers a practical, wrinkle-free forming process for unidirectional composites with potential for industrial application.

1 INTRODUCTION

Curved C-channel structures are commonly used in aircraft fuselages as lightweight, high-stiffness frame components. These elements offer an efficient moment of inertia and enable easy access for joining processes such as riveting and bonding. When paired in a fuselage cross-section, they function similarly to I-beam webs, effectively sharing structural loads with the skin under pressure and bending. Their geometry also allows for relatively simple manufacturing processes. As aircraft structures evolve toward more efficient and lightweight designs, forming such curved components from fiber-reinforced composites has become increasingly desirable.

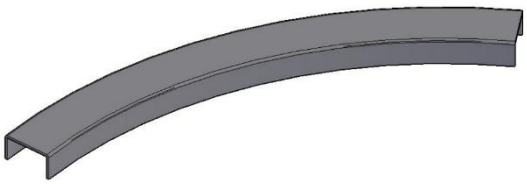

Figure 1: A curved C channel.

Among composite materials, unidirectional (UD) carbon fiber prepregs are widely used in the aerospace industry, where the strength-to-weight ratio plays a crucial role. During forming, longitudinal deformation along the fiber direction is limited due to the high directional stiffness of the fibers. As a result, plies with different fiber orientations require distinct deformation modes. This mismatch necessitates interply slippage—the relative movement between adjacent laminate layers—when shaping complex geometries using UD prepregs with quasi-isotropic layups, such as (0/90/45/–45)s, which contain multiple plies with different fiber orientations within a laminate [1, 2, 3]. Forming such stacks over double-curved molds introduces resistance to deformation and promotes buckling or wrinkling. Wrinkle defects are not only visually undesirable but also detrimental to structural performance, affecting dimensional accuracy and load-bearing capabilities. These issues have limited the widespread industrial adoption of composite forming, especially for aerospace-grade structures.

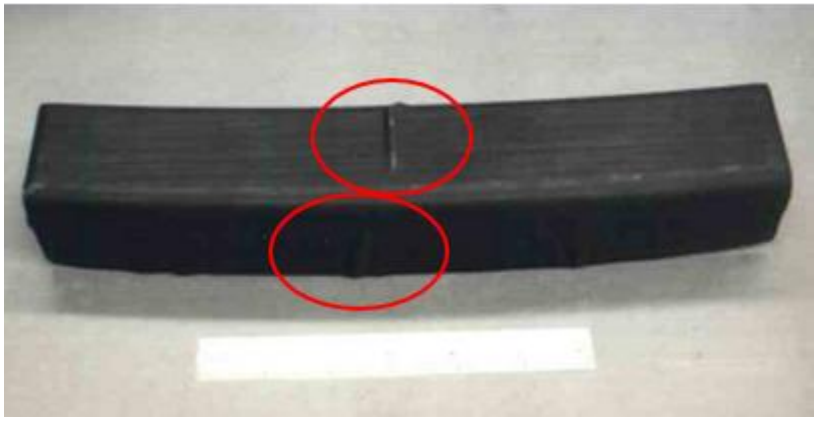

Figure 2: laminate wrinkle on a curved C channel part.

Double Diaphragm Forming (DDF) is one of the most established techniques used to address these challenges. In this method, the composite laminate is placed between two elastic diaphragms, and vacuum is applied to draw the laminate tightly against the forming tool. The elastic tension in the diaphragms applies pressure from both sides, helping to prevent out-of-plane buckling. While DDF is effective for thin laminates, it becomes less reliable with increased thickness or complex stacking sequences. For quasi-isotropic laminates, the combined effects of internal strain, limited ply compatibility, and interply shear resistance lead to persistent wrinkling.

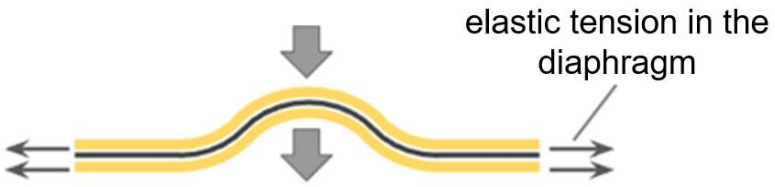

Figure 3: illustration of diaphragm pressure generated by the elastic tension.

Experimental results confirm this limitation. Curved C-channels formed with quasi-isotropic stacking using DDF consistently showed severe wrinkling along the flanges and curved surfaces, regardless of component size. This observation suggests that the fundamental mechanics of interply behavior and laminate deformation must be reconsidered. It also highlights the need for alternative forming strategies that reduce or eliminate interply slippage while maintaining compatibility with existing composite manufacturing workflows.

Figure 4: laminate wrinkling formed during double diaphragm forming process.

This research addresses the limitations of conventional forming methods by exploring a sequential forming technique for unidirectional prepregs. Instead of forming a thick laminate at once, thin layers are shaped individually and laminated progressively to build up the required thickness. By forming each ply or small stack directly on the mold surface, interply slippage is minimized or eliminated. This approach offers better conformity to complex shapes and prevents wrinkle formation, paving the way for more precise, defect-free composite components suitable for demanding applications.

2 A NEW FORMING METHOD FOR WRINKLE-FREE LAMINATES

Wrinkling in quasi-isotropic composite laminates remains a significant challenge in forming double-curvature geometries, especially when using unidirectional (UD) fiber prepregs. This issue arises primarily due to the limited interply slippage needed to accommodate the different in-plane deformation behaviors of plies with varying fiber orientations. In contrast, cross-ply laminates (e.g., 0°/90° or ±45°) can deform through a trellising mechanism, in which adjacent plies rotate locally relative to each other, reducing the need for slippage. However, quasi-isotropic layups—which combine multiple cross-ply orientations such as 0°/90° and ±45°—introduce conflicting deformation patterns among plies. In Figure 5, the trellising deformation of the blue laminate requires longitudinal slippage of the red ply (thick section). This mismatch increases interply resistance, elevates internal stresses, and often leads to out-of-plane buckling or wrinkle formation. Similar behavior has been observed in dry woven fabric composites as well [2, 4, 5, 6].

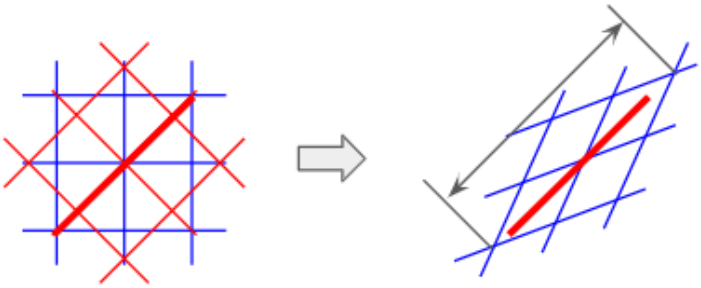

Figure 5: Illustration of the necessary interply slippage between plies with different fiber orientations during in-plane deformation. In quasi-isotropic laminates, misaligned fiber directions (e.g., ±45° vs.

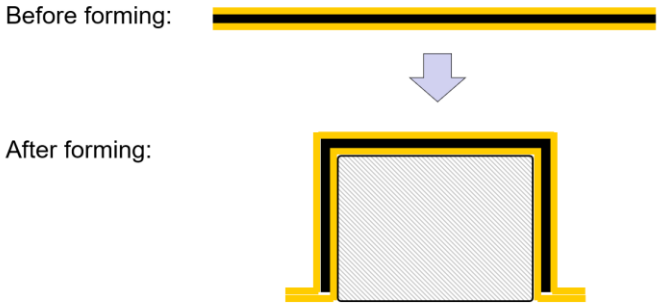
0°/90°) require longitudinal slippage to accommodate trellising, leading to increased interply shear and potential wrinkling during forming.

To address this challenge, a new forming approach is proposed that eliminates the need for interply slippage by sequentially forming multiple thin laminates, one layer at a time, on top of previously shaped layers. In this method, each ply or sub-laminate is formed directly onto the tool surface or a pre-formed layer. By avoiding the bulk deformation of a thick laminate stack, the material can more easily conform to complex geometries without inducing significant interlaminar shear strains.

A critical requirement of this approach is to support the laminate from the both sides to suppress out-of-plane buckling during forming—while ensuring that no material remains trapped between the laminate and the tool. In conventional double diaphragm forming (DDF), the laminate is supported by diaphragms on both sides; however, one diaphragm remains between the tool and the laminate, as shown in Figure 6, and cannot be easily removed after forming.



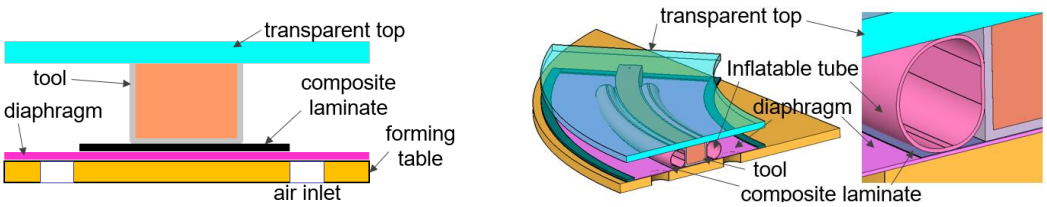


Figure 6: Schematic showing one of the diaphragms trapped between the composite laminate and the forming tool after forming with DDF.

To overcome this limitation, the proposed method employs inflatable tubes or long balloons placed adjacent to the tool surface to support the laminate during forming. As the forming completes, the balloons are fully deflated and removed, allowing the laminate to make direct contact with the tool surface.

The process begins by placing a thin composite prepreg on the diaphragm and the supporting table. A forming tool is then positioned on top of the laminate, as shown in Figure 7(a). Note that the color representing the diaphragm has been changed in Figure 7—from yellow in Figure 6 to a new color—to indicate the use of a natural rubber sheet. Figure 7(b) provides an angled view of the same setup, where inflatable tubes are placed adjacent to the forming tool. The composite laminate located beneath the inflatable tubes is visible in the magnified image. A top plate holds the tool in place throughout the forming process as the diaphragm inflates and exerts upward pressure against it. This top plate can be made from a transparent material, such as polycarbonate, to enable real-time observation of the forming progression.

(a) cross sectional view (b) angled view with inflatable tubes

Figure 7: Schematic diagrams to illustrate the setup with tool on the laminate and diaphragm.

During forming, air pressure inflates the diaphragm, pressing the laminate toward the tool while the inflatable tube, positioned between the laminate and the tool, applies localized pressure to support the laminate. As forming progresses, air within the inflatable tube is gradually released to maintain appropriate contact pressure without obstructing the forming process. Figure 8 illustrates how the inflatable tubes deform while the diaphragm inflates. Once forming is complete, the inflatable tube is fully deflated and removed. The next ply is then placed and formed in the same manner. By repeating this process layer by layer, the total laminate thickness is gradually built up, reducing interply stress and effectively preventing wrinkle formation.

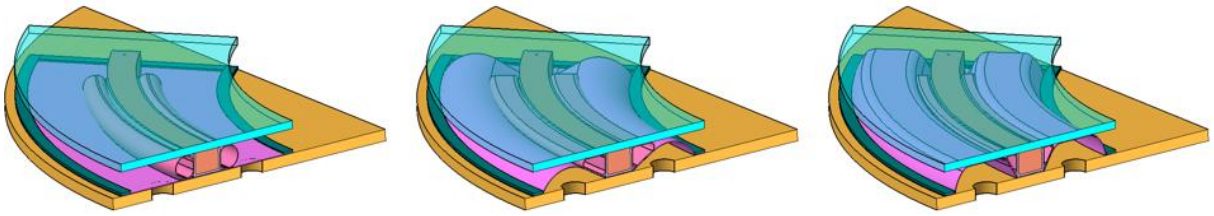

Figure 8: As the diaphragm inflates, the laminate deforms and the inflatable tubes are squeezed and exert supporting pressure on the laminate to prevent out of plane buckling.

This approach offers several advantages. First, it enables wrinkle-free forming of quasi-isotropic layups by sequentially forming thin laminates. Second, because the laminate is formed directly on the tool surface, in-place curing is possible without the need for repositioning. Third, the sequential nature of the process supports semi-automation, allowing integration of preform cutting, layer placement, and forming into a continuous workflow. Finally, desired stacking sequences such as $(0/90/\pm45)_s$ can be achieved by alternating between (0°/90°) and (±45°) layups during each cycle. This method offers a practical path forward for producing geometrically accurate, structurally sound composite parts with complex shapes. It opens new possibilities for forming high-performance UD laminates for aerospace and automotive applications, where shape fidelity and defect minimization are essential.

Figure 9 illustrates the progression of the forming process and indicates the point at which the inflated tube or balloon is removed—after Step 4—to allow the laminate to form directly on the tool surface. Step 6 demonstrates the repeatability of the process for building up laminate thickness.

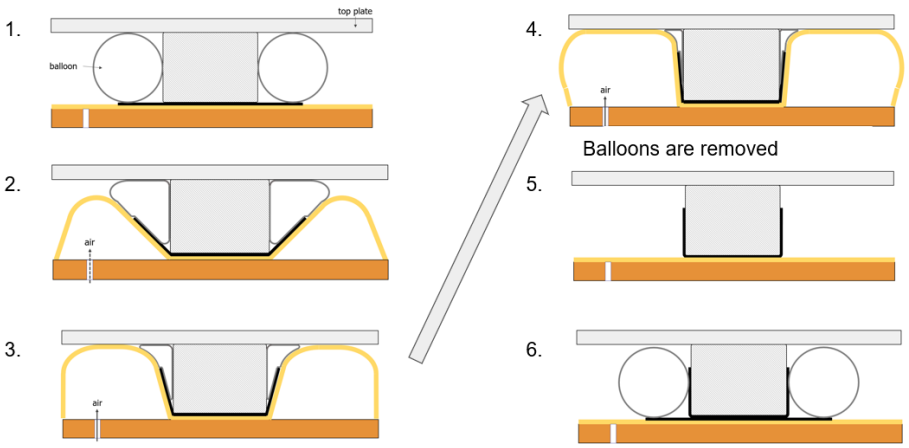

Figure 9: Step-by-step sequence of the proposed sequential forming process.

3 PRODUCED PARTS

Two composite parts with curved C-channel geometries were produced using the newly developed wrinkle-free forming method. The primary goal of the experiments was to evaluate the feasibility of sequentially forming cross-ply unidirectional (UD) laminates without introducing interply shear or laminate wrinkling. The first part, with dimensions of 30 cm in length and a channel height of 3 cm, was manufactured using a mold embedded with heating elements for in-situ curing. The laminate configuration consisted of eight plies arranged in a quasi-isotropic sequence: (0°/90°/+45°/−45°)s. This part was successfully cured, but localized defects such as bridging were observed, particularly in regions with high curvature. These defects indicated partial separation between the laminate and the tool surface during forming, prompting design refinements in the support structure.

The second part incorporated improvements including refined support mechanisms and better laminate placement, minimizing the chances of interlaminar bridging. A mixed-material mold—constructed from aluminum for structural rigidity and wood for thermal insulation—was used to facilitate even heat distribution. The same stacking sequence and dimensions were used, and inflatable bladders were employed beneath the diaphragm to maintain consistent pressure on the laminate from both tool and air-side surfaces. Notably, the second part demonstrated successful wrinkle-free forming, with no signs of buckling or delamination. Visual inspection and surface flatness assessments confirmed the structural integrity of the part.

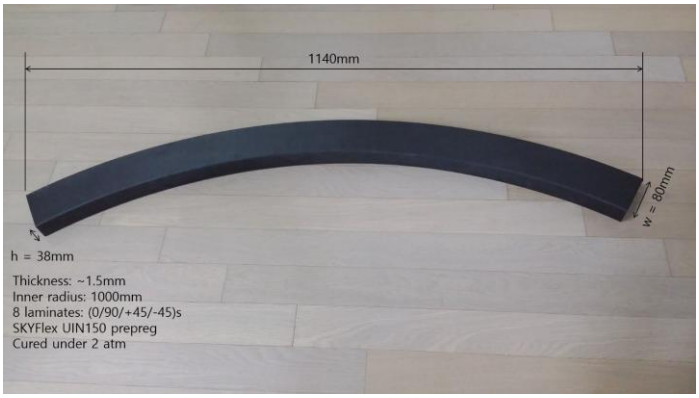

Figure 10: dimensions of the second curved C channel without wrinkles.

The successful fabrication of these components validates the proposed method's capability to form complex geometries in composite laminates without the introduction of defects typically encountered in double-diaphragm forming. Moreover, the modularity of this process allows for scaling to larger parts and different ply orientations, marking a significant advancement in out-of-autoclave composite

4 THICKNESS MEASUREMENT

Thickness uniformity across composite structures is essential for maintaining mechanical performance and ensuring predictable load-bearing behavior. To assess the effectiveness of the newly developed forming process, detailed thickness measurements were conducted on the second, wrinkle-free curved C-channel part. The specimen was marked with adhesive tapes at evenly spaced 5 cm intervals along the circumference to establish consistent measuring points. A micrometer equipped with extensions was used to measure the thickness of the top surface and both flanges, accounting for curved and constrained geometries.

The average thickness of the top surface was measured to be 2.17 mm, with a standard deviation of 0.05 mm. This indicates that the forming process provided excellent consistency in the laminate stacking and consolidation. The inner and outer flanges were measured separately to evaluate local variation. The average thicknesses were found to be 2.15 mm for the inner flange and 2.12 mm for the outer flange,

with no significant thickness gradient observed across the part height.

Further evaluation was conducted at high, middle, and low sections along the vertical height of the flange to analyze possible variations due to gravity or differential compaction pressures. The thickness values recorded were within ±0.1 mm of the average, demonstrating that the laminate layers remained well-aligned and that the support method effectively minimized thickness deviation. The measurement results confirm that interply slippage and wrinkling were successfully suppressed, allowing even consolidation of the laminate throughout the part.

These findings demonstrate the viability of the sequential cross-ply stacking and forming approach for producing geometrically complex, multi-ply composite parts with tight dimensional tolerances. The precise control over laminate thickness is particularly important for applications in aerospace structures, where uniform mechanical properties and dimensional accuracy are essential.

5 CONCLUSIONS

A novel forming method was developed to eliminate wrinkling in quasi-isotropic unidirectional composite laminates. By supporting the laminate from both sides using removable diaphragms and inflatable bladders, the process avoids interply slippage and enables direct forming on the tool surface. This method facilitates sequential cross-ply laminate stacking and in-situ curing, addressing key limitations of traditional double-diaphragm forming.

Two curved C-channel parts were produced, with the second part exhibiting wrinkle-free geometry and uniform thickness. Measurements showed an average thickness of 2.15 mm with minimal variation, confirming consistent consolidation throughout the part.

The proposed process is scalable and compatible with semi-automated manufacturing, making it a practical solution for industries requiring lightweight, high-integrity composite structures. It offers a reliable approach for forming complex geometries without defects, particularly in aerospace and advanced structural applications [2, 6].

ACKNOWLEDGEMENTS

This work builds upon the authors' earlier contributions, including U.S. Patent No. US11745408B2 and the publication titled "Forming Wrinkle-Free Curved C Channel with Unidirectional Fiber Reinforced Composites," published in the International Journal of Precision Engineering and Manufacturing-Green Technology [1, 7]. The present study expands and refines the forming process itself—now the focal point of this work—through revised explanations, enhanced illustrations, and additional discussion.

The authors gratefully acknowledge the mentorship of Professor Timothy Gutowski during the first author's earlier academic training, which provided foundational experiences that contributed to this research. This work was fully self-funded by the authors.

ABSTRACT

In the context of composite manufacturing process development, digital twins are often used to conduct parametric studies in order to determine the optimum process parameters without the need of extensive trial-and-error experiments. Process simulation using finite element (FE) method has become a well-established tool for performing such tasks. However, the major drawback of this method is the high computational cost (especially in the context of preforming when draping dry materials), which restricts calculations to a limited set of configurations that must be carefully selected by experts. Therefore, modern approaches increasingly focus on surrogate modeling using artificial intelligence. One possible surrogate model architecture is the image-based U-Net model that maps input images to resulting output images. When trained with sufficient data, this kind of model is able to predict results for different draping parameters quite accurately for draping tool geometries included in the training data (see [1]). When it comes to unknown tool geometries (that were not within the training data), however, predictions become unreliable. This paper describes the generation of a parametric tool that covers a range of different tool geometries in order to expand the prediction accuracy for unseen geometries. By training the surrogate model on draping tools with different similarities to a reference, it can interpolate within this similarity range, enabling accurate predictions for unknown draping tools that lie between known configurations. The parametric tooling uses a similarity measure to evaluate the degree of similarity between two tools of different similarities to a certain reference tool. The goal is to use these generated tools within a routine to automatically create training data and then train the surrogate using the simulation results for the varying tools. The developed parametric draping tool uses Free Form Deformation and the *Downhill Simplex method* to achieve shapes of different similarities.

1 INTRODUCTION

Over the last decades, artificial intelligence (AI)-based surrogate modeling became an increasingly popular strategy for approximating the complex behavior of various processes with faster yet still reliable alternatives. It is already applied across different disciplines such as biomedical applications [2], environmental science [3] or material science [4]. In the field of material forming and process simulation, there are also multiple applications in standard manufacturing such as metal forming [5, 6]. Most recent advances also show the use of surrogate models within the field of textile draping and composite manufacturing [7, 8]. Reported approaches range from rather low complexity (e.g., using linear regression models), to metamodeling [9] and neural networks of different complexities [10] up to highly complex full simulation models (e.g., using Position-Based Dynamics approaches) [8].

A quite common approach for the approximation of process parameters is the use of convolutional neural networks (CNNs) – especially in form of a U-Net architecture. U-Nets, originating from the field of biomedical image segmentation [2], are supervised learning models, usually trained on labeled images, where each data entry contains an input with an associated output image. A properly trained model allows for a readily available prediction, with only moderately complex architecture.

In a preliminary study, we established the applicability of a U-Net surrogate model to predict the draping behavior of a fabric onto a rib tool [1]. Findings confirmed the ideal suitability of the image-based surrogate to approximate the draping behavior and provide accurate predictions for the rib tool geometry it was trained on. However, the main disadvantage of those kind of models is their poor extrapolation capabilities, meaning that the model cannot provide accurate predictions for draping tools that were not included in the training data. This means, if we want to use the surrogate model for a new draping tool geometry, a whole new training data, including the new tool geometry, must be generated annihilating the time-savings by this approach. The objective of this study is therefore to create a parametric tool that enables the generalization of the U-Net surrogate model in order to enhance the prediction quality of unseen geometries.

2 METHODS

The idea of creating a parametric draping tool is based on the assumption that U-Net surrogate models are capable of interpolating between similar solutions (i.e., data augmentation, see [2]). The surrogate model used in [1] should therefore be expanded by training with tools of different similarities, enhancing generalizability and thus, the overall applicability of image-based surrogate models. To implement this approach, we developed a python script that is able to targetedly modify surfaces based on a reference surface in order to achieve tools with different degrees of similarity to the reference. The following subsections show a detailed description of the generalization concept, script architecture, working principle and algorithm specifics.

2.1 Overall Objective and Generalization Concept

In the aircraft industry, component and draping tool design play a crucial role in ensuring the component's structural integrity within the whole assembly. Oftentimes, tool geometries need to be slightly adapted in order to suit the varying application requirements. This results in various draping tools that differ in shape while still maintaining a certain degree of similarity. To ensure that the image-based surrogate model manages to deal with those kind of variations, they need to be reflected within the training data. In order to achieve that, we developed the following concept for the parametric tool creation:

First, a set of representative tool geometries (derived from real-world application components) must be defined. These serve as reference tools for creating variations with different degrees of similarity. The user provides their surface topology as *.stl* meshes. Examples of such geometries (e.g., based on typical aircraft components) are shown in Figure 1.

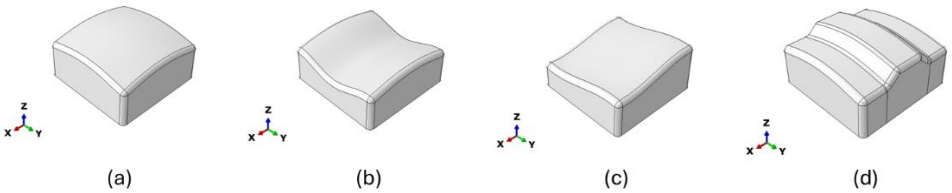

Figure 1: Examples of representative reference tools for aircraft components: (a) spheric calotte, (b) saddle-shaped, (c) double sine and (d) curved hat profile

Modifications of such tools are always limited to manufacturing constraints, such as maximum z-displacements. Therefore, additionally to the reference tools, the user needs to define the manufacturing constraints that limit maximum displacements and thus the distortion of the whole profile. These displacement constraints are based on user expertise, resulting in a maximum possible "dissimilarity" for the tool variations of a respective reference.

For proof of concept, we used a double sine (i.e., *Usecase 1*) and a parabolic geometry (i.e., *Usecase 2*) as tool references:

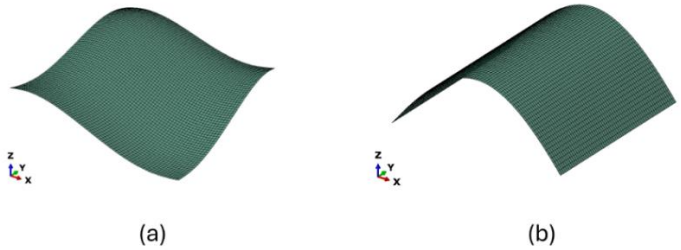

Figure 2: Reference meshes for (a) *Usecase 1* and (b) *Usecase 2*.

The developed routine should systematically generate variations with different similarities to those two geometries, while satisfying the predefined manufacturing constraints (which define the maximum dissimilarity for each shape). In a subsequent step the variations can be used for training the surrogate model, enabling a generalization of the model.

2.2 Script architecture

The developed python script includes the targeted surface modification, similarity assessment and export of created tools as *.stl* files. It can be divided into three main building blocks composing the algorithm:

a) Tool Deformation using Free Form Deformation (FFD)
b) Similarity Measure
c) Solver

Tool Deformation. The deformation of the tool is done via Free Form Deformation (FFD) using the python modules *splinepy* and *gustaf* [11]. This specific technique is used to deform geometrical objects by enclosing them with a hull based on 3D curves (e.g., B-splines or NURBS). By transforming the spline control points of the hull, the contained geometry can then be deformed [12] (see Figure 3). When selecting a reference tool (in our case an FE mesh, e.g., a double sine geometry), the number of spline points in each direction of a cartesian coordinate system can be specified. Distinct control points can then be selected to deform the tool.

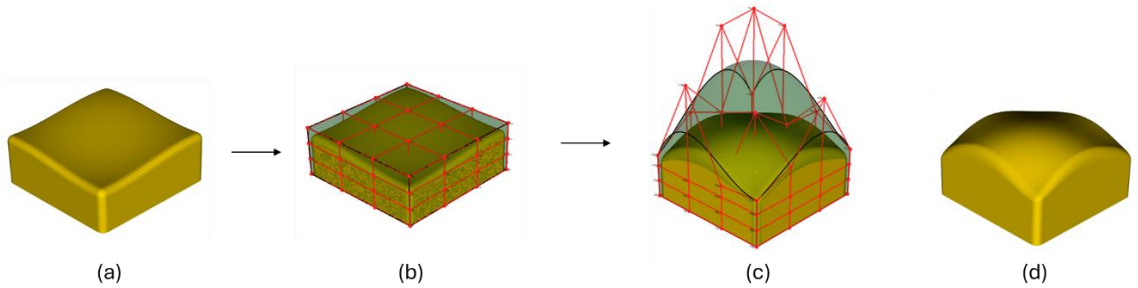

Figure 3: Schematic sketch of the working principle of FFD for a (a) double sine geometry as initial configuration, (b) enclosed in a spline hull and an exemplary deformed configuration (c) with and (d) without spline hull.

Similarity Measure. The similarity measure used to assess the degree of similarity between a reference mesh and the deformed mesh is the root mean square value (RMS) of the nodal distances d_i between the reference mesh and the deformed mesh (see equation (1)).

$$RMS = \sqrt{\frac{1}{n}\sum_{i} \boldsymbol{d}_i^2} \tag{1}$$

Different strategies for the similarity measure (such as the structural similarity index (SSIM) [13] or the comparison of histograms) were analyzed, however, the RMS measure provided the most suitable solution since the other approaches implied a loss of spatial correspondence (due to data summarization for histograms 2D conversion for SSIM).

Due to the manufacturing constraints explained above, the magnitude of the RMS value is limited to certain bounds. This constraint is implemented by calculating a maximum RMS value within predefined displacement bounds and normalizing the RMS value as shown in equation (2):

$$RMS_{norm} = \frac{RMS}{RMS_{max}} \tag{2}$$

This simultaneously ensures comparability between the RMS values of different configurations of the deformed mesh by normalizing the RMS value to a range of [0,1]. Spline control points can be displaced to achieve a certain similarity to the reference while considering the manufacturing constraints. The maximum possible RMS value is specific to the reference geometry as well as depending on the displacement bounds in z-direction. The RMS_{max} value is therefore determined in the following manner:

- *(1) Calculate Candidate z-values*. For each node in the reference mesh, the z-coordinate that lies furthest away from the point (within predefined bounds, either in positive or negative z-direction) is calculated.
- *(2) Enforce Neighbor Constraint*. The extreme values for the z-coordinates are adjusted so that a point does not exceed a fixed distance threshhold to its neighbors. This is done iteratively until convergence.
- *(3) Local Refinement*. The z-values with respected neighbor constraints are then again optimized to maximize the deviation (i.e., the RMS value).

Figure 4 shows a schematic visualization of the working principle in a 2D case:

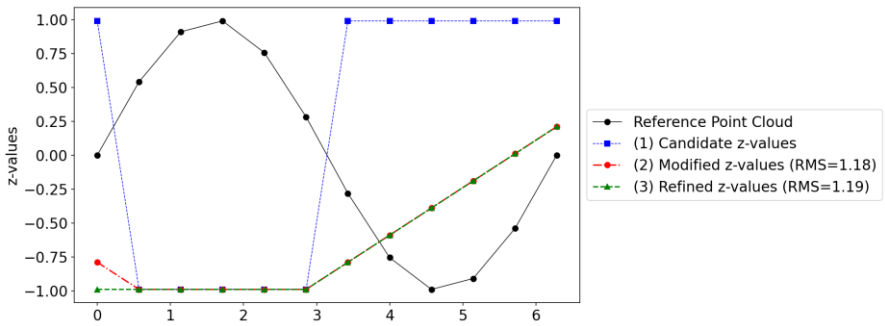

Figure 4: Schematic visualization of the working principle of the algorithm to determine RMS_{max} shown by the example of a 2D reference point cloud and the calculated (1) candidate values, (2) modified values based on the neighbor constraint and (3) refined values to maximize the RMS value.

Using this metric, different similarities to the reference within the design space can be determined by displacing the spline control points along the z-axis. Thereby, we can obtain shapes with different similarity to a reference, as demonstrated in Figure 5.

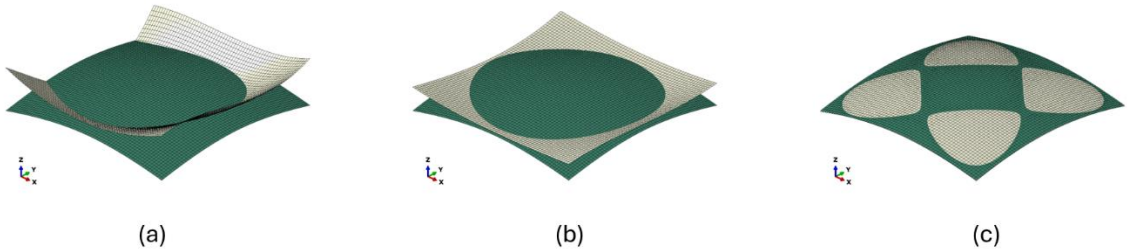

Figure 5: Possible solutions for (a) total dissimilarity (i.e., $RMS_{norm} = 0$), (b) medium similarity (i.e., $RMS_{norm} = 0.5$) and (c) total similarity ($RMS_{norm} = 1$) to the reference.

To automatically determine the spline displacement values necessary to achieve a possible configuration with target RMS value, we used the solver described in the following paragraph.

Solver. In order to determine a certain transformation array (i.e., array of z-displacements) for the spline control points to achieve a target similarity of the current deformed mesh to the reference mesh, an optimization algorithm was used. This algorithm enables a targeted topography modification to achieve a certain target value (T_v) for the similarity. Different optimization algorithms were analyzed on their suitability for the topography modification. For our purpose of optimizing the RMS value, we needed a derivative-free optimization algorithm, whereby the *Downhill Simplex Method (*also known as *Nelder-Mead method*) suited our application best since it allows for the optimization of non-linear functions with multiple parameters. In our case, the parameters to be optimized are the z-displacements of the spline control points and the objective function $f(\boldsymbol{x})$ to be minimized is the difference between the target value T_v and the normalized RMS value of the nodal distances $\boldsymbol{d}(\boldsymbol{x})$ between reference and deformed mesh (depending on the current z-displacement array $\boldsymbol{x}$ of the spline points):

$$f(\boldsymbol{x}) = T_v - RMS_{norm}\big(\boldsymbol{d}(\boldsymbol{x})\big), \tag{3}$$

The found geometry for a specific T_v is thereby one candidate solution that depends on the chosen starting point $\boldsymbol{x_0}$**.** Different starting points lead to different solutions which would all qualify for expanding the interpolation space of the surrogate model.

2.3 Topography Modification Procedure

Based on the three building blocks in section 2.1, the topography modification procedure is done using the *Downhill Simplex* algorithm combined with the FFD for the tool deformation and the similarity measure. Before delving into the working principle of the algorithm, we want to clarify the *terminology* to enhance understanding:

- A ***vertex*** (n-dimensional) in the context of the *Downhill Simplex Method* is one full candidate solution. It contains n entries which, in our case, reflects the number spline control points for which the z-displacement can be modified (e.g., $n = 16$).
- A ***simplex*** is a collection of $n + 1$ vertices (i.e., in our case, 17 arrays with dimension $n + 1$ each).
- The goal is to minimize the value of the ***objective function*** $f(\boldsymbol{x})$ where $\boldsymbol{x} \epsilon \mathbb{R}^n$ (in our case $\boldsymbol{x} \epsilon \mathbb{R}^{16}$). We want to reach a certain degree of similarity based on the similarity measure RMS_{norm}. Therefore, our objective is to reach a target value T_v by:

$$\min|f(\boldsymbol{x})| = \min|T_v - RMS_{norm}(\boldsymbol{x})| \tag{4}$$

To get a clear understanding of the topography modification via *Downhill Simplex Method*, the 6 individual steps (performed within a loop) are as follows [14]:

0) Initialization of Simplex Δ

The procedure starts by defining a **starting point** $\boldsymbol{x_0}$ and a **step size** s. The starting point x_0 is defined by our initial z-displacement of the spline points, which is an array of size n (i.e., number of modifiable spline points):

$$\boldsymbol{x_0} = [x_{01}, x_{02}, \dots, x_{0n}] \tag{5}$$

The initial simplex Δ then consists of $n + 1$ entries, whereby $\boldsymbol{x}_0$ initially serves as our first vertex within the simplex:

$$\Delta = \{\boldsymbol{x_0}, \boldsymbol{x_1}, \dots, \boldsymbol{x_n}\} \tag{6}$$

The residual 16 arrays are created by iteratively creating modified copies of $\boldsymbol{x}_0$ in the following manner:

$$\boldsymbol{x_i} = \boldsymbol{x_0} + s \cdot \boldsymbol{e}_i, \tag{7}$$

where s is the defined step size and $\boldsymbol{e_i} \in \mathbb{R}^n$ is the standard basis vector with 1 in the i-th position and 0 elsewhere.

The objective function f is then evaluated at each entry of the simplex Δ, to get a score for each vertex:

$$f_i = f(\boldsymbol{x_i}) \quad \text{for } i \in [0, n], \tag{8}$$

resulting in a set of pairs:

$$\{(x_i, f(x_i))\}_{i=0}^{n} \tag{9}$$

1) Order Vertices

In a second step, the set of pairs is sorted by score, from best to worst: $f(\boldsymbol{x_1}) \leq f(\boldsymbol{x_2}) \leq \cdots \leq f(\boldsymbol{x_{n+1}})$, with $\boldsymbol{x_1}$ being the vertex with the best score and $\boldsymbol{x_{n+1}}$ being the vertex with the worst score.

2) Compute Centroid of Simplex

The centroid $\boldsymbol{x_c}$ of the simplex is calculated without considering $\boldsymbol{x_{n+1}}$ (i.e., without the array with the worst score):

$$\boldsymbol{x_c} = \frac{1}{n}\sum_{i=1}^{n} \boldsymbol{x_i} \tag{10}$$

3) Reflection

The worst vertex $\boldsymbol{x_{n+1}}$ is then reflected using the centroid $\boldsymbol{x_c}$ by:

$$\boldsymbol{x_r} = \boldsymbol{x_c} + \alpha(\boldsymbol{x_c} - \boldsymbol{x_{n+1}}), \tag{11}$$

with α being the reflection coefficient. The reflected vertex $\boldsymbol{x_r}$ is then again evaluated using the objective function $f(\boldsymbol{x_r})$. If $\boldsymbol{x_r}$ achieves a better score than the second worst result $\boldsymbol{x_n}$, but not better than the best result $\boldsymbol{x_1}$, the worst result $\boldsymbol{x_{n+1}}$ is replaced by $\boldsymbol{x_r}$ and the iteration is terminated:

$$\boldsymbol{x_{n+1}} \leftarrow \boldsymbol{x_r} \qquad \text{if } f(\boldsymbol{x_1}) \leq f(\boldsymbol{x_r}) < f(\boldsymbol{x_{x+1}}) \tag{12}$$

Else the iterations move on to step 4a) or 4b), based on the score of the reflected vertex $\boldsymbol{x_r}$.

4a) If $f(\boldsymbol{x_r}) < f(\boldsymbol{x_1})$: Expansion

If the reflected array $\boldsymbol{x_r}$ achieves a better score than the best array $\boldsymbol{x_1}$, the expansion step is performed as follows:

$$\boldsymbol{x_e} = \boldsymbol{x_c} + \gamma(\boldsymbol{x_r} - \boldsymbol{x_c}), \tag{13}$$

with γ being the expansion coefficient. If the evaluation of $f(\boldsymbol{x_e})$ achieves a better score than $f(\boldsymbol{x_r})$, the expanded array $\boldsymbol{x_e}$ replaces the worst array $\boldsymbol{x_{n+1}}$:

$$\boldsymbol{x_{new}} = \begin{cases} \boldsymbol{x_e} & \text{if } f(\boldsymbol{x_e}) < f(\boldsymbol{x_r}) \\ \boldsymbol{x_r} & \text{otherwise} \end{cases} \tag{14}$$

$$\boldsymbol{x_n} \leftarrow \boldsymbol{x_{new}} \tag{15}$$

In either case, the current iteration is terminated, and the next iteration is started at step 1).

4b) If $f(\boldsymbol{x_r}) \geq f(\boldsymbol{x_n})$: Contraction

In case that the reflected array $\boldsymbol{x_r}$ performs worse than the second worst result $\boldsymbol{x_n}$, the contraction step is performed as follows:

- If $f(\boldsymbol{x_r}) < f(\boldsymbol{x_{n+1}})$: **Outside Contraction**

$$\boldsymbol{x_{co}} = \boldsymbol{x_c} + \gamma(\boldsymbol{x_r} - \boldsymbol{x_c}), \tag{16}$$

with γ being the contraction coefficient. If the contracted vertex $\boldsymbol{x_{co}}$ performs better than the reflected vertex $\boldsymbol{x_r}$, the worst vertex $\boldsymbol{x_{n+1}}$ is replaced by the contracted point $\boldsymbol{x_{co}}$ (i.e., $\boldsymbol{x_{n+1}} \leftarrow \boldsymbol{x_{co}}$), the iteration is terminated and the next iteration is started at step 1). Else, the iteration continues with step 5).

- If $f(\boldsymbol{x_r}) \geq f(\boldsymbol{x_{n+1}})$: **Inside Contraction**

$$\boldsymbol{x_{ci}} = \boldsymbol{x_c} - \gamma(\boldsymbol{x_{n+1}} - \boldsymbol{x_c}), \tag{17}$$

with γ being the contraction coefficient. If the contracted vertex $\boldsymbol{x_{ci}}$ performs better than the worst vertex $\boldsymbol{x_{n+1}}$, the worst vertex $\boldsymbol{x_{n+1}}$ is replaced by the contracted point $\boldsymbol{x_{ci}}$ (i.e., $\boldsymbol{x_{n+1}} \leftarrow \boldsymbol{x_{ci}}$) and the iteration is terminated (next iteration from step 1) on). Else, the iteration continues with step 5).

5) Reduction / Shrink (if expansion and contraction fail)

This step shrinks the simplex to narrow down to a local optimum, in case steps 3) and 4) fail. Thereby, all vertices of the simplex (except the best vertex $\boldsymbol{x_1}$) are replaced using:

$$\boldsymbol{x_{red}} = \boldsymbol{x_1} + \sigma(\boldsymbol{x_i} - \boldsymbol{x_1}), \tag{18}$$

with σ being the shrink coefficient. That way, all vertices are moved towards the best vertex and the next iteration starts at step 1).

In our case, for each step from 3) to 5), the current mesh is modified (using the current parameter set of the simplex), the nodal distances to the reference mesh, the corresponding RMS value is calculated, and the objective function is evaluated. Based on the respective score of the objective function, a decision is made to terminate the iteration or to continue with a subsequent step. This process is repeated until a certain termination criterion (also checked within each evaluation step) is reached.

2.2.1 Dynamic penalty

The z-displacement contraints are implicitly contained in the target value through RMS_{max}. However, this constraint also needs to be forwarded to the solver in order to ensure parameter exploration within the constraints. Therefore, we adapted the *Downhill Simplex* algorithm by including a dynamic penalization approach. This penalty is designed to constrain the z-displacements in compliance with manufacturing constraints and thereby prevent excessive deformations. The idea behind the dynamic penalty is to discourage displacements that deviate significantly from the residual displacements:

First, the bounds for the tolerable distance range are calculated using the interquartile range (IQR) and the lower (b_l) and upper (b_u) bound are defined as:

$$b_l = Q1 - i * IQR,\ b_u = Q3 + i * IQR, \tag{19}$$

with $Q1$ and $Q3$ being the lower and upper quartile and i being a multiplier that can be adapted according to the desired sensitivity to outliers. The entries of the spline point displacement array $\boldsymbol{x}$ are then filtered as 'below', 'above' or 'within' the bounds. For outliers below the lower bound, the individual penalty magnitude p_i is then calculated by:

$$p_i = (b_u - x_i)^2 \tag{20}$$

Similarly, the penalty for outliers above the upper bound is calculated as:

$$p_i = (x_i - b_l)^2 \tag{21}$$

We decided on a quadratic penalty function so that the solution performs exponentially worse with each point lying outside the IQR and with increasing distance. Before evaluating the individual score $f(\boldsymbol{x})$ of each step, the sum of all penalties $\sum p_i$ is added. This way, excessive distortions are considered rather unsuitable and the algorithm searches for alternative solutions.

2.3 Usecases for the Proof of Concept

For the proof of concept, we used the double sine and the parabolic geometry shown in Figure 2 as reference mesh and a plate geometry as initial mesh for the deformation. We conducted a parametric study with target values reaching from 0 (i.e., total dissimilarity) to 1 (i.e., identical meshes) in steps of 0.1 to evaluate the functionality of the developed routine. The hull for the FFD of our component consists of 4 x 4 x 2 spline control points, whereas only the top control points ($n = 16$) were enabled for the z-displacement (i.e., displacement in height direction).

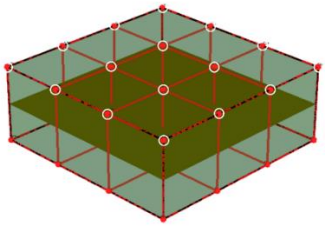

Figure 6: Spline hull for the deformation of the initial mesh for the usecases, with the modifiable control points marked in white.

This constraint was imposed to keep the calculation effort within a reasonable time. The parameters for the topography modification were chosen as follows:

- starting point $\boldsymbol{x_0} = [0,0,\dots,0] \in \mathbb{R}^{16}$
- step size $s = 0.1$
- the reflection, expansion, contraction and shrink coefficients were set to standard values [14]: $\alpha = 1, \gamma = 2, \rho = 0.5, \sigma = 0.5$

The convergence criterion is based on the number of consecutive iterations with improvements below $10e^{-6}$. The procedure is terminated as soon as 100 consecutive improvements below that threshold are reached.

3 RESULTS

The parametric studies were conducted on the two generic geometries: the double sine and the parabolic geometry. The following sections contain the results of the RMS_{max} determination as well as the parametric study.

3.1 RMS_{max} for the Usecases

Usecase 1. The automatically determined value for RMS_{max} resulted in 0.3. This value is reached when the points of the deformed mesh are furthest away from the reference, without leaving the space bounds and without violating the constraint for excessive distortion. A surface with those extreme values is shown in Figure 7:

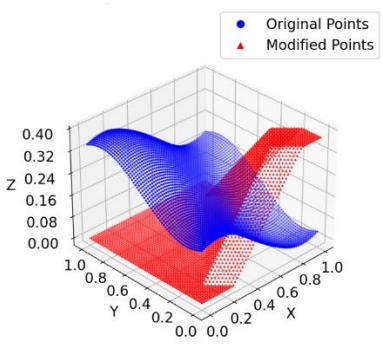

Figure 7: Configuration within the space bounds that leads to the highest RMS_{max} value for *Usecase 1* with reference mesh (blue) and modified mesh (red).

Usecase 2. As for *Usecase 1*, the maximum RMS value was automatically determined by calculating the deformed configuration which would lead to the largest distances between reference and deformed mesh. The RMS_{max} resulted in 0.3 (also similar to *Usecase 1*). The following figure shows the theoretical configuration that achieves the highest RMS value:

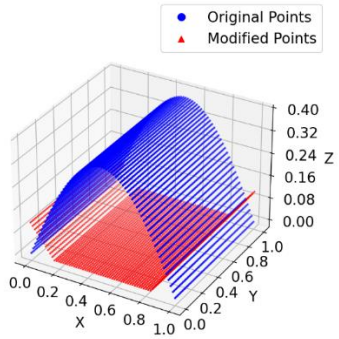

Figure 8: Configuration within the space bounds that leads to the highest RMS_{max} value for *Usecase 2* with reference mesh (blue) and modified mesh (red).

Even though these configurations are not possible to be reached using FFD (since the spline points always ensure a smooth surface without rough edges), they give an indication for the maximum possible RMS value that cannot be exceed by any of the tool modifications using FFD – thus it is suitable for normalization.

3.2 Results Parametric Study for the Usecases

Usecase 1. The surface modification was performed using a double sine geometry as a reference mesh and a planar geometry as deformable mesh. An exemplary mesh modification result for $T_v = 1$, including the hull and the modified spline points, is shown in Figure 9. The initial mesh (Figure 9a) is deformed by modifying the top row of spline control points in order to achieve a configuration similar to the reference mesh (Figure 9b).

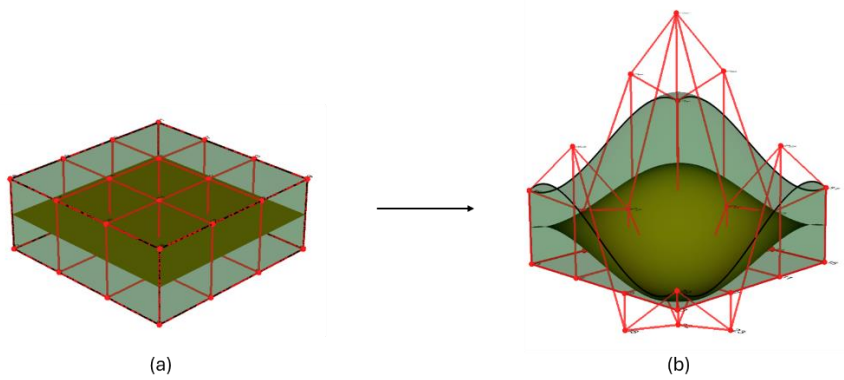

Figure 9: (a) Initial mesh and (b) deformed configuration for $T_v = 1$ with an achieved objective value of $f(\boldsymbol{x}) = 0.0019$

This procedure was done with target values from 0 to 1 in steps of 0.1. Figure 10 shows the resulting deformed meshes for the different target values (including the achieved score from the objective function) in superposition to the reference mesh.

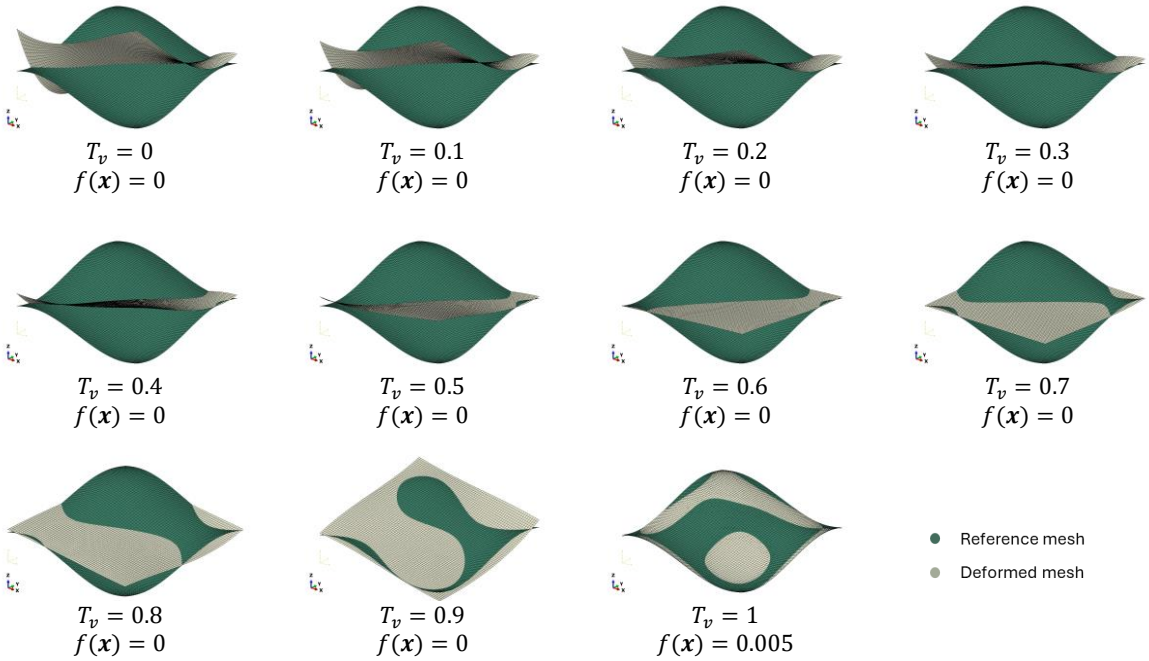

Figure 10: Resulting meshes depending on the target value, with the achieved objective value $f(\boldsymbol{x})$ indicating the difference to the respective desired target value for the double sine reference mesh.

For all target values except $T_v = 1$, the optimization algorithm found a solution matching the specified target RMS value. For a uniform starting point $\boldsymbol{x_0} = [0,0,\dots,0] \in \mathbb{R}^{16}$, the deformed meshes for $T_v = 0$ to $T_v = 0.5$ only show varying degrees of the same geometric shape. This indicates that the algorithm found the same local minimum for those target values, converging toward it to varying degrees. To mitigate this behavior, alternative starting points can be selected for those configurations to guide the algorithm toward a different local optimum. In case of $T_v = 1$, the RMS value only deviates by about 0.2 % from the target. Looking at the superposition of the reference and the deformed mesh in Figure 10, the meshes only deviate slightly. From a manufacturing perspective, these slight deviations from the desired tool shape will not affect the draping result drastically. The precision of the draping tool is therefore sufficient for the generation of tools with different degrees of similarity.

Usecase 2. Similar to *Usecase 1*, the surface modification was done using a parabolic geometry as reference mesh and a planar geometry as deformable mesh. Figure 11 shows an exemplary deformation result for $T_v = 1$ including the hull and the modified spline control points.

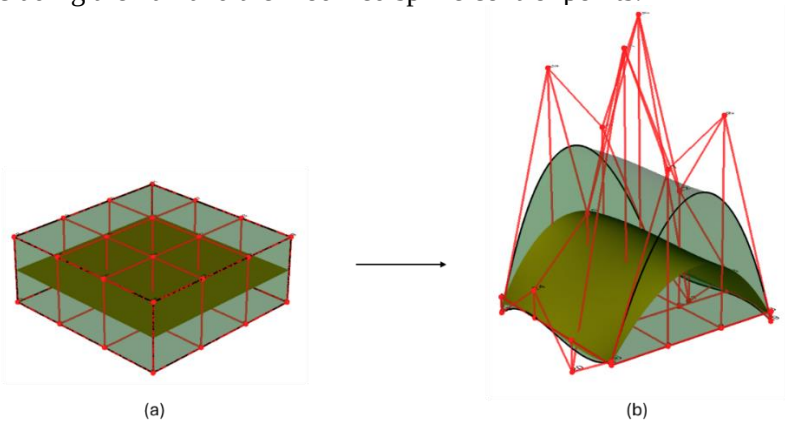

Figure 11: (a) Initial mesh and (b) deformed configuration for $T_v = 1$ with an achieved objective value of $f(\boldsymbol{x}) = 0.0018$.

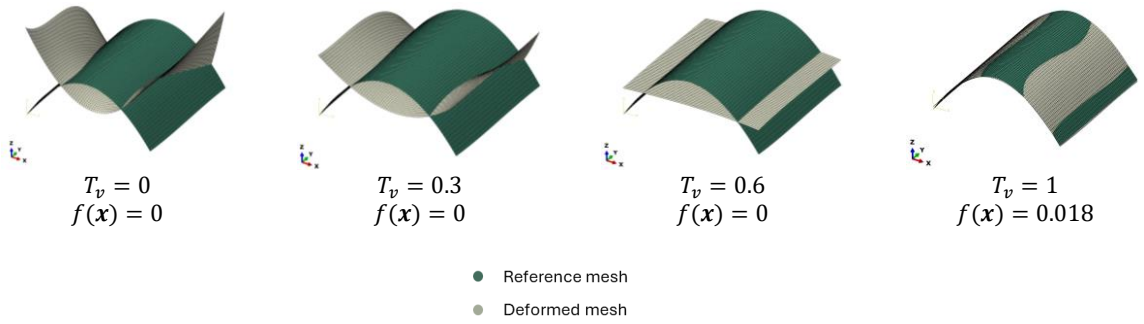
Again, for each target value from 0 to 1 (in steps of 0.1), a deformed configuration was calculated. As for *Usecase 1*, the algorithm found solutions matching the specified target value, except for $T_v = 1$. Since for this usecase, the solver also tends to converge to the same local minimum (but to different extents) for target values below $T_v = 0.5$, only selected results are shown in Figure 12:



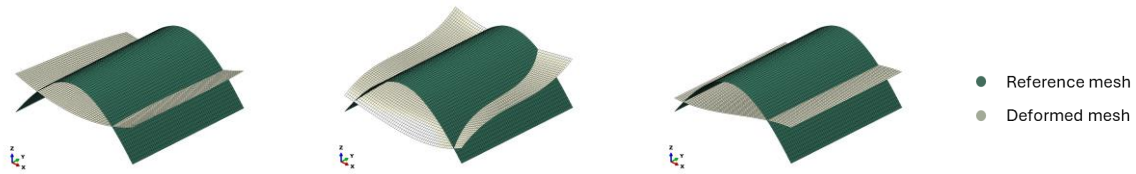


Figure 12: Resulting meshes depending on the target value, with the achieved objective value $f(\boldsymbol{x})$ indicating the difference to the respective desired target value for the parabolic reference mesh.

To demonstrate the dependency of the solution on the chosen starting point $\boldsymbol{x_0}$, Figure 13 shows different solutions calculated for $T_v = 0.5$ for different starting points $\boldsymbol{x_0}$.

$$\boldsymbol{x_0} = \begin{bmatrix} 0, & 0, & 0, & 0, \\ 0, & 0, & 0, & 0, \\ 0, & 0, & 0, & 0, \\ 0, & 0, & 0, & 0] \end{bmatrix} \quad \boldsymbol{x_0} = \begin{bmatrix} -0.1, & 0.1, & -0.1, & 0.1, \\ -0.1, & 0.1, & -0.1, & 0.1, \\ -0.1, & 0.1, & -0.1, & 0.1, \\ -0.1, & 0.1, & -0.1, & 0.1] \end{bmatrix} \quad \boldsymbol{x_0} = \begin{bmatrix} -0.2, & -0.2, & 0.2, & 0.2, \\ -0.2, & -0.2, & 0.2, & 0.2, \\ -0.2, & -0.2, & 0.2, & 0.2, \\ -0.2, & -0.2, & 0.2, & 0.2] \end{bmatrix}$$

Figure 13: Resulting meshes for $T_v = 0.5$ depending on the starting point $\boldsymbol{x_0}$ (with the achieved objective value $f(\boldsymbol{x})$ for the parabolic reference mesh).

All resulting geometries match the desired T_v of 0.5. The starting point, however, influences the resulting shape. This emphasizes the need for further investigations concerning the selection of the starting point $\boldsymbol{x}_0$. Beside that, the interaction between the three building blocks of the routine works quite well since linking the three components (FFD, similarity measure and optimization algorithm) provides a plausible set of configurations for the different target values and shapes can be controlled using different starting points.

4 CONCLUSIONS

The developed routine provides a robust, repeatable way to generate draping tools of different similarities for generic shapes such as a double sine and a parabolic geometry. There is still potential for improvement concerning the tendency of solutions within a certain target to converge to the same solution but with varying degrees. A detailed study on the starting point $\boldsymbol{x_0}$ selection as well as a more in-depth analysis on the penalty function are planned for future studies to guide the optimization algorithm toward different local optimum solutions from the outset. Additional next steps are to include real component tools in the representative tool set. If this step works out well, the U-Net surrogate model explained in [1] should be trained with the different tools and the prediction quality should be evaluated.

ABSTRACT

Accurately predicting flow behavior in dry fiber preforms is essential for many liquid molding processes, including resin transfer molding (RTM). One of the main challenges in RTM is obtaining precise permeability values to ensure complete saturation of the preform during infusion. Conventionally, permeability predictions are made using flow experiments on compacted dry fiber layers or by predictive flow simulation assuming an idealised preform. During RTM, the fabric undergoes initial compaction, subsequent relaxation at the arrival of the resin flow front, and eventually full saturation. To address the complex fluid-structure interactions, one approach would be to model the preform deformation during compaction and then study the change in fiber volume fraction during the steady state flow of resin. In this work, a mechanical model accounting for the frictional contact between the yarns was developed in order to predict the displacement during the initial compaction of the dry yarn assembly. The post-compaction deformed geometry is subsequently used within one-way coupled fluid-structure interaction simulations to predict the final fiber distribution within the modelled domain as well as the resultant steady state saturated permeability.

1 INTRODUCTION

Fiber-reinforced polymers (FRPs) are known for their high specific strength, excellent stiffness-to-weight ratio and durability, making them ideal for applications across civil infrastructure, aerospace, wind energy, marine, and automotive industries. Vacuum-assisted resin transfer molding (VARTM) is a widely adopted method for manufacturing large-scale composite structures, such as wind turbine blades. In VARTM, resin is infused into a dry fiber preform under near-vacuum conditions by maintaining a small pressure differential between the inlet and the outlet. This slow vacuum-driven infusion, followed by curing in external ovens, eliminates the need for expensive autoclaves. However, VARTM-produced components often exhibit local variations in fiber volume fraction, as the final saturation is influenced by the interplay between the resin's flow capacity (commonly defined by the preform's permeability) and the localized compaction pressure (leading to fiber deformation) [1,2]. The overall permeability of the VARTM mold system, which includes the core, the fiber preform, the distribution media and the peel ply, is affected by the geometric features occurring across multiple scales. At the macro scale (cm to m), elements such as the distribution media, the peel ply, the release film, and the flow channels in the core significantly influence the global resin flow. At the meso-macro scale (mm to cm), the type of weave or the non-woven structure, as well as the lay-up sequence within the laminate, govern how resin propagates through the layers. At the micro-meso scale (µm to mm), factors such as the intra-yarn and the inter-yarn spacing and the packing arrangement become more critical for local permeability. In essence, the macro-scale permeability dictates the resin distribution speed across the mold (helping to prevent large dry spots) while the meso- and the micro-scale permeabilities govern the uniformity of the resin infusion between fibers and the saturation levels (i.e. they impact the inter- and intra-tow micro-void formation).

During VARTM, the dry fiber preform undergoes a sequence of mechanical and fluid interactions beginning with compaction during vacuum bagging, followed by partial relaxation as the resin front

arrives, and concluding with full saturation. These stages introduce complex fluid-structure interactions due to both infusion and compaction effects. Typically, researchers have taken a two-step approach to predict permeability and flow behavior [3]. The first step addresses preform deformation, modeling the yarn's behavior using elastic or hypoelastic properties to capture its deformation during compaction [4] then studying the permeability based on change of fiber volume fraction [5]. Studies have considered fiber displacement due to shear deformation in angle-ply reinforcements [6] due to draping and yarn slippage of woven fiber layups [7], but a significant challenge remains in exporting the predicted deformed geometry to create a fluid domain for flow analysis.

In this study, a model to simulate the yarn deformation and the displacement during the initial compaction of a dry fiber assembly was developed using the mechanical solver within ANSYS Workbench. Realistic boundary conditions corresponding to the vacuum bagging step were applied alongside appropriate contact definitions to prevent yarn interpenetration and to accurately replicate the physical compaction behavior. Following the mechanical simulation, the deformed yarn geometry was transferred to the CFD software ANSYS FLUENT to evaluate the resulting flow behavior and assess the impact on permeability. Key parameters such as the change in global fiber volume fraction (V_f), the yarn slippage, and the potential overlap were analysed to compare the permeability between the undeformed and the compacted configurations of the fiber preform. The use of one-way fluid-structure interaction (FSI) coupling within the unified ANSYS Workbench environment enabled a more refined estimation of both the initial mechanical compaction and the corresponding local flow characteristics to propose more accurate, deformation-dependent permeability predictions.

2 STRUCTURAL MODEL - COMPACTION

The deformation of the fiber layup has been studied in the linear elastic regime (Equation 1) for UD glass fibers considering frictional contact between the yarns. Here, $\boldsymbol{\sigma}$ and $\boldsymbol{\varepsilon}$ are the stress and the strain tensor of the material respectively, while the material properties E of the UD fiber correspond to those of Epoxy E-Glass UD with orthotropic elastic properties (Table 1). A static structural analysis is performed in this study while implementing a displacement-based control for the compaction of yarn layups.

$$\boldsymbol{\sigma} = E\,\boldsymbol{\varepsilon} \tag{1}$$

Table 1: Material properties of Epoxy E-Glass UD (Orthotropic) fiber composite.

Epoxy E-Glass UD	**Values**	**Unit**
Density (ρ)	2000	kg/m^3
Young modulus X direction (E_x)	45000	*MPa*
Young modulus Y direction (E_y)	10000	*MPa*
Young modulus Z direction (E_z)	10000	*MPa*
Poisson's ratio XY (v_{xy})	0.3	
Poisson's ratio YZ (v_{yz})	0.4	
Poisson's ratio XZ (v_{xz})	0.3	
Shear modulus XY (G_{xy})	5000	*MPa*
Shear modulus YZ (G_{yz})	3846.2	*MPa*
Shear modulus XZ (G_{xz})	5000	*MPa*

Initially an idealised yarn layup consisting of three layers of unidirectional (UD) fibers is placed between two plates. For simplicity, the same frictional contact type has been assumed between the yarns and between the yarn and the mould plate [8], with a friction coefficient value of 0.2. A fixed support was applied to the bottom face of the bottom plate (label A in Figure 1), which fully restrained all translational and rotational degrees of freedom for the bottom plate. The top face of the top plate (label B in Figure 1) was subjected to a displacement of 3mm in the Y-direction. To avoid rigid body motion, the out-of-plane displacement of the yarn side faces across XY plane is set to zero with no translation

along X axis except the translation and compaction along Y-axis (label C in Figure 1). Additionally, on the side face of yarn YZ-plane, the out-of-plane displacement is also set to zero keeping Y-axis free to move (label D in Figure 1). To avoid excessive penetration between the yarns, the pinball radius is set to 0.05mm. The direct numerical scheme with sub-steps control has been considered, thus accounting for over 200 sub-steps allowing large deflection for the yarns. The final displacement of the top plate (0.21 mm) to the maximum allowable distance has been simulated with 3 intermediate displacement load states.

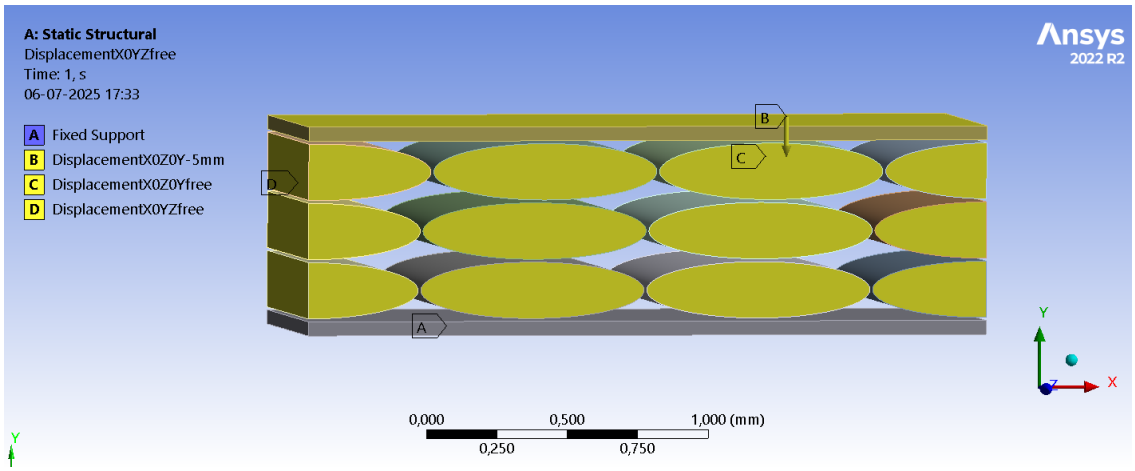

Figure 1:Load state and the boundary conditions for compaction of yarn layup.

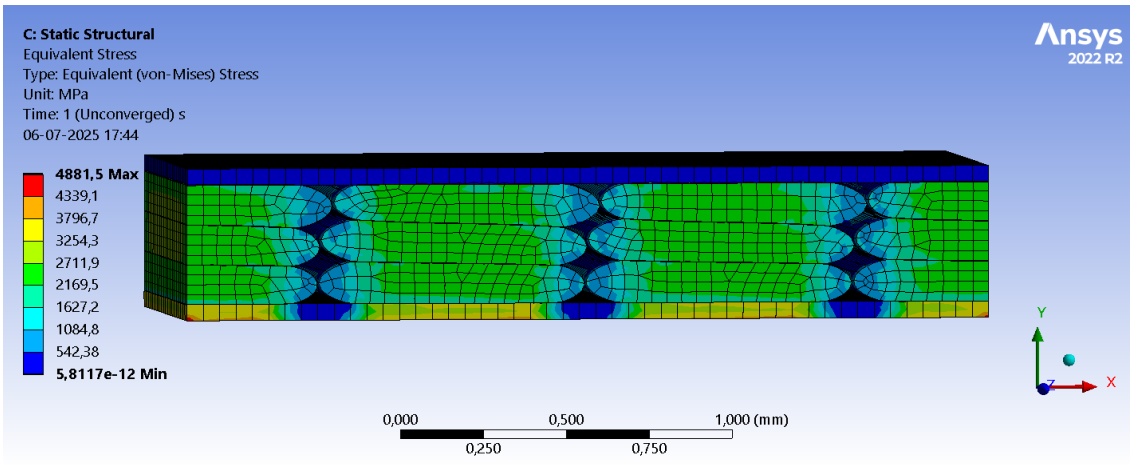

Figure 2: Equivalent stress observed on the layup and the compaction plate.

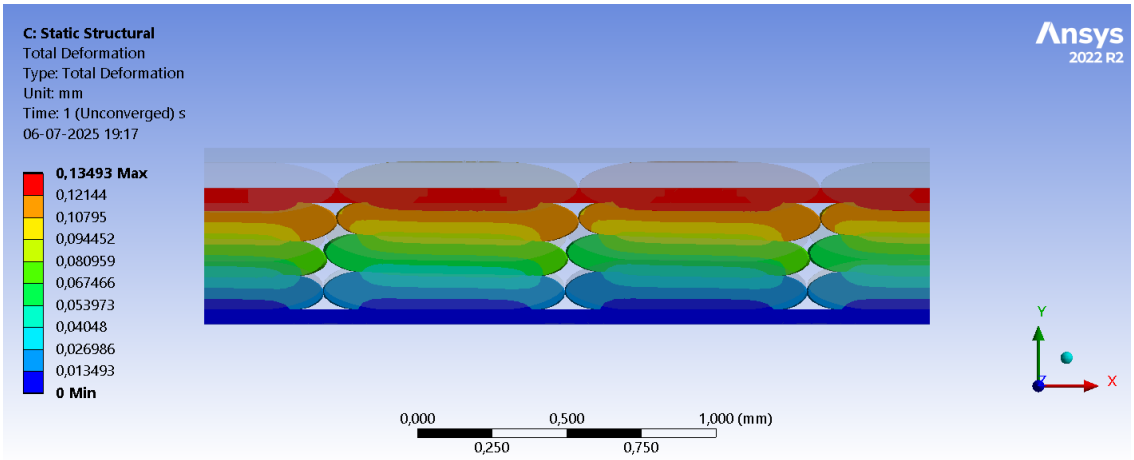

Figure 3: Deformed state of compacted yarn layup and yarns overlap

Figure 2 illustrates the equivalent stresses during the final displacement load state of the top plate. Stress concentrations are visibly evident around the interfaces between the yarn layup, indicating that each yarn experiences substantial mechanical loading as the top plate closes the gap. The symmetrical stress patterns highlight uniformity and periodicity within the internal structure. Figure 3 illustrates the total deformation field in the compacted yarn layups. The central zones, where the yarns are closely packed, exhibit higher deformation magnitudes, suggesting significant compaction induced displacement and mechanical interaction. Additionally, yarn slippage/overlap is also observed between yarn in a layer. These overlapping areas are critical in modeling realistic fiber architecture behavior, as they reflect the actual physical phenomena encountered during manufacturing processes. It is estimated that the global fiber volume fraction V_f increases from 46.54% to 62.55%, while the intra fiber V_f of each yarn is updated from 64% in undeformed configuration to 67.28% (in Table 2) in the deformed state.

Table 2: Change in local intra yarn and global preform fiber volume fraction.

Preform Configuration	**Local intra yarn v_f [%]**	**Global V_f [%]**
Undeformed	64	46.54
Deformed	67.28	62.55

3 FLUID MODEL – PERMEABILITY

The compacted yarn layup has been extracted for subsequent CFD simulations to estimate the permeability and predict the flow behaviours. The surface maps of the compacted yarn from the deformed stated are curated to create a suitable mesh for the flow simulation within ANSYS Fluent. It has been assumed that the intra yarn fiber volume fraction (v_f) is 64%. In the Gebert model [9], the micro-scale longitudinal (k_{ll}) and transverse ($k_\perp$) permeability characterization is based on the geometrical arrangement of individual fibers and utilize the fiber diameter and the volume fraction of the yarn. Equation 2, provide the analytical permeability for the hexagonal packing of the individual fiber arrangement in the unit cell of a yarn. Intra-yarn permeability ($k_{ll}, k_\perp$) has been predicted from the Gebert's model considering fibers are arranged in a hexagonal pattern.

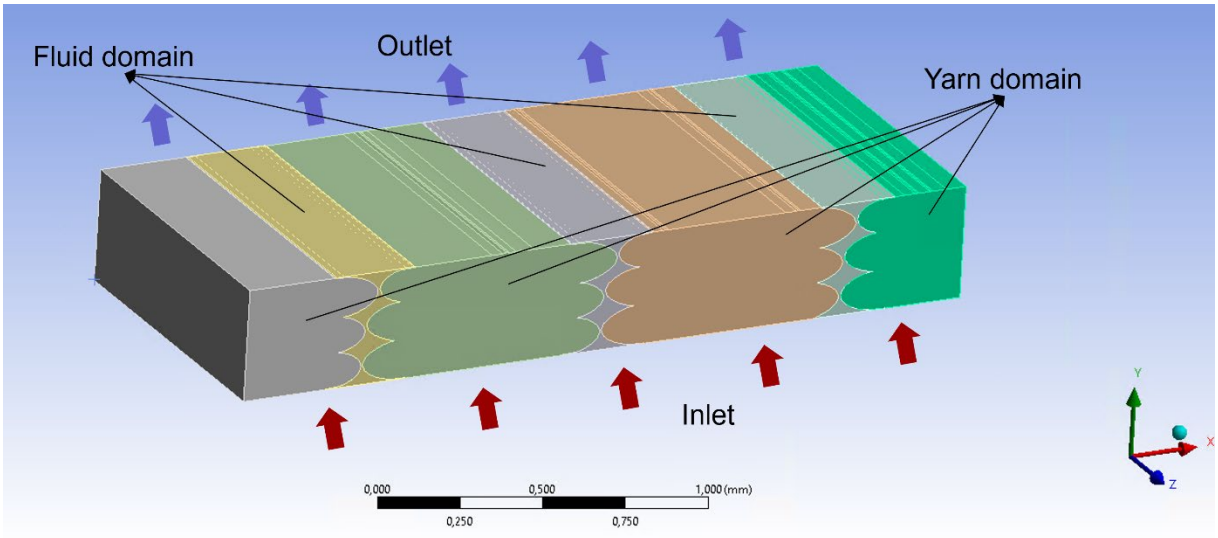
$$k_{ll} = \frac{8r^2}{53}\frac{(1-v_f)^3}{v_f^2}$$
$$k_\perp = \frac{16}{9\pi\sqrt{6}}\frac{\left(\sqrt{\frac{v_{fmax_hex}}{v_f}}-1\right)^{2.5} r^2}{v_f^2} \quad (2)$$

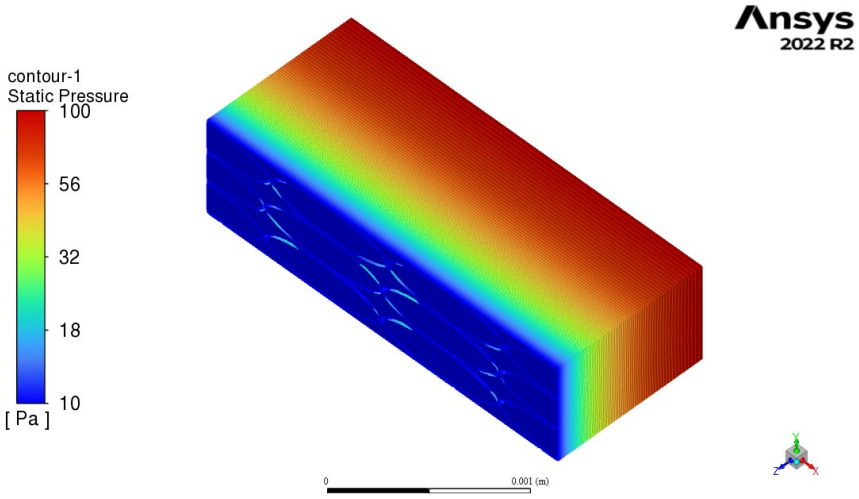
Here, v_{fmax_hex} refers to the maximum $v_f (= \frac{\pi}{2\sqrt{3}})$ achieved in the hexagonal packing when the circular fiber touches each other within a yarn. A resin with density (ρ) of 1212kg/m^3 and viscosity (μ) of 0.09 Pa.s has been used as the fluid medium, with the inlet and the outlet pressure being set at 100 Pa and 10 Pa respectively along the fiber direction of the yarn. A schematic of the flow simulation has been shown in Figure 4.

As depicted in Equation 3, Darcy's law has been used to describe the fluid flow behaviour in the porous media.

$$v = \frac{1}{\mu} \boldsymbol{K}.(\nabla P + \rho g) \tag{3}$$

where the volume averaged Darcy velocity v was correlated to the pressure gradient ∇P, the dynamic resin viscosity μ, as well as the resin density ρ, through the permeability tensor $\boldsymbol{K}$ and g the gravitational constant. Moreover, to ensure the resin flow between the porous yarn and the adjacent flow channels, the Brinkmann model has been used. The meso-scale permeability [10] is then estimated based on the calculated flowrate across the outlet surface and the applied pressure gradient between the inlet and the outlet.





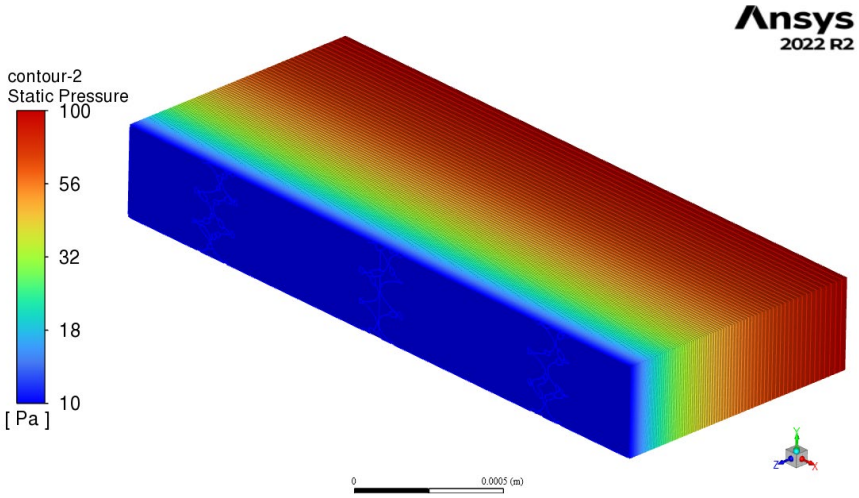


Figure 4: Flow configuration of the deformed preform considering porous yarn.

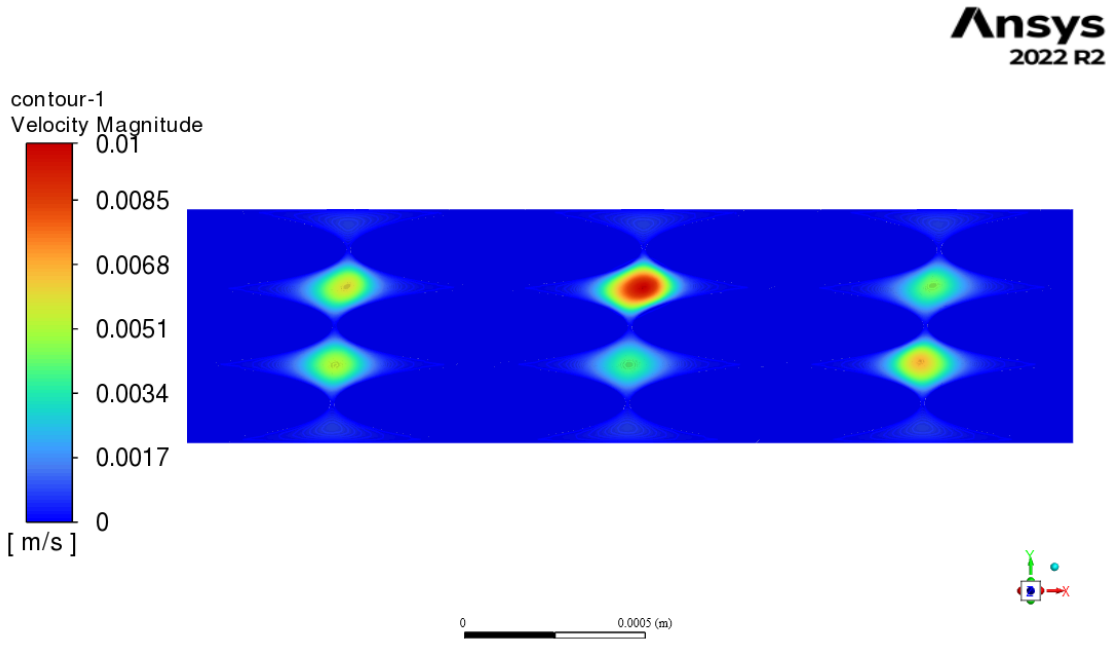
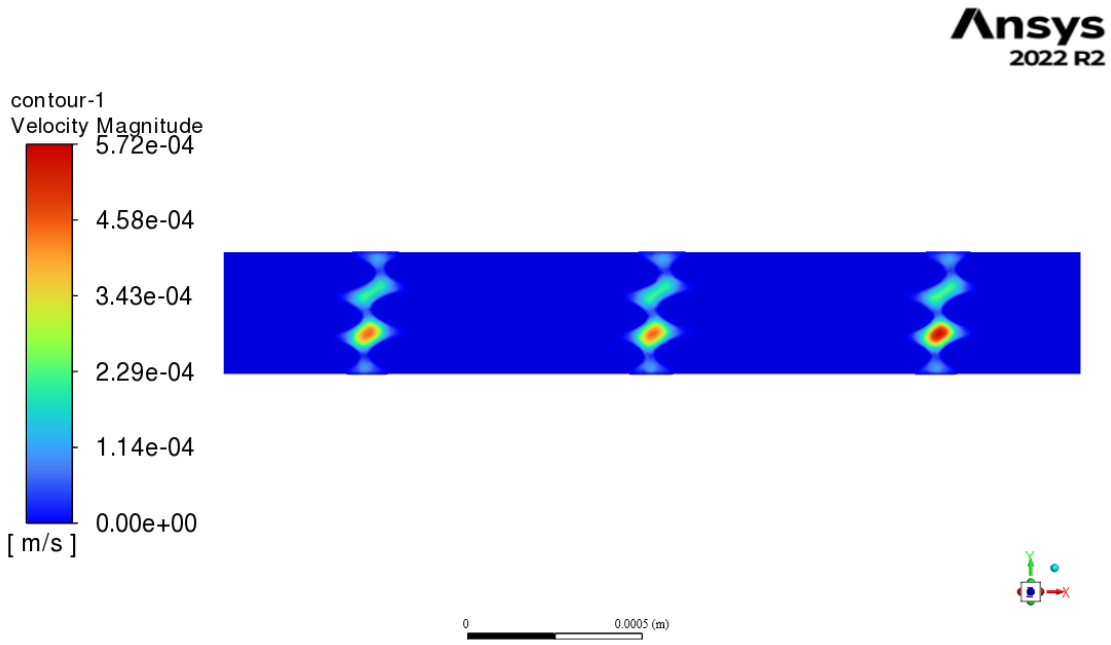
The pressure profiles presented in Figure 5 shows a smooth and continuous gradient from the inlet to the outlet, indicating that a steady-state resin flow has been established in both the undeformed and deformed configurations of the preform. This steady gradient suggests that the flow front has fully propagated through the domain and the pressure distribution has stabilized across the fiber assembly. However, a closer examination of the undeformed configuration reveals that the yarn boundaries near the outlet face exhibit localized pressure variations when compared to the surrounding matrix. This discrepancy may be attributed to the idealized geometry in the undeformed state, where uniform fiber packing and regular channel pathways may not accurately capture the true resin flow resistance encountered at the microstructural level. In contrast, the deformed configuration accounting for the compaction-induced yarn displacement and the change in both the local and the global fiber V_f shows more realistic flow resistance and pressure drop behavior.



(a)



(b)

Figure 5: Infusion pressure profile in (a) undeformed and (b) deformed state of the preform.

In Figure 6, the velocity profiles during resin infusion through the fiber preform in both the undeformed and deformed states are presented. It is observed that, in the undeformed configuration, the velocity profile reveals significantly higher peak value up to approximately 0.01 m/s in the intra yarn spaces. Thus, the uniform geometry of the undeformed preform, containing relatively large open channels, allows for an easier resin passage. Correspondingly, as shown in Table 3, the undeformed preform exhibits a higher permeability. In contrast, the deformed configuration shows significantly lower flow velocity (around 5.7e-4 m/s) with flow localized along narrower paths. The deformation caused by the mechanical compaction and the yarn displacement altered the internal geometry of the preform, consequently increasing the flow resistance and reducing the overall permeability (by 2-orders of magnitudecompared to the undeformed state). From the contour line of velocity profile, it is also noted that level of yarn saturation in the intra yarn porous space is comparatively low in the deformed configuration than the undeformed state.

(a)

(b)

Figure 6: Velocity profile in (a) undeformed and (b) deformed state of the preform.

Table 3: Estimated permeability in undeformed and deformed state of preform.

Preform configuration	**Global V_f [%]**	**Permeability [m^2]**	**Mass flow rate [kg/s]**
Undeformed	46.54	1.8572e-10	6.4826459e-07
Deformed	62.55	5.4767e-12	1.3291301e-08

This clearly demonstrates that ignoring the preform deformation can lead to substantial overestimation of flow and permeability. Upon incorporating these deformations, the resulting flow pattern becomes more constrained and non-uniform, better reflecting real manufacturing conditions. These findings emphasize the critical role of coupled fluid-structure interaction modelling in accurately predicting the resin infusion behavior in composite manufacturing processes.

4 CONCLUSIONS

This study presents an integrated numerical approach to model compaction-induced deformation and its influence on resin flow in dry fiber preforms during VARTM. By employing a one-way fluid-structure interaction (FSI) framework within ANSYS Workbench, the yarn deformation under mechanical compaction was accurately captured, and the resulting deformed geometry was utilized to simulate the resin flow and predict the permeability. The analysis revealed that compaction significantly alters the internal geometry of the preform, increasing the global fiber volume fraction and reducing the available flow channels, which in turn leads to a substantial decrease in permeability by nearly two orders of magnitude compared to the undeformed configuration. The pressure and the velocity profiles demonstrate that idealized undeformed geometries overestimate the flow uniformity and the resin saturation. It is thus necessary to incorporate the deformation-dependent flow domains within VARTM simulations to enhance the permeability prediction accuracy (and improve the reliability of composite manufacturing process modelling).

Keywords: Liquid Composite Molding, Natural Fiber, Moisture Effect , Controlled flow rate

ABSTRACT

This paper introduces a new method to perform liquid composite molding with a controlled resin flow rate, enabling the manufacture of plant fiber-reinforced composites with varying water contents. The manufacturing of plant fiber composites is still poorly controlled, as existing techniques are often adapted from synthetic fiber composites, despite the hydrophilic nature of natural fibers making such transpositions problematic. We propose that by monitoring fiber water content, it is possible to master the manufacturing process and optimize the structural integrity of the final part. To achieve this, we developed a novel infusion method that maintains a constant resin flow front velocity and allows processing at a target Capillary number (*Ca*). Our results show that drying natural fibers is not always necessary for successful infusion. This work demonstrates that composite parts can be manufactured while preserving fiber integrity, reducing energy consumption, and minimizing environmental impact.

1 INTRODUCTION

The manufacturing of plant fiber-reinforced composites has been a challenge since the beginning of the 21st century. It has been established that the plant fibers specificities, all the more so flax fibers, differ from those of synthetic ones. One of the major differences between these two types of materials lies in the hydrophilic nature of plant fibers. Many studies have shown that during the processing of such composites, controlling the amount of water contained by the fibers to improve understanding microstructural material state [1]. Moreover, manufacturing processes used for plant fiber-reinforced composites are mostly carried out through the direct transposition of methods and technologies used for the production of synthetic ones. This approach does not ensure preservation of the structural integrity of the flax fibers, nor does it optimize the properties of the composite material produced.
Liquid composite molding processes (LCM) such as resin infusion are commonly used in many industrial fields to fabricate composites [2]. In liquid resin infusion, the pressure difference between the polymer bucket and the mold outlet drives the polymer flow [3]. As the polymer flow front progresses into the fibrous preform, the pressure gradient decreases. Consequently, the velocity v of the polymer flow front also decreases with time. Using the capillary number (*Ca)* in injection process, where μ is the liquid viscosity and γ the liquid/gas surface tension, authors [4] have demonstrated the necessity to monitor polymer flow front velocity in order to minimize the void content in the final composite part.
In addition to these physical parameters, the water contained by plant fibers can have a significant impact during processing. Due to the hydrophilic nature of plant fibers, their moisture sorption mechanisms have been widely studied in a wide range of humid environments [5]. Authors have highlighted that “water sorption in fibers and their composites has been found to significantly affect their dimensional and structural properties”. Therefore, when compressing preforms, hygro-thermal

conditions must also be controlled and monitored, in order to take hygro-mechanical specificities of plant fibers into account. Other authors [6], [7] showed that water contained in plant fibers also influences the resin crosslinking.

Recently, a low-tech dedicated setup has been developed in the laboratory allowing to control the flow front velocity *v*. This study aims to introduce a unique research tool in the field of composite manufacturing by liquid infusion process allowing scientist the study of natural fibers processability at controlled *Ca*. Using fiber's moisture management, it is first proposed to measure the influence of humidity on properties and manufacturing of natural fiber reinforced composites. A second outlook for this work is to show that our new setup enables the manufacturing of optimized plant fiber-reinforced composite parts by piloting resin flow at the appropriate *Ca*.

This work is the starting point of a project that aims at bringing new insights on liquid composites manufacturing processes using low environmental impact technologies and to the formation of microstructural defects.

2 EXPERIMENTAL SECTION

2.1 Description of the research tool

The upper mold is a 20 mm thick transparent glass to prevent mold deformation and the lower part of the mold is an aluminum plate of 10 mm thick (figure 1a). Spacers of predefined thickness are placed on the side of mold to obtain final parts of the target thickness. In this study, spacers of 3 mm will be use to reach 30 % volumetric fiber fraction with 4 flax plies. Two grooves are cut in the lower part of the mold and seals are placed in them creating two cavities: the inner cavity in which the preform is placed, and the outer cavity in which a vacuum is done (figure 1b). This vacuum is referred to as *peripheral vacuum* reaches -980 mbar and is the first novelty of this method. Because vacuum is not directly applied on the preform stack as in most of LCM processes, the resin is allowed to freely go through the preform. In addition, the *peripheral vacuum* applies on the preform a constant pressure of around 0.1 MPa which is used for fiber compaction. The second novelty of this method is the use of a peristaltic pump to transfer resin from the reservoir to the preform. A peristaltic pump can transfer fluids without exposing them to contamination for example for sterile or corrosive fluids. It is mainly used for pharmaceutical, medical and agro application. The principle is that a flexible tubing is mounted inside a circular pump housing with rotating rollers. As the rollers turns, the tube is compressed then released continuously causing the fluid to circulate in one direction (figure 1a). With the combination of these two principles, fiber preform can be impregnated at controlled flow rate and constant flow front velocity. The pump is a Masterflex™ L/S™ capable of delivering a constant flow rate from 0.36 to 3400 mL/min, with a reverse flow option that is particularly useful for cleaning the hoses after manufacturing. Hoses are made from silicone with an outer diameter of 7 mm and an inner diameter of 5 mm. Before the preform impregnation, both parts of the mold are waxed and polished with a release agent to facilitate demolding. The preform is then positioned inside the mold, with a gutta seal placed around it to minimize edge effects during the impregnation. Then the peripheral vacuum is applied to compact the preform. After compaction, a 15 minutes relaxation phase is done to reach target thickness before starting impregnation. The resin will first full the space at the inlet of the cavity where there are no fibers (figure 2a). Once this space is full, the resin will go through the preform with a perfect straight line of flow front (figure 2b). Once filled, the resin progresses through the preform with a straight flow front (Figure 2b). When the resin reaches the end of the preform, the pump is stopped and the inlet tube is clamped to prevent leakage. The tube is then cut, and any remaining resin is returned to the reservoir using the pump's reverse function. The tube is cleaned with ethanol followed by water, allowing it to be reused. Demolding is done by releasing the peripheral vacuum. Disposable items include the section of hose embedded in cured resin, the gutta seal, and the resin container.

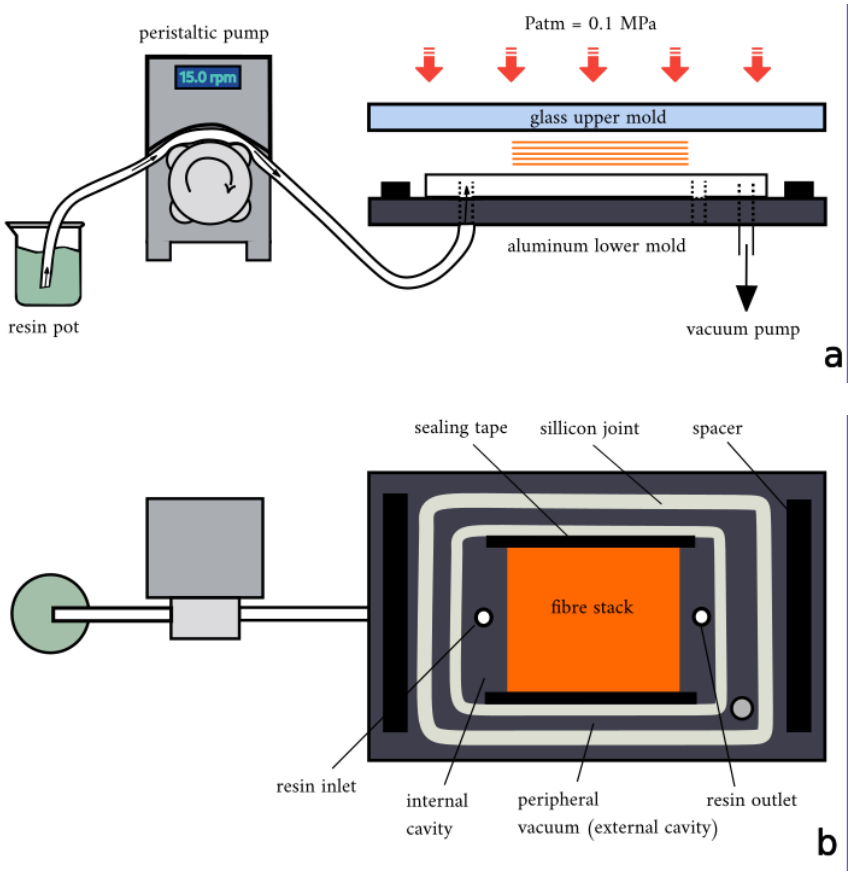

Figure 1: Schematic representation of the *THMClight* experimental setup

The fabrics used are 2 x 2 linen twills with a weight per unit area of 300 g/m^{2}meter supplied by *Depestel (Teillage Vandecandelaere, France)*. The polymer used is an epoxy-amine system consisting of *Greenpoxy SR8100* epoxy precursor and *SD8824* amine hardener, both supplied by *SICOMIN*. The experimental setup was designed to be low-tech, requiring only long-life equipment and very few consumables (hoses, mixing pot, sealant tape).

For conditioning, the linen fabrics were stored in a humidity-controlled enclosure at a constant temperature of 23°C. The storage time for the plies was based on a prior assessment of the time required to reach water saturation. Parameters and resulting water content are described in table 1.

Designation	**HR0%**	**HR50%**	**HR70%**	**HR90%**
Relative humidity	0	50	700	90
Temperature	103	23	23	23
Conditioning time (h)	24	24	24	24
Water content (wt%)	0 - 2	7,6	9,9	16,7
Density (kg/m^3)	1490	1470	1465	1420

Table 1: Preform conditioning

2.2 Measuring the flow front velocity

Since the main objective of the THMClight is to impregnate fibrous preforms at a controlled flow rate, it is essential to measure the flow front velocity. THMClight is, above all, a research tool designed to help scientists and industrial partners better understand impregnation mechanism. The upper mold is made of glass allowing user to observe the progression of the resin flow front. A camera is installed above the experimental set up to capture the entire impregnation phase (figure 2). After the recording, the flow front velocity of the resin is measured with FIJI (ImageJ). After setting the scale, a straight line was drawn between the edge of the preform at the onset of impregnation and the resin front. A value noted as *Xt*, corresponding to the position of the resin front over time, was then determined (figure 2).

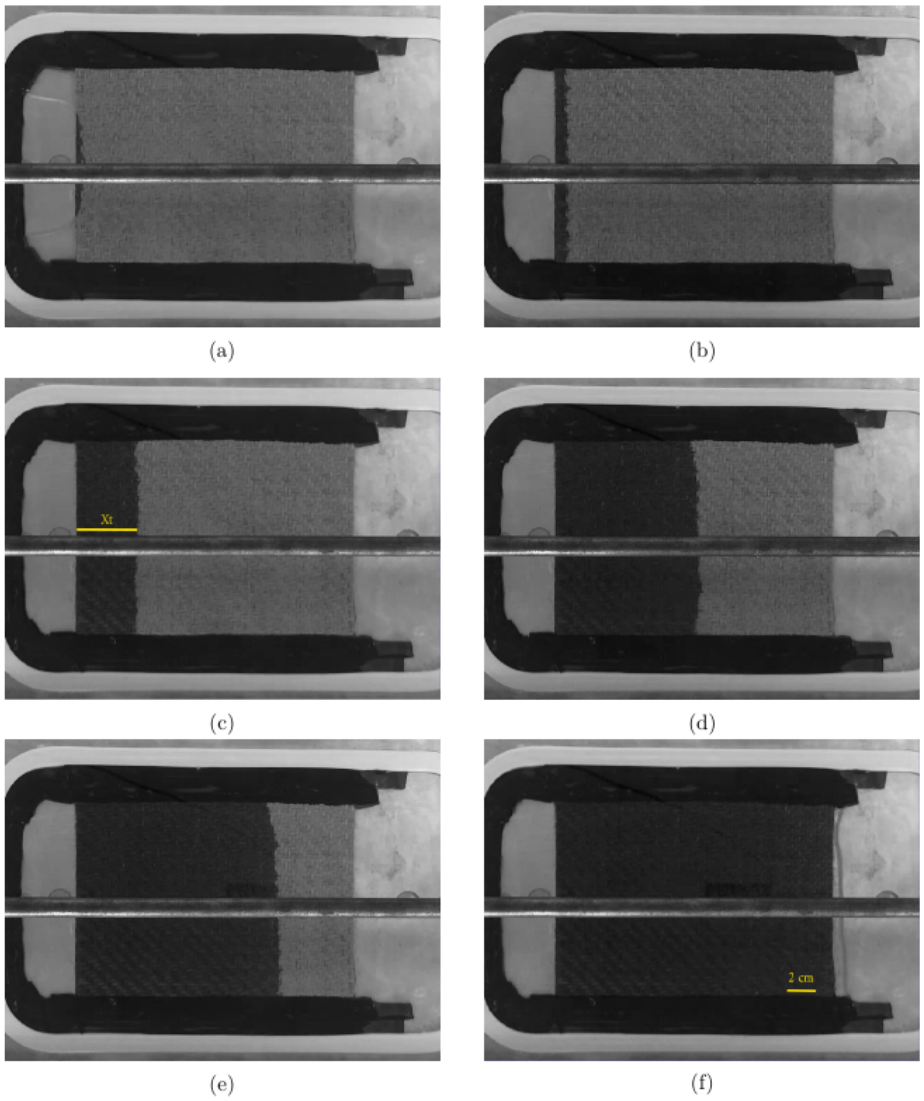

Figure 2: Resin flow front progression through a dry preform at constant rate

By plotting the graph $Xt = f(t)$, a series of data points was obtained, enabling the characterization of the resin front advancement profile. A linear regression of this dataset (constrained to pass through the origin) is performed to determine the velocity at which the resin front propagates through the preform.

3 RESULTS

3.1 Validation of the tool

The main objective of the T*HMClight* was to allow liquid composite manufacturing at constant resin flow front. Validation of the tool was conducted by manufacturing composite plates reinforced with dry flax fibers at a flow rate corresponding to optimal capillary number ($Ca_{opt} \cong 10^{-3}$) as proposed by other researchers [8], [9], [10], [11]. The pump speed was set to 15 rpm (22.5 mL/min) and manufacturing done in triplicate to demonstrate the robustness of the method. The evolution of the resin front position over time for each trial is shown in figure 3.

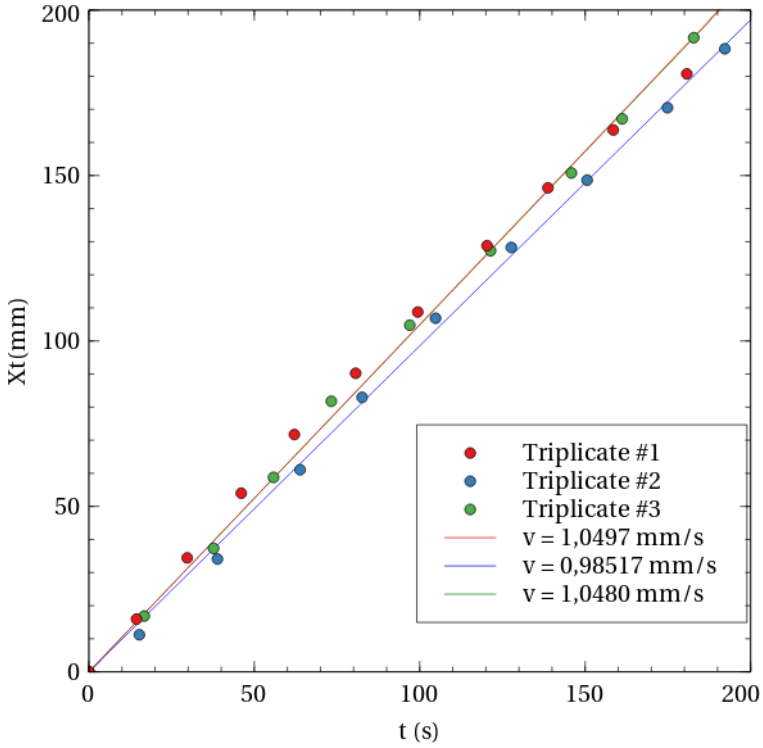

Figure 3: Resin flow front position (Xt) over time during manufacturing (Q = 22,5 mL/min)

Each point on the graph corresponds to the position of the resin front along the plate over time. A measurement was taken approximately every 2 cm along the plate. During controlled flow impregnation, the resin front formed a straight line with an angular deviation between 0 and 5°. Edge effects that can distort this front were occasionally observed and are attributed to poor distribution of the yarns along the parting line typically due to the absence of a yarn in the X-direction. Owing to the regularity of the resin front, the *Xt* values could be measured at the center of the plate during impregnation. The resulting plot is a linear function,which confirms that the resin front advances at a constant velocity. The average value of the flow front rate is $1{,}02 \pm 0{,}03$ mm/s which is in good agreement with other researchers that succeed to impregnate synthetic fibers at controlled flow rate [8], [11].

3.2 Influence of preform water content

Multiple composite plates were manufactured using different flow rates to target various *Ca*. Preform with various fiber water contents were also used to assess the influence of natural fiber humidity on the manufacturing. Table 2 summarizes the parameters set for the experiment and figure 4 shows the calculated *Ca* after based on the front velocity measurements for each plate.

Target *Ca*	Velocity *v* (m/s)	Flow rate *Q* (mL/min)
$1{,}0.10^{-3}$	$1{,}37.10^{-4}$	2,93
$7{,}68.10^{-3}$	$1{,}05.10^{-3}$	22,5
$2{,}0.10^{-2}$	$2{,}39.10^{-3}$	51
$2{,}75.10^{-2}$	$3{,}76.10^{-3}$	80

Table 2: Parameters for target *Ca* determination

The range of Capillary numbers studied allowed evaluation of the influence of flax fiber water content from low flow rate ($Q = 3$ mL/min, $Ca = 1.10^{-3}$) to high flow rate ($Q = 86$ mL/min $Ca = 2{,}75.10^{-2}$). At low flow rate of resin (close to Ca_{opt}) fiber water content had a little effect on the flow front velocity since the target *Ca* was reached for all humidity levels. However, at higher flow rates, significant variations in the calculated Capillary number were observed, reflecting changes in flow front velocity. Although, preforms containing 7 - 10 wt% water content show the closest values to target capillary number. This result strengthen the idea of a strict control of the fiber water content during manufacturing.

3.3 A deformed preform after manufacturing

During several manufacturing trials, deformation of the preform was observed after resin impregnation. For example, the figure 5 shows the deformation of a 16.2wt% water content preform manufactured at the same flow rate of resin used during the validation of the method. The deformation of the preform can be a consequence of a high fiber water content and a high flow rate of resin. In order to show this phenomenon we built a phase diagram with the flow rate of resin and the fiber water content. The diagram is shown figure 6 and evidences the effect of a high capillary number and fiber water content on the preform during manufacturing.

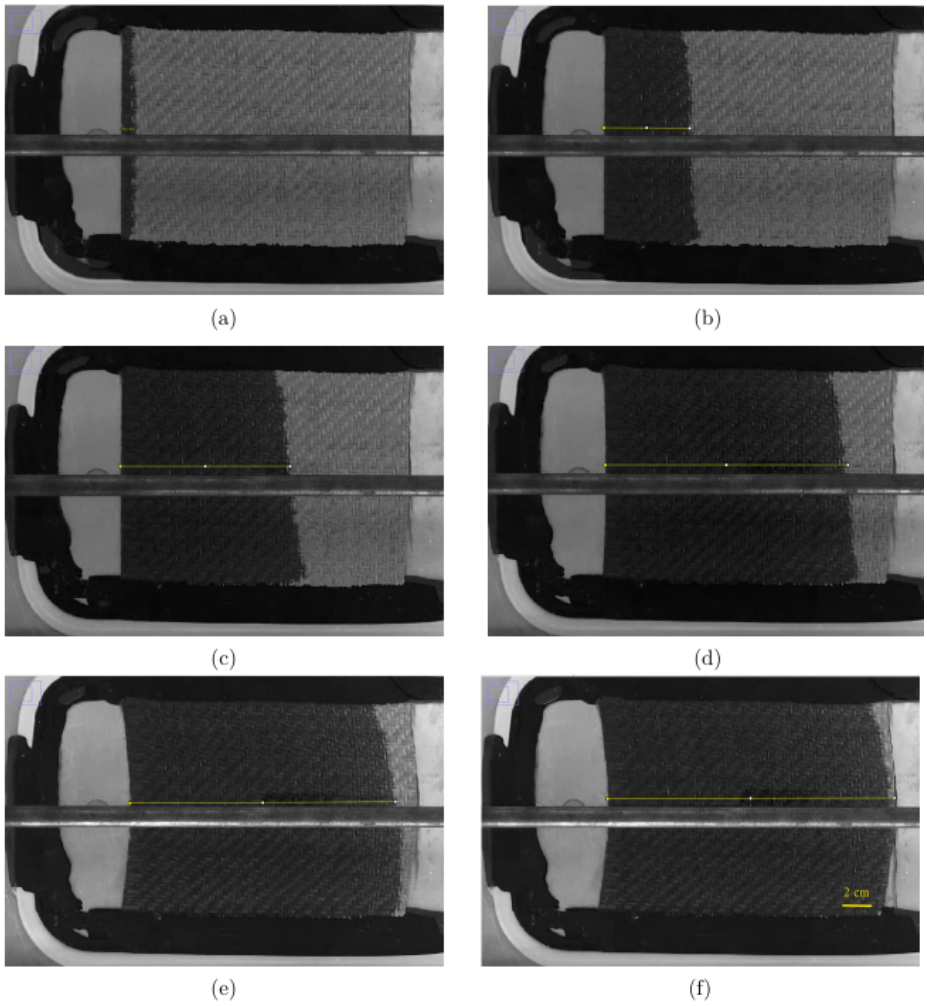

Figure 5: Resin flow front progression through a preform with 16,2wt% water content

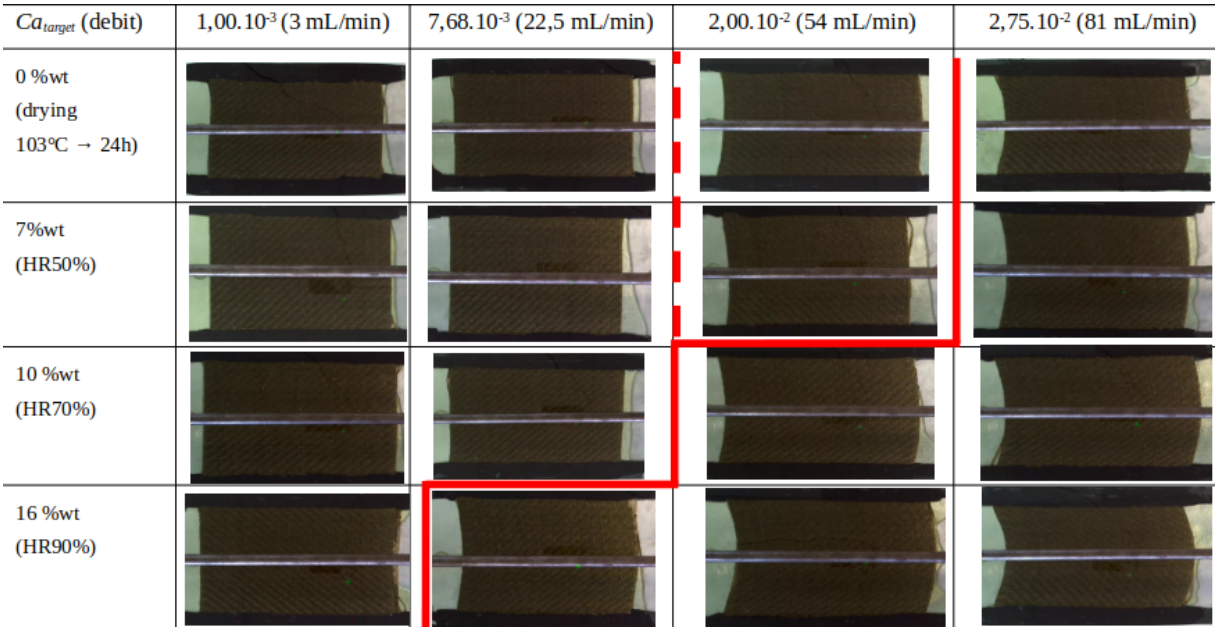

Figure 6: Processability window

During impregnation, the resin applies a pressure on the fibrous preform in the thickness direction. As the resin progresses through the preform, the applied pressure increase. If this pressure exceeds the compaction (holding) pressure applied to the preform stack, the preform may slip, leading to deformation of the final part (figure 7).

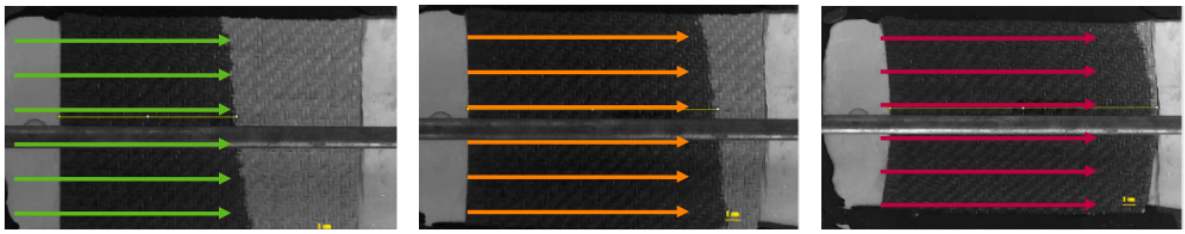

Figure 7: Illustration of the threshold pressure phenomenon observed during the controlled infusion process

The threshold pressure can be calculated by using Terzaghi's law [12]. The threshold pressure is then assimilated to the effective stress in this case σ_{eff}.

$$\sigma_{eff} = \sigma_{tot} - P_0 \quad (1)$$

with σ_{eff} the effective stress in MPa, σ_{tot} the total stress applied on the preform in MPa and P_0 the pressure applied by the resin in MPa. P_0 is calculated using the following equation based on Darcy's law:

$$P_0 = (Q/A)^2 (\mu/K)t \quad (2)$$

with Q the flow rate of resin in m^3/s, A the section of the preform corrected by the volumetric fiber fraction in m^2, μ the dynamic viscosity of the resin in Pa.s, K the permeability of the preform in m^2 and t is time in s.

In this study, permeability was taken as $K = 5.10^{-10}$ m^2 based on previous work [13], [14]. For the total stress, a constant initial force of $\sigma_{tot} = 0.1$ MPa is applied. The preform relaxes during compaction, therefore, the total stress needed to reach target thickness decreases due to this relaxation and tends to an asymptotic value. A recent work of our team on NCF flax preform showed that the relaxation phenomenon increases with the fiber water content. Since this study is on 2 x 2 flax twill preform we approximate the total stress value in function of the preform water content following the table below.

Average water content wt%	Relaxed σ tot (MPa)
0	0,08
7,6	0,07
9,9	0,06
16,7	0,05

Table 3: Values of the total stress σ_{tot} applied on the preform after relaxation for different preform water content

Effective stress has been calculated for varous combination of flow rate and fiber water content and results are plotted in figure 8. It gives rise to a surface plot representing the threshold pressure, described as effective stress. When the pressure applied by the resin on the preform exceeds the value of effective stress, slippage occurs. This chart allow the manufacturer to know which thermo-hygrometric conditionning should be applied to the preform to allow manufacturing at target flow rate (*Ca*) without causing slippage of the preform.

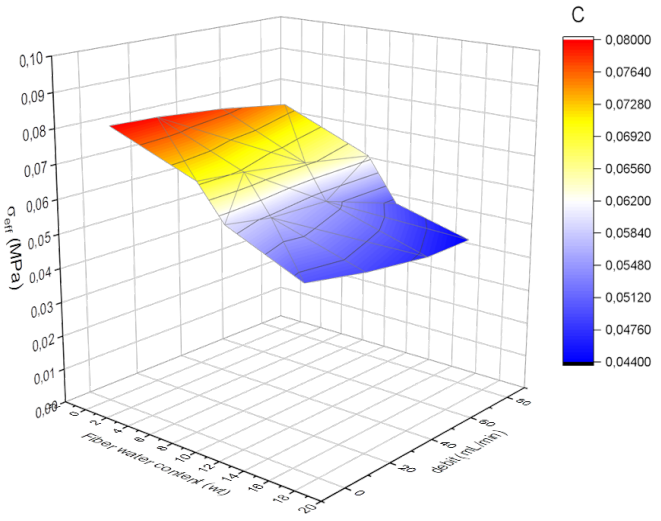

Figure 8: 3D representation of effective stress calculation
with flow rate and water content variations

3.3 Mechanical properties

The mechanical properties of composites made with the *THMClight* at various water contents were assessed using flexural trial test. The stress at break and the flexural modulus have been plotted in an Ashby diagram (figure 8).

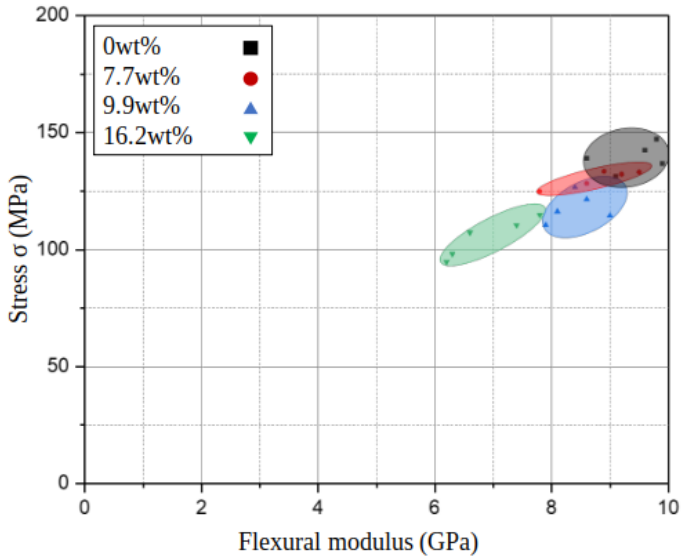

Figure 9: Effect of preform water content on mechanical
properties of flax / epoxy composites

A clear degradation in both flexural modulus and flexural stress is observed as the moisture content increases from 0% to 16wt%. Composites produced from dry preforms (0wt%) exhibit the highest

mechanical performance, with an average flexural modulus of approximately 9 GPa and a flexural stress near 180 MPa. In contrast, composites manufactured with highly humid preforms (16wt%) show significantly reduced properties, with a modulus of ~6 GPa and strength below 130 MPa. However, we would like to point out the fact that the gap in mechanical performances between dry preform composites and 7wt% water content composites are not so different and can. Considering this, a composites reinforced by a preform that contains 7wt% can be suitable for a particular application. This brings the idea of a more reasonable conception of composite parts. If the drying phase is not mandatory to satisfy mechanical requirements then it should be avoid for cost and energy savings.

4 CONCLUSIONS

In this work we successfully developed a new research tool and a potential industrial method for composite part production. The *THMClight* system enables the manufacturing of composite plate at controlled flow rate of resin with a low-tech experimental setup. By controlling the flow rate, it becomes possible to maintain a constant resin flow front, allowing manufacturing at a target Capillary number and thus minimizing void content. Using this LCM method, the influence of natural fiber water content on manufacturing has been studied. Results showed that at optimal *Ca*, humidity has a limited effect on capillary number but at higher *Ca* significant variations can be observed. Due to hydrophilic nature of flax fiber, preform with high water content slipped during manufacturing at several flow rates. This was attributed to a decrease in permeability with increasing moisture content, leading to a higher fiber volume fraction. Consequently, the pressure exerted by the resin exceeded the compaction pressure from the mold, resulting in fiber movement. Mechanical testing revealed that composites made from dry preforms did not exhibit significantly superior properties compared to those made from preforms containing 5–7 wt% water. This opens the door to reconsidering the necessity of drying preforms prior to manufacturing. If mechanical requirements can be met without a drying phase, the process can be made more energy- and cost-efficient. By mastering the effect of water content during process it is then possible to avoir drying phase of preform that is energy consumming and cost effective for industrials. This will also reduce carbon footprint of natural fiber reinforce composite manufacturing.

ABSTRACT

We conduct a series of experiments on impregnation of viscous fluid into woven fibre bundles placed between parallel plates to simulate resin impregnation near the substrates in VARTM method. This study particularly focuses on the impact of anisotropy in fibre bundle spacing on macrovoids formation. It is found that flow near the flow front changes by varying anisotropy in fibre bundle spacing. We reveal that aspect ratio of the space among fibre bundle dramatically affects macrovoid formation.

1 INTRODUCTION

Fibre-reinforced plastic (FRP) is a composite material manufactured by impregnating fluid, such as epoxy or phenolic resin, into fibre bundles. FRP exhibits high strength and stiffness, together with low weight and ease of processing. Due to its superior specific strength compared to metals, FRP has been widely used as a substitute for metallic materials in various applications, including aerospace components and automotive bodies. Among the forming techniques for FRP, one notable method is Liquid Composite Molding (LCM). One prominent example is the VARTM (Vacuum Assisted Resin Transfer Molding) method, which accelerates resin impregnation by using vacuum pump, has numerous advantages and ability to mold materials and manufacture in any type of shape with a wide range of spatial scales with low cost. However, it also has the disadvantage that entrapments of gas remained in the mold are prone to occur due to unintended insufficient impregnation during the resin flow. Entrapped gas, or void, can cause stress concentration and significantly decrease the trustworthiness of manufactured composites. To maintain quality of composite materials, it is essential to elucidate the conditions for void formation and suppression. Two types of voids have been defined: microvoids which form within fibre bundles, and macrovoids which form between fibre bundles [1]. This study focuses on the latter, as it has more significant impact on tensile and compressive strength of materials [2]. Extensive research has been conducted on the behavior of fluid impregnation within fibre bundles in the VARTM process. Total volume of residual voids varies with some factors such as the capillary number (Ca), a dimensionless number representing the characteristic velocity of fluid, and wettability [3,4].

$$\mathrm{Ca} = \frac{\mu U}{\sigma}, \tag{1}$$

where μ, σ, and U, represent the viscosity, the surface tension, and the impregnation velocity of the test fluid, respectively. When Ca is small—that is, when capillary forces dominate—the test fluid preferentially flows between the fibre tows and gradually fills the interior of each tow. In this regime,

macrovoids are prone to form between fibre bundles. Conversely, when Ca is large, the formation of macrovoids is suppressed; however, micro-voids tend to form within the fibre bundles with higher probability. Although the optimal capillary number (Ca) depends on multiple factors, including the structure of fibre bundles and is therefore difficult to determine uniquely, a value of $Ca \approx 10^{-3}$ is regarded as effective threshold for suppressing void formation across various conditions [5,6]. Furthermore, it has been experimentally demonstrated that increasing the contact angle at the solid-liquid interface—i.e., reducing wettability—suppresses deformation of the flow front, thus reducing macrovoid formation even under low Ca conditions [7,8]. It has also revealed that wettability has a significant influence on flow patterns within porous media, particularly on void geometry and residual void content through X-ray 3D scanning of fluid displacement in carbon fibre preforms [8]. This study targets on woven fibre bundles placed between parallel plates to simulate resin impregnation near the substrates in the VARTM method, and particularly focuses on the impact of anisotropy in fibre bundle spacing on the viscous fluid impregnation dynamics.

2 EXPERIMENTS

The experimental apparatus used in this study is schematically illustrated in Fig. 1. To prepare a mold, we settle the single-layer woven glass fibre mat between acrylic flat plates on both sides, which are fixed by jigs made of SUS. To prevent gas-liquid leakage into or out of the mold, an O-ring is installed between each acrylic plate and the jig. The inlet of the mold is connected to a reservoir of test liquid, and the outlet is connected to a vacuum pump (DA-60D, ULVAC, Inc., Japan) to create a pressure difference within the mold, each via rubber tubes. The pressure difference within the mold is adjusted using two regulators (IRV 10-C08L, SMC, Corp., Japan) connected between the outlet of the mold and the vacuum pump, and measured with a pressure meter (MT300-D01, Yokogawa Test & Measurement Corporation, Japan). 350-cSt silicone oil (KF-96-350 CS, Shin-Etsu Chemical Co., Ltd., Japan) is employed as test liquid, and fluorescent particles are mixed in the liquid as tracers for visualization. Light emitting diode (LED) (AITEC SYSTEM, Co., LTD., Japan) is placed to visualize the flow front of the impregnating liquid with white light. Additionally, a continuous laser light of 532 nm in wavelength is irradiated at the imaging area through a half-mirror to excite the fluorescent particles to visualize particle behavior in the liquid. The images of the impregnation process are recorded by using charge-coupled device (CCD) camera (C9300 − 221, Hamamatsu Photonics, K.K., Japan) of 640 x 480 pixel at 20 fps from the underside of the mold with 60 mm lens (Micro-Nikkor 60mm f/2.8D, Nikon, Inc., Japan). To prevent the CCD camera from receiving the laser light, a short-pass filter is placed between the CCD camera and the half mirror. Before conducting each experiment, the sealed container containing the test liquid is subjected to ultrasonic vibration for one hour to obtain a uniformly dispersed mixture of particles. Also, the test liquid is degassed under -90 kPa for at least three hours to remove residual air within the liquid. Figure 2 shows the woven glass fibre mats (Featherfield, K.K., Japan) with different anisotropies in fibre bundle spacing used in this study. Fibre bundles aligned in the main flow direction are referred to as warp, while those oriented in the spanwise direction are referred to as weft. The aspect ratios of the gaps, where neither warp nor weft fibre bundles are present, are varied as (a) 1:1, (b) 1:3, and (c) 3:1. The fibre mat used in each experiment consisted of fibres with a diameter of 17 μm.

The density per area is (a) 550 g/m², and (b) and (c) 462 g/m². The test liquid is silicone oil as aforementioned, whose kinematic viscosity, density, and surface tension are 350 mm^2/s, 967.4 g/m^3, 21.1 mN/m respectively. All experiments are conducted under constant conditions at a room temperature of 22 °C.

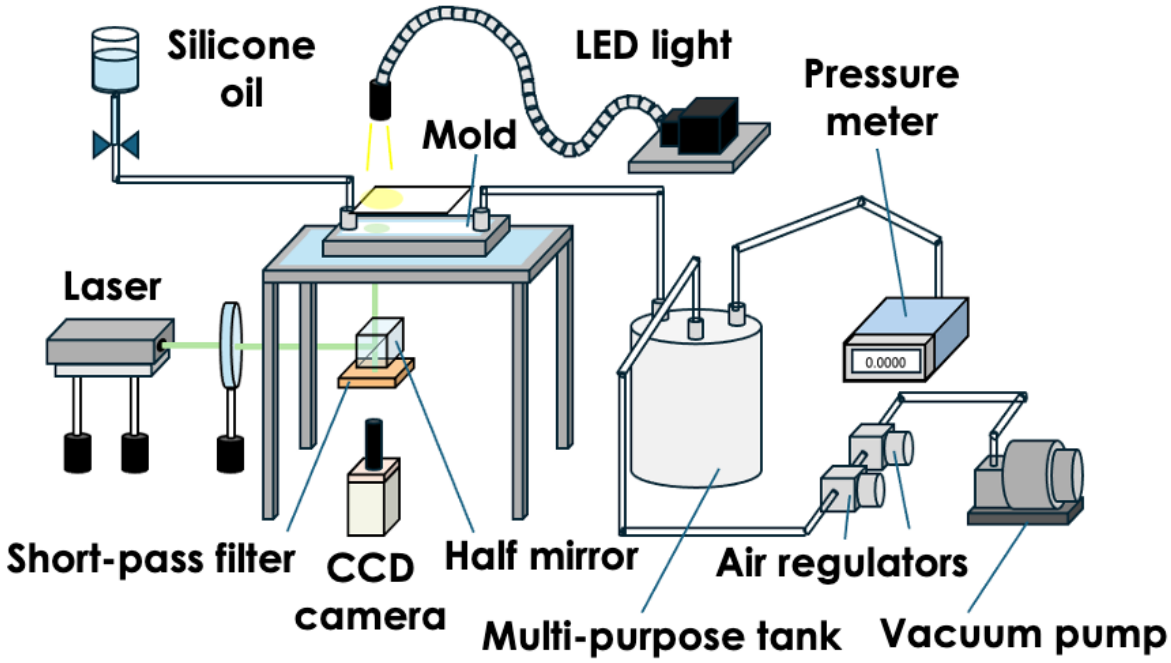

Figure 1: Experimental apparatus for visualizing impregnation process into woven glass fibre mats in mold.

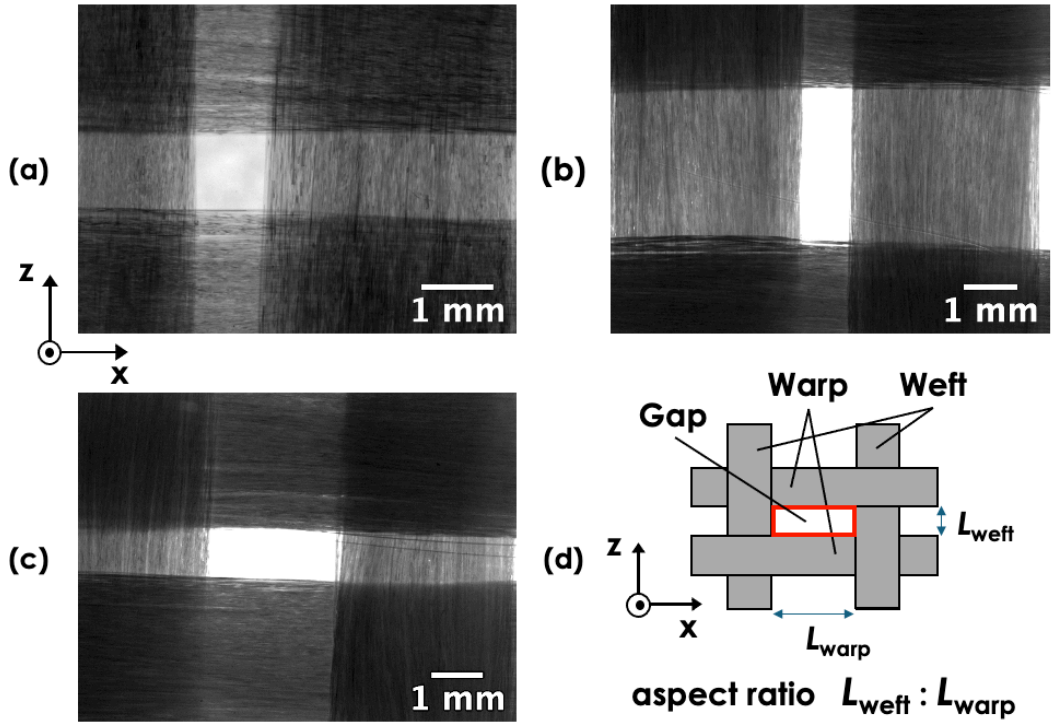

Figure 2: Three types of woven glass fibre mats with anisotropy in fibre bundle spacing. Aspect ratio of each gaps, $L_{weft} : L_{warp}$, is (a) 1:1 (b) 1:3 (c) 3:1.

3 RESULTS&DISCUSSION

Figure 3 shows a representative example of impregnation behavior. The left three columns represent experimental results, and the rightmost column shows results of numerical simulation [9]. The experimental results include instantaneous fields near the flow front at two representative time points ($t - t_0 = 0$ [s],10 [s]) and pathline images obtained by integrating instantaneous fields over these time intervals. Under all conditions, the warp fibre bundles in the upper left and lower right crimp are positioned in the foreground (from the viewing side), and the same applies to the weft fibre bundles in the upper right and lower left crimp. This study replicates the flow front behavior in the snap-off process, as previously observed by simulation [7] and by experiments [7,10]. Snap-off refers to a phenomenon in which advancing flow front moves around the gap, resulting in spontaneous filling of the weft fibre at the downstream side of the gap and disconnection of the non-wetting phase [11]. The flow behavior near the flow front is visualized by tracking fluorescent particles. Under each condition, at the upstream side of the gap, the liquid near the flow front moves around the gap, resulting in a flow velocity component in the z-axis direction at both the upper and lower sides. As impregnation progresses, the liquid flows along the warp fibre bundles in the lower-right crimp (as indicated as (iii)), resulting in dominant flow velocity component in the x-axis direction. In contrast, in the upper-right crimp (i), the liquid permeates along the weft fibre at the downstream side of the gap (ii), resulting in a flow velocity component in the z-axis direction. This phenomenon is particularly noticeable in Panel (c). These results are well reproduced by the present numerical simulation (rightmost column in Fig. 3) for each gap geometry. The liquid motion along the weft fibres in the downstream side of the gap (ii) enhances the curvature of the flow front near the boundary between the gap and weft fibre bundle (as shown at the right edge of the gap), thereby increasing the Laplace pressure. As a result, it suppresses macrovoid formation by inducing detachment of the interface at the warp fibre edge in the gap. This tendency is particularly pronounced under the condition of a 3:1 aspect ratio gap (Panel (c)), supporting the results by Matsuzaki et al. [12], which showed that macrovoid formation is less likely in fibre mats with lower $L_{\mathrm{weft}} / L_{\mathrm{waft}}$. It is important to note that the weft and warp fibre bundles have different thicknesses in their study.

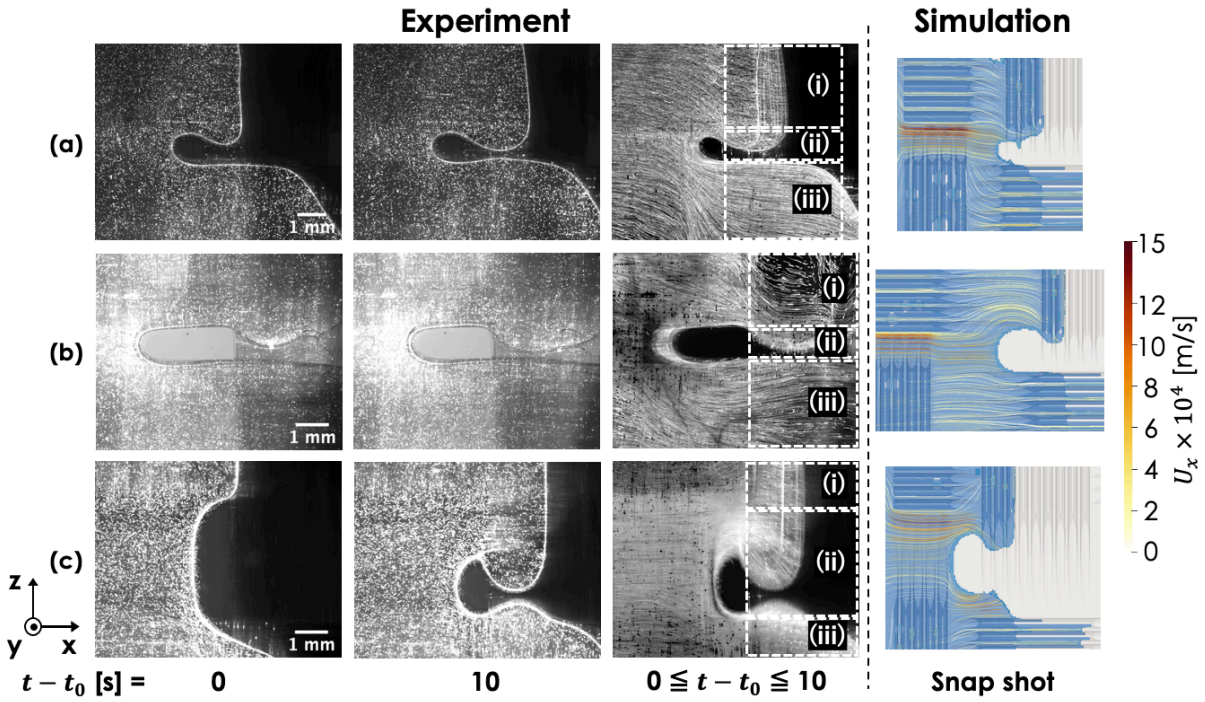

Figure 3: Representative examples of impregnation behavior under each gap aspect ratio: (a) 1:1, (b) 1:3, and (c) 3:1. The left three columns represent experimental results, while the rightmost column shows numerical results.

Figure 4 shows an instantaneous field of the observation region captured by the CCD camera. A dashed line in the figure indicates the evaluation line defined for evaluating the representative impregnation velocity of the liquid. The left panel shows the raw image data, while the right panel displays the velocity field obtained via PIV analysis, overlaid on the raw image. PIV data are processed using filter based on the discrete cosine transform (DCT) [13]. The impregnation velocity of the test liquid is evaluated using the velocity data obtained from the PIV. We define the representative impregnation velocity $\overline{U_{x,20s}}$ as the time-averaged x-direction velocity along the inspection line over 20-second interval, selected after the flow front has sufficiently advanced and the flow has stabilized. The same evaluation method is applied under all aspect ratio conditions.

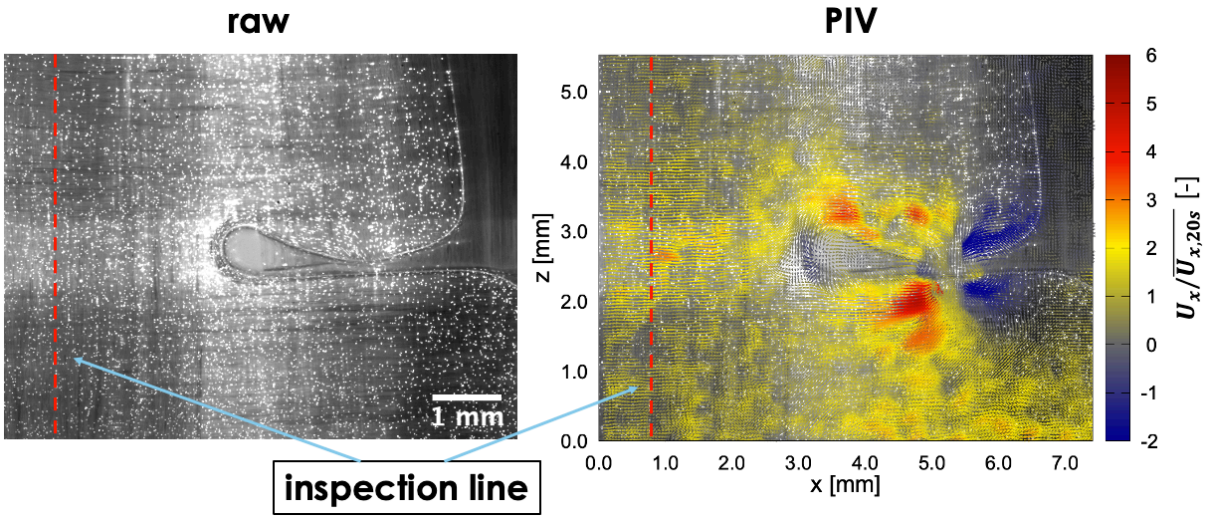

Figure 4: Instantaneous field of observation region with dashed evaluation line used for evaluating $\overline{U_{x,20s}}$ The left panel shows the raw image data, while the right panel displays the velocity field obtained from the PIV, visualized using the filter based on DCT.

Figure 5 shows instantaneous field immediately after snap-off for each aspect ratio condition. The left two columns represent experimental results, and the rightmost column shows results by the numerical simulation [9]. The first column of experimental results illustrates the raw instantaneous field overlaid with a schematic of the local fibre orientation and highlighted gas-liquid interfaces. The closed interfaces entrapped in the gap region are marked in green, while the leading flow front is highlighted in pink. The second column of experimental results displays a magnified view of the velocity vector field obtained by the PIV (with DCT filter) focusing on the snap-off region, with the gas-liquid interfaces emphasized in the same color scheme. The color distribution in the vector field is determined by the x-direction velocity normalized by the representative impregnation velocity $\overline{U_{x,20s}}$ defined above. The same image processing and analysis procedure is applied to all aspect ratio conditions (a)1:1, (b)1:3, and (c)3:1. Regarding the velocity field, particularly in conditions (a) and (c), large velocity vectors are observed along the gas-liquid interfaces. Along the interface highlighted in green, positive velocities appear both above and below a negative velocity region located near the snap-off region. In contrast, along the interface highlighted in pink, the velocity near the snap-off region is positive, while negative velocities are observed above and below it. This velocity distribution is attributed to the rapid deformation of the gas-liquid interface caused by snap-off, which draws in the surrounding liquid and leads to the expansion of the constriction between gas-liquid interfaces in the x-direction. Although a similar tendency is observed under the condition of a 1:3 aspect ratio gap (Panel (b)), no prominent velocity distribution appears in any region. The tendency for the constricted region to exhibit an opposite velocity to that of upper and lower regions is also well reproduced by the present numerical simulations for each gap shape. In the presentation, we also incorporate experimentally obtained shear fields into

our discussion, alongside the results of numerical results.

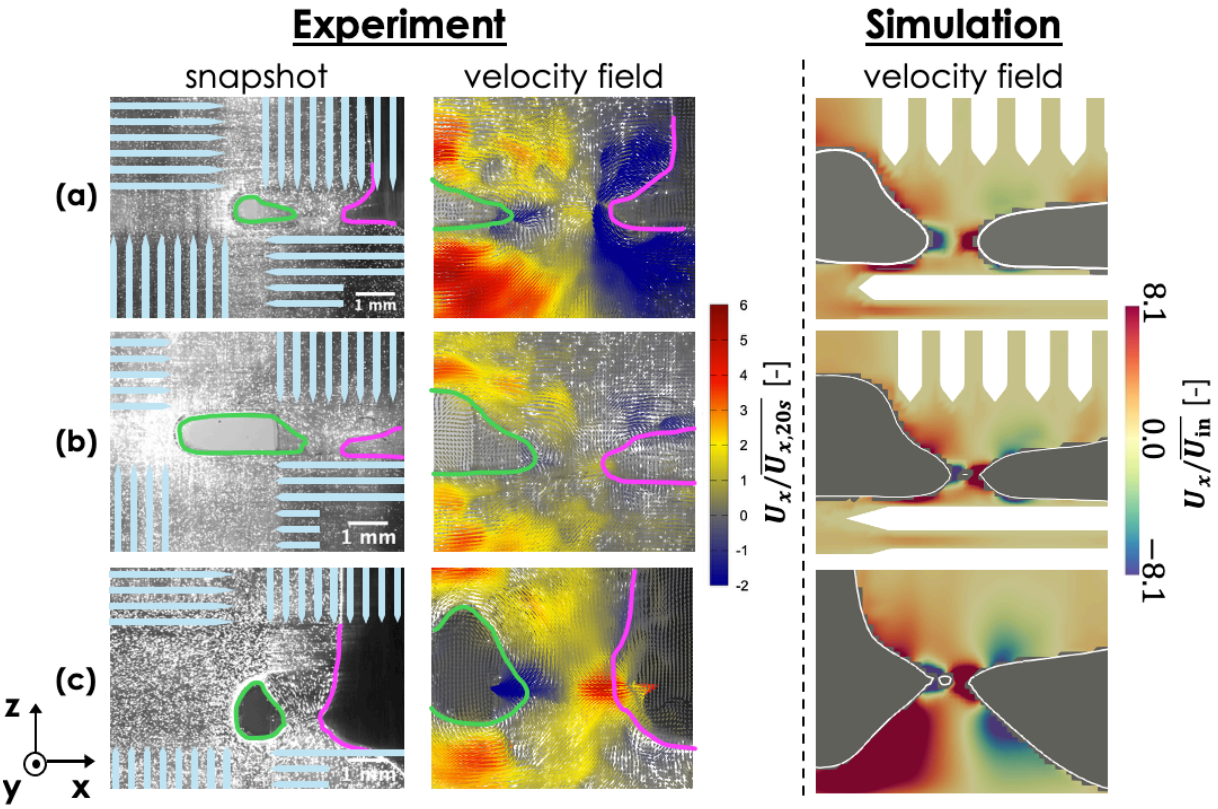

Figure 5: Velocity fields immediately after snap-off for each aspect ratio: (a) 1:1, (b) 1:3, and (c) 3:1. The left two columns show the experimental results, and the rightmost column shows the numerical simulation results. The left column presents raw image data, while the center column displays a magnified view of velocity field obtained via the PIV. In both experimental columns, a schematic of the local fibre orientation and highlighted gas-liquid interfaces are overlaid.

3 CONCLUDING REMARKS

This study investigates the impregnation behavior of a viscous fluid into woven fibre bundles placed between parallel plates, with particular focus on the impact of the anisotropy in fibre bundle spacing influences the impregnation behavior. We prepared three kinds of fibre mats with different gap aspect ratio: 1:1, 1:3, and 3:1. We mixed fluorescent tracer particles into test liquid to examine impregnation behavior. For each aspect ratio condition, comparisons between experimentally obtained pathline and velocity fields predicted by numerical simulations showed good agreement in overall trends. The results demonstrated that the magnitude of spanwise velocity along weft fibres in the downstream of the gap has a significant impact on macrovoid formation in this system.

Conclusions

The proposed digital twin can achieve low computational times, which allow:

- A timely prediction of future results
- The calibration of intrinsic material properties, leading to a self-adjusting behaviour

Remote computing capability eliminates the need for extensive computational hardware on the shop floor

© INEGI all rights reserved

Future work

- Enhance property calibration methods
- Validate system through increasingly complex manufacturing scenarios
- Add additional phenomena to the digital twin (curing, distortion, etc)

ABSTRACT

Urban Air Mobility (UAM) faces demanding challenges on weight reduction, efficiency, and sustainability in electric vertical take-off and landing (eVTOL) aircrafts. This research presents and compares three ultra-lightweight composite panel manufacturing concepts, tailored for interior applications, using adaptive moulds and fibre placement technologies. The first concept is a selectively reinforced panel using Tailored Fibre Placement (TFP) with functional integration, achieving surface weights as low as 1.640 g/m². The second is a selectively reinforced sandwich panel, topology optimized and realized using TFP with towpregs, reducing weight further to 650 g/m². The third concept employs robotic near-net-shape Automated Fibre Placement (AFP) of bindered or prepreg tapes directly onto adaptive moulds. Although highly automated and capable of 3D deposition, this approach is currently limited to straight fibre paths and less suited for function integration. Comparative results show trade-offs between flexibility, automation, material efficiency, and design complexity. The integration of adaptive tooling and modular placement strategies opens new pathways for rapid, cost-effective, and sustainable production of composite panels. While this work focuses on aircraft cabin interiors, the presented methods demonstrate broader applicability for next-generation lightweight structures across the UAM sector and beyond.

1 INTRODUCTION

Recent technological developments in the field of electrical vertical take-off and landing (eVTOL) have contributed to further interest and innovations in the field of urban air mobility (UAM) [1]. Nevertheless, a number of challenges concerning the power-to-weight ratio and electrical efficiency must be overcome before eVTOLs can be realised. The overall weight reduction is an important factor as it results in lowered energy consumption or allows for batteries with higher capacities [2]. In addition, studies have shown that the utilisation phase is responsible for up to 99 % of emissions in aviation, and sustainability highly depends on the use of lightweight components [3].

This is where ultra-lightweight approaches become very attractive. The efficiency of composite materials can be improved by optimizing their orientation, taking full advantage of their anisotropic properties. Topology optimization aims to generate load optimized structures, often enabled by additive manufacturing approaches. Thanks to the high degree of design freedom, the material can be optimally distributed, resulting in an increased performance [4]. The use of composites for these structures offers the potential for further optimization of the performance and the lightweight character. The production of composite structures with oriented fibres is crucial for their realization. Automated Fibre Placement (AFP) [5] technologies offer great freedom for the manufacturing of these structures. The Dry Fibre Placement (DFP) is used in a process named Crosslayer [6]. It uses spread dry carbon fibre tows (FixedTows or tapes) that are fixed by the application of an auxiliary binder system [7]. They are placed linearly by activating the binder system, mostly by heating, and enabling adhesion to the tooling surface [8]. That way, load-optimized preform layups are automatically produced near-net-shape [6–9]. Another preform manufacturing approach is the Tailored Fibre Placement (TFP). This process uses embroidery

technology to place continuous fibres according to the load paths in a 2D plane [10]. Different fibres like carbon fibres (CF), glass fibres (GF), and natural fibres (NF) can be used. The dry fibres are stitched on an embroidery base material using a zig-zag stitch pattern. Thanks to the variable orientation of fibres, the resulting preforms can be highly optimized in terms of load-bearing ability and material efficiency. For the selective reinforcements, anisotropic topology optimization can be applied depending on the supporting material layup [11].

Especially cabin interior panels, which are non-structural, are predestined for implementing ultra-lightweight construction approaches. Nowadays, interior panels for commercial aircraft are made of sandwich panels, manufactured as a combination of honeycomb core and glass fibre reinforced plastic (GFRP) face sheets in closed press tools [12]. With standard surface weights higher than 2.000 g/m^2 [13], they have great potential for material savings in the final part and for reducing production waste by developing more efficient processes. As the established production process for sandwich panels is complex, expensive, time-consuming, and hardly automated [12,14], production costs can be significantly reduced by the automated, modular, and versatile manufacturing strategies presented in this research. To unfold the full potential of quickly customizable preforming processes, an adaptive mould is investigated. The surface of this mould can be manipulated to different shapes automatically, which can reduce investment costs, storage costs, and production times [15]. The flexibility gained by the combination of adaptive tooling and fibre placement processes can help reduce the gap between design and production, and enable the fabrication of complex geometries. Though showcasing the manufacturing abilities using the example of cabin interior panels, this paper aims to provide an insight on the versatile application possibilities enabled by variable axial fibre placement technologies in general, not only for UAM applications.

2 METHODS AND MATERIALS

This research aims to introduce and compare three manufacturing methods for tailoring UAM interior panels to achieve significant weight savings at the expense of rigidity. All methods include the use of adaptive moulds and are based on the AFP technologies which are presented next.

2.1 Adaptive tooling

Most samples were produced on the adaptive mould “Mini” from Adapa A/S (Aalborg, Denmark), which is shown in Figure 1.

Figure 1: Adaptive mould Adapa "Mini"

The flexible membrane allows for the generation of double-curved continuous surfaces that can be transformed within minutes. It is controlled by 64 pistons in an 8 × 8 configuration. This results in an active area of 600 mm × 600 mm, and a maximum area of 850 mm × 850 mm. As a constraint, the minimum radius is 400 mm. It must be noted, that the “Mini” is the research mould from Adapa A/S, larger moulds are available in different sizes and can provide areas of up to 9.000 mm × 9.000 mm.

2.2 Tailored Fibre Placement

In this work, a TFP machine TCWM-102 from Tajima Industries Ltd. (Kasugai, Japan), as shown in Figure 2, is used. This twin-head machine has two continuous feeding devices installed and offers a maximum working area of 1.550 mm × 950 mm.

Figure 2: TFP embroidery machine Tajima TCWM-102

2.3 Dry Fibre Placement

The dry fiber tapes are produced from CF with a spreading machine from M&A Dieterle GmbH (Ottenbach, Germany) and can be processed with a Crosslayer placement head of the same company. Basically, the Crosslayer end effector actively feeds bindered or pre-impregnated tape material, activates the adhesive with an IR-lamp and presses it to the tool surface [6]. This is usually done on the Crosslayer portal machine with a working area of 2.000 mm × 1.000 mm. Both machines are presented in Figure 3.

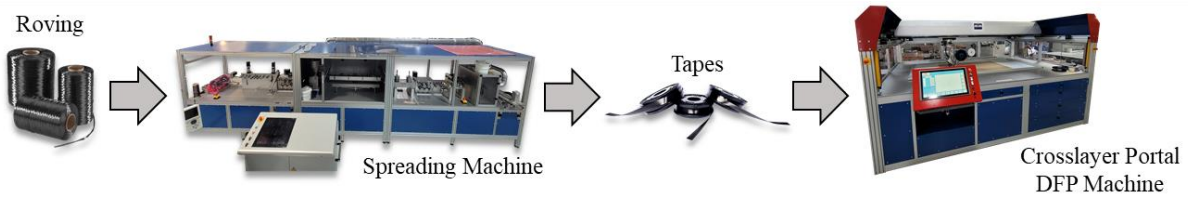

Figure 3: Spreading machine for tape production and Crosslayer portal machine for DFP

2.4 Universal Robot UR20

Figure 4 a) displays the collaborative robot (cobot) Universal Robots UR20 from Teradyne Robotics GmbH (Munich, Germany) with a maximum payload of 20 kg. One major advantage of the cobot is, that it does not need any safety housing, so its application possibilities are very flexible. For robotic AFP, a modified Crosslayer tape placement end effector, shown in Figure 4 b), is mounted. This tool can be used to directly apply tapes to 2D- or 3D-shaped surfaces.

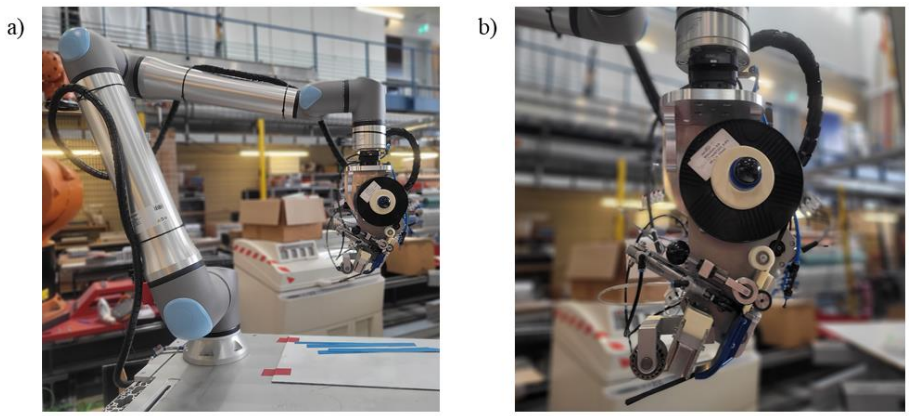

Figure 4: Robotic DFP: a) Cobot UR20; b) Crosslayer placement head

2.5 Materials

During the manufacturing experiments, CF rovings of different filament counts are used. A 12K CF roving Tenax™-E HTS40 F13 12K from Teijin Carbon Europe GmbH (Wuppertal, Germany) is used for towpreg production. For dry TFP processing, a 50K roving Sigrafil® C T50 from SGL Carbon SE

(Wiesbaden, Germany) is used. The 30K roving Pyrofil™ TRH50 30K from Mitsubishi Chemical Corporation (Tokyo, Japan) is used for the production of tapes for the DFP process.

The GF base material for embroidery is E-glass woven fabric HexForce 02116 1260 TF970 from Hexcel Corporation (Stamford, Connecticut, USA). It was purchased from Wela Handelsgesellschaft mbH (Geesthacht, Germany). It weighs 105 g/mm^2. As an alternative, NF base material flax fibre twill 2/2 fabric ampliTex™ 5040 from Bcomp Ltd. (Fribourg, Switzerland) with 300 g/m^2 is chosen.

As a core material, pressure stable polyester nonwoven Soric® XF 6 with a thickness of 6 mm is chosen. In addition to its core function, it can also serve as an infusion medium. The dry weight of Soric® XF 6 is 345 g/m^2, the infiltrated weight is 3.600 g/m^2. It is produced by Lantor B.V. (Veenendaal, Netherlands) and was purchased from Gaugler & Lutz GmbH & Co. KG (Aalen-Ebnat, Germany).

Two resin systems are used throughout the experiments. Both possess low viscosity and long pot life. For the towpreg production, EPIKOTE™ Resin MGS RIMR 135 is used in combination with EPIKURE™ Curing Agent MGS RIMH 137 from Hexion B.V. (Rotterdam, Netherlands). All other Infusions are done with Epoxy Resin L and Hardener GL2 from R&G Faserverbundwerkstoffe GmbH (Waldenbuch, Germany). Especially for optical applications, the high transparency of this resin is beneficial.

3 DESIGN AND MANUFACTURING CONCEPTS

This chapter presents and compares three distinct manufacturing concepts, each implemented in the form of ultra-lightweight panel prototypes, which are described in Chapter 4. All approaches are developed to be compatible with adaptive mould systems, supporting both, dry fibre placement followed by resin infusion, or prepreg-based processing routes. The concepts differ in their design philosophies, functional integration capabilities, and fibre placement strategies, yet all target significant weight reduction and high shape adaptability – key features for next-generation aerospace interior components, especially within Urban Air Mobility (UAM) applications.

3.1 Selectively Reinforced Panel

The first concept is a tailored ceiling panel with integrated functionality, following a design-driven and bionically inspired approach. Drawing inspiration from nature, in this case leaves, the panel design emphasizes load path efficiency and multifunctionality. The central design feature is the selective reinforcement of fibre paths, strategically placed to mimic natural vein structures for optimized mechanical performance. A distinguishing element of this panel is the integration of connection functions. By including loops at the distal ends of the fibre arms, simple mechanical attachment without additional hardware is enabled.

Furthermore, the base material is variable, supporting the use of different materials for focus on aesthetics, lightweight design or sustainability. The TFP reinforced base is stacked together with optional added layers onto the tool surface. The whole panel is then infiltrated using vacuum assisted resin infusion (VARI) or vacuum assisted process (VAP®). This concept is illustrated in Figure 5.

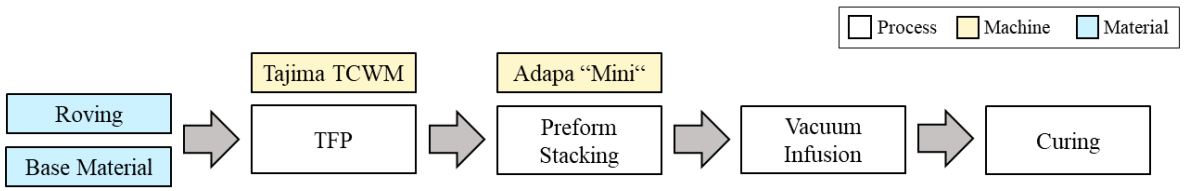

Figure 5: Process diagram of the manufacturing process for the selectively reinforced panel

3.2 Selectively Reinforced Sandwich Panel

The second concept adopts a methodical, performance-optimized approach focused on maximizing mechanical stiffness through sandwich panel construction. This concept relies on the well-established mechanical principle that panel height contributes significantly to bending stiffness, which is enhanced by employing a low-density core material and stiff top and bottom skins. Selective reinforcement is

applied only where structurally necessary, thereby reducing the overall fibre volume and optimizing material usage. The design process, illustrated in Figure 6, is driven by topology optimization, which informs the creation of a modified reinforcement grid, termed the “Opti-Grid”, that serves as the basis for TFP paths.

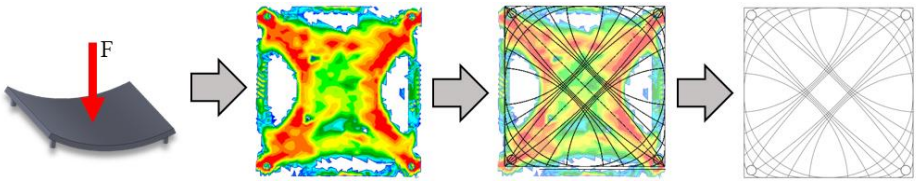

Figure 6: Design process of the "Opti-Grid", starting from solid reference model, going through topology optimization and resulting in an optimized fibre path

For the panel fabrication using TFP technology, it is necessary to use material with compatibility to the embroidery process. The core material must be stitchable, flexible, and capable of maintaining its height under needle load and under surface load. Experiments demonstrated high potential for the lightweight Soric® XF polyester core material. To avoid filling this porous core material with resin, an alternative to vacuum infusion is needed. At this point, pre-impregnated rovings, so-called towpregs, were chosen to be placed with TFP. Towpreg-based TFP offers a resin-contained process with minimal resin waste, making it well-suited for low-mass applications. A known downside of this approach is the contamination of embroidery equipment with pre-impregnated material, requiring periodic cleaning.

The embroidery-based process deposits fibres directly onto two substrates: One layer is placed directly onto the Soric® XF core material, the other is stitched onto a base layer of the glass fibre woven fabric. These preforms are subsequently stacked and shaped on the adaptive mould, followed by vacuum bagging and curing. Figure 7 illustrates the concept of this process, which eliminates the vacuum infusion step.

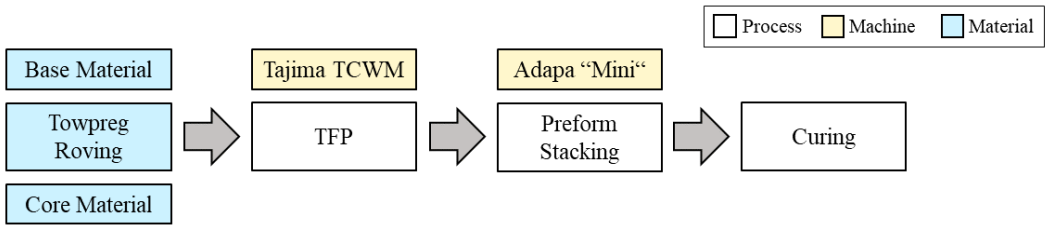

Figure 7: Process diagram of the manufacturing process for the selectively reinforced sandwich panel

3.3 Near-Net-Shape Robotic AFP Panel

The third manufacturing concept employs automated, robotic near-net-shape fibre placement of fibre tapes. This approach leverages an industrial robotic setup wherein spread fibre tapes are applied directly to the adaptive mould surface in their final geometry, avoiding intermediate draping or reshaping steps. The consistent-width bindered dry fibre tapes are prepared from carbon fibre rovings with the M&A Dieterle spreading unit. These are used either dry or pre-infiltrated within a Crosslayer placement head, that is guided precisely over the adaptive mould surface by an UR20 robotic arm. The placement head consists of a tape supply for a film spool and uses an infrared (IR) heating unit to activate the binder or resin on the tapes. Subsequently, a roller system presses the tape with defined force, controlled by the UR20 onto the tool surface. This approach is limited to linear fibre paths due to the nature of the spread tape material and the placement head, but enables highly repeatable and efficient processing. The direct 3D deposition onto the adaptive mould aims to eliminate common defects like wrinkles or bridging, often found in manually draped laminates. Using this process, either monolithic or sandwich design can be realised. For sandwich panels, a core is placed on the bottom reinforcement layer and then covered with the top reinforcement layer. Figure 8 gives an overview on the robotic AFP process with dry bindered tapes and with prepreg tapes.

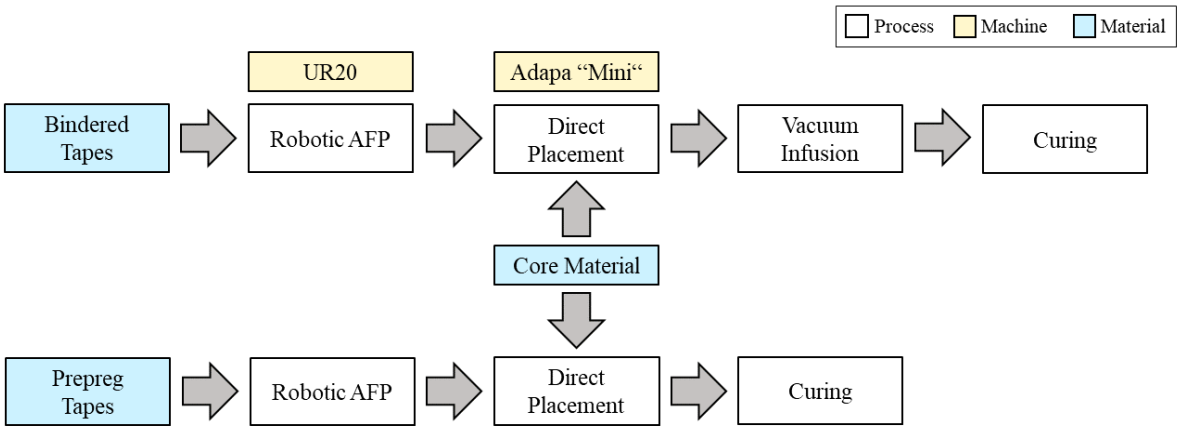

Figure 8: Process diagram of the manufacturing process for the robotic AFP panel with bindered tapes or with prepreg tapes

4 RESULTS

The selectively reinforced panel and the selectively reinforced sandwich panel are evaluated on the basis of the production of panel prototypes. For the robotic AFP, the concept is assessed based on calculations. All three processes differ in their intended application, in their weight, and in their stiffness.

4.1 Selectively Reinforced Panel

The prototype for this manufacturing concept is a cabin interior ceiling panel with a length of 2.400 mm. For this prototype, the moulding area of the lab-scale Adapa "Mini" was too small. Therefore, a standard tooling made from Polyurethane (PU) was used. The TFP process and the resulting panel are presented in Figure 9.

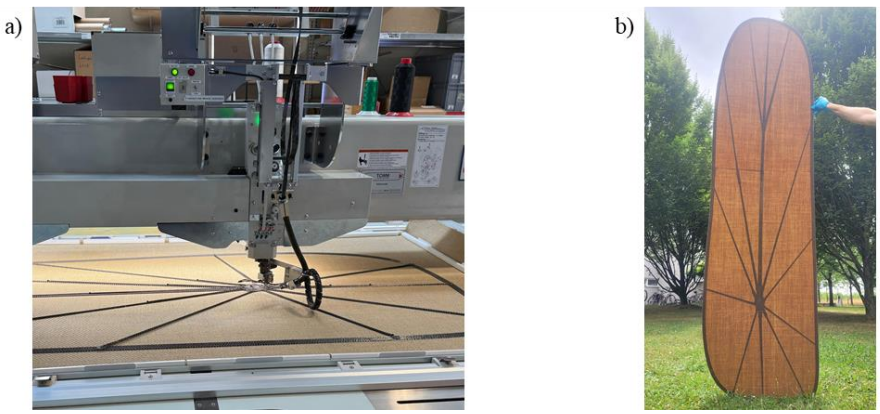

Figure 9: Manufacturing of cabin interior ceiling panel prototype: a) TFP on NF base with CF; b) front side of final NF panel prototype

The NF reinforced panel structure includes two layers of ampliTex™ 5040 woven flax fabric and weighs 2.700 g, which converts to 1.640 g/m^2. Connector functions were successfully integrated in this structure while creating an aesthetic bionically inspired panel. This concept showcases the potential of design-centric fibre placement to integrate functionality without compromising lightweight objectives.

4.2 Selectively Reinforced Sandwich Panel

This panel, sized 700 mm × 700 mm, was produced on the Adapa mould with a radius of 400 mm. Towpreg TFP was done with 12K CF roving, preimpregnated with epoxy resin system RIMR 135/ RIMH 137, on the GF base material and on the Soric® XF core. The needle and the fibre guide unit of the TFP machine had to be cleaned thoroughly after these works.

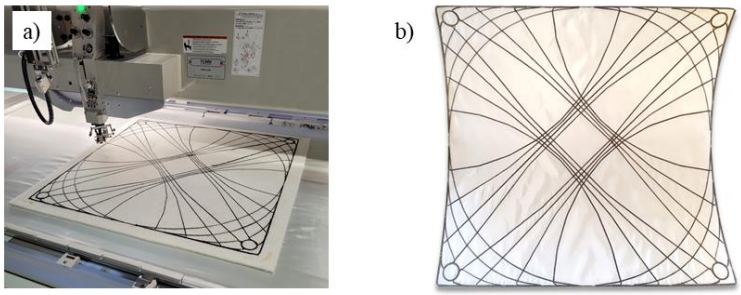

Figure 10: Manufacturing of selectively reinforced sandwich panel: a) TFP on core material with towpreg; b) panel prototype

The resulting prototype demonstrates excellent mass reduction at 320 g, which is equivalent to a surface weight of 650 g/m². This approach highlights how methodically placed fibres in a lightweight sandwich architecture can yield high mechanical efficiency with minimum material usage.

4.3 Near-Net-Shape Robotic AFP Panel (Concept)

The feasibility is proven for this third manufacturing approach. The DFP end effector was successfully implemented and tested in combination with UR20. First layups have been realized on the Adapa “Mini”, one of them shown in Figure 11.

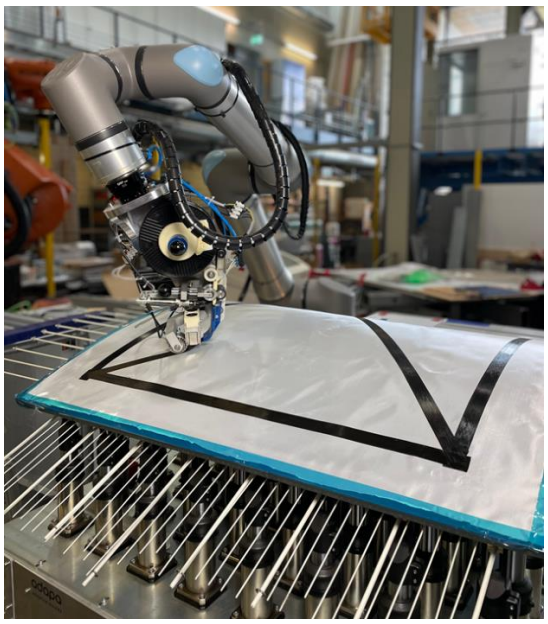

Figure 11: DFP with UR20 on adaptive mould Adapa "Mini"

As no prototype panel was manufactured to date, the concept is evaluated on the basis of weight calculations for a 700 mm × 700 mm sized panel. For the DFP panel with subsequent vacuum infusion setup, the core material is fully filled with epoxy resin. Therefore, this material is the most robust, but also by far the heaviest. The final weight can be calculated with the following formula:

$$m_{panel} = m_{core} \times (w_{panel} \times l_{panel}) + m_{tape,\ infiltrated} \times l_{fibre\ path} \times n_{tape\ layers} \quad (1)$$

The surface weight of the infiltrated core material is $m_{core} = m_{core,\ infiltrated} = 3.600$ g/m², the panel width is $w_{panel} = 0{,}7$ m, and the panel length is $l_{panel} = 0{,}7$ m. The weight of an infiltrated 30K tape is $m_{tape,\ infiltrated} = 3$ g/m and the totalled length of the fibre path for top and bottom layer is $l_{fibre\ path} = 18$ m. For $n_{tape\ layers} = 1$, this results in a potential panel weight $m_{panel,\ DFP} = 1.818$ g, or 3.710 g/m². Therefore, the robotic DFP processing route is not very promising. This is why future research aims to include the

AFP of prepreg tapes. The goal is to combine non-infiltrated Soric® XF with 30K CF prepreg tape. For a 700 mm × 700 mm sized sandwich panel, the part weight is also calculated using equation (1). The same values as above are used here, only varying the weight of the core $m_{core} = m_{core,\,dry} = 345$ g/m^2. This results in a potential panel weight $m_{panel} = 223$ g, which is equivalent to 455 g/m^2. Compared to the TFP sandwich panel, weight is mainly saved thanks to the renunciation of GF base material.

Although the near-net-shape robotic AFP obtains the highest automation potential, it is limited by a less flexible fibre architecture due to the restriction to straight-line paths. Therefore, this concept does not currently support function integration, like loops for the mounting of connectors. Nevertheless, this technique provides a high-throughput, robust solution for producing contoured interior panels with excellent material distribution and very low manual labour input.

4.4 Comparison

Each of the three approaches demonstrates a viable path toward highly efficient, lightweight, and application-specific composite panel manufacturing. The three approaches are compared in Table 1.

Feature/Concept	**Selectively Reinforced Panel**	**Selectively Reinforced Sandwich Panel**	**Near-Net-Shape Robotic AFP Panel Concept**
Fibre Placement Process	TFP	TFP	Robotic AFP
Fibre Material	Roving	Towpreg	Bindered Tape / Prepreg Tape
Fibre Placement Geometry	Variable Axial Design	Variable Axial Design	Straight Lines
Near-Net-Shape	2D	2D	3D
Compatible with Adaptive Moulds	Yes	Yes	Yes
Design Philosophy	Aesthetic & Functional	Stiffness Optimization	Process Efficiency
Functional Integration	Connectors	Connectors	Not Integrated
Process Automation	Medium	Medium	High
Areal Weight (g/m²)	1.640	650	3.600* (infusion) 455* (prepreg) *calculated values

Table 1: Comparison of flexible manufacturing concepts

The selective panel emphasizes design and function, the sandwich panel highlights mechanical performance via structural optimization, and the robotic AFP concept provides industrial scalability with streamlined automation. The choice between them ultimately depends on the specific application context, performance priorities, and available production infrastructure.

5 CONCLUSIONS

This process study presented and compared three advanced manufacturing strategies for ultra-lightweight composite cabin interior panels, all leveraging variable axial fibre placement technologies in combination with adaptive tooling. The findings highlight the immense potential of tailored fibre architectures to significantly reduce component weight while enabling either structural optimization or functional integration.

The selectively reinforced panel demonstrated that variable axial fibre placement using TFP allows integration of secondary functionalities such as mechanical connectors without compromising aesthetics

or sustainability. The proposed multifunctional concept is particularly efficient in scenarios where design, functionality and material diversity are of the utmost importance.

The selectively reinforced sandwich panel emphasized performance-driven design, utilizing topology optimization to guide fibre placement for maximum stiffness-to-weight ratios. Through the use of stitchable cores and towpregs, this method eliminated vacuum infusion, achieving the lowest prototype areal weight (650 g/m²) while simplifying processing.

The robotic AFP concept, although still under development, highlighted the benefits of high automation and near-net-shape capability. While limited by its restriction to straight fibre paths, the use of dry or prepreg tapes in combination with adaptive moulding shows promise for future high-throughput manufacturing, especially with further refinement of resin handling and tool-path generation.

Overall, the study reveals that each concept offers unique advantages depending on the application focus – be it function, performance, or scalability. Adaptive moulds played a key enabling role in reducing tooling complexity, cost, and development time, demonstrating their compatibility with all presented processes.

Future research will explore mechanical characterization, long-term durability, and the integration of sensors or active components. Ultimately, these approaches support the growing need for sustainable, lightweight, and functionally integrated solutions not only in UAM but across all mobility sectors.

Neither the European Union nor the granting authority can be held responsible for them.

This work is focused on the AFP process parametrization and the digitalization of the dry preform using on-line monitoring systems (*digital twin*)

Objectives*:*

- To understand the effect of the **AFP process parameters** on the dry fiber preform quality (***tape adhesion***) and, at the end, on the composite mechanical performance.
- To analyze the influence of AFP parameters on **resin permeability** behavior, and, at the end, on the RTM processing performance.
- To **digitalize the dry-fiber preform** manufacturing based on **on-line quality control systems *(SmartHub tool)***.

To give input from experimental data to process modelling / digital twin – data workflow
To contribute to the CAELESTIS ISE *(interoperable simulation ecosystem)*

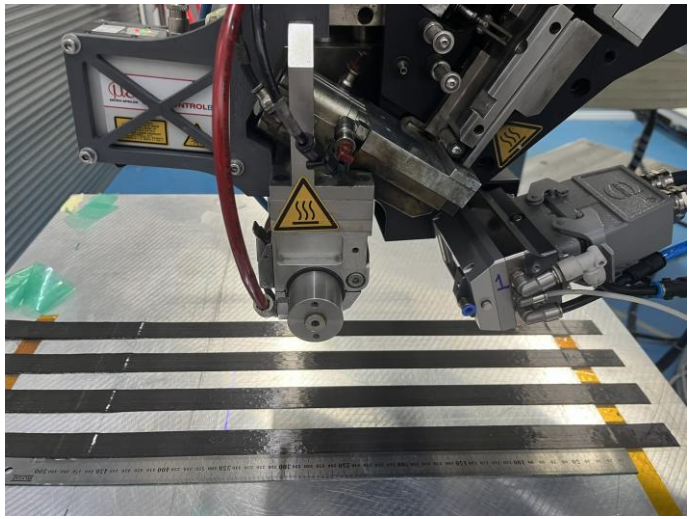
Dry Carbon Fiber AFP process parameters – SoA and AIMEN expertise

Heat Source	Dry Fiber	Heat power (W)	Temperature at nit point (ºC)	Compaction force (N)	Deposition speed (mm/s)		[Ref]
					1ª	Other	
Laser 3 kW	Carbon fiber + epoxi/ thermoplastic binder	-	200	446	-	400	[6]
Laser	Carbon fiber 24K (weight in área: 194 g/m^2) + thermoplastic binder	800	200 (800 m/s)	200	400	800	[5]
			320 (400 m/s)				
Laser 3 kW	Carbon fiber + binder	200	200	446	-	400	[4]
		357	300				
Hot Gas Torch	-	-	176	311	25,4	100	[3]
Laser	PRISM TX1100	-	160	160	-	200	[7]
Laser 6 kW	Carbon fiber	-	-	446	-	100,200,400,800	[8]
Laser	Carbon fiber 24K UD (weight in área: 194 g/m^2) + thermoplastic binder	800	250	200	-	100	[9]
IR halogen lamp	Carbon fiber	360	110	-	-	850	[10]
Laser	Carbon fiber (HFW160PA)	-	160	160	-	200	[11]
Laser	Carbon fiber 24K Ud (weight in area;:194 g/m^2) + thermoplastic binder	800	250	200	-	1000	[12]

Determination of process window

The DOE parameter levels (V, Pres, Pow) have been adjusted based on the AIMEN AFP equipment, our expertise and the experimental previous works.



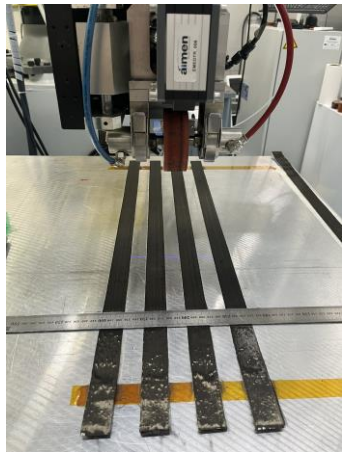
Funded by the European Union

Funded by the European Union. Views and opinions expressed are however those of the author(s) only and do not necessarily reflect those of the European Union or [EUROPEAN CLIMATE, INFRASTRUCTURE AND ENVIRONMENT EXECUTIVE AGENCY (CINEA)]. Neither the European Union nor the granting authority can be held responsible for them.

Selection of parameters levels to perform AFP DOE

Factor	Measurement unit	Min	Max	Variable type
Head/roll pressure	N	250	500	Quantitative
Deposition velocity	mm/s	100	400	Quantitative
Heating source power (5 zones)	W	100 (10%)	400 (40%)	Quantitative

- Pressure < 250 N results in pulling/dragging effect of the dry CF (no adhesion)
- Velocities > 400 mm/s surpasses the AFP head reliability with dry CF (velocity not uniform for the short sample length)
- Power > 400 W makes the fibers and binder burn.



Funded by the European Union

Funded by the European Union. Views and opinions expressed are however those of the author(s) only and do not necessarily reflect those of the European Union or [EUROPEAN CLIMATE, INFRASTRUCTURE AND ENVIRONMENT EXECUTIVE AGENCY (CINEA)]. Neither the European Union nor the granting authority can be held responsible for them.

Evaluation of adhesion between dry CF layers

Peeling test

- Quantitative evaluation of adhesion between layers using an adapted set-up for peeling test [1-2]:
  - ✓ Able to measure the adhesion between layers *(there are not standards for dry fiber)*
  - ✓ No large quantities of material are required for this analysis (*usually requires to manufacture a complete laminate to be injected and later analyzed)*
- The samples have been made using 4 CF layers.
- Peeling length: 135 ± 5 mm.
- Peeling test was performed by holding 1 or 2 layers (no difference found)

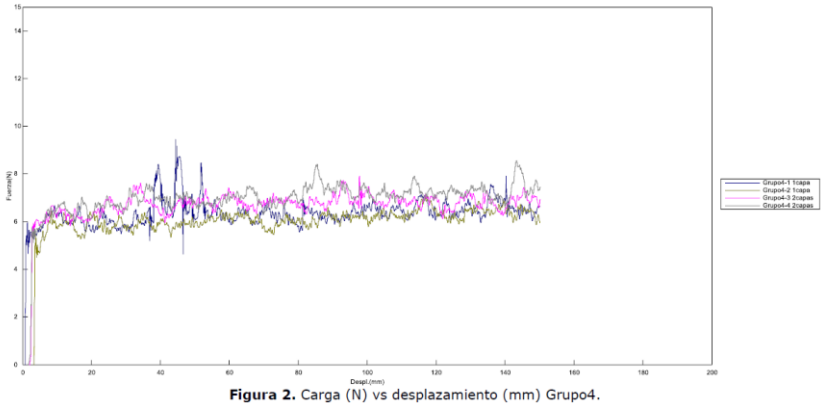


Figura 2. Carga (N) vs desplazamiento (mm) Grupo4.

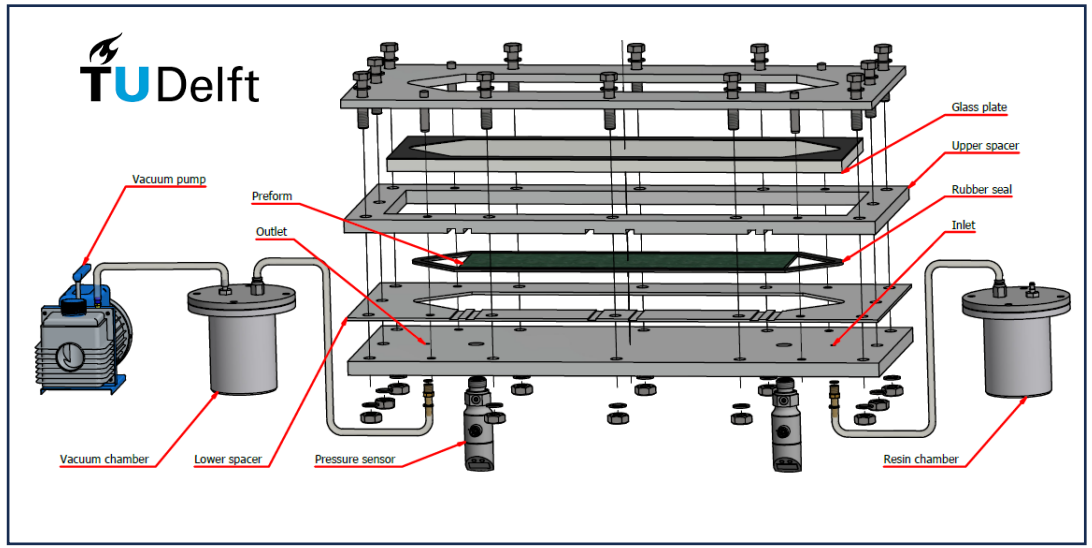
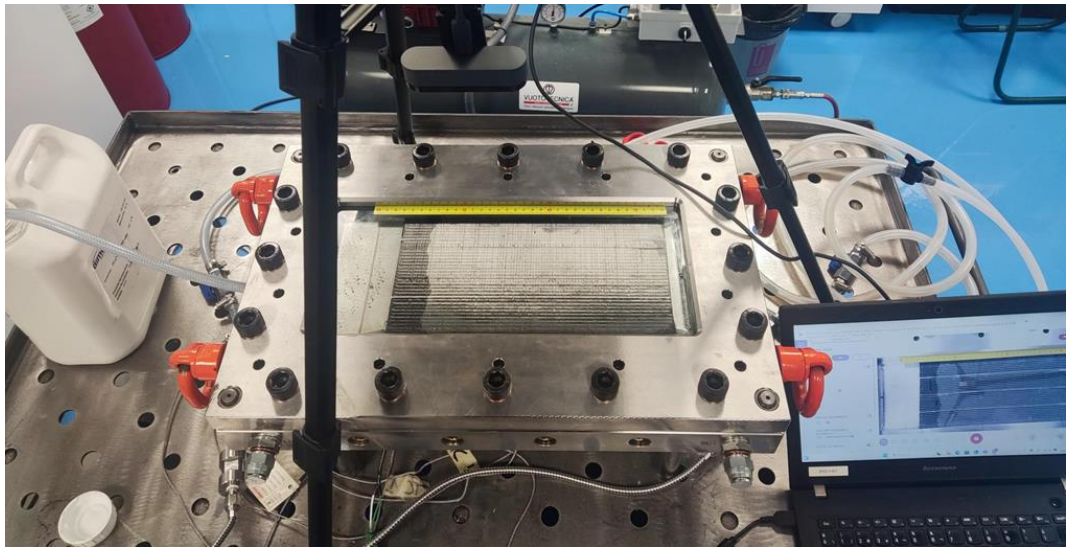
Funded by the European Union

Funded by the European Union. Views and opinions expressed are however those of the author(s) only and do not necessarily reflect those of the European Union or [EUROPEAN CLIMATE, INFRASTRUCTURE AND ENVIRONMENT EXECUTIVE AGENCY (CINEA)]. Neither the European Union nor the granting authority can be held responsible for them.



Permeability tests



Darcy´s Law can provide the **preforms' permeability** (in-plane) along the linear flow direction (k):

- x_{ff} is the flow front position at the injection time t_{ff}
- Φ is the porosity of the preform
- μ is the viscosity of the injected fluid that is used for the tests *(calibrated oil)*
- ΔP is the pressure difference between the inlet and the outlet locations (constant)

$$K = -\frac{x_{ff}^2 \cdot \Phi \cdot \mu}{2 \cdot \Delta P \cdot t_{ff}}$$

Preforms 2mm thickness, 11 layers, layup 0°)

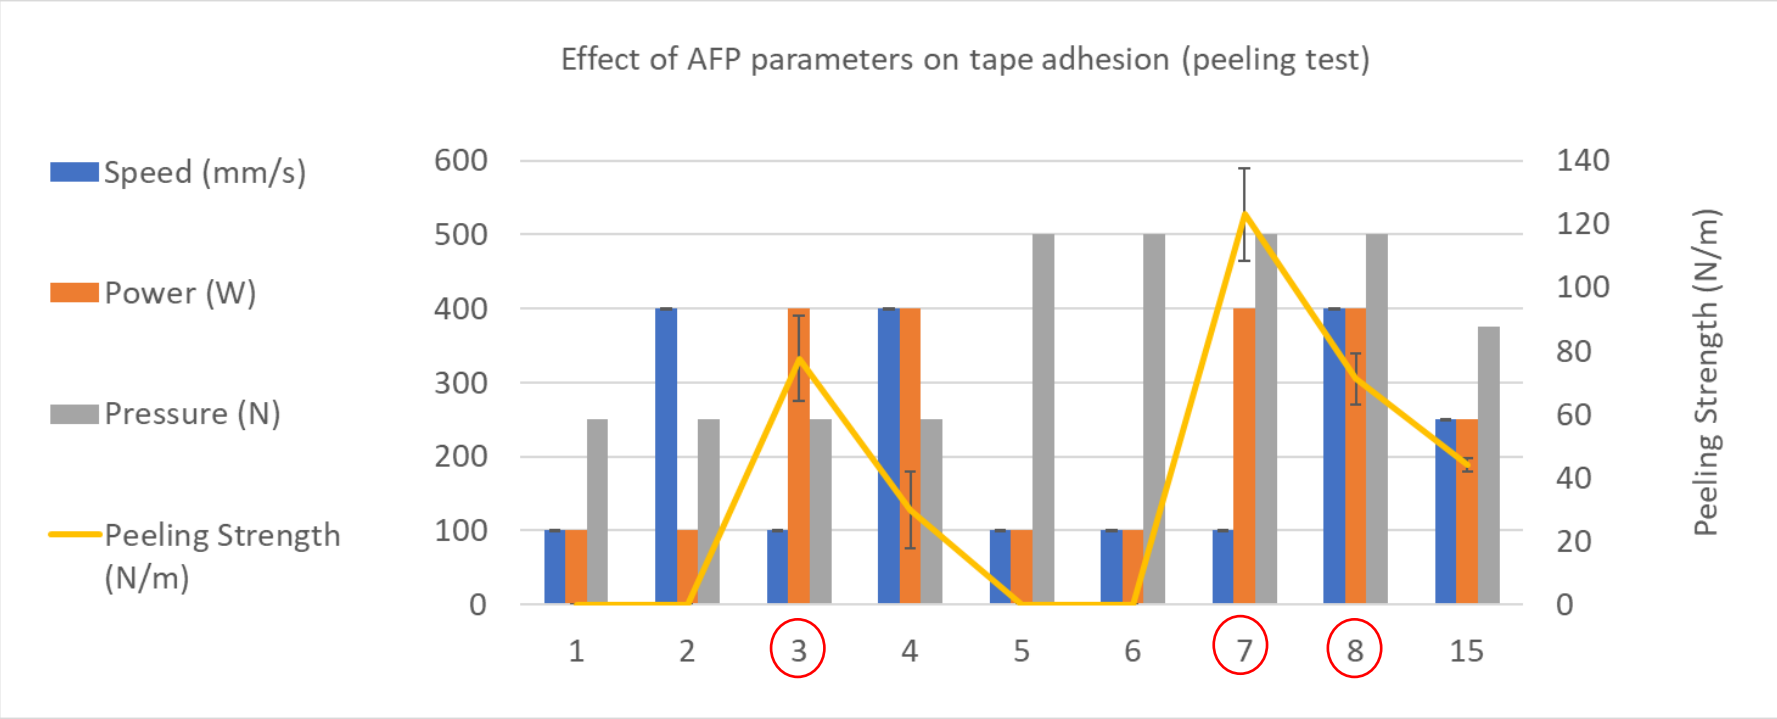
Tape adhesion – peeling strength

Samples	Speed (mm/s)	Power (W)	Pressure (N)	Peeling strength (N/m)	ST. Dev.
1	100	100	250	No adhesion	
2	400	100	250	No adhesion	
3	100	400	250	77,6 ±13,5	13,5
4	400	400	250	29,7 ±12,1	12,1
5	100	100	500	No adhesion	
6	100	100	500	No adhesion	
7	100	400	500	123,0 ±14,7	14,7
8	400	400	500	71,2 ±8,1	8,1
15	250	250	375	44,1 ±2,2	2,2



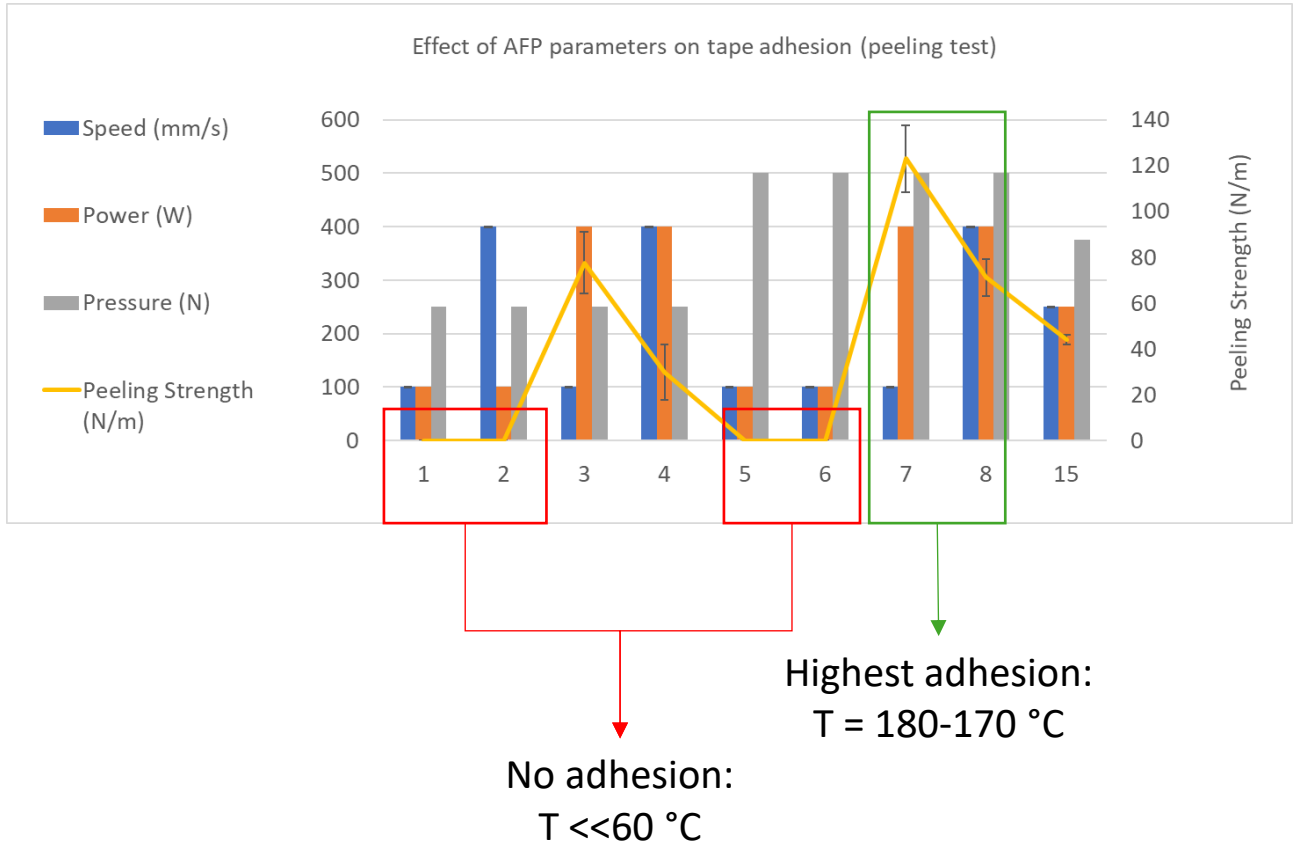
Funded by the European Union

Funded by the European Union. Views and opinions expressed are however those of the author(s) only and do not necessarily reflect those of the European Union or [EUROPEAN CLIMATE, INFRASTRUCTURE AND ENVIRONMENT EXECUTIVE AGENCY (CINEA)]. Neither the European Union nor the granting authority can be held responsible for them.

Tape adhesion – peeling strength

The higher peel strength values occur:

- ✓ At higher power
- ✓ At lower speed

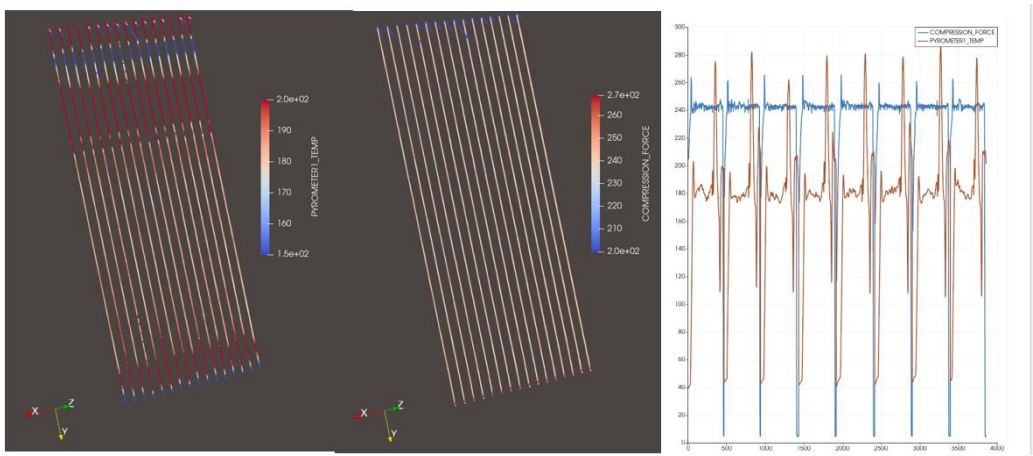


Both parameters have influence on the temperature input on the tape.

It seems that pressure is the lowest influent parameter.

Funded by the European Union

Funded by the European Union. Views and opinions expressed are however those of the author(s) only and do not necessarily reflect those of the European Union or [EUROPEAN CLIMATE, INFRASTRUCTURE AND ENVIRONMENT EXECUTIVE AGENCY (CINEA)]. Neither the European Union nor the granting authority can be held responsible for them.



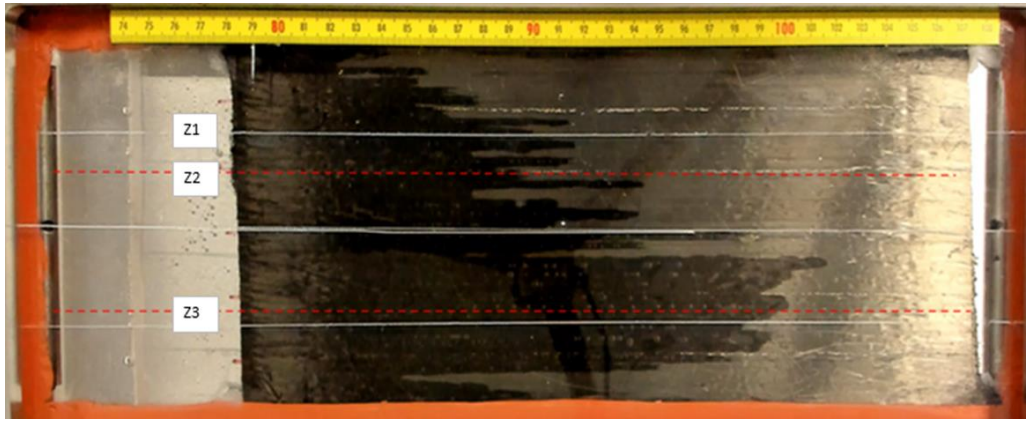
Tape adhesion – peeling strength

No adhesion:
T <<60 °C

Highest adhesion:
T = 180-170 °C

Thermal camera data on real time

TeXtreme



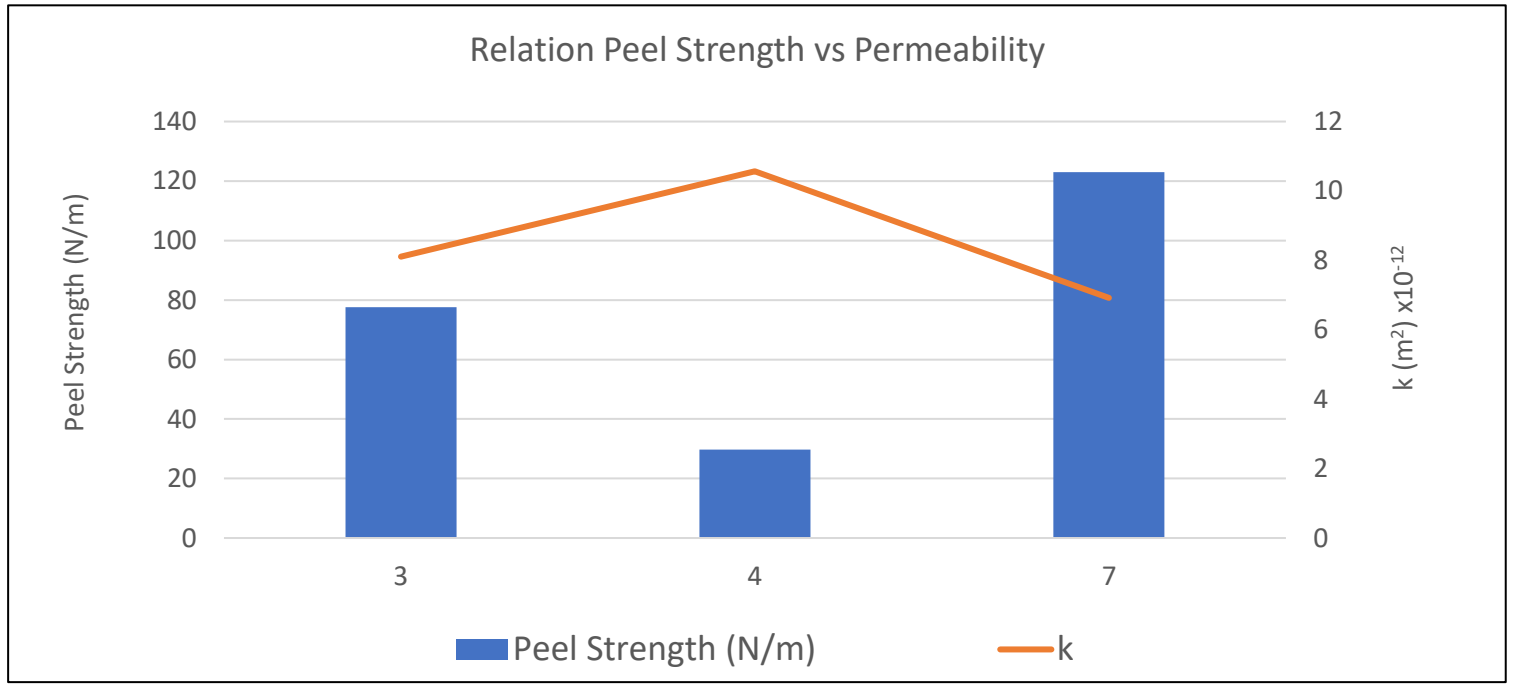
Binder: Spunfab® PA1206 6 g/m2
Tm: 160-170 °C

Funded by the European Union

Funded by the European Union. Views and opinions expressed are however those of the author(s) only and do not necessarily reflect those of the European Union or [EUROPEAN CLIMATE, INFRASTRUCTURE AND ENVIRONMENT EXECUTIVE AGENCY (CINEA)]. Neither the European Union nor the granting authority can be held responsible for them.

Permeability tests

	Permeability (m^2) x(10^{-12})				
Sample	k_{Z1} (zone 1)	k_{Z2} (zone 2)	k_{Z3} (zone 3)	Mean	Peeling Strength (N/m)
# 3	7,0354	8,1455	9,1325	8,1045	77,6
# 4	10,204	9,8208	26,6957	10,5661	29,7
# 7	4,2073	9,6302	-	6,9188	123,0



- Race-tracking (*fast resin channels*) have been observed in all the samples due to the gaps between tapes.
- The permeability has been estimated discarding the fast tracks.

Reference permeability values using similar material/process were not found. Some UD-CF studies showed values between 6-20 x10^{-12} m^2.

Funded by the European Union

Funded by the European Union. Views and opinions expressed are however those of the author(s) only and do not necessarily reflect those of the European Union or [EUROPEAN CLIMATE, INFRASTRUCTURE AND ENVIRONMENT EXECUTIVE AGENCY (CINEA)]. Neither the European Union nor the granting authority can be held responsible for them.

Permeability results

- ✓ Higher peel strength (higher compaction) results in lower permeability.
- ✓ Less dry fiber preform compaction results in a better permeability.

Low dry fiber preform compaction means better permeability but… how this can affect during RTM in the %resin?

Neither the European Union nor the granting authority can be held responsible for them.

Conclusions and future work

- ✓ The AFP parameter that has more influence in the compaction (peel strength) of the dry fiber is the heating input (resulted from laser power and velocity).
- ✓ The optimum AFP process T > T_m *(binder activation)* T < $T_{degradation}$
- ✓ The higher permeabilities occur at the lower compaction of the dry preform.
- ✓ The "SmartHub" tool allow us the on-line quality control and manufacturing data analysis

On-going next steps:

- ✓ To study the effect of the dry fiber preform quality on the RTM process and on the mechanical properties of the final laminates.
- ✓ To give input to the CAELESTIS simulation workflow

Next generation of hydrogen pressure vessel

Type I Solid metal shell

Type II Metal shell with composite overwrap

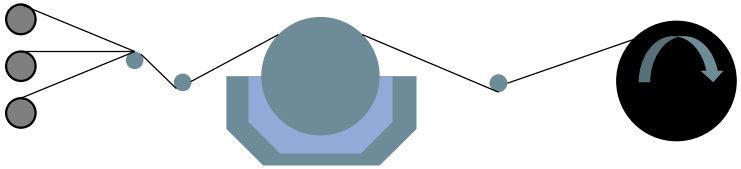
Type III Metal liner with composite overwrap

Type IV Thermoplast liner with composite overwrap

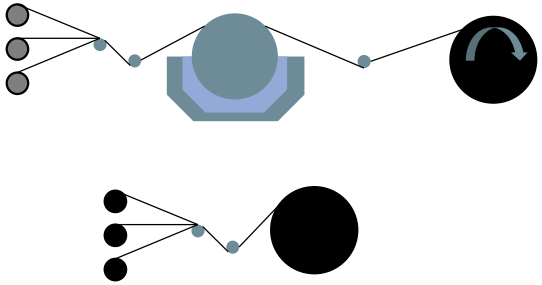
HDPE/PA – thermoplastic liner acts as hydrogen barrier

Type V **Linerless** composite shell

Simpler/cheaper manufacturing process



10-20% lighter than type IV vessels



Improved exploitation of **vessel space**

Development of optimized composite for permeation reduction

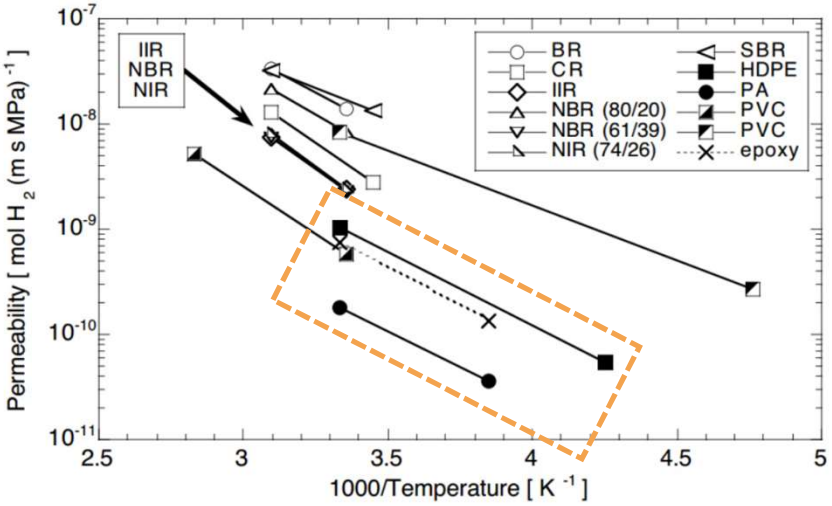
Manufacturing methods

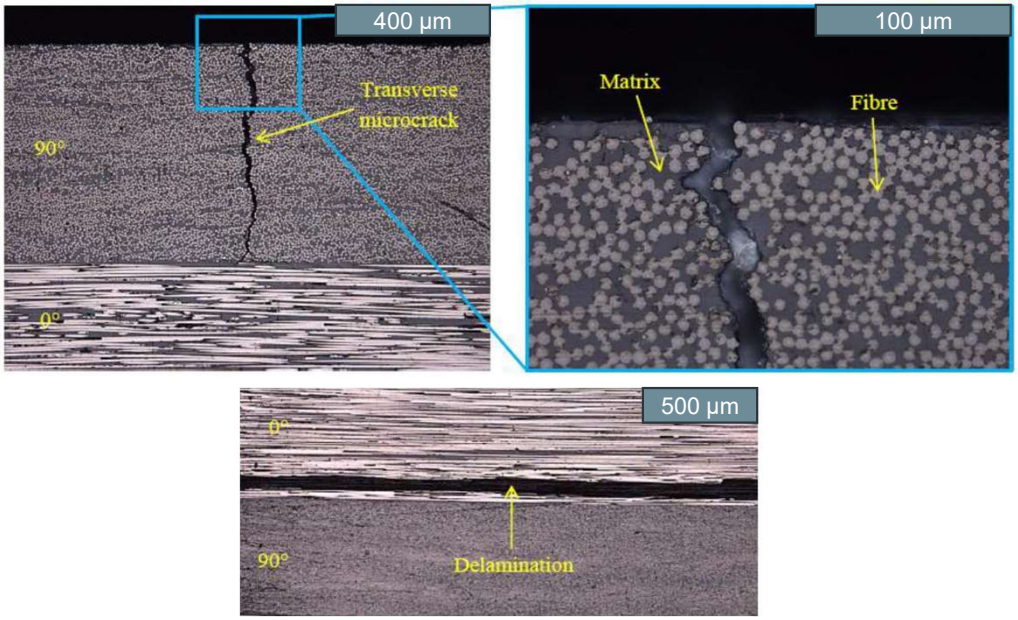
Wet-winding (state of the art)

- **Low viscosity**
- Winding speed up to **60 m/min**
- Variation in FVC

Towpreg winding

- **High viscosity.**
- Winding speed up to **240 m/min**
- Pre-impregnated products allow precise FVC control





Towpreg winding improves process precision significantly

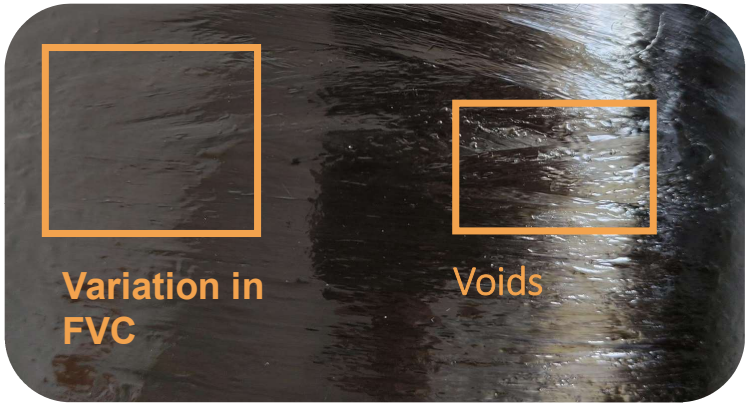
https://www.addcomposites.com/post/filament-winding; download: 06.01.2025

Next generation of hydrogen pressure vessel

Permeability of different polymers at varying temperature:

Crack formation in composite leads to permeation pathways – crack initiation and reduction necessary

Polymers for Hydrogen Infrastructure and Vehicle Fuel Systems, Barth **2013**;
Damage and permeability in linerless composite cryogenic tanks, David M. Grogan **2015**



Manufacturing and material challenges

Type V

Challenges:

Cracks in composite due to mechanical/thermal stress might **lead to leakage**

Optimisation of manufacturing to **avoid defects**

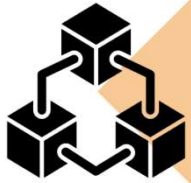
wet-wound structure

- How can we improve the composite material to minimize crack formation/propagation?
- How can we improve the manufacturing process to reduce irregularities and defects?

OVERVIEW

Development of Type V resin systems for pressure vessels

Optimizing process control for Towpreg manufacturing



Mechanical testing of filament wound composites

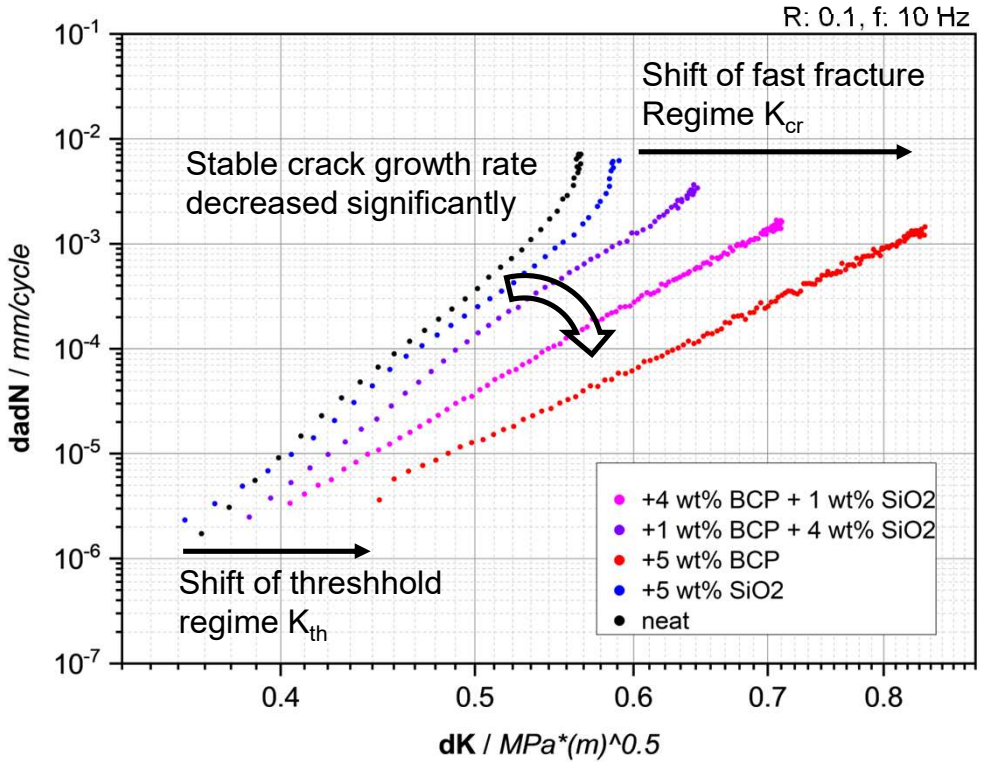
- Plateau for Digitow-2

G_{IC} – benefits from higher BCP concentrations

- More ductile resin allows significantly higher toughening – dispite minor **E** differences
- 3 % BCP sweet spot between mechanical + fracture mechanical properties

Fatigue crack propagation



CT-specimens

Crack propagation

- ASTM E647-2
- Curves from single specimen
- Following crack propagation through mechanical signal

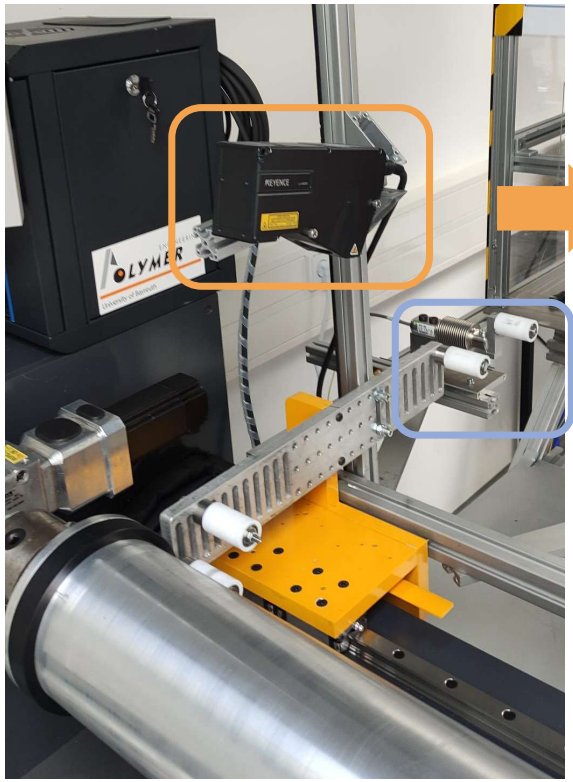
Potential synergistic effects

combining BCP + SiO_2-NP ?

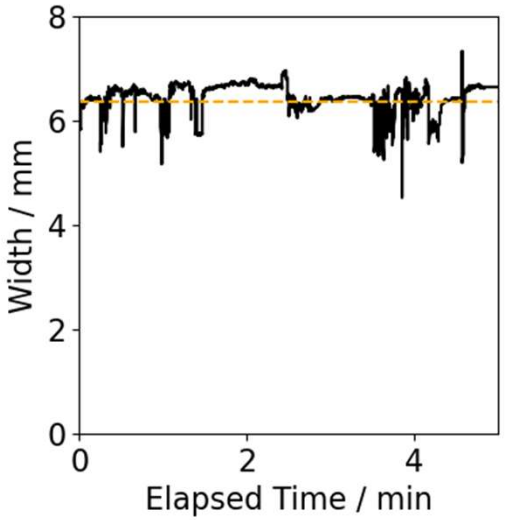
BCP decreases crack growth significantly up to 5 wt%

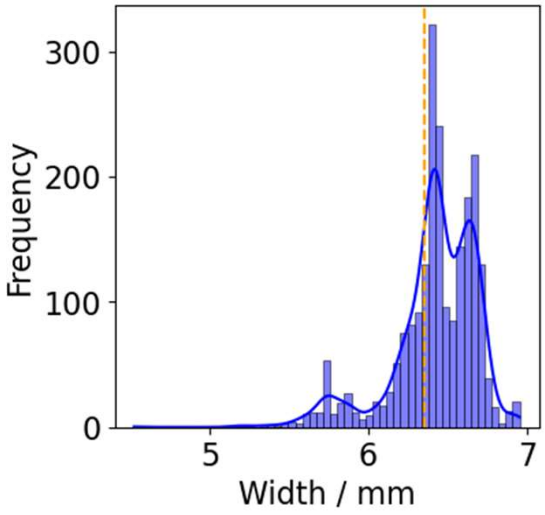
Overview

Development of Type V resin systems for pressure vessels



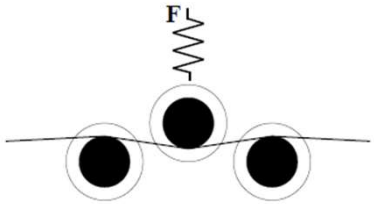
Optimizing process control for Towpreg manufacturing





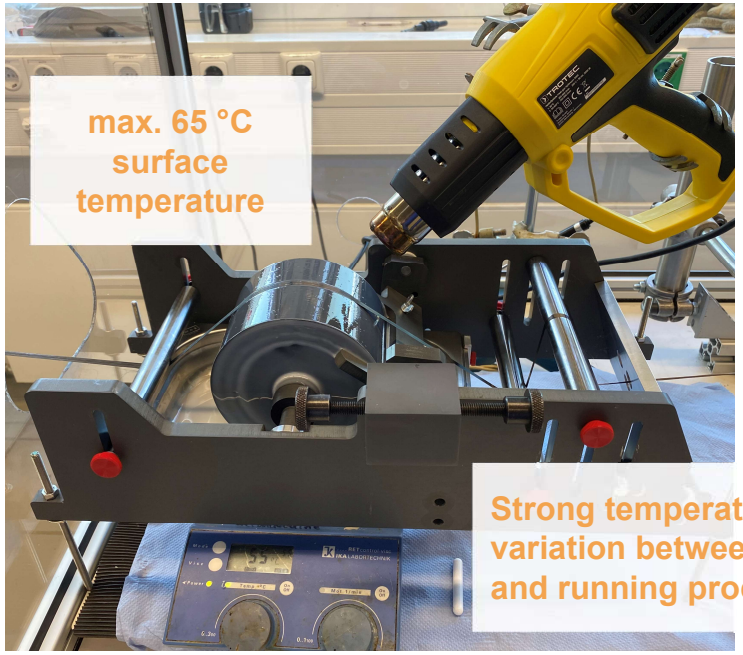
Mechanical testing of filament wound composites

Modifications of the winder unit – SC filament winder (ETC)



Width measurement

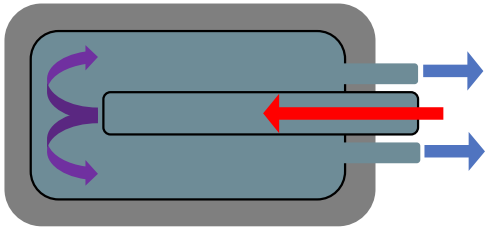
Fiber tension measurement



Fiber tension up to
100 N / Roving measurable

Consistent unwinding process – consistent impregnation process

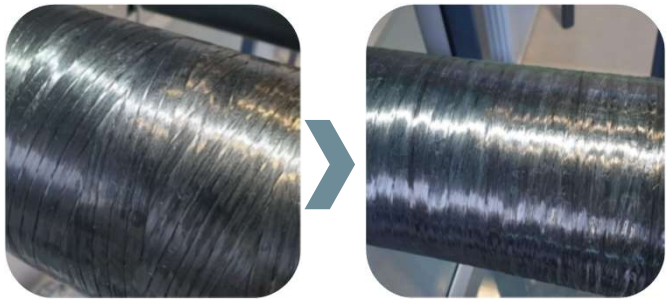
Modifications of the winder unit



Impregnation

Low heat transfer

Constant surface temperature of up to 95 °C

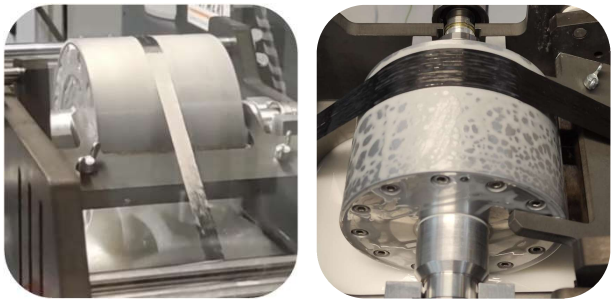


More stable and precise parameter tuning possible

How to manufacture Towpregs?

Winding tension

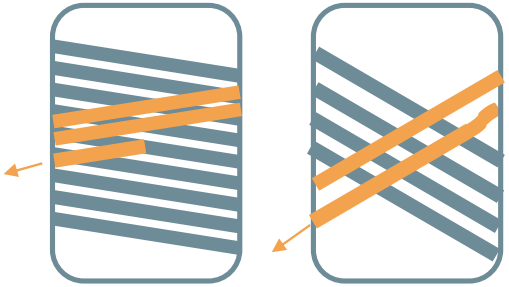
- Low roving tension < 1350 cN
- Tension too high:



Rovings “merge”

After winding | 2 h @ RT

Impregnation temperature

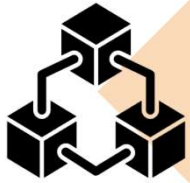


- Low enough to allow consistent impregnaton
- High enough to avoid de-wetting

70 °C | 85 °C

Winding pattern

- Low winding angles < 70 ° show increase in fiber rupture due to uptake of underlaying filaments



Sweet spots in fiber tension and impregnation temperature to be found!

Overview

EXFOLIATION AND DISPERSION OF MXENE IN EPOXY RESIN USING DISPERSING AGENTS AND THREE-ROLL MILLING

Kristina Zukiene, Daiva Milasiene, Vladimir Spacek, and Daiva Zeleniakiene

MXene. Structure and Properties

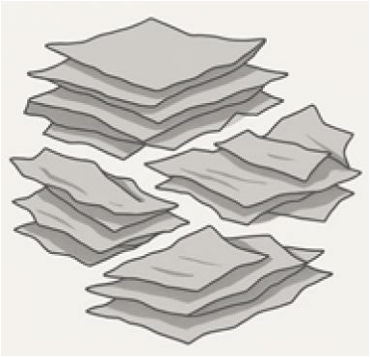
- MXenes, a rapidly emerging class of 2D transition metal carbides, nitrides, and carbonitrides, possess a unique layered structure.
- Their outstanding electrical conductivity, large surface area and controllable surface chemistry make them ideal for the production of advanced composites.

Overcoming Dispersion Challenges in Epoxy

Polarity Mismatch

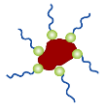
Polar functional groups hinder dispersion of MXene in polymer matrices, leading to agglomeration and limiting broader application.

Dispersion-driven performance



Insufficient dispersion limits performance in advanced composites (e.g., EMI shielding, electrical conductivity).

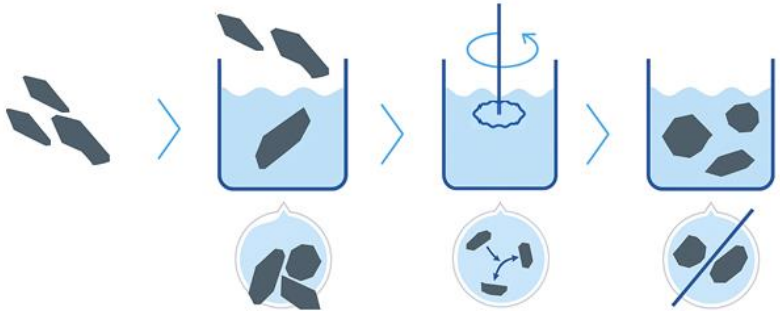
Need for effective methods to achieve homogeneous dispersion.



Aim

- To identify the most effective dispersant for achieving homogeneous dispersion of $Ti_3C_2T_x$ MXene powder in an epoxy resin matrix, and to evaluate the performance of three-roll milling techniques in facilitating uniform MXene distribution.

$Ti_3C_2T_x$



Dispersant

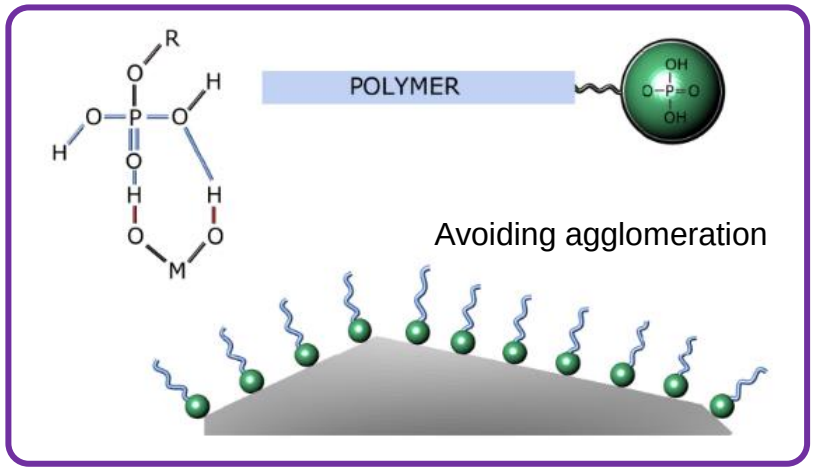
Three-Roll Milling

Strategies for Enhanced Dispersion

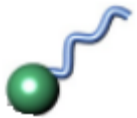
Dispersing Agents

Surfactants and copolymers reduce surface tension and provide steric or electrostatic repulsion, preventing MXene aggregation.

Three-Roll Milling



Applying high shear forces effectively exfoliates and disperses 2D nanoparticles within the polymer matrix.

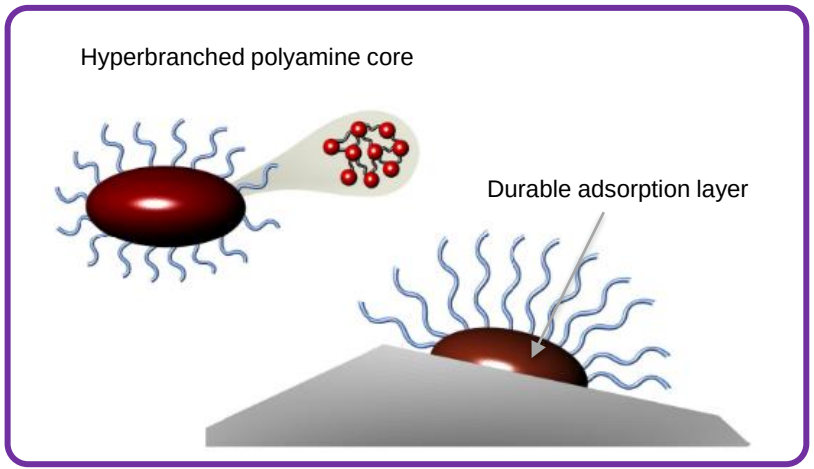


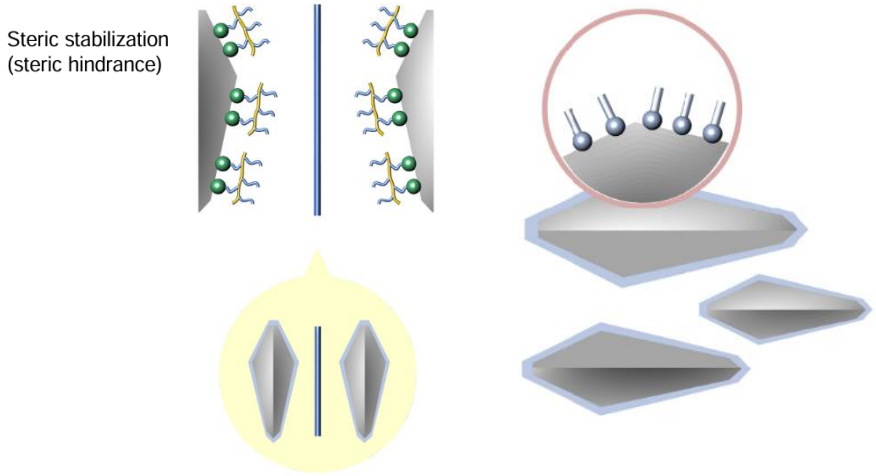
Materials

- **MXene $Ti_3C_2T_x$** (Laizhou Kai Kai Ceramic Materials Co., Ltd, Shandong Province, China)
- **CHS-EPOXY® 520 Bisphenol-A-based epoxy resin** (Spolchemie Company, Czech Republic)
- **Curing agent - Jeffamine D230:Jeffamine D2000 4:1** (Huntsman Corporation, The Woodlands, TX, USA)
- **Dispersants - DISPERBYK-180 and BYK-9076** (BYK-Chemie GmbH, Wesel, Germany)

Introducing Steric Dispersing Agents

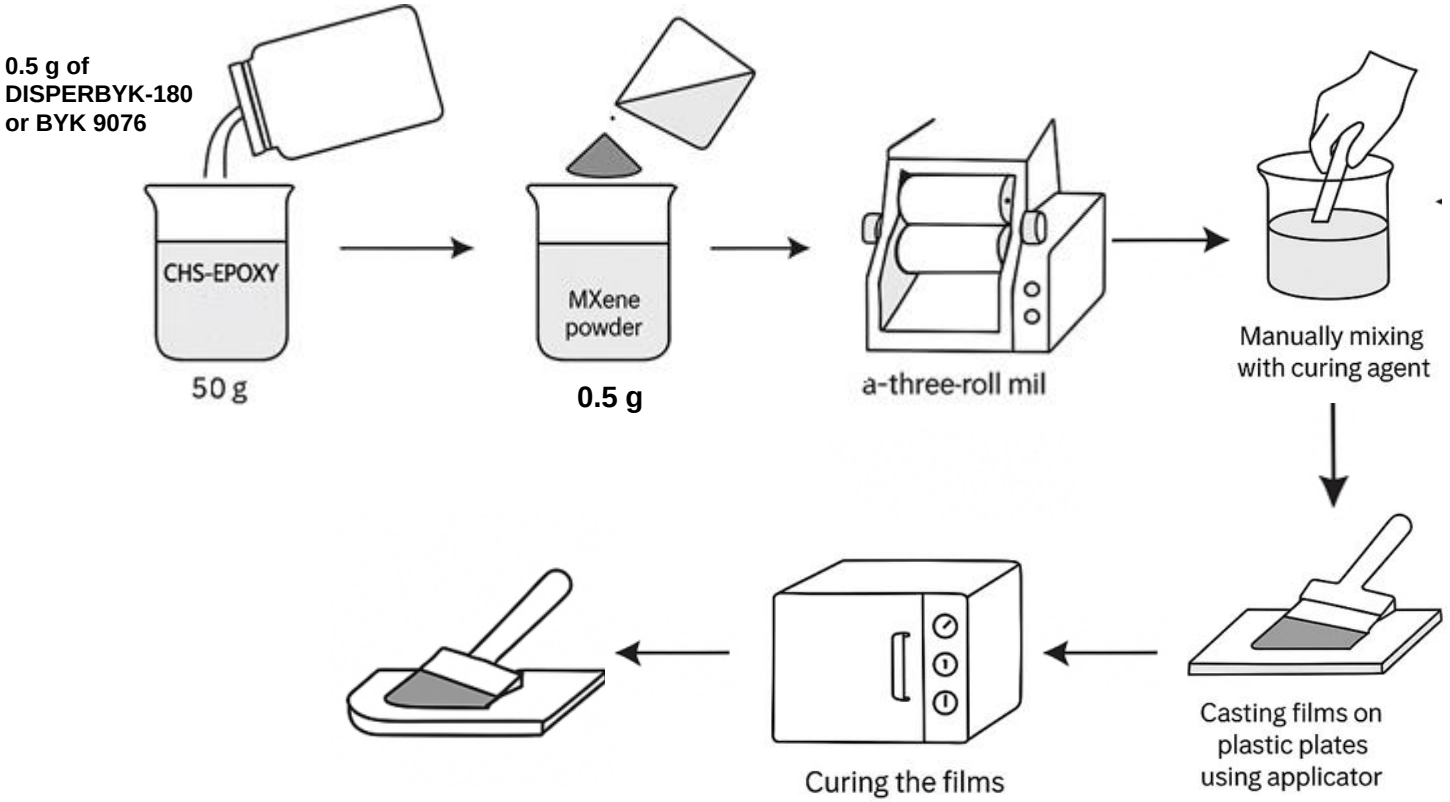
- **DISPERBYK-180** is a hydroxy-functional carboxylic acid ester with particles-affinic groups.
- **DISPERBYK-180** deflocculates particles by means of steric stabilization. As a result of the small particle sizes can be achieved.





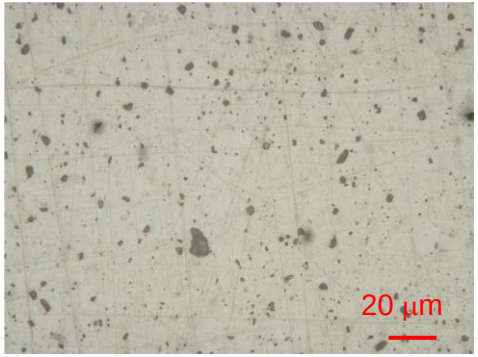
Acidic particle-affinic group

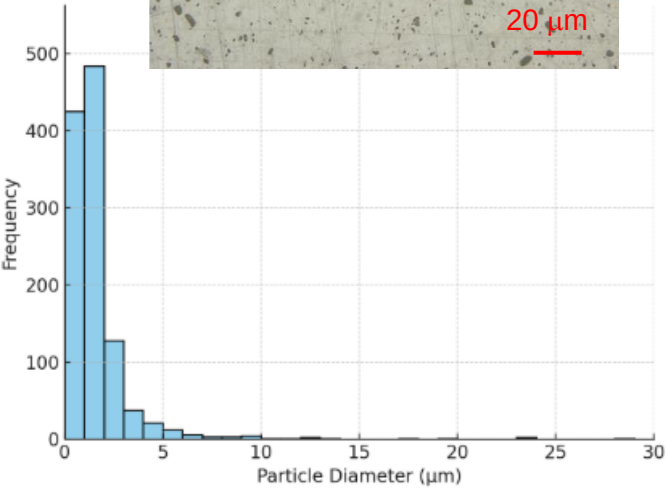
Solvent/resin-affinic part



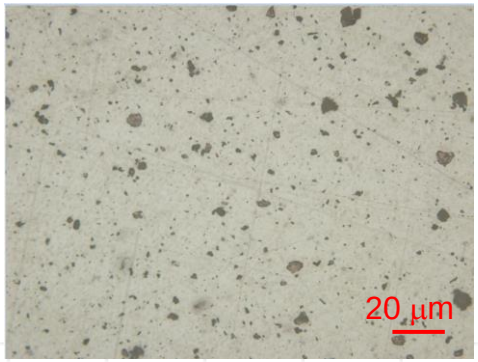
Introducing Steric Dispersing Agents

- **BYK-9076** is an alkylammonium salt of a high molecular weight copolymer containing amine groups and carboxylic functionalities.
- **BYK-9076** separate particles by means of **steric stabilization**. It also generates a uniform electrical charge in the particles (**electrostatic stabilization**). The resulting repulsion effect and the steric stabilization prevent any aggregation.

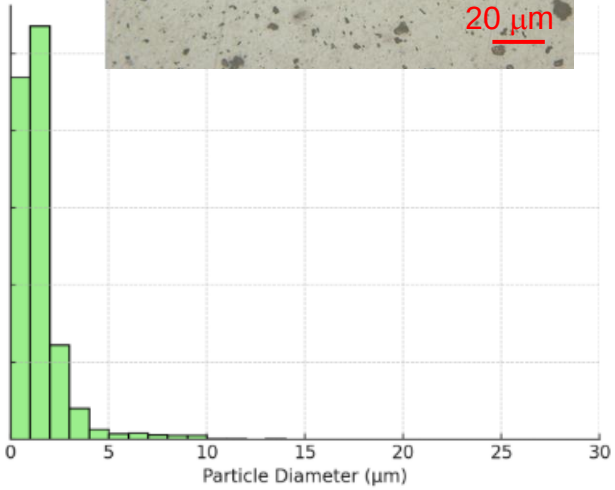




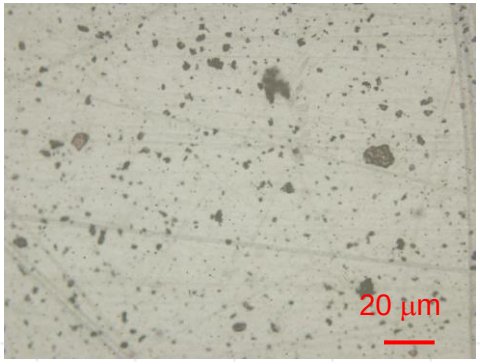
Preparation of MXene/Epoxy Films

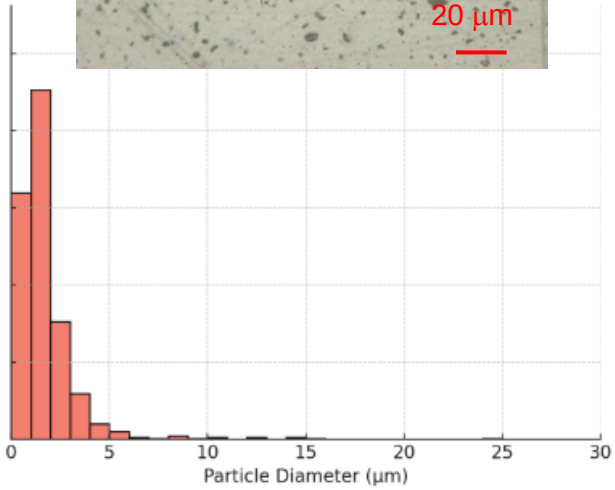


MXene Distribution in Epoxy Matrix

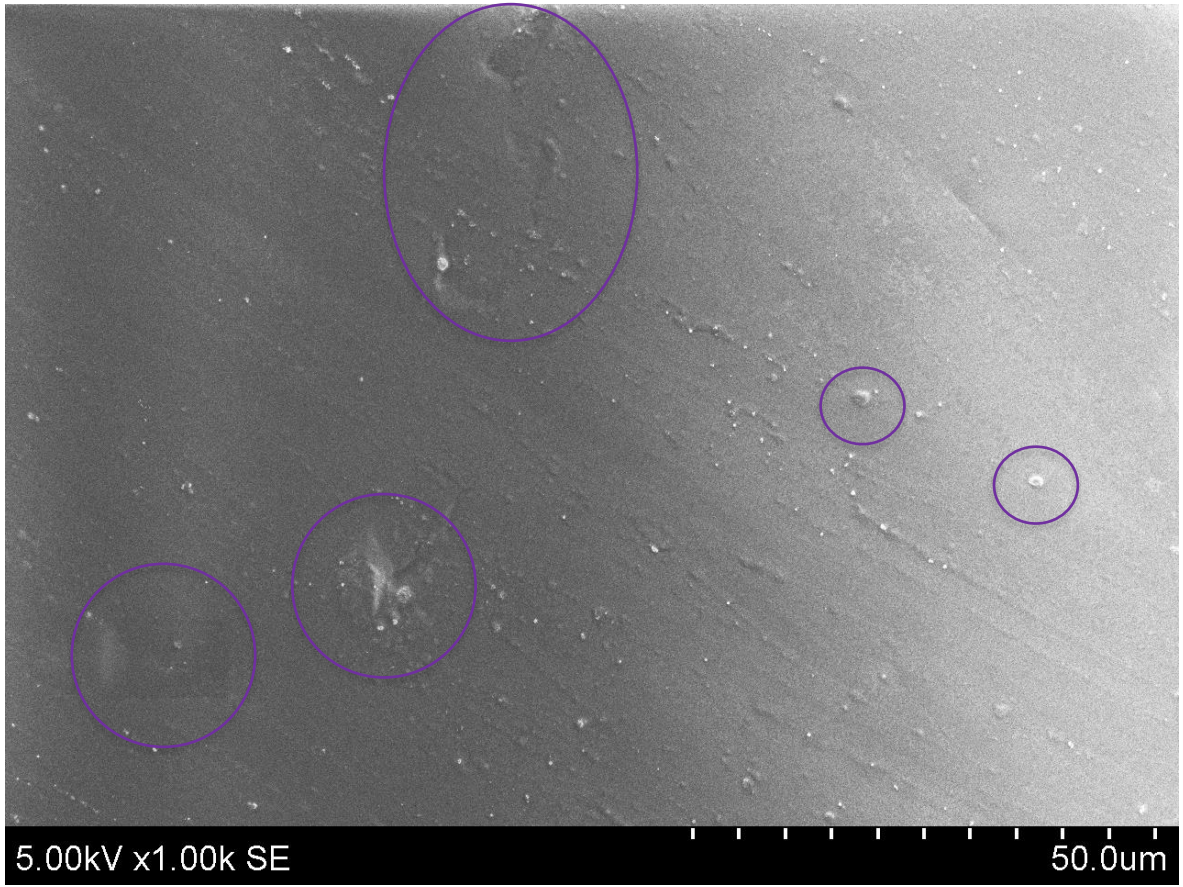


Without Dispersant

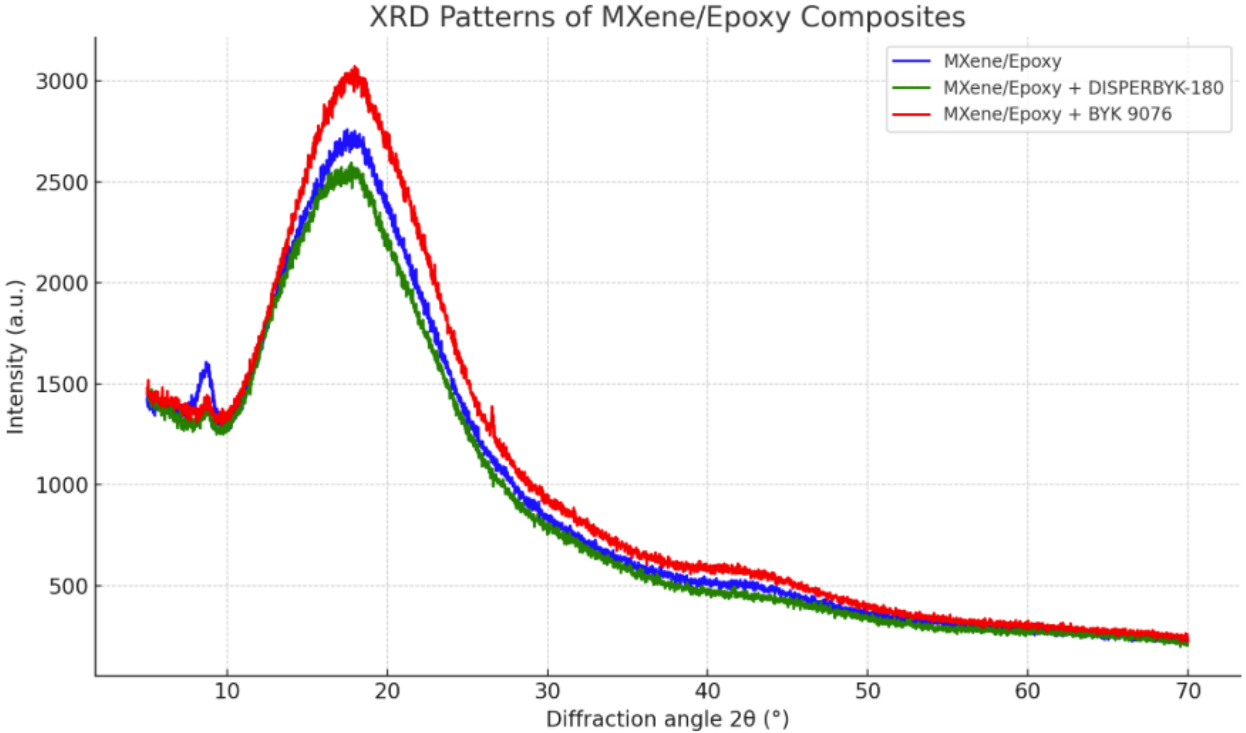




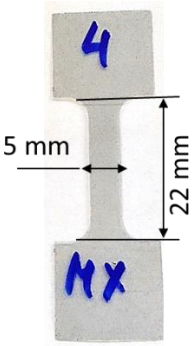
With BYK-9076

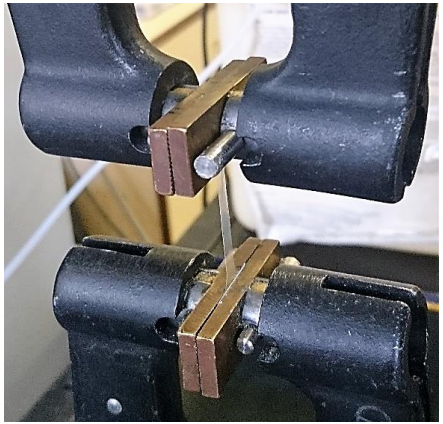


With DISPERBYK-180



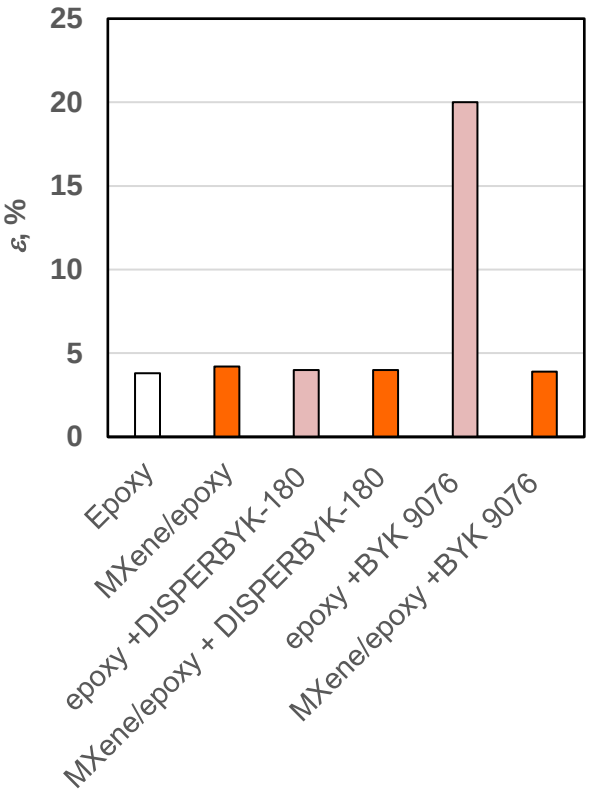
MXene Distribution in Epoxy Matrix



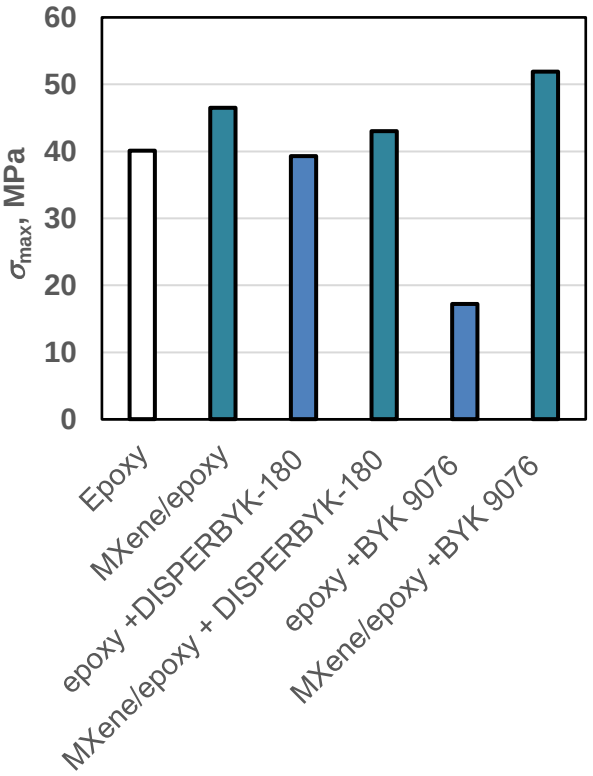


The Structural Properties of MXene/Epoxy Composites

The reduced intensity and broadening of the (002) peak at 8° in XRD patterns indicate improved exfoliation of MXene layers.



Impact on Mechanical Properties



Tensile Testing Parameters

- **Equipment**: Testing Machine (Admel Lhomargy, France)
- **Load Cell**: 100 N
- **Crosshead Speed**: 1 mm/min
- **Gauge Length**: 22 mm.

Conclusions

- Effective exfoliation and homogeneous dispersion of MXene in epoxy resin were achieved through a synergistic approach combining dispersing agents with high-shear three-roll milling.
- The use of dispersants and high-shear three-roll milling ensured a uniform distribution of exfoliated MXene throughout the epoxy matrix, minimising agglomeration.
- BYK-9076 acts as an effective dispersant and compatibiliser for MXenes in an epoxy matrix. It can also be used to functionalise the MXene surface, enhancing compatibility with the polymer matrix and improving the mechanical properties of the nanocomposite.

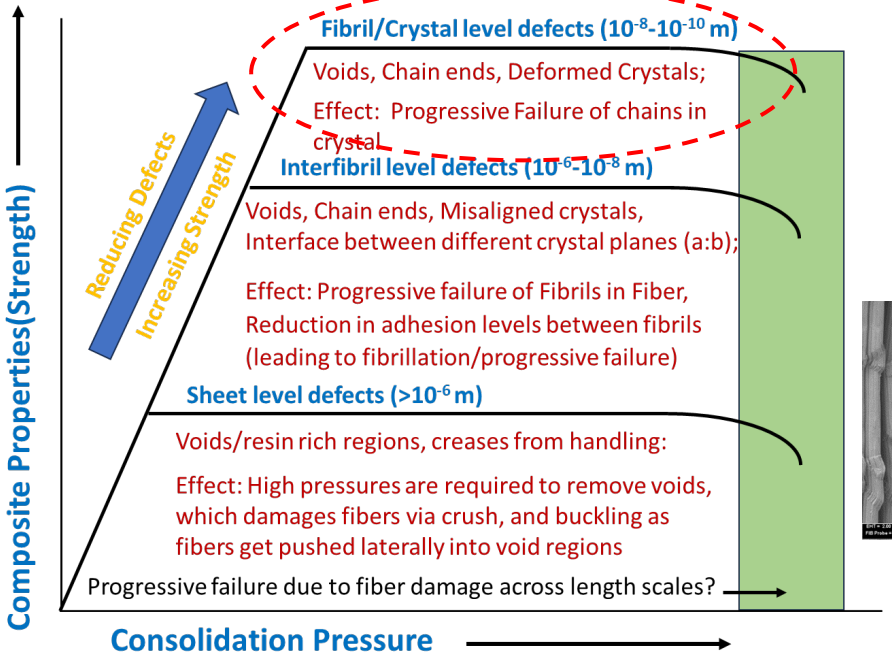
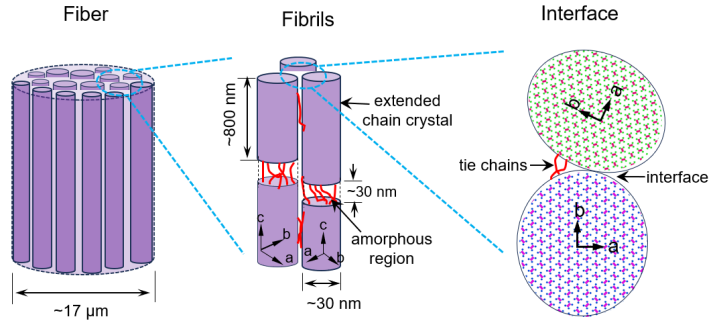
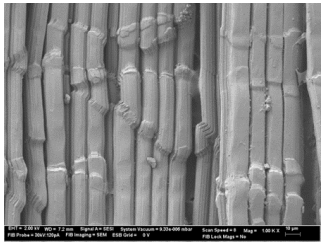
Molecular Dynamics-derived Mode I Traction Laws for Crystalline UHMWPE Fibrils



Iveena Mukherjee, **Nuwan Dewapriya**, John W. Gillespie Jr. and Joseph M. Deitzel

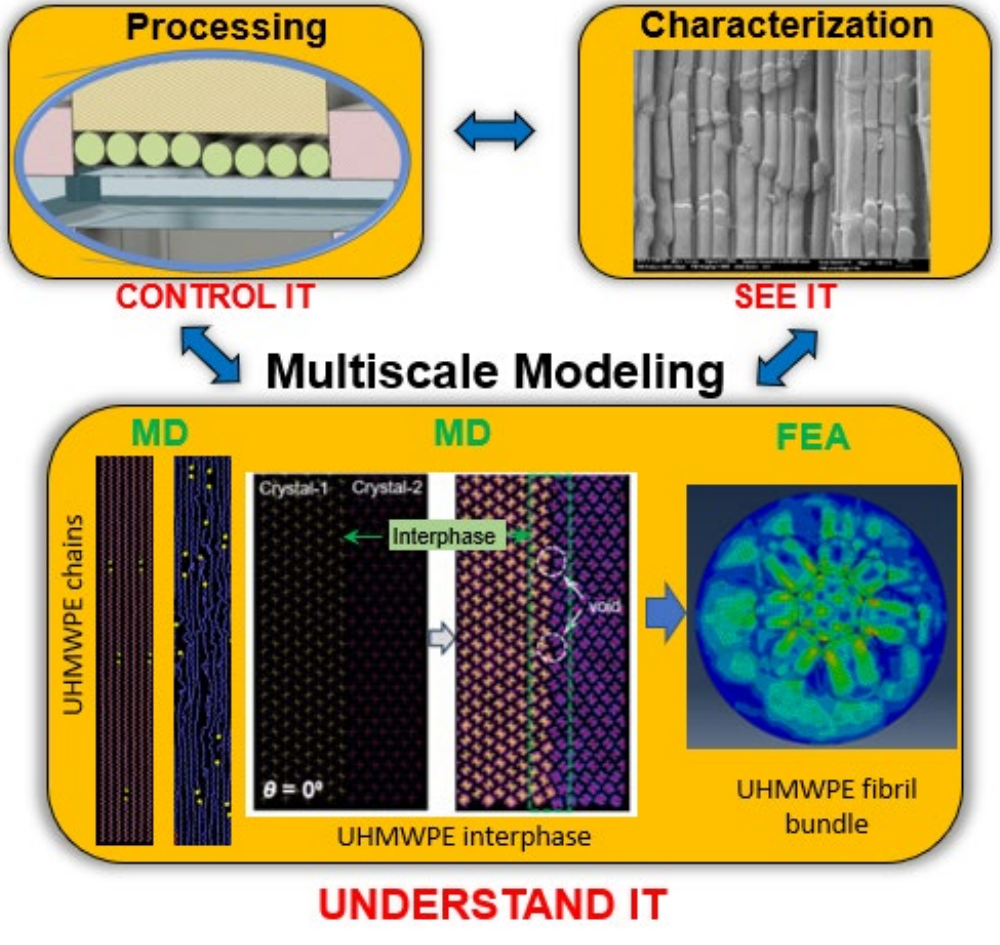




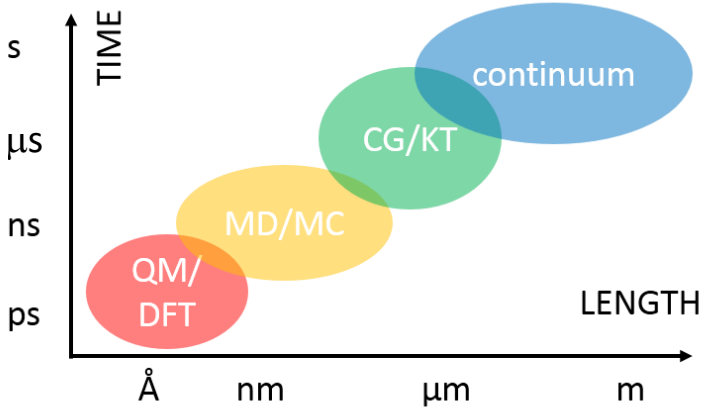
UNIVERSITY OF DELAWARE
CENTER FOR COMPOSITE MATERIALS
Celebrating 50 Years

Overall Problem Statement - UHMWPE

Goal: Understand how **consolidation process variables** (temp., pres., and time) can be used to **control composite microstructure** (*reduce voids, minimize filament damage*) in order to **improve composite performance** (*reduce weight, maximize energy absorption*).

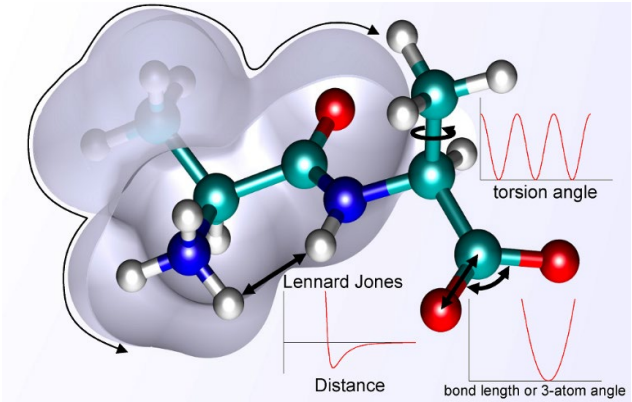


Hypothesis: *Void content reduction will increase tensile strength until a plateau strength is achieved*



- Plateau strength is governed by the remaining critical defects at lower length scales
- Process optimization provides a route to control critical defects and increase plateau strength
- Excessive consolidation pressure may damage fibers at all length scales and reduce strength

Technical Approach



Research Method: Molecular Dynamics (MD)

- MD simulations are widely used to study the structures and properties of materials at the nanoscale.
- MD solves Newton's equation of motion ($F=ma$), and it is much faster than QM and DFT simulations.
- Atomic interactions are described by interatomic potential fields.
- Selection of the proper potential is very important for accurate predictions of properties.
- We use AIREBO-M (developed for hydrocarbons) to model polyethylene.
- Used LAMMPS, OVITO.

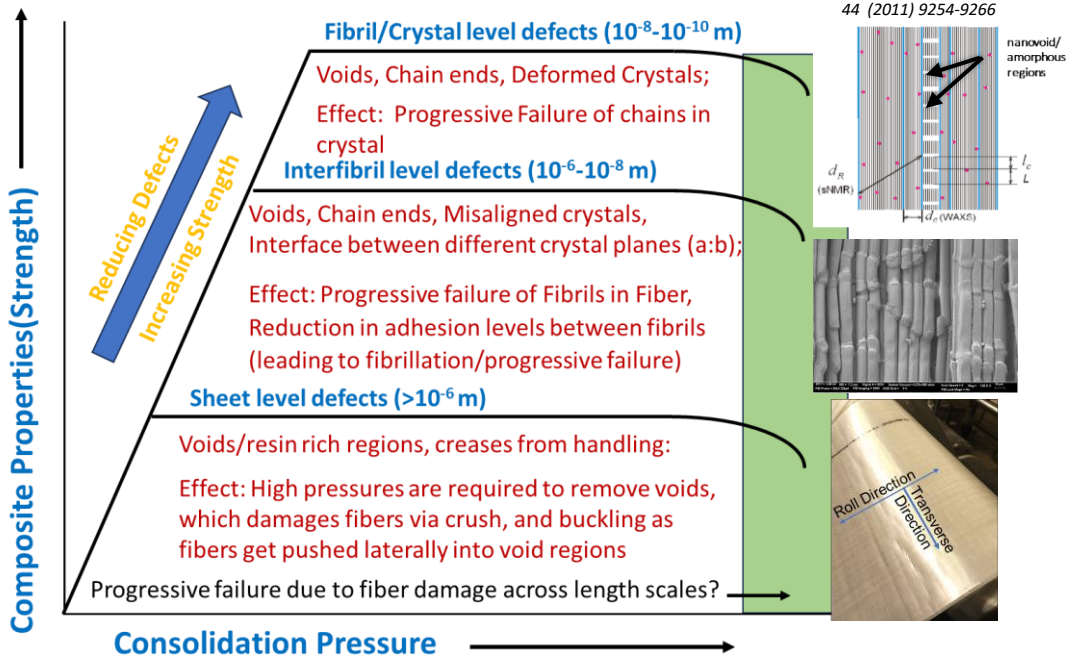
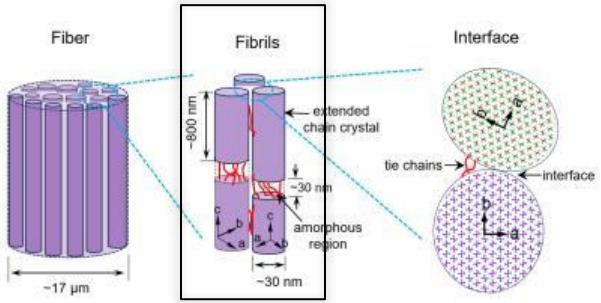
Effect of Consolidation Pressure on Void Reduction and Effective Properties in a Stochastic UHMWPE Fibril Array

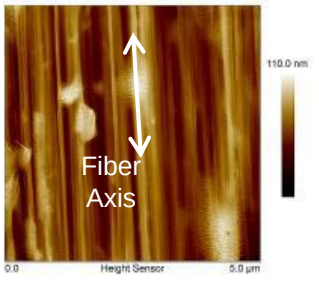


Dr. Abdalsalam Fadeel, Dr. Joseph M. Deitzel, Prof. Jack Gillespie

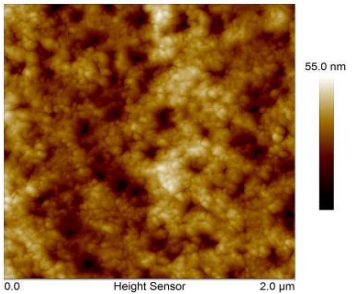
Date: August 4-8, 2025



UNIVERSITY OF DELAWARE
CENTER FOR COMPOSITE MATERIALS
Celebrating 50 Years

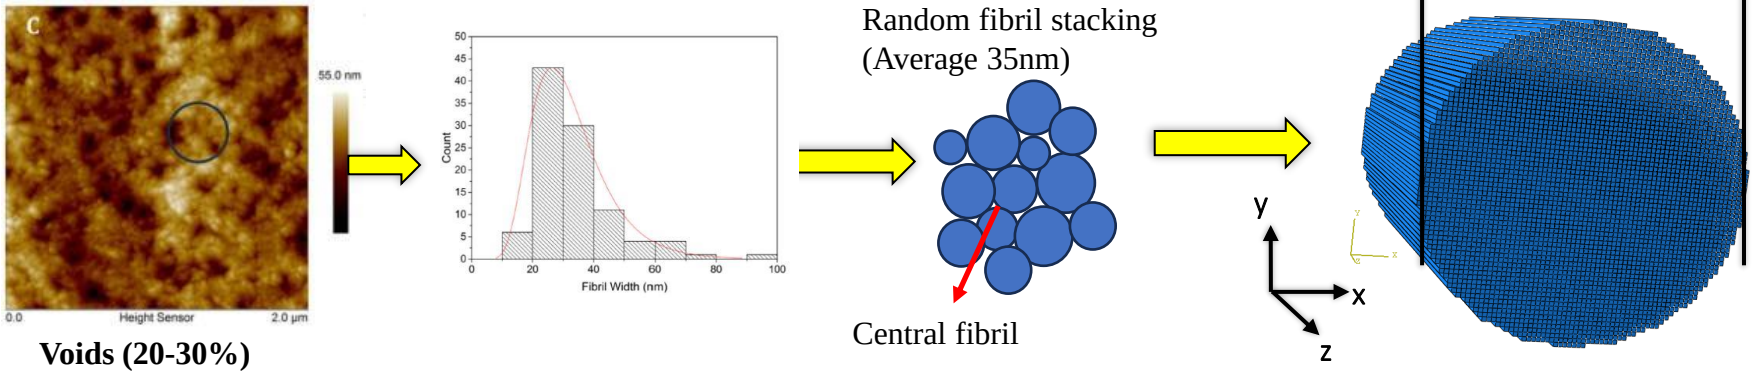


OVERVIEW



Goal: Understand how consolidation process variables Temperature(T), Pressure(P) and time (t) control composite microstructure (*Reduce voids*, *Increase fiber volume fraction*, *Minimize filament damage*) to improve composite performance (*Reduce weight*, *Maintain Performance*, *Reduce dynamic deflection*, *Maximize energy absorption*).

Litvinov et al., Maromolecules 44 (2011) 9254-9266



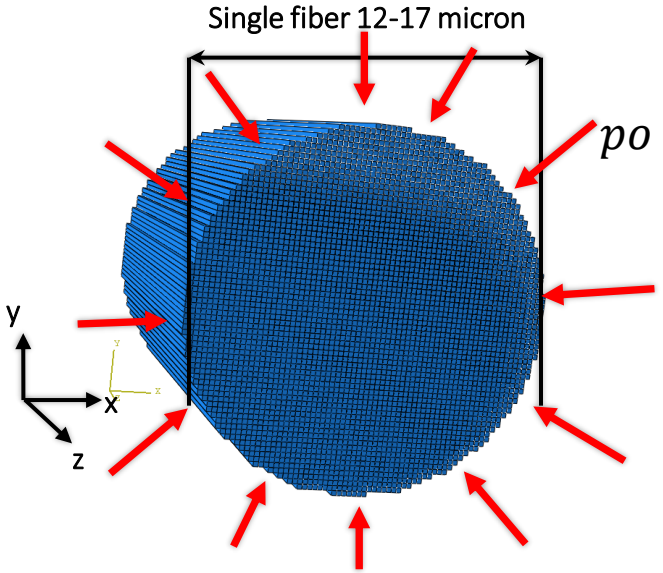
AFM images of the microtomed surface of the UHMWPE fiber

PROBLEM STATEMENT AND MODELING OBJECTIVE

- What is the effect of consolidation pressure on the stochastic fibril level microstructure within a fiber at processing temperature?
  - Fibril deformation, shape, and fibril-fibril contact areas.
  - Inter-fibril void content.
- What is the effect of microstructure on the effect properties of the fiber at room temperature?

Single fiber 12-15 microns
contains 200,000+ fibrils.

Voids (20-30%)



- Based on AFM imaging, the microstructure of polyethylene (PE) fibers consists of aligned fibrils and interstitial voids. Under hydrostatic pressure, this structure undergoes reformation, directly influencing fiber performance.
- The following objectives are pursued:
  - **Develop** a methodology to correlate consolidation pressure with microstructural evolution.
  - **Predict** inelastic deformation, contact area growth, and progressive void reduction.
  - **Determine** effective isotropic mechanical properties using finite element analysis (FEA).

APPROACH

- **Develop a methodology to apply hydrostatic pressure on a fibril array**
  - Constant diameter
  - Stochastic diameter distribution

- **Use a methodology to predict microstructure evolution.**
- **Define RVE for constant fibril diameter and statistical fibril diameter distribution**
  - Fibril diameter distribution
  - Equivalent interstitial void content

- **Develop methodology to calculate effective properties of the fibril array as a function of hydrostatic pressure/void content**

MODELING STRATEGY FOR FIBRIL ARRAYS

- **Step 1: Uniform Fibrils Model**
  - Used to demonstrate methodology and validate simulation approach
  - Enables use of RVE to save computational time
- **Step 2: Statistical Geometry Generation**
  - Generated fibril array geometries from statistical fibril diameter data.
  - Used the Monte Carlo method to reduce the array size while preserving representative fibril diameter distribution and interstitial void content.
- **Step 3: Realistic Simulation of Fibril Microstructure Subjected to Hydrostatic Pressure During Consolidation at 125C**
  - Optimal configuration applied to validated model
  - Leads to realistic and accurate predictions with reduced complexity

MATERIAL INPUT PROPERTIES USED IN MODELS

- The data are based on molecular dynamics (MD) simulations of UHMWPE at sheet process conditions:
- 125 °C over a wide range of consolidation pressure

- According to N. Dewapriya et al. (2023, 2024), the most recent mechanical properties were obtained from MD simulations conducted at a strain rate of 10^9/s at 125 °C.

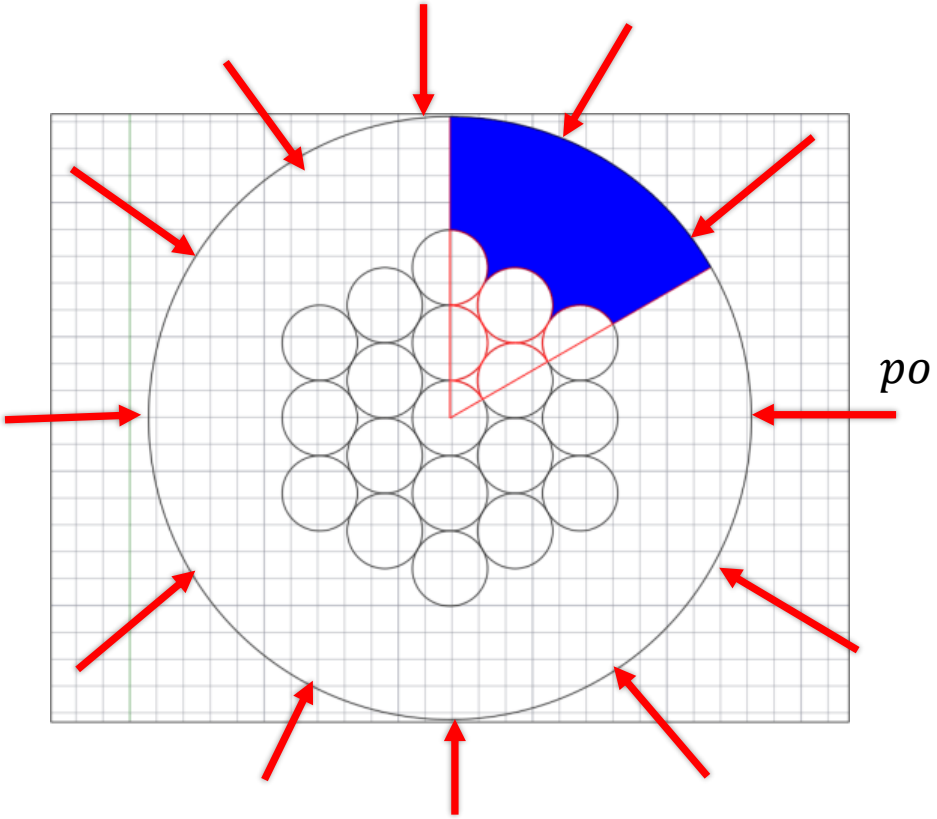
- The yield stresses $\sigma_{ay}, \sigma_{by}, and\ \tau_{aby}$ correspond to the a-direction, b-direction, and a–b shear plane, respectively.

- These values were used to define the anisotropic yield behavior.

- This table summarizes the elastic properties used in the plane strain FEA model.

E_a, GPa	E_b, GPa	E_c, GPa	G_{ab}, GPa	G_{bc}, GPa	G_{ca}, GPa
3.346	4.3	263.53	2.78	1.30	1.77
ν_{ab}	ν_{bc}	ν_{ac}	σ_{ay},GPa	σ_{by},GPa	τ_{aby},GPa
0.48	0.006	0.007	0.34	0.093	0.213

STEP 1: UNIFORM FIBRILS MODEL



Key Steps in Modeling Hydrostatic Pressure on Fibril Arrays

1. Hexagonal Packing and Void Content Estimation

- Select the optimal fibril ring geometry and number of rings to replicate initial void content.
- Perform convergence study to ensure accuracy and model stability (see next slide).

2. Pressure Application Strategy

- Establish a method for uniform hydrostatic pressure application across the external surface of outermost fibril in the array.
- Surround fibrils with an incompressible matrix material to transmit uniform hydrostatic pressure (details in Slide 9).
- All fibril surfaces are frictionless

To reduce computational cost and improve simulation efficiency, the RVE was modeled using one-eighth of the circular fibril array as shown above.

STEP 1: UNIFORM FIBRILS MODEL

Key Steps in Modeling Hydrostatic Pressure on Fibril Arrays

1- Hexagonal Packing and Void Content Estimation

Table 1. Comparison of void fraction values obtained analytically from Equation (1) and measured using AutoCAD, as a function of the number of fibrils derived from Equation (2).

Number of rings (n)	Void Fraction (Theoretical)	Void Fraction (CAD)	Number of of fibrils (N)
1	0.042142104	0.042	7
2	0.06088869	0.0608	19
3	0.069691669	0.069	37
4	0.074742231	0.0747	61
5	0.078007966	0.078	91

- Equations (1) and (2), derived from uniform circular geometry, show excellent agreement with AutoCAD results for n=1 to 4, validating their accuracy for larger ring counts.

$$Voids\ Fraction = \frac{n^2\left(\sqrt{3}-\frac{\pi}{2}\right)}{n^2.\left(\sqrt{3}-\frac{\pi}{2}\right)+\pi\left(\frac{1}{6}+\frac{n(n+1)}{2}\right)} \quad \text{....(1) , } n \text{ is the number of rings}$$

$$N(n) = 1 + 3n(n+1) \quad \text{..... (2), } N \text{ is the number of fibrils}$$

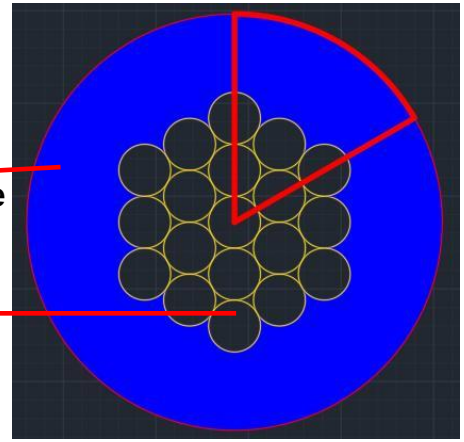
- However, due to computational limitations associated with ABAQUS simulations, and considering that our goal is to approximate the methodology rather than achieve full convergence, selecting two rings is deemed appropriate for the current model.

STEP 1: UNIFORM FIBRILS MODEL

Key Steps in Modeling Hydrostatic Pressure on Fibril Arrays

Constitutive Model for Incompressible Material

- The blue region is modeled using a Mooney–Rivlin hyperelastic material:



Strain Energy Function:

$$U = C_{10}(\bar{I}_1 - 3) + C_{01}(\bar{I}_2 - 3) + (1/D_1)(J^{el} - 1)^2 \quad \ldots..(1)$$

Material Constants:

$$\mu_0 = 2(C_{10} + C_{01}), \qquad K_0 = 2/D_1$$

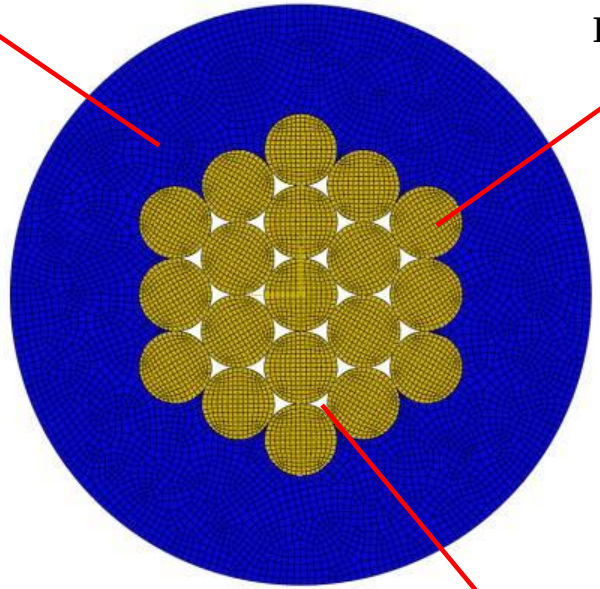
μ_0 Shear modulus

Schematic of the micromechanical model.

- The shear modulus was reduced to ensure the matrix can carry the applied pressure without stress relaxation (see Equation 2) based on Ogden, R.W. (1997) and Bonet, J., & Wood, R.D. (2008).

Incompressible Material Cauchy Stress Tensor:

$\sigma = -p\,I + \mu\,B$ ……. (2), $B=FF^T$ is the left Cauchy-Green deformation tensor. μ is the shear modulus



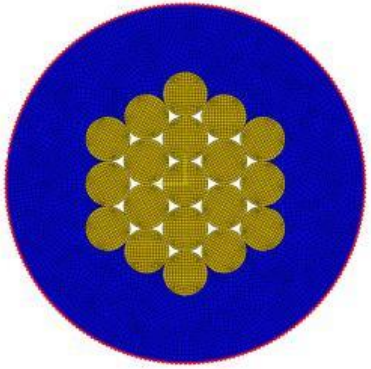
- Thus, the lowest value of the shear modulus will ensure the material accurately carries the hydrostatic pressure.

STEP 1: UNIFORM FIBRILS MODEL

UNIVERSITY OF DELAWARE
CENTER FOR COMPOSITE MATERIALS
Celebrating 50 Years

Element Type for Incompressible Region: ABAQUS

- 3D hybrid elements were used in the finite element model.
- The element type selected is C3D8H, which is appropriate for modeling incompressible materials.
- These elements are ideal for capturing the behavior under uniform hydrostatic pressure.
- The mesh ensures accurate stress transmission through the incompressible matrix to the fibril structure.



Element Type for Fibril Region

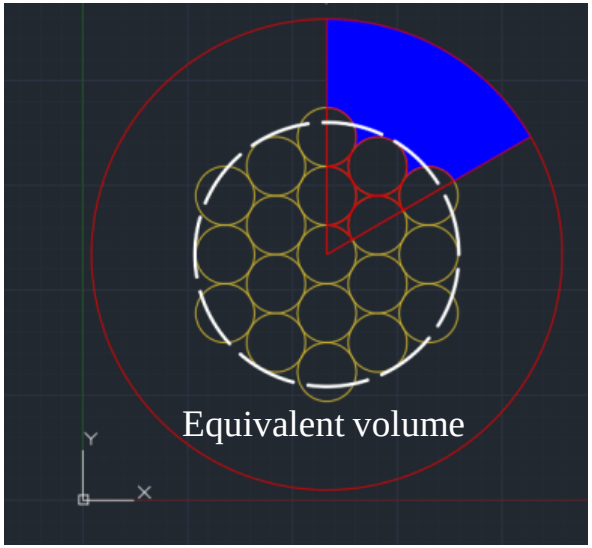
- Fibrils were modeled using 3D brick elements (C3D8) with full integration.
- A nonlinear mesh convergence study was conducted to balance accuracy and computational cost.
- Although modeled in 3D, plane strain boundary conditions were applied on surfaces normal to the cross-section.

The void region

STEP 1: UNIFORM FIBRILS MODEL

Volume Change and Equivalent Property Estimation

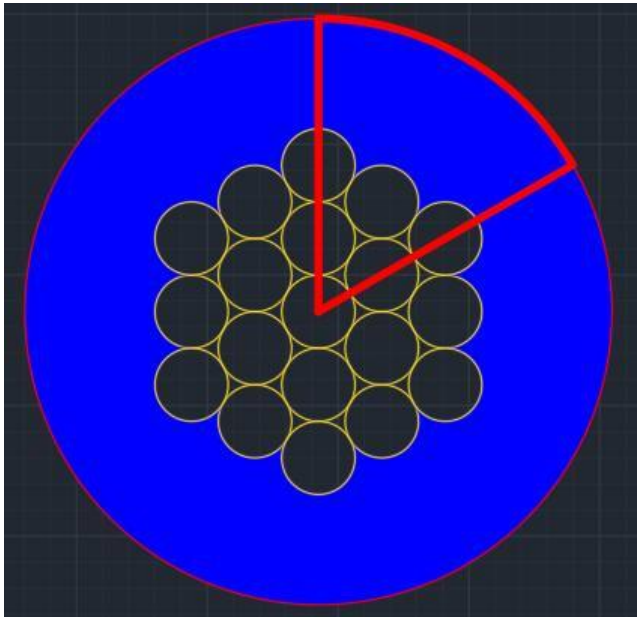
For 2D plane strain conditions, the following equations are used to calculate the equivalent mechanical properties:



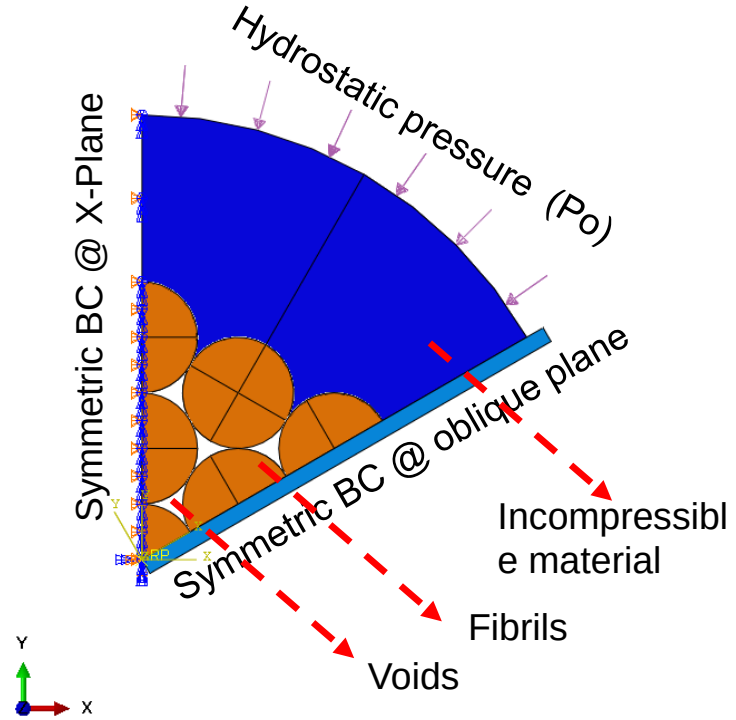
$$K = -V\frac{dP}{dV} \ldots\ldots\ldots (1) \quad K = \frac{E}{2(1+\nu)(1-2\nu)} \ldots\ldots\ldots (2)$$

$$\varepsilon_r = \frac{-P}{E}(1+\nu)(1-2\nu) \ldots\ldots\ldots (3)$$

Based on the extracted data for volume change and strain variation with applied pressure, the following equivalent mechanical properties can be computed:



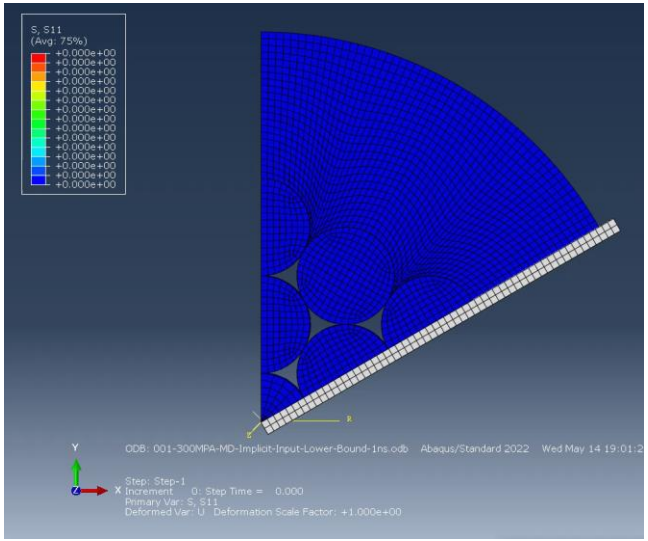
- **Equivalent Elastic Modulus (E)**
- **Bulk Modulus (K)**
- **Stress–Strain Relationship**



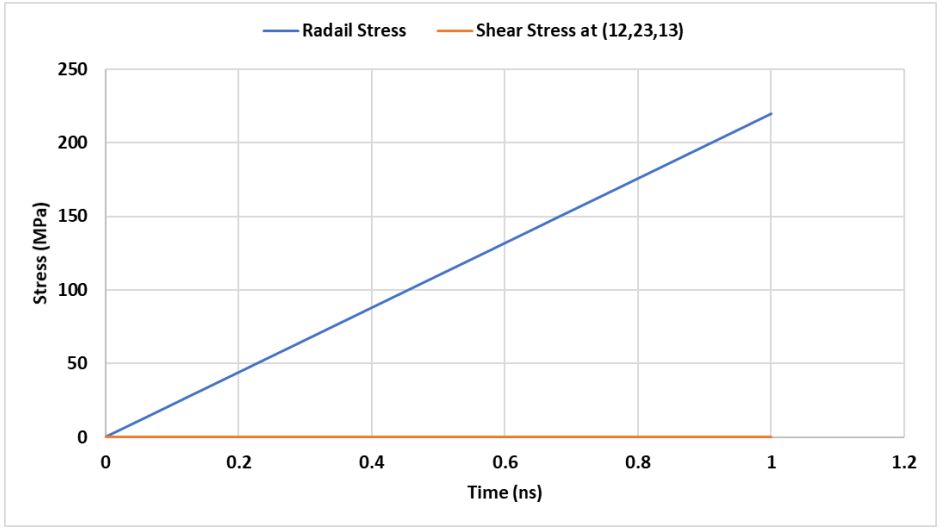
These values are determined by solving the constitutive relations shown in the equations above.

- Equivalent volume representations were computed for both fibrils and voids based on their volumes.
- All final results and visualizations were based on these equivalent circle approximations.

STEP 1: UNIFORM FIBRILS MODEL



- The repeated geometric pattern was constructed using AutoCAD and employed for representative volume element (RVE) micromechanical modeling. Periodic boundary conditions (PBCs) were applied to simulate the infinite material response. Additionally, symmetry boundary conditions were imposed along the X-plane and an oblique plane inclined at 30 degrees to the horizontal, as illustrated.

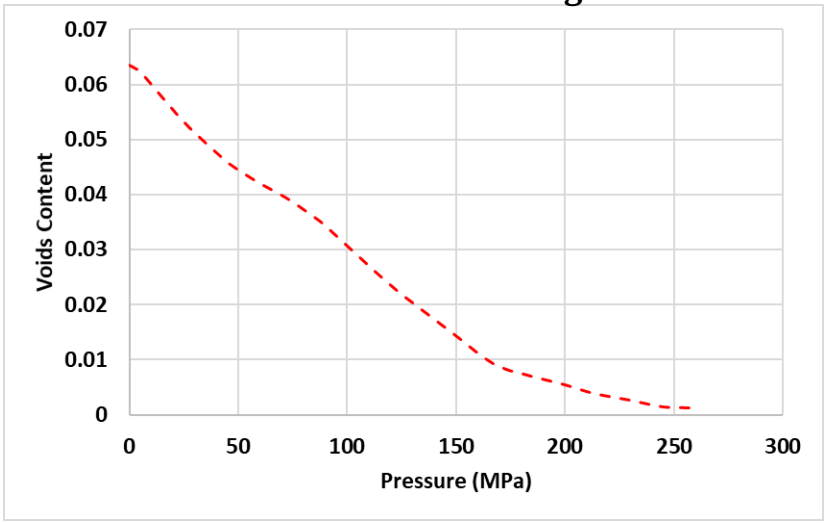


STEP 1: UNIFORM FIBRILS MODEL

UNIVERSITY OF DELAWARE
CENTER FOR COMPOSITE MATERIALS
Celebrating 50 Years

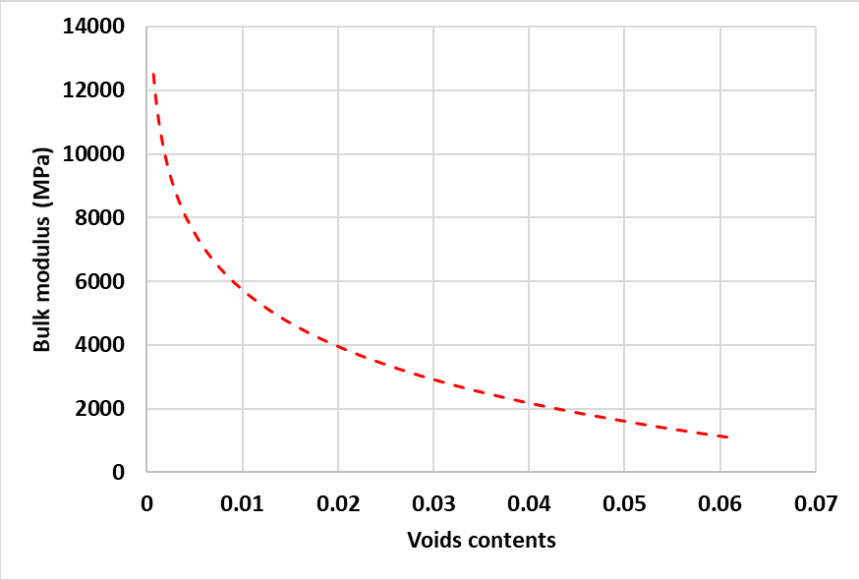
Initial Results: Incompressible Material Response Under Hydrostatic Loading

S11=Radial stresses=Applied pressure



- The **radial stresses** in the incompressible material are **uniform** and match the applied hydrostatic pressure.
- **Shear stresses remain negligible**, confirming the incompressible material behavior.
- These results validate the pressure transfer mechanism and satisfy **Equation (2)** (Ogden, R.W. (1997) and Bonet, J., & Wood, R.D. (2008)) $\sigma = -p\,I + \mu\,B$ ……. (2)

STEP 1: UNIFORM FIBRILS MODEL



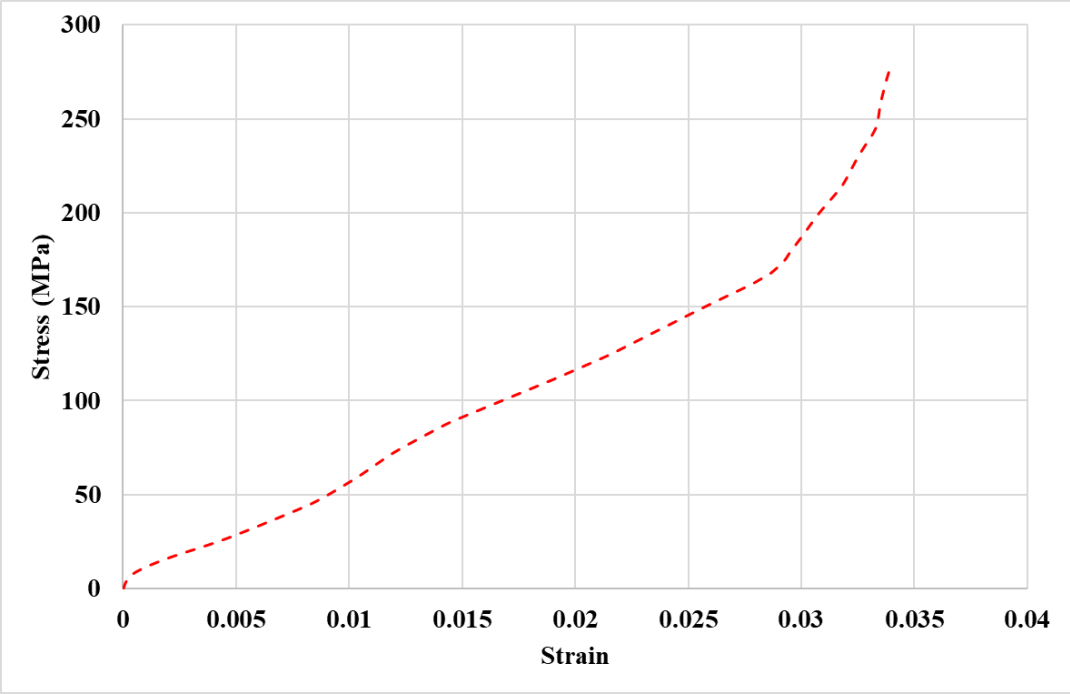
Void Reduction and Deformation Stages at 125C

- In the MD configuration, complete void elimination occurs at an applied pressure of approximately **250 MPa (1% void content is achieved at 160 MPa)**.
- The void reduction process can be categorized into **three distinct stages**:
  - **Elastic deformation (0 to 50 MPa)**
  - **Elastic-plastic softening (50 to 150 MPa)**
  - **Bulk modulus stiffening (150 to 250 MPa)**
- The initial void fraction for the uniform fiber array with two rings is **6.31%**.
- The structure undergoes **inelastic deformation** until a fully void-free configuration is achieved at 250 MPa.

STEP 1: UNIFORM FIBRILS MODEL

Plane Strain Bulk Modulus vs. Void Content at 125C

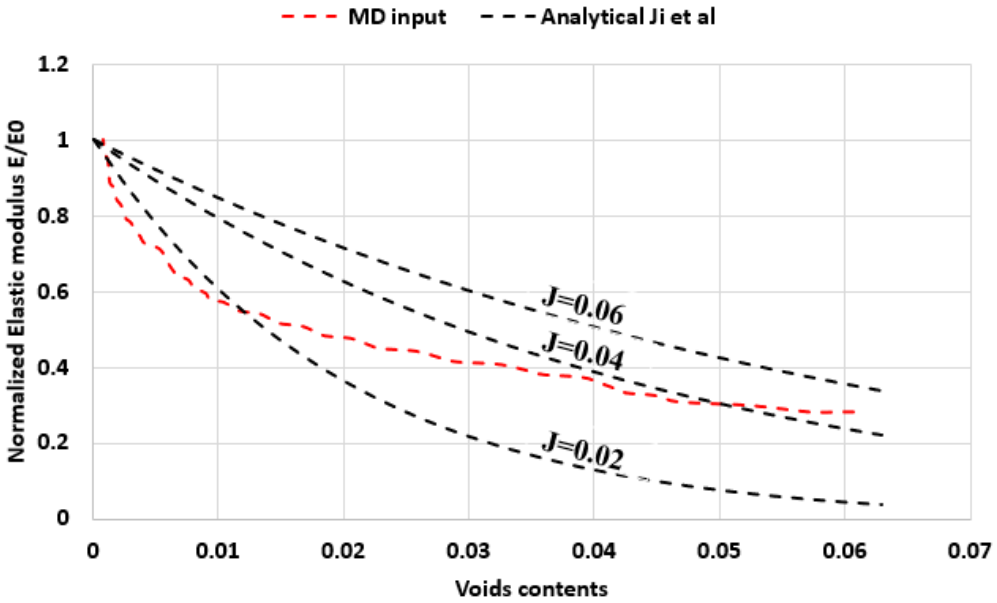
The bulk modulus was calculated from the volume-pressure plot, considering the equivalent volume changes of the fibrils and voids.



$$K = -V\frac{dP}{dV} \quad \ldots\ldots\ldots (1)$$

At an initial void content of 6.3%, the bulk modulus is at its minimum value of 1101.8 MPa. As pressure increases, voids collapse and stiffness rises. When the void fraction approaches zero, the bulk modulus rapidly increases and converges toward the fully dense value of 55,750 MPa, as predicted by Equation (2). This trend is clearly shown in the plot, where the bulk modulus increases sharply as porosity diminishes.

$$K = \frac{E}{2(1+\nu)(1-2\nu)} \quad \ldots\ldots\ldots (2)$$

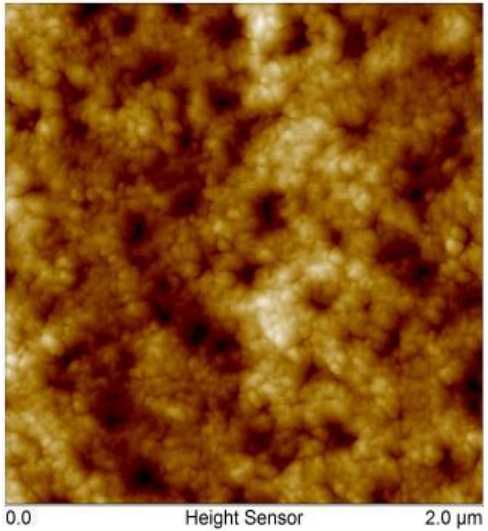


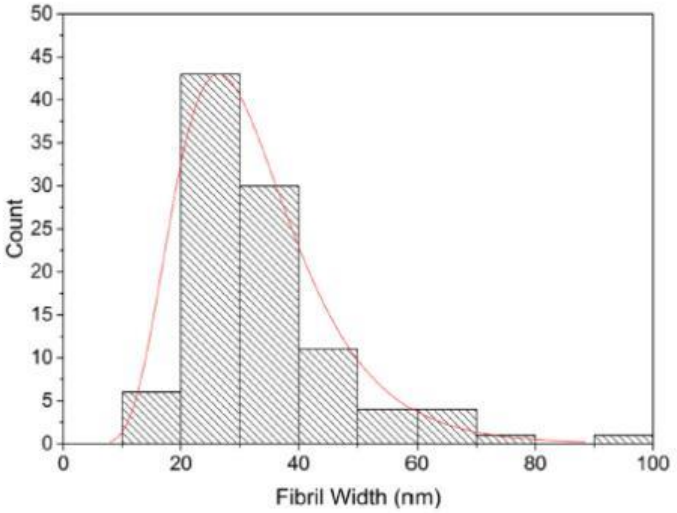
STEP 1: UNIFORM FIBRILS MODEL

Effective Stress-Strain of the model under hydrostatic pressure

The effective elastic strain response exhibits a typical three-stage behavior: an initial elastic regime, a plateau region, and a final densification phase. Densification occurs at a lower strain due to the influence of the bulk modulus.

STEP 1: UNIFORM FIBRILS MODEL





The normalized elastic modulus was compared to the analytical inverse correlation proposed by Ji et al. (2006) for the effect of porosity on mechanical properties:

$E/E0 = (1 - P)^{\frac{1}{J}}$, where P is the void content and J is the fractal parameter. A value of J=0.04 provided the best correlation with the data.

•The elastic modulus at **zero porosity** tends to match the modulus of the **constituent material** used in the simulation or experiment.

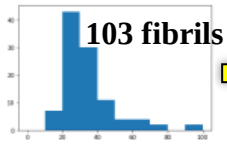
STEP 2: STATISTICAL GEOMETRY GENERATION

Morphology of UHMWPE Fiber (McDaniel et al., 2015)

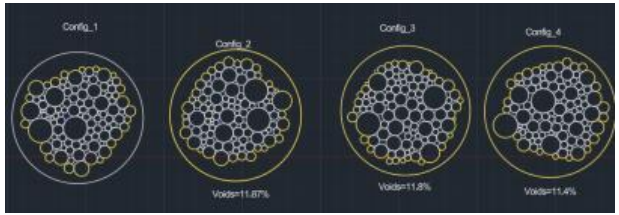
- AFM imaging reveals aligned fibrils with interstitial voids in PE fibers.
- Surface fibrils show width variations following a log-normal distribution.
- Direct measurements validate the statistical trend across the fiber surface.
- This distribution serves as a baseline for structural modeling.

STEP 2: STATISTICAL GEOMETRY GENERATION

UNIVERSITY OF DELAWARE
CENTER FOR COMPOSITE MATERIALS
Celebrating 50 Years



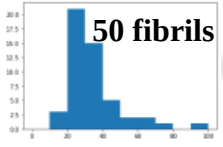
- **Efficient Modeling Through Monte Carlo and CAD**



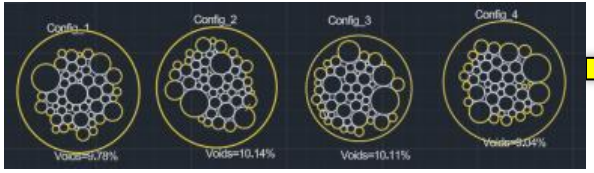
1.Statistic representative

CAD/VBA Modeling Output

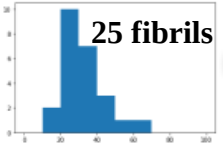
Statistical Parameters of Void Content



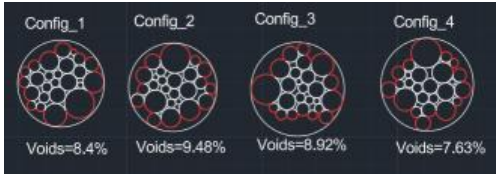
Reduce the number of fibrils



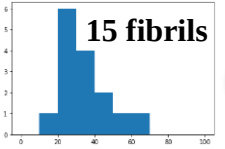
10 configurations



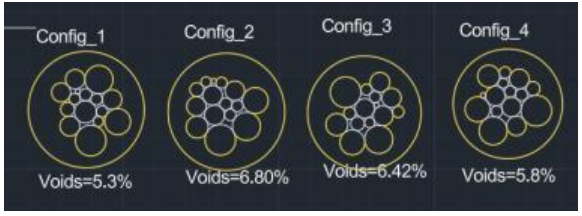
Mean (μ)	Standard deviation (σ)
10.4%	2.76%



10 configurations

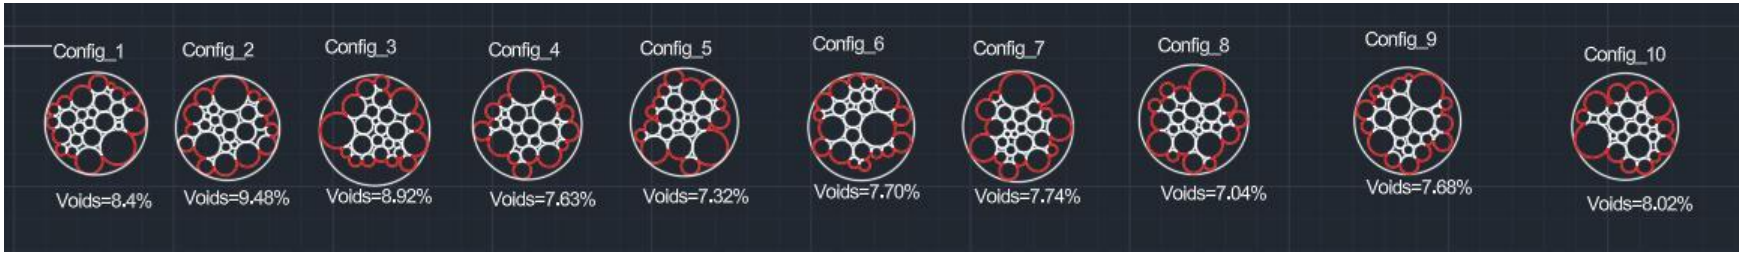


Mean (μ)	Standard deviation (σ)
9.30%	3.17%



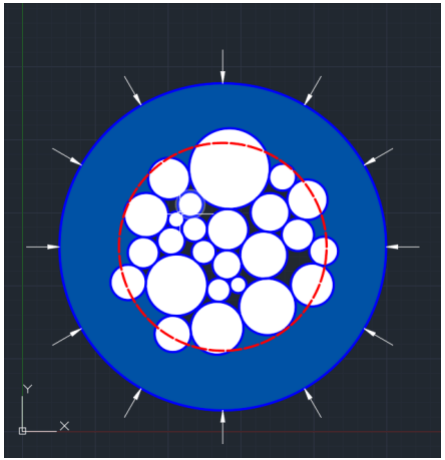
10 configurations

Mean (μ)	Standard deviation (σ)
8.01%	2.84%



10 configurations

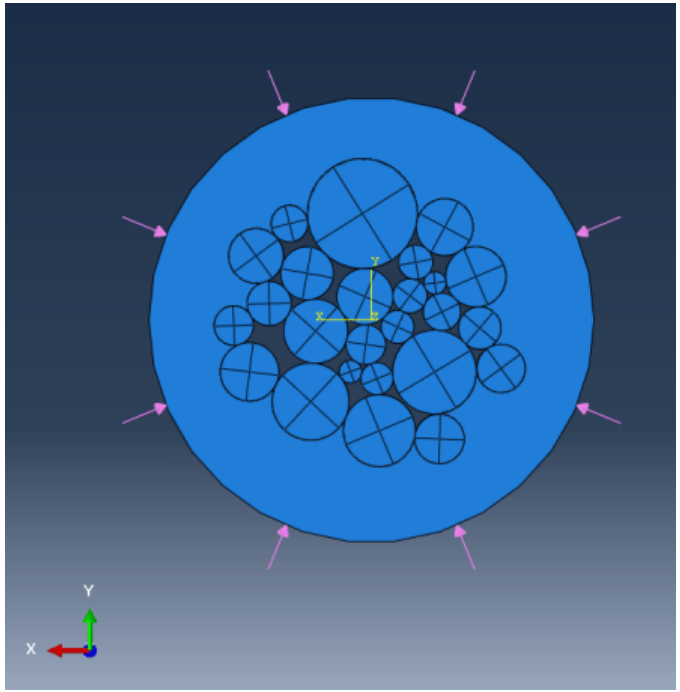
Mean (μ)	Standard deviation (σ)
6.24%	4.0%



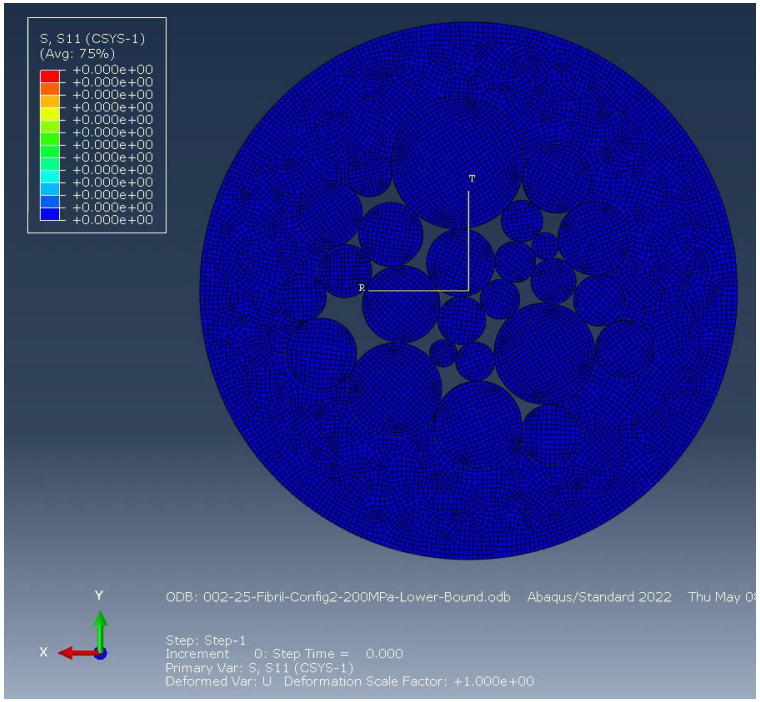
- We applied Monte Carlo sampling to statistical fibril data and used CAD to generate ten configurations for each case.
- The 25-fibril model balanced accuracy and efficiency, reducing simulation time by over 86% compared to the full model.

STEP 3: REALISTIC SIMULATION

•One representative geometry out of ten configurations was selected for detailed FE simulation.



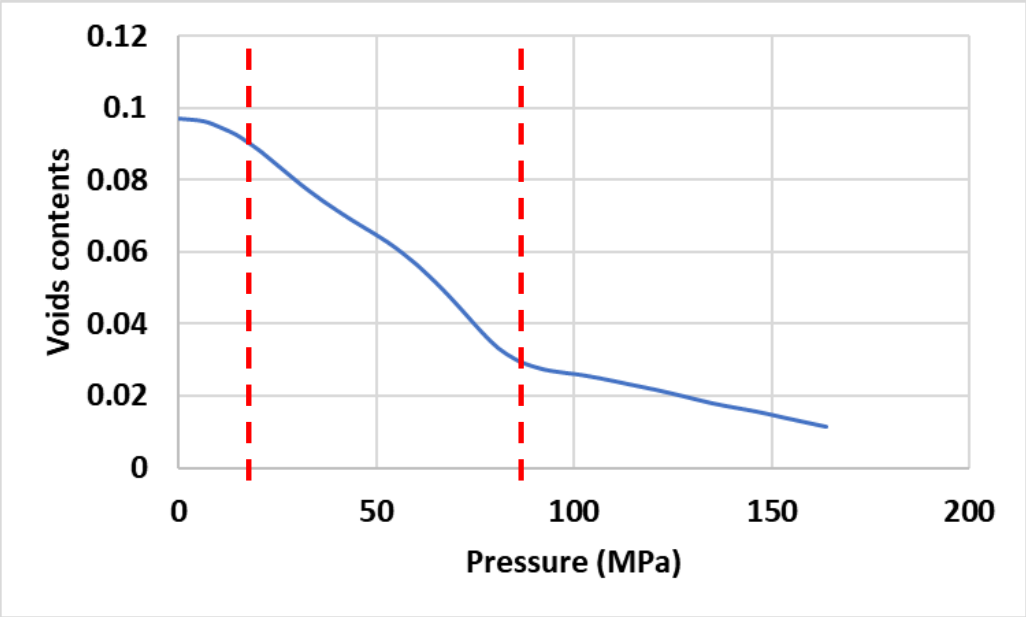
- Based on CAD-generated distributions, multiple fibril array configurations were created.
- Among these, one configuration was selected for finite element modeling in ABAQUS.
- Configuration 2, characterized by the largest initial void content, was chosen to represent the most critical case for assessing consolidation and mechanical response



- Schematic of the model for 25-fibril arrays with initial voids of 9.48%.
- The red-dash line is the equivalent radius for the fibrils and voids with equivalent volume.

STEP 3: REALISTIC SIMULATION

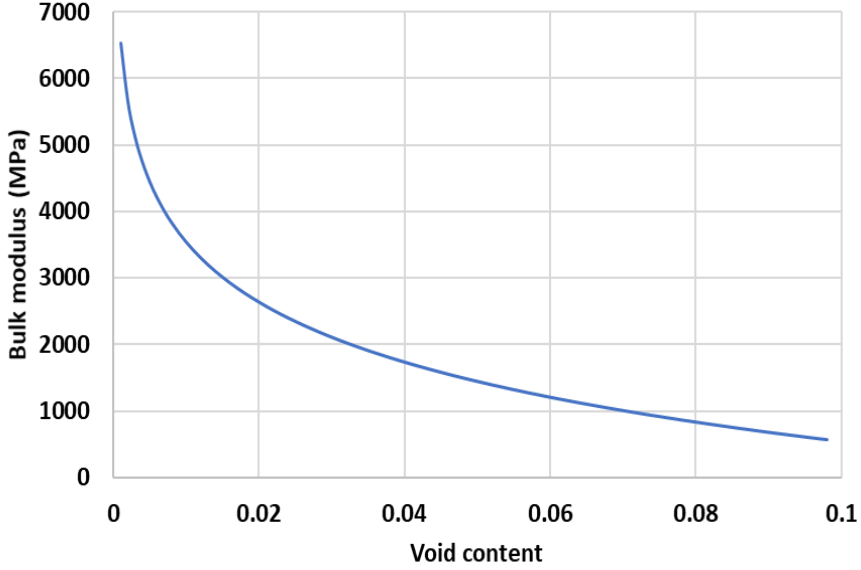
•**The results: Contour plots.**



•The same modeling approach used for the uniform fibril array was applied to the stochastic configuration. However, in this case, hydrostatic pressure was applied uniformly along the entire circumference of the fibril array to accurately simulate realistic compaction behavior. Voids gradually decrease with increasing pressure. Complete void-free occurs at 166 MPa.

STEP 3: REALISTIC SIMULATION

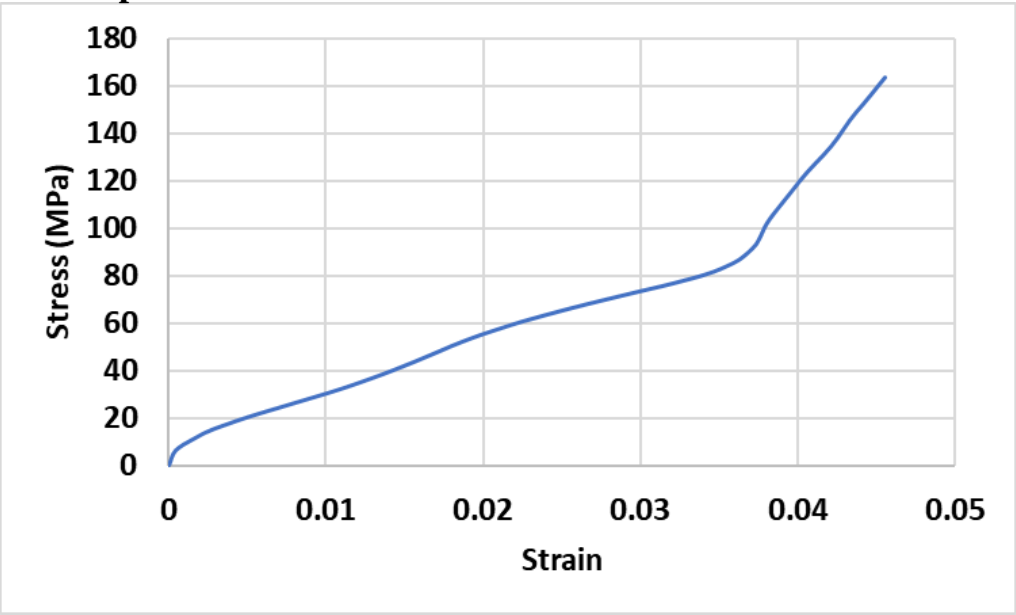
- **Void's content reduction with increasing hydrostatic pressure at 125C**



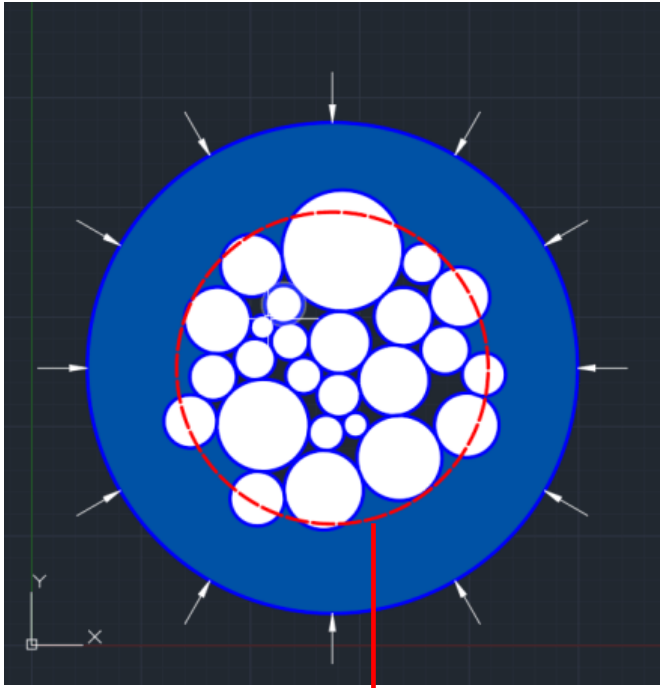
- Initial void content is 9.48% (0.0948) is much closer to the measured porosity
- Three stages of the plots (Elastic deformation, Elastic-plastic softening, Bulk modulus stiffening) exist.
- Hydrostatic pressure of 160 MPa reduced Void Content to 1% for the Stochastic fibril array (9.48% to 1%). In comparison, 160MPa reduced Void Content from 6.3% to 1%).
- Predicted evolution of microstructure for Stochastic fibril array is more realistic (fibril shape, contact and relative orientation of PE crystals) for FEA simulations considering fibrillation failure modes

EQUIVALENT BULK MODULUS WITH VOID CONTENTS

UNIVERSITY OF DELAWARE
CENTER FOR COMPOSITE MATERIALS
Celebrating 50 Years



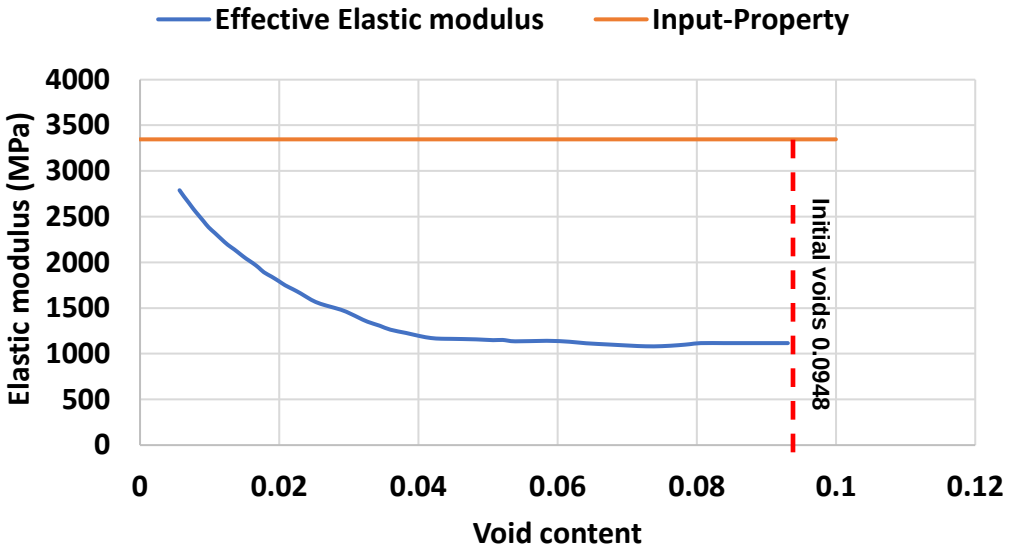
➢ **The results :Bulk Modulus Evolution During Void Elimination , Based on MD at 125C Input**



- For the plane strain condition, the effective bulk modulus K is calculated from the volumetric strain vs. pressure plot using the relation: $K = -\frac{\Delta P}{\Delta V/V}$ ……. (1)
- Analytically, the bulk modulus of the fully dense constituent material (from MD input properties) is determined from Equation (2): $K = \frac{E}{2(1+\nu)(1-2\nu)}$ … … … (2)
- Substituting the MD-derived values yields: K=56.1 GPa
- As void content vanishes, the effective bulk modulus approaches that of the solid, confirming pressure-induced densification and stiffness recovery.

STEP 3: REALISTIC SIMULATION

- **The results: The equivalent stress-strain, Based on MD at 125C Input**



Equivalent volume

- Effective stress–strain computed at the red-dotted effective circle, it can be seen that the stages are Elastic deformation, Elastic-plastic softening, Bulk modulus stiffening.

EQUIVALENT ELASTIC MODULUS WITH VOIDS (125C⁰)

The results: Effective elastic modulus, Based on MD at 125C Input

- At an initial void content of 9.48%, the elastic modulus was 1115.9 MPa. As voids diminished, stiffness increased steadily, reaching 3345 MPa at zero porosity. The void-free modulus closely matches the solid input property, confirming the correlation.

CONCLUSIONS AND FUTURE WORK

- A novel micromechanical model was developed to simulate the effect of consolidation pressure on polyethylene (PE) fibril arrays with interstitial voids.
- The model incorporates fibril distribution and void content inspired by AFM imaging.
- A Mooney–Rivlin hyperelastic model successfully represented the incompressible polymer, transmitting uniform hydrostatic pressure.
- Parametric studies confirmed the model's ability to capture inelastic fibril deformation, void collapse, and contact area growth.
- The evolved microstructure provides a realistic basis for multiscale modeling of fibril interaction and compaction behavior.
- The methodology enables prediction of effective mechanical properties as functions of microstructural change.
- Plane strain bulk modulus, Young’s modulus, and stress–strain response show nonlinear increases with pressure.
- As voids are eliminated, the effective properties approach those of fully dense fibrils.

Future Work:

- Use the predicted microstructure to evaluate effective mechanical properties at room temperature (RT).
- Apply the predicted contact areas between fibrils to model defibrillation behavior under axial and transverse loading conditions.

ABSTRACT

Sustainable composites made of a thermoplastic polyphenylene sulfide matrix reinforced with recycled carbon fibers were produced and infiltrated with a bio-based phase change material to enhance their temperature resistance. By varying molding pressure, the void content of the composites was controlled, thereby allowing for variable phase change material content. Flexural testing revealed that the inclusion of phase change material enhances the flexural modulus of the composites. Similarly, the thermal conductivity of the composites was found to improve with the addition of phase change material, which filled the pore spaces within the composite that prevented effective heat transfer. While typically viewed as a detriment, we showed that targeted porosity infiltrated with a phase change material can enhance the functionality of composites with minimum flexural stiffness loss.

1 INTRODUCTION

Carbon fiber reinforced polymers are the material of choice for high performance structures subjected to moderate thermal loads. For more intense thermal loading, microvascular composites offer sustained high temperature performance that is otherwise limited by the polymeric matrix[1]. However, structures do not always undergo sustained thermomechanical loading, instead often experiencing brief temperature excursions during operation in applications such as batteries and motors in electric vehicles and aircraft during acceleration or take-off/landing. As such, the active cooling of composites may not always be the most appropriate design choice due to the additional complexity and weight associated with the hardware required to actively pump the coolant through vasculature. Phase change materials (PCMs) offer a passive alternative to active cooling.

Few authors have studied the use of PCMs as a means of thermal regulation in composite materials. Casado et al.[2] filled cavities in an injection molded rail flanged plate with PCM to extend fatigue life by more than 400% through reduced temperature rise of the polyamide matrix. Yoo et al. [3,4] incorporated PCM microcapsules into a glass fiber/epoxy laminate to enhance thermal energy storage. They found that the PCM led to a decrease in thermal conductivity, an increase in thermal storage capacity, an increase in dimensional stability, and a significant decrease in the mechanical properties of the composites. The thermal stability of the composites was unaffected by the inclusion of PCM. Fredi et al. [5] mixed paraffin microcapsules into carbon fiber/PMMA composites and found that the activation energy of PCM composite glass transition was not significantly impacted by the PCM with a melting point of 43 °C. Their dynamic mechanical analysis (DMA) results indicated that the embedded PCM caused a brief pause in the gradual storage modulus decrease during heating.

In this study, we investigated the manufacturing of recycled carbon fiber composites containing embedded phase change materials. Unlike the prior work, which focused primarily on microcapsules mixed into the resin, we show that low-cost sustainable composites containing PCM can be produced using a scalable vacuum infiltration process. We showed that recycled carbon fiber nonwoven preforms can be used to manufacture composites with highly connected porosity when processed by compression molding following the author's prior work[6]. Recycled carbon fibers offer a significant reduction in carbon emissions, while maintaining near virgin fiber mechanical properties. The PPS matrix offers high toughness, solvent resistance, and is commonly found in under-the-hood automotive applications. We

produced samples with varying molding pressures and resin content to induce varying void content, which was characterized by density measurements and optical microscopy. We filled the connected pore space with a biobased PCM having a heat storage capacity near 200 Jg^{-1} using a vacuum infiltration process. We then characterized flexural performance and transverse thermal conductivity. This work sets the foundation for creating multifunctional composites for thermal energy storage using sustainable reinforcement and PCMs.

2 MATERIALS AND METHODS

2.1 Carbon Fiber

Recycled carbon fiber preforms, provided by Gen2 Carbon (formerly ELG Carbon Fibre), containing fibers recovered via a pyrolysis process and then upcycled into a nominally 200 gm^{-2} nonwoven fabric produced using carding and cross-lapping processes, were used in this work. Prior testing revealed that the fibers exhibit standard modulus properties[7]. Fiber length was greater than 25 mm, for which mechanical properties significantly exceeding typical short fiber composites have been realized. The use of recycled carbon fibers makes this reinforcement choice both low cost and sustainable. Reducing manufacturing waste and re-using fibers from end-of-life parts aids in the development of a circular economy for composite materials.

2.2 Polyphenylene Sulfide

Polyphenylene sulfide (PPS) is a semicrystalline aromatic thermoplastic offering high toughness, solvent resistance, and performance comparable to many common structural epoxies. The high melt temperature of the polymer, in combination with the high levels of crystallinity that enables its use well beyond its glass transition temperature, makes PPS a strong candidate for applications in which thermal resilience is required. PPS films of 0.127 mm thickness (Solvay, Ryton QC160P) were purchased from CS Hyde for use as the matrix in the composites manufactured in this study. In addition to the beneficial thermal, mechanical, and chemical properties of PPS, the recyclability of thermoplastic matrix composites is of key importance to the development of a circular economy for composites materials. PPS can be melt processed to form new composites from end-of-life components and manufacturing waste[8], unlike traditional thermosets that are typically pyrolyzed or chemically digested for fiber recovery and subsequent integration into new parts.

2.3 Phase Change Materials

A commercially-available PCM was purchased (Entropy Solutions, PureTemp). The material, referred to as 48X, was a white wax as a solid and a clear, low viscosity liquid as a melt. According to the manufacturer, the 48X PCM shows a melting point of 48 °C, a thermal conductivity of 0.25 $W\ m^{-1}\ K^{-1}$, and a heat storage capacity of 230 $J\ g^{-1}$. PCMs are emerging as an option to improve the thermal efficiency of buildings through thermal energy storage[9]. Their integration into low-cost composite materials would enable new architectural designs with enhanced sustainability.

2.4 Composite Manufacturing

Composites were manufactured through a compression molding process. Relative to traditional composite manufacturing techniques such as autoclave and oven curing of thermosets, compression molding is a rapid and low energy process capable of meeting high volume demand. First, organosheets, or single plies of carbon fiber reinforced thermoplastic, were produced by compressing a single nonwoven layer between two PPS films at 300 °C and 1 MPa pressure for 5 minutes, followed by cooling under pressure to 60 °C. The organosheets were then cut into 150 mm × 150 mm plies and placed in a closed mold of the same dimensions to form plaques for testing. Due to anisotropy in the preforms[6], special care was taken to track the laminate orientation. Processing times and temperatures were the same for organosheets and composite plaques, while the pressure used to manufacture plaques was varied from 0.5 to 4 MPa to achieve differing levels of porosity.

Samples were cut from the plaques for flexural, thermal conductivity, and dynamic mechanical analysis testing using a wet diamond saw and subsequently milled to the final dimensions. Once at the

final dimensions, the density of the composites was evaluated using an analytical balance and measurements of the length, width, and thickness. Some of the samples were evaluated as-cut, while others were infiltrated with the PCM before testing. Initial density measurements using a helium pycnometer revealed that the porosity within the uninfiltrated samples was highly connected. PCM infiltration was achieved by placing the samples in a beaker of PCM melt inside a vacuum oven for 10 minutes at greater than 26" Hg.

2.5 Micrographic Analysis

Specimens extracted from the plaques were polished for optical microscopy. Images were acquired at 200X resolution (0.96 μm/pixel) over a 12.7 mm wide section of the composites using a Keyence VHX-7100 automated stage microscope. The fiber volume fraction was determined by segmenting the images in ImageJ and using a pixel-counting script developed in MATLAB. This method has been shown to yield good agreement with measurements using Archimede's Principle[7]. Multiple cross sections were evaluated to capture local variability.

2.6 Flexural Testing

Flexural testing was performed on samples according to the ASTM D790 standard on specimens of 50.8 mm × 12.7 mm at a span-to-depth ratio of 16 at a strain rate of 1% per minute. Five samples containing PCM and five neat samples were tested per molding condition. Additionally, neat PCM samples were tested.

2.7 Thermal Conductivity

Transverse (through-thickness) thermal conductivity was measured using the double-sided transient plane source method (TPS 2500S, Hot Disk). Three measurements were taken per sample at each molding pressure on neat samples. The neat samples were then infiltrated with PCM and re-tested to ensure that local microstructural variability did not significantly influence the measurement.

3 RESULTS AND DISCUSSION

3.1 Multiscale Characteristics

The composites were evaluated at both the bulk and microstructure scales to elucidate the effects of varying pressure during molding. The density of the composites was found to increase as a function of the applied molding pressure, as shown in Figure 1. Previous work by the author[10] has shown that increasing the molding pressure leads to greater fiber compaction and enhanced consolidation. Too little pressure leads to porosity due to resin starvation. Interestingly, the density measured by helium pycnometry was largely consistent, ranging from 1.482 to 1.507 g/cc. The void-free density was estimated to be 1.494 g/cc based on the densities of the constituent components. This indicates that the pores within the composite were highly connected.

The void content before and after infiltration with the PCM is also shown in Figure 1. A major reduction in void content was apparent when comparing the measured density for PCM infiltrated composites with the theoretical density of a composite in which all the voids were filled with PCM. For samples molded at pressures of 2 and 4 MPa, the initial porosity was so low that the PCM had no significant effect on further decreasing porosity. This indicates that there is a limit to the pore connectivity in the composites.

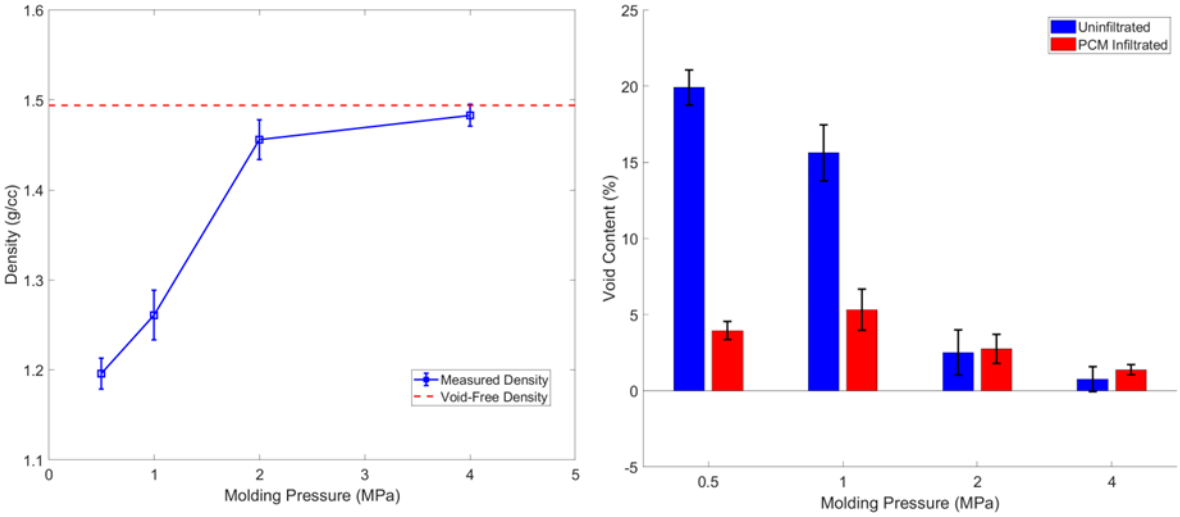

Figure 1: Additional molding pressure significantly increases composite density (left) and most of the voids are filled with PCM (right).

Example optical micrographs acquired for the samples are shown in Figure 2 and the resulting fiber volume fraction analysis is found in Table 1. For low molding pressure, significant interlaminar voids are present, indicating that resin migrated either from the center of the preforms and toward the interfaces or from the interfaces and to the center during consolidation. The high loft of recycled carbon fiber nonwovens makes this behavior likely to occur, although additional study is required to understand the mechanism. As the pressure increased to 1 MPa, the voids became more dispersed and spherical in shape, indicating entrapped gas as opposed to resin migration. At and above 2 MPa, the voids were nearly gone, with a consistent distribution of fibers. Likewise, the fiber volume fraction was a function of the total applied pressure, in addition to the matrix film thickness. The maximum was achieved at or beyond 2 MPa molding pressure, representing complete infiltration of the matrix film. The fiber content saturates at this level as there is no way of removing excess resin in the closed mold used in this study. For discontinuous fiber composites, this represents a significant improvement over incumbent materials such as long fiber thermoplastics and injection molding compounds.

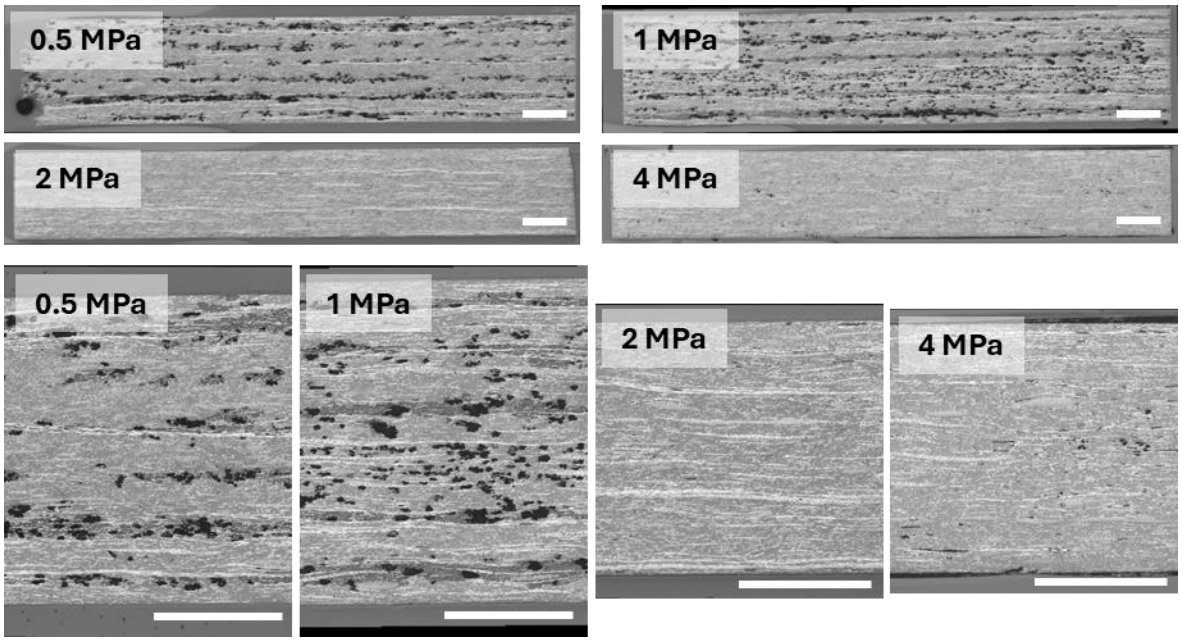

Figure 2: Representative micrographs of compression molded composites before infiltration.

Molding Pressure	Fiber Volume Fraction (%)
0.5 MPa	27.73 ± 1.64
1 MPa	26.89 ± 1.77
2 MPa	35.25 ± 2.23
4 MPa	33.65 ± 1.51

Table 1: Fiber volume fraction measured from optical micrographs

3.2 Flexural Testing

Flexural testing of the neat PCM revealed extremely low mechanical properties. The flexural strength was 1.17 MPa ± 0.019 MPa and the flexural modulus was 0.41 GPa ± 0.09 GPa. A simple Rule of Mixtures approximation for the properties of the infiltrated composites is as follows:

$$P_{infiltrated} = P_{composite}(1 - V_{PCM}) + P_{PCM}V_{PCM} \quad (1)$$

where P refers to the property (strength or modulus) of interest for the composite or PCM phase and V refers to the volume fraction of each phase. Due to the small volume of PCM and its low mechanical properties compared to the composite, the PCM is not expected to contribute significantly to the mechanical properties of the infiltrated composites.

Surprisingly, flexural testing of the composites revealed a significant increase in modulus in the samples containing PCM, as shown in Figure 3. This modulus increase cannot be simply explained by the Rule of Mixtures but instead is likely the result of more complex micromechanical mechanisms that require further exploration. It is theorized that the filled voids may provide an elastic support for fibers subjected to bending within the composite. Due to the small fiber diameter, bending of fibers near voids is expected to be significant. By filling the void with PCM, the neighboring fibers can be supported against bending. Future work will be required to evaluate this proposed mechanism of stiffness retention.

The flexural strength of the composites was not significantly improved by the addition of PCM, indicating that the reduction in void space did little to change the failure of the composites. This behavior is expected from the Rule of Mixtures, as the strength of the neat PCM was very low relative to the composite strength. It is worth noting the error bars in Figure 3. The variability in properties is more significant for the composites manufactured at lower molding pressures. Much of this variability may be attributed to the microstructural inhomogeneity in discontinuous fiber composites, in which regions of fiber misorientation or variable fiber volume fraction may lead to premature localized failure that is amplified by inhomogeneous void distribution. Hence, the lower the void content, the less variable the strength. The variability in this work could be better understood with further testing that is beyond the scope of this manuscript. Despite this limitation, the trends are clear: the flexural strength of composites infiltrated with PCM is largely unaffected, while their flexural modulus generally improves.

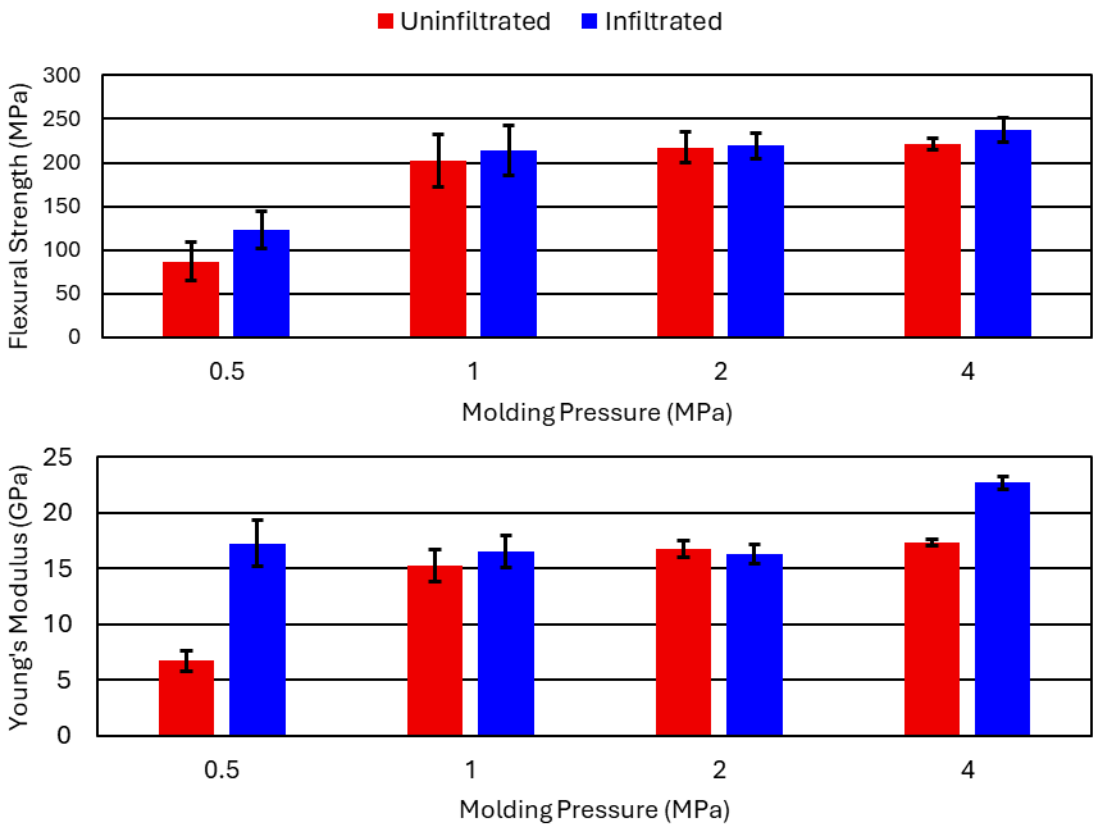

Figure 3: Flexural strength (top) and modulus (bottom) of neat and PCM-containing composites manufactured at different molding pressures.

3.3 Thermal Conductivity

The measured transverse thermal conductivity of the composites is shown in Figure 4. The thermal conductivity of the neat PPS was reported as 0.30 W m^{-1} K^{-1} by the manufacturer. The transverse thermal conductivity of composites is matrix-dominated due to the matrix regions separating fibers. Furthermore, the transverse thermal conductivity of carbon fibers is typically much lower than the axial thermal conductivity. Due to these properties, in combination with the high void content of the composites manufactured at low molding pressures, the thermal conductivity of composites molded below 2 MPa was lower than even the neat polymer. However, the addition of PCM to fill the porosity led to a significant increase in the transverse thermal conductivity of the composites despite its low thermal conductivity. For all molding pressures tested, the infiltrated composites reached approximately their full thermal conductivity with the addition of PCM.

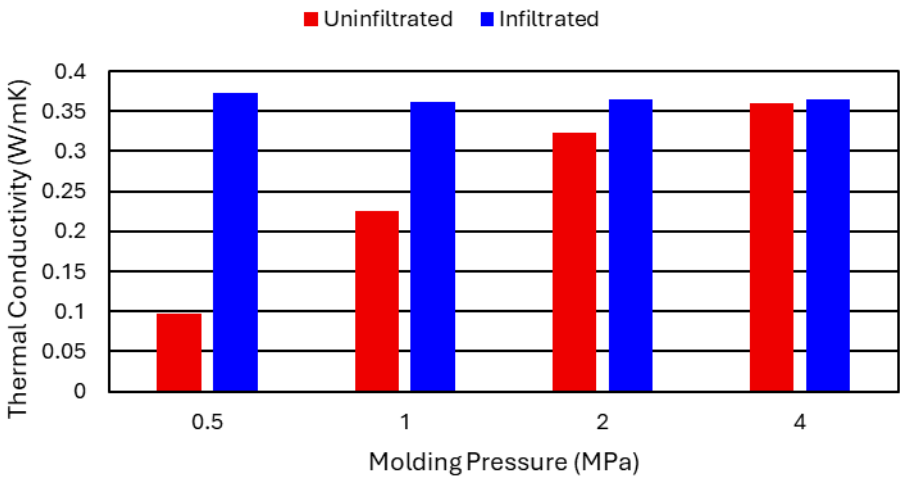

Figure 4: Thermal conductivity of neat and PCM-containing composites manufactured at different molding pressures.

9 CONCLUSIONS

In this work, we developed low-cost, sustainable composites containing embedded phase change materials. The use of low-cost recycled carbon fiber reinforcement, an easily recyclable thermoplastic matrix, and rapid compression molding processing makes such materials attractive to high volume markets in which cycle and time and cost are key factors driving decision making. We showed that porosity in these composites can be controlled by varying the applied pressure during molding. After molding, parts can be vacuum infiltrated with a PCM melt in a scalable process. The embedded PCM offers several benefits, including synergistically enhanced flexural modulus and improved thermal conductivity. The PCM is also anticipated to enable brief excursions beyond typical use temperatures or sensing through thermal energy storage. This work shifts the paradigm of void content in composites from a detriment to a beneficial feature. Beyond the ability to withstand brief thermal excursions, this material system also adds passive thermal energy storage capabilities. The addition of PCM into sustainable composites may aid in an acceleration of the shift to composite materials in the transportation and construction industries by integrating additional thermal regulation capabilities without the need for active coolant pumping.

Future work will seek to evaluate the pore morphology of these composites, understand the impact of the embedded PCM on the activation energy of transition processes in the composites, and exploring the viscoelastic and fatigue properties of these materials. The use of recycled carbon fibers paired with a thermoplastic matrix and bio-based PCM makes this material a strong candidate for low carbon footprint multifunctional composites.

ACKNOWLEDGEMENTS

We acknowledge Dayakar Penumadu for providing access to the Hot Disk system for thermal conductivity measurements and microscopy facilities. We thank David Harper and Joshua Crabtree for helpful discussions in the formulation of this concept. We are grateful to Andy Baker for providing us with machining expertise for sample preparation.

ABSTRACT

Conformal Load-Bearing Antenna Structures (CLAS) are multifunctional composite materials that integrate structural and radio communication capabilities, offering significant potential for aerospace applications. While these structures are named for their load-bearing capabilities, experimental studies validating their electromechanical performance under mechanical loading remains limited. This paper presents proof-of-concept experimental methodologies for characterising the electrical behaviour of embedded patch antennas within composite laminates subjected to tensile and flexural loads.

To minimize interference from test fixtures, custom setups using low-dielectric polymer components were developed, enabling antennas to radiate primarily into free space. Microstrip-fed rectangular patch antennas were fabricated using glass/epoxy laminates with laser-cut copper foil. Electrical performance was assessed during loading, including return loss, resonant frequency and radiation pattern.

Results show that mechanical strain induces predictable shifts in resonant frequency consistent with theoretical models. Flexural testing confirmed that fixture design and proximity to dielectric and conductive material surfaces influence antenna performance. Realised gain measurements under bending reveal the impact of laminate deformation on antenna radiation pattern.

These findings demonstrate the feasibility of simultaneous mechanical and radio frequency (RF) testing methodologies for assessing CLAS performance and for supporting design workflows that combine simulation and experimental verification. This work contributes to advancing multifunctional composite technologies through rigorous electromechanical characterisation, aiding future integration of conformal load-bearing antenna structures into high-performance aerospace systems.

1 INTRODUCTION

Conformal load-bearing antenna structures (CLAS) are a class of multifunctional composite structures capable of functioning as antennas for radio communication in addition to their role as load-bearing structural components. Multidisciplinary technology development driven by the CLAS concept over the past few decades has led to many configurations, but patch antennas (and arrays) made by layering thin copper foil into laminated structures are commonly featured and many designs rely on this fundamental building block. Understanding how these elements perform under load is essential to understanding the coupled mechanical-electrical behaviour of these structures, and critical to designing high performing aerospace vehicles.

Literature studies on CLAS have primarily focused on novel methods to manufacture different configurations of antennas and less focus has been paid to electromechanical performance. Some studies have looked at the performance of antennas after a loading or damage event [1], though most are limited to simulation studies [2]. The use of simulations is a natural choice for designers, as commercially available software is necessary to design patch antennas given the interaction between electromagnetic

radiation and surrounding structural material. This study presents methods for collecting experimental antenna performance data of these structures under load to confirm the findings of simulation studies.

The performance of an antenna against its design parameters can be measured in many ways: realised gain, radiation pattern, resonant frequency, bandwidth, impedance, polarisation and more. These measures can range from single values such as centre/resonant frequency, to multi-dimensional functions such as realised gain which is a function of two polar coordinates and frequency.

An additional consideration is that many antenna measurements are in fact measurements of a larger electrical network. Commonly this includes coaxial cables used to carry electrical signals, and connections between elements. In the case of antennas embedded into composite laminates, there is generally a standard radio frequency (RF) connector (such as Type N or SMA [3, 4]) attached to the composite and soldered to the active element or feed network. Electrical measurements of a CLAS are therefore measurements of the antenna, feed network including solder joints, RF connectors and cables.

The breadth of measurable characteristics, complexity of measured data, and the requirement for a whole-of-system approach means that experimental testing requires some thought and care, whether one is seeking to compare different antennas, compare the performance of a loaded CLAS to an unloaded CLAS, or perform quality assurance on as-manufactured CLAS. One final complication is that conductive or dielectric materials near an antenna influence its radiation pattern. Experimentally characterising antenna performance on aircraft such as UAVs is complicated by the influence of nearby aircraft body [5, 6] for example. Measured experimental results for combined mechanical and RF testing are therefore a function of any apparatus used for fixturing and applying load.

This paper describes some proof-of-concept experimental measurements of antenna characteristics that largely focus on the following research questions:

1. Can we modify standard mechanical tests to reduce the influence of test fixtures on measured antenna characteristics?
2. Can we collect antenna performance data of load-bearing antenna structures under load to compare with simulation studies?

The remainder of this paper is structured as follows:

- Section 2 outlines the theoretical basis for predicting frequency shifts in microstrip-fed patch antennas under mechanical load.
- Section 3 details the design and fabrication of experimental specimens.
- Section 4 describes the testing methodologies developed to minimise fixture interference during tensile and flexural loading.
- Section 5 presents and analyses the electromechanical performance results.
- Section 6 concludes with key findings and recommendations for future research.

2 MICROSTRIP-FED RECTANGULAR PATCH ANTENNA

Figure 1 shows the typical design of a microstrip-fed rectangular patch antenna on a dielectric substrate with a ground plane. The following geometric parameters of the rectangular patch antenna determine the characteristics of the antenna:

- Length (L): determines frequency of fundamental mode
- Width (W): chosen to maximise radiation efficiency
- Substrate height (h): determined by application
- Relative permittivity (ε_r): material property
- Microstrip width (W_0): chosen to match impedance of source; function of h and ε_r
- Recess length (y_0): chosen to match impedance of patch

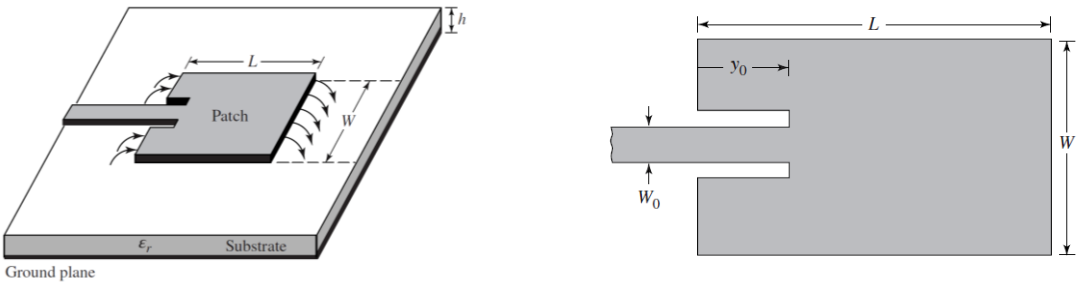

Figure 1: Typical design of a microstrip-fed rectangular patch antenna [7]

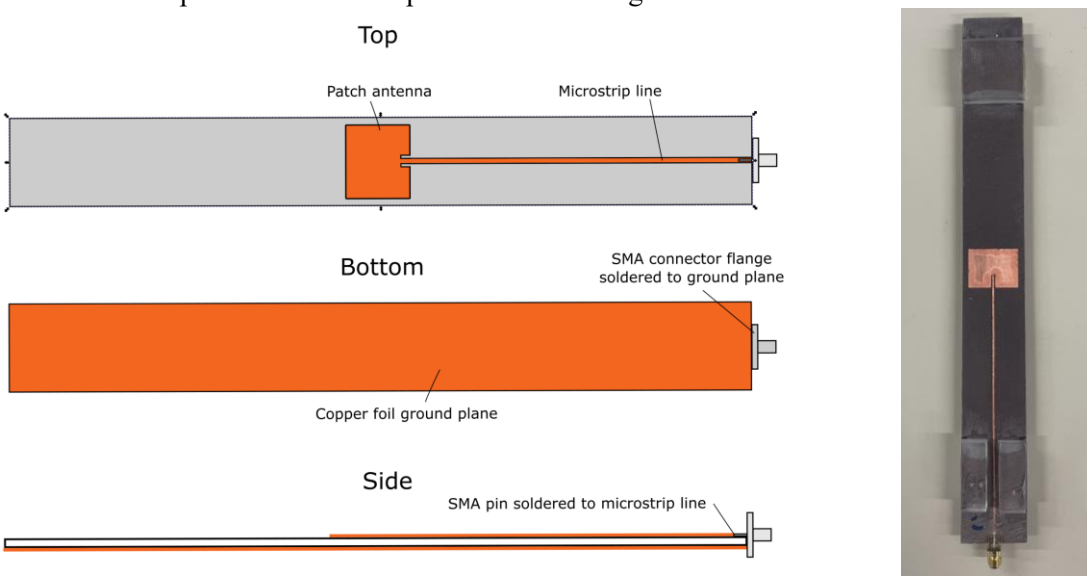


Modelling the antenna as a resonant cavity between patch and ground plane [7], the frequency of the fundamental mode, f_{010}, is ultimately a function of patch length, patch width and substrate height (Equation 1); however the influence of patch length is greater than patch width or substrate height.

$$f_{010} = \frac{c}{2L_{eff}\sqrt{\epsilon_{r,eff}}} \quad (1) \qquad \epsilon_{r,eff} = f(W,h) \quad (2) \qquad L_{eff} = f(L,W,h) \quad (3)$$

Mechanical strain of a conformal load-bearing antenna structure can change the characteristic frequency of the antenna. Since the fundamental mode of a rectangular patch antenna depends strongly on patch length, strain along the length direction of a rectangular patch changes the resonant frequency of the antenna; a positive change of length will decrease the frequency. While many conformal load-bearing antennas are not designed using rectangular patches, any planar antenna undergoing strain will change characteristics in a similar fashion. The rectangular patch is a simple, easy to analyse design for studying general trends and answering our research questions.

3 EXPERIMENTAL SPECIMENS

Figure 2 shows the specimen design used in this work for investigating the effect of tensile loading along the length direction (L) of a microstrip-fed rectangular patch antenna. The Tensile Specimen consists of a fibre-reinforced composite laminate having a laser-cut copper foil patch antenna and microstrip feed on the top side and a copper foil ground plane on the bottom side. These specimens are manufactured using two layers of 8-harness satin weave glass/epoxy prepreg, and the copper foil elements are laid up into the laminate prior to vacuum bag cure in an oven.

(a) (b)

Figure 2: Specimen design used to investigate the effect of tensile loading

The microstrip line is terminated by an SMA connector; the pin is soldered to the microstrip, and the ground flange is soldered to the ground plane. Perspex tabs are bonded onto both sides of the specimen at each end. The tabs serve two purposes: to ensure that standard mechanical testing machine grips do not contact the microstrip and to ensure an air gap above the microstrip. If a dielectric material were to sit on the surface of the specimen, over the microstrip, this would change the characteristic impedance of the microstrip and affect antenna performance.

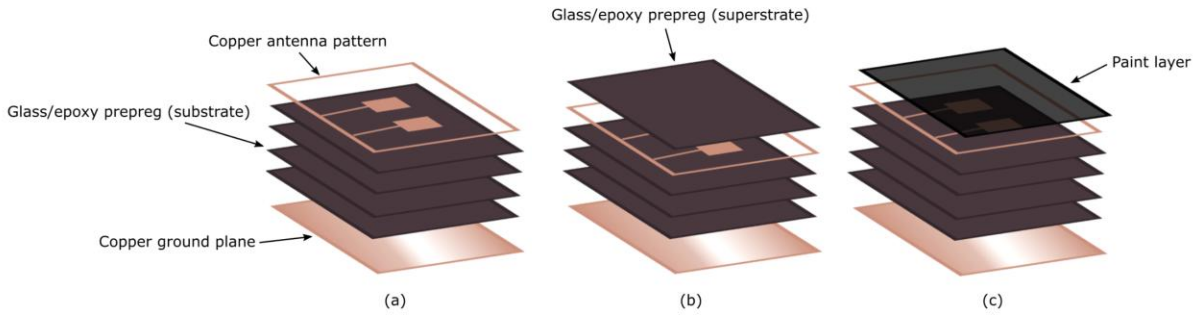
A similar design of specimen is used for flexural testing (Flexural Specimen A in Table 1), however no tabs are bonded to these samples. Flexural Specimen B is an alternative flexural testing specimen design where the total height of the laminate is kept fixed, but the active antenna element is embedded one ply beneath the surface. Since flexural strain is dependent on distance from the neutral axis, the antenna elements in Flexural Specimens A and B experience different levels of strain for the same radius of curvature. The microstrip and patch dimensions are adjusted to take into account the effect of the superstrate ply on effective permittivity and microstrip impedance.

Table 1: Specimen parameters for tensile and flexural testing experiments

Specimen Parameter		Tensile Specimen	Flexural Specimen A	Flexural Specimen B
Patch length, L	[mm]	18.9	30.8	30.3
Patch width, W	[mm]	23.9	39.1	38.3
Substrate height*, h	[mm]	0.55	1.10	0.825
Superstrate height, h^+	[mm]	–	–	0.275
Material	–		E-Glass/epoxy	
Substrate relative permittivity, ε_r	–	4.3	4.3	4.3
Microstrip width, W_0	[mm]	0.96	1.90	1.39
Recess length, y_0	[mm]	6.2	10.1	9.9
Specimen length	[mm]	250	210	210
Specimen width	[mm]	30	65	65

*Due to manufacturing variability, the cured substrate height is observed to vary by up to 5% from these nominal values.

Figure 3 shows layup schematics for the two flexural specimens, and for a case where paint is applied as a cosmetic coating to Flexural Specimen A. These schematics are not to scale and are intended to illustrate that the antennas are fabricated by manufacturing a larger composite laminate panel containing multiple antennas, which are later waterjet cut from the panel. While Figure 3 shows two patch antennas per panel, this process scales to higher numbers of antenna per panel.



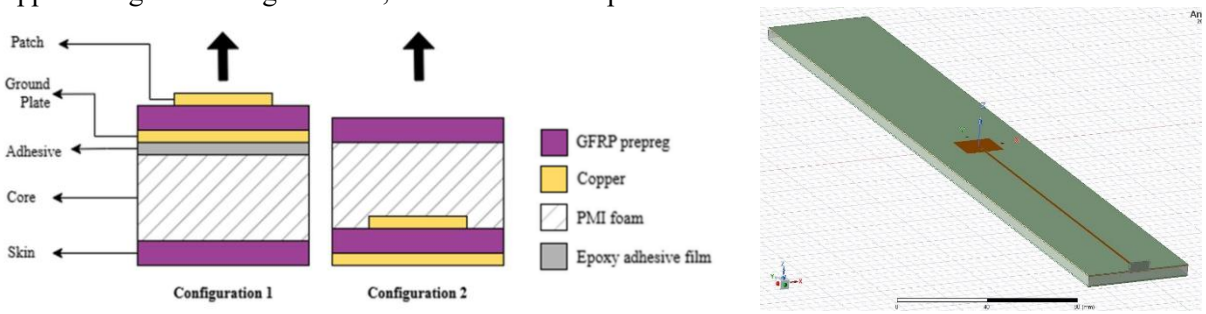


Figure 3: Layup schematics for (a) Flexural Specimen A, (b) Flexural Specimen B, (c) Flexural Specimen A with paint

The final experimental specimen type produced for this study is a sandwich-structured composite panel; its design form is very similar to the Tensile Specimen and Flexural Specimen A, with the inclusion of a polymethacrylimide (PMI) foam core and an additional face sheet/skin, as shown in Figure

4. Two configurations for this specimen exist; Configuration 1 is designed to undergo flexural strain of the opposite sign to Configuration 2, i.e. tensile vs compression strain.

(a) (b)

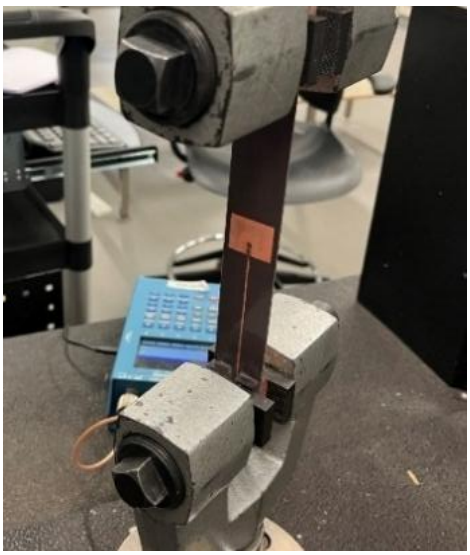
Figure 4: (a) Layup configurations for the Sandwich Panel test coupons, (b) Ansys HFSS model of Configuration 1

Table 2: Specimen parameters for sandwich panel antennas for flexural testing

Specimen Parameter		Sandwich Panel
Patch length, L	[mm]	10.1
Patch width, W	[mm]	13
Substrate height, h	[mm]	0.275
Substrate material	–	E-Glass/Epoxy
Core material	–	PMI foam (3mm)
Substrate relative permittivity, ε_r	–	4.3
Microstrip width, W_0	[mm]	0.54
Recess length, y_0	[mm]	3.4
Specimen length	[mm]	350
Specimen width	[mm]	50

4 EXPERIMENTAL METHODOLOGIES

Figure 5 shows the experimental test setup for tensile testing; a tensile testing machine is used to load specimens in tension while a Vector Network Analyser (VNA) is used to measure return loss, S_{11} (Equation 4). The specimens are loaded to 2% nominal strain, which is calculated by crosshead displacement. Periodically during the tests, at increments of 0.25% nominal strain, each sample is analysed using the VNA and S_{11} measured. A video extensometer is also used to measure the average strain over the length of the patch. From each S_{11} curve, the resonant frequency (minimum in return loss) value is recorded so that a change in frequency can be observed as a function of applied strain.



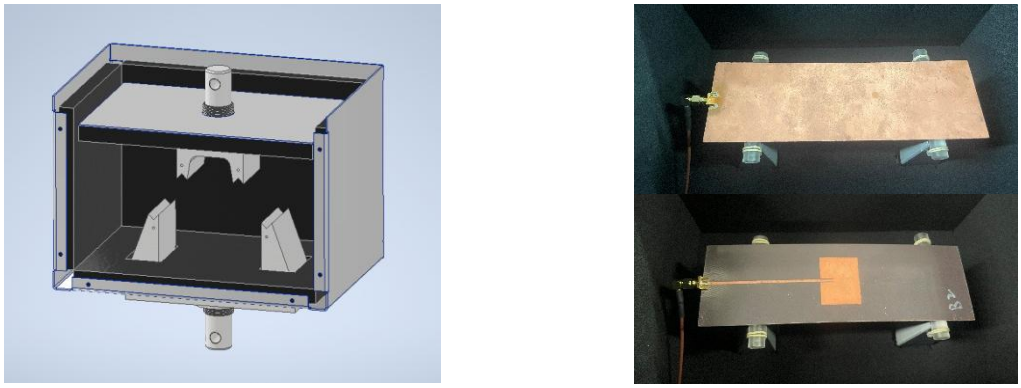


Figure 5: Experimental test setup for tensile testing

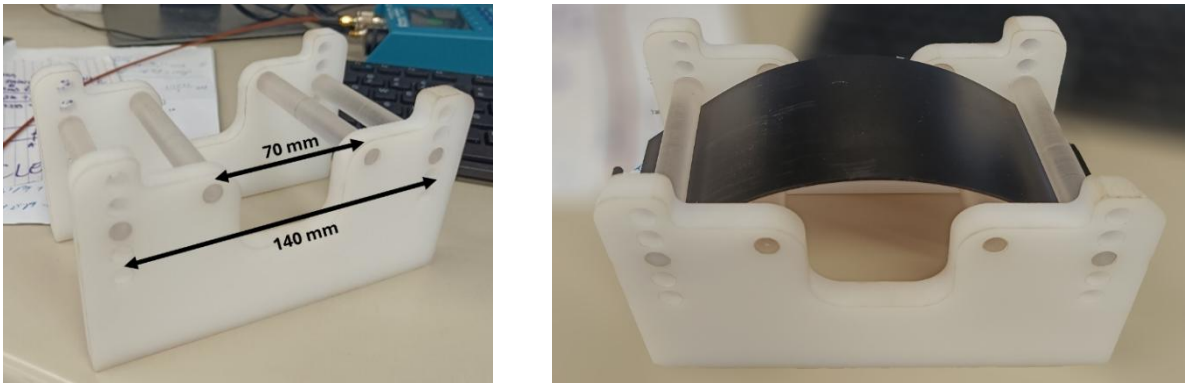
$$S_{11}(dB) = 10\log\left(\frac{Reflected\ Power}{Incident\ Power}\right) \qquad (4)$$

For flexural testing, multiple experimental setup concepts have been developed and trialled. Traditional four-point bending test fixtures for universal test machines are made of steel, including the loading pins. The close proximity of the loading pins to the microstrip, and the proximity of both the four-point bending fixture and the universal test machine to the antenna during testing make conventional flexural testing undesirable for composite laminates with embedded antenna elements. The main goals of the developed experimental setup concepts were to:

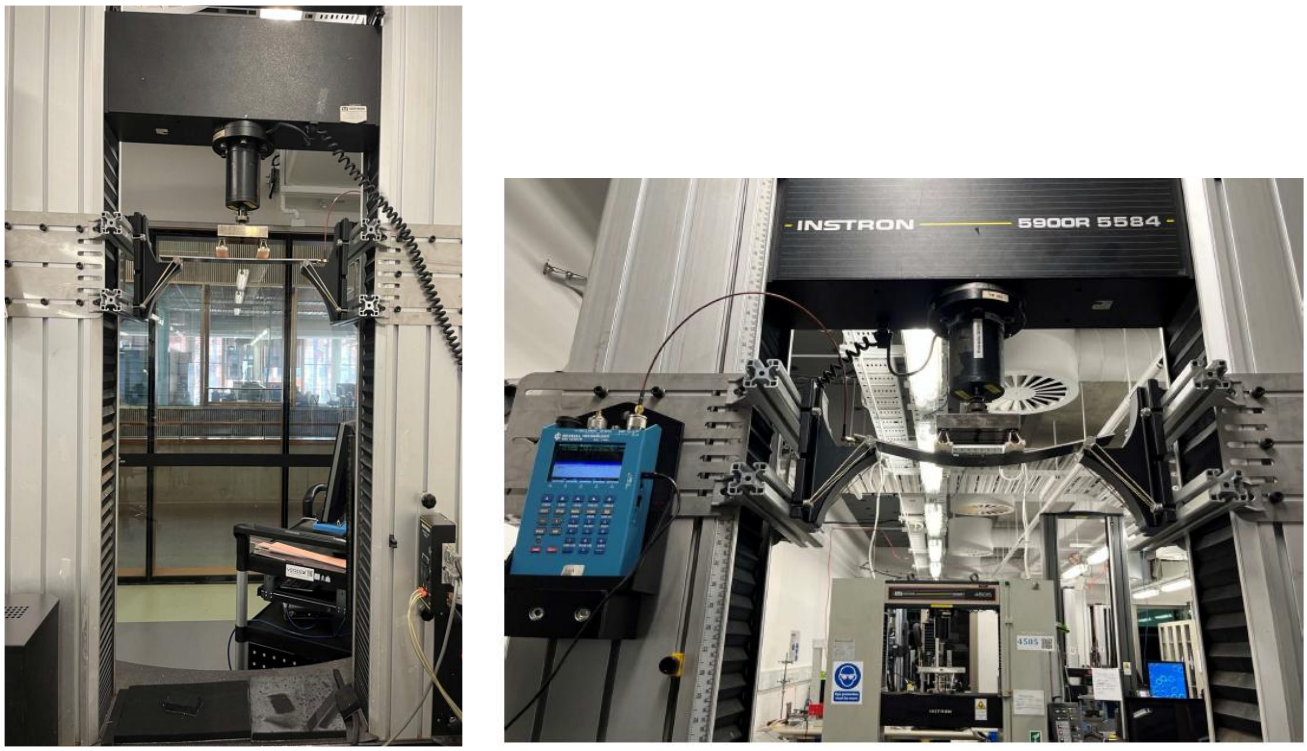


1. Replace all text fixture structure with polymer fixtures to reduce influence on antenna.
2. Replace loading pins with polymer pins to reduce influence on microstrip and antenna.
3. Reduce the amount of radiated power that could be reflected back to the antenna, either by:
    a. Absorbing the radiation, or
    b. Allowing the antenna to radiate into as much free space as possible.

Figure 6 shows the first of these concepts, a small anechoic box designed to fit to a universal test machine. The chamber is lined with RF absorbing foam, rated to the frequencies of interest of the antennas under test. Four-point bending fixtures have been designed and 3D printed from PLA, and polycarbonate loading pins are used. Figure 6(b) shows Flexural Specimens sitting in the test chamber (without the top loading fixture or top of box present). An access hole allows routing of a coaxial cable for VNA testing of the antenna while under load. Conventional four-point bending testing can be performed on these samples with a slow rate of crosshead displacement and continuous recording of the VNA to yield resonant frequency and bandwidth of the antenna at different strain levels.

(a) (b)

Figure 6: Anechoic box concept for flexural testing of multifunctional composite laminates



(a) (b)

Figure 7: Test fixture for placing multifunctional composite laminates under flexural strain without external loading.

Figure 7 shows a text fixture that is designed to place multifunctional composite laminates under flexural strain without the use of an external loading device such as a universal test machine. The motivation for this concept is to allow for radiation pattern testing of the antenna while it is under flexural strain. For example, this test fixture can be used in a conventional antenna pattern measurement setup in an anechoic chamber that simulates free space. The test fixture outer pins can move, so that five discrete levels of flexural strain or curvature can be applied to the test specimen. Figure 7(b) shows a painted Flexural Specimen A installed into the test fixture and deformed into the "20mm" position, which is equivalent to 20 mm of crosshead displacement if the anechoic box loading fixture were used in a universal test machine.

A set of experiments was performed to compare four-point bending using the developed anechoic box concept (Figure 6) to four-point bending using the static testing fixture designed to eliminate the need for external loading (Figure 7). Using the universal testing machine and anechoic box fixture, five Flexural Specimen A type samples were loaded such that the patch antenna is put into tensile strain; the patch elongates and theory predicts a drop in resonant frequency. VNA measurements were taken at 0, 5, 10, 15 and 20 mm of crosshead displacement. Similarly, three Flexural Specimen A type samples were placed in the static testing fixture at curvatures equivalent to 0, 10 and 20 mm of crosshead displacement. Changes in resonant frequency were calculated for each specimen and the results of this analysis are shown in Section 5.

Finally, a concept has been developed for performing four-point bending in a universal testing machine, utilising low-dielectric polymer supports, where the antenna is allowed to radiate mostly into free space (see Figure 8(a)). The antenna faces straight down into over a metre of free space, under which RF absorbing foam rests on the testing machine structure. Figure 8(b) shows a little more detail including VNA connected to the test specimen during loading. As for the previous concepts, this setup allows for the measurement of S_{11} of the antennas to investigate how resonant frequency shifts with flexural deformation. Specimens are loaded to 30 mm of crosshead displacement, with return loss measurements taken at 5 mm increments of crosshead displacement.

5 EXPERIMENTAL RESULTS

Six Tensile Specimens were manufactured for this work and loaded in tension using the methodology described in Section 4. Figure 9 shows an example of S_{11} curves obtained for a single specimen, at nine levels of crosshead displacement. Figure 10 shows the main result of this testing: the change in frequency for all six specimens is shown (marker average, error bars min and max) along with the change in frequency predicted by basic theory model presented in Section 2. Note in Figure 10, the x-axis is the average strain across the patch measured using video extensometer, ϵ_{patch}, whereas the strain values listed in in Figure 9 are nominal strains calculated from crosshead displacement.

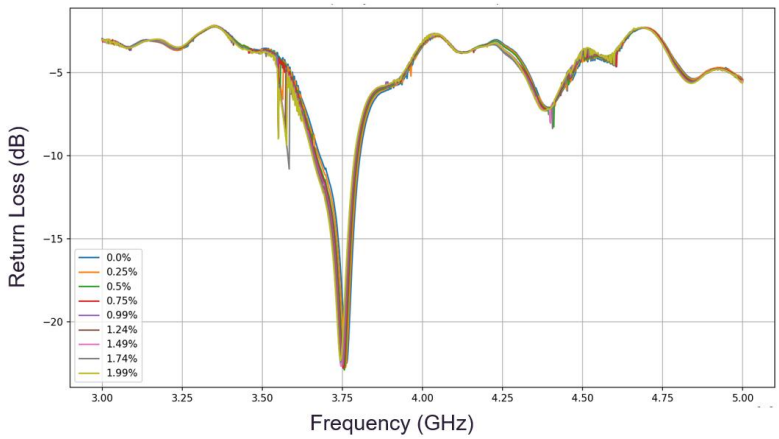

Figure 9: Example of return loss vs frequency data for tensile specimen.

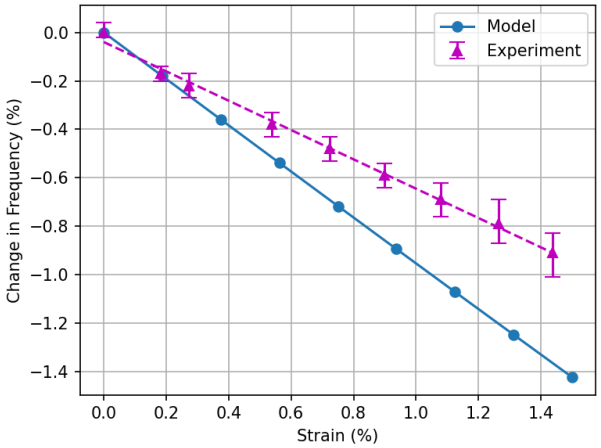

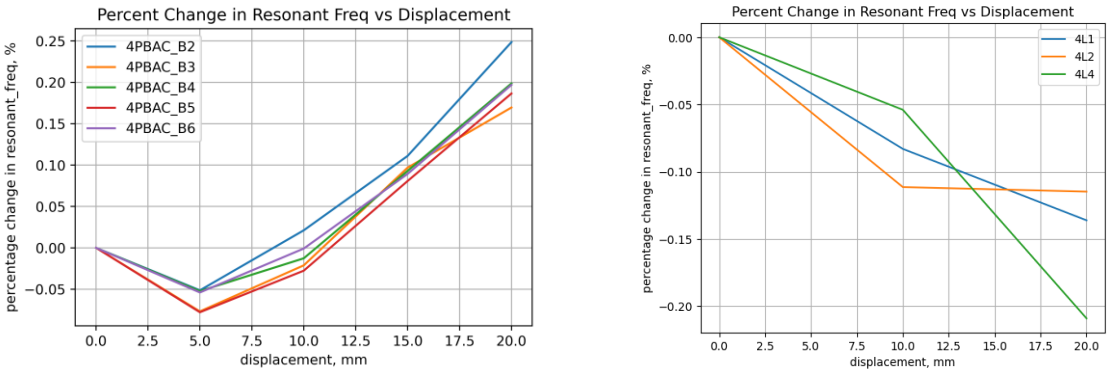

Figure 10: Measured vs. theoretical resonant frequency shift in tensile specimens as a function of strain of patch (measured with video extensometer).

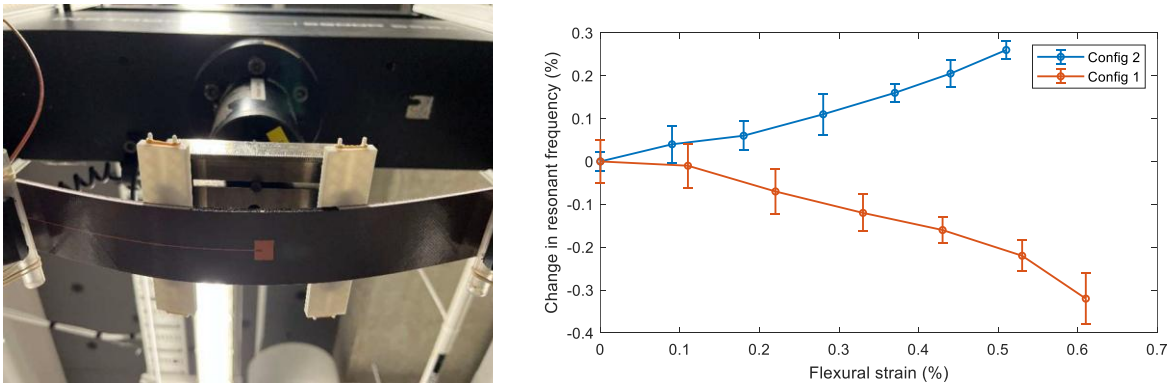
The experimental data for tensile testing agrees somewhat with the predictions of basic theory, which are obtained using Equation 1 with L_{eff} calculated from $L(1 + \epsilon_{patch})$. The relatively narrow spread of results and good linearity of the experimental trend are promising results for this testing concept. The discrepancy between model and experiment of approximately 25-40% is similar to that reported in literature for strain-sensing patch antennas [e.g. 9,10]. We noted during our testing, out-of-plane deformation of the specimens were observed due to the unsymmetrical layup of the composite; copper is much stiffer than the glass/epoxy substrate and one side of the specimen has a ground plane occupying the entire face. This out-of-plane deformation is not captured by the basic model and could easily explain the results; this deformation also makes numerical simulation of the coupled mechanical-electrical problem challenging using commercial software such as Ansys HFSS.

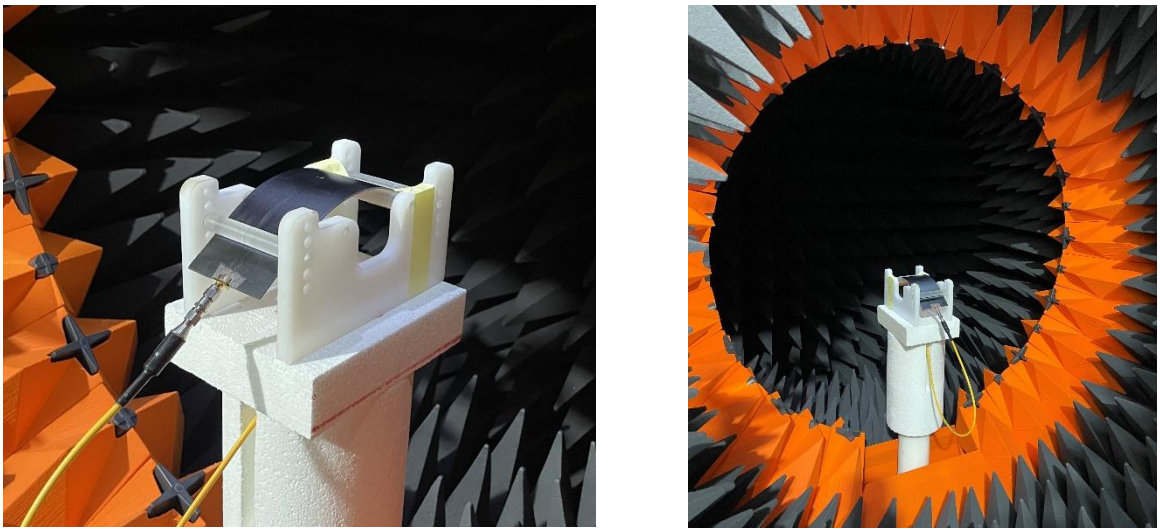


(a) (b)

Figure 11: Change in resonant frequency vs crosshead displacement for (a) anechoic box concept, and (b) static test fixture.

Figure 11 shows the main results comparing the anechoic box test setup to the static test fixture. Figure 11(a) shows an initial decrease in resonant frequency for all samples as predicted, but then a steady increase in resonant frequency for all samples as flexural strain increases. On further observation and analysis, the authors have concluded that the frequency increase is likely due to the antenna element moving closer to the bottom of the loading fixture and internal surface of the box as it strains, due to curvature of the part. The stand-off distance between the antenna and absorbing foam not remaining constant during testing is not desirable for fair comparison of experimental data points. Ultimately, the findings of these experiments have led to the abandonment of the anechoic box concept by the authors.

Figure 11(b) shows a general downward trend of resonant frequency for the static test fixture experiments, which is in good agreement with predictions. There is a large spread in the data, which may be attributed to the difficulty of precise and repeatable positioning of the specimen within the current fixture design. This concept does not have an issue with the antenna moving closer to a surface during testing, as the antenna is radiating into free space above the test fixture.



The final four-point bending testing concept was trialled using Sandwich Panel specimens described in Section 3. Figure 12(a) shows a specimen of Configuration 1 in the text fixture; the side of the specimen with an antenna is under tension, and the length of the patch should increase, leading to a decrease in resonant frequency. Specimens of Configuration 2 on the other hand, with an antenna on the back face sheet, and are placed under compression in this setup, and this should lead to an increase in the resonant frequency. The results in Figure 12(b) confirm these trends, with the two configurations seeing a frequency trend of approximately equal magnitude but opposite sign. These results represent a successful proof-of-concept of using low-dielectric polymer material for a conventional four-point bending experimental apparatus while ensuring the antenna is radiating into mostly free space.

(a) (b)

Figure 12: (a) Sandwich Panel specimen (Configuration 1) bending under load, (b) change in frequency vs. flexural strain for Sandwich Panel specimens (Configurations 1 and 2).

Based on the success of the static test fixture in simple tests for resonant frequency, some preliminary experiments were performed to measure the radiation pattern of specimens under different levels of curvature. Near-field measurements were acquired in an *MVG Starlab* system and processed to approximate far-field gain. Figure 13 shows Flexural Specimen A (painted) in the static test fixture, secured to the central plinth of the *Starlab* system. Realised gain was calculated relative to a standard gain antenna, for frequencies between 2.0 and 3.0 GHz, in 101 steps of 10 MHz, for a 3D field in steps of 3 degrees for azimuth and 3 degrees for elevation. This was repeated for each specimen in the undeformed (0 mm) and deformed (20 mm equivalent crosshead displacement) cases.

(a) (b)

Figure 13: Flexural Specimen A (painted) in the static test fixture, secured to the central plinth of the MVG Starlab system.

Figure 14 shows the maximum realised gain at each frequency between 2.0 and 3.0 GHz for Flexural Specimens A and B, each in the undeformed and deformed state. This shows peak realised gain occurs at 2.41 GHz in all tests.

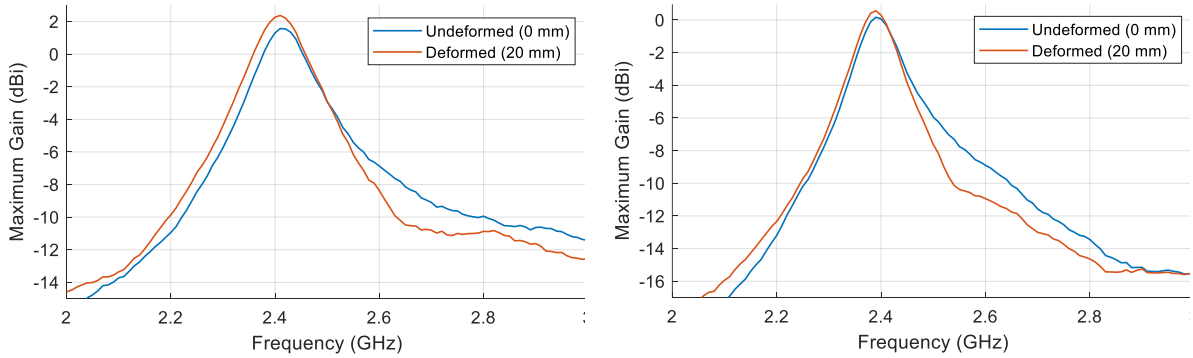


Figure 14: Maximum realised gain vs. Frequency for (a) Flexural Specimen A, painted and (b) Flexural Specimen B.

The antenna radiation patterns at 2.41 GHz are shown in Figure 15 (E-plane) and Figure 16 (H-plane). The E-plane results show that the main lobe of both undeformed specimens has a flat top, separated into two peaks. Flexural deformation of the structures produces a protrusion of this lobe directly away from the patch. The H-plane intersects with this protrusion, and the H-plane results show a consistent increase in gain under deformation.

The effect of laminate curvature on radiation pattern appears identical in form and magnitude between specimen types. This is despite the patch antenna undergoing a different strain magnitude; the patch in Flexural Specimen B is closer to the neutral axis of bending and therefore will experience a lower degree of in-plane strain due to bending. It can therefore be concluded that the change in radiation pattern is attributed to the deformation, i.e. the change of shape, and not a strain effect. Similar results have been shown for wearable antennas, where there is change of shape but no substrate strain [e.g. 11].

These results represent a successful proof-of-concept of using a static test fixture made from low-dielectric polymer material for the measurement of radiation patterns of conformal load-bearing antenna structures under flexural loads.

6 CONCLUSIONS

This paper describes successful proof-of-concept experimental work to reduce the influence of test fixtures on measured electrical characteristics of conformal load-bearing antenna structures. The developed experimental setup concepts focus on using low-dielectric polymer materials for test fixtures and redesigning experiments such that antennas propagate mostly into free space.

Methods for performing conventional tensile and flexural testing of multifunctional composite laminates have been demonstrated that allow for simultaneous performance characterisation of embedded antennas. The observed trends in data collected during these proof-of-concept experiments tend to agree with predictions made using basic theory of rectangular patch antennas. A methodology that allows conformal load-bearing antenna structures to be fixed under flexural strain while radiation pattern measurements are made has been successfully demonstrated.

This work is an important step towards developing design workflows that include verifying the results of coupled mechanical-electrical numerical simulations with experimental data. For complicated structures, experimental testing is not a feasible pathway toward designing conformal load-bearing antenna structures that perform as expected in real-world applications, and numerical simulations must fill this gap. Experimental work of the type described in this paper can be used to verify and validate simple simulation cases to increase confidence in the results of the design workflow.

Keywords: Carbon nanotubes, Carbon nanoplatelets, Nanocomposites, Polymer fibres, Mechanical strength, Thermal conductivity

ABSTRACT

The paper examines the reinforcing effect of carbon-based nanomaterials on high-performance polymer fibres. Based on various experimental studies, which show that even with relatively high contents of carbon-based nanomaterials - despite their exceptionally high mechanical properties - only modest increases in strength are achieved, the present study investigates whether this suggests that the initially promised enhancements cannot be fully realized. The paper then extends the analysis to explore the potential for improving thermal conductivity by adding carbon-based nanomaterials. The primary focus is on reinforcing high-performance polymer fibres. Both analytical and numerical modelling are employed. The results demonstrate that, for realistic carbon nanotube (CNT) contents and aspect ratios, the extraordinary strength of CNTs cannot be fully exploited in high-performance polymer fibres. However, the addition of carbon nanoplatelets (CNPs) can significantly enhance the thermal conductivity of these fibres.

1 INTRODUCTION

Since their discovery, carbon-based nanomaterials and in particular carbon nanotubes (CNTs) [1], have been extensively studied as a reinforcement to develop composites with superior mechanical, thermal and electrical properties due to their exceptional properties [2]. However, despite their strength (~100 GPa) which is an order of magnitude greater than the strongest carbon fibre (~7 GPa), the initial expectations have not been realised [3]. Weak interfacial adhesion to the polymer matrix, agglomeration, and random orientation are some of the limiting factors [3]. A key parameter to better utilize the intrinsic properties of CNTs is to orient them along the loading axis for example by applying an electric field [4]. An alternative method is to align the CNTs during polymer processing, for example by fibre spinning [5]. In this way, polymer fibres reinforced with CNTs can be produced, with the promise of achieving superior properties [5,6]. However, while some improvement in mechanical properties is observed, none of these reinforced fibres exhibit mechanical performance comparable to that of commercial high-performance fibres.

Carbon-based nanomaterials can also be used to enhance other properties, such as the thermal conductivity of polymers or polymer fibres, due to their exceptional thermal conductivity. For example, graphene nanoplatelets (GNPs) have a thermal conductivity ranging from 1000 to 5300 $W \cdot m^{-1} \cdot K^{-1}$ [7]. Siginifcant imrpovements in thermal conductivity have been reported for a range ogf polymers. For example with 10 wt % GNPs in polyvinyl alcohol matrix, an increase in thermal conductivity of about 1800% has been reported [8].

Based on the above, it appears that carbon-based nanomaterials have a strong positive effect on enhancing the thermal properties of polymers, whereas their effect on improving mechanical properties is generally insignificant. Even in cases where a significant increase in the strength of polymer fibres is

reported, there remains the question of whether this improvement is an indirect effect resulting from a modification of the polymer matrix by the nanofiller [9].

The paper, therefore, focuses on polymer fibres and aims to address whether carbon-based nanomaterials can, even in theory, effectively reinforce such fibres in terms of strength. In parallel, it seeks to determine the maximum limits of thermal conductivity that can be achieved. CNTs will be used to address the first part of the question, and GNPs the second. Analytical and numerical models will be employed, assuming that the carbon-based nanomaterials are perfectly aligned and homogeneously dispersed within the polymer fibre.

2 MODEL DESCRIPTION

In this section, the models used in the present paper are briefly presented.

2.1 Analytical modelling of mechanical behaviour

A large number of analytical micromechanical models exist for analysing the mechanical response of aligned single-fibre composites. In the present work, the model developed by Sørensen [10], originally developed to study debonding initiation and growth from a fibre break for an infinitely long fibre, is employed (see Fig. 1). This model accounts for interface debonding, sliding due to friction, and residual stresses. Previous work has shown that modelling a single fibre (CNT) yields results similar to those obtained for multiple aligned CNTs embedded in a polymer fibre [9].

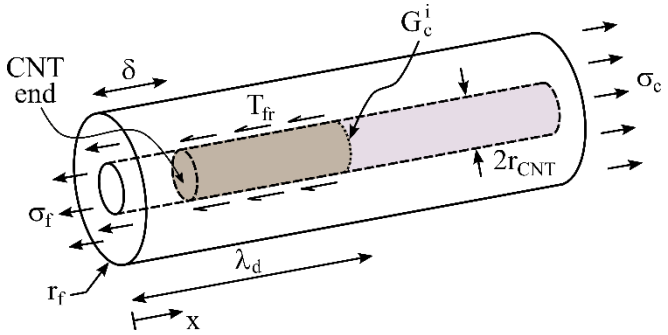

Figure 1: A single aligned CNT in a polymer fibre.

In Fig. 1, σ_c is the applied stress in the CNT reinforced polymer fibre. When σ_c reaches a critical value, σ_c^i, interface debonding initiates from the CNT end (at $x = 0$ in Fig.1). The debonding initiation stress is given by [10]:

$$\frac{\sigma_c^i}{E_c} = \frac{(1 - V_{CNT})E_f}{E_c}\Delta\epsilon^T + 2\sqrt{\frac{(1 - V_{CNT})E_f}{E_c}\left(\frac{G_c^i}{E_{CNT}\, r_{CNT}}\right)} \tag{1}$$

where E_c is the Young's modulus of the CNT-reinforced polymer fibre and E_f the Young's modulus of the polymer fibre itself. r_{CNT} is the radius of the CNT and V_{CNT} the CNT volume fraction. $\Delta\epsilon^T$ is the misfit strain. G_c^i is the mode II (shear) fracture energy and influences σ_c^i. Assuming a linear softening traction separation cohesive law, the maximum interface peak traction is:

$$\hat{T} = 0.5\, G_c^i\, \delta \tag{2}$$

where δ is the critical tangential interface separation. The frictional stress, T_{fr}, results in an increase of the applied stress, σ_c, as the debond length, λ_d, increases [10]:

$$\frac{\sigma_c}{E_c} = \frac{\sigma_c^i}{E_c} + 2\left(\frac{T_{fr}}{E_{CNT}}\right)\left(\frac{\lambda_d}{r_{CNT}}\right) \tag{3}$$

where E_{CNT} is the Young's modulus of the CNT. The debond length is given by [10]:

$$\frac{\lambda_d}{r_{CNT}} = \frac{E_{CNT}}{2\,T_{fr}}\left(\frac{\sigma_c}{E_c} - \frac{(1-V_{CNT})E_f}{E_c}\Delta\epsilon^T\right) - \frac{E_{CNT}}{T_{fr}}\sqrt{\frac{(1-V_{CNT})E_f}{E_c}\left(\frac{G_c^i}{E_{CNT}r_{CNT}}\right)} \tag{4}$$

2.2 Finite element modelling of thermal behaviour

As mentioned in the previous Section, the thermal conductivity enhancement of the polymer fibres is examined using graphene nanoplatelets (GNPs) with in-plane dimensions λ_x and λ_y, and out-of-plane thickness λ_z. The GNPs are assumed to be perfectly aligned along the y-axis, forming a regular staggered 3D array within the polymer fibre, as shown in Fig. 2. The Representative Volume Element (RVE), highlighted in Fig. 2, is used to evaluate the effective conductivity of the GNP-reinforced polymer fibres.

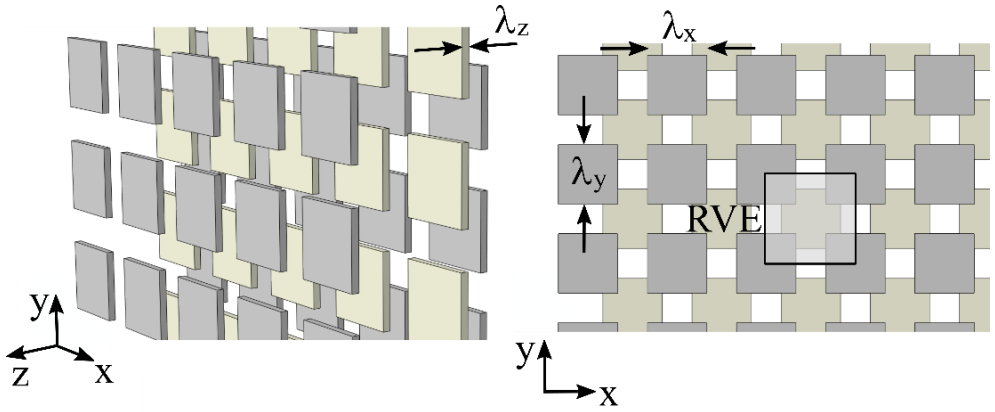

Figure 2: Representative Volume Element (RVE) of a polymer fibre containing CNPs.

The RVE shown in Fig. 2 is analysed using the commercial finite element software Abaqus. It should be noted that, within the RVE, the outer GNPs have a thickness of $\lambda_z/2$. Periodic boundary conditions are applied using the Micromechanics Plugin for Abaqus. The effective thermal conductivity is calculated in all three principal directions.

3 RESULTS: MECHANICAL PERFORMANCE OF CNT-REINFORCED FIBRES

Fig. 3 shows the debonding initiation stress, σ_c^i, as function of the polymer fibre's Young's modulus, and the interface peak traction for 10% CNT volume fraction. Assuming zero interfacial frictional stresses are zero, σ_c^i corresponds to the strength, σ_f^u of the CNT-reinforced polymer fibres. These strength values can then be directly compared with the superimposed strengths of various commercial high-performance polymer fibres. The CNT Young's modulus was assumed to be 1 TPa.

If we consider the Spectra 900 fibre with σ_f^u equal to 2.1 GPa, then an interface peak traction greater than 110 MPa is required to increase the strength from 2.1 to 3 GPa (a 30% increase). However, this interface peak traction exceeds the shear strength of the fibre itself. Similar results are observed also for the Zylon HM fibre. To achieve a strength increase of approximately 30%, the interface peak traction must exceed 125 MPa. It may be added that for a CNT volume fraction of 1%, achieving a fibre strength of 3 GPa for Spectra 900 would require an interface peak traction of 200 MPa (results not shown). However, for the Zylon HM fibre, a slightly lower interface peak traction (75 MPa) is required to achieve a strength increase of about 30%. This value is still relatively high compared to the shear strength of high-performance polymer fibres.

The results above assume, as previously mentioned, the absence of frictional stresses, and therefore can be considered a lower-bound estimate of the strength of CNT-reinforced polymer fibres. Next, in Fig. 4 the effect frictional stresses is considered (Eqs. 3 and 4). It can be seen that the applied stress increases linearly with the debond length after debonding has initiated. It is assumed that the debond length increases in a stable manner; therefore, the applied stress at which the CNT is fully debonded provides an estimate of the strength of the CNT-reinforced polymer fibre.

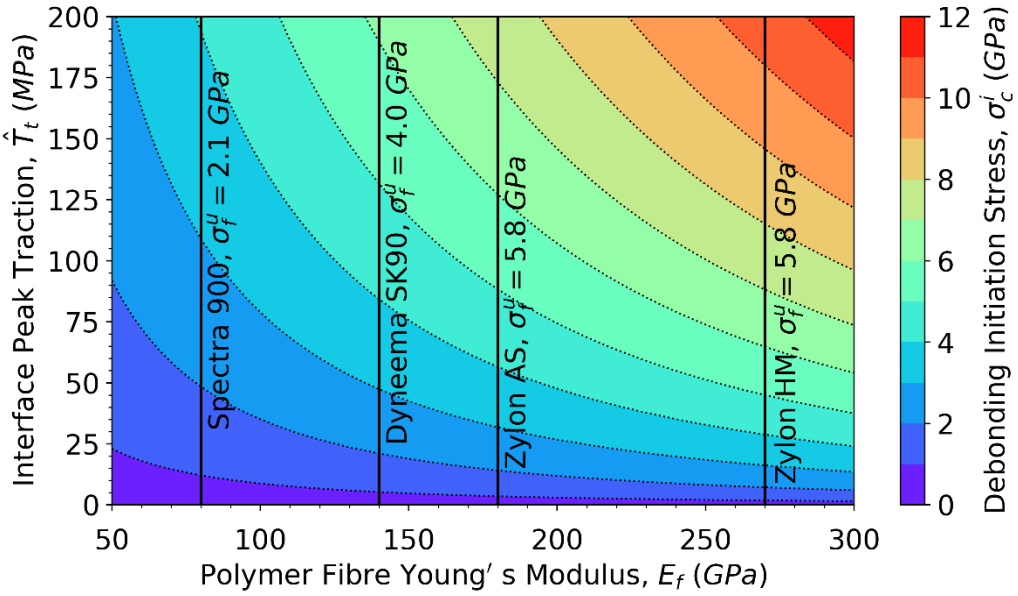

Figure 3: Debonding initiation stress, σ_c^i, as a function of the polymer fibre Young's modulus, E_f, and the interface peak traction, $\hat{T}$. V_{CNT}=10%, δ=5 nm, T_{fr}=0.

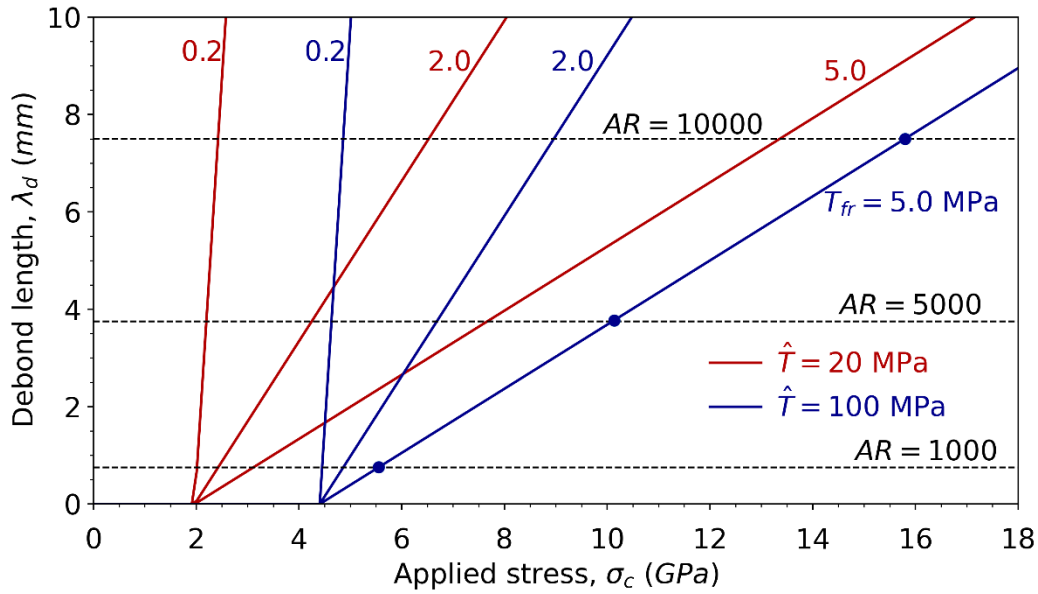

Figure 4: Debond length, λ_d, as a function of the applied stress, σ_c, for different interface frictional stresses, T_{fr}. V_{CNT}=10%, δ=5 nm. The dashed lines show when the CNT becomes fully debonded for the corresponding aspect ratio.

In Fig. 4, the debond length is plotted against the applied stress for two different interface peak tractions (20 and 100 MPa). As expected, a higher peak traction delays the onset of debonding. Afterwards, the debond length increases linearly with applied stress. Fig. 4 also presents results for three different values of interfacial frictional stress: 0.2, 2, and 5 MPa. If we consider the case of $\hat{T}$ =100 MPa and an interface frictional stress equal to 5 MPa, the strength of the CNT-reinforced fibre is approximately 5.5 GPa - an increase of about 20% compared to the stress at debonding initiation. This result corresponds to CNTs with an aspect ratio (AR) of 1000. If the aspect ratio is 5000, the strength of the CNT-reinforced fibre increases to approximately 10.1 GPa, representing an increase of about 55%. Finally, for an aspect ratio of 10000, the strength reaches 15.8 GPa - an increase of more than 70% compared to the debonding initiation stress. It should be noted that these significant increases in strength

require a high interfacial frictional stress. As shown in Fig. 4, if the frictional stress is 0.2 MPa, then the fibre strength for a CNT aspect ratio of 10000 is approximately 4.9 GPa, corresponding to an increase of only about 8% compared to the debonding initiation stress.

4 RESULTS: THERMAL PERFORMANCE OF CNP-REINFORCED FIBRES

In this section, the results for thermal conductivity of the polymer fibre reinforced with GNPs (Graphene Nanoplatelets) are presented. In Fig. 5, the principal thermal conductivity of the GNP-reinforced polymer fibres is plotted as a function of the GNPs' in-plane conductivity and the axial conductivity of the polymer fibres. Typical values for some commercial high-performance fibres (also used in the previous section on mechanical response) are 5–10 W/m·K for Dyneema fibres [11] and approximately 13 W/m·K for Zylon fibres [12]. It is worth mentioning that the thermal conductivity of isotropic (bulk, unaligned) polyethylene is around 0.3 to 0.5 W/m·K [13]. The GNP volume fraction is set to 1%. The in-plane thermal conductivity of the GNPs varies from 0 to 5000 W/m·K, with 5000 W/m·K likely representing the upper limit [14]. For practical applications, values on the order of 1700 to 2000 W/m·K are more realistic [15].

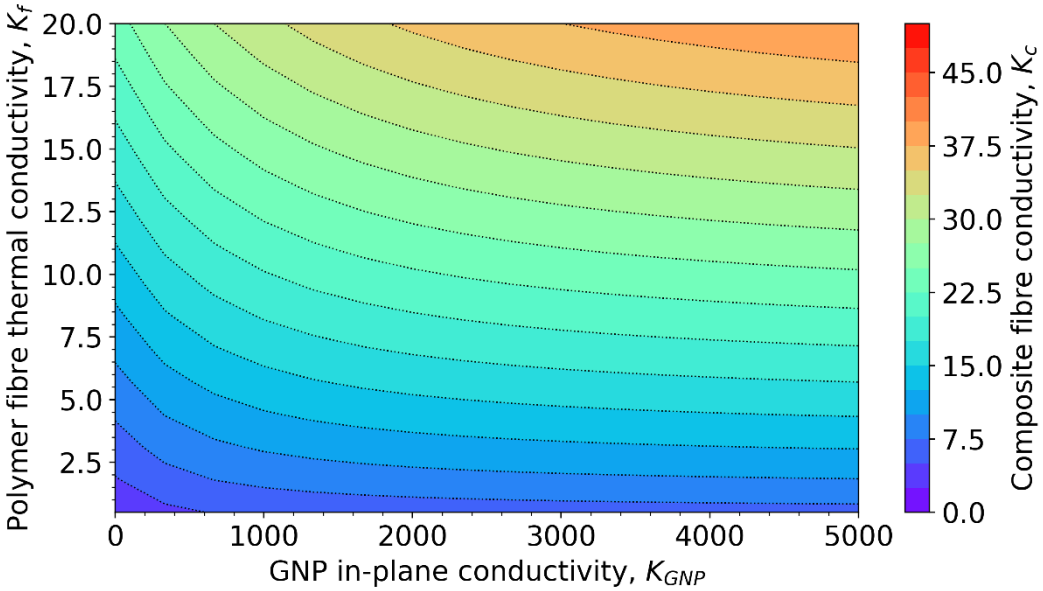

Figure 5: Principal thermal conductivity of the GNP-reinforced polymer fibre, K_c, as a function of the GNP in-plane thermal conductivity, K_{GNP} and the axial polymer fibre thermal conductivity, K_f. $V_{GNP} = 1\%$ and the aspect ratio $AR = \lambda_y/\lambda_z$=500 with $\lambda_x = \lambda_y$. The thermal conductivity is given in W/m·K.

If we consider Dyneema or Spectra polymer fibres with a thermal conductivity of 9.6 W/m·K and add 1% by volume of GNPs, the thermal conductivity of the composite fibre reaches 18 W/m·K when the conductivity of the GNP is 1750 W/m·K. If the conductivity of the GNP is 5000 W/m·K, then the conductivity of the composite fibre becomes 22.1 W/m·K. In the first case, the conductivity of the Dyneema or Spectra polymer fibres increases by approximately 1.9 times, while in the second case it increases by nearly 2.3 times. A similar trend is observed for Zylon fibres, assuming an intrinsic thermal conductivity of 13.5 W/m·K. When the in-plane thermal conductivity of the GNPs is 1750 W/m·K, the effective conductivity of the reinforced fibre increases to 22.65 W/m·K - approximately a 1.7-fold enhancement. For a GNP in-plane conductivity of 5000 W/m·K, the fibre conductivity reaches 27.61 W/m·K, representing nearly a twofold increase.

It is also interesting to consider the effect of adding GNPs to bulk isotropic polyethylene with a thermal conductivity of 0.5 W/m·K. Adding 1% by volume of GNPs with a thermal conductivity of 1750 W/m·K results in composite fibres with a conductivity of 4.6 W/m·K (more than a 9-fold increase). Adding GNPs with a thermal conductivity of 5000 W/m·K produces composite fibres with a thermal

conductivity of 6.2 W/m·K (approximately a 12-fold increase). Therefore, GNPs have a more pronounced impact when the base polymer fibre has a lower thermal conductivity..

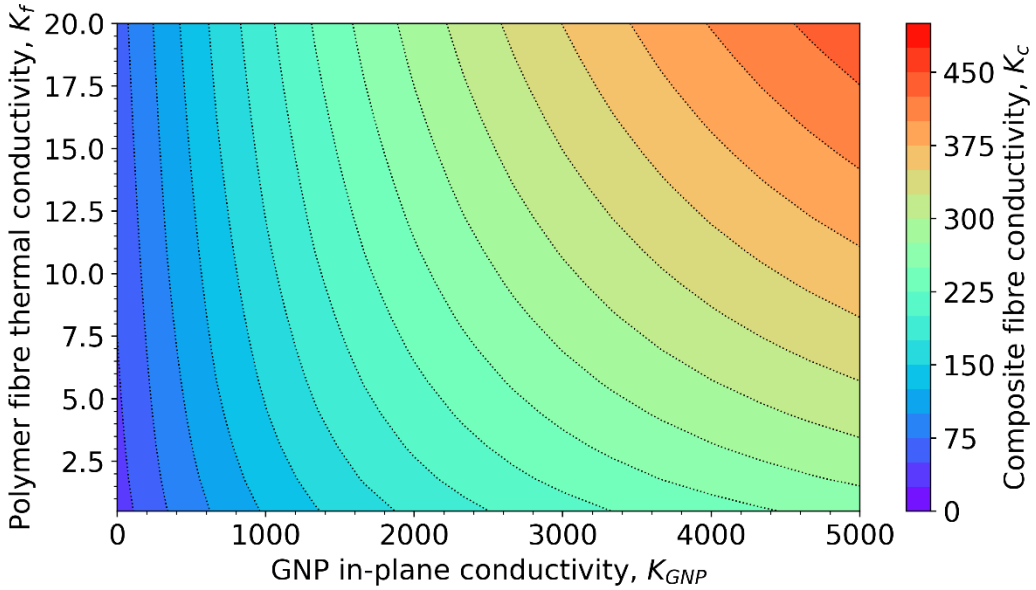

Figure 6: Principal thermal conductivity of the GNP-reinforced polymer fibre, K_c, as a function of the GNP in-plane thermal conductivity, K_{GNP} and the axial polymer fibre thermal conductivity, K_f. $V_{GNP} = 10\%$ and the aspect ratio $AR = \lambda_y/\lambda_z$=500 with $\lambda_x = \lambda_y$. The thermal conductivity is given in W/m·K.

Fig. 6 is similar to the previous figure, but with V_{GNP} increased to 10%. It can be seen that for Dyneema or Spectra fibres with a thermal conductivity of 9.6 W/m·K, the resulting composite fibre has a thermal conductivity of 135 W/m·K (14 times higher) when the GNPs have a thermal conductivity of 1750 W/m·K. For a Zylon fibre and assuming that K_{GNP} is 1750 W/m·K, the composite fibres have a thermal conductivity of 144 W/m·K (10 times higher). The trends are similar to those described for the case where V_{GNP} equals 1%, but the thermal conductivities obtained for the reinforced fibres are now much higher. In all cases, the enhancement of thermal conductivity is greater when the starting polymer fibre has a lower thermal conductivity.

It should be noted that higher thermal conductivities can be obtained, for example, by increasing the aspect ratio whilst maintaining the same GNP volume fraction. In the present work, we have chosen to use the simplest staggered 3D distribution of GNPs and have fixed the aspect ratio, whilst also using $\lambda_x = \lambda_y$.

5 CONCLUSIONS

In the present work, the effect of reinforcing high-performance polymer fibres with carbon-based nanomaterials was investigated using simulations, with the aim of determining whether carbon-based nanomaterials can enhance the mechanical and thermal properties of the fibres.

It was shown that several conditions must be met simultaneously, such as exceptional aspect ratio of CNTs, substantial frictional stresses, and significant volume content of CNTs, in order to achieve an increase of several times (3-4 times) in the polymer fibre strength.

On the other hand, it was shown that adding only small amounts (1% by volume) of GNPs increases the thermal conductivity of polymer fibres by a factor of 2. Increasing the content of GNPs to 10% results in an increase by a factor of 15 for Dyneema fibres, using a typical thermal conductivity of 1750 W/m·K for the GNPs.

Therefore, it can be argued that carbon-based nanomaterials are promising materials for enhancing the thermal properties of polymer fibres, but not the mechanical properties.

ABSTRACT

Self-reinforced polyethylene (PE) composites offer advantages of interfacial compatibility, enhanced mechanical performance, and full recyclability potential due to their homopolymer composition. This study investigates the effect of cooling rate during composite fabrication on the mechanical and thermal properties of self-reinforced PE composites consisting of ultrahigh molecular weight polyethylene (UHMWPE) fabric and high-density polyethylene (HDPE) matrix. Composite sheets with 50 wt.% fabric content were manufactured using powder impregnation and hot compaction techniques, with cooling rates varied from 0.76 to 424.92 °C/min through controlled air cooling, cold metal block transfer, and ice immersion methods. The uniaxial quasi-static tensile testing revealed bilinear stress-strain behavior, presumably attributed to yarn de-crimping followed by the elastic behavior of the composite, with modulus values ranging from 2.2 to 3.8 GPa in the initial region and higher values (8.1 to 11.3 GPa) in the elastic region. Mechanical properties showed minimal dependence on cooling rate. Thermal analysis revealed that the melting temperature (T_m) of HDPE decreased from ~130 °C to ~126.5 °C with increasing cooling rate, following a linear correlation with logarithmic cooling rate. The total degree of crystallinity of the PE composites (i.e., the sum of crystallinity of HDPE matrix and UHMWPE fabric) decreased from ~85% to ~75% with increasing cooling rate, approaching the theoretical mixing rule value of 72.4%. These findings suggest that self-reinforced PE composites exhibit relative insensitivity to cooling rate variations in the range of 0.76 to 424.92 °C/min, which may be attributed to low interfacial strength between PE matrix and PE fabric compared to conventional fiber-reinforced composites.

1 INTRODUCTION

Self-reinforced thermoplastic composites are materials in which both the matrix and the reinforcing phase consist of the same polymer, with the benefits of interfacial compatibility, enhanced mechanical performance, and the potential for full recyclability and re-processing [1–3]. The self-reinforced polyethylene (PE) composites are also known for its lightweight, low energy cost during manufacturing, waterproof and high durability. These composites are typically manufactured by consolidating highly oriented PE fibers or films into a bulk matrix, utilizing the high crystallinity and molecular alignment of the reinforcement to achieve significantly higher tensile strength and stiffness than the isotropic PE [2,4]. During composite manufacturing, the control of thermal history is critical to maintain fiber orientation and ensuring optimal interfacial bonding between the fiber and the matrix [3,5]. It has been reported that polyether ether ketone (PEEK) matrix as a semi-crystalline thermoplastic polymer exhibited a transition from brittle to ductile performance as the cooling rate became faster [6,7]. Whether such a transition could be observed for other semi-crystalline polymer composites such as the self-reinforced PE composites is unknown. In this work, we present the

preliminary studies on the mechanical and thermal properties of self-reinforced PE composites affected by the cooling rates during manufacturing.

2 EXPERIMENTAL

2.1 Powder Impregnation

PE composite sheets were fabricated from ultrahigh molecular weight polyethylene (UHMWPE) fabric (Avient Corporation) and high-density polyethylene (HDPE) powder (Microthene FA70000, LyondellBasell), with 50 wt.% of fabrics, by powder impregnation and compression molding techniques. The UHMWPE fabrics and HDPE powders were used as received.

Two 6" × 4" (152.4 mm × 101.6 mm) pieces were cut from the plain weave UHMWPE fabric, with the cutting direction aligned parallel to the warp and weft fiber directions. The HDPE powder was poured into a 250-micron sieve and sprayed onto the mold by manually vibrating the sieve above the mold. Figure 1(a) shows the top layer of HDPE powder distributed on a piece of UHMWPE fabric. A total of three layers of powder and two layers of fabric were alternately laid up in a mold, as shown in Figure 1(b).

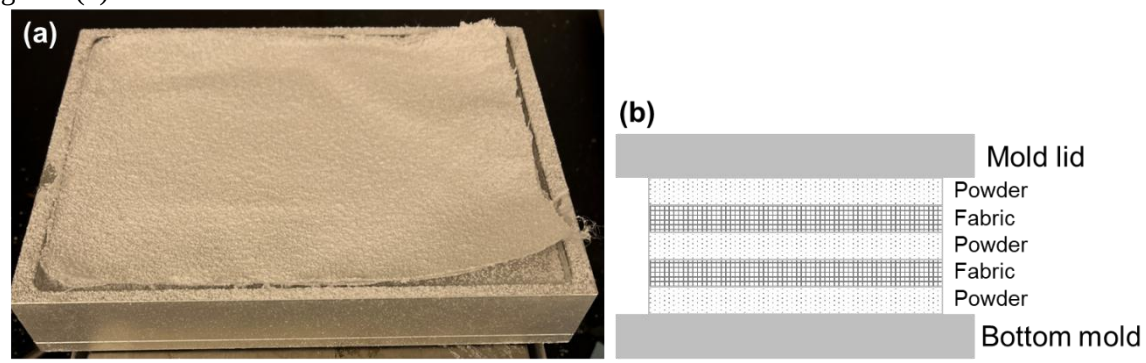

Figure 1. (a) The HDPE powder deposits on the top of, in between, and at the bottom of two UHMWPE fabrics in a mold. (b) Layup of UHMWPE fabric and HDPE powder layers in the mold.

2.2 Compression Molding with Different Cooling Rates

The mold was transferred to a hot press (Carver) pre-heated to 140 °C, and held at 1100 lbs (approximately 45.8 psi or 0.3 MPa) for 15 min on the compression molder before cooling down in place. The processing parameters were optimized in a previous study [8]. A typical temperature profile during compression molding is shown in Figure 2, where the temperature inside the mold were in between 135 °C and 140 °C for more than 10 min. The temperature range was chosen to completely melt the HDPE powder but keep the fabric intact. The compression molder was equipped with an air-cooling accessory. By adjusting the cooling air pressure, cooling rates ranging from 0.76 °C/min to 3.61 °C/min were obtained.

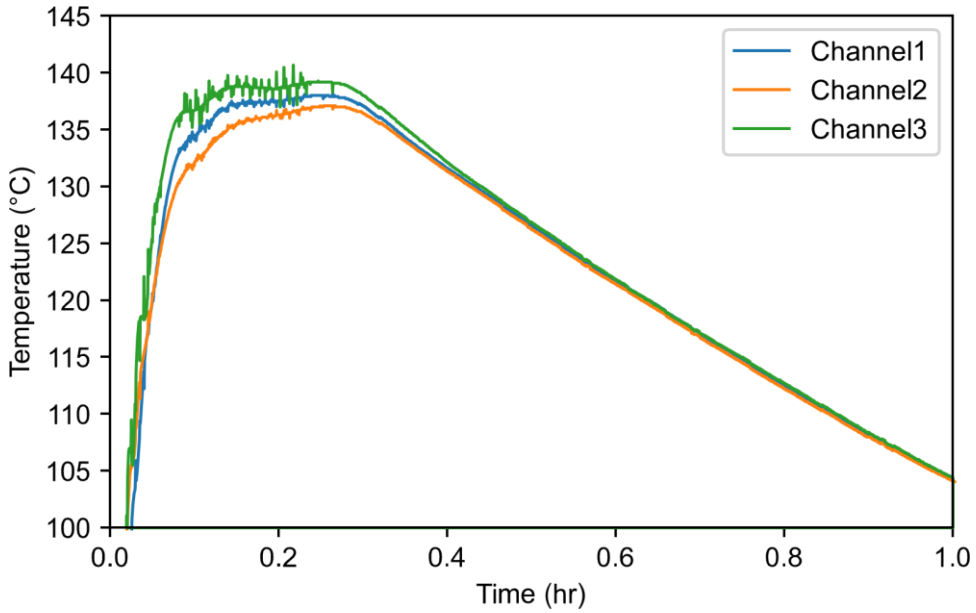

Figure 2. Temperature readings of three thermocouples placed at three different locations inside the mold, in between the composite and mold lid.

Higher cooling rates (above 50 °C/min) were achieved by transferring the mold onto cold metal blocks (Figure 3a) and into an ice bucket (Figure 3b). A second batch using the ice-immersion method was performed to achieve an even higher cooling rate up to 424.92 °C/min. The cooling rates were calculated from the initial cooling periods (e.g., above 100 °C), as listed in Table 1.

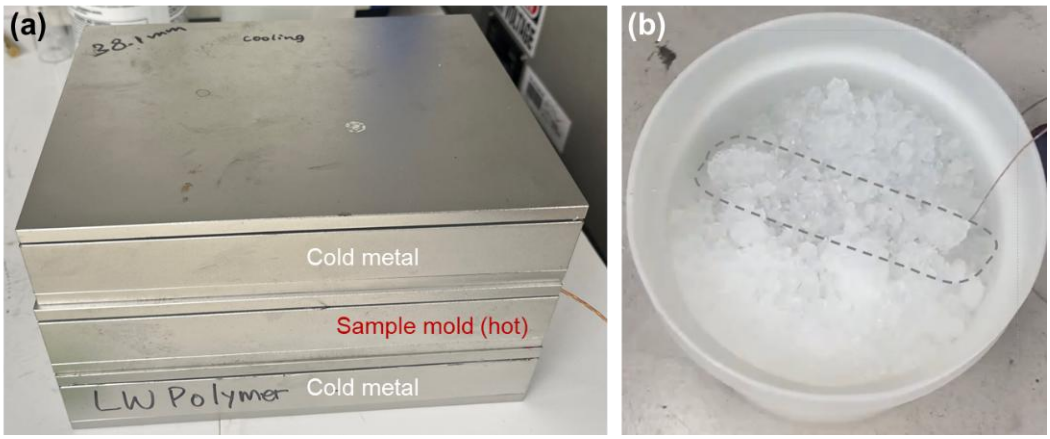

Figure 3. (a) Cooling down the mold with composite sample in between two empty metal molds initially at 25 °C. (b) A mold immersed in a bucket of ice. The grey dashed line indicates the location of the mold.

Table 1. Cooling rate at the initial cooling period using different cooling methods.

Cooling Method	Cooling Rate (°C/min)
Adjusting cooling air pressures on the compression molder	0.76
	0.80
	1.18
	3.61
Cold metal blocks	62.48
Ice immersion	167.27
	424.92

2.3 Tensile Testing

From each composite sheet, five rectangular specimens of 0.5” × 5” (12.7 mm × 127 mm) were cut along the principal fiber orientations (0°/90°). Uniaxial quasi-static tensile tests were performed at room temperature on an Instron 5582 test frame at a controlled displacement rate of 2 mm/min. The crosshead movement direction was aligned with the yarn axis. A gauge section of 2.6” (66 mm) long and full width was pre-speckled and monitored by the digital image correlation (DIC, Correlated Solutions) cameras for strain calculation.

2.4 Thermal Analysis

Melting and crystallization behaviors of as-purchased UHMWPE fabric, HDPE powder, and the composite specimens were characterized on the Differential Scanning Calorimetry (DSC, TA Instruments Q2000) in cyclic temperature ramps between 0 and 200 °C. The heating and cooling rates were 10 °C/min. The tests were performed under N_2 gas flow of 50 mL/min.

The melting point (T_m) was determined as the temperature corresponding to peak maxima of the melting peaks in the first heating cycle. The enthalpy (ΔH) was calculated as the trapezoidal area under the heat capacity curve, as shown in Figure 4. The baseline for peak area calculation was chosen to be the line connecting the 60 °C and 180 °C points. These two points were chosen as they were located on the flat portion of the heat capacity curve at each side of the peak. Degree of crystallinity (χ) was calculated as a ratio of heat of fusion (ΔH_f) measured on the endothermic peaks (during heat cycles) to the heat of fusion of 100% crystalized PE (ΔH_f^0 = 293 J/g [9]).

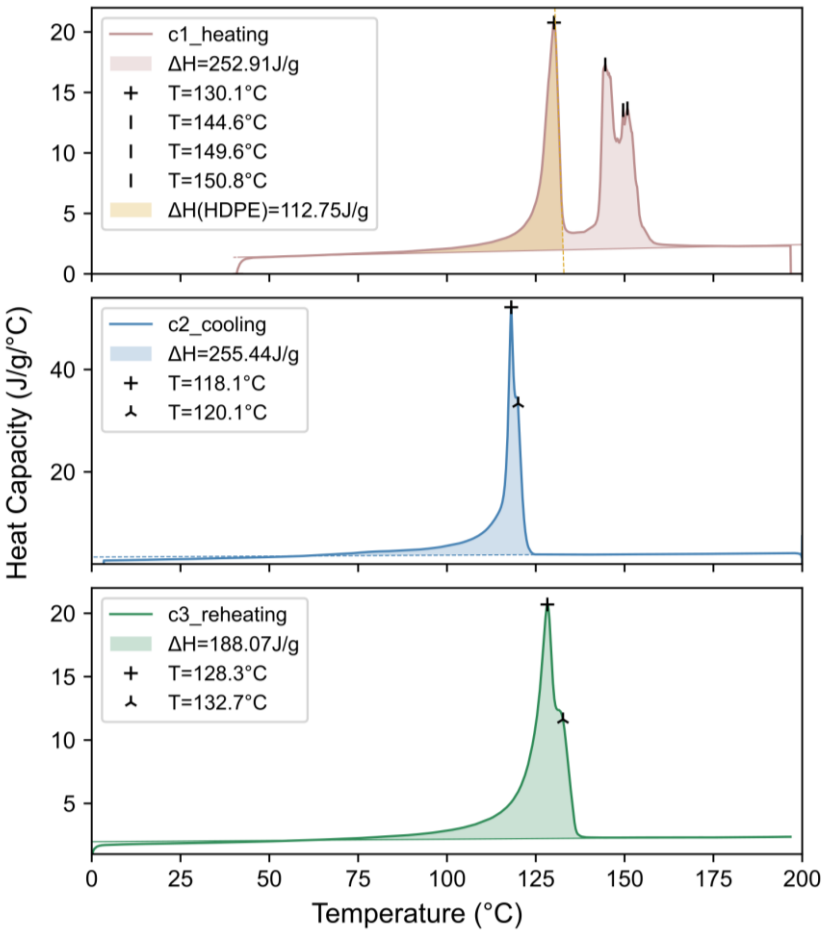

Figure 4. Heat capacity in three cycles of DSC test for a self-reinforced PE composite: c1 – initial heating from 40 to 200 °C, c2 – cooling cycle from 200 to 0 °C, c3 – re-heating from 0 to 200 °C. The shaded area represents enthalpy (ΔH). The dashed line represents the baseline for area calculation.

2.5 Microscopic Imaging

The cross-section of square samples of 0.5" × 0.5" (12.7 mm × 12.7 mm) cut from composite sheets were imaged on an Olympus DSX1000 microscope. Prior to imaging, the cross-section was first grinded using sandpapers of 180 grit, 600 grit and 1200 grit, and then polished with two pads each soaked with 3 μm and 0.5 μm polishing solution. In between the grinding and polishing steps, the surface was cleaned with soap and water, rinsed with ethanol and dried using compressed air.

3 RESULTS

3.1 Tensile Properties

Tensile properties along the longitudinal direction were obtained by uniaxial tension test. The actual strain rate as calculated from DIC strain was approximately 3×10^{-4}/s. Representative stress-strain curves are shown in Figure 5 for composites obtained at different cooling rates.

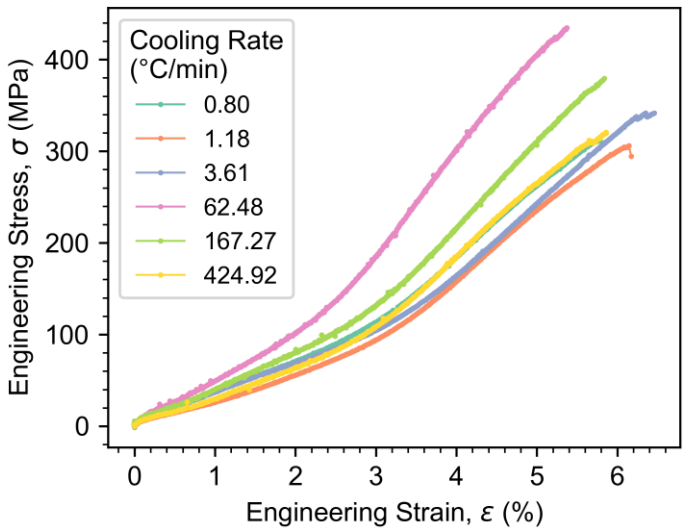

Figure 5. Engineering stress vs. engineering strain for PE composites under uniaxial tension. The strain was obtained by DIC. One curve out of five replicates was plotted for composites made at the same cooling rate.

All curves in Figure 5 showed a bilinear behavior, with the slope becoming steeper at around 2 – 3% strain. Opposite to the typical stress-strain behavior of polymers, the transition at around 2 – 3% strain was not a yield point but the onset of a hardening region. For a single yarn detached from woven fabric, a small toe region within 1% strain was associated with fiber de-crimping, i.e., straightening and realigning of the yarn, where the stress almost did not increase and the modulus was near-zero [10,11]. It was assumed that the initial linear region (below 2 – 3 % strain and 100 MPa) observed for PE composites in Figure 5 was a result of de-crimping of yarns in the specimen. The modulus of the initial linear region ranged from 2.2 to 3.8 GPa, much higher than the modulus of pure HDPE (0.8 GPa), suggesting that a portion of yarns had contributed to the stiffness of the composite while other yarns were not fully straightened. The second linear region (beyond 3% strain) corresponds to the elastic behavior of the composites. The modulus of the composite was calculated from the second linear region.

The modulus, tensile strength and ultimate elongation were plotted as a function of cooling rate as shown in Figure 6. The mechanical properties did not show a significant dependence on the cooling rate. The largest differences were observed when the cooling rate increased from 3.61 °C/min to 62.48 °C/min, where the average strength and modulus increased by 57.74 MPa (16%) and 3.15 GPa (39%) respectively. The strength and modulus slightly decreased with cooling rates above 62.48 °C/min. Several factors may explain why mechanical properties remain unaffected by cooling rate: (1) the crystal morphology and crystal size of self-reinforced PE composites were not affected by cooling

rates in the investigated range, though effects might become apparent at lower cooling rates; (2) the interfacial strength between PE matrix and PE fabric (0.5 – 2 MPa) was low, compared to carbon fiber(CF)/epoxy matrix (60 – 100 MPa) or CF/PEEK (30 – 50 MPa).

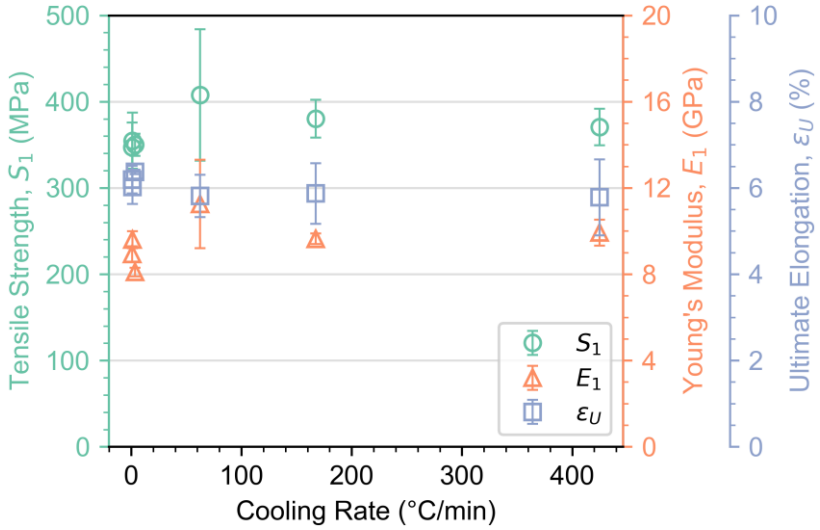

Figure 6. Tensile strength and modulus of the UHMWPE/HDPE composites as a function of cooling rate.

3.2 Microscopic Morphology

Figure 7(a) showed the micrographs of the as-received fabric, confirming a plain weave architecture. Warp yarns can be clearly observed from the cross-sectional images of the PE composites, as exemplified in Figure 7(b). The presence of crimped yarns supports the hypothesis that yarn de-crimpling was associated with the low-stiffness initial linear region on the stress-strain curve.

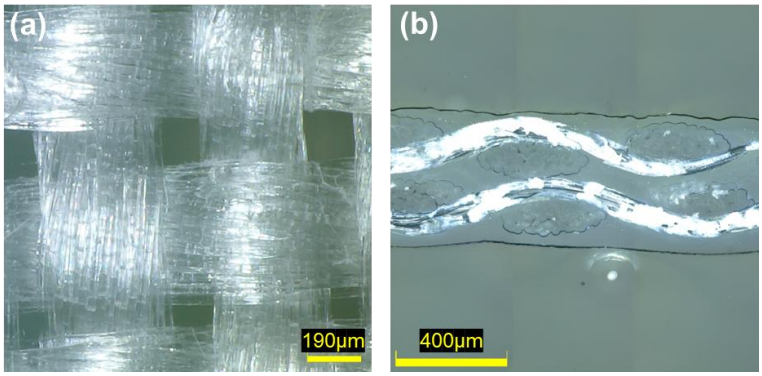

Figure 7. Microscopic images of (a) UHMWPE woven fabric as received, (b) cross-section of the self-reinforced PE composite cooled down at 167.27 °C/min.

3.3 Thermal Properties

It is well-established that thermal properties of semi-crystalline polymers are affected by cooling rates [12,13]. From the DSC signals as exemplified in Figure 4, the HDPE matrix and UHMWPE fabric in the PE composite showed separate endothermic peaks in the initial heating cycle, but these peaks collapsed into one peak with a shoulder in the re-heating cycle, since the effects of processing histories specifically the cooling rates on thermal properties of composites were erased by annealing the samples at 200 °C, i.e., the PE crystals had melted and re-crystalized. Therefore, thermal properties, including the T_m of HDPE and χ of the composites, were determined from the first heating cycle.

The heat capacity signals in the first heating cycle were plotted in Figure 8 for one representative sample of the three replicates of the PE composites made at the same cooling rate. Two melting peaks were visible: the melting of HDPE located between 126 °C to 130 °C, and the melting of UHMWPE located above 140 °C. The UHMWPE peak was a convolution of multiple split peaks, which is a signature for highly-oriented UHMWPE fibers with draw ratios typically above 50. The split peaks correspond to transitions of different crystal phases, such as transition from orthorhombic into hexagonal crystals [14].

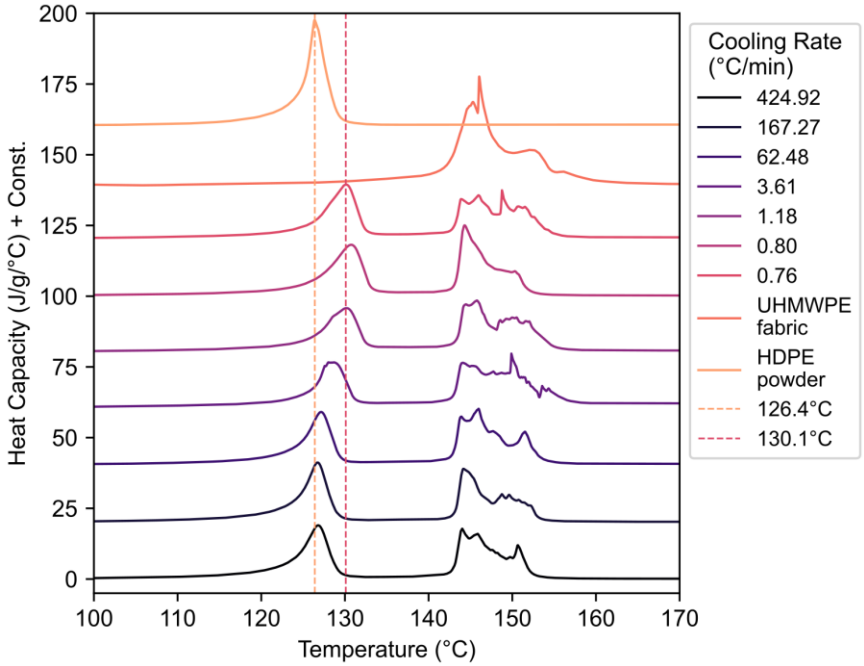

Figure 8. Heat capacity during the initial heating ramp of PE composites manufactured with difference cooling rates, and the as-received HDPE powder and UHMWPE fabric samples. One out of three replicates were plotted. The curves were vertically shifted for clarity.

As shown in Figure 8, the melting peaks of UHMWPE in the composite were not affected by cooling rate, which was expected considering that the manufacturing temperature of the composites (140 °C) was below the melt temperature of highly oriented UHMWPE crystals. However, T_m of HDPE shifted from ~130 °C to ~126.5 °C as the cooling rate increased, approaching the T_m of as-received HDPE powder. The qualitative trend was within expectation as higher cooling rates promoted formation of imperfect crystals with a lower T_m. The decrease in the T_m of HDPE was most significant when the cooling rate was slow (below 62.48 °C/min). Phenomenologically, T_m of HDPE showed a linear correlation with the log of cooling rate, as shown in Figure 9.

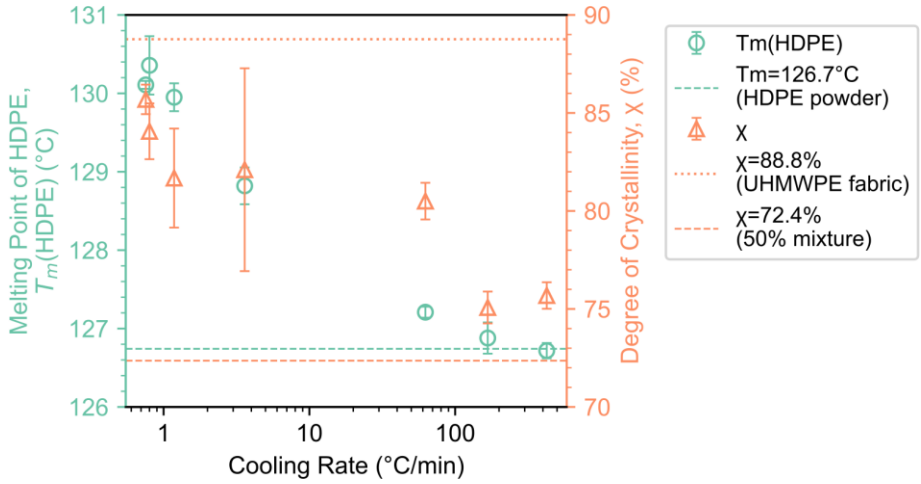

Figure 9. T_m of HDPE and the total degree of crystallinity (χ) of the UHMWPE and HDPE portions in the self-reinforced PE composites, as a function of cooling rate. The green dashed line represents the T_m of as-received HDPE powder. The orange dashed line represents the theoretical χ of composites based on the mixing rule. The dotted orange line represents the χ of as-received UHMWPE fabric.

Crystallinity of the composite (χ) was calculated based on the area under the heat capacity curve, as demonstrated in Figure 4. The χ decreased with cooling rate from ~85% to ~75%, as shown in Figure 9, approaching the average crystallinity based on the mixing rule (72.4%) for a composite consisting of 50 wt.% fabric and 50 wt.% matrix. The χ decreased most rapidly in two regions: (1) when cooling rates were below 1.2 °C/min, and (2) from 62.48 to 167.27 °C/min. In both regions the modulus of the composite showed a slight decrease, as shown in Figure 6.

4 SUMMARIES

In summary, self-reinforced PE composites were manufactured from UHMWPE fabric and HDPE matrix by powder impregnation and compression molding. The cooling rates were varied from 0.76 °C/min to 424.92 °C/min. The mechanical and thermal properties of UHMWPE/HDPE composites were not significantly affected by cooling rates. The melt temperature of HDPE matrix decreased with cooling rates and linearly correlated with the logarithmic cooling rates. The total degree of crystallinity of the composites decreased with cooling rates especially in the ranges of 0.76 – 1.18 °C/min and 62.48 – 167.27 °C/min, where the modulus also decreased slightly.

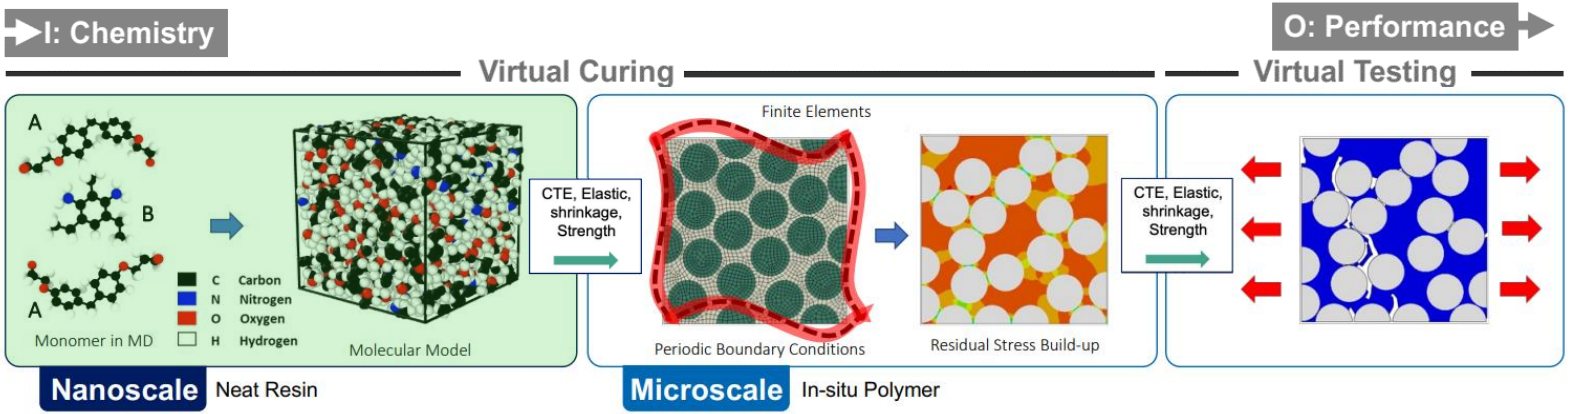
MOLECULAR MODELING OF A BISMALEIMIDE RESIN

TREVOR WAVRUNEK
MICHIGAN TECHNOLOGICAL UNIVERSITY
ADVISOR: DR. GREGORY ODEGARD

CMMR Lab™

MOTIVATION: NEXT GENERATION COMPOSITES



- Polymer-CF composites are dominant materials for high specific strength & stiffness applications
- Significant potential improvement in specific properties with polymer nanocomposites
- Multiscale simulation can significantly cut down on material design costs (ICME)

Rocket Lab Electron (2023)

The Institute for Ultra-Strong Composites by Computational Design *NASA* (2017).

ROLE OF MOLECULAR SIMULATION

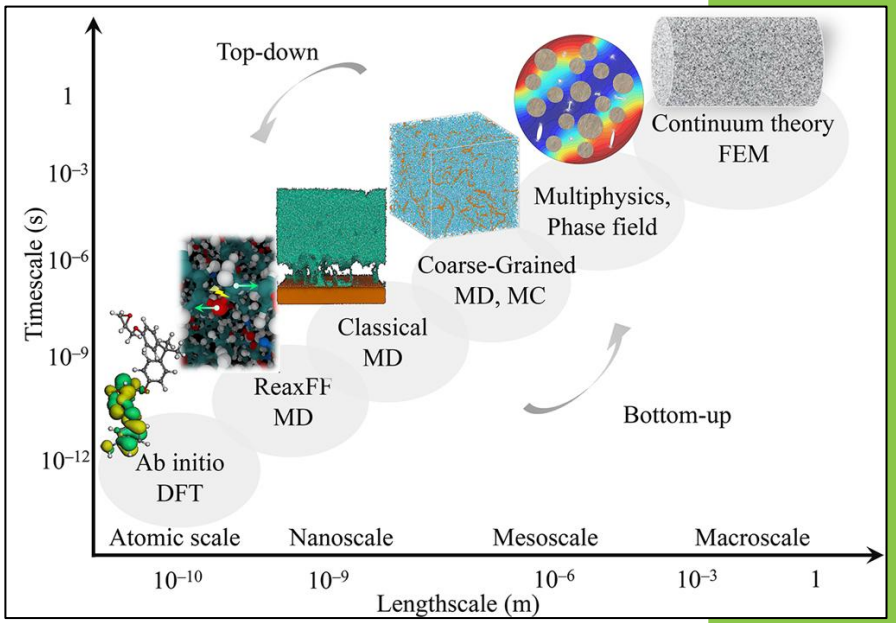
- MD directly informs residual stress buildup and cracking from chemical and thermal factors
- Experimental methods to obtain mid-cure properties are difficult or nonexistent

Shah, S. P., et. al, *Mech Adv Mater Struc* **30**, 486–497 (2021).

MOLECULAR DYNAMICS

- **Premise:**

  Atoms' dynamic behavior can be modeled using classical physics.

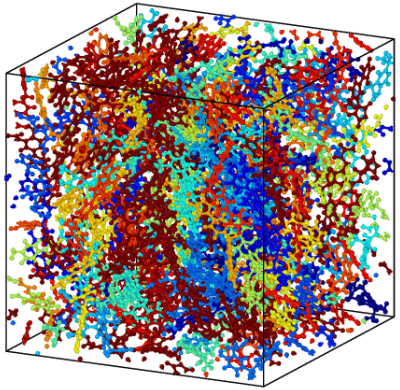


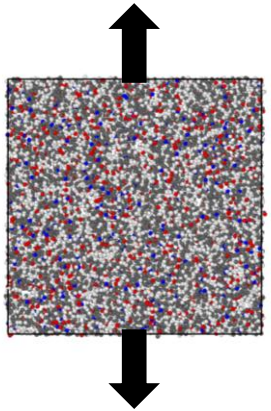
- Numerical, iterative solution of a dynamical physics problem using classical equations of motion:

$$m_i \ddot{\boldsymbol{r}}_i = \boldsymbol{f}_i = -\frac{\partial}{\partial \boldsymbol{r}_i} E_{pot}$$

$$E_{pot} = E_{bond} + E_{angle} + E_{torsion} + E_{nonbond}$$

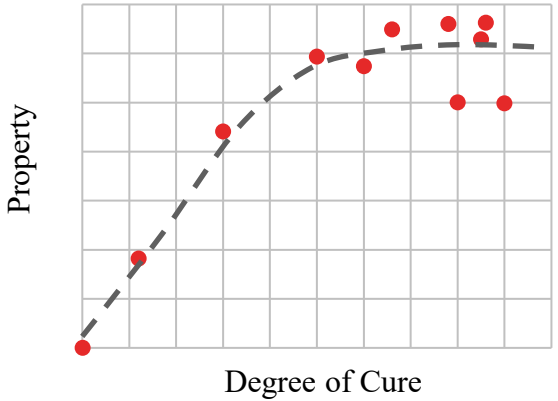
- Energies are calculated with the help of (usually) empirical forcefields





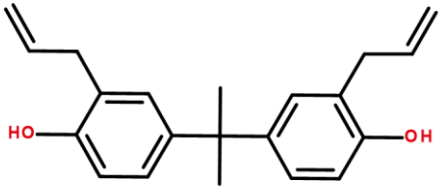
Lin, K. & Wang, Z. *Commun Mater* **4**, 1–16 (2023).
Riniker, S. *J. Chem. Inf. Model* ***15*** *565-578 (2018).*

PROJECT GOAL

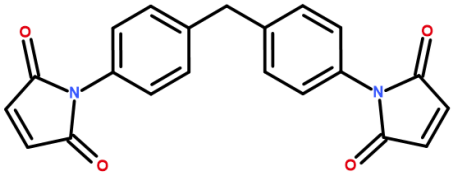


Predict the thermomechanical property evolution and polymer structure of a 3-component HP Bismaleimide resin as a function of degree of cure for use in a multi-scale model.

Virtual Polymerization



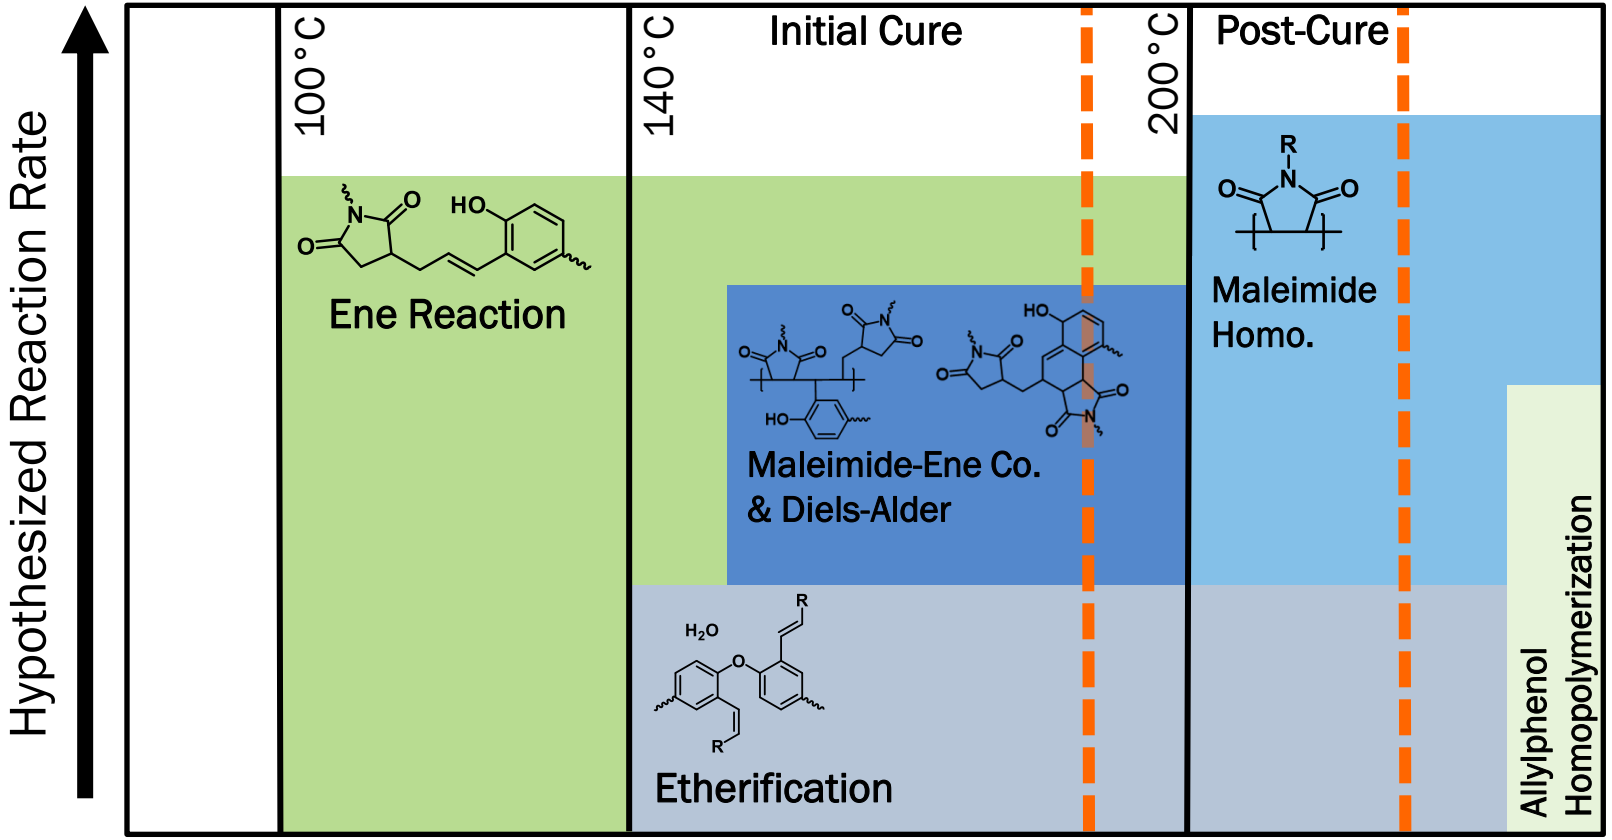
Simulated Tests



Process Insights

BISMALEIMIDE RESIN

- High-performance variant based on a classic 2-component system
  - Easily processable
  - Good adhesion to fibers
  - Great thermal properties
- Utilizes 2-stage cure:
  1. “Initial Cure”
  2. “Post Cure”



o,o’-diallylbisphenol A
(DABPA)

4,4’-Bismaleimidodiphenylmethane
(BMPM)

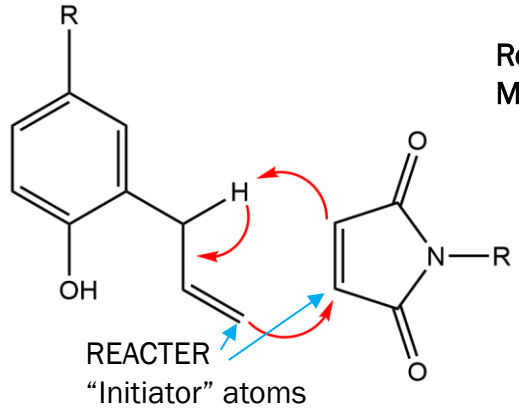
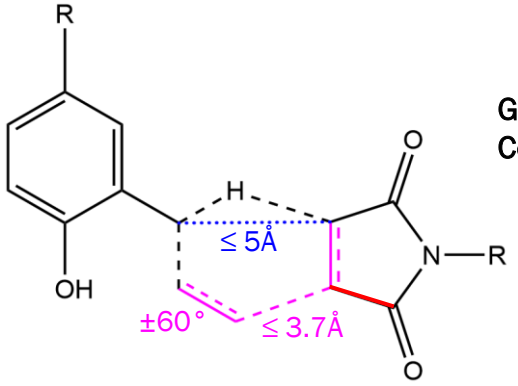
SIMULATION PARAMETERS

- x5 replicates, 15k atoms
- 2-stage polymerization with ramps
  - NVT, ρ=1.2 g/cc during production
  - Temperature +100K from resin datasheet
- Mechanical testing at 1e8 s^{-1}
  - RFR analysis, no PCFF-2xe
- Annealing simulation
  - 50 K/ns heating rate
  - Hyperbola fit + bilinear regression used



KINETIC AND GEOMETRIC PARAMETERS

- Arrhenius Equation



$$p(reaction) = Ae^{-\frac{E_a}{R(T+T')}}$$

- Pre-exponential taken as order of magnitude
- Non-constrained pre-exponential (A) and E_a tuned to match experimental data

Reaction	A $(mol\text{-}s)^{-1}$	E_a (kcal/mol)	Source
Ene	1e6	16.9	[1]

ABSTRACT

The phenomenon of *scale effect* in composite materials is defined by reduced damage onset associated with a decrease in ply thickness. This effect has garnered renewed interest with the advent of low-grammage prepregs, prompting an upsurge in research into the use of ultra-thin plies in composite laminate manufacturing. In this regard, previous studies have primarily concentrated on the effects of the use of ultra-thin plies in the case of cross-ply laminates subjected to cyclic tensile loads.

Given this context, the present experimental study explores the integration of ultra-thin plies in multidirectional CFRP composite laminates, specifically in open-hole configurations, to assess damage evolution under tension-tension fatigue. The analysis compares quasi-isotropic laminates consisting of conventional thickness plies with their equivalent versions incorporating 90º ultra-thin plies, maintaining the same stacking sequences. Additionally, two distinct stacking sequences are investigated. The primary objective is to assess the impact of 90º ultra-thin plies and their distribution through the laminate thickness on damage evolution, aiming to identify potential improvements in laminate performance.

Following quasi-static tensile characterisation, the open-hole specimens are subjected to tension-tension fatigue testing with a stress ratio of R=0.1, where the maximum stress represents a fraction of the ultimate tensile strength. Damage onset and progression during cyclic loading are monitored using ultrasonic inspection. The results demonstrate that laminates with ultra-thin plies exhibit slower damage evolution and reduced sensitivity to the presence of the open hole at equivalent load levels. Moreover, the findings underscore the critical role of stacking sequence reorganization, particularly in mitigating free-edge damage mechanisms.

These observations suggest that multidirectional laminates featuring ultra-thin plies deliver superior performance under tensile fatigue loading. The results support their potential for enhanced structural durability, reinforcing the viability of implementing ultra-thin ply technology at an industrial scale.

1 INTRODUCTION

Recent interest in understanding the so-called *scale effect* [1] has driven growing research on the use of ultra-thin plies in the fabrication of composite laminates. Several studies have examined how these plies influence the performance of cross-ply laminates subjected to cyclic tensile loading [2]. Findings consistently show that the damage mechanisms in 90° plies vary significantly depending on whether the plies are of conventional or ultra-thin thickness, with the latter delaying damage initiation and leading to a less severe onset of degradation.

Following the approach of these previous studies, the present study explores whether incorporating ultra-thin plies can enhance the mechanical response of quasi-isotropic laminates. In particular, it focuses on open-hole carbon fibre/epoxy laminates [3], comparing configurations made entirely with conventional plies to those where only the 90° plies are replaced by ultra-thin plies.

In this regard, previous investigations into open-hole quasi-isotropic specimens have primarily examined how ply thickness influences mechanical performance under quasi-static [4–7] and cyclic tensile loading [8–9]. For instance, in [9], tension–tension fatigue tests compared laminates made with thin, intermediate, and thick plies—where all plies were uniformly scaled in thickness—focusing on stiffness degradation and internal damage evolution via X-ray radiography.

In contrast, the present work adopts a different strategy. Two laminate configurations with identical stacking sequences were designed: one composed entirely of conventional plies, and another where only the 90° plies were substituted with ultra-thin plies. Both configurations were tested using two distinct stacking sequences, ensuring identical proportions of 0°, ±45°, and 90° orientations. Following specimen fabrication, cyclic tensile tests were performed on open-hole samples to assess how 90° ply thickness and placement influence damage initiation and growth, especially around the hole. To track damage progression, non-destructive ultrasonic inspections were carried out at predefined cycle intervals, enabling a direct comparison of the four laminate designs and potential performance gains.

The paper is organised into four main parts. Section 2 outlines the manufacturing process of the open-hole specimens. Section 3 details the experimental methodology, including the procedures and results for static and cyclic tensile testing as well as damage assessment. Finally, Section 4 presents the key conclusions and discusses potential directions for future research.

2 MANUFACTURING PROCESS

The open-hole tensile specimens used in this experimental programme were designed in accordance with the specifications provided in [10]. The central hole, located at the midpoint of both the specimen's length and width, was drilled and reamed following the recommendations of the standard to minimise any risk of damage in its vicinity. Since the presence of the hole generates an adequate stress concentration to induce failure, no additional tabs were employed.

Two stacking sequences were selected: $[+45/-45/0/90]_{2s}$, as recommended by the standard [10], and $[+45/90/-45/0]_{2s}$. For each stacking sequence, two laminate configurations were fabricated. The first consisted entirely of plies with conventional thickness (150 g/m²), while the second replaced the 90° plies with ultra-thin plies (50 g/m²), keeping all remaining plies at the conventional 150 g/m² grammage. This approach enabled a direct comparison between the two configurations without increasing the total ply count or manufacturing time.

The laminates were produced using TP 402/T700SC carbon fibre/epoxy prepreg supplied by North Thin Ply Technology and were cured using a standard autoclave process. The resulting four specimen types, along with their geometric parameters—length (L), width (w), thickness (t), and hole diameter (Ø=w/6)—are summarised in Table 1.

Specimens	*L* (mm)	*w* (mm)	*ø* (mm)	*t* (mm)	Stacking sequence	90º ply grammage (g/m^2)	0° and ±45° ply grammage (g/m^2)
OH.A	200	36	6	2.7	$[+45/-45/0/90]_{2s}$	150	150
OH.B				2.2		50	
OH.C				2.6	$[+45/90/-45/0]_{2s}$	150	
OH.D				2.1		50	

Table 1: Dimensions of the specimens.

3 EXPERIMENTAL PROGRAMME

3.1 Quasi-static tests

Quasi-static tensile tests were carried out to determine the tensile strength (σ_U) of the laminates. This value represents a key parameter for defining the load levels used later in cyclic testing. The strength values were computed based on the ultimate load and the gross cross-sectional area. For each of the four laminate configurations, five specimens were tested. Testing was performed using an Instron 4483 universal testing machine equipped with a 150 kN load cell.

The results, summarised in Table 2, include the mean σ_U for all specimen types, accompanied by their standard deviation and coefficient of variation. Overall, laminates incorporating ultra-thin 90° plies (OH.B and OH.D) exhibited higher tensile strength compared to those made exclusively with conventional plies. Additionally, the stacking sequence $[+45/90/–45/0]_{2s}$ produced slightly higher strength values than the $[+45/–45/0/90]_{2s}$ sequence.

Specimens	Stacking sequence	σ_U (MPa)	SD (MPa)	CV (%)
OH.A	$[+45/-45/0/90]_{2s}$	387.94	7.48	1.93
OH.B		446.74	6.10	1.36
OH.C	$[+45/90/-45/0]_{2s}$	415.29	24.52	5.90
OH.D		465.36	40.69	8.74

Table 2: Tensile strength (σ_U) for all specimen types.

3.1 Cyclic tests

The tensile fatigue performance of open-hole composite specimens was assessed through tension–tension (T–T) fatigue testing, conducted at a stress ratio of R=0.1. For each specimen configuration, the tensile strength (σ_U) was first determined to establish a baseline reference. The maximum applied stress for fatigue testing corresponded to 80% of the respective tensile strength for each configuration.

Four specimens from each configuration were tested under these conditions. All experiments were performed using an Instron 8801 universal dynamic testing machine equipped with a 100 kN load cell, operating at a loading frequency of 3 Hz.

Fatigue tests were periodically interrupted at predefined intervals—specifically, after 2,500; 5,000; 10,000; 20,000; 50,000; 75,000; 100,000; 150,000; and 200,000 load cycles—to evaluate the evolution of damage. At each interruption, ultrasonic inspection was employed to monitor damage initiation and propagation, facilitating comparative assessment of the different specimen configurations. The progression of damage is depicted for representative specimens in Figures 1 and 2, with OH.A and OH.B shown in Figure 1, and OH.C and OH.D in Figure 2.

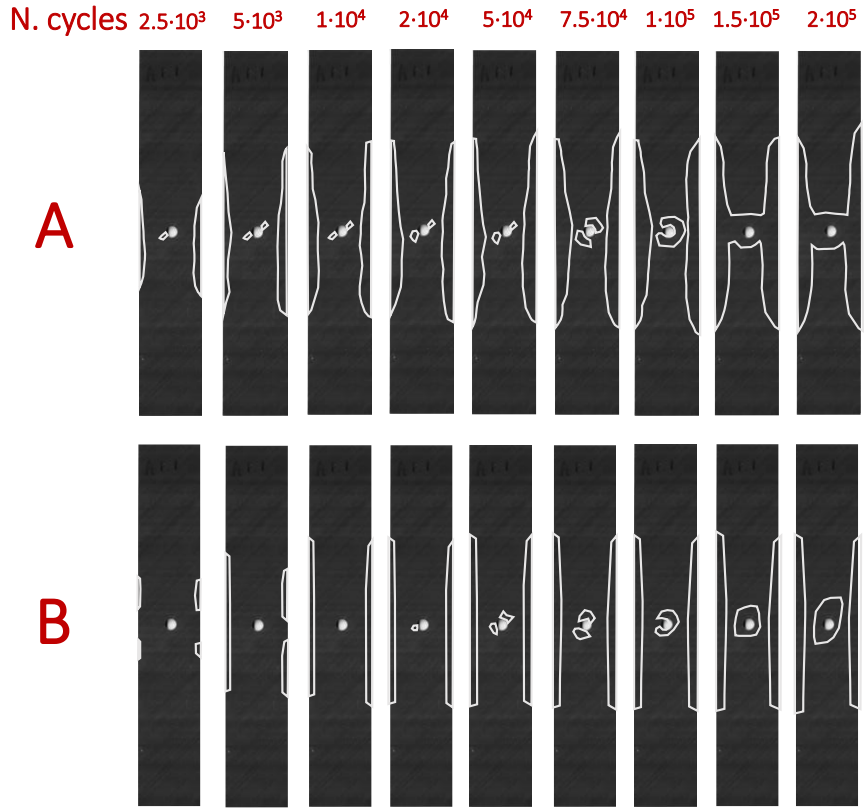

Figure 1: Evolution of the extent of damage for laminates OH.A and OH.B.

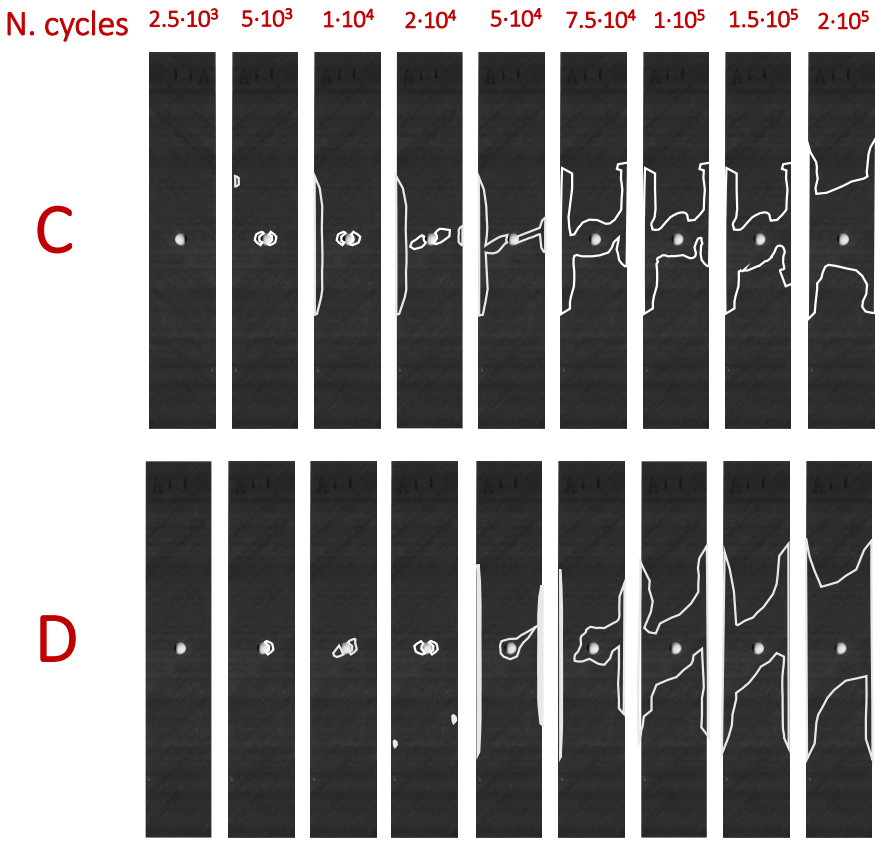

Figure 2: Evolution of the extent of damage for laminates OH.C and OH.D.

Comparative analysis of OH.A and OH.B specimens highlights the beneficial role of incorporating ultra-thin 90° plies within the $[+45/–45/0/90]_{2s}$ laminate. In OH.B specimens, free-edge damage was observed to initiate at a higher number of cycles relative to OH.A. Moreover, damage surrounding the open hole tended to manifest only after the free-edge damage had extended along the specimen free-edges, excluding the clamped regions. Consequently, the delayed onset of free-edge damage in OH.B specimens correspondingly postpones the initiation of hole-adjacent damage, effectively retarding the overall damage progression mechanism.

In the comparison shown in Figure 2 for specimens with the $[+45/90/-45/0]_{2s}$ stacking sequence (OH.C and OH.D), a delay in the initiation of free-edge damage is again observed due to the inclusion of ultra-thin 90° plies. However, this delay does not influence the overall progression of damage. Beyond approximately 100,000 load cycles, the extent of free-edge damage becomes nearly identical in both specimen types. Furthermore, unlike the behaviour noted for the $[+45/90/-45/0]_{2s}$ laminate, the delayed free-edge damage does not coincide with a postponed onset of damage around the hole. Consequently, the free-edge and open-hole damage mechanisms appear to evolve independently.

4 CONCLUSIONS

The experimental results indicate that substituting conventional 90° plies with ultra-thin plies in quasi-isotropic open-hole laminates enhances tensile fatigue performance for the $[+45/–45/0/90]_{2s}$ configuration. The use of ultra-thin plies delays the progression of the damage mechanisms, highlighting their potential as a design feature for improving fatigue life. These findings underscore the suitability of ultra-thin 90° plies for quasi-isotropic laminates subjected to cyclic tensile loading and support their potential adoption in industrial applications.

In contrast, this benefit is not evident for the $[+45/90/-45/0]_{2s}$ configuration. Although the initiation of free-edge and open-hole damage is postponed by incorporating ultra-thin 90° plies, the overall damage levels in both laminate types converge after extended cycling.

Future work will focus on refining the understanding of damage evolution in quasi-isotropic open-hole laminates through advanced inspection methods capable of resolving through-thickness damage localization. Such approaches will help clarify the contribution of ultra-thin plies to damage progression. Additionally, numerical modelling will be employed to optimise laminate design strategies incorporating ultra-thin plies.

Keywords: 3D woven composite; sandwich panels; flexural performance; impact properties; damage analysis.

ABSTRACT

Metal-faced sandwich panels with solid composite cores are increasingly used in structural applications due to their high strength-to-weight ratio, excellent fatigue resistance, stiffness, and superior impact tolerance. These characteristics make them ideal for demanding environments in aerospace, automotive, and defence sectors. However, conventional sandwich structures are often limited by core materials that lack sufficient delamination resistance and fail to distribute loads efficiently under extreme conditions. This study investigates the mechanical enhancement of fibre metal laminate (FML) sandwich panels by incorporating 3D-woven fabric-reinforced composite cores. Three weave architectures—3D orthogonal, 3D angle-interlock, and 3D warp-interlock—were explored across three stuffer-to-binder yarn ratios: 1:2, 1:1, and 2:1. Flexural testing revealed that the 3D angle-interlock cores exhibited the highest load-bearing capacity due to their inclined binder yarns that engage more effectively under bending stress. In contrast, 3D orthogonal cores demonstrated superior flexural stiffness, attributed to the near-vertical alignment of binder yarns enhancing through-thickness shear resistance. Panels with higher stuffer-to-binder ratios (2:1) consistently achieved greater peak loads and deflections, indicating enhanced energy absorption due to the increased volume of in-plane stuffer yarns. Notably, the 1:2 stuffer-to-binder ratio with an orthogonal weave offered a balanced improvement in both metrics. These findings offer valuable insights for designing high-performance sandwich composites for critical applications in the aerospace and defence sectors.

1 INTRODUCTION

Metal-faced sandwich panels with solid composite cores are advanced lightweight structural materials that combine the durability and strength of metal facesheets with the tailored properties of a solid composite core [1,2]. Typically, the facesheets are made from metals such as aluminum or stainless

steel, which provide excellent flexural stiffness, damage tolerance and surface hardness. The core, on the other hand, is a homogeneous composite material—often a polymer matrix composite—that offers excellent fatigue resistance, shear strength, and energy absorption. These characteristics make these composites ideal for demanding structural applications in aerospace, automotive, and defence sectors.

A lot of literature has already been published showing excellent fatigue resistance [3–5] and impact damage tolerance [6–8] of metal-faced sandwich panels with 2D and UD cores. They exhibit exceptional fatigue resistance, as the fibre layers act to arrest and slow the growth of cracks that initiate in the metal layers, significantly extending the material's lifespan under cyclic loading. FMLs are also highly damage-tolerant, maintaining much of their structural integrity even after sustaining impact or localized damage [9]. However, the flexural performance of conventional sandwich structures can be limited by the properties of the core material, which may struggle to effectively mitigate delamination and distribute loads under extreme conditions [10–12]. Numerous studies have investigated the flexural performance of metal-faced solid core sandwich structures, particularly those with unidirectional (UD) and 2D FRP cores. Lawcock et al. [13] reported that the flexural behaviour of CARALL laminates is highly influenced by the bonding strength at the metal–composite interface, which affects interlaminar shear but not tensile strength. To enhance flexural performance, several researchers have focused on improving interfacial adhesion in FML sandwich composites [14–16]. However, in designs prioritizing flexural modulus, increasing layer thickness has been shown to reduce flexural modulus linearly, with minimal impact on flexural strength [17].

Recent advancements in 3D-woven composites have demonstrated their potential to enhance the mechanical performance of FMLs over traditional two-dimensional (2D) woven and unidirectional (UD) composites, particularly in demanding engineering applications. One of the primary benefits is their superior resistance to delamination, a common failure mode in 2D and UD composites where layers separate under flexural or impact loading. This is achieved by incorporating fibers in the through-thickness (z) direction, which greatly enhances the structural integrity and reduces the risk of layer separation. Offering improved resistance to delamination, higher energy absorption, and more efficient load transfer [18,19]

The 3D-woven preforms can also be further modified to tailor the mechanical performance of the metal-faced sandwich composite panels by varying the weave architecture and stuffer-to-binder ratio of the woven preforms. As these two parameters are critical while determining the mechanical performance of the 3D-woven composites. Varying these parameters can further help analyse the change in the impact and flexural performance of the 3D-woven core-based metal-faced sandwich composite panels.

2 MATERIAL AND METHODS

2.1 Materials

The sandwich panels used in this study incorporate three different types of 3D-woven solid composite core preforms: 3D orthogonal, 3D angle interlock, and 3D-warp interlock. All 3D core preforms are 4-layer to maintain consistency. A total of 9 core fabric preforms were fabricated, varying weave architecture and three different stuffer to binder ratios (1:2, 1:1, 2:1). The facesheets used are made of aluminium (Al-6063) with a thickness of 0.5mm. All samples were designed with identical dimensions: a core height of 2 mm and facesheet thickness of 0.5 mm. PLEXUS MA311 adhesive was used to bond the aluminium facesheets and core. The construction parameters of the core preforms are listed in Table 1. All core fabrics were fabricated using 600 tex E-glass rovings on a customized 3D rigid rapier weaving loom. A pictorial representation of the 3D orthogonal, 3D angle interlock, and 3D-warp interlock preforms is shown in Figure 1. All composite cores were consolidated using the Vacuum-Assisted Resin Transfer Moulding (VARTM) process, employing Epoxy LY556 resin and Aradur HY951 hardener.

Table 1: Construction parameters of 3D Solid Structures for core

Weave	3D orthogonal	3D angle interlock	3D warp interlock
Stuffer linear density (tex)	600	600	600
Binder linear density (Denier)	300	300	300
Filler linear density (Denier)	600	600	600
Number of stuffer layers	4	4	4
Number of filler layers	5	5	5
Stuffer + binder ends per inch	1:2 - 22 1:1 - 30 2:1 - 36	1:2 - 22 1:1 - 30 2:1 - 36	1:2 - 22 1:1 - 30 2:1 - 36
Filler ends per inch	10	10	10

2.2 Preparation of sandwich panels

The sandwich structures were assembled using a hand layup method (illustrated in Fig. 2). Prior to bonding, the aluminium surfaces were sandblasted and cleaned with ethanol to improve adhesive bonding by removing surface contaminants. A uniform pressure was applied during bonding by placing a metallic plate of known weight over the sandwich assembly to expel entrapped air and ensure even adhesive distribution. To maintain a consistent adhesive layer, jigs were used to control the bond-line thickness, particularly at the corners. After the bonding process, the sandwich panels were allowed to cure at room temperature as per the adhesive manufacturer's recommendation. Following curing, the bonded sandwich panels were cut into standard test specimens using a precision band saw cutting machine. All specimens were inspected for uniformity in geometry and absence of visible defects before further testing.

2.3 Three-point bending

The three-point bending (TPB) tests on sandwich panels are conducted according to the ASTM D7264 standard. A characteristic label was used for each specimen to facilitate the analysis. The TPB tests were carried out on sandwich beams with different core types and aluminium and composite sheets of equivalent thickness. The span-to-width ratio was kept at 16:1, and the width of the sandwich panels was kept at 20mm. The Zwick Roell Z250 UTM machine was used for the tests with a crosshead speed of 2 mm/min for all TPB tests.

The flexural strength and flexural stiffness of the sandwich composite panels were calculated using equations 1 and 2,

$$\sigma_f = \frac{3P.L}{2bd^2} \tag{1}$$

Where σ_f is the flexural strength (MPa), P is the maximum load prior to failure (N), L is the span length (mm), b and d are the sandwich width (mm) and thickness (mm), respectively.

$$D = \frac{l^2.a.\Delta P}{16 f_1} \tag{2}$$

Where, D is the flexural stiffness (N.mm^2), l is the span length (mm), a is overhanging arm length (mm), $\Delta P/f1$= slope of linear load-deformation curve (N/mm).

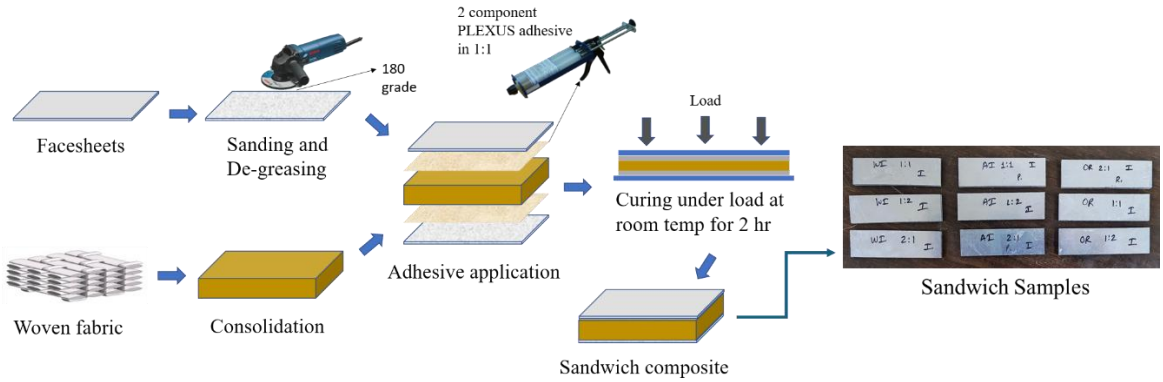

Figure 2: Sandwich preparation by Hand-layup process and final prepared 3D woven composite core sandwich panels

3 RESULTS AND DISCUSSION

3.1 Flexural Performance of Sandwich Composites

Figure 3 (a) and (b) illustrate the flexural strength and flexural stiffness, respectively, of aluminium-faced sandwich composites reinforced with 3D orthogonal, 3D angle-interlock, and 3D warp-interlock FRP cores. Each core configuration was studied at three different stuffer-to-binder yarn ratios: 1:2, 1:1, and 2:1.

From Fig. 3(a), it is evident that the 3D angle-interlock core sandwich panels consistently exhibited the highest flexural strength across all three stuffer-to-binder ratios. This was followed by the 3D orthogonal and then the 3D warp-interlock structures. The superior performance of the angle-interlock

architecture can be attributed to the orientation of its binder yarns, which are inclined rather than aligned purely in the thickness (Z) direction. This inclined arrangement enhances load transfer along the loading axis, thereby improving the panel's capacity to resist bending loads. Notably, the flexural strength increases with higher stuffer-to-binder ratios (from 1:2 to 2:1) in all three architectures, likely due to the increased volume of load-bearing stuffer yarns enhancing in-plane strength.

In contrast, the trend in flexural stiffness, as shown in Fig. 3(b), presents a different behaviour. The 3D orthogonal core sandwich panels demonstrated the highest flexural stiffness, especially prominent at the 1:2 stuffer-to-binder ratio. The orthogonal architecture benefits from binder yarns aligned nearly in the Z-direction, which enhances through-thickness stiffness and improves resistance to deformation under bending. The near-orthogonal arrangement of the binder, stuffer, and filler yarns contributes to a more integrated and rigid structure, improving shear stress transfer across the laminate. This results in a more uniform stress distribution during bending.

Interestingly, the flexural stiffness of the angle-interlock and orthogonal cores are nearly comparable at the 1:1 and 2:1 ratio, indicating that at equal or higher stuffer to binder ratios, angled binders can achieve stiffness close to that of orthogonal binders as the collective binder effect reduces per unit area. However, for the 1:2 ratio, the 3D orthogonal cores outperform the other two, while the warp-interlock configuration consistently shows the lowest flexural strength and stiffness in both graphs. This can be linked to the limited number of through-thickness binders in the warp-interlock design, which reduces the panel's resistance to both bending and shear deformation.

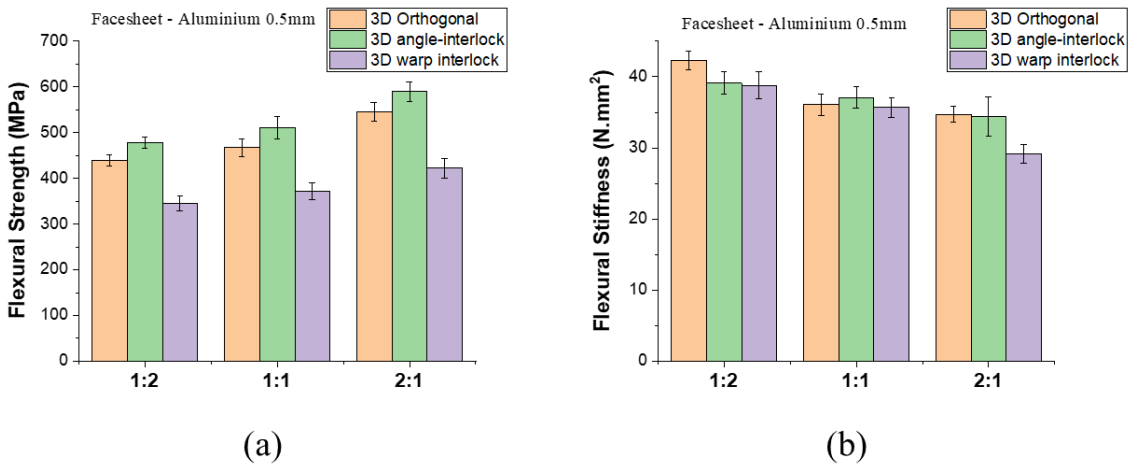

Figure 3: (a) Flexural strength; (b) flexural stiffness of sandwich panels with different core weave architecture and stuffer-to-binder ratio.

Figure 4 presents the load–displacement responses of sandwich panels with 3D orthogonal (OR), 3D angle-interlock (AI), and 3D warp-interlock (WI) composite cores under three different stuffer-to-binder ratios (1:2, 1:1, and 2:1). Specifically, Figure 2(a) compares the load–displacement curves of the three core architectures at a fixed 1:2 ratio, while Figures 4(b), 4(c), and 4(d) illustrate the effect of stuffer-to-binder ratio on the flexural behaviour of OR, AI, and WI cores, respectively.

From Figure 4(a), it is evident that the angle-interlock (AI) core exhibited the highest peak load, followed by the orthogonal (OR) and warp-interlock (WI) cores. The superior flexural load capacity of the AI core can be attributed to its angled binder yarns, which are better aligned with the direction of applied bending loads, allowing for enhanced load transfer and energy absorption. In contrast, the WI core, which contains fewer effective through-thickness reinforcements, shows the lowest peak load and early softening in the curve, indicating a reduced ability to resist delamination and through-thickness shear.

Figures 4(b–d) further reveal that increasing the stuffer-to-binder ratio consistently enhances the flexural load capacity across all core types. This trend is most evident in the AI and OR cores, where the 2:1 ratio configurations reach the highest peak loads. The improvement in performance at higher stuffer-to-binder ratios is due to the greater number of in-plane stuffer yarns per unit area, which directly contribute to carrying bending stresses. These yarns offer enhanced resistance to tensile and compressive forces developed on the tension and compression sides of the core during flexure.

Interestingly, the difference between the 1:2 and 1:1 configurations is minimal in terms of peak load, suggesting that the in-plane reinforcement (stuffers) is similar in both cases. However, a closer look at the slope of the initial linear region reveals that flexural stiffness is higher in the 1:2 ratio panels, especially for the OR cores (Fig. 2b). This increased stiffness can be attributed to the greater number of binder yarns in the through-thickness (Z) direction, which improve shear resistance and contribute to structural rigidity. On the other hand, the 2:1 configuration, despite showing the highest load-bearing capacity, exhibits slightly lower stiffness, particularly in WI cores (Fig. 4d), likely due to the reduced binder content, which weakens through-thickness integrity.

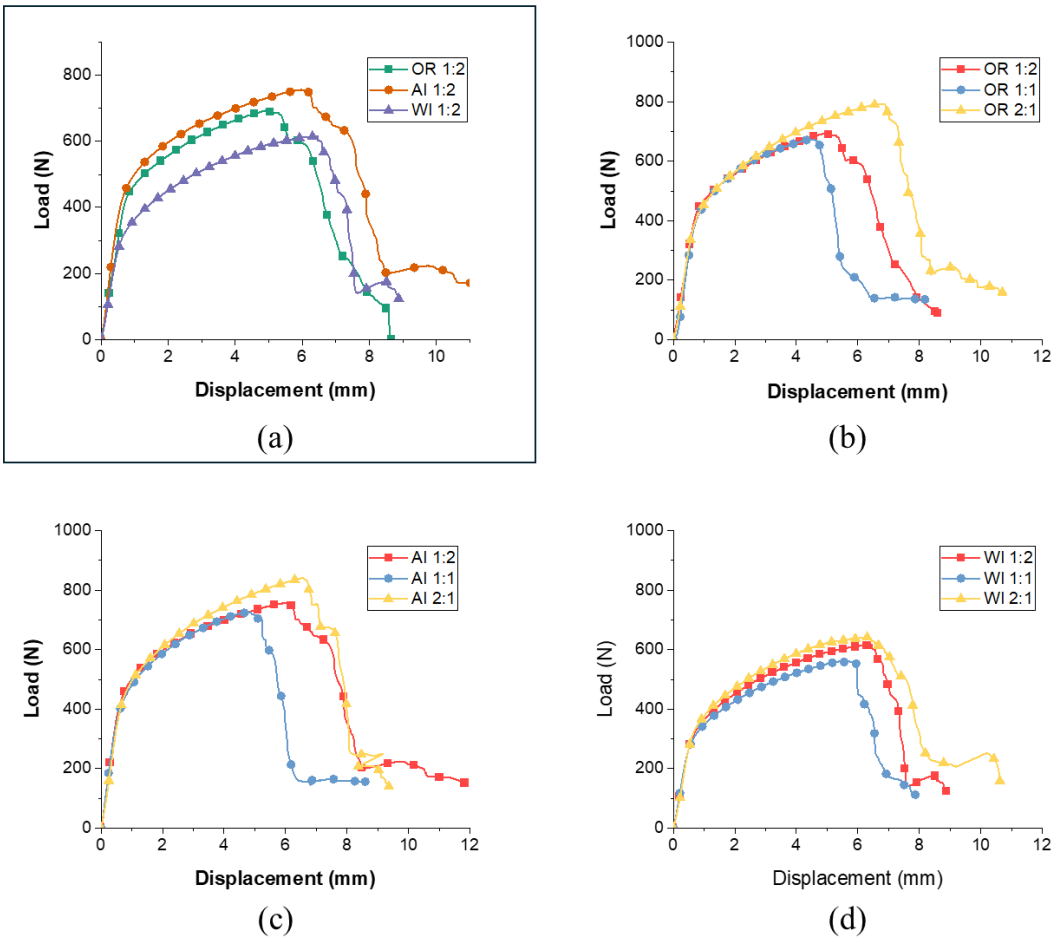

Figure 4: Load–displacement curves of sandwich panels with 3D OR, AI, and WI cores. (a) Comparison at 1:2 ratio; (b–d) effect of stuffer-to-binder ratios on OR, AI, and WI cores, respectively.

Figure 5 shows the post-flexural failure images of the sandwich panels reinforced with 3D angle-interlock, 3D orthogonal, and 3D warp-interlock composite cores, each tested at three different stuffer-to-binder ratios (1:2, 1:1, and 2:1). A consistent observation across all samples is the absence of

debonding or delamination between the core and the aluminum facesheets, indicating effective adhesive bonding and good interfacial integrity.

The dominant failure mode observed is a combination of core shear/yield, followed by bottom facesheet yielding under tension. During bending, the compressive stresses on the top face are absorbed without fracture, while the core initially undergoes localized deformation. As the loading progresses, the tension side of the panel (bottom facesheet) yields, ultimately leading to final failure. Samples with higher stuffer-to-binder ratios (2:1) exhibit larger deformation before failure, as evident from their more pronounced bending in Figure 5. This is because a higher ratio indicates greater in-plane stuffer yarn content, which enhances the core's ability to resist bending loads, delays the onset of failure, and allows more energy absorption. In contrast, the 1:2 specimens exhibit relatively smaller deformation, correlating with earlier onset of failure and reduced energy absorption due to fewer stuffer yarns available to share the in-plane tensile and compressive stresses.

These visual observations are in agreement with the flexural load-displacement curves presented earlier (Figure 4), where panels with a 2:1 ratio showed the highest load-bearing capacity and deflection before failure. While the external damage is visible, the internal core damage mechanisms, such as microcracking, yarn pull-out, or delamination within the core layers, remain areas of ongoing investigation and will be further studied using micro-computed tomography (μCT) analysis for comprehensive damage assessment.

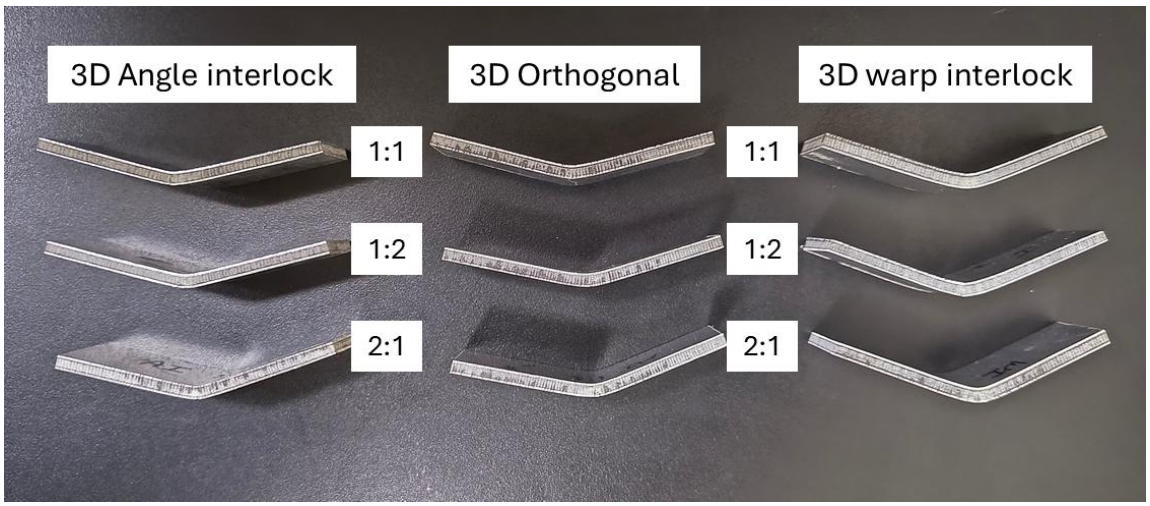

Figure 5: Fractured sandwich samples of different weave architecture (3D orthogonal, angle interlock, and warp interlock) and stuffer-to-binder ratio (1:2, 1:1, 2:1)

9 CONCLUSIONS

This study investigated the flexural behaviour of aluminium-faced sandwich composite panels reinforced with three different 3D woven core architectures—orthogonal, angle-interlock, and warp-interlock—at varying stuffer-to-binder ratios (1:2, 1:1, and 2:1). The results demonstrated that both core architecture and stuffer-to-binder ratio significantly influence the flexural strength, stiffness, and failure mechanisms of the sandwich panels.

Among the three architectures, the 3D angle-interlock core exhibited the highest flexural strength, attributed to its inclined binder yarns that effectively engage under bending loads. The 3D orthogonal core showed superior flexural stiffness, especially at lower stuffer-to-binder ratios, due to its vertically aligned Z-binders, which enhance through-thickness shear resistance. The 3D warp-interlock cores consistently exhibited lower mechanical performance, likely due to fewer effective through-thickness reinforcements.

An increase in the stuffer-to-binder ratio led to improved flexural load capacity across all core types, confirming that higher stuffer content enhances in-plane load distribution. However, this came at the expense of slightly reduced stiffness due to a corresponding decrease in binder yarns. Post-fracture analysis revealed that all panels failed through a combination of core shear/yielding and bottom facesheet tension failure, without any evidence of core–face debonding, indicating robust interfacial adhesion. The deformation profiles and fracture characteristics observed in flexural testing were consistent with the load-displacement behaviour, validating the role of textile architecture and yarn orientation in tailoring sandwich panel performance

ABSTRACT

As part of the research project “ExSaZell – Efficiency and Performance Enhancement of Thermoplastic Honeycomb Cores through Innovative, Extrusion-Based, Foamed Cellular Wall Systems with Sandwich Structure”, an advanced three-layer cellular wall concept was developed in collaboration of ThermHex, Kunststoff-Zentrum Leipzig (KUZ), and HTWK Leipzig. This approach utilizes the co-extrusion of polypropylene into a multi-layer flat film, followed by continuous thermoforming into honeycomb cores. The resulting cell walls consist of two dense outer layers and a foamed, lower-density inner layer. This structured wall design enables significant improvements in mechanical performance, particularly under compressive loads, while maintaining a constant core density. The integration of a foamed middle layer reduces the overall material mass and increases the effective wall thickness, thereby enhancing buckling resistance, a critical parameter for honeycomb core performance under compressive and shear stresses. Initial industrial trials demonstrated an increase of 21.8% in flatwise compressive strength compared to a conventional monolithic thermoplastic core of equivalent density. The internal structuring was achieved via the targeted addition of a chemical blowing agent and nucleating agent into the base polymer of the inner layer. The concept development and industrial trials conducted by ThermHex were supported by nonlinear finite element analyses (FEA) from HTWK Leipzig and morphological as well as mechanical testing by KUZ Leipzig. The results underline the potential of this sandwich cell wall concept to replace traditional honeycomb core materials in lightweight applications, offering both economic and ecologic advantages through improved resource efficiency, recyclability, and production cost reductions.

INTRODUCTION

The global demand for transport services, whether by air, land, or water, continues to grow [1]. The automotive industry is currently one of the fastest-growing sectors, and this growth is accompanied by an increasing demand for lightweight components [2]. In 2018 alone, 95 million light vehicles were sold worldwide, and this number is expected to rise to 110 million units per year by 2025 [1], [3]. This sustained expansion in the transport sector, however, leads to significant energy consumption and increasing emissions of greenhouse gases, particularly carbon dioxide (CO_2) [1], [2], [4].

To address these challenges and enhance fuel efficiency, vehicle lightweighting is a crucial strategy [5]. Studies indicate that reducing vehicle mass by 10% not only lowers raw material consumption but also cuts car fuel consumption by between 6% to 8% [4]. Every 100 kg removed from a motor vehicle reduces CO_2 emissions by 9 grams per kilometer [2]. For Battery Electric Vehicles (BEVs), the specific consumption saving achievable through 100 kg mass reduction, known as the Energy Reduction Value (ERV), ranges from 0.47 to 1.17 kWh/(100 km × 100 kg), with larger vehicles and more dynamic driving cycles exhibiting higher ERV values [6]. Lightweighting also offers advantages beyond raw material and fuel efficiency [2], such as improved energy efficiency, reduced noise, vibration, and harshness (NVH) [1], and enhanced energy absorption capabilities [3], [5]. Furthermore, lighter materials like aluminum absorb impact better than steel in accidents. Vehicle weight is identified as the most significant factor influencing fuel consumption, accounting for approximately 70% to 75% of total fuel use [2], [4]. For instance, a 30% mass reduction on the body-in-white (BIW) structure of a typical compact car (e.g. Volkswagen Golf) over a lifetime road performance of 150,000 km can lead to fuel savings of around 398 liters (equivalent to ~998 kg CO_2 savings). This implies a saving of approximately 0.3 L/100 km for each car [5]. Overall, studies suggest that a total vehicle weight reduction of up to 12.6% can be achieved, which translates to a CO_2 emission reduction of 25.2 grams per kilometer [4].

In this context, sandwich structures have emerged as a prevalent method for replacing traditional, heavier materials. A typical sandwich structure comprises two solid, force-absorbing face sheets and a lightweight core material that keeps these face sheets separated. This design allows for achieving high mass-specific bending stiffness, strength, and optimal fatigue resistance, while simultaneously reducing the overall weight and cost of the component [7]. Sandwich panels can also be formed into complex shapes, enabling significant component consolidation and simplifying manufacturing processes [3], [5]. Their applications span from floors for heavy-duty trailers and air cargo containers [7], [8] to components for electric vehicles, including vehicle floors and exterior panels [1], [8], [9].

The core of a sandwich structure plays a critical role in the overall mechanical performance of the component, as it spaces the face sheets apart and primarily withstands shear and compressive forces [1]. Honeycomb cores are particularly interesting due to their excellent strength-to-weight ratio and good sound and thermal insulation properties [1], [10]. Various materials are used for honeycomb cores, including paper honeycomb, polypropylene (PP) honeycomb, aluminum honeycomb, and phenolic Nomex aramid fiber honeycomb [1], [9], [10]. It is important to note, however, that most "conventional" sandwich cores (such as traditional honeycomb, wood, or foam) generally contribute only marginally to the overall bending stiffness of the structure, serving primarily as low-density spacers [10].

Despite their shared classification as "honeycomb cores", significant differences exist in the properties and application areas of various materials. Nomex aramid fiber honeycomb, for instance, is extremely lightweight, non-metallic, and offers a unique profile of properties including a high strength-to-weight ratio, toughness, corrosion, fatigue, and impact resistance, as well as fire resistance and good dielectric and thermal insulation characteristics [10]. These superior properties make Nomex suitable for high-performance applications, such as airplane secondary components, but carry an extremely high carbon footprint and can only be calcinated at the end of lifecycle[10]. In contrast, thermoplastic honeycomb cores are characterized by efficient production techniques, their good flexibility and ease of formability, making them more cost-effective and adaptable for automotive applications like electric car floors [9]. Paper honeycomb, known for its low-cost raw material, compressibility during conversion, and low transportation cost, finds wide application in flat commodity products and packaging applications [1].

The selection of the appropriate honeycomb core material thus heavily depends on the specific application, performance requirements, and economic considerations. While the advantages of high-performance honeycombs like Nomex are undeniable in specialized fields, a key challenge for the automotive industry lies in developing cost-effective yet high-performing honeycomb solutions that meet the demands of mass production and optimally define and utilize the specific role of the honeycomb core in the overall bending stiffness of the sandwich structure.

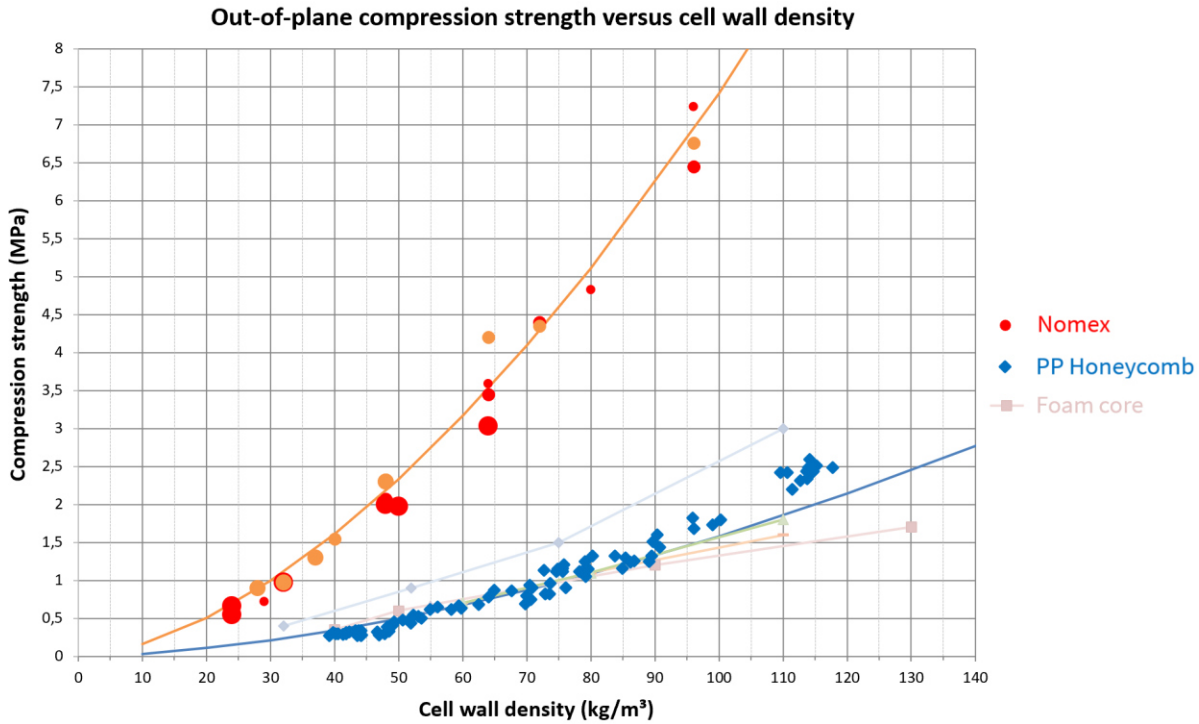

Figure 1: Honeycomb and foam cores in density dependent compression strength [11]

Conventional methods for producing sandwich components are hardly suitable for mass production due to their time and cost. To overcome this, the "ThermHex" honeycomb production process was developed and patented by EconCore N.V., which enables continuous in-line production of thermoplastic honeycomb cores [12]. This technology is applied in industrial scale by EconCore's daughter company ThermHex Waben GmbH in Germany.

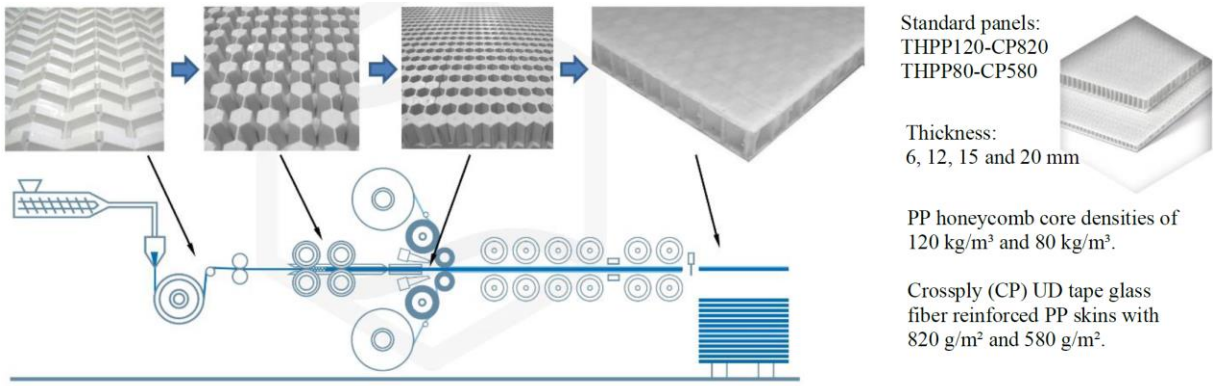

Figure 2: Continuous production of thermoplastic honeycomb sandwich panels [12].

Unlike stepwise batch methods, all production steps take place on a single line, starting with the extrusion of a flat film, followed by rotational vacuum forming, folding, laminating, and cutting [12], [13].

This inline efficiency allows for the production of over more than a million square meters of honeycomb cores per year at speeds of up to 10 meters per minute and cost advantages of more than 20% vs. traditional PP cores [12]. The inline-lamination of face sheets from thermoplastic tape laminates during honeycomb core production also enables the manufacturing of sandwich panels for large-scale series production with short cycle times. ThermHex honeycomb cores find wide application, for example in truck bodies and automotive interiors [12].

RESEARCH OBJECTIVE AND INVESTIGATED VARIANTS

A significant innovation in cell wall structure is being pursued in the research project "ExSaZell - Efficiency and performance enhancement of thermoplastic honeycomb cores through innovative, extrusion-based, foamed cellular wall systems with sandwich structure", a collaboration of Thermhex, Kunststoff-Zentrum Leipzig and HTWK Leipzig. The main interest of this research lies in further sub-structuring the cell wall via co-extrusion. A recurring problem in sandwich structures is the stability failure (buckling) of the cell walls oriented perpendicular to the face sheets under compressive and shear loads. An increase in buckling stiffness at constant weight and identical honeycomb core material is only possible through further structuring of the cell walls themselves.

The project's core innovation involves designing the honeycomb cell walls themselves in a sandwich construction consisting of a layered A-B-A cross sectional substructure. Here, the individual cell walls consist of a core layer (B) with lower density and outer face layers (A) with higher stiffness. PP serves as the material basis, where the individual layers, although chemically homogeneous, can vary through compounding or additivation to achieve specific properties. This allows for the use of high-strength PP homopolymers (PPH) or reinforced PP in the outer layers and lighter PP copolymers (PPC) in the inner layer. The subsequent crucial step for further density reduction and property enhancement is foaming the mid-layer (B) of the cell wall. This is expected to enable a weight-specific increase in the mechanical properties of the honeycomb core by up to 25%.

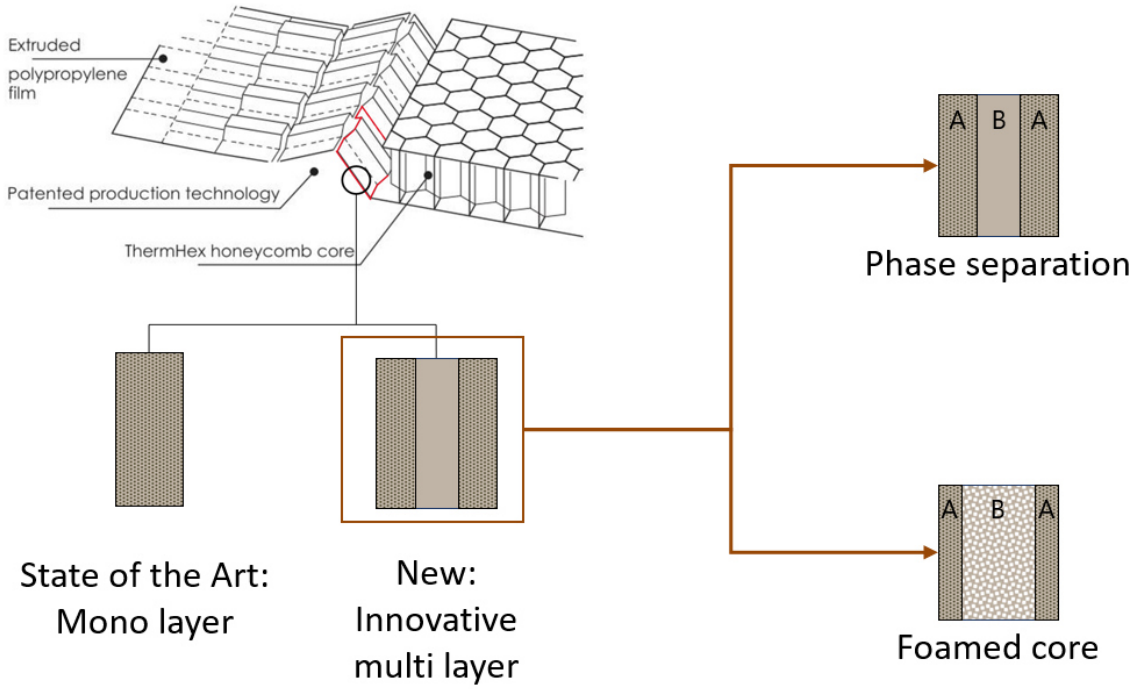

Figure 3: Multi-layer cell wall approach

The project primarily investigates three variants of cell wall structuring:

1. **Mono layer (reference):** This represents the current state of the art, where the cell walls consist of a homogenized polypropylene compound. This variant is characterized by good mechanical properties and efficient production.
2. **Phase separation:** The goal is a complete demixing of the components, enabling higher weight-specific properties through the use of stiffer/stronger materials in the outer layers and tougher materials in the core layer. This allows for gradients in stiffness and density.
3. **Foamed mid-layer:** In this variant, the density of the core layer (B) is reduced by foaming. This enables a greater cell wall thickness at constant weight and thus leads to increased buckling stiffness and better specific properties of the honeycomb core.

NUMERICAL MODELING

For the Finite Element Analysis (FEA) of honeycomb structures, the unit cell approach was employed in Ansys, leveraging the inherent regular and periodic pattern of hexagonal cell cores. This method significantly simplifies the model by considering only a single hexagonal unit cell, including its adjacent cell walls. The modeling was performed using “SOLSH190” Solid Structural Shell elements, allowing for a parametrically designed model with flexible adjustment of cell wall height, the distance between cell walls, the cell angle, and the thickness ratio of L-walls to W-walls. To enable a comprehensive material investigation, each cell wall was divided into two outer elements enclosing one middle element. This subdivision allowed for the free selection of mechanical properties for the outer and inner layers, as well as the mass fraction between two different materials.

This simulation approach enabled a detailed investigation of various material configurations. As for the reference variant, a monolayer honeycomb core was established where both outer and inner material layers were assigned identical mechanical properties, representing the homogeneous material mixture of the current production's PPH and PPC. The second variant was designed as a phase-separated honeycomb core, specifically assigning PPH properties to the outer layers and PPC properties to the inner layers of the cell walls. This distinction facilitates the analysis of the mechanical response of a heterogeneous material distribution. Furthermore, the model accounted for the foaming of PPC by treating it as a homogenized material with an effective 22.5% reduction of its original mechanical properties, reflecting the impact of the foaming process. It's important to note that the mechanical properties of both PPH and PPC materials were determined through tensile testing of the corresponding virgin materials, which was carried out by KUZ Leipzig. For the numerical model, a “Bilinear Isotropic Hardening” (BISO) material model was utilized, incorporating a tangential modulus of 17.2 MPa (see Table 1).

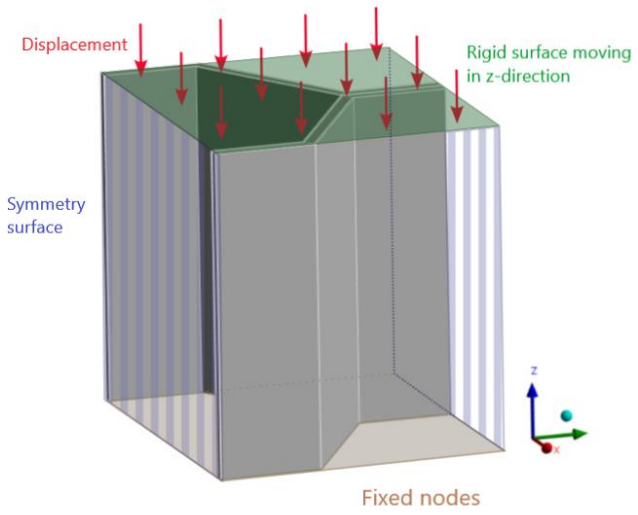

Figure 4: Unit-Cell with boundary conditions

To optimize computational efficiency for the nonlinear buckling analysis, the inherent X and Y axis symmetry of the honeycomb core allowed for the simulation of a quarter-section of the structure (see Figure 4). Specific boundary conditions were applied to represent the core's behavior under compressive loading: The bottom nodes were fixed to prevent any free translations or rotations, ensuring a stable base. Conversely, the nodes on the opposing (top) side were designated as "one-dimensional displacement nodes," constraining their movements in the X and Y directions, along with rotations about each axis, thereby permitting translation only along the Z-axis. Frictional contact was implemented between the cell walls to prevent unrealistic sliding or interpenetration during deformation. The nonlinear buckling analysis was then conducted by applying a displacement of 10^{-3} mm in the negative Z-direction to these top nodes.

Engineering constant		Polypropylene Homopolymer (PPH)	Polypropylene Copolymer (PPC)	Polypropylene Copolymer (foamed)
ρ	[g/cm³]	1.03	0.9	0.6975
E	[MPa]	1750	1440	1116
ν_{12}	–	0.3	0.3	0.3
K	[MPa]	1408	1200	930
G	[MPa]	650	554	430
σ	[MPa]	36	27	21
E_t	[MPa]	17.2	17.2	17.2

MANUFACTURING AND MORPHOLOGICAL CHARACTERIZATION

ThermHex, leveraging its established production capabilities, can realize all three variants investigated in this research project. For the reference variant, the manufacturing process is straightforward. A single extruder is sufficient to melt the PP granulate. This molten material is then extruded through a dedicated die to form a PP foil, which is subsequently folded into the honeycomb core structure on the production line. The production of the phase-separated variant requires a more advanced setup. A second "co-extruder" is integrated into the process, allowing for the separate melting of two distinct material mixtures: one for the outer layer (Layer A) and another for the inner layer (Layer B). A specialized extrusion die, featuring a three-layered feedblock, then co-extrudes these materials simultaneously to create the desired three-layered foil. Finally, the foamed variant is achieved by incorporating a chemical foaming agent into the polypropylene granulate used for the inner layer. The foaming agent type and concentration were selected after an empirical benchmarking study of various combinations of different blowing and nucleating agents as well as their respective concentrations in a pre-investigation by ThermHex and KUZ. The blowing agent decomposes within the extruder, releasing gas. While this gas remains dissolved under pressure inside the extruder, upon exiting the die, a sudden pressure drop causes it to expand rapidly under the formation of gas bubbles, creating the desired cellular structure that is then fixed as the extrudate cools. To validate the desired geometrical and morphological aspects of the produced honeycomb core variants, X-Ray Computed Tomography (CT) scans were performed. CT scanning was chosen due to its ability to non-destructively visualize internal structures and confirm the distinct three-layer configuration of the honeycomb core, allowing clear differentiation of the layers through the material. This method also offered significant advantages in specimen preparation and contrast resolution compared to alternative techniques like optical microscopy, streamlining the validation process.

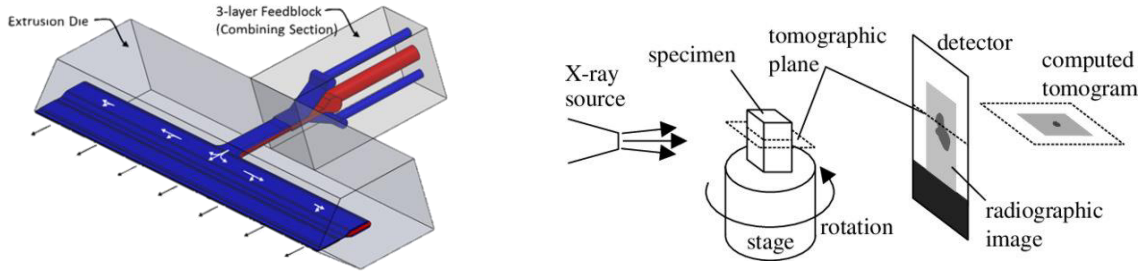

Figure 5: Schematic representation of coextrusion die system (left) and computed tomography for morphology assessment of produced specimens

EXPERIMENTAL MECHANICAL TESTING

Mechanical properties of each variant were evaluated using 100x100 mm² specimens tested under ASTM C365 conditions. This standard test method, officially titled "Standard Test Method for Flatwise Compressive Properties of Sandwich Cores," defines the procedure for measuring the flatwise compressive strength and modulus of core materials used in sandwich structures. Essentially, it assesses the load a core can withstand when compressed perpendicular to its surface (flatwise), thereby simulating the stresses sandwich cores experience in real-world applications.

RESULTS

The desired geometrical and morphological aspects of the produced honeycomb core variants were validated using Computed Tomography (CT) scans. Figure 6 displays scans of the reference configuration (1, top), phase-separated (2, middle), and foamed variants (3, bottom). The reference variant scan shows a consistent wall thickness of 0.23 mm. A tapering effect, caused by the vacuum thermoforming process, appears after the bending area and is visible in all variants. As expected, the reference core's material remains homogeneous. In the phase-separated and foamed variants, the distinct three-layer structure is clearly visible in the respective CT scans 2 and 3. This is due to the density difference between PPH (higher) and PPC (lower). The phase-separated variant's outer layers are 0.022 mm thick (≈ 20% of total thickness), while the foamed variant's outer layers are 0.016 mm thick (≈22% of total thickness). The cellular structure in the foamed variant is distinct. The extrusion process causes significant pore elongation, resulting in a more needle-shaped form rather than an ellipsoid. The average pore size is 90 x 20 x 250 µm³ (x, y, z). These CT images confirm that all three designed variants can be successfully manufactured in a production-like setting, validating their desired morphological characteristics.

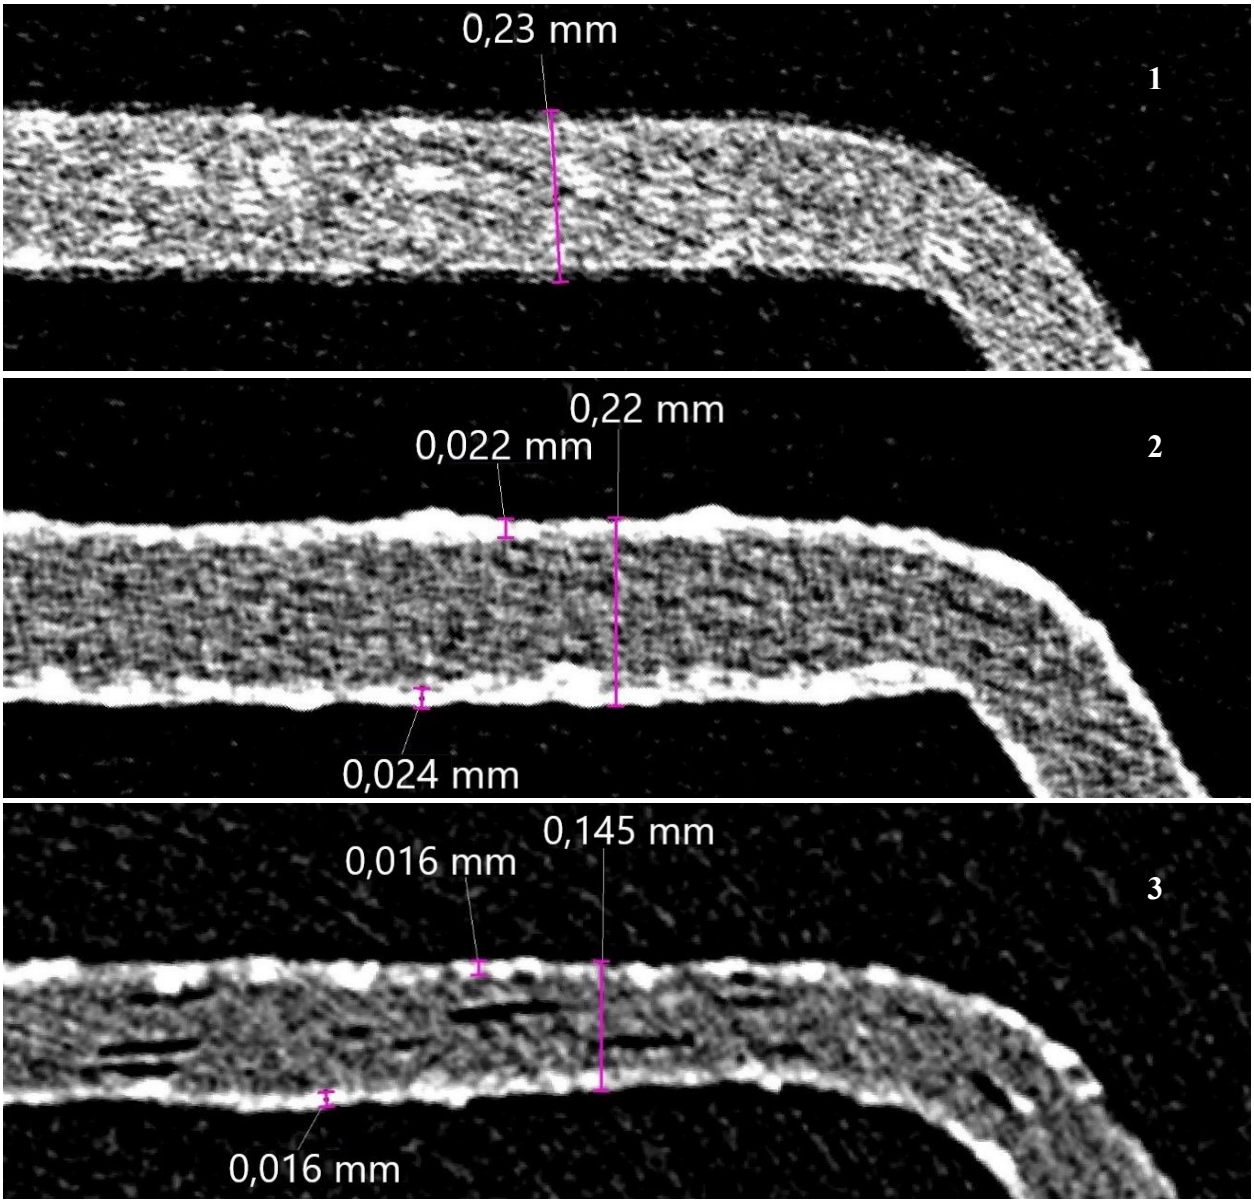

Figure 6: CT scan of developed specimens' cross section

The nonlinear buckling analysis under compressive loading yielded effective normal stresses and normal strains for each element until failure, which are presented in the form of stress-strain curves (see Figure 7). Initially, all configurations exhibit a linear elastic response, characterized by a proportional increase in effective normal stress with increasing strain. Upon reaching a critical stress level, local or global buckling phenomena initiate within the structure, marked by the attainment of a maximum point on the curve. Beyond this peak, the structural stability is compromised, and nonlinear effects become dominant. The post-peak behavior is governed by a combination of progressive buckling-induced instabilities and, depending on the material response, plastic deformation within the cell walls. This results in a reduction of the effective normal stress with further strain. The reference variant, with its homogeneous material composition, exhibited a maximum stress of 1.5 MPa. In contrast, the various three-layer core configurations (with outer layer thicknesses of 10%, 33%, 50%, and 90% and equal core density of 80 kg/m³) demonstrated significantly improved performance, achieving peak stresses ranging from 2.2 to 2.3 MPa. The highest peak stress was observed in the third variant, which incorporated a foamed middle layer, reaching a significant improvement up to 2.4 MPa.

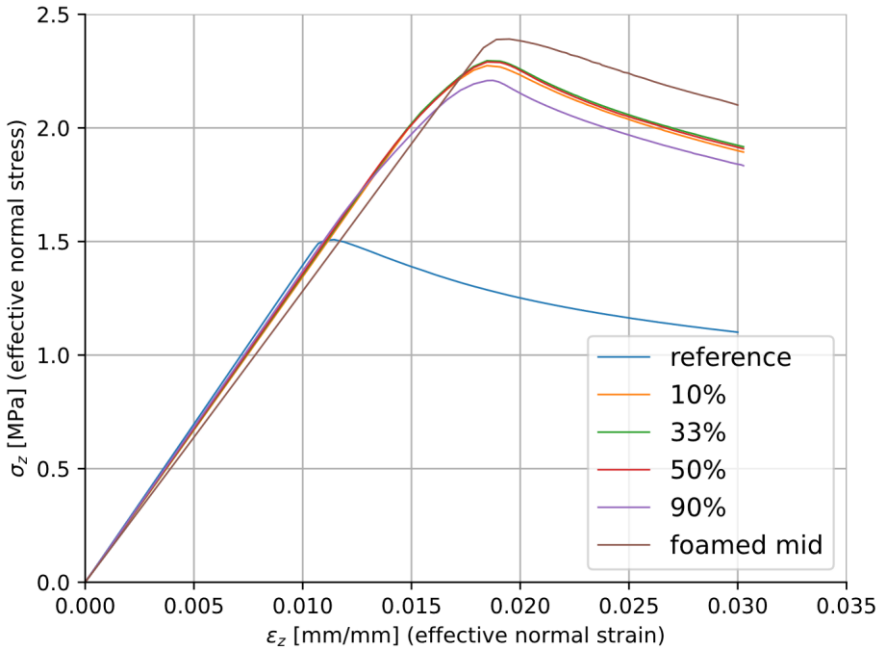

Figure 7: Stress-strain curves under compressive loading in FEA with varying layer thickness ratio (2xA/B)

Figure 8 displays an exemplary comparison of compression strength (in MPa) versus cell wall density (in kg/m³). These results from experimental mechanical testing validate the significant improvements achieved by the new honeycomb core designs. The phase-separated design, featuring high-density outer layers and a low-density core, showed a 12% improvement in compression strength, increasing from 1.19 MPa for the reference non-foamed honeycomb core to 1.33 MPa. Further enhancing performance, the introduction of a foamed middle layer in the third variant led to a 22% increase in compression strength, achieving 1.45 MPa. Notably, the density of all tested specimens remained consistent within usual process variation, ranging from approximately 81 to 83 kg/m³. This confirms that the new designs maintain weight efficiency while substantially improving mechanical properties.

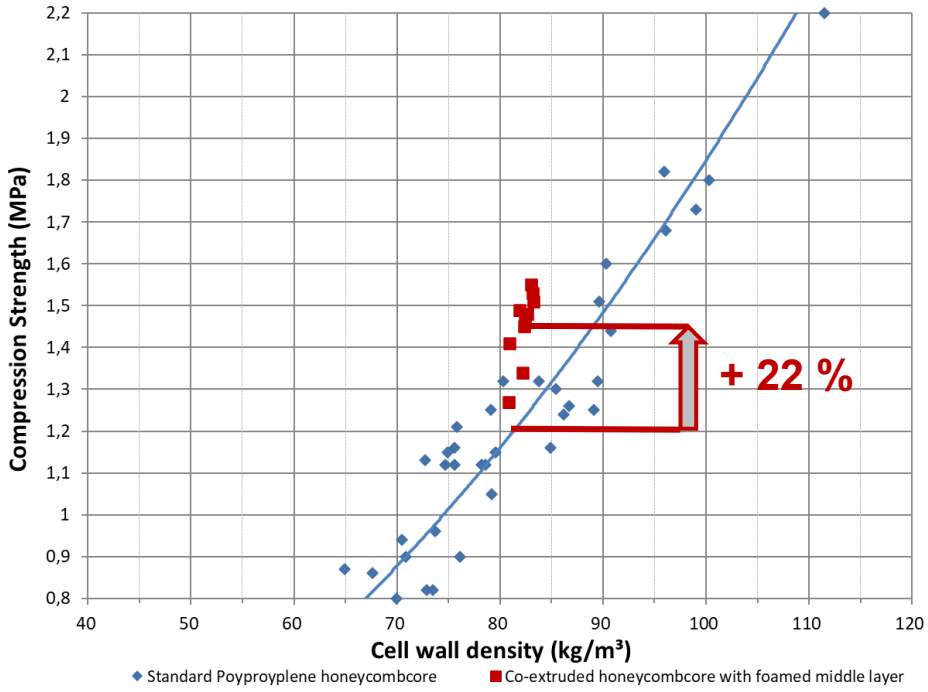

Figure 8: ThermHex honeycomb compression strength versus cell wall density

A comparison between the experimentally tested and numerically simulated compression strengths reveals an overestimation by the simulation. For the reference non-foamed honeycomb core, the average tested compression strength was 1.19 MPa, while the simulation yielded a higher value of 1.5 MPa, indicating an overestimation of 26%. Similarly, for the phase-separated variant, the tested compression strength was 1.33 MPa, compared to a simulated value of 2.0 MPa, representing an overestimation of 50%. The foamed variant also showed this trend, with a tested strength of 1.45 MPa and a simulated strength of 2.4 MPa, resulting in an overestimation of 65% (see Table 2).

		Reference	Phase separation	Foamed mid-layer
ρ	[kg/m³]	82.57	81.01	82.90
$R_{m,real}$	[N/mm²]	1.19	1.33	1.45
$R_{m,sim}$	[N/mm²]	1.5	2.0	2.4
Δ	[%]	26	50	65

Table 2: Comparison of experimental and simulated compression strengths

DISCUSSION

The observed discrepancies between simulated and experimentally determined compression strengths highlight several areas for consideration and potential refinement in the numerical model. Firstly, a primary source of potential overestimation lies in the material property input for the simulation. The mechanical properties of the PPH and PPC utilized in the model were derived from standardized tension tests on virgin material specimens. This approach inherently does not fully account for the effects of the extrusion and elongation processes that the material undergoes during the manufacturing of the thin honeycomb foils. These processes are known to induce molecular orientation and potentially alter the mechanical properties in a way not captured by bulk virgin material testing, likely leading to a reduction in actual performance compared to theoretical values. More accurate testing methods specifically designed for thin-section foils, or an alternative approach to determine the in-situ material properties of the extruded and elongated film, would be highly desirable for improving simulation accuracy. Secondly, the geometrical idealization of the honeycomb core in the simulation presents another potential source of deviation. The numerical model assumes perfectly straight cell walls, uniform cell distances, and precise angles. In reality, the manufacturing process invariably introduces imperfections and defects within the cell walls. These real-world flaws can act as stress concentrators or local weak points, promoting premature buckling and thus contributing to the lower experimental compression strengths compared to the idealized simulated performance. Future simulation efforts could benefit from incorporating representative manufacturing imperfections into the geometric model. This modification together with boundary conditions that not only allow for idealized z-direction displacement of the nodes, but also more realistic secondary in-plane-displacements can reduce the delta observed between testing and FEA. Other potential influences can include the imperfect test environment leading to uneven loading in flatwise compression tests if the load plates are not perfectly parallel. Despite these quantitative discrepancies, the parametric nature of the simulation model enables effective qualitative differentiation between variations in material properties and the relative proportions of outer and inner layers. This functionality provides a robust framework for informing design strategies, supporting the optimization of material selection and structural configurations during early-stage development and prototyping, even in the absence of precise numerical agreement with experimental results. The increasing delta of simulation vs. experiment for more challenging to produce configurations also hint at further improvement potential with more fine tuned manufacturing processes thereof.

The present investigation demonstrates that thermoplastic honeycomb cores can be significantly enhanced through sandwich-style cell wall structures, improving both mechanical performance and weight efficiency. Phase-separated and foamed middle-layer designs exhibit substantial gains in compression strength – 12% and 22% increases, respectively – without significant density variation.

This approach offers a notable advancement in enhancing structural performance without additional weight, critical for industries where material mass is a key design constraint. A salient advantage of this development is its recyclability. Exclusive utilization of thermoplastic materials without fiber reinforcement ensures uncompromised recyclability. This directly aligns with sustainability objectives by facilitating straightforward end-of-life recycling processes. First samples following a closed-loop approach by using post-consumer regranulate in the inner layer have already been manufactured in another coextrusion project by ThermHex. Consequently, these innovations position the novel honeycomb core configurations as highly promising for high-performance, lightweight applications, particularly within the automotive industry. Their synergistic combination of enhanced mechanical strength, consistent low density, and excellent recyclability presents significant potential for reducing vehicle mass, improving fuel efficiency, and contributing to more sustainable manufacturing.

CONCLUSION

This investigation successfully demonstrates that advanced thermoplastic honeycomb cores can be significantly enhanced through innovative sandwich cell wall structures, leading to improved mechanical performance and weight efficiency. The research explored three key variants: a monolayer reference, a phase-separated design, and a foamed mid-layer configuration. Significant performance gains were achieved with the new designs. The phase-separated variant showed a 12% increase in compression strength (from 1.19 MPa to 1.33 MPa), while the foamed mid-layer design delivered an even more remarkable 22% increase (reaching 1.45 MPa) compared to the reference. Crucially, these improvements were accomplished while maintaining a consistently low density across all tested samples (approx. 81-83 kg/m³), confirming their weight efficiency. Numerical simulations further supported these findings, predicting peak stresses up to 2.4 MPa for the idealized foamed variant. The feasibility of continuous production for all three variants was validated using the established production process at company ThermHex, Germany. Computed Tomography (CT) scans confirmed the successful creation of the desired morphological properties in a production-like environment. A major sustainability advantage of these materials lies in their uncompromised recyclability, stemming from the exclusive use of thermoplastics without fiber reinforcement. This characteristic aligns with sustainability goals by enabling straightforward end-of-life recycling, making these novel honeycomb cores highly promising for lightweight applications, particularly in the automotive industry, to reduce vehicle mass and improve fuel efficiency or allow for compensation of heavier electronics integration.

However, challenges in production and reproducibility were identified. A notable discrepancy was observed between simulated and experimental compression strengths, with simulations overestimating results by 26% to 65%. This overestimation is primarily attributed to using virgin material properties in simulations, which do not fully account for the effects of extrusion and elongation processes on thin foils, as well as idealized geometrical models and boundary conditions not reflecting real-world manufacturing and test setup imperfections. Despite these quantitative differences, the parametric simulation model remains valuable for qualitative differentiation and early-stage design optimization. Future work will focus on further developing hierarchical or hybrid designs to continuously optimize the properties of these advanced honeycomb core structures.

For future industrial implementation, further research and development efforts are essential to optimize the reproducibility and consistency of the manufacturing process. As with the scaling of any novel material system, achieving stringent process control and minimizing variabilities in material distribution and cellular morphology will be critical for ensuring robust and predictable performance across larger production batches and enabling widespread adoption of these advanced honeycomb core designs.

Keywords: Sustainable sandwich composites, Flax/epoxy composites, Recycled PET core, Low-velocity impact, Low-temperature

ABSTRACT

This study investigates the response to low-velocity impact of sustainable and conventional sandwich beams tested at two temperatures: room temperature and -40°C. The sustainable sandwich beams are made by two flax/epoxy skins with a recycled PET foam core, while the conventional beams use glass/epoxy skins and a PVC foam core. Both types of sandwich beams were impacted with energies ranging from 2.5 J to 20 J using a drop-weight tower, and their responses were evaluated in terms of absorbed energy, peak force, energy absorption ratio, and effective flexural modulus. The results indicate that the conventional structure exhibits superior impact performance and lower temperature sensitivity. However, the flax/PET sandwich beam achieved peak loads comparable to the conventional sandwich, with minimal variation due to temperature, and demonstrated efficient energy absorption at low impact energies under cold conditions.

1 INTRODUCTION

Sandwich structures are widely employed in the aerospace, automotive, marine, and rail sectors due to their excellent stiffness-to-weight ratio, high energy absorption capacity, and superior performance under flexural loads. These structures are made of two stiff composite skins and a lightweight core. They offer additional benefits such as thermal and acoustic insulation. Conventional sandwich cores are often made from synthetic materials and include polymeric foams, honeycombs, or corrugated sheets [1].

During operation, sandwich panels may be subjected to accidental low-velocity impacts, such as tool drops during maintenance or debris strikes in high-speed trains. Depending on the impact energy level, these impacts can result in barely visible damage or catastrophic failure. One of the main drawbacks of these structures is their limited impact resistance [1], especially in cases where internal damage may not be externally detectable. Prior studies have extensively characterized the impact behaviour of traditional sandwich structures combining synthetic cores and composite skins [2], though most focus on ambient conditions.

However, in real-world applications such as cryogenic storage, Arctic operations, or aerospace thermal cycling, these structures may be exposed to low temperatures. At these temperatures, core and matrix brittleness typically increases, and mismatched thermal expansion coefficients between skin and core can introduce residual stresses [1], significantly modifying impact response.

Due to growing environmental concerns and the increasing demand for sustainable materials, research has intensified into the development of bio-based sandwich structures. Natural fibres such as flax have emerged as a promising alternative to glass fibres thanks to their relatively high specific strength, low density, and renewable origin [3], [4]. However, there are certain limitations to their use, including high moisture uptake, reduced thermal stability, and a strong dependency of mechanical properties on processing conditions or seasonal variations [5].

Recycled polymeric foams, particularly thermoplastic-based materials, have attracted increasing attention as sustainable core alternatives. Thermoset polymers such as polyurethane or Polymethacrylimide are difficult to recycle, whereas thermoplastics like polyethylene terephthalate (PET) are widely available and industrially recycled. PET foams offer favourable mechanical properties, including high specific strength and stiffness, along with low thermal conductivity [6]. These features, combined with the large volume of post-consumer PET waste, make them an attractive ecological solution for sandwich core applications.

Despite the growing interest in sustainable alternatives, the impact behaviour of these eco-sandwich configurations, particularly at sub-zero temperatures, remains insufficiently explored [1], [7]. Moreover, findings obtained for specific core–skin combinations and geometries cannot be generalized, as their response is highly dependent on structural configuration, stacking sequence, and test conditions.

This study investigates the low-velocity impact behaviour of sandwich beams made from flax/epoxy skins combined with recycled PET foam cores. The performance is compared against a conventional configuration comprising glass/epoxy skins and a PVC foam core. Tests were conducted at both room temperature and −40°C to assess the influence of temperature on structural performance. The analysis focuses on critical mechanical response parameters such as peak impact force, absorbed energy, effective flexural stiffness, and failure mechanisms observed via high-speed imaging. The findings aim to enhance the understanding of sustainable sandwich composites and support their future implementation in structural applications subjected to impact loading.

2 MATERIALS AND METHODS

2.1 Materials

A sustainable sandwich structure was analysed and compared to a conventional reference configuration. Both were manufactured with identical stacking sequences and resin systems, but differed in fibre type and core material. The sustainable sandwich was made by two composite skins of a symmetric laminate with four plies of a flax/epoxy woven fabric with a fibre content of 49%, supplied by Simcas Composites (EPC 300-F200T-5043-52-1000). The lay-up sequence used was [0/90]s. The core was made from a recycled PET foam (ArmaPET GR200, 200 kg/m³), provided by Composites Quimiber.

The reference sandwich used the same stacking sequence and resin system, but incorporated a glass fibre woven fabric (EPC300-G200T-40-1270) in place of flax. The core of the reference configuration was a PVC foam (Divinycell HP200, 200 kg/m³), supplied by DIAB.

Rectangular beam specimens with dimensions of 270 mm in length and 50 mm in width were extracted from the manufactured sandwich panels. All specimens featured a core thickness of 10 mm and skin

thicknesses of 1.2 mm. The fabrication process was carried out at the Composite Materials Laboratory of the Instituto Nacional de Técnica Aeroespacial (INTA), in strict adherence to the manufacturing guidelines specified in the technical datasheets of the materials.

2.2 Low velocity impact test

Low-velocity impact tests were performed using a drop-weight impact tower (CEAST Fractovis 6875). The striker had a semicylindrical head of 20 mm in diameter and a total mass of 3.995 kg. A piezoelectric load cell mounted on the striker allowed for the continuous recording of the impact force. The impact velocity was measured using a photoelectric sensor, which also activated a rebound prevention system to ensure single-impact events. The tests were conducted according to ASTM D7136, covering impact energies of 2.5, 5, 7.5, 10, 12.5, 15, 17.5, and 20 J. All configurations were tested at room temperature and at -40°C. At least five specimens were tested per configuration.

From the force-time signal recorded during each impact, the displacement of the striker tip was computed via double integration, using the initial impact velocity as a starting point. Assuming continuous contact between the striker and the specimen, this displacement was taken as representative of the vertical deflection at the mid-span of the beam. The energy transferred to the specimen was calculated as the area under the resulting force–displacement curve. Energy-time plots were constructed accordingly. In tests where no catastrophic failure occurred, the final energy value on the curve was interpreted as the absorbed energy during damage progression. In contrast, for specimens that failed during impact, the maximum value reached was considered as the absorbed energy up to failure, as the curve does not drop afterward (Sánchez et al., 2005).

2.3 Digital image correlation method (DIC)

Each test was recorded using a PHOTRON FASTCAM SA-Z high-speed camera, positioned perpendicular to the front face of the specimen and operating at 30,000 frames per second. The footage was processed using a 2D Digital Image Correlation (DIC) technique, which enabled the visualization and analysis of the strain fields developed during the impact event. The speckle pattern was designed such that each spot covered approximately 3–5 pixels to ensure high correlation accuracy.

In this study, the DIC method was employed as a verification tool to assess the validity of the Euler–Bernoulli beam theory under low-velocity impact conditions. **Figure 1** presents as an example the strain distribution obtained from a flax/PET sandwich specimen impacted at 12.5 J under room temperature conditions.

Figure 1 (a) show the vertical strain component ε_{yy}. The mean strain along the beam length remains close to zero, showing that the transverse deformation is negligible. However, a localized compressive region is clearly observed beneath the impactor (C_0), corresponding to core indentation and local crushing phenomena. In contrast, at a remote location away from the impact zone (P_0), the strain remains negligible, further supporting the assumption of negligible vertical strain in the global response.

Figure 1 (b) represents the longitudinal strain field ε_{xx}. Two virtual extensometers were defined: E_0 on the upper skin and E_1 on the lower skin. The results indicate that the top face experiences compressive strains, while the bottom face undergoes tensile strains, consistent with pure bending behaviour. These

observations confirm that the global deformation of the sandwich beam under the studied impact conditions adheres to the assumptions of Euler–Bernoulli beam theory.

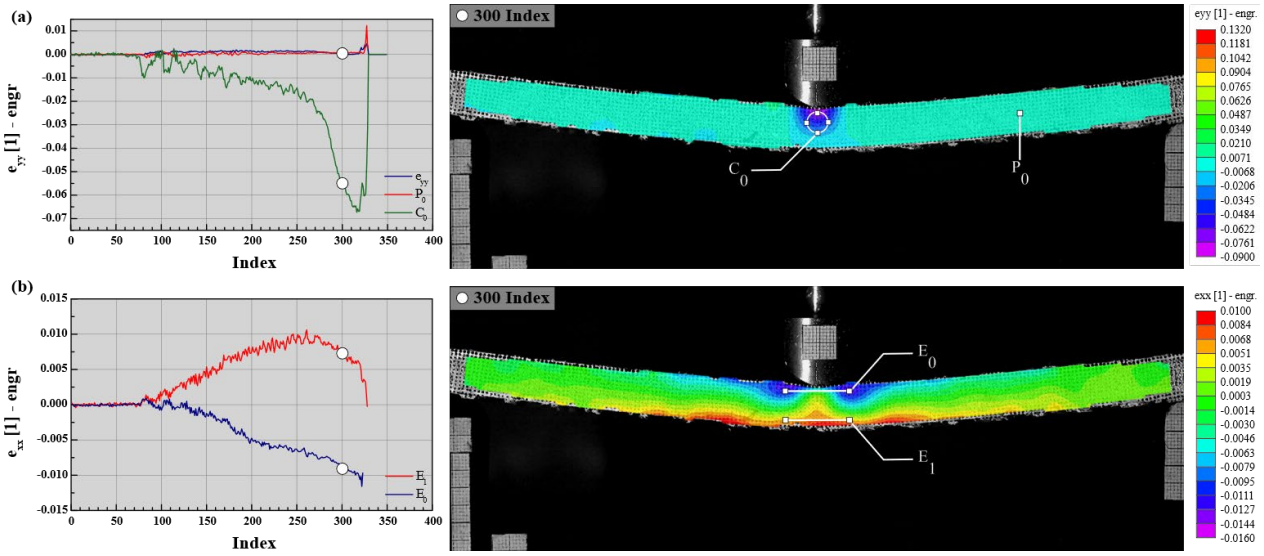

Figure 1. (a) Transverse strain distribution and (b) longitudinal strain distribution in the Flax/PET sandwich beam under low-velocity impact at −40 °C.

Based on these results, the effective Young's modulus of the system was subsequently estimated using the beam bending equation for a 3-point bending configuration:

$$E_{eff} = \frac{L^3}{4bh^3}\left(\frac{F}{\delta}\right) \quad (1)$$

where L is the span length, b the beam width, h the total thickness, F the applied load, and δ the mid-span deflection.

3 RESULTS AND DISCUSSION

This section examines the main results obtained from the low-velocity impact tests conducted on the sustainable (Flax/PET) and conventional (Glass/PVC) sandwich beams. The variables analysed include absorbed energy, energy absorption ratio, peak impact force, and equivalent flexural modulus, under two temperature conditions: room temperature (20°C) and sub-zero temperature (−40°C). Additionally, high-speed recordings were used to correlate the failure evolution with the load evolution.

3.1 Energy absorption and energy ratio

Figures 2-3 show the evolution of the absorbed energy and the energy ratio, respectively, as a function of the impact energy for both sandwich configurations at room temperature and -40°C. In all cases, the absorbed energy increases linearly with impact energy up to a threshold, beyond which the curve either plateaus or, in specific configurations, begins to decrease slightly. This behaviour marks a transition from sub-critical damage mechanisms, such as matrix cracking and fibre debonding [8], to more severe failure modes, including core shear, indentation, or partial perforation.

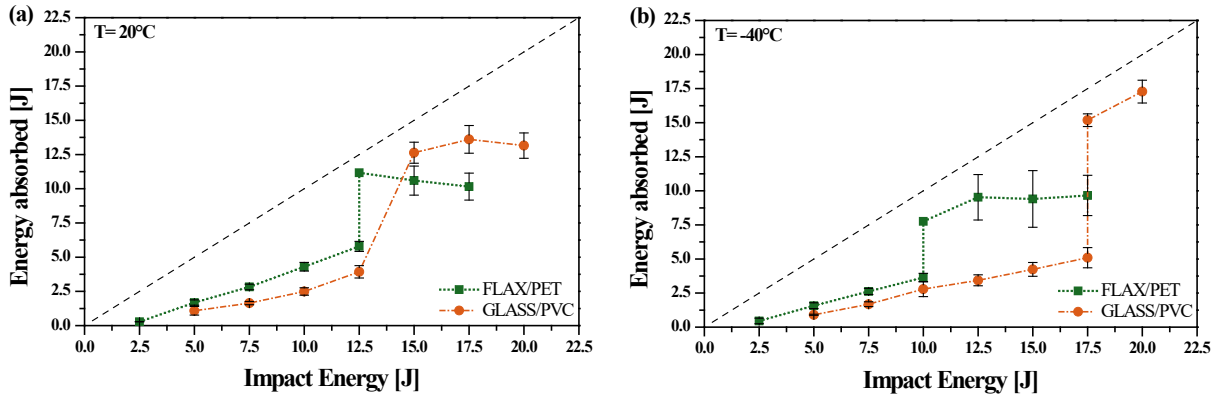

Figure 2. Absorbed energy as a function of impact energy for both sandwich configurations: (a) room temperature and (b) −40°C.

For the Flax/PET sandwich, the absorbed energy increases significantly with impact energy, but shows a sharp rise at 12.5 J under ambient conditions and 10 J at -40°C, indicating a shift in the dominant failure mode. This behaviour is also reflected in the energy ratio, as shown in **Figure 3**. The Flax/PET system reaches values near unity at the transition energy, indicating that nearly all the impact energy is dissipated through irreversible damage. Beyond this point, the ratio tends to decrease, as the structure is no longer capable of absorbing additional energy, suggesting that the beams are close to complete collapse.

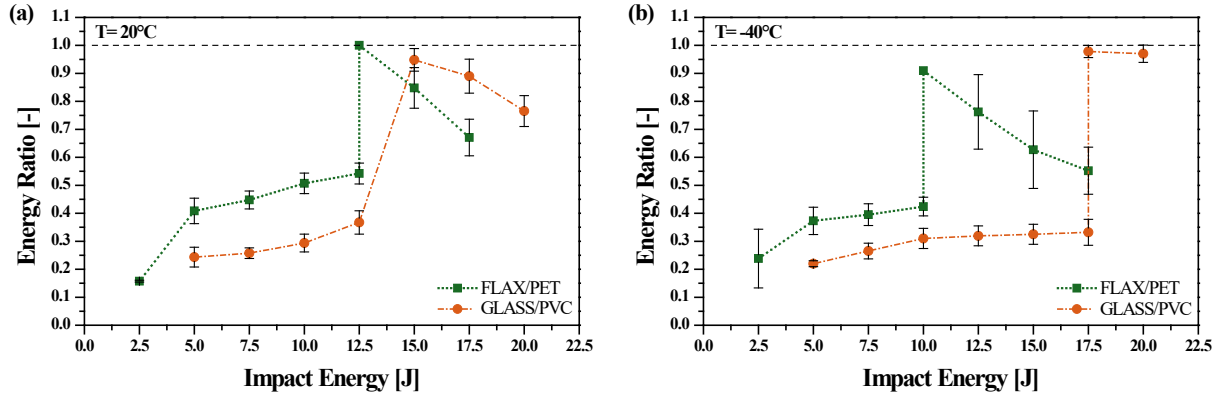

Figure 3. Energy absorption ratio as a function of impact energy for both sandwich configurations: (a) room temperature and (b) −40°C.

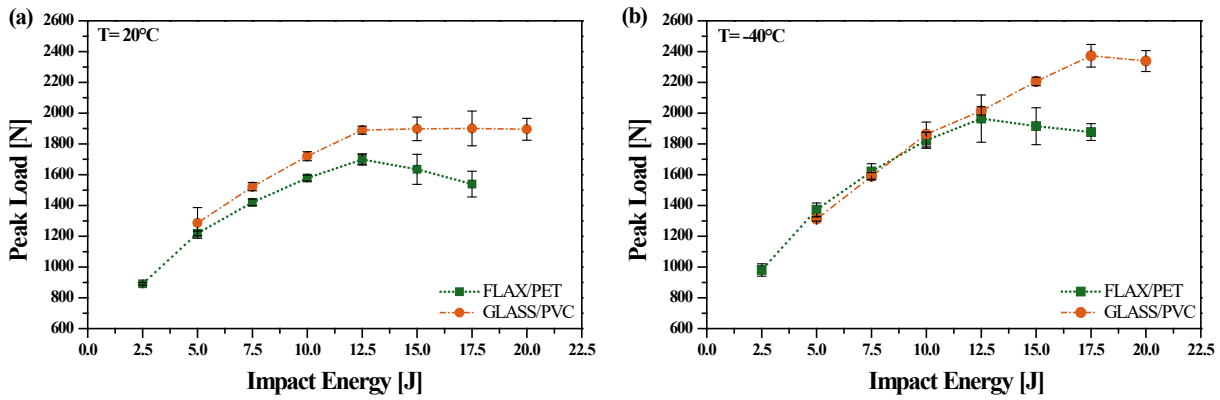
Meanwhile, the Glass/PVC configuration displays a more gradual increase in both absorbed energy and energy ratio. No clear transition is observed at room temperature, although the data suggests that the threshold energy lies between 12.5 J and 15 J. Additionally, the influence of temperature on this configuration appears to be limited, as the overall trends between 20°C and -40°C remain relatively similar. This implies that the onset of extensive damage occurs at slightly higher energies compared to the PET configuration, albeit with less efficient energy dissipation.

At higher impact energies (15 J at 20°C and 17.5 J at −40°C), the energy ratio of the Glass/PVC system surpasses that of the Flax/PET sandwich. However, this apparent advantage does not reflect superior energy

absorption performance, but rather the fact that the PVC structure is still resisting and has not yet reached complete failure. By comparison, the PET system has already undergone its full damage progression and begins to lose efficiency as the dominant failure modes saturate. Overall, these results demonstrate that the Flax/PET sandwich exhibits superior energy absorption performance, particularly under moderate impact energies and cold environments, although it is related to a higher level of damage.

3.2 Peak load and failure response

Figure 6 shows the variation of the peak impact force as a function of impact energy. In all cases, the peak load increases with energy until a threshold value is reached, beyond which the growth rate diminishes. This trend reflects the onset of damage mechanisms and the associated reduction in structural stiffness.



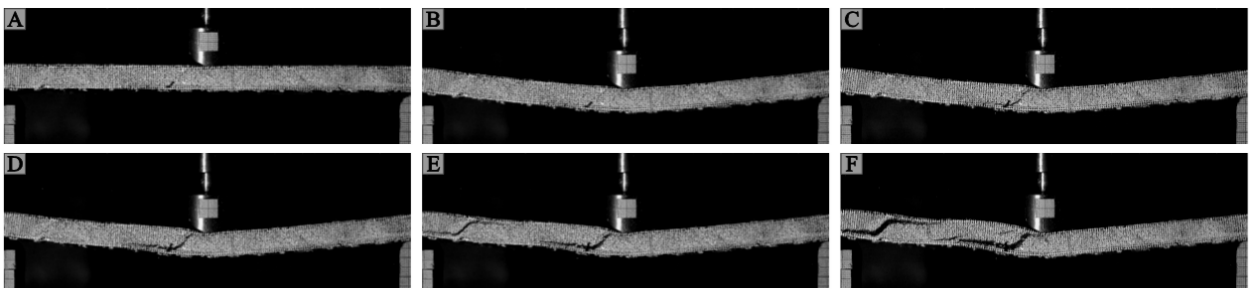


Figure 6. Peak impact force as a function of impact energy for both sandwich configurations: (a) room temperature and (b) −40°C.

In the Flax/PET sandwich, the peak load exhibits a similar trend at both temperatures, with nearly identical values across the entire energy range. This indicates that the mechanical properties of the PET foam, namely stiffness and strength, are minimally affected by the temperature reduction.

As shown in **Figure 7**, multiple diagonal cracks initiate just after the point of maximum load, coinciding with a sudden drop in the measured force. This damage sequence is captured in frames A to F, and involves the formation of diagonal shear cracks at approximately 45° within the PET foam core (frame C), followed by their propagation through the core thickness (frame D), and subsequent core-skin debonding beneath the impactor (frames E and F). This damage sequence compromises the structural integrity of the beam and prevents elastic recovery, thereby resulting in full energy absorption without rebound.

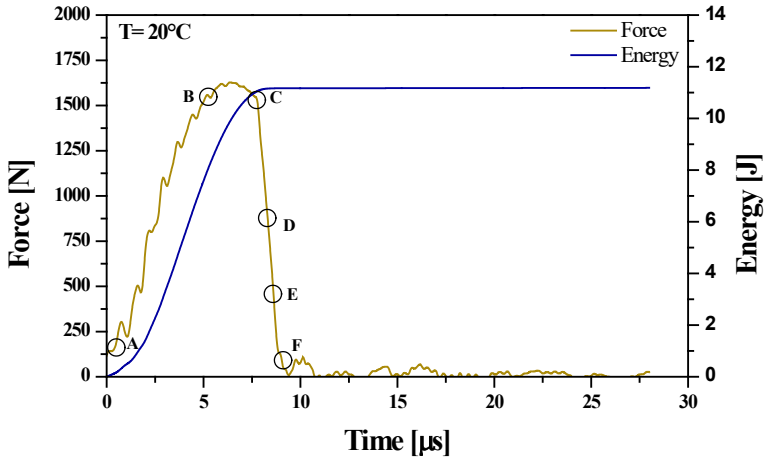

Figure 7. Force–time and energy–time curves for PET-core sandwich at 12.5 J and 20°C.

In contrast, the response of the Glass/PVC sandwich differs significantly beyond the threshold energy. As observed in **Figure 6**, temperature has little influence below the threshold, where peak force remains stable. This limited thermal sensitivity aligns with observations by Castellanos et al. [1], who studied PVC-core sandwiches with carbon/vinylester skins under -50°C impacts. However, while those authors reported a decrease in peak force at low temperature, our results show an increase at -40°C once the threshold energy is exceeded. This discrepancy may stem from the lower temperature sensitivity of the glass/epoxy skins used in this work, which are less brittle compared to the carbon/vinylester laminates employed by Castellanos et al. [1]. Additionally, differences in specimen geometry and impact configuration, such as the use of rectangular panels and hemispherical impactors, could further contribute to the different behaviour observed.

At the threshold energy, barely any damage is observed in the PVC core. As shown in **Figure 8**, damage is confined to compressive failure of the upper skin, with no significant visible damage in the core region. This damage pattern begins with localized core crushing (frame C), followed by top skin failure (frame D). The absence of rebound confirms that the residual energy remains trapped within the damaged structure, likely due to plastic collapse and progressive fracture in the core. The force–time curve of the Glass/PVC beam does not exhibit a sharp drop to zero, unlike the Flax/PET sandwich, which is consistent with a more localized and gradual failure mode.

These results indicate that the Glass/PVC sandwich beam sustains higher peak loads and exhibits delayed damage initiation compared to the Flax/PET sandwich.

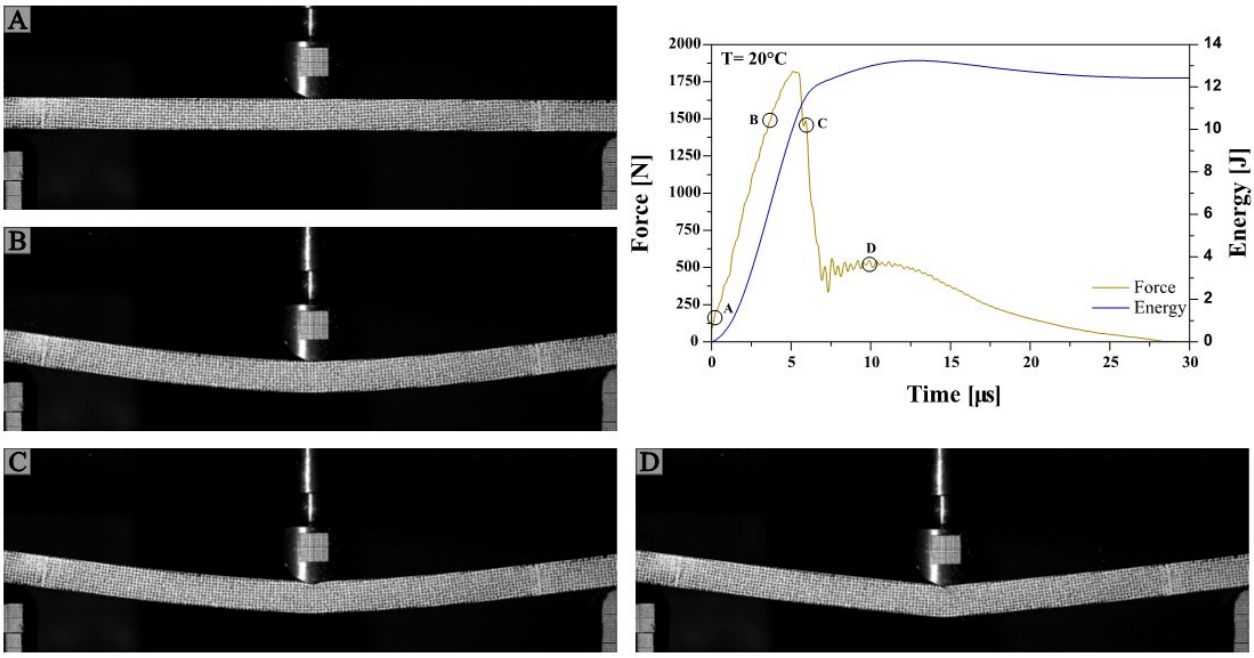

Figure 8. Force–time and energy–time curves for PVC-core sandwich at 17.5 J and 20°C.

3.3 Effective flexural modulus

Figure 9 shows the evolution of the effective flexural modulus as a function of impact energy, estimated from the linear portion of the force–displacement curve under the assumption of Euler–Bernoulli beam behaviour. The effective modulus remains nearly constant across the studied energy range, indicating that both sandwich systems are relatively insensitive to the associated strain rate. A difference of approximately 10% is observed between the Flax/PET and Glass/PVC configurations.

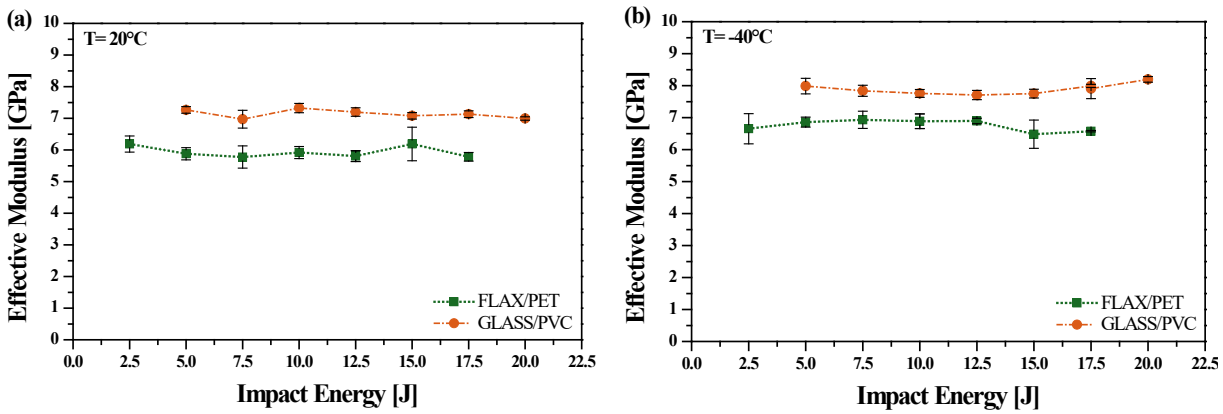

Figure 9. Effective flexural modulus as a function of impact energy: (a) room temperature and (b) −40°C.

Both materials exhibit a slight increase in stiffness at −40 °C compared to room temperature, with gains of approximately 20% for Flax/PET and 15% for Glass/PVC. This suggests a temperature-induced stiffening effect. Interestingly, this trend contrasts with the energy absorption behaviour, where both systems displayed

increased brittleness. These results indicate that, despite a reduction in damage tolerance at low temperatures, the initial elastic response of both configurations improves moderately.

4 CONCLUSIONS

This study analysed the low-velocity impact response of two sandwich beam configurations tested at two temperatures. In the energy range and thermal conditions considered, sandwich beams manufactured with natural and sustainable materials exhibited inferior performance compared to conventional sandwich structures composed of glass/epoxy skins and PVC foam cores. This outcome is consistent with the superior mechanical properties of the constituent materials in the reference system. In particular, the Glass/PVC sandwich showed a higher threshold energy, and its impact response remained largely unaffected by temperature variations.

Additionally, the conventional sandwich exhibited a progressive and localized failure mode, whereas the Flax/PET configuration showed a more abrupt and catastrophic failure when subjected to impact energies at or above its threshold. However, in terms of peak impact force, the Flax/PET system demonstrated performance comparable to the reference sandwich, with limited temperature sensitivity. These results suggest that, while sustainable sandwich structures can match the load-bearing capacity of conventional designs, their damage tolerance and energy thresholds are more susceptible to environmental conditions. Therefore, further improvements in core toughness and interfacial strength are required to enhance their impact resistance and make them more competitive in demanding applications.

ABSTRACT

Honeycomb structures, inspired by nature, are widely valued for their remarkable strength-to-weight ratios, making them indispensable in aerospace, automotive, and other engineering applications. This study explores the mechanical performance of functionally graded honeycomb structures with various thickness gradation configurations. Seven designs, including uniform and staged thickness variations, were analyzed through finite element method (FEM) simulations and validated with experimental testing to assess their behavior under compressive loading. The results demonstrate that incorporating thickness gradation significantly enhances mechanical properties compared to uniform designs. Staged configurations improved compressive strength, energy absorption, and crushing force efficiency, with the number and placement of thickness variations playing a critical role. While increasing the number of gradation stages refined stability and crushing force efficiency, it also resulted in trade-offs, such as reduced load-bearing capacity and energy absorption. Designs with strategically placed thin regions outperformed others in terms of energy dissipation and stability, highlighting their suitability for applications requiring controlled deformation and impact resistance. This study provides valuable insights into the design and optimization of functionally graded honeycomb structures, offering a pathway for developing lightweight, high-performance materials tailored to specific engineering needs.

1 INTRODUCTION

Honeycomb structures, inspired by the natural design of beehives, have long been recognized for their outstanding combination of low density and high stiffness [1], making them ideal for a range of applications across industries such as aerospace [2], automotive [3], architecture [4], and biomedicine [5]. The unique cellular configuration of honeycombs offers exceptional strength and energy absorption [6-9], particularly in sandwich composite designs, which are widely used in critical structures where weight reduction and impact resistance are paramount [10, 11]. Under out-of-plane loads, honeycombs exhibit high stiffness due to axial extension or compression of their cell walls, which provide structural support [12]. However, the in-plane stiffness of honeycomb structures remains relatively low, primarily due to the bending stresses arising from the distinct geometry of the cells [13].

Recent advancements in honeycomb design have sought to optimize their mechanical properties, particularly to enhance the in-plane behavior of these materials. This has led to efforts to adjust the geometry of honeycomb cells, including the angles of hexagonal cells, to create tailored materials suited for specific applications. One notable development in this field involves the integration of auxetic materials—materials that exhibit a negative Poisson's ratio—into traditional honeycomb structures [14, 15]. These auxetic designs, such as hybrid honeycombs with split vertical struts, have been shown to significantly improve compressive strength, energy absorption, and the overall deformation patterns of honeycombs, which are crucial for controlled collapse and maintaining structural integrity in dynamic load conditions [16].

Alongside these geometric optimizations, the concept of functionally graded materials (FGMs) has emerged as a promising approach to enhance honeycomb performance. FGMs allow for a gradual variation in material properties across the structure, resulting in improved strength, durability, and environmental resistance [17]. This gradual change in properties, unlike traditional composites that feature abrupt transitions, enables the design of more efficient structures with tailored mechanical characteristics, such as modulus, density, and thermal conductivity [18-20]. Initially developed for aerospace applications requiring efficient thermal barriers, FGMs have since expanded into sectors such as biomedical, chemical, nuclear, and energy engineering, where high- performance materials are critical [21].

Building on these advancements, recent research has explored functionally graded honeycomb structures, which incorporate varying geometries of unit cells across their panels to achieve tailored mechanical properties. By adjusting the geometries, honeycomb structures can exhibit enhanced stiffness-to-weight ratios, which is particularly beneficial for lightweight mechanical and aerospace applications. The introduction of FGMs into these gradient honeycombs has demonstrated improvements in overall stiffness, shear modulus, and bending performance, further enhancing the suitability of these structures for applications that demand precise mechanical performance and optimized strength-to-weight ratios [22- 24].

In this study, we focus on the design and manufacturing of functionally graded honeycomb structures with linear thickness variations in the out-of-plane direction in each stage. Specifically, seven configurations are considered:

1. Uniform average thickness
2. A single-stage thick-thin variation
3. A double-stage thick-thin-thick variation
4. A double-stage thin-thick-thin variation
5. A triple-stage thin-thick-thin-thick variation
6. A quadruple-stage thin-thick-thin-thick-thin variation
7. A quadruple-stage thick-thin-thick-thin-thick variation

To validate these designs, finite element method (FEM) simulations were performed to predict mechanical performance under out-of-plane compressive loading. Experimental tests using a universal testing machine (UTM) were carried out to validate these simulations and characterize key mechanical properties, including stiffness, densification displacement, mean crushing force, and energy absorption capacity. This study aims to deepen the understanding of functionally graded honeycombs and their potential applications in high-performance scenarios, such as in aerospace, automotive, and packaging industries, where tailored mechanical responses are essential for optimized structural performance.

2 MATERIALS AND METHODS

2.1 Materials

Esun PLA+ filaments which are known for their combination of low melting point and high strength were used in this study for printing functionally graded honeycomb structures. The dog-bone shaped tensile test specimens, 165 mm in length and 19 mm in width, were produced using Bambu Lab P1S 3D printer. The tensile properties of the filaments were obtained by tensile tests using a UTM equipped with a 50 kN load cell according to ASTM D638 standard. The stress strain data of the filaments under tensile loading are depicted in Figure 1.

All samples were printed with 100% infill value as it ensures uniform mechanical properties across the material. This helps the object retain its shape and structural integrity especially under prolonged applied loads. The recommended nozzle temperature for Esun PLA+ filament is reported to be between 210-230 °C, therefore, 220 °C was selected for 3D printing. The installed nozzle has 0.4 mm extrusion diameter for finer resolution of samples. Bed temperature of 50 °C provided adequate adhesion and minimized warping effects for the samples. Additionally, the printing speed of 100 mm/min was found to be sufficient for desirable quality of the samples.

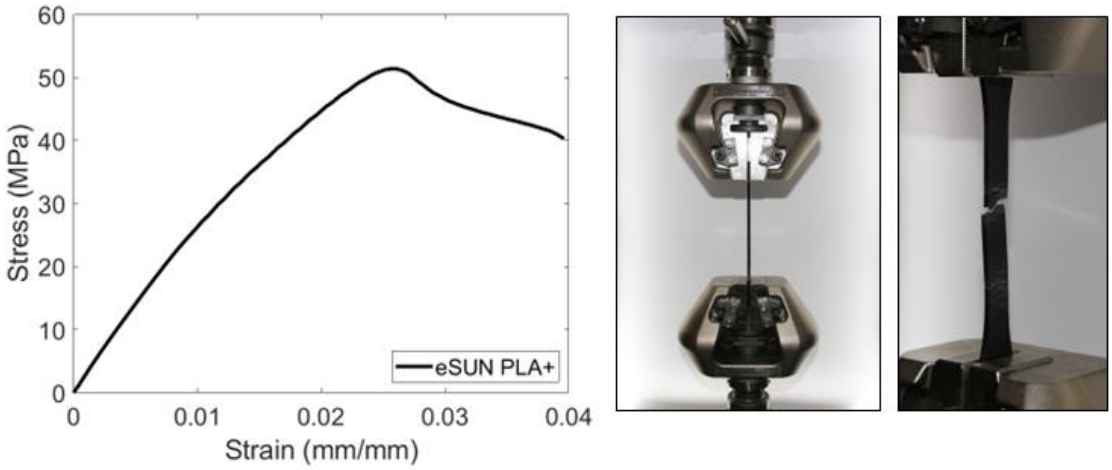

Figure 1: Esun PLA+ material experimental tensile stress-strain curve and testing apparatus.

2.2 Design and Fabrication of Graded Honeycomb Structures

The unit cell used in this study is shown in Figure 2 where parameters L, H, t_1, t_2, t_{avg}, and θ represent the side length, unit cell height, thickness of the thin section, thickness of the thick section, average thickness where $t_{avg} = (t_1 + t_2)/2$, and interior angle of the unit cell, respectively. The geometrical dimensions of the honeycomb unit cells are as follows: the side length L is 15 mm, the unit cell height H is 30 mm, the thickness t_1 is 0.5 mm, t_2 is 1.5 mm, t_{avg} is 1 mm, and the interior angle θ is 30°. For this study, the average thickness of 1 mm was maintained across all samples to ensure equal mass, regardless of variations in the design pattern. This approach eliminates the need to use mass-normalized, specific values for comparison. A double-stage unit cell is shown in Figure 2, clarifying the average thickness concept for tapered configurations.

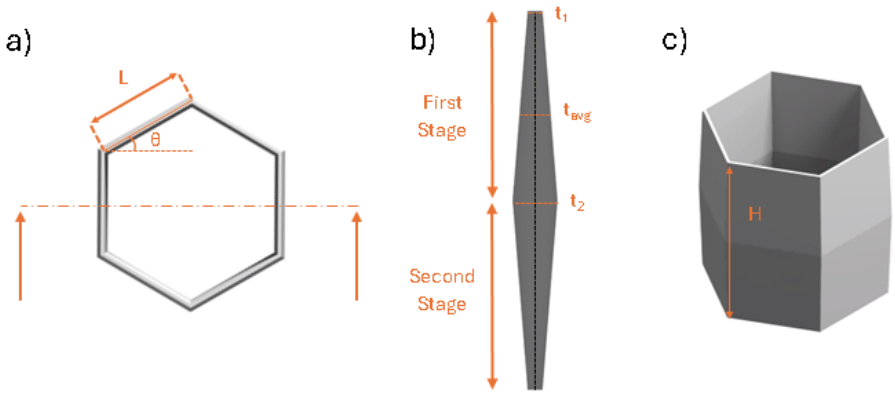

Figure 2: An illustration of a double-stage unit cell: a) Top view, b) side view of a single cell wall, and c) isometric view of the unit cell.

Model designs of honeycomb unit cells were developed using CATIA V5 software. The models were generated with a symmetric design approach, where the unit cells are arranged radially around a central origin point, leading to an axisymmetric design. This circular distribution facilitates compression testing by allowing the samples to be directly tested without the need for additional plates. Moreover, this design minimizes the area occupied by the samples, allowing them to fit efficiently within the standard circular plates of the UTM machine.

A systematic approach was adopted for naming different honeycomb configurations based on their thickness variations. The naming convention uses a combination of letters and numbers to represent the configuration type, ensuring clarity and brevity. The prefix H was used for all structures, indicating the honeycomb geometry. Depending on the variations in the thickness, U stands for uniform thickness whereas SS, DS, TS, and QS refer to linear thickness variations in a single stage, a double stage, a triple stage, and a quadruple stage in an alternating thinning and thickening sense. Then, numeric characters were used in between to describe the thickness values at the top face of honeycombs getting in contact with the load applying platen in mm.

This design scheme leads to only one configuration in honeycombs with an odd number of stages since having a thin or thick cell wall at the top face generates the same configuration, upside down. However, for an even number of stages, two different configurations arise and the top face thickness becomes important. For example, H-0.5SS stands for a single stage honeycomb where the thickness linearly varies between 0.5 and 1.5 mm from top to bottom. On the other hand, H-1.5QS denotes a sample with four stages where in each sample the thickness varies between 0.5 and 1.5 mm with the thickness at the top face is 1.5 mm. To maintain consistency, the codes and their corresponding configurations have been documented in Table 1. Furthermore, computer aided designs (CAD) of the corresponding configurations are depicted in Figure 3.

Configuration Description	**Honeycomb**
Uniform thickness of 1 mm	H-1U
Single stage variation (0.5 mm to 1.5 mm)	H-0.5SS
Double stage with 1.5 mm thickness at the top face	H-1.5DS
Double stage with 0.5 mm thickness at the top face	H-0.5DS
Triple stage with 0.5 mm thickness at the top face	H-0.5TS
Quadruple stage with 1.5 mm thickness at the top face	H-1.5QS
Quadruple stage with 0.5 mm thickness at the top face	H-0.5QS

Table 1: Configuration descriptions and their corresponding codes.

2.3 Energy Absorption Characteristics

The energy absorption characteristics of cellular structures are primarily described using six key indices: densification displacement (x_d), mean crushing force (F_m), peak force (F_{max}), crushing force efficiency (e_f), and energy absorption (EA). Among these, the most prominent parameters are x_d and F_m. The expressions of these parameters are obtained based on the energy absorption efficiency approach as noted by Li et al. [25] and detailed below.

The energy absorption efficiency $\eta(x)$ is defined as:

$$\eta(x) = \frac{1}{F(x)H}\int_{x_y}^{x} F(\bar{x})d\bar{x} \tag{1}$$

where $F(x)$ represents the compressive force, H is the specimen height, and x_y denotes the displacement value at the end of the linear region. The densification displacement corresponds to the displacement at which $\eta(x)$ achieves its maximum value, determined by:

$$\left.\frac{d\eta(x)}{dx}\right|_{x=x_d} = 0 \tag{2}$$

The peak force is the maximum compressive force observed until densification begins. The mean crushing force, a critical parameter reflecting the energy absorption capability of the structure in the plateau phase, is then calculated as follows:

$$F_m = \frac{\int_{x_y}^{x_d} F(\bar{x})d\bar{x}}{x_d - x_y} \tag{3}$$

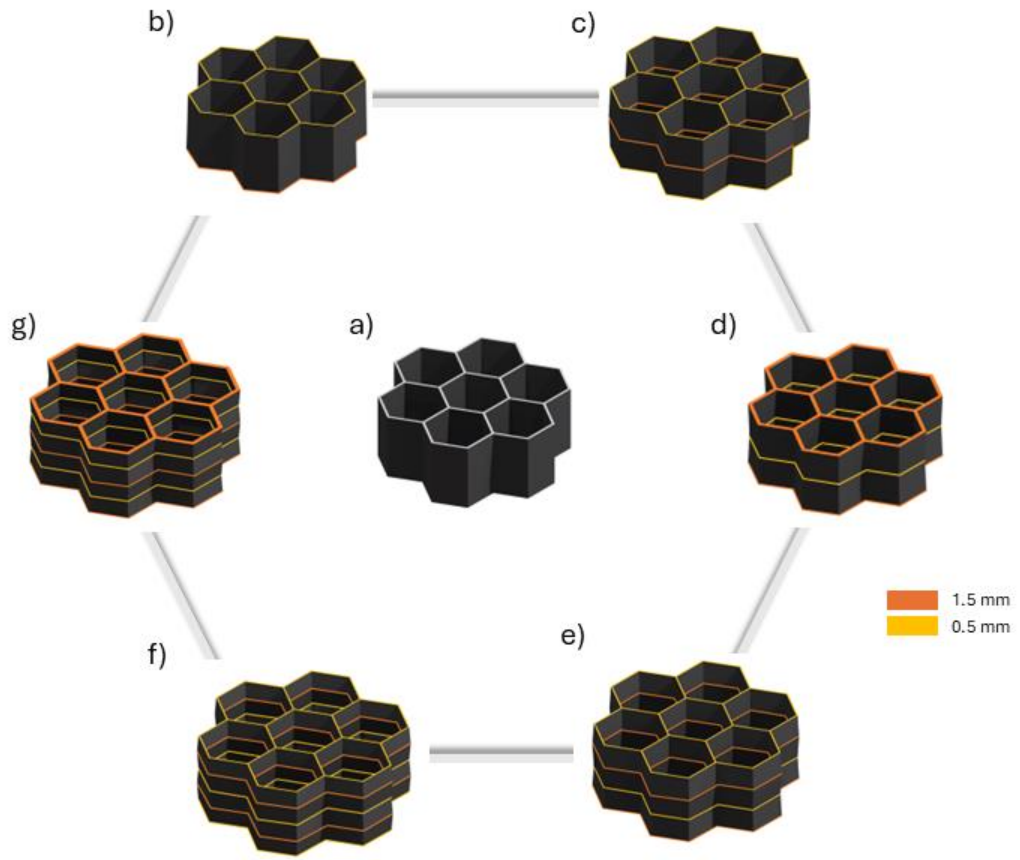

Figure 3: Computer aided drawing designs of functionally graded honeycomb lattice structures: a) H-1U, b) H-0.5SS, c) H-0.5DS, d) H-1.5DS, e) H-0.5TS, f) H-0.5QS, and g) H-1.5QS.

Energy absorption represents the total energy absorbed by the cellular structure during compression and is determined as the area under the force-displacement curve:

$$EA = \int_0^{x_d} F(\bar{x})d\bar{x} \tag{4}$$

Furthermore, the crushing force efficiency is the ratio of the mean crushing force to the peak force:

$$e_f = \frac{F_m}{F_{max}} \tag{5}$$

Finally, stiffness is a material or structure's fundamental resistance to elastic deformation when a force is applied. It is quantitatively measured as the ratio of force to displacement $\boldsymbol{k = F/\delta}$, typically in N/m. In our study, it specifically refers to the initial out-of-plane compressive stiffness of honeycomb structures, where a balance of stiffness and controlled deformation is key for effective energy absorption in impact applications.

2.4 Finite Element Analysis

ABAQUS commercial software was employed to analyze the mechanical behavior of honeycomb structures under compression loading and validate experimental findings. To perform the simulations, a dynamic-explicit solver with smooth loading was selected, which is suitable for quasi-static loading conditions. A total time step of 0.05 s was considered to expedite the simulations while retaining quasi-static conditions. To confirm the validity of the quasi-static analysis conducted using the dynamic-explicit solver, the kinetic energy values must be negligible compared to the internal energy values [26]. This verification is illustrated in Figure 4 which confirms the accuracy of the simulation model.

A general contact approach was used to model interactions between the structural components, with a friction coefficient of 0.2. The lower surface was fixed while the upper surface underwent axial displacement loading to replicate the boundary conditions of the experimental tests. The structure was meshed using C3D8R elements, and a mesh size of 0.3 mm was used.

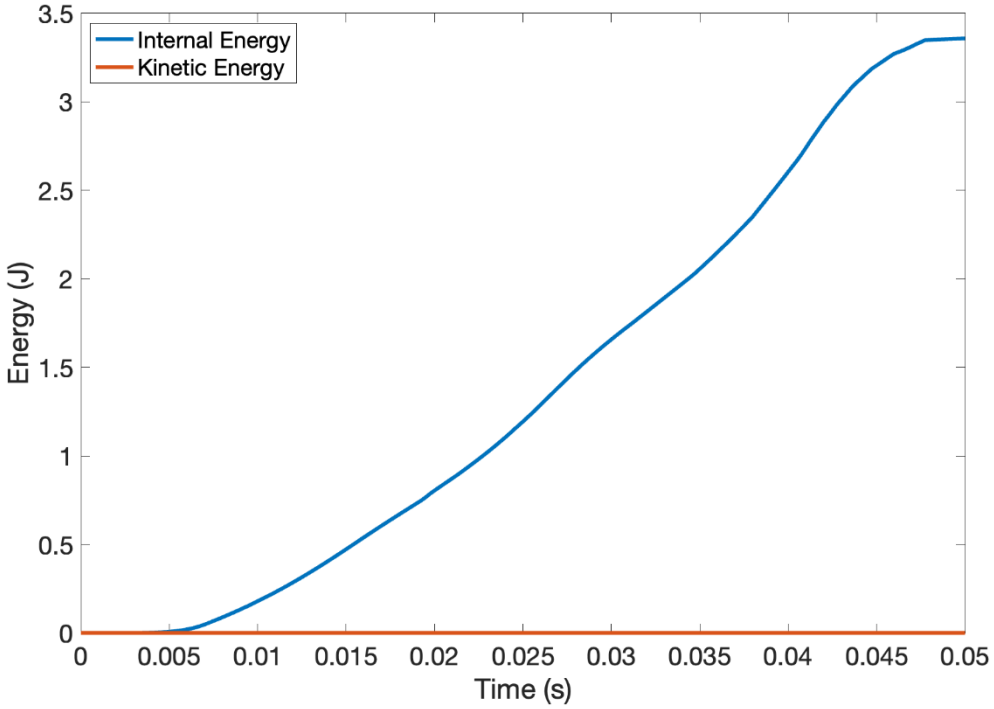

Figure 4: Internal and kinetic energies for H-1U under out-of-plane FEM compression test.

2.5 Experimental Characterization

Compression testing of physical samples were carried out by Shimadzu AGS-X UTM with a 50 kN load cell. Samples were subjected to compression tests with a persistent displacement rate of 3 mm/min until 80% strain is achieved for each model. At least three samples were tested according to ASTM C365 guidelines, and the obtained force-displacement data were utilized to calculate mechanical properties including peak force, densification displacement, energy absorption, mean crushing force, and crushing force efficiency.

3 RESULTS AND DISCUSSION

As an illustrative case, the experimental results obtained from three different samples and the finite element analysis results of H-1U samples are shown in Figure 5 where EXP stands for the experimental data. Based on the results presented in Figure 5, the printing quality among three different samples is quite similar, evinced from the force-displacement behavior of the samples showing almost identical results until around 6 mm, beyond which the impurities start altering the behavior. Furthermore, the FEM and experimental results are in close agreement, indicating the accuracy of the FEM simulations.

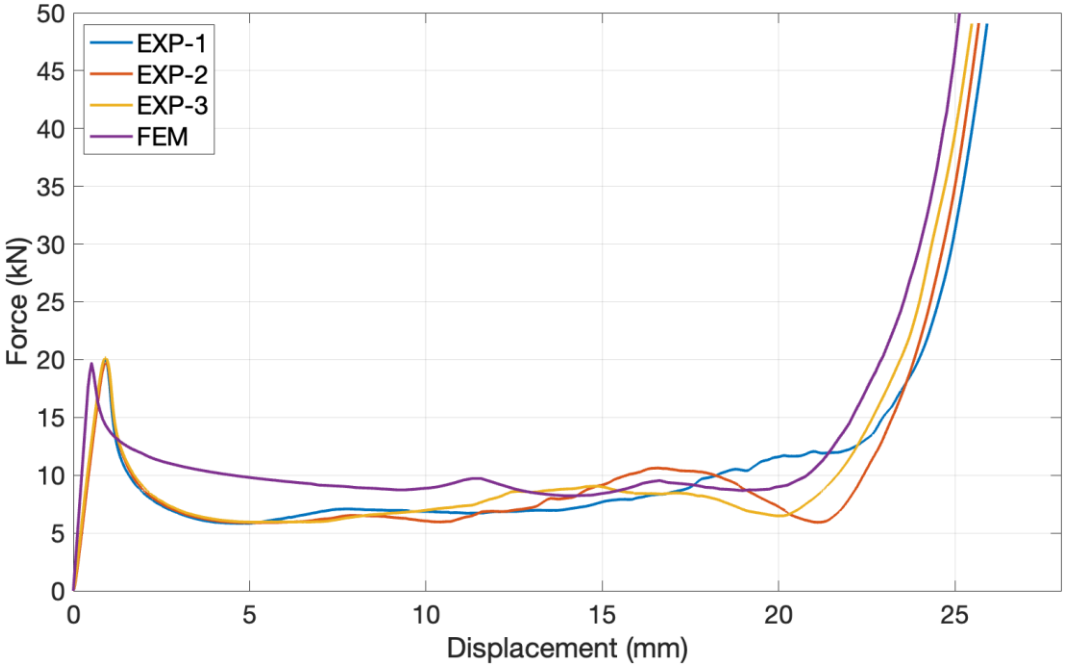

Figure 5: Experimental and numerical (FEM) out-of-plane force-displacement curves for H-1U.

A MATLAB code which utilizes the force displacement curves as inputs was developed to calculate the important performance metrics pertinent to mechanical characteristics of honeycomb structures in the out-of-plane direction such as densification displacement, peak force, mean crushing force, crushing force efficiency, and energy absorption. The force-displacement curves for FEM and experimental tests are shown in Figures 6 and 7, respectively. The performance metrics obtained via the developed MATLAB code are tabulated in Table 2. The tabulated results provide a comprehensive overview of the mechanical performance of seven distinct honeycomb configurations; each designed with variations in out-of-plane thickness. By analyzing key metrics such as stiffness, densification displacement, mean crushing force, and energy absorption, one can discern clear trends and identify optimal designs for specific applications.

Regarding initial deformation behavior, the uniform H-1U configuration stands out with the longest linear region (0.94±0.01 mm), indicating its superior ability to withstand elastic deformation before permanent yielding. In contrast, designs like H-0.5SS, H-0.5DS, and H-0.5TS, characterized by thinner top sections or a single-stage linear variation, exhibit significantly lower linear regions, suggesting they begin to deform plastically much earlier. This trade-off implies that while H-1U is more resilient to initial deformation, the graded designs might be more suitable for applications where controlled, early initiated plastic deformation is a desired mechanism for protection systems.

When considering the structure's capacity for energy absorption through deformation, the densification displacement becomes crucial. Here, H-0.5TS configuration excels, demonstrating the highest densification displacement (23.99 ± 0.31 mm). This indicates that the triple-stage design with a thin top face can effectively absorb energy over a larger deformation range before fully compacting. Similarly, H-0.5QS and H-0.5SS also show high densification displacements, positioning these graded structures as superior choices for impact protection and scenarios requiring prolonged energy dissipation. Conversely, H-1.5DS, which features a thick top face, exhibits the lowest densification displacement, suggesting a more rapid compaction and thus a smaller effective energy absorption range.

In terms of load-carrying capacity and energy absorption efficiency, the peak force, mean crushing force, and crushing force efficiency metrics offer valuable insights. H-0.5TS consistently leads in both peak force (22.72 ± 2.98 kN) and mean crushing force (11.90 ± 0.28 kN), highlighting its robust load-bearing capacity and effective energy absorption during the crushing phase. While H-0.5TS shows strong performance, H-0.5DS distinguishes itself with the highest crushing force efficiency (66.87 ± 5.03%). This high efficiency suggests a very stable and consistent crushing behavior after the initial peak load, which is highly beneficial for predictable energy dissipation in crashworthiness applications.

In contrast, the uniform H-1U and the thicker top-faced H-1.5DS and H-1.5QS configurations generally exhibit lower crushing force efficiencies, indicating a more abrupt force drop after the peak load.

The ultimate measure of a structure's impact resistance is its total energy absorption capacity. The results overwhelmingly favor the graded designs, with H-0.5TS absorbing a remarkable 281.98 ± 10.64 J of energy, significantly outperforming all other configurations. H-0.5QS and H-0.5SS also demonstrate excellent energy absorption capabilities, reinforcing the benefits of functional grading for impact protection. The H-1.5DS, with its thicker top face, shows the lowest energy absorption, underscoring that certain grading strategies are more effective for maximizing energy dissipation.

Finally, regarding stiffness, which reflects the structure's resistance to initial elastic deformation, H-1.5DS exhibits the highest value (25.60 ± 1.33 N/m). The uniform H-1U also demonstrates good stiffness. While the graded designs like H-0.5TS and H-0.5QS show comparable stiffness values, those with thinner top faces (H-0.5SS and H-0.5DS) tend to be slightly less stiff. This suggests that for applications demanding maximum initial rigidity, configurations with uniform thickness or thicker starting layers might be marginally preferable, though the differences in stiffness among most graded samples are not as dramatic as the differences in energy absorption.

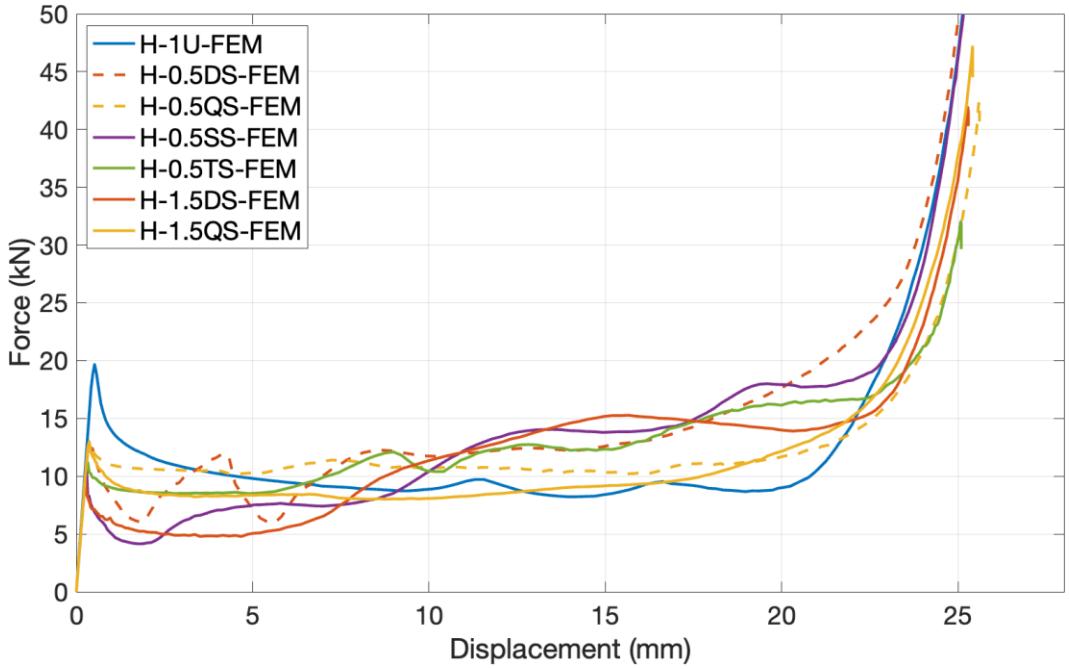

Figure 6: Force-displacement curves of honeycomb samples from FEM analyses.

Sample	x_y (mm)	x_d (mm)	F_{max} (kN)	F_m (kN)	e_f (%)	EA (J)	K (kN/mm)
H-1U	0.94 ± 0.01	21.01 ± 0.88	19.79 ± 0.23	7.80 ± 0.23	39.41 ± 1.39	167.02 ± 10.98	24.38 ± 0.26

4 CONCLUSIONS

This study thoroughly investigated the compressive behavior of various honeycomb structures, comparing uniform (H-1U) and functionally graded designs. The experimental and FEM simulation results showed very good agreement, validating the simulation approach adopted. Through a user-friendly MATLAB script, key performance metrics including compressive force, mean crushing force, crushing force efficiency, energy absorption, densification displacement, and stiffness were evaluated.

The results demonstrate that functionally graded honeycomb structures offer significant advantages over uniform designs, particularly in energy absorption capacity and crushing force efficiency. The triple-stage configuration (H-0.5TS), characterized by a thin top face, consistently emerged as the superior design for applications demanding high impact resistance and effective energy dissipation, absorbing a remarkable 281.98 ± 10.64 J of energy. While uniform designs like H-1U showed longer elastic region (resilience to initial elastic deformation) and H-1.5DS exhibited the highest stiffness, the overall gains in energy absorption and controlled crushing behavior observed in graded structures like H-0.5QS and H-0.5SS were substantial.

In conclusion, although certain graded designs may demonstrate earlier permanent deformation or exhibit slightly reduced initial stiffness, their enhanced capacity for energy dissipation—achieved through controlled deformation and prolonged energy absorption—renders them highly advantageous. These results underscore the potential of functionally graded structures to enable tailored mechanical responses, offering significant promise for high-performance applications in impact-critical sectors such as aerospace and automotive engineering.

Keywords: Short fiber-reinforced composite, Viscoelasticity, Random fields, Multiscale, Tensile creep test

ABSTRACT

Short fiber-reinforced composites, such as Polybutylene Terephthalate with a fiber mass fraction of 30%, exhibit enhanced mechanical properties due to embedded reinforcing short fibers. However, the reinforcing fibers and hence the microstructural randomness cause pronounced spatially distributed viscoelastic behavior, resulting from microstructural randomness. This study presents a combined experimental and numerical investigation to model and analyze the local distribution of viscoelastic parameters in short fiber-reinforced composites, both at the microscale and component level. In the experimental context, the viscoelastic behavior of the material is characterized using tensile testing at the component level and nanoindentation at the microscale. These analyses reveal significant variability in the creep properties of fiber-reinforced specimens compared to those of unreinforced Polybutylene terephthalate. The numerical multiscale simulation is based on random fields, where the viscoelastic behavior is described through a generalized Maxwell model by using a Prony series representation. With this, a connection between the microscale and component level is established. Therefore, at the microscale, artificial microstructures are generated based on statistical descriptors of fiber geometry and orientation. The material properties of the homogenized material are obtained through numerical simulations that respect Hill's condition. In order to account for the stochastic nature resulting from the microstructure at the component level, spatially varying material parameters are represented via second-order Gaussian random fields, discretized using the Karhunen-Loève expansion. With the presented multiscale approach, the spatial randomness of the viscoelastic behavior is successfully incorporated into numerical simulations. The findings of the numerical simulation exhibited a robust alignment with the experimental data, thus providing additional support for its practical relevance.

1 INTRODUCTION

Short Fiber-Reinforced Composites (SFRCs) are formed by combining two or more constituent materials during an injection molding process [2]. In this specific case, thermoplastic Polybutylene terephthalate (PBT) is generally used as the matrix, while short fibers are utilized to provide mechanical reinforcement, resulting in increased stiffness and strength. However, polymer-based composites, such as PBT GF30 (with 30% fiber mass fraction), exhibit time-dependent deformation under sustained mechanical loads, a phenomenon generally referred to as viscoelasticity. This behavior is primarily attributed to the viscoelastic nature of the polymer matrix [5]. Since PBT GF30 can be processed by injection molding, its applications are found in the automotive, aerospace, and electronics industries. For these applications, a precise characterization of viscoelastic behavior is essential for reliable performance prediction [9].

The generalized Maxwell model is a widely used approach to describe the viscoelastic response of SFRCs [13]. This model conceptualizes the behavior of the material using a network of springs and dashpots, respectively representing elastic and viscous effects [13]. Due to its standardized structure, the Maxwell model is implemented in most commercial Finite Element Method (FEM) software packages [1]. The numerical implementation is typically based on the representation of the Prony series [13].

Although the addition of short fibers enhances the mechanical properties of SFRCs, it also introduces a notable drawback, such as the spatial heterogeneity of mechanical properties at the component level [10]. This heterogeneity is derived from the microstructure of the material itself [4, 11], which is primarily influenced by the manufacturing process, such as mold injection [2]. During mold injection, variations in flow velocity and the resulting shear forces in the cross-section of the melt flow cause non-uniform microstructural characteristics [2]. Consequently, this results in spatially distributed mechanical properties at the microscale and component levels.

The probabilistic nature of the microstructure is characterized by probability density functions of fiber length, fiber diameter, and fiber orientation [4, 12]. Due to the considerable disparity in the length scales, where the fiber length is much smaller than the overall dimensions of the component, a multiscale approach is essential to accurately capture the mechanical behavior of the SFRCs at the component level [10].

One potential framework for modeling the spatial distribution of mechanical parameters is to utilize random fields, thereby allowing for the representation of the behavior of inhomogeneous materials at the component level [14]. The numerical discretization of these random fields is based on the Karhunen-Loève expansion [7]. In this work, a two-dimensional cross-section of a standardized tensile test specimen, conforming to DIN EN ISO 527-2 type 1A, is used within a numerical framework to model at the component level and in an experimental context. First, the entries of the anisotropic elasticity tensor are determined using an artificial microstructure, which is described in detail in [10, 12]. The artificial microstructure is generated based on the probabilistic characteristics of fiber length, fiber orientation, and fiber diameter. The numerical simulation at the microscale is conducted using linear elastic modeling for both the fibers and the matrix material. Finally, the component-level numerical results obtained using a second-order Gaussian random field are compared with the experimental tensile creep data.

2 THEORETICAL FRAMEWORK

Viscoelasticity effects are defined as a time-dependent deformation process that occurs under constant load and temperature conditions, involving both elastic and viscous contributions. This phenomenon is of particular significance in polymer-based materials, which exhibit viscoelastic behavior, combining time-independent elasticity with time-dependent viscous flow. Due to the heterogeneity of the material, these time-dependent mechanical properties are spatially distributed. To effectively capture and analyze this phenomenon, a probabilistic approach is necessary.

2.1 Viscoelasticity

Creep is a component of viscoelasticity, defined as the time-dependent deformation of a material under constant load and temperature. This phenomenon is commonly observed in polymer-based materials, which exhibit a combination of elastic and viscous behavior [13]. This behavior is often referred to as viscoelastic behavior. Creep deformation is generally understood to occur in three stages: primary, secondary, and tertiary creep, as demonstrated in Figure 1, which presents a schematic representation of the strain ε, as a function of time t.

As illustrated in Figure 1 the primary creep stage is characterized by a deceleration in the strain rate. It occurs immediately after stress application, with the initial strain $\varepsilon(0)$ representing the elastic response. A constant strain rate marks the secondary creep stage and is crucial to evaluating long-term material behavior. This is usually the longest stage. In the tertiary creep stage, the strain accelerates rapidly, ultimately leading to material failure.

The total strain $\varepsilon_{\text{total}}(t)$ over time of the specimen under constant loads, as schematically presented in Figure 1, can be expressed additively as

$$\varepsilon(t) = \varepsilon_{\text{total}}(t) = \varepsilon_{\text{linear elastic}} + \varepsilon_{\text{creep}}(t). \tag{1}$$

Here, $\varepsilon_{\text{linear elastic}}$ represents the immediate strain response upon the application of stress, following Hooke's law for linear elasticity. This component remains constant over time and does not contribute to the time-dependent deformation behavior of the material. However, the creep deformation $\varepsilon_{\text{creep}}(\text{t})$ accounts for the viscoelastic deformation that evolves under sustained loading, including all three stages.

In this study, the focus is on the primary and secondary stages because capturing the tertiary stage is time-consuming and experimentally challenging.

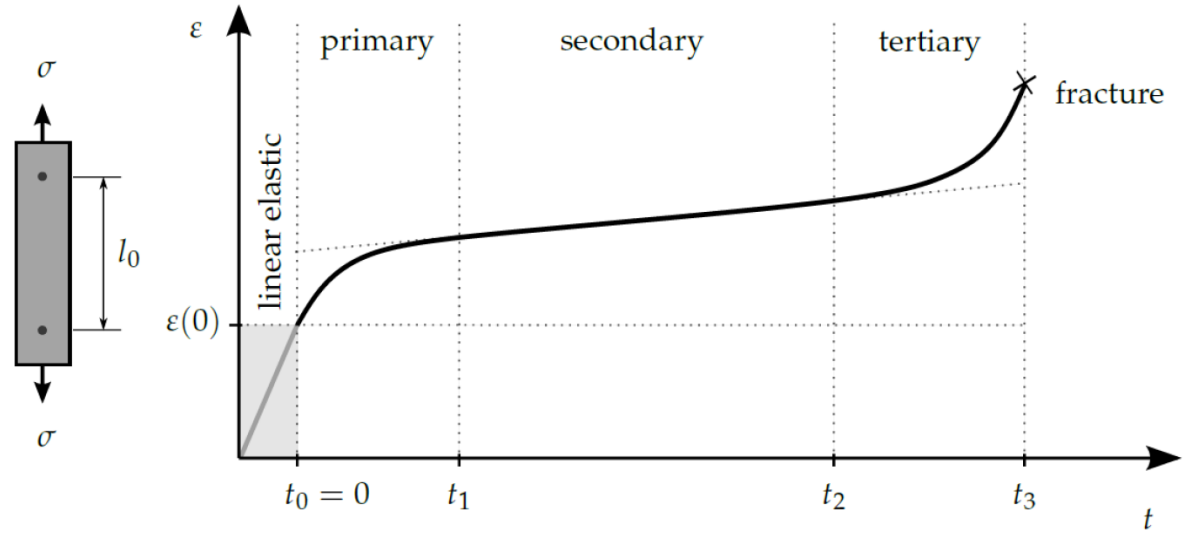

Figure 1: Schematic representation of the typical behavior of creep strain ε, which is divided into three distinct stages, while constant load σ and temperature T are applied to a sample.

The mathematical models are derived using rheological elements that describe the stress-strain relations for the viscoelastic behavior [13]. These elements are depicted in Figure 2, where the spring element represents Hooke's law with stiffness K_{eq}. According to Newton's law, a dashpot is defined as a purely viscous material characterized by its dynamic viscosity, denoted by η. When the spring and dashpot are connected in series, it is referred to as the Maxwell element. Furthermore, by employing a parallelization approach with the N_i-th Maxwell elements and the equilibrium spring K_{eq}, the concept of the generalized Maxwell model is introduced.

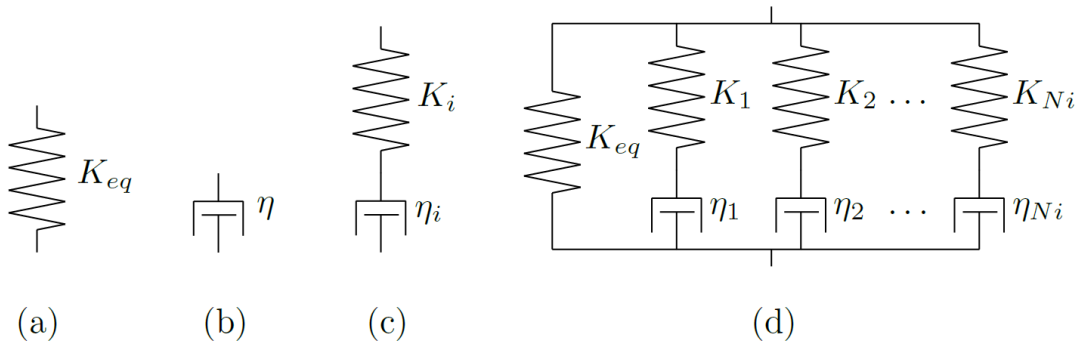

Figure 2: Representation of rheological elements to describe viscoelasticity: a) a spring with the stiffness K_{eq} following Hooke's law, b) a dashpot representing purely viscous behavior, c) a Maxwell element consisting of a spring and dashpot in series, and d) a generalized Maxwell model.

For the generalized Maxwell model with $K_{Ni} = 1$, as detailed in [13], the stress-strain relationship for viscoelastic materials is formulated as a differential equation

$$\frac{\mathrm{d}\sigma(t)}{\mathrm{d}t} + \frac{K_1}{\eta_1}\sigma(t) = \left(K_{eq} + K_1\right)\frac{\mathrm{d}\varepsilon(t)}{\mathrm{d}t} + \frac{K_{eq}K_1}{\eta_1}\varepsilon(t). \tag{2}$$

This differential equation models the viscoelastic response of complex materials, encompassing stress relaxation and creep behavior [13].

A commonly used approach to characterize the time-dependent viscoelastic response is the Prony

series, which can be derived by applying the Laplace transform to the differential formulation of the generalized Maxwell model [13], as demonstrated in Equation 2. The Prony series effectively describes the time-dependent deformation behavior of materials, expressed as [13]

$$K(t) = K_{eq} + \sum_{i=1}^{N_i} K_i \, e^{-t/\tau_i}. \tag{3}$$

The relaxation function $K(t)$ characterizes the time-dependent decrease in material stiffness due to viscoelastic effects. Each exponential term corresponds to a Maxwell element with a distinct relaxation time τ_i, which captures different rates of stiffness relaxation [13]. In practical applications, the parameters of the Prony series K_{eq}, K_i, and τ_i are determined by fitting the Prony series to experimental data. The fitting process typically involves applying optimization techniques to minimize the discrepancy between the model's predictions and observations [5, 8]. The result of this process is a viscoelastic model that is tailored to the material under investigation.

2.2 Karhunen-Loève expansion

2.2.1 Second-order Gaussian random field

Quantities that are derived from random experiments and governed by the rules of probability theory are known as random variables, denoted as $Z(\omega)$. In a mechanical context, specific material properties, such as Young's modulus, are not constant but instead vary due to natural heterogeneity uncertainty. A well-known approach to representing this distribution is the Gaussian distribution, which is characterized by its first two statistical moments and thereby defines the normal distribution [14]. The statistical moments are the expected value, μ, and the standard deviation, σ.

By extending the random variable $Z(\omega)$ to the spatial coordinates x, over the defined domain, one speaks of a random field [14]

$$Z(x) = Z(\omega, \boldsymbol{x}). \tag{4}$$

A Gaussian random field is fully characterized by the mean value $\mu(\mathbf{x})$, the standard deviation $\sigma(\mathbf{x})$, and the dimensionless correlation coefficient $\rho(x_1, x_2)$ [6, 14]. The correlation coefficient is a measure of the relationship between two points, $\mathbf{x_1}$ and $\mathbf{x_2}$, of a random field. When combined with the covariance, it can be expressed as

$$\rho_{12} = \rho_{Z_1,Z_2} = \frac{Cov[Z_1, Z_2]}{\sigma_1 \sigma_2}. \tag{5}$$

One speaks of the auto-correlation when Z_1 and Z_2 are from the same random field $Z(\mathbf{x})$. Otherwise, it involves cross-covariance and cross-correlation.

It is assumed that the random fields are homogeneous. This indicates that the mean value and the standard deviation are independent of spatial coordinates and thus remain constant over a realization [14]. Additionally, the correlation is translation-independent and is therefore described by relative coordinates $\boldsymbol{\xi}$.

2.2.2 Karhunen-Loève expansion of Gaussian random field

The Karhunen-Loève (KL) expansion provides a comprehensive framework for representing second-order Gaussian stochastic random field, functioning as a probabilistic analog to the classical Fourier transform [7]. This expansion is expressed as follows

$$X(\omega, \boldsymbol{x}) = \sum_{n=0}^{\infty} \sqrt{\lambda_n}\ \phi_n(\boldsymbol{x})\, Z_n(\omega), \tag{6}$$

where $Z_n(\omega)$ is an uncorrelated random variable, and λ_n and $\phi_n(\mathbf{x})$ are eigenpairs of a Fredholm integral of second-order. This Fredholm integral of second-order is written as

$$\int_D Cov[Z_1, Z_2]\ \phi_n(\boldsymbol{x_1})\, \mathrm{d}\boldsymbol{x_1} = \lambda_n\, \phi_n(\boldsymbol{x_2}). \tag{7}$$

Moreover, the correlation must be established before generating a random field. However, a closed solution is feasible only for a limited number of correlation functions and domain shapes. Consequently, numerical methods are necessary. Furthermore, the random field is divided into deterministic and stochastic components, which are represented as

$$\begin{aligned} Z(\omega, \boldsymbol{x}) &= \mu(\boldsymbol{x}) + \alpha(\omega, \boldsymbol{x}) \\ &= \mu + X(\omega, \boldsymbol{x}). \end{aligned} \tag{8}$$

Here, the mean of the random field $\mu(\mathbf{x})$ represents the deterministic part of it, while $\alpha(\omega, \mathbf{x})$ represents the stochastic part with an expected value of zero.

For the numerical generation of random fields, the optimal linear estimation expansion method is employed, as introduced in [6]. First, the covariance matrix, denoted by $\mathbf{C}$, is calculated for the predefined and discretized two-dimensional shape using the triangular function. The two-dimensional model of the tensile test specimen is schematically illustrated in Figure 3. This step is expressed as

$$\boldsymbol{C}(\boldsymbol{x_1}, \boldsymbol{x_2}) = \rho(\xi_1, \xi_2), \tag{9}$$

where $\mathbf{C}$ is a N $\times$ N symmetric positive semi-definite matrix.

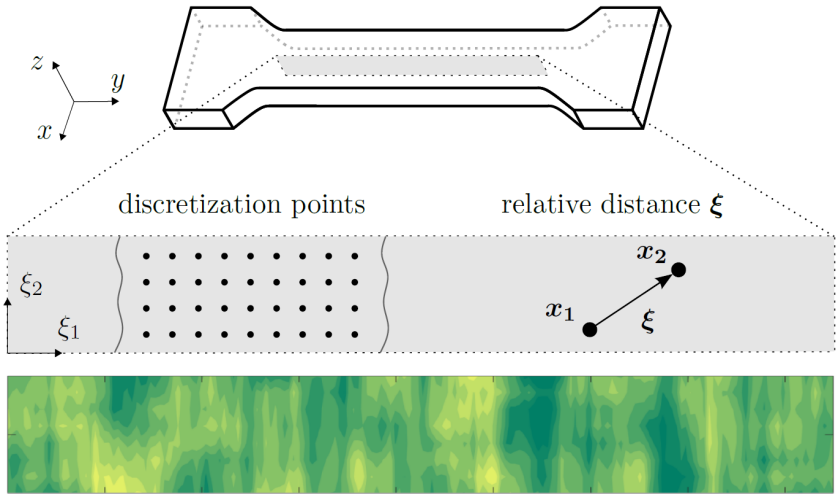

Figure 3: Standard tensile test specimen featuring a two-dimensional model representation, illustrating the discretization points and the relative distance $\boldsymbol{\xi}$ between the points $\mathbf{x_1}$ and $\mathbf{x_2}$ are shown schematically. Furthermore, a numerically generated second-order Gaussian random field for this two-dimensional model is exemplified.

This leads to the eigenvalue problem

$$\boldsymbol{C}(\boldsymbol{x_1}, \boldsymbol{x_2})\, \phi_n = \lambda_n\, \boldsymbol{\phi_n}, \tag{10}$$

where the eigenpair (λ_n and $\phi_n(\mathbf{x})$) are determined. Furthermore, the eigenpair is used for the M-th truncated random fields $\hat{Z}$.

$$\hat{Z}(\omega, \boldsymbol{x}) = \mu + \sum_{n=1}^{M} \sqrt{\lambda_n}\, \phi_n(\boldsymbol{x}) Z_n(\omega). \tag{11}$$

This approximation is referred to as the truncated Karhunen–Loève expansion. An exemplary representation of a second-order Gaussian random field is provided in Figure 3.

2.3 Multiscale modeling framework

A Representative Volume Element (RVE) is crucial for modeling heterogeneous materials, such as SFRCs. The RVE must be sufficiently large to capture the statistical features of the heterogeneity while remaining small enough to function as a material point at the component level and independent of the RVE size, as demonstrated schematically in Figure 4 a). In contrast, smaller domains that do not fully satisfy these criteria are referred to as Statistical Volume Elements (SVEs). The purpose of SVEs is to investigate the variability of effective properties resulting from microstructural randomness.

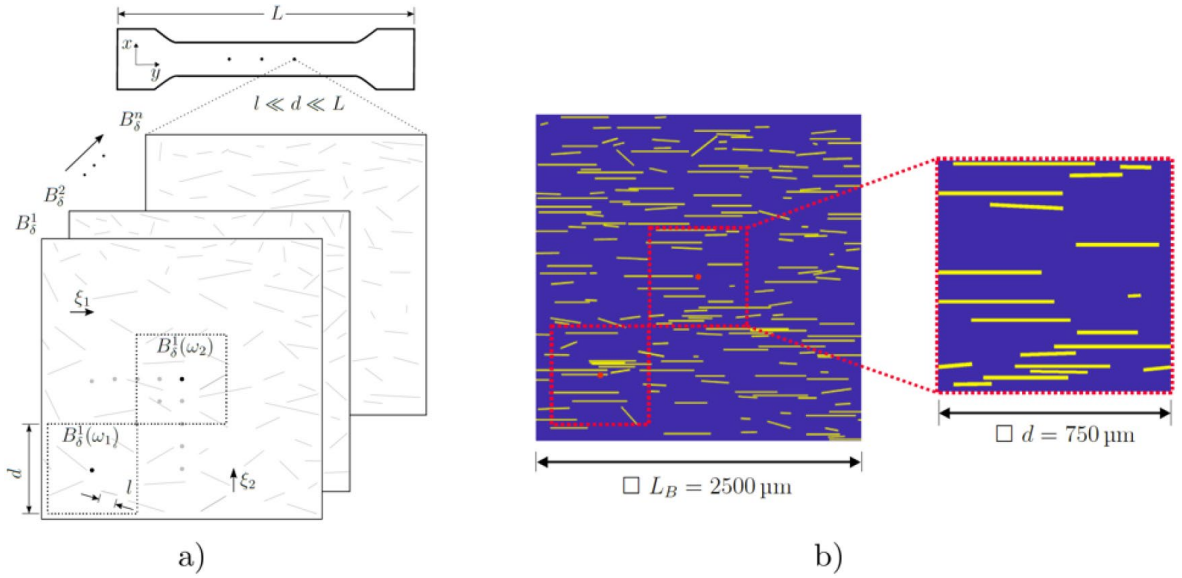

Figure 4: Representation of the definition of the scale $l \ll d \ll L$ based on a tensile test specimen: a) various unique microstructures at different positions at the component level, and b) numerically modeled artificial microstructure.

Using the numerically modeled artificial microstructure, as depicted in Figure 4 b), the material properties are determined by Hill's condition [3]

$$\langle \boldsymbol{\sigma} : \boldsymbol{\varepsilon} \rangle = \langle \boldsymbol{\sigma} \rangle : \langle \boldsymbol{\varepsilon} \rangle. \tag{12}$$

The generation of this artificial microstructure, considering the probabilistic characteristics of fiber length, fiber diameter, and fiber orientation, as detailed in [10-12]. The properties of the materials used for the linear elastic model are summarized in Table 1.

	Fiber	PBT (Matrix)
Young's modulus	83.9 GPa	2.67 GPa
Poisson's ratio	0.22	0.41
Density	2500 kg m^{-3}	1300 kg m^{-3}

Table 1: Fiber and PBT (matrix) material properties for modeling the artificial microstructure.

The effective material properties can be calculated by applying three independent load cases for each type of boundary condition, namely Dirichlet and Neumann types, to the numerical artificial microstructure. By averaging $\langle\cdot\rangle$ the properties calculated in the domain, the homogenized material properties are written as

$$\langle \boldsymbol{\sigma} \rangle = \mathbf{C}^{\text{eff}} : \langle \boldsymbol{\varepsilon} \rangle \tag{13}$$

and

$$\langle \boldsymbol{\varepsilon} \rangle = \mathbf{S}^{\text{eff}} : \langle \boldsymbol{\sigma} \rangle \tag{14}$$

where $\mathbf{C}^{\text{eff}}$ and $\mathbf{S}^{\text{eff}}$ represent the effective stiffness and the compliance tensor, respectively. In the case of time-dependent behavior, the relation exemplarily for stiffness behavior is written as

$$\langle \boldsymbol{\sigma}(\boldsymbol{t}) \rangle = \mathbf{C}^{\text{eff}}(\boldsymbol{t}) : \boldsymbol{\varepsilon_0} \tag{15}$$

Here, only the matrix material is modeled as viscoelastic using a Prony series with a single branch, as shown in Figure 2, with $K_{Ni} = 1$. These Prony parameters, which were obtained through experimental means and are specific to unreinforced PBT, are listed in Table 2. This is achieved by fitting the experimental data with the Levenberg-Marquardt algorithm. The identified Prony parameters for PBT are applied exclusively to the matrix phase of the artificial microstructures, with the corresponding results shown in Figure 10 a) for five different microstructures. The five microstructures considered are subdomains (d) extracted from the larger volume (LB) shown in Figure 4 b).

	Prony parameters for matrix		
Brunch	K_{eq} [GPa]	K_1 [MPa]	τ_1 [s]
1	2.5	119.54	108.92

Table 2: Prony parameter obtained through fitting the experimental data of the unreinforced material PBT.

3 EXPERIMENTAL INVESTIGATION

This section presents the motivation for employing the probability modeling approach to model spatially distributed mechanical properties. The experimental findings are presented at the microscale and component level of PBT and PBT GF30. This is achieved through a tensile creep test at the component level and nanoindentation at the microscale.

3.1 Materials used in composite

In this comprehensive experimental investigation, a standardized tensile test specimen is utilized, which is directly molded with reinforced fibers (PBT GF30) and without fibers (PBT). The matrix material is a thermoplastic Polybutylene Terephthalate, representing the primary component, which is marketed under the trade name ULTRADUR B 4520 by BASF. The reinforcing component of the composite is E-Glass, designated as FGCS 3540 and provided by STW. The manufacturing of all specimens was carried out using an injection molding process at Kunststoff-Zentrum Leipzig GmbH.

3.2 Experimental setup and specimen preparation

3.2.1 Investigation at the microscale

For the experimental investigation at the microscale, a ZHN nanoindenter from ZwickRoell, equipped with a Berkovich indenter, was used. To do this, a small specimen is removed from the tensile test sample, as illustrated in Figure 5. The extracted specimen was prepared by grinding and polishing, as detailed in [4]. The nanoindentation tests are performed with a force of 1750 mN and a hold phase of 300 s. The creep value Cr represents the viscoelastic property and is expressed as

$$\text{Creep} = Cr = h_2 - h_1, \tag{16}$$

where h_2 and h_1 are the maximum depth of the indentation test and the beginning of the holding phase, respectively, as shown in Figure 6.

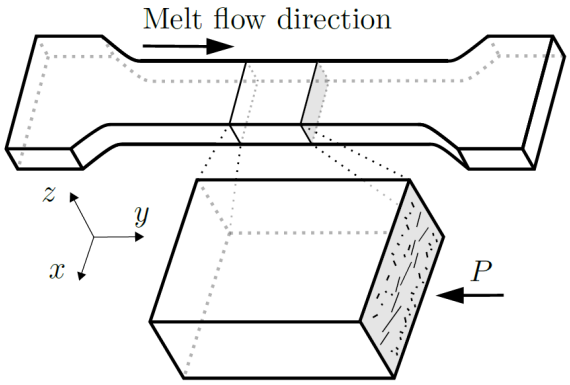

Figure 5: A small sample is extracted from the tensile test specimen. The gray marked surface is of interest for the indentation test.

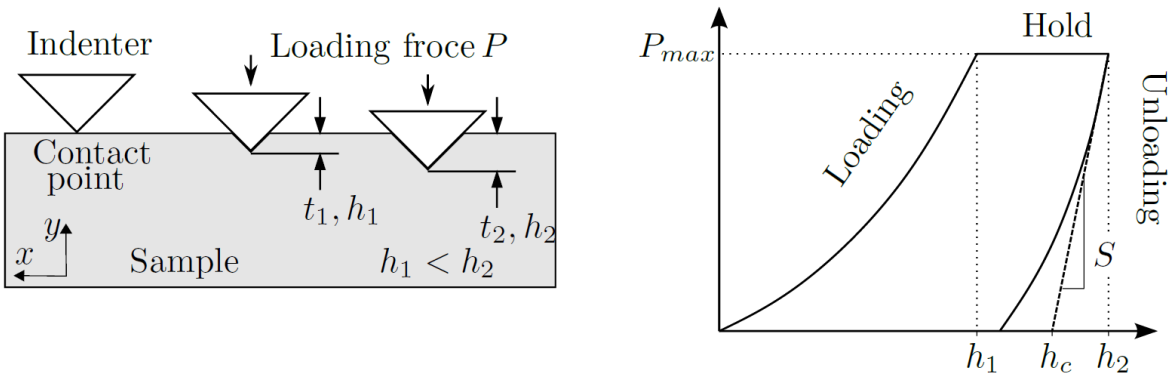

Figure 6: Schematic representation of the nanoindentation curve derived from the indentation test. This includes an example of the nanoindentation test procedure, illustrating the search for the contact point, the beginning of the hold phase at h_1, and the end of the hold phase at h_2.

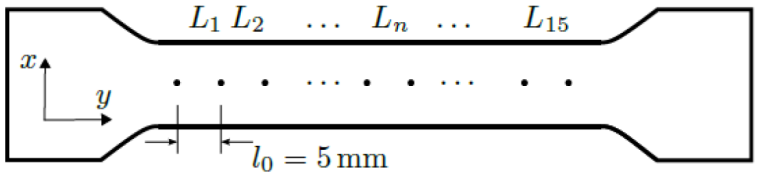
3.2.2 Investigation at the Component level

For the experimental investigation at the component level, the specimen is divided into $L = 15$ areas, each with an initial length of 5 mm, as depicted in Figure 7. Creep behavior in these areas is measured using the ARAMIS 3D digital image correlation system. Consequently, the assessment of creep behavior is conducted within these designated areas, allowing for the determination of its local distribution across the specimen. A detailed description of this experimental setup and conditions can be found in [5].



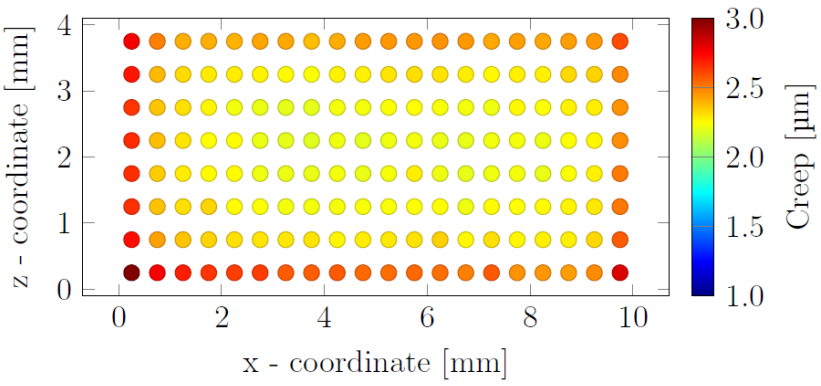


Figure 7: Tensile test specimens were divided into 15 areas with an initial length of 5 mm to measure local viscoelasticity properties.

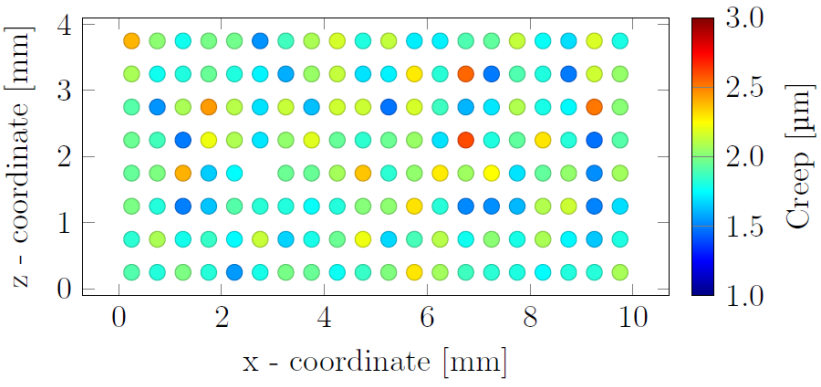

3.3 Experimental results and validation

3.3.1 Experimental results at the microscale

To evaluate the variations in microscale viscoelastic behavior, nanoindentation measurements were conducted across the specimen's cross-section, as shown in Figure 5 and 6. The distribution of creep values is displayed in Figure 8. For PBT, the unreinforced matrix exhibits a fairly uniform response. In contrast, PBT GF30 exhibits significant variability in microscale viscoelastic behavior, indicating microstructural heterogeneity resulting from the embedded short fibers.

(a) PBT

(b) PBT GF30

Figure 8: Creep value Cr of 160 measurement points over the cross-section, a) represents the unreinforced material PBT, and b) the short fiber-reinforced material PBT GF30.

3.3.2 Experimental results and validation at the component level

This microscale trend is also observed at the component level, as demonstrated in Figure 9, which illustrates the distribution of the viscoelastic parameter K_i. In that figure, the local distribution of K_i, as introduced in Equation 3, is presented. This distribution is derived from the Prony series after five

minutes of creep testing for both PBT and PBT GF30 using the Levenberg-Marquardt method. The unreinforced PBT specimen shows a relatively uniform distribution of K_i values. Conversely, the PBT GF30 specimen exhibits a substantial increase in scatter, indicative of considerable spatial variability resulting from the limited fiber reinforcement.

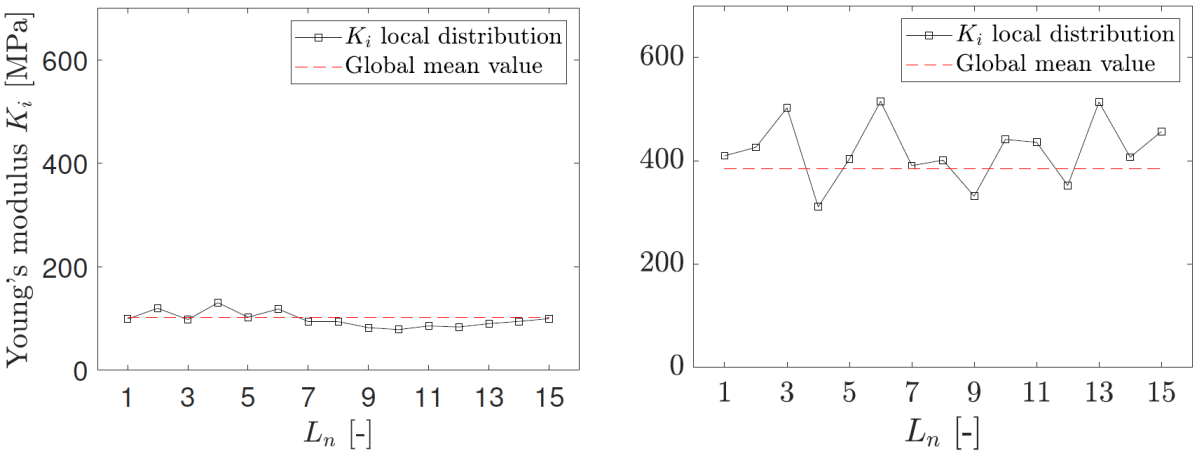

Figure 9: The local distribution at the component level for one specimen, as introduced in Figure 3, shows the Prony parameter K_i obtained by fitting Equation 3 using the Levenberg-Marquardt algorithm. The global mean value is obtained experimentally over a length of 75 mm and represents 20 specimens.

Finally, Figure 10 b) presents a comparison between the experimental creep data and the numerically predicted results obtained using the Karhunen-Loève based stochastic modeling approach. The close agreement observed demonstrates the model's ability to accurately capture the spatially varying viscoelastic behavior of the fiber-reinforced composite. The 15 areas introduced in Figure 7 at the component level are illustrated here, aligning with both the experimental and numerical data.

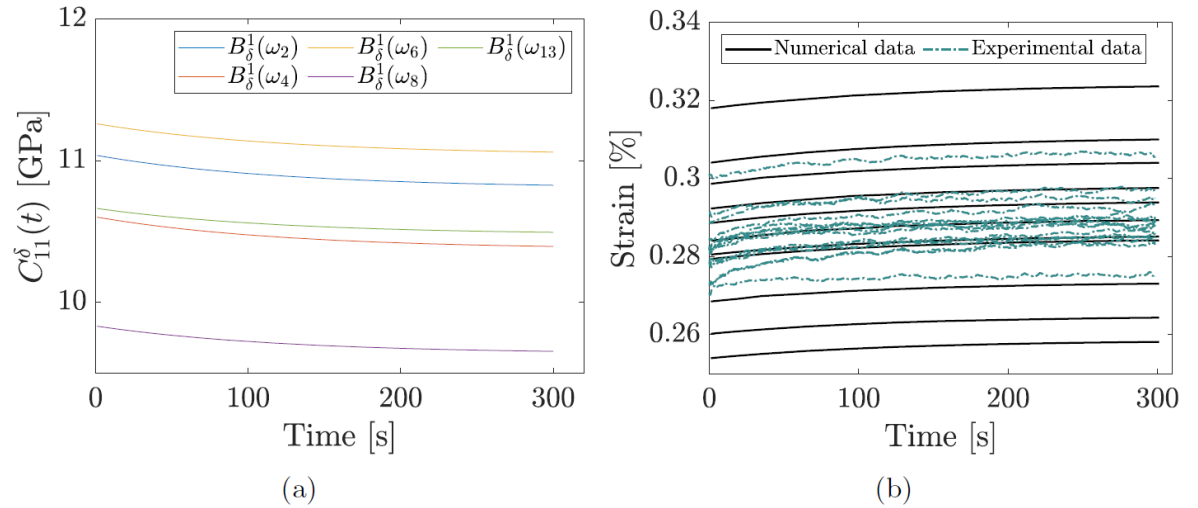

Figure 10: Numerical results include a) numerical results of $C_{11}(t)$ of the time-dependent at five different artificial microstructures, and b) a comparison between experimental creep data and numerical results modeled using the Karhunen-Loève approach, all 15 areas are shown.

4 CONCLUSION

The experimental investigations on both the component level and microscale demonstrate that the presence and distribution of short fibers significantly influence the spatial distribution of viscoelastic properties. The obtained results clearly indicate the need for a probabilistic modeling approach to accurately capture the behavior of the distributed mechanical properties. In this context, the Karhunen-Loève expansion is a suitable method that offers a compact and efficient representation of second-order Gaussian random fields. The numerical results derived from this approach demonstrate strong agreement with the experimental data, providing further validation of its applicability.

Keywords: NDT, Rayleigh scattering, Detection of delamination, CFRP laminates, Distributed strain sensing

ABSTRACT

Carbon fiber reinforced plastic (CFRP) offers excellent properties such as low weight and high strength, but internal delamination caused by impact or fatigue is difficult to detect. To address this, we explored the use of Rayleigh scattering-based optical fiber sensors that measure surface strain distributions via Rayleigh scattering to detect delamination in real time. A CFRP laminate was prepared with artificial delamination of 35 mm or 55 mm in length at two depths: the 10th layer (1.0 mm from the surface) and the 50th layer (3.5 mm deep). Three-point bending tests were conducted, and strain distributions were measured using a distributed fiber-optic sensor. Finite element analysis (FEM) was also performed to verify the experimental results. The strain profiles from both the test and simulation showed good agreement. At the delamination tip, the strain curve exhibited a valley for shallow delamination and a peak for deeper ones. FEM results revealed that the shape and magnitude of the surface strain anomaly are sensitive to delamination depth, especially when the delamination is near the sensing surface. When the sensor was on the tensile side, characteristic strain valleys and peaks were observed around the delamination tip, varying with depth. On the compressive side, the effect was less pronounced unless the delamination was close to the surface. These findings suggest that depth estimation is possible by placing sensors on both sides of the laminate.

1 INTRODUCTION

CFRP laminated plates, known for their light weight, high strength, and high rigidity, are widely used in aircraft and other applications due to their ability to be integrally molded with stringers. However, interlaminar delamination caused by impact or fatigue is difficult to detect visually. Therefore, non-destructive testing (NDT) methods are essential for ensuring safety during regular inspections.

Conventional NDT techniques such as ultrasonic testing, X-ray inspection, and infrared thermography have been introduced and play an important role in aircraft maintenance. However, these methods require halting operations and are limited in scanning range, resulting in prolonged inspection times and increased operational costs. To reduce downtime and improve reliability, real-time structural health monitoring (SHM) is gaining attention [1].

Real-time SHM involves embedding sensor systems directly into the structure and monitoring during operation. If wide-area measurements can be achieved using a minimal number of sensors and a compact measurement system, SHM of large-scale structures—such as aircraft—could become feasible even in-flight.

Various sensor systems have been studied, including micro piezoelectric elements and electrical resistance-based sensors. Among these, distributed optical fiber sensors are particularly well-suited for detecting delamination between stringers and skins, as they can monitor strain over long distances using a single fiber. However, the commonly used Optical Time Domain Reflectometry (OTDR)

technique, while cost-effective, has limited spatial resolution (on the order of sub-meters) and is inadequate for detecting delamination at the centimeter scale required for aircraft structures.

Therefore, we focus on a Rayleigh scattering-based distributed optical fiber sensor using Optical Frequency Domain Reflectometry (OFDR), which offers spatial resolution on the order of millimeters. By measuring strain and temperature distributions, it becomes possible to detect damage more precisely [2]. Our previous work demonstrated that delamination tips could be identified at the millimeter level by analyzing surface strain distributions measured at 1 mm intervals. In particular, Mode I and Mode II delamination tips were detected by observing peaks in the strain profiles. However, the influence of delamination depth and specimen thickness on this detection method has not been fully explored.

In this study, we conducted three-point bending tests and finite element analysis (FEA) to investigate how the depth and thickness of delamination affect surface strain distributions, aiming to clarify the detection limits and improve reliability in practical SHM applications.

2 EXPERIMENTAL METHOD

3.1 Rayleigh scattering distribution sensor

A Rayleigh scattering-based distributed sensor measures the backscattered light along the length of an optical fiber and detects local strain changes using the cross-correlation method on the spatial frequency distribution of the scattered signal. Rayleigh scattering originates from refractive index mismatches at the core-cladding interface and reflects geometrical changes in the fiber. Unlike Brillouin scattering, Rayleigh scattering does not involve a frequency shift proportional to strain. However, OFDR (Optical Frequency Domain Reflectometry) provides extremely high spatial resolution, allowing hundreds of data points per millimeter. The resulting frequency spectrum shifts toward lower frequencies when the fiber is stretched. By performing cross-correlation with a reference spectrum, the amount of frequency shift can be quantified and converted to strain. In this study, the spatial interval over which the spectrum is analyzed is defined as the gauge length, which can be adjusted post-measurement.

Strain distributions were measured using a Rayleigh scattering-type distributed optical fiber sensor (ODiSI A-50, LUNA Technologies). The system supports measurement ranges from 1 to 50 meters, with a minimum spatial resolution (pitch) of 1 mm, a strain measurement range of ±10,000 με, resolution of 1 με, and a sampling rate of up to 5 Hz, allowing simultaneous acquisition of strain and temperature distributions.

3.2 Experimental method

In this study, unidirectional CFRP specimens were fabricated using 60 plies of CFRP prepreg (TR350C100S, Mitsubishi Chemical) through hot press molding. To introduce delamination, a 0.1 mm thick Teflon sheet was placed between the 50th and 51st plies. Specimens with delamination lengths of 35 mm, 45 mm, and 55 mm were prepared by varying the length of the Teflon insert.

A three-point bending static test was conducted with a support span of 100 mm and a displacement rate of 0.5 mm/min (Figure 2). A fiber optic sensor was bonded to the bottom surface using instant adhesive (Figure 3). Additionally, the specimens were tested in both upright and inverted orientations, positioning the delamination at either 10 or 50 plies from the measurement surface. The load was paused at a predetermined value, and strain distributions were recorded during the test. Strain analysis was performed with a 1 mm measurement pitch and a 10 mm gauge length.

3.3 Analysis method

Finite element analysis was conducted using Abaqus with a two-dimensional model of the three-point bending test. The material properties were longitudinal Young's modulus E_L=137GPa, transverse modulus E_T=9.76GPa, shear modulus, G_{LT}=5.17GPa, Poisson's ratio ν_{LT}=0.32. While the experiments focused on delamination at two depths (10 and 50 plies), the simulation covered a broader range of delamination depths. To evaluate the influence of plate thickness, simulations were also performed using a 9 mm thick model—twice the experimental specimen thickness.

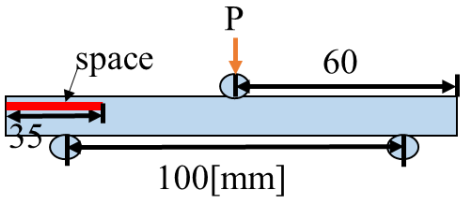

Figure 2:3-point bending test

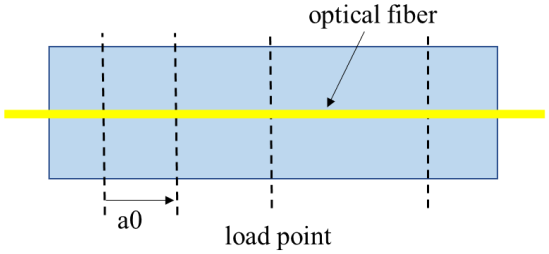

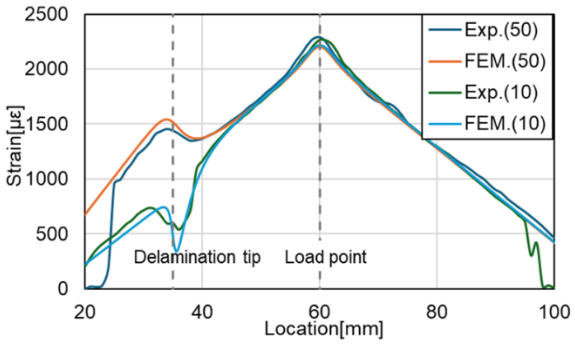

Figure 3: Location of optical fiber sensor

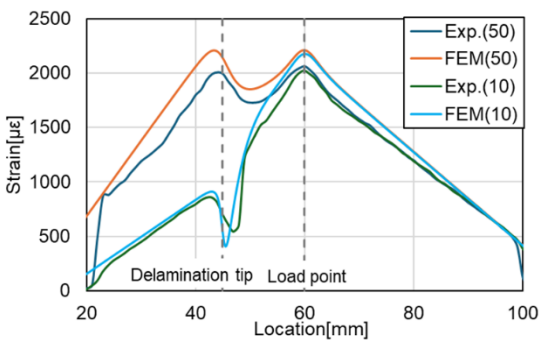
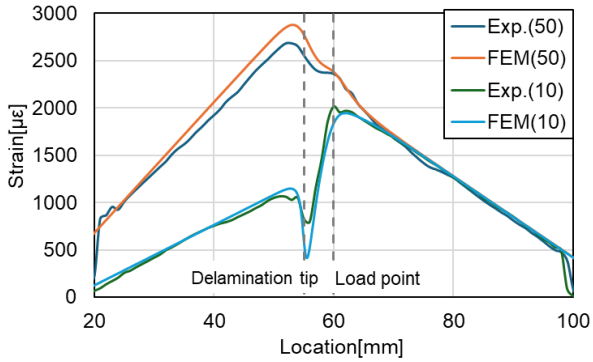


3 EXPERIMENTAL RESULTS AND DISCUSSION

3.1 Detection of position of delamination tip



Figures (a)–(c) show the strain distributions obtained from the optical fiber sensor, along with the corresponding finite element analysis (FEA) results under the same load, for specimens with delamination lengths of 35 mm, 45 mm, and 55 mm, respectively. The horizontal axis represents the distance from the specimen edge, and the numbers 10 and 50 indicate the delamination depths from the sensor surface, expressed as ply numbers.

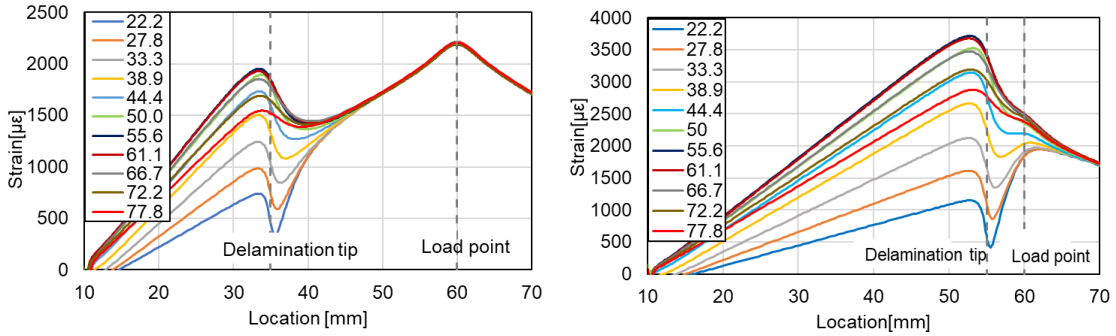
(a) 35mm delamination

(b) 45mm delamination

(c) 55mm delamination

Figure 4: Measured and FEM-calculated strain distribution at 3-point bending tests.

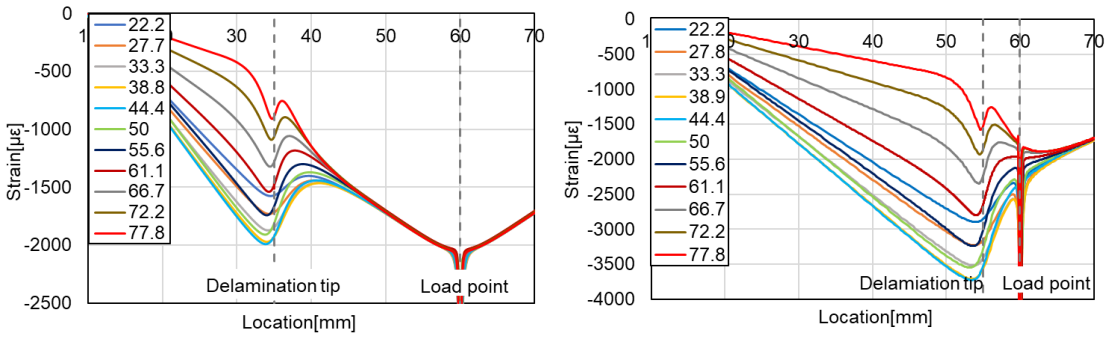
As shown, the experimental and FEA results show good agreement across all delamination lengths, confirming that the Rayleigh scattering-based distributed sensor provides highly accurate and spatially resolved strain measurements.



In all cases, a consistent relationship was observed between the surface strain distribution and the delamination front: a peak appeared 1 mm to the left of the delamination tip, and a sharp valley was observed 1 mm to the right when the delamination was close to the sensor surface. Notably, at a delamination length of 55 mm, the maximum global strain was located near the delamination tip rather than at the loading point

3.2 Effect of depth-wise position of delamination

The measurement surfaces were set as the upper and lower surfaces, and FEM analysis was performed by changing the delamination position. Figure 5 shows the strain distribution when the measurement surface was set as the lower surface, for delamination lengths of 35 mm and 55 mm. Figure 6 shows the strain distribution when the measurement surface was set as the upper surface, for delamination lengths of 35 mm and 55 mm. In both figures, the delamination depth is expressed as a percentage of the thickness from the lower surface.



From Figure 5, it was found that the delamination depth reaches a maximum value 1 mm to the left of the delamination tip at all positions. As the depth increases toward the 50% thickness position of the specimen (depth 2.25 mm), the maximum value increases, but from 50% depth to 66.7% depth, the maximum value remains almost unchanged. Additionally, this trend was found to be independent of the delamination length.

Figure 6 shows the compression side, where strain is negative. However, when the delamination depth is close to the sensor (61.1−77.8%), a sharp valley appears compared to the tensile side shown in

(a) Delamination length of 35mm (b) Delamination length of 55mm

Figure 5: Surface strain distribution on the tensile side at 3-point bending tests with delamination exists at various depth..

(a) Delamination length of 35mm (b) Delamination length of 55mm

Figure 6: Surface strain distribution on the compressive side at 3-point bending tests with delamination exists at various depth.

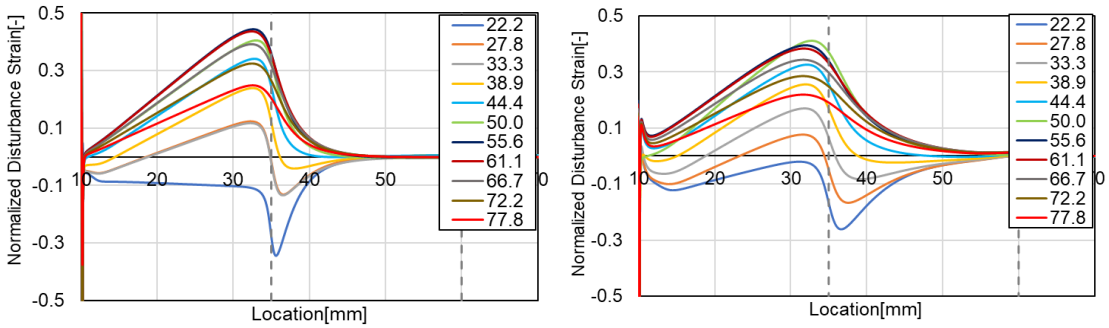


Figure 5, indicating that the strain perturbation at the delamination tip differs between the tensile and compression sides. This is because the tensile side layer is subjected to concentrated loads due to the fulcrum, whereas the compressive side receives loads through the peel surface. When measuring the compressive side, similar to the tensile side, the depth of the peel from the sensor surface increases as the delamination depth progresses toward the center, causing the valley depth of the strain peak to increase, but decreases as the peel moves away from the center.

Based on the above results, it was found that determining the delamination depth is difficult using only the peak height measurement of one side, except when the delamination depth is near the sensor surface. Therefore, it is considered necessary to place sensors on both the upper and lower surfaces to achieve accurate delamination depth determination. Rayleigh scattering-type distribution sensors can measure a very long range with a single sensor, so it is believed that simultaneous measurement of both upper and lower surfaces through appropriate sensor placement enables the identification of depth positions.

3.3 Relationship between strain perturbation peak and depth-wise position

It has been clarified that the peak height of strain is influenced by the depth position. Therefore, to quantitatively clarify this relationship, the strain distribution on the surface of a laminated plate without delamination was used as a reference, and the strain distribution in the presence of delamination was subtracted to obtain the perturbation distribution caused by delamination. The normalized distribution of the perturbation relative to the load point strain is shown in Figure 7. Additionally, to investigate the influence of plate thickness, FEM analysis was also performed for a plate thickness of 9 mm.

From the figure, it can be seen that in both thicknesses, when the delamination is inserted at a depth of 33.3% from the measurement surface, a clear valley is observed. On the other hand, as the delamination moves away from the measurement surface, only peaks appear. It was found that up to a

(a) 4.5mm thickness (b) 9mm thickness

Figure 7: Perturbation of strain by delamination at 3-point bending tests.

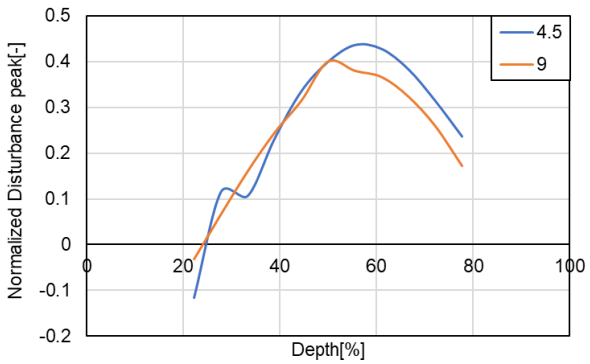

Figure 8: Relationship between normalized perturbation peak caused by delamination at 3-point bending tests for specimens of 4.5- and 9-mm thicknesses.

depth of 50%, the size of the peaks increases monotonically with the depth of the delamination. This trend is similar regardless of thickness, indicating that the size of the peaks is a useful feature for estimating depth. On the other hand, it was also found that as the thickness increases, the peak shapes of the peaks and valleys become less pronounced. Therefore, it was found that although plate thickness affects the distribution of strain perturbations caused by delamination, it is likely possible to detect the depth from the perturbation peak within the range from the measurement surface to the central thickness.

Figure 8 shows the relationship between the height of the disturbance peak and the delamination depth position normalized by plate thickness for plate thicknesses of 4.5 mm and 9 mm, respectively. From the figure, it can be seen that in the case of a thickness of 9 mm, the depth increases monotonically up to 50%, and the peak value decreases monotonically beyond 50%. However, in the case of 4.5 mm, it can be seen that the depth decreases once at 33.3%. This is likely due to stress concentration at the support point influencing the perturbation distribution.

In summary, regardless of plate thickness, it was found that the depth of delamination can be estimated from the height of the perturbation peak. Additionally, when the delamination depth is close to the sensor surface, the height of the perturbation valley is a better indicator.

4 CONCLUSIONS

In this study, we investigated the effects of delamination depth and plate thickness on the detection of interlaminar delamination in CFRP using a Rayleigh scattering-type distribution sensor. Experimental and FEM analysis results showed good agreement, demonstrating that the spatial resolution and accuracy of the sensor are sufficient for detecting the leading edge position of interlaminar delamination. Furthermore, the analysis results indicated that the position of the delamination depth is strongly correlated with the normalized strain peak. This correlation showed a similar trend even when the plate thickness varied. However, since the peak height is maximum near the center of the specimen, it is necessary to determine whether the delamination depth is close to the sensor surface. However, when the delamination depth is near the sensor surface, a characteristic valley is observed, making identification easy.

Therefore, by using this sensor on both the upper and lower surfaces, it was found that it is possible to simultaneously determine the position and depth of the interlaminar delamination tip.

Keywords: Wind turbine blade, Polymer-matrix composites, Spar cap components, Non-destructive testing, Acoustic emission

ABSTRACT

Wind energy is an essential renewable energy source; however, the disposal of end-of-life (EoL) wind turbine blades (WTBs) presents significant challenges. Repurposing EoL WTB components, such as spar caps, for use in the construction sector is a sustainable alternative; however, pre-existing damage can affect their mechanical performance. This study investigates an acoustic emission (AE)-based approach that incorporates improved *b*-value (I*b*-value) analysis to assess the structural integrity of EoL WTB spar cap specimens. Tensile and bending tests are performed at 23 °C and 67 °C to evaluate damage propagation for potential construction applications. AE data analysis confirmed the method's effectiveness in detecting early degradation. Furthermore, the influence of temperature on the mechanical properties of the composite material is investigated. The findings indicate that I*b*-value analysis is a viable non-destructive testing method for assessing structural repurposed EoL WTB components under various loading conditions. The extension of this approach to other EoL WTB components has the potential to enhance circular economy strategies in the wind energy and construction sectors.

1 INTRODUCTION

Wind power is a crucial renewable energy source, with a substantial volume of end-of-life (EoL) wind turbine blade (WTB) material anticipated globally by 2050 [1], with Germany contributing a major share [2]. However, the management of EoL WTBs poses significant challenges due to the

environmental impact of disposal [3]. The utilization of composites as the primary material in WTBs is predominantly attributable to their high specific mechanical properties [4]. However, their thermoset-based polymer matrix makes recycling difficult [5]. Under circular economy principles [6], the repurpose strategy offers a promising alternative [7-9], especially for structural components of EoL WTBs [10]. By repurposing EoL WTB composite components in a second life application with a new function, this strategy seeks to extend the service life of the composite materials while preserving their structural integrity. Unidirectional (UD) reinforced spar cap beams, which are characterized by their excellent mechanical properties, are assumed to be suitable for repurposing in large quantities in various industrial sectors, including the construction industry. However, the possibility of pre-existing damage resulting from the manufacturing process or the first life cycle cannot be discounted, as this may lead to mechanical degradation [11]. Understanding these effects and defining their reliability is essential for the structural repurpose of EoL WTB components in second-life applications.

Previous research has presented a method for assessing the structural integrity of composite components using acoustic emission (AE) testing combined with I*b*-value analysis [12, 13]. AE is a well-established, non-destructive testing (NDT) technology with high resolution. The *b*-value analysis, which monitors the cumulative amplitude distribution, demonstrated sufficient feasibility with modification. The improved *b*-value (I*b*-value) was combined to assess the structural integrity of EoL WTB spar cap specimens [14]. The method has been studied and concluded to be effective in identifying early damage propagation under tensile loading at room temperature (RT).

However, the robustness of this technique for other loading conditions and at elevated temperatures (ET) remains to be validated. This study explores the feasibility of I*b*-value analysis for tensile and bending loading at ET conditions, considering repurpose in the construction sector. The ET of 67 °C is determined in accordance with a German guideline (*BUEV recommendations*) that holds validity in the construction sector. To this end, tensile and bending tests are carried out at RT (23 °C) and ET (67 °C). The AE data collected during these tests are used to perform a comparative behavior analysis of the tensile and bending specimens at RT and ET. The present study focuses on the *b*-/I*b*-value analysis to evaluate the reliability of this method in different loading scenarios.

2 MATERIALS AND METHODS

2.1 Materials and EoL WTB specimen preparation

An EoL WTB (E40 wind turbine; Enercon, Germany) with a service life of approximately 20 years is used as the base material in this study. The WTB extends along a longitudinal direction (LD) measuring 19.3 m, while the transverse direction (TD) is perpendicular to the LD, with a maximum width of 1.92 m (Figure 1a). The spar cap component (Figure 1a, Section A-A), consists of glass fiber-reinforced polymer (GFRP) composites. The extraction of UD GFRP spar cap samples is conducted in alignment with the sectioning approach described by Joustra *et al.* [10].

Initially, TD cuts are performed using a wire saw to separate the EoL WTB segments (Figure 1a, dashed lines). Subsequent to this, LD cuts are performed to extract the shear web and sandwich elements from the spar cap beams (Figure 1b). The spar cap beams are then cut (Figure 1c) into square-shaped components measuring 200 mm in length (Figure 1d) and are further processed into tensile and bending specimens. Consequently, one side of each spar cap component is flattened with a CNC router, following the process of wheel cutting to obtain samples with a thickness of 4 mm. Any sharp edges are smoothed with sandpaper. For tensile testing, 1.6 mm thick GFRP tabs are bonded to 50 mm of both ends of each tensile sample using an epoxy film adhesive (UCS-I-95; UCS, China), resulting in a gauge length of 100 mm. The final tensile specimens have overall dimensions of 200 x 20 x 4 mm (Figure 1e). The specimens for the bending tests are produced from the tensile specimens through the use of a waterjet machine and measure 80 x 20 x 4 mm (Figure 1f). The glass fiber volume fraction of the UD specimens is estimated to be approximately 43.9% (density glass fiber: 2.48 g/cm^3, density matrix: 1.19 g/cm^3). As the tests are planned at ET, the glass transition temperature of the matrix material is determined to be 100 °C using differential scanning calorimetry (DSC) in accordance with ISO 11357.

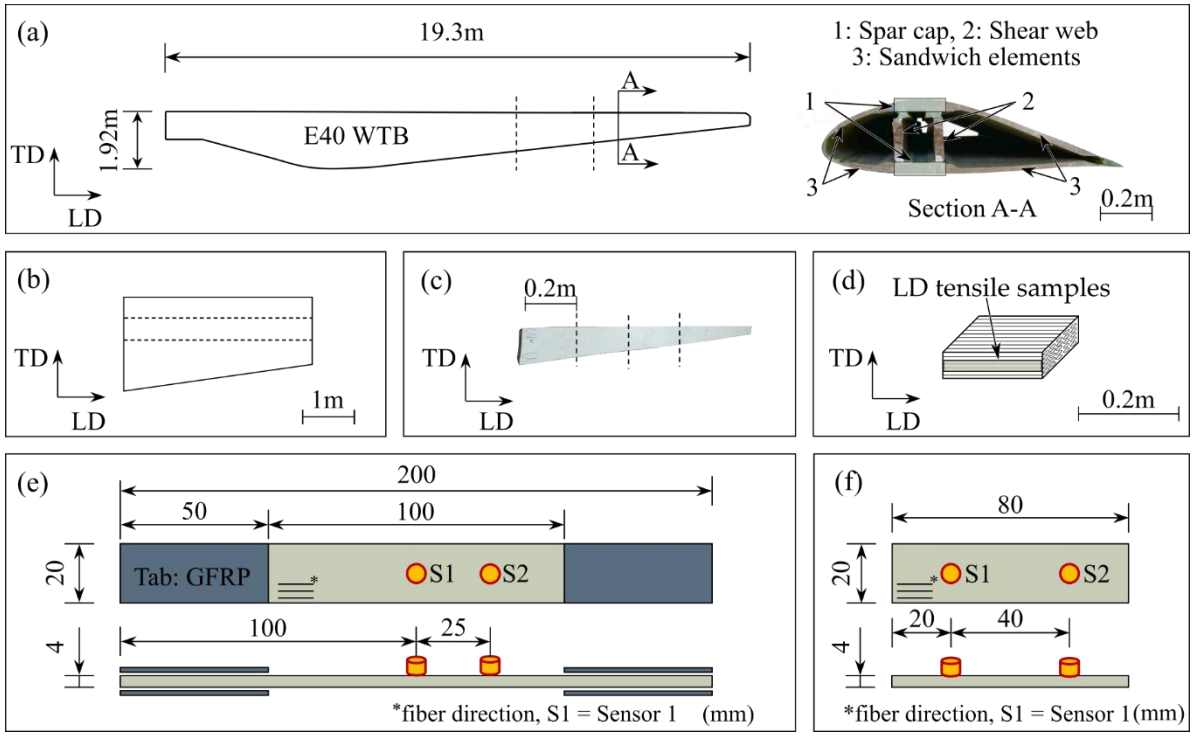

Figure 1: Preparation process of EoL spar cap specimens: (a) EoL WTB; (b) EoL WTB segment; (c) Spar cap beam; (d) Square-shaped spar cap component; (e) Dimensions of tensile specimens and sensor locations; (f) Dimensions of bending specimens and sensor locations.

2.2 Material characterization at different temperatures

The mechanical properties of the prepared EoL specimens are evaluated through tensile and bending tests performed at two different temperatures: room temperature (RT, 23 °C) and elevated temperature (ET, 67 °C). Tensile tests are conducted following the standards outlined in ASTM D3039 and are carried out on a universal testing machine equipped with a temperature chamber (Instron 5985; Instron, USA) at a crosshead speed of 0.5 mm/min (Figure 2a). The selection of this strain rate is driven by the objective of minimizing the strong overlap of AE signals, especially after 50 % of the specimen life when signal density increases significantly. In order to reduce measurement noise, neither an extensometer nor a strain gauge is used. A minimum of seven tensile specimens are tested at each temperature condition. In addition, bending tests are conducted at RT and ET, following ASTM D790, and are performed on a universal testing machine equipped with a temperature chamber (Instron 5985; Instron, USA) at a crosshead speed of 0.9 mm/min (Figure 2b). The span length is 33.6 mm. A minimum of six bending specimens are tested at each temperature condition. AE monitoring is performed simultaneously during the material characterization tests.

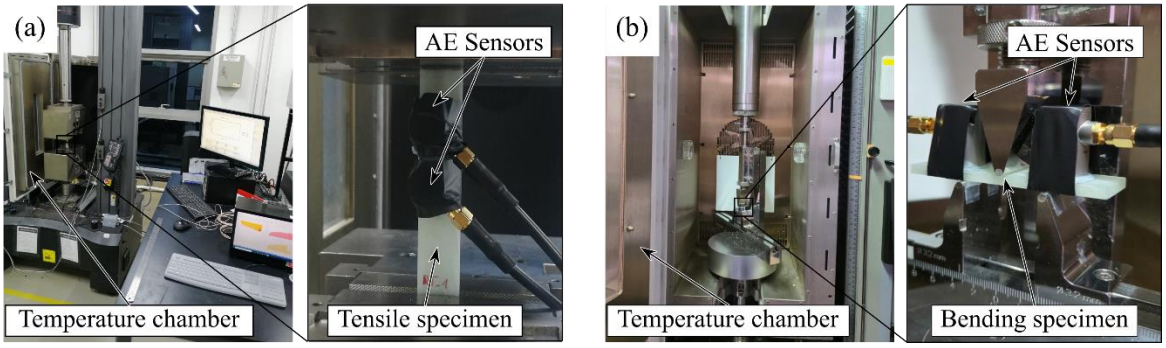

Figure 2: (a) Tensile test equipment; (b) Bending test equipment.

2.3 Acoustic emission testing

Wide-range piezoelectric AE sensors (IDK-AES-H150; IDK Co., Ltd., Republic of Korea) with a frequency range of 100-900 kHz were used for AE monitoring. During both tensile and bending tests, two AE sensors are attached to each specimen and secured with silicone grease (HIVAC-G; Shin-Etsu, Japan) and vinyl tape (Figure 2a and Figure 2b). The locations of the sensors (S1 and S2) are labeled "S" in Figure 1e and Figure 1f. The sensor placement remained constant throughout all experiments for both testing temperatures.

Before the experiments, the sensitivity of both AE sensors is verified. The AE signals are amplified using preamplifiers (IDK-AMP-S001-40/60; IDK Co. Ltd., Republic of Korea) with a gain of 40 dB_{AE}. During the testing phase, AE signals exceeding the 40 dB_{AE} threshold are detected with a digitizer (IDK-DAQ8; IDK Co. Ltd., Republic of Korea) at a sampling rate of 5 MSPS per channel. The AE signals are recorded under the conditions listed in Table 1. The time parameters are set as follows: peak definition time (PDT) at 200 µs, hit definition time (HDT) at 400 µs, and hit lockout time (HLT) at 4000 µs. Additionally, the amplitude, energy, and frequency characteristics of the AE signals are calculated and recorded, with the centroid frequency serving as the primary frequency characteristic for GFRP. AE signal analysis is based on key features including raw amplitude, hit frequency (hits per second), and AE frequency (peak frequency). Data processing is carried out using MATLAB software (version R2024a, MathWorks, USA).

	Threshold	Pre-amplifier	Sampling conditions		
			Sampling rate	Pre-trigger	Length[1]
Value	40	40	5	100	1000
Unit	dB_{AE}	dB_{AE}	MSPS	μs	µs

[1]Length: Recording time for each acoustic emission (AE) signal after the AE signal exceeds a certain threshold.

Table 1: Acoustic emission testing conditions.

As shown in previous studies, the dominant failure modes in UD reinforced specimens include matrix cracking, interfacial failure, and fiber breakage/fracture [15]. In FRPs, AE signals typically fall within the 100 kHz to 600 kHz range when a band-pass filter is applied, with specific frequency ranges corresponding to distinct fracture modes. High frequencies (400 - 600 kHz) are indicative for fiber breakage/fracture, low frequencies (100 – 220 kHz) correspond to matrix cracking, and intermediate frequencies (220 – 400 kHz) are associated with interfacial failure mechanisms. Multiple specimens are tested under each temperature condition (tensile and bending), resulting in minimal variation in AE parameters and characteristics. This reproducibility enabled the selection of a representative dataset for further analysis.

2.4 *b*-/I*b*-value analysis

For *b*-/I*b*-value analysis, the amplitude of AE signals is recorded, and the cumulative distribution function (CDF) is plotted according to Equation (1):

$$N(A) = \int_{A}^{\infty} n(A')dA' \tag{1}$$

here, A denotes a specific amplitude, while A' is an auxiliary amplitude variable used for integration, n(A') is the number of AE hits corresponding to each particular amplitude, and N(A) represents the cumulative number of hits with amplitudes equal to or greater than A. Although A' is mathematically equivalent to A, the distinction is introduced for notational clarity. In AE analysis, the amplitude A [dB_{AE}] is defined by Equation (2), using a reference voltage 1 µV as V0.

$$A = 20 * log_{10}\frac{V_1}{V_0} \tag{2}$$

The concept of *b*-value was introduced by Gutenberg through the Gutenberg-Richter equation, which is defined as the negative slope of the CDF, as shown in Equation (3). Originally developed for seismological analysis, this method has also been applied to materials such as concrete [16].

$$log_{10} * N(A) = a - bA \tag{3}$$

where a is an empirical constant, and b is the *b*-value, representing the slope of the linear relationship, typically determined by the least-square method. The *b*-value remains positive as long as the CDF shows a declining trend. In the early damage phase, dominated by microcracking, many low-amplitude and few high-amplitude AE signals are recorded, resulting in a high *b*-value (green line, Figure 3a). As macrocracks develop, the number of high-amplitude AE signals increases, shifting the CDF and reducing the *b*-value (orange line, Figure 3a) [17]. This decline near failure indicates that the *b*-value effectively reflects structural health. In composite materials, where multiple cracks propagate independently, tracking major crack regions using the mean value (μ) and standard deviation (σ) of AE amplitudes is more practical. This localized form of analysis, known as the I*b*-value, was introduced by Shiotani [18] and further studied by Jung and Na [12]. The I*b*-value is described in Equation (4):

$$log_{10} * N(A) = a - IbA \ldots (\mu - \alpha_1\sigma < A < \mu + \alpha_2\sigma) \tag{4}$$

α_1 and α_2 are constants defining the lower $(\mu - \alpha_1\sigma)$ and upper $(\mu + \alpha_2\sigma)$ amplitude limits (Figure 3b). The amplitude range is $(\alpha_1 + \alpha_2)\sigma$, typically with an $\alpha_1 : \alpha_2$ ratio of 1:1 or 1:2; in this study, both were set to 1. The parametric values are calculated after every 500 AE hits for the tensile specimens and after every 100 AE hits for the bending specimens (i.e., 1st to 100/500th, 1st to 200/1000th, ..., up to 400/2000th). The slopes of *b*-/I*b*-values are determined using the least-squares method. High values indicate a dominance of microscopic fractures, while low values suggest increasing macroscopic fracture activity (i.e., large amplitude signals).

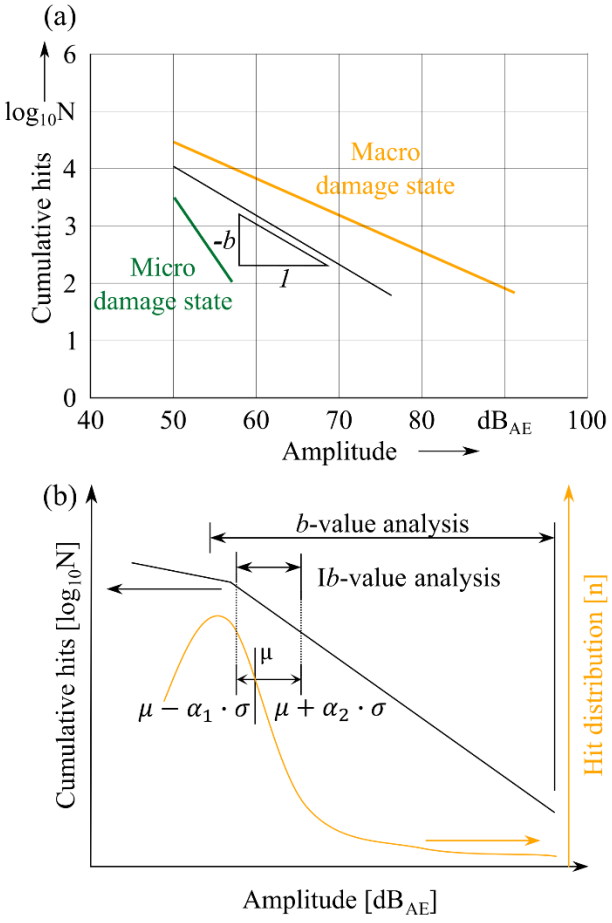

Figure 3: (a) Interpretations and (b) Definition of *b*-/I*b*-value analysis [14].

3 RESULTS

3.1 Analysis of the failure behavior of the EoL spar cap composites at RT and ET

Tensile loading: The RT tensile specimens show an average ultimate tensile strength (UTS) of 683 MPa, while the ET specimens exhibit a slightly lower average UTS of 598 MPa. The UTS represents 100 % of the tensile specimen lifetime and marks the point of total failure. At both test temperatures, the tensile specimens exhibit linear elastic stress-strain behavior until they reach total failure. The influence of different temperature settings on material behavior under tensile loading is explored in the frequency domain. Figures 4a and 4b present the acoustic emission (AE) frequency analysis results for the RT and ET specimens, respectively.

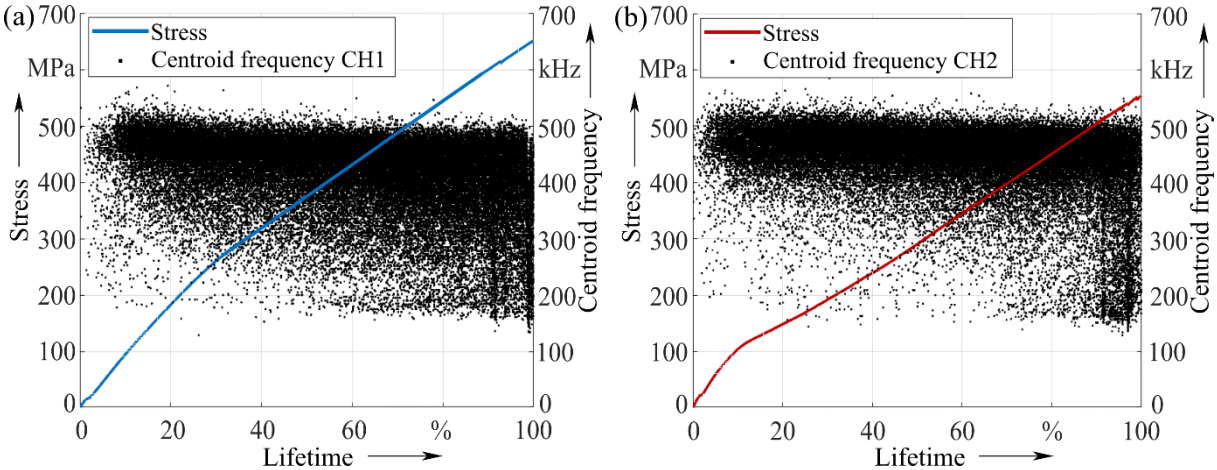

Figure 4: Centroid frequency range as the total hits for (a) RT and (b) ET tensile specimens.

The overall frequency range is broad; however, distinct preferred centroid frequency ranges are identified. For both RT and ET specimens, high frequencies (400 – 600 kHz) associated with fiber breakage are dominant. As the specimen's approach total failure, a significant number of intermediate (220 – 400 kHz) and low frequency (100 – 220 kHz) hits are detected. In particular, the RT specimens exhibited a significantly higher number of mid-frequency hits (corresponding to interfacial failure) compared to the ET specimens from 20% lifetime onward. This trend is also illustrated in Figure 5.

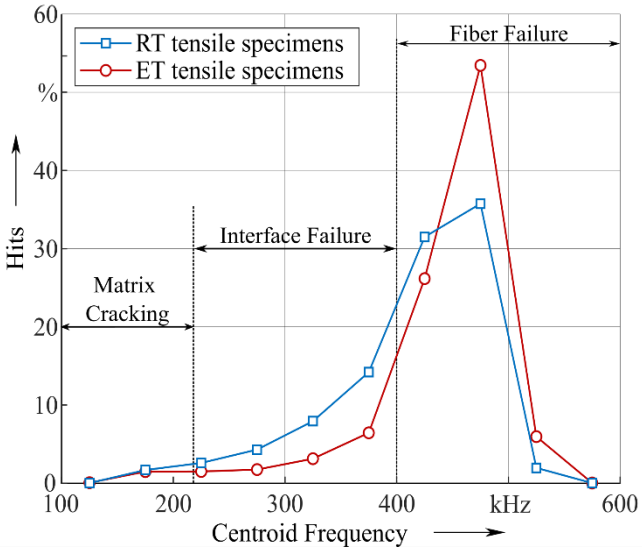

Figure 5: AE distribution showing the centroid frequency at RT and ET (each AE hit fraction was normalized to the total number of AE hits).

In the context of ET, the polymer matrix undergoes partial softening, resulting in a reduction of its load-carrying capacity and the appearance of slight ductility. These two effects have opposing implications for interfacial adhesion: softening tends to weaken the interface, while increased ductility may enhance it. However, the overall impact appears to be dominated by the negative influence of matrix softening. Considering the significant mismatch in mechanical properties between the fibers and the matrix, as well as the intrinsic brittleness of the fibers, the potential benefits of increased ductility appear to be negligible in tensile specimens loaded in LD.

Bending loading: The RT bending specimens exhibit an average ultimate flexural strength (UFS) of 1,174 MPa, while the ET specimens show a reduced average UFS of 890 MPa. UFS is defined as the maximum bending load a specimen can sustain before complete structural failure. Although the EoL bending specimens display a moderate reduction in bending strength under ET conditions, their mechanical performance remains comparatively high. Analogous trends are observed in the tensile specimens tested at ET. These findings underscore the viability of repurposing EoL spar cap components in structural second life applications, including those exposed to ET, such as in the construction sector.

Figures 6a and 6b present representative stress–strain curves and trend lines under bending load, along with corresponding AE hits in the frequency domain. Up to approximately 60% of the specimen's lifetime, both curves exhibit a similar slope ($b_{RT1} = b_{ET1}$), indicating comparable stiffness during the initial loading phase. Beyond this point, a reduction in slope is observed ($b_{RT2} < b_{RT1}$; $b_{ET2} < b_{ET1}$), particularly in the ET specimens. The secondary linear slope (b_{ET2}) is lower than that of the RT specimens (b_{RT2}), which may contribute to the lower UFS under ET conditions.

The AE data also reflect this transition. During the initial 60% of the lifetime, the AE signals predominantly lie within a narrow frequency range of 400–600 kHz for RT and ET bending specimens, a range associated with fiber breakage. After this point, the frequency distribution becomes significantly broader. In addition to high-frequency events, intermediate- and low-frequency AE hits (100–400 kHz) are increasingly apparent, suggesting the onset of additional damage mechanisms such as matrix cracking or interfacial debonding.

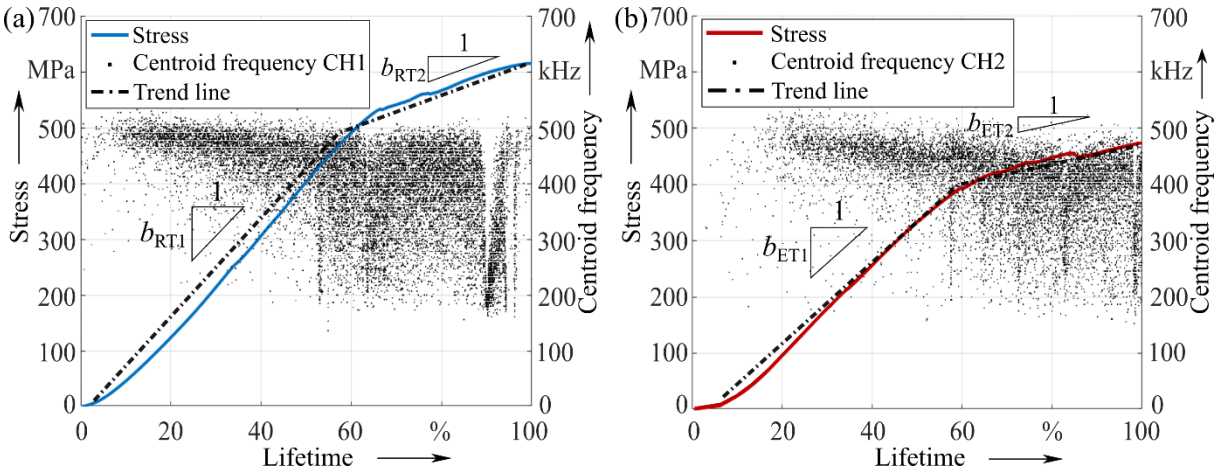

Figure 6: Centroid frequency range as total hits for (a) RT bending and (b) ET bending specimens.

Fundamentally, since tensile failure dominates in this material system, the AE distribution of centroid frequencies observed under bending closely resembles that observed in tensile failure. The centroid frequency ranges remain generally similar for the bending specimens tested at both temperatures. Notably, the ET specimens exhibit a slightly higher number of high-frequency AE hits compared to those tested at RT. This trend is illustrated in Figure 7.

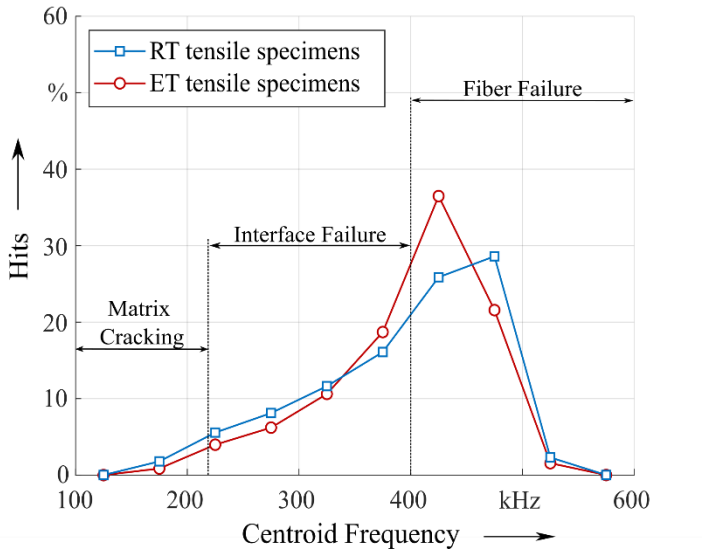

Figure 7: AE distribution for both bending temperatures (each AE hit fraction was normalized to the total number of AE hits).

3.2 *b*-/I*b*-value analysis of tensile and bending tests at different temperatures

The *b*-/I*b*-value analysis uses data from the first 30% of the specimen's lifetime to ensure sufficient AE activity and to allow the specimen to undergo complex microdamage behavior in the early stages. This period typically exhibits numerous microcracks and rising *b*-values, which do not reliable indicate structural integrity. To improve data quality, the first 50 AE hits—primarily considered noise—are excluded from the analysis.

As shown in Figure 8, the *b*-value does not exhibit a consistent trend over the lifetime of the tensile and bending specimens tested at RT and ET. Depending on the loading condition, the *b*-value either increases or decreases, indicating variability rather than a clear progression. This inconsistency suggests a potential overemphasis of micro-cracks activity in the results. Consequently, the *b*-value is not considered valid as a reliable indicator in terms of SHM purposes.

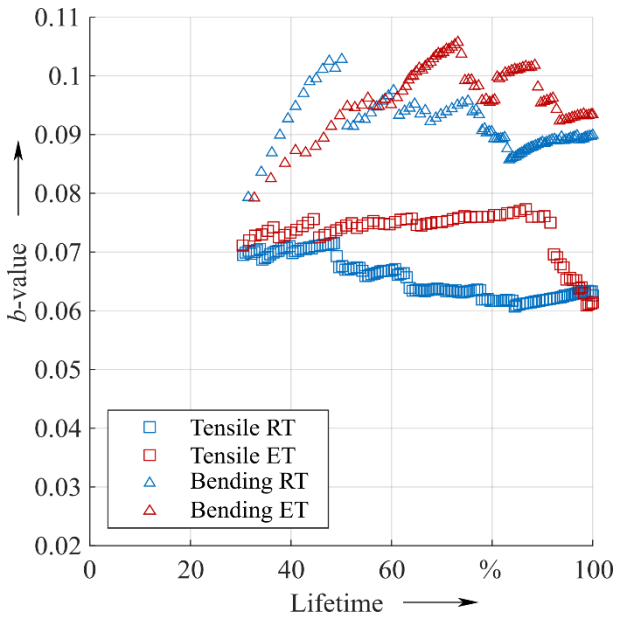

Figure 8: Lifetime dependence of *b*-values during tensile and bending tests at RT and ET.

The I*b*-value analysis presented in Figure 9 shows a decreasing trend for both tensile and bending specimens, indicating greater reliability as a damage assessment criterion. It demonstrates potential for representing the structural health of EoL composite materials.

The final I*b*-value for the tensile tests (Figure 9a) ranges from 0.05 to 0.055 at RT, and increases slightly to approximately 0.06 under ET conditions. This increase may result from temperature-induced changes in the matrix properties or a weakened fiber-matrix interface.

In bending tests (Figure 9b), the final I*b*-value ranges from 0.055 to 0.06 at RT and increases slightly to approximately 0.065 under ET conditions. At both temperatures, the I*b*-value exhibits a two-phase trend: a typical decreasing phase followed by a slower decreasing phase beginning at approximately 60% of the specimen's lifetime. This transition corresponds to the change in slope observed in the stress-strain response, indicating a shift from major crack propagation to the final failure phase, which is characterized by the formation of numerous microcracks. Sudden jumps in the I*b*-value are likely caused by the abrupt formation of individual microcracks.

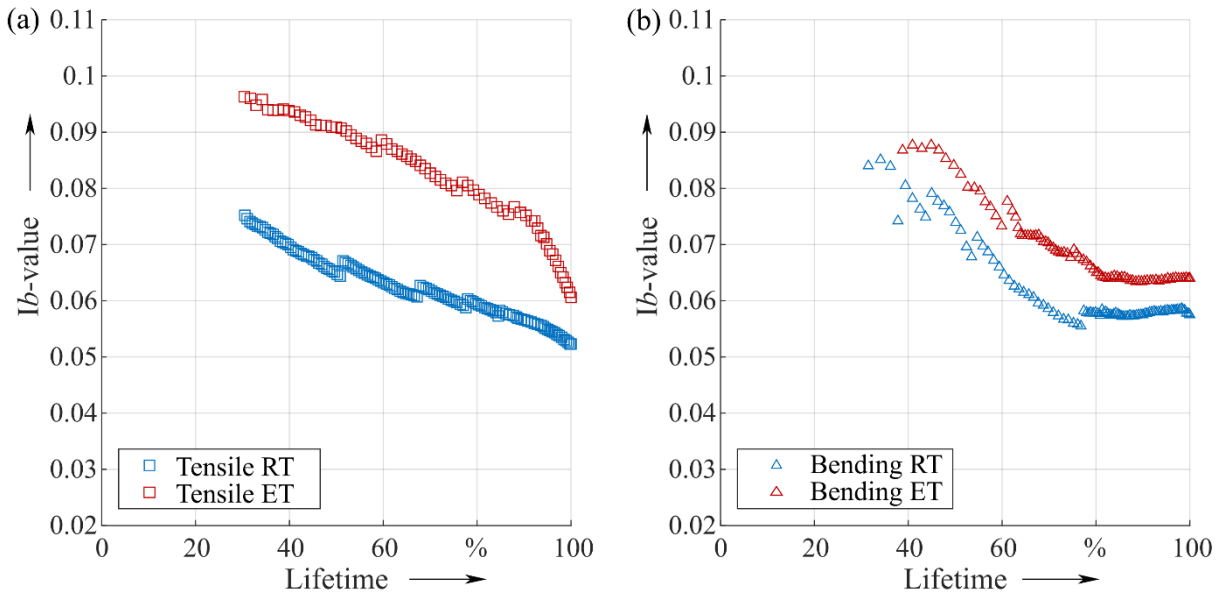

Figure 9: Lifetime dependence of I*b*-values during (a) tensile tests at RT and ET and (b) bending tests at RT and ET.

3.3 Comparison I*b*-value analysis for tensile and bending specimens

The I*b*-value is found to be sensitive to varying loading conditions. Therefore, its interpretation as an indicator of structural condition should be adapted to the specific loading scenario. The corresponding Ib-values, categorized by load scenario, are summarized in Table 2.

I*b*-value tensile RT	I*b*-value tensile ET	I*b*-value bending RT	I*b*-value bending ET	Structural condition
I*b* > 0.1	I*b* > 0.1	I*b* > 0.1	I*b* > 0.1	No/slight damage
0.1 > I*b* > 0.07	0.1 > I*b* > 0.08	0.1 > I*b* > 0.07	0.1 > I*b* > 0.075	Moderate damage
0.07 > I*b* > 0.06	0.08 > I*b* > 0.07	0.07 > I*b* > 0.06	0.075 > I*b* > 0.065	Severe damage
0.06 > I*b*	0.07 > I*b*	0.06 > I*b*	0.065 > I*b*	Near to fracture

Table 2: Structural health assessment criteria based on I*b*-values for repurposed EoL composites under different loading conditions.

Based on these criteria, the following assumptions can be made:

- If the structural condition is classified as moderately damaged, repair of the monitored structure is recommended.
- If the Ib-value indicates severe damage, structural replacement should be considered as a viable option.
- If the structure approaches fracture, safety concerns arise, and immediate intervention may be necessary.
- If loading conditions are considered in the interpretation of the Ib-value, the feasibility of Ib-value analysis for SHM of repurposed GFRP beams is further supported.

4 DISCUSSIONS

The results demonstrate that the I*b*-value exhibits a consistent decreasing trend, independent of the applied loading condition. This observation supports the reliability and repeatability of I*b*-value analysis across both tensile and bending load scenarios. Since second life applications of composite components may involve varying dominant loading scenarios, this dependency must be carefully considered when employing the I*b*-value as a structural health indicator. Notably, final failure in all cases occurred at an I*b*-value of approximately 0.06, suggesting that this value may serve as a threshold indicator of critical damage. Under ET conditions, the final I*b*-values tended to be slightly higher than those observed at RT. This behavior likely reflects the combined influence of increased microcrack generation and thermal softening of the matrix. Given the comparable internal structural conditions of the specimens, it is reasonable to attribute the dominant effect to the latter, indicating that matrix weakening under ET contributes more significantly to the observed increase in I*b*-value.

This study advances the current understanding of the I*b*-value approach by examining its response not only to different loading modes but also to variations in temperature. The ability of the I*b*-value to capture damage evolution under these divers' conditions highlights its potential as a robust diagnostic tool for SHM.

However, this study also has certain limitations. Notably, the behavior of the I*b*-value under cyclic bending loading, especially beyond the onset of phase 2 (where damage localization becomes dominant), remains unexplored. Future research should address this aspect and explore the scalability of the approach, for example, by applying it to larger structural elements such as 1000 mm long spar cap beams. Additionally, validating the technique across different composite components from EoL WTBs would support a broader assessment of its applicability for SHM in sustainable energy infrastructure.

5 CONCLUSIONS

This study presents an AE-based structural integrity assessment of EoL WTB components subjected to varying loading and temperature conditions. Key AE features, namely peak amplitude, cumulative hits, and centroid frequency, are evaluated in accordance with established failure analysis methodologies. Compared to RT specimens, ET specimens exhibit slightly reduced UTS and UFS, reflecting temperature-dependent material degradation.

In the *b*-/I*b*-value analysis, a representative segment extraction method based on mean values is introduced. The results show that the *b*-value does not exhibit a consistent trend over the specimen lifetime, limiting its reliability. In contrast, the I*b*-value demonstrates a more robust and reproducible response, establishing it as a more reliable indicator of structural degradation.

Regardless of the specific form a monitoring criterion may take, the findings highlight the need for standardized methods to track the evolution of dominant crack regions during progressive failure. As the repurposing of composite materials gains increasing relevance, SHM approaches tailored to previously serviced materials under different loading conditions are essential. In particular, ensuring the structural integrity of components during the early stages of their second application is critical. The extended I*b*-value approach proposed in this study provides a promising foundation for SHM of repurposed composites and shows potential for practical implementation in industrial sectors such as wind energy and construction.

Keywords: Carbon fibre, Recycling, Mechanical properties, Forming

ABSTRACT

To facilitate the future application of mechanically shredded production scrap of polyamide 6-carbon fiber (PA6-CF), a comprehensive assessment of its potential use cases is essential. As a first step, the influence of selected process parameters on the processing behavior and quality of the resulting laminates was systematically investigated. Based on 3-point bending and tensile tests possible applications of flake laminates with structural or visual requirements are looked at and compared to sheet molding laminates out of chopped carbon fiber tape reinforced thermoplastics (SM-CTT). The results indicate that the mechanical properties of the recycled PA6-CF flake laminates are comparable to those of SM-CTT materials, suggesting analogous fields of application. Despite minor surface defects, a largely smooth surface finish was attainable. From an ecological standpoint, a significant advantage of this recycling approach is the direct reutilization of production scrap without the need for fiber-matrix separating or the addition of external materials.

1 INTRODUCTION

Lightweight construction is a key technology for enhancing resource and energy efficiency across various industries, particularly in the transportation sector. In automotive engineering, reducing mass-dependent driving resistances contributes significantly to the reduction of energy consumption and greenhouse gas emissions. [1] Fiber-reinforced polymer composites (FRPs; if carbon-fiber-reinforced: CFRPs), in particular thermoplastic-based variants (tFRPs), offer high potential for lightweight design due to their excellent specific mechanical properties. Compared to thermoset systems, tFRPs enable shorter processing times, lower material costs and improved end-of-life recyclability. [2, 3]

Especially organosheets, a semi-finished tFRP, offer significant weight-saving potential. Organosheets are typically manufacturers in flat sheet form through consolidation processes and later shaped into complex parts using thermoforming or pressforming techniques. Despite careful planning, the production with organosheets often generates considerable scrap, particularly in high-volume processes. [4, 5]

This paper investigates a strategy for the reutilization of production scrap from thermoplastic composite manufacturing. The aim is to evaluate the material and structural performance of reprocessed crap material and to assess its suitability for reintegration into functional components. By establishing methods for the reuse of tFRP production waste, the overall sustainability and material efficiency of composite-based lightweight systems can be significantly improved.

Traditional recycling approaches for composite waste include mechanical processing, thermal recycling or the separation of individual components through solvolysis. After the mechanical recycling of thermoplastics, shredded waste can be reused via processes such as injection molding or extrusion. However, the original fiber length is significantly reduced, leading to a decrease in the mechanical properties of the recycled material. [6, 7]

An innovative and promising recycling alternative takes advantage of the thermoplastic matrix and its re-meltability and re-moldability – fibers and matrix are not separated. Because the production waste can vary greatly in size, the approach starts by segmenting tFRP scrap into cm-sized more manageable pieces, called flakes. In the next step the flakes can be consolidated into a semi-finished product by evenly distributing, heating them above melting point and compressing them. The semi-finished product can be manufactured like organosheets by thermoforming or pressforming techniques. This method facilitates the creation of a new type of laminate that combines material and energy efficiency, making it suitable for applications with moderate mechanical property requirements. [7] This not only undermines the ecological and economic benefits of lightweight construction but also presents a largely untapped secondary resource.

2 PROCEDURE/METHOD

The semi-finished laminate, a consolidated panel, could be used in two different use cases of thermoforming: applications with structural requirements and visible parts. A simple isothermal manufacturing process is looked at to reduce process complexity. To ensure a stable thermoforming process the process conditions for the semi-finished product must be evaluated. Based on differential scanning calorimetry (DSC) and Design of Experiments, the main process parameters for the isothermal manufacturing process including pre-heating temperature, pre-heating duration, press force, cavity temperature and press time are varied. This is to analyze the effect of the parameters on the mechanical properties. Three-point-bending tests are carried out to analyze the mechanical properties. A low bending stress and flexural modulus should indicate insufficient consolidation. Consolidation was also assessed visually and qualitatively based on surface continuity and absence of visible delamination. An additional qualitative assessment was performed using tap test, in which the acoustic response of the sheet was evaluated. A high-pitched, metallic sound is indicative of proper consolidation, while a dull sound may suggest internal defects or insufficient consolidation. Goal is a flake laminate which is fully consolidated and could reach structural or visual requirements.

After finding the best process parameters, the mechanical properties of the process are analyzed and compared to traditional materials like SM-CTT. In the second application for visible parts the focus is on fiber cohesion and surface defects, evaluating whether the panel could meet visual requirements.

3 EXPERIMENTAL INVESTIAGTIONS

3.1 Materials

The experimental procedure involves using PA6-CF tape with a fiber mass content of 60 wt.% from Envalior GmbH (Germany) as the virgin material, which is consolidated, and chopped into flakes measuring 6 mm to 14 mm in equivalent diameter. According to the tape manufacturer, the tape properties are the following:

Properties	Unit	Typical Data	Test Method
Density	(kg/m³)	1450	ISO 1183
Fiber content (V/V)	(%)	49	ISO 11667
Tensile modulus – 0°	(GPa)	135	ISO 527-4
Stress at break – 0°	(MPa)	1700	ISO 527-4
Strain at break – 0°	(%)	1.4	ISO 527-4
Melting temperature	(°C)	220	ISO 11357-1

Table 1: Properties of the PA6-CF tape according to the datasheet.

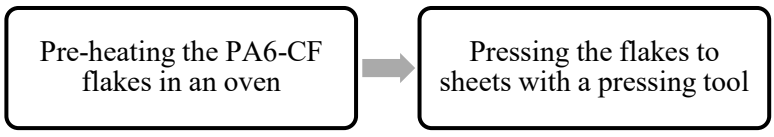

Figure 1 shows the PA6-CF tape after consolidating and chopping in the form of flakes. This material has a three-dimensional, voluminous, loose structure.

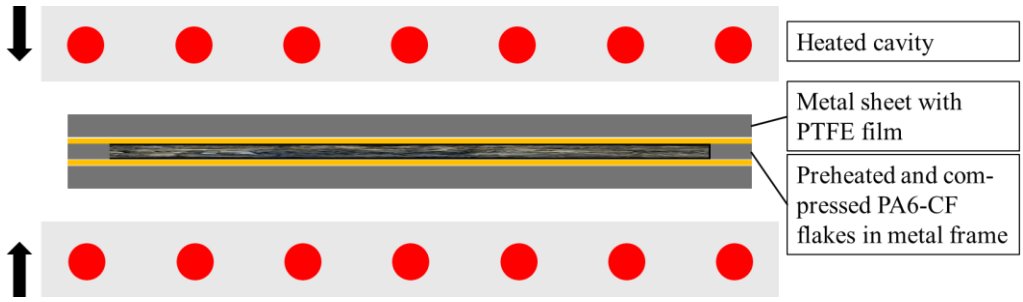
Figure 1: Chopped flakes.

3.2 Manufacturing

The isothermal process includes two main manufacturing steps:



The series of pictures in Figure 2 illustrates the manufacturing process.

1. Evenly distributed flakes on a metal sheet

2. Heating in the oven

3. Pressing tool with preheated flake material

4. Consolidated flake laminate

Figure 2: Manufacturing process of flake laminates by isothermal process.

For pre-heating, the tFRP-flakes are evenly distributed between two metal sheets. To contain the flakes and prevent material leakage during pressing, a 2 mm thick metal frame is inserted between the sheets. This also leads to equal sheet thicknesses. To enhance demoldability one side of each sheet is lined with polytetrafluorethylene (PTFE)-film. The stack is heated in a convection oven of the company Nabertherm GmbH (Germany), type TR 240. In order to identify suitable process conditions for pre-heating, the relevant parameters were systematically varied as follows:

- Pre-heating temperatures: 225 °C, 250 °C, 275 °C
- Pre-heating duration: 10 min, 12.5 min, 15 min, 17.5 min, 20 min

The weight of the covering metal sheet compresses the CFRP flakes, resulting in a pre-compacted structure. After completing the pre-heating cycle, the stack is manually transferred to the pressing tool with a planar mold cavity. The size of the cavity measures 350 mm x 300 mm. Both halves of the mold are equipped with electrically heated cartridges for temperature control. Consolidation is carried out using a servo-motorized screw press (Synchropress GmbH (Germany), type: 1M-300) under the following process parameters:

- Forming pressure: 20 bar, 40 bar, 80 bar
- Cavity temperature: 80 °C, 100 °C, 120 °C
- Holding time: 30 s, 60 s, 120 s

The forming pressure p is set using the known area of the cavity A and the set pressing force F (cf. Equation 1).

$$\boldsymbol{p = F/A} \tag{1}$$

After passing the holding time the press returns to the starting position and the stack can be ejected manually.

3.3 Sample preparation and test methods

Mechanical properties are evaluated through three-point bending and tensile tests, following DIN EN ISO 14125 and DIN EN ISO 527-4 standards, respectively. Both geometries can be cut out of the produced flake-laminate sheets by waterjet cutting. For tensile tests the specimen measures 250 mm x 25 mm. Three-point bending samples measure 100 mm x 15 mm. Since PA6 tends to absorb water, the specimens were dried at 80 °C for 5 hours in a climate chamber and afterwards conditioned at 23 °C and 50 % relative humidity for 8 hours. Tests are performed on a servo-electric (type: Criterion C45.105) universal testing machine from MTS Systems Corporation (USA) with a testing speed of 2 mm/min. To assess potential anisotropy, specimens are extracted in both the 0° and 90° directions.

4 RESULTS

4.1 Influence of process parameters on degree of consolidation and mechanical properties

The pre-heating temperature has a significant impact on the degree of consolidation and resulting mechanical properties of the PA6-CF flake laminates. At a pre-heating temperature of 225 °C, approximately 5 °C above the peak melting point determined via DSC, insufficient consolidation was observed. The produced laminates were fragmented and unsuitable for mechanical testing. Increasing the pre-heating temperature to 250 °C improved consolidation significantly, as indicated by a smoother surface appearance and enhanced structural integrity. Further increasing the temperature to 275 °C yielded to no noticeable differences in surface quality and mechanical properties compared to 250 °C, as confirmed by three-point bending tests (bending stress: (102.52 ± 19.23) MPa vs. (116.34 ± 22.11) MPa; flexural modulus: (10812.64 ± 1401.88) MPa vs. (10614.54 ± 990.77) MPa).

In a subsequent experimental series, the influence of pre-heating duration was investigated. A pre-heating duration of 10 minutes resulted in poor consolidation with extensive surface defects and fragmentation. Extending the duration to 12.5, 15 and 17.5 minutes led to notable improvements (bending stress: (103.64 ± 13,87) MPa, (102.52 ± 19,23) MPa, (165.95 ± 16.18) MPa; flexural modulus (8820.65 ± 1245.19) MPa, (10812.64 ± 1401.88) MPa, (12556.67 ± 1930.39) MPa), indicating more complete consolidation. The characteristic metallic sound during tap testing further supported this observation. However, further extending the duration to 20 minutes, caused a decline in mechanical performance (bending stress: (120.79 ± 25.14) MPa; flexural modulus: (11138.02 ± 4250.62) MPa). Since thermal degradation at this temperature and time frame is unlikely, the decrease in properties is attributed to extended transfer durations between oven and press, which may have led to a significant drop in laminate temperature before pressing.

The press force also influenced the consolidation outcome. At 250 °C pre-heating temperature, a forming pressure of 20 bar was insufficient to ensure complete consolidation, resulting in visibly defective surfaces. Pressures of ≥ 40 bar were required to obtain nearly defect-free laminate surfaces at this temperature. No significant mechanical differences were observed between samples pressed at 40 bar and 80 bar (bending stress: (102.52 ± 19.23) MPa vs. (97.19 ± 11.26) MPa; flexural modulus: (10812.64 ± 1401.88) MPa vs. (9733.37 ± 647.42) MPa). At elevated pre-heating temperatures, a pressure of 20 bar was found to be adequate.

The pressing tool enables a slow, controlled cooling of the laminate, which promotes crystallization and improves mechanical performance. However, variation in temperature did not lead to significant differences in three-point bending properties between 80 °C and 100 °C temperature (bending stress: (114.41 ± 24.34) MPa vs. (102.52 ± 19.23) MPa; flexural modulus: (9415.86 ± 1899.78) MPa vs. (10812.64 ± 1401.88) MPa). At 120 °C both values declined by approximately 50 %, indicating suboptimal cooling conditions.

A holding time of 60 seconds in the press yielded the best mechanical performance (bending stress: (102.52 ± 19.23) MPa; flexural modulus: (10812.64 ± 1401.88) MPa). A shorter duration of 30 seconds led to lower values (bending stress: (82.68 ± 13.37) MPa; flexural modulus: (7454.42 ± 1242.22) MPa), while an extended time of 120 seconds show no further benefit (bending stress: (80.66 ± 21.64) MPa; flexural modulus: (8133.93 ± 1166.30) MPa).

The results underline the importance of carefully controlled pre-heating temperature and duration and indicate them as the two main controlling process parameters of the whole process. Heat loss during manual transfer between oven and press – characteristic of this isothermal process – can result in suboptimal consolidation and surface defects, as the material temperature may fall below the ideal processing range. To counteract this the pre-heating temperature must be set above peak melting point indicated by DSC.

Based on these results, the following process parameters should at least be achieved to ensure sufficient consolidation and mechanical performance for the investigated material:

- Pre-heating temperature: > 250 °C
- Pre-heating duration: > 17.5 minutes
- Forming pressure: > 25 bar
- Cavity temperature: 100 °C
- Press holding time: 60 s

Initial trials were conducted using reduced amount of flake material compared to the amount used in the subsequent production of full-sized laminate sheets. To evaluate the internal heat-up behavior of larger flake stacks, a thermocouple was embedded centrally during pre-heating. At an oven setpoint of 250 °C, the core of the stack required more than 65 minutes to reach the target temperature of 250 °C. This suggests that prior specimens processed with lower flake mass may not have fully reached processing temperature, potentially explaining earlier inconsistencies. By increasing the oven temperature to 275 °C this duration was reduced to 23.5 minutes, while at 290 °C the target temperature was achieved after 17.5 minutes.

These findings demonstrate the relatively slow heat transfer into the flake material. To ensure that the flakes remain above melting temperature during transfer to the mold and subsequent consolidation, the oven temperature and pre-heating duration must be adjusted.

Based on the results of these thermal evaluations, the process parameters in Table 2 were selected to produce flake laminates for three-point bending and tensile tests. The forming pressure was maintained at 25 bar, the cavity temperature was set to 100 °C, and a consistent holding time of 60 s was applied in all cases.

Sample	**Pre-heating temperature** (°C)	**Pre-heating duration** (min)
275°C_24min	275	24
275°C_29min	275	29
290°C_19min	290	19
300°C_19min	300	19

Table 2: Pre-heating temperatures and durations for the manufacturing process of different samples.

4.1 Mechanical properties in comparison to similar laminates

The processed sheets have a shiny and nearly defect-free surface and a metallic sound which indicates sufficient consolidation. They would be suitable for visual applications. The investigation of mechanical properties will show if the sheets can also be used in structural parts with mechanical requirements.

The mechanical characterization of the PA6-CF flake laminates was conducted via three-point bending and tensile testing. A comparison of specimens oriented in 0° and 90° direction revealed no statistically significant anisotropy, suggesting that the laminates exhibit quasi-isotropic behavior. As a result, test data are presented independent of extraction direction.

Figure 3 illustrates the average bending stress and flexural modulus values obtained for various processing parameters (cf. Table 2).

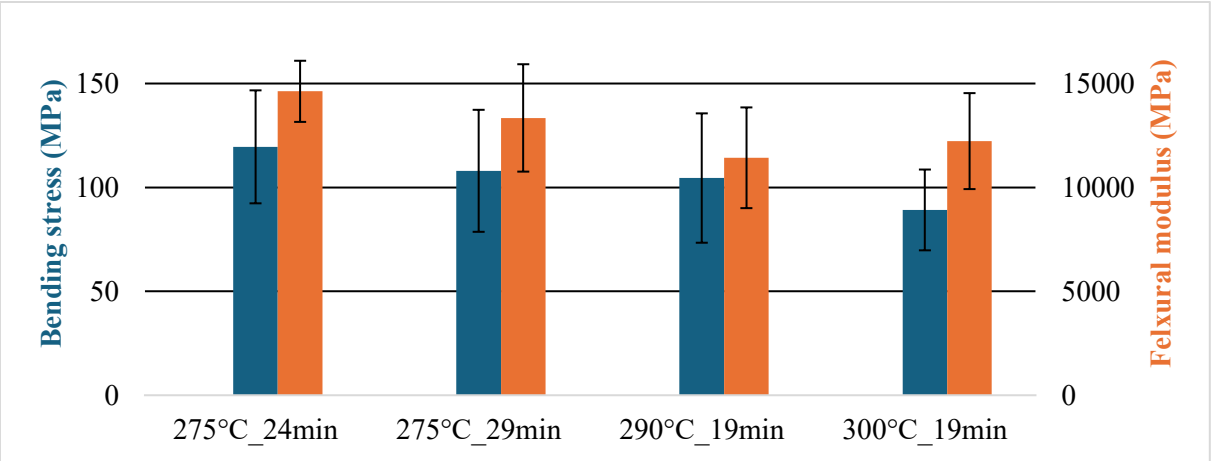


Figure 3: Average bending stress and flexural modulus of consolidated PA6-CF flake laminates.

The flexural modulus ranges from 11426.07 MPa (290°C_19min) to 14623.23 MPa (275°C_24min) with standard deviations between 1470.71 MPa and 2584.05 MPa. Notably, samples processed at an oven temperature of 275 °C with varying pre-heating durations yielded nearly identical flexural moduli within the margin of experimental uncertainty. Laminates processed at 290 °C and 300 °C with shorter pre-heating durations (19 minutes) achieve comparable modulus values. The relatively high standard deviation is attributed to process-related fluctuations, particularly variable transfer times between oven and press. Because of this instability and a slow heat transfer into the flake material the small changes in temperature or pre-heating duration have little to no significant impact on the flexural moduli.

Bending stress values vary between 89.17 MPa (300°C_19min) and 119.52 MPa (275°C_24min) with standard deviations from 19.44 MPa to 31.13 MPa. Across all variants, the bending stress results remain at a comparable level, reinforcing the hypothesis that inconsistent transfer times may have led to temporary temperature drops below the optimal consolidation window.

For reference, the flexural modulus of pure PA6, as specified in the material data sheet [8] of the material used in [9], is 1961 MPa which is approximately one-sixth of the values obtained for the flake laminates. In contrast, a PA6-CF with a similar fiber volume fraction exhibits a flexural modulus of 98112.4 MPa [10]. In comparison the flake laminates reach approximately 14,9 % of the flexural modulus of virgin continuous fiber composite, making them suitable for applications with moderate mechanical requirements.

Table 3 summarizes the tensile test results for PA6-CF flake laminates and compares them with reference materials, including pure PA6, SM-CTT with similar fiber volume content and the virgin continuous PA6-CF tape. The tensile modulus could only be determined for the 275°C_29min test series, as the slopes of the linear elastic regions in the other specimens exhibited significant variability, preventing a consistent evaluation.

Material	Tensile modulus (MPa)	Stress at break (MPa)	Strain at break (%)	Tensile Strength (MPa)
PA6-CF flake laminates				
275°C_24min	-	14.80 ± 9.32	0.01 ± 0.003	16.96 ± 9.45
275°C_29min	42.84 ± 3.64	23.09 ± 10.32	1.56 ± 1.1	31.46 ± 6.94
290°C_19min	-	27.47 ± 7.46	0.01 ± 0.002	27.75 ± 7.2
300°C_19min	-	22.97 ± 11.91	0.01 ± 0.003	26.84 ± 9.26
References				
Pure PA6 [11]	52000	-	28.70	28.70
SM-CTT (3t) (V/V=52.4 %) [9]	33.2 ± 2.9	-	0.9 ± 0.1	259.6 ± 39.1
PA6-CF tape (0°) [12]	135000	1700	1.4	1910

Table 3: Average mechanical properties for PA6-CF samples with different pre-heating temperature and duration and references from literature.

The highest mechanical performance among the flake laminates was achieved with a pre-heating regime of 275 °C for 29 minutes. The observed scatter in mechanical data is likely a result of uncontrolled variations in transfer time.
The tensile modulus of the flake laminates exceeded that of the SM-CTT reference, indicating their suitability as a replacement in applications where stiffness is a primary design criterion. However, the tensile strength and strain-at-break values fell significantly short of those achieved by continuous fiber-reinforced PA6-CF tape due to the inherently random fiber orientation in the flake structure. This structural limitation reduces the ability of the fiber phase to effectively carry axial load, which is reflected in the lower mechanical performance metrics.
The 275°C_29min reach roughly half of the values as SM-CTT and PA6-CF tape at strain at break when considering the high standard deviation. The tensile strength of the flake laminates was comparable to neat PA6 and reached approximately one-tenth of the SM-CTT reference. Despite this, the performance enhancement relative to the matrix alone demonstrates the reinforcing effect of the flakes and underscores the viability of this material for cost-sensitive, less demanding applications.
The mechanical properties show that some values are higher than pure PA6 and similar to SM-CTT. The PA6-CF tape has, as could be expected, better mechanical properties. Concluding that PA6-CF flake laminates are recommendable for visual applications or applications with medium to low standards on mechanical properties.

5 CONCLUSIONS

This study demonstrates the feasibility of manufacturing PA6-CF flake laminates via an isothermal compression molding process using recycled material. The mechanical characterization revealed that, despite their randomly oriented microstructure, the laminates exhibit quasi-isotropic behavior and provide significantly enhanced stiffness compared to pure PA6. Although they fall short of the mechanical performance achieved by continuous or chopped fiber-reinforced tapes (e.g., SM-CTT or virgin PA6-CF), their performance is sufficient for structural applications with low to moderate mechanical demands, as well as for purely visual or semi-structural components as an intermediate layer or filling material.
The findings suggest that flake laminates offer a sustainable alternative to more resource-intensive fiber composites, particularly in contexts where full structural load-bearing capacity is not critical.

Overall, the study highlights the potential of mechanically recycled FRP composites in lightweight design and resource-efficient component production, supporting circular economy principles within tFRP processing.

ACKNOWLEDGEMENTS

Many thanks go to Johannes Terhechte of W8SVR for providing the virgin material and Winand Kok and Hans Luinge of Spiral RTC for shredding. Further thanks go to all former and current colleagues as well as students at the Chair for Automotive Lightweight Design and Chair of Plastics Technology and Plastics Processing who supported this study.

ABSTRACT

The increase in composite waste from decommissioned wind turbine blades must be managed through recycling to alleviate environmental issues. To provide a competitive alternative to traditional virgin composites, this study investigates the potential use of waste wind turbine blades (WWTB) as a sustainable reinforcement material in secondary polypropylene (PP) composites. WWTB and a coupling agent (maleic anhydride-grafted polypropylene, or MAPP) were combined to create PP composites through extrusion and injection moulding. To assess their recyclability and performance retention, these composites underwent three reprocessing cycles, which included the addition of manufacturing waste produced during extrusion. The samples were characterized using Fourier transform infrared (FTIR) spectroscopy, Differential scanning calorimetry (DSC), tensile test, three-point bending test, and melt flow index (MFI). Due to the compatibilization, the composites exhibited an increase in mechanical properties compared to both uncompatibilized composites and pure PP. The reprocessed composites in the second and third cycles further exhibited improved mechanical performance, attributed to lower melt temperature and screw speed during injection moulding. FTIR analysis revealed that the functional groups remained unaffected across reprocessing cycles. Upon MAPP addition, DSC revealed higher melting points and crystallinity of composites, and reprocessing had little effect on the degree of crystallinity. Furthermore, following repeated reprocessing, the MFI values increased, suggesting a reduction in the molecular weights of the composites.

1 INTRODUCTION

Global Wind Energy Council (GWEC) has increased its growth estimate for 2024–2030 (1210GW) by 10% [1]. The onshore installed capacity is expected to reach over 5000 GW by 2050, with offshore contributing 1000 GW [2]. As the wind energy industry grows, 330,000 t/year of composite materials manufactured from wind turbine blades will be deposited or burned globally until 2028, and 418,000 t/year between 2028 and 2040 [3]. Circularity of materials has received more attention from industry and scholars in recent years, especially in the wind energy sector, which generates enormous amounts of outdated turbine components, such as blades [4].

Steel, copper wire, hardware, and outfitting make up 85% of wind turbine components. The remaining 15% consists mostly of waste glass or carbon fibre composites from wind turbines, which are environmentally hazardous due to their 60% reinforcing fibre and 40% resin content. The cross-linked polymer chains of thermoset resins, such as polyester and epoxy, further complicate recycling. Recycling such composite wastes is quite challenging since these blades have been designed to endure extreme mechanical and environmental stresses for many years [2], [5], [6]. Recent years have seen several studies on the recycling of waste fiber-reinforced epoxy resins (WFREs) by pyrolysis [7] and chemical treatment [3], emphasizing the breakdown of epoxy resins to recover high-value carbon fibers. However, thorough research is still needed to recover glass fibers using these two techniques.

On the other hand, mechanical recycling, which involves grinding the composite to generate a mixture of single fibres, resin chunks, and fibre matting embedded in resin, is one of the simplest methods for handling decommissioned blades out of all the recycling systems now in use [8]. Due to its lower energy consumption of 0.1–4.8 MJ/kg and lower process cost compared to the value of recycled material, mechanical recycling is the most sought-after recycling method among industries [9].

In 2024, Pu et al. developed polypropylene composites via injection moulding by using wind turbine blade waste as a filler up to 50 wt% along with other compatibilizers. These composites exhibited a significant increase of 37.3% of tensile strength, 147.3% of tensile modulus, and 165.5% of flexural strength [10]. Similarly, Mamanpush et al. used such wind turbine blade waste as a feedstock alongside high-density polyethylene (HDPE) to extrude profiled composites. Such secondary composites showed improved mechanical and physical properties and further proving the potential capability of using waste wind turbine blades in secondary polymer composites [11].

However, the price of virgin glass fibre, which is approximately €2/kg [12] should be considered while recycling glass fibers from wind turbine blades. The lower energy demand for recycling (10–20 times lower) compared to the embodied energy of manufacturing for virgin glass (13–32 MJ/kg) [13] is equally imperative. To tackle such competitiveness in the raw materials, many investigations have been done in the past related to the reprocessing capability of glass fibre reinforced polypropylene composites. Colucci et al. investigated how recycling affected the performance behaviour of virgin glass fibre/polypropylene composites using injection moulding. However, the samples were only mechanically recycled once, and the mechanical characteristics were found to be lower than those of non-recycled polypropylene [14]. Chen et al. investigated the impact of three (3) injection moulding machine processing cycles on the characteristics of long glass fibre and PP. Their results demonstrated that the thermo-mechanical, rheological, and thermal characteristics of the composite are not significantly affected by mechanical recycling [15]. A similar investigation of reprocessing was done by Touati et al. on isotactic polypropylene (PP)/Cloisite 15A (OMMT) (5 wt.%) nanocomposites in the presence of maleic anhydride grafted polypropylene used as a compatibilizer [16]. Achukwu et al. confirmed that glass fibre reinforced polypropylene composites can be reprocessed for a maximum of 3 cycles without significant deterioration of mechanical properties or chemical structure [17].

Up until now, research on the reprocessing of glass fibre-reinforced polypropylene (GF-PP) composites has mostly focused on systems that use virgin glass fibres; similarly, manufacturing waste produced during the reprocessing process has received less attention. Therefore, to make the secondary composites more competitive against virgin composites, the current study examines the effects of 3 reprocessing cycles on secondary polypropylene composites reinforced with waste from shredded wind turbine blades, a non-virgin, post-industrial source of glass fibre. And to better replicate actual recycling situations, this work not only uses the recycled reinforcement but also ingeniously combines manufacturing waste generated during extrusion with the shredded secondary composites. For fair comparison, these composites were compared with pure PP.

2 MATERIALS AND METHODOLOGY

2.1 Materials

For the fabrication of the novel secondary polymer composites, a primary raw material, specifically mechanically recycled waste wind turbine blade (WWTB), was obtained from PreZero Gestion De Residuos SA (Spain), exhibiting a particle size of below 20 mm. It was further sieved, and the size fraction above 500 µm was considered for extrusion. The matrix utilized in this work is a thermoplastic polymer, specifically polypropylene (SABIC PP 520P), acquired from Resinex (Netherlands). At 2.16 kg of load and 230°C, the melt flow rate of PP is 10.5 g/10min. A coupling agent, maleic anhydride-graft-polypropylene (MAPP), was purchased from Sigma Aldrich (Netherlands).

2.2 Composite preparation and reprocessing

Different formulations (*Table 1*) of PP and WWTB were used to produce new secondary composites using two major processing methods: twin-screw extrusion and injection moulding. At first, the primary and secondary feeders of twin screw extruder (HAAKE Rheomex OS twin screw, ThermoFischer) were supplied with PP + MAPP and WWTB, respectively at 110 rpm rotation speed at processing temperatures of 180 °C for zone 1 and zone 2, 190 °C for zone 3 up to zone 8 and 200 °C for zone 9 and zone 10. Thoroughly compounded granules or pellets were extruded for three different cycles. Then, the dried pellets were used to produce tensile (75 mm × 5 mm × 2 mm) and bending specimens (80 mm × 10 mm × 4 mm) using a BOY XS injection moulding. The following parameters were used for injection moulding: melt temperature (200 °C), mould temperature (210 °C), injection speed (110 mm/s), injection time (15 s), cooling time (15 s), and cycle time (120 s).

In the first cycle, virgin PP was compounded with WWTB to produce secondary composites without a coupling agent. Similarly, for composites with a coupling agent, MAPP was compounded with virgin PP and WWTB (*Figure 2*). Later, a similar procedure was used for an additional two cycles, where the shredded composites, along with the corresponding pellets from the same cycle, which can be considered as manufacturing waste, were compounded to produce new composites. For instance, to produce a second cycle composite, tested samples from the first cycle were shredded and mixed with the pellets of corresponding composition from the first cycle, which are then extruded and injection moulded into second cycle composites, as shown in *Figure 1*.

From here on, the following nomenclature has been adopted for each composition: XA/YB/ZC, where X corresponds to the concentration of polypropylene by weight, Y to the recycled material from WWTB by weight, and Z to the coupling agent by weight. Similarly, A, B, and C correspond to the short names of the material. For instance, 73PP/25RM/2CA is a formulation with 73 wt.% of polypropylene, 25 wt.% of recycled material from WWTB, and 2 wt.% of coupling agent.

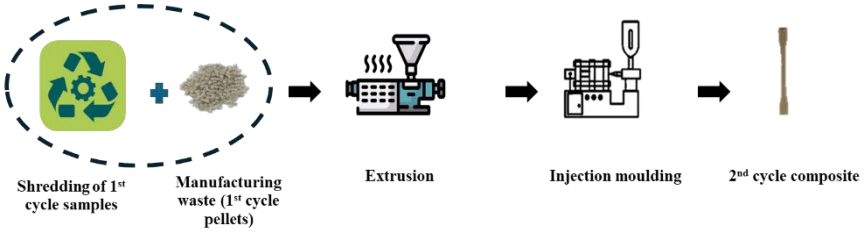

Figure 1: Illustration of the reprocessing method for each cycle

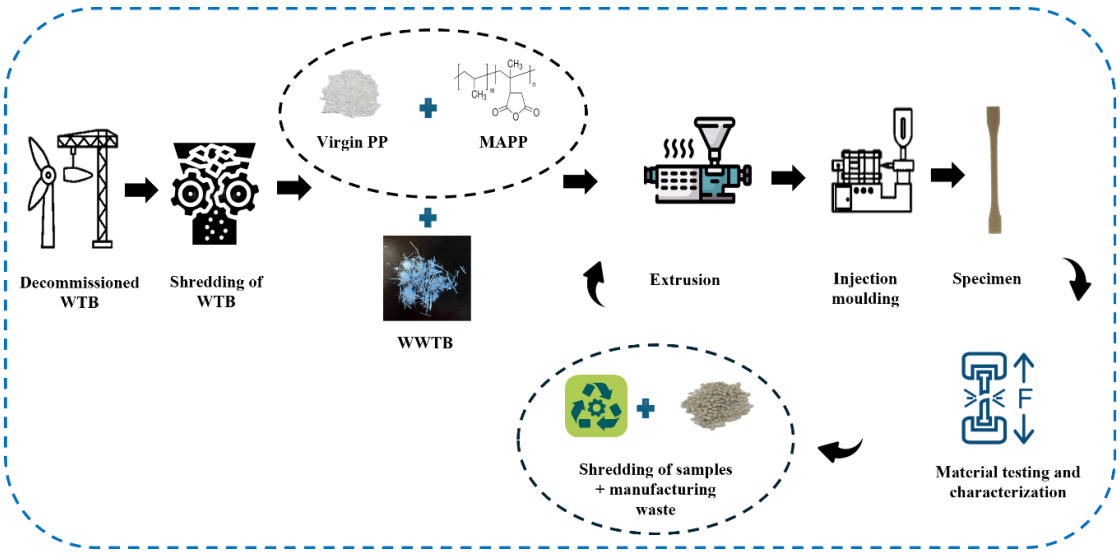

Figure 2: Schematic representation of the reprocessing of secondary composites

Table 1: Formulation of secondary polymer composites

Sample	Polypropylene (wt.%)	Recycled material (wt.%)	Coupling agent (wt.%)
100PP	100	0	0
75PP/25RM	75	25	0
50PP/50RM	50	50	0
73PP/25RM/2CA	73	25	2
48PP/50RM/2CA	48	50	2
70PP/25RM/5CA	70	25	5
45PP/50RM/5CA	45	50	5

2.3 Characterization

Chemical (structural) analysis

Fourier transform infrared spectroscopy (FTIR): This technique was employed to characterise the functional groups present in the secondary composites after multiple reprocessing cycles. Using the Frontier Spectrometer from Perkin Elmer, Fourier transform infrared spectroscopy was conducted in the range of 400 cm^{-1} to 4000 cm-1 with 20 scans per measurement.

Thermal analysis

Differential scanning calorimetry (DSC): The degree of crystallinity (X_c), melting and crystallization behaviours of all the extruded samples were determined using DSC – Q2000 (TA Instruments Co., Ltd., USA). The analysis was carried out in a temperature range between -90 °C and 220 °C under a nitrogen atmosphere with a flow rate of 50 mL/min and employing 5 °C/min for both heating and cooling cycles. All the samples were subjected to two heating and one cooling cycle. The following equation was used in the calculation of X_c:

$$Xc = \frac{\Delta H_m}{\Delta H_m^*} \times 100 \qquad (1)$$

Where ΔH_m denotes the melting enthalpy of the PP in the composition and ΔH_m^* enthalpy of melting of fully crystalline PP, taken as 209 J/kg [18].

Mechanical testing

Tensile and three-point bending test: To determine the tensile and flexural properties of the injection moulded composites, both tensile and three-point bending tests were conducted according to ISO 527 – 2 and ISO 178, respectively, using a Zwick Roell ZW010 equipped with a 2.5 kN load cell. The standard test parameters of 5 mm/min and 10 mm/min cross-head speed were used for the tensile test and bending test, respectively. However, tensile testing of third-cycle PP was conducted at a cross-head speed of 50mm/min. The flexural tests were carried out up to 10% deformation. The results were determined based on the average of five samples for each composition.

Rheology

Melt flow rate (MFR): Measurement of the MFI for all the extruded samples was performed according to ISO 1133-1 (Method A) with Cflow Extrusion Plastometer (Zwick Roell 4100). A standard method by using an applied weight of 2.16 kg at 230 °C was used. Melt flow rate (MFR) was calculated according to equation (2):

$$MFR = \frac{600m}{t} \qquad (2)$$

Where m denotes the average mass, in grams, of the cut-offs, and t denotes the cut-off time interval, in seconds

3 RESULTS AND DISCUSSION

Chemical (structural) analysis

The possible chemical structure changes within the composites for different reprocessing cycles were examined by FT-IR spectra *(Figure 3*). In all the reprocessing cycles of PP, the medium CH_2 bending vibration was observed at 1457 cm^{-1}, whereas the C–H stretch bond is represented by the absorption band at 2950 cm^{-1}. Also, CH_3 bending vibrations were obtained approximately at 1375 cm^{-1} [17]. Touati et al. also reported a weak intensity carbonyl band that represents MAPP compatibilizer at 1720 $cm^{-1,}$ and the FT-IR spectra of pure PP did not show this carbonyl band [16]. The stretching vibration of the Si-O bonds inside SiO_2 is responsible for the peak at 1100 cm^{-1} [10]. Similar results were observed by several researchers, which indicate that no significant structural change, such as oxidative degradation, has occurred even after multiple reprocessing cycles of reinforced PP composites [16], [17], [19].

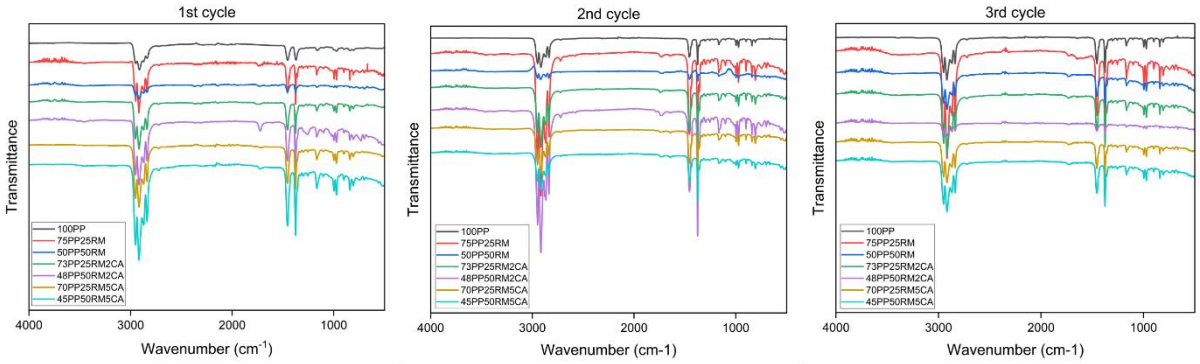

Figure 3: FTIR spectra of all the composites at different reprocessing cycles

Thermal analysis

The DSC thermograms, as shown in *Figure 4* represent the melting and cooling curves of all the extruded samples for different reprocessing cycles. The melting point of pure PP in the first cycle was 162.91 °C. However, with the addition of WWTB, the melting point of the composites 75PP25RM and 50PP50RM increased to 165 °C. Meanwhile, after the compatibilization, the melting points of the composites were reduced. A similar behaviour was observed by Hassan et al [18].

The ΔH_m is an essential parameter since its value is directly correlated with the polymer's total crystallinity content [20]. Similar to Hassan et al. report, ΔH_m of both uncompatibilized and compatibilized composites reduced compared to pure PP, which is attributed to the reduction of the degree of crystallinity of the PP matrix with the incorporation of fibres. The incorporation of glass fibres disrupts the linear crystallizable arrangement of the PP chains, resulting in a reduced degree of crystallinity and an increased proportion of flexible amorphous material[18]. On the other hand, the integration of MAPP into the composites has enhanced the level of crystallinity, which indicates that the coupling agent's presence has enhanced the matrix nucleation [21], [22]. In addition, Pu et al. reported that the composites with a lower amount of WWTB augment the crystallinity due to the nucleation-inducing effect of WWTB, which can be seen from *Figure 5*. However, the increased viscosity at larger WWTB contents prevented PP chains from arranging regularly, which resulted in a noticeable reduction in crystallinity [10].

The melting and crystallization points of compatibilized and uncompatibilized composites had an insignificant decrease after three cycles, except PP, where melting and crystallization points increased as the number of reprocessing cycles increased. The crystallinity index of all the composites, including PP, exhibited a negligible reduction after the second cycle extrusion, however, the X_c of PP after the second cycle was not considered here due to an inappropriate value. In the third cycle, X_c of PP had a slight reduction compared to the first cycle. Meanwhile, X_c of all the other composites either had a slight improvement or similar values even after three reprocessing cycles.

Mechanical testing

Tensile properties

The tensile properties of the first cycle secondary composites, such as 75PP25RM, which are WWTB reinforced PP composites, had a similar tensile strength to pure PP, with a higher stiffness. However, further reductions in tensile strength were observed with increased recycled material content. The 50PP50RM composites exhibited a lower tensile strength due to poor interfacial strength between the matrix and recycled fibre from WWTB, which consists of epoxy residue on its surface. For this reason, it can be assumed that the stress applied cannot be transferred from the matrix to the fibres [23]. However, the problem of poor adhesion was addressed with the addition of a coupling agent, which led to a slight improvement of 9% in those composites after the addition of 2 wt% (48PP50RM2CA) and 5 wt% (70PP25RM5CA) coupling agent compared to pure PP. Moreover, the higher weight percentage of CA showed an improvement in the stiffness of the composite while maintaining a good tensile strength, as shown in *Figure 6*.

In the second and third cycles, the tensile properties of all the composites, including pure PP, have been increased compared to their counterparts from the first cycle. According to Huang et al. this improvement in the tensile could be attributed to several processing factors of injection moulding such as lower screw speed and lower melt temperature. Less damage to the PP molecular chains results in higher molecular densities and which in turn increases the tensile strength of reprocessed composites. Similarly, at lower melt temperature, the arrangement of molecular chains will not disorganize, resulting in higher tensile strength [24].

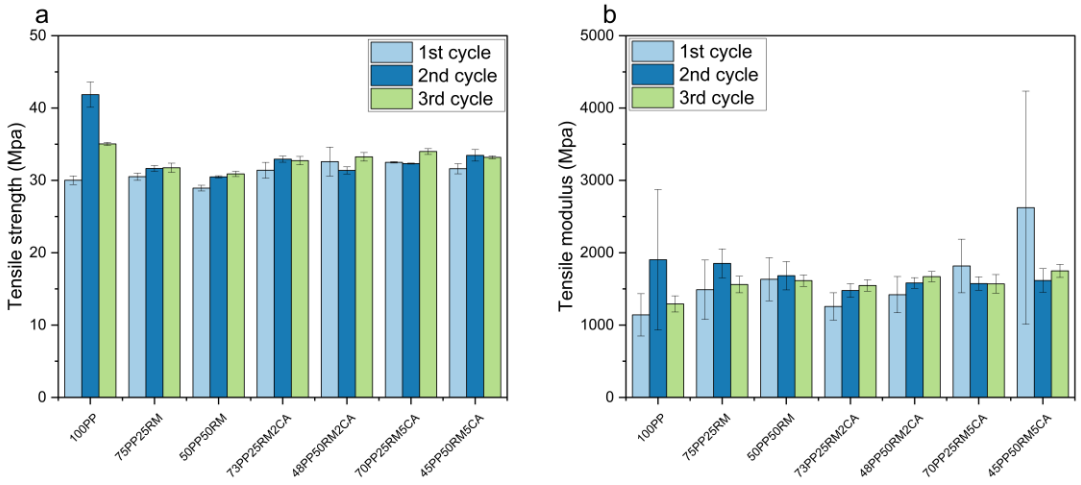

Figure 6: Tensile strength (a) and Tensile modulus (b) of different composites at three reprocessing cycles

Flexural properties

Unlike tensile properties, there were some significant improvements in the flexural properties of the secondary composites, even without a CA, over pure PP, as shown in *Figure 7*. In the first cycle, the flexural strengths showed an increase in all the composites, with 50PP50RM and 45PP50RM5CA exhibiting the highest changes of 18% and 21%, respectively. However, the samples without a CA had high stiffness, as indicated by their higher flexural modulus compared to all the other samples with a coupling agent, which shows the positive effect of using a CA on the secondary composites. The second cycle composites, however, exhibited an improvement in their flexural properties. All the second-cycle composites showed an increase in flexural strength compared to their counterparts from the first cycle. The flexural modulus of all the composites with a CA, except 45PP50RM5CA, was increased, making them stiffer than the composites without a CA, which had a lower flexural modulus compared to the first

cycle. Despite having a reduction in the flexural strength in the third cycle, these composites performed better than their counterparts from the first cycle. Similar observations were made in terms of flexural modulus. Again, these improvements can be attributed to the processing parameters of injection moulding.

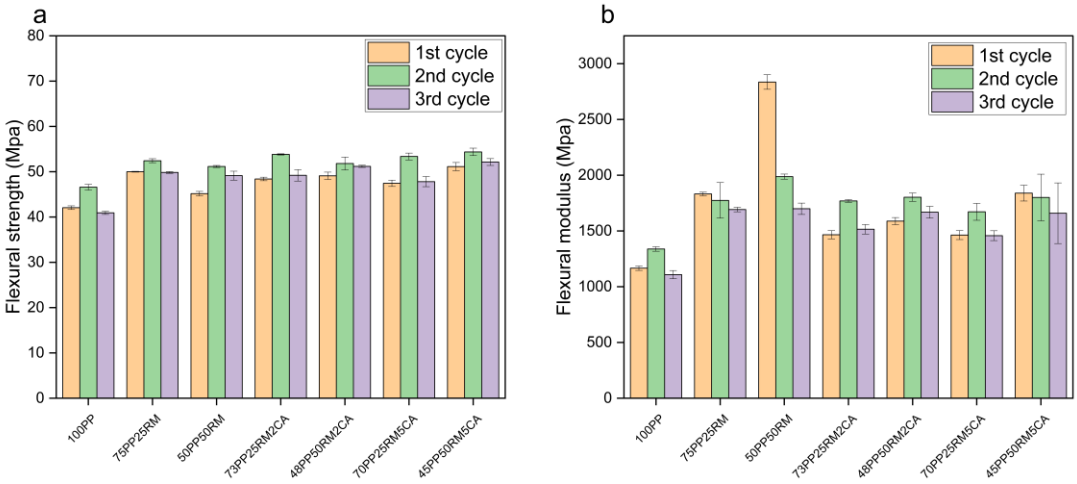

Figure 7: Flexural strength (a) and Flexural modulus (b) of different composites at three reprocessing cycles

Rheology

Melt flow index (MFI)

The MFI of composites was determined to study the effects of reprocessing on viscosity and molecular weight. *Figure 8* shows the MFI of pure PP and different composites with and without CA for three reprocessing cycles. For pure PP, MFI progressively increased with every reprocessing cycle, beginning from 10.5 g/10min up to 13.2 g/10min in the third cycle, resulting in a 25% increase. A similar trend was observed with all the other composites, suggesting a decrease in the molecular weight of polypropylene during the three reprocessing cycles.

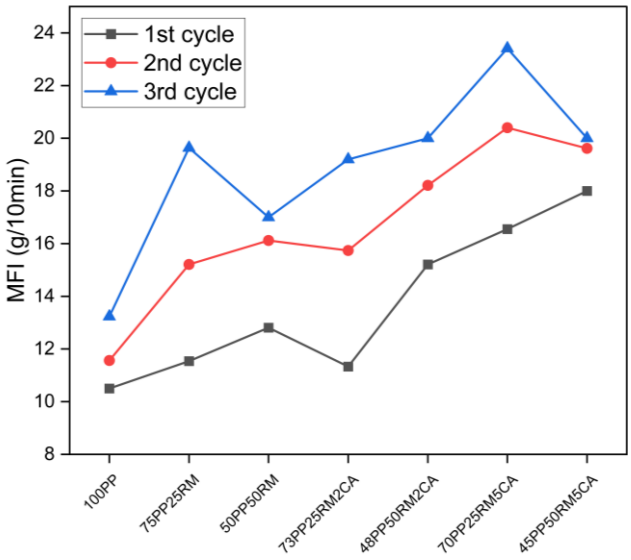

Figure 8: MFI properties of different secondary composites subjected to three reprocessing cycles

In addition, an increasing trend of MFI was observed with the higher dosage of CA in the composites. The highest increase of MFI of 41% was observed for the 70PP25RM2CA composite when it was reprocessed for the third time. The Ara´ujo et al. confirm that an increase in the MFI results in a drop in the melt viscosity and, as a result, a negative change in the molecular weight of the plastic and also noticed that reduction in intermolecular interaction and entanglements results in a decrease in polymer viscosity, which in turn causes a decrease in molecular weight and polymer chain length [25]. Spicker et al. also showed that their PP subjected to ten reprocessing cycles had improved MFI, decreased average molecular weight and viscosity, all of which corresponded to the occurrence of β-scission reactions [26].

4 CONCLUSIONS

In order to make the secondary polymer composites more competitive against virgin composites, reinforcement from WWTB was used to prepare PP composites via injection moulding and thereafter subjected to 3 reprocessing cycles along with manufacturing waste derived during extrusion. The resulting polymer composites were examined in terms of their mechanical, thermal, rheological, and structural properties. Therefore, it may be concluded that:

- The addition of coupling agent (MAPP) to the secondary composites showed a positive effect of 9% improvement in tensile strength of 48PP50RM2CA and 70PP25RM5CA. Similarly, a 21% improvement was seen in the flexural strength of 45PP50RM5CA. Higher amounts of WWTB and MAPP had a positive impact on the mechanical properties. In 2nd and 3rd cycle composites, tensile and flexural properties were further improved, which can be attributed to the lower screw speed and melt temperature of injection moulding;
- FT-IR spectra showed that functional groups present in the composites were unaffected even after 3 reprocessing cycles, which proves that the degradation is thermo-mechanical, not thermo-oxidative;
- Melting points of uncompatibilized composites were increased to 165 °C. The integration of MAPP into the composites has enhanced the degree of crystallinity, which indicates that the coupling agent's presence has enhanced the matrix nucleation. In all the composites, including pure PP, a slight reduction or similar degree of crystallinity was observed even after 3 reprocessing cycles;
- The MFI of all the composites was increased after 3 reprocessing cycles, suggesting a decreased viscosity and lower molecular weight, all of which happened due to the β-scission reactions.

The findings of this study demonstrate the potential of waste wind turbine blades (WWTB) as a viable reinforcement material in secondary polypropylene composites. The ability of these composites to undergo reprocessing with performance trends comparable to those reinforced with virgin glass fibres highlights their promise as a competitive and sustainable alternative to conventional virgin composites. Furthermore, a detailed comparative study has to be done between these secondary composites and virgin PP-GF composites.

ABSTRACT

The growing demand for epoxy fibre-reinforced composites raises significant environmental concerns due to the large amounts of waste produced. This study investigates the use of vitrimers - polymers that combine the durability of thermosets with the reprocessability of thermoplastics- to reduce such waste. Our approach involves substituting traditional, irreversible epoxy matrices with inherently reversible epoxy vitrimer systems.

We present a novel vitrimer system synthesized from a conventional epoxy monomer, a carboxylic acid curing agent, and an organotin catalyst. The material is synthetized via a simple one-pot process using easily accessible raw materials, to enhance its suitability for industrial adoption. The catalyst's thermal properties contribute to the generation of a robust network that resists degradation during reprocessing. In addition, vitrimerization is used to convert a cured, traditional epoxy material into a vitrimer, highlighting the potential for waste valorization. Finally, an efficient chemical recycling method is presented for epoxy vitrimer composites, showcasing the potential for material recovery in composite applications.

1. INTRODUCTION

Epoxy fibre-reinforced composites are widely used in industries such as aerospace, automotive, and construction. However, they generate a lot of waste, largely due to the use of epoxies as matrix materials. The underlying issue lies in their chemistry: traditional epoxy resins, which belong to the thermosetting class of polymers, form irreversible, covalently crosslinked networks **[1]**. While this structure provides them excellent thermomechanical properties -at a reasonable cost and with great versatility-, it also makes them extremely difficult to recycle or repair, and impossible reshape. As the market for these composites continues to grow, a surge in waste is expected, amplifying environmental concerns and underscoring the urgent need for innovative solutions **[2]**.

Vitrimers, a new class of dynamic polymers discovered in 2011 **[3, 4]**, have emerged as a promising solution for designing materials that generate less waste. Above a critical topology freezing temperature (Tv), their networks can rearrange without losing covalent connectivity thanks to accelerated associative bond exchange reactions, allowing them to flow and fully relax stresses **[5, 6]**. When used as matrices, vitrimers enable the development of recyclable, repairable, weldable, and reshapable composites **[7-14]**. However, their heavy reliance on expensive or commercially unavailable raw materials has so far hindered their adoption by industry **[15-31]**.

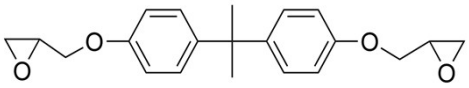
In this work, we demonstrate the potential of epoxy vitrimers to address both future and existing epoxy composite waste. First, we present a recyclable epoxy matrix that maintains its thermal and dynamic properties after recycling, offering a viable strategy to reduce future waste generation. We also present a simple chemical recycling method that enables the recovery of fibres with clean surfaces within two hours. Furthermore, we show that fully cured, irreversible epoxy thermosets can be converted into reprocessable vitrimers through a vitrimerization process **[32]**, providing a promising route for valorising existing epoxy waste.

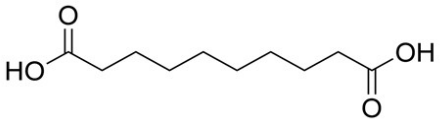
2. MATERIALS AND METHODS

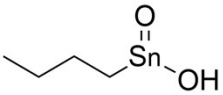
2.1 Materials

Matrix. The formulation was based on D.E.R. 332 diglycidyl ether of bisphenol A (DGEBA, eew 177.0 g/mol, Sigma-Aldrich) as diepoxy monomer and sebacic acid (SA, meq 101.2 g/mol relative to the epoxy group, Sigma-Aldrich) as curing agent. Monobutyltin oxide (Sn, meq 208.8 g/mol, Tokyo Chemical Industry) was employed as catalyst. Chemical structures are presented in **Table 1**.

Reinforcement. 3K twill weave carbon fibre fabric (200gsm, Enhanced Composites) was used to reinforce the matrix.







Role	Chemical compound	Chemical structure
Monomer	Diglycidyl ether of bisphenol A (DGEBA)	
Curing agent	Sebacic acid (SA)	
Catalyst	Monobutyltin oxide (Sn)	

Table 1: Chemical structures of the raw materials used

2.2 Sample preparation and recycling

Preparation and recycling of epoxy samples. Overall, four matrix materials were developed and compared (see **Figure 1**). First, two initial epoxy systems were synthetized: a vitrimer (v), as well as a conventional thermoset (TS) prepared without any catalyst. Both systems were then reprocessed to produce a recycled vitrimer (Rv) and a vitrimerized thermoset (vTS). The formulations were prepared using a 1:1 ratio of epoxy to carboxylic acid functional groups, with the catalyst added at 5 % molar equivalent (meq.) relative to the epoxy.

The two initial epoxy systems (v and TS) were prepared by mixing SA powder with DGEBA using an overhead stirrer at 60 °C and 250 rpm for 24 hours. For the vitrimer system (v), the catalyst (Sn) was then added to the mixture, followed by an additional 30 minutes of stirring. After mixing, the formulations were degassed at 90 °C for 4 hours. The curing process was completed by heating the samples for 8 hours at 145 °C, followed by 8 hours at 160 °C. The recycled vitrimer (Rv) was prepared by cryo-grinding the original vitrimer (v) into a powder, followed by compression molding at 200 °C for 1 hour, under approximately 5 MPa of pressure. In case of the vitrimerized vitrimer (vTS), the conventional thermoset (TS) was cryo-ground together with the catalyst, added at 5 % meq. relative to the epoxy group, and then processed using the same compression molding conditions.

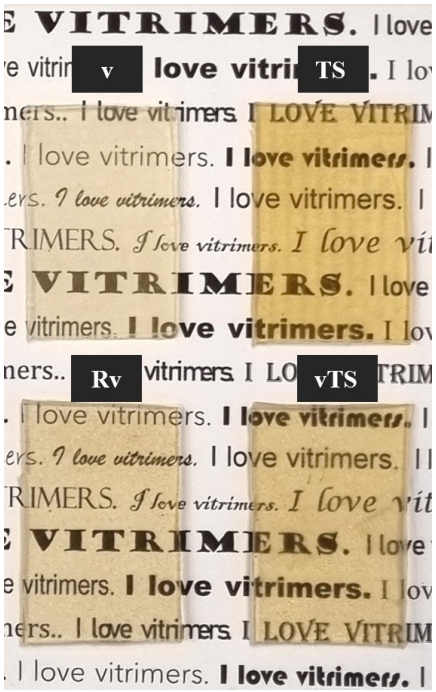


Figure 1: Preparation of two original (v, TS) and two recycled epoxy systems (Rv, vTS).

Preparation and recycling of fibre-reinforced epoxy samples. A vitrimer composite sample (CFRv) was manufactured using carbon fibres and the original vitrimer (v) resin developed in the first part of the study. Eight plies were placed in a steel mold and stacked in a 0/90° ply orientation. As each layer was positioned, the degassed resin was gradually poured between the plies to ensure proper impregnation. Once the lay-up was complete, the composite was compression-molded overnight at 145 °C under a pressure of approximately 5 MPa.

To evaluate the recyclability of the fibre-reinforced composite material, a solvolysis procedure was conducted. A composite sample measuring approximately 15 mm × 15 mm × 3 mm was immersed in about 35 mL of diethylene glycol and heated at 180 °C for 2 hours. For comparison purposes, fibres were recovered after both 10 minutes and 2 hours of immersion using tweezers, then washed with acetone and fully dried for 1 day at 160 °C before characterization.

2.3 Sample characterization

Dynamic mechanical analysis (DMA) was carried out using a TA Instruments DMA 850 and a film tensile clamp geometry. A sinusoidal stress with a frequency of 1 Hz and an amplitude of 10 µm was applied while the temperature was increased from –20 °C to 150 °C at a constant rate of 1 °C/min, following a 20-minute soak period.

Thermogravimetric analysis (TGA) was conducted using a NETZSCH TG 209F1 Libra analyzer to evaluate the thermal stability of the materials. Samples were heated from 35 °C to 800 °C at a constant rate of 10 °C/min under a nitrogen atmosphere.

Stress relaxation behavior was studied using a TA Instruments Discovery HR30 rotational rheometer fitted with a torsion clamp. Measurements were taken at multiple temperatures above the glass transition temperature (Tg), with each temperature held for 4 hours. A constant strain of 1 % was applied at each step, and the temperature was increased in 10 °C increments from 150 °C to 200 °C.

Scanning Electron Microscopy (SEM) was used to visually evaluate the quality of the recycled fibres. The analysis was performed using a FEI Nova NanoSEM 450 FEGSEM equipped with an ETD detector. Samples were prepared by applying a 10 nm carbon coating prior to imaging.

3. RESULTS AND DISCUSSION

3.1 Impact of matrix reprocessing on its thermal properties

The impact of matrix reprocessing on the thermal properties of the materials was evaluated using DMA, with a focus on the glass transition temperature (Tg) and rubbery storage modulus (see **Figure 2**).

First, a comparison between the original vitrimer (v) and thermoset (TS) reveals that the vitrimer has a higher Tg and rubbery plateau (measured at T = Tg + 30 °C). This is likely caused by an increase in crosslink density, resulting from the addition of the tin catalyst to the network, expected to accelerate curing and promote branching reactions in this diepoxy-diacid vitrimer systems **[33]**. This is consistent with the rise in storage modulus at high temperatures, implying that the material continues to undergo reactions that increase its crosslink density. Moreover, comparing the peak heights of tan delta for v and TS reveals that TS exhibits a higher peak, indicating greater molecular mobility within its network **[34, 35]**. This is expected for non-catalyzed diacid-diepoxy systems, where polyaddition reactions between epoxy and carboxylic acid groups likely dominate **[36, 37]**, resulting in the formation of long, linear hydroxyester chains **[33, 38]**.

It is interesting to note that the recycled vitrimer (Rv) shows a 6 % reduction in Tg and a 20 % lower rubbery storage modulus values compared to v, along with a slightly higher tan delta peak height. This suggests a material with greater flexibility, which is unexpected for a recycled material.

When comparing the original (TS) and vitrimerized (vTS) thermosets, an increase in Tg and rubbery plateau, as well as a decrease in tan delta peak height, is observed for vTS. The introduction of rigid domains into the network could be responsible for this effect, correlating with the visible shoulder at low temperatures indicative of microstructural variation **[39]**. Such heterogeneity could originate from inadequate integration of the catalyst into the network, leading to the formation of non-dynamic thermoset regions, further characterized by shorter chains than those of TS due to potential chain scission occurring during reprocessing. Still, despite these noticeable differences, the Tg and storage modulus values indicate that the vitrimerization process doesn't compromise such thermomechanical properties.

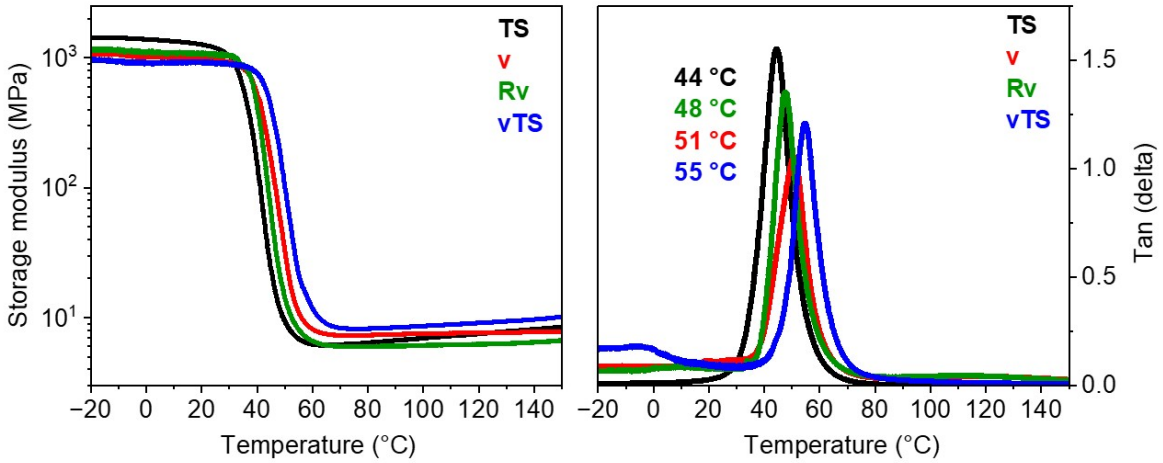

Figure 2: DMA of conventional thermoset (TS), original vitrimer (v), recycled vitrimer (Rv), and vitrimerized thermoset (vTS). Temperature-dependent evolution of the storage modulus and tan delta.

TGA results (see **Figure 3**) further support the preserved thermal stability of the vitrimer system after reprocessing: the original (v) and recycled (Rv) vitrimers exhibit nearly identical thermal degradation profiles. Specifically, their initial degradation temperatures (T_{onset}), defined as the temperatures at which 5 % weight loss occurs, are 328 °C and 331 °C, respectively. Their peak degradation temperatures (T_{max}), corresponding to the maximum rate of weight loss determined from the derivative thermogravimetric (DTG) curves, are 414 °C and 415 °C. And their residual weight at 800 °C falls within the range of 15 - 17 %. While the vitrimerized thermoset (vTS) exhibits very

similar behaviour, a slight distinction is observable, with its T_{onset}, T_{max}, and residual weight reaching 345 °C, 423 °C, and 17 %, respectively. This subtle increase in thermal stability might be attributed to a higher proportion of irreversible -hence more stable- bonds in the network compared to the non-vitrimerized vitrimers.

In contrast, the conventional thermoset (TS) exhibits a notably higher initial degradation temperature (approximately 60 °C above that of the vitrimer systems) highlighting the commonly observed trade-off between thermal stability and reversibility. A lower onset of degradation in vitrimers is indeed expected, given their ability to flow at elevated temperatures.

Overall, the similarity in thermal degradation profiles among v, Rv, and vTS indicates that neither the recycling process nor vitrimerization significantly affected the thermal resistance of the matrix. In particular, the nearly identical behavior of v and Rv confirms that the material remained largely unaffected by the recycling process, which aligns with the DMA results and underscores the excellent thermal robustness of the vitrimer system. In addition, the comparable thermal stability of Rv and vTS reinforces the potential of vitrimerization as an effective approach for thermoset recycling, enabling material recovery without loss of thermal performance.

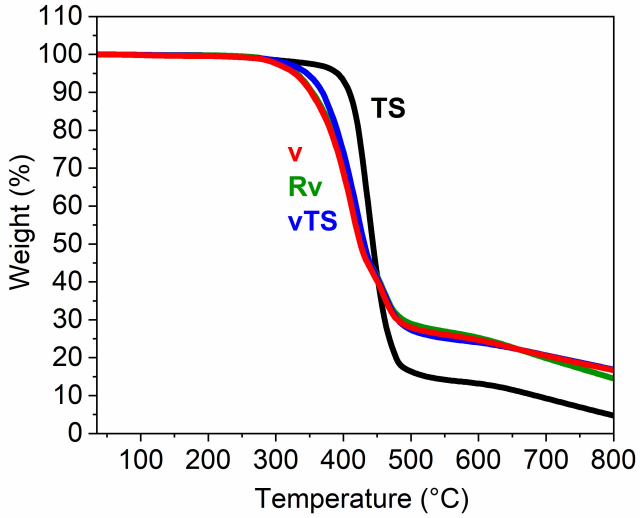

Figure 3: TGA curves for conventional thermoset (TS), original vitrimer (v), recycled vitrimer (Rv), and vitrimerized thermoset (vTS).

3.2 Impact of matrix reprocessing on its dynamic properties

Stress relaxation experiments were conducted to assess the dynamic behavior of the vitrimer systems and evaluate the effect of reprocessing on their flow properties. In such tests, a constant strain is applied, and the decrease in stress over time is monitored. At 200 °C, the original (v) and recycled (Rv) vitrimers exhibit full stress relaxation, while the vitrimerized thermoset (vTS) shows slightly reduced relaxation due to the presence of non-exchangeable covalent crosslinks. In contrast, the conventional thermoset (TS) shows negligible relaxation, as expected given the absence of dynamic bond exchanges (see **Figure 4**).

The characteristic stress relaxation times were determined using the Maxwell model of stress relaxation **[5]**. The results show that the recycled vitrimer (Rv) relaxes at a rate nearly identical to that of the original vitrimer. For instance, at 200 °C, both systems exhibit a relaxation time of 10 minutes. This highlights that the recycling process preserved the dynamic behavior of the vitrimer network. Interestingly, the vitrimerized thermoset (vTS) displays notably slower stress relaxation kinetics. At 200 °C, the relaxation time of vTS is 23 minutes -more than twice that of v and Rv. Stress relaxation in vitrimers is primarily governed by the rate of dynamic exchanges **[5, 34, 40]**, namely, in this case, transesterification reactions between hydroxyl and ester groups **[41, 42]**. Therefore, the slower stress relaxation observed in vTS indicates that the dynamic exchanges occur at a reduced rate. A greater proportion of irreversible bonds may account for this, by increasing the network's rigidity and the

average distance between dynamic moieties. Such a phenomenon could result from insufficient or uneven catalyst incorporation, a common challenge in vitrimerization **[32, 43]**.

In summary, the results confirm that an irreversible thermoset can be transformed into an inherently recyclable material through vitrimerization. In the case of Rv, the findings highlight that the recycling process has minimal impact on the dynamic properties of the vitrimer. However, the slower stress relaxation observed in vTS implies that the vitrimerization process impacted the material's dynamic properties, possibly due to suboptimal incorporation of the catalyst into the network. To improve this, reducing the particle size of the thermoset powder or increasing the compression molding time could be considered **[43]**.

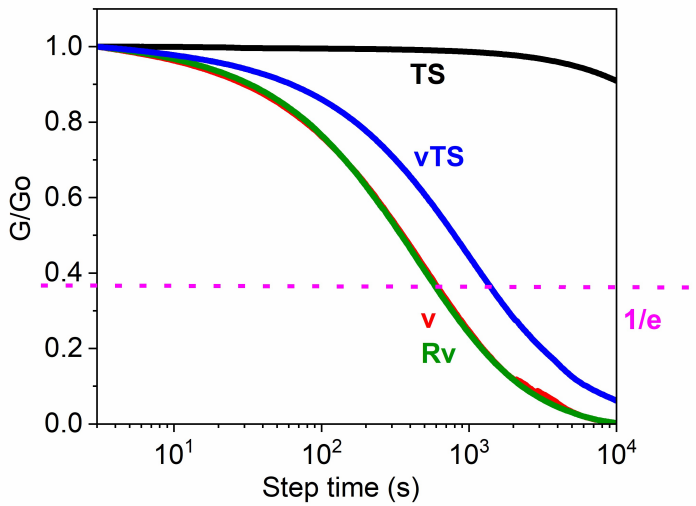

Figure 4: Stress relaxation behaviour at 200 °C for conventional thermoset (TS), original vitrimer (v), recycled vitrimer (Rv), and vitrimerized thermoset (vTS).

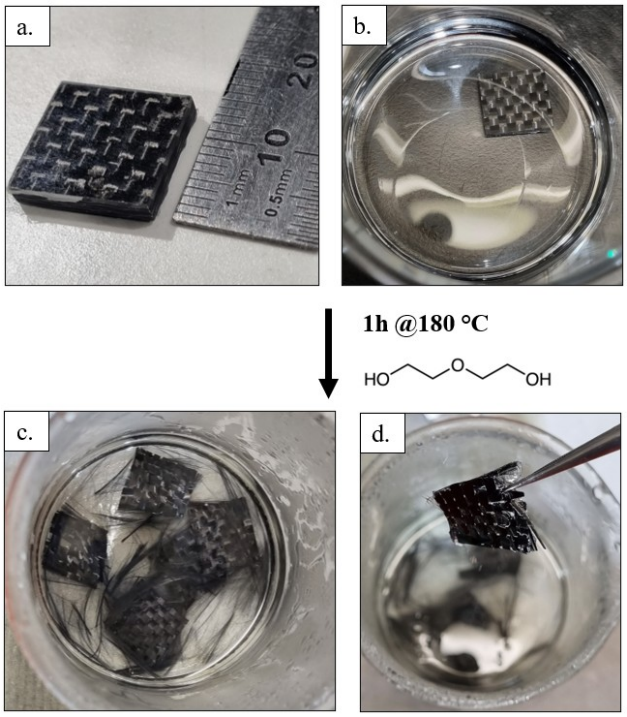
3.3 Impact of composite recycling on fibre quality

The chemical recycling process (see **Figure 5**) enabled to separate the fibres from the vitrimer matrix (v) after only 10 minutes of immersion in diethylene glycol (diEG). The solvent's active role in dynamic transesterification exchanges allows the vitrimer matrix to depolymerize, thereby enabling the separation of fibres from the matrix **[4, 44]**. Both the temperature of the process and the amount of solvent used significantly influence the rate of depolymerization.

It is worth noting that the dissolved matrix could be recovered and reused to produce a new chemically recycled vitrimer matrix. However, in practice, complete removal of the solvent remains a challenge. The recovered material typically retains residual solvent, resulting in a plasticized matrix with considerably higher flexibility than the original due to a higher amount of hydroxyl groups. While this may restrict its suitability for some applications, it could also offer opportunities in others where enhanced flexibility is desirable.



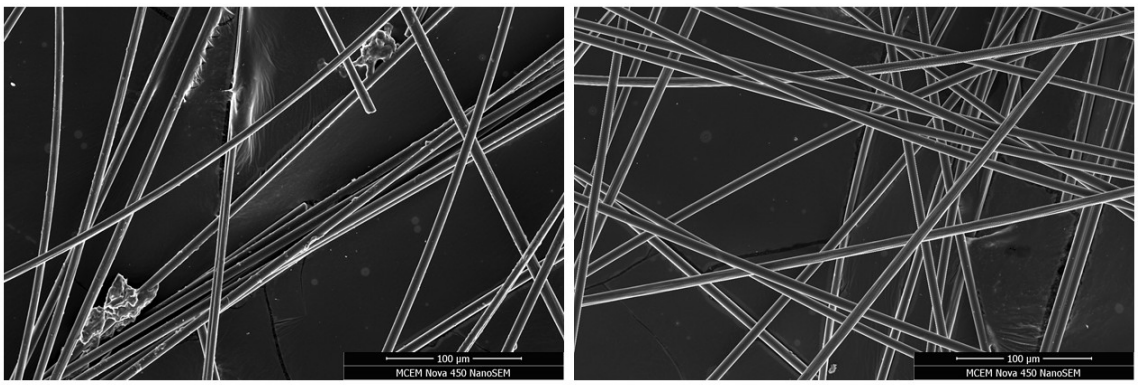


Figure 5: Pictures of composite chemical recycling: a) Preparation of CFRv sample, consisting of the original vitrimer (v) reinforced with carbon fibres. b) Sample immersion in diethylene glycol (diEG) at 180 °C. c) Fibres easily separated from the depolymerized matrix after 1 hour of immersion. d) Fibre recovery for characterization.

The surface quality of the recovered fibres was evaluated using SEM after immersion in diEG for two different immersion durations: 10 minutes and 2 hours (see **Figure 6**). SEM images reveal that, after 10 minutes, matrix residues are still clearly visible on fibre surface, whereas after 2 hours, these residues have substantially disappeared, indicating a more complete matrix depolymerization. To further assess fibre cleanliness and confirm the preservation of fibre quality, TGA will be conducted on the recovered fibres.

Overall, these results illustrate the strong potential of vitrimer-based matrices to facilitate composite recycling and enable the recovery of high-value materials.

After 10 min chemical recycling **After 2 h chemical recycling**

Figure 6: SEM images of recycled fibres after 10 minutes (left) and 2 hours (right) of recycling, showing a visual comparison of their quality.

4. CONCLUSIONS

The vitrimer system developed in this work was synthesized using a conventional epoxy monomer, the biobased and affordable sebacic acid as curing agent, and an organotin catalyst. The resulting material exhibited a glass transition temperature of 51 °C and a characteristic stress relaxation time of 10 minutes at 200 °C. The synthesis process, combined with the material's thermal robustness and the accessibility of its raw materials, supports its industrial relevance. First, it was shown that this vitrimer system can be recycled without compromising its thermal and dynamic performance. After recycling, the material largely retained its Tg, rubbery plateau, thermal stability, and stress relaxation behavior, highlighting its excellent reprocessability. Additionally, a chemical recycling method was implemented to recover fibres from vitrimer-based composites. After two hours of immersion in diethylene glycol at 180 °C, SEM images revealed clean fibre surfaces. To tackle existing composite waste, the vitrimerization of fully cured conventional epoxy thermosets was also explored. The process successfully converted a thermoset into a reprocessable material, able to flow and significantly relax stresses at high temperature. A slight increase in Tg, rubbery plateau, and thermal stability was noticed compared to the original vitrimer, possibly due to the introduction of irreversible bonds into the network. While no loss of thermomechanical properties was observed, the results reveal a notably slower stress relaxation response -at least twice as slow as the original vitrimer-, which could be attributed to a higher proportion of irreversible bonds in the network, in line with our DMA and TGA results. This phenomenon could be explained by an inadequate integration of the catalyst into the network.

Overall, this study demonstrates the potential of epoxy vitrimers as a more sustainable alternative to conventional epoxy matrices for reducing composite waste. By substituting traditional, irreversible epoxy systems with dynamic, reprocessable vitrimer networks, this approach addresses both future and existing composite waste streams. Ultimately, this research aims to support a more environmentally responsible composite industry.

Sustainable alternatives to thermoset polymers for aerospace composites: a comparison using LCA

Andrea Bologna, Antonio Mattia Grande

Department of Aerospace Science and Technology (DAER), Politecnico di Milano

ICCM24, Baltimore, August 7 2025

Outline

- Introduction
- What is LCA?
- Scope definition
- Case study
- LCA modelling
- LCA results
- Conclusions

Introduction: European policies framework

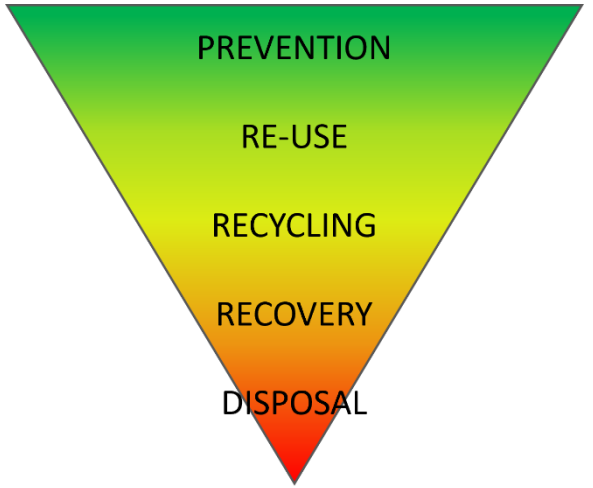
- Aviation makes up for 13.9% of transport emissions and it's responsible for 4% of total EU GHG emissions [1]
- Emissions produced by general aviation could triple by 2050 according to ICAO [2]
- ICAO drew a resolution to decarbonise aerospace industry with sustainable market-based measures [2]
- EASA drew the European Aviation Environmental Report, one of the chapters is dedicated to technology and design [3]

Introduction: AAM market expectations

Total equivalent CO_2 emissions of a traditional aircraft life cycle:

- >99% from the use phase
- <1% from production and EoL [4]

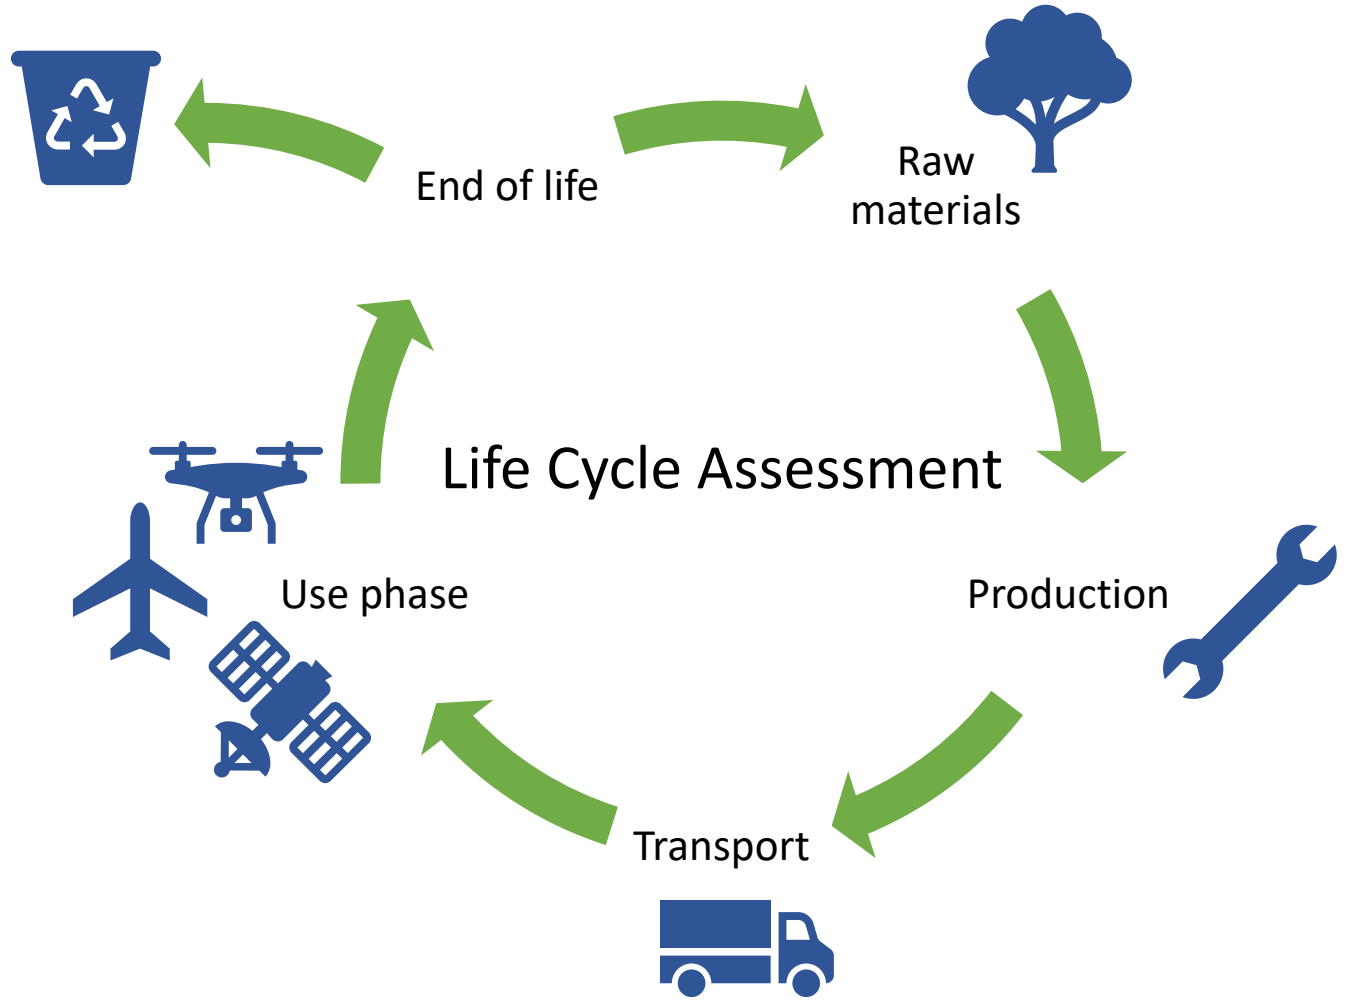
$m \approx 10^{4/5}$ kg



$m \approx 10^{3}$ kg

What about UAM?
Market value forecast of 74 billion USD in the US for civil EVTOLs in 2035 [5]

Shorter lifecycle



Higher environmental impact from production and EoL: ranging from 20% to 75% according to different scenarios [6], [7]

What is LCA?

LCA phases:

1) Goal and scope definition
2) LCI (Life Cycle Inventory)
3) LCIA (Life Cycle Impact Assessment)
4) Interpretation of the results

Scope definition

Scope definition:

Carry out a **preliminary comparison between different polymeric matrices**, analysing the Global Warming Potential associated to the production and EoL phases of an EVTOL.

Polymeric matrix	**Characteristics**
Thermoset resin	Epoxy resin is considered the standard solution in aerospace industry.
High-performance thermoplastics	Like the ketone family (PEEK, PEKK, etc.), high mechanical performance and chemical stability, offers the possibility to be reshaped.
Covalent adaptable networks	Similar to thermoset resins, but through a certain stimulus they can be reshaped. Still at research stage.

Case study

Functional unit: EVTOL structure, mass = **1465.5 kg**

Assumptions:

- The same fibers are used for all the matrices
- The use phase is neglected since the performance of the aircraft is expected to be similar in all cases
- The small difference in terms of performance is difficult to quantify

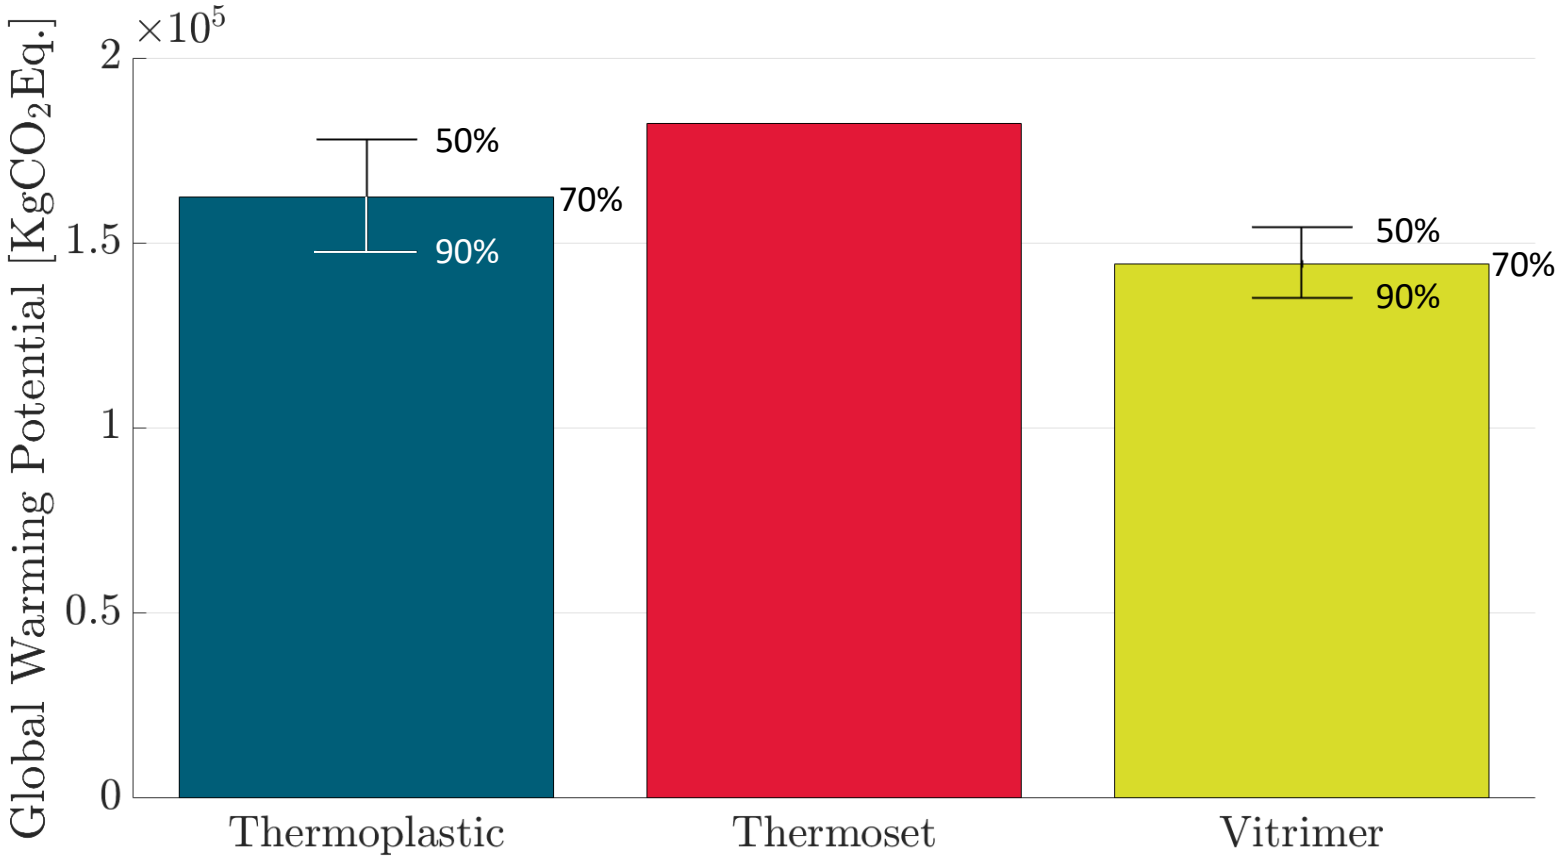
credits: NASA

Mass fraction for each material [7]

	Aluminium	Steel	Titanium	Carbon fiber	Glass fiber	Polymeric Matrix
Mass fraction	0.173	0.093	0.066	0.294	0.119	0.256

LCA modelling

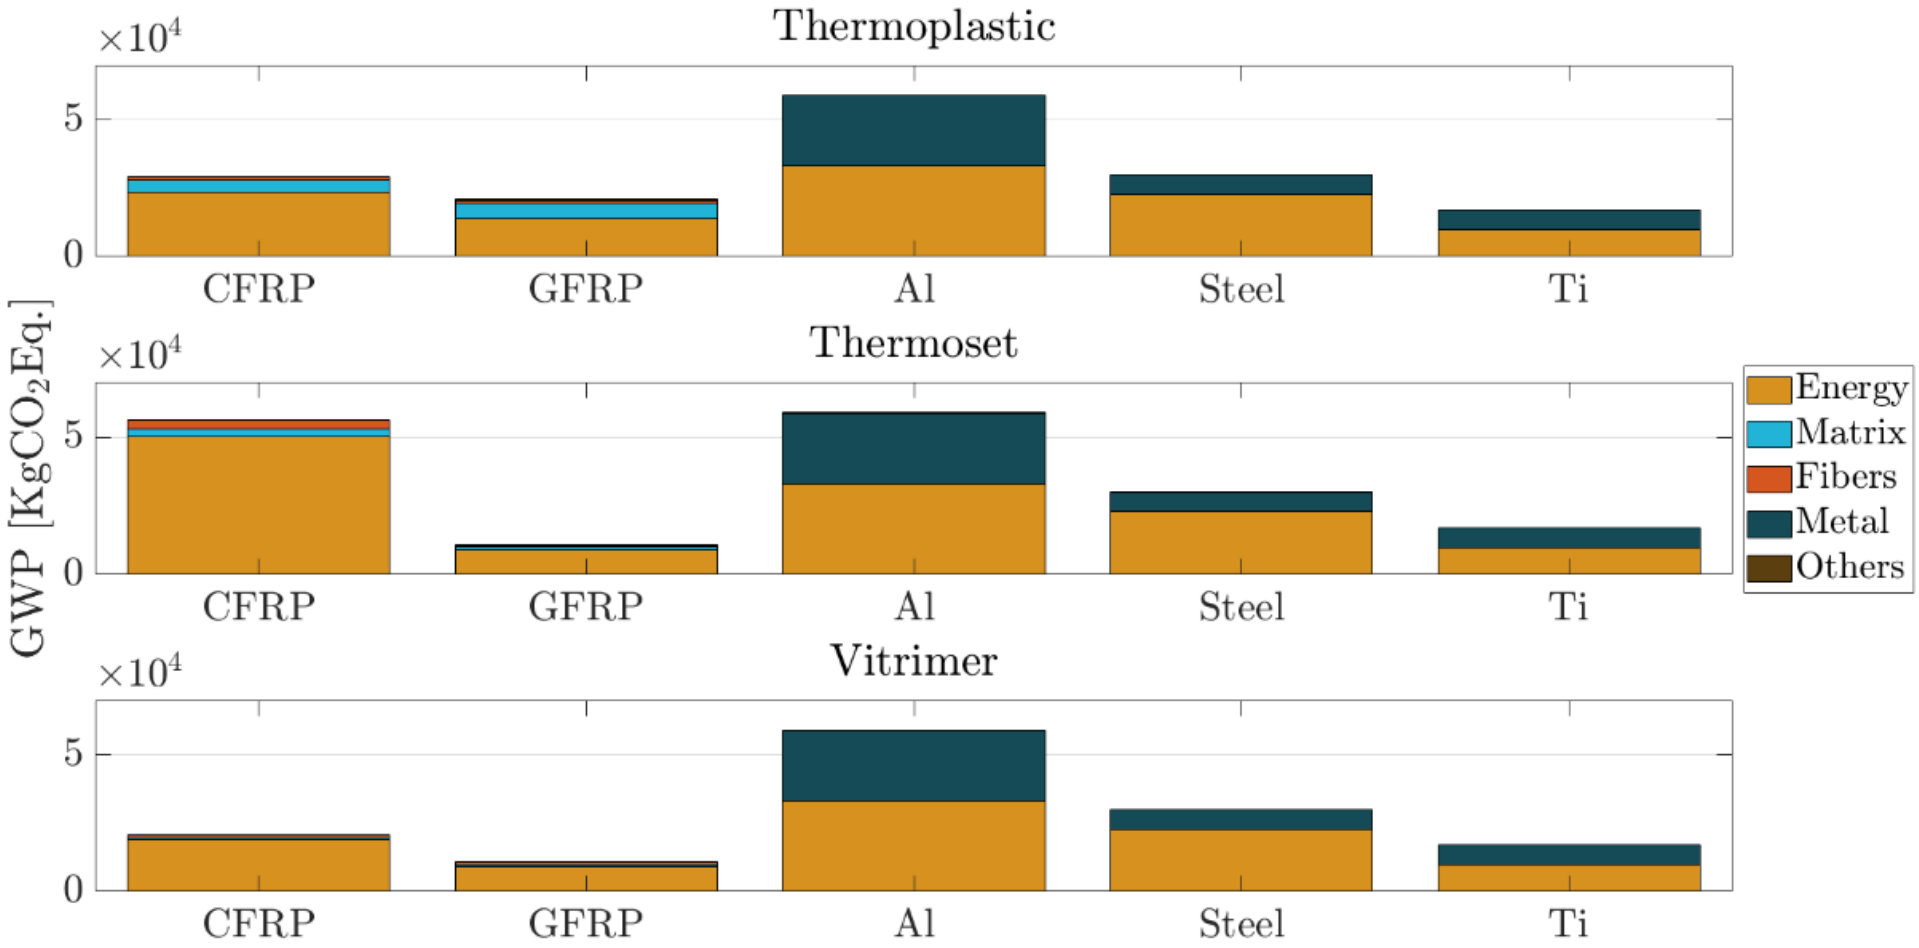
Thermoset resin:
- Autoclave curing
- Mechanical recycling: industry adopted best option



Thermoplastic matrix:
- Production by thermoforming
- EoI mix of recycling and reshaping

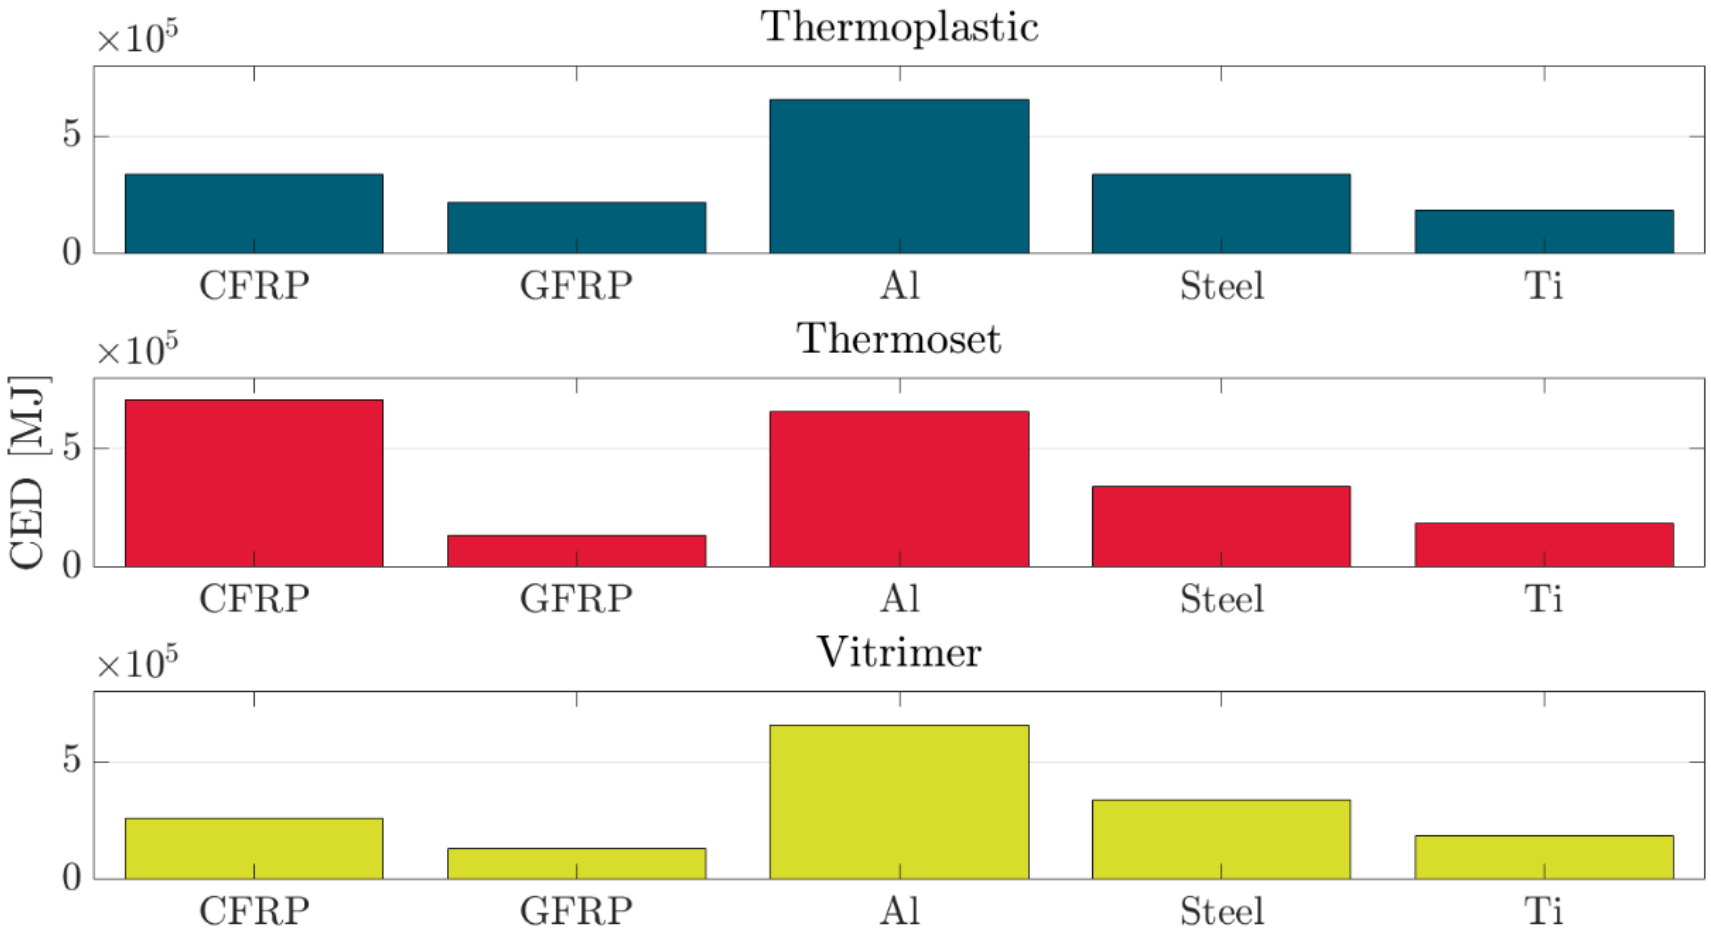
Vitrimer:
- Production like thermoset
- EoL like thermoplastic

LCA results: GWP 1/2



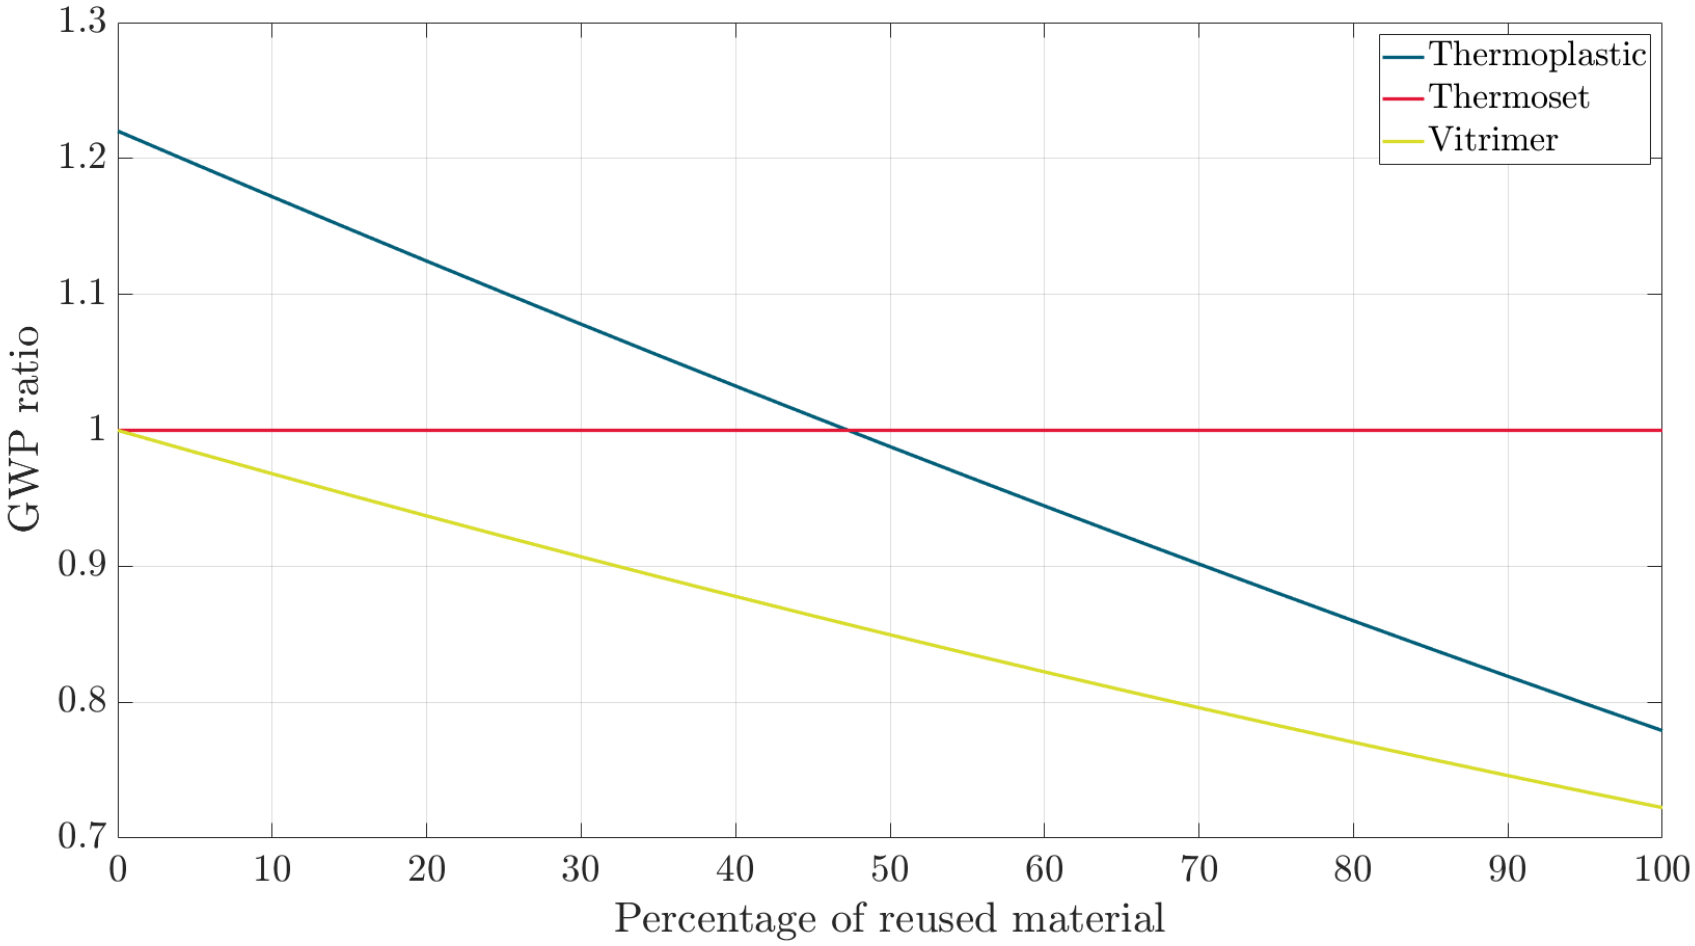
- Results obtained using the ReCiPe 2016 method
- The lowest CO_2 emissions can be achieved with vitrimers
- The percentage of reused material strongly impact the GWP
- Thermoset resin results as the worst option in all the considered scenarios

	Thermoplastic	Vitrimer
Avoided emissions	10.9%	20.8%



LCA results: GWP 2/2

- PEEK production produces more emissions with respect to thermoset resins
- Most of the GWP comes from energy production



LCA results: CED

Looking at Cumulative Energy Demand (CED) it is clear that composites material request the highest energy for they production, which can be strongly mitigated by reuse strategies

LCA results: sensitivity analysis

The breakeven point which justifies the adoption of PEEK is obtained when almost 50% of the material is reused.

Conclusions

- Decarbonization is of paramount importance in the aerospace industry
- Looking at new trends, production and EoL will be more relevant
- Reshaping composite materials could give a relevant contribution

Future developments

- The LCA database should be widened with better quality data
- How many times the reshaping can be carried out with limited degradation of the material
- How environmental effects will impact the reshaping possibility and the performance

Mapping the Global Flow of Fiber-Reinforced Polymer Composites and Supply Chain Energy Requirements

Presenter: Zhuoer Li

Authors: Zhuoer Li, Dr. Daniel Cooper*

University of Michigan

*drcooper@umich.edu

Motivation to Decarbonize FRPC Production

Fiber-reinforced polymer composites (FRPCs) are becoming increasingly used across transport, electronics, wind energy and other sectors

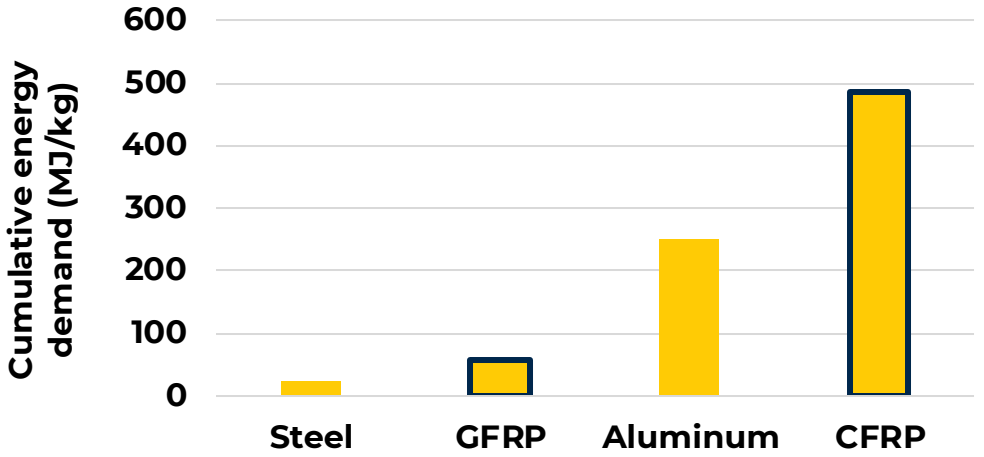

Fig. 1. Cumulative energy demand of materials

However, their production comes with environmental problems such as:

- High energy and emission intensities
- Low recycling rate at end-of-life (~2%)
- High process scrap rate (*e.g., prepreg cutting waste ~ 30-40%*) with most scrap landfilled

Aim: understanding decarbonization priorities within the global FRPC supply chain

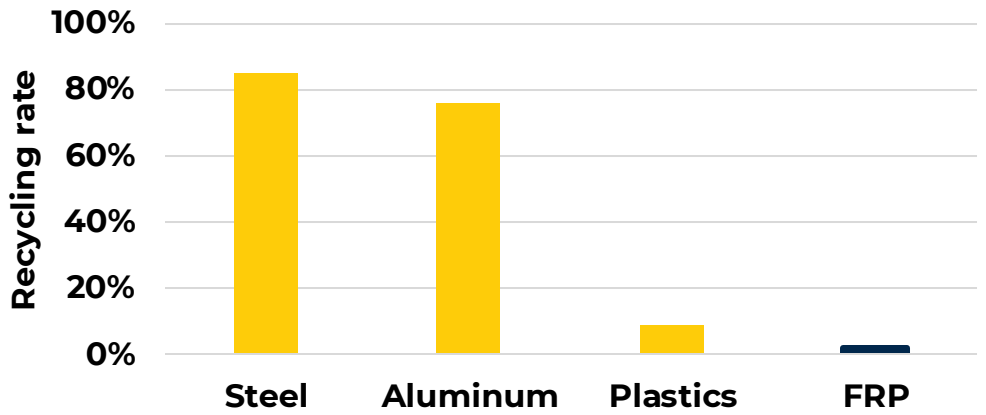

Fig. 2. Global recycling rate of materials

Life Cycle Analysis for Process-level Impacts

MICHIGAN ENGINEERING
UNIVERSITY OF MICHIGAN

Life cycle analysis (LCA)

- Most common method
- Focus on process-level impacts
- Examples findings for LCAs on FRPC:
  - A CFRP automotive part need ~ 4 times the **primary energy** of a steel one (Das, 2011; Ghosh et al., 2021)
  - High **resource depletion, water consumption** (Wegmann et al., 2022; Walker and Thies, 2022)
  - Bio-based composites need double the **land use** of C/GFRP and steel (Walker and Thies, 2022)

Limitations of LCA

Lacking material quantity considerations (intensity vs. demand), limiting guidance for research and investment prioritization

Table 1. An example of quantity & impact

	Glass fiber	**Carbon fiber**
Global production	~6,000 kt	~1,00 kt
Primary energy intensity	~22 MJ/kg	~350 MJ/kg

Material Flow Analysis - Environmental Impacts With Material Quantity Considerations

MICHIGAN ENGINEERING
UNIVERSITY OF MICHIGAN

Material flow analysis (MFA)

- Characterizes how a given material is transformed through a supply chain
- Enables the impact assessment across a supply chain on an equal footing

Existing MFA on FRPC

- J. Rybicka et al. (2015) mapped 4 different processes to capture FRPC mfg. scrap flows
- Shuaib et al., (2015) mapped the UK CFRP and GFRP supply chains
- Hamid et al. (2025) mapped global composites waste from wind turbine blades

Current Gap

There is only process-level, sectorial and regional, low-resolution supply-chain-level MFA on FRPC

To identify decarbonization priorities, we conducted an MFA on the global FPRC supply chain

This research: Material flow analysis (MFA) + Energy Analysis to Reveal FRPC Decarbonization Priorities

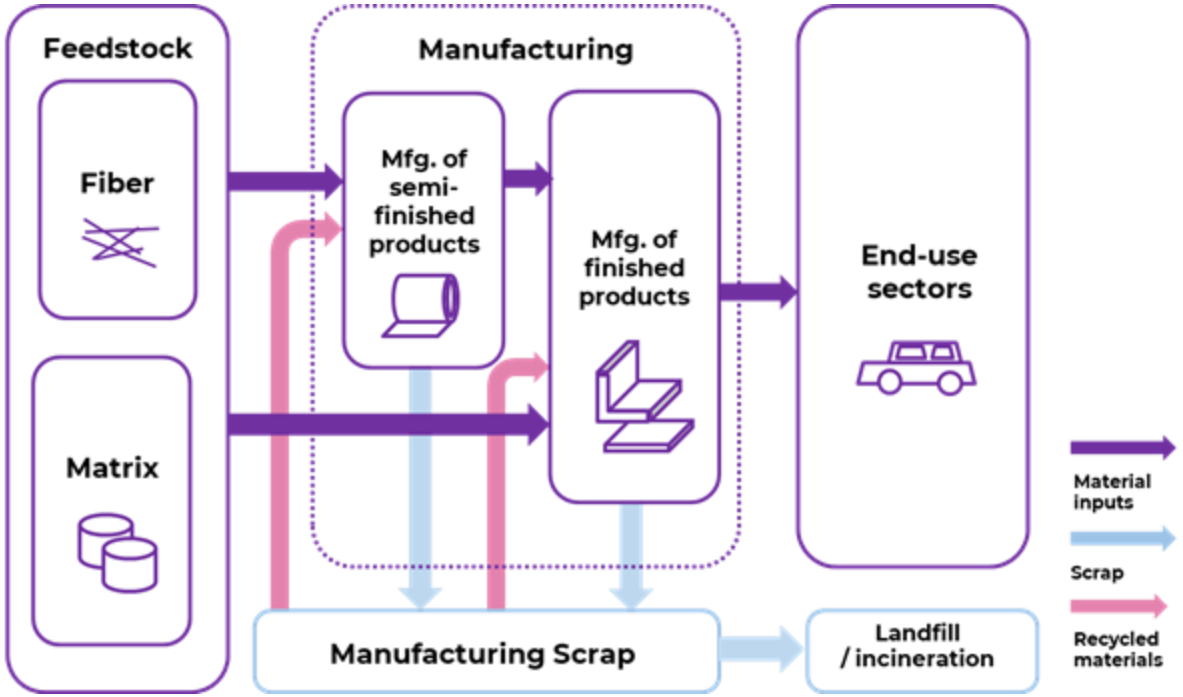
MICHIGAN ENGINEERING
UNIVERSITY OF MICHIGAN

Key contributions: using MFA to quantify the material efficiency and energy demand in global fiber reinforced polymer composite supply chain

1. Model the **mass** flows and their uncertainties in the global FRP composite supply chain with Bayesian inference

2. Quantify the **primary energy** attributable to FRP materials, processes and end-use sectors

3. Identify the **decarbonization opportunities** in the global FRPC production system



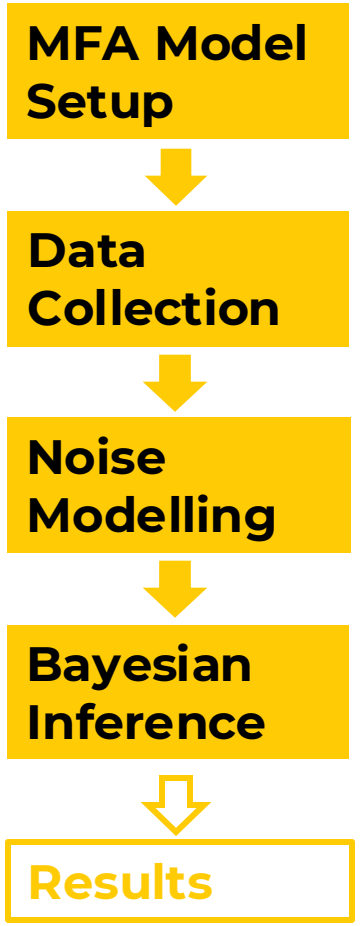


Fig. 3. Scope of this material flow analysis.

Bayesian Inference

Results

Data collection

- Material production and demand - market reports (e.g., JEC), research articles, OEM websites
- Primary energy intensities - Ecoinvent 3 database, LCA studies, industry reports (e.g., JCMA)

Data Format	Examples
Mass Flow Data	
Flow values (in kt)	The amount of aramid paper used in aramid honeycomb production is 3.4 kt globally.
Transfer coefficients (0 – 100%) (e.g., Scrap & recycling rates)	The process yield for GFRP prepreg production is 93%.
Technical coefficients (0 – 100%) (e.g., Fiber/matrix mass ratios)	The typical fiber fraction of open molded parts are 50 wt.% (40 vol.%). 32% of the composite products in marine application were manufactured via spray-up in 2022.
Percentage share of any process in a sum of processes (0 – 100%)	The volume of composite products in construction accounts for 26% of the total composite market in 2022 (JEC, 2023).
Node throughputs (in kt)	The volume of global composites market in construction applications was 3.3 mt in 2022 (JEC, 2023).
Sum of nodes (in kt)	The total volume of thermoset composites in the market is 7.8 Mt in 2022 (JEC, 2023).
Energy Intensity Data	
Primary energy intensities (in MJ/kg)	The primary energy intensity of glass fiber direct roving is 28 MJ/kg.

MFA Data Noise Modelling Using Pedigree Matrix

MICHIGAN ENGINEERING
UNIVERSITY OF MICHIGAN

MFA Model Setup
↓
Data Collection

Noise Modelling
↓
Bayesian Inference
↓
Results

Why modelling data noise?

- Data are not 100% reliable or correct
- Enable transparent decision-making

Pedigree Matrix Approach

- For a given data, **assign data quality scores** (1-4, smaller numbers mean higher quality) for **5 data quality metrices** (reliability, completeness, temporal correlation, geographical correlation, other correlation)

- Calculate: **coefficient of variation (CV)** for normal distribution or **uncertainty parameter (U)** for lognormal distribution using:

For each quality metric: $CV_i = a * e^{b*(score_i - 1)}; U_i = 1 + \frac{CV_i}{100}$

Total noise for data: $CV_{total} = \sqrt{\sum CV_i^2}; U_{total} = \exp(\sqrt{\sum \ln(U_i)^2})$

$a_{not\ sensitive} = 0.375;\ a_{medium\ sensitive} = 0.75;\ a_{highly\ sensitive} = 1.5; b = 1.105$

Laner et al. "A novel approach to characterize data uncertainty in material flow analysis and its application to plastics flows in Austria." 2016

Uncertainty Quantification via Bayesian Inference

MICHIGAN ENGINEERING
UNIVERSITY OF MICHIGAN

MFA Model Setup

Data Collection

Noise Modelling

Bayesian Inference

Results

Data inconsistencies and uncertainties

- Discrepancies across data sources
- Various forms
- Data scarcity

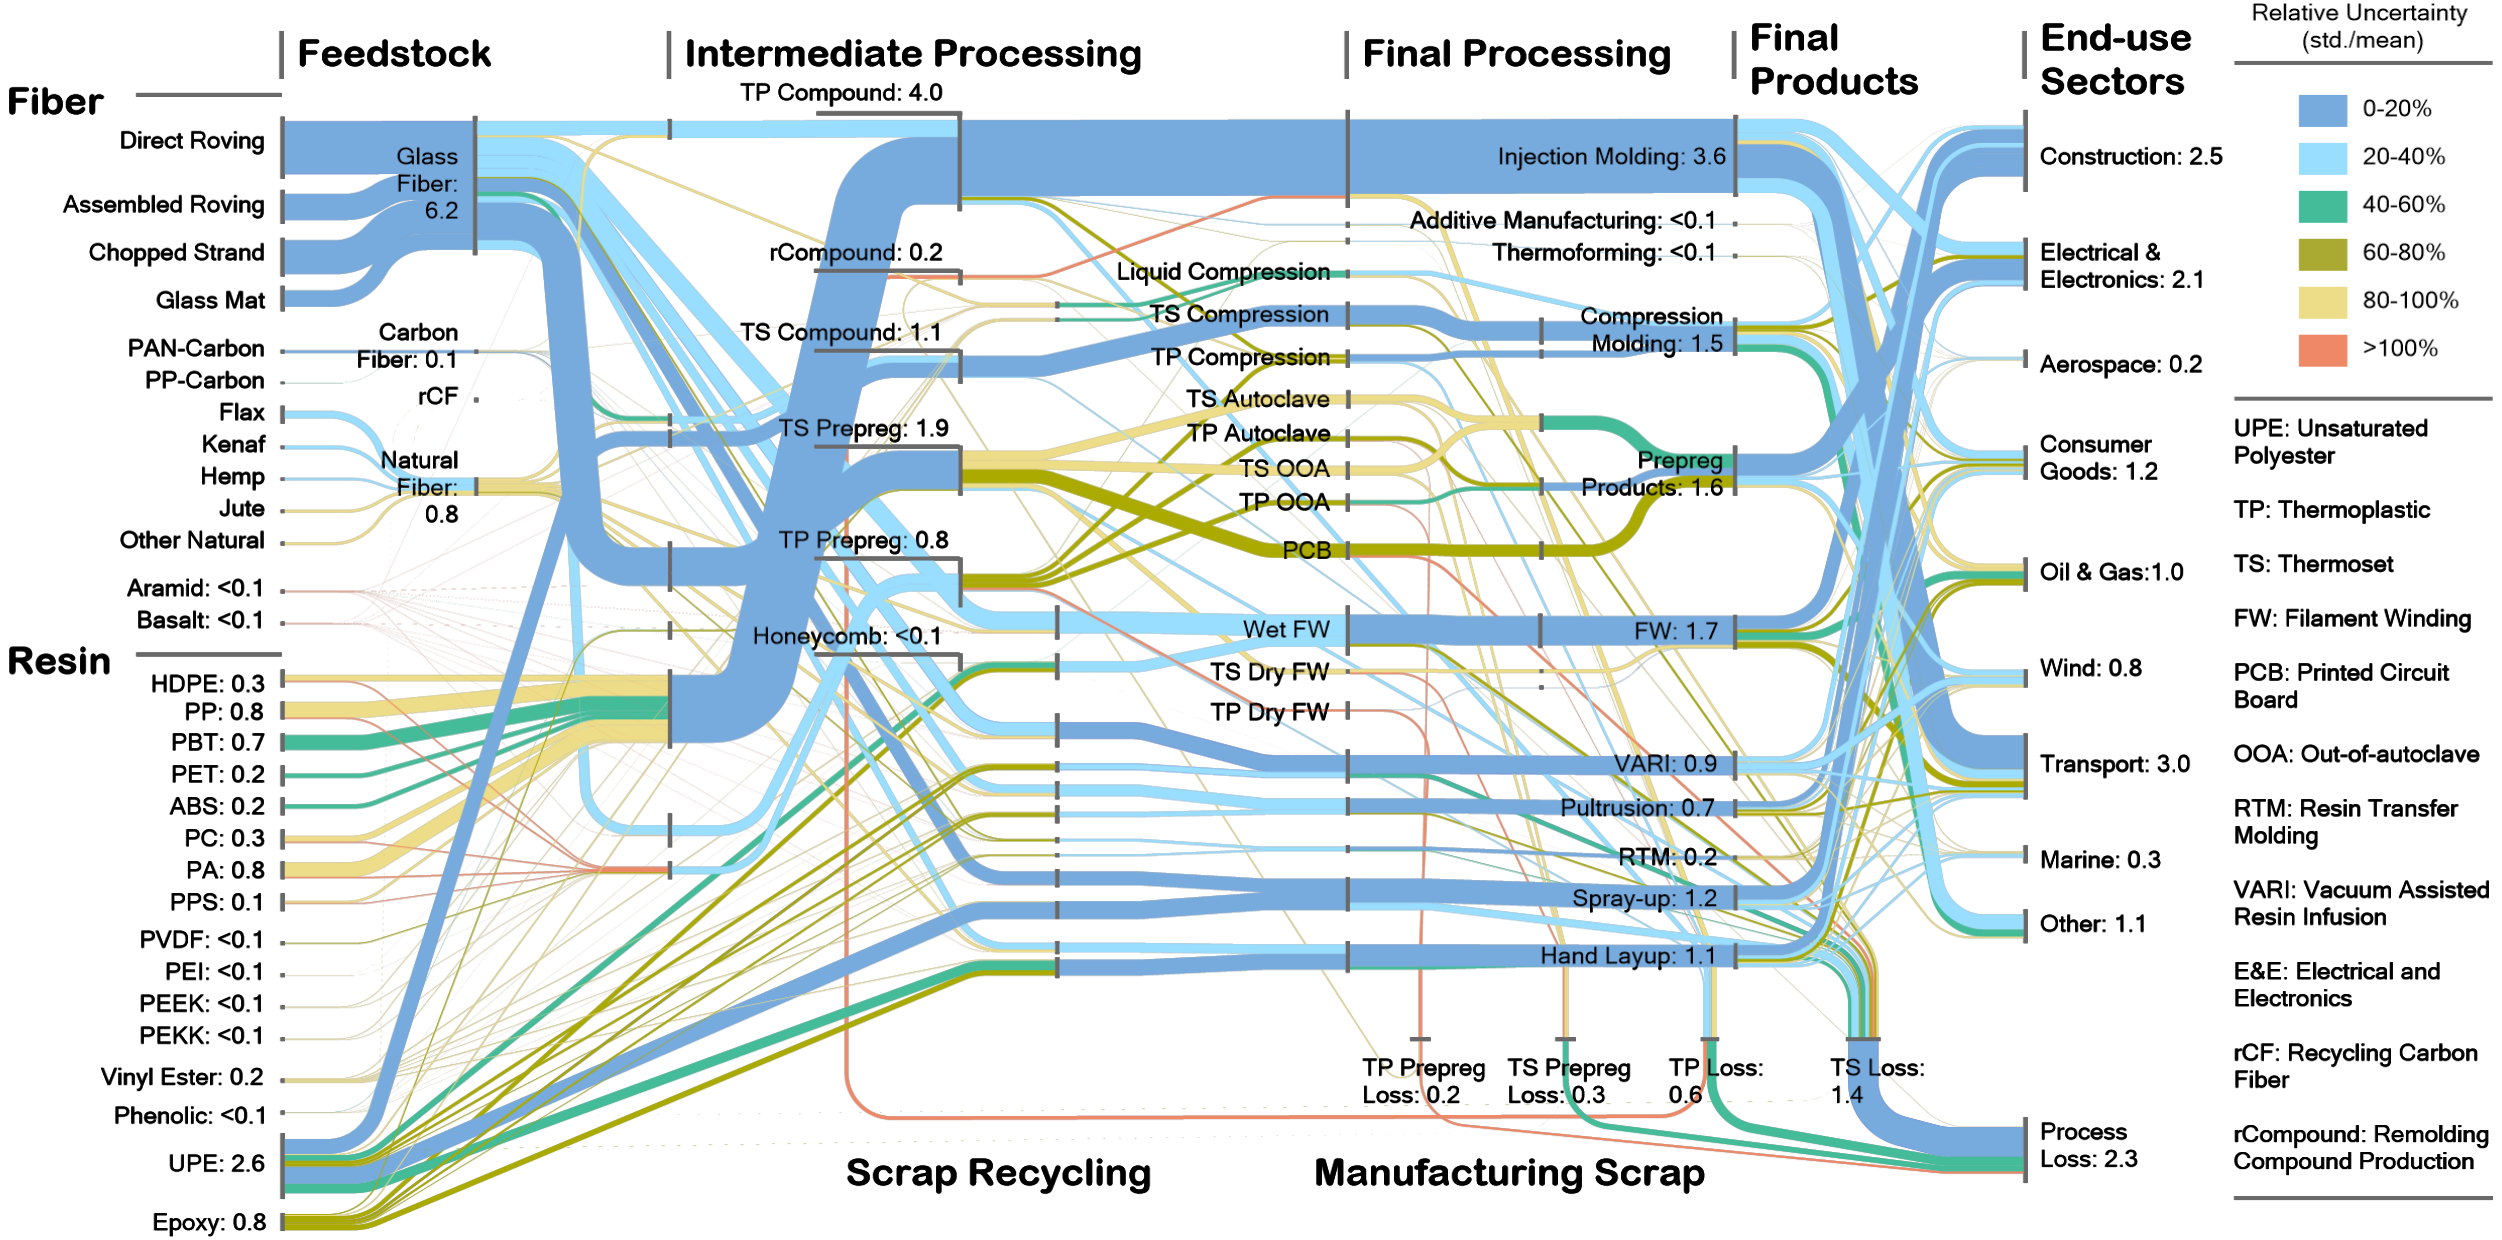
Bayesian inference (BI)

BI uses **probability distributions** to represent data record with uncertainties and enables **updating of model parameter (material flow) uncertainties** as more data is collected (Lupton and Allwood, 2018)

Likelihood
Data records (with noise)

Priors
Initial knowledge (weakly informed)

$$P(\theta|D) = \frac{P(D|\theta)P(\theta)}{P(D)}$$



Posterior
Updated knowledge

Marginal likelihood
Normalizing factor

Bayes' Theorem

θ: model parameters
D: data records

Results – Global Flow of FRP Composites in 2024 (in Million tons)

TP: Thermoplastic

TS: Thermoset

FW: Filament Winding

PCB: Printed Circuit Board

OOA: Out-of-autoclave

RTM: Resin Transfer Molding

VARI: Vacuum Assisted Resin Infusion

E&E: Electrical and Electronics

rCF: Recycling Carbon Fiber

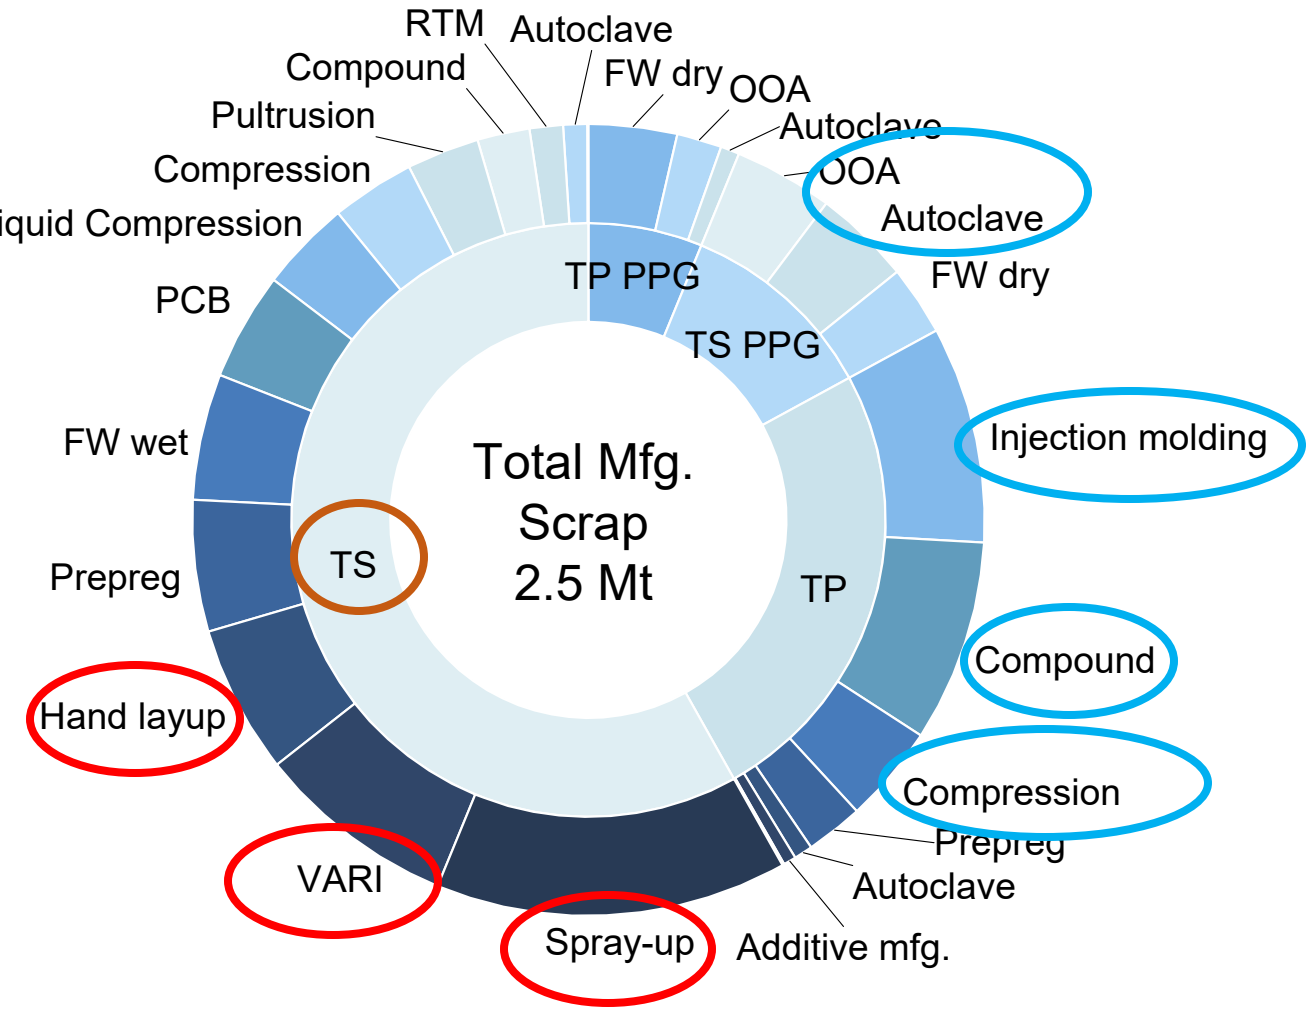
rCompound: Remolding Compound Production

Key information: material throughputs (thickness of flows), data uncertainty (color of flows), scrap flows

Material Efficiency of the Global FRPC Supply Chain

Scrap primarily come from

- **Thermoset processes** (>50%)
- **High-throughput processes** (injection molding, TP compound production, compound production)
- **Manual processes or semi-manual processes** (spray-up, hand layup, vacuum assisted resin infusion VARI etc.)



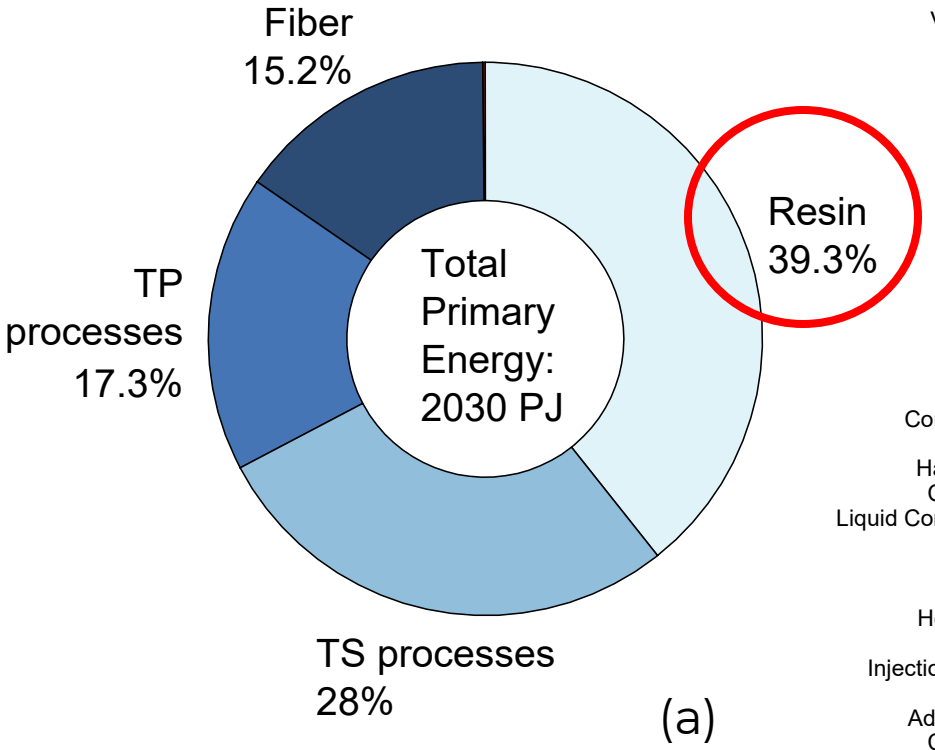


Fig. 5. Manufacturing scrap profile
(TS: thermoset; TP: thermoplastic; PPG: prepreg)

Primary Energy Demands of FRPC Materials and Processes

Energy Hotspots

- **Resin**, especially **unsaturated polyester (UPE)**
- **Autoclave curing**
- **Glass and natural fibers** (vs. carbon)

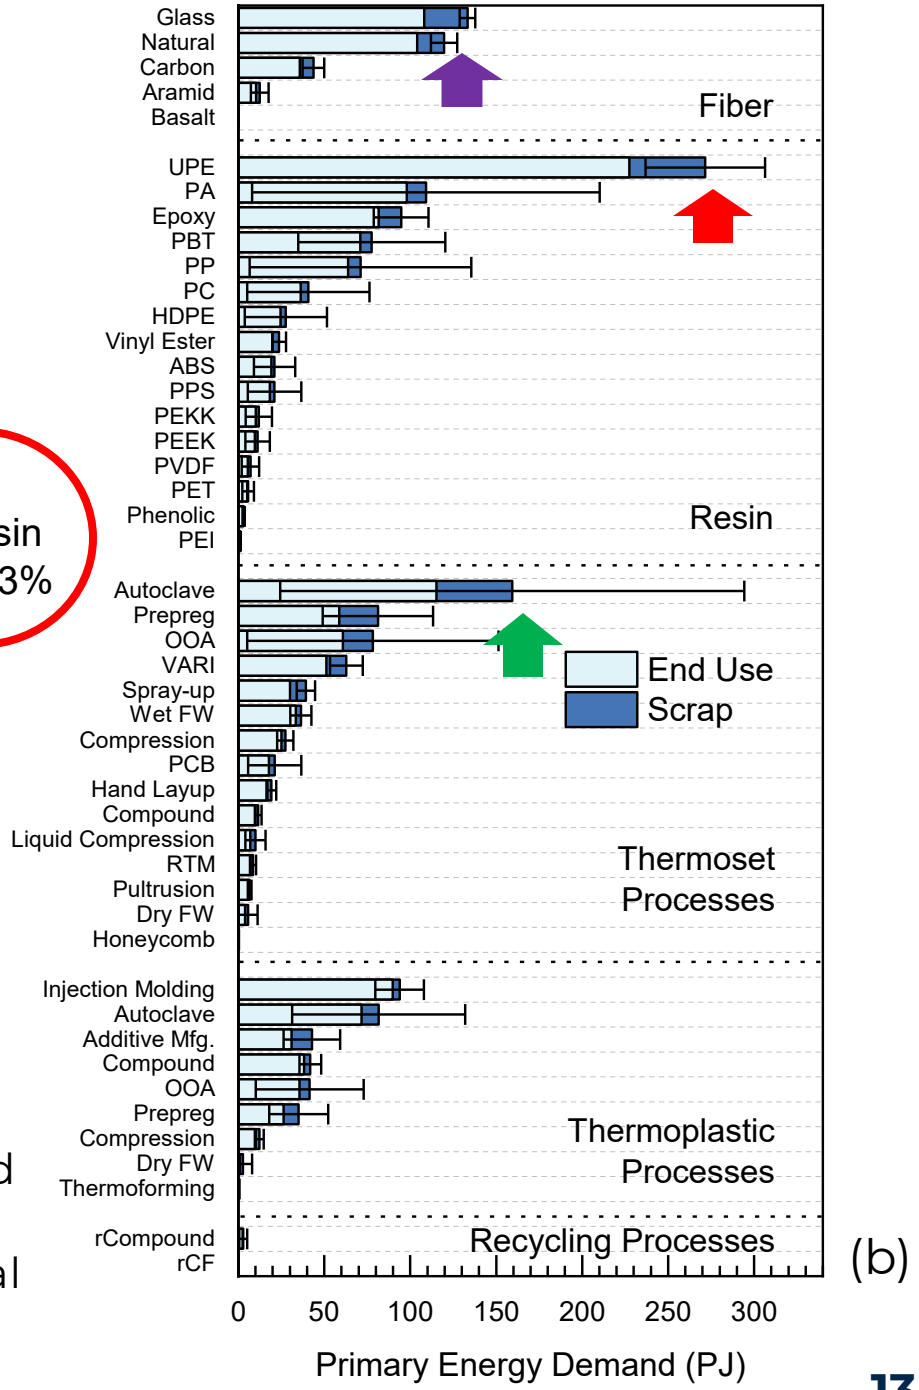

Fig. 6. (a) Total primary energy demand and
(b) primary energy demand by material and processes.

Attributing Primary Energy to Processes/Sectors

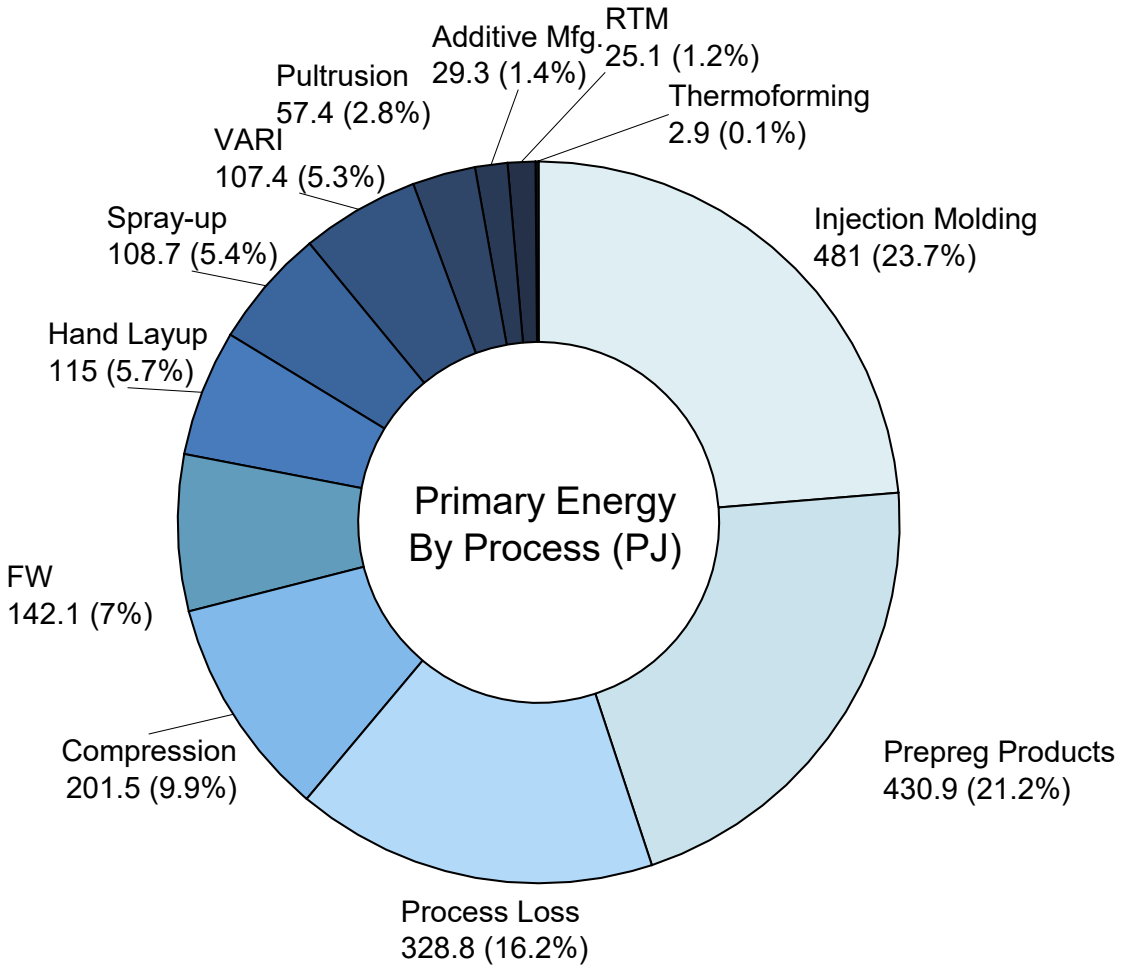

Fig. 7. Primary energy attributable to mfg. processes

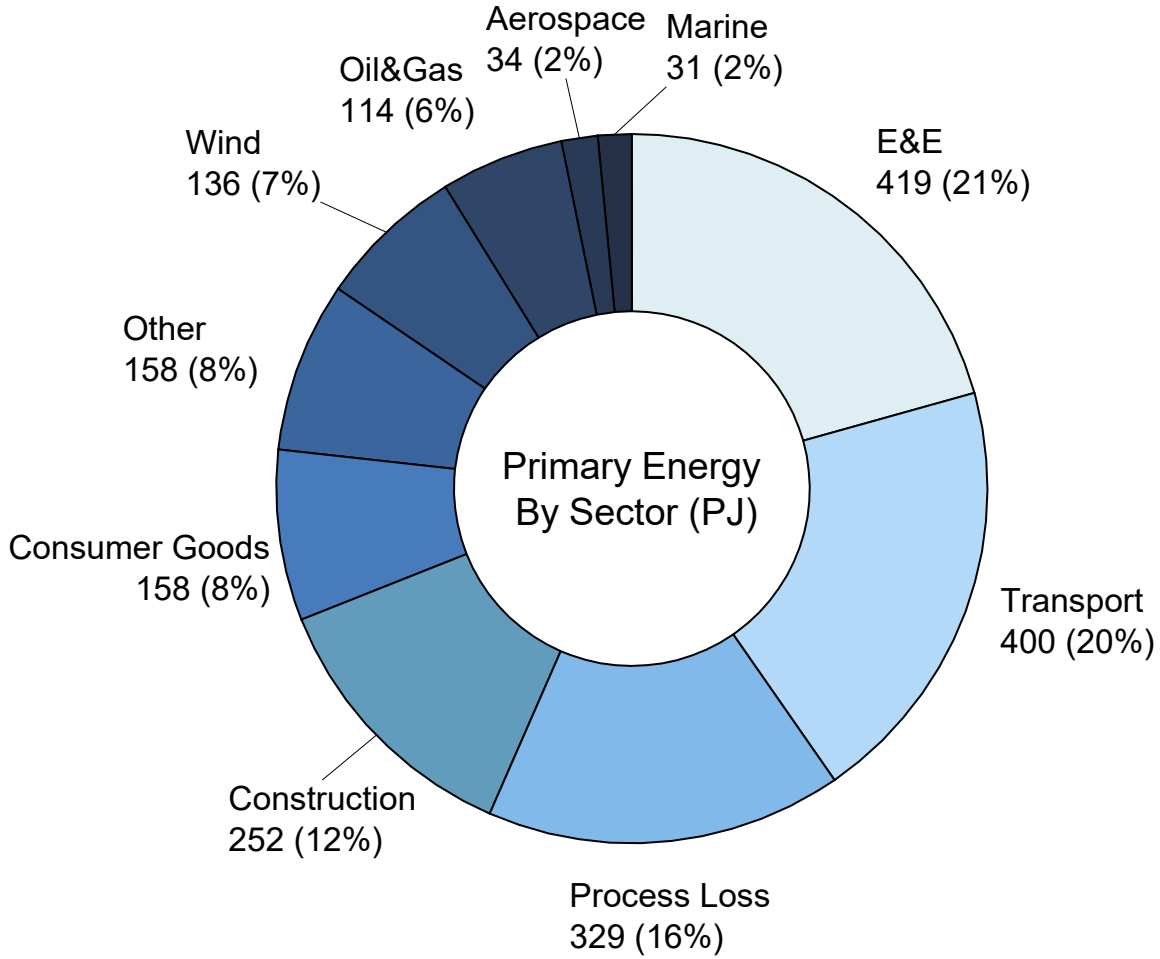

Fig. 8. Primary energy attributable to end-use sectors

Conclusions

MICHIGAN ENGINEERING
UNIVERSITY OF MICHIGAN

This study provides a new perspective on the material efficiency and energy demand distributions within the global FRPC supply chain.

Key take-aways

- **Low-value materials** and **high-throughput processes** have **large material and energy footprints** and **should be prioritized for decarbonization efforts.**
- **Resin production** accounts for **most primary energy requirement**. Substitution with bio-based options can potentially have a great impact on supply chain decarbonization.
- **Manufacturing scrap generation is significant** and scrap recycling remains minimal. **Yield improvement should focus on high-throughput processes manual processes.**

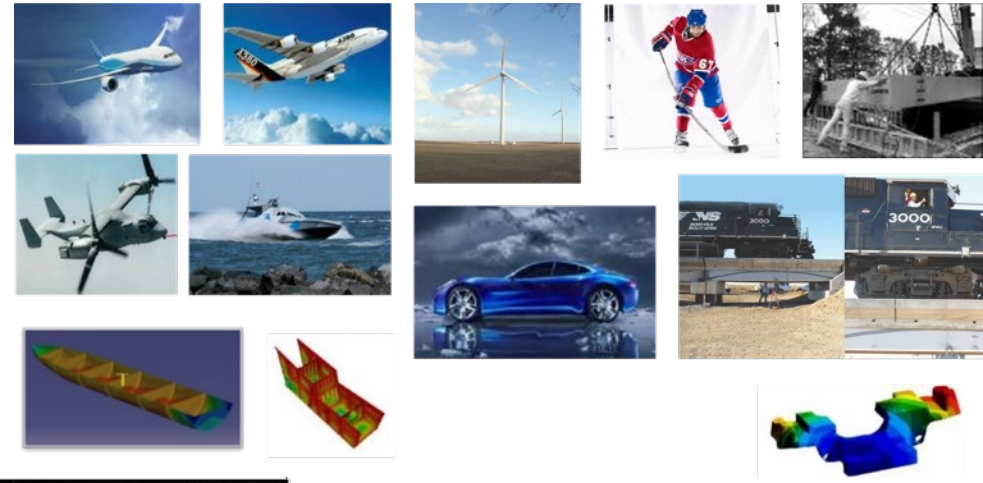
Multiple Iteration of Recycling of Carbon Fiber Composites Enable by TuFF Technology

August 7, 2025

Joseph M. Deitzel, Ph.D.

University of Delaware Center for Composite Materials

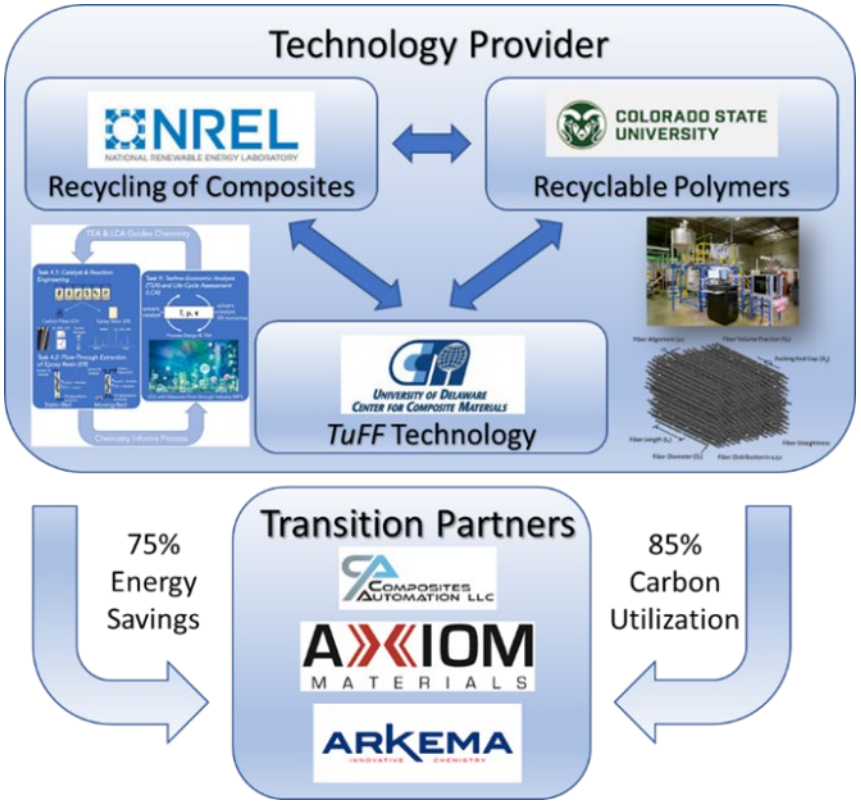


UD-CCM At a Glance-50 Years

- Founded in 1974, CCM is an internationally recognized interdisciplinary center of excellence for composites education and research
  - Started in Mechanical Engineering
  - College-wide interdisciplinary center in 1978 timeframe (ME, CHE, MSE program)

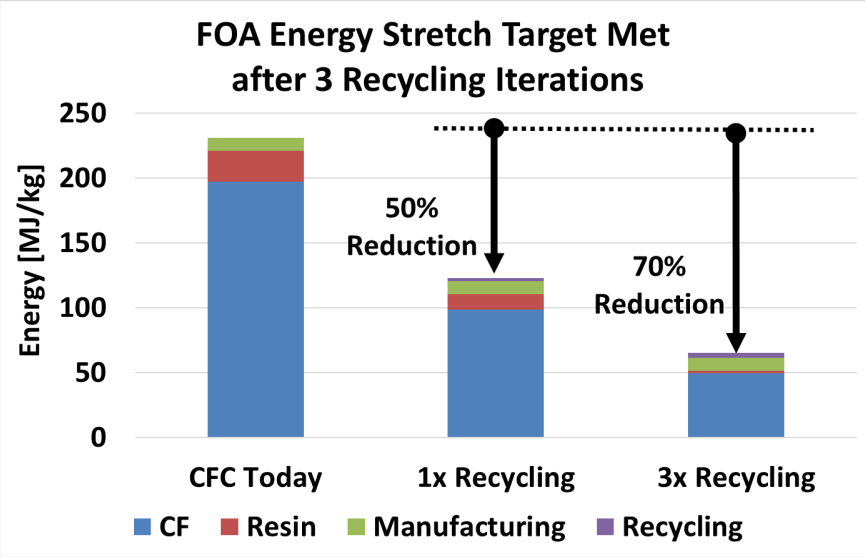
- Three-Part Mission
  - Conduct basic and applied research
  - Educate scientists and engineers
  - Transition technology to industry

- More than 3000 alumni working in Industry, Government Labs or Academia



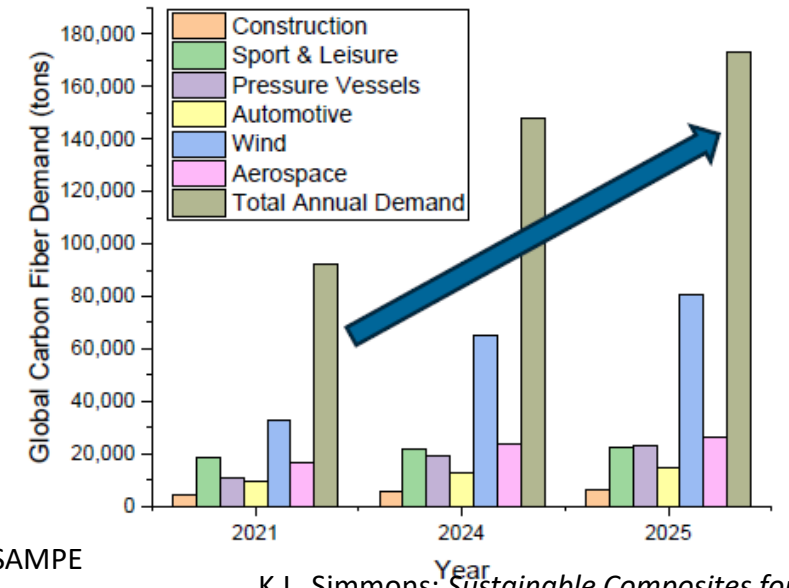
Circular Economy of Composites Enable By the TuFF Process

DOE/EERE/ Advanced Manufacturing Office (AMO) DE-EE000303



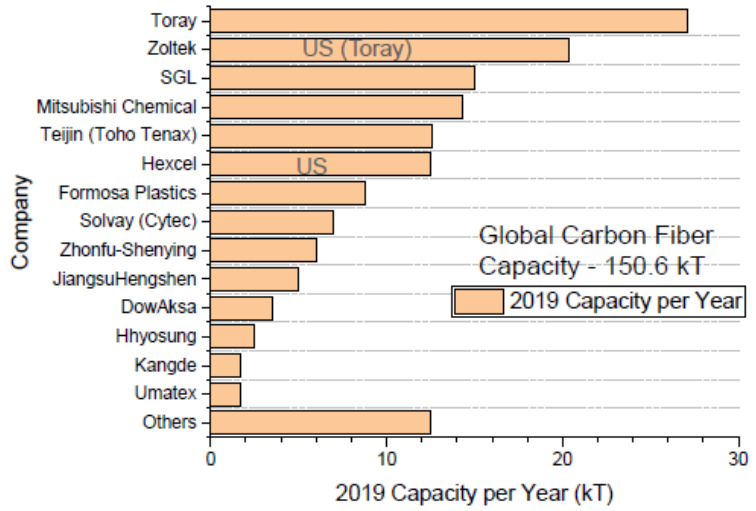
Goal: Demonstrate for commercial Carbon/Epoxy and Carbon-Elium composites can undergo ***multiple*** recycling iterations and maintain near full property translation.

- ***Separate the CFC polymer and fiber content with catalyst and fiber recovery (NREL lead)***
- ***Demonstrate a new class of recyclable by-design polymers (CSU lead)***
- ***Process the recycled carbon fiber content into high-performance CFCs (UD-CCM lead)***



- ***Transition partners***
  - ***Axiom Materials: Pre-Preg manufacture***
  - ***Composites Automation: Composite fabrication***
  - ***Arkema: Resin production***
- ***Monthly technical meetings are held with DoE and Partners to share information and address challenges***

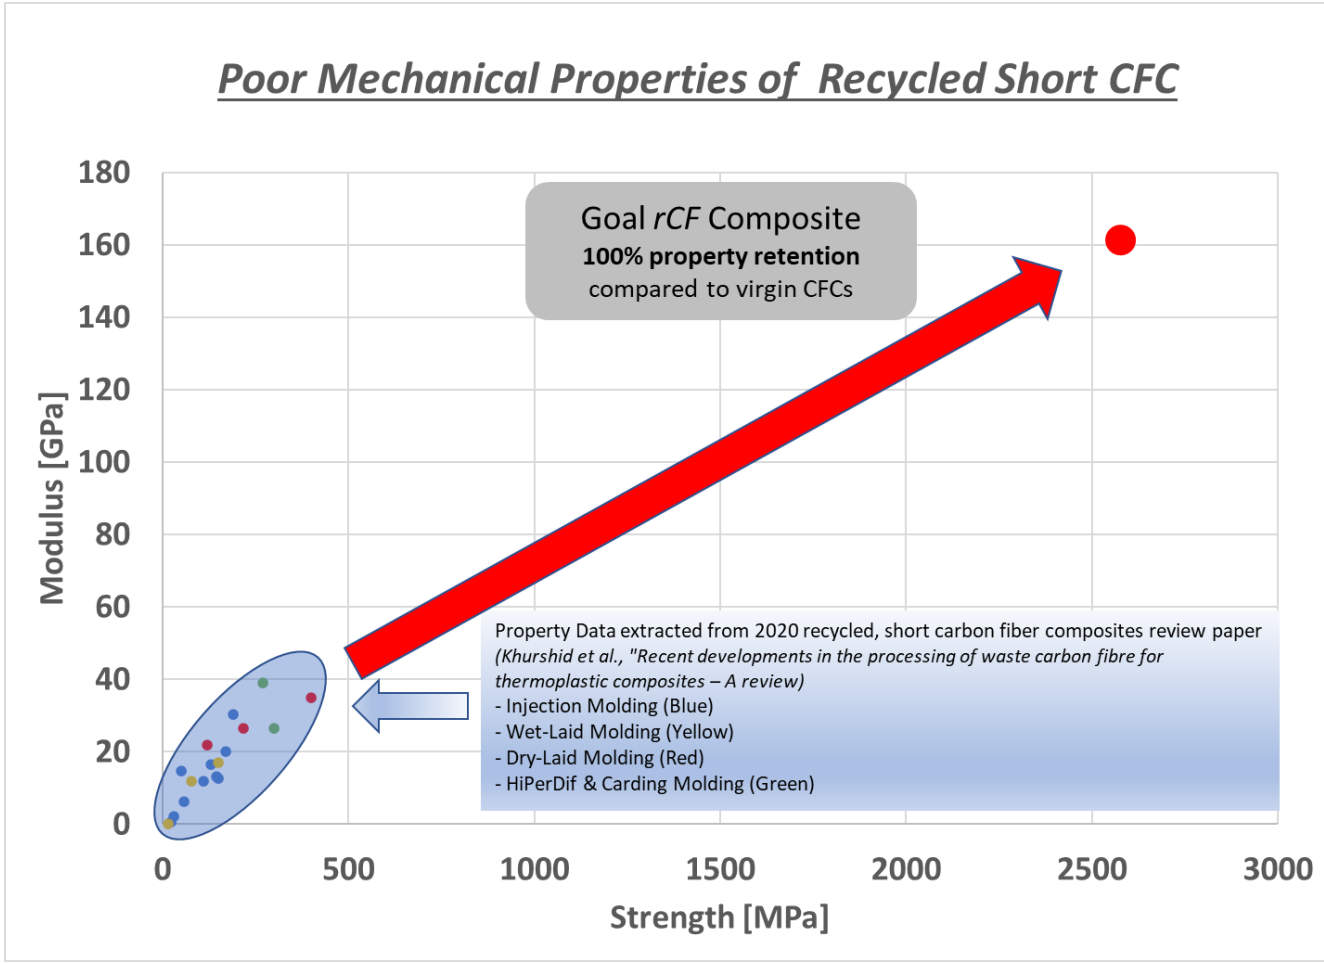
Composite Recycling Motivation:
Energy Savings, Supply Chain Stability, Environmental Stewardship



Data source: Suzuki, T; Takahashi, J;; The Ninth Japan International SAMPE Symposium; 2005

Zhang et al Composites Part B: Engineering Volume 250, 1 February 2023, 110463

Data from https://www.igtpan.com/Ingles/mercado-carbono.asp

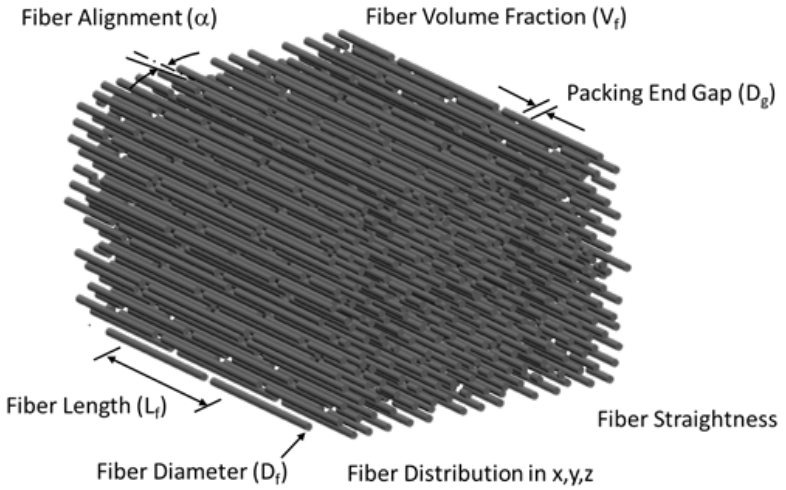


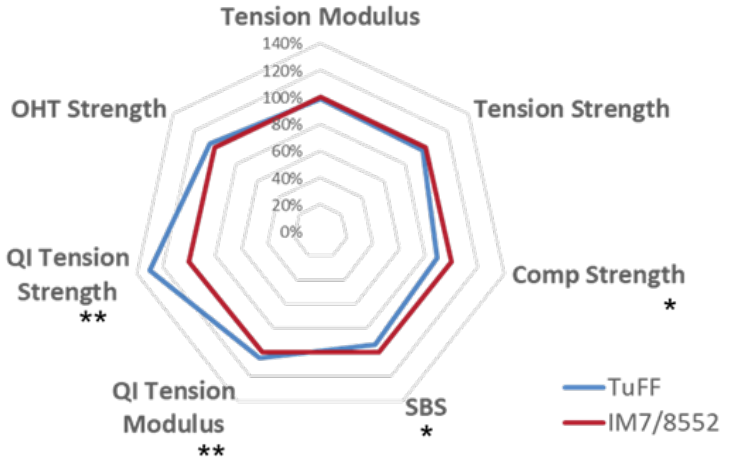
K.L. Simmons; *Sustainable Composites for Hydrogen Delivery and Storage*, SAMPE 2024

- CFC recycling approach can allow multiple iterations with fiber recovery, 50% energy saving after first recycling and ~70% after 3 recycling steps
- Majority of Industry predictions indicate Carbon fiber demand to exceed current world capacity
  - Growth in demand (10-13%) expected to exceed supply in the next decade(Drivers Wind, Pressure Vessels, etc)
  - ***Recycled/Waste CF sources can potentially expand domestic sources of carbon fibers for non-aerospace applications***

Challenges of Recycled CFC

- Recycling processes such as ***pyrolysis, thermolysis or solvolysis*** exist and have shown to recover *rCF* without significant fiber degradation
- Typically, size reduction (conversion to short fiber) is an inherent process step during fiber recovery
- Current state-of-the-art *rCF* are used as filler in injection molding and other low-performance processes
  - Low fiber volume fraction parts
  - Aspect ratio low ➔ reducing properties
  - Inherent ***value*** of CF lost
  - Down-cycled parts vs. true recycling
- Potential solutions
  - Maintaining original format: Recycling of fabric and tow
  - Aligned Discontinuous Fiber (HiPerDif, TuFF)

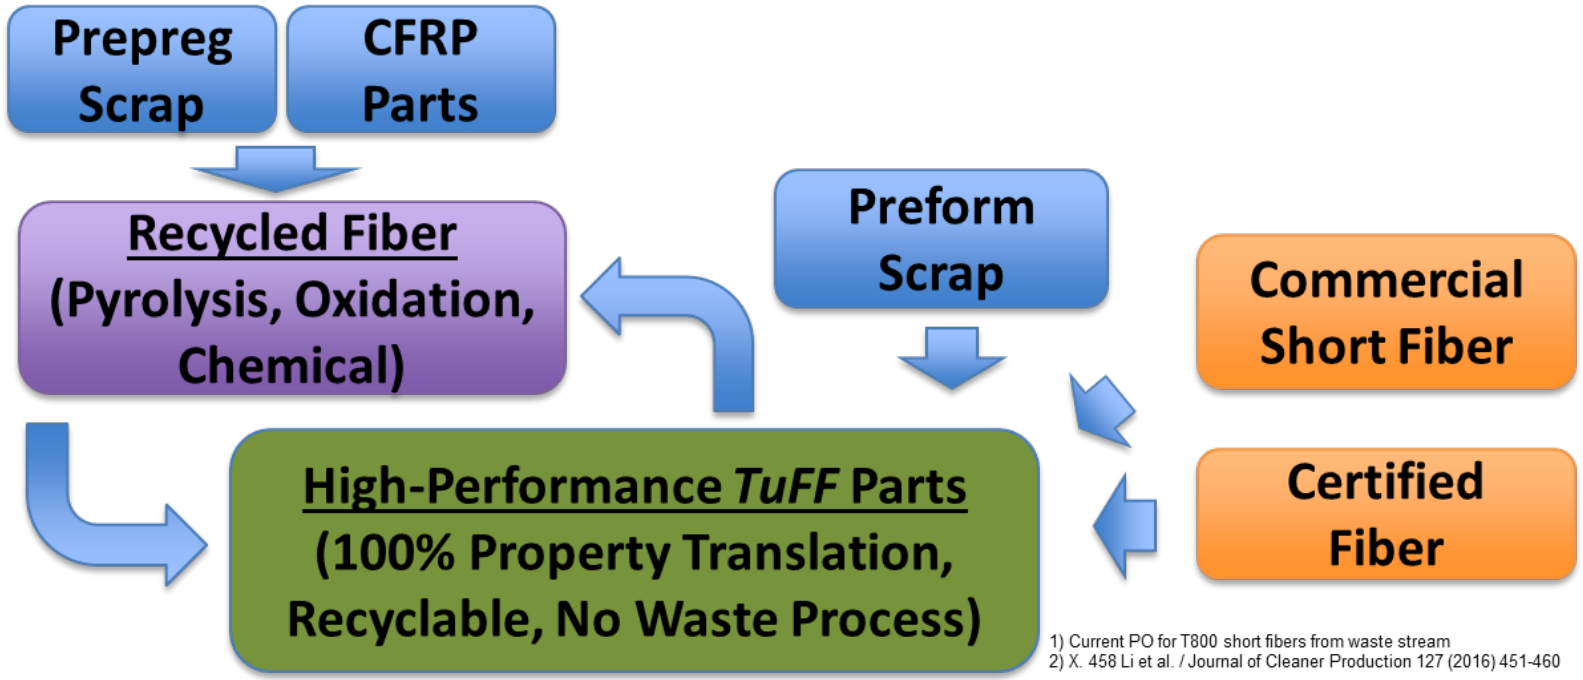




2017-Tailorable Universal Feedstock and Forming (TuFF)

TuFF is a <u>feedstock</u> comprised of a <u>highly-aligned</u> short fiber microstructure in tape, sheet and blank formats

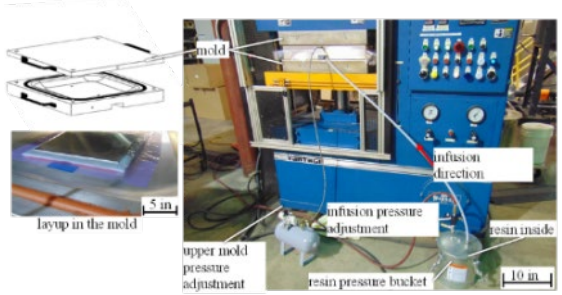
- Millimeter long short fiber with filament level alignment control: > 95% ($\pm$ 5 $^{\circ}$)
- High fiber volume fraction >57%
- Properties equivalent to continuous fiber composites >370ksi (2.55GPa) strength and >23msi (159GPa) stiffness
- In-plane stretch allows metal-like forming at high throughputs
- Thin ply formats for improved damage tolerance and minimum gage designs (30gsm to standard areal weight)
- <u>Enables recycling of carbon fiber composites</u>



Two US Patents (10,669,659 B2 & 11,047,078) "ALIGNED DISCONTINUOUS FIBER PREFORMS, COMPOSITES AND SYSTEMS AND PROCESSES OF MANUFACTURE"

*** Compression Strength and SBS are resin dominated (PEI vs 8552 Epoxy)**
****QI comparison is thin-ply (60 gsm FAW) to thick-ply (192 gsm FAW)**
OHT Strength is from TuFF1, Rest are TuFF2; Normalized values

TuFF Enables Closed-Loop Recycling of Carbon Fiber Composites

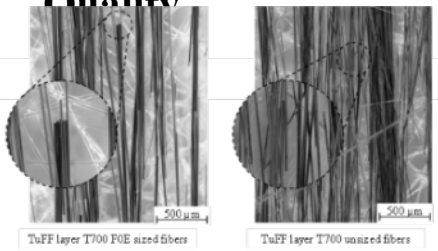


1) Current PO for T800 short fibers from waste stream
2) X. 458 Li et al. / Journal of Cleaner Production 127 (2016) 451-460

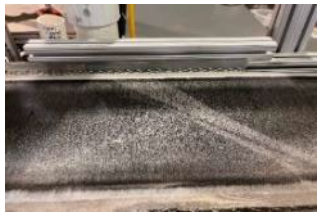
- Waste/Recycled fibers reduce material cost and environmental burden
  - Waste fiber price[1] ~$5/lb for intermediate modulus CF
  - Recycled fiber cost[2] estimated at ~$1.5/lb
- Commercial recycling processes exist and create discontinuous fiber material

➔ ***TuFF* process is key to convert recycled/waste fibers into high-performance parts**

➔ **Key challenges include fiber strength retention, fiber-resin adhesion, fiber length distribution, dispersion and alignment quality**



Recycled TuFF Process



VARTM/High Pressure Bladder Mold

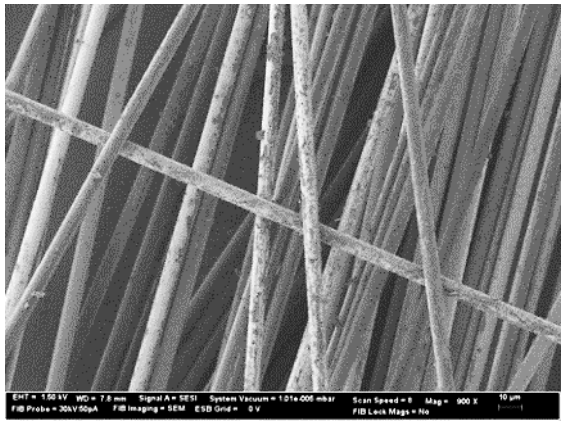
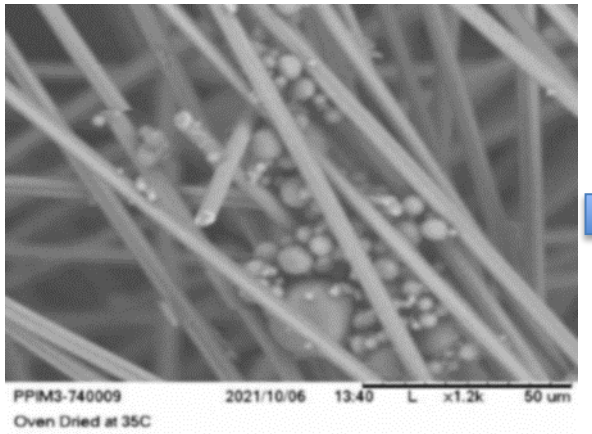
Solvolysis



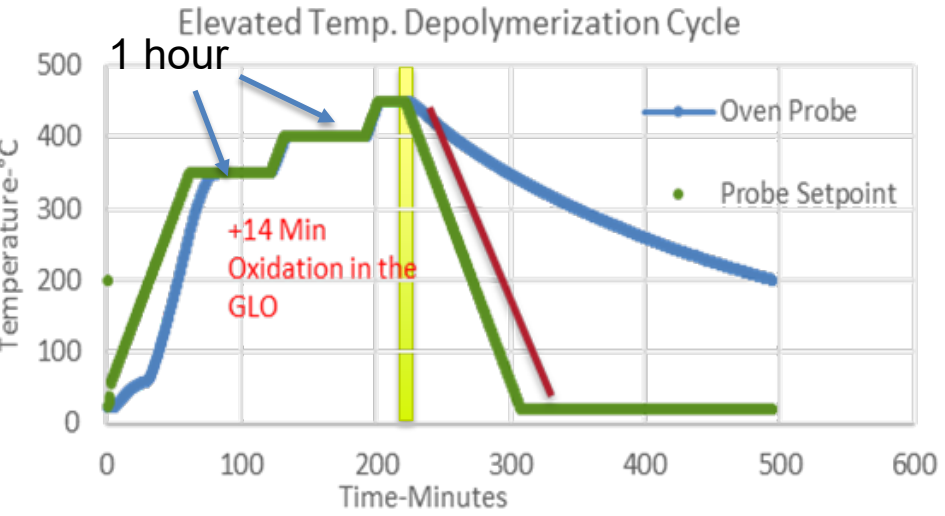
Challenges for Incoming Recycled Feedstock: Residue!



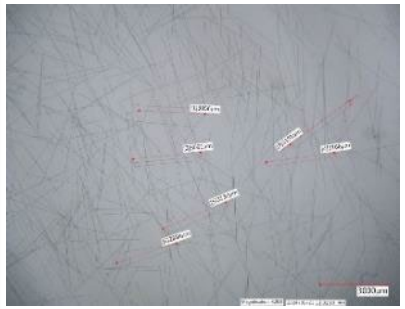
Waste Fiber T800
Dry fiber(minor residue)

Recycled T700/Elium
Thermolysis(~2% residue)

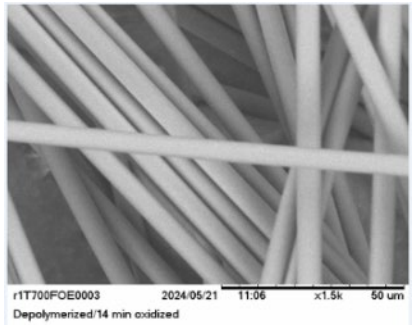
Recycled T800 Epoxy Prepreg
Solvolysis(5-10% Residue)



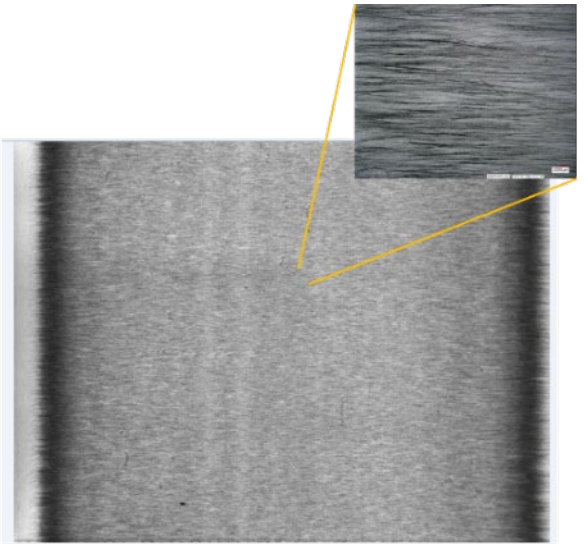
TuFF sheet made with
recycled T800



- Challenges of recycling prepreg and end-of-life parts for use in TuFF.
  - Residual material from recycling process can inhibit dispersion and resin adhesion
  - Broad distribution of fiber lengths
- Need for more efficient recycling approach and/or post recycling cleaning step
  - Elevated temperature oxidation- can harm fiber properties
  - Surfactants to aid in dispersion-requires chemicals that might adversely effect resin adhesion
  - Low temperature(50°-70°C) oxidative(ozone) cleaning-Potentially viable, but less efficient



Cleaning: Elevated Temperature Oxidation



Recycling leaves ~2% residue
(Low MW Oils and Char)

Recycled T700
dispersed in water

Recycled T700 SEM

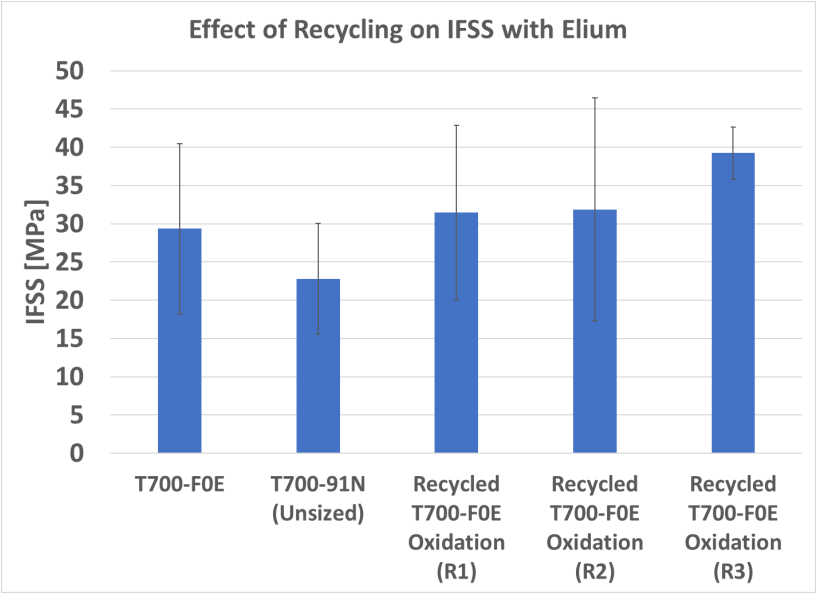
Elium/T700 FoE Recycle Iteration 2

Adhesion Promotion for Recycle Fibers

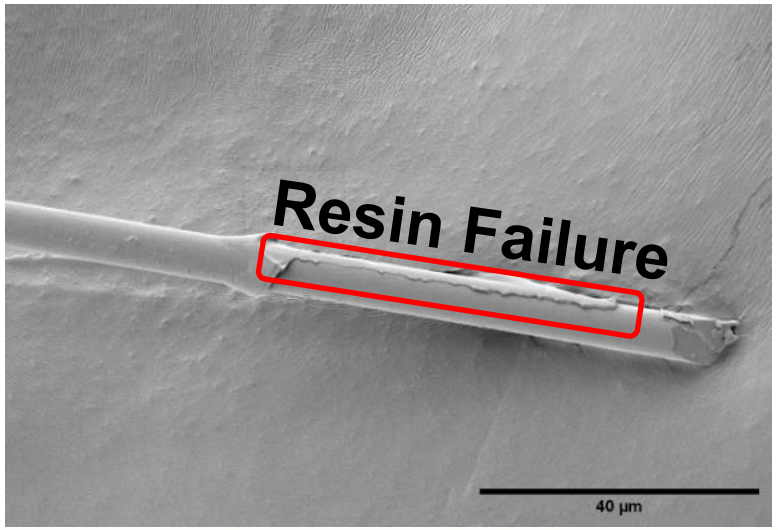
Fiber Pullout Steps



Laser Cut Cast Elium Film

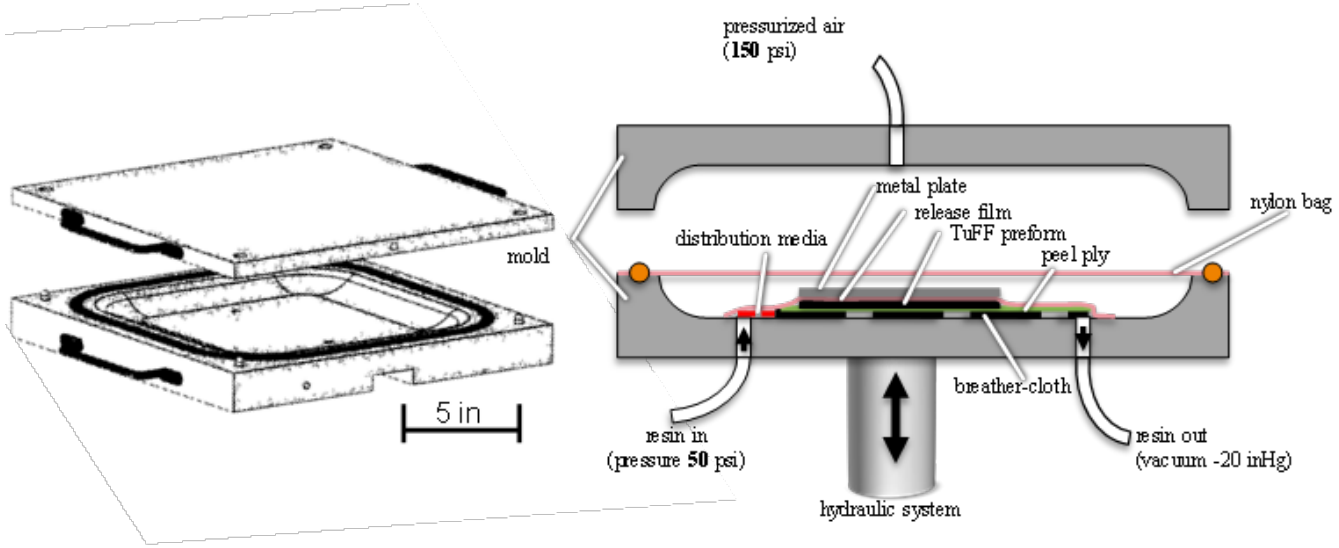
Laser Cut Sample on Aluminum Crucible

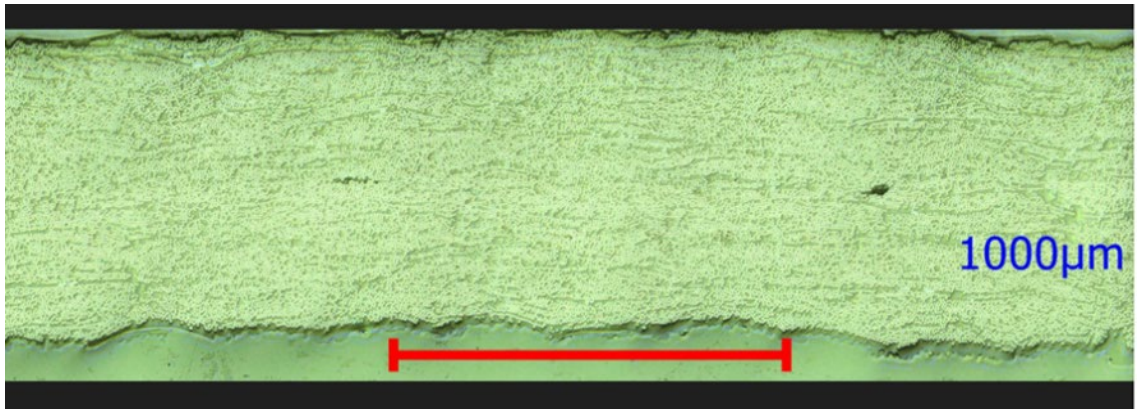
Sample with Fiber ready for Pullout testing



Sample Loaded in Pullout Test Fixture

Measure Diameter and Embedded Length in the SEM

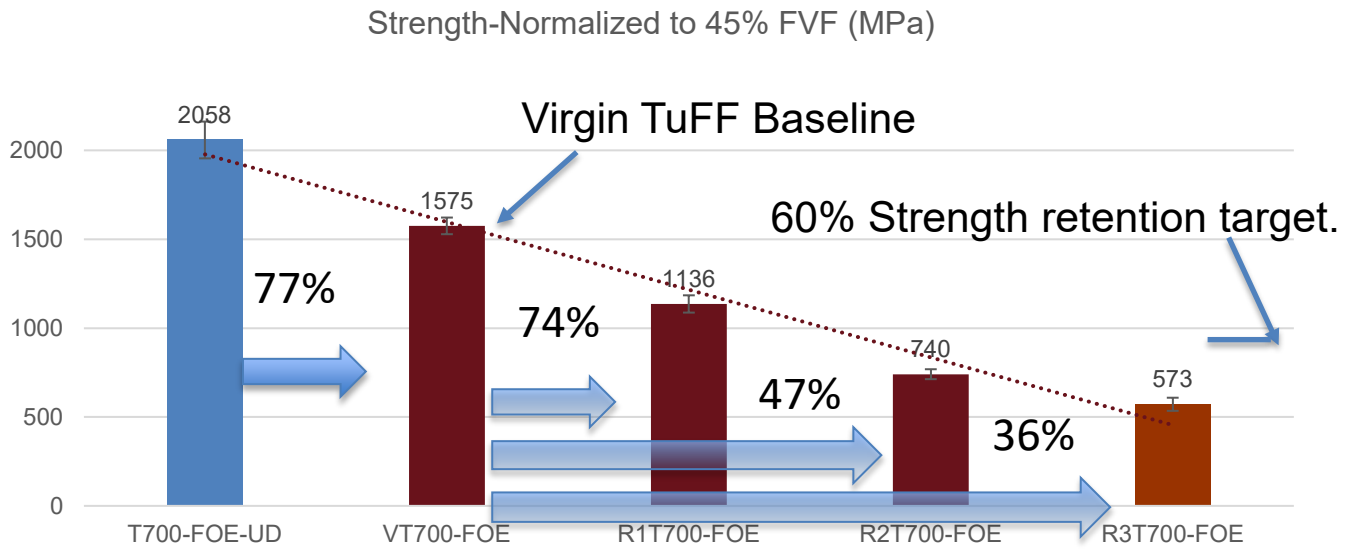


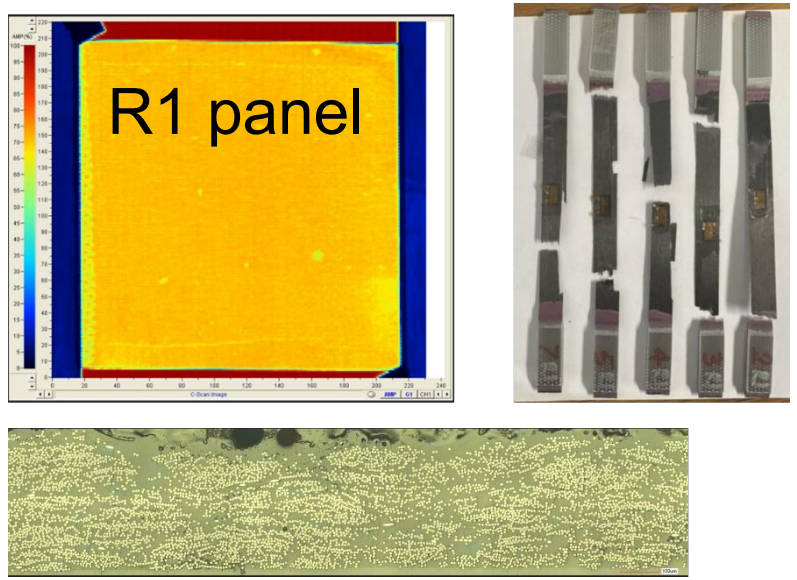


- Measured IFSS for Recycled fibers is comparable to Virgin fiber
- Mixed Mode(resin yielding) failure is observed in all cases
- IFSS for Elium resin system is (~30 MPa) is much lower than what is typical for Epoxy-CF systems(~78 MPa))

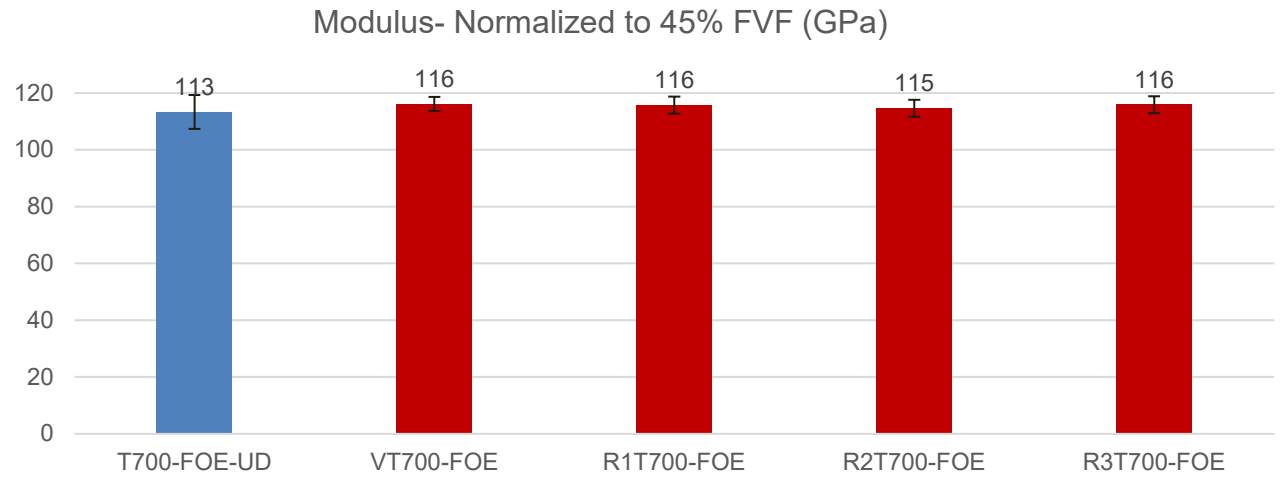
Evaluating Failure Mode

High Pressure Bladder Molding



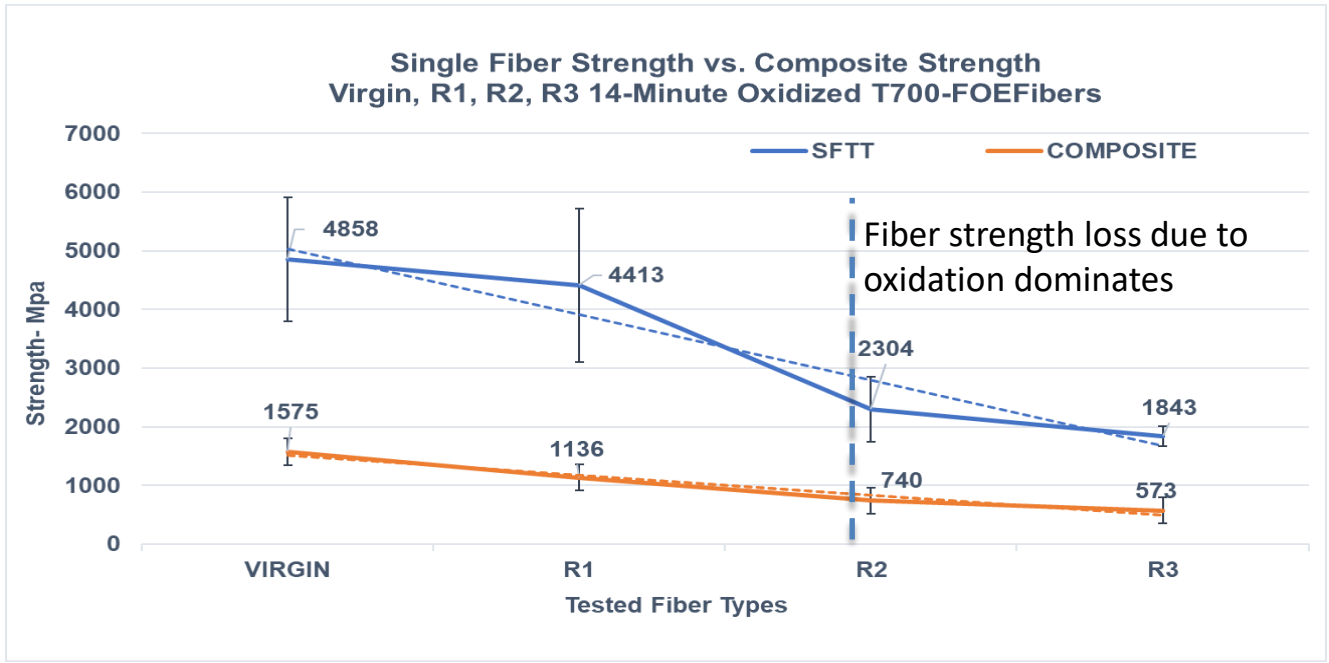


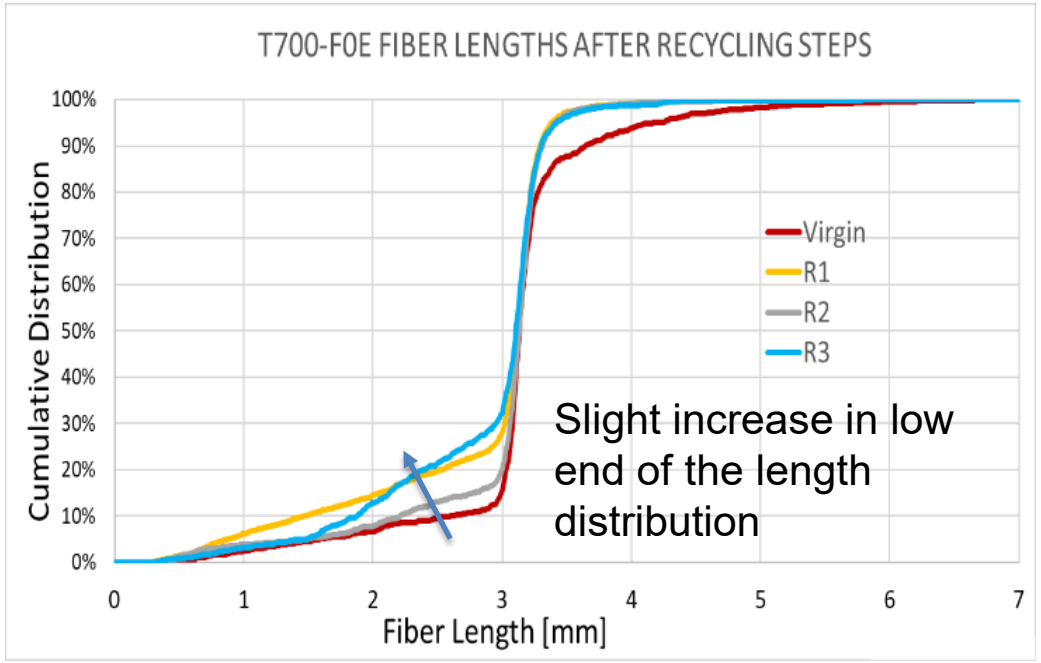
- Infusion parameters: 50 psi resin pressure, 200 psi bladder pressure for a total 150 psi consolidation pressure
- Polymerization:4 hours at 25 °C, 2 hours 80 °C under pressure



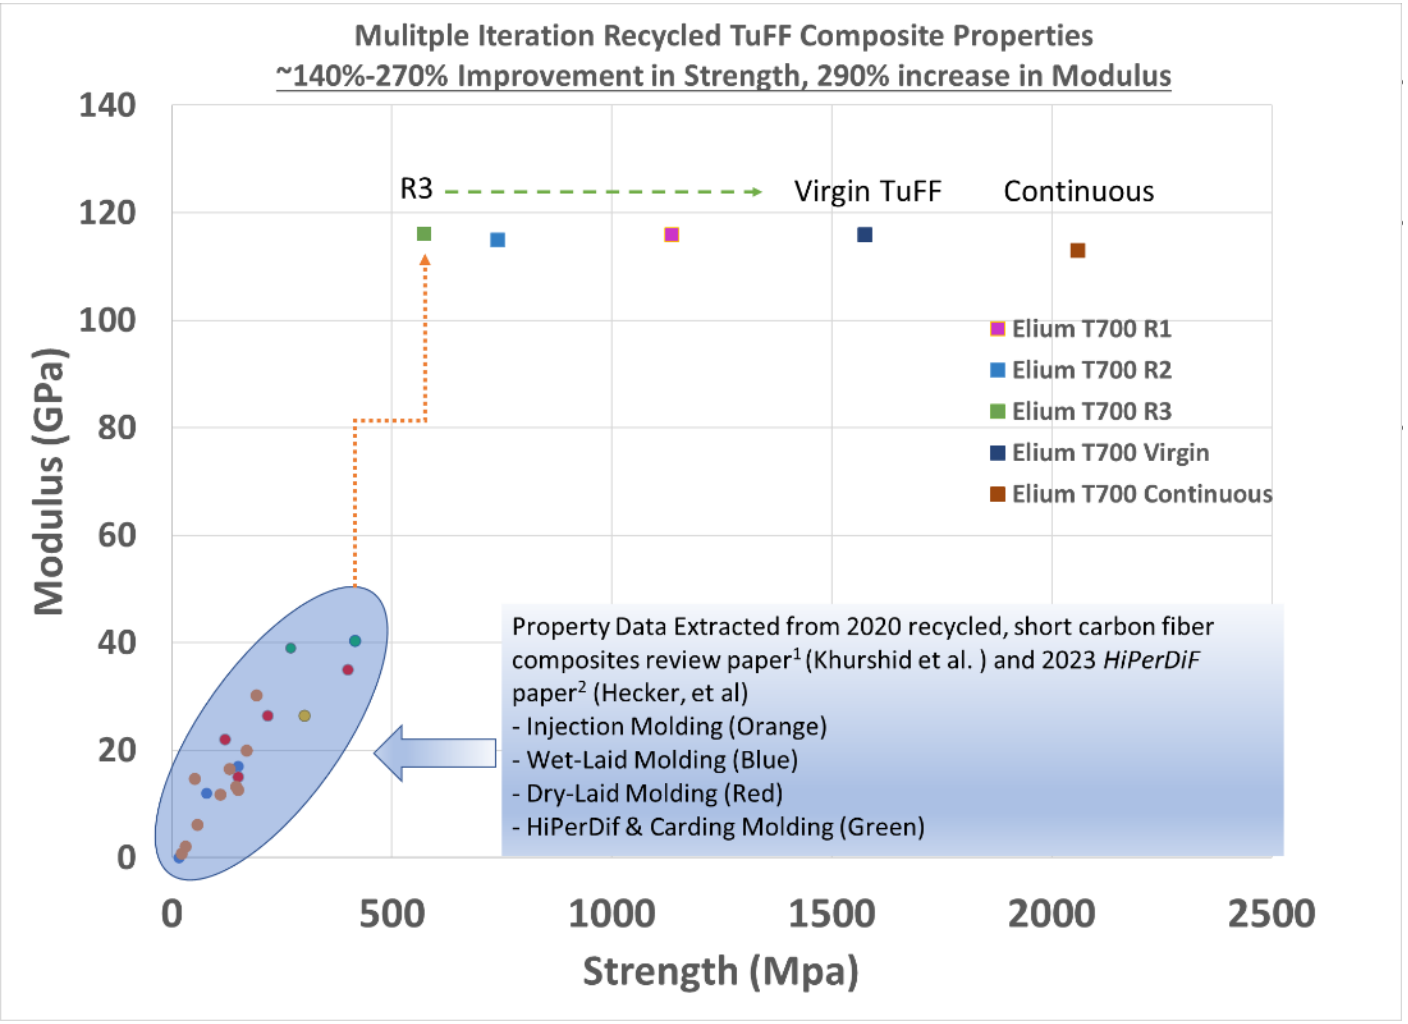
- Elium/T700 FOE Composite cross section
  - Arkema recommended Sizing
  - 1 mm thick panel with ~55% FvF

Strength, Modulus, SFTT and Fiber Length Measurements





- We see 100 % retention of Stiffness across 3 recycling iterations
- Strength reduces with recycling iteration

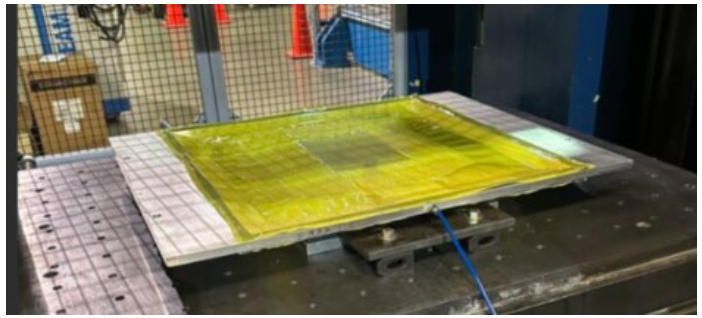


Strength, Modulus, SFTT and Fiber Length Measurements

- Potential reasons for Strength reduction include:
  - Cumulative effect of multiple oxidative cleaning steps
  - Increase in low end of the fiber length distribution
    - Shorter fibers could lead to more end clusters

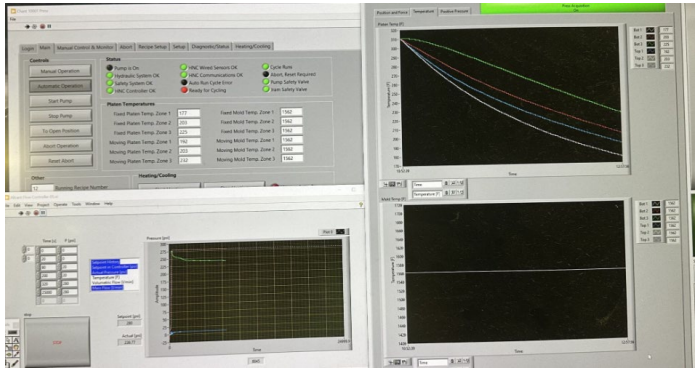
Multi-Iteration Elium/T700 Recycling Summary

100% Translation of Modulus, independent of # of recycling iterations



Third iteration of recycled fibers show ~140% improvement in strength over majority of reported recycled short fiber composites

Key factors in reduction of composite strength include:



- Loss of filament strength due to multiple oxidative cleaning steps
- Small scale clusters of fiber end groups
- Broadening of fiber length distribution
- Fiber/Resin Adhesion

1. Muhammad Furqan Khurshid , Martin Hengstermann, Chokri Cherif, Journal of Composite Materials 54(14)
2. Hecker, Marcelle D., et al. ,Composites Part A: Applied Science and Manufacturing, 173 (2023): 107651.

Forming Elium-infused Virgin and R3 T700 blanks via Bead Mold Setup

- Forming experiments with virgin and recycled TuFF blanks were successful
- The virgin blank had previous surface defects coming from the VARTM processing (After a pressure drop, leftover entrapped air formed a strip)
- Bead Mold Process conditions are as follows:
  - Heat press up to 155 ˚C
  - Prepare the blank in the mold, bag, and vacuum
  - Close the press and wait 20 minutes to get to the required resin viscosity
  - Increase pressure up to 280 psi and dwell 5 minutes
  - Start the cool-down process, remove the part

Commercial Prepregging of TuFF

(Axiom, Composite Automation and UD-CCM)

Axiom Commercial Prepreg line

CA-TuFF material being run

Final TuFF/Epoxy prepreg

- 120 gsm T700-50C TuFF dry preform with 2 64 gsm Axiom 2201 UD resin films
  - One film layer is used the carrier(100 ft roll fabricated at CA and transported to Axiom for prepreg processing)
  - No significant modification to the prepreg line was necessary

Summary & Opportunities for *rCF*

- Aligned discontinuous fiber formats have potential to re-capture original carbon fiber performance for rCF
  - *TuFF* formats have demonstrated 100% modulus and 74% strength to date for rCF compared to Virgin TuFF composites
- rCF quality must approach virgin carbon fiber quality
  - Surface cleanliness, eliminate polymer residue
    - Recycle-by-Design Resins!
  - Minimize or eliminate fiber flocks(cm) and fiber end aggregations(Microns to MM)
  - Approaches to reduce incoming breadth of fiber distribution
    - Too small – may affect strength translation
    - Too long – may affect formability
  - Sizing of rCF – may be needed
- Allows other unique part manufacturing processes enabled by the in-plane extensibility of *TuFF*

ABSTRACT

Vitrimers retain the structural integrity of thermosets while exhibiting flow-like properties under certain conditions, enabled by heat-activated dynamic bond exchange reactions. In this study, the effects of off-stoichiometric ratios in tailoring the properties and reprocessability of imine-epoxy vitrimers, focusing on a para-substituted imine-epoxy vitrimer is studied and compared to a standard thermoset based upon diglycidyl ether of bisphenol A. Furthermore, this work enabled an exploration of transimination—secondary bond exchange reaction where imine groups interact with unreacted amines—alongside imine metathesis. Stoichiometric balance starting from epoxy excess to amine excess were systematically varied to explore the impact upon static thermal and mechanical properties, as well as dynamic behaviour including the temperature of vitrimisation (T_v), adhesion, malleability and remouldability. These findings highlight how off-stoichiometric designs can optimize repairability and durability in highly aromatic epoxy vitrimers through dynamic imine chemistry, advancing the development of sustainable, reprocessable composites.

1 INTRODUCTION

Vitrimers are covalently crosslinked polymer networks modified with dynamic or reversible bonds capable of undergoing bond exchange reactions. These reactions enable topological rearrangements within the network without compromising the overall crosslink density.[1] The exchange can be triggered by external stimuli such as changes in temperature, pH, light, or the presence of chemical additives.[2-4] Examples of dynamic bonds commonly used in vitrimers include ester bonds, boronic esters, imines, and disulfide linkages.[5] As a result of the dynamic behavior, vitrimers can exhibit thermoplastic-like flow under specific conditions, a property not inherent in conventional thermosets, offering advantages in terms of recyclability, remouldability, and repair after curing.[6, 7]

Imines are particularly attractive due to their thermally activated bond exchange reactions and catalyst-free reprocessing. They undergo two types of bond exchange reactions, i.e., imine metathesis, which involves exchange between imine groups, and transimination, which occurs through reaction with free amine groups.[8] Since amine-based hardeners are commonly used in epoxy networks, varying the amine-to-epoxide stoichiometry can influence the amount of unreacted amine groups present in the cured network. These residual amines may participate in transimination reactions with imine bonds, not only during reprocessing but potentially during the curing process itself. This raises the question of how stoichiometry influences not only the curing process but also the post-cure properties and reprocessability of imine-based vitrimers. While off-stoichiometric formulations are

typically avoided in traditional thermosets due to their negative impact on thermal and mechanical properties, vitrimers may tolerate or even benefit from such formulations. Investigating this could provide valuable insights into how vitrimers differ from conventional thermosets, especially in terms of thermal and mechanical properties, reprocessability, and hydrolytic stability.

The role of stoichiometry in crosslinked polymers, particularly epoxy amine networks has been studied for many years and the relationships are well understood.[9-12] For the best combination of mechanical, thermal and physical properties, a stoichiometric, or small epoxide group excess is typically used because it will produce a homogenous network and provide the best opportunity for complete cure and a minimum of remaining reactive groups. Recent examples of systematic studies on epoxy networks and epoxy vitrimers include Senanayake et al. (2024) that reported on the impact of stoichiometry on the properties of epoxy/acid thermosets.[13] Jing and Xie (2022) investigated the effect of stoichiometry on the properties and reprocessability of epoxy/acid vitrimers facilitated by Zn^{2+}-catalyzed transesterification which was the first type of vitrimer reported. They varied the epoxy-fatty acid ratio and obtained glass transition temperatures between 20°C and 30°C and tensile strength between 2 to 4 MPa that decrease with increasing epoxy/acid ratio due to decreasing crosslink density.[14] Sheng and Guo (2023) did a similar study, varying the epoxy/acid ratio and found that the epoxy content increased glass transition temperature due to higher proportion of the rigid aromatic epoxide backbone from 40°C to 63°C and increased tensile strength increased from 26 to 43 MPa. In terms of repairability using a scratch test, increasing epoxy content enhanced repairability highlighting the importance of stoichiometry. [15]

In this work, an imine epoxy resin synthesized in house has been cured with diethyl toluene diamine (DETDA) using a range of stoichiometries from epoxy to amine excess and characterized for their static and dynamic properties. Various thermal, thermomechanical, and mechanical techniques were used to compare and contrast the dynamic network compared with a traditional epoxy amine network. Key dynamic properties such as material flow, topology freezing temperature, activation energy of dynamic behaviour, stress relaxation time, and adhesion strength were determined enabling dynamic behaviour to be better understood.

2 EXPERIMENTAL

2.1 Materials

Vanillin, 4-Aminophenol, benzyltriethylammonium chloride, (±)-epichlorohydrin, and 0.1N nitric acid in glacial acetic acid were purchased from Sigma-Aldrich (Missouri, USA). Isopropanol, ethanol, dichloromethane, and methanol were purchased from Chem-supply. Diethyltoluenediamine, DETDA 100, was purchased from Huntsman Corporation (Everberg, Belgium).

2.2 Sample Preparation

The para-substituted epoxy imine, pVAPI, was synthesized by mixing vanillin (0.02 mol) and 4-aminophenol (0.02 mol) in 30% aqueous ethanol at 50°C for two hours according to the following reaction sequence in Figure 1.

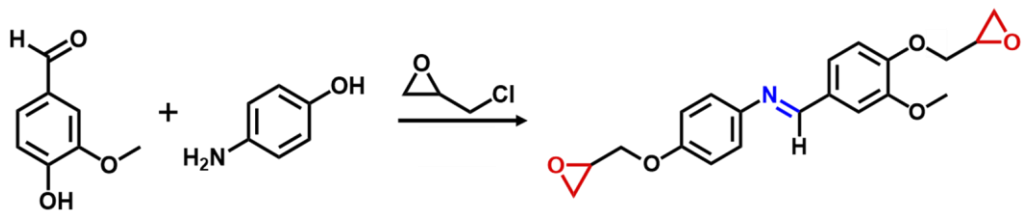

Figure 1: Synthesis of *p*VAPI epoxide from vanillin and *p*-aminophenol.

The precipitate was filtered, washed with deionized water, and dried overnight in an oven at 60°C. Epoxidation of pVAPI was carried out by mixing pVAPI (0.02 mol), epichlorohydrin (0.10 mol) and

benzyltriethylammonium chloride catalyst (2 mol %). The mixture was refluxed at 90°C for 2 hours. A water isopropanol solution of sodium hydroxide (0.10 mol) then added and mixing continued for 2 hrs at 60°C. After filtering, the product was concentrated in vacuo at 100°C then washed several times with deionized water. Finally, pVAPI epoxide was dried over anhydrous magnesium sulfate, and then isolated in vacuo. The yield for pVAPI epoxy was 98%.

The resin systems were prepared by mixing pVAPI epoxide and DETDA together using epoxide to active hydrogen ratios of 1:0.5, 1:0.7, 1:0.9: 1:1.2 and 1:1.5. The formulations were degassed and mixed together at 120°C for 10 minutes then poured into pre-heated silicone moulds and cured in a convection oven at 120°C for 2 hours, 150°C for 2 hours and 177°C for 5 hours. DGEBA-DETDA formulations were prepared in a similar manner.

2.3 Characterization

Dynamic thermomechanical analysis was conducted with TA Q800 DMA. Samples with dimensions of 12×50×2.5 mm^3 were prepared and placed in a dual cantilever fixture. A force amplitude of 15 µm with frequency of 1 Hz was applied from 30°C to 250°C at a rate of 3°C/min. The glass transition temperature, T_g, was determined from peak of the tan δ, and the crosslink density (υ_e) was calculated from the rubbery modulus, E_r, at $T_r = Tg + 50°C$, and with R which is the real gas constant, using the equation,

$$\upsilon_e = E_r/(3RT_r) \quad (1)$$

Thermal stability and degradation studies were done with Netzsch TG 209 F1 Libra. Samples of about 5 mg were prepared in Al_2O_3 pans. The temperature was ramped from 30 to 800°C at 10°C/min under nitrogen. Samples were characterized based upon the temperature at 5% mass loss, $T_{5\%}$, the temperature at the maximum rate of degradation, T_{max}, and the char yield at 800°C.

Thermomechanical analysis was conducted with the Netzsch Hyperion TMA. Polymer samples were cut into 5 mm disks with a drill press and placed in between ceramic plates. A force of 0.05 N was applied to ensure good contact between the samples. The temperature was increased from 30°C to 270°C at 3°C/min. The coefficients of thermal expansion for the glassy and rubbery regions were calculated from the slope before and after the glass transition temperature.

Flexural testing were conducted using an Instron 68TM-50 Universal Testing Machine. Flexural tests was based on ASTM D790 wherein resin bars with dimensions 12×60×2.5 mm^3 were prepared using a span-to-thickness ratio of 16:1, a crosshead displacement speed of 1.3 mm/min, and a 50 kN load cell. The modulus was measured from the slope of the stress−strain curve up to a flexural strain of 0.2%, and the flexural strength was measured from the maximum failure load.

To investigate test repeated adhesion, cured vitrimers placed on composite substrates were overlapped to an extent of 25 mm x 25 mm clamped together with a force of around 8 kN, and heated at 200°C for 3 hours in an oven. Adhesion was assessed according to a simple lap shear test using an Instron 5967 Universal Testing Machine

5 DISCUSSION

The cured resins are shown in Figure 2 illustrating the effect of stoichiometry on the colour of the cured resins. Clearly, imine networks become increasingly darker with higher levels of amine, reflecting the increasing vulnerability towards oxidation. In comparison the DGEBA DETDA networks are much less darker.

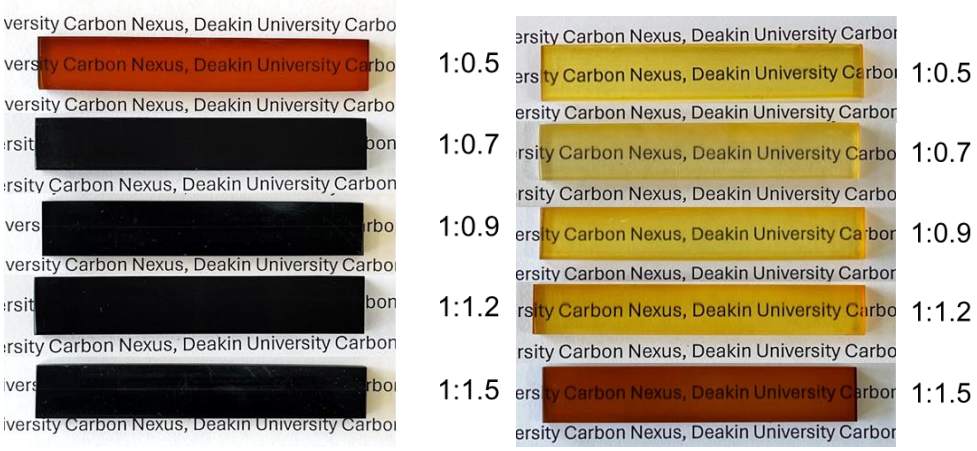

Figure 2: Images of the *p*VAPI-DETDA (left) and DGEBA-DETDA (right) networks after cure.

To evaluate the effect of stoichiometry on the thermomechanical properties of the vitrimer and non-vitrimer networks, dynamic mechanical analysis was performed. The DMTA spectra are shown in Figure 3 and the results are summarized in Table 1. Increasing amine content results in higher storage modulus and lower glass transition temperature which is also reflected in the lower crosslinking densities determined. All vitrimers have glass transition temperatures above 130°C, due to the rigid nature of the imine backbone. Unreacted amine groups led to a decrease in crosslinking density which is commonly observed in network polymers. The DMTA for the DGEBA DETDA networks had a higher storage modulus as well as lower glass transition temperature and crosslinking density.[10, 16] The tan delta peaks for all networks are symmetrical single peaks indicating homogeneous and fully cured networks formed even in the presence of excess epoxide and amine.

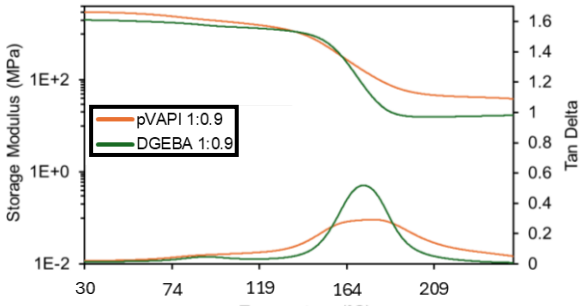

Figure 3: DMTA traces of the VAPI and DGEBA networks for 1:0.9 stoichiometry.

Thermomechanical analysis was performed to evaluate the effect of stoichiometry on the thermal expansion and dimensional stability. Figure 4 compares the raw thermogram from the DGEBA and pVAPI networks which show different behaviour. The DGEBA network appears quite standard with an inflection point corresponding to T_g, while the pVAPI imine does not appear to display an inflection point at T_g, again likely due to its rigid nature. The effect of stoichiometry on the CTE is shown in Table 1 where it can be seen that there is a gradual decrease in CTE with increasing amine content. In general the CTE of the DGEBA non vitrimer networks are lower than the vitrimer networks, suggesting it is more tightly constrained in the network.[10]

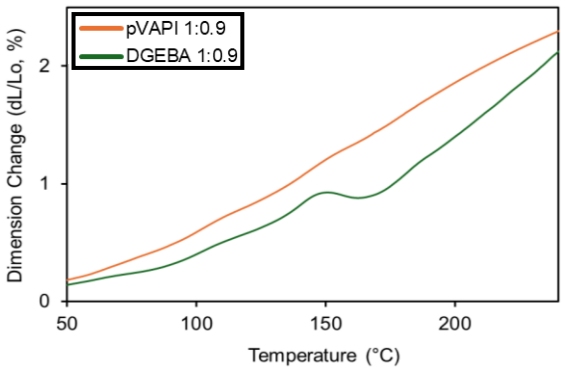

Figure 4: TMA traces of the VAPI and DGEBA networks for 1:0.9 stoichiometry.

The TGA thermograms show a typical mass loss transition in Figure 5. The important point to note is that the imine networks have a lower onset of degradation temperature and a high char yield compared to the DGEBA DETDA networks. As can be seen from the results, the effect of stoichiometry only has a modest impact upon degradation temperatures and char yields.[17]

[a]Determined by the peak of tan δ. [b]Determined from the extrapolated onset of E'. [c]υ_e is the crosslink density per unit volume from the DMA curves at T_g + 40°C.

The mechanical properties of the pVAPI and DGEBA networks are shown in Table 2 which highlight the effect of stoichiometry for both networks, the vitrimer and non-vitrimer. An example of the stress strain curve for the 1:0.9 stoichiometry in Figure 6 in particular highlights their brittle failure, particularly for pVAPI. For the pVAPI network, increasing amine content increases the modulus and strength but does not significantly affect the strain at break. These trends are opposite to that of the benchmark thermoset which exhibits decreasing modulus and strength as well as increasing strain at break with increasing amine content. During curing, bond exchange reactions may be activated by the high temperature needed for curing which relaxes internal stress and decreases defects in the network leading to better mechanical properties. Increasing the ratio increases the number of amines that can participate in transimination reactions resulting in higher flexural modulus and strength. However, the strain at break remains the same with increasing amine content. This could be due to the similar chemical composition of the vitrimers.[14]

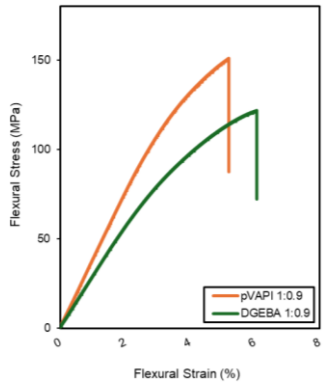

Figure 6: Flexural stress-strain curves for the pVAPI and DGEBA 1:0.9 networks.

Table 2: Summary of the mechanical properties of *p*VAPI-DETDA and DGEBA-DETDA networks.

Network	Flexural Strength (MPa)	Flexural Modulus (GPa)	Flexural Strain at Break (mm/mm)
*p*VAPI-DETDA 1:0.5	126	3.4	0.05
*p*VAPI-DETDA 1:0.7	150	3.9	0.05
*p*VAPI-DETDA 1:0.9	150	3.7	0.06
*p*VAPI-DETDA 1:1.2	155	3.9	0.06

DGEBA-DETDA 1:0.9	122	2.9	0.08
DGEBA-DETDA 1:1.2	108	2.5	0.09
DGEBA-DETDA 1:1.5	95	2.7	0.11

Reversible or debondable adhesion of the vitrimers as a function of stoichiometry was investigated using lap shear. The load recovery is shown in Figure 7, where it can be seen that with increasing amine content, the load force increases. Clearly polymer chain diffusion and entanglement is therefore able to occur despite the fact that the polymer networks are fully cured. This highlights the molecular mobility of the imine functional group under heat and pressure. It is proposed that the dynamic covalent behaviour promotes transimination and imine metathesis between the surfaces enabling adhesion as the functional groups diffusion across the surfaces. Elevated temperatures increase the rate of these reversible exchange reactions that lead to topology rearrangements allowing faster chain diffusion. This experiment demonstrates the reprocessability of the VAPI vitrimer network while no diffusion for the DGEBA network was observed at all, despite efforts to do so. Figure 7 also shows the failure surfaces after re-processing highlight cohesive failure for stoichiometric and amine access networks.

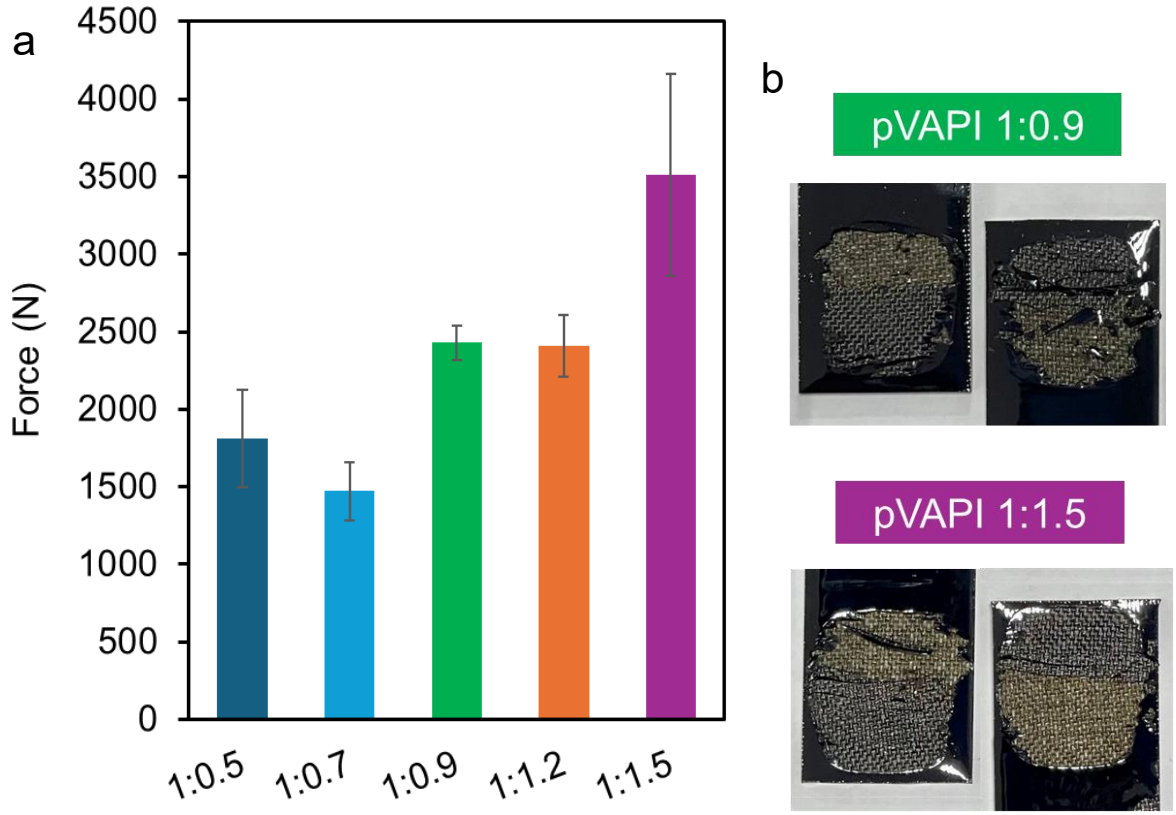

Figure 7: (a) Lap shear applied force of pVAPI-DETDA networks after welding the cured resins at 200°C for 3 hours. (b) Lap shear failure images of pVAPI-DETDA 1:0.9 and 1:1.5.

9 CONCLUSIONS

This study explored the impact of epoxide-amine stoichiometry on the properties and reprocessability of a highly aromatic imine-based epoxy vitrimer. This research provides insight into the bond exchange mechanism as a function of amine content and its application to the development of a reversible or debondable adhesive. The vitrimer properties were highly tunable achieving Tg's ranging from 120-210°C and flexural strength ranging from 120 to 160 MPa. This study is part of a broader study into the efficacy of imines as functional groups for high performance yet dynamic networks, and these results present excellent results that suggest that excellent mechanical and thermal properties, along with very good dynamic behaviour can go together in some high-performance networks.

ABSTRACT

Composites have a strength-to-weight ratio, approximately nine times that of steel, making them desirable for demanding applications such as in wind turbine blades, aircraft and automotives. However, their commercial viability is constrained by logistical challenges, including the necessity for refrigerated transport and storage, as well as their inability to be molded or welded post-curing. Carbon fiber pre-pregs require refrigeration and must be maintained in a frozen state until use, complicating logistics and increasing waste due to spoilage during power outages. This study investigates the potential of vitrimers as a solution to rejuvenate out-of-date or improperly cured pre-pregs. Vitrimers are crosslinked polymer networks modified with dynamic bonds that undergo bond exchange reactions at elevated temperatures. This results in material flow which enables thermoforming and bonding even after curing which is not possible for existing thermosets. In this work, carbon fiber pre-pregs based on diglycidyl ether of bisphenol A, DGEBA, are cured to varying degrees of cure, and cured with an already fully cured imine-containing epoxy vitrimer, *p*VAPI-DETDA. The mechanical and thermal properties of the resulting laminates were characterized through three-point bending tests, dynamic mechanical analysis (DMA), thermogravimetric analysis (TGA), differential scanning calorimetry (DSC), and microscopy. The laminates demonstrated high glass transition temperatures of up to 177°C, degradation temperatures reaching 387°C, flexural strengths up to 1.31 GPa, and flexural moduli up to 105 GPa. These findings suggest that vitrimers can significantly mitigate waste and energy consumption while addressing the logistical limitations associated with thermoset carbon fiber pre-pregs. Moreover, this approach could enable the transport of composites similar to sheet metals, eliminating the need for refrigeration and enhancing their commercial potential.

1 INTRODUCTION

Fiber-reinforced polymer composites (FRPs) are advanced hybrid materials composed of a reinforcement—commonly fibers such as carbon, glass, or natural fibers—and a matrix, which can be a thermoset or thermoplastic polymer, ceramic, or metal.[1] Among these, carbon fiber-reinforced polymer (CFRP) composites are particularly attractive due to their high strength-to-weight ratio, excellent thermal stability, and mechanical robustness. These attributes make them ideal for aircraft structures, vehicle components, and wind turbine blades.[1-4]

CFRPs can be manufactured using various techniques, including hand lay-up, vacuum infusion, compression molding, and prepreg processing. Prepregs—fibers pre-impregnated with a polymer resin—are widely used, especially in the aerospace industry.[5-8] These prepregs are typically stored and transported in a frozen state to inhibit premature curing. Upon reaching the end user, they are

maintained under cold storage conditions until they are layed up in molds and consolidated under heat and pressure into the desired composite structure. For instance, aerospace manufacturers such as Boeing receive large rolls of prepregs that are kept frozen until final forming, requiring energy-intensive logistics. However, challenges arise when there are disruptions such as power outages or transportation delays.[9] In such cases, premature curing reactions between the epoxide and amine components may initiate, resulting in increased stiffness or boardiness of the prepreg. Boardy prepregs indicate partial cure, which reduces the availability of reactive functional groups essential for good interfacial bonding during composite formation. In severe cases where the prepregs are nearly or fully cured, they become non-adherent and unsuitable for further processing, leading to disposal and material wastage. This issue is rooted in the inherent intractability of thermosets, whose permanent crosslinked networks cannot be reshaped or remolded once cured.

To address this problem, the use of vitrimers is proposed—a class of crosslinked polymers that incorporate dynamic covalent bonds, enabling network rearrangement under specific conditions. Unlike conventional thermosets, vitrimers can exhibit thermoplastic-like flow behavior at elevated temperatures due to dynamic bond exchange reactions that facilitate topological reconfiguration. This property allows vitrimers to interdiffuse and entangle across interfaces, forming strong bonds even with thermosets. Furthermore, when vitrimers possess complementary functional groups, they can form covalent linkages with unreacted groups on partially cured prepreg surfaces, enabling chemical rejuvenation. Remarkably, vitrimers can achieve such interactions even when fully cured, offering post-curing reprocessability and welding capability.[10-13]

In this study, we exploited the weldability and reprocessability of an epoxy vitrimer based on dynamic imine bonds to rejuvenate out-of-date thermoset prepregs and maintain usability despite their boardy nature. Specifically, the initial cure state, i.e., the availability of residual functional groups affects vitrimer-assisted recovery. Thermoset prepregs of varying cure levels were interleaved with fully cured vitrimer single plies derived from *p*VAPI-DETDA, a vitrimer from an imine-epoxide synthesized from vanillin and 4-aminophenol, and the amine hardener diethyltolunediamine (DETDA), and hot-pressed into laminates. The resulting materials were characterized using differential scanning calorimetry (DSC), dynamic mechanical analysis (DMA), thermogravimetric analysis (TGA), and flexural testing to evaluate thermal and mechanical performance. Our results confirm that the vitrimer can effectively rejuvenate prepregs with sufficient unreacted functional groups by enabling covalent bonding. In cases where functional group availability is limited, vitrimer chain diffusion and physical entanglement still result in moderate property recovery. This study demonstrates that imine-epoxy vitrimers can extend the usability of out-of-date or improperly cured prepregs, offering a sustainable route to reduce composite material waste and retain performance.

2 METHODOLOGY

2.1 Sample Preparation

The vanillin-based imine-containing epoxide monomer was synthesized according to the method reported by Zhao, et al. (2018).[13] The resulting imine-epoxide, *p*VAPI epoxide, was then mixed with diethyltoluenediamine (DETDA) in a 1:1.5 ratio and dissolved in dichloromethane. Unidirectional carbon fibers were then impregnated with the mixture, the solvent was removed, vacuum bagged, and then cured in an oven at 120°C for 2 hours, 150°C for 2 hours and 177°C for 5 hours under vacuum. Thermoset prepregs were prepared from diglycidyl ether of bisphenol A (DGEBA) and DETDA in a 1:0.9 ratio. Unidirectional carbon fibers were impregnated with the mixture, vacuum bagged, and processed accordingly. Partially cured and fully prepregs were cured in an oven at 80°C and 150°C for 6 hours, respectively. As benchmark for out-of-date prepregs, a fresh uncured prepreg was prepared. This was done to simulate different stages of cure of improperly cured or out-of-date prepregs.

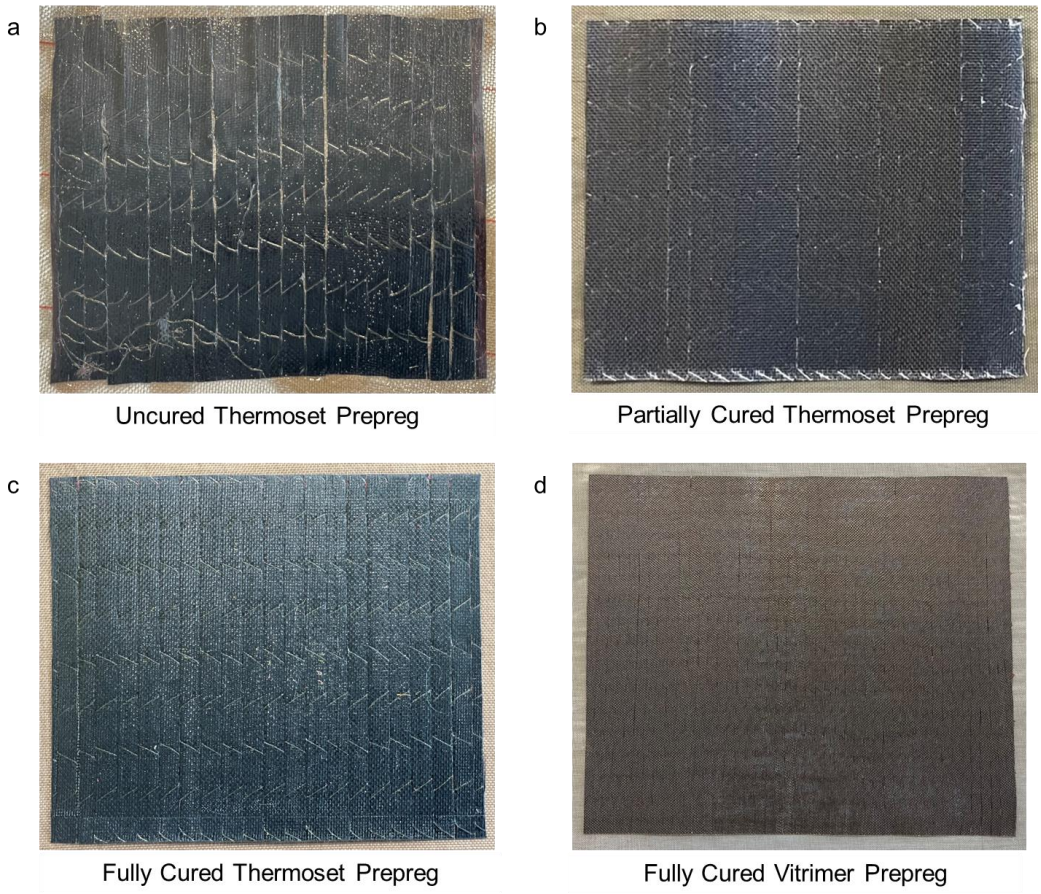

Figure 1: Images of (a) uncured, (b) partially cured and (c) fully cured DGEBA-DETDA carbon fibre prepregs and (d) fully cured *p*VAPI-DETDA carbon fibre prepreg.

Laminates designated as Unc VTCF, Par VTCF, and Ful VTCF, were then prepared from 8 alternating layers of uncured, partially cured and fully cured DGEBA-DETDA pre-pregs, respectively, with fully cured *p*VAPI-DETDA vitrimer single plies. The consolidation was done in a hot press at 200°C for 3 hours as shown in Figure 2. The pressure was kept constant at 2 tons.

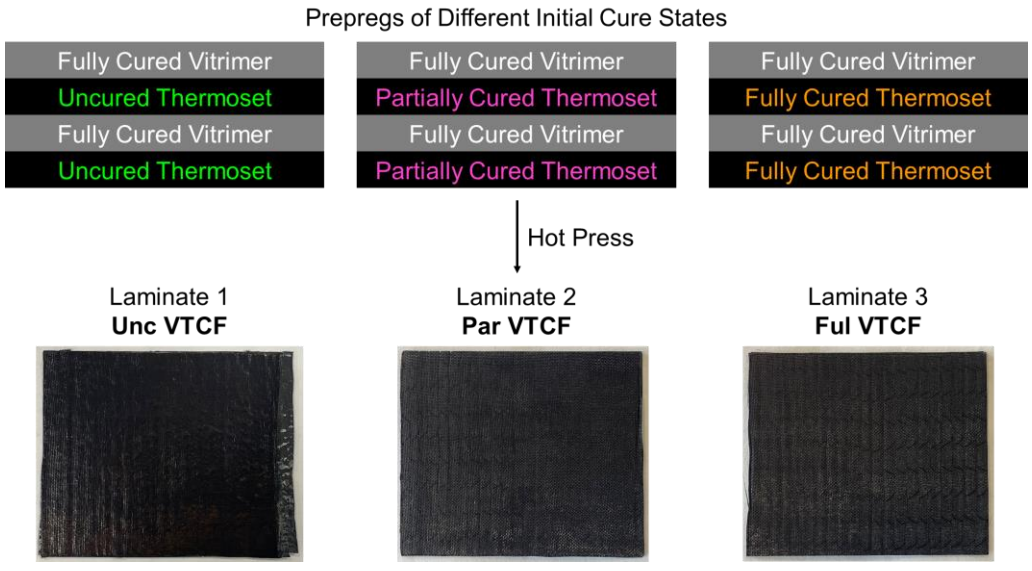

Figure 2: Schematic illustration of composite fabrication from alternating layers of the fully cured vitrimer single plies and thermoset prepregs of different initial cure states.

2.2 Thermal Analysis

Dynamic thermal analyses were done with Netzsch DSC 214 Polyma. Samples were prepared in concavus aluminum pans with lids pierced. The temperature was ramped from 30 to 320°C at a rate of 10°C/min under nitrogen. The data was processed with Proteus Analysis version 7.1.0 (2017, Netzsch-Geratebau GmbH, Germany).

Thermal stability and degradation studies were done with Netzsch TG 209 F1 Libra. Samples were prepared in Al_2O_3 pans. The temperature was ramped from 30 to 800°C at a rate of 10°C/min under nitrogen or air. The data was processed with Proteus Analysis version 8.0.2 (2020).

Dynamic thermomechanical analysis was conducted with TA Q800 DMA. Samples with dimensions of 12×32×3 mm^3 were prepared and placed in a single cantilever fixture. A force amplitude of 15 µm with frequency of 1 Hz was applied from 30°C to 300°C at a rate of 3°C/min. The data was processed with Universal Analysis version 4.5A.

2.3 Mechanical Testing

Flexural testing was conducted with Instron 68TM-50 Universal Testing Machine. Flexural tests were based on ASTM D790 wherein samples with dimensions 12×65×3 mm^3 were prepared and placed on support beams with a span of 48 mm. At least 10N was applied at a rate of 1.3 mm/min until fracture. The data was processed with BlueHill version 4.38.

3 RESULTS AND DISCUSSION

3.1 Preparation of Single Plies of Various Initial Cure States

Differential scanning calorimetry (DSC) was employed to assess the initial cure states of the uncured, partially cured, and fully cured thermoset prepregs, as well as the fully cured vitrimer single ply used in laminate fabrication. The DSC thermograms of the uncured and partially cured prepregs exhibited exothermic peaks beginning around 130°C, indicating that the curing reactions were incomplete. Notably, the uncured prepreg displayed a significantly larger exothermic peak area compared to the partially cured sample, reflecting a lower extent of initial cure of the former. The absence of a glass transition in the partially cured prepreg further confirms that it had not reached full cure. In contrast, both the fully cured thermoset prepreg and vitrimer single ply exhibited clear glass transition temperatures, consistent with complete network formation. These findings verify that the prepreg samples represent distinct cure states, validating their selection for studying the influence of initial cure on performance of the resulting laminates and the efficiency of vitrimers in rejuvenating out-of-date or improperly cured thermoset prepregs.

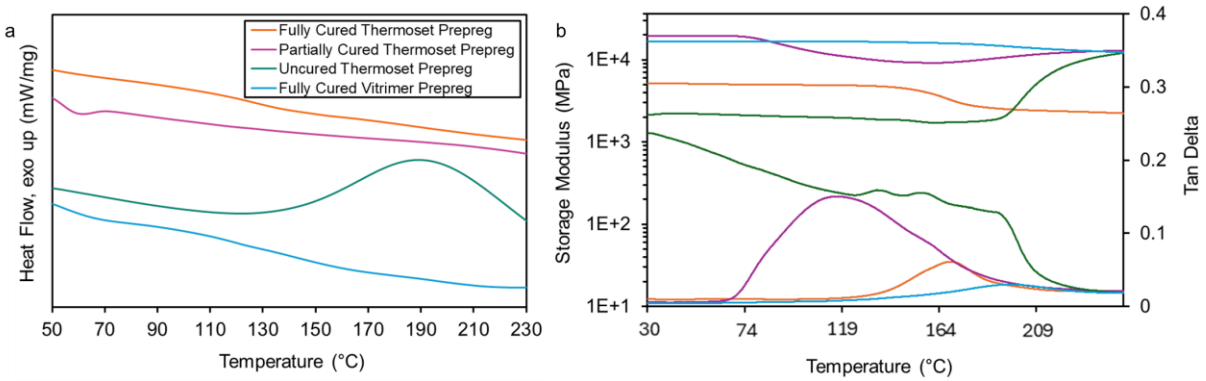

Figure 3: (a) DSC and (b) DMA thermograms of vitrimer and thermoset prepregs showing different stages of initial cure.

To further evaluate the curing states of the thermoset prepregs and the vitrimer single ply, dynamic mechanical analysis was performed, as illustrated in Figure 3. The tan δ and storage modulus curves for the uncured prepreg, Unc VTCF, are characteristic of an uncured network, displaying small tan δ peaks at around 131°C and 149°C. These peaks are followed by an increase in storage modulus, indicative of ongoing curing reactions during the thermal sweep. The partially cured prepreg, Par VTCF, exhibited a broad tan δ curve extending from approximately 60°C to 200°C, suggesting continued curing throughout the analysis along with glass transition. This is further supported by an increase in the storage modulus following the broad peak, similar to the uncured sample, further confirming in situ network formation during the analysis. In contrast, the fully cured prepreg, Ful VTCF, and the vitrimer single ply, *p*VAPI-DETDA, both displayed symmetrical, single tan δ peaks, signifying that their polymer networks were homogeneous and fully cured. Their storage modulus curves reveal a distinct glass transition followed by a rubbery plateau, further confirming their fully cured state. The measured glass transition temperatures, Tg, were 165°C for Ful VTCF and 192°C for *p*VAPI-DETDA. Notably, the ambient storage modulus and Tg of the vitrimer single ply exceeded that of Ful VTCF, suggesting that the selected vitrimer formulation does not compromise—and may even enhance—the thermal and mechanical performance of the resulting composite. This finding supports the suitability of the vitrimer for high-performance composite applications. Additionally, the broader and less intense tan δ peak observed for *p*VAPI-DETDA, compared to Ful VTCF, implies the presence of additional molecular motions at elevated temperatures. This broadening can be attributed to dynamic bond exchange reactions inherent to vitrimers, in addition to conventional segmental motion of the polymer chains. Overall, the DMA results clearly demonstrate the distinct stages of cure in the prepregs under investigation, confirming that the starting materials possess varying degrees of cure, which is essential for this work.

3.2 Fiber-Resin Content of Laminates

To determine the resin content of composites fabricated from alternating layers of the fully cured imine-epoxy vitrimer, *p*VAPI-DETDA, and DGEBA-DETDA prepregs in uncured, partially cured, or fully cured states, thermogravimetric analysis was employed. The analysis was initially performed under oxidative conditions to ensure complete degradation of the resin matrix. At 600°C, the carrier gas was switched from air to nitrogen to inhibit oxidation of the carbon fiber. The mass of the carbon fiber was estimated from the residual mass. All laminates exhibited char yields of approximately 70%, indicating a consistent composition with around 30% resin and 70% fiber content.

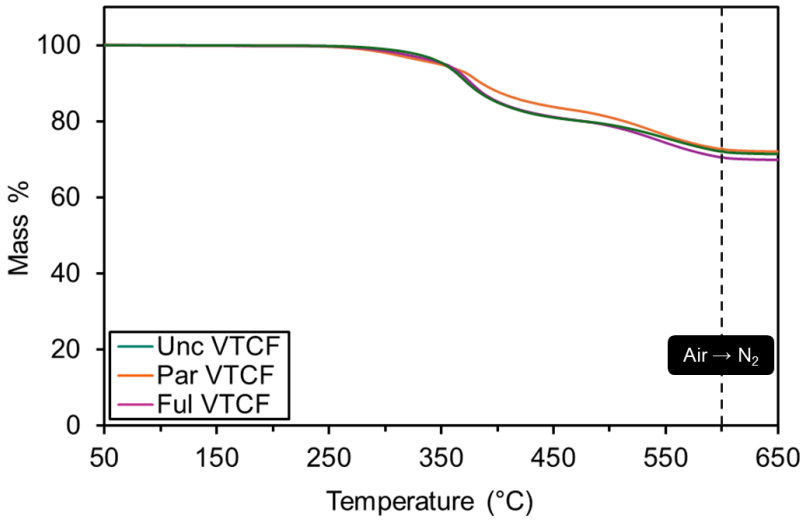

Figure 4: TGA thermograms of laminates from alternating layers of the fully cured vitrimer single plies and thermoset prepregs of different initial cure states under air atmosphere followed by nitrogen atmosphere.

3.3 Thermal Properties of Laminates

To assess how the initial cure state of thermoset prepregs influences the thermal properties of the resulting laminates, differential scanning calorimetry (DSC) was performed. All laminates exhibited DSC thermograms with no significant residual exothermic peaks, confirming complete curing across samples. The measured glass transition temperatures (Tg) were all comparable, around 140°C, indicating that the initial degree of cure of the prepregs had minimal impact on the final thermal properties of the composites. Interestingly, the laminate fabricated from the partially cured prepreg showed the highest Tg among the samples. This result may be attributed to the identical chemical composition of all laminates. Although variations in the initial cure states would typically lead to differences in crosslinking density after final curing, these differences were not reflected in the Tg values. This suggests that the fully cured vitrimer matrix may have facilitated effective network integration and crosslinking, contributing to the recovery or uniformity of thermal properties regardless of the prepreg's initial cure state.

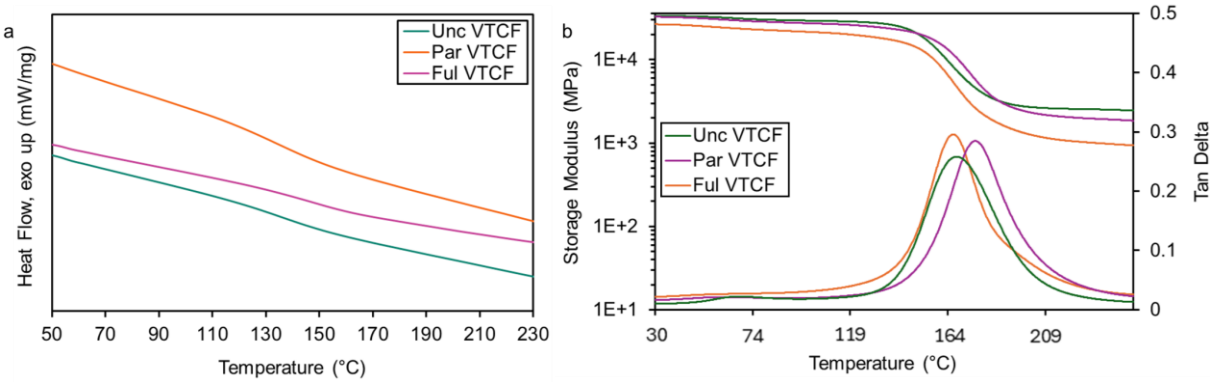

Figure 5: (a) DSC and (b) DMA thermograms of laminates from alternating layers of the fully cured vitrimer single plies and thermoset prepregs of different initial cure states.

To evaluate and compare the mechanical performance and viscoelastic behavior of laminates fabricated from prepregs with varying degrees of cure and vitrimer single plies, dynamic mechanical analysis was performed, as presented in Figure 5. All laminates exhibited symmetrical single peaks in their tan δ curves, indicating homogenous polymer networks and complete curing. The measured glass transition temperatures, Tg, were 169°C for the laminate from uncured prepregs, 177°C for that from partially cured prepregs, and 167°C for that from fully cured prepregs. These Tg values are relatively close, in alignment with differential scanning calorimetry results, and suggest effective integration of the vitrimer into all prepreg states, contributing to enhanced crosslinking. Furthermore, the Tg values lie between those of the neat DGEBA–DETDA and *p*VAPI–DETDA vitrimer single plies, reinforcing successful vitrimer integration.

Notably, the Tg of the laminate from partially cured prepregs was the highest among the three, implying that vitrimers can significantly improve the performance and usability of out-of-date prepregs with residual reactivity. Conversely, the lowest Tg was observed in the laminate from fully cured prepregs, which is consistent with their reduced number of available functional groups for vitrimer bonding, thereby limiting network rejuvenation. These observations highlight the influence of the initial cure state of the prepreg on the ability of the vitrimer to bond and rejuvenate the out-of-date prepreg. This trend is consistent with the storage modulus results. The storage moduli of laminates from uncured and partially cured prepregs were comparable, while the laminate from fully cured prepregs exhibited a lower modulus. Similarly, crosslink density followed the same pattern with the highest crosslink density observed was in the laminate from uncured prepregs, followed by that from partially cured prepregs, and with the lowest in the fully cured group. The comparable storage modulus and crosslinking density between the uncured and partially cured systems indicate that the presence of available reactive groups is critical for vitrimer integration. Moreover, this shows that a vitrimer single

ply is effective in restoring the mechanical properties and thermal properties of out-of-date prepregs without significant performance loss.

The effect of the prepreg cure state on the thermal stability and degradation behavior of resulting laminates was assessed with thermogravimetric analysis (TGA) under both non-oxidative and oxidative conditions, as illustrated in Figure 6. All laminates, prepared by alternating layers of fully cured imine-epoxy vitrimer single plies and DGEBA-DETDA prepregs in uncured, partially cured, or fully cured states, exhibit unimodal degradation within the range of 350–450°C. This degradation is primarily attributed to the thermolytic cleavage of C–N and C–O bonds. The onset degradation temperatures were measured to be 351°C, 353°C, and 359°C for laminates containing uncured, partially cured, and fully cured prepregs, respectively. A similar trend is observed in the maximum degradation temperatures, i.e., 375°C, 378°C, and 387°C for laminates from uncured, partially cured, and fully cured prepregs, respectively. The narrow range of these values suggests that the initial cure state of the prepregs has only a minor influence on the thermal stability and degradation behavior of the resulting composites. These properties are predominantly dictated by the chemical composition and molecular structure. Since all composites were fabricated from the same epoxy and hardener systems in fixed ratios, the observed thermal behaviors are consistent. Nonetheless, the observed differences align with the curing state, where a higher initial degree of cure correlates with slightly elevated onset and peak degradation temperatures. Laminates incorporating fully cured prepregs demonstrated the highest thermal stability, followed by those with partially cured and uncured prepregs. These elevated degradation temperatures which are significantly above typical service conditions indicate excellent thermal stability, affirming the suitability of these materials for high-performance structural applications. Notably, the degradation temperatures of the composites are substantially higher than those of the pure vitrimers, suggesting that interlayering with conventional high-performance thermosets can enhance the thermal stability of vitrimer-based systems. In terms of char yield, all laminates show values around 70%, indicating a resin content of approximately 30%. This consistency confirms that comparisons reflect the effect of cure state rather than differences in resin loading. In conclusion, the cure state of the out-of-date prepregs has only a minor impact on the thermal degradation behavior of the composites under non-oxidative environments. Even in laminates composed of fully cured prepregs and vitrimer single plies, degradation temperatures remain around 380 °C, reinforcing their potential for high-performance applications.

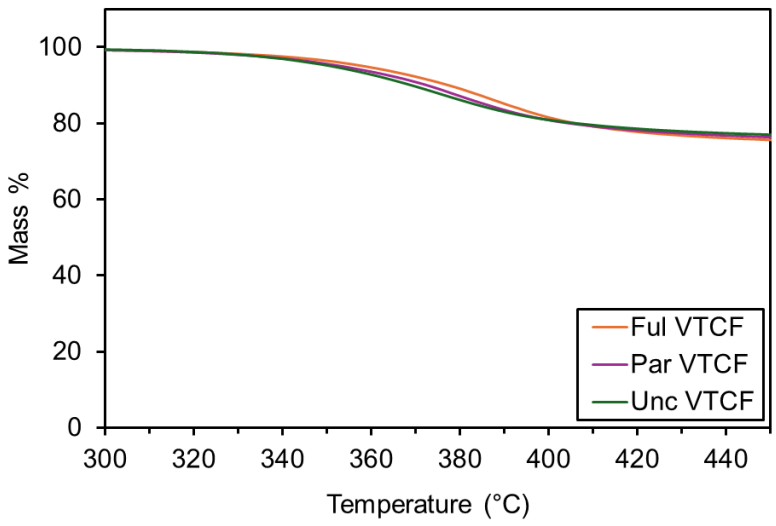

Figure 6: TGA thermograms of laminates from alternating layers of the fully cured vitrimer single plies and thermoset prepregs of different initial cure states under nitrogen atmosphere.

Under oxidative conditions as shown in Figure 4, the thermograms of the laminates composed of alternating layers of fully cured imine-epoxy vitrimer single plies and uncured prepregs display an initial unimodal degradation between 350–450°C, primarily resulting from the thermolytic cleavage of

C–N and C–O bonds just like under non-oxidative conditions. In contrast, laminates incorporating partially or fully cured prepregs exhibit bimodal degradation within the 300–450°C range. This bimodal behavior suggests that oxidative conditions amplify the influence of voids and interfacial adhesion differences introduced during laminate fabrication. The presence of partially or fully cured prepregs likely leads to poorer adhesion, increased void formation, or both. The onset degradation temperatures are 353°C, 354°C, and 349°C for laminates containing uncured, partially cured, and fully cured prepregs, respectively. Maximum degradation temperatures are 370°C, 375°C, and 385°C for laminates containing uncured, partially cured, and fully cured prepregs, respectively. While the overall trends are consistent with those observed under non-oxidative conditions, the laminate derived from fully cured prepregs displays the lowest onset degradation temperature. This indicates that, under oxidative conditions, the influence of defects such as poor interfacial adhesion and voids is more pronounced. Nevertheless, the difference in onset degradation temperatures compared to laminates prepared from uncured and partially cured prepregs remains relatively minor. A secondary degradation peak appears around 550°C in all samples, corresponding to the oxidative decomposition of residues formed by the epoxy networks which is not observed under non-oxidative conditions. To estimate resin content, the carrier gas was switched from air to nitrogen at 600°C to prevent oxidation of the carbon fiber. All laminates exhibited char yields near 70%, indicating a consistent resin content of approximately 30% and confirming that thermal behavior differences arise from prepreg cure state rather than formulation differences. In summary, the cure state of aged prepregs has only a minor effect on the thermal degradation behavior and stability of the laminates under both oxidative and inert conditions. Even laminates composed of fully cured prepregs and vitrimer plies degrade at high temperatures, 370–385°C, reinforcing their potential for high-performance structural applications.

3.4 Mechanical Properties of Laminates

The mechanical performance of composites fabricated from alternating layers of imine-epoxy vitrimer single plies and DGEBA-DETDA prepregs that were initially uncured, partially cured, or fully cured were evaluated via three-point bending tests, as illustrated in Figure 7. All laminates exhibited brittle failure, as indicated by the abrupt fracture observed in the stress–strain curves.

The flexural moduli for laminates fabricated from uncured, partially cured, and fully cured prepregs were 105 GPa, 105 GPa, and 98 GPa, respectively. These values are similar in value, suggesting that the modulus is predominantly dictated by the carbon fiber reinforcement, given its significantly higher stiffness relative to the matrix materials. Both the vitrimer and thermoset matrices are inherently stiff materials, which also contributes to the consistently high modulus values. The identical moduli of the laminates from uncured and partially cured prepregs, and their slightly higher values compared to those from fully cured prepregs, indicate that the vitrimer is highly effective in restoring or maintaining mechanical performance across varying cure states. When functional groups are available, as in the uncured and partially cured states, the vitrimer can form covalent bonds across the interface through transimination with unreacted amine groups, preserving interfacial integrity and mechanical performance. The slightly lower modulus observed in the laminate from fully cured prepregs suggests some reduction in adhesion efficiency due to limited availability of functional groups; however, the value remains high, implying that good bonding was still achieved through interfacial chain diffusion and entanglement by the vitrimer. Interlaminar adhesion plays a critical role in the mechanical performance of fiber-reinforced composites. Strong bonding between adjacent plies enables efficient stress transfer and uniform load distribution during bending. In contrast, poor interfacial adhesion can result in stress concentration at ply interfaces, leading to delamination, premature cracking, and failure under flexural loads. Insufficient bonding compromises load transfer, causing reductions in both flexural strength and stiffness.

The flexural strengths of the laminates from uncured, partially cured, and fully cured prepregs were 1.3 GPa, 1.1 GPa, and 0.7 GPa, respectively. These results confirm that the vitrimer was able to bond effectively across all prepreg conditions, including the fully cured state. The comparable strengths between laminates from uncured and partially cured prepregs suggest that the vitrimer successfully

underwent transimination reactions with unreacted amine groups at the interface, promoting strong interfacial bonding. The reduced strength observed in the laminate from fully cured prepregs likely arises from limited chemical reactivity due to the scarcity of available functional groups. In this case, vitrimer adhesion may rely more heavily on physical chain diffusion and entanglement as well as secondary interactions across the interface. Despite this limitation, a strength of 0.7 GPa was achieved, indicating that the vitrimer can still form mechanically robust interfaces with fully cured thermosets. Moreover, the presence of voids can further compromise mechanical performance by serving as stress concentrators, reducing the effective load-bearing volume of the composite. Voids typically arise during fabrication due to limited resin flow, particularly when bonding to fully cured prepregs. These defects reduce flexural strength and stiffness and contribute to early crack initiation and propagation during loading. Hence, the effects of differences in initial cure states of the prepregs resulting in differences in adhesion efficiency and void formation likelihood are more pronounced in the measured values of the flexural strength compared to the flexural modulus.

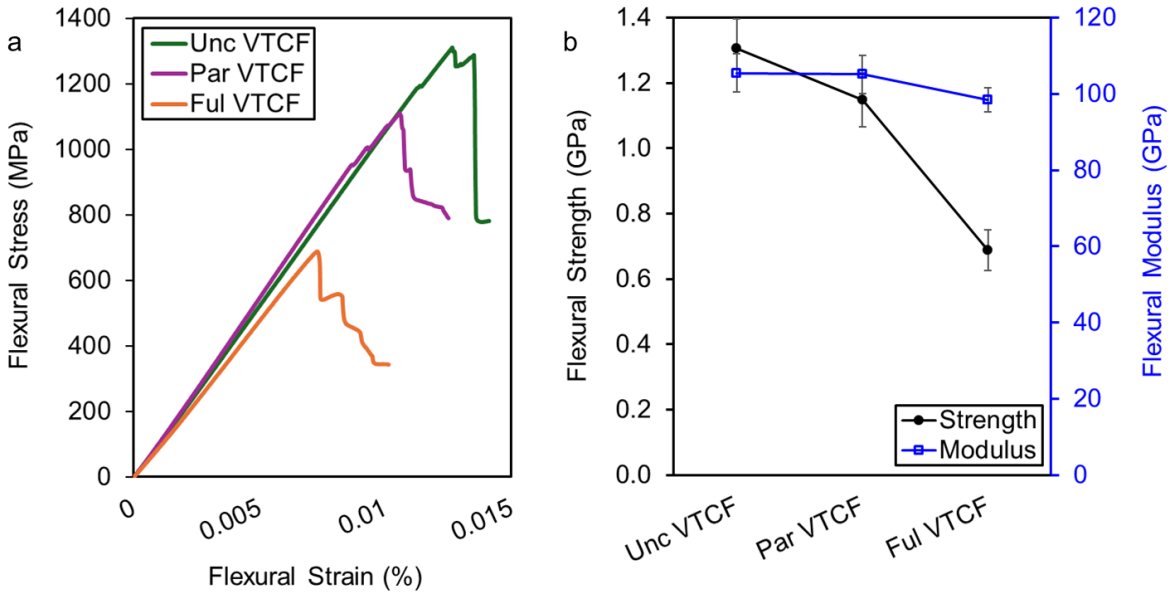

Figure 7: (a) Representative flexural stress-strain curves, (b) flexural strength and modulus of laminates from alternating layers of the fully cured vitrimer single plies and thermoset prepregs of different initial cure states.

Importantly, the mechanical performance of the laminate fabricated from partially cured prepregs is nearly equivalent to that from fresh uncured prepregs. This finding underscores the capacity of vitrimers to rejuvenate prepregs that have undergone partial cure and become boardy. It highlights the potential of imine-based vitrimers in restoring and reprocessing out-of-date prepregs for high-performance structural applications. Additionally, the initial cure state of the prepreg critically influences the bonding efficacy of the vitrimer and the extent of void formation, both of which significantly impact the resulting mechanical properties. For high-performance carbon fiber composites, optimizing interlaminar adhesion and minimizing void content are essential to maximizing flexural strength, stiffness, and toughness. Weak bonding or high void density can severely degrade performance, underscoring the importance of interfacial engineering when integrating vitrimer systems with thermoset prepregs.

3.5 Microscopy of Laminates

To evaluate the effect of initial cure states on the consolidation of the layers, optical images were obtained. Microscopy shows good consolidation in all samples. However, voids are present. The number of voids also increased as the initial cure state was more towards full curing. This could also

be the reason for the lower mechanical properties observed. But adhesion between the vitrimer and thermoset prepregs can be seen from optical images even if the prepreg was initially fully cured. This indicates that vitrimers can adhere to thermosets at different initial stages of cure. They are able to diffuse and entangle across the interface aside from covalent interactions with unreacted groups at the surface.

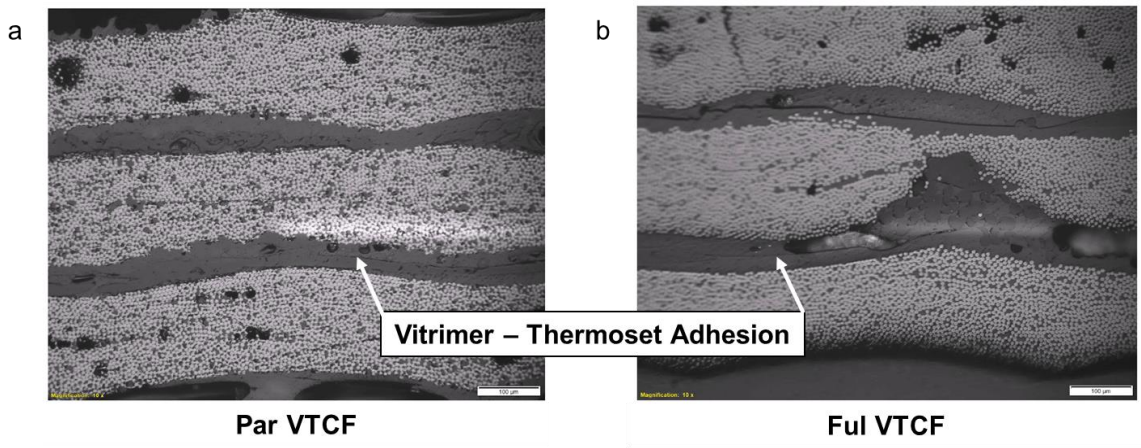

Figure 8: Optical images of cross-sections of the carbon fibre composites fabricated from alternating layers of the fully cured vitrimer single plies and (a) partially cured or (b) fully cured thermoset prepregs.

4 CONCLUSIONS

In this study, we leveraged the inherent weldability of fully cured imine-epoxy vitrimers and assessed their effectiveness in rejuvenating improperly cured or out-of-date thermoset prepregs. Traditional thermoset prepregs require refrigerated storage and transport, making logistics complex and increasing material waste due to spoilage during power outages. To simulate these conditions, thermoset prepregs from diglycidyl ether of bisphenol A, a commercially available resin, were pre-cured at varying temperatures to represent different degrees of initial cure, then interleaved them with fully cured vitrimer carbon fiber single plies. The resulting composites were evaluated for their thermal and mechanical properties. The results demonstrate that the initial cure state of the thermoset prepregs plays a critical role in dictating the resulting laminate properties. Laminates made with partially cured prepregs, i.e., cured at 80°C, exhibited thermal and mechanical properties comparable to those made with freshly prepared prepregs. This indicates that the presence of residual reactive groups such as unreacted amines allows for transimination reactions at the interface, forming covalent bonds between the vitrimer and thermoset, and near-complete property recovery. In contrast, prepregs cured at 150°C, which are fully crosslinked and lack functional groups capable of undergoing transimination, resulted in laminates with reduced mechanical properties. In this case, bonding was limited to physical mechanisms such as interfacial chain diffusion and entanglement. Nevertheless, microscopy confirmed ply adhesion, and thermal properties remained comparable with those of laminates made from fresh or partially cured prepregs, indicating partial recovery and successful consolidation. These findings highlight the critical role of interfacial chemistry specifically the availability of dynamic covalent bonding sites in determining the efficiency of vitrimer-assisted rejuvenation. Fully cured vitrimers can still adhere to fully cured thermoset prepregs and provide property recovery to a notable extent, even in the absence of covalent bonding. This capability presents a promising strategy to extend the usability of out-of-date prepregs, reduce material waste, and alleviate the challenges associated with refrigerated transport in composites manufacturing.

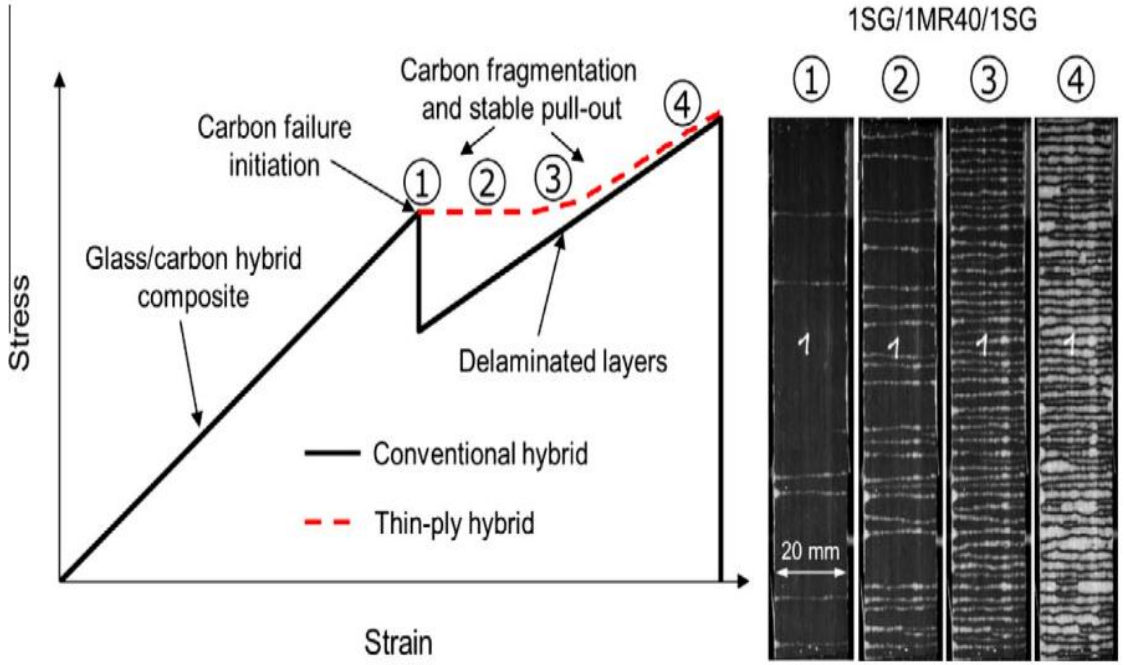
NEXTCOMP

Aim: Develop a new generation of hierarchical composite materials to improve the compressive performance of fibre-reinforced composites.

Challenge: The longitudinal compressive strength of fibre-reinforced composites can be as low as half of their longitudinal tensile strength.

A collaboration between the University of Bristol and Imperial College London to address the challenges of longitudinal compression of composites.

Hierarchical problem



Modified from sources including; ST Pinho et al., On longitudinal compressive failure of carbon-fibre-reinforced polymer: from unidirectional to woven, and from virgin to recycled, *Philosophical Transitions of the Royal Society A*, Vol. 370, Issue 1965, 2012, 1871-1895; R Gutkin et al., On the transition from shear-driven fibre compressive failure to fibre kinking in notched CFRP laminates under longitudinal compression, *Composites Science and Technology*, Vol. 70, Issue 8, 2010, 1223-1231.

CONCLUSION

High modulus fibres can be used to increase the initial stiffness of fibre reinforced composite laminates.

Hybridization of M55J fibres demonstrates an increase in the compressive performance.

The failure mechanism shows compressive fragmentation of M55J fibres that eventually lead to delamination followed by catastrophic failure of the hybrid laminate.

The compressive strain of M55J shows a knee point at 0.49% against the literature's baseline value of 0.31% indicating an increase in the compressive performance.

Increasing M55J thickness reduces the maximum compressive strains of the hybrid laminate.

Carbon/carbon hybrid laminates show higher failure stresses and lower failure strains than glass/carbon hybrids.

ABSTRACT

In this study we propose a novel localized hybridization concept to enhance longitudinal compressive performance of composites containing open holes. The concept involves hybridization in the form of selective placement of individual boron fibres locally near the vicinity of a hole within 0° plies of a quasi-isotropic laminate made from a carbon-epoxy prepreg. The manufacturing of these novel hybrid laminates is realized using an in-house developed fibre placement fixture to precisely place the boron fibres at the required locations. The mechanical performance of the manufactured concept is benchmarked against a non-hybrid baseline laminate under quasi-static compressive loading following the ASTMD6484 standard. The proposed hybridisation strategy results in a significant (≈35%) increase in compressive strength over the corresponding baseline laminate. The improvement in compressive performance can be attributed to changes in failure mechanisms due to the presence of the boron fibres within the hybrid laminates, as revealed by post-test failure analysis (using X-ray scans and scanning electron microscopy) and finite element simulations. Our research demonstrates the success of this first of its kind locally hybrid design aimed at improving open hole compressive performance.

1 INTRODUCTION

Composite structures often include features like holes to serve various operational purposes, including cable or pipeline routing, fastener installations, and other functional requirements. However, these holes typically lead to localized stress concentrations [1]. Under compressive loading, these stress concentrations may result in microbuckling and unstable kink band growth near the hole edge, leading to catastrophic failure [2,3]. Hence, to improve the overall load-bearing capacity of such structures, it becomes crucial to devise a strategy to delay or suppress the progression of damage arising in the form of kink band growth from the hole.

In a previous study, by using commercial boron-carbon hybrid prepregs, Garulli et al. [4] observed that, for an edge-notched laminate under compression, both in-plane and out-of-plane kinking in carbon fibres can be arrested by the presence of boron fibres [4]. When the propagating kink band reaches a boron fibre, damage is interrupted and deflected by formation of a longitudinal split at the boron-epoxy interface. This work aims to utilize this deflection mechanism by developing an open hole-focused design wherein a patch of boron fibres is placed in accordance with the localized stress distribution around the hole.

The process involves hybridization of 0° plies of a quasi-isotropic carbon epoxy laminate by placing individual boron fibres aligned at 0° direction selectively at regular intervals in the transverse direction from the hole edge as shown in Fig. 1. To realize this, an in-house manufacturing procedure has been developed. The performance of hybrid laminates is benchmarked against a non-hybrid baseline laminate configuration under open hole compression as per ASTM D6484 test standard [5]. This study provides a practical localized approach for designers to enhance compressive strength near structural features like open holes, without affecting the overall global structural performance.

2 CONCEPT DESIGN, MATERIALS AND MANUFACTURING

2.1 Concept Design

In this work, we aim at improving the open hole compressive performance of a quasi-isotropic laminate ($[45_{10}/-45_{10}/0_{10}/90_{10}]_{3S}$) by embedding boron fibres within the block of 0_{10} plies resulting in a hybrid laminate ($[45_{10}/-45_{10}/0_{\text{Hybrid}}/90_{10}]_{3S}$) Each 0_{Hybrid} ply-block comprises of boron fibres embedded in the centre of 10 ultrathin carbon epoxy plies. However, the length of the boron fibres is relatively short compared to the overall length of the carbon fibres in 0° plies. Fig. 1 presents a schematic representation of 0° plies of a baseline and hybrid laminate samples tested in this work. The presence of the boron fibres is restricted to a local region in the vicinity of the hole resulting in a localized hybrid ply configuration. Fig. 1(c) presents a close-up view of the region near the hole for a hybrid sample showing distribution of the boron fibres. The variation in length of boron fibres follows the profile of variation of longitudinal stress with respect to the transverse distance from the edge of the hole.

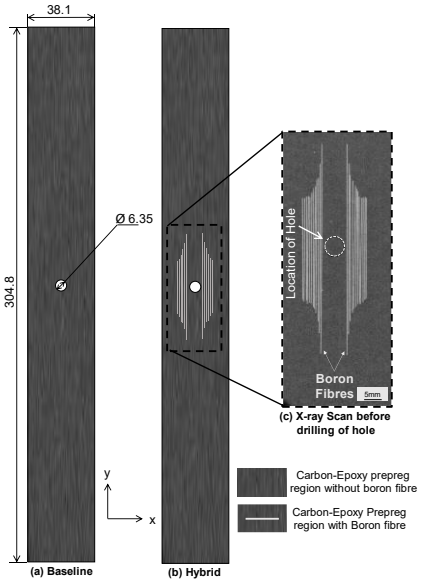

Figure 1: Schematic representation a 0° ply in the open hole specimens used in this study (a) baseline (non-hybrid) specimen (b) hybrid specimen (c) X-ray scan obtained during manufacturing stage, showing distribution of boron fibres within one hybrid 0° ply (note-figure (a) and (b) not to scale, all dimensions are in mm).

2.2 Materials

The required laminates were manufactured using a 15 gsm MR70/TP402 prepreg. The properties of this material have been reported by Garulli et al. [6]. For hybridization, 4-mil boron fibres supplied by Speciality Materials have been used. Boron fibres exhibit a unique combination of high compressive strength, high modulus and a large diameter [7]. The key material properties of boron fibres are presented in Table 1.

Property	Units	4-mil boron fibre
Diameter	µm	102
Density	g/cc	2.61
Thermal Expansion	PPM/°C	4.5
Tensile Strength	MPa	4000
Tensile Modulus	GPa	428
Compression Strength	MPa	>6000
Hardness	Knoop	3200

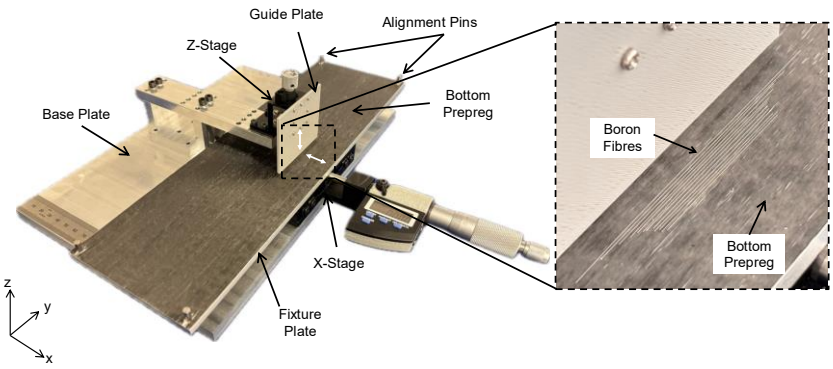

Table 1: Properties of the boron fibre used in this work [7].

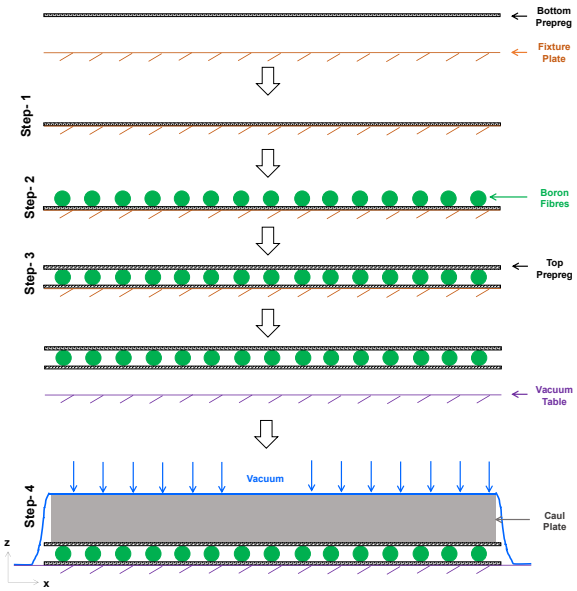
2.3 Manufacturing



The manufacturing of the hybrid laminates was performed by a procedure developed in-house specifically for this study. As can be seen in Fig.1 (c), the hybrid plies contain individual boron fibres of different lengths placed at specific locations in the vicinity of the hole. This requirement led to the development of an in-house fibre placement fixture as shown in Fig. 2 (a). The overview of the whole process is presented in the form of a schematic diagram in Fig. 2 (b). The first step involves placing one ply of MR70/TP402 prepreg over the bottom plate of the fixture. The next step (Step-2 in schematic) involves placing the boron fibres one by one at required locations on the bottom prepreg. The guide plate provides a straight edge to align boron fibres parallel to the 0° direction (y-direction in Fig. 2(a)). The pitch between the boron fibres is controlled by moving the bottom plate with respect to the guide plate in x-direction. The bottom plate of the fixture is mounted over a linear x-stage which allows relative motion between the guide plate and the bottom plate in the x-direction as shown in Fig. 2(a). Once all

the required fibres are placed on the bottom prepreg, the guide plate along with the z-stage is removed from the fixture and another prepreg ply laid up on top of the previously arranged boron fibres and bottom prepreg, as shown in Step-3 in the schematic. Thereafter, the stack containing the two prepreg layers sandwiching the array of boron fibres between them, is brought onto a vacuum table and is subjected to vacuum for 30 minutes (Step-4). A caul plate is used during this step as shown in Step-4. Thereafter, the whole process (except Step-2) is repeated until four more top and bottom prepreg plies are added to the hybrid ply block.

In the end, one hybrid ply block comprises of a total of ten MR70/TP402 plies containing one array of boron fibres embedded in the middle. This one hybrid ply-block is represented as 0_{Hybrid} in the overall stacking sequence of $[45_{10}/-45_{10}/0_{\text{Hybrid}}/90_{10}]_{3S}$. In a similar way a total of six such hybrid 0° ply blocks are prepared and a final layup of $[45_{10}/-45_{10}/0_{\text{Hybrid}}/90_{10}]_{3S}$ is stacked. The curing of the layups is performed as per the curing parameters specified by manufacturer's datasheet [8]. The baseline laminates with stacking sequence $[45_{10}/-45_{10}/0_{10}/90_{10}]_{3S}$ were manufactured using similar manufacturing conditions except the process for the baseline laminates does not require the steps mentioned in Fig. 2 (b) due to the absence of boron fibres. The test specimens were machined out of the cured panels and the holes were drilled and reamed carefully to final dimensions as per ASTM D6484 [5]. The nominal dimensions of the specimens are shown in the schematic in Fig. 1 (a).

(a)

(b)

Figure 2: (a) Image of the fibre placement fixture used
(b) Schematic representation of the steps involved in preparing a hybrid ply;

3 TESTING AND MODELLING

3.1 Testing Methodology

The proposed hybrid concept was assessed against the baseline configuration by testing samples containing open holes subjected to compressive loading following the procedure described in ASTM D6484 [5]. A total of five samples for each configuration were tested. The load was introduced at a constant crosshead displacement rate of 1 mm/min. The test was stopped once a significant drop in load was observed. During the test, digital image correlation was employed to study development of strains in the vicinity of the hole. Fig. 3 shows an image of the test setup showing the main components. After the test, the samples were carefully removed from the test fixture. For the purpose of visual examination, digital photographs of tested specimens were obtained using a flatbed scanner. Thereafter, representative samples from both the baseline and hybrid configuration were further examined using two-dimensional X-ray scans. The specimens were then carefully dissected along the fracture path to examine the fracture surface using a scanning electron microscope (SEM).

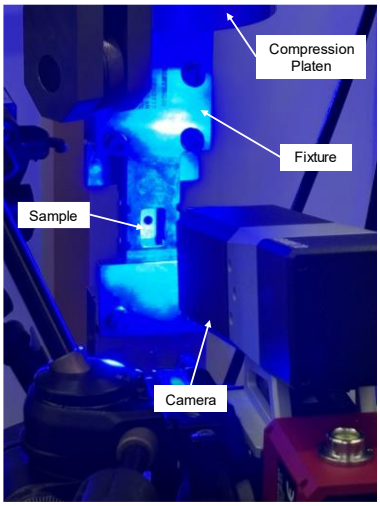


Figure 3: Experimental setup used for open hole compression testing using ASTM D6484.

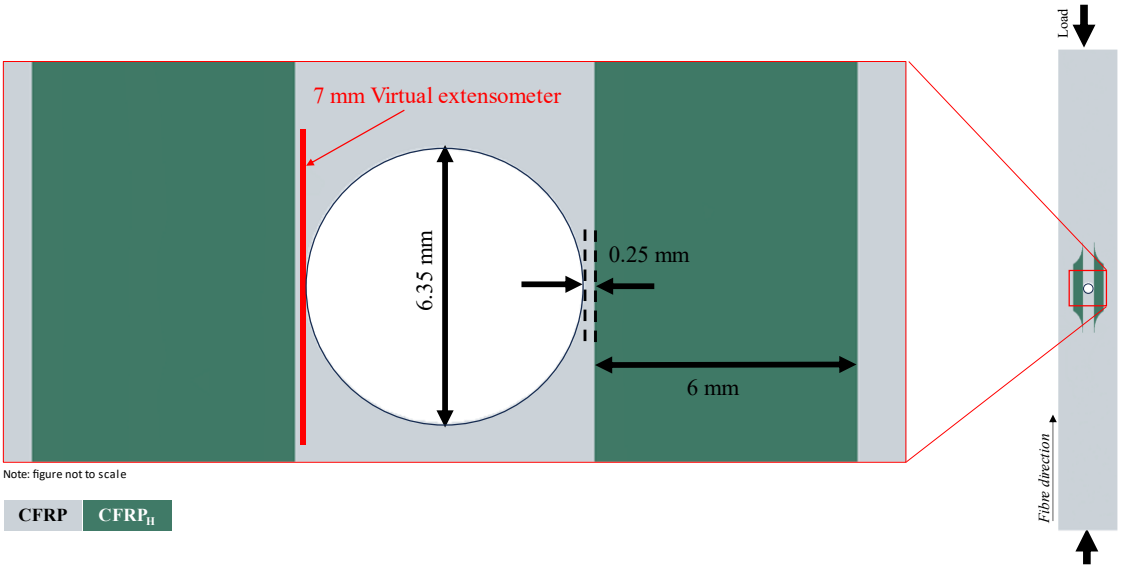
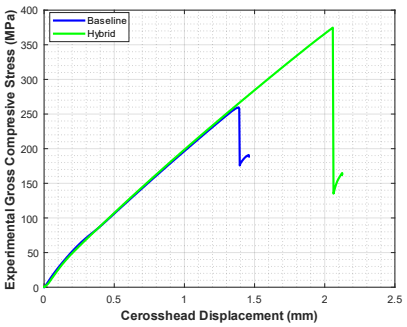
3.2 Finite Element (FE) Modelling

A mesoscale modelling approach was used to understand the local stiffening effects due to the presence of additional reinforcement in the form of boron fibres around the hole. Two specimen models were generated: baseline and hybridised. Both specimen models follow the experimental specimen's dimensions as shown in Figs. 1 (a) and 4. The baseline specimen model consisted entirely of a carbon fibre reinforced polymer (CFRP) with uniform material properties. In the hybridised specimen model, the position, size, and shape of the hybrid regions ($CFRP_H$) were defined according to the boron fibre placement used in the experiments (Section 2.1). Both CFRP and $CFRP_H$ regions were modelled as homogeneous and linear-elastic within the specimen models for computational efficiency. The numerical simulation was conducted using Abaqus 2024 [9]; a uniform compression displacement (maximum displacement = 3 mm) was applied at the transverse edge of the specimen models. Implicit static analysis was used. Throughout the numerical simulation of each specimen model, the local strain ε_y^{local} was measured by a 7 mm virtual extensometer at the edge of the hole as shown in Fig. 4. The data obtained from this virtual extensometer was compared with the data obtained from a comparable 7 mm virtual extensometer used in processing DIC data, to obtain experimental strain data.





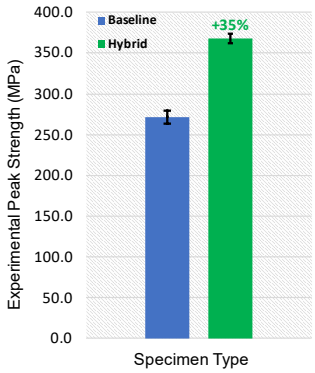


Figure 4: FE model geometry (0° ply) for the hybridised specimen]

4 RESULTS

The experimental gross compressive stress-crosshead displacement plots for a representative hybrid and a baseline sample are shown in Fig. 5 (a). It can be observed that both laminate configurations follow a similar loading trace with a catastrophic drop in load towards the end of the test. However, the stress and displacement at which this drop occurs is significantly different. Fig. 5 (b) shows a bar graph of average gross compressive strength of five samples under each configuration (Baseline and Hybrid). It is observed that the hybrid samples exhibit close to 35% higher compressive strength compared to the baseline samples. To understand the influence on localized stiffness around hole due to presence of boron fibres, the local strain from DIC and the FE model are plotted against the gross compressive stress for the same representative baseline and hybrid samples in Fig. 6 (a). These results from both the model and experiments indicate an increase in local stiffness in the vicinity of the hole. Fig 6 (b) shows a corresponding change in local compressive modulus for both laminates. Further, a bar graph showing difference in stress concentration at the edge of the hole within 0° plies of both baseline and hybrid configurations is shown in Fig. 6(c).

(a)

(b)

Figure 5: (a) Trace of experimental compressive stress with respect to crosshead displacement for a representative hybrid and baseline sample (b) Bar graph showing the average gross strength observed experimentally in each laminate configuration. Note- The error bars in Fig. (b) indicate a ± 1 standard deviation interval.

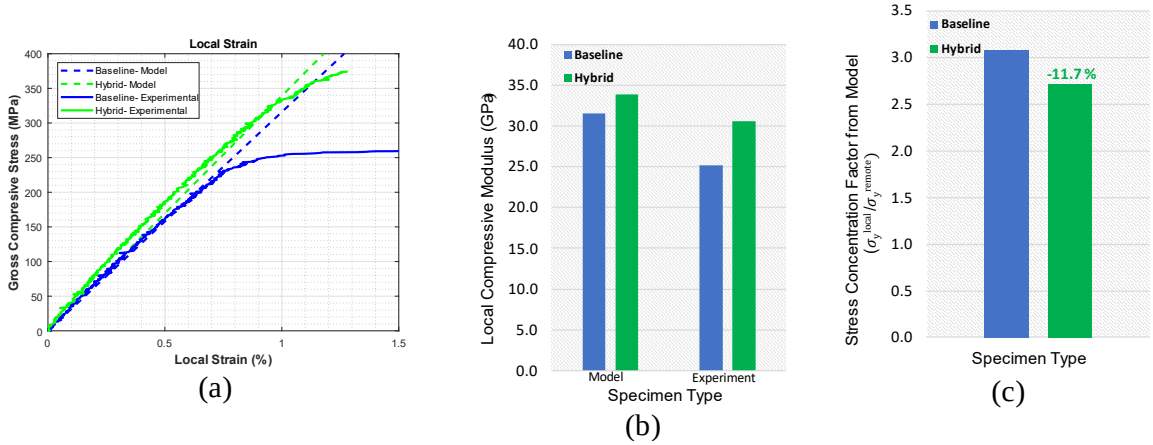

Figure 6: (a) Trace of gross compressive stress with respect to local strain for baseline and hybrid configurations using a virtual extensometer near the edge of the hole obtained from the mesoscale FE model and experiments (b) Bar graph showing the localized compressive modulus observed both experimentally and with the mesoscale FE model in each laminate (c) Bar graph showing the stress concentration factor at the edge of the hole observed with the mesoscale FE model in each laminate

The post-test X-ray scans are shown in Fig.7. These scans reveal a difference in the extent of the spread of damage between baseline and hybrid configurations. It can be noted that the damage in the longitudinal direction is more widespread in case of hybrid samples, suggesting a difference in the internal failure mechanisms. Fig. 8 shows the SEM micrographs obtained after dissecting the samples along the fracture path growing transverse to the loading.

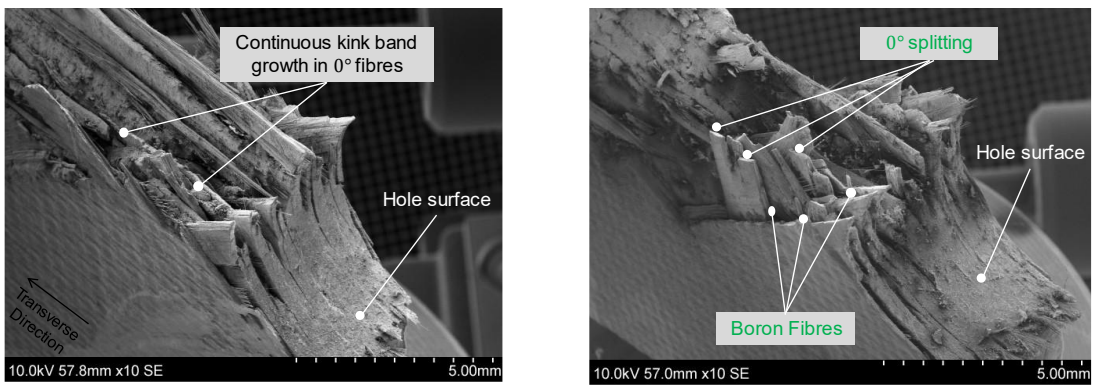

Figure 8: Post OHC SEM micrograph of (a) Baseline (b) Hybrid samples

5 DISCUSSIONS

The results presented in Section 4 show that the proposed local hybridization design about an open hole in quasi-isotropic CFRP laminates was successful in significantly improving the compressive performance. The increase in compressive strength of the hybrid laminate when compared to the baseline one was close to 35%. This improvement can be attributed partially to the reduction in the stress concentration at the hole edge (Fig. 6(c)) and partly to the formation of longitudinal splits within the 0° ply in the case of the hybrid laminates (Fig. 8 (b)). These longitudinal splits interrupt the unstable progression of kink bands in the transverse direction. This phenomenon is similar to the one reported by Garulli et al. [4] where they studied the damage mechanisms in boron-carbon hybrid laminates under compressive loading for edge-notched specimens. In fact, the presence of the longitudinal splits in the hybrid laminates leads to the formation of isolated strips of carbon fibres. This isolation of strips of carbon fibres results in a delay of the unstable kink band growth in a 0° ply, thus increasing the overall load and displacement (Fig. 5 (a)) at which catastrophic failure occurs. The presence of boron fibres (Fig. 6(b)) influences the local stiffness as observed by stress-local strain plots obtain from DIC and the FE model. On the other hand, the baseline samples exhibited evidence of continuous kink band growth (Fig. 8(a)), resulting in catastrophic failure at a lower load.

6 CONCLUSIONS

This research demonstrates the potential to increase the compressive strength of CFRP laminates structural features using a first-of-its-kind tailored strategy exploiting boron fibres to stop kink band propagation. Ultra-thin CFRP prepreg plies were reinforced locally using boron fibres. This has been achieved developing an in-situ manufacturing process for individual boron-fibre placement locally within the plies. The performance of hybrid boron-carbon laminates was assessed against baseline laminates under open-hole compression. The hybrid laminates exhibited an improvement of by 35% open hole compressive strength compared to baseline non-hybrid quasi-isotropic laminates.

In conclusion, this study underscores the efficacy of a localized hybridization approach in improving the compressive performance with insignificant influence on stiffness and weight of the laminates, thus offering a practical localized solution for designers to improve compressive strength near structural details such as open hole features without affecting the overall structure at a global level.

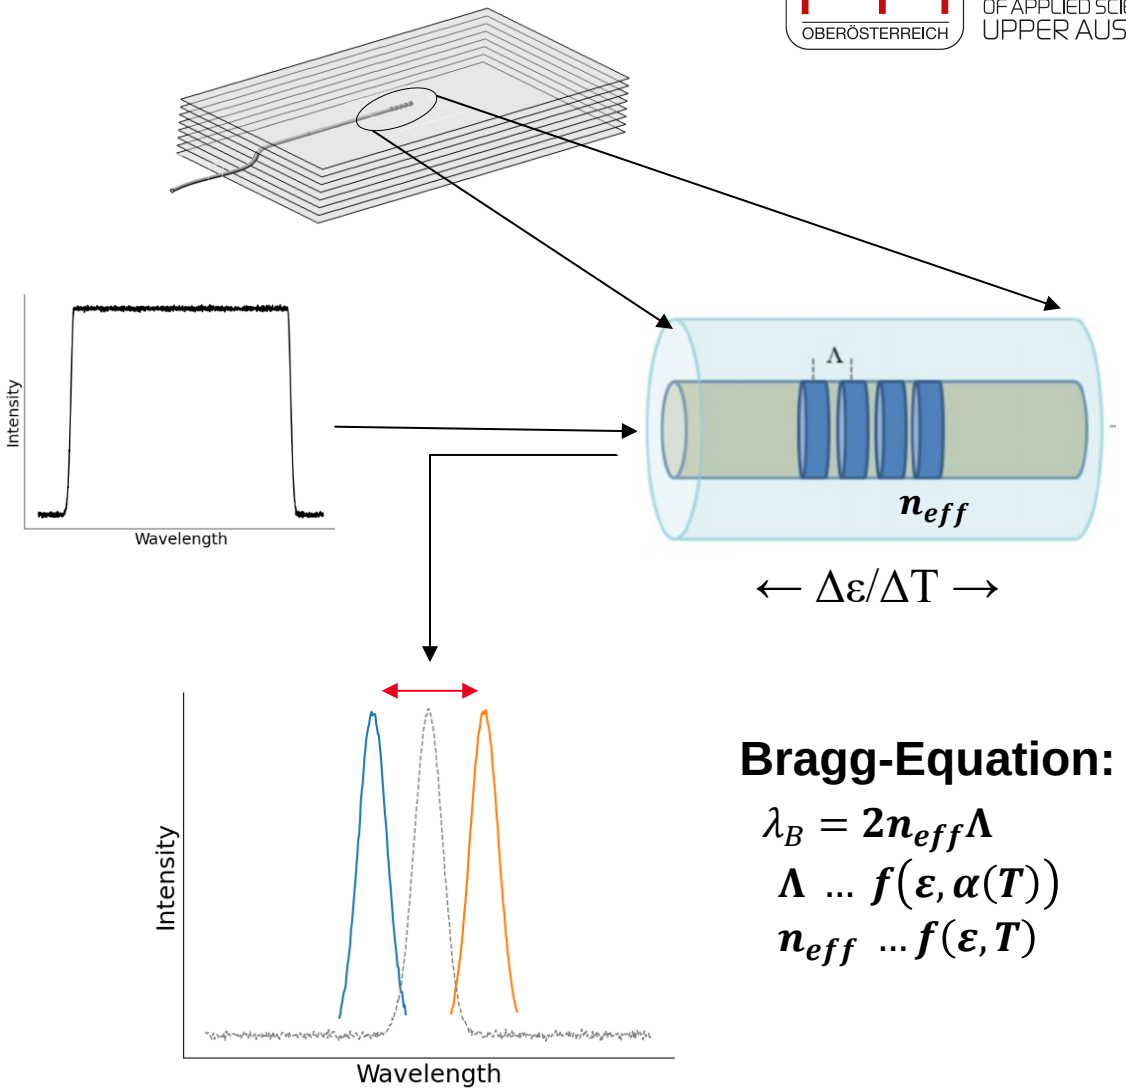
FBG Introduction



- **grating in the core of an optical fiber**
- **Small size ⌀150 µm, high sensitivity**
- **Acts as a wavelength-selective filter/mirror**
- **Sensitive to strain and temperature**
- **Wavelength shift:**

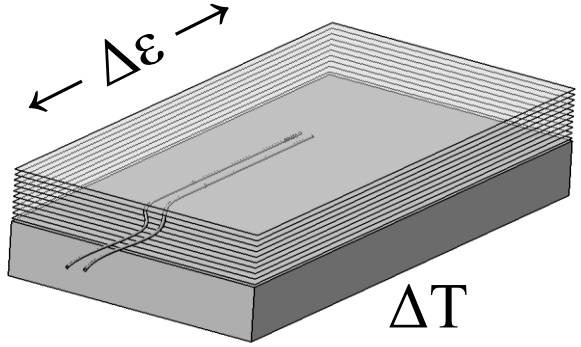
$$\Delta\lambda_B = (1 - p_e)\Delta\varepsilon + (\alpha + \zeta)\Delta T$$

p_e … photo − elastic constant

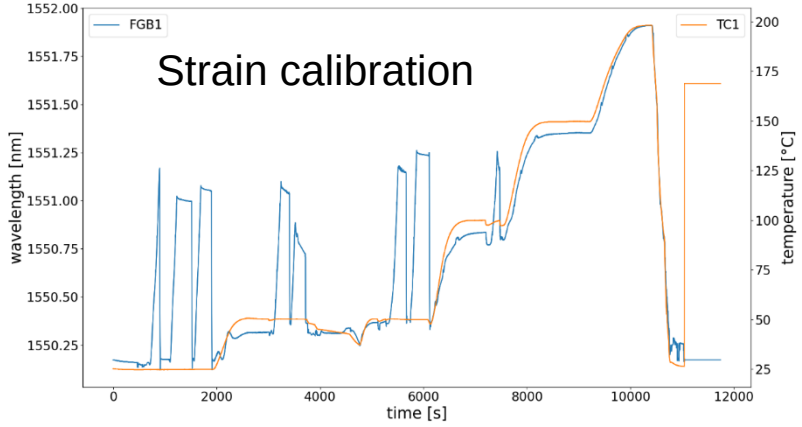
α … coefficient of thermal expansion

ζ … thermo − optic coefficient

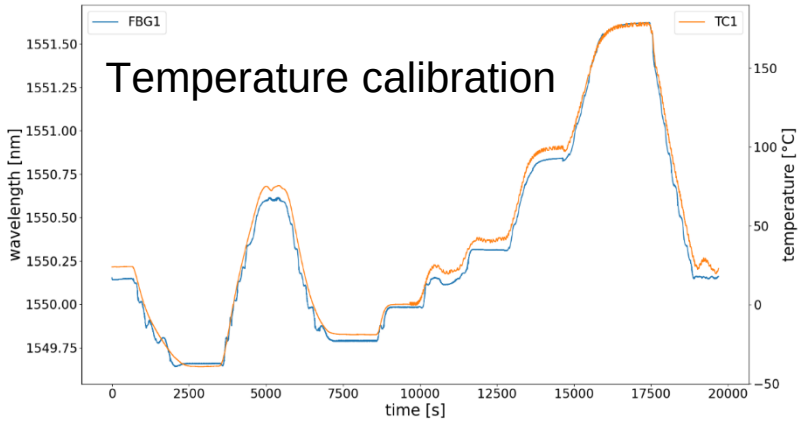
Bragg-Equation:



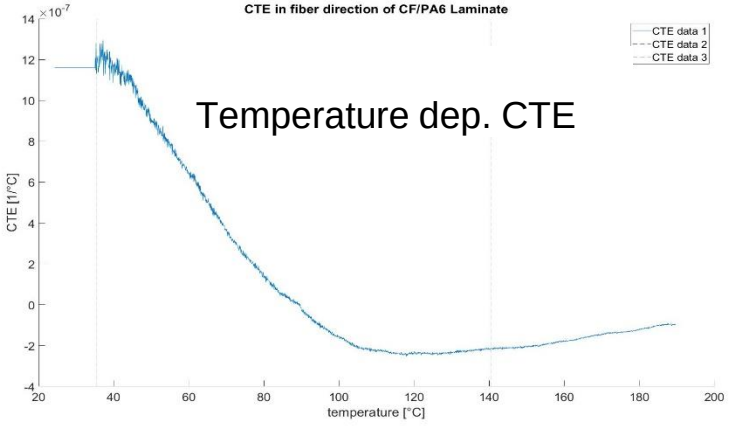
$\lambda_B = 2n_{eff}\Lambda$



Λ … $f(\varepsilon, \alpha(T))$

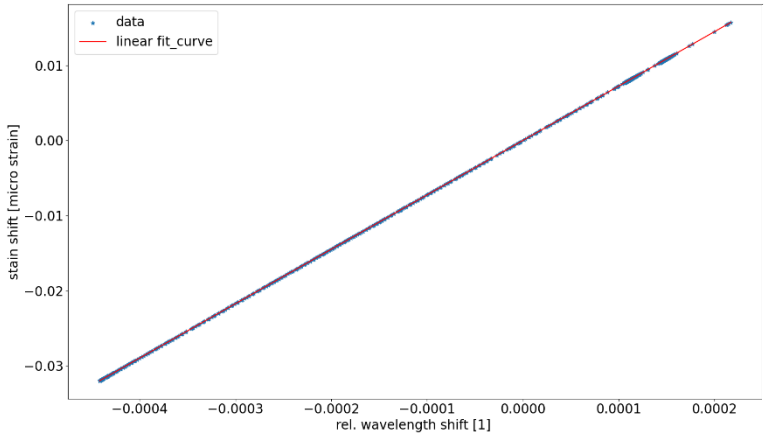


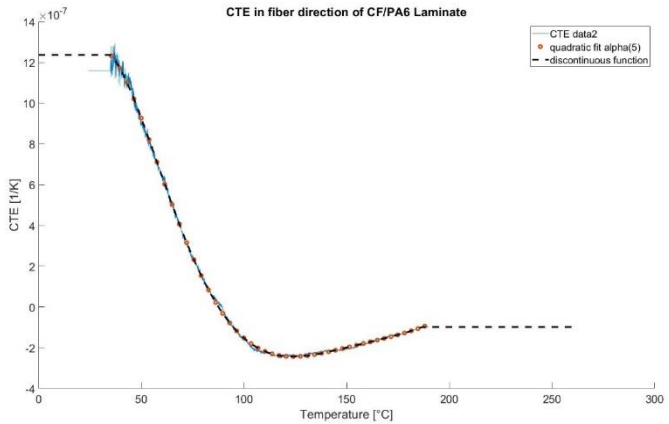
n_{eff} … $f(\varepsilon, T)$

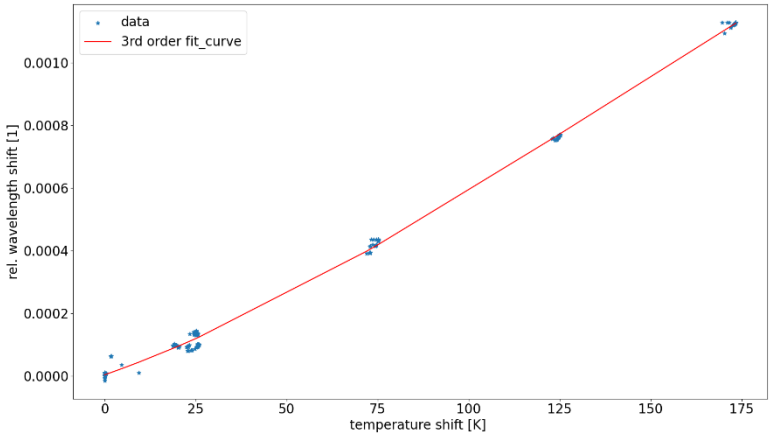


Calibration Method

- **In-situ calibration with embedded FBG and thermo-couple in tensile test rig with temperature camber**
- **Strain calibration in range of 1500με**
- **Temperature in range -40°C – +180°C**
- **Temperature dependent CTE from TMA**







Calibration Models

- **Emperical calibration model with least square**
- **Total sensitivity:** $(\lambda - \lambda_0)_{\boldsymbol{total}} = (\lambda - \lambda_0)_{\varepsilon} + (\lambda - \lambda_0)_{\boldsymbol{\alpha}} + (\lambda - \lambda_0)_{\boldsymbol{T}}$
- **Strain sensitivity:** $(\lambda - \lambda_0)_{\varepsilon} = K_{\varepsilon} \Delta\varepsilon$
- **CTE sensitivity :** $(\lambda - \lambda_0)_{\alpha} = \alpha(T) \cdot \Delta T \cdot K_{\varepsilon}$
- **Temperature sensitivity :** $(\lambda - \lambda_0)_{T} = p_0 + p_1 \Delta T + p_2 \Delta T^2 + p_{\boldsymbol{3}} \Delta T^{\boldsymbol{3}} - \alpha(T) \cdot \Delta T \cdot K_{\varepsilon}$

ABSTRACT

Binder-stabilised preforms offer significant advantages in structural composite manufacturing, enhancing handling, repeatability, and overall process efficiency. However, the heterogeneous structure of the fabric, influenced by fibre orientations, binder powder distribution, and stitching patterns, presents challenges for process control and performance prediction. A detailed characterisation of these microstructural features is essential for optimising manufacturing parameters and ensuring consistent material properties. Laser microscopy combined with image analysis provides a powerful tool for quantifying these structural variations. Classical segmentation techniques, however, struggle to accurately delineate key features due to low contrast and complex material interfaces. In this work, we employ a deep learning-based segmentation approach using a U-Net model to overcome these challenges. The model enables robust segmentation of microscopy images, allowing for the extraction of critical microstructural properties, such as binder coverage, particle size distribution, and anisotropy, providing a quantitative basis for further analysis. The findings highlight the potential of deep learning in advancing automated image analysis for composite materials, paving the way for more data-driven approaches in material characterisation and process optimisation.

1 INTRODUCTION

Binder-powdered glass fibre fabrics show potential in composite manufacturing to create stable preforms that enable efficient, large-scale production e.g. for the wind turbine industry. Applying a polymer binder powder to the glass fibre fabrics gives the consolidated preforms mechanical stability upon activation (i.e. heat treatment under glass transition temperature), allowing them to be manipulated and transported. This stabilisation is essential for vacuum-assisted resin transfer moulding (VARTM) and similar processes, where consistent fibre distribution within preforms helps improve the flow of resin and, consequently, the overall quality of the final composite material.[1–5] Moreover, the use of binder powdered fabrics has the potential to parallelise the production stage, where the glass fibre fabrics are placed in the mould, ultimately reducing the lead time and cost associated with large-scale composite manufacturing.[6–8]

Despite the potential for widespread industrial application of binder powdered glass fibre fabrics (BP-GFF), current knowledge on the microstructural influence of binder powders is limited, particularly concerning how they interact with the fibres. The complex morphology of the binder powders and their heterogeneous distribution within the fibre preform poses multiple challenges for modelling the process. Existing methods often rely on simplified assumptions that do not capture the intricacies of the binder distribution and do not accurately represent the fibre-matrix interface.[9] This gap in robust modelling methodologies limits the predictability and optimisation of the manufacturing process, making it difficult to standardise quality control measures. As a result, there is a pressing need for more advanced characterisation techniques to facilitate accurate preform structure modelling and enhance binder powder composites' reliability.

Laser scanning confocal microscopy offers a promising approach by providing high-resolution imaging of BP-GFFs, enabling detailed analysis of the binder's distribution and morphology.[10]

These high-resolution images can be segmented through advanced image processing techniques to characterise the binder topology. Traditional segmentation methods, such as intensity threshold and feature-based segmentation, perform poorly for segmenting the laser microscopy images as the segmentation classes do not have separation in the intensity values nor the basic features. More recent advancements in machine learning, particularly convolutional neural networks (CNNs), allow for improved accuracy in segmenting complex, irregular structures. Badran et al. (2020) employed a deep neural network to segment 3D tomography images of SiC–SiC composites (i.e where fibre and matrix were made of same material), thereby facilitating automated analysis of fibre distribution and matrix cracking.[11] Hong et al. (2021) developed a deep learning model to segment short fibres in glass fibre reinforced concrete using X-ray micro-computed tomography images.[12] Guo et al. (2023) demonstrated the use of a U-Net for precise fibre segmentation in time-resolved computed tomography (CT) scans.[13] Vorobev et al. (2023) applied deep learning models to segment structural defects in polymer composite CT images, improving the detection of defects.[14] Dong et al. (2024) applied a U-Net model for segmenting 2D optical images to characterise the microstructure of fibre-hybrid polymer composites.[15]

In this study, we train and deploy a deep CNN based on U-Net to improve the segmentation of binders and glass fibres in laser scanning microscopy images of BF-GFFs.

2 DATA

The considered fabrics are Unidirectional Non-Crimp glass fibre Fabrics (UD NCF) and Biaxial (Biax) glass fibre fabrics, to which a semi-transparent polymer binder powder has been applied on the top surface of the fabrics. Both fabrics were acquired with the binder powder already applied.

The laser microscopy images are obtained using an Olympus LEXT laser microscope[16] using a 10X zoom objective and stitching multiple scans to cover more surface area than a single scan can. An example of a 4x4 stitched microscopy image of a UD NCF BP-GFF is shown below in fig. 1.

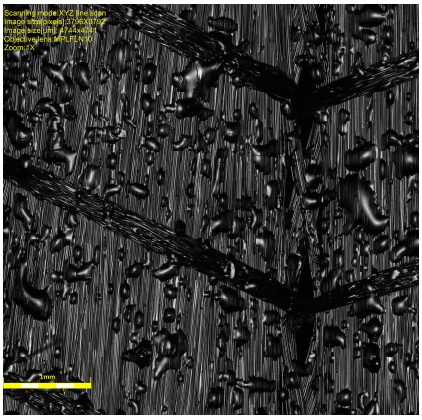

Figure 1: Laser scanning microscopy image of a UD NCF glass fibre fabric with polymer binder powder applied.

3 METHODS

3.1 Classical image segmentation methods

As seen on the microscopy image, the segmentation of binder powder and glass fibres is not a trivial task. The inherent features making the task difficult are, among others: 1) No significant contrast between binder powder and glass fibres. 2) Binder powders are semi-transparent, and the glass fibre structures come through. 3) The low contrast stitching makes the binder powder difficult to detect. Furthermore, manual segmentation is not a viable solution either, as even for quite small surface areas as the one shown in Fig. 1, there will be hundreds of particles present, making manual annotation of every one of them impractical.

These image features make it a difficult task to obtain good segmentations through classical imaging techniques. Intensity threshold and watershed methods will yield poor results, as there is no clear separation between classes in the intensity spectrum. More advanced methods, like the implementation [17] of the Structure Tensor method, which has previously been used to characterise fibre directions [18], can usually segment fibre images due to the directional information in the images. However, as the binder powder is semi-transparent, the directional information of the underlying glass fibres is also found in areas containing binder particles. Furthermore, the areas with stitching are also without any directional information and will therefore falsely be classified as binders. Therefore, these methods are inadequate for the segmentation task at hand.

3.2 Deep Learning segmentation

The dataset for training the deep learning segmentation model is established by cropping the original dataset into 512x512-pixel patches. Given the 8 original high-resolution images, this yields a total of 278 image patches. Of those, 90% (250 patches) will be used for training, and 10% (28 patches) will be used as the validation set during training. To guide the training, the images are partially annotated, separating areas that are binder powder and areas that are not binder powder. These masks have been encoded into three classes: {0, 1, 2} = {Unknown, Not Binder Powder, Binder powder}. Similarly to the original images, the masks are cropped into 278 patches, such that each training image patch has a corresponding mask patch holding some ground truth information.

The architecture used for the deep learning segmentation task is a U-Net, originally proposed by Ronneberger et al. (2015) [19]. In comparison with other architectures, U-Nets have proved excellent performance in image segmentation as the visual information is restored through the encoder-decoder architecture. 2) U-Nets do, in general, perform well on smaller datasets. The chosen architecture is further of the type utilising the deep CNN ResNet34 [20] as the backbone, where the ResNet34 is pre-trained on the ImageNet dataset [21]. The loss function used in the training of the U-Net is weighted categorical cross-entropy loss [22], where the classes {0, 1, 2} are assigned weight {0.0, 1.0, 1.0}, meaning no weight on the areas having no label and equal weight on the labelled areas. The network is trained using an ADAM optimiser for 200 epochs, showing a convergence of the training and validation losses in Fig. 2.

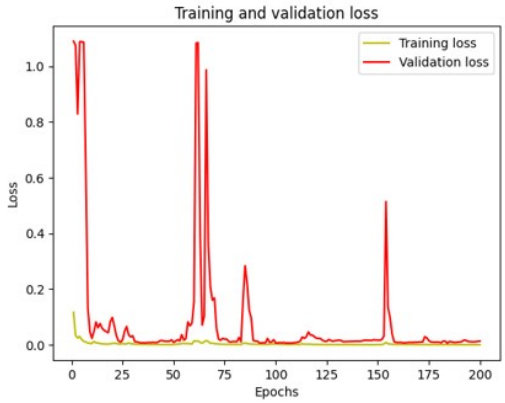

Figure 2: Training and validation loss curves for the U-Net segmentation model over 200 epochs.

4 RESULTS

The segmentation for a microscopy image produced by the U-Net segmentation model is shown in Fig. 3. The model has not seen this microscopy image during training, and therefore, it can be used to validate the model's performance.

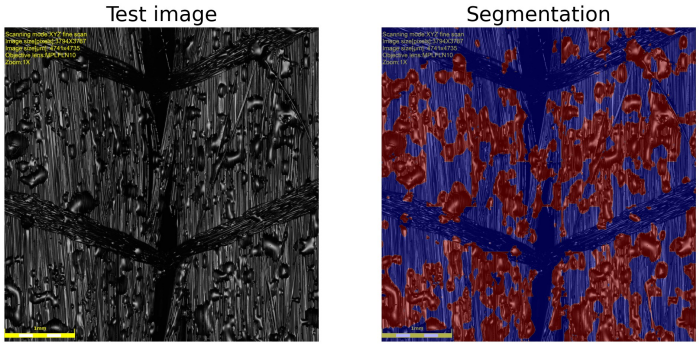

Figure 3: Microscopy image of a UD NCF BP-GFF (left) and corresponding U-Net segmentation output (right). Red pixels indicate binder powder; blue pixels indicate non-binder regions. This image was not part of the training set and is used for model validation.

Conferring Fig. 3, it can be difficult to assess whether the segmentation is a proper pixel-wise division of the microscopy image into the classes: binder powder and not binder powder. But certain metrics can aid in the assessment of the quality of the segmentation. The Intersection-over-Union (IoU) and Dice scores, both commonly used in the realm of image segmentation, are used in this study.

$$IoU = \frac{|A \cap B|}{|A \cup B|}, \quad Dice = \frac{2|A \cap B|}{|A| + |B|} \tag{1}$$

where A and B are the segmentation and annotation, respectively.

To properly compare the performance of each of the segmentation methods, IoU and Dice scores are computed for each of the methods against the annotation mask. The scores are only computed with regard to the annotated area corresponding to known classes. Furthermore, the confusion matrix is computed to evaluate the classification. The image used for validation is an image of UD NCF glass fibre fabrics that was acquired on the Olympus LEXT [16] from another sample, on another day, and that has not been part of either the training or the validation dataset. The image is the one shown in Fig. 3. This is to verify the robustness of the method, as it has to work on data that has not been seen by the model, while acquired under similar conditions to the training data.

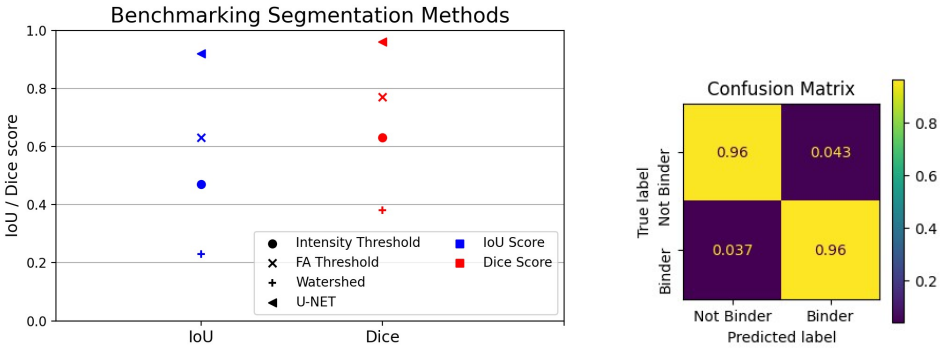

Figure 4: (Left) Intersection-over-Union (IoU) and Dice scores comparing classical and deep learning segmentation methods. (Right) Normalised confusion matrix for the U-Net model, showing 96% classification accuracy and balanced performance across classes.

As discussed, the scores in Fig. 4 demonstrate the fundamental limitations of classical methods in segmenting the microscopy images. The watershed approach fails to produce a meaningful segmentation, while intensity thresholding performs slightly better but remains insufficient for obtaining reliable segmentation results. This outcome is expected, as the image intensity spectrum lacks clear class separation. The structure tensor method using a fractional anisotropy measure

achieves a further improvement over the previous methods. However, its segmentation quality remains inadequate for meaningful post-processing. The U-Net segmentation model improves the scores significantly, as is seen in Fig. 4 (Left), where both IoU and Dice scores indicate a near-perfect match to the annotations. To further quantify the performance of the U-Net segmentation model, the normalised confusion matrix, Fig. 4 (Right), provides insights into how the classification performs and where it classifies incorrectly. Here it can be seen that the model correctly predicts 96\% of the pixels in each class, with a very low and equal rate of misclassification. This shows that there is no clear bias in the segmentation model. In total, this indicates that the segmentation model is successful and that the segmentation can be used for further processing.

The U-Net segmentation results provide a foundation for further analysis of material properties in the microscopy images. By leveraging the U-Net segmentation model, key characteristics such as binder coverage, particle size distribution, and particle aspect ratios can be quantified. These derived properties offer valuable insights into the material's composition and morphology, enabling a more detailed assessment. The U-Net segmentation model indicates that the binder coverage is approximately 50% in the microscopy image in Fig. 1, whereas the binder coverage is only approximately 34% in a similar microscopy image of a Biax glass fibre fabric. This indicates that the assumption of homogeneous binder powder distribution is inadequate.

Another derived result using the U-Net segmentation model is the particle size distribution. Using the ensemble of microscopy images acquired the particle size distribution is calculated. The resulting binder powder particle size distribution for assumed circular particles is shown in Fig. 5.

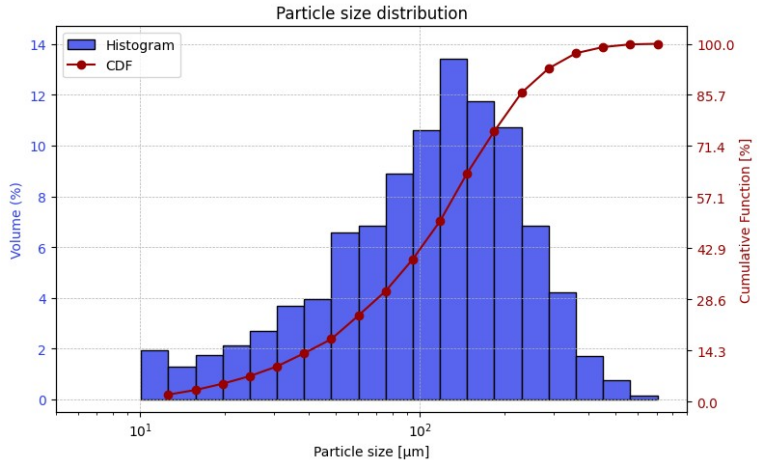

Figure 5: Distribution of binder powder particle sizes extracted from segmented microscopy images using the U-Net model. Particle sizes are estimated assuming circular geometry.

Furthermore, the binder powder particle aspect ratios, defined as the ratio of the longest axis to the shortest axis of the segmented particles, are of interest. First, to check whether the assumption of circular particles used for the particle sizes was violated, but secondly, because the binder powder morphology is of interest and poorly studied. Figure 6 summarises the binder powder particle aspect ratios of the particles in the microscopy images segmented using the U-net segmentation model.

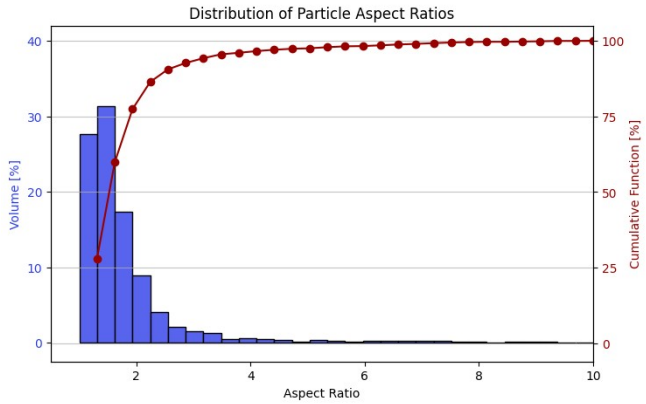

Figure 6: Distribution of aspect ratios (longest/shortest axis) of U-Net segmented binder particles, indicating general circularity.

The particle aspect ratios are as seen on Fig. 6, indicating that the particles are mostly approximately circular in shape, even though a smaller portion has slight ellipsoidal tendencies. It does, however, confirm that in general, it is not unreasonable to assume circular particles. These findings align well with microscopy image observations, e.g. see Fig. 1.

To give a more comprehensive understanding of the distribution of the binder powder on the glass fibre fabrics, one can investigate the binder coverage on smaller scales than the full microscopy images. This is because the region of influence for the particles is a lot smaller than the areas scanned, which makes it of interest to investigate whether there are areas with better or worse local coverage of the binder powder. The region of influence can be a moving window of a certain size, necessarily bigger than any individual powder particle. Using this moving window approach, a heatmap of local binder powder coverage percentages is constructed. Such a heatmap is overlaid on the example image (i.e. Fig. 1) in Fig. 7 below, where the moving window size is shown.

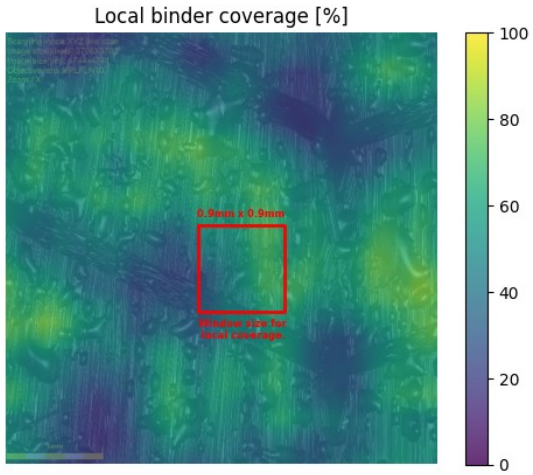

Figure 7: Heatmap of local binder powder coverage overlaid on the microscopy image from Fig. 1. The coverage is computed using a moving window approach to highlight spatial heterogeneity.

As seen in Fig. 7, the binder powder particles do not have a uniform coverage of the glass fibre fabric. Especially areas with stitching are lacking binder powder particles, resulting in near-zero coverage. Still, the deficient binder powder coverage is not limited to the stitching, as other areas are affected as well. Similarly, there are areas containing a lot of binder powders, which as a result yield the inhomogeneous distribution as indicated on the heatmap in Fig. 7.

To further quantify the local binder coverage of the considered fabrics, all of the microscopy images are considered to form a full distribution of local binder powder coverage percentages. That distribution is visualised in Fig. 8 below.

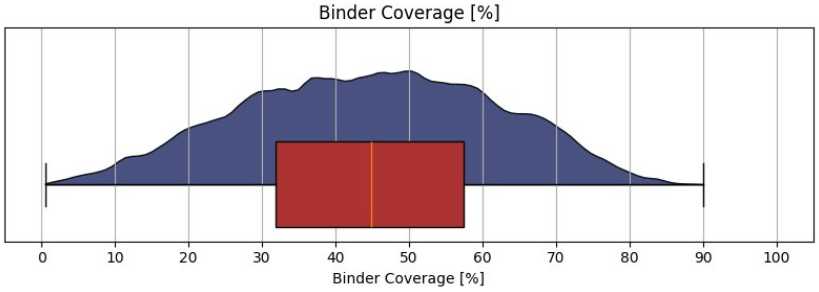

Figure 8: Distribution and boxplot of local binder powder coverage across all microscopy images.

The local binder powder particle coverage has a mean (and median) of approximately 47% but a standard deviation of approximately 17%-pts. The percentiles imply that 50% of the considered areas have a binder powder coverage between 32% and 57%, and that 95% of the considered areas have a binder powder coverage between 12% and 75%. This shows a wide range of local binder powder coverage, underlining the heterogeneous nature of the considered binder-powdered glass fibre fabrics.

5 CONCLUSIONS

Our findings using a U-Net deep CNN on partially annotated images suggest significantly improved segmentation of the microscopy images, resulting in accurate characterisation of the binder morphology and distribution. By comparing traditional and deep learning-based segmentation techniques, insights can be gained into the accuracy and reliability of each approach, paving the way for standardised, robust practices to characterise the binder powders applied to glass fibre fabrics. It has been shown how the distribution of local binder powder coverages has a large spread and can attain values from barely any binder powder to almost only binder powder. These insights contribute to a deeper understanding of the heterogeneity of the considered binder powder fabrics and the implications for composite processing and performance. The robust segmentation model developed highlights the potential for advanced automated image analysis tools for composite materials, which can pave the way for more data-driven approaches for material characterisation and better-informed processing.

Keywords: Polymer Composites, Heat Damage, Kinetic Model, Residual Strength, Modeling

ABSTRACT

Composites are increasingly utilized in structural applications for military and commercial aircraft due to their high specific strength and stiffness. Despite these advantages over metal components, there is a significant risk if these structures are exposed to fires or high-temperature exhaust gas impingement. After an elevated temperature exposure, the composite properties may be significantly compromised even if minimal visible damage is apparent. Consequently, it is desired to have a rapid heat damage assessment and failure prediction tool based on operational and inspection data. This paper presents our efforts on developing models and simulation tools to predict residual strength of carbon/epoxy composites exposed to heat. A thermal decomposition kinetic model was developed based on the thermogravimetric data for the 5320-1 composite material. The residual short beam shear (SBS) strength of the composite was measured and related to the mass loss of the samples subjected to isothermal heating. Based on these results, a residual strength model was developed to predict the residual SBS strength of composite exposed to heat. The model has been validated and used to simulate degradation of carbon/epoxy composites subjected to isothermal heating. In addition, it was shown that the kinetic model derived for 5320-1 composites may be used with the residual strength data of other carbon/epoxy composites to develop a residual strength model for those composites.

1 INTRODUCTION

Aircraft polymer composite components are often exposed to extreme temperatures due to thermal events including exhaust impingement, engine fires, fuel fires, equipment overheating, brake fires, and lightning strikes. During thermal exposure, a chemical change in the matrix can occur and results in a reduction of composite mechanical properties. These chemical changes are difficult to detect with traditional Nondestructive Inspection (NDI) techniques (hardness, ultrasonic, visual inspection). This is classified as incipient heat damage. While some experimental methods such as Fourier Transform Infrared Spectroscopy (FTIR) technique may be used to inspect and disposition incipient heat damage on composite structures [1], development of a multi-physics model is desired to predict the structural response for a given temporal and spatial evolution of thermal environment.

To predict the post-fire mechanical response of single skin, flat composite laminates, Gibson et al. [2] proposed a model to predict the residual strength of polymer composites assuming the material has 100% and 0% strength left for the charred and uncharred portions of the material, respectively. Mouritz et al. [3, 4] proposed a simple two-layer model, one for the thermally affected region to have reduced or zero mechanical properties and a completely undamaged region with original mechanical properties. These models do not consider the property degradation in the resin decomposition region and cannot predict the residual strength of composites with incipient heat damage.

The goal of the present work is to develop a tool to predict residual strength of carbon/epoxy composites after a known time and temperature event. The time at temperature is such that the strength degradation is detectable whereas the physical damage (delamination) has not occurred yet. This is the region of highest interest for predictive capability and the focus of our efforts in this project. The mechanical property evaluation is focused on matrix sensitive short beam shear (SBS) strength test.

2 EXPERIMENTAL

2.1 Materials

Cycom 5320-1 prepreg (T650-35 3K plain weave fabric with resin content of 36%) manufactured by Solvay was used for making composites with single vacuum bag process. According to the manufacturer, Cycom 5320-1 is a toughened epoxy resin prepreg system designed for vacuum-bag-only (VBO) or out of autoclave (OOA) manufacturing of primary structural parts. The 5320-1 composites are also supported by an extensive set of multi batch mechanical and physical property databases [5].

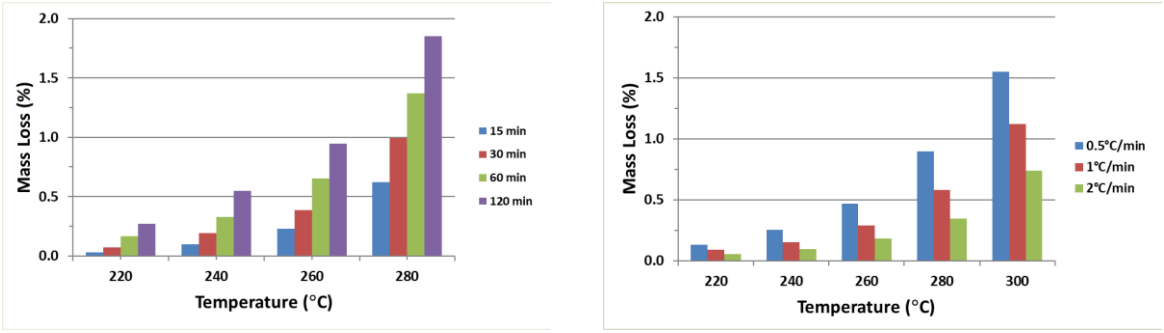
2.2 Methods

Laminate and Test Coupon Preparation. Composite panels were fabricated using 16 pies of prepreg with single vacuum bag process cured in a convection oven with curing cycle recommended by the prepreg manufacturer. The cured panel has thickness of 0.122 inches. The panels were machined to generate test coupons with nominal dimension of 0.75”×0.25”×0.125” for thermal aging, mass loss and SBS tests. The coupons were dried at 80°C for 48 hours in a convection oven before used in the following treatments. The mass of dried samples was measured and used to calculate the mass loss of the composite after thermal aging.

Thermal Aging. Thermal aging of composite samples (SBS test coupons) was performed in a convection oven (Heratherm OMH60). A mineral wool insulation sheet was mounted in front of oven chamber to minimize the temperature drop when the oven door was opened. A small opening (3" × 1") was cut out on the sheet to allow the samples passing through the sheet. Two types of heating — isothermal heating and constant rate heating — were performed for thermal aging. To conduct the constant rate heating, heat oven to 50°C first, place composite samples (6 SBS test coupons as a set) in the oven and close the door. The oven was heated to target temperatures at the set heating rate. The samples were taken out of the oven when the target temperature was reached. The mass of aged samples was measured when the samples were cooled down.

Mass Loss Measurement. After heat exposure, the mass of the coupons was measured with balance with precision of 0.0001g. The mass loss of the samples is equal to the difference between the mass of the samples before and after heat exposure.

Short Beam Shear (SBS) Test. Short beam shear test for the aged samples was performed at room temperature on ADMET Expert 2611 Tester based on ASTM D2344 standard. The displacement rate was 0.05 inches/minute. Five specimens were evaluated to get average strength for each set of samples.



3 RESULTS AND DISCUSSION

3.1 Mass Loss and Kinetic Model of Composites

Mass Loss of the Composites. Mass loss (%) of 5320-1composites (SBS coupons) subjected to isothermal heating and constant rate heating is shown in Figure 1(a) and (b), respectively. The mass loss (%) is defined as $(m_0\text{-}m)/m_0 \times 100\%$, where m_0 and m are original mass and instantaneous mass at t, respectively. In general, mass loss depends on the aging time and temperature for isothermal heating. The higher temperature or longer time, the greater the mass loss values. For constant rate heating, the lower the heating rate, the greater the mass loss values. It is thus believed that mass loss can be a good indicator for severity of incipient heat damage of the composites.

Kinetic Model. According to the literature, the model or a mathematical description of the mass loss data is usually sought in terms of a `kinetic triplet' (i.e., Arrhenius parameters A and E, and the reaction model, $F(\alpha)$, also called the conversion function) which is related to the experimental data as follows [6]

NAVAIR Public Release SPR# 2025-0430. Distribution Statement A - Approved
for public release; Distribution is unlimited.

(a) (b)

Figure 1: Mass loss (%) of 5320-1 composites subjected to (a) isothermal and (b) constant rate heating.

$$\frac{d\alpha}{dt} = Aexp\left(-\frac{E}{RT}\right)F(\alpha) \tag{1}$$

where R is gas constant, T is temperature (K), α is the extent of conversion defined as

$$\alpha = (m_i - m)/(m_i - m_f) \tag{2}$$

where m_i, m and m_f are the initial, instantaneous and final mass of the material, respectively. For mass loss data obtained at a constant heating rate dT/dt=β, dα/dt in Eq.(1) can be replaced with β dα/dT:

$$\frac{d\alpha}{dT} = \frac{A}{\beta}exp\left(-\frac{E}{RT}\right)F(\alpha) \tag{3}$$

or

$$Ln\left(\beta\frac{d\alpha}{dT}\right) = -\frac{E}{RT} + Ln(A) + Ln(F(\alpha)) \tag{4}$$

For a fixed degree of progress α, the plots of Ln(βdα/dT) versus 1/T show parallel lines with a slope equal to –E/R, which leads to a method known as Friedman method for determining the activation energy E in the literature [7]. To get the α data, one needs not only initial and instantaneous mass of the material, but also the final mass of the material. If the final mass is not available or applicable, a fraction of mass loss α* as defined in

$$\alpha^* = (m_i - m)/m_i \tag{5}$$

may be used. Let

$$\lambda = m_i/(m_i - m_f) \tag{6}$$

we have

$$\alpha^* = \alpha/\lambda \tag{7}$$

With α being replaced with λα*, Eq.(1) can be rewritten as

$$\frac{d\alpha^*}{dt} = A^*exp\left(-\frac{E}{RT}\right)f(\alpha^*) \tag{8}$$

where A^* (=A/λ) and f(α*) represent the pre-exponential parameter and reaction model corresponding to α*. From this equation it follows that

$$Ln\left(\beta\frac{d\alpha^*}{dT}\right) = -\frac{E}{RT} + Ln(A^*) + Ln(f(\alpha^*)) \tag{9}$$

Comparing Eq.(9) and Eq.(4), it is apparent that the activation energy E can also be determined from dα*/dT. Figure 2 shows Ln α* as a function of temperature for 5320-1 composites subjected to constant

rate heating. As seen in the figure, d Ln α*/dT is a constant at a fixed heating rate, it is thus more convenient to use d Ln α*/dT instead of dα*/dT for the calculation. Rewrite Eq.(9) as

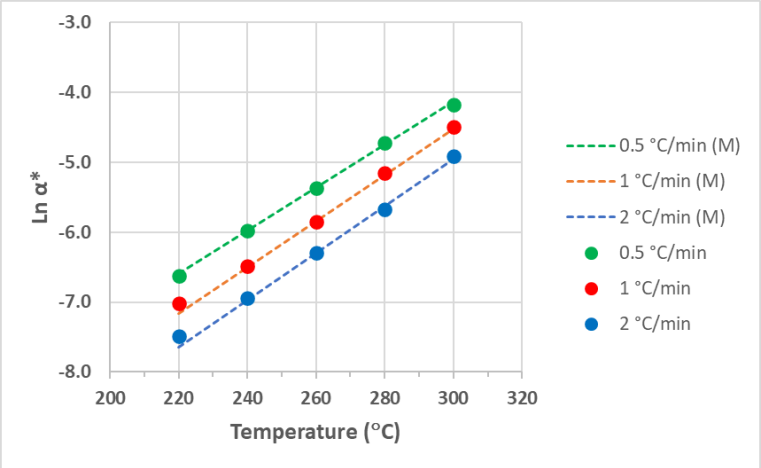


Figure 2: Ln α* as a function of temperature for 5320-1 composites subjected to constant rate heating. Closed circles represent measured data, dotted lines represent model predicted values.

$$Ln\left(\beta\frac{dLn(\alpha^*)}{dT}\right) = -\frac{E}{RT} + Ln(A^*) + Ln\big(f(\alpha^*)\big) - Ln(\alpha^*) \tag{10}$$

then the activation energy E can be determined from plots of Ln (β dLnα*/dT) versus $1/T$ at fixed α* levels. The result can be represented by

$$E = aLn\,\alpha^* + b = 19.22Ln\,\alpha^* + 230.92\ (kJ/mol) \tag{11}$$

From Eqs.(10)-(11) and the mass loss data, $f(\alpha^*) = \alpha^{*n}$ (where n is a constant) and A^* can be determined, Eq.(8) thus becomes

$$\frac{d\alpha^*}{dt} = A^* exp\left(-\frac{E}{RT}\right)\alpha^{*n} \tag{12}$$

Integration of Eq.(12) gives the α* of the composites subjected to isothermal heating

$$\alpha^* = \left[A^* kExp\left(-\frac{b}{RT}\right)(t - t_0) + (\alpha^*{}_0)^k\right]^{1/k} \tag{13}$$

where α^*_0 is α* at t_0 and $k = a/(RT)$-n+1, a and b are defined in Eq.(11). Given t_0 (=15 min) and α^*_0, the mass loss of composite at any time $t > t_0$ and T can be predicted using this equation. For composites subjected to constant rate heating, the mass loss becomes

$$\alpha^* = \alpha_0^* exp\left[\frac{A^*}{\beta} exp\left(-\frac{E_0}{RT_0}\right)(\alpha_0^*)^{n-1}(T - T_0)\right] \tag{14}$$

where α^*_0 is α* at T_0 and E_0 is the activation energy at $\alpha^* = \alpha^*_0$. The mass loss predicted using Eq.(14) and T_0 = 260°C is presented in Figure 2. As seen in the figure, the calculated values are in very good agreement with measured data for all heating rates and temperatures. The mass loss values calculated from Eq.(13) (data are not presented here) also agree with the measured data for the samples subjected to isothermal heating.

3.2 SBS Strength of Composites

Short beam shear strength of 5320-1 composites subjected to isothermal heating is given in Figure 3. Figure 4 shows the plots of SBS reduction versus mass loss for 5320-1 composites subjected to isothermal heating. Apparently, the relationship between SBS reduction and mass loss for a fixed aging

NAVAIR Public Release SPR# 2025-0430. Distribution Statement A - Approved
for public release; Distribution is unlimited.

time (15, 30, 60 and 120 minutes) can be represented by a linear equation. This means that, given exposure/aging time, the SBS strength reduction is proportional to the mass loss of the material.

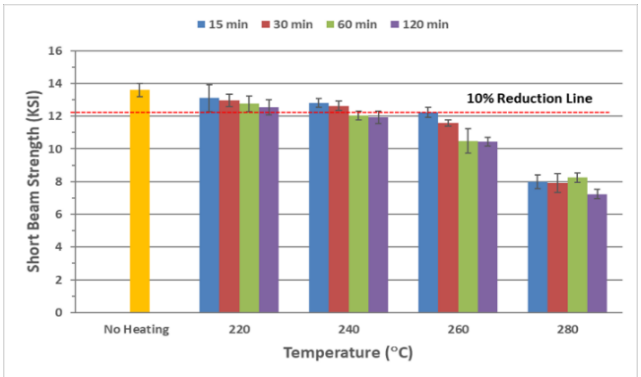

Figure 3: Short beam shear strength of 5320-1 composites subjected to isothermal heating.

The slope of lines was plotted against exposure time in Figure 5. The data can be fitted by a power law equation $y = 205.24x^{-0.452}$. Combining the results obtained from Figs.(4) and (5), we have:

$$\frac{\Delta F}{F_0} = ct^d \frac{\Delta M}{M_0} = 205.24t^{-0.452}\alpha^* \tag{15}$$

where $\Delta F = F_0 - F$, $\Delta M = M_0 - M$, M_0 and F_0 are the original mass and SBS strength of the material (no heat exposure), M and F represent the mass and SBS strength of the composite exposed to heat for t minutes.

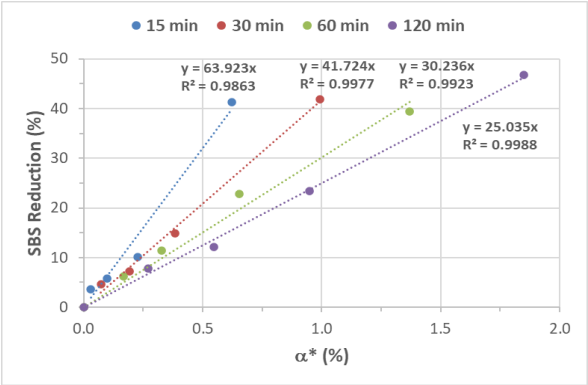

Figure 4: Plots of SBS strength reduction versus mass loss of 5320-1 composites subjected to isothermal heating with aging times indicated.

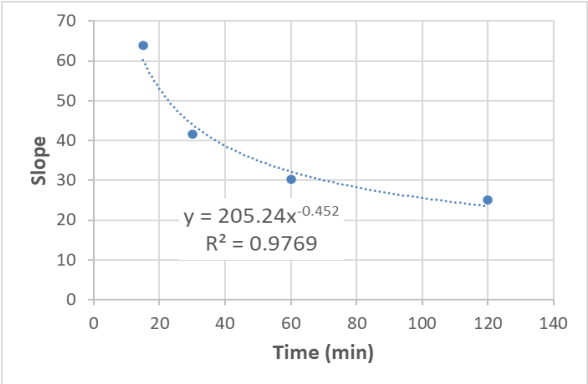

Figure 5: The plot of slope of lines in Figure 4 versus aging time.

NAVAIR Public Release SPR# 2025-0430. Distribution Statement A - Approved for public release; Distribution is unlimited.

3.3 Residual Strength Models for 5320-1 Composites

Based on the above equations, models have been developed to predict the residual SBS strength of the composites subjected to isothermal heating. From

$$F = F_0\left(1 - \frac{\Delta F}{F_0}\right) \tag{16}$$

it follows that

$$F = F_0\left\{1 - ct^d\left[A^*kExp\left(-\frac{b}{RT}\right)(t - t_0) + (\alpha^*{}_0)^k\right]^{1/k}\right\} \tag{17}$$

To verify/validate the residual strength models, the residual strength of 5320-1 composites subjected to isothermal heating were calculated from Eq.(17). The results together with the testing data are presented in Figure 6. As seen in the figure, the measured and predicted residual strengths are in very good agreement for all aging temperatures and times or heating rates. In fact, the predicted values are within the error bars of measured data in most cases. In other words, the difference between predicted and measured strength values are generally within the experimental errors. The result confirmed that the residual strength model works well for the composites.

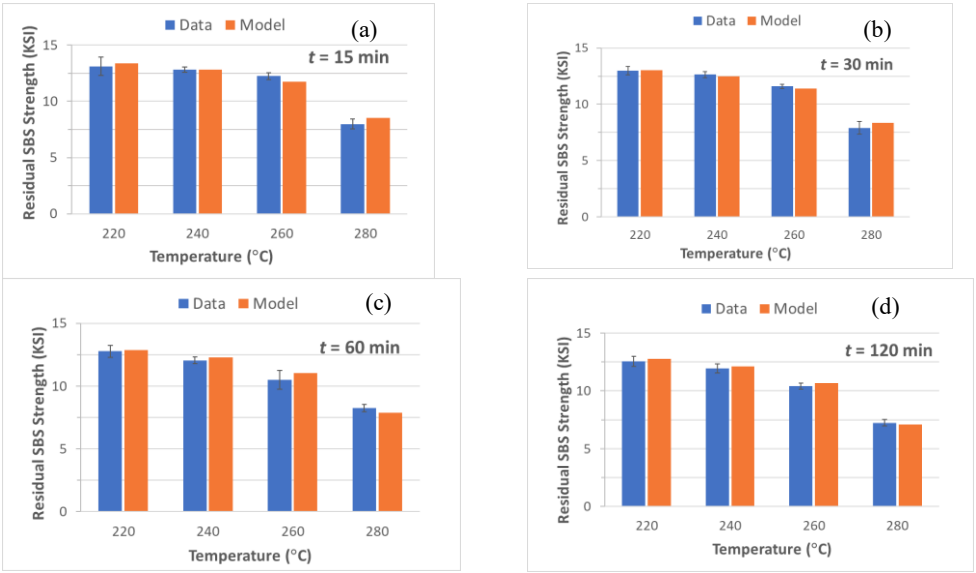

Figure 6: Comparison of model predicted and measured short beam strength for 5320-1 composites subjected to isothermal heating at 220~280°C for (a) 15, (b) 30, (c) 60 and (d) 120 minutes.

3.4 Residual Strength Prediction for Other Composites

A novel residual strength model has been developed and demonstrated successfully for short beam strength of CYCOM 5320-1 composite system. As lots of experimental work is needed to establish the residual strength models, a model or method is desired for prediction of residual strength of general carbon/epoxy composites (not limited to 5320-1) with no or minimal amount of experimental work required.

It was noticed that there were residual strength data sets (such as SBS, flexural and/or compressive strength data) for various carbon/epoxy composites exposed to heat with exposure conditions reported in the literature (see [8] for example). We have tried to "predict" the residual strength of the materials using our model (for 5320-1 composites) and then compare the result with the testing data to see how our model works for those materials. While good agreement between "predicted" and tested data was seen in some cases, poor results were observed in most cases. This means our model may not be

applicable to other materials in general. However, if our model is adapted to the new material and property first, it is possible to predict residual strength of the material without need for additional experiments. Below we will explain this further with some examples.

Figure 7(a) and (b) present the SBS strength reduction of dry and wet IM6/3501-6 carbon fiber/epoxy composites (data obtained from Ref [8]) versus mass loss of CYCOM 5320-1 exposed to heat with condition given in Ref [8], respectively. As seen in the figure, for either dry or wet samples, the SBS strength reduction of IM6/3501-6 and mass loss of dry 5320-1 composite can be represented by a linear equation as shown in the following equation:

$$\frac{\Delta F}{F_0} = c_x \alpha^*_S \tag{18}$$

where $\Delta F = F_0 - F$, F_0 and F are the original and instantaneous SBS strength of IM6/3501-6, α^*_S represents the mass loss of dry 5320-1 composite exposed to heat (obtained from Eq.(13)), c_x is the slope of the line which equals to 25.743 and 35.912 for the dry and wet IM6/3501-6 samples, respectively. Eq.(19) gives the residual SBS strength model (adapted model) for IM6/3501-6 subjected to isothermal heating

$$F = F_0(1 - c_x \alpha^*_S) = F_0 \left\{ 1 - c_x \left[A^* k Exp\left(-\frac{b}{RT}\right)(t - t_0) + (\alpha^*_0)^k \right]^{1/k} \right\} \tag{19}$$

where the expression for α^*_S was from Eq.(13). The measured and model predicted SBS strength of dry and wet IM6/3501-6 composites are shown in Figure 7(c) and (d), respectively. As seen in the figures, the model predicted and measured SBS strengths are in excellent agreement.

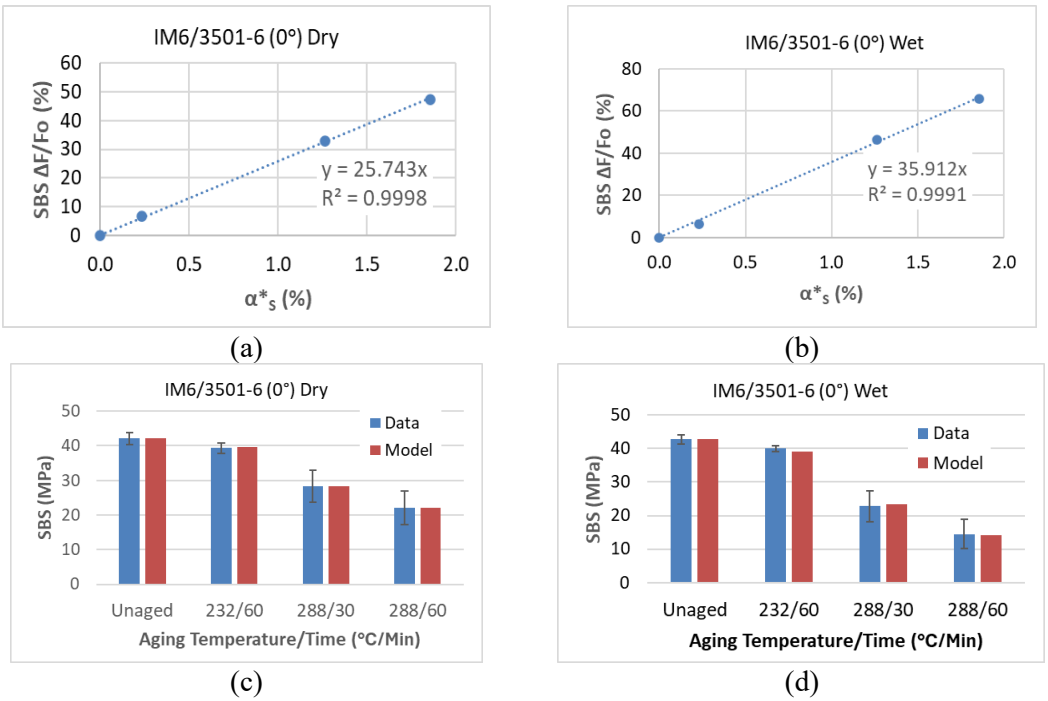

Figure 7: SBS strength reduction of dry (a) and wet (b) IM6/3501-6 carbon/epoxy composites versus mass loss of CYCOM 5320-1 exposed to heat. Comparison of measured and model predicted SBS strength of dry (c) and wet (d) IM6/3501-6 composites exposed to heat.

Similar results were obtained for residual flexural strength of IM6/3501-6 composites (Figure 8) with testing data obtained from Ref [8] as well. As seen in the figure, the flexural strength reduction of IM6/3501-6 and mass loss of dry 5320-1 composite can be represented by a linear equation, with slope being 32.819 and 31.315 for the dry and wet samples, respectively. A residual flexural strength model

can be derived for dry or wet IM6/3501-6 composites. As shown in Figure 8(c) and (d), the model predicted flexural strengths are in very good agreement with the testing data.

In summary, the adapted model can be derived by a) plotting strength reduction ($\Delta F/ F_0$) against mass loss (α^*_s) of 5320-1, b) finding relation $\Delta F/ F_0 = f(\alpha^*_s)$ (= $c_x\alpha^*_s$ in above examples) and, c) getting residual strength $F = F_0\,[1\text{-}f(\alpha^*_s)]$.

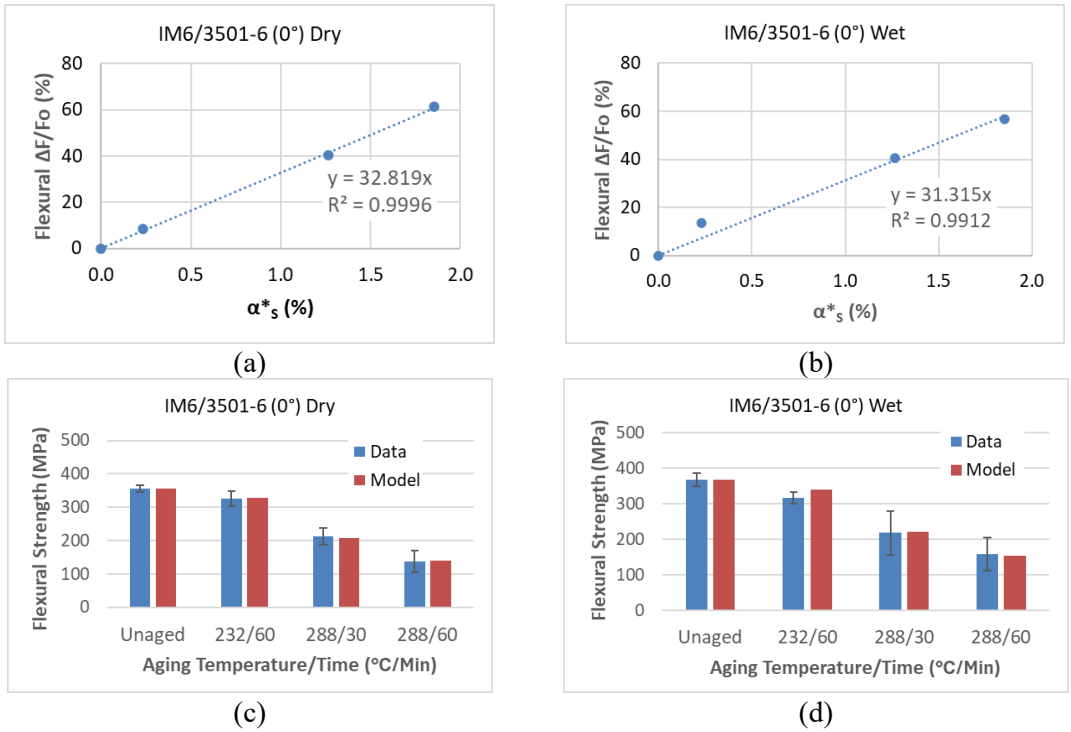

Figure 8: Flexural strength reduction of dry (a) and wet (b) IM6/3501-6 carbon/epoxy composites versus mass loss of CYCOM 5320-1 exposed to heat. Comparison of measured and model predicted flexural strength of dry (c) and wet (d) IM6/3501-6 composites exposed to heat.

4 CONCLUSIONS

Efforts have been made to model and simulate the incipient heat damage of carbon/epoxy composites exposed to excessive heat. A decomposition kinetic model has been developed based on the non-isothermal thermogravimetric data for the composite coupons for short beam shear (SBS) test. The result shows that the decomposition reaction can be represented by a power law model, and the reaction model may be determined without presuming the form of the model beforehand. The kinetic model has been verified using both non-isothermal and isothermal thermogravimetric data. The model predicted mass loss values are in excellent agreement with the experimental data. A quantitative relationship was established between mass loss and short beam shear (SBS) strength reduction of the composites subjected to isothermal heating. Based on the relationship and the kinetic model, a residual strength model has been developed to predict the residual strength of composites. The residual SBS strength of composites exposed to heat was measured and compared with the model predicted data. The result showed that the model predicted and measured strengths are in excellent agreement. In addition, the kinetic model derived for 5320-1 composites may be used with the residual strength data of other carbon/epoxy composites to establish a residual strength model for those composites.

Keywords: Carbon Nanofiber, Z-Threaded Carbon Fiber Reinforced Polymer, ILSS

ABSTRACT

Previous studies have shown that carbon nanofiber (CNF) z-threaded carbon fiber-reinforced polymer (ZT-CFRP) laminates exhibit improved mechanical performance in comparison to traditional carbon fiber-reinforced polymer (CFRP) laminates when exposed to extreme elevated temperatures. Z-threaded reinforcement is a technique for strengthening the through-thickness of a laminate by introducing perpendicularly aligned carbon nanomaterial to be threading into the continuous fiber array. Improved performance has already been observed in properties such as interlaminar shear strength (ILSS) without extreme heat exposure, but there has also been evidence that z-thread inclusion may mitigate strength loss due to thermal degradation of the matrix. This study examined how ILSS was diminished in both CFRP and ZT-CFRP samples with matrix degradation caused by extreme temperature exposure. Test samples were heated to 350 ˚C for 10 minutes and then allowed to return to room temperature. SBS testing in accordance with ASTM D2344 was conducted on both untreated and heat-treated samples for comparison. All samples were at room temperature during testing. It was found that ZT-CFRP samples (with 0.5wt% CNF concentration the matrix) exhibited higher ILSS with and without heat treatment over the traditional CFRP samples with and without heat treatment by +33.96% and +25.12%, respectively. ZT-CFRP ILSS was found to decrease by 10.584 MPa (-14.56%) after the extreme heat treatment, while CFRP ILSS decreased by only 4.627 MPa (-8.53%). Microscopic image analysis was also performed to provide insight into how the CNF z-threads may have provided a mechanism for retaining ILSS performance even with matrix thermal degradation.

1 INTRODUCTION

The high strength-to-weight ratios of carbon fiber reinforced polymers (CFRP) have caused it to become an increasingly used and researched material for structural designs. One of the disadvantages of CFRP is that they are anisotropic, with higher mechanical performance being restricted to loadings acting in the direction of the embedded reinforcing fibers. Even with the use of different stacking orientation techniques that can introduce more planar isotropy tendencies, there is still no reinforcing mechanism along the through-thickness of the composite. All reinforcement is confined to the plane of the fiber arrays. The novel Z-threaded nanomaterial reinforcement technique is a proven method for

increasing the through-thickness capabilities of CFRP. Within Z-threaded CFRP (ZT-CFRP), carbon nanomaterial is aligned and threaded perpendicularly through the reinforcing fiber array. A depiction of the concept of ZT-CFRP is provided in Figure 1 with carbon nanofibers (CNF) acting as the nanomaterial reinforcement.

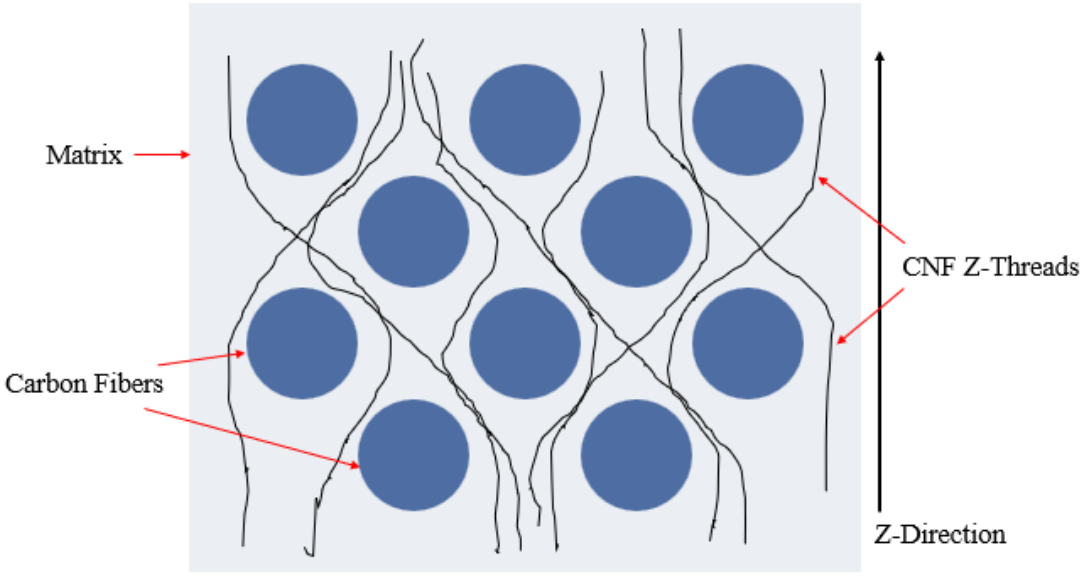

Figure 1: Illustration of ZT-CFRP showing how the nanomaterial reinforcement is threaded perpendicularly through fiber array.

Previous studies have already shown that ZT-CFRP exhibits improved through-thickness dependent material properties in comparison to traditional CFRP composites. This includes strengthened mechanical properties such as Mode-I delamination toughness [1] and longitudinal compressive strength [2], along with improved electrical [3, 4] and thermal conductivities [5]. Interlaminar shear strength (ILSS) is a mechanical property that saw significant increase in performance in comparison to traditional CFRP. With the inclusion of 1 wt% CNF z-threads, a 17% improvement in ILSS was observed. Traditional CFRP samples exhibited an average ILSS of 64.89 MPa while ZT-CFRP samples exhibited an average of 75.92 MPa [6].
